The Baermann procedure is used to recover larvae of parasites such as *Aelurostrongylus, Strongyloides* and *Filaroides* from fecal specimens. Larvae of these and similar parasites must be alive; therefore this procedure must be performed on fresh feces. The Baermann apparatus is a glass or plastic funnel with a piece of clamped flexible rubber or plastic tubing attached to the stem. Three to 10 grams of fresh feces is enclosed in two layers of gauze sponge or cheesecloth that is secured with rubber bands and placed on a wire mesh platform inside the funnel. Warm water (not hot water) is placed in the funnel until it covers the fecal specimen. The apparatus is allowed to stand undisturbed for approximately 6 hours (some allow the specimen to stand overnight). Any larvae that are present are collected by slowly opening the clamp and allowing 5-10 mL of liquid to flow into a centrifuge tube. The tube is centrifuged gently for a few minutes. The supernatant is removed and the sediment is examined for larvae.

Fecal Culture for Parasites

Numerous techniques have been used to culture parasites such as *Giardia, Tritrichomonas,* and *Pentatrichomonas* from canine or feline feces (see ch. 207, 211, and 276). Generally, these procedures require resources that are not readily available in the veterinary hospital. Samples should be submitted either to reference or academic laboratories if fecal culture is to be attempted. One exception might be *Tritrichomonas blagburni*. This agent causes large bowel diarrhea in cats and can be grown with relative ease in a commercially available culture system (Feline In Pouch™, Biomed Diagnostics, White City, OR). A very small amount of freshly voided feces (approximately 0.05 grams) or feces contained on a moistened cotton-tipped rectal swab can be added to the In Pouch. The In Pouch is incubated for 24 hours at 37°C and then held at room temperature and examined every 2 days for 10 days. Media in the In Pouch system allows the few organisms that may be present to reproduce, thus increasing the likelihood of recovering the motile protozoa. The In Pouch can be maintained at room temperature if an incubator is not available. However, organisms will appear in higher numbers sooner following preliminary incubation at 37°C.

Immunologic and Molecular Techniques

Several techniques have been developed to identify specific proteins or DNA from parasites in fecal specimens.[10-15] Immunologic techniques include enzyme-linked immunosorbent assays (ELISA) and

fluorescent antibody tests. ELISA is a technique used to detect the presence of either an antibody or an antigen in a fecal sample. An indirect ELISA is usually employed to detect antibodies to known antigens. The best known fecal ELISA procedure is SNAP *Giardia* (IDEXX Laboratories, Westbrook, ME) (see ch. 221 and 276). This test captures *Giardia* cyst wall proteins (CWP) present in the feces of *Giardia*-infected animals. To conduct the assay, a small sample of feces is mixed with an antibody/enzyme conjugate in a bulb. The bound antigen-antibody/enzyme mixture formed in the fecal/reagent emulsion is transferred to the SNAP device. Additional specific antibodies located on the solid substratum of the SNAP device trap the CWP/antibody/enzyme conjugate as they move over the antibody-containing spot. When the cassette is snapped, wash solutions and substrate are released. The wash solution eliminates non-bound CWP and the substrate is converted to a visible blue product by the enzyme. The SNAP *Giardia* test is an excellent method of confirming *Giardia*-induced cases of diarrhea in dogs and cats. The test is recommended only for testing samples from animals with clinical signs consistent with *Giardia* infection. Testing should not be conducted as a screening procedure on healthy animals. ELISA tests that detect antigens to canine intestinal worms have also been developed by commercial laboratories.[16] A direct fluorescent antibody assay is also commercially available for diagnosis of *Giardia* and *Cryptosporidium*. The Merifluor *Cryptosporidium*/*Giardia* assay (Meridian BioScience, Inc, Cincinnati, OH) contains a fluorescein isothiocyanate–labeled monoclonal antibody specific for cyst wall antigens. The Merifluor test requires the presence of cysts in feces for a positive result. Consequently, this test is not as sensitive as the SNAP *Giardia* assay. The Merifluor test also requires an epifluorescence microscope, which is usually not available in veterinary hospitals. An ELISA-based card that tests for *Giardia* and *Cryptosporidium* (ImmunoCard STAT!) is also available from Meridian.

There are many examples of the application of molecular techniques to fecal diagnosis of parasitic infections. Molecular techniques are particularly helpful for detection of parasites when present in low numbers. Fecal molecular diagnostic assays are usually available only in academic and reference laboratories. It is likely that commercialized, user-friendly versions of these tests will be available in the future.

Diagnostic Resources

Several diagnostic manuals can assist diagnosticians in identifying internal parasites.[17-20]

CHAPTER 82

Nasoesophageal, Esophagostomy, Gastrostomy, and Jejunal Tube Placement Techniques

Stanley Leon Marks

Overview

Use of enteral feeding devices to deliver nutrients into the lower esophagus is indicated for animals who cannot ingest adequate calories on their own, but who have sufficient gastrointestinal (GI) function to allow digestion and absorption of liquid-diet formulas. The diet for each patient depends, in part, on the selected route of feeding, the functional status of the GI tract, and the animal's nutrient requirements. Other factors, such as cost, availability, and ease of use may be considered. Animals fed liquid formulas via nasoesophageal or jejunostomy feeding tubes are limited to receiving about 1.0-1.3 kcal per mL. When using human enteral formulas for longer than 2 weeks, particularly in cats, one should remember that many of these formulas contain <20% of calories as protein and lack the essential amino acids taurine and arginine. There are several techniques from which to choose for obtaining enteral access. The technique used depends on the anticipated duration of enteral support, aspiration risk, integrity of the GI tract, the pet's temperament, the clinician's expertise, and the animal's ability to tolerate anesthesia.

Enteral Feeding Tube Material and Access Devices

Most feeding tubes are made of red rubber, polyurethane or silicone elastomer. The main shortcoming of silicone is related to its stiffness and flexibility. Silicone feeding tubes require thick side walls to obtain tube wall integrity or stiffness; therefore, their internal diameter is smaller than the internal diameter of a similar sized polyurethane tube, which may lead to clogging.[1] Further, silicone is known for "notch sensitivity:" propagation of a defect after being nicked or torn.[1] Feeding tubes made of silicone and/or polyurethane co-polymers, or other polymer end groups, are being developed for the softness of silicone and durability/wall thickness of polyurethane. French (F) units measure the outer lumen diameter of a tube (each French unit is equal to 0.33 mm).

Nasoesophageal Tubes

Indications and Choices

Nasoesophageal tubes are a simple and efficient choice if nutritional support is planned for <10 days in a dog or cat with a normal nasal cavity, pharynx, esophagus, and stomach.[2] Nasoesophageal tube feeding is contraindicated in animals who are vomiting, comatose, or who lack a gag reflex. Polyvinylchloride (Infant Feeding Tube, Argyle Division of Sherwood Medical, St. Louis, MO) or red rubber tubes (Robinson catheter, Sherwood Medical, St. Louis, MO) are the least expensive, but polyvinylchloride tubes may harden within 2 weeks of insertion and cause irritation or ulceration of the pharynx or esophagus. Tubes made of polyurethane (MILA International, Inc., Erlanger, KY) or silicone (Global Veterinary Products, Inc., New Buffalo, MI) are more expensive, less irritating, longer lasting, and more resistant to gastric acid. An 8-French, 91 cm tube with or without a tungsten-weighted tip is suitable for dogs weighing >15 kg. 5-French tubes are more suitable for cats and smaller dogs.

Placement

Feeding tubes should terminate in the distal esophagus, reducing risk of reflux esophagitis. Placement is facilitated by ensuring that the tube is no longer than the length from nose tip to the seventh or eighth intercostal space.[3] Use tape to mark the appropriate length. Desensitize the nasal cavity with 0.5-1 mL of 0.5%

proparacaine hydrochloride and tilt the head up to allow it to coat the nasal mucosa. Lubricate the tip of the tube with 5% viscous lidocaine prior to passage. Maintaining the animal's head at a normal angle, avoiding hyperflexion or overextension, as the tube tip is gently directed caudoventrally. It should pass with minimal resistance through the ventral meatus, nasopharynx and into the esophagus. Nasoesophageal intubation is more difficult in dogs with long narrow nasal passages and extensive turbinate structures. The small ventral ridge at the proximal end of the canine nasal passage necessitates first directing the tip of the tube dorsally over that ridge and into the nasal vestibule (Figure 82-1; also see ch. 238).[2] The tube can then be directed in a caudoventral-medial direction while pushing the external nares dorsally.[4] This maneuver opens the ventral meatus and guides the tube into the oropharynx.

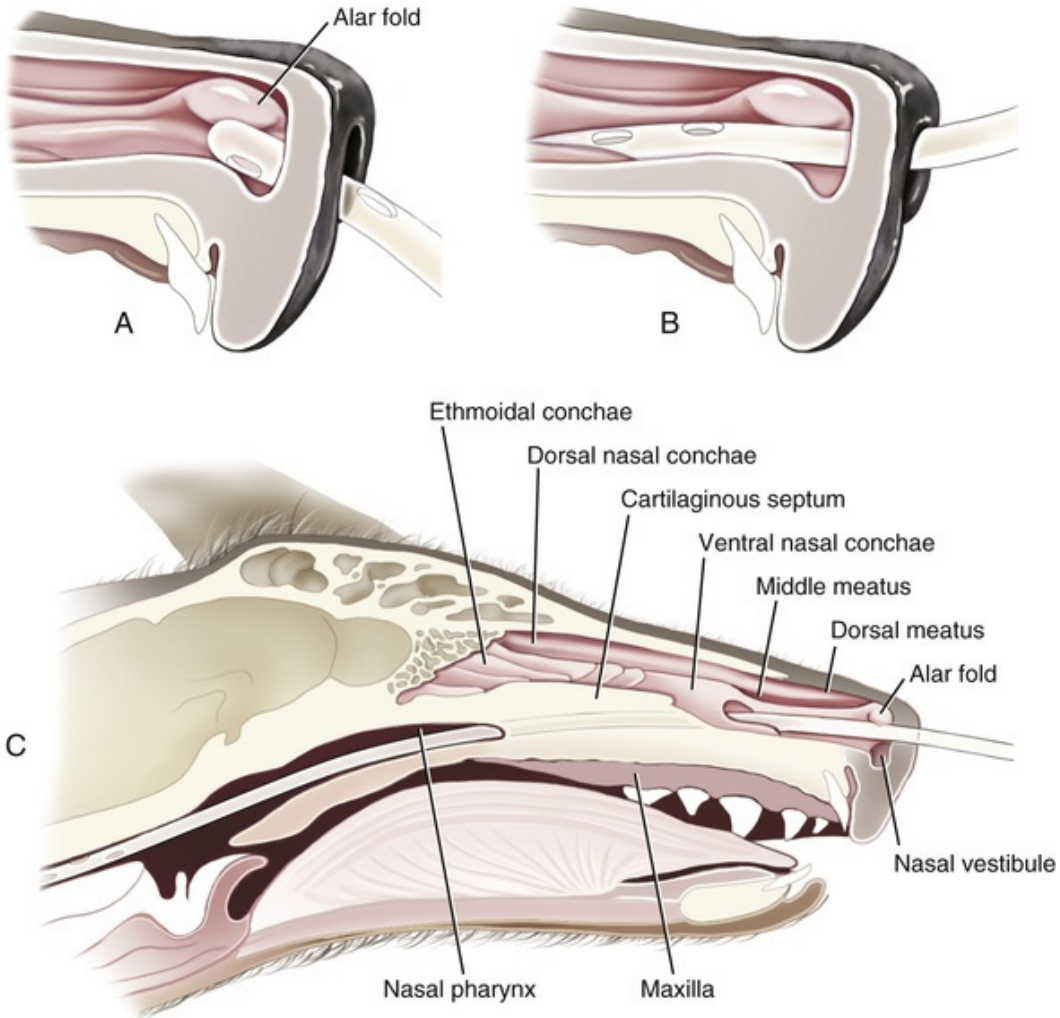

FIGURE 82-1 Parasagittal section showing step-wise insertion of a nasoesophageal tube through the ventral meatus of a dog. **A,** The presence of a small ventral ridge at the rostral end of the nasal passage necessitates directing the tip of the tube dorsally to clear the protuberance. **B,** Once past the protuberance, the tube is aimed medially and ventrally and advanced into the ventral meatus. **C,** Tube through ventral meatus and nasal pharynx. (Reprinted with permission from Crowe DT: Clinical use of an indwelling nasogastric tube for enteral nutrition and fluid therapy in the dog and cat. *J Am Anim Hosp Assoc* 22:675-682, 1986.)

If the tube does not pass with relative ease into the oropharynx, the tip may have gone through the middle meatus, reaching the ethmoid turbinate. The tube then should be withdrawn and re-directed. Once the tube has been passed correctly to the level of the marker, it should be sutured or glued as close to the nostril as possible (Figure 82-2, *A*; Superglue, Loctite Corp., Cleveland, OH). A second tape tab should be secured to the dorsal midline skin between the eyes (Figure 82-2, *B* and *C*). Tubes must not exit laterally nor come in contact with the whiskers of cats. An Elizabethan collar is usually required for dogs, not cats, to prevent inadvertent tube removal. Tube removal is facilitated by clipping hair attached to the glue.

FIGURE 82-2 **A,** The tip of the nasoesophageal tube has been lubricated and passed into the ventral meatus by positioning the animal's head in a normal angle of articulation. **B,** The tube should be secured as close to the nostril as possible, with either suture material or glue. **C,** The nasoesophageal tube can be secured to the skin on the dorsal midline between the eyes with tape "butterflies."

After placement, tube position should be checked by injecting 5 to 10 mL of air while ausculting the cranial abdomen for borborygmus, by infusing 3 to 5 mL of sterile saline or water through the tube and observing for a cough response,[2] or by obtaining a lateral thoracic radiograph. Placement verification can also be accomplished with an end-tidal CO_2 monitor; tubes placed within the esophagus or stomach yield no CO_2. Diets are fed full strength on continuous (pump infusion) or bolus feeding schedules.

Complications and Disadvantages

The most common complications associated with the use of nasoesophageal tubes include epistaxis, dacrocystitis, rhinitis, tracheal intubation (pneumonia), and vomiting.[2] A major disadvantage of nasoesophageal feeding tubes is their small diameter, necessitating the use of liquid enteral formulas. Canned pet foods diluted with water invariably clog feeding tubes.

Esophagostomy Tubes

Overview and Material

Esophagostomy feeding tubes are easily inserted, requiring only heavy sedation or light general anesthesia and intubation with a cuffed endotracheal tube. Three basic techniques for placement of a midcervical esophagostomy tube have been described that are minimally invasive and require no specialized endoscopic equipment.[5-7] The patient should be placed in right lateral recumbency. Clip and aseptically prepare from the left mid-cervical region to the thoracic inlet.[5-7] The left side is preferred because the esophagus lies slightly left of midline. A 14- to 20-French red rubber catheter (Robinson catheter, Sherwood Medical, St. Louis, MO), silicone catheter (Global Veterinary Products, Inc., New Buffalo, MI) or polyurethane catheter (MILA International, Inc., Florence, KY) should be pre-measured from the mid-cervical esophagus to the seventh or eighth intercostal space and marked to ensure termination of the catheter in the distal esophagus.[3]

Technique Using Curved Carmalt, Mixter, or Schnidt Forceps

Advance the right-angle forceps into the midcervical esophagus from the oral cavity. Use the angle of the jaw and the point of the shoulder for landmarks to help ensure that the tip of the forceps can be palpated externally in the midcervical region. Push the curved tips of the forceps laterally at the mid-cervical esophagus, so they can be palpated below the skin. Use a No. 11 scalpel blade to make a stab incision through the skin only, exposing the SC tissue and the esophageal muscle layers. Be careful to avoid the jugular and maxillofacial veins. Exteriorize the tip of the forceps from the esophageal lumen through the skin incision. Guide the advancing forceps through the esophageal muscle layers, carefully dissect the esophageal mucosa off the tip of the forceps with a scalpel blade, use the forceps to grasp the distal end of the feeding tube, and draw the tube out of the oral cavity. Secure the distal end of the feeding tube using the forceps to ensure that the tube remains exteriorized while the proximal end of the tube is pulled out of the animal's mouth. Retroflex the proximal tip of the feeding tube and advance it in an aboral direction across the pharynx and down the esophagus, while slowly retracting on the external end of the tube 2 to 4 cm. A wire guide can be used to facilitate advancing the proximal tip of the feeding tube into the esophagus. The exteriorized portion of the tube will be observed to rotate in a cranial direction as the tube moves down the esophagus, indicating correct placement. Retention sutures (Chinese finger-trap suture), using 2-0 polypropylene, secure the tube's distal end to the skin. Another method of securing the tube involves passing heavy suture on a taper needle through the skin next to the tube and into the periosteum of the wing of the atlas. Antibiotic ointment and gauze dressing should cover the incision site, while the tube and entire site are loosely bandaged with gauze.

Correct tube placement (mid- to distal esophagus) should be confirmed with radiographs. Be certain that the tube does not extend beyond the lower esophageal sphincter and predispose the patient to gastroesophageal reflux. Feeding can begin after complete recovery from anesthesia. The tube esophagostomy-skin interface should be examined daily during the first week for evidence of infection or leakage of food or saliva. The stoma site can be kept clean with a topical antiseptic solution (1 : 100 Betadine solution in 0.9% saline). Once nutritional support is no longer needed, cut the Chinese finger-trap anchoring suture and remove the tube. The wound should be allowed to heal by second intention.

Percutaneous Feeding Tube Applicator Technique

An Eld percutaneous applicator is inserted into the midcervical esophagus via the oral cavity, the distal tip is palpated, and an incision is made through the skin and subcutaneous (SC) tissue over that tip.[8] Activate the spring-loaded instrument (Figure 82-3, *A*) to advance the trocar through the esophageal wall and incision (Figure 82-3, *B*). The distal end of the feeding tube is secured to the eyelet of the trocar with suture material. The Eld device and attached feeding tube are retracted into the esophagus and exteriorized via the oral cavity. The feeding tube is then redirected into the midcervical esophagus after inserting a wire stylet into the distal tip of the feeding tube. The tube is secured to the skin as described above.

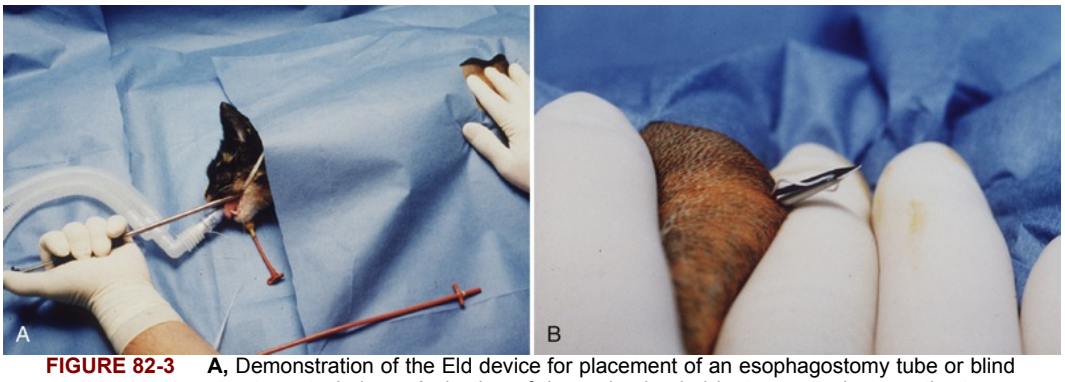

FIGURE 82-3 **A,** Demonstration of the Eld device for placement of an esophagostomy tube or blind percutaneous gastrostomy technique. Activation of the spring-loaded instrument advances the trocar through the esophageal or gastric wall. **B,** Suture material is attached to the exteriorized eyelet of the trocar which is retracted into the lumen of the instrument, and carefully removed out of the esophagus and out the mouth of the animal. The exteriorized suture material is attached to a feeding tube. (Courtesy Dr. Larry A. Eld.)

Percutaneous Needle Catheter Technique

With this method, an esophagostomy introduction tube (Van Noort esophagostomy tube set, Global

Veterinary Products, Inc., New Buffalo, MI) (Figure 82-4) is introduced into the midcervical esophageal area. The slot in the distal portion of the tube is palpated, and a Peel-Away sheath needle (Global Veterinary Products) is introduced into the distal portion of the tube. The needle is removed from the sheath and a 10-French catheter is introduced through the sheath to the distal third of the esophagus. The sheath is peeled away and the esophagostomy tube carefully removed. The feeding tube is secured as described. This technique is limited by the small diameter of the feeding tube (10 French), only allowing administration of water and liquid enteral formulas.

FIGURE 82-4 Photograph of the esophagostomy tube set, illustrating the esophagostomy introduction tube, 10-gauge, 5-cm long Peel-Away sheath needle, and a 10-French silicone catheter. (Courtesy Smiths Medical ASD, Inc., Minneapolis, MN.)

Complications

Despite potential for esophageal scarring, fistulas or strictures, none has been reported. A common minor complication is peristomal inflammation. Peristomal abscessation is infrequent.[5-7] Most inflammatory reactions are mild and responsive to cleaning and topical antibiotics. Less common complications include vomiting the tube into the oral cavity and tube obstruction.[5-7]

Gastrostomy Tubes

Indications and Contraindications

Gastrostomy tube feeding is indicated for long-term (weeks to months) nutritional support of anorectic or dysphagic animals with adequate GI function to allow digestion and absorption of feeding solutions. Gastrostomy tubes have a relatively large diameter (20 to 24 French), allowing use of blended pet food and medications. Gastrostomy tube feeding is contraindicated in animals with persistent vomiting, decreased consciousness, or GI obstruction. Caution should be exercised in conditions under which the stomach cannot

be apposed to the body wall (severe ascites, adhesions, space-occupying lesions).

Placement and Material

These can be placed using the percutaneous endoscopic gastrostomy (PEG) or blind percutaneous gastrostomy (BPG) techniques.[9-12] A variety of feeding tubes can be utilized for gastrostomy feeding: latex, polyurethane, and silicon tubes with French-Pezzer mushroom, balloon, bumper, or silicone dome tips (Figure 82-5). The silicone catheters can be purchased from Global Veterinary Inc., New Buffalo, KY or US Endoscopy, Mentor, OH; polyurethane from MILA International, Inc., Erlanger, KY; and latex catheters from BARD Urological Division, Murray Hill, NJ. One can modify the catheters by cutting off and discarding the flared open end and then cutting off two 2-cm pieces to be used as internal and external flanges from the same cut end. The end opposite the mushroom tip is trimmed to facilitate introduction into the larger opening of a disposable plastic micropipette. Make a small stab incision through the center of each flange and slide one flange over the cut end of the catheter until it rests against the mushroom tip. The other 2-cm piece of tubing will be used as an external flange that lies against the abdominal wall.

FIGURE 82-5 Gastrostomy tubes illustrating the various materials and catheter tips; from left to right, French red rubber catheter, silicone balloon catheter, silicone mushroom catheter, latex mushroom catheter, silicone catheter with dome, polyurethane catheter with bumper.

Percutaneous Endoscopic Gastrostomy Technique and Complications

Placement of gastrostomy tubes necessitates brief anesthesia. The animal should be placed in right lateral recumbency so that the stomach tube can be placed through the greater curvature of the stomach and the left body wall. Preparation for either percutaneous procedure involves surgical prep of the skin caudal to the left costal arch. The endoscope is introduced into the stomach and the stomach is carefully inflated until the abdomen is distended but not drum tight. The left body wall is transilluminated with the endoscope to ensure that the spleen is not positioned between the stomach and body wall. An appropriate site for insertion of the tube is determined by endoscopically monitoring digital palpation of the gastric wall. A small incision is made in the skin with a scalpel blade, and an IV catheter (16 to 18G, 1.5-2 inch long) is stabbed through the body wall into the lumen of the stomach (Figure 82-6, *A*). The stylet is removed and nylon or polyester suture is threaded through the catheter into the stomach lumen. The suture material is grasped with the endoscope biopsy forceps (Figure 82-6, *B*), and both endoscope and forceps are carefully withdrawn through the esophagus and out the mouth. The suture material is secured to the feeding tube and gentle traction is applied to the suture at its point of exit from the abdominal wall (Figure 82-6, *C*). The feeding tube is pulled out through the body wall, the mushroom end draws the stomach wall against the body wall (Figure 82-6, *D*), and the tube is anchored here by the external flange placed over the catheter at the skin surface (Figure 82-6, *E*). The endoscope is then reinserted into the stomach to verify the correct placement of the mushroom against

the gastric mucosa. If mucosal blanching is observed, tension applied to the tube should be reduced to avoid ischemia and necrosis. A plastic clamp is placed over the tube and the tube capped with a Y-port connector. A stockinette jacket (San Jose Surgical Supply, Inc., San Jose, CA) is fitted to protect the tube (Figure 82-6, *F*).

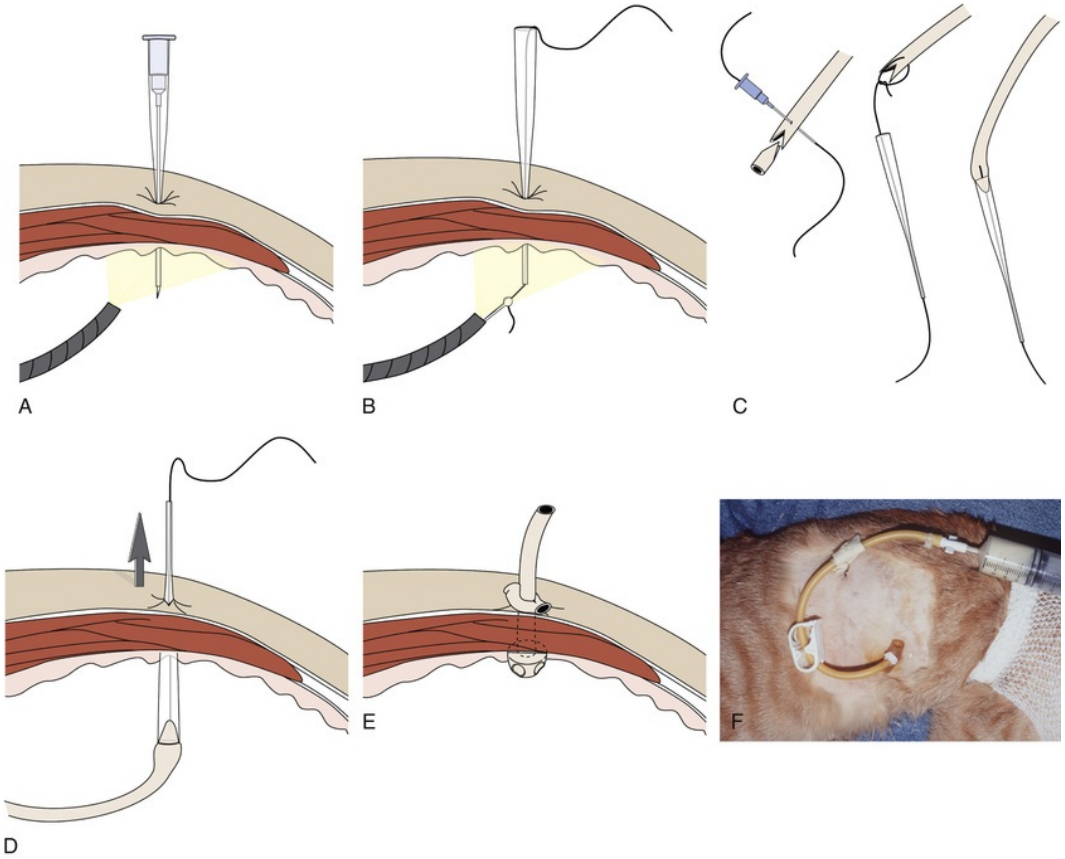

FIGURE 82-6 Percutaneous endoscopic gastrostomy (PEG) technique. **A,** With the animal in right lateral recumbency, the endoscope is introduced into the stomach, and the stomach is insufflated with air. The left body wall is transilluminated with the endoscope to ensure that the spleen is not between the stomach and the body wall. A 16-18G sheathed catheter pierces transabdominally into the insufflated stomach lumen. **B,** The catheter stylet is removed, and nylon suture is advanced through the catheter until it can be grasped with endoscopic retrieval forceps. The nylon suture is pulled out through the mouth as the endoscope is withdrawn. **C,** The suture material is secured to the feeding tube and water-soluble jelly is applied liberally to the catheter sheath and the mushroom-tip catheter. **D,** The lubricated catheter is drawn down the esophagus and into the stomach as the assistant applies traction on the suture exiting the abdominal wall. **E,** The catheter is advanced until the mushroom tip rests gently against the gastric mucosa. Endoscopy should be repeated to confirm the correct position of the mushroom tip. An external flange is fitted down the tube against the skin to prevent the tube from slipping into the stomach. **F,** Gastrostomy feeding tube in place in a cat, with the clamp in the open position. The stockinette jacket is pulled over the gastrostomy tube once feeding is completed. (Redrawn from Washabau R, Day MJ: *Canine and feline gastroenterology*, St Louis, 2013, Saunders. Drawings created by John Doval and Stanley Marks, UC Davis.)

PEG tube related complications caused by incorrect placement include splenic laceration, gastric hemorrhage, or pneumoperitoneum. PEG tubes may result in delayed complications of vomiting, aspiration pneumonia, tube extraction, tube migration, and stoma infection.[9,10,13] Minor complications include pressure necrosis at the stoma site and cellulitis.[9,10,13] Chances of splenic laceration are minimized by insufflating and trans-illuminating the stomach prior to needle or catheter placement into the abdominal wall. A discordant number of large-breed dogs have had the major complication of the stomach falling off the silicone dome end of the gastrostomy tube. The stoma has appeared normal in affected dogs and feeding may commence without knowledge of the detachment. Detachment has occurred despite placement of an internal flange between dome and gastric mucosa. Dogs heavier than 30 kg, particularly those that have delayed wound healing, should therefore have their gastropexy site reinforced with an Entuir secure GI suture anchor set (Cook Medical Inc., Bloomington, IN). This anchors the anterior stomach wall to the abdominal wall and

reduces risk of gastropexy site breakdown.

Blind Percutaneous Gastrostomy Technique and Complications

The non-endoscopic, non-surgical gastrostomy tube placement technique begins with a length of vinyl or stainless steel tubing (diameter 1.2 to 2.5 cm) purchased from a hardware store, or an Eld Gastrostomy Tube Applicator (Jorgensen Laboratories, Loveland, CO) or gastrostomy tube introduction set (Global Veterinary Inc., New Buffalo, KY).[11,12] The Eld Gastrostomy Tube Applicator is the only device with an internal trocar. The Cook gastrostomy tube introduction set contains a wire threaded through an introduction needle. The distal tip of a stainless steel tube can be flared and deflected 45 degrees from the long axis to help displace the lateral body wall. The lubricated tube is passed through the mouth, into the stomach and advanced until the end displaces the stomach and lateral abdominal wall. Positioning the patient's head beyond the table edge and lowering the proximal tube end facilitates identifying its tip through the body wall. For the Cook gastrostomy introduction set or similarly prepared device, a percutaneous needle is introduced into the lumen of the introduction tube while an assistant firmly holds the distal tube tip between two fingers. A skin nick is made over the end of the tube and a 14-gauge needle advanced into the introduction tube lumen (Figure 82-7, *A*). Proper positioning of the needle is confirmed by moving the hub from side to side and feeling the needle tip strike the inside of the tube. A guide wire included in the kit is threaded through the lumen of the needle, into the tube, and out the mouth of the patient. The introduction tube is removed and the threaded end of the guide wire secured to an adapter which fits snugly into the end of a feeding tube (Figure 82-7, *B* and *C*). Gentle traction is applied to the guide wire at its point of exit from the abdominal wall, facilitating placement of the mushroom end of the feeding tube against the gastric mucosa. The feeding tube is secured in an identical fashion to the PEG tube procedure described above.

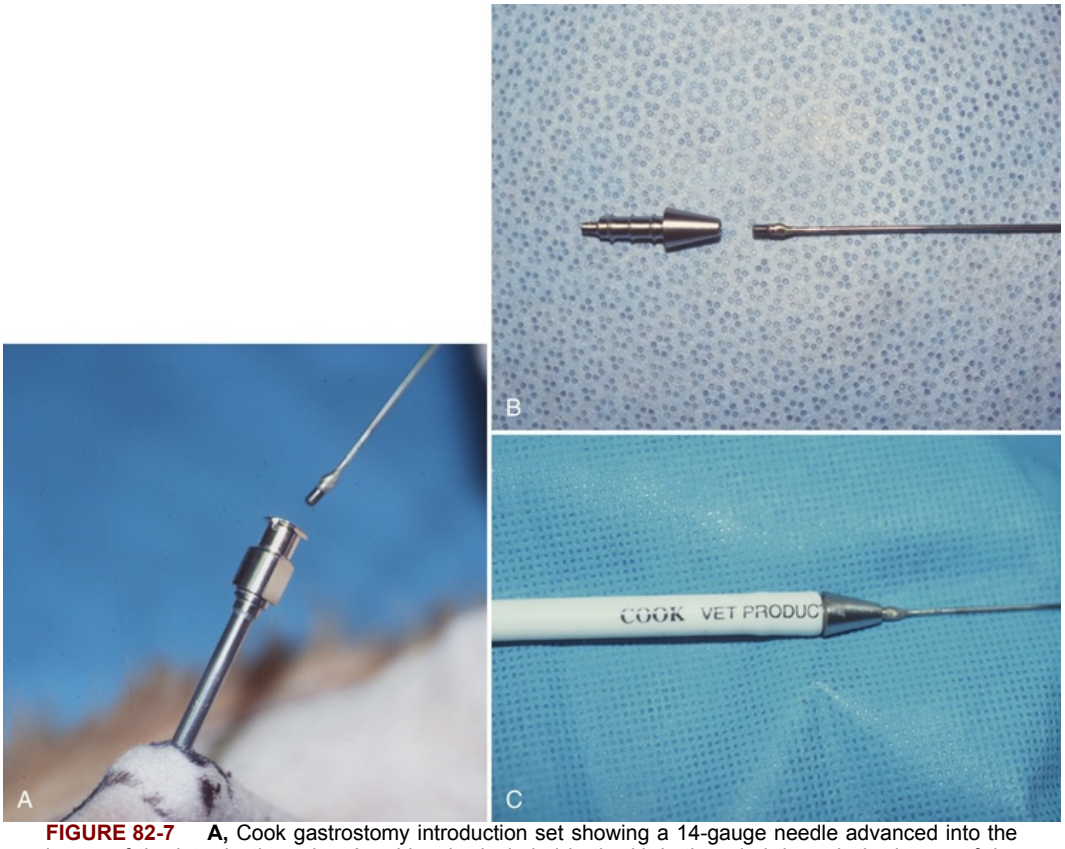

FIGURE 82-7 **A,** Cook gastrostomy introduction set showing a 14-gauge needle advanced into the lumen of the introduction tube. A guide wire included in the kit is threaded through the lumen of the needle, into the introduction tube, and out the mouth of the patient. **B** and **C,** Following the removal of the introduction tube from the animal, the threaded end of the guide wire is secured to an adapter that fits snugly into the end of the feeding tube. Gentle traction is applied to the guide wire at its point of exit from the abdominal wall to position the mushroom of the tube against the gastric mucosa.

Complication rates are similar for BPG and PEG. However, risk of penetrating spleen, stomach, or

omentum is greater if the stomach is not insufflated with air prior to positioning the tube against the lateral abdominal wall.[14] Contraindications to using the "blind" technique include esophageal disease and severe obesity, which precludes accurate palpation of the tube against the abdominal wall. In either case, gastrostomy tubes should be placed surgically.

Jejunostomy Tubes

Indications and Options

Dogs and cats unable to tolerate intragastric or intraduodenal feeding, but who have normally functioning distal small intestine and colon, are candidates for jejunostomy.[15] Specific indications for jejunostomy tube feeding include gastric outlet obstruction, gastroparesis, recurrent/potential aspiration, proximal small bowel obstruction, and partial gastrectomy. Jejunal tube feeding reduces stimulation of the pancreas and can be used for nutritional support of patients with severe pancreatitis.[15] Surgically placed jejunostomy tubes are commonly used for long-term feeding. An alternative to the surgical jejunostomy technique is placement percutaneously. These include percutaneous jejunostomy or gastrojejunostomy (PEG-J) tubes placed under fluoroscopic or endoscopic guidance. The advantage of the PEG-J technique is that it allows ready access to the stomach for aspiration of gastric luminal contents.

Placement and Complications

Four sequential steps must be followed to achieve successful PEG-J tube placement in dogs and cats: (1) routine PEG placement; (2) deep guide wire passage into the small intestine; (3) endoscope retraction leaving the guide wire in place; and (4) jejunostomy feeding tube placement over the guide wire.[16,17] Briefly, the animal is anesthetized and placed in right lateral recumbency. A PEG tube is routinely placed and the external portion of the tube trimmed to a length of 6 inches, maximizing the amount of jejunostomy tube that can be passed into the small intestine. Placement of a 65-cm jejunostomy tube (Gastro-Jejunal feeding tube, Wilson-Cook Medical Inc., Winston-Salem, NC) works well in cats, whereas a jejunostomy feeding tube ≥95 cm is recommended for most dogs. A standard loop snare is passed through the PEG tube into the stomach using an endoscope. The snare is opened and the endoscope advanced through it toward the pylorus. The animal is then positioned in left lateral recumbency, and the endoscope is advanced as far down the small intestine as possible. The accessory channel of the endoscope is flushed with water to facilitate rapid passage of a guide wire that is passed down the biopsy channel into the small intestine. As the endoscope is carefully retracted into the stomach, the tip of the endoscope is pulled past the open snare, which is then closed snugly on the guide wire. The endoscope is then removed from the animal with the resultant extension of the guide wire out the oral cavity. The closed snare is then pulled out through the gastrostomy tube, facilitating the exit of a portion of the guide wire from the opening of the gastrostomy tube. The snare is then released, an assistant gently pulls the proximal end of the guide wire through the gastrostomy tube, leaving the distal (aboral) end in the small intestine. The jejunostomy tube is flushed with water, activating lubricant on its inner surface. The jejunostomy tube is threaded over the guide wire under endoscopic guidance until its proximal end is seated in the gastrostomy tube. The guide wire is then removed from the PEG-J tube, and abdominal radiographs are taken to confirm adequate placement of the jejunostomy tube 40 to 60 cm distal to the pylorus. Passage of the jejunostomy tube far into the jejunum is critical for preventing the catheter from migrating retrograde into the stomach.

Endoscopically assisted placement of an esophagojejunostomy (EJ) feeding tube in 5 chronically anorexic dogs with pancreatitis was well tolerated in each. Tube occlusion, transient vomiting and loose stool were the most common complications.[18] Endoscopically assisted nasojejunal feeding tube placement has been used in dogs.[19,20] Facial irritation, sneezing, and the narrow 8-French tubes clogging limit use of this modality to patients anticipated to only need short-term nutritional support (<7 days).

Removal of Esophagostomy, Gastrostomy and PEG-J Tubes

Unlike gastrostomy tubes, an esophagostomy tube can be removed the same day it is placed without concern of leakage or development of secondary complications. The dressing and sutures are removed while the tube is held in place. The tube is then occluded by kinking and removed with gentle traction. The ostomy site should be cleaned, antibiotic ointment applied, covered with a light dressing for 24 hours which is then removed for ostomy site inspection. Skin sutures are not needed, as it should close within 24 to 36 hours.

For PEG tubes and PEG-J tubes, it is recommended that the PEG tube be left in place for a minimum of 3

weeks. Patients who are severely debilitated or receiving immunosuppressive therapy may require longer for formation of a peritoneal seal. The tube should be removed only when oral food intake is sufficient to meet the patient's caloric requirement (see ch. 172 and 174). One method of Pezzer PEG tube removal is to cut it at the body wall and push the mushroom tip into the stomach to be passed in the feces. This method is safe in medium- to large-size dogs because the mushroom and internal flange should easily pass in feces. A second method involves inserting a stylet into the tube to flatten the mushroom tip while exerting firm traction on the tube. This assumes the tip has not been cut with a scissors before placement. This second method is recommended for cats and small dogs because the mushroom can obstruct the intestine. Removal of the MILA catheter is accomplished by deflating the bumper, after removal of the Y-port adapter. Catheters with a dome (US Endoscopy) are removed by gentle but firm traction on the tube. The gastro-cutaneous tract should seal with minimal or no leakage within 24 hours.

Replacement of Gastrostomy and Esophagostomy Tubes

PEG tubes may malfunction or be prematurely removed by the patient, requiring replacement. If a gastrostomy tube is removed within 3 weeks of placement (before complete establishment of the gastrocutaneous tract), iodinated contrast material can be injected via the stoma site to determine if the gastrocutaneous tract is still intact, or a PEG procedure could be performed to evaluate the gastric mucosa and verify correct positioning of the replacement gastrostomy tube. If a tube is inadvertently removed once the gastrocutaneous tract is well healed, one can replace the original catheter with a balloon-type catheter (Flexiflo Gastrostomy tube, Ross Laboratories, Columbus, OH)[21] or a low-profile gastrostomy device (LPGD, Bard Interventional Products Division, Murray Hill, NJ) (Figure 82-8, *A*). Neither catheter type requires an endoscopic procedure or anesthesia for placement. The gastrostomy "button" is a small, flexible silicone device that has a mushroom-like dome at one end and two small wings at the other that lie flush with the outer abdominal wall (Figure 82-8, *B*). A one-way anti-reflux valve prevents reflux of gastric contents through the top of the tube. There are two types of LPGDs: obturated and non-obturated. The obturated device has an enlarged mushroom tip that must be stretched for placement in the stomach by using a special introducer[22] (Figure 82-8, *C*). The non-obturated tube works like a Foley catheter and does not require forceful entry into the gastrostomy stoma. The length of the gastrocutaneous fistula must be precisely determined to guide correct selection of the appropriate "button" shaft length. This is accomplished with a special stoma-measuring device provided with the kit. LPGD advantages include durability, decreased likelihood of inadvertent removal by the patient, and their aesthetically pleasing appearance for owners.[23]

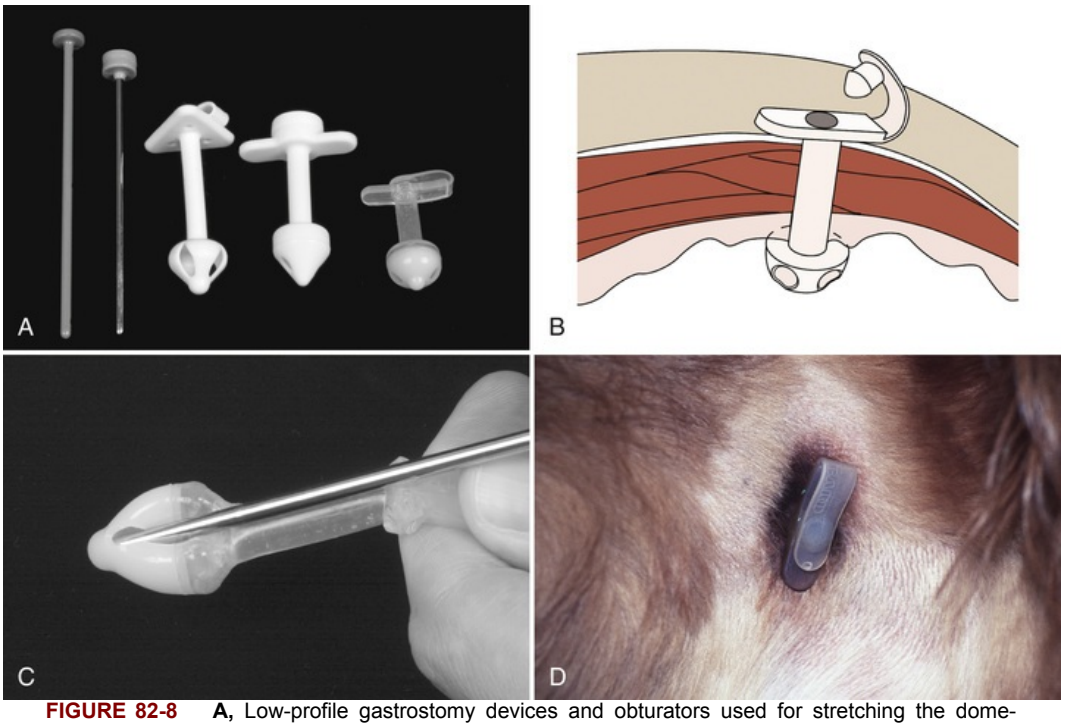

FIGURE 82-8 **A,** Low-profile gastrostomy devices and obturators used for stretching the dome-

shaped tip of the device. From left, The Ross Laboratories Stomate low-profile device, The Cook low-profile device, and the Bard "Button" low-profile device. **B,** Low-profile gastrostomy device with small outer wings of the device lying flush against the skin of the abdominal wall. For feedings, the small plastic plug is removed and a feeding adapter is connected to a syringe. **C,** Correct technique for stretching the dome-shaped tip of the low-profile gastrostomy device with an obturator. The dome should not be stretched by passing the obturator through the lumen of the device as it will compromise the integrity of the anti-reflux valve located adjacent to the dome. **D,** Low-profile gastrostomy device after placement in a dog showing the aesthetic appearance of the device that fits flush against the animal's skin.

An alternative low-profile device that can be used in lieu of a regular PEG tube or replacement low-profile device is a one-step or "initial placement" low-profile PEG tube (One Step Button, now renamed as EndoVive Low Profile Percutaneous Endoscopic Gastrostomy kit; Boston Scientific, Natick, MA) (Figure 82-9, *A* and *B*). The one-step avoids need for a second procedure to replace the original PEG tube. Tubes are available in 18 and 24 French diameters and range in stoma length from 1.2 to 4.4 cm. Use of silicon spacers supplied by the manufacturer (Figure 82-9, *C*) helps ensure that devices can be adapted to animals with different stoma tract length requirements. In a study evaluating complications and outcomes of one-step low-profile gastrostomy devices for long-term enteral feeding in dogs and cats, the devices were well tolerated and the most common complications were relatively minor: peristomal swelling and mucopurulent peristomal discharge.[24]

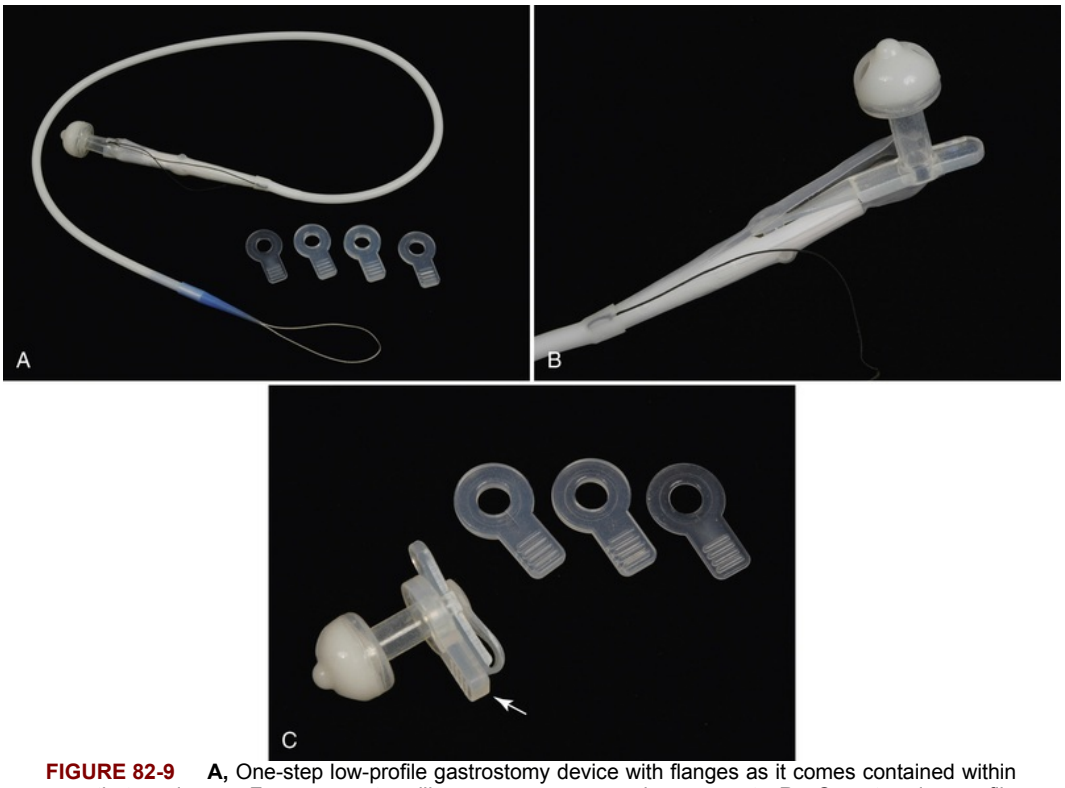

FIGURE 82-9 **A,** One-step low-profile gastrostomy device with flanges as it comes contained within a catheter sleeve. Four separate silicone spacers are also present. **B,** One-step low-profile gastrostomy device with flanges released after tearing the surrounding catheter sleeve open by pulling on the attached black suture material. **C,** One-step low-profile gastrostomy device separated from catheter sleeve, showing a single 5-mm silicone spacer (arrow) inserted over the shaft, and three other separate silicone spacers of varying thickness.

Complications of Enteral Feeding

Gastric Pressure Necrosis

Gastric pressure necrosis can occur from either the mushroom of the PEG tube or flange eroding the mucus layer of the stomach due to excessive tension being exerted on the PEG tube during placement. Overzealous PEG tube traction before placement of the external flange flush against the skin can also cause pressure necrosis, which appears red, swollen, and moist. To minimize these problems, be sure that the PEG tube can

be rotated following placement and leave a 1-cm space between the external flange or the bumper and the skin.

Feeding Tube Displacement

This is relatively common, particularly with nasoesophageal and PEG-J tubes. Displacement of the tube can lead to aspiration, diarrhea, or peritonitis in pets with a gastrostomy tube. Gastrostomy tubes should be marked with tape or a marking pen at the level of the skin to help verify tube position. Since stomach detachment from the abdominal wall, with subsequent intraperitoneal leakage, can occur in large-breed dogs, an internal flange or T-fasteners should be placed to minimize the chance of this complication.

Tube Obstruction

Obstruction of the feeding tube is one of the most common complications of enteral feeding.[25] Obstructions are usually caused by formula coagulation, although they can be caused by tablet fragments, kinks in the tubing, or precipitation of medications. Nasoesophageal tubes are prone to obstruction because of their small diameter. Obstructions may be three times more frequent in patients fed by continuous versus bolus feedings.[26] Sucralfate and acid suppressants have been reported to precipitate with enteral formulas, causing tube obstruction.[26] Warm water infused with gentle pressure and suction will relieve most obstructions. For more unyielding obstructions, carbonated water is instilled into the tube and allowed to remain for 1 hour before applying gentle pressure and suction. Pancreatic enzyme infusions and meat tenderizer have also been advocated to dissolve tube obstructions.[25] On rare occasions, passing an angiographic wire is needed to unclog the tube. Tube obstructions can be minimized by flushing with warm water before and after administering medications or feedings. Tubes should also be flushed after checking for gastric residuals because the acid pH will cause the formula to coagulate in the tube. Elixir forms of medication should be used rather than crushed tablets whenever possible. Tablets should be crushed and dissolved in water prior to administration through a feeding tube if no alternative form is available.

Leakage Through Ostomy Sites

Mild leakage at the stoma site can occur for the first few days following feeding tube placement. Persistent leakage may indicate tube dysfunction, peristomal infection, or a stoma that is too large for the tube. Signs of inflammation with or without discharge or fever may be indicative of stoma site infection which must be differentiated from fasciitis. If it is a simple wound infection, it can usually be treated topically with a dilute Betadine solution and more frequent dressing changes. Systemically administered antibiotics are usually reserved for patients with systemic signs of infection.

Aspiration

Pulmonary aspiration (see ch. 242) is a common complication of enteral feeding, although the actual incidence is difficult to determine. Risk factors for aspiration include impaired mental status, neurologic injury, absence of a cough or gag reflex, mechanical ventilation, and previous aspiration pneumonia.[27] The source of the aspirated material should be identified because withholding gastrostomy feedings or placing a jejunostomy feeding tube in a patient will have no benefit if the patient aspirated oropharyngeal secretions. Although controversial, most authors agree that post-pyloric feeding reduces risk of aspiration.[28] In addition, continuous feedings have been shown to induce less gastroesophageal reflux than bolus feedings.[29]

Diarrhea

Diarrhea is the most commonly cited complication associated with tube feeding in human and animal patients, with an incidence ranging from 2.3% to 63%.[30,31] The clinical implications of enteral feeding-related diarrhea are significant. Severe diarrhea leads to fluid, electrolyte, and nutrient loss, as well as considerable patient distress. Diarrhea in tube-fed patients occurs due to multiple factors, including hypoalbuminemia, hyperosmolar or high fat diets, infected diets, or antibiotic therapy.[30,31] The incidence of diarrhea in enterally fed patients taking antibiotics far exceeds the incidence in normally fed patients taking the same antibiotics. Antibiotic-associated diarrhea may arise from overgrowth of enterobacteria *(Klebsiella, Proteus, Pseudomonas)* or from proliferation of *Clostridium difficile*.

CHAPTER 83

Care of Endoscopic Equipment

Valerie Walker, Susan Cox, Katie Douthitt

Overview

Endoscopes and the instruments which accompany them are a significant investment. Initial cost coupled with subsequent expenses for repairs can be sizeable. A great deal of frustration can be avoided and money can be saved if personnel understand the handling, cleaning and general care required of such equipment. In large busy practices, written policies and guidelines for cleaning, disinfecting (E-Box 83-1), handling, and conducting endoscopy procedures can help prolong the lifespan of this equipment. Disregarded or forgotten steps, especially in the cleaning process, can lead to losing an endoscope to repair for extended periods.

E-Box 83-1

Endoscope Cleaning Guidelines

A. Pre-cleaning performed immediately post-procedure to remove gross debris (also see Video 83-1).
   a. With clean water, wipe down insertion tube.
   b. Aspirate water then air through suction channel until water aspirated is clear.
   c. Attach air/water channel cleaning valve (if available).
   d. Flush water, then air through channels.
   e. For endoscopes containing an elevator channel or auxiliary water channel—flush with water, then air.
   f. Disconnect from unit.
   g. Place water resistant cap to protect electrodes (videoscopes).
   h. Move endoscope to reprocessing room.

B. Leak testing (also see Video 83-2)
   a. Inspect leak tester.
   b. Attach the leak tester to the venting connector.
   c. Immerse endoscope in clean water.
   d. Engage the leak tester and watch for air bubbles for 2 minutes.
      i. The A-rubber at the bending section will enlarge slightly; this is normal.
      ii. If there is a leak at the bending section, deflecting the distal tip under water can increase the success of finding smaller leaks.
      iii. Leaks from the biopsy channel will appear as bubbles emanating from the distal tip.
      iv. If a continuous flow of air bubbles is detected, or a continuous drop in pressure is visualized, stop the cleaning process and call your manufacturer or repair center.
      v. If a leak is detected and repairs must be made, the repair center may require you to continue the cleaning process to avoid cross contamination.
   e. If no bubbles or drop in pressure is seen, release pressure (hand-held) and leave attached to endoscope for 30 additional seconds, ensuring all air is removed.

C. Manual cleaning (also see Video 83-3)
   a. Remove all valves and biopsy port cover.
   b. Use a recommended enzymatic cleaner detergent solution. Dilute according to manufacturer's specifications.
   c. If using an endoscope basin, immerse the scope.
   d. Thoroughly wipe down all external surfaces. Use a soft brush to clean within the ridges of the control knobs and elevator channel opening if applicable. Clean the distal tip and remove any debris from the air/water nozzle.

e. Insert cleaning brush into suction valve port. Brush from valve port toward the light guide connector until the brush emerges from the suction adapter port. Repeat until clean.
f. Insert the brush from the suction valve port toward the insertion tube until you reach the biopsy port. Angle the brush to enter channel. Repeat until clean.
g. Insert a channel opening cleaning brush into the suction valve port and biopsy port. Care must be taken when inserting the brush into the air water valve port. Debris can be pushed into the channel and an obstruction may occur resulting in repairs.
h. Using clean enzymatic solution, attach the recommended suction cleaning adapter(s) and aspirate cleaning solution through all channels. Observe fluid streaming from all channels, including the air/water channel at the distal tip.
i. Repeat this process with clean water, then air until fluid is removed from endoscope. This prevents dilution or contamination of the high-level disinfectant.
j. Inspect and clean all valves and biopsy port.

D. High-level disinfecting (also see Video 83-4):

a. Use test strip or approved device to ensure the minimum recommended concentration specific to product is used.
b. If using an automated endoscope reprocessing (AER) unit, attach appropriate connections. Start unit as directed.
c. If using a large basin or tub, leave suction cleaning adapter in place to flush product into channels until no bubbles are observed.
d. The duration of contact time with endoscope will vary. Read label instructions for time and temperature variations.
e. Rinse endoscope with water and air. An AER will do this process for you.
f. Flush with 70% isopropyl alcohol to assist in the drying process.
g. Hang scope vertically to dry.
h. Place valves on clean surface to air dry.

Many organizations offer hands-on endoscope training sessions for veterinarians and technicians. For the remainder of this chapter, a gastroscope with 4-way deflection and air/water and suction capabilities will be used in describing care.

Nomenclature

Gastroscopes (Figure 83-1) start out as long hollow tubes. In order to visualize an object, thin filaments (light bundles) drive the light from the guide or terminal end, through the umbilical tube, control handle, insertion tube and finally to the distal tip of the tube. Image bundles travel from the eyepiece to the distal tip. This is the description of a fiberoptic endoscope, or fiberscope. A camera can be attached to the eyepiece allowing the image to be seen on a monitor for easier visualization and group participation. Videoscopes incorporate a video chip behind the objective lens, converting the image to a digital signal transmitted through connection wires to a monitor, eliminating the need for an eyepiece or camera head (indirect visualization) (see ch. 91, 96, 108, and 113).

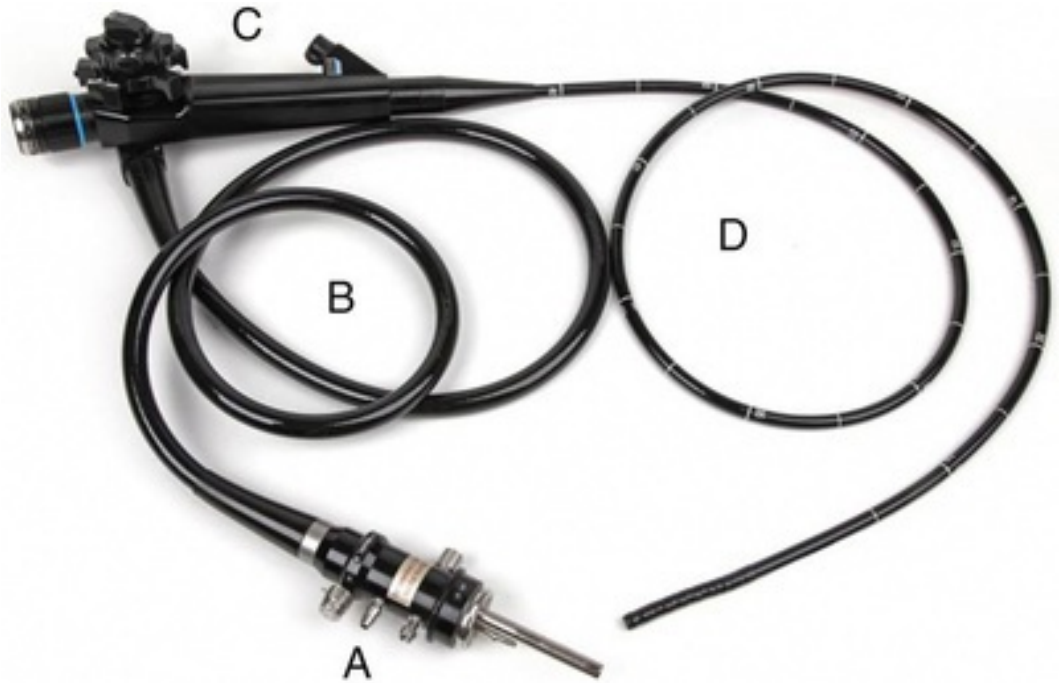

FIGURE 83-1 Sections of a videoscope. **A,** Light guide or terminal end. **B,** Umbilical tube. **C,** Control handle. **D,** Insertion tube.

Insufflation, suction and water capabilities are controlled by 2 valves housed in ports within the control handle. Depressing the top valve (suction) allows for fluid to be drawn into the biopsy-instrument channel and out the suction port at the light guide end. Insufflation from the distal tip occurs when the endoscopist lightly covers the hole at the top of the lower air/water valve (closest to the insertion tube). Water from the bottle attached at the light guide is controlled when the endoscopist depresses the lower valve. The water spray function acts as a clearing mechanism for the objective lens located at the distal tip. Angulation is controlled by thin wires attached to 2 dials on the control handle that connect to a mesh at the bending section (Figure 83-2). These wires act as a pulley system, allowing the distal tip to angulate when engaged. All channels of the endoscope are sealed at endpoints, keeping internal components dry. Water intrusion can cause fiberoptics to become brittle and break. Such breakage causes loss of light and an impaired image (Figure 83-3).

FIGURE 83-2 Bending section of a clear-sheathed demonstration endoscope. Thin wires from the control section **(A)** are attached to the metal mesh **(B)** surrounding the bending section, allowing for angulation of the distal tip.

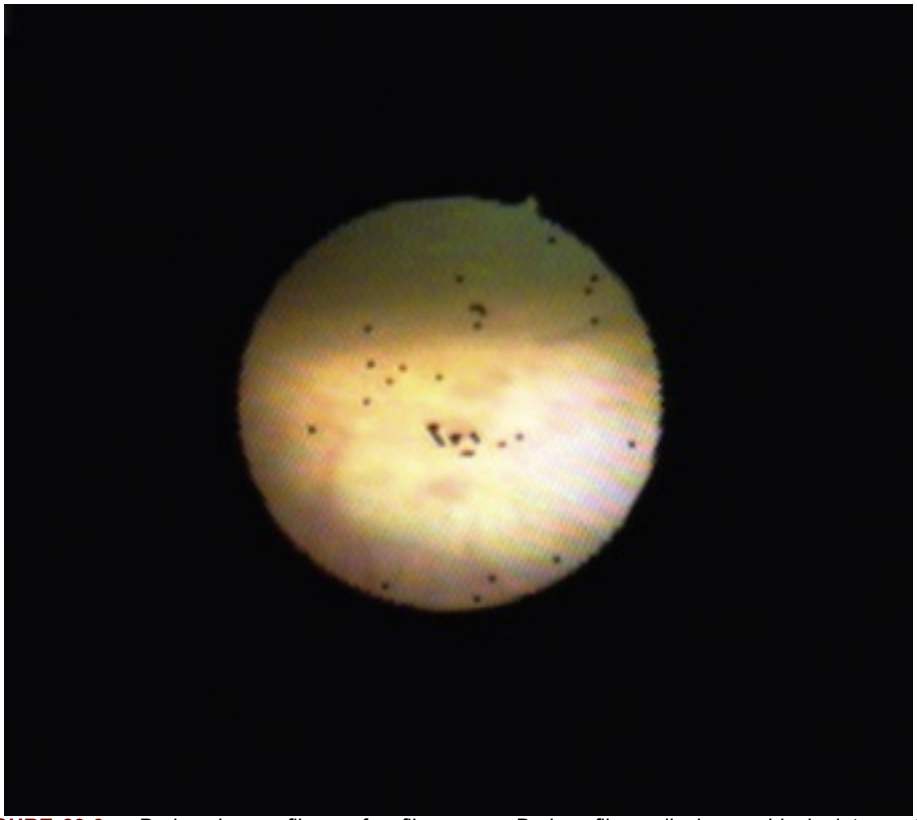

FIGURE 83-3 Broken image fibers of a fiberscope. Broken fibers display as black dots on the

image.

Handling

Endoscopes are typically designed for the control handle to be grasped in the left hand while the right hand continuously holds the insertion tube. The insertion tube should never be moved or twisted independent of the control handle ("torquing"). The "boot" of an endoscope is the junction between the control handle and the insertion tube. Scoping with the "boot" of the endoscope at a 90° angle could damage internal components of the scope. The insertion tube should never be dropped or dragged over sharp objects, such as teeth, when passing the endoscope through the oral cavity. When transporting an endoscope, it should be held with the terminal end and insertion tip in one hand and close to the body, on a cart with sides and sturdy wheels, or in a bin with a tight fitting lid. When not in use, valves should be removed for drying and endoscopes suspended from an endoscope hanger, away from traffic.

Instrumentation

A speculum must always be in place when passing an endoscope through the oral cavity. Use of small sections of cut-off 1 mL syringe barrels can be utilized as a speculum for small dogs and cats.[1] All forceps should be in the closed position before entering the instrument channel. Instrumentation should also be inspected for sharp edges that could damage the channel. Biopsy forceps "wings" should be visible to the endoscopist when extended outside the endoscope before being opened within the patient (Figure 83-4). The instrument channel size determines the outer diameter (OD) of the forceps. For example, endoscopes with a 2.0 mm diameter instrument channel require a 1.8 mm instrument. Length is also a factor. Instrumentation should be 13-15 cm longer than the insertion tube for ease of visualization and movement within the patient.

FIGURE 83-4 Biopsy forceps in a bladder. Note that the wings of the forceps are easily seen before opening the instrument. Deploying in the instrument channel could cause tears leading to water

intrusion.

“Bedside” Testing and Cleaning (Video 83-1)

Testing the endoscope's air, water and suction capabilities before each procedure is done to ensure that all features of the endoscope are functioning. Immediately following each procedure, those functions should be tested again. When flushing the channels, alternate between water and air using an all-channel irrigator valve which replaces the air/water valve.[2] This creates agitation within the channel. If a video endoscope is used, place a protective cap over the electrodes before exposing the endoscope to liquids. The outside of the endoscope, wiped clean of any debris, is transferred to a cleaning station for leak testing and manual cleaning.

Leak Testing (Video 83-2)

Leak testing ensures that the inside of the endoscope is free from water intrusion.[3,4] There are various leak testing devices available (hand-held manometers, automated units). The endoscope should be immersed in clear water for 2 minutes to check for leaks, which appear as air bubbles. The A-rubber (the thin sheath of rubber surrounding the distal tip) should appear slightly inflated when the leak tester is engaged. Bending the distal tip will stretch the A-rubber slightly, allowing for bubbles to appear if the endoscope is compromised. If an endoscope fails a leak test, cleaning should cease and the endoscope dried and sent for repair. Additional cleaning could introduce more fluid and further damage the endoscope.

Manual Cleaning (Video 83-3)

The purpose of manually cleaning endoscopes is to reduce the number of bacteria present before high level disinfection (HLD). Flushing with an enzymatic cleaning solution and brushing accessible channels removes protein-rich material, e.g., blood, tissue. Left in the endoscope, such debris can solidify when combined with HLD solutions, resulting in channel blockage. Manual cleaning should be initiated as soon after use as possible. Biofilm is defined as a group of bacteria that can adhere to endoscope channels and secrete a polysaccharide that cannot be removed with HLD.[4,5] Prompt attention to manual cleaning prevents biofilm formation. Fresh enzymatic cleaning solution should be prepared each time an endoscope is cleaned.[4] Dilution and temperature can alter effectiveness. It is therefore recommended that directions be carefully followed when diluting.

Brushing channels is the next step. Channel brushes must be in good condition, including intact bristles and rounded or covered tips. Some endoscope models have specific brushes for each channel; one should check the manufacturer's guidelines. Brushes should pass out through the channels and be cleaned before removal. Brushing should continue until the brush comes through clean. The brush should be passed straight through —back and forth movement could erode the channel.

The following channels should be brushed:

- Suction valve housing through the umbilical tube and out the suction port at the terminal end
- Suction valve housing through the suction/instrument channel and out the distal tip (angle brush to enter channel)
- Entrance to suction/instrument channel

When brushing is complete, attach the appropriate cleaning adapters and flush the enzymatic solution through channels. Pay particular attention to the appearance of the solution exiting the air/water channel at the distal tip. This channel is too small to brush and can become easily blocked. A forceful sideways stream should be observed. If specified by manufacturer guidelines, allow the endoscope to soak in the solution. Flush with water, then air. Fluid left in channels could dilute the HLD, decreasing its effectiveness. Wipe down the entire endoscope with a soft cloth, with particular attention around control handles and valve housings.

Valves, water bottles and biopsy ports should also be manually cleaned prior to HLD. Pipe cleaners or small brushes are used on the valve stem holes. The hole on the suction valve stem is revealed when depressed. Instrumentation (biopsy forceps, oral speculae) should be similarly cleaned. Wire coil-wrapped forceps should undergo ultrasonic cleaning and steam sterilization.

High-Level Disinfection (Video 83-4)

Overview

Endoscopes have been given a "semi-critical" designation on the Spaulding Classification of Medical Devices and Level of Disinfection. Therefore, endoscopes should receive high-level disinfection after every procedure.[6] A high-level disinfectant (HLD) is defined as a chemical germicide approved by the FDA capable of destroying all viruses, vegetative bacteria, fungi, mycobacteria and most bacterial spores.[3] One study demonstrated that all infections resulting from endoscopic procedures were the result of a breach in cleaning/disinfecting protocols.[7]

There are many types of HLDs on the market (see FDA approved list).[8] Check with the manufacturers' guidelines regarding which HLDs are compatible with their endoscopes. Some solutions are available with a 28-day efficacy. Although these solutions are more practical than the 14-day HLDs, they contain surfactants which can be difficult to rinse away. Temperature variations can also alter the effectiveness of the HDL solution and may require longer soaking times.[3] All solutions should be handled and diluted according to manufacturer recommendations. Test strips that measure maximum effective concentration should be used and logged daily.[3,9] HLDs should be changed if the test strip is negative, even if the end date has not been reached. Protective equipment, such as gloves and face shields, should be worn at all times when working with HLDs. Some HLDs have a noxious odor. Always use the HLDs in a well-ventilated area or under a fume hood.

HLDs can be used with endoscopes for manual disinfection or with an automated endoscope reprocessor (AER).

Manual Disinfection

Use a basin with a tight-fitting lid to prevent splashing. Immerse the entire endoscope in the HLD. Attach a 60 mL syringe filled with the HLD solution to the all-channel irrigator port(s); flush until all channels are in contact with the HLD solution, and no air bubbles are seen. Also include all accessory instrumentation, including mouth speculae, water bottles, cleaning brushes and valves. Cover the basin and allow the endoscope to remain in the HLD for the recommended exposure time. When the end of the soaking time has been reached, gently flush the endoscope with air to purge the HLD from the channels and remove. Flush the endoscope with water for the time period recommended by the manufacturer.

Drying the endoscope can be as important as manual cleaning and high-level disinfection.[10] Inadequately dried endoscopes can become a source of contamination. First, flush channels with 60 mL of 70% isopropyl alcohol to facilitate the drying process. Dry all endoscope channels with forced air or adapt the suction unit to fit the all-channel irrigator. Hang on an endoscope hanger with all ports open (Figure 83-5). Also remove, rinse and dry all accessory instrumentation.

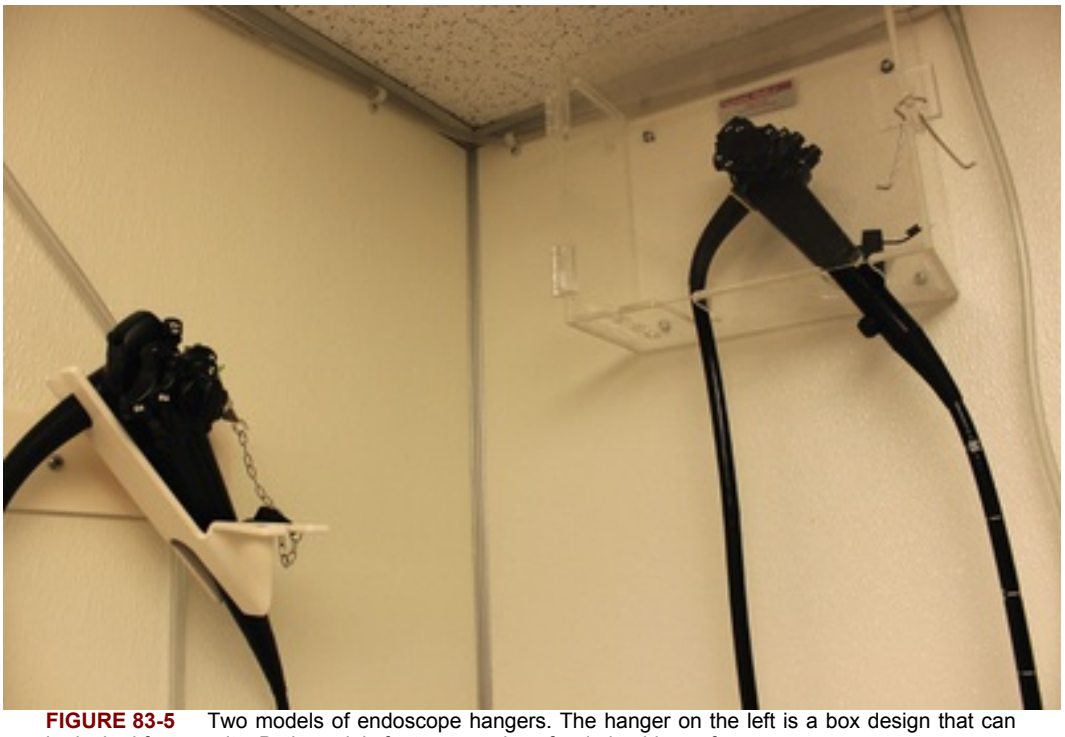

FIGURE 83-5 Two models of endoscope hangers. The hanger on the left is a box design that can be locked for security. Both models feature openings for drying biopsy forceps.

Automated Endoscope Reprocessor

For a busy practice that utilizes endoscopes on a daily basis, an automated reprocessor may be indicated. Advantages over manual disinfection include decreased personnel exposure time to HLDs, and consistent temperature and time controls. Reprocessors do not take the place of manual pre-cleaning.

The endoscope is connected to the reprocessor through the all-channel irrigator. A full cycle includes enzymatic solution flush, de-ionized (DI) water flush, HLD circulation, and final DI water flush. An air flush completes the process. An alcohol flush port is also included. Accessory instrumentation can be placed inside the unit as well. Sharp objects such as dental probes should be processed separately as they could shift in the basin and pierce the endoscope. The endoscope should be wiped off with a soft cloth, air-dried and placed on an endoscope hanger.

Endoscope Storage

Endoscopes should be stored vertically on endoscope hangers (see Figure 83-5). When stored in cases, moisture left in the channels can harbor bacteria. The exception to this are fragile ultrathin endoscopes, which are dried thoroughly and kept in cases. Endoscopes should be stored high enough so the distal tip does not touch the floor.

Documentation

Endoscopy reports often include a short history, the procedure performed, the endoscope used, and the features of interest (see ch. 113). A video/image log documents a brief description of each figure and endoscope used. A damage log may be kept for each endoscope in the inventory and include the personnel involved, procedure performed and date of repair and return. Damage logs can track trends and can pinpoint corrections that can be implemented to keep the endoscope in working order. Material Safety Data Sheets (MSDS) for HLDs and enzymatic solutions should be readily available.

E-Box 83-1 reviews the aforementioned techniques and provides a reference guide to cleaning and disinfecting a gastroscope.

CHAPTER 84

Hyperbaric Medicine

Melissa L. Edwards

Client Information Sheet: Hyperbaric Oxygen Therapy

History

Hyperbaric medicine is the use of pressure (greater than 1 atmosphere absolute [ATA]) (Box 84-1) in the treatment of disease. It dates back to the mid 1600s. The discovery of oxygen in 1775 by John Priestly had a profound effect on hyperbaric medicine.[1] References to the use of hyperbaric oxygen in animals can be traced back to a study in rabbits in 1887.[2] The practice of modern hyperbaric medicine began around the mid 1950s[3] and typically involves the patient breathing >21% oxygen while under pressure, referred to as hyperbaric oxygen therapy (HBOT). This chapter will primarily discuss HBOT as the hyperbaric medical intervention most commonly practiced today.

Box 84-1

Pressure Conversions

1 atm = 101.3 kPa = 14.7 psi

Atmosphere absolute (ATA) = atmospheric pressure (atm) + gauge pressure (converted to atm)

atm, Atmospheres; *kPa,* kilopascals; *psi,* pounds per square inch.

Physiology

There are two primary effects of HBOT and several secondary effects. The first, primary mechanical effects of pressure, account for HBOT's effect on bubbles and gas-containing cavities within the body. As pressure increases the volume of gas decreases (Boyle's law) in addition to increasing solubility, which enhances resorption and elimination of gases (Henry's law) such as nitrogen. This is the primary reason for its use in conditions such as decompression sickness (bends),[4] and gas embolism as a procedural or surgical complication.[5] In cases such as bowel ileus with significant distention, where other treatment options have been unsuccessful, these effects would also be beneficial.[6] A recent study in humans suggested that in some conditions hyperbaric air may be just as effective as HBOT,[7] which would indicate an additional direct pressure effect. The mechanical effects are also responsible for barotrauma complications that can be associated with hyperbaric treatments discussed later.

The second primary effect of HBOT is increased oxygenation of plasma and ultimately tissues. The dissolved oxygen in plasma is the most bioavailable. Theoretically 100% oxygen delivered at 3 ATA can dissolve enough oxygen in plasma to meet normal resting oxygen requirements of the body without hemoglobin.[8] The increased concentration of oxygen in the plasma increases the driving force to help deliver oxygen to compromised tissues as it increases the rate and depth of diffusion (Fick's law). Oxygen is a necessary part of cellular function and its delivery can be compromised due to injury or illness. At the same time the oxygen demands of those tissues may be increased, further damaging the cells if sufficient oxygen cannot be obtained. The delivery of oxygen to cells can be affected by many factors including anemia, toxin exposure, decreased blood flow (hemorrhage, thromboembolism) and inflammation or edema since oxygen is more soluble in lipid than water. Blood and tissue oxygen tensions not only increase during HBOT but have

been shown to remain elevated for over an hour after.[9] Hyperoxygenation is the primary mechanism in the treatment of such conditions as severe anemia, carbon monoxide (CO) poisoning and compromised surgical grafts and flaps.[10] In CO poisoning, the increased oxygen tension helps dissociate CO from hemoglobin[11] as well as mitigating mitochondrial oxidative stress while this is occurring.[12]

Hyperbaric oxygen therapy has several secondary effects. These include vasoconstriction, antimicrobial effects, anti-inflammatory and immunomodulatory effects as well as neovascularization. In healthy tissue, vasoconstriction occurs to limit the effect of hyperoxia; however, oxygen delivery is maintained because of the higher plasma oxygen concentration. In compromised tissue, on the other hand, this vasoconstrictive effect is blunted, allowing increased oxygen delivery to compromised tissue. Cellular energy is preserved to inhibit swelling and edema formation[13] and may be due in part to HBOT's effect on nitric oxide production helping to maintain vascular responsiveness as noted in a septic shock model.[14,15] This can also decrease vasogenic edema and intracranial pressure (ICP) via decreased brain blood flow and blood-brain barrier permeability.[16,17]

Increased oxygen levels can have direct and indirect antimicrobial effects. Direct effects (both bactericidal and bacteriostatic) are not just seen in anaerobic infections,[18,19] they can also be effective in fungal infections as well as inhibiting some bacterial toxin formation.[20] Indirect antimicrobial effects arise from the maintenance of oxidative killing mechanisms in leukocytes and enhanced neutrophil phagocytic activity.[21] HBOT has also been shown to have synergistic effects with some antibiotics.[18]

It may seem counterintuitive, but many of the anti-inflammatory and immunomodulatory effects of HBOT are due in large part to the increased production of reactive oxygen species (ROS) and reactive nitrogen species (RNS).[22,23] The reactive species lead to increased growth factor production, stem and progenitor cell mobilization, decreased neutrophil adhesion and sequestration, modulation of chemokine production and enhanced reactive species scavenging.[22] Increased growth factor production and stem/progenitor cell mobilization lead to neovascularization and the effects HBOT has in many wound healing applications such as dermal wounds,[24] burns[25] and bone healing.[26] The neovascularization further improves oxygen delivery stimulating fibroblast proliferation and collagen production[27-32] which promotes ongoing wound repair. In ischemic, reperfusion and inflammatory conditions the modulation of macrophages and neutrophils can decrease further tissue damage and hypoxia locally as well as systemically. In addition to these anti-inflammatory effects, HBOT is also immunomodulatory via several mechanisms including major histocompatibility complex protein alterations,[33] interleukin 10^{11} and tumor necrosis factor alpha expression.[34]

Indications

Many of the same conditions exist in our veterinary patients as in humans so our veterinary use of HBOT is often based on the accepted human indications with the understanding that many of these were established from animal research models. HBOT use in human medicine can vary by organization and country but generally includes 14 well-accepted indications with decompression sickness and idiopathic sudden hearing loss being less relevant in veterinary medicine. Table 84-1 is a list of the remaining indications that are accepted by the Undersea and Hyperbaric Medical Society[35] and the mechanisms of action. As HBOT becomes more widely available in veterinary medicine pet insurance plans are beginning to cover it as a recognized primary and adjunctive therapeutic option similar to the insurance coverage in human medicine for these accepted conditions. As research continues, additional conditions may be found that benefit from HBOT. A list of some of these potential conditions is found in Table 84-2 along with the proposed mechanisms of action.

TABLE 84-1

Veterinary Applicable Indications from Accepted Human Sources[35]

ACCEPTED INDICATIONS	MECHANISM
Air or gas embolism	Hyperoxygenation Decreased gas bubble size

	Inflammatory modulation
Toxicities (carbon monoxide, cyanide)	Hyperoxygenation (carbon monoxide washout, ischemia) Inflammatory modulation
Clostridial myositis and myonecrosis	Antimicrobial Antibiotic synergy Toxin inhibition
Crush injury/compartment syndrome Acute traumatic ischemias	Hyperoxygenation Vasoconstriction Inflammatory modulation
Arterial insufficiencies (central retinal artery occlusion, select problem wounds)	Hyperoxygenation Angiogenesis Inflammatory modulation +/− Antimicrobial
Severe anemia	Hyperoxygenation Immunomodulation
Intracranial abscess	Antimicrobial Decreased edema Antimicrobial synergy
Necrotizing soft tissue infections	Antimicrobial Hyperoxygenation Inflammatory modulation Antimicrobial synergy
Osteomyelitis (refractory)	Hyperoxygenation Antimicrobial Antibiotic synergy Enhanced osteogenesis
Delayed radiation injury (soft tissue and bone)	Neovascularization Inflammatory modulation Stem cell mobilization
Compromised grafts/flaps	Hyperoxygenation Neovascularization Vasoconstriction/decreased edema
Acute thermal burn injury	Hyperoxygenation Vasoconstriction/decreased edema Neovascularization Inflammatory modulation Antimicrobial

TABLE 84-2

Other Potential Applications for HBOT

OTHER POTENTIAL CONDITIONS	PROPOSED MECHANISM
Envenomations (snake bite, brown recluse spider)	Hyperoxygenation Vasoconstriction/decreased edema
Other infections (aerobic, anaerobic, fungal, hepatic abscess, peritonitis, pyothorax)	Hyperoxygenation Antimicrobial Antimicrobial synergy
Sepsis	Hyperoxygenation Antimicrobial Inflammatory modulation

Tetanus	Antimicrobial Decreased toxin production
Lyme disease	Immunomodulatory +/− Antimicrobial (>2.4 ATA)
Asphyxia (birth, near hanging, near drowning)	Hyperoxygenation Vasoconstriction/decreased edema Inflammatory modulation
Bone healing (fracture, grafts)	Hyperoxygenation Neovascularization
Post cardiopulmonary arrest	Hyperoxygenation Vasoconstriction/decreased edema Inflammatory modulation
Ileus	Decreased gas bubble size and clearance
Pancreatitis	Hyperoxygenation Vasoconstriction/decreased edema Antimicrobial Inflammatory modulation
CNS injury (IVDD, traumatic brain injury, vascular events [stroke, FCE], degenerative myelopathy, vestibular disease)	Hyperoxygenation Vasoconstriction/decreased edema Inflammatory modulation
Immune-mediated disease (IBD, IMHA)	Immunomodulatory
Myocardial contusions	Hyperoxygenation Inflammatory modulation
Perianal fistulas	Hyperoxygenation Immunomodulatory Antimicrobial Neovascularization
Acute frostbite	Hyperoxygenation Vasoconstriction/decreased edema
Immediate post-operative swelling, compromised tissue (GDV, FB, wounds)	Hyperoxygenation Vasoconstriction/decreased edema
Thromboembolic disease	Hyperoxygenation Inflammatory modulation
Sports injuries	Hyperoxygenation Inflammatory modulation

ATA, Atmosphere absolute; *CNS*, central nervous system; *FB*, foreign body; *FCE*, fibrocartilaginous embolism; *GDV*, gastric dilation-volvulus; *IBD*, inflammatory bowel disease; *IMHA*, immune-mediated hemolytic anemia; *IVDD*, intervertebral disk disease.

Contraindications

Although the only absolute contraindication for HBOT is untreated pneumothorax, other conditions necessitate critical evaluation of the risks versus benefits before making a final treatment decision. Some of these relative contraindications include asthma, pulmonary bulla, history of thoracic or otic surgery, uncontrolled high fever (may potentiate oxygen induced seizures), poorly controlled seizure disorder, pregnancy (fetal effects are unknown), upper respiratory infection, pacemaker (ensure device has been pressure-tested and at what depth) and anxiety that may preclude treatment. These contraindications are primarily to limit known side effects of barotrauma and oxygen induced seizures. Medications or other

interventions may be able to mitigate some of these conditions allowing HBOT.

Complications

The complications associated with HBOT are generally related to barotrauma (middle ear, sinus, pulmonary), the toxic effects of oxygen (seizures, oxidative stress, pulmonary oxygen toxicity), and decompression sickness. These complications are infrequent and with careful patient evaluation prior to prescribing HBOT, monitoring during therapy and knowledge about the physiology and mechanisms of action of HBOT, veterinary practitioners can maintain HBOT as a relatively safe therapeutic option.

Equipment and Safety

There are 3 main types of chambers currently in use in hyperbaric medicine, low pressure (typical working pressure of 1.2-1.4 ATA) monoplace chambers, high pressure (typical working pressure of 2-2.5 ATA) monoplace chambers and high pressure multi-place chambers. The high pressure monoplace chambers are most often used in veterinary medicine at this time with veterinary specific models available. These chambers typically use oxygen as the compressive gas, unlike the low pressure and multi-place chambers that use air for compression, and have the patient breathe supplemental oxygen if prescribed. The low-pressure chambers are still relatively new by comparison and differences in therapeutic efficacy have not been studied.

There are some safety considerations when working with high-concentration oxygen in a pressurized environment including the risk of spontaneous combustion and explosion hazards. These situations are rare but certain safety precautions can help to mitigate them including patient and chamber grounding, ensuring that no exposed metal or high static fabrics are allowed in the chamber, and no electrical devices or flammable materials such as oil-based products are allowed in the chamber. In 2011 a veterinary certified hyperbaric technologist training and certification program was instituted through the National Board of Diving & Hyperbaric Medical Technology in conjunction with the Veterinary Hyperbaric Medical Society to further the safety and quality of veterinary hyperbaric medicine.[36]

Treatment Protocol (Dive)

There is currently no consensus on treatment protocols for HBOT. Typical recommendations in human and veterinary medicine are for 1-2 hour dive sessions (including compression and decompression) with 100% inspired oxygen at 1.5-3 ATA, 1-3 times daily, with a minimum of 4 hours between dive sessions to minimize the chance of oxygen toxicity. In acute conditions and toxicities, like gas embolism and carbon monoxide poisoning, timing may be very important and HBOT should be initiated as soon as possible. Treatment plans vary depending on the condition being treated and the tolerance of the patient, but in this author's experience begin with 1 hour treatments at 2 ATA twice daily in acute conditions until significant clinical improvement has been made, then decreased to once daily and 2-3 times weekly in more chronic conditions. Envenomation often only needs 1-2 treatments for clinical effect.

Treatments are generally well tolerated by veterinary patients based on their willingness to repeatedly enter the chamber and how relaxed they appear during the treatment. Anxious patients can be given a mild sedative including narcotics, benzodiazepines or acepromazine if needed to facilitate treatments. Discontinuation of a treatment may be necessary if distress is noted during a dive.

Summary

Hyperbaric oxygen chambers are increasing in availability in veterinary medicine. HBOT, as a primary therapy or adjunct to other standard therapies, should be considered in disease conditions where its use has been shown to be beneficial. Understanding the physiologic effects of HBOT will also guide treatment in non-accepted conditions and further research to aid in expanding the scope of indications for its use. Pursuit of the recently developed certified hyperbaric technologist–veterinary credential by those involved in administering HBOT will help increase the appropriate, efficacious and safe use of this treatment modality.

CHAPTER 85

Otoscopy, Ear Flushing, and Myringotomy

David Stephen Sobel

When one considers the more common presentations by small animal patients to general practitioners, aural disease is at or near the top of the list. Clinical signs related to aural disease often are easy for owners to observe, frequently are dramatic in their presentation, often negatively impact the patient's quality of life, and can become chronic, with long-term adverse consequences. Fortunately, aural disease usually is readily diagnosed and, with appropriate and timely intervention, it is one of the more rewarding groups of diseases to treat in small animal practice (see ch. 237).[1-4]

To this end, minimally invasive surgery and diagnostic methods, especially otoendoscopy, have tremendous utility in both general practice and referral settings. Both diagnostic and therapeutic techniques are simple to learn and to perfect, and present the sort of utility that makes the associated time and financial investments tremendously worthwhile.[5]

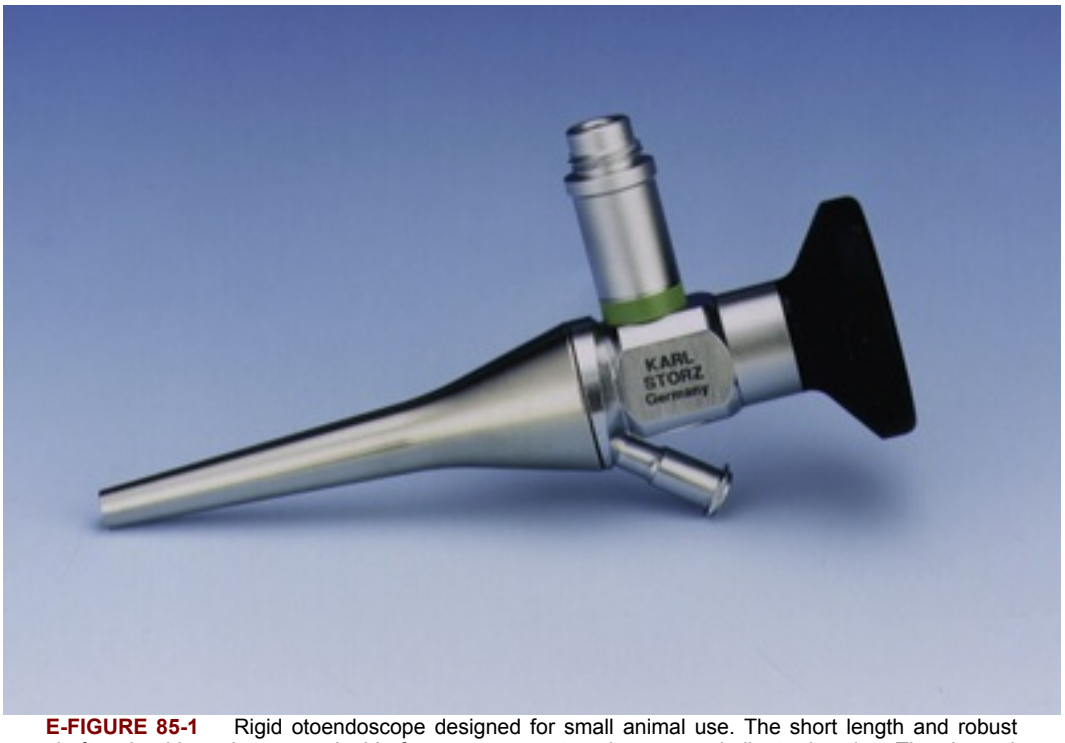
While small animal practitioners have been well accustomed to using hand-held otoscopes as a diagnostic tool for decades, modern endoscopic equipment and techniques enable the veterinarian to enjoy dramatically improved visualization of aural structures. Additionally, the modality offers the opportunity to document, monitor, and categorize a patient's disease and the progress made in management. Perhaps most importantly, the ability to intervene therapeutically is markedly enhanced with minimally invasive surgical (MIS) techniques.

Indications

Otoendoscopy is of great utility in differentiating diseases of the outer or external ear (e.g., otitis externa) and its adnexa, from diseases of the tympanum and middle ear (e.g., otitis media). Common clinical signs of aural disease include foul aural odor, head shaking, aural discharge, pain on palpation of the pinna and external aural structures, pawing at the head, and hearing loss. Less commonly, owners may observe anorexia or dysphagia, ataxia and balance problems, and the presence of abnormal resting nystagmus. Careful physical exam can reveal peripheral neurologic signs and cranial nerve anomalies (see ch. 259).

Equipment

Generally, equipment includes a video monitor, a medical-grade endoscopic video camera, an otoendoscope, a light source, and accessories. Most purpose-engineered single-piece otoendoscopes have a single portal to which a bridge can be attached to allow for irrigation and insertion of accessory instrumentation. Alternatively, a small-diameter, multipurpose rigid endoscope can be used; they generally are smaller in diameter and are housed in a removable protective sheath, with multiple ingress ports for fluids and instrumentation (E-Figures 85-1 to 85-3). Optionally, the kit includes mechanized irrigation/suction apparatus, devices to record procedure and store images, and a surgical energy source for electrosurgery, radiosurgery, and/or laser (E-Figures 85-4 and 85-5).



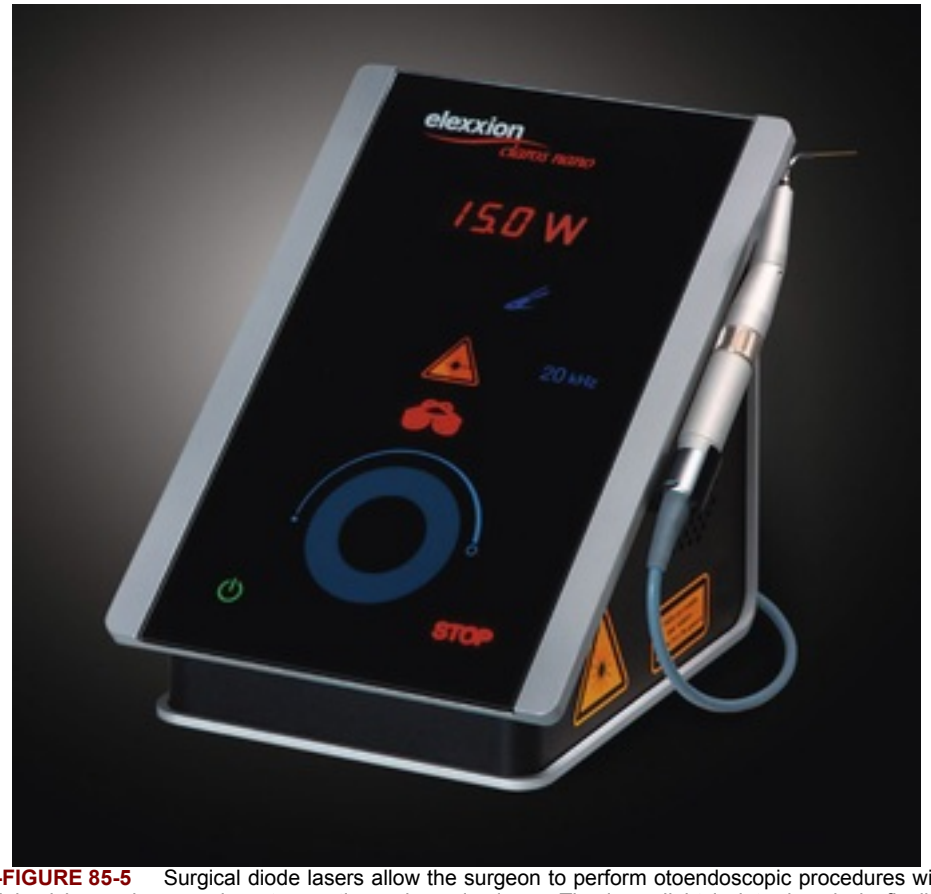
E-FIGURE 85-1 Rigid otoendoscope designed for small animal use. The short length and robust shaft make this endoscope valuable for exam room otoendoscopy and client education. The channel allows for introduction of instrumentation or irrigation/aspiration. (Image courtesy KARL STORZ GmbH & Co KG.)

E-FIGURE 85-2 Rigid otoendoscope and camera. The addition of a high quality endoscopic camera allows for improved ergonomics in otoendoscopy as well as improved visualization and magnification. (Image courtesy KARL STORZ GmbH & Co KG.)

E-FIGURE 85-3 The 2.7 mm 30-degree rigid endoscope set can be used for a variety of companion animal endosurgical procedures, including otoendoscopy. The length allows for excellent access to the horizontal canal and tympanum in even the largest of patients with a variety of accessory instrumentation to facilitate therapeutic and diagnostic intervention. (Image courtesy KARL STORZ GmbH & Co KG.)

E-FIGURE 85-4 Mechanical instrumentation for irrigation and aspiration makes deep ear flushing far more efficient and expedient. This device combines a suction pump and an irrigation pump (with variable pressure). Using the bi-valved handpiece, the operator can perform the ear flushing through a small bore catheter or via the endoscope instrument channel. (Image courtesy KARL STORZ GmbH &

Co KG.)



E-FIGURE 85-5 Surgical diode lasers allow the surgeon to perform otoendoscopic procedures with minimal hemorrhage and post-operative pain and edema. The laser light is introduced via flexible quartz fibers available in a variety of diameters and shapes. Shown is a 15W 810 nm surgical diode. (Photo courtesy Elexxion AG.)

Clinical Anatomy

The external ear can be delineated by the external pinna, to and including the vertical canal. This includes the pinna, the cartilaginous support structures of the adnexa, and the vertical canal. By definition, the tympanum is considered the terminus of the external ear and the beginning of the middle ear. There are notable species and breed differences of the morphology of the external ear, which affect the length of the vertical canal and the angle of the junction of the vertical and horizontal canals. The beginning of the vertical canal generally is identified by the intertragic notch, separating the cranial and caudal cartilaginous ridges. The intertragic notch is a helpful anatomic landmark for the endoscopist in mapping out the presence of lesions in the vertical canal. The epithelial surface of the vertical canal is squamous and secretory, with an increase in ceruminous (modified sebaceous) glands as the vertical canal extends to the horizontal canal to the tympanum. Hair follicles generally are confined to the proximal portions of the vertical canal, but can exist to the level of the tympanum. The presence of hair is often related to breed or somatotype. A ridge of firm, minimally compliant cartilage can serve as a landmark between the vertical and horizontal canal, but depending on breed and somatotype, this landmark can be indistinct. Patients with an acute horizontal-vertical canal angle can prove a challenge to the beginning endoscopist. Patients with a less acute angle, including cats and brachycephalic dogs, have a horizontal canal that is easier to navigate and, as such, a tympanum that is more readily visualized.

The tympanum is a thin, glistening membrane at the terminus of the horizontal canal. In the normal ear, its pars flaccida is visualized dorsolaterally and, in most dogs, will account for approximately one third of the visible field. The pars tensa occupies the ventral two thirds of the visible tympanum. It tends to be the portion

of the tympanum most commonly observed as ruptured in cases of otitis media. In patients with a normal, lucent tympanum, a ventral bony ridge separating the tympanic cavity from the bulla can be seen. Caudodorsally, the manubrium of the malleus in the middle ear often can be seen through the tympanum. Frequently, when the tympanum is diseased, its opacity limits visualization of these landmarks. Severe middle ear disease can produce marked bulging of the tympanum, notable in the pars flaccidum, and demonstrative of fluid in the middle ear. Should the pressure compromise the integrity of the tympanum, it is most commonly the pas tensalis that is the first portion breached. However, in patients with tympanic rupture due to underlying middle ear disease, it often is difficult to differentiate the individual portions of the tympanum. When the tympanum is ruptured, either due to middle ear disease or iatrogenically, careful cleaning and suction/irrigation can reveal the middle ear structures (Figure 85-6).

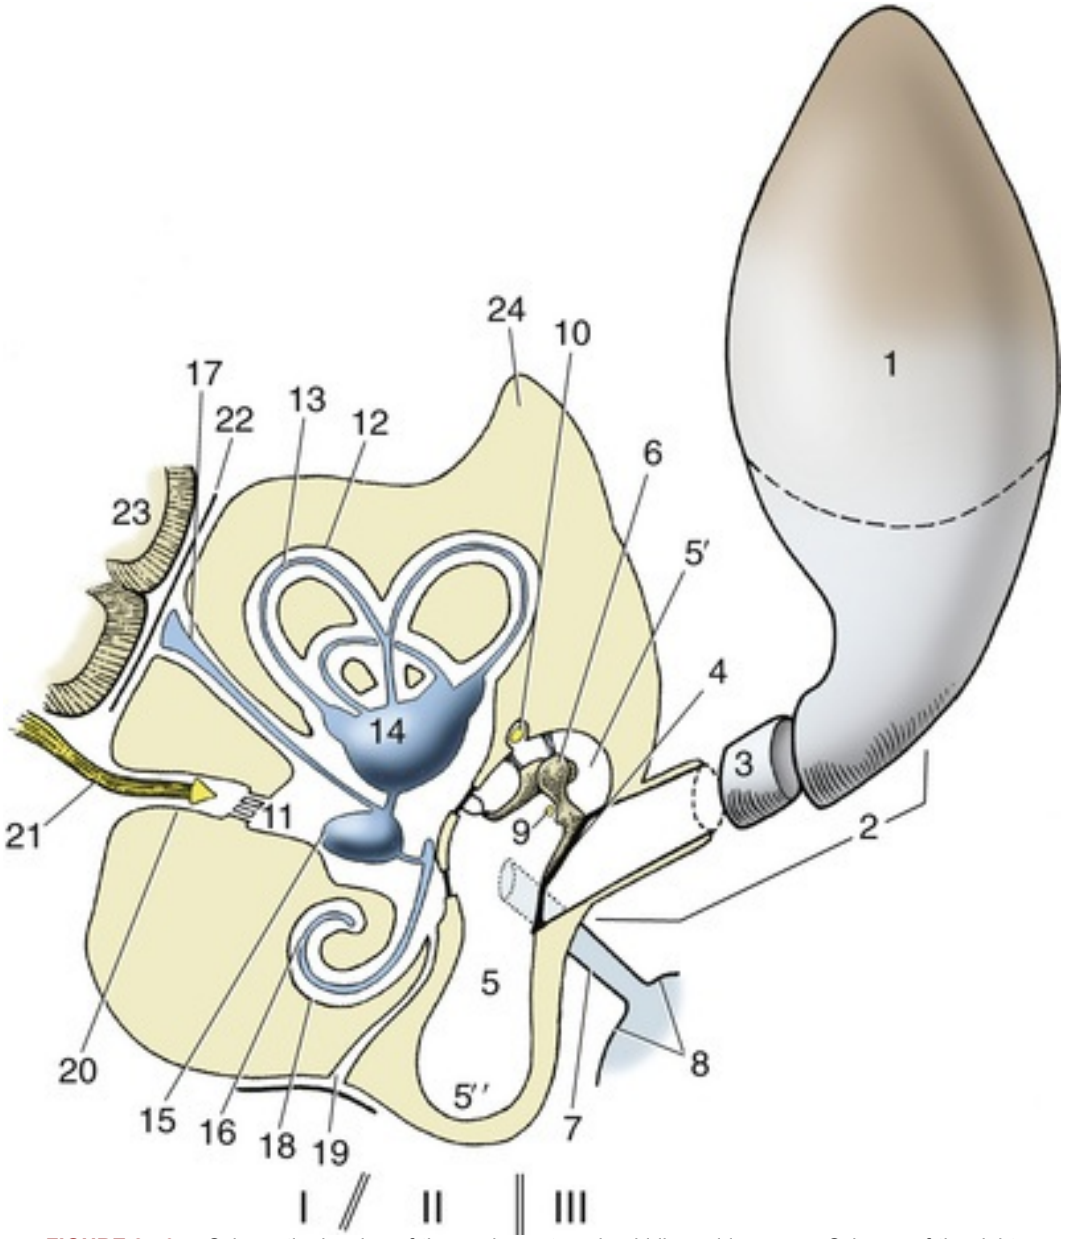


FIGURE 85-6 Schematic drawing of the canine external, middle and inner ear. Schema of the right ear, caudal view. Note that the sizes of the structures shown are out of proportion to each other. *I,* Internal ear; *II,* middle ear; *III,* external ear. 1, Auricle; 2, external acoustic meatus; 3, annular cartilage; 4, tympanic membrane; 5, tympanic cavity; 5′, epitympanic recess; 5″, tympanic bulla; 6, auditory ossicles; 6′, malleus; 6″, base of stapes in vestibular window; 7, auditory tube; 8, nasopharynx; 9, chorda tympani; 10, facial nerve; 11, vestibule; 12, semicircular canals; 13, semicircular ducts; 14, utriculus; 15, sacculus; 16, cochlear duct; 17, endolymphatic duct; 18, cochlea; 19, perilymphatic duct; 20, internal acoustic meatus; 21, vestibulocochlear nerve in internal acoustic meatus; 22, meninges; 23, brain; 24, petrous temporal bone. Saunders.)

Otoendoscopic Exam

A complete history, physical examination, and preoperative diagnostic workup are essential first steps (see ch. 237). Premedication should include an opioid drug for analgesia. General anesthesia is induced via protocols based on patient risk profile, practitioner preference, and duration of the procedure. The patient is intubated and maintained under inhalant anesthesia.

Otoendoscopy is best performed on a "wet table" or surgical sink to reduce fluid pooling. Lateral recumbency, with the ear of interest on the nondependent side, is preferred to sternal recumbency for an easier, more complete examination. The endoscopic equipment cart is placed near the ventral aspect of the patient. The operator stands on the dorsal-facing side, near the patient's shoulder. The monitor is placed cranial to the patient, facing the operator. This allows the operator to hold the endoscope in a neutral position relative to the head, and for the monitor to display structures in an anatomically correct orientation (E-Figure 85-7).

E-FIGURE 85-7 Otoendoscopy is performed in a canine patient using a rigid otoendoscope and a mechanical irrigation and aspiration device. The flushing procedure is done via the instrument channel of the endoscope using a tomcat urinary catheter to accurately direct irrigation and aspiration.

For irrigation, an IV fluid bag and standard IV administration set are connected to the ingress port of the endoscope. Gravity flow is usually adequate, but manual pressure, a "squeeze bag," or a fluid pump can be used for increasing the rate and pressure of fluid flow. An irrigation/aspiration pump also is employed. The fluid should be non-ototoxic, and should be clear and free of dextrose. Appropriate choices include normal saline, lactated Ringer's solution, and other isotonic crystalloids (e.g., Normosol-R).[6,7]

For examinations on awake or sedated patients, clean, disinfected equipment can be used. However, if surgical intervention is planned, all equipment should be sterilized according to manufacturer's instructions.

Much endoscopic equipment is not safe for steam/heat sterilization methods, and either "cold soak" sterilizing fluids (such as glutaraldehyde-containing products) or ethylene oxide gas must be employed. Equipment sterilization is essential if the procedure involves obtaining samples for microbial culture.

For an otoendoscopic exam on an anesthetized patient, the procedure begins with a visual, open endoscopic examination of the visible portions of the pinna. If there is substantial ceruminous otic debris obscuring visualization, a standard ear cleaning is advised prior to attempting otoendoscopy. In all cases where culture samples are to be taken, sample collection should be performed prior to more invasive aural procedures. If bacterial cultures of the vertical or horizontal canals are to be taken, instrumentation must be prepared in strict aseptic manner to minimize the possibility of contamination of samples submitted to the laboratory. Culture of aural exudate should be taken as early as possible in the examination procedure, to minimize the risk of contamination from superficial flora being flushed into the ear canal. Samples for culture and for cytology can be retrieved via flush, directly with a culturette, or sampling the material with a grasping forceps.[8]

The operator assembles the endoscope, camera, light guide cable, irrigation fluid, and associated accessories and holds the endoscope in his or her dominant hand. The pinna is gently grasped in the nondominant hand and gently pulled laterally and very slightly caudodorsally. The endoscope is introduced into the vertical canal, slowly and gently, at an angle of ≈90° to the patient's skull. The flow of irrigant is begun, slowly and with minimal pressure at first, allowing for the gentle dislodging and evacuation of adherent ceruminous material. The bottom (medialmost aspect) of the vertical canal is visualized, and the otoendoscope is tilted to reveal the horizontal canal, with visualization of the tympanum in the far field. Care must be taken to avoid excessive torsion or bending of the shaft of the endoscope as the horizontal canal is entered, to avoid both iatrogenic injury and equipment damage.[9-12] If a biopsy is to be taken, a complete aural examination should be performed first because post-biopsy hemorrhage complicates visualization.

Deep Ear Cleaning/Aural Flushing

A deep cleaning is indicated if there is marked aural discharge that suggests disease of either the horizontal canal or middle ear. Essentially, a deep ear cleaning is a continuation of the irrigation performed with a standard otoscopic examination. If the volume of exudate necessitates a more aggressive cleaning, increased irrigation pressure will likely be needed, using pressure on the bag, or a pump (see Otoscopic Exam, above). Ideally, a mechanized suction/irrigation pump can be employed to allow for intermittent lavage followed by suction to expedite cleaning of the ear canal.[13,14] Purpose-made lavage catheters can be purchased, or a polypropylene tomcat catheter can be employed, cut to a manageable length. Purpose-made catheters are introduced via the instrument channel of the otoendoscope, offering the operator excellent visualization of the endoscopic field and an ability to monitor progress of the lavage. Lavage solutions should be the same as those used for the standard otoendoscopic exam. The use of ceruminolytic or ototoxic solutions should be avoided if the tympanum is compromised or its integrity is uncertain.

Excision of Aural Masses

Diode laser fibers in various diameters can be used via the instrument channels of otoendoscopes to ablate, debulk, vaporize, or resect aural masses (Video 85-1). This author favors the use of an 810 nm wavelength diode at powers ranging from 4-8 W. Each laser has unique properties necessitating effective and safe protocols for each device; this wavelength of laser light provides excellent tissue vaporization and cutting in a fluid medium, and is very effective in the presence of blood, providing excellent hemostasis and helping to maintain a continually visible surgical field. While it is unlikely that laser excision or vaporization provides clean surgical margins in aggressive neoplastic lesions, the device has significant utility in removing a variety of common mass lesions of the ear canal[15,16] (Figures 85-8 and 85-9). Ear masses and other diseases of the ear are discussed further in ch. 237.

FIGURE 85-8 Otoendoscopic view of an aural mass in a canine patient. The mass was determined to be arising from the ventral floor of the horizontal ear canal, adherent to the pars tensalis of the tympanum. Removal necessitated a small myringotomy along the ventral edge of the pars tensalis. The mass was determined via histopathology to be a benign lymphoplasmacytic polyp.

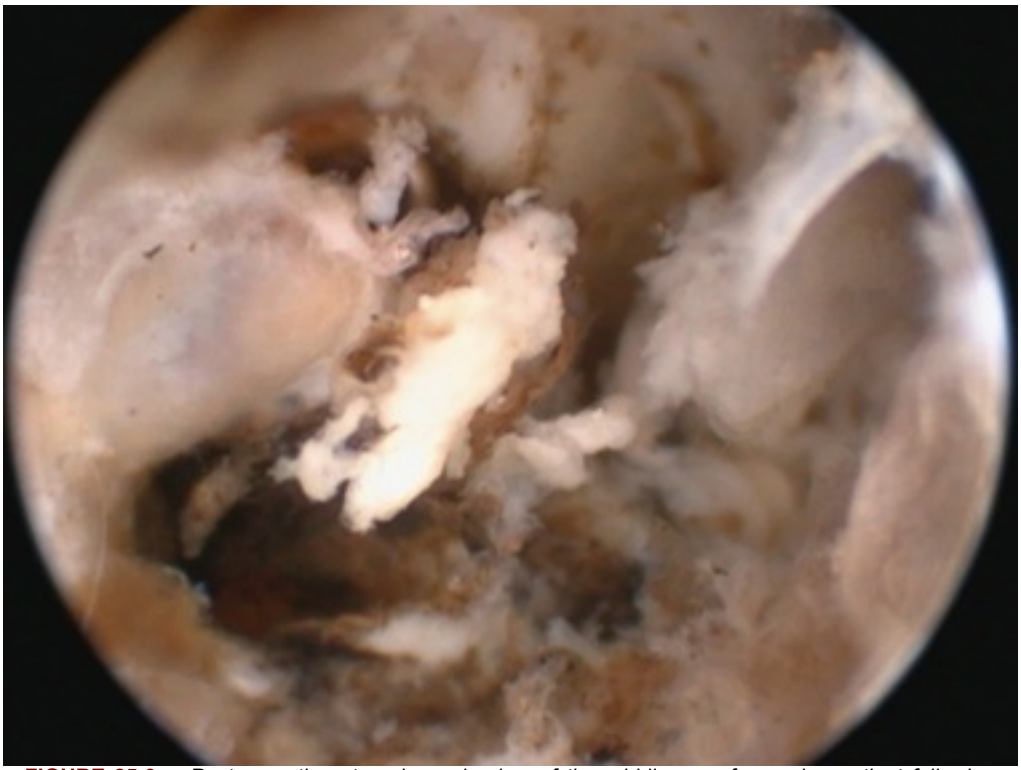

FIGURE 85-9 Post operative otoendoscopic view of the middle ear of a canine patient following laser endoscopic resection of an aural mass arising from the middle ear and extending into the tympanic bulla. A large portion of the tympanum was incised to allow for adequate exposure of the lesion, with evident damage to the ossicles. This lesion was determined via histopathology to be of

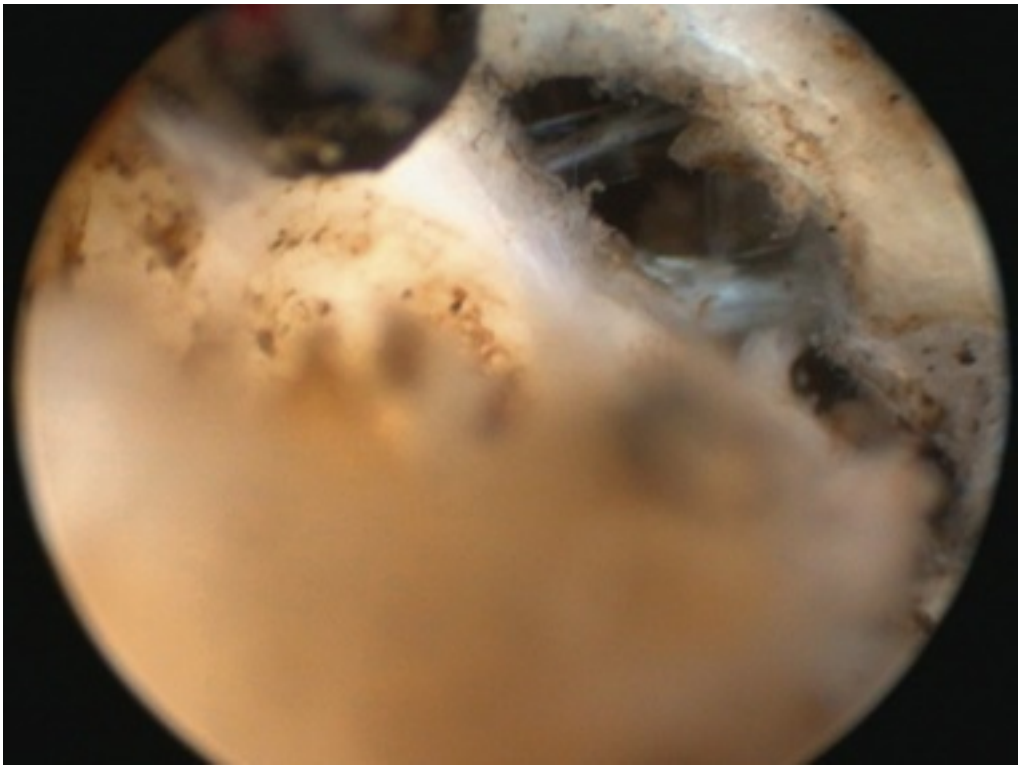
benign nature demonstrating the dramatic middle ear damage that can result from even benign disease.

Myringotomy

Historically, veterinarians have been reticent to perform myringotomies. Indeed, iatrogenic myringotomy, when performed during otoendoscopic exam, has often been treated as a surgical crisis. Recent studies have demonstrated the previously underreported prevalence of otitis media in dogs (in particular) and the utility of myringotomy in the management of these diseases.[17,18]

Myringotomy is a simple and safe procedure that can be performed during a standard otoendoscopic exam in an appropriately anesthetized patient (Videos 85-2, 85-3, and 85-4). It should be considered in any patient with endoscopically visible evidence of disease of the tympanum and/or middle ear, typically manifesting as decreased opacity of the tympanum and abnormal anatomy of the tympanum. Bulging of the tympanum into the horizontal canal suggests clinically significant fluid accumulation in the middle ear that can benefit from drainage (see Video 85-2). Myringotomy can be performed via a simple perforation using a tomcat catheter with the end cut to a sharp bevel (see Video 85-3), or with a purpose-made myringotomy knife (see Video 85-4). One of the great frustrations to the practitioner performing a myringotomy is the rapidity with which the tympanum can heal: myringotomies can begin to heal within 72 hours, leading to chronic otitis media, whereas patency should last for at least 7-14 days to allow for adequate drainage of the middle ear. The use of diode lasers is an effective tool for performing myringotomy with the added feature of delayed tissue healing, as with any form of thermal energy used in surgery. The diode laser is set to very low power, a slender 400-600 micron fiber is used, and the pars flaccidum of the tympanum is identified. With empyema behind the tympanum, the most common region of bulging is the slightly more redundant pars flaccidum. The tympanum is cut in a cruciate fashion, centered in the pars flaccidum. The pars tensalis is to be avoided if possible, given its anatomic proximity to the manubrium of the malleus. However, chronic disease of the tympanum often makes it difficult to identify regions of the tympanum clearly. When the tympanum is incised, it is common to see a rush of dark or purulent fluid entering the horizontal canal from the middle ear, which should be collected directly for cytologic examination and bacterial culture and susceptibility testing (see Video 85-4). The pressure of irrigant inflow should be reduced at this point and gentle flushing will result in lavage of the middle ear[19-21] (E-Figures 85-10 and 85-11).



E-FIGURE 85-10 Intraoperative view of a laser myringotomy being performed in a canine patient. The incision is being made in the dorsal aspect of the pars tensalis. The incision is being made in a cruciate pattern extending from the dorso-rostral aspect proceeding caudo-ventrally. A second incision will be made in the opposite direction. This incisional pattern minimizes the likelihood of premature healing and recurrence of fluid or debris accumulation in the middle ear.

E-FIGURE 85-11 Intraoperative view of a laser myringotomy being performed in a feline patient. Note the bulging portion of the pars flaccidum on the left of the image.

Complications of Otoendoscopy

Even with a modest degree of experience, otoendoscopy is an extremely safe procedure associated with minimal surgical morbidity and rare surgical mortality. If otitis media is not adequately treated post-myringotomy, further delayed healing can occur. This can lead to a pattern of progressively worsening otitis media that can become refractory to common antimicrobial therapy. Aggressive topical and systemic antibiotic therapy is important for adequate and timely resolution of otitis media and healing of the tympanum. Rarely, patients experience a transient caloric- or pressure-induced head tilt or, more rarely, nystagmus, Horner's syndrome, or facial nerve paresis/paralysis. These complications, when noted, are usually mild and self-limiting.[21]

CHAPTER 86

Scraping, Fine-Needle Aspiration, and Biopsy of Skin and Subcutaneous Tissues

Ralf S. Mueller, Sonya V. Bettenay

Skin Scrapings

Skin scrapings used as aids in diagnosing cutaneous ectoparasites are classified as either superficial or deep. These two types of scraping have distinct uses for identifying different parasites and differ substantially in their procedural approach.

Superficial Skin Scrapings

Indication

Superficial skin scrapings are used to detect mites living on the skin surface or burrowing within the stratum corneum such as *Cheyletiella* spp., *Otodectes cynotis, Sarcoptes* spp. and *Notoedres cati*. Both *Cheyletiella* and *Sarcoptes* mites can be difficult to find; about 50-70% of pets with either of these parasites have positive scraping results.[1,2] Results may be <50% when there is an early infestation with fewer mites. Cats with *Notoedres cati* typically have abundant mites. Preferred anatomic sites for scraping vary. In the dog suspected of having scabies, the elbows, ear margins, lateral hocks, and ventrum are commonly affected. In cats, *Notoedres cati* affects the head. In both dogs and cats, *Cheyletiella* mites inhabit the dorsal trunk and typically cause scaling. *Otodectes cynotis* is most frequently associated with otitis externa, but may produce a head and neck pruritus and rarely a generalized dermatitis. Superficial skin scrapings should be performed in any scaly or pruritic dog or cat.[3]

Procedure

Mineral oil is applied to the affected skin in a thin film to facilitate the gathering of scale and surface debris and increase the chance of positive results.[1] Nonexcoriated scaly and/or papular sites are selected and a dulled, #10 scalpel blade is used to sample the surface of a large area (at least 5 × 5 cm). Hairy dogs with suspected scabies should be clipped first; use the clippers only in the direction of hair growth and leave 1-2 mm of hair—i.e., not a surgical clip—the aim being to keep the surface scale or crust that may be present. Clipping is not indicated in pets that might have cheyletiellosis. The oil is then gently scraped off the surface, as if "buttering bread" (E-Figure 86-1) in the direction of hair growth and transferred onto a glass microscope slide. This "large oil volume" technique provides multiple slides for examination, providing an excellent chance of success.

E-FIGURE 86-1 The technique for removing the oil from the skin is similar to that used when "buttering bread."

Microscopic Technique

A coverslip is applied to distribute the debris evenly—mites may be missed if covered by debris—and to speed microscopic evaluation by reducing need for continuous adjustment of focus. Scanning (4 × objective, 10 × ocular) power is used and the condenser of the microscope lowered to increase contrast. Skin scrapings for ectoparasites should be examined within a few hours of sample collection, because mites can actually walk off a slide if left too long.

Interpretation

One mite or egg is diagnostic and should be considered reason to initiate miticidal therapy. A negative scraping does not rule out presence of mites and diagnostic therapy may still be indicated.

Deep Skin Scrapings

Indication

Deep skin scrapings are performed to detect *Demodex* mites. In the dog, *Demodex canis* lives in the hair follicle; a longer-bodied *Demodex* mite *(Demodex injai)* is suspected to live in the sebaceous glands.[4-6] Canine demodicosis is characterized clinically by alopecia, comedones, papules, pustules, scales, and crusts and must be considered for almost any dog with inflammatory or non-inflammatory skin disease. Demodicosis in the cat is less common, typically secondary to systemic disease and affecting the head.[7,8] A ventral alopecia pattern has also been reported.[9]

Procedure

Ideally, follicular papules or pustules over an area of at least 1 × 1 cm should be sampled. Mite counts are higher when the skin is squeezed (prior to and during scraping) in an attempt to push the mites out from the depths of the follicles.[10] Using a mineral-oil-covered #10 blade, skin is scraped in the direction of hair growth until capillary bleeding is observed (Video 86-1). Trichograms (hair plucks, placed in mineral oil on a glass

slide for examination) provide an alternative test that is particularly useful in pets with periocular or pedal lesions. Trichograms are almost as reliable as deep skin scrapings, if sufficient hair shafts over the same 1 × 1 cm area are plucked.[10,11]

Interpretation

Demodex canis is a normal component of the cutaneous fauna and an occasional mite can be found on the skin scraping of normal dogs. If only one mite is found, but clinical signs are compatible, further scrapings, trichograms, or a biopsy are indicated.[3] It is important to note in the clinical record the site of scraping and the relative numbers of adults, larvae, nymphs, and eggs per low power field (LPF). Assessment of response to therapy is based on comparison of these numbers at subsequent monthly visits.

Fine-Needle Aspiration

Indication

Fine-needle aspiration is frequently performed on nodules in the skin or subcutis as the "first step" when attempting to differentiate neoplasia from inflammation or infection.

Procedure

The nodule should be firmly fixed between thumb and forefinger of one hand; a 20- or 22-gauge needle is then gently inserted into the nodule with the other hand and redirected several times without completely withdrawing it from the nodule. The needle is then withdrawn and the cells within the lumen of the needle are expelled by attaching an air-filled 5 mL syringe and blowing the content onto a glass slide. This method is particularly suitable for small nodules. Control of the needle tip is sufficient that even in lively dogs it is unlikely for a needle to penetrate through the nodule into normal underlying tissue possibly transferring neoplastic cells.

If no cells are obtained using the previously described technique, a "suction method" may be used. The needle is first attached to a 10 mL syringe before being inserted into the nodule and aspirated multiple times. Suction should be interrupted when the needle is redirected and particularly when being withdrawn, to avoid sucking cells into the syringe where they may not be retrievable. The needle is then separated from the syringe, the plunger drawn back, the syringe and needle reattached, and the contents blown onto a glass slide. The material is then spread as with blood smears, dried, stained with a modified Wright's stain (Diff-Quik), and examined.

Interpretation

If a uniform cell population is identified, then a neoplastic cause is likely. Characteristics of neoplastic cell populations are described elsewhere (see ch. 93). Histopathology is necessary to define tumor grade, enable a prognosis, and contribute to decisions regarding the next course of action. If inflammatory cells such as neutrophils and macrophages dominate, then infection is possible and the next step is a bacterial and/or fungal culture of the deep tissue to differentiate sterile inflammation from an infectious cause.

Getting the Most From a Skin Biopsy (E-Box 86-1)

E-Box 86-1

Ten Tips to Obtain a Better Skin Biopsy Result

1. Do not use aseptic technique to prepare the skin surface.
2. Before starting, spend 5 minutes looking for a representative range of lesions.
3. Select multiple (4-6) samples that represent the range of lesions from normal to most severely affected.
4. In inflammatory or alopecic skin disease, if possible, include a normal sample from the dorsum, not the ventrum.
5. Draw a follicle orientation line (on the trunk this is in the direction from the nose to the tail tip) in all samples.
6. Use 6- to 8-mm punches or an elliptical biopsy except on noses and paws.

7. Handle the biopsy specimen carefully; treat it like wet tissue paper even when excising.
8. Give the pathologist a succinct history, your physical findings and your differential diagnoses.
9. Use an incisional biopsy when a neoplasm is suspected, provided this can be followed by a second procedure for wide excision if indicated.
10. Ensure adequate formalin fixation through correct volume and/or partial incisional slicing of larger tumors.

Site selection and biopsy methodology can make the difference between success and failure to obtain a specific diagnosis.[3,12] Even "inconclusive results" can rule out some differential diagnoses.

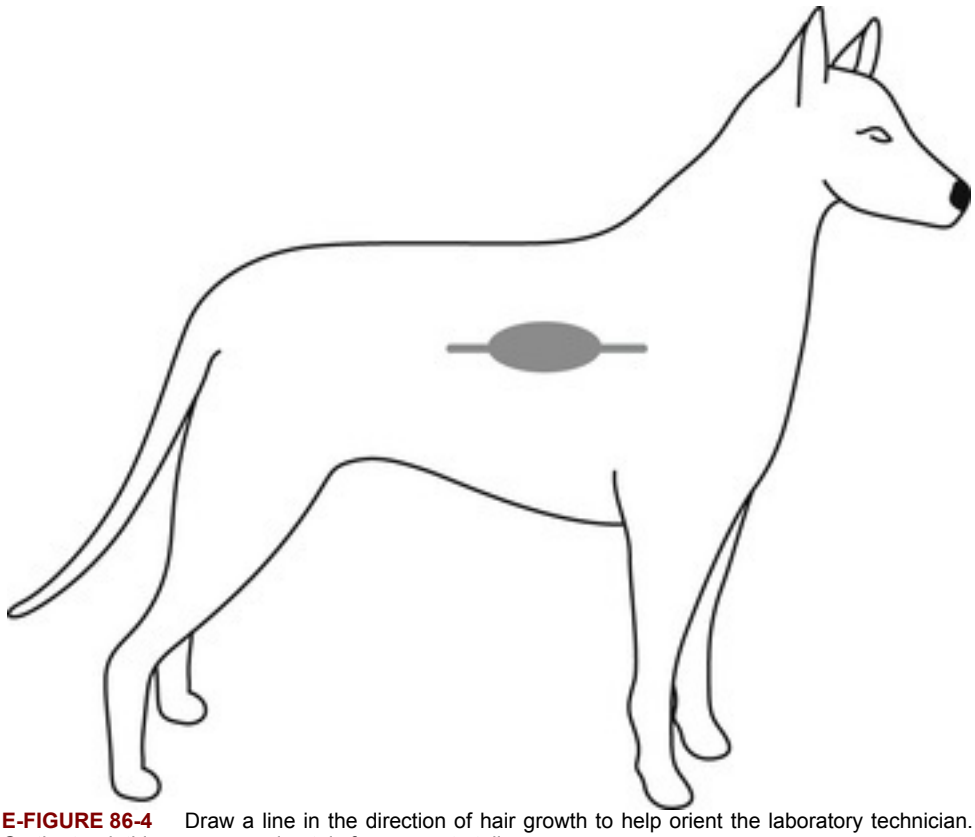
Site Selection

A careful examination of the entire animal for the most representative range of lesions is the first step in biopsy site selection. Taking multiple samples from well-chosen sites helps to avoid inconclusive results. In a pustular disease, erythematous macules develop into papules, then pustules and finally crusts/erosions. Sampling each of these stages supplies the widest range of lesions, but wherever possible, multiple pustules should be sampled. Depigmenting lesions should be biopsied in an active area (i.e., gray color) rather than the final stage (i.e., white).

Alopecic areas should be sampled in the center of the most alopecic area as well as in junctional and normal areas. On submission, identifying sites biopsied can be achieved by placing samples in separate, carefully labeled, bottles of formalin, or through the use of tissue dyes marking different lesion types with a different color (E-Figure 86-2). When assessing alopecia, where possible, avoid the glabrous (nonhaired) areas of the body as they contain fewer hair follicle units and smaller sebaceous glands. A line drawn prior to biopsy on the skin in the direction of the hair growth, using a waterproof pen, indicates the direction needed for cutting the follicles longitudinally (Figure 86-3 and E-Figure 86-4).[13]

FIGURE 86-3 Draw a line in the direction of hair growth. This technique has revolutionized the interpretation of follicular pathology. Do not draw over fragile lesions like pustules, which may rupture with pressure.

E-FIGURE 86-2 Dye can be used to identify specific skin biopsies. It is spread thinly on the pannicular surface and *must* dry before the tissue is placed in the formalin (allow 1-2 minutes).



E-FIGURE 86-4 Draw a line in the direction of hair growth to help orient the laboratory technician. On the trunk this runs approximately from nose to tail.

In dogs and cats with severe inflammatory disease, clues with regard to the follicular growth characteristics may be present only in adjacent normal skin. Ulcerated areas should be avoided, unless deep dermal, vascular, or pannicular pathology is suspected. When sampling an ulcerated lesion, use an elliptical incision either to completely excise the ulcer with adjacent normal skin or oriented from the center of the lesion to include adjacent "normal or intact" skin.

Surgical Technique

Overlying hair should be clipped only in the direction of hair growth and gently removed to preserve any scale and crusts. Crusts should be left on the skin and included in the biopsy as they may contain microorganisms, inflammatory, or acantholytic cells that may help establish a diagnosis. Write "please cut in crusts" on the submission form. No aseptic preparation is performed, except when excising solitary nodules. Infection resulting from a lack of surgical preparation is almost never seen. General anesthesia is indicated for facial or paw biopsies and may also be necessary for larger excisional biopsies. Local anesthesia, with or without sedation, is a practical alternative for many pets with truncal biopsies. SC injection of 1 or 2 mL of xylocaine without adrenaline (lidocaine without epinephrine) usually provides adequate local anesthesia. The maximum amount of xylocaine used depends on body weight. The site is marked to enable easy relocation and the needle entry point should be outside the proposed biopsy area to avoid tissue disruption within the biopsy.[13]

Wedge/Ellipse versus Punch Biopsy

The punch biopsy is quick, relatively atraumatic, and often recommended when infectious, inflammatory, and endocrine dermatoses are suspected. Disposable, new, 8-mm punches are preferred. Four- and six-mm punches are reserved for biopsies of footpads, nasal planum, mucocutaneous junctions, or eyelids.

Punch Biopsy Sampling

Hold the punch at a 90° angle to the surface of the skin, firmly brace the surrounding skin, and rotate the punch in one direction with continuous, but relatively little, pressure. When the skin no longer "turns" with the punch rotation, sufficient depth has been reached to free the dermis from its underlying attachment. The punch is removed and any blood is carefully blotted. Grasp the tissue gently at the base and sever the SC attachments. Under no circumstance should the dermis or epidermis be squeezed as this leads to "crush artefact" and may result in a sample that is unreadable or misinterpreted as scarring. The use of ophthalmic instruments such as iris scissors and forceps is recommended.

Excisional/Incisional Sampling

The wedge or elliptical biopsy should be employed as an excisional technique when a deep dermal or panniculus lesion is suspected. This method should also be used when removing a solitary nodule or fragile lesion (such as vesicles). It is also used when there appears to be a range of changes radiating from the center to the edge of a lesion (e.g., central ulceration or alopecia and adjacent normal tissue can be included in the ellipse) (Figure 86-5, *A* and *B*).

FIGURE 86-5 **A,** Rule of thumb—include 100% lesional or nonlesional skin when sampling with a punch biopsy. **B,** The histopathology technician will usually section the elliptical biopsy specimen along the midline of the long axis of the ellipse. Orientation of the ellipse across the junction between abnormal and normal tissues will allow the pathologist to view the skin from affected, through active, to nonaffected areas and so gain the best possible appreciation of the stages of the disease and hence the etiology. (Courtesy Medizinische Kleintierklinik.)

In the case of a suspected neoplasm, an incisional biopsy may be indicated. This allows an accurate diagnosis without concern of contaminating surrounding tissue or compromising any subsequent surgical intervention. Cytology may diagnose malignancy without the need for a biopsy, but it cannot replace the prognostic information obtained from the assessment of margins and vessels that histopathology allows.

Once the biopsy has been obtained, the wound is closed routinely.

Fixation of Tissue

The biopsy sample surface should be gently blotted prior to placing it in formalin. A minimum volume of formalin, approximately 10 times the sample volume, is needed for adequate fixation. In cold climates, the addition of one part alcohol to nine parts formalin will prevent freezing during shipping. Large tissue pieces should be sectioned into 1-cm slices to allow adequate formalin penetration *without* sectioning through the nodule completely. To retain the original orientation for margin assessment leave the sections attached at the base (adipose tissue).

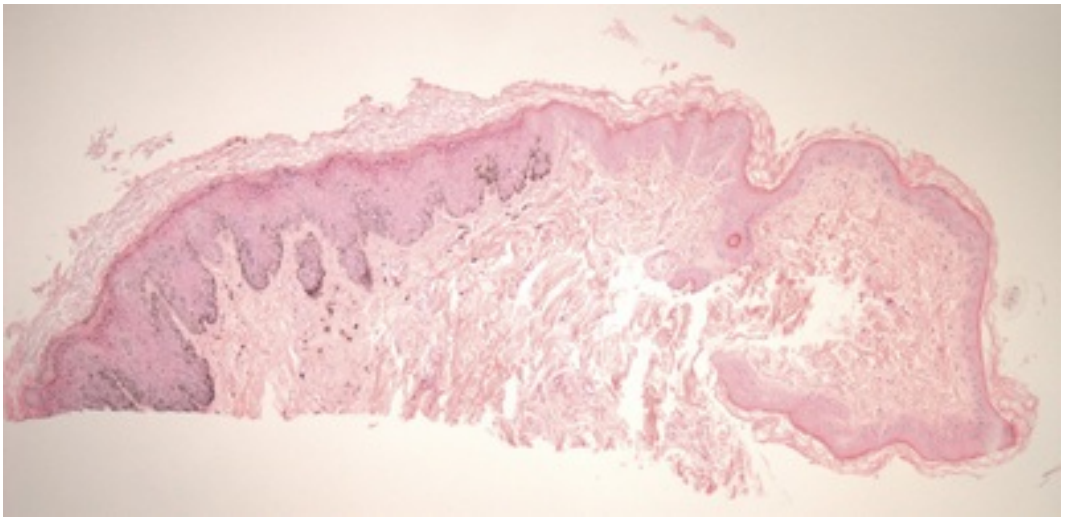
Shave Biopsies

On the pinnae, cartilage is found directly under an extremely thin dermis and the panniculus is absent. With punch and wedge techniques, cartilage may inadvertently be damaged and a permanent change in the shape of the pinna may result. The shave biopsy is a fast technique to diagnose diseases of the epidermis or dermoepidermal junction (such as lupus or pemphigus), but which needs to be performed under general anesthesia. The outside of the ear needs to be clipped; the concave/inner pinna may not. A scalpel blade is held in one hand; the pinna is bent over the index finger of the other hand (E-Figure 86-6). On the stretched and bent convex surface, the scalpel blade enters the skin at an angle of approximately 20°, only to a depth where capillary bleeding is observed. At that depth, the incision is continued parallel to the surface of the skin until a specimen, approximately 5 × 5 mm (0.25 × 0.25 inches), is obtained. This sliced-out specimen is an extremely thin piece of skin that should be placed with the dermal surface down on a piece of a tongue depressor or cardboard to avoid distortion during fixation (E-Figure 86-7).

E-FIGURE 86-6 Shave biopsy. The pinna is bent over the index finger of one hand and a scalpel is used to obtain the biopsy specimen.

E-FIGURE 86-7 The very thin shave biopsy specimen is placed with the dermal surface down on a piece of a tongue depressor or cardboard—allow 1 minute for adhesion and place the tissue side in contact with the formalin.

Three minutes of firm digital pressure or use of a silver nitrate stick typically stops hemorrhage and suturing is not usually necessary. There is typically no scarring. Shave technique is only useful for diseases of the epidermis and upper dermis, as the depth of the specimen with proper technique will not reach below the midfollicular level (E-Figure 86-8) and deep dermal changes such as vasculitis and disorders of the cartilage cannot be evaluated.



E-FIGURE 86-8 Histopathology of a shave biopsy will reveal changes in the epidermis and upper dermis, as the depth of the specimen with proper technique will reach the midfollicular level.

Interpretation—Making a Diagnosis

One of the major reasons to perform a skin biopsy is to obtain a diagnosis. The second aim, even in the absence of a confirmed diagnosis, is to rule out differential diagnoses. In order for the pathologist to look for subtle clues and to interpret unusual changes, a list of clinical lesions and differential diagnoses must be included with the submission. Choose a pathologist with an active interest in dermatopathology or a dermatologist with advanced dermatopathology training.

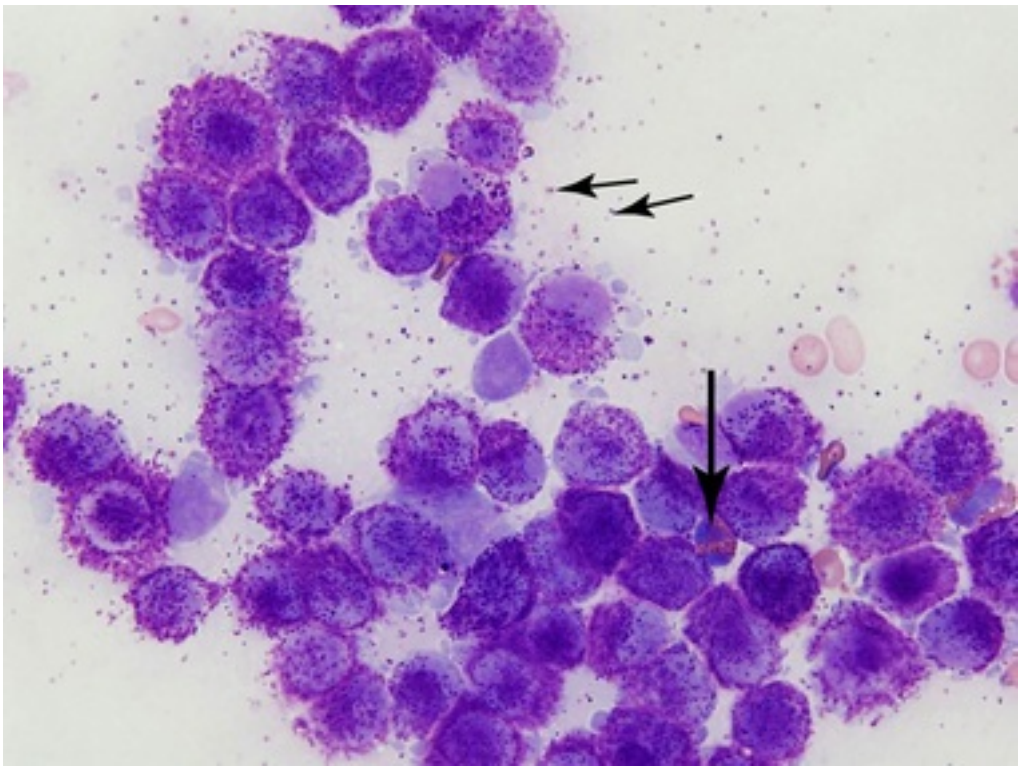
CHAPTER 87

Cytology of the Skin and Subcutaneous Tissues

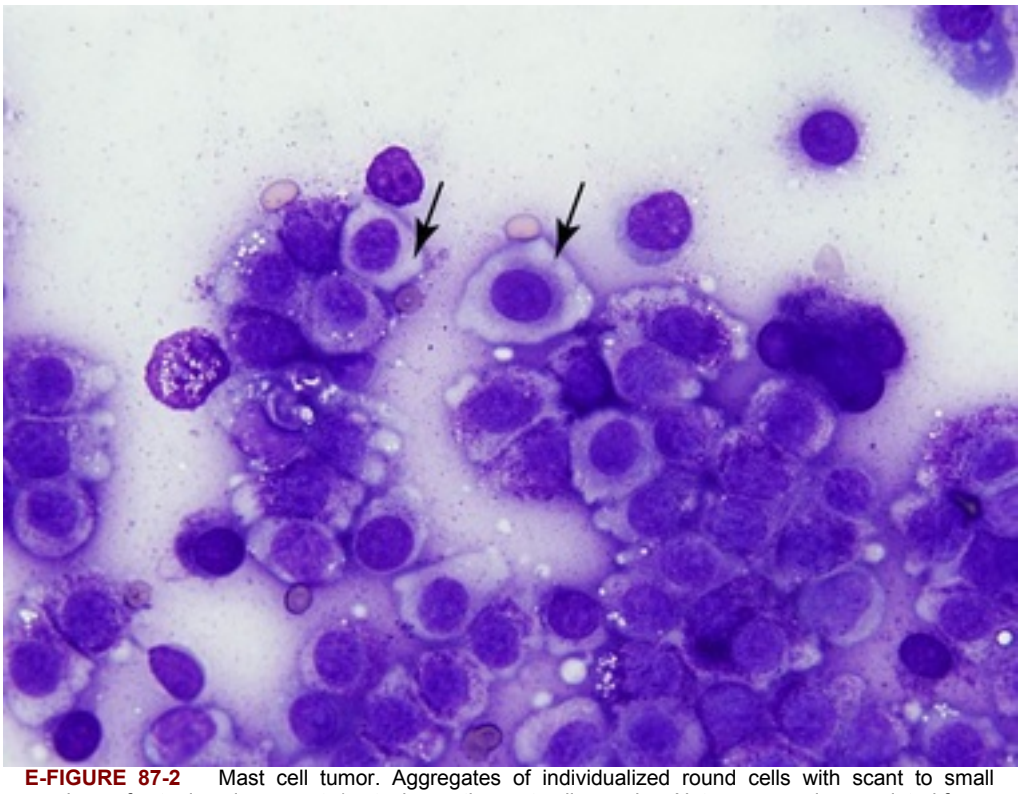
Ryan M. Dickinson

Evaluation of fine-needle aspirates (FNAs) or impression smears of skin lesions is a relatively inexpensive, fast, and accurate method of obtaining a diagnosis or providing a list of differential diagnoses when taking into account the patient's signalment, relevant clinical history, and other diagnostic information. Assessment of cytologic samples provides many advantages, including visualization of fine cellular detail (subtle, yet important nuclear and cytoplasmic features) and morphology of small organisms (e.g., bacteria [including mycobacteria] and protozoa). At the same time, interpretation of FNAs can be challenging and it requires distinguishing real from artifactual background material (e.g., stain precipitate). Thus, the diagnosis of many lesions requires the expertise of a formally trained clinical pathologist. However, clinicians with an interest in cytology may be able to make straightforward diagnoses or be able to categorize the disease process prior to submitting cytologic samples to a reference laboratory. Cytopathologic evaluation can help guide a clinician towards the appropriate therapy or pursuit of additional diagnostic testing, if required, to obtain a definitive diagnosis.

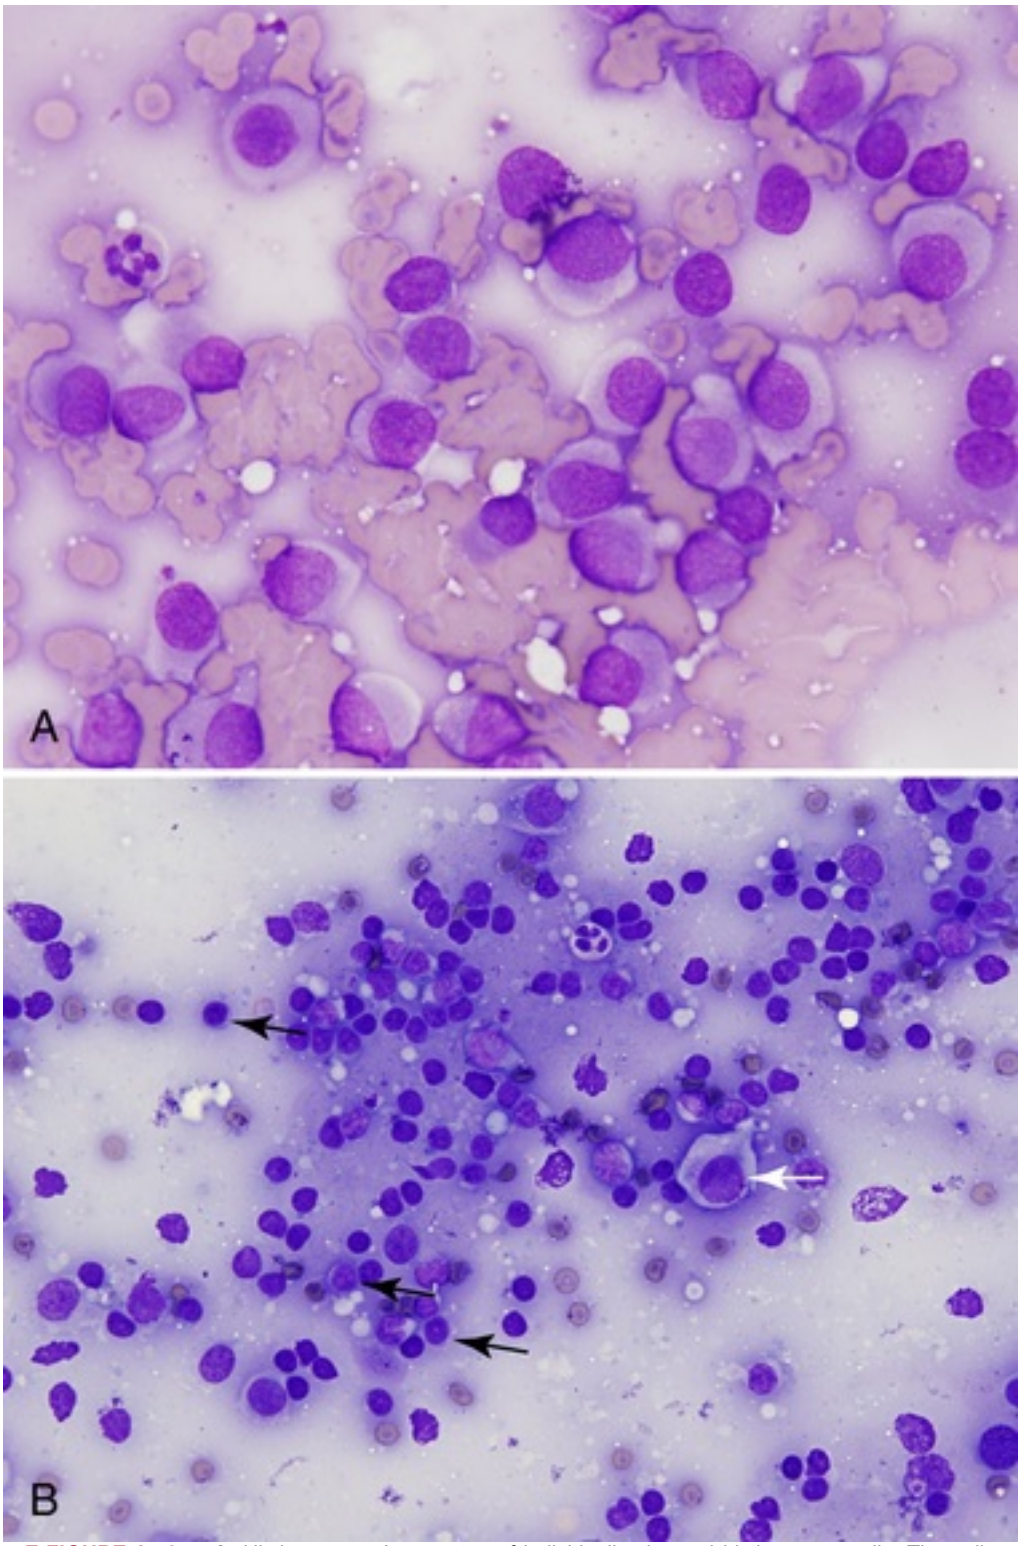
Important examples of cutaneous and subcutaneous masses where fine-needle aspiration can be useful for cytopathologic diagnosis include mast cell tumor (E-Figures 87-1 and 87-2), histiocytoma (E-Figure 87-3, *A* and *B*), lymphoma (E-Figure 87-4), plasmacytoma (E-Figure 87-5), hepatoid adenoma (E-Figure 87-6), keratin-filled cystic structures (E-Figure 87-7), sebaceous adenoma (E-Figure 87-8), squamous cell carcinoma (E-Figure 87-9), trichoblastoma (basal cell tumor; E-Figure 87-10), hemangiopericytoma/perivascular wall tumor (E-Figure 87-11), metastatic osteosarcoma (E-Figure 87-12), myxosarcoma (E-Figure 87-13), melanoma (E-Figure 87-14), abscesses (E-Figure 87-15), and systemic mycoses (blastomycosis: E-Figure 87-16).



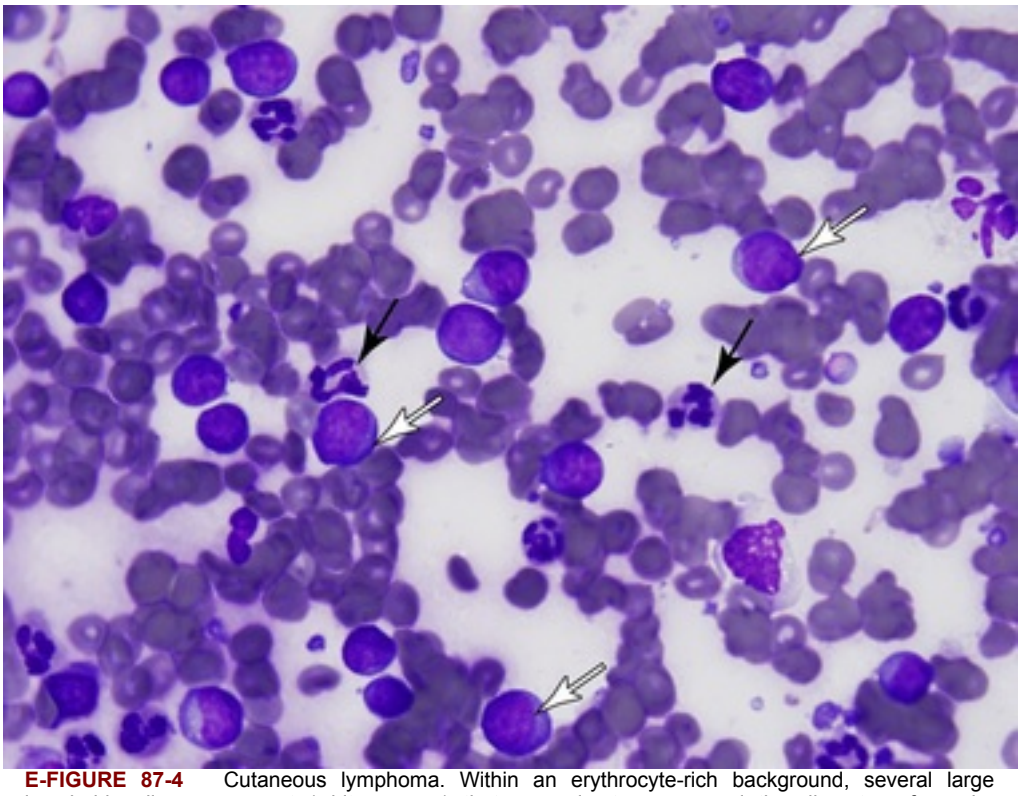
E-FIGURE 87-1 Mast cell tumor. Aggregated yet individualized round cells with many intracytoplasmic magenta/metachromatic granules. Note fewer extracellular mast cell granules as well (small arrows). Few eosinophils are present (large arrow). Modified Wright's stain ×1000.



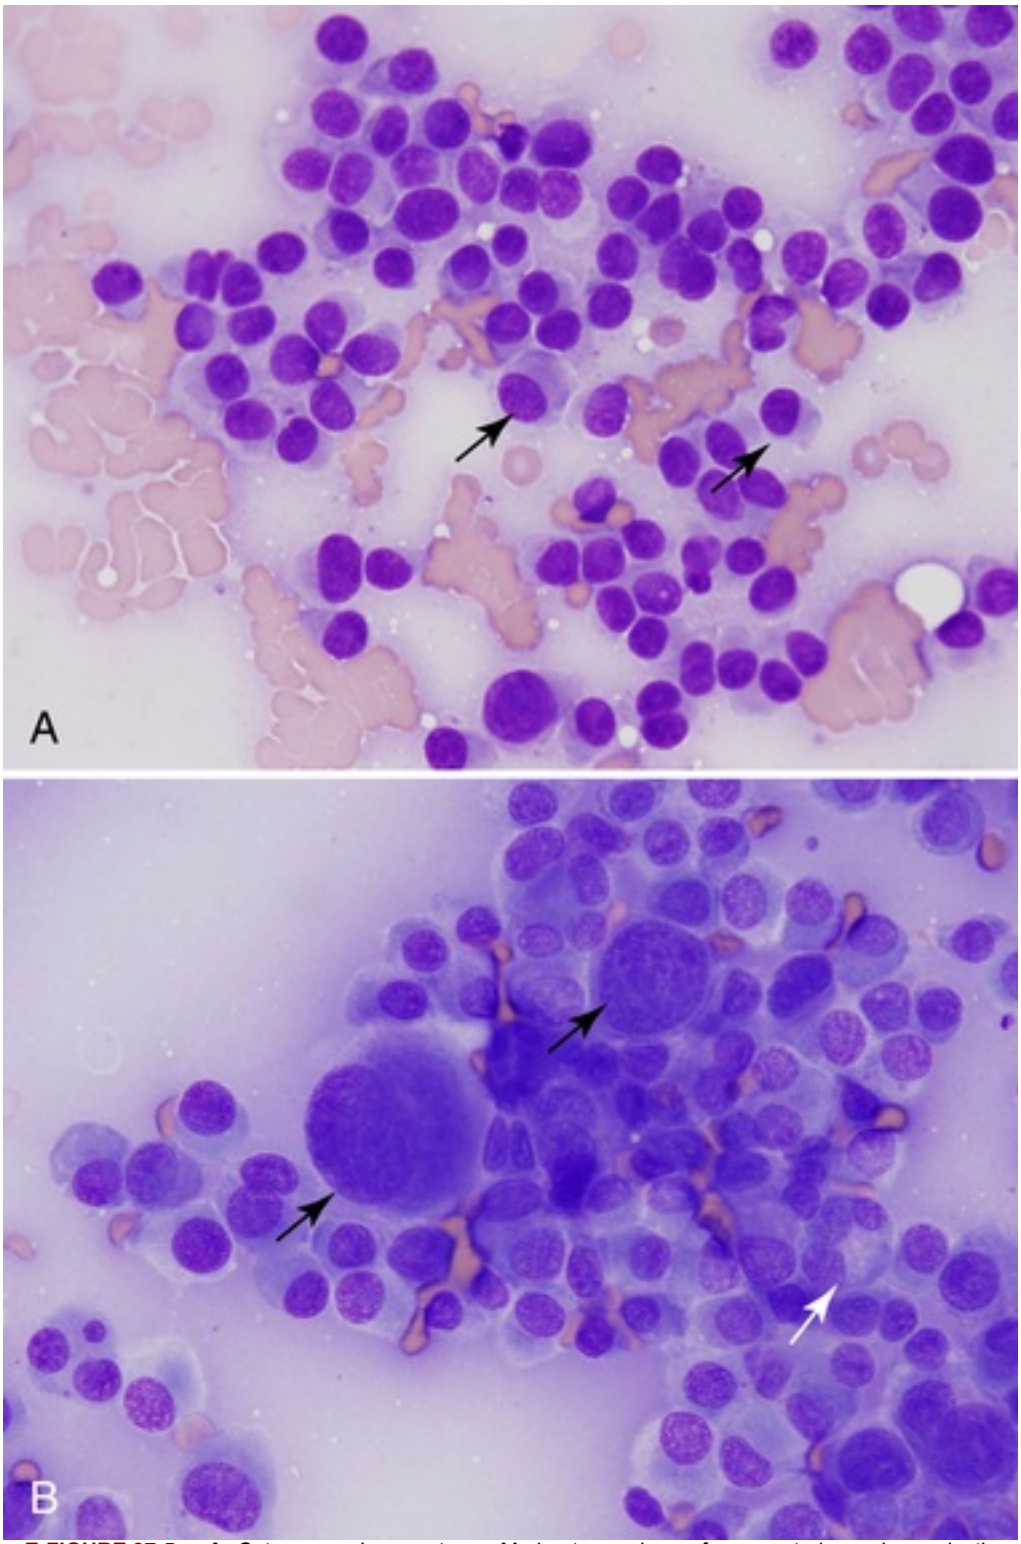
E-FIGURE 87-2 Mast cell tumor. Aggregates of individualized round cells with scant to small numbers of cytoplasmic magenta/metachromatic mast cell granules. Note very poorly granulated forms (arrows). In some cases, Diff-Quik stain may not stain mast cell granules very well, so the absence of striking staining patterns of granules should not be used as a basis for ruling out mast cell tumor. Modified Wright's stain ×1000.



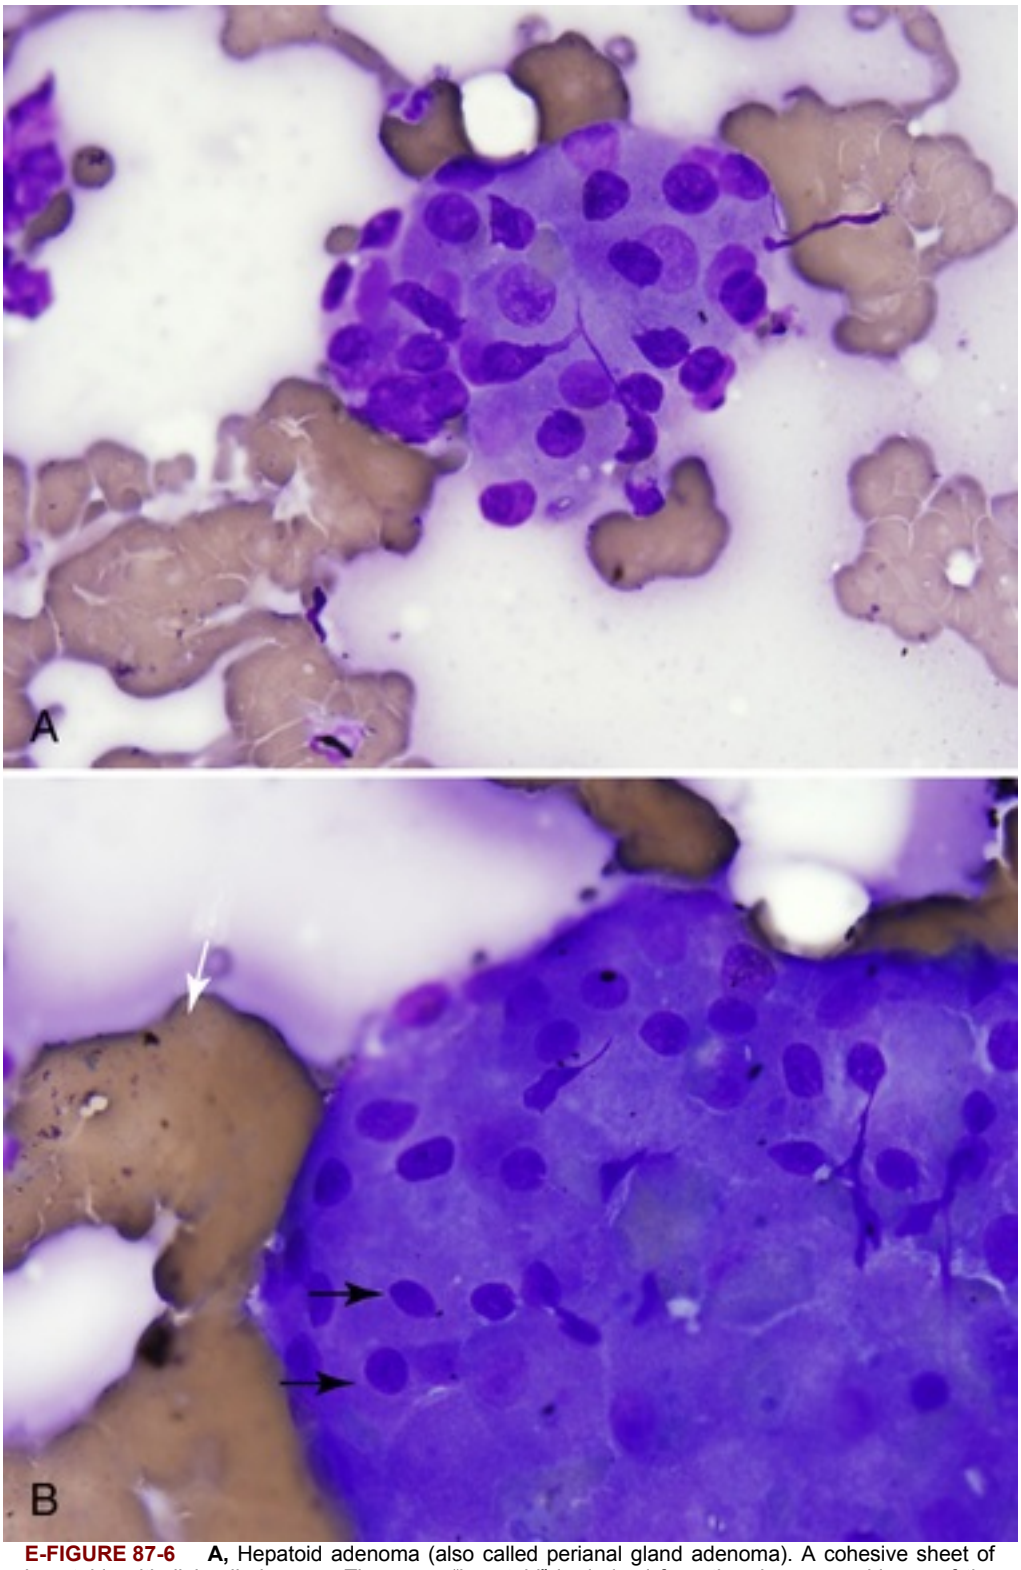
E-FIGURE 87-3 **A,** Histiocytoma. Aggregates of individualized round histiocytoma cells. The cells have moderate nuclear to cytoplasmic ratio with moderately abundant fine, amphophilic, scarcely vacuolated cytoplasm. Nuclei are round in this image, though they sometimes can appear indented or kidney-bean shaped. Modified Wright's stain ×1000. **B,** Regressing histiocytoma. A mixed population of cells is present. Small lymphocytes (black arrows) outnumber the fewer histiocytoma cells (white arrow). Infiltrates of small lymphocytes are “attacking” the neoplastic histiocytoma cells. Regression of cutaneous histiocytomas more often occurs in dogs <2 years of age. Modified Wright's stain ×500.



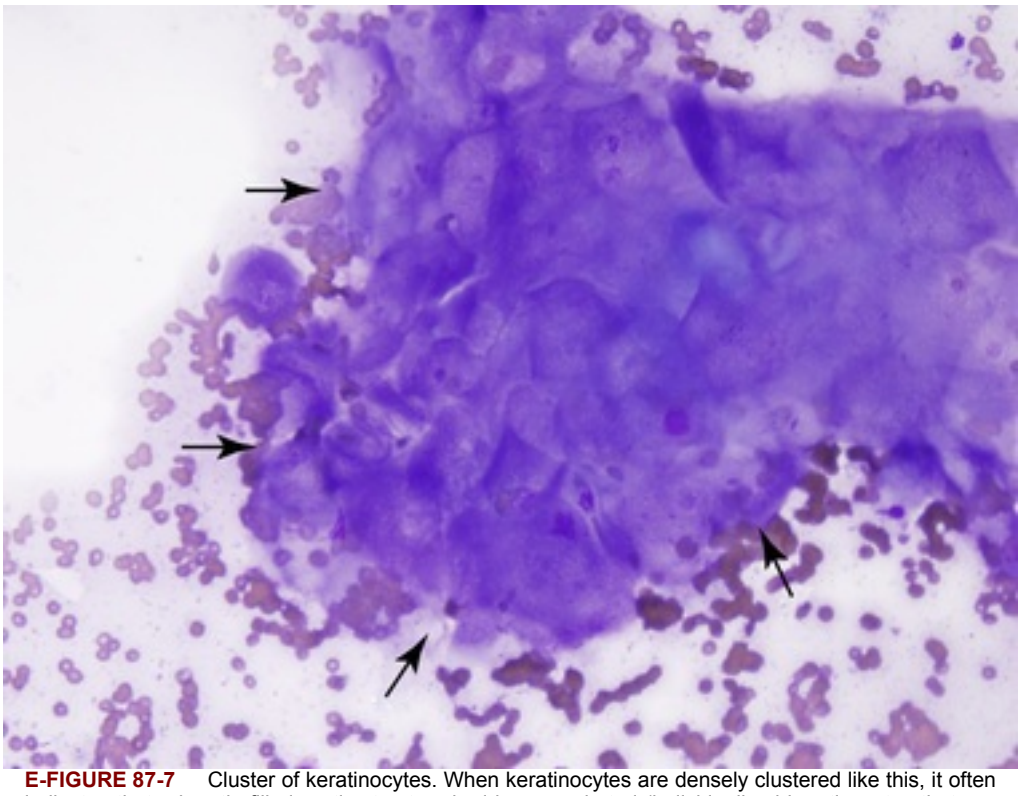
E-FIGURE 87-4 Cutaneous lymphoma. Within an erythrocyte-rich background, several large lymphoid cells are present (white arrows) that approximate or exceed the diameter of nearby neutrophils (black arrows). Note the high nuclear to cytoplasmic ratio of the lymphoid cells. Modified Wright's stain ×1000.



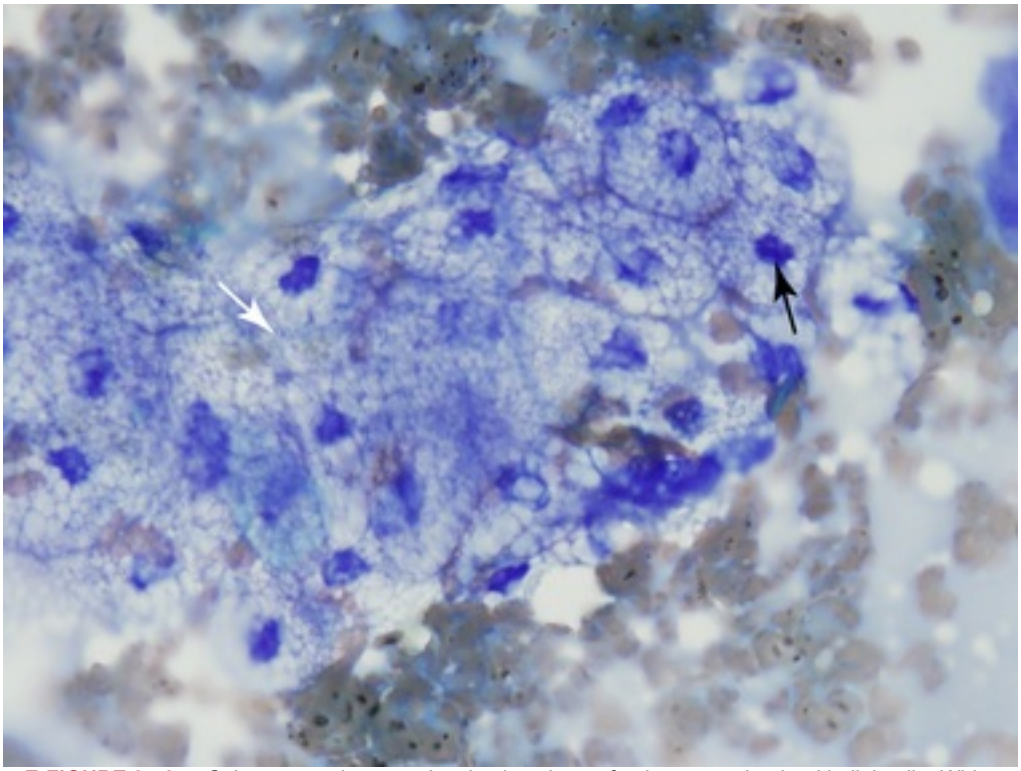
E-FIGURE 87-5 **A,** Cutaneous plasmacytoma. Moderate numbers of aggregated round, neoplastic plasma cells are present. Plasma cells often have an eccentrically placed nucleus within the cytoplasm (arrows). Mild pleomorphism in this population. The lesion was benign. Modified Wright's stain ×1000. **B,** Cutaneous plasmacytoma. There are moderate numbers of aggregated round, neoplastic plasma cells that are markedly pleomorphic. Note marked karyomegaly (black arrows) and presence of a trinucleate form (white arrow). This lesion was also benign. Modified Wright's stain ×1000.



E-FIGURE 87-6 **A,** Hepatoid adenoma (also called perianal gland adenoma). A cohesive sheet of hepatoid epithelial cells is seen. The name “hepatoid” is derived from the close resemblance of the epithelial cells of the perianal gland to hepatocytes. Modified Wright's stain ×600. **B,** Hepatoid adenoma. A dense cohesive sheet of hepatoid epithelial cells is surrounded by dense aggregates of erythrocytes (white arrow). Black arrows indicate small nuclei from basaloid reserve cells that often surround the larger hepatoid epithelial cells. Modified Wright's stain ×1000.



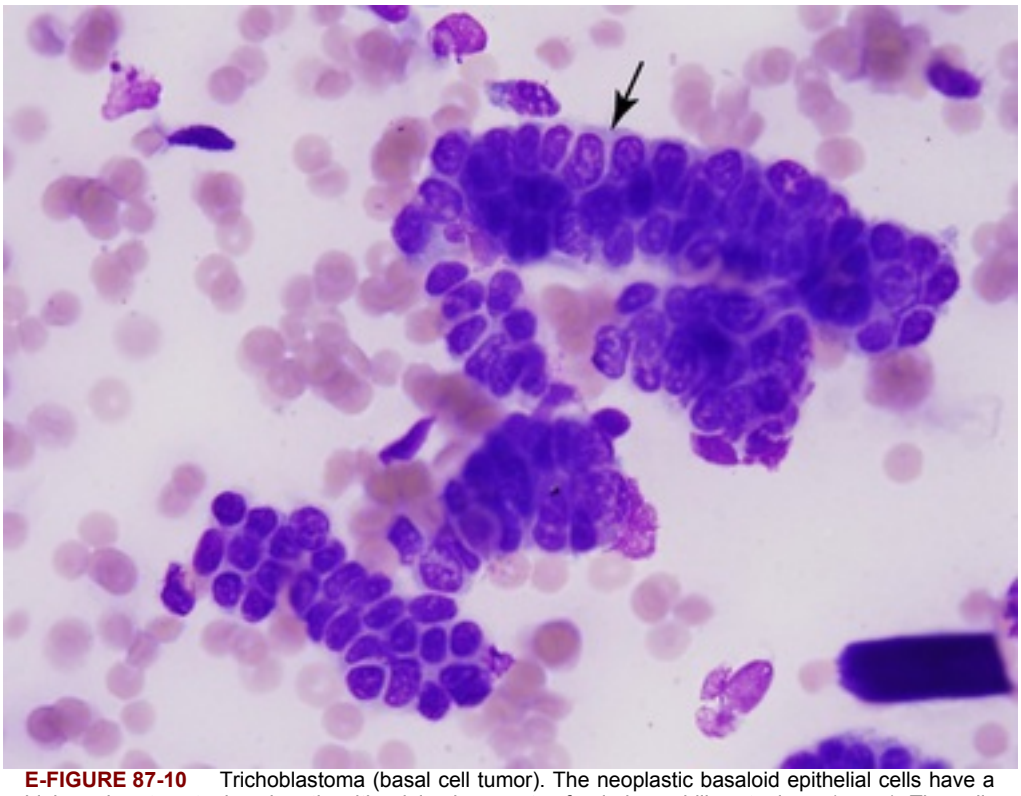
E-FIGURE 87-7 Cluster of keratinocytes. When keratinocytes are densely clustered like this, it often indicates that a keratin-filled cystic structure had been aspirated (individualized keratinocytes that are loosely scattered, by contrast, may reflect surface epidermal contamination). Arrows highlight the edge of the aggregate. Histologic evaluation of a biopsy often is indicated, to assess the wall of the cystic lesion to provide a definitive diagnosis. Modified Wright's stain ×400.



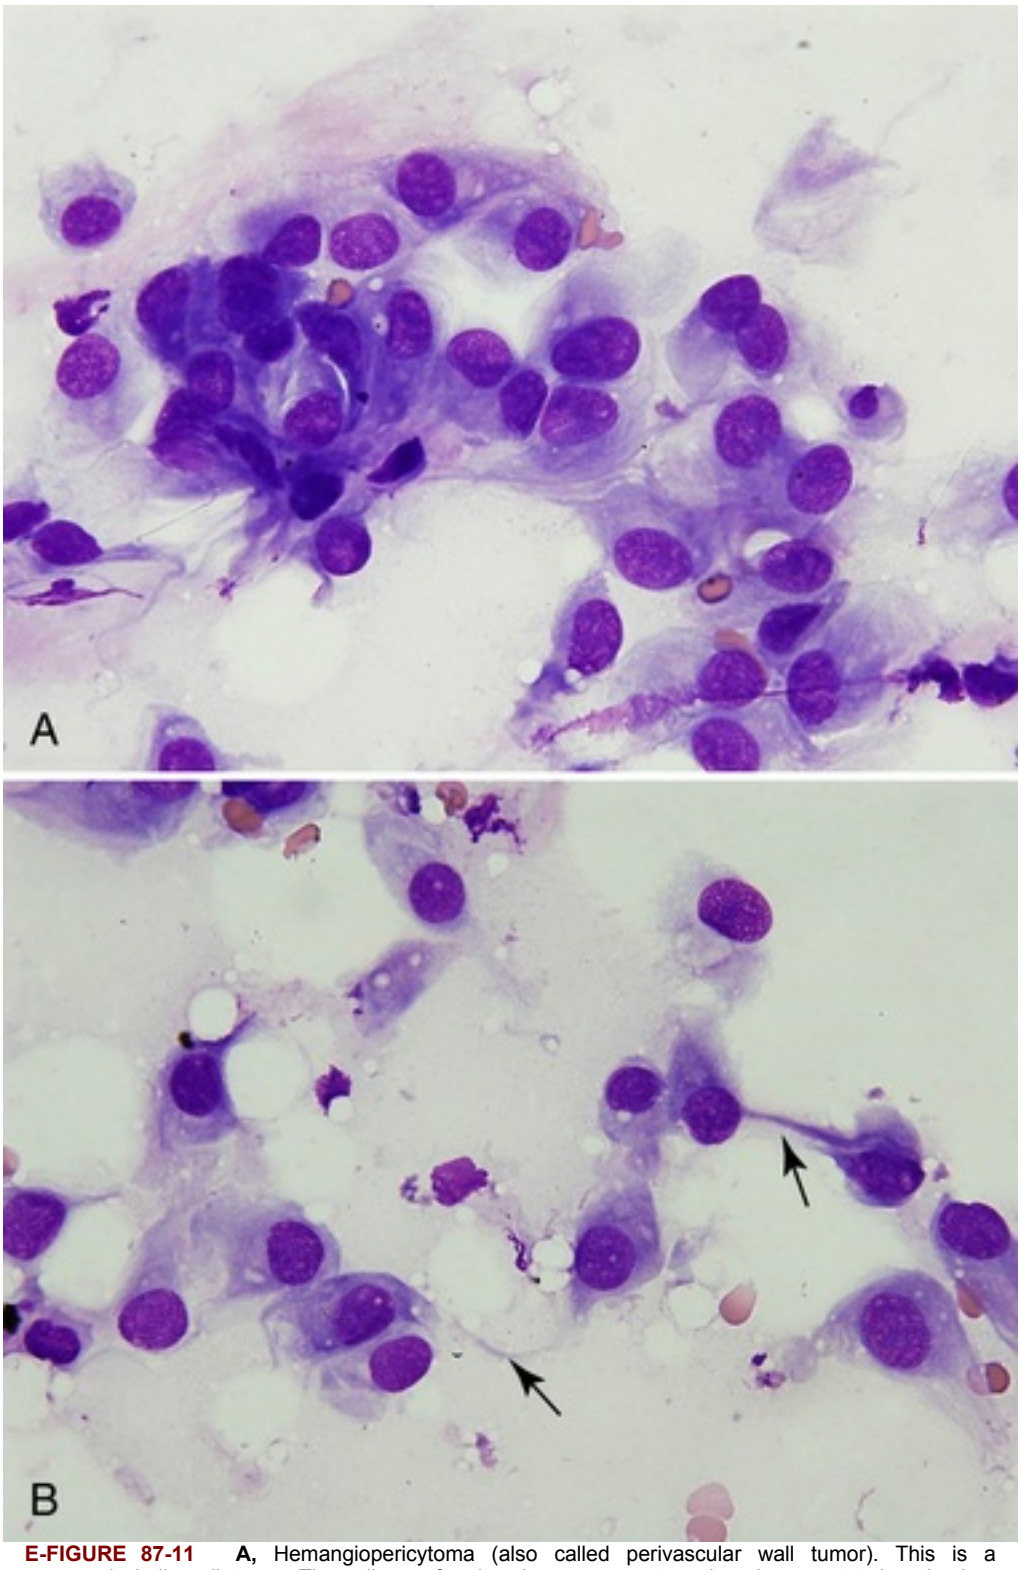
E-FIGURE 87-8 Sebaceous adenoma. A cohesive sheet of sebaceous gland epithelial cells. White arrow highlights the highly foamy cytoplasm. Black arrow highlights round nucleus with condensed

chromatin that is similar to neighboring nuclei. Modified Wright's stain ×600.

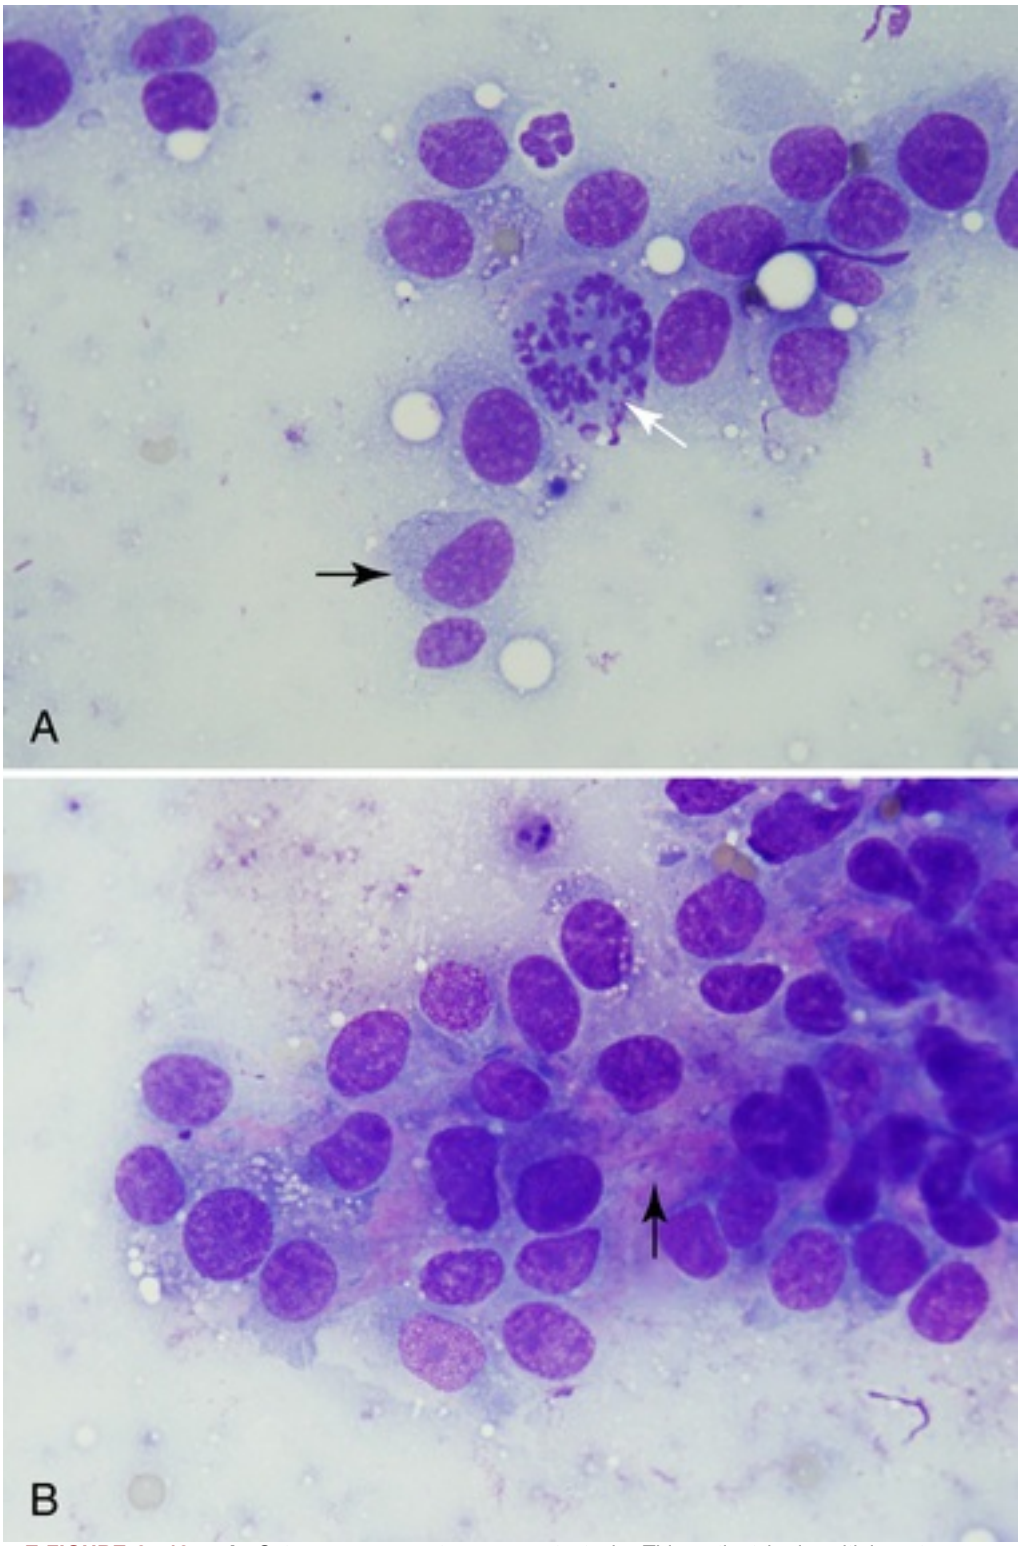
E-FIGURE 87-9 Squamous cell carcinoma. A cohesive sheet of neoplastic squamous epithelial cells. The dark purple nuclei are “immature” and quite large given the relatively “mature” fine smooth peripheral cytoplasm (black arrow). Perinuclear vacuolation (white arrows) often is found in neoplastic squamous cells. These cells can readily individualize and scatter loosely in the background. Modified Wright's ×1000.



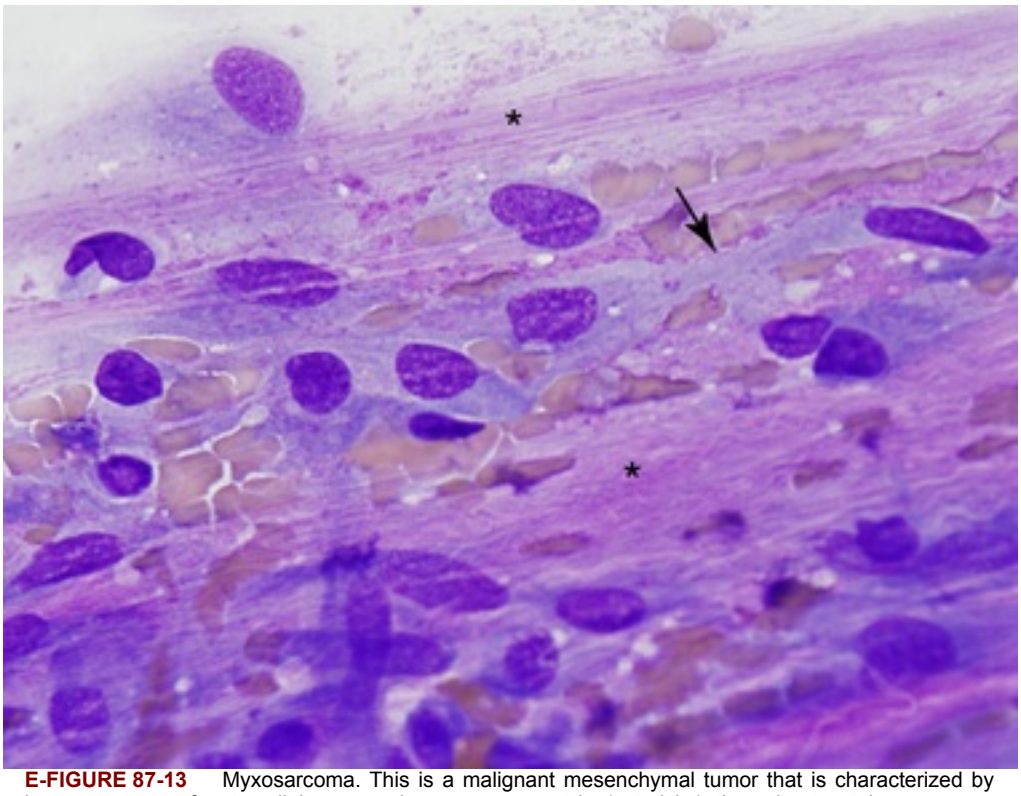
E-FIGURE 87-10 Trichoblastoma (basal cell tumor). The neoplastic basaloid epithelial cells have a high nuclear to cytoplasmic ratio with minimal amounts of pale basophilic cytoplasm (arrow). The cells form tightly cohesive sheets and often there is a “cobblestone” appearance to the sheets. Modified Wright's stain ×1000.



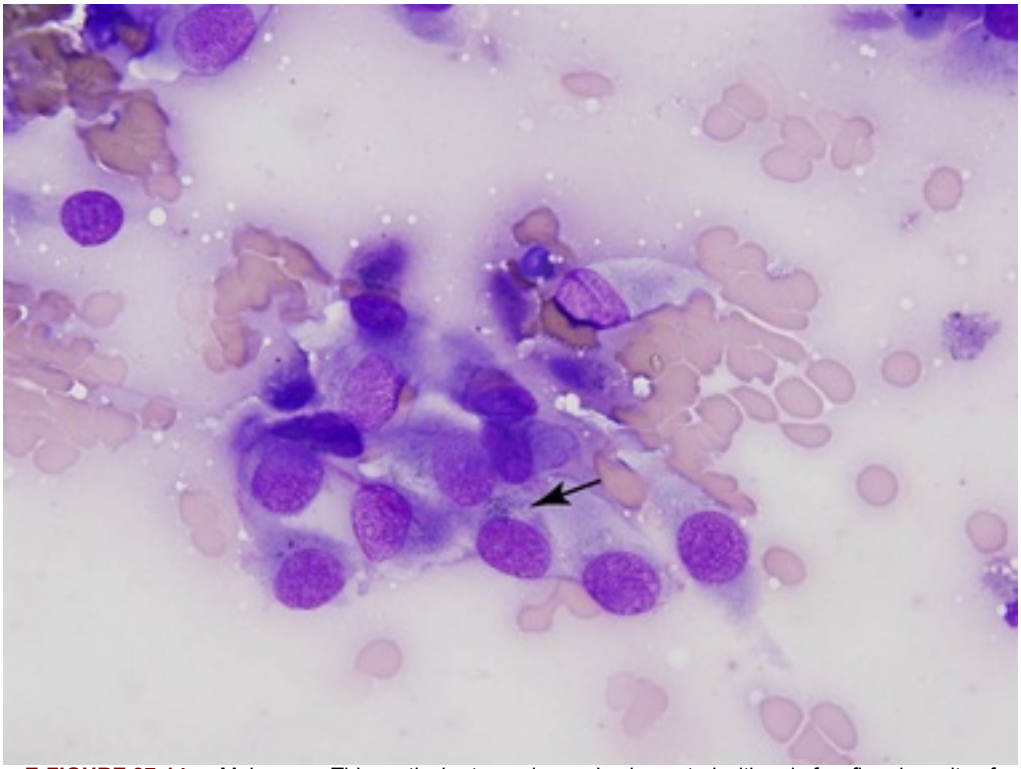
E-FIGURE 87-11 **A,** Hemangiopericytoma (also called perivascular wall tumor). This is a sarcoma/spindle cell tumor. The cells are forming dense aggregates, though are not truly cohesive. Modified Wright's stain ×1000. **B,** Hemangiopericytoma/perivascular wall tumor. Note the fine, tapering cytoplasmic terminations of the tumor cells (arrows). Modified Wright's stain ×1000.



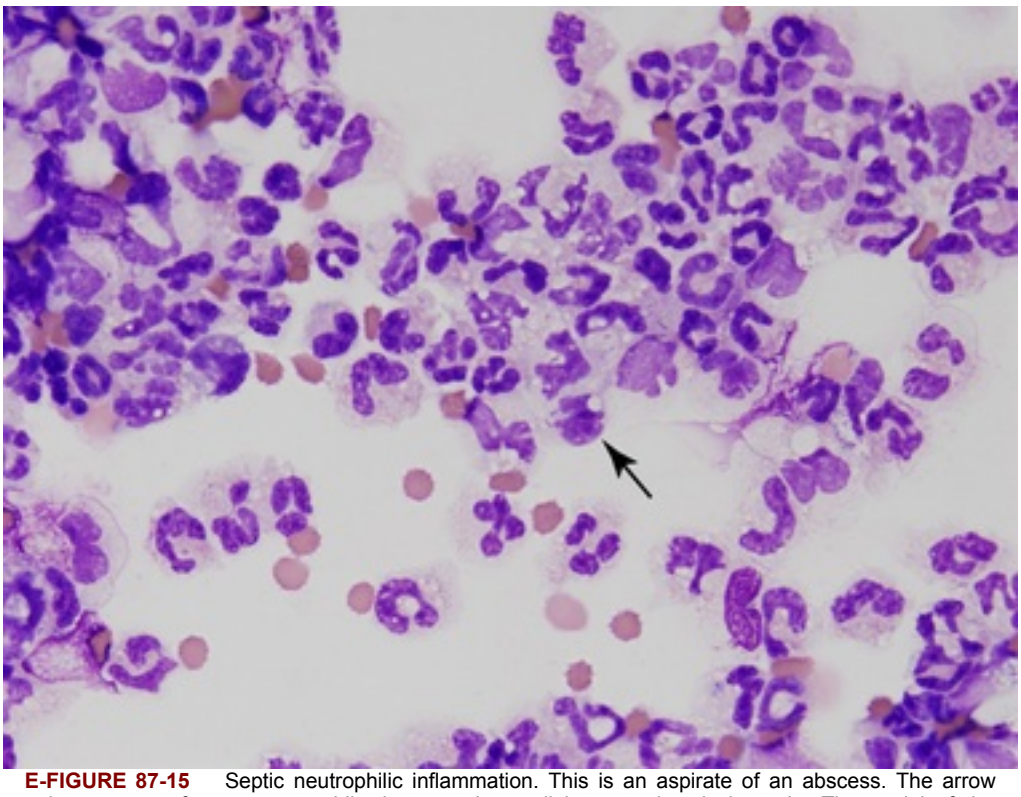
E-FIGURE 87-12 **A,** Osteosarcoma—cutaneous metastasis. This patient had multiple cutaneous metastases of osteosarcoma many months following amputation of a forelimb for previously diagnosed osteosarcoma of the proximal humerus. The tumor cells are round (black arrow) with no classic spindle shaped cells despite the fact that this is a mesenchymal tumor. The white arrow indicates a bizarre mitotic figure. Diff-Quik ×1000. **B,** Osteosarcoma. The arrow highlights magenta streaming extracellular matrix (osteoid) produced by the tumor cells. Diff-Quik ×1000.



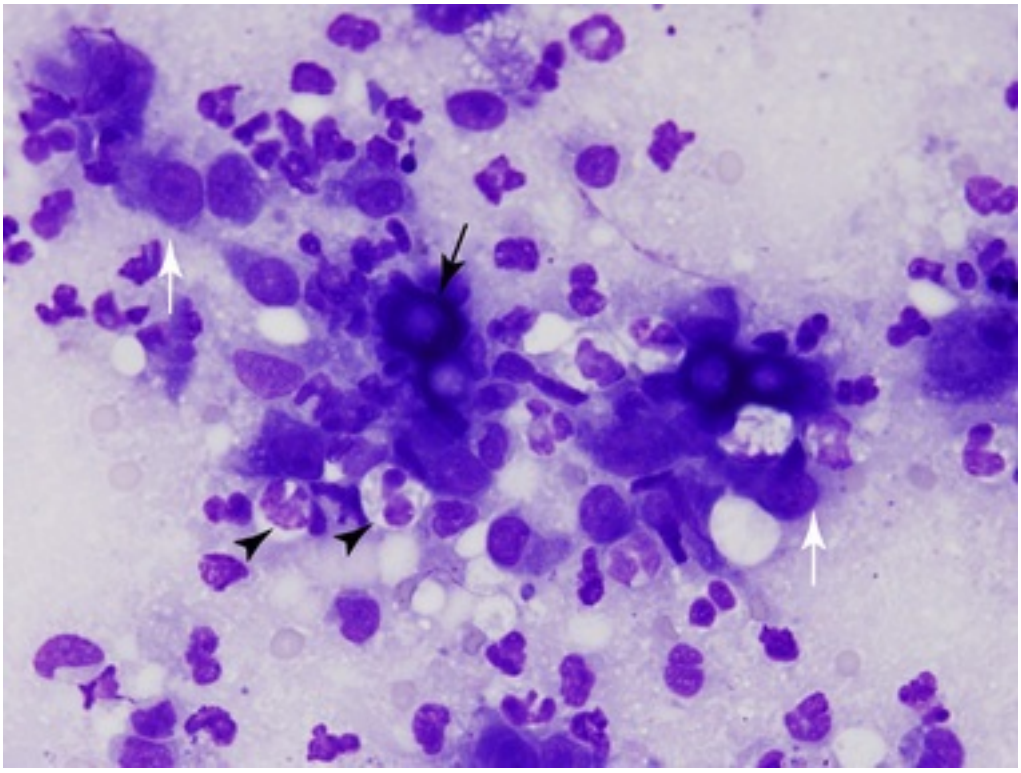
E-FIGURE 87-13 Myxosarcoma. This is a malignant mesenchymal tumor that is characterized by large amounts of extracellular streaming magenta matrix (asterisks) throughout cytology smears. During initial aspiration, the material can appear grossly mucoid. The arrow highlights tapering cytoplasmic terminations of the neoplastic spindle cells. Modified Wright's stain ×1000.



E-FIGURE 87-14 Melanoma. This particular tumor is poorly pigmented with only few fine deposits of intracytoplasmic melanin pigment (arrow). Neoplastic melanocytes often vary in shape, size, and degree of pigmentation. Modified Wright's stain ×1000.



E-FIGURE 87-15 Septic neutrophilic inflammation. This is an aspirate of an abscess. The arrow points to one of many neutrophils that contain small intracytoplasmic bacteria. The nuclei of the neutrophils are mildly swollen with relatively pale chromatin, suggesting degenerative change. Modified Wright's stain ×1000.



E-FIGURE 87-16 Cutaneous blastomycosis. White arrows highlight epithelioid macrophages (found in fungal infections and other chronic inflammatory processes such as with inflammation targeting foreign bodies). Black arrow highlights a *Blastomyces* sp. broad-based, budding yeast among clusters of neutrophils (arrowheads) and macrophages. Modified Wright's stain ×1000.

Many diseases and disorders can be diagnosed by cytopathologic evaluation of FNAs of skin lesions, and several excellent resources prepared by leaders in the field of veterinary cytopathology provide excellent descriptive detail and images of neoplasia, infectious and noninfectious inflammation, hyperplasia, and processes associated with tissue injury in domestic animals.[1,5,6] The reader is encouraged to refer to these resources for more detailed descriptions of specific diseases and conditions. This chapter focuses on optimization of sample preparation and on keys to deriving the best information from an FNA. Ch. 86 addresses technical aspects of collecting samples.

When evaluating a cytology smear, it is essential to view as many of the areas as possible to ensure the interpretation is made using representative cells from a lesion. This requires optimal smear preparation. The contents of a needle are discharged onto one edge of the slide, typically the edge closest to (but not touching) the frosted/labeled edge of the slide. Once the cellular contents are discharged onto the smear, very gentle pressure is all that is required during the smearing process. Overzealous application of pressure can cause cells to rupture, obscuring essential nuclear and cytoplasmic morphology and often precluding an interpretation. Smear the contents to within one-quarter of the opposite edge. The middle one-half of the slide should contain the majority of cells. Automated staining machines used by reference laboratories (modified Wright's stain or some other Romanowsky-type stains) often stain the middle half to two-thirds of the slide and any material outside this portion of the slide would be left unstained by such machines. Quick stains such as Diff-Quik will stain any portion of the slide that contacts the fixing/staining solutions. If a fluid sample is retrieved, a direct smear should be prepared immediately; the remaining fluid should be stored in a sterile tube if culture is desired, and an EDTA tube to prevent cell clotting so that additional smears can be made if needed. The feathered edge often contains large cells/clusters and organisms. Inadequate smearing leads to thick, three-dimensional, crowded clusters of cells, precluding assessment of individual cell morphology (Video 87-1). Appropriate smear technique more often yields excellent quality samples with highly cellular monolayers of intact cells, which increases diagnostic accuracy.

Impression smears of a biopsy specimen (or those made directly from a skin lesion) can provide important cytologic findings. Following collection of tissue, it is important to make a small incision in the superficial surface, avoiding the deep or lateral aspect of the lesion as this can obscure biopsy margins when the tissue is evaluated histologically. If it is possible to collect two tissue samples, one can be used for preparing imprints for cytologic evaluation and the other can be placed in buffered formalin for histologic processing. Impressions of ulcerated areas of a skin mass can yield many cells; however, often there are disproportionately large numbers of inflammatory cells, ruptured cells, and surface bacterial colonies that could mask the primary diagnosis. The impression smears should be kept away from the formalin container once it is opened as even trace amounts of formalin vapors can deleteriously affect the staining quality of the smears. Smears should be submitted in a tightly sealed container to protect the glass from breaking and also to protect from formalin vapors in case a concurrently shipped separate formalin container breaks during transit.

Keys to Consider When Submitting or Evaluating Cytologic Samples

1. When submitting smears to a reference laboratory, a brief yet complete clinical history should be included, as well as the exact anatomic location of the sampled lesion (e.g., clarify whether a site listed as "thoracic mass" indicates a skin mass on the thorax or an intrathoracic or mediastinal mass. If it is a skin mass, is it dermal? Subcuticular? Deeply attached?). This information allows a pathologist to provide the best answer possible.
2. Thorough evaluation of the smear(s). It is important to avoid making a premature diagnosis based on evaluation of only a few fields. Not all fields contain the exact same combinations of cells. Evaluation starts using a low-power objective. Many microscopes have a 4× lens (yielding 40× magnification when combined with the 10× ocular objectives) as the lowest setting. Using the lowest magnification to scan the whole slide allows the examiner to appreciate patterns of cellular arrangements; monolayers of cells can then be evaluated at higher magnification (400×-1000×) for cellular detail. It is important to avoid using high-power objectives initially, as important features on other areas of the slide can be missed.
3. Familiarity with the objective lenses. The 40× lens requires a glass coverslip unless it is an oil immersion lens. If the image is blurry or out of focus when using a dry lens, this could indicate that the objective

contains oil or that a coverslip is required. Glass coverslips can easily be placed over the sample by placing a drop of oil on the slide and then applying the coverslip.

4. Recognition of ruptured cells and avoidance of overinterpretation of their components. Following rupture, cytoplasmic details can become extensively altered and cytoplasmic fragments can sometimes be misconstrued as other elements, such as infectious organisms. Nuclei from ruptured cells can become markedly swollen, leading to spurious anisokaryosis that can be misinterpreted as a criterion of malignancy in an otherwise non-neoplastic population. Avoiding poorly stained areas also is important, as they may contain misleading features.
5. Recognizing artifacts in the background (e.g., stain precipitate, fabric fibers). Conversely, however, relevant "background" material should not be ignored. It could reflect a clinically significant finding (e.g., magenta deposits of extracellular secretory material or connective tissue matrix).
6. Recognizing that poorly cellular smears might not be fully representative of a lesion. Although less common, this also can be true of highly cellular smears.
7. Awareness that more than one type of process could be present.
8. Objectivity in the evaluation and interpretation. Using the essential clinical information that is available is crucial, but premature interpretation based on hasty presumptions also must be avoided.

Septic Versus Non-Septic Inflammation

When evaluating for infectious agents, it is best to become familiar with optimal magnifications to be used when searching for a given type of organism and whether the organism would be expected to be intracellular, extracellular, or possibly both. In general, it is best to follow the rule of evaluating the smear with a low-power objective for areas that contain monolayers containing inflammatory cells. It is helpful to recognize that some patterns of cell collections are more commonly found in certain situations. For instance, if *Blastomyces dermatitidis* infection is suspected, this organism often can be detected initially at 100-200× magnification and, if needed, confirmed at 400× magnification since it is a larger organism (7-15 micron diameter[1]) that is typically surrounded by dense clusters of neutrophils and epithelioid macrophages in variable proportions. The organism remains extracellular with few exceptions where the organism may be within the cytoplasm of a multinucleate giant macrophage. Bacterial organisms, by contrast, are much smaller than fungal organisms (1-4 micron, depending on the organism) and often are found within neutrophils and less often within a macrophage, although extracellular bacteria sometimes can be numerous in a smear. Bacterial organisms can be detected at 200-400× magnification; however, higher magnification (often requiring an oil immersion lens; 500×-1000× magnification) usually is required for detailed morphologic assessment of bacteria. Negative-staining mycobacterial organisms likewise can be both extracellular and intracellular within macrophages. It is worth remembering that in some septic lesions, bacteria are readily visible, whereas in others the organisms may be very few. It is not recommended to completely rule out an infectious component if infectious agents cannot be found in a smear, and appropriate microbial culture should be considered for cases where underlying infection is still a plausible consideration.

Neoplastic Versus Non-Neoplastic Lesions

Many continue to conceptualize lesions strictly as being "neoplastic versus inflammatory," possibly considering that either one process or the other is represented in a smear. In reality it is quite common that neoplastic cells are admixed with inflammatory cells due to a variety of reasons (e.g., necrosis within a tumor and cytokine production by tumor cells that attract inflammatory cells). Thorough evaluation of a smear is important since one may encounter a lesion that has exfoliated mainly inflammatory cells, but closer inspection reveals that smaller numbers of neoplastic cells are present among the inflammatory cells. Depending on whether the cellular yield is fully representative, it is certainly possible that only inflammatory cells exfoliate during an FNA of a neoplasm and that the main neoplastic component of a lesion was not directly sampled. In addition to strictly categorized neoplastic lesions, there is also a collection of less common *reactive* cell proliferations like reactive cutaneous histiocytosis, which is neither truly a clonal neoplastic proliferation nor an infectious process (see ch. 350).

Benign Versus Malignant Tumors

Many cytopathology textbooks list the cytologic "criteria of malignancy" one must consider when evaluating and interpreting neoplastic lesions in order that benign tumors might be differentiated from malignant

tumors. Terms such as *anisocytosis* (variation in cell size), *anisokaryosis* (variation in nuclear size), and *pleomorphism* (variation in overall cellular appearance) are terms that help describe the morphology of a cell population. Recognition of prominent and variably sized nuclei, variable nuclear chromatin pattern, variation in cytoplasmic composition, presence of binucleate/multinucleate cells, and presence of mitotic figures are additional features that provide important information about the expected biologic behavior of a tumor population. In many cases, these features are helpful in identifying a malignant lesion, but there are exceptions. For example, a benign cutaneous plasmacytoma may consist of well-differentiated, easily recognizable plasma cells (monomorphic morphology), but it is common that a benign cutaneous plasmacytoma is populated by very pleomorphic plasma cells that have frequent multinucleate forms and marked anisocytosis and anisokaryosis within the population. These cytomorphologic features can be quite striking, but they may not indicate that the biologic behavior of the tumor is any more aggressive than a plasmacytoma populated by monomorphic plasma cells. Conversely, a classic example of a malignant tumor that has a "benign" appearance is an apocrine adenocarcinoma of the anal sac. This tumor typically is populated by loosely cohesive epithelial cells that have minimal anisocytosis and anisokaryosis, and unremarkable chromatin features with rare mitotic figures; however, the tumor is aggressive, with strong potential for local invasion and distant metastasis. An experienced cytopathologist is aware of exceptions such as these and many others. For this reason, the best outcomes can be reached when clinicians and pathologists have solid working relationships and excellent communication when pursuing a cytopathologic diagnosis.

Types of Neoplastic Lesions

There is a large variety of cutaneous neoplastic lesions. As with any other organ system, the tumor types can be placed into large, general categories of round cell, epithelial, and mesenchymal, noting that within these broad categories, tremendous morphologic variation still exists.

More common canine and feline cutaneous round cell, epithelial, and mesenchymal tumors are listed here, with the respective approximate percentages of all skin tumors (data obtained from different sources), noting that there are other tumor types from these three general categories that occur less commonly and are not listed (Table 87-1).

TABLE 87-1

Prevalence of Canine and Feline Skin Tumors, by Category

	PERCENTAGE OF CUTANEOUS TUMORS	
NEOPLASM	**DOG**	**CAT**
Round Cell Tumors		
Mast cell tumor	16.8%2	16.5%2
Histiocytoma	8.4%2	
Plasmacytoma	1.5%3	Rare
Lymphoma	1%3	2.8%3
Epithelial Tumors		
Squamous cell carcinoma	6%2	10.4%2
Perianal gland adenoma or carcinoma	8-18%3	
Sebaceous adenoma	6.5%2	2.8%2
Basal cell tumor/trichoblastoma	2.6%4	2%4
Hair follicle tumors (trichoepithelioma and similar lesions)	6-7%3	1%3
Mesenchymal Tumors		
Lipoma	9%3	5%3

Fibrosarcoma	1.5%3	17.4%2
Melanocytoma/malignant melanoma	3-4%/0.8-2%3	1.3%/0.4-2.8%3
Hemangiopericytoma	4.4%2-7%3	

Round cell tumors typically are identified on smears by the presence of individualized round cells with round nuclei. Cytoplasmic and nuclear features vary between cell types. In some instances, tumors that are generally classified as "mesenchymal" will have a round-cell morphology. For example, melanoma cells can be found as round, polygonal, spindle and even in cohesive-appearing sheets. Also, there are rare cases of cutaneous metastasis of osteosarcoma and the neoplastic cells in primary and metastatic sites for osteosarcoma can mainly be round.

Epithelial tumors typically are identified by the presence of cohesive sheets, whereas individualized cells occur less frequently (e.g., with squamous cell carcinoma). The cytoplasm can vary in appearance and if the lesion is of glandular origin the cytoplasm may contain secretory vacuoles. With cystic hair follicle tumors and similar lesions, it is common that FNA might yield predominantly dense aggregates of mature anucleate keratinocytes with minimal or no representation of the wall of the cyst, making it difficult to arrive at a specific diagnosis. In such cases, it is important to consider performing a biopsy, as it will allow for architectural assessment of the cyst wall and for presence of additional features such as inflammation in foci where the cyst may have ruptured or even features that might suggest a less common malignancy.

Mesenchymal tumors are identified by the presence of individualized cells that often have spindle or polygonal shape (though round cell forms certainly are possible). The cytoplasmic margins of the cells often are tapered and occasionally indistinct. Nuclei may be round or oval and again, cytoplasmic and nuclear features can vary between lesions. The number of cells that exfoliate with mesenchymal lesions can vary, ranging from sparse to abundant. With high-yield smears, dense clusters of spindle cells can be found; scrutiny often allows the evaluator to realize that the clusters are not truly cohesive. Benign lipomas are included in the mesenchymal category and may be underrepresented in literature reports. Aspiration of adipocyte sheets is a common finding. Interpreting the significance of the adipocyte sheets in absence of a good clinical history is a challenge since aspiration of normal subcuticular fat can have identical cytomorphologic appearance as a lipoma. This is important because if a cutaneous lesion is targeted but the needle misses the mass and only the surrounding subcuticular fat is retrieved, an erroneous diagnosis of a lipoma could be made. If a lesion is clinically suspected to be something other than a lipoma and only adipocytes are retrieved during aspiration, re-collection of an aspirate (or biopsy of the lesion) may be indicated.

When to Biopsy

Since FNA typically can lead to a diagnosis quickly, clinicians often await the results of the FNA prior to deciding whether to collect a biopsy of a lesion. However, both types of samples can certainly be collected and submitted concurrently. If the samples are collected at the same time, the clinician also has the option of preserving the biopsy in formalin and deciding to submit it if the FNA results do not provide a definitive diagnosis. Cytopathologic evaluation has advantages, though a more complete "picture" of a process can be created when cytology smear results are combined with biopsy results. Histologic evaluation of a biopsy does not provide as much detail with respect to individual cell morphology. However, the major advantage is that architectural features can be assessed, which can be highly informative. For example, when pathologists evaluate mammary masses, histologic evaluation is critical since identification of features such as capsular invasion and lymphatic invasion (which cannot be assessed during cytopathologic evaluation of an FNA smear) will distinguish between a benign and malignant lesion if the tumor's cytomorphology is not convincingly definitive.

CHAPTER 88

Abdominal Ultrasonography

Rachel E. Pollard

Abdominal ultrasound has become a common and valuable tool in the diagnostic arsenal for small animal practitioners (also see ch. 143). A fundamental understanding of ultrasound physics and imaging principles can allow the user to make basic diagnoses. Moreover, a consistent and repeatable methodology for performing an abdominal ultrasound examination will minimize errors, omissions, and missed lesions.

Ultrasound Physics

Medical ultrasound functions in a way similar to sonar. A sound beam of a specific frequency (megahertz [MHz]) is sent into the area of interest by the transducer. The transducer waits for the returned echoes and "listens" for their amplitude (intensity) and location (directly related to how long it takes for the echo to return). Once the ultrasound beam enters the area of interest, it can be absorbed, refracted, or reflected. If the beam is absorbed, no ultrasound waves will return to the transducer and, consequently, no information becomes available for generating an image. Similarly, if the ultrasound waves are refracted, their pathway is altered such that they do not return to the transducer. Thus, only ultrasound waves that enter the body, encounter an object (tissue), and are reflected directly back to the transducer are used to generate an image. Highly reflective structures will appear bright (gas, mineral), whereas parenchymal organs will be variable in their reflectivity and appear as shades of gray.

Tissue Characteristics

Most organs are described according to their size, shape, echogenicity (brightness) and echotexture (parenchymal pattern). Size and shape are self-explanatory terms and will not be further discussed. Echogenicity is assessed on a relative scale in comparison to other organs and to what is anticipated as normal. An object or tissue that is anechoic has no echogenicity and is black. An object that is bright in comparison to other objects or the anticipated norm is hyperechoic. An object that is dark in comparison to other objects or the anticipated norm is hypoechoic.

A relative scale of normal tissue echogenicity can be established (Table 88-1). It is essential to compare tissues to one another in order to establish true echogenicity since tissue brightness can also be affected by machine settings. However, using this scale of relative echogenicities, one can define pathologic changes. For example, a fibrotic or fat-infiltrated liver will become more hyperechoic than it should be in comparison to other organs because it has been infiltrated by more hyperechoic tissue. Similarly, an edematous or congested spleen will become more hypoechoic than it should be in comparison to other organs since it contains more fluid than it should.

TABLE 88-1

A List of Tissues in Order of Relative Echogenicity from Darkest (Fluid) to Brightest (Mineral, Gas)

TISSUE	ECHOGENICITY
Water/fluid	Anechoic
Renal medulla	Hypoechoic
Renal cortex	Medium echogenicity
Liver	Medium echogenicity

Spleen	High echogenicity
Prostate	Hyperechoic
Fibrous tissue, fat	Very hyperechoic
Mineral, gas	Most hyperechoic

The assessment of tissue echotexture is more subjective. Most normal organs have a smooth and homogenous echotexture. Changes in echotexture result in a heterogeneous appearance to the tissue, either focally or diffusely, and often accompany a change in echogenicity. Terms to describe diffuse changes in echotexture might include *coarse*, *mottled*, or *nodular* while focal lesions would be described as *complex*, *mixed echogenicity*, or *mass*.

Performing the Complete Abdominal Ultrasound Examination (Video 88-1)

Preparation

Before the ultrasound evaluation begins one must ensure that the animal is comfortable. It is recommended that the ultrasound exam be performed in a dimly lit room with as little traffic as possible. The ultrasound machine is placed adjacent to and to the right of the dorsally-recumbent dog's or cat's head, and the transducer is held in the right hand. Restraint of the pet is typically accomplished by having technicians hold the animal's legs and head while performing the exam. A foam pad cut into a wedge (V-trough) is used as a comfortable positioning device to hold an animal on its back during the examination. In the event that an animal is highly stressed or aggressive or that the ultrasound examination is lengthy, chemical restraint may be indicated.

For adequate ultrasound scanning, hair needs to be clipped from the ventral abdomen to reduce artifacts and provide better visualization of abdominal organs. The hair should be clipped from the xiphoid caudally to the inguinal region with the lateral margins of the clip following the costal arch and extending roughly half way up the flank. Alcohol or a water solution should then be applied to moisten the skin, displace air associated with the hair follicles, and remove the surface layer of grease, which can be present on the skin surface. The final preparation includes applying liberal amounts of coupling gel to the abdomen. This sonographic gel should be manually worked into the shaved skin surface for optimal acoustic coupling.

Getting Started

The image orientation dot or symbol on the screen should be positioned on the left side of the image display. This dot correlates to a mark, line, dot, or light on the transducer. This indicator should be directed toward the head of the animal for the longitudinal scan plane and directed toward the animal's right side (toward the machine and sonographer) for the transverse scan plane. When performing the ultrasound scan, the transducer should not be lifted from the skin when moving to another region; instead slide the transducer along the abdomen until the next area of interest is encountered.

Region 1: The Liver

To begin the scan, the transducer should be placed in a longitudinal orientation adjacent to the xiphoid process with the transducer angled craniodorsally at 60°. This position will give the sonographer a longitudinal image of the liver. Beginning the evaluation with the liver allows images of the liver to be obtained before the dog or cat has an opportunity to swallow air into the stomach. Air has the potential for blocking out some or all of the liver. Additionally, the liver resides in the deepest portion of the abdomen and is normally relatively homogenous. Machine depth, time gain compensation (TGC), and the overall gain can be set appropriately.

Once an adequate longitudinal image of the liver is obtained, the transducer should be angled back and forth from the left to the right to “interrogate” the liver. The gallbladder is best visualized by pointing the transducer toward the animal's right elbow with the transducer just to the right of the xiphoid process. For transverse scanning of the liver, the transducer is rotated counterclockwise so the indicator is toward the animal's right. As with the longitudinal plane, it is recommended to use a “fanning” motion to interrogate the liver instead of making large sliding movements with the transducer. The transducer should then be moved with a sliding motion toward the left to visualize the stomach. Complete evaluation of the stomach is usually

not attainable due to the variable amounts of gas present within the gastric lumen.

Region 2: Left Pancreatic Limb, Spleen, Left Kidney

With the transducer in the longitudinal orientation, the stomach is positioned to the left (cranial) of the display. The area on the caudalmost aspect of the stomach represents the greater curvature and fundic portion of the stomach and is one of the landmarks for the left pancreatic limb. Other landmarks include the splenic vein, spleen, and transverse colon. In the normal animal, the pancreas is not usually visualized.

As the transducer is moved to the animal's left across the abdomen in a caudal and lateral direction, the spleen should be visible in the "near" field. The dorsal extremity of the spleen lies adjacent to the lateral surface of the gastric fundus and can extend into the far field along the left lateral body wall (dorsally). After the dorsal aspect of the spleen is assessed, the display depth can be reduced so as to allow the sonographer to evaluate the more superficial body and tail of the spleen. Either the transverse or the longitudinal plane can be used to evaluate the spleen with equal effectiveness.

The transducer should then be moved caudally in the longitudinal imaging plane along the lateral surface of the abdomen until the left kidney is visualized. Once the left kidney is located, imaging the organ in the longitudinal plane initially is usually easiest and most informative. This plane allows the sonographer to evaluate kidney size and shape along with visualization of the corticomedullary definition. The transducer can then be rotated counterclockwise to produce a transverse kidney image. The transverse plane of the kidney is the most sensitive image for detecting renal pelvic dilation.

Region 3: The Left Adrenal

The landmarks used for the left adrenal are the medial aspect of the left kidney, the left renal vessels, and the abdominal aorta. To locate the adrenal, one must first locate the left kidney in a longitudinal plane and then aim medially to look for the aorta in the far field. By dropping or lowering the proximal portion of the transducer toward the table, the aorta will come into view. The normal adrenal gland lies in close proximity to the lateral wall of the aorta. The renal artery and vein are seen adjacent to the caudal surface of the adrenal and act as the most caudal landmark. When the abdominal aorta is identified in a longitudinal plane, the adrenal can be located by fanning the sound beam dorsally or ventrally. In most animals, it is necessary to increase the hand pressure placed on the transducer to obtain adequate visualization of the adrenal.

Region 4: Urinary Bladder, Prostate/Uterus, Sublumbar Lymph Nodes

The transition to this region requires the transducer to be drawn down the left side of the abdomen in a caudal and medial manner. The descending colon and multiple loops of small intestine (jejunum) are seen during the transition. The urinary bladder is usually easiest to identify in the longitudinal plane; however, in some animals with a small bladder, or a large, gas-filled descending colon, the transverse plane may be the easiest. The complete evaluation of the bladder requires both the longitudinal and transverse planes to be acquired because small bladder lesions such as polyps or early tumors can be easily missed. In the male dog, it is recommended to scan the bladder from both sides of the prepuce in both imaging planes for a complete evaluation. It is best to image the urethra in the longitudinal plane initially and then move to the transverse plane. Hand pressure should be increased slightly as compared to that used for the urinary bladder and the transducer should be kept as close to midline as possible. In most animals the transducer must be angled in the caudal direction 10° to 40° to obtain images dorsal to the pubis. In the intact male, the prostate is hyperechoic (see Table 88-1), symmetrical on either side of midline, oval in shape, with the urethra in its center. The prostate in neutered males is usually quite small and hypoechoic. The remnant of the prostate can be somewhat difficult to visualize in dogs that were neutered at an early age.

The body of the uterus, unlike the uterine horns, is usually visible adjacent to the urinary bladder. The location of the uterine body is somewhat variable but usually dorsal and lateral to the bladder. It is advantageous to locate the uterine body in the transverse plane and then rotate the scanhead to image the uterus in the longitudinal plane.

The iliac (sublumbar) lymph nodes are identified deep (dorsal) to the urinary bladder, where the abdominal aorta branches to become the external iliac vessels and terminal aorta. Visualization of these nodes is inconsistent in the normal animal and depends on technique and machine settings. It is easiest to find the nodes using the transverse plane because this gives the sonographer the best opportunity to visualize the aortic branches. The sublumbar lymph nodes can usually be visualized cranial to and between the vascular branches. The bifurcation of the caudal vena cava is also apparent in the caudal lumbar region on the right

side of the aorta and can be identified based on the ability to compress its lumen with increased transducer pressure.

Region 5: The Right Kidney, Duodenum/Right Pancreatic Limb

During the transition from the region of the bladder to the right kidney one is usually able to visualize more small intestine and the ascending colon. The small intestine lies medial to the region of the right kidney, as does the ileocolic junction. The right kidney lies in a more cranial and lateral location than one would expect. In the dog, the best way to visualize the right kidney is to place the transducer medial to the 13th rib and direct the sound beam cranially and perhaps a bit laterally. In the cat, the right kidney is usually easily seen and can be imaged directly from the right side without the interference of the ribs and the associated costal arch. Complete evaluation of the right kidney consists of both the longitudinal and transverse projections. Transducer pressure should be moderate for evaluation of the kidney, as the overlying small intestine needs to be displaced to limit imaging artifacts secondary to intestinal gas.

The descending duodenum and associated right pancreatic limb are in close proximity to the right kidney. Transducer pressure should be decreased from that used to image the right kidney and the depth of the display can often be decreased to increase resolution. The duodenum is located by fanning laterally from the kidney in the longitudinal plane. The right pancreatic limb is inconsistently visualized in the normal animal and lies adjacent to the medial aspect of the descending duodenum.

Region 6: The Right Adrenal

As with the left adrenal, in order to locate the right adrenal the sonographer must locate the kidney and the great vessels. Landmarks utilized in visualizing the right adrenal gland include the right kidney and the caudal vena cava. Adequate imaging of the adrenal requires the transducer to be directed in a dorsal and medial direction starting from a longitudinal view of the right kidney. This adrenal gland lies parallel to the vena cava and is often seen in the far field adjacent to the wall of the vessel.

Region 7: The Mid-Abdomen

Evaluation of the mid-abdomen includes the mesenteric lymph nodes and the small intestine along with the associated omentum. The technique for the mid-abdomen includes variations in transducer pressure and imaging planes. One should attempt to visualize loops of the small intestine in both a transverse and longitudinal plane.

The mesenteric or jejunal lymph nodes lie in clusters associated with the mesenteric vessels in the mid-abdomen. These nodes are inconsistently visualized in the normal dog but often can be seen in the cat. They are usually in close association with the cranial mesenteric artery adjacent to the body of the second lumbar vertebra. The lymph nodes can be either round or fusiform in shape and often will have the same echogenicity as the spleen. In the young animal, the mesenteric nodes are sometimes easily visualized and can appear prominent.

Summary

As with radiographic interpretation, a good abdominal ultrasound examination requires a solid knowledge of anatomy and a systematic approach. A basic knowledge of physics and tissue characteristics is also useful. The assessment of organ size, shape, echogenicity, and echotexture coupled with an understanding of what causes alterations in these four factors is the basis of all ultrasound diagnoses.

CHAPTER 89

Abdominal Ultrasound

Aspirations and Biopsies

Eric J. Herrgesell

Background

Ultrasound-guided tissue sampling has become a routine procedure in many small animal veterinary hospitals. Percutaneous ultrasound-guided procedures have gained popularity because precise needle placement is possible. This results in a safer collection procedure and a relatively high diagnostic yield. Not only peripheral lesions, but "deep-seated" tissues, can usually be sampled. Compared to blind procedures, ultrasound guidance has greater potential for more accurate diagnosis with less soft-tissue trauma. It is appreciated that ultrasound patterns are generally nonspecific regarding specific diagnoses and samples are required for a definitive diagnosis. In recent years, advancements in ultrasound machine quality and imaging potential have greatly improved the utilization of ultrasound-guided soft-tissue aspirate or biopsy.

One benefit of ultrasound-guided tissue sampling is that general anesthesia is not usually necessary, especially with fine-needle aspiration (FNA) procedures. Heavy sedation or anesthesia may be indicated for core biopsy procedures to minimize movement and pain perception. Decisions regarding use of sedatives or anesthetic agents should be made based on the nature of the patient and the lesion in question (see ch. 138). Usually, short-acting sedatives or anesthetic agents are utilized. One limitation of using ultrasound-guided tissue sampling is that some lesions cannot be adequately visualized. This is often due to superimposed gas or mineral density, either of which may cause significant ultrasound artifact. One should avoid passing a needle through any unrelated organ or tissue to limit hemorrhage or trauma.

In human medicine, a variety of specialized transducers has been developed. These include transesophageal and intracavitary transducers to facilitate diagnostic ultrasound and tissue sampling. When such transducers become more available for veterinary medicine, ultrasound-guided sampling will improve further. The standard transducers readily available in veterinary practice, either curvilinear or linear, are typically utilized for ultrasound-guided biopsy and cytology procedures. In general, curvilinear transducers are superior for deeper tissue sampling due to better orientation and imaging capabilities. Linear transducers are usually excellent for sampling superficial tissues or smaller lesions.

Indications

Evaluation of samples obtained via percutaneous ultrasound guidance can be beneficial in understanding the nature of diffuse parenchymal abnormalities or mass lesions involving one or multiple organs. Ultrasound-guided new methylene blue marking of a specific mass or soft tissue foreign body may be useful. Using ultrasound as "therapy" is mostly limited to drainage of fluid. Obtaining fluid from an abscess, cyst, pleural space, peritoneal cavity, or the pericardial sac can relieve pressure while also providing samples for cytological analysis (see ch. 74, 102, and 111). It is also somewhat common to utilize ultrasound-guided cytology samples to evaluate bone lesions.

Materials

Choosing an ultrasound transducer appropriate for a specific task depends on the type and location of a lesion and the preference of the sonographer. For lesions <2 cm in depth, a linear transducer may be chosen because of its higher resolution and spatial orientation. For lesions deeper than 2 cm, a curvilinear or sector transducer is most often indicated.

Of the cytology needles typically available in veterinary practice, either a 1.5 inch 22- or 25-gauge needle is utilized for tissue sampling. The range of needle size does vary and some practitioners favor 20-gauge needles. However, 25-gauge needles usually provide excellent samples for cytological analysis with less blood contamination. For deeper lesions, either a 2½ or 3½ inch 22-gauge spinal needle can be used.

Core biopsies are typically obtained with a needle containing a stylet and a biopsy port. These specialized needles are available in manual and automated configurations. The biopsy instrument is often a "Tru Cut" needle with numerous variations available. Typical core biopsy needles range from 14- to 20-gauge, providing tissue samples of 1 to 2 cm in length. Shorter core biopsy needles are easier to orient. Typical core biopsy needle sizes include 9 and 15 cm needle lengths, but these may vary. Automated needles, i.e., spring-loaded, usually provide excellent samples. Some ultrasound needles and ultrasound biopsy instruments have echogenic substances pre-attached to the shaft of the needle, providing better needle visualization during biopsy or aspiration procedures. Also, some ultrasound equipment manufacturers provide biopsy guides that attach to a specific transducer. These biopsy guides are not interchangeable. Biopsy guides help with needle placement by reducing motion. However, the biopsy guide may require use of longer needles as these guides are attached to the transducer approximately 2 cm from the patient transducer interface.

Techniques

Safe and successful collection of samples is reliant on placing the lesion within the focal zone of the transducer and on the ability to introduce the sampling device into the lesion. There are three factors of motion that must be considered: the patient, the transducer, and the needle. Patient motion is inevitable due to breathing and other minor movements. Patient movement can usually be limited with sedation or anesthesia. Once the lesion to be sampled is identified, one should place a hand on the patient with the transducer centered over the lesion to reduce some motion. The goal is to have the ultrasound transducer "attached" to the patient. This process is similar to resting the hand above an eye, with a tube in that hand, before applying ointment. Once the transducer is stabilized against the patient, the needle can be advanced into the lesion.

Orientation of both needle and transducer are critical factors in obtaining satisfactory samples with minimal tissue trauma. Transducers usually available for veterinary use have an "indicator." This is either a raised portion of the transducer housing or a light parallel to the crystals within the transducer. The indicator should be aligned with the imaging plane of the transducer. Basically, transducer and needle should form a V (Video 89-1). Advancing the needle in this plane facilitates visualizing most or all of the core biopsy needle length. The tip of the needle can also be visualized within the lesion in question. The goal is to have the lesion centered under the ultrasound transducer in order for the needle to extend through superficial tissues and terminate within the lesion without crossing a visceral structure.

There are numerous techniques recognized and utilized in veterinary practice to collect cytology samples (see ch. 93 and 95). One technique is to place the needle into the lesion and then advance and retract the needle approximately 1 to 1.5 cm, if possible, within the lesion while providing gentle suction. Spinal needles or standard hypodermic needles should be attached to a 3 mL syringe. Once blood or tissue is seen within the hub of the needle, the procedure should be terminated and the slide is prepared. Other methods for obtaining a sample are recognized, including using the needle without a syringe attached. Another procedure involves attaching an "extension set" to the needle, placement of the needle within the lesion, and then using the up-and-down sampling technique. The extension set creates mild negative pressure and can provide adequate cytological samples without employing as much negative pressure. When using a spinal needle, advance the needle into the lesion with the stylus in place. Once the needle is within the lesion, remove the stylus and obtain a sample either with an extension set or use a 3 mL syringe and gentle negative pressure or suction. One should always attempt to avoid passing the needle through multiple organs or viscera to obtain a tissue sample as this can result in unnecessary tissue trauma and complicate interpretation.

The procedure for ultrasound-guided drainage of fluid is similar to obtaining a tissue sample (see ch. 90 and 102). However, once the needle is placed into the fluid-filled space, there is no need for up-and-down manipulation. If a large amount of fluid is to be drained, the practitioner should consider using a three-way stopcock and an extension set (see Video 90-1). The stopcock allows the practitioner to repeatedly fill and empty the syringe by depositing the removed fluid into a container without moving the needle. This helps to avoid air contamination within the cavity/structure being drained while not losing the fluid location. Needle size is dependent, among many factors, on the condition of the patient, volume of fluid to be removed, and its viscosity.

Ultrasound-guided marking of either nodular lesions or, more commonly, foreign body abscess lesions using sterile dye with ultrasound guidance is popular. Soft-tissue foreign body lesions, especially those caused by grass awns, are recognized in various geographic regions. Identification of a lesion that appears compatible with a foreign body abscess or soft tissue granuloma is usually relatively straightforward. Surgical approach and evaluation of such lesions can be optimized with an ultrasound-guided "marker" placed on the lesion. One can inject about 0.1 mL of new methylene blue into the lesion immediately prior to surgical exploration. This technique results in a tissue blush that the surgeon can visualize during an exploratory surgery.

Ultrasound-Guided Procedures

Sedation and Positioning

Commonly, patients are sedated and placed in dorsal recumbency. For biopsy procedures, most clinicians use deep sedation or general anesthesia to reduce movement and pain. For ultrasound-guided core biopsy techniques, a clotting profile may be warranted because of enhanced chance of bleeding. For cytological sampling, the smaller needle causes less trauma and there is less concern about hemorrhage. Decisions regarding pre-procedure clotting profiles should be made on a case-by-case basis. The organs sampled most frequently include liver, spleen, kidney, and lymph nodes. Gastrointestinal mass lesions are also, but less commonly, sampled. The best position for the patient changes if, for example, a soft tissue structure on the lateral aspect of the abdomen is to be sampled.

Liver

Ultrasound-guided sampling from liver parenchyma is usually performed from the left side. The liver can be well visualized, there is adequate hepatic tissue, and one should be able to avoid the gallbladder and major vessels. Adequate visualization of the stomach is necessary via cranial angulation of the transducer and needle/biopsy device. Special attention should be paid to the diaphragm, a recognizable curvilinear echogenic structure cranial to the liver.

In some situations, collection of biliary fluid is warranted and would be performed from the right side of the patient. The approach to the gallbladder is from the ventral aspect of the animal with the needle then introduced into the ventral aspect of the gallbladder. While dependent on hepatic size, the gallbladder is usually cranial and slightly right of midline. If the gallbladder is quite cranial, it may become difficult to sample.

Spleen

Ultrasound-guided FNA of the spleen is commonly performed. Biopsy of the spleen, by contrast, is far less commonly indicated. Any aspect of the spleen can be sampled. Placing the needle is usually based on the spleen's ultrasonographic appearance. Most commonly, the spleen is located on the left and sampled from that side of the abdomen. Splenic vasculature resides on the dorsal, medial aspect of the spleen when the animal in dorsal recumbency. This location limits accidental perforation of the vasculature. An abnormal spleen is often enlarged, providing significant parenchyma for safe sampling.

Kidney

Renal cytology or biopsy may be indicated if there is significant enlargement, loss of parenchymal detail/echogenicity, or a mass. Core biopsy samples should be obtained from the caudal aspect of the kidney. Orientation of the biopsy should be from a medial to lateral approach to aid in avoiding penetration of the dorsal aspect of the kidney where the larger blood vessels are located. Renal cortical biopsies are usually most useful. Biopsy of the cortex and medullary junction can result in significant hemorrhage. Use of Doppler to identify vascular structures prior to biopsy can be valuable. Cytological samples can be obtained from any portion of the kidney. However, the cortex or region of interest should be sampled without extending the needle into the renal pelvis or medial aspect of the kidney to avoid hemorrhage.

Lymph Nodes

Lymph node sampling is common because lymphoma and other round cell neoplasias are frequently

encountered. Since lymphoma is highly exfoliative and because cytology can be confirmative, lymph nodes are usually sampled with FNA (see ch. 95). If a core biopsy sample is needed, Doppler should be employed first to identify the surrounding vasculature. Lymph nodes are usually poorly to moderately vascular. The technique used is similar to that used for obtaining samples from other visceral organs. The lymph node should be centered on the imaging field of the ultrasound transducer and the needle or biopsy instrument advanced to or slightly beyond the central portion of the structure. Transducer pressure can be critically important because lymph nodes are usually somewhat mobile within the abdomen.

Complications

Complications related to obtaining tissue samples via ultrasound guidance are fairly uncommon. Reduction of complications is reliant upon the skill and experience of the sonographer/clinician. The most common complication is hemorrhage. Less commonly, peritonitis may follow inadvertent perforation of the gastrointestinal tract. Neoplastic lesions involving the lower urinary tract, specifically transitional cell neoplasia, can be accidentally seeded into the abdomen. One should not use ultrasound guidance for sampling most lower urinary tract mass lesions.

CHAPTER 90

Abdominocentesis and Diagnostic Peritoneal Lavage

Oriana Raab

Abdominocentesis

Definition and Purpose

Abdominocentesis is the percutaneous removal of abdominal fluid using a needle or catheter. The procedure is routinely performed for diagnostic and therapeutic purposes.

Abdominocentesis can be carried out to obtain fluid for analysis if there is a high suspicion of effusion based on physical examination or if imaging indicates its presence. Analysis of abdominal fluid can aid in the diagnosis of abdominal hemorrhage, neoplasia, sterile or septic peritonitis, and hollow organ (gallbladder, gastrointestinal tract, uterine, or urinary tract) rupture (see ch. 74).[1] Abdominocentesis can also be performed to remove large amounts of fluid from patients that are experiencing effusion-related clinical signs such as dyspnea, inappetence, and signs of abdominal discomfort.

Contraindications and Considerations

Before performing abdominocentesis, the clinician should consider the benefits versus the risks of the procedure, particularly when a blind puncture is to be attempted. Abdominocentesis should be performed with caution in patients with hemostatic abnormalities. In these cases, percutaneous insertion of the needle or catheter along the avascular midline using ultrasound guidance can help to minimize bleeding. Close monitoring is recommended following the procedure.

Structural impediments to the safe introduction of a needle or catheter can include the gravid uterus, distended urinary bladder, distended intestine, or a large abdominal mass. Gentle manual expression or urethral catheterization should be performed prior to abdominocentesis in patients with extremely large urinary bladders. The intestine typically floats in abdominal fluid and will generally move safely out of the way of a slowly advancing catheter.

Abdominocentesis should be performed after radiographic and/or ultrasonographic evaluation has been completed. Without prior imaging, it can be difficult to determine whether free air present in the abdominal cavity was introduced iatrogenically during the procedure or whether it was caused by pathologic rupture of a hollow organ.[1,2]

Complications of Procedure

Complications including hemorrhage, local infection or peritonitis, and intestinal perforation, are uncommon; however, they can be minimized with the use of ultrasound guidance. The risk of a subcutaneous hematoma can be lessened by avoiding needle or catheter placement in the vicinity of the caudal superficial epigastric vessels, which lie paramedian and adjacent to a longitudinal line drawn between the nipples.[2] The use of an over-the-needle catheter rather than a hypodermic needle can also help to decrease the risk of penetration or laceration of an organ or blood vessel and minimize the chance of false-positive results[3]; however, the use of a catheter in thicker-skinned or obese patients, or those with extensive body wall movement (e.g., panting dogs) could lead to kinking of the catheter, making it ineffective.

Sedation/Analgesia

Abdominocentesis typically is performed in conscious animals using physical restraint. The use of a sedative could be warranted depending on the patient's temperament. The administration of an analgesic or

instillation of a local anesthetic in the region where the needle or catheter is to be placed should be considered, particularly when large-gauge catheters are utilized or when diagnostic peritoneal lavage is performed.

Sample Collection

Collection tubes that should be available during fluid sampling include EDTA (lavender top) tubes for cytologic analysis, total nucleated cell count, protein measurement and packed cell volume; and plain (red top) tubes and culturette swabs for biochemical analysis and bacterial culture and sensitivities. Additional tests can be performed depending on the clinical circumstances (see ch. 17).

Preparation, Equipment and Techniques

There are several acceptable methods for obtaining a sample of abdominal fluid. Ultrasound should be utilized whenever possible to confirm the presence of abdominal effusion and to guide needle placement for fluid aspiration (see ch. 143). If ultrasound is unavailable, a single blind puncture or four-quadrant technique can be performed. However, it is important to remember that blind abdominocentesis might be unsuccessful in patients with small volumes of abdominal fluid, or in patients with effusion confined to the retroperitoneal space.

Regardless of the technique chosen, patient preparation is the same. The ventral abdomen should be clipped free of fur and surgically prepared using antiseptic scrub and isopropyl alcohol. The individual performing the procedure should wear sterile gloves to ensure asepsis.

Depending on the size of the patient, a sterile 18- to 22-gauge, 1 to 1.5 inch (2.5-4 cm) needle or 16- to 22-gauge over-the-needle catheter may be utilized. If a catheter is utilized, prior to the procedure, 2 to 4 small fenestrations can be made in staggered positions at the distal third of the catheter using a sterile #10 or #11 scalpel blade (Video 90-1). Fenestrations should be no larger than one third of the catheter circumference and should be spaced far enough apart so that they do not weaken the shaft and lead to catheter breakage.[2] The creation of fenestrations lessens the chance of obstruction of the catheter by loose tissue such as omentum and increases the likelihood of obtaining a fluid sample.[3,4] Considerably lower false-negative results can be expected with the use of a dialysis catheter or fenestrated over-the-needle catheter, which have multiple side holes, rather than a hypodermic needle, which has a single end hole.[3,4] Additional equipment needed includes an appropriate sized syringe and collection tubes.

Simple Ultrasound-Guided Abdominocentesis

The patient may be placed in dorsal or lateral recumbency. The ultrasound transducer should be kept sterile via the use of a sterile sleeve or aseptic preparation. Using ultrasound guidance, a needle or over-the-needle catheter of appropriate size is directed percutaneously into a fluid pocket and the contents are gently aspirated.

Simple Blind Abdominocentesis

The patient may be placed in lateral recumbency or the procedure may be performed with the patient standing. A needle or over-the-needle catheter of appropriate size is percutaneously inserted on the ventral midline approximately 2 to 4 cm caudal to the umbilicus. Alternatively, the needle or catheter is inserted 1 to 2 cm to the right of the midline to avoid splenic penetration. A syringe of appropriate size is attached for gentle aspiration (closed method) or the needle or catheter is inserted, gentle abdominal compression is applied and fluid is collected from the hub without attaching a syringe (open method).[3]

Blind Four-Quadrant Abdominocentesis

If simple blind abdominocentesis is unsuccessful, a blind, four-quadrant technique may be attempted. The patient may be placed in dorsal or lateral recumbency, or with cooperative patients, some clinicians perform this technique with the animal standing, to increase fluid yield through gravitational draw of fluid ventrally. Using the umbilicus as the center point, a needle or over-the-needle catheter of appropriate size is inserted into the cranial dependent quadrant, the cranial nondependent quadrant, the caudal dependent quadrant and the caudal nondependent quadrant (or equivalent sequence if the patient is dorsally recumbent or standing).

Fluid may be collected via an open or closed method as described above. Placing needles (without attached syringes) in more than one quadrant at a time provides an air vent that may allow fluid to flow. Any positive tap in any quadrant completes the procedure.[2]

Large Volume Abdominocentesis

Patients who are hemodynamically stable but experiencing respiratory compromise or discomfort may have larger amounts of fluid removed to alleviate their clinical signs. The technique is identical to that of a simple abdominocentesis described previously except that a larger bore over-the-needle fenestrated catheter is used. Once the catheter is inserted, sterile extension tubing and a syringe with a 3-way stopcock are attached to permit aspiration and removal of abdominal fluid (Figure 90-1; see Video 90-1).

FIGURE 90-1 Equipment needed for therapeutic abdominocentesis. From left to right (all sterile): large syringe (here, 35 cc), 3-way stopcock, gloves, catheter, extension set, scalpel blade.

The main safety concern with large-volume abdominocentesis is hemodynamic changes; blood pressure initially falls as intra-abdominal pressure decreases.[5] However, relief of intra-abdominal hypertension can confer hemodynamic and constitutional benefits (e.g., improved appetite and demeanor) in patients with tense ascites. Although the procedure uncommonly leads to pronounced hypotension, blood pressure assessment (see ch. 99) may be performed following the procedure. There is no consensus with regards to fluid withdrawal rate.

Diagnostic Peritoneal Lavage

In cases in which the fluid pocket is too small or in a location that cannot be safely aspirated, or when peritonitis or other effusive disease is suspected, diagnostic peritoneal lavage (DPL) is an alternative to abdominocentesis. Historically, lavage (using a dialysis catheter or fenestrated over-the-needle catheter) was superior to blind abdominocentesis for detecting free intra-abdominal blood and other materials such as bile, urine, chyme, feces and exudate[6]; however, centesis techniques could yield superior results when performed with ultrasound guidance (see ch. 143). As with abdominocentesis, radiographs or ultrasound should be performed prior to DPL as the procedure can confound subsequent imaging by the iatrogenic introduction of fluid and possibly air into the abdominal cavity.[7] The urinary bladder should be emptied prior to the procedure to avoid inadvertent trauma to the bladder. If the patient cannot void on its own, gentle manual expression or urethral catheterization should be performed.

The patient is placed in lateral or dorsal recumbency. Conscious sedation and analgesia are provided. The ventral abdomen is clipped free of fur and aseptically prepared. Local anesthetic is then infiltrated into the midline skin and body wall, 2 to 3 cm caudal to the umbilicus. A small release incision is made in the skin with a #10 or #11 scalpel blade. Using aseptic technique, including sterile gloves, a commercial DPL catheter (or 14-gauge to 16-gauge fenestrated 2.5- to 5.5-inch [8-18 cm] over-the-needle catheter, or a fenestrated 18-gauge, 2-inch [5 cm] over-the-needle catheter in cats and very small dogs) is inserted percutaneously into the abdominal cavity.[6] After the peritoneum is penetrated, the catheter is carefully advanced in a dorsocaudal direction while the stylet is withdrawn. If the catheter does not advance easily, it could still be in the subcutaneous tissue or against an organ, and it should be repositioned. If fluid drains freely from the catheter, samples should be collected. If no fluid drains, once the catheter is seated to the hub, sterile extension tubing is connected and sterile, warmed physiologic saline (20 mL/kg) is infused into the abdominal cavity by holding the saline bag above the patient to counter intra-abdominal pressure. The catheter is then occluded with a sterile injection cap. After taking precautions to secure the catheter, the abdomen is massaged or the animal is gently rotated from side to side to distribute and mix the fluid in the peritoneal cavity. The patient is then turned on its side and a sterile collection system is attached to the catheter; the bag is placed at a level below the patient and the effluent is collected via gravity drainage. If no fluid is obtained, a syringe may be attached to the catheter for gentle aspiration. Samples of the obtained fluid are then submitted for cytologic, microbiologic and/or biochemical analysis. Complete removal of the infused fluid is not necessary and typically is not possible.

CHAPTER 91

Laparoscopy

Keith Richter

Client Information Sheet: Laparoscopy

The use of laparoscopy for diagnostic and therapeutic purposes has increased tremendously in human and veterinary medicine during the last 15 years. This acceptance of laparoscopy stems from technologic advances in equipment, improved access and training, and superior results for many procedures achieved with this less invasive modality. Many of the procedures will gain acceptance due to their ease, effectiveness, and reduced morbidity. Advantages of laparoscopy over open surgery include less postoperative pain, a lower infection rate, improved visualization in many cases, and a shorter hospitalization time. Laparoscopy also has some advantages over other minimally invasive procedures, such as ultrasound and ultrasound-guided biopsy.

Equipment

Light is transmitted from a remote light source via a fiberoptic light cable to the rigid fiberoptic laparoscope (telescope). Size and viewing angles of laparoscopes vary. A forward-viewing (0°), 5.0-mm outer diameter, 35-cm long scope is preferred for most dogs and cats. Since most laparoscopic instruments are also 5 mm in diameter, this provides versatility by allowing the scope and instruments to be interchangeable with the same size cannula. Smaller scopes have a smaller image with less field of view. In addition, a greater light intensity is needed for smaller scopes. Scopes up to 10-mm diameter can also be used. Though these have slightly better image quality and allow more light than 5-mm diameter scopes, the difference is small and they only provide an advantage in quite large dogs. Scopes are available in various degrees of angulation of view, including 0° (direct forward viewing) up to 70°. The 0° angle is easier to use and generally preferred for most procedures. A 30°-angle scope can be used to view structures to the side of the tip, and through rotation, to expand the field of view. Angled scopes are more difficult for inexperienced operators with regards to spatial orientation. Most scopes have no biopsy channel. Operating scopes have a 5- or 6-mm channel, with an eyepiece extending from the proximal end. These scopes allow introduction of instruments through the same puncture as the scope. The disadvantage of operating scopes is the limited ability to manipulate instruments passing through the channel. Usually the accessory or secondary puncture technique is preferred (see below).

Video capabilities can be achieved with a handheld charged coupling device (CCD) video camera mounted on the eyepiece. These cameras have high resolution, magnify images 5 to 15 times, and provide a clear image. The use of video is essential for operative laparoscopy. A bright light source (usually 150 to 300 watts) is required to adequately illuminate the abdomen.

To visualize abdominal structures, a pneumoperitoneum must be created. This lifts the viscera away from the abdominal wall and is accomplished by insufflating gas through tubing attached to a Veress needle. The latter has a spring-loaded blunt inner portion and an outer cannula with a sharp point. The sharp point is used to penetrate the abdominal wall; then the inner blunt portion is protruded past the sharp point and left in that position to avoid traumatizing abdominal viscera. The abdomen can then be continually insufflated as needed to complete a procedure. Carbon dioxide (CO_2) is the gas recommended because it is rapidly absorbed, minimizing the risk of air embolism. The latter is a reported complication of laparoscopy using nitrogen, which is absorbed more slowly than CO_2.[1] Room air is the slowest gas to be absorbed. The disadvantage of CO_2 is that it is slightly more irritating to the peritoneal surface and therefore requires a slightly higher plane of anesthesia. Gas is infused with an automatic insufflator. These devices regulate flow rate and intra-abdominal pressure. Initial infusion of gas should be slow (1 L/min) to allow gradual accommodation to the increased intra-abdominal pressure. Once optimal insufflation pressure is reached, a higher flow rate can be used to maintain the desired pressure. Ideally, intra-abdominal pressure should not

exceed 10 mm Hg (cats and small dogs) to 15 mm Hg (large dogs). In most cases, arterial blood gas parameters remain within acceptable limits.[2] Excessive abdominal pressure decreases venous return to the heart and causes decreased ability to ventilate.

The laparoscope is introduced into the abdomen with the use of a trocar/cannula assembly. The cannula is a metal or hard plastic sleeve with a one-way valve that permits passage of instruments (such as the trocar, laparoscope, and accessory instruments) and prevents gas escape. The trocar is a sharp-pointed stylet that is used to penetrate the abdominal wall. It is removed, leaving the cannula in place so that the laparoscope can then be introduced. Accessory puncture sites are made for additional trocar/cannula assemblies, which allows introduction of blunt metal probes, suction tips, cautery instruments, grasping forceps, "spoon," or "clamshell" style (oval cup) biopsy forceps, and a wide variety of surgical instruments. These instruments are elongated, narrower versions of standard surgical instruments. Laparoscopy can guide the insertion of needle biopsy instruments for sampling kidney and other deep tissues. They are inserted directly through the abdominal wall without the need for a cannula. The use of stapling equipment has enabled surgeons to perform procedures such as vessel ligation and bowel resection.

Indications for Laparoscopy

Common indications for laparoscopy are for hepatobiliary evaluation. Laparoscopy allows procurement of large specimens (similar in size to surgical biopsies) using a 5-mm "spoon" or "clamshell" forceps. This approach yields tissue of superior diagnostic quality as compared with needle biopsies. The latter has an approximate 50% concordance with histologic findings from surgical biopsies.[3] Furthermore, the ability to visualize the liver gives the clinician a better feel for pathologic processes. Additional indications for laparoscopy are listed in Box 91-1.[4-29]

Box 91-1

Indications for Laparoscopy

- Biopsy of the liver, pancreas, kidney, spleen, prostate, intestine, mesentery, omentum, and the parietal peritoneum[4-13]
- Stage abdominal tumors
- Guide aspiration of the gallbladder, loculated ascites, abdominal cysts or abscesses[7]
- Guide transabdominal intrauterine artificial insemination[7]
- Evaluation of abdominal trauma
  - Hepatic and splenic laceration, diaphragmatic hernia, bladder rupture, renal rupture, abdominal hernia
- Variety of surgical procedures[14-29]
  - Ovariectomy/Ovariohysterectomy
  - Gastropexy
  - Cholecystectomy
  - Cystic calculi removal
  - Adrenalectomy
  - Splenectomy
  - Cryptorchid removal
  - Jejunal feeding tube placement
  - Bowel resection
  - Nephrectomy

Technique

It is preferred to perform laparoscopy with the animal under general anesthesia. The position of the dog or cat and location of the various puncture sites will depend on the procedure, size of patient, and organ being examined. Because the liver is the most common organ examined and biopsied, this procedure will be described in detail.

Laparoscopy-Guided Liver Biopsy (Video 91-1)

The main advantage of laparoscopy-guided biopsy is the ability to obtain large biopsy samples and to visualize the liver, biliary tree, and other abdominal organs. With experience, the gallbladder can be examined, palpated with a blunt probe, and the bile duct traced to its entry into the duodenum. In this manner it can be determined whether a common bile duct or cystic duct obstruction exists. In addition, because focal lesions of the liver can be directly visualized, an appropriate biopsy site can be selected while avoiding other intrahepatic structures (gallbladder and portal vessels). Hemorrhage can be observed and, when excessive, controlled with direct compression with a blunt probe over the biopsy site. Alternatively, electrocautery or application of a hemostatic material (Gel-Foam) can be used to control hemorrhage. Compared with laparotomy, much less anesthetic time is usually required. A complete laparoscopic examination can be completed and multiple hepatic biopsies obtained in 10 to 15 minutes. Because only a 0.5- to 1.0-cm incision is made, less risk exists for wound dehiscence and infection.

The animal is placed in left dorsal oblique recumbency at a 45° angle. This position allows visualization of both sides of the liver, gallbladder, bile duct, pancreas, duodenum, and much of the abdominal viscera. It avoids the falciform ligament which might be encountered with a midline approach. The puncture sites should be surgically prepared and draped. The Veress needle (for insufflation) is inserted through a small stab incision (using a No. 11 blade) on the midline just to the right of the umbilicus. Prior to insufflation, the Veress needle is aspirated to confirm that no viscus has been entered. Saline (6 to 8 mL) is then infused to ensure free flow into the abdominal cavity. The abdomen is then insufflated with gas to an appropriate pressure as determined by a pressure gauge on an automatic insufflator (see above) or when the abdominal wall is tympanic to the touch. Once the desired degree of pneumoperitoneum is attained, a 0.5- to 1-cm skin incision is made on the right lateral abdomen between the last rib and the flank. The incision is adjusted in a cranial direction for larger animals, in a caudal direction for smaller animals, and should take into account the size of the liver. The trocar and cannula assembly is then "popped" into the abdominal cavity with a twisting motion. Extending the forefinger down the shaft of the cannula or grasping the cannula ≈3 cm from the tip with the free hand will prevent inadvertent insertion of the assembly too far into the abdomen. The trocar is removed and laparoscope inserted into the abdominal cavity through the cannula. The remote light source is connected to the laparoscope with a fiberoptic cable and the liver examined. The insufflation line is then switched from the Veress needle to this cannula. The Veress needle is removed, its incision extended to 0.5 cm, and a second cannula is introduced under direct visualization. This allows introduction of a blunt probe, which can be used to palpate the liver and gallbladder. The probe should also be used to lift up each lobe of the liver to examine the dorsal surface and to move omentum aside in order to trace the bile duct to its duodenal entry point. The right limb of the pancreas should also be examined.

Once the abdomen has been examined, a suitable place on the liver is selected for a biopsy site. The author prefers using a laparoscopic "spoon" or "clamshell" type of biopsy instrument. This can be placed through the same accessory cannula as the blunt probe, thus avoiding an additional puncture site. This type of instrument results in less hemorrhage than biopsy needles and obtains much larger specimens. Repeated twisting of the shaft or retracting the closed jaws into the advanced cannula will prevent ripping of liver tissue and result in less bleeding. The number of biopsies obtained depends on the risk of bleeding and the anticipated need of adequate tissue. Multiple samples from various areas of the liver are recommended (observing for hemorrhage after each sample). Often, liver biopsy specimens are obtained for histopathologic examination, aerobic and anaerobic culture, and heavy metal (copper, zinc, iron) quantification. If excessive bleeding occurs, the blunt metal probe is used to put direct compression over the biopsy site. Suction can also be applied to clear the field if bleeding cannot be adequately assessed. If bleeding is not controlled, an electrocautery probe can be used to stop the bleeding. Alternatively, laparoscopic forceps can be used to place a piece of a hemostatic material (Gel-Foam) on the bleeding biopsy site. Once the biopsy samples are obtained, the clinician completes the procedure by removing all instruments, evacuating all the gas through opened cannula valves, and suturing the puncture sites. More detailed descriptions of laparoscopic liver biopsy techniques have been previously published.[4-8]

Potential complications of the procedure include those related to a general anesthetic, excessive bleeding, inadvertent organ damage during instrument introduction, over-distention of the abdomen with gas, air embolism, or tension pneumothorax if the diaphragm is inadvertently punctured (as abdominal gas enters the thoracic cavity). Meticulous attention to technique together with experience minimizes the incidence of complications. Postoperative pain should be anticipated, and this should be addressed with appropriate analgesics.

Laparoscopic Surgery

Many laparoscopic surgical procedures are currently being performed on dogs and cats (see Box 91-1).[14-29] Limitations of laparoscopic surgery include the two-dimensional image, restricted freedom of movement of the instruments, restricted sense of touch, limited opportunity to move the position of instruments once cannulae have been placed, and the need for extensive training. Controlled studies are necessary to substantiate the role of all laparoscopic procedures in veterinary medicine. As clinicians and equipment manufacturers address technical limitations, many surgical procedures performed within a body cavity should be amenable to laparoscopic surgery.

CHAPTER 92

Bone Marrow Aspiration and Biopsy

Valerie MacDonald

Overview

Abnormal complete blood count (CBC) results are typically the primary indication for bone marrow evaluation. Unexplained abnormalities such as non-regenerative anemia, neutropenia, thrombocytopenia, or markedly high blood cell counts should prompt bone marrow evaluation, as should the presence of immature blast cells or atypical mature cells on a blood smear. Other reasons include searching for organisms that cause systemic infections such as *Leishmania, Cytauxzoon,* and *Histoplasma* species, or looking for occult neoplasia when abnormalities are found on physical examination, diagnostic imaging, or a serum biochemistry profile. Certain cancers are definitively diagnosed through bone marrow evaluation, including multiple myeloma, lymphoma, and histiocytic sarcoma, and these procedures also are valuable for follow-up of patients undergoing treatment. Iron stores also can be subjectively evaluated by way of bone marrow aspiration or biopsy.[1]

There are very few contraindications to bone marrow aspiration, as the risk of bleeding from this procedure is very low. Thrombocytopenia is not a contraindication and in fact, bone marrow aspiration often is used for finding the underlying cause of thrombocytopenia. However, a severe coagulopathy involving deficiency or impairment of coagulation factors is a concern and marrow aspiration should be delayed until it is controlled. The risk of causing a bone fracture is low but it can occur if an inappropriately sized needle is used for a patient or if the bone is already compromised by disease.

Making the decision of whether to do an aspiration versus a biopsy, or both, can depend on the clinician's differential list and what exactly is being searched for. Many times, aspiration and core biopsy complement each other and both can be required. Individual cell morphology is best evaluated with cytopathologic examination of marrow aspirate smears that can highlight few or very small organisms or subtle cell features that can aid in identification of cell lineages. Bone marrow core biopsies give information on the architecture of the marrow, overall cellularity, and the presence of myelofibrosis, necrosis, and mass lesions within the marrow space.[2]

Materials and Equipment

To obtain high-quality samples, it is important to select appropriate materials and equipment. The size of the needle should be appropriate to the patient and the site being aspirated. A Rosenthal needle or Illinois sternal iliac needle is available for a bone marrow aspirate while the Jamshidi biopsy needle generally is reserved for bone marrow biopsies, although aspirates can also be obtained with this instrument (Figure 92-1). This author has used the Illinois needle for bone marrow biopsies as well as aspirates, especially in cats and small dogs. These needles are available in various sizes and lengths. A 15-gauge Illinois sternal iliac needle is most commonly used for dogs and an 18-gauge needle is available for cats and small dogs. A 1-inch (2.5 cm) needle can be sufficient for many animals, but a 1½-inch (4 cm) needle is required for large-breed dogs. Jamshidi biopsy needles are available in 13-gauge and the larger 8-gauge size, with the latter being reserved for larger dogs. All needles must be sterile, and all consist of two pieces—the hollow stainless steel needle and a solid stylet. The Illinois sternal iliac needle has a removable plastic cap and needle guard and can be re-sterilized for additional use, but the tip usually becomes dull quickly and one-time use is recommended. The Jamshidi needle does not have a needle guard and also can be re-sterilized, but it too might quickly become dull, making future use more difficult and potentially painful for the patient.[3]

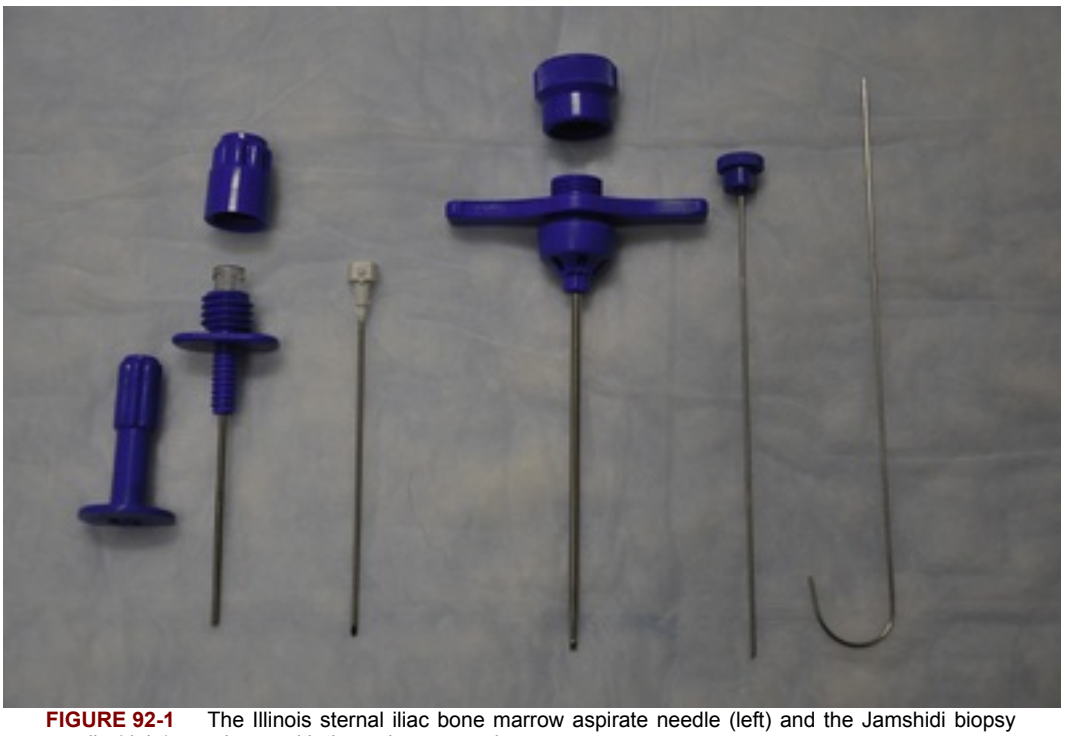

FIGURE 92-1 The Illinois sternal iliac bone marrow aspirate needle (left) and the Jamshidi biopsy needle (right) are shown with the stylet removed.

Recently, a battery-powered drill (OnControl Bone Marrow [OBM] Biopsy System, Vidacare) has been used for bone marrow aspiration and biopsy in humans and in healthy cats.[4] This device in humans is reported to yield better quality marrow biopsy cores, more quickly and with less patient pain when compared to the Jamshidi method.[5] In the cat study, the OBM was suitable for use in adult cats and the technique was easier and shorter in comparison to the manual method of collection. The drill does produce more heat than the manual collection method; however, the histologic thermal artifact did not significantly affect sample quality (Dickinson RM: personal communication, November 1, 2014). A different study evaluated the same device in both dogs and cats and found that good-quality aspirates could be obtained, marrow core samples were of increased size, and the core samples were judged to be of significantly better diagnostic quality.[6]

Because aspiration and biopsy are painful procedures, general anesthesia or heavy sedation with analgesia is recommended. The site should be shaved and surgically prepared, and a local anesthetic block performed, starting with the periosteum, subcutaneous tissues, and then the skin with 1% to 2% lidocaine. A nonsteroidal anti-inflammatory drug or tramadol should be provided for the patient if not contraindicated after the procedure is completed (see ch. 164).

Surgical gloves should be worn and all instruments and supplies kept within a sterile field. A small surgical drape could be used for helping to maintain a sterile field. A small stab incision is made in the skin with a #11 scalpel blade. Other required equipment includes microscope slides, 12-mL syringe, sterile anticoagulant (4% disodium- or dipotassium-EDTA), Petri dish or weigh boat, and forceps or pipette. An assistant should be available to help, and the slides should be laid out at an angle before starting the procedure, as noted below.

Preparation and Site Selection

Before starting the procedure, it is important to ensure that the stylet is properly aligned within the needle and, if the needle guard is being used, that all attachments are snug but not overtightened. A secure grip of the needle should be maintained by holding it in a modified pencil grip against the palm of the hand. The needle guard on the Illinois sternal iliac needle has a lip on the end where the finger and thumb can rest. This hold permits the application of firm pressure away from the operator (into the bone), and provides stability and precise control for placement of the instrument into the marrow. Some clinicians may find it helpful to keep their dominant forearm tucked in close to their hip, which may reduce shoulder strain and create a bracing effect if the needle tip slips off the bone.

The most common sites for obtaining a sample are the greater tubercle of the proximal humerus, the iliac crest of the pelvis, and the trochanteric fossa of the proximal femur. The humerus generally is the preferred

site but site selection can depend on the clinician's preference and the patient's condition and size. The trochanteric fossa may be used in cats or small dogs and the iliac crest is most easily accessed in thin dogs and large cats where the crest is easily palpable.[7] Sternal bone marrow aspiration in dogs is not commonly performed despite the fact that the sternum is easily accessible and associated with less pain from aspiration compared to other sites. One study evaluated samples taken from the sternum of clinically normal dogs and found that aspiration of marrow from this site was feasible, safe, and that sample quality was equivalent to that of samples from the humerus or ilium.[8]

Procedure: Bone Marrow Aspiration

For sampling the proximal humerus, the animal should be placed in lateral recumbency. It is easiest to sample the patient's humerus that is the same as the clinician's dominant hand. The right-handed clinician stands ventral to the patient and uses the left hand to grasp the patient's right forelimb distal to the elbow, slightly rotating it externally to stabilize it. The lateral aspect of the greater tubercle is the target site for aspiration: a flattened, roughened area of bone where muscle and fat coverage are minimal and the needle is least likely to slip off the bone. The needle should be placed through the stab incision and aligned along the long axis of the bone. Firm pressure is applied, with repetitive, back-and-forth twisting motions to advance the needle through the cortex (Figure 92-2).

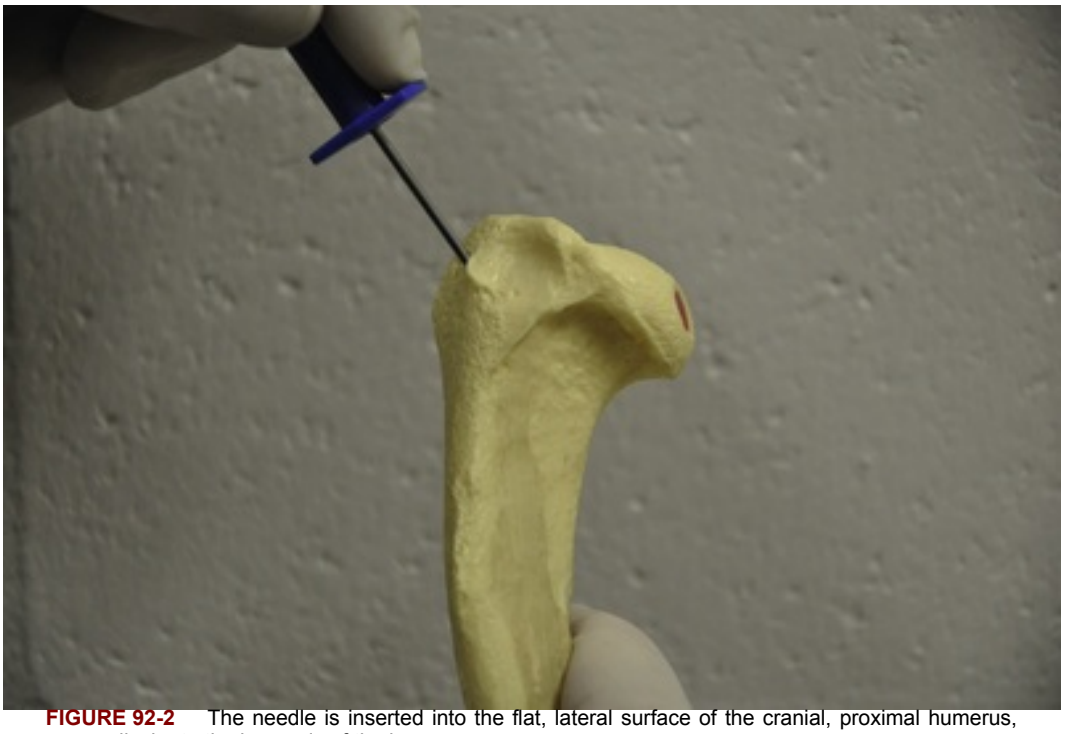

FIGURE 92-2 The needle is inserted into the flat, lateral surface of the cranial, proximal humerus, perpendicular to the long axis of the humerus.

For the proximal femur, the animal is placed in lateral recumbency. The trochanteric fossa is located by palpation of the greater trochanter. The fossa is located just medial to the trochanter. The limb should be adducted and rotated medially to minimize the risk of sciatic nerve damage. The needle is directed so it is parallel to the shaft to the femur, to allow placement within the marrow cavity (Figure 92-3).

FIGURE 92-3 The needle is inserted medial to the greater trochanter into the trochanteric fossa.

For the iliac crest, the animal should be in sternal or lateral recumbency. The clinician should palpate the widest portion of the dorsal border of the iliac crest. The needle is advanced into the middle of the crest, aiming slightly caudal to the vertical line through the iliac crest (Figure 92-4).

FIGURE 92-4 The needle is positioned into the middle of the widest portion of the dorsal border of the iliac crest and directed ventrally.

Regardless of the site chosen for aspiration, the procedure of aspiration is identical, as are the pitfalls. If the needle does not remain perpendicular to the cortex, it may be seated within it (or parallel to it) rather than through it. By maintaining a steady forward pressure from the palm of the hand combined with a twisting

rotation, the needle should penetrate the cortex and advance into the marrow space. It is important not to go too far through the cavity and come out through the opposite cortex. Some clinicians may sense a decrease in resistance that indicates they have entered the marrow cavity but others may not appreciate the sensation. If the needle is properly seated, it should not move on its own but rather should move in unison with the limb when the needle is manipulated.

Once the needle is firmly seated, the cap and stylet are removed. A 12 mL syringe is attached to the end of the needle. The clinician rapidly pulls back the plunger until the smallest flash of blood is seen, and then stops suctioning. It can be tempting to harvest as much marrow as possible in these situations but ongoing suction causes hemodilution, reducing sample quality.

The entire needle is removed (with the syringe attached) from the bone, and the contents of the syringe and needle are placed onto glass slides or into a collection dish. Alternatively, the syringe alone can be removed first and its contents expelled onto glass slides or into a dish containing EDTA; however, this author believes the best sample is actually contained within the needle.

If the marrow sample is placed onto glass slides, especially if there is no EDTA in the syringe, it is important to quickly prepare the slides to avoid sample clotting (see ch. 93 and 95). Therefore, having an assistant to smear the samples on the slides is best practice. The slides should be laid out at an angle prior to collection. The clinician should quickly place a drop of sample at the top of each slide while the assistant follows behind placing a second clean slide perpendicular to the first slide and gently spreading the marrow spicules across the slides, then rapidly air drying.

If using a Petri dish or weigh boat, the clinician should place the sample in the container, tilt the container to allow the blood to drain away, and gently pick up the marrow spicules with the end of a pipette or forceps. The spicules should be placed on a glass slide, and gently crushed with a second clean glass slide. The marrow and blood remaining in the container can be transferred to an EDTA vial in case additional slides need to be prepared.

To ensure an adequate sample has been obtained, the clinician should stain and examine one slide to look for evidence of cellularity (Figure 92-5, *A*). A cursory microscopic evaluation should reveal densely stained marrow particles populated by mixed hematopoietic cells with variable amounts of fat and hemorrhage (Figure 92-5, *B*). If cellularity is low or uncertain, a second attempt should be made to collect an adequately cellular sample. In some pathologic conditions like myelofibrosis or aplastic anemia, cellularity will be poor regardless of the best technique and in those cases a bone marrow biopsy should be collected. The slides should be submitted along with a recent CBC. It is preferable to have the CBC taken on the same day as the aspirate, as accurate interpretation of the bone marrow depends on the findings from the peripheral blood.

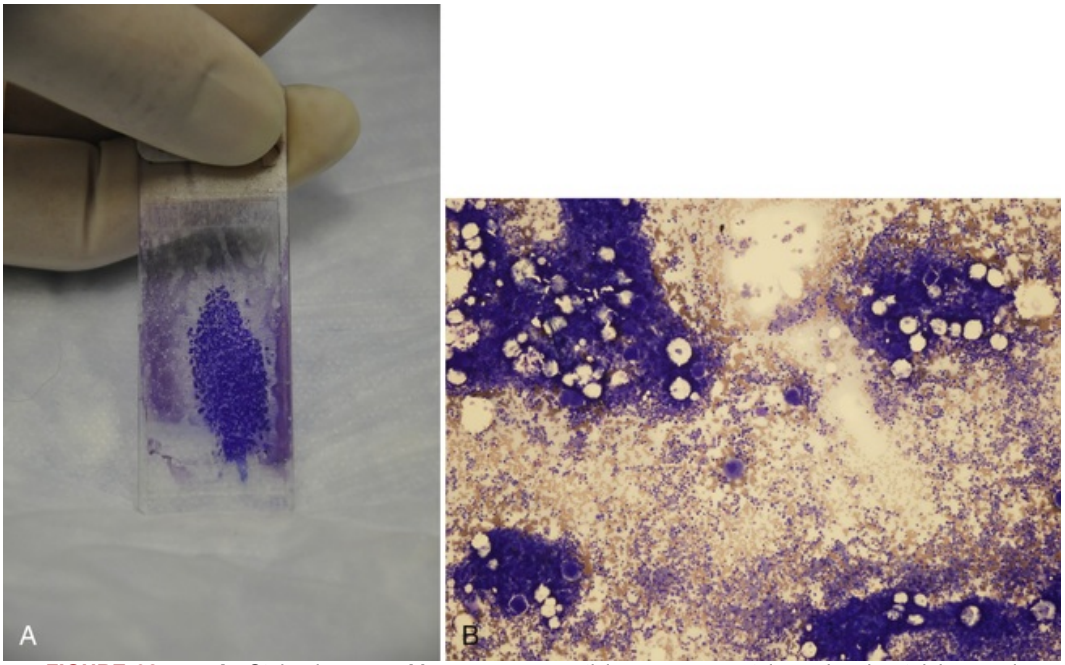

FIGURE 92-5 **A,** Stained smear. Many marrow particles are present in a deeply staining oval grouping surrounded by blood. The smear quality is excellent. **B,** Microscopic appearance of a bone marrow aspirate. Four densely cellular marrow particles are seen as “islands” with marked stain uptake

—one in each corner of the image—surrounded by looser monolayers of mixed hematopoietic cells.

Procedure: Bone Marrow Core Biopsy

A bone marrow core biopsy can be performed from the same site on the patient or from a completely different site. All of the sites for bone marrow aspiration are the same for marrow biopsy. One study evaluated a combined technique (using the same needle and site for the aspirate and biopsy) in comparison to obtaining a biopsy directly from the opposite humerus.[2] The authors found that the marrow length was shorter and hemorrhage artifact was more common using the combined technique. However, there were no differences in cellularity, megakaryocyte count, myeloid/erythroid ratio, iron stores, or diagnostic quality.

The needle should be inserted in the same way as for aspiration; however, once the needle has become embedded in the cortex, the stylet is removed. Then, the needle is advanced an additional centimeter, or slightly more in large dogs. Once the needle is deeply seated and secured, the clinician breaks the biopsy fragment loose of its deep attachments by slightly rocking the needle back and forth in a variety of directions. The clinician then removes the biopsy needle from the bone with outward traction and a continued twisting motion. The biopsy sample is removed from the needle by using a shepherd's hook to push it retrograde (out the handle end) with a Jamshidi needle, or using the needle's own stylet in the usual position to force the sample normograde and out the tip if using an Illinois needle.[9]

Before placing the sample in 10% buffered formalin, the clinician can roll it on a glass slide for cytological analysis. It is important to avoid placing cytology slides in the same package as formalin samples, as the formalin will fix the slides and deleteriously affect their staining.

CHAPTER 93

Cytology of Internal Organs

Lamberto Viadel Bau

Background

"Cytology," as a diagnostic tool, refers to the microscopic assessment of cells. Cytology samples can be obtained from practically any internal organ of small animals. Most often, cytology samples are obtained via fine needle aspiration (FNA) by placing the needle tip well into a target tissue. The plunger of the syringe, to which the needle is connected, allows for gentle aspiration after the needle is placed. Ideally, cells representative of that tissue are aspirated into the needle-syringe. Sometimes cytology samples are submitted after tissue has been gently pressed onto a glass slide (impression smear). These, and additional methods of collecting samples, are presented in Video 93-1. The most commonly submitted internal organ cytology samples are from liver, spleen, lymph nodes and thyroid glands.

Indications/Advantages

Overview: Inflammation versus Neoplasia

The primary objective of an internal organ cytological evaluation is to distinguish inflammation from neoplasia. Cytology, such as obtained with FNA, should be considered a "minor" procedure. It is often the first and least invasive diagnostic step in understanding the nature of suspicious or worrisome tissue. Biopsy assessment can be used to support a cytologic diagnosis or suspicion (submission of an actual "piece" of tissue). Biopsy can also be utilized if cytologic evaluation is inconclusive. In addition to being less expensive and less invasive, an advantage of cytology versus biopsy would include its immediate results. In contrast, biopsy samples usually require time for fixing and cutting the submitted tissue before slides can be stained and assessed.

Before or After Biopsy

Quick cytology of tissue obtained via biopsy, prior to submission, can be used to determine if a re-biopsy is indicated. Cytology may suggest that a biopsy specimen is likely to be representative, of good quality, and should be submitted. Cytology can be performed on slides after tissue impression or FNA. Some cancers can be reliably diagnosed via cytology (mastocytoma, transmissible venereal tumor, some lymphomas, carcinomas and melanomas). Other neoplasms (mesenchymal origin tumors, for example) exfoliate few cells and are more difficult to identify with cytology.

Multiple Masses, Recurrence, Metastasis

Fine needle aspiration of suspicious tissue is recommended when multiple masses or lesions are present, potentially indicating whether there are one or several processes present. Cytology of each (or more than one) may be of value in identifying an area to be selected for biopsy. Cytologic evaluation of tissue can be used to confirm the presence of metastases or to demonstrate local recurrence of a previously treated neoplasia. Such information can be useful when deciding the next step in care.

Cytology versus "Blind" Biopsy, Making the Most of Your Clinical Pathologist

Rather than "blind" surgical removal of a mass, a previously obtained cytological diagnosis enables the surgeon to better appreciate the tissue being extirpated. The clinical pathologist should be able to contribute

valuable insight, for example: by recommending margins to employ when excising a mass. Perhaps a non-surgical therapeutic modality should be considered prior to surgery. Intraoperative cytology of suspicious tissue can aid in deciding whether it should be removed, what the excision margins should be, or whether alternative sites should be considered for biopsy.

Disadvantages or Limitations

Even with the best techniques, cytology is not always informative. Some pathological processes cannot be detected or confirmed by cytology alone. Owners should be made aware of limitations and possible complications. Like any test, non-diagnostic results are common and frustrating. Cytology samples occasionally contain too few cells, non-representative cells, or are hemodiluted. Cytology results can provide false negatives, as might occur if necrosis seems obvious but the sample was obtained from the center of a large, rapidly growing tumor. Clinician-induced altered cell appearance, due to poor technique, can become diagnostic traps known as "malignancy imitating processes." Fine needle aspiration of tumors that do not readily exfoliate may not allow diagnosis, assessment of architecture, or invasion of the vasculature or lymphatics. Another complicating factor is benign tumors that imitate malignancies (histiocytomas, some parathyroid tumors) and some malignant tumors that appear benign (well-differentiated carcinomas, lymphocytic lymphomas). It can be challenging to distinguish normal tissue from hyperplastic tissue. It may be difficult to separate hyperplasia from dysplasia or neoplasia. Finally, cytologic diagnoses are usually nonspecific regarding tissue of origin, e.g., "carcinoma".

Complications and Contraindications

Serious complications secondary to obtaining a sample for cytology are quite uncommon. Complications do occur, including hemorrhage, release of bioactive substances (mastocytoma), organ rupture or laceration, pneumothorax, and sepsis or peritonitis (if an abscess ruptures, leaks, or drainage from a needle exiting an infected area occurs). Spread of tumor cells via the needle's exit path is extremely uncommon, but has been documented with splenic hemangiosarcoma, renal carcinoma, bladder transitional cell carcinoma, and ovarian tumors. FNA is contraindicated if there is high risk of hemorrhage or if anesthesia is both required but contraindicated.

Specimen Preparation (see Video 93-1)

The quality of the cytology specimen is of key importance for correct diagnosis. One should avoid using poor quality swabs, for example, because they often deposit "material artifacts" that could lead to diagnostic errors. After aspiration is complete and the needle removed from the patient, the plunger of the syringe should be advanced to expel needle and syringe content onto a labelled slide. The material should then be spread like a blood smear with the goal of creating a smooth single layer of cells. One needs to be quite gentle creating the smear to prevent cell distortion or lysis. Lysis, for example, may lead to unusual staining artifacts or large numbers of bare nuclei.

If only liquid is obtained on aspiration, it should be transferred to an EDTA tube, mixed, and centrifuged for 5 minutes at 1,000-1,500 rpm. Most of the supernatant can then be removed. A drop of supernatant can be mixed with a drop of sediment to create the cytology smear. No aspirated material should be discarded until it is demonstrated that there are adequate cells for submission. Imprints can be made of tissue, after which slides are dried, fixed and stained with Diff-Quik (Video 93-2).

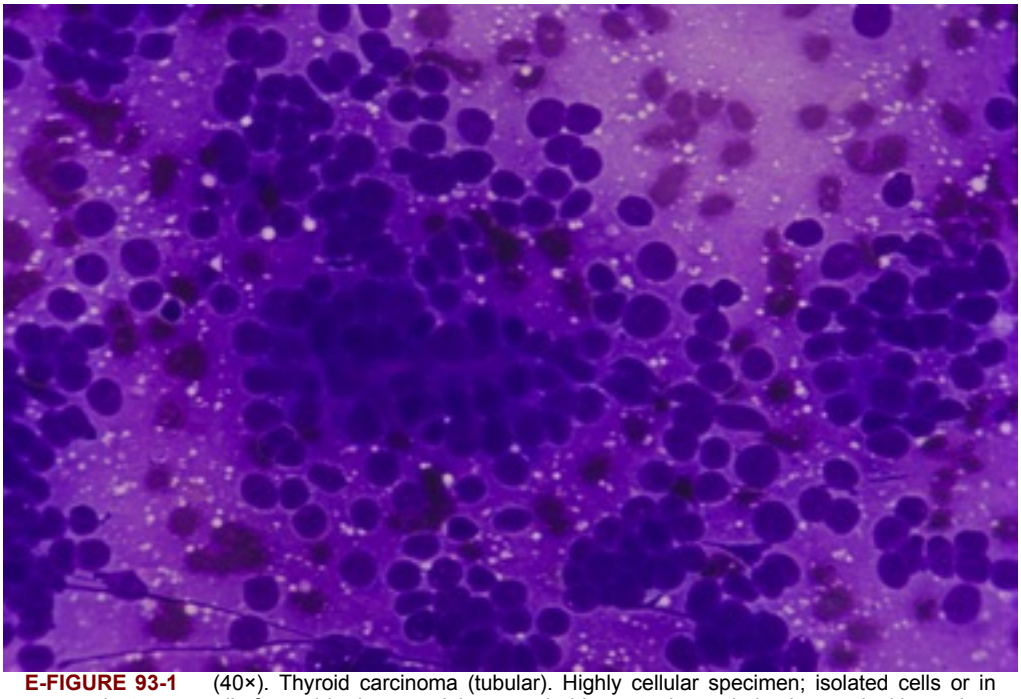
Sending Samples to a Laboratory

As some diseases are difficult to interpret, cytology specimens should be sent to a clinical pathologist for confirmation of any serious diagnosis. Clinical pathologists are trained to recognize artifacts or cell damage caused by poor sample preparation. Inadequately fixed or hemodiluted specimens are common. Other frequent issues include insufficient cells ("dry aspirates"), artifacts from contamination by ultrasound gel (purple-reddish amorphous material) or by cotton grains from surgical gloves. Formalin vapors can seriously alter cell morphology and staining quality (formalin and cytology samples should not be shipped in the same container). Adequate packaging is needed to prevent slides from breaking during transport. Every specimen should be clearly labelled and accompanied by a written review of the animal's clinical history, all test results, treatments employed, and their response. The more informed the clinical pathologist, the better the interpretations and recommendations. Difficult and complicated cases should be discussed.

Cytology of Different Internal Organs

Thyroids

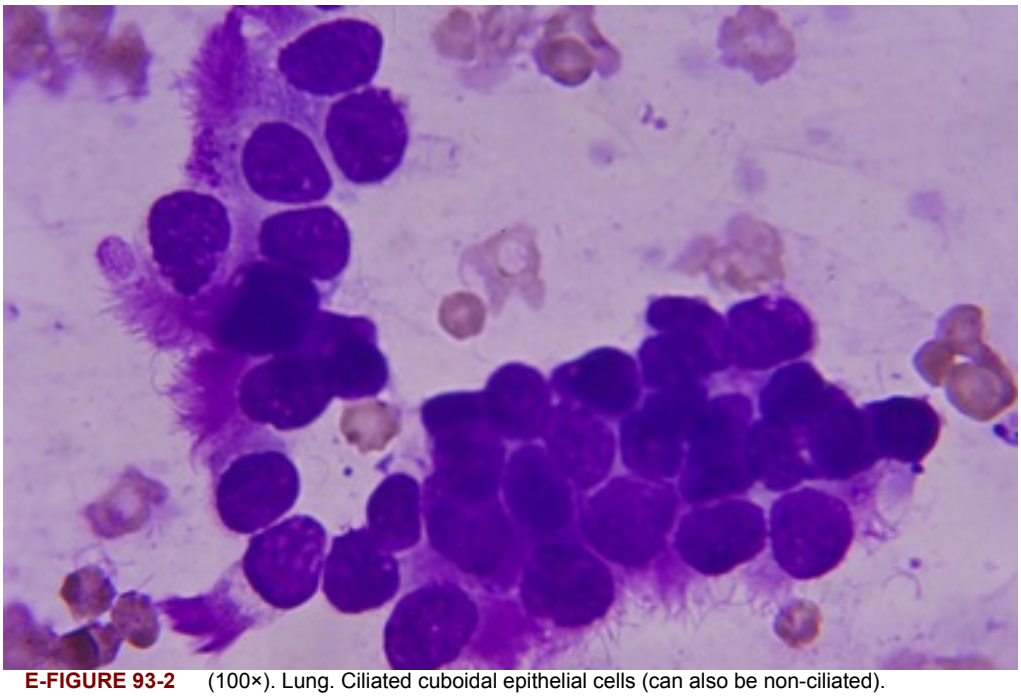
Blood contamination is usually significant and specimens are usually highly cellular, forming groups of bare nuclei on a pale blue cytoplasmatic background. Pink (colloid) amorphous material can be associated with some cell groups. Malignant thyroid carcinomas commonly invade surrounding cervical structures and commonly metastasize (E-Figure 93-1). Thyroid masses in cats are usually benign adenomas (uniform nuclei population without malignancy criteria) or adenomatous hyperplasia.



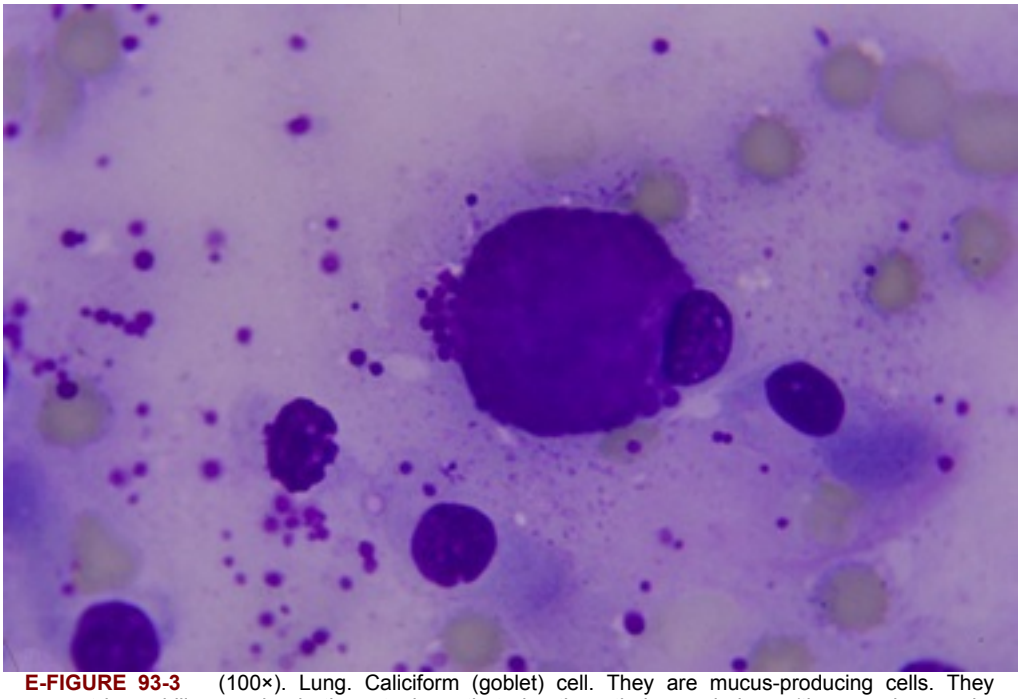
E-FIGURE 93-1 (40×). Thyroid carcinoma (tubular). Highly cellular specimen; isolated cells or in groups that are usually formed by bare nuclei on a pale blue cytoplasmatic background without clear limits. In the center of the image, there is an acinus with colloid substance inside.

Lung

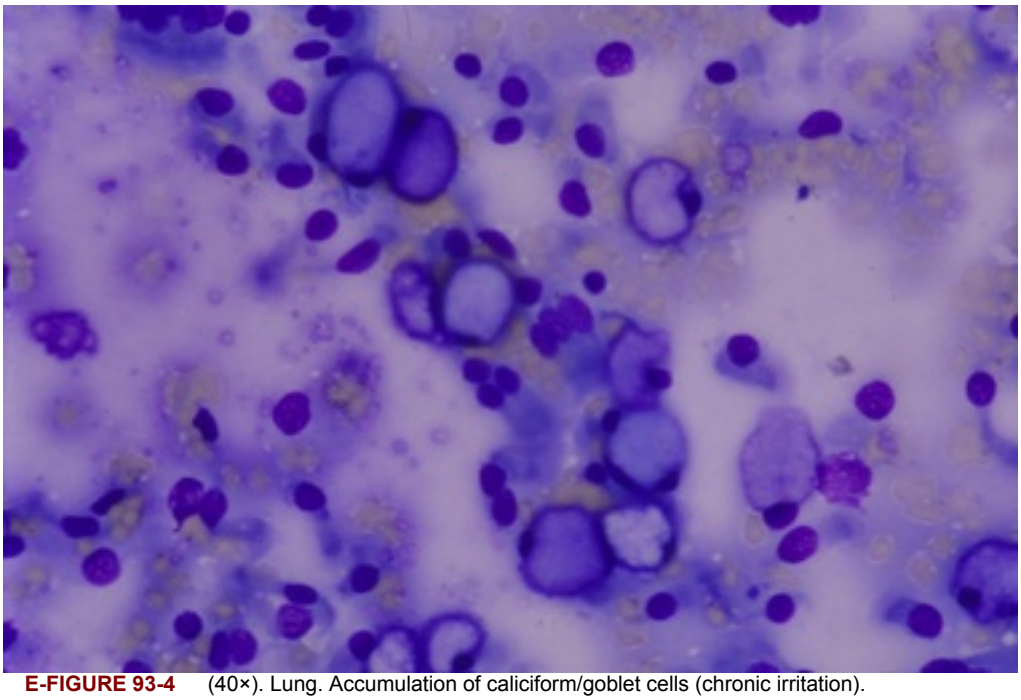
Normally, lung cytology consists of ciliated epithelial cells (E-Figure 93-2), mucus-producing cells (caliciform/goblet, E-Figures 93-3 and 93-4), and macrophages (common in bronchoalveolar lavage specimens and must be distinguished from neoplastic cells, E-Figures 93-5 and 93-6). Increased mucus is non-specific. Caution is required to not mistake groups of alveolar cells (round or cuboidal, E-Figure 93-7) as neoplastic cells. Blood contamination is common (erythrophagocytosis is indicative of pathological hemorrhage). Bacterial infection is usually associated with purulent inflammation. Pyogranulomatous inflammation is typical of mycotic infection and culture is advisable. Reactive hyperplasia is common (respiratory cells with a more cubic morphology). Squamous metaplasia due to chronic inflammation is difficult to distinguish from squamous neoplasia. Most pulmonary masses are neoplastic, but primary lung tumors (usually solitary carcinomas) are uncommon. Pleural fluid rarely includes tumor cells. Cytology cannot reliably distinguish primary (large number of epithelial cells in lamina) from metastatic carcinomas (E-Figures 93-8 through 93-10). Neoplasms of mesenchymal origin in the lung are often metastatic (E-Figures 93-11 and 93-12). Non-lung tissue may be aspirated by mistake. Accidentally obtained tissue is often lymph node, thymus, fat or abdominal organ tissue (hepatocytes and mesothelial cells). Care must to taken not to mistakenly believe these to be metastatic tumor cells of pulmonary origin.



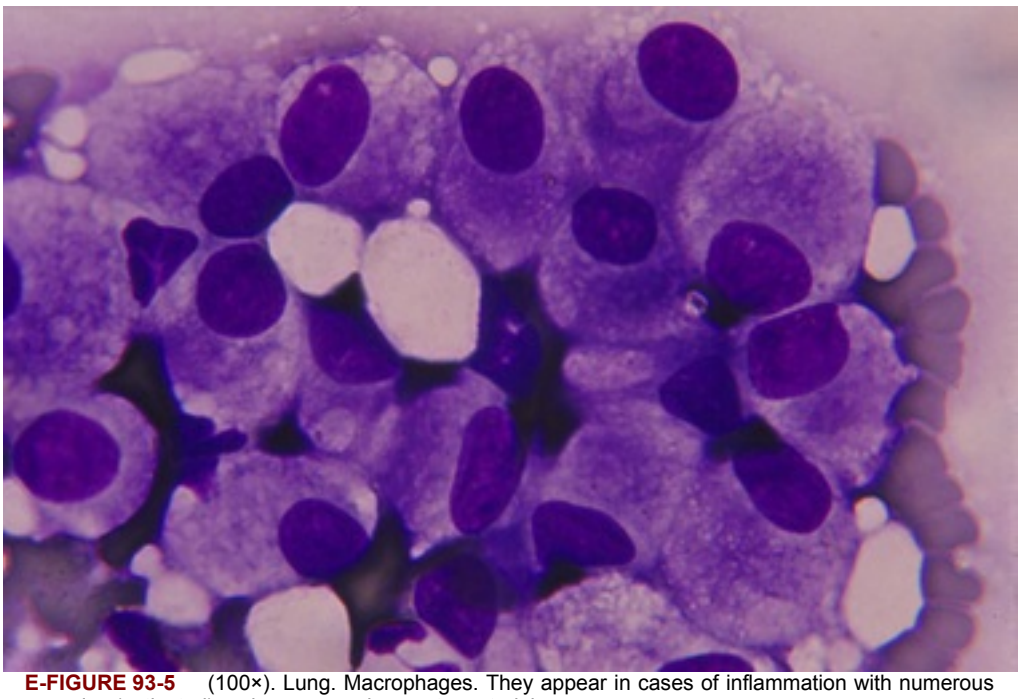
E-FIGURE 93-2 (100×). Lung. Ciliated cuboidal epithelial cells (can also be non-ciliated).



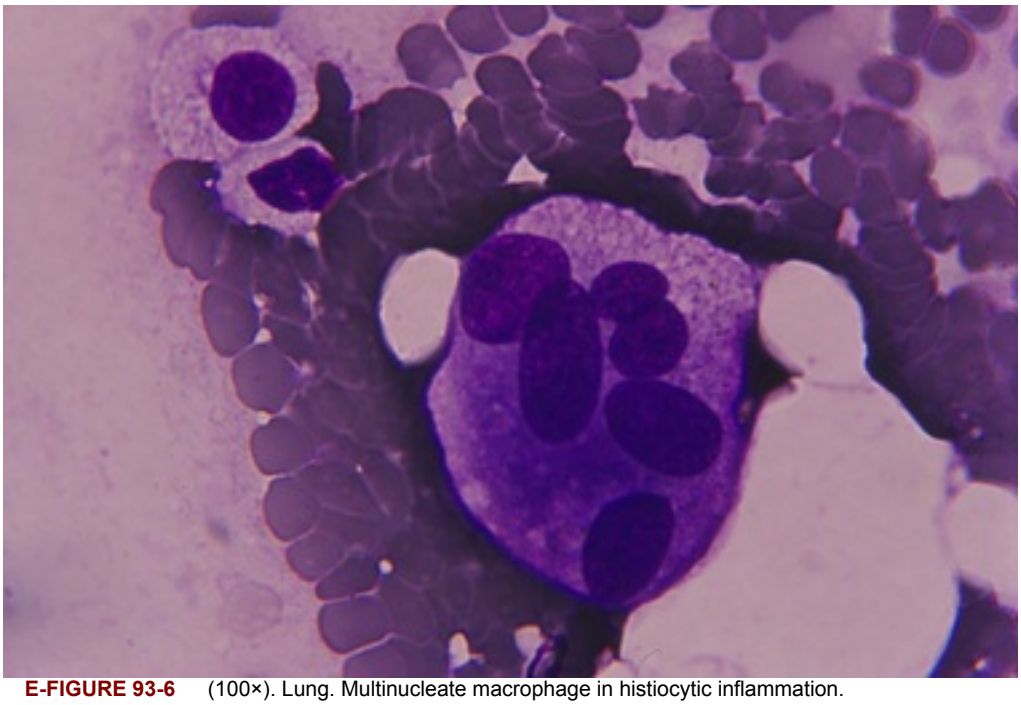
E-FIGURE 93-3 (100×). Lung. Caliciform (goblet) cell. They are mucus-producing cells. They present basophilic granules in the cytoplasm that give them their round shape (the granules can be spread throughout the specimen).



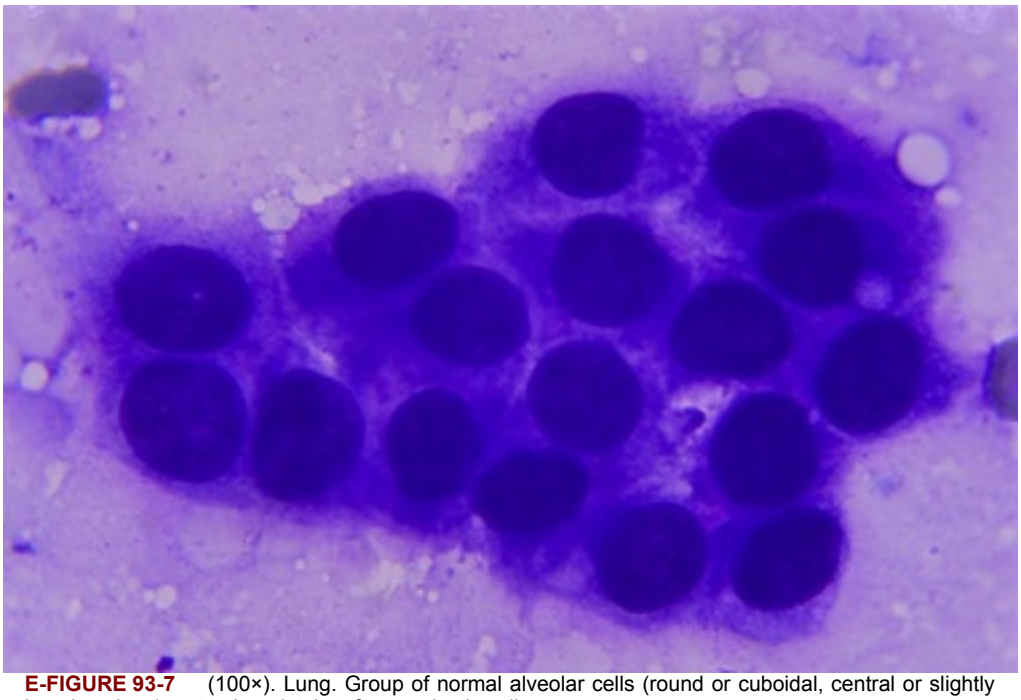
E-FIGURE 93-4 (40×). Lung. Accumulation of caliciform/goblet cells (chronic irritation).



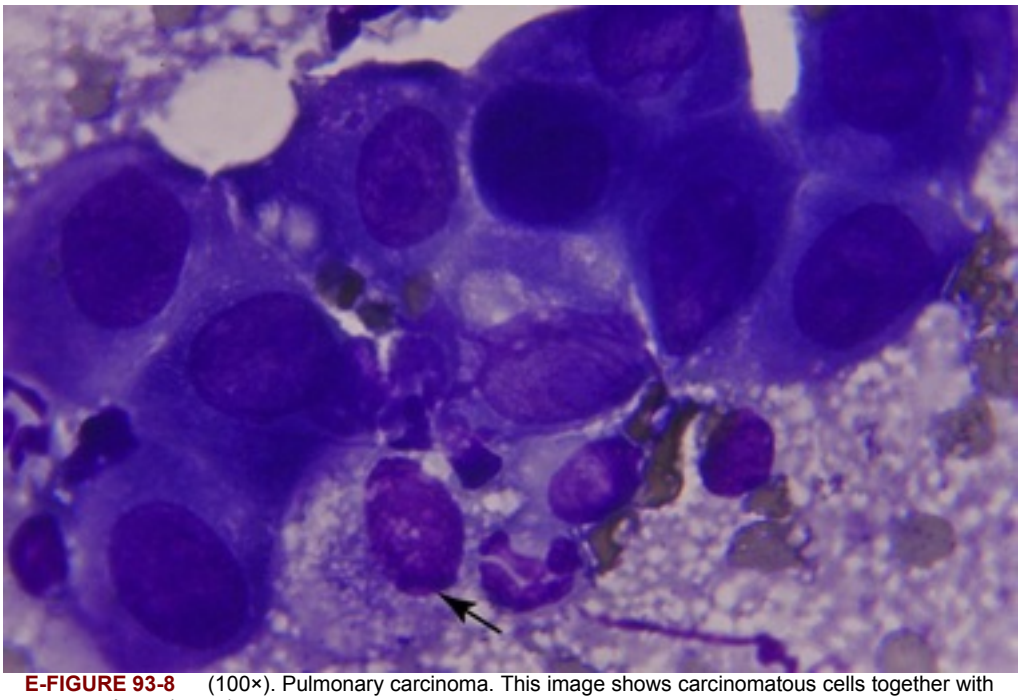
E-FIGURE 93-5 (100×). Lung. Macrophages. They appear in cases of inflammation with numerous vacuoles (activated) and can carry phagocyte material.



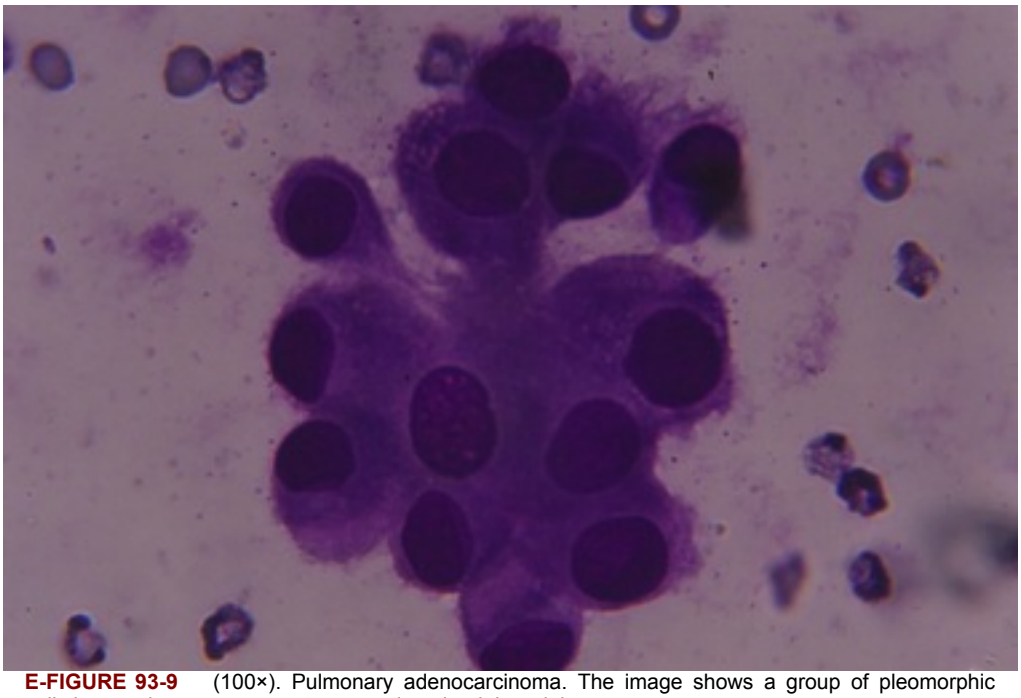
E-FIGURE 93-6 (100×). Lung. Multinucleate macrophage in histiocytic inflammation.



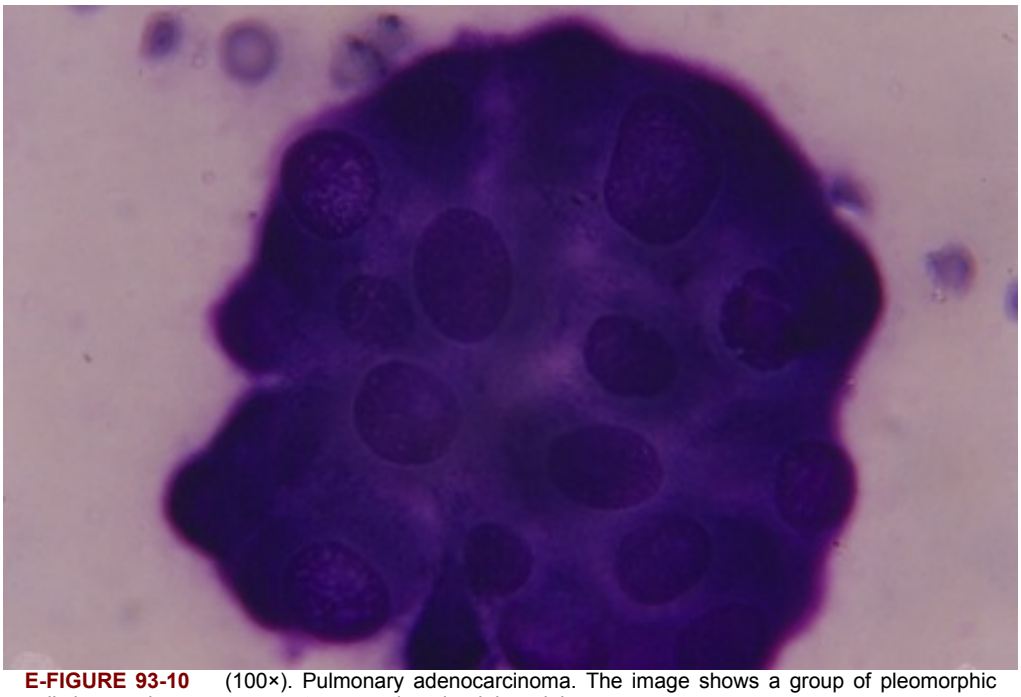
E-FIGURE 93-7 (100×). Lung. Group of normal alveolar cells (round or cuboidal, central or slightly basal nucleus), not to be mistaken for neoplastic cells.



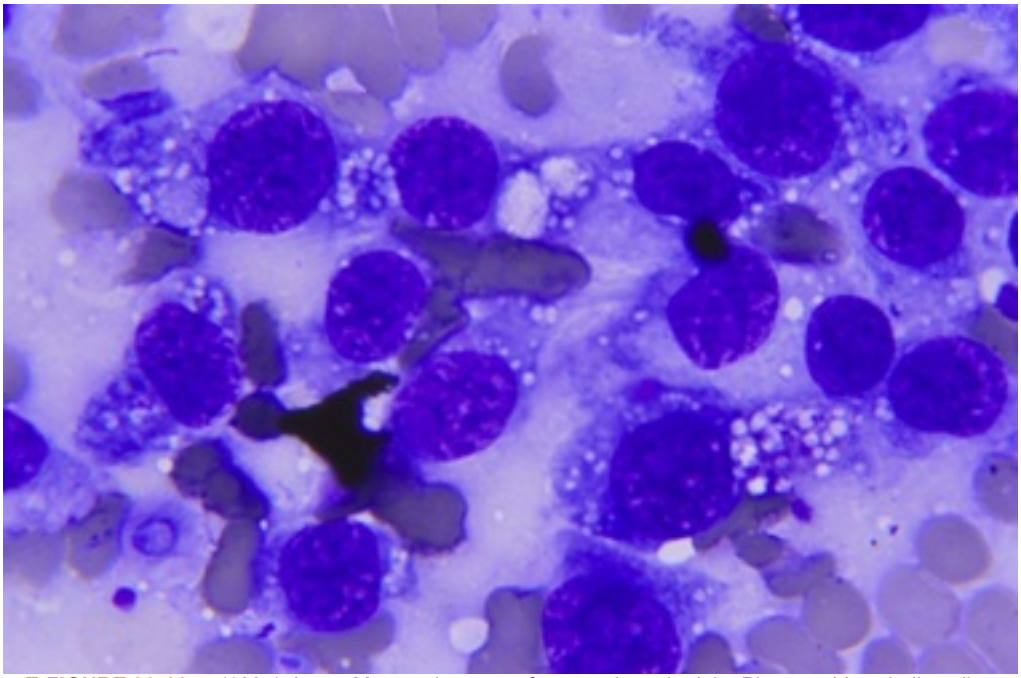
E-FIGURE 93-8 (100×). Pulmonary carcinoma. This image shows carcinomatous cells together with a macrophage (arrow).



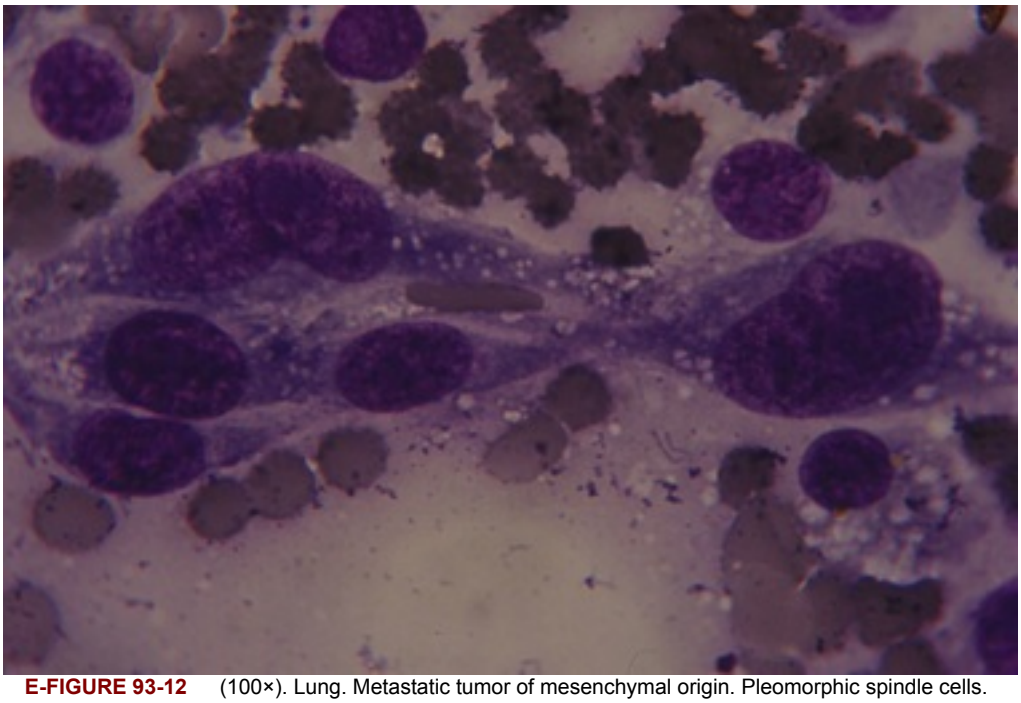
E-FIGURE 93-9 (100×). Pulmonary adenocarcinoma. The image shows a group of pleomorphic cells in an acinar arrangement, suggesting glandular origin.



E-FIGURE 93-10 (100×). Pulmonary adenocarcinoma. The image shows a group of pleomorphic cells in an acinar arrangement, suggesting glandular origin.



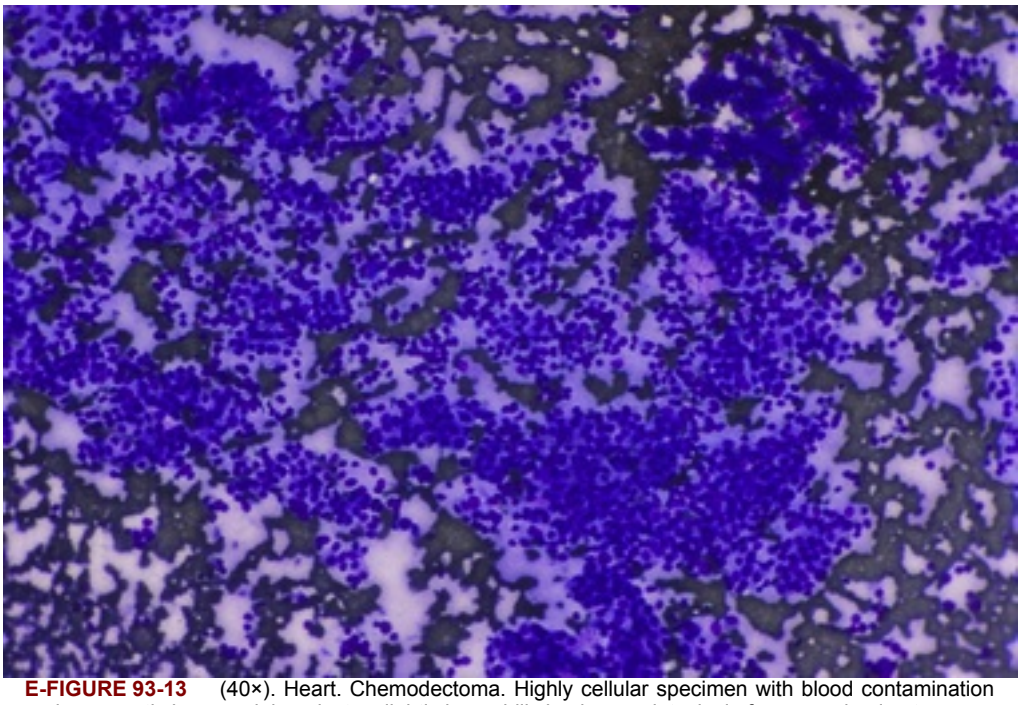
E-FIGURE 93-11 (100×). Lung. Metastatic tumor of mesenchymal origin. Pleomorphic spindle cells.



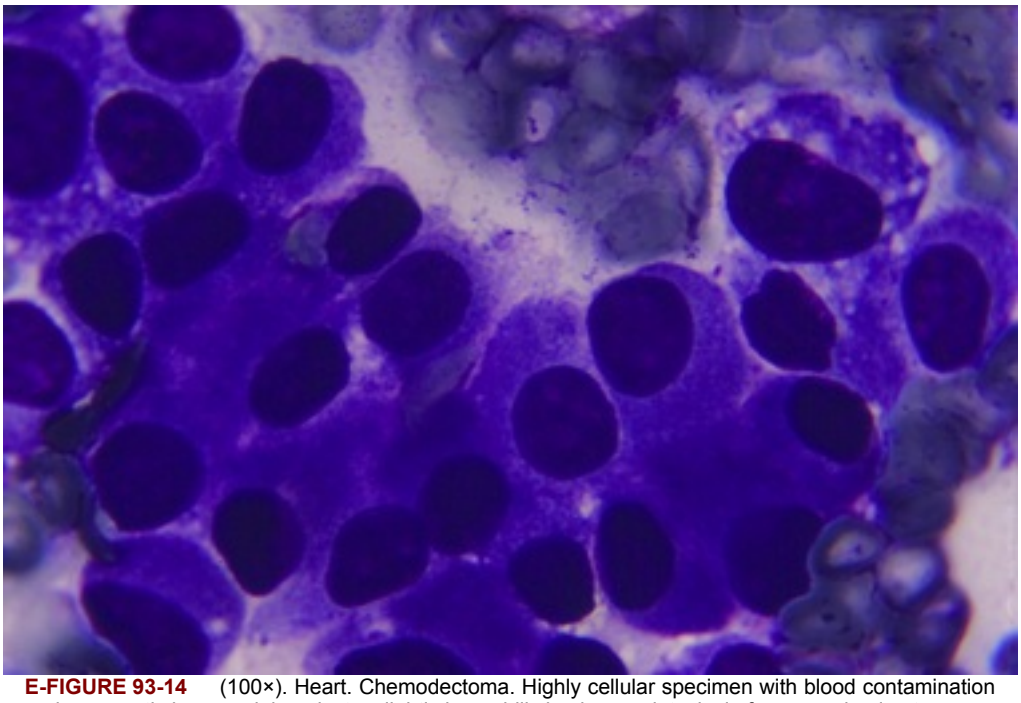
E-FIGURE 93-12 (100×). Lung. Metastatic tumor of mesenchymal origin. Pleomorphic spindle cells.

Heart

General anesthesia is usually required to obtain a specimen. Primary heart tumors are rare. The most often described cardiac tumor, hemangiosarcoma, is most often located in the right atrium, highly malignant, and often causes pericardial effusion. Heart base tumors and chemodectomas are less common (E-Figures 93-13 and 93-14).



E-FIGURE 93-13 (40×). Heart. Chemodectoma. Highly cellular specimen with blood contamination and apparently bare nuclei against a slightly basophilic background, typical of neuroendocrine tumors.



E-FIGURE 93-14 (100×). Heart. Chemodectoma. Highly cellular specimen with blood contamination and apparently bare nuclei against a slightly basophilic background, typical of neuroendocrine tumors.

Thymus

Cranial mediastinal masses are aspirated to distinguish between thymoma (uncommon) and thymic lymphoma. Thymomas are usually associated with large groups of large epithelial cells and small, medium, and large-sized lymphocytes. Thymic lymphoma is usually represented by a predominance of medium-sized and large lymphocytes.

Liver

Normal cytology consists of a moderate number of hepatocytes (in small groups, cells with abundant blue cytoplasm with a granular appearance, E-Figure 93-15), red blood cells due to blood contamination, and epithelial cells from the biliary tract (cuboidal, not to be mistaken for neoplastic cells, E-Figure 93-16). Vacuolar degeneration is due to accumulated fat (feline hepatic lipidosis, E-Figure 93-17) or accumulation of glycogen and water ("steroid hepatopathy" in dogs). Hepatic cytology is not sensitive for the diagnosis of inflammatory processes. It is important to be able to distinguish hyperplastic liver nodules (E-Figure 93-18) from cirrhosis or neoplasia. In dogs, hepatocellular neoplasia (E-Figures 93-19 and 93-20) is more common than cancer derived from the biliary system (cholangiocellular, E-Figure 93-21). Primary hepatic tumors are uncommon. Hepatocellular carcinoma (see E-Figure 93-19) is the most common liver tumor and is characterized by cell aggregates. Some well-differentiated carcinomas and adenomas are morphologically similar to normal hepatocytes and those of hyperplastic nodules. Non-epithelial tumors such as hemangiosarcoma are less common (Figure 93-22). The most common hemolymphatic hepatic neoplasia is lymphoma (E-Figure 93-23, generally formed by lymphoblasts).

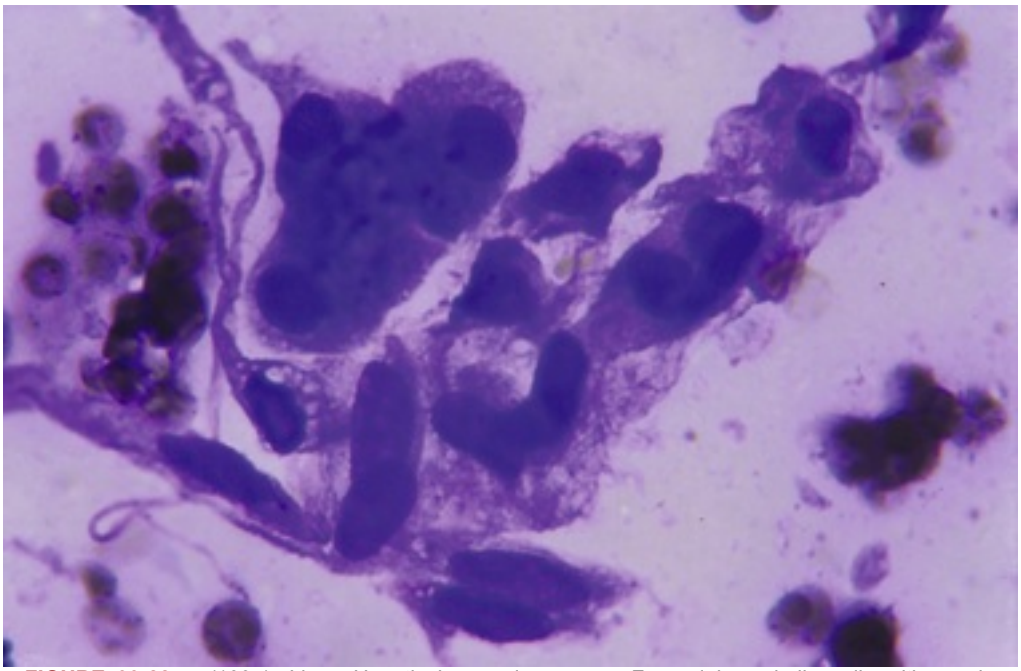


FIGURE 93-22 (100×). Liver. Hepatic hemangiosarcoma. Formed by spindle cells with poorly defined cell borders. Cell size varies from one sarcoma to another, from very uniform to marked anisocytosis and anisokaryosis.

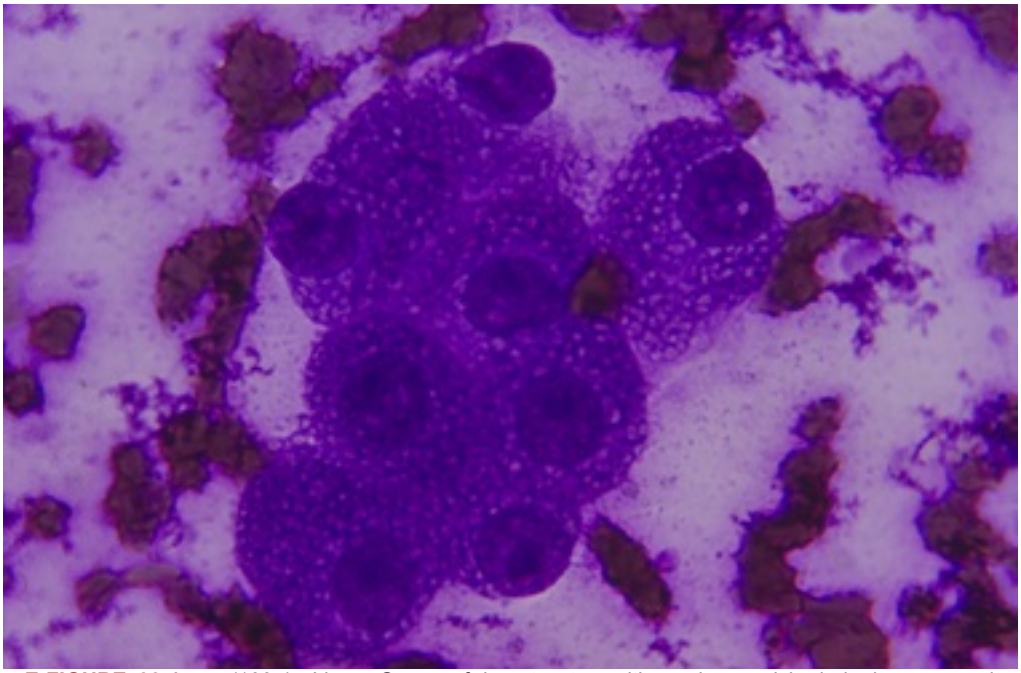
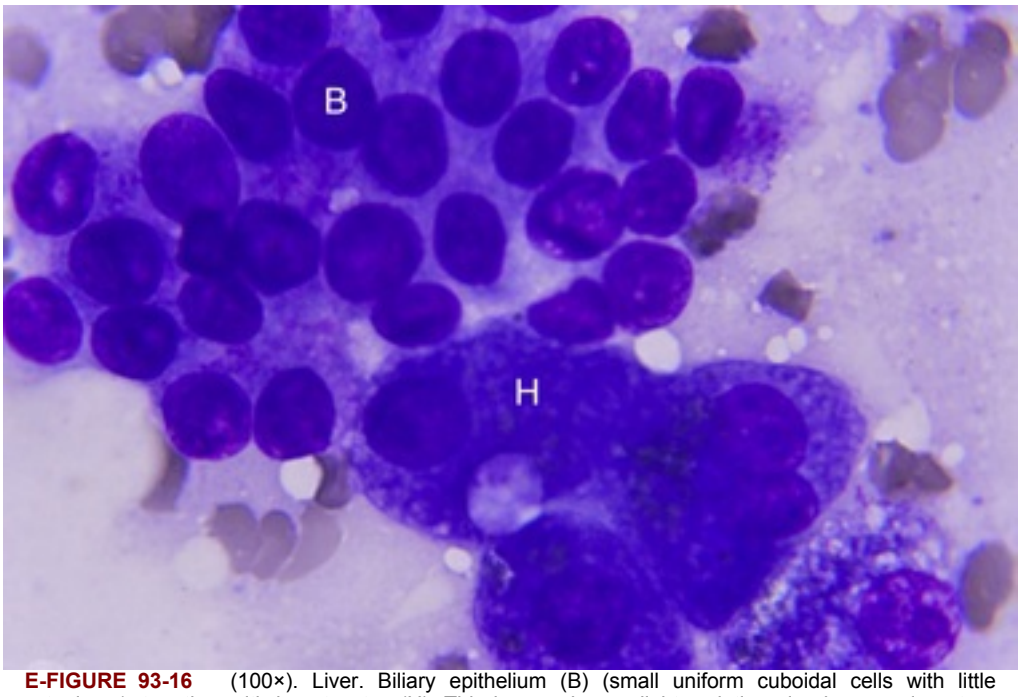
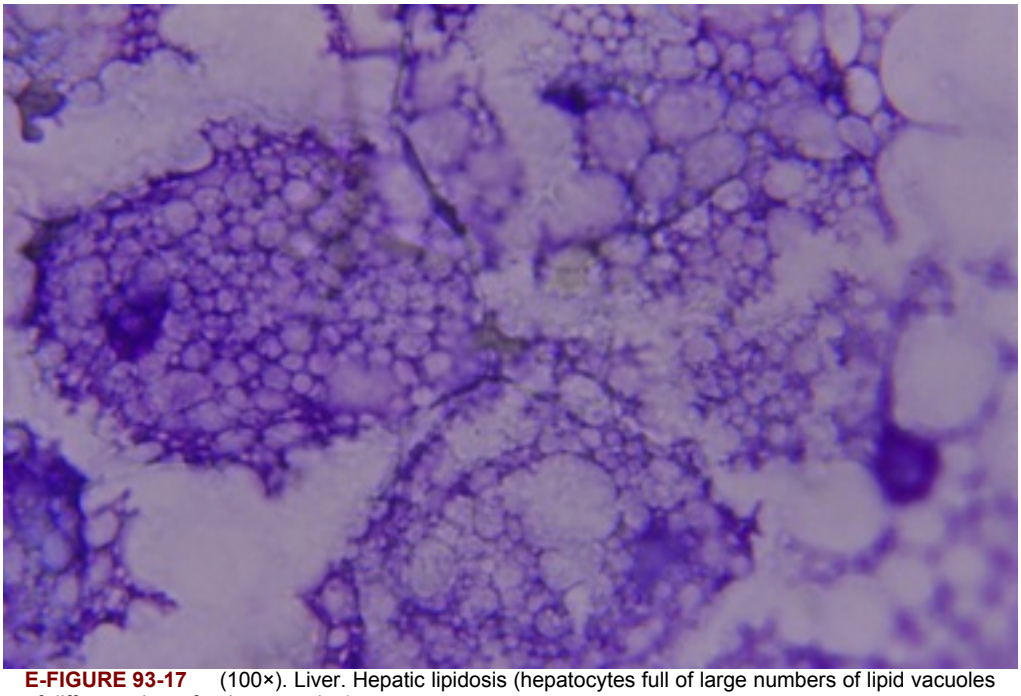


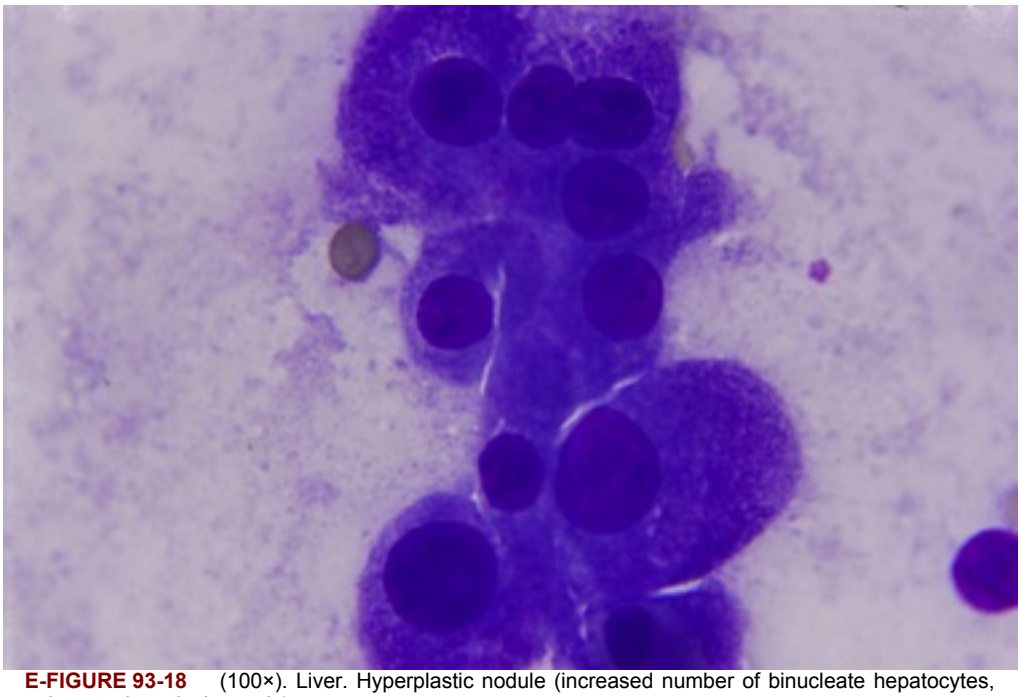
E-FIGURE 93-15 (100×). Liver. Group of hepatocytes with oval or polyhedral shape, round peripheral nucleus, abundant blue cytoplasm with little stained or pale pink organelles that normally give it a granular appearance.



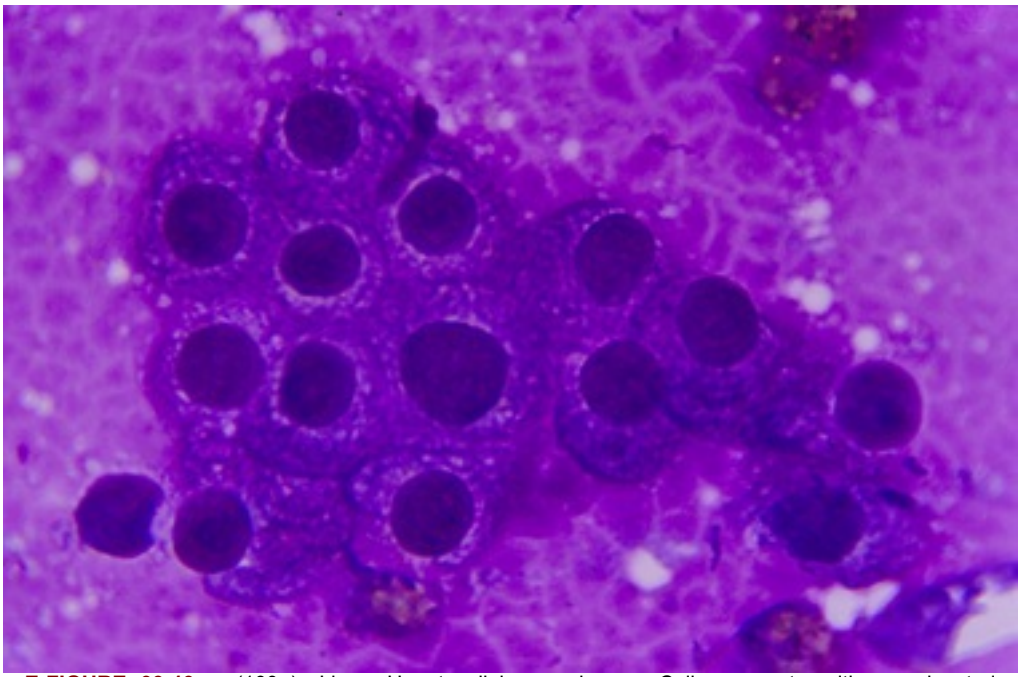
E-FIGURE 93-16 (100×). Liver. Biliary epithelium (B) (small uniform cuboidal cells with little cytoplasm), together with hepatocytes (H). This image shows slight variations in shape and contour suggesting reactivity status (hyperplasia).



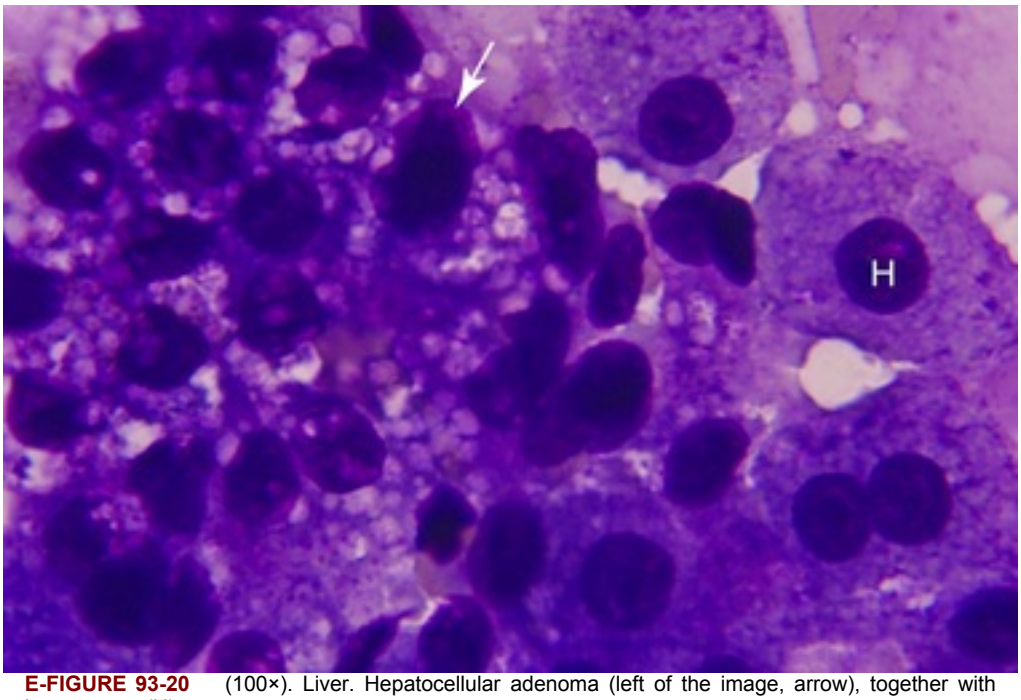
E-FIGURE 93-17 (100×). Liver. Hepatic lipidosis (hepatocytes full of large numbers of lipid vacuoles of different sizes, fat degeneration).



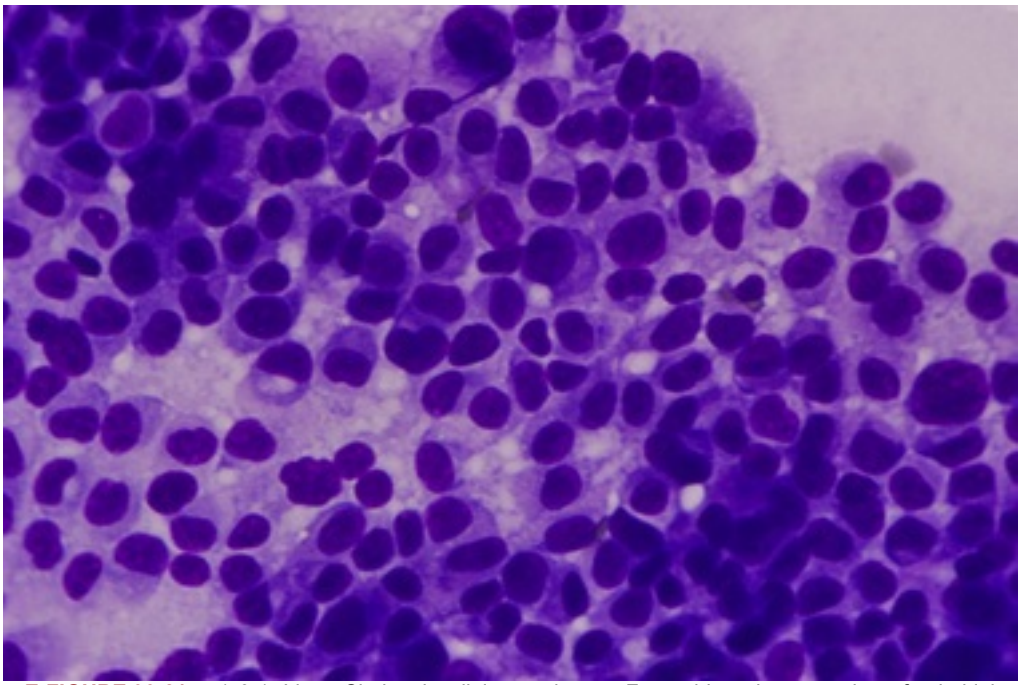
E-FIGURE 93-18 (100×). Liver. Hyperplastic nodule (increased number of binucleate hepatocytes, anisocytosis, anisokaryosis).



E-FIGURE 93-19 (100×). Liver. Hepatocellular carcinoma. Cell aggregate with an elevated nucleus/cytoplasm ratio. Cytological diagnosis is only possible in the presence of marked atypia. A histopathological evaluation is generally required.



E-FIGURE 93-20 (100×). Liver. Hepatocellular adenoma (left of the image, arrow), together with hepatocytes (H).

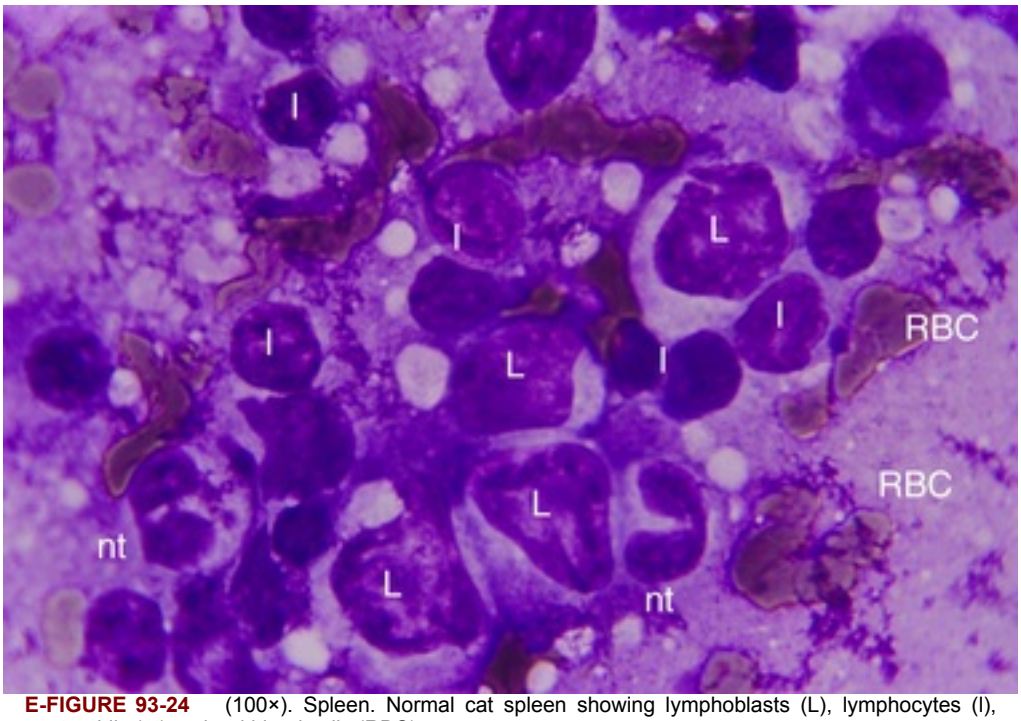


E-FIGURE 93-21 (40×). Liver. Cholangiocellular carcinoma. Formed by a large number of cuboidal cells with moderate anisokaryosis that does not show its malignancy. The nodular or diffuse form can be difficult to distinguish from nodular hyperplasia, cirrhosis or chronic hepatitis. A histopathological evaluation is required for its diagnosis.

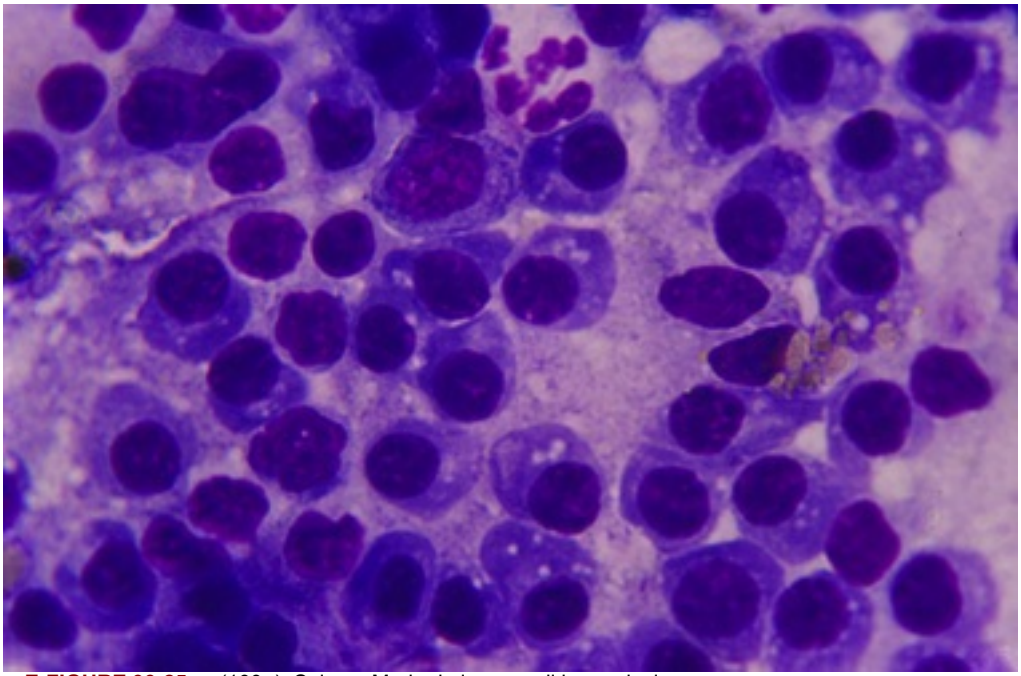
E-FIGURE 93-23 (100×). Liver. Lymphoma. Normal hepatocytes together with neoplastic lymphoblasts (L). Only in a few cases is lymphoma formed by small neoplastic lymphocytes.

Spleen

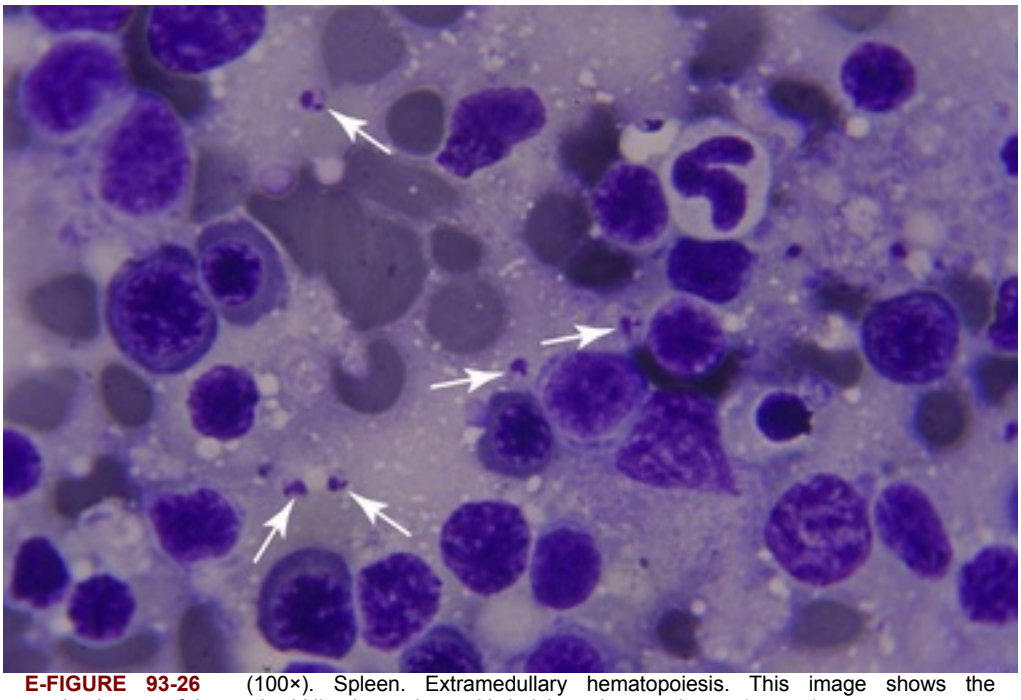
Normal splenic cytology includes hemodiluted small and medium-sized lymphocytes, lymphoblasts, plasma cells, stromal cells, and macrophages (E-Figure 93-24). Macroscopically, hyperplasia may appear nodular or diffuse. Microscopically, the cytology is consistent with chronicity (macrophages, plasma cells and lymphoblasts). Possible causal agents should be sought within macrophages (*Histoplasma* spp., *Leishmania* spp.) and red blood cells (*Mycoplasma, Babesia* and *Cytauxzoon* spp.). Heinz bodies could indicate toxic damage. Severe plasma cell hyperplasia (E-Figure 93-25) includes a differential diagnosis of ehrlichiosis, leishmaniasis, extramedullary plasmacytoma, or multiple myeloma. Lymphoid hyperplasia can be associated with some viral diseases. The presence of extramedullary hematopoiesis suggests increased erythroid precursors (E-Figure 93-26) and granulocyte and megakaryocyte precursors (E-Figure 93-27). Hematomas (relatively common) or extramedullary hematopoiesis can be associated with hyperplasia or neoplasia. The most common splenic tumors in dogs are hemangioma and hemangiosarcoma (E-Figures 93-28 and 93-29) and in cats are mastocytomas (E-Figure 93-30) and lymphoma. Lymphoma (E-Figures 93-31 and 93-32) or chronic lymphocytic leukemia can be a cytological diagnostic challenge because their cytological appearance is similar to that of a normal or hyperplastic spleen. In malignant histiocytosis, there is a predominance of abnormal and immature macrophages.



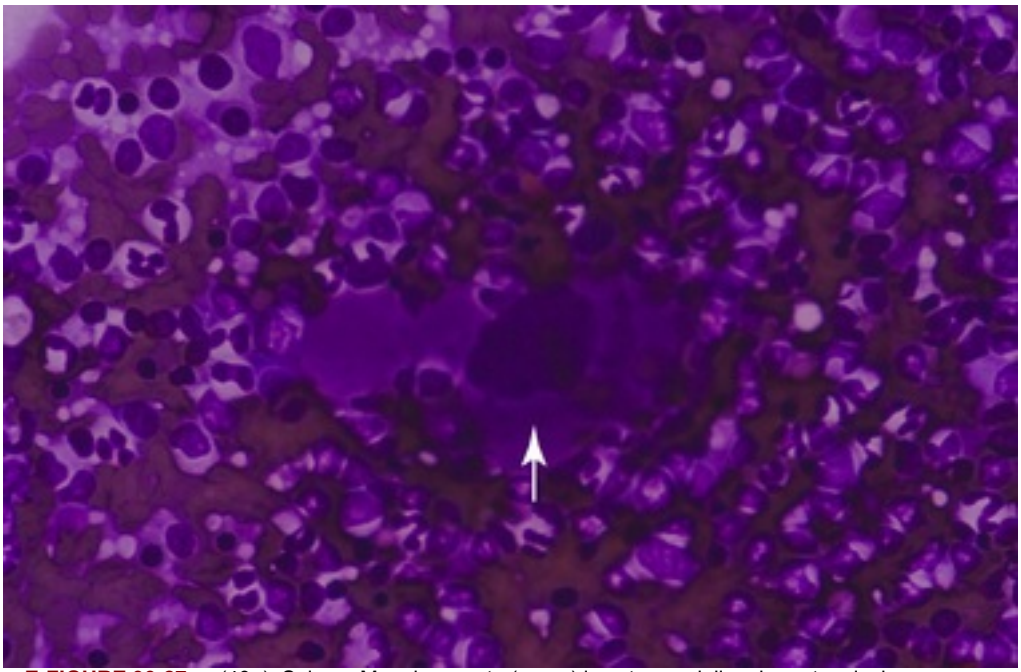
E-FIGURE 93-24 (100×). Spleen. Normal cat spleen showing lymphoblasts (L), lymphocytes (l), neutrophils (nt) and red blood cells (RBC).



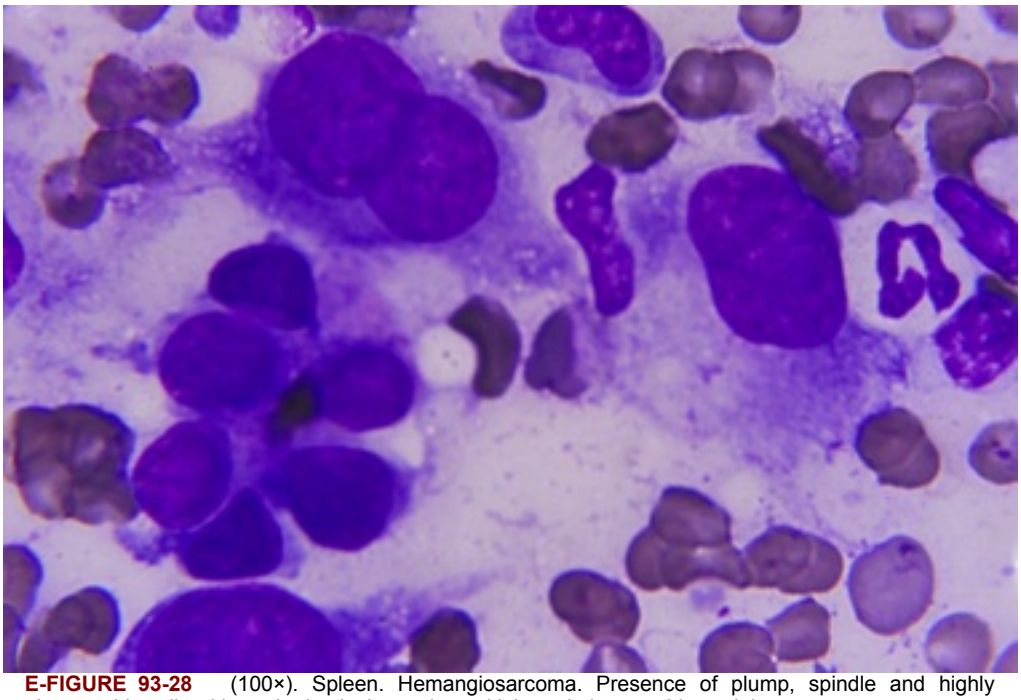
E-FIGURE 93-25 (100×). Spleen. Marked plasma cell hyperplasia.



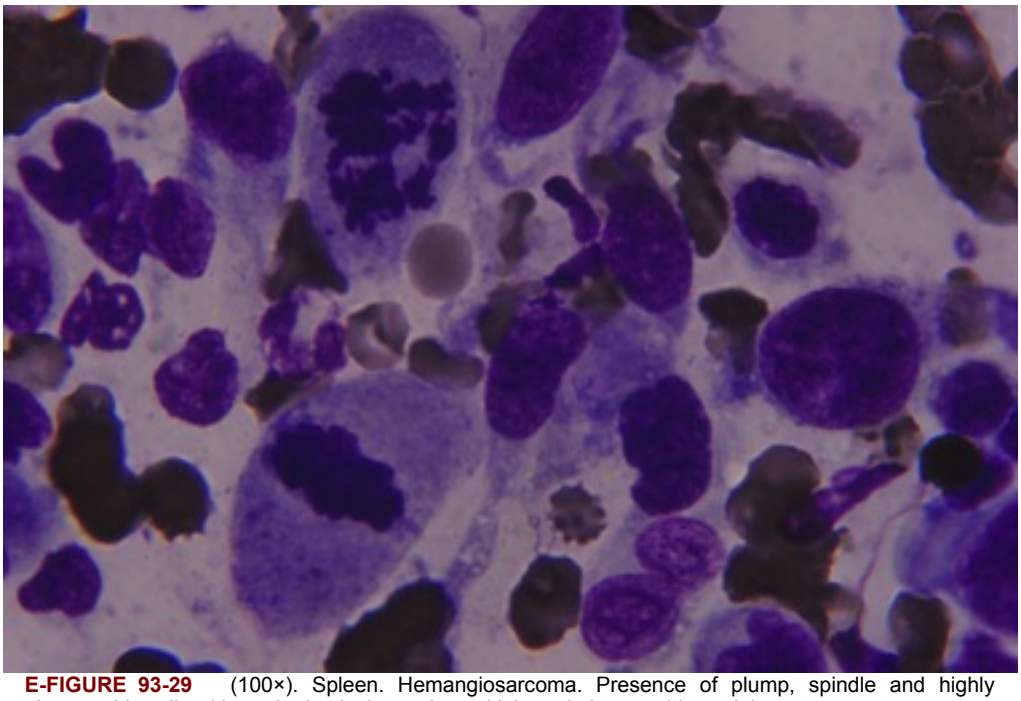
E-FIGURE 93-26 (100×). Spleen. Extramedullary hematopoiesis. This image shows the predominance of the erythroid line in a spleen with *Leishmania* amastigotes (arrows).



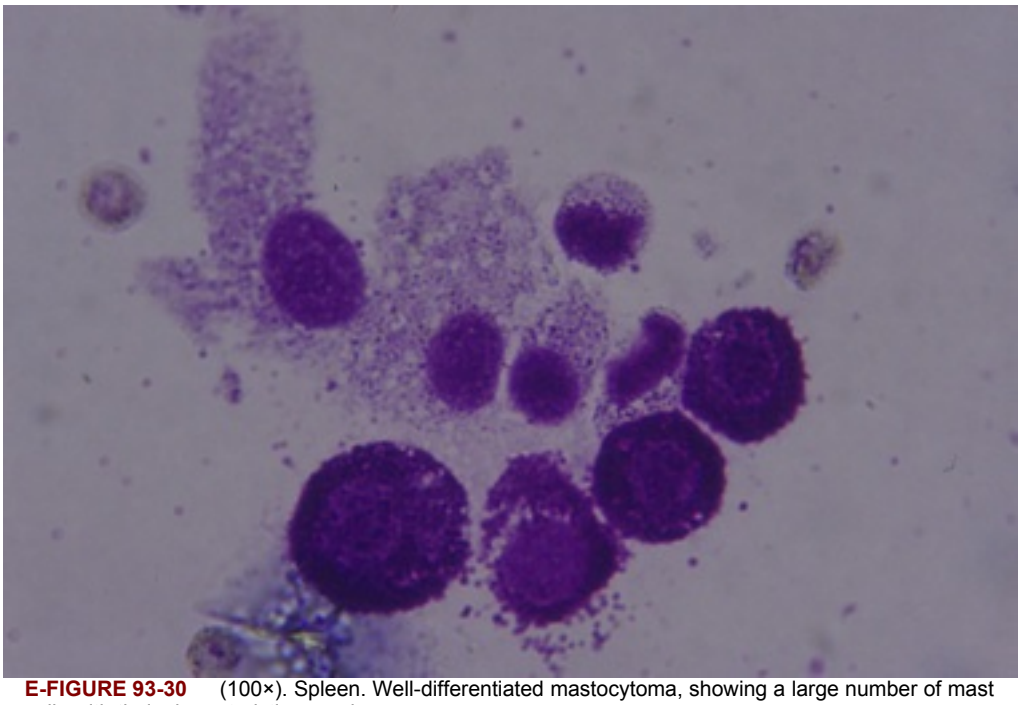
E-FIGURE 93-27 (40×). Spleen. Megakaryocyte (arrow) in extra-medullary hematopoiesis.



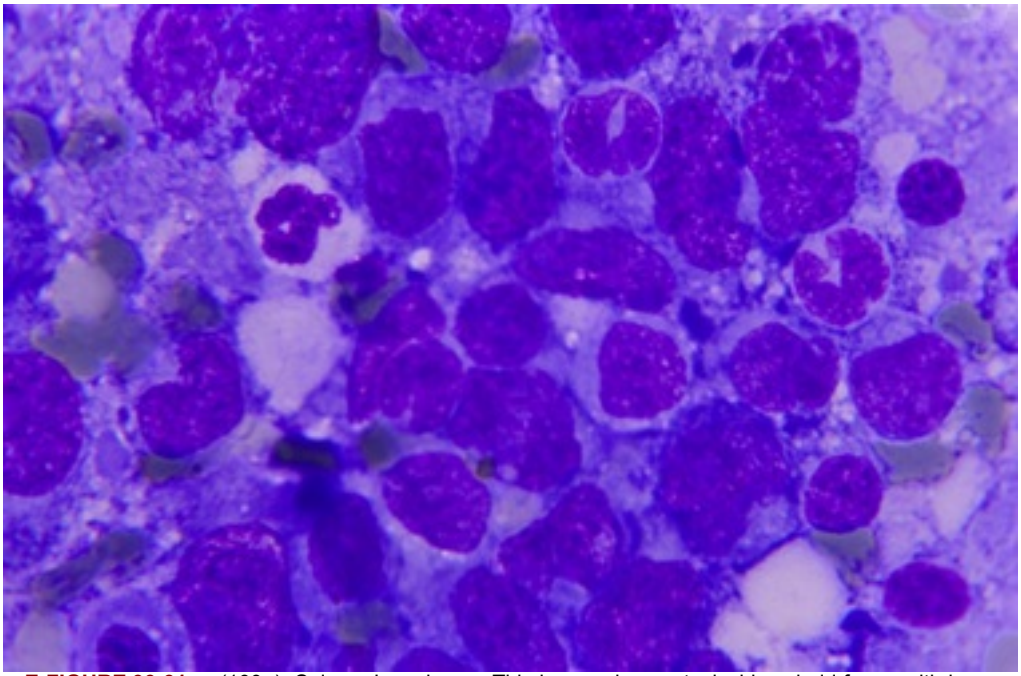
E-FIGURE 93-28 (100×). Spleen. Hemangiosarcoma. Presence of plump, spindle and highly pleomorphic cells with marked anisokaryosis, multiple and pleomorphic nuclei.



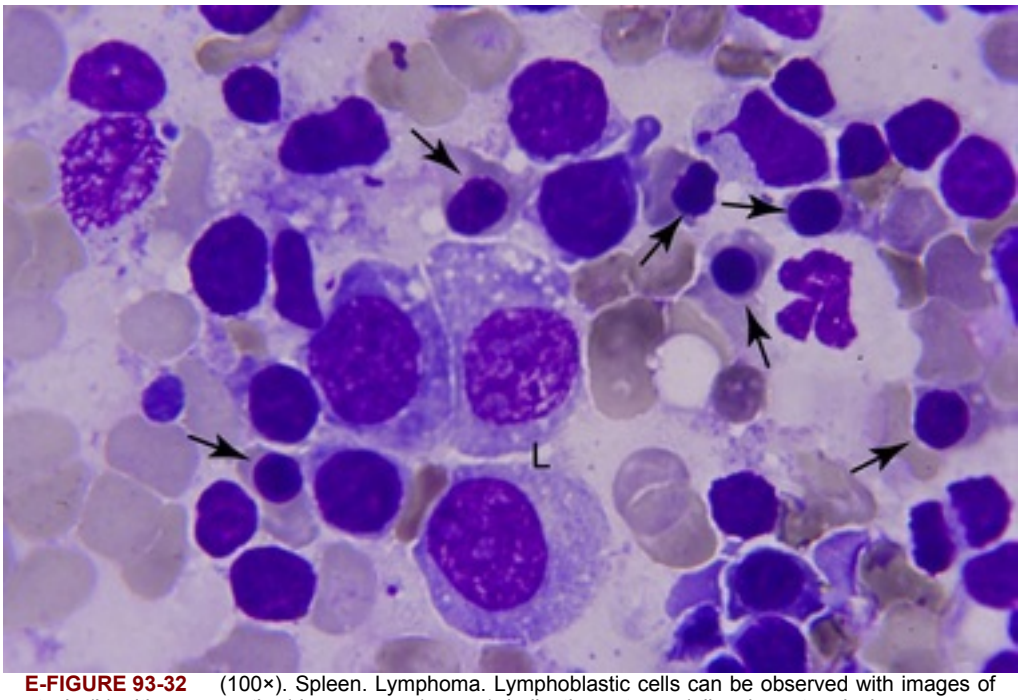
E-FIGURE 93-29 (100×). Spleen. Hemangiosarcoma. Presence of plump, spindle and highly pleomorphic cells with marked anisokaryosis, multiple and pleomorphic nuclei.



E-FIGURE 93-30 (100×). Spleen. Well-differentiated mastocytoma, showing a large number of mast cells with their characteristic granules.



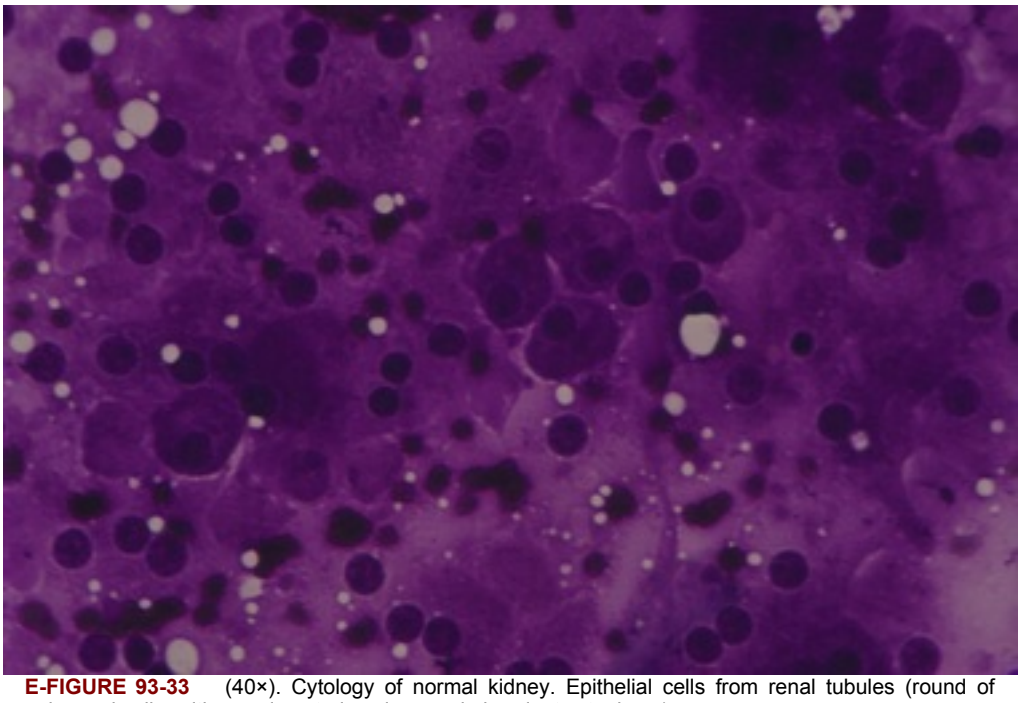
E-FIGURE 93-31 (100×). Spleen. Lymphoma. This image shows atypical lymphoid forms with large nuclei and irregular contours.



E-FIGURE 93-32 (100×). Spleen. Lymphoma. Lymphoblastic cells can be observed with images of atypia (L) with some erythroid precursors (arrows), indicating extramedullary hematopoiesis.

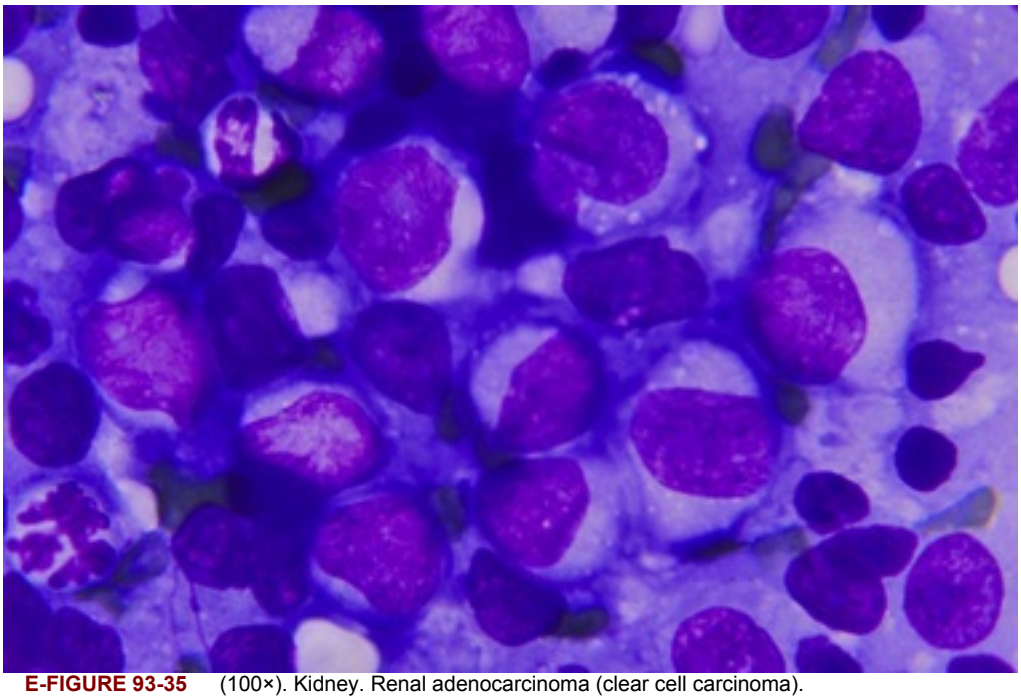
Kidney

It is preferable to sedate or anesthetize dogs and cats for this procedure. Fine needle aspiration may be indicated if there is evidence of atypical renal enlargement or suspicion of a cyst, abscess or neoplasia. Little information is gained from aspirating atrophic kidneys. Complications are uncommon but excessive hemorrhage has been reported. Normal cytology includes round (E-Figure 93-33) or polygonal cells in cords (E-Figure 93-34), fragments of renal tubules, often with some blood contamination. Metastatic tumors are more common than primary tumors. Epithelial tumors are most common in older dogs (mostly carcinomas, E-Figures 93-35 and 93-36). Some tumors (adenocarcinoma and melanoma) may be bilateral. The most common renal tumor in cats is lymphoma.



E-FIGURE 93-33 (40×). Cytology of normal kidney. Epithelial cells from renal tubules (round of polygonal cells, with round central nucleus and abundant cytoplasm).

E-FIGURE 93-34 (10×). Cytology of normal kidney. Fragments of renal tubules.



E-FIGURE 93-35 (100×). Kidney. Renal adenocarcinoma (clear cell carcinoma).

Lymph Nodes

Aspiration is indicated when a node or nodes is/are enlarged or irregular. The purpose of cytology is to identify any neoplastic process. Cytology of normal lymph nodes includes small lymphocytes with lesser numbers of lymphoblasts (E-Figure 93-37) and immunoblasts. In hyperplasia (reactive lymphadenopathy), the enlarged node may have normal cytological characteristics but greater cell polymorphism and macrophage counts. Increased macrophage numbers are also seen in granulomatous lymphadenitis, but the macrophages tend to form groups (E-Figure 93-38) or may appear to blend into multinucleate cells. A predominance of plasma cells (plasmacytic hyperplasia, E-Figure 93-39) typically follows strong antigen stimulation. Attempts should always be made to detect parasites such as *Leishmania* spp. (E-Figure 93-40), but false negatives are common. As with cytology of the spleen or liver, there can be extramedullary hematopoiesis (E-Figure 93-41). Lymphoma (primary neoplasia) is cytologically divided into small- or large-cell lymphomas. Small-cell lymphoma (lymphocytic lymphoma) usually appears cytologically as a monotonous population of well-differentiated small lymphocytes which often fragment to produce varying sized cytoplasmatic pieces called lymphoglandular bodies (Figure 93-42). Medium- and large-cell lymphomas, called lymphoblastic lymphoma (E-Figures 93-43 and 93-44), typically include more than 50% lymphoblasts and abundant lymphoglandular bodies. Fewer lymphoglandular bodies may aid in distinguishing benign hyperplasia (E-Figure 93-45) from a malignant process. Morphological characteristics can be affected by the fixation and drying techniques used. The existence of lymphoma-imitating processes may interfere with establishing a definitive diagnosis. The most common neoplasms to metastasize to lymph nodes are carcinomas (E-Figure 93-46), mastocytomas, and malignant melanomas (E-Figure 93-47).

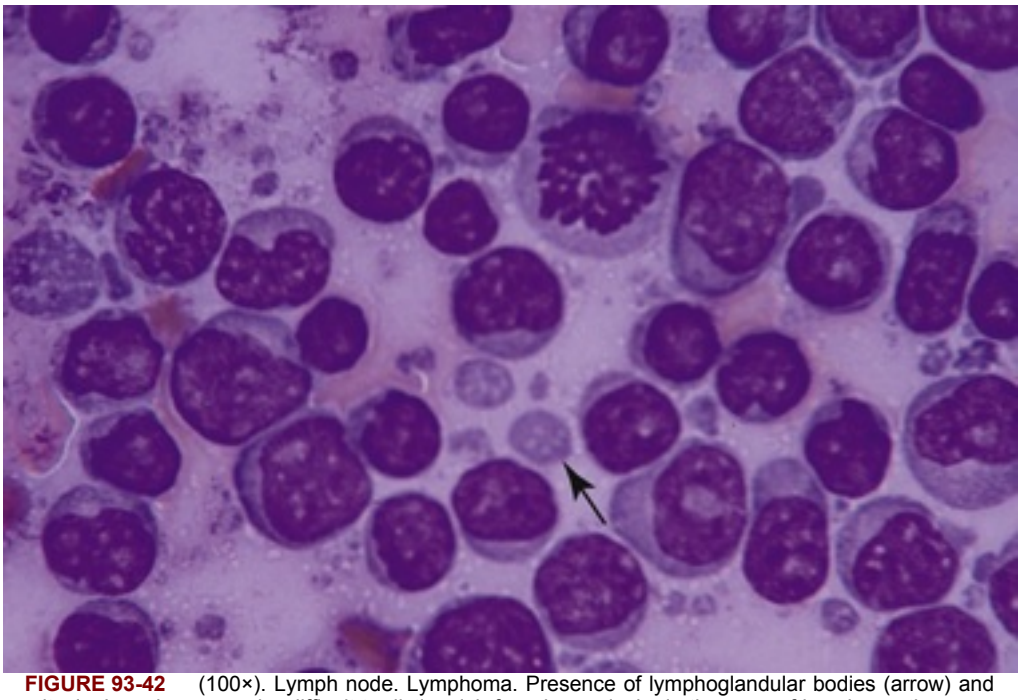


FIGURE 93-42 (100×). Lymph node. Lymphoma. Presence of lymphoglandular bodies (arrow) and mitosis. Lymphoma can be difficult to distinguish from hyperplasia; in the case of lymphoma there are generally more lymphoglandular bodies as a result of cell damage and the cell population is more homogeneous.

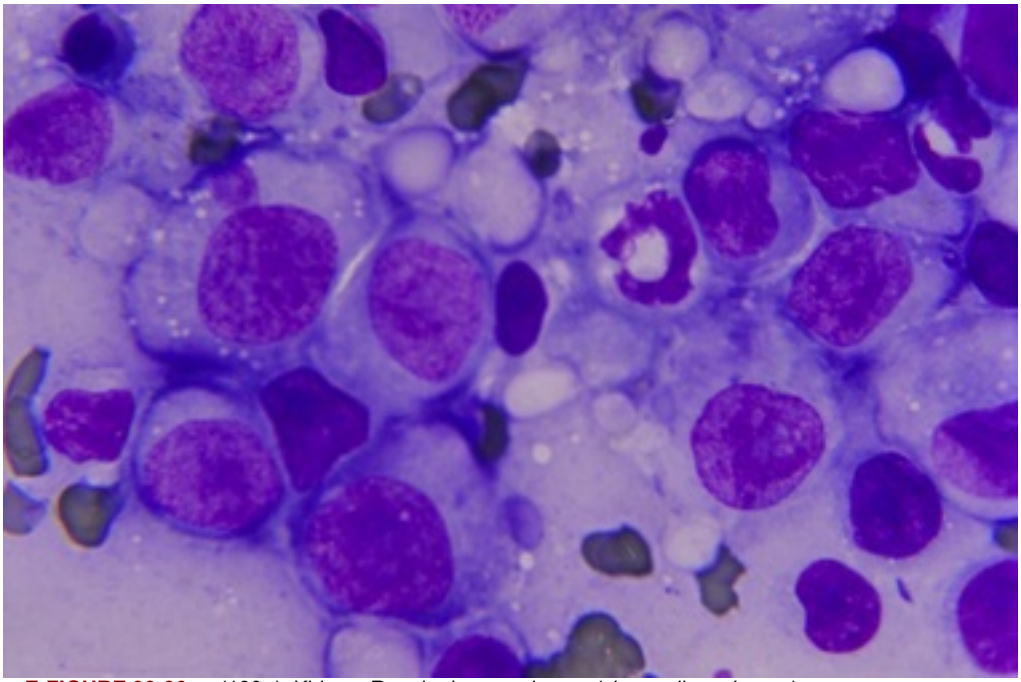
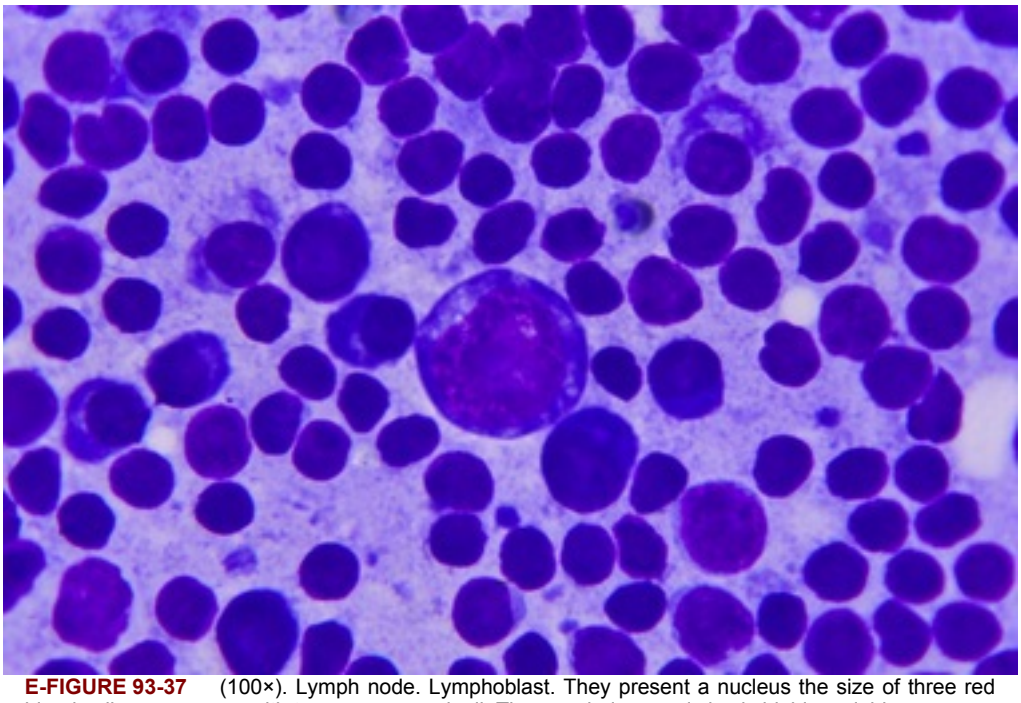
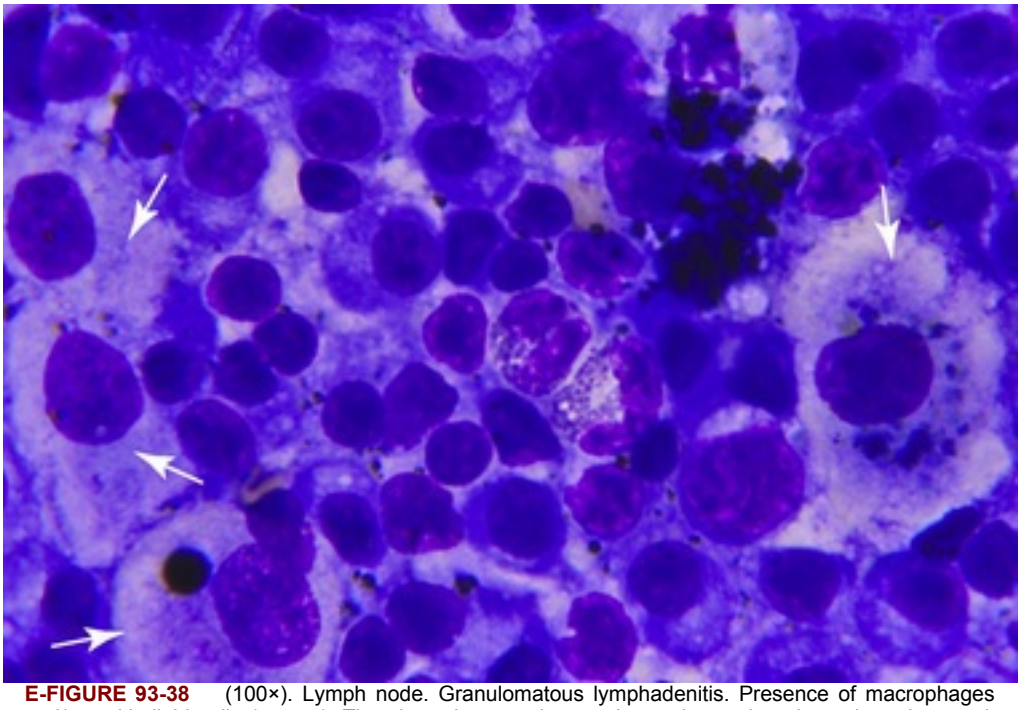


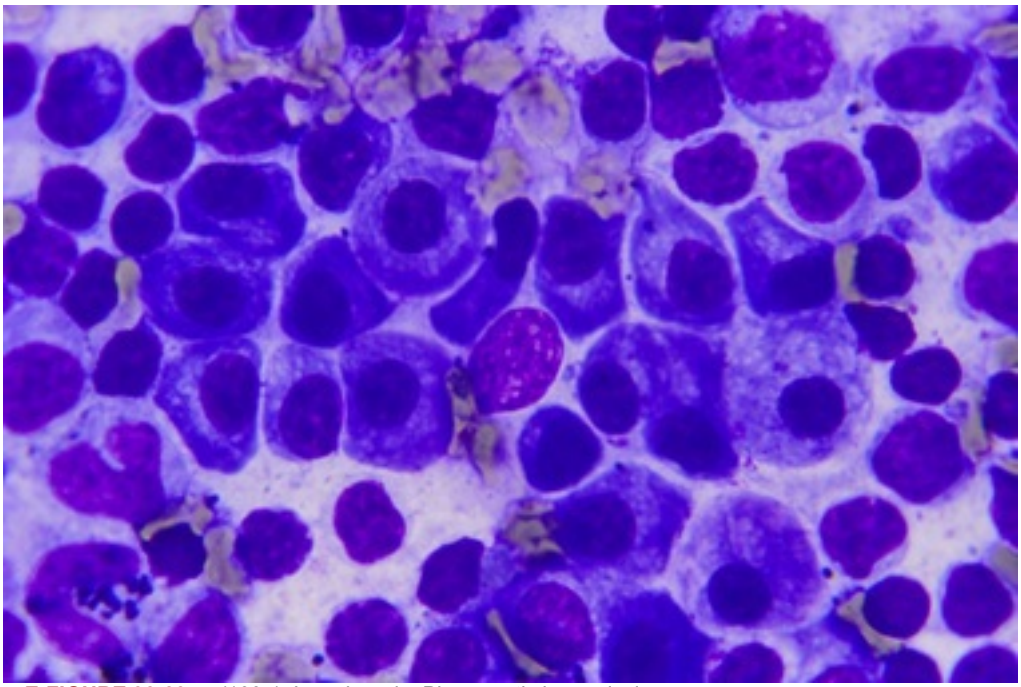
E-FIGURE 93-36 (100×). Kidney. Renal adenocarcinoma (clear cell carcinoma).



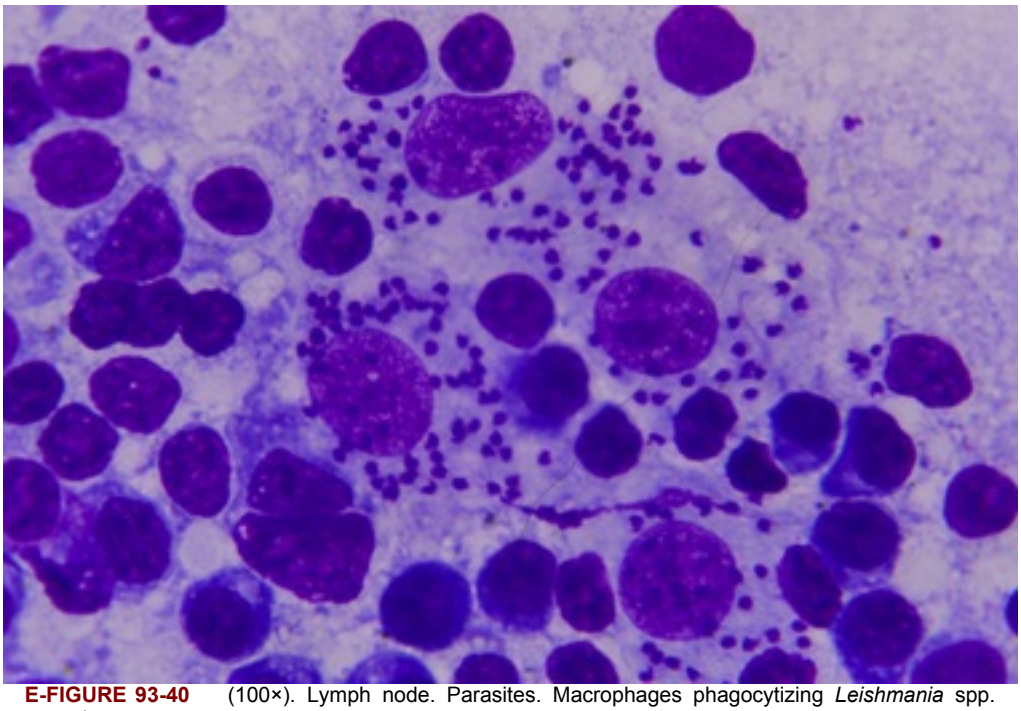
E-FIGURE 93-37 (100×). Lymph node. Lymphoblast. They present a nucleus the size of three red blood cells on average, with two or more nucleoli. The morphology and size is highly variable.



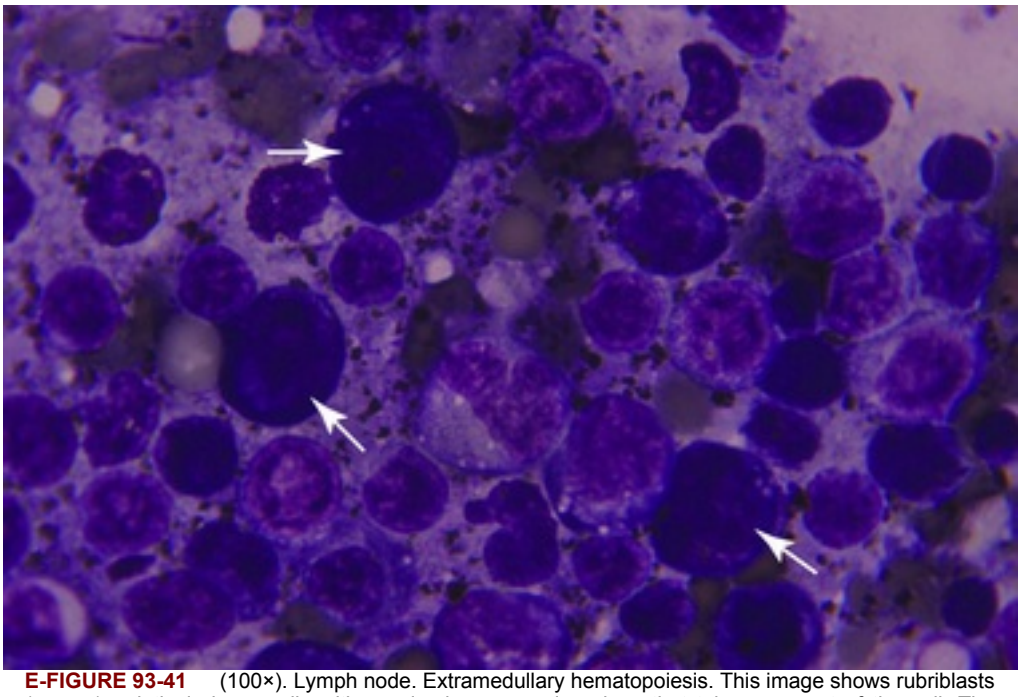
E-FIGURE 93-38 (100×). Lymph node. Granulomatous lymphadenitis. Presence of macrophages and/or epithelioid cells (arrows). They have large, pale cytoplasm; the nucleus is oval or elongated, with one or more visible nucleoli.



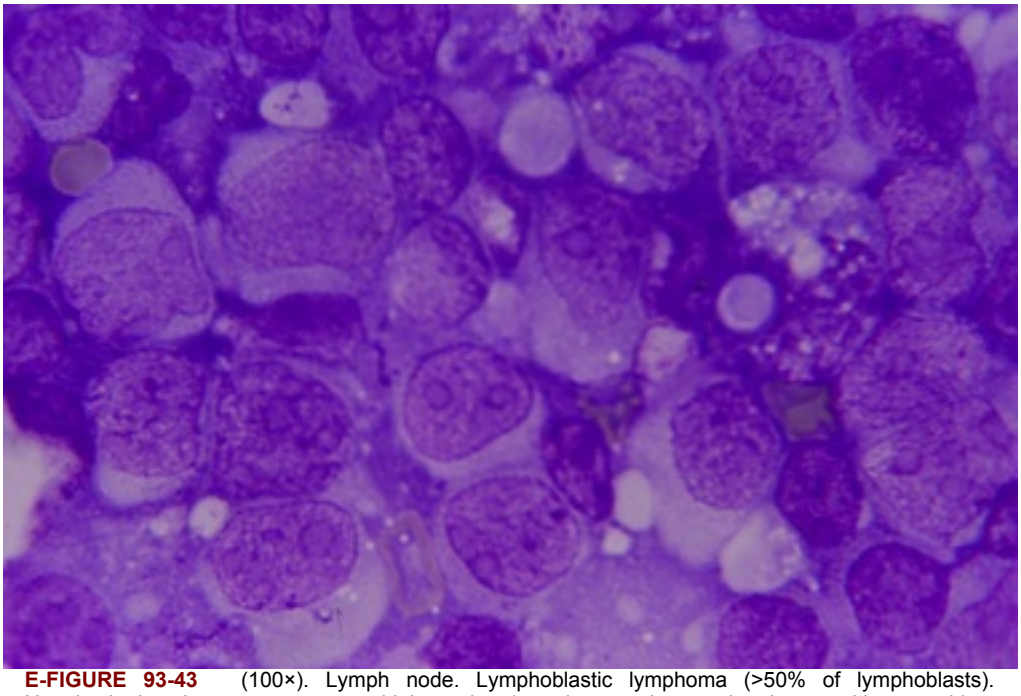
E-FIGURE 93-39 (100×). Lymph node. Plasmacytic hyperplasia.



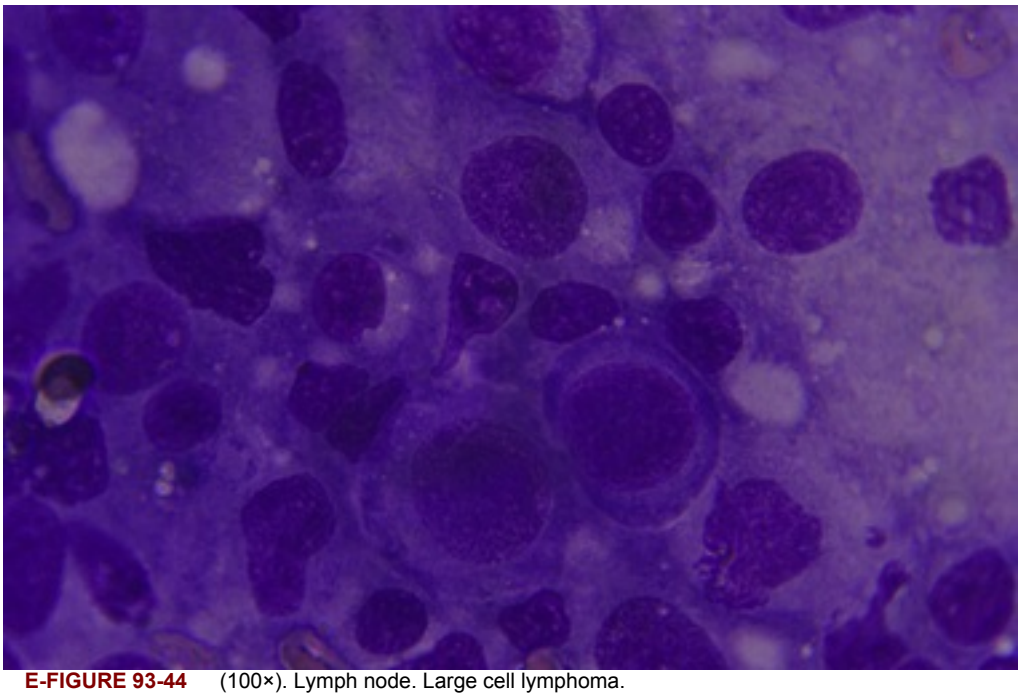
E-FIGURE 93-40 (100×). Lymph node. Parasites. Macrophages phagocytizing *Leishmania* spp. amastigotes.



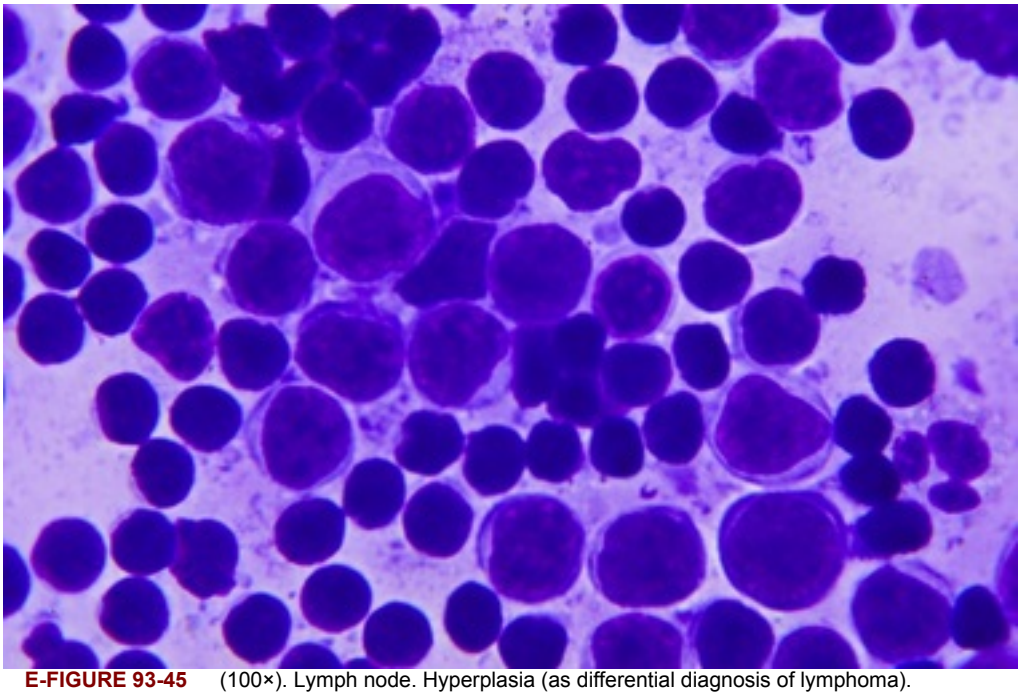
E-FIGURE 93-41 (100×). Lymph node. Extramedullary hematopoiesis. This image shows rubriblasts (arrows), relatively large cells with a voluminous round nucleus that takes up most of the cell. The small amount of cytoplasm is highly basophilic (very dark blue).



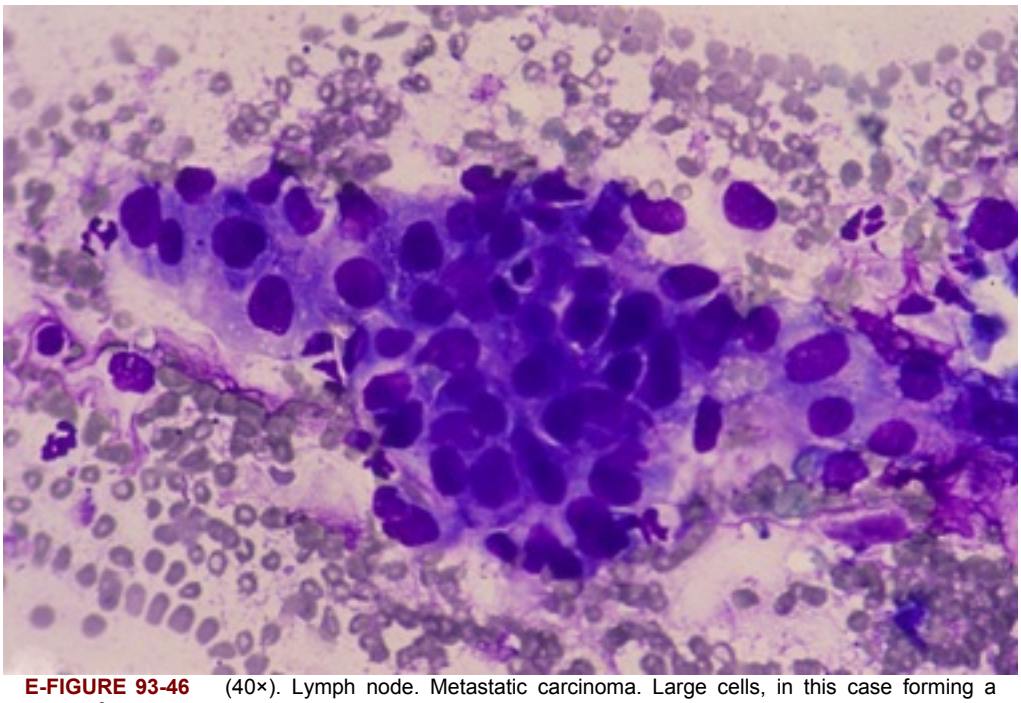
E-FIGURE 93-43 (100×). Lymph node. Lymphoblastic lymphoma (>50% of lymphoblasts). Neoplastic lymphocytes present a high nucleus/cytoplasm ratio, nearly always with an evident nucleolus. Lysate cells (bare nuclei) and cells with partial lysis present nucleolar tumefaction, imitating lymphoblasts.



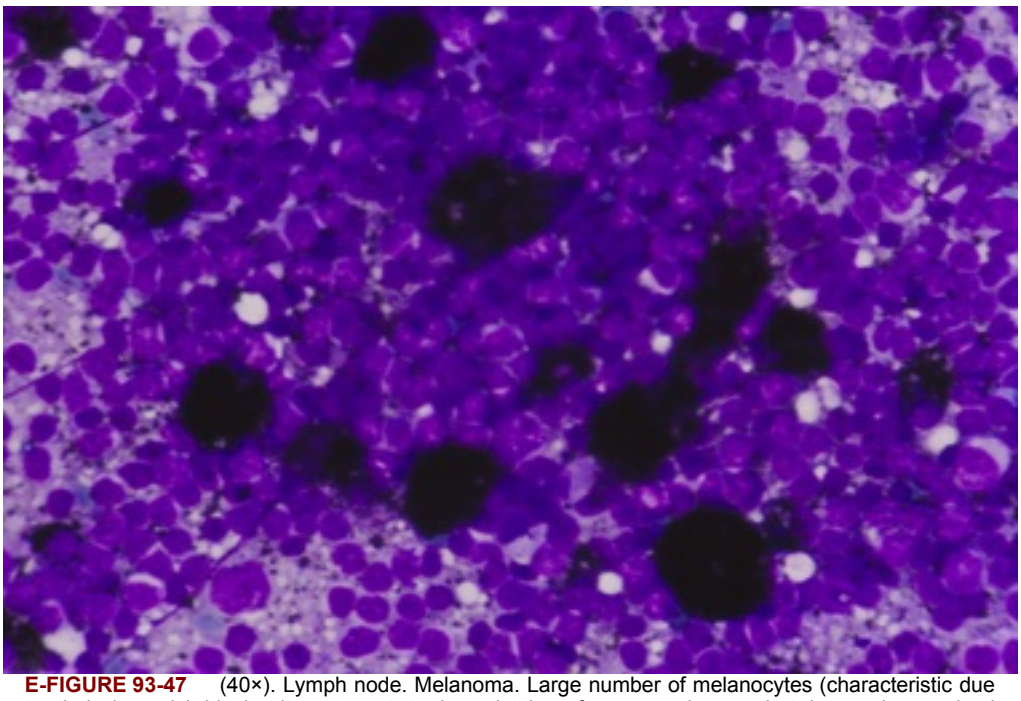
E-FIGURE 93-44 (100×). Lymph node. Large cell lymphoma.



E-FIGURE 93-45 (100×). Lymph node. Hyperplasia (as differential diagnosis of lymphoma).



E-FIGURE 93-46 (40×). Lymph node. Metastatic carcinoma. Large cells, in this case forming a group of squamous appearance.

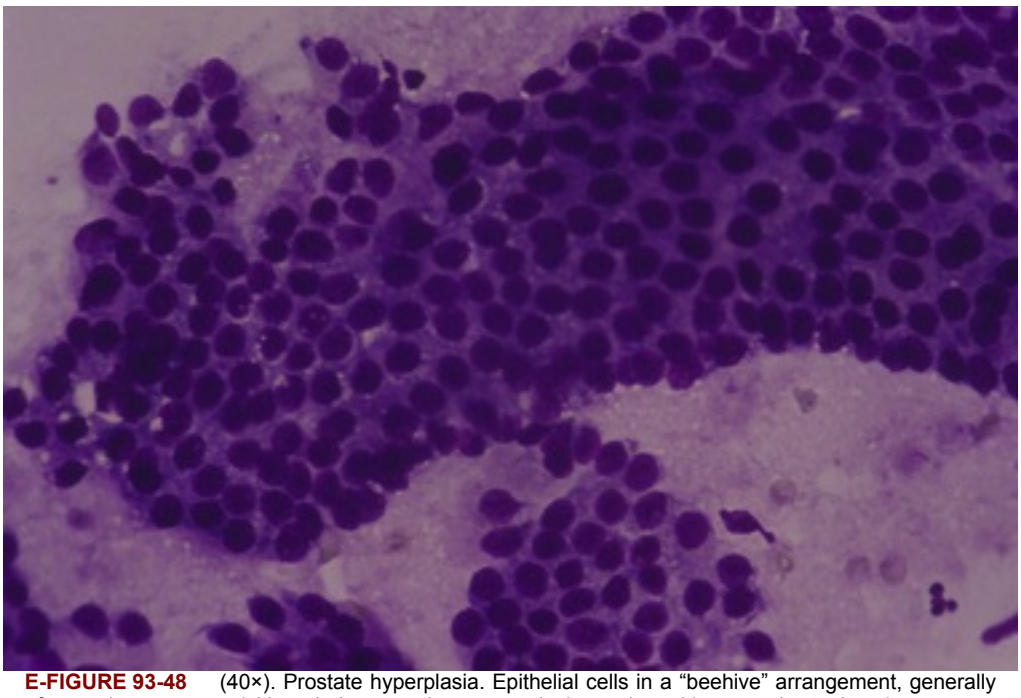


E-FIGURE 93-47 (40×). Lymph node. Melanoma. Large number of melanocytes (characteristic due to their brownish-black pigment, not to be mistaken for macrophages that have phagocytized pigments).

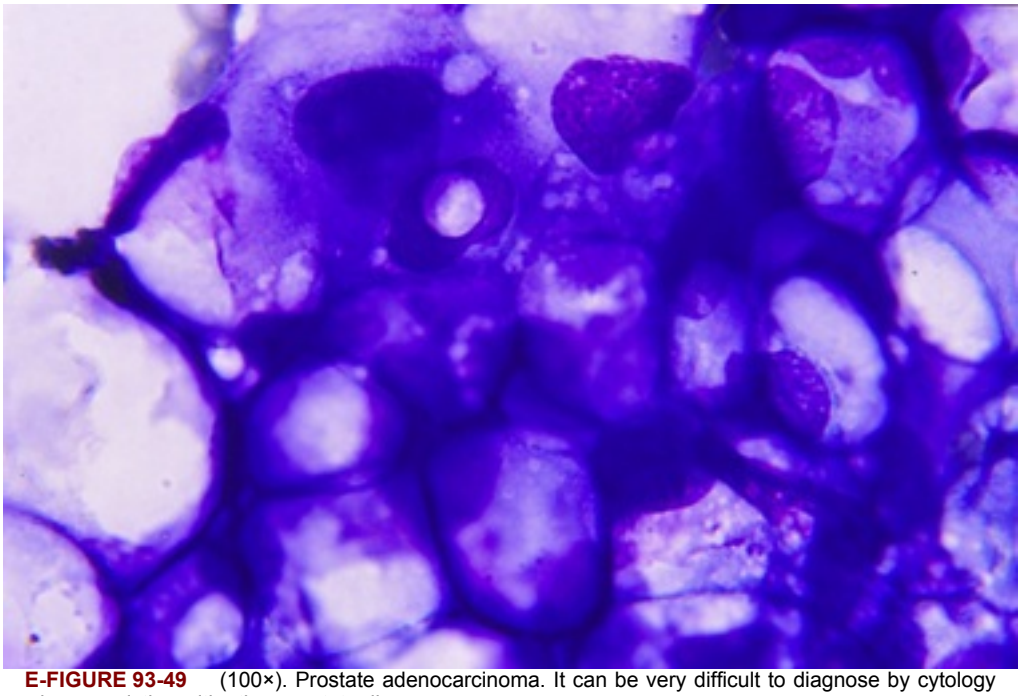
Prostate

Prostatic cytology is normally typified by groups of cubic or cylindrical cells in "beehive" arrangements. In benign prostate hyperplasia, cells appear normal but with a slightly increased nucleus/cytoplasm ratio (E-Figure 93-48). Prostate abscesses have large numbers of neutrophils, many of them degenerated. In squamous metaplasia, there are large numbers of squamous cells which may be difficult to distinguish from

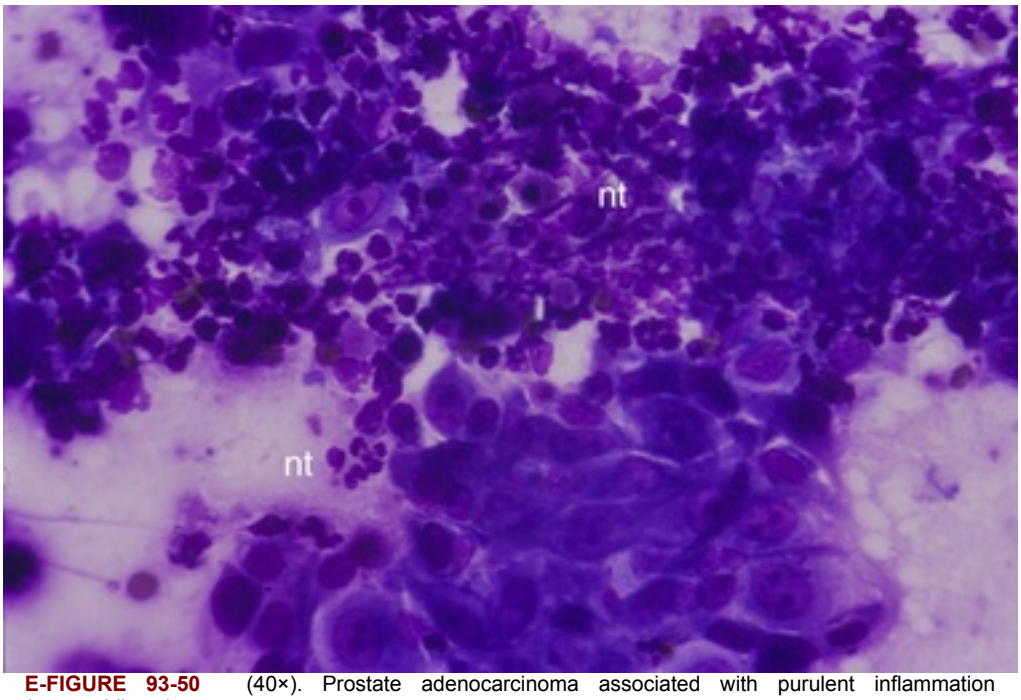
contamination with squamous cells of the distal urethra when samples are obtained by massage. Prostate neoplasias are uncommon and typically malignant. Adenocarcinoma, the most common tumor of the prostate, is difficult to diagnose with cytology (E-Figures 93-49 and 93-50). Transitional cell carcinoma is less common.



E-FIGURE 93-48 (40×). Prostate hyperplasia. Epithelial cells in a "beehive" arrangement, generally of normal appearance (although there can be some anisokaryosis and increased cytoplasm).



E-FIGURE 93-49 (100×). Prostate adenocarcinoma. It can be very difficult to diagnose by cytology when coexisting with other prostate diseases.



E-FIGURE 93-50 (40×). Prostate adenocarcinoma associated with purulent inflammation (neutrophils, nt).

Others

Urethral discharges (ch. 44), semen (ch. 111 and 318), urinary sediment (ch. 72), traumatic prostate or bladder aspirates (ch. 111), and transtracheal and bronchoalveolar lavage specimens (ch. 101) are each submitted to clinical pathologists on occasion. Such examinations can be of value.

CHAPTER 94

Arthrocentesis and Arthroscopy

Jonathan D. Dear

Client Information Sheet: Arthrocentesis and Arthroscopy

Anatomy and Physiology

Synovial joints are composed of two or more articulating bones with a superficial layer of articular cartilage, synovium and synovial fluid. Some joints may also contain intra-articular menisci, ligaments or fat pads. The synovium is a thin membrane of synoviocytes spanning the articulating bones to create an enclosed "compartment." Synoviocytes are characterized as either type A (phagocytic) or type B cells that secrete hyaluronan and other components into joint and surrounding extracellular fluid (ECF) spaces. Synovial fluid is a dialysate of plasma and is, in health, relatively acellular. Synovial fluid not only lubricates cartilage, but it also delivers nutrients to this tissue that has little direct blood supply. The elastic and thick viscosity of joint fluid accounts for its lubricating qualities. Any condition that causes joint inflammation may lead to abnormally porous synovial vessels and an accumulation of ECF, inflammatory mediators, and leukocytes in the joint space. This process decreases joint fluid viscosity, causes pain, and increased susceptibility to structural damage and development of arthritis.

Background and Indications

Arthrocentesis, joint fluid aspiration, is a technique for obtaining fluid from distal joints. Potentially valuable information, gained from gross and cytologic analysis of joint fluid, may aid in determining cause of swollen joints, lameness, fever, or polysystemic disease. While not technically challenging, there is a steep learning curve to these procedures. Once competent and confident, joint fluid analysis can be employed as a diagnostic aid in a variety of scenarios. It is particularly useful in evaluating dogs with obvious joint abnormalities, but also for dogs with fever of unknown origin (FUO) and those with vague signs of malaise. Indications for arthrocentesis are thoroughly reviewed (see ch. 14, 15, 31, 48, and 59). Joint fluid analysis is also reviewed (see ch. 74). The goals of this chapter are to review the techniques and approaches to acquiring samples for cytologic and microbiologic assessment.

Results of arthrocentesis can be helpful in differentiating osteoarthritis from immune-mediated, infectious or neoplastic processes. The joint fluid analysis should complement information acquired from the history, physical examination, orthopedic and neurologic evaluations, laboratory and imaging studies. When indicated, radiographs of affected joints and limbs should precede arthrocentesis as the development of hemarthrosis can lead to difficulty in radiograph interpretation.

Techniques

Overview

The decision regarding the joint or joints to aspirate should be determined using the information gathered from clinical history, physical exam and orthopedic evaluation. On physical examination, however, joints may not be obviously abnormal in patients with shifting leg lameness, systemic illness, fever, or suspected immune-mediated polyarthritis. In these pets, one may choose to aspirate multiple joints (usually carpus and tarsus) to increase diagnostic yield. Results of arthrocentesis should be interpreted in the context of the patient's overall condition. While results of joint fluid analysis may provide insight into a patient's disease, it rarely provides a definitive diagnosis.

Patient Preparation and Positioning

Since joint disease may be painful, adequate analgesia, sedation or anesthesia should be provided. Sedation, as a minimum, is not only imperative for fractious or excitable patients, but it also allows safe joint fluid aspiration from calm pets, minimizing risk of the needle causing intra-articular harm. After the patient is sedated or anesthetized, they should be positioned in lateral recumbency. Often the carpal joint is aspirated from the medial aspect of the leg, requiring access to the dependent thoracic limb. There is also a technique using a dorsal or anterior approach to the carpal joint. Elbow, stifle and tarsus joints are usually aspirated using a lateral approach, requiring access to the nondependent or upper limb. Prior to arthrocentesis, the joints should be clipped and prepped aseptically alternating chlorohexidine with alcohol. Sterile gloves, needles and syringes should be used. Draping is not necessary. To reduce chances of the procedure causing joint trauma, blood contamination or pain, first manipulate the joint to find the degree of flexion that allows the largest "window" into the synovial space. Flexing the leg can be done by the veterinarian performing the arthrocentesis or by a technician. Should the veterinarian prefer to manipulate the leg and joint, they must perform the joint aspirate with one sterile hand (usually the dominant hand) and one non-sterile hand (usually the nondominant hand).

Sample Acquisition (Video 94-1)

Small (22-25 gauge), short needles are usually used for arthrocentesis as they are less likely to cause joint damage. The needle should be attached to a small (typically 3 cc) syringe, ensuring a good seal between needle and syringe. Before introducing the needle into the joint space, break "the seal" in the syringe to allow for smooth movement of the plunger. The needle should be inserted slowly into the joint, perpendicular to the skin. The carpal joint is shallow, while the elbow, stifle and tarsus joints may require insertion of the entire needle to retrieve fluid. If bone or cartilage is encountered or no joint fluid aspirated, the needle should be withdrawn slightly and redirected.

Gentle and intermittent negative pressure should be applied with the plunger once the needle has passed through the skin and into joint space. While only a small amount of fluid is required for analysis, sometimes as much as 0.5-1 mL can be easily aspirated from abnormal joints. Avoid excessive negative pressure which may lead to hemorrhage, reducing the value of most samples. Negative pressure should be completely released prior to withdrawing the needle from the patient to avoid blood contamination from the skin or SC tissues. Discard any needle and syringe with blood contamination. One may not be able to withdraw more than 0.2 mL from a normal joint. Thus, apparent absence of fluid may be indicative of a healthy joint.

Anatomic Landmarks (Figure 94-1)

The carpus joint is sampled at the proximal radiocarpal joint either along its medial or dorsal aspect. When using the dorsal approach, care should be taken to avoid the cephalic vein which courses across the joint surface. The tibiotarsal joint is accessed from the lateral aspect along the talus; again, care should be taken to avoid the superficial blood vessels in the area. The needle should be advanced parallel to the axis of the metatarsals, perpendicular to the tibia. The stifle can be aspirated from either medial or lateral approach. From either approach a longer needle (often 1½ inch) is generally required as the synovial fluid tends to accumulate caudal to the patellar fat pat.

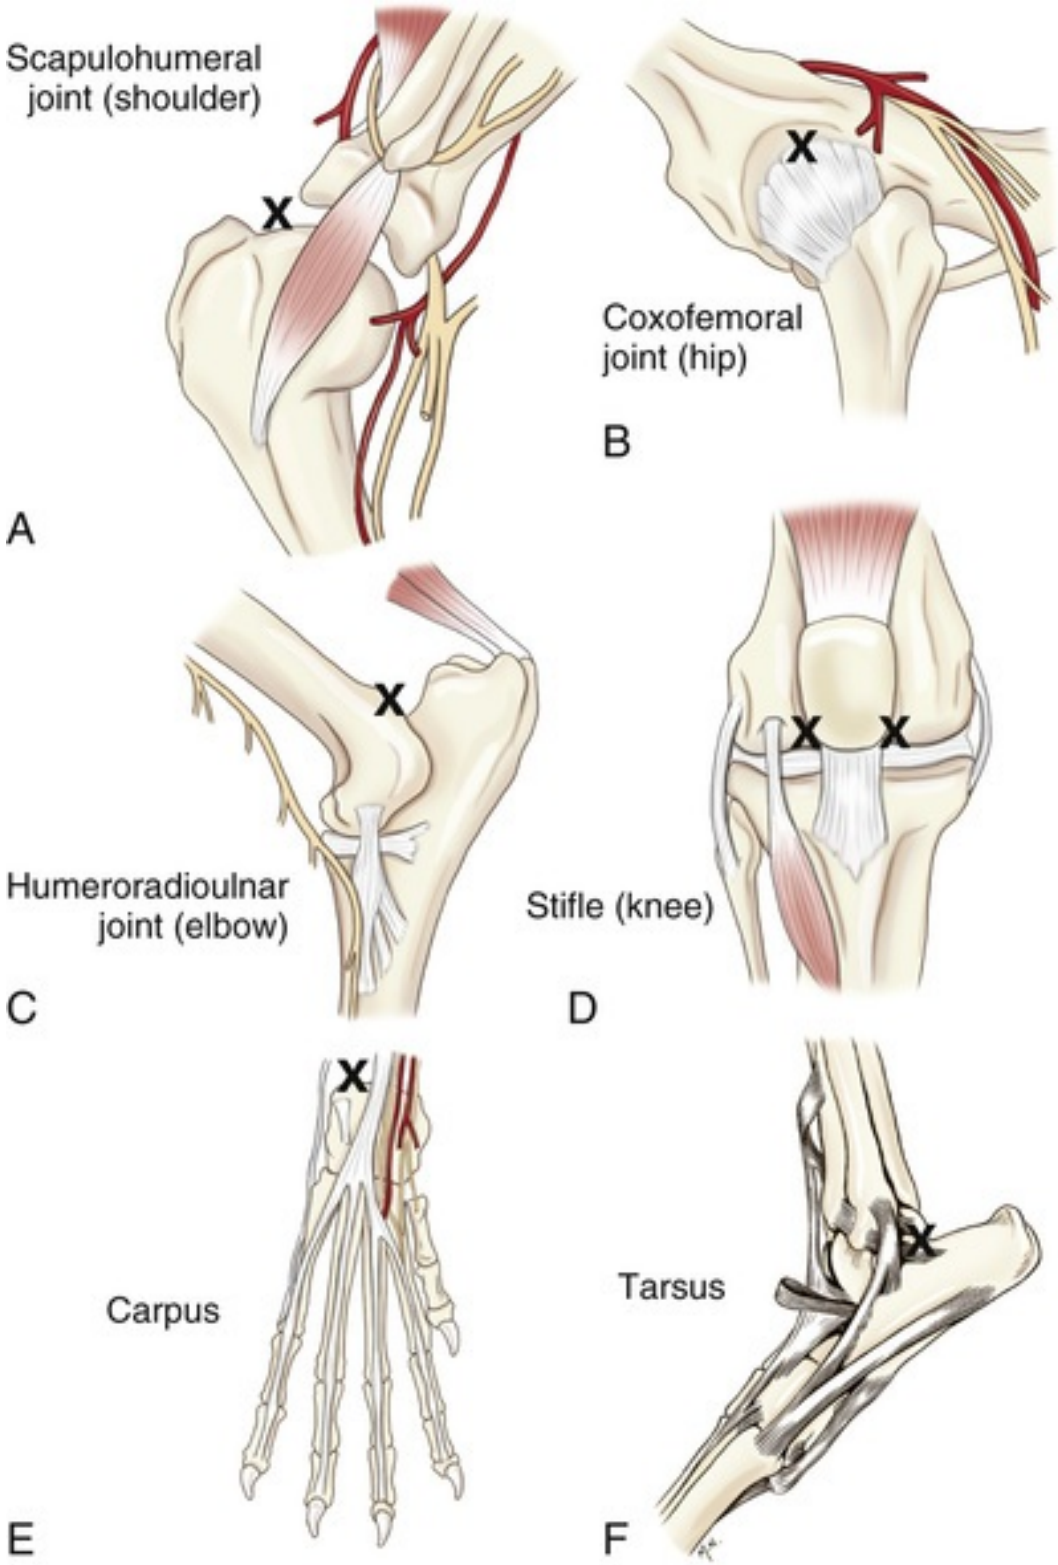


FIGURE 94-1 Sites of canine arthrocentesis (marked with an X). (**F,** From Evans HE, de Lahunta A: *Miller's anatomy of the dog,* ed 4, St Louis, 2013, Saunders.)

Fluid Handling

Synovial fluid should be submitted for cytologic analysis in an EDTA-containing tube and/or as prepared slides. This may depend on the volume of fluid aspirated. Slides can be prepared by dropping a small amount

of joint fluid onto a glass slide near the frosted edge and slowly spreading the sample across the slide using a second slide (see Video 95-1). Joint fluid and/or prepared slides should be evaluated by a clinical pathologist for color, turbidity, cellularity, differential cell count and cytologic inspection for infectious organisms or exfoliate neoplastic cells (E-Figures 94-2 through 94-5 and Table 94-1). A crude test of synovial fluid viscosity can be performed by stringing the sample between the thumb and index finger. Normal joint fluid should string 3-5 cm while joint fluid from affected joints will be less viscous and string shorter lengths. Lack of viscosity is due to lack of hyaluronan. It is recognized that assessing viscosity with one's fingers is subjective and may yield incorrect impressions.

TABLE 94-1

Cytologic Characteristics of Synovial Fluid

CONDITION	COLOR	TURBIDITY	VISCOSITY	TOTAL PROTEIN (g/dL)	NUCLEATED CELLS (cells/mcL)	DIFFERENTIAL (%)	
						Mono	PMN
Normal	Colorless	Clear	High	<2.5	<3,000	>95	<5
Degenerative joint disease	Colorless	Clear	Variable	<2.5	<5,000	>90	<10
Trauma	Colorless to yellow	Hazy	Decreased	Variable	2,500-3,000	>75	<25

Both *Ehrlichia* and *Anaplasma* spp. can induce polyarthritis, but organisms are variably identified on cytology. (Courtesy D. Schwartz, DVM, William Pritchard Veterinary Medical Teaching Hospital, UC Davis.)

E-FIGURE 94-5 A photomicrograph of synovial fluid from a dog with immune-mediated polyarthritis. The cytologic features of IMPA include marked increased cellularity (mostly nondegenerate polymorphonuclear cells) with a notable absence of intra- or extracellular bacteria. (Courtesy A. Adedeji, DVM, William Pritchard Veterinary Medical Teaching Hospital, UC Davis.)

If the sample is of adequate volume and if clinically indicated, synovial fluid should be submitted for microbial culture and susceptibility testing in a sterile tube or culturette tube. If immediate results are needed, basic fluid analysis can be performed by assessing the total solids, color, turbidity, and microscopic appearance. The nucleated cell count can be roughly estimated by multiplying the number of nucleated cells per high power field by 1000. While the presence of intracellular bacteria is compelling evidence for a septic process, many cytologic features are subtle. Patients with septic arthritis often have non-degenerate neutrophils. Therefore, care must be used when interpreting in-house joint fluid evaluation. Full description of joint fluid analysis is available in ch. 74.

CHAPTER 95

Lymph Node Aspiration and Biopsy

Takuo Ishida

Background

Lymphadenopathy (enlargement of the lymph node) is a concern because its differential diagnoses include a wide variety of worrisome pathologies. Enlarged lymph nodes are associated with neoplastic, infectious or immunologic conditions. Precise diagnosis, based on histologic evaluation of a biopsy, is mandatory to initiate appropriate treatment. The techniques usually utilized to obtain tissue from any enlarged peripheral or internal node are non-aspiration fine needle biopsy (FNB) or fine needle aspiration (FNA) for cytology. Cytology is both sensitive and specific in diagnosing neoplasia regardless of whether it is primary or metastatic.[1,2] Lymph node cytology, in combination with specific microbiologic techniques, is also of potential value for detecting evidence of infectious disease including leishmaniasis, ehrlichiosis, cryptococcosis, *Neorickettsia* infection, *Mycobacterium* infection, and others.[3-5]

It is advisable to sample more than one, if multiple nodes are enlarged. Biopsy or FNA of submandibular lymph nodes are usually avoided if others are available for sampling. Changes due to oral infection or from salivary gland cell contamination can make microscopic evaluation difficult. One should also try to avoid aspirating from the central area of severely enlarged nodes because of the possible sampling of necrotic tissue.[6] Superficial sampling may give inconclusive results due to central proliferation of indolent lymphoma cells in the node.[7]

The gold standard for trying to understand a cause for lymph node enlargement is to excise the entire node and have it submitted for histologic evaluation. Since the main purpose of histopathology is to obtain information on the tissue architecture, this method should always be considered if the patient can be safely anesthetized. Needle-core biopsies of lymph nodes can be attempted using manually-operated or automatic (Tru-Cut type) needles because the technique is straightforward and requires only sedation or light anesthesia. However, samples obtained in this manner often fail to provide proper and adequate samples for histopathology. The needle-core technique can be used when tissue architecture is not important for diagnosis, as in suspected infectious disease.

Lymph Node Cytology Techniques (Video 95-1)

Peripheral Nodes

Initially, one can attempt to obtain cells via non-aspiration FNB of the enlarged peripheral or intra-abdominal lymph node. A sterile 20- to 22-gauge (for large dogs) or 22- to 23-gauge (for small dogs and cats) needle is used. The skin over the peripheral lymph node should be gently cleaned with ethanol or isopropyl alcohol. The skin should be surgically prepared, if one is to biopsy an internal lymph node. While grasping the superficial node with one hand or with the ultrasound guide, the needle is held by the thumb and forefinger of the other hand. The needle is then inserted into the tissue, pulled back to the cortex without withdrawing, and redirected again deeper into the gland in a slightly different direction. Redirection of the needle and probing different areas is a procedure that should be repeated several times (5 times is excellent). Cells and fluid will collect within the needle lumen by capillary action (Figure 95-1, *A*). The needle is then removed from the node.

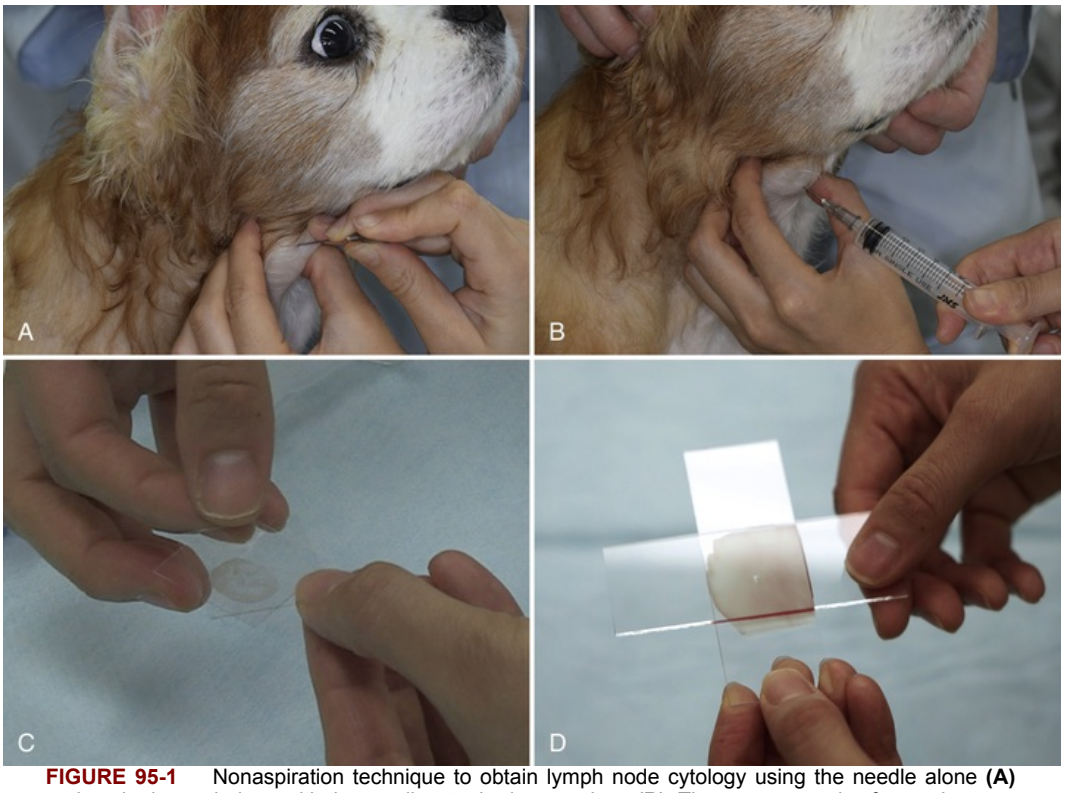

FIGURE 95-1 Nonaspiration technique to obtain lymph node cytology using the needle alone **(A)** and aspiration technique with the needle attached to a syringe **(B).** The smear samples for cytology are made either with two coverslips **(C)** or two glass slides **(D).**

Internal Nodes

If the tissue to be biopsied resides in the thoracic cavity, FNA should always be carried out with the needle attached to a 3- or 6-mL sterile syringe to avoid development of pneumothorax. The technique described here can also be used if an initial attempt at FNB failed to give adequate cells for an accurate cytologic diagnosis (Figure 95-1, *B*). Holding the lymph node or ultrasound guide with one hand, a sterile needle attached to a sterile syringe is inserted into the structure of interest. While pulling back on the plunger to generate a vacuum, the syringe held by the other hand should then be pulled back slightly. The needle tip should remain in the cortex area of the node. Then the vacuum pressure is released, and the needle should be advanced in a different direction before again applying vacuum. This needle redirection should be repeated more than once, 5 times whenever possible. When finished, the vacuum is again released and the needle gently withdrawn.

The needle should then be removed from the syringe and the syringe filled with air before being reattached to the needle. For both FNB and FNA, any material inside the needle should be gently expelled onto a clean coverslip or slide by gently pushing the plunger of the syringe down while the needle tip is positioned just above the slide. One should avoid ejecting a "jet" of material from the syringe. For the coverslip smear preparation, a second clean coverslip is placed on top of the first. The material between coverslips will naturally begin to spread after the weight of the upper coverslip is applied. The tip of each coverslip should be held separately and pulled apart horizontally just as the spreading sample material reaches the ends of each coverslip (Figure 95-1, *C*). Using this technique, fragile juvenile lymphocytes can be well preserved if 60% horizontal and 40% vertical motions are applied when separating the coverslips. The coverslips should be immediately air-dried or heat can be gently applied while holding the coverslip.

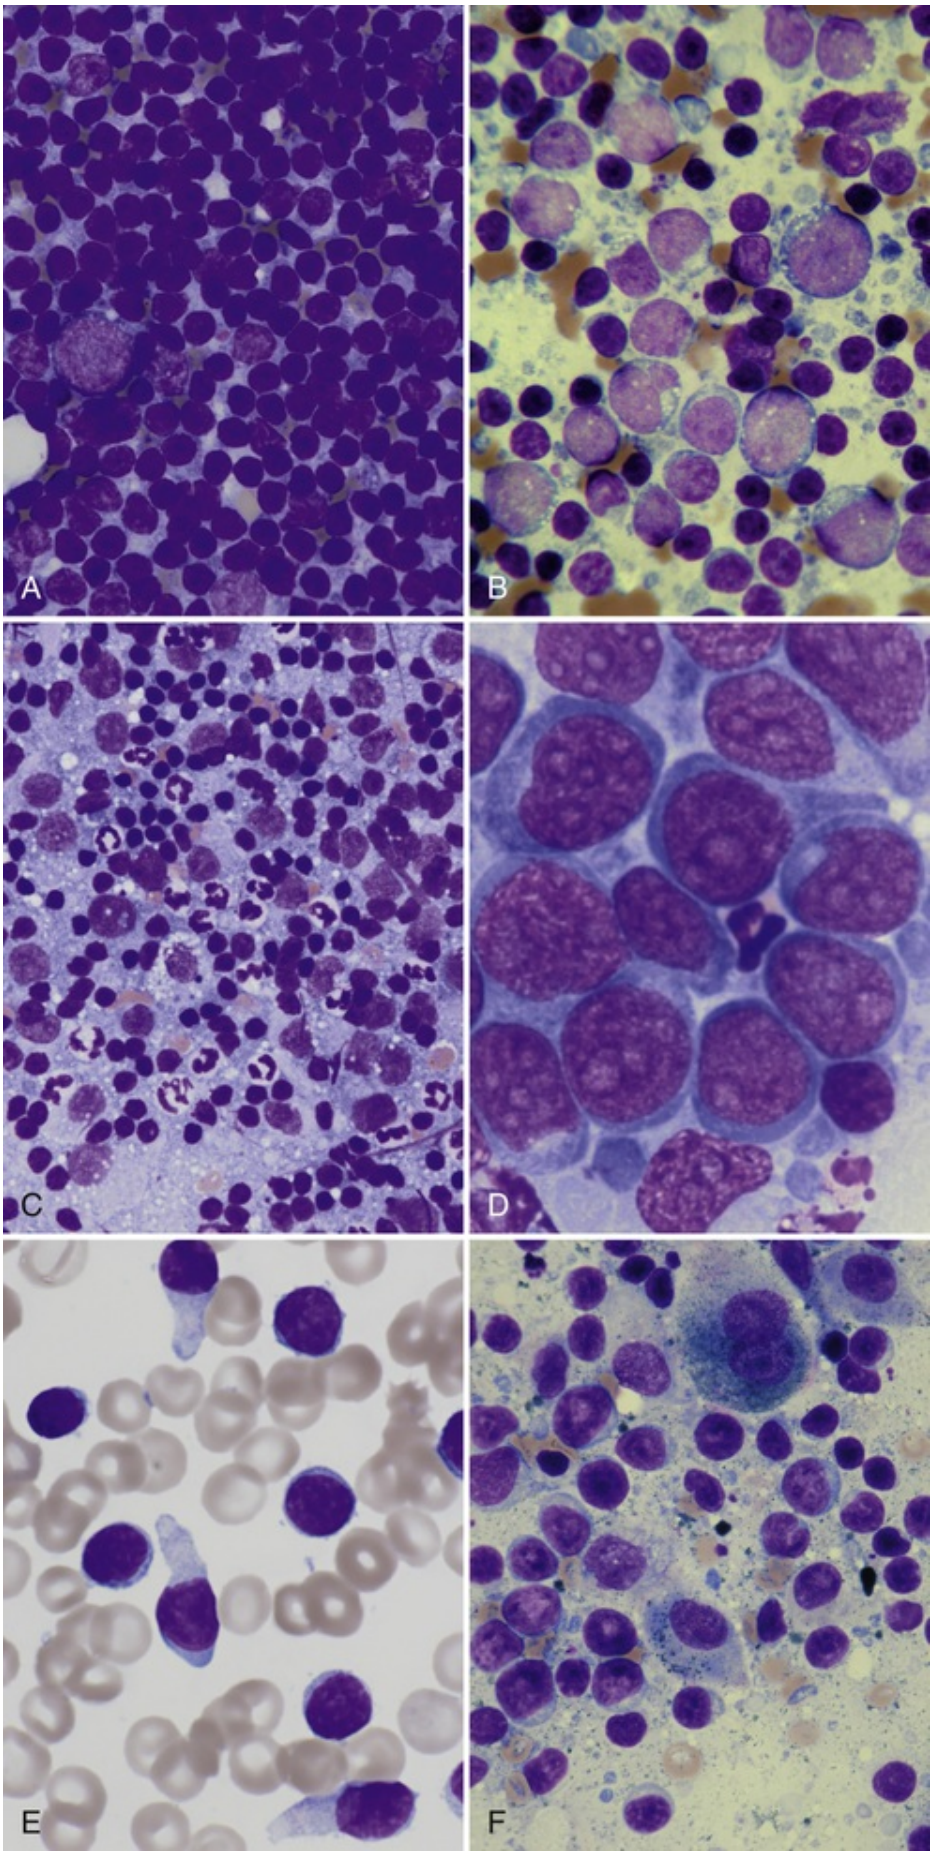
Similar high-quality smears can be made by using thin pre-cleaned glass slides. The sample is expelled gently on the first slide one-third of the distance from the top and a second slide is placed at right angles over the sample. The sample material will spread with the weight of the top slide and the top slide is then gently pulled away from the bottom (Figure 95-1, *D*). The smear on the bottom slide usually is best for evaluation. The slide should be immediately air-dried.

For "in-house" evaluation of cytology specimens, the air-dried coverslips or slides are fixed with fresh methanol for 2 to 5 minutes and stained with Wright-Giemsa stain. It is important that the methanol be fresh (>95%), that adequate fixation time be allowed, and that the stain solution is prepared fresh by using a proper

phosphate buffer of pH 6.2. A Diff-Quik type quick stain may be used for initial evaluation, but the final diagnosis should be made on the properly prepared Romanowsky-type stains such as Wright-Giemsa or May-Grünwald-Giemsa. When submitting the smear preparations to a reference veterinary laboratory, air-dried, unfixed samples can be mailed, but not with formalin-fixed histopathology specimens, as the formaldehyde gas fixes the specimen resulting in poor staining results with Romanowsky-type staining.

Lymph Node Cytology Interpretation

Cytologic evaluation of lymph nodes, in general, will provide one of the following findings: normal, hyperplasia (reactive), inflammation, lymphoma, metastatic neoplasm, or extramedullary hematopoiesis.[6] Normal lymph node cytology has approximately 90% well-differentiated small lymphocytes and up to 10% medium and large lymphocytes (Figure 95-2, *A*). Plasma cells, histiocytes (macrophages) and neutrophils are usually present in small numbers. A few mast cells per slide can also be identified.[8]



A
B
C
D
E
F

FIGURE 95-2 Cytologic appearances of lymph node samples. **(A)** Normal with >90% small lymphocytes, **(B)** hyperplasia with increased numbers (<30%) of medium and large lymphocytes, **(C)** inflammation with increased numbers of inflammatory cells (pyogranulomatous inflammation in this case), **(D)** high-grade lymphoma with an increased number of blast cells, **(E)** low-grade lymphoma suspected with a monotonous increase of small lymphocytes, and **(F)** metastatic neoplasm (malignant melanoma in this case).

Increased numbers (usually 15-30%) of medium and large lymphocytes are seen in the reactive or hyperplastic node. A majority of cells from hyperplastic nodes (>50%) are small lymphocytes (Figure 95-2, *B*). The percentage of the medium and large cells can be as high as 50% in some cytologic specimens. Examination of additional slides or histologic examination of a biopsy may be needed to differentiate hyperplasia and neoplasia.[9,10] In hyperplasia, the number of plasma cells is frequently increased and the number of other inflammatory cells mildly increased. Lymphoid hyperplasia is usually associated with antigenic stimulation due to one of several etiologies: infection, inflammation, immune-mediated disorders and neoplasia. Additional tests may be required to confirm a diagnosis.

Lymphadenitis is classified as suppurative, eosinophilic, histiocytic or pyogranulomatous on the basis of inflammatory cells.[11] Suppurative lymphadenitis is characterized by increased numbers of neutrophils (>5%). Neutrophil counts >20% of cells obtained are consistent with infection within the node or with secondary inflammation, perhaps from draining an infected area. Eosinophilic lymphadenitis is diagnosed if increased numbers of eosinophils (>3%) are noted. If histiocytes are >3-5% of the cells, histiocytic lymphadenitis is likely. Pyogranulomatous lymphadenitis has increases in both histiocytes and neutrophils (Figure 95-2, *C*). Pyogranulomatous lymphadenitis is often associated with fungal, *Leishmania*, *Neorickettsia* or *Prototheca* infections.

Cytologic diagnosis of high-grade lymphomas can be achieved by detecting >50% medium or large lymphocytes (Figure 95-2, *D*). However, additional examinations including histopathology, immunophenotyping and polymerase chain reaction assessment of clonality are usually used for establishing a diagnosis based on the latest World Health Organization (WHO) classification.[12] The histologic evaluation is best done with the largest section of a node possible. Nodes from pets with low-grade lymphoma, on the other hand, are usually composed of an almost uniform group of small lymphocytes, making diagnosis with cytology difficult (Figure 95-2, *E*). Again, histology and other diagnostic procedures are needed. The presence of cells not normally seen in the lymph node (e.g., epithelial cells or melanocytes) or the presence of normal component cells in excessive numbers (e.g., mast cells) confirms a diagnosis of metastatic neoplasia (Figure 95-2, *F*).

CHAPTER 96

Rhinoscopy, Nasal Biopsy, and Nasal Flushing

Caroline Page

Rhinoscopy

Rhinoscopy is an integral component of the diagnostic investigation of nasal disease, and allows for the examination of the nasal cavity, nasopharynx, and in some circumstances the sinuses. It is indicated for evaluation of patients with nasal congestion, stertor, nasal discharge, epistaxis, sneezing and reverse sneezing. Rhinoscopy is contraindicated in patients with abnormal hemostasis, or if the cribriform plate is defective. It should be used with caution when there is hypertension, as severe bleeding could ensue. Before performing rhinoscopy, it is essential to have a basic understanding of nasal anatomy (see ch. 238). It is imperative to collect a complete history, to ascertain duration of signs, to note presence of nasal discharge, and whether the clinical signs are sudden or progressive, bilateral or unilateral. With physical examination, pay particular attention to nasal asymmetry, hypopigmentation, nature of any discharge, and identify signs of systemic illness, coagulation problems, or hypertension (see ch. 29, 157, and 197). Look for dental disease, which can result in nasal discharge secondary to fistula formation (see ch. 27 and 272). The greatest chance of diagnostic success in patients with nasal disease will be achieved by correlating clinical and anamnestic information with the rhinoscopy findings, advanced imaging and histopathology. Advanced imaging using computed tomography (CT) or magnetic resonance imaging (MRI) is a useful accompaniment to rhinoscopy, by providing detailed information about the extent and anatomic location of disease. These imaging techniques are far superior to radiographs in evaluation of nasal disease. Lesions identified on CT or MRI can be targeted with the scope for closer inspection and biopsy.[1] Imaging should always be performed prior to rhinoscopy, as disruption of the nasal mucosa or bleeding from scope trauma may affect imaging results. Pre-anesthetic screening for patients undergoing rhinoscopy should include complete blood count, biochemistry, coagulation parameters and chest radiographs. If there is epistaxis, blood pressure should be measured (see ch. 99), and systemic disease ruled out, e.g., tick borne disease (see ch. 218). The procedure can be painful, and pain-relieving drugs like opiates should be included in the anesthetic protocol. Nerve blockade, either infraorbital or maxillary, using bupivacaine and lidocaine (judiciously in cats) may be a useful adjunct to provide a reduction in the sneeze reflex and pain relief during the procedure.[2]

After imaging, the anesthetized patient is positioned in sternal recumbency with the muzzle directed ventrally. A double endoscopic examination using rigid and flexible endoscopes provides the most comprehensive evaluation of the nasal cavity and nasopharynx.[3] Rigid endoscopes are preferred by most clinicians for anterograde examination of the nasal cavity. Thirty-degree, angled visual field endoscopes allow for greater visibility with less movement of the scope than with 0-degree visual field scopes. For small dogs and cats a 1.9 mm scope is appropriate, and a 2.7 mm scope for those over 10 kg. Flexible endoscopes can be retroflexed to allow full assessment of the nasopharyngeal area. In patients with turbinate destruction (for example, with fungal rhinitis), a flexible scope can be maneuvered into the frontal sinus to aid diagnosis[4] and treatment. High-definition flexible video scopes allow good visualization of nasal tissue and some clinicians prefer these over rigid scopes for rhinoscopy.

The examination begins with evaluation of the nasopharynx. A mouth gag is placed to protect the scope and the endotracheal tube is fully cuffed to protect the airway. The nasopharynx is not packed as this interferes with drainage of liquid though the mouth. Culture samples can be taken (Video 96-1) at this point with a sterile swab inserted into the nostril. This can result in bleeding, which may interfere with visualization. Alternatively, tissue samples can be submitted for culture at the end of the procedure from biopsy specimens. The retroflexed flexible endoscope is inserted into the mouth and hooked over the soft palate to view the nasopharynx. Moving the scope rostrally allows full inspection of the nasopharynx. The nasopharynx, choanae and soft palate should be evaluated for polyps, stenosis, mucosal color and texture,

discharge, tumors or mites. The opening to the eustachian tubes may be visualized (see ch. 238). During this part of the procedure the patient may require deeper anesthesia due to the sensitivity of the area. Brush samples can be taken for cytology, and biopsies can be obtained from abnormal tissue using an endoscopic biopsy instrument.[5] Caution must be taken not to damage the scope by passing an instrument through the channel while the scope is in the retroflexed position. Instead, the biopsy instrument must be passed to the tip of the scope before the scope is flexed. Some clinicians use a rigid scope to examine the nasopharynx in an anterograde fashion; however, this can result in significant bleeding.

A rigid endoscope is then used to examine the nasal cavity in an anterograde approach. The scope is inserted initially at an angle, and then straightened to pass the alar cartilage. The scope is gently advanced and each meatus is examined. Continuous saline irrigation removes mucus and aids visualization. The nasal cavity is examined for presence of abnormal mucus, hyperemia, lysis, mucosal texture, and the presence of polyps, masses, and foreign bodies. Nasal turbinates have a varied appearance in different breeds and individuals.[6] Rostral turbinates are pink and smooth and the caudal ethmoid turbinates appear more tan in color with a corrugated texture. To avoid damage to the cribriform plate, measure the distance to eye level and do not pass this point with the scope. It is important to note that severe inflammatory changes can be found microscopically in macroscopically normal nasal cavities,[7] so biopsies should always be obtained[8] (see below). Patients must be monitored closely during recovery because if the mouth is closed and the nose is obstructed the pet may not be able to breathe. A mouth gag to hold the mouth open may be required until consciousness is regained. Extubation should be performed as late as possible, ideally when the gag reflex returns.

Nasal Biopsy

Before performing nasal biopsies, ensure the patient has adequate coagulation ability (see ch. 196) and a cuffed endotracheal tube. There are several techniques for obtaining a nasal biopsy. The goal of biopsy is to obtain tissue of adequate diagnostic quality. Biopsies can be procured using endoscopic biopsy forceps through the instrument channel of the scope. This provides accurate placing in the area of interest and great visibility, and is useful where there are focal lesions. However, with this method the sample size is very small and samples may be of poor quality for histopathological examination, especially if a small diameter scope or flexible scope is used. Alternatively, a larger biopsy instrument can be guided to the area of interest adjacent to the scope which allows a larger sample size to be taken (Figure 96-1). Maneuverability of the biopsy instrument can be difficult with this method, especially in a small nose. An effective way to obtain good quality sample sizes in most nasal diseases is blind biopsy. This involves passing the biopsy instrument into the nasal cavity and obtaining tissue without endoscopic guidance. The distance to the area of interest can be measured from imaging results and then marked on a biopsy instrument with tape before being passed into the nose (Figure 96-2). This technique produces comparable results to guided biopsies for nasal cancer diagnosis.[9] Several biopsies should be taken, more if the sample sizes are small. It is important to be aware of nasal anatomy when taking biopsies and not to pass the instrument further than eye level to avoid damage to the cribriform plate.

FIGURE 96-1 Cup forceps, top to bottom, 1.9 mm, 2.7 mm, 4 mm. The 4 mm instrument can be used to take blind biopsies to obtain better quality tissue samples than the smaller sizes.

FIGURE 96-2 Tape marks the biopsy instrument to the area of interest based on imaging, and to prevent advancing the instrument past the level of the medial canthus to avoid cribriform plate damage.

Nasal biopsies usually result in moderate, self-limiting bleeding. Methods of post-biopsy hemostasis, if required, are instillation of phenylephrine, epinephrine, or several drops of the Chinese herb Yunnan Baiyao mixed in water. Cold packs applied to the bridge of the nose post-procedure can also be useful, as can flushing with cool saline into the nose which results in mucosal vasoconstriction.

Biopsy samples can be wrapped in saline soaked tissue (Kimwipes) or in a biopsy cassette and submitted in formalin.

Nasal Flushing

Nasal flushing (Video 96-2) is a useful procedure, which can remove mucus for palliation of chronic rhinitis, aid in foreign body removal, help to debulk some nasal tumors for palliative treatment or prior to radiation therapy, and prepare for topical treatments in fungal rhinitis. Nasal flushing is a suboptimal way of collecting quality diagnostic samples, and biopsy is preferred. Some lesions may not exfoliate well, or be located too caudally for flushing to collect a tissue sample.

There are various methods of nasal flushing depending on the purpose it is being performed for. Nasal flushing can be performed either forwards, through the nose into the nasopharynx, or backwards, from the nasopharynx out through the nostrils.

To remove mucus in patients with chronic rhinitis and to attempt to debulk tumors, the technique is as follows. The patient is positioned in sternal recumbency as described above, and a 12 or 35 cc syringe for smaller patients or 60 cc syringe for larger patients is filled with sterile saline, and flushed through the nose. The syringe tip can be directly inserted into the nose, or alternatively, a Christmas tree adapter can be used (Figure 96-3). The contralateral nostril is compressed to allow the flow to pass into the nasopharynx and out through the mouth. Vigorous force can be applied to produce a traumatic flush capable of debulking tumor tissue and removing fungal plaques. This technique can be combined with transnasal curettage for more effective tumor debulking.[10] Airflow restoration will be evident by low or no resistance to flushing with the fluid easily exiting through the mouth.

FIGURE 96-3 Nasal flushing technique. The contralateral nostril is occluded to allow flow from the nose into the mouth.

A retrograde flush may be useful if the cribriform plate has damage and a minimally invasive technique is needed to take samples from the rostral nasal cavity or in some foreign body situations. A long polypropylene catheter can be heated with a flame 1-2 cm from the tip for two seconds and molded to a hook shape to fit

easily into the nasopharynx. Saline can then be flushed as above. The patient often requires deeper anesthesia during this procedure due to the sensitivity of the nasopharynx.

Flushing the sinuses in patients with fungal rhinitis is a very effective way to debride fungal plaques prior to topical treatment, which aids in the success of therapy. Patience and several liters of saline are required. A red rubber catheter can be passed with a biopsy instrument at the end of a flexible endoscope and deposited into the sinus where flushing can be targeted. Alternatively, a forceful flush through the instrument channel of the flexible endoscope adjacent to the plaque is another useful technique in this situation as is vigorous anterograde flushing as above.

CHAPTER 97

Respiratory and Inhalant Therapy

Laura A. Nafe

By definition, respiratory therapy is the administration of aerosolized therapy for management of acute or chronic respiratory conditions. In veterinary medicine, our ability to administer inhaled medications in this manner is limited due to the inability of dogs and cats to coordinate inspiration with activation of a metered dose inhaler (MDI) or nebulization device. Methods utilized in human pediatric respiratory therapy have been adopted in small animal veterinary medicine with success in appropriate patients.

Nebulization

Nebulization is the delivery of a substance via small droplets, facilitating delivery of sterile saline or a medication (usually diluted in saline to facilitate transport) to the respiratory tract directly. The particle size delivered varies depending on the type of nebulizer being used, with most devices delivering particles between 0.5 and 10 microns. Effective penetration of the lower airways is achieved in most patients with particles less than 3-5 microns in size.[1]

Types of Nebulizers

A variety of nebulizers is available for management of respiratory disorders. Although all nebulizers are capable of delivering saline or a medication, the power mechanism, portability, convenience, and particle size delivered vary. Most common nebulizers are either ultrasonic or gas-pressure-driven. Many veterinary hospitals and clinics may have a nebulizer to be used for inpatient care, but these nebulizers may be cumbersome for outpatient care due to large size. Particle size delivered is important when considering what region of the respiratory tract is being targeted. For example, larger particles (2-10 microns) will be deposited in the upper respiratory tract and are beneficial for upper airway (nasal, laryngeal, tracheal) inflammatory diseases.[1] Smaller particles will travel farther in the respiratory tract before being deposited, and are therefore more useful for lower airway diseases. In general, nebulizers that generate smaller particles and provide portability are more expensive, typically ranging from $150-250. For long term nebulization at home, the author prefers the Omron vibrating mesh nebulizer (Omron Healthcare, Inc., Lake Forest, IL) (Figure 97-1). In some geographical areas, there may be a respiratory pharmacy nearby that is willing to rent a nebulizer to a patient for a specified period of time.

FIGURE 97-1 Omron vibrating mesh nebulizer (Omron Healthcare) with facemask attached.

Benefit of Nebulization

Nebulization is an important aspect of respiratory therapy for patients with acute respiratory conditions, providing hydration or medication delivery directly to the affected area while minimizing systemic adverse effects. Of particular importance is the delivery of water droplets to help improve mucociliary clearance of respiratory secretions and mucus. Nebulization is not commonly performed chronically at-home, but for inpatient care, it plays an important role in management of common respiratory conditions.

Indications for Nebulization

In order to understand the indications for saline (0.9% NaCl) nebulization, one must understand the role of mucus present in the respiratory tract. Mucus is an adhesive gel consisting of water and glycoproteins mixed with serum, functioning to trap debris and bacteria to enhance removal from the respiratory tract.[2] Clearance of mucus is an important respiratory defense mechanism accomplished by an effective mucociliary apparatus and the cough reflex.[3] In order for the airway cilia to function appropriately, there must be a serous layer to facilitate movement of the cilia, and therefore mucus, in an upward motion.[3] In addition to rehydration of the mucociliary apparatus with intravenous fluid therapy, nebulization provides these patients with direct delivery of saline via droplets to the respiratory tract, thus hydrating the mucous layer to facilitate expulsion by the patient via mucociliary clearance and coughing. Saline nebulization is most commonly administered in patients with pneumonia, specifically aspiration pneumonia (see ch. 242).

Indications for nebulized medications include resistant bacterial infections, inflammatory airway diseases (see ch. 241), and treatment or prevention of bronchoconstriction with antimicrobials, glucocorticoids and bronchodilators being delivered for each condition, respectively.

How to Perform Nebulization

When providing saline nebulization, approximately 3-5 mL of normal saline (0.9% NaCl) is placed in the nebulization cup and when powered the nebulizer will convert this volume of liquid into saline droplets over a period of time (typically 10-20 minutes). There are multiple techniques that can be utilized to ensure the nebulized droplets are directed into the respiratory tract. Since most dogs and cats breathe through the nose, the nasal turbinates may trap some of the saline particles. In dogs that are panting, many of these particles may be trapped in the back of the mouth and/or swallowed due to the lack of deep inspiration. The author has found a facemask or small tent to be useful in facilitating delivery in patients that will tolerate these additions. In most cases, nebulization should be followed by coupage or light exercise (if tolerated by the patient) to further improve expulsion of respiratory secretions (Video 97-1). Contraindications to coupage include regurgitation, recent thoracic surgery, and recumbency. If the patient is recumbent, frequent repositioning to limit atelectasis and improve movement of airway secretions is an important aspect of patient care.

Nebulized Medications

There is minimal evidence to support the use of nebulized medications in small animal veterinary medicine. Although most medications that are water soluble can be administered via nebulization, the most commonly nebulized drug classes are antibiotics (e.g., gentamicin), anti-inflammatories (e.g., fluticasone propionate), and bronchodilators (e.g., albuterol). Other medications that have been evaluated for nebulization in a research setting include lidocaine, xylitol, and N-acetylcysteine.

A clinician may consider nebulized aminoglycoside treatment in canine patients with multi-drug resistant bacterial pneumonia (e.g., *Bordetella bronchiseptica, Pseudomonas* spp.), usually as an adjunct treatment to systemic antimicrobial therapy. The advantage of nebulized aminoglycoside therapy is the ability to administer an appropriate antibiotic with low risk of systemic adverse effects (e.g., nephrotoxicity).[4] Clinicians should keep in mind that aerosolized antibiotics may cause irritation to the airways and dosage calculation is often approximate, with it being impossible to estimate what percentage of the drug will reach the site of infection. The author doses gentamicin at 6-8 mg/kg diluted in 5-10 mL of saline administered once daily via facemask. Do not exceed 25 mg/mL concentrations as it may decrease drug delivery.

Glucocorticoid agents are more commonly delivered via metered dose inhaler to patients with inflammatory airway disease, and in a medium or large breed dog nebulization is likely more effective in targeting the lower airways. Budesonide has been evaluated for nebulization in humans, although no studies have evaluated nebulized glucocorticoids in dogs.[5] When considering this route of administration, the clinician must consider the limitations of nebulization, especially cost, as these patients will likely require lifelong therapy.

Like glucocorticoids, bronchodilator agents are most commonly delivered via metered dose inhaler. Nebulized albuterol (0.5% albuterol; 1.25 mg/cat diluted in 2 mL of saline repeated q 1-4 h PRN) is occasionally used as a one-time treatment for feline patients presenting with status asthmaticus (see ch. 241) or as pre-treatment for those undergoing a procedure that may induce or worsen bronchoconstriction (e.g., bronchoalveolar lavage; see ch. 101). If available, nebulized albuterol is preferred over MDI for emergency management of feline status asthmaticus, as patients in respiratory distress are often not taking adequate breaths, minimizing effective delivery to the lower airways with a spacer device. Although an injectable bronchodilator (e.g., terbutaline) is preferred in these situations, cats with significant heart disease may not be good candidates for parenteral beta-2 adrenergic receptor agonists or methylxanthine bronchodilator agents. Administration of beta-2 adrenergic receptor agonists is not typically recommended in dogs with respiratory disease, as bronchoconstriction is not a common feature of canine respiratory disease. Parenteral and oral administration of methylxanthine bronchodilator agents is used in feline and canine respiratory disease, but inhaled therapy has not been evaluated.

Nebulized lidocaine (4% without preservatives diluted to 2%; 2 mg/kg q 8 h for 2 weeks) was recently evaluated as a potential novel anti-inflammatory and bronchodilating agent for management of feline asthma.[6] Although no overt adverse effects were observed, lidocaine was only found to reduce airway hyperactivity and should not be used as monotherapy for management of asthma.[6] In specific cases, nebulized lidocaine may provide an alternative bronchodilator option in cats with heart disease.

Xylitol, a five-carbon sugar, is thought to hydrate the mucus layer and have potential antibacterial properties. As a result, this therapy has been investigated as a potential management strategy for cystic fibrosis in humans. A small safety study evaluated nebulized xylitol administration for 14 consecutive days in

research beagle dogs and found no adverse effects.[7] The use of nebulized xylitol in veterinary clinical medicine has not been evaluated and cannot be recommended until further safety and efficacy information is available.

N-acetylcysteine, an antioxidant and mucolytic, is occasionally administered parenterally, orally or via nebulization as a mucolytic agent. Evidence suggests that nebulized N-acetylcysteine may promote bronchoconstriction and resultant airflow limitation in cats with experimentally-induced asthma when delivered via endotracheal nebulization.[8] Diseases that result in excessive mucus production in dogs (e.g., pneumonia, ciliary dyskinesia) may benefit from N-acetylcysteine. However, the risk of bronchoconstriction during or after nebulized N-acetylcysteine is a concern, detouring the use of this treatment by most clinicians, and is not recommended by the author. Pre-treatment with a bronchodilator is recommended if this treatment is administered.

Limitations of Nebulization

Although nebulization of medications is an attractive option for many patients with respiratory disease, there are limitations that should be considered. First, there is concern for the amount of drug that is delivered to the affected area, with particle size playing an important role in the area being medicated. Second, the expense associated with purchasing or renting a nebulization device and the cost of the medication can be substantial. Third, the time required to deliver the medication appropriately may be labor-intensive for many caretakers, especially for patients with chronic conditions requiring multiple treatments per day indefinitely. Lastly, there is always potential for a medication to cause further irritation to the airways, in particular with antibiotics and bronchodilator agents. It is important to consider these limitations when recommending nebulized medications.

Metered Dose Inhaler

Delivery of medications via pressurized MDI is the standard of care for management of many human respiratory conditions and is gaining popularity in veterinary medicine. The main limitation of MDI therapy in dogs and cats is the inability to coordinate respiration with the release of the actuation. The use of a facemask and space chamber improves this limitation and makes delivery of medications via MDI a good option in small animal respiratory medicine.

Benefit of MDI

Like nebulization, delivery of medications via MDI allows treatment of a condition locally while minimizing systemic side effects of the medications being used. Unlike nebulization, administration of MDI is not labor-intensive and is well tolerated by most patients after appropriate acclimation to the facemask/chamber device. In fact, many cat owners find inhaled delivery of medications easier than oral administration.

Indications for MDI

Respiratory diseases that result in inflammation and/or bronchoconstriction can be managed with MDI therapy. In dogs, common diseases managed with glucocorticoids delivered via MDI include chronic bronchitis (see ch. 241), eosinophilic bronchopneumopathy (see ch. 242), and potentially tracheal collapse (see ch. 241) and lymphoplasmacytic rhinitis (see ch. 238). As mentioned earlier, dogs do not develop true smooth muscle bronchoconstriction, and therefore, do not benefit from beta-2 adrenergic receptor agonist medications (e.g., albuterol). In cats, common diseases managed with medications delivered via MDI include feline asthma (see ch. 241), chronic bronchitis (see ch. 241), and potentially lymphoplasmacytic rhinitis (see ch. 238).

How to Administer Medication via MDI

Cats and dogs cannot coordinate inspiration with release of the aerosolized medication from a MDI, making an aerosol-holding chamber or spacer device a necessary component of MDI therapy. A variety of spacer devices, all equipped with an exhalation valve, are available for purchase with most costing approximately $40-80/space chamber. The MDI fits on one end of the spacer, and the other end of the spacer has an attachment for the facemask. Shaking the MDI prior to delivery is necessary, as this opens an internal valve within the canister. The MDI should then be attached to the space chamber with facemask, and the space

chamber should be placed over the nose and mouth of the patient, ensuring a tight fit to maximize delivery of the aerosolized medication to the patient's airways (Figure 97-2; Video 97-2). With the actuation of the device, the MDI delivers a precise dose of the aerosol drug into the space chamber. The space chamber serves as a holding device for the aerosol so that the cat or dog can inhale it over a period of time. It is important to watch the patient take 7-10 adequate breaths, as it is natural for the dog or cat to stop breathing when the facemask is placed over the nose and mouth.

FIGURE 97-2 Administration of a medication via MDI, showing the entire inhalation device, equipped with facemask, space chamber, and MDI (Aerokat Trudell Medical International).

Medications Delivered by MDI

Glucocorticoids are the most commonly administered medications via MDI in small animal respiratory therapy, with fluticasone propionate being preferred because it is the most potent (18 times as potent as dexamethasone) and has the longest half-life.[9,10] In addition, the majority of inhaled medication (approximately 70% or more) will be deposited in the oropharynx after delivery and will be swallowed. Of the steroids available for inhalation, fluticasone is poorly absorbed in the gastrointestinal tract, and therefore, minimal systemic side effects will result.[9] Fluticasone (110 mcg q 12 h), budesonide (only available as dry powder MDI) (200 mcg q 12 h), and flunisolide (250 mcg q 12 h) have been investigated and found to be effective in management of feline inflammatory airway with minimal systemic adverse effects.[11-13] Although used often clinically, there is little evidence to support the use of inhaled glucocorticoids in canine inflammatory airway diseases.[14,15] Fluticasone is often preferred due to availability and efficacy; an alternative glucocorticoid may be chosen for particular patients based on ease of dosing, cost, and/or availability.

Beta-2 adrenergic receptor agonist medications (e.g., albuterol) are delivered via MDI in feline respiratory medicine, most commonly for management of acute respiratory distress secondary to bronchoconstriction. Racemic (R,S)-albuterol is not recommended for chronic management, as the S-enantiomer is associated with airway hyperactivity and promotes airway inflammation.[16] If chronic bronchodilator therapy via MDI is desired, daily treatment with levalbuterol, the R-enantiomer of albuterol, is recommended. The racemic

formulation of albuterol can be used for rescue therapy as needed for respiratory distress.

Limitations of MDI

As with nebulization, there are limitations that should be considered when recommending treatment with inhaled medications. There is always concern for the amount of drug that is actually delivered to the lower airway; this is especially true in any patient >7-10 kg. The expense associated with purchasing a MDI can be financially limiting for owners over time. In humans, inhaled glucocorticoids can increase the risk of respiratory infections, in particular oral *Candida* infections. Lastly, there is always potential for a medication to cause further irritation to the airways, in particular with bronchodilator agents (e.g., racemic albuterol).

Inhaled Chemotherapy and Immunotherapy

Treatment of pulmonary neoplasia, primary and metastatic, with inhaled chemotherapy has been minimally evaluated in small animal veterinary medicine. This technique offers a method of increasing exposure of the lung tumor to the chemotherapy agent, while minimizing systemic adverse effects. Delivery of cisplatin to a specific lung lobe via bronchoscopy with a specialized catheter has been described in normal, healthy dogs.[17] Aerosols of interleukin (IL)-2 liposomes have been evaluated in 9 dogs with pulmonary neoplasia with positive results and minimal toxicity, representing a promising potential therapy in specific cases.[18] Limitations of inhaled therapy for neoplasia are many, including need for specialized equipment, anesthesia, risk of human exposure, and expense. For specific cases (e.g., non-resectable primary lung tumor), inhaled chemotherapy may be a viable option for motivated clients.

CHAPTER 98

Pulse Oximetry

Steven Epstein

Overview and Basic Principles

SpO_2 versus SaO_2

Pulse oximetry utilizes light to measure the amount of arterial blood hemoglobin saturated with oxygen. This diagnostic aid became available in the early 1980s for people and has since been employed in veterinary medicine. Pulse oximeters calculate the percent saturation of oxygen (SpO_2). The SpO_2 is used as surrogate for the arterial oxygen saturation value (SaO_2) that is directly measured by a CO-oximeter.

Pulse Oximetry Principles

Forms of Hemoglobin in Blood

An understanding of basic pulse oximeter principles allows recognition of situations in which a reading may incorrectly estimate SpO_2. The majority of hemoglobin in healthy adults exists in one of two forms: oxyhemoglobin with an oxygen molecule bound to its heme group or deoxyhemoglobin, also called "reduced hemoglobin," that has no bound oxygen. Methemoglobin and carboxyhemoglobin are two additional forms of hemoglobin with altered oxygen binding capabilities present in low concentrations. Methemoglobin has an oxidized iron component of the heme group. Carboxyhemoglobin has bound carbon monoxide molecules.

Light Absorptive Patterns

Pulse oximetry takes advantage of the different forms of hemoglobin absorbing unique spectra of red and infrared light (Figure 98-1). Most conventional pulse oximeters emit light at two wavelengths (660 nm and 940 nm) to exploit the light-spectral absorption qualities of oxyhemoglobin versus those of deoxyhemoglobin. Light from the unit either reflects back to the probe/sensor or is transmitted through the tissue to a sensor. These two forms of pulse oximetry are referred to as "reflectance" or "transmittance." The relative quantities of different light wavelengths passing through or absorbed by a tissue are measured by the pulse oximeter, determining the proportion of oxyhemoglobin to reduced hemoglobin and calculating the SpO_2. This calculated number is generated with an algorithm that evaluates a series of pulses, based on a calibration curve generated in humans. Results in cats and dogs have only minor differences that should not limit interpretation.[1] The algorithm utilized was generated from healthy people whose oxygen saturations were reduced from 100% to approximately 70%.[2] Thus, readings of <70% should not be used quantitatively, but only as a marker of severe hypoxemia.[3]

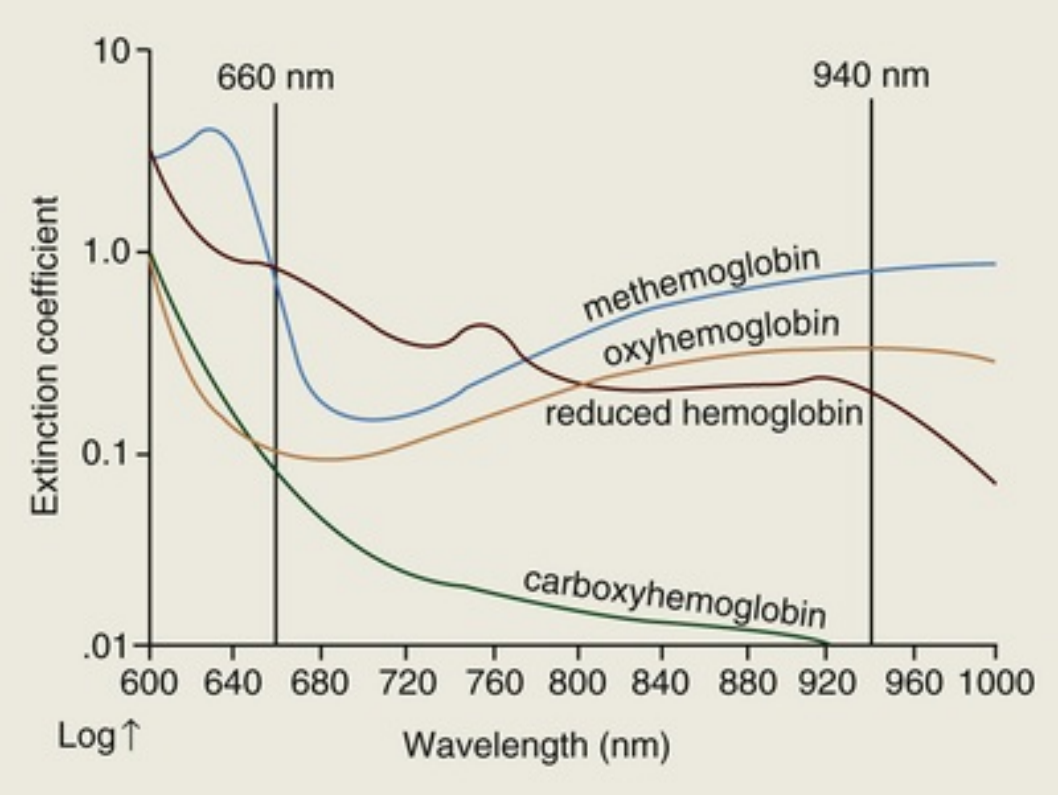

FIGURE 98-1 Extinction coefficients (absorption ratio) shown over a range of wavelengths for reduced hemoglobin, oxyhemoglobin, carboxyhemoglobin, and methemoglobin. The lines at 660 and 940 nm represent the red and infrared wavelengths, respectively, used by most pulse oximeters.

Pulsatile Nature of the Assessment

In addition to differences in light absorption, the second major principle of pulse oximetry is the need for pulsatile arterial blood flow. Light generated by pulse oximeters is inevitably transmitted through tissues that absorb some spectra of light: fat, capillary blood, venous blood, connective tissue. To exclude these patterns from the calculations, a complex filter is integrated into the unit to remove non-pulsatile segments of the signal (Figure 98-2). Thus, pulse oximeters function most reliably when placed over tissues with good pulsatile arterial blood flow. Modern pulse oximeters visually display a pulse intensity graphic to aid the operator in determining the ability of the machine to detect pulsatile flow. If the machine cannot detect an accurate pulse rate, the number generated should not be trusted.

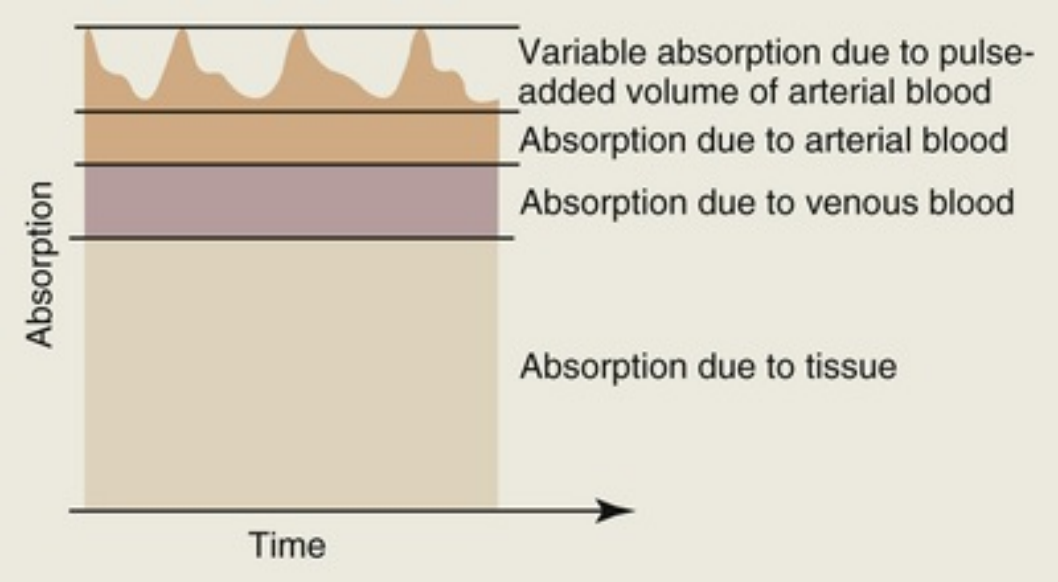

FIGURE 98-2 Sources of absorption of light as it passes through tissue. The pulse oximeter is able to recognize the change in absorption associated with a pulse and can then calculate the difference in absorption of red and infrared light at the peak of each pulse.

Technique of Obtaining a Pulse Oximeter Reading

Site Selection

As thick fur or pigmented skin can interfere with the pulse oximeter, such sites are avoided or a small patch of fur may be shaved. Common sites used in dogs are the tongue (if anesthetized), lips (Figure 98-3, *A*), pinna, vulva/prepuce, gastrocnemius tendon area, base of the tail, or occasionally a skin fold (Video 98-1). Common sites used in a cat are the tongue (if anesthetized), lips, pinna or across a digit (Figure 98-3, *B*). Results from several sites in both dogs and cats vary somewhat. Accuracy is better in dogs than cats.[4,5] If hypovolemia or hypothermia is suspected, the extremities should be avoided due to decreased peripheral perfusion.

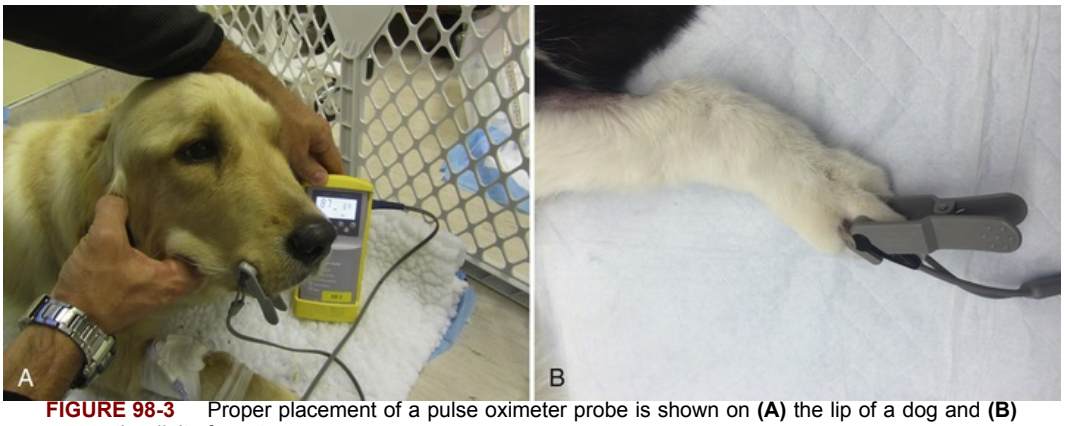

FIGURE 98-3 Proper placement of a pulse oximeter probe is shown on **(A)** the lip of a dog and **(B)** across the digit of a cat.

Obtaining a Reliable Reading

After the probe is placed on the patient, it should be held in place with the animal still to avoid motion artifact. Pulse oximetry units have been developed to function despite some patient movement, but are not more accurate in hypoxemia than older models.[6] After the unit displays a reading, the pulse rate displayed

should be verified manually. If the rates do not match, the oximetry reading is unlikely to be accurate. The probe should be moved to different sites until the unit reading matches the manually determined pulse rate with good signal strength. When the pulse oximeter displays a consistent reading, that number should be used. If the probe is to be left in place for continuous monitoring, the probe position may need to be changed every few hours as clip compression may cause a regional decrease in perfusion, creating inaccuracies.

Interpreting a Pulse Oximeter Reading

Oxygenation versus Ventilation

Pulse oximetry is a noninvasive method of continuously or intermittently monitoring oxygenation in either awake or anesthetized patients. Due to its ease of use, pulse oximetry is often the test first used to evaluate oxygenation status. Arterial blood gas analysis (see ch. 128) is technically more demanding but considered a more accurate assessment of pulmonary function. Pulmonary function is a combination of the lung's oxygenating and ventilating capacity, while pulse oximetry only assesses the oxygenation component. Ventilation is assessed by blood gas analysis (arterial or venous) or capnography, which can be combined with pulse oximetry to get a global view of pulmonary function.

Hypoxemia

The relationship between the SpO_2 and the partial pressure of oxygen dissolved in arterial blood (PaO_2) is dependent on the oxyhemoglobin dissociation curve. Hypoxemia is present when the PaO_2 is <80 mm Hg, corresponding to a pulse oximeter value of 93-95% under normal conditions. As the oxyhemoglobin dissociation curve can shift due to patient body temperature, pH and PCO_2, the cutoff value of 93% on a pulse oximeter for diagnosing hypoxemia must be used with caution as it will not reflect the same PaO_2 in all patients. Despite this limitation, pulse oximetry has been useful in monitoring critically ill small animals.[7,8] There is also the suggestion that routine use of pulse oximetry in anesthetized cats may reduce risk of anesthetic-related mortality by allowing recognition of problems earlier.[9]

For most animals breathing room air, a pulse oximeter reading of >95% would be considered normal and would correspond to a PaO_2 >80 mm Hg. Small decreases in oxygenating ability may lower pulse oximeter readings below reference ranges and may indicate mild decreases in oxygenation status. If a patient is placed on 100% inspired oxygen, such as under anesthesia, this should raise the PaO_2 to about 500 mm Hg, corresponding to a SpO_2 of 100%. A PaO_2 of 120-500 mm Hg gives the same 100% result on the pulse oximeter. In this scenario, a decrease in SpO_2 below the "reference range" indicates severe decrease in oxygenation status as the patient's PaO_2 had to decline from 500 mm Hg to <80 mm Hg before change is detected. Such a decrease should immediately be investigated.

Other Factors Affecting Pulse Oximetry

Apart from the above-mentioned limitation in the SpO_2 reflecting a patient's PaO_2, there are additional factors that may alter the ability of the SpO_2 to accurately reflect SaO_2. Thus, some find pulse oximeter readings as more random than reliable. One report documented a pulse oximeter reading of 99% with an appropriate plethysmography tracing despite the pulse oximeter having slipped off the patient.[10] Knowledge of pulse oximeter limitations can aid the clinician to trust a generated number or to look for a concurrent disease known to alter results.

Increases in the amounts of methemoglobin or carboxyhemoglobin can significantly alter pulse oximeter readings. Normal methemoglobin concentrations in dogs and cats are <1%.[11] Increases in methemoglobin can represent a congenital condition or are caused by any of a variety of drugs: benzocaine, nitrates, sulfa antibiotics, or acetaminophen. As methemoglobin levels increase, the patient's SpO_2 will change until a plateau is reached in the range of 82-86% regardless of oxygen concentrations inspired.[12] Pulse oximeter readings can markedly overestimate a patient's SaO_2, as methemoglobin values can reach 70% before being fatal.[11]

Carbon monoxide poisoning causes high concentrations of carboxyhemoglobin, most commonly encountered after being trapped in a house fire. At the spectra of light used by most pulse oximeters, oxyhemoglobin cannot be distinguished from carboxyhemoglobin. This causes the pulse oximeter to

overestimate blood oxyhemoglobin in both clinical and experimental settings. Even with carboxyhemoglobin levels reaching 70%, SpO_2 readings were still 90% or greater.[13,14]

A variety of pigments can also affect the ability of the pulse oximeter to accurately read. Vital dyes used in advanced clinical procedures or therapeutically may lower pulse oximeter readings. Lowered readings have been demonstrated with methylene blue used as in treating methemoglobinemia or as an ultrasound-deposited marker for surgery. Indocyanine green, used for measuring blood flow, also has lowered results.[15] Fluorescein, however, does not appear to affect pulse oximetry readings. Hyperbilirubinemia effects on pulse oximetry readings have not been consistent. Initial evidence suggesting that hyperbilirubinemia did not affect pulse oximeter readings based on studies done on patients with diseases associated with increases in carboxyhemoglobin. Newer evidence suggests severe hyperbilirubinemia can overestimate true oxygen saturation.[16,17] It seems unlikely that mild to moderate hyperbilirubinemia will interfere with pulse oximetry readings.

Severe anemia has been associated with inaccurate pulse oximetry readings. In one study, pulse oximetry readings in dogs were accurate with hematocrits as low as 10%. If the hematocrit is <10%, pulse oximeters overestimate true SaO_2.[18] Additionally, if anemia is treated with a hemoglobin-based oxygen carrier such as polymerized bovine hemoglobin (Oxyglobin), there can be a dose-dependent increase in the difference between SpO_2 and SaO_2.[19] Despite these limitations, pulse oximetry can be a valuable tool to the clinician in patient assessment.

CHAPTER 99

Blood Pressure Measurement

Rebecca L. Stepien

Acute blood pressure (BP) measurement is required to diagnose hypertension or hypotension or to exclude these diagnoses as a cause for clinical signs in a patient. Multiple BP measurement techniques are available; each is associated with advantages and disadvantages.

Patient Selection

Blood pressure measurements are assessed as one part of a clinical evaluation that includes the patient history, physical examination findings, results of other diagnostic testing, and evaluation of concomitant medications, including anesthetics and sedatives. Many BP measurement techniques have test characteristics that require low diagnostic cutoff values for maximum sensitivity to hypertension (maximum opportunity to correctly identify an abnormally high value). Unfortunately, low diagnostic cutoff values also are associated with increased numbers of false-positive diagnoses. As a result, many BP measurement techniques are best able to correctly identify truly hypertensive patients as abnormal when the test is applied to patient populations with clinical signs or diseases likely to be associated with systemic hypertension. Routine "screening" BP measurements in clinically normal patients may assist the clinician in establishing a typical baseline BP value for an individual patient, but abnormally high BP values obtained from clinically normal patients must be viewed with caution due to the high incidence of false-positive readings in this patient population.

Indications for Blood Pressure Assessment

Blood pressure measurement should be part of the diagnostic evaluation for any feline or canine patient with clinical signs associated with systemic hypertension, known or suspected systemic diseases known to be associated with systemic hypertension, or both. Clinical signs of systemic hypertension occur when there is hypertensive damage to various organ systems ("target organ damage"). The organ systems most frequently affected include the eyes, kidney, brain, and heart. Damage to these systems may be overt (e.g., retinal detachment or seizures) or may be subtle, requiring the clinician to have a high index of suspicion for systemic hypertension when examining patients with subtle or vague clinical abnormalities.

Blood pressure assessment is indicated when any of the overt or subtle signs of end-organ damage are detected (Table 99-1). Conversely, if systemic hypertension is diagnosed, these body systems should be carefully evaluated for damage in conjunction with further diagnostic testing for causative diseases. In cases of renal disease, diagnostic testing for causative disease and target organ damage involve the same testing.

TABLE 99-1

Overt and Subtle Signs of Target Organ Damage with Recommended Testing Required to Assess Extent of Damage

ORGAN SYSTEM AFFECTED	OVERT CLINICAL SIGNS	SUBTLE CLINICAL SIGNS	RECOMMENDED TESTS
Eyes	• Acute blindness • Complete or near complete retinal detachment	• Behavior changes related to unrecognized vision loss • Bullous retinal detachment • Retinal hemorrhages	• Detailed direct or indirect funduscopic exam

	• Hyphema	• Tortuous retinal arteries • Periarterial subretinal infiltrates • Papilledema	
Kidneys	• Weight loss/inappetence • Polyuria/polydipsia • Palpable renal abnormalities • Azotemia • Increased urine protein/creatinine ratio	• Decreased urine-concentrating ability with normal creatinine/BUN • Increased urine protein/creatinine ratio with normal creatinine/BUN	• Assessment of creatinine and serum urea nitrogen concentrations • Urinalysis, with particular attention to urine specific gravity and protein content • Urine culture if required to rule out infection as a cause of proteinuria • Urine protein/creatinine ratio or other assessment of urine protein loss • Imaging, typically ultrasound, ± renal biopsy
Brain	• Seizures • Changes in mentation • Obtundation/coma	• Focal facial seizures • Depression • Photophobia • Behavioral changes (e.g., hiding)	• Detailed neurologic examination • Serum chemistry to rule out electrolyte and glucose abnormalities • Brain imaging (e.g., MRI)
Heart	• New murmur • New gallop heart sound	• Acute heart failure after fluid administration • Left ventricular hypertrophy on echocardiogram	• Echocardiographic examination

BUN, Blood urea nitrogen; *MRI*, magnetic resonance imaging.

Cats

The most common reason for clinical presentation of hypertensive cats is ophthalmic abnormalities. Although other causes of intraocular hemorrhage (e.g., coagulopathy) and retinal detachment (e.g., inflammatory disease) should be ruled out, immediate measurement of systemic BP guides the course of the diagnostic evaluation in these patients. For cats with neurologic signs (e.g., dull mentation or focal facial seizures) in addition to ophthalmic signs, diagnosis of critical levels of hypertension and immediate therapy can lead to rapid improvement in BP and relief of clinical signs.

Suspicion or diagnosis of diseases proven to be associated with systemic hypertension in cats (renal insufficiency or thyrotoxicosis) should lead to BP assessment. Other findings that may indicate BP assessment is warranted include palpable goiter or unexplained left ventricular hypertrophy. Systemic BP should be assessed in cats whenever auscultatory cardiac abnormalities (e.g., gallop heart sound, left-sided systolic murmurs), radiographic, electrocardiographic, or echocardiographic findings are consistent with hypertrophic myocardial disease involving the left side of the heart. Systemic hypertension (and hyperthyroidism in cats over 8 years of age) should be excluded by appropriate testing before a diagnosis of idiopathic hypertrophic cardiomyopathy is made. Early recognition of abnormal BP typically leads to evaluation for other systemic diseases, especially renal insufficiency.

Dogs

Although ophthalmic abnormalities, including retinal hemorrhage and detachment and hyphema, are as common in dogs with systemic hypertension as in cats, systemic hypertension in dogs is most often diagnosed when BP is evaluated as part of the clinical workup of dogs with systemic disease known to be associated with hypertension. In dogs, the diseases most frequently associated with elevations in BP are protein losing renal disease, acute or chronic renal failure of any etiology, hyperadrenocorticism, diabetes mellitus, and pheochromocytoma. In the case of renal disease, signs of renal dysfunction may be subtle (e.g., proteinuria without azotemia). Renal disease cannot be completely excluded based on a normal creatinine or serum urea nitrogen concentration, and a urinalysis should be performed to assess concentrating ability and protein loss. As with cats, systemic hypertension should be ruled out as a cause of left ventricular thickening of unknown etiology. Lastly, BP should be evaluated in dogs with any type of intracranial neurologic signs or ocular findings suggestive of systemic hypertension.

Hypotension

Dogs and cats that are presented with clinical signs of low cardiac output (e.g., weak peripheral pulses, cold extremities), shock, blood loss, or obtundation should be evaluated for hypotension. In some cases, hypotension is diagnosed clinically based on the constellation of history, presenting signs, and suspected clinical diagnosis (see ch. 127 and 159). Accurate measurement of BP is important in any hypotensive patient to confirm the diagnosis and to provide baseline data for monitoring the response to therapy. BP evaluation methods differ in their sensitivity to low BP. Automated noninvasive techniques (i.e., oscillometric techniques) may fail to detect a pulse when hypotension is present, and operator-reliant techniques for pulse detection (e.g., Doppler sphygmomanometry) can be unreliable if the pulse signal is difficult to discern. Of the methods typically used in acute BP measurement, arterial cannulation is the most accurate method of documenting and monitoring hypotension.

Choosing a Blood Pressure Measurement Technique

Acute Diagnostic Blood Pressure Measurement

Detection of systemic hypertension may prompt additional testing for an underlying disease condition. Therefore, it is often preferable to measure BP acutely (i.e., during a clinical examination or diagnostic evaluation), rather than hospitalizing patients and placing indwelling arterial catheters. When a technique to measure BP in a particular animal is chosen, specific issues to be considered include the availability of equipment, the availability of "normal" values to use for comparison, the skill and experience of the person making the measurement, and specific issues related to the animal (e.g., size, obesity, temperament).

Many studies have been performed in anesthetized and conscious dogs and cats and have rendered conflicting results regarding the accuracy of various noninvasive measurement methods to predict BP measured invasively via implanted telemetry devices or arterial catheters in peripheral arteries. Published validation studies, often performed on healthy young animals, have indicated that choice of measurement method (e.g., oscillometry, Doppler ultrasound, high definition oscillometry) and the specific technique details (e.g., position of patient during measurement, cuff position, anesthetized vs. conscious patient) have a large impact on the precision and accuracy of BP measurement in dogs and cats, but at this time, there is no consistent advantage or disadvantage to any of the noninvasive techniques to assess BP outlined below. Ultimately, the types of studies that are most helpful to the clinician are those that develop normal ranges of measured BP using specific devices in clinical patients (i.e., patients of varying ages, breeds and health status). Alternatively, a well-performed study using normal animals may be used to develop normal values for noninvasive methods if they are compared to a valid invasive method. Further, the technique used in a specific study must be accurately reproduced in the clinic for the suggested "normal values" to be valid. To date, few studies have addressed the ability of these techniques to discern "normal" from "abnormal" in a conscious clinical population. Therefore assessment of BP values obtained may involve comparisons with normal values or comparison with values known to be associated with clinical signs.

Continuous Blood Pressure Monitoring: Conscious Patients

The monitoring of BP over time requires either continuous measurement (arterial catheterization) or repeated measurements, recorded automatically (oscillometric or high definition oscillometric [HDO] methods) or manually (Doppler sphygmomanometric methods). Arterial catheterization has the greatest number of advantages in conscious patients. Blood pressure obtained via arterial cannulation is accurate when the technique is used correctly and the values obtained are objective and repeatable (no manual pulse detection is required). A particularly important advantage is that the system can be secured to continue BP measurement when the animal moves. The major disadvantages are the technical skills and equipment required to maintain an arterial catheter and transducer system. Noninvasive methods are commonly used to take serial BP measurements in conscious animals. Although noninvasive BP measurements appear to be technically simple to obtain, they are subject to marked inaccuracy with animal movement, poor pulse pressure, arrhythmia, or inconsistent technique. *When repeated BP measurements are obtained using these methods for monitoring, animal posture, limb position, cuff size and cuff position should be identical for the repeated recordings.*

Continuous Blood Pressure Monitoring: Anesthetized Patients

Blood pressure monitoring by most clinical methods is accurate and repeatable in anesthetized animals. The primary confounding problem of patient movement is absent in these patients, which renders them ideal subjects for BP measurement. Nonetheless, differences between values obtained by invasive methods (arterial

catheterization) and noninvasive methods have been documented in numerous studies of dogs and cats. These studies indicate that numeric values obtained by means of noninvasive methods often underestimate true BP. In the case of anesthetized animals, this may result in an erroneous diagnosis of hypotension, but it seldom leads to the more dangerous error of overestimating BP in these patients. In any case, the marked hypotensive effects of many anesthetic agents should be taken into account when assessing BP in an anesthetized patient.

Blood Pressure Measurement Techniques

Regardless of the technique chosen to assess BP in clinical patients, written records of the technique and results should be kept on a standard form, including cuff size and site, values obtained, rationale for excluding any values, the final (mean) result, and interpretation of the results by a veterinarian. It may be helpful to record assessment of patient demeanor during measurement (e.g., calm, agitated, panting, etc.) to help determine the need for confirmatory measurements.

Arterial Puncture or Arterial Cannulation ("Invasive" or "Direct" Technique)

Direct BP measurement involves advancing a needle attached to a pressure transducer directly into an artery to measure BP. This procedure may be performed acutely to obtain instantaneous BP readings, or BP can be measured over time through the use of an indwelling arterial catheter instead of a needle. Invasive BP measurements are typically used during anesthetic procedures, in critical care patients when ongoing BP information is desired, or to document or exclude hypertension acutely as a clinical diagnosis in dogs. Acute arterial puncture is seldom used for clinical diagnosis of hypertension in cats.

Direct BP measurement is usually performed by means of puncture of the femoral artery in dogs. Use of local anesthesia is strongly recommended for this procedure and when used, the procedure is well tolerated by most dogs. The patient is gently restrained in lateral recumbency. Approximately 5 minutes prior to arterial puncture, 1 to 2 mL of 2% lidocaine hydrochloride is injected subcutaneously over the area in which the femoral pulse is palpated in the dependent hind limb. A 22-gauge, 1-inch needle is attached to a transducer and flushed with heparinized saline, ensuring that no bubbles remain in the transducer. The transducer is zeroed at the level of the sternum in the laterally recumbent dog. The femoral pulse is palpated in the femoral triangle, and the needle is carefully advanced into the femoral artery (Figure 99-1) until a satisfactory pressure waveform is recorded on the monitor screen.

FIGURE 99-1 Invasive blood pressure measurement via direct arterial puncture in a dog. A 22-gauge needle (with an attached pressure transducer, previously flushed with heparinized saline and zeroed) is advanced into the femoral artery at the level of the palpable pulse in the femoral triangle after local anesthetic infiltration (see text).

A sample of the tracing is recorded, and the needle is withdrawn. Firm pressure is applied to the area of arterial puncture for a minimum of 5 minutes after measurement. The patient should be monitored closely for at least 1 hour after the procedure for any complications related to hematoma formation. Systolic, diastolic, and mean BP values from five consecutive cardiac cycles during normal sinus rhythm are averaged to obtain a representative value for the patient. When use of an arterial catheter is preferred, the catheter is usually inserted into the dorsal pedal artery. A local anesthetic may be used as described previously.

Oscillometric Technique

Oscillometric BP measurement involves the use of an automated detection system and a cuff that is wrapped around a limb or tail over an artery. The cuff is inflated automatically to a pressure that causes occlusion of the artery and then slowly deflated. The machine detects oscillations in the vessel wall as the occlusion is eased, and the pressure at which oscillations are maximal is recorded as the mean arterial pressure. The monitor using algorithms specific to the technique then calculates systolic and diastolic pressures. This technique uses data from many cardiac cycles to render a single reading and is therefore unsuitable for use in animals with rapidly changing BP.

Oscillometric BP measurement methods are more accurate in dogs than in cats. This measurement method may return inaccurate results if the patient is not motionless (e.g., trembling or panting), has a weak or irregular pulse, or has a small artery (i.e., most cats). Use of a cuff of appropriate size is extremely important to ensure accurate measurements. Cuff width should be approximately 40% of the circumference of the limb or tail in dogs and approximately 30% of the appendage circumference in cats. When used on the tail, the cuff is wrapped snugly high on the tail head with the dog in sternal or lateral recumbency. Although tail cuffs can be used in standing animals, animal movement often interferes with accurate measurement. Limb cuffs are wrapped around the forelimb distal to the elbow or around the mid metatarsus at the level of the superficial plantar arterial arch (Figure 99-2). In all cases, the center of the inflatable bladder on the cuff should be centered over the artery that will be compressed. The center of the inflatable bladder is often indicated on the cuff by a small arrow.

FIGURE 99-2 Correct placement of a limb cuff for oscillometric measurement of blood pressure (BP) via the dorsal pedal artery in a dog. The cuff tubing is attached to the oscillometric BP monitor for readings and the patient is gently restrained in lateral recumbency.

To maximize accuracy, the cuff should be at the level of the heart during readings; therefore lateral or sternal recumbency is preferred, and use of limb cuffs in standing patients should be avoided. In cats, tail cuffs return more repeatable measurements than limb cuffs. Typically, the cat rests in sternal recumbency during readings (Figure 99-3).

FIGURE 99-3 Correct placement of a tail cuff for oscillometric readings in a cat. The cat is relaxed and minimally restrained in sternal recumbency.

In all cases, best results are obtained when the patient is minimally restrained and soothed during the

procedure. A short acclimation period prior to measurement is recommended to allow patients to become calmer. A series of at least five readings are obtained at approximately 1-minute intervals. Any readings that are clearly erroneous are discarded. The multiple readings are then averaged to obtain a representative result (Video 99-1).

Oscillometric techniques are valuable in anesthetized dogs and cats to monitor trends in BP. Because the animal is immobilized and BP shows less variability over time, repeatable and accurate readings can be obtained over time in both dogs and cats.

High-Definition Oscillometric Technique

High-definition oscillometry is a variation of the conventional oscillometric method of BP measurement, but detects oscillations of the blood vessel in real time to measure pulse amplitude and is purported to have the ability to assess a wider range of BP values as well as the ability to detect arrhythmias. Cuff and limb positions are similar to those of conventional oscillometric devices, but cuff sizing is divided into two options based on weight of the dog. Attempts to validate and develop data for precision and accuracy of measurements using this technique in anesthetized and conscious dogs and cats have rendered variable results. Based on these evaluations, there is no consistent advantage to clinical use of this type of device vs. conventional oscillometry or Doppler sphygmomanometry. Regardless of device and technique used, body and limb position as well as cuff size and position should remain consistent for any individual dog and cat.

Doppler-Ultrasonic Technique (Doppler Sphygmomanometry)

Doppler ultrasonic flow detection through the use of a piezoelectric crystal allows detection of flow in a peripheral artery. Hair is clipped just proximal to the palmar metacarpal pad at the level of the superficial palmar arterial arch for forelimb measurement; over the dorsal pedal artery for hindlimb measurement; or on the ventral aspect of the tail for tail measurement (Videos 99-2 and 99-3). An occluding cuff (sized as outlined for oscillometric techniques) is placed proximal to the point of flow detection (midradius in the forelimb, proximal to the hock in the hindlimb, or proximal to transducer placement on the tail), and measurements are obtained with the cuff at the level of the heart. Ultrasonic coupling gel is placed on the concave surface of the Doppler transducer, and the transducer is held in position during measurements (Figure 99-4) or fixed in position using adhesive tape.

FIGURE 99-4 Measurement of blood pressure via Doppler sphygmomanometry from the forelimb of a cat with acute blindness due to retinal detachment. Note that the inflatable cuff is at the same level as the heart in the sitting and comfortably restrained animal.

An audible pulse signal is obtained, and the cuff is inflated with a bulb attached to a pressure gauge. The cuff is inflated to a pressure no less than 40 mm Hg above the audible cut-off point of the signal. The cuff is then slowly deflated, and the pressure at which the Doppler signal is again audible is recorded as the systolic pressure. The cuff is deflated further, and the pressure at which the audible signal abruptly changes in pitch or becomes muffled is recorded as the diastolic pressure.

The Doppler flow detection system of BP measurement is considered the most accurate and repeatable of studied noninvasive BP measurement techniques in conscious cats. It is frequently used in dogs but may provide spurious high readings in some individuals. When abnormal readings are obtained by this method from dogs, care should be taken to make sure the abnormal readings are repeatable over multiple measurement periods. The advantages of this technique include flexibility with regard to motion, low pressure, small vessels, or the presence of arrhythmias, as well as speed of measurement. The rapidity of the measurement techniques allows for prompt assessment of changing BP, but meticulous attention must be paid to obtaining strong, audible signals in order to obtain the most accurate BP readings. This technique is also the most operator dependent of the techniques discussed. Accurate identification of diastolic pressures improves with operator practice, and BP measurement using Doppler ultrasonic flow detection techniques is most accurate if a few well-trained individuals in a practice are responsible for this diagnostic test and perform the test frequently.

CHAPTER 100

Chest Tube Placement

Tim B. Hackett

Space-occupying lesions in the pleural space reduce tidal volume, decrease lung compliance, and cause a restrictive breathing pattern. Restrictive breathing is characterized by rapid, shallow respirations and dull lung sounds (see ch. 139 and 244). In some cases, such as with tension pneumothorax, increased intrathoracic pressures can impair venous return to the heart, resulting in circulatory shock and further compromise of oxygen supply to vital organs. While radiographs are used to diagnose air and fluid in the pleural space, in emergency settings these conditions can be simultaneously diagnosed and treated by rapid thoracocentesis (see ch. 102). Once removed, fluid can be evaluated to determine the likely source (Table 100-1; ch. 74). Diaphragmatic hernia and intrathoracic masses may require additional imaging for a definitive diagnosis. Ultrasonographic examination is an excellent way to identify pleural fluid (see ch. 244).

TABLE 100-1

Common Causes of Pleural Effusion in Small Animals

TYPE OF EFFUSION	PROTEIN (g/dL)	CELL COUNT (/mcL)	ETIOLOGY
Modified transudate	<2.5	<500-1000	Right heart failure Pericardial disease Hypoalbuminemia Neoplasia Diaphragmatic hernia
Exudate	>3.0	>5000	Feline infectious peritonitis Neoplasia Diaphragmatic hernia Lung lobe torsion Pyothorax
Chylous	>2.5	>500	Idiopathic Cardiomyopathy Heartworm disease Neoplasia Lung lobe torsion Tuberculosis
Hemorrhage	>3.0	>1000	Trauma Coagulopathy Neoplasia Lung lobe torsion

Effusions are classified based on protein content and cell count.

Thoracostomy tubes are routinely placed in surgery following open thoracotomy to maintain negative intrapleural pressure. These short-term thoracostomy tubes allow normal expansion of the lungs as the visceral pleura of the lungs are brought back in contact with the parietal pleura of the chest wall. These tubes are not only useful to maintain negative intrapleural pressure, they also provide a means to administer repeated applications of intrapleural local anesthetics. With normal lung tissue and appropriate surgical closure, these tubes can usually be removed 6 to 12 hours postoperatively after several repeated negative aspirates. Inexpensive feeding tubes are often used for short-term postoperative thoracic drainage. The

surgeon will place these while the thorax is still open to confirm proper positioning. Thoracostomy tubes are also necessary in patients with intrathoracic disorders requiring repeated thoracocentesis to maintain negative intrapleural pressure and normal tidal volume. Examples of diseases requiring thoracostomy tubes include traumatic and idiopathic pneumothorax, pyothorax, chylothorax, and neoplastic pleural effusions. A variety of tubes is available and their selection is based on clinician preference and clinical use. Most conditions can be managed with a single tube, though cases of bilateral pyothorax usually require bilateral tube placement.

Basic Equipment and Types of Thoracostomy Tubes

To place a thoracostomy tube, the disposable materials needed include a chest tube, a tubing adapter to take the lumen of the tube down to a standard Luer connection, a three-way stopcock, 20 gauge orthopedic wire, extension tubing, large caliber suture to maintain tube position, and large volume syringes. Sterile instruments needed include curved forceps or hemostats, a scalpel handle and blade, towel clamps, and a surgical drape.

Commercially available chest tubes or red rubber catheters can be used (Figure 100-1). The red rubber catheter is the least expensive, and is often used for short-term, post-thoracotomy cases. These are flexible, can easily kink, and are more reactive than polyvinyl chloride commercial tubes making them undesirable for long-term use. Red rubber tubes are also nearly impossible to see radiographically without the use of contrast.

FIGURE 100-1 Commonly-used thoracostomy tubes: **A,** thoracostomy tube with trocar stylet; **B,** red rubber feeding tube/urethral catheter.

Commercial tubes are available in different sizes, ranging in diameter from 14 to 40 French. The commercial tubes are usually open at the end and have oval side holes. They also have a radiopaque line that runs the length of the tube to the side hole furthest from the tip of tube. This mark is important when evaluating tube placement radiographically. All holes should be within the thoracic cavity. If the side hole furthest from the tip is under the skin, air can be aspirated from outside the chest.

While sizes have traditionally been selected by matching the chest tube to the diameter of the mainstem bronchus, other factors should also be considered. Thoracostomy tubes are invasive and painful. If smaller tubes are sufficient, they might be better choices for chronic effusions and continuous, or mild, pneumothorax. Larger tubes should be considered with highly cellular effusions and large volume, continuous pneumothorax.

More recently, smaller products have become available, including over-wire kits and Veress needle style, spring-loaded catheter systems (Figure 100-2). The Veress systems have a blunt safety cannula housed within the sharp, beveled hollow needle and a safety color change indicator. These systems are potentially safer when there are concerns about pockets of fluid or concerns about the lung adhering to the parietal pleura. These systems usually contain small caliber tubes and can be indicated when palliative tubes are expected to be in place for long periods of time. The landmarks and technique described in the following section should be modified based on the localization of large fluid pockets, which are best assessed with ultrasonographic examination (see ch. 244).

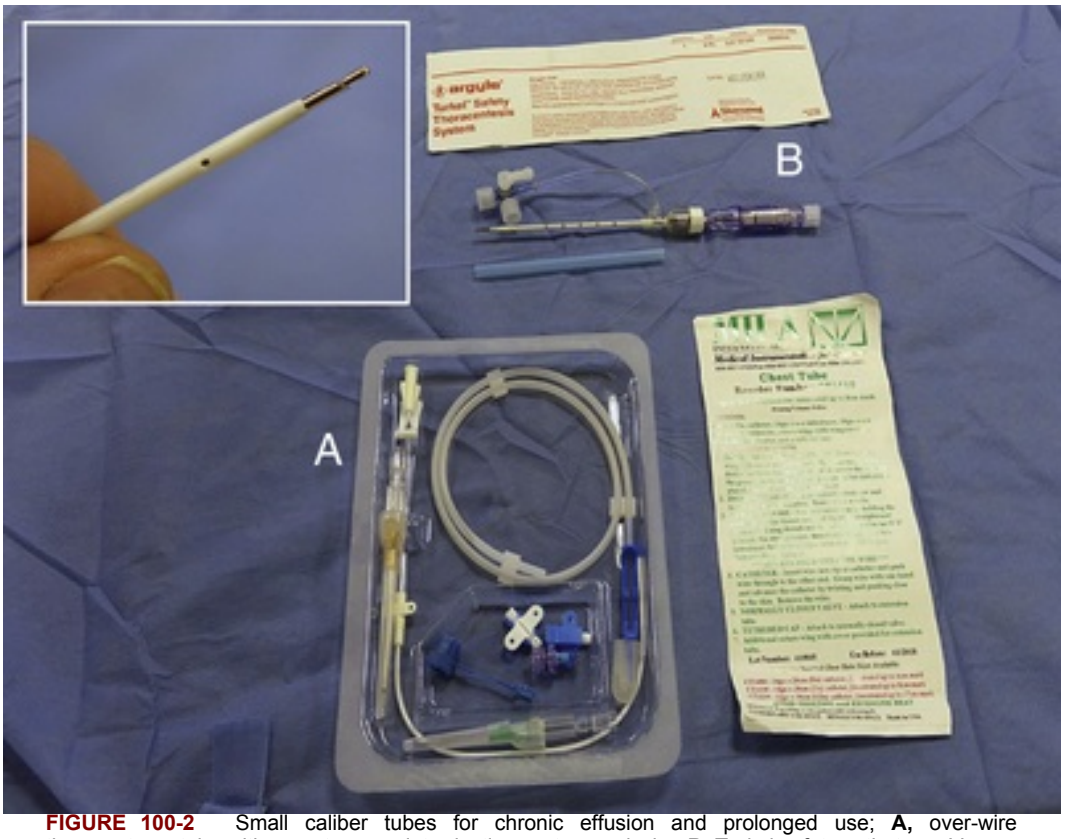

FIGURE 100-2 Small caliber tubes for chronic effusion and prolonged use; **A,** over-wire thoracostomy tube with percutaneous introduction system and wire; **B,** Turkel safety catheter: a Veress needle, with spring-loaded intraluminal cap to prevent iatrogenic laceration of the lung (inset).

Techniques

Several techniques have been described to place thoracostomy tubes. Whenever possible, the procedure is performed under general anesthesia. Usually the patient can be stabilized with thoracocentesis alone, though in some emergency cases tube placement might be necessary to establish normal tidal volume and minimize pleural air accumulation. In these cases, the clinician might place the tube with the patient under sedation and local anesthesia. In general, patients are held in lateral recumbency and the lateral chest wall is clipped and prepared aseptically (Videos 100-1 and 100-2). A skin incision is made over the ninth to eleventh intercostal space, and then the skin is pulled cranially to the site of tube entry at the level of the mid-thorax. The tip of the curved forceps is inserted into the skin incision and blunt dissection is used to separate the intercostal muscles, taking care to avoid the intercostal vessels and nerves caudal to the rib. If the patient is intubated and ventilated, there is little concern about air entering the pleural space during the procedure. Insertion of a tube with an internal stylet into the pleural space without prior chest wall dissection could put the patient at risk of iatrogenic injury to intrathoracic structures. Instead, the tube with internal stylet is gently manipulated through the hole created by blunt dissection. If a stylet is not used, the tip of the tube is grasped by the curved forceps and inserted into the hole created by blunt dissection. The thoracostomy tubes are placed into the chest with the tip barely reaching the cranioventral thorax. Over-insertion risks kinking the tube. When the skin is released and retracts caudally, a subcutaneous tunnel is formed from the skin incision to the point of entry into the thorax. This prevents air from entering the skin incision when the thoracostomy tube is removed. If the patient is intubated and ventilated, there is no reason to mechanically clamp the tube. Clamping the tube can create small punctures in the tube, potentially resulting in air leakage into the thoracic cavity. Making the necessary connections takes little time and insignificant quantities of air admitted during the procedure can then easily be removed. Once the connections are secured to the tube, evacuation of the pleural space can begin immediately. The chest tube should be attached to the skin with a self-tightening knot and all connections secured with cerclage wire. Chest tubes are painful and will result in a restrictive breathing pattern owing to the discomfort felt with normal respirations. Most patients with indwelling chest tubes should receive both systemic and local analgesia.

Intermittent Versus Continuous Suction

Following thoracostomy tube placement, intermittent or continuous suction techniques can be used. During the first few hours, the volume of air or fluid should be evaluated through intermittent aspiration. With small volume accumulation and appropriate monitoring, the intermittent technique can be manageable. Other advantages of the intermittent technique are that it is harder for the patient to accidentally remove the tube or traumatize it when a light bandage covers it.

Continuous suction is usually only indicated when there is rapid accumulation of air leading to repeat and frequent episodes of respiratory distress. Continuous suction requires a vacuum source and a closed system. It is important that the negative pressure is less than 20 cm H_2O and that the system does not allow air to enter the patient if the suction is turned off. Commercially available systems have replaced the three-bottle system with three separate chambers (Figure 100-3). The chamber closest to the patient is the largest and is used to quantitate fluids coming from the patient. The suction tube from the patient is connected to this chamber at an opening near the top. A tube from the top of the first chamber goes from the top of the chamber into the second chamber, opening approximately 1 centimeter under water. This is the water seal chamber and serves two functions. During continuous suction, any air seen bubbling into this chamber means air is coming from the patient (or a leak between the patient and this chamber). The other function is to prevent air being drawn into the patient if suction is discontinued. The third chamber, farthest from the patient and closest to the suction device, modulates the negative pressure. There is a tube from the top of this chamber open to outside air and terminated near the bottom. When water is added to this chamber and the suction turned up until air is drawn from the top to the bottom (as evidenced by bubbles coming from the tube), the pressure of the vacuum equals the depth of the tube. For a desired vacuum of 20 cm of H_2O, the chamber is filled to 19 cm (the additional 1 cm of water creates the water seal in the second chamber).

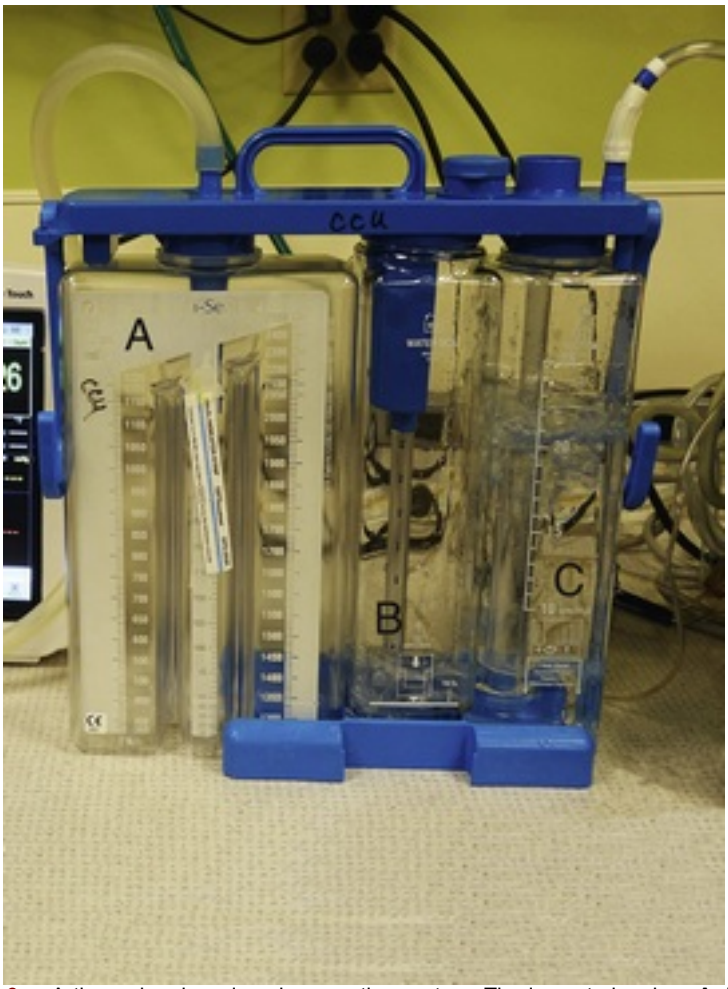

FIGURE 100-3 A three-chamber pleural evacuation system. The largest chamber, **A,** is connected to the patient's chest tube and can quantify the volume of liquid removed. The middle chamber, **B,**

creates a water seal that prevents air from being drawn back into the patient if suction is interrupted. Bubbling noted in this middle chamber indicates air production from the patient or connected tubing. The third chamber, **C,** is connected to the suction apparatus and moderates the negative pressure applied to the patient. When suction is applied and air is seen to bubble in this chamber, the negative pressure applied to the patient (cm H_2O) equals the depth of this tube.

Troubleshooting Continuous Air Production

Patients that continually produce air from a chest tube 12 to 24 hours after placement should be evaluated for leaks within the tubing or suction system. The system should be investigated between the pleural space (including radiographs to confirm all the tube side holes are within the thoracic cavity) and skin incision, and between the tube connections and the suction apparatus. The most common sites of leakage are the tube, from either a side hole just under the skin or a hole placed by a clamp, and the Christmas tree connection closest to the tube. A small amount of fluid placed in the tube at the Christmas tree might reveal a leakage site by bubbles drawn into the tube when negative pressure is applied (see Video 100-2).

The thoracostomy tube is removed when it is no longer indicated. Patients on continuous suction for a pneumothorax should be weaned by switching to intermittent aspiration at progressively longer intervals. Thoracic radiographs are recommended just prior to removal of the tube to ensure that the disorder has resolved. If stable, the animal is sedated with a combination sedative analgesic, holding sutures are removed, and the tube is withdrawn in a steady, rapid motion. The skin incision can be closed or left open and a light antiseptic bandage is placed over the hole.

CHAPTER 101

Transtracheal Wash and Bronchoscopy

Tekla M. Lee-Fowler

Bronchoscopy and airway sampling techniques are useful tools for investigating airway disease. Tracheobronchoscopy allows visualization of the trachea and airways while providing access for sample collection. Airway wash techniques, independent of bronchoscopic guidance, include transtracheal wash, endotracheal wash, and bronchoalveolar lavage (blind technique). Procedure choice should be based on patient stability, whether the disease is focal or diffuse, goals of diagnostics and operator skill level.

Transtracheal Wash

Overview and Indications

A transtracheal wash can be performed to obtain samples from the proximal respiratory tract in medium- to large-size dogs. Results of this procedure can be quite informative in dogs with diffuse pulmonary disease. One major advantage of the transtracheal wash is that the patient is awake-to-minimally-sedated. Since they are not anesthetized, patients often cough during the procedure, increasing sample return and the likelihood of obtaining material from lower airways. Transtracheal wash is not suitable for aggressive or extremely anxious dogs. Hemostatic abnormalities, severe pyoderma of the neck, and respiratory distress could each be considered contraindications for this procedure.[1]

Procedure

The dog is placed in sternal recumbency and gently but firmly restrained by an assistant who is holding the head with the nose pointing upward. The ventral portion of the neck, beginning at the larynx and including the proximal portion of the trachea, is clipped and aseptically prepared. With sterile gloved hands, the target area can be palpated. Needle placement will be either through the cricothyroid ligament or on midline between two adjacent tracheal rings. An intradermal and SC injection of 2% lidocaine is administered over the target area. At least 10 minutes is required for local anesthesia to take effect. The cricothyroid ligament is located between the thyroid cartilages cranially and the cricoid cartilage distally. A 16- to 19-gauge through-the-needle IV catheter is inserted through the target area and into the tracheal lumen. Once the needle tip reaches the lumen, the needle should be angled downward (toward the thorax) and the catheter advanced into the airway and down the trachea. When the catheter is in place, the needle can be withdrawn from the trachea and covered with the attached needle guard. Warm sterile 0.9% saline (5-20 mL) is infused through the catheter using a syringe.[2] Suction is applied using the syringe plunger to retrieve as much of this fluid as possible. In the absence of coughing, coupage can facilitate return of sample. Generally, recovery of fluid is much less than with other techniques, with 10% or less of the instilled volume typically recovered.[1,2] It may be necessary to instill additional aliquots of saline until an adequate sample is retrieved; the total volume instilled will depend on the dog's size and respiratory stability. Although the recovered volume may be small, the amount should be adequate for cytology, culture and sensitivity.

Complications

Complications of transtracheal wash are uncommon. Transient SC emphysema is the most frequently described complication. Other complications include tracheal laceration, endotracheal hemorrhage, infection at the puncture site, and transient worsening of respiratory status.

Endotracheal Wash

An endotracheal wash can be utilized in dogs and cats, and is particularly useful in small dogs and cats for which a transtracheal wash is not suitable. This technique requires anesthesia, allows sampling of the proximal respiratory tract, and differs from a blind bronchoalveolar lavage in that the catheter is only advanced to the level of the carina. To prepare the sterile red rubber urinary catheter prior to the procedure, a sterile blade or scissors is used to create an open-ended catheter by removing the distal end of the catheter just above the lateral openings. A syringe adapter is attached to the proximal end of the catheter (Figure 101-1).

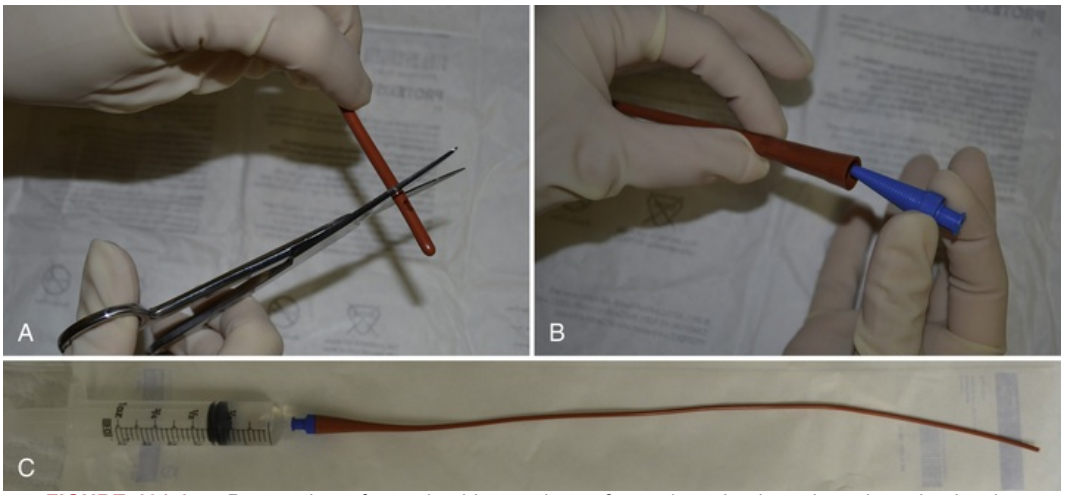

FIGURE 101-1 Preparation of a red rubber catheter for endotracheal wash or bronchoalveolar lavage blind technique. **A,** Sterile scissors are used to create an open-ended catheter by removing the distal end of the catheter just above the lateral openings. **B,** A syringe adapter is attached to the proximal end of the red rubber catheter. **C,** A prepared catheter with a preloaded syringe of sterile saline attached.

The patient is intubated with a sterile endotracheal tube, and the open-ended sterile red rubber urinary catheter is passed through the endotracheal tube lumen to the approximate level of the carina. 5-20 mL of warm sterile 0.9% saline is infused through the red rubber catheter, via the syringe, and negative pressure is applied to retrieve the sample. Coupage may be performed to facilitate sample collection. The volume of sample recovered is similar to that of the transtracheal wash. This process may need to be repeated to obtain adequate sample. Total volume of saline used is dependent upon the patient size and respiratory status.

Bronchoalveolar Lavage: Blind Technique

Bronchoalveolar lavage (BAL) can be performed without endoscopic guidance when diffuse disease is present. This sampling method differs from those described above by providing sample from the lower airways. This technique is most successful in small to medium-sized pets. Substitution of the red rubber catheter with a feeding tube has been described for larger dogs.[3] Preparation of the red rubber catheter prior to BAL involves using a sterile blade or scissors to produce an open-ended catheter by cutting the catheter just above the distal side openings. A syringe adapter is also attached to the proximal end of the red rubber catheter (see Figure 101-1).

The patient is anesthetized with a short-acting IV anesthetic, intubated with a sterile endotracheal tube, and placed in lateral recumbency. If the disease process is more marked on one side, the patient should be positioned with that side down. An open-ended sterile red rubber urinary catheter is passed through the endotracheal tube until it is gently wedged and cannot be advanced further. Withdrawing the catheter a few millimeters, rotating the catheter slightly and gently advancing again until wedged will help ensure that the catheter is wedged within an airway and not becoming lodged at an airway division. Once the catheter is in place, warmed sterile 0.9% saline is instilled through the catheter and immediately aspirated. The volume infused has not been standardized and recommendations vary from 5-30 mL aliquots to using 2-5 mL/kg. An additional aliquot may need to be infused to recover adequate volume. The volume of sample recovered should be 40-50% of the total volume instilled. After the sampling is complete, the patient is placed on 100% oxygen for about 5-10 minutes (see ch. 131).

Bronchoscopy

Overview

Tracheobronchoscopy, utilizing a flexible bronchoscope, is a tool for visually inspecting mucosal surfaces of the trachea and lobar bronchi. Additionally, specific sites for sample acquisition can be chosen for pets with focal disease. The patient is anesthetized with an IV anesthetic and maintained with either IV or gas anesthesia. With the latter option, the bronchoscope is passed through the endotracheal tube utilizing a T-adapter. However, internal endotracheal tube diameter becomes a limiting factor in small patients. In small dogs and cats, IV anesthesia and direct intubation with the bronchoscope is often necessary. It is helpful to intubate these patients with a small diameter (5-Fr), sterile, red rubber catheter alongside the bronchoscope to provide supplemental oxygen during bronchoscopy. Supplemental oxygen can also be supplied through the biopsy channel of the bronchoscope.

Initial Visual Evaluation

Inspection of the trachea should include assessing appearance of the mucosa, the amount of secretions present, and any evidence of collapse. The carina should then be identified and each lung lobe should be systematically examined (Figure 101-2 and Video 101-1). The endoscopist must note the presence of abnormalities such as mucus plugs, mucopurulent debris, hemorrhage, foreign bodies, static or dynamic collapse of airways, masses or nodules, and parasites (see ch. 241).

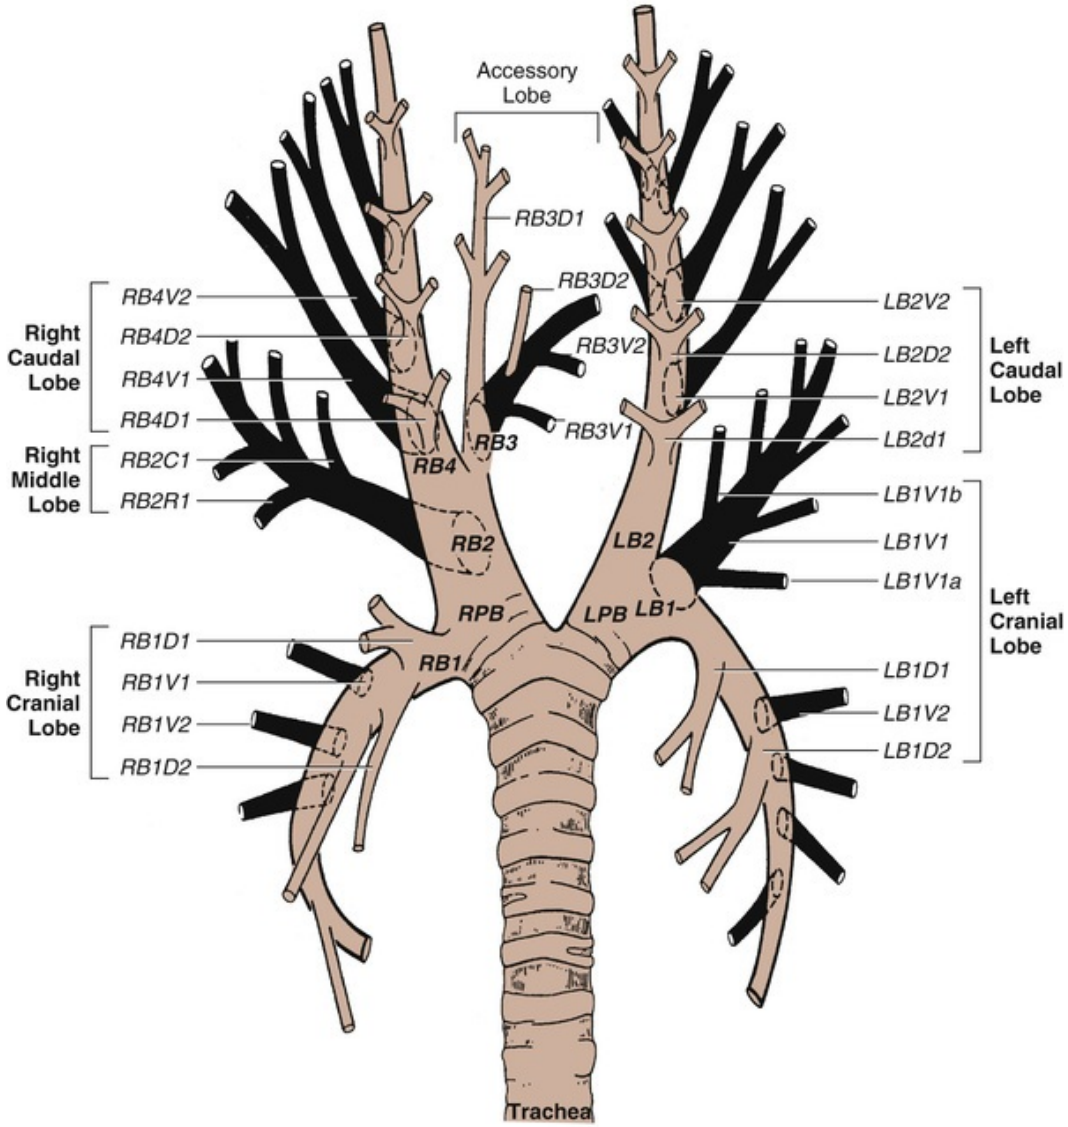

FIGURE 101-2 Diagram of normal bronchial anatomy in dogs. Each lobar bronchus is subdivided into segmental bronchi: *V1,* first ventral segmental bronchus; *V2,* second ventral segmental bronchus; *D1,* first dorsal segmental bronchus; *D2,* second dorsal segmental bronchus; *C1,* first caudal segmental bronchus; and *R1,* first rostral segmental bronchus. Segmental bronchi are subdivided into subsegmental bronchi: *V1a,* first subsegmental bronchus; *V1b,* second subsegmental bronchus. *LB1,* Lobar bronchus of left cranial lung lobe; *LB2,* lobar bronchus of left caudal lung lobe; *LPB,* left main stem bronchus; *RB1,* lobar bronchus of right cranial lung lobe; *RB2,* lobar bronchus of right middle lung lobe; *RB3,* lobar bronchus of accessory lobe; *RB4,* lobar bronchus of right caudal lung lobe; *RPB,* right main stem bronchus. (From Amis TC, McKiernan BC: Systematic identification of endobronchial anatomy during bronchoscopy in the dog. *Am J Vet Res* 47:2649, 1986.)

Brush Catheter

The airway mucosal surface can be sampled using a bronchoscope brush catheter. The brush is covered by a plastic sheath that can be pulled back once the brush is in its desired location. With the bronchoscope in the desired location, this small sampling brush is passed through the sampling channel. Once the brush catheter is visualized, it is uncovered, gently scraped against the mucosa, then retracted back into the sheath, and removed from the scope. The brush can be cultured and then gently rubbed on a glass slide for cytology.

Biopsy

In a similar method, the bronchoscope is placed in the desired location and the biopsy instrument is inserted into the sampling port (biopsy channel). The bronchoscope is then used to guide the instrument to the desired

location and the biopsy taken. Samples can be submitted for culture and histopathology. This technique is primarily indicated for sampling proliferative tissues or masses within the airways. A technique has been described for transbronchial biopsy of more peripheral tissue, particularly in the caudal lung lobes; however, complications such as bleeding, pneumothorax, small sample size and likelihood of sample crush artifact could outweigh benefits.[4]

Transbronchial Fine Needle Aspirate

This method is primarily indicated for obtaining samples from lymph nodes or masses impinging on the airways. While visualizing the compressed area with the bronchoscope, a transbronchial needle catheter is passed through the sampling channel. When the needle catheter is visualized, the needle is uncovered, advanced through the mucosa between the cartilage rings of the bronchus and into the impinging lymph node or mass (see ch. 95). A syringe is used to apply negative pressure to obtain an aspirate. The needle is withdrawn without suction, recovered, and retracted from the scope. Samples can be used for cytology slides. Possible complications are similar to biopsy, including hemorrhage and pneumothorax.

Bronchoalveolar Lavage: Endoscopic

This is a commonly used sampling technique to obtain lower airway cytology and culture sample and is performed after all lobes have been inspected. The bronchoscope is directed into the desired bronchus and then advanced until it is wedged or is occluding the airway. With the lumen of the airway centered in the image, warm sterile 0.9% saline is instilled into the sampling port and immediately aspirated. Aspiration can be performed by manual aspiration with a syringe or via suction pump aspiration.[5] The volume of saline to be infused has not been standardized in veterinary medicine. Aliquot volumes of 10-30 mL or a "dosage" of 2-5 mL/kg (small to medium-sized dogs and cats) have been recommended. About 40% to 50% of the sample should be retrievable. The lightly anesthetized animal may cough, producing a better sample. Coupage can also be performed during aspiration to facilitate sample recovery. This procedure can be repeated to obtain adequate samples depending on volume of saline used, patient size, and patient respiratory status. In cats, sampling two different lung segments may provide more accurate cytologic results.[6] Bronchoalveolar lavage fluid can be submitted for culture and sensitivity and cytological evaluation.

Possible complications of BAL include decline in oxygen saturation, bronchospasm, and pneumothorax. It is advised to provide supplementation with 100% oxygen to all animals immediately after BAL (see ch. 131). This can usually be discontinued shortly thereafter. Additionally, animals with significant respiratory disease may benefit from pre-BAL-oxygenation with 100% oxygen. Bronchospasm as a complication of bronchoscopy and BAL is most commonly seen in cats. Premedicating cats with suspected lower airway disease using a bronchodilator may reduce this complication.[7]

CHAPTER 102

Thoracocentesis/Pericardiocentesis

Robert Prošek

Thoracocentesis

Thoracocentesis, also referred to as a chest tap or pleural tap, is both a diagnostic and often therapeutic (emergency) procedure to remove pleural air or fluid from the thoracic cavity. Indications for thoracocentesis are respiratory distress (increased respiratory rate and inspiratory effort) and dull lung sounds (often a fluid line can be identified with effusion) confirmed by thoracic radiographs (pleural effusion, pneumothorax) and/or ultrasound (effusions) (Figure 102-1, *A* and *B*; see ch. 149). Potential contraindications to thoracocentesis include severe coagulopathies and diaphragmatic hernias. Penetration of intestinal loops or liver should be avoided (ultrasound guidance will be needed) while potential complications of thoracocentesis include hemothorax, iatrogenic pneumothorax, laceration of intrathoracic organs, and acute death from the stress of over restraint.

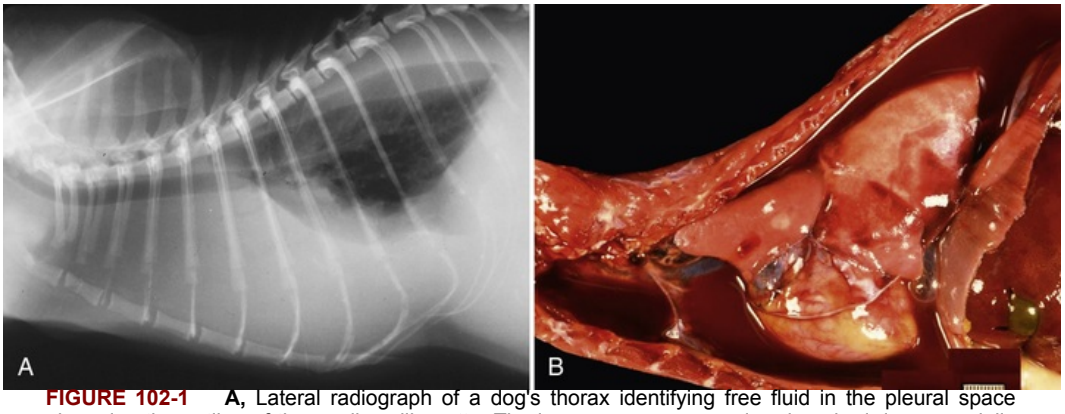

FIGURE 102-1 **A,** Lateral radiograph of a dog's thorax identifying free fluid in the pleural space obscuring the outline of the cardiac silhouette. The lungs are compressed and pushed dorso-caudally by the fluid. **B,** Necropsy view of an open thorax with free pleural fluid surrounding the lungs and compressing them.

With all the aforementioned considerations, thoracocentesis overall still is a simple procedure. The two most common techniques involve either the "butterfly" catheter or plastic catheter that has fenestrations. In cats and small dogs a ¾ to ⅞ inch (2 to 3.5 cm) butterfly needle or 22-23 gauge needle (author prefers butterfly), in medium dogs and large cats a 1 inch (2.5 cm) needle or 20-22 gauge over-the-needle catheter, and in large dogs a 1.5 inch (4 cm) needle or a longer 14-20 gauge over-the-needle catheter are the commonly preferred instruments to use for this procedure. The butterfly catheter, needle or fenestrated catheter is attached to an extension set (with a butterfly catheter, the extension set is usually not needed), a three-way stopcock and a syringe (10 to 60 mL depending on the size of the animal) to withdraw fluid or pleural air. If fluid is being removed, a graduated cylinder or bowl to collect and quantify the amount of fluid removed is needed (Figure 102-2).

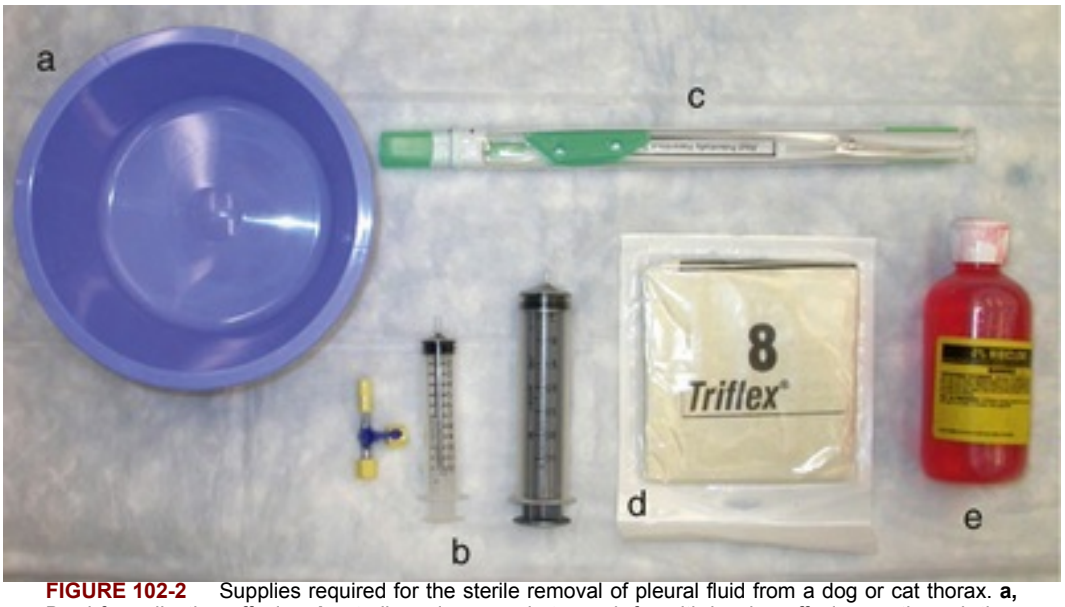

FIGURE 102-2 Supplies required for the sterile removal of pleural fluid from a dog or cat thorax. **a,** Bowl for collecting effusion; **b,** sterile syringes and stopcock for withdrawing effusion; **c,** through-the-needle central venous catheter for accessing the pericardial space; **d,** sterile gloves; **e,** aseptic scrub solution.

The patient is most commonly placed in sternal recumbency or standing for removing pleural effusion or a pneumothorax. If necessary, a lateral recumbent position can be used for tapping a pneumothorax. If the patient shows signs of severe respiratory distress and dull lung sounds, a thoracocentesis might need to be performed without further diagnostics. Otherwise radiographs will help to identify the location of the intercostal space for penetration. This is typically at the seventh or eighth intercostal space (ICS) at the level of the costochondral junction for fluid or the eighth or ninth ICS near the costochondral junction for air. Ultrasonography may be required to identify smaller pockets of fluid collection (see ch. 149). It may be advisable to pre-oxygenate the patient before the procedure and/or to provide a flow of oxygen during thoracocentesis. Clip and aseptically prepare the region to be tapped. Prepare a sterile environment for gloves, needles and syringes to be used (see Figure 102-2). A local anesthetic may be administered; however, it is often difficult to insert the needle into the same space that the centesis needle will be placed. Insert the needle just cranial to the rib (closed system as described above with three-way stopcock and syringe) to avoid the intercostal vessels and nerves that run caudal to the rib. Apply gentle suction on the syringe to generate negative pressure. Once the position of the needle is determined to be satisfactory, if fluid is obtained the needle should be oriented ventrally and if air is obtained the needle oriented dorsal to the body wall to reduce the risk of laceration of the adjacent lung lobe. The needle should be removed if frank blood is aspirated, if lungs can be felt rubbing against the needle or if the patient is moving excessively. Fluid initially removed is placed in sterile tubes for evaluation and cytology. If bloody fluid is removed and is thought to be whole blood, it will clot when placed in a red top tube. Blood from a hemothorax should not clot (minus bleeding disorders), whereas blood from the heart or blood vessels will clot. If an over-the-needle catheter technique is used, frequent kinking of the catheter may occur with patient movement or tachypnea due to pressure from the muscles of respiration. To help stabilize the catheter, the hand holding the catheter can be rested against the patient to try to prevent excessive movement or if all fails leave the stylet inside the catheter and be cautious about movement since the end of the catheter tip is a sharp point and can cause serious intrathoracic damage. Aspiration should continue until the fluid flow stops while aspiration of air should continue until negative pressure is reached (if negative pressure is never obtained, concern for tension pneumothorax exists and a chest tube with continuous suction might be needed; see ch. 100). Removing all the air from the thorax initially can be dangerous since the injured lung can re-expand and in doing so the rent in the lung tissue may reopen. Thus, removal of air should likely stop when the patient is seen to be breathing with less distress.

Samples of fluid extracted from the thorax should be submitted for fluid analysis, cytologic examination and culture/sensitivity as indicated. Chylous effusions are examined against whole blood for paired triglyceride levels. A portion of the fluid should be stored sterilely if future culture is anticipated. Post-centesis, the patient should be monitored for signs of respiratory distress suggesting accumulation of fluid or air or resulting from iatrogenic hemothorax or pneumothorax. Other than keeping the dog or cat at rest and warm and watching for recurrence of signs, no significant post-tap attention is usually required.

Pericardiocentesis

Pericardiocentesis also is referred to as a pericardial tap or pericardial drainage. This procedure involves inserting a catheter to remove a volume of pericardial effusate for diagnostic purposes and more often for the therapeutic relief of life-threatening pericardial tamponade associated with pericardial effusion. Prior to the procedure, if the patient is not critical, echocardiography is recommended to confirm the diagnosis. Cardiac neoplasia is a major cause of pericardial effusion and tumors are often easier to identify pre-centesis since the pericardial fluid often outlines the mass. Also, if inadvertent cardiac puncture occurs during pericardiocentesis, the diagnosis of the initial cause of the pericardial effusion increases the diagnostic challenge. Echocardiography can also yield information if pericardial effusion is due to an atrial tear, as a pericardial clot can often be visualized (Figure 102-3). Pericardiocentesis in this situation would be contraindicated as moving the clot can induce a reoccurrence of acute pericardial hemorrhage. Reviewing the echocardiogram, pericardial effusion is seen as an anechoic/hypoechoic space between the epicardium and the pericardium while pleural fluid also accumulates outside of the pericardial sac in the pleural space (Figure 102-4; Video 102-1) (see ch. 104 and 254). Pericardial effusion can increase intrapericardial pressures resulting in varying degrees of hemodynamic compromise. When intrapericardial pressure equals or exceeds the right ventricular diastolic filling pressure and right atrial pressure, cardiac tamponade occurs with clinical signs of right-sided heart failure and cardiogenic shock developing. Intravenous fluids may increase preload as the patient is prepared for pericardiocentesis if signs of cardiogenic shock are noted; however, significant intravenous fluid may also overwhelm the vascular system resulting in further extravasation of fluid, vascular overloading and heart failure. Supplemental oxygen may often help temporarily while the procedure is being performed.

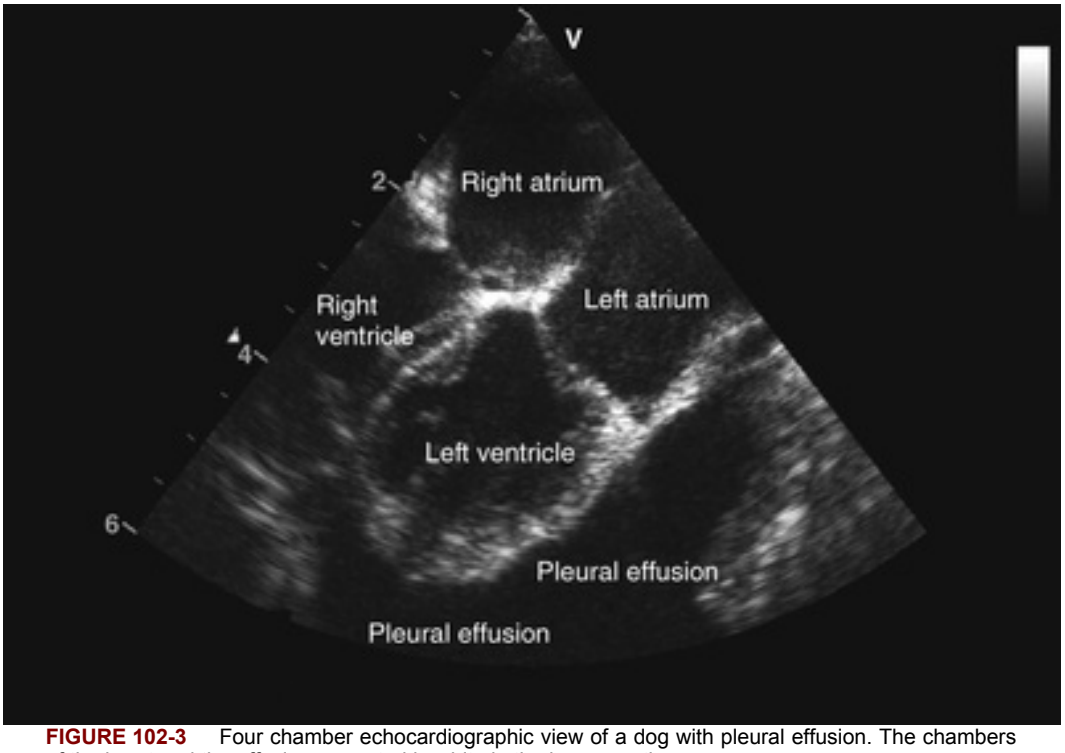

FIGURE 102-3 Four chamber echocardiographic view of a dog with pleural effusion. The chambers of the heart and the effusion are noted in white in the image on the screen.

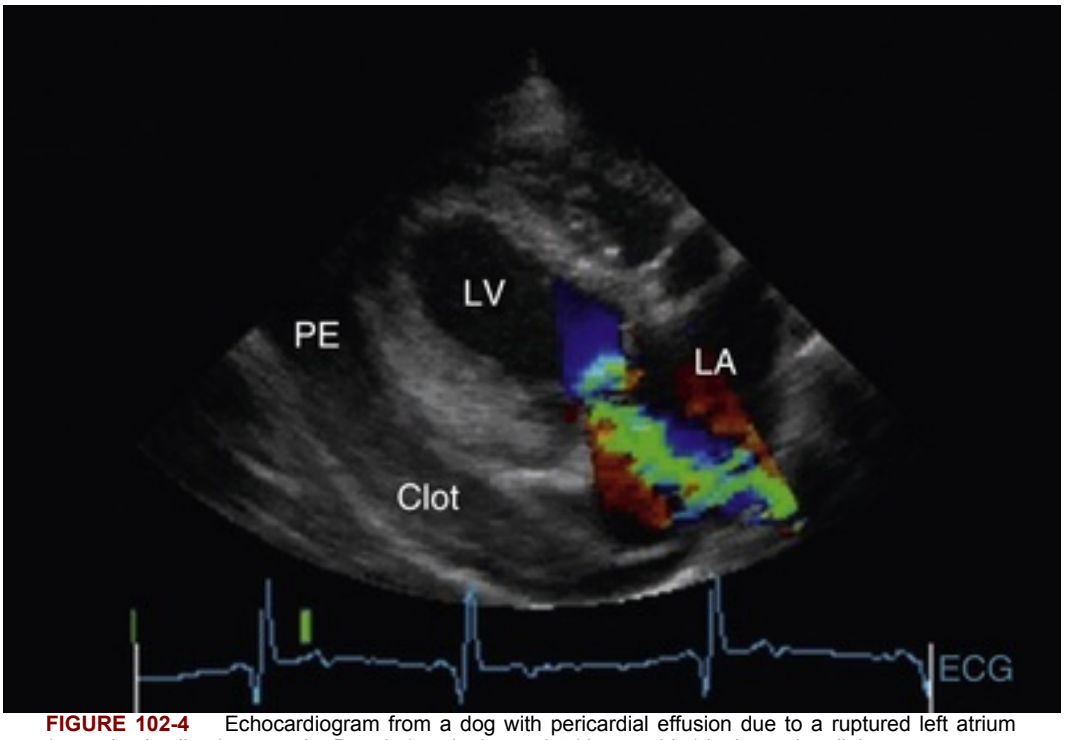

FIGURE 102-4 Echocardiogram from a dog with pericardial effusion due to a ruptured left atrium (see mixed yellow/green color Doppler) and a large clot (dense white) in the pericardial sac.

Pericardiocentesis (Video 102-2) is performed with the patient in left lateral recumbency, inserting the needle through the right hemithorax, typically at the costochondral junction of the right fourth or fifth intercostal space cranial to the rib. Ideally, the designated site for centesis is confirmed with ultrasound or if not available, by counting intercostal spaces on thoracic radiographs (see Figure 102-1). The right-sided approach is used to avoid laceration of a major coronary vessel and to a lesser degree to penetrate the larger cardiac notch, an area where the lungs do not cover the heart. The thoracic region to be tapped is widely clipped of hair and aseptically prepared.

Clip and surgically clean and prepare the region of the thorax to be approached. Prepare to have all of the following items immediately at hand to place on a sterile environment: a syringe for administering 2% lidocaine for local anesthesia (adding 0.1 to 0.2 mL of 8.4% sodium bicarbonate warmed to body temperature may decrease the initial discomfort of the lidocaine local anesthetic); sterile gloves; a #11 scalpel blade; a three-way stopcock; an extension set; a 14-gauge over-the-needle catheter or central venous catheter; several large sterile syringes; 6 mL syringes; a graduated cylinder or bowl to collect the fluid in; lavender and red top tubes for samples of the extracted fluid and possibly tissue glue (Figure 102-5).

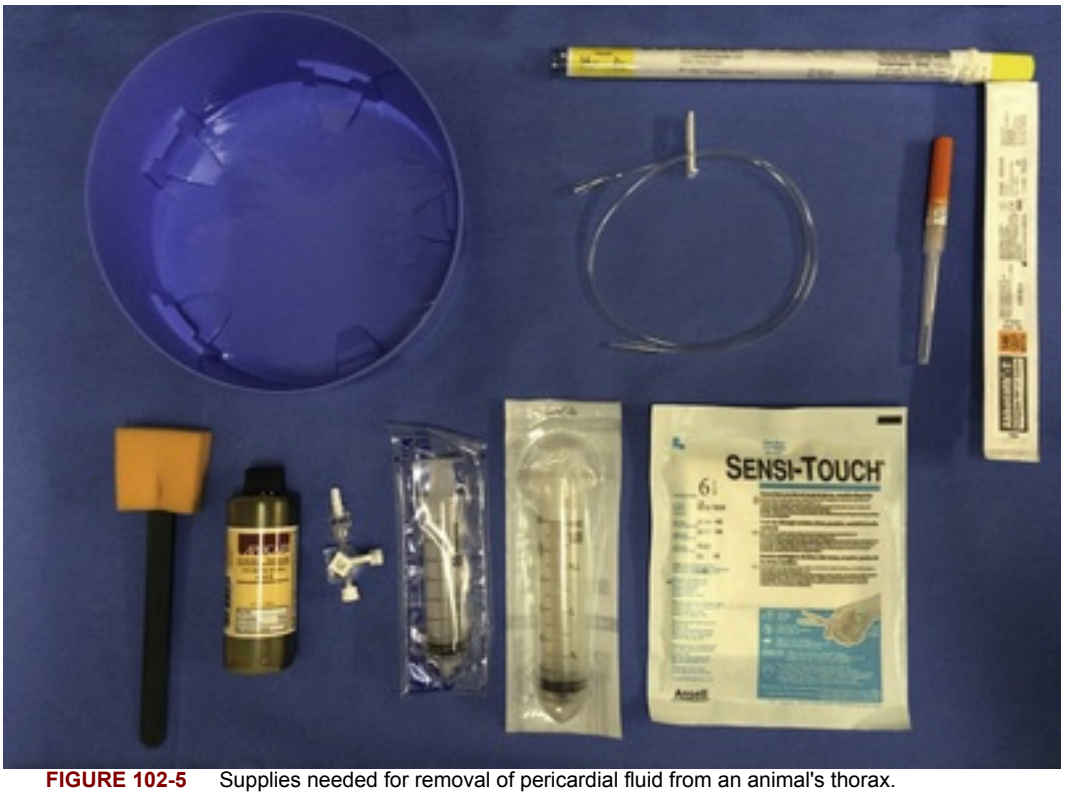

FIGURE 102-5 Supplies needed for removal of pericardial fluid from an animal's thorax.

The area for local anesthesia with 2% lidocaine is infused SC and IM in about a 2 cm^2 region (see Video 102-1). The patient's electrocardiogram should be monitored (reminder: pericardial effusion typically causes small QRS complexes). After sterile gloving, the catheter is attached to an extension set, which in turn is connected to a three-way stopcock and syringe. If needed, a scalpel blade can be used to make a small 2-3 mm skin incision. The needle or catheter-stylet combination is inserted through the skin (perpendicular to the thoracic wall into the thoracic cavity) while another person is drawing back on the syringe plunger to create negative pressure and the needle is slowly advanced towards the pericardium. Initially, a flash of serosanguineous fluid may be seen in the catheter when pleural effusion is present. Continue slowly advancing the needle until a flash of pericardial effusion is seen within the catheter (pericardial fluid is generally but not always hemorrhagic or "port wine" in color). This is usually confirmed by noting the fluid exits the needle in a soft pulsating manner as the heart beats and pushes the fluid to a lower pressure region. Once in the pericardial sac the catheter-stylet is advanced another 2-3 mm farther into the thorax, maintaining negative pressure as the catheter is advanced over the stylet to seat the catheter within the pericardial sac (monitor for arrhythmias throughout, repositioning the catheter as needed or removing it if life-threatening ventricular tachycardia develops). Remove the stylet and reconnect the extension set with the three-way stopcock attached to fill and drain the syringe into a bowl. The fluid removed should be quantified as to amount withdrawn, and if the etiology is not evident, it should be submitted for fluid analysis and cytology and culture as indicated.

Potential complications include arrhythmias (premature ventricular complexes and tachycardia), rapid reaccumulation of the effusion, cardiogenic shock (with malignancies such as hemangiosarcoma), atrial tearing and cardiac puncture. Cardiac puncture due to the catheter being advanced into the heart may not result in significant complications as long as the catheter is quickly withdrawn and repositioned. A coronary artery laceration complication is minimized using the right-sided approach. Withdrawn fluid that clots, either in the syringe or bowl, should alert the clinician that the catheter tip is in the heart, especially if flow is strongly pulsatile, or due to a rapidly bleeding pericardial effusion. Post-tap, the patient's comfort and body temperature are maintained and usually the animal rapidly becomes brighter and more mobile as the signs of cardiac tamponade regress. Radiographs and echocardiography post-tap are likely to be marred by pleural effusion as some of the fluid in the pericardial sac has leaked into the pleural space. Ultrasound examination helps to identify that the fluid has been successfully removed and the signs of cardiac tamponade have been relieved (see ch. 104, 149, and 254).

CHAPTER 103

Electrocardiography

Erin Anderson

Electrocardiography is a common, non-invasive diagnostic tool that records the electrical activity of the heart from the body surface. The resultant recordings, called electrocardiograms (ECGs, EKGs) provide valuable information about the heart rate, heart rhythm, function of the cardiac conduction system, and—with variable sensitivity and specificity—structural changes to the cardiac chambers.[1-6] Indications for obtaining an electrocardiogram include audible arrhythmias, clinical signs that could be caused by arrhythmias (such as lethargy, exercise intolerance, syncope), and assessment of antiarrhythmic therapy in patients with pathologic arrhythmias. Electrocardiograms also are commonly monitored in patients undergoing echocardiography or general anesthesia and in those with electrolyte abnormalities or critical morbidity who require intensive monitoring.

The Physics of Electrocardiography

What the ECG documents is the averaged voltage from the action potentials generated in the myocardium over time. At rest, myocytes have a negative internal charge with respect to the outside of the cell, where the charge is positive. As myocytes depolarize, the electrical charge becomes transiently positive inside the cells and negative outside the cells, creating a region of opposite charge (or polarity) compared to the adjacent non-depolarized cells.[7,8] This difference in polarity is called a dipole, and electrical currents flow readily between dipoles.[2] From the surface of the skin, negative and positive electrodes record the magnitude and orientation of the electrical wavefront; wavefronts are comprised of multiple dipoles between the electrodes (i.e., the net vector of electrical activity).[6-8] Each pair of one negative and one positive electrode constitutes a lead. Between one and 10 different leads may be used to record a surface ECG, with each lead offering a different "vantage point" from which to assess cardiac electrical activity. When the net vector of electricity moves parallel to the lead, a large amplitude deflection is recorded. When the net vector of electricity moves perpendicular to the lead, an isoelectric deflection is recorded: either flatline, or with equal amounts of the deflection existing above as below the baseline. In addition to the orientation of electricity in relation to the lead, the amplitude of the recorded deflection also depends on the voltage of the electrical wavefront, the distance of the lead from the source, and the conducting medium between the source of electricity and the electrodes.[2,6] The polarity of the deflection is determined by whether the net vector of electricity moves toward the positive or negative electrode.

Three standard leads (I, II, and III) and three augmented leads (aVF, aVL, and aVR) commonly are assessed in veterinary electrocardiography. These standard leads are generated by the combinations of electrodes on each forelimb and the left hindlimb, a configuration originally described by Willem Einthoven and still referred to as Einthoven's triangle (Figure 103-1).[9] Leads I, II, and III are bipolar, meaning that they are created by one positive and one negative electrode. In contrast, the augmented leads are unipolar, and they are created by one positive electrode and the average of the other two electrodes (a neutral reference point). The augmented leads create smaller deflections because they are unipolar, but the deflections are amplified by ECG machines (thus, the term "augmented"). Together, these six leads create a comprehensive assessment of cardiac electrical movement from various points along the frontal plane of the animal. Additionally, precordial chest leads are available for unipolar measurement of electrical activity from four different points along the dorsal and ventral planes. Recording these leads requires placement of one positive electrode at each of several specific points around the thorax (Table 103-1).[10] The leads are created by these positive electrodes and one "indifferent electrode" theoretically produced at the common junction of the three bipolar electrodes.[2,3] The nomenclature of the unipolar precordial leads originated in human cardiology but was

subsequently adapted for use in canines (see Table 103-1).[10,11]

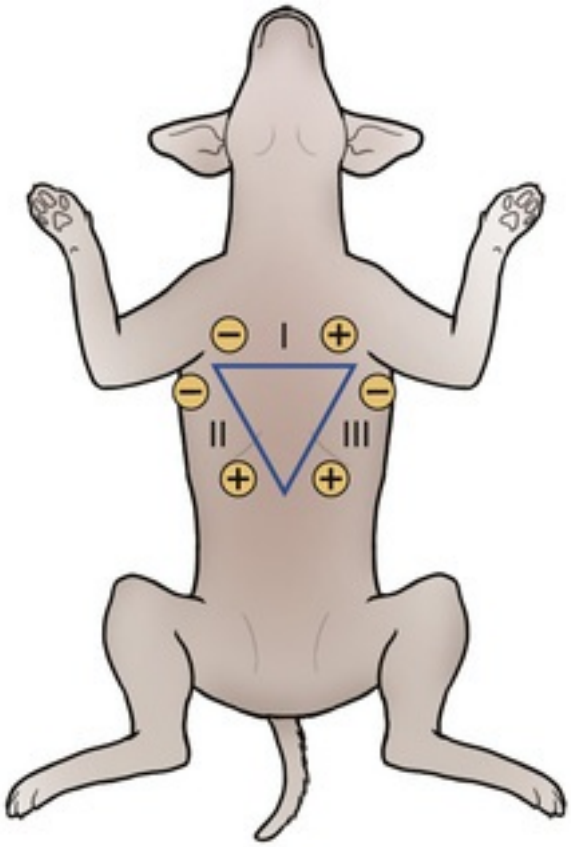

FIGURE 103-1 Einthoven's triangle is an equilateral triangle formed around the center of the heart. It is comprised of three electrodes, one on each of the forelimbs and one on the left hindlimb. Combinations of these three electrodes create three bipolar leads as follows: Lead I is created by a positive electrode on the left forelimb and negative electrode on the right forelimb. Lead II is created by a negative electrode on the right forelimb and positive electrode on the left hindlimb. Lead III is created by a negative electrode on the left forelimb and positive electrode on the left hindlimb. (Adapted from Ettinger SJ, Suter PF: *Canine cardiology,* Philadelphia, 1970, Saunders.)

TABLE 103-1

Electrode Position for Precordial Chest Leads

LEAD	CHEST LOCATION
V_1 (CV_5RL)	Fifth intercostal space, right parasternum
V_2 (CV_6LL)	Sixth intercostal space, left parasternum
V_4 (CV_6LU)	Sixth intercostal space, left costochondral junction
V_{10} (V_6)	Dorsal spinous process of T7

In whole, this creates 10 different recorded leads, all of which provide unique vantage points for "viewing," assessing, and measuring cardiac electrical activity. From these recordings, one can count the heart rate and identify the heart rhythm. There are also various reported criteria with variable degrees of sensitivity and specificity for identifying chamber enlargement and conduction disturbances (Table 103-2).[2,3,6,11-18]

TABLE 103-2

References Ranges for Normal Electrocardiograms in Dogs and Cats

	DOGS	CATS
Heart rate (beats per minute)	70-160 (adult dogs); 60-140 (giant breeds), 80-180 (toy breeds); up to 220 in puppies	140-240 in hospital setting (can be as low as 100-120 in home environment)
P wave amplitude (in millivolts [mV])	≤0.4	≤0.2
P wave duration (in milliseconds [msec])	<40 (up to 50 in giant breeds)	<40
P-R interval (in msec)	60-130 (varies inversely with heart rate)	50-90 (varies inversely with heart rate)
R wave amplitude (in mV)	0.5-2.5 or 3.0 in leads II, III, and aVF; <3 mV in V10 (V6); <5 mV in V2 and V4	<0.9
QRS duration (in msec)	<60	<40
Q-T interval (in msec)	150-250 (varies inversely with heart rate)	70-200 (varies inversely with heart rate)
ST segment (in mV)	<0.2 mV depression in limb leads and <0.25 mV depression in precordial leads; <0.15 mV elevation in leads II and III; coving or slurring of the ST segment may indicate abnormal repolarization.	No depression or elevation
T wave	Can be positive, negative, or biphasic; amplitude is <25% of R wave amplitude; positive in lead V1 and negative in V10(V4); positive in V10 in Chihuahuas	Can be positive, negative, or biphasic, but usually positive; amplitude should be <0.3 mV.
Mean electrical axis	+40° to +100°	0° to +/−180°

Recording the Electrocardiogram

Recording the ECG (Video 103-1) requires first restraining the patient in right lateral recumbency. This is the preferred patient position because the majority of published reference intervals for measurements of waves, complexes, and the mean electrical axis were obtained from animals in right lateral recumbency.[14-19] Recordings from sternal or left lateral recumbency or a standing position are often sufficient for interpreting the heart rate and rhythm, but the size and orientation of different deflections are altered to varying degrees.[1,19-22] Importantly, the patient should be restrained on the floor, a rubber or foam mat, or a non-metal table and not on a conductive surface. One or two assistants should be behind the patient with arms draped over the patient's neck and lateral left limbs, grasping the dependent (right) fore- and hindlimbs to maintain restraint. The patient's forelimbs should be drawn cranially and hindlimbs drawn caudally, such that the humerus and femur of each fore- and hindlimb, respectively, are perpendicular to the trunk (Figure 103-2). This avoids artifactual deviations in recorded parameters that have been reported in cats that spontaneously "tuck" their limbs.[20-22]

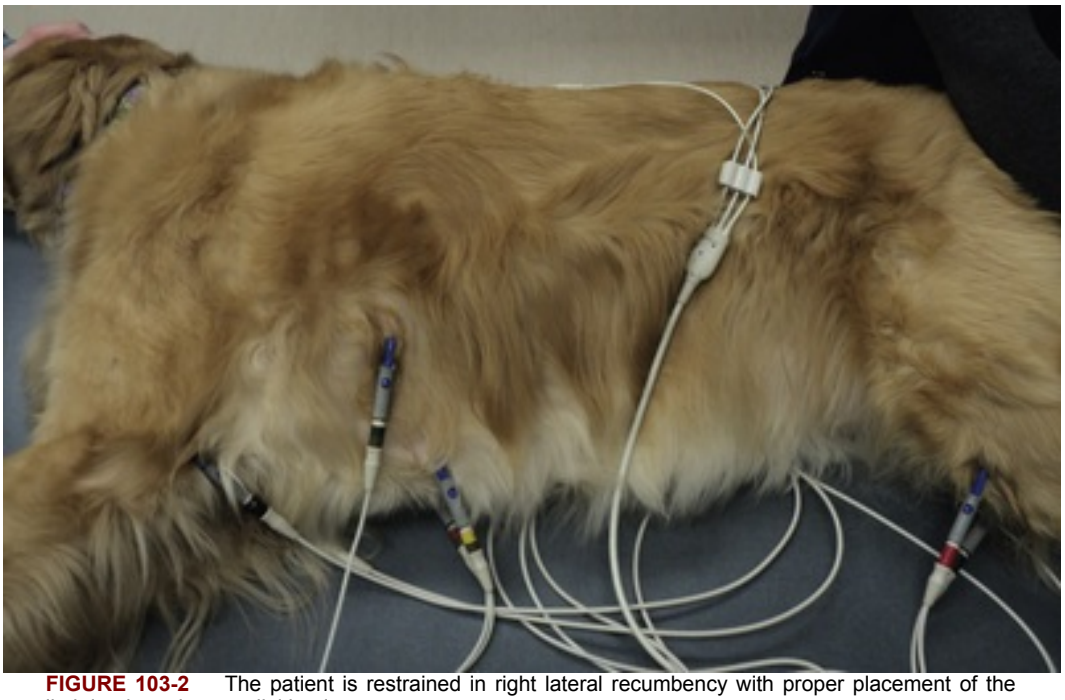

FIGURE 103-2 The patient is restrained in right lateral recumbency with proper placement of the limb leads and precordial leads.

The recording electrodes commonly are incorporated into alligator clips, small metal plates, or self-adhesive patches, any of which can be attached directly to the skin. The electrodes are color-coded: the white electrode is placed on the right forelimb, the black electrode on the left forelimb, the green electrode on the right hindlimb, and the red electrode on the left hindlimb. If alligator clips are used, the forelimb clips are affixed to the skin directly proximal to the elbows, the hindlimb clips directly over the stifles, and the precordial electrodes in their respective locations (see Table 103-1). When metal plates are used, the flat surface of the plate should make full contact with the caudal aspect of the metacarpus or metatarsus**.** Self-adhesive patches usually are affixed to the palmar (or plantar) surface of the paw, against the unhaired paw pads, so that removal of the patch is atraumatic. Contact between the skin and electrodes of the clips or plates should be optimized by moistening the skin with a conducting liquid or ECG paste, before or after affixing the electrodes in their appropriate position.[23] The patient should be encouraged to remain as calm and still as possible throughout recording in an effort to avoid the baseline artifact that comes from panting, purring, or muscle motion. Electrical interference (such as electrocautery or 60 Hz alternating current) should be avoided as much as possible by ensuring appropriate grounding via the use of a grounding electrode and adequate contact between electrode and skin.[3] Another tool for controlling artifactual electrical interference is the use of ECG filters, which filter out signals above a selected frequency. Filters can unintentionally distort the ECG signal and lead to an artifactually high frequency response, which reduces the R wave amplitude (the highest frequency component of the ECG spectrum) and/or dampens other subtle but clinically important high frequency features of the ECG (e.g., notching or ST slurring).[24,25] In order to maximize the use of filters in veterinary electrocardiography, 50 Hz filters are ideally used in dogs, and 150 Hz filters are ideally used in cats.[26]

The ECG can be recorded at various paper speeds, most commonly 25 and/or 50 millimeters/second on dedicated, calibrated paper. The amplitude calibration can be altered as necessary to produce complexes of various heights. Calibration should be optimized to produce complexes that are easily visible and measurable; 10 millimeters/millivolt is standard, but 20 mm/millivolt will make deflections larger (which can be particularly helpful in cats), and 5 mm/millivolt will make deflections smaller.

As many leads as possible should be recorded for several depolarizations or, ideally, for several minutes. Assessing more than one lead helps the clinician better understand the cardiac electrical activity (similar to the way thorough evaluation of thoracic radiography requires two orthogonal projections instead of a single lateral projection). Assessing the electrocardiographic recording requires interpreting the heart rate, rhythm, criteria for chamber enlargement, and mean electrical axis. This material is discussed further in ch. 248 (Cardiac Arrhythmias) with normal references ranges reported in Table 103-2.[1-6,13-18,27-32]

Ambulatory Monitoring

Extended ambulatory ECG monitoring can be achieved with an external cardiac event monitor, a Holter monitor, or an implantable loop recorder.[33-37] External cardiac event monitors and Holter monitors both feature surface electrodes adhered to the patient's skin and attached to a portable monitor, which is worn by the patient. Holter monitors continuously record the ECG for 24 or 48 consecutive hours. This is commonly pursued for one of several purposes: (1) to investigate intermittent clinical signs that are suspected of having an arrhythmic etiology; (2) to evaluate the extent and severity of a known arrhythmia; or (3) to investigate the need for, or efficacy of, antiarrhythmic therapy.[2,3,6,33,34] In contrast, an external cardiac event monitor will continuously monitor the ECG but only record it after physical depression of a "trigger" button on the device.[35] In this way, the monitor can be worn for the duration of battery life (usually 5-7 days); this longer monitoring period increases the likelihood of recording events that do not occur daily, potentially offering a higher diagnostic yield than a 24-hour Holter monitor.[6,35,36] Capturing the ECG during an episode of collapse can either implicate a cardiac arrhythmia as the inciting cause or acquit arrhythmogenic causes if the heart rate and rhythm are appropriate.

Internal events monitors like implantable loop recorders (ILRs, the Reveal monitor) are subcutaneously-implanted devices that can be programmed for manual and/or automatic recording of ECG in animals with very infrequent episodes of syncope, collapse, or weakness.[37,38] The recording device remains in the subcutaneous space on the thorax and can be activated via an owner-operated "remote control" device applied to the thorax when clinical signs arise. The data are retrieved with the use of software on a pacemaker interrogator, a device that is in common usage among veterinary cardiologists. These loop recorders are easy to implant, carry a low risk of complications, and can be left in place until an event is captured or the end of battery life (often several months). In veterinary medicine, ILRs have been reported to provide a diagnostic yield of 48-58% in dogs with intermittent weakness and/or syncope.[37,38]

Perhaps the newest device available for ECG recording is an application available on iPhones. The AliveCor Veterinary Heart Monitor incorporates wireless electrodes into a specialized smartphone case. Using this application and device, one must simply make contact between the case and the left side of the thorax of a patient restrained in right lateral recumbency. Comparison of the human-specific application (AliveCor Heart Monitor) to a standard diagnostic 6-lead ECG in 46 dogs and 23 cats showed identical instantaneous heart rate calculations, very accurate 15-second rhythm recordings, and high intra-observer agreement regarding rhythm diagnosis.[39] The AliveCor recordings produced different polarity complexes occasionally in dogs and frequently in cats.[39] This method of wireless ECG offers an innovative and widely available complement to standard electrocardiography.

CHAPTER 104

Echocardiography

Marie-Claude Bélanger *

Echocardiography is a unique noninvasive tool that provides substantial information about cardiac size, structure, and function. Since its introduction by Edler and Hertz in Sweden in 1953,[1,2] clinical echocardiography has become an essential component of small animal cardiovascular diagnostic evaluations[3-10] (see ch. 250-255).

Principles of Ultrasound Physics[6-8]

Propagation of sound waves is favored by fluids and soft tissue and inhibited by bone, metal, and air. The basic idea of any ultrasound is that the probe emits a pulse of sound that penetrates the target tissue. A portion of that emitted ultrasound will go through the organ and will be lost, whereas another portion of the ultrasound will be reflected back to the probe. If much of the sound is reflected back, as from the myocardium, for example, the structure is said to be *hyperechoic* and will appear on the screen as a whiter image. When very little of the sound is captured back, as in blood or effusions, the structure is called *hypoechoic* and appears dark on the screen.

The echocardiographic ultrasound beam is generated by a phased-array transducer (probe) that consists of a series of small piezoelectric crystals that produce sound waves that travel in cycles. Sector scanning probes usually are preferred in echocardiography because of the necessity to use probes with small footprints that will allow imaging of the heart through the narrow intercostal spaces of small animals.

The frequency of a transducer is determined by the number of cycles it sends out per minute. High-frequency transducers (7.5-10 MHz) emit more cycles per time unit and thus have shorter wavelengths (low penetrating power). These transducers reflect sound from smaller structures and therefore produce a better image definition and resolution but less tissue penetration than low-frequency transducers. Low-frequency transducers have deeper penetration and produce superior Doppler signals but the resulting image has poorer resolution. In other words, the higher the frequency of the probe, the less tissue penetration is achieved. The choice of transducer therefore is determined by the size of the patient, since tissue penetration is inversely proportional to the frequency of the probe. Cats and small dogs usually require 7- to 10-MHz transducers. A 5-MHz probe is appropriate for most dogs. Very large dogs might require a 2.5- to 3.5-MHz transducer to obtain optimal tissue penetration. Some transducers have a frequency bandwidth allowing a single probe to operate at multiple frequencies. This useful feature allows the sonographer to adjust to the proper frequency on a given patient, without changing probes.

Equipment[5-8]

The quality of images obtained from echocardiographic studies depends on the sophistication and technology of the ultrasound machine, the skill and experience of the operator, as well as individual patient characteristics. Most veterinary sonographers position dogs and cats in lateral recumbency and approach the thorax from underneath. This position favors a larger acoustic window and better image quality since gravity improves the degree of contact between the cardiac structures and the chest wall. A special table (purchased or custom-made) with adjustable openings is used for creating a large and stable acoustic window (Figure 104-1). Echocardiograms also can be performed from a standing position, particularly in giant-breed dogs.

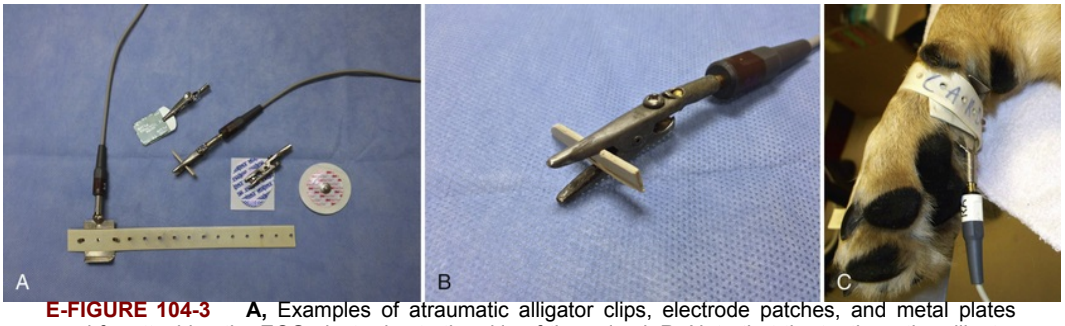
FIGURE 104-1 Typical setting for echocardiographic studies in small animals. Rectangular (here) or semicircular cutouts allow the transducer to be introduced from the bottom of the scanning table.

Technical Aspects[5-8,10]

In animals, the fur usually is clipped to improve transducer-skin contact and image quality, and coupling gel is applied over the right or left precordial thoraces. It is important to remember to obtain owners' and breeders' consent before clipping fur. Clipping sometimes is unnecessary in dogs with very short or sparse hair. The application of isopropyl alcohol or water can sometimes replace the coupling gel since it provides good but briefer contact. The animal is gently restrained in lateral recumbency on an echocardiographic table (see Figure 104-1 and E-Figure 104-2, *A* and *B*). One experienced restrainer is usually adequate. Sandbags also can be placed over the hindlimbs to limit the need for an additional restrainer. The patient's forelimbs should be pulled cranially in order to keep the elbows out of the area of interest. However, this position should not be exaggerated, as it can sometimes become uncomfortable in older animals with orthopedic diseases.

E-FIGURE 104-2 **A,** The animal is held in lateral recumbency with the shaved thoracic window over the hole. The examiner is scanning from the right parasternal location. **B,** Adequate positioning of the animal with only one restrainer. An Elizabethan collar can sometimes be useful in fractious cats as a means of protection for the restrainer. (**B,** Image reproduced with permission from Elsevier, Inc., and courtesy of Côté E: Echocardiography: common pitfalls and practical solutions. *Clin Tech Small Anim Pract* 20:156-163, 2005.)

Simultaneous ECG is obtained during the echocardiographic examination to allow accurate timing of measurements. Electrodes are attached to the skin (standard color code; see ch. 103) with atraumatic alligator clips, electrode patches, or metal plates held by bracelets (E-Figure 104-3, *A-C*).



E-FIGURE 104-3 **A,** Examples of atraumatic alligator clips, electrode patches, and metal plates used for attaching the ECG electrodes to the skin of the animal. **B,** Note that the teeth on the alligator clips have been sanded away and filled with solder to be more comfortable for the animal. **C,** Metal plates held by bracelets are particularly easy to use, comfortable for the patient, and reusable.

An echocardiogram usually can be performed in dogs and cats without chemical restraint since the procedure is painless, quiet, and peaceful. On the other hand, sedation has the advantage of minimizing stress, examination time, and poor image quality in squirmy patients (see ch. 138). An Elizabethan collar sometimes can be useful to protect technicians from cats that are fractious but are not good candidates for sedation (see E-Figure 104-2, *B*). Truly uncooperative, anxious, or aggressive animals in which an underlying cause of discomfort has not been found (e.g., painful joint disease, pulmonary edema, etc.) could require sedation. Table 104-1 lists sedation protocols used for echocardiography. Animals with overt clinical signs of congestive heart failure (CHF) should have such signs relieved with diuretics before the echocardiogram is performed, since the echocardiographic results will rarely change the immediate treatment plan (see ch. 247).

TABLE 104-1

Suggested Sedation Protocols for Echocardiography

SITUATIONS	DRUGS
Canine Sedation Protocols	
Most asymptomatic dogs needing sedation	Butorphanol 0.2 mg/kg ± midazolam 0.2 mg/kg IM or IV or if very uncooperative: butorphanol 0.2 mg/kg IM + acepromazine 0.025-0.05 mg/kg IM in the same syringe

Aggressive asymptomatic dog	Hydromorphone 0.1 mg/kg + midazolam 0.2 mg/kg IM in the same syringe
If sedation needed rapidly	Butorphanol 0.2-0.3 mg/kg IV
Puppies	Acepromazine 0.005 mg/kg + buprenorphine 0.01 mg/kg IV Or Butorphanol 0.2 mg/kg ± midazolam 0.2 mg/kg IM or IV
Dog with congestive heart failure or pathologic arrhythmia	Butorphanol 0.2 mg/kg ± midazolam 0.2 mg/kg IM or IV (treat with furosemide before ultrasound if dyspneic due to cardiogenic pulmonary edema)
Feline Sedation Protocols	
Most asymptomatic cats needing sedation	Butorphanol 0.2 mg/kg IM or IV or if very uncooperative: butorphanol 0.2 mg/kg IM + acepromazine 0.05 mg/kg IM in the same syringe
Aggressive asymptomatic cat	Acepromazine 0.05-0.1 mg/kg + hydromorphone 0.1 mg/kg SC or IM Or in very aggressive cats: dexmedetomidine 10 mcg/kg IM then reverse with atipamezole 100 mcg/kg IM when procedure is complete (inject same volume of atipamezole as used for dexmedetomidine)
Kittens	Butorphanol 0.2 mg/kg IM
Cat with congestive heart failure or pathologic arrhythmia	Butorphanol 0.2 mg/kg (+ acepromazine 0.025 mg/kg if uncooperative) IM (treat with furosemide before sedation if dyspneic due to cardiogenic pulmonary edema)

The Normal Echocardiogram: Image Acquisition, Standard Views, and Sequence[5-8,10,11]

A comprehensive echocardiographic study includes two-dimensional (2-D), M-mode, and finally, Doppler imaging. The examination always starts with the 2-D study, which provides orientation, reference, and diagnostic clues for M-mode and Doppler imaging (see E-Table 104-8). The most important information given by an echocardiogram often is not confined to the screen of the machine. It is essential to combine the echo findings with the observation of the patient itself. An accurate diagnosis combines a good physical examination and thorough history with an echocardiographic examination. Moreover, echocardiography should never replace thoracic radiographs since it does not give comparable information regarding the lungs such as the presence of cardiogenic pulmonary edema.

2-D Echocardiography

Two-dimensional echocardiography is used for evaluating the cardiac structural changes resulting from congenital defects or other cardiac diseases. It produces a real-time anatomic representation of the heart throughout the cardiac cycle. A complete 2-D study includes the imaging of all valves, proximal segments of great vessels, and relative sizes and wall thicknesses of the cardiac chambers (Video 104-1).

Two-dimensional echocardiography provides images of thin "slices" of the heart and blood flow. Each of these standard slices is conventionally defined by the position of the transducer on the animal (the transducer's *location* in the *acoustic window*) and the image plane of the heart (or *view*). Images are obtained from standard locations, which allow for specific portions of the heart to be visualized in detail. The right parasternal, left cranial parasternal, left apical, and subcostal positions are used most often, but a multitude of planes can be obtained to better visualize a distinct part of the heart.

Most of the heart is covered by sonographically impenetrable structures such as bones (ribs and sternum) and lungs. However, the right lung does not cover the heart completely (the cardiac notch), and there is an area just dorsal to the sternum at the fourth or fifth intercostal space where the pericardium lies directly beneath the chest wall. This region corresponds to the *right parasternal window*. For most patients, placement of the probe on the area of the right hemithorax where the heartbeat is palpable is generally the best starting point. For canine brachycephalic breeds, where the thoracic conformation is ventrodorsally compressed, the best acoustic window is obtained by placing the probe closer to the sternum or more ventrally than usual. The marker of the probe should be pointing toward the animal's shoulder in order to obtain a standard long-axis, four chamber view (Figure 104-4, *A* and *B*). The views that are routinely obtained at the right parasternal location are the long-axis four chamber view (see Figure 104-4), the long-axis left ventricular outflow view

(Figure 104-5), and the different short-axis views (Figure 104-6). The long-axis view is obtained with an imaging plane that transects the heart parallel to its long axis from apex to base, whereas a perpendicular imaging plane reveals the short-axis views (see Figures 104-4 and 104-6). Technically, this means that the short-axis views can be obtained from the long-axis views by a 90° rotation of the probe, but minor adjustments are necessary for each individual patient. The echocardiographer must always adjust the depth and gain settings to optimize the image on the monitor. By convention, the heart, on a 2-D view, should occupy two-thirds to three-fourths of the screen. The subcostal or subxiphoid position is used specifically to evaluate the left ventricular outflow tract (LVOT) in the dog (Figure 104-7). The image obtained from the subcostal view often can be improved by having the dog inhale after occluding its mouth and nostrils for 5 seconds. Inspiration shifts the diaphragm caudally and pushes the heart toward the transducer.

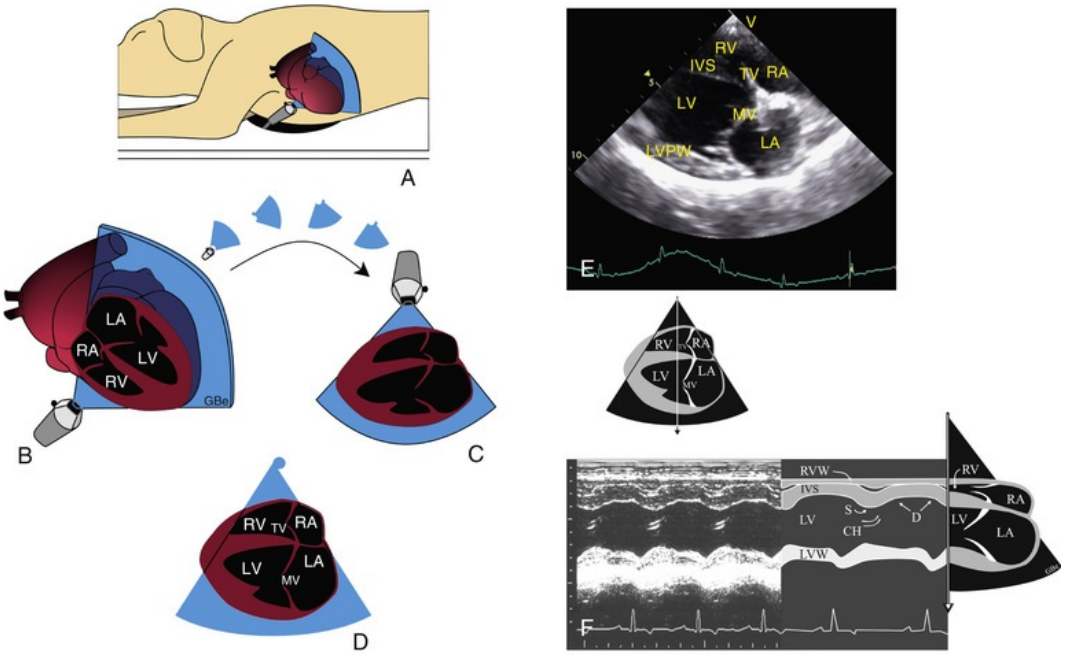


FIGURE 104-4 **A,** Typical positioning of the animal for visualization of the right parasternal long-axis view. In most dogs, the long axis of the heart is parallel to an imaginary line connecting the shoulder to the xiphoid. **B,** Spatial orientation of the right parasternal location, long-axis four-chamber view. **C,** Spatial orientation of the right parasternal location, long-axis four-chamber view as observed on the ultrasound monitor. **D,** Illustration of the different cardiac structures observed via this window. **E,** 2-D image of the right parasternal location, long-axis four-chamber view. **F,** Corresponding M-mode image obtained from this window. FIGURE 104-6 Standard 2-D echocardiographic study obtained from the right parasternal location, short-axis views at the level of **(A)** the apex, **(B)** the papillary muscles, **(C)** the chordae tendineae (CH), **(D)** the mitral valve, **(E)** the aorta, and **(F)** the pulmonary arteries. *AMV,* Anterior mitral valve leaflet; *APM,* anterior papillary muscle; *AS,* atrial septum; *CaVC,* caudal vena cava; *CrVC,* cranial vena cava; *IVS,* interventricular septum; *LA,* left atrium; *LC,* left coronary aortic cusp; *LPA,* left pulmonary artery; *LV,* left ventricle; *NC,* noncoronary aortic cusp; *PA,* pulmonary artery; *PMV,* posterior mitral valve leaflet; *PPM,* posterior papillary muscle; *PV,* pulmonary valve; *RA,* right atrium; *RAu,* right auricle; *RC,* right coronary aortic valve cusp; *RPA,* right pulmonary artery; *RV,* right ventricle; *RVO,* right ventricular outflow; *S,* systole; *TV,* tricuspid valve. (Modified from Thomas WP, Gaber CE, Jacobs GJ, et al: Recommendations for standards in transthoracic two-dimensional echocardiography in the dog and cat. Echocardiography Committee of the Specialty of Cardiology, American College of Veterinary Internal Medicine. *J Vet Intern Med* 7:247-252, 1993.)

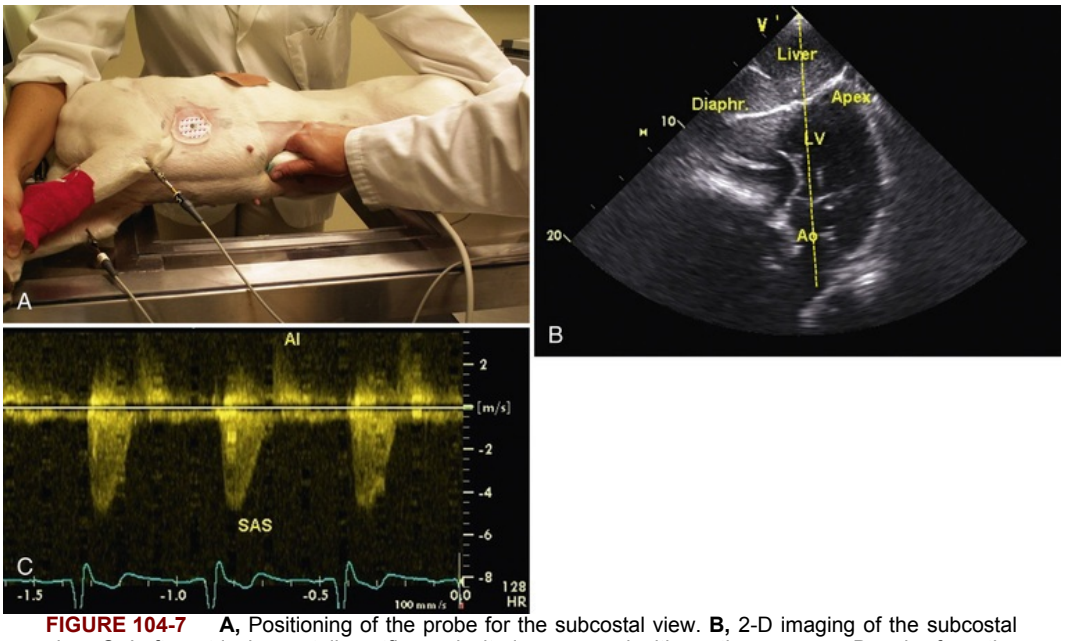

FIGURE 104-7 **A,** Positioning of the probe for the subcostal view. **B,** 2-D imaging of the subcostal view. **C,** Left ventricular systolic outflow velocity is measured with continuous-wave Doppler from the subcostal view, in a dog with severe subaortic stenosis. *AI,* Aortic insufficiency; *AO,* aorta; *LV,* left ventricle; *SAS,* high-velocity flow consistent with subaortic stenosis.

The second half of the echocardiographic study consists of the left-sided views. One should always perform the echocardiogram on both sides of the thorax. Evaluating only the right side is similar to the auscultation of only one lung: some information is gained but much information is missed. As opposed to the right parasternal location, there are two acoustic windows on the left side. The left cranial parasternal views are obtained at the level of the fourth intercostal space, whereas the left caudal (apical) parasternal views are best visualized through the animal's fifth to sixth intercostal spaces (Figure 104-8). These views can be obtained with the patient in left lateral recumbency. Alternatively, some sonographers obtain these views by keeping the patient on its right side and moving the transducer over the left side of the thorax.

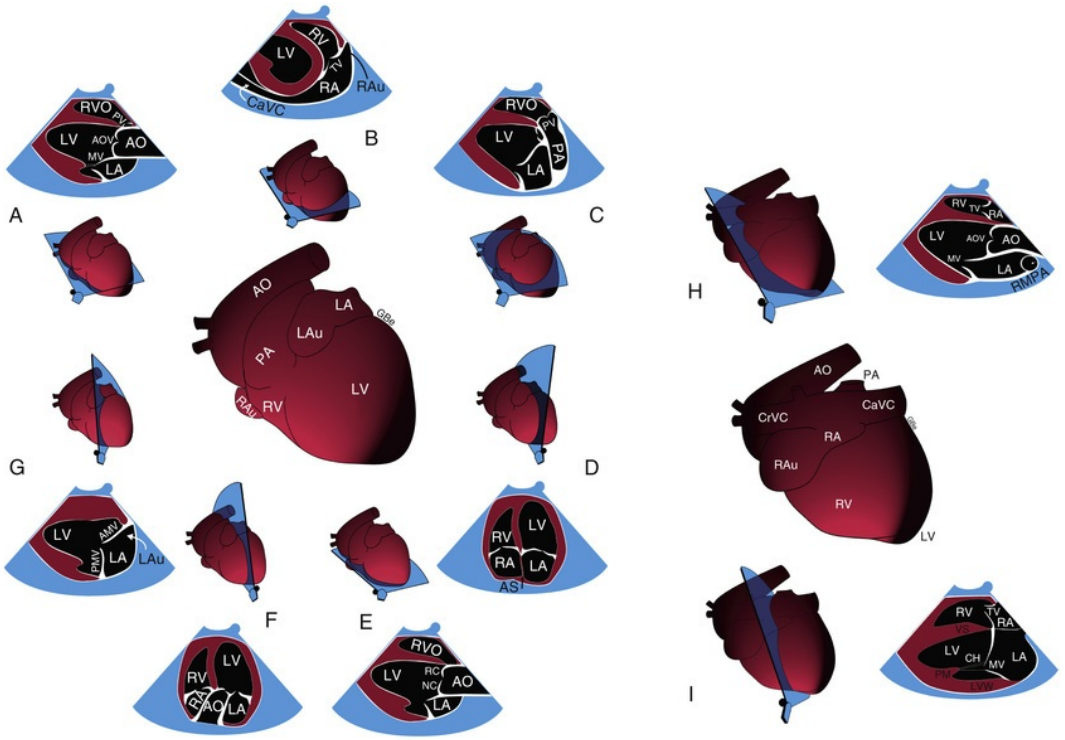

FIGURE 104-8 Standard 2-D long-axis views. **A,** Left cranial parasternal view optimized for the aortic root. **B,** Left cranial parasternal view optimized for right atrium and auricle. **C,** Left cranial parasternal view optimized for the right ventricular outflow tract and main pulmonary artery. **D,** Four-chamber inflow view from the left caudal (apical) parasternal position. **E,** Left caudal (apical) parasternal view optimized for visualization of the left ventricular outflow tract. **F,** Five-chamber left ventricular outflow view from the left caudal (apical) parasternal position. **G,** Left caudal (apical) parasternal location, two-chamber view optimized for visualization of the left ventricular inflow and left auricle. **H,** Left ventricular outflow view from the right parasternal position. **I,** Four-chamber right parasternal long-axis view. *AO,* Aorta; *AOV,* aortic valve; *AMV,* anterior mitral valve leaflet; *AS,* atrial septum; *CaVC,* caudal vena cava; *CH,* chordae tendineae; *LA,* left atrium; *LAu,* left auricle; *LV,* left ventricle; *LVW,* left ventricular wall; *MV,* mitral valve; *NC,* noncoronary aortic valve cusp; *PA,* pulmonary artery; *PM,* papillary muscle; *PMV,* posterior mitral valve leaflet; *PV,* pulmonary valve; *RA,* right atrium; *RAu,* right auricle; *RC,* right coronary aortic valve cusp; *RMPA,* right pulmonary artery; *RV,* right ventricle; *RVO,* right ventricular outflow; *TV,* tricuspid valve. (Modified from Thomas WP, Gaber CE, Jacobs GJ, et al: Recommendations for standards in transthoracic two-dimensional echocardiography in the dog and cat. Echocardiography Committee of the Specialty of Cardiology, American College of Veterinary Internal Medicine. *J Vet Intern Med* 7:247-252, 1993.)

To obtain specific views of the cardiac structures or optimize the quality of images, the operator must always remember that the transducer can be moved in at least 3 different ways as illustrated in Figure 104-9:

- *Rotation* or *twisting:* rotation of the transducer in a single position to view the corresponding intersecting or perpendicular planes.
- *Tilting:* the transducer tip is repositioned in a rocking motion or angled to image different structures in the same plane.
- *Translation* or *sliding:* movement of the transducer to a different position on the patient's thorax to examine a specific cardiac structure from the best location; e.g., moving from one intercostal space to another.

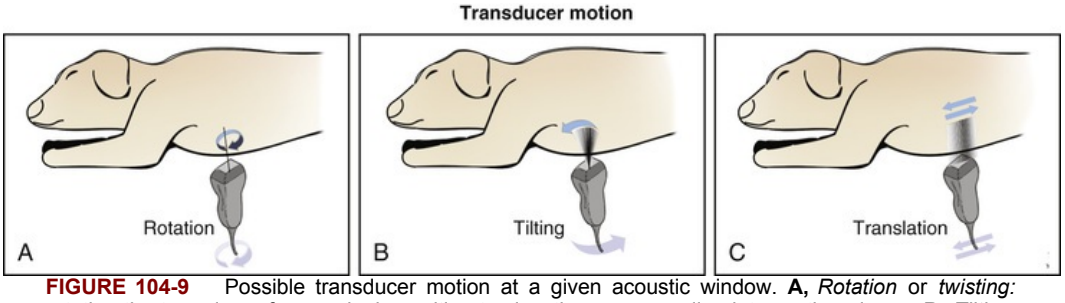

FIGURE 104-9 Possible transducer motion at a given acoustic window. **A,** *Rotation* or *twisting:* rotating the transducer from a single position to view the corresponding intersecting planes; **B,** *Tilting:* rocking the head of the probe to image different structures in the same plane or adjacent planes; and **C,** *Translation* or *sliding:* moving the transducer to a different position on the thorax to examine a specific cardiac structure from the best location.

M-Mode Echocardiography

M-mode refers to real-time *motion-mode*. M-mode echocardiography is used for evaluating the phasic motion of the cardiac structures during the cardiac cycle. M-mode echocardiography is complementary to the 2-D echocardiogram since it has a higher sampling rate (faster frame rate), allowing better resolution of rapidly moving structures. It is especially useful to record subtle changes in wall and valve motion and historically has been used for performing measurements of chamber diameters and wall thicknesses.[12-16] The M-mode image is viewed on a video screen, where depth of the structures is plotted on the Y axis and time is shown on the X axis. Only the structures transected by the cursor are seen on the M-mode images. The steerable cursor scrolls across the heart, and the associated changes in thickness or position of the structures are recorded on the screen as the cardiac chamber of interest fills and empties (Figure 104-10).

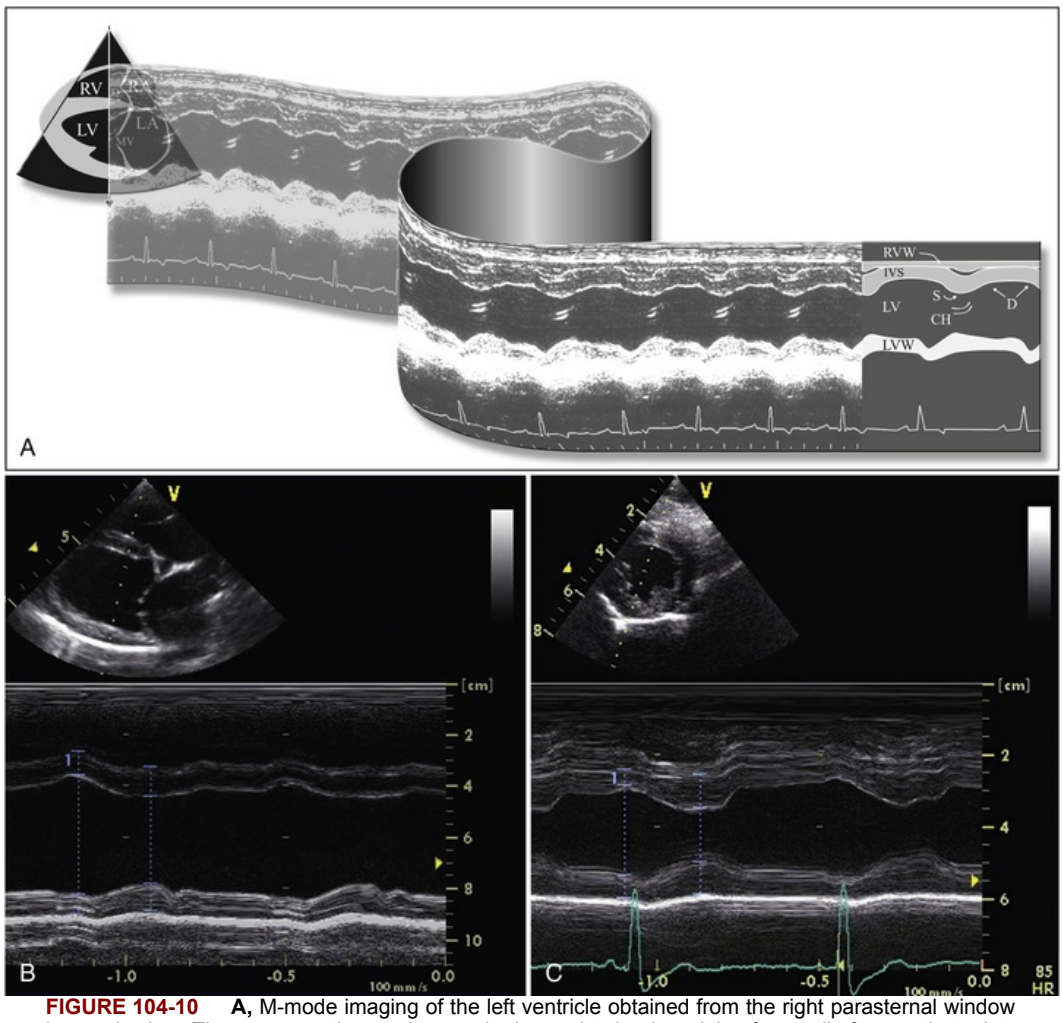

FIGURE 104-10 **A,** M-mode imaging of the left ventricle obtained from the right parasternal window long-axis view. The cursor on the monitor can be imaged to be the origin of a scroll of paper that prints as the ventricles fill and empty. **B,** M-mode right parasternal long-axis view and **(C)** right parasternal short-axis view.

In veterinary medicine, M-mode echocardiography generally is performed only from the right parasternal location (long- and/or short-axis views). The usual M-mode echocardiogram includes an evaluation of the left ventricle (LV; see Figure 104-10), mitral valve, and aortic root (Figure 104-11).

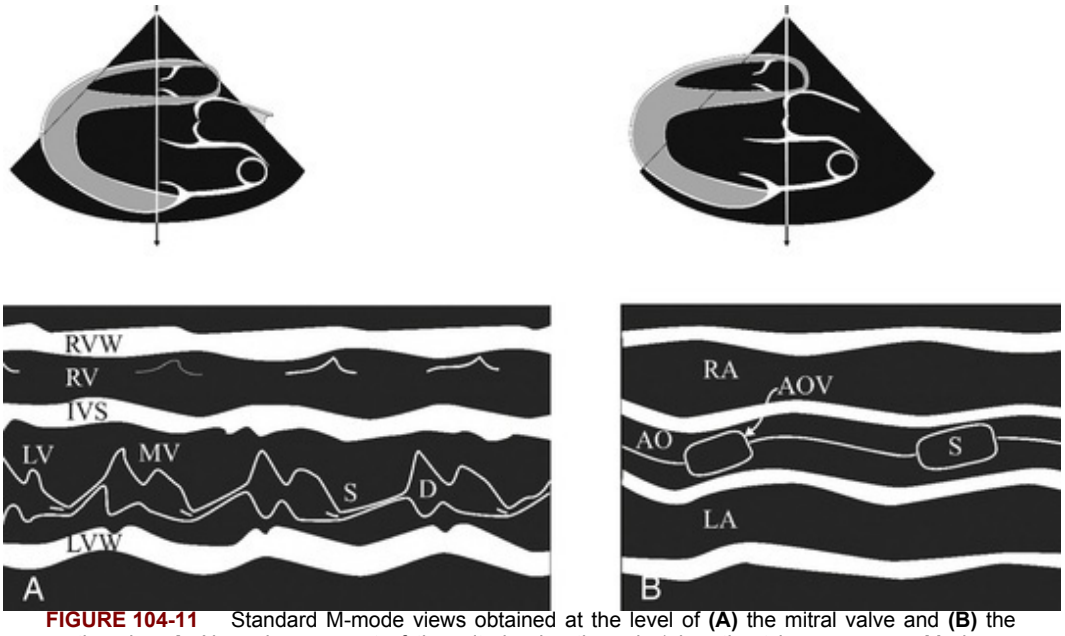

FIGURE 104-11 Standard M-mode views obtained at the level of **(A)** the mitral valve and **(B)** the aortic valve. **A,** Normal movement of the mitral valve through 1 heartbeat is seen as an M shape. During rapid ventricular filling (early diastole), the mitral valve is forced to open, with its leaflets moving toward the interventricular septum and LV free wall. As ventricular filling progresses, the pressure in the LA equalizes with the LV pressure and the mitral leaflets move toward each other. Finally, the mitral leaflets open again during atrial contraction. Closure of the mitral valve occurs after atrial systole. **B,** During diastole, the line in the middle of the aorta represents the closed aortic cusps. During systole, the aortic valve opens toward the walls of the aorta, remains open during the systolic ejection of blood, and then rapidly closes at the end of systole. *AO,* Aorta; *AOV,* aortic valve; *D,* diastole; *IVS,* interventricular septum; *LA,* left atrium; *LV,* left ventricle, *LVW,* left ventricular wall; *MV,* mitral valve (anterior leaflet); *RA,* right atrium; *RV,* right ventricle; *RVW,* right ventricular wall; *S,* systole.

As recommended by the American Society of Echocardiography (ASE), end-diastolic LV measurements are taken at the onset of the QRS complex (or the frame after mitral valve closure) and end-systolic measurements are made at the level of the maximum inward excursion of the interventricular septum.[17] The *leading edge* method is used (i.e., the measurements of each echo line are made beginning at the edge that is closest to the transducer). The sonographer should be aware that a tremendous potential exists for artifacts and error when the M-mode image is obtained in a suboptimal plane (e.g., tangential slices).

The LV M-mode study provides absolute measurements of the LV walls and chamber during systole and diastole (Tables 104-2 through 104-5). It can be performed using the right parasternal long-axis four chamber view or the right parasternal short-axis view at the level of the papillary muscles (see Figure 104-10). These M-mode measurements also are used for calculating the ejection phase indices described in the section on the evaluation of systolic function.

Ao_D, Aortic root diameter in diastole; *EPSS*, E-point to septal separation; *FS*, fractional shortening; *IVS_{ED}*, interventricular septal thickness at the end of diastole; *IVS_{ES}*, interventricular septal thickness at the end of systole; *LA_S*, left atrial diameter in systole; *$LVID_{ED}$*, left ventricular internal diameter at the end of diastole; *$LVID_{ES}$*, left ventricular internal diameter at the end of systole; *LVW_{ED}*, left ventricular posterior wall thickness at the end of diastole; *LVW_{ES}*, left ventricular posterior wall thickness at the end of systole.

These measurement guidelines are based on the author's experience and published data.

An important limitation of M-mode is the standardized position of samples, which means regional or focal lesions can be missed. It is for this reason that 2-D measurements of LV parameters are gaining favor, especially in cats being evaluated for hypertrophic cardiomyopathy.[18-21]

Doppler Echocardiography

Spectral and color flow Doppler imaging are used for evaluating blood flow velocity and direction within the heart and great vessels.[5,6,22,23] During the 19th century, Christian Doppler made the first description of the physical principles used in Doppler echocardiography when he noted through his observations of the light emitted by stars that the speed of a moving source of waves (light, sound) relative to the observer is responsible for the perceived frequency of that wave.[24] The change in frequency between sound transmitted by a structure and sound received by it is called the *Doppler shift*. One experiences the Doppler shift every day. For example, when standing on an overpass, we hear the sound of a car approaching toward us at a higher pitch than the sound we hear when the same car is moving away from the overpass. The engine is emitting the same sound when passing under the overpass, but we hear a change in pitch dependent upon the speed and the direction of the car (Figure 104-12).

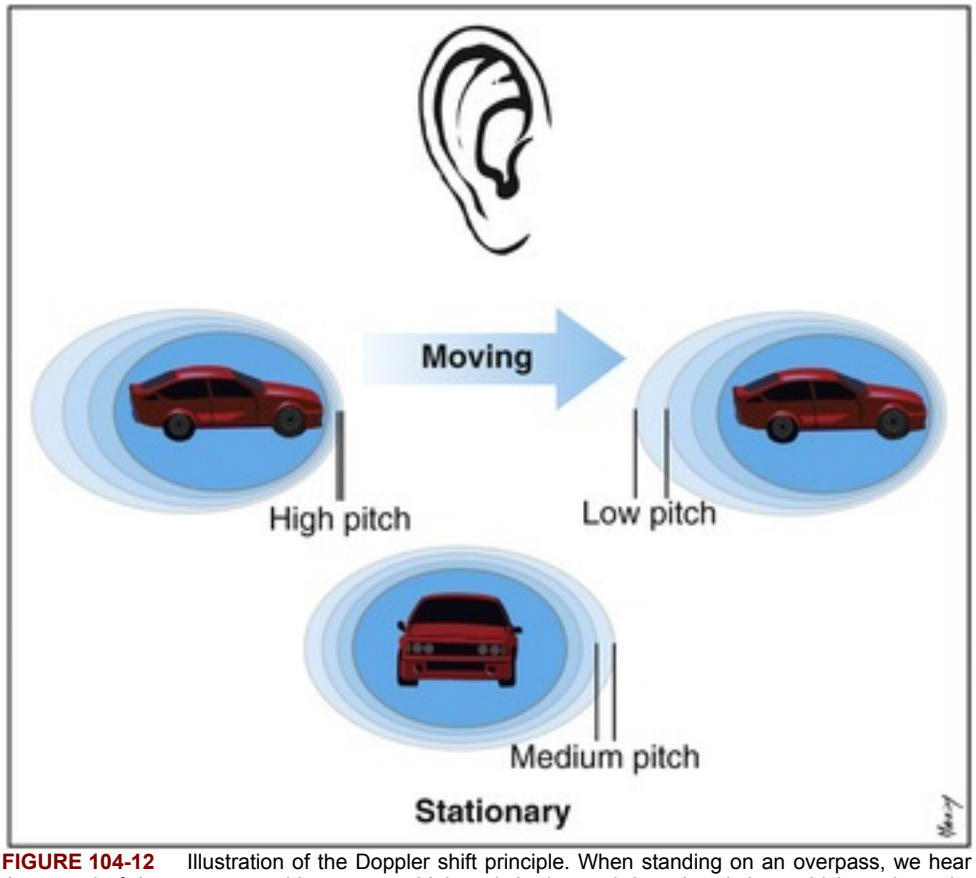

FIGURE 104-12 Illustration of the Doppler shift principle. When standing on an overpass, we hear the sound of the car approaching us as a higher-pitched sound than the pitch at which we hear the same car moving away from us. The engine is emitting the same sound, and the speed and direction of the car are responsible for the change in pitch that we hear.

In echocardiography, the Doppler principle relies on the fact that the transducer generates ultrasound waves that are reflected by red blood cells. The frequency of the reflected sound wave depends on the direction and velocity of the red blood cells and the transmitted frequency. Since the ultrasound frequency emitted from the transducer and the velocity of sound in blood are known, the velocity of red blood cells can be calculated and plotted in the form of curves called *envelopes*, that describe blood movement in a given area of the heart. These flow signals are displayed with time on the horizontal axis and velocity on the vertical axis (see Figure 104-7, *C*).

When the transmitted sound waves encounter red blood cells moving toward the transducer, they are reflected back at a frequency that is higher than that at which they were sent, producing a positive Doppler shift or positive deflection on the screen (Figure 104-13). The opposite effect occurs when the sound waves hit red blood cells moving away from the transducer, producing a negative Doppler shift. Thus, Doppler echocardiography assesses both the direction and the velocity of moving blood (or myocardium—see Tissue Doppler, below). Blood moving toward the transducer creates a positive frequency shift that is encoded red on color Doppler and is shown above the baseline of the spectral Doppler display. Blood flow moving away from the transducer is blue and, conversely then, is displayed as a negative flow profile under the baseline (see Figure 104-13).

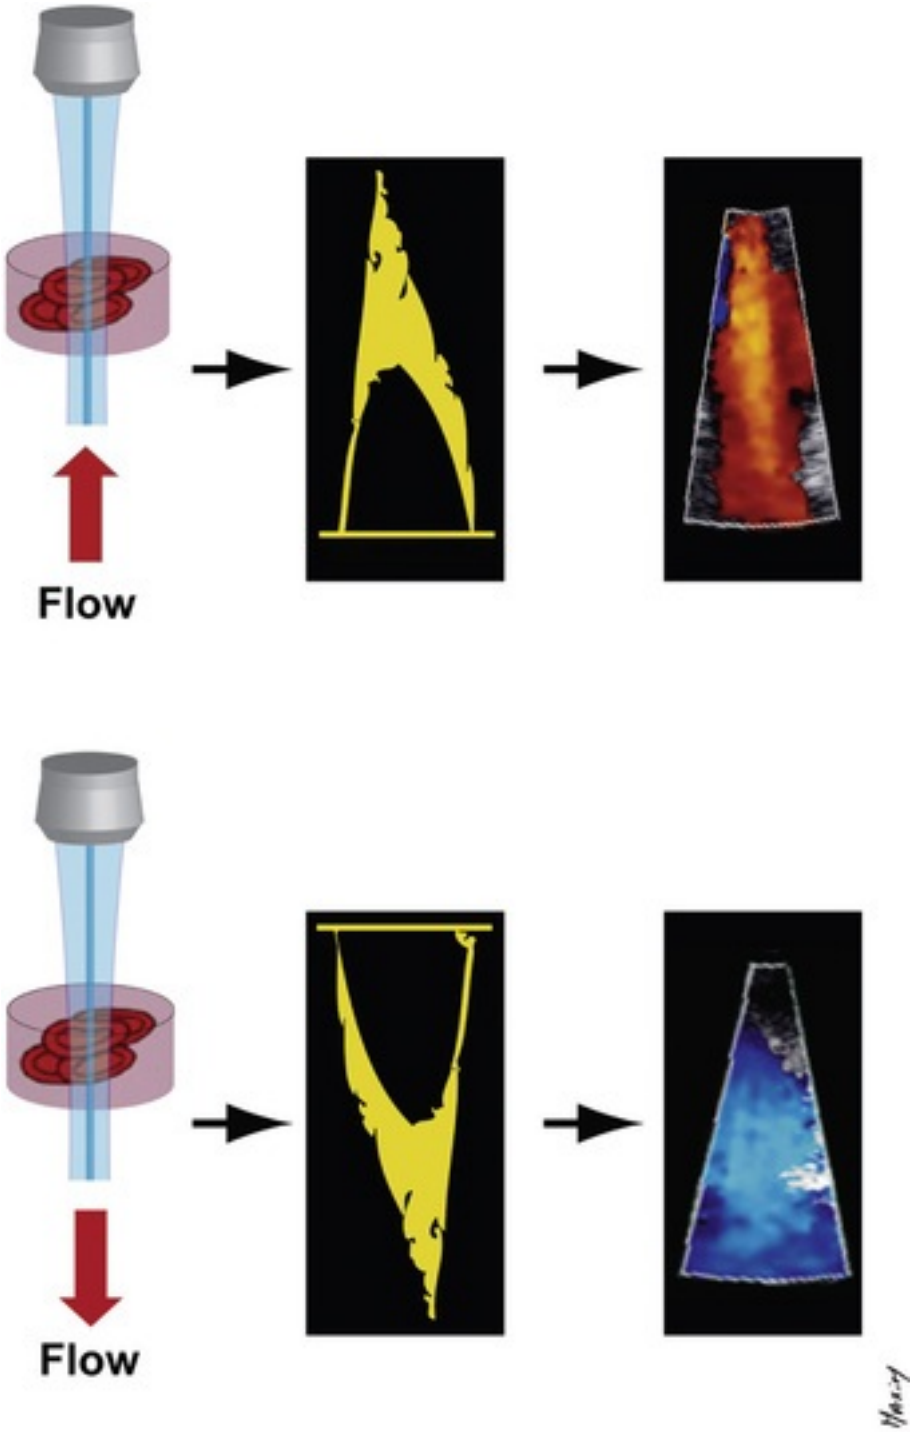

FIGURE 104-13 Doppler imaging of blood flow. When the ultrasound waves encounter blood moving toward the transducer, they produce a positive deflection on the monitor with spectral Doppler, and a red signal on color Doppler. The opposite effect occurs for red blood cells moving away from the transducer, producing a negative deflection on spectral Doppler and a blue signal on color Doppler.

Spectral Doppler

Cardiac spectral Doppler studies use imaging planes that align the sound beam to be parallel with the blood flow. A marker is represented on the cursor line that corresponds to the sampling volume or *gate* where the flow is interrogated (Figure 104-14). This parallel beam positioning is in contrast to M-mode, in which the beam is oriented in a perpendicular manner to visualize the cardiac structures. When performing Doppler studies, care should be taken to align the Doppler beam with the jet flow (intercept angle <20-25°) in order to minimize the underestimation of flow velocity. Parallel alignment of the ultrasound beam measures the true

or maximum velocity of the blood flow. In contrast, perpendicular alignment to flow will show a velocity of zero. Therefore, a wider angle of interrogation will result in a false reduction in the measured velocity as compared to the real velocity (Figure 104-15). Some ultrasound machines have a feature that corrects poor alignment of the beam with the jet flow (often called *angle correction*). However, this type of correction is inaccurate since correction of inappropriate angulation in one dimension or plane does not correct for the other two dimensions.

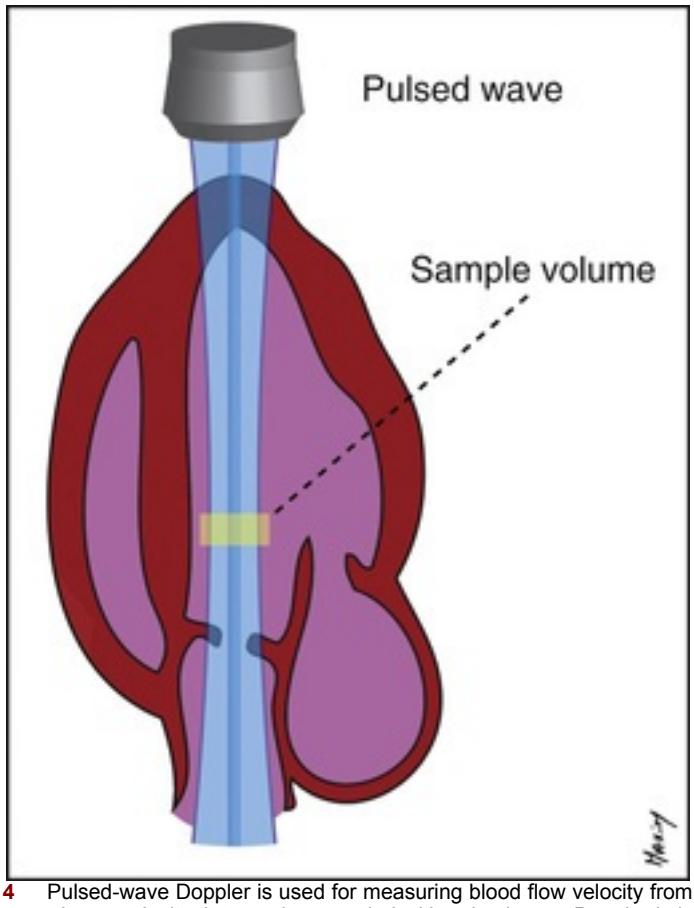

FIGURE 104-14 Pulsed-wave Doppler is used for measuring blood flow velocity from a distinct area of the heart; the maximum velocity that can be recorded with pulsed-wave Doppler is less than that of continuous-wave Doppler.

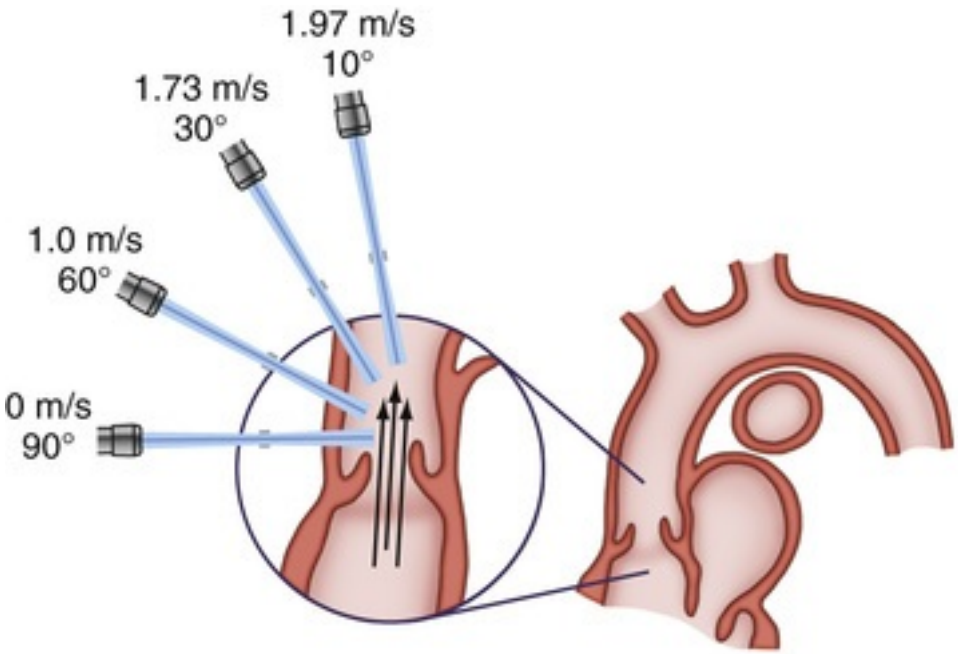

FIGURE 104-15 Effect of the angle of interrogation of flow on the obtained velocity.

Two types of spectral Doppler are used clinically: pulsed-wave Doppler (PW) and continuous-wave Doppler (CW). An intermediate between PW and CW Doppler, called *high pulse-repetition frequency* (HPRF), is another form of spectral Doppler that is used less frequently. It allows the operator to increase the pulse-repetition frequency above the Nyquist limit and thereby reduce aliasing (see PW Doppler section, below, for further explanation).

Spectral Doppler evaluations are helpful in the assessment of pressure gradients, intracardiac chamber pressures, regurgitant fractions, shunt ratios, valvular area/effective orifice area, and cardiac output. Spectral Doppler often is used for calculating *instantaneous pressure gradients* (ΔP, in mm Hg) across a stenotic area, regurgitant valve, or shunt. The maximum pressure gradient is calculated from the maximum flow jet velocity (v, in m/s) using the modified Bernoulli equation:

$$(\Delta P) = 4v^2$$

The peak pressure gradient is used in combination with the determination of the effective orifice area and other 2-D and M-mode echocardiographic findings in the clinical assessment of stenosis severity (see ch. 250).

Pulsed-Wave Doppler

Pulsed-wave (PW) Doppler uses a single crystal transducer that transmits and receives the Doppler signal. Short pulses of ultrasound are produced and the returning echoes from a small sample segment (called *sample volume* or *gate*) along the ultrasound beam are analyzed (see Figure 104-14).

The main advantage of PW Doppler is the possibility of interrogation of direction, velocity, and spectral characteristics (laminar versus turbulent) of the blood flow from a distinct anatomic region of the heart or blood vessels. Laminar flows are characterized by the similarity of the red blood cell velocities within the blood vessel or heart, which creates a Doppler signal with less disparity in velocity and little spectral broadening, as shown in Figures 104-16 and 104-17. Due to friction, normal blood flow is always slightly slower near the walls of a vessel, which gives the signal a typical parabolic profile. Flow across the cardiovascular system normally is laminar and its velocity rarely exceeds 2 m/s in healthy dogs and cats,[22,25-27] with a notable exception in some healthy Boxers.[28-30] Turbulence is observed when blood cell motion becomes disorganized and produces various eddies and whirls or different velocities and directions. It often is generated by an underlying structural lesion. Turbulent flow profiles are broad, and the area under the curve is filled in because the transducer is receiving many frequency shifts associated with variable velocities (Figure 104-17).

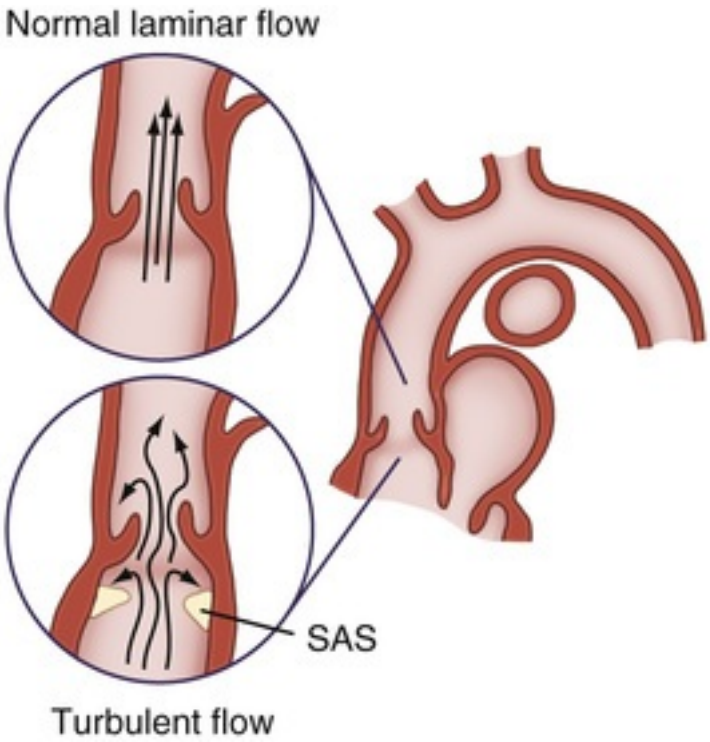

FIGURE 104-16 Laminar flows are characterized by the similarity of the red blood cells velocities. Due to friction, blood flow is always slightly slower near the walls of a vessel, which gives the signal a typical parabolic profile. Turbulent flow profiles are associated with variable velocities. *SAS,* Subaortic stenosis.

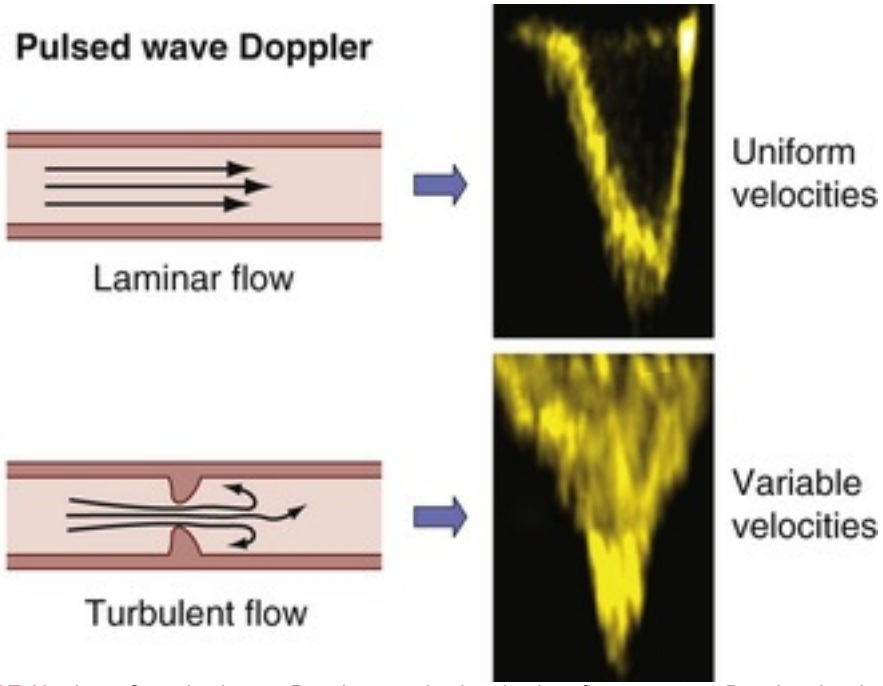

FIGURE 104-17 On pulsed-wave Doppler examination, laminar flows create a Doppler signal with less disparity in velocity and little spectral broadening. Turbulent flow profiles are broad, and the area under the curve is filled in because the transducer is receiving many frequency shifts associated with variable velocities.

The disadvantage of PW Doppler is that it relies on a maximum measurable velocity called the *Nyquist limit,* which cannot be exceeded because of a limited pulse repetition frequency. In other words, PW Doppler

is only accurate when measuring low, normal, or slightly elevated velocities. When the Nyquist limit is exceeded, a phenomenon called *aliasing* will be observed on the Doppler tracing (Figure 104-18). A simple change of probe can usually overcome this limitation since the Nyquist limit is determined by the frequency of the transducer used. A lower frequency probe increases the ability to record higher velocities at any given range. The main drawback of this trick is a reduction in the quality of the output. For these reasons, interrogation of a high velocity flow, as seen in stenotic valvular lesions, is usually achieved with continuous-wave (CW) Doppler.

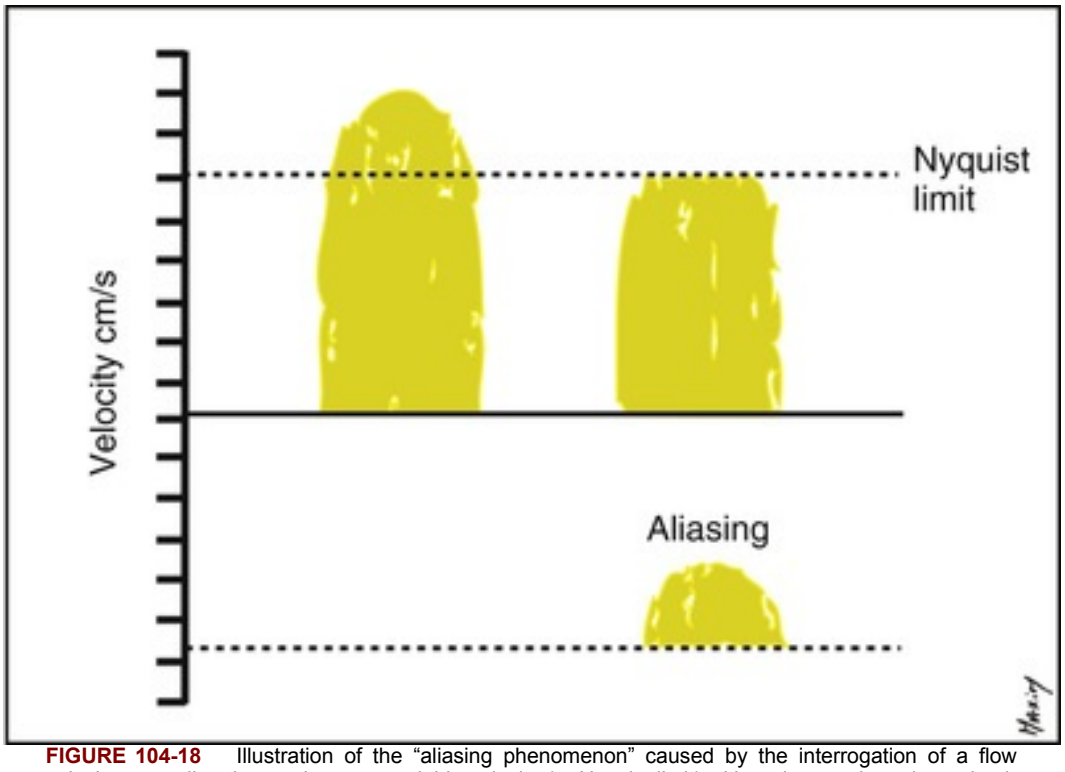

FIGURE 104-18 Illustration of the "aliasing phenomenon" caused by the interrogation of a flow velocity exceeding the maximum recordable velocity (or Nyquist limit) with a given probe using pulsed-wave Doppler.

PW Doppler is very useful in the evaluation of transvalvular blood flow patterns. Diastolic flow across the atrioventricular (AV) valves has similar patterns characterized by an initial high-velocity signal associated with rapid ventricular filling, called the *E wave,* followed by a smaller velocity signal produced by blood flow from atrial contraction, the *A wave* (Figure 104-19).

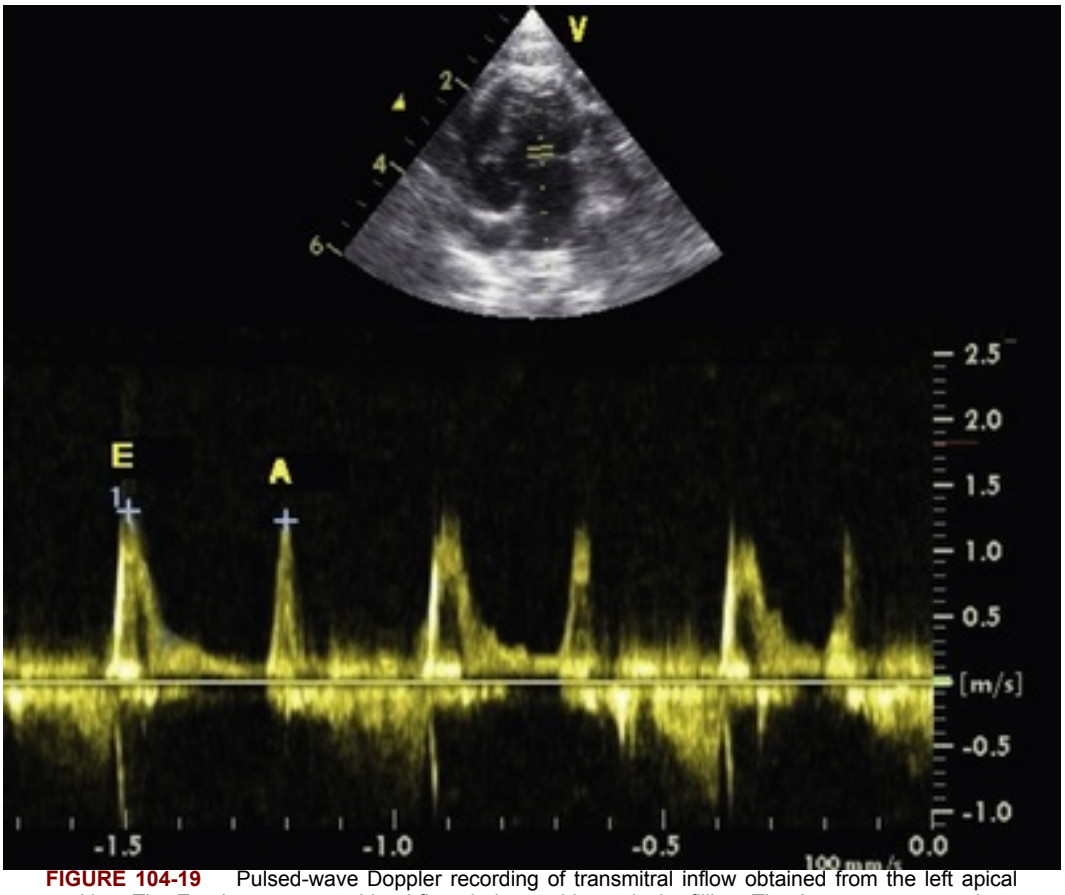

FIGURE 104-19 Pulsed-wave Doppler recording of transmitral inflow obtained from the left apical position. The E-point represents blood flow during rapid ventricular filling. The A wave corresponds to blood flow during atrial contraction. Simultaneous ECG display recorded but not shown.

The flow patterns across the semilunar valves are characterized by a rapid acceleration during ejection followed by a more gradual deceleration (Table 104-6). The variance of these valvular flow patterns, like the transmitral flow profile, is studied to identify different cardiac diseases (Figure 104-20).

TABLE 104-6

Reference Intervals for Spectral Doppler Velocities in Dogs and Cats (m/s)

	CANINE	FELINE
Mitral Valve		
Peak E wave	0.7-1.0	0.6-0.8

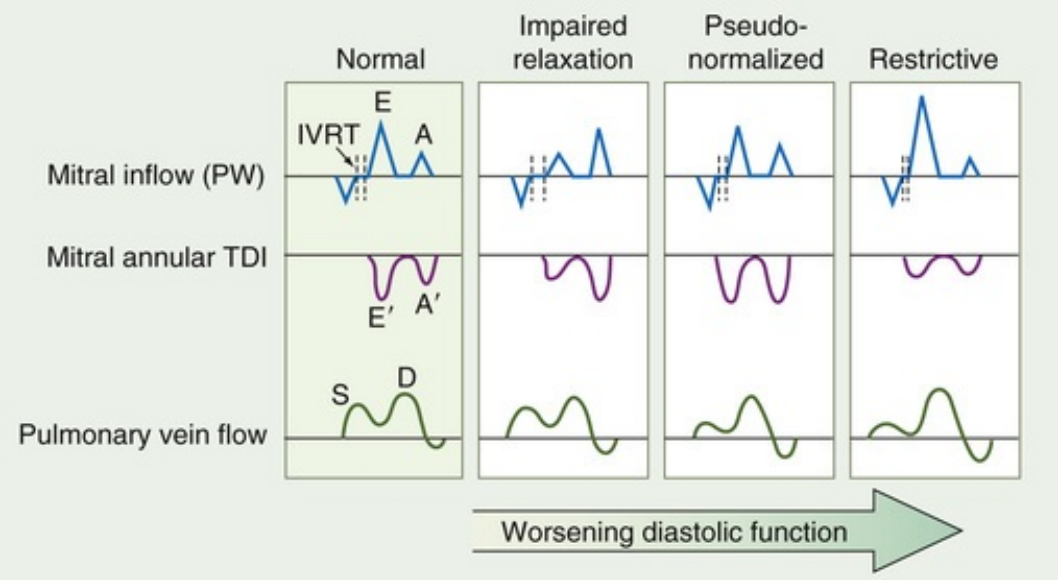

FIGURE 104-20 Schematic representation of various mitral inflow, mitral annular tissue Doppler imaging (TDI), and pulmonary vein flow profiles. *PW,* Pulsed wave.

Continuous-Wave Doppler

CW Doppler uses dual crystals for simultaneous transmission and reception of the Doppler signal. Very high velocity flows can be recorded with CW Doppler since there is no Nyquist limit; the continuous nature of the ultrasound beam in CW Doppler results in an essentially infinite pulse repetition frequency (PRF), and therefore there is no theoretical limit to the maximal velocity that could be recorded by CW Doppler techniques.[31] The disadvantage of CW Doppler is that the specific location and characteristic of flow cannot be documented since all velocities are measured along the cursor line (Figure 104-21).

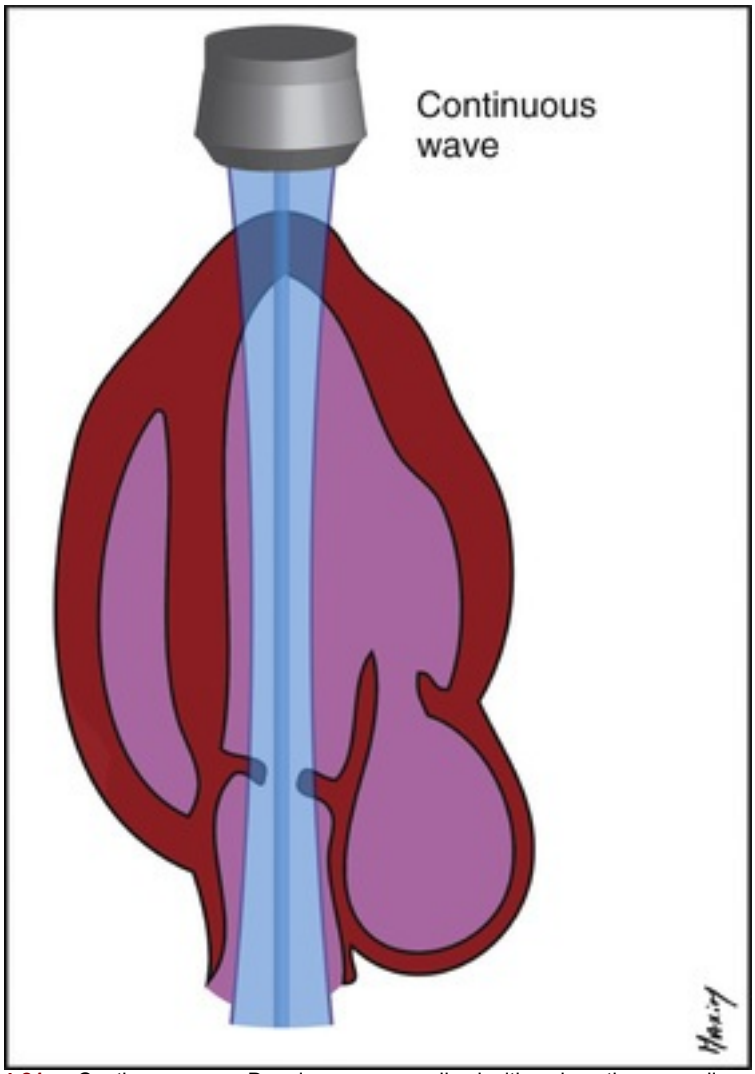

FIGURE 104-21 Continuous-wave Doppler measures all velocities along the cursor line.

PW and CW Doppler are complementary modalities; PW Doppler is indicated when the operator wants to know where a specific area of abnormal flow is located, whereas CW Doppler will document the maximal velocity across the abnormal flow.

Color-Flow Doppler

Color-flow Doppler is a form of PW Doppler that allows visual evaluation of direction and velocity of blood flow through the heart. Its primary clinical use is the detection of flow disturbances. The Doppler shift is encoded with a color map that usually uses red, blue, and green to produce other color shades such as cyan, yellow, and white. Conventionally, blood moving toward the probe is coded red, whereas blood moving away from the probe is coded blue. This color map configuration is called the BART display (Blue/Away and Red/Toward). Color Doppler is very helpful to appropriately align with flow jets, search for jets of insufficiency, describe the size and shape of regurgitant jets, identify other areas of turbulent flow, and confirm some cardiac shunts seen on 2-D echocardiograms (Figure 104-22). Turbulent flow is characterized by disparate velocities within the sampled area, which appear as disorganized flow with a typical mosaic pattern (see Figure 104-22; Video 104-2). Several transducer positions and planes are used for finding the optimal color-flow imaging of a specific cardiac structure.

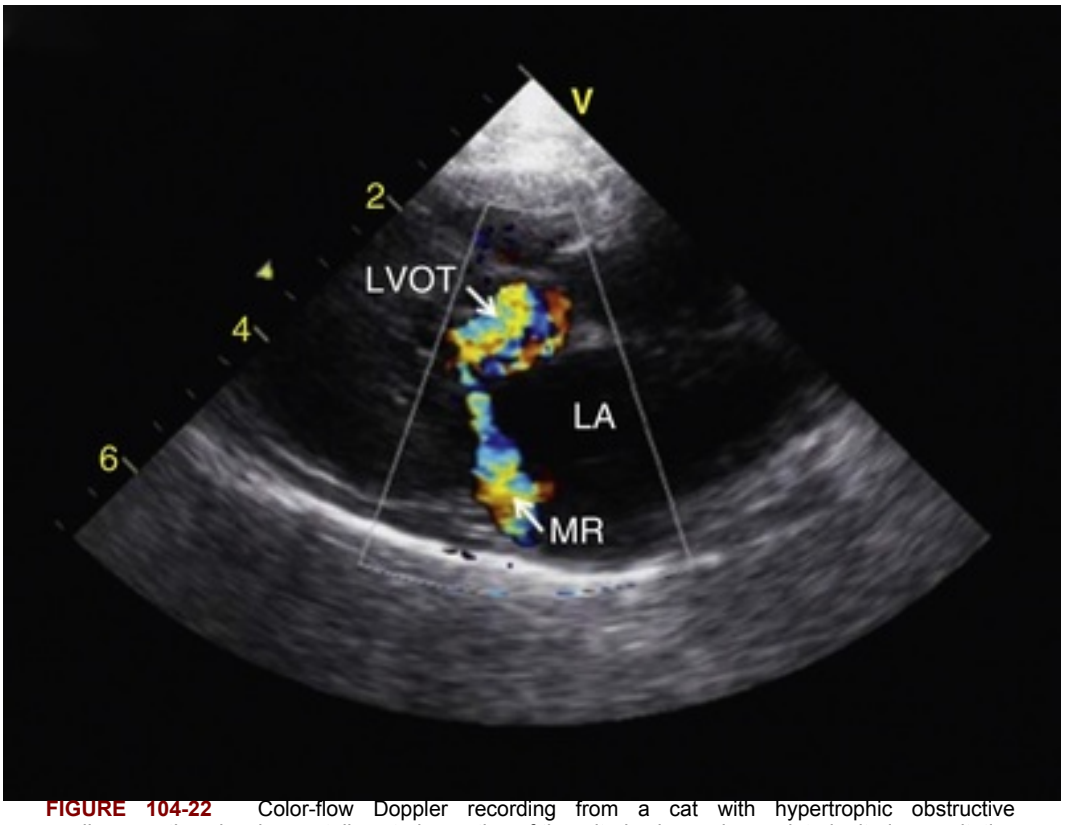

FIGURE 104-22 Color-flow Doppler recording from a cat with hypertrophic obstructive cardiomyopathy, showing systolic anterior motion of the mitral valve and associated mitral regurgitation (MR) and turbulence in the left ventricular outflow tract (LVOT). *LA*, Left atrium.

Artifacts

Image artifacts are unfortunately a common component of the echocardiogram. An inexperienced sonographer often is confronted with the possibility of missing a lesion (false-negative exam) or misdiagnosing a normal structure as a pathologic finding (false-positive exam). Oblique or tangential imaging of cardiac structures is a common pitfall of the echocardiographic study. Some artifactual images can be mistaken as masses or pseudomasses. A simple way to differentiate a real mass from an artifact is to examine the perpendicular plane where that mass is seen. If the mass cannot be confirmed in the perpendicular plane, then the most likely explanation is that it is artifactual. Again, the most common cause of a false-negative echocardiogram is failure to examine the heart completely (i.e., from multiple windows). Many publications describing common echocardiographic artifacts in animals are available elsewhere.[6-8,32]

Repeatability and Reproducibility in Veterinary Echocardiography

Quantitative echocardiography, especially involving serial echocardiographic measurements, often is used for evaluating the long-term outcome of cardiac diseases or drug efficacy. However, the small size of the canine and feline heart, stress and motion caused by restraint, duration of the procedure, and many other technical factors can result in suboptimal images or inaccuracies in measurement and interpretation of echocardiograms. Within-day and between-day coefficients of variation can be as high as 22% for routine M-mode measurements in cats.[33] Similarly in dogs, most coefficients of variation for these parameters are <20%.[34,35] These results suggest that differences >20% for parameters during serial echocardiograms should be considered to reflect genuine change. Also, variability and reproducibility are known to improve when a single experienced operator acquires and measures serial echocardiographic data.

Special Echocardiographic Techniques

Other echocardiographic techniques can provide useful information in the imaging of the canine and feline

heart. These techniques include tissue Doppler imaging[36-51] and its derivatives, tissue tracking, strain, and strain rate[52-56]; speckle tracking imaging[57-60]; contrast echocardiography[61-63]; transesophageal echocardiography (TEE)[64-69]; and three-dimensional echocardiography (3-DE).[70-74] Although very useful in the clinical setting, some of these imaging methods have a limited application in veterinary medicine since they require expensive equipment. Transesophageal echocardiography necessitates general anesthesia, which increases the time and cost (and a potential danger) of the procedure.

Transesophageal Echocardiography

TEE uses a specialized transducer mounted on a flexible, steerable endoscope tip (Figure 104-23).[64,65] The heart is imaged through the esophageal wall (Figure 104-24). The image quality is improved with TEE because of closer proximity of the cardiac structures to the transducer and the lack of intervening lung and bone structures. TEE is considered a complementary technique that especially allows better imaging of cardiac structures above the AV node such as the atria and pulmonary veins. TEE also is very helpful in assisting many interventional cardiology procedures (see ch. 122).[66,67,69]

FIGURE 104-23 A specialized flexible probe containing a steerable ultrasound transducer at its tip is used for performing transesophageal echocardiography.

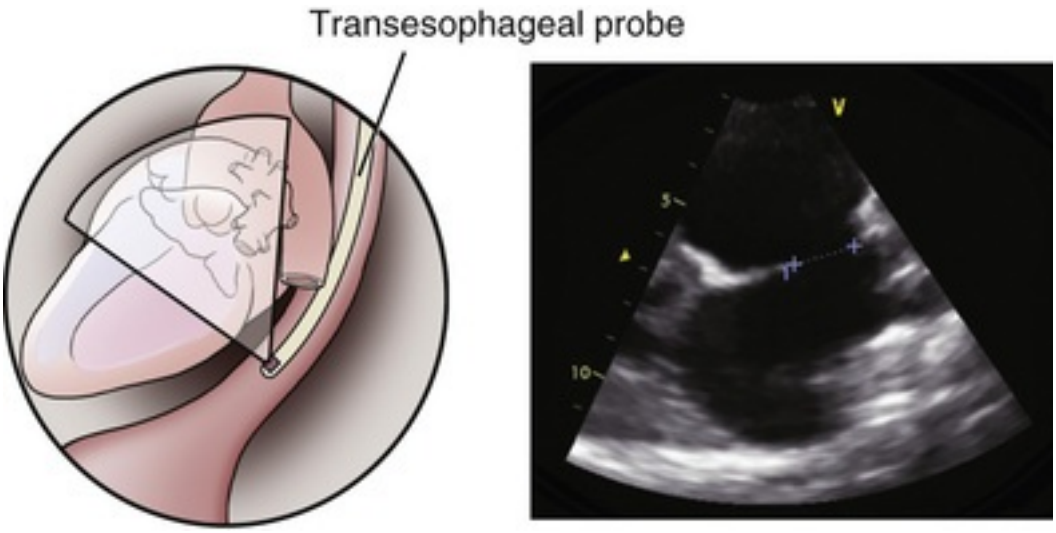

FIGURE 104-24 Illustration of transesophageal echocardiography with real-time 2-D imaging of a large atrial septal defect in a dog.

Three-Dimensional Echocardiography

3-DE is not yet a standard part of the routine clinical echocardiographic examination in animals and humans. It provides a more detailed anatomic description of cardiac defects and masses in all three spatial dimensions (Figure 104-25).[71] It is now also used in the quantification of chamber volumes (Video 104-3).[70,72-74] The ability to "slice" the heart in multiple planes and to reconstruct three-dimensional images of specific cardiac structures on the awake patient makes 3-DE echocardiography unique for characterizing the morphology of many congenital malformations (see ch. 250). Four-dimensional echocardiography refers to 3-DE performed in real-time display.

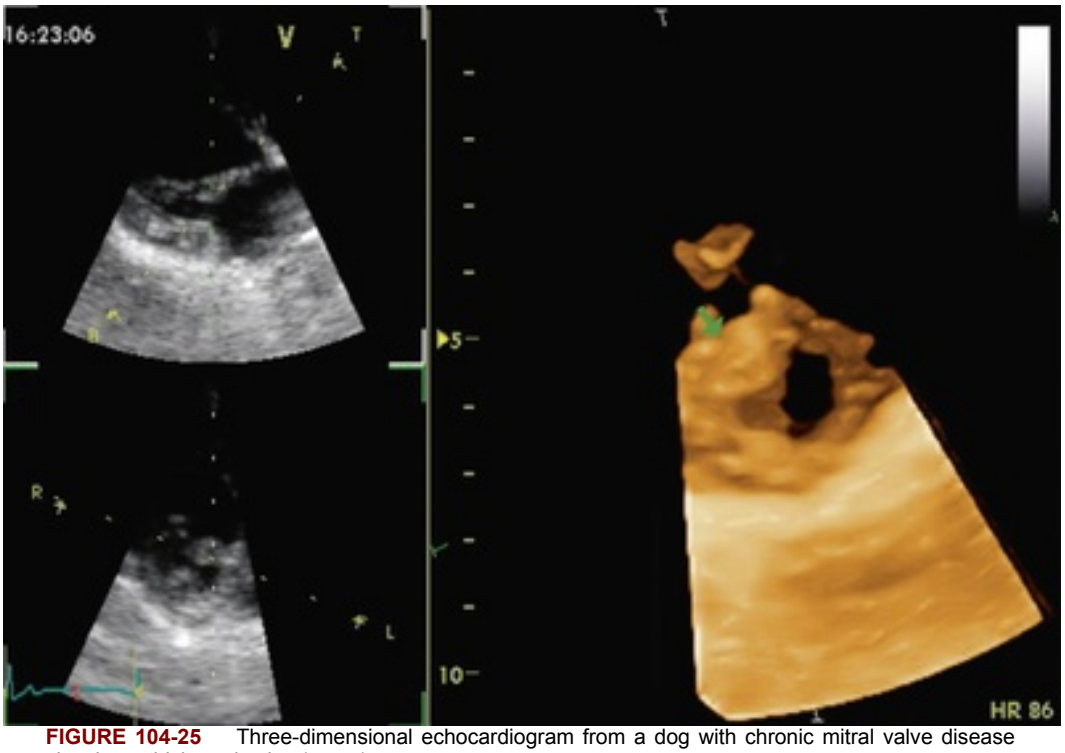

FIGURE 104-25 Three-dimensional echocardiogram from a dog with chronic mitral valve disease showing a thickened valve (arrow).

Contrast Echocardiography

Contrast echocardiography is another useful imaging method in the clinical evaluation of the cardiovascular system. It has four main applications: detection of shunts, enhancement of Doppler signals, left ventricular opacification, and demonstration of myocardial perfusion.

The microbubble technique was one of several contrast echocardiographic media to be used initially[61] and it remains the most widely utilized in small animal cardiology today. Microbubbles are created by back-and-forth injection of 3-10 mL of physiologic sterile saline through a 3-way stopcock, between 2 syringes (Figure 104-26). Injection in a peripheral vein can help to confirm right-to-left intracardiac shunting. Microbubbles reflect ultrasound and do not cross pulmonary or systemic capillaries; they dissolve and are reabsorbed in the pulmonary vasculature. Therefore, the microbubbles injected in the cephalic vein will stay on the right side of the heart in a normal patient. When right-to-left shunting is present, microbubbles will also be observed in the left side of the heart (Videos 104-4 and 104-5). In veterinary medicine, agitated saline (prepared as described above) is still the preferred contrast agent for the right side of the heart.

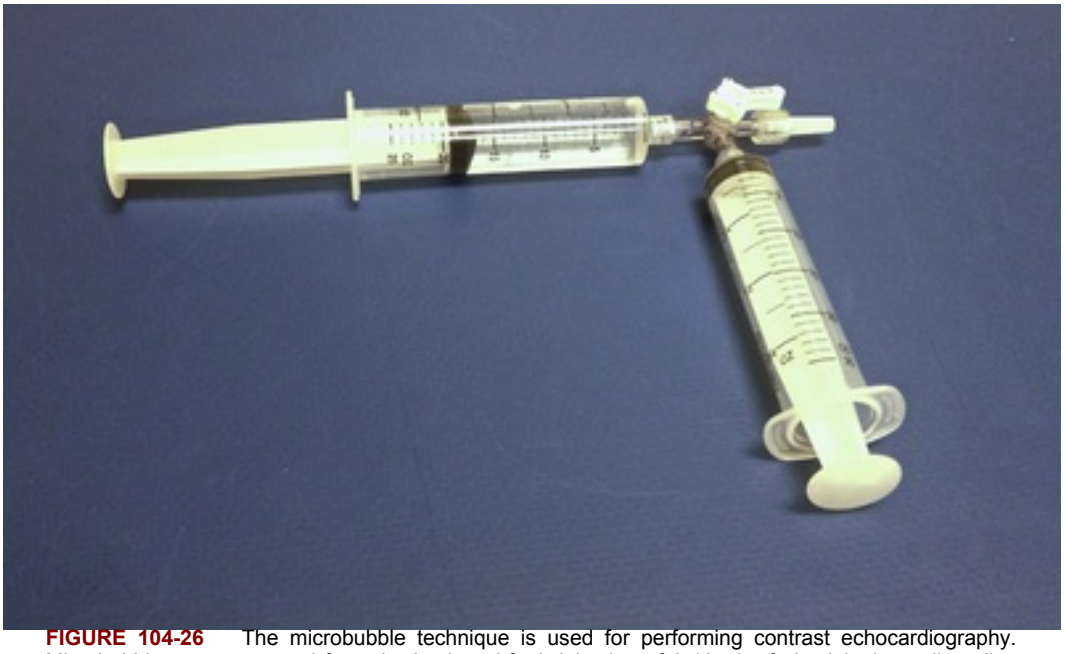

FIGURE 104-26 The microbubble technique is used for performing contrast echocardiography. Microbubbles are generated from the back-and-forth injection of 3-10 mL of physiologic sterile saline between 2 syringes connected by a three-way stopcock.

Commercially available contrast agents also can be used in echocardiography to improve diagnostic accuracy.[62,63] They consist of low-solubility fluorocarbon gas in stabilized microspheres encapsulated with denatured albumin. Contrast agents act by increasing ultrasound scattering and thereby enhancing the cardiac chambers, myocardial echogenicity, and Doppler signals. They are particularly useful for the assessment of intracardiac thrombi or masses in the heart.

Tissue Doppler Imaging (TDI) and "Derived Techniques" (Tissue Tracking, Strain, and Strain Rate)

TDI is the method of choice for non-invasive assessment of regional myocardial function in humans and is increasingly used in veterinary medicine.[36-56] TDI uses the same principles as conventional Doppler except that the target or reflector is the motion of the myocardial tissue rather than the flow of red blood cells. TDI is especially useful in evaluating diastolic function because the diastolic velocity of the myocardium is much less dependent on preload conditions than is transmitral blood flow. Pulsed-wave TDI can be performed in real time by placing a sample gate over a portion of the myocardium to record a positive or negative Doppler shift. The pattern of myocardial motion is similar to, but inverted and slower than, the transmitral flow (Figures 104-20 and 104-27).

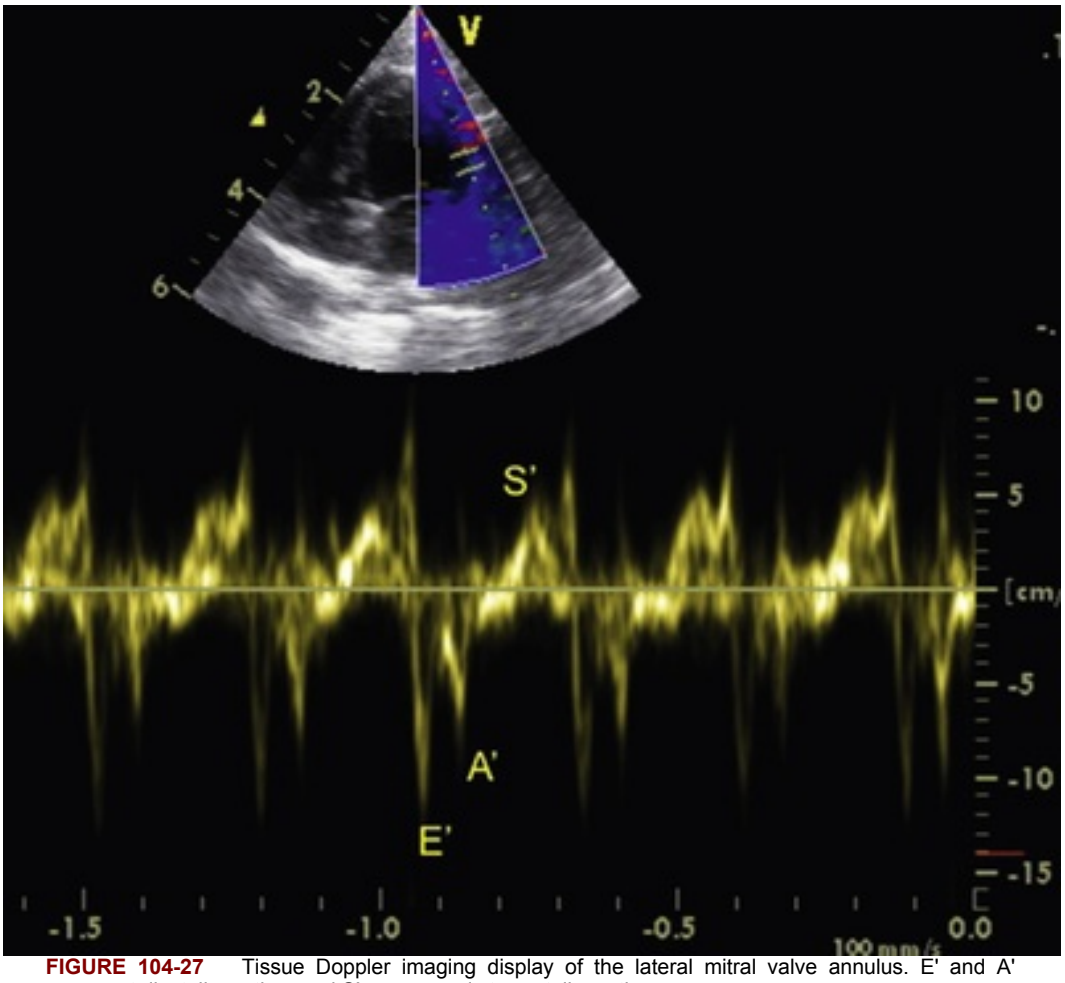

FIGURE 104-27 Tissue Doppler imaging display of the lateral mitral valve annulus. E' and A' represent diastolic motion, and S' corresponds to systolic motion.

Simultaneous color TDI of various areas of the heart can also be obtained by placing a sector of color over the myocardium and then saving the video loop for off-line analysis. A gate is then placed on a specific area of the myocardium, from the retrieved loop. The corresponding systolic and diastolic movements of the specific area are displayed (Figure 104-28). The advantage of this TDI modality is that motion from multiple areas of the myocardium under the color sector can be analyzed and compared offline from one stored loop. Color TDI can thereby reduce beat-to-beat variability.

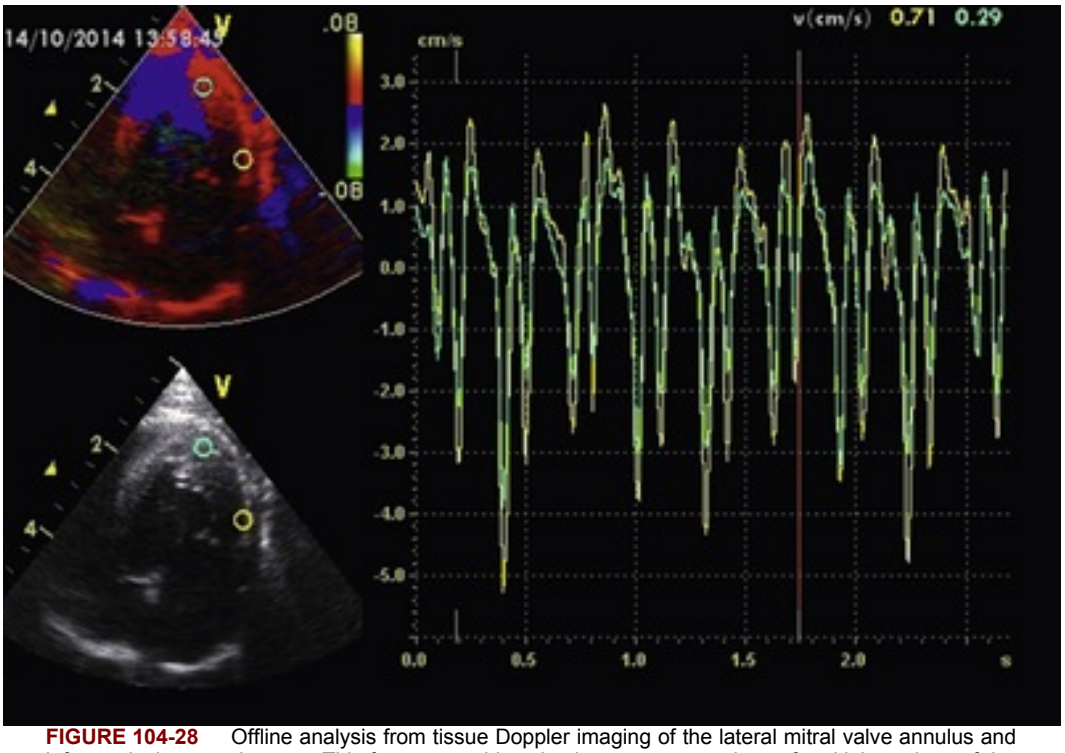

FIGURE 104-28 Offline analysis from tissue Doppler imaging of the lateral mitral valve annulus and left ventricular apex in a cat. This feature provides simultaneous comparison of multiple regions of the left ventricular myocardium.

LV myocardial tissue Doppler signals are recorded from the left apical four-chamber view using PW Doppler. The sample gate can be located at the levels of the mitral annulus, basal ventricular wall, and apex. TDI now is commonly used in veterinary cardiology, particularly in the evaluation of feline hypertrophic cardiomyopathy.

Tissue imaging technology also includes tissue tracking and strain rate imaging.[52-56] Tissue tracking allows the measurement and visualization of longitudinal motion in each myocardial segment during systole and diastole. Strain measures compression and distension of myocardial segments ("deformation magnitude") and strain rate imaging expresses strain changes per time interval. Myocardial strain and strain rate are measured using color TDI or more recently by speckle tracking imaging.

Speckle tracking is a new tissue imaging technology, which provides additional information on myocardial contractility and relaxation.[57-60] Speckle tracking determines myocardial deformation from continuous frame-by-frame tracking of a small image block of natural acoustic markers called "speckles." These markers are small areas of higher echogenicity that are caused by reflections, refraction, and scattering of echo beams. By tracking such speckles in the wall of the left ventricle throughout the cardiac cycle, it is possible to obtain information on the direction and velocity of myocardial motion. Comparing the motion of individual speckles to each other allows the analysis of the deformation of the myocardium or in other words the magnitude of myocardial fiber relaxation (diastole) or contraction (systole).

Evaluation of Cardiac Structure and Function

Cardiac Size and Chamber Dilation

Cardiac chamber dimensions traditionally have been determined by M-mode echocardiography, with reference intervals reported for several breeds of dogs[75-92] and for cats[11,93-97] and increasingly are obtained via 2-D echocardiography, especially in cats.[18-20] Tables 104-2 to 104-6 contain published reference intervals for dogs and cats; Table 104-7 summarizes the most common etiologies for anomalies in chamber size. M-mode measurements vary with body size, body surface area, breed, and sedative drugs. They also are modified by situations like fear and stress, which can significantly affect the heart rate and myocardial function of our patients. Therefore, reported reference intervals always should be regarded as approximate. The effect of breed can be minimized with specific calculations; in a post-hoc analysis, Cornell et al. logarithmically transformed LV M-mode values from 494 dogs weighing 2-95 kg and found a good

correlation to body weight using this approach.[15]

TABLE 104-7

Common Causes of Chamber Anomalies

	DILATION	REDUCTION IN VOLUME	WALL THICKENING
LV	Volume overload • Mitral regurgitation • Left-to-right shunting • Aortic insufficiency Dilated cardiomyopathy High-output state • Hyperthyroidism • Anemia	Volume depletion • Severe dehydration • Hypoadrenocorticism • Hypovolemic shock Inadequate blood return to the left heart • Dirofilariasis • Tetralogy of Fallot	Pressure overload • Aortic stenosis • Systemic hypertension Hypertrophic cardiomyopathy Infiltrative myocardial disease
RV	Volume overload • Tricuspid regurgitation • Atrial septal defect Dilated cardiomyopathy	Cardiac tamponade Volume depletion	Pressure overload • Pulmonic stenosis • Tetralogy of Fallot • Cor pulmonale • Pulmonary hypertension • Dirofilariasis Feline hypertrophic cardiomyopathy
LA	Mitral regurgitation/dysplasia Dilated cardiomyopathy Left-to-right shunting Mitral stenosis		
RA	Tricuspid regurgitation/dysplasia Dilated cardiomyopathy Right-to-left shunting Tricuspid stenosis Cor pulmonale • Dirofilariasis • Pulmonary hypertension		

LA, Left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

The *left atrial–to-aortic ratio* (LA : Ao ratio) is used for estimating the degree of left atrial enlargement. Multiple techniques have been described including 2-D (diameter, area, surface) and M-mode methods. The M-mode method compares the diameter of the left atrium in systole to the diameter of the aorta in diastole. This ratio is best obtained from the right parasternal short-axis view, but it may also be evaluated from the right parasternal long-axis view. The M-mode LA : Ao ratio is criticized because of the subjectivity of the cursor placement. This method underestimates the left atrial size when the cursor does not reach the body of the left atrium. Conversely, it overestimates the relative left atrial size when a tangential plane of the aorta is obtained. The reported reference interval for M-mode-derived LA : Ao ratio in normal dogs and cats is <1.3. Other 2-D echocardiographic methods have been described by Rishniw and Erb for estimation of left atrial size.[98] One method measures the LA : Ao ratio from the right parasternal short-axis view of the aorta and left atrium on the first frame that shows aortic valve closure. The internal diameter of the aorta is measured along the commissure between the closed noncoronary and right coronary aortic valve cusps (Figure 104-29). The left atrial internal diameter is measured from a line parallel to the commissure between the noncoronary and left coronary aortic valve cusps to the distant margin of the left atrium. A 2-D LA : Ao ratio >1.6 in dogs and >1.5 in cats suggests left atrial dilation, as does an absolute LA diameter >16 mm in cats.[99]

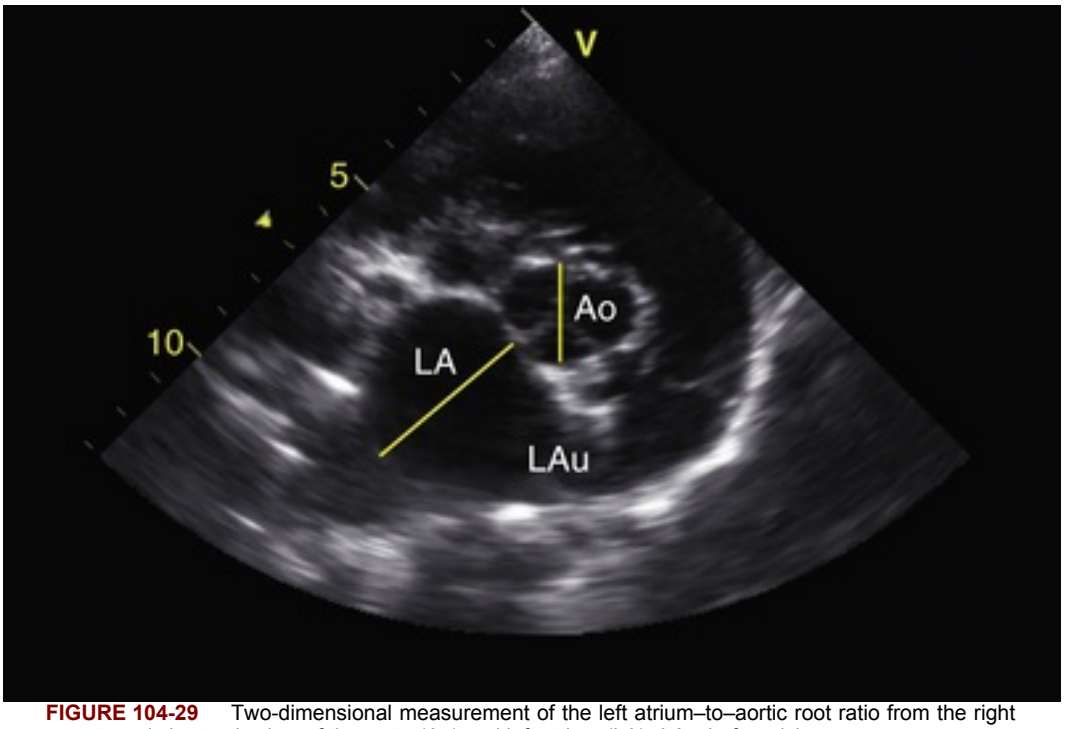

FIGURE 104-29 Two-dimensional measurement of the left atrium–to–aortic root ratio from the right parasternal short-axis view of the aorta (Ao) and left atrium (LA). *LAu,* Left auricle.

Systolic Function

Virtually all forms of cardiac disease can be associated with a certain degree of systolic and diastolic dysfunction. Evaluation of these dysfunctions can provide valuable prognostic information. Systolic dysfunction is characterized by impaired contractility and reduced ejection fraction. Many echocardiographic techniques to assess systolic dysfunction have been described.[5-8] The following parameters are those that are frequently used in clinical veterinary cardiology.

Ejection phase indices are used for quantifying LV systolic performance. They are calculated from linear M-mode measurements or more often nowadays from 2-D still images, and they include the *fractional shortening* (FS), the *stroke volume* (SV), and the *ejection fraction* (EF). The *end-systolic diameter* is also by itself a good indicator of LV performance and it is a more specific index of myocardial contractility than the fractional shortening. M-mode methods of volume determination have a limited correlation with more invasive methods, so these indices should rather be calculated from 2-D–specific echocardiographic methods. Also, the examiner should always remember that these indices all are significantly influenced by ventricular loading conditions (preload and afterload), such that changes could be due to heart rate, hydration status, or other variables, rather than intrinsic myocardial function.

Fractional Shortening

FS is the percent change in diameter of the ventricular cavity from diastole to systole. It provides a rough index of systolic function. Severe LV systolic dysfunction will usually be associated with a very low FS. Despite its many limitations, FS is the clinical index used most commonly in the evaluation of global LV systolic function in veterinary medicine, although improved methods for calculation of ejection fraction are gradually making FS obsolete. It is important to understand that FS is not a measure of contractility since it also depends on loading conditions. In other words, an abnormal FS can be caused by alterations of preload, afterload, or contractility. For example, a low FS can be observed because of hypovolemia (decreased preload), sedation with an alpha-2 agonist (increased afterload), or decreased systolic function (e.g., dilated cardiomyopathy). The reference interval for FS values in healthy dogs is 24-49%, with great variation among breeds (see Table 104-3).[75-92] The reference interval for FS values in healthy cats is 33-66%.[13,93-96] FS is calculated as follows:

$$FS\,(\%) = \frac{EDD - ESD}{EDD} \times 100$$

where *EDD* is the left ventricular internal diameter at the end of diastole (cm) and *ESD* is the left ventricular internal diameter at the end of systole (cm). Since the FS is calculated by M-mode, it is important that the measurements of the ventricular walls are made on an image that is a true transverse view of the LV (see Figure 104-10).

Left Ventricular Volume and Ejection Fraction

Determination of left ventricular volumes (LVV) and derived EF is essential to evaluate LV systolic function precisely. Many experimental models and formulas have been described in dogs to assess LVV by use of M-mode and 2-D echocardiography. Left ventricular end-diastolic volume (LVV_{ED}) and end-systolic volume (LVV_{ES}) can be estimated by the Teichholz method, the bullet method, and the disc summation method (i.e., Simpson's rule). The latter is considered the more accurate echocardiographic method in veterinary medicine.[99] As discussed above, the M-mode–derived Teichholz method, which is calculated automatically during M-mode measurements, is less accurate because it is calculated from only one dimension, which can introduce a level of error of up to 100% in a diseased heart. Consequently, the ASE recommends the use of 2-D methods involving fewer geometric assumptions, such as in the disc summation method (Figure 104-30).[17] This method is particularly more accurate when the heart has an irregular, enlarged, or asymmetrical shape, as in many of the canine and feline cardiomyopathies.

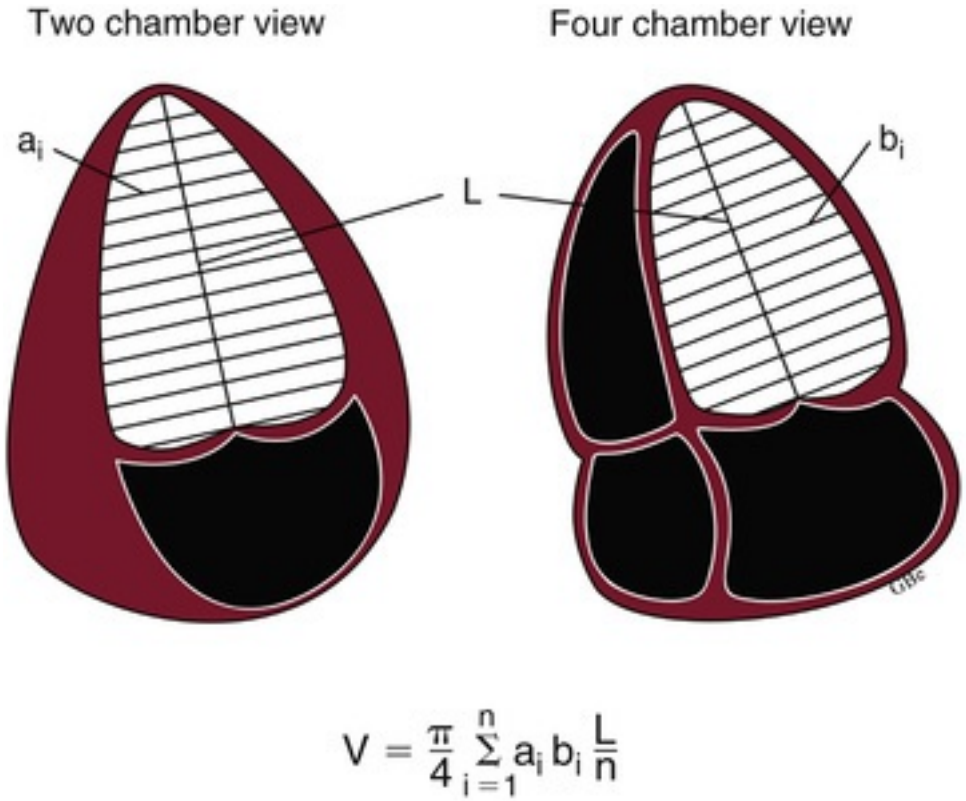

FIGURE 104-30 Disc summation (Simpson's method) to estimate left ventricular volumes.

In healthy dogs, the reference interval for LVV_{ED} indexed to body surface area (BSA) is 47.6 ± 8.4 mL/m^2 and for LVV_{ES} indexed to BSA it is 15.9 ± 3.9 mL/m^2.[5,6]

Stroke Volume

The SV and, ultimately, the cardiac output (CO) can be calculated from the LV end-systolic and end-diastolic volumes. SV is computed as follows:

$$SV\ (mL) = LVV_{ED} - LVV_{ES}$$

Cardiac Output

2-D and Doppler echocardiography can be used for calculating the CO, which ultimately reflects global LV performance. The *cardiac index* (CI) is the CO indexed for body surface area (BSA) in order to take into account body size variation between animals.

$$CI\ (mL/min/m^2) = CO/BSA$$

BSA is calculated from body weight using the formula:

$$BSA\ (m^2) = (10.1 \times w^{2/3}) \times 10^{-4}$$

where *w* is body weight in grams. CO is the product of HR and SV:

$$CO\ (mL/min) = HR \times SV$$

CO can be calculated from the SV determined by the assessment of LVV by Simpson's rule of summation of discs. Alternatively, the continuity equation can be used for evaluating the CO by use of Doppler. The continuity equation is based on the theory of conservation of mass applied to fluids, which specifies that flow through a given area of a conduit must equal flow through an adjacent area over a given time. Accordingly, SV ejected normograde through a valvular orifice during systole is equal to the flow that passes through the valve as expressed by this equation:

$$SV = A \times VTI$$

where *A* is the cross-sectional area of the orifice calculated from the diameter measured by 2-D echocardiography and *VTI* is the velocity-time integral of the pulsed-wave Doppler signal across the valvular orifice.

$$\text{Since } A = D^2 \times (\pi/4)$$

$$\text{therefore, } CO = HR \times D^2(\pi/4) \times VTI$$

Virtually any valve or area in the heart can be used for calculating the CO, but the left ventricular outflow tract and aortic valve are used most often.

Ejection Fraction

The EF is a rough index of LV cardiomyocyte shortening, since it is the percentage of the LVV_{ED} ejected with each heartbeat. It also corresponds to the LV stroke volume, and is the 3-D volumetric equivalent of the FS. The EF is the ratio of the left ventricular SV to the LVV_{ED} as calculated here:

$$EF\ (\%) = \frac{LVV_{ED} - LVV_{ES}}{LVV_{ED}} \times 100$$

In healthy dogs, the reference interval for the EF calculated from LVV assessed by Simpson's rule of discs is 66.5% ± 6.4.[5,6] It is generally accepted that an EF <40% indicates systolic dysfunction.

E-Point to Septal Separation

The *E-point to septal separation* (EPSS) is most useful for the assessment of left ventricular dilation and systolic dysfunction. EPSS measures the distance from the maximum opening of the mitral valve (E-point) to the adjacent endocardial aspect of the interventricular septum (Figure 104-31). In the normal heart, the mitral valve opens in diastole and its anterior leaflet almost contacts the interventricular septum. In dilated hearts, both decreased active filling in early diastole (due to myocardial diastolic dysfunction) and ventricular dilation/eccentric hypertrophy occur. As a result, the tip of the mitral valve does not reach the septum. In healthy dogs, the reference interval is EPSS <6 mm and in healthy cats it is <4 mm.[5,6] Reports in human medicine have shown that the size of the left ventricle alone does not alter the EPSS unless systolic dysfunction is present.

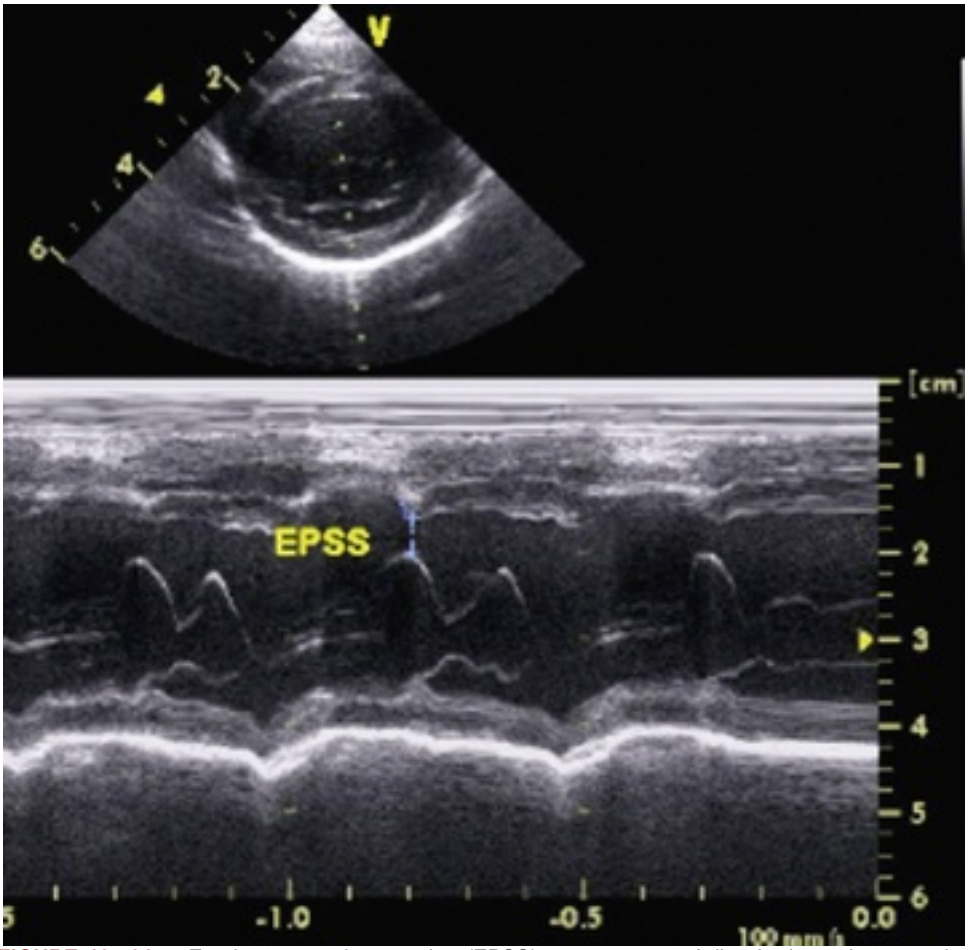

FIGURE 104-31 E-point to septal separation (EPSS) measurement. A line is drawn between the interventricular septum and the maximum initial opening of the mitral valve (E-point).

LV dP/dt

The calculation of LV change in pressure over a period of time *(dP/dt)* has proven to be a sensitive and accurate method to assess LV systolic function.[60,100] It represents the rate of increase in the LV pressure.

When measured during the period of isovolumetric contraction, it is a relatively load-independent measure of ventricular inotropy. Echocardiographically, LV dP/dt typically is calculated from the spectral display of a mitral regurgitation signal (Figure 104-32). To determine dP/dt, one calculates the time difference from the point at which the velocity is 1 m/s to when it is 3 m/s. The time between these two time points represents the period during which a known increase pressure (32 mm Hg, from the modified Bernoulli equation: $[4 \times 3^2] - [4 \times 1^2]$) occurs in the LV. A reduced dP/dt indicates a decreased LV systolic function. dP/dt is calculated as follows:

$$\text{dP/dt (mm Hg/s)} = 32 \text{ mm Hg} \div \text{time (seconds)}$$

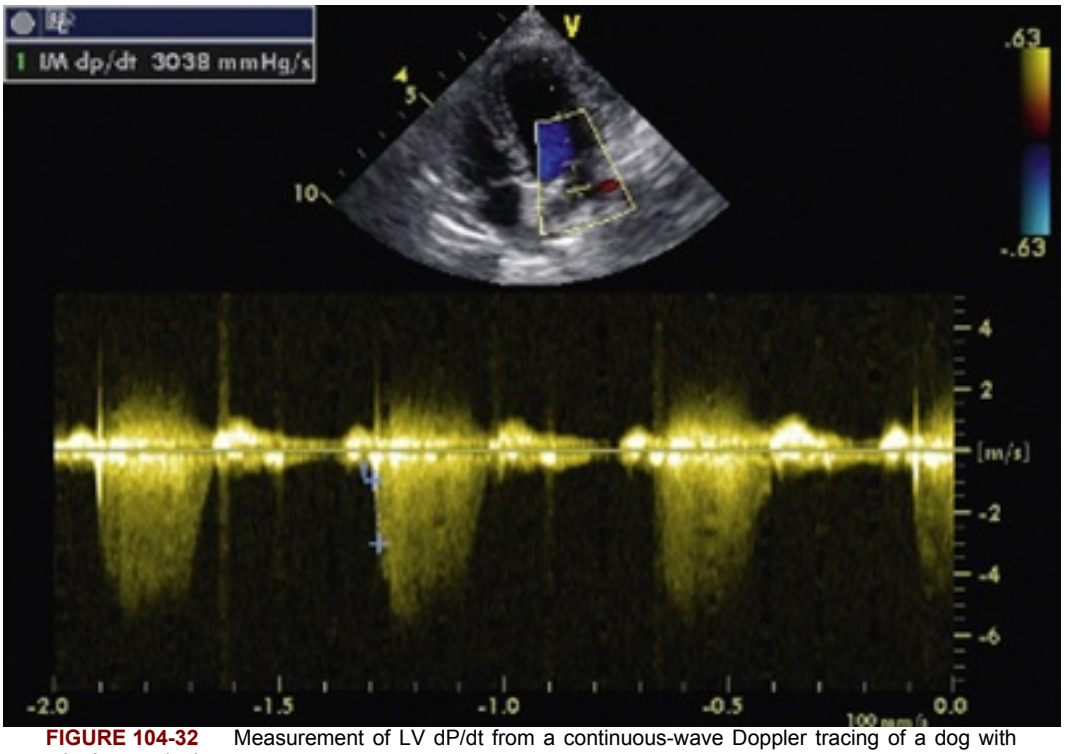

FIGURE 104-32 Measurement of LV dP/dt from a continuous-wave Doppler tracing of a dog with mitral regurgitation.

Diastolic Function

Normal diastolic function allows normal filling of the ventricles. Ventricular diastolic dysfunction implies an abnormality during one or more of the 4 phases of diastole: isovolumic relaxation, rapid ventricular filling, diastasis, and/or atrial contraction. Many echocardiographic techniques have been described to assess diastolic function. Currently in veterinary medicine, Doppler techniques evaluating transmitral flow profiles (E and A waves) and/or pulmonary vein flow profiles (S, D, A waves)[26,43,101-103]; isovolumic relaxation time (IVRT)[26,43,103]; and TDI of the mitral annulus (see above)[36-51] are the most useful in the clinical setting (see Figure 104-20).

Transmitral Flow

This parameter represents the instantaneous diastolic LA to LV pressure gradient (across the MV).[26,43,101-103] In normal animals, peak E wave velocity exceeds peak A wave velocity so E/A ratio >1. In general, when decreased ventricular compliance is present, the velocity during rapid ventricular filling, or E wave, is decreased and the active atrial contraction velocity, or A wave, is increased, making the E/A ratio less than 1—the typical delayed relaxation pattern. Unfortunately, interpretation of abnormal transmitral flow is

sometimes confusing because of a transient pattern called "pseudonormalization," where the E/A ratio seems to normalize while progressive diastolic dysfunction occurs (e.g., feline hypertrophic cardiomyopathy). With pseudonormalization, an increased LA pressure causes early opening of the MV and increased passive filling of the LV (E wave is tall because LA to LV pressure gradient is increased). Also, ventricular pressure rises more rapidly than normal causing the late diastolic LA to LV gradient to be lower than normal, resulting in a smaller A wave. This phenomenon is thought to be transient and occurs when increased LV stiffness has led to elevated LA pressure. However, as LV stiffness and LA pressure continue to rise even further, additional changes in the filling pattern occur, sometimes resulting in a restrictive transmitral flow pattern. Such a *restrictive pattern* is characterized by tall (often >1 m/s) and narrow E waves, and small A waves. Many animals have fast heart rates (>160 beats/min) that result in summation of the E and A waves precluding interpretation of the transmitral flow pattern, although this problem can be corrected in many cats by brief application of pressure to the nasal planum.[104] Pulmonary vein flow patterns and TDI can be used for resolving this limitation.

Pulmonary Vein Flow

Pulmonary vein flow reflects changes in LV compliance and LA and LV filling pressures.[26,43,101-103] Evaluation of pulmonary vein flow typically is performed via the left apical view. The sample volume of the cursor is placed in the pulmonary vein and the PW Doppler flow signal is recorded. Normal pulmonary vein flow profile consists of diastolic (D), systolic (S), and atrial reversal (A or AR) waves (see Figure 104-20).

Unlike conventionally measured transmitral or pulmonary venous flows, TDI is less dependent on preload and minimally affected by LA pressure, and is therefore very useful to further evaluate suspected pseudonormal patterns in particular. Evaluation of diastolic function with TDI often is achieved by placing the sample-gate at the level of the basalmost left ventricular free wall, just adjacent to the mitral annulus. The pattern of myocardial motion is similar, but inverted and lower in velocity, compared to conventional transmitral flow (see Figure 104-27).

Isovolumic Relaxation Time (IVRT)

IVRT is the time interval between aortic valve closure and mitral valve opening.[26,43,101-103] Impaired ventricular relaxation causes prolongation of IVRT, whereas decreased ventricular compliance and elevated ventricular filling pressures are associated with a shortened IVRT. IVRT is determined from a left apical four-chamber view. Using PW Doppler, a sample volume is positioned midway between the aortic and mitral valves to simultaneously record both the aortic outflow and mitral inflow (Figure 104-33). IVRT is the time (*x* axis) from the end of the aortic flow envelope to the beginning of the adjacent mitral flow envelope. It is known to increase with age and decrease with a faster heart rate. The reference interval for IVRT in healthy dogs and cats is 41-65 ms and 36-54 ms, respectively.

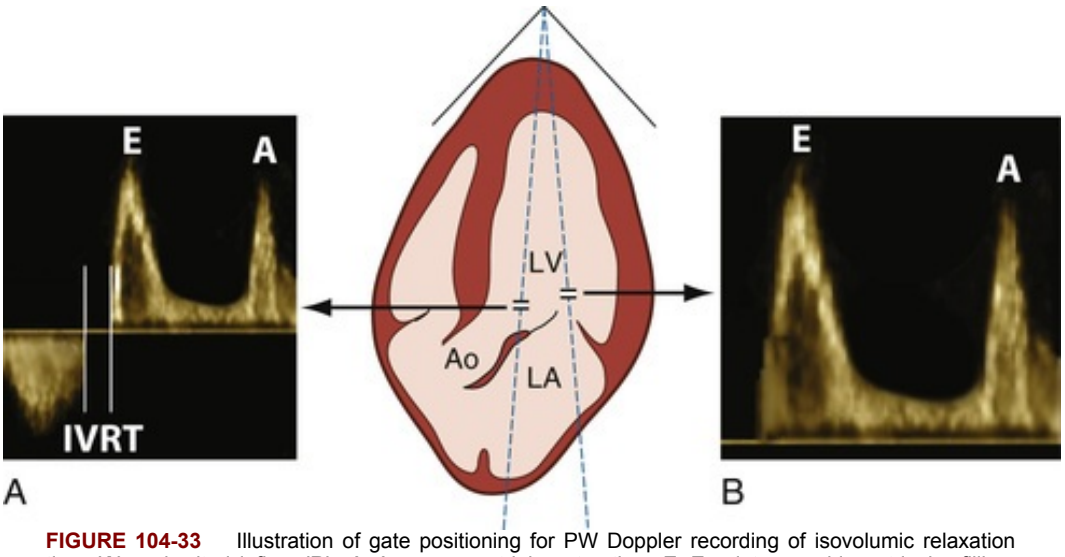

FIGURE 104-33 Illustration of gate positioning for PW Doppler recording of isovolumic relaxation time **(A)** and mitral inflow **(B).** *A,* A wave or atrial contraction; *E,* E-point or rapid ventricular filling; *IVRT,* isovolumic relaxation time.

Assessment of Global Cardiac Function

Myocardial Performance Index (MPI) or Tei Index

The MPI or Tei index reflects global myocardial function and includes both diastolic and systolic time intervals. It correlates well with both systolic and diastolic function of the right and left ventricles in dogs and is used for assessing overall cardiac function.[100,105,106] In animals, the Tei index can be used to identify subclinical dilated cardiomyopathy, or global dysfunction associated with valvular regurgitation and pulmonary hypertension. It can also be measured by TDI. The Tei index, a unitless value, is calculated as follows:

$$\text{MPI} = (\text{IVRT} + \text{IVCT})/\text{LVET} = (\text{MCO} - \text{LVET})/\text{LVET}$$

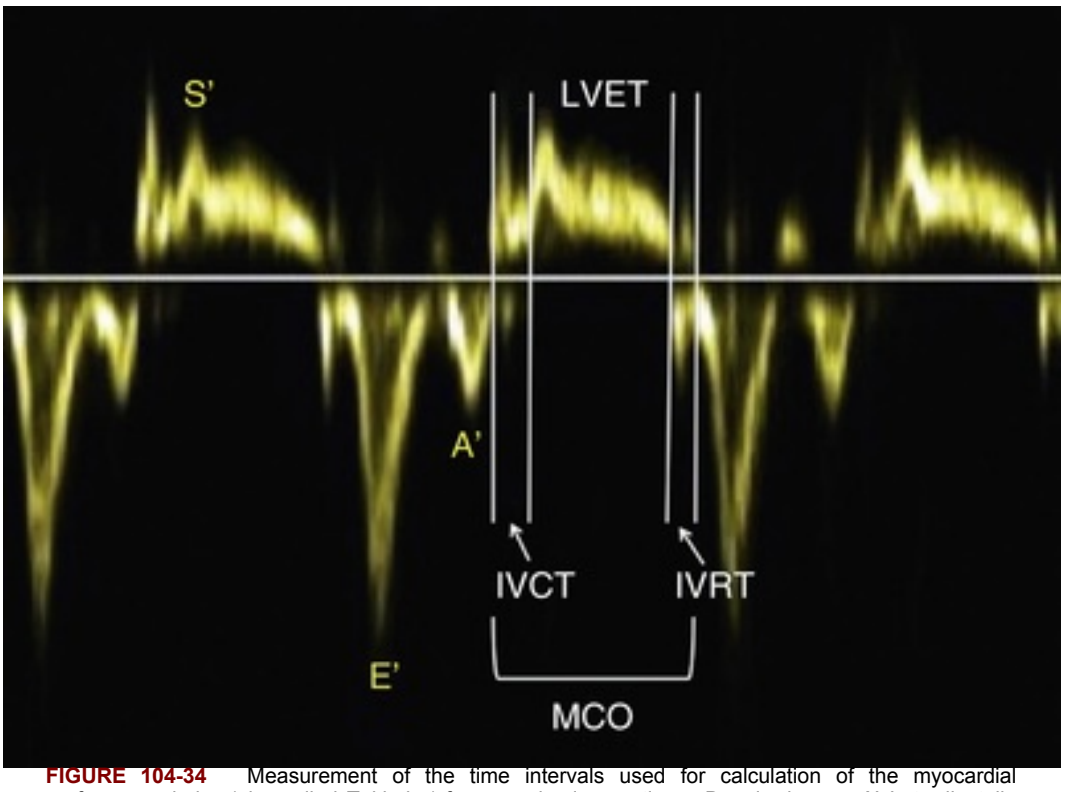

FIGURE 104-34 Measurement of the time intervals used for calculation of the myocardial performance index (also called *Tei index*) from a pulsed-wave tissue Doppler image. *A'*, Late diastolic myocardial motion; *E'*, early diastolic myocardial motion; *IVCT*, isovolumic contraction time; *IVRT*, isovolumic relaxation time; *LVET*, left ventricular ejection time; *MCO*, mitral closure to opening; *S'*, systolic myocardial motion.

where MCO is the time from mitral valve closure to reopening, i.e., from mitral valve closure in one heartbeat to mitral valve opening in the next heartbeat. Reference intervals for MPI are 0.38 ± 0.1 for dogs weighing 3-15 kg; 0.41 ± 0.1 for dogs weighing 15.1-35 kg; and 0.45 ± 0.1 for dogs weighing 35.1-55 kg.

E-TABLE 104-8

Tips to Optimize Echocardiographic Imaging in Small Animals

SITUATION	TIPS
To obtain the right parasternal long-axis view	The dot on the probe should point toward the shoulder of the animal

To obtain the right parasternal short-axis view	The dot on the probe should point toward the elbow of the animal
Structures from the right side of the heart are difficult to image	Image the right side of the heart from the left parasternal location
A specific cardiac structure is difficult to visualize	Remember the 3 ways to move the probe: sliding, tilting, and twisting
For the right parasternal location on brachycephalic breeds	The probe should be positioned closer to the sternum in comparison to other breeds
Unable to optimize the imaging of one extremity of the heart (apex or base)	Slide one intercostal space cranially or caudally
Horizontal lines with a hazy image are observed	Add some coupling gel to improve poor transducer contact
Decreased resolution of the structures in the lateral field	Decrease the overall gain
Poor near-field resolution/image quality in very small patients	Change to a higher frequency probe

CHAPTER 105

Urine Collection

Amanda Callens, Joseph W. Bartges

This chapter is enhanced with the following electronic assets at **ExpertConsult.com:** 4 Videos.

Background

Urinalysis is an integral component of a minimum database, along with complete blood cell counts and blood chemistry evaluation (see ch. 72). In some patients, urine culture is indicated in addition to or after review of the analysis. As with any sample evaluation, urine collection method can influence results.[1,2] It is imperative that urine samples be collected and handled properly for accurate results and to protect patients from traumatic complications or nosocomial infections by using good technique. There are several collection methods available to obtain urine from a patient including voiding, transurethral catheterization, and cystocentesis.

Collection Methods

Voiding

Methods and Containers

"Free catch" of naturally voided urine is commonly used to collect samples for analysis and is easy to do in most male dogs. A container lid is easy for most owners to use when collecting urine from female dogs: first slide the lid under the dog when she begins to urinate, collect 5-10 cc (1-2 teaspoons), pour the lid contents into the container and close. With these methods, one gains not only a urine sample for analysis, but one also has the opportunity to watch the patient urinate and determine if the process appears normal or abnormal. For indoor cats, one straightforward method is to place the cat in a room overnight that has a litter box with non-absorbable litter or a box from which most litter has been removed, leaving enough for scratching but not enough for absorption. The following morning, urine can be poured into a container. Disposable, sterile, inexpensive containers with tight fitting lids are available and help in good sample management. When an owner obtains a free catch sample from a dog or cat, use of improvised containers is discouraged as they may contain contaminants that alter results. Use of a sterile collection container does not ensure sterility as it is not a closed system. Use of transparent containers can be helpful in assessing color and turbidity.

Manual compression of the bladder also should result in urine flow, allowing easy collection. A consistent method is to palpate and isolate the bladder. Then, one should place moderate-but-firm pressure over as much of the bladder as possible. This is easiest when the bladder can be placed in one hand, as can be done with most cats. Both hands may be needed for either gender of either species. Hard pressure, intermittent or continuous, should be avoided.[3]

Advantages

The advantage of collecting naturally voided urine is that it is not associated with any patient risk. When free catch collection methods are used, urine flows through the distal urethra, genital tract, hair, and skin. These areas, however, can contaminate the sample with their bacterial populations. Ideally, the urine should be collected mid-stream to decrease these concerns. The risk of harming a dog or cat using manual collection is minimal, but exists as the urinary bladder may be traumatized if excessive pressure is used. Bladder palpation, much less compression, can be difficult to impossible if the bladder contains little or no urine.

Transurethral Urinary Catheter Procedure

Materials and Patient Preparation

A sterile, flexible, rubber urinary catheter similar to or smaller than the diameter of the patient's urethra should be used. In general, feline patients tend to be more difficult to catheterize than canine patients and females are more difficult than males. As veterinary patients vary greatly in size and cooperation, equipment and technique varies as well. The French (Fr) measurement scale is most commonly used in determining the diameter of catheters. Each unit in Fr is equal to $\frac{1}{3}$ mm. To convert the Fr size into millimeters divide the Fr size by three. In cats, a 3.5- or 5-Fr catheter is often used; in dogs, a 5- or 8-Fr catheter is usually appropriate. Catheters can have single or multiple fenestrations, or "eyes." These fenestrations are present to enable urine flow from the bladder. Flared-end catheters are preferred; otherwise, the catheter may migrate into the urethra.

Before placing any catheter through the urethra, cleanse the area around the catheter insertion site with water and germicidal soap. The soapy solution should be rinsed completely before catheterization, as it can alter analysis results. Soapy contamination may result in a cloudy appearance to the urine as well as causing cell lysis, bacterial inhibition, and enzymatic changes. If there are copious amounts of fur, clip the hair before cleaning.[4]

Catheter Placement

When placing the catheter, it is important to estimate the length of the urethra from the distal urethral orifice to the caudal aspect of the bladder. This length should be mentally noted on the catheter to avoid overinsertion. Overinsertion may cause damage to the bladder mucosa where the tip and/or body of the catheter rub on the bladder wall, causing abrasion. Rarely, catheters have tied a knot within the bladder after too much length was inserted, requiring surgical removal. The use of a stylet may be necessary with less rigid catheters, being inserted into the catheter lumen to increase rigidity. It is easier to insert a catheter with a stylet in place. Some catheters come with a stylet pre-placed and others require a separately sterilized stylet. The catheter should be coated with a sterile water-based lubricant before being inserted into the urethra. Proper lubrication improves patient comfort and compliance, and facilitates insertion by decreasing resistance from surrounding tissue while minimizing trauma.

It is important to maintain clean technique throughout the catheterization process. The catheter should not come in contact with any unsterile objects. Handling of the catheter should be done with sterile gloves after removing it from its sterile packaging, by manipulating the catheter within the sterile packaging (Figure 105-1), or by handling with sterile instruments. If resistance is met while passing a lubricated catheter, it should be removed or gently redirected. The catheter can be reinserted with a gentle rotating motion. Persistent, forceful pressure should not be used. If resistance persists, the diameter of the catheter should be re-evaluated and a smaller diameter catheter employed.

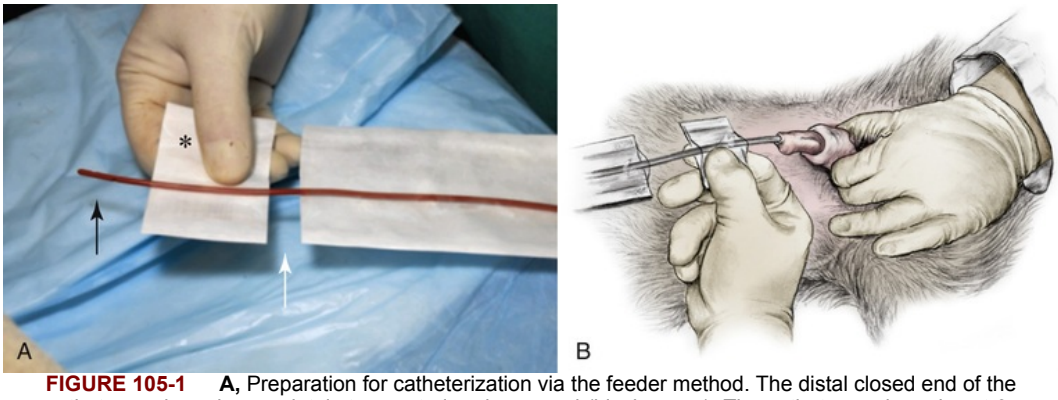

FIGURE 105-1 **A,** Preparation for catheterization via the feeder method. The distal closed end of the catheter package is completely transected and removed (black arrow). The catheter package is cut 3-5 cm from the cut end by making 2 cuts from both sides of the package without cutting the catheter (white arrow). The catheter package tab (asterisk) is then used to feed the catheter. **B,** Urethral catheterization of a male dog. A portion of the catheter's package is used to aseptically advance the catheter through the urethra.

Once the catheter is successfully passed through the urethra into the urinary bladder lumen, it is important to verify proper positioning. Ideally, the catheter should be passed until the "eye" of the catheter is just inside the bladder lumen. This positioning can be verified by passing the catheter while putting gentle negative pressure with a syringe attached to the distal end of the catheter. Once urine is obtained through the catheter and into the syringe, the fenestrated portion of the catheter has reached the bladder lumen.

Risk of Trauma

These methods carry the most risk of trauma and/or iatrogenic bacterial urinary tract infection. However, they are inexpensive and can be done without sedation or anesthesia in most dogs. Cats require sedation or anesthesia, unless obtunded. In this procedure, the catheter tip should always be well lubricated with sterile gel.

Male Dogs—Procedure

Male dogs are typically standing on the floor, standing on a table, or laterally recumbent for catheterization. The os penis in male dogs contains the urethra, which runs within the long axis of the shaft. This bone allows the penis to easily be exteriorized from the sheath and held during cleansing, lubricated catheter insertion and advancement. This procedure is well-tolerated and does not usually require sedation, especially if the clinician purposefully chooses a catheter diameter that is small.

Female Dogs—Procedure

There are numerous methods used for collecting urine from female dogs, two of which are presented here. With the female standing, one may place a gloved and lubricated finger, palm down, into the vaginal vault to gently palpate the urethral opening. Once the urethral papilla is felt, one can pass the catheter along the ventral aspect of the inserted finger using the other hand. As the catheter tip reaches the inserted fingertip, placing gentle downward pressure encourages the catheter to enter the urethra rather than continuing forward in the vaginal vault (Figure 105-2). One may choose to place a vaginal speculum into the vulvar opening to visualize the urethral opening and the catheter entering it (Figure 105-3). Use of a speculum often seems uncomfortable and may not be tolerated without sedation or anesthesia. Use of a speculum risks traumatizing the dog.

FIGURE 105-2 Urethral catheterization of a female dog. An index finger is placed over the urethral orifice to guide the catheter ventrally into the urethra.

FIGURE 105-3 Appearance of urethral orifice in a female dog as visualized during endoscopic examination.

Cats—Procedure (Videos 105-1, 105-2, 105-3, and 105-4)

It is rare to pass a catheter into the bladder of cats for urinalysis. However, if the urethra is obstructed, knowing how to insert and pass a bladder catheter in cats can be vital (see Video 105-1). In obtunded or anesthetized males, the penis can usually be gently grasped between thumb and index finger, extended caudally to straighten the urethra, and the lubricated catheter gently inserted and advanced to the level of the obstruction or into the bladder (see ch. 107). Passing a catheter in female cats utilizes the same approach as with female dogs. However, cats are so small that this procedure is rarely employed.

Cystocentesis

Definition, Indications, Equipment

Cystocentesis involves percutaneous needle puncture of the urinary bladder for the purpose of removing urine directly via aspiration. Cystocentesis can be performed for diagnostic purposes, such as sample collection for urinalysis or urine culture. Cystocentesis can be employed for therapeutic uses by providing decompression of the urinary tract in cases of obstructive disease. Cystocentesis is usually associated with little risk of iatrogenic complications and is better tolerated than transurethral catheterization. Cystocentesis is the preferred collection method when a sterile urine sample is needed or preferred. The equipment usually employed is a sterile 3 or 6 mL syringe and 22-gauge, 1½ inch needle.

Technique in Cats and Small Dogs

Cystocentesis is best done with cats placed in dorsal recumbency but may be accomplished in lateral recumbency. In dogs it is most commonly performed with the patient in dorsal recumbency or standing (Figure 105-4). The urinary bladder should be localized and immobilized regardless of patient position. The

skin area to be penetrated by the needle should be cleaned with an antiseptic solution. A needle attached to the syringe is inserted through the ventral or lateral abdominal wall. When inserting the needle, it is important to angle the tip from cranial to caudal towards the trigone so that as urine is aspirated and the urinary bladder contracts, it contracts along the needle, minimizing risk of traumatizing the bladder mucosa with the needle tip. While the bladder and needle are immobilized, urine is aspirated into the syringe. Once the desired volume is obtained, aspiration ceases and then the needle is removed.

FIGURE 105-4 Cystocentesis may be performed with the patient in dorsal recumbency, particularly if the procedure is being done when the urinary bladder cannot be palpated. The site for needle insertion is generally at a point midway between the umbilicus and the pelvic brim. Normally, the clinician's left hand would be applying pressure to the abdomen to stabilize the bladder, but the hand is moved away here to improve visualization.

Technique in Large Dogs

In larger dogs, it can be difficult to palpate and immobilize the bladder for cystocentesis. If the bladder is not palpable due to patient size, one can use landmarks to guide the needle. One approach is to visualize the two most caudal pairs of mammary glands and draw lines between the last mammary gland on one side and the second to last gland on the other side and the last mammary gland on the contralateral side with the second to the last gland on the opposite side resulting in an "X." The needle is inserted where the two lines intersect. Ultrasound can be used to guide cystocentesis (see ch. 88 and 143). Ultrasound permits visualization of urinary bladder and needle during the procedure. The patient is positioned in dorsal recumbency and the needle is inserted under the transducer. It is essential to avoid puncturing the transducer. With ultrasound, it is not necessary to palpate the bladder or use landmarks to locate the bladder.

General Protocols

During cystocentesis, the needle should never be redirected when within the abdominal cavity, to avoid traumatizing any intra-abdominal organ. No negative pressure should be applied to the syringe with the plunger while inserting the needle or removing the needle from the abdomen. Constant suction potentiates contamination of the sample, the bladder, the peritoneal cavity, and organs as the needle passes through bowel loops and other abdominal, SC, or dermal structures.

The length of needle inserted varies as required by patient size. For larger patients, it may be necessary to insert the needle to the hub to achieve enough depth to reach the bladder. In smaller patients, it may only be

necessary to insert the needle a short distance. If the needle is inserted and no urine aspirated when negative pressure is applied, one may need to insert the needle further or retract it slightly, depending on patient size and bladder volume. If urine is not obtained on the first try, then the same technique can be used, either cranial or caudal to the first site, being conscious to stay on midline if the patient is in dorsal recumbency. A new sterile needle should be used with each attempt. If urine is not successfully retrieved, it may be necessary to visualize the bladder using ultrasound guidance.

Sample Management

If collected urine is not analyzed immediately, it should be refrigerated to slow degeneration of cells and inhibit bacterial growth (see ch. 72). The amount of time between collection and analysis, as well as refrigerating urine, increases likelihood of crystal formation; therefore, the clinician should take into account these factors when interpreting a urinalysis. If urine is obtained via cystocentesis, the needle must be changed before transferring the sample into a sterile submission vial or container. Failure to replace the used-contaminated needle with one that is new and clean can affect analysis results. If urine is collected for analysis only, a small amount should always be saved in a sterile container and refrigerated, in case the submitted sample demonstrates signs of active inflammation. If inflammatory cells are identified, the stored sample can be submitted for culture and sensitivity testing to rule in or out bacterial infection. Red blood cells may be observed on urinalysis with cystocentesis collection, but this blood is usually inconsequential and in quite small amounts. This blood is often caused by the needle puncturing the bladder and/or skin during collection. Resulting hematuria is usually microscopic and short-lived.

CHAPTER 106

Management of Urinary Catheters

Amanda Callens, Joseph W. Bartges

Indications

Urethral catheterization may be used for ensuring urethral patency in patients with obstructive disease, for urine drainage away from recumbent dogs or cats, to know the urine volume produced in hospitalized patients, to collect diagnostic samples (see ch. 105), or to perform diagnostic radiographic procedures.[1] Urethral catheter placement in an intensive care setting is commonly used to monitor urine volumes (see section on "ins and outs," below). Closed system collection of urine is most accurate for measuring urine output and best for avoiding infection. Dogs or cats who have recently undergone bladder surgery may have catheters placed to avoid overdistention. In this scenario, the catheter is used to maintain low pressure in the bladder, reducing tension on the suture sites and providing optimal healing conditions. Similarly, patients with recent bladder trauma may benefit from an indwelling urinary catheter.

Urethral obstruction refers to any structural or functional abnormality that impairs normal urine outflow (see ch. 107). Obstruction of urine flow increases pressure within the lower urinary tract, which can damage mucosa and lead to inflammatory cell infiltrates. Prolonged excessive pressure can lead to nerve and detrusor muscle damage. Finally, pressure may extend to the upper urinary tract where glomerular filtration rates decrease and azotemia develops or worsens.[2]

Indwelling Urinary Catheter Care

Preparation and Instrumentation (Videos 106-1 and 106-2)

The goals of urinary catheter care are to maintain patency and decrease likelihood of inducing nosocomial infections.[3] Catheter care begins during placement with clean technique, where avoiding contamination is imperative (see ch. 105). The perivulvar or peripreputial area should be clipped and prepped with antiseptic, such as a 1 : 40 chlorhexidine solution. The area should be washed with diluted chlorhexidine scrub, the vulvar or preputial pouch flushed, and the area cleansed again. Any instruments that might be used for catheter placement should be gathered and, once sterile packets are opened, laid out on a sterile field. In addition to the catheter and a spare (that might be slightly larger or smaller in diameter), one usually needs sterile lubricating gel, a stylet (if need is anticipated), visualization tools, and a syringe containing sterile fluid for balloon inflation, if a Foley catheter is being placed.

Closed Collection Systems (Video 106-3)

Indwelling urinary catheters should be incorporated into a closed collection system. Required materials are catheters, adapters, sterile tubing, and a collection bag. Once the catheter is placed, an adapter should be tightly connected to collection tubing. A tight connection helps avoid leakage from the collection set and decreases likelihood of inadvertent detachment. Once all tubing is connected, a reservoir bag can be secured to the distal end of the system to hold urine until emptied. Sterile pre-packed single-use collection bags with one way valves to prevent urine from refluxing back into the line are available. These bags often contain a drain at the distal end with easy open/close valves. Alternatively, empty IV fluid bags can be used. Used IV bags, however, do not provide the safeguards of purpose-made bags nor should they be considered sterile, if not re-sterilized after use. If traditional IV fluid lines are used for collection tubing, their clamps should either be disabled or removed to avoid unintentional clamping of the line that will obstruct urine outflow.

Securing the System (Video 106-4)

Dogs and cats are likely to remove indwelling catheters if no preventative measures are taken, making it imperative that deterrents be used to prevent a patient from interfering with their indwelling catheter. Securing the catheter at multiple points is recommended through a combination of catheter balloon inflation, suturing, and stress loops on legs or tail to avoid inadvertent removal. The steps taken to secure a catheter in place and to keep the patient from self-removal cannot be overemphasized, as catheter removal often leads to a second round of sedation, additional time, need for a new catheter, unnecessary patient stress, and owner expense.

Personnel

Appropriate maintenance of the catheter and collection system is essential to maintain patency, decrease risk of infection, and prevent self-removal. Catheter care protocols should ensure constant appropriate monitoring and care. Personnel should be certified for being able to provide consistent appropriate care.

Monitoring and Care

It is important to always wash one's hands and don disposable gloves before handling urinary catheters and lines to protect patients and personnel from contamination during examination. Gloves should be changed if they become soiled. New gloves should be used with each patient. The collection bag and tubing should be placed at a level lower than the patient to encourage urine drainage. This decreases the likelihood of backflow or stagnant urine within lines. Urine pooling in collection lines can lead to sediment buildup and occlusion. Avoid placing the collection bag and/or tubing on floors.

All connections should be checked and secured frequently. When urethral diameter is larger than catheter diameter, leakage will be noted at the catheter insertion site. In this case, the catheter should be replaced with a larger size. If leakage is noted at a connection site, those sites should be cleaned and tightened. Catheter and collection system cleanliness must be maintained by periodically wiping down the lines with antiseptic solution. Skin around the catheter should be gently cleaned and monitored for signs of infection. Urine volumes should not be measured using marks on a reservoir, as this is unreliable. Instead, the urine should be poured into a measuring beaker for an accurate volume reading. Tracking volume of urine produced is imperative. Urine should be assessed for appearance every 2 to 4 hours. At this time, the collection bag should be emptied and volume recorded. Normal urine output is about 1-2 mL/kg/h or more depending on fluid rates and the cause for illness.

Complications

A patient with an indwelling urinary catheter should have an empty bladder that is flaccid. If a large bladder is palpated, it must be addressed immediately. Occlusion can result if flocculent material gathers in the catheter or collection system. To rule out an occluded system, the catheter can be flushed with 5-10 mL sterile saline. This volume should easily flow into the catheter and be easily retrieved. If the saline does not flow easily, then the catheter is kinked or occluded and must be removed. If urine flows easily into the catheter, but cannot be aspirated, then the catheter position is likely inappropriate; most commonly, the catheter has migrated caudally from the bladder into the urethral lumen. This will allow fluid to be flushed in but not retrieved.

An empty collection bag at the end of any checkpoint may be a serious concern, indicating either a problem with the collection system or failure to produce urine. Immediate attention should be given to such patients. If catheter location is in question, abdominal radiography or ultrasonography can help visualize the catheter and verify its location. A catheter that has migrated distally into the urethra should never be reinserted, as bacteria and debris may have accumulated at the catheter tip. Migrated catheters should be replaced. Occlusions distal to the catheter can be identified by flushing saline into the collection system, away from the patient. If saline cannot be flushed, then the collection system should be replaced. If lines are kinked, the occlusion must be resolved. If an area is likely to re-occlude (re-kink), that catheter and/or tubing should be replaced or repositioned. If lines become loose or disconnected, they should be re-secured and, if there is a defect, replaced.

Catheter-Associated Urinary Tract Infection

Catheter-induced bacterial urinary tract infections (UTI) are common (see ch. 330). Bacteria may migrate along the outside or through the lumen of any catheter. There is an increased risk of bacterial UTI with pre-

existing urinary tract disease or with urothelial damage. Bacterial UTI occurs in >50% of animals with an indwelling urethral catheter for 4 days.[3] Systemic antibiotic therapy, while an indwelling catheter is in place, decreases frequency of bacterial UTI; however, when bacterial UTI occurs, the organisms exhibit a greater degree of antimicrobial resistance. Therefore, prophylactic antibiotic therapy for patients with an indwelling urinary catheter is NOT recommended. Antibiotics should only be given in patients with indwelling urinary catheters if infection is present.

Infection monitoring includes temperature checks and submitting urine for culture and sensitivity testing, if indicated. Patients with indwelling urinary catheters should be observed closely for development of fever, pyuria, or discomfort. Catheters can remain in place as long as signs of infection (fever, purulent discharge, odor) are not observed. However, since urinary catheters are invasive and carry risk of infection, they should be removed as soon as indicated.

Urinary tract infection may occur if bacteria are introduced during catheterization. Risk of iatrogenic infection increases with various issues, including the following: if the urinary tract is traumatized, when aseptic technique is not used, in the presence of vaginal or preputial discharge, with immunosuppressed patients, and after repeated catheterizations. Trauma leading to infection can be induced if too much force is applied during catheterization, inadequate lubrication is applied, or urethral obstruction was present at time of catheterization.

Monitoring "Ins & Outs"

Monitoring fluid volumes, both intake and outflow, can be vital for critically ill patients, especially those with conditions associated with rapid dehydration or at risk for fluid overload. Fluid volumes "in" include IV fluids, parenteral nutrition, and enteral water intake. Fluid volumes "out" include urine output, vomitus, and estimates of loose or watery stool volumes. Together, these are known as the "ins and outs."

Patients with renal insufficiency represent an excellent example of a clinical condition in which knowing ins and outs is imperative because overhydration is common and consequences are worrisome. By measuring fluid losses, an appropriate volume can be replaced, avoiding over-hydration. In pets with polyuric renal failure, dehydration is a risk because of their inability to concentrate urine. One can match ins and outs by replacing the volume out in one time period with the volume "in" in the next (see ch. 129, 322, and 324). Any dog or cat receiving high fluid rates should have ins and outs monitored. These patients must be monitored closely for signs of fluid overload.

Urine output volume should never be zero. If no urine is noted the collection system and the bladder size should immediately be assessed. Possible issues leading to an empty urine collection bag include occlusion within the system, a leak between connections in the system, or a displaced catheter. If the urine output is in fact zero then oligoanuria may be occurring and should be addressed immediately (see ch. 322).

CHAPTER 107

Unblocking of the Urethra

Jody P. Lulich, Carl A. Osborne

Overview

A variety of methods exists for unobstructing the urethra. However, safely restoring urine flow without causing trauma to the urinary tract requires stabilizing the patient, knowing the underlying cause, selecting anesthetic protocols that completely relax the urethra, employing a gentle and cautious technique, and incorporating appropriate aftercare.

Patient Management

Prior to unobstructing the urethra, it is important to ensure that the patient is sufficiently stable to undergo anesthesia. Complete urethral relaxation is usually essential to clear an obstruction. Most dogs and cats with a urethral obstruction are metabolically stable. However, about 15% of obstructed cats and fewer dogs require therapy for hyperkalemia, hypocalcemia, hypothermia, acidosis, dehydration, and/or azotemia (Table 107-1). An IV access line should be placed in all patients to administer fluids, anesthetics, electrolytes, etc.

TABLE 107-1

Minimizing Metabolic Consequences of Urethral Obstruction

CONSEQUENCE	INDICATIONS TO TREAT	THERAPY
Hypothermia (see ch. 49)	Core temperature <99° F (<37.2° C) or cardiac decompensation	Heating pad Heat lamps Infuse only warm saline into the bladder
Hypovolemia (see ch. 127 and 129)	Azotemia Cardiovascular collapse	Replace deficits in 2 to 12 hours with 0.9% saline Consider an initial bolus of fluids to rapidly correct hypovolemia if needed (10 to 30 mL/kg) Although saline has been recommended because patients are often hyperkalemic, any balanced replacement electrolyte solution will help
Azotemia	If serum creatinine is greater than 3 mg/dL	Replace fluid deficits with balanced electrolyte solutions Decompressive cystocentesis to promote renal excretion
Acidemia (see ch. 128)	If blood pH <7.1-7.2	Administer ⅓ to ½ of the dose of $NaHCO_3$ (0.3 × BW in kg × base deficit) administered over 15 min. Rapid or excessive administration of bicarbonate may exacerbate hypocalcemia. Fluid administration to correct hypovolemia Decompressive cystocentesis to promote renal excretion
Hyperkalemia (see ch. 68)	Weakness or shock due to cardiovascular depression	To promote potassium excretion: 1. Decompressive cystocentesis 2. Fluid administration with potassium-sparing fluids To promote intracellular translocation of potassium, consider one of the following: Correct metabolic acidosis with sodium bicarbonate (mmol = ⅓ [0.3 × BW in kg × base deficit]) or

		Administer 0.1 U/kg regular insulin IV with 1 gram of glucose per unit of insulin administered To antagonize adverse cardiac effects: 50 to 100 mg/kg calcium gluconate slow (2-5 min) IV Concomitant hypocalcemia and acidemia contribute to worsened heart function
Hypocalcemia (see ch. 69)	Hypocalcemic tetany or hyperkalemic cardiac decompensation	50 to 100 mg/kg calcium gluconate slow (2 to 5 min) IV with cardiac monitoring

Determining the Cause

Knowing the cause of an obstructed urethra is essential in planning to re-establish urine flow and prevent re-obstruction. For example, cats with calcium oxalate urethroliths should have the stone flushed into the urinary bladder immediately, followed by minimally-invasive or surgical removal (see ch. 124). To achieve this level of coordinated care, survey radiography prior to urethral clearance is essential. While urethroscopy is accurate for verifying, localizing and determining cause of an obstruction (see ch. 108), it can be technically challenging and cumbersome during an emergency.

Clinical signs of dysuria are similar, regardless of whether or not a patient has urethral obstruction. Therefore, one must verify an obstruction prior to urethral catheterization. Use of urethral catheterization to diagnose obstruction may not be reliable and carries the risk of iatrogenic perforation. Likewise, inability to manually express the urinary bladder can be misleading and dangerous (i.e., rupture). If feasible, evaluation of the urinary tract should include external palpation of perineum and distal urethra, rectal palpation of urethra and pelvic canal, and evaluation of perineal reflexes, tail reflex and hind limb proprioception. Consider observing attempts at voiding urine followed by assessment of bladder size (e.g., survey abdominal radiography, ultrasonography). Small bladders are consistent with pollakiuria. A large bladder is consistent with urethral obstruction. Survey abdominal radiographs provide a global assessment of the urinary tract, verify bladder size, and may allow visualization of radiodense objects within the entire urinary system, but specifically within the urethral lumen. In some scenarios, antegrade or retrograde contrast urethrography is indicated.

Anesthesia

Since the urethra is highly innervated, it can be one of the most difficult areas to successfully anesthetize. To avoid iatrogenic urethral trauma, complete urethral relaxation and analgesia are necessary. Type and degree of sedation/anesthesia vary depending on patient status and veterinarian preference, but for complete urethral relaxation a combination of systemic and local anesthetics (i.e., lumbar or caudal epidural) are recommended. On occasion, complete urethral relaxation will be sufficient for a urethral plug to pass. It has been suggested that unobstructing moribund cats be attempted without sedation, using only intraluminal instillation of a local anesthetic agent (e.g., lidocaine) or with an epidural. However, initial stabilization (e.g., decompressive cystocentesis, IV fluids) followed by a balanced anesthetic protocol is recommended. Adding local anesthetics to flushing solutions is not effective because there is not sufficient contact time nor drug concentration to anesthetize the urethral mucosa. Use of anesthetics that may increase urethral tone should be avoided; for example, dexmedetomidine, a relatively selective alpha 2-adrenergic agonist, may stimulate alpha-1 adrenergic receptors, induce constriction of the proximal urethra and impede urethral clearance.

Unobstructing the Feline Urethra

Overview

Several techniques can be employed for removing an intraluminal urethral obstruction. Technique selection should be based on underlying cause, need/willingness to perform decompressive cystocentesis, and severity of life-threatening metabolic abnormalities (Table 107-2). To minimize urethral trauma, one should never use a catheter to force or push luminal contents; rather, the catheter is the vehicle through which one can use flushes of fluid to dilate the urethra and propel luminal contents out. To do this, one should assemble an open-ended urethral catheter (e.g., olive tipped, tomcat), IV extension tubing, and a saline-filled syringe (Figure 107-1, Video 107-1). The IV tubing allows one person to extend the urethra and carefully advance the catheter while an assistant manages the syringe when flushing is indicated. Scenarios are invariably

encountered in which the clinician without assistance must attempt to unblock a urethra. We still recommend attaching IV extension tubing between the catheter and syringe. If the syringe and catheter are connected directly, it becomes difficult to empty the syringe without inadvertently forcing the catheter further into the urethra and sometimes through the urethral wall.[1] Remember that small syringes provide greater flushing force than larger ones. There are four techniques to unobstruct the feline urethra. We have the greatest success using retrograde flushing while occluding the distal urethral orifice (the second procedure listed below).

TABLE 107-2

Characteristics of Methods to Relieve Urethral Obstruction in Male Cats

PROCEDURE	RETROGRADE FLUSHING WITHOUT URETHRAL OCCLUSION	RETROGRADE FLUSHING WITH URETHRAL OCCLUSION	ANTEGRADE EXPULSION VIA URINARY BLADDER EXPRESSION	ANTEGRADE EXPULSION VIA PHARMACOLOGIC MANIPULATION
Indications	• Matrix crystalline plugs • Blood clots	• Matrix crystalline plugs • Urethroliths • Blood clots • Solid foreign material	• Matrix crystalline plugs • Blood clots • Mural edema or inflammation • Urethral spasm	• Matrix crystalline plugs • Blood clots • Mural edema or inflammation • Urethral spasm
Contraindications	Inadequate anesthesia	Inadequate anesthesia	• Urethroliths • Inadequate anesthesia • Solid foreign material	• Urethroliths • Solid foreign material
Analgesia or sedation	Consider	Consider	Consider	Yes
Anesthesia	Yes	Yes	Yes	Not applicable
Decompressive cystocentesis	Not necessary	Yes	No	Yes, multiple
Potential advantages	• No need for cystocentesis • Rapid reversal of azotemia	• Very successful • Rapid reversal of azotemia	• Avoid iatrogenic urethral trauma • Reduced cost • Plug is flushed out	• Avoid iatrogenic urethral trauma • Reduced cost
Potential disadvantages	Urethral trauma or inflammation	Urethral trauma or inflammation	• Bladder rupture, uroabdomen, or hemoabdomen • Poor success	• Bladder trauma, uroabdomen, or hemoabdomen • New technique, requiring further validation

FIGURE 107-1 After exteriorization of the penis, an olive-tipped urethral catheter (attached to

intravenous extension tubing) is inserted into the distal urethral lumen (**A,** Video 107-1). Using a moistened gauze sponge, the distal urethral lumen is occluded around the shaft of the urinary catheter with the thumb and first finger; the urethra is pulled caudally to eliminate the urethral flexure **(B).** To clear the urethra, saline is flushed in a retrograde direction through the extension tubing, urethral catheter and urethral lumen into the urinary bladder.

Retrograde Flushing without Decompressive Cystocentesis or Occluding the Distal Urethra

1. Gently massage the distal urethra by rolling it between your thumb and forefinger with the goal of disrupting the continuity of any urethral plug. Exteriorizing the penis will facilitate this process.
2. Assemble the urethral catheter, IV extension tubing, and large (20 to 60 mL) saline-filled syringe. Evacuate air from the lines by flushing saline through the assembled apparatus.
3. Exteriorize the penis, pulling gently caudally and dorsally (i.e., parallel with the vertebral column).
4. Without excessive force, slowly insert the tip of the urinary catheter into the urethra and advance the catheter to the site of obstruction.
5. While keeping the penis exteriorized and extended caudally (usually accomplished by pulling the prepuce caudally), flush large quantities of physiologic saline into the urethral lumen, allowing it to reflux back out of the external urethral orifice with pieces of the plug. As the plug disrupts, advance the catheter slowly toward the urinary bladder.
6. When the tip of the catheter reaches the urinary bladder, empty the bladder through the catheter.

Retrograde Flushing with Occlusion of the Distal Urethral Orifice (see Video 107-1)

1. Perform decompressive cystocentesis, if needed, using a 22-gauge, 1.5-inch needle attached to IV extension tubing, 3-way stop-cock and syringe. Most but not all urine should be removed.
2. Select an olive-tip urethral catheter (or other suitable catheter) to flush fluid into the urethra. Assemble the urethral catheter, IV extension tubing, and small syringe (3 to 12 mL) filled with normal saline. Evacuate air from lines by flushing saline through the apparatus.
3. Exteriorize the penis caudally and dorsally (i.e., parallel with the vertebral column).
4. Without using excessive force, slowly insert the tip of the urinary catheter into the urethra and advance the catheter toward the site of obstruction.
5. With the catheter in place, occlude the urethra around the catheter shaft using your first finger and thumb. Placing a moistened gauze sponge or pad between the urethra and your fingers will minimize trauma to the surface of the urethra.
6. Extend the urethra caudally and dorsally while an assistant presses the syringe plunger to flush urethral contents into the urinary bladder. By preventing reflux of solutions out of the external urethral orifice, this maneuver dilates the urethra, releasing the plug, and allowing it to flow into the urinary bladder. Additional flushing may be needed to completely clear the urethra. To avoid overdistension of the urinary bladder, use small volumes (e.g., 6 mL) of saline to flush. Repeat the decompressive cystocentesis as needed.
7. Once the urethral lumen is cleared, advance a longer catheter slowly toward the urinary bladder. Empty the bladder.

Antegrade Evacuation via Bladder Compression

1. Massage the distal urethra by rolling it between your thumb and forefinger with the goal of disrupting the continuity of any urethral plug. Exteriorizing the penis will facilitate this process. The plug can also be disrupted by flushing large quantities of saline into the urethra (see retrograde flushing without occluding the distal urethra for this technique).
2. Ensure that the plane of anesthesia is deep and the urethra completely relaxed (see Video 107-1). Provide steady, but not excessive, manual pressure on the urinary bladder to evacuate the plug. Avoid excessive bladder pressure because it may result in trauma, reflux of potentially infected urine into the ureters, and/or rupture the bladder wall.

Antegrade Evacuation via Pharmacologic Relaxation of the Urethra[2]

1. Administer buprenorphine (0.01 mg/kg or 0.075 mg/cat) IM q 8 h and acepromazine (0.25 mg/cat) IM q 8 h. In one study, cats were also given 0.1 mg medetomidine IM q 24 h.
2. Some also advocate placing cats in a dark, quiet environment to minimize stimulation.
3. Perform decompressive cystocentesis as needed to keep bladder small (at least three times a day).
4. Cats are expected to begin urinating within 3 days. If unsuccessful, reassess the diagnosis and the need to select another method of clearing the urethra.

Unobstructing the Canine Urethra

Overview

Although urethral plugs have been reported in dogs, the most common cause for intraluminal urethral obstruction in male dogs is urethrolithiasis and in older females it is urethral neoplasia. Retrograde urohydropropulsion with urethral occlusion is recommended to clear the urethra of uroliths.[3] As with the cat, complete urethral anesthesia is essential for success without harming the urethral lining.

Technique

1. Perform decompressive cystocentesis, if needed, using a 22-gauge, 1.5-inch needle attached to IV extension tubing, 3-way stopcock and syringe. Most, but not all urine should be removed.
2. Fill one 6 mL syringe with 3 mL of saline and another 6 mL syringe with 3 mL of sterile water-soluble lubricant. Attach these two syringes with a 3-way stopcock. Mix the contents of both syringes together by emptying one syringe into the other several times. After inserting a urethral catheter into the tip of the dog's penis, inject 3 to 6 mL of the mixture to lubricate around the urethrolith(s).
3. To flush uroliths into the urinary bladder, insert a large bore flexible catheter into the distal end of the urethra.
4. Have an assistant insert his or her gloved finger into the rectum. Press ventrally on the pelvic floor to occlude the pelvic urethra between your finger and the floor of the pelvis.
5. Using your thumb and first finger, occlude the distal urethral orifice around the shaft of the flexible catheter. Placing a moistened gauze sponge between the urethra and your fingers will minimize trauma to the surface of the urethra and provide a more secure occlusion.
6. Fill a large syringe (e.g., 20 to 60 mL) with sterile isotonic solution (e.g., saline, LRS, etc.). Never flush more than 50% to 75% of the estimated bladder capacity (normal bladder capacity is about 8-10 mL/kg BW).
7. Firmly attach syringe and catheter; turn the syringe upside down so that the plunger is on top of the table. Hold the syringe by the barrel and empty the syringe forcefully by using your body weight to press the plunger down.
8. Once the pelvic urethra dilates, occlusion of the pelvic urethra is released while fluid is continually flushed through the urethra, propelling urethroliths into the urinary bladder.
9. In the majority of cases, uroliths can be successfully flushed into the bladder without intraurethral lubrication or pelvic urethral occlusion (steps 2, 4, and 8).

Post-Obstruction Care

After the urethra has been unblocked, additional care may be needed to prevent re-obstruction and further stabilize the patient (Table 107-3). If urethral clearance is not successful or perineal edema develops, consider contrast urethrocystography to determine the cause. If the urethra has been unobstructed recently (2 weeks to 2 months), urethral tear and subsequent strictures are common, often requiring repeated dilation (see ch. 124) or surgical intervention (e.g., urethrostomy).

TABLE 107-3

Patient Management Strategies Following Relief of a Urethral Obstruction

CONSEQUENCE	INDICATION TO TREAT	THERAPY
Urethral swelling	Poor urine stream, azotemia	Indwelling transurethral catheterization is commonly performed in cats When indicated, 3 to 5 Fr flexible urinary catheters composed of material that

		minimizes foreign body inflammatory reactions are preferred Catheters will need to be secured in place and preferably connected to a closed collection system In most cases catheters can be removed in 1 to 2 days
Residual plug precipitates and urine debris	Poor urine stream	Intravenous or subcutaneous fluid therapy can be used to increase urine output, dilute precipitate concentration, and increase their evacuation during voiding Using a transurethral catheter, gently fill and remove instilled saline. Be careful not to cause additional trauma or over-distend the bladder. Most urethral plugs in cats and dogs are composed of struvite. Consider foods to dissolve and prevent struvite as soon as severe metabolic consequences of obstruction (e.g., azotemia, acidemia, hyperkalemia) abate.[4]
Urethral spasm	Poor urine stream	Primarily a concern in cats The diagnosis is based on conjecture To relax the proximal urethra (smooth muscle): phenoxybenzamine 2.5 to 7.5 mg/cat PO q 12 to 24 h or prazosin 0.25 to 0.5 mg/cat PO q 12 to 24 h To relax the distal urethra (skeletal muscle): diazepam 1-2.5 mg/cat PO q 8 h or dantrolene 0.5 to 2 mg/kg PO q 12 h To relax proximal and distal urethra: Acepromazine 1.1 to 2.2 mg/kg PO q 12-24 h
Pain (see ch. 126)	Vocalization, excessive licking of genital area, irritable demeanor, difficult unobstruction	Consider pain medications that are unlikely to cause additional disease. Use of non-steroidal anti-inflammatory drugs in dehydrated (e.g., post-obstructive diuresis) and hypotensive (e.g., prazosin or acepromazine administration) conditions is contraindicated. Consider opioids and other safer drugs.
Post-obstructive diuresis	Anticipate post-obstructive diuresis in all patients that develop azotemia (e.g., creatinine >4 mg/dL)	The quantity of fluid lost is variable and sometimes profound Adjust fluid replacement rate based on clinical signs, perfusion parameters, body weight and/or urine output For every gram of body weight lost, consider replacing it with 1 mL of a balanced electrolyte solution
Detrusor atony	Should be anticipated in patients with extensive and prolonged bladder distension	Extended (2 to 5 days) transurethral indwelling catheterization is best Drugs to relax the urethra are listed above Drugs to promote bladder contraction: bethanechol 5 to 15 mg/dog PO q 8 h or 1.25 to 5 mg/cat PO q 8 h Manually express the urinary bladder 3 to 5 times a day. Do not express the bladder unless the cause of obstruction has been resolved and the patient is comfortable.
Urinary tract infection (see ch. 330)	Urinary instrumentation/catheterization	In patients without systemic or renal infection, consider prophylactic antimicrobials for 1 to 3 days after removal of short-term urinary catheters. Antimicrobials may need to be administered longer if the urinary tract is likely to remain damaged or take longer to recover. With confirmed infections, antimicrobial selection should be based on culture and susceptibility results and administered for a minimum of 7-10 days
Hypokalemia (see ch. 68)	Serum potassium levels below 3.0 mEq/L (3.0 mmol/L)	Supplement intravenous fluids with potassium chloride in those patients undergoing profound diuresis. Resume nutrition as soon as possible.
Anemia (see ch. 135)	The need for blood is rare. Hematocrits less than 13-15% or clinical signs of anemia (e.g., hyperpnea, depression, anorexia).	Consider packed red blood cells (see ch. 130)

CHAPTER 108

Cystoscopy and Urethroscopy

Julie K. Byron

Overview

Uroendoscopy (cystoscopy and urethroscopy) is a minimally invasive technique which allows assessment of the lower urinary and distal reproductive tract that can be important for diagnosis and treatment of a variety of disease processes. Uroendoscopy allows visual evaluation of the vaginal vestibule, vagina, urethra, urinary bladder, and ureteral openings. In some cases, the endoscope may be passed into the ureters for luminal evaluation as well. Diagnostic and therapeutic procedures can also be performed via urinary endoscopy including biopsy, urolith retrieval or lithotripsy, and laser surgical procedures (see ch. 124 and 329-337). Uroendoscopy can be a valuable part of the diagnostic and therapeutic management of urinary tract diseases and can yield different information than that gained from other imaging modalities due to magnification of the luminal surfaces.

Equipment

The term "endoscope" is a general term that may be applied to both flexible and rigid cystourethroscopes. Both rigid and flexible endoscopes may be used. Rigid cystourethroscopes consist of three parts: the telescope, sheath, and bridge (Figure 108-1). These may be separate components or integrated by the manufacturer. The glass fiber telescope provides an angled view of 0°, 12°, 30°, or 70° from the tip of the scope. The author prefers a 30° view which allows for visualization of all areas of the bladder with less manipulation as well as good visualization of the working field when using instruments (Figure 108-2). The sheath contains the irrigation and operating channels and the bridge has the light-source and camera connections as well as the instrument port. Rigid endoscope systems come in a variety of diameters and lengths. For small animal cystourethroscopy, three sizes are generally recommended: 4.0 mm × 30 cm for medium to large female dogs, 2.7 mm × 18 cm for small and medium female dogs, and 1.9 mm × 18 cm for female cats and male cats with a perineal urethrostomy (Figure 108-3). Additionally, a flexible or semi-flexible 5 Fr endoscope may be used to examine male cats. Male dogs with urethras that will accommodate an 8 Fr diameter catheter can be examined using a flexible 7.5 Fr × 70 cm fiberoptic or digital scope human ureteroscope. A flexible endoscope may also be used to evaluate larger female dogs in absence of a rigid cystourethroscopy system.

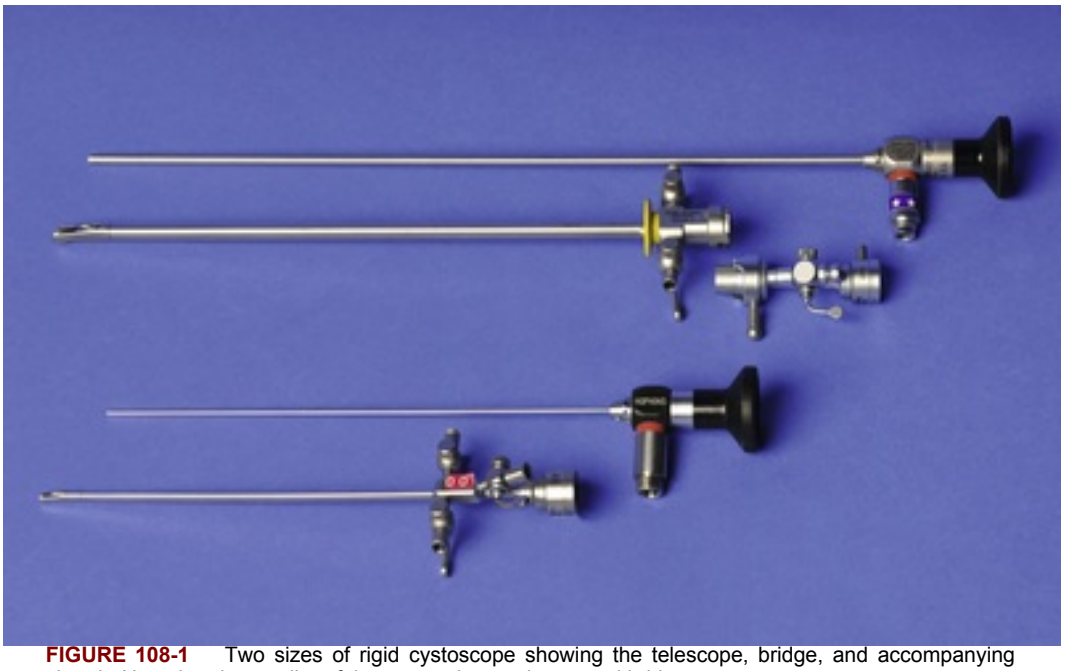

FIGURE 108-1 Two sizes of rigid cystoscope showing the telescope, bridge, and accompanying sheath. Note that the smaller of the scopes has an integrated bridge.

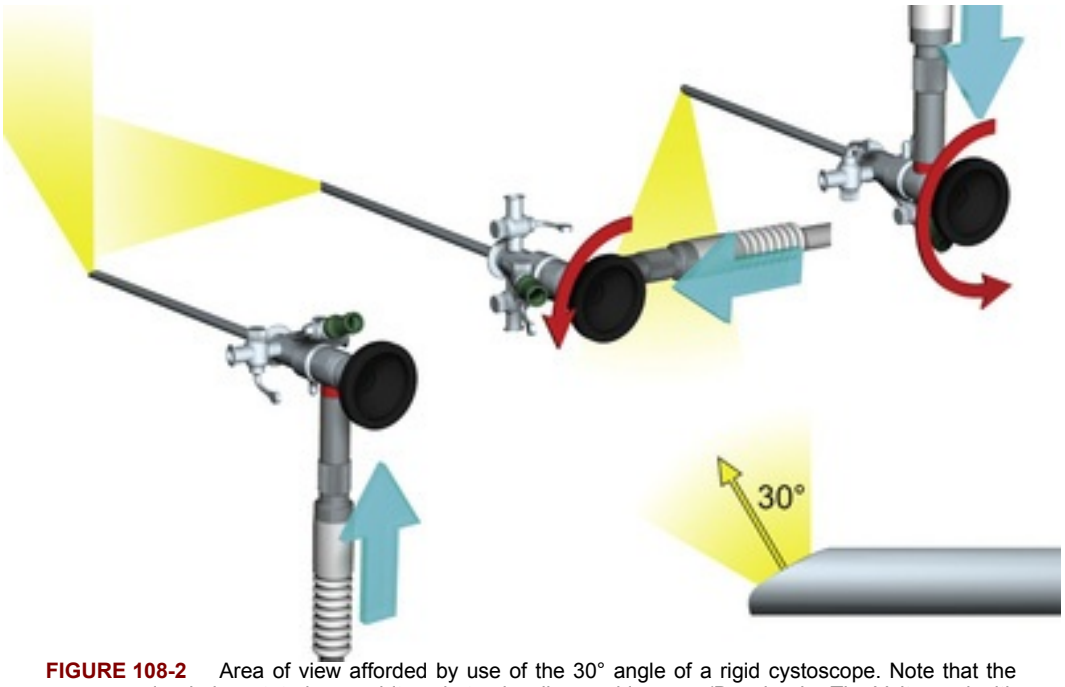

FIGURE 108-2 Area of view afforded by use of the 30° angle of a rigid cystoscope. Note that the scope need only be rotated around its axis to visualize a wide area. (Drawing by Tim Vojt, used with permission from The Ohio State University.)

FIGURE 108-3 The three most commonly used sizes of assembled rigid cystoscopes: 4.0 mm × 30 cm, 2.7 mm × 18 cm, and 1.9 mm × 18 cm.

There is a variety of accessories and instruments available for rigid and flexible endoscopes. At least one good quality biopsy forceps that fits through the operating channel is required for obtaining tissue samples. In addition, stone retrieval baskets, grasping forceps, and cautery tips are available.

Rigid endoscope systems require a light source, camera, video monitor, and preferably an image capture system that allows for data storage onto CD or DVD. There are several manufacturers of these systems and they are often purchased as part of a package with the endoscopes. Some incompatibilities exist between systems, so it is best to use components from the same manufacturer or verify their compatibility prior to purchase.

The best light sources for video uroendoscopy are xenon with automatic intensity adjustment. Halogen light sources can be used as well, but have a lower intensity and image quality than xenon lights. Although many rigid and flexible endoscopes have eyepieces, a camera and video system are essential for proper detailed viewing and documentation of uroendoscopic studies. Cameras are generally available in one- or three-chip models. The three-chip has higher image quality due to 3-color capture and processing and produces better images in low-light conditions, although one-chip models are adequate for most applications. Ideally, the camera has a focusing system and image capture controls mounted on the operating head or via foot-pedal operation. A wide range of image capture systems is available from state-of-the-art high definition video to those that record only still images. Since dynamic imaging is desirable in uroendoscopy, a system that provides capture and recording of both still and video images is preferable.

Patient Preparation and Procedure

Female Dog and Cat

Uroendoscopy can be performed with the patient in dorsal or lateral recumbency. The use of sterile technique is important to minimize iatrogenic contamination of the urinary tract. The endoscope is either gas- or liquid-sterilized and sterile gloves are worn during the procedure. Some practitioners also don a sterile gown for the procedure, although this is not a universal practice in routine diagnostic uroendoscopy. The endoscopist is generally seated at the caudal end of the animal and the tail is secured out of the operating region. The external genitalia of the anesthetized patient is shaved and surgically prepared. The patient is aseptically draped and a small opening is cut in the drape to access the vulvar opening. The endoscopist assembles the scope and its components and attaches the light and camera cables. Appropriate white balancing and focusing are performed according to the system's requirements. The irrigation and efflux lines are attached and the scope is liberally coated with sterile water-based lubricant. Sterile 0.9% NaCl is passed through the irrigation channel to distend the anatomy and improve visualization. The scope is passed into the vaginal vestibule and the vulvar folds are gently grasped around the scope to allow for fluid distension of the

chamber.[1]

Normal Appearance in the Female

The mucosa of the vestibule is light pink in color and smooth (Video 108-1). The vaginal opening, surrounded by a ridge of tissue, the cingulum, is seen at the craniodorsal aspect of the vestibule. Ventral to this is the smaller urethral opening. There may be a thin band of tissue crossing the opening dorso-ventrally of the vagina, which has been called a hymenal membrane. A thicker band referred to as the mesonephric remnant is often associated with abnormalities of development of the urethra and ureter (Figure 108-4).[2] The urethral opening is often covered by a dorsal fold of tissue in the intact female dog and should not be interpreted as a mass lesion. This fold of tissue is not present in the spayed female dog. Lateral to the urethral opening are fossae, which may contain crypt-like areas. These can be normal findings and should not be mistaken for ectopic ureter openings.

FIGURE 108-4 Thin mesonephric remnant dividing the vaginal orifice.

Evaluation of the vagina may occur before or after investigation of the urethra and bladder; however, if substantial vaginal mucus or discharge is present, the vagina should be viewed last. The vaginal mucosa is pink with a prominent longitudinal fold running along the dorsal wall. The scope is passed cranially until the caudal aspect of the cervix is reached. This has a folded appearance and passage of the scope beyond this point may be difficult and is rarely performed during routine urologic examinations.

The scope is redirected into the urethra and slowly passed cranially into the bladder. The urethra also has a dorsal fold, particularly prominent in the female cat, and generally has smooth, light pink mucosa. The length of the urethra may vary between normal dogs. Care must be taken to keep the scope centered in the lumen, a visual angle that will depend on the type of scope used. The author uses a 30° angled scope which requires keeping the lumen in the lower third of the visual field. Once the vesicourethral junction is reached, the bladder is drained of urine and re-distended with saline to provide a clear view. Distension of the bladder is essential to get an adequate evaluation of the ureters and bladder wall; however, over-distension will cause tearing of the urothelium and hemorrhage. To prevent this, the bladder should be manually palpated through the abdomen by an assistant and distension ceased when it is slightly firm. If bleeding occurs, the bladder can be drained of fluid and chilled saline infused to induce vasoconstriction and reduce the impact on visibility. The infusion of cold fluid may cause the patient's body temperature to drop, and this should be closely

monitored, especially when multiple cycles of chilled fluid are infused and drained.

When the bladder is fully distended, the trigone is examined. The ureters are located dorsolateral to midline as two crescent-shaped slits in the bladder wall that face each other as mirror images. An inverted V- or Y-shaped ridge may run cranially from the openings and join at midline. Verification of their patency should be made by observing the pulsatile urine flow from each ureter. The cystoscope is then passed cranially to the apex of the bladder and the entire bladder wall is examined. The bladder mucosa is light pink with a fine vascular pattern. Occasionally the bladder wall will be semi-transparent and abdominal organs may be faintly visualized from the lumen. It is important to examine all areas of the bladder interior in order not to miss small lesions or calculi, which may fall to its dependent aspect. Manual palpation and manipulation of the bladder through the abdomen can assist in a full evaluation, as can rotation of the scope around its axis. After completion of the exam, the efflux channel is opened and the fluid is drained from the bladder.

Male Dog and Cat

Uroendoscopy of the male is generally performed with a flexible endoscope. An assistant may be required to exteriorize the penis from the prepuce and atraumatic hemostats or stay sutures may be necessary to maintain retraction, particularly in the male cat. The endoscope is prepared and lubricated as with the female. The endoscopist gently introduces the flexible tip of the endoscope into the external urethral orifice (Figure 108-5). Infusion of saline facilitates distension of the urethra ahead of the scope. It is important not to use the scope tip itself to dilate the urethra as this can cause injury to the delicate urothelium that may be interpreted as a lesion. For this reason, the urethral mucosa must be evaluated both on insertion and withdrawal to differentiate iatrogenic lesions. Very small adjustments in scope angle and external manipulation of the penis and perineal region may facilitate maintaining the urethral lumen within the visual center of the scope (Video 108-2). As the scope is passed from the perineal urethra into the prostatic urethra of the dog, tiny prostatic duct openings may be noted in the mucosa. These indentations are generally not seen in the male cat. The colliculus seminalis is a dorsal mound of tissue that sits at the level of the openings of the ductus deferens. It should not be mistaken for a mass lesion; and the ductus openings should not be mistaken for ectopic ureters. Examination of the trigone, ureters, and bladder lumen is as with the female, but may be difficult due to the small size of the endoscope in relation to the size of the bladder lumen. Care must be taken to keep the tip of the scope close to the bladder wall to avoid missing lesions.

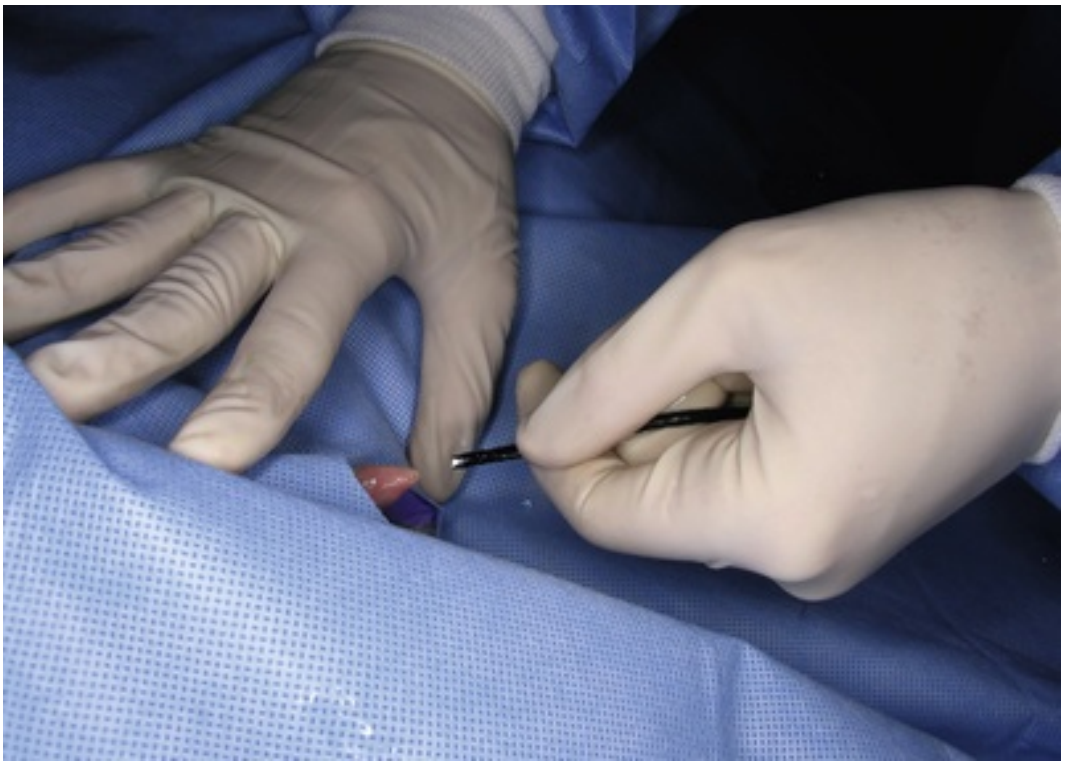

FIGURE 108-5 Careful insertion of the flexible tip of the urethroscope into the external urethral orifice.

Postoperative Management and Complications

Despite strict attention to asepsis, the mild to moderate trauma to the urinary tract and the proximity of the anus may increase the likelihood of iatrogenic contamination during uroendoscopy. It is therefore recommended to place patients on 5-7 days of broad-spectrum antibiotics after the procedure.[1,3] Alternatively, patients may receive an intraoperative intravenous injection of a broad-spectrum antibiotic.

Both dogs and cats may experience a moderate amount of discomfort and pollakiuria after uroendoscopic procedures. The author prefers to administer epidural analgesia with a combination of ropivacaine and morphine pre-operatively, which improves pain control and can facilitate relaxation of the urethra.[4] Additional pain medication such as a non-steroidal anti-inflammatory drug or mild opiate may be used for 2-3 days. Mild hematuria may also occur in patients after cystoscopy. This is generally short-lived and self-limiting but owners should be advised of its presence.

Several complications may arise during uroendoscopy. The most common complication is failure to be able to safely advance the cystoscope through the lumen of the urethra. Lodging of the endoscope in the urethra can be avoided by proper selection of scope size for the patient and appropriate lubrication. The endoscope, whether flexible or rigid, should never be forced through the urethra. This can lead to urethral damage or "hair-pinning" and lodging of a flexible scope in the urethra. Gentle pressure and, especially in the case of males, proper use of fluid to dilate the urethra ahead of the scope should be sufficient to allow for passage. If this is not successful, a smaller diameter scope should be used.

Perforation of the lower urinary tract is also a risk with uroendoscopy, particularly in patients with a severely diseased urethra or bladder wall.[5] The endoscopist must be attentive to the degree of fluid distention in the bladder and release any overfilling through the efflux channel. Depending on the size of the damage, surgical repair may be necessary to correct a bladder tear. Rupture of the urethra can also occur, but may not require surgical intervention. Placement of a urinary catheter for several days may be sufficient to allow for healing of the defect. The careful selection of an appropriately-sized scope and gentle technique will minimize these risks.

Cystoscopy and urethroscopy can be a valuable tool in the assessment of the lower urinary tract, and as noted elsewhere in this text, they allow for minimally invasive therapeutic as well as diagnostic procedures. Comfort with the normal appearance of the urinary tract and knowledge of possible complications can make its practice safe and practical in many circumstances.

CHAPTER 109

Peritoneal Dialysis

Alexa M.E. Bersenas

Client Information Sheet: Peritoneal Dialysis

Overview

Peritoneal dialysis (PD) is a form of dialysis that utilizes the surface area of the peritoneum for removal of uremic toxins. It requires repeat instillation of a biocompatible solution into the abdominal cavity, a dwell time for transfer of uremic solutes from the blood through the peritoneum and into the solution, and subsequent evacuation of the solution from the abdominal cavity. Advantages of PD are that it is a relatively simple procedure and does not require complex equipment. Compared to hemodialysis (see ch. 110), it can be a preferred option for patients who are hemodynamically unstable, or of very low body weight (as there is no extracorporeal circuit), or at risk of bleeding (avoids anticoagulation). Removal of uremic toxins is gradual, with less risk of dialysis disequilibrium syndrome.[1]

Peritoneal dialysis relies on the principles of diffusion, ultrafiltration, and convection for solute and fluid removal. Molecules in high concentration in the blood diffuse across the peritoneal membrane into the dialysate solution until equilibrium is reached. Dialysate solution contains dextrose, at variable concentrations, to provide an osmotic draw, which draws fluid from the patient's circulation into the peritoneum, termed ultrafiltration. This ultrafiltration, or movement of water, promotes the movement of solutes, referred to as solvent drag, which creates a route for elimination of solutes from the bloodstream. By providing ultrafiltration, PD can be an effective method for removing excess fluid from patients that are fluid-overloaded.

In veterinary medicine, PD principally is indicated for the management of potentially reversible acute kidney injury (AKI; see ch. 322). Other reported indications for PD include treatment of certain dialyzable intoxications (e.g., ethylene glycol, ethanol, barbiturates, sodium monofluoracetate, severe hepatic encephalopathy; see ch. 152 and 281) and for the management of hypo- or hyperthermia (see ch. 49 and 134), refractory congestive heart failure (see ch. 247), and for pre-surgical management of unstable patients with urinary tract obstruction/leakage (see ch. 150).[2,3]

Preparation

Selecting patients with AKI for PD relies on considering urine production and the metabolic condition of the patient. Anuria, or oliguria (urine production < 0.5 mL/kg/h), and/or an inability to regulate water homeostasis, hyperkalemia, or abnormal acid base status, warrants dialysis implementation.[4] More recently, in humans, an improved outcome appears to occur with early implementation of PD, such as when creatinine > 5 mg/dL (>442 micromol/L) or BUN > 75 mg/dL (>27 mmol/L), even in the absence of overt signs of uremia.[5,6] More than any numerical value, the progression of the disease and the patient's clinical condition and prognosis should be considered when deciding whether to initiate PD.

Peritoneal dialysis relies on obtaining peritoneal access using a multi-fenestrated catheter. Soft "permanent"-type catheters should be used; semi-rigid acute catheters are less ideal, short-term alternatives.[1] Both can be used immediately after insertion. Semi-rigid acute catheters are inserted using a sharp trocar device and are associated with increased risk of bowel perforation, dialysate leak, discomfort, and should not be left in place for more than 72 hours due to high risk of peritonitis.[1,2] Several different types of soft "permanent" PD catheters have been used; Tenckhoff PD catheters are the most frequently used in human medicine, although Swan neck catheters are gaining popularity.[1,7] Commercial PD catheters have 1-2 Dacron

cuffs. These serve to anchor the catheter by fibroblast ingrowth. Cuffs are positioned in the rectus abdominis muscle +/– the subcutaneous space prior to skin exit. Dacron cuffs decrease the risk of infection and dialysate leak; however, these advantages are delayed, which is not helpful in the acute PD setting. In veterinary medicine, alternative catheters that have been used successfully when PD catheters are not accessible include the Jackson Pratt surgical suction drain and the Blake silicon drain.[3,8]

Procedure

Catheters can be placed surgically, percutaneously, or laparoscopically using local anesthesia (with sedation if needed).[1,3,9] Surgical placement is recommended in human pediatric medicine, and appears to be associated with better success in veterinary medicine.[1,10] Regardless of insertion technique, strict aseptic technique is mandated. Prophylactic antibiotic administration using a first generation cephalosporin (e.g., cefazolin) is recommended prior to PD insertion.[1,11] In order to establish successful early use of the catheter, and decrease dialysate leak, placement of PD catheters off midline is preferred, through the rectus abdominis muscle.[7] Regardless of technique, a subcutaneous tunnel is recommended to exit the skin approximately 5 cm away from the abdominal access point[1] (Box 109-1).

Box 109-1

Key Points for Successful PD Catheter Placement and Early Function

- Ensure the urinary bladder is empty
- Provide prophylactic antibiotics (e.g., cefazolin) at the time of PD catheter insertion
- Use a paramedian approach
- Position the tip of the catheter in the caudal abdomen (pelvic cavity)
- Ensure good closure of the rectus sheath around the PD catheter
- Include a subcutaneous tunnel prior to catheter exit
- Confirm excellent flow of dialysate prior to securing the PD catheter

A mini-surgical approach for PD catheter placement (Videos 109-1 and 109-2) requires the patient to be in dorsal recumbency, with aseptic preparation of the ventral abdomen. A 2-3 cm para-umbilical incision is made to the right of midline, over the planned, locally anesthetized abdominal entry site, and extended through the rectus muscle (external sheath, muscle, and internal sheath). The parietal peritoneum is definitively identified and incised (it is discrete from the internal sheath of the rectus muscle off midline).[3] The catheter (with stylet, or aided by hemostats) is advanced through the incision into the caudal abdomen. At the abdominal entry site, the distal (external) end of the PD catheter is tunneled subcutaneously before exiting the skin. Prior to further closure, the catheter should be connected aseptically to (1) dialysate, and (2) a closed collection system (using a Y system), and the catheter should be tested. A small volume of dialysate (5-10 mL) should be easy to flush and retrieve; otherwise, catheter repositioning is warranted.[3] Subsequently, snug closure of the rectus sheath (e.g., pursestring suture) around the catheter is necessary for early catheter use with less risk of dialysate leakage.[12] Alternatively, with the use of a trocar, the PD catheter can be tunneled under the external sheath of the rectus abdominis muscle, to exit the skin 5 cm from the abdominal access point.[3,13] This method allows full closure of the external sheath of the rectus muscle overlying the PD catheter. Thereafter, final closure of the skin incision is performed. The catheter exit site should be covered with a sterile bandage. External suture fixation is not recommended at the skin exit site; however, catheter movement should be prevented, to allow healing and decrease the risk of inadvertent catheter removal and exit site infections.[11] If a laparotomy is warranted or preferred for PD catheter placement, an omentectomy is advised, to decrease the likelihood of obstruction to dialysate flow.[9,14]

For percutaneous PD catheter placement, the abdomen should be filled with prewarmed (to body temperature), sterile physiologic saline first, to decrease the likelihood of inadvertent organ penetration. In human medicine, PD catheter placement using a Seldinger technique with sequential dilations of the body wall has been reported to be fast and provide successful dialysis.[15,16] However, percutaneously placed

catheters have an increased incidence of dialysate retention in veterinary medicine.[10]

Once the catheter is in place, dialysis can begin, and everyone involved must always follow strict aseptic technique. Hand sanitizing and use of sterile gloves is indicated for any manipulation of the PD line or catheter. The circuit should be a closed system, preferably a Y system, with the three arms of the Y made up of (1) PD catheter from patient, (2) line from dialysate solution, and (3) line to closed collection bag. This type of 3-way system decreases the risk of infection. Every line connection should be covered with chlorhexidine-soaked dressings, and access ports (dialysate bags, drug vials, PD access) should be scrubbed with chlorhexidine and alcohol prior to penetration.[14,17] Spiking of new dialysate bags is the most frequent source of contamination; flushing the dialysis line before infusing ("flush before fill" technique) is advised.[11]

Commercial peritoneal dialysate solutions are buffered balanced electrolyte solutions (contain sodium, magnesium, calcium and chloride at varying concentrations); the majority use dextrose as the osmotic agent. Standard dextrose concentrations are 1.5%, 2.5% and 4.25%. Commercial dialysate solutions use lactate or bicarbonate as the buffer; both are well tolerated by the peritoneum.[18] Dialysis fluids can be prepared using intravenous fluids if commercial products are not available.[1,3,14] Lactated Ringers solution (LRS) is the most similar to commercial dialysate. The concentration of potassium in LRS is 4 mmol/L (4 mEq/L) which generally allows correction of mild to moderate hyperkalemia, and is ideal once the patient is normokalemic.[1] Alternatively, 0.9% NaCl can be utilized as a dialysate solution if a potassium-free solution is deemed necessary (severe clinical signs of hyperkalemia noted in the patient). In such instances, sodium bicarbonate should be added to the solution (30-45 mmol/L). If using non-commercial products, dextrose supplementation is needed. Using 50% dextrose solution added to a 1 L bag of dialysate, 30 mL, 50 mL, or 85 mL are added to make approximately 1.5%, 2.5% and 4.25% dextrose solutions, respectively.[3] Unfractionated heparin often is recommended as an additive to decrease the risk of clot formation and catheter occlusion. It is routinely added to the dialysate solution at 500 U heparin/L (range 250-1000 U heparin/L) at least for the initial PD exchanges and up to the first 5 days of therapy.[3] Heparin is minimally absorbed at this dosage range.[2] In the case of confirmed septic peritonitis, antibiotics as additives to dialysate solution are preferred.[2,19] Absolutely strict aseptic technique is required when mixing solutions. Any additives should be drawn from sterile, previously unused vials. Dialysate should be warmed to body temperature for improved tolerance.

Generally, a 2.5% dextrose-containing solution is used at the onset of dialysis to optimize ultrafiltration and solute removal. However, the concentration of dextrose is determined by the fluid status of the patient. A 4.25% dextrose solution is selected for fluid-overloaded patients. Once the patient is euvolemic, a 1.5% dextrose solution is used.

At initiation of PD, dialysate exchanges occur hourly, throughout the 24-hour day. Dialysate is instilled into the abdomen over 5-10 minutes. The inflow time should be kept to a minimum to maximize time on dialysis.[2] A 30-45 minute dwell time is allocated, to allow for diffusion and ultrafiltration to occur. Subsequently the abdomen is emptied, by gravity, over 15-20 minutes.[1-3] The ultrafiltration rate is maximal at the beginning of a PD exchange, when dextrose concentration is at its maximum. Intraperitoneal volume peaks at about 120-180 minutes of dwell time. A dwell time <30 minutes usually is not adequate.[2] Recommended dialysate volumes range from 10-40 mL/kg. At the onset of dialysis, 10 mL/kg should be attempted. If this is well-tolerated, increased volumes will improve uremic clearance, but will also predispose to dialysate leakage. Dialysate volumes can be increased over 2-3 days. During dialysate infusion, and dwell, the patient should be monitored for respiratory compromise and signs of abdominal discomfort. Exchanges should be continued at 1- to 2-hour cycles, until uremic control is achieved; subsequently, dwell times can be extended to 4-6 hours. Patients with oliguria or anuria will frequently require several (3-7) days of PD before a positive response in urine production can be noted or assessed.[3]

During PD, patient monitoring is paramount. Serial body weight measurements and re-assessment of hydration are mandatory, every 4-12 hours, with changes in PD orders reflecting changes in patient status. Patient's "ins" (IV fluids, medications, enteral feeds) and "outs" (urine production, dialysate retrieval, vomitus, etc.) should be tabulated every 4-12 hours (see ch. 106). Once the patient is euvolemic, "ins" should be matched to "outs." Other monitoring includes continuous ECG and blood pressure assessments (see ch. 103 and 99), serum electrolyte measurements (see ch. 67, 68, and 69), and blood gas monitoring (see ch. 75 and 128) along with packed cell volume, total solids and blood glucose determinations at least every 12-24 hours. Daily serum creatinine determination is ideal until improvement is well established.

Complications

Catheter malfunction, most often slow or incomplete outflow, is frequently encountered and may be associated with catheter migration, omental wrapping, or fibrin clot/occlusion.[2,3] Any retention of dialysate should be promptly noted. On occasion, a difference in dialysate retrieval is recuperated at the next exchange. Should this not be the case, patient repositioning, delivery of enema(s), or aseptic flushing of the PD catheter using a prefilled 20 mL syringe, can be attempted. Alternatively, PD catheter systems can be connected to active continuous suction devices (collection bulbs).[8] Other documented complications include dialysate leak, extravasation of fluid in tissue compartments (perineal/pelvic limb edema), lack of uremic control, unpredictable fluid removal rates, intra-abdominal hemorrhage, progressive hypoalbuminemia, pleuroperitoneal communications (pleural effusion), hyperglycemia, catheter exit-site infections, and peritonitis.[1,3]

Outcome

PD does not treat the renal insult, but allows time for renal recovery. PD can provide effective reduction in circulating concentrations of uremic toxins.[10] The available human literature, though limited, suggests that PD can provide uremic control similar to that which is achieved with extracorporeal methods.[20] Prognosis and renal recovery depend heavily on the underlying cause of renal injury. Overall mortality rate for AKI in dogs is 60%[21]; reports for survival after the initiation of PD range from 24-80%[10,22,23]; an improved response is noted in patients with AKI secondary to leptospirosis,[23] and urinary tract obstruction,[10] likely due at least in part to control of the inciting cause. Cats might also have a better outcome with PD than dogs, with reported survival rates of 45% and 83%.[8,10]

CHAPTER 110

Continuous Renal Replacement Therapy/Hemodialysis

Mark J. Acierno, Mary Anna Labato

Overview

Extracorporeal blood purification therapies are a collection of modalities that employ the principles of diffusion, convection and adhesion to remove toxins, as well as correct a patient's fluid, electrolytes and acid/base balance. In veterinary medicine, these modalities have primarily been employed in the treatment of acute kidney injury (AKI; see ch. 322); however, they have also been successfully used for the management of chronic kidney disease (CKD; see ch. 324), and toxin exposures (see ch. 151 and 152). The most commonly employed extracorporeal therapies in dogs and cats include intermittent hemodialysis (IHD), continuous renal replacement therapy (CRRT), and therapeutic plasma exchange (TPE).

The principles of extracorporeal blood purification were first described in 1914 when researchers anticoagulated a dog and directed its blood from an artery into an apparatus called "vividiffusion"[1] (Figure 110-1). This device divided blood into straw-like semi-permeable membranes, which were bathed in solution. It was noted that by changing the composition of the solution, the concentration of solutes in the patient's blood could be altered.[1] Although this vividiffusion apparatus, constructed from a glass cylinder and hand-made semi-permeable membranes seems rudimentary by today's standards, it has served as the prototype for all modern dialyzers. The dialyzer still functions as an "artificial kidney."

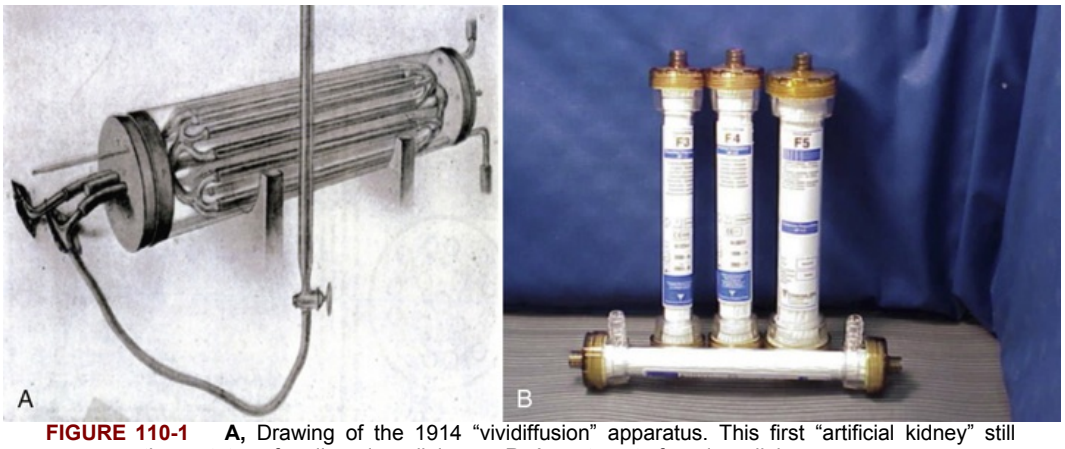

FIGURE 110-1 **A,** Drawing of the 1914 "vividiffusion" apparatus. This first "artificial kidney" still serves as the prototype for all modern dialyzers. **B,** Assortment of modern dialyzers.

Blood Purification

Diffusion is the tendency for molecules in solution to move from an area where they are in a high concentration to an area where they are in a lower concentration.[2] As patient blood enters the dialyzer, it is divided and travels inside thousands of straw-like semi-permeable membranes that are bathed in solution called dialysate.[3] Dialysate contains precisely measured concentrations of electrolytes and buffers.[3] Molecules can be made to diffuse out of the blood, across the membrane and into the dialysate by ensuring that their concentration in the dialysate is lower (e.g., creatinine). In addition, beneficial substances can be made to

move from the dialysate into the blood by increasing their concentration in the dialysate (e.g., bicarbonate).[4] After leaving the dialyzer, the exhausted dialysate is discarded and the purified blood is returned to the patient. The primary limitation of diffusion is the size of the molecule that will pass through the membrane. Generally, the likelihood that a molecule will pass across the membrane is inversely proportional to its size. Thus small molecules such as urea pass readily while larger molecules diffuse more slowly or not at all even if they physically could fit through the membrane. In addition, because the movement of molecules is guided by concentration gradients, a continuous supply of fresh dialysate is needed.

During convection, the patient's blood enters the dialyzer and is divided and travels inside thousands of straw-like semi-permeable membranes where it is subjected to a positive transmembrane pressure.[2] This causes fluid, called ultrafiltrate, to be forced out of the blood and across the membrane. The ultrafiltrate carries uremic toxins, electrolytes and other small molecules[2,5] which are discarded. A sterile balanced electrolyte solution is then added to the patient's blood to replace the ultrafiltrate. Unlike diffusion, it is the size of the pores in the semipermeable membrane that determines which solutes can be removed. All molecules small enough to fit through the pores of the membrane will pass at the same rate. Thus, convection can effectively remove an increased number of larger molecules than diffusion.[2,6] Convection can be used to quickly remove fluids in overhydrated patients. Nevertheless, convection is technically challenging, as the ultrafiltrate must be replaced with great accuracy or acid/base, electrolyte and fluid imbalances can occur.

Adsorption is the tendency of molecules in blood to stick to surfaces in the extracorporeal circuit and be removed from circulation. Studies have suggested that certain dialyzer membranes may remove cytokines associated with sepsis; however, at this time there is no clinically proven benefit.[5,7] Hemoperfusion involves the placing of an absorptive substance, often carbon or resins, in the extracorporeal blood path in order to trap and remove drugs and toxins. Although first described in the 1940s, it is only infrequently utilized in human or veterinary medicine.[8]

Intermittent Hemodialysis

For decades, IHD has remained the standard of care for patients needing treatment of AKI, CKD or for the removal of certain toxins (e.g., ethylene glycol).[9] This is the treatment commonly referred to as "dialysis." Patients are treated for finite periods of time, often 4-6 hours, after which they are cared for as typical hospital patients. In some cases, they can even be sent home. IHD is primarily a diffusive technology. Since significant changes in blood composition need to be made in relatively short periods of time, large amounts of dialysate need to be produced on-site. Since only a thin semipermeable membrane separates blood and dialysate, the dialysate must be relatively pure in order to prevent contaminants or endotoxins from being introduced into the patient's blood.[10] This requires a significant investment in both equipment and maintenance.[10]

Manufacturing dialysate requires that ordinary tap water be specially treated. Water is first passed through a sediment filter to remove gross contaminants. Then it is exposed to carbon, which extracts chlorine and chloramines. A reverse osmosis water filter removes remaining dissolved solutes. The water is then delivered to the dialysis machine, which heats the water and mixes it with bicarbonate and an electrolyte (acid) solution to produce dialysate. Since the entire fluid pathway is at risk for contamination, a proper maintenance program involving disinfection and bacterial surveillance is essential.

Continuous Renal Replacement Therapy

CRRT is a newer extracorporeal blood purification therapy, which combines the principles of diffusion and convection to produce four different treatment modalities: slow continuous ultrafiltration (SCUF), continuous veno-venous hemodialysis (CVVHD), continuous veno-venous hemofiltration (CVVH), and continuous veno-venous hemodiafiltration (CVVHDF).[11] Many CRRT systems can also perform therapeutic plasma exchange (TPE). As its name implies, CRRT is a continuous modality and once a patient begins treatment, therapy continues until renal function returns, the patient is transitioned to intermittent dialysis (IHD) or the patient is euthanized. Potential advantages of CRRT over IHD include better control of fluids, acid/base and electrolyte balance in hemodynamically unstable patients[12,13]; however, in veterinary medicine, much of the appeal is likely due to CRRT's reliance on pre-packaged fluids which do not require a significant investment in water purification facilities or the ongoing maintenance associated with producing dialysate. The obvious tradeoff is that patients receiving treatment require extensive 24 hour a day care and monitoring.

Slow continuous ultrafiltration (SCUF) (Figure 110-2) is a purely convective modality.[11] As the patient's blood enters the straw-like semipermeable membranes of the dialyzer, it is exposed to a positive

transmembrane pressure that forces fluid out of the blood. The hemoconcentrated blood is then returned to the patient. While SCUF has been used in the treatment of diuretic resistant congestive heart failure in people, its utility in veterinary medicine is unclear.[2]

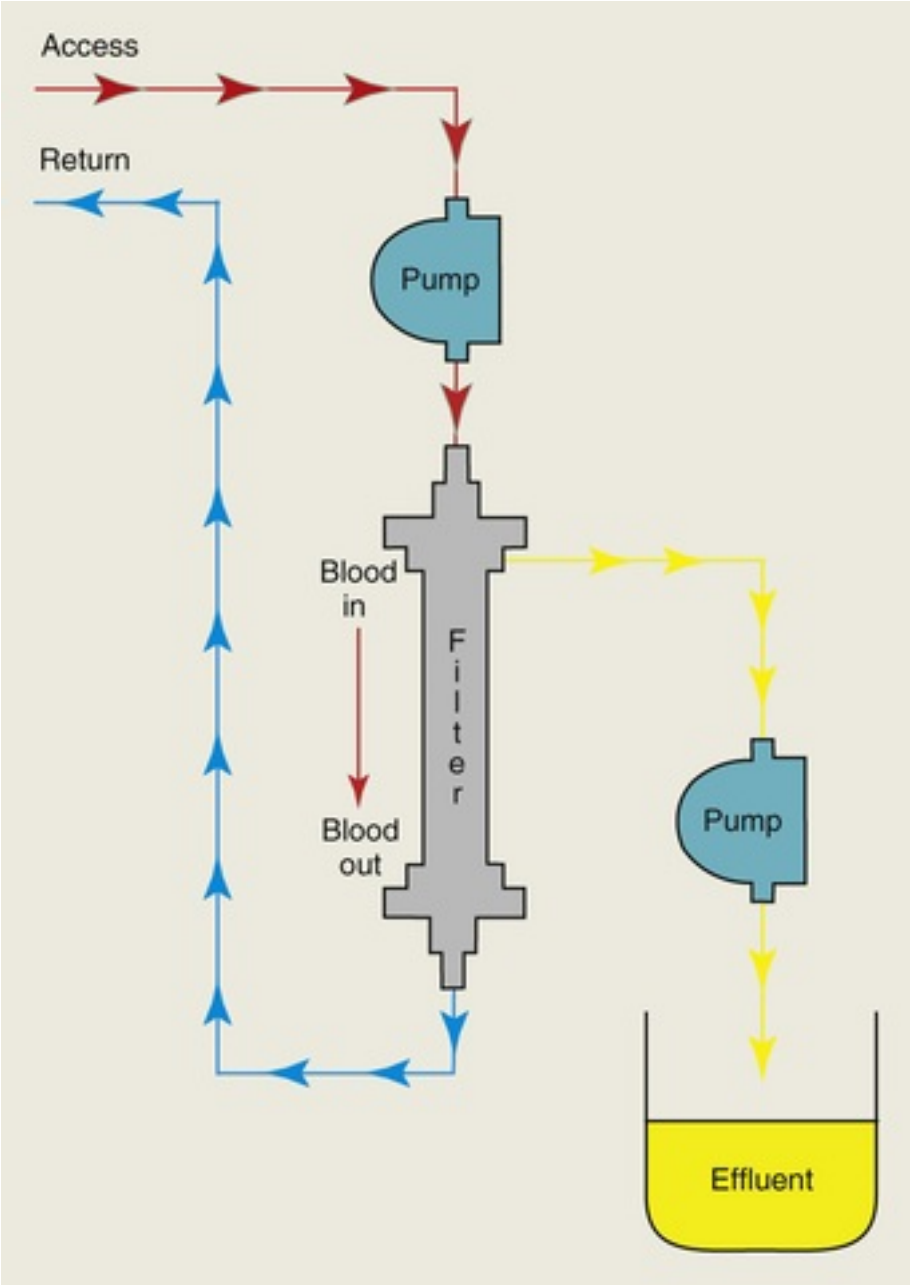

FIGURE 110-2 Slow continuous ultrafiltration (SCUF)—a purely convective modality which generates ultrafiltrate that is not replaced. (From Acierno MJ, Maeckelbergh V: Continous renal replacement therapy. *Compend Contin Educ Vet* 30:264-280, 2008.)

Continuous veno-venous hemofiltration (CVVH) (Figure 110-3) is also a convective modality; however, in CVVHD, the ultrafiltrate is replaced with a sterile balanced electrolyte solution.[2,14,15] The solution can be added to the blood before or after the dialyzer. When added after the dialyzer, a positive transmembrane pressure forces fluid out of the blood resulting in increasing hemoconcentration within the straw-like semipermeable membranes of the dialyzer.[2] Prior to returning the patient's blood, a sterile balanced electrolyte solution, called "replacement fluid," is added to restore the blood to a physiologic packed cell volume. Adding fluid after the dialyzer is an extremely efficient way to remove uremic toxins; however, as the blood becomes hemoconcentrated, there is a risk that the blood will sludge and clot. This limits the

amount of fluid that can be removed.[2] Alternatively, "replacement fluids" can be added to the blood before the dialyzer resulting in hemodilution. The excess fluid is then removed in the dialyzer by convection.[2] This is less likely to result in dialyzer clotting but is also significantly less efficient.[16]

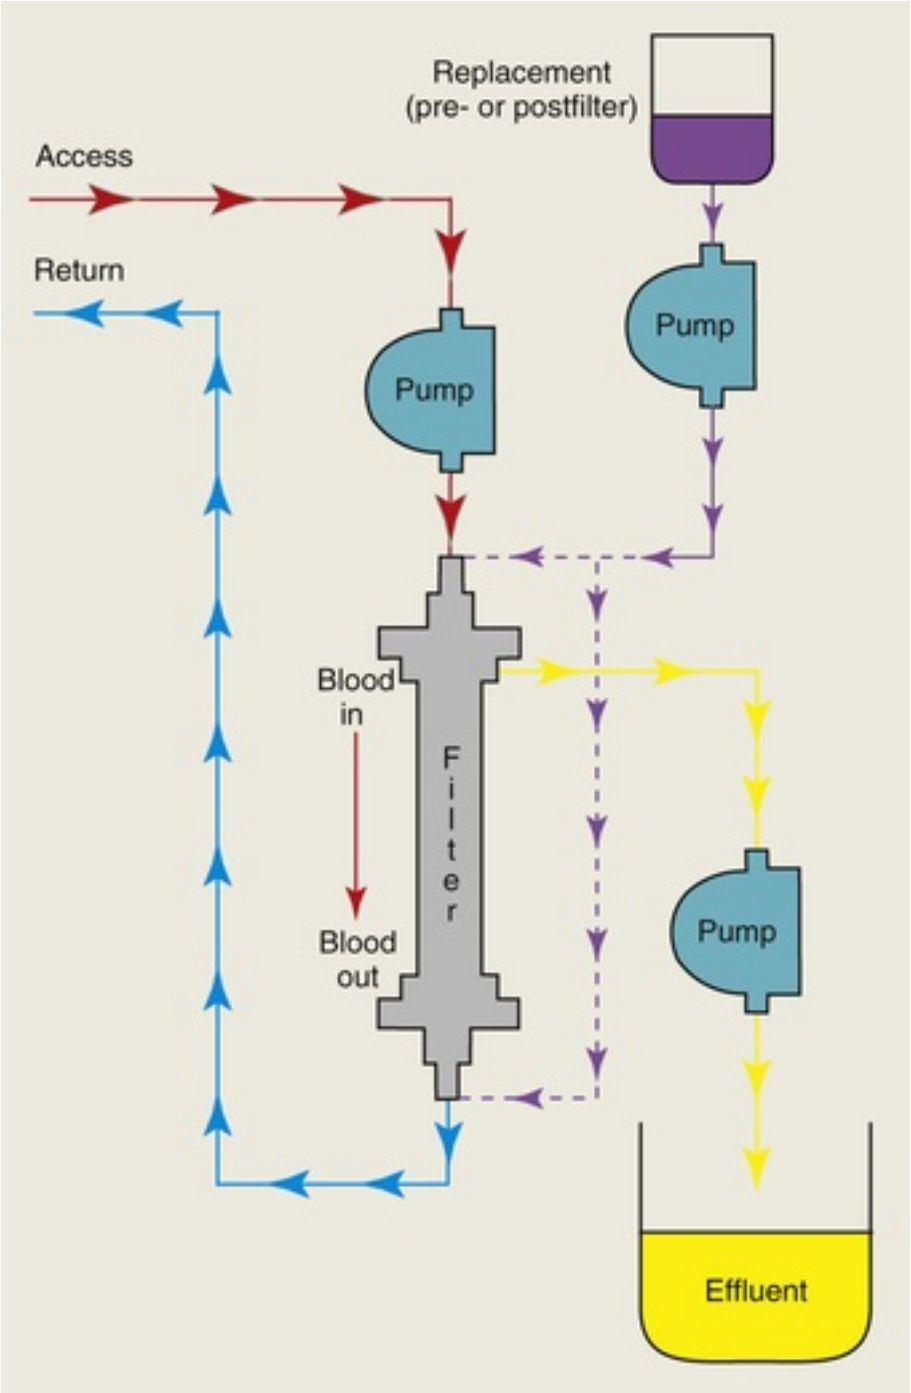

FIGURE 110-3 Continuous veno-venous hemofiltration (CVVH) is a convective modality that generates ultrafiltrate. Unlike SCUF, the ultrafiltrate is replaced with a sterile balanced electrolyte solution. This fluid can be added before or after the dialyzer. (From Acierno MJ, Maeckelbergh V: Continous renal replacement therapy. *Compend Contin Educ Vet* 30:264-280, 2008.)

Continuous veno-venous hemodialysis (CVVHD) is a diffusive therapy that closely resembles IHD (Figure 110-4).[11] Blood enters the dialyzer where it is divided and travels inside thousands of straw-like semipermeable membranes that are bathed in dialysate. Substances that are in relatively high concentration in

the blood leave the blood and enter the dialysate while substances whose concentration is higher in the dialysate enter the blood.[3]

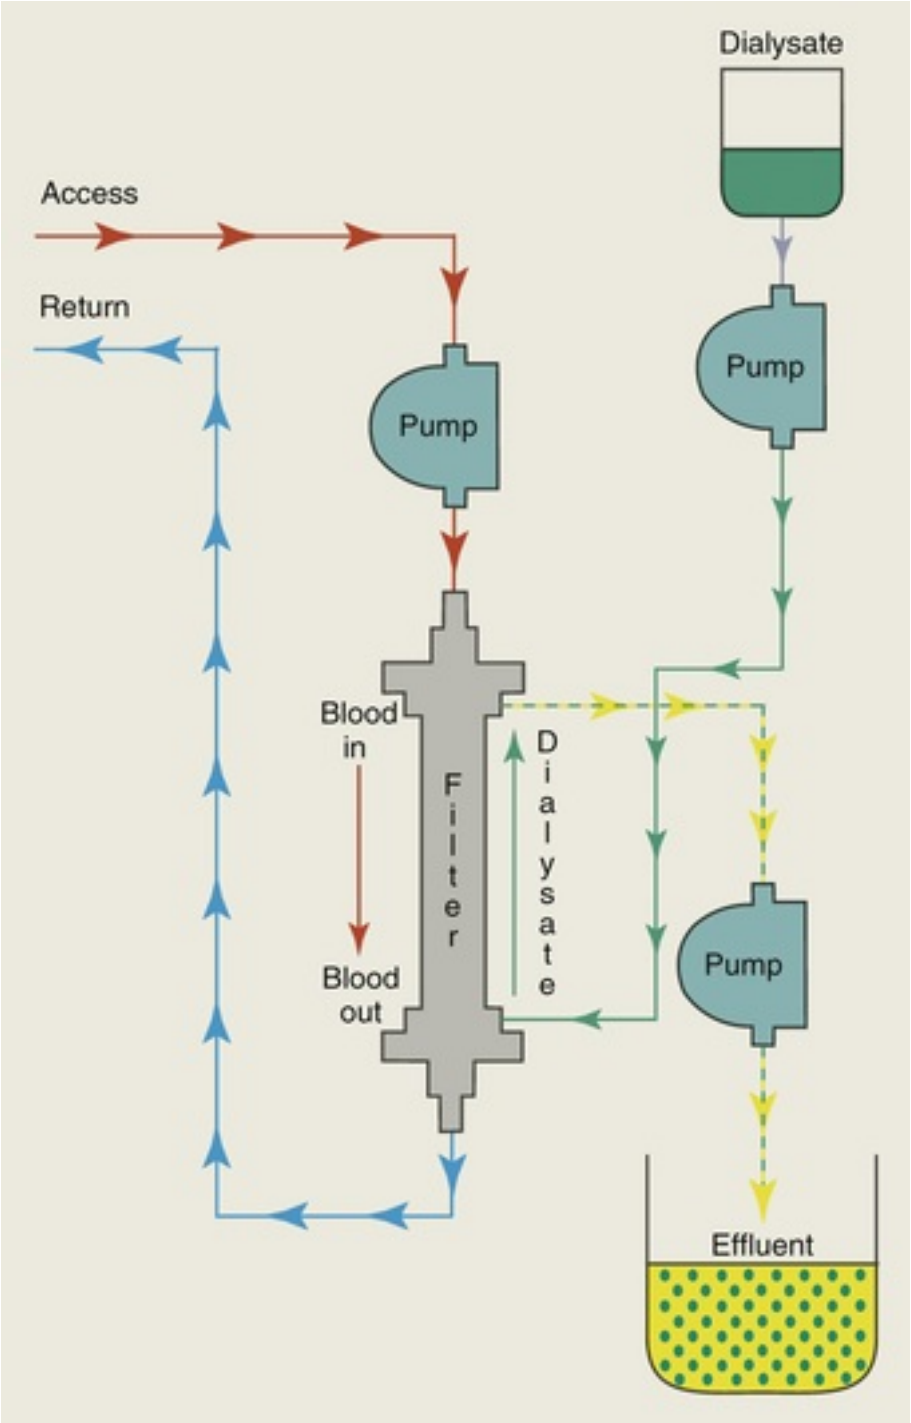

FIGURE 110-4 Continuous veno-venous hemodialysis (CVVHD) is a diffusive therapy in which the movement of small molecules is guided by their relative concentration in the dialysate. (From Acierno MJ, Maeckelbergh V: Continous renal replacement therapy. *Compend Contin Educ Vet* 30:264-280, 2008.)

Continuous veno-venous hemodiafiltration (CVVHDF) combines the diffusive aspects of CVVHD with the convective aspects of CVVH (Figure 110-5).[11] Blood flowing through the dialyzer's straw-like semipermeable membranes are bathed in dialysis solution and exposed to a positive transmembrane pressure so that both

diffusion and ultrafiltration guide the movement of solutes.[2] Because the operator can selected the amount of diffusion and ultrafiltration that takes place within the dialyzer, CVVHF gives the greatest control over the treatment administered.

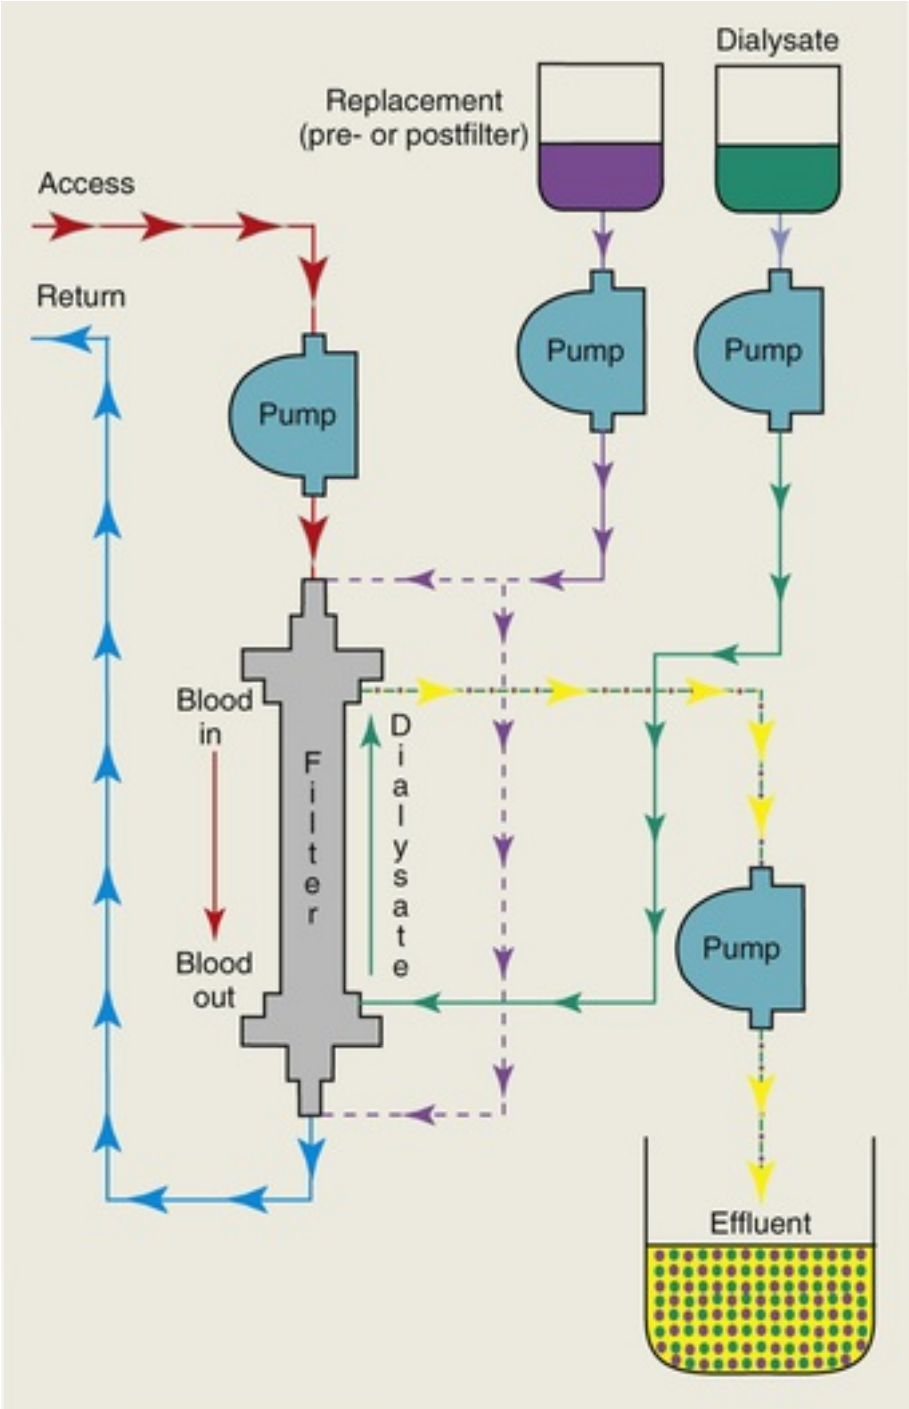

FIGURE 110-5 Continuous veno-venous hemodiafiltration (CVVHDF) combines the diffusive aspects of CVVHD with the convective properties of CVVH. Diffusion guides the movement of smaller uremic toxins and electrolytes while convection facilitates the movement of larger molecules and fluids. (From Acierno MJ, Maeckelbergh V: Continous renal replacement therapy. *Compend Contin Educ Vet* 30:264-280, 2008.)

For the treatment of AKI patients, it is unclear which CRRT modality is superior. Convective modalities (CVVH, CVVHDF) have the advantage of being able to remove larger "middle-sized" molecules and

therefore more closely mimic the function of the kidney.[17] Nevertheless, it is not clear what role these molecules play in the pathogenesis of AKI or uremia. Diffusive modalities (CVVHD) are equally effective in removing smaller molecules such as urea and creatinine and are associated with fewer dialyzer failures.[16,18]

Therapeutic Plasma Exchange

Therapeutic plasma exchange is a convective modality that utilizes a specialized dialyzer to separate plasma from the cellular components of blood. The patient's blood enters the dialyzer where it is divided into thousands of straw-like semipermeable membranes. The blood is then exposed to a positive transmembrane pressure that causes a plasma-like ultrafiltrate to be forced out. The ultrafiltrate, which includes albumin and globulins, is discarded while the cellular components are mixed with a colloid solution and returned to the patient.

In theory, any number of colloid solutions could be used including plasma, albumin, as well as synthetic colloids; however, in human studies, use of fresh frozen plasma has been associated with significant morbidity and mortality.[19] In veterinary medicine, hydroxyethylstarch (Hetastarch) has been used with no known adverse reactions. TPE is useful for the removal of autoantibodies, immune complexes, and highly-protein bound toxins.

In people, TPE is used to treat some autoimmune conditions (e.g., thrombotic thrombocytopenic purpura, myasthenia gravis, acute antibody-mediated renal allograft rejection, hyperviscosity syndrome), some intoxications (mushrooms) and some drug overdoses.[20] While the current veterinary literature includes case reports in which TPE was utilized in the treatment of a variety of immunological, infectious and neoplastic diseases,[21-24] it seems plausible that TPE would be efficacious in the treatment of some intoxications. Specifically, TPE is likely to be effective in the removal of toxins that demonstrate a low volume of distribution (V_d < 0.2 L/kg) and are highly protein bound (>80%).[20,25,26] Substances with a low volume of distribution remain primarily in the intravascular space where TPE can remove them. Many drugs are highly protein bound which results in long half-lives. While this makes them difficult to remove using IHD, TPE is ideally suited to remove protein-bound substances.

It's important to note that because TPE is a convective process, as the patient's plasma is removed, the blood traveling in the straw-like semipermeable membranes of the dialyzer becomes increasingly hemoconcentrated. As this occurs, the risk of clotting the dialyzer increases. Therefore, on each pass through the dialyzer, only a portion of the patient's plasma is actually removed by convection while the rest is mixed with a colloid and returned. Thus, removal of a substance by TPE is limited as the substance of interest is continuously being diluted by the colloid. While an estimated 63% of plasma solutes are removed on the first plasma volume exchange (PV = [(0.08 × wt/kg) × (1−HCT)]), an additional one half plasma volume exchange removes only an additional 15% of solutes and each subsequent exchange is increasingly less efficient.[27,28] Therefore, current treatment recommendations are for 1.5 plasma exchanges over 2-3 hours to remove approximately 78% of a substance of interest from the intravascular space.[20,28]

Anticoagulation

Despite being made of highly biocompatible materials, the catheter and extracorporeal circuit will activate the coagulation pathways.[29,30] This can lead to issues involving catheter blood flow, clotting of the dialyzer, and represents time that the patient cannot receive treatment. Also, the extracorporeal circuit can contain a significant portion of a patient's blood which will be lost if clotting occurs; therefore, appropriate anticoagulation is essential. There are two commonly employed methods of anticoagulation: heparin and citrate.

A constant rate infusion of heparin has historically been the most widely employed method of anticoagulation for extracorporeal procedures. Heparin binds to and causes a conformation change in antithromin.[31] This increases its activity by as much as 1,000 times. Antithrombin inactivates thrombin, factor X, and other proteases involved in blood clotting.[32] Heparin is effective and can be inexpensively monitored using an automated activated clotting timer.[33,34] Due to systemic anticoagulation, the primary risk in veterinary patients is uncontrolled hemorrhage. Monitoring activated clotting time and adjusting the heparin infusion rate can minimize this risk. In people, type II heparin induced thrombocytopenia (HIT) poses a serious risk. This can affect up to 5% of human patients and is the result of antibodies that activate platelets leading to thromboembolic events.[35] Type II HIT has not been documented to occur in cats and dogs.

Recently, there has been interest in regional anticoagulation using citrate to chelate calcium in the extracorporeal circuit.[36] Calcium is an important cofactor throughout the clotting cascade and blood cannot clot in its absence.[37] As blood enters the extracorporeal circuit, citrate is infused which chelates calcium, rendering the blood unable to clot.[37] Calcium chloride is then infused directly to the patient to maintain serum calcium at physiologic levels. The primary benefit of citrate is that the patient is not systemically anticoagulated. Significant risks of hypocalcemia and alkalosis occur,[37,38] necessitating frequent calcium and acid/base monitoring. Regional anticoagulation is popular in humans but its use in veterinary therapy is limited.

Blood Access

Extracorporeal therapies require significant blood flow rates; therefore, appropriate vascular access is essential. In most patients, the only vein large enough to provide this access is the jugular; therefore, these vessels should not be used for other purposes (e.g., blood draw). Dialysis catheters are made of highly biocompatible material such as polyurethane or silicone and designed so that there is minimal mixing of processed and unprocessed blood. While there are many variations, most catheters are either "catheter within a catheter" or "side by side" design (Figure 110-6). In all but the smallest patients, a dual-lumen dialysis catheter can be placed using the modified Seldinger technique. Typically, an 11-14 Fr catheter is placed in large dogs while smaller dogs and cats receive a 7 Fr catheter. In the smallest patients, one single lumen 5 Fr neonatal dialysis catheter can be placed in each jugular vein.

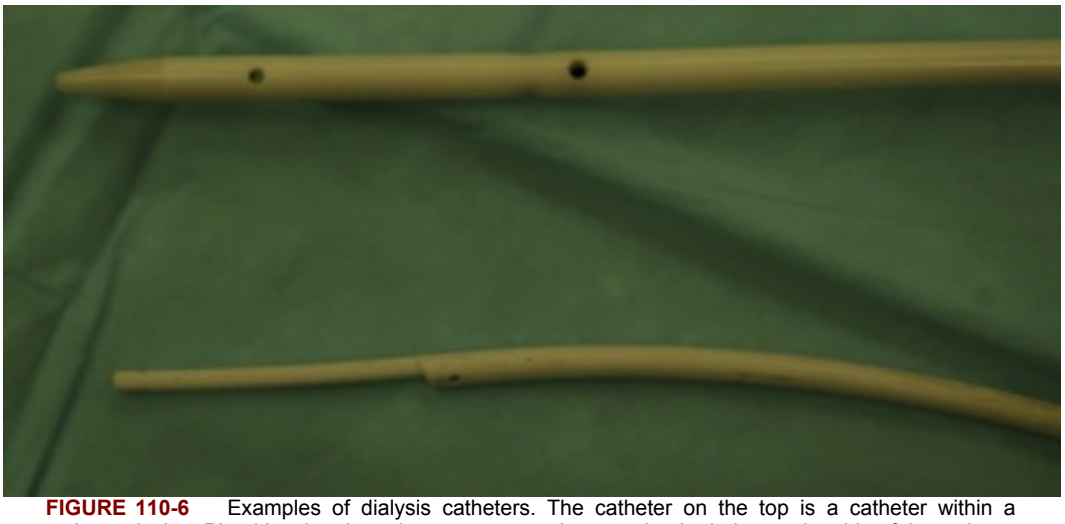

FIGURE 110-6 Examples of dialysis catheters. The catheter on the top is a catheter within a catheter design. Blood is taken in to the extracorporeal system by the holes on the side of the catheter and ejected at the tip. This minimizes recirculation, the mixing of purified and patient blood. The catheter on the bottom of the picture is an example of a "side by side" or double "D" catheter.

Complications

Problems associated with inappropriate anticoagulation and clotting are perhaps the most challenging aspect of providing extracorporeal therapies. Issues regarding clotting of the dialysis catheter and impaired blood flow are common.[39] With patients receiving CRRT over long periods of time, the entire circuit can become rendered inoperable because of blood clots in the extracorporeal circuit. Conversely, some patients develop bleeding at the catheter site after days of receiving heparin.

Hypotension is another potential complication. Although likely multifactorial, it is thought to be at least partly the result of the large amount of blood needed in the extracorporeal circuit.[40] In an attempt to address this problem in smaller patients, pediatric dialyzers and blood lines can be used and the blood pathway can be primed with colloids or blood.

Dialysis disequilibrium syndrome (DDS) can be a major concern when treating azotemic veterinary patients with IHD.[41,42] Although several theories have been proposed, it seems likely that DDS is related to

urea's role as an osmotically active particle.[43,44] As urea accumulates in the blood it diffuses into various tissues throughout the body. Each of these tissues can accept and lose urea at different rates. It is believed that as urea is rapidly removed from blood, there can exist a differential such that urea is higher in some tissues than in the blood.[44] The brain is one example of a tissue that loses urea more slowly than can be removed by IHD. In this case, urea acts as an osmotically active particle causing brain swelling resulting in mentation changes, seizures, coma or death.[44] Replacing urea in the blood with another osmotically active molecule such as mannitol is one strategy to help prevent DDS; another is to avoid rapid urea reductions. Because of its slow nature, dialysis disequilibrium syndrome has not been reported in CRRT.

Indications

The primary indication for CRRT is to control azotemia in cases of AKI where kidney function is likely to return in a relatively short period of time. This makes managing the injury significantly easier and provides time for the kidneys to heal. Anuria and oliguria are not the standards for treatment of AKI; rather, the decision to start therapy should be based on a patient's response to conventional therapy. Electrolyte imbalances, fluid overload and significant azotemia that does not respond to conventional therapy are all indications for treatment. CRRT has been used for treatment of AKI secondary to infectious diseases, heat stroke, and intoxications as well as for treating tumor lysis syndrome. CRRT can also be used in acute kidney injury cases where kidney function is not expected to quickly recover so these cases can be stabilized and transferred to a center offering IHD. In human medicine but not veterinary medicine, it has also been used for the treatment of diuretic resistant heart failure.

IHD is more flexible, offering opportunities to treat AKI as well as CKD patients and an array of intoxications. The ability of IHD to remove toxins is dependent on the substances' characteristics including: size, protein binding, and volume of distribution. The larger the molecule, the more tightly it binds to protein and the more widely it disperses throughout the body, the less likely IHD is to be helpful in treating an exposure. Listings of drugs and toxins that can be effectively removed by IHD and or CRRT are available and maintained by centers offering these modalities.

Measuring Efficacy

Calculations have been developed to help determine if the therapy delivered by a blood purification modality is adequate for patient treatment. Two of the more commonly utilized formulas are the urea reduction ratio (URR) and Kt/V. The URR represents the percent reduction in urea as a result of the therapy provided. It is simply calculated as [(pre-treatment urea − post treatment urea)/pretreatment urea] × 100. Its utility lies in its simplicity and its ability to predict clinical outcomes in people[45]; however, it does have limitations. The URR ignores urea being generated by the body during the procedure.[46] This might be a negligible factor during IHD, but during CRRT it can be significant. Indeed, after the initial CRRT treatment period when blood urea nitrogen (BUN) is reduced into the normal range and is no longer decreasing, the URR effectively becomes 0%. Clearly the body is producing urea and CRRT continues to remove it, but the URR is unable to account for it. In addition, URR does not account for urea that is convectively removed with excess bodily fluids.[46] This leads to an understatement in the urea removed from overhydrated patients.

Kt/V is closely related to the URR; however, it more accurately reflects urea removed by extracorporeal therapies.[46] Kt/V is a unitless number where K is a measurement of urea clearance expressed in mL/min.[47] Total solute removal per period of time is then defined as the product of K (mL/min) and time (minutes) that the patient receives treatment. Dividing Kt by the volume of urea distribution (mL) normalizes this product. Since urea is approximately equally distributed in all body water compartments V can be approximated as 60% of body weight in kilograms.[48] Kt/V calculations account for both urea being generated by the body and urea that is convectively removed with excess bodily fluids. For this reason, the Kidney Disease Outcomes Quality Initiative (KDOQI) group has adopted the Kt/V as the standard for dialysis adequacy determination in people.[49] In veterinary medicine, Kt/V is important for developing CRRT prescriptions as well as for comparing extracorporeal treatments between patients and modalities while the URR is invaluable for developing safe and effective IHD prescriptions.[52] The specifics of calculating Kt/V are discussed elsewhere.[50,51]

CHAPTER 111

Prostatic Diagnostic Techniquess

Michelle Anne Kutzler

Before beginning any diagnostic techniques, a cursory examination of the prostate should be performed by concomitant rectal and abdominal palpation (see ch. 2). Rectal palpation permits examination of only the dorsal or dorsocaudal aspect of the prostate. Concomitant abdominal palpation not only allows for the cranial aspects of the prostate to be examined but also facilitates better palpation per rectum because the prostate can be pushed into or near the pelvic canal. During palpation, the prostate should be evaluated for size, symmetry, surface contour, mobility, and pain. The normal prostate is bilobed, symmetric, smooth, movable, and nonpainful. Based on history, clinical signs, general physical examination, and palpation findings, the clinician should then determine which combination of the following prostatic diagnostic techniques will most likely yield an accurate diagnosis.

Prostatic Imaging

Ultrasonography

Abdominal ultrasonography is the best imaging modality for evaluation of the prostate because it is a safe, noninvasive method that allows for precise measurements to be taken as well as evaluation of the prostatic parenchyma (see ch. 88). To image the prostate, the transducer is placed against the ventral abdominal wall cranial to the pubis. The prostate should be imaged in both longitudinal (sagittal) and transverse planes to ensure that all areas of the prostate are seen. The true longitudinal plane can be confirmed by observing the hypoechoic urethra. Prostate dimensions are measured on both the longitudinal and transverse planes (Figure 111-1). Prostate length and height are measured on longitudinal images. Length is defined as the maximum prostatic diameter along the urethral axis, while height is defined as the maximum prostatic diameter perpendicular to the axis of the length in the longitudinal view.[1] For a castrated dog, normal prostatic height is about 1 cm. The prostate width is determined from the transverse view, which is obtained by rotating the transducer 90°. The volume of each prostatic lobe can then be calculated using the formula for volume of an ellipse where V (cm^3) = (length × width × height) × 0.523.[2] The total prostatic volume can then be estimated by summing the measures for the left and right lobes. As both age and body weight influence the prostate volume in an intact dog, the expected volume of a normal prostate can be calculated from the formula V (cm^3) = (0.867 × body weight [in kg]) + (1.885 × age [years]) + 15.88.[3]

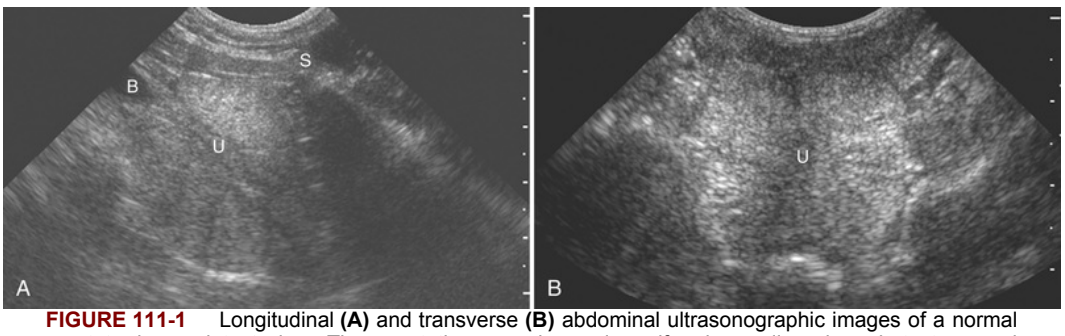

FIGURE 111-1 Longitudinal **(A)** and transverse **(B)** abdominal ultrasonographic images of a normal prostate in an intact dog. The prostatic parenchyma is uniformly medium in echotexture and moderately hyperechoic compared to surrounding structures, with a hypoechoic prostatic urethra (U). Note the anechoic bladder neck (B) and pubic bone shadow (S) on the longitudinal image.

The ultrasonographic appearance of a normal prostate from a intact dog is characteristic: there is a hypoechoic parenchyma with moderately echogenic stippling present in a uniform pattern throughout the gland, similar to that of the spleen, with a capsule that is echoic and has smooth margins.[4] The urethra generally is hypoechoic compared to the prostatic parenchyma, running lengthwise between the two lobes. In contrast, the ultrasonographic appearance of a prostate from a castrated dog is slightly hypoechoic compared to surrounding fat and adjacent structures, such that the urethra is more difficult to visualize. The echogenicity within the prostate should be assessed for focal, multifocal, or diffuse changes in texture. Increased echogenicity and coarse echotexture are associated with hyperplasia, inflammation, infection, and neoplasia (Video 111-1). Ultrasonography allows for determination of the presence or absence of cysts within the prostate. The size, number, and location of the cysts should be identified and noted. The luminal contents of the cysts should be characterized as hypoechoic or anechoic. Parenchymal mineralization also can be observed and it is frequently associated with neoplasia in neutered dogs.[5] However, mineralization occasionally can develop with chronic prostatitis in intact dogs.

Although ultrasound can detect enlargement and changes in the internal prostatic architecture, these features are not pathognomonic for a specific disease. Ultrasonographic appearance of the prostate does not correlate well with culture results, nor does the presence and number of cysts correlate with the presence of infection.[6,7] However, compared to radiography, ultrasonographic imaging is more sensitive in assessing focal or regional parenchymal disease.[8-10] Ultrasonography also has been proven to be a useful method for evaluating responses to pharmacologically-induced prostatic involution.[11,12]

Radiography

The location, size, and contour of the prostate also can be evaluated via caudal abdominal radiography. A normal prostate does not displace the colon or bladder from their normal positions. Radiographically, the prostate has a soft-tissue opacity and its identification is influenced by the differential subject opacity of surrounding tissues. In dogs, radiographic diagnosis of prostatomegaly can be made when the prostate dimensions exceed 70% of the pubic-promontory distance on a lateral radiograph[8] (Figure 111-2). However, prostatic size can vary from a slight enlargement to more than 20 times the normal size, and the severity of enlargement cannot be used to make a diagnosis or prognosis.[13] In addition, the exact dimensions of the prostate often cannot be determined due to superimposition of osseous structures or by lack of abdominal serosal detail from the absence of fat, the presence of ascites, or focal peritonitis associated with prostatitis.[13] The ability of radiography to identify parenchymal changes associated with disease is limited to mineralization, which can be indicative of neoplasia in neutered dogs or chronic inflammation in intact dogs.[5] With caudal abdominal radiography, evidence of sublumbar (medial iliac and hypogastric) lymph node enlargement may be observed from ventral displacement of the colon.[14] In addition, proliferative, lytic, or mixed bony lesions involving the lumbar vertebral bodies and pelvic bones can be identified.[14]

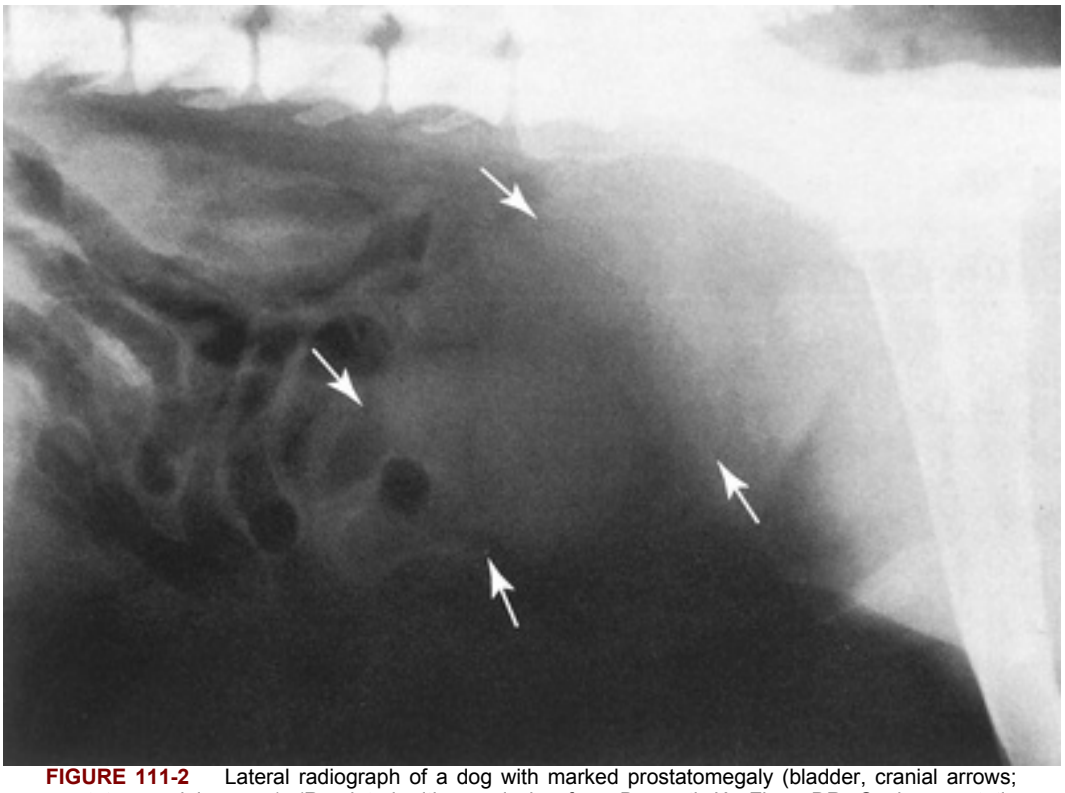

FIGURE 111-2 Lateral radiograph of a dog with marked prostatomegaly (bladder, cranial arrows; prostate, caudal arrows). (Reprinted with permission from Barsanti JA, Finco DR: Canine prostatic diseases. In Ettinger SJ, editor: *Textbook of veterinary internal medicine,* ed 3, Philadelphia, 1989, Saunders, p 1864.)

Distention retrograde contrast urethrocystography (DRCU) has been described as a method for determining prostatic integrity.[15] In a normal prostate, minimal positive contrast will be identified in the prostatic parenchyma near the urethra (urethroprostatic reflux). However, larger volumes of contrast material accumulating within the prostatic parenchyma (intraprostatic reflux) have been reported to occur with all types of prostate diseases.[16] Irregularity or an undulant pattern to the prostatic urethral surface has been associated with benign prostatic hyperplasia, chronic bacterial prostatitis, and neoplasia[15] (Figure 111-3). Narrowing of the prostatic urethral diameter during DRCU has been reported to occur in association with benign prostatic hyperplasia, prostatic abscessation, and neoplasia.[7] However, since the prostatic urethral diameter varies in dogs with normal prostates because of the degree of bladder distention, changes in prostatic diameter must be interpreted cautiously.[17] In addition, the absence of positive results on contrast studies does not rule out the presence of prostatic disease.[7]

Other Imaging Modalities

Both computed tomography (Figure 111-4) and magnetic resonance imaging (Figure 111-5) are excellent methods for prostatic imaging as well as imaging of adjacent structures where metastasis could be a concern. Because dogs commonly are used as models for prostatic diseases in humans, there is abundant published information on the use of these techniques in dogs. Magnetic resonance imaging is an accurate modality to assess changes in canine prostatic volume: it is highly correlated with the weight of the excised prostates.[18] However, there is scarce information in the veterinary literature on the usefulness of these tools for diagnosing prostatic disease in the dog.[14,19,20] In veterinary practice, both technologies are expensive to perform, not uniformly available, and require immobilization with general anesthesia.

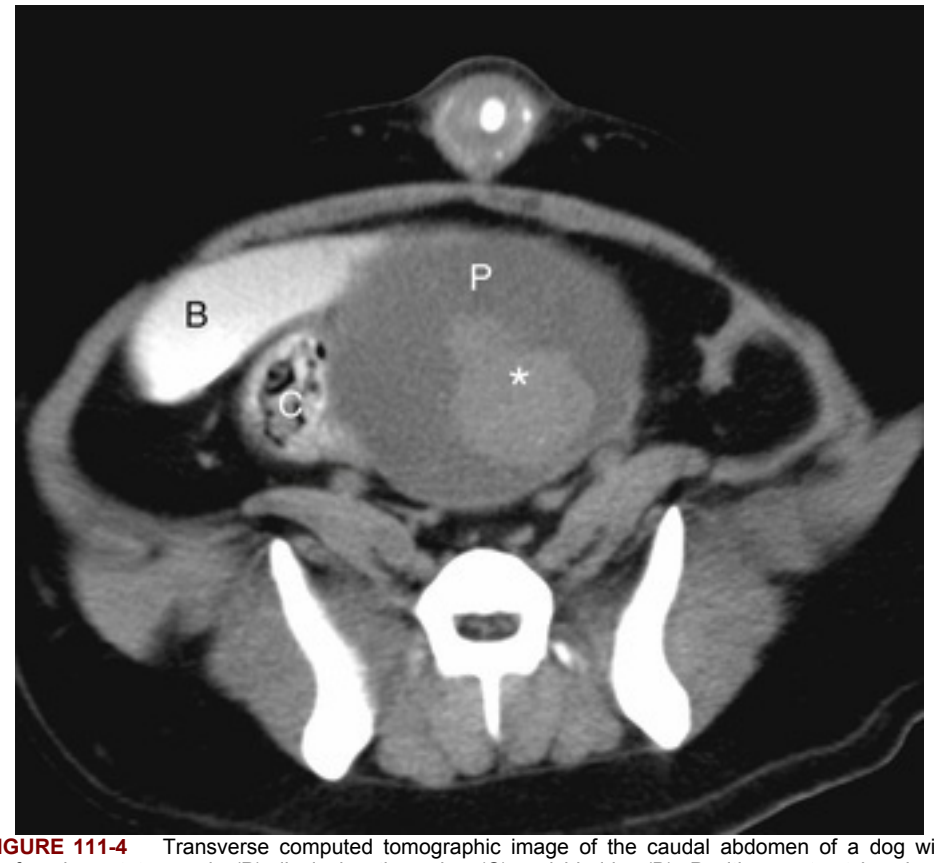

FIGURE 111-4 Transverse computed tomographic image of the caudal abdomen of a dog with profound prostatomegaly (P) displacing the colon (C) and bladder (B). Positive contrast has been placed into the bladder. Note the irregular, high attenuating mass within the prostate (asterisk).

Prostatic Sample Collection

Prostatic fluid should be assessed by cytologic evaluation and quantitative bacterial culture in any dog suspected to have prostate disease. Prostatic fluid can be obtained either by ejaculation or by prostatic massage and traumatic catheterization, where ejaculation is the preferred method of collection especially in cases of suspected bacterial infection and concomitant cystitis. For cystic conditions, fine-needle aspiration of the prostate with abdominal ultrasonographic guidance can yield the most diagnostic prostatic fluid samples (see ch. 89). Depending on the differential diagnoses, prostatic tissue samples might also need to be evaluated to confirm cytologic evaluation, determine appropriate treatment strategies, and provide the most accurate prognosis.

Ejaculation of Prostatic Fluid

The technique to collect prostatic fluid (collection of the third fraction) via ejaculation has been previously described[21] (Video 111-2). To ejaculate a dog, the prepuce is retracted caudally and digital pressure is applied to the base of the penis, proximal to the bulbus glandis. Intense pelvic thrusting occurs with ejaculation. Prostatic fluid (3rd fraction of the ejaculate) can be collected aseptically by ejaculation as long as the collection containers are changed after the combined 1st/2nd fractions are collected. The first two fractions flush out any normal flora colonizing the distal urethra so that the prostatic fluid sample is not contaminated with normal urethral flora. During collection of the third fraction, care must be taken to prevent the tip of the penis from touching the inside of the sterile collection container to avoid contamination of the sample with normal penile mucosal flora. The combined 1st/2nd fraction sample should be saved for semen evaluation if indicated. Cytologic evaluation of the prostatic fluid immediately after collection will aid in determining if an aseptic sample has been obtained. A sample that has been contaminated from the mucosal surface of the penis will contain squamous epithelial cells with Gram-positive cocci but lack neutrophils.[22] If there is concern that the prostatic fluid was contaminated during collection, a second ejaculate can be collected after a 1-2 hour rest period.

Prostatic Massage and Traumatic Catheterization

If the dog will not ejaculate, a prostatic massage and traumatic catheterization should be performed. If cystitis is known to be present, it is preferable to treat the dog with an appropriate antibiotic (e.g., ampicillin) that does not penetrate the prostate before doing the prostatic wash. After the cystitis has been treated successfully, the wash may be performed.

The technique for prostatic massage and traumatic catheterization has been previously described and must be executed carefully.[22] Briefly, using aseptic technique, the bladder is catheterized and all the urine is removed. The bladder is then flushed with sterile saline (5 mL) and this sample is withdrawn and saved (PM-1). The catheter is subsequently retracted so that the tip is distal to the prostate. The prostate is then massaged per rectum for about 1 minute to express a quantity of prostatic fluid into the urethra where it can be collected with a urinary catheter. Sterile saline (5 mL) is slowly infused into the catheter, while occluding the urethral orifice. Thus, the prostatic fluid is flushed into the bladder. The catheter is then advanced into the bladder as aspiration is performed and the sample (PM-2) is collected. The prostatic wash sample should be fixed on a glass slide, stained with hematoxylin and eosin, and evaluated for cellularity (Figure 111-6). By comparing the cytologic examination and quantitative bacterial culture results from both prostatic wash specimens (PM-1 and PM-2), the precise location of the problem can be determined[23]: evidence of infection in both samples is more consistent with cystitis, whereas evidence of infection only in PM-2 supports prostatitis. Prostatic massage is not without risks. In cases of acute prostatitis or prostatic abscess, there is a possibility of triggering septicemia by forcing bacterial organisms into the bloodstream or causing peritonitis.[24] Also, there is the uncertainty as to whether prostatic fluid has been obtained.

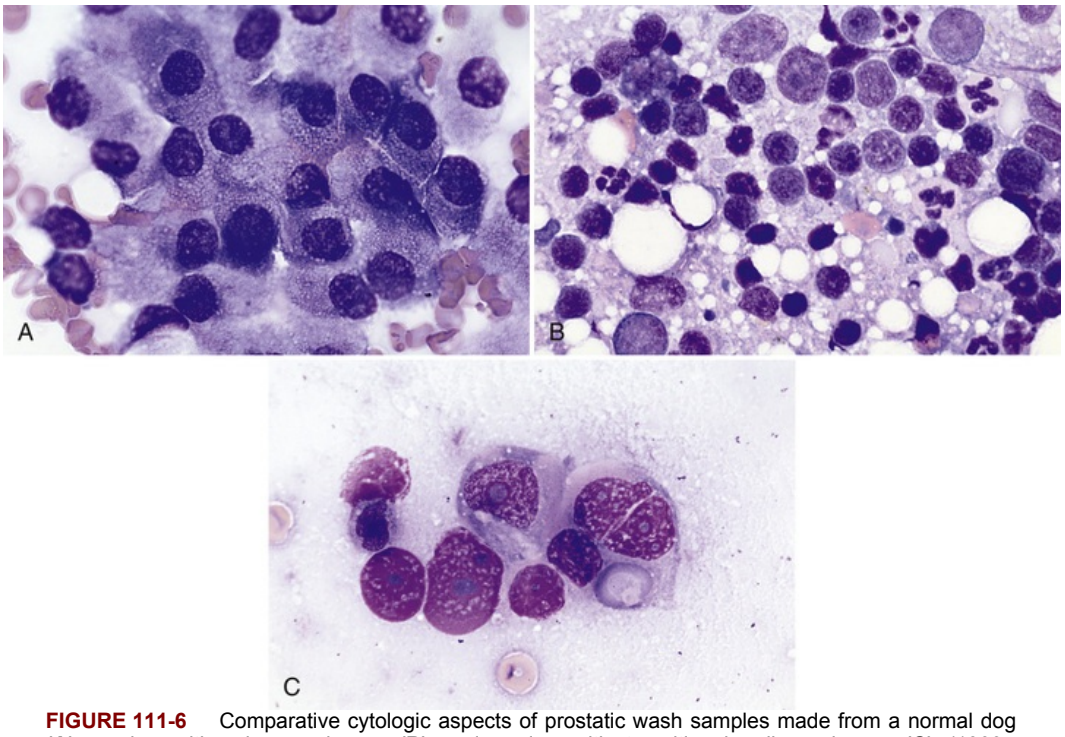

FIGURE 111-6 Comparative cytologic aspects of prostatic wash samples made from a normal dog **(A),** a dog with adenocarcinoma **(B)** and a dog with transitional cell carcinoma **(C)** (1000× magnification). The neoplastic prostatic epithelial cells **(B** and **C)** show multiple signs of malignancy, including anisocytosis, anisokaryosis, increased nuclear to cytoplasmic ratio, multiple nucleoli, and multiple nuclei.

Fine-Needle Aspiration

Fine-needle aspiration (FNA) techniques for collecting prostatic fluid samples have been reviewed.[22] If this technique is to be used, the skin surface through which the needle is inserted should be clipped and aseptically prepared. Once the needle enters the prostate, aspiration should be performed as the needle is redirected several times within the gland (see ch. 89 and 93). Negative pressure is then slowly released and the needle is withdrawn. About 17% of FNA samples are nondiagnostic due to low cellularity.[25] Diagnosis made by FNA could be discordant from a diagnosis made by histopathology if aspiration of fibrotic tissue results in low cellularity or if aspiration of inflamed or dysplastic tissue is misinterpreted as neoplasia.[25] Accuracy can be improved when the technique is combined with abdominal ultrasonography (Video 111-3). If prostatic neoplasia is suspected, a prostatic biopsy can give a greater diagnostic yield than FNA.[26] Complications associated with FNA have included hematuria and periprostatic hemorrhage.[22,26] In addition, aspiration of a sterile intraprostatitic cyst can result in the formation of a prostatic abscess.[27]

Prostatic Biopsy

Percutaneous prostatic biopsy techniques have been reviewed.[28] Careful selection and preparation of patients for biopsy are essential. Prostatic biopsies are not recommended if bacterial prostatitis is suspected unless neoplasia is also suspected or if existence of bacterial prostatitis cannot be confirmed by other tests.[29] Antibiotics should be started 48 hours before a prostatic biopsy is performed if bacterial infection is suspected. A fluid or air-filled urethral catheter can be passed before prostatic biopsy samples are taken to better define the prostatic urethra ultrasonographically and avoid damaging it. The biopsy site should be clipped and prepared aseptically. Ultrasound guidance should be used for performing a prostatic biopsy because it allows for accurate placement of the biopsy instrument. "Blind" prostatic biopsies are not recommended. Ultrasound guidance reduces the risk of post-biopsy complications (hematuria, dissemination of infection, laceration of major blood vessels, urethral fistulation, orchitis, inadvertent puncture of adjacent organs).[27] In addition, ultrasound guidance increases the diagnostic yield of the biopsy sample because

diseased tissue can be targeted. The ultrasound transducer should be covered with a sterile sleeve and sterile acoustic coupling gel should be used. The biopsy instrument (e.g., spring-loaded Tru-Cut type) should be directed tangentially to avoid the central prostatic urethra. The biopsy instrument can be introduced freehand or through a clip-on ultrasound guide. The clip-on guide ensures that the needle remains in the plane of the ultrasound beam. However, the guide limits the maneuverability of the biopsy instrument and can be awkward.

For additional information regarding the application and interpretation of these diagnostic techniques related to specific canine prostatic diseases, see ch. 337.

CHAPTER 112

Gastric Intubation and Lavage

Deborah C. Silverstein

Gastric Intubation

Placement of a tube through the mouth into the stomach, also known as orogastric intubation, is performed for the purpose of removing gastric contents, decompressing a distended stomach (e.g., gastric dilation-volvulus), lavaging the stomach, and/or administering medications or diagnostic solutions (e.g., barium). Although the procedure itself is not difficult, the potential benefits and risks should be weighed prior to placement of an orogastric tube.

Indications and Complications

The primary indications for orogastric intubation include decompression of a dilated stomach (see ch. 275), toxin removal from the stomach with or without lavage (e.g., potentially lethal toxins, intoxicated patients with an altered level of consciousness requiring controlled decontamination, or those that may form a bezoar or obstruction within the stomach or bowel; see ch. 151), and medication or diagnostic solution administration into the stomach. Potential complications to consider include esophageal or gastric wall damage or perforation, regurgitation followed by aspiration of gastric contents, and adverse effects of general anesthesia. Animals that are critically ill or severely intoxicated could be at higher risk for anesthesia-related complications.

Procedure

Once the patient is identified as a candidate for orogastric intubation, the anesthetic protocol should be chosen according to the patient's systemic status. The main supplies necessary are shown in Figure 112-1 and include:

- Equipment and drugs for induction, maintenance, and monitoring of general anesthesia (not all shown); ensure cuff of endotracheal tube is functional and inflated during procedure
- Orogastric (stomach) tube
- Water-soluble lubricant
- Tape or permanent marker
- Gauze
- Mouth gag
- Receptacle for drainage
- Warm water or isotonic fluid for lavage
- Funnel, bilge pump or stomach pump (Figure 112-2)
- Stool or chair
- Charcoal if indicated
- Suction apparatus (precautionary)

FIGURE 112-1 The supplies necessary for gastric intubation and lavage are presented. Note that the anesthesia drugs and monitoring equipment are not in the picture.

FIGURE 112-2 A JorVet Thirsty Stomach Pump (Jorgensen Laboratories, Inc., Loveland, CO) is pictured. This can be used in place of a funnel to pump through an orogastric tube and into the stomach quickly.

Once the endotracheal tube is in place, the cuff should be inflated prior to the procedure to help prevent aspiration of stomach contents or lavage fluid. The orogastric tube should be a single-lumen, semi-rigid tube with a smooth tip to avoid mucosal trauma. The clinician should choose a tube with the largest diameter possible for the patient's esophagus (approximately the same diameter as an endotracheal tube for the given animal). A 12 Fr red rubber catheter may be adequate for small puppies, whereas an 18 Fr red rubber catheter may be used in adults up to 15 kg, and a formal orogastric tube should be used in dogs weighing >15 kg. Measurement of the tube should be performed using the nares and the last rib as landmarks (Figure 112-3, *A*) and the tube should be marked with either a piece of white tape (Figure 112-3, *B*) or a permanent marker.

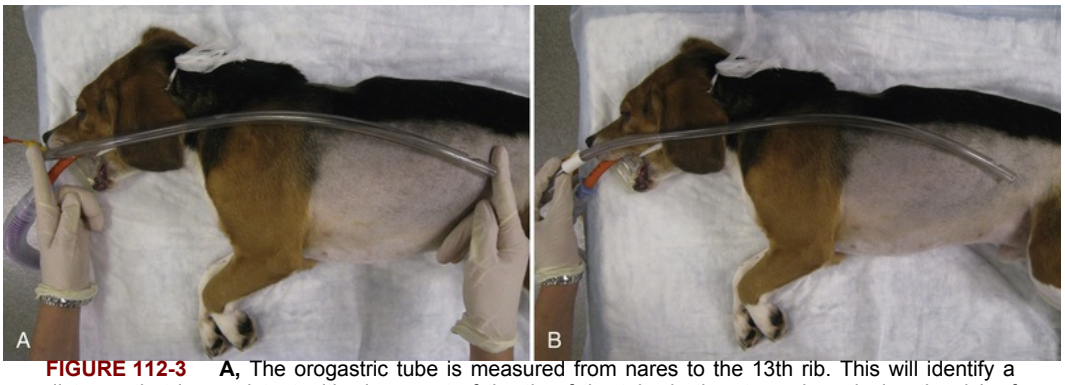

FIGURE 112-3 **A,** The orogastric tube is measured from nares to the 13th rib. This will identify a distance that is consistent with placement of the tip of the tube in the stomach, reducing the risk of over-insertion (gastric wall trauma), under-insertion (esophageal position of the tube tip), or, if the patient's trachea were not intubated with an endotracheal tube, misplacement (intra-tracheal). **B,** A piece of tape is placed on the tube to mark the distance from the tip of the nose to the 13th rib. Alternatively, the operator could use a permanent marker.

There is some controversy as to whether animals should be sedated or anesthetized prior to passing the orogastric tube. The author's preference is to anesthetize the patient and place an endotracheal tube with the cuff inflated to help protect the airway in case the animal regurgitates or vomits during the procedure. The exception may be neonates that are having an orogastric tube passed for a feeding and do not typically exhibit the gag reflex during the procedure (see ch. 171). Suction catheters and additional necessary equipment should always be available prior to starting the procedure so the oropharynx can be cleaned prior to extubation, or in the event of regurgitation or vomiting following orogastric extubation.

Once the patient is anesthetized and the endotracheal tube is placed, the mouth can be maintained in the open position using either a mouth gag or inner roll of tape, if necessary. Water-soluble lubricant should be applied to the end of the orogastric tube and the tube advanced slowly into the esophagus, located in the left dorsal aspect of the pharynx. The other end of the tube should always be lower than the dog (and inside a collection container) to allow for gravitational drainage. The tube is advanced gently to the predetermined length to reach the stomach. Dogs with gastric dilation-volvulus might require slight forward pressure with a twisting motion to aid with entry through the cardia into the stomach (Video 112-1). If there is continued resistance to passage of the tube, the operator can blow a small amount of air into the tube while gently advancing it (it is recommended that a piece of gauze be placed over the end prior to doing this to avoid contamination of the operator's mouth). Animals with severe distention of the stomach may require percutaneous trocarization of the stomach prior to successful passing of the orogastric tube. Once the tube is advanced to the premeasured length, there should be some fluid or gastric contents apparent in the collection container below the level of the patient; if not, careful ballottement of the abdomen may increase pressure and help increase flow through the tube (see ch. 17). If gastric contents are occluding the tube and preventing drainage, 10-30 mL of warm water can be flushed into the tube to dislodge the obstruction.

In order to prevent fluid from leaking out of the tube and into the esophagus or pharynx during removal, the tube should be tightly kinked ≈10 cm from the operator's end prior to removal. The kink should be maintained firmly until the tube is fully removed from the animal. The mouth and pharynx should be closely inspected for residual fluid or stomach contents and cleaned with gauze or suction as needed.

Gastric Lavage

Removal of gastric contents via orogastric intubation is referred to as gastric lavage. It is most commonly performed in an attempt to remove toxic material from the stomach or to empty the stomach prior to gastrotomy. It rarely has been used as a cooling technique or to confirm bleeding from the upper gastrointestinal (GI) tract.

The American Academy of Clinical Toxicology has concluded that the poisoned patient should not receive routine GI decontamination and clinical evidence in humans has shown no clear benefit of gastric lavage over activated charcoal for the treatment of toxin ingestion.[1,2] However, lavage currently is performed at many human hospitals and it still is a part of the current recommendation for the treatment of small animals in specific scenarios, despite limited evidence.[3-5] Before emesis or gastric lavage is performed, the clinician should always ensure that Bailey's "GI decontamination triangle" questions have been adequately answered[6]:

1. Is the ingested toxin likely to cause significant effects?
2. Is GI decontamination likely to change the outcome?
3. Do the risks of GI decontamination outweigh the potential benefits in this particular patient?

Patients that might benefit from gastric lavage include animals that have ingested a potentially harmful amount of toxin within 1 hour of presentation, but where induction of emesis is not deemed appropriate due to neurologic impairment (or emesis is not effective at removing gastric contents; also see ch. 151). If animals have ingested a very small amount of a toxin, or have already vomited prior to presentation, the potential risks and benefits of gastric lavage should be considered because the procedure is not benign, and activated charcoal administration may prove to be a safer option. There are exceptions, especially when very large amounts of a dangerous substance have been ingested. Gastric lavage is not indicated for the treatment of food bloat (without torsion) or ingestion of material that solidifies in the stomach, such as polyurethane adhesive (e.g., Gorilla Glue); the latter requires gastrotomy for removal. Gastric lavage is contraindicated in animals that have ingested caustic or volatile substances since esophageal reflux, mucosal damage, and aspiration pneumonia could result. Three canine studies have evaluated the effectiveness of gastric lavage for reducing the bioavailability of different markers (sodium salicylate or barium sulfate).[7-9] As expected, gastric lavage at 15 minutes recovered a much greater amount of the marker than at 30 or 60 minutes. All three studies showed <15% recovery at 1 hour post-administration of marker. Another study examined dogs that were given 500 mg/kg of aspirin, then lavaged and given activated charcoal (1.5 g/kg) 30 minutes after drug administration.[10] There was a 37% reduction in peak plasma salicylate concentration in the treated group compared to the control group, confirming the fact that early lavage (and charcoal therapy) may be worthwhile. It is not known how this treatment compares to induction of emesis in neurologically intact animals that have ingested non-corrosive toxins.

The primary risks of gastric lavage include anesthesia-related complications, aspiration of stomach contents, and trauma to (or perforation of) the esophagus or stomach. The incidence of GI tract perforation is very low in people,[2] and is assumed to be low in small animals, but there are no definitive data to prove or disprove this assumption in veterinary medicine. Excessive absorption of hypotonic lavage fluid could lead to water intoxication with hyponatremia and hypochloremia, but this is unlikely if a majority of the fluid is drained following administration. It is helpful to record the volume of fluid that is infused and retrieved to avoid excessive water administration. In order to perform gastric lavage, a single- or double-lumen orogastric tube should be placed as described above, the animal positioned in lateral recumbency, and the endotracheal tube cuff checked for inflation. Approximately 10-30 mL/kg of warm lavage fluid (e.g., isotonic saline or water) is infused into the stomach using a stomach pump, bilge pump, or gravity flow through a funnel (note: never use a hose). Once the fluid has been infused, the operator's end of the orogastric tube should be directed into the designated container and the effluent passively drains via gravity flow (Video 112-2). While fluid is infused, and when it is being drained, the stomach should be palpated to monitor for overdistention and gently balloted to assist with emptying of the lavage fluid, respectively. Suction should never be used for emptying the stomach as this may cause mucosal trauma. The retrieved stomach contents should be examined for foreign material or toxins and submitted for toxicologic analysis, if indicated. The infuse-drain cycle should be repeated several times (typically 5-10 times) in order to effectively clean out the stomach. The animal can be turned to the opposite recumbency for additional gastric lavages, as indicated, but it is important to check the endotracheal tube position and cuff inflation after repositioning. Following the final lavage cycle, activated charcoal (1-5 g/kg), with or without a cathartic, can be administered through the orogastric tube and into the stomach (and flushed in with water), if indicated. It is important that the stomach not be distended prior to recovery and extubation, in order to minimize the chance of vomiting and aspiration. There is no proven advantage to the use of pre-lavage activated charcoal administration in human medicine. This was previously thought to decrease intestinal absorption of toxin that could be advanced into the duodenum during the lavage.[2]

Following gastric intubation +/− lavage, the animal should remain endotracheally intubated with the cuff inflated until sternal and swallowing. Extubation should not be delayed in cats, however, due to risk of laryngospasm. Therefore, cats should either have a reduced dose of activated charcoal administered, or it can be given after recovery. Supplies for oropharyngeal suction should be readily available during recovery in case there is fluid in the mouth or pharynx that can be removed easily prior to extubation. The patient should be monitored closely for evidence of nausea or regurgitation and treated accordingly.

CHAPTER 113

Gastrointestinal Endoscopy

M. Katherine Tolbert

Overview

Standard upper (esophagogastroduodenoscopy, EGD) and lower (colonoscopy, proctoscopy) gastrointestinal (GI) endoscopy are techniques that allow for visualization of the lumen and mucosal lining of the oropharynx, esophagus, stomach, proximal duodenum, ileum, colon and rectum. Advanced endoscopy procedures, including video capsule endoscopy (see ch. 276) and interventional endoscopy (see ch. 123), allow for assessment of additional sections of the GI tract. With proper equipment and operator training, GI endoscopy is a minimally invasive technique that can be used for a variety of diagnostic and therapeutic interventions. Diagnostic procedures include biopsy and collection of tissue or fluid for histopathologic examination, cytology, culture and/or infectious disease testing. Therapeutic GI endoscopic procedures include retrieval of ingested foreign bodies, dilation of esophageal and rectal strictures, polypectomy, and placement of enteral feeding tubes and stents. Unlike for human patients, no guidelines have been established to identify animals most likely to benefit from GI endoscopy; however, the indications for GI endoscopy are similar. Common indications for pursuit of GI endoscopy in companion animals include the presence of chronic GI signs (vomiting, diarrhea, weight loss) that persist despite trial therapies, signs compatible with active or chronic GI bleeding (hematemesis, melena, hematochezia, unexplained chronic iron deficiency anemia), dysphagia and/or regurgitation, and/or for therapeutic indications mentioned above. First-line diagnostic tests and empirical therapy (e.g., diet trial, anthelmintics) should be considered prior to pursuit of endoscopy as a diagnostic tool.

Equipment

Endoscope cost, frequency of use, and versatility guide the type of endoscope and endoscopic equipment purchased. The characteristics of standard endoscopic equipment used for canine and feline GI endoscopy are listed in Table 113-1.

TABLE 113-1

Characteristics of Endoscopes and Associated Equipment Commonly Used for Canine and Feline GI Endoscopy

ENDOSCOPE TYPE	FLEXIBLE VIDEOENDOSCOPE PREFERRED FOR MOST APPLICATIONS
Insertion tube diameter and length	5.9*-11 mm; 100-160 cm
Instrument channel	2.0-2.8 mm
Endoscope characteristics	4-way deflection of at least 180° in one plane × 90° in 3 planes; forward viewing
Tower	Monitor, image capture system
Endoscopy performance equipment	Portable or wall suction, irrigation instrumentation, biopsy forceps, retrieval instrumentation (baskets, snares, etc.), cytology brushes, injection needles, cautery
Additional equipment	Cassettes with sponges, glass slides, formalin jars, endoscopy cleansing solutions, endoscope cleaning adaptors, pressure (leak) tester

Light source	Xenon light source and cable

*Smaller diameter endoscopes might be preferred for exclusively feline practices.[1]

Flexible video endoscopes with an image capture system are preferred for most GI endoscopic procedures. Video endoscopy is more expensive and requires the use of a video monitor; however, this technology provides superior resolution and is a better diagnostic tool compared to fiberoptic endoscopes. Rigid endoscopes can be used for esophagoscopy and proctoscopy, and can be useful in the dilation of strictures, retrieval of foreign bodies, and biopsy of tumors in the proximal esophagus, distal colon, and rectum. However, rigid endoscopes are limited in their diagnostic capabilities because of inadequate reach and inflexibility. Smaller diameter flexible endoscopes can be preferred for intubation of the duodenum of small patients, but they sacrifice the diameter of the instrument channel, which restricts the size of biopsy samples. Smaller diameter endoscopes also result in less effective simultaneous suction while an instrument is in the instrument channel. Endoscopes ≤100 cm in length might not reach the duodenum or ileocecocolic junction in large- to giant-breed dogs. Therefore, if practice finances only allow for the purchase of one endoscope for both canine and feline GI endoscopy, a mid-size diameter flexible endoscope (5.0-6.0 mm) with the largest instrument channel possible (≥2.2 mm) and an insertion tube length of at least 120 cm is recommended.

The quality of endoscopic GI biopsy samples has a major impact on the consistency and accuracy of the histopathologic exam in both dogs and cats. When gastric and duodenal tissue samples are of a lower quality, a larger number of them will be needed to identify lesions.[2] Therefore, much attention should be paid to both the quality of the biopsy technique as well as biopsy instrumentation. Endoscopic biopsy forceps are available in a myriad of sizes (large, standard, pediatric cup), shapes (round, oval) and styles (spikes, alligator teeth). A recent study performed in healthy dogs demonstrated that size but not biopsy cup shape or presence of a spike had a significant influence on adequacy of histologic assessment.[3] Large capacity forceps were superior to small capacity forceps in providing specimens with less crush artifact and of higher quality and adequacy for histopathologic exam. Additional studies will need to be performed to determine if these findings translate to dogs and cats with gastrointestinal disease; however, using the largest cup biopsy forceps to obtain GI tissue samples is recommended.

Patient Preparation

Endoscopy often is useful to further characterize an abnormality (e.g., filling defect, stricture) identified on barium contrast radiography. However, unless the severity of signs dictates immediate examination, endoscopy should be delayed at least 24 hours following administration of barium because barium can hinder visualization of the GI mucosa and can obstruct the endoscope instrument channel if aspirated (Figure 113-1).

FIGURE 113-1 Duodenoscopy in a dog immediately following administration of oral barium. Barium can be observed adhering to the intestinal mucosa.

A fasting period of 12-24 hours and 24-48 hours is recommended for EGD and lower GI endoscopy, respectively. Water should be restricted up to 2-4 hours before the procedure; however, intravenous fluids should continue to be administered to prevent dehydration in animals with severe vomiting and/or diarrhea. Unless concern exists for vomiting and aspiration, a GI lavage solution (e.g., polyethylene glycol [GoLytely]) should be administered 12-18 hours prior in addition to multiple warm water enemas in preparation for colonoscopy.[4] The total dosage is 60-120 mL/kg (higher dosage recommended, barring nausea) in dogs and 60 mL/kg in cats. The solution should be divided into 2 fractions, administered 2-4 hours apart (2 or 3 fractions, 2 or more hours apart in cats), and administered slowly via an oro- or nasogastric tube to reduce the chance of vomiting and aspiration (see ch. 112); administration should be stopped if there is evidence of nausea (e.g., ptyalism) or vomiting.[5] Enemas, which should be administered well before or after administration of GI lavage solutions to further minimize the risk of vomiting the lavage solution, are given until the colonic fluid is clear (see ch. 114). Precautions against triggering nausea are warranted with gastric lavage solutions because their aspiration can be catastrophic. If possible, drugs affecting GI motility or sphincter tone should be withheld prior to GI endoscopy. Although there often is concern regarding premedication with opioids and alpha-2 agonists prior to GI endoscopy, hydromorphone with or without glycopyrrolate, butorphanol, and medetomidine have been demonstrated not to have a significant effect on the intubation of the feline pylorus by an experienced endoscopist. Therefore, these drugs can be reasonable choices to premedicate cats prior to EGD,[6] and the same approach has been extrapolated to dogs.

GI endoscopy often is performed in dedicated endoscopy suites, with the dog or cat under general anesthesia to reduce stress and anxiety associated with the procedure. A cuffed endotracheal tube is used for preventing complications such as aspiration pneumonia. The animal is positioned in left lateral recumbency for flexible GI endoscopy (to suspend the right-sided pylorus) unless a percutaneous endoscopic gastrostomy (PEG) feeding tube is being placed, in which case the animal is positioned in right lateral recumbency to allow percutaneous access to the gastric fundus. A mouth gag is recommended to prevent trauma to the endoscope; however, spring-loaded mouth gags should not be used in cats as cats lack an internal carotid artery and therefore are susceptible to post-anesthetic blindness secondary to mouth gag–associated compression of the maxillary artery.[7]

Esophagogastroduodenoscopy

Esophagogastroduodenoscopy always should be performed systematically and with the same approach, to ensure a comprehensive examination. With the animal's neck in extension, the flexible endoscope is passed along midline into the caudal oropharynx and through the pharyngoesophageal sphincter, which lies dorsal to the larynx (Video 113-1). When the tip of the endoscope has entered the proximal esophagus, air is insufflated to open the collapsed lumen. Manual compression of the proximal esophagus by an assistant can be necessary to maintain esophageal insufflation for visualization throughout the cervical and thoracic esophagus. The esophageal lumen is kept in the middle of the viewing field. The esophageal mucosa is pale-pink and, in cats, submucosal vessels often are visualized. The trachea can be observed to slightly compress the proximal esophagus extraluminally, and the heartbeat can be seen transmitted through the wall of the thoracic esophagus. Unlike the canine esophagus, which is comprised entirely of striated muscle, the distal third of the feline esophagus has a herringbone appearance due to its composition of smooth muscle in this area. The gastroesophageal sphincter generally is closed. The endoscope might need to be angled slightly dorsally, with air insufflation, to pass through the sphincter and into the gastric cardia. The stomach of healthy dogs and cats is darker in color than is the esophagus, and the gastric mucosa is arranged into rugal folds in the fundus and body. The endoscopist should minimally distend the stomach with air to allow for separation of the rugal folds and performance of a cursory examination. Inspection of the mucosal lining and luminal contents (e.g., presence of bile, food) of the gastric cardia, fundus, body, incisura angularis, and pyloric antrum is performed to ensure that endoscopic artifacts are not mistaken for lesions during later examination. A full examination should be postponed until after inspection and biopsy of the duodenum, to avoid paradoxic motion of the endoscope and difficulty in crossing the pyloric sphincter secondary to gastric distension. Following the cursory exam of the stomach, the endoscope is advanced in the minimally-distended stomach along the greater curvature towards the pyloric antrum and through the pyloric sphincter. The endoscope tip should be kept in line with the center of the pyloric orifice. Light to moderate force applied by the endoscope tip against the pyloric sphincter with intermittent insufflation of air can be necessary to advance through a closed pyloric sphincter. A smaller diameter endoscope (<9 mm) is needed to traverse the pyloric canal of small cats. Occasionally, a “fold” may be present over the pyloric sphincter, making access more difficult in some animals. Temporarily positioning the animal into right lateral recumbency can rectify this problem. Following intubation of the pyloric sphincter, a brief “red out” occurs as the walls of the pylorus close around the tip of the endoscope. The endoscope tip is directed ventromedially (typically, downward and to the right on the screen) to enter into the lumen of the proximal duodenum. With gentle force, the endoscope tip is advanced slowly, away from the wall of the proximal duodenum, through the cranial duodenal flexure, and into the descending duodenum. If substantial resistance is felt, the endoscope tip should be retracted and minor adjustments should be made. The healthy small intestinal mucosa is pale-pink with a shag carpet appearance created by the villi. The major duodenal papilla (and occasionally the minor duodenal papilla in dogs) can be visualized following entry into the descending duodenum (see ch. 274). Peyer's patches can be identified in the canine descending duodenum. Care should be taken to examine the mucosa when the endoscope first is being passed through the descending duodenum, because the duodenum is more friable than the esophagus and stomach, and iatrogenic endoscopic trauma could result in the appearance of mucosal lesions upon retraction of the endoscope (Figure 113-2). After advancing through the descending duodenum, the endoscope is passed through the caudal duodenal flexure into the transverse and ascending duodenum. Generally, the jejunum can be reached in small dogs and cats when using a moderate-length endoscope. Duodenal biopsies then are taken as the endoscope is retracted towards the pyloric sphincter.

FIGURE 113-2 Duodenoscopy in a dog. Endoscope-induced hemorrhage can be visualized at 12 o'clock.

The pyloric antrum can be examined fully following retraction of the endoscope from the pyloric sphincter. As the insertion tube (endoscope body) continues to be retracted, the rugal folds of the greater curvature should be inspected prior to fully distending the stomach to complete the examination. When insufflating, care should be taken to avoid overinflating the stomach because this can alter the appearance of the gastric mucosa, result in respiratory depression from diaphragm impairment, and cause vagally-mediated bradycardia. Retroversion of the endoscope ("J maneuver") is performed to visualize the incisura, cardia, and fundus. With the endoscope along the greater curvature in the moderately distended stomach, the endoscope tip is deflected 180° so that the shape of the endoscope resembles the letter J. The endoscope then can be retracted towards the gastroesophageal sphincter to obtain a close-up view of the cardia and fundus. Following examination, biopsies should be collected from each region of the stomach.

After completion of the EGD exam and collection of biopsy samples, air and liquid should be completely evacuated from the stomach and esophagus with suction to reduce the risk of bloat, reflux and aspiration.[1,8,9]

Lower GI Endoscopy

Colonoscopy is an easier technique to perform for beginners compared to an EGD procedure. Following a digital rectal examination to evaluate for the presence of a perineal hernia and rectal masses and/or strictures, a well-lubricated endoscope is inserted past the anal sphincter into the rectum (Video 113-2). An assistant aids in air insufflation of the rectal lumen by closing the perianal tissue manually around the endoscope. The endoscope is advanced into the descending colon with the colonic lumen maintained in the center of the viewing field at all times, except when traversing flexures. If the colon has been adequately prepped, the healthy colonic mucosa appears to be pale-pink to slightly orange, shiny, and smooth. When the splenic flexure is encountered, the endoscope tip is directed dorsally while the endoscope is gently advanced against the colonic mucosa. With some minor adjustments, the endoscope generally glides easily into the transverse colon. The hepatic flexure follows the fairly short segment of the transverse colon. The endoscope is advanced gradually into the ascending colon, where the ileocecocolic junction can be viewed.

Biopsy of the ileum is recommended in all cats and dogs with signs of small intestinal disease, unless there is concern for perforation. The jejunum and ileum are the most common segments of bowel affected with inflammatory bowel disease and alimentary lymphoma in cats.[10] Thus, if endoscopy is pursued rather than exploratory laparotomy, colonoscopy and ileal biopsy should be included with EGD. Visualization of the ileal

mucosa often is not possible nor recommended in small dogs and cats, especially when a pediatric endoscope is not available; therefore, unless concern for perforation exists, blind ileal biopsy must be performed (Figure 113-3). In medium- to large-breed dogs, the ileocolic valve can be traversed but doing this might require the assistance of biopsy forceps to serve the function of a stylet. Once the closed biopsy forceps are gently advanced beyond the valve, the endoscope is passed over the forceps into the ileal lumen. If necessary to rectify difficulty in traversing the ileocolic valve because of an oblique valve angle, the animal can be temporarily placed in right lateral recumbency. Following biopsy of the ileum, the cecum can be inspected with the endoscope tip sitting at the cecocolic orifice. As with EGD, complete examination and biopsy of the colonic wall is performed as the endoscope is retracted towards the rectum.[1,8,9]

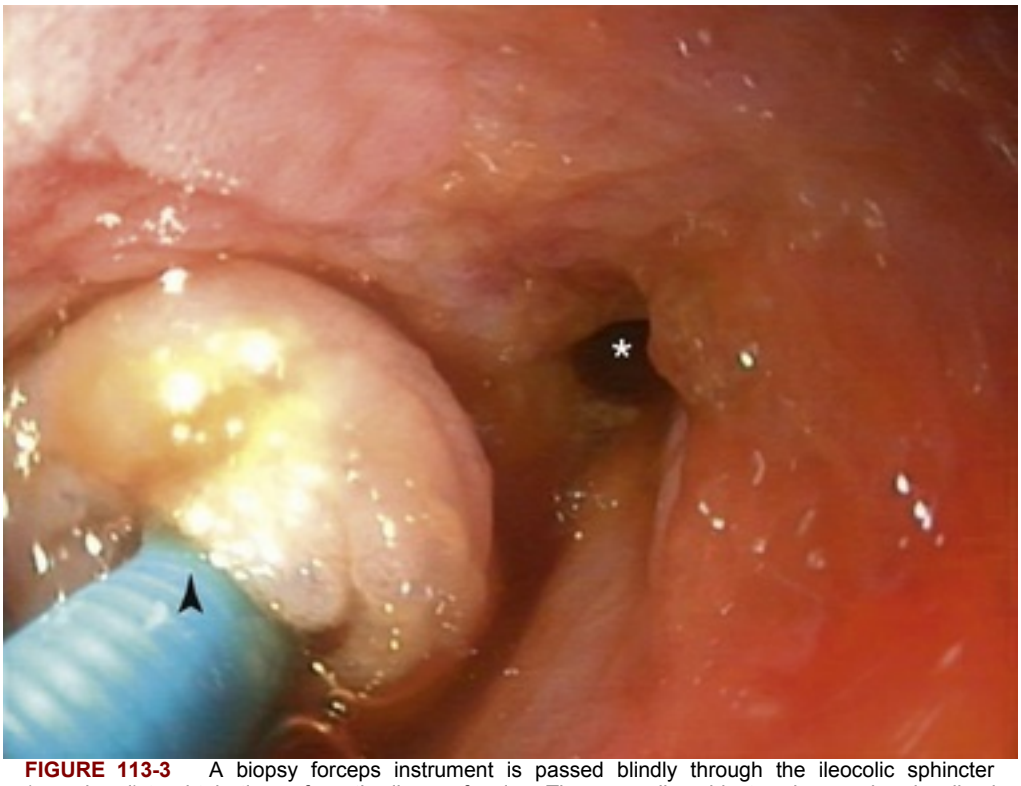

FIGURE 113-3 A biopsy forceps instrument is passed blindly through the ileocolic sphincter (arrowhead) to obtain tissue from the ileum of a dog. The cecocolic sphincter also can be visualized (asterisk).

Endoscopic Examination and Biopsy

During GI endoscopic procedures, the endoscopist should evaluate the GI mucosa for the presence of hyperemia, vascularity, edema, discoloration, hemorrhage, erosions and/or ulcerations, friability and other mucosal lesions. Luminal contents including food, bile, and other fluid should be noted. A standardized endoscopy report, such as that supplied by the World Small Animal Veterinary Association (WSAVA) International GI Standardization Group, should be used for documenting and standardizing GI endoscopic examinations: duodenal mucosa, colonic mucosa, the complete EGD procedure, and the complete colonoscopy procedure each can be recorded in detail with such forms[11] (E-Figures 113-4 and 113-5).

E-FIGURE 113-5 Standardized form for lower gastrointestinal endoscopy.

Whether the endoscopist or the endoscopy assistant obtains the biopsies is based on personal preference and the experience of the endoscopist. In order to obtain GI biopsies, the biopsy instrument is advanced through the instrument channel just beyond the tip of the endoscope. Depending on the desired biopsy location in the GI tract, the forceps are opened and either advanced straight ahead (more often with blind biopsies) or directed perpendicular to the mucosal wall. Once resistance is appreciated, the forceps are closed and retracted towards the endoscope. The number of biopsies needed from each region of the GI tract for histologic examination depends on the quality of the biopsied tissue and the specific disease process involved.[2] Approximately 6-28 samples typically can be required.[12] At the author's institution, at least 10-12 biopsies are taken in each region of the GI tract. More biopsies are taken from areas containing lesions than presumably normal areas. Biopsies thought to be poor in quality are discarded and not included in the count. Great care should be taken when removing tissue from biopsy forceps and unfolding it so as not to damage

the sample. The endoscopy team should have an open line of communication with the diagnostic laboratory to ensure that tissue is oriented and prepared according to the specific laboratory's requirements.[12] A review of basic principles for orienting and mounting GI tissue can be found in a consensus statement published by the WSAVA GI Standardization Group.[11] Gastrointestinal biopsy tissue should be evaluated and critiqued by the histopathologic laboratory according to the standardized classification system developed by the WSAVA GI group.[11,13] Additional biopsy samples also can be obtained for cytologic impression smears and/or infectious disease testing.

Endoscope Cleaning and Storage

To increase instrument shelf life and decrease the likelihood for transmission of infectious diseases between patients, endoscopes and instrumentation should be thoroughly cleaned and disinfected immediately following each procedure in accordance with manufacturer recommendations.[14,15] This process is described in ch. 83.

Complications

Complications from GI endoscopy are infrequent but can include aspiration pneumonia (see ch. 242), reflux esophagitis (see ch. 273), GI perforation (see ch. 279), and excessive hemorrhage (see ch. 135).[5] Sinus bradycardia and respiratory compromise also can occur secondary to overdistension of the stomach, although these signs generally are temporary if distension is corrected immediately by deflation of the stomach. Sudden blindness and neurologic deficits are also possible in cats if a spring-loaded mouth gag is used.[7]

CHAPTER 114

Enemas and Deobstipation

Stefan Unterer

Constipation is retention of feces within the colon or rectum associated with infrequent bowel movements (i.e., <3-4 defecations per week) and/or dyschezia (i.e., straining to defecate). It is a major concern in cats[1] and is observed occasionally in dogs.[2-5] Early recognition of constipation helps prevent progression to obstipation (impaction), a severe form of constipation, which cannot be resolved without medical intervention. If obstipation occurs, enemas are required, and manual extraction of impacted feces followed by dietary modification,[6] laxatives, and prokinetics can be necessary.[1] Obstipated cats with megacolon characterized by irreversible smooth muscle dysfunction are often refractory to medical treatment and might require a colectomy.[7-9] Colonic impaction can be suspected from the history and is confirmed by abdominal palpation, digital rectal examination, and imaging studies (Box 114-1, Figure 114-1). See also ch. 277.

Box 114-1

Clinical and Radiographic Parameters Indicating Constipation

History

- Tenesmus ani
- Dyschezia
- Passing hard feces
- Absence of defecation for >2 days
- Recurrent episodes of constipation

Physical Examination

- Hardened feces in colon
- Distention of the colon
- Colorectal narrowing/stenosis on digital exam
- Painful lesion in peri- or rectoanal area

Radiographic Changes

- Colonic size
  - Maximal diameter of the colon/L5 length ratio >1.5 (cats)
  - Maximal diameter of the colon/L7 length ratio >1.5 (dogs)
- Fecal opacity
  - > Fluid or soft tissue density
  - Foreign material/bone chips

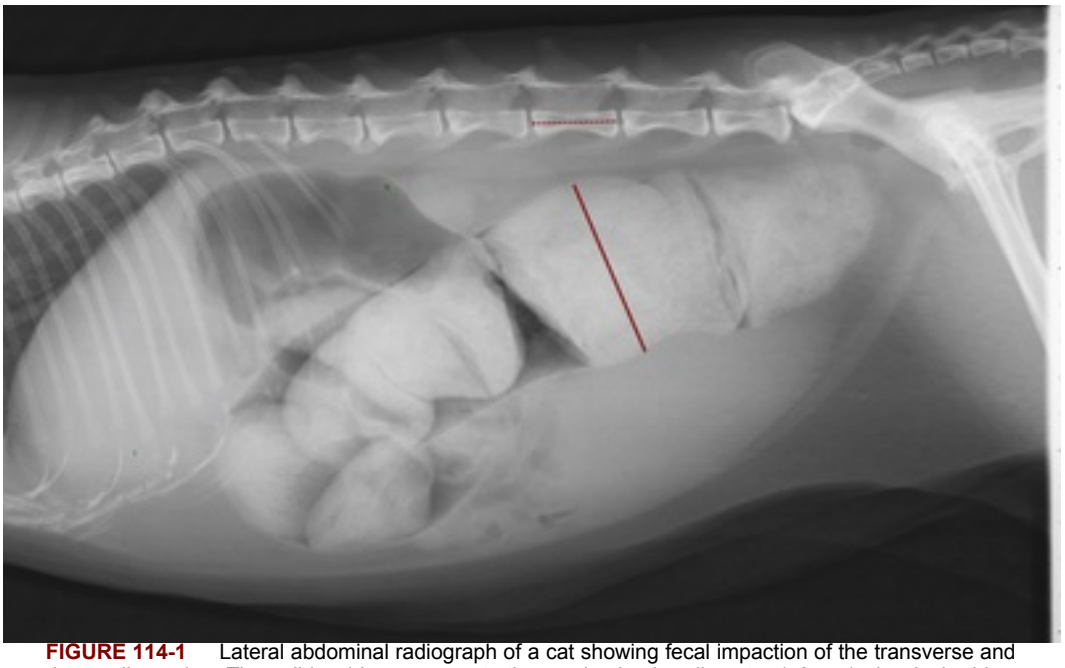

FIGURE 114-1 Lateral abdominal radiograph of a cat showing fecal impaction of the transverse and descending colon. The solid red bar represents the maximal colon diameter (48 mm); the dashed bar indicates the vertebral length of L5 (21 mm). The ratio of maximal colon diameter to L5 length is 2.3, which suggests the diagnosis of a megacolon. The high opacity of the feces (nearly bone dense) indicates dehydration and hardening of the feces. Note: In less severe radiographic changes, the diagnosis of constipation can only be made in association with information from history and physical examination.

Enemas and Manual Extraction: When to Use What

The efficacy of enemas and manual extraction of impacted feces is influenced by the cause and severity of the problem (Box 114-2). Mild constipation frequently can be managed with rectal suppositories or microenemas (low volume enemas with osmotic and stimulant activity on the colon and rectum such as Microlax 5 mL tubes) (Box 114-3), with or without oral lactulose and psyllium-/fiber-enriched diets as needed. Moderate constipation in a cooperative patient can generally be managed with macroenemas (large volume enemas to soften hard feces and to distend and stimulate colon and rectum, such as 10 mL/kg isotonic saline mixed with 5-10 mL lactulose and 5-10 mL mineral oil) without sedation. Patients with severe constipation may require enemas plus manual evacuation of feces performed under general anesthesia.

Box 114-2

Guidelines to Assess the Degree of Constipation

Mild Constipation

- First episode of constipation
- Absence of defecation for >2 days, but <4 days
- Straining with defecation
- Passing hard feces
- Hardened feces in colon
- Normal colonic size

Moderate Constipation

- Recurrent episodes of constipation (not always present)
- Absence of defecation for >2 days
- Straining without defecation (not always present)
- Hardened feces in colon

- Moderately enlarged colon
- Increased fecal density

Severe Constipation/Obstipation

- Recurrent episodes of constipation refractory to medical treatment
- Absence of defecation for >2 days
- Straining without defecation (not always present)
- Hardened feces in colon
- Significantly enlarged colon
  - Maximal diameter of the colon/L5 length ratio >1.5 (cats)
  - Maximal diameter of the colon/L7 length ratio >1.5 (dogs)
- Increased radiographic fecal density

Box 114-3

Useful Drugs for Deobstipation

Enemas and Suppositories

• Rectal suppositories		
• Docusate sodium	emollient laxative	1-3 tubes
• Bisacodyl	stimulant laxative	1-3 tubes
• Glycerin	osmotic laxative	1-3 tubes
• Microenema combining		1-3 tubes
• Sodium citrate	osmotic laxative	
• Sorbitol	osmotic laxative	
• Sodium lauryl sulfoacetate	lubricant laxative	
• Macroenema combining		
• Isotonic saline solution	softening feces	5-10 mL/kg
• Lactulose	osmotic laxative	5 mL per cat
		10 mL per dog
• Mineral oil	lubricant laxative	5 mL per cat
		10 mL per dog

Note: Docusate sodium should not be combined with mineral oil!

Pain Management with Minimal Influence on Colonic Motility

• Metamizole	20-50 mg/kg IV diluted	q 8-24 h
• Butorphanol	0.1-0.3 mg/kg IV, IM, SC	q 1-4 h
• Buprenorphine	10-20 mcg/kg IV, IM, SC	q 6-8 h

Anesthesia Protocol

• Premedication		
• Midazolam	0.1-0.3 mg/kg IV	*and*
• Butorphanol	0.1-0.3 mg/kg IV	
• Induction		

• Propofol	2-6 mg/kg IV	*or*
• Alfaxalone	1-2 mg/kg IV	
• Intubation (mandatory to prevent aspiration) and oxygen supply		
• Maintenance		
• Propofol	1-2 mg/kg IV	q 10-20 min *or*
• Alfaxalone	0.5-1 mg/kg IV	q 10-20 min *or*
• Inhalational anesthetics	(isoflurane, sevoflurane)	

Enemas and Manual Extraction: How to Do It (Figure 114-2)

Patient Preparation

General anesthesia is necessary to manually extract feces, but is not needed for simple enemas unless the patient is so painful that it is difficult to insert the enema tube. If anesthesia/sedation will be performed, an orthopedic examination (to rule out pain during positioning; see ch. 353 and 355) and a neurologic examination (to rule out neuromuscular disorders; see ch. 259) should be performed first. The patient should be rehydrated and metabolic abnormalities corrected before sedation or anesthesia (see ch. 128 and 129). Antibiotic treatment (e.g., amoxicillin/clavulanic acid 20 mg/kg IV q 8 h) could be indicated if there are signs of sepsis (i.e., hypo- or hyperthermia, tachycardia, tachypnea, leukopenia, leukocytosis, left shift). Medications that slow intestinal transit (e.g., diphenoxylate, atropine, loperamide) should be avoided.[10] Anesthetized patients must be intubated to prevent aspiration.

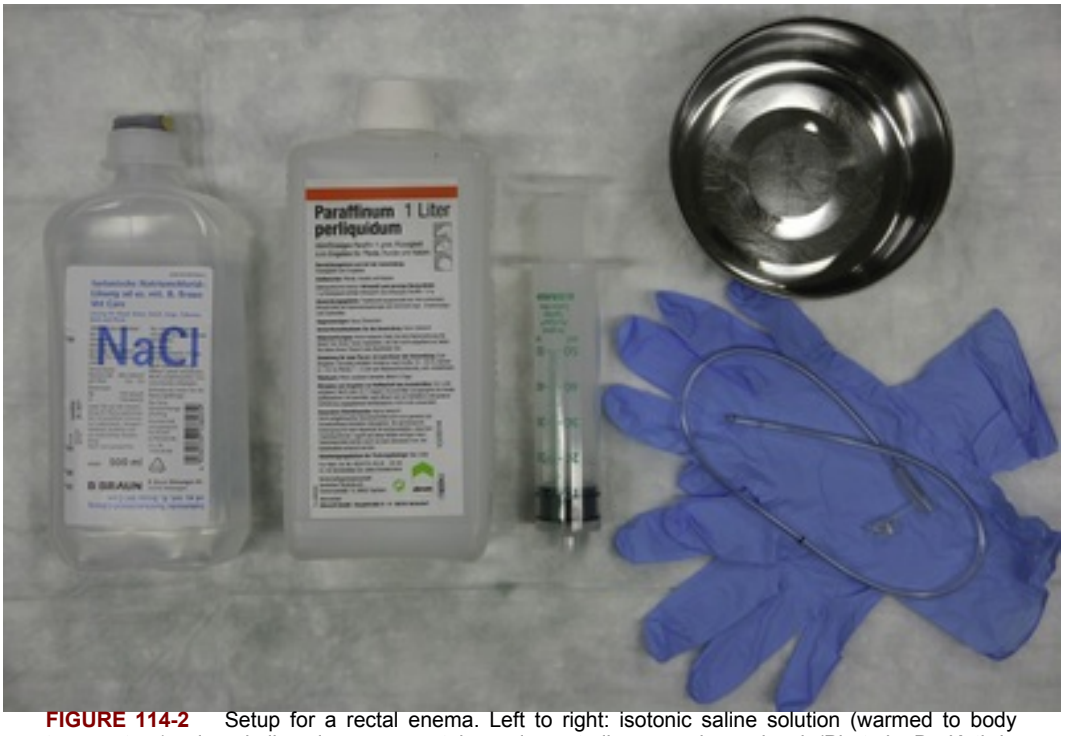

FIGURE 114-2 Setup for a rectal enema. Left to right: isotonic saline solution (warmed to body temperature), mineral oil, syringe, enema tube and nonsterile exam gloves, bowl. (Photo by Dr. Kathrin Busch.)

A thorough examination of the anus and the rectum is paramount in evaluating patients before attempting manual extraction of feces. The perianal area should be evaluated for painful conditions (e.g., perianal fistulas, anal sacculitis), obstructive lesions (e.g., anal sac and perianal neoplasia), and swelling or excessive laxity due to perineal hernia. A digital rectal examination should be performed to identify fecal impaction, anorectal stricture, pelvic canal stenosis, rectal mass, or outpouching of the rectal wall (i.e., perineal hernia). If

an underlying cause is identified, it should be treated as early as possible after deobstipating the patient to prevent further episodes of constipation and loss of colonic dysfunction by overdistention.

Materials and Setup

The procedure should be done in an easily cleanable environment (e.g., dental table, dog bath) without the danger of contaminating clean areas. Copious amounts of lubricant and a big bowl with about 50-100 mL/kg of warm (37° C) tap water (or isotonic fluid in cats and small dogs) should be available. The person performing the procedure as well as any assistant should wear waterproof aprons. Enema tube size depends on the patient's size and ranges from feeding tubes for cats and small dogs (i.e., 4 mm [12 French] tubes) to larger diameter tubes for big dogs (i.e., 7 mm [22 French] for 10-20 kg and 10 mm [30 French] for >20 kg). A 1-2 liter bag attached to the enema tube is an easy way of allowing gravity flow to infuse the fluid into the colon. A fluid pressure bag or rubber ball pump can facilitate instillation of fluids, but care must be taken to not instill fluids too fast or to distend the colon to the point of causing pain, vomiting, or perforation.

Contraindicated Types of Enemas

Rarely, administration of large volumes of tap water can produce water intoxication (i.e., acute hyponatremia) if the enema is retained.[11] Hypertonic sodium phosphate (e.g., Fleet) enemas can cause life-threatening hypernatremia, hypocalcemia, and hyperphosphatemia in cats and in dogs if the enema fluid is retained.[12,13] The safest option is an enema consisting of warm isotonic saline solution to soften impacted feces, sometimes with mineral oil as a lubricant (see Figure 114-2 and Box 114-3).

Technique

Under digital control, a well-lubricated tube (see above) is introduced into the colon. The length of insertion of the tube in the proximal part of the descending colon is determined by measuring the distance from the anus to the last rib. Stiff catheters/tubes should not be used. While slowly administering large volumes (10-20 mL/kg) of fluid, the tube should be gently inserted as far as possible into the colon, up to this limit. If resistance occurs while advancing the tube, the tube should not be forced further orad; rather, the clinician should try to reposition the tube by gently twisting it, while advancing it, so as to avoid causing trauma to the colorectal mucosa. Catheters should be introduced very gently into the large intestine to prevent perforation of the overly distended and fragile colonic wall. An attempt to carefully pass a very small catheter (feeding tube) alongside the impaction can be made in order to deliver fluid past the site of initial obstruction and lubricate the more proximal (orad) parts of the obstruction. The fluid should be instilled over 2-5 minutes. If vomiting or abdominal discomfort is noted, then the fluid was likely administered too quickly and is causing inappropriate colonic distention. Cats and small dogs are especially prone to such problems. After instillation of the enema and waiting for 5-15 minutes (depending upon how hard the feces are), with the anal orifice held closed by an assistant, the fecal mass should be broken down by gentle abdominal massage and compression of the colon over 10-15 minutes. This is supposed to manually propel small fecal pieces into the rectum, which can then be evacuated by digital manipulation. In severely impacted animals, this procedure will have to be repeated several times. Abdominal massage might not be sufficient to break down severely impacted material. The consistency of the impaction can be almost cement-like, in which case the surgeon/veterinarian will have to manually "chip away" small pieces from the distal end of the impaction via the rectum. Sometimes bone shards are embedded in the impaction, which have to be evacuated carefully with the distal end of the shard inside the palm of the surgeon's hand and the proximal end guarded behind the tip of the index or middle finger to avoid trauma to the mucosa. In severe cases of fecal impaction, sponge forceps can be introduced rectally to gently break down the fecal mass. To avoid damage to the colorectal mucosa, it is safer to introduce the forceps through a rigid colonoscope and remove the impacted feces under visual control. To improve patient recovery and avoid severe stress to the colonic wall, the whole procedure should not extend longer than 60 minutes.

Endpoint and Further Management

Complete removal of the impacted material can be an unrealistic goal, especially in larger dogs. A balance should be struck between removing as much material as possible and not endangering the integrity of the colon wall or prolonging general anesthesia in an unstable patient (e.g., elderly cats with underlying renal and/or cardiac disease). A young, healthy dog that has ingested bones can tolerate a longer procedure, both in

terms of fragility of the colon wall and adverse anesthetic effects, than can an elderly cat with megacolon that has chronic kidney disease. Even if removal of the impacted feces has only been partially successful, most patients will pass the remainder of the feces over the next 24 hours (especially if promotility drugs and topical lubricants are administered). Hospitalization could be necessary to ensure optimum hydration and analgesia in severe cases. Pain management can be necessary, but it is important to avoid narcotics, which slow intestinal transit (see Box 114-3). Nonsteroidal anti-inflammatory analgesics should be avoided due to potential gastrointestinal side effects.[14] Antibiotic treatment should be considered in immunocompromised patients with significant colonic mucosal trauma predisposing to bacterial translocation.

Evaluation of Treatment Success and Long-Term Managment

Repeating abdominal radiographs after deobstipating the patient might help assess treatment success and could reveal signs of colonic perforation (e.g., loss of serosal detail, free intra-abdominal air) if such a complication has occurred. After the patient has recovered from anesthesia, oral lactulose (0.5-1 mL/kg PO q 8-12 h), dietary modification (i.e., psyllium-/fiber-enriched diets) and colonic prokinetic medication (e.g., bisacodyl PO q 24 h: 5 mg for cats and dogs <10 kg; 10 mg for dogs 10-20 kg, 15 mg for dogs 20-30 kg and 20 mg for dogs >30 kg; or tegaserod 0.05-0.1 mg/kg q 24 h) are indicated. Analgesics and antiemetics can be used as needed. On the following day, the degree of constipation should be reevaluated radiographically. If hard feces are still present in the colon, enemas and/or manual extraction should be repeated. Continuation of medical treatment is recommended for at least 1-3 weeks and may need to be pursued long-term. Normal bowel function and defecation should be evaluated 1 and 3 weeks after removal of impacted feces and every week after changing medical treatment (e.g., discontinuation of prokinetics and lactulose) by history (i.e., daily defecation, no tenesmus, no dry/hardened feces in litterbox), physical examination (i.e., no enlarged impacted colon) and abdominal radiographs (i.e., normal-size colon, normal fecal density).

Summary

Recurrent episodes of prolonged, severe constipation can produce permanent loss of colonic smooth muscle function. It is important to identify patients with a predisposition for constipation early in the course of the disease, to eliminate underlying causes of constipation, and to prevent recurrences using dietary modification, laxatives, and/or promotility agents as needed.

CHAPTER 115

Cerebrospinal Fluid Collection, Analysis, and Myelography

John Henry Rossmeisl Jr.

Indications and Contraindications for Cerebrospinal Fluid Collection

Cerebrospinal fluid (CSF) collection and analysis are important aspects of the diagnostic evaluation of animals with disease of the nervous system (see ch. 259).[1-3] Collection of CSF is also indicated prior to the subarachnoid injection of contrast media (myelography), or intrathecal delivery of therapeutics. Although there are no absolute contraindications to CSF collection, the relative risks of the procedure require careful consideration in patients with intracranial hypertension, brain herniations, vertebral column trauma, thrombocytopenia or other bleeding disorders, and in cases of known or suspected epidural or paravertebral infections.[2,3] Patients with these conditions can be identified by performance of appropriate laboratory investigations and diagnostic imaging techniques, such as magnetic resonance imaging (MRI), prior to CSF collection.

Equipment, Techniques, and General Considerations

Standard equipment required for collection of CSF includes electric shears, sterile gloves, 20- to 22-gauge, 38 mm (1.5 in) to 63.5 mm (2.5 in) spinal needles with stylets, surgical scrub solutions, and sterile glass (red top) collection tubes without anticoagulant.[1-3] There are two sites from which CSF may be collected: the cerebellomedullary cistern (cisternal tap) and the lumbar region (lumbar tap). As net CSF flow occurs from a rostral to caudal direction, it is preferred to collect CSF caudal to the anatomic level of the disease process being investigated.[2,3] Thus, cisternal taps are typically performed in patients with intracranial disease, and lumbar taps in those with spinal cord lesions. Cisternal CSF taps are less likely to be iatrogenically contaminated with peripheral blood compared to lumbar taps.[3] Regardless of the sampling site, CSF collection is performed with the patient in a surgical plane of anesthesia, and the hair overlying the region should be clipped and the skin aseptically prepared. Approximately 1 mL of CSF per 5 kg of body weight may be safely removed during CSF collection.[2,3]

Cerebellomedullary Cisternal CSF Collection

The anesthetized patient should be intubated, with ventilatory support available. The optimal length and diameter of the spinal needle used is dictated by the size of the patient. As the cistern can lie only a few millimeters below the skin surface in neonates, cats, and small dogs, some clinicians use small (25 or 27 gauge) hypodermic or butterfly needles to collect CSF from these patients. The animal should be positioned in lateral recumbency, so that the dependent side is identical to the dominant hand of the person collecting the fluid, with the dorsal aspect of vertebral column and skull facing the operator and close to the edge of the table. An assistant should hold the head in a 90° flexed position with the nose parallel to the table top (Video 115-1).[1,3]

The desired position for placement of the spinal needle can be accomplished by palpation of several landmarks. To identify midline, a right-handed operator palpates the caudal aspect of the occipital protuberance with the index finger of the left hand and moves the finger caudally while applying firm digital pressure to identify the cranial aspect of the spinous process of the axis. If the dorsal arch of the atlas can be palpated along this line, the needle should be placed just cranial to it, perpendicular along the line between the axis and occipital protuberance. If the dorsal arch of atlas cannot be located, as is often the case, the wings

of the atlas are palpated, and a line coursing perpendicular to the long axis of the vertebral column immediately cranial to and connecting the cranialmost aspects of the two wings of the atlas is visualized (Figure 115-1, *A*; see Video 115-1). The needle should be inserted perpendicularly to the skin at the point where this line intersects with the line connecting the external occipital protuberance to the spinous process of the axis along the dorsal midline.

FIGURE 115-1 Procedure for collecting cerebrospinal fluid (CSF) from the cerebellomedullary cistern of a dog. **A,** The operator palpates the desired landmarks for needle insertion (white lines superimposed on the patient) with the non-dominant hand. **B,** Once the spinal needle is in place, as confirmed by CSF flow, it is digitally stabilized by the operator and CSF collected into sterile red top tubes.

Once inserted, the needle should be directed parallel to the table top and advanced in 1-2 mm increments in order to penetrate the muscle and fascia. Some operators prefer to stop advancing after an insertion of several millimeters, remove the stylet, and check for CSF flow. To remove the stylet, a right-handed operator would place the hypothenar aspect of the palmar surface of the left hand on the dorsal aspect of the cervical region and skull for support and immobilize the needle with the left thumb and index finger. The stylet is then removed with the thumb and index finger of the right hand (see Video 115-1). If no CSF flow is observed, the stylet is reinserted into the needle, the needle is advanced another 1-2 mm, and the operator checks again for CSF, with this procedure being repeated until CSF is obtained. If the needle tip hits bone, the needle is withdrawn 1-2 mm and redirected slightly cranially or caudally to the original trajectory. In some instances, penetration of the dura will result in a distinct loss of resistance or tactile "pop" that is transferred through the needle to the operator.[1,3] Once CSF flow is observed, the CSF opening pressure can be measured, if desired; otherwise collection of CSF should proceed by allowing the fluid to passively drop from the needle hub into the sterile glass collection tubes (Figure 115-1, *B*; see Video 115-1) until the desired volume is obtained, and then the needle is withdrawn. Temporary manual occlusion of the jugular veins can be performed to increase CSF flow. When possible based on the patient size, the author prefers to collect CSF into separate 0.75 to 1 mL aliquots to allow for dedication of samples for routine biochemical and cytological analyses, as well as ancillary serological, biomarker, or genetic assays, as indicated.[2,3]

If whole blood is observed in the needle, the needle should be withdrawn and the procedure repeated using a new needle, as this usually indicates that the vertebral venous plexus has been penetrated.[1] If the CSF is observed to have a blood-tinged appearance, iatrogenic bleeding from puncture of a meningeal vessel will often clear as CSF drips from the needle, and the cleared CSF may be collected into a second sterile container. Rotating the needle may also help to clear iatrogenic hemorrhage. Mild to moderate amounts of blood contamination do not prohibit interpretation of CSF results.[4,5]

Lumbar CSF Collection

Depending on the operator's preference, the patient may be placed in sternal or lateral recumbency. Recently, ultrasound- and electrostimulation-guided approaches to lumbar puncture have been described for dogs.[6,7] The pelvic limbs should be extended toward the head in order to facilitate opening the interarcuate space. This procedure may require the use of long (88 mm [3.5 in]) spinal needles in large-breed dogs. The L5-L6 space is the most common site for lumbar CSF collection, although L4-L5 can be used in dogs, and L6-L7 in

cats.[3]

The author prefers to perform lumbar taps using a paramedian approach (Video 115-2). The cranial aspects of the iliac wings are palpated using the left index finger, which then is moved craniad to palpate the spinous process of L6. The needle is positioned just lateral to the midline alongside the caudal edge of the L6 spinous process, and directed cranioventrally through the ligamentum flavum into the vertebral canal. Advancement of the needle should occur with the proximal aspect of the needle angled approximately 45° caudally relative to the desired needle insertion point into the ligamentum flavum. If the needle strikes bone, it may be "walked off" the edge of the dorsal lamina into the interarcuate space. As the needle penetrates the dura, it is possible, but difficult, to collect CSF from the dorsal subarachnoid space. Thus, many clinicians elect to further advance the needle to the floor of the vertebral canal and then retract the needle 1-2 mm into the ventral subarachnoid space, at which time the stylet is removed and CSF flow evaluated. Mechanical stimulation of the spinal cord and nerve roots in this area may result in a visible or palpable twitch of the pelvic limbs or tail. If this is observed, the needle should be advanced 1-2 mm, and the stylet removed to evaluate CSF flow.[1,3]

CSF typically flows more slowly in lumbar collection compared to the cisternal collection. As such, some clinicians advocate connection of a 2.5-3 mL syringe with a short extension set to the spinal needle and to allow for gentle aspiration of CSF from the lumbar region. If lumbar CSF collection using these techniques is unsuccessful, the procedure may be attempted at the L4-L5 site.

CSF Sample Processing and Analysis

CSF samples ideally are processed for analysis within 4 hours of collection.[3,8,9] If rapid processing is not possible, the addition of autologous serum (100 mcL serum/1 mL of CSF) or 6% hydroxyethyl starch (1 : 1; vol : vol) may improve the stability of the sample for up to 48 hours.[8,9]

Routine analyses performed on CSF include gross inspection for color and turbidity, assessments of a total protein and glucose concentrations, total nucleated and red blood cell counts, white blood differential count, and cytopathological review of cellular constituents typically made following cytocentrifugation procedure.[2,3,10] It should be noted that while abnormalities of CSF are sensitive for the detection of CNS disease, the results are extremely non-specific, and with a few exceptions, rarely provide a definitive diagnosis. Thus, CSF analysis should be integrated with the history, physical and neurologic examinations, diagnostic imaging findings, and other diagnostic tests in order to be maximally useful. The analytical techniques and principles of CSF interpretation have been reviewed elsewhere, and descriptions of CSF abnormalities associated with specific diseases are reviewed in the sections of this textbook covering neurological disorders (see ch. 33-35, 260-261, 265-267, and 270).[1-3,10]

Complications of CSF Collection

Risks associated with cerebellomedullary cisternal collection include rapid shifts in intracranial contents (brain herniations) associated with needle placement into the subarachnoid space in patients with intracranial hypertension. Most other potential complications are related to technical errors, or risks associated with anesthetizing patients with neurological disease.[3,11] Inadvertent advancement of the needle into the neural parenchyma may result in fatal brainstem dysfunction, but may also be associated with no observable adverse effects.[11] Complications of lumbar CSF collection include failure to obtain a diagnostic CSF sample due to significant iatrogenic blood contamination, and failure to obtain CSF ("dry tap").[3] Hematomyelia resulting in neurological deterioration has also been rarely reported following lumbar CSF collection.[12]

Myelography

Myelography, which is the radiographic study of the vertebral column and spinal cord following subarachnoid injection of contrast media, can be performed by either cisternal or lumbar (Video 115-3) injection, with the anesthetized patient in lateral recumbency.[13] Needle placement occurs as described above for CSF collection, although fluoroscopic guidance may be used to facilitate needle positioning, and CSF should be obtained for analysis prior to the injection of contrast material. Non-ionic contrast agents (iohexol or iopamidol, 180 to 300 mg iodine/mL) are typically used for veterinary applications.[13] The volume of contrast injected ranges from 0.3 mL/kg to 0.45 mL/kg body weight, and is dependent on both the site of

injection and the anticipated location of the lesion based on the neurological examination. For example, when performing a cervical myelogram via a lumbar injection, a higher contrast dosage is often necessary.

Once the desired needle position is obtained, a test injection is performed by connecting the contrast–dose-containing syringe and primed extension set to the spinal needle and infusing approximately 0.5 mL of contrast, after which subarachnoid contrast injection is confirmed with radiography or fluoroscopy. Once subarachnoid administration is confirmed, the remainder of the calculated contrast dose can be administered, the needle removed, and a series of lateral, ventrodorsal, and if necessary, additional (oblique, traction, flexion, extension, opposing lateral) radiographic views obtained of the region of interest of the vertebral column.[13,14] The goals of interpretation require recognition of abnormal myelographic patterns (extradural, intradural-extramedullary, intramedullary) in order to specifically describe the neuroanatomic location of any observed lesions and subsequently generate a refined set of differential diagnoses based on the imaging features present.

Although cervical injection is technically easier, it is more likely to be associated with intracranial contrast media accumulation, which increases the risk for post-myelographic seizures.[13,15] Tilting the patient 30° by lifting the head may help mitigate intracranial contrast accumulation. With cervical injections, the bevel of the needle should be directed caudally prior to injection. Lumbar injections should be performed with the bevel of the needle facing cranially, and can be performed by applying more pressure on the plunger of the syringe, which may facilitate the flow of contrast past an obstructive lesion.

Complications of Myelography

Obtaining a diagnostic myelogram is heavily dependent on the technical expertise and experience of the operator. Failure to obtain a diagnostic study can often be attributed to operator errors such as inadvertent epidural, intraparenchymal, or subdural contrast injection, or patient-inherent factors, such as obesity or degenerative vertebral column disease, that complicate ideal injection technique.[13,16] In addition, particularly with cervical injections, severe spinal cord swelling or compression may inhibit the flow of contrast caudal to the lesion, which may necessitate subsequent performance of a lumbar myelogram, although obstruction to contrast flow can sometimes be overcome by tilting, flipping, or rolling the patient carefully.[17]

Seizures are a common complication of myelography, and have been reported to occur in 3-21% of dogs undergoing the procedure.[15,17,18] Significant risk factors for post-myelographic seizures include large-breed dogs, cervical spinal cord lesion location, cerebellomedullary cisternal injection technique, and use of large volumes of contrast media.[17,18] Myelography can be associated with transient or permanent decline in neurologic status, which may occur as a result of the transient chemical meningomyelitis induced by the contrast injection, or following accidental injection of contrast into the spinal cord parenchyma or central canal.[19] The risk for a decline in neurologic function following myelography may be higher in patients affected by inflammatory myelopathies, chronic spinal cord compression, or neurodegenerative diseases. Rare but potentially fatal complications associated with myelography include cardiac arrhythmias and arrest, contrast medium infusion into the brainstem parenchyma with cisternal injection, and intracranial subarachnoid hemorrhage induced by lumbar myelography.[20,21]

Muscle and Nerve Biopsy

Kerry Smith Bailey

Neuromuscular diseases encompass diseases of muscles (myopathies; see ch. 354), nerves (neuropathies; see ch. 264 and 268), and the point at which the two meet (junctionopathies; see ch. 269). Diagnosis is based on interpretation of the neurologic examination, electrodiagnostic procedures including electromyogram (EMG) and nerve conduction studies (see ch. 117), and histopathologic evaluation of muscle and nerve. Examination of specific components of the motor unit, including intrafascicular nerve branches, neuromuscular junctions, myofibers and supportive connective and vascular tissues, and peripheral nerves, allows for more definitive classification of the pathologic process and helps target therapy.

Muscle Biopsy

Preparation for Performing Muscle Biopsy

Once it is determined a patient has neuromuscular disease that necessitates a muscle biopsy, several preparatory steps must be taken. Conventional formalin fixation techniques alone are not appropriate for muscle specimens because they greatly limit the information obtained. Muscles are metabolically very active tissues, and evaluation of specific enzyme localization and storage products can be important to a diagnosis. Fresh frozen sections are needed for these histochemical stains and enzyme reactions. Because of the unique handling and processing of the specimen, routine submission to most commercial pathology laboratories is not recommended. Additionally, the destination laboratory's specific instructions for selection, handling, and transportation of the specimen should always be obtained prior to sample collection. Specimens should be shipped to arrive at the laboratory within 24 to 48 hours and should not arrive at the laboratory during a weekend or holiday. Hence, the procedure needs to be planned accordingly.

Selection of Muscle

The muscle selected for biopsy should be affected by the disease process, as evidenced by clinical signs (atrophy, hypertrophy, myalgia, or weakness) or abnormal EMG results. Ideally, an affected but functional muscle should be selected. In acute disease, a more severely affected muscle should be selected, while in chronic end-stage disease, a less-affected muscle may be selected to avoid the atrophy and replacement of myofibers with connective tissue and fat that coincides with end-stage disease.

The biopsy procedure should be associated with low morbidity so an easily identified muscle with a minimal surgical approach is recommended. The muscle fibers should be oriented in a single direction and the specimen should be obtained from a site devoid of tendinous insertions and aponeuroses. The site should be free of artifacts induced by EMG needle insertion or intramuscular injections. Insertion of needles can induce localized necrosis and phagocytosis, "needle myositis," and could interfere with interpretation.

Commonly used muscles include the lateral head of the triceps brachii (distal third), vastus lateralis (distal third), cranial tibial (proximal third) and temporalis muscles. Diagnosis of generalized neuromuscular disease necessitates biopsy specimens from both thoracic and pelvic limb muscles. If a nerve biopsy is planned, biopsy of the cranial tibial muscle combined with a common peroneal nerve biopsy allows one surgical approach.

Some disease processes require specific muscles to be harvested. For example, the temporalis muscle is biopsied to diagnose masticatory myositis. A common mistake to avoid when performing a biopsy of the temporalis muscle is sampling the frontalis muscle, which is a thin muscle located directly under the skin, overlying the temporalis muscle. This muscle is not affected in masticatory myositis and will not give the information needed to make that diagnosis. In addition, diagnosis of congenital myasthenia gravis is based on the demonstration of decreased numbers of acetylcholine receptors in biopsies of external intercostal muscles.

Muscle Biopsy Procedure

Open muscle biopsy procedures performed under general anesthesia are recommended. Punch biopsies obtained under sedation provide too small a sample, with poor orientation of the muscle fibers. Typically, the procedure is performed following electrodiagnostic testing. To avoid EMG needle insertion artifacts, EMG is typically performed on one side of the body and the muscle biopsy is performed on the other.

Routine surgical preparation is required (Video 116-1). Then the skin and fascia overlying the muscle are incised, allowing visualization of myofiber orientation. Two parallel incisions are made with a #11 scalpel blade, parallel to the direction of the myofibers and approximately 1 to 2 cm long, 0.5 cm apart and 0.5 cm deep. The isolated muscle is removed from the surrounding muscle with a scalpel blade or scissors. Care must be taken to avoid excessive tissue handling and trauma. The tissue is then wrapped in a saline-dampened sterile gauze sponge and then placed in a dry, water-tight contained such as a 10 mL red top tube. This tissue must be refrigerated and then shipped on ice. Another smaller piece of muscle tissue is then collected adjacent to the original site and placed in 10% buffered formalin.

Wound closure is routine and it is recommended to apply a cold compress to the site postoperatively to minimize swelling and to aid in comfort. Complications (infection and hematoma) are uncommon and usually are the result of the animal interfering with the surgical site.

Transport

The quality of the information obtained from the biopsy depends on the quality of the specimen that arrives at the laboratory. Fresh muscle biopsy samples must arrive at the laboratory within 24 to 48 hours of collection. They need to be shipped under refrigeration. Many laboratories request that 5 mL of the animal's serum be shipped along with the muscle biopsy specimen.

Muscle Biopsy Interpretation

The following muscle features are assessed for variation from normal: fiber size (atrophy, hypertrophy, hypotrophy) and profile (polygonal, round, angular); fiber type proportions and distribution patterns (fiber type grouping); numbers and position of nuclei (peripheral vs. random and central); myonecrosis and regeneration; cellular infiltration; connective and vascular tissue morphology; intramuscular nerve morphology; and muscle fiber type selectivity or prevalence for the pathologic changes observed.

Nerve Biopsy

Selection of Nerve

As with muscle specimen selection, the nerve should be affected by the disease process as evidenced by abnormal electrophysiologic findings or clinical neurologic abnormalities in areas innervated by the nerve (atrophy, hypotonia, hyporeflexia, paresis, and/or sensory deficits). When possible (as with generalized neuromuscular disease) the nerve selected should be easily harvested with low morbidity, have established normal electrophysiology and morphometric data available, and innervate a muscle that is routinely biopsied. The common peroneal nerve typically is selected when generalized disease is present as it meets the above criteria and because of its flat anatomy and easily identified fascicles. It is a mixed nerve containing motor, sensory and autonomic nerve fibers. Other mixed nerves that can be biopsied readily are the tibial nerve and the ulnar nerve. When a predominantly sensory neuropathy is suspected, biopsy of the cutaneous sensory nerves, such as the caudal cutaneous antebrachial nerve in the thoracic limb or the caudal cutaneous sural nerve in the pelvic limb, is recommended.

Nerve Biopsy Procedure (Common Peroneal Nerve)

Biopsies are performed with the patient under general anesthesia, and they often follow biopsy of the ipsilateral cranial tibial muscle (Video 116-2). The common peroneal nerve is palpable on the lateral aspect of the distal femur and it extends caudally to the proximal tibia. A 6- to 8-cm incision is made over the region, following standard surgical preparation of the site. The fascia of the biceps femoris muscle is exposed and the nerve can be palpated through the fascia. A small incision (4 to 5 cm) is made in the fascia, taking care to elevate the fascia to avoid inadvertent damage to the nerve. The nerve can be seen as it passes over the lateral head of the gastrocnemius muscle. Careful blunt dissection of the fat and fascia from around the nerve helps

to isolate it. A 5-0 or 6-0 silk suture is placed through the caudal one-fourth to one-half of the nerve at the proximal end of the biopsy site, allowing minimal gentle traction as a 3- to 4-cm fascicular biopsy is excised using fine iris scissors. If individual fascicles of nerve are difficult to visualize, gently spreading the nerve with a scalpel handle may allow better definition of fascicles. The initial incision may then be accurately made with a #11 scalpel blade.

The incision is closed routinely. Complications can include temporary proprioceptive deficits, lameness, and knuckling of the distal pelvic limb on the side of the biopsy that typically resolve within 3 to 4 days.

Nerve Specimen Processing

The sample should be placed in 10% formalin or glutaraldehyde (based on the preference of the laboratory). To minimize artifact formation during fixation, the biopsy must be prevented from contracting (to maintain length); methods include pinning the nerve at either end with 25-gauge needles to a tongue depressor, or suturing around the nerve at either end onto the wooden stem of a cotton-tipped applicator. A nerve specimen also may be frozen in liquid nitrogen if specialized biochemical analysis is required.

Nerve Specimen Interpretation

Examples of pathologic changes seen in nerve biopsies include axonal degeneration, axonal dystrophies, and primary demyelination. Knowledge of the variations that might be seen in apparently normal animals is essential to interpreting peripheral nerve biopsy specimen pathologic findings. In older animals, axonal degeneration and demyelination can be a normal finding and should not be interpreted as pathologic. Similarly, lack of use of a limb can result in loss and abnormalities of myelinated nerve fibers that should not be interpreted as a primary disease process.

CHAPTER 117

Electromyography and Nerve Conduction Velocity

David Lipsitz, D. Colette Williams

Overview

Disorders involving any component of the neuromuscular system (peripheral nerve, muscle, neuromuscular junction) cause identical clinical signs. A thorough neurological examination may not demonstrate the component affected (see ch. 259). Electrodiagnostic testing (EDX, Video 117-1) aids in localizing lesions within the neuromuscular system and is useful in selection of nerve and muscle biopsy sites (see ch. 116). To eliminate patient discomfort and movement, EDX is usually performed with the dog or cat under general anesthesia.[1-3]

Electromyography (EMG)

Background

Electromyography (EMG) is a method for detection and display of insertional, spontaneous and voluntary electrical activities in skeletal muscle. Veterinary EMG focuses on the electrical activity of single muscle fibers or small groups of myofibers. Use of EMG is based on the inherent electrical state of healthy skeletal muscle and changes in excitability patterns associated with disease. With few exceptions, normal resting muscle is electrically and mechanically silent. Denervated muscle fibers and fibers damaged by primary muscle disease may spontaneously depolarize, resulting in readily detectable abnormal activity.

Uses, Electrodes, Limitations

EMG may aid in defining mononeuropathies (see ch. 268), polyneuropathies (see ch. 268), myopathies (see ch. 354), and in differentiating neurogenic disease from disuse atrophy. EMG findings are not specific, but distinctions can be made on review of neurological examination results, distribution of affected muscles, and results of nerve conduction studies. EMG can be used to select an affected muscle for biopsy in diseases where only specific muscles are involved, such as masticatory muscle myositis. Disuse atrophy, diseases of neuromuscular transmission, and disease restricted to myelin or sensory neurons, fail to induce EMG abnormalities.

The most commonly used EMG electrodes are concentric (coaxial) needle electrodes. In addition to visual inspection of EMG waveforms, characteristic sounds assist interpretation. The sensitivity of the EMG examination can be enhanced by performing multiple insertions into a specific muscle and by sampling a number of different muscles. EMG abnormalities may be patchy in their distribution within a muscle (often seen in myositis) or limited to particular groups of muscles (i.e., those with the same innervation).

EMG Normal Event Definitions

Although normal muscles at rest are electrically silent, activity can be detected in normal skeletal muscle.

- *Insertional activity* is caused by the mechanical stimulation of muscle fibers and disruption of membranes by placement of the EMG needle; it should subside soon after electrode movement stops (within a few hundred milliseconds).
- *Miniature end-plate potentials (MEPP)* result from the spontaneous release of single quanta of acetylcholine from nerve terminals inducing partial depolarization of postsynaptic myofiber membranes. This activity is focal and can only be detected with the electrode positioned near the motor point of the muscle. The sound resembles that of the "seashore."

- *End-plate spikes* are associated with MEPPs and occur when enough acetylcholine is released to completely depolarize a single muscle fiber. This activity should not be confused with fibrillation potentials. Random high-pitched "popping" sounds are typical of this event.
- *Motor unit action potentials (MUAP)* result from summation of individual myofiber action potentials associated with activity in a single motor unit within the electrode's recording range. They are present during muscle contraction and have a regular clicking sound, similar to a "wind-up toy." Multiple overlapping MUAPs can be seen when several motor units are activated. These events are not routinely evaluated in veterinary EDX.

EMG Abnormal Event Definitions

These EMG activities are not necessarily spontaneous but are abnormal.

- *Increased insertional activity* is prolonged firing of muscle fibers due to mechanical irritation induced by the electrode.
- *Decreased insertional activity* is diminished activity secondary to loss of muscle fibers (adipose and connective tissue do not react to electrode placement).
- *Giant MUAPs* are large, often polyphasic potentials, which suggest reinnervation of muscle fibers. Collateral branching of healthy axons results in a greater number of myofibers being innervated by a given motor neuron (the histological correlate is fiber type grouping).

EMG Spontaneous Activity

This is the collective term for the following events; they are rated from 0 (normal) to 4+ based on their distribution within the muscle and the number present:

- *Fibrillation potentials* and *positive sharp waves* arise from depolarization of the T-tubular system or the surface sarcolemma. They result from similar pathological processes but have different morphology due to their orientation with respect to the electrode. These often occur together and the sound can be described as "bacon frying" or "rain on a tin roof."
- *Myotonic discharges* result from delayed relaxation of single muscle fibers due to ion channel defects; the discharges have a distinct pattern of waxing and waning in amplitude and firing rate. They produce the classic "dive bomber" sound.
- *Complex repetitive discharges* are the result of spontaneous firing in a single myofiber which induces firing in adjacent muscle fibers; they do not wax and wane like myotonic discharges but maintain the same amplitude and frequency throughout, ending abruptly. This sound has been described as similar to "machine gun fire." Previously used terms included pseudomyotonic or bizarre high frequency discharges.

Single Fiber EMG

Single fiber EMG (SFEMG) is a sensitive test of neuromuscular transmission. Techniques for recording SFEMG have been described in both cats and dogs. In SFEMG, individual myofiber action potentials are recorded by specialized needle electrodes. Minute latency variations occur between consecutive action potentials of the normal muscle fiber. Jitter is the term for this phenomenon. It is a measure of the safety factor of neuromuscular transmission. Excessive jitter is associated with disorders of the neuromuscular junction, whereby the safety factor is reduced.

Motor and Sensory Nerve Conduction

Overview

Nerve conduction testing is necessary for nerve function determination. Methods have been developed for independently examining both motor and sensory components. The nerves commonly tested are the peroneal, tibial, radial and ulnar. Motor nerves may be examined by stimulating a peripheral nerve and recording the compound muscle action potentials (CMAP) generated by a muscle innervated by that nerve.

Motor Nerve Conduction Velocities (MNCV)

MNCV are calculated by measuring the latency difference between the CMAP responses after stimulating at a

minimum of two sites along the nerve and by measuring the distance between these sites, using the formula: MNCV (m/s) = Distance (mm) / $Latency_{proximal}$ − $Latency_{distal}$(ms). This calculation is necessary as it takes neuromuscular junction transmission time and myofiber depolarization time out of the equation. Additional stimulus sites provide segmental information, helpful in assessing the distribution of the nerve disorder. Variations of this technique can be used to examine the integrity of the neuromuscular junction (repetitive stimulation) or the proximal nerve segment and nerve roots (late waves [f-wave and H-reflex]).

Sensory Nerve Conduction

Background

Sensory nerve conduction is evaluated by stimulating a cutaneous nerve (that lacks motor axons) and recording the sensory nerve action potential (SNAP) at sites along the nerve. Sensory nerve action potentials are recorded directly from the nerve itself; thus, only one stimulation site is required to calculate the conduction velocity but simultaneous recordings can be obtained from multiple sites along the nerve and spinal column. SNAPs are more temporally dispersed and are quite small when compared to CMAPs (microvolt versus millivolt range). Signal averaging a large number of individual responses is necessary to obtain interpretable recordings. Most background noise is random with respect to the stimulus and tends to average out, whereas the signal of interest is time-locked and enhanced.

Abnormalities

Abnormalities of nerve conduction studies include the following:

- Slowing of conduction
- Excessive temporal dispersion
- Decreased amplitudes of CMAP (can be neuropathic or myopathic) or SNAP. Diminished responses may occur at all sites or be more pronounced with increased distances (conduction block)
- Severely affected nerves may require the use of very high stimulus intensities to induce a response

A comprehensive EDX examination involves the use of all of the tests described here, often in multiples nerves. These are crucial in determining the functional integrity of the neuromuscular system in patients with neuromuscular disorders (see ch. 269).

CHAPTER 118

Artificial Insemination in the Dog

Catharina Linde Forsberg

Overview

Factors Affecting Vaginal or Intrauterine Artificial Insemination (AI)

AI success in dogs is dependent on a number of factors: breed, age, health, fertility, timing of insemination in relation to ovulation, one versus two inseminations, location of semen deposition (cranial vagina or into the uterus), quality of the freshly ejaculated semen (number of live, normal, motile spermatozoa), and handling of semen. Methods for AI in bitches include vaginal deposition of semen using a rigid plastic catheter or a catheter with an inflatable cuff (the Mavic or Osiris catheters). Semen can also be deposited using a transcervical intrauterine (TCI) technique with the Scandinavian/Norwegian catheter or endoscopic equipment. Semen can also be deposited via surgical or laparoscopic intrauterine insemination. Use of surgery to perform AI or embryo transfer in an animal is not considered ethical and may be illegal in some countries.

An international survey among small animal reproduction veterinarians indicated that surgical AI, although controversial, currently still is the most commonly used technique in dogs, especially with frozen-thawed semen, with low numbers of spermatozoa, or if semen is otherwise of inferior quality.[1] The number of veterinarians becoming competent with TCI is increasing. Use of the Scandinavian/Norwegian catheter is straightforward. The development of better-adapted endoscopic equipment has made TCI more broadly available. Owner interest has also increased use of TCI. Use of camera-equipped endoscopes is appreciated by breeders who can watch on the monitor as semen is injected into the uterus.

Timing the Insemination

AI timing (see ch. 119) is crucial, especially when using frozen semen whose sperm have a reduced survival time after thawing. Measuring serum progesterone [P] concentrations is commonly used for determining optimal days for breeding or AI. Luteinizing hormone testing to identify the preovulatory surge requires more frequent blood samplings. The bitch should be inseminated 2-5 days after ovulation, coinciding with the completion of maturation of the released oocytes. [P] at this stage is usually 10-20 ng/mL (30-60 nmol/L), but daily results may vary as much as 30-40% among healthy bitches. There is no evidence of diurnal secretory patterns.[2]

Semen Dose/AI

In the United States, a single AI with about 100×10^6 progressively motile spermatozoa (≥50%) has been considered adequate. In Europe, 150 to 200×10^6 live, normal, motile spermatozoa per breeding unit are used and two AIs are preferred per estrous cycle.[3-7] In a study of surgical AI using fresh or frozen-thawed semen, a dose of $>200 \times 10^6$ progressively motile sperm was more likely to result in whelping as compared with results using sperm counts of $100\text{-}200 \times 10^6$ or $75\text{-}125 \times 10^6$.[8] Another study comparing pregnancy success after endoscopic TCI and surgical AI of frozen-thawed semen found that pregnancy rates were greater ($P \leq 0.06$) when $>100 \times 10^6$ live, motile, normal sperm were inseminated, regardless of method.[9] Pregnancies have, however, been achieved with as few as 20×10^6 fresh spermatozoa deposited surgically at the tip of the uterine horn and with two doses of 50×10^6 frozen-thawed spermatozoa deposited into the uterus through the cervix with the aid of an endoscope.[10,11]

Vaginal deposition of fresh or frozen-thawed semen requires approximately 10 times as many spermatozoa to obtain the same whelping rates and litter size as by intrauterine deposition.[10,12] Pregnancy rates after endoscopic TCI of frozen-thawed semen (65%) were significantly higher than rates after surgical AI (45%).[9] To limit the volume of semen lost via backflow from the vagina, extended semen volumes should not exceed 1-3 mL for intrauterine AIs and 3-5 mL in vaginal AIs, depending on the size of the bitch.[1,4-6,13-16] Anecdotally, it has been suggested that inseminating slowly over 10-20 minutes allows administration of three to four times more semen, improving pregnancy rates and litter size. This is clearly an area where the veterinary community will benefit from research and experience.

How Many Times Should the Bitch Be Inseminated?

Theoretically, a single AI performed at the optimum time during estrus into the uterus of a healthy fertile bitch with semen of good quality should be adequate for maximizing pregnancy rates and litter size. However, clinical data indicate that two AIs, 24-48 hours apart, result in significantly higher pregnancy rates and litter sizes.[6,12,13,17,18] If only one insemination is possible, emphasis should be placed on determining the "optimum time" for AI, i.e., 2-5 days following the beginning of ovulation.

Results after AI in the Dog

Pregnancy rates range from 85-90% in dogs after natural matings under optimal conditions. Results with AI can be similar. When semen of good quality, even frozen-thawed, is inseminated via TCI at the appropriate time into the uterus of healthy bitches, whelping rates have been as high as 87.5%.[6,9,16,19] Whelping rates after intrauterine AI in dogs are significantly higher than those after vaginal AI. This is true for frozen-thawed (51% better), chilled (44%), and fresh (30%) semen.[1,18] Litter size using intrauterine AI of frozen-thawed semen is also significantly larger than by vaginal AI. Litter sizes are estimated to be 25-30% smaller in bitches receiving frozen semen compared to fresh and chilled.[12-14,16,18] Results also depend on breed, size, age, fertility of the dog and bitch, season of the year and numerous other factors.[8,16,20,21]

AI Techniques in the Dog

Palpation of the Canine Cervix and Uterus

One must be consistently able to abdominally palpate the cervix in order to develop competence in transcervical AI. This concept is emphasized when using the Scandinavian/Norwegian catheter technique to deposit semen into the uterus without injuring the patient. When using an endoscope to visualize and then catheterize the cervix, manual manipulation of the cervix and uterus can be useful. The anatomy of the caudal genital tract of the bitch is shown in Figure 118-1. The bitch should have an empty bowel and bladder to facilitate palpation. In order to palpate the cervix, a rigid canine AI catheter (Figure 118-2) is introduced into the vagina. This is facilitated when the vulva is raised to just below the anus, similar to the posture taken when a bitch stands for a male dog during breeding.

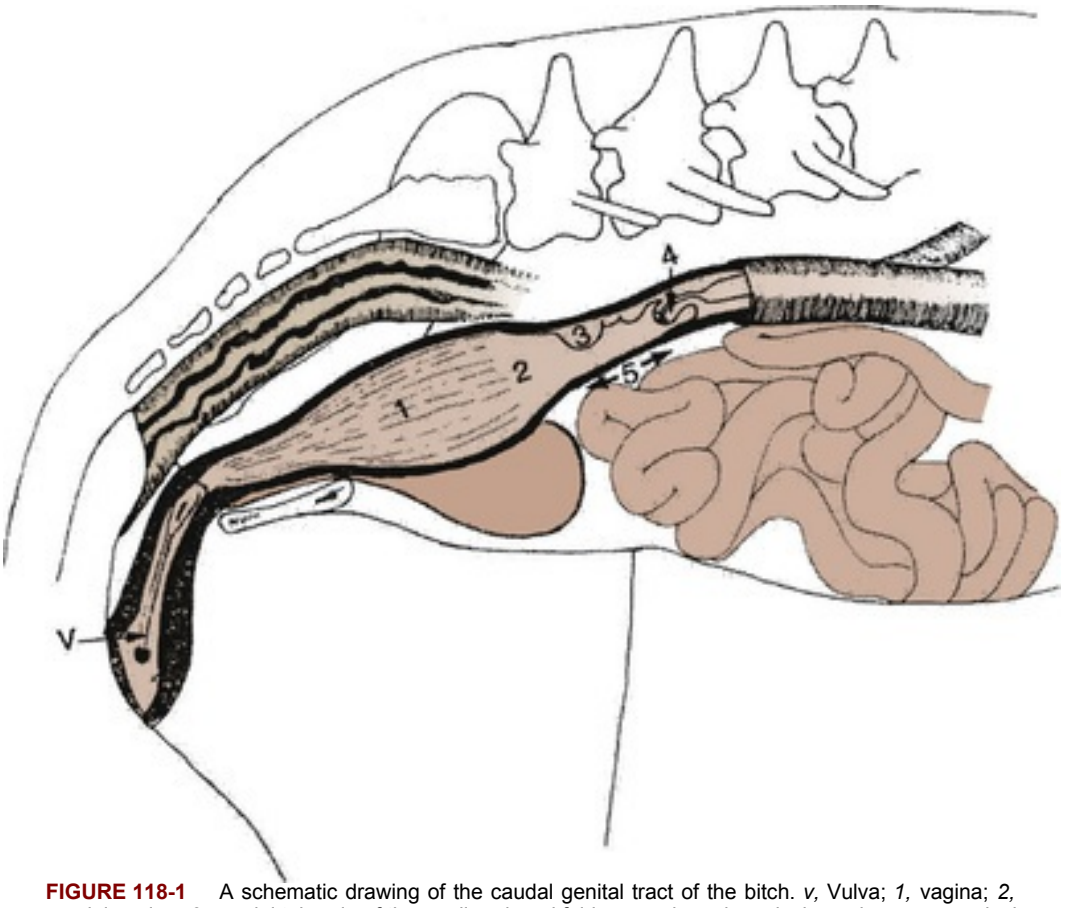

FIGURE 118-1 A schematic drawing of the caudal genital tract of the bitch. *v,* Vulva; *1,* vagina; *2,* cranial vagina; *3,* caudal tubercle of the median dorsal fold; *4,* cervix and cervical canal; *5,* paracervical region. (From Lindsay F: The normal endoscopic appearance of the caudal reproductive tract of the cyclic and non-cyclic bitch: post-uterine endoscopy. *J Small Anim Pract* 24(1):1-15, 1983.)

FIGURE 118-2 Three sizes of the Scandinavian/Norwegian AI catheter for dogs, and two sizes of rigid plastic single-use vaginal AI catheters.

By inserting the catheter along the left or right side of the vestibule of the vagina, accidental insertion into the centrally located urethral opening can be avoided. Because the urethral opening of the bitch is located at the pelvic brim, it is surprisingly easy for the plastic AI catheter, or a thin, rigid endoscope, to be unintentionally introduced into the urinary bladder. Apart from the hazards of perforating the bladder with the catheter, it is obvious that no pregnancy would follow after an AI when this occurs. Thus, the position of the catheter should always be checked by palpation before depositing semen. If the catheter is in the urinary

bladder, the cranial part of the vagina and the cervix can be palpated above the catheter and will not move in synchrony when the tip of the catheter is moved up and down. The walls of the urinary bladder usually are thinner than those of the vagina and the tip of the catheter stands out more distinctly than if it were in the vagina.

When the tip of the catheter has been advanced to a position immediately cranial to the pelvic brim, its position should be checked by palpation. Cranially, the vagina in most bitches slopes slightly downward. However, in some breeds (especially the sight hounds, many of which have an arched loin), the vagina may have a more dorsal direction (see Figure 118-1). The cranial end of the catheter should now be lowered closer to the abdominal wall to make it more accessible to palpation. When the catheter tip can be palpated and its correct position in the vagina thus checked, it is carefully advanced while continuously being palpated, until it reaches the paracervical area. This is the narrow, cranial portion of the vagina created by the dorsal, median postcervical fold and can be palpated as a 1- to 2-cm long, usually somewhat firm structure. It ends at the cervix, which in a bitch in estrus is a 0.5- to 1.5-cm, hard, rounded to ovoid, freely movable structure (see Figure 118-1).

The rigid plastic AI catheters, which have a diameter of 5 mm, may be too wide to be introduced into the paracervical area in some bitches, especially those of the smaller breeds or those that have not given birth to a litter of pups. Consequently, it is hardly ever possible to pass the outer protecting sheath of the Scandinavian/Norwegian catheter, which has a diameter of 10 mm, into the paracervical area. Once the cervix has been identified, the corpus uteri and the uterine horns can be palpated in front of this structure. This can be achieved by lowering the tip of the catheter and closing the tip of the thumb against that of the index finger above the catheter, then lifting the cranial end of the catheter in such a way that the cervix and the uterine horns are pulled upward between the fingers. Their size and consistency then become evident. (This method of palpating the uterus is also useful for early pregnancy detection and to examine bitches with suspected endometritis or pyometra.)

Vaginal Insemination

Vaginal AI is usually performed with a rigid plastic single-use catheter (20 to 45 cm long and 5 mm in diameter) (see Figure 118-2), which is introduced into the cranial vagina, as previously described, as close to the cervix as possible. With the catheter in place in the cranial vagina, a syringe containing the semen is attached and the hindquarters of the bitch then elevated before infusing the semen. After deposition of the semen dose, the catheter is withdrawn and the bitch is held with elevated hindquarters for 5 to 10 minutes to facilitate the transport of spermatozoa toward the oviducts. The bitch should also be "feathered" around the vulva and perineal region to stimulate uterine contractions. Spermatozoa may reach the tip of the uterine horn within 30 seconds to 1 minute during a natural mating and within about 30 seconds to 2 minutes after a vaginal AI if the bitch is held with elevated hindquarters. If the bitch is standing normally, transport of sperm into the uterus and oviducts is less efficient. One can also use either a Mavic or an Osiris catheter for vaginal AI. These have an inflatable cuff that occludes the distal vagina, preventing backflow of semen. It is intended to mimic the copulatory tie. These catheters usually are left in the vagina for 10 minutes after the AI while the bitch is free to move around (Figure 118-3).

FIGURE 118-3 The Mavic catheter for vaginal AI in dogs has an inflatable cuff and comes in three sizes. (Copyright MOFA Global 2014.)

Intrauterine Insemination Using the Scandinavian Catheter

The Scandinavian/Norwegian catheter (see Figure 118-2) is a 1- to 2-mm-wide steel catheter with a 0.75- to 1-mm diameter tip that comes in four different lengths: 20, 30, 40 or 45 cm. It is used with a 10-mm diameter outer nylon sheath to protect the bitch during placement. The medium-sized, 30 cm catheter fits most small, medium-sized, and large bitches. Giant breeds may require longer catheters. However, vaginal length varies more with breed than with size. Some large-breed bitches, sight hounds for example, have a relatively short vaginal vault.

Intrauterine AI with the Scandinavian/Norwegian catheter is performed with the non-sedated bitch standing. Most bitches in estrus readily accept this type of handling. In case light sedation should be required (in a large, obese, or nervous bitch), 1 to 3 mg/kg xylazine IM or IV can be used. The nylon sheath is first introduced into the vagina as far as possible. If lubrication is necessary, a small amount of Vaseline (or other non-spermicidal lubricant) can be used. If the nylon sheath is introduced together with the inner steel catheter, the tip of the steel catheter must be completely covered by the nylon sheath. The cranial end of the nylon sheath should be palpated cranial to the pelvic brim as previously described. If the tip of the sheath is lowered toward the abdominal wall, the cervix usually can be palpated a few centimeters in front and above the catheter. The steel catheter then is advanced through the sheath until its tip reaches the ventral fornix. To achieve this, the cranial vagina and cervix are manipulated to create an alignment between the catheter and the cervix.

The cervix is then fixed between the thumb and the index finger, taking care not to squeeze the canal closed, and by applying a slightly downward traction at the corpus uteri, it is tilted so that the angle of the cervical canal becomes more horizontal. The tip of the steel catheter is then carefully withdrawn while pushing it repeatedly against the surface of the cervix in search of the cervical canal opening. Touching the opening has been described as similar to touching cartilage (i.e., “crispy”). Once the opening is found, the catheter is held in place and the cervix is gradually worked over the catheter. The cervical canal is 5 to 10 mm long and not always completely straight (see Figure 118-1). Thus, slight pressure may be needed while rotating the catheter to ease it through. In most bitches, the tip of the catheter easily can be felt in front of the cervix in the corpus uteri, but sometimes this sensation is not distinct. In a few bitches, the catheter can only be introduced halfway through the cervix. This partial advancement, however, is often sufficient for depositing semen successfully.

The syringe containing semen is firmly connected to the catheter. Semen should be slowly infused into the uterus while gentle pressure is applied with thumb and index finger around the cervix to prevent backflow. Sometimes there is resistance to infusion if the opening of the catheter is pressed too hard against the endometrial mucosa. A slight downward traction at the corpus uteri or of the cervix usually alleviates the compression, allowing infusion. To be assured that the catheter tip is in the uterus, 1 to 2 mL of physiologic saline can be infused. If the catheter is in the correct uterine body position, the fluid can easily be infused. If the catheter is in the paracervical region of the vagina, however, there will be an almost immediate backflow of saline between the catheter and the nylon sheath. After intrauterine deposition of the semen, the catheter is withdrawn. To minimize backflow of semen and to facilitate uterine transport of spermatozoa toward the oviducts, the bitch may be held with elevated hindquarters for 5 to 10 minutes after the AI while being feathered around the vulva and perineal region to stimulate uterine contractions and sperm transport.

Learning this technique requires practice, but once learned it is a quick procedure requiring only a few minutes. At least 95% of attempts are successful. It is recommended that, initially, organ specimens be obtained for training purposes and anatomic study. First attempts, whenever possible, should be made in medium-sized, calm, non-obese bitches that have previously whelped litters, as they are usually easier to catheterize. Perforations may occur if the catheter is introduced blindly or with force, but when catheterization is performed carefully and correctly, the technique is safe. (This technique can be used for other infusions—for instance, for intrauterine infusion of contrast medium for hysterographic examinations of the bitch with suspected uterine lesions.)

Intrauterine Insemination Using Endoscopic Visualization of the Cervix (Video 118-1)

Transcervical intrauterine insemination can be performed on standing, non-sedated bitches using a fiberoptic endoscope. Although the use of a flexible endoscope has been found useful in Beagles, most practitioners use rigid endoscopes.[11,22,23] Various rigid endoscopes developed for humans have been used for AI in the bitch. Currently, the most commonly used endoscope for insemination is the Storz human uretero-renoscope, with a working length of 42.5 cm and a diameter of 3.15 mm at the tip (Karl Storz Veterinary Endoscopy, or MOFA Global). The endoscope can be used together with a camera and monitor (Figures 118-4 and 118-5).

FIGURE 118-4 The Storz uretero-renoscope with a working length of 42.5 cm and a diameter of 3.15 mm at the tip. (Copyright MOFA Global 2014.)

FIGURE 118-5 Transcervical intrauterine AI using a Storz uretero-renoscope with a working length of 42.5 cm and a diameter of 3.15 mm at the tip, here equipped with an insufflator, and a camera and monitor. (Courtesy Dr. Stuart Mason.)

MOFA Global has developed a set of three endoscopes of different lengths (Figures 118-6 and 118-7). Both medium (35 cm) and large (50 cm) length endoscopes accommodate up to 8 Fr sized catheters or two smaller catheters for advanced procedures. The small TCI endoscope is designed for toy breeds and cats and is 15 cm in length. These endoscopes (Storz, as well) also come with a special device, the TCI shunt (Figure 118-8), available in 16- and 21-cm lengths. The shunt is used by introducing it into the vestibule of the vagina and then advancing the tip past the urethral opening. Then, its cuff is inflated to create an airtight seal and fixed position in the caudal vaginal vault. The endoscope can then be introduced through the shunt. This shunt system acts as a stabilizing platform for the endoscope during the TCI procedure. This may be especially useful in the early stages of endoscopic TCI training. It does, however, restrict the mobility of the scope. Thus, if a bitch makes a sudden move, the endoscope cannot be quickly withdrawn, increasing risk for vaginal perforation.

FIGURE 118-6 Equipment for transcervical intrauterine AI. (Copyright MOFA Global 2014.)

FIGURE 118-7 Three sizes of endoscopes for TCI in dogs and cats. (Copyright MOFA Global 2014.)

FIGURE 118-8 The so-called TCI shunt, which comes in two lengths, has an inflatable cuff and can be used with the Storz uretero-renoscope and the three sizes of endoscopes developed by MOFA Global. (Copyright MOFA Global 2014.)

A 6-8 Fr dog urinary catheter, or a custom-made longer and thinner (3-5 Fr) catheter, is passed through the operating channel of the sheath. The endoscope is introduced into the vagina and advanced until the external os of the cervix can be visualized. The urinary catheter is then manipulated into the cervical opening and further into the uterus. Insufflation of air distends the vagina and improves the field of vision. To guide the endoscope through the often tortuous vaginal vault, it can be quite helpful to let the urinary catheter lead the way by 1 or 2 cm, thus indicating the correct direction. If the opening of the cervical canal is directed away from the endoscope and thus out of sight, the cervix can be manipulated by pushing or lifting it with the tip of the endoscope, or with the catheter, while moving the instrument from side to side below the cervix. Similar to when using the Scandinavian/Norwegian catheter, correct positioning of the endoscope tip in relation to the cervix can be established with abdominal palpation. Palpation may also be used to change the cervix's position when needed for better alignment. After semen has been deposited into the uterus, the catheter and the endoscope are removed and the bitch may be held with elevated hindquarters for 5 to 10 minutes to prevent backflow of semen, as previously described.

The advantage of this technique is direct visualization of the cervical opening and intrauterine infusion of the semen. However, it requires skilled manipulation of the scope and catheter. Although equipment may be expensive, practitioners specializing in canine reproduction and AI should obtain at least one endoscope of a size that fits most breeds. The equipment can also be used for diagnostic procedures, such as endometrial biopsy and intrauterine culture and cytology.

Intrauterine Insemination Using Surgery (Video 118-2)

Surgical intrauterine insemination is still used in many countries, despite ethical concerns. To improve chances of a pregnancy and litter size, surgical AI may be combined with TCI or vaginal AI, at a 24-48 hour interval. For surgery, the bitch is placed under general anesthesia and in dorsal recumbency. The ventral abdomen is clipped and sterilized and a 4- to 6-cm incision made midway between the pubis and the umbilicus, through the linea alba. The uterus is elevated through the incision and the needle of the syringe containing the semen is inserted either into the lumen of the uterine body or into the cranial area of each horn at a 45° angle with the bevel of the needle up. The semen is slowly injected into the uterus. It should flow easily with obvious distention of the uterine horns or the needle may be repositioned. A saline-moistened gauze should be held over the injection site after the needle is withdrawn to prevent backflow of semen. After 1 minute the gauze is removed, the uterus replaced into the abdomen, and the wound closed using routine methodology. To avoid backflow of semen through the cervical canal, the bitch should be positioned with her rear elevated while she recovers from anesthesia. The risks associated with surgery and anesthesia, in general, and the limited number of surgical AIs that can be performed in a bitch are obvious disadvantages. Surgical AI can be more costly, more time consuming, and is less successful when compared with TCI.[9]

Intrauterine Insemination Using Laparoscopy

Techniques for laparoscopic AI in dogs are well-described, but this approach is not yet commonly used.[24] Concerns regarding equipment cost and the need for general anesthesia have slowed the use of laparoscopy.

CHAPTER 119

Vaginoscopy and Vaginal Cytology in Dogs

Cheryl Lopate

Client Information Sheet: Vaginoscopy and Vaginal Cytology Examination

Indications

Vaginal cytology and vaginoscopy can be used to determine the stage of the bitch's estrous cycle, the presence of inflammation in caudal reproductive tract or to help elucidate the source of bloody vulvar discharge in the spayed or intact bitch.[1-7] The vaginal epithelium changes in response to circulating estrogen concentrations, be they endogenous or exogenous.[1-5,8,9] Vaginal cytology and vaginoscopy may be used to help in determining the optimal time to breed a bitch (in combination with progesterone and/or luteinizing hormone [LH] testing), to assess for the presence of infection or inflammation within the genitourinary tract, to elucidate the influence of estrogen on the patient, and to search for malignant cells.[1,2,5-9] There are various cell types that may be seen on vaginal cytology including epithelial cells, white blood cells (WBC), red blood cells (RBC), bacteria, and macrophages.[1-5,10]

Procedure for Obtaining a Sample

Vaginal cytology smears are best obtained using some type of guarded technique so the tip of the swab is not contaminated with skin, clitoral, vestibular or urinary tract secretions. A guarded or double guarded cytology swab or the use of a vaginal speculum (otoscope cone, short proctoscope, or small dual-bladed speculum) is useful in this regard. Either a clean cotton-tipped applicator or a cytobrush may be used. Acrylic tipped swabs cause more cellular damage and do not provide as high quality a specimen as cotton. A drop or two of physiologic saline (0.9%) may be added to the cotton applicator tip to minimize cell injury while the swab is obtained, particularly in bitches that are suspected to be in anestrus, since basal cells are particularly fragile. Initially, the speculum or guarded swab is passed at an angle about 45-70 degrees from horizontal, starting at the dorsal commissure of the vulva and maintaining the swab dorsally in the vestibule to avoid the urethral meatus (Figure 119-1, *A-F*; Video 119-1). Once the pelvic rim is reached the speculum or guarded swab is slid cranially within the vaginal canal. The swab, once fully seated, should be twirled back and forth for 10 to 15 seconds to exfoliate cells from the vaginal wall and then the swab is pulled out through the speculum or guarded outer sheath. After the swab is removed a light source may be attached to the speculum device and the color, texture and nature of the vaginal epithelium assessed visually; air insufflation with a hand bulb may be necessary in some cases. Once the swab is obtained, it should immediately be rolled gently onto a clean microscope slide, air-dried and stained with Wright-Giemsa stain. Alternatively, trichrome or Papanicolaou stains may be used.

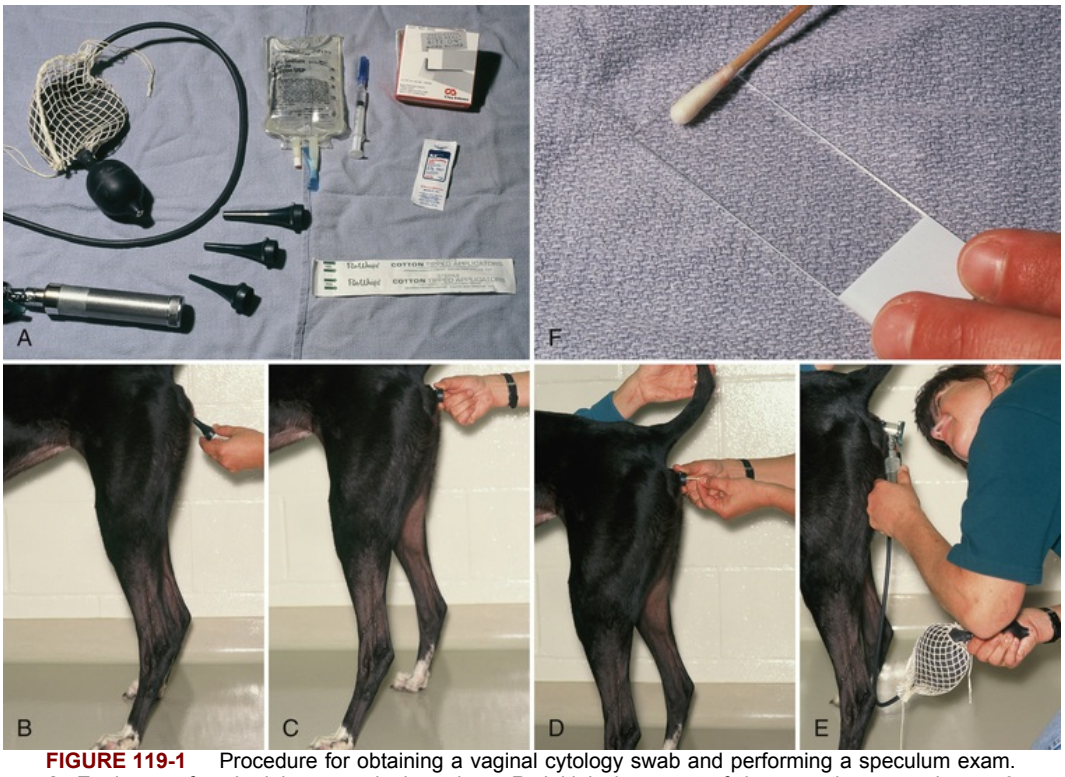

FIGURE 119-1 Procedure for obtaining a vaginal cytology swab and performing a speculum exam. **A,** Equipment for obtaining a vaginal cytology. **B,** Initial placement of the speculum cone is 45-70 degrees from horizontal. **C,** Once the rim of the pelvis is reached, the tip of the speculum is rotated to horizontal or a slight downward direction to allow full seating of the speculum in the vestibulum. **D,** The cytology swab or brush is slid cranially as far as possible and then rotated back and forth for 10-15 seconds. **E,** After removing the swab, a light source is attached to the speculum to allow visualization of the vaginal mucosa—air insufflation may be necessary to get adequate visualization. **F,** The cytology swab is gently rolled on a microscope slide and air dried before staining.

Cell Types Present on Cytology

Epithelial Cells

The epithelial cell types that may be present on a vaginal cytology slide include basal, parabasal, intermediate, nucleated superficial and anucleated superficial cells (Figure 119-2, *A* and *B*). Variations of these cells include metestrual cells, which are epithelial cells (typically parabasal and intermediate cells) that have engulfed a WBC (macrophages), and foam cells which are parabasal or intermediate epithelial cells that contain unstained cytoplasmic granules (Figure 119-2, *C* and *D*). Basal cells are the smallest of all the epithelial cell types and are round, with a large, centrally located nucleus and deeply basophilic cytoplasm when stained with Wright-Giemsa stain, which is readily available in almost any veterinary clinic. Parabasal cells are larger than basal cells with a round, smaller nucleus, that may be slightly eccentric in location, and less basophilic cytoplasm than basal cells. Intermediate cells are larger still, with smaller nuclei, that may be central to slightly eccentric in location. Small intermediate cells have cellular margins that are still round and cytoplasm is clear to very lightly basophilic, while large intermediate cells (sometimes called nucleated superficial cells) have a normal appearing nucleus. The edge of these cells have angled borders. Nucleated and anucleated superficial cells are the largest of the epithelial cells, with angled borders and either a smaller, pyknotic centrally located nucleus and lightly stained cytoplasm or are completely anucleated. Superficial cells are also sometimes called cornified cells.[1-5,10]

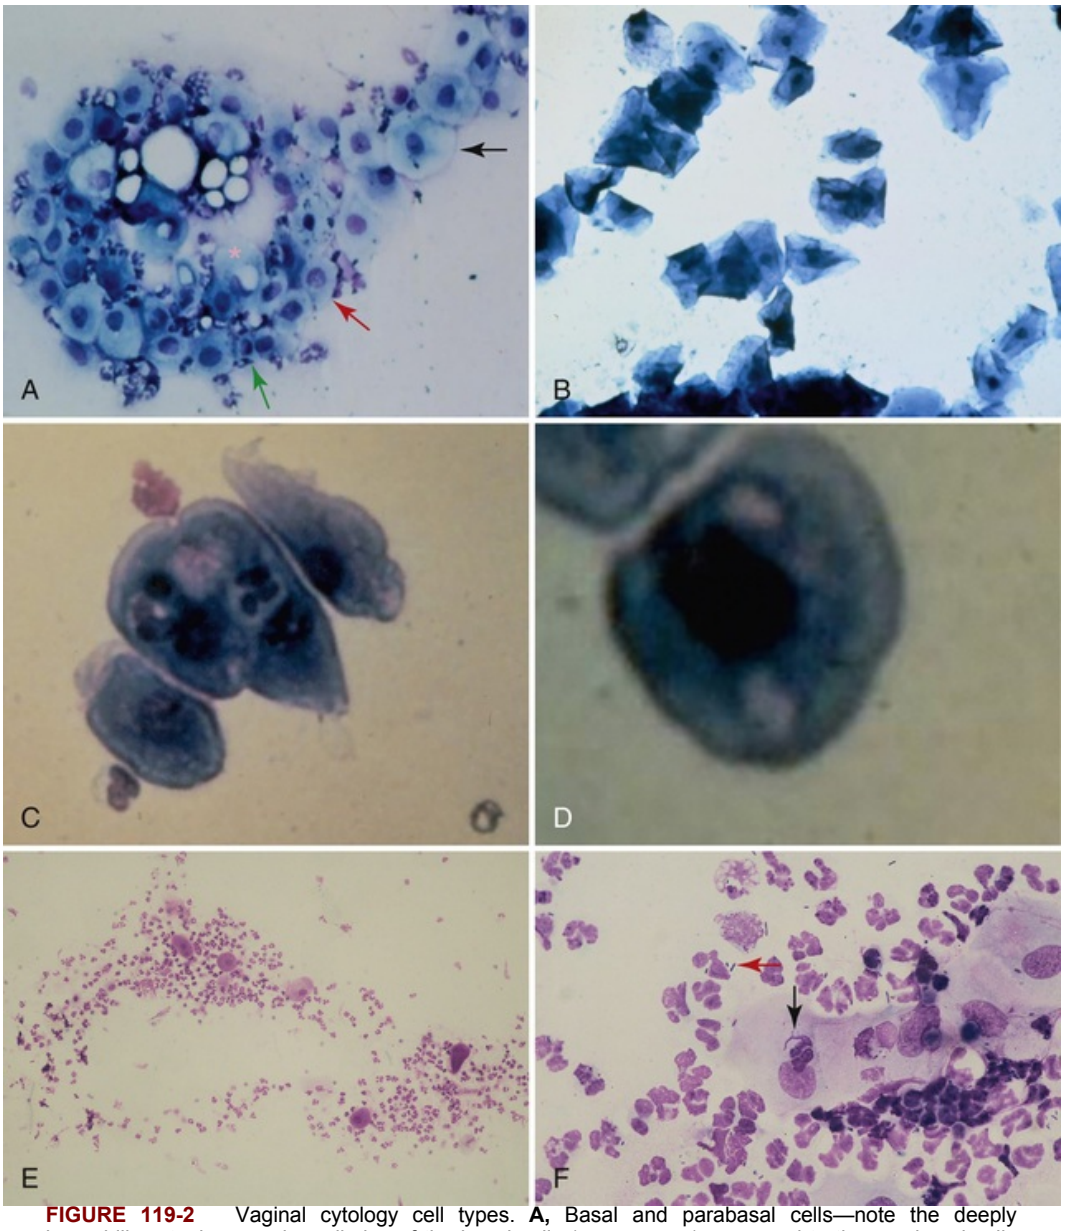

FIGURE 119-2 Vaginal cytology cell types. **A,** Basal and parabasal cells—note the deeply basophilic cytoplasm and small size of the basal cells (green arrow) compared to the parabasal cells (red arrow); intermediate cells (black arrow)—note the larger size, round cell margins, lightly stained cytoplasm; and foam (pink star). **B,** Superficial cells—nucleated and anucleated—note the angled cell border, large cell size. Some anucleated cells have pyknotic nuclei while others are completely anucleated. **C,** Metestrual cell—note the neutrophil being engulfed by the intermediate cell. **D,** Foam cell—note the clear granules in the cytoplasm of the parabasal cell. **E** and **F,** Vaginitis—note the large numbers of neutrophils with intracellular (red arrow) and extracellular bacteria and metestrual cells (black arrow).

White Blood Cells (Figure 119-2, *E*)

Neutrophils, typically non-degenerate are the predominant type of WBC present although occasional lymphocytes or eosinophils may be noted (particularly post abortion). In cases of vaginitis, endometritis, metritis and pyometra, degenerate neutrophils may predominate.[1-7]

Red Blood Cells

During proestrus, estrus and occasionally diestrus, red blood cells may be noted. They emanate from the endometrial capillaries that become leaky under the influence of estrogen and diapedesis ensues. As the bitch

progresses through the estrous cycle, the number of RBC typically declines.[1-5]

Bacteria (Figure 119-2, *F*; Video 119-2)

Bacteria are normally found on vaginal cytology smears. There are numerous species of bacteria that are found as part of the normal flora of bitches. They may be found in very high numbers early in proestrus and tend to decrease during estrus and are minimal during mid-late diestrus. Normally, there is a mixed population of cocci and rods, although often, cocci predominate.[5,11-17]

Metestrual and Foam Cells (see Figure 119-2, *C* and *D*)

During diestrus epithelial cells are known to be phagocytic and are seen in the form of metestrual cells. Foam cells are also present during diestrus—their function is not known.[1-5]

Contaminants and Other Cell Types

Fungal spores and yeast as well as urine crystals or talc crystals from exam gloves may be noted. Spermatozoa may be seen on vaginal cytologies.[1,2]

Neoplastic Cells

Cells from transmissible venereal tumors, squamous cell carcinomas, transitional cell carcinomas, leiomyosarcomas, lymphosarcoma, and metastatic mammary adenocarcinoma may be noted on cytology smears.[1,2,6,7]

Cyclic Changes during the Estrous Cycle[1-5,18] (Table 119-1; Video 119-3)

Anestrus

During anestrus the vaginal mucosa is not under any significant hormonal influence and is very thin. Cytologically, basal cells predominate, although occasional parabasal cells may also be noted. Often when cytologies are obtained during anestrus, the cytoplasm may be stripped from these fragile cells resulting in only nuclei being visible on the smear. Usually there are very few, if any bacteria or neutrophils during this stage of the cycle. There is often heavy mucus present. Speculum exam may reveal a dark red, streaky pattern to a dark, blotchy pink color. The mucosa is flattened with no crenulation or edema present.

TABLE 119-1

Cell Types Present on Vaginal Cytology Slides during the Estrous Cycle of the Bitch

	BASAL CELLS	PARABASAL CELLS	INTERMEDIATE CELLS	NUCLEATED SUPERFICIAL CELLS	ANUCLEATED SUPERFICIAL CELLS	RBC	WBC	FOAM AND METESTRU/ CELLS
Early proestrus	++	++	++	+/−	−	+++	+	−
Mid proestrus	−	+/−	+	+	+/−	++	−	−
Late proestrus	−	−	+/−	++	++	+	−	−
Estrus	−	−	−	+/−	+++	+/−	−	−
Diestrus	+	++	++	+/−	−	+/−	+	+
Anestrus	++	+	+	+/−	−	−	+/−	−

Vaginitis*	+/−	+/−	+/−	+/−	+/−	+/−	+ - ++ +	+

*The types of epithelial cells present and the presence or lack of RBC will depend on the stage of the cycle the vaginitis is noted.

Proestrus Cytology

During early proestrus, the vaginal epithelium begins to proliferate under the influence of estrogen. Initially, dark blood may be first noted and then quickly changes to a bright red, often voluminous, discharge. Cytologically basal and parabasal cells, along with intermediate cells are noted in early proestrus. There may be low to moderate numbers of neutrophils and heavy bacterial contamination during early proestrus, with the neutrophils disappearing by mid-proestrus, and bacterial numbers decreasing through proestrus and into early estrus, until there are far less bacteria visible. The numbers of RBC decrease as proestrus continues. As mid-proestrus approaches the numbers of superficial cells are increasing as the cells of the vaginal wall differentiate under the influence of estrogen. By mid to late proestrus, cytology reveals predominantly superficial cells, with some nucleated, some pyknotic and some anucleated. As proestrus proceeds through late proestrus to early estrus, the numbers of anucleated superficial cells increase and the numbers of nucleated superficial cells decrease.

Proestrus Vaginoscopy (see Video 119-1)

In early proestrus the mucosa is pink and edematous (Figure 119-3, *A*). As estrogen concentrations increase and the vaginal wall thickens, the mucosa begins to blanch and progresses from pink to light-pink and finally to white in color. The edema in the vaginal walls starts to diminish and the mucosa begins to crenulate, or wrinkle, resulting in the development of many folds (Figure 119-3, *B*).

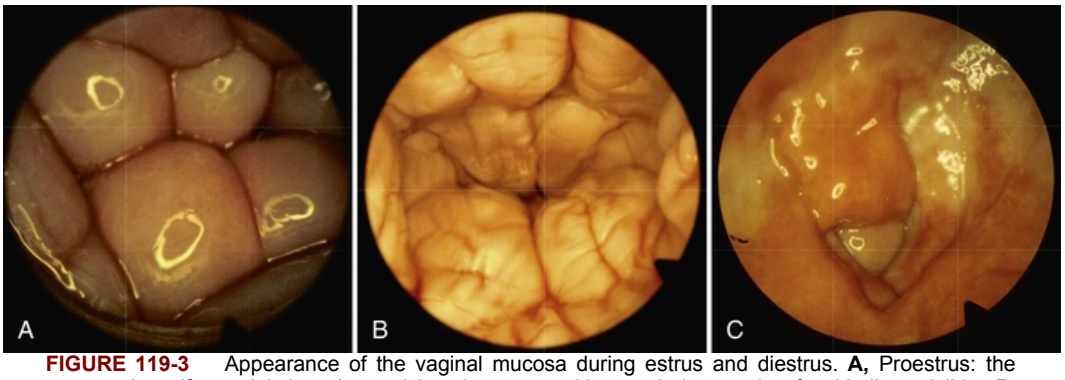

FIGURE 119-3 Appearance of the vaginal mucosa during estrus and diestrus. **A,** Proestrus: the mucosa is uniform pink in color and is edematous with rounded mounds of epithelium visible. **B,** Estrus: the mucosa is light pink–white with prominent folds or wrinkles; note the uniform color. **C,** Diestrus: mucosa is blotchy pink. Early in diestrus folds may still be visible, but very quickly the folds begin to flatten out; note the different shades of pink present.

Estrus Cytology and Vaginoscopy

As estrogen concentrations decline and ovulation occurs, all cells are superficial epithelial cells, primarily anucleated, although in some bitches, there may still be a large percentage of nucleated superficial cells present. There are decreasing numbers of RBC in most bitches but some may still have significant numbers through estrus. There are no WBCs. There can be minimal to moderate bacterial presence but this should be considered normal as long as there are no WBCs noted. The background is typically clear of debris and mucus. The cytology remains this way throughout the fertile period. Towards the end of the fertile period heavy exfoliation of superficial cells begins and clumping of superficial cells may be noted on cytology. It is not possible to directly correlate a specific cytology with ovulation but in many bitches ovulation occurs in correlation with maximal cornification (70-90% anucleated superficial cells).[8,9] Speculum examination reveals a white and crenulated mucosa throughout estrus and the number of folds and cross-folds increases as the fertile period progresses (see Figure 119-3, *B*).

Diestrus Cytology

There is a dramatic change in cellular characteristics at the onset of diestrus. The numbers of superficial cells decrease precipitously and the numbers of intermediate and parabasal cells increase. Within 24 hours of the onset of diestrus, neutrophils return. There may or may not be RBC in early diestrus but within a few days of the onset of diestrus, RBC presence ceases. Metestrual cells and foam cells appear within the first few days of diestrus. Bacterial numbers may be low to numerous (especially if breeding occurs). Early proestrus and early diestrus may be difficult to differentiate cytologically. Speculum examination reveals a blotchy (two-tone), pink–dark pink or red color with rapid flattening of the vaginal folds. Touching the mucosa with the end of a speculum or an endoscope results in rosette formation (first blanching of the mucosa with immediate refilling with blood) (Figure 119-3, *C*).

Other Reproductive Disorders That Vaginal Cytology May Be Helpful in Elucidating

Infection

Vaginal cytology may be used to diagnose infection within the genitourinary tract, including vaginitis, endometritis, pyometra, urethritis, cystitis, vestibulitis, clitoritis or vulvitis. Further diagnostics must be performed to elucidate the site of infection.[1,2,6,7,16,17,19]

Neoplasia

Transmissible venereal tumors, squamous cell carcinomas, transitional cell carcinomas, leiomyosarcomas, lymphosarcoma, and metastatic mammary adenocarcinoma may exfoliate cells into the vaginal canal that may be visible on cytology. Further diagnostics must be performed to determine the location and type of neoplasia present.[1,2,6,7]

Other Causes of Vulvar Hemorrhagic Discharge

Trauma, vaginal angiomatous neoformation, vascular ectasia or coagulopathy may also cause bloody vulvar discharge and need to be differentiated from proestrus hemorrhagic discharge through additional diagnostic procedures.[1,2,6,7,20,21]

CHAPTER 120

Overview of Interventional Medicine

Chick Weisse

Introduction

Minimally invasive surgical procedures are playing an important and growing role in veterinary medicine. As these therapies have developed over the years in human surgery, the benefits in terms of reduced morbidity, mortality, analgesia, time to recovery, hospitalization times, and even cost in some circumstances are beyond dispute. In addition, these therapies have provided the means to treat underlying conditions not amenable to more traditional approaches. These same arguments can be made in favor of the use of these procedures in veterinary patients; however, the science has not yet caught up to the practice in our profession. The background on specific diseases is covered elsewhere within the textbook.

Interventional Radiology/Interventional Endoscopy

Following the description of percutaneous arterial catheterization by Sven Ivar Seldinger in 1953, angiography developed into a widely-utilized and essential medical diagnostic tool.[1] Technological advances in imaging and medical devices have since helped transform this once diagnostic modality into a sub-specialization with enormous therapeutic potential. Interventional radiology (IR) involves the use of contemporary imaging techniques such as fluoroscopy and ultrasonography to selectively access vessels and other structures in order to deliver different materials for therapeutic reasons. Interventional endoscopy (IE) utilizes the recent advances in endoscopy to perform image-guided therapy alone or in conjunction with fluoroscopy. Endourology and interventional gastroenterology are some of the more common combined uses in which the operator(s) uses endoscopy to access an orifice such as the ureterovesical junction within the urinary bladder or the major duodenal papilla to subsequently use IR techniques under fluoroscopic guidance to access the upper urinary tract or biliary tract, respectively. Both IR and IE techniques provide therapeutic options for diseases once deemed untreatable—often now the standard of care for a variety of human conditions.

Advantages and Disadvantages

The use of IR and IE techniques in veterinary patients has the potential to provide a number of advantages compared to more traditional therapies. These procedures are minimally invasive and can therefore theoretically lead to reduced peri-operative morbidity and mortality, shorter anesthesia times, and shorter hospital stays. Examples of such procedures with reported advantages over traditional open surgical procedures might include treatment for feline ureteral obstructions or canine intrahepatic shunts.[2,3] Some less equipment-intensive procedures can result in reduced costs as well. While the equipment necessary to perform these techniques can often be expensive in terms of disposables and initial capital investment, the high (and rising) costs of hospitalization in tertiary referral and specialty hospitals can be dramatically reduced with these often outpatient or single night stay procedures. The more traditional “invasive” surgical therapies may be less expensive to perform; however, the prolonged intensive care unit (ICU) stays, postoperative care, transfusions, etc. can often add up to even higher veterinary bills. The majority of the IR/IE procedures performed at the author's institution are similar in cost to the comparative surgical therapy. The exceptions would be a variety of laparoscopic-assisted procedures (ovariohysterectomy, bladder stone removal, gastropexy, gastrointestinal biopsies). Perhaps the greatest advantage of these procedures is the ability to treat conditions for which more traditional therapies are contraindicated, associated with excessive morbidity, or unavailable to veterinary patients. Examples include sclerotherapy for renal hematuria, embolization or chemoembolization of nonresectable tumors or vascular anomalies, etc.

The primary disadvantages of IR/IE include the required technical expertise which is not currently available at most veterinary advanced training institutions, the specialized equipment necessary (wide range of endoscopes, fluoroscopy with or without digital subtraction capabilities), and the initial capital investment necessary to provide a suitable inventory of catheters, guide wires, balloons, stents and coils. Training labs and courses available at the major specialty college symposia as well as privately-run training labs are now commonplace.

Equipment

Operating Rooms/Angiography Suites

As most of these procedures are minimally invasive (performed through natural orifices or small holes in the skin), traditional sterile operating rooms (ORs) are not required, but recommended. During the learning process, and even for experienced interventionalists, open surgical conversion may be necessary. Performing these procedures within a sterile environment so open surgical conversions can be performed quickly and efficiently facilitates this. Additionally, hybrid approaches are often used in which small surgical approaches are performed to facilitate access for interventional therapies. In both circumstances, the pet owners should consent to open procedures prior to the procedure and the patient should be clipped and prepared for full surgical access if necessary. More standard, predictable endoscopy and interventional procedures can be performed in endoscopy or clean angiography suites, respectively.

Additional equipment needs require larger OR environments. Aside from common needs such as anesthesia machines, OR tables, and surgical equipment, the ideal room should provide ample space for a "crash cart," equipment cabinets, lasers, vessel sealing devices, lithotripters, and movement of the C-arm away from the table for additional surgical space. A control room station in the OR is recommended for fully integrated ORs; these are currently rare in veterinary medicine but growing in number due to flexibility to perform multiple different therapeutic modalities within the same space.

For many of the more commonly performed IR procedures, a traditional fluoroscopy unit is sufficient. Operators wear full lead (or similar) gowns, thyroid shields, caps, gowns, and masks. The more common fluoroscopy units currently available in veterinary hospitals are often "multi-purpose units," a combination digital radiography and fluoroscopy unit built into one system. While these are suitable for general fluoroscopy needs, the relative immobility of these units to rotate, the non-sterile environments in which they are standardly installed, and the inability to permit surgeons standing on both sides of the patient concurrently make them poor choices for many of the currently performed IR/IE procedures except the more standard cardiac interventions, or tracheal and urethral stenting.

Alternatively, mobile C-arm units may already be available in the OR in many larger referral veterinary hospital settings. Often these units are suitable for the more basic, non-vascular IR procedures and most endourological procedures. A C-arm fluoroscopy unit has the advantage of mobility of the image intensifier (or more recently digital flat panel detector), permitting multiple tangential views without moving the patient. In addition, many of these units may be able to receive software upgrades such as cardiovascular packages in order to improve performance according to the desired technique. Compared to the more expensive, larger, fixed (ceiling or floor-mounted) units which provide superior image resolution, the mobile C-arms are easily moved from room to room, have fewer radiation regulations (leaded walls not necessary but may vary by state), and can be purchased, leased or even rented at a fraction of the cost. Often overlooked during purchasing of this equipment is the OR table. While some standard OR tables are sufficiently thin to permit fluoroscopy when the patients are small and placed at the end of the table, specially designated "fluoroscopy surgery tables" are available in a variety of designs. These more expensive fluoroscopy tables are often equipped with a "floating" tabletop configuration to facilitate patient positioning without moving the more bulky C-arm.

As these procedures are often performed by surgeons or internists without recent training in radiation safety, it is important to refresh one's knowledge on the rather substantial radiation exposure that can occur during some of the more prolonged interventional procedures. The operator is encouraged to review radiation safety guidelines and reduce exposure as much as possible, minimize exposure time and beam size, and maximize shielding and distance from the beam. Non-essential people should not be in the suite during fluoroscopy, particularly when "runs" are performed as the radiation exposure levels are often increased. Radiation dosimetry badges should be worn and regularly evaluated to monitor for increased exposure.

Standard fluoroscopy, available on most veterinary multi-purpose and mobile C-arm units, is acceptable for the more common respiratory, urinary, and gastrointestinal procedures. Digital subtraction angiography (DSA) is highly recommended (and some might say required) for the vascular procedures, particularly when

performed in small caliber vessels with overlying boney and/or gas-filled structures that might otherwise interfere with image resolution. DSA is a computer software–processing program that takes an initial non-contrast fluoroscopic image (the "mask") and subtracts it from subsequent images during a "run" (or series of recorded images). This permits improved vascular imaging and resolution without overlying structures obscuring the view, allows the operator to access smaller structures more reliably, and requires much less contrast than would be necessary otherwise (Figure 120-1). DSA is required for super-selective angiograms of small caliber vessels and those vessels in the head (or where there is substantial bone which makes angiogram visualization difficult), particularly when delivering toxic (chemotherapy) or embolic substances that could reflux into, or enter, non-target vessels leading to vital structures. "Road-mapping" capabilities on some systems permit saving these contrast studies and placing them over real-time fluoroscopy images to provide a "vascular map" for guide wire, catheter, embolic, or stent manipulations.

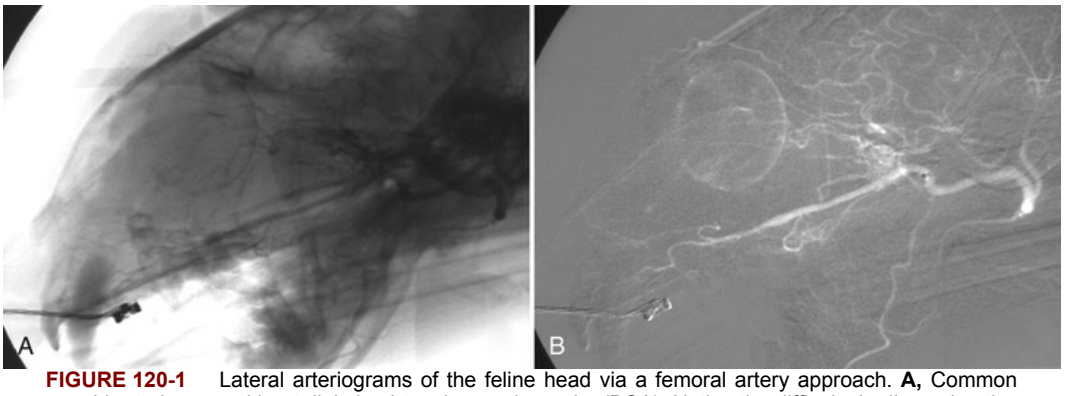

FIGURE 120-1 Lateral arteriograms of the feline head via a femoral artery approach. **A,** Common carotid arteriogram without digital-subtraction angiography (DSA). Notice the difficulty in discerning the small, complex vasculature. **B,** The same common carotid arteriogram using DSA to remove the underlying boney structure of the skull. Notice the clearly defined vascular anatomy now evident. (From Weisse C, Mayhew P: Basics of minimally invasive surgery. In Tobias KM, Johnston SA, editors: *Veterinary surgery: small animal*, St Louis, 2012, Elsevier.)

Endoscopy

The most common endoscopes used during IE procedures are rigid rod-lens cystoscopes and flexible fiberoptic ureteroscopes. Rigid cystoscopy using telescope diameters ranging from 1.9 to 6.5 mm is commonly performed in female animals to aid in urethral, urinary bladder, and ureteral access (see ch. 124). Similar scopes are used for antegrade rhinoscopy (see ch. 96). The scope sheath provides a smooth rounded edge to protect the mucosa and the telescope, as well as provides three separate ports for fluid irrigation, fluid drainage and a working channel for passage of a wide variety of interventional devices (biopsy forceps, needles, baskets, laser fibers, guide wires, stents, etc.). The 30° angle of view is the most commonly used cystoscope/rhinoscope allowing excellent visualization of the nasal cavity and bladder wall, as well as the ureteral orifices. Flexible ureteroscopes (2.5-2.8 mm diameter with a 1 mm working channel) are used for lower urinary tract access in male dogs and for ureteral access in dogs >18 kg. These scopes tend to have considerably diminished image resolution (compared to the rod-lens technology of rigid scopes), smaller working channels limiting devices and irrigation, and weaker illumination.

Ancillary Imaging Equipment

Aside from the endoscopes, a "tower" will be a necessary capital investment. This is a multi-tiered cart comprised of the camera control box, light source, monitor, and often data recording devices. Light sources are typically halogen or xenon with the latter being preferred due to closest similarity to natural light. If possible, multiple monitors (or at least a single monitor on an articulating arm/platform) are recommended to facilitate observation from multiple locations around the surgical table as these patients vary in size, positioning, and entry site among the wide variety of procedures currently performed. Designing the interventional suite with as much flexibility as possible will maximize the usefulness of the room. It is much easier to move the monitor than to relocate the often-cumbersome endoscopy towers. Data recording devices have become routine components allowing storage of images and videos of the procedures, recommended to

be saved as part of the patient record and facilitating review at a later date if/when procedures need to be repeated. Endoscopes are typically gas- (or sometimes cold-) sterilized; sterilization is necessary prior to any endourological procedures. Occasionally, ultrasonography is useful for percutaneous needle access into vessels or other structures such as the renal pelvis or percutaneous urethral access.

IR/IE Instrumentation

Access

Prior to any interventional procedure, luminal access is first necessary. This is the first and perhaps one of the most important parts of any interventional procedure as the chosen access location can make a difficult procedure easy, or an easy procedure difficult. Venous access is often performed percutaneously, while vascular cut-down for access to the femoral artery (or branches) or carotid artery is performed to permit arterial ligation at procedural completion. Ligation of the femoral and carotid arteries is safely tolerated in dogs and prevents post-operative hemorrhage that can be significant in animals often discharged the same day. Although reported otherwise, ligation of both carotid arteries in dogs may not be universally tolerated.[4] Some cats have safely tolerated ligation of both carotid arteries. Standard intravenous catheters or entry needles can be used for vascular access. "Gauge" is defined as the number of needles or catheters that can be placed next to one another to sum up to 1 inch; therefore larger gauge needles have smaller lumens. For instance, a 22 gauge needle has a smaller lumen than an 18 gauge needle. Once more experienced in these procedures, the operator will soon memorize which catheters accommodate suitable guide wire diameters. A "single-wall puncture" or "modified Seldinger" technique is preferred for vascular access to avoid double wall vessel perforation, particularly in coagulopathic patients in whom additional vascular punctures could increase the risk of hematoma formation.

Guide Wires

Once vascular access is achieved, or a targeted orifice (e.g., the ureterovesical junction [UVJ]) is identified, guide wire access is obtained. Standard spring guide wires (polytetrafluoroethylene [PTFE/Teflon], stainless steel, nitinol, etc.) are available in a wide range of diameters, lengths, stiffness, tip configurations, and surface coatings (Figure 120-2). In general, the guide wires currently used in veterinary patients range from 0.014″ to 0.038″ diameter and lengths from 150 cm to 300 cm. For larger vessels or lumens, access is typically obtained with an 18 gauge catheter followed by 0.035″ or 0.038″ guide wire placement. In smaller vessels or lumens, access may be obtained more easily and safely with a 22 gauge catheter followed by a 0.018″ guide wire. Urethral and ureteral luminal access is often achieved using similar angled hydrophilic guide wires[a] in the 0.018 to 0.035″ diameter range depending upon patient size.

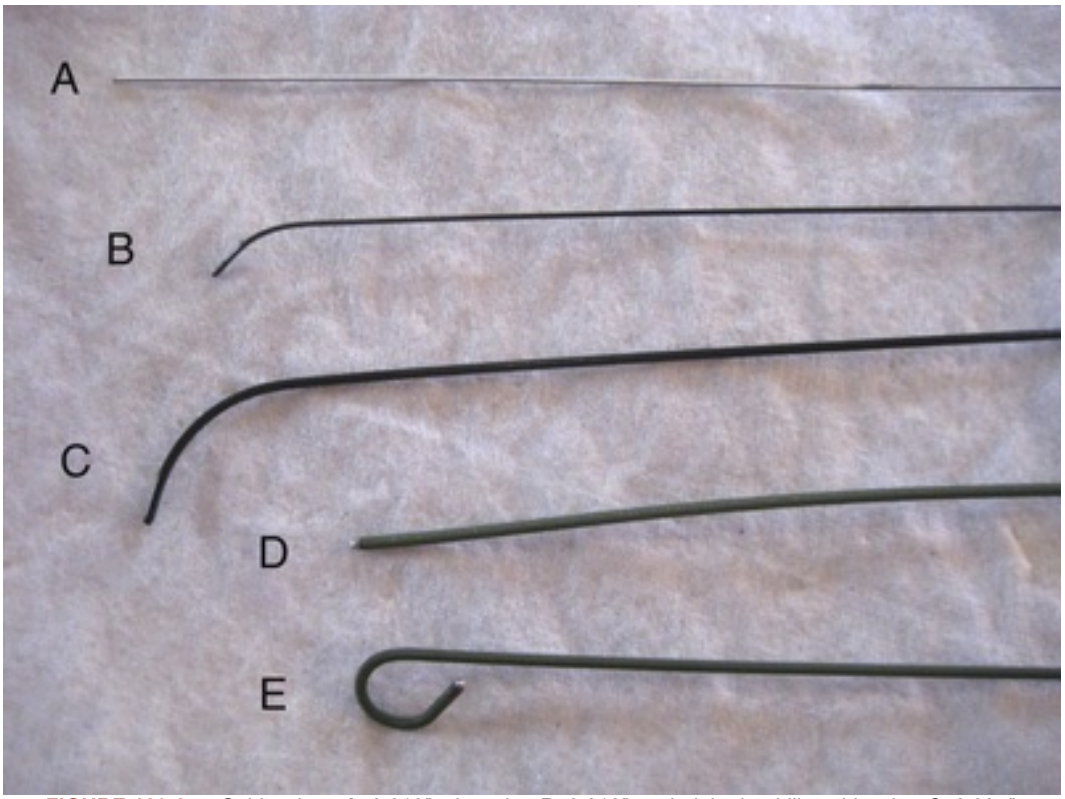

FIGURE 120-2 Guide wires. **A,** 0.018″ microwire. **B,** 0.018″ angled, hydrophilic guide wire. **C,** 0.035″ angled, hydrophilic guide wire. **D,** 0.035″ straight PTFE wire. **E,** 0.035″ Rosen PTFE wire.

Introducer Sheaths

Introducer sheaths[b] are composed of the sheath (basically a catheter), the associated dilator, a hemostasis valve, and a side port (Figure 120-3). They are used for almost all vascular procedures (see ch. 122), particularly those in which multiple devices may be exchanged, to permit safe, controlled, dilation of the entry vessel and subsequent protection from vascular damage or hemorrhage during the procedure. The side ports permit simultaneous flushing or sampling or contrast angiography if necessary. The check flow diaphragm prevents back-bleeding through the sheath while permitting placement of various sized catheters, balloons, stent delivery systems, or other devices that could otherwise result in trauma to the vessel or surrounding tissues. Sheaths are unique in that they are named for their inner diameters (ID) compared to all other devices that are named for their outer diameters (OD). This helps the operator choose what size sheath will be necessary for placement of a certain size stent delivery system, for instance. The typical sizes used range from 4-12 French (Fr). Three Fr is equal to 1 mm; therefore, a 6 Fr sheath has a 2 mm inner diameter but its outer diameter will be larger depending upon the thickness of the sheath. The author commonly uses introducer sheaths for endourological procedures as well, placing them in the urethra, up the ureter, and even percutaneously into the kidney, or into the urethra during perineal access (see ch. 124).

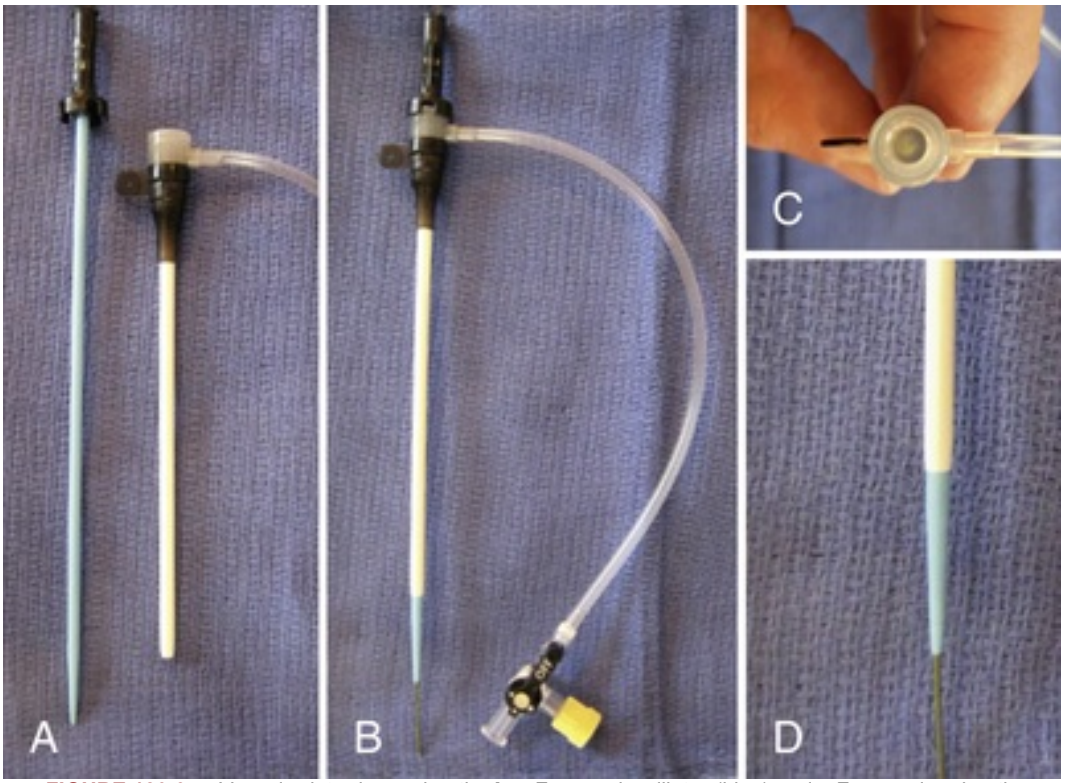

FIGURE 120-3 Vascular introducer sheath. **A,** 7 Fr vascular dilator (blue) and 7 Fr vascular sheath (white). **B,** Vascular sheath with vascular dilator and guide wire in place. **C,** Diaphragm of vascular sheath with dilator removed, demonstrating hemostasis valve. **D,** Tip of vascular sheath with dilator placed over guide wire. Notice the smooth transition from the sheath to the dilator and down to the diameter of the guide wire. (From Weisse C, Mayhew P: Basics of minimally invasive surgery. In Tobias KM, Johnston SA, editors: *Veterinary surgery: small animal*, St Louis, 2012, Elsevier.)

Selective Catheters

Selective catheters are used in combination with compatible guide wires to select different structures in order to perform contrast studies, obtain samples, or deliver materials (Figure 120-4). Pre-shaped angiography catheters are routinely 4 or 5 Fr and tapered to 0.035″ or 0.038″ guide wires. Most catheters are end-hole only (to prevent embolic delivery anywhere besides the tip of the catheter) but some have multiple side holes useful for power injection of contrast in high-flow vessels such as for cardiac angiography (pigtail catheters for instance; see ch. 122). The most commonly used catheter shapes include the hockey stick tip ("Berenstein")[c] and C-shaped or "Cobra"[d] tip. For access into vessels originating at very acute angles, reverse-curve catheters can be used in which the tips are angled backwards. Microcatheters[e,f] (typically 3 Fr or less) are used in combination with microwires[g,h] (typically 0.014″-0.018″) and passed coaxially through the pre-shaped catheter in order to access second- or third-generation vessels without causing vessel occlusion or spasm.

FIGURE 120-4 Selective catheters. **A,** Marker pigtail catheter. Note the radio-opaque markers on the shaft as well as the multiple fenestrations permitting rapid contrast injection without fear of damage to the vessel wall compared to an end-hole catheter. **B,** Rim (reverse-curve) catheter ideal for access from one external iliac artery to the ipsilateral internal iliac or contralateral external or internal iliac arteries. **C,** Cobra-type catheter with gentle bend facilitating access into first-order arterial branches off the aorta or vena cava. (From Weisse C, Mayhew P: Basics of minimally invasive surgery. In Tobias KM, Johnston SA, editors: *Veterinary surgery: small animal*, St Louis, 2012, Elsevier.)

Balloons

Occlusion balloons (low pressure, high compliance) are used for temporary occlusion of a vessel to facilitate angiography or redirect embolization materials away from a non-target organ. These balloons can also be used as flow-directed catheters to allow blood flow to direct the catheter towards difficult to access sites, particularly in cardiac interventions (see ch. 122). Balloon angioplasty catheters[i] (high pressure, low compliance) are typically filled with dilute contrast agent under pressure in order to dilate and efface strictures or stenoses of the blood vessels or other lumens such as the esophagus, rectum, nasopharynx, trachea, or urethra (see ch. 121, 123, and 124).

Drainage Catheters

Drainage catheters provide surgical or percutaneous removal of fluid collections (e.g., pleural fluid, peritonitis, abscess, etc.) or diversionary procedures (e.g., nephrostomy, cholecystostomy, gastric, etc.). Both locking- and non–locking-loop conformations are available and can be placed using a modified Seldinger technique (over the guide wire) or a trocar technique (direct puncture). The locking-loop catheters[j] are

typically preferred due to the suture locking mechanism that secures the catheter loop, minimizing premature catheter withdrawal (Figure 120-5). More recently, a subcutaneous ureteral bypass (SUB)[k] device has been described, composed of a locking-loop nephrostomy and cystostomy tube connected subcutaneously to divert urine around ureteral obstructions (Figure 120-6) (see ch. 124).[5,6]

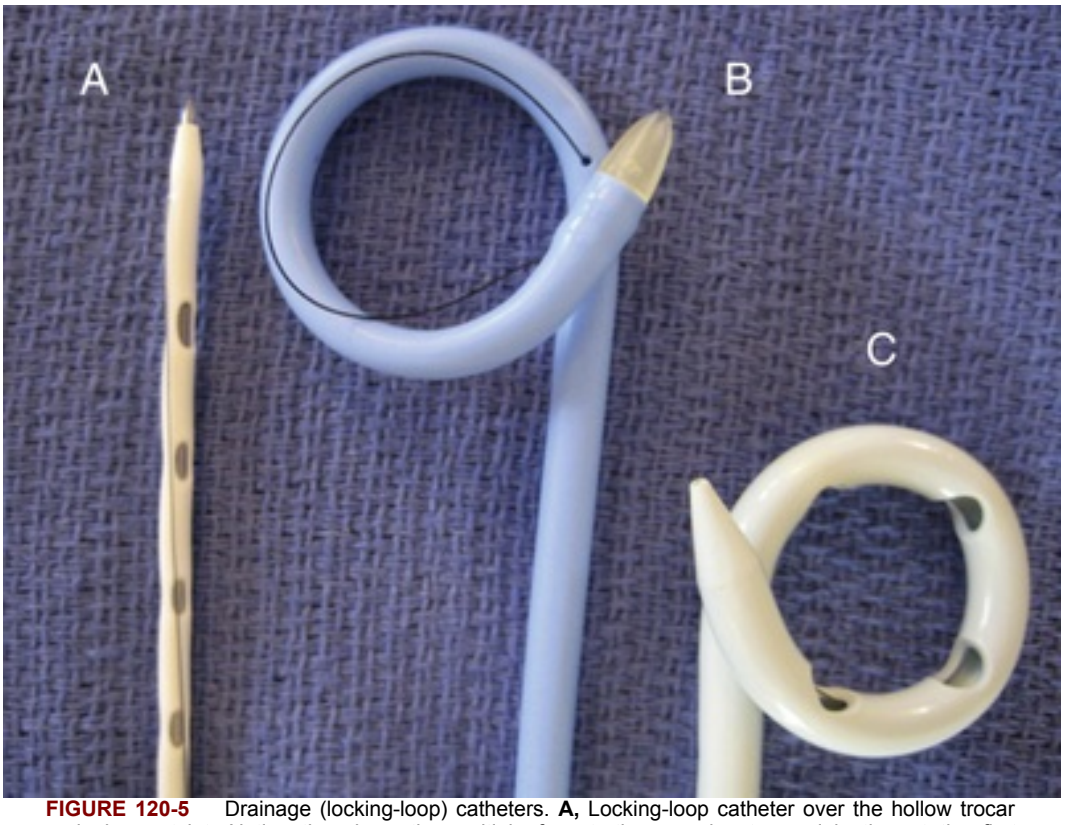

FIGURE 120-5 Drainage (locking-loop) catheters. **A,** Locking-loop catheter over the hollow trocar and sharp stylet. Notice the sharp tip, multiple fenestrations, and suture originating at the first fenestration and extending proximally to the most proximal fenestration. **B,** Similar locking-loop catheter with stylet and hollow trocar removed. Notice the retaining suture currently loose. **C,** Similar locking-loop catheter with retaining suture locked tight, drawing proximal and distal fenestrations together and forming a secure loop with internalized fenestrations to facilitate drainage. (From Weisse C, Mayhew P: Basics of minimally invasive surgery. In Tobias KM, Johnston SA, editors: *Veterinary surgery: small animal*, St Louis, 2012, Elsevier.)

Two nephrostomies and a urethral catheter placed following radical excision of the urinary bladder, distal ureters and proximal urethra.

Stents

Stents are tubular structures designed to re-establish patency of a lumen that has become obstructed. They are available in a variety of materials, shapes, sizes, and designs that define their suitability for a particular structure or environment.

Stents can be most easily categorized by some of their properties including material (metallic versus non-metallic) and design (self-expanding versus balloon expandable and/or covered versus uncovered) (Figure 120-7). An individual stent is typically named for its diameter and length. Metallic (or similar) stents are typically supplied pre-mounted within a delivery system (self-expanding stents) or on a balloon catheter (balloon-expandable stents). Delivery systems are named for their outer diameters and can sometimes limit the ability to place the associated stent in our smaller veterinary patients.

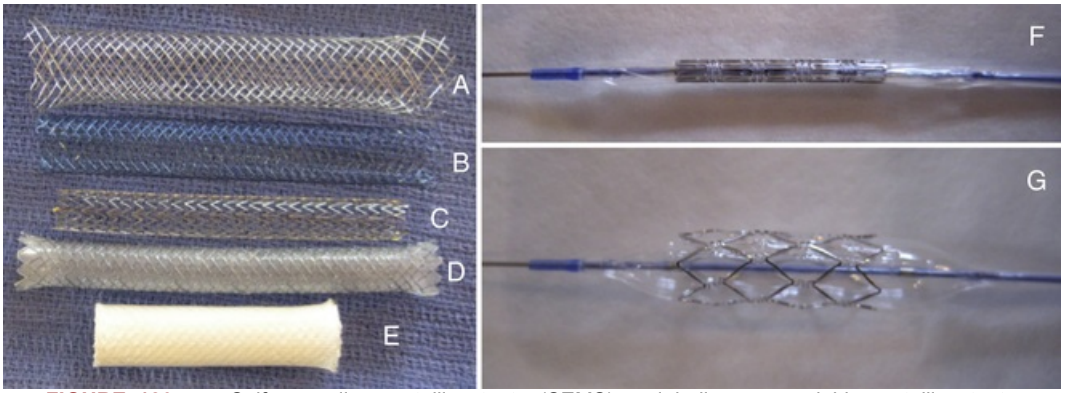

FIGURE 120-7 Self-expanding metallic stents (SEMS) and balloon-expandable metallic stents (BEMS). **A,** Stainless steel mesh SEMS (Wallstent, Boston Scientific Corporation). **B,** Nitinol mesh SEMS (Vet Stent-Trachea, Infiniti Medical, LLC). **C,** Nitinol laser-cut SEMS (Vet Stent-Urethra, Infiniti Medical, LLC). **D,** Silicone covered nitinol mesh stent graft (Vet Stent, Infiniti Medical, LLC). **E,** Polyester covered mesh stent graft (Wallgraft, Boston Scientific Corporation). **F,** BEMS compressed

onto percutaneous transluminal angioplasty balloon before dilation. **G,** Expanded BEMS subsequent to balloon dilation. (From Weisse C, Mayhew P: Basics of minimally invasive surgery. In Tobias KM, Johnston SA, editors: *Veterinary surgery: small animal*, St Louis, 2012, Elsevier.)

Self-expanding metallic stents (SEMS) are the most commonly used stents in veterinary medicine and their use has been described clinically (or experimentally) in the respiratory, cardiovascular, urinary, gastrointestinal, and hepatobiliary tracts of animals (see ch. 121-124). Mesh SEMS, composed of an interwoven strand (or strands) of fine wire, are most commonly used for tracheal stenting but can be used elsewhere in the body. In general (but not uniformly), mesh SEMS[l] are "reconstrainable," meaning at some defined point before complete deployment the stent can be recaptured within the delivery system and repositioned or removed. This functionality is particularly useful when imprecise positioning would be unacceptable. Unfortunately, these same stents typically undergo a variable degree of "foreshortening" encountered during stent deployment. As the stent expands during release from the delivery system it will shorten to assume its ultimate diameter and length. This shortening will depend upon the degree to which the stent ultimately expands within the lumen and can often be difficult to predict exactly, particularly by more novice operators. Reconstrainability and foreshortening must be understood and anticipated when mesh SEMS are being used. Woven or braided SEMS are also made from metallic wire but often of much thinner gauge to create a softer, almost fabric-like stent, and currently are not widely used in veterinary medicine; however, they have been used in the respiratory and gastrointestinal tracts of veterinary patients. Laser-cut SEMS[m,n] are produced from a narrow tube of metal in which a laser cuts the stent design that is later expanded to create the ultimate stent dimensions. Following a finishing and coating process, the stent is cooled and crimped onto a low-profile delivery system to permit placement through small entry sites. Upon reaching body temperature, the crimped nitinol (or similar shape-memory metal) stent changes properties and resumes its original stent diameter and length. These characteristics have revolutionized stent design and the laser-cut stents are one of the most commonly used SEMS in interventional radiology. These stents are rarely reconstrainable and have minimal foreshortening permitting precise placement across focal lesions, although once deployment from the delivery system begins the process cannot be reversed. In veterinary medicine, laser-cut SEMS are most commonly used in the urethra[7] or vasculature.[8,9] Grafts, or stent grafts, refer to stents with coatings or coverings (covered stents) such as silicone and various types of polytetrafluoroethylene (Teflon/PTFE) materials placed inside, outside, or surrounding the underlying metal structures. While these stents can be useful to prevent ingrowth of strictures or tumors through the stent interstices, disadvantages such as increased cost, larger delivery systems, and risk of occluding adjacent lumens particularly in the vascular systems generally limit their routine use.

Balloon-expandable metallic stents (BEMS)[o] are pre-mounted (compressed) onto a balloon catheter, positioned across the lesion, and as the balloon is inflated the stent expands. The balloon is then deflated and removed and the stent remains in place. BEMS are ideal for precise placement of short, rigid stents in areas that are not likely to be compressed externally. Disadvantages include the relatively short lengths available, poor flexibility, and static response to compression (i.e., if compressed the stent will remain compressed and not expand). BEMS are routinely used for nasopharyngeal stenoses (short strictures often surrounded mostly by bone) and occasionally elsewhere.[10]

Non-metallic stents (Figure 120-8) are primarily constructed of different polyurethane compounds for use in the urinary tract (e.g., ureteral stent) or bioabsorbable compounds (e.g., polydioxanone, etc.).[11] Ureteral stents[p] are available in a variety of sizes, lengths, configurations, and durometers (a measure of the material stiffness). These stents are placed over a guide wire and positioned with the use of a "pusher" catheter that advances over the guide wire behind the stent. Ureteral stents can be placed surgically, endoscopically, or percutaneously, and either temporarily (e.g., following shockwave lithotripsy of a nephrolith, or after ureteral reanastomosis) or permanently (e.g., for neoplastic obstruction or ureteroliths).[2,12]

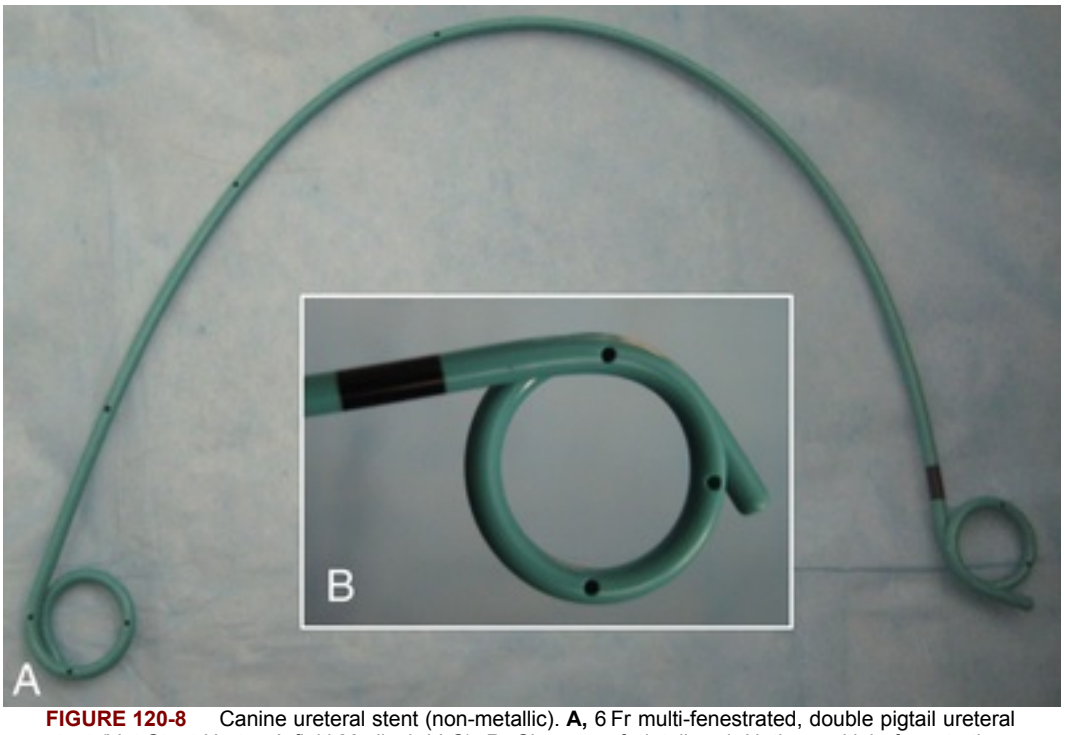

FIGURE 120-8 Canine ureteral stent (non-metallic). **A,** 6 Fr multi-fenestrated, double pigtail ureteral stent (Vet Stent-Ureter, Infiniti Medical, LLC). **B,** Close-up of pigtail end. Notice multiple fenestrations to facilitate urine drainage. (From Weisse C, Mayhew P: Basics of minimally invasive surgery. In Tobias KM, Johnston SA, editors: *Veterinary surgery: small animal*, St Louis, 2012, Elsevier.)

Embolics

Embolics are compounds or devices used to obstruct blood flow to a structure in order to reduce hemorrhage, attenuate blood supply, occlude vascular anomalies, or improve local concentrations of certain chemical or biological substances via prolonged elution or delivery. These agents are most commonly classified as mechanical or particulate, temporary/biodegradable or permanent, and solid or liquid (see ch. 125).

The most commonly used embolics in veterinary patients are the permanent mechanical devices used for relatively large vessel occlusion such as thrombogenic embolization coils[q] and custom woven nitinol vascular plugs and occluders[r] (Figure 120-9) (see ch. 122). These coils are now available in multiple sizes, wire diameters, coil conformations (e.g., straight, helical, complex), and detachable versions. A variety of more complex occlusion devices that are reconstrainable, repositionable and removable, are available for congenital cardiac malformations (e.g., patent ductus arteriosus, atrial septal defect, ventricular septal defect, etc.) but have also been used elsewhere in the cardiovascular systems of veterinary patients.[13-16] Particulate and liquid embolics are used to embolize the higher-order vessels and capillary beds when more distal embolization is preferred for tumor ablation or vascular malformations.[17] This ensures more definitive distal tissue ischemia (and reduced risk of revascularization) but increases the risk of tissue necrosis. The most commonly used permanent particulate agents include polyvinyl alcohol particles[s] and more recently hydrogel microspheres.[t] These are available in various particle sizes ranging from 45 to over 1000 microns and embolization results from initial mechanical vascular occlusion followed by permanent fibrin ingrowth. A variety of drug-eluting hydrogel microspheres is available and these have been demonstrated to provide a controlled release of doxorubicin for weeks to months.

FIGURE 120-9 Various embolic agents. **A** and **B,** Vascular plugs of various sizes. **C,** Thrombogenic embolization coils in delivery catheter and deployed. **D,** Polyvinyl alcohol (PVA) embolic particles. **E,** Ethiodized oil liquid embolic.

Liquid embolics have the advantage of passing through the capillary beds of tumors and vascular malformations or lymphatics, permitting complete tissue destruction through to the venous circulation (see ch. 125). Glue (most commonly n-butyl cyanoacrylate)[u] has been used the most and has been reported for use in vascular arteriovenous fistulas, arteriovenous malformations, and thoracic duct embolizations[18] in veterinary patients. When mixed with ethiodized oil (Lipiodol)[v] in a 1 : 1 to 1 : 4 ratio, the polymerization rate can be slowed to mimic the speed of blood flow through the vascular bed; this is important to prevent embolization distal to the target site. The iodinated oil also lends radiopacity to the mixture. Care must be taken to avoid gluing the catheter into the vessel being embolized and additional training is recommended before attempting one of these procedures.

Laser

Lasers have become an increasingly important tool in veterinary surgery and interventional endoscopy for tissue ablation, coagulation, and stone management. The diode laser is a continuous laser that emits light at a wavelength of 980 nm. This type of laser energy has a high simultaneous absorption in water and hemoglobin making this a good laser for cutting and coagulating tissues such as during intramural ectopic ureter laser ablation or cutting the tissue of a persistent paramesonephric remnant (see ch. 124).[19] A holmium : YAG (Hol : YAG) pulsed laser falls in the near infrared portion of the electromagnetic spectrum (2100 nm) with the energy absorbed in <0.5 mm of fluid, making it an ideal surgical laser for endourologic applications like laser lithotripsy. The laser energy is delivered to the surface of the uroliths using flexible quartz fibers with

multiple different diameters (200, 365, 550 microns) guided through the working channel of small diameter flexible or rigid cystoscopes/ureteroscopes. The Hol : YAG laser combines tissue cutting and coagulation properties, as well as the ability to fragment stones upon contact.[20] Although the various commercial models of lithotripters vary slightly, the pulse duration, energy, and frequency chosen are based upon the particular application.

Contrast Agents

Low osmolarity, non-ionic iodinated contrast media such as iohexol[w] are most commonly used in interventional radiology. While ionic contrast agents are less expensive, the hypertonicity and associated cation (often sodium) can result in problems for those patients with concurrent renal or cardiac disease. Non-ionic contrast agents are not hypertonic and do not dissociate in solution and are therefore safer for compromised patients for intravascular use. The low osmolality of iohexol compared to ionic contrast media with similar iodine concentrations should result in fewer osmolality-related side effects. Iohexol is available with different iodine concentrations that should be reported when used; the author typically uses between 240 to 350 mgI/mL and often dilutes 1 : 1 or 2 : 1 saline : contrast. Complications associated with intravascular contrast media are typically mild and relatively uncommon but can include nausea, vomiting, pain, anaphylaxis, hemodynamic effects, and most notably nephrotoxicosis. Contrast-induced nephropathy remains incompletely understood but likely results from a combination of direct cytotoxicity and prolonged vasoconstriction and impaired renal vascular autoregulation.[21] For high-risk patients, alternatives to iodinated contrast media such as gadolinium or carbon dioxide can be considered. Patients should be well hydrated before use (Iohexol package insert)[22] and while a safe dosage has not been determined, the author tries to use less than 2-3 mL/kg during standard vascular interventional procedures.

Miscellaneous Devices

There are countless ancillary devices designed to facilitate minimally invasive procedures that are beyond the scope of this chapter. Examples include baskets and snares for retrieval of vascular or intraluminal foreign bodies or stones, biopsy devices, intra- and extracorporeal lithotripters, thrombectomy devices, and flow-switches or adapters to help perform coaxial procedures using microcatheters to name just a few.

CHAPTER 121

Respiratory Interventional Therapies

Matthew W. Beal

Client Information Sheet: Respiratory Interventional Therapies

Image-guided therapies have changed veterinary medicine in the past decade by providing alternatives to traditional surgical procedures in a minimally invasive fashion. These procedures often are performed through natural orifices, thus minimizing patient morbidity. Two of the most common respiratory interventions in veterinary medicine are tracheal stent placement for the management of tracheal collapse and nasopharyngeal balloon dilation with or without stent placement for the management of nasopharyngeal stenosis.

Tracheal Collapse

Introduction and Patient Selection

Tracheal collapse is a diffuse disease that affects the trachea, mainstem bronchi, and lobar bronchi. It is important to remember that all treatment of tracheal collapse is merely palliative, but that such palliation can be lifesaving when it dramatically improves the patient's clinical signs. Numerous approaches to treatment of tracheal collapse have been proposed, ranging from medical management to placement of extraluminal tracheal ring prostheses.[1] Recently, placement of intraluminal, self-expanding metallic stents (SEMS) has gained popularity and is currently the treatment of choice for management of tracheal collapse in dogs whose quality of life is compromised by manifestations of airway obstruction and cough or the medical management thereof (see ch. 241).[2-6]

There are four general phenotypes of the tracheal collapse syndrome that can present to veterinarians. One population of dogs presents with signs of airway obstruction. This is usually due to collapse of the cervical and thoracic inlet portions of the trachea. Stridorous breathing is most obvious during inspiration; however, stridor during both phases of respiration is common and suggests fixed airway obstruction. Airway obstruction in this population of dogs can be severe and can often lead to a vicious circle of dyspnea and worsening airway obstruction.[6] Severe episodes of airway obstruction can culminate in the need for emergency veterinary care including, but not limited to, sedation (acepromazine 0.02 mg/kg IV, butorphanol 0.3 mg/kg IV, or both), oxygen therapy (see ch. 131), cooling measures, and corticosteroids and/or antibiotics if needed. Some dogs will require emergency intubation to bypass the obstruction, and potentially require emergency tracheal stent placement. Although the phenotype of this population is airway obstruction, it is important to recognize that there is, very often, some degree of intrathoracic collapse and cough as well.[7] Despite the concurrent intrathoracic disease, intraluminal tracheal stent placement is highly effective at relieving airway obstruction and alleviating clinical signs of dyspnea. This population would also be amenable to extraluminal tracheal ring prostheses. Until a definitive work evaluating both acute and long-term outcomes is completed comparing similar populations of dogs managed with prosthetic rings versus those managed with intraluminal tracheal stent placement, we will not know the superiority of one procedure over the other.

A second population of dogs with tracheal collapse tends to be older and presents purely with cough and very little, if any, evidence of airway obstruction (no stridor). The phenotype of these dogs is intrathoracic collapse with cough. This population is least amenable to stent placement because the airways beyond the stent continue to collapse. This population is optimally managed medically (see ch. 124). Clinical signs usually can be controlled for many years in this population.

The third population of dogs is a combination of the first two populations. They manifest with both airway

obstruction and severe cough. In this patient population, tracheal stent placement will relieve the airway obstruction component of the disease, thus improving clinical signs, but it will not relieve the cough that is associated with collapse of the intrathoracic airways including the mainstem and lobar bronchi. However, persistent cough can be controlled through medical management.

A fourth and final population of dogs presents with inspiratory and expiratory dyspnea consistent with fixed airway obstruction resulting from tracheal ring malformation/inversion. In this condition, rather than collapsing dorsoventrally, dorsal collapse is accompanied by inversion of the ring ventrally, giving the entire ring a "w" shape cross-sectionally. Based on the author's experience, the Yorkshire Terrier appears to be the breed most affected by this condition. Dogs with this problem commonly present for evaluation of a "tracheal mass" due to a soft tissue density emanating from the ventral trachea as seen on lateral cervicothoracic radiographs (Figure 121-1, *A* and *B*). Tracheal stent placement in this condition is not recommended because it is difficult to evert the inverted segment of the ring even with substantial balloon dilation of the tracheal stent once in place. As a consequence, the stent might not contact the tracheal mucosa over the full 360° of its circumference, thus predisposing to recurrent infection and potentially inflammatory tissue formation. Prosthetic ring placement should be considered in this patient population.

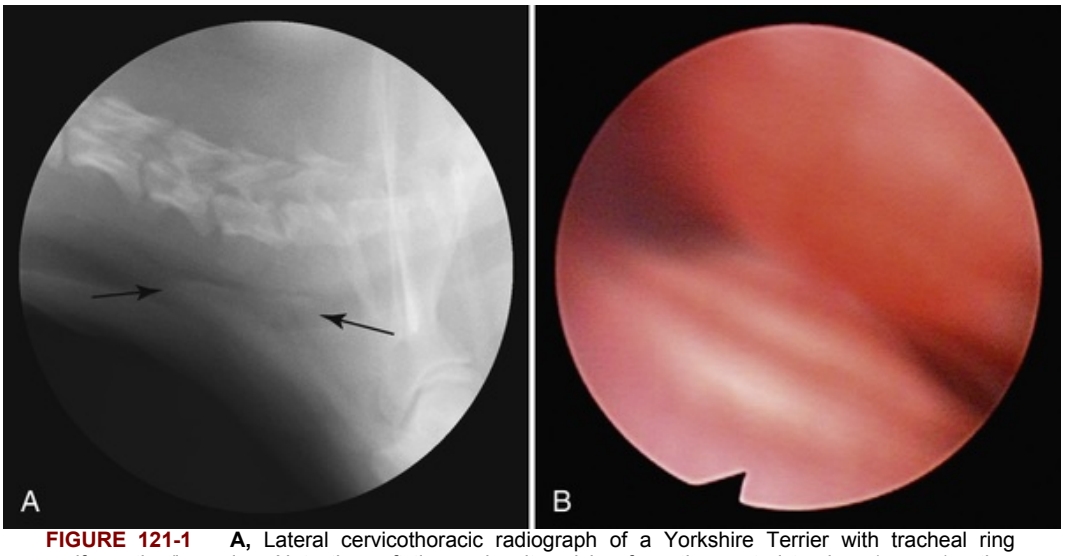

FIGURE 121-1 **A,** Lateral cervicothoracic radiograph of a Yorkshire Terrier with tracheal ring malformation/inversion. Note the soft tissue density arising from the ventral trachea (arrows) rather than the typical dorsoventral flattening seen in most dogs with tracheal collapse. **B,** Endoscopic view of the dog in **A.** Notice the ventral tracheal ring bulging dorsally into the lumen (5 to 9 o'clock positions).

Diagnostic Evaluation

Diagnostic evaluation is critical to select the ideal patient populations for tracheal stent placement. Thoracic radiography, fluoroscopy, oropharyngeal and laryngeal examination, and tracheobronchoscopy routinely allow for optimal characterization of the disease process affecting the large airways of dogs presenting with clinical signs consistent with, or a known complaint of, tracheal collapse.

Imaging performed using negative pressure ventilation has been described and is used by some for evaluation of the extent of tracheobronchial collapse, but fluoroscopic evaluation of the spontaneously breathing patient is of excellent diagnostic utility and is very physiologically useful to help assess the structural changes in the trachea during spontaneous breathing, stridor, and cough. Fluoroscopic studies should include a true lateral evaluation of the pharynx to rule out pharyngeal collapse, evaluation of the entire trachea, carina, and mainstem bronchi during all phases of respiration, during stridor (if present), and during cough. The region of collapse should be identified in reference to static anatomic landmarks such as vertebral bodies. During stent placement, these reference points can be utilized to ensure that the stent covers the most severely affected portion of the trachea.

Oropharyngeal and laryngeal examinations are performed to rule out concurrent laryngeal collapse, dysfunction, or other structural abnormalities. Additional upper airway abnormalities including, but not limited to elongation of the soft palate, upper airway neoplasia, and epiglottic retroversion, can be identified

concurrently.

Tracheobronchoscopy allows for detailed evaluation of the lumen of the trachea, grading of the severity of collapse in each anatomic region of the trachea and mainstem bronchi, as well as identification of other lesions including tracheal ring malformation/inversion and the presence of mass lesions due to neoplasia.

Treatment

A variety of different types of stents has been placed into the tracheal lumen of dogs with tracheal collapse.[2-6] The current recommendation is the utilization of a commercially-available mesh, self-expanding metallic stent made from nitinol.[a] Most of the stents utilized for the palliation of clinical signs of tracheal collapse in veterinary medicine come in a uniform diameter design or in a tapered design[b] in which the cervical portion of the stent is wider than the thoracic portion. The tracheal conformation of many dogs is tapered, and, as a result, a tapered design will allow the entire stent to expand closer to its nominal (relaxed) diameter. This can make the stent less susceptible to failure.

With the patient placed under routine general anesthesia using an endotracheal tube that includes a radiopaque marker to improve visualization, the patient should be placed in true lateral recumbency on a fluoroscopy table, with the neck extended such that the entire trachea is straight. The cricoid cartilage should be visualized fluoroscopically, as should the carina. An esophageal marker catheter[c] should be positioned over a hydrophilic guidewire[d] in the esophagus to serve as a reference for calibration of measuring tools (Figure 121-2, *A*). Use of an esophageal marker catheter is critical to obtaining appropriate measurements. The endotracheal tube should be repositioned just beyond the larynx (see Figure 121-2, *A*); often the cuff of the endotracheal tube resides within the larynx. Next, the anesthetist should deliver a positive pressure breath that is held at 20 cm H_2O and a static image should be acquired. This image will be used for identifying the maximum tracheal diameter in the cervical, thoracic inlet, and intrathoracic regions. Making multiple measurements from additional images will help ensure appropriate sizing (Figure 121-2, *B*). Computed tomography can also be utilized for optimal stent sizing, as radiographic measurements of tracheal stent size may underestimate true tracheal dimensions by approximately 1 mm.[8]

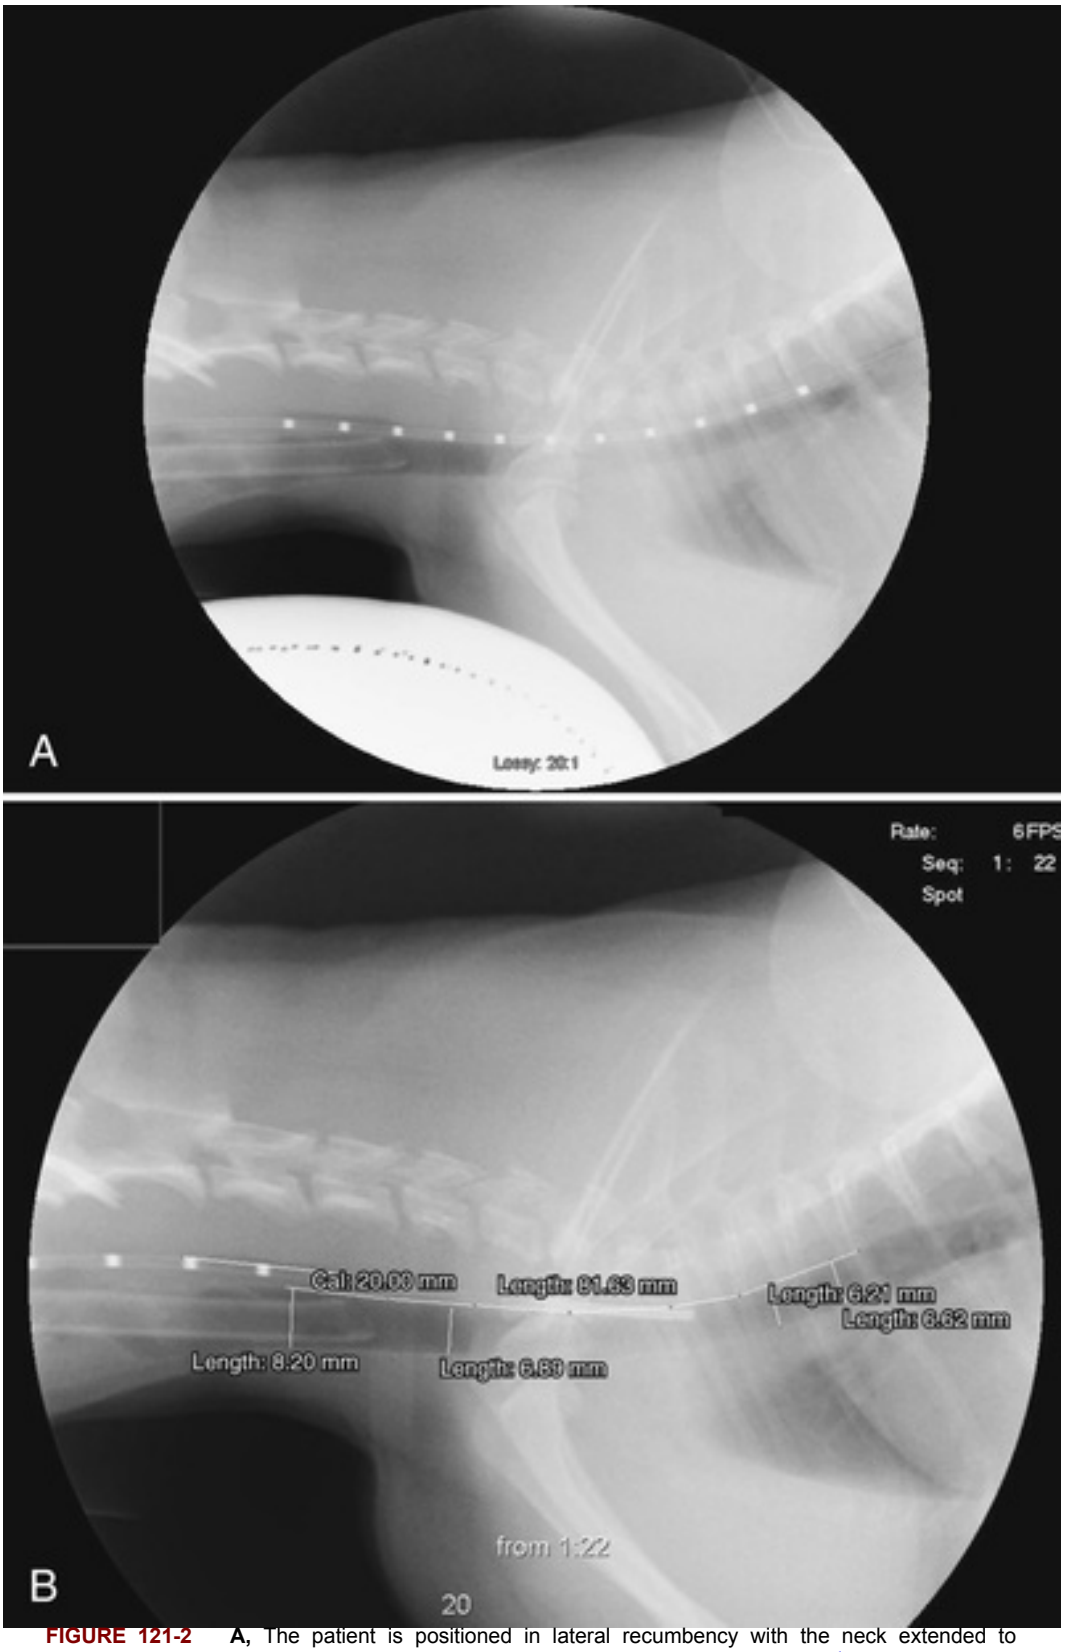

FIGURE 121-2 **A,** The patient is positioned in lateral recumbency with the neck extended to straighten the trachea. A 5 Fr marker catheter[c] has been placed over a guidewire[d] in the esophagus for calibration of measuring instruments. **B,** Measurements of the cervical, thoracic inlet, and intrathoracic tracheal diameters as well as length are made during a 20 cm H_2O positive-pressure breath.

When selecting a uniform diameter stent, a stent diameter should be chosen that is 10% to 20% greater than

the maximal tracheal dimension (usually the cervical measurement). A tapered stent may be considered when the difference in tracheal diameter is >2 mm between the cervical and intrathoracic trachea. A tapered stent may be selected that is 10% to 20% greater in diameter than both the cervical and intrathoracic measurements.

The primary goal when choosing stent length is to appropriately span the entire portion of the trachea that, based on diagnostic evaluation, shows significant collapse. Anatomic boundaries of the region(s) of collapse that were referenced during diagnostic evaluation are used for determining the boundaries of the length of the trachea that needs to be covered by the stent. Measurements of this length are determined (see Figure 121-2, *B*). Because the entire trachea is most often affected to some degree by tracheal collapse, the secondary goal is to span the entire trachea from approximately 1 cm caudal to the cricoid cartilage to approximately 1 cm cranial to the carina. Choosing stent length can be challenging because mesh self-expanding metallic stents foreshorten when deployed. This means that as the stent expands, it becomes shorter in length until it reaches its nominal diameter. For example, a 12 × 65 mm stent[a] is 12 × 65 mm when fully opened (nominal diameter); however, if it only opens to 10 mm, it will be 83 mm in length.[e] Because a stent size is chosen that is 10% to 20% greater in diameter than the maximal tracheal diameter, it should not expand completely, and, as a result, will be longer than the nominal length. When utilizing a tapered stent design, because the stent will more closely achieve its nominal diameter along its entire length, foreshortening is somewhat easier to predict. Shortening charts greatly aid the operator in choosing the appropriate stent length.[e]

Stent deployment most often is performed through a bronchoscope adapter placed between the endotracheal tube and the anesthesia circuit. This adapter allows for the maintenance of the connection to the anesthesia circuit during stent deployment. Tracheal stents most often are deployed using fluoroscopic guidance and according to manufacturer instructions (Video 121-1). Special caution must be exercised during deployment to ensure that the carina, cricoid cartilage, and the endotracheal tube locations are all visualized, such that the stent is deployed in the correct location. In most cases, the endotracheal tube is removed over the delivery system during the final stages of deployment and then very gently replaced using the delivery system as a stylet when the procedure is complete. Post-deployment radiographic imaging should be performed to ensure appropriate apposition of the stent to the tracheal mucosa (Figure 121-3). If there are obvious gaps, the stent can be gently "touched up" with the cuff of the endotracheal tube or using an appropriate diameter dilation balloon.

FIGURE 121-3 Post-deployment radiographs illustrating appropriate tracheal stent placement. The stent begins approximately 1 cm distal to the cricoid cartilage and spans the area of collapse determined through fluoroscopy.

When the tracheal stent is deployed in the appropriate location, the expected outcome is immediate and complete relief of airway obstruction. Because of the presence of a tracheal foreign body (stent) as well as

concurrent mainstem bronchial collapse in many dogs, coughing will occur or persist after stent placement. The author routinely administers hydrocodone (0.22 mg/kg PO q 6 h), a 2- to 4-week tapering course of prednisone (initiated at 0.5 mg/kg PO q 12 h), and a 10-14 day course of antibiotics with efficacy against *Mycoplasma* sp. Some degree of medical management may need to be continued to control coughing. Coughing can be a risk factor for stent fracture. Recheck examinations are generally performed at 1 and 3 months after the procedure to assess for stent shortening and to reassess clinical signs.

Complications

Complications after tracheal stent placement are well documented.[9,11-13] Acute complications (undersizing, malpositioning of the stent) are largely avoided through appropriate measuring, stent selection, and deployment and generally should not occur. Acute complications most often are dealt with by removing the stent and replacing it with an appropriately-sized and -positioned stent. Delayed complications that have been documented include stent shortening with collapse cranial to the stent, bacterial tracheitis, inflammatory tissue formation within the stent, and stent fracture.[5,10-13] Common manifestations of these signs are a recurrence of signs of airway obstruction or an acute or progressive worsening of cough. Owners should be warned at the time of discharge, and at each recheck examination, that evidence of these signs should immediately trigger reevaluation. Evaluation of return of airway obstruction or worsening of cough should include a thorough history and physical examination coupled with radiographic evaluation of the neck and thorax with the forelimbs positioned both cranially and caudally to allow for visualization of the tracheal lumen, which can help identify intraluminal inflammatory tissue formation or fracture (Figure 121-4). If the stent is not fractured, endoscopic evaluation of the tracheal lumen is performed to evaluate for inflammatory tissue formation and to acquire samples for aerobic and *Mycoplasma* sp. culture. Antibiotic therapy should be instituted based on results of this testing.

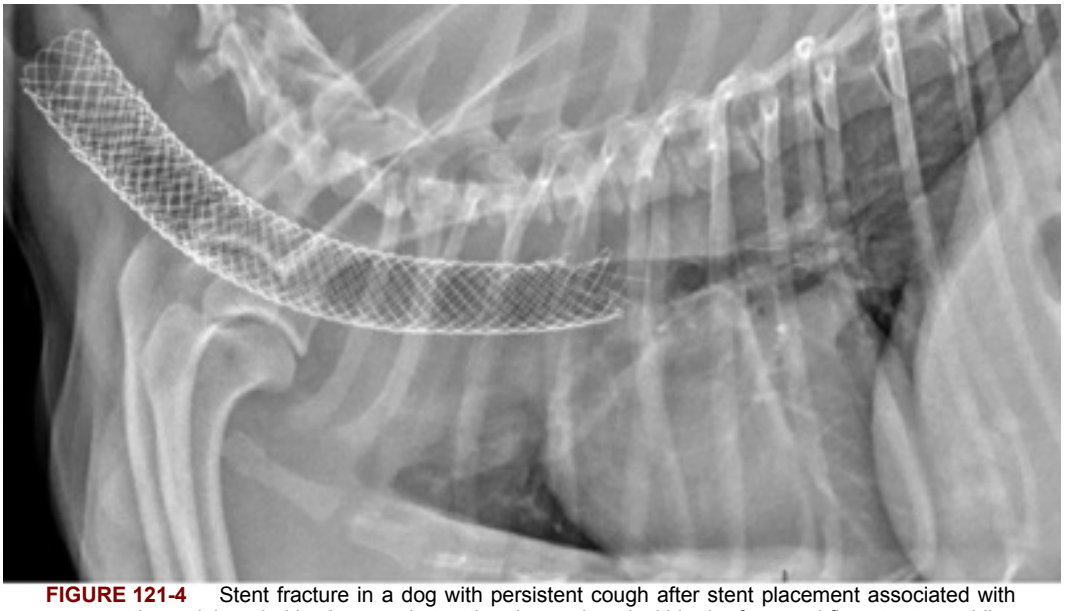

FIGURE 121-4 Stent fracture in a dog with persistent cough after stent placement associated with recurrent bacterial tracheitis. A second stent has been placed within the fractured first stent, providing an adequate tracheal lumen diameter.

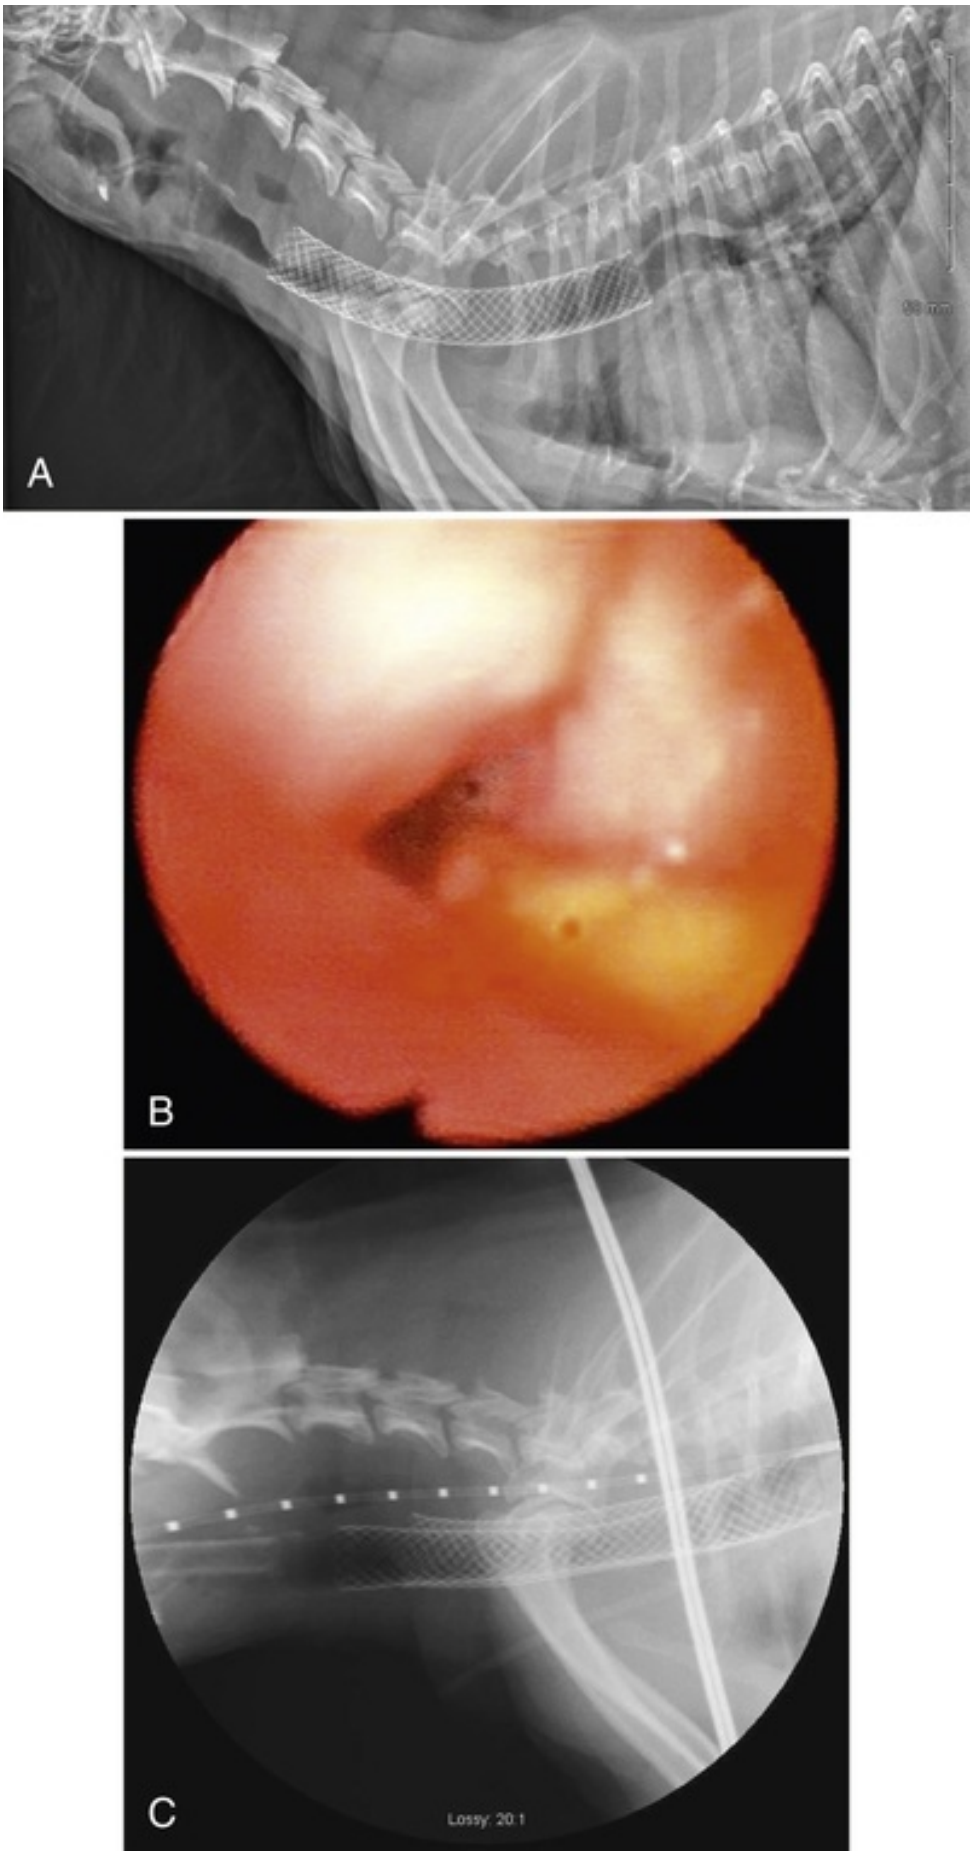
Identification of inflammatory tissue formation (Figure 121-5) within the stent is most often treated with high-dosage corticosteroids coupled with treatment of bacterial processes based on culture and sensitivity testing (see above).[10] In some cases, regression is possible, whereas in others it is not. If inflammatory tissue formation is causing significant signs of airway obstruction, deployment of a new stent of the same diameter to marginalize the inflammatory tissue to the periphery of the lumen will be necessary (Figure 121-5, *C*). Secondary stent placement for inflammatory tissue formation should always be coupled with concurrent medical management of this condition.



A
B
C
Lossy: 20:1

FIGURE 121-5 **A,** Lateral thoracic and cervical radiograph demonstrating a soft tissue opacity cranial to the stent, dorsally, and within the stent. **B,** Inflammatory tissue formation causing severe stenosis of the tracheal lumen in a dog with a tracheal stent placed 1 year prior. Note the ingrowth, especially in the right and left corners of the image, and very narrow lumen. Copious purulent material was also present in the lumen of the trachea. Cytologic examination was consistent with severe bacterial tracheitis. **C,** A second stent has been placed within the original stent and extends beyond the cranial edge of the original stent to marginalize the inflammatory tissue. Notice that the presence of inflammatory tissue within and cranial to the original stent prevents the second stent from opening completely and thus results in longer length.

Tracheal stent fracture is minimized through appropriate patient selection and stent sizing, and through improvements in stent design and manufacturing processes. In the event of stent fracture, the fractured stent can be stabilized by deployment of a stent of the same size within the original stent. It should be noted that the new stent will be slightly longer than the original because it will not achieve the same diameter as the original stent (Figure 121-5, *C*). In addition, when the new stent is placed, it must be placed through the true lumen of the original stent, rather than between the failed wires of the original stent.

Nasopharyngeal Stenosis

Etiology

Nasopharyngeal stenosis (NPS) is a narrowing or complete membranous occlusion of the nasopharynx (see ch. 238). Numerous etiologies have been reported, including upper airway infection, inflammation secondary to aspiration rhinitis (regurgitation or vomiting) or inflammation secondary to chronic rhinitis, trauma, surgery, expansile masses, or ulceration.[14] In one case series, 3/3 cats had concurrent lymphoplasmacytic rhinitis.[14] NPS can also be congenital, similar to choanal atresia. In dogs, regurgitation or vomiting with secondary aspiration rhinitis is the most likely etiology.[15]

Diagnostic Evaluation

NPS most often results in signs of stertor, gagging, inspiratory and expiratory difficulty (due to fixed airway obstruction), and nasal discharge. Inspiratory effort is often more severe than expiratory effort. These signs are coupled with the need to breathe through the mouth some or all of the time depending on the severity of the stenosis. When the mouth is opened manually, the stertorous breathing usually ceases. Signs are most often chronic.

Numerous diagnostic imaging modalities can aid in the diagnosis of NPS. Although lateral radiographic projections and positive contrast rhinography[16] may help, cross-sectional imaging (computed tomography [CT] or magnetic resonance imaging [MRI]) coupled with retroflexed rhinoscopy is the gold standard for diagnosis. Cross-sectional imaging allows for multiplanar reconstruction, which will allow for determination of the location of the stenotic lesion, its length, and measurement of the dimensions of the normal nasopharynx rostral and caudal to the stenosis (Figures 121-6, *A-D*). These measurements will aid in treatment planning. The most common site for NPS appears to be just caudal to the junction of the hard and soft palate.[14]

Treatment

Surgery was the early treatment of choice for NPS, but it has largely been abandoned in favor of minimally-invasive treatment options due to concerns about recurrence of stenosis after surgical intervention. Currently, balloon dilation with or without placement of a nasopharyngeal stent is the treatment of choice.[14-18] Balloon dilation and nasopharyngeal stent placement are best performed using fluoroscopic and endoscopic guidance concurrently. Balloon dilation may be attempted in all patients prior to nasopharyngeal stent placement; however, most imperforate lesions and those that are >1-2 mm thick are probably optimally managed by nasopharyngeal stent placement.

Balloon dilation for the management of NPS using a multipurpose dilation balloon or angioplasty/valvuloplasty balloon has been reported with mixed success.[14-16,18] Repeat balloon dilation (rather than stent placement) is the treatment of choice for stenotic lesions that are located in the mid- to caudal soft palate. Measurements of the normal nasopharynx rostral and caudal to the NPS are utilized to plan for the size of balloon needed. In reported feline cases, balloon dilation of NPS most often is performed with a 10-15 mm balloon[16-18]; a 10-12 mm balloon usually will be effective, with the smallest risk of injury. A 2 cm balloon length usually is adequate, but a 4 cm balloon might be necessary in some dogs. Because passage of guidewires, catheters, and other devices through the nose stimulates the patient, utilization of local or regional anesthetic techniques in addition to general anesthesia is advisable.

Using fluoroscopy, the patient is positioned in true lateral recumbency. Retroflexed rhinoscopy is performed to achieve continuous visualization of the stenotic lesion. A 0.035 inch (0.88 mm) × 150 cm angled-tip, standard-stiffness hydrophilic guidewire[d] is advanced from the nostril through the ventral meatus and across the NPS (if patent) (see Figure 121-6, *D*). The guidewire is then advanced into the distal esophagus. If the stenotic lesion is imperforate, a catheter or vascular sheath is advanced retrograde through the ventral nasal meatus and against the central portion of the NPS. A sharp two-part trocar catheter[f] is advanced through it and centrally across the membrane to create an opening that allows for passage of a guidewire. Fluoroscopic guidance and concurrent retroflexed rhinoscopic guidance are critical to ensure that the direction of puncture is appropriate to avoid penetration of the cranial vault. Depending on the size of the stenotic lesion, a 6- to 8-French vascular dilator may be advanced over the guidewire to pre-dilate the lesion. The vascular dilator is removed and the balloon dilation catheter is advanced over the guidewire. Retroflexed rhinoscopy and fluoroscopy can be utilized to ensure that the balloon is across the lesion. Using a pressure inflator,[g] the balloon is inflated with diluted iodinated contrast medium in saline. Inflation will result in visualization of a "waist" in the balloon at the location of the stenosis. Further inflation will result in a "loss of waist" as the stenosis is broken down. Inflation generally is held for approximately 2 minutes and is repeated 2-3 times. The balloon is removed over the guidewire and the nasopharynx is examined using retroflexed rhinoscopy to ensure that the stenosis is resolved. Oropharyngeal examination is performed to evaluate the palate for injury. Local endoscopic injection of triamcinolone (0.2 mg/kg) has been utilized and a tapering dosage of corticosteroids (prednisone or prednisolone initiated at 0.5 mg/kg PO q 12 h) is recommended.[14,15] In some animals, balloon dilation might need to be repeated if restenosis occurs. Balloon dilation with local infusion of mitomycin C might also help minimize the chance of recurrent stenosis.[14] It should be noted that if the stenotic lesion is imperforate, simple balloon dilation, although initially effective, is unlikely to result in long-term resolution of clinical signs due to recurrence of stenosis. Instead, covered stent placement will most likely be necessary (see below).

Nasopharyngeal stent placement has been described as a treatment option for management of NPS in dogs and cats.[14,16-19] A stent simply prevents the re-formation of the NPS. Stents used for NPS are available in various forms including balloon-expandable metallic stents (BEMS),[h] covered BEMS which have a covering (often polytetrafluoroethylene [PTFE, Teflon]) to prevent tissue ingrowth and restenosis, and silicone stents constructed from tubular silicone medical devices.[14,16-19] Covered BEMS are most often utilized when the

lesion is imperforate. Non-covered BEMS are utilized in most other lesions and are less expensive; however, they still carry a risk of tissue ingrowth and restenosis.

Placement of BEMS and covered BEMS is performed using a technique that is similar to that described above for balloon dilation. However, BEMS sizing is critical to prevent migration. A stent size should be chosen that is 10% to 20% larger than the normal nasopharynx rostral and caudal to the lesion. The stent should not extend to within 1 cm of the caudal aspect of the soft palate.[14] After placement of a guidewire[d] across the lesion (see Figure 121-6, *D*), balloon dilation should be performed as described above to a diameter of 4-6 mm, or approximately half the diameter of the normal adjacent nasopharynx, to ensure that the BEMS delivery system can be passed across the stenosis. A recommended technique is to pre-dilate the stenosis (see above), which will allow for over-the-wire placement of a vascular sheath across the lesion. The BEMS can then be placed into the vascular sheath and positioned within the sheath across the lesion. The sheath protects the stent while it is being positioned. Once the stent is in position, the sheath is retracted and the stent remains in position for deployment (Figure 121-7, *A* and *B*). A pressure inflator[g] is utilized for BEMS and covered BEMS deployment and is inflated as described above. A loss of waist indicates that the stenosis has been broken down. Retrograde rhinoscopy is utilized to confirm that the stenosis has been relieved (Figure 121-7, *C* and *D*). If a non-covered BEMS is utilized, a tapering dosage of corticosteroids as described above is indicated. It is critically important to recognize that BEMS and covered BEMS undergo plastic deformation. Dorsal digital pressure on the soft palate will deform the stent and obstruct the nasopharynx. In the event this occurs, the stent can be opened via balloon dilation.

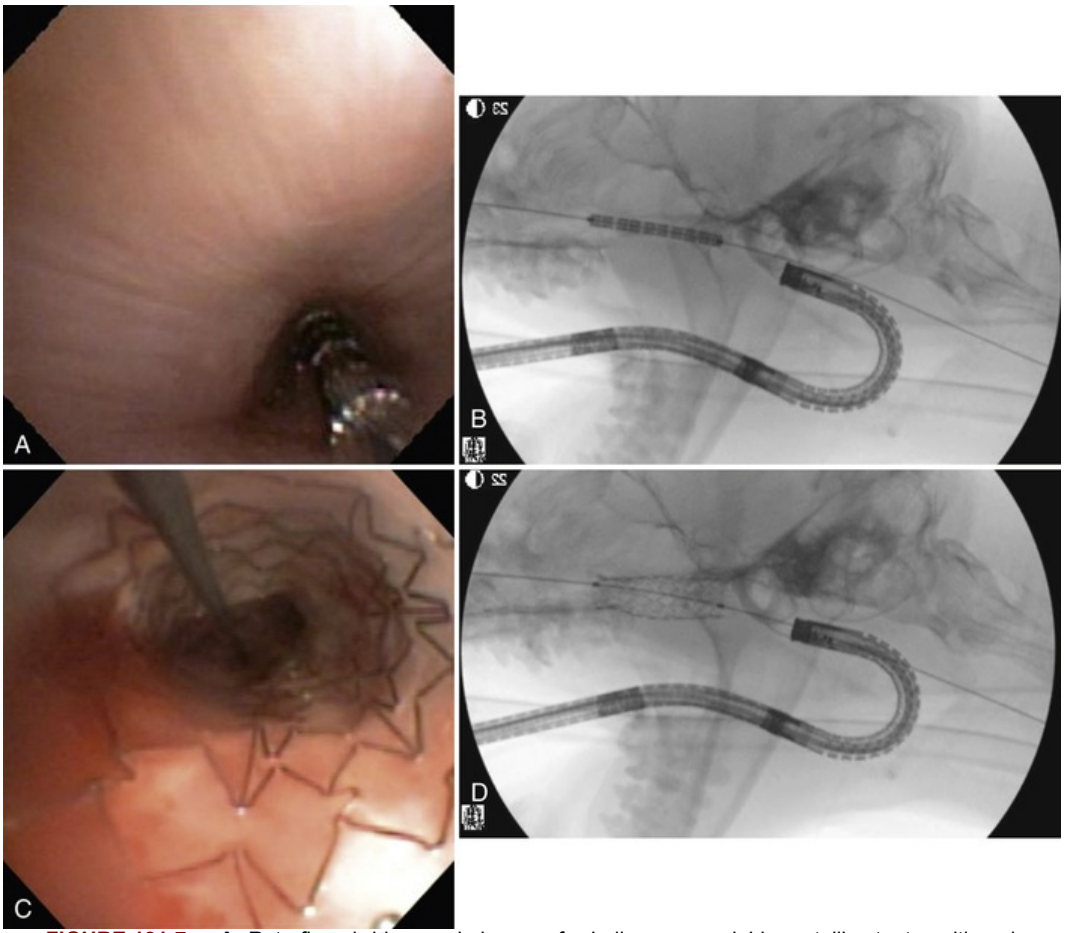

FIGURE 121-7 **A,** Retroflexed rhinoscopic image of a balloon-expandable metallic stent positioned across the stenotic lesion before deployment. **B,** Fluoroscopic image of a balloon-expandable metallic stent placed across the stenotic lesion before deployment. **C,** Retroflexed rhinoscopic image of a balloon-expandable metallic stent correctly deployed across the stenotic lesion. Notice that the choanae now are visible rostrally. The diameter of the lumen of the nasopharynx in relation to the guidewire in this image is dramatically larger than in Figure 121-6, *A*. **D,** Fluoroscopic image of a balloon-expandable metallic stent correctly deployed across the stenotic lesion.

An alternative stent placement technique recently has been described and used successfully in cats with NPS.[17] This technique involves balloon dilation or forceps dilation of the NPS followed by placement of a segment of 24-28 French (8-9.33 mm diameter) tubular silicone across the lesion (see ch. 238). This segment of tubing is left in place for approximately 3-4 weeks and is then removed. In this series, 14/15 cats had complete, long-term resolution of clinical signs and the remaining 1/15 demonstrated improvement.[17]

Expected Outcomes

Following recovery from general anesthesia for balloon dilation or stent placement for NPS, complete relief of airway obstruction is expected. Recurrence of clinical signs usually is indicative of restenosis. When present prior to intervention, clinical signs related to concurrent disease processes such as chronic rhinitis are expected and should be managed concurrently.

Complications

Complications of balloon dilation or BEMS placement for NPS are uncommon. Two cases of palatal erosion after BEMS placement have been documented but may have been related to patient factors or previous procedures.[19] In another study, recurrent obstruction of a BEMS with hair material was identified in a cat with a stent positioned in the caudal nasopharynx for management of NPS in that location.[14] Tissue ingrowth into non-covered BEMS has also been documented. If obstructive, placement of a covered BEMS within the non-covered BEMS will alleviate the problem.

Minor complications including minor bleeding and bradyarrhythmias are expected. Bradycardia has been documented during or immediately following (10-15 min) balloon dilation for the management of NPS. The exact mechanism is unknown; however, it is suspected to be related to stretching of the pharynx and/or compression of vagal afferents.[14,16] Anticholinergic responsiveness is expected and these medications can be given if needed or included preemptively as part of premedication.

CHAPTER 122

Cardiovascular Interventional Therapies

Brian A. Scansen

Angiography (angiocardiography) refers to the administration of contrast agents into the vascular system with imaging visualization, to outline and characterize vascular and cardiac structures. In the middle of the twentieth century and until the 1980s, angiography and cardiac catheterization were performed solely for diagnostic purposes.[1-3] However, the recognition that the veterinarian could intervene in cardiovascular diseases, guided by fluoroscopic imaging, became reality with the development of transvenous pacing systems,[4,5] balloon dilation catheters,[6,7] and coils/devices for vascular occlusion.[8,9] The breadth of small animal diseases that can now be treated by a minimally-invasive, transcatheter approach continues to expand. This chapter provides an overview of the equipment required for cardiovascular intervention, as well as the indications and therapeutic strategies currently employed in small animal cardiovascular medicine.

Preparation for Cardiovascular Catheterization

Performing diagnostic or interventional studies within the heart and vasculature requires detailed knowledge of the equipment used and the technical skills of catheterization, as well as an understanding of thoracic and cardiovascular anatomy. The catheterization laboratory should be a sterile space, with sufficient storage for a multitude of commonly used catheters, wires, and devices; high-quality fluoroscopic imaging, optimally with rotational capability or bi-plane; portable ultrasound for vascular access and transesophageal echocardiography; a power injector for rapid delivery of iodinated contrast; anesthetic and hemodynamic monitoring equipment for intravascular pressure recording; a sufficient number of monitors for visualization of live images and pertinent hemodynamic parameters; and a safety or crash cart for stocking of supplies required for emergent intervention, including a cardioverter-defibrillator (Figure 122-1).

FIGURE 122-1 Photograph of a catheterization laboratory. Optimally, such a space should contain: (1) ample storage for catheters, wires, and devices; (2) a crash cart with defibrillator and emergency medications; (3) a transesophageal echocardiography system; (4) a radiolucent table; (5) a fluoroscopic C-arm; (6) monitors that can be moved within comfortable sight for the operator; (7) hemodynamic recording equipment; and (8) a computer terminal for charting, access to the electronic record, and access to archived patient images. Not shown is a power injector, useful for controlled injections of contrast.

Prior to intervention, an understanding of thoracic anatomy and image interpretation is important for

appropriate diagnosis, planning, and equipment selection as well as during catheterization to verify the intervention is being performed at the correct site and to troubleshoot unexpected findings or complications. The thorax is a complex 3-dimensional shape with a wide variation in the radiographic opacity of thoracic structures; furthermore, the heart is a rapidly moving organ with a complex spatial relationship. These realities complicate interpretation of a 2-dimensional fluoroscopic image, which is made more challenging by the high rate of blood flow within the beating heart that results in a temporally brief period available for contrast and chamber visualization as contrast agents are quickly ejected and diluted following injection.

The difficulty in evaluating cardiovascular anatomy due to the complex structure of the thorax can be mitigated by review of multiple image planes, selective injection of iodinated contrast material in specific locations, use of a power injector, and by digital-subtraction angiography (DSA). Many human catheterization laboratories, particularly those that are used for the treatment of congenital heart disease, now employ biplane fluoroscopic systems that provide real-time imaging of two orthogonal views to improve anatomic guidance. There is also a new generation of fluoroscopic systems that perform rotational angiography to circumferentially record a single injection from all angles and create a 3-dimensional reconstruction of the anatomic structure. Alternatively, some systems have the capability of importing anatomic landmarks from cross-sectional imaging studies (computed tomography [CT] or magnetic resonance imaging [MRI]) onto the 2-dimensional fluoroscopic image to improve guidance during the intervention. Few veterinary catheterization facilities have these capabilities, but most current veterinary interventions can be performed using a portable C-arm–mounted fluoroscope that easily rotates the field of view around the thorax to numerous projection angles. The fluoroscopic system chosen should provide high resolution (at least a 512 × 512 and optimally a 1024 × 1024 matrix), generate sufficient energy to penetrate the thorax of a large dog, and be capable of displaying and recording fast frame rates (25-30 frames per second or higher). The rapid heart rates of dogs and cats cause contrast filling of the structure of interest to be temporally brief and a frame-by-frame review of a recorded angiographic run often is needed to visualize the structures of interest and perform measurements. Fast frame rates prevent the operator from "missing" the lesion during contrast injection into a high-flow organ such as the heart.

Generally, it is not possible by hand injection to achieve a sufficiently tight bolus of contrast to optimally opacify a chamber of the heart in medium-sized and larger dogs. Automated power injectors overcome this limitation by allowing the operator to program the volume, flow rate, and pressure of an injection to maximize opacification of the heart or great vessels within 1-2 cardiac cycles. Importantly, angiographic catheters and high-pressure tubing should be in place if a power injector is used. An end-hole catheter is a poor choice for recording an angiographic study, particularly within the heart, as the full force of the injection is directed through the single end hole and catheter recoil is likely. Additionally, if the end hole is against a vessel wall or the endocardium, a high-pressure injection may damage the structure of interest. The preferred angiographic catheter is one with the largest diameter possible for the task, of the shortest feasible length, and with multiple side holes and a closed or tapered tip—all to maximize flow and minimize trauma. For intracardiac injections and angiographic studies in large vessels, the author prefers the Berman or pigtail catheter.

Contrast agents employed for angiocardiography are almost exclusively iodine-based (carbon dioxide gas rarely is used as a negative contrast agent). Iodine has a relatively high atomic weight, which equates to radiodensity, and the degree of opacity with this agent is directly proportional to the total amount of iodine in the image. Second-generation contrast agents (developed in the 1970s) are non-ionic monomers, which attach an amide group to an iodinated benzoic ring and prevent dissociation in solution. These agents cause far fewer adverse reactions than did early generation agents and are termed low-osmolar agents because the particles do not dissociate once in solution. These agents still have an osmolality 2-3 times that of the blood (e.g., 550-850 mOsm/kg for most agents); iohexol is an example of a second-generation contrast agent that is commonly used in veterinary medicine. The only commercially available third-generation agent is iodixanol, which is an iso-osmolar dimer made by combining two non-ionic tri-iodinated benzoic rings together. This arrangement does not dissociate in solution, has an iodine:particle ratio of 6:1, and has the same osmolality as blood (290 mOsm/kg). Although no studies are available in veterinary medicine, a meta-analysis of human patients at risk for contrast-induced nephropathy found a lower risk of adverse reaction for iodixanol compared to iohexol.[10] The viscosity of the contrast agent is also important as this affects the flow rate during injection. Warming the contrast can decrease viscosity and allow for more rapid injection rates. Last, iodinated contrast agents are available in various concentrations and smaller volumes are needed to create comparable degrees of radiopacity if highly concentrated solutions are used. Rare contrast reactions are reported in animals and both the agent used as well as the total amount of contrast given likely are important in the risk of this occurrence.[11,12] However, recommendations vary widely and no prospective studies are

available. In general, the author attempts to keep the cumulative dosage of contrast for a cardiovascular procedure to <720 mg iodine/kg, but has given animals as much as 2400 mg iodine/kg without apparent adverse effects. For animals with renal impairment, more conservative values and concurrent fluid diuresis should be employed.

Most contrast studies and interventions for cardiovascular disease are performed with the animal positioned in right or left lateral recumbency. Lateral positioning allows the operator to monitor dorsal-ventral and cranial-caudal motion of catheters and wires as they are advanced into the thorax. Right-to-left lateral deflection, however, is less clearly visualized. Although less commonly used than lateral imaging for cardiac intervention, the ventrodorsal projection allows visualization of left-to-right laterality and the cranial-caudal position of catheters introduced into the thorax. The location of catheters or wires in the dorsal-ventral plane, however, is challenging. Several additional imaging planes are used in human medicine to highlight and optimize imaging of cardiac structures. Variations from the traditional lateral or ventrodorsal projection are typically given by an angle, which refers to the position of the image intensifier in relation to the animal's thorax in a ventrodorsal position. Commonly used angulations in human medicine include the right and left anterior obliques (RAO and LAO, respectively) with variable cranial or caudal angulation. Typically, the image intensifier is rotated 30° to the animal's right (RAO) or left (LAO) and a variable 10° to 30° of cranial or caudal angulation may also be employed. Altering the angle of the C-arm can elongate structures (e.g., the left ventricular outflow tract in subaortic stenosis) or provide a more directly perpendicular visualization plane during device deployment (e.g., the atrial septum for closure of an atrial septal defect). These viewing angles have not been standardized in veterinary medicine and are largely operator- and case-dependent. In practice, adjusting the angle of the C-arm is most useful to optimize an angiogram for measurement, such as improving visualization of the minimal ductal diameter of a patent ductus arteriosus (PDA), or to compensate for suboptimal positioning of the animal on the table.

Right Heart Interventions

Cardiac Pacing

Permanent transvenous cardiac pacing is discussed in detail in ch. 248 and 249.

Balloon Pulmonary Valvuloplasty

Congenital pulmonary valve stenosis (PS) has been reported as the third most commonly diagnosed congenital heart defect of dogs in North America,[13] though more recent reports from Europe suggest it is the most common canine congenital heart defect.[14] Without therapy, dogs with valvular PS are at risk for clinical signs including exercise intolerance, syncope, sudden cardiac death, congestive heart failure, and cyanosis from a right-to-left shunt (see ch. 250).[15,16]

Balloon pulmonary valvuloplasty (BPV) was first performed in a dog in 1980[17] and reported in a child in 1982.[18] There is evidence that BPV improves the clinical outcome of human and canine patients with valvular PS, both with a reduction in clinical symptomatology and an improvement in survival.[15,19,20] The procedure now is routinely performed in clinical canine practice with low morbidity and mortality for those animals with a severe gradient or the presence of clinical signs referable to their disease.

Prior to intervention, an attempt should be made to characterize the valve morphology and to estimate the balloon size required. Transthoracic echocardiography with Doppler is the current standard of care in veterinary cardiology for evaluation of pulmonary valve morphology, annular size, and severity of stenosis (Figure 122-2). Valves that are severely dysplastic (redundant tissue, annular hypoplasia, or a subvalvular fibrous ring) are less likely to respond to BPV and clients should be so advised. The author still recommends BPV in such cases as it is difficult to quantify the degree of valvular fusion by echocardiography alone, and despite such fusion, BPV still can produce a partial response. The author has attempted stent implantation into the right ventricular (RV) outflow tract and across the annulus of such dogs with fair improvement in clinical signs and a reduction in pressure gradient.[21]

FIGURE 122-2 Echocardiographic images from dogs with pulmonary valve stenosis. Valve morphology may vary from a fused, doming valve in a Cavalier King Charles Spaniel **(A)** to a thickened and dysplastic valve in an English Bulldog **(B)** to a narrowed and hypoplastic pulmonary valve annulus in a Boxer dog **(C).** The best candidate for balloon pulmonary valvuloplasty is the fused, doming valve as shown in panel **A**. In all images the pulmonary valve is denoted by the arrow with the aorta (Ao) and pulmonary artery (PA) labeled.

An estimation of the pressure gradient across the stenotic valve is obtained by continuous wave spectral Doppler (see ch. 104), guided by color Doppler imaging to optimize alignment parallel to the direction of the turbulent jet. Most cardiologists consider the stenosis mild at a gradient of 10-49 mm Hg, moderate at 50-79 mm Hg, and severe when the gradient is ≥80 mm Hg. The decision to pursue BPV should be made with the pressure gradient in mind, with greater benefit from the procedure likely in dogs with severe stenosis. As with all Doppler estimates, the velocity measured is dependent not only on the orifice of the valve, but also on the flow across the valve at the time of measurement and the systolic function of the RV. Changes in the dog's sympathetic tone, intravascular volume status, or intrinsic RV function can alter the velocity measured.

There are many balloon dilation catheters available on the market, with varying profiles, materials, sizes, and maximal pressure. The most commonly used balloon dilation catheters in veterinary medicine are made by a human pediatric device company and include the TYSHAK and Z-MED lines of balloon dilation catheters. TYSHAK balloon dilation catheters are made of a thin, minimally-compliant thermoplastic elastomer and have a relatively low maximal burst pressure. They are, however, low profile and most sizes can accommodate a 0.035" guidewire making them a commonly selected catheter for BPV in dogs. Z-MED balloon dilation catheters are made from a thicker thermoplastic elastomer, which provides a greater maximal burst pressure, though requiring a larger introducer size. The author uses the Z-MED line of balloon dilation catheters for BPV in dogs with dysplastic valves (thick, redundant tissue or a subvalvular fibrous ridge) and the TYSHAK line of balloons for those with pure valve fusion or small dogs whose vasculature is too small for the required Z-MED introducer size. As discussed in the section below on subaortic stenosis, very high pressure ATLAS balloons also can be used for high pressure BPV with fair success in the author's experience.

The BPV procedure is performed from a transvenous approach, either via the external jugular vein or via the femoral vein. The jugular vein is preferred for small dogs as it affords a larger size vessel and therefore a larger introducer sheath can be used than otherwise would be possible if using the femoral vein. The femoral vein typically is used when an arterial study is desired concurrently given the close relationship of the femoral artery and vein. Percutaneous access with an appropriately-sized introducer is achieved with the animal in lateral (jugular vein) or dorsal (femoral vein) recumbency. A vascular sheath is selected that is at least one French (Fr) size larger than what is required by the anticipated balloon dilation catheter. The right heart is catheterized and intracardiac pressures are measured to evaluate starting right ventricular pressure and transpulmonary gradient. **Note:** *It is always preferable to cross cardiac valves antegrade with a flow-directed (balloon-tipped) catheter or one with a J-tip or pigtail. Theoretically, advancing an end-hold catheter across the valve can perforate a valve leaflet, ensnare chordae tendineae, or otherwise damage the valve apparatus. A balloon-tipped or pigtail catheter, however, will preferentially enter the true valve orifice and minimize trauma to the valve.* Right ventriculography is performed with an appropriate angiographic catheter (typically a Berman catheter) and the pulmonary annulus is measured to size the balloon (Figure 122-3 and Video 122-1). The angiographic measurement is compared to the echocardiographic measurement of pulmonary annulus diameter and a balloon is chosen with a diameter ≈1.3 times the annulus diameter.

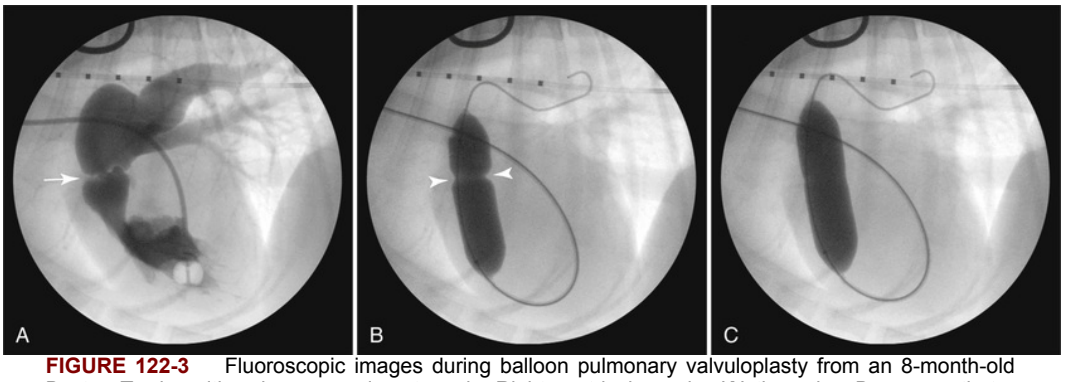

FIGURE 122-3 Fluoroscopic images during balloon pulmonary valvuloplasty from an 8-month-old Boston Terrier with pulmonary valve stenosis. Right ventriculography **(A)** through a Berman catheter highlights the right ventricular lumen and the fused, doming pulmonary valve (arrow). A balloon dilation

catheter is advanced over a guidewire and rapidly inflated, resulting in a stenotic waist (arrowheads) at the pulmonary annulus **(B).** With greater pressure generation in the balloon, the waist is torn and the valvuloplasty is complete **(C).**

A balloon wedge pressure catheter is floated across the pulmonary valve and out a distal branch pulmonary artery. The left pulmonary artery (the more dorsal branch pulmonary artery when viewed from a lateral image) is preferred, as it provides a smoother and more secure path for advancement of the balloon dilation catheter as compared to the right pulmonary artery. Next, a J-tipped exchange-length guidewire (typically >180 cm length) is selected and advanced through the wedge pressure catheter and its tip is placed within the distal branch pulmonary artery. The J-tip is preferred as it will be less traumatic to the distal pulmonary artery. The diameter and stiffness of the guidewire chosen will depend on the size of the dog and the stiffness of the balloon dilation catheter to be used. Guidewires of 0.035″ diameter in a standard stiffness or super-stiffness are preferred for BPV. In small dogs or those with severe RV hypertrophy, super-stiff guidewires place too much pressure on the tricuspid valve and the RV endocardium, particularly when they are advanced from a jugular venous approach. For larger dogs, the standard stiffness guidewires are overly flexible and do not maintain the balloon in a proper position during inflation; as such, super-stiff guidewires are preferred for large dogs or inflexible balloon dilation catheters. For very small dogs, the chosen balloon dilation catheter may not accept a 0.035″ guidewire. In such instances, a 0.018″ or 0.025″ guidewire can be used, but such wires provide even less stability during advancement and inflation of the balloon dilation catheter and stiffer varieties should be selected when possible.

The next step is balloon preparation. First, the protective plastic sheath around the balloon is removed. A three-way stopcock is attached to the catheter's balloon port, with a pressure inflation device connected to one of the stopcock's ports and a 12 mL Luer-lock syringe attached to the other. A mixture of iodinated contrast and isotonic saline (from 1:1 to 1:3, contrast to saline) is drawn into the inflation device and 3-4 mL of a similar mixture is drawn into the syringe. For larger balloons, a lesser proportion of contrast to saline should be used as the rate of balloon deflation is partially dependent on the viscosity of the fluid; contrast is necessary to visualize inflation, but results in a slower deflation rate. The balloon dilation catheter is then purged of air by drawing back with the syringe through the three-way stopcock opened to the balloon. The central lumen of the balloon dilation catheter is then flushed with heparinized saline and slowly advanced over the guidewire to a position spanning the pulmonary valve annulus. Projecting a reference image of the RV angiogram can aid in proper positioning of the balloon; platinum marker bands on the balloon dilation catheter allow the operator to adequately center the annulus, or site of stenosis, to the balloon. Many cardiologists place the balloon markers with one third of the balloon length past the site of stenosis and two thirds preceding the stenosis. Even so, the operator will need to hold traction on the balloon dilation catheter during balloon inflation to brace against the force of RV systolic contraction and blood flow. Rapid inflation of the balloon is performed under live fluoroscopy to visualize the development of a waist at the site of stenosis and to allow retraction/advancement of the catheter if the position changes (see Figure 122-3 and Video 122-2). The pressure generated by the inflation device should be monitored and increased to the nominal pressure of the balloon. Exceeding this nominal pressure (the pressure at which the balloon reaches its advertised diameter) can be done if the stenotic waist persists, but the burst pressure of the balloon should not be exceeded. Once the desired pressure is reached, or if the balloon migrates from the site of stenosis, rapid deflation of the balloon is performed. The duration of inflation should not exceed 5-6 seconds. A precipitous drop in systemic pressure is expected, with recovery rapid within the following 5-10 seconds. The desired outcome with BPV is resolution of the stenotic waist and the lack of waist on subsequent re-inflations. Typically, 2-4 inflations are performed to confirm the waist was engaged and has resolved. Right ventricular pressures and the transpulmonary gradient are again measured and, if the result is satisfactory, all equipment is removed. The vascular sheath is removed and hemostasis achieved with a purse-string suture around the access site as well as 5 minutes of direct manual pressure. A neck bandage is placed if the jugular vein was the point of access, to keep the site clean as the animal is recovered. The prognosis for BPV is generally good if a significant reduction in pressure gradient can be achieved.[15,19,22]

The coronary arterial anatomy is of particular importance in brachycephalic dogs; these dogs are reported to be at risk for anomalous coronary arterial circulations characterized by either a single right coronary ostium or single left coronary ostium (see ch. 250).[23-25] In such cases, the coronary artery that lacks a patent ostium arises from the contralateral coronary artery and passes adjacent and cranial to the pulmonary valve annulus or, rarely, in between the aortic and pulmonary valve annuli. Evaluation of coronary anatomy in brachycephalic dogs with PS should include imaging of the coronary ostia, either by aortic angiography during catheterization or cross-sectional imaging such as CT angiography prior to intervention (Figure 122-4).

Performing BPV with a standard size balloon (balloon-to-annulus ratio of 1.2 to 1.5) in a dog with a coronary artery anomaly can result in coronary artery avulsion, damage, and/or death.[26] BPV using a more conservative ratio of 0.9 to 1.0 in such dogs has been reported with some reduction in stenosis severity.[27] The long-term benefit of conservative ballooning in these dogs remains uncertain, but may be considered.

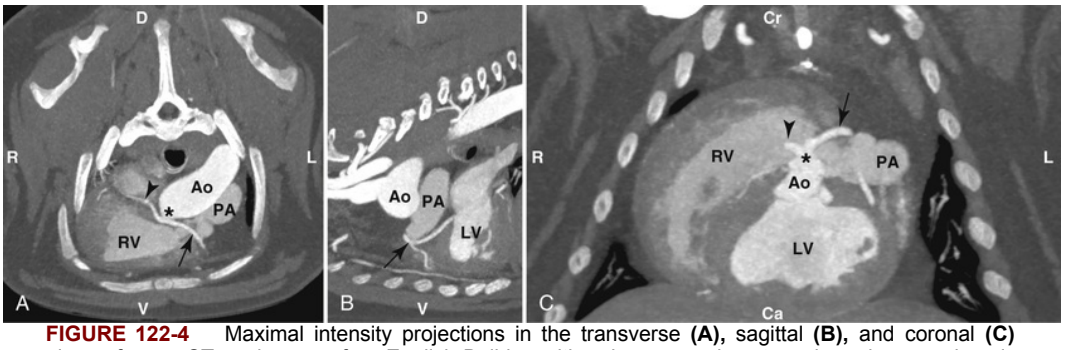

FIGURE 122-4 Maximal intensity projections in the transverse **(A),** sagittal **(B),** and coronal **(C)** planes from a CT angiogram of an English Bulldog with pulmonary valve stenosis and a prepulmonic left coronary artery. The single coronary ostium (asterisk) can be seen arising from the aortic root and giving off both the right (arrowhead) and left (arrow) coronary arteries. The left coronary artery takes a prepulmonic course, wrapping around the stenotic pulmonary valve; this is a relative contraindication to balloon pulmonary valvuloplasty. *Ao,* Aorta; *Ca,* caudal; *Cr,* cranial; *D,* dorsal; *L,* left; *LV,* left ventricle; *PA,* pulmonary artery; *R,* right; *RV,* right ventricle; *V,* ventral.

Heartworm Extraction

Dogs with caval syndrome from severe heartworm infection require emergent intervention to alleviate the mechanical obstruction to blood flow and halt ongoing hemolysis (Figure 122-5) (also see ch. 255). They are poor anesthetic candidates, but extraction of the worms is the only effective means to improve their clinical condition. In the most severely affected patients, extraction may be performed with light sedation and local analgesia to avoid further hemodynamic compromise from anesthetics. Stabilization of the patient should be performed during preparation for heartworm extraction, which can include fluid resuscitation, blood products to normalize bleeding disorders, and vasopressor medications.

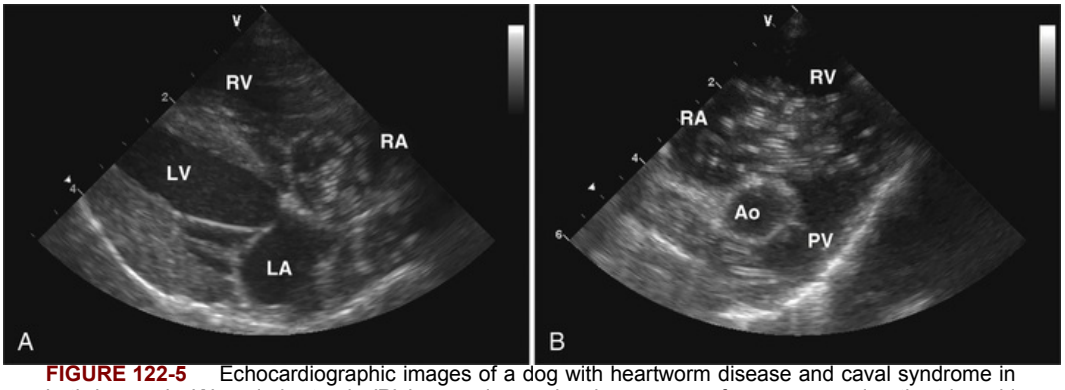

FIGURE 122-5 Echocardiographic images of a dog with heartworm disease and caval syndrome in both long axis **(A)** and short axis **(B)** image planes showing a mass of worms spanning the tricuspid valve and requiring worm extraction. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *PV,* pulmonary valve; *RA,* right atrium; *RV,* right ventricle.

To extract the worms, the dog is placed in left lateral recumbency and the skin over the right external jugular vein is clipped and surgically prepped. A 4-5 cm incision is made over the proximal right external jugular vein and the vein is isolated by blunt dissection. Suture or vessel loops are placed proximal and distal to the planned site of venous access to control the vein and limit hemorrhage. Tenotomy scissors are used for creating a 2-3 mm incision in the lateral wall of the jugular vein. The preferred extraction equipment is then advanced directly into the vein or through a vascular sheath to control hemostasis. Several techniques have

been reported, including passage of a snare catheter with a nitinol gooseneck snare.[28] Alternatively, an endoscopic retrieval basket,[29] alligator forceps,[30] or specially designed flexible forceps[31] may be used. A snare catheter comes in various sizes and is passed into the circulation through the vascular sheath to the level of the right atrium. The nitinol gooseneck snare is a loop set at a right angle to the end of a semi-stiff wire. The snare is passed through the catheter and advanced into the right heart. The loop is manipulated under fluoroscopic guidance with the goal of ensnaring the worms; echocardiographic guidance may be helpful. The loop is tightened as it is retracted back into the catheter and the worms are held firmly and withdrawn at the site of venous access in concert with the snare catheter. When using a snare catheter, it is important to apply gradual tension when tightening to avoid lacerating the worms, which would spill more dirofilarial debris and antigens into the circulation. Repeated passes into the right heart are performed until several negative passes have been achieved and/or brief cardiac ultrasound shows no more worms in the right heart or pulmonary trunk. The jugular vein is repaired or ligated at the end of the procedure and the skin incision closed routinely. On recovery, medical stabilization for hematologic and biochemical derangements is continued and adulticide treatment is scheduled over the following 1-2 months once the animal's clinical status has stabilized. Caval syndrome in the cat is much less common than in the dog and is associated with a lesser worm burden. However, similar interventional techniques have been reported in cats with caval syndrome and heartworm disease including use of alligator forceps,[32] endoscopic basket-type forceps,[33] a horsehair brush,[32] and a nitinol snare.[28] It is critically important to avoid damage to the worms during extraction in cats as severe anaphylactic-like reactions can occur, resulting in hypotension and death.[34]

The prognosis for caval syndrome historically has been guarded to poor. A review of 42 cases found that half of the dogs were euthanized or discharged with the intention of euthanasia at the time of diagnosis.[29] Of the 21 dogs in which heartworm extraction was attempted, 2 dogs died during the procedure, 4 dogs died in the postoperative period, 1 dog had no worms extracted due to distal migration, and 14 dogs had successful worm extraction and survived to discharge. Survival in the 14 dogs after successful extraction ranged from 2 to 56 months, with a mean of 24 months. Of the 21 dogs that underwent attempted extraction, 12 had disseminated intravascular coagulation and 9 of these dogs survived. As such, heartworm extraction should be considered for all dogs with caval syndrome and a successful outcome can be possible even for those with a severe bleeding disorder at the time of diagnosis.

Intracardiac Stenting for Central Venous Obstruction

In rare cases, intracardiac neoplasia can result in impaired venous return and obstruction of cranial or caudal vena caval flow, causing facial swelling or cavitary effusion.[35,36] Historically, medical therapy was the preferred therapeutic strategy for this condition, with variable results. However, deployment of intracardiac stents now has been reported for this condition and can palliate disease by restoring normal venous return. In a series of three cases, stent placement from caudal to cranial vena cava resulted in resolution or substantial reduction in clinical signs with survival of 5.5 to >22 months.[37]

Echocardiography is necessary to establish the diagnosis and evaluate the degree of venous obstruction (Video 122-3). Cross-sectional imaging with CT angiography or MR angiography can be useful to characterize the 3-dimensional extent of the tumor and the vena caval diameter, but is not mandatory. Stent selection is made with the intent to size 10-20% greater than the vena caval diameter to achieve sufficient purchase of the stent against the wall, and provide anchoring of the stent cranial and caudal to the right atrium. Both woven and laser-cut self-expanding stents have been used for this indication and there are advantages to each. The woven stent allows for reconstrainment, but suffers from foreshortening, while the laser-cut stent must be deployed at one time, but remains the length at which it resides in the delivery system.

The dog typically is placed in dorsal recumbency to allow access to both the neck and inguinal region and the right external jugular vein and left femoral vein regions are clipped, aseptically prepped, and draped. Vascular access is achieved through either jugular or femoral vein, depending on the site of obstruction, and a large introducer sheath (10 Fr) is advanced and sutured in place. For cranial vena caval obstruction, femoral venous access may be preferable due to swelling in the head and neck. Angiography, often DSA, is performed proximal and distal to the obstruction and vena caval measurements are made using a calibrated marker catheter. A guidewire is advanced across the right atrium, which may require a snare catheter to facilitate passage to the distal cava. Hemodynamic measurements may be taken above and below the obstruction to document a pressure gradient; collateral venous pathways are likely to have developed in this condition and absence of a pressure gradient suggests sufficient collaterals are present and stent placement may not improve clinical signs. The stent is deployed over the guidewire, with care taken to engage 4-5 cm or more in

both venae cavae (Figure 122-6). Transatrial placement helps to avoid stent migration across the tricuspid valve by securing its position in both the cranial and caudal venae cavae. It also can prevent excessively large tumor thrombi from dislodging and migrating to the pulmonary circulation. Following stent deployment, repeat angiography and pressure gradients should be performed. Tumors of the right atrium that lead to obstruction might release vasoactive substances and the anesthesiologist or anesthetist should be prepared for marked changes in blood pressure or heart rate as the tumor is compressed by the stent.[36] The venous access site is closed routinely, often by placement of a superficial pursestring suture. Follow-up depends on the nature of the disease, though repeat stent implantation has been performed if cavitary effusion recurs.[37] The prognosis is fair, with all reported cases showing improvement in clinical signs after transatrial stenting. However, this procedure is merely palliative and progressive disease from the primary tumor is likely. Survival of several years after stent implantation is possible.

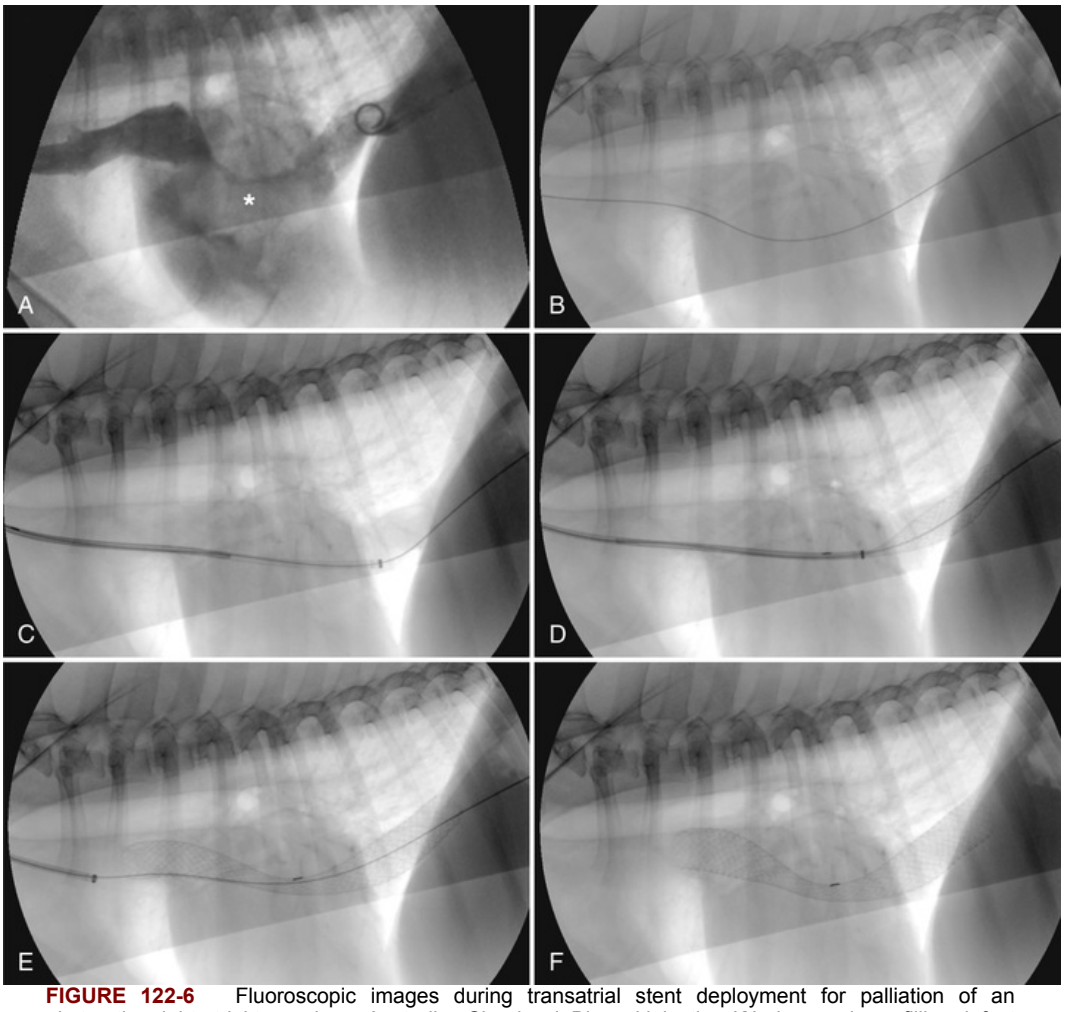

FIGURE 122-6 Fluoroscopic images during transatrial stent deployment for palliation of an obstructive right atrial tumor in an Australian Shepherd. Bicaval injection **(A)** shows a large filling defect in the body of the right atrium (asterisk). A guidewire is advanced across the right atrium from cranial vena cava to caudal vena cava **(B).** Over the guidewire, a delivery sheath is advanced **(C).** The stent is deployed from the caudal vena cava and through the body of the right atrium **(D).** The cranial aspect of the stent is deployed into the cranial vena cava **(E).** Once the wire and sheath are removed, the stent remains to push the tumor away and restore patency of caudal vena caval inflow **(F).**

Left Heart Interventions

Patent Ductus Arteriosus

Patent ductus arteriosus (PDA) is a common congenital heart defect in dogs, reported as the most common defect in some surveys (see ch. 250).[13,38] It also occurs in cats, albeit with less frequency.[38] Without therapy,

the prognosis is poor and therefore, closure of the ductus, either by surgical ligation or interventional occlusion, is necessary.[39,40]

Transcatheter therapy for PDA in dogs was first reported in 1994.[41] In the initial decade of transcatheter PDA therapy, transarterial or transvenous coil delivery was the predominant method used for ductal closure. Thereafter, human implants of variable design[42-48] were reported for PDA occlusion in dogs and in 2007, a device designed and optimized for canine anatomy came on the market.[49,50] The canine-specific device, the Amplatz Canine Duct Occluder (ACDO), is now the preferred transcatheter device for PDA occlusion in dogs due to an excellent safety and efficacy record and ease of deployment.[51] There remains a subset of small dogs, however, for which vascular access of sufficient size to deliver an ACDO is not possible; in these small dogs, coils remain a useful technique to achieve ductal closure. A nitinol device for small canine PDAs has been evaluated with good results, but is not yet commercially available.[52]

The technique for nearly all cases of transcatheter PDA occlusion begins with the animal in dorsal recumbency and access to the femoral triangle (typically the right side is chosen). Dorsal recumbency is used for ease of access and catheter advancement in the inguinal region; once access is achieved, the animal or fluoroscope can be turned to visualize the procedure from a lateral imaging plane. For the ACDO and transarterial coil delivery, the femoral artery is isolated by surgical cut-down and a combination of blunt and sharp dissection (Figure 122-7). Percutaneous access can be used for transvenous coil delivery through the femoral vein; percutaneous access also is feasible for a transarterial approach, although hemorrhage is a greater concern postoperatively for femoral arterial access. The author has used vascular closure devices[53] successfully in dogs to close percutaneous femoral arterial access, specifically the Mynx closure device; however, the thin subcutaneous tissue of puppies makes vascular closure devices more of a challenge in young dogs undergoing PDA intervention and typically a surgical approach with either repair or ligation of the femoral artery is employed. Arterial access first is achieved with a 22-gauge over-the-needle catheter and a 4-Fr micropuncture set with a 0.018″ wire. The micropuncture set is exchanged over a 0.035″ angled hydrophilic guidewire for a long vascular sheath of sufficient internal diameter to deliver the desired ACDO (Table 122-1). The long sheath is advanced to the aortic isthmus over the guidewire, after which the guidewire and dilator are removed. Angiography is performed through the long sheath and delineates ductal anatomy and minimal ductal diameter in most dogs (Figure 122-8, *A* and Video 122-4). If sufficient contrast flow cannot be provided through the sheath, a pigtail catheter is advanced through the vascular sheath and a power injection is performed in the ascending aorta; in the author's experience, this rarely is necessary. A measurement of the minimal ductal diameter at the pulmonary ostium is made from the angiographic image and compared to transesophageal measurements of minimal ductal diameter. An appropriate ACDO is chosen with a central waist that is 1.5 to 2.0 times the minimal ductal diameter. The hydrophilic guidewire and sheath dilator are then placed back into the vascular sheath and directed across the PDA into the pulmonary trunk under fluoroscopic guidance, taking care to not engage the pulmonary valve with the stiff dilator or sheath. The dilator and guidewire are removed and the device prepared for implantation. The screw-tip connection of the delivery cable to the ACDO should be tested by removing the device and screwing it back onto the delivery cable. The device must screw on and off easily or it should not be implanted in the animal. When tightening, the device should be turned until it stops (fully tight) and then turned back one-half turn; it should not be over-tightened. While on the delivery cable, the ACDO is vigorously flushed and purged of all air bubbles by extruding and reconstraining the device under saline. The ACDO is then advanced into the long sheath and passed out into the pulmonary trunk, taking care to extrude only the pulmonary artery disc. The entire system (sheath, delivery cable) is then withdrawn until the open pulmonary artery disc engages with the pulmonary ostium of the PDA (Figure 122-8, *B*). Slight tension is placed on the system to ensure the disc is flush with the PDA and this tension is maintained as the sheath is slowly retracted over the delivery cable to expand the ductal disc within the PDA ampulla (Figure 122-8, *C* and Video 122-5). It is common to require a slight forward advancement of the delivery cable after the ductal disc is deployed to allow it to regain its cupped shape. The position of the device on the fluoroscopic image should be compared to the prior angiogram to confirm it is in the correct location of the PDA. Gentle pushing/pulling on the delivery cable helps to confirm the device is appropriately seated; however, even an optimally positioned device can be pushed out or pulled out of the PDA if too great a force is exerted. The author typically waits 5 minutes after deployment and performs an angiogram through the long vascular sheath to confirm ductal closure (see Video 122-5). If a small amount of central flow is still observed, it will likely close without further intervention (Figures 122-8, *D* and *E*; see also Video 122-5). If contrast flow is noted cranial or caudal to the waist, around the device, the device is improperly positioned and should be re-

deployed. A similar effect, or failure of the ACDO to adopt the correct shape, can be caused by an ACDO with a proximal disc that is too large for the animal's ductal ampulla. If satisfactorily implanted, the device is deployed by counterclockwise rotation of the delivery cable, using either the supplied pin or a hemostat, and the cable and sheath removed (Figure 122-8, *F*; see also Video 122-5). The femoral artery is repaired, ligated, or otherwise controlled and the skin closed. The animal is kept sedated and quiet overnight and echocardiography performed the next day to confirm persistent ductal occlusion.

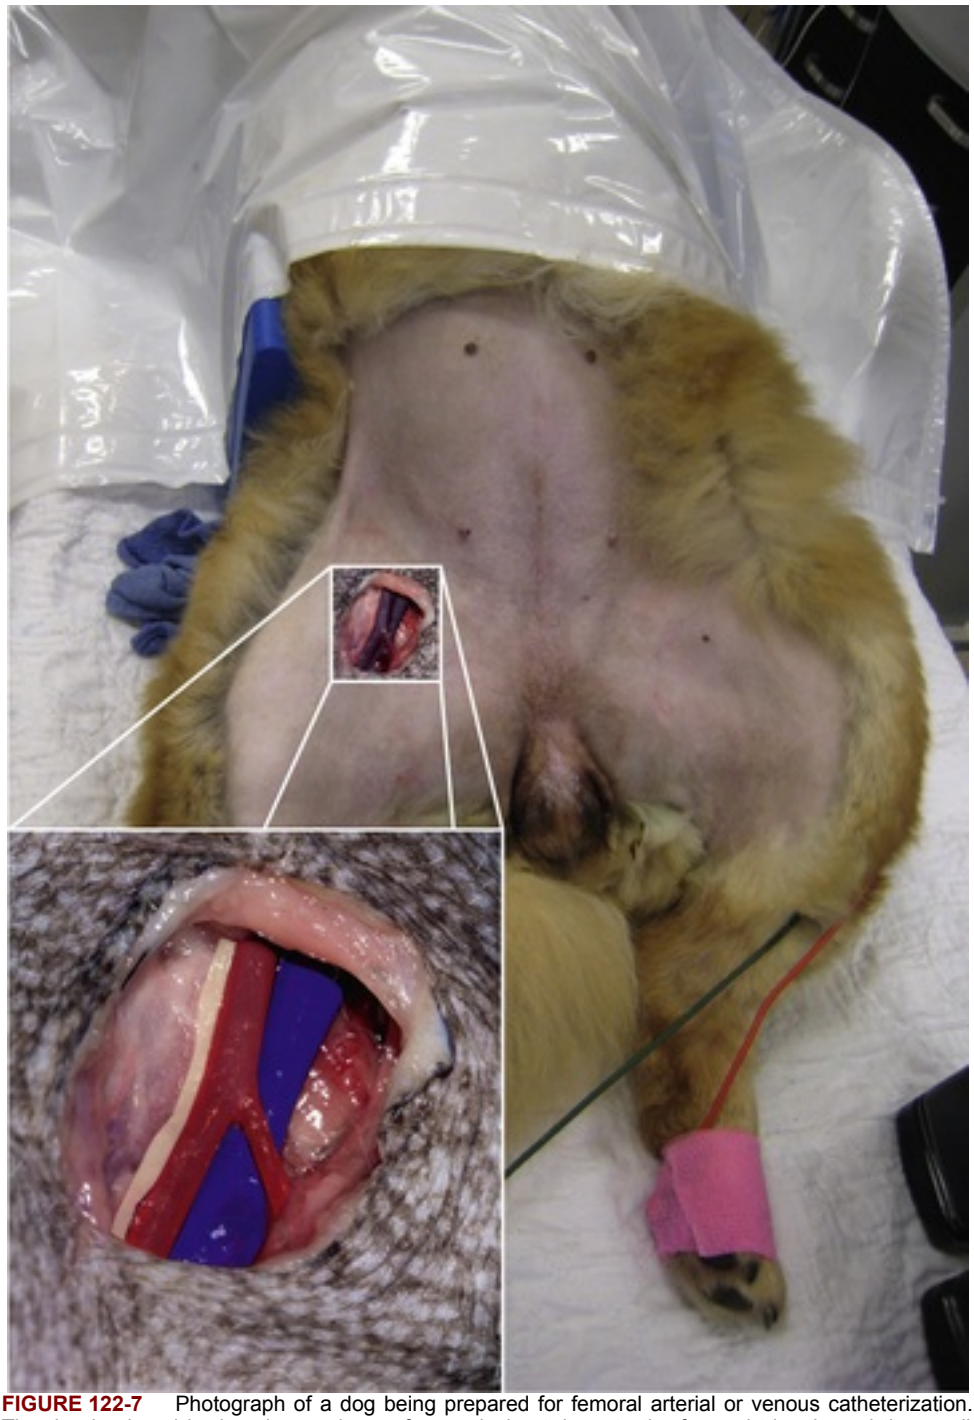

FIGURE 122-7 Photograph of a dog being prepared for femoral arterial or venous catheterization. The dog is placed in dorsal recumbency for surgical cut-down to the femoral triangle and the small inset represents this location within the limb. The enlarged inset shows the relationship of the femoral nerve (off-white overlay), common femoral artery (red overlay), and common femoral vein (blue overlay) as they lie in a cranial to caudal direction, respectively.

TABLE 122-1

List of Amplatz Canine Duct Occluder Device Sizes and Requirements for Delivery System Internal Diameter in Both Inches and Millimeters (mm)

DEVICE SIZE (central waist in mm)	MINIMUM INTERNAL DIAMETER OF DELIVERY SYSTEM (inches/mm)	RECOMMENDED DELIVERY SHEATH SIZE (French)

14	0.099″/2.51	7

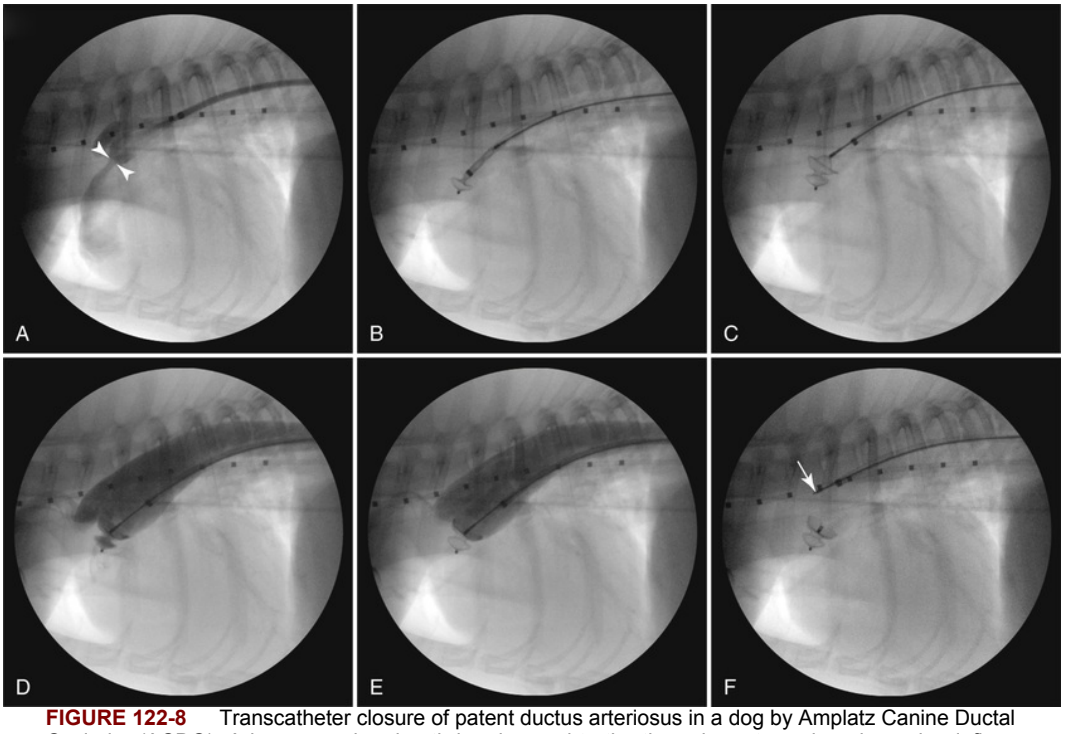

FIGURE 122-8 Transcatheter closure of patent ductus arteriosus in a dog by Amplatz Canine Ductal Occluder (ACDO). A long vascular sheath is advanced to the thoracic aorta and angiography defines the ductal location **(A)**, anatomy, and minimal ductal diameter (between arrowheads). The pulmonary disc is then deployed in the pulmonary trunk **(B)** and brought back against the pulmonary ostium before deployment of the ductal disc **(C).** Initial angiography shows mild flow through the center of the device **(D),** with complete closure noted at 10 minutes post-deployment **(E).** Counterclockwise rotation of the delivery cable results in release of the device **(F)** from the cable screw (arrow).

The procedure for transarterial coil delivery is comparable to that described for ACDO deployment, except a 4-Fr or 5-Fr catheter is used for vascular access either alone or through an introducer sheath. As most cases undergoing transarterial coil delivery relate to insufficient vascular size, the catheter is placed directly into the vessel with a hemostatic valve or Tuohy-Borst adapter placed on the catheter hub to control hemorrhage

rather than through a sheath. Angiography is as described above, through the catheter rather than a sheath. Coil selection is also based on the minimal ductal diameter, with a coil loop diameter chosen that is twice the minimal angiographic ductal diameter; typically 0.038″ or 0.035″ coils are chosen for small dogs. The catheter is positioned in the ductus, the position is verified by hand contrast injections, and the coil is carefully advanced through the catheter to the ductal ampulla (Figure 122-9). If detachable coils are used, they are mounted on the delivery cable and advanced into the catheter. The catheter is retracted to expose the coil and, once positioning is appropriate, the coil is released by counterclockwise rotation of the delivery cable. If non-detachable coils are used, they are advanced with a straight-tipped guidewire of the same thickness as the coil. The drawback to non-detachable coils is that reconstraint or repositioning is not possible; as such, confirmation of appropriate size and location of deployment is paramount to success. The author reserves transarterial coil delivery for dogs of small size (typically 2.0 to 3.5 kg) and with a narrow ductal ostium on the pulmonary side, as these cases appear most amenable to coil occlusion. Reports of smaller coils being deployed in even smaller dogs (1-2 kg), either from a carotid or femoral arterial approach, exist in the literature.[54,55] If the dog weighs <2.5 kg, the author typically recommends surgical ligation.

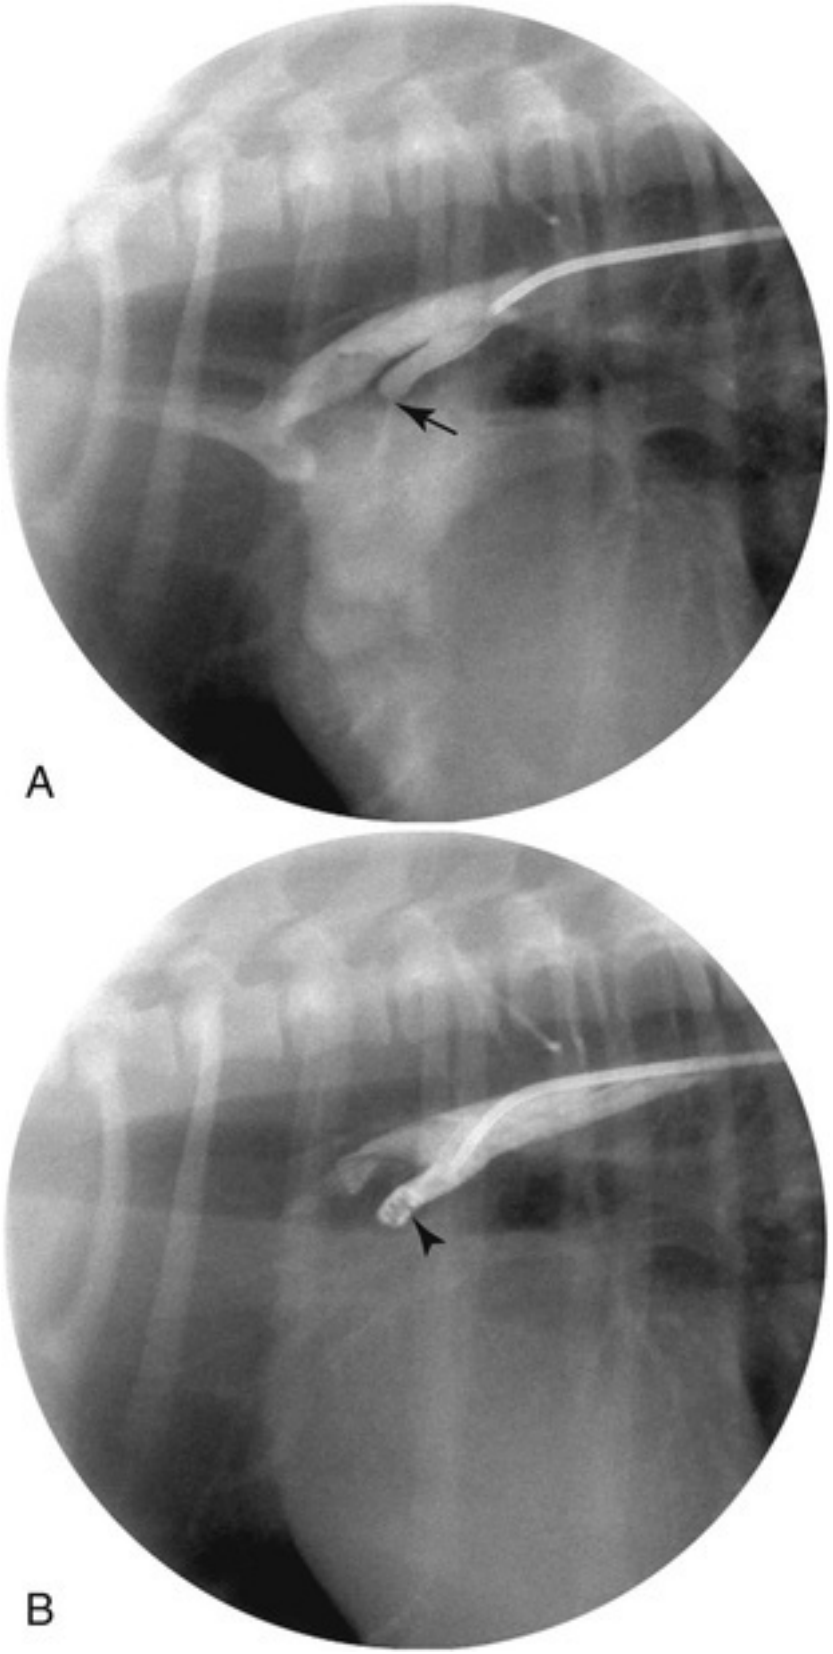

FIGURE 122-9 Fluoroscopic images during transarterial occlusion of patent ductus arteriosus (PDA) in a small dog. An angled (KMP) catheter is advanced to the aortic isthmus and an angiogram **(A)** highlights the location and minimal ductal diameter (arrow) of the PDA. The coil is delivered to the ductal ampulla and extruded via a guidewire. Upon delivery, a repeat angiogram **(B)** confirms the coil location (arrowhead) and cessation of ductal flow.

Transvenous coil delivery is also possible in small dogs or cats via retrograde cannulation of the ductus.[9,48,56] This technique allows for easier vascular access in small patients as the jugular or femoral vein are larger and more pliable than is the femoral artery. Catheterization of the PDA from venous access requires placement of an end-hole catheter into the pulmonary trunk with a straight-tipped flexible guidewire advanced across the ductus to the descending aorta. The delivery is comparable to that described for transarterial coil delivery, though the detachable coil system is preferred to allow the coil to be exposed in the descending aorta and then withdrawn into the ductal ampulla prior to release and then the delivery cable retracted to the pulmonary trunk, leaving a small segment of coil spanning the ductal ostium (Figure 122-10).

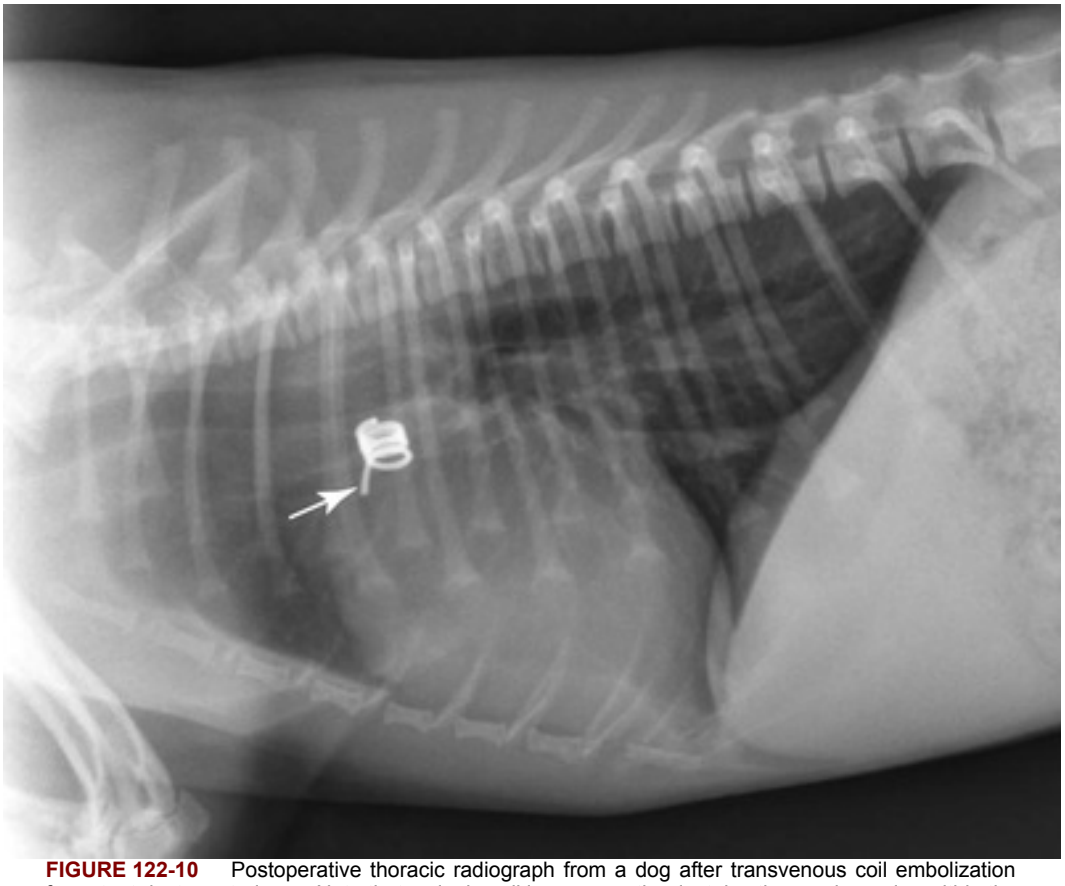

FIGURE 122-10 Postoperative thoracic radiograph from a dog after transvenous coil embolization for patent ductus arteriosus. Note that a single coil loop spans the ductal ostium and remains within the pulmonary trunk (arrow). (Image courtesy Jason Arndt, DVM, DACVIM [Cardiology]; ACCESS Specialty Animal Hospital, Los Angeles, California.)

The prognosis of transcatheter PDA occlusion is very good, with perioperative survival rates of 90-100% and median survival of >11.5 years.[47,51,57,58] Factors reported to have a negative effect on survival time include the preoperative presence of clinical signs, concurrent congenital heart disease, large breed, older age, increased weight, and severe mitral regurgitation documented within 24 hours of ductal closure.[40]

Balloon Aortic Valvuloplasty

Subaortic stenosis (SAS) is a common congenital defect of large-breed dogs; valvular aortic stenosis is more rarely encountered (see ch. 250).[14,59] Interventional therapy for SAS remains controversial, with a prospective case-control study showing no survival benefit for balloon aortic valvuloplasty (BAV) compared to medical therapy (atenolol) alone.[60] New developments in interventional treatment options, including cutting balloon (CB) and high pressure balloon (HPB) valvuloplasty, have been attempted in dogs with SAS with reasonable short and mid-term results.[61-63] However, long-term results remain unknown and no comparison to medical therapy or the natural history of the disease has been made. Currently, the author advises CB and HPB BAV for SAS in dogs that display clinical signs (syncope, weakness, congestive heart failure) or for very severe

stenotic gradients (e.g., >150 mm Hg instantaneous pressure gradient) given the uncertain benefit of therapy.

The approach for BAV is typically via a carotid artery cut-down. The dog is positioned in either dorsal or lateral recumbency and the ventral and lateral neck (either right or left) are clipped, aseptically prepped, and draped. A 3-4 cm incision is made along the lateral border of the trachea and blunt and sharp dissection used for exposing the common carotid artery, which must be carefully separated from the vagosympathetic trunk. Suture or vessel loops are passed around the carotid artery, cranial and caudal to the proposed access site, to stabilize the vessel during access. Arterial puncture is performed with an 18-gauge over-the-needle catheter or arterial access needle, and a vascular sheath of 1 to 2 Fr sizes larger than required by the desired HPB is advanced into the vessel. The left heart is catheterized with a marker pigtail catheter and left ventriculography is performed to delineate the site of subaortic obstruction as well as left ventricular size and function, presence of mitral regurgitation, coronary arterial anatomy, and other concurrent defects (Figure 122-11 and Video 122-6). The greatest challenge is crossing the aortic valve in these dogs as aortic valve excursion is limited by reduced forward flow, and extensive poststenotic dilation allows the catheter to wander in the ascending aorta. Rarely, the pigtail catheter will advance alone through the valve orifice. Alternatively, a guidewire with a long and floppy tip can be used for *gently* probing the aortic orifice and with repeated attempts will cross in most cases. Following angiography, the angiographic catheter is removed over a 0.018" guidewire that is pre-shaped with a 540 to 720 degree curve at the end, which will enable it to seat in the left ventricular apex. Over this wire the CB is advanced to the level of the subaortic ridge and rapidly inflated. Size selection of CB is based upon the minimal stenotic diameter of the left ventricular outflow tract, with a balloon chosen at a roughly 1 : 1 ratio to the stenotic diameter. Currently, the largest size of commercially available CB is 8 mm in diameter, which is large enough to engage the subaortic ridge of most dogs, though not all. After 2-3 inflations, the CB is deflated and removed from the animal, with the pigtail catheter placed again over the 0.018" guidewire. The guidewire is exchanged for an ultrastiff 0.035" guidewire with a long floppy tip. The end of the 0.035" guidewire is also pre-shaped with a 540 to 720 degree curve and placed in the left ventricular apex. A HPB is then chosen—typically the ATLAS or ATLAS GOLD line of HPBs—as these develop pressures of 12 to 18 atmospheres. Both of these balloon designs work well, but it is important to understand the differences between the two lines of balloon dilation catheters. The primary difference is the length of the shoulders, that portion of the balloon that tapers at each end. The original ATLAS HPB has long shoulders; as such, the 2 cm length balloons in the ATLAS HPB line are best for most BAV in dogs. In the ATLAS GOLD HPB line, the shoulders are more comparable to standard balloons and 4 cm length balloons work well for most dogs. The diameter of HPB chosen is based on the true aortic valve annulus and sized 0.9-1:1 for balloon to aortic valve diameter. For smaller dogs in which the smallest ATLAS HPB (12 mm diameter) is too large, the CONQUEST HPB can be selected, which also has very high burst pressures (up to 30 atm) and comes in appropriate lengths. The HPB is advanced over the 0.035" guidewire to the level of the subaortic lesion and rapidly inflated. As with BPV, successful inflation involves the appearance of a stenotic waist, which resolves with increased pressure and is not apparent on subsequent inflations (Figure 122-12 and Video 122-7). Following 2 to 3 inflations across the outflow tract, the HPB is removed and an aortic root injection is typically performed to evaluate the degree of aortic insufficiency. Pressures are again measured and the change in gradient evaluated compared to preoperative values. Once satisfactory results are achieved, the balloon dilation catheter is removed, often requiring constant negative pressure during retrieval to allow passage through the sheath, or the sheath and catheter are removed as a unit if excess tension is encountered during retrieval through the sheath due to the large profile common to deflated HPBs. The carotid artery is repaired with 5-0 or 6-0 monofilament suture and the surgical exposure closed routinely in three layers. Care should be taken to allow the carotid access site to bleed temporarily prior to repair, to be certain any thrombus around the introducer sheath is removed through the access site prior to closure. The neck is bandaged routinely and the dog recovered with monitoring of the cardiac rhythm and administration of analgesia, sedation, and prophylactic antibiotics.

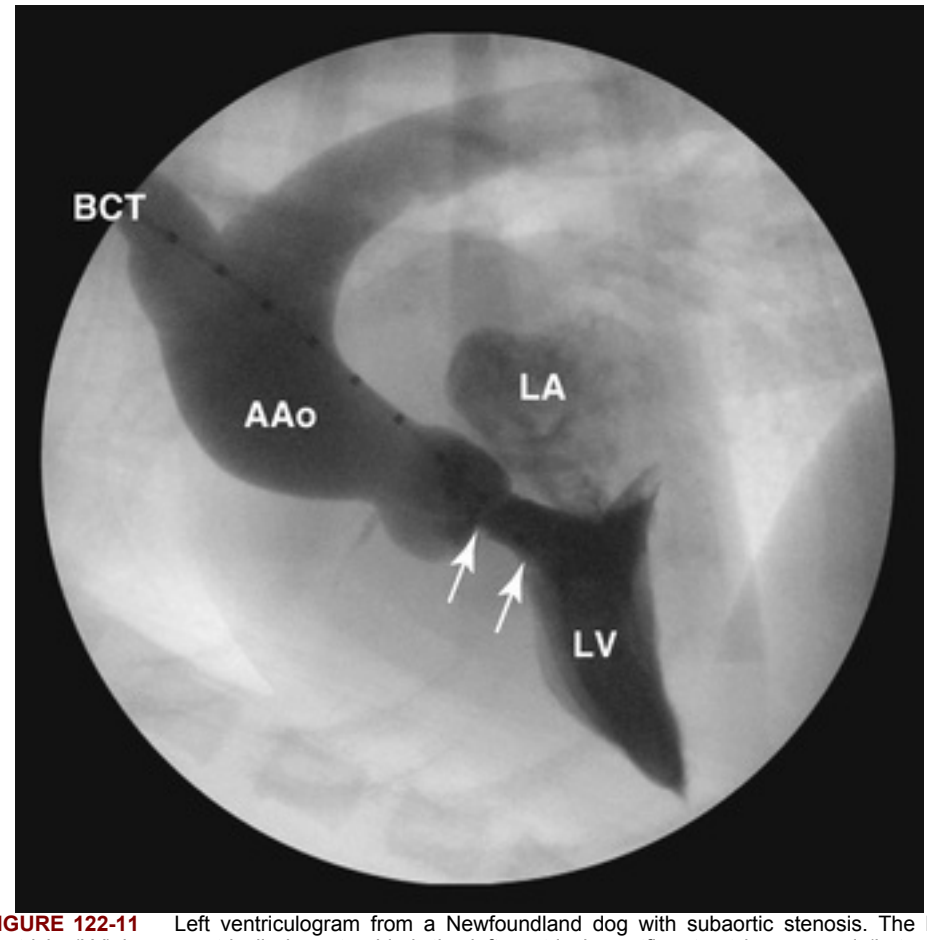

FIGURE 122-11 Left ventriculogram from a Newfoundland dog with subaortic stenosis. The left ventricle (LV) is concentrically hypertrophied, the left ventricular outflow tract is narrowed (between arrows), there is mild mitral regurgitation back into the left atrium (LA), and there is post-stenotic dilation of the ascending aorta (AAo) and brachycephalic trunk (BCT).

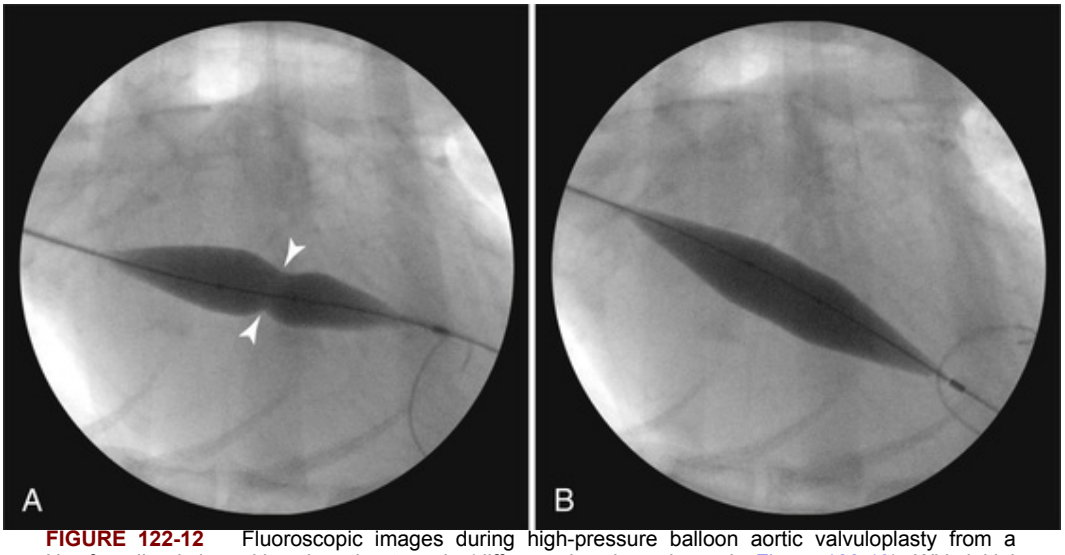

FIGURE 122-12 Fluoroscopic images during high-pressure balloon aortic valvuloplasty from a Newfoundland dog with subaortic stenosis (different dog than shown in Figure 122-13). With initial inflation **(A),** the indentation from the subaortic lesion creates a waist (arrowheads). With higher pressure **(B),** the waist is abolished as the subaortic ring is torn.

A similar approach to BAV can be undertaken for dogs with valvular aortic stenosis. However, the CB is

not used; rather the TYSHAK and Z-MED lines of balloon dilation catheters are utilized as described for BPV if these dogs have fusion of apparently normal aortic valve cusps because they do not require scoring and high pressure tearing of the fibrous tissue that is present in SAS. For aortic valvular stenosis with valve dysplasia (thickened, hypoplastic leaflets), BAV with the ATLAS or ATLAS GOLD line of HPBs may be required to achieve sufficient radial force on the valve. The ratio of balloon diameter to aortic valve annulus for conventional BAV in the setting of valvular aortic stenosis is chosen as 0.9-1:1 to limit the risk of postoperative aortic insufficiency.

The prognosis for CB and HPB BAV is unclear, though an interim analysis of 28 dogs that underwent this procedure for SAS found a decrease in peak systolic pressure gradient from a mean of 143 mm Hg to 78 mm Hg at 1 day after BAV, 84 mm Hg at 1 month, 89 mm Hg at 3 months, 92 mm Hg at 6 months, and 116 mm Hg at 12 months post-BAV.[63] Six dogs had died after BAV, including three dogs euthanized for progressive myocardial failure, one dog euthanized for syncope, and two dogs that died suddenly.[63] In the author's experience, a reduction in gradient is achievable and clients report improved exercise capacity. However, the gradient typically is reduced to the high moderate range (70-80 mm Hg) and substantial obstruction persists. As the procedure is costly and involves arrhythmic and anesthetic risk, it is of uncertain benefit though a randomized prospective study is required to answer this question. In the absence of such a study, the author reserves this procedure for cases that display clinical signs or that are at high risk for clinical signs based on the severity of cardiac remodeling and peak systolic pressure gradient as described above.

Septal Defect Occlusion

Large defects in the atrial or ventricular septum lead to left-to-right shunting of blood, pulmonary overcirculation, and either pulmonary vascular disease or left-sided congestive heart failure (see ch. 250). Closure of such defects is not common in veterinary medicine due to the scarcity and cost of open-heart surgery. However, transcatheter options have been described that allow for closure of both atrial septal defects[64, 65] (ASD) and ventricular septal defects[66-68] (VSD) by minimally invasive methods and without cardiopulmonary bypass.

Transcatheter closure of ASD is performed by a transvenous approach—either jugular or femoral venous access (Figure 122-13). Transcatheter techniques can only be applied to ASDs of the ostium secundum type at this time, as sufficient tissue around the defect is required to seat and hold the device in place; optimally, the defect should have septal tissue around 75% of the circumference to consider transcatheter closure.[65] All cases reported in dogs have used the Amplatzer septal occluder (ASO), though other devices are commercially available. The center with the largest case experience advises a jugular venous approach for canine ASD closure,[65] though the author has successfully performed the technique from a femoral venous approach and this was the approach used in the first reported canine case.[64] The defect is sized by transthoracic and transesophageal echocardiography and this size is confirmed in the catheterization laboratory using a balloon sizing catheter (Amplatzer sizing balloon II). The device is selected to match or be minimally larger (0.5-1 mm) than the largest diameter measured. The optimal imaging planes to determine maximal dimension by echocardiography have not been determined in animals; therefore, use of a sizing balloon is advised to determine the device required. The device is attached to the delivery cable and carefully purged of air by immersion in saline and repeated retraction into the delivery system followed by saline flush through the delivery system.

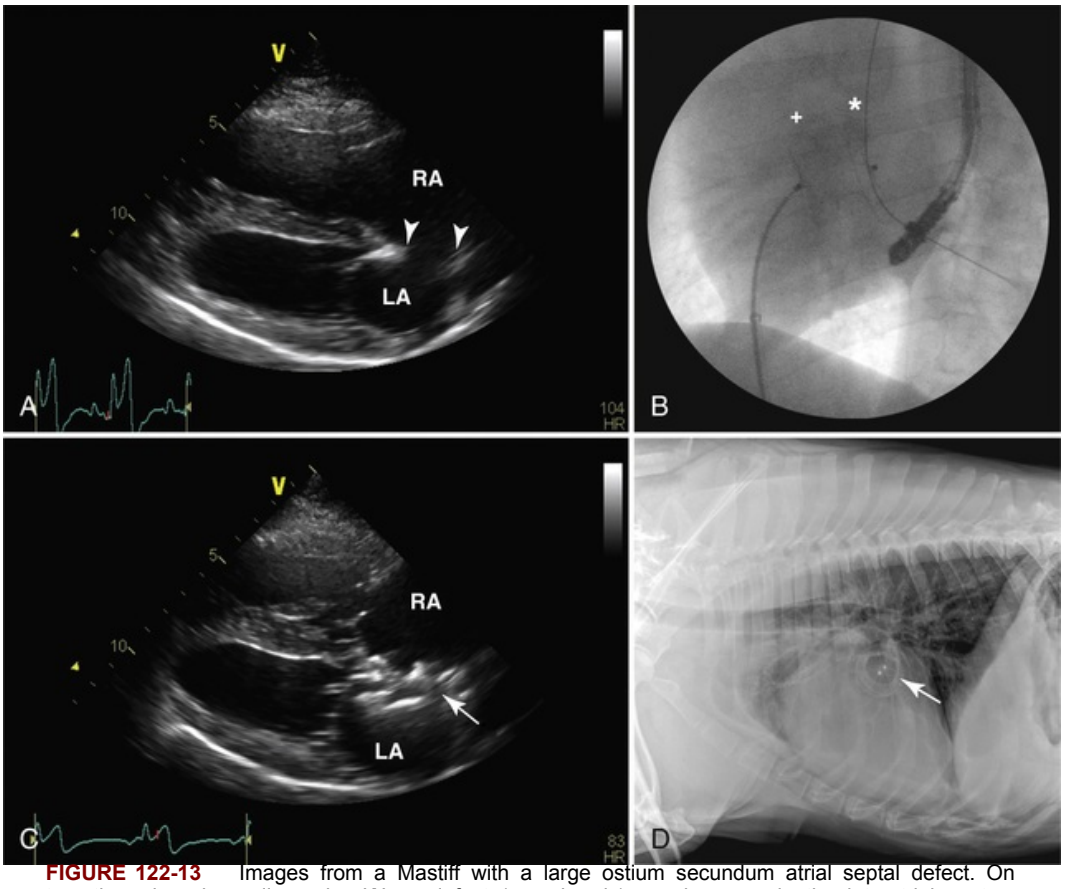

FIGURE 122-13 Images from a Mastiff with a large ostium secundum atrial septal defect. On transthoracic echocardiography **(A),** a defect (arrowheads) can be seen in the interatrial septum between the left atrium (LA) and right atrium (RA). Fluoroscopic delivery **(B)** of an Amplatzer septal occluder requires deployment of the distal retention disc (asterisk) on the left atrial side and the proximal retention disc (plus sign) on the right atrial side of the septum. A transesophageal echocardiography probe can also be seen in this image. After closure, the device (arrow) can be seen spanning the defect on both echocardiography **(C)** and thoracic radiography **(D).**

A delivery sheath, the Amplatzer TorqVue 45° Delivery System supplied by the manufacturer of the ASO, is advanced over a guidewire, across the atrial septum and into the left atrium. Once the left heart is catheterized, the animal is heparinized with 100 U/kg unfractionated heparin IV to limit thrombotic risk. The prepared device is advanced into the delivery sheath, allowing for some back-bleeding through the device to confirm all air has been removed. The device is then advanced to the left atrium and the distal retention disc (left atrial disc) deployed (see Figure 122-13). Careful tension is then placed on the entire delivery system as the distal retention disc is retracted against the atrial septum and the central waist is deployed by retracting the delivery sheath over the delivery cable. In animals with minimal rim tissue, it is very easy to pull the device through the ASD, so gentle traction and transesophageal guidance are mandatory. If the waist is appropriately seated in the ostium of the ASD, the proximal retention disc (right atrial disc) is then deployed (Video 122-8). All planes of the device are investigated by transesophageal echocardiography to confirm the device is appropriately positioned and that the distal and proximal discs are on the appropriate side of the septum (left and right, respectively) in all planes. Minimal manipulation of the delivery cable can be performed to assess the stability of the ASO, though as noted above it is easy to dislodge even an appropriately deployed device. If it is determined that the device is appropriately positioned and stable, the ASO is released from the screw tip of the delivery cable by counterclockwise rotation of the cable, either with the supplied pin or a hemostat, and the cable and sheath are removed (see Video 122-8). The femoral access site is repaired, ligated, or otherwise controlled and the skin closed. The animal is kept sedated and quiet overnight and echocardiography is performed the next day to confirm device position and assess ASD closure.

The technique for transcatheter VSD closure is comparable to that described for transcatheter ASD closure. The type of VSD most amenable to transcatheter closure is the muscular-type defect, surrounded entirely by muscular septum on all sides.[68] However, transcatheter closure of membranous-type defects has also been

reported in the dog with specific, asymmetric devices available.[67]

The outcome of transcatheter ASD and VSD closure appears good, with case reports and case series describing event-free survival in several dogs.[65,68] However, embolization of these devices is a risk and can be devastating as surgical retrieval may be required via advanced surgical techniques that are not available at all veterinary centers.[65,69] Additionally, thrombosis of the device is a risk and therapy with clopidogrel (2 mg/kg PO q 24 h) is advised for 6 months post-implantation.

Hybrid Interventions

A hybrid procedure refers to a procedure that utilizes a surgical approach combined with image-guided intervention.[70-72] Examples in veterinary medicine include delivery of balloon dilation catheters directly through the left atrium via echocardiographic guidance for treatment of mitral stenosis[73] or cor triatriatum sinister[74] as well as perventricular VSD occlusion[75] and transatrial ASD occlusion.[69] Future options for mitral valve repair or replacement also are likely to use a hybrid approach given the complexities of left heart access and the large delivery systems required of these techniques.[76]

Perventricular Ventricular Septal Defect Occlusion

As an example of the hybrid approach to cardiac disease, devices used for closing VSDs described above via a transcatheter approach can also be delivered directly through the right ventricular wall and guided by echocardiography.[75,77] The indication for such a technique is dictated by animal size; the transcatheter devices often require delivery systems of 9 Fr diameter and larger, which may be too large for vascular access in small dogs or cats. In such cases, a right lateral thoracotomy can be performed to expose the right ventricular free wall and beating heart. A pursestring suture is placed around the proposed access site prior to myocardial puncture to control hemorrhage. A vascular access needle is inserted directly across the right ventricular free wall, guided by echocardiography, through which a guidewire is placed and the desired delivery system advanced (Figure 122-14 and Video 122-9). Echocardiographic and fluoroscopic guidance can then proceed as is done with the transcatheter delivery of the same device. A hybrid approach such as this not only overcomes the challenge of vascular access in a small dog, it also allows for a more direct path to the defect, which can make deployment of the device more straightforward than a conventional, percutaneous approach. The drawback to hybrid techniques is an increased morbidity associated with the approach, but such morbidity is typically low in dogs.

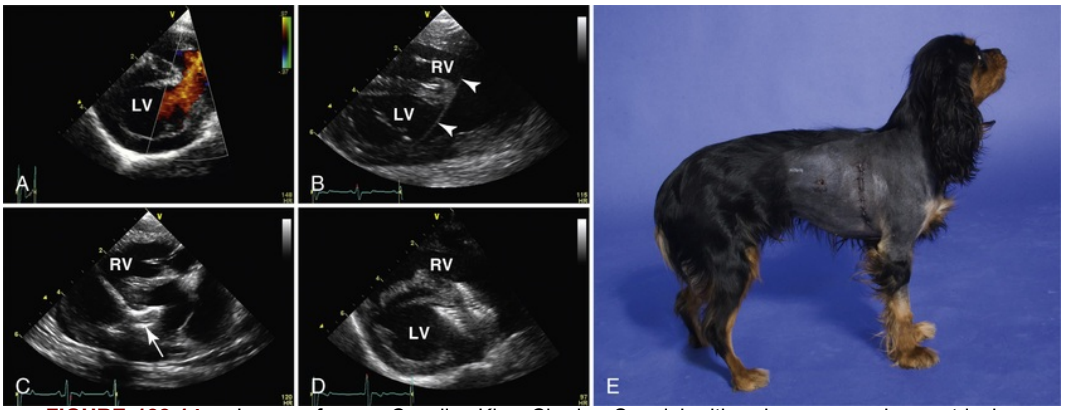

FIGURE 122-14 Images from a Cavalier King Charles Spaniel with a large muscular ventricular septal defect (VSD) undergoing hybrid perventricular VSD closure. **A,** The defect on preoperative transthoracic echocardiography. **B,** An epicardial echocardiographic image showing the guidewire (arrowheads) traversing the right ventricular (RV) free wall and crossing the VSD into the left ventricle (LV). **C,** The sheath across VSD with deployment of the distal retention disc (arrow) in the LV. **D,** The postoperative transthoracic echocardiogram with the device in place and spanning the interventricular septum. **E,** A photograph of the dog 2 days after surgery showing the site of right lateral thoracotomy that provided access to the beating heart for perventricular delivery of the Amplatzer muscular ventricular septal occluder. Caudal to the surgical incision is a small incision from the postoperative thoracostomy tube placement.

CHAPTER 123

Gastrointestinal Interventional Therapies

Allyson C. Berent

Esophageal Balloon Dilation, Bougienage, and Stenting

Indications and Background

Esophageal obstructions in dogs and cats are most commonly associated with a foreign body or an acquired esophageal stricture. Other causes include esophageal neoplasia and extraluminal compressions from vascular ring anomalies (see ch. 273).[1-3] Strictures occur secondary to mucosal injury and this is commonly the result of severe gastroesophageal reflux, caustic mucosal damage, or trauma.[2-25] Since the esophageal mucosa is lined by non-keratinized, stratified squamous epithelial cells, the acidity and enzymes in gastric fluid can result in severe mucosal and muscular injury, leading to circumferential narrowing and an esophageal stricture.[16]

Various treatments for esophageal strictures have been reported including bougienage, balloon dilation, esophageal resection and anastomosis, and salvage esophageal stenting.[1-22,26] Esophageal strictures are notoriously a frustrating condition for veterinarians to treat because they are difficult to cure, are typically recurrent, and can be highly refractory to dilation.[26] Treatments using topical therapies to decrease stricture recurrence like triamcinolone injections[12,16] or mitomycin C[22] have been used. Previous retrospective studies evaluating esophageal balloon dilation suggest a good outcome in up to 75% of cases where a gruel diet is tolerated,[2,4-9] and only 14-25% of patients are reported to return to eating normal dry food. In humans, refractory strictures are those that fail to resolve despite more than three dilation procedures,[13-15] and this is commonly seen in veterinary patients as well.

Balloon dilation and bougienage are the most commonly considered treatment options in dogs and cats with esophageal strictures.[2-9] Esophageal stents (Video 123-3) are reserved for those cases where balloon dilation or bougienage fails.[18-21,26] The use of various types of stents was recently retrospectively reported[26] in a group of nine dogs: biodegradable, self-expanding plastic stents (SEPS), self-expanding metallic stents (SEMS), as well as covered and uncovered stents. These stents were found to ultimately improve the dysphagia, but were met with a common complication of discomfort when swallowing, profound chronic nausea, hypersalivation, and migration. Due to the high likelihood of poor tolerance, this procedure is reserved for those pets that have failed serial balloon dilation, and should be considered a salvage procedure. A covered stent is typically recommended so that if the stent is poorly tolerated it can be endoscopically removed. Stents seem to be far better tolerated for malignancy than benign strictures.[1,23]

Equipment

For evaluation of an esophageal obstruction, a standard flexible gastrointestinal endoscope is used (see ch. 83 and 113). Ideally, all bougie or balloon dilation procedures should be done under concurrent fluoroscopic guidance. This allows the operator to see when the entire stricture is effaced, which is not possible with endoscopic imaging alone (E-Figure 123-1). Many strictures result in esophageal muscular fibrosis, as well as mucosal, and if the fibrous band of the mucosa is sufficiently effaced, the muscular component may remain intact, resulting in recurrence.

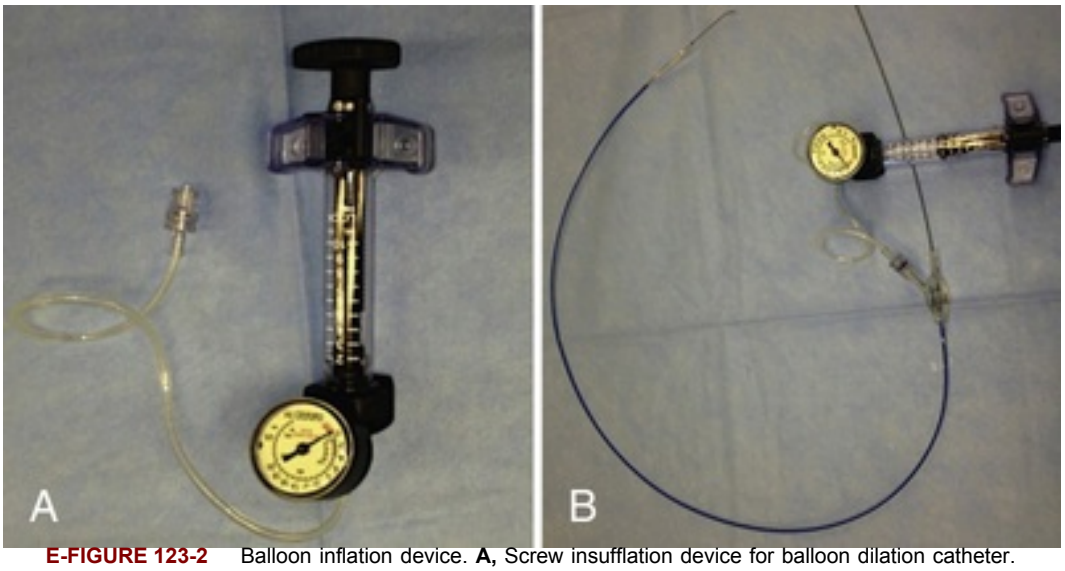
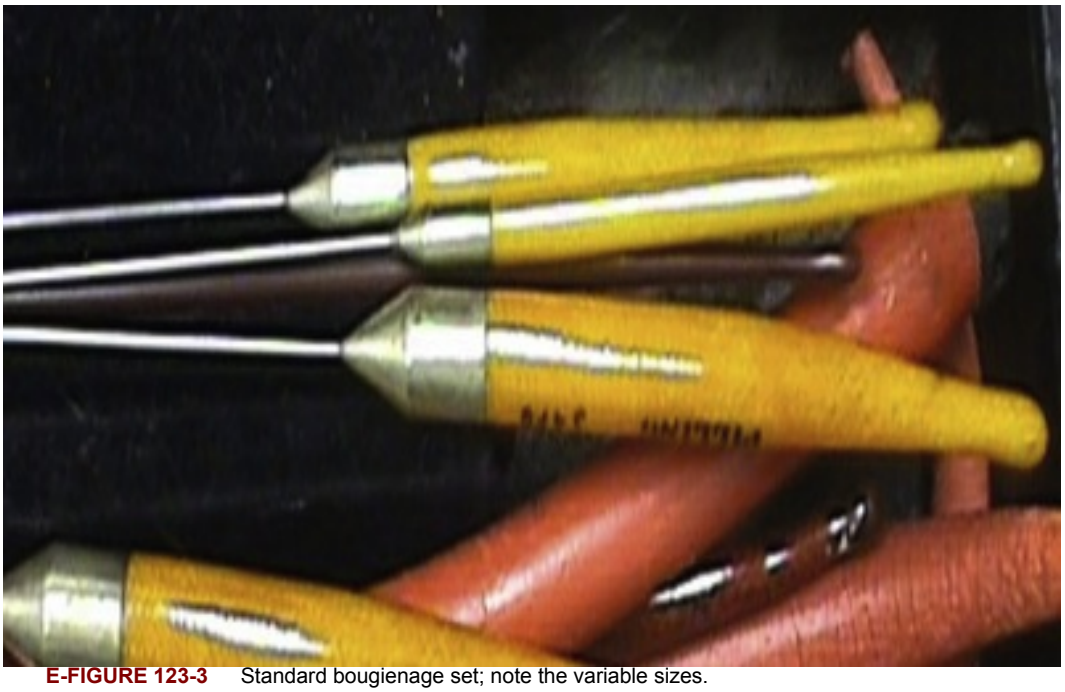
E-FIGURE 123-1 Endoscopic and fluoroscopic images during balloon dilation of an esophageal stricture in a dog. **A,** Endoscopic image of a stricture in the esophageal lumen. **B,** Guide wire passed through the stenosis. **C,** Deflated balloon passed over the guide wire, through the stenosis. **D,** Inflation of the balloon within the stricture. **E,** Fluoroscopic image of the dog in lateral recumbency during balloon dilation of the stricture. Notice the narrowing in the center of the balloon and the endoscope sitting in front of the balloon. **F,** Fluoroscopic image of the stricture during balloon dilation showing the severe narrowing of the esophagus, which is a muscular stenosis that is very difficult to break. **G,** Endoscopic image of the dog after balloon inflation when a waist was still present during fluoroscopy supporting that endoscopic visualization alone may underestimate the degree of stricture defacement. **H,** Endoscopic image after the stricture was effaced on fluoroscopic imaging showing the desired longitudinal mucosal tear (top of image).

Balloon dilation catheters can be variable or fixed in diameter, and some are placed over a guide wire, while others have a soft tip and closed end. For proper dilation, an insufflation device is required. The amount of force required to properly efface a fibrous band can be upward of 6-12 ATM of pressure, where digital hand inflation reaches only 1-4 ATM of pressure (E-Figure 123-2). A wide variety of balloon sizes should be available (6 mm to 30 mm diameter). Bougienage dilator sets (E-Figure 123-3) are recommended to be placed under fluoroscopic guidance.



E-FIGURE 123-2 Balloon inflation device. **A,** Screw insufflation device for balloon dilation catheter. **B,** Balloon dilation catheter with two ports on the end, one for a guide wire and the other for a balloon dilation device.

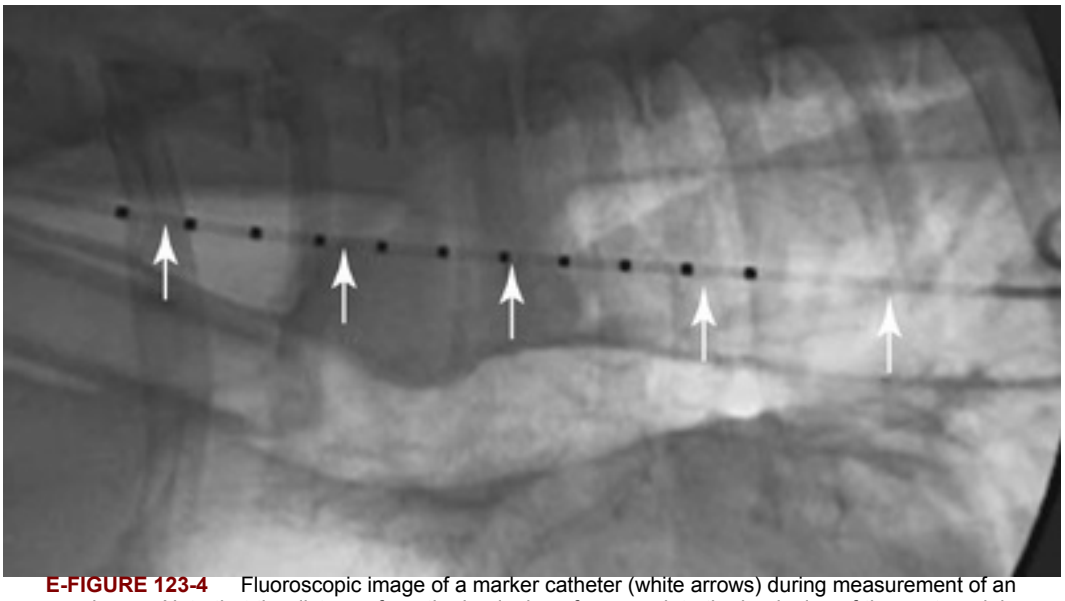


E-FIGURE 123-3 Standard bougienage set; note the variable sizes.

Techniques

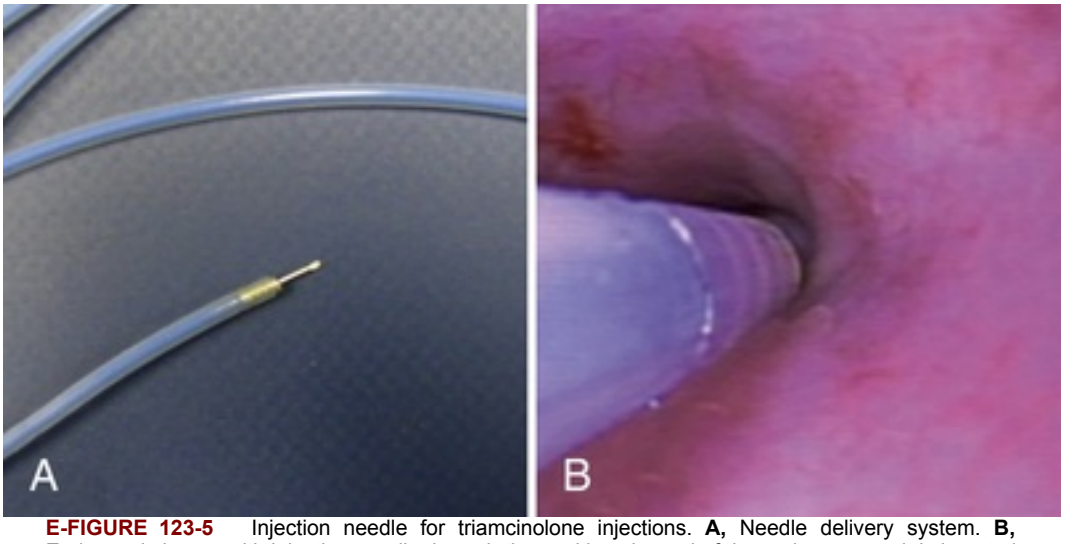
Balloon Dilation Procedure

Using endoscopic guidance, a balloon size is chosen based on the length of the stricture and the diameter of the normal esophagus. This can be estimated during endoscopy; however, a more accurate determination is typically done using a marker catheter, contrast/air, and fluoroscopic imaging (E-Figure 123-4). Once a balloon size is chosen, then this is advanced through the lumen of the stricture watching with endoscopic visualization. Using a guide wire helps to prevent iatrogenic trauma or esophageal perforation. A balloon is chosen that is 2 cm or more longer than the stenosis, and the diameter of the balloon should be equivalent to the diameter of the esophagus measured using fluoroscopy caudal to the stenosis. If fluoroscopy is not used, then an estimated diameter is chosen using the outer diameter of the endoscope for a reference. In this case, it is typically recommended to start small (≈6 mm) and work up in 2 mm increments until the lesion is visually torn and good apposition of the balloon is against the esophageal mucosal wall when inflated. Since endoscopic visualization is only confirming mucosal effacement of a stricture, fluoroscopy is used to confirm muscular effacement as well (see E-Figure 123-1).



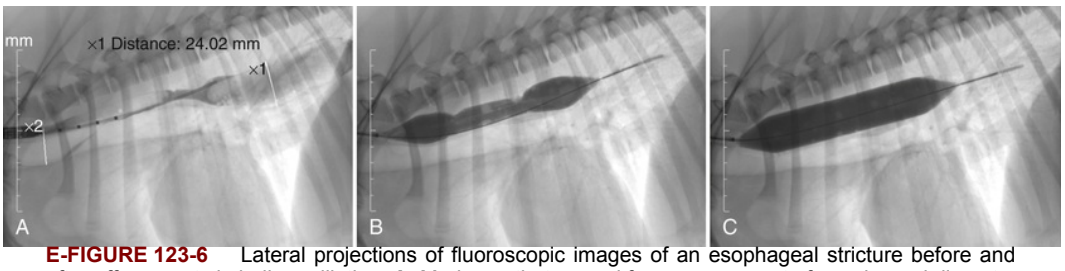
E-FIGURE 123-4 Fluoroscopic image of a marker catheter (white arrows) during measurement of an esophagus. Note that the distance from the beginning of one mark to the beginning of the next mark is 10 mm.

Prior to balloon dilation, superficial injections of local steroids (triamcinolone) may be utilized to help reduce stricture re-formation. Triamcinolone injections are done using a 23- to 25-gauge, 4- to 5-mm length endoscopic injection needle, preloaded with the appropriate dose of triamcinolone (6-8 mg/patient in 0.5 mL aliquots per quadrant up to 0.3 mg/kg). After injection, a bleb of fluid should be visualized under the mucosal tissue (E-Figure 123-5).

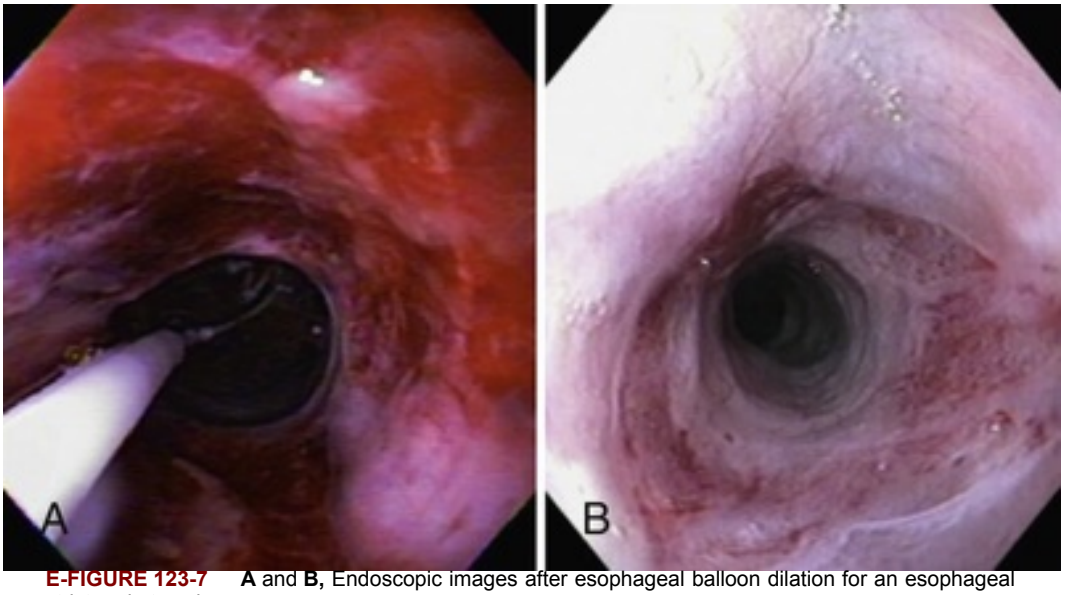


E-FIGURE 123-5 Injection needle for triamcinolone injections. **A,** Needle delivery system. **B,** Endoscopic image with injection needle through the working channel of the endoscope as it is inserted under the esophageal mucosa for injection.

If balloon dilation is being done under fluoroscopic guidance, the inflation device is filled with a 50% contrast solution so that the dilation can be visualized. If no fluoroscopy is being used, then saline infusion is acceptable. Once across the stenosis and the stricture is engaged, the inflation device is used to inflate the balloon to the recommended pressure while the balloon is tightly held in place at the mouth. Some degree of superficial mucosal tearing and bleeding is expected. In general, the procedure is complete when the stricture is effaced based on fluoroscopy (E-Figure 123-6), or the mucosal tearing seen endoscopically extends linearly beyond the stricture, deep into the submucosa, or excessive bleeding is seen (E-Figure 123-7).



E-FIGURE 123-6 Lateral projections of fluoroscopic images of an esophageal stricture before and after effacement via balloon dilation. **A,** Marker catheter used for measurement of esophageal diameter and stricture length. **B,** Balloon dilation showing the waist of the esophageal stricture. **C,** Effacement of the stricture when the balloon is fully inflated. (Courtesy Dr. Chick Weisse.)



E-FIGURE 123-7 **A** and **B,** Endoscopic images after esophageal balloon dilation for an esophageal stricture in two dogs.

A recommended interval between balloon dilation varies per clinician and institution. No consensus or standard has been established in either human or veterinary medicine.[13-15] There is very little data to support that frequent, small intervals of balloon dilation is better.[2-9]

Bougienage Procedure[3]

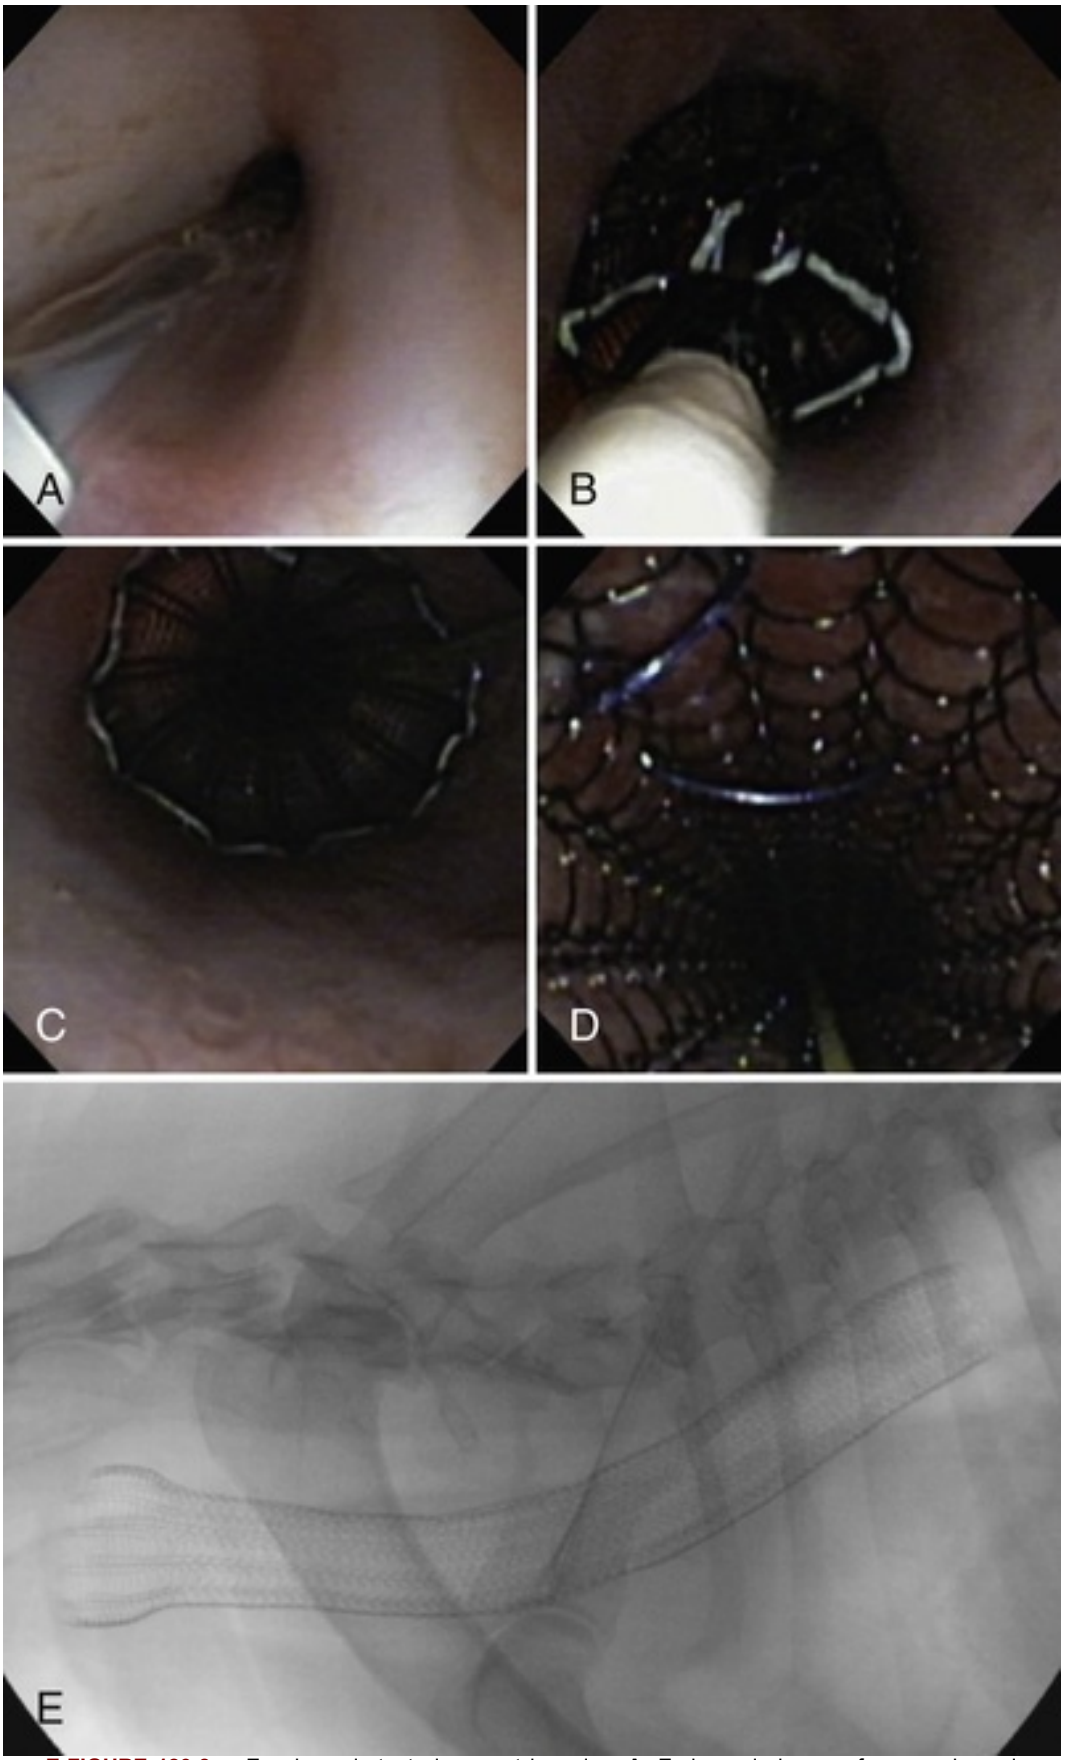
The bougie size is selected based on estimations of stricture diameter, as discussed above for balloon dilation. The initial bougie is typically 1-2 mm larger than the stricture meatus, and is subsequently increased in 1-2 mm increments until the lesion is similar in size to the normal esophagus.

Topical mitomycin C (MMC) infusions have been performed in cases of refractory strictures.[22] Mitomycin C is an antibiotic and antineoplastic drug that is produced by *Streptomyces caespitosus* resulting in inhibition of fibroblast proliferation. This has been shown in children with esophageal strictures to hold benefit in preventing recurrence.[22] In veterinary medicine, the author typically uses 2.5-5.0 mL of a 0.1% solution soaked on a gauze sponge and placed endoscopically over the stricture site topically for 5 minutes and then the site is flushed with saline. Gloves should be worn when using this material.

Esophageal Stenting

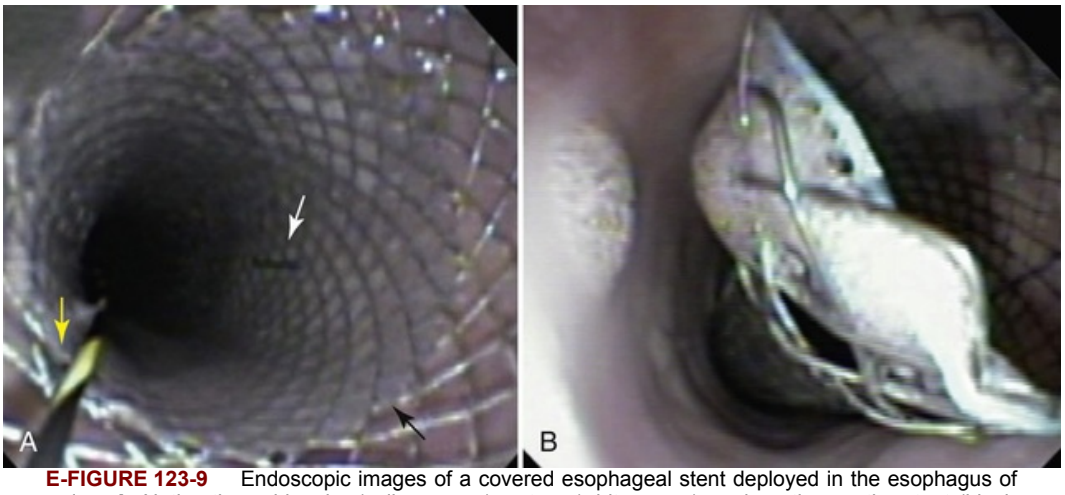
For esophageal stent placement, dogs are placed in lateral recumbency and the entire esophagus is visualized using fluoroscopic and endoscopic guidance. The ventral cervical region of the dog is clipped and aseptically prepared in order to place tacking sutures on the cranial aspect of the stent to prevent stent migration. Once the stricture is visualized, the esophagus and stricture are measured using a guide wire and marker catheter combination. The stricture is pre-ballooned partially, to permit safe passage of the endoscope through the

lumen to visualize the most caudal aspect of the abnormal tissue. Length is typically measured to ensure at least 1-2 cm of esophagus is stented both cranial and caudal to the location of the stricture. The patient is placed in dorsal recumbency and the C-arm is rotated so that a lateral image is projected during stent placement to accurately see stent deployment. If possible, the cranial aspect of the stent is extended to cross the level of the thoracic inlet so that it can be safely and easily sutured in place through the esophageal wall to prevent migration. Sutures can also be placed endoluminally using a double lumen endoscope. This procedure should not be done unless the operator is very comfortable understanding various types of stent deployment (E-Figures 123-8 and 123-9). Based on limited data[26] the author recommends a covered stent (see E-Figure 123-9) that is sutured in place, and then it can be removed if it is poorly tolerated.



E-FIGURE 123-8 Esophageal stent placement in a dog. **A,** Endoscopic image of an esophageal stent delivery system being placed over a guide wire through an esophageal stricture. **B,** Stent deployment using endoscopic imaging. **C,** Image of the rostral aspect of the esophageal stent after

deployment. **D,** Two sutures seen through the interstices of the esophageal stent. **E,** Endoscopic image of the esophageal stent after deployment.



E-FIGURE 123-9 Endoscopic images of a covered esophageal stent deployed in the esophagus of a dog. **A,** Notice the guide wire (yellow arrow), suture (white arrow), and coating on the stent (black arrow). **B,** Notice the endoscopic image of the dog-bone shape of the stent.

Follow-up

Patients are typically discharged the same day as the procedure and treated with a proton pump inhibitor and sucralfate. Repeat balloon dilation can be performed as needed based on clinical signs of recurrence.

Complications

The most severe complication seen with treatment of esophageal strictures is esophageal tearing, resulting in a pneumomediastinum, pneumothorax, and potentially pyothorax. Most tears do not require surgical correction and will heal by second intention, but require the placement of a percutaneous endoscopic gastrostomy (PEG) tube. Esophageal stricture recurrence post-dilation is also seen in a majority of dogs.[3-9]

Outcome

Success rates vary depending on the outcome measures. Balloon dilation is reported to have a success rate of 77-88%,[2-9] but the definition of success can be persistent regurgitation <50% of the original presentation, or the tolerance of any dietary consistency, including those dogs that can only be fed liquid or gruel. A study evaluating the use of bougienage in dogs and cats found a "good" outcome, with tolerance of solid food and minimal regurgitation, in 70% of dogs and 75% of cats.[3]

In the author's experience, a greater success has been achieved since using the combination of endoscopy and fluoroscopy to break each stricture, as a false sense of effacement is commonly seen if endoscopy alone is utilized.

Special Considerations

Esophageal stents should only be considered when traditional dilation attempts have failed.

Alternatives

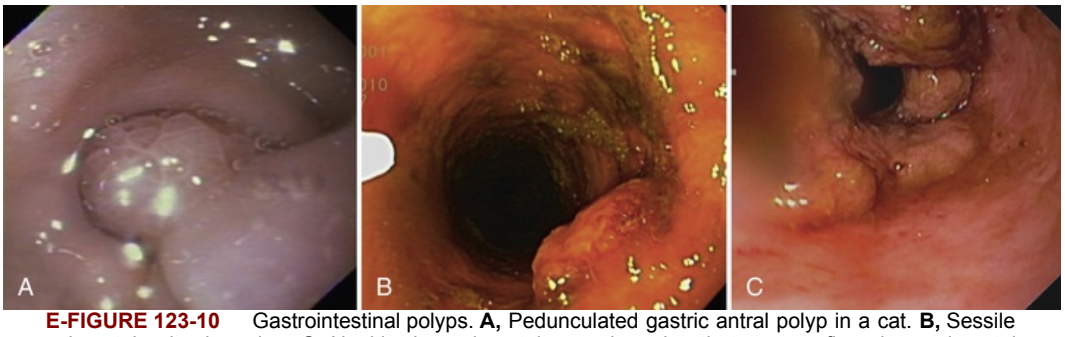
The author has placed an esophageal feeding tube through the lumen of a stricture after balloon dilation to prevent the edges of the stricture from coaptating, in hopes of maintaining a lumen and allowing a mechanism for feeding if the stricture recurs, without the need for a gastrostomy tube. This has been met with good preliminary success, but these data are not published. Another alternative is the use of an experimental device that is currently being investigated using serial balloon dilations daily.

GI Polypectomy/Electrocautery

Indications and Background

Gastrointestinal (GI) polyps are rare findings in veterinary medicine, and are most commonly in the stomach or at the colorectal junction.[24,25,27] In human medicine, malignant transformation of polyps is a major concern, necessitating screening and removal.[28] In dogs, colorectal masses are rare, and when diagnosed are either adenocarcinoma (≈60%), adenomatous polyps (≈20%), or carcinoma *in situ* (≈15%).[24,25] Approximately 18% of diffuse/multiple polyps and 7% of solitary polyps are documented to undergo a malignant transformation in dogs,[24] making timely removal ideal. If the mass is single, sessile or pedunculated, and the biopsy is suggestive of a benign condition like adenomatous polyp or carcinoma *in situ,* then endoscopic polypectomy, with or without endoscopic mucosal resection (EMR), can be recommended. Alternatively, if the mass is atypical (a "napkin ring" or "apple core shape"), poorly marginated, progressing in size and shape, or the histopathology is malignant and invasive, then surgical resection should be recommended.

A polypectomy procedure is one in which you can endoscopically remove a mass lesion with an electrosurgical snare. EMR is used when the polypoid mass is more broad-based and flattened, or sessile, and a "lift" is required in which fluid is injected into the submucosa to separate the mucosa from the muscular layer of the luminal wall, making full resection more effective and safe. Gastrointestinal polyps are typically superficial pedunculated masses with a narrow stalk. Sessile or flattened polyps are more commonly seen in the colon (E-Figure 123-10).



E-FIGURE 123-10 Gastrointestinal polyps. **A,** Pedunculated gastric antral polyp in a cat. **B,** Sessile colorectal polyp in a dog. **C,** Napkin ring colorectal mass in a dog that was confirmed as colorectal adenocarcinoma.

Equipment

Snare polypectomy requires the use of a standard gastrointestinal endoscope with a working channel large enough to accommodate the proper size snare device. This is typically 2.0 or 2.8 mm in diameter. Video gastroduodenoscopy improves visibility and is recommended. For electrocautery, a cautery pad should be placed on the exterior of the patient for grounding. A routine cautery unit with a proper adaptor and foot pedal is required (E-Figure 123-11). A standard endoscopic basket retrieval device is used to remove the polyp. If EMR is to be performed, an injection needle is required, and either saline or methylene blue should be used for the infusion (Figure 123-12 and E-Figure 123-13).

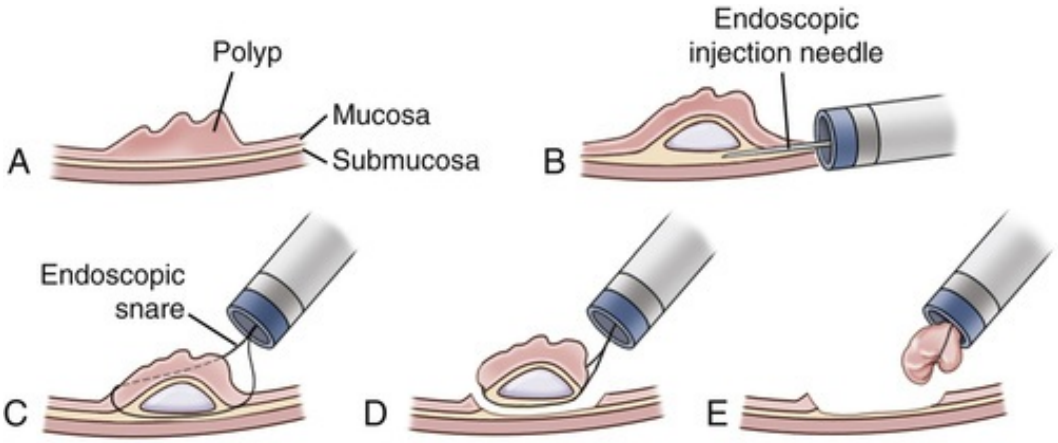
E-FIGURE 123-13 Gastric polypectomy using endoscopic mucosal resection and methylene blue injection. **A,** Polypoid mass in the stomach of a cat. **B,** Saline and methylene blue is injected at the base of the mass. **C,** Lift of the lesion. **D** and **E,** The snare encircles the lesion and is closed down at the base. **F,** Perpendicular positioning of the snare helps to encompass the base of the lesion. **G,** Cautery is applied and discoloration of the polyp can be observed before removal. **H,** Removal of the polyp from the surface of the stomach with the lesion free within the gastric lumen. (From Weisse C, Berent A: *Veterinary image-guided interventions*, Hoboken, NJ, 2015, John Wiley & Sons, Inc.)

Sessile polyps may require the use of an over-the-scope EMR cap. These allow suction to be applied to a lesion to more successfully perform the EMR and submucosal infusion during electrocautery (E-Figure 123-14).



E-FIGURE 123-14 **A-E,** Endoscopic mucosal resection with a plastic cap (EMRC).

Techniques

Each patient should be treated with broad-spectrum antibiotics, covering for intestinal microflora, and the patient should be prepared for a standard gastroscopy or colonoscopy. A thorough gastroscopy or colonoscopy should be performed to identify the location, size, shape and appearance of each polyp. If a flat or sessile polyp is seen, then a saline lift is done to see if it easily moves away from the submucosa. If it does, this is often a sign that the lesion is superficial and a polypectomy is indicated[29-31] (Video 123-2).

For sessile or flattened lesions, a "fluid" lift can be done using either saline, 5% dextrose in water (D5W), or a mixture of D5W and epinephrine and/or methylene blue. A 1 : 9 solution of epinephrine (0.1 mg/mL): D5W and then 1-2 drops of methylene blue is useful.[29] The blue color is often not taken up by the polypoid lesion, only the submucosal tissue, making a clear demarcation between the normal and abnormal tissues during resection.

The mass is manipulated to assess the base and determine if a lift is needed (see Figure 123-12).[27] If a lift is necessary then an endoscopic injection needle is inserted under the base, into the submucosal layer, and a fluid pocket is created. A "bleb" should be clearly visualized (see Figure 123-12, *C* and *D*). Then the snare device is placed around the base of the mass, including the bleb. This bleb allows a deeper cauterization while protecting the muscular layers from thermal burn and perforation. The snare device is attached to the electrocautery unit. The unit is set to monopolar coagulation at a power of 15-20 watts. Caudal traction is placed on the mass to protect the distal cranial wall. Once removed, the site is thoroughly evaluated with endoscopic visualization, insufflation, +/− contrast, to ensure there is no perforation. If any questionable areas are seen, and tissue integrity is lost, then endoscopic clips can be used to secure any defects. This technique is similarly done in the stomach for gastric lesions (see E-Figure 123-13).[32-34] It is harder to perforate the stomach than the colon during a polypectomy due to the relative thickness of the tissue. If a lesion is sessile, then an EMR can be done using a transparent plastic cap (EMRC, see E-Figure 123-14), allowing suction to pull the lesion away from the wall for a deeper cauterization.

Follow-up

After polypectomy, patients are typically discharged the same day. After colorectal polypectomy, metronidazole is recommended along with a high fiber diet. Rectal examinations to examine the location of polypectomy can be considered every 3-6 months. For gastric polyps, a proton pump inhibitor and canned food are recommended for a few days.

Complications

Perforation of the GI tract, hemorrhage, recurrence and incomplete resection are possible but rare. A post-polypectomy syndrome is reported in human medicine[29-34] resulting from transmural burning and late perforation. With experience, and the availability of EMR, the incidence of these complications has reduced dramatically.[30,31]

Outcome

Once complete excision for a benign mass is accomplished, the prognosis for recovery and resolution of hematemesis, vomiting, hematochezia or tenesmus is excellent.[29-34]

GI Stenting

Indications and Background

Obstructions of the GI tract secondary to strictures or tumors occur most commonly in the descending colon at the colorectal junction (see ch. 277 and 278).[25,35-38] Tumors have also been seen at the gastric cardia, pyloric antrum, and proximal duodenum.[39,40] In humans, stenting of GI malignant obstructions is commonly reported, and is typically considered as a palliative treatment for nonresectable neoplasia, or as a "bridge" to a more definitive surgery, providing immediate endoluminal decompression and improved quality of life.[37-40] If surgery is contraindicated, or not possible, stenting is considered a good long-term solution, with clinical success rates approaching 90%, and technical success rates as high as 92-100%.[37-40]

Gastroduodenal stenting of the stomach or duodenum is not commonly performed in veterinary medicine. It has been done for malignant obstruction of the gastric cardia, pyloric outflow tract, and duodenum in the author's practice. Stenting should be reserved for cases where traditional surgical resection is not recommended. The location of the major and minor duodenal papillae should be appreciated prior to duodenal stenting as compression of a tumor in this region could result in a biliary or pancreatic duct obstruction. If the lesion is obstructive, resulting in vomiting and malnutrition, then stents are the most useful.

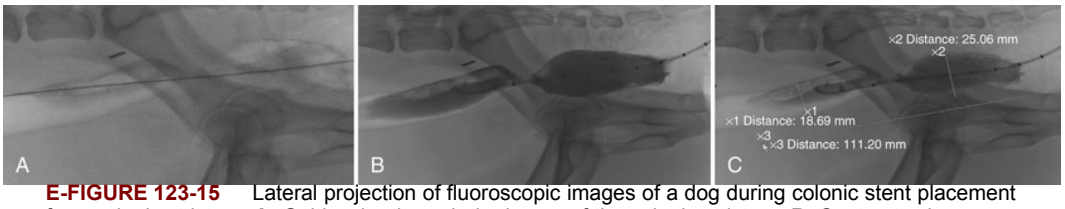
Feline GI adenocarcinoma is an aggressive form of GI neoplasia, most commonly found at the colorectal junction (see ch. 278). It is associated with distal metastasis 75% of the time, making partial colectomy a difficult treatment option. If a colectomy is performed, cats with metastasis had a much lower median survival time (MST) than those without (49 and 259 days, respectively).[41,42] Outcomes in dogs after partial colectomy had a longer MST (22 months) than those that did not have surgery (15 months).[25]

In both dogs and cats palliative stenting[35,36] can be considered, and is often chosen over more aggressive surgeries due to the outpatient nature, minimal morbidity, and low complication rates. Stenting will only be useful to treat obstipation caused by the obstructive lesion.

Colonic strictures have been treated with stents as well.[37,38] For strictures, covered stents are typically used due to the high risk of ingrowth of tissue. Migration is the biggest problem with covered, retrievable stents (>60%), and stricture recurrence can be seen after stent removal in approximately 50%.[37,38]

Equipment

Standard flexible GI endoscopes are needed. If the stent is to be placed through the working channel of the endoscope, then an appropriately sized delivery system must be used. The scope is used to evaluate and biopsy the lesion, and pass a guide wire (0.035" hydrophilic angle-tipped 260 to 400 cm long) through the lumen of the obstruction, and then standard fluoroscopy is used to monitor the guide wire and accurately deploy the stent. A marker catheter is used to estimate the luminal diameter and obstruction length so an appropriate stent size can be chosen (E-Figure 123-15).



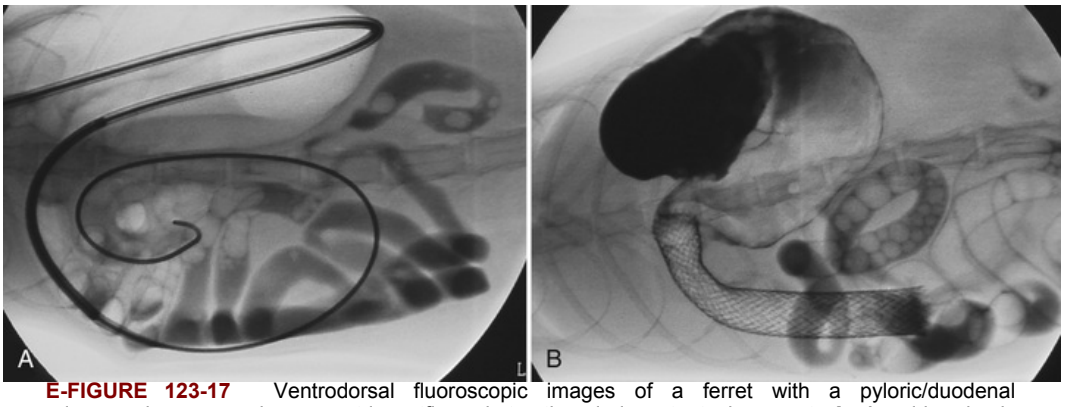
E-FIGURE 123-15 Lateral projection of fluoroscopic images of a dog during colonic stent placement for a colonic stricture. **A,** Guide wire through the lumen of the colonic stricture. **B,** Contrast colonogram using a marker catheter across the stenosis for measurement of the colonic lumen. **C,** Using the marker catheter for magnification, the diameter and length of the colon and stent location are measured.

Gastrointestinal stents are typically woven, metallic, and self-expanding. Some stents are covered and others uncovered. The uncovered stents are typically used for malignant obstructions, whereas a covered stent is for strictures. Colonic stents have a flare at the distal end to prevent aboral migration (E-Figure 123-16). Covered stents have a string at one end to endoscopically retrieve the stent.

E-FIGURE 123-16 A covered gastrointestinal stent. Notice the dog-bone shape to the stent to prevent migration and the string on the end of the stent for removal.

Techniques

Gastroduodenal stenting (E-Figure 123-17) is performed by gaining access across the obstructive lesion using fluoroscopy and gastroduodenoscopy (see also ch. 113). A guide wire is advanced through the working channel of the endoscope, in the GI lumen, and through the lumen of the tumor. Using fluoroscopic guidance, the wire is advanced aborad beyond the obstruction. Next, the endoscope is removed over the wire, as the wire is monitored under fluoroscopic visualization to ensure it remains across the obstruction. A marker catheter is advanced over the guide wire and a contrast study is done to measure the diameter of the lumen and the length of the obstruction for appropriate stent sizing. Once the stent is chosen, it is deployed under fluoroscopic guidance. In some instances for upper GI stenting it is deployed through the working channel of the endoscope for stent positioning. The endoscope is then used to assess stent location and contrast can be used to confirm luminal patency.



E-FIGURE 123-17 Ventrodorsal fluoroscopic images of a ferret with a pyloric/duodenal adenocarcinoma causing a gastric outflow obstruction during stent placement. **A,** A guide wire is advanced from the mouth, into the stomach, across the pylorus and duodenum and into the proximal jejunum. Over the wire is the delivery system with a non-deployed self-expanding woven metallic stent placed across the obstruction. **B,** The SEMS after deployment documenting patency of the proximal duodenum and pylorus. (From Weisse C, Berent A: *Veterinary image-guided interventions*, Hoboken, NJ, 2015, John Wiley & Sons, Inc.)

Colonic stenting (Figure 123-18 and E-Figure 123-19) is performed using colonoscopic guidance similar to that described above. Using a marker catheter, a colonogram is performed and an appropriate stent size is chosen. The stent is then deployed, being careful to prevent it from being more caudal than the rectoanal junction (see Figure 123-18 and E-Figure 123-19). Once the stent is deployed, the endoscope is advanced into the colon to ensure proper placement. If the stent is covered, the distal end can be sutured to the rectal mucosa to prevent stent migration.

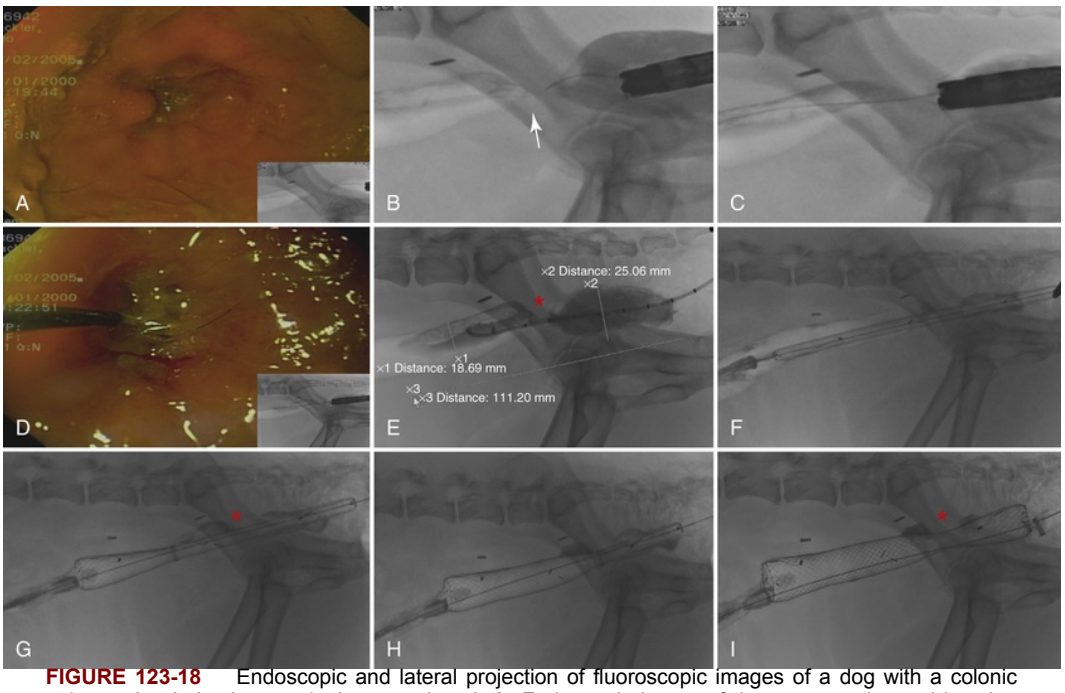


FIGURE 123-18 Endoscopic and lateral projection of fluoroscopic images of a dog with a colonic stricture that is having a colonic stent placed. **A,** Endoscopic image of the severe colorectal junction stricture. **B,** Fluoroscopic image of a guide wire entering the lumen of the stricture (white arrow) during colonoscopy. **C,** Wire through the lumen of the stricture. **D,** Endoscopic image of the wire entering the lumen of the stricture. **E,** Marker catheter through the lumen of the stricture (red asterisk) as contrast is injected to measure the colonic diameter. **F,** Stent in the delivery system placed over a guide wire imaged on a lateral projection during fluoroscopy. **G,** Deployment of the stent across the stenosis (red asterisk) under fluoroscopic guidance. **H,** Stent as it is being deployed across the stricture. **I,** Fluoroscopic image of the stent after it is fully deployed. Red asterisk is the location of the stricture.

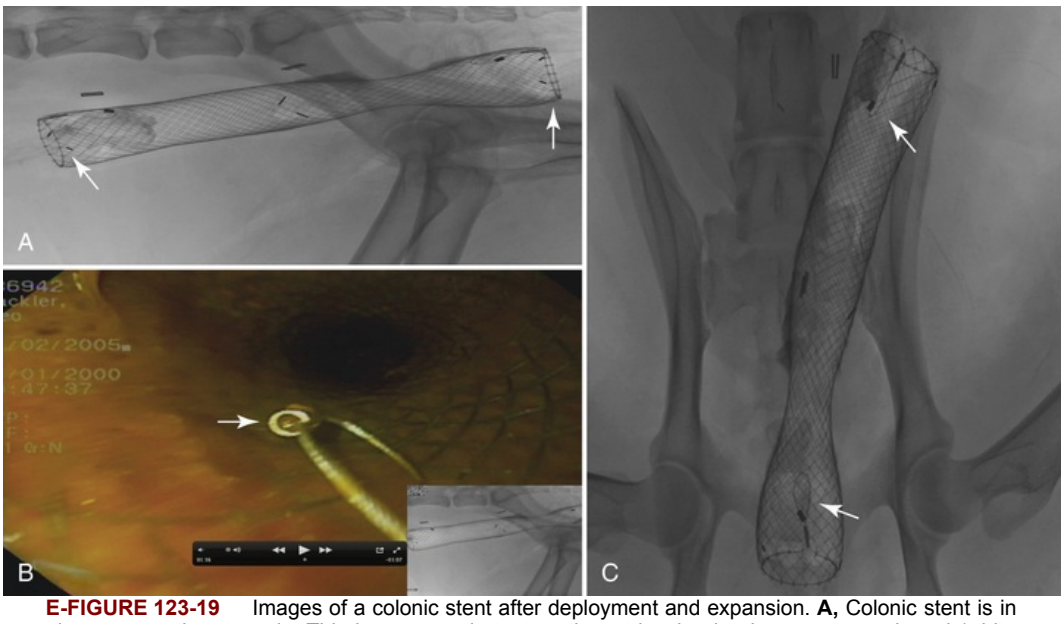


E-FIGURE 123-19 Images of a colonic stent after deployment and expansion. **A,** Colonic stent is in place across the stenosis. This is a covered stent so the retrieval string is seen on each end (white arrows). **B,** Endoscopic image of colonic stent after deployment. Notice the retrieval string (white arrow) at the distal end. You can see the colon is now patent. **C,** A ventrodorsal image of the colonic stent after deployment with the retrieval strings (white arrows).

Follow-up

Patients with gastroduodenal stents should be fed small meals often for the first few days. For gastric cardia stents, antacid therapy and antiemetics should be continued aggressively. Patients with colonic stents are treated with a low residue diet, stool softeners, and broad-spectrum antibiotics.

Complications

Tissue ingrowth into an uncovered stent and migration of a covered stent are the most common complications seen in both human and veterinary medicine. Fecal incontinence of colorectal stenting can occur, but is rarely seen if the stent is positioned in front of the anus. For colonic tumors, tenesmus can be associated with infiltration of the pelvic nerves, and despite de-obstipation being successful with the stent, continued straining and discomfort may be seen.

Other potential complications, that have not yet been seen in the author's experience, include GI perforation, irritation, intractable tenesmus, persistent vomiting, stent shortening and associated re-obstruction, and hemorrhage.

Outcome

Only a small number of dogs and cats have had stents placed in both the upper and lower GI tract. For colonic stenting, the MST for malignancy in our cases was approximately 6 months (range, 19-274 days). Patients with malignancy died of distant tumor effects.

Special Considerations

Stents placed for GI obstructions will benefit the patient, but if the patient is straining or vomiting due to the presence of the disease and the local effects on the nerves, rather than a physical obstruction, then a stent will likely not help.

Endoscopic Retrograde Cholangiography and Biliary Stenting (ERC/BS)

Indications and Background

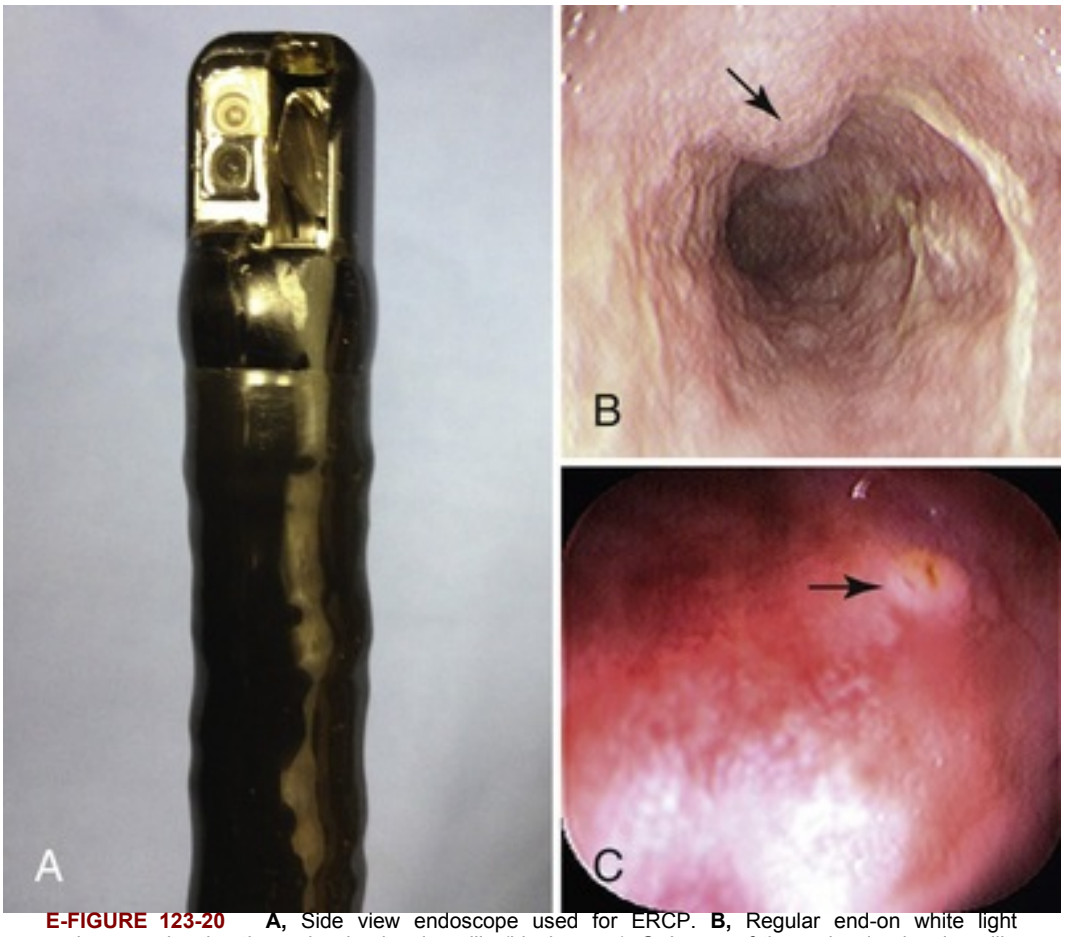
Diagnostic imaging using endoscopic retrograde cholangiopancreatography (ERCP) was first reported in

veterinary patients in 2005.[43-46] This series reported on diagnostic ERCP in 30 clinical dogs with vague GI signs, showing success to be associated with the size of the patient.[43] Then, in 2014 the same group reported on diagnostic ERCP in 4 research cats.[46] The first report of the use of endoscope retrograde cholangiography (ERC) with decompressive biliary stenting (ERC/BS) for the treatment of an extrahepatic biliary duct obstruction (EHBDO) was more recent.[47] ERCP is a minimally invasive technique that combines endoscopy and fluoroscopy to image the extrahepatic biliary system and pancreatic ducts. In the last few decades ERCP has been considered the best option for improving the diagnosis, and simultaneous treatment, of biliary and exocrine pancreatic diseases in humans.[48,49] Traditional surgical treatment options in veterinary medicine have been met with high surgical mortality rates in dogs and cats, ranging between 25-73% and 50-75%, respectively, and are discussed in more detail in ch. 280, 281, and 288.[50-53] In humans, similar problems have encouraged less invasive treatments like ERCP and biliary stenting.[48,49]

Cannulation of the duodenum was possible in 8 of 9 dogs, ERC was successful in 6 of 9 dogs, and stent placement was possible in 5 of 6 dogs recently.[47] This study was performed prior to using the pediatric ERCP scope, which improves duodenal cannulation, making procedure success higher for the smaller patients. None of these procedures were met with any major complications. This procedure is considered very difficult and should ideally be done in stable patients by someone well experienced with pediatric ERCP.

Equipment

A side-view duodenoscope (E-Figure 123-20) is required to perform this procedure and it is available in two sizes, 11.3 mm and 7.5 mm. The smaller pediatric scope has a smaller working channel (2.0 versus 3.2 mm), only accommodating smaller instruments (wires, catheters, and stents). A fluoroscopic C-arm is needed for visualization of the common bile duct (CBD) and gallbladder during the ERC/BS. A sphincterotome catheter appropriately sized for the endoscope is needed for cannulation of the major duodenal papilla (MDP). An exchange length soft-tipped guide wire is needed (typically 480 cm long). An electrocautery unit, with foot pedal and hand adaptor, is needed if sphincterotomy is to be performed (E-Figures 123-11 and 123-21). Various types of biliary stents are available, including both plastic and metallic (E-Figure 123-22). The polyurethane plastic stents have antimigration flanges to prevent migration. These stents are considered temporary and can be removed endoscopically with gentle traction. The metallic stents are self-expanding in design and typically permanent (if uncovered). The stent must fit through the working channel of the endoscope (3.2 mm in the larger scope and 2.0 mm for the smaller scope) and be long enough for the endoscopic deployment (typically a delivery system of 180 cm).



E-FIGURE 123-20 **A,** Side view endoscope used for ERCP. **B,** Regular end-on white light endoscopy showing the major duodenal papilla (black arrow). **C,** Image of the major duodenal papilla (black arrow) using side-view duodenoscope.

Techniques

The differing anatomy of dogs and cats should be appreciated before considering this procedure (E-Figure 123-24). The patient is placed under general anesthesia in left lateral recumbency. Previous reports recommend *dorsal recumbency for cats*[46] and *sternal recumbency for dogs*,[43-45] but the author has found left lateral recumbency to work well. The side-view duodenoscope is placed into the stomach and the duodenum is entered. In cats, it has been recommended to use diluted topical methylene blue for better visualization of the MDP.[46]

Once the MDP is visualized (Figure 123-23), the sphincterotome catheter is angled to cannulate the CBD using the working channel lever and the sphincterotome wire. Once the catheter is positioned into the opening of the MDP, the guide wire is used to advance up the duct to document proper placement and ensure the CBD is entered. Once the wire is seen going up the CBD on fluoroscopy, the catheter is advanced and a bile sample is taken for culture and cytology. Then, a retrograde contrast study is done using a 50% mixture of iohexol : saline. The CBD can accommodate 5-10 mL of contrast, but the pancreatic duct should not be injected with more than 1-2 mL. Once the CBD is visualized, the guide wire is readvanced through the sphincterotome into the CBD until it is beyond the obstructive lesion, and into an intrahepatic duct or the gallbladder. Then the appropriately-sized biliary stent is advanced over the wire, through the working channel of the endoscope, and into the CBD, traversing the opening of the CBD at the MDP into the duodenum (see E-Figure 123-22 and Figure 123-23). Typically, feline patients accommodate a 5 French (Fr) plastic stent, and canine patients vary depending on their size (6-8.5 Fr plastic or 6-8 mm SEMS). In the author's experience, the length of the stents required in cats has been 3-5 cm long, and in dogs is 4-12 cm long. The length is measured fluoroscopically using the sphincterotome or the endoscope to adjust for magnification. Plastic stents are deployed using a pushing catheter through the endoscope, over the guide wire. The delivery system of the metallic stent is ensheathed using endoscopic and fluoroscopic guidance over the guide wire, ensuring the distal end of the stent crosses the MDP and approximately 5 mm of the stent is within the duodenal lumen (Video 123-1).

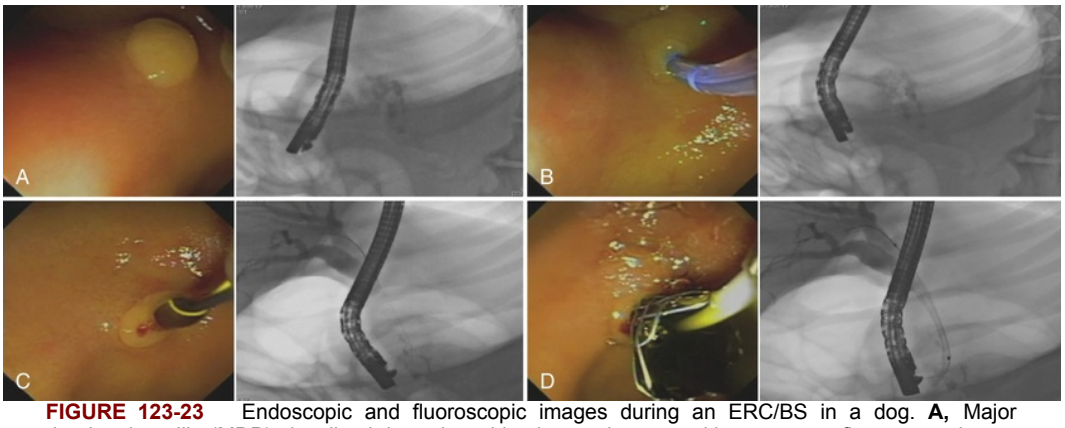

FIGURE 123-23 Endoscopic and fluoroscopic images during an ERC/BS in a dog. **A,** Major duodenal papilla (MDP) visualized through a side-view endoscope with concurrent fluoroscopy image being used simultaneously. **B,** Cannulation of the MDP with a sphincterotome visualized under endoscopy and fluoroscopy simultaneously. **C,** Guide wire cannulating the MDP and up the CBD visualized in both endoscopic and fluoroscopic images. Notice the contrast material in the severely dilated intrahepatic ducts. **D,** Stent deployed in the CBD and exiting the MDP visualized on both endoscopy and fluoroscopy simultaneously.

For benign and temporary conditions like pancreatitis, a plastic stent is recommended as it can be easily removed endoscopically.[48,49] If a tumor or stricture is present, then a covered metallic stent is recommended in humans.[48,49] In veterinary medicine, uncovered metallic stents have been used in 2 dogs and 2 cats with success, all of which were for biliary strictures of the CBD. Sphincterotomy is recommended by some physicians for distal MDP strictures, but this is not routinely used in veterinary medicine.

Follow-up

After successful biliary stenting, most patients will need standard supportive therapy for pancreatitis, perioperative antibiotics, and ursodeoxycholic acid (UDCA; ursodiol) supplementation. Once the patient is discharged broad-spectrum antibiotics are continued for 6 weeks. Serial hepatobiliary ultrasound and blood work is recommended (1 week, 1 month, then every 3 months for 1 year, then every 6 months thereafter). For permanent stents, the author continues UDCA and metronidazole therapy for life.

Complications

During ERCP, pancreatitis can be induced by infusing the pancreatic duct with contrast material, and care should be taken before any contrast study is done, knowing the anatomy of which papilla is being cannulated (major or minor duodenal papilla), and knowing the direction of the wire for the common bile duct versus the pancreatic duct at the orifice of the major duodenal papilla (E-Figure 123-24). Pancreatitis is induced in 5-20% of people during ERCP.[48,49] Additionally, perforation of the duodenum, CBD or pancreatic duct, bleeding, and biliary reflux into the intrahepatic ducts is possible with cannulation, sphincterotomy, and retrograde infusions, respectively.

Outcome

To date, few clinical cases in veterinary medicine have had ERC/BS performed, with only 7 research dogs and 2 canine patients reported.[47] In the author's practice, 8 patients (5 dogs and 3 cats) have had ERC/BS attempted. Four of 5 dogs and 1 of 3 cats were successful endoscopically and the liver biochemical parameters returned to baseline following decompression over the long term. The one failed canine patient had a large mass at the MDP, making cannulation not possible. The size of these patients ranged from 2.7 kg up to 41 kg. All patients survived to discharge and the first dog that had ERC/BS performed survived for over 2 years.

Alternatives

The author has been investigating the use of a subcutaneous intestinal biliary bypass device (SIBB) for bypass of the biliary tract using a cholecystostomy tube connected subcutaneously to a duodenostomy tube using a shunting port. To date, the experience with this device is still elementary and is currently under clinical

investigation. Externalized cholecystostomy tubes are also a temporary option (see Figure 123-27).[54]

PT(C)E: Percutaneous Transvenous (Coil) Embolization

Indications and Background

Portosystemic shunts (PSS) are vascular anomalies connecting the portal vein to the systemic circulation, resulting in a gamut of clinical signs. Intrahepatic portosystemic shunts (IHPSS) represent a much more complex correction than that of extrahepatic portosystemic shunts (EHPSS) due to their large size, and intrahepatic location.[55,56]

Pre-operative imaging including CT angiography can be very useful to help plan the surgical or interventional procedure. Various surgical options[55-61] have been described (see ch. 284) but this section will focus on percutaneous transvenous (coil) embolization (PT(C)E) via the jugular vein for the treatment of both IHPSS and specific types of EHPSS. Some techniques for PTE use various other devices for embolization, like vascular plugs, but coils are the most common device used.[62]

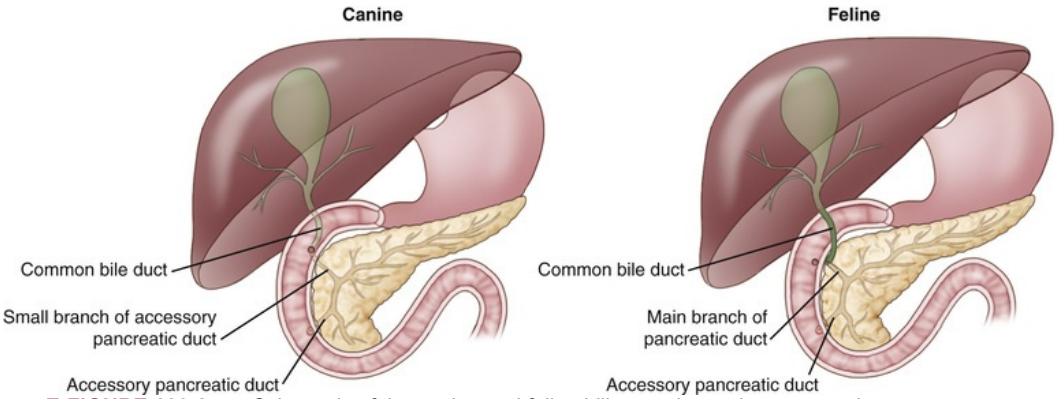
Interventional treatment has become far more common for the treatment of IHPSS in the last decade due to the higher complication rates seen with surgical treatment of IHPSS (29-77%)[57,58,60,61] compared to EHPSS (0-23%).[58-60,63] Percutaneous transvenous (coil) embolization (PT(C)E) has been described from various institutions within the past decade, with the largest series most recently reporting 100 dogs.[62] Similar intravascular techniques have been described for treatment of both IHPSS and EHPSS, in both dogs and cats, and for both partial and complete attenuation.[62,64] The peri-operative complications rates were much lower with the PT(C)E procedure, with similar long-term clinical results as that previously reported with surgical correction for those dogs that survived the surgery.

Equipment

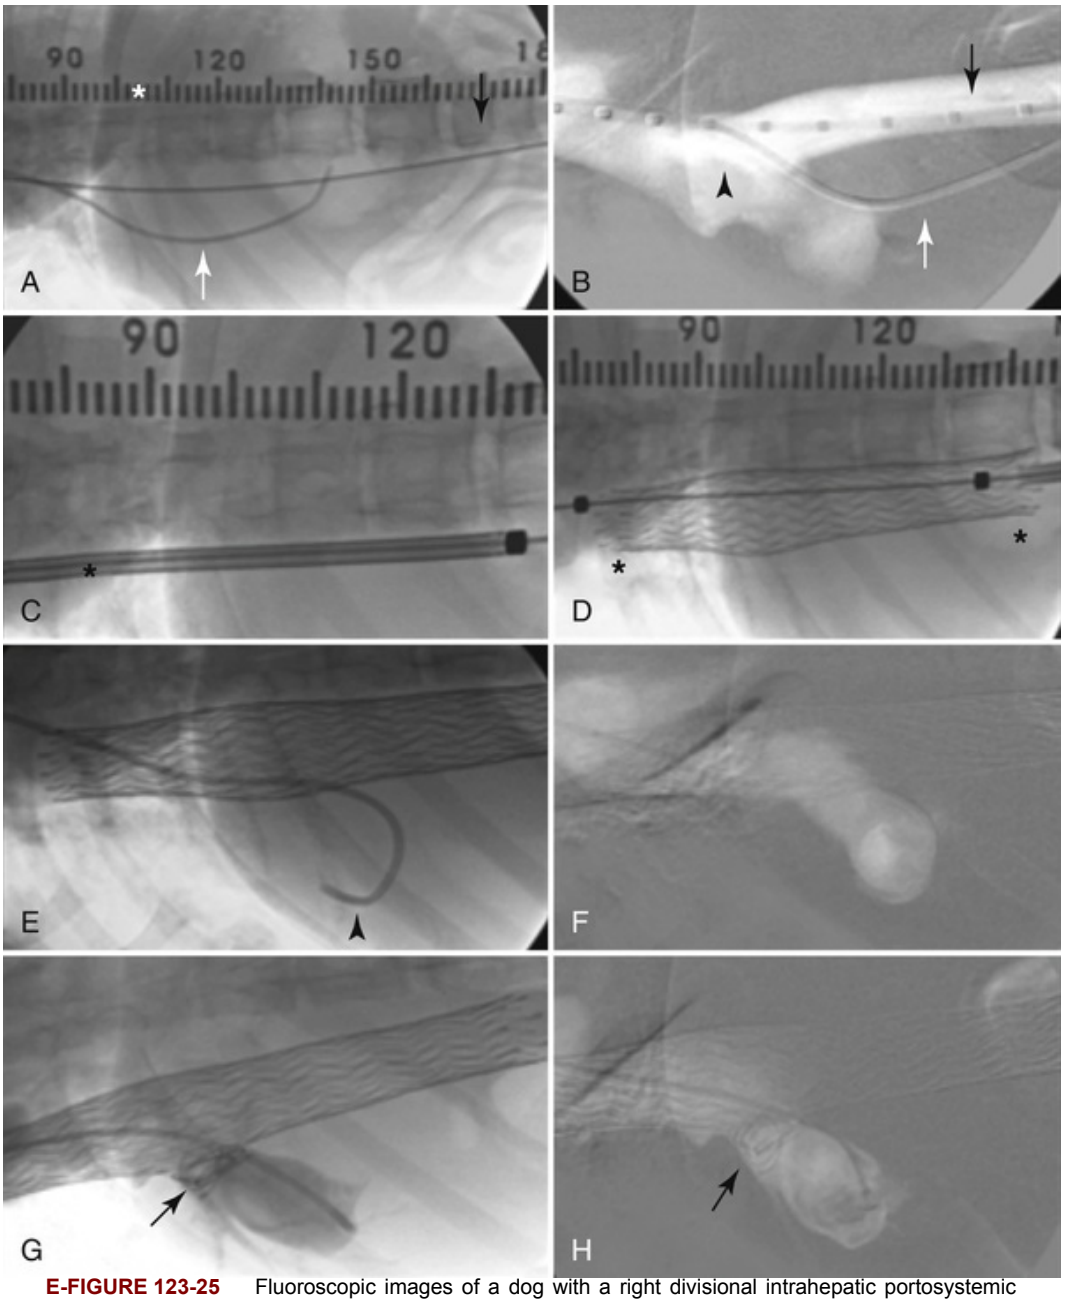
Equipment needed for PT(C)E includes a high-quality fluoroscopy unit that allows digital subtraction angiography (DSA). Various angiographic catheters (Cobra catheter, Berenstein catheter, marker catheter for measuring, various guide wires, embolic coils, and laser cut caval stents) are needed for this procedure. For cases where complete vascular occlusion is possible, then a vascular plug might be used. The standard coil used is a 0.035″ 8 mm diameter and 5 cm length stainless steel coil. Contrast is typically used at a dosage of 2-4 mL/kg and is diluted to a 50% mixture with sterile saline.

Techniques

Patients are placed under general anesthesia using drugs safe for liver dysfunction. Perioperative antibiotics are used before and during the procedure, and broad-spectrum antibiotics are continued for 2 weeks following the procedure. Patients are placed in dorsal recumbency and jugular access is obtained, through the right jugular vein. A radiopaque stent guide is placed under the dog on the fluoroscopy table to aid in stent deployment (E-Figure 123-25). The neck is clipped, aseptically prepared, and sterilely draped. Percutaneous jugular access is obtained through the placement of a vascular access sheath. A hydrophilic guide wire is advanced through the catheter, into the cranial vena cava, through the right atrium and then into the caudal vena cava. Next, the angiographic Cobra catheter is advanced over the wire and the shunting vessel is carefully selected until the portal vein is cannulated. Digital subtraction venography is performed to confirm the location and anatomy of the portal vein and shunting vessel. Then, a positive pressure caudal cavagram under positive pressure ventilation and a simultaneous caudal vena cavagram and portogram is performed using a marker catheter to measure for stent size. Portal venous pressures are obtained and compared to the central venous pressures in the caudal vena cava. If the resting portal pressure is greater than 16 mm Hg (21 cm H_2O) or the portal vein and CVP gradient is greater than 8 cm H_2O, then the procedure is not performed. If these pressures are under these parameters, then the portal vein catheter is removed and the marker catheter is removed over a polytetrafluoroethylene (PTFE, Teflon) guide wire for stent placement.



E-FIGURE 123-24 Schematic of the canine and feline biliary and exocrine pancreatic tracts.



E-FIGURE 123-25 Fluoroscopic images of a dog with a right divisional intrahepatic portosystemic

shunt during percutaneous transvenous coil embolization. **A,** Guide wire is down the caudal vena cava (black arrow) and a catheter is in the shunt (white arrow) through the right hepatic vein. A stent guide is under the dog (white asterisk). **B,** A dual angiogram using digital subtraction angiography (DSA) of the caudal vena cava (black arrow) and the shunt (white arrow). Notice where they come together at the caudal vena cava (black arrowhead). **C,** Stent on the delivery system in the caudal vena cava (black asterisk). **D,** Stent after deployment (black asterisks). **E,** Catheter (black arrowhead) placed through the interstices of the stent to place coils in the right hepatic vein. **F,** Angiogram showing the mouth of the shunt is covered by the stent. **G,** Coils (black arrow) inside the right hepatic vein being caged off by the stent. **H,** DSA study after coils are deployed (black arrow).

Next, the stent is deployed under fluoroscopic guidance in the caudal vena cava, using the stent guide to mark the appropriate location. Once the stent is deployed, the Cobra catheter is placed into the portal vein through the stent for a repeat portovenogram ensuring proper stent placement across the mouth of the shunt. Then portal pressures are obtained and if appropriate another catheter is advanced into the mouth of the shunt through the interstices of the stent for coil deployment, as the portal catheter measures continuous pressures. Coils are added until the shunt mouth is covered or the shunt pressures increase by approximately 6-7 mm Hg (≈8-9 cm H_2O) or maximal pressures approach 16 mm Hg (≈21 cm H_2O). Repeat angiography is performed at the completion of the procedure.

Follow-up

Patients are typically discharged 2 days after the procedure and are continued on all liver dysfunction medications for the following month. A proton pump inhibitor is continued for life. After 1 month, the liver medications are slowly weaned over the following 1-2 months, and the diet is transitioned to a normal adult maintenance diet. Blood work profiles are monitored regularly. If clinical signs return, or evidence of liver dysfunction persists on blood work, then medications can be reinstituted and evaluation for the need of additional coils is recommended.

Complications

Most of the complications reported are those pertaining to IHPSS, as there is little data on PT(C)E of EHPSS. In a recent study of 100 dogs with IHPSS,[62] the perioperative mortality rate was 5%, with a 13% perioperative complication rate. During the PT(C)E procedure, coil migration into the pulmonary circulation is possible; however, this has been substantially reduced with the addition of a caudal vena cava stent prior to coil deployment. Additionally, portal hypertension during embolization is possible, but this too is uncommon clinically after PT(C)E.

Postoperative seizures were approximately 6%, similar to that reported previously.[62,63] Portal hypertension, which has been commonly reported for surgical correction of IHPSS, was very uncommon with PT(C)E.[62] This is likely due to the location of the attenuation. In this study, 20% of dogs required additional coils to improve shunt attenuation over time, and at some point, before or after PT(C)E, 20% of dogs demonstrated signs of GI bleeding.[62] Severe GI bleeding is the most common complication seen in dogs with IHPSS, regardless of the treatment modality, and this has decreased to under 3% since the advent of life-long proton pump inhibitor therapy.[62] There are many theories as to why gastric ulceration occurs so commonly in dogs with IHPSS (hypergastrinemia, hypoprostaglandinemia, abnormal intestinal blood flow, poor mucosal integrity, abnormal mucus production, abnormal cell turnover). In the preliminary evaluation of serum gastrin levels, hypergastrinemia does not seem to be the cause.

Outcome

PT(C)E should be considered a safe, fast, and effective therapy for canine intrahepatic portosystemic shunts when performed by an operator well trained in interventional techniques.[62] PT(C)E resulted in a fair to excellent outcome in over 80% of patients and a median survival time of over 6 years. The perioperative mortality rate was 5%, far lower than that reported with traditional surgery.[62]

Special Considerations

Pet owners should be aware that approximately 5% of dogs have sufficient portal vein perfusion found during angiography to allow complete IHPSS occlusion, which can be done with various devices like vascular

plugs, vascular coils, or a covered stent.[62] Additionally, 10% of dogs have multiple intrahepatic shunts at the time of angiography, and about 5% have pre-existing elevated portal vein pressures, precluding the procedure from safely being performed.[62]

HAVM

Indications and Background

Hepatic arteriovenous fistulae/malformations (HAVM) are rare vascular anomalies involving multiple arterial communications to the portal vein (E-Figure 123-26) (see ch. 284). Since they usually involve multiple, rather than single communications the term malformation, rather than fistula, is more appropriate. These communications are usually from the hepatic artery, but have also been seen to involve the gastroduodenal artery (GDA), left gastric artery (GA), and phrenic artery. Due to the high pressure arterial blood shunting to the portal vein, there is severe chronic portal hypertension (often with subsequent massive ascites) that results in multiple EHPSS to decompress the portal vein.

E-FIGURE 123-26 DSA during treatment of a HAVM in a dog. **A,** DSA with a catheter in the hepatic artery showing the HAVM. **B,** Angiogram using DSA after glue embolization showing another branch (white arrows) feeding the HAVM. **C,** Glue embolization of that new branch (white arrows). **D,** Final angiogram after glue is polymerized. *GDA,* Gastroduodenal artery; *HA,* hepatic artery; *HAVM,* hepatic arteriovenous malformation; *LGA,* left gastric artery; *SA,* splenic artery.

Treatment options for HAVM include liver lobectomy, ligation of the nutrient artery, or fluoroscopically guided HAVM glue embolization (HAVM-GE) of abnormal arterial vessels.[65,66] Regardless of the therapy chosen for this condition, 75% of dogs will continue to require dietary or medical therapy due to the persistent portosystemic shunting that occurs through the multiple acquired EHPSS.[65]

Equipment

A good quality fluoroscopy unit that has DSA, and the ability to obtain orthogonal views, is necessary to avoid non-target embolization and ensure all contributing vessels are embolized. Femoral arterial access is needed. Protective eyewear is required when handling the glue material. The glue should only be handled on a special embolization table to ensure that no saline or blood is in contact with the glue to avoid premature polymerization. Supplies needed include a vascular access sheath (4 Fr), a micropuncture set, a 4 Fr Cobra catheter, a hydrophilic angle-tipped guide wire (0.035”), contrast material (iohexol), a Tuohy-Borst adapter, a flow switch, a few microcatheter-microwire combinations, four to six 1 mL polycarbonate syringes, cyanoacrylate glue (1-5 mL), ionized poppyseed oil (Ethiodol), and tantalum.

Techniques

For glue embolization of HAVM, access is obtained via the femoral artery. Under fluoroscopic guidance, access is obtained into the hepatic artery. Hepatic arteriography is performed to demonstrate the location, anatomy, and extent of the HAVM. Then, super-selective microcatheter access is obtained into each contributing branch of the HAVM (see E-Figure 123-26). Hepatofugal blood flow is seen as the contrast

material enters the portal vein traveling caudally until it reaches the multiple EHPSS where it travels through the caudal vena cava cranially. Glue embolization is performed with cyanoacrylate mixed (typically in a 1 : 1 to 2 : 1 ratio) with Ethiodol, an iodized poppyseed oil that is radiopaque and slows polymerization of the glue. Powdered tantalum can be added to lend additional radiopacity to the mixture. The glue polymerizes and occludes the small communications of the malformation. This is done until the HAVM is completely (or nearly completely) occluded. Once the nidus of the HAVM is embolized, the femoral artery is ligated at the access point and the incision is closed.

Follow-up

After HAVM-GE, improvement in the ascites should be seen due to the decrease in portal hypertension. Blood work is repeated the day after the procedure and then again at 1, 3, and 6 months and then every 6 months thereafter. Repeat procedures are recommended if the ascites persists or liver function worsens.

Complications

Complications associated with glue embolization include non-target embolization (glue entering unintended vessels such as the portal system, the extrahepatic shunts or pulmonary circulation). Other locations of non-target embolization include occlusion of proximal arterial vessels like the common hepatic artery, the gastroduodenal artery, and/or the splenic/left gastric artery. Additionally, polymerization of the catheter tip into the vessel wall is possible. Portal vein thrombosis is possible due to the stagnancy of the blood flow in the portal vein after decreasing the arterial flow into the HAVM.

Outcome

Perioperative survival was 100% in dogs undergoing HAVM-GE, with or without partial hepatectomy, compared to 75% to 91% of dogs undergoing surgery alone, but only 4 dogs had HAVM-GE in this study.[65] Recurrence of arteriovenous communications can occur and recurrence of clinical signs has been seen requiring additional embolization procedures, and this is seen in approximately 30% of cases. Long-term survival is considered fair to good with this interventional technique.

All patients have persistent acquired EHPSS due to portal hypertension, and these do not regress, resulting in the need for lifelong medical and dietary management.

Special Considerations

Glue embolization is considered one of the more complicated interventional procedures in human medicine, and human interventionalists undergo specialty training in the use of glue prior to performing this type of procedure. This should be considered the case in veterinary medicine as well.

Miscellaneous Hepatobiliary Interventions

Other diseases of the hepatobiliary system that can be treated with interventional radiology/endoscopy techniques include *chemoembolization* for benign or malignant nonresectable liver tumors, *arterial embolization for severe intractable GI bleeding,* and *cholecystotomy tube placement* (see above and Video 123-4).

Chemoembolization is described in ch. 125. Arterial embolization for GI bleeding is rarely needed, and is done using fluoroscopic guidance via the femoral artery through the cranial mesenteric artery, gastroduodenal artery, and/or caudal mesenteric artery. If a lesion is seen, then coil embolization or gel foam embolization can be considered.

Cholecystostomy tubes can be placed using either laparoscopic guidance, ultrasound guidance, or surgically assisted (Figure 123-27). Ideally, this is done with laparoscopic and fluoroscopic assistance. The liver is punctured with the sharp trocar of the locking-loop pigtail catheter, which is advanced through the liver parenchyma and into the fundus of the gallbladder. The catheter is then advanced off the stylet once the sharp trocar is removed and the tube is then locked in place and gravity drainage is used for biliary decompression. Using a feeding tube, the bile should be given back to the patient enterally for protection of the GI immunogenic barrier (see Video 123-4).

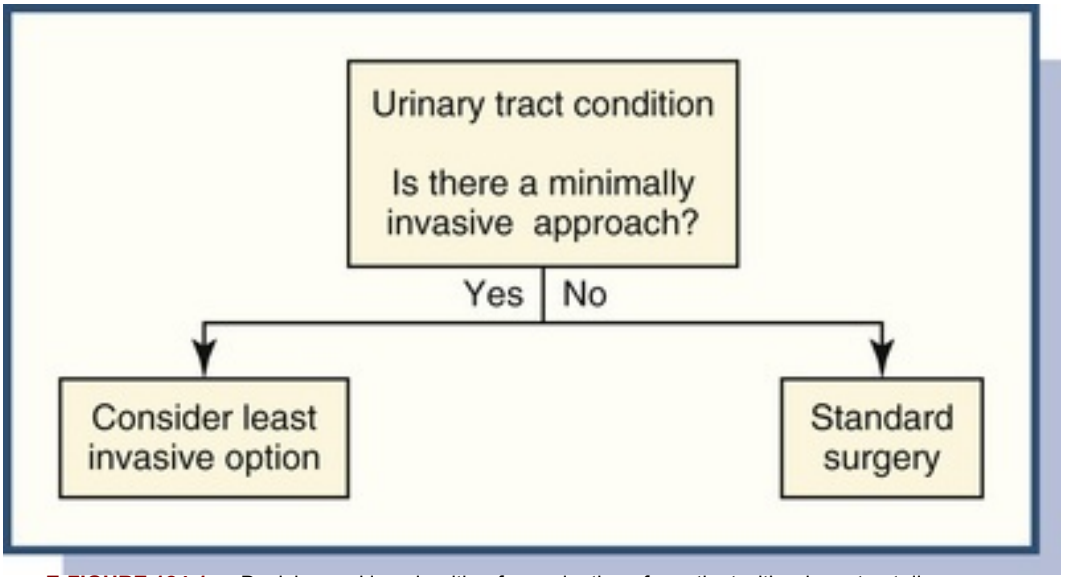
CHAPTER 124

Urologic Interventional Therapies

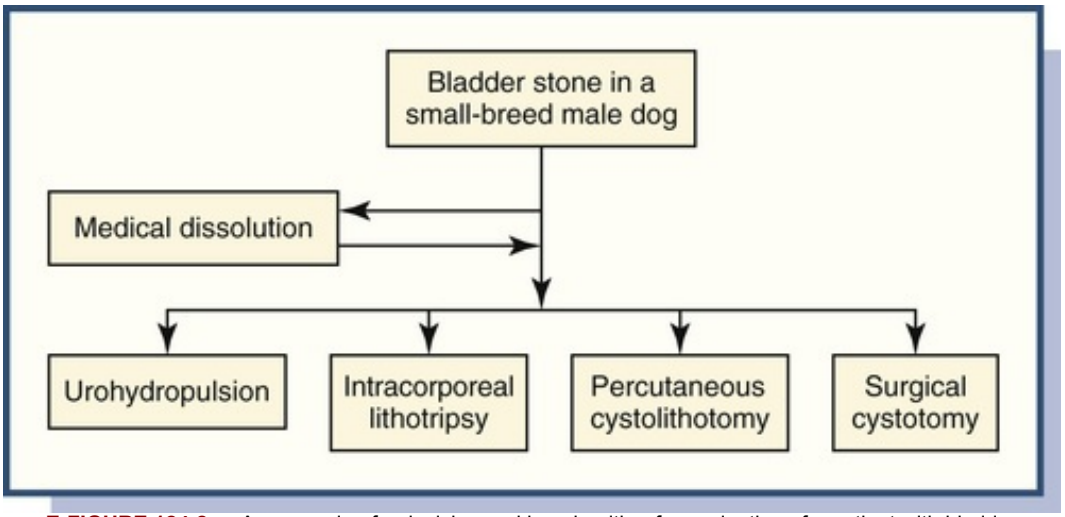
Marilyn E. Dunn, Allyson C. Berent

Client Information Sheet: Urologic Interventional Therapies

Interventional urology (also known as endourology) refers to the specialty of urology in which endoscopes, fluoroscopy, and other instruments are used for accessing, under direct visualization, structures inside the urinary tract. As opposed to traditional surgery, access most commonly is achieved through natural orifices and the procedures are done internally either without, or with few, external incisions. Minimally invasive approaches have a multitude of advantages over standard surgery, such as shorter hospitalization times, little to no recovery time, and less discomfort. Another application of endourology is for patients in whom traditional therapies are not available, are associated with poor outcomes, are contraindicated, or have failed. The authors feel that minimally invasive procedures should be considered and discussed with owners of pets suffering from urinary tract disorders. Algorithms can be used for aiding in the decision-making process (E-Figures 124-1 and 124-2). The entire urogenital system can be accessed from the vulva/penis, through the urethra, into the bladder, up the ureter and into the renal pelvis. While at times appearing technically simple, these procedures have been associated with serious complications when performed by inadequately trained personnel and should be referred to a formally trained and experienced specialist. There is a learning curve associated with these procedures and experience is critical in obtaining the best outcomes.



E-FIGURE 124-1 Decision-making algorithm for evaluation of a patient with urinary tract disease.



E-FIGURE 124-2 An example of a decision-making algorithm for evaluation of a patient with bladder stones. Procedures are considered in order from least to most invasive.

Equipment

Sterility and Drapes

Although the prepuce, vagina and distal urethra have a normal bacterial flora, the authors use sterile drapes and equipment, and thoroughly disinfect the material used between patients. Sterile waterproof drapes are available that preserve sterility while working with continuous saline flush.

Endoscopes

Rigid or flexible cystoscopes are indicated for specific procedures, as described below (see ch. 83 and 108).

Imaging

Fluoroscopy is used in a variety of these procedures and precautions must be taken to ensure safety of all personnel involved. Operators must wear appropriate radiation protection equipment and an effort should be made to minimize exposure time and beam size and maximize shielding and distance. A radiation monitoring badge should be worn at all times. The two most commonly used fluoroscopy units in veterinary medicine are the mobile C-arm and the fixed multipurpose unit. Digital radiography allows rapid serial image acquisition, allowing some interventional urologic procedures to be performed in hospitals without access to fluoroscopy. The most commonly used contrast agents in veterinary endourology are low-osmolarity, nonionic contrast media such as iohexol.

Guidewires, Catheters, Sheaths

The materials needed for the various procedures described in this chapter are detailed in the specific sections, below (see E-Table 124-1). In order to gain access to the urinary tract, hydrophilic guidewires generally are used. These guidewires have nitinol cores and are coated with hydromers to produce wires that are extremely lubricious and slippery when moistened. Once wire access has been achieved, an introducer sheath often is placed next, to facilitate entry into the lumen over the guidewire. Sheaths are named for their *inner* diameter, whereas catheters, delivery systems, and dilators are named for their *outer* diameter; for example, an 8 Fr catheter will fit into an 8 Fr sheath because the outer diameter of the catheter is 8 Fr, and the inner diameter of the sheath is 8 Fr.

E-TABLE 124-1

Commonly Used Equipment in Interventional Urologic Procedures

ITEM	SIZES	DOG	CAT	USES	PROCEDURES
Hydrophilic angled guidewire	0.035 inch 0.018 inch	0.035 inch 0.018 inch	0.035 inch (bladder, urethra) 0.018 inch (ureter, urethra)	Gain access to the upper and lower urinary tract	Various
Open-ended ureteral catheter	3 Fr 4 Fr 5 Fr	3 Fr (0.018 inch guidewire 4 Fr (0.025 or 0.018 inch guidewire) 5 Fr (0.035 inch guidewire)	3 Fr (0.018 inch guidewire)	Ureter: ureteral contrast study	Ectopic ureters, ureteral stricture
Locking loop pigtail drainage catheter	8.5 Fr 12 Fr	8.5, 10.2, 12, 14 Fr	8.5 Fr	Draining the bladder, renal pelvis	Nephrostomy tube, cystostomy tube
Berenstein catheter	4 Fr (0.035 inch guidewire, 5 Fr and > introducer sheath)	4 Fr	4 Fr	Contrast cystourethrogram	Urethral stenting
Introducer sheath	4, 5, 6, 7, 8, 9, 10 Fr	6, 7, 8, 9, 10 Fr (standard 8 Fr will accommodate the majority of stent delivery systems)	4, 5, 6, 7, 8 Fr (females, males with PU)	Maintain access to the urethra or renal pelvis	Urethral stenting
Marker catheter	5 Fr	5 Fr	5 Fr	Accepts guidewire up to 0.038 inch	Radiopaque metallic markers at 1 cm intervals allow sizing
Urethral stent	5-12 mm in diameter, 30-80 mm in length	Sized for the patient	Sized for the patient	Delivery system ≥6 Fr, accepts 0.035 inch guidewire	Urethral stenting
Diode laser	400 and 600 micron fiber			Cut tissue in the case of CLA-EU	CLA-EU
Ho : YAG laser	200, 400 and 600 micron fiber			Stone fragmentation (contact mode) and tissue cutting (non-contact mode)	Laser lithotripsy and CLA-EU
Endotip screw trocar	6 mm and 10 mm trocar			Accepts 1.9 and 2.7 mm cystoscope for stone removal	PCCL
Ureteral stents	2.5, 3.7, 4.7 and 6 Fr	3.7, 4.7, and 6 Fr diameter by 12-32 cm lengths depending on patient	2.5 Fr diameter by 12, 14, 16 cm length		
UPJ balloon	5 Fr and 6 Fr	Patient dependent	Not used in cats	Ureteral occlusion for intraluminal infusion	Sclerotherapy For IRH
Peel-away sheath	14 or 16 Fr	Patient dependent		Urethral access sheath for rigid male cystoscopy	Perineal urethral access
Ultrasonic/pneumatic	22 Fr	22 Fr in a 24 Fr sheath		Intracorporeal	ENL (PCNL or

lithotripsy*				lithotripsy for nephrolithiasis	SENL)
Subcutaneous ureteral bypass (SUB)	SUB1001K SUB2001K	SUB1001K SUB2001K	SUB1001K	Condition necessitating ureteral bypass	Placement of a subcutaneous ureteral bypass for ureteral obstruction
Artificial urethral sphincter	Lumen diameter: 4, 6, 8, 10, 12, 14 and 16 mm Width: 11 mm for 4 and 6, 14 mm for 8-14	8, 10, 12, 14, 16 mm × 14 mm width	4, 6 mm × 11 mm width	Treatment of sphincter mechanism incompetence	Placement of an artificial urethral sphincter for urinary incontinence

*Cyberwand Dual Ultrasonic Lithotriptor, Olympus, Gyrus/ACMI, Southborough, MA.

The items listed in the equipment section are recommended for individuals to have on site prior to performing these procedures. As size of catheters and guidewires vary greatly from one patient to another, it is essential to have a reasonable inventory to ensure the use of appropriately-sized material tailored to each patient.

CLA, Cystoscopic laser ablation; *ENL*, endoscopic nephrolithotomy; *EU*, ectopic ureters; *IRH*, idiopathic renal hematuria; *PCCL*, percutaneous cystolithotomy; *PCNL*, percutaneous nephrolithotomy; *PU*, perineal urethrostomy; *SENL*, surgically-assisted nephrolithotomy.

Stents

Stents are designed to establish patency of a lumen and are available in a variety of materials, shapes, and designs. Stents can be classified as metallic versus nonmetallic, self-expanding versus balloon-expandable, and uncovered or covered. The most commonly used stents in veterinary medicine are metallic, composed of nitinol, a nickel-titanium alloy. Nonmetallic stents, such as urethane double-pigtail stents, most often are placed in the ureter. Laser-cut stents are used primarily in the urethra and blood vessels (see ch. 122).[1]

Percutaneous Antegrade Urethral Catheterization

Indication

Urethral obstruction when standard retrograde urethral catheterization cannot be achieved. It is most commonly done in male cats with urethral tears secondary to trauma from serial attempts to catheterize (see ch. 107 and 335).

Equipment

0.035-inch hydrophilic angled wire, 5 Fr urinary catheter (cats), 18 gauge IV catheter, 3-way stopcock, iodinated contrast medium, fluoroscopy or digital radiography.

Procedure

The patient is placed under general anesthesia in lateral recumbency and the ventrolateral abdomen and the perineum are clipped, aseptically prepped, and draped. An 18 ga IV catheter is inserted transcutaneously into the apex of the urinary bladder, directing the catheter tip toward the trigone. The stylet is removed and an extension set with a 3-way stopcock is attached to an empty syringe and a syringe containing a 50 : 50 mixture of saline and contrast. Contrast is injected under fluoroscopic guidance until the bladder is distended and the proximal urethra is visible. The stopcock is removed, and a guidewire is inserted through the catheter and manipulated towards and down the urethra and advanced until it exits through the penis or vulva. A urinary catheter with the tip cut off is advanced in a retrograde manner over the wire and into the urinary bladder. The guidewire is removed by pulling it through the urinary catheter and the IV catheter is removed from the bladder[2,3] (Figure 124-3).

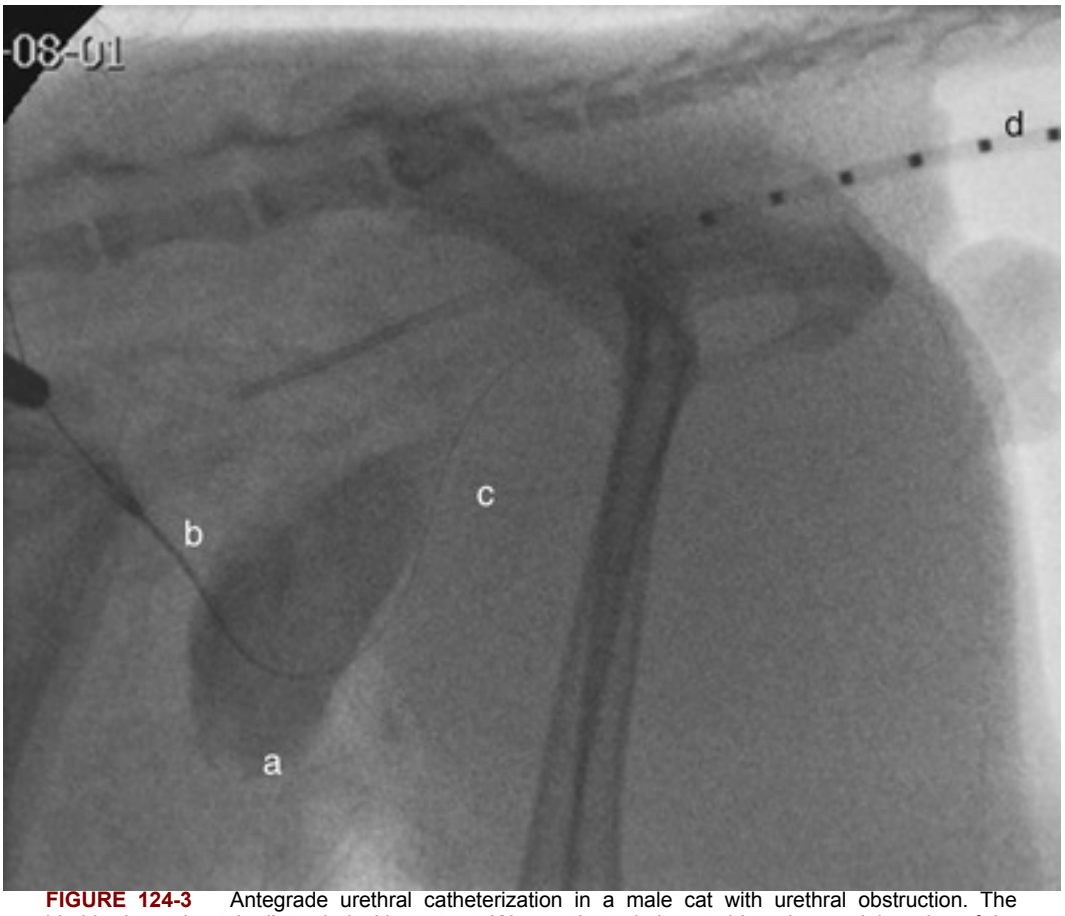


FIGURE 124-3 Antegrade urethral catheterization in a male cat with urethral obstruction. The bladder is moderately distended with contrast **(A),** a catheter is inserted into the cranial portion of the bladder **(B)** and a guidewire is passed through the catheter and can be seen in the urethra **(C).** A marker catheter **(D)** is in the colon to take measurements for a urethral stent.

Special Considerations

For urethral tears, the urinary catheter should be left in place for 5-10 days to allow complete healing.

Outcome and Follow-up

In a small study, percutaneous antegrade urethral catheterization was successful in 7/9 male cats. Within 6 weeks, all of these cats underwent perineal urethrostomy for recurrence of urethral obstruction.[2]

Complications

Inability to achieve access and, rarely, bladder rupture and leakage of urine and contrast into the peritoneal cavity.

Alternatives

Perineal urethrostomy, intermittent cystocentesis, cystostomy tube or urinary catheter placed by cystotomy.[4,5]

Percutaneous Cystostomy Tube Placement

Indications

Functional or mechanical urethral obstruction not amenable to medical therapy (see ch. 107 and 335). A cystostomy tube can be used as a temporary or permanent implant in conditions such as urethral, trigonal, and prostatic neoplasia; granulomatous urethritis; urethral stricture; dyssynergia; neurologic disease; and

urethral/bladder trauma.[3]

Equipment

Locking loop pigtail drainage catheter, hydrophilic angled guidewire, urinary catheter, 3-way stopcock, extension set, iodinated contrast medium, fluoroscopy or digital radiography.

Procedure

The patient is placed under general anesthesia and in right or left lateral recumbency. The abdomen is clipped, ensuring to clip laterally on the side the tube will be placed, and aseptically prepped. The caudal portion of the bladder is palpated and held in position as the craniolateral aspect of the bladder is accessed with a needle attached to an extension with a 3-way stopcock and 2 syringes. One syringe contains contrast and the other is used for withdrawing urine. Contrast is injected into the bladder, the extension set is disconnected, and a guidewire is passed quickly through the needle. The guidewire is looped in the bladder or can exit through the urethra. The needle is withdrawn over the guidewire and the locking loop pigtail catheter is passed over the wire and into the bladder under fluoroscopic guidance. The locking loop pigtail catheter is advanced into the bladder so that all fenestrations are well within the bladder, and then the guidewire is withdrawn. The loop is locked by pulling on the string and secured through the locking mechanism. The catheter is gently pulled so that the bladder wall is against the abdominal wall, and the catheter is secured using a finger trap suture.

Tube withdrawal: The tube should have been in place 10-14 days prior to removal.[6] A guidewire is inserted through the tube under fluoroscopic guidance to ensure that the loop is fully undone and the locking loop catheter is straight. The catheter is withdrawn with the guidewire, and an occlusive bandage is left in place for 24 hours. Urine leakage through the stoma is normal for 2-3 days following tube removal.[3,6]

Special Considerations

When placed for neoplastic urinary tract disease, there have been concerns regarding seeding of the abdominal cavity and skin.

Outcome

Effective means to provide long-term bladder emptying.

Follow-up

Bacterial infections only should be treated if the patient shows associated clinical signs, and targeted antimicrobial therapy based on culture and sensitivity is recommended.

Complications

Recurrent bacterial infections are common and occurred in up to 86% of patients in one study.[6] Slipping of the tube out of the bladder can result in uroperitoneum. Obstruction of the tube is possible; however, flushing the system or passing a guidewire through the tube can help relieve the obstruction.

Alternatives

Urethral stenting or surgically placed cystostomy tubes.

Cystoscopic Basket Retrieval of Lower Urinary Tract Stones

Indications

Removal of urethral and bladder stones not amenable to medical dissolution and too large to be evacuated with voiding urohydropulsion (see ch. 107, 331, and 332). Basket retrieval can be considered in female dogs with stones <5 mm in diameter, male dogs with stones <4 mm in diameter, and female cats with stones <3 mm in diameter.[3,7]

Equipment

Rigid or flexible cystoscope, stone basket that can be passed through the channel of the cystoscope.

Procedure

The patient is anesthetized and placed in dorsal (females) or lateral (males) recumbency. The vulva/prepuce and surrounding area are clipped, prepped, and draped. Cystoscopy is used for visualizing the stone(s). A stone basket is passed through the channel of the scope and the stone is grasped. Under continuous saline flush, the basket is pulled towards the tip of the scope and the scope along with the basket are withdrawn. If resistance is felt, the flush pressure can be increased in order to help dilate the urethral lumen and the basket can be gently rotated. If resistance is still felt, the basket should be opened to release the stone and another technique used in order to avoid damage to, or perforation of, the urethra.

Special Considerations

In the presence of urethral stricture/inflammation, the clinician should be prepared to remove the stone using another technique.

Follow-up

Stone recurrence is a concern.

Complications

Urethral stricture or perforation is possible during retrieval of embedded or sharp-edged stones.

Alternatives

Lithotripsy, percutaneous cystolithotomy, or cystotomy.

Intracorporeal Lithotripsy of the Lower Urinary Tract

Indications

Removal of urethral and bladder stones not amenable to medical dissolution and too large to be removed by cystoscopic-guided basket retrieval (see ch. 331 and 332).[7-10]

Equipment

Rigid or flexible cystoscope, holmium : yttrium aluminium garnet (Ho : YAG) laser with a fiber that can be passed through the scope channel/electrohydraulic lithotriptor, stone basket (optional).

Procedure

The patient is anesthetized and placed in dorsal (females) or lateral (males) recumbency. The vulva/prepuce and surrounding area are clipped, prepped, and draped. Cystoscopy is used for visualizing the stone. The tip of the laser fiber is placed in direct contact with, and perpendicular to, the surface of the urolith. The stone is fragmented by the laser's energy transmitted directly to the stone, creating a shock wave that induces fragmentation. Stones are fragmented until the pieces are small enough to be voided using urohydropulsion or removed with a stone retrieval basket (Figure 124-4, *A-C*).

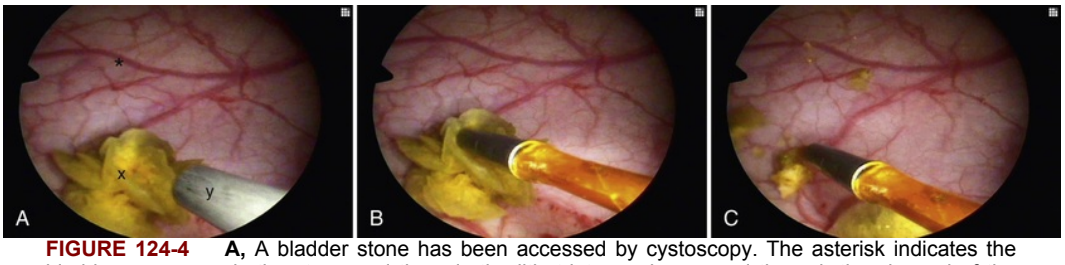

FIGURE 124-4 **A,** A bladder stone has been accessed by cystoscopy. The asterisk indicates the bladder mucosa, x is the stone and the y is the lithotriptor probe passed through the channel of the endoscope. **B,** The lithotriptor probe has come into contact with the stone. **C,** The stone has been fragmented.

Special Considerations

The major challenge is removal of stone fragments from the urinary tract, especially in male dogs. Success depends on careful patient selection (Table 124-2).

TABLE 124-2

Selection Criteria for Intracorporeal Lithotripsy

Patient characteristics	Size	Any female dog or female cat Male dogs >7 kg*
	Sex	Females are easier than males (easier to remove fragments by voiding urohydropulsion in females)
	Location	Urethral stones easier than bladder stones (easier evacuation of stone fragments)
Stone characteristics	Diameter	<2-3 cm females* <1 cm in males*
	Number	<5 stones in females*

*Patients with stones that do not satisfy these criteria are good candidates for minimally invasive stone removal by percutaneous cystolithotomy (PCCL).

Outcome

The Ho : YAG is effective on all stone types.[11] Complete urolith removal is achieved in 100% of dogs with urethroliths, 83-96% of female dogs with cystoliths, and 68-81% of male dogs with cystoliths.[7-10]

Follow-up

Stone recurrence is a concern.

Complications

Self-limiting urethral edema, and mild hematuria. Bladder perforation by the laser is a rare occurrence and can be treated by leaving a urinary catheter in place for 24-48 hours.[7-10]

Alternatives

Percutaneous cystolithotomy, surgical cystotomy and/or urethrotomy.

Transvesicular Percutaneous Cystolithotomy (PCCL)

Indications

Removal of urethral and bladder stones not amenable to medical dissolution and too large or too numerous to be removed by voiding urohydropulsion, cystoscopy-guided basket retrieval, or lithotripsy (see ch. 331 and

332). This antegrade approach through the bladder apex can also be used for gaining access to the urethra, bladder, and ureters.[3,12]

Equipment

Urinary catheter, standard surgical instruments, laparoscopic threaded cannula with diaphragm, rigid and flexible cystoscopes, stone basket.

Procedure

The patient is anesthetized and placed in dorsal recumbency. The ventral aspect of the abdomen and prepuce/vulva are clipped, prepped, and draped. A urinary catheter is placed and sterile saline infused until the bladder apex is palpable. A 2 cm ventral midline skin incision is made over the bladder apex. The incision is extended into the abdominal cavity, the bladder apex is identified, and is grasped with tissue forceps. Stay sutures are placed and a stab incision is made at the bladder apex. The laparoscopic cannula is screwed in place and directed toward the urethral lumen. A rigid cystoscope is advanced through the cannula into the bladder and the stones are identified and removed with the stone basket. To remove sediment/small stones, the diaphragm of the cannula is removed and the bladder is flushed while applying suction to the lumen of the cannula. Once all bladder stones are removed, the urethra is examined through anterograde passage (through the cannula) of the flexible scope in male dogs and cats and the rigid scope in female dogs. Stones in the urethra can be removed with a stone basket or flushed into the bladder and removed. The cannula is withdrawn and the bladder incision and abdomen are closed[12] (Figure 124-5, *A* and *B*).

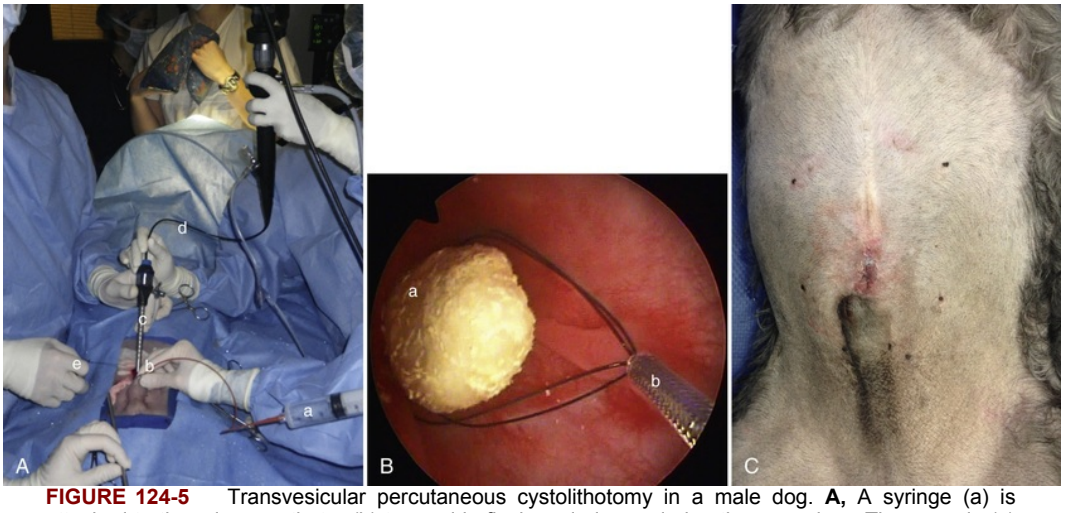

FIGURE 124-5 Transvesicular percutaneous cystolithotomy in a male dog. **A,** A syringe (a) is attached to the urinary catheter (b) to provide flush or drainage during the procedure. The cannula (c) is inserted into the apex of the bladder and a flexible scope (d) is inserted through the diaphragm of the cannula then into the bladder and urethra. The entire system is closed, preventing leakage and providing bladder and urethral distension. Stay sutures (e) help retract the bladder during the procedure. **B,** A stone (a) is being grasped by a 4 pronged stone basket (b) passed through the working channel of a rigid cystoscope inserted through a laparoscopic cannula. **C,** A very small (1.5 cm) skin wound caudal to the umbilicus and cranial to the prepuce is visible following the procedure.

Outcome

Complete stone removal is achieved in 96% of patients.[12]

Follow-up

Stone recurrence is a concern. Skin sutures can be removed in 10-14 days.

Complications

Wound infection, dehiscence, and uroabdomen are rare potential complications associated with the transabdominal approach.

Alternatives

Surgical cystotomy and/or urethrotomy.

Urethral Stenting

Indications

Relief of urethral obstruction and restoration of a urine stream in a patient with partial or complete urethral obstruction (see ch. 335). A urethral stent is a permanent implant and therefore careful consideration of the underlying condition is important. Urethral stents most commonly are placed to relieve obstruction caused by urethral, trigonal, and/or prostatic neoplasia.[13-17]

Equipment

Hydrophilic angled weasel wire, marker catheter, 14 Fr red rubber urinary catheter, appropriately sized self-expanding laser-cut nitinol urethral stent, Berenstein catheter (males), introducer sheath, iodinated contrast, fluoroscopy or digital radiography.

Procedure

The patient is placed under general anesthesia and in lateral recumbency. The prepuce or vulvar region is prepped and draped. A marker catheter inserted in a urinary catheter is advanced into the terminal portion of the colon under fluoroscopic guidance. The marker catheter is essential for accurate selection of stent size. A 0.035 inch guidewire is introduced into the urethra under fluoroscopic guidance and advanced until it curls into the bladder. An introducer sheath (usually 8 Fr) is slid along the guidewire into the distal urethra in males and up to and advanced gently past the obstruction in females. A contrast cystourethrogram is performed, using the sheath in females or a Berenstein catheter advanced over the guidewire and through the sheath in males. A 50 : 50 mixture of iodinated contrast and sterile saline is injected to ensure full bladder distension, creating a clear distinction between the urethra, trigone, and bladder. Contrast is injected continuously while withdrawing the catheter into the distal urethra under fluoroscopic guidance. The size and length of the obstruction can be determined along with measurement of the maximal urethral diameter. A voiding cystourethrogram (manual compression of the bladder under fluoroscopic guidance) can further assist in visualizing the obstruction.

Stent selection: A stent with a diameter 10-15% greater than the maximum diameter of the urethra near the obstruction is selected. The length of the obstruction is calculated and the stent length is chosen in order to ensure coverage of the entire obstruction along with 0.5-1 cm additional stent length cranial and caudal to the obstruction. Under fluoroscopic guidance, the stent is passed over the guidewire, into position, and deployed. The stent is not reconstrainable and once deployment has been initiated, it cannot be stopped. Once patency is confirmed, the stent delivery system, sheath, guidewire, and marker catheter are withdrawn[13,15] (Figure 124-6, *A-C*).

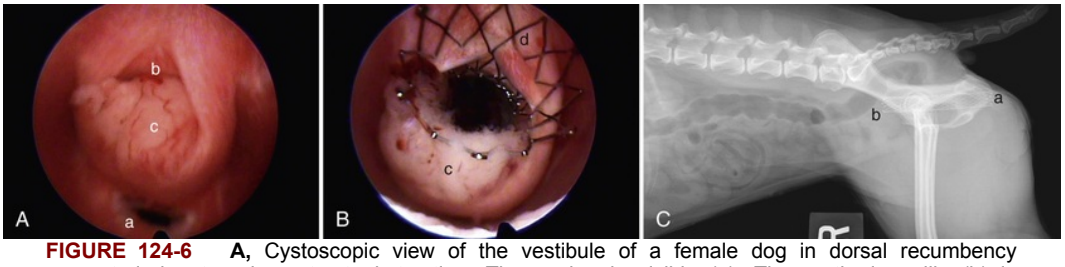

FIGURE 124-6 **A,** Cystoscopic view of the vestibule of a female dog in dorsal recumbency presented due to urinary tract obstruction. The vagina is visible (a). The urethral papilla (b) is completely filled by a mass (c) determined to be a transitional cell carcinoma. **B,** A urethral stent has been placed and is seen slightly protruding from the urethral papilla (d) into the vestibule and compressing the mass (c) that had previously obstructed the urethral lumen. **C,** Lateral radiograph of the same patient showing a urethral stent placed in the mid and distal urethra. The most distal end of

the stent terminates at the urethral papilla (a) and the proximal end in the proximal urethra (b).

Special Considerations

Unlike in tracheal stenting (see ch. 121), where the carina and larynx must be avoided, a urethral stent can extend to the trigone cranially and can "bird beak" out of the papilla and into the vestibule caudally if the obstruction involves the trigonal outflow tract or urethral papilla, respectively. Placing an inappropriately small stent will increase the risk of migration. Some patients with chronic obstructions can have concurrent bladder atony. Care must be taken when performing rectal palpation, administering an enema, or taking a rectal temperature, as the stent could become damaged or dislodged.

Outcome

Urethral stenting has a success rate of 97.5%-100% for relief of both benign and neoplastic obstructions. Survival times are variable and are a function of the underlying disease.[13-15]

Follow-up

Regular urinalysis with culture is recommended, as one third of dogs develop a urinary tract infection following stent placement.[13-15]

Complications

Urinary incontinence rates of 12.5% are reported in patients undergoing urethral stenting for benign obstruction and 26%-41% in patients with neoplastic obstruction. Neither stent length, diameter, location nor sex were predictors of incontinence.[13-15] Recurrence of obstruction due to tissue growth (more common with benign strictures) occurs in 12.8%-17%, stent migration in 12%, and persistent dysuria and stranguria in 19% of patients.[13-15] Cats are at risk of ureteral obstruction with placement of a proximal urethral stent given the location of their ureteral orifices.[17]

Alternatives

A urinary catheter, urethral resection and anastomosis, urethrostomy, or placement of a percutaneous cystostomy tube. Patients with obstructive neoplasia can undergo ultrasound-guided endoscopic diode laser ablation. Benign urethral strictures can be balloon dilated.

Ultrasound-Guided Endoscopic Laser Ablation of Transitional Cell Carcinoma of the Lower Urinary Tract

Indications

Debulking of bladder and urethral transitional cell carcinoma in dogs (see ch. 351). This technique also can be used for establishing a urine stream in patients with obstructive neoplastic disease caused by other neoplasms. A similar technique can be used to laser-ablate benign tumors and polyps from the urinary tract.[18,19]

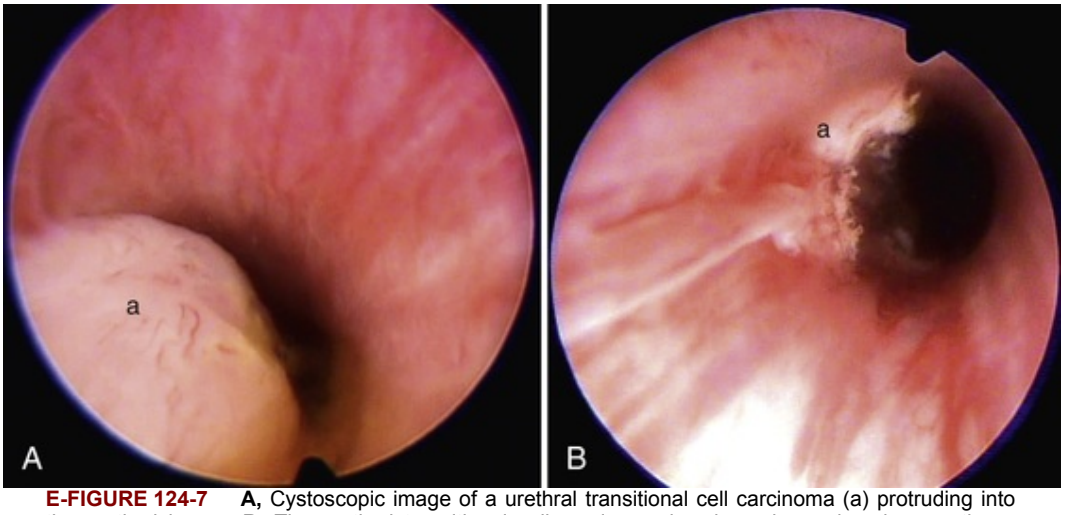
Equipment

Rigid cystoscope, Foley urinary catheter, diode laser with laser fiber that can be passed through the scope channel, ultrasound, and experienced ultrasonographer.

Procedure

The patient is anesthetized and placed in dorsal recumbency. The vulva/prepuce and surrounding area are clipped, prepped, and draped. The cystoscope is advanced to within 2-5 mm of the tumor and the region is simultaneously observed by abdominal ultrasound. Laser energy absorbed by the tumor increases tissue temperature, resulting in protein denaturation and making the tissue more hyperechoic on ultrasound.

Monitoring allows tumor ablation without penetration of the bladder wall. The resulting denatured, avascular tissue will slough within several days. At the end of the procedure, a Foley urinary catheter is placed in dogs with tumor in the urethra and trigone to avoid urethral obstruction while waiting for devitalized tissue to slough[18] (E-Figure 124-7, *A* and *B*).



E-FIGURE 124-7 **A,** Cystoscopic image of a urethral transitional cell carcinoma (a) protruding into the urethral lumen. **B,** The urethral transitional cell carcinoma has been lasered and some tissue remains adhered to the urethra (a).

Special Considerations

This procedure has a steep learning curve for both endoscopist and ultrasonographer. It is considered palliative, and chemotherapy should be maintained to improve outcome.

Outcome

Rapid resolution of urethral obstruction and improvement in clinical signs are reported, with a mean survival time of 380 days.[18]

Follow-up

The urinary catheter is left in place 3-7 days with urethral lesions, and 1-2 days with lesions of the trigone. 50% of patients develop bacterial cystitis postoperatively.[18] Bacterial cystitis or tumor regrowth/spread should be considered if lower urinary tract signs recur. Patients may undergo multiple laser treatments and follow-up ultrasound or cystoscopic examinations can aid in early identification of tumor recurrence.[18]

Complications

Despite relief of urethral obstruction, many dogs remain persistently dysuric and pollakiuric, which can improve over time. 34% of dogs demonstrate gross hematuria lasting 1-2 days, and 5% develop scar tissue at the cystourethral junction, necessitating subsequent laser treatments. Rarely, seeding of the tumor to other previously unaffected areas of the urinary tract has been reported. Urethral and bladder perforation are possible, with subsequent seeding of the abdomen with tumor cells.[18]

Alternatives

Urethral catheterization, urethral stent placement, urethral resection and anastomosis, urethrostomy, or placement of a percutaneous cystostomy tube.

Treatment with Urethral Bulking Agents for Sphincter Mechanism

Incompetence

Indications

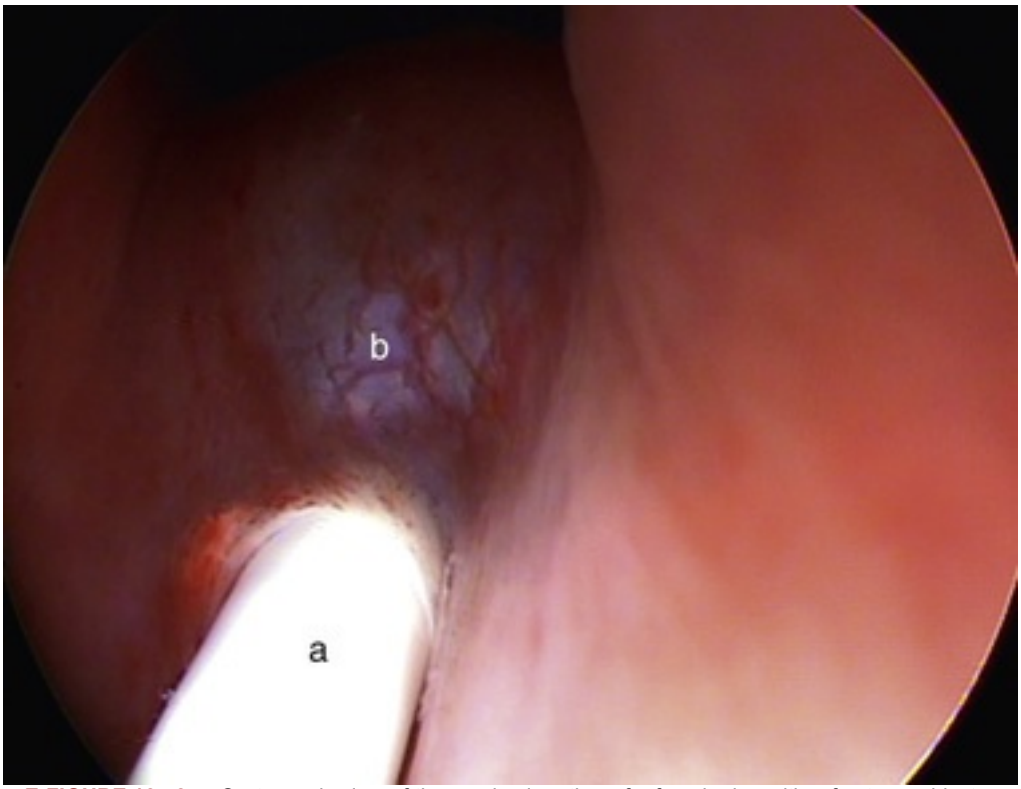
Treatment of urinary incontinence in dogs and cats with sphincter mechanism incompetence refractory to standard medical therapy (see ch. 46 and 333).

Equipment

Rigid cystoscope, injection needle furnished by the manufacturer of the bulking agent, cross-linked bovine collagen (limited availability) (injection needle: 5 Fr 23 ga) or polydimethylsiloxane (injection needle: 5 Fr 20 ga) with injection device.

Procedure

The patient is anesthetized and placed in dorsal recumbency. The vulva/prepuce and surrounding area are clipped, prepped, and draped. The ureterovesicular orifices, trigone, and proximal urethra are identified by cystoscopy. The cystoscope is withdrawn to the level of the proximal urethra, approximately 1-1.5 cm caudal to the bladder neck or at the location of the proximal urethra where the lumen appears to be the smallest. The urethral bulking agent is injected submucosally in 3 locations: at the 2, 6, and 10 o'clock positions, approximately. The needle is inserted so that its bevel is pointed towards the lumen and inserted superficially into the submucosa. The bulking agent is injected until a bleb is visualized that approaches midline (E-Figure 124-8). Once the volume has been administered, the needle is held in place for 60 seconds to allow the compound to congeal, as premature withdrawal of the needle will result in product leakage into the lumen. At the end of the procedure, the urethral lumen should be closed by the blebs. In males, a perineal or percutaneous cystolithotomy approach can be used for gaining access to the proximal urethra.[20-22]



E-FIGURE 124-8 Cystoscopic view of the proximal urethra of a female dog with refractory sphincter mechanism incompetence. An injection needle (a) is inserted into the submucosa and a bulking agent is injected. The submucosal bleb (b) significantly reduces the urethral lumen.

Special Considerations

The major drawbacks are lack of sustained efficacy and therefore, the need for repeated injections. The author will choose injection of a bulking agent in older female dogs with urethral sphincter mechanism incompetence refractory to medical therapy given the ease and minimal invasiveness of the technique. An artificial urethral sphincter is chosen in younger dogs as it can be placed at the time of spaying and has better long-term results.

Outcome

Continence rates using collagen in female dogs vary from 53-68%, with a mean duration of 17-21 months. Improved continence rates of 75% have been reported in dogs having undergone collagen injections and treated with an alpha-agonist.[21-23] A study using polydimethylsiloxane in female dogs reported continence rates of 86% 1 month after injection; however, long-term outcome was not available.[20]

Follow-up

If patients remain incontinent, a second injection of bulking agent can be done. Medical therapy consisting of estrogen and/or the use of alpha-agonists improves response to therapy.

Complications

Persistent incontinence is the main complication. Inability to urinate is infrequent and if it occurs, it can be treated with placement of an indwelling urethral catheter for 24-48 hours. No hypersensitivity reactions to collagen have been reported in cats and dogs; however, 3 dogs treated with polydimethylsiloxane experienced an acute allergic reaction (blepharedema and urticaria) managed successfully with diphenhydramine.[21]

Alternatives

Diapers, confinement, and limiting the patient to areas that are easy to clean; placement of an artificial urethral sphincter; colposuspension with or without urethroplasty.[24]

Artificial Urethral Sphincter (AUS) Placement

Indications

Treatment of urinary incontinence in dogs and cats with sphincter mechanism incompetence refractory to standard medical therapy (see ch. 46 and 333).

Equipment

Standard surgical instruments, artificial urethral sphincter with injectable access port, Huber needle, Penrose drain, ruler.

Procedure

The patient is anesthetized and placed in dorsal recumbency. The ventral abdomen is clipped, prepped, and draped. A median caudal ventral celiotomy is performed to expose the bladder and urethra. Using blunt dissection of the periurethral connective tissue, a 1.5 cm space is created circumferentially around the urethra. In females, the urethra is dissected away from the vagina; in males the bladder is retracted cranially to expose the urethra caudal to the prostate. The urethral circumference is measured using a Penrose drain placed loosely around the urethra. The length of the drain provides a measurement of the outer urethral circumference. The circumference measurement is divided by 50%, indicating the size of the AUS. The tubing is primed by retrograde infusion of sterile saline using a polyurethane catheter inserted down the tubing to remove air. The saline is withdrawn and its volume is noted prior to placement. The cuff is placed around the urethra and the ring is closed using suture placed through the eyelets. In a typical, medium-size female dog, the cuff is placed 3 cm caudal to the bladder neck whereas in a typical, medium-size male dog it is placed 2 cm caudal to the prostate. In smaller dogs and cats, the cuff should be placed as far caudal from the trigone

as possible to prevent cranial migration and kinking of the cuff during micturition. The cuff is left empty and is inflated 6 weeks post-operatively if incontinence persists. The right or left ventral body wall lateral to the incision is dissected between the subcutaneous tissue and ventral rectus muscle sheath, creating a pocket for the access port. The tubing is passed through the ventral body wall and inserted onto the male adaptor of the access port and the plastic boot is advanced to cover the junction. The port is sutured to the ventral rectus sheath, lateral to the midline incision. The bladder is inflated with saline and manually expressed to ensure urethral patency. The abdomen is lavaged and the celiotomy incision closed routinely[25-27] (Figure 124-9, *A* and *B*).

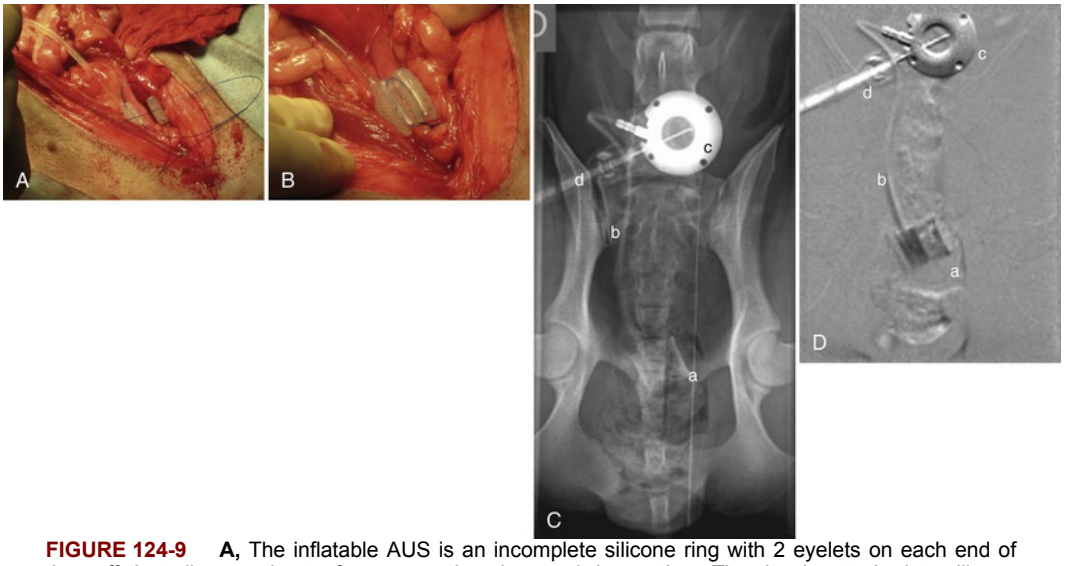


FIGURE 124-9 **A,** The inflatable AUS is an incomplete silicone ring with 2 eyelets on each end of the cuff that allows a ring to form once placed around the urethra. The ring is attached to silicone tubing that is attached to a subcutaneous access port. The cuff has been placed loosely around the urethra and suture has been passed through each eyelet. **B,** The eyelet sutures have now been attached and the cuff is in place around the urethra. The tubing leading from the cuff is visible. **C,** Ventrodorsal radiograph of a female dog with an AUS undergoing a contrast study. The cuff around the urethra filled with contrast is visible (a), the tubing leading towards the port is also filled with contrast (b). The access port is visible (c) along with the inserted Huber injection needle (d). **D,** The same image is seen under digital subtraction allowing better visualization of contrast material within the system.

Special Considerations

Only Huber needles should be used with the access port. Inflating the cuff before the periurethral tissue has healed could interfere with urethral vascularization. The AUS can be palpated transrectally and verified to ensure it has not slipped. If a leak in the system is suspected, patency can be checked by injecting contrast into the access port[28] (Figure 124-9, *C* and *D*). In dogs with pelvic bladders, a cystopexy can be performed at the same time as placement of the AUS to facilitate cuff placement and avoid entrapment of the ureters. Cystoscopy and urinary catheter placement should be avoided peri- and postoperatively as they could induce mucosal lesions, increasing the chance of intraluminal stricture formation.

Outcome

92% of dogs have shown marked improvement in continence, with 33%-45% of patients not needing cuff inflation.[25,26]

Follow-up

The patient should wear an Elizabethan collar until the skin sutures are removed. If incontinence persists, estrogen and/or an alpha-agonist can be administered.

Cuff inflation 6 weeks post-op: The area over the access port is clipped and prepped, and 0.1-0.2 mL of sterile

saline is injected into the port using a Huber needle. Patients then should be observed to urinate, before discharge, to ensure inflation has not resulted in urethral obstruction. If the patient is unable to urinate, 20% of the injected volume is withdrawn from the port. AUS inflation is repeated until continence is improved or signs of urethral obstruction occur. The volume injected each time should be noted to ensure that the maximal filling volume is not exceeded.

Complications

Minor complications include temporary worsening of incontinence during the first 14 days after surgery (19%), mild stranguria (7%) and seroma formation over the access port (11%). Urinary tract infections are observed in 61% of female dogs during long-term follow-up. In reported case series, major complications have occurred in 7-17% of dogs, with urethral obstruction at 1.5-23 months after surgery. Causes were intraluminal webbing in 1 dog that had undergone concurrent cystoscopy, and 4 cases of extraluminal stricture; 2 of these were treated by removal of the AUS (which resolved the obstruction in 1 case), and the other 2 underwent placement of urethral stents, which also resolved the obstruction.[25-27]

Alternatives

Diapers, confinement, and limiting the patient to areas that are easy to clean. Cystoscopic injection of a urethral bulking agent. Colposuspension with or without urethroplasty.[24]

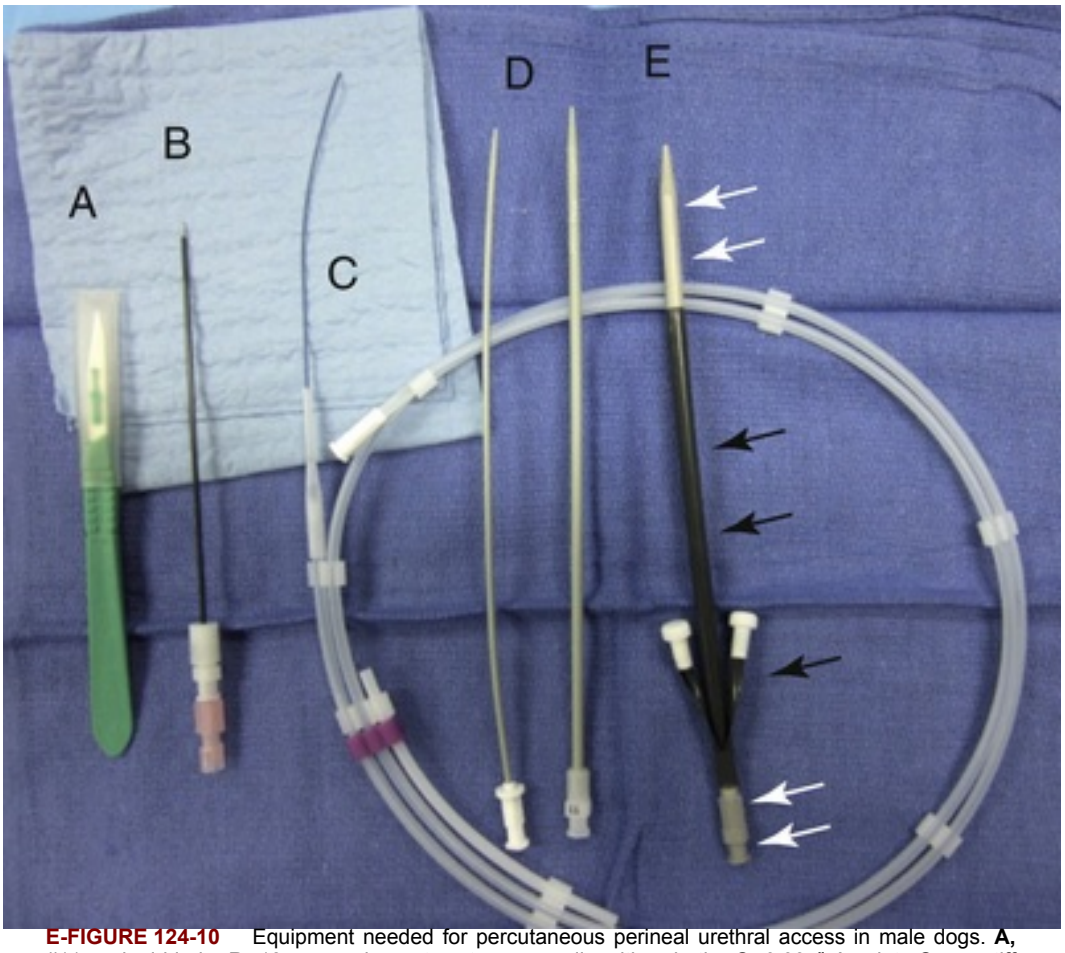
Percutaneous Perineal Access for Canine Rigid Male Cystourethroscopy

Indications

Perineal access into the urethra makes rigid cystourethroscopy possible in male dogs, resulting in dramatically improved visualization. This approach is particularly useful for endoscopic ureteral interventions in male dogs (e.g., laser ablation of ectopic ureters, sclerotherapy or ureteroscopy for idiopathic renal hemorrhage, ureteral stenting).

Equipment

A 2.7 mm rigid cystoscope, C-arm fluoroscope, 18-ga trocar needle, 0.035" Amplatz super-stiff guidewire, 0.035" angle-tipped hydrophilic guidewire, 8 Fr Foley urinary catheter, 14 Fr peel-away sheath, contrast material, and serial vascular dilators (8 Fr, 10 Fr, 12 Fr, 14 Fr) (E-Figure 124-10).



E-FIGURE 124-10 Equipment needed for percutaneous perineal urethral access in male dogs. **A,** #11 scalpel blade. **B,** 18-ga renal puncture trocar needle with echotip. **C,** 0.035" Amplatz Super-stiff guidewire. **D,** Vascular dilators. **E,** Peel-away sheath (black arrows) with dilator (white arrows).

Procedure

The perineal approach is performed with the patient placed in dorsal recumbency and the hindlimbs pulled cranially (Figure 124-11). The prepuce and perineal areas are clipped and prepared aseptically. A pursestring suture is placed in the anus. This positioning allows access for both retrograde flexible urethroscopy and perineal urethral access. Following flexible urethroscopy, an 8 Fr Foley catheter is placed and the urinary bladder is filled with diluted iohexol (50%). The C-arm fluoroscopy unit is positioned transversely across the dog in order to project a lateral image (see Figure 124-11). The catheter is pulled back into the ischial urethra and the balloon is filled with a 50% mixture of contrast. A 4-5 mm midline perineal skin incision is made into the pelvic urethra at the level of the ischium. An 18-ga trocar needle is placed, under fluoroscopic and ultrasound guidance, into the urethral lumen (see Figure 124-11). The needle is aimed such that it penetrates the balloon on the Foley catheter. The sharp stylet is removed and the hollow trocar is then advanced further, into the pelvic urethra, and a urine sample is collected to confirm proper location. Then the 0.035" Amplatz super-stiff guidewire is advanced and coiled into the urinary bladder under fluoroscopic guidance. The C-arm is rotated into a dorsoventral projection. The 18-ga catheter is removed over the wire and serial dilators (8 Fr, 10 Fr, 12 Fr, 14 Fr) are used for dilating the tract (see Figure 124-11) to accept a 14 or 16 Fr peel-away sheath. Once the 14 or 16 Fr sheath is within the mid-pelvic urethra, the dilator is removed and the 2.7 mm rigid cystoscope is placed through the sheath and rigid urethrocystoscopy is performed (Figure 124-12). Upon completion of the intervention, the sheath is removed. The puncture heals by second intention, and the patient is discharged the same day.

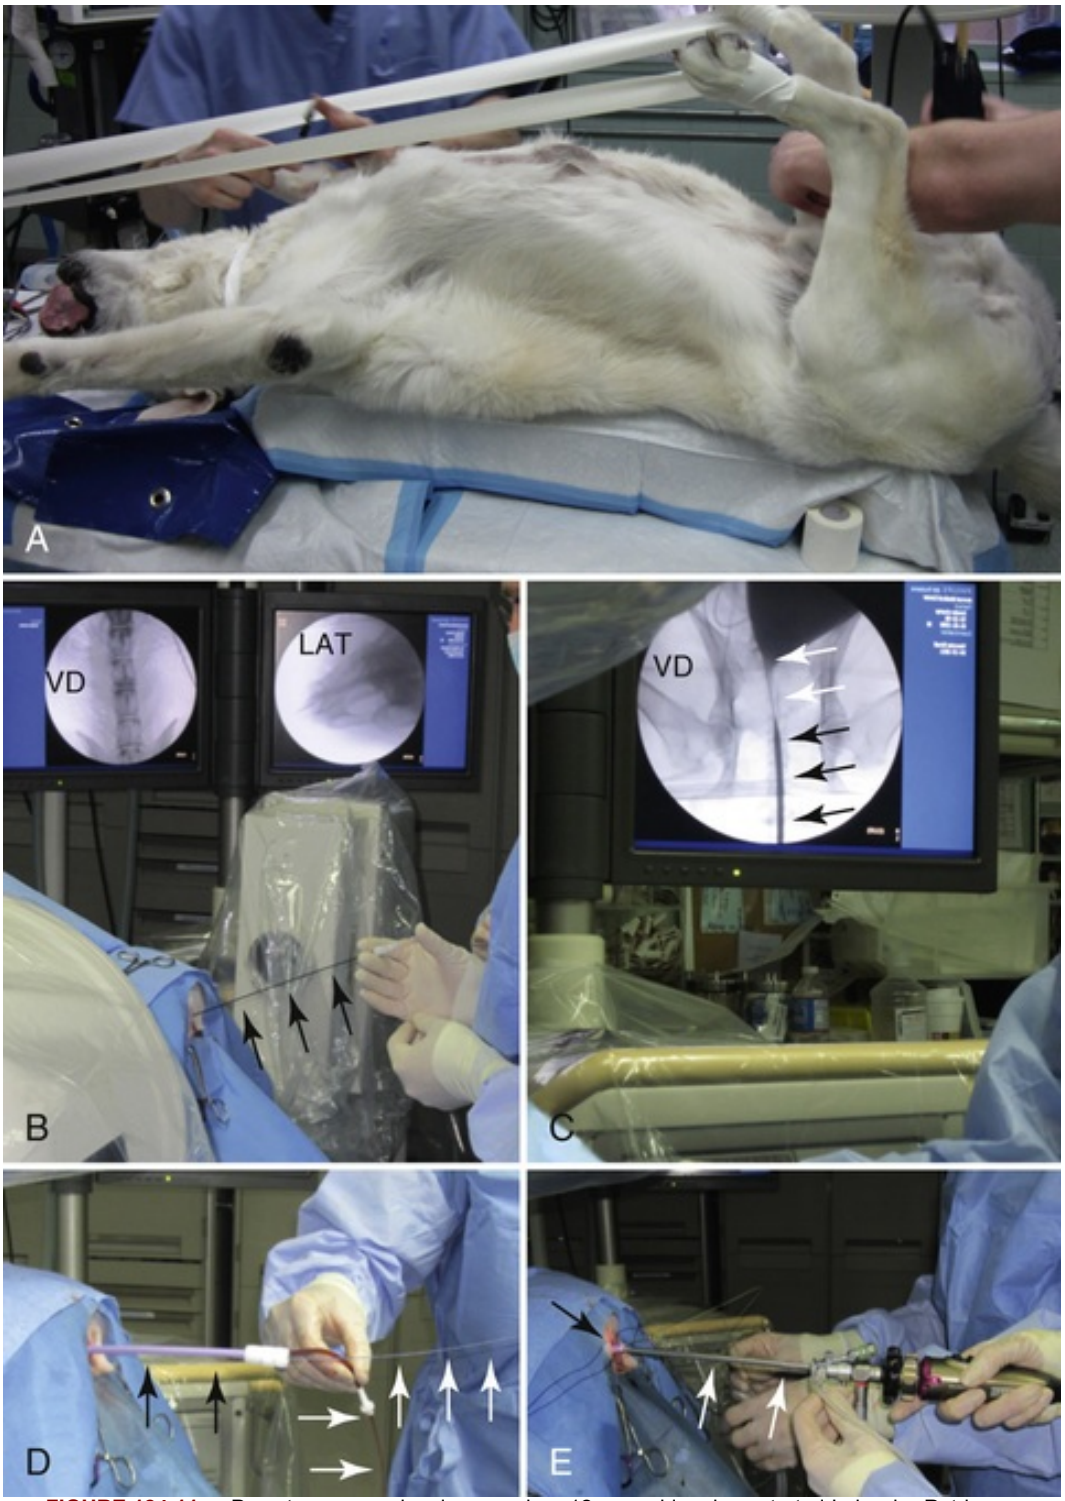


FIGURE 124-11 Percutaneous perineal access in a 12-year-old male castrated Labrador Retriever. **A,** Dorsal positioning of the dog with the tail off the end of the table. **B,** Fluoroscopy C-arm angled to image through the dog in a lateral projection. Notice the needle (black arrows) during percutaneous puncture, and the fluoroscopy images showing the ventrodorsal (VD) and lateral (LAT) projection. **C,** Fluoroscopic imaging showing the sheath (black arrows) over the guidewire (white arrows) on the fluoroscopy monitor once urethral access was obtained. **D,** Serial dilation (black arrows) over the guidewire (white arrows). **E,** Rigid endoscope (white arrows) entering the sheath for rigid cystoscopy. (Photo courtesy Dr. Chick Weisse.)

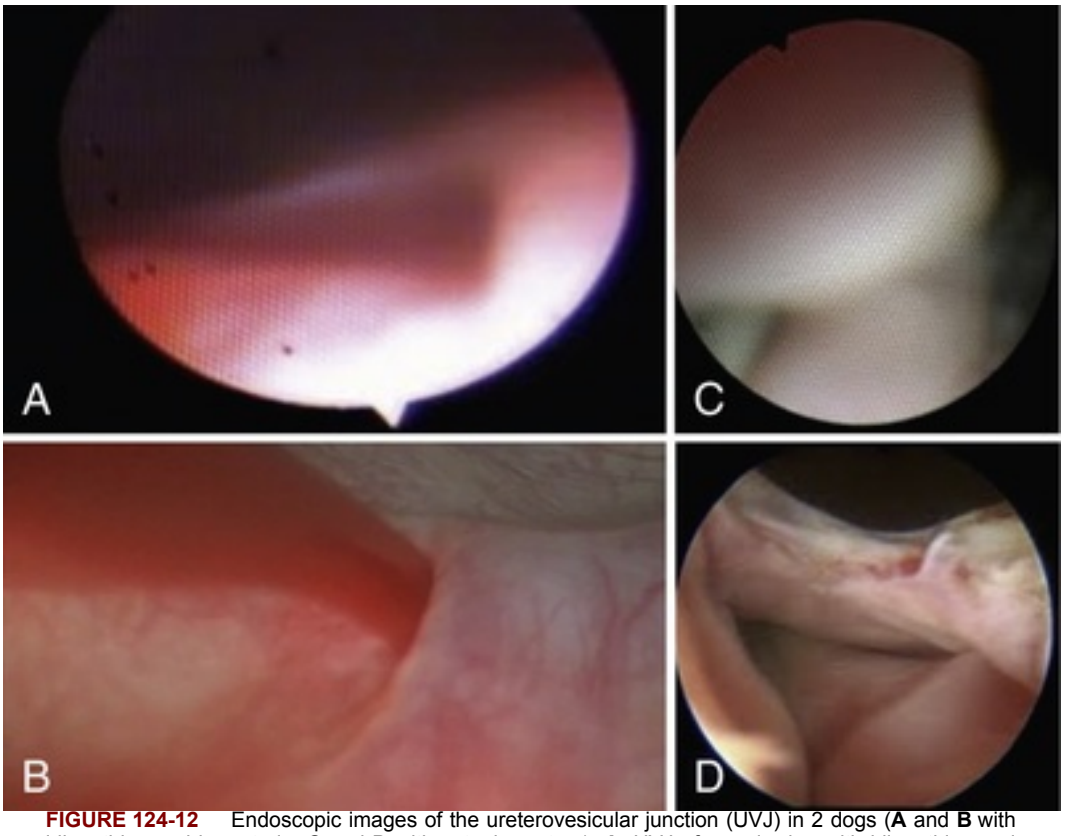

FIGURE 124-12 Endoscopic images of the ureterovesicular junction (UVJ) in 2 dogs (**A** and **B** with idiopathic renal hematuria; **C** and **D** with ectopic ureters). **A,** UVJ of a male dog with idiopathic renal hematuria showing blood jetting out of the orifice during flexible cystoscopy. **B,** Same dog as in image **A** using the rigid endoscope after perineal access. **C,** Male dog with a guidewire in his ectopic ureteral orifice during flexible cystoscopy. **D,** Same dog as image **C** after laser ablation of the ectopic ureteral orifice using the rigid cystoscope after perineal access is obtained.

Outcome

In a report of 10 dogs,[29] access time typically was <30 minutes, half the cases went home the same day as the procedure, and the only complication encountered was one dog leaking urine through the perineal incision 6 hours postoperatively, which did not recur. No long-term complications were identified in any of the dogs with a median follow-up time of ≈7 months and some >3 years.

Follow-up

The patient is recovered with no special treatments for the perineal approach, as treatments are based on the underlying condition that was treated (e.g., ureteral stent, ectopic ureter, renal hematuria).

Complications

The most concerning potential complications from the percutaneous perineal approach are hemorrhage from the vascular cavernous tissues of the ischial urethra and stricture formation.[29,30] Hemorrhage has not been a problem to date, likely due to the stretching (dilation) of the tissues rather than tearing or cutting that occurs during surgical urethral exposure/access. Strictures also are unlikely to occur with longitudinal incisions, rather than circumferential ones, as has been demonstrated experimentally in the urethra.[31,32]

Endoscopic Laser Ablation of Vestibulovaginal Remnants (ELA-VR)

Indications

Dogs affected by vestibulovaginal remnants, including persistent paramesonephric remnant (PPMR), vaginal septum (VS), or dual vaginas (DV), are suggested to display various signs like natural breeding difficulties,

persistent urinary incontinence, vaginal pooling of urine, chronic recurrent urinary tract infections, dysuria, vaginitis, dystocia, and vulvar dermatitis.[33-35] In a recent study,[34] endoscopic laser ablation of vestibulovaginal septal remnants (ELA-VR) was shown to improve continence scores and decrease urinary tract infections in affected dogs. However, the small number of dogs with isolated, single malformations limited the significance of correcting these lesions. As the current implications of these malformations remain unknown, having an effective, minimally invasive treatment option such as endoscopically-guided laser ablation is ideal.

Equipment

Typically, rigid cystoscopes with a 30° lens are used. Saline infusion is used for maintaining visibility, and this is ideally run on a pressure system to keep the vaginal vault distended. A guidewire and open-ended ureteral catheter are used for evaluating the length and location of the remnant. A laser used for ablating the membrane is either a diode or an Ho : YAG laser.

Procedure

The patient is placed in dorsal recumbency and the vulva is clipped and aseptically prepared. The cystoscope is advanced into the vestibule using saline irrigation on a pressure irrigation system. The vaginal opening is identified and each compartment is evaluated with the scope. The guidewire and ureteral catheter are advanced into one of the vaginal compartments, either using the working channel of the cystoscope or guided alongside the cystoscope. Next, the scope is removed over the wire/catheter combination and re-advanced into the vestibule next to the catheter (Figure 124-13). The scope can be advanced into the contralateral compartment to evaluate the length of the septum. Each malformation is classified as either a PPMR (<1 cm), VS (>1 cm) or DV (entire vagina to the cervix) based on measurements of the septum with the open ended ureteral catheter (1 cm marks throughout its length).

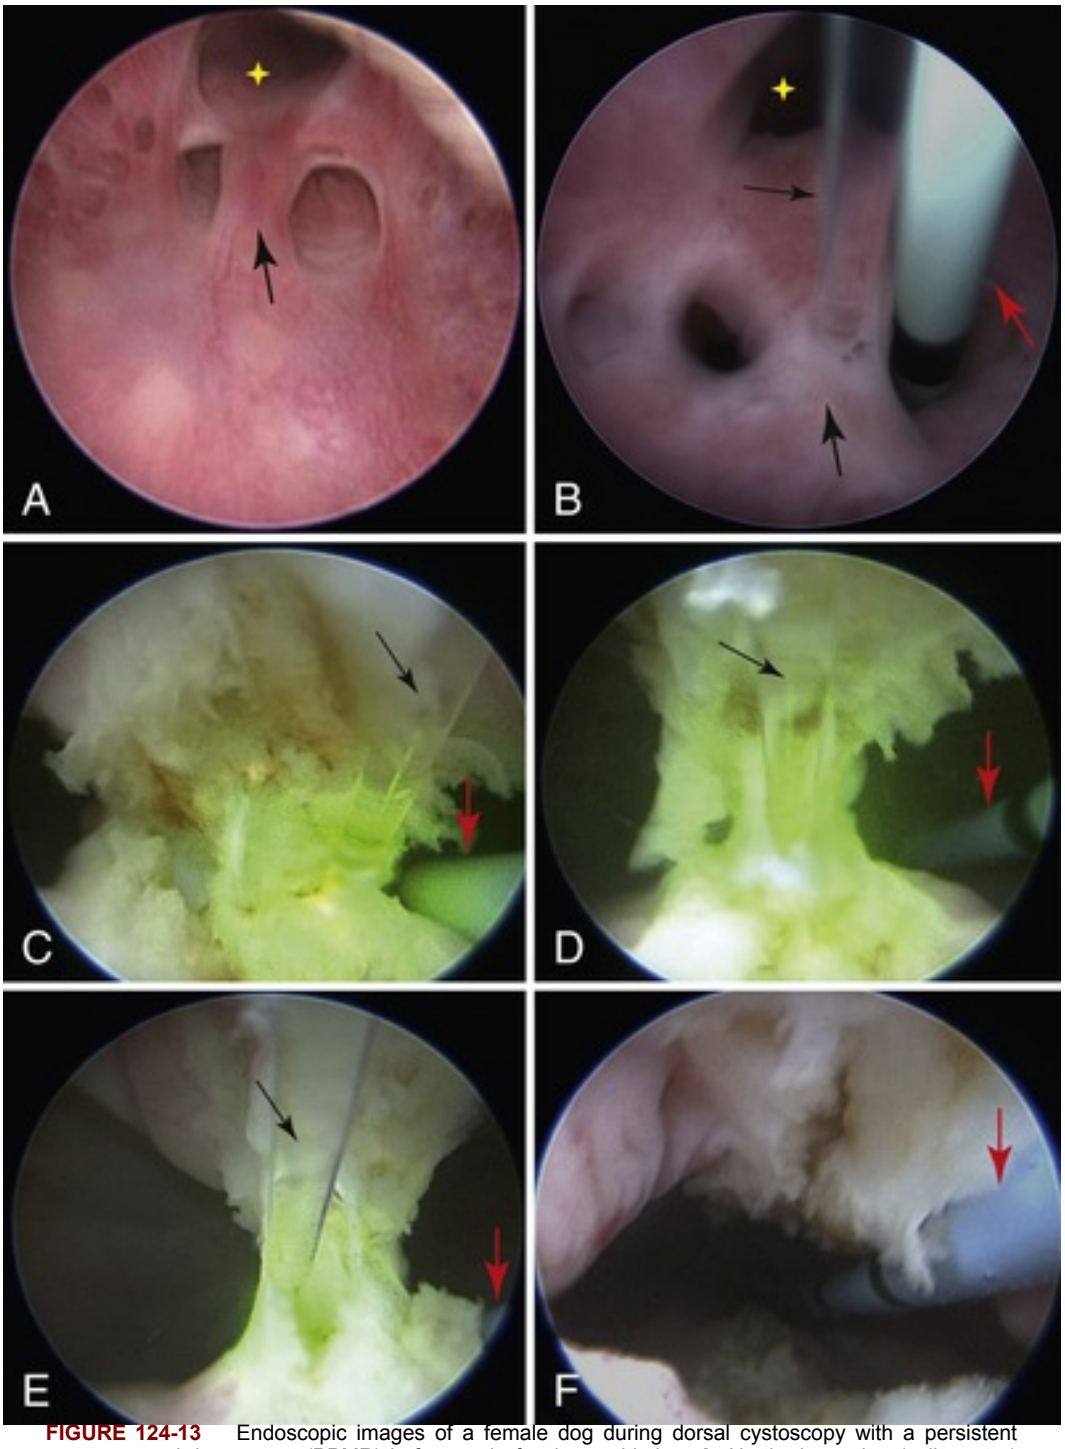

FIGURE 124-13 Endoscopic images of a female dog during dorsal cystoscopy with a persistent paramesonephric remnant (PPMR) before and after laser ablation. **A,** Urethral opening (yellow star) sitting just above (ventral to) the vaginal opening. The vaginal opening is covered by a dorsoventral band of tissue (black arrow), which is the PPMR. **B,** An open-ended ureteral catheter (red arrow) through one compartment of the vaginal opening while a laser (small black arrow) is directed onto the band of tissue (black arrow) through the working channel of the cystoscope. **C-E,** The laser (thin black arrow) progressively cutting the band of tissue while monitoring both compartments of the vagina with the ureteral catheter (red arrow). **F,** The entire remnant is cut showing one vaginal compartment.

A laser fiber is then placed inside the working channel of the endoscope (diode laser at 18-22 watts) and the malformation is laser-ablated from the caudal aspect to the most cranial aspect. The catheter is used for marking the contralateral vaginal compartment until the vagina is one open tube with one opening (see Figure 124-13). The vestibule is infused topically with a 1 : 1 mixture of bupivacaine (0.3 mg/kg) and sterile isotonic saline mixture for local transurethral analgesia.

Outcome

In a recent study, continence scores, vaginitis, and urinary tract infections all were improved after endoscopic guided laser ablation.[34] This finding is difficult to attribute to the correction of the VVSR, as most dogs underwent treatment of other congenital malformations, like ectopic ureters, concurrently. In 30 dogs in which this procedure was performed, no dog had re-formation of the VVSR.[34]

Follow-up

The patients are discharged the same day as the procedure. Owners are provided with an analgesic to be administered for signs of discomfort as needed. Bacterial culture of urine is performed 2-4 weeks after antibiotic therapy in all patients, and recommended at 8 weeks, 3 months, 6 months, and then every 6 months thereafter if the patient has had chronic urinary tract infections.

Complications

Complications with this procedure are possible and can include urethral tears, vaginal tears, and mucosal trauma. In a recent study evaluating ELA-VR, 5/36 dogs (14%) had immediate, mild, postoperative dysuria that resolved within the first 24-72 hours post-endoscopy.[34] Laser perforation of the vaginal wall occurred in one dog, without clinically significant consequences.

Alternatives

The alternative is open surgical resection of the lesion.

Cystoscopic-Guided Laser Ablation of Canine Intramural Ectopic Ureters

Indications

Correction of intramural ectopic ureters in females and males (see ch. 336). The diagnosis can be made/confirmed by cystoscopy and laser ablation can be performed at the same time.[36,37]

Equipment

Rigid or flexible cystoscope, hydrophilic angled guidewire, open-ended ureteral catheter, iodinated contrast medium, fluoroscopy or digital radiography, diode or Ho : YAG laser with a fiber that can be passed through the scope channel.

Procedure

The patient is anesthetized and placed in dorsal recumbency. The vulva/prepuce and surrounding area are clipped, prepped, and draped. Complete cystoscopy and vaginoscopy are performed to identify the site of the ectopia and identify concurrent anomalies. Once the ectopic ureteral orifice is identified, an angled hydrophilic guidewire is advanced through the working channel of the scope and passed into the ureter under fluoroscopic guidance. An open-ended ureteral catheter is advanced over the guidewire into the distal ureter. The guidewire is then removed and a retrograde ureteropyelogram is performed using iodinated contrast medium diluted 50 : 50 with sterile saline. The intramural path of the ureter can be confirmed and other anomalies of the renal pelvis and ureter can be assessed. The medial wall of the ectopic ureter is lasered until the ureteral orifice is situated within the trigone (Video 124-1). Retrograde contrast urethrocystography confirms correct positioning and ensures that no perforation of the urinary tract has occurred[36,37] (Figure 124-14, *A-C*).

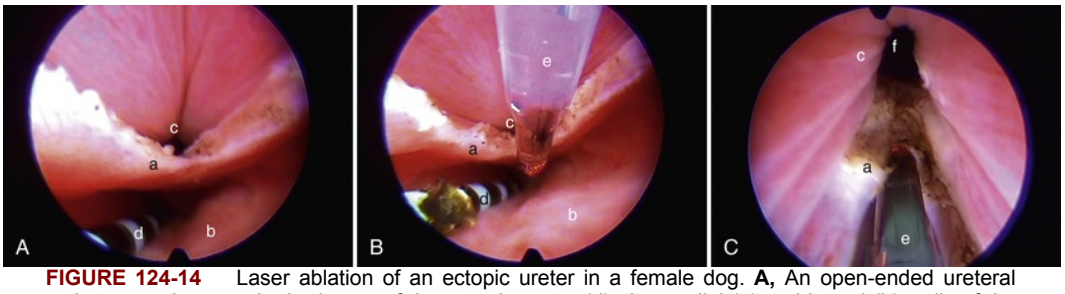

FIGURE 124-14 Laser ablation of an ectopic ureter in a female dog. **A,** An open-ended ureteral catheter can be seen in the lumen of the ectopic ureter (d), the medial (a) and lateral (b) walls of the ectopic ureter are visible along with the lateral wall of the urethra (c). **B,** The laser probe (e) is seen ablating the medial wall (a) of the ureter. **C,** The ectopic ureter has been lasered into the proximal urethra, the trigone along with the bladder lumen (f) are visible.

Special Considerations

Dogs with ectopic ureters can have various other anomalies of the genitourinary tract, including vestibulovaginal remnants, urethral sphincter mechanism incompetence, hypoplastic bladder, pelvic bladder, renal agenesis, renal dysplasia, and ureteral strictures. 93% of dogs with ureteral ectopia can have a vestibulovaginal remnant, which can be laser-ablated at the time of correction of the ectopia. Treatment of lower urinary tract infections is recommended prior to cystoscopic laser ablation if such infections are causing clinical signs.[36,37] Laser ablation of ectopic ureters in male dogs is best accomplished by fluoroscopic-assisted perineal urethral access allowing passage of a rigid scope into the pelvic urethra.[38]

Outcome

Cystoscopic laser ablation results in continence rates of 47% in female dogs 6 months following the procedure. Continence rates increase to 77% with the addition of therapy for urethral sphincter mechanism incompetence (see ch. 336).[29] Success rates are higher in male dogs.[31] Persistent incontinence is secondary to other concurrent urinary tract anomalies, such as urethral sphincter mechanism incompetence, which is reported in 75-89% of female dogs with ectopic ureters.[39,40]

Follow-up

Treatment of sphincter mechanism incompetence as needed. Regular urine cultures, as 30% of dogs are diagnosed with a urinary tract infection within 6 months following the procedure.[36]

Complications

Neither recurrence of the ectopia nor stricture at the ureterovesicular orifice has been reported. Perforation of the lower urinary tract is a rare occurrence and can be treated by leaving a urinary catheter in place for 24-48 hours. Patients can present with self-limiting mild dysuria and pollakiuria.

Alternatives

Surgical correction of ectopic ureters. The authors consider cystoscopic ablation as the standard of care for the correction of intramural ectopic ureters.

Treatment of Nephrolithiasis

Indications

Removal of nephroliths in canine and feline patients is only indicated if they are considered complex and problematic. The criteria for a complicated nephrolith and need for removal would be the following: if there is a partial or complete ureteropelvic junction (UPJ) obstruction resulting in progressive hydronephrosis; renal parenchymal loss is occurring due to stone growth; severe chronic hematuria; signs of renal pain are appreciated; or if recurrent urinary tract infections are occurring despite appropriate medical management of

an infected nephrolith. The main indication for removal of upper tract uroliths in cats is when the nephrolith moves into the ureter and becomes an obstructive ureterolith. If this occurs, then ureteral decompression with a subcutaneous ureteral bypass device (SUB, see below) is recommended over nephrolithotomy. Options for interventional removal of nephroliths are extracorporeal shockwave lithotripsy (ESWL) (dogs only)[41-43] and endoscopic nephrolithotomy (ENL; percutaneous or surgically-assisted endoscopic nephrolithotomy [PCNL or SENL] can be performed in both dogs and cats).[44,45]

Equipment

There are many machines available for *ESWL*, with the most common being a dry lithotriptor. These units are mobile. The *ENL* procedure requires a puncture needle for renal access (18 ga), an angle-tipped hydrophilic guidewire, and a dilation set for endoscopic renal access (18, 24, or 30 Fr). A nephroscope of appropriate size (22 Fr) is necessary for the lithotrite to fit within the working channel. The author prefers the dual-probe ultrasonic lithotrite.* If a smaller nephroscope is needed, then the Ho : YAG laser, as mentioned above, can be used for laser lithotripsy. If the procedure is done percutaneously, then a 6 Fr locking-loop pigtail catheter is needed. All patients have an appropriate sized ureteral stent placed after completion of the procedure.

Procedure

Extracorporeal Shockwave Lithotripsy

Once a patient is placed under general anesthesia, ESWL (E-Figure 124-15) can be performed by placing the patient in various oblique positions, using fluoroscopic guidance, so that accurate targeting via the lithotriptor is possible. The hair overlying the entry point of the shock waves is clipped and coupling gel is used for ensuring transmission of the shockwaves into the body and onto the stone and avoiding air bubbles from attenuating the shock waves at the skin surface. The urolith is placed in the focal spot on fluoroscopy using the machine's integrated targeting system. Shock waves then are delivered to induce urolith fragmentation and this is gated to the heart rate and rhythm to avoid fatal arrhythmias.

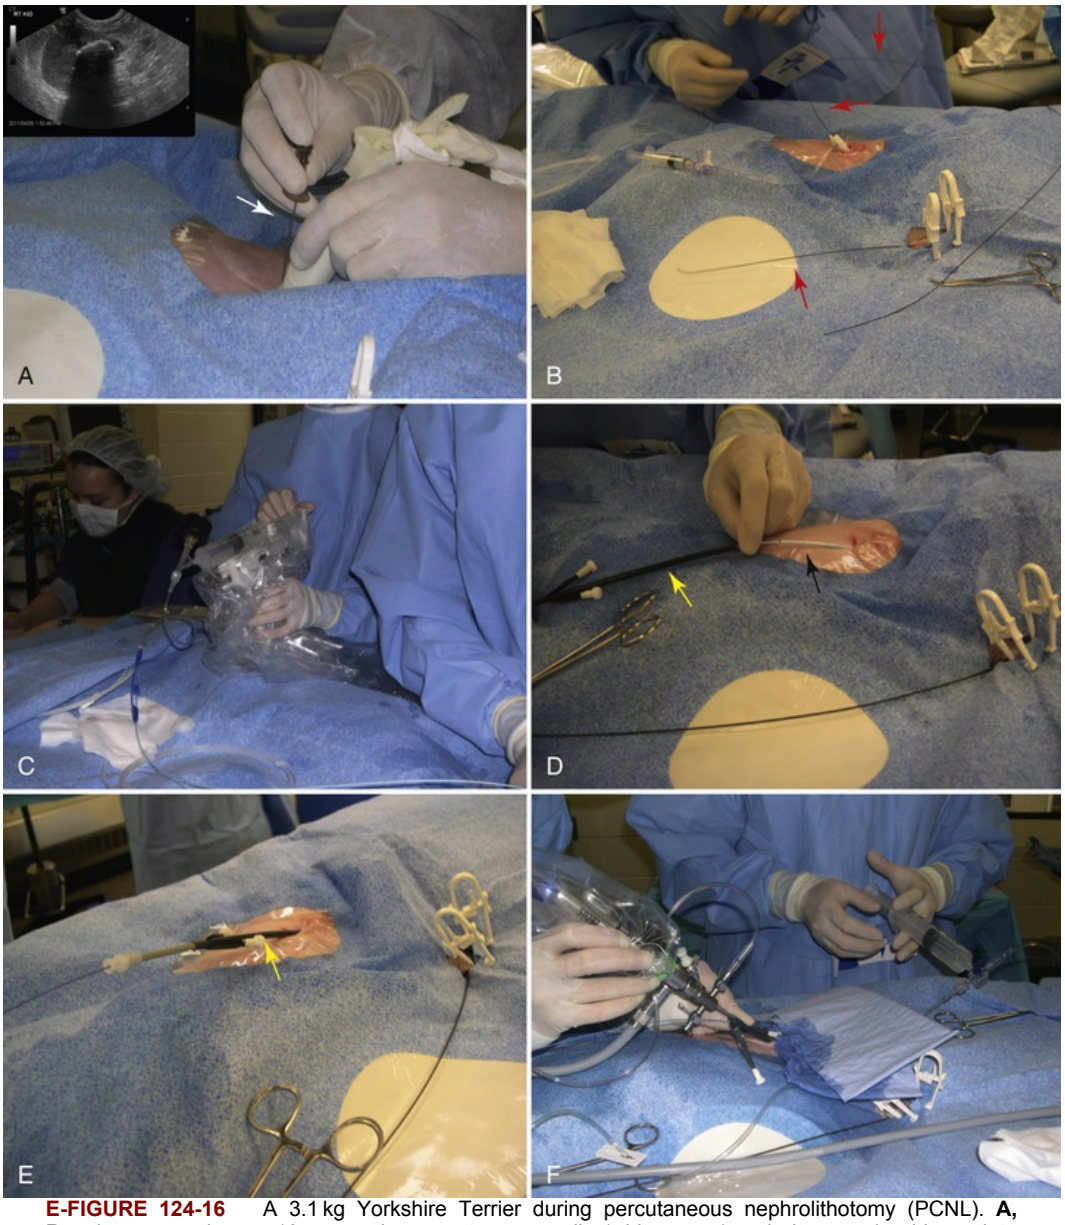
Endoscopic Nephrolithotomy *(E-Figure 124-16 and Figure 124-17)*



E-FIGURE 124-16 A 3.1 kg Yorkshire Terrier during percutaneous nephrolithotomy (PCNL). **A,** Renal access using an 18-ga renal access trocar needle (white arrow) and ultrasound guidance into the renal pelvis. **B,** Guidewire access (red arrows) into the renal pelvis, down the ureter, into the urinary bladder and out the urethra. **C,** Inflation of the balloon/sheath combination, creating a tract into the renal pelvis. **D,** Sheath (yellow arrow) passing over the balloon (black arrow). **E,** Sheath inside the kidney. **F,** Scope inside the sheath for nephroscopy.

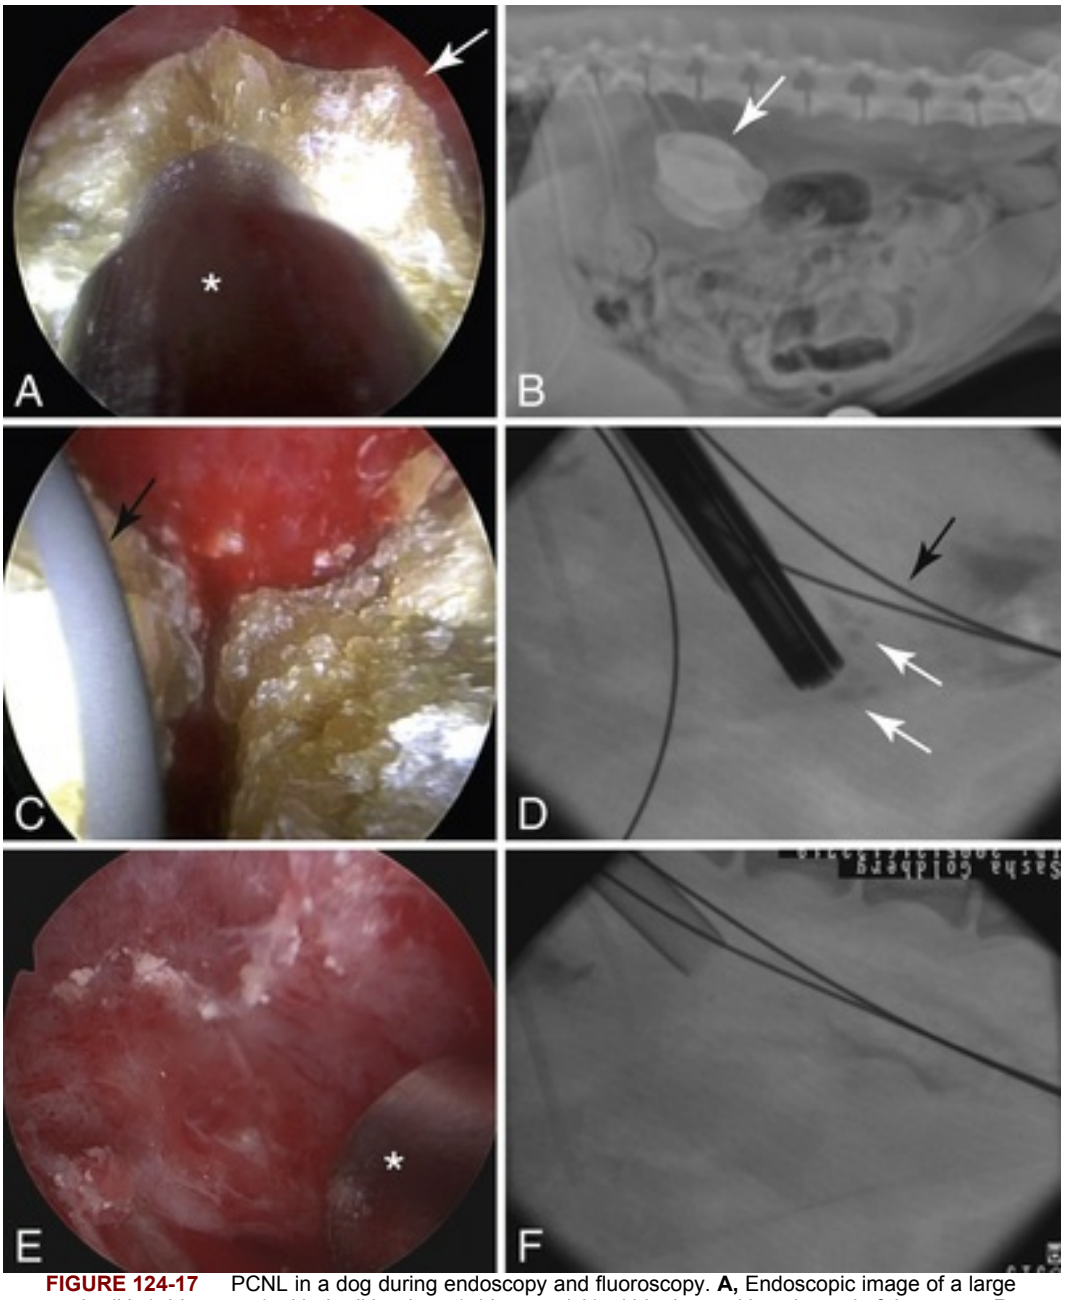


FIGURE 124-17 PCNL in a dog during endoscopy and fluoroscopy. **A,** Endoscopic image of a large nephrolith (white arrow) with the lithotripter (white asterisk) within the working channel of the scope. **B,** Lateral radiograph of a dog with large bilateral nephroliths (white arrow). **C,** Nephroscopic image after the stone is broken with a guidewire (black arrow) within the lumen of the renal pelvis. **D,** Fluoroscopic image of the nephroscope within the renal pelvis monitoring the location of all stone fragments (white arrows). Note the guidewires maintaining through and through access (black arrow). **E,** Renal pelvis after removal of the entire nephrolith. **F,** Fluoroscopic image showing all stone fragments after being removed.

ENL is done either percutaneously (PCNL) or surgically assisted (SENL). For PCNL, the patient is placed in lateral recumbency and the area of the kidney and the vulva/prepuce are clipped of hair and aseptically prepared. Using ultrasound guidance, an 18 ga renal access needle is used for puncturing the renal pelvis through the greater curvature of the kidney. Using fluoroscopic imaging, a ureteropyelogram is performed, and then a guidewire is placed antegrade into the renal pelvis, down the ureter, and into the urinary bladder, where it is then passed out the urethra to obtain through-and-through access. A tract is then dilated over the guidewire into the renal pelvis, using a balloon/sheath combination so that rigid nephroscopy can be performed to get intracorporeal access to the nephrolith. Then, the nephroscope and lithotriptor are used for breaking up the large stone and removing the fragments until the renal pelvis is clear of stone material, guided by endoscopy and fluoroscopy. Finally, once complete, a ureteral stent is placed to ensure post-

operative ureteral patency. If this is done percutaneously, then a locking-loop pigtail nephrostomy tube is placed to ensure a nephropexy is made. If this procedure is done surgically assisted (SENL), the same approach is used, but on completion of the procedure, the access point is closed using a mattress suture, which avoids the need for a nephrostomy tube.

Special Considerations

Most kidney stones in dogs and cats are not considered complex, meaning that they should not be removed. Careful consideration should be used prior to deciding to remove kidney stones, as the potential renal damage done, particularly with a surgical nephrotomy, typically does not justify removal. Prior to choosing the best procedure for nephrolith removal, stone size, patient size, and stone type should be considered. Exchanging a non-obstructive nephrolith for an obstructive ureterolith is contraindicated and concurrent ureteral stenting may be necessary to prevent this from occurring. Cystine stones are ESWL-resistant, and ENL should be considered when needed. Stone recurrence also is common, so medical management should be implemented appropriately to reduce the likelihood of this complication (see ch. 331 and 332). All of the procedures described above, like the other procedures in this chapter, should only be performed by trained operators.

Outcome

ESWL and ENL are safe, minimally invasive procedures, and can be highly effective when performed correctly.[46,47] Endoscopic nephrolithotomy (ENL) typically is more effective (90-100%)[46,48] than ESWL (50-80%)[47] when a single treatment is desired, and has been shown in people to have minimal effect on kidney function when compared to all other options.[48] However, it is important to realize that ENL is more difficult to perform and is more invasive than ESWL. In a recent report of 9 dogs and 1 cat (12 renal units) in which ENL was performed, the median stone size was 2 cm (0.7-5 cm) and the median pre- and 3-month post-operative serum creatinine concentration were 1.3 mg/dL (0.8-9.1 mg/dL) and 1.1 mg/dL (0.6-6.1 mg/dL), respectively.[45] Successful removal of all stones was documented in 92% of renal units with one procedure, and no patient died from the ENL procedure, similar to results reported in humans.[45,46,48] In a series of 140 dogs with nephroliths or ureteroliths treated by ESWL, the most common complication was the development of ureteral obstruction, occurring in approximately 10% of dogs.[41] The risk of ureteral obstruction has declined with the use of concurrent endoscopic ureteral stent placement.

Follow-up

After ESWL, dogs are treated with intravenous fluid therapy for 12-36 hours. Abdominal radiographs are taken at 24 hours to evaluate nephrolith fragmentation, and ultrasound is performed to confirm no ureteral obstruction has developed. If a ureteral stent is placed concurrently, dogs often are discharged the same day as the procedure. After ENL, pain medication is administered for 24 hours, while the patient is hospitalized and receiving IV fluids. Patients are discharged within 24-36 hours, and follow-up imaging and bloodwork are performed 2 weeks later. Once all stone fragments are confirmed to have been eliminated, the ureteral stent is removed either endoscopically or using fluoroscopic guidance. The renal pelvis can remain dilated for a few weeks/months, depending on the size of the stone that was removed and the length of time the stone was present. For PCNL, the nephrostomy tube is assessed with a urine culture in 5-7 days, and at 1 month it is removed. This should be done over a guidewire and can be done at the same time as ureteral stent removal.

Complications

The most common complication with ESWL is ureteral obstruction (10%).[41] Additional complications that can occur include pancreatitis, cardiac arrhythmias, transient hemorrhage, and the need for more than one procedure (15-30%).[41] ESWL is not recommended for treatment of nephroliths in cats because the feline ureter is only 0.3 mm in diameter, whereas a typical nephrolith fragment after ESWL has a diameter of ≈1 mm. Therefore, fragmentation of nephroliths in cats is prohibitively likely to result in ureteral obstruction. In addition, feline kidneys can have a tendency to hemorrhage more with ESWL compared to canine kidneys.

For ENL, the main risks are hemorrhage, ureteral perforation, and urine leakage from the renal access point. If the procedure is done percutaneously (PCNL), then a nephrostomy tube remains indwelling for a minimum of 4 weeks to create a nephropexy; otherwise, urine leakage can occur while the nephrostomy site

heals. Nephrostomy tube dislodgement and urinary tract infections should be considered and careful monitoring should be implemented. With SENL the access point is closed with a suture once the procedure is complete.

Regardless of which procedure is performed, the biggest risk is stone recurrence; this warrants monitoring and appropriate preventive measures.

Alternatives

The alternative to ESWL or ENL is a surgical nephrotomy, nephrectomy, or leaving the stone within the kidney. <5% of all stones require removal and care should be taken when deciding the best approach for each patient.

Treatment of Benign Ureteral Obstructions

Indications

Benign ureteral obstructions are a clinical problem seen with greater frequency in dogs and cats over the past decade (see ch. 329).[49-61] This condition most commonly is associated with ureterolithiasis and/or ureteral strictures. Interventional options have become a common treatment modality due to the lower morbidity and mortality rates reported when compared to traditional surgical techniques[52,54,56,57,60,61] (Table 124-3). To date, the recommended interventional treatments for ureteral obstructions are endoscopic ureteral stent placement for dogs and placement of a subcutaneous ureteral bypass (SUB) device in cats.

Equipment

Various rigid and flexible endoscopes are needed for retrograde ureteral stent placement in dogs. This is possible in any size female dog and male dogs weighing >6 kg. Guidewires and catheters are needed for each procedure, and size depends on the size of the stent and catheter that ultimately are used (E-Table 124-4). The SUB device[†] is a specialized 6.5 Fr nephrostomy tube that is connected to a cystostomy tube through a shunting port that is placed subcutaneously, creating an artificial ureter.

E-TABLE 124-4

Guidelines for Equipment Used for Ureteral Stenting in Dogs and Cats

URETERAL STENT SIZE (FRENCH)	GUIDEWIRE SIZE	OPEN-ENDED URETERAL CATHETER SIZE	RIGID CYSTOSCOPE LENS SIZE (WORKING CHANNEL DIAMETER)	OVER-THE-NEEDLE CATHETER SIZE (GAUGE)
2.5-feline	0.018″	3 Fr or 0.032-0.034″ ureteral dilator	1.9 mm (3 Fr)	21 or 22
3.7-small dog	0.025″	4 Fr	2.7 mm (5 Fr)	20
4.7-medium/large dog	0.035″	5 Fr	2.7 mm (5 Fr)	18
6.0-large dog/cancer stent	0.035″	5 Fr	4 mm (6 Fr)	18

Procedure

Ureteral Stents

Ureteral stents are most commonly placed cystoscopically in dogs. This is performed in a retrograde manner through the ureterovesicular junction (UVJ). This is not possible when the obstruction is due to a trigonal tumor covering the UVJ (see below). For endoscopic ureteral stent placement, the patient is placed in dorsal recumbency and the vulva or prepuce is clipped and aseptically prepared. In a female dog, a 30° cystoscope is used for routine cystoscopy, and an appropriately sized, angle-tipped, hydrophilic guidewire/ureteral catheter combination is used for cannulating the ureter. Once the catheter is in the distal third of the ureter, the wire is removed, and under fluoroscopic guidance, a retrograde ureteropyelogram is performed. Then the wire is re-advanced through the catheter, up the ureter, around the obstruction, and into the renal pelvis (Figure 124-18). The wire is removed from the catheter and contrast is injected into the renal pelvis. The wire is re-advanced and coiled within the renal pelvis, and the catheter is removed over the guidewire, monitoring with fluoroscopic guidance to ensure the wire remains coiled within the renal pelvis. During this withdrawal, the ureteral length is measured using the catheter and monitoring the UVJ through the endoscope. Then an appropriate-size stent is chosen based on the ureteral diameter and ureteral length. This double pigtail ureteral stent then is placed over the guidewire, through the working channel of the endoscope, up the ureter, and is coiled on the wire into the renal pelvis. Once a curl is seen in the renal pelvis, then the wire is withdrawn into the cystoscope and a pusher catheter is used for pushing the distal end of the stent into the urinary bladder.

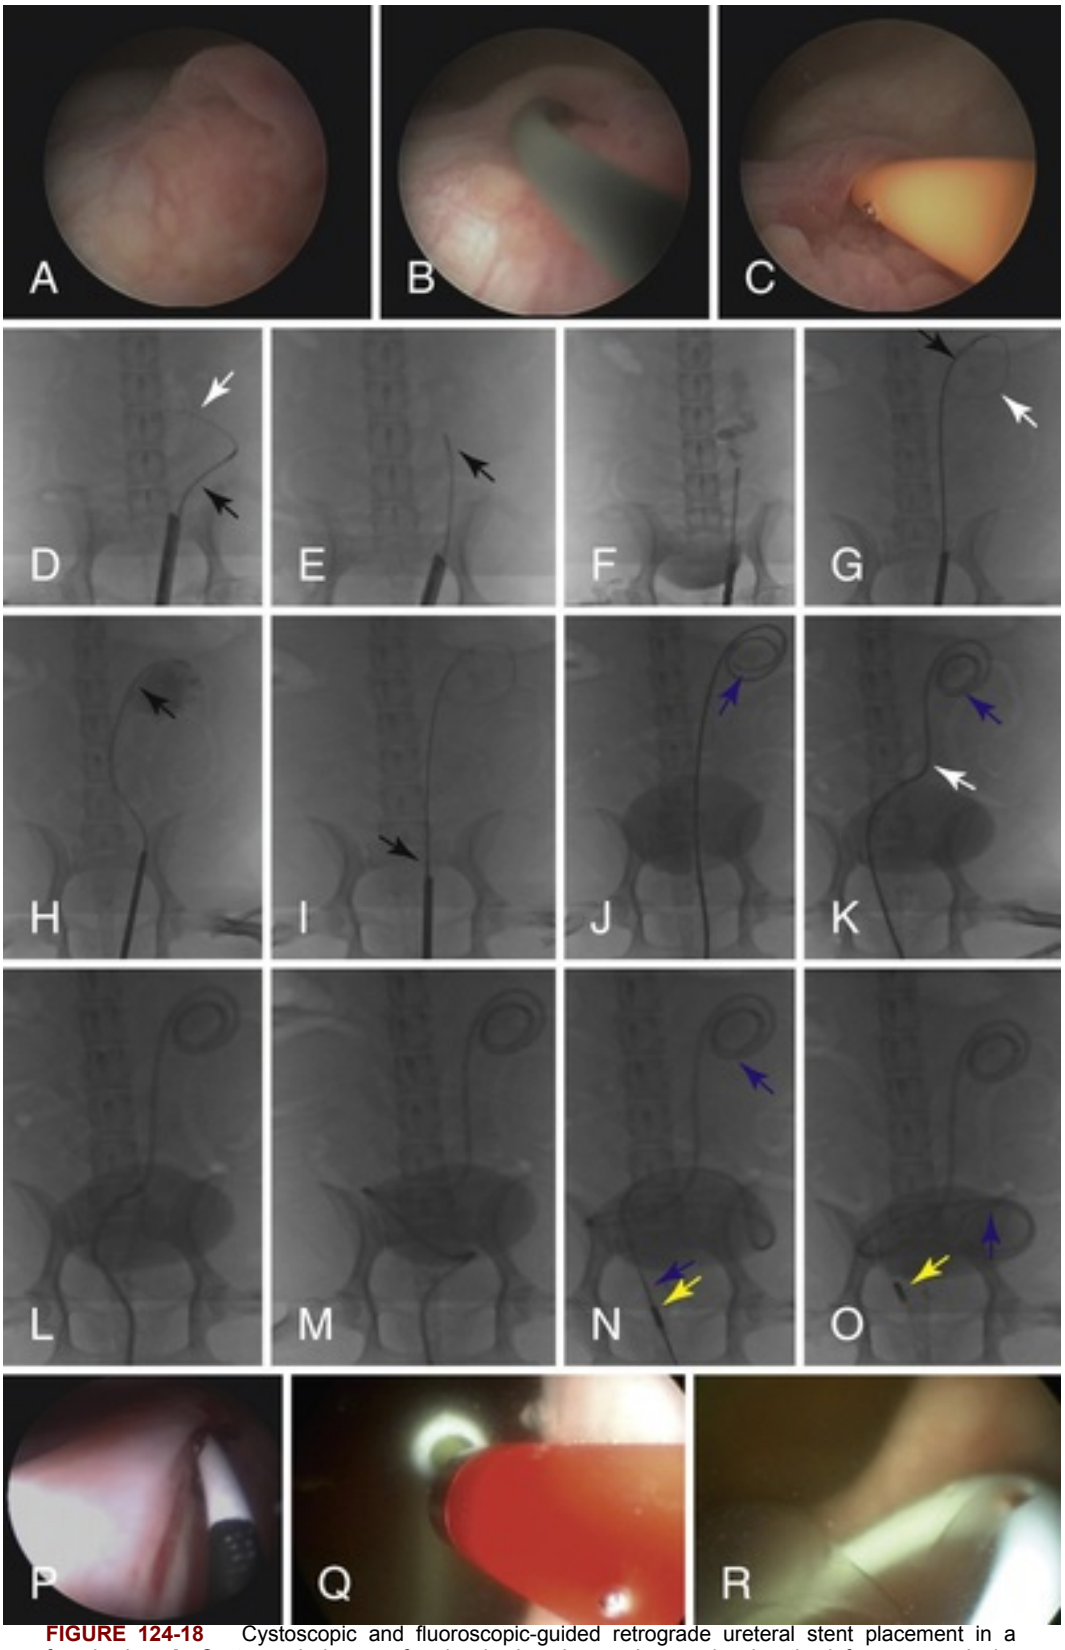

FIGURE 124-18 Cystoscopic and fluoroscopic-guided retrograde ureteral stent placement in a female dog. **A,** Cystoscopic image of a dog in dorsal recumbency showing the left ureterovesicular junction (UVJ). **B,** Guidewire being advanced into the ureteral lumen from the UVJ. **C,** Open-ended ureteral catheter being advanced over the guidewire into the ureteral lumen. **D,** Fluoroscopic image of the guidewire (white arrow) and open-ended ureteral catheter (black arrow) being advanced retrograde up the ureter. **E,** The wire is removed and the catheter remains in the ureter for a retrograde ureteropyelogram. **F,** Retrograde ureteropyelogram being performed, outlining the ureteral obstruction. **G,** Guidewire (white arrow) advanced back into the catheter and curled within the renal pelvis with the ureteral catheter (black arrow) advanced to the renal pelvis. **H,** Contrast seen within the renal pelvis

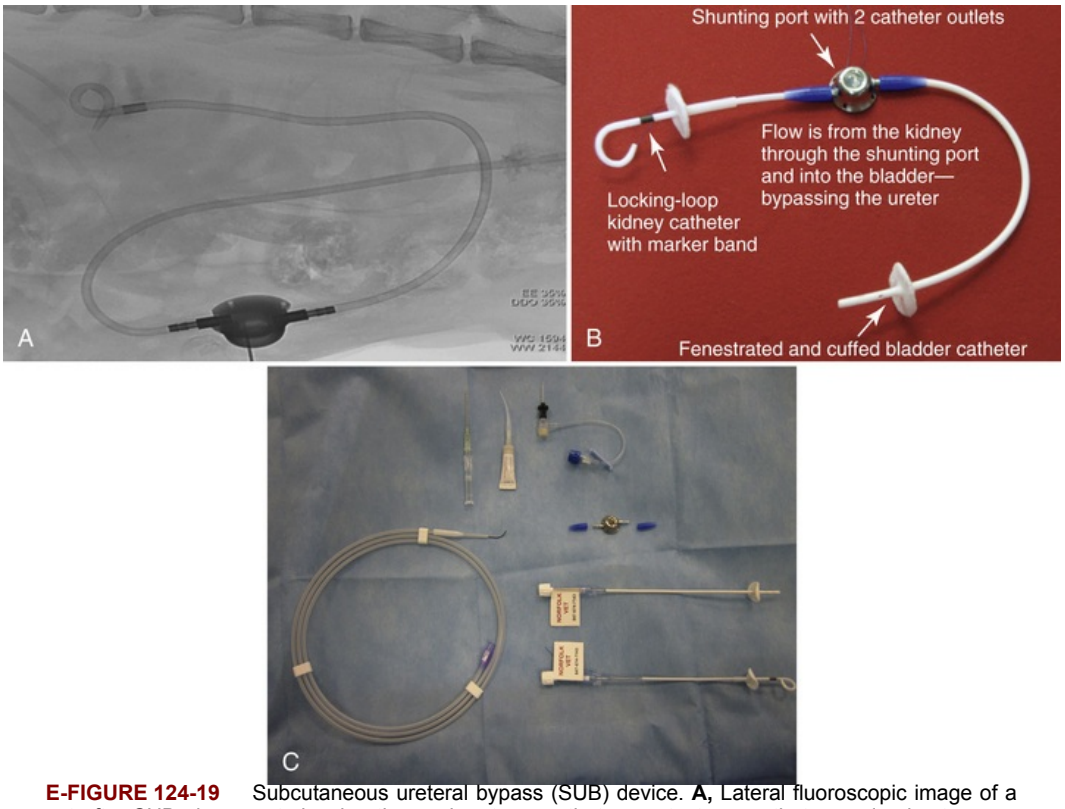
after a pyelogram was performed through the ureteral catheter (black arrow). **I,** The ureteral catheter (black arrow) is pulled back over a guidewire from the UPJ in image **(H)** to the UVJ in image **(I)** allowing for measurement of the ureteral length for stent sizing. **J,** The ureteral stent (blue arrow) is advanced over the guidewire and curled within the renal pelvis. The bladder is filled with contrast to be able to mark the UVJ under fluoroscopy. **K,** Once the proximal loop of the stent (blue arrow) is within the renal pelvis the guidewire is retracted (white arrow). **L,** The guidewire is pulled back to the distal end of the stent within the urethra. Notice the distal end of the stent is folding into the bladder once the wire is not within the lumen. **M,** The distal end of the stent is being pushed into the urinary bladder. **N,** The pusher catheter (yellow arrow) has a radiopaque mark to mark the distal end of the stent. Notice the wire is crossing the junction between the stent (blue arrows) and pusher. The stent is coiling within the urinary bladder. **O,** The entire distal end of the ureteral stent is coiled within the urinary bladder (blue arrow) and the pusher catheter is in the urethra (yellow arrow). **P,** Endoscopic image of the ureteral stent as it exits the UVJ. The black mark seen is an endoscopic marker to alert the endoscopist when the distal loop of the pigtail is beginning. **Q,** Endoscopic image of the junction of the ureteral stent and the pusher catheter as they both exit the working channel of the endoscope. Notice the guidewire is through the lumen of both catheters. **R,** Once the stent is within the bladder the pusher catheter and wire are completely removed and fluid is seen draining through the fenestrations of the stent ensuring patency.

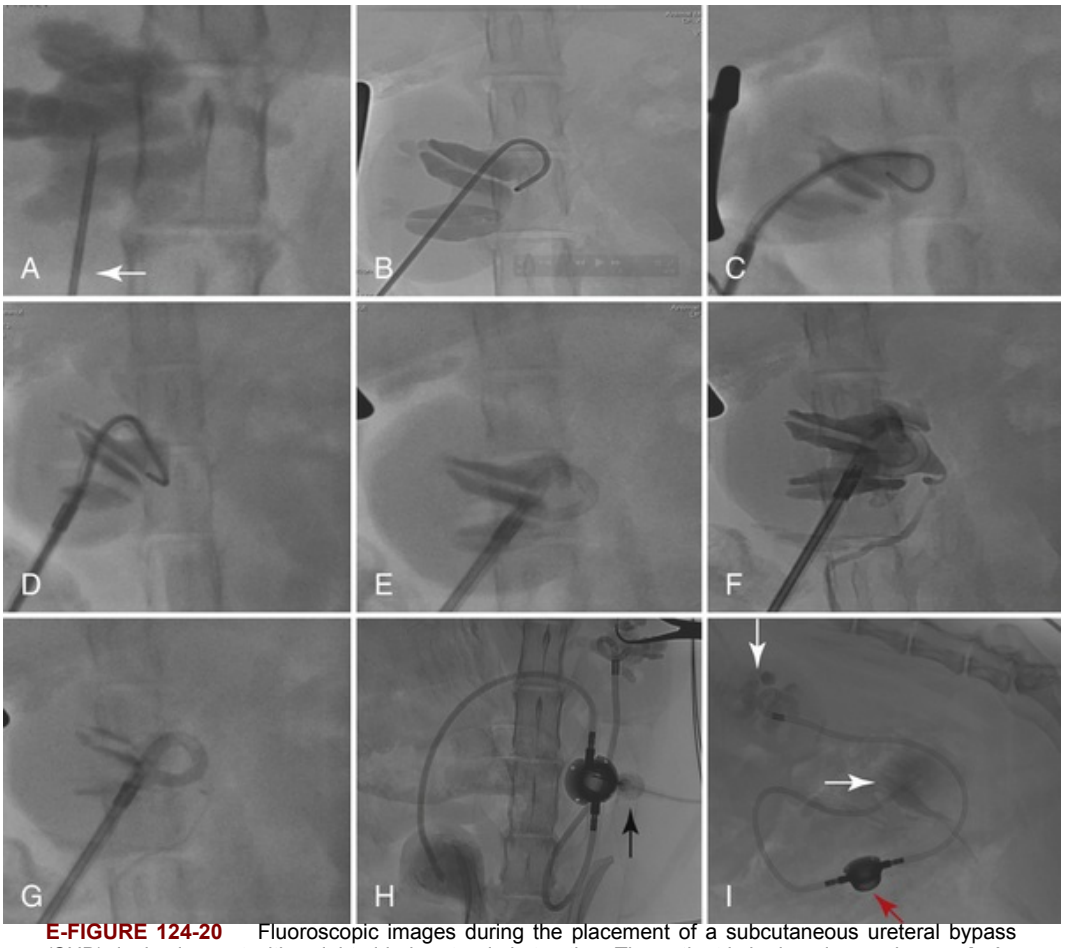
If pyonephrosis is present, as it has been in ≈25-30% of dogs with ureteral obstruction in the authors' practice, then once the renal pelvis is catheterized with the open-ended ureteral catheter, this pelvis should be flushed and drained to provide adequate pelvic lavage prior to placing the ureteral stent. Care is taken to remove as much of the purulent debris as possible.

SUB Device

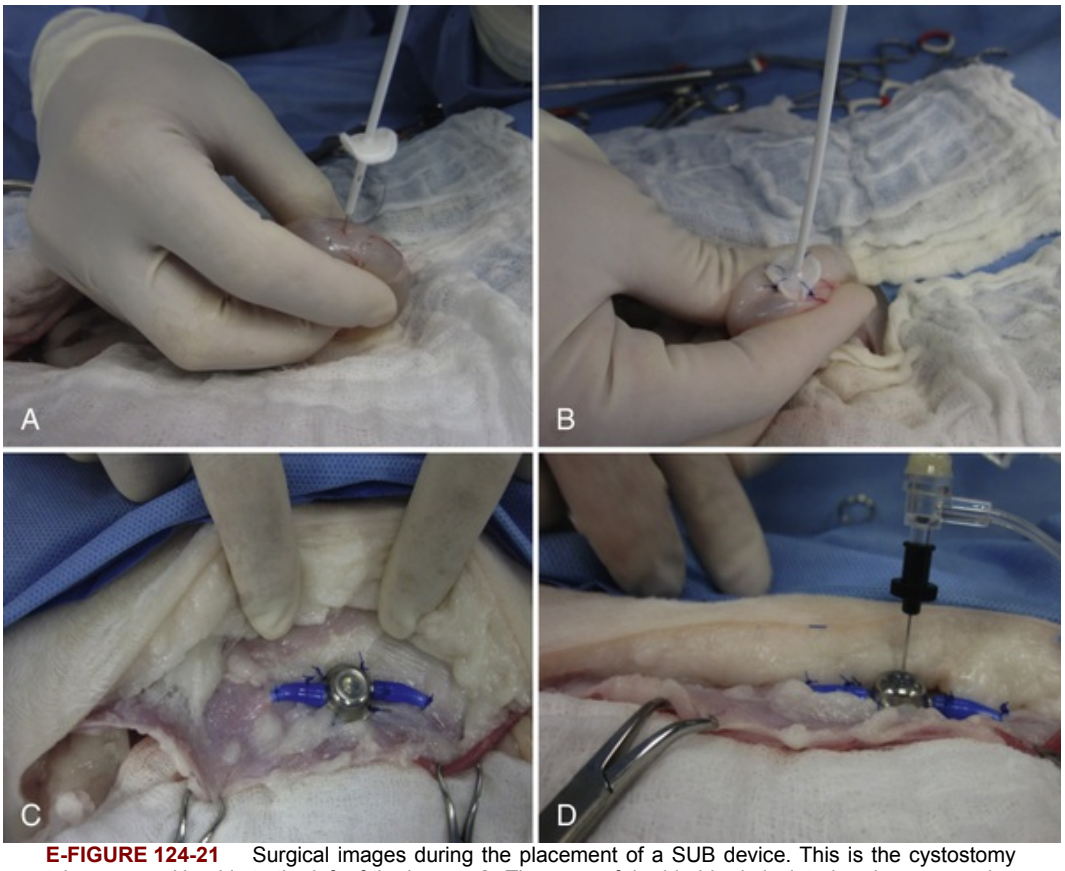
The SUB device (E-Figure 124-19) typically is used for all causes of ureteral obstructions in cats, but is used only rarely in dogs. This device has simplified the treatment of ureteral obstructions. The bladder apex and affected kidney are exposed through a ventral midline celiotomy. Using the modified Seldinger technique, an 18 ga catheter is advanced through the caudal pole of the kidney and into the renal pelvis. An antegrade pyelogram is performed and then a J-tipped 0.035" guidewire is advanced through the catheter and coiled within the renal pelvis (E-Figure 124-20). The 18 ga catheter is removed over the wire while monitoring under fluoroscopic guidance, and the locking-loop nephrostomy tube is advanced over the wire, so that it can be coiled within the renal pelvis. The string is then locked. Next, the urinary bladder apex is isolated and a pursestring suture is placed using 3-0 monocryl suture (E-Figure 124-21). A #11 scalpel blade is used for making a small stab incision in the bladder (in the center of the pursestring suture) and the cystostomy catheter is advanced into the bladder lumen using the hollow trocar. The sharp stylet is removed and the pursestring is tightened. Then, suture is used for securing the Dacron/silicone cuff to the bladder wall (full thickness), using 3 interrupted sutures. After the first suture, sterile cyanoacrylate glue is used for gluing the Dacron cuff to the bladder serosa. Then the final 2 sutures are placed so that the catheter is secure. Finally, the nephrostomy and cystoscopy tubes are connected to the subcutaneous shunting port (E-Figures 124-21 and 124-22). The skin and subcutaneous tissues lateral to the incision are dissected down to the abdominal musculature and the catheters are passed through the body wall, leaving enough room for the shunting port and some tubing to connect to the male-to-male adaptor (≈6 cm). The nephrostomy catheter is passed caudally and the cystostomy catheter cranially, which helps to prevent kinking. The blue cuff is advanced over the nephrostomy catheter and the port is attached. The pin of the port is used for securing the locking string so that the pigtail of the catheter is locked (see E-Figure 124-22). The locking string is cut using a #11 blade, ensuring that none of it protrudes from the catheter once it is advanced over the barbs of the port. This is a site of potential leakage. The same procedure is done for the bladder catheter, cranial to the port. Once the system is closed, both catheters are clamped off using digital pressure and the port is injected with saline to ensure there is no leakage. Care should be taken to ensure that no fluid is flushed up into the kidney catheter using digital pressure on the tubing, as that could over-distend the pelvis. Then, the port is secured to the body wall using permanent suture material. Finally, the system is drained of fluid using a non-coring Huber needle and the system is flushed with contrast under fluoroscopic guidance. Digital subtraction radiology is recommended to monitor for leakage at the kidney, bladder, and port, as well as any kinking of the device. Once patency is confirmed, the subcutaneous tissue is closed and topical bupivacaine is infused into the pocket. Then, the abdomen is flushed copiously with warm saline and closed routinely. A final fluoroscopic image is taken to ensure no kinking of the catheters is seen prior to complete closure.



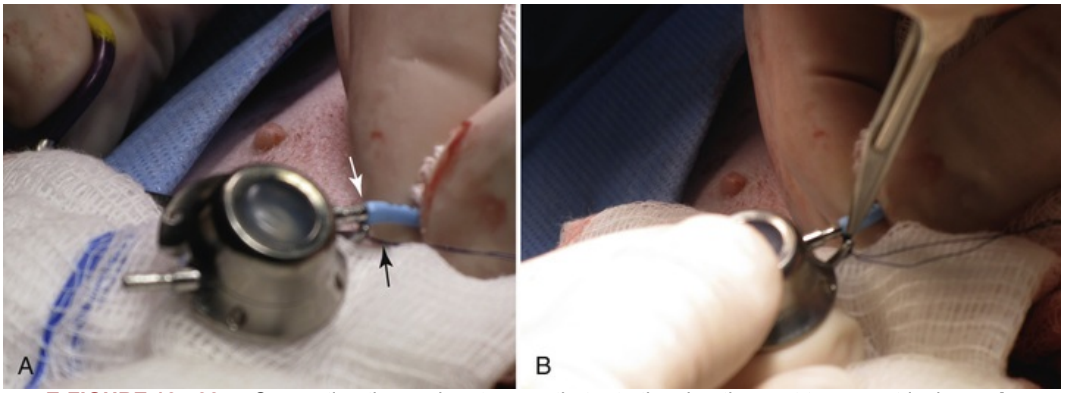
E-FIGURE 124-19 Subcutaneous ureteral bypass (SUB) device. **A,** Lateral fluoroscopic image of a cat after SUB placement showing the nephrostomy catheter, cystostomy catheter, and subcutaneous shunting injection port. **B,** The device assembled outside of the patient. **C,** Each piece of the device and the equipment needed for SUB placement: an 18 gauge over-the-needle catheter, a 0.035" angle-tipped hydrophilic guidewire or "J-tipped" guidewire, the nephrostomy and cystostomy catheter, sterile tissue glue (cyanoacrylate), the shunting injection port with the cuffs that secure the junction on the catheters and a Huber needle used to flush and inject the access port, connected to a T-port connector.



E-FIGURE 124-20 Fluoroscopic images during the placement of a subcutaneous ureteral bypass (SUB) device in a cat with a right-sided ureteral obstruction. The patient is in dorsal recumbency. **A,** An 18-gauge catheter (white arrow) is advanced into the renal pelvis from the caudal pole of the kidney. This is usually how the initial pyelogram is done unless the renal pelvis is < ≈6-7 mm. **B,** The "J"-tipped wire is passed through the renal catheter, and allowed to bend within the renal pelvis. **C,** The locking-loop nephrostomy catheter is being advanced over the "J"-tipped wire as it is making the bend along the renal pelvis. **D,** The coil of the nephrostomy catheter over the wire. **E,** The wire removed as the pigtail is made by locking the loop of the nephrostomy catheter. **F,** Ureteropyelogram performed showing the dilated renal pelvis and proximal tortuous ureter, which is obstructed mid-ureter by stones. Notice there is no leakage at the entry point of the nephrostomy tube at the caudal pole of the kidney. **G,** Draining of the renal pelvis through the nephrostomy tube showing patency. **H,** The SUB device is flushed with a 22-ga non-coring Huber needle (black arrow) prior to closing the abdomen. Notice the pyelogram, cystogram, and no leakage of contrast is seen from any junction of the system (port, kidney, bladder). **I,** Lateral fluoroscopic image of the SUB device. The white arrows are the nephrostomy and cystostomy tube and the red arrow is the shunting port.



E-FIGURE 124-21 Surgical images during the placement of a SUB device. This is the cystostomy tube access. Head is to the left of the image. **A,** The apex of the bladder is isolated and a purse-string suture is made. Then a stab incision is made through the center and into the lumen for the cystostomy catheter to be advanced into the bladder lumen using the sharp stylette. **B,** Once the catheter is within the bladder lumen, the pursestring is tightened around the catheter and the Dacron cuff is sutured using 3 interrupted sutures to the bladder wall. **C,** The subcutaneous tissue is dissected off the ventral abdominal wall on the ipsilateral side of the obstruction just lateral to the incision and the nephrostomy catheter and cystostomy catheter are passed through the body wall and connected to the shunting port. **D,** The shunting port is gently sutured to the ventral body wall musculature to avoid tissue necrosis and port loosening and a Huber needle inserted into the shunting port to test the SUB device prior to closing the abdomen and to ensure there is no leakage.



E-FIGURE 124-22 Connecting the nephrostomy catheter to the shunting port to prevent leakage. **A,** The locking-loop nephrostomy catheter being connected to the pin of the shunting port (white arrow), with the locking string (black arrow) being pulled until it is entrapped. **B,** The string is entrapped on the first rung of the pin and then cut flush with the pin using a #11 blade.

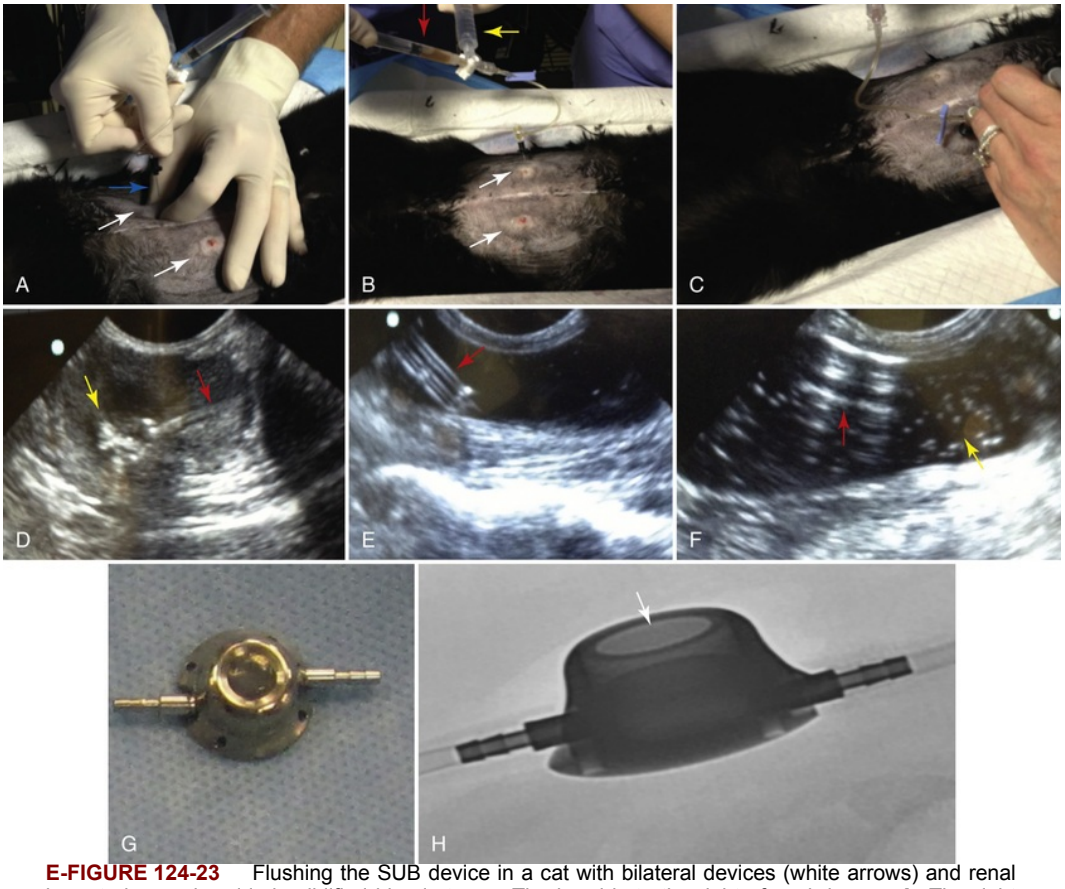
Special Considerations

Proper training on the use of stents and ureteral bypass devices is recommended prior to considering performing these procedures. Good-quality imaging and endoscopic expertise should be available. Endoscopic ureteral stenting in male dogs is possible with flexible cystoscopy, but sometimes percutaneous perineal access for rigid cystoscopy makes this procedure easier.

Follow-up

Patients with ureteral stents or SUB devices need to be monitored very carefully. Feline patients are at high risk of developing post-obstructive diuresis and if careful fluid replacement therapy is not employed, fluid overload can occur (see ch. 129). Care is taken to maintain an appropriate fluid balance using enteral hydration when possible. Treatment with broad spectrum antibiotics (including a fluoroquinolone) for 2 weeks is recommended to help prevent post-operative biofilm development on urinary devices.[62] Routine urinary tract ultrasonography focusing on the renal pelvis diameter, stent location, ureteral diameter, presence of any free fluid, and location of stent/SUB catheters in the urinary bladder, is performed to ensure there is no evidence of stent/SUB device migration, occlusion, or encrustation. The authors recommend performing a urine culture every 3-6 months, and a SUB flush every 3-6 months.

The SUB device should be flushed using either ultrasonographic or fluoroscopic guidance at 1 week, 1 month, and then every 3 months thereafter to ensure both the nephrostomy and cystostomy tubes are patent (E-Figure 124-23).



E-FIGURE 124-23 Flushing the SUB device in a cat with bilateral devices (white arrows) and renal hematuria causing dried solidified blood stones. The head is to the right of each image. **A,** The right access port is being palpated and the Huber needle (blue arrow) is being advanced into the silicone diaphragm of the port in a perpendicular manner. **B,** Once the needle is in place, a urine sample is taken for analysis and culture and to ensure access is appropriate (red arrow). Then, using a 2-way stopcock and T-connector, sterile saline is infused into the port. **C-F,** The infusion is monitored using ultrasound guidance to ensure the renal pelvis does not over-distend and bubbles are seen in the pelvis **(D)** and urinary bladder **(E** and **F)** during infusion. **G and H,** The SUB shunting port **(G)** showing the shape of the flat silicone top **(H)** where the needle should be perpendicularly inserted (white arrow).

Outcome/Complications

The most critical need for success in ureteral interventions is the operator having appropriate training and experience. These are some of the more difficult interventional radiology/interventional endoscopy cases being performed. In addition, the anesthetic procedure should be handled with caution, as these patients have renal disease and, often, concurrent heart disease.

In a recent retrospective study of 128 obstructed cats with 158 obstructed ureters treated interventionally via stenting or SUB device placement, the median survival time was 762-923 days (3 days to >6 years) for all causes of death, and >1442 days for those dying from renal causes.[56] In another retrospective evaluation of 44 dogs (57 ureters) treated with ureteral stents for benign ureteral obstructions, the median survival time was >1158 days and 68% of dogs were still alive at the time of last follow-up.[61] Another study evaluating 13 dogs with pyonephrosis that underwent ureteral stent placement in addition to renal pelvic lavage revealed excellent long-term survival; recurrence of urinary tract infection occurred in ≈50% of dogs, nearly all of which could be cleared without the need for further intervention.[60]

Complications are separated into 4 categories: procedural (during device placement), perioperative (within the first week, typically during hospitalization), short-term (1 week to 1 month) and long-term (>1 month) (see Table 124-3).

Alternatives

A locking-loop nephrostomy tube technique has been reported for successful ureteral decompression in dogs and cats prior to definitive treatment of ureteral obstruction.[63] These tubes work very well, but with the advent of the SUB device, surgical time is similar for a definitive intervention (SUB) as compared to a temporary one (nephrostomy tube), so the locking-loop nephrostomy approach rarely has been necessary, to date, in the authors' practice.

Treatment of Malignant Ureteral Obstructions

Indications

Decompression of a ureteral obstruction secondary to trigonal neoplasia that is resulting in ureterovesicular junction (UVJ) occlusion can be done using an antegrade approach under ultrasonographic and fluoroscopic guidance (see ch. 351).[64]

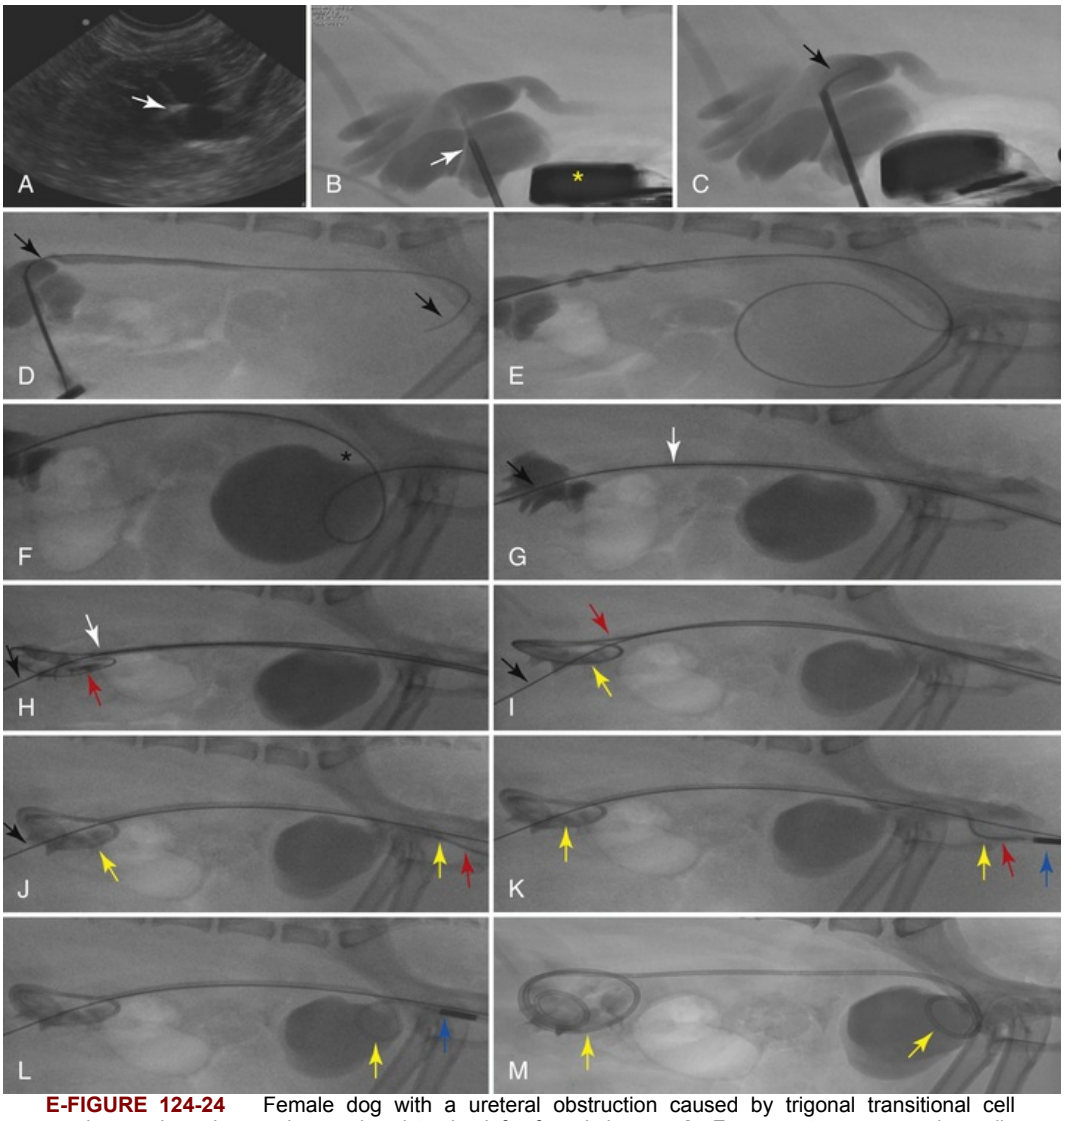
Equipment

Fluoroscopy and ultrasound, in addition to a renal puncture needle, contrast, guidewires, catheters, access sheaths, and ureteral stents, are needed for this procedure.

Procedure

The patient is anesthetized and the area of the kidney and vulva or prepuce is clipped and aseptically prepared. The patient is placed in lateral recumbency, with the obstructed kidney facing up (E-Figure 124-24). A 3 mm skin incision is made where the ultrasound probe shows the best renal access. With ultrasound guidance, an 18 ga renal access trocar needle is used for puncturing the kidney through the greater curvature toward the ureteropelvic junction (UPJ) (see E-Figure 124-24). Once the needle tip is visualized in the renal pelvis, the sharp stylet is removed and an extension set with a 3-way stopcock connected to one empty and one diluted (50%) contrast-filled syringe is connected to the needle. A urine sample is obtained and then contrast is injected to fill the renal pelvis and proximal ureter under ultrasound guidance. Then, a stiff 0.035″ angle-tipped hydrophilic guidewire is used for cannulating the renal pelvis, and is angled down the ureter to the UVJ and into the urinary bladder. This is monitored with fluoroscopic guidance. Once the tumor is crossed, the wire is then advanced down the urethra until through-and-through access is accomplished. Then, a 7 Fr × 45 cm (female) or 55 cm (male) sheath is advanced retrograde, up the urethra, into the ureter through the UVJ, and up to the renal pelvis. Care is taken to ensure the dilator of the sheath does not puncture the renal parenchyma. Once the dilator is removed, a contrast study is performed through the side port of the sheath to obtain a pyelogram for a second guidewire. Then a standard angle-tipped hydrophilic guidewire (0.035″) is advanced up the sheath and coiled within the renal pelvis next to the safety through-and-through wire. The sheath is then withdrawn from the UPJ to the UVJ, leaving both wires in the renal pelvis, while

monitoring under fluoroscopic guidance. This allows measurement of the ureteral length for stent sizing. Finally, the sheath is replaced over the second guidewire, next to the safety wire, is advanced to the renal pelvis as previously described, and the proper-sized stent is placed over this guidewire, through the sheath. Once a coil is seen within the renal pelvis, the sheath is withdrawn, maintaining the stent within the renal pelvis and monitoring the distal end of the stent so that it is appropriately pushed into the urinary bladder under fluoroscopic guidance (see E-Figure 124-24).



E-FIGURE 124-24 Female dog with a ureteral obstruction caused by trigonal transitional cell carcinoma; lateral recumbency, head to the left of each image. **A,** For percutaneous renal needle access (white arrow), ultrasound is used. **B,** Fluoroscopic ureteropyelogram during contrast infusion with ultrasound guidance (yellow asterisk). **C,** The angle-tipped hydrophilic guidewire (black arrow) is advanced down the ureter under fluoroscopic guidance to the level of the UVJ obstruction **(D). E,** The wire is negotiated through the obstruction and into the urinary bladder. It is aimed out the urethra at the trigone. **F,** The wire is passed out the urethra with the assistance of a cystourethrogram. Notice the space-occupying effect of the tumor in the dorsal bladder wall at the UVJ (black asterisk). **G,** A ureteral dilator and sheath (white arrow) are passed retrograde over the guidewire (black arrow) to the renal pelvis. **H,** A second guidewire (red arrow) is advanced through the sheath, retrograde, and coiled up within the renal pelvis. Notice the initial access safety wire (black arrow) is still in place and the sheath (white arrow) remains at the UPJ. **I,** The sheath is removed off both guidewires and the ureteral length is measure by marking the distance from the UPJ to the UVJ. It is then replaced only over the second wire (red arrow); the double pigtail ureteral stent (yellow arrow) is advanced over that guidewire. The safety-wire (black arrow) remains in place. **J,** Once the ureteral stent (yellow arrows) is coiled within the renal pelvis proximally, the guidewire and sheath are pulled back so that the wire is only in the part of the stent within the urethra (red arrow) and the sheath is only within the distal urethra. **K,** The ureteral stent (yellow arrows) is being pushed into the urinary bladder with a pusher catheter (blue arrow). Notice the wire (red arrow) is crossing the junction of the stent and pusher to keep both together. Notice the stent starting to buckle. **L,** The stent is then pushed into the urinary bladder (yellow

arrow) and the pusher catheter (blue arrow) and safety wire are removed **(M).**

Special Considerations

Conversion for surgical placement is rare, but one should be prepared to do this if the interventional procedure is unsuccessful.

Outcome

In a study of 12 dogs (15 ureters) that had ureteral stents placed for ureteral obstructive neoplasia, 1 dog required surgical conversion.[64] All patients survived to discharge and the median survival time from the time of diagnosis was 285 days (range, 10-1571 days) and following stent placement, it was 57 days (range, 7-337 days).

Follow-up

We recommend waiting a minimum of 1 week before starting, or resuming, chemotherapy, due to the risk of post-obstructive diuresis and associated dehydration. Urinary tract ultrasound examinations and urine cultures should be obtained at 2 weeks, 6 weeks, and then every 3 months thereafter. Appropriate complete blood counts and serum biochemistry profiles should also be done. All clients should be encouraged to consult with an oncologist. After stent placement, and if the patient is not azotemic, treatment with chemotherapy and nonsteroidal anti-inflammatory drugs has been shown to prolong survival.

Complications

The biggest risk is ureteral perforation resulting in uroabdomen or a puncture hole in the kidney that remains when access across the tumor is not obtained. If stent placement is unsuccessful, surgical conversion is recommended. If a stent is properly placed, then any puncture should heal within a few days and conversion is not needed. Other potential complications include stent migration, stent irritation, chronic infections, and stent occlusion. All of these are rare.

Alternatives

A SUB system can be used, but it requires surgical placement. For cases where the tumor is localized to the urinary bladder +/− proximal urethra, the entire bladder and proximal urethra have been removed via a radical cystectomy and both renal pelvises have had a SUB catheter placed. Then, both kidney catheters are connected to a 3-way port (Figure 124-25) and a third catheter is placed down the urethra or into the vagina. These dogs have been completely incontinent of urine, but if the procedure is done appropriately, only microscopic disease will remain.

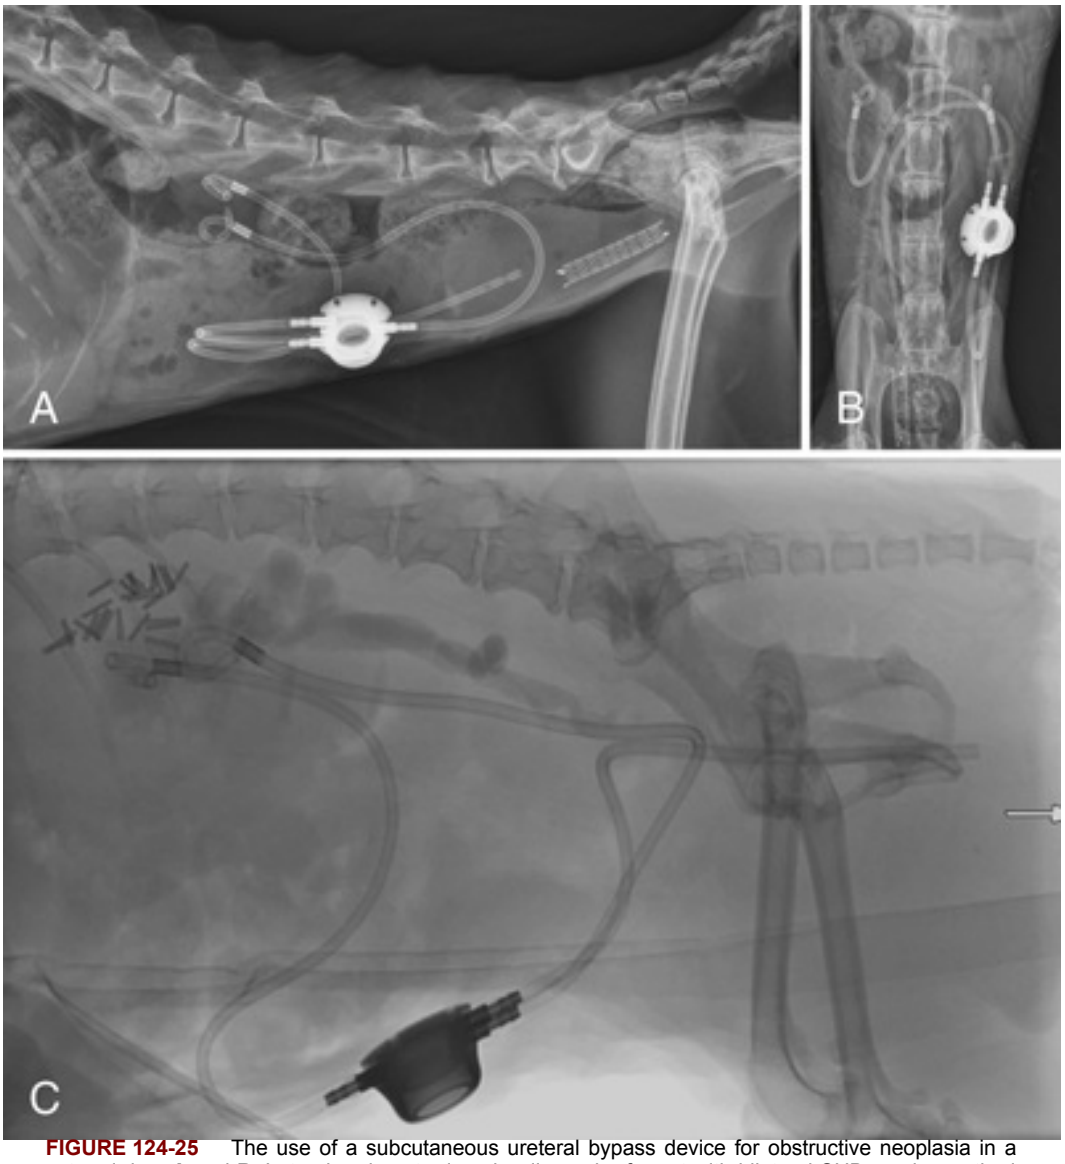


FIGURE 124-25 The use of a subcutaneous ureteral bypass device for obstructive neoplasia in a cat and dog. **A** and **B,** Lateral and ventrodorsal radiograph of a cat with bilateral SUBs and a urethral stent for trigonal obstructive neoplasia. Notice the 3-way shunting port connecting 2 kidney catheters to a bladder catheter. **C,** Fluoroscopic image of a dog after bilateral SUBs and a radical cystectomy. Notice the cystostomy catheter is down the urethra after a radical cystectomy was performed.

Treatment of Idiopathic Renal Hematuria

Indications

Idiopathic renal hematuria is a rare condition that is seen in young, large-breed dogs, and has also been reported in older dogs and cats of various ages. This condition results in persistent port-wine colored urine, and may be progressive, become bilateral, result in ureteral or urethral obstructions due to blood clots, or result in progressive anemia.[65-68] The lesion usually is of benign origin and may be an angioma, hemangioma, or ulcerative lesion of the renal pelvis (pyelitis). If any of these conditions occurs, then treatment for this condition can be considered using a renal-sparing option like sclerotherapy or ureteroscopy with endoscopic electrocautery. Traditionally, ureteronephrectomy has been performed for treatment of this condition, but >30% of affected animals develop bilateral disease over time; however, the lesion is nearly always benign and does not involve the nephrons, making nephrectomy unnecessary.[65-68]

Equipment

A cystoscope (rigid or flexible) is needed to diagnose which renal unit is bleeding. Perineal access should be performed in male dogs once the diagnosis is made based on flexible endoscopy. A UPJ balloon is used for ureteral occlusion sclerotherapy infusions and these come in 5 and 6 Fr sizes; a stiffened 0.035" angle-tipped hydrophilic guidewire is used for placing this catheter. For sclerotherapy, a sterilized liquid 0.5-1% silver nitrate solution, in addition to a 1 : 1 : 3 ratio of 1 part 5% povidone iodine:1 part 76% meglumine diatrizoate (76MD):3 parts sterile 5% dextrose in water (D5W) is used.

Instead of saline irrigation during endoscopy, 5% D5W is used. This helps to prevent red blood cell lysis, improving the visibility during cystoscopy. In addition, D5W prevents silver salt development during sclerotherapy with silver nitrate, and aids conduction during Bugbee electrocautery, if necessary.

For ureteroscopic electrocautery, a 0.035" stiffened angle-tipped hydrophilic guidewire is used with a ureteral access sheath to advance the flexible ureteroscope. Irrigation is done manually through the ureteroscope using D5W. Once a lesion is found in the renal pelvis, a Bugbee cautery electrode (1-2 Fr) is used in either blend or coagulation mode through the working channel of the ureteroscope to ablate the lesion. This small-diameter electrode maintains the flexibility of the ureteroscope within the renal pelvis. If necessary, a ureteral access sheath can be used for maintaining ureteral patency during ureteroscopy. An open-ended ureteral catheter and appropriately sized ureteral stent are needed at the completion of the procedure.

Procedure

Diagnostic cystoscopy is performed to identify which ureter has blood coming from it (Figure 124-26; see ch. 108). Then, using a rigid cystoscope, a guidewire and open-ended ureteral catheter combination are used for cannulating the bleeding ureter/kidney. Once the catheter is midway up the ureter, a retrograde ureteropyelogram using endoscopic and fluoroscopic guidance is performed to assess for any luminal defects.

FIGURE 124-26 A cystoscopic image of a dog in dorsal recumbency with a left-sided urine jet with severe upper tract hematuria.

Sclerotherapy

Sclerotherapy typically is performed first (Figure 124-27). The contrast material used is 76% MD, as this is the recommended mixture for povidone iodine to provide cauterization in humans.[69] The guidewire is advanced to the renal pelvis and then a UPJ balloon is advanced over the guidewire. Once the catheter is in the proximal ureter, the balloon is inflated with air (0.4 mL) and the lumen of the ureter is occluded. The patient is tilted into a 20° Trendelenburg position (hindlimbs higher than kidneys) to enhance accumulation of contrast material in the renal pelvis. Next, the contrast is used for measuring the renal pelvis collection;

accurately determining this volume will allow appropriate renal pelvis filling, to avoid overdistension or parenchymal backfilling. Once this volume is determined, then 2 infusions of a povidone iodine solution (1 : 1 : 3; 1× 5% PI: 1× 76% MD: 3× D5W) are performed, with a dwell time of 10-20 minutes each. Once each dwell is passively drained from the catheter, then 2 more infusions of liquid sterile 0.5-1% silver nitrate solution are administered, with a dwell time of 10-20 minutes each. This is not mixed with any contrast nor diluted with any fluid.[70,71] Finally, the solution is drained and a guidewire is re-advanced up the catheter and coiled in the renal pelvis for a ureteral stent to be placed.

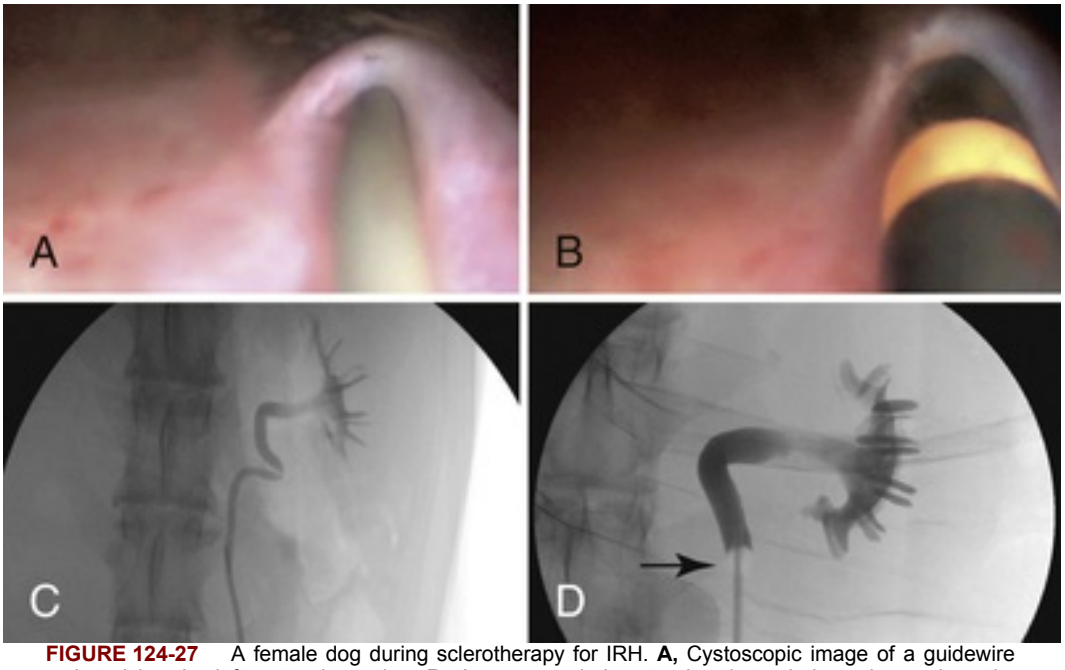

FIGURE 124-27 A female dog during sclerotherapy for IRH. **A,** Cystoscopic image of a guidewire catheterizing the left ureteral opening. **B,** An open-ended ureteral catheter being advanced up the ureter over the guidewire. **C,** A fluoroscopic image during a ureteropyelogram through the ureteral catheter. **D,** A UPJ balloon catheter (black arrow) occluding the ureteral outflow during sclerotherapy infusion.

Ureteroscopy with Electrocautery

Ureteroscopy with electrocautery is reserved for dogs weighing >20 kg, and preferably is performed after a ureteral stent has been in place for at least 1-2 weeks to allow for passive ureteral dilation, which makes navigation in the ureter and renal pelvis easier.[72] A guidewire is passed up to the proximal ureter, avoiding the renal pelvis to prevent iatrogenic trauma. Then, a ureteral access sheath that can accommodate the flexible ureteroscope is advanced over the guidewire under fluoroscopic guidance. Once the sheath is in the ureter, then the ureteroscope is advanced over the guidewire, up the ureter, using D5W for irrigation. Once in the renal pelvis, irrigation is used cautiously to avoid overdistension. Once a bleeding lesion is seen, the Bugbee cautery electrode probe (Figure 124-28) is advanced into the working channel of the ureteroscope and the lesion is cauterized using 12-25 W in contact mode. When complete, then a ureteral stent is delivered over a guidewire and placed as described above.

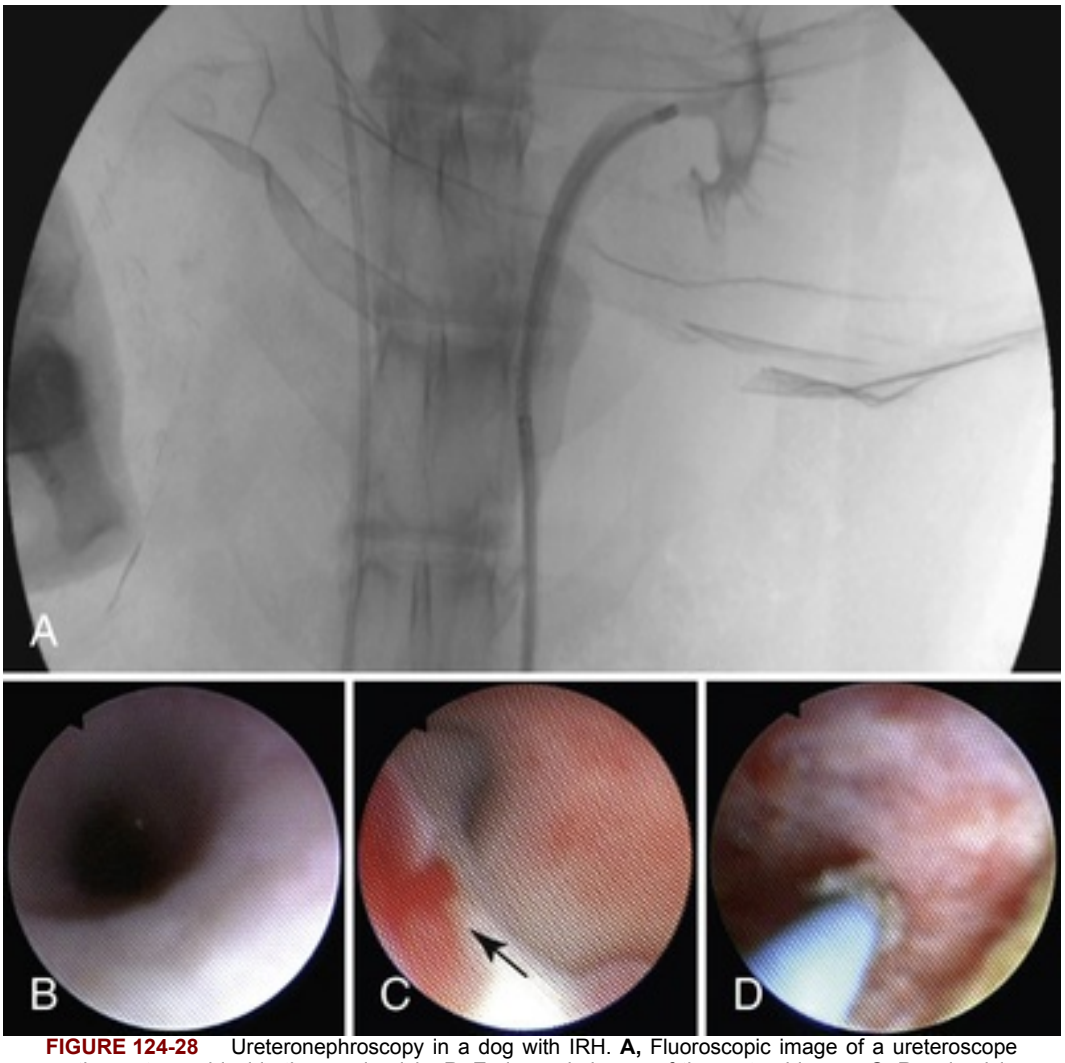

FIGURE 124-28 Ureteronephroscopy in a dog with IRH. **A,** Fluoroscopic image of a ureteroscope up the ureter and inside the renal pelvis. **B,** Endoscopic image of the ureteral lumen. **C,** Renal pelvis bleed visualized (black arrow). **D,** Electrocautery probe within the renal pelvis.

Special Considerations

This procedure should be done by those trained in endourology, ureteral catheterization, and ureteral stenting. It should not be done without fluoroscopic guidance, which is used for measuring the filling volume of the renal pelvis.

Outcome

In a study in which sclerotherapy was used for the treatment of IRH, complete cessation of macroscopic hematuria occurred in 4/6 dogs within a median of 6 hours (range, immediately post-operatively to 7 days).[67] Two additional dogs improved, one moderately and one substantially. None of the dogs required nephrectomy. Ureteroscopy for electrocautery only has been performed in a small number of patients and this is typically reserved for larger patients that have failed sclerotherapy. To date the authors have seen cessation in bleeding in >80% of renal units in which sclerotherapy has been performed.

Follow-up

The bleeding is expected to subside within 24-48 hours after sclerotherapy or electrocautery. Antibiotics are used for 2 weeks after ureteral stenting placement to prevent biofilm formation.[62] After 2-6 weeks, if the bleeding resolves, the stent should be removed. If the bleeding does not stop, then retrograde ureteroscopy

and nephroscopy can be performed, as the stent would have allowed for passive ureteral dilation, making this procedure much easier.

Complications

The most substantial risk is perforating the ureter during cannulation or excessive renal filling/distension resulting in nephritis or pelvic rupture. By using fluoroscopy and endoscopy together, the appropriate filling volume of the renal pelvis during sclerotherapy is ensured. Also, the risk of post-sclerotherapy ureteritis and post-ureteroscopy edema exists, so the operator should be comfortable with retrograde ureteral stent placement.

Alternatives

Selective renal arterial embolization has been considered for this condition, but is not typically needed unless a vascular anomaly is identified on angiography, which has not yet been the case. Ureteronephrectomy should be avoided whenever possible.

CHAPTER 125

Neoplastic Interventional Therapies

Chick Weisse

Interventional radiology (IR) involves the combination of minimally invasive approaches and contemporary imaging modalities to gain access to specific organs in order to deliver a variety of devices or medications for therapeutic purposes (see ch. 120). IR techniques are being increasingly utilized to help manage humans with cancer (interventional oncology, IO) in which traditional therapies have failed or have been demonstrated to provide insufficient benefit. Interventional oncology has been referred to as the "fourth pillar" of oncological care along with medical, surgical, and radiation therapies. Veterinarians have traditionally had little to offer patients with non-resectable or metastatic tumors. Surgery is uncommonly indicated when resections have a high likelihood of substantial morbidity and low likelihood of improved survival times. The relatively limited efficacy of intravenous chemotherapy for macroscopic disease, and the cost, occasional morbidity, and tumor resistance associated with radiation therapy have stimulated the search for additional therapeutic options. Initial results have been promising and regional techniques such as palliative stenting for malignant obstructions, transcatheter chemotherapy, trans-catheter arterial embolization/chemoembolization, and more recently percutaneous tumor ablation, are becoming increasingly investigated.

Palliative Stenting for Malignant Obstructions

Indications and Background

Animals are routinely euthanized for local effects of a tumor rather than the systemic effects associated with a large cancer burden. While these conditions can occur in any lumen such as those of the respiratory (see ch. 121), gastrointestinal (see ch. 123), and cardiovascular (see ch. 122) systems[1-5] (Figure 125-1), one of the more common examples is malignant obstruction of the urinary tract. Life-threatening signs associated with complete urinary tract obstruction or perceived diminished quality of life can lead to owner-elected euthanasia, even when tumor staging confirms localized disease. Minimally invasive endoluminal urethral stenting, and endoscopic or percutaneous ureteral stenting, has been performed in humans to relieve both lower and upper tract obstructions. While endoscopic-guided laser ablation is a common therapy for the typically superficial transitional cell carcinomas (TCCs) experienced in humans, this is not the recommended treatment for the less common and more aggressive, muscle-invasive TCC. Considering the reported TCC laser ablation[6] complications reported in dogs, cost, extended hospitalization times, need for repeat procedures (≈47%), possible limitation to females, and otherwise similar outcomes, stenting appears to compare favorably.

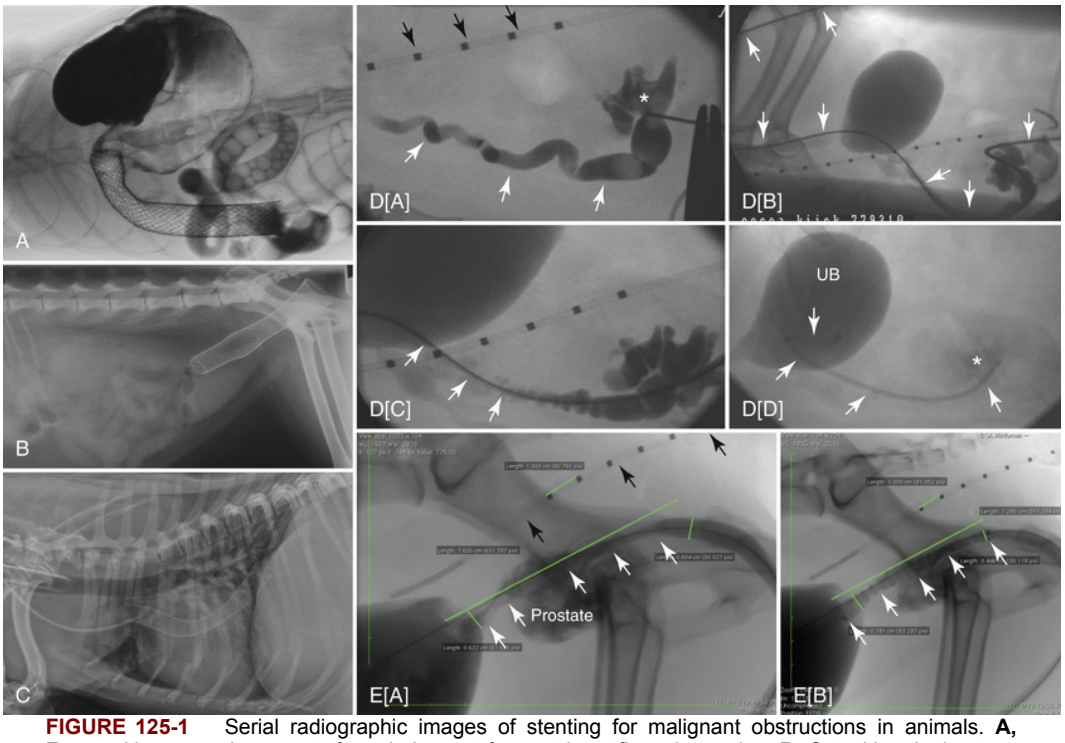

FIGURE 125-1 Serial radiographic images of stenting for malignant obstructions in animals. **A,** Ferret with *per os* placement of a pyloric stent for gastric outflow obstruction. **B,** Cat with colonic stent. **C,** Dog with trans-atrial stent spanning cranial vena cava to caudal vena cava for cardiac mass and venous obstruction. **D,** Dog with percutaneous placement of pigtail stent for urothelial tumor ureteral obstruction (dorsal is to the bottom of the image and cranial is to the right). **D[A],** Needle placement in renal pelvis (asterisk) with contrast ureterogram (white arrows); a measuring catheter (black arrows) shows radiopaque marks that are 1 cm apart from the beginning of one mark to the beginning of the next mark. **D[B],** Guide wire (white arrows) advanced down ureter and out urethra. **D[C** and **D],** Pigtail stent advanced over guide wire spanning obstruction. **E,** Canine prostatic tumor with urethral obstruction (white arrows) before **[A]** and immediately following **[B]** stent placement. Measuring catheter (black arrows, as in **D[A]**) is seen in the descending colon.

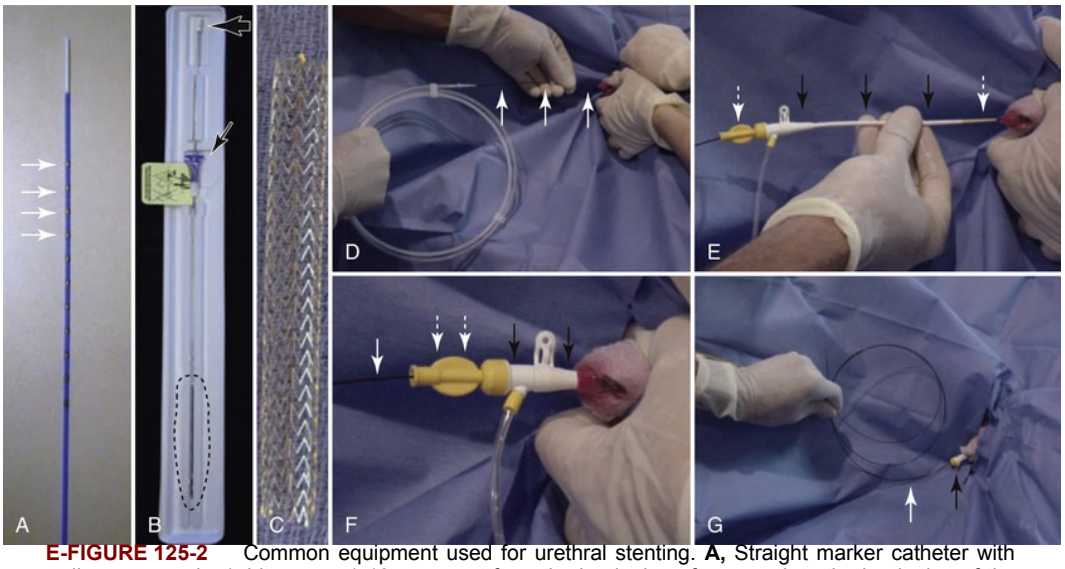
Equipment

Common equipment used for urethral stenting is listed in Box 125-1 and E-Figure 125-2.

Box 125-1

Equipment for Urethral Stenting

- Straight marker catheter[a] with 14 Fr red rubber catheter
- Angiography procedure pack (drapes, bowls, etc.)
- 0.035″ angled, hydrophilic guide wire[b]
- 7 or 8 Fr (or appropriately sized) vascular introducer sheath[c]
- 3-0 Nylon suture material
- 4 Fr hockey stick (“Berenstein”) catheter[d]
- Iohexol contrast agent[e]
- Sterile saline irrigation solution
- Laser-cut, self-expanding metallic stent on delivery system[f]



E-FIGURE 125-2 Common equipment used for urethral stenting. **A,** Straight marker catheter with radiopaque marks (white arrows) 10 mm apart from the beginning of one mark to the beginning of the next mark. This catheter is usually placed within a 14 Fr red rubber catheter that is advanced into the rectum and colon. **B,** Stent delivery system with constrained laser-cut, self-expandable metallic (nitinol) stent (SEMS) (black dotted line) inside the delivery sheath with Y-piece (black arrow) containing diaphragm and side-port. The hub (block arrow) is flushed with saline, as is the side-port (black arrow), prior to use in order to flush out any air. **C,** A deployed urethral SEMS—these should NOT be deployed outside the patient as they are typically NON-RECONSTRAINABLE stents. **D,** 0.035″ angled, hydrophilic guide wire (white arrows) advanced into urethra of a male dog. **E** and **F,** ≈7 Fr introducer sheath (black arrows) and dilator (white dotted arrows) advanced over-the-wire up to the penis and sutured to the prepuce. **G,** The dilator is removed and the penis released. The sheath (black arrow) provides access throughout the procedure. (From Weisse C: Urethral stenting. In Weisse C, Berent A, editors: *Veterinary image-guided interventions,* ed 1, Hoboken, NJ, 2015, Wiley-Blackwell.)

Urethral Stenting Technique (Figure 125-3)

The patient is placed under general anesthesia and positioned in lateral recumbency on a fluoroscopy table. A marker catheter[a] is placed within a 14 Fr red rubber catheter, introduced per rectum, and gently advanced into the descending colon under fluoroscopic guidance. Perioperative antibiotics are routinely used, unless the patient is already receiving systemic antibiotic therapy. A 0.035″ angled, floppy-tip hydrophilic guide wire[b] is inserted into the urethral orifice and advanced into the urinary bladder under fluoroscopic guidance. A 7 or 8 Fr vascular sheath[c] and dilator are placed over the guide wire and advanced into the urethra. In males, a 4 Fr angiographic catheter[d] is advanced over the wire and into the urinary bladder; in females use of the sheath is sufficient. After achieving bladder access with the catheter (male) and/or sheath (female), the urinary bladder is distended with an approximately 50 : 50 mixture of iohexol[e] and sterile saline. It is important to completely fill the urinary bladder so you do not mistake an undistended urinary bladder for the proximal urethra.

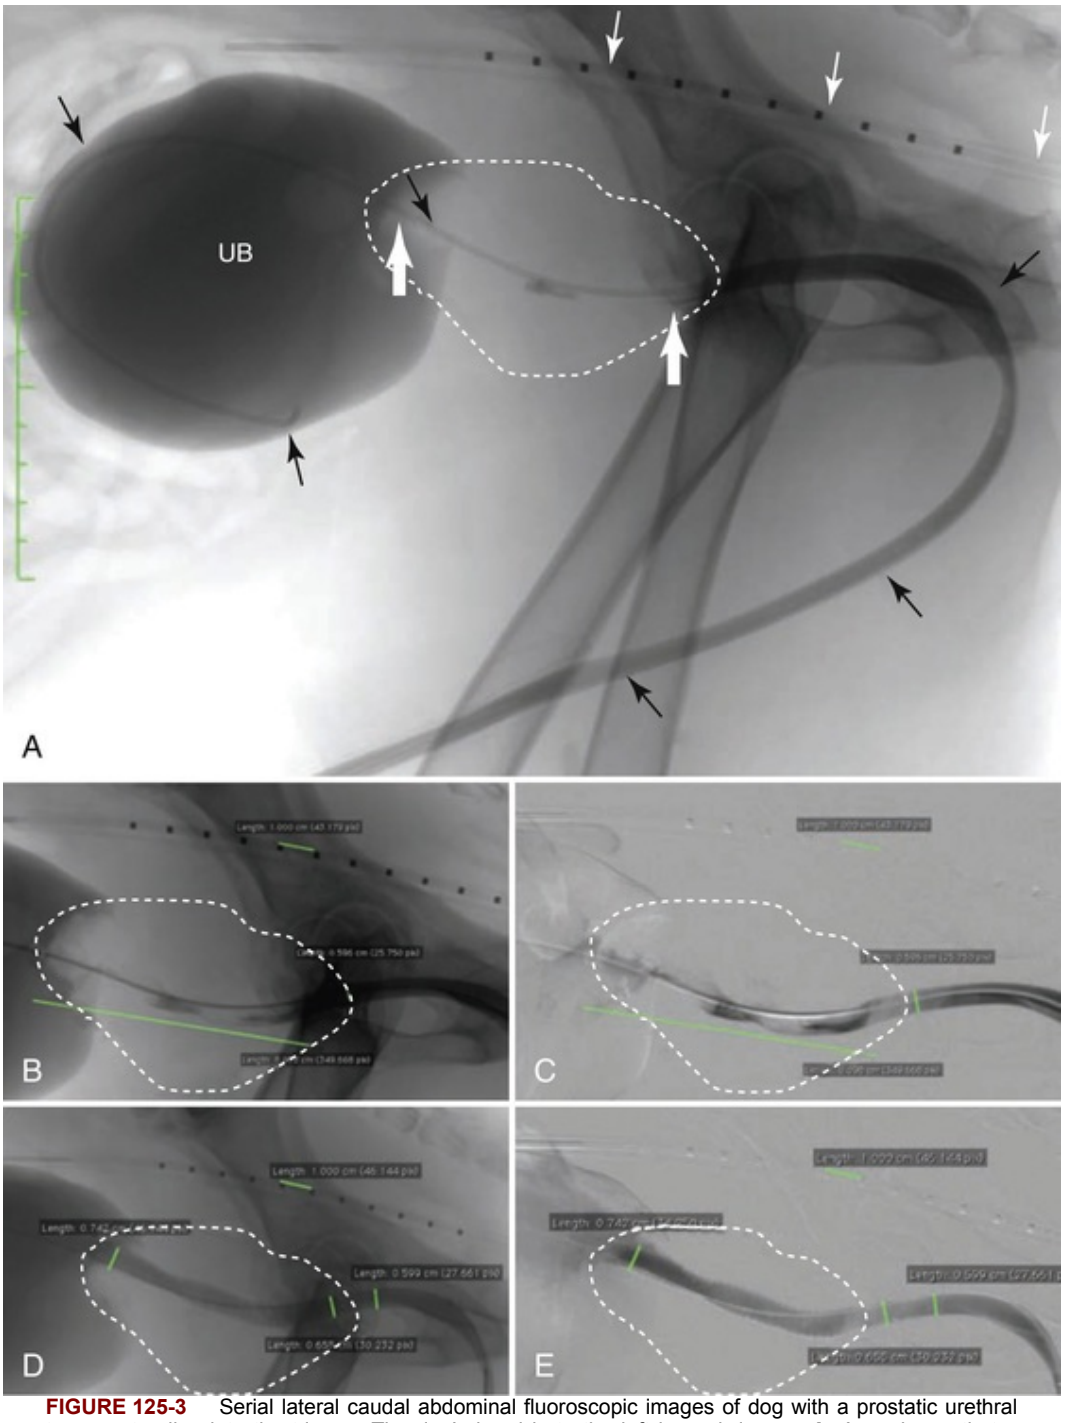


FIGURE 125-3 Serial lateral caudal abdominal fluoroscopic images of dog with a prostatic urethral tumor extending into the trigone. The dog's head is to the left in each image. **A,** A marker catheter (white arrows) has been placed within a 14 Fr red rubber catheter and introduced per rectum in order to calibrate the radiographic images for magnification. A 4 Fr Berenstein catheter (black arrows) has been placed into the bladder over a 0.035″ angled hydrophilic wire that was subsequently removed to fill the bladder with saline and contrast. A urethrogram is performed through the sheath (alternatively the Berenstein catheter can be used) demonstrating a filling defect/obstruction caused by the tumor (white dotted lines) at the level of the trigone and proximal urethra. The urethral narrowing is observed between both white block arrows. Fluoroscopic **(B)** and subtracted **(C)** images with maximal urethral measurements showing both views can be helpful in identifying the extent of the obstruction. Maximal urethral diameter of ≈6 mm and necessary stent length determined to be ≈80 mm. Fluoroscopic **(D)** and subtracted **(E)** contrast urethrocystogram images following 8 × 80 mm laser-cut SEMS placement demonstrating patency of the urethra through the malignant obstruction has been re-established. (From Weisse C: Urethral stenting. In Weisse C, Berent A, editors: *Veterinary image-guided interventions,* ed 1, Hoboken, NJ, 2015, Wiley-Blackwell.)

Following bladder distension, a fluoroscopy run is recorded to determine the stenosis length and normal

urethral diameter. The length of the urethral obstruction and maximal diameter of the adjacent normal urethral lumen are extrapolated using the colonic marker catheter as a reference to account for radiographic magnification. The stent diameter is chosen by matching the normal urethral diameter caudal to the urethral obstruction. The stent length is chosen to span the obstructed portion of the urethra. The author prefers laser-cut self-expanding metal stents (SEMS)[f] due to ease of use, predictable and precise placement, available lengths, flexibility, biocompatibility, self-expanding nature, and documented outcomes. In general, it should be assumed that laser-cut SEMS are not reconstrainable unless otherwise specified on the stent packaging. The stent delivery system is flushed with sterile saline according to manufacturer recommendations. Using fluoroscopic guidance it is advanced over the wire, positioned across the malignant obstruction, and deployed. A repeat positive contrast cystourethrogram is performed to document immediate patency of the previously occluded urethra.

Follow-up

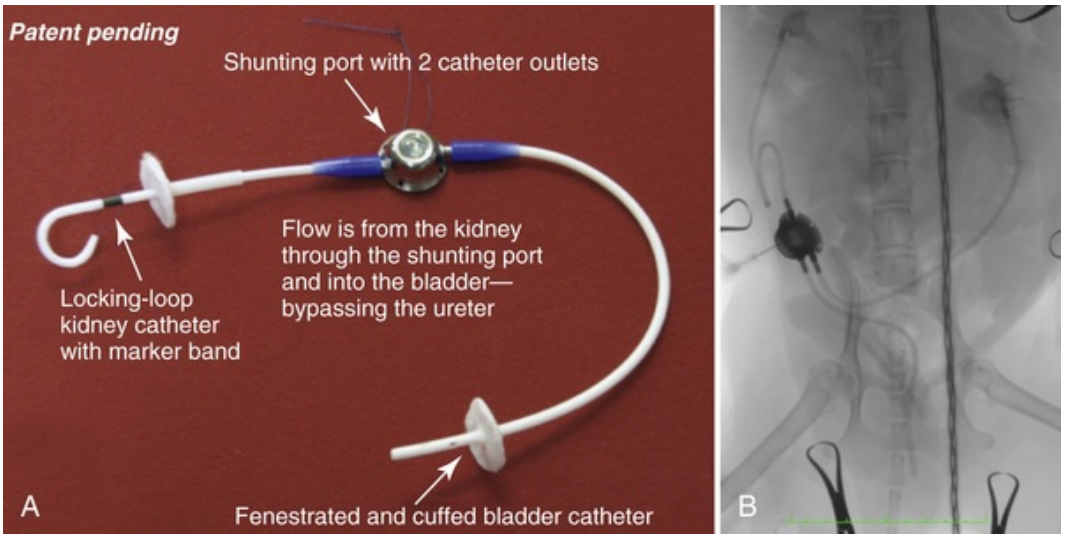
Patients are routinely discharged the same day as the procedure after demonstrating the ability to urinate. Analgesics are uncommonly necessary, antibiotics are prescribed until urine culture results are available, and nonsteroidal anti-inflammatory drugs (NSAIDs) are continued if not contraindicated. Recheck is typically performed through the oncology service for continuation of chemotherapy according to the delivery schedule.

Outcomes and Possible Complications

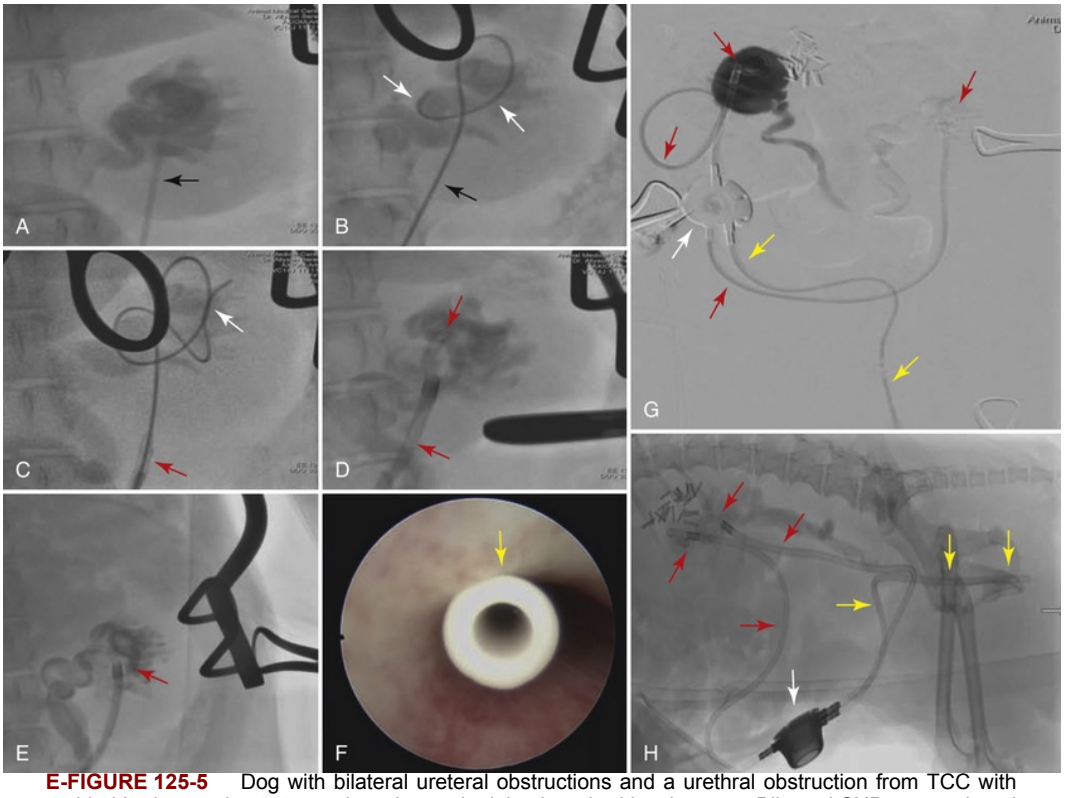
IO techniques involving the urinary tract are generally rapid, safe, minimally invasive, and effective, and reported complications have been minor and uncommon. Stented malignant urethral obstructions are immediately relieved in 97% of patients with mild to absent stranguria in 75% of patients and performed on an outpatient basis.[7-9] Animals receiving chemotherapy and NSAIDs (in addition to stenting) demonstrated prolonged survival times (250 days) in partially to completely obstructed patients with low morbidity (limited to 25% major incontinence rates).[9] Recently, similar positive outcomes, low morbidity, and similar incontinence rates have been reported with urethral stenting in cats with benign or malignant urethral obstructions.[10] A recent series of canine malignant ureteral obstructions treated with percutaneous ureteral stent placement demonstrated that similar techniques can be used in upper tract obstructions. The technique was successful in 11/12 dogs with all azotemic patients demonstrating reduction in blood urea nitrogen (BUN) and creatinine levels, and a reduction in the degree of hydronephrosis in the 10 dogs for which it was evaluated post-operatively.[11] This (typically) outpatient procedure is technically demanding when done percutaneously, but it can be performed via a small open surgical technique for those without prior interventional training.

Special Considerations and Alternatives

Local surgical resection is often incomplete due to the common trigonal location, or non-durable when apical tumors are removed due to skip metastases or *de novo* TCC tumors elsewhere within the lower urinary tract. Recently, a combination interventional/surgical procedure has been described to facilitate en bloc resection of the distal ureters, bladder, and proximal urethra to provide more aggressive oncological resections in hopes of improving tumor-free margins in these often diffuse, complex surgical cases (E-Figures 125-4 and 125-5).[12] Alternatively, regional chemotherapy administration may provide improved biological response rates as described below.



E-FIGURE 125-4 Subcutaneous ureteral bypass (SUB).[9] **A,** The SUB device *ex vivo* demonstrating the components. **B,** SUB device with 3-way shunting port placement following radical excision of distal ureters, urinary bladder and proximal urethra, and placement of bilateral nephrostomies and urethral catheter in a dog with extensive TCC.



E-FIGURE 125-5 Dog with bilateral ureteral obstructions and a urethral obstruction from TCC with no bladder lumen due to tumor invasion and minimal urethral involvement. Bilateral SUBs were placed with a radical cystectomy to remove all gross disease. Fluoroscopic images **A-E** and **G** are in dorsal recumbency during surgery. **A,** Renal access using an 18-ga catheter (black arrow) into the renal pelvis from the caudal pole of the kidney. **B,** Guide wire (white arrows) coiling within the renal pelvis, advanced through the catheter (black arrow). **C,** Nephrostomy catheter (red arrow) being advanced over the guide wire (white arrow). **D,** Locking-loop pigtail nephrostomy tube (red arrows) within the renal pelvis. **E,** Contrast study through the catheter (red arrow) during a pyelogram, showing patency of the catheter and no leakage. **F,** Cystoscopy image of the urethral catheter (yellow arrow) coming down the urethra after radical cystectomy. **G,** Dorsoventral projection during a digital subtraction image while performing a contrast study through the three-way shunting port (white arrow) showing both renal pelvises filling through the two nephrostomy catheters (red arrows) and the urethral catheter (yellow arrows). **H,** Lateral fluoroscopy image showing the entire system with the red arrows outlining the two

nephrostomy catheters and the yellow arrows the urethral catheter after the bladder was removed. The white arrow is the three-way shunting port of the SUB device. (From Berent A: Interventional management of canine malignant ureteral obstructions. In Weisse C, Berent A, editors: *Veterinary image-guided interventions,* ed 1, Hoboken, NJ, 2015, Wiley-Blackwell.)

Intra-Arterial (IA) Chemotherapy Delivery

Indications and Background

Current therapies for bulky tumors not amenable to complete surgical resection include chemotherapy, radiation therapy, and surgical debulking, but none is consistently able to produce durable remissions. Specific tumor cell lines tend to be more sensitive to certain chemotherapeutic agents, and increasing the concentration of these drugs tends to increase both tumor cell death and systemic toxicity. Studies confirm both higher achieved levels of chemotherapy within the targeted tissues as well as improved tumor remissions in laboratory animals when IR techniques are used to deliver drugs superselectively.[13-15]

Equipment

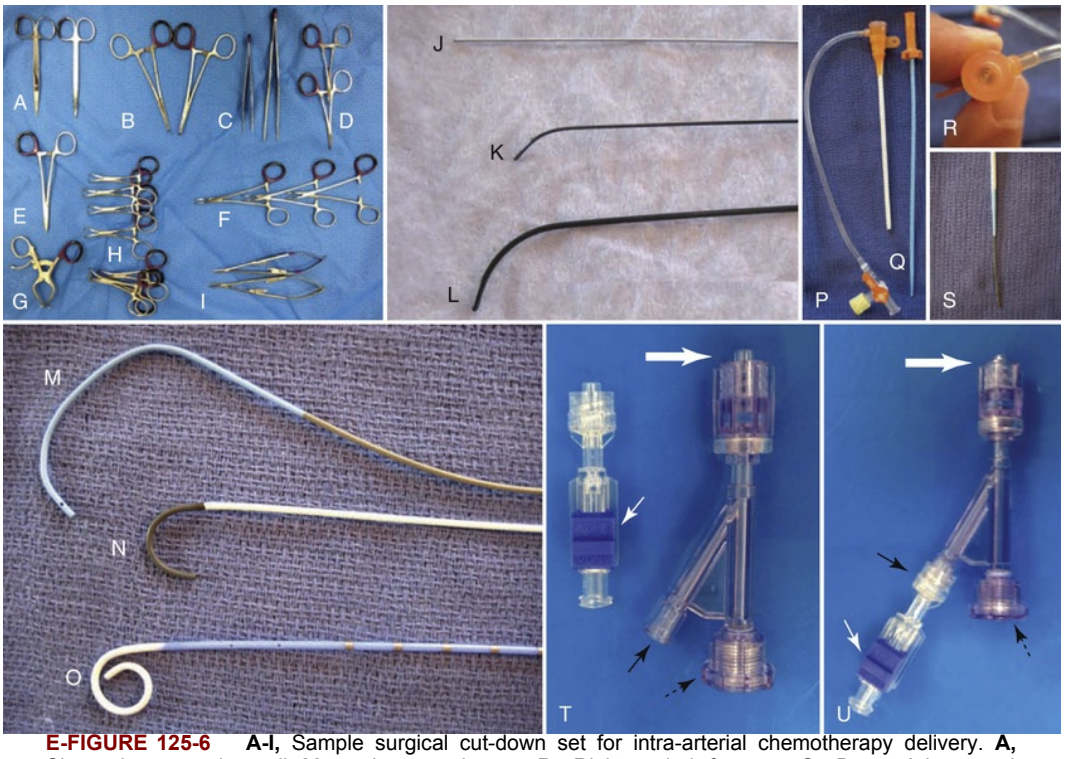
Common equipment used for intra-arterial chemotherapy delivery is listed in Box 125-2 and E-Figure 125-6. IA chemotherapy procedures require a fluoroscopy unit with exceptional imaging detail to identify very small caliber vessels using digital subtraction angiography (DSA) and road mapping, as well as the ability to obtain orthogonal imaging when necessary. Failure to identify collateral vessels could lead to non-target delivery and potentially severe consequences.

Box 125-2

Equipment for Intra-Arterial Infusion

- Surgical cut-down set (see E-Figure 125-6)
- Angiography procedure pack (drapes, bowls, etc.)
- 18 Gauge intravenous catheter
- 0.035″ angled, hydrophilic guide wire[b]
- 4 or 5 Fr (or appropriately sized) vascular introducer sheath[c]
- 3-0 Nylon and 3-0 monofilament absorbable suture material
- 4 Fr hockey stick (“Berenstein”), Cobra and or Rim catheters[d]
- Tuohy-Borst adapter[h] and Flo-Switch[i]
- 1.7 to 3.0 Fr microcatheter[j,k] with compatible 0.014-0.018″ microwire[l,m]
- Iohexol contrast agent[e]
- Sterile saline irrigation solution
- Chemotherapy

[l]0.018 Transend or V-18 microwire, Boston Scientific, Natick, MA.



E-FIGURE 125-6 **A-I,** Sample surgical cut-down set for intra-arterial chemotherapy delivery. **A,** Sharp-sharps and small Metzenbaum scissors. **B,** Right-angled forceps. **C,** Brown-Adson and DeBakey forceps. **D,** Mosquito hemostats. **E,** Needle drivers. **F,** Kelly hemostats. **G,** Small Gelpi retractors. **H,** Small Babcock towel clamps. **I,** Castroviejo needle drivers for vessel repair. **J-L,** Guide wires. **J,** 0.018″ microwire. **K,** 0.018″ angled, hydrophilic guide wire. **L,** 0.035″ angled, hydrophilic guide wire. **M,** 4 Fr Cobra catheter. **N,** 4 Fr reverse curve RIM catheter. **O,** 4 Fr marker pigtail catheter for aortogram and measurements if needed. **P-S,** Vascular introducer sheath. 4 Fr vascular introducer sheath **(P)** made up of shaft (white) with 4 Fr inner diameter, hemostasis valve **(R)** to prevent bleeding, three-way stopcock (yellow cap) to flush and/or aspirate, and 4 Fr dilator (blue, **Q**) to make smooth transition from the sheath down to the 0.035″ guide wire **(S). T-U,** Flo-switch (**T,** small white arrow) and Tuohy-Borst adapter (**T,** black arrows and white block arrow), which connect (**U**, black arrow) to form a hemostasis valve (dotted black arrow) and side-port that can be switched on or off (white arrow) for flushing or aspirating. This device is attached to the hub of the 4 Fr catheter (at white block arrow) and allows coaxial passage of a microcatheter/microwire through the 4 Fr catheter. (From Weisse C: Intra-arterial chemotherapy infusion. In Weisse C, Berent A, editors: *Veterinary image-guided interventions,* ed 1, Hoboken, NJ, 2015, Wiley-Blackwell.)

Technique (see E-Figure 125-6)

The patient is placed under general anesthesia and the groin or neck is clipped and scrubbed for either femoral or carotid arterial access via surgical cut-down. A 4 or 5 Fr introducer sheath[a] is placed and a combination 0.035″ angled, hydrophilic guide wire[b] and 4 or 5 Fr reverse-curve catheter[c] (femoral) or 4 Fr Berenstein catheter[d] (carotid) is advanced under fluoroscopic guidance to the terminal aorta. A DSA delineates the vascular anatomy and a microcatheter/microwire combination is used to gain super-selective access to one of the terminal arteries feeding the tumor (e.g., prostatic artery or vaginal artery in the case of lower urinary tract tumors). Standard therapy involves the total systemic chemotherapy dose mixed with an equal volume of iohexol contrast injected under fluoroscopic guidance to ensure flow down the target artery without reflux into non-target vessels. The catheter and sheath are removed and the femoral or carotid artery ligated. The cut-down site is closed in three layers and the patient recovered.

Follow-up

The patient is typically discharged the same day with the same medications prescribed following intravenous (IV) use of the same chemotherapies. Oral NSAIDs are continued if indicated and typically IA treatments are alternated with IV therapies to address systemic (non-regional) disease. Restaging is often performed according to the oncologist's recommendations.

Outcomes and Possible Complications

These techniques have been described in clinical veterinary cases,[16] and a study performed at the author's institution is supporting the potential of this therapeutic approach. Retrospectively, two statistically similar populations of dogs with urothelial carcinoma received either (1) intravenous carboplatin and oral NSAIDs, or (2) super-selective intra-arterial carboplatin and intra-arterial meloxicam (see E-Figure 125-2). The intra-arterial group demonstrated statistically significantly greater reduction in tumor length, and percent length, width and unidimensional measurements compared with the intravenous group. The intra-arterial group was also statistically more likely to achieve a positive tumor response as characterized by modified RECIST criteria. In addition, the intra-arterial group was statistically significantly less likely to develop certain adverse events, including anorexia and lethargy, following chemotherapy compared to the intravenous group. Complications are uncommon and typically limited to the same adverse events anticipated following intravenous therapy.

Special Considerations and Alternatives

Although reported to be safe, care must be taken during repeated carotid access. The author has seen temporary neurological sequelae (blindness, circling, etc.) following bilateral carotid artery ligation in dogs, even when staged. This is uncommonly necessary, as performing femoral access distally provides ample opportunity to re-use the femoral artery more proximally on multiple occasions. The author has successfully used a unilateral femoral artery up to five times.

Trans-Arterial Embolization (TAE)/Chemoembolization (TACE)

Indications and Background

Embolization refers to the delivery of a device or material to interrupt blood flow. Chemoembolization involves super-selective intra-arterial chemotherapy delivery in conjunction with subsequent particle embolization. Intra-arterial chemotherapy for liver tumors has been shown to result in a 10- to 50-fold increase in intra-tumoral drug concentrations when compared to systemic intravenous chemotherapy administration.[17] Subsequent particle embolization results in tumor cell necrosis through ischemia and paralyzes tumor cell excretion of chemotherapy resulting in increased local concentrations and minimized systemic toxicity. While TAE and TACE have been performed in other areas, the liver is the most commonly treated organ.

Equipment

Common equipment used for TAE/TACE is listed in Box 125-3 and E-Figure 125-7. Embolization procedures require a fluoroscopy unit with exceptional imaging detail to identify very small caliber vessels using DSA and road mapping, as well as the ability to obtain orthogonal imaging when necessary. Failure to identify collateral vessels could lead to non-target delivery and potentially severe consequences.

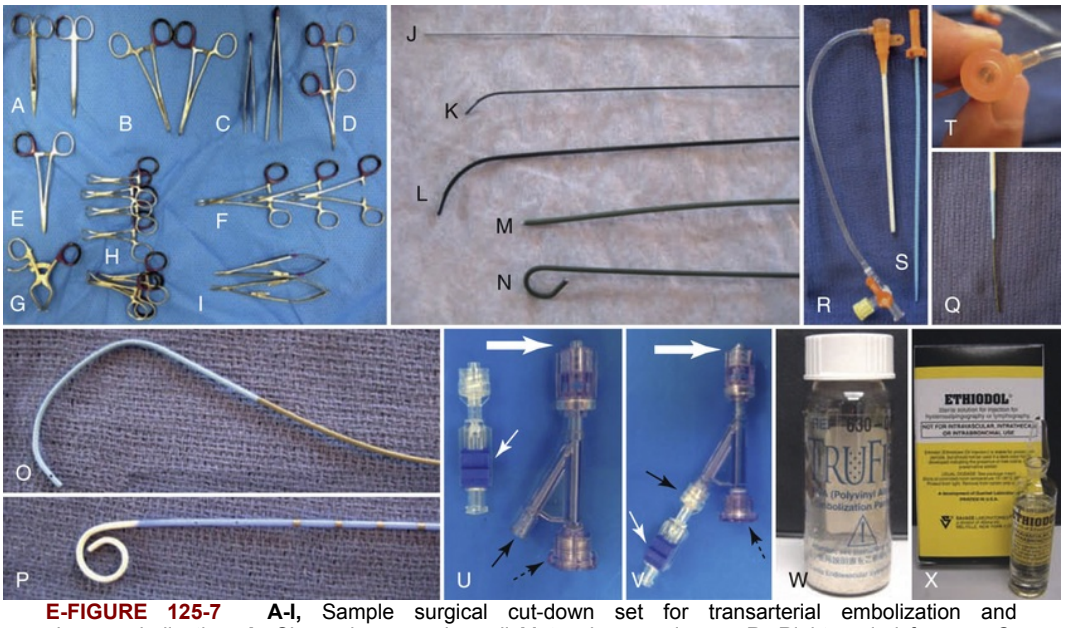
Box 125-3

Equipment for TAE/cTACE/DEB-TACE

- Surgical cut-down set (see E-Figure 125-7)
- Angiography procedure pack (drapes, bowls, etc.)
- 18 Gauge intravenous catheter
- 0.035″ angled, hydrophilic guide wire[b]
- 4 or 5 Fr (or appropriately sized) vascular introducer sheath[c]
- 3-0 Nylon and 3-0 monofilament absorbable suture material
- 4 Fr hockey stick (“Berenstein”), Cobra and or Rim catheters[d]
- Tuohy-Borst adapter[h] and Flo-Switch[i]
- 1.7 to 3.0 Fr microcatheter[j,k] with compatible 0.014-0.018″ microwire[l,m]
- Iohexol contrast agent[e]

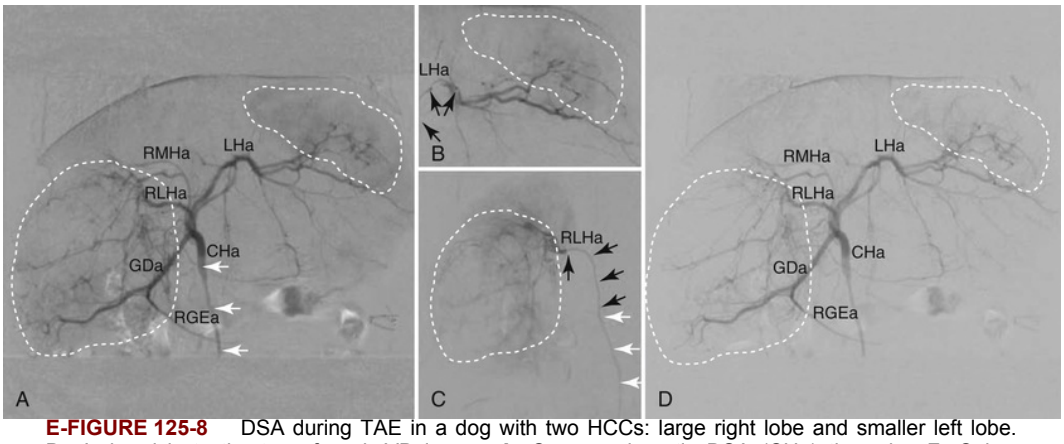
- Sterile saline irrigation solution
- Chemotherapy
- PVA[n], lipiodol[o], and/or drug-eluting beads (DEBs)[p]

[P]LC/DC Bead 100-300 mcm hydrogel microspheres, Biocompatibles UK Limited, Farnham, UK.



E-FIGURE 125-7 **A-I,** Sample surgical cut-down set for transarterial embolization and chemoembolization. **A,** Sharp-sharps and small Metzenbaum scissors. **B,** Right-angled forceps. **C,** Brown-Adson and DeBakey forceps. **D,** Mosquito hemostats. **E,** Needle drivers. **F,** Kelly hemostats. **G,** Small Gelpi retractors. **H,** Small Babcock towel clamps. **I,** Castroviejo needle drivers for vessel repair. **J-N,** Guide wires. **J,** 0.018″ microwire. **K,** 0.018″ angled, hydrophilic guide wire. **L,** 0.035″ angled, hydrophilic guide wire. **M** and **N,** 0.035″ straight PTFE wire **(M)** and 0.035″ Rosen PTFE wire **(N),** both of which are uncommonly used for this procedure. **O,** 4 Fr Cobra catheter. **P,** 4 Fr marker pigtail catheter for aortogram and measurements if needed. **Q-T,** Vascular introducer sheath. 4 Fr vascular introducer sheath made up of shaft (white) with 4 Fr inner diameter, hemostasis valve **(T)** to prevent bleeding, three-way stopcock (**R,** yellow cap) to flush and/or aspirate, and 4 Fr dilator (**S,** blue) to make smooth transition from the sheath down to the 0.035″ guide wire **(Q). U-V,** Flo-switch (**U,** small white arrow) and Tuohy-Borst adapter (**U,** black arrows and block white arrow), which connect **(V)** to form a hemostasis valve (dotted black arrow) and side-port that can be switched on or off (white arrow) for flushing or aspirating. This device is attached to the hub of the 4 Fr catheter (at white block arrow) and allows coaxial passage of a microcatheter/microwire through the 4 Fr catheter. **W,** Polyvinyl alcohol particles. **X,** Iodinated poppyseed oil. (From Weisse C: Liver tumors/metastases (TAE/cTACE/DEB-TACE). In Weisse C, Berent A, editors: *Veterinary image-guided interventions,* ed 1, Hoboken, NJ, 2015, Wiley-Blackwell.)

Technique for Hepatic TAE/TACE (E-Figure 125-8)



E-FIGURE 125-8 DSA during TAE in a dog with two HCCs: large right lobe and smaller left lobe. Dog's head is to the top of each VD image. **A,** Common hepatic DSA (CHa) through 4 Fr Cobra catheter (white arrows) demonstrating left hepatic artery (LHa) feeding left tumor (white dotted line) and right lateral hepatic artery (RLHa) feeding right tumor (white dotted line). Also visible are the right medial hepatic artery (RMHa), gastroduodenal artery (GDa), and right gastroepiploic artery (RGEa). **B,** Superselective microcatheterization (black arrows) of the LHa with DSA showing perfusion of left tumor prior to TAE. **C,** Microcatheterization (black arrows) of the RLHa with DSA showing perfusion of right tumor prior to TAE. **D,** Post-TAE CHa DSA demonstrating similar hepatic perfusion (no non-target embolization) with absent perfusion/embolization of both tumors (white dotted lines). (From Weisse C: Liver tumors/metastases (TAE/cTACE/DEB-TACE). In Weisse C, Berent A, editors: *Veterinary image-guided interventions,* ed 1, Hoboken, NJ, 2015, Wiley-Blackwell.)

Femoral artery sheath access followed by a 4 Fr Cobra catheter and 0.035″ angled hydrophilic guide wire (E-Figure 125-7) are used in combination to select the celiac artery and common hepatic artery. Common hepatic arteriography is performed using a 50 : 50 dilution of iohexol[e] : saline. A 1.7 to 3 Fr microcatheter[j,k]/microwire[l,m] combination is used to super-select the particular vessel supplying the tumor bed, ensuring catheter placement is not occlusive within the often very small caliber vessels. Super-selection is the goal to minimize non-target embolization. The appropriate size of polyvinyl alcohol (PVA) or other embolization particles is chosen on the basis of vascular architecture. Use of undersized particles carries the risk of extreme distal vascular occlusion and increases the risk of necrosis and tissue sloughing. The use of inappropriately large particles carries the risk of proximal vessel thrombosis, which may allow for development of collateral vessels that bypass the proximal occlusion and re-establish perfusion to the tumor. The author has used PVA-200 particles[m] (180-300 micron) or 100-300 micron PVA hydrogel microspheres[n] for liver embolization. The chosen embolic is prepared as a slurry with iodinated contrast material and embolization is performed under fluoroscopic visualization using digital road-mapping software. Care is taken to prevent reflux of particles into non-target vessels. A similar technique is used for oily ("conventional" or cTACE) or drug-eluting bead (DEB)-TACE; however, refer to manufacturer instructions for information regarding handling, drug loading, and administration. The systemic dose of chemotherapeutic agent (typically doxorubicin) is selected and either mixed with iodinated poppyseed oil[o] to form the oily suspension (cTACE) or with the drug-eluting beads (DEB-TACE). A lobar treatment can be performed using the cTACE technique but only superselective access should be used for DEB-TACE. Embolization can continue until near-stasis of blood flow if the treatment is to be repeated; if performed once, complete stasis can be attempted. Selective arteriography is performed to evaluate the success of the procedure after all particles are flushed out. If embolization is successful, no flow is seen in the target artery feeding the tumor. The microcatheter is withdrawn and repeat common hepatic (or other) angiography is performed through the 4 Fr catheter to identify other feeding vessels. If more vessels are found, the procedure can be repeated or performed subsequently in the future.

Following embolization, all catheters and sheaths are removed. Hemostasis is typically achieved with femoral artery ligation. All animals recover from anesthesia in an intensive care unit for monitoring. Peri-operative medical management is standard for these patients.

Follow-up

The procedure is generally repeated at 6-week intervals and tumor response (restaging) evaluated following two treatments.

Outcomes and Possible Complications

These techniques have demonstrated improved tumor responses and prolonged survival times when compared to more traditional therapies in humans with HCC.[18-20] The author has performed TAE, Lipiodol-based TACE, and DEB-TACE in dogs with benign and malignant liver tumors in which surgery was unsuccessful or was declined. In general, stable disease or partial remissions are anticipated following therapy, with better responses in more vascular tumors. These procedures require an intimate knowledge of the local vascular anatomy to prevent non-target embolization but can otherwise be expected to result in fewer than 10-15% major complications when performed by experienced operators. Reported complications[21] in the human literature include hemorrhage at the vascular access site, non-target embolization complications (skin necrosis, damage to normal parenchyma), hepatic infarction/abscessation, acute renal failure (for liver tumors), and post-embolization syndrome, a collection of clinical signs characterized by malaise, fever, and pain. The author's experience over the past 10 years suggests similar risks in veterinary patients as well as reduced systemic exposure to chemotherapy, minimal morbidity, and improved tumor response rates when compared to systemic chemotherapy.[22-24] In a small, prospective series of HCC dogs receiving DEB-TACE, the identical canine patient had serum chemotherapy measurable for only a median 30-180 minutes (versus 720 minutes following intravenous administration) and 1/40th of the total systemic chemotherapy exposure (area under the curve) versus the same dose administered intravenously.[24] Chemoembolization has been performed elsewhere throughout the body and its use will likely expand.

Special Considerations and Alternatives

For smaller tumors, percutaneous ablation techniques can be considered, although these have not been routinely performed in veterinary patients.[25-27] Radiofrequency ablation as well as microwave ablation, laser thermal ablation, cryoablation, and percutaneous ethanol injection tend to be most effective with a few (<3) small (<4 cm diameter) lesions. These circumstances are fairly uncommon in the author's clinical experience; however, with the routine use of more advanced imaging techniques in veterinary medicine, lesions of this size and number may become increasingly apparent during tumor re-staging procedures, making tumor ablation techniques a reasonable option in the future.

CHAPTER 126

Pain Physiology, Identification, and Management in the Acute Care Setting

Lisa Moses

Contemporary practice of veterinary medicine recognizes pain assessment and management as an integral part of good medicine. Rapidly changing cultural attitudes about the importance of companion animals have focused veterinary attention on pain management as both a welfare issue and a client demand. Accordingly, the practice of pain medicine has shifted and expanded. This chapter will provide an update on the understanding of the basic mechanisms of pain biology besides giving the reader an overview of pain behaviors, clinical pain assessment, and practical approaches to pain management in the acute care setting. Specifics of analgesic therapy are covered in ch. 164 and 166. Chronic pain is covered in ch. 356. Drug dosages, routes, and intervals in this chapter are based on published references and the author's experience, and should be confirmed by the attending clinician and adapted as necessary based on the specifics of each case.

Understanding the basic nature of pain as a biological process removes some of the uncertainty of pain assessment and treatment in patients who cannot self-report. In the most simplistic description, the sensation of pain is the final result of central nervous system processing of sensory stimuli. The stimuli must be sufficiently intense (i.e., noxious) to cause depolarization of high threshold pain receptors, *nociceptors*.[1] The standard, widely used definition of pain from the International Association for the Study of Pain (IASP) is "An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[2] Although pain is a conscious perception and this perception is subjective, there are biochemical events caused by pain that accompany this perception and these events can occur even without conscious perception (i.e., during general anesthesia). This definition of pain includes verbal and non-verbal humans and non-human animals. It is generally accepted that animals are likely to experience pain in a way that is similar to humans, since the "machinery" by which pain happens in the body is nearly identical.[3] Despite this commonality, the clearly different behavioral and emotive components of pain complicate our assessment of pain in veterinary species. Because of this, the cornerstone of reasonable pain assessment and management is an anthropomorphic approach of identifying expected pain levels we would feel for any given noxious event.[4]

Current Concepts of Pain Physiology

Pain signaling is the heavily modified sum of complex processes at multiple anatomic levels. The signal consists of peripheral nerve excitation, regional exchanges within the dorsal horn of the spinal cord, and activation of ascending and descending circuits between the spinal cord and supraspinal locations. The entire system has a large capacity for change in response to persistent or intense signals (plasticity) and can be thought of as a pro-nociceptive positive feedback loop.[5]

Nociception is the biological process by which noxious stimuli (i.e., those capable of producing tissue damage) are detected and transmitted by unique sensory receptors called nociceptors. This process might or might not result in the conscious perception of pain.[6] Neural processing of the encoded information can be thought of in several steps, each of which encompasses complex modification of the information. The steps are: *transduction* of the signal into an action potential, *transmission* of the information from the periphery to the spinal cord, *modulation* of the information within the spinal cord, *projection* from the spinal cord to the brain and lastly, *perception* of pain (Figure 126-1). Because of the complexity of signal modification, there rarely is a linear relationship between noxious stimulation and pain perception.[7]

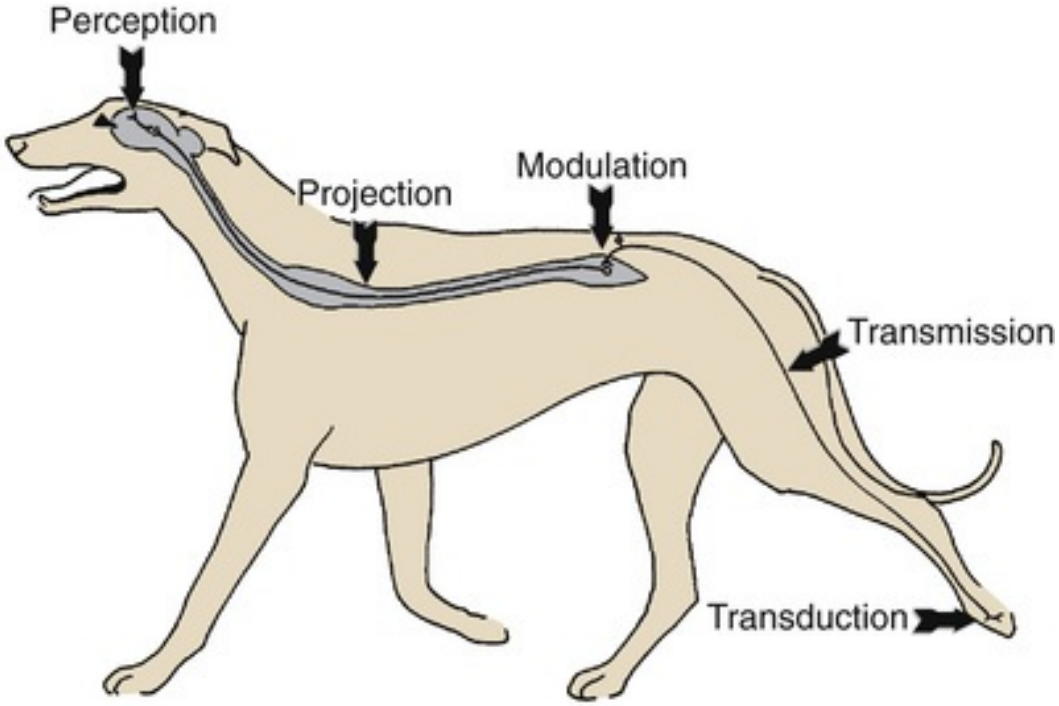

FIGURE 126-1 Schematic pathways in the neuroanatomic description of pain. Noxious stimuli are transduced into electrical stimuli, transmitted to the spinal cord (where peripheral ascending and descending modulation occurs), and finally are relayed to the brainstem and brain for perception. Descending pathways from higher centers also modulate pain signals.

Transduction

Transduction of the initial noxious stimuli occurs via nociceptors. Nociceptors are peripheral, free nerve endings of some C-fiber and A-delta–fiber sensory neurons (and fewer A-beta–fiber neurons).[8] These afferent pseudounipolar neurons have cell bodies in the dorsal root ganglia and the trigeminal ganglia (for cranial nerves) and terminate in the superficial layers of the dorsal horn of the spinal cord[5,9] (Figure 126-2).

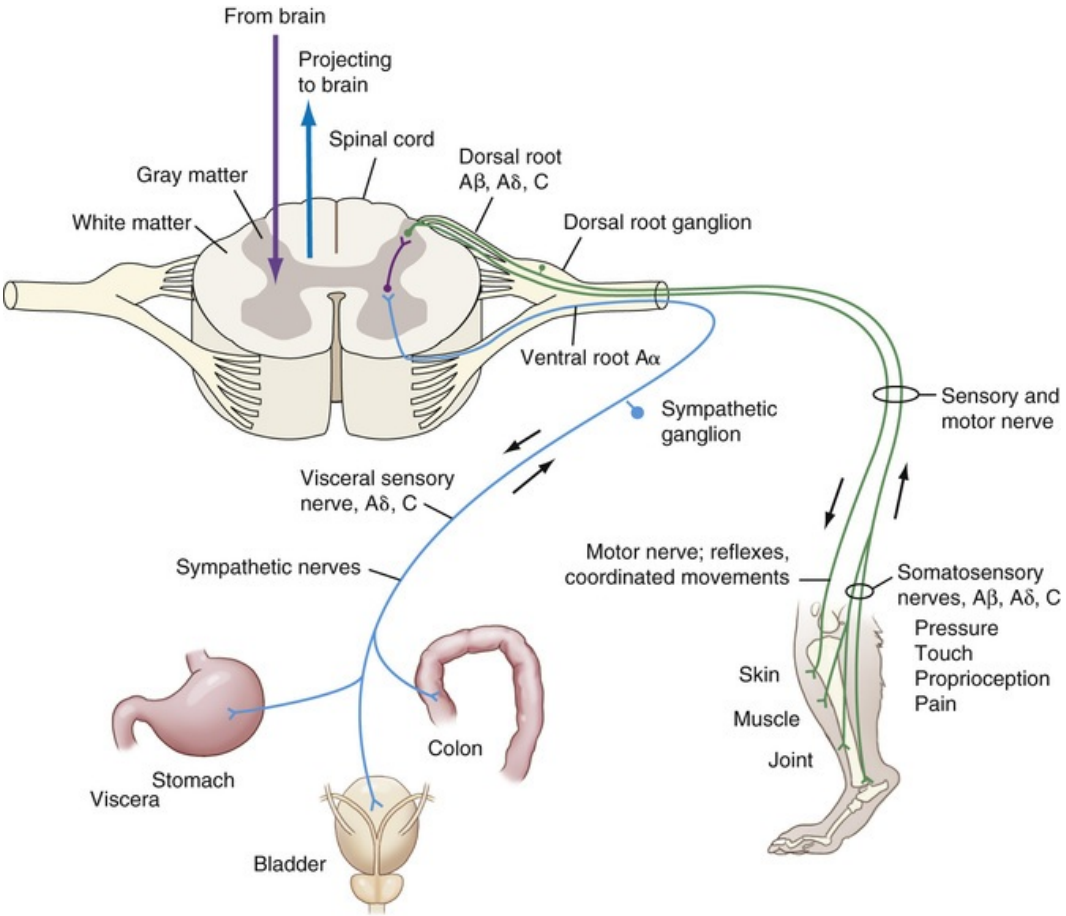

FIGURE 126-2 This illustrates a highly simplified schematic view of transduction and transmission via afferent sensory nerve fibers pathway from the periphery and viscera to the spinal cord. (Adapted from Muir WW: Physiology and pathophysiology of pain. In Gaynor JS, Muir WW, editors: *Handbook of veterinary pain management*, ed 2, St Louis, 2009, Mosby Elsevier, p 33.)

Unmyelinated C-fibers' nociceptors respond to chemical, mechanical, and thermal (termed polymodal) noxious stimulation. Myelinated A-delta–fibers rapidly respond to high intensity mechanical stimulation, with some also responding to thermal stimulation.[5] Transduction of the stimulus occurs by triggering a conformational change in an ion channel leading to the generation of an electrical action potential. Many chemicals released by tissue damage can trigger signal transduction, among them protons, bradykinins, leukotrienes, substance P, histamine, potassium, and prostaglandins.[10] Identification of the specific receptor molecules, ligands, and details of the subsequent signal is an active area of research and a therapeutic target. Acid-sensitive ion channels (ASIC), transient receptor potential vanilloid 1 channels ($TRPV_1$, activated by heat and various ligands including capsaicin), tetrodotoxin (TTX)-sensitive and -resistant sodium channels, purine receptors, and voltage-gated calcium channels all are examples of receptors expressed on nociceptors.[1,5]

Transduction of noxious stimuli is different than in other types of sensory processing. Nociceptors only respond to noxious stimuli and do not adapt to persistent stimulation by firing less. Indeed, rather than causing a decrease in firing of the nociceptor, continuous or rapid stimulation can lead to a decrease in the threshold of response.[4] This is termed sensitization, and it contributes to peripheral sensitization and hyperalgesia (described in more detail below).[6] Thirty to fifty percent of C-fiber and A-delta–fiber nociceptors are classified as silent nociceptors because prior to exposure to inflammatory mediators and neuropeptides, they are either unresponsive or responsive only to very high mechanical stimulation. However, after exposure to these chemical activators, they are recruited and respond to stimuli (i.e., become sensitized), thereby increasing the response to further noxious stimuli.[9]

Transmission and Dorsal Horn Processing

Transmission of the pain signal from the nociceptor delivers it to the superficial layers of the gray matter of

the dorsal horn of the spinal cord. Transmission of the nociceptive signal continues via the axons of second-order neurons that cross the spinal cord and form ascending spinothalamic tracts that extend to the thalamus, where they synapse on third-order neurons that project to the sensory cortex.[5]

Within the dorsal horn are three functional groups of neurons that interact with first order, afferent neurons: interneurons, propriospinal neurons, and projection neurons.[11] The transmitted action potential causes opening of pre-synaptic voltage-gated calcium channels and the release of either excitatory or inhibitory neurotransmitters at synapses on second-order neurons. Substance P and glutamate are important excitatory neurotransmitters. Glutamate can bind to N-methyl-D-aspartate (NMDA), AMPA and mGlu types of excitatory amino acid receptors.[1] Substance P is a ligand for G-protein coupled neurokinin-1 (NK-1) receptors. Gamma-aminobutyric acid (GABA) and endorphins are common inhibitory signalers that interact with GABA receptors and mu and delta opioid receptors, respectively.[1]

The interneurons and projection neurons that encode nociceptive information are either wide dynamic range neurons (WDR or convergent neurons) or nociceptive-specific neurons.[9] Nociceptive-specific neurons only respond to high intensity noxious stimuli, but WDR neurons can be stimulated by low intensity stimulation from A-beta, A-delta, and C fibers. WDR second-order neurons can change their response to match patterns of persistent response in nociceptors experiencing sustained discharge (i.e., after tissue injury).[5] This is one of the many mechanisms of neuroplasticity in pain signaling and it is important in chronic inflammatory and chronic neuropathic pain.[12]

The neurotransmitters produced by cell bodies in the dorsal root ganglia are released at both the central and peripheral ends of the neuron. This dual signal triggers both central pain processing events and peripheral tissue effects like redness, swelling, and tenderness.[5]

Projection of Pain Signals (Ascending Pain Pathways)

Neurons that project to supraspinal locations synapse in the medulla, midbrain, and thalamus, and then project further to cortical centers.[13] The subcortical sites include the reticular formation, the periaqueductal gray matter of the midbrain, and the nucleus raphe magnus of the medulla. The subcortical sites are responsible for the non-conscious reactions to pain like arousal and physiological responses including endocrine responses.[7]

Modulation of Pain Signals

An important concept in pain physiology is *neuroplasticity,* here specifically referring to the ability of neurons to change their excitability, gene expression (i.e., changes in receptors and neurotransmitters), and structure in response to noxious stimuli and tissue injury. Neuroplasticity is how heightened pain sensitivity, or sensitization, can follow noxious stimuli. This sensitization can occur at the level of peripheral signal transduction *(peripheral sensitization)* or in the dorsal horn at the second order neurons *(central sensitization).* Sensitization can occur within minutes or over the course of a long period of time and at many levels.[1] When the noxious stimulus is prolonged or sufficiently intense to cause sensitization, then hyperalgesia and allodynia may occur. *Hyperalgesia* is increased pain from a given noxious stimuli including both a lower threshold to response and a more intense response. This change can occur in the injured tissue (primary hyperalgesia), but can also occur in adjacent, non-injured tissue (secondary hyperalgesia). *Allodynia* means pain from a stimulus that does not normally cause pain. A recognizable example of this is the burning sensation caused by tepid water on sunburned skin. Primary hyperalgesia occurs from peripheral sensitization, while secondary hyperalgesia and allodynia are believed to be a consequence of central sensitization.[14] *Windup* is a phenomenon related to, but different from primary hyperalgesia and central sensitization. Windup is defined as a progressive increase of activity in dorsal horn cells *during* repetitive activation of primary afferent C-fibers. Central sensitization is a phenomenon that occurs *after* noxious stimulation, which can be propagated autonomously or with a low level noxious stimulation and can amplify subsequent responses.[15]

Besides central sensitization, there is substantial communication between signaling pathways and many different pathways that further result in modification and plasticity of the signal and ultimately, pain perception.[1]

Pain signals are subject to both facilitation and inhibition by way of descending pathways from supraspinal regions to the dorsal horn. Important neurotransmitters involved in the process of descending facilitation

include: substance P, glutamate, cholecystokinin, and nerve growth factor. Important neurotransmitters involved in the process of descending inhibition of pain signals include: adenosine, cannabinoids, dopamine, GABA, norepinephrine, and serotonin.[1] An example of the complexity of this system is that there is no anatomical separation between facilitation and inhibitory pathways. This means it is possible for a single supraspinal stimulus and the same neurotransmitter to simultaneously trigger both facilitation and inhibition of pain.[12]

Descending inhibitory pathways, originating from multiple supraspinal locations, constitute an endogenous pain-relieving system thought to be responsible for the huge variation in pain perception noted between individuals, and for the placebo effect.[16] The endogenous pain-inhibiting system is of great interest to clinicians and researchers, since most of the pharmacological and non-pharmacological methods of producing analgesia (e.g., the placebo effect, transcutaneous electrical nerve stimulation, acupuncture) manipulate this endogenous system.[12,13,16] The descending inhibitory circuits are largely opioid-sensitive systems and three groups of endogenous opioids have been well-studied: enkephalins, endorphins, and dynorphins.[10,16] Analgesic drugs, including nonsteroidal anti-inflammatories (NSAIDs), serotonin/norepinephrine reuptake inhibitors, cannabinoids, and exogenous opioids work, at least in part, by mimicking the effect of endogenous opioids.[16] A few of the specific inhibitory mechanisms worth noting are (1) the descending noradrenergic system, in which spinal alpha$_2$ adrenergic receptors are the main players, (2) the stress-induced analgesia system associated with endogenous cannabinoids and beta endorphins, and (3) the diffuse noxious inhibitory control system, which, when lost, plays a major role in chronic pain states.[16]

Perception of Pain Signals

Cortical signals determine the three parts of the experience of pain: sensory-discriminative, motivational-affective, and evaluative-cognitive.[9] The sensory-discriminative component includes the location, intensity, and type of pain perceived. The motivational-affective component includes behaviors that lead to avoidance of pain and to emotional reactions. The evaluative-cognitive component includes past experiences of pain and behaviors learned as a result. This can positively or negatively affect the perception of pain. The above mentioned "stress induced analgesia system" is one mechanism by which the evaluative-cognitive component of pain perception is affected (i.e., the perception of pain is reduced by physiological stress). Perception of pain is controlled by various cortical regions, the most important of which are the primary and secondary somatosensory cortices, the insular cortex, the anterior cingulate cortex, the thalamus, and the amygdala.[9]

Visceral pain perception is quite different from somatic pain perception for a number of structural reasons. Visceral afferent innervation is much less dense than are somatic afferents, it is spread over multiple spinal segments rostral and caudal to the origin, the spinal neurons involved also receive concurrent input from somatic regions, and the viscera have dual extrinsic innervation from either vagal or pelvic and spinal nerves.[9] As a result of this architecture, visceral pain is poorly localized, diffuse and can be *referred pain* (perceived as adjacent to, or even distant from, the site of origin).[10] Clinically, visceral pain can have a poor correlation with the extent of tissue injury and it is often accompanied by obvious autonomic and emotional reactions. Although distention, traction, ischemia, and inflammatory mediators are noxious to visceral organs, some visceral organs do not respond to noxious stimuli unless they are already inflamed or distended.

Clinical Pain Taxonomy and Nomenclature

The IASP publishes a regularly updated list of pain term definitions and clinical pain classifications, which is used as the general reference for this information.[17] Pain can be classified on the basis of location, intensity, character, etiology, pathophysiology, or even response to treatment.[18] Because of the many variables, the IASP uses a five-axis model (region, system, temporal pattern, intensity, and etiology) of pain taxonomy for use in human patients. For veterinary patients, there is no standardized method of classifying clinical pain. Most of the veterinary literature focuses on etiology and temporal pattern, so knowledge of the related terminology is important. It is important to note, however, that many references have slightly different definitions of relevant terms because they use different pain classification schemes.

Nociceptive pain arises from actual or threatened damage to non-neural tissue and is due to the activation of nociceptors. *Physiological pain* is the transient, protective process that initiates avoidance strategies *prior* to tissue damage. Clinical pain (sometimes called *pathological pain*) results from *actual* tissue damage and it

provokes a longer or more intense avoidance/behavior pattern. *Acute pain* results from surgical or other trauma to tissues, responds to treatment, resolves when the tissue lesion is healed, and is considered a clinical sign.[7] In some classification schemes *inflammatory pain* (pain produced by tissue inflammation) is considered to be another term for acute pain. *Neuropathic pain* is pain associated with damage to, or a lesion of, peripheral or central nervous system tissue. The damage can be caused by deformation, compression of surrounding tissues, or an altered milieu; direct injury is not required to cause neuropathic pain. *Chronic pain* (which is, confusingly, also sometimes called pathological pain) is a maladaptive disease state defined by the IASP as "pain without apparent biological value that persists beyond normal tissue healing time."[2] Further refinement of this definition includes the idea that chronic pain is a disease of the nervous system that can be present without a demonstrable or sufficiently significant structural lesion to explain its persistence. As discussed above, pain-related neuroplasticity can ensure that pain is maintained without external stimulation, or can be due to abnormal processing of pain signals *(functional pain)*.[3] Chronic pain can be a changeable fusion of inflammatory, neuropathic, and functional pain.[1] Woolf elegantly simplifies the classification of pain into three different entities. Two are functional and adaptive: nociceptive pain and inflammatory pain (acute could be used interchangeably here). The third classification is maladaptive, non-protective pathological pain, which is further subdivided into neuropathic and dysfunctional pain. Dysfunctional pain occurs with no damage or inflammation.[19] This system has the advantage of being encompassing and clinically relevant.

Pain Identification in the Acute Care Setting

As pain is a subjective state and our patients cannot speak to us, we are obligated to assess their pain through the lens of our own observations and prejudices. Despite this handicap, it is quite possible to manage acute pain effectively. Box 126-1 details key principles of acute pain identification that form the foundation for effective pain identification. This information is a synopsis of research into species differences in pain response and extensive work validating pain scaling for dogs and cats. Veterinarians often are reluctant to treat pain unless they have abundant evidence that pain is present. Unfortunately, this approach fails to effectively treat animal pain. Unlike other vital signs, there is no objective measure of this fundamentally subjective state.[3] Our patients can mask signs of pain until pain is substantial, and pain is harder to treat when it is more severe. A judicious approach avoids under- and overtreatment of pain and adapts to the patient's needs as they evolve.

Box 126-1

Key Principles for the Identification of Acute Pain

- Signs of pain vary widely between species, age, and between individuals.
- Knowledge of the patient's normal behavior and temperament, particularly prior to the onset of pain, improves pain assessment.
- Frequent re-assessment and identification of trends improves pain assessment accuracy.
- Reassessment at regular intervals after providing analgesic therapy provides a clinically useful guide to adjusting pain management plans.
- Having a single or a few trained observers improves pain assessment accuracy by reducing interobserver variability.
- The most accurate observer is often the person who spends the most time with the patient.
- Acute pain is most accurately assessed when objective measures are combined with behavioral observations and response to interaction.
- There are no universal or pathognomonic pain behaviors or objective measures.
- Likewise, the lack of certain behaviors or objective measures does not negate the possibility of pain in a patient.
- Pain scales are not sensitive enough to justify withholding or reducing analgesic therapy; they are most useful to confirm the suspicion of pain or to suggest continuing analgesic therapy.
- Anxiety, fear, non-pain related discomfort (like nausea or a full bladder), and opioid-caused dysphoria may confuse pain assessment. Since behavioral states of distress can worsen pain perception, addressing these conditions may improve analgesia.

Pain identification in animals requires that we consciously use observational skills developed by our experiences as clinicians. Our prior knowledge of the patient's posture, reactions to examination, vocalizations, and gait are tremendously helpful in assessing pain because we usually recognize deviations from those earlier observations. Pain can be indicated by the expression of abnormal behaviors and/or the change in, or absence of, normal behaviors.[20] We might already subconsciously register these changes without interpreting them as evidence of pain, but they are often key pieces of evidence. For example, noticing that a cat no longer makes a greeting noise when approached could be subtle but also significant. Box 126-2 lists behaviors typical of dogs and cats with acute pain.

Box 126-2

Acute Pain Behaviors in Dogs and Cats

Movement/Activity

- Restlessness or continuous activity
- Circling or thrashing
- Reluctance to move, lie down, or rise
- Excessive sleeping (cats, in particular)
- Escalating aggression when approached or handled
- Hiding (cats, in particular)
- Tail flicking (cats)

Vocalizations

- Spontaneous vocalizations without movement or interaction
- Purring, hissing, spitting, yowling (cats)
- Whimpering/howling/growling (dogs)
- Increased vocalization with movement or on palpation of affected area

Posture

- Sleeping or resting positions that are unusual or different from normal (i.e., lateral recumbency in a hospitalized cat)
- "Prayer" position (see ch. 143)
- Leaning against side of cage or wall, slumping
- Hunched posture when standing
- Weight shifted off affected limbs or difficulty standing still
- Rolling over on back or other submissive posture
- Abnormal tail carriage
- Rigid posture

Gait

- Lameness
- Stiff gait

Changes in Facial Expression

- Squinting of eyes
- Abnormal carriage of ears
- Holding whiskers in abnormal position (cats)
- Avoidance of gaze

Loss of Normal Bodily Functions

- Anorexia
- Reluctance to eliminate

- Poor or excessive grooming

Social Behavior

- New or escalating aggression or fear when approached, handled or when near other animals
- Avoidance of familiar people or avoidance of any interaction
- Seeking of constant reassurance

Physiological Indicators

- Panting or tachypnea, open-mouth breathing (cats)
- Tachycardia
- Hypertension

Note: Many of these indicators may also be generated by anxiety, fear, sedation, or the effects of medications in addition to pain. Patients exhibiting these behaviors should be screened for other potential causes such as dysphoria or discomfort from non-painful sources.

Pain recognition starts with assigning a level of expected pain for the specific patient in its specific situation. Several authors have used this process as a pre-emptive scoring system to guide analgesic therapy.[4,7] Box 126-3 lists expected levels of pain for common surgical or diagnostic procedures, injuries, and illnesses. This information can be used as a starting point when formulating a pain management plan.

Box 126-3

Expected Levels of Pain for Common Surgical or Diagnostic Procedures, Injuries, and Illnesses

Severe to Excruciating Pain

- Acute neuropathic pain such as that experienced with cervical intervertebral disc herniation, nerve injury due to trauma, or widespread neurological tissue inflammation
- Bone tumors
- Pathological fractures
- Extensive necrotizing cutaneous or visceral inflammation as in necrotizing fasciitis or peritonitis
- Severe polytrauma
- Necrotizing pancreatitis or cholecystitis

Moderate to Severe Pain

- Hollow organ distension
- Visceral organ capsule distention
- Mesenteric, gastric, testicular or splenic torsions
- Pleuritis and peritonitis
- Ureteral, urethral or biliary obstructions
- Limb amputation
- Post-operative fracture repair or intra-articular surgery
- Ear canal ablation
- Post-operative thoracotomy
- Thrombosis or ischemia
- Intra-ocular or corneal disease or injury/enucleation
- Onychectomy
- Cancer pain
- Postoperative routine laparotomy
- Soft tissue trauma
- Whelping or queening
- Thoracolumbar intervertebral disc disease

- Polyarthritis
- Juvenile inflammatory musculoskeletal diseases such as panosteitis and hypertrophic osteodystrophy
- Extensive dental extractions and oral mucosal inflammation

Mild to Moderate Pain

- Minimally invasive orthopedic procedures such as removal of an external fixator
- Diagnostic endoscopy
- Dental procedures
- Cutaneous mass removals
- Cystotomy
- Anal sacculectomy
- Castration

Mild or Brief Pain

- Bone marrow aspiration
- Urinary catheterization or cystocentesis
- Phlebotomy
- Placement of nasogastric or nasoesophageal feeding tubes, nasal oxygen cannulas, intravenous and arterial catheters
- Drain and suture removal
- Bandage change

This information is intended to provide a rough estimate of expected pain and will vary depending upon the specific context and individual patient factors.

Adapted from Mathews KA: Pain assessment and general approach to management. *Vet Clin North Am Small Anim Pract* 30:729-752, 2000.

Physiological and Behavioral Indicators of Pain

No measurable physical exam or biochemical parameter is pathognomonic for pain or free of influence from non-pain sources. Blood pressure, heart rate, and respiratory rate are non-specific indicators of pain that are most useful when combined with behavioral indicators.[21] Noting trends in these measures can help confirm that a patient has uncontrolled pain and can also help assess the efficacy of the chosen pain management plan.

Assessment of posture, mobility, interactive behavior, and vocalization generally are more valuable measures of pain in animals (see Box 126-3). As with all pain assessment, changes, and trends in these indicators are probably the most accurate use of this information.

Pain Scales

Many pain scoring tools have been developed for use in veterinary patients and they are the subject of intense research. Despite this, few of them are fully validated using accepted methods of statistical analysis and they are not widely used in clinical practice. Most pain scales for dogs and cats were designed for use in post-operative and trauma patients and may not be applicable to those with spontaneous non-surgical pain, as in acute pancreatitis.[22] This is particularly true in patients who are sedated or too ill to generate typical pain behaviors.

Pain scales are valuable when they serve to trigger regular pain assessment and adjustment of pain management. They are too insensitive and nonspecific to justify withholding of analgesics. A frequent criticism of pain scoring tools is that they cannot distinguish dysphoria, stoicism, or anxiety from pain. Use of good clinical judgment should override a pain score if there is a suspicion that the score is inappropriate. The principles listed in Box 126-1 should be kept in mind regardless of whether a specific scaling tool is used.

Downloadable examples of well-researched acute pain scales (including the CGMPS short form and the CSU tool for dogs and cats) can be found by searching key words "pain scales" on the home page for the International Veterinary Academy of Pain Management (IVAPM; www.IVAPM.org) and on the home page of

the Association of Veterinary Anaesthetists (http://www.ava.eu.com/vets-and-nurses).[22,23]

Pain Management as a Standard of Practice

Reluctance to recognize and treat pain in veterinary patients has changed dramatically in the past decade. The American Animal Hospital Association's mandate that pain be considered a vital sign and assessed in every patient is a strong statement of this change. Nevertheless, repeated surveys of veterinary practitioners across the world have shown large variability in both pain recognition and treatment.[24,25] Particularly insidious are persistent myths about analgesia provisions in animals: namely, that some postoperative pain is beneficial for recovery and that treatment often carries the risk of serious side-effects.[26] Both ideas are contradicted by research and practice guidelines issued by the American College of Veterinary Anesthesia and Analgesia, the World Small Animal Veterinary Association Global Pain Council, and the American Animal Hospital Association.[3,27]

Treatment of acute pain achieves important medical goals, besides fulfilling our professional obligation to prevent and relieve suffering of animals. Pain produces biological stress, or a physiological attempt to preserve biological functioning in the face of threats (i.e., environmental, emotional or physical) to homeostasis. Distress can be defined as a biological state when the physiological cost of stress is high enough to cause negative effects on primary biological functions.[26] Pain has a complex relationship with biological stress and distress, being both a cause and an effect. It is intuitively obvious that pain *causes* distress. Pain also can result *from* distress because anxiety and fear lower the nociceptive threshold and amplify pain perception. An understanding of the implications of the stress response on physiology has led us to realize that untreated or undertreated pain is an important contributor to neurohumoral, immunological, and hematological effects of biological stress. The pathophysiologic consequences of pain can include increased cardiac work and oxygen demand, vagal inhibition, hypoxemia, hypercarbia, atelectasis, ileus, nausea, vomiting, oliguria, thromboembolism, fatigue, sedation, and fear.[26,27,29] Many of these effects are due to pain's ability to stimulate an autonomic response. Additionally, pain causes dysfunction in the immune system due to neuroendocrine-mediated pathways.[9] These effects can demonstrably increase morbidity, mortality, and prolong hospital stays in people and, we infer, veterinary patients.[30]

Strategies for Acute Pain Management

Ch. 138, 164, and 166 provide drug dosing guidelines and clinical essentials. In addition, the World Small Animal Veterinary Association has freely downloadable pain management guidelines for a variety of clinical situations (http://www.wsava.org/educational/global-pain-council).

Having a goal-directed strategy has been shown to improve outcome and reduce adverse events in many disciplines of clinical medicine. Pain management is likely no different, and, at the very least, goals ensure that all facets of pain control are being considered. General goals of acute pain management are: (1) maximize comfort, (2) normalize physiologic homeostasis as much as possible, (3) reduce the risk of future chronic pain and (4) minimize adverse effects of pain management.[31] The clinical recommendations below will reference how they meet these goals.

An important starting place is the understanding that pain is harder to treat when it has been untreated or undertreated and windup or hyperalgesia has already occurred. Since this can happens in minutes after initiation of nociception, treatment plans should be geared towards providing comprehensive pain relief immediately rather than losing an opportunity for pain prevention by gradually ramping up to full treatment.

Other factors should be considered when formulating an acute pain management plan. The patient's age, general health and body condition, temperament, pain history, expected course of treatment, and whether the patient is being treated in a hospital setting or as an outpatient should be weighed when developing a plan. The patient's caretakers must be taken into consideration, since financial constraints, compliance and expectations will have a large impact on the plan. Although the consideration of all these factors transforms the planning process into a skilled art, success depends upon this calculation.

Perhaps the most important factors for ensuring successful acute pain management are individualization of the treatment plan and the use of frequent assessment of response to treatment as a guide for plan adjustments. Becoming comfortable with the usual response to commonly-used therapies provides a solid starting point and some degree of predictability. It can be helpful to design standardized strategies for mild, moderate, and severe pain to provide an initial basis for formulation of an individualized plan.

When analgesic therapy fails to provide pain relief, factors other than inadequate dose should be

considered. Although it seems obvious, we might not realize that some patients will experience much more severe pain than others, and some can have atypical responses to analgesic strategies that are usually effective. Unexpected signs of pain can also be due to non-pain-related distress from various conditions such as nausea, a full bladder, or hypothermia. Compliance by the patient or the person administering drugs should be evaluated as well. Some patients' pain might not be relieved without the use of more complicated multi-modal strategies or the use of non-pharmacological therapies.

Pharmacological methods of analgesia are the cornerstone of therapy, whether given regionally or systemically. The main categories of analgesic drugs are local anesthetics, NSAIDs, opioids, and adjunctive analgesics. Non-pharmacological methods of pain control can greatly improve analgesia in veterinary patients, while lowering the risk of adverse effects of drug therapy.

Preventive Analgesia

As mentioned previously, management of pain ideally begins as *preventive analgesia.* The concept of *pre-emptive analgesia* did not bear up to expected success, but new understanding of surgical nociception has updated this concept.[32] In contrast to other types of pain etiologies, the patient is anesthetized when surgical nociception first occurs (incision), so administering analgesics prior to surgery seems not as important as continuing sufficient analgesia during and after the procedure. During other pain states, the most significant nociception occurs during the injury itself. In patients undergoing diagnostic and surgical procedures, effective analgesia is most successful when the level and duration of analgesia are capable of sufficiently quashing nociception until the nociceptive input has stopped.[31] The patient can benefit from this powerful tool when the clinician includes analgesic agents in anesthesia protocols. Using opioids, alpha$_2$ agonists, and ketamine in premedication and induction protocols will accomplish this and will also augment sedation. Local and regional anesthesia/analgesia provisions should be included in every protocol, since they are capable of blocking nociceptive input completely. NSAIDs are also fundamental to preventive analgesia because of their ability to block and treat inflammation. The beneficial impact of simple approaches like local infiltrative blocks and single doses of NSAIDs should not be underestimated. They are cost-effective, low-risk, and can have significant benefit for current and future/chronic pain control in a given patient.

Multimodal Analgesic Strategies

Of course, preventative analgesia is not possible for patients with trauma and spontaneous illness. *Multimodal analgesia* (sometimes called balanced analgesia) strategies can be the most effective by improving analgesia while reducing risk of adverse effects. Multimodal analgesia can also reduce sensitization and the subsequent development of chronic pain. The rationale for multimodal analgesia is that combining two or more therapies (drugs or non-pharmacological therapy) is more effective because different therapies target a different part of the complex signaling process and work synergistically.[33] This also can allow lower overall dosages of drugs that carry the risk of adverse effects. Reviews of multimodal analgesia in human postoperative patients show that NSAIDs, local anesthetic techniques, parenteral alpha$_2$ adrenergic agonists, and alpha-2-delta–1 subunit calcium channel blockers (e.g., gabapentin, pregabalin) are opioid-sparing and effective.[34] Empirical data to show the effectiveness of multimodal analgesia in veterinary medicine are limited mostly to experimental situations and combinations of opioids and NSAIDs in clinical patients.

Locoregional Analgesia

Local and regional analgesia using agents such as lidocaine (e.g., up to 1-2 mg/kg SC, total cumulative dosage if given in multiple sites), bupivacaine (e.g., 0.5-1 mg/kg SC, total cumulative dosage if given in multiple sites), mepivacaine, or ropivacaine can fulfill many of the goals stated above for analgesia. Other classes of drugs, like opioids and alpha$_2$ agonists, are increasingly being used in combination with local anesthetics to extend the duration and efficacy of local analgesia.[35] Although complete anesthesia can be achieved with many of these techniques, published dosages for local anesthetic infusions more often provide analgesia without complete loss of sensation or motor function.

Most techniques are simple enough to require only minimal training (e.g., local infiltrative blocks, topical anesthesia, incisional line blocks, ring blocks). Some techniques require extra training, but still are easily mastered, safe, and cost-effective (e.g., intra-testicular blocks, oral/dental blocks). Single-dose epidural injections have low complication rates and can provide analgesia for up to 24 hours in patients undergoing

orthopedic surgery, celiotomy or thoracotomy, or those who have sustained major trauma.[36]

Surgical placement of wound diffusion (soaker) catheters for provision of continuous local blockade after limb amputation, thoracotomy, laparotomy, or total ear canal ablation, for example, enables patients to be comfortable and mobile without the need for large doses of systemic analgesics.[37] A related technique, continuous peripheral nerve block, involves percutaneous placement of an indwelling catheter near a peripheral nerve for continuous blockade. This technique still is rarely used in veterinary medicine and does require ultrasound guidance. It allows human patients to have improved analgesia postoperatively, reduced opioid use, and shortened hospital stays.[38]

Other regularly used techniques require more specialized equipment and training. These techniques, including single dose nerve-locator and ultrasound guided regional blockade and epidural catheter placement are capable of substituting for all or part of the commonly used systemic analgesic drugs associated with more side effects.[39]

Step-by-step techniques for provision of locoregional analgesia are widely available in the veterinary literature and in multi-media formats (see above). Additionally, hands-on workshops are part of major veterinary conferences throughout the year.

Systemic, Pharmacologic Analgesia

Pharmacological provision of systemic analgesia given orally or via parenteral routes is the mainstay of acute pain management.

NSAIDs are highly effective against acute pain due to their diverse anti-inflammatory effects. Examples include (as initial dosages for dogs) carprofen 2.2 mg/kg PO q 12 h or meloxicam 0.1 mg/kg PO q 24 h, or for cats, robenacoxib 1 mg/kg PO q 24 h × 3 days. Although chronic use of NSAIDs carries a substantial risk of adverse effects in patients with pre-existing gastrointestinal (GI), renal, or hepatic disease, they have minimal cardiovascular risks in veterinary patients. They also can provide effective analgesia when given short-term, thereby avoiding some of the risks of chronic use. Acetaminophen (paracetamol), usually considered to be an analgesic without anti-inflammatory effects, is being re-evaluated as a possible anti-inflammatory agent and might be useful in the dog (e.g., 10-15 mg/kg PO q 12-24 h), despite being highly toxic to cats.[40,41]

Opioids are considered the prototypical therapy for acute pain management due to their safety and efficacy. Opioids have few or easily-managed cardiovascular effects, are in large part reversible, and are readily titrated to effect. Current understanding of the diversity of opioid receptor types, location, and pharmacogenomics has led to novel delivery methods, new clinical uses, and reduction in unwanted effects.[42] For example, buprenorphine administered via the oral transmucosal route in cats has become routine in veterinary medicine after it was realized that buprenorphine administered by this route is highly bioavailable and produces reliable analgesia in the cat.[43] Another example is the growing interest in peripheral effects of opioids because of the premise that targeting opioid receptors in the periphery would avoid undesirable central nervous system effects.[7]

Opioids are underutilized in clinical veterinary medicine[44] despite their relative safety and efficacy. Commonly cited reasons are fear of adverse effects and controlled substance restrictions. In general, adverse effects are dosage-related and can be minimized when dosing is titrated to effect. Sedation, dysphoria, respiratory depression, and emesis are less when pain is more severe.[45] Respiratory depression rarely is clinically significant in conscious veterinary patients, in contrast to human patients.[46]

For hospitalized patients, injected opioids (e.g., in dogs, methadone 0.1-0.4 mg/kg IV or IM, or hydromorphone 0.025-0.1 mg/kg IV or IM; in cats, buprenorphine 0.02 mg/kg IV or PO transmucosally, or oxymorphone 0.05 mg/kg IV or IM) can be given as needed, as bolus therapy, and/or as continuous rate infusions (CRI). Although CRI use often is relegated to patients with severe pain, it may help avoid adverse effects in patients with less severe pain. Combining opioids of different functional classes often occurs in veterinary patients, but the effects are unpredictable.[47,48] Layering of different pure mu-receptor agonists (i.e., oral or bolus dosing in addition to a CRI) can allow for fine-tuning of pain control and adverse effect management.

Other Analgesics Useful for Acute Pain Management

Alpha$_2$ adrenergic receptor agonists (alpha$_2$ agonists) have profound analgesic effects besides their well-known sedative, anxiolytic, and muscle relaxant properties. Analgesia is increased when alpha$_2$ agonists are used with opioids.[49] The precise mechanism of action for anti-nociception is not fully understood, but it appears to

relate to spinal alpha$_2$ adrenergic receptor stimulation, which is involved in pre- and post-synaptic modulation of pain signals and the descending modulation system.[49] Alpha$_2$ agonists do have profound cardiovascular effects even at very low dosages. They also have effects on most other body systems due to the widespread nature of the adrenergic receptor and some non-adrenergic receptor effects. Many of these effects are dosage-dependent, however, and do not preclude cautious use. Alpha$_2$ agonists (e.g., dexmedetomidine 0.5-1 mcg/kg IV as a bolus and 0.5-1 mcg/kg/h CRI) can be used as part of sedation or anesthesia protocols to provide analgesia, as intermittent injections or CRI in hospitalized patients or as part of epidural and locoregional drug combinations.

Gabapentin and pregabalin, related antiepileptic drugs with anti-hyperalgesic and anxiolytic effects, may have a role in the management of acute pain (e.g., for gabapentin in dogs, for short term acute/perioperative analgesia and possibly anxiolysis, in gabapentin-naïve patients: 10-15 mg/kg PO q 8-12 h; this will be sedating in naïve patients; and for pregabalin: 1-2 mg/kg PO q 12 h for cats and 2-4 mg/kg PO q 12 h in dogs, but probably best used for chronic pain). These medications have long been used for managing neuropathic pain, but more recently have been studied in perioperative pain. Gabapentin premedication reduces pain score, opioid use, the incidence of postoperative nausea and vomiting (PONV), and development of chronic pain in human patients undergoing a variety of orthopedic and soft-tissue surgeries.[50] Pregabalin produced a dose-related decrease in postoperative opioid use and PONV when used in a variety of perioperative situations.[51] There are pharmacokinetic data for gabapentin and pregabalin in dogs and cats but very limited investigation of them as analgesics.[52] Extrapolation from use in people has generated anecdotal reports of use in veterinary acute pain management. It seems likely that some of the sedative and anxiolytic effects can be beneficial in acute pain management in addition to direct anti-nociceptive effects. Of note is that gabapentin and pregabalin are excreted completely via renal mechanisms and that the dosage range is very large.

NMDA receptor inhibitors: Ketamine is a well-researched analgesic agent in veterinary species. Use of sub-anesthetic bolus or CRI doses (e.g., 0.5-1 mg/kg IV in dogs and cats +/− IV CRI at 5-20 mcg/kg/min) reduces anesthesia and opioid requirements, increases opioid efficacy and probably reduces the development of chronic pain. Methadone (e.g., 0.1-0.4 mg/kg IV or IM) also has NMDA inhibitory properties that augment its usefulness as an analgesic.

Serotonin and norepinephrine reuptake inhibitors have a greater role in chronic pain management, but tramadol has been used extensively in veterinary medicine. Most veterinary research has focused on the use of injectable tramadol as a way to decrease anesthetic requirements. There is scant evidence in the veterinary literature that tramadol is an effective analgesic for acute pain; most clinical studies utilizing tramadol for post-operative pain show that it is less efficacious than NSAIDs.[53] Tramadol (e.g., for dogs: 3-5 mg/kg PO q 6-12 h, and for cats: 1-2 mg/kg PO q 12-24 h) has a unique combination of effects: weak mu opioid receptor activity and serotonin/norepinephrine reuptake inhibition. In laboratory dogs, tramadol has limited metabolism to the active opioid form and shows large interindividual variation in bioavailability.[54] Anecdotally, some treated patients appear to have much more pronounced opioid effects than others. Additionally, efficacy appears to be very individually variable. New information about adverse effects in people, including serious hypoglycemia and hyponatremia, could temper the idea that tramadol is a safer alternative to NSAIDs.[53] Tramadol does lower seizure threshold and is now Food and Drug Administration controlled as a schedule IV drug in the United States.

Corticosteroids certainly inhibit inflammatory pain, but their far-reaching effects on non-target tissues limit their use as analgesics. For treatment of inflammatory diseases, e.g., immune-mediated polyarthritis or steroid-responsive meningoencephalitis, corticosteroids fulfill a dual role of treating the underlying disease and providing analgesia. They have a role in local or regional analgesia, as part of protocols for intraarticular, epidural, topical, ocular, otic, or other localized inflammation and acute pain. As long as a patient has no specific contraindication and is not concurrently receiving an NSAID, corticosteroids can be useful as a very short-term and/or localized anti-inflammatory agent.[56]

Anxiolytic drugs have an important role in acute pain management, particularly in the hospitalized patient (e.g., gabapentin [see dosage listed above], dexmedetomidine [see dosage listed above], or acepromazine [not an anxiolytic, but does produce physiologic tranquilization] at a starting dosage of 0.01-0.02 mg/kg IM, IV, or PO transmucosally). Understanding of the physiological connection between anxiety and altered pain signaling has led to the realization that reducing anxiety can directly impact pain perception. In addition, benzodiazepines and other sedatives that provide muscle relaxation can augment analgesia in patients with pain caused by musculoskeletal disease. The potential drawback that must be considered is whether excessive sedation with anxiolytic drugs could mask pain behaviors. See ch. 138 for essential clinical use.

Non-Pharmacological Methods of Analgesia

In the context of acute pain management, non-pharmacological therapies can provide analgesia largely through manipulation of endogenous pain-inhibitory systems. Some interventions like distraction via feeding or going for a walk are similar to effective methods used in babies, like suckling and swaddling.[57] We often mistake the effectiveness of these interventions as proof that our patients are not painful, although distraction and environmental modification are recognized methods of invoking endogenous analgesia.[58] More active analgesic interventions can also be useful in acute pain management. Widely used examples are rehabilitative therapies including massage, aqua- and cryotherapy, orthoses, acupuncture, low level laser therapy and transcutaneous electrical nerve stimulation (see ch. 355). Published studies establishing clinical success of many of these methodologies remain sparse despite the elucidation of mechanism of action in experimental settings, in particular for acupuncture.[59] This likely will continue to be true given the difficulties in designing adequate methods for providing controls with non-pharmacological therapies. Anecdotally, these methods can augment analgesia and reduce the need for pharmacological management.

Management of Distressing, Non-Painful Conditions

Patients can experience unnecessary suffering from non-pain-related sources during the course of medical treatment. Common examples are nausea, sleep deprivation, hunger, delayed eliminations, fear, uncomfortable bandages, and uncomfortable ambient environments. We tend to accept these conditions as part of medical therapy, but most of them can be reduced easily with thoughtful treatment and environmental enrichment. Reduction of non-pain-related suffering can immediately reduce pain perception and analgesic requirements, thereby reducing adverse effects.

Pain Management for Diagnostic Procedures

Diagnostic and minor medical procedures rarely are investigated in terms of pain, and frequently are overlooked as sources of pain in small animal patients.[60,61] For hospitalized patients, minor procedures can substantially increase pain and distress, particularly since the cumulative effects from different types of interventions might not be recognized. In adults and children, procedural pain, as it is termed, is a well-researched subject.[63] Likewise, pain due to husbandry procedures in farm animals and minor experimental procedures in laboratory animals is better researched than in small animal patients.

Examples of pain-inducing procedures often performed with inadequate analgesia include diagnostic imaging, endoscopy, bone marrow aspiration, centesis of visceral cavities or joints, cerebrospinal fluid collection, bandage changes, and central line placement. It is important to consider whether individual patients undergoing minor procedures are at higher risk for pain due to preexisting chronic pain, distress/anxiety, or from exacerbation of pain due to the primary diagnosis. Use of short-term analgesics, particularly local anesthetic techniques, single doses of opioids, NSAIDs, alpha$_2$ agonists, or anxiolytics are very effective for this purpose. Equally important is attention to non-pharmacological methods of comfort such as padded surfaces, care with joint manipulation while under anesthesia, removal of insufflated gas or fluid after endoscopy, management of the ambient environment to minimize noise, temperature extremes, etc., and grouping treatments to give patients adequate undisturbed time to recover and rest.

Adverse Effects of Acute Pain Treatment

Treatment of acute pain rarely is accompanied by serious adverse effects. Most adverse events can be "treated" by passage of time and adjusting future treatments to the individual. Few other aspects of clinical practice need to be individualized as much as drug choice and dosages for pain management, despite the abundance of published doses and protocols. Perhaps the most common adverse event is excessive sedation or excitation/dysphoria that impairs normal functioning in outpatients or delays discharge from the hospital. This can be prevented by adjusting starting dosages of opioids and other medications that have sedative effects, like alpha$_2$ agonists and gabapentin, at the beginning of therapy. Knowledge of the patient's past reactions to analgesics and sedatives and their baseline temperament are very helpful. Sedation might be a welcome effect immediately post-op and usually does not require treatment. If oversedation or dysphoria requires treatment, then opioids can be partially reversed with low dosages of butorphanol (starting at 0.05 mg/kg IV) or titrated mu-receptor antagonists (e.g., naloxone 0.002-0.01 mg/kg IV, titrated to effect and given in a diluted form to help reduce full reversal of analgesia). If oversedation is a common problem, the

clinician should consider starting with lower dosages of opioids and sedatives as a rule. Use of shorter-acting opioids, like fentanyl, can help as well. Some opioids are associated with less sedation or dysphoria; methadone and buprenorphine are examples.

Gastrointestinal effects of acute pain therapy (excluding NSAID induced GI toxicosis) do not necessarily mean that analgesic therapy has to be stopped. Consider whether inadequate treatment of pain, particularly visceral pain, potentially is the cause of the signs rather than analgesics. Visceral pain can be responsible for all of the same signs. Layering of anti-emetics and pro-kinetic treatments commonly is used for people and can be helpful in veterinary patients. Reduced dosing or multimodal therapy that allows lower dosing of individual drugs may be all that is required.

Other opioid adverse effects that can be seen with acute pain management are urine retention and opioid-induced hyperalgesia (OIH). Urine retention is a rare complication that can occur with both systemic and epidural opioid administration. This effect resolves as the drugs are metabolized, but until then can be managed with opioid antagonists, detrusor muscle stimulants, and catheterization.[46] OIH is reported rarely in veterinary medicine, but could be underrecognized. Anecdotally, it is most often seen in veterinary patients given high dosages of mu-receptor agonists for longer than typical periods, i.e., in severe polytrauma patients or hospitalized, terminally-ill cancer patients. OIH may be hard to distinguish from inadequately treated pain because opioid dosages are escalated as pain increases. In experimental animals and human patients, OIH can be prevented or improved by concurrent use of NMDA blockade with ketamine or methadone, dosage reduction, and multimodal analgesia.[62]

CHAPTER 127

Shock

Teresa M. Rieser

A brief history of the development of understanding of the cardiovascular system and shock demonstrates how far we have progressed in our knowledge of this crucially important topic. Cladius Galen, also known as Galen of Pergamum, began our understanding of circulation by proposing that there were two types of blood: nutritive blood which was enriched within the liver with nutrients and vital blood which was imbued with pneuma, the vital spirit inspired from the air which was crucial to life. Galen did not, however, believe that blood returned to the heart for recirculation.[1,2] Galen's ideas were widely accepted until 1628 when William Harvey who was the court physician of both King Charles I and King James I, published *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus*. This work questioned Galen's teachings and proposed that the heart pumped blood through the arteries and into the veins and then back to the heart. Harvey lacked, however, the ability to demonstrate how the arteries and veins communicated; this was done in 1661 by Malpighi when he visualized capillaries microscopically.[2,3] These works set the groundwork for our modern understanding of the circulatory system.

Shock has been appreciated as far back as the early Greeks including both Hippocrates and Galen.[3] In the 1700s, descriptions of shock and death were documented, and many different terms were used to describe shock including "final sinking of vitality."[2,4] The term "shock" did not become popular until Edwin A. Morris used the term in his American Civil War text *A Practical Treatise on Shock after Operations and Injuries*. Now, we appreciate a variety of underlying causes of shock and the profound danger it poses to our patients. In this chapter we discuss what shock is, the different types of shock, the hemodynamic alterations unique to each type of shock and treatment goals.

Shock has been defined as the state in which profound and widespread reduction of effective tissue perfusion leads first to reversible, and then if prolonged, to irreversible cellular injury.[5] To understand that definition and its implications some understanding of basic physiology is essential.

Molecular oxygen is a substrate for a variety of enzymatic cellular reactions needed for biosynthesis, energy production and molecular modification. The majority of the oxygen is used within cells by the mitochondrial electron transport system in order to generate adenosine triphosphate (ATP) via aerobic respiration.[6] The rate of mitochondrial oxygen consumption is primarily determined by the rate of ATP utilization by the cell. When the mitochondrial electron transport system becomes deranged, then the consumption of oxygen continues but the generation of ATP does not.[6] As the mitochondria consume oxygen, the intracellular pO_2 decreases and a gradient is created which favors the movement of oxygen from the interstitial space into the cell. In steady state conditions, the rate of oxygen utilization will match that of oxygen diffusion into the cells.[6] The gradient between the mitochondrial and extracellular pO_2 has been found to be about 2 to 4 mm Hg. In addition, mitochondrial pO_2 will increase or decrease in parallel with the extracellular pO_2.[6] As extracellular pO_2 decreases, the availability of oxygen to the mitochondria decreases as well until it reaches a critically low level. Now electron transport and oxygen consumption within the mitochondria becomes oxygen supply dependent. When the extracellular supply of oxygen decreases even further, aerobic oxidative phosphorylation stops and ATP levels fall. At this point, phosphofructokinase is stimulated and anaerobic glycolysis commences. This switch to anaerobic metabolism results in the rapid depletion of cellular glycogen stores and the accumulation of intracellular lactate and inorganic phosphates.[7] Anaerobic generation of ATP is inefficient but it does allow the cell to survive for a brief period of time. Some cell types such as neurons are unable to generate ATP anaerobically and therefore are especially vulnerable to hypoxic injury. Eventually the depletion of ATP causes failure of the Na^+K^+ pumps in the cell membrane, cell swelling and death.[6,7]

The vascular system's main purpose is to always provide an adequate supply of oxygen to every cell in the

body.[6] Oxygen delivery (DO_2) is the product of cardiac output (CO) and arterial oxygen content (CaO_2). CO is determined by heart rate (HR) and stroke volume (SV). Another way to consider cardiac output is its relationship to systemic vascular resistance and blood pressure using the following equation:

$$CO = (MAP - RAP)/SVR$$

where MAP is mean arterial pressure, RAP is right atrial pressure and SVR is systemic vascular resistance. RAP is much lower than MAP so this can be further simplified to:

$$CO \cong MAP/SVR$$

This is a useful relationship to bear in mind when considering how to address shock clinically.[8]

CO can be measured invasively in veterinary patients using multiple different types of indicator dilution methodologies or non-invasively using a partial carbon dioxide rebreathing method (NICO). Although this is not commonly done,[9] CaO_2 is determined by hemoglobin concentration (Hb), hemoglobin saturation (SaO_2) and the partial pressure of oxygen dissolved in the arterial blood (PaO_2) (see ch. 75 and 128). The hemoglobin concentration must be multiplied by the Huffner factor, which is a species-specific constant that describes the amount of oxygen in milliliters that can be carried per gram of hemoglobin.[10,11] The Huffner factor is 1.39 in the cat and ranges from 1.34 to 1.39 in the dog.[10] The PaO_2 must be multiplied by 0.003, which is the Bunsen solubility coefficient for oxygen in blood. This converts the PaO_2 from mm Hg to milliliters.[11] Putting this all together results in the following equation:

$$DO_2 = [(1.34 \times Hb \times SaO_2) + (0.003 \times PaO_2)] \times (HR \times SV)$$

Because the contribution from the PaO_2 is very small compared to that of saturated hemoglobin this portion of the equation is sometimes omitted for expediency. This equation is useful to keep in mind as it underscores the various therapeutic targets that may be altered during treatment of the shock patient. Oxygen consumption (VO_2) is relatively constant at rest but may be altered by changes in metabolic rate. Examples include exercise or the pathophysiologic stress of sepsis.[10] VO_2 can be expressed with the following equation:

$$VO_2 = CO \times (CaO_2 - CvO_2)$$

where CvO_2 is the oxygen content of venous blood. This equation can be more practically expressed as:

$$VO_2 = CO \times 1.34 \times Hb\ (SaO_2 - SvO_2)$$

where SvO_2 is the venous oxygen saturation. Bringing all of this together is the idea of the oxygen extraction ratio (OER). The OER describes how efficiently the body is extracting oxygen for use at the end tissues.[10]

$$OER = VO_2 / DO_2$$

A normal OER has been estimated to be roughly 0.25. This means that in a normal animal only 25% of the delivered oxygen is extracted for cellular use.[10]

Types of Shock

In older references, shock was usually divided into three broad categories: hypovolemic, cardiogenic and distributive (also called vasodilatory).[12] While these types of shock clearly exist, there are additional clinical groups that must be considered[13-15] (Box 127-1). It is also valuable to remember that clinical patients may have components of different types of shock. An example would be a patient with septic shock; this animal will have evidence of distributive shock but it may also have signs of hypovolemic shock due to third space losses of volume and metabolic shock.

Box 127-1

Functional Classifications of Shock with Examples

Hypovolemia: a decrease in effective circulating volume
- Blood loss
- Trauma
- Profound dehydration

Distributive: inappropriate vasomotor tone
- Sepsis/SIRS
- Anaphylaxis
- Neurogenic

Cardiogenic: decreased forward flow
- Congestive heart failure
- Cardiac arrhythmias
- Drug overdose (anesthetics, calcium channel blockers, beta-blockers)

Obstructive: decreased forward flow or venous return
- Cardiac tamponade
- Massive pulmonary thromboembolism
- Neoplasia
- Tension pneumothorax
- Gastric dilatation-volvulus

Metabolic: abnormal cellular metabolism
- Toxic: bromethalin, cyanide
- Hypoglycemia
- Cytopathic hypoxia in sepsis

Hypoxemic: decreased CaO_2
- Anemia
- Severe pulmonary disease
- Methemoglobinemia
- Carbon monoxide intoxication

Hypovolemic shock occurs when there is a decrease in the effective circulating volume. This may be seen with blood loss but it may also be seen with contraction of the extracellular fluid compartment due to profound dehydration. All animals that have dehydration have some degree of hypovolemia but they do not all exhibit shock. Distributive shock has a decrease in systemic vascular resistance but may also have focal regions of vasoconstriction. The most common example is sepsis or systemic inflammatory response syndrome but this can also be seen with neurogenic shock or anaphylactic shock. In cardiogenic shock, there is failure of the heart to generate adequate forward flow. This may be due to either systolic or diastolic disease. An example would be a patient with severe dilated cardiomyopathy or severe cardiac arrhythmias. In obstructive shock, there is either an impediment to forward flow or an impediment to venous return. Examples include cardiac tamponade and gastric dilatation-volvulus. Metabolic shock occurs when DO_2 is adequate but VO_2 is deranged. Examples include the cytopathic hypoxia that is seen in sepsis[16] or bromethalin intoxication where there is an uncoupling of oxidative phosphorylation.[17] Finally, hypoxic shock can occur when there is a decrease in CaO_2. This could be seen with anemia where the decrease in hemoglobin can have profound effects on DO_2 or with severe pulmonary disease where hemoglobin concentration is adequate but poor gas exchange prevents saturation with oxygen.

Clinical Signs

Shock is a remarkably dynamic process and its clinical signs may vary with not only the underlying cause but also if the shock is compensated or uncompensated. Detection of compensated shock may be challenging as the clinical signs can be quite subtle. One finding that tends to be found across all types of shock is altered mental status. Patients with shock will range from obtunded to comatose with the more severe impairments of mentation found in decompensated shock. Indeed, this physical exam parameter is considered a "window" to the patient's status in human medicine.[13,18] The other clinical signs of shock are similar for most types of shock. This is due to the compensatory mechanisms that shock triggers within the body. As cardiac output and blood pressure decrease, first there is an increase in sympathetic tone. This results in peripheral vasoconstriction and increase in heart rate and an increased respiratory rate. Next there is an upregulation of the renin angiotensin aldosterone system, which promotes the reabsorption of sodium and water to bolster the effective circulating volume.[19] There is also additional direct vasoconstriction and the release of vasopressin, which causes further vasoconstriction and sodium and water reabsorption.[20] These compensatory mechanisms are seen clinically as pale mucous membranes, tachycardia and tachypnea. As shock progresses from a compensated to an early decompensated state, additional signs such as a prolonged capillary refill time and poor pulse quality may be appreciated. In addition, the increased vasoconstriction will result in cold extremities. Measurement of blood pressure will usually reveal hypotension (see ch. 99 and 159). A decrease in urine output may also be seen. Initially this may be in response to a decrease in effective circulating volume and is an appropriate response but as hypotension worsens, renal blood flow and glomerular filtration rate will be negatively impacted, resulting in pathophysiologic oliguria.[21] As shock progresses even further into late decompensated or irreversible shock the animal may now be bradycardic, comatose, have a prolonged capillary refill time, weak to absent pulses and marked hypothermia (see ch. 49).

In addition to the physical examination, a number of diagnostic tests and monitoring parameters may be used to determine the severity of shock and to guide therapy. One of the basic tests that can be used in both diagnosis and monitoring is the blood pressure. Patients in decompensated shock will often have a decreased blood pressure (see ch. 99). Central venous pressure may also be of utility in guiding therapy, especially in judging the response of the patient to intravenous fluids (see ch. 76). Blood lactate measurement is another valuable tool (see ch. 70). Animals with shock will tend to have an increased lactate level. Lactate is also useful in guiding therapy, with the goal of normalizing lactate as promptly as possible. Normal lactate is less than 2.5 mmol/L and an elevation greater than 7.0 mmol/L would be considered severe.[22-24] While some confounding factors such as liver disease and sample collection may affect lactate measurements, it is still an important part of the management and diagnosis of the shock patient.[22,23] Base excess is another value that has been shown to be of value in humans with shock and recently was correlated with transfusion requirements and mortality in veterinary patients with blunt trauma.[25] Mixed venous oxygen saturation (SvO_2) and central venous oxygen saturation ($ScvO_2$) are two additional values that are closely monitored in human shock resuscitation. Because the measurement of SvO_2 requires sampling from the pulmonary artery, $ScvO_2$ which is taken from the cranial vena cava is more readily accessible. A decrease in $ScvO_2$ is indicative of either a decrease in DO_2 or an increase in VO_2 while an increase in $ScvO_2$ may be seen with cytopathic hypoxia. Because the normal OER is about 25%, a goal of an $ScvO_2$ of greater than 70% is recommended.[13,18,26] A study in critically ill veterinary patients showed a failure to normalize $ScvO_2$ despite the normalization of the more traditional parameters that we seek to correct in shock.[26] A final area of interest is the direct visualization of the microcirculation using side-stream darkfield imaging. This methodology allows for the capillary density as well as the proportion of perfused capillaries and increases in heterogeneity of blood flow to be evaluated in readily accessible areas such as the sublingual area in humans. Abnormalities detected with this type of imaging have been associated with negative outcomes in human medicine.[13]

Treatment

The treatment of shock can be distilled down to the idea of improving oxygen delivery as soon as possible; there is a narrow therapeutic window before cellular energetics become deranged and cannot be reversed. In humans, this early goal directed therapy has been shown to be of considerable benefit and in veterinary medicine there is evidence that it is a desirable goal as well.[13,27] With the equations for DO_2 and CO in mind, treatment can be approached logically. Fluid therapy is indicated for most forms of shock with the exception of cardiogenic. Here the goal is to normalize blood pressure, central venous pressure, and the physical

parameters of heart rate, pulse quality, capillary refill time, mentation and urine output (Figure 127-1). In most instances a balanced crystalloid solution is reasonable but synthetic colloids and hypertonic saline can also be used. In the case of the shock patient with head trauma, hypertonic saline is the preferred fluid for resuscitation.[28,29] "Small volume resuscitation," which is also known as limited volume resuscitation, uses resuscitative fluids in small volumes to achieve moderate increases in hemodynamic stability. In this type of resuscitation, synthetic colloids and hypertonic saline take center stage as they allow for expansion of the effective circulating volume in excess of the administered fluid volume. The goal here is to minimize the deleterious effects seen with over-aggressive crystalloid resuscitation.[30] If the animal is not responsive to fluid therapy or the animal is deemed to be volume replete, a catecholamine vasopressor such as dopamine or norepinephrine may be considered. Another option would be the drug vasopressin, which may be efficacious in patients that are refractory to other pressor agents.[20] If the patient has cardiogenic shock, fluids should be avoided and instead drug therapy with an inotrope or antiarrhythmic may be indicated to improve cardiac function. Other treatment goals include the maximization of hemoglobin saturation with oxygen therapy and if the animal is anemic, blood products should be used to increase hemoglobin concentration (see ch. 130). If additional abnormalities are identified such as hypoglycemia or intoxications, these issues must also be addressed promptly. Early recognition of shock and prompt therapy to restore oxygen delivery to the tissues are key in the successful treatment of shock (Figure 127-1).

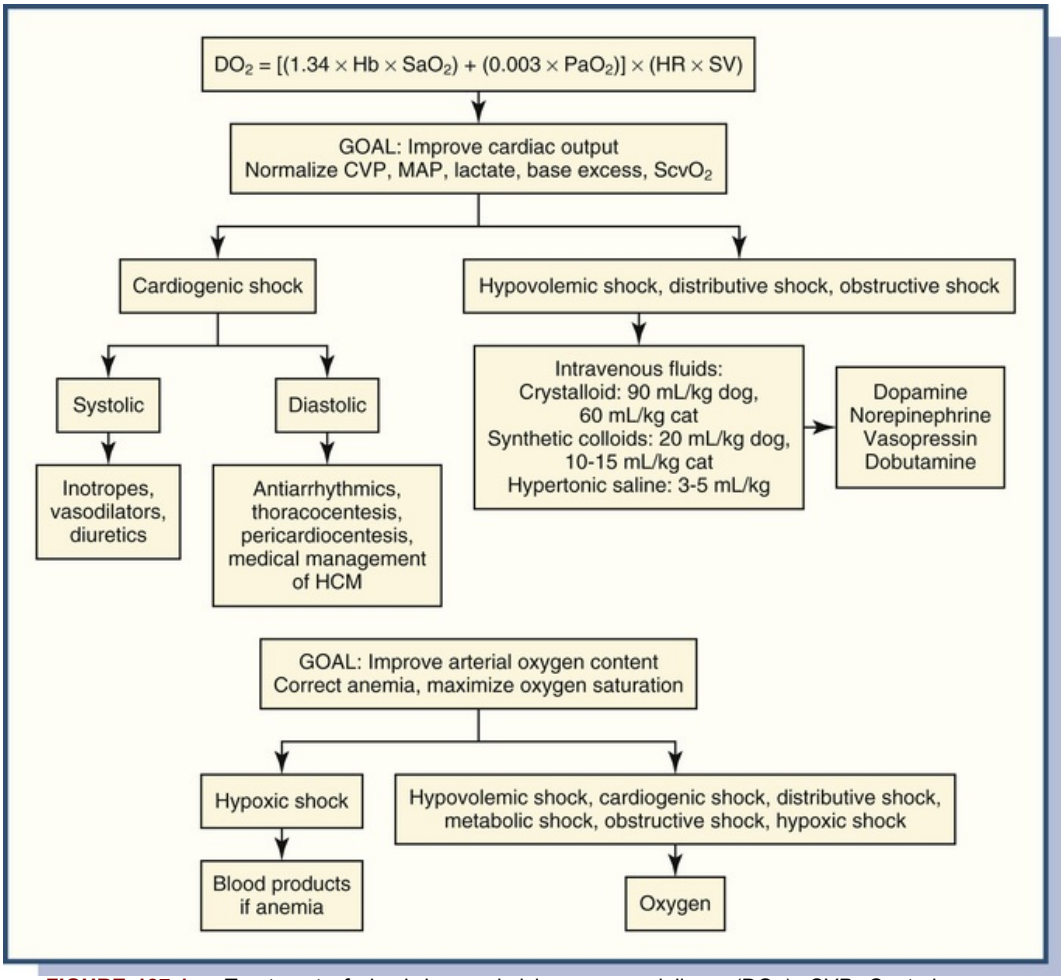

FIGURE 127-1 Treatment of shock by maximizing oxygen delivery (DO_2). *CVP,* Central venous pressure; *HCM,* hypertrophic cardiomyopathy; *MAP,* mean arterial pressure.

CHAPTER 128

Acid-Base, Oximetry, and Blood Gas Analysis

Marie E. Kerl

Acid-base and oxygenation disorders are common in dogs and cats with respiratory or metabolic abnormalities secondary to trauma, intoxication, or naturally occurring disease. Accurate point-of-care testing devices are widely available and affordable, making blood-gas testing a standard of care for emergency and specialty practices. Correct test interpretation and appropriate therapeutic response rely on maintaining a working knowledge of both acid-base and respiratory physiology and pathophysiology.

Blood gas testing may be performed using either arterial or venous blood. However, only arterial blood can be used to assess oxygenation; acid-base parameters other than partial pressure of oxygen (PO_2) may be evaluated using either arterial or "mixed venous" samples. The term "mixed venous" refers to venous blood collected from the main pulmonary artery, which is obviously not practical in a clinical setting. Jugular or peripheral venous blood is used, since those samples are easier to obtain (see ch. 75 and 76). Samples should be drawn into syringes that are coated with 1 : 1000 heparin to prevent clot formation, or into specialized blood gas syringes (Vital Signs, Englewood, CO) containing pelleted heparin (Figure 128-1, *A* and *B*). The syringe should be made airtight immediately following collection to prevent contamination with room air, which could alter gas measurements. The sample should be analyzed within 15 minutes of collection or placed on ice.

FIGURE 128-1 **A,** Arterial blood gas sampling kits contain a heparinized syringe and devices to render the syringe impervious to air. The advantage of these syringes is that arterial pressure will cause blood to fill the syringe chamber to the level at which the plunger is drawn. **B,** The syringe in the arterial blood gas sampling kit contains pelleted heparin as an anticoagulant in a sufficient amount to anticoagulate the maximum quantity of blood in the syringe.

Basic Acid-Base Physiology

An acid is a hydrogen ion (H^+, i.e., proton) donor, and a base is a proton acceptor. Hydrogen ions are nonvolatile or fixed acids produced by normal metabolism of proteins and phospholipids, and excreted by the kidneys. Acids are represented by the notation HA, which signifies a hydrogen ion and any negatively charged particle. When placed in solution, HA dissociates into H^+ (acid) and A^- (base). A base combines with an acid to lower the amount of acid in solution, or to buffer the solution.

Carbon dioxide (CO_2) is a volatile acid, or fat-soluble gas, that can combine with water in the presence of carbonic anhydrase to form carbonic acid (H_2CO_3). Carbon dioxide is formed during normal carbohydrate and fat metabolism and is excreted via the respiratory system. These two sources of acid (H^+ and CO_2) are interrelated, as is shown in the carbonic acid equation:

$$H^+ + HCO_3^- \leftrightarrow H_2CO_3 \leftrightarrow H_2O + CO_2$$

This chemical reaction can proceed in either direction, depending on the availability of substrate on either side of the equation. Carbonic anhydrase catalyzes this reaction, and this enzyme is found widely in multiple body tissues and on red blood cells.

By definition, *pH* is the negative log of the hydrogen ion concentration. An acid gain results in a decrease in blood pH (acidemia), whereas an acid loss results in an increased pH (alkalemia). Acid can be gained

systemically from reduced renal elimination of a naturally occurring compound or from ingestion of an exogenous acid source. Changes in CO_2 influence the H^+ concentration, as evidenced by the carbonic acid equation. As CO_2 is eliminated by increasing respiratory rate and alveolar ventilation, carbonic acid dissociates to form more CO_2. In turn, H^+ and bicarbonate (HCO_3^-) combine to form more carbonic acid. Elimination of CO_2 through ventilation effectively lowers the H^+ concentration and increases pH. Conversely, as CO_2 concentration increases from hypoventilation, pH decreases.

Buffers act to bind H^+, preventing large fluctuations in pH. Buffer systems include nonbicarbonate buffers (proteins and phosphates), which are primarily intracellular, and HCO_3^-, which is the primary extracellular buffer. Bicarbonate is an effective buffer because it exists in relatively large concentrations compared with other buffers, is generated by renal tubular cells, and participates in the carbonic acid equation to produce CO_2 that can be eliminated through ventilation. The HCO_3^- buffer system, therefore, is considered an open system that can continue to buffer as long as the respiratory system is functional. In disease states causing HCO_3^- to be lost excessively from the urinary or gastrointestinal (GI) system, CO_2 and H_2O combine to form carbonic acid, which dissociates to increase H^+ and causes acidemia. For more in-depth discussion, readers are referred to references provided.[1-3]

Acid-Base Disorders

According to the Henderson-Hasselbalch equation, which is

$$pH = 6.1 + \log(HCO_3^- / (0.03 \times PCO_2))$$

pH can be characterized by changes in HCO_3^- and partial pressure of carbon dioxide (PCO_2). Because a predictable change in HCO_3^- occurs with gain or loss of H^+ ions, HCO_3^- can be used for correctly identifying acid-base abnormalities arising from metabolic disorders. Acidemia or alkalemia resulting from a primary respiratory disorder will show a corresponding change in PCO_2. Increases in PCO_2 occur with respiratory acidosis, and decreases in PCO_2 occur with respiratory alkalosis. In metabolic acidosis, acid accumulation results in gain of H^+ that is buffered by bicarbonate, resulting in low measured HCO_3^-; and in metabolic alkalosis, an H^+ decrease has the opposite effect. Commonly available commercial blood gas analyzers typically measure pH and PCO_2 and calculate HCO_3^-.

This equation also can be used for predicting the way compensatory mechanisms engage to lessen the degree of change in pH. When metabolic acidosis develops, the respiratory system is stimulated to increase the respiratory rate to eliminate CO_2 from the lungs and create respiratory alkalosis. Likewise, with a primary respiratory disorder, the opposite metabolic disorder is generated. The respiratory system provides rapid compensation, changing with the onset of a metabolic disorder in minutes. Metabolic compensation occurs more slowly, taking days before becoming maximally effective. With either system, compensatory mechanisms should slow as the pH approaches normal, and compensation should never completely normalize the pH.

Base excess, which is expressed in milliequivalents per liter (mEq/L), is the amount of base above or below the normal buffer base, a value calculated by taking into account the expected change in HCO_3^- secondary to acute changes in PCO_2. The general rule of thumb is that the HCO_3^- concentration rises about 1 to 2 mEq/L for each acute 10 mm Hg increase in $PaCO_2$ above 40 mm Hg, to a maximum increase of 4 mEq/L, and that the HCO_3^- concentration falls 1 to 2 mEq for each acute 10 mm Hg decrease in $PaCO_2$ below 40 mm Hg, to a maximum decrease of 6 mEq/L. This negative base excess may be referred to as a *base deficit*.

By convention, a simple acid-base disorder is limited to the primary disorder and the appropriate compensatory response. A mixed disorder is one in which at least two separate abnormalities occur simultaneously. These abnormalities can both result in acidosis (i.e., metabolic acidosis and respiratory acidosis), can both result in alkalosis (i.e., metabolic alkalosis and respiratory alkalosis), or can be a combination of acidosis and alkalosis (e.g., metabolic acidosis and respiratory alkalosis). It takes cautious examination of a patient and blood gas results to avoid attributing the latter scenario to simple compensation.

Normal values at sea level for venous blood gas interpretation are pH, 7.35 to 7.45; PCO_2, 40 to 45 mm Hg; and HCO_3^-, 19 to 24 mEq/L. Base excess normally should be −5 to 5 mEq/L. An algorithm for interpretation of blood gas values is provided in Figure 128-2.

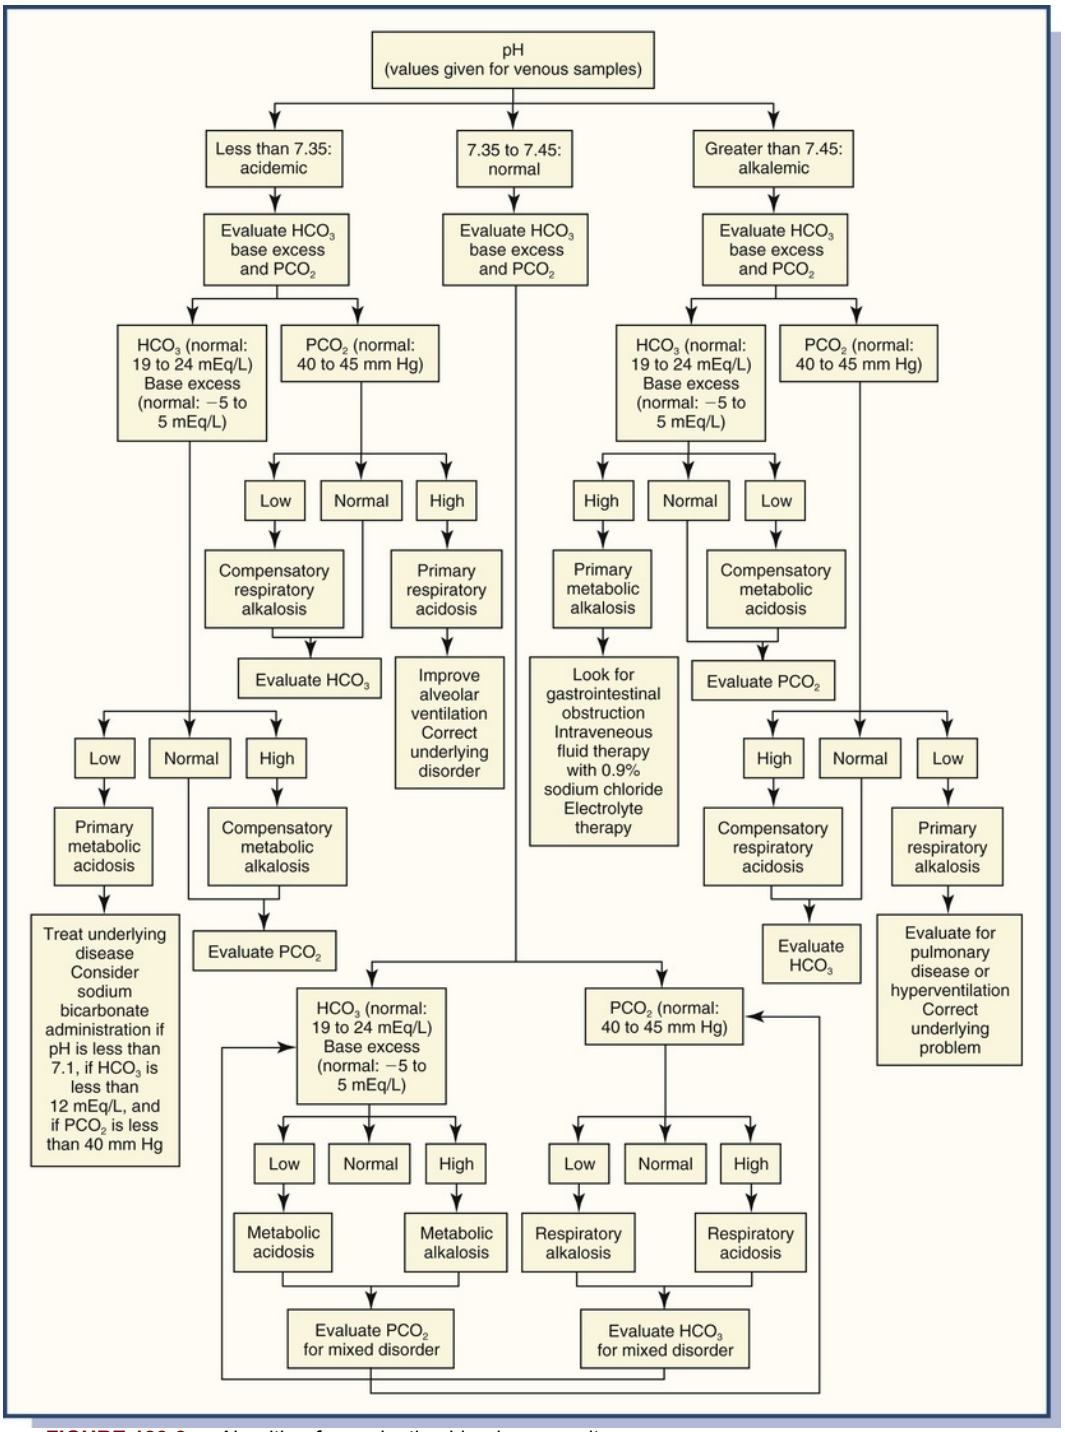

FIGURE 128-2 Algorithm for evaluating blood gas results.

Respiratory Acidosis

Respiratory acidosis results from an increased partial pressure of CO_2 in the blood (hypercapnia). Hypercapnia can be caused by any condition that prevents normal pulmonary gas exchange, including

impaired circulation, reduced respiratory rate or effort, circulation of blood to nonventilated portions of the lung, or impaired gas diffusion. Diffusion impairment is the least likely cause of hypercapnia, because CO_2 is ≈20 times more diffusible than is oxygen. Therefore, profound diffusion impairment is necessary before hypercapnia results. Disorders that can cause respiratory acidosis include circulatory failure from cardiopulmonary arrest, nervous system disease (central, spinal, or neuromuscular junction), respiratory muscle failure (e.g., severe hypokalemia), physical impairment of ventilation (e.g., pleural space disease, pain, thoracic wall disease, external constriction), or primary pulmonary disease (e.g., alveolar flooding, interstitial disease, pulmonary thromboembolism).[4] Iatrogenic respiratory acidosis results from inadequate ventilatory monitoring and assistance under general anesthesia.

Clinical signs of hypercapnia are consistent with the disorder that is causing hypoventilation. While some causes of hypoventilation are easier to detect clinically (e.g., upper airway obstruction), others present a greater diagnostic challenge. Lower motor neuron disease causing decreased chest wall movement can be difficult to identify without a complete neurologic examination (see ch. 259) and careful observation. End-tidal CO_2 can be monitored noninvasively in animals under general anesthesia when they have endotracheal tubes in place and are on closed-circuit breathing loops, or are receiving mechanical ventilation. In animals with regular respirations in which alveolar gas exchange is occurring, end-tidal CO_2 approximates $PaCO_2$.[5]

Treatment for respiratory acidosis involves correcting the underlying disorder by increasing alveolar ventilation. Chronic respiratory acidosis should be corrected slowly. Sodium bicarbonate should not be administered to treat respiratory acidosis because this drug exacerbates hypercapnia by donating substrate for the carbonic acid equation. Increasing the inspired oxygen concentration can be lifesaving; however, with severe hypercapnia, stimulation for respiration becomes driven by hypoxemia. In those situations, oxygen therapy and resolution of hypoxemia can result in decreasing the rate of voluntary respiration, which in turn can promote hypercapnia. The hypoxic drive for respiration remains adequate below a dissolved oxygen content of arterial blood (PaO_2) of 60 mm Hg. It is not necessary to administer supplemental oxygen with the goal of normalization of oxygenation.

Respiratory Alkalosis

Respiratory alkalosis results from an increase in ventilation through which more CO_2 is eliminated than is produced by normal metabolic function. Hypocapnia develops, and alkalemia ensues. Causes of respiratory alkalosis include hypoxemia produced by pulmonary, circulatory, or other abnormalities that result in hyperventilation; primary pulmonary diseases that stimulate ventilation independently of hypercapnia; central nervous system disorders; and iatrogenic tachypnea/hyperpnea in animals receiving assisted ventilation. Chronic respiratory alkalosis is usually well-compensated.

Treatment of animals with respiratory alkalosis primarily is aimed at the underlying cause of tachypnea or hyperpnea (e.g., treatment for bacterial pneumonia, resolution of anxiety-associated tachypnea via administration of a sedative). As with respiratory acidosis, there are few clinical signs suggesting this specific acid-base disorder. Oxygen supplementation (see ch. 131) can be useful in support of these animals while the underlying disease is addressed.

Metabolic Acidosis

Metabolic acidosis often results from a gain of H^+ through ingestion of an acid into the body, increased production of an endogenous acid, or failure to eliminate an acid load by the renal tubular cells. Metabolic acidosis also can be caused by a loss of HCO_3^- buffering ability. Differentiating these two causes of metabolic acidosis is important both for the diagnosis of the underlying disorder and for determining the correct therapeutic intervention.[6]

Dissociation of acid into the H^+ ion and the corresponding anion occurs in the circulation. When acid accumulates, HCO_3^- combines with H^+ to buffer the acid load, while the anion remains in solution. Because electroneutrality must be maintained as anions accumulate following acid dissociation, some other circulating anion must decrease correspondingly. The anion gap (AG), the difference between measured cations and measured anions, is useful in the classification of disorders causing metabolic acidosis. Anion gap, which is calculated from four common cations and anions measured on a serum biochemistry profile, is calculated using the following formula:

$$AG = [Na^+ + K^+] - [Cl^- + HCO_3^-]$$

Although ranges for AG can vary somewhat based on the reference ranges of serum electrolyte concentrations for various laboratories, a reference value of 16 ± 4 mEq/L is typical. When metabolic acidosis exists with an increased AG, there usually has been a gain of organic acid. Causes of anion gap metabolic acidosis include ethylene glycol intoxication, uremia, tissue hypoxia (e.g., lactic acidosis), diabetic ketoacidosis, salicylate intoxication, and other unusual intoxications (e.g., drugs, alcohol). Metabolic acidosis characterized by a normal anion gap is caused by loss of bicarbonate buffers or a failure to excrete H^+ ions, with a corresponding increase in chloride to maintain electroneutrality. This often is referred to as a *hyperchloremic metabolic acidosis*. Hyperchloremic metabolic acidosis occurs less commonly than metabolic acidosis with an increased anion gap, and is caused by renal tubular acidosis (failure of the renal bicarbonate buffer or hydrogen excretory system) or by severe diarrhea and loss of intestinal bicarbonate.[7] Iatrogenic hyperchloremic metabolic acidosis also can occur with administration of an alkali-free chloride-containing crystalloid solution, such as 0.9% sodium chloride (0.9% NaCl) for intravenous volume replacement.

Abnormalities associated with metabolic acidosis include lethargy, decreased cardiac output, systemic hypotension, and decreased hepatic and renal blood flow. These changes can be referable to the acidemia, to the underlying disorder causing the acid-base disorder, or both. Unless the patient has some impairment of normal ventilatory ability, compensatory mechanisms cause an increase in the respiratory rate, which allows the animal to eliminate CO_2 generated by carbonic acid formation, mitigating acidosis.

One study has described the incidence, nature, and etiology of metabolic acidosis in ill and injured dogs and cats. Blood gas values from dogs and cats were reviewed retrospectively when they presented for emergency care at a university teaching hospital over a 13-month period. Metabolic acidosis was defined as a standardized base excess (SBE) in dogs of <−4 mmol/L and in cats <−5 mmol/L. A total of 1,805 dogs and cats were included; of these, 887 (49%) had a metabolic acidosis (753 dogs, 134 cats). Primary metabolic acidosis was the most common disorder in dogs, whereas the mixed acid-base disorder of metabolic acidosis and respiratory acidosis was most common in cats. Hyperchloremic metabolic acidosis was more common than a high AG metabolic acidosis; 25% of dogs and 34% of cats could not be classified as having either a hyperchloremic metabolic acidosis or a high AG metabolic acidosis. Metabolic acidosis was associated with a wide variety of disease processes. Mixed acid-base disorders occurred frequently in this population and routine categorization of metabolic acidosis based on the presence of high AG or hyperchloremia could be misleading in a large proportion of cases.[8]

A second study reviewed blood gas results obtained following cardiopulmonary arrest in dogs and cats at a university teaching hospital. Venous samples were obtained either during cardiopulmonary resuscitation (CPR, 24 samples) or following return of spontaneous circulation (ROSC, 18 samples). Changes indicating metabolic acidosis and hyperlactatemia were present in all samples, and increased PCO_2 was identified in 88% of samples collected during CPR and in 61% of samples obtained following ROSC. Hyperkalemia was seen in 65% of the samples. When compared to samples obtained during CPR, samples obtained within 5 minutes of ROSC had a higher pH and venous PO_2.[9]

Treatment should be aimed at correcting the underlying disorder, which typically involves improving tissue perfusion (e.g., appropriate intravenous fluid therapy), eliminating ingested toxin, and/or correcting metabolic, renal, or GI disease. Intravenous fluid treatment with a balanced electrolyte solution is a reasonable choice to manage most etiologies of small animal metabolic acidosis, since these fluids provide a buffer that is converted to bicarbonate. With severe metabolic acidosis (pH <7.15 and HCO_3^- <12 mEq/L), injectable sodium bicarbonate may be administered judiciously according to the following formula:

$$\text{Bicarbonate dosage (mEq)} = 0.3 \times \text{body weight (kg)} \times \text{base deficit}$$

Half of this dose should be administered slowly intravenously over 6 hours, and the acid-base status should be reevaluated prior to continuation of therapy. Rapid correction of metabolic acidosis can cause a number of undesired side-effects, including hyperosmolarity, hypernatremia, and hypokalemia. Hypocalcemic tetany (see ch. 298) can be caused by shifting of calcium from the ionized to the complexed form after bicarbonate administration. Paradoxical central nervous system acidosis occurs when CO_2 generated following bicarbonate administration crosses the blood-brain barrier and provides substrate for conversion to carbonic acid and hydrogen ions, essentially fueling acid production in the central nervous

system. Iatrogenic metabolic alkalosis also can occur after administration of bicarbonate.

Metabolic Alkalosis

Metabolic alkalosis is generated by loss of chloride in excess of extracellular fluid volume, which often occurs as a result of upper GI fluid loss or sequestration. Administration of a thiazide diuretic also can cause chloride wasting. Rarely, metabolic alkalosis could be caused by overzealous administration of sodium bicarbonate or another organic anion, or by hyperaldosteronism (i.e., Conn's syndrome), which causes sodium retention in excess of chloride. The most common clinical problem associated with metabolic alkalosis in small animal practice is gastric outflow obstruction. During gastric outflow obstruction, appropriate renal compensation prevents an acid-base disorder until hypovolemia induced by vomiting results in aldosterone release. Aldosterone increases renal uptake of sodium. Normally, sodium is reabsorbed with bicarbonate or chloride, or is exchanged for potassium. Because gastric fluid has high chloride and potassium concentrations, animals with gastric outflow obstruction become systemically depleted of these electrolytes so that renal reabsorption of sodium can only occur with concurrent bicarbonate uptake.

As with other acid-base disorders, clinical signs of metabolic alkalosis are dictated by the underlying disorder generating the acid-base abnormality. Muscle twitching and seizures have been reported in animals with metabolic alkalosis. Signs associated with concurrent potassium depletion can include weakness, cardiac arrhythmias, renal dysfunction, and GI motility disturbances (see ch. 68).

Treatment of metabolic alkalosis is directed at resolving the underlying cause. Intravenous 0.9% NaCl is the fluid of choice to replace volume deficits and normalize chloride concentrations since these patients often are chloride-depleted. Fluids should not contain buffer (e.g., not lactated Ringer's solution). Pyloric outflow obstruction often is addressed through surgical modification of the pylorus, or by removal of an obstructing foreign body. In animals with profuse vomiting not associated with obstruction, drug therapy to minimize gastric hydrochloric acid excretion could be warranted (e.g., famotidine, omeprazole). Because animals with metabolic alkalosis often have concurrent hypokalemia, cautious intravenous potassium chloride supplementation often is indicated.

Oxygenation

Hypoxemia can occur as a result of a low concentration of inspired oxygen, hypoventilation, diffusion impairment, ventilation-perfusion mismatch, or pulmonary shunting.[4] Two methods are available to assess oxygenation in an emergency setting: measurement of PaO_2 and measurement of peripheral oxygen saturation (SpO_2) by pulse oximetry. A pulse oximeter is a noninvasive device that calculates hemoglobin oxygen saturation by measuring differences in absorption of two wavelengths of light (red and infrared) by oxygenated and deoxygenated hemoglobin (see ch. 98). The measured light absorption values are applied to a preset nomogram, and a value for SpO_2 is determined. If tissue perfusion is adequate, SpO_2 approximates arterial hemoglobin saturation (SaO_2).[5]

The advantage of oximetry as a monitoring tool is that it provides continuous, noninvasive determination of hemoglobin oxygen saturation. Technical aspects that help ensure accuracy include placing the probe on nonpigmented, moist skin with adequate perfusion (usually the tongue, the buccal, vaginal, or preputial mucosa, or the ear pinna), avoiding probe movement and light pollution, and monitoring the pulse rate to ensure accurate pulse signal transmittance. In poorly perfused tissues, the SpO_2 can be falsely low compared with the SaO_2. If inaccuracy of oximetry is suspected, the arterial blood gas PaO_2 should be obtained to evaluate oxygenation (see ch. 75). In patients with alterations of hemoglobin concentration causing increased carboxyhemoglobin or methemoglobin, oximetry can be normal despite severe patient hypoxemia. Oximetry does not evaluate the PCO_2 and cannot be used for determining ventilation status.

The hemoglobin saturation of oxygen and partial pressure of oxygen (PaO_2) both contribute to arterial oxygen content (CaO_2) according to the following formula:

$$CaO_2\ (O_2\ mL/dL) = \{SaO_2\ (\%) \times \text{hemoglobin}\ (g/dL) \times 1.34\ (O_2\ mL/g)\} + \{PaO_2\ (mm\ Hg) \times 0.003\ (O_2\ mL/dL/mm\ Hg)\}$$

Therefore, SpO_2, which approximates SaO_2, provides an estimation of hemoglobin saturation, whereas PaO_2 estimates dissolved oxygen in blood. According to the formula listed, hemoglobin saturation is the biggest determinant of arterial oxygen content. Increasing the PaO_2 by increasing the inspired oxygen concentration has a minimal effect on blood oxygen content, whereas increasing the SaO_2 has a greater potential effect. In an anemic patient, increasing the arterial oxygen content would best be accomplished by increasing hemoglobin by transfusion of a product containing red blood cells (see ch. 130).

According to the oxyhemoglobin dissociation curve, an SaO_2 of 90% corresponds to a PaO_2 of 60 mm Hg. This value is clinically important in that small decreases beyond this point in either partial pressure of oxygen or oxygen saturation of hemoglobin can have tremendous clinical consequences for oxygenation. The goal of treatment for hypoxemia is to maintain the SpO_2 above 90% and the PaO_2 above 60 mm Hg. Sometimes this can be accomplished through supplemental oxygen therapy. Methods of increasing the inspired oxygen content include use of an oxygen chamber, tent or mask administration, placement of an indwelling nasal oxygen catheter, or mechanical ventilation with an increased fraction of inspired oxygen (see ch. 131). Other methods to correct hypoxemia are related to correcting the underlying cause. For instance, hypoxemia in an animal with severe pneumothorax or pleural effusion would be accomplished through thoracic drainage while hypoxemia related to airway obstruction would be addressed by relief of the obstruction.

CHAPTER 129

Crystalloid and Colloid Fluid Therapy

Christopher G. Byers

Client Information Sheet: Crystalloid and Colloid Fluid Therapy

Fluid Distribution and Microvascular Barrier

Fluid Compartments

Total body water (TBW) comprises 60% of body weight.[1] The two main fluid compartments in the body are the intracellular fluid (ICF) and extracellular fluid (ECF). The ICF compartment comprises approximately 60% of TBW and the ECF compartment makes up the other 40% (Figure 129-1).[1] Intracellular fluid is found inside the bi-layered cell plasma membrane and is in osmotic equilibrium with the ECF. While ICF and ECF differ markedly in electrolyte composition, their osmolalities are essentially equal due to the high water permeability of most cell membranes.

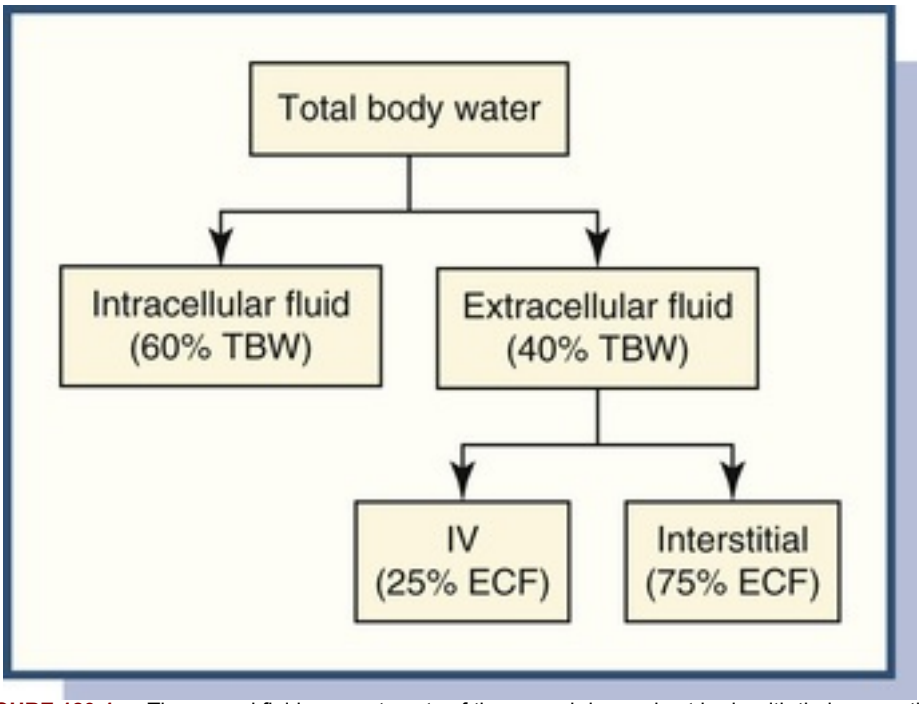

FIGURE 129-1 The normal fluid compartments of the normal dog and cat body with their respective contributions to total body water. *ECF*, Extracellular fluid; *IV*, intravascular; *TBW*, total body water.

The ECF is divided into three chambers: the interstitial compartment, the intravascular compartment, and the third space (see Figure 129-1).[1] The interstitial compartment is the fluid space that surrounds cells and allows movement of ions, proteins, and nutrients across cell membranes. Approximately 75% of ECF is located in the interstitial compartment and is continuously turned over and recollected by the lymphatic vessels. The intravascular compartment comprises approximately 25% of the ECF, and fluids do not normally

collect in the third space.[1] Common examples of the third space, also referred to as transcellular fluid, are the peritoneal fluid, pleural fluid, cerebrospinal fluid, aqueous humor of the eye, fluid within the digestive tract, synovial fluid, and renal tubular fluid.

Traditional Starling's Forces

Movement of fluid across capillary walls is essential for maintaining a continuous exchange of oxygen and carbon dioxide between the body's cells and the blood supply. As mentioned earlier, fluid within the body is contained in distinct compartments; some resides in cells (intracellular compartment), some resides around the cells (interstitial fluid), and some resides within blood vessels (intravascular space).[1] There is a continuous exchange between these compartments that provides nourishment to cells and removes waste products. Two major forces, hydrostatic pressure and oncotic pressure, are involved that work against each other to produce this fluid movement.

Hydrostatic pressure is the pressure exerted by any fluid in a confined space. If fluid is in a container, there will be some pressure applied to the wall of that container. If one pictures a column-shaped container, one can see the pressure pushing against its wall is greater at the bottom than at the top partly due to the force of gravity. Capillaries are the equivalent of a column-shaped container turned on its side. As fluid moves through a capillary, hydrostatic pressure causes fluid to move into the interstitial compartment. This movement also means the hydrostatic pressure decreases as the blood moves from the arteriolar to the venous end of the capillary. The fluid pushed out through the capillary wall by hydrostatic pressure is called filtrate.

Another force that contributes to fluid movement across capillary walls is oncotic pressure. Blood contains plasma proteins that displace some water in blood, and less water in the intravascular compartment creates a concentration gradient between the intravascular and interstitial spaces. Plasma proteins seemingly pull water into the intravascular compartment while the force of osmosis equalizes the amount of water in the intravascular compartments and the interstitial fluid.

The relationship between hydrostatic pressure and oncotic pressure to promote fluid movement across capillary walls can be described by the following equation[2]:

$$J_v = K_f([P_c - P_i] - \sigma[\pi_c - \pi_i])$$

where:

- J_v is the net fluid movement between compartments
- K_f is the filtration coefficient
- P_c is capillary hydrostatic pressure
- P_i is interstitial hydrostatic pressure
- σ is the reflection coefficient
- π_c is capillary oncotic pressure
- π_i is interstitial oncotic pressure

Endothelial Glycocalyx

According to traditional Starling's forces, hydrostatic pressure pushes water out of capillaries and oncotic pressure pulls fluid into the intravascular compartment.[2] The difference between these pressures decides whether water leaves capillaries or is pulled back into them. Since Dr. Starling originally published his hypothesis, further research regarding fluid dynamics has emerged. We now know the luminal surface of endothelial cells is lined with a glycocalyx of membrane-bound macromolecules comprised of sulfated proteoglycans, hyaluronan, glycoproteins, and plasma proteins; simply the key role of the endothelial glycocalyx (EGC) was not appreciated by Dr. Starling, but it is a vital regulator of vascular permeability.[3]

The high resorption of interstitial fluid in the venular segments of the microcirculation postulated by Dr. Starling does not happen. Filtration across the vascular barrier is largely independent of the bulk colloid concentration surrounding the vessel. In regions with high intravascular pressure, the inwardly directed oncotic pressure gradient across the EGC prevents flooding of the interstitial space in conjunction with the

high resistance to flow within the narrow strand gaps of the endothelium.[3] Within low-pressure sections, free and easy access of plasma constituents toward the parenchymal cells allows a highly effective exchange of nutrients and waste products, but the fluid shift is modest if the endothelial surface layer is intact because of the low hydrostatic and oncotic pressure gradients in these segments.[3]

The EGC is present throughout a diverse range of microvascular beds and macrovessels. The principal role of the EGC is to maintain the vascular permeability barrier.[3] Other meaningful roles of the endothelial glycocalyx include shielding vascular walls from direct exposure to blood flow and mediating shear-stress-dependent nitric oxide production by the endothelium.[3] The EGC also promotes retention of vascular protective enzymes (i.e., superoxide dismutase) and helps preserve the intravascular concentration of coagulation inhibition factors (i.e., antithrombin, the protein C system and tissue factor pathway inhibitor) in the endothelium.[3] The EGC also helps modulate the inflammatory response by preventing leukocyte adhesion and binding of chemokines, cytokines and growth factors in the endothelium.[3]

Tissue Safety Factors

Extracellular edema forms as excess fluid accumulates in the interstitial compartment; this accumulation occurs as a result of abnormal leakage from the intravascular compartment to the interstitial compartment and/or a failure of the lymphatics to return fluid from the interstitium to the intravascular compartment. Altered capillary filtration occurs due to an increased capillary filtration coefficient, increased capillary hydrostatic pressure (i.e., excess renal retention of water and sodium; elevated venous pressure and constriction; decreased arteriolar resistance) and/or decreased capillary oncotic pressure (i.e., loss of and/or reduced production of plasma proteins). Inadequate lymphatic return of fluid to the intravascular compartment occurs secondary to neoplasia, various infections, postoperative complications and/or congenital/developmental abnormalities.

Several mechanisms exist in the body to help prevent the formation of extracellular edema.[4] The interstitial compartment does not accommodate a large volume of fluid, and thus the interstitial hydrostatic pressure increases rapidly to prevent further extravasation.[5] Increased movement of fluid from the intravascular compartment to the interstitium reduces the interstitial oncotic pressure; combined with increased lymph flow, albumin is washed out of the interstitium, thus reducing the interstitial oncotic pressure.[6] Lastly, increased interstitial pressure drives augmented lymph flow that helps remove the fluid.[7]

Fluid Types

Crystalloids

Crystalloids contain variable amounts of electrolytes, water and dextrose (Table 129-1); crystalloids may also be characterized by tonicity and their effect on acid-base status. Crystalloids are used either to *replace* sodium loss or *maintain* the status quo. *Replacement* fluids contain sodium at concentrations similar to normal plasma (≈140 mmol/L) while *maintenance* fluids have sodium concentrations similar to normal total body concentration (70 mmol/L). Replacement crystalloids and maintenance crystalloids may also be classified as isotonic and hypotonic, respectively (Table 129-2). Approximately one-third of administered isotonic replacement fluid remains in the intravascular space and two-thirds enter the interstitial space.

TABLE 129-1

Composition of Commonly Available Crystalloids Used in Dogs and Cats

FLUID	pH	Na^+ (mEq/L)	Cl^- (mEq/L)	K^+ (mEq/L)	Mg^{2+} (mEq/L)	Ca^{2+} (mEq/L)	GLUCOSE (g/L)	OSMOLARITY (mOsm/L)	BUFFER (mEq/L)
0.9% NaCl	5.0	154	154	0	0	0	0	308	0
Normosol-R	6.4	140	98	5	0	3	0	296	Acetate 27
Veterinary Plasma-Lyte A	7.4	140	98	5	3	0	0	294	Acetate 27
LRS	6.5	130	109	4	0	3	0	272	Lactate 28

0.45% NaCl	5.0	77	77	0	0	0	0	154	0
D5W	4.0	0	0	0	0	0	50	252	0
Normosol-M in 5% dextrose	5.5	40	40	13	3	0	50	364	Acetate 16
Plasma-Lyte M in 5% dextrose	5.5	40	40	16	3	5	50	376	Acetate 12

D5W, 5% dextrose in water; *LRS*, lactated Ringer's solution.

TABLE 129-2

Common Commercially Available Fluids Used in Dogs and Cats

FLUID TYPE	EXAMPLES
Isotonic crystalloid/replacement	0.9% sodium chloride Normosol-R Plasma-Lyte Lactated Ringer's solution (LRS)
Hypotonic crystalloid/maintenance	0.45% sodium chloride (with or without dextrose) 5% dextrose in water (D5W) 0.45% sodium chloride Normosol-M in 5% dextrose Plasma-Lyte M in 5% dextrose
Hypertonic saline	7% sodium chloride (HTS)
Colloids	Plasma (fresh frozen, frozen) Hydroxyethyl starches (i.e., Hespan, VetStarch) Human serum albumin (HSA) Canine serum albumin (CSA)

Common examples of *replacement* fluids are lactated Ringer's solution (LRS), Plasma-Lyte, Normosol-R and 0.9% sodium chloride. The first three have potassium concentrations similar to plasma and contain a lactate, acetate, or gluconate buffer to maintain a physiological pH. Animals, particularly cats, normally lose potassium through urine, and this loss is augmented during dehydration, aldosterone release and sodium conservation. Accordingly, replacement fluids should be supplemented with potassium when used long-term. Normal saline (0.9% sodium chloride) contains no potassium or buffers, and is the fluid of choice for hypercalcemia and hyperkalemia given it contains no calcium or potassium. Normal saline may exacerbate volume overload, metabolic acidosis, heart disease, and hypertension.

Maintenance fluids are simply designed to replace daily sodium losses and are appropriate for long-term administration. Dextrose is commonly supplemented to approximate plasma tonicity and prevent hemolysis. These lower-sodium fluids do not stay in the intravascular space, do not meaningfully expand blood volume, and thus should never be used for volume resuscitation.

Hypertonic saline may be used for rapid intravascular volume expansion, as it pulls fluid primarily from the interstitial compartment. Volume expansion is short lived, as the sodium redistributes throughout the extracellular compartment quickly. Hypertonic saline is available as both 7-7.5% and 23% solutions, and the latter must be diluted prior to administration. Do not administer hypertonic saline faster than 1 mL/kg/min to avoid vagally mediated bradycardia and potential cardiopulmonary arrest.

Colloids

Colloids are large molecules that remain in the intravascular space due to the Gibbs-Donnan equilibrium. Smaller volumes compared to crystalloids are required to achieve intravascular expansion, and thus when used appropriately are less likely to induce hemodilution, hypoproteinemia, extracellular edema and fluid overload.[8]

Synthetic colloids, most notably dextrans and hydroxyethyl starches (HES), contain high molecular weight particles that allow these fluids to increase colloid osmotic pressure (COP). As albumin is the main

contributor to COP, colloids are advantageous in the treatment of hypoalbuminemia due to their ability to increase COP. The HES most commonly used in veterinary medicine are hetastarch, pentastarch, and tetrastarch. The differences between hetastarch, pentastarch, and tetrastarch are the average molecular weight of the particles and the degree of substitution of glucose units on the starch particle with a hydroxyethyl group. Serum alpha-amylase degrades HES, and elimination occurs through the kidneys. Therefore, measured serum amylase levels will increase in patients receiving artificial colloid solutions.

Several numbers are used to describe unique qualities of HES solutions, including:

1. *Concentration:* Concentration mainly influences the initial volume effect. A common concentration, 6%, is iso-oncotic *in vivo*, and thus 1 L replaces 1 L of blood loss. Concentrations range from 6-10%.
2. *Mean molecular weight (MW):* Hetastarch has an average molecular weight (450 kDa), pentastarch (260 kDa) and tetrastarch (130 kDa). Larger molecules are degraded more slowly, and accordingly, solutions with a higher average molecular weight last longer.
3. *Molar substitution (MS):* Molar substitution refers to the modification of the original substance by the addition of hydroxyethyl groups. The higher the degree of molar substitution, the greater the resistance to degradation; consequently, the fluid remains in the intravascular space longer. A value of 0.7 indicates the HES preparation has an average of seven hydroxyethyl residues per 10 glucose subunits. Starches with this level of substitution are called hetastarches, and similar names are applied to describe other levels of substitution (0.4—tetrastarch; 0.5—pentastarch; 0.6—hexastarch).
4. *C2:C6 ratio:* The C2-C6 ratio refers to the site where substitution occurs on the initial glucose molecule. The higher the C2:C6 ratio, the longer is the T1/2 and subsequently the longer is the persistence in the blood. Synthetic colloids have been associated with side effects, including affecting coagulation and increasing the potential for volume overload due to the efficacy of expanding intravascular volume.

Hemoglobin-based oxygen carriers (HBOC; i.e., Oxyglobin) are ultra-purified, polymerized, stroma-free bovine hemoglobin products that promote oxygen off-loading at the tissue level and are potent colloids. The hemoglobin is suspended in a modified LRS solution, has an osmolality of 300 mOsm/L, and has a 3-year shelf life. Administration of HBOCs does not required blood typing and/or cross matching. The potential beneficial effects of HBOCs stem from their COP and vasoconstrictive properties; they are efficient scavengers of nitric oxide (NO) and thus can help combat severe vasodilation commonly observed in patients with systemic inflammatory response syndrome (SIRS), severe sepsis and septic shock.[9,10] Given these fluids are bovine products, one-time use is recommended because of the potential for antibody formation and subsequent immunologic reactions. HBOCs do cause a patient's mucous membranes, sclera and urine to turn red or yellow, and will affect colorimetric diagnostic blood and urine tests. The availability of HBOCs is currently extremely limited due to decreased commercial production.

Natural colloids are also available for infusion. Fresh frozen plasma (FFP) is collected and spun within 6 hours and frozen ideally at −70°C for up to 1 year. This fluid contains stable clotting factors (II, VII, IX, X), labile clotting factors (V, VIII), von Willebrand factor, fibrinogen and albumin; it does not contain red blood cells and platelets. Indications for FFP administration are replacement of all clotting factors, anticoagulant rodenticide intoxication, von Willebrand disease and hemophilia (A and B). A common dosage for replacement of clotting factors is 10-20 mL/kg. Frozen plasma (FP) is collected similarly to FFP but is stored for longer than 1 year. It contains stable clotting factors, fibrinogen and albumin, but does not contain red blood cells, platelets and labile clotting factors. Fresh plasma may be used for hemophilia B, and is administered at similar doses as for FFP. Use of FFP and FP to treat hypoalbuminemia is not practical or safe except in very small patients (cats, toy breed dogs) due to the potential for hypervolemia.

With progressive hypoalbuminemia, the COP similarly decreases, contributing to a fluid shift from the intravascular space to the interstitial space to potentially cause edema if tissue safety factors are overwhelmed. Serum albumin (SA) has been used in critically ill patients to help support blood pressure and to aid in the treatment of significant hypoalbuminemia. Currently two types of serum albumin are available for administration: human serum albumin (HSA) and canine serum albumin (CSA). Human serum albumin has been used successfully in both dogs and cats, but both acute and delayed immunologic reactions have been documented.[11,12] This product is available as a solution, and may be infused in 4-hour aliquots over 4-72 hours. Canine serum albumin is available as a lyophilized powder for reconstitution with sterile saline. Concentrations currently range from 4-25% and do not contain any preservatives and thus must be administered within 6 hours. Infused albumin remains in the intravascular space for 24 hours, and therefore close monitoring for fluid overload is required. The reported dosages for both HSA and CSA range from 100 mg/kg to 6.3 g/kg.

Fluid Plans

Hypovolemia vs. Dehydration

Hydration status is a measure of interstitial fluid content and is determined by evaluating skin turgor, moisture (or lack thereof) of the mucous membranes and possibly enophthalmos. Volume status is a measure of tissue perfusion and is initially evaluated by checking heart rate, capillary refill time (CRT), mucous membrane color and blood pressure (see ch. 99). Hypovolemic animals commonly have prolonged capillary refill times, tend to have pale mucous membranes and are often (but not always) hypotensive; while dogs may present with tachycardia, most cats either have normal heart rates or bradycardia. If hypovolemia is severe, one may see obtundation, weak peripheral pulses, and lack of venous distension when the veins are occluded. Hypovolemia may, of course, exist concurrently with dehydration but one must replace volume before rehydrating.

One should not treat hypovolemia by determining the patient's hydration status and then calculating (based on % dehydration and body weight) the fluid administration over the next 6-12 hours. Treatment of hypovolemia should be finished within 1-2 hours of presenting to the hospital. This type of resuscitation routinely requires rapid administration of large volumes of fluids intravenously. These are known as "shock boluses" of replacement crystalloids: 40-50 mL/kg for cats, 20-90 mL/kg for dogs (see below). Typically, one should give a portion (1/3 or 1/4 dose) of the total volume and then reassess endpoints of resuscitation to determine if more volume is truly necessary. Indiscriminate use of the terms dehydration and hypovolemia risks confusion and therapeutic errors. The pathophysiology of both dehydration and volume depletion must be understood if these conditions are to be properly recognized and appropriately treated whether they occur separately or together.

Route of Administration

Common routes of fluid administration in dogs and cats include intravenous (peripheral, central or peripherally inserted central [PIC]) catheters (see ch. 75 and 76), subcutaneous, enteral, intraosseous (see ch. 77), and intraperitoneal (see ch. 90 and 109). According to Poiseuille's Law, flow of non-compressible/Newtonian fluids, including blood, is maximal when diameter is widest and length is shortest. Accordingly for patients with hypovolemia, a short length and large bore intravenous catheter is recommended. If venous access is not immediately possible, the intraosseous route may be used until vascular access is achieved. Commonly accessed intraosseous sites in the emergency room are the proximal femur and cranial tibial crest (see ch. 77). The subcutaneous route is not appropriate for hypovolemic patients as peripheral vasoconstriction severely limits absorption. With mild dehydration, the subcutaneous route may suffice. Dextrose should not be delivered subcutaneously, and potassium delivered via this route may induce patient discomfort. Subcutaneous fluids are commonly administered at 10-20 mL/kg per site.

Enteral water supplementation is commonly used in the intensive care unit, but is generally under-utilized in veterinary medicine. Given that a patient's gastrointestinal tract is able to receive and handle fluids, enteral water may be used to help prevent villous atrophy, and may be combined with other forms of enteral nutritional support (see ch. 189).

Volume and Rate of Administration

When determining the most appropriate fluid volume and rate of administration, the astute clinician should ask the following questions (Figure 129-2):

- Is the patient hypovolemic?
- Is the patient dehydrated?
- What are the patient's daily physiologic requirements?
- Are there any ongoing losses? If yes, how much?

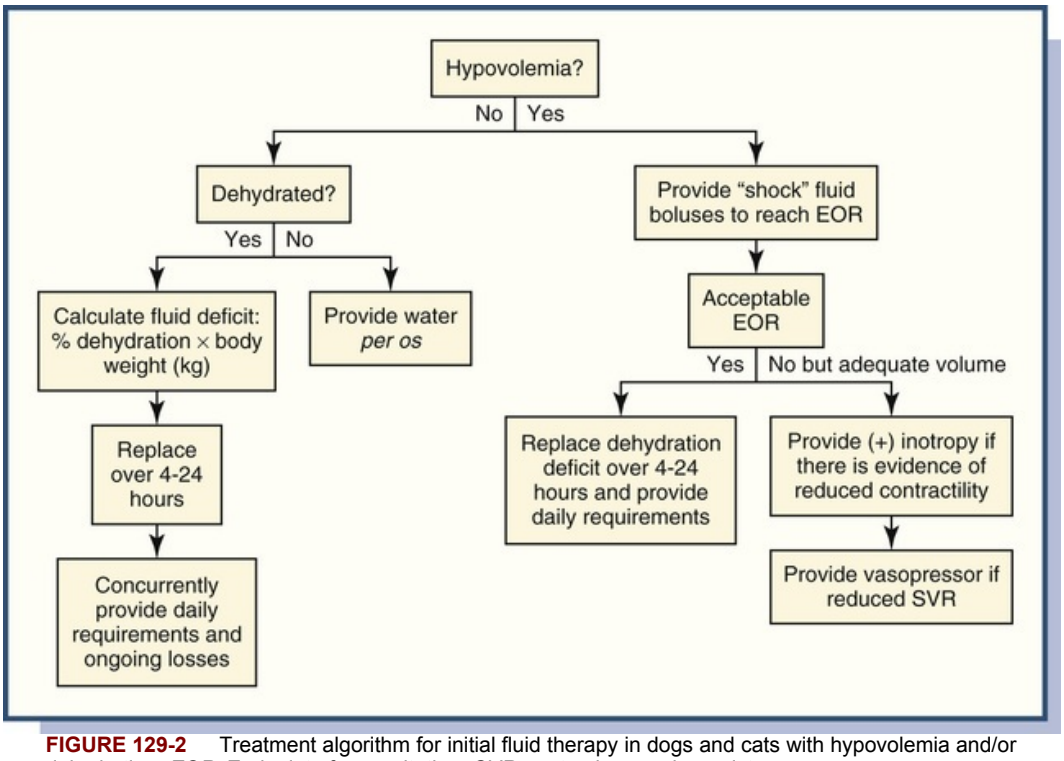

FIGURE 129-2 Treatment algorithm for initial fluid therapy in dogs and cats with hypovolemia and/or dehydration. *EOR*, Endpoint of resuscitation; *SVR*, systemic vascular resistance.

By answering these questions, one is addressing the three major components of fluid administration (Table 129-3):

1. Resuscitation
2. Replacement
3. Maintenance

TABLE 129-3

Components of Fluid Therapy

COMPONENT	QUESTIONS ADDRESSED
Resuscitation	Is the patient hypovolemic?
Replacement	Is the patient dehydrated? Are there any ongoing losses?
Maintenance	What are the patient's daily physiologic requirements?

During fluid resuscitation, intravascular volume is restored with intravenous fluid administration. Hypovolemic patients required fluid resuscitation, and the volume infused depends on the stage of shock (Table 129-4 and ch. 127).

- *Compensatory:* Cardiac output is increased due to catecholamine release; common clinical signs include normal vital signs (or mild tachycardia), injected mucous membranes (see Video 144-1), rapid CRT, normotension and normal blood pressure.
- *Early decompensatory:* Blood is preferentially distributed to the heart and brain, and lactic acidosis with tissue hypoxia occurs; common clinical signs include tachycardia, pale mucous membranes, prolonged CRT, depressed mentation, hypothermia and hypotension.
- *Late decompensatory:* This is a stage of autoregulatory escape, indicating the brain and heart can no longer maintain sympathetic-mediated vasoconstriction so vasodilation occurs in all organs (including heart/brain) to cause circulatory collapse; common clinical signs include bradycardia, severe hypotension, absent CRT, weak or absent peripheral pulses, hypothermia, obtundation, and oliguria.

TABLE 129-4

Stages of Shock and Associated Clinical Signs

CLINICAL STAGE	CHARACTERISTICS	CLINICAL SIGNS
Compensatory	CO increases due to catecholamine release	Normal vitals or slightly increased HR Injected mm (d) Rapid CRT (<1 second) Normal BP Normal mentation
Early decompensatory	Blood preferentially distributed to heart and brain Lactic acidosis and tissue hypoxia occur	Tachycardia (d) Pale mm Prolonged CRT Depressed mentation Hypothermia Hypotension
Late decompensatory	Autoregulatory escape	Bradycardia Severe hypotension Absent CRT Weak or absent pulses Hypothermia Oliguria Obtundation

BP, Blood pressure; *CO*, cardiac output; *CRT*, capillary refill time; *(d)*, dog; *HR*, heart rate; *mm*, mucous membranes.

Stabilizing interventions for patients with shock (see ch. 127) should target endpoints of resuscitation (EOR), particularly:

- Restoration of normal vital signs
- Normalization of abnormal mentation
- Restoration of normal blood pressure (systolic >80-90 mm Hg; see ch. 99 and 159)
- Normal serum lactate (<2.5 mmol/L; see ch. 70)
- Central venous oxygen saturation ($S_{cv}O_2$) >70%
- Packed cell volume (PCV) >25%
- Urine output (UOP) >1 mL/kg/h
- Pulse oximetry (S_pO_2; see ch. 98) >93% at F_iO_2 = 21%
- Central venous pressure (CVP; see ch. 76) = 5-10 cm H_20

An isotonic crystalloid should be administered at "shock" rate (dogs: 20 mL/kg, up to 90 mL/kg; cats: 10 mL/kg, up to 50 mL/kg) over 15 minutes and then one should reassess EOR.[13] With hypoproteinemic hypovolemia, administration of a synthetic colloid (i.e., hydroxyethyl starches) may be appropriate; these fluids should be delivered over 20-30 minutes (dogs: 5 mL/kg, up to 20 mL/kg; cats: 2-5 mL/kg, up to 10 mL/kg) and EOR should be reassessed after each bolus.[13]

After effectively addressing hypovolemia, an appropriate fluid therapy plan must address dehydration, daily physiologic requirements, and ongoing losses. Isotonic crystalloids should be used for fluid replacement (correcting dehydration and replenishing ongoing losses). Clinical signs of dehydration include tacky mucous membranes, decreased skin turgor, enophthalmia, and prolonged capillary refill time. The volume required to correct dehydration is the product of the estimated percentage of dehydration and body weight in kilograms, and should be delivered over approximately 4-24 hours depending on a patient's risk for hypervolemia (Table 129-5). After correcting dehydration, a patient's fluid therapy plan should be reevaluated. Ongoing losses may be estimated by weighing diarrhea and vomitus, and frequent weight monitoring is recommended to help gauge a patient's fluid status.

TABLE 129-5

Estimating Dehydration Based on Clinical Signs

% DEHYDRATION	PHYSICAL EXAMINATION ABNORMALITIES
<5	No specific abnormalities; history of fluid loss (diarrhea, vomiting)
6-8	Enophthalmia, dry mucous membranes, mildly/moderately decreased skin turgor
10-12	Enophthalmia, dry mucous membranes, weak peripheral pulses, depression, markedly decreased skin turgor
12-15	Stupor, coma, death

Daily physiologic requirements, also termed maintenance requirements, may be calculated with one the following formulas:

- (30 × BW in kilograms) + 70 = mL/day
- $80 \times BW^{0.75}$ = mL/day

Both isotonic and hypotonic crystalloids may be appropriate and the ultimate choice of crystalloid type should be determined based on a patient's volume status and serum electrolyte concentrations. Fluids should always be titrated to effect. Fluid therapy is commonly employed during the peri-anesthetic period. Potential benefits of providing fluids to healthy patients during the peri-anesthetic period include cardiovascular support, the ability to counter potential anesthesia-induced adverse reactions (i.e., vasodilation), and the correction of normal ongoing losses.

Hypotensive Resuscitation

Hypotensive resuscitation is a method of fluid resuscitation that has been advocated by some for stabilization for patients with uncontrolled hemorrhage and planned surgery to attain hemorrhage control. Two types of hypotensive resuscitation have been described: limited volume resuscitation (permissive hypotension) and delayed resuscitation. To perform limited volume resuscitation, conservative volumes of intravenous fluids are administered prior to achieving definitive control of hemorrhage. The fluids improve but do not normalize blood pressure and tissue perfusion, but rather target a specific pre-operative blood pressure range (mean arterial pressure 40-60 mm Hg). Patients who receive delayed resuscitation receive no volume resuscitation until definitive control of hemorrhage has been attained. Suitable fluid resuscitation targeting appropriate endpoints of resuscitation is instituted once hemorrhage has been controlled.

The value of hypotensive resuscitation in veterinary patients is relatively controversial.[14-17] The timing of resuscitation and reestablishment of hemostasis is seemingly critical, as most studies documenting successful use of this technique had uniquely short preoperative times. The majority of veterinary trauma patients with intra-abdominal hemorrhage spontaneously achieve hemostasis, do not require surgical intervention, and should not receive hypotensive fluid resuscitation. Patients with non-traumatic hemorrhage commonly have pre-operative wait times longer than those in published studies, and therefore hypotensive resuscitation results in protracted hypotension and contributes to the development of SIRS and multiple organ dysfunction syndrome. While hypotensive resuscitation may be beneficial for some patients, one must carefully weigh the benefits against the potential risks of prolonged hypotension in a patient.

Early Goal-Directed Therapy

The profound inflammation associated with SIRS and sepsis induces vascular leakage secondary to endothelial dysfunction. Subsequently, fluid extravasation results in relative and absolute hypovolemia, hypoperfusion and possibly septic shock. Fluid therapy is the mainstay of resuscitation of patients with SIRS, sepsis, severe sepsis and septic shock. In 2001 Rivers et al introduced the concept of early goal-directed therapy (EGDT), a specific algorithm for managing patients presenting with septic shock.[18] Aggressive fluid resuscitation to achieve specific endpoints was recommended. In-hospital mortality was 30.5% in the EGDT group and 46.5% in standard therapy group, a finding that was statistically significant.[18] Patients in the EGDT group also had significantly higher mean $S_{cv}O_2$, lower lactate, lower base deficit, and higher pH than the patients assigned to standard therapy.[18] Subsequently clinical guidelines, the Surviving Sepsis Campaign Guidelines (SSCG), for the management of human patients with severe sepsis and septic shock were developed and are routinely updated.[19,20]

Aggressive initial fluid resuscitation is considered the cornerstone of initial therapy for human and veterinary patients with severe sepsis and septic shock. The SSCG recommend immediately instituting

volume resuscitation in affected people according to an explicit protocol; specifically crystalloids are the recommended initial fluid of choice and the initial fluid challenge should be at least 30 mL/kg. Within the first 6 hours of therapy, one should target:

- Mean arterial pressure (MAP) ≥65 mm Hg
- Central venous pressure (CVP) 8-12 mm Hg
- Urine output (UOP) ≥0.5 mL/kg/h
- Central venous oxygen saturation ($S_{cv}O_2$) ≥70%

Interestingly, despite the SSCG, there is marked variation in the type of resuscitation fluid used in human patients worldwide. In the United States, crystalloids are the initial recommended resuscitation fluid. More than 50% of fluid resuscitations in Australia are performed with mainly albumin and in European countries almost 50% of resuscitations are done with mainly hydroxyethyl starches. Vasopressors should be used within 6 hours for those patients with hypotension despite aggressive initial fluid resuscitation. Transfusion with packed red blood cells to maintain a packed cell volume (PCV) greater than 30% and vasopressor therapy may also be indicated. Serial monitoring of perfusion parameters, most notably lactate, should be pursued, and one should seek to normalize lactate levels as rapidly as possible.

Despite the SSCG, to date the optimal composition and volume of resuscitation fluid is not known, and remains a highly controversial topic in human emergency and critical care medicine. Furthermore, prospective randomized controlled trials have not been conducted in veterinary medicine; thus, the ideal guidelines for resuscitation of veterinary patients with SIRS, sepsis, severe sepsis and septic shock are similarly unknown at this time.

Since the publication of the sentinel study by Rivers et al, subsequent studies have been conducted to document the potential benefits of early goal-directed therapies. Results have been mixed depending on patient population studied. The ARISE study in 1600 human patients with early septic shock failed to show a reduction of all-cause mortality at 90 days despite utilizing EGDT interventions.[21] Certainly continued investigation, particularly prospective studies in dogs and cats, is sorely needed.

Fluid Additives

Potassium supplementation is commonly required for veterinary patients, particularly those who receive large volumes of replacement fluids. Common causes of hypokalemia include gastrointestinal fluid loss, diuresis and anorexia, and administration of bicarbonate, insulin and/or dextrose can induce a hypokalemic state due to intracellular shifting if concurrent potassium supplementation is not provided (see ch. 68). Common clinical signs of hypokalemia are muscle weakness, abnormal gait/ambulation, ileus, cervical ventroflexion (particularly in cats), and dysrhythmias (atrial and/or ventricular premature contractions). Electrocardiography may also document a prolonged Q-T interval (>0.25 seconds). Potassium deficits may be quite variable, and supplementation is patient-dependent; the rate of supplementation should generally not exceed 0.5 mEq/kg/h without strict attentive patient monitoring.

Supplementation of B vitamins is relatively commonplace in veterinary patients, particularly in a critical care setting. These vitamins will be inactivated with exposure to ultraviolet light, but are relatively stable for approximately 72 hours in environments with fluorescent lights and minimal exposure to natural sunlight. All B vitamins are water-soluble, and thus are only stored in the body for a few days. They are also commonly lost in polyuric diseases, and deficiency can contribute to anorexia. Thiamine deficiency has been associated with neurologic deficits (see ch. 12), and cobalamin deficiency is common in patients with exocrine pancreatic insufficiency and distal small intestinal disease (see ch. 292 and 276). Supplementation with pure thiamine or cobalamin, respectively, is recommended if deficiency in either vitamin is suspected or confirmed, as vitamin B complex solutions do not contain enough of either thiamine or cobalamin.

Magnesium has multiple important functions as a cofactor in enzymatic reactions, contributor to the tertiary structure of proteins, and participant in cell membrane function (see ch. 68). Hypomagnesemia is relatively common in veterinary critical care patients, and deficiency has been associated with prolonged hospitalization.[22] Hypomagnesemia should be suspected in patients with refractory hypokalemia. Mild hypomagnesemia is often corrected by infusing magnesium-containing fluids, and marked deficiency (ionized magnesium <0.35 mmol/L) should be addressed with a constant rate infusion of magnesium sulfate or chloride at an initial dose of 0.75-1 mEq/kg/day for 24 hours followed by a 50% dosage reduction for an additional 3 to 5 days.

Monitoring

With the provision of fluid therapy comes the requirement to monitor a patient's response to that intervention. Multiple parameters may be readily evaluated to assess a patient's response to prescribed fluid therapy. Common physical variables are:

- Body weight: The change in a patient's body weight is a non-invasive method for evaluating fluid gain or loss on a day-to-day basis. As several variables (feces in colon, degree of urinary bladder filling, insensible losses, etc.) predispose this measurement to errors, one is encouraged to measure a patient's body weight at the same time of day using the same scale to minimize variability.
- Mucous membranes: Dehydrated patients frequently have dry mucous membranes. Thus, a change from tacky mucous membranes to moist ones commonly indicates a positive response (i.e., improved hydration) to fluid therapy.
- Capillary refill time: Patients with poor perfusion typically have prolonged capillary refill times (>2 seconds), and poor perfusion frequently arises from hypovolemia. An improving CRT suggests improved perfusion.
- Skin turgor: Evaluation of a patient's skin turgor or degree of "skin tenting" has been historically used to assess various degrees of dehydration. Overhydrated patients are commonly described as having a gelatinous feeling to their skin and may readily develop gravity-dependent edema (see ch. 18). Geriatric patients and underweight patients have reduced turgor normally and overweight/obese patients commonly have increased skin turgor; thus, evaluation of skin turgor in these patients is an unreliable indicator of hydration status and response to prescribed fluid therapy.
- Heart rate: Compensatory and early decompensatory hypovolemic shock in dogs and occasionally cats is associated with a reflex tachycardia. Cats do not consistently develop this compensatory response due to concurrent sympathetic and vagal stimulation. Providing appropriate bolus fluid therapy to hypovolemic dogs and some cats will resolve the compensatory tachycardia, indicating a positive response to prescribed fluid therapy.

In addition to readily measured physical variables, trained medical personnel may easily measure other values with minimal patient discomfort, particularly:

- Blood pressure (BP; see ch. 99): Marked hypovolemia can overwhelm a patient's homeostatic responses to result in hypotension (mean arterial pressure <60 mm Hg). Hypertension is exceedingly rare in patients with fluid overload due to the large capacitance of the venous circulation, and patients may manifest hypotension without hypovolemia due to either reduced cardiac contractility and/or reduced systemic vascular resistance.
- Urine output (UOP): A normal UOP is 1-2 mL/kg/h, and values of 0.5-1 mL/kg/h and less than 0.3 mL/kg/h indicate oliguria and anuria, respectively.
- Central venous pressure (CVP; see ch. 76): Central venous pressure is the pressure within the lumen of the cranial vena cava and is believed to be equivalent to right atrial pressure. A patient's CVP is influenced by cardiac output (CO), venous return and venous tone, and thus this variable estimates the relationship between blood volume and capacity. Excluding myocardial dysfunction and/or increased pulmonary resistance, CVP is a reliable indicator of an effective circulating blood volume. In dogs and cats, a normal CVP range is 0-10 cm H_2O, and measurements should always be compared with previous data; trends in CVP are uniquely more useful than singular measurements for assessing a patient's response to fluid therapy.
- Lactate (see ch. 70): Hypoperfusion secondary to a reduction in effective circulating volume readily results in tissue hypoxia that induces Type A lactic acidosis. Improving tissue perfusion via fluid resuscitation may resolve the Type A hyperlactatemia. However, tissue hypoxia may occur without volume depletion (i.e., reduced cardiac output [CO], decreased SVR, decreased arterial oxygen content [PaO_2]) and Type B lactic acidosis may occur without hypoxia, and thus lactate values must be interpreted carefully.

Measuring the amount of fluid provided to a patient, as well as all of the eliminations of a patient, is essential for providing the best fluid therapy. Serially and accurately monitoring a patient's "ins and outs" is invaluable and potentially challenging, but the astute clinician must be keenly aware of all possible sources of fluid loss from a patient, particularly losses via urine, feces, vomitus, blood, and cavitary effusions. A patient's treatment sheet should accurately document both the volume of fluid administered to and the total amount of eliminations from a patient in a given time period.

Complications/Controversies

Fluid Overload

While healthy animals are generally quite tolerant of excessive fluid administration, debilitated patients are less able to endure excessive volume. Signs of fluid overload and overhydration include weight gain, restlessness, tachypnea, dyspnea, serous nasal discharge, chemosis (cats), adventitious lung sounds (i.e., crackles), tachycardia, gallop rhythm (cat), coughing and jugular venous distension.

Synthetic Colloids

Measurements of urine specific gravity should be made prior to administration of certain hydroxyethyl starches, particularly hetastarch. Hetastarch molecules greater than 50 kD are freely filtered by the glomerulus, and falsely cause high refractometer readings. Total solids (TS) measurements via refractometry are also affected, as hetastarch yields a value of 4.5 g/dL alone and 3.0 g/dL when mixed 1 : 1 with a hypooncotic diluent.[23] Thus, TS measurements in patients receiving hetastarch as a constant rate infusion for more than 24 hours tend to trend toward a range of 3.0-4.5 g/dL. Thus, direct measurement of serum albumin and/or colloid osmotic pressure (COP) in these patients provides a more accurate assessment of a patient's oncotic status.

Hydroxyethyl starches have been recommended for resuscitation in patients with hypoalbuminemia and/or sepsis given their ability to induce a more rapid and lasting circulatory stabilization than crystalloids. The use of HES has been called into question and, indeed, advised against in some human patients given various adverse reactions reported in randomized clinical trials, most notably coagulation alterations, immunologic reactions, increased incidence of acute kidney injury and need for renal replacement therapy (see ch. 110).[24]

To date, no study in dogs or cats has documented acute kidney injury secondary to HES administration, and thus clinicians are cautioned not to extrapolate and apply experience with these fluids in humans to dogs and cats. With that being said, it may be prudent to limit the use of HES in patients with pre-existing renal injury and/or those at risk for renal tubular injury.

Hydroxyethyl starches have been implicated in inducing several coagulation abnormalities in various patient populations, including dogs and cats. Certainly the potential to induce a bleeding disorder must be considered when contemplating the use of HES in septic patients. Both *in vitro* and *in vivo* studies in dogs and cats have documented adverse effects on platelet function and coagulation.[25-27] However, the clinical relevance of these studies is not yet truly known, and clinical prospective investigation is warranted. At this time, use of HES in patients with pre-existing coagulation abnormalities is cautioned.

Although immediate and delayed immunologic reactions to HES have been rarely documented in humans, only anecdotal reports of such reactions exist in veterinary medicine to the author's knowledge.

Albumin

Although human and canine albumins have significant amino acid homology, some important differences exist between the two molecules, thus raising concerns over antigenicity. A recent retrospective study of 64 dogs that received HSA did not identify any significant problems.[28] Nevertheless, the current recommendation is that one should not administer HSA after more than 1 week from the initial dosing due of the increased risk of foreign antigenicity. Both HSA and canine albumin are hyperoncotic solutions, and thus fluid overload and overhydration are possible.

CHAPTER 130

Blood Transfusions, Component Therapy, and Oxygen-Carrying Solutions

Anthony C.G. Abrams-Ogg, Shauna Blois

Client Information Sheet: Blood Transfusions and Blood Component Therapy

Sources of Blood Products

Transfusion refers to infusion with whole blood (WB) or its components, listed with indications in Table 130-1. Components are prepared by WB centrifugation and separation. Component use focuses transfusion on specific patient needs, minimizes wastage, and reduces risk of reactions. WB and components may be purchased from commercial blood banks. Alternatively, WB may be collected in a clinic using human or veterinary blood bank supplies. Donors should be negative for regionally relevant infectious diseases.[1,2] Details of donor selection and blood collection are provided in videos for this chapter (Videos 130-1 to 130-5) and references.[3-16] Blood component preparation is not advocated for most clinics because of the need for specialized equipment and quality assurance programs. If a clinic wishes to produce its own blood products, extensive descriptions are available.[8-11,17-21]

TABLE 130-1

Blood Products and Their Indications

PRODUCT	DESCRIPTION	COMMENT*	SPECIFIC INDICATION
Fresh whole blood (fresh WB)	Stored at RT <24 hours. Refrigerated for 48 hours (hemostatic properties likely maintained for longer times). One dog unit ≈450 mL. One cat unit ≈60 mL.	Minimal red cell storage lesion. Maximum hemostatic properties.	Acute blood loss.
Stored whole blood (stored WB)	Refrigerated >48 hours. One dog unit ≈450 mL. One cat unit ≈60 mL.	Stored in CPDA$_1$ up to 3 weeks. Vitamin-K dependent clotting factors are stable.	Acute blood loss. Suitable to treat vitamin-K antagonist poisoning.
Packed red blood cells (pRBC, referred to as red cells in human medicine)	Prepared by hard centrifugation of fresh WB and removal of plasma. Stored under refrigeration.	Stored in Adsol, Nutricel, Optisol up to 3 weeks.[170-173]	Hemolytic anemia. Chronic non-regenerative anemia. Acute blood loss (+ crystalloid or colloid).
Fresh-frozen plasma (FFP)	Prepared by centrifugation of whole blood for pRBC or PRP and removal of plasma.	Stored for up to 1 year. 8 hour restriction is based on preserving temperature-labile human FVIII; loss is 20-30%. Dog FVIII is more stable and the 8 hour definition is overly restrictive for dogs. Dog vWf	Bleeding or anticipated bleeding due to coagulopathy of any cause or vWD. Was advocated in past for

	Frozen solid at −18° C or colder within 8 hours of collection. Fresh plasma is plasma transfused <8 hours after collection. Treating donor with DDAVP may increase vWf yield.	is stable for ≥24 h, and FFP frozen within this period is acceptable for treating vWD.[174]	the treatment of pancreatitis but there is no supporting evidence. Colloidal plasma volume expansion.
Regular plasma (RP)	FFP >1 year old, or plasma separated from red cells >8 hours, stored at −18° C or colder.	Stored up to 5 years. Lower level of vWf than in FFP; slightly lower FVIII, FV; negligible differences between FFP and regular plasma with respect to albumin, globulins, alpha-macroglobulins, vitamin-K dependent factors and antithrombin. Minimal loss FV and FVIII in fresh RP over 2 weeks.[36,150]	As good as FFP to treat vitamin-K antagonist poisoning. Colloidal plasma volume expansion.
Cryoprecipitate (CRYO)	Prepared by removal of supernatant (cryopoor plasma) of partially thawed FFP. Treating donor with DDAVP may increase vWf yield. 1 unit is CRYO prepared from 1 unit of plasma.[175]	Enriched in FVIII and vWf. Stored at −18° C or colder for up to 1 year.	Bleeding or anticipated bleeding due to hemophilia A or vWD.
Cryosupernatant	See CRYO.	Enriched in albumin and antithrombin.	Nephrotic syndrome.
Albumin solution	Prepared by ethanol extraction of cryopoor plasma.	Human preparations of 5%, 20%, 25%. Lyophilized dog albumin commercially available from ABRI.	Short-term colloidal plasma volume expansion.
Intravenous immunoglobulin (IVIG)	Prepared by ethanol extraction of cryopoor plasma.	Inconsistently available to veterinarians.	Human IVIG has been used intermittently in treatment of canine ITP and other immune disorders. Of no benefit and potentially harmful in canine IMHA.[176]
Platelet-rich plasma (PRP)	Prepared by light centrifugation of fresh WB and removal of platelet-poor plasma. 1 unit is PRP extracted from 1 unit of WB.	Stored at RT under constant agitation for 3-7 days.	Bleeding or anticipated bleeding due to thrombocytopenia.
Platelet concentrate (PC)	Prepared by hard centrifugation of PRP; or by hard centrifugation of fresh WB followed by centrifugation of buffy coat; or by plateletpheresis.	Stored at RT under constant agitation for 3-7 days. Cryopreserved leukoreduced PC by plateletpheresis commercially available from ABRI. AABB standards specify ≥ 5.5×10^{10} platelets in ≥90% of units; CoE standards specify ≥ 6.0×10^{10} in ≥75% of units.	Bleeding or anticipated bleeding due to thrombocytopenia.
Granulocyte concentrate (GC)	Prepared by centrifugation of fresh WB and removal of buffy coat; or by leukapheresis.	Rarely used in clinical veterinary medicine. Stored at RT 24 hours without agitation.	Neonatal sepsis. Sepsis secondary to neutropenia. Dosage: 1×10^9 granulocytes/kg in a

	1 unit GC is extracted from 1 unit of WB. Donor may be treated with granulocyte colony stimulating factors.		volume of 15 mL/kg.
Pooled adult serum	Prepared by centrifugation of clotted blood. Serum from several donors is pooled.	Pups: 20 mL/kg PO or 20-40 mL/kg SC. Kittens: 50 mL/kg IP or SC q 8 h.	Failure of passive transfer. The higher dosage in kittens was more effective and may be considered for pups.

*Storage times are those used at authors' institution.[170]

AABB, American Association of Blood Banks; *ABRI*, Animal Blood Resources International, Stockbridge, MI, USA; *CoE*, Council of Europe; *FVIII*, factor VIII; *IMHA*, immune-mediated hemolytic anemia; *RT*, room temperature; *vWD*, von Willebrand disease; *vWf*, von Willebrand factor; *WB*, whole blood.

Blood banking was developed for logistics. It is acceptable to only have donors in-clinic or on-call, but a blood donation may not be completed in sufficient time to treat an emergent patient. Also, blood may not be delivered in sufficient time from a blood bank. For these reasons, having a unit of WB always on hand is recommended, although there is the economic risk the unit may expire. Although blood banking facilitates logistics and component use, there is evidence of deleterious effects of transfusing older red cells in humans, although these effects are not as well documented in dogs and not in cats.[22-28] Fresh WB also has superior hemostatic properties than many combinations of components.[29-32] These points must be considered when deciding between storing blood in donors or in plastic bags. The change in blood components during banking is referred to as a storage lesion.[33] Leukoreduction, the removal of white cells from blood components, is extensively practiced in some human blood banks, and is emerging in dogs, to reduce storage lesions and certain transfusion reactions.[34-39] There are various techniques, which all increase expense and result in some loss of red cells and platelets. Leukoreduction is most often accomplished by filtration at the time of blood collection.

Indications for Transfusion and "Triggers"

Anemia is the most common reason to give a transfusion (see ch. 198 and 199). A transfusion trigger refers to a specific cell count at which a transfusion will be recommended.[40] Triggers are guidelines only and should not be acted on without supporting clinical signs, other indicators and/or anticipated cell losses.[41-49] For acute bleeding causing hypovolemia, a common trigger for red cell transfusion is a packed cell volume (PCV) of 20-25% for dogs and 15-20% for cats. For immune-mediated hemolytic anemia (IMHA), a common trigger is 15-20% for dogs and 10-15% for cats. These are lower than for blood loss because animals are less hypovolemic and there are concerns with aggravating the primary disease. For chronic non-regenerative anemia, a common trigger is 12-15% in dogs and 8-12% in cats. Dogs adapt to anemia with increased synthesis of 2,3-diphosphoglycerate. Cats with chronic anemia have water retention such that PCV underestimates red cell mass.[50,51] The amount to be transfused is *estimated* with[52-54]:

$$\text{Volume of donor blood to be transfused (mL)} = \text{Recipient weight (kg)} \times \text{90 (dog) or 66 (cat)} \times \frac{\text{Recipient desired PCV} - \text{current PCV}}{\text{PCV of anticoagulated donor blood product}}$$

Alternatives to red cell transfusion include hypertonic saline for hemorrhagic shock, and oxygen-carrying

solutions for anemia of all causes.[55-58] The only commercially available oxygen-carrying solution is Oxyglobin (OPK Biotech), a hemoglobin-based oxygen carrier (HBOC) based on polymerized bovine hemoglobin. It is currently available in the EU and South Africa, and potentially in other countries by special import. The benefits of Oxyglobin are universal compatibility, low infection risk and 3-year shelf-life. Disadvantages are short duration of effect (half-life of 18-43 hours) and development of hemoglobinemia, hemoglobinuria and icterus, which may interfere with patient monitoring. An HBOC increases systemic and pulmonary arterial pressure by causing plasma volume expansion and vasoconstriction. This may be beneficial in hemorrhagic shock, but may cause circulatory overload, especially in cats, with chronic anemia, heart or kidney disease. The product is licensed for dogs at a dosage of 15-30 mL/kg at a maximum rate of 10 mL/kg/h. It may be given in 5 mL/kg increments as a vasoconstrictor. It is not licensed for cats, but recommended dosages include 5-10 mL/kg at a maximum rate of 2 mL/kg/h, and, for hypotension, 0.2-3 mL/kg boluses over 5-10 minutes, to a maximum of 10 mL/kg over 30 minutes.[56,57,59]

The main indication for transfusion of plasma products is coagulopathy with overt or anticipated bleeding.[60-64] Initial dosages are 10-30 mL/kg of fresh-frozen plasma (FFP) or regular plasma, and 1 unit/10 kg of cryoprecipitate (CRYO). FFP is not a specific treatment for disseminated intravascular coagulation (DIC) or pancreatitis and should only be used when there is bleeding.[60,65] Plasma is occasionally used in dogs and cats to transfuse albumin as a colloid to treat hypovolemia, but synthetic colloids are preferred. Plasma is not used in humans as a colloid, but this is because albumin solutions are available for this use. Human and bovine albumin solutions have been used in dogs and cats without side effects, but severe acute and delayed hypersensitivity reactions have also been reported.[55,66-75] Commercial canine albumin is available as an alternative.[76] Plasma and albumin solutions may also be used to improve plasma oncotic pressure and reduce edema. Unfortunately this is inefficient, but will provide short-term benefit. About 22.5 mL/kg is required to raise plasma albumin by 0.5 mg/dL (5 g/L).[53] 40% of total body albumin is normally found in the plasma and 60% in the interstitium, with the ratio shifted towards plasma in hypoproteinemia. Upon albumin transfusion, the ratio shifts back towards the interstitium. Frequent large volume plasma transfusions or albumin transfusions are needed to maintain albumin levels, especially if hypoproteinemia is caused by protein loss.

Platelet transfusion is best with thrombocytopathia or thrombocytopenia due to reduced platelet production, less beneficial with platelet consumption (DIC), and least beneficial in immune-mediated thrombocytopenia (ITP).[17,42,77-80] A dose of 1 unit/10 kg of platelet-rich plasma (PRP) or platelet concentrate (PC) will raise the platelet count in a dog by ≈30 × 10^9/L, and one third of the transfused platelets will be consumed per day. Transfusing when bleeding is noted or prior to invasive procedures will reduce the number of transfusions compared to transfusion to prevent spontaneous bleeding. Red cell transfusion will also reduce bleeding as bleeding time is inversely correlated with PCV, and thus transfusions to correct anemia in ITP will also ameliorate bleeding.[81-83] FFP contains platelet microparticles and will also ameliorate bleeding.

Compatibility Testing

Many components of blood are antigenic; a blood incompatibility exists when a donor antigen will incite an immunologic response in the recipient. Red cell incompatibilities are due to blood groups, which are inherited antigens on red cell surfaces.[84] A simple blood group is where an individual is either positive or negative for the antigen (two alleles). A blood group system is where there are three or more alleles. Knowledge of blood group phenotypes across species has evolved from early experimental transfusions, to serologic studies using polyclonal antisera prepared from sensitized animals or animals with natural antibodies, to the development of monoclonal antibodies (MoAbs) and flow cytometry to recognize antigens, and molecular studies to define antigen structure. Most recently DNA studies have been used to describe genotypes. Breeding studies and pedigree analyses have been used to determine modes of inheritance. Common or high frequency antigens are those expressed in >92% of individuals.

Severity of a hemolytic reaction depends on recipient alloantibody titer (the higher the worse), class (IgM worse than IgG), temperature of activity (warm antibodies worse than cold), binding affinity (the higher the worse), donor red cell antigen expression (the higher the worse) and antigen dose (the more red cells transfused the worse). The severity of reaction varies from peracute shock to delayed hemolysis, where a transfusion does not last as long as expected.

Serologic compatibility tests to prevent hemolysis include crossmatching, antibody screening, and blood-

typing.[85-89] A crossmatch is an *in vitro* simulation of what will happen *in vivo* with transfusion, and is the most comprehensive. It may be performed using slide (E-Box 130-1) and tube methods (Figures 130-1 through 130-3). Detecting agglutination/hemolysis at any step indicates incompatibility, but the quicker/stronger the test reaction, the worse the transfusion reaction. If a laboratory reports incompatibility, the point in the crossmatch at which it was detected and its strength should be clarified. Antibody screening is a modified major crossmatch using red cells of a known blood group thus screening for recipient antibodies against that group. Blood-typing is a modified minor crossmatch, where antiserum specific to the antigen in question is used. For some antigens, MoAbs, plant lectins or other agents have replaced polyclonal antiserum. Agglutination reactions using serologic techniques by experienced personnel remain the reference methods for blood-typing.

E-Box 130-1

Rapid Slide Crossmatch and Blood-Typing[53,112,168,179]

Either serum or plasma can be used. Serum may reduce rouleaux. Plasma is more convenient and in cats rouleaux formation is nearly as strong in serum as in plasma. Rouleaux is increased with hyperglobulinemia and inflammation. Donor and recipient controls are important to observe for rouleaux and autoagglutination. Separate pipettes or syringes must be used for all solutions and care taken not to touch red cells with an agglutinating solution pipette/syringe or vice versa.

A. Performance of crossmatch

1. Collect 0.5-1 mL blood in an EDTA tube from recipient and donor. A segment of anticoagulated blood from the donor blood bag may be used. Clearly label tubes.
2. Centrifuge tubes at standard speed for the centrifuge in use (usually about 1000 × g for 5-10 minutes) to separate red cells from plasma/serum. If a centrifuge is not available, allow EDTA specimens to sit at room temperature for 1 hour until red cells have settled. Using separate pipettes for each sample, transfer plasma to separate tubes. Clearly label.
3. Optional: Wash red cells. Add 0.5-1 mL of packed red cells to a tube and fill the remainder of the tube with saline/phosphate-buffered saline (PBS). Mix by inverting the tube and centrifuge at 1000 × g. Discard supernatant and repeat twice.
4. Optional: Prepare ≈4% donor and recipient red cell suspensions by mixing 0.2 mL packed red cells and 4.8 mL saline. Use a separate pipette for each mixture and clearly label. Dilution of red cells in saline retards rouleaux formation and facilitates microscopic observation, but results in less dramatic macroscopic agglutination.
5. Label four glass slides as: (a) Donor control, (b) Major X-match, (c) Minor X-match, and (d) Recipient control. Onto each slide place: (a) Two drops (50 mcL) of plasma and one drop (25 mcL) of undiluted red cells; or (b) One drop (25 mcL) of plasma and one drop (25 mcL) of red cell suspension.

a. Donor control: Donor red cells and donor plasma
b. Major X-match: Donor red cells and recipient plasma
c. Minor X-match: Recipient red cells and donor plasma
d. Recipient control: Recipient red cells and recipient plasma

6. Gently rock slides back and forth and observe for *macroscopic agglutination within 1 minute* (see Figure 130-1). The macroscopic agglutination reaction may be graded as:

0 (neg): no agglutination
1+: small aggregates after 30 sec
2+: many small aggregates with 15 sec
3+: large aggregates within 10 sec
4+: large aggregates within 5 sec

This may also be used to grade reactions on agglutination typing cards.

7. Place on a coverslip and observe the wet mounts for *microscopic agglutination within 2 minutes*. Agglutination must be distinguished from rouleaux. This is easy to do with strong agglutination but is difficult with weak agglutination. Rouleaux formation may be very intense, especially when using undiluted red cells, and is macroscopically indistinguishable from agglutination (see Figure 130-1, *A*-*C*). Microscopically, in aggregates of agglutinated red cells, the cells are rafted together, randomly oriented, and superimposed on each other (see Figures 130-2 and 130-3). Rouleaux appear as a "stack of coins" (see Figures 130-2 and 130-3). Small aggregates and single rouleaux can be distinguished, but strong rouleaux will clump together and form a tertiary structure, thus resembling medium-to-large aggregates. Close inspection of the edges of the clumps helps in making the distinction. Note that rouleaux can form concurrently with aggregates, and may stick to them. Under 5 minutes most rouleaux will be single formations. Placing a coverslip on the preparation will disperse some rouleaux. Both rouleaux and aggregates can be observed to be "sticky" as they pull apart.

A slide test using *undiluted* red cells is superior for comparing strong macroscopic agglutination to rouleaux. Strong agglutination is usually evident within 1 minute and reaches a maximum reaction within 3 minutes (see Figure 130-1). After 1 to 2 minutes desiccation of the sample on the slide results in

rouleaux formation beginning at the edges of the sample. However, rouleaux formation of equivalent intensity to strong agglutination requires 5-10 minutes to form. Microscopically large aggregates and rouleaux can be identified, but small aggregates cannot be identified because of the high density of red cells.

A slide test using *diluted* red cells is superior for distinguishing agglutination and rouleaux microscopically and for detecting weak agglutination. Macroscopic rouleaux formation begins within 2 to 3 minutes; as the slides are rocked the red cells swirl and become unevenly distributed, mimicking macroscopic rouleaux.

B. Interpretation of crossmatch

8. Positive *major* crossmatch: Use of this donor will result in a severe transfusion reaction. In cats, macroscopic agglutination denotes type B recipient and type A or AB donor. (Minor crossmatch is negative.) In dogs, macroscopic agglutination denotes probable anti-DEA 1, anti-DEA 4, or anti-*Dal* antibodies.
9. Positive *minor* crossmatch: In cats, macroscopic agglutination denotes type A or type AB recipient and type B donor. (Major crossmatch is negative.) In the likely event that the recipient is type A, use of this donor may cause a mild acute transfusion reaction and/or delayed hemolysis due to anti-A antibodies in donor and anti-B antibodies in recipient. In dogs, minor crossmatch is rarely of significance.

C. Back-typing (cats)

10. Major crossmatch is performed as above using red cells from a known type A or type B donor. A saline control should be performed at the same time.

D. Blood-typing (cats)

11. To detect type A red cells or A antigen on type AB red cells, minor crossmatch is performed as above using plasma from a known type B donor. Plasma is stable at −18° C or colder for at least 1 year.
12. To detect type B red cells or B antigen on type AB cells, *Triticum vulgaris* lectin ("wheat germ agglutinin") is used.
    a. Source of lectin is Sigma-Aldrich, *Triticum vulgaris* lyophilized powder, SKU L9640, available in 10 mg, 25 mg, and 100 mg quantities.
    b. Dissolve the lectin powder in saline/PBS to prepare a stock solution of 1 mg/mL (100 mcg/mL), e.g., mix 10 mg with 10 mL saline/PBS. Freeze in 0.1 mL to 1.0 mL aliquots. The frozen stock solution is documented to be stable for at least 1 month; anecdotally it has been used for at least 2 years.
13. Mix one 0.1 mL aliquot stock solution with 0.16 mL saline/PBS to achieve a ≈64 mcg/mL test solution. Other dilution volumes may be calculated using the formula: (100 mcg/mL) (volume of stock solution) = (64 mcg/mL)(volume test solution), and solving for volume of test solution. The test solution is stable under refrigeration for at least several days.
14. Mix two drops (50 mcL) of test solution and one drop (25 mcL) of undiluted red cells and grade agglutination reaction as per crossmatch.

Cat Red Cell Antigens

The main blood group in cats is the A-B system.[89-94] Simplified, the A antigen is due to *N*-glycolyl neuraminic acid (NeuGc) and the B antigen is due to *N*-acetyl neuraminic acid (NeuAc) (mnemonic: type B has Ac).[95,96] The enzyme CMAH converts NeuAc to NeuGc. The genes encoding CMAH of type A and type B cats have been sequenced and mutations identified in the gene of type B cats that render the enzyme non-functional, leaving type B cats with NeuAc.[97,98] A cat's phenotype may be type A, type B or type AB. Type A and type B are allelic and follow simple Mendelian inheritance with *A* dominant *b*.[99] A type A cat may be *AA* or *Ab;* a type B cat is *bb*. The inheritance of type AB is not fully understood.[100] There is not an *ab* allele at the same locus as *A* and *b,* and type A and type AB CMAH genotypes are the same.[91] Proposed genetics of the A-B system is $A > a^{ab} > b$, where a^{ab} is at a different gene locus.[91] Most domestic shorthair (DSH) cats are type A, with prevalence of type B <10% in eastern North America, northern and southwest continental Europe, northern England and Scotland, and South Africa. Areas with DSH type B prevalence of 10-20% include the west coast of North America, Ireland, regions in southern England, Italy, Greece, Israel, and New Zealand. Areas with >20% type B cats include regions in southern England, Turkey and Australia. For pedigree cats, in

all breeds except the British Shorthair, Rex breeds, Turkish Angora and Turkish Van, type A is most common, while in these four breeds type A and type B are about equally distributed. Abyssinians, Birmans, Himalayans, Somalis, Persians, Scottish Folds and Persians are 10-25% type B. Type AB is rare in all breeds with the notable exception of the Ragdoll cat in Italy with a prevalence of 25%.[101]

The majority of type B cats have natural high-titer anti-A antibodies.[102,103] About one third of type A cats have low-titer anti-B antibodies. Type AB cats do not have either. Natural antibodies are not present at birth, but develop by 2-3 months.[102,104] The average half-life of transfused type-matched red cells is 21-29 days. Transfusing a type A cat with type B (or type AB) blood may cause delayed hemolysis but only a minimal, if any, overt reaction; average transfused red cell half-life is 2 days. The cat may become sensitized and have a more severe reaction upon subsequent transfusions. Transfusing a type B cat with type A (or type AB) blood is likely to cause a severe, often fatal, reaction, which may occur with as little as 0.5 mL; average transfused red cell half-life is 1.3 hours.[105-109] Type AB cats are compatible with type A or type AB blood, and are compatible with type B red cells, but not with type B whole blood because of anti-A antibodies in the latter.

Point-of-care typing is easily accomplished with current commercial kits, including the Rapid Vet-H Feline (DMS) agglutination card, and the immunochromographic (IC) Quick Test A + B (Alvedia) and Rapid Vet-H IC (DMS) tests. Grading the reaction is encouraged (see E-Box 130-1). The A antigen is detected using anti-A MoAb and the B antigen is detected using wheat germ lectin or using anti-B MoAb.[95,110,111] The Rapid Vet-H Feline card has been available for two decades and accurately identifies the type A antigen in type A cats and the type B antigen in type B cats, typically with strong (2-4+) reactions (see E-Box 130-1). However, the A and B antigens are not always identified in type AB cats, and both type A and type B cats have been mistyped as type AB.[112-116] Mistyping a type A cat as type AB is not that serious as it is likely to be transfused with type A blood. Mistyping a type AB cat as type B is more concerning, because of the potentially severe anti-A reaction following transfusion of type B blood, and this is one reason confirmation of type B is recommended. Fortunately type AB is rare. However, for this reason any type AB card result should be confirmed. Confirmation of type B or type AB may include washing red cells and repeating a test, performing back-typing, and submission to a reference or research laboratory. Genotyping may also be performed to distinguish type B from type A/AB cats.[91,98] Confirmation of any result is recommended for any weak reaction (1+), autoagglutination, or result in a FeLV-positive cat. The newer IC tests both use anti-A and anti-B MoAbs. They are not affected by rouleaux and autoagglutination. They have even better performance than the typing card, and will likely replace it.[115,117] However, problems with AB typing still occur and the same caveats apply as with the agglutination cards for confirming certain results.

Many studies have calculated risks for transfusion reactions based on blood type prevalence and alloantibody titers, but acting on these risks is misguided. The risks may be low but the consequences high. A compatibility test is easy to perform and no risk is worth taking. The admonition "B careful" should be remembered whenever performing a transfusion.

In addition to the A-B system, the *Mik* blood group was reported in 2007.[118] *Mik* appears to be a high-frequency antigen, but *Mik*-negative cats may have natural antibodies that can cause an acute hemolytic reaction.[98,118] The only way to detect *Mik* incompatibility is by crossmatch.

Mild crossmatch incompatibilities have been seen in type-matched transfusion-naïve cats, and have also developed in repeatedly transfused cats.[119-121] These incompatibilities suggest that other blood groups exist, but are more likely to be associated with delayed hemolysis rather than acute reactions. In addition, incompatibilities have been associated with chronic kidney disease, neoplasia and other disorders, suggesting that alloantibodies to unidentified blood groups may be acquired.[86,119] Crossmatching in addition to blood-typing is not routine in cats, but is recommended if possible, especially in cats receiving repetitive transfusions. Expertise is required to detect subtle incompatibilities; therefore crossmatching is usually performed at reference laboratories. There is now a gel column crossmatch kit for dogs and cats (RapidVet-H, DMS), and a kit by Alvedia for cats is under development, which should facilitate point-of-care crossmatching. However, the number of donors is often restricted, and there may be no choice but to give a transfusion with A-B matched but mildly crossmatched incompatible blood. The ultimate incompatibility is with dog blood. Transfusion of dog blood to cats is discouraged, but cats do not have natural antibodies against dog red cells (although dogs have NeuGc and NeuAc). Over 60 cats have received xenotransfusions with no acute reactions and this may be considered if a life-saving transfusion is needed.[122] However, delayed hemolysis and sensitization will occur, and repeat transfusion is likely to be fatal.

Dog Red Cell Antigens

Over 12 antigens have been reported in dogs.[87,88,123,124] In the DEA (dog erythrocyte antigen) system, 1.1, 1.2, 3, 4, 5, 6, 7, and 8 were defined by internationally standardized antisera. Antisera for DEA 6 and 8 are no longer available; limited supplies of the others are available, although more may be produced by sensitization. Reactions to DEA 1.1/1.2 have the most significance. Recent studies by flow cytometry indicate that DEA 1.1 and 1.2 are not separate antigens, but represent a continuum of antigen expression.[125,126] The recommendation was made to type dogs as DEA 1 positive or negative. As with other dog antigens, the molecular structure and genotype of DEA 1 is not known,[127] and there may be other factors that accompany the varying expression of DEA 1 rendering some DEA 1 dogs incompatible with each other. That accounts for earlier reports of incompatibilities between DEA 1.1 and DEA 1.2 dogs. Overall world-wide prevalence of DEA 1 is about 45%, with some breed and regional differences.[124,128-132] Boxers, Border Collies, Doberman Pinschers, German Shepherd Dogs, Flat-Coated Retrievers and Greyhounds are more likely to be DEA 1-negative, while Bernese Mountain Dogs, Dalmatians, Golden Retrievers, Great Danes, Rottweilers and Saint Bernards are more likely to be DEA 1-positive. A survey in São Paulo, Brazil, reported a >90% prevalence of DEA 1. Native Turkish breeds had an overall prevalence of DEA 1 of 65%.

In addition to DEAs, some Dalmatians, and then Doberman Pinschers, Shih Tzus and other breeds were reported negative for *Dal* antigen.[133,134] It is a high-frequency antigen in mixed-breed dogs and may be the same antigen as DEA 6.[124,134]

Dogs have either no, or only weak, natural antibodies and there is no evidence that they are sensitized by pregnancy.[123,135,136] An acute alloimmune hemolytic reaction will not occur in a naïve recipient, but dogs lacking a certain DEA will be sensitized upon transfusion of red cells bearing that DEA, and will be at risk for future IgG-mediated hemolytic reactions. By convention, a dog is considered potentially sensitized by 4 days post-transfusion. Acute reactions with hemoglobinemia, hemoglobinuria and icterus have been described for DEA 1, DEA 4, *Dal*, and an undefined common antigen.[133,137-139] Sensitization to other antigens will reduce half-life of transfused red cells, which normally ranges in dogs from 43-104 days. Regardless of prevalence rates, all dogs should be either typed for DEA 1 or transfused with DEA 1-negative blood. Current commercial kits that use anti-DEA 1 MoAb for point-of-care typing are the Rapid Vet-H Canine (DMS) agglutination card, the IC Quick Test DEA 1.1 (Alvedia), and, in the European Union, QuickVet (DMS) that detects agglutination by altered light transmission.[140-144] Grading the reaction is encouraged (see E-Box 130-1) and 1+ results should be taken as inconclusive. The cards reliably detect DEA 1-negative dogs, but some false-positive reactions occur, especially in IMHA.[142,145] Because of the risk for sensitizing a mistyped DEA 1-negative dog, some clinics restrict the cards for selecting DEA 1-negative donors. The IC test has excellent performance and false-positives are rare.[140,142] False-negatives may occur in anemic dogs because the reaction line is hard to see, and for such a result the test should be repeated after concentrating the red cells.[142] The QuickVet test had a similar performance to the agglutination card.[141] Blood-typing and antibody screening for DEA 3, 4, 5, and 7 are only available at ABRI. Ideally all donors should have such typing done, but this is often not practical and incompatibilities to DEA 3, 5 and 7 are likely to be mild.[124] Crossmatching is not standard-of-care for a dog receiving its first transfusion, although mild crossmatch incompatibilities may exist.[87,123,124,135-137] However, *crossmatching is essential for any dog receiving a subsequent transfusion,* and historically was ideally performed in a reference laboratory that could incorporate an indirect Coombs test. In addition to the RapidVet-H gel kit, the LAB TEST XM (Alvedia) is available which incorporates a Coombs reagent. Studies evaluating these kits are in progress. If these are not available, a slide or tube crossmatch will identify risk of severe reaction.

Non-Red Cell Incompatibilities

These are discussed in Transfusion Reactions. The only readily available compatibility test is to give a test dose of the transfusion, where the transfusion is given at an initial rate of 0.25 mL/kg/h for the first 15-30 minutes. A negative test dose does not preclude a later or delayed reaction.

Autotransfusion

Autotransfusion addresses both the need for a donor and compatibility problems. There are three types: preoperative donation, perioperative acute normovolemic hemodilution, and scavenging/salvaging. In

preoperative donation, patient blood is collected and banked using standard techniques 2-3 weeks before a procedure to give time for regeneration while minimizing red cell storage lesions.[146] In perioperative hemodilution, blood is collected from the patient immediately before surgery and replaced with three times the withdrawn volume with crystalloid or equivalent colloid solution to a target hematocrit of 20-28%. In acute blood loss, the main problem is volume depletion and not red cell loss. In salvaging, intrathoracic or intraabdominal blood is collected and reinfused. It has been practiced for >30 years for trauma patients in veterinary emergency clinics and the reader is referred to detailed descriptions.[147-149]

Administering a Transfusion

Hands should be thoroughly washed prior to handling blood products and extreme care taken when connecting transfusion lines to avoid contamination.

Refrigerated WB and pRBC are not routinely warmed as this may decrease red cell viability and promote microbial growth. For rapid administration, where chilled infusions may cause arrhythmias, and for animals at risk for hypothermia, the products may be warmed to room temperature over 30-60 minutes or the IV line passed through an infusion warmer. Warming by immersing the blood bag in warm water or microwave warming is discouraged. Frozen plasma products should be thawed in a 37-38° C water bath or incubator. A canine unit (≈200 mL) takes about 30 minutes to thaw.[150] Agitating the bag will speed up the process. Microwaving is possible.[151]

A transfusion may be given through any vein (or artery). If IV access is not possible, the intraosseous route (see ch. 77) is preferred. Intraperitoneal transfusion is not recommended. The smallest recommended catheter size for red cell transfusion in dogs is 20 ga and in cats 22 ga.

A transfusion should be given via special sets that contain in-line filters and spikes to connect to the blood bags. A set for an adult human contains a 170-260 micron filter and may be used for standard dog units. Cat and toy-breed dog transfusions are better delivered through human pediatric sets (which contain 40-200 micron filters), because less volume remains in the line when the transfusion is complete. A cat, but not dog, transfusion may also be given through an 18 micron neonate filter.[152,153] If a pediatric set is not available, an adult set may be used and crystalloid fluid used to slowly flush in the remaining transfusion, or the transfusion may be placed in a burette and aseptically "piggy-backed" into the regular fluid line. The same IV line should not be used to deliver 5% dextrose (may cause clumping and hemolysis) or lactated Ringer's (calcium may facilitate microcoagulation). Normal saline, PlasmaLyte 148, and PlasmaLyte A may be given concurrently and may also be used to dilute a transfusion. If a transfusion is being given with intent to deliver platelets, the set should be free of latex, which may trap platelets. Ideally an IV line is changed after transfusion to minimize risk of microbial growth in the line. Transfusions may be delivered by gravity, volumetric infusion pumps (verify safety with manufacturer), syringe pumps, or intermittent slow bolus injection.

During the test dose, the patient is continually observed and vital signs recorded every 5 minutes. After the test dose, the standard transfusion rate is 5-10 mL/kg/h and vital signs are recorded every 15-30 minutes. The maximum rate is 22 mL/kg/h, reserved for critical situations. Human standards specify a transfusion should be complete within 4 hours to reduce risks of microbial growth, but this time may be extended if the risk of volume overload is considered greater than the risk of infection. Units may be subdivided into aliquots and one aliquot refrigerated. When dividing a unit, care must be taken to transfer red cells gently to avoid hemolysis and to avoid contamination. A transfusion log should be kept, recording information from the blood bag label, recipient, date, time, and patient parameters.

Adverse Consequences of Transfusions (Transfusion Reactions)

Transfusion reactions are categorized as immunological and non-immunological, and as acute and delayed. Immunological reactions are due to red cell, plasma protein, and white cell and platelet antigens. Acute reactions are those occurring within 2 days (often within 1-2 hours) of starting a transfusion. Delayed reactions are typically clinically less severe and occur 2 days or longer post-transfusion. The signs of an acute immunological reaction include weakness, tremors, agitation, vocalization, fever, tachycardia/arrhythmias, hypotension, polypnea/dyspnea, salivation, vomiting, elimination, seizures, urticaria/angioedema, and cardiopulmonary arrest. Transfusion reactions are probably under-recognized, but are reported to occur in 3.3-28% of dogs and 1.2-8.7% of cats.[18,44-47,61,78,154-157] Transfusion reactions are not linked with increased risk of death in type-matched dogs receiving pRBC transfusions, but complications impact patient clinical

status.[22]

Acute Immunologic Transfusion Reactions

The pathogenesis of hemolytic reactions is discussed in Compatibility Testing. The severe reaction of type B cats to type A red cells resembles anaphylaxis (see ch. 137).[105,107-109] The most common signs are recumbency, stretching of limbs, hypotension, bradycardia and apnea within two minutes of starting the transfusion and lasting up to five minutes. Less severe reactions are associated with milder hypotension, tachycardia and polypnea. Hemoglobinuria and hemoglobinemia may be undetectable. Tachycardia and polypnea occur during recovery, which may take several hours. Hypertension and arrhythmias follow a severe reaction for about 30 minutes. Pulmonary edema may develop.

Acute hemolysis in dogs causes signs of an immunologic reaction plus hemoglobinuria and hemoglobinemia.[133,137-139] Fever is common but angioedema is not. Acute kidney injury and DIC are uncommon sequelae. Severity of the reaction is correlated with the number of red cells destroyed.

Febrile, non-hemolytic reactions, characterized by a temperature increase of >1 °C, are the most common immunologic reactions of type-matched transfusions in cats and dogs.[18,22] Fever may occur during or after transfusion, range from mild to >41.0° C, be accompanied by vomiting and tremors, and resolve in 1-12 hours. It may be caused by white cell antigens, and bioactive substances that accumulate in stored blood. These reactions are not life-threatening, but interfere with patient status and monitoring for sepsis and hemolysis. Pre-treatment with acetaminophen in dogs may help prevent such reactions, but is only recommended if there is a history of previous deleterious febrile reactions. Donor rotation and fresh red cell products may also reduce risk. Leukoreduction reduces risk in humans and may do so in dogs.

Transfusion-related acute lung injury (TRALI) is one of the most common causes of transfusion mortality in humans. It is characterized by non-cardiogenic pulmonary edema. The majority of human cases are due to *donor* antibodies reacting with *recipient* leukocytes, when using blood from previously pregnant donors who have developed antibodies through exposure to fetal blood. TRALI is unlikely to occur in dogs and cats due to the low rate of previously pregnant donors and different placentation. However, TRALI may arise from different mechanisms, and post-transfusion non-cardiogenic pulmonary edema has been seen in dogs.[22,158] Such dogs were critically ill and the role of transfusion and primary disease in causing acute respiratory distress syndrome (ARDS) is not known.

Allergic transfusion reactions range in severity from mild urticaria, angioedema and erythema, to severe anaphylaxis, bronchoconstriction and effusions, and occur within minutes to hours of starting a transfusion, even if there has been no reaction to a test dose.[53] These are believed to be primarily reactions to gamma globulins and are IgE-mediated. Fever is not typical. The risk of allergic reactions increases with transfusion rate, possibly because some reactions are anaphylactoid. Allergic reactions can occur in a naïve recipient and the risk may increase with multiple transfusions. For animals receiving multiple transfusions, donor rotation and pre-treatment with antihistamines may be considered, especially if there is a history of allergic reactions. Pre-treatment with antihistamines should be considered if a rapid transfusion rate is necessary, but does not guarantee that a reaction will not occur. If a recipient requiring a red cell transfusion has a history of severe allergic reactions, then red cells should be washed prior to transfusion.

Delayed and Other Immunologic Transfusion Reactions

Delayed hemolysis is discussed in Compatibility Testing. *Immune-complex disease* is at least one mechanism of delayed reaction to human serum albumin. *Platelet alloimmunization* occurs rapidly with repetitive transfusions in dogs, resulting in platelet transfusions becoming ineffective. The onset of platelet alloimmunization may be delayed or prevented by donor rotation, leukoreduction, blood product irradiation, and cyclosporine.[159-161] *Post-transfusion purpura* may rarely occur within 1 to 2 weeks post-transfusion and last up to 2 months. Antibody response to transfused platelets is generalized to the recipient's platelets. Immunosuppression may hasten recovery.[162] *Transfusion-related immunomodulation* (TRIM) is a broad term encompassing both the pro-inflammatory and immunosuppressive effects of transfusion, and is associated with beneficial and detrimental effects.[48-63] Factors in TRIM include neutrophils, lymphocytes, proteins and cytokines. The main beneficial TRIM effect is reduced rejection of solid organ transplants. Negative effects include hematopoietic stem cell transplant rejection, transfusion-related graft-versus-host disease (immunological attack on recipient bone marrow causing pancytopenia), and increased susceptibility to infection. Both pro-neoplastic and antineoplastic effects have been associated with TRIM. Leukoreduction and

blood product irradiation help reduce neutrophil and lymphocyte contributions to TRIM, respectively.

Acute Non-Immunologic Transfusion Reactions

Pre-transfusion hemolysis may be caused by improper blood banking, bacterial contamination of blood bags, and rough handling of blood during administration. Reactions to hemolyzed blood mimic alloimmune hemolytic reactions.[154] *Bacterial contamination* of blood products is always a risk, especially in leukoreduced products, resulting in signs of acute sepsis that mimic other reactions.[164] Several reactions are related to *large volume transfusions*, especially *massive transfusions* that exceed patient blood volume. Blood products exert a significant colloid effect, and, as with HBOCs, higher and/or rapid volume transfusions may cause *circulatory overload*. Most blood products use citrate as anticoagulant, which is metabolized to bicarbonate after transfusion. Large transfusion volumes can overwhelm this metabolic pathway, leading to hypocalcemia (citrate intoxication). Liver dysfunction, hypothermia, and hypovolemia increase risk. Clinical signs include tremors, seizures, and arrhythmias. Confirmation requires measurement of ionized calcium. Other complications of massive transfusions include dilution thrombocytopenia, dilution coagulopathy, hypomagnesemia, acid-base disturbances, and hypothermia.[165,166] Ammonia accumulates in stored red cells and ideally products <2 weeks old should be used with liver dysfunction.

Diagnosis and Treatment of Transfusion Reactions

A transfusion should be immediately stopped at the first sign of a reaction; treatment is then symptomatic.[53,157,167-169] Because signs of transfusion reactions overlap, the patient must be re-examined and observed for other signs that may indicate which reaction is occurring. With red cell transfusions, a blood sample should be examined for hemoglobinemia; a urine sample should be examined later for hemoglobinuria. Fluid therapy should be continued to ensure renal perfusion and kidney function should be monitored. Hypotension, regardless of cause, should be treated with fluid boluses ± pressor agents. The cornerstone of treating an acute anti-A reaction in a type B cat is treatment of hypotension; antihistamines with corticosteroids are not routinely used. If fever is present, rule-outs include hemolysis, febrile non-hemolytic reactions, and sepsis. If there are signs of an allergic reaction, antihistamines and/or corticosteroids may be given. If a rate-dependent allergic-like reaction has subsided, the transfusion may be resumed at 10-25% of the previous rate.

The blood bag should be re-examined for particulate matter and discoloration. If the transfusion is cancelled, the blood bag and IV line should not be discarded but kept in a refrigerator in the event that culture of the blood bag, microscopic examination, or post-transfusion crossmatching is desired.

CHAPTER 131

Oxygen Therapy

Kate Hopper

Acknowledgment: The author and editors gratefully acknowledge Dr. Claire R. Sharp's contribution to this chapter.

Oxygen therapy is an essential supportive care measure routinely administered to critically ill pets. Oxygen therapy increases the fraction of inspired oxygen (F_IO_2) in an attempt to increase the oxygen content of the arterial blood (CaO_2). In order to provide appropriate oxygen therapy, it is necessary to choose the most appropriate method of administration, to be able to measure or estimate the F_IO_2 provided, and to monitor the effects of therapy. The F_IO_2 may be recorded as a percentage (21% to 100%) or a decimal (0.21 to 1.0). The concentration of oxygen in room air is always 21%. Supplemental oxygen can provide an F_IO_2 of 30% to 100% depending on the technique and equipment utilized.

Indications and Goals of Oxygen Therapy

Oxygen therapy aims to increase the delivery of oxygen to the tissues (DO_2). The determinants of DO_2 are hemoglobin concentration ([Hgb]), arterial blood oxygenation, and cardiac output (CO) as described by the equation in Box 131-1.[1]

Box 131-1

The Oxygen Delivery (DO_2) Equation

$$DO_2 = CO \times CaO_2$$

$$CaO_2 = ([Hgb] \times 1.34 \times SaO_2) + (0.003 \times PaO_2)$$

CaO_2, Arterial blood oxygen content; *CO,* cardiac output; *Hgb,* concentration of hemoglobin in g/dL; *PaO_2,* partial pressure of oxygen in arterial blood in mm Hg; *SaO_2,* arterial saturation of hemoglobin.

Decreased blood oxygen concentration (hypoxemia) and the associated respiratory distress are the primary indication for oxygen therapy. Hypoxemia can be suspected based on the patient's clinical signs and/or may be documented directly with pulse oximetry or arterial blood gas analysis. Clinical signs suggestive of hypoxemia include respiratory distress (dyspnea), tachypnea, cyanosis, and even apnea. Hypoxemia is confirmed based on a partial pressure of arterial oxygen (PaO_2) <80 mm Hg or an arterial oxygen saturation of hemoglobin (SaO_2) <95%. Severe hypoxemia is present when the PaO_2 is <60 mm Hg or the SaO_2 is <90%.[1] Ideally, oxygen therapy is adjusted as needed for the patient to maintain a PaO_2 of 80 to 120 mm Hg, and an SaO_2 between 95% and 100%. A higher PaO_2 is of little clinical benefit assuming the patient has an adequate hematocrit and stable cardiovascular status, since these animals often will tolerate mild to moderate hypoxemia (PaO_2 of 60 to 80 mm Hg).

Other indications for oxygen therapy include severe anemia (decreased [Hgb]), hemodynamic compromise (decreased CO) and carbon monoxide poisoning. Provision of oxygen therapy can improve DO_2 in situations of low [Hgb] and/or low CO, based on the DO_2 equation. Unfortunately, however, this improvement will be minimal if hemoglobin is already maximally saturated, since oxygen dissolved in the plasma (PaO_2) only accounts for a small percentage of overall DO_2 compared to hemoglobin-bound oxygen. In these cases, definitive therapy should involve blood transfusion to increase [Hgb] and measures to improve CO, respectively. Thus, the goal of oxygen therapy in patients with anemia or hemodynamic compromise is to maximally increase CaO_2 in an attempt to increase DO_2 until more definitive therapy can be instituted. To this aim, the highest possible F_IO_2 should be provided.

An uncommon but important indication for oxygen therapy is carbon monoxide poisoning. In these cases, oxygen therapy will both attenuate tissue hypoxia and accelerate the elimination of carbon monoxide binding to hemoglobin.[2]

Supplemental oxygen is recommended in all unstable emergency patients until they are adequately stabilized and their requirement for ongoing oxygen therapy can be fully assessed.

Techniques

Oxygen therapy requires a source of oxygen, either from an oxygen tank, an in-wall system, or an oxygen concentrator. There are several ways in which this oxygen can be delivered to the patient. The chosen technique is based on availability of equipment, patient demeanor, and severity of disease. Techniques for providing oxygen therapy are listed below in order from least invasive to most invasive. These include an oxygen cage, flow-by, mask, modified Elizabethan collar or oxygen hood, nasal prongs, nasal cannulae, transtracheal, and endotracheal with or without positive pressure ventilation.

Oxygen Cage

An oxygen cage allows administration of a known F_IO_2 to patients, in a low-stress, noninvasive manner. It is particularly effective for cats in respiratory distress, as they may quickly decompensate when handled. Advantages include patient comfort, the ability to control F_IO_2 accurately, and the ability to provide very high F_IO_2 when required. Additionally, purpose-built, commercially available oxygen cages are able to remove carbon dioxide (CO_2) (soda lime) and tightly control temperature and even humidity. Disadvantages may be that oxygen cages are expensive and can require high oxygen flow rates, so they are a more expensive method of oxygen delivery than most other methods. It has been suggested that monitoring and treatment might necessitate interruption of oxygen delivery when using an oxygen cage. However, this problem is rare if the small patient-handling doors are used and if constant oxygen flow and/or addition of flow-by oxygen is utilized during animal handling. Large dogs can become overheated in oxygen cages, and the temperature should be monitored closely. A temporary oxygen cage can be made by covering a cat carrier with a plastic bag and inserting an oxygen hose. It is important to make several holes in the bag to allow heat and CO_2 to escape. This technique is particularly useful for the cat that looks so distressed that handling the cat might be detrimental, or for transport of a small patient that requires oxygen therapy. If a "homemade" oxygen cage is utilized, there is also a concern that dangerous levels of CO_2 and heat can accumulate.[3] As such, it has been recommended that adequate cage ventilation is essential and CO_2 concentrations should be monitored using a portable CO_2 meter.[3]

Flow-by Oxygen

The simplest way to administer oxygen is by directing oxygen gas flow toward the patient's mouth and nose (E-Figure 131-1). Tubing or a Bains circuit connected directly to a regulator and flow meter on an oxygen source is ideal for this technique. A Bains circuit or circle system (with anesthetic gases flushed out) attached to an anesthetic machine also is effective. An oxygen flow rate of 2 to 3 L/min will provide an F_IO_2 of approximately 25% to 40%.[4] This technique is most suitable for short-term administration of oxygen during initial triage and stabilization of emergency patients. This is an easy mode of administration and generally is well tolerated. The disadvantages are that it is labor intensive, wastes oxygen, and the exact F_IO_2 delivered cannot be determined. Additionally, some pets resent gas flow directed at their face, precluding effective

oxygen delivery using this technique.

E-FIGURE 131-1 Flow-by oxygen provided via a Bains circuit. The oxygen source is held 2 to 4 cm from the animal's mouth and/or nose.

Mask Oxygen

A face mask will allow administration of a higher F_IO_2 than can be achieved with flow-by oxygen. It is possible to deliver 60% or higher F_IO_2, and the exact F_IO_2 can be measured by placing an oxygen sensor in the mask alongside the animal's nose (E-Figure 131-2).[4] Disadvantages include the possibility for heat and CO_2 to accumulate in tight-fitting face masks, and animals in respiratory distress often resent the placement of a face mask. Care must be taken when using a face mask to avoid causing corneal trauma with the edge of the mask.

E-FIGURE 131-2 A face mask is a noninvasive method of oxygen therapy that can deliver reasonably high F_IO_2 levels as shown by the oxygen sensor pictured.

Elizabethan Collar

An Elizabethan collar with an oxygen source secured inside and the front covered with clear plastic wrap is a cheap, readily available method by which a reasonable F_IO_2 can be administered (E-Figure 131-3). It is important to make a window in the top of the plastic wrap to prevent accumulation of heat and CO_2. There are also commercially available oxygen hoods that function in a similar manner. Flow rates of 0.5 to 1 L/min can provide an F_IO_2 of 30% to 40%.[5] At higher oxygen flow rates, an F_IO_2 of 60% to 70% can be delivered and oxygen therapy for long periods of time is feasible. It may be difficult to tightly control the F_IO_2 with this approach, and some animals with respiratory distress will not tolerate the placement of the collar.

E-FIGURE 131-3 An Elizabethan collar covered with clear plastic wrap can be used to provide oxygen therapy for long periods of time. As the oxygen sensor pictured shows, this technique can deliver high F_IO_2 levels. It is essential to have a window in the plastic wrap to reduce the accumulation of heat and carbon dioxide.

Nasal Prongs

A simple method of oxygen administration is placement of human nasal prongs (Figure 131-4). These tend to be practical only in medium-sized dogs or larger. The advantages of nasal prongs are their ease of placement and ready availability. The disadvantages include the ease in which they can be dislodged and the fact that the exact F_IO_2 delivered cannot be measured. It can be assumed that the F_IO_2 delivered would be less than that achieved with a nasal oxygen catheter at a similar flow rate (Table 131-1), since the prongs are short and some oxygen is likely lost to the environment.

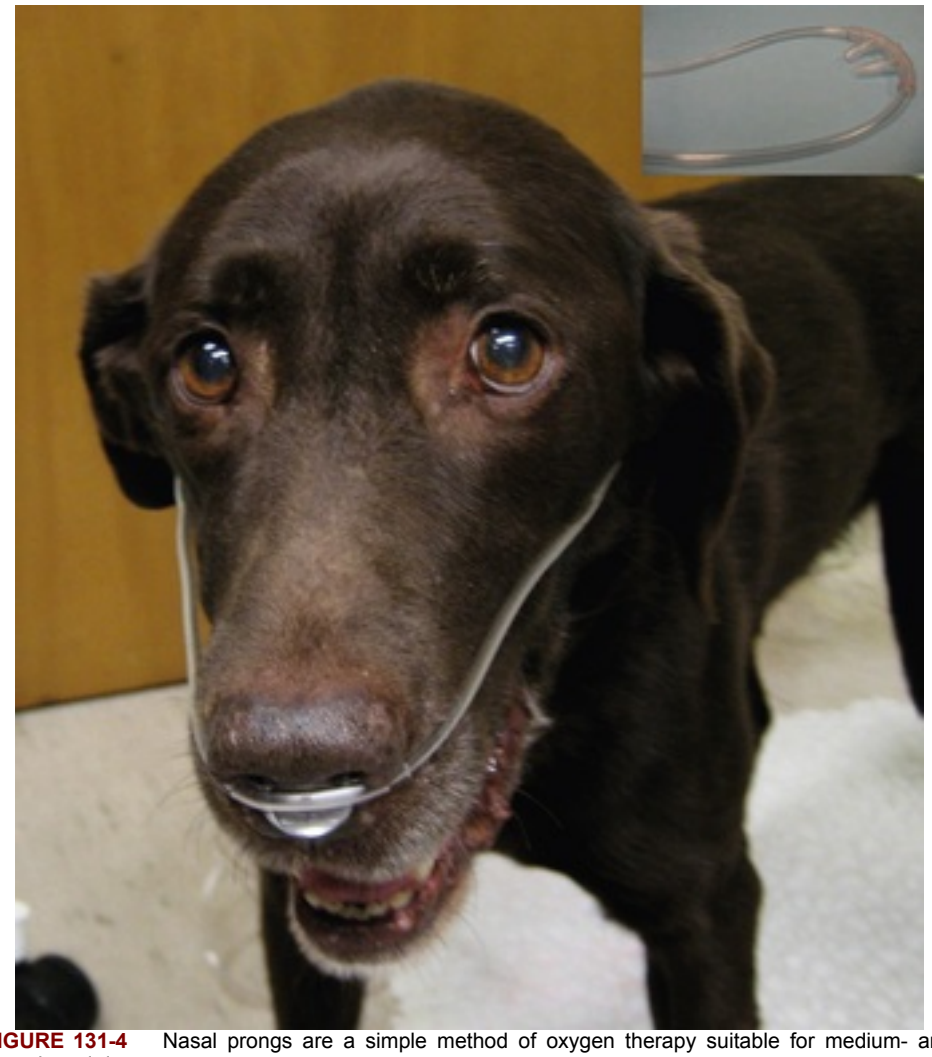

FIGURE 131-4 Nasal prongs are a simple method of oxygen therapy suitable for medium- and large-breed dogs.

TABLE 131-1

F_IO_2 Reported for Unilateral and Bilateral Nasal Oxygen Catheters at Varying Oxygen Flow Rates

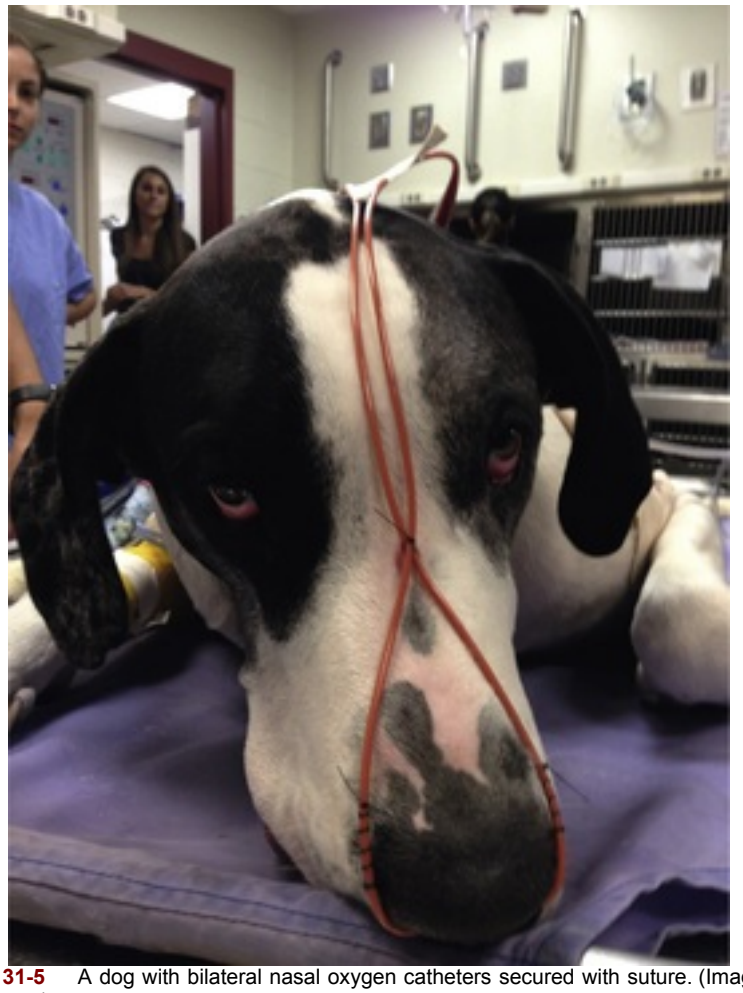
	F_IO_2 (%) MEAN ± SD	
OXYGEN FLOW RATE (mL/kg/min)	UNILATERAL CATHETER	BILATERAL CATHETERS
50	29.8 ± 5.6	36.4 ± 5.9
100	37.3 ± 5.7	56 ± 11.9
200	57.9 ± 12.7	77.3 ± 13.5

From Dunphy ED, Mann FA, Dodam JR, et al: Comparison of unilateral versus bilateral nasal catheters for oxygen administration in dogs. *J Vet Emerg Crit Care* 12:245-251, 2002.

Nasal Oxygen Catheter

A nasal oxygen catheter generally is well accepted by most pets and can supply an F_IO_2 of 37% to 58% with oxygen flow rates of 50 to 200 mL/kg/min. Bilateral nasal oxygen catheters can provide an F_IO_2 of up to 77%

(see Table 131-1) (E-Figure 131-5).[6] Nasal oxygen catheters have the advantage of allowing hands-on patient assessment and management without interruption of oxygen therapy. Unfortunately, many patients with severe respiratory distress will not tolerate the restraint required for placement, and some individual animals are extremely adept at removing the catheters. Other disadvantages include nasal mucosal irritation and difficulty in determining the actual F_IO_2 delivered (although it can be approximated from the information in Table 131-1). In order to reduce nasal irritation, the administered oxygen should first pass through a bubble humidifier and local anesthetic should be administered into the nose as required.



E-FIGURE 131-5 A dog with bilateral nasal oxygen catheters secured with suture. (Image courtesy Dr. Claire Sharp.)

The nasal oxygen catheter should be a soft, smooth-tipped catheter such as an infant feeding tube, red rubber catheter, or commercially available nasal oxygen catheter. Such catheters should be placed in the ventral meatus of the nose after application of local anesthetic (such as proparacaine ophthalmic drops, or 2% lidocaine gel) with the tip advanced to the level of the medial canthus of the eye (Figure 131-6). The catheter should be secured as close to the nares as possible and then across the side or dorsal aspect of the head with sutures, staples, and butterfly tape or cyanoacrylate adhesive (see Figure 131-6).

FIGURE 131-6 Prior to placement, the nasal oxygen catheter is premeasured to the level of the medial canthus (inset, upper left). Following instillation of local anesthetic (inset, upper right), the catheter is guided into the ventral meatus to the premeasured length. It is then secured with sutures, staples, and/or suitable adhesive.

Transtracheal Oxygen

Transtracheal oxygen delivery requires the placement of a catheter into the trachea. A humidified oxygen source is then connected directly to the catheter and flow rates of 50 to 200 mL/kg/min used. Transtracheal oxygen therapy will provide a higher F_IO_2 for the same oxygen flow rate compared to nasal oxygen administration. A flow rate of 50 mL/kg/min is reported to provide an F_IO_2 of 40% to 60%.[7] A transtracheal catheter can be placed percutaneously or via a keyhole incision in the trachea. Both techniques require some operator skill, and strict aseptic technique is required. This technique can be useful for the mobile animal and those intolerant of other oxygen administration methods. It also could be indicated when other less invasive methods of oxygen administration have not been successful. The placement of a transtracheal catheter requires animal restraint and/or general anesthesia, which may be contraindicated in an animal with respiratory distress. This technique also can be utilized as a short-term life-saving procedure in pets with a complete upper airway obstruction, and oxygen can be administered through a tracheostomy tube. Aggressive gas flow rates in this setting should be avoided to prevent barotrauma.

Positive Pressure Ventilation

When hypoxemia cannot be corrected with oxygen therapy, or if a patient requires an F_IO_2 >60% for long periods of time (24 to 48 hours), endotracheal intubation and positive pressure ventilation, ideally with a mechanical ventilator, is indicated. Positive pressure ventilation often will allow correction of hypoxemia at a lower F_IO_2.

Humidification

Inspired gases are normally humidified by the upper airways. The delivery of dry gas to the nose, trachea, or lower airways can cause irritation, inflammation, and thickening of airway secretions. For this reason any oxygen administration method that delivers high gas flows intranasally or intratracheally should use

humidified gas.[8] This is especially important if oxygen therapy is provided for more than a few hours. Humidification is most simply achieved by use of a bubble humidifier, filled with sterile water, and attached to the oxygen source (E-Figure 131-7). The entire unit can be sterilized between patients. Intubated patients on mechanical ventilation need humidification by either a passive heat-moisture exchanger or an active heated humidifier.

E-FIGURE 131-7 A bubble humidifier attached to the oxygen regulator. The black hose is the oxygen tubing to the patient. This is a simple and effective method of humidification of oxygen.

High-Flow Oxygen Therapy

High-flow oxygen therapy (HFOT) is a newer approach to nasal oxygen therapy that requires a specialized machine that provides heated humidified gas at high flow rates. This technique increases the patient's F_IO_2 (most machines allow the operator to adjust the amount of oxygen in the delivered gas so F_IO_2 can be manipulated). In addition, the high flow rates will increase the pressure in the upper airways, a form of continuous positive airway pressure (CPAP). The heated, humidified gas increases patient comfort and acceptance of the high flow rates. It is used in human patients as an alternative to noninvasive ventilation, usually with flow rates ranging from 40 to 60 L/min.[9] These high flow rates are needed to increase airway pressure enough to gain benefit from the CPAP effects. A small pilot study of sedated normal dogs reported a significantly higher PaO_2 in the animals receiving HFOT at 20 to 30 L/min compared to traditional nasal oxygen administration.[10] Veterinary patients may be less tolerant of HFOT without sedation and it is unknown if the higher flow rates of 40 to 60 L/min would be feasible in small animal patients. Gastric distension is a potential concern with this technique. One of six dogs in the pilot study developed gastric distension with relatively low flow rates of HFOT.

Monitoring

Patient monitoring is essential to determine when oxygen therapy is indicated, to ensure that sufficient oxygen supplementation is provided, and to avoid excessive oxygen supplementation. The first priority of oxygen administration should be the resolution of life-threatening hypoxemia, improvement of oxygen delivery and the relief of respiratory distress. As effective monitoring often is impossible during acute respiratory compromise, high F_IO_2 levels should initially be used.

Monitoring of pets receiving oxygen therapy includes physical examination, arterial blood gases, and/or pulse oximetry. Respiratory rate and effort, heart rate, and anxiety levels are usually easily evaluated and can be useful in assessing response to oxygen therapy.

Arterial blood gas analysis includes measurement of the PaO_2 and is the gold standard for evaluation of arterial oxygenation. Assessment of arterial blood gases requires an arterial blood sample and a blood gas analyzer. The normal or "expected" PaO_2 is dependent on the F_IO_2 and the barometric pressure. A useful rule of thumb is that the normal PaO_2 in a patient at sea level is approximately 5 times the F_IO_2 measured in percent. For example, for a patient breathing room air (21% oxygen) at sea level, the normal PaO_2 is approximately 100 mm Hg while the normal PaO_2 with an F_IO_2 of 100% at sea level is approximately 500 mm Hg. The expected PaO_2 for a given F_IO_2 when at a high altitude is lower due to the decrease in barometric pressure. As previously mentioned, the goal of oxygen therapy is to maintain a PaO_2 of 80 to 120 mm Hg. If the PaO_2 is <70 to 80 mm Hg, the F_IO_2 should be increased; if the PaO_2 is >120 to 150 mm Hg, the F_IO_2 should be decreased. The exact range of PaO_2 targeted with oxygen therapy will depend on the clinical scenario and the accuracy and frequency of monitoring. Reevaluation of oxygenation status following any change in F_IO_2 is always important.

In the absence of arterial blood gas analysis, pulse oximetry can be utilized. Pulse oximetry evaluates the arterial saturation of hemoglobin with oxygen (SpO_2). Hemoglobin saturation is determined by the PaO_2, and this relationship is defined by the oxygen-hemoglobin dissociation curve. A PaO_2 of 80 mm Hg correlates to an SpO_2 of approximately 95%, while a PaO_2 of 60 mm Hg correlates to an SpO_2 of approximately 90%. Consequently the aim of oxygen therapy is to maintain an SpO_2 >90% and where possible >95%. When the SpO_2 is 99% to 100% consistently, the F_IO_2 should be gradually decreased until the F_IO_2 at which the SpO_2 decreases is identified. The F_IO_2 should then be set at or just above this point in an attempt to avoid the use of unnecessarily high F_IO_2.

Oxygen Toxicosis and Guidelines for Oxygen Administration

Intensive oxygen therapy places patients at risk of oxygen toxicosis. Oxygen toxicosis is associated with pulmonary dysfunction and failure; the associated damage often is severe and irreversible. Oxygen toxicosis is thought to occur as a result of lipid peroxidation, increased endothelial permeability and leukocyte infiltration into the lung. Blindness also has been reported as a consequence of oxygen toxicosis in people, especially neonates.

Oxygen toxicosis is a function of the F_IO_2 administered and the duration of oxygen exposure. The general recommendation for dogs and cats is to avoid the administration of 100% oxygen for longer than 12 to 24 hours and in situations of long-term oxygen therapy the F_IO_2 should be maintained at <60%.[11,12] In addition, there is no way to predict an individual animal's susceptibility to oxygen intoxication. This leads to the recommendation that the F_IO_2 should always be titrated to the lowest level a patient can tolerate.[12]

CHAPTER 132

Sepsis and the Systemic Inflammatory Response Syndrome

Amy E. DeClue

The systemic inflammatory response syndrome (SIRS) refers to the clinical manifestations of a complex physiologic response to a nonspecific insult of either infectious or noninfectious origin. Heart rate, respiratory rate, body temperature, and white blood cell count are the clinical criteria used for categorizing patients with SIRS in veterinary medicine (Table 132-1), though these criteria have neither ideal sensitivity nor ideal specificity. These criteria have been used for determining the severity of illness and prognosis in critically ill animals. In one study of 500 dogs, mortality was significantly associated with the number SIRS criteria fulfilled.[1] Terminology used for describing the severity of sepsis and SIRS is listed in Box 132-1.[2]

TABLE 132-1

SIRS Criteria in Dogs and Cats

SIRS CRITERIA	DOG	CAT
Body temperature	>102.6° F (39.2° C) or <99° F (37.2° C)	>103.5° F (39.7° C) or <100° F (37.8° C)
Heart rate (beats/min)	>140	>225 or <140
Respiratory rate (breaths/min)	>40	>40
White blood cell count	>19,500/mcL or <5,000/mcL or >5% bands	>19,500/mcL or <5,000/mcL or >5% bands

Box 132-1

Definitions Pertaining to Sepsis and SIRS[2]

Bacteremia—the presence of viable bacteria in the blood stream.

Systemic inflammatory response syndrome (SIRS)—a clinical syndrome caused by systemic inflammation of infectious (i.e., sepsis) or noninfectious origin. In dogs, the diagnosis of SIRS is based on fulfillment of at least 2 of 4 criteria: tachycardia, tachypnea, hypo- or hyperthermia, and either leukocytosis, leukopenia or >5% bands.

Sepsis—1. systemic inflammatory response to infection or 2. life-threatening organ dysfunction caused by a dysregulated host response to infection.

Severe sepsis—this terminology has fallen out of favor and is generally not used.

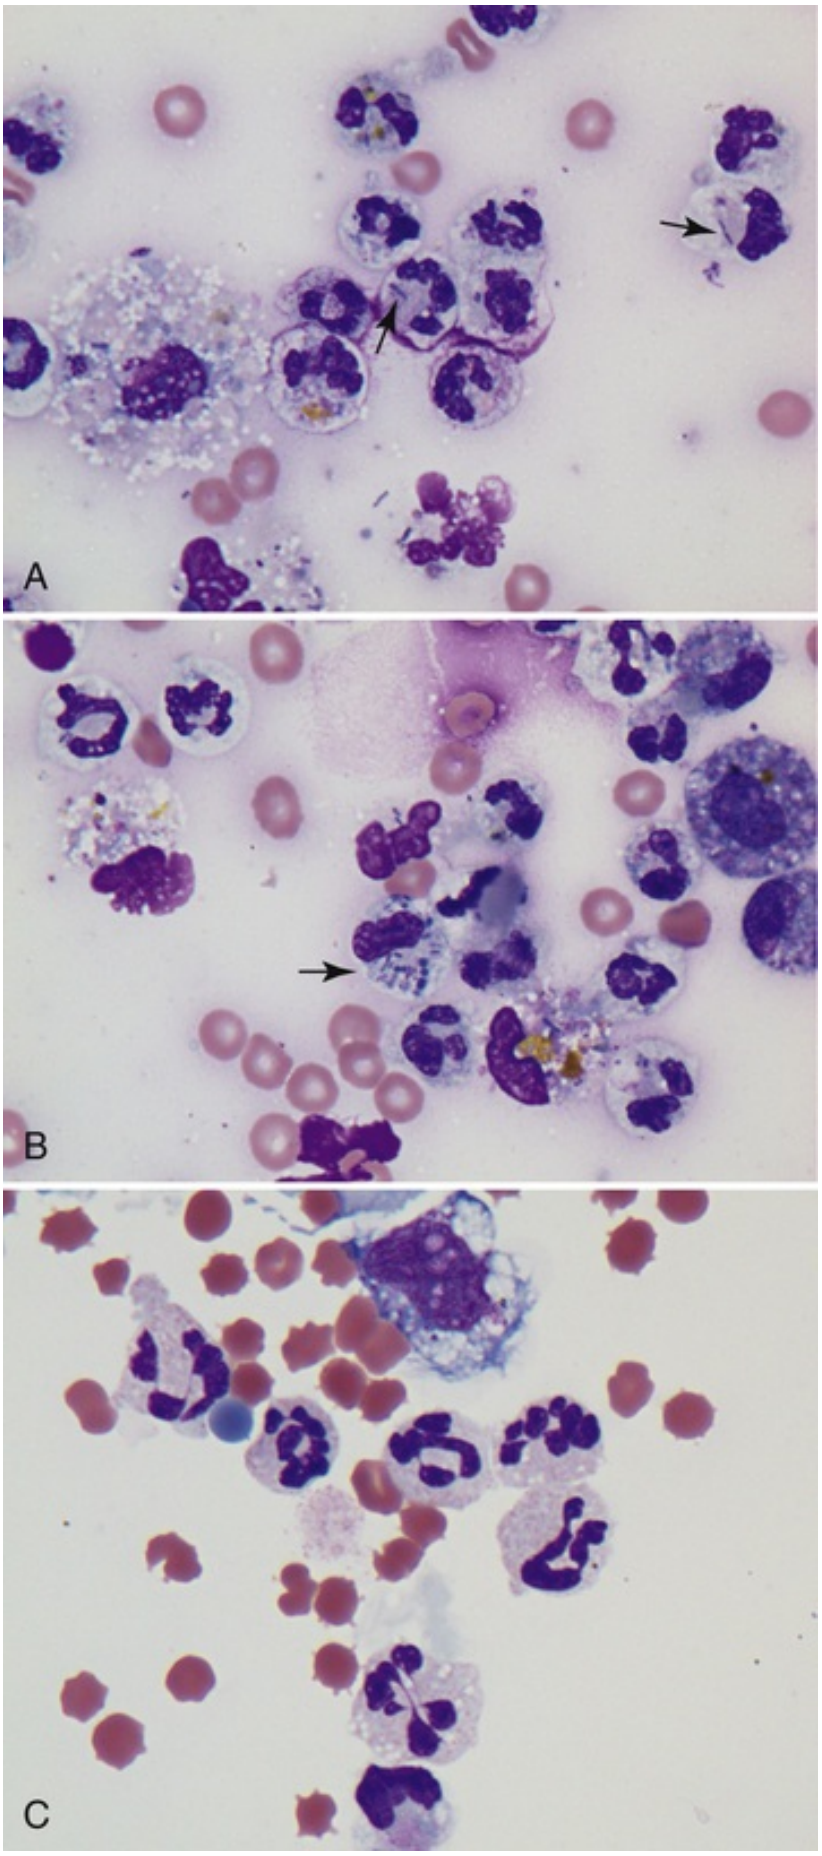
Septic shock—1. the systemic inflammatory response to infection with hypotension despite adequate fluid resuscitation along with the manifestations of hypoperfusion or 2. subset of sepsis in which underlying circulatory and cellular/metabolic abnormalities are profound enough to substantially increase mortality. Generally, this is sepsis with either persisting hypotension requiring vasopressors to maintain a MAP ≥65 mm Hg or a serum lactate >2 mmol/L despite adequate volume resuscitation in people.

Multiple organ dysfunction syndrome (MODS)—altered function of 2 or more organs secondary to SIRS such that homeostasis cannot be maintained without intervention.

Acute respiratory distress syndrome (ARDS)—a pulmonary inflammatory disorder characterized by noncardiogenic pulmonary edema, neutrophilic inflammation and hypoxemia.

Data from Singer M, Deutschman CS, Seymour CW, et al: The Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3). *JAMA* 315(8):801-810, 2016.

In dogs and cats, Gram-negative bacterial infections are the most common cause of sepsis, with *E. coli* being the most common isolate.[3-12] However, any organism (e.g., fungus, parasite, virus, protozoan) could result in sepsis. Sepsis most commonly originates from the abdomen, followed by the respiratory tract in dogs,[3,4] and in cats, sepsis commonly is associated with septic peritonitis, pyothorax, and hepatic abscessation (Figure 132-1).[8-13]



A
B
C

FIGURE 132-1 Photomicrographs of peritoneal fluid from a dog with bacterial peritonitis **(A** and **B)** and with sterile peritonitis **(C).** Suppurative inflammation is noted in all photos. Note the many intracellular bacteria (arrows) in the septic exudate **(A** and **B)** but not in the sterile exudate **(C).** (Photos courtesy Dr. Linda Berent from the University of Missouri.)

Pathogenesis

Sepsis is a complex, variable, and prolonged host response that is triggered by infection. Both pro- and anti-inflammatory responses are involved and, based on the type of response, can result in inflammation and tissue damage, immunosuppression and infection, or recovery. The manifestations of sepsis vary based on both pathogen and host factors. Pathogen factors include the type of pathogen, load, virulence, and site of inoculation, while host factors include genetic factors, anatomic regions of infection, and comorbid diseases. Sepsis is not simply the induction of inflammation, but rather it is induction of an imbalance in the immune system such that physiologic homeostasis can no longer be maintained.

Classically, sepsis has been considered an imbalance between hyper-inflammatory and hypo-inflammatory responses.[14] The hyper-inflammatory response largely has been blamed for the morbidity and mortality associated with sepsis. The hyper-inflammatory response is observed in the beginning of sepsis and is characterized by activation of the innate immune system and production of a cytokine storm. This leads to leukocyte recruitment and the classic manifestations of sepsis. Billions of dollars and many years have been spent trying to identify treatments to dampen the hyper-inflammatory response during sepsis. Little attention was previously given to the hypo-inflammatory response, also known as the compensatory anti-inflammatory response syndrome (CARS). Increasingly, the importance of the anti-inflammatory aspects of the immune response to sepsis-induced morbidity and mortality has been realized.[15]

The innate immune system is predominately responsible for the initial manifestations of sepsis and is primarily activated by danger associated molecular patterns (DAMPs). DAMPs include highly conserved molecules found in or on pathogens. These molecules are referred to as pathogen associated molecular patterns (PAMPs). The innate immune system recognizes PAMPs using pattern-recognition receptors including Toll-like receptors, C-type lectin receptors, retinoic acid inducible gene 1-like receptors, and nucleotide-binding oligomerization domain-like receptors. A second class of DAMPs involved in sepsis come from the host. Tissue damage leads to release of damage-associated molecular patterns or alarmins such as high-mobility group protein B1, S100 proteins, RNA, DNA, and histones.

In the initial phases of an infection, PAMPs (e.g., endotoxin from Gram-negative bacteria; exotoxins, peptidoglycans, and superantigens from Gram-positive bacteria; and fungal cell wall material) induce systemic inflammation initially through activation of local innate immune cells (Figure 132-2). For example, during Gram-negative sepsis, lipopolysaccharide (LPS), the glycolipid component of the cell wall of Gram-negative bacteria, is released. The lipid A portion of LPS binds to LPS binding protein. LPS is recognized via macrophage cell surface receptors like CD14. The main function of CD14 is to transfer LPS to Toll-like receptor (TLR)-4 and MD-2 for subsequent cellular activation. Once LPS binds to these cell surface receptors, the macrophage becomes activated. Activation of inflammatory cells results in the production of multiple inflammatory mediators that have been implicated in the induction and maintenance of sepsis.

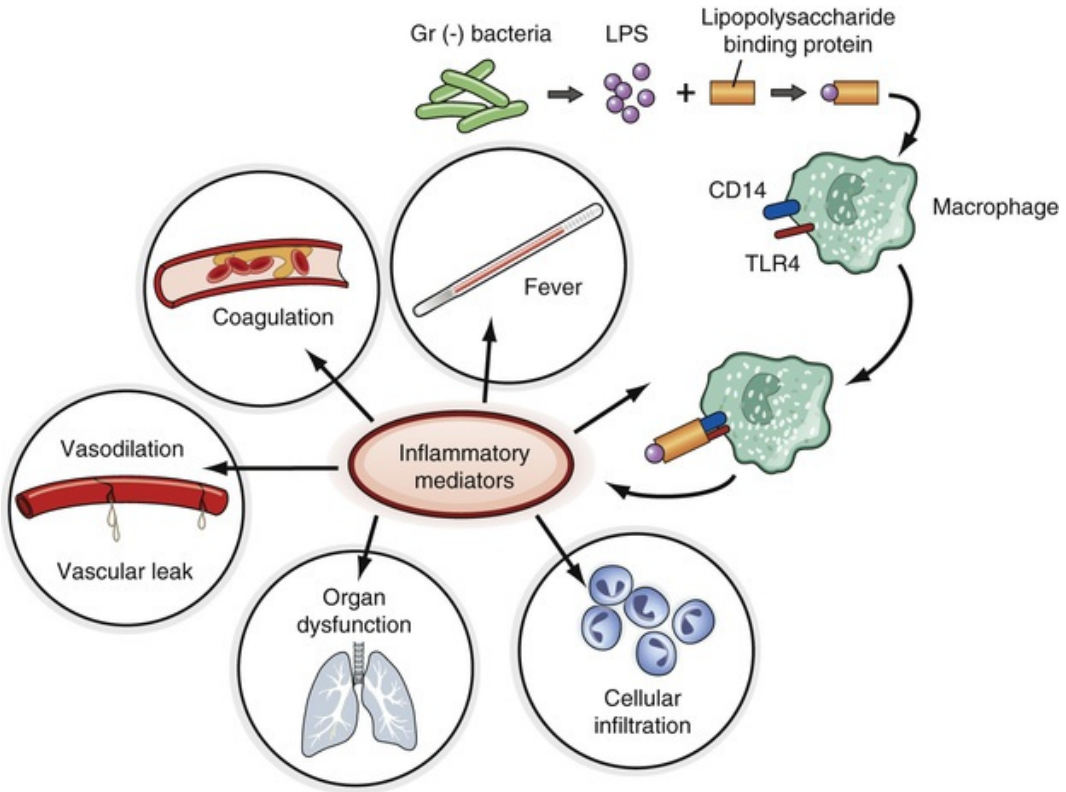


FIGURE 132-2 Pathophysiology of Gram-negative sepsis.

There are many inflammatory mediators involved with sepsis and SIRS. Tumor necrosis factor (TNF)-alpha, interleukin (IL)-6, nitric oxide, and leukotrienes are examples of important mediators contributing to the process of sepsis in dogs and cats.[16-22] Production of these inflammatory mediators results in activation of vascular endothelial cells and upregulation of adhesion molecules. These inflammatory messages enter into the local milieu and then into the systemic circulation. Neutrophils, monocytes, and lymphocytes travel to the site of infection based on these inflammatory mediator signals, secrete a second wave of inflammatory mediators, and provide killing mechanisms for microorganism clearance. Neutrophils also release neutrophil extracellular traps that consist of filamentous DNA containing histones and granular proteins. Neutrophil extracellular traps have beneficial effects such as enhanced bacterial killing but they also interact with the coagulation system and may promote thrombosis. The transition from a localized infection/ inflammatory focus to sepsis is dependent on the systemic circulation of inflammatory messages and activation of immune cells distant to the initial source of infection.

The adaptive immune system is involved in the pathogenesis of sepsis. Antigen presenting cells that have ingested a pathogen activate the adaptive immune response. Subsequently, naïve T cells proliferate and effector cells are generated. Early in the course of sepsis, naïve T cells differentiate into Th1 cells and Th17 cells, which produce additional cytokines such as TNF, IL-2, IL-12, interferon (IFN)-gamma, and leukotrienes or IL-17A, respectively, which typically drives a pro-inflammatory phenotype. Conversely, an anti-inflammatory phenotype is observed when there is a Th2 response, in part due to production of cytokines such as IL-4, IL-5, IL-9, IL-10 and IL-13. The balance between the Th1/Th17 and Th2 response contributes to the clinical manifestations of a pro-inflammatory shift, anti-inflammatory shift, or recovery.

The compensatory anti-inflammatory response syndrome (CARS) is characterized by varying immunoparalysis or relative lack of immune response to infection.[15,23,24] Immunoparalysis is the result of a loss of lymphocytes, dendritic cells, endothelial cells, gastrointestinal (GI) epithelial cells, and thymocytes. The predominant mechanism for this loss is apoptosis.[25] During the hyper-inflammatory response, activation of inflammatory cells leads to nuclear translocation of NF-kappa-B and IL-1beta activation, both of which induce apoptosis of adaptive immune cells. People with sepsis have depletion of CD4+ and CD8+ T cells, B cells, and dendritic cells.[23] The anti-inflammatory cytokine IL-10 is produced in abundance, leading to suppressed CD8+ T cell function and reduced monocytic production of pro-inflammatory cytokines. A reduction in cytokine production by, and expression of, inhibitory receptors on T cells also is observed during

immunoparalysis. There is an increase in T regulatory cells and myeloid-derived suppressor cells, which contributes to immune cell quiescence.[23] The neuro-inflammatory reflex leads to norepinephrine release in the spleen and production of acetylcholine by CD4+ T cells, which in turn targets alpha-7 cholinergic receptors on macrophages, suppressing cytokine production. There is a reduction in HLA-DR expression by myeloid cells, which results in a reduction of antigen presentation. Clinically, immunoparalysis leads to an inability to fight and eliminate infection, and the development of new infections from opportunistic or otherwise normally weakly virulent organisms.[25] Reactivation of latent viruses is another possible sequela.

The classical pathophysiologic model of sepsis is a systematic progression through a hyper-inflammatory phase followed by resolution during the hypo-inflammatory phase.[23] However, this paradigm has changed. It is now recognized that sepsis is a continuum, where the animal may vacillate between hyper- and hypo-inflammatory states and that the hypo-inflammatory state itself plays a role in morbidity and mortality.[23,24] Therefore, animals with sepsis can have a pro-inflammatory shift or an anti-inflammatory shift. Ultimately, the unchecked pro-inflammatory cascade leads to inflammatory cell infiltration, altered thermoregulation, vasodilation, vascular leakage, activation of coagulation, hemodynamic instability, and multiple organ failure. Conversely, animals that have an anti-inflammatory shift develop opportunistic infections that could also result in death.[25]

Clinical Aspects

Clinically, dogs can have either a hyperdynamic or hypodynamic response during sepsis. The hyperdynamic response is characterized by fever, brick red mucous membranes, tachycardia, and bounding pulses. As the disease process progresses, a hypodynamic response characterized by hypotension, pale mucous membranes, and hypothermia can be observed. Often, dogs will have GI or respiratory signs associated with endotoxemia. Hyper- or hypoglycemia, hypoalbuminemia, azotemia, hyperbilirubinemia, and increased alanine aminotransferase and/or alkaline phosphatase concentrations, leukocytosis, neutrophilia with a left shift or leukopenia, anemia, and thrombocytopenia are clinicopathologic abnormalities that have been recognized during sepsis. Evidence of coagulopathy, including decreased protein C and antithrombin concentrations, prolonged prothrombin time and partial thromboplastin time, and increased D-dimer concentrations, has been documented in dogs with naturally acquired sepsis.[3,26] Many dogs with sepsis have myocardial dysfunction and vasodilation, leading to hypotension. Poor perfusion, tissue hypoxia, and cellular metabolic derangements can lead to metabolic acidosis (see ch. 128).

Cats with sepsis can develop clinical signs and clinicopathologic abnormalities that are similar to those of dogs during sepsis with a few exceptions. Bradycardia, hypothermia, and signs of abdominal pain are frequent, unique findings in cats with sepsis.[6,11,13] Cats also appear to develop septic shock more readily than dogs do, and typically the hyperdynamic phase is not recognized during feline sepsis. The mechanisms by which these characteristic manifestations develop are unknown.

Sepsis commonly results in multiple organ dysfunction syndrome (MODS) in humans. Pathogenesis of organ failure (e.g., kidney injury) during MODS is multifactorial but centers around the development of mitochondrial dysfunction. Circulatory collapse, microcirculatory changes, hypoxemia, and inflammation lead to tissue ischemia, reduced mitochondrial function, and thus reduced cellular energy production.[27] The current definition of MODS in dogs is ≥2 forms of organ dysfunction (Table 132-2) in an animal with appropriate risk factors although the criteria to define individual forms of organ dysfunction vary and are at times conflicting.[27,28] The incidence of sepsis-induced MODS is not known in dogs or cats with sepsis although cardiovascular, GI, hepatic, renal, endocrine and respiratory dysfunction/failure have been recognized.[29-34]

TABLE 132-2

Definitions of Organ Dysfunction in Dogs

ORGAN SYSTEM	CRITERIA
Renal	An increase in creatinine concentration ≥0.5 mg/dL from presurgical values without evidence of pre- or postrenal azotemia

Cardiovascular	Hypotension sufficiently severe to require vasopressor therapy
Respiratory	Need for supplemental oxygen administration or mechanical ventilation; determined based on clinical assessment, blood gas analysis (alveolar-arterial gradient >10 mm Hg) and/or results of pulse oximetry (SpO_2 < 95%)
Hepatic	Plasma or serum total bilirubin >0.5 mg/dL
Coagulation	PT or PTT >25% above the upper reference limit and/or platelet count ≤100,000/mcL

Adapted from Kenney EM, Rozanski EA, Rush JE, et al: Association between outcome and organ system dysfunction in dogs with sepsis: 114 cases (2003-2007). *J Am Vet Med Assoc* 236:83-87, 2010.

Diagnosis

A complete patient evaluation including history, physical examination, blood pressure, complete blood count (CBC), serum biochemical profile, urinalysis, blood gas analysis, coagulation profile, and appropriate diagnostic imaging should be performed in any critically ill patient. The diagnosis of sepsis is accomplished by demonstrating evidence of infection and systemic inflammation (i.e., SIRS). Infection can be identified via culture, cytology (see Figure 132-1), histopathology or serology. In patients where bacterial infection is suspected, culture and sensitivity should always be performed so that antibiotic selection can be tailored to the particular organism. Based on clinical findings, specimens should be collected from blood, urine, wound exudate, peritoneal fluid, bronchoalveolar lavage fluid and synovial fluid prior to antibiotic administration. For patients with suspected bacterial peritonitis, a peritoneal fluid glucose concentration that is at least 20 mg/dL lower than a blood glucose concentration measured concurrently is diagnostic for septic peritoneal effusion.[5] In some cases, identification of infection is difficult and/or delayed, and a presumptive diagnosis of infection based on the clinical picture will be necessary. However, care should be taken to consider noninfectious differentials for SIRS when appropriate (e.g., acute pancreatitis, autoimmune disease, and envenomation).

Treatment

The severity of sepsis varies from patient to patient. Some patients will require advanced life support measures to survive while others will require only general supportive care. The key aspects of sepsis treatment include (1) initial hemodynamic stabilization, (2) alleviating the inciting cause and (3) intensive supportive care. The treatment of sepsis can be organized roughly into initial resuscitation (i.e., first 1-6 hours) and long-term management (i.e., >6 hours until discharge from the hospital). Initial resuscitation includes not only restoration of hemodynamic homeostasis, but also alleviating the inciting cause through administration of antimicrobial drugs and/or debridement. Recently, the concept of early goal-directed therapy has become more prevalent in human medicine. Goal-directed therapy is based on the idea of tailoring treatment to specific physiologic parameters thought to be associated with restoration of homeostasis and improved outcome.

Initial Resuscitation: Restoration of Hemodynamic Stability

Initial hemodynamic resuscitation of animals with sepsis is important for restoration of homeostasis. While there are no generally accepted, standardized initial resuscitation protocols for animals, guidelines have been established for people. These guidelines are outlined in the Surviving Sepsis Campaign: International Guidelines for Management of Severe Sepsis and Septic Shock.[35] The authors recommended protocolized, quantitative resuscitation (i.e., goal-directed therapy) of patients with sepsis-induced tissue hypoperfusion. The purpose of early goal-directed therapy in people is to achieve each of the following goals during the first 6 hours of intervention: (1) central venous pressure = 8-12 mm Hg, (2) mean arterial pressure ≥65 mm Hg, (3) urine output ≥0.5 mL/kg/h, (4) superior vena cava oxygenation saturation ≥70% or mixed venous oxygen saturation ≥65%, (5) resuscitation that is targeted to normalize lactate in patients with increased blood lactate concentrations.[35] While these goals have not been specifically tested in randomized, multicenter trials in animals, the general concepts behind the goals could have value in veterinary patients if tailored to the unique physiologic parameters of the species.

Achieving hemodynamic support goals can be accomplished using boluses of isotonic crystalloids or colloids (see ch. 129). Then, ongoing fluid therapy should be tailored to the needs of the patient to provide for maintenance requirements, correct interstitial hydration deficits, replace ongoing losses, and continue to

correct any hemodynamic derangements. Animals with sepsis will have a propensity to develop interstitial edema, including subcutaneous and pulmonary edema, because of increased vascular permeability and decreased blood colloid osmotic pressure. Administration of colloid fluids (e.g., hydroxyethyl starch) may help prevent interstitial edema and should be considered for volume resuscitation and during maintenance of sepsis patients, in addition to crystalloid fluid support. In several clinical trials in people with sepsis, hydroxyethyl starch has increased the risk of acute kidney injury and mortality. However, in goats with experimental endotoxemia, hydroxyethyl starch did not alter creatinine clearance or ultrastructural tubular integrity, indicating that there might be species variation in patients' responses to colloids.[37] No prospective evidence supporting or refuting this phenomenon is available in dogs and cats with sepsis at this time. However, in a retrospective study, critically ill dogs receiving hydroyxethyl starch did not have significantly increased blood creatinine or incidence of acute kidney injury compared to dogs receiving crystalloid fluids for up to 90 days post treatment.[53] Additionally, there are readily available, affordable, and safe alternative colloids (e.g., human albumin) that are used in people, but such alternatives (e.g., fresh frozen plasma), when used in appropriate quantities, might not be as effective at rapid volume expansion, can be cost-prohibitive in dogs and cats, and could be associated with additional risks (e.g., transfusion reaction, disorders of coagulation, transmission of infectious disease). Thus, while the judicious use of hydroxyethyl starch should be considered, the possible risk of kidney injury should not impede its use in animals requiring colloid oncotic pressure support. Additionally, the use of 0.9% NaCl has fallen out of favor in people with sepsis because of the amount of chloride in the solution (Table 132-3). Administration of a chloride-rich solution induces shock in animal models, promotes metabolic acidemia, induces a pro-inflammatory shift, reduces renal perfusion, increases the risk of acute kidney injury in people with sepsis, and increases mortality in adult and pediatric human patients with sepsis.[38] In dogs, administration of 0.9% saline reduces renal blood flow and glomerular filtration rate.[39] For these reasons, the use of a balanced electrolyte solution like Plasmalyte is recommended.

TABLE 132-3

Composition of Common Crystalloid Fluids and Plasma

FLUID	Na (mEq/L)	Cl (mEq/L)	pH	BUFFER
0.9% NaCl	154	154	5.6	None
Lactated Ringer's solution	130	109	6.6	Lactate
Normosol R	140	98	6.6	Acetate/gluconate
Normosol M	40	40	5.0	Acetate
Plasmalyte-148	140	98	7.4	Acetate/gluconate
Plasma	140	100	7.4	Bicarbonate

Despite aggressive volume resuscitation, some patients will require additional support to maintain normal blood pressure and perfusion. The most efficacious, safest treatment for septic shock has not been determined in dogs or cats. Prior to administration of any sympathomimetic drug, care should be taken to ensure that the patient is not hypovolemic. Since the goal of treating septic shock is to maintain tissue perfusion, medications that cause vasoconstriction should be used only if necessary. Positive inotropic drugs (e.g., dobutamine) can be a good initial management choice for septic shock since they help combat decreased cardiac output caused by myocardial dysfunction without inducing peripheral vasoconstriction. If volume resuscitation and positive inotropic support have failed to restore blood pressure, a vasopressor agent (e.g., dopamine, norepinephrine, epinephrine, or vasopressin) could be added. Although there are no clinical trials evaluating these drugs for the treatment of naturally-occurring sepsis, epinephrine was found to adversely affect organ function, systemic perfusion, and survival compared to the use of norepinephrine or vasopressin[40] and had detrimental effects on gastric mucosal pH and plasma lactate concentrations compared to dobutamine and norepinephrine[41] in experimental canine sepsis. Relative adrenal insufficiency has been documented in dogs with sepsis and refractory hypotension[32] and should be considered in any dog or cat requiring vasopressor therapy during sepsis (see ch. 133).

Initial Resuscitation: Alleviate the Cause

A key aspect of treating sepsis centers on the identification and eradication of the inciting cause. Shock is a primary contributor to morbidity and mortality during sepsis (see ch. 127). Since the pathogen is the driving force for immunostimulation, physiologic response, and shock, eradication of the pathogen should downregulate these responses.[42] Therefore, clinicians should consider how to improve the rapidity of pathogen clearance. Optimizing pathogen clearance involves early administration of appropriate antimicrobials and source control when indicated (E-Table 132-4).[42]

E-TABLE 132-4

Factors to Consider When Administering Antimicrobials to Optimize Pathogen Clearance during Sepsis

GOALS	CONSIDERATIONS
Early administration	Administration within 30-60 minutes of presentation or of identification of sepsis
Maximizing antimicrobial potency	Maximize bioavailability (IV administration)
	Maximize the speed at which the antimicrobial becomes bioavailable
	Consider loading doses for some antimicrobials
	Use -cidal antimicrobials when possible
	Apply pharmacokinetic principles to maximize potency; time- vs. concentration-dependency
	Consider combining multiple antimicrobials with different mechanisms of action
	Provide broad-spectrum coverage
	Consider antibiotic penetration into the infection microenvironment and anatomic location; community- vs. hospital-acquired infection
Pathogen removal/reduction in pathogen exposure	Source control via surgical debridement

Adapted from Kumar A: An alternate pathophysiologic paradigm of sepsis and septic shock: implications for optimizing antimicrobial therapy. *Virulence* 5:80-97, 2014.

Although stringent efforts should be made to identify the cause of sepsis, early antimicrobial treatment is critical for survival and should not be withheld pending culture results in a patient showing clinical features consistent with sepsis. Broad-spectrum, bactericidal antimicrobial agents (e.g., fluoroquinolone + penicillin) administered IV should be instituted as quickly as possible, ideally within the first 30-60 minutes. Antibiotic therapy should be selected based on the most likely type of organism given the site of infection. Depending on the source of infection, surgical debridement may be necessary for infection control. Once culture-specific antibiotic sensitivity is determined, the antibiotic with the narrowest spectrum of activity should be chosen and administered until there is complete clinical resolution. The remainder of therapy centers on maintenance of tissue perfusion, management of organ failure, and intensive supportive care (Figure 132-3).

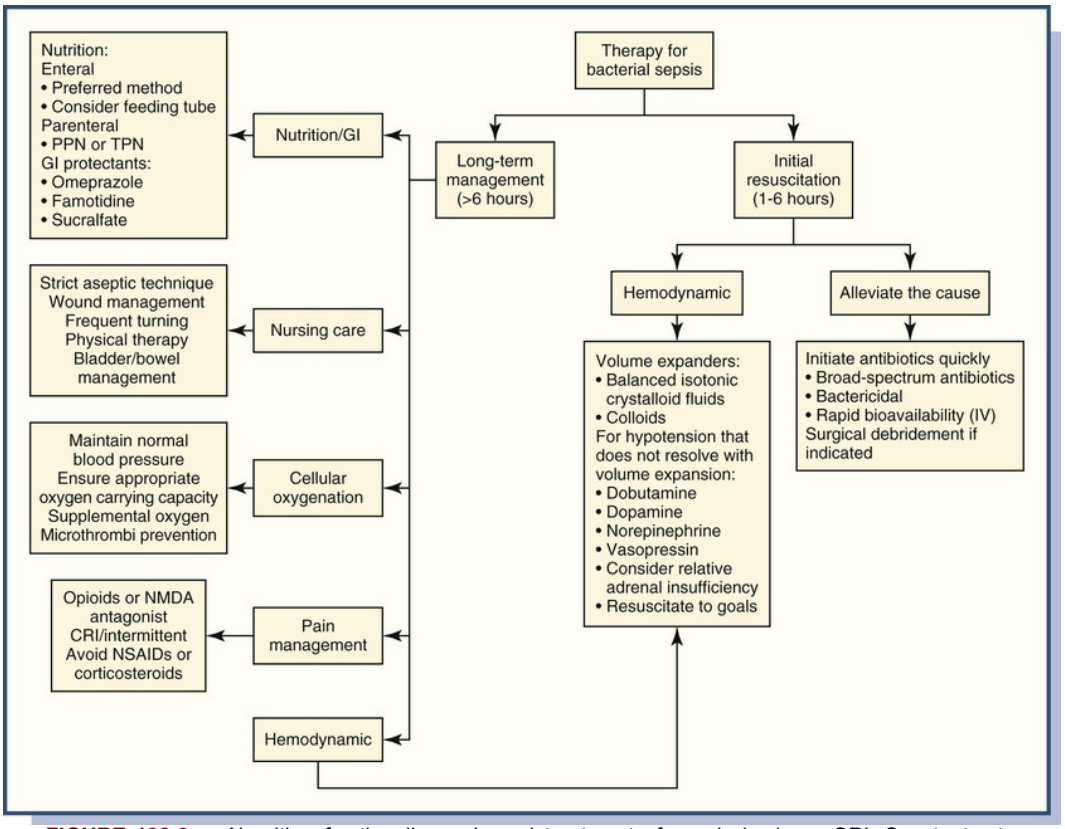

FIGURE 132-3 Algorithm for the diagnosis and treatment of sepsis in dogs. *CRI*, Constant rate infusion; *GI*, gastrointestinal; *NMDA*, N-methyl d-aspartate; *NSAID*, nonsteroidal anti-inflammatory drug; *PPN*, partial parenteral nutrition; *TPN*, total parenteral nutrition.

Long-Term Management: Supportive Care

Bacterial translocation from the GI tract can contribute to systemic inflammation during sepsis. Early placement of a feeding tube (see ch. 82) and initiation of enteral or, in patients with vomiting, parenteral nutrition will help maintain GI barrier function (see ch. 189). Additionally, medication aimed at maintaining normal GI protective mechanisms (e.g., omeprazole, famotidine, sucralfate) could be considered. Hyperglycemia can be a complication of nutritional therapy, especially parenteral nutrition. Hyperglycemia has been associated with increased inflammation and a poorer prognosis in people with sepsis and SIRS. Although the importance of glucose homeostasis in cats with sepsis is unknown, iatrogenic hyperglycemia should be avoided.

Oxygenation, acid-base status, packed-cell volume or hemoglobin concentration, and organ function should be closely monitored. Along with maintaining good tissue perfusion, maximizing cellular oxygenation will help maintain tissue viability and avoid multiple organ dysfunction. This can be accomplished by ensuring good oxygen carrying capacity, providing supplemental oxygen when indicated (see ch. 131), and preventing microthrombi formation (see ch. 197 and 256). For the majority of patients with sepsis, acid-base abnormalities are related to lactic acidosis secondary to poor tissue perfusion (see ch. 128). Typically these abnormalities will resolve with resolution of hypotension and normalization of perfusion (see ch. 129). Therefore, bicarbonate administration rarely is needed and in fact might be contraindicated. When organ dysfunction is recognized, specific therapy aimed at maintaining homeostasis should be considered. In some cases, peritoneal or hemodialysis (see ch. 109 and 110), plasma or blood transfusion (see ch. 130), positive inotropic agents (see ch. 159) and mechanical ventilation (see ch. 139) could be necessary.

Finally, care should be taken to ensure adequate patient comfort including management of pain (see ch. 126), careful catheter maintenance (see ch. 106), bladder/bowel care, and frequent patient turning/movement to prevent decubital ulcers. Almost all patients with sepsis will require analgesic administration for pain management. Although many analgesics like ketamine[43] and buprenorphine[44] can offer specific anti-inflammatory advantages during endotoxemia, some might be detrimental. Morphine, for instance, augments the inflammatory response to endotoxin, has a detrimental effect on mean arterial pressure, and increases

mortality in endotoxemic rats.[44,45] It is not known if morphine is detrimental during canine or feline sepsis.

Sepsis is a systemic inflammatory disease, so it is logical that strategies aimed at immunomodulation or altering the consequences of inflammation have been proposed as novel therapies for sepsis. Many anti-inflammatory therapies have been evaluated in human clinical trials with little success. For example, despite their strong anti-inflammatory properties, the use of corticosteroids for the treatment of sepsis has fallen out of favor due to their lack of efficacy combined with their immunosuppressive, GI ulcerogenic, and prothrombotic effects.[46,47] One exception could be the use of low or physiologic dosages of corticosteroids for management of relative adrenal insufficiency during sepsis (see ch. 133).[48] Although relative adrenal insufficiency is recognized in dogs with sepsis, the administration of corticosteroids in this subset of patients has not been studied.[32]

The only anti-inflammatory therapy with some positive benefit that has been tested in canine clinical trials is polymyxin E. Polymyxin E binds to endotoxin from Gram-negative bacteria, preventing the interaction between endotoxin and the immune system. In a placebo-controlled clinical trial, dogs with parvoviral enteritis that were treated with polymyxin E (12,500 IU/kg, IM q 12 h) had significantly improved hydration, capillary refill time, pulse quality, and lower plasma TNF concentrations than did the control group.[49] Possible adverse events associated with polymyxin E include neurotoxicosis, nephrotoxicosis, respiratory arrest, cardiovascular dysfunction and histamine-mediated hypersensitivity. However, the adverse effects of polymyxin are dosage-dependent; thus, the use of low-dosage (1-2 mg/kg) polymyxin, which maintains considerable anti-endotoxin activity yet avoids adverse effects, has been advocated. Although our experience in dogs is limited, and the adverse effects should be carefully considered, polymyxin E could be a potential treatment for Gram-negative sepsis in dogs, and further study is warranted. Newer immunomodulatory therapies including immunostimulants are being evaluated in experimental models and human clinical trials and could be options for management of sepsis in animals in the future.

Prognosis

Mortality rates for dogs and cats with sepsis range from 48-79% despite comprehensive management.[11,26,32,50-52] In the dog, multiple organ dysfunction and ionized hypocalcemia and, in the cat, persistent ionized hypocalcemia, are associated with a poorer outcome. As our understanding of sepsis grows, new therapies aimed at more effective supportive care and restoring a normal pro- and anti-inflammatory balance could help decrease morbidity and mortality.

CHAPTER 133

The Endocrine Response to Critical Illness

Johan P. Schoeman

Overview

Investigations into the endocrine alterations that accompany critical illness have led to identification of endocrine biomarkers of severity, predictors of mortality and harbingers of recovery.[1-13] Critical illness, caused by any of a plethora of disparate conditions, can result in activation of adrenal gland glucocorticoid (GC) and catecholamine synthesis, which are fundamental components of the stress response and essential for survival.[14] The magnitude of response is dependent on, *inter alia,* marked individual variation, gender differences, stages of illness, severity, degree of systemic inflammatory response, sepsis or septic shock.[15-19] Further, the conditions accompanying critical illness, i.e., hyper- or hypoglycemia, hypotension and pain, together with any pre-admission treatment or use of endocrine response-modifying medications, also influence endocrine responses at the various stages of critical illness.[20,21] The focus of this chapter is a review of endocrine alterations in response to severe homeostasis disruption. It will cover the hypothalamic-pituitary-adrenal (HPA) axis, the hypothalamic-pituitary-thyroidal (HPT) axis, and, in less depth, the somatotropic, lactotropic and gonadal response to critical illness.

Hypothalamic-Pituitary-Adrenal Axis

The HPA axis is generally upregulated through extensive immune-neuroendocrine interactions in response to critical illness. This process culminates in increased serum total and free cortisol concentrations, commensurate with the degree of illness and positively correlated with mortality.[10,22-35] The increases in circulating cortisol concentrations have been attributed to cytokine-CRH mediated adrenocorticotropic hormone (ACTH) secretion (interleukin [IL]-6, IL-1beta and tumor necrosis factor [TNF]-alpha) as well as non-ACTH factors that directly stimulate the adrenals and decrease the rate of cortisol metabolism. Slowing cortisol metabolism significantly prolongs the half-lives of endogenous and exogenous cortisol.[36-40] Adrenal microenvironment and the integrity of the adrenal endothelial vasculature also have roles in these responses.[41,42]

In contrast to these processes, impaired HPA responses have also been demonstrated and attributed to some of the same cytokines.[43-45] These impaired responses have been given several descriptions: adrenal failure/insufficiency (AI) in critical illness, relative adrenal insufficiency (RAI), and critical illness-related corticosteroid insufficiency (CIRCI).[24,31,46-56] Studies have been carried out to characterize and diagnose this ill-defined adrenal dysfunction in critically ill humans,[57] dogs,[49,58,59] mice,[60] and rabbits.[61] The test used most often to diagnose this condition was the ACTH stimulation test.[62] However, results were not consistent, in part because different ACTH preparations, routes of injection, dosages and testing protocols were employed.[63-68] Further, some studies assessed total cortisol, while others assessed "free," "salivary," or interstitial cortisol concentrations.[69-73] The magnitude of the free cortisol response to ACTH was much higher than the total cortisol response, especially if the patient was hypoalbuminemic due to decreases in corticosteroid binding globulin (CBG).[22,74-76] Further, different studies used different criteria to define AI, including basal total cortisol, ACTH-stimulated cortisol, delta cortisol (the ACTH-stimulated minus the basal cortisol), and the cortisol to ACTH ratio.[19,77-79]

For example, one study noted that the incidence of AI varied from 6.25% to 75% depending on which criterion was employed.[19,51,80] Uncertainty regarding the endocrine response to critical illness is due, in part, to current test protocols failing to identify the patients who are GC-deficient at the cellular level. These are the

individuals who should benefit from supplementation with GCs.[19] In this regard, the measurement of nuclear and cytosolic GC receptors may become important biomarkers for diagnosis and treatment of CIRCI.[81,82]

The quest to better understand adrenal dysfunction in critical illness has also led to changed thinking regarding GC therapy. Several studies in adrenalectomized animals demonstrated that the adrenal response was essential for survival.[83-85] In addition, GCs were shown to have physiologically logical ubiquitous effects that could be beneficial for patients in shock: increases in blood glucose concentrations, stabilization of membranes, sensitization of vascular receptors to the vasoconstrictive effects of catecholamines, reducing the overwhelming inflammatory response and other immune-modulating effects.[86-90] However, several meta-analyses demonstrated that the massive GC doses advocated in the 1960s and 1970s worsen prognosis, explaining why this approach was discontinued.[91-94]

Identifying relative forms of adrenal dysfunction in critical illness, in contrast, led to recommendations of low-dose GC usage, an approach further supported with documentation of rather incredulous positive responses in critically ill people in Scotland with extremely low agonal serum cortisol concentrations.[95,96] Another study then documented survival benefits of supplementing both GC and mineralocorticoids in a large French multicenter study.[97] Low-dose GC supplementation in critical illness then became the standard of care and the practice gained momentum in people. Yet, studies from countries in which the adrenal function–modifying sedative etomidate was not used demonstrated much lower incidences of RAI. Then, the confounding effect of this drug on the above studies became known, prompting re-evaluation of low-dose GC use in critical illness, which found no survival benefits.[20,98-106] On the contrary, higher re-infection rates and more side-effects in the GC-treated group were demonstrated. Yet, more rapid shock reversal in GC-treated patients has been consistently shown in this and other studies.[106-109]

Thus, the current consensus is that a vasopressor-resistant hypotensive condition responsive to GCs exists in critical illness. Since this condition can be independent of adrenal dysfunction, ACTH stimulation testing is no longer recommended.[106,110-113] Recent findings further called into question the AI theory, since cortisol responsiveness to ACTH was shown to be normal despite prolonged illness.[114] Additionally, the diminished ACTH concentrations in more prolonged illness are now explained by negative feedback from the elevated cortisol, rather than by pituitary failure.[40] Despite having demonstrated the existence of a GC responsive condition, the issues of GC dosage and for whom it is indicated are still matters of debate.[115-119] A seminal study demonstrated that a portion of the increased GC concentrations in some critically ill patients was a result of decreased GC metabolism, rather than increased synthesis. The result is prolonged GC half-life.[40] Thus, the current hydrocortisone dosage for humans (200 mg/day; 3 mg/kg/day) may be as much as 3 times more than is needed.[40]

While RAI has been demonstrated in septic dogs and another case report, it is not known whether GC supplementation is indicated for such conditions.[49,58,120] Neither is it known which GCs are most efficacious nor their optimal dosing strategy. Results from studies on dogs and extrapolation from the human experience over the past 40 years suggest that GC therapy be reserved for a cohort of hypotensive, septic dogs that do not respond to adequate fluid therapy and vasopressor support. In this scenario, it is recommended that 0.5 mg/kg/day of hydrocortisone be given.

Hypothalamic-Pituitary-Thyroid Axis

In contrast to the HPA axis, the function of the HPT axis is uniformly downregulated during critical illness.[121-127] Longitudinal studies in critically ill humans have shown marked initial reductions in tri-iodothyronine (T_3) and increases in reverse T_3 (rT_3) concentrations in the circulation, within 2 hours of an acute illness. This pattern is the result of altered peripheral conversion of thyroxine (T_4).[128,129] These changes are often accompanied by transient increases in T_4 and thyroid-stimulating hormone (TSH) concentrations. T_4 and TSH concentrations then return to low normal levels, inappropriate for the degree of T_3 suppression and suggesting an altered feedback set point for the HPT axis.[11,130] Conversely, reduced thyroid-releasing hormone (TRH) expression, indicating a central origin to HPT axis dysfunction, has also been demonstrated.[131-134] As illness progresses, the normal nocturnal surge in TSH is abolished and pulsatile TSH release is markedly reduced.[129,135-137] During more prolonged illness, T_4 and TSH concentrations decline while circulating T_3 concentrations are low to undetectable, indicating that central neuroendocrine dysfunction is potentially superimposed upon peripheral adaptations.[138] Low thyroid hormone

concentrations correlate with degree of illness. Thyroid hormone concentrations have been incorporated in endocrine predictive indexes for critically ill humans that have shown similar associations with mortality in critically ill dogs.[10,139-146] Marked reductions in T_3, T_4 and free T_4 concentrations have been documented in dogs with sepsis and free T_4 is less affected by illness than is total T_4 (see ch. 299).[143,144,147]

Pathophysiological studies have demonstrated the role of three deiodinase enzymes (D1, D2 and D3) in these thyroid hormone reductions. For example, reduced D1 and D2 activity cause decreased peripheral conversion of T_4 to T_3, whereas upregulated D3 activity causes T_4 to be converted to rT_3.[148] Similarly, cytokines such as TNF-alpha, IL-1 and IL-6 have been investigated as putative mediators of the low T_3 syndrome.[131,149-151] GCs and dopamine have been implicated in longer-term central HPT axis suppression.[21,152-157] TSH is the first hormone of the HPT axis to rise as the disease process resolves and, in human critical care, is interpreted as a positive prognostic indicator—a sensitive harbinger of recovery.[11-13]

These changes in the thyroid axis seen during acute illness have been interpreted as an adaptation to reduce energy expenditure, similar to those during starvation, and are seen as beneficial, not requiring intervention.[158,159] Nonetheless, clinicians became interested in whether long-term critically ill patients would derive hemodynamic or survival benefit from thyroid hormone supplementation. In this regard, supplementation with T_3 would be preferable, given the decreased peripheral conversion of T_4 in critical illness. However, due to the putative involvement of hypothalamic and pituitary dysfunction in this condition, the use of TRH therapy would be more sensible.[138] Moreover, treatment with hypothalamic-releasing factors allows the body to make use of its feedback systems to ensure optimal levels of circulating and tissue hormones.[138] As a result, several studies using different thyroid hormone preparations have been performed.[160,161] The combined treatment with TRH and growth hormone–releasing peptide (GHRP) has led to normalization of the thyroid axis with concomitant normalization of insulin-like growth factor 1 (IGF-1) levels and a reduction of catabolism markers.[137,162] Certain patients, especially those that had myocardial infarcts or cardiac surgery, seem to derive hemodynamic benefit from thyroid hormone supplementation.[163-165] In contrast, some studies have shown no benefit of thyroid hormone supplementation and others have demonstrated deleterious effects and an increased risk of mortality.[166-170]

There is no indication that thyroid hormone treatment is either beneficial or harmful in critically ill dogs.[171] Accordingly, extrapolation from human studies suggests to refrain from supplementing critically ill dogs with thyroid hormones. If a patient is on prolonged life support, it is indicated to administer both GHRP and TRH.[124]

Somatotropic, Gonadal and Lactotropic Axes

These axes have not been thoroughly investigated in critically ill dogs. Studies on people during the first few hours to days of an acute illness have demonstrated dramatic changes in the growth hormone (GH) profile and a state of peripheral growth hormone resistance, partly triggered by cytokines.[172] Both the amount of circulating GH and its pulse frequency increase, yet levels of insulin-like growth factor 1 (IGF-1) and several IGF-binding proteins decrease.[172,173] This disparate response of the somatotropin axis is appropriate because the direct lipolytic and insulin-antagonizing effects of GH are enhanced, while the IGF-1–mediated effects are attenuated. Resultantly, circulatory glucose and fatty acid levels increase, whereas costly and less vital anabolism, which is largely IGF-1–mediated, is postponed.[174] The relative hyposomatotropism resulting from a lack of pulsatile growth hormone secretion is believed to contribute to the wasting syndrome that characterizes prolonged human critical illness.[175,176]

Regarding the lactotropic axis, pulsatile release of prolactin, which is initially activated in response to disease, becomes impaired in chronic phases of critical illness.[177,178] Similarly, there is evidence for hypogonadotropism and Leydig cell failure, particularly in men with prolonged critical illness, ostensibly due to a hypothalamic-pituitary-gonadal dysfunction.[179-181] Testosterone concentrations become extremely low in the presence of suppressed mean luteinizing hormone (LH) concentrations and pulsatile LH secretion.[180,181] Currently, no consensus has been reached on the value of supplementation with GH, prolactin or testosterone in critical illness.

In conclusion, critical illness is characterized by uniform dysregulation of the hypothalamic-pituitary-peripheral axes, independent of the underlying condition. A clear biphasic pattern is discernable in most axes.

Low peripheral effector hormone levels of T_3, testosterone and IGF-1, despite an active pituitary, typify the acute phase. Herein, the high cortisol levels, in the presence of low ACTH levels, are notable exceptions. Conversely, low peripheral effector hormone levels, coinciding with uniform suppression of the neuroendocrine axes predominantly of hypothalamic origin, are characteristic of the prolonged phase of critical illness.

CHAPTER 134

Heatstroke

Elisa M. Mazzaferro

Client Information Sheet: Heatstroke/Hyperthermia

Hyperthermia is defined as a severe elevation in body temperature that ranges from 40.5° C (104.9° F) to 43° C (109.4° F) after an animal has been exposed to elevated ambient temperature or has performed strenuous activity.[1,2] Pyrogenic hyperthermia is associated with an increase in the hypothalamic thermoregulatory center set point in response to a variety of endogenous or exogenous pyrogens, and in most cases is a normal physiologic process (see ch. 48).[2,3] Nonpyrogenic hyperthermia, however, is abnormal and results from an inability to dissipate heat.[1] Exertion or exercise by animals in locations with high environmental temperature and elevated ambient humidity can cause hyperthermia in as little as 30 minutes, particularly in animals without access to shade or opportunity to cool down and rest.[2,4,5] This can result in exertional heatstroke or exertional hyperthermia when animals cannot dissipate heat.

Pathophysiology

Body temperature is maintained by the hypothalamic thermoregulatory center. Thermoregulation allows the core body temperature to remain constant despite exposure to a wide range of environmental and physiologic conditions.[3] Heat balance occurs through the actions of heat gain and dissipation mechanisms. Heat gain occurs through oxidative metabolism of foodstuffs, exercise or increased metabolic activity, and elevated environmental temperature.[2,3] Heat-dissipating mechanisms help prevent the excessive gain of heat and include behavioral changes such as seeking a cooler location, circulatory changes such as peripheral vasodilation, evaporative cooling primarily in the form of respiratory heat exchange, radiation, and convection (see ch. 49).[2] When environmental temperature increases and approaches body temperature, evaporative heat loss becomes important to maintain normothermia.[2,3] Animals that lack sweat glands depend primarily on the dissipation of heat from evaporative cooling from the respiratory system by panting.[2,6] When body temperature increases, the thermoregulatory center in the hypothalamus is activated and sends a relay of signals to the panting center. This is a basic reflex mechanism by which an animal responds to heat excess and dissipates heat to prevent hyperthermia. As air comes in contact with the mucous membranes of the upper airways, evaporative cooling occurs (see ch. 238).[6] If high ambient humidity is present, however, evaporative cooling mechanisms are not as effective and body temperature can continue to rise despite the body's efforts to cool itself.[2,7] As core body temperature rises, there is a concomitant increase in metabolic rate, which results in further accumulation of heat. A second method of cooling can occur by convection, in which an overheated animal lies on a cooler surface and the body heat is passively transferred to the cooler surface.

A number of factors can increase the risk of heatstroke, including high ambient humidity, upper airway obstruction, laryngeal paralysis, brachycephalic airway syndrome, collapsing trachea, obesity, and a previous history of hyperthermia or heat-induced illness.[4] In addition, lack of shade and a lack of a cooling down period after exercise can predispose an animal to developing exertional heatstroke or exertional hyperthermia. It is recommended that any animal that works or exercises in a hot, humid climate without acclimation must be allowed time to rest in a cool, shady place with plenty of water every 30 to 60 minutes.

The differential diagnosis of heatstroke or hyperthermia must be considered in any animal with a rectal temperature >40.5° C (>104.9° F) and no signs of infection. Pyrogenic hyperthermia results from a reset and increase in the hypothalamic thermoregulatory center set point in response to any number of endogenous or

exogenous pyrogens. Nonpyrogenic hyperthermia, however, results from the body's inability to adequately dissipate heat. Therefore, antipyretic agents are often ineffective in reducing body temperature in animals with heat-induced illness and are actually contraindicated due to potentially adverse side-effects. Differential diagnoses in patients with rectal temperatures >40.5° C (>104.9° F) include inflammatory diseases of the central nervous system such as meningitis and encephalitis, and hypothalamic mass lesions that affect the thermoregulatory center. Other potential differential diagnoses include malignant hyperthermia in affected animals, particularly Labrador Retrievers, and unwitnessed seizure activity. Toxins such as xylitol, amphetamines, metaldehyde, bromethalin, strychnine, and tremorgenic mycotoxins can also cause seizures and muscle fasciculations to such an extent that core temperature rises.

Early in hyperthermia, an increase in dead space ventilation occurs, with little effect on carbon dioxide elimination.[6] As hyperthermia progresses, however, metabolic acidosis can occur.[3] The effects of prolonged hyperthermia override the body's normal adaptive mechanisms, and cerebrospinal fluid hypocapnia and alkalosis, factors that normally decrease panting, are no longer effective, and panting continues. Additionally, as core body temperature increases, the body compensates by triggering peripheral vasodilation.[3,6] Increased blood flow to the skin and periphery can help to decrease heat by convective mechanisms. To help maintain adequate blood pressure, splanchnic vessels constrict to maintain adequate circulating volume.[6] Further, circulating catecholamines increase heart rate and cardiac output in an attempt to increase peripheral circulation in the face of relative and absolute hypovolemia caused by vasodilation and a decrease in circulating plasma volume.[3] Early in hyperthermia, there is an increase in cardiac output and decrease in peripheral vascular resistance.[6] As hyperthermia progresses, however, blood pressure and cardiac output decrease.[6] As perfusion to vital organs is decreased, widespread organ damage can result.

As body temperature rises, thermal injury occurs to neuronal tissue, cardiac myocytes, hepatocytes, renal parenchymal and tubular cells, and the gastrointestinal (GI) barrier.[3] Additionally, oxidative phosphorylation and enzymatic activities are reduced, causing a decrease in the production of energy. The combined effects of decreased organ perfusion, enzyme dysfunction, and uncoupling of oxidative phosphorylation lead to a decrease in aerobic glycolysis and an increase in tissue oxygen debt, both of which contribute to increased lactate production and lactic acidosis within 3 to 4 hours of initial heat-induced injury (see ch. 70 and 128).[3]

The kidneys are affected by direct thermal injury to the tubular and parenchymal cells. Decreased renal blood flow and hypotension further contribute to hypoxic damage to the tubular epithelium and cell death (see ch. 322). With disease progression, thrombosis of renal vessels can occur with disseminated intravascular coagulation (DIC). Consistent findings in the urinalyses of severely hyperthermic animals with severe renal injury are renal tubular casts and glycosuria. Rhabdomyolysis also can be associated with severe myoglobinuria and pigment-associated damage to the renal tubular epithelium.[3]

The GI tract is a key player in multiorgan failure associated with hyperthermia.[3] Decreased mesenteric perfusion and thermal injury to enterocytes often results in a disruption of the GI mucosal barrier with subsequent bacterial translocation (see ch. 274). Bacteremia and elevation of circulating bacterial endotoxin concentrations can lead to sepsis, systemic inflammatory response (SIRS), and multiorgan failure.[3] In one study that investigated mesenteric blood flow in experimentally-induced prolonged hyperthermia in dogs, circulating plasma endotoxin concentration increased significantly, and was associated with a higher risk of death.[7] Clinically, patients with severe hyperthermia often present with hematemesis and severe hematochezia with sloughing of intestinal mucosa.

Thermal injury to hepatocytes results in decreased hepatic function, with elevations in concentrations of hepatocellular enzyme activities (alanine aminotransferase [ALT] and aspartate aminotransferase [AST]), and total bilirubin (see ch. 282 and 283).[1,4] Necropsy findings in one retrospective study of 42 dogs with hyperthermia found centrilobular hepatic necrosis, diffuse tissue congestion, evidence of hemorrhagic diathesis, and pulmonary infarction.[4] Persistent hypoglycemia in affected patients can be associated with hepatocellular dysfunction and depletion of hepatic and muscle glycogen stores. Decreased hepatic macrophage function and portal hypotension can also predispose the patient to bacteremia with associated sepsis and SIRS.

Hyperthermia also induces widespread endothelial damage, one of the key players in the development of DIC (see ch. 197).[8] All elements of Virchow's triad, which consists of vascular endothelial injury, venous stasis, and a hypercoagulable state, occur during hyperthermia. Sluggish blood flow during periods of hypotension and decreased production of clotting factors due to hepatic injury both contribute to DIC. Exposure of subendothelial collagen and tissue factor causes widespread platelet activation, consumption of clotting factors, activation of the fibrinolytic pathway, and subsequent DIC. A study in which hyperthermia

was induced by extracorporeal circulation of heated blood caused thrombocytopenia, elevated fibrin degradation products, prolonged clotting times and spontaneous bleeding.[9] Massive global thrombosis associated with DIC can result in multiorgan failure and death. In a retrospective study of naturally occurring heatstroke in dogs, DIC occurred in more than 52% of cases, and was a risk factor for death.[1]

Finally, hyperthermia can cause direct damage to neurons, neuronal death, and cerebral edema.[10,11] Thrombosis or intracranial hemorrhage can also occur with DIC. Damage to the hypothalamic thermoregulatory center, localized intraparenchymal bleeding, infarction, and cellular necrosis can all lead to seizures. Altered levels of consciousness are among the most common clinical signs of heat-induced illness (see ch. 148). As hyperthermia progresses, severe central nervous system depression, seizures, coma, and death can occur. The potential for reversal of cerebral edema is related to the duration of the neurons' heat exposure. Severe mentation abnormalities are associated with a negative outcome. In one retrospective study of dogs, the only presenting clinical sign that was negatively associated with outcome was the animal being comatose.[4] An unfavorable outcome also was associated with the development of stupor, coma, or seizures within 45 minutes of presentation.[4]

Clinical Signs

Patients with heat-induced illness or hyperthermia often have a history of excessive panting, collapse, vomiting, ataxia, hypersalivation, seizures, or diarrhea. Listlessness, muscle tremors, altered level or loss of consciousness, hematuria, cyanosis, epistaxis, swollen tongue, head tremors, vocalizing, stridor, and mydriasis have been described with less frequency. Changes in mentation, oliguria, vomiting, hematemesis, diarrhea, respiratory distress, icterus, and petechiation can occur almost immediately after heat-induced illness, or could become apparent 3 to 5 days after the inciting event. Therefore, all animals that have sustained heatstroke and hyperthermia should be watched carefully during this period of time.

Laboratory Changes

Animals with hyperthermia should have serial complete blood counts, serum biochemical analyses, coagulation profiles, arterial blood gases (see ch. 75 and 128), venous lactates (see ch. 70), and urinalyses (see ch. 72) performed. In many cases, elevated blood urea nitrogen (BUN) and creatinine concentrations[1,4] exist, reflecting both prerenal (hypovolemia, dehydration) and renal (tubular necrosis) azotemia. Serum creatinine concentration >1.5 mg/dL has been associated with a higher fatality rate.[1] Alterations and elevations in hepatocellular enzyme function secondary to hepatocellular thermal injury or hepatic thrombosis are also demonstrated with elevated ALT, AST, alkaline phosphatase, and total bilirubin concentrations.[1,4] However, hypocholesterolemia, hypoalbuminemia, and hypoproteinemia were associated with a less favorable outcome. Total bilirubin and creatinine were higher in nonsurvivors than survivors. Elevations in creatine kinase (CK) and AST are secondary to rhabdomyolysis. Blood glucose is inconsistently decreased. In patients whose blood glucose concentration remains low despite aggressive supplementation, or is <47 mg/dL, a less favorable outcome is observed.[1,4] Packed cell volume and total solids may be increased secondary to hypovolemia and dehydration with subsequent hemoconcentration.[1] Thrombocytopenia, prolonged prothrombin time and activated partial thromboplastin time and elevated fibrin degradation products can be observed if DIC is present. Destruction or consumption of clotting factors can occur. In some dogs and cats, thrombocytopenia might not become apparent until several days after the initial insult. Thrombocytopenia is one of the most common clinicopathologic abnormalities observed in animals with heat-induced illness.[1] However, there was no significant difference in platelet counts of survivors versus nonsurvivors in one case series.[1] The presence of coagulation abnormalities might or might not be associated with an increased risk of mortality.[1] In one study, a calculated discomfort index, but not environmental temperature, was significantly associated with the development of DIC.[1] Nucleated red blood cells (nRBC) occur in 68% of dogs with heatstroke, with higher relative and absolute nRBC numbers significantly associated with an increased risk of acute kidney injury, DIC, and death.[12,13] Results of arterial blood gas analyses can be variable, as respiratory effort can be increased in heatstroke, producing a respiratory alkalosis. However, metabolic acidosis, with increased circulating lactate, can produce a metabolic acidosis, thus a mixed acid-base disturbance can occur. The need for administration of sodium bicarbonate is a negative prognostic indicator.[3,4]

Treatment

Treatment goals are to manage the hyperthermia, provide cardiovascular support, and treat any complications associated with hyperthermia. Cornerstones of therapy include restoration of circulating blood volume, improving glomerular filtration and renal blood flow, stabilizing electrolyte balance, and providing broad-spectrum antibiotics to minimize complications of bacterial translocation and sepsis.

Early recognition of hyperthermia and instituting early cooling measures are important. First, the clinician should move the animal to a cool area in the shade or indoors, away from direct sunlight. Next, the animal should be sprayed with cool but not cold water. Cool packs can be placed in the axillary and inguinal regions. Air conditioning or cool fans can also help dissipate heat and improve convective cooling mechanisms. It is important to cool the patient to 39.4° C (103° F) within 30 to 60 minutes of initial presentation but to avoid overcooling. As the thermoregulatory center becomes deranged in animals with heat-induced illness, overcooling below 39.4° C will cause a rapid drop in core temperature. Animals brought to a veterinarian within 90 minutes of the inciting event have a more favorable prognosis than animals seen later.[1] Animals cooled prior to presentation by their owners may or may not have a more favorable prognosis and decreased risk of mortality than animals not cooled at the time of initial injury.[1,4] Overcooling can also be injurious, as patients who were hypothermic when presented were more likely to die.[4] If cooling persists when body temperature is <39.4° C (103° F), shivering can occur, which will increase metabolic rate and further increase core body temperature. Immersion in ice baths or cold water is absolutely contraindicated, as cold water immersion causes peripheral vasoconstriction and prevents vasodilation, one of the animal's primary methods of cooling. Vasoconstriction results in further elevation of core body temperature and thus should be avoided at all costs. Massaging the skin can increase peripheral circulation, improve peripheral blood flow, and improve heat loss. Other methods of cooling that have been described but offer no real advantage or improvement of clinical outcome include administration of cool intravenous fluids, gastric lavage, cold-water enemas, and cool peritoneal lavage. Placing alcohol on the footpads has been described, but can further complicate overcooling and thus should not be performed.

Intravenous fluid administration should be tailored to each patient's individual needs, and can be selected and delivered based on central venous pressure (see ch. 76), acid-base and electrolyte status (see ch. 128), blood pressure (see ch. 99), thoracic auscultation, and colloid oncotic pressure. A balanced electrolyte fluid such as Normosol-R, Plasmalyte-M, or lactated Ringer's can be given as determined by calculated dehydration deficits (see ch. 127). If a free water deficit is present, as evidenced by hypernatremia, the clinician should calculate the free water deficit and replace it slowly over a period of 24 hours, to prevent further cerebral edema from occurring. Experimental evidence has also suggested that the use of hydroxyethyl starch may be superior to the use of saline alone to resuscitate animals with hyperthermia.[14]

Oxygen should be administered to animals with signs of upper airway obstruction (see ch. 139). If laryngeal paralysis is present, sedative and anxiolytic agents such as acepromazine should be considered. In cases of severe upper airway obstruction and laryngeal edema, glucocorticoids can also be administered to decrease airway edema. General anesthesia with airway intubation or the placement of a temporary tracheostomy to bypass upper airway obstruction should be considered.

The use of empiric glucocorticoids in patients without signs of airway obstruction is controversial, as they can further impair renal perfusion and predispose to GI ulceration. Their empiric use is not justified and is not advised.

Broad-spectrum antibiotics such as a second-generation cephalosporin (cefoxitin 30 mg/kg IV q 8 h), ampicillin (22 mg/kg IV q 6 h) or ampicillin-sulbactam (20-30 mg/kg IV q 8 h) in combination with enrofloxacin (10 mg/kg IV q 24 h), and sometimes metronidazole (10 mg/kg IV q 8 h) should be administered to decrease bacteremia. Non-nephrotoxic antibiotics should be administered; since compromised renal function is a serious concern in patients with hyperthermia, aminoglycoside antibiotics should be avoided.

Antipyretic agents such as dipyrone, flunixin meglumine, deracoxib, meloxicam, carprofen, and etodolac are contraindicated for a number of reasons. First, these agents act to decrease the set point of the thermoregulatory center in patients with a fever, not hyperthermia, and are therefore ineffective for heatstroke. Antiprostaglandins are only effective on lowering body temperature in dogs with a true fever. Their use may also worsen hypothermia, if present. Second, at high dosages these agents have been shown to decrease renal perfusion and can predispose the patient to GI ulceration.

Urine output should be quantitated and calculated to observe if oliguria or anuria is present (see ch. 105 and 106). After volume resuscitation, urine output should be 1 to 2 mL/kg/h (see ch. 322). If urine output is less, a constant rate infusion of dopamine at 3 to 5 mcg/kg/min can be started to increase renal perfusion and urine output. The presence of persistent oliguria or anuria potentially can be treated with peritoneal or

hemodialysis (see ch. 109 and 110). Ventricular dysrhythmias should be monitored via ECG and treated when necessary (see ch. 248).[5] Seizures should be controlled with diazepam (see ch. 136).

Prognosis

Severe hyperthermia can result in widespread organ failure and must be recognized and treated promptly. In most cases, the prognosis is guarded to grave, depending on the presence of underlying diseases and complications. Mortality rates are directly associated with the duration and intensity of hyperthermia. In one study, the mortality rate was 50%.[1] Obesity, acute kidney injury, and DIC all increase the risk of death associated with hyperthermia.[1] Permanent damage to the kidneys, liver, and brain can occur, including permanent changes in the hypothalamic thermoregulatory center that can predispose the patient to further hyperthermic episodes.[3] In most cases, the clinician must give a guarded prognosis. If death is going to occur, it usually happens within the first 24 hours of the incident.[1,4] If an animal survives past 48 hours of hospitalization, the outcome is generally good.[4] Animals who present with coma or hypothermia after a hyperthermic event generally have a very grave prognosis, even with extremely aggressive therapy (Figure 134-1). A newer approach to severity scoring for heatstroke in dogs has been proposed, and it could help provide a more accurate prognosis for affected dogs.[15]

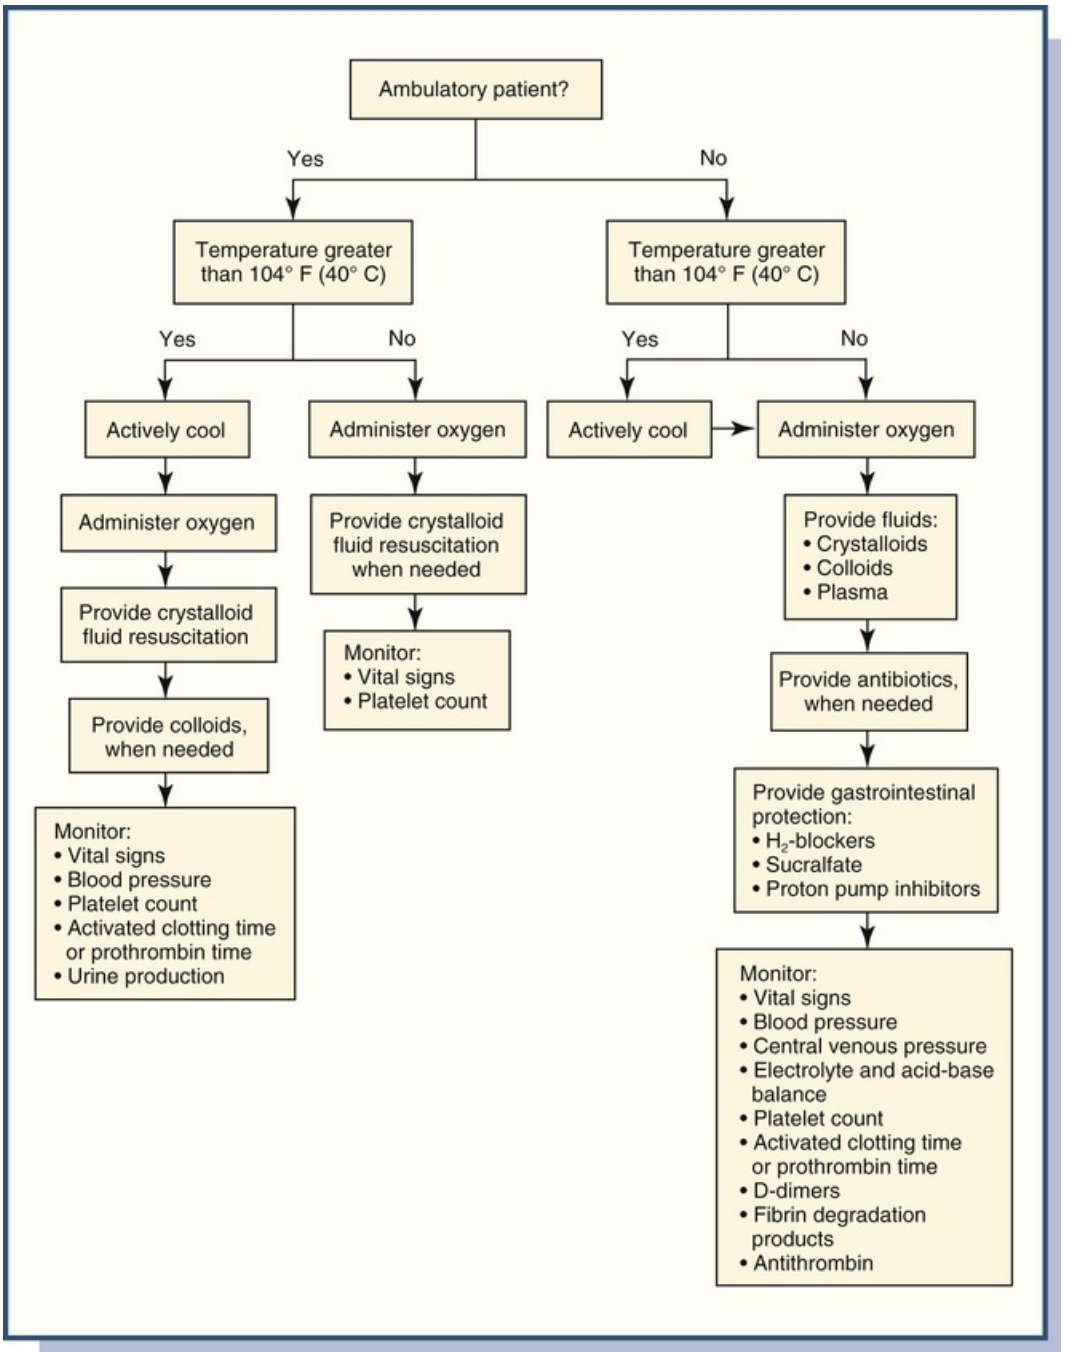

FIGURE 134-1 General algorithm for approach to the patient with heatstroke. The approach can be tailored to the individual patient, with more aggressive monitoring in the most critically ill animals.

CHAPTER 135

Hemorrhage

Armelle de Laforcade

Client Information Sheet: Hemorrhage

Hemorrhage stems from the ancient Greek word *haimo* (blood) and *rrhagia* (excessive flow) and refers to escape of blood from the circulatory system. While bleeding and hemorrhage are often used interchangeably, the term "hemorrhage" refers to *excessive* bleeding that might be difficult to stop. Clinical manifestations of hemorrhage can vary and cardiovascular compromise from resulting hypovolemia might require emergent therapy. Hemorrhagic shock refers to a state of reduced tissue perfusion and tissue oxygen delivery, where cellular oxygen demand outweighs supply.

Acute hemorrhage in companion animals is a common consequence of blunt or penetrating trauma, but can also occur secondary to coagulopathy, neoplasia, or as a complication following surgery.[1,2] While external bleeding is readily identified, internal hemorrhage can be difficult to recognize, as clinical signs can vary based on organs affected; a higher index of suspicion might be required for rapid diagnosis. The most common sources of blood loss in the traumatized patient include wounds (external bleeding), abdomen (due to hepatic or splenic injury), retroperitoneal space (due to renal or perirenal injury), the pleural space, and at the site of pelvic or long bone fractures. Neoplasia is a leading cause of non-traumatic internal bleeding in both dogs and cats, resulting from tumor rupture or invasion of local vessels by tumor cells. Hemangiosarcoma (both primary tumors and metastases) is the most common tumor associated with hemorrhage in dogs and cats, and it can result in intermittent, slow, or acute hemorrhage in the clinical setting.[3-5] Other reported forms of neoplasia associated with hemorrhage in the dog include malignant mesothelioma, metastatic carcinoma, rib osteosarcoma, pulmonary carcinoma, and lymphoma.[5,6] Nearly half of cats with tumor-associated spontaneous hemorrhage have hepatic involvement.[4,7] Hemostatic alterations can result in clinical signs of blood loss. Bleeding disorder-associated hemorrhage results from toxin ingestion (anticoagulant rodenticide), immune-mediated thrombocytopenia, and severe reductions in hemostatic factors and platelets. Finally, iatrogenic causes of hemorrhage should be considered, following surgery or any invasive procedure (Box 135-1).

Box 135-1

Diseases Associated with Hemorrhage

Anticoagulant rodenticide ingestion
Neoplasia
Hepatic failure
Immune-mediated thrombocytopenia
Thrombocytopathia
Congenital factor deficiency
Disseminated intravascular coagulation
Iatrogenic

An acute drop in circulating blood volume of <20% of total blood volume can often be compensated for in the absence of severe underlying disease through modifications of the cardiovascular system. In the short term, reduced venous return to the heart results in a drop in cardiac preload and end-diastolic left ventricular volume. The resulting drop in cardiac output and systemic arterial blood pressure increases baroreceptor

activity in the walls of the aortic arch and in the carotid sinus, leading to venoconstriction (increasing venous return), increased cardiac contractility and increased heart rate. These changes have the net effect of increasing cardiac output. Increased systemic vascular resistance secondary to arteriolar vasoconstriction contributes to normalization of systemic blood pressure. These are considered non-sustainable, short-term changes to restore perfusion and tissue oxygen delivery. A more sustainable mechanism for restoring circulating volume occurs through renal changes in salt and water retention mediated by the renin angiotensin aldosterone system. Renin release triggered by a drop in systemic arterial blood pressure ultimately causes angiotensin II and aldosterone synthesis/release from the adrenal cortex. Other factors contributing to the release of renin include sympathetic stimulation and reduced glomerular filtration rate (GFR) resulting in reduced flow through the distal renal tubule. Aldosterone increases renal sodium resorption by the late distal tubule and collecting ducts, while angiotensin II acts directly on the proximal tubule to enhance sodium resorption and causes vasoconstriction of the renal efferent arterioles, minimizing the fall in GFR.[8]

Clinical signs associated with hemorrhage vary depending on the nature and severity of bleeding. Acute loss of 15-30% of blood volume classically results in an elevated resting heart rate while cardiovascular collapse becomes apparent with losses exceeding 40% of blood volume (30-35 mL/kg in dogs and 20-25 mL/kg in cats). In the emergent setting, hyperdynamic femoral pulses in the presence of mucous membrane pallor is very useful in establishing an early index of suspicion for blood loss and the resuscitative strategy can be modified accordingly. The physical exam finding of a pendulous abdomen or a severely swollen limb in the case of long bone fractures likewise is useful for raising the index of suspicion for bleeding. Bleeding into the retroperitoneal space is usually painful, and a hunchbacked stance (lordosis) can be helpful to prompt an abdominal ultrasound examination. For both retroperitoneal and pleural space hemorrhage, the use of a bedside ultrasound for AFAST and TFAST exams, respectively, can allow for rapid identification of bleeding (see ch. 143 and 149).[9] In the absence of melena or hematochezia, severe gastrointestinal bleeding resulting from immune-mediated destruction of platelets can be difficult to detect yet it can lead to acute and profound blood loss requiring emergent therapy.

Hemorrhage commonly is manifested by a parallel reduction in packed cell volume (PCV) and total solids (TS) (Table 135-1). Cortisol-induced splenic contraction in the dog, however, often masks the drop in PCV in acute hemorrhage, and reduced TS (often with a normal or even slightly increased PCV) is considered a more sensitive indicator of acute blood loss. A reduction in both PCV and TS more commonly is seen following fluid resuscitation. In instances where sampling of effusion is possible, a fluid PCV close to or even exceeding the peripheral PCV is most common with acute hemorrhage while a PCV < 10% typically is indicative of a non-hemorrhagic effusion.

TABLE 135-1

Changes in Hematocrit and Total Solids in Response to Hemorrhage

	PACKED CELL VOLUME	TOTAL SOLIDS
Acute hemorrhage	Normal	↓
Subacute hemorrhage	↓	↓

As with hypovolemic shock (see ch. 127), emergent therapy for hemorrhage consists of intravascular volume replacement to minimize the detrimental effects of systemic hypoperfusion on oxygen delivery. However, subtle changes in resuscitative strategy with early identification of acute hemorrhage are required. In the setting of acute hemorrhage, large volumes of crystalloids over a short period of time can accelerate blood loss due to the sharp rise in intravascular hydrostatic pressure. Clinically, then, an initial positive response to fluid therapy is followed by accelerated bleeding and worsening signs of hypoperfusion (tachycardia, mucous membrane pallor and poor pulse quality), weakness/collapse, and worsening anemia. Unlike with hypovolemic shock, optimal resuscitation in the setting of hemorrhage consists of conservative administration of isotonic crystalloids, and early administration of blood products (see ch. 129 and 130).[10] The term "hypotensive" or "low volume" resuscitation is used to indicate this type of conservative approach where isotonic crystalloids are administered in 10-20 mL/kg aliquots to achieve a blood pressure considered minimally acceptable for renal perfusion. Generally, a systolic blood pressure of 80-90 mm Hg is considered a reasonable target to ensure a mean arterial pressure of 60 mm Hg.[11,12]

Red blood cell transfusions are generally recommended when the PCV drops to 20-25% or when clinical signs of anemia including resting tachycardia, weakness, and lethargy become apparent (see ch. 130). General guidelines such as these are complicated in the setting of acute and ongoing hemorrhage, where the most striking finding could be a profound reduction in TS in the face of milder drop in PCV. In these cases, it is considered acceptable to initiate blood transfusions earlier, at a PCV of 26-28%. The use of blood products early in resuscitation should be considered in cases of severe hemorrhage. Hemorrhage results in the loss of all blood components (red blood cells, platelets, and plasma) so that fresh whole blood is a logical choice when a transfusion is needed. Since fresh whole blood often is not immediately available, the use of stored blood products is most commonly employed in this situation. Packed red blood cells are administered first, using a starting dosage of 10 mL/kg. With severe ongoing hemorrhage, packed red blood cell transfusions often are repeated, and at some point during or soon after resuscitation, a dilutional coagulopathy should be ruled out through coagulation testing. If available, fresh frozen plasma or frozen plasma should be coadministered, especially in cases where a need for surgical disease is identified.

Administration of blood products equivalent to one complete blood volume (90 mL/kg in a dog, 40-60 mL/kg in cats) in a 24-hour period, or half of a blood volume in a 3-hour period, is referred to as *massive transfusion*. The most predictable complication of massive transfusion is hypocalcemia due to cumulative administration of anticoagulant. Other possible complications include thrombocytopenia, prolonged prothrombin time and activated partial thromboplastin time, transfusion reaction, and hypothermia.[2,13]

Autologous transfusion can be considered in dogs with cavitary hemorrhage where blood can be removed easily. Various methods have been described for autotransfusion using commercially available kits as well as basic supplies. Blood that is autotransfused must always be administered using a filter. Another important consideration is potential dissemination of neoplastic cells or gastrointestinal material in the case of a ruptured viscus.[14,15]

Recent attention has been given to the potential role of fibrinolysis in the bleeding patient. In people, fibrinolysis is considered a contributing factor in the coagulopathy associated with trauma, and anti-fibrinolytic agents have been incorporated into practice. Excessive fibrinolysis has been found to play a role in post-operative bleeding in Greyhounds, and the pre-operative administration use of aminocaproic acid in this breed is now commonly employed (3-4 mg/kg [500 mg per Greyhound] PO q 8 h for 5 days beginning the night of surgery).[16] A recent study has also documented hyperfibrinolysis in a population of dogs with spontaneous hemoperitoneum.[17] Given the limited availability of blood products and their impact on the overall cost of care, the potential role of altered fibrinolysis and anti-fibrinolytic agents is of growing interest in veterinary medicine. Identification of altered fibrinolysis is challenging, and the growing use of viscoelastic testing such as thromboelastography and rotational thromboelastometry in the veterinary setting will likely be useful in identifying disease states where fibrinolysis should be investigated as a potential cause for hemorrhage (see ch. 196).

Other therapies in the patient with hemorrhage should target the underlying disease. Vitamin K therapy is initiated concurrently with coagulation factor replacement when anticoagulant rodenticide intoxication is strongly suspected or confirmed. Animals bleeding as a result of an invasive procedure should be re-evaluated frequently, and a second procedure may be required to correct the defect in vascular integrity if there is ongoing hemorrhage. Studies evaluating blood product use have suggested that gastrointestinal blood loss accounts for a significant portion of total blood products administered.[18]

CHAPTER 136

Status Epilepticus

Alireza A. Gorgi

Client Information Sheet: Status Epilepticus

Status epilepticus (SE) is a serious medical emergency with significant morbidity and mortality. It is most often defined as an epileptic seizure lasting longer than 5 minutes or two or more seizures without return of consciousness in between the episodes.[1] This is different than acute repetitive seizures in people, which are usually referred to as cluster seizures (CS) in veterinary patients. Although the definition of cluster seizures is inconsistent in the veterinary literature, clinically it is considered to be two or more seizures within a 24 hour period of time, between which the patient regains consciousness[2,3] (Video 136-1; also see ch. 35, 258, and 260).

The true prevalence of SE and CS is questionable in veterinary medicine, since no large-scale studies have been performed to date. However, according to the information that is available in the literature, the prevalence of SE in dogs varies from 2.5%, to 16%, to 59% in separate studies.[4-7] The prevalence of CS in dogs with idiopathic epilepsy has been reported to be 41%.[5] The true prevalence is most likely lower since most published studies consist of the skewed population of patients that presented to referral centers. No association exists between the occurrences of SE and CS.[5]

In one study, intact male dogs had twice as many episodes and intact female dogs had significantly more frequent CS than neutered male or female dogs.[5] The effect of sex hormones on seizure activity is well known in people.[8] It has been shown that estrogen and progesterone consistently enhance and inhibit neuronal excitability, respectively, while the effect of testosterone on neuronal excitability is less consistent.[8] Therefore, neutering intact female dogs with SE or poorly regulated and frequent seizures appears to be of clinical value in improving the seizure control while the efficacy of neutering intact male dogs with SE or CS to improve their seizure control is questionable. Another study indicated that no reliable conclusions could be made about the effects of sterilization on control of seizures in male or female dogs.[9] Further studies are required to determine the effects of sex hormones in dogs and cats.

Although natural death occurs in a fairly small number of cases with SE (2% to 5%), the overall mortality, mainly from euthanasia, has been reported anywhere from 23% to 38% in dogs.[4,5,7] Euthanasia is directly associated with the frequency of the cluster seizure episodes.[5] This study suggests that the frequency of CS is a more important factor for an owner's decision for euthanasia than is the severity of the seizure episodes.[5]

In dogs with idiopathic epilepsy, the mean lifespan of the SE group was 8.3 years compared to dogs without SE having a median life span of 11.3 years.[4] The only variable that was significantly different between dogs with and without SE was body weight. The dogs with higher body weight were more likely to develop SE.[4] The same study indicated that early and appropriate seizure treatment was not a significant factor in reducing the possibility of SE in dogs with idiopathic epilepsy. Low serum antiepileptic drug (AED) concentrations in epileptic dogs has been associated with SE (5.7% of dogs with SE were due to low drug levels).[6] Similar to people and experimental studies in rodents, presence of high seizure density (CS or SE) and not high seizure frequency increases the risk for being refractory to AEDs.[10] German Shepherds and Boxers were significantly more likely to suffer from CS.[5]

The underlying pathophysiology for SE is complex and multifactorial. Overall, the routine mechanisms that terminate an isolated seizure episode become ineffective. The failure could be due to excessive excitation or inadequate inhibition.[11-13] Alterations in the functional characteristics of gamma-aminobutyric acid receptors, glutamate-mediated excitotoxicity, defects in adenosine receptor agonism, and activation of N-methyl-D-

aspartate receptors are some likely contributing factors.[11-13]

It is a known fact that prolonged seizure activity could cause substantial neuronal injury in the brain. Concurrent hypotension, hyperthermia, and hypoxia are important contributing factors to further brain damage. Inability to meet the significantly increased metabolic demands of the brain during an ongoing seizure is detrimental to the brain. There is a significantly higher potential for permanent brain damage with a seizure lasting 30 minutes or longer. This is the main reason why historically SE was defined as a seizure lasting longer than 30 minutes. One of the major rationales for changing the definition to the recent one (5 minutes) is to start medical intervention prior to the high risk of irreversible neuronal injury.[14,15]

Systemic consequences are often present with prolonged seizure activity. High levels of catecholamines are released, which could result in cardiovascular effects such as systemic hypertension, sinus tachycardia, and other cardiac arrhythmias. Hyperthermia is another consequence of SE resulting from excessive muscle activity and increased sympathetic tone that could result in body temperature elevating to life-threatening levels (see ch. 134). Impaired respiratory function and hypoxemia are some of the other concerns with prolonged seizure activity, which in severe cases could lead to multi-organ failure (see ch. 132).

The underlying causes of SE in dogs were idiopathic in 37.5%, symptomatic in 39.8%, and reactive in 22.7% of cases.[11] In another study the underlying causes of seizures were idiopathic in 26.8%, symptomatic in 35.1%, reactive in 6.7%, due to low serum antiepileptic drug concentrations in 5.7%, and undetermined in 25.8% of cases.[6] Dogs with SE secondary to idiopathic epilepsy or intoxication tend to have a more favorable outcome.[6,11] A negative outcome (death or euthanasia) has been correlated with granulomatous meningoencephalitis, development of partial status epilepticus, and loss of seizure control after 6 hours of hospitalization.[6] In dogs with juvenile epilepsy, SE has been associated with poor outcome.[16] Identification of the underlying cause of seizure is important in treatment of SE and ideally should be treated before resulting in irreversible brain damage. Some of the abnormalities that require immediate assessment and treatment include glucose (see ch. 61), sodium (see ch. 67), and calcium (see ch. 69) dysfunctions.

A complete history and minimum database of hematology, serum biochemical profile, and urinalysis should be performed in every patient presenting with SE. If the patient is receiving maintenance AEDs, blood drug levels should be evaluated. Many of these patients will require advanced imaging such as brain magnetic resonance imaging (MRI) and cerebrospinal fluid analysis once they are more stable to undergo general anesthesia. One should keep in mind that elevated liver values (especially alanine aminotransferase) are commonly observed immediately following seizure activity, predominantly secondary to hypoxemia. Elevated muscle enzyme concentrations could also be present secondary to prolonged seizure activity. Metabolic acidosis is often observed in SE patients and resolves with cessation of seizure activity (see ch. 128). Patients with respiratory acidosis and hypoxemia may require oxygen therapy (see ch. 131). Continuous and repetitive assessment of neurological status (see ch. 259), cardiovascular and respiratory status, urine output, and body temperature is of paramount importance in SE patients. Routine monitoring of blood pressure and heart rate to indirectly evaluate for increase in intracranial pressure (Cushing's reflex) may be warranted. For more information regarding differential diagnoses, diagnostic approach, and treatment for seizures, refer to ch. 35, 260 and 261.

The basic principle and goal of treatment for patients with status epilepticus, like any other acute seizure, is immediate cessation of all of the seizure activity. The current treatment of SE, not only in veterinary patients but also in human patients, is predominantly by use of drugs that were developed decades ago. The treatment recommendations are predominantly based on clinical experience and data from human medical and experimental rodent studies.[14] In veterinary medicine, the response to treatment is usually evaluated by termination of gross seizure activity. Electroencephalographic (EEG) monitoring in dogs and cats with SE has shown that even with cessation of clinical seizures after induction of anesthesia, distinct epileptiform patterns (Figure 136-1) were present in all animals.[17] This finding strongly suggests that EEG monitoring would be useful in SE patients, but continuous EEG monitoring is presently rarely available in veterinary intensive care unit settings. Non-convulsive seizures (Video 136-2) have also been sporadically reported in veterinary patients.[18] Further investigations are necessary to evaluate EEG monitoring in SE patients and define therapeutic endpoints.[17,18]

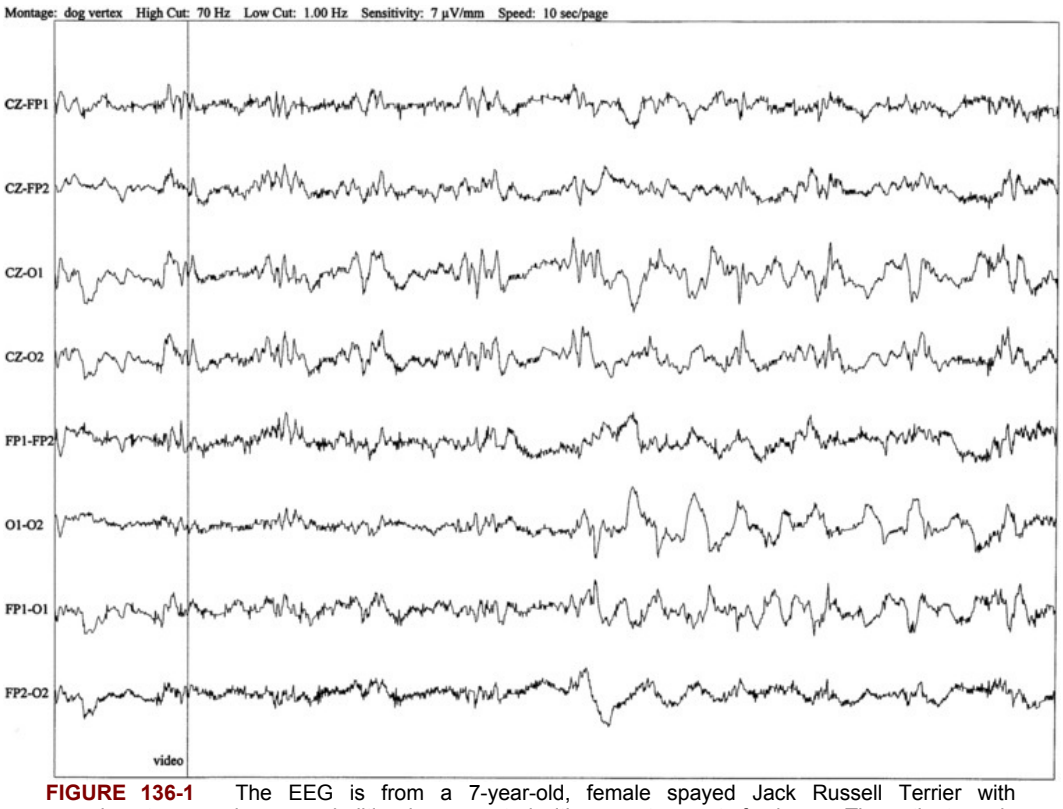

FIGURE 136-1 The EEG is from a 7-year-old, female spayed Jack Russell Terrier with granulomatous meningoencephalitis who presented with an acute onset of seizures. The patient was in non-convulsive SE (only little eye and ear twitches) but unconscious with epileptiform spikes on the EEG (EEG showed continuous seizure activity indicating this was non-convulsive SE). (Courtesy Dr. Dennis O'Brien.)

When treating a patient in SE, an AED should be administered IV immediately. Due to their rapid onsets of action and strong antiepileptic properties, benzodiazepines are the drug of choice for the initial treatment.[19] Diazepam is the drug of choice in small animals.[19] Intravenous administration (0.5-1 mg/kg in dogs and 0.25-0.5 mg/kg in cats) is the preferred method but if this route is not possible, diazepam could also be given rectally (1-2 mg/kg in dogs and 1 mg/kg in cats) or by the intranasal route (0.5 mg/kg in dogs).[19-21] Dogs receiving maintenance phenobarbital require the upper end of the dosages for intravenous or rectal administration of diazepam.[22] In dogs, mean plasma concentration is achieved in about 2, 10-15, and 5 minutes after intravenous, rectal, and intranasal administration of diazepam, respectively.[19-21] Intramuscular administration of diazepam is unreliable and not recommended. Fatal hepatic necrosis has not been reported with intravenous diazepam administration in cats. Lorazepam is the benzodiazepine of choice for treatment of SE in people but does not appear to have any advantage to diazepam in dogs.[23,24] Midazolam (0.2-0.4 mg/kg in dogs and 0.07-0.2 mg/kg in cats) has also been used for treatment of SE.[2,25] Intravenous administration is the route of choice but midazolam could also be administered intramuscularly and achieve reliable peak plasma concentration in 15 minutes.[25,26] Intranasal administration of midazolam (0.2 mg/kg) also appears to be effective in dogs.[27] Rectal administration of midazolam is not recommended as absorption is unreliable which results in erratic systemic availability and plasma concentrations.[24] Midazolam exhibits stronger effects against lidocaine-induced seizures compared to diazepam in dogs but further studies are required in clinical patients.[26]

Immediately after successful use of benzodiazepines, barbiturates should be administered for long-term management of seizures. Phenobarbital is the drug of choice and the most commonly used barbiturate in veterinary patients. Intravenous loading of phenobarbital (16-24 mg/kg IV) will allow the drug to achieve a rapid steady state serum concentration.[2] This could be given in one dose or divided in a few doses (often time to effect) over 12-24 hours. The author prefers administering small boluses in 30-120 minute intervals not to exceed 20 mg/kg over 24 hours. Maintenance phenobarbital therapy should be continued after completing the loading dose. If clinically warranted, a constant rate infusion of benzodiazepines could be used

simultaneously while administering the loading dose of phenobarbital.

Since benzodiazepines and phenobarbital possess cardiopulmonary depression properties, continuous respiratory and cardiovascular monitoring is necessary. This is especially important when using higher dosages or the combination therapy.

If phenobarbital is ineffective or clinically contraindicated, parenteral levetiracetam could be utilized in combination with or as an alternative to phenobarbital. A prospective controlled study in dogs showed that levetiracetam (30-60 mg/kg IV) was safe and appeared to be effective in treatment of SE in dogs.[28] The drug seems to be most effective when administered at 8 hour intervals. The dosage is 20 mg/kg IV q 8 h in cats.[29] The drug causes noticeably less sedation compared to phenobarbital and has a wide safety margin, making it a desirable medication for refractory cases.[28,29] Rectal administration of levetiracetam appears to be effective in dogs.[30] In the author's experience, when AEDs are used appropriately, the majority of patients do respond to the aforementioned treatments. Mannitol or hypertonic saline may be required if evidence of increased intracranial pressure is present. In refractory SE patients, additional treatment (predominantly anesthetic agents) may become necessary. Propofol has been used as intermittent boluses (2-8 mg/kg IV) or as a constant rate infusion (0.1-0.6 mg/kg/min titrated to effect or up to 6 mg/kg/h) to stop the motor activity associated with seizures.[31-33] Anesthetic agents such as ketamine (2-8 mg/kg IV boluses) or isoflurane (1% to 2% minimum alveolar concentration) are additional alternatives for treatment of refractory SE patients.[14,34,35] Some of the other potential therapeutic options include administration of sodium bromide (600 mg/kg IV over 24 hours), pentobarbital (3-15 mg/kg IV to effect or 0.5-4 mg/kg/h), or zonisamide (8-12 mg/kg PO q 12 h).[32,33,36] Anesthetic agents could cause profound sedation and cardiopulmonary depression; therefore, close monitoring and possible respiratory support (endotracheal intubation and/or ventilator support) may be required. Anesthetic agents often stop the motor activity associated with seizures; however, additional investigations are required to determine their effect on seizure activity present on continuous EEG monitoring. Initiation of long-term chronic treatment is of paramount importance after controlling the seizure activity in SE patients.

In summary, SE is a serous medical condition with complex and multifactorial underlying pathophysiologic mechanisms. Benzodiazepines are the first-line treatment options followed by phenobarbital or levetiracetam as second-line therapy options. In refractory cases, anesthetic agents such as propofol are the third-line therapy options. A timely, methodical, and common sense approach is essential for successful treatment of patients with SE.

CHAPTER 137

Anaphylaxis

Lori S. Waddell

Anaphylaxis is an acute, life-threatening allergic reaction resulting from massive, generalized release of mast cell mediators, including histamine. Anaphylaxis can be triggered by venoms from insects and reptiles (see ch. 156); medications such as hormones, antibiotics, nonsteroidal anti-inflammatory drugs, anesthetics, and sedatives; parasiticides; and other miscellaneous drugs and foods (Box 137-1; see also ch. 191). Immediate recognition and treatment of anaphylaxis in a dog or cat are essential for a successful outcome.

Box 137-1

Causes of Anaphylaxis

Venoms

Insects of the Hymenoptera order—bees, wasps, ants
Spiders—black widow, brown recluse
Lizards—Gila monster, Mexican beaded lizard
Snakes—pit vipers (rattlesnakes, copperheads, water moccasins), coral snakes

Hormones

Insulin
Corticotropin
Vasopressin
Parathyroid hormone
Betamethasone
Triamcinolone
Glucocorticoids

Antibiotics

Penicillins—amoxicillin, ampicillin, procaine penicillin
Chloramphenicol
Lincomycin
Gentamicin
Tetracycline
Sulfonamides
Cephalosporins
Polymyxin B

Nonsteroidal Antiinflammatory Drugs

Aspirin
Ibuprofen

Anesthetics and Sedatives

Acepromazine
Ketamine
Barbiturates
Lidocaine and other local anesthetics
Narcotics

Diazepam

Antiparasitics

Dichlorophen
Levamisole
Piperazine
Dichlorvos
Diethylcarbamazine
Thiacetarsamide

Miscellaneous

Blood products
Aminophylline
Asparaginase
Doxorubicin
Calcium disodium edetate
Iodinated contrast media
Neostigmine
Amphotericin B
Vaccines
Allergen extracts—pollens, molds, foods
Enzymes—chymotrypsin and trypsin
Vitamins—vitamin K, thiamine, and folic acid
Dextrans and gelatins

Foods

Milk
Egg white
Shellfish
Legumes
Fruits—citrus
Chocolate
Grains

Physical Factors

Cold
Heat
Exercise

Pathogenesis

Hypersensitivity reactions are classified as one of four types, depending on immunologic response: type I, immediate (immunoglobulin E [IgE]-dependent); type II, cytotoxic (IgG-, IgM-dependent); type III, immune complex (IgG- or IgM-complex-dependent); and type IV, delayed (T lymphocyte-dependent). Anaphylaxis can be caused by either an anaphylactic or anaphylactoid reaction. Anaphylactoid and anaphylactic reactions have exactly the same clinical appearance and are treated identically. Anaphylaxis is defined as a type I, IgE-mediated hypersensitivity reaction with an interaction of antigen and IgE antibody on the surface of sensitized mast cells. This interaction causes the release of histamine and other inflammatory mediators. Sensitization requires previous exposure to an antigen or hapten, which can range in size from a protein to a small, low–molecular weight drug. Proteins act directly as an antigen, while the smaller drug molecules bind to cells and act as haptens. IgE is produced by and bound on the surface of mast cells and basophils by high-affinity receptors (FcεRI) for the Fc portion of the immunoglobulin. When an antigen causes cross-linkage of two surface IgE molecules, the mast cell is activated and primary and secondary mediators are released (Table 137-1).

TABLE 137-1

Mediators of Inflammation in Anaphylaxis

MEDIATORS	EFFECTS
Primary	
Histamine	Increased vascular permeability, vasodilation, constriction of smooth muscle of bronchi and GI tract, increased mucus production
Proteases	Kinin production, activation of complement, initiation of disseminated intravascular coagulation
Heparin	Anticoagulation, urticaria, immune modulation
ECF-A	Eosinophil chemotaxis
NCF-A	Neutrophil chemotaxis
Secondary	
Prostaglandin E_2	Vasodilation, increased vascular permeability
Prostaglandin D_2	Bronchoconstriction, increased vascular permeability, pulmonary vasoconstriction, peripheral vasodilation
Prostacyclin	Vasodilation, inhibition of platelet aggregation
Leukotrienes	Bronchoconstriction, increased vascular permeability, vasodilation, increased WBC chemotaxis
Thromboxane A_2	Increased platelet aggregation, smooth muscle contraction
Platelet-activating factor	Platelet aggregation, platelet sequestration, increased platelet thromboxane production, increased vascular permeability, vasoconstriction, and bronchoconstriction

ECF-A, Eosinophilic chemotactic factor of anaphylaxis; *GI*, gastrointestinal; *NCF-A*, neutrophil chemotactic factor of anaphylaxis; *WBC*, white blood cell.

The cross-linking of the FcεRI receptors activates tyrosine kinases, which cause activation of phospholipase C, leading to production of diacylglycerol and inositol triphosphate. These mediators increase intracellular calcium concentrations and activate multiple protein kinases. Phosphorylation of myosin, found in intracellular filaments, causes granules to move to the cell surface, fuse, and release the primary mediators of anaphylaxis: histamine, heparin, tryptase, kallikreins, proteases, proteoglycans, eosinophilic chemotactic factor of anaphylaxis (ECF-A), and neutrophil chemotactic factor of anaphylaxis (NCF-A). Cross-linking of the FcεRI receptors also activates phospholipase A_2, which produces arachidonic acid from membrane phospholipids, resulting in release of the secondary mediators: leukotrienes, prostaglandins, thromboxanes, and platelet-activating factor. The protein kinases also alter gene expression, causing synthesis and secretion of other cytokines (interleukin [IL]-4, IL-5, IL-6, IL-13, tumor necrosis factor-alpha, macrophage inflammatory protein-1alpha), responsible for the late-phase inflammatory response. Release of the inflammatory mediators is rapid: granule exocytosis occurs within seconds to minutes, activation of the arachidonic acid cascade in minutes, and cytokine synthesis and secretion within 2-24 hours.

Anaphylactoid reactions cause anaphylaxis without IgE. There are two types; the first results from antigen binding to IgG molecules, which then cross link the IgG (FcyRIII) receptors on macrophages. This results in complement activation, coagulation activation, and release of platelet activating factor but not histamine release. The second occurs when a substance directly triggers degranulation of mast cells and basophils without immunoglobulin. Heat, cold, exercise, some drugs including nonsteroidal drugs and opioids, ethanol, and contrast agents can trigger this type of reaction and do not require previous sensitization. The term anaphylactoid is not typically used anymore as it is clinically indistinguishable from anaphylaxis and the clinical diagnosis and treatment are the same.

Anaphylaxis results in hypovolemia and vasodilation, potentially leading to severe hypovolemic shock (see ch. 127 and 129). Histamine and the leukotrienes are potent vasodilators that also increase vascular permeability, allowing leakage of protein and fluid into the interstitial space. There are three types of histamine receptors that contribute to the signs seen during anaphylaxis. Activation of H_1 receptors results in pruritus and bronchoconstriction and stimulates endothelial cells to produce nitric oxide, a potent vasodilator that significantly contributes to hypotension. H_1 receptors also mediate coronary artery vasoconstriction and cardiac depression. H_2 receptors stimulate gastric acid production, as well as causing coronary artery and systemic vasodilation and increasing heart rate and myocardial contractility. H_3 receptors are located on presynaptic terminals of sympathetic effector nerves that innervate the heart and systemic vasculature and

they inhibit endogenous norepinephrine release from sympathetic nerves.[1] Activation of the H_3 receptors results in worsened signs of anaphylactic shock because it inhibits normal compensatory sympathetic responses.

Clinical Manifestations

Anaphylaxis can result in hypotension, bronchospasm, urticaria, erythema, pruritus, pharyngeal and laryngeal edema, arrhythmias, vomiting, and hyperperistalsis. Clinical signs are dependent on species and method of exposure. In dogs, the liver and gallbladder are considered the shock organs, and clinical signs result from hepatic vein congestion and portal hypertension. Abnormalities on bloodwork typically include increased alanine aminotransferase (ALT) values. Ultrasound examination will show a thickened gallbladder with a distinctive striated pattern.[2] Initial signs can include excitement, vomiting, defecation (often diarrhea), and then can progress to respiratory distress, collapse secondary to hypovolemic shock, and death within 1 hour if not treated. A dog with anaphylaxis can have generalized wheals, angioedema (particularly of the face), pruritus (E-Figure 137-1), pale mucous membranes, poor capillary refill time, tachycardia, poor pulse quality, and appear depressed or even collapsed. Severe cases can result in respiratory distress secondary to upper airway obstruction from laryngeal and pharyngeal edema.

E-FIGURE 137-1 Dermal manifestations of anaphylaxis in a Chesapeake Bay Retriever that received a cephalosporin. Urticaria, pruritus, and angioedema are present. (From Silverstein DC, Hopper K, editors: *Small animal critical care medicine*, St Louis, 2009, Saunders.)

In cats, the lungs are considered the shock organ, and respiratory distress is the first sign in cats with anaphylaxis. Respiratory distress results from airway obstruction secondary to laryngeal edema, bronchoconstriction, and increased mucus production. Other signs in cats include severe pruritus, vomiting, diarrhea, depression, hypotension, and death. On physical examination, cats in anaphylactic shock usually present in severe respiratory distress, with pale mucous membranes, poor capillary refill time, poor pulse quality, and wheezes on auscultation.

The most severe anaphylactic reactions are generally seen if the antigen is given by parenteral injection. Oral ingestion often causes vomiting, diarrhea, urticaria, and angioedema. Inhalation can result in rhinitis and bronchospasm. Topical administrations can cause conjunctivitis and urticaria with or without systemic signs. In general, patients that have the most rapid onset of clinical signs after exposure to an antigen develop the most severe signs of anaphylactic shock.

Diagnosis

Diagnosis of systemic anaphylaxis is based on the history of exposure and peracute onset of clinical signs. Clinical signs often occur within seconds to minutes of exposure. Oral exposure can cause a delay of ≥30 minutes before clinical signs appear.

Treatment

Initial treatment of a dog or cat with anaphylaxis consists of the basics of emergency medicine and the administration of epinephrine (Figure 137-2). A patent airway and effective breathing/ventilating should be confirmed immediately. Respiratory distress can result from upper airway obstruction, necessitating intubation with an endotracheal tube or tracheostomy if intubation is not possible. If respiratory distress without airway obstruction is present, oxygen should be administered by mask or flow-by during initial assessment and stabilization, and then by nasal catheter or oxygen cage (see ch. 131). Cardiovascular dysfunction must be treated with drugs and/or fluids as indicated. Vascular access is essential for treatment. Hypovolemic shock is a significant contributor to morbidity and mortality in anaphylaxis. Hypovolemia occurs secondary to increased vascular permeability and venous pooling. Fluid therapy, often starting with a shock bolus of crystalloids at a dose of 90 mL/kg in dogs and 60 mL/kg in cats, is indicated (see ch. 127 and 129). Ongoing crystalloid therapy usually will be necessary at rates higher than maintenance to keep up with ongoing losses and will need to be tailored to the individual patient. Additional fluid therapy may include artificial or natural colloids. If a coagulopathy is present, blood products, especially fresh frozen plasma, could be necessary (see ch. 130). This should be given at a dose of 10 to 20 mL/kg over several hours (or faster if needed for volume resuscitation). Fluid therapy is guided by clinical parameters including heart rate, pulse quality, mucous membrane color, capillary refill time, respiratory rate and effort, and packed cell volume (PCV) and total solids.

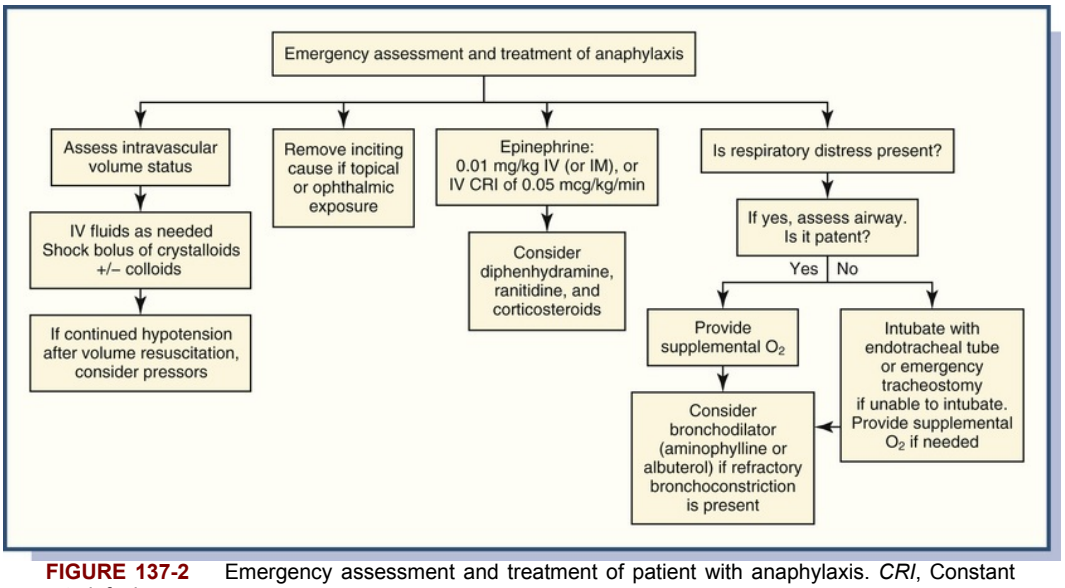

FIGURE 137-2 Emergency assessment and treatment of patient with anaphylaxis. *CRI*, Constant rate infusion.

Epinephrine is the mainstay of therapy for treatment of systemic anaphylaxis. Traditionally, a dosage of 0.01 mg/kg given slowly IV is recommended, although 0.02 mg/kg can be given into the trachea if the patient is intubated and IV access cannot be obtained. A maximum dose of 0.5 mg IV for patients weighing >40 kg is recommended. Epinephrine also can be administered IM at a dosage of 0.01 mg/kg. Doses can be repeated every 5-15 minutes as needed. Epinephrine is useful because of its inotropic and chronotropic effects on the heart as well as vasoconstriction. Epinephrine also causes bronchodilation and increased intracellular concentrations of cyclic adenosine monophosphate, which decreases synthesis and release of inflammatory mediators of anaphylaxis. A single dose of epinephrine given IV, IM, or SC after maximal hypotension had developed did not produce a sustained improvement in hemodynamic parameters in a study on dogs with induced anaphylactic shock; only the IV dose produced a transient improvement (<15 minutes) in mean

arterial pressure, stroke volume, and pulmonary wedge pressure.[3] A later study of anaphylaxis induced in dogs showed that administration of epinephrine by constant rate intravenous infusion (CRI) was the only route that caused sustained improvement in hemodynamic parameters compared to the nontreatment group and the groups that received a bolus given IV, SC, or IM.[4] The dosage used for the IV CRI was 0.05 mcg/kg/min. These studies suggest that epinephrine acts primarily as a vasopressor rather than specifically improving immunologic recovery. Consideration should be given to administering epinephrine as a CRI rather than an IV bolus. Heart rate, rhythm, and blood pressure should be monitored when giving epinephrine, especially when it is given IV, because of its ability to cause cardiac arrhythmias and systemic hypertension. Epinephrine and fluid therapy should begin to improve clinical signs within minutes of being administered. Dogs and cats ideally will be fully stabilized within an hour.

Other medications that can be useful in the treatment of systemic anaphylaxis include vasopressors, glucocorticoids, antihistamines, aminophylline, and atropine. Dopamine at a dosage of 5-10 mcg/kg/min IV CRI or norepinephrine at a dosage of 0.01-1 mcg/kg/min IV CRI can be used if refractory hypotension is present.[5] Vasopressin (0.5-1.25 mU/kg/min IV CRI) can be used if the patient is refractory to fluid and catecholamine therapy.[5] Aminophylline or a selective beta$_2$ agonist such as albuterol may be used if bronchoconstriction is refractory to epinephrine. It will cause bronchodilation, increase respiratory drive, and increase contractility of the muscles of respiration. An aminophylline dosage of 10 mg/kg IV for dogs and 5 mg/kg IV for cats is recommended. Atropine at a dosage of 0.02 to 0.04 mg/kg IV or IM should be used if bradycardia is present despite epinephrine administration. Glucocorticoids are useful in blocking the arachidonic acid cascade and reducing the severity of late-phase anaphylactic reactions. Dosages of 1 to 2 mg/kg IV for dexamethasone have been recommended unless the patient has developed anaphylaxis from administration of one of the glucocorticoids, as cross-reaction may occur. It is essential that glucocorticoids not be used in place of epinephrine in the emergency situation because they have little effect on the immediate stages of anaphylaxis. Antihistamines competitively bind at the histamine receptors and block its effects. Diphenhydramine, an H_1 blocker, should be administered at 1-4 mg/kg IM in dogs and 0.5-2 mg/kg in cats to reduce pruritus and angioedema. If given IV, it should be given slowly, over 5-10 minutes at a lower dosage of 0.5-1 mg/kg, to reduce the risk of cardiac arrhythmias and hypotension. The H_2 blockers such as ranitidine (1 mg/kg IV) or famotidine (0.5 mg/kg IV) can be used for decreasing gastric acid secretion stimulated by histamine. These antihistamines are not very useful in the acute, life-threatening stage of anaphylaxis, but can be helpful after a dog or cat has been stabilized. In one study, pretreatment of dogs with the experimental H_3 blocker thioperamide maleate resulted in increased heart rate and improved left ventricular stroke work, but its clinical usefulness in naturally-occurring anaphylaxis after the onset of signs remains to be determined.[1]

Intense monitoring of a dog or cat for 72 hours after the anaphylactic episode is essential. There are reports of biphasic reactions that can occur up to 3 days later.[5] Monitoring should include respiratory rate and effort, heart rate and rhythm, blood pressure, pulse oximetry and/or arterial blood gases, coagulation parameters, renal and hepatic function, PCV, total solids, and glucose. Additional supportive care, such as ventilatory support, should be provided as needed. Avoidance of the trigger for anaphylaxis is prudent in the future. Careful questioning of the owner about recent exposure to insects, reptiles, foods, topical therapies, and medications and prevention of re-exposure is essential (see Box 137-1). The prognosis for a patient presenting with anaphylaxis is variable, depending on the severity of onset and progression of reaction. The earlier the patient receives appropriate therapy, the better the prognosis. This is especially important since death can ensue in 1 hour or less from time of exposure.

CHAPTER 138

Sedation and Anesthesia in Critical Care

James S. Gaynor

Who Deserves Sedation and Anesthesia in the Critical Care Unit?

Sedation and anesthesia for critically ill patients in the intensive/critical care unit deserves the same attention to detail as does anesthesia for patients undergoing a surgical procedure. The patients most likely to require sedation or anesthesia likely have some degree of dysfunction related to one or more organ system (renal, hepatic, cardiac, or respiratory). These patients may need to be sedated or anesthetized for a number of reasons, including but not limited to urethral obstruction; ultrasound-guided biopsies of the kidney, liver, or other organ; endoscopy; bronchoscopy; long-term ventilation; long line placement; or just calming based on a patient's underlying demeanor or due to current disease.

Drugs for Sedation and Anesthesia

There are multiple drugs that can be used to sedate or anesthetize critically ill patients. They are covered in much greater detail elsewhere.[1,2] The concepts of drug reversibility and short duration are important to consider for this particular set of patients. It is key to recognize that a drug that has a short duration of action may not have a short metabolic half-life. This can occur due to redistribution of the drug to muscle and fat.

Opioid Agonists and Antagonists (Table 138-1)

The opioids of greatest concern are the mu receptor agonists. The mu receptor agonists provide variable degrees of sedation (drug and dosage dependent) but induce the greatest amount of analgesia. They are completely reversible. Opioids always have the potential to induce dysphoria with or without sedation in dogs and cats. This undesirable effect occurs less often in older, sicker, debilitated dogs. Opioid-induced dysphoria occurs more frequently in cats. All opioids can increase parasympathetic tone with subsequent decrease in heart rate. There is no clear recommendation with regard to co-administration of a low-dose anticholinergic to prevent bradycardia or whether to wait for bradycardia to occur. An advantage of most opioids is that they minimally decrease cardiac contractility, cardiac output and perfusion, making them ideal for sicker patients.

TABLE 138-1

Drugs Used for Sedation and Anesthesia

DRUG	DOG DOSAGE	CAT DOSAGE	COMMENT
Opioid Agonist and Antagonists			
Fentanyl	2-5 mcg/kg IV 2-10 mcg/kg/h IV 5-10 mcg/kg SC, IM	2-5 mcg/kg IV 2-10 mcg/kg/h IV	SC, IM administration likely to induce dysphoria
Hydromorphone	0.05-0.1 mg/kg IV 0.05-0.1 mg/kg/h	0.05-0.1 mg/kg IV 0.05-0.1 mg/kg/h	May induce hyperthermia in cats

	IV 0.1-0.2 mg/kg SC, IM	IV 0.1 mg/kg SC, IM	
Oxymorphone	0.05-0.1 mg/kg IV 0.05-0.1 mg/kg/h IV 0.1 mg/kg SC, IM	0.05-0.1 mg/kg IV 0.05-0.1 mg/kg/h IV 0.05-0.1 mg/kg SC, IM	May induce hyperthermia in cats
Morphine	0.1-0.3 mg/kg IV 0.25-1 mg/kg SC, IM	NA	Cats are unlikely to develop analgesia at conventional dosages due to their low ability to convert morphine to morphine-6-glucuronide
Methadone	0.1-0.3 mg/kg IV 0.25-1 mg/kg SC, IM	0.05-0.1 mg/kg IV 0.05-0.1 mg/kg/h IV 0.1-0.3 mg/kg SC, IM	Feline euphoria likely, rather than dysphoria
Butorphanol	0.1-0.4 mg/kg IV 0.25-0.5 mg/kg SC, IM	0.1-0.25 mg/kg IV 0.2-0.4 mg/kg SC, IM	Mild to moderate pain control only; duration of analgesia ≈45 min in dogs, 4 h in cats
Nalbuphine	0.1-0.5 mg/kg IV 0.1 mg/kg/h IV 0.25-1 mg/kg SC, IM	0.1-0.25 mg/kg IV 0.05-0.1 mg/kg/h IV 0.25-0.5 mg/kg IM	Mild to moderate short-term pain control only; no inherent behavioral effects when used alone
Buprenorphine	0.01-0.03 mg/kg IV, SC, IM	0.24 mg/kg SC	Canine dosage provides mild to moderate pain control of short duration; feline dosing provides maximal analgesia for 24 h
Naloxone	1-2 mcg/kg IV 10 mcg/kg IV, SC, IM	1-2 mcg/kg IV 10 mcg/kg IV, SC, IM	Low-dose for partial reversal and to aid extubation; high dosages to completely reverse opioid
Alpha-2 and Benzodiazepine Antagonists			
Dexmedetomidine	0.5-1 mcg/kg IV 0.5-1 mcg/kg/h IV 3-5 mcg/kg IV, SC, IM	0.5-1 mcg/kg IV 0.5-1 mcg/kg/h IV 3-10 mcg/kg IV, SC, IM	Low dosages to potentiate opioid-induced analgesia sedation in the ICU; higher dosages to induce sedation with or without an opioid
Midazolam	0.1-0.2 mg/kg IV, SC, IM	0.1 mg/kg IV	Doses greater than 5 mg induce little more sedation but likelihood of greater excitement
Diazepam	0.1-0.2 mg/kg IV	0.1 mg/kg IV	Doses greater than 5 mg induce little more sedation but likelihood of greater excitement
Anticholinergics			
Glycopyrrolate	0.005-0.01 mg/kg IV, SC, IM	0.005-0.01 mg/kg IV, SC, IM	Does not cross blood-brain or placental barriers
Atropine	0.01-0.04 mg/kg IV, SC, IM	0.01-0.04 mg/kg IV, SC, IM	Crosses blood-brain and placental barriers and may induce sedation
IV Induction Agents and Sedatives			
Propofol	3-4 mg/kg IV to	3-5 mg/kg IV to	Give slowly to effect to decrease dosage, apnea, and hypotension

	effect 10-20 mg/kg/h IV	effect 10-20 mg/kg/h IV	
Etomidate	1 mg/kg IV 0.5-1 mg/kg/h IV	1 mg/kg IV 0.5-1 mg/kg/h IV	Precede with IV benzodiazepine to prevent myoclonus
Alfaxalone	2-3 mg/kg IV 6-9 mg/kg/h IV	5 mg/kg/h IV 7-11 mg/kg/h IV	Give slowly to effect to decrease dosage, apnea, and hypotension

ICU, Intensive care unit; *NA*, does not apply.

Fentanyl

Fentanyl is a potent opioid with relatively short duration of action in most dogs: approximately 20-30 minutes when administered intravenously.[3] Duration of action extends to 40 minutes when administered by other routes. Intravenous fentanyl with or without another sedative may be ideal for short duration needs.

Hydromorphone

Hydromorphone has a relatively short duration of action when administered intravenously: approximately 40-60 minutes.[4] Duration of action extends to approximately 3 hours when administered subcutaneously or intramuscularly.

Oxymorphone

Oxymorphone is more potent than hydromorphone, indicating that the dosage required to get an equivalent effect is actually lower. Duration of action is similar to hydromorphone.

Morphine

Morphine has the highest likelihood of inducing vomiting with the initial dose. Morphine can also induce histamine release and potentially hypotension in hypovolemic dogs when administered IV.[5] These properties may make morphine less desirable in more critically ill animals. An exception might be in dogs with pulmonary edema. The increased capacitance of large vessels may improve clinical signs associated with pulmonary edema and induce some sedation with low dosages IV in dogs.[6] The ability of morphine to induce analgesia is related to morphine's conversion to morphine-6-glucuronide (M6G) via the first-pass effect. Data suggest that cats produce little to no M6G.[7] As such, morphine should not be administered to cats for analgesia purposes.

Methadone

Methadone induces less sedation than morphine but does not induce vomiting in virtually 100% of patients.[8] Duration of action lasts about 45 minutes when given IV and about 4 hours IM or SC. Methadone tends to induce euphoria rather than dysphoria in cats, a great advantage for this species and the people around them.

Butorphanol

Butorphanol works as a kappa receptor agonist and a mu receptor antagonist. It induces mild sedation and has a ceiling effect for analgesia, providing only mild to moderate pain control. Even at higher dosages, butorphanol induces pain control for only 45 minutes in dogs,[9] with sedation lasting for several hours. Mild to moderate analgesia duration lasts about 4 hours in cats. Butorphanol should be used cautiously, as it precludes the use of other opioids that are better analgesics for a period of time since butorphanol will antagonize these drugs effects at the mu receptor.

Nalbuphine

Nalbuphine has a similar receptor profile as butorphanol but is very unlikely to induce sedation by itself.[10] It can induce a synergistic analgesic and sedative effect when combined with alpha-2 agonists, such as dexmedetomidine. The lack of inherent behavioral affects can be advantageous when it is desirable to antagonize an opioid's sedation but still retain some analgesia.

Buprenorphine

Buprenorphine has been classified as a partial mu agonist and a mu antagonist, indicating that at typical dosages, it can only induce mild to moderate pain control. Newer data indicate that at higher dosages, buprenorphine can induce maximal pain control in cats for a duration of 24 hours.[11,12] This may be desirable in some cats but buprenorphine should be used with caution in the critical care unit as opioid antagonists do not easily reverse it. As a mu receptor antagonist, buprenorphine can reverse the effects of mu receptor agonists, such as hydromorphone. There is little to no benefit to the use of buprenorphine for significantly ill dogs.

Naloxone

Naloxone can be used in a dose-response manner to induce different effects. Low-dose naloxone can partially reverse an opioid and facilitate extubation by increasing laryngeal reflex activity. Some analgesia and sedation will remain. Higher-dose naloxone can completely reverse the sedative and analgesic effect of opioids (except buprenorphine). Depending on time of administration compared to that of the opioid, the patient may become re-narcotized since naloxone has a relatively short half-life.[13] Redosing of naloxone may be necessary.

Dexmedetomidine

Dexmedetomidine is an alpha-2 agonist which can provide moderate to intense sedation, analgesia, and muscle relaxation. Micro-doses can also synergistically increase sedation and analgesia already induced by opioids. These beneficial effects do not come without potential side-effects. Dexmedetomidine increases parasympathetic tone and decreases sympathetic tone, resulting in bradycardia, decreased stroke volume, decreased cardiac contractility, decreased cardiac output, and decreased overall perfusion.[14] Dexmedetomidine also decreases oxygenation. As such, dexmedetomidine should always be used cautiously but even more so in sicker patients. As mentioned above, the low dosage of dexmedetomidine is useful in patients already receiving opioid infusions. Micro-dose dexmedetomidine appears to have minimal cardiac effects.

Midazolam and Diazepam

These benzodiazepines can be very useful in combination with opioids as patients become older and more debilitated. Benzodiazepines have a much higher likelihood of inducing excitement in younger, healthy dogs. As patients get sicker, it is possible to even intubate a patient with just a benzodiazepine. The greatest difference between midazolam and diazepam is that the former is water soluble and the latter is in a propylene glycol base.[15] The aqueous solubility of midazolam makes it more user-friendly, allowing it to be mixed with virtually any drug without the concern of precipitation. Midazolam also has better uptake via non-IV routes. Diazepam should be administered slowly as large doses of propylene glycol can induce bradycardia.

Sevoflurane

Although sevoflurane is thought of as an anesthetic, low dosages can be safely used for sedation. Sevoflurane does not possess a noxious odor compared to isoflurane and therefore is very amenable to be used as an inhaled sedative.[16] Patients can be masked or boxed for moderate to heavy sedation without producing high anxiety and escape behavior. Because the negative effects are dose-dependent and the likelihood for significant decreases in cardiac output is minimized, sevoflurane may be the most desirable approach to sedation for sicker, highly stressed (fractious) cats. The noxious odor associated with isoflurane precludes its humane use for box or mask sedation or induction of anesthesia.

Sevoflurane is also the most desirable gas anesthetic for maintenance of anesthesia. Its low blood gas solubility coefficient allows rapid induction, recovery, and most importantly changes in depth of anesthesia. Practitioners should always strive for maximal control for anesthetized patients. Sevoflurane provides that control better than any other gas anesthetic and is insignificantly more expensive than others.[17]

Atropine and Glycopyrrolate

These anticholinergics can be used to prevent and/or treat bradycardia from increases in parasympathetic tone related to opioid and alpha-2 agonist administration. Their use with alpha-2 agonists is a bit controversial but one can argue the benefit of increasing heart rate to increase cardiac output. Under anesthesia, all patients benefit from a normal sinus rhythm. Awake, non-anesthetized patients tolerate deviations from normal sinus rhythm much better than those who are anesthetized. Anesthetics disturb cardiac function to a significant degree.

The greatest differences between atropine and glycopyrrolate revolve around penetration of the blood-brain barrier and placental barrier, the former being more important in more critical patients. Atropine crosses the blood-brain barrier and can induce sedation.[18] It can also cross the placental barrier and induce sedation in neonates during a cesarean section. Glycopyrrolate does not induce these effects and is preferred.[18]

Propofol

Propofol can be administered at low dosages for sedation or higher dosages for induction of anesthesia and maintenance of anesthesia. Propofol can induce vasodilation, decreased cardiac contractility and respiratory depression in a dose-dependent manner. The slower that propofol is administered IV for induction of anesthesia, the lower the dosage becomes with fewer side-effects. Propofol is appropriate for most sick patients. Other choices should be considered for patients with significant cardiac disease or those with significant hemodynamic dysfunction. Continuous infusion propofol may be desirable to gas anesthesia, relative to some cardiovascular variables.[19] This approach does not allow quite the same control as sevoflurane or as rapid recovery.

Etomidate

Etomidate has been the stand-by drug for higher risk patients for centuries. It induces less overall effect on the cardiovascular system. There are side-effects to consider. In addition to adrenal cortical suppression of debatable clinical importance, etomidate produces myoclonus upon induction.[20] It should be preceded by or followed with an IV benzodiazepine. Prior benzodiazepine administration may be more desirable as it will prevent the myoclonus; however, there is a possibility of transient excitement from it. It is possible that a benzodiazepine following etomidate will not prevent the myoclonus, resulting in undesirable muscle rigidity for the duration of the effects of etomidate.

Alfaxalone

Alfaxalone is a newer drug which can be used in a similar fashion as propofol for sedation, induction, and maintenance of anesthesia. Slower administration permits lower dosage and fewer cardiopulmonary and other adverse effects. Propofol induces a better recovery than alfaxalone when administered for short-term sedation alone or as an infusion.[21] Alfaxalone and propofol provide better hemodynamic stability than gas anesthesia.

Protocols (Figure 138-1)

There is an infinite combination of protocols for sedation and anesthesia. One first needs to determine the goal to be accomplished and then whether sedation or anesthesia is most appropriate. The practitioner then should determine the combination of drugs that can achieve the goal with the fewest undesirable effects. Common sedation protocols may encompass a combination of a benzodiazepine and an opioid or a low-dose alpha-2 agonist and an opioid. A combination of an opioid and propofol or alfaxalone can also be appropriate. In sicker patients, drugs via the IV route facilitate better control. All patients should receive supplemental oxygen regardless of the protocol. Anesthesia is typically accomplished with a sedation protocol followed by induction to anesthesia.

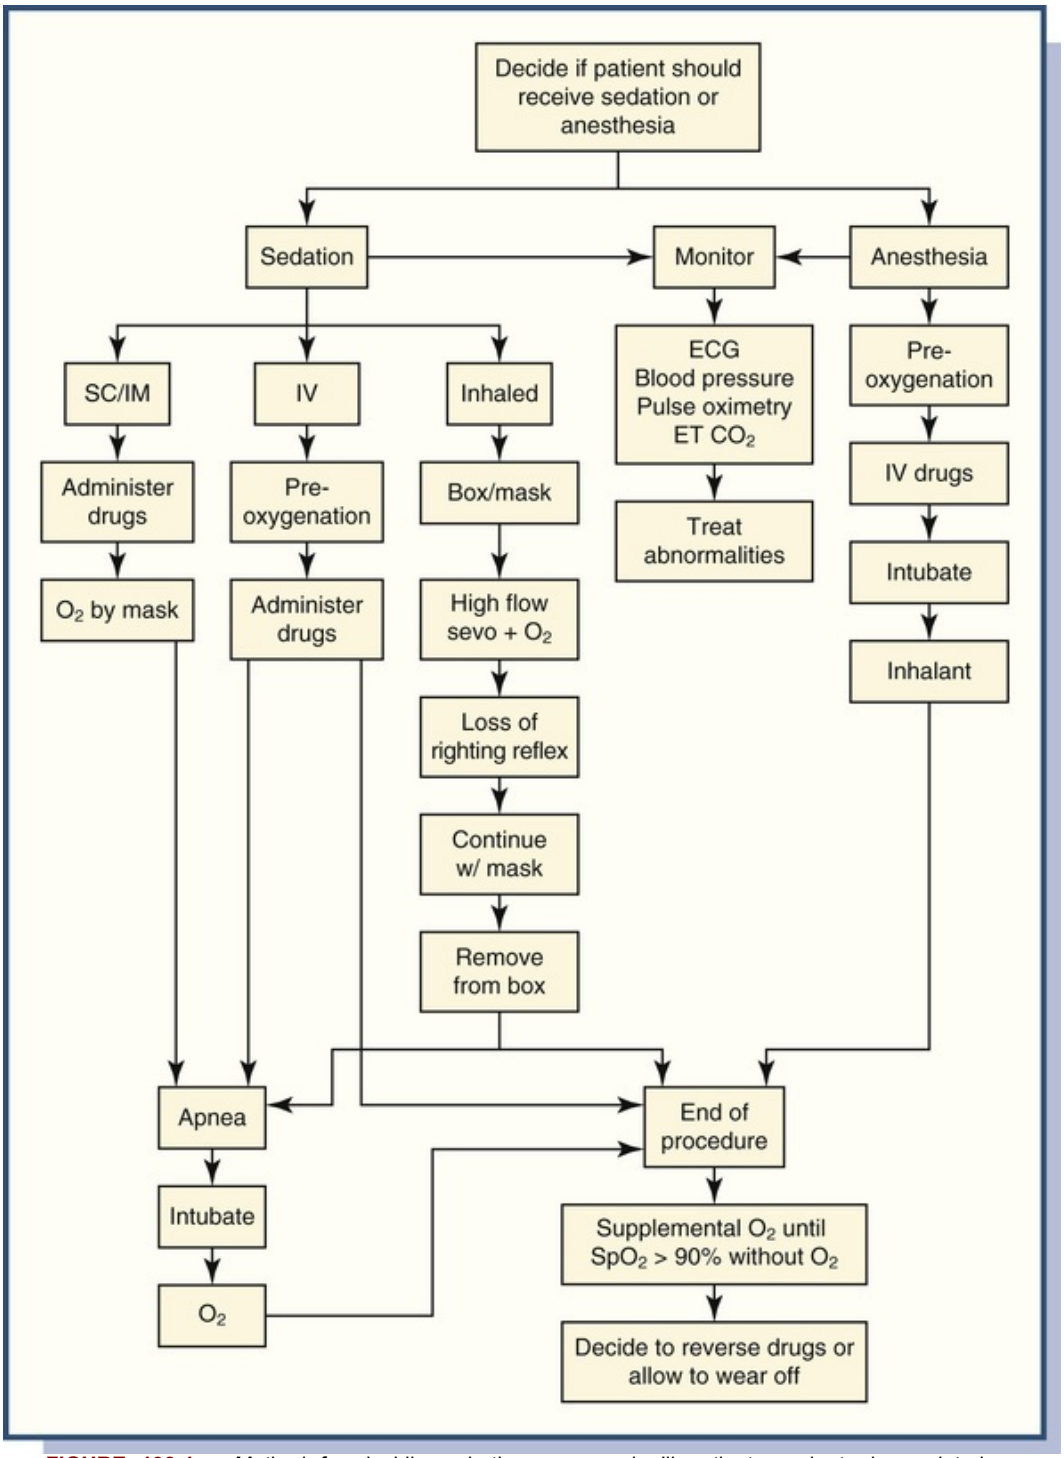

FIGURE 138-1 Method for deciding whether a severely ill patient needs to be sedated or anesthetized. *ECG,* Electrocardiogram; *ET,* end-tidal; *sevo,* sevoflurane; *SpO2,* oxygen saturation (%).

Monitoring and Recovery

Monitoring of vital signs by a dedicated anesthetist is always important when sedating or anesthetizing patients. This concept becomes even more important in more critical patients. Monitoring of sedated patients should include blood pressure and ECG monitoring at a minimum (see ch. 99 and 103). Pulse oximetry (see ch. 98) and capnography should be included if possible. Sedated patients should always receive supplemental oxygen, especially if pulse oximetry is not possible (see ch. 131).

Anesthetized patients should have ECG, blood pressure, and oxygen saturation monitored at the minimum. Capnography should be monitored if available, as a rapid decrease in expired carbon dioxide can represent acute changes in cardiac output.[22]

Recovery from sedation and anesthesia should be closely monitored for adverse events. Patients should have oxygen saturation monitored until it is proven they can maintain adequate oxygenation (>90% saturation) without supplemental oxygen. Patients may need to remain intubated, receive oxygen by mask or nasal cannula or be placed in an oxygen cage for some period of time to allow appropriate oxygenation until sedation or anesthesia have worn off.

CHAPTER 139

Initial Evaluation of Respiratory Emergencies

Carol R. Reinero

Dogs and cats presenting with the chief complaint of respiratory distress require determination of the general cause in order to streamline the diagnostic and therapeutic approach in a timely fashion. One scheme to classify the causes of respiratory distress involves the following eight categories: (1) upper airway obstruction, (2) lower airway obstruction, (3) flail chest, (4) abdominal enlargement, (5) pulmonary parenchymal disease, (6) pleural cavity disorders, (7) pulmonary thromboembolism (PTE), and (8) "look-alike" syndromes. This classification system is useful because the first four causes usually can be recognized quickly at the time of initial assessment by the physical appearance of the dog or cat, the cycle of respiration predominantly affected, and audible sounds that might be heard resulting from certain disorders. The remaining four causes will require additional diagnostic testing to establish a definitive diagnosis. Also, see ch. 28 for additional information about chief complaints involving abnormal respirations.

Eight Major Categories of Respiratory Distress

Upper airway obstruction is due to mechanical or functional narrowing of the large airways (pharynx, larynx, or trachea cranial to the thoracic inlet) and includes intraluminal or extraluminal masses (neoplasia, granuloma, abscess, blood clots, polyps), foreign bodies, laryngeal paralysis, laryngeal collapse, elongated soft palate, everted laryngeal saccules, tracheal collapse, tracheal stenosis, or tracheal stricture (see ch. 238, 239, and 241). Obstruction of the trachea within the thoracic cavity is included in the category of *lower airway obstruction*. Lower airway obstruction also can be caused by narrowing of the bronchial lumen due to bronchospasm, accumulation of mucus or other exudate, bronchial wall edema, or diffuse bronchomalacia. The classic example of a disease associated with the first three of these changes is feline asthma. Asthma in dogs is an exceedingly rare diagnosis, but lower airway obstruction in dogs can be seen with severe chronic bronchitis due to bronchomalacia, which is associated with passive collapse of the airways on exhalation. *Flail chest* results from trauma to the thoracic cavity, where there is destabilization of a portion of the rib cage (i.e., multiple adjacent ribs are fractured at two different locations, leaving a segment that is detached from the rest of the rib cage). Paradoxical respiration is seen so that, as an animal inhales, the thoracic wall segment is sucked inward, and as the animal exhales, the segment is displaced outward (see ch. 245). *Severe abdominal enlargement* can put pressure on the diaphragm and make it more difficult for the thoracic cavity to expand on inhalation. Examples of conditions associated with abdominal enlargement include ascites, gastric dilation, hepatosplenomegaly, abdominal masses, pregnancy, or pyometra (see ch. 18). *Pulmonary parenchymal diseases* are disorders affecting the terminal and respiratory bronchioles, interstitium, alveoli, or vasculature. They can be associated with infiltration by infectious microorganisms, inflammatory cells, or neoplastic cells; the airspaces can be filled with edema fluid or foreign material; or lung tissue can be replaced with fibrotic tissue. Examples of conditions affecting the pulmonary parenchyma include infectious pneumonia (bacterial, fungal, viral, protozoal, and parasitic), aspiration pneumonia/pneumonitis, interstitial lung diseases, pulmonary edema (cardiogenic or noncardiogenic), hemorrhage, neoplasia, and acute respiratory distress syndrome (ARDS) (see ch. 242). *Pleural cavity disorders* arise when the space between the parietal and visceral pleura, which normally contains just a small amount of fluid for lubrication, fills with fluid (pleural effusion), air (pneumothorax), a mass, or abdominal organs (e.g., diaphragmatic hernia) (see ch. 244). *Pulmonary thromboembolism* refers to obstruction of blood flow in the pulmonary arteries by a thrombus or by an embolus formed in the systemic venous system or right side of the heart. Any condition causing an abnormality in blood flow, endothelial damage, or hypercoagulability can predispose to thromboembolism (see ch. 243). Finally, *look-alike syndromes* are conditions that result in apparent difficulty in breathing due to nonrespiratory causes, such as pain, severe anemia, hyperthermia, acidosis, drugs (e.g., opioids), and hypotension.

Evaluation of the pattern of breathing (Figure 139-1) can be useful to help localize the region of the

respiratory tract that is affected. A "distance" examination in which the animal is observed for auditory and visual clues should be followed by a "hands-on" examination. In an emergency situation, the first four causes of respiratory distress (upper and lower airway obstruction, flail chest, and abdominal enlargement) should be discernible on initial examination of a patient. Dogs and cats with upper respiratory obstruction (Video 139-3) will have a characteristic stridorous or squeaking noise that is readily audible, even without a stethoscope. Additionally, respiratory distress will occur on inhalation. Dogs and cats with a lower airway obstruction should have an audible wheeze (although sometimes a stethoscope is required to hear quieter wheezes). In these cases, respiratory distress will occur predominantly on exhalation, the so-called "expiratory push" (Video 139-2). Visual examination will reveal if flail chest (with paradoxical respiration) or abdominal enlargement (with increased inspiratory effort and no audible noise) is present.

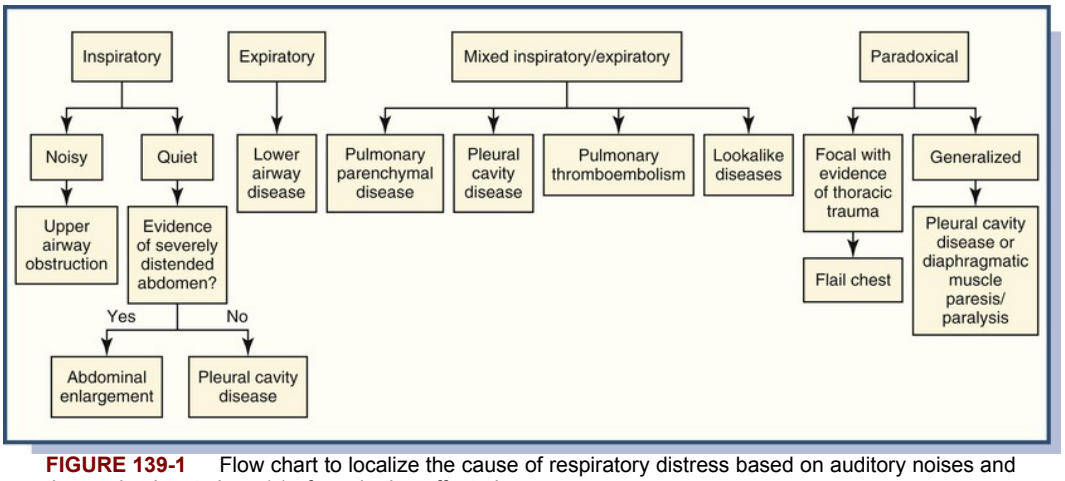

FIGURE 139-1 Flow chart to localize the cause of respiratory distress based on auditory noises and the predominant phase(s) of respiration affected.

For the remaining four causes of respiratory distress, physical examination could provide additional useful clues. Thoracic auscultation might reveal absent or quiet lung sounds, which are compatible with pleural cavity disease; crackles, which support pulmonary parenchymal disease; and murmurs or arrhythmias, which could indicate pulmonary parenchymal disease associated with underlying cardiac disease (cardiogenic pulmonary edema), pleural cavity disease (especially in cats), or PTE. Physical examination can increase the index of suspicion for look-alike diseases if very pale/white mucous membranes are seen (severe anemia), substantially elevated body temperature is measured, or signs of pain are elicited on palpation. Additional diagnostics commonly are required to discriminate these four causes of respiratory distress.

In an emergency situation, if there are decreased pulmonary or cardiac sounds on auscultation or while not absolutely pathognomonic for pleural cavity disease, if there is a paradoxical breathing pattern (Video 139-1), it is prudent to proceed directly to thoracocentesis both as a diagnostic and as a therapeutic measure; focused assessment with ultrasound can quickly identify a pocket of pleural effusion, if one exists, for safest thoracocentesis (see ch. 149). Removal of any air or fluid will help stabilize the patient for further diagnostics (see ch. 102).

Radiography

Radiography likely is the single most important diagnostic tool for patients in respiratory distress. It is important to attempt to localize the cause of respiratory distress as described above, because if disease is localized to the upper airways, cervical and thoracic radiographs should be performed. For suspected dynamic airway collapse, inspiratory and expiratory cervical and thoracic radiographs are required to highlight the obstructed area during the different phases of the respiratory cycle. Even with upper airway obstruction, it is still important to obtain thoracic radiographs to evaluate for noncardiogenic pulmonary edema (which can result from severe upper airway obstruction) and for metastatic disease if the airway obstruction is due to a mass. Significant thoracic radiographic changes can include intrathoracic tracheal narrowing (collapse or obstructive mass), a bronchial pattern with or without hyperinflation (lower airway disease), an interstitial or alveolar pattern (pulmonary parenchymal disease), or evidence of pleural cavity

disease (pleural effusion, pneumothorax, pleural mass, loss of a clear border of the diaphragm, or a blunted tortuous vessel with uneven vascular diameters and distribution of blood flow between lung lobes [PTE]). Other nonspecific thoracic radiographic findings can include cardiomegaly, pulmonary nodules, or atelectasis.

Additional Diagnostics

Additional diagnostic testing beyond the scope of this chapter can be planned based on results of the radiographic examination to more precisely identify the underlying disease process. Other useful diagnostics can include some of the following: complete blood count, serologic titers for infectious diseases, fecal examination (see ch. 81), heartworm testing (see ch. 255), advanced thoracic imaging (ultrasound, fluoroscopy, or computed tomography), abdominal imaging (looking for related disease in the abdominal cavity; see ch. 88), fundic examination (see ch. 11), arterial blood gas analysis (see ch. 75), fine needle aspiration for cytology/culture (see ch. 89 and 93), laryngeal examination, transtracheal or endotracheal wash, bronchoalveolar lavage (see ch. 101), bronchoscopic examination (see ch. 101), bronchial mucosal or mass biopsies, and biopsies obtained by a key-hole procedure, thoracoscopy, or thoracotomy.

Management

It is crucial to keep in mind that many diagnostic tests must await appropriate patient stabilization. Any dog or cat with respiratory distress should benefit, to some degree, from the provision of supplemental oxygen (see ch. 131). In patients with suspected upper airway obstruction, sedation can minimize struggling and markedly improve respiratory comfort (see ch. 28 and 138). Securing an airway by oral intubation or tracheostomy can be required in some cases. In dogs, monitoring body temperature and cooling as needed is an important aspect of medical management, since panting to dissipate heat can be markedly impaired. Finally, an anti-inflammatory dose of corticosteroids can help reduce swelling in the upper airways. For cats with lower airway obstruction, minimal handling, bronchodilators (injectable or inhaled) to relieve bronchoconstriction, and corticosteroids, can provide symptomatic relief (see ch. 97). Bronchodilators likely are of less benefit to dogs with lower airway obstruction, as the most common diseases in this category are intrathoracic tracheal collapse and diffuse bronchomalacia—neither of which is associated with smooth muscle constriction of the bronchi. Sedation and an anti-inflammatory dose of corticosteroids also could be useful in these cases. For animals with flail chest in the emergent situation, placing the patient in lateral recumbency with the affected side down, and pain management, are important. For patients with abdominal distension, addressing the underlying disorder in the abdominal cavity is required. For patients with pulmonary parenchymal disease, initial therapeutics can include: empiric trial with furosemide if there is evidence of heart failure; judicious fluid therapy if there is no evidence of heart failure; airway humidification; nebulization; coupage; antimicrobials; and/or anti-inflammatory drugs (see ch. 97). For animals with pleural cavity disease, thoracocentesis can be helpful therapeutically if there is fluid or air accumulation (see ch. 102). For patients with PTE, oxygen supplementation is usually the main means of stabilization, although the ventilation : perfusion mismatch that is a hallmark of PTE can limit the efficacy of oxygen supplementation; once a diagnosis of the condition is made, anticoagulants and/or thrombolytics can be considered (see ch. 131 and 243). Finally, patients with a look-alike syndrome generally will not be oxygen-responsive since the disease is not primarily of the respiratory system, and a search for nonrespiratory diseases should be made and the underlying disorder addressed appropriately.

Summary

Having a scheme to classify the causes of respiratory distress can help in the approach to patients presenting in an emergency situation. Identification of audible noises (stridor and wheeze) and breathing patterns (inspiratory distress, expiratory distress, paradoxical breathing, and mixed inspiratory and expiratory distress) assists in localizing the site of respiratory disease. After stabilizing the patient, appropriate diagnostics and therapeutics can be targeted to focus on the location and underlying cause of the respiratory signs.

CHAPTER 140

Cardiopulmonary Arrest and CPR

Daniel John Fletcher, Manuel Boller

Cardiopulmonary arrest (CPA) is a complete cessation of blood flow, ventilation, and oxygenation of the blood. Left untreated, CPA results in irreversible ischemic injury and ultimately death. Treatment is referred to as cardiopulmonary resuscitation (CPR). It is initially focused on restoring blood flow and oxygen delivery to tissues using chest compressions and positive pressure ventilation, delaying the onset of ischemic injury to the brain and other vital organs, and restoring blood flow to the heart to achieve return of spontaneous circulation (ROSC). Rapid identification of CPA and immediate institution of high quality CPR are essential if the progression of CPA to death is to be interrupted. In 2012, the Reassessment Campaign on Veterinary Resuscitation (RECOVER) initiative published the first evidence-based veterinary CPR guidelines.[1,2] The results of this extensive evidence review are summarized in the algorithm shown in Figure 140-1.

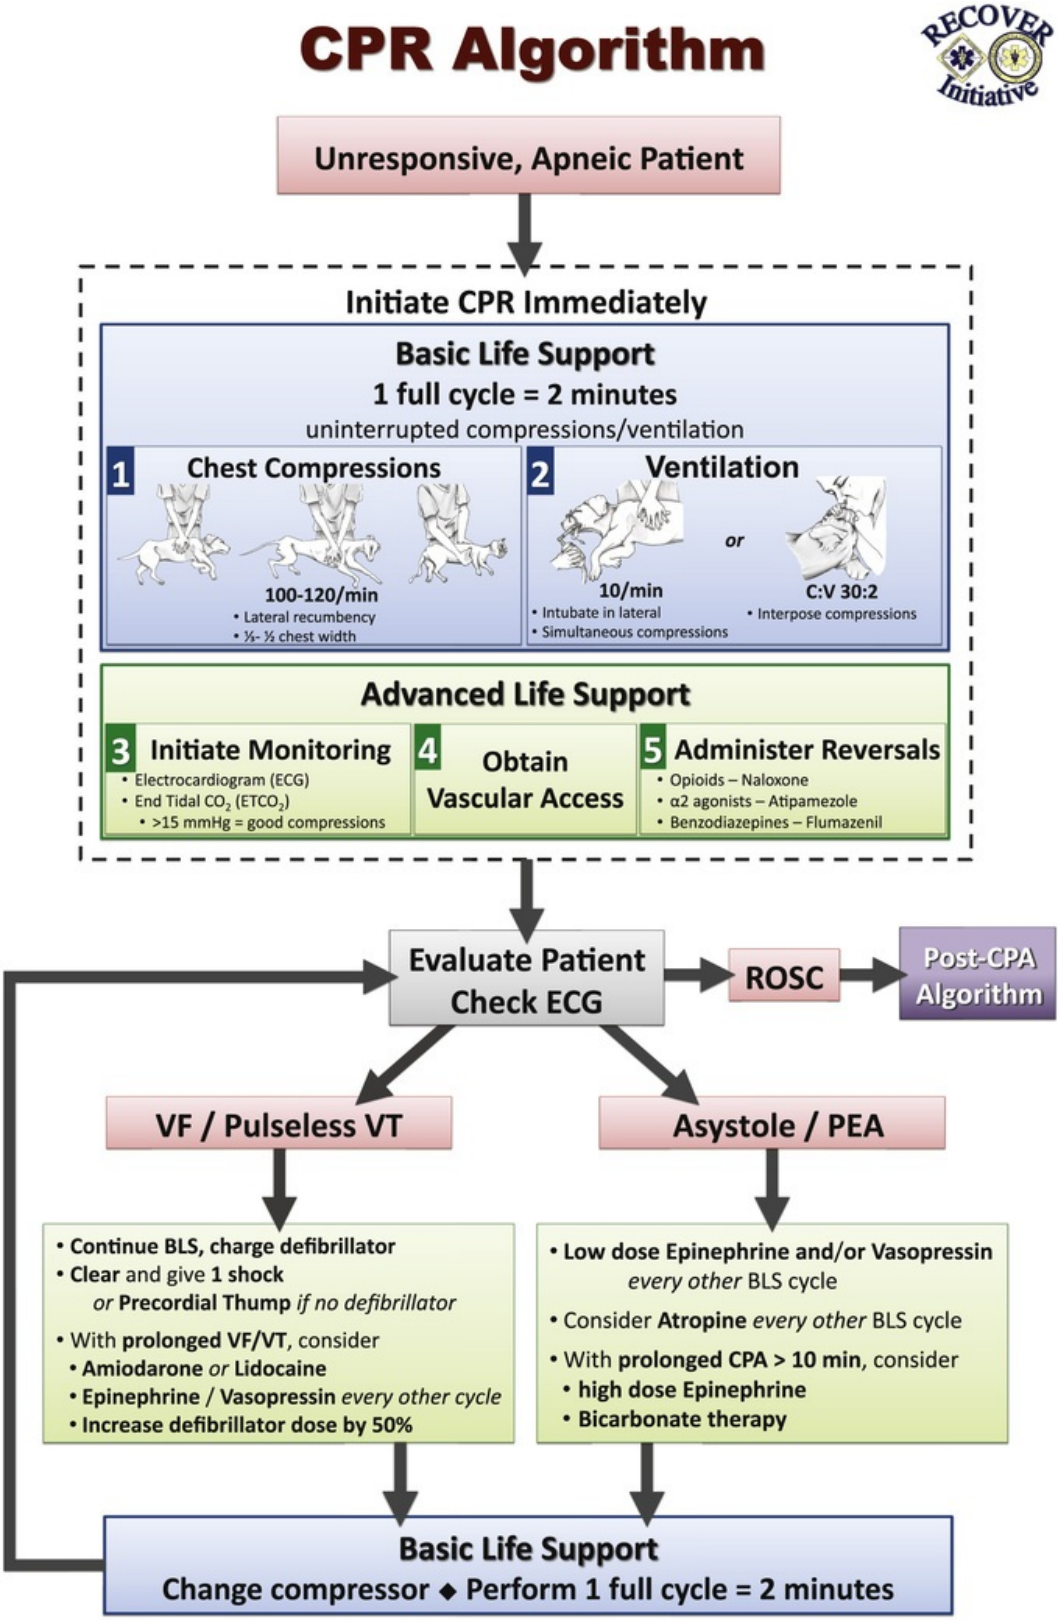

FIGURE 140-1 RECOVER CPR algorithm chart. *BLS,* Basic life support; *CPA,* cardiopulmonary arrest; *CPR,* cardiopulmonary resuscitation; *C:V,* compression to ventilation ratio; *$ETCO_2$,* end tidal CO_2; *PEA,* pulseless electrical activity; *ROSC,* return of spontaneous circulation; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia. (Reproduced with permission from Fletcher DJ, Boller M, Brainard BM, et al: RECOVER evidence and knowledge gap analysis on veterinary CPR. Part 7: Clinical guidelines. *J Vet Emerg Crit Care [San Antonio]* 22[Suppl 1]:S102-131, 2012.)

Diagnosis of CPA

Cardiopulmonary arrest is an important differential diagnosis in any acutely unresponsive patient. It is a clinical diagnosis based on the presence of unconsciousness and apnea. A rapid, standardized airway-breathing (AB) assessment of 5-10 seconds duration and focused on ruling out CPA should be undertaken immediately when a patient is unresponsive.

Visual inspection of the airway should include opening the mouth, pulling out the tongue, and examining the oral cavity to identify any masses, swellings, or foreign objects. Suction or gentle swabbing should be attempted first to clear the airway, and digital palpation reserved for cases in which that approach does not resolve the issue. A laryngoscope should be used if available. In all cases, if the patient responds to manipulation of the airway, the AB exam should be halted as CPA has been ruled out.

The breathing assessment in an unresponsive patient is targeted at the rapid identification of apnea by observing the patient for chest excursions, by feeling for chest movements, by ausculting for lung sounds, or by using a glass slide or cotton in front of the nares to identify airflow. In obviously apneic patients, the airway exam may be done using a laryngoscope during intubation as described in the Basic Life Support (BLS) section below.

Although a full ABC assessment (airway, breathing and circulation) was previously advocated, a circulation assessment when evaluating an unresponsive patient is currently not recommended as it was found unreliable.[1,3-7] Nevertheless, if a circulation assessment is undertaken, it should not prolong the ABC assessment beyond 5-10 seconds. If uncertainty about the diagnosis of CPA persists after these 10 seconds, CPR should be initiated immediately rather than performing any additional diagnostic assessment.[1] Evidence suggests a strong association between delay in initiation of CPR and mortality.[8-10]

Initiation of CPR

The two primary aspects of CPR are basic life support (BLS) and advanced life support (ALS). The dashed box at the top of the CPR algorithm (see Figure 140-1) encloses the essential steps in initiating CPR. The goal is to complete all five of these tasks in the first 2 minutes, but the team should complete them in the order recommended.

Basic Life Support

BLS is focused on restoration of circulation, ventilation, and oxygenation of the blood. In the absence of good quality BLS, ROSC is unlikely. BLS consists of chest compressions and positive pressure ventilation.

Chest Compressions

The goals of chest compressions are to provide (1) pulmonary blood flow for excretion of carbon dioxide (CO_2) and oxygenation of pulmonary capillary blood, and (2) oxygen delivery to tissues to maintain cellular metabolism. If optimal external chest compressions are provided, only approximately 25 to 40% of a normal cardiac output may be generated.[11,12] Therefore, chest compression technique must be meticulous.

After a 5-10 second AB assessment for confirmation of CPA, chest compressions must be initiated immediately. Any delays may worsen outcomes.

In most cases, the patient should be placed in right or left lateral recumbency for chest compressions, and the chest compressed one third to one half its width with each compression. Full elastic recoil of the chest in between compressions is important to maximize blood flow to heart and brain.[13,14] The chest should be compressed at a rate of 100 to 120 per minute in all dogs and cats. Because it can take a full minute of chest compressions to attain a steady state arterial blood pressure, compressions should be delivered in uninterrupted 2-minute cycles whenever possible.[15-17] Rotation to a new compressor after each cycle reduces rescuer fatigue and poor compression quality.[18,19]

The two theories explaining the generation of systemic blood flow using external chest compressions (i.e., cardiac pump and thoracic pump theory) direct the recommended hand position on the chest based on chest conformation.[20,21] In medium- and large-breed dogs with round chest conformations (width and depth of the chest approximately equal, e.g., Labrador Retrievers, Golden Retrievers, Mastiffs), compressions over the highest point on the lateral thoracic wall with the patient in lateral recumbency will maximally compress the chest and increase intrathoracic pressure (E-Figure 140-2, *A*). In contrast, in medium to large breed dogs with a keel-chested conformation (significantly deeper than wide, e.g., sight hounds), compressions should be

focused directly over the heart (E-Figure 140-2, *B*). In markedly flat-chested dogs (chests significantly wider than deep, e.g., English Bulldogs), placing the patient in dorsal recumbency and focusing compressions over the sternum may be the most effective approach (E-Figure 140-2, *C*).

E-FIGURE 140-2 Recommended chest compression techniques according to chest conformation and animal size. **A,** For large, round-chested dogs, chest compressions over the widest portion of the chest are reasonable, with the animal in either left or right lateral recumbency. **B,** In keel-chested (i.e., deep, narrow-chested) dogs, chest compressions directly over the assumed location of the heart are reasonable, with the animal in either left or right lateral recumbency. **C,** In barrel-chested dogs such as English Bulldogs, compressions over the mid-sternum may be considered, with the animal in dorsal recumbency. **D,** In cats and small dogs (<10 kg) with compliant chests, the use of a one-handed technique with the stronger hand wrapped around the sternum directly over the heart and the other hand around the back may be considered.

Compressor posture also affects chest compression quality. Using locked elbows with fingers interlaced and one hand on top of the other while keeping the shoulders directly above the hands allows compressions to be driven by core abdominal muscles rather than the arms (Figure 140-3). This approach reduces fatigue, allowing maximal compression force for a longer period of time. To optimize posture, the rescuer should stand on a stool, kneel on the table behind the patient, or place the patient on the floor and kneel behind, as necessary.

FIGURE 140-3 Correct posture during chest compressions. The open arrows indicate the four critical elements of rescuer posture: (1) the hands are stacked such that one focal compression point results, (2) the shoulders are positioned vertically above the compression site, (3) the arms are straight with locked elbows, and (4) the compression force is generated by the core muscles and not the arms. Note that the resuscitator is positioned towards the dorsal aspect of the animal to minimally compromise access of other team members to the limbs and trunk.

Small dogs and cats have higher thoracic compliance due to their narrow chest conformation and more elastic rib cages. Chest compressions should be focused over the heart in most cases (E-Figure 140-2, *D*). A one-handed technique may be attempted in these patients by wrapping the hand around the chest at the level of the sternum (see E-Figure 140-2, *D*). Compressions are accomplished by pushing the thumb against the fingers on the other side of the chest, aiming to compress from the apex to the base of the heart. Because of the high thoracic compliance in these patients, this one-handed technique may reduce the risk of over-compressing the chest to more than one half its width.

Ventilation

The second priority of BLS is positive-pressure ventilation. The RECOVER guidelines recommend initiating ventilation as soon as possible in dogs and cats with CPA.[1,3] Dogs and cats commonly experience primary respiratory arrests, so ventilation is a critically important component of resuscitation, unlike adult people with out-of-hospital cardiac arrest that predominantly have CPA of primary cardiac etiology.[10,22-26]

The animal should be intubated as soon as possible. Intubation in lateral recumbency in both dogs and cats is easily accomplished, so chest compressions should continue during endotracheal (ET) tube placement. Mouth-to-snout or mask-to-snout ventilation is an acceptable, but inferior alternative if an ET tube is not immediately available. Mouth-to-snout ventilation is accomplished by closing the patient's mouth with one hand, extending the neck to align the nares and the spine, and making a seal over both nares with the mouth. Two quick breaths (i.e., inspiratory time of 1 second) are administered by blowing firmly into the nares to inflate the lungs while watching the chest rise to ensure breath delivery.

Compression of the lungs during chest compressions makes simultaneous chest compression and mouth-to-snout ventilation ineffective. For non-intubated patients, the 30:2 BLS technique is used, in which 30 chest compressions are delivered and compressions are then paused briefly while two breaths are administered as quickly as possible. Alternating compressions and ventilations are done in 2-minute cycles, with compressor rotation every 2 minutes to reduce fatigue. In intubated patients, chest compressions and ventilations can be administered concurrently as long as the ET tube cuff is inflated. This approach minimizes pauses in chest compressions, improving blood flow to the tissues. Patients that are intubated with an inflated ET tube cuff

should receive one breath every 6 seconds with an inspiratory time of 1 second. Excessive ventilation is harmful and should be avoided.[27]

Advanced Life Support

The next priority is implementation of the initial aspects of ALS. ALS includes drug and fluid therapy, as well as defibrillation. The RECOVER CPR algorithm lists in priority order the first three steps of ALS initiation, including attachment of monitoring devices, obtaining vascular access, and administration of reversal agents (see Figure 140-1). The CPR team leader should assign ALS interventions in the order listed on the algorithm.

Initiate Monitoring

Many commonly used monitoring devices, such as pulse oximeters and blood pressure monitors, are of little to no use during CPR because of motion artifact.[28] However, electrocardiogram (ECG; see ch. 103) and end tidal carbon dioxide ($ETCO_2$) monitors are essential, and should be attached as soon as possible after the initiation of BLS.[1]

Drug and defibrillation therapy will largely be guided by the ECG arrest rhythm. Therefore, the highest priority during the initiation of ALS is attaching ECG leads so that at the end of the first 2-minute cycle of chest compressions the ECG can be evaluated during the brief pause during the change in compressor when motion artifact is not present. If the ECG is not attached by the end of the first cycle of BLS, it will be another 2 minutes before an opportunity to diagnose the rhythm emerges, delaying the institution of ALS therapies.

$ETCO_2$ monitors are resistant to motion artifact, and $ETCO_2$ monitoring is strongly recommended during CPR. The $ETCO_2$ reflects the amount of CO_2 present in the alveoli. Because alveolar CO_2 arises from the tissues and is delivered to the lungs by blood flow, it is proportional to pulmonary blood flow and positively correlates with cardiac output.[29-31] If good blood flow is being generated by high quality chest compressions, the $ETCO_2$ will be higher than if blood flow is low. Because minute ventilation also affects $ETCO_2$, consistent ventilation according to the BLS guidelines is essential if $ETCO_2$ is used to evaluate the effect of BLS on blood flow. If the $ETCO_2$ is less than 15 mm Hg, the approach to BLS should be critically evaluated by team members and altered in an attempt to address the issue.[32] Another use of $ETCO_2$ during CPR is early identification of ROSC without stopping compressions.[33-35] Identification of a sudden, rapid rise in $ETCO_2$ is indicative of the increased blood flow of ROSC, and should prompt the rescuers to assess the pulse.

Obtain Vascular Access

If the patient has an intravenous (IV) catheter in place, its patency should be confirmed. In dogs and cats, presence of an IV catheter prior to CPA was associated with ROSC.[10] In patients without pre-existing IV access, a catheter should be placed as soon as possible (see ch. 75 and 76). Repeated or prolonged attempts at percutaneous catheterization are not recommended. Venous cutdown procedures are relatively simple and facilitate more rapid catheter placement.[36] Veins closest to the heart (cephalic or jugular) should be prioritized over those more distant (lateral and medial saphenous).[37] During chest compressions, cephalic cutdowns may be less challenging than jugular cutdowns. The dependent limb is usually easier to access because the vessel runs medially. Intraosseous (IO) catheters in the femur are often easy and quick to place in puppies and kittens (see ch. 77).[36] In adult animals, commercial IO drill devices facilitate very rapid placement, usually along the medial humerus.

Administer Reversals

Naloxone (0.04 mg/kg IV/IO) may be used to reverse opioids, flumazenil (0.01 mg/kg IV/IO) for benzodiazepines, and atipamezole (0.1 mg/kg IV/IO) or yohimbine (0.1 mg/kg IV/IO) for alpha$_2$-agonists. A drug and dosing chart including recommended dosing of reversal agents should be readily available (Figure 140-4).

CPR Emergency Drugs and Doses

		Weight (kg)	2.5	5	10	15	20	25	30	35	40	45	50

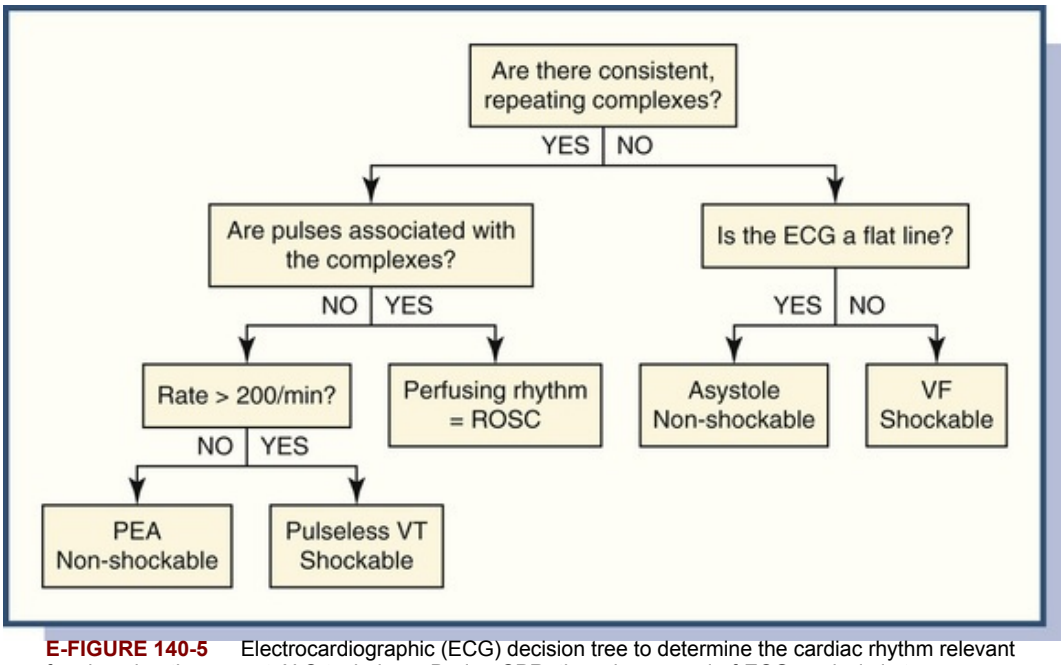
Part 7: Clinical guidelines. *J Vet Emerg Crit Care [San Antonio]* 22[Suppl 1]:S102-131, 2012.)

Evaluation of the ECG

The next step in the ECG algorithm (see Figure 140-1) is evaluation of the ECG (also see ch. 248). The correct ALS therapies can only be chosen if the ECG rhythm diagnosis is accurate. All members of the team should look at the ECG monitor during the pause in chest compressions between cycles, and the team leader should call out the rhythm diagnosis. If team members disagree about the rhythm diagnosis, opposing views should be debated after chest compressions have been restarted. The primary goal of CPR ECG analysis is to differentiate: (1) shockable arrest rhythms, (2) non-shockable arrest rhythms, and (3) perfusing rhythms.

ECG Algorithm

A simple algorithm can be used to make a rhythm diagnosis during the inter-cycle pauses in BLS (E-Figure 140-5). The rescuers should take only 3-5 seconds to evaluate the ECG, and if ROSC has not obviously occurred, resume chest compressions. Before pausing chest compressions, one rescuer should prepare to palpate a pulse or apex beat.



E-FIGURE 140-5 Electrocardiographic (ECG) decision tree to determine the cardiac rhythm relevant for choosing the correct ALS technique. During CPR, the primary goal of ECG analysis is to answer a single question: is the rhythm shockable or non-shockable? *ECG*, Electrocardiogram; *PEA*, pulseless electrical activity; *ROSC*, return of spontaneous circulation; *VF*, ventricular fibrillation; *VT*, ventricular tachycardia.

Once chest compressions are paused, determine if there are consistent, repeated complexes present in the ECG. The shape of the complexes is inconsequential. In some cases, there may be more than one type of complex, but the complexes will repeat consistently. If there are repeated complexes and no clear signs of effective circulation (e.g., no apex beats, no pulse, and $ETCO_2 < 30$ mm Hg), the team should quickly estimate the rate. If the rate is less than 200 per minute, this rhythm is most likely pulseless electrical activity (PEA), a non-shockable arrest rhythm. If the rate is greater than 200 per minute, the rhythm is most likely pulseless ventricular tachycardia (pulseless VT), a shockable rhythm.

In the absence of consistent, repeated complexes in the ECG, the next question is whether the ECG is a flat line. If so, this is most likely asystole, a non-shockable arrest rhythm. If there is random, non-flat activity on the ECG, this is most likely ventricular fibrillation (VF), a shockable arrest rhythm. VF can take on different appearances, but the random, chaotic activity is a consistent feature.

Choosing the Correct ALS Therapy

If a shockable arrest rhythm is diagnosed (VF or pulseless VT), defibrillation therapy is the highest priority. If a non-shockable arrest rhythm is diagnosed (asystole or PEA), vasopressor therapy and, potentially, vagolytic therapy are prioritized. If ROSC is diagnosed, post-cardiac arrest (PCA) care is initiated to reduce the risk of recurrence of CPA.[1,38]

Regardless of the arrest rhythm, BLS should be resumed for a full 2 minutes while the correct ALS therapies are administered (blue box at the bottom of the CPR algorithm, Figure 140-1). At the end of each 2-minute cycle of BLS, the arrest rhythm is diagnosed, BLS resumed and the correct ALS interventions are administered. These repetitions of 2-minute cycles are continued until ROSC is achieved or the CPR attempt is aborted.

ALS Therapy

Differentiation of shockable and non-shockable arrest rhythms is imperative because ALS measures for these two types of arrest rhythms are markedly different.

Treatment for Shockable Arrest Rhythms

Electrical defibrillation is the most efficacious therapy for the shockable arrest rhythms.[39] Other therapies

have been investigated, but in the absence of electrical defibrillation, the prognosis is grave.[40,41] However, shockable rhythms were reported to occur in about 1 out of 3 dogs, and 1 out of 5 cats during CPR, suggesting that many patients may be resuscitated successfully even in the absence of an electrical defibrillator.[10]

The goal of defibrillation is to stop the uncoordinated ventricular contractions by simultaneously transitioning as many myocardial cells as possible into a refractory period, allowing synchronized electrical activation of the heart with restoration of coordinated contractions.[42,43] Electrical defibrillators may be either monophasic or biphasic. Biphasic defibrillators are preferred, as lower currents are required for defibrillation and VF is terminated more effectively.[1,39] The dosing chart in Figure 140-4 can be consulted for recommended dosing schemes for both types of defibrillators.

When a shockable rhythm is identified at rhythm check, chest compressions should continue until everything is ready for defibrillation. After defibrillation, chest compressions should immediately resume for 2 minutes until the next rhythm check, as direct conversion to a perfusing rhythm is less likely. In a recent prospective observational study, only 27% of successfully defibrillated animals achieved a perfusing rhythm immediately post-shock.[10] At the end of each 2-minute cycle of BLS, the patient should be defibrillated as long as the rhythm identified is shockable. Subsequent defibrillator doses may be increased by 50% to a maximum dosage of 10 J/kg. All team members should be trained on equipment operations and safety precautions pertinent to defibrillation to prevent injury.

If an electrical defibrillator is not available, a precordial thump (mechanical defibrillation) may be attempted. A precordial thump is a strong blow administered directly over the patient's heart. Although there are a few case reports of successful conversion to a perfusing rhythm using a precordial thump, more recent data show a dismal success rate, and a precordial thump should never be used if an electrical defibrillator is available.[40,41,44]

For patients with prolonged CPA due to a shockable arrest rhythm despite multiple defibrillation attempts, adjunctive antiarrhythmics can be considered. Amiodarone is the most efficacious drug for this purpose, but has only been shown to be useful as an adjunct to electrical defibrillation.[39] Lidocaine may be considered as an alternate but less efficacious therapy. The use of a vasopressor may be considered in patients unresponsive to repeated attempts of defibrillation to redirect blood flow from the periphery to the core organs.

Treatment for Non-Shockable Arrest Rhythms

ALS therapies for the non-shockable arrest rhythms are primarily focused on maximizing perfusion to the heart, lungs and brain, counteracting conditions that may have contributed to CPA, and addressing metabolic derangements secondary to ischemia.

Vasopressors

By increasing peripheral vascular resistance, vasopressors lead to preferential distribution of blood flow toward the core (e.g., heart, lungs, brain), maintaining perfusion to these vital organs.[45] In contrast to defibrillation, which should be done every cycle (i.e., every 2 minutes), vasopressors should be administered every other cycle (i.e., every 4 minutes).

The best studied vasopressor used for CPR is epinephrine, a catecholamine that causes peripheral vasoconstriction by stimulating alpha$_1$ receptors.[46] Using 1 : 1,000 dilution (1 mg/mL) initially, low dosages (0.01 mg/kg IV/IO) are recommended. With prolonged CPR (greater than 10 minutes), a higher dosage (0.1 mg/kg IV/IO) may be considered, but has been associated with lower rates of survival to discharge and should only be used with that understanding. Epinephrine also may be administered via ET tube (0.02 mg/kg low-dose; 0.2 mg/kg high-dose). It should be administered through a long catheter (such as a red rubber feeding tube) fed through the ET tube after diluting the epinephrine 1 : 1 with sterile isotonic saline or sterile water.

Vasopressin is an alternative to epinephrine during CPR; it can be expected to be of similar or higher efficacy.[39,47-52] Its vasoconstrictive effects are achieved via activation of peripheral V1 receptors. Vasopressin may be used instead of or in addition to epinephrine during CPR at a dosage of 0.8 U/kg IV/IO. As with epinephrine, it should be administered every other cycle of BLS (i.e., every 4 minutes). Vasopressin also can be administered via ET tube using the same technique as described for epinephrine.

Anticholinergics

Studies examining the use of atropine, an anticholinergic drug, during CPR provide no evidence of a harmful

effect at the recommended dosage but also show no consistent benefit.[39] Therefore, atropine at a dosage of 0.04 mg/kg IV/IO may be considered for routine use during CPR in dogs and cats with non-shockable arrest rhythms. In addition, in dogs and cats with evidence of increased vagal tone at the time of CPA, it is reasonable to administer atropine as part of ALS. Therefore atropine may be administered every other cycle (i.e., every 4 minutes) during CPR in patients with documented bradycardic arrest or in animals with diseases predisposing to high vagal tone, such as gastrointestinal, respiratory, or ophthalmic diseases. Atropine also may be administered via ET tube (0.08 mg/kg) as outlined previously.

Other ALS Therapies

Intravenous Fluids

In patients with documented or suspected hypovolemia, IV isotonic crystalloid fluid boluses may improve cardiac output during CPR by increasing cardiac preload and should be considered using standard dosing protocols (20-30 mL/kg over 20 minutes in dogs, 10-20 mL/kg over 20 minutes in cats) (also see ch. 129). In euvolemic or hypervolemic patients, IV fluids may increase right atrial pressure with no increase in aortic pressure, decreasing perfusion of the brain and heart.[53] Fluid bolus administration should therefore be avoided in these patients.

Alkalinization Therapy

Sodium bicarbonate (1 mEq/kg IV, once) may be beneficial in patients with pre-existing severe acidemia (e.g., pH < 7.1) or with prolonged CPA, as severe tissue acidosis will lead to peripheral vasodilation and metabolic disturbances (see ch. 128).[39] However, these may be rapidly resolved with ROSC, and bicarbonate should be reserved for patients with prolonged CPA (greater than 10 minutes), ideally only after documenting severe acidemia (pH < 7.0).

Open-Chest CPR

While closed-chest CPR generates approximately 30% of a normal cardiac output, direct cardiac massage during open-chest CPR (OC-CPR) yields markedly better results and improves ROSC rates and survival to discharge.[54-59] Because OC-CPR is more invasive and expensive, and requires intensive aftercare, clients frequently decline this option. However, if a client requests OC-CPR, it should be implemented without delay if CPA occurs. In patients with pleural space disease, pericardial disease, or significant thoracic wall defects, OC-CPR should be strongly recommended. Closed-chest CPR is also unlikely to be effective in giant-breed, round-chested dogs. In patients that develop CPA during abdominal or thoracic surgery, direct cardiac massage is likely the only viable option for CPR.

Prognosis

Unfortunately, little epidemiological CPR data are available in veterinary medicine, limiting our ability to infer prognostic information for dogs and cats with CPA.[10,22,32,60] Reported survival rates are very low, but as in human medicine, it is likely that one of the most important prognostic indicators is the underlying cause. Patients with untreatable or progressive chronic diseases have a poor prognosis if they develop CPA. However, dogs and cats developing CPA in the perianesthetic period have survival-to-discharge rates approaching 50%.[26] Therefore, the circumstances of the arrest are important. Prompt identification of CPA, rapid initiation of high quality CPR, and adherence to these evidence-based guidelines have the potential to improve survival rates.

CHAPTER 141

Cardiac Emergencies

Manuel Boller

Cardiac emergencies in dogs and cats constitute a group of acutely occurring conditions clinically characterized by respiratory distress, circulatory crisis, or both. Implicated precipitating problems include "backward failure" (e.g., congestive heart failure, CHF), or "forward failure," e.g., cardiogenic shock due to cardiac arrhythmias, obstructive shock due to cardiac tamponade or thromboembolic disease, or a combination thereof. While cardiac emergencies often are life-threatening and require expedient and effective care, therapy is distinctly different from the treatment given for non-cardiac causes of respiratory distress and circulatory shock. Timely identification of a cardiac etiology predominantly is based on the physical examination and cageside tests. A two-phase therapeutic approach is recommended. The initial step consists of early initiation of the appropriate emergency care with the aim of stabilizing the patient. Once this is achieved, further characterization of the cardiac condition and refinement of treatment as appropriate becomes possible. This chapter discusses recognition, acute management, and expected outcome of dogs and cats with cardiac emergencies.

Heart Failure

Cardiac failure, in broad terms, is a condition in which the heart is reduced in its capacity to eject blood into the pulmonary and systemic arterial circulation in a way that achieves sufficient tissue perfusion, or to receive venous blood to allow adequate draining of the microvascular beds. When the heart's inability to eject and receive blood leads to pleural or peritoneal effusion or edema, the resulting syndrome is referred to as CHF (see ch. 246).

Breathing difficulty is the most common presenting complaint for dogs and cats with acute CHF in the emergency setting.[1] It indicates advanced heart failure, most commonly due to chronic valvular heart disease (CVHD) or dilated cardiomyopathy (DCM) in dogs and hypertrophic cardiomyopathy (HCM) in cats.[1,2] The challenge initially exists in differentiating a cardiac cause of respiratory distress from causes other than heart disease. The severity of dyspnea in many dogs or cats with CHF precludes important diagnostics such as thoracic radiography from being performed until stabilization of the patient is achieved. Combined consideration of findings from history, signalment, physical exam, initial cageside diagnostics, and the response to initial therapy is applied in a pattern recognition process to accept or refute the preliminary working diagnosis of CHF. Information on congestive heart failure also is presented in ch. 246 and 247.

Signalment and historical findings can provide important information in support of cardiac causes of respiratory distress. Dogs with CHF due to CVHD are typically of old age and small size (<20 kg), including small mixed-breed dogs.[3] In contrast, CHF with DCM occurs more commonly in middle-aged dogs of large to giant breeds.[2,4] CHF in cats occurs more frequently in young to middle-aged animals but cats of any age can be affected.[1,5-8] Domestic short- and long-haired cats predominate, but inherited HCM has been reported for several breeds (e.g., Maine Coon, Ragdoll, British Shorthair, Persian, Himalayan).[1,8-11] CHF is more common in male dogs and cats.[1,2] Historical findings can include coughing, which is commonly reported in dogs but is not specific for CHF. In cats, coughing is more commonly associated with asthma, not CHF. History-taking should also include inquiries on alternative explanations for respiratory distress, e.g., clinical signs of laryngeal paralysis, the occurrence of vomiting or regurgitation, etc.

A focused initial major body system assessment will allow for rapid gathering of more evidence for or against CHF. Animals with CHF typically have an increase in respiratory rate and effort commensurate with the severity of pulmonary edema or pleural effusion. As characteristic for pulmonary parenchymal disease, but not specific to CHF, an increased inspiratory and expiratory effort is in support of pulmonary parenchymal diseases, including cardiogenic pulmonary edema. An increase in respiratory effort that is

predominantly inspiratory, with stertor or stridor, can be interpreted as evidence against a cardiac etiology, as these signs suggest the upper airway as the source of dyspnea (see ch. 28). In some cases however, the addition of CHF as co-morbidity may lead to exacerbation of a pre-existing, subclinical upper airway obstruction or a latent tracheal collapse. In the absence of an upper airway issue, an asynchronous or paradoxical breathing pattern can suggest the presence of pleural effusion (see ch. 139).[12,13] Dyspnea with markedly prolonged expiratory time provides evidence for obstructive lower airway disease. In cats, this points towards feline asthma, a major differential diagnosis for CHF, especially if it coexists with coughing.[12,14] On pulmonary auscultation, end-inspiratory crackles can indicate pulmonary edema, but are found inconsistently in dogs and infrequently in cats with CHF.[1] Dull ventral lung sounds can indicate pleural effusion. In small-breed dogs, the absence of a heart murmur renders CHF a less likely diagnosis. The likelihood of CHF increases with the intensity of the systolic heart murmur[15,16]: in a retrospective study of 578 dogs (<20 kg) with CVHD, a murmur of soft (grade I-II/VI), moderate (grade III/VI), loud (grade IV/VI) and thrilling (grade V-VI/VI) intensity was associated with a CHF probability of 0%, 8%, 20% and 47%, respectively.[15] In contrast, dogs afflicted by DCM can have a soft systolic murmur, if any, and an auscultable tachyarrhythmia.[4] Approximately 50% of cats with CHF are found to have an auscultable heart murmur, gallop sound, arrhythmia, or some combination thereof at presentation[7]; while heart murmurs also are common in cats without CHF (e.g., 52% of cats with normal hearts),[7] gallop sounds and arrhythmias are markedly more prevalent with cardiomyopathy, particularly when CHF is present.[7] Pale mucous membrane color, prolonged capillary refill time, and poor pulse quality can be signs of cardiogenic shock, but similar signs occur in patients with hypovolemic shock. A large proportion of dogs and cats with respiratory distress due to CHF, however, will present without concurrent cardiogenic shock. Hypothermia is a more common occurrence in cats than in dogs with CHF.[1,8]

Three-lead ECG is a suitable initial diagnostic that can be conducted with minimum animal restraint, and is essential for characterization of common arrhythmias and the basis for specific antiarrhythmic therapy (see ch. 103). Focused cageside ultrasonography of lungs and heart can be executed with the patient in sternal recumbency, and with minimal distress to the animal; it can provide important information concerning the presence or absence of CHF. A focused ultrasound examination of the thorax (TFAST), abdomen (AFAST), or both allows identification of pneumothorax and pleural, pericardial, and abdominal effusions (see ch. 143 and 149).[17] The characteristic sonographic appearance of wet lung as opposed to dry lung supports the presence of a pulmonary parenchymal disease process.[17] Distribution of the lung fields identified as wet (e.g., dorsal versus ventral, and cranial versus caudal) provides initial clues on the etiology of the lung abnormality, and assists in the diagnosis of cardiogenic pulmonary edema.[18] Echocardiographic determination of left atrium (LA) size in proportion to the aortic diameter (Ao) on the level of the aortic valve (LA/Ao ratio) in 2-D parasternal short axis view is of great value.[19] The presence of moderate to marked LA enlargement, especially an LA/Ao ratio >2 : 1, makes CHF the most likely diagnosis in the dyspneic pet (Figure 141-1).[7,20-22] The extent of training required to gain proficiency in focused critical care echocardiography remains open, but it appears feasible for clinicians who are not specialists in cardiology to acquire such skills.[23,24] Thoracic radiography is highly effective in differentiating non-cardiogenic from cardiogenic origin of respiratory distress, but may not be well-tolerated. While thoracic radiographs should never cause stress or worsen dyspnea, a dorsoventral projection, taken with the patient in sternal recumbency, often can be obtained with the least stress to the patient because this posture already is preferred spontaneously by these animals (versus dorsal recumbency). The radiographic diagnosis of CHF is based on the presence of cardiomegaly, venous congestion and distribution of pulmonary interstitial to alveolar opacities, whereby species differences exist between dogs and cats. Determination of the vertebral heart scale (VHS) can be used to objectively describe cardiomegaly, with normal values described as 9.7 ± 0.5 in dogs, and 7.5 ± 0.3 in cats.[25,26] A VHS > 9.0 has been identified as a highly specific marker for CHF in cats with respiratory distress.[27] Radiographs are not a sensitive, but are a specific, tool for identifying left atrial enlargement in cats with CHF.[28,29] The radiographic appearance of the lungs of dogs with CHF is characterized by predominantly perihilar, interstitial to alveolar opacity, with unilateral involvement being common in dogs with CVHD.[30] No particular distribution of pulmonary edema predominates in cats.[1,28,31] Pleural effusion and pulmonary venous enlargement (> than pulmonary artery) have been found in 51% and 49% of cats with CHF, respectively.[28] Compared to cats, dogs with CHF due to either CVHD or DCM more commonly have radiographic evidence of pulmonary venous congestion and less commonly have pleural effusion.[1,4]

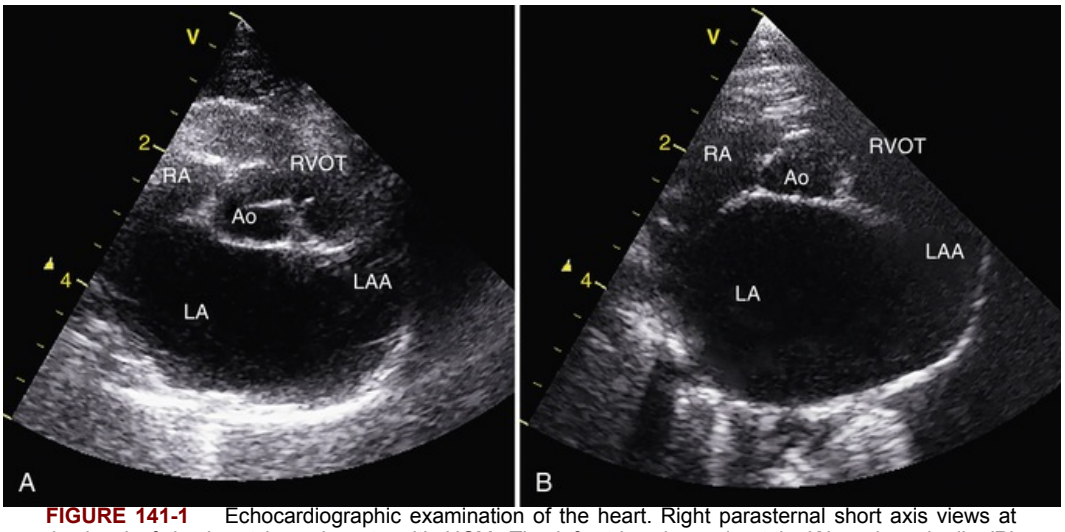

FIGURE 141-1 Echocardiographic examination of the heart. Right parasternal short axis views at the level of the heart base in cats with HCM. The left atrium is moderately **(A)** and markedly **(B)** enlarged when compared to the aortic diameter. *Ao,* Aorta; *LA,* left atrium; *LAA,* left atrial appendage, left auricle; *RA,* right atrium; *RVOT,* right ventricular outflow tract. Clinicopathological changes, foremost electrolyte abnormalities, azotemia, and liver enzyme alterations, are common in dogs and cats presented with CHF and tend to worsen during hospitalization.[1] Recognizing these changes primarily is of importance for therapeutic decision-making, but can also be of prognostic value in some instances (e.g., hyponatremia, azotemia).[2,32,33] Similarly, the assessment of global hemodynamic indices, such as arterial blood pressure (see ch. 99) or lactate values (see ch. 70), can help in determining the extent of circulatory instability of the patient. Hypotension was found in 15% of cats and dogs with CHF at presentation, and twice as often over the course of hospitalization, in one case series.[1]

An increasing body of literature examines the value of circulating cardiac biomarkers to identify heart disease. The neuroendocrine markers amino-terminal pro B-type natriuretic peptide (NTproBNP), c-terminal BNP (cBNP) and the myocardial cell injury marker cardiac troponin-I (cTnI) have received particular attention in veterinary medicine. Canine and feline assays have been validated for all three markers and, at the time of writing, point-of-care tests for cTnI and feline NTproBNP are available. Evidence suggests that these biomarkers can assist in differentiating cardiac from non-cardiac causes of respiratory distress in dogs and cats, albeit with varying accuracy.[34-41] The adjunct diagnostic value of these tests is undisputed, while their limitations as stand-alone tests require consideration.[42-47] They are discussed further in ch. 246 and 247.

The emergency therapeutic approach to dogs and cats with CHF consists of oxygen supplementation, stress minimization, and administration of drugs to resolve pulmonary edema and cardiogenic shock, as applicable, and will temporally overlap with the diagnostic evaluation mentioned above. All animals with respiratory distress should receive supplemental oxygen by the least stressful methodology available (see ch. 131).[48] Placement of a peripheral IV catheter on presentation is recommended whenever possible (see ch. 75). Mild sedation by means of opioid administration can be considered in select patients with CHF and high levels of anxiety, for the purpose of reducing oxygen consumption, sympathoadrenergic tone, and possibly cardiac preload (see ch. 138). Titration of butorphanol in increments of 0.05 mg/kg IV or IM (dog and cat) to a total dosage of 0.2 mg/kg IV or IM constitutes a reasonable approach. For acute management of cardiogenic pulmonary edema, furosemide is of central importance as it reduces *de novo* edema formation through reduction of pulmonary capillary pressure, thereby re-establishing the balance between edema clearance and production.[49] High initial dosing (e.g., 2-6 mg/kg q 2-6 h, dogs and cats) should be given IV whenever possible, using judicious and brief physical restraint to minimize stress; the IM route is an alternative route when IV access cannot be achieved but often is less effective. A good response consists of visibly improved respiratory effort in 20-45 minutes. Generally, a daily maximum cumulative dose should not exceed 12 mg/kg IV and/or IM, and a more judicious approach is required for animals where CHF is complicated by hemodynamic instability, azotemia, or serum electrolyte abnormalities. Accordingly, continuous monitoring of circulatory function and judicious determination of serum electrolyte concentrations and renal values are recommended during the initial intensive diuresis of dogs and cats, with a higher frequency of such assessments in patients who have pre-existing kidney disease or who are inappetent.[49] A furosemide loading dose followed by a constant rate infusion has been proposed as more effective and safer alternative to

intermittent bolus administration, but insufficient evidence currently exists to recommend this approach for routine implementation.[50,51] Once respiratory distress has resolved, the acute IV dosage is reduced to the minimum effective oral dosage for chronic administration, typically in the range of 2-4 mg/kg/day.

Nitroprusside, a potent arterial and venous vasodilator, can be used in normo- or hypertensive dogs and cats with severe acute CHF in which initial administration of diuretics alone failed to achieve rapid resolution of respiratory distress. Its administration as a constant rate infusion requires careful titration under continuous monitoring of arterial blood pressure to prevent harm due to hypotension (see ch. 99). To achieve this, the infusion rate is started at a very low rate (1-2 mcg/kg/min constant rate infusion [CRI] IV in dogs; 0.5 mcg/kg/min CRI IV in cats). The rate is increased in 0.5-1 mcg/kg/min increments (maximal infusion rate 5 mcg/kg/min) every 15 minutes as long as the systolic or mean arterial blood pressure remains above 100 mm Hg or 70 mm Hg, respectively, and until pulmonary congestion (e.g., crackles, respiratory distress) resolves.[52]

Oral vasodilators used for afterload reduction in refractory CHF include amlodipine in dogs (0.05-0.1 mg/kg PO q 8-12 h) and cats (0.625 mg/cat PO q 24 h) and hydralazine in dogs (0.5-2 mg/kg PO q 8-12 h) and they require titration under arterial blood pressure monitoring.[3] The angiotensin converting enzyme inhibitors enalapril (0.5 mg/kg PO q 12-24 h, dog; 0.5 mg/kg PO q 24 h, cat) and benazepril (0.25-0.5 mg/kg PO q 12-24 h, dog; 0.125-0.25 mg/kg PO q 24 h, cat), are best used once a stable diuretic dosage has been established. Dosage reduction is required in animals with azotemia. Dogs presenting with cardiogenic shock due to CVHD or DCM could benefit from an intravenous constant rate infusion of dobutamine (3-10 mcg/kg/min IV), a preferential $beta_1$-adrenoceptor agonist with positive inotropic, lusitropic, chronotropic and dromotropic effects. Additional agonistic effects on $beta_2$-adrenoceptors are associated with vasodilation, so that the net effect on cardiac output may be larger than on arterial blood pressure. The proarrhythmic effect of dobutamine limits its use at higher dosages and in animals with pre-existing ventricular tachycardia. Pimobendan, a drug frequently used in dogs with CHF, is recommended for use in dogs with CVHD and DCM in the acute or chronic stages of CHF (0.25-0.3 mg/kg PO or IV q 12 h).[3,53,54] Pimobendan currently is not licensed for use in the cat with heart failure, but evidence points towards a beneficial effect in patients with CHF in this species as well.[55-58] Thoracocentesis should be conducted in dogs and cats with voluminous pleural effusion because it provides diagnostic information and, depending on its relative contribution to dyspnea, can lead to substantial and immediate relief from respiratory distress. Thoracocentesis, as it is a low risk procedure if executed correctly (see ch. 102), can be conducted on the basis of physical examination only, with no preceding radiographic or sonographic confirmation of pleural effusion required, if a strong suspicion of pleural effusion exists. A transudative effusion is expected with CHF. Finally, dogs and cats in which dyspnea is severe enough to pose an imminent threat to the animal's life may require positive pressure ventilation to allow more time for other treatment to become effective. A recent retrospective study including six cats and 10 dogs with severe CHF reported relatively short ventilation times (30 ± 21.3 hours) and favorable survival to discharge rates (62.5% overall; 77% in cases treated after 2005) compared to other pulmonary parenchymal diseases requiring mechanical ventilation.[59-62]

The majority of dogs and cats with new-onset acute CHF are expected to survive this initial episode and be discharged for chronic care. Reported survival to discharge percentages range from 56% to 80%.[1,2] For animals surviving to hospital discharge, the median duration of hospitalization was 3 days (range, 1-9 days) in one study.[1] However, it is important for the pet owner to understand early that, except for CHF caused by surgically correctable defects (e.g., patent ductus arteriosus, pulmonic stenosis) or reversible diseases (e.g., taurine-deficient DCM in dogs), the underlying heart condition will be irreversible; daily treatment and ongoing monitoring will be required; additional episodes of respiratory distress requiring hospitalization will occur; and a large proportion of animals will have a good quality of life but will survive for 1 year or less. Reported survival times differ based on species, pathophysiology, disease severity and co-morbidities. In animals presenting with CHF severe enough to require hospitalization, reported median survival times are 2.5-5 months (range, 0-14) for dogs with DCM, 9 months (8-15) for dogs with CVHD, 18 months for cats with HCM (0-147), and 3 months (0-27) for cats with any cardiomyopathy.[8,33,63-66]

Arrhythmias

Cardiac arrhythmias are commonly encountered in the canine and feline emergency population either as a consequence of systemic disease or due to a primary cardiac disorder. Arrhythmias consist of a disturbance of rate or site of cardiac electrical impulse formation or its conduction through the heart (see ch. 248). The

primary acute concern is the resulting impediment to effective cardiac blood flow generation, with the consequence of clinically relevant reduction of tissue perfusion (e.g., circulatory shock, syncope) or deterioration into a sustained non-perfusing rhythm (e.g., pulseless ventricular tachycardia, ventricular fibrillation) (see ch. 30 and 140). An ECG examination subsequent to the physical exam finding of an inappropriately high or low heart or pulse rate, or an irregular heart beat or pulse is of central importance to identify and characterize an arrhythmia and to guide therapeutic decisions (see ch. 103).

Severe bradyarrhythmias can cause weakness or syncope. Intoxication with calcium blockers, beta-blockers, digoxin, and other compounds, and the presence of electrolyte abnormalities (e.g., hyperkalemia) should be considered as possible etiologies, as treatment of these reversible disorders is distinctively different from treatment of arrhythmias caused by primary cardiac disorders.[67,68] Sinus node dysfunction (sick sinus syndrome, SSS) and third-degree atrioventricular blocks (AVB) are primary cardiac disorders that are common causes of syncope (Figure 141-2, *A*). While most asymptomatic dogs with SSS or high-degree AVB do not need treatment, those with clinical signs often require pacemaker therapy (Figure 141-2, *B*) to improve quality of life and survival (see ch. 249).[69-72] Temporary cardiac pacing as a short-term bridge to permanent pacemaker implantation or transthoracic pacing should be considered in acute, life-threatening conditions such as patients with SSS or third-degree AVB causing syncope and a heart rate <40 beats/minute (dogs) or <90 beats/minute (cats).[73-78]

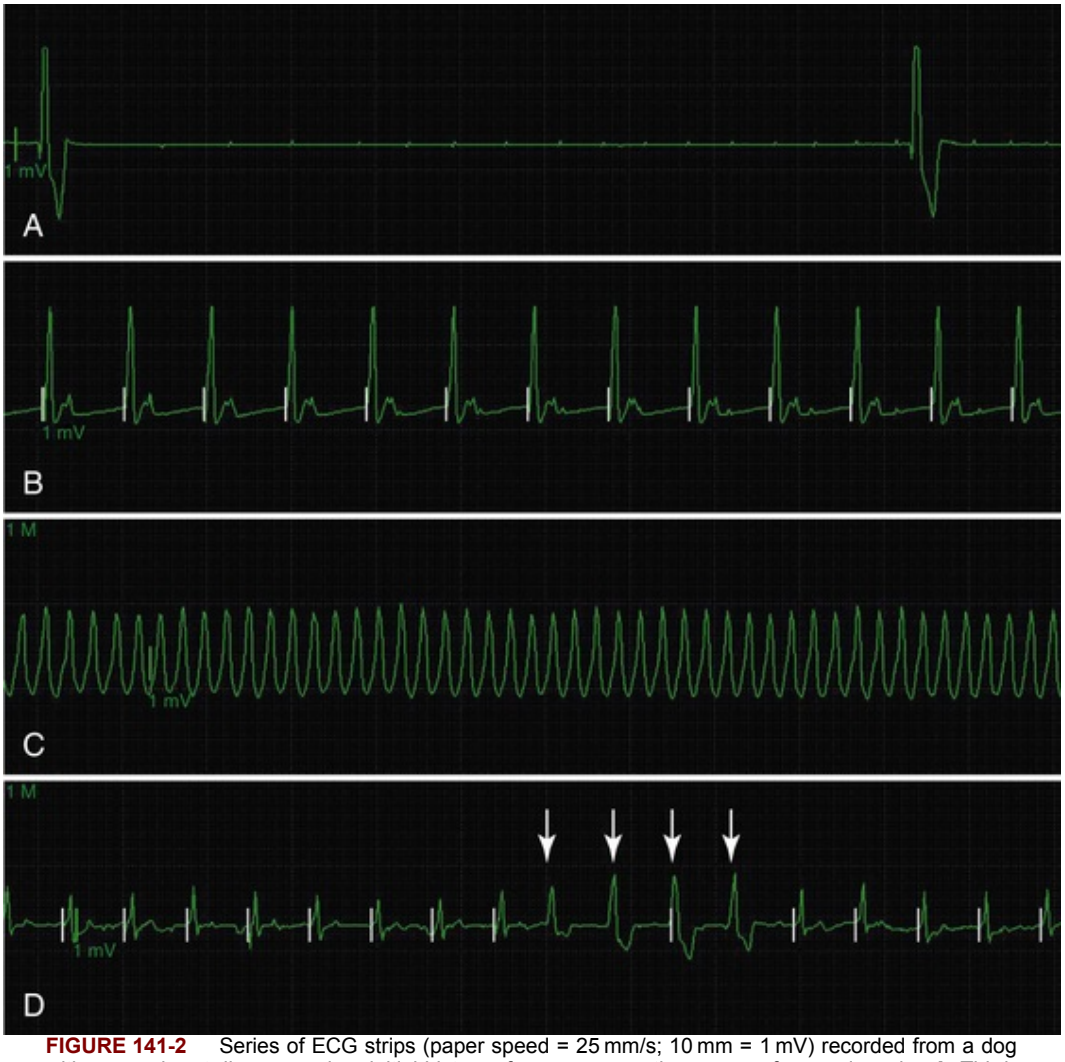

FIGURE 141-2 Series of ECG strips (paper speed = 25 mm/s; 10 mm = 1 mV) recorded from a dog with severe heart disease and an initial history of syncope over the course of several weeks. **A,** Third-degree atrioventricular block with two escape beats occurring with an interval of 10.5 seconds. **B,** Appropriate ventricular capture at a rate of 65 beats per minute after pacemaker implantation, which resolved initial syncope. White vertical bars represent pacing markers. **C,** Ventricular tachycardia (VT) at 230 beats per minute and syncope occurred several weeks after pacemaker implantation. **D,** Normal sinus rhythm with persistence of ventricular premature complexes (white arrows) during antiarrhythmic

treatment. (Images courtesy Dr. John Rush.)

Severe tachyarrhythmias can lead to weakness, syncope, cardiogenic shock, and sudden cardiopulmonary arrest. This can arise as an isolated cardiac rhythm abnormality, as a complicating component of structural heart disease (e.g., DCM), or as an exacerbation of low cardiac output conditions in such systemic diseases as severe sepsis or septic shock.

Differentiation between supraventricular (SVT) and ventricular tachycardia (VT) is important, and is discussed in ch. 248. Atrial fibrillation (AF) is the most common SVT in dogs and is indicative of structural heart disease in non-giant-breed dogs and of severe left atrial enlargement in cats.[79-81] The ECG findings of AF are characterized by a highly irregular rhythm (i.e., variable beat-to-beat R-R interval) with varying conduction dependent rate, by the absence of P waves, and by an undulating baseline (f waves) (Figure 141-3). Other forms of SVT occurring in both dogs and cats do often have P waves, even though these are sometimes buried in the preceding QRS complexes or T waves and often are difficult to identify. These forms of SVT can be sustained or intermittent, typically have constant R-R intervals, and, in their more severe forms, can create significant circulatory compromise with weakness or collapse. Examples include atrial flutter and atrioventricular reciprocating tachycardias, and they occur much less commonly in dogs and cats than in humans. Beyond the immediate decrease in cardiac output that these SVTs can cause when they are very rapid, SVTs that are sustained for several days to weeks can lead to remodeling of the heart with a resulting DCM-like phenotype.[82,83]

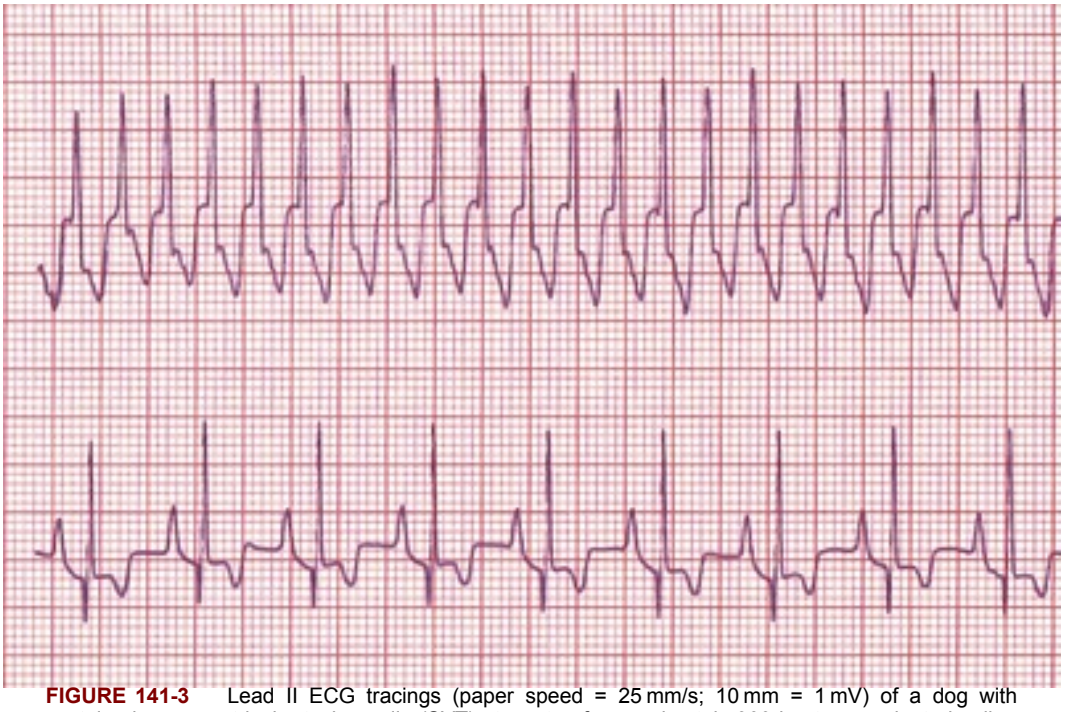

FIGURE 141-3 Lead II ECG tracings (paper speed = 25 mm/s; 10 mm = 1 mV) of a dog with sustained supraventricular tachycardia (SVT) at a rate of approximately 300 beats per minute leading to collapse of the animal (top tracing). Intravenous administration of diltiazem led to conversion to sinus rhythm at a rate of 120 beats per minute (bottom tracing). (Images courtesy Dr. John Rush.)

In addition to the reversal of potential precipitating causes (e.g., electrolyte and acid-base disturbances, anemia), the control of CHF as appropriate, and the application of the inconsistently and only temporarily effective ocular or carotid vagal maneuvers (see ch. 248), administration of antiarrhythmic drugs is recommended. In syncopal patients or those with very rapid SVT (e.g., sustained heart rate >200/min in large dogs, >240/min in small dogs, >260/min in cats), acute therapy can consist of diltiazem (dogs: 0.1-0.2 mg/kg IV over 2-3 minutes; begin low and uptitrate to effect; consider even lower starting dosage if structural heart disease, e.g., DCM; follow by 5-20 mcg/kg/min CRI IV if needed) or esmolol (dogs and cats: 0.1-0.5 mg/kg IV, in 0.1 mg/kg increments; followed by 50-100 mcg/kg/min CRI IV if needed). The negative inotropic effects of esmolol warrant careful use in dogs with severely diminished left ventricular systolic function. In less acute cases, oral diltiazem (0.8-1.5 mg/kg PO q 8 h, dog [plain, non-sustained-release formulation]; 3 mg/kg PO q

12 h, dog [sustained-release formulation]; 7.5 mg/animal PO q 8 h, cat [plain formulation; sustained-release not recommended in cats]), atenolol (0.25-1 mg/kg PO q 12-24 h, dog; 6.25-12.5 mg/cat PO q 12-24 h), or sotalol (1.5-3.5 mg/kg q 12 h PO, dog; 10 mg/animal PO q 12 h, cat) can be used for initiating chronic control of arrhythmias. Consultation with or referral to a cardiologist is recommended. Sotalol is a reasonable choice in animals with coexisting SVT and VT.

The requirement for treatment of VT depends on the heart rate, whether the rhythm is associated with circulatory compromise (e.g., if there is concurrent structural heart disease), and whether there are ECG features that suggest a heightened risk for deterioration into a non-perfusing rhythm, such as pulseless VT or ventricular fibrillation (see ch. 140). In any case, treatment should be accompanied by an investigation into causes of VT, such as electrolyte abnormalities (e.g., hypokalemia, hyperkalemia, hypocalcemia, hypomagnesemia), intoxications (e.g., chocolate, bronchodilators), myocardial hypoxia (e.g., hypoxemia, anemia, myocardial ischemia), trauma (i.e., traumatic myocarditis), inflammation (i.e., myocarditis), conditions associated with systemic inflammatory response syndrome (SIRS), sepsis or ischemia/reperfusion injury (e.g., GDV), splenic disease, cardiac neoplasia, and adult-onset or congenital heart disease in advanced stages. Reversible causes of VT need to be addressed before or in conjunction with pharmaceutical reduction of the arrhythmia load. Ventricular premature contractions occurring at a low rate of 60-120 per minute (i.e., accelerated idioventricular rhythm, or AIVR) commonly occur in critically ill dogs and typically do not warrant pharmaceutical intervention, but instead continuous monitoring and correction of reversible precipitating causes. High-rate VT (e.g., dog >180 bpm, cat >250 bpm) can lead to circulatory compromise and generally needs to be treated with antiarrhythmic drugs (see Figure 141-2, *C* and *D*). In veterinary medicine, the importance of the R on T phenomenon (i.e., ectopic QRS complex superimposed on the preceding T wave) is unclear and the benefit of antiarrhythmic treatment solely based on this abnormality has not yet been established.

Acute treatment of VT is first attempted with lidocaine boluses (2 mg/kg IV, repeat up to a total of 4 doses in no less than 30 minutes, dog; 0.5-1 mg/kg IV once, cat) titrated to terminate the VT, and once achieved, is followed by a continuous rate infusion (30-80 mcg/kg/min CRI IV, dog; 10-40 mcg/kg/min CRI IV, cat). Vomiting and sedation can occur at higher dosages. If not effective, slow boluses of procainamide (2-4 mg/kg IV, q 3-5 min, 16 mg/kg maximum dose, dog; 1-2 mg/kg IV once, cat) can be administered, followed by a CRI (25-50 mcg/kg/min IV, dog; 10-20 mc/kg/min IV, cat). Amiodarone is very effective in terminating VT and its use can be considered in dogs where lidocaine and procainamide failed to control the arrhythmia. A single slowly administered dose (5 mg/kg IV, dog) is followed by an oral regimen (10 mg/kg PO q 1 h for 7 days; 5 mg/kg PO q 12 h thereafter, dog). Intravenous amiodarone administration will predictably lead to an acute hypersensitivity reaction in dogs, including hypotension, collapse, urticarial and facial edema, an effect caused by the solvent in the intravenous formulation.[84] A new aqueous formulation of amiodarone is available and is devoid of this side-effect.[85] Subacute and chronic treatment may succeed with oral administration of antiarrhythmics, including mexiletine, sotalol and amiodarone with efficacy of maintenance treatment being preferentially assessed by Holter monitoring (see ch. 248).

Cardiac Tamponade

An abnormal accumulation of fluid between the visceral and parietal pericardium is referred to as pericardial effusion (PE).[86-95] The clinical syndrome of cardiac tamponade occurs when this fluid accumulation increases to the extent that right ventricular diastolic collapse occurs and hemodynamic compromise ensues, leading to hypoperfusion due to circulatory (obstructive) shock with weakness, collapse and, if left untreated, ultimately death. The volume of PE required to cause cardiac tamponade is influenced by the rate of fluid accumulation and pericardial compliance, such that a relatively small effusion can elicit a profound hemodynamic effect in some cases, but not in others. The details of clinical presentation, diagnostic confirmation, and treatment of cardiac tamponade are discussed in ch. 254, and pericardiocentesis is described in ch. 102.

Feline Aortic Thromboembolism

While aortic thromboembolism is a rare occurrence in dogs, it is a frequently-seen feline cardiac emergency.[8,96-112] Feline aortic thromboembolism (FATE) most commonly occurs in association with severe heart disease. FATE is thought to be initially very painful and can lead to local ischemic tissue loss and severe systemic illness due to reperfusion injury. It is difficult to treat effectively, will often reoccur, and carries an overall guarded short-term and poor long-term prognosis.[98-100] Most commonly, thromboembolic occlusion occurs in the distal aorta as it bifurcates into the iliac arteries; however, occasionally other vessels such as the

brachial, mesenteric, renal, or cerebral artery can be affected in isolation or in combination.[98,99,101] Cats of any age and gender can be affected with the more common signalment being male (especially when HCM is concurrently present), and middle aged to old.[98,99] Please see ch. 256 for a detailed discussion of FATE.

CHAPTER 142

Diabetic Ketoacidosis and Hyperglycemic Hyperosmolar Syndrome

Mauria O'Brien

Diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar syndrome (HHS) are two serious and potentially life-threatening complications of diabetes mellitus (DM) whose pathophysiology and treatment are similar. It is reasonable to suggest that the conditions are two points on the spectrum of decompensated diabetes. Both disorders are characterized by hyperglycemia that stems from an absolute or relative insulinopenia combined with an excess of counterregulatory or "stress" hormones. Patients with DKA or HHS are often quite ill, their management challenging, and concurrent conditions that can substantially affect prognosis common. Fluid, electrolyte and acid-base disturbances can be significant (see ch. 128).

The definition for each entity varies slightly depending on the reference consulted. The diagnosis of DKA includes the presence of hyperglycemia, glucosuria, ketonemia or ketonuria with an increased anion gap metabolic acidosis.[1] HHS is now defined as a syndrome of severe hyperglycemia (>600 mg/dL) and, depending on species and veterinary reference, a serum osmolality >320 mOsm/kg.[2-6] The syndrome was previously defined by a lack of ketones but now includes those with and without detectable ketonemia/ketonuria.[7,8] HHS is uncommon, with few original veterinary studies published. Many conclusions have been drawn from human reviews.[7,8]

Pathophysiology

Hyperglycemia develops when insulin is absent or deficient. Insulin is the key which allows cells to utilize glucose. Despite increased serum glucose concentrations, cells become starved for energy without insulin. Most cells then use free fatty acids (FFAs) as an energy source. Lipolysis generates and liberates FFAs into the circulation. Hepatocytes uptake FFAs and convert them primarily into triglycerides and, to a lesser degree, into ketones.[9] Insulin hinders lipolysis through the inhibition of hormone-sensitive lipase, the enzyme responsible for the hydrolysis of triglycerides into FFAs. Brain cells are unique in that they do not require insulin for glucose uptake, but unlike most tissues, the brain cannot use fatty acids for energy but can utilize ketones.[9] Ketone bodies can provide as much as two-thirds of the brain's energy needs during fasting or starvation.[10] Uncomplicated diabetics, in a state of starvation, convert most excess FFAs to triglycerides and ketone production is low enough as to be manageable by the body.[9]

DKA is characterized by an increased glucagon (GC) to insulin ratio, leading to a state of enhanced gluconeogenesis via inhibition or stimulation of certain glycolysis-pathway enzymes.[11-13] A study of diabetic dogs in which GC and insulin concentrations were measured suggested that the ratio is more relevant than the individual hormone values.[12] Another study supports this concept, as a few dogs with DM had normal insulin concentrations but still developed measurable ketones.[14] With a relative or absolute lack of insulin in DKA, cellular demand for glucose stimulates the release of GC, which increases gluconeogenesis and promotes glycogenolysis. In the absence of insulin, GC activates adipose cell lipase thereby increasing the concentration of FFAs and inhibiting hepatic storage of triglycerides. Due to a complex second messenger cascade system, a small amount of GC leads to synthesis of large amounts of glucose. Even with depleted hepatic glycogen stores, GC accelerates gluconeogenesis and increases the extraction rate of amino acids from the circulation to act as available substrates. As a result, serum glucose concentrations increase and, without insulin present, hyperglycemia develops.[9]

GC also promotes ketogenesis by shifting hepatocyte production of triglycerides to the production of FFAs. Normally, insulin inhibits malonyl CoA, which in turn inhibits fatty acid oxidation and production of FFAs.

In the absence of insulin, malonyl CoA activity is low and GC stimulates FFA uptake into the mitochondria by increasing hepatic levels of carnitine. Carnitine is a carrier protein used by the enzyme carnitine palmitoyltransferase I which shuttles FFAs into the mitochondria. From this point the FFAs can either enter the citric acid cycle or be converted into acetoacetate (AcAc) and beta-hydroxybutyrate (BHA). In DKA, the citric acid cycle becomes overwhelmed and ketogenesis prevails. As ketone concentrations increase, they cannot be efficiently metabolized and hyperketonemia results. The normal ratio of serum BHA to AcAc is 3 : 1; in DKA states this ratio can increase as high as 10 : 1 (Figure 142-1).[10]

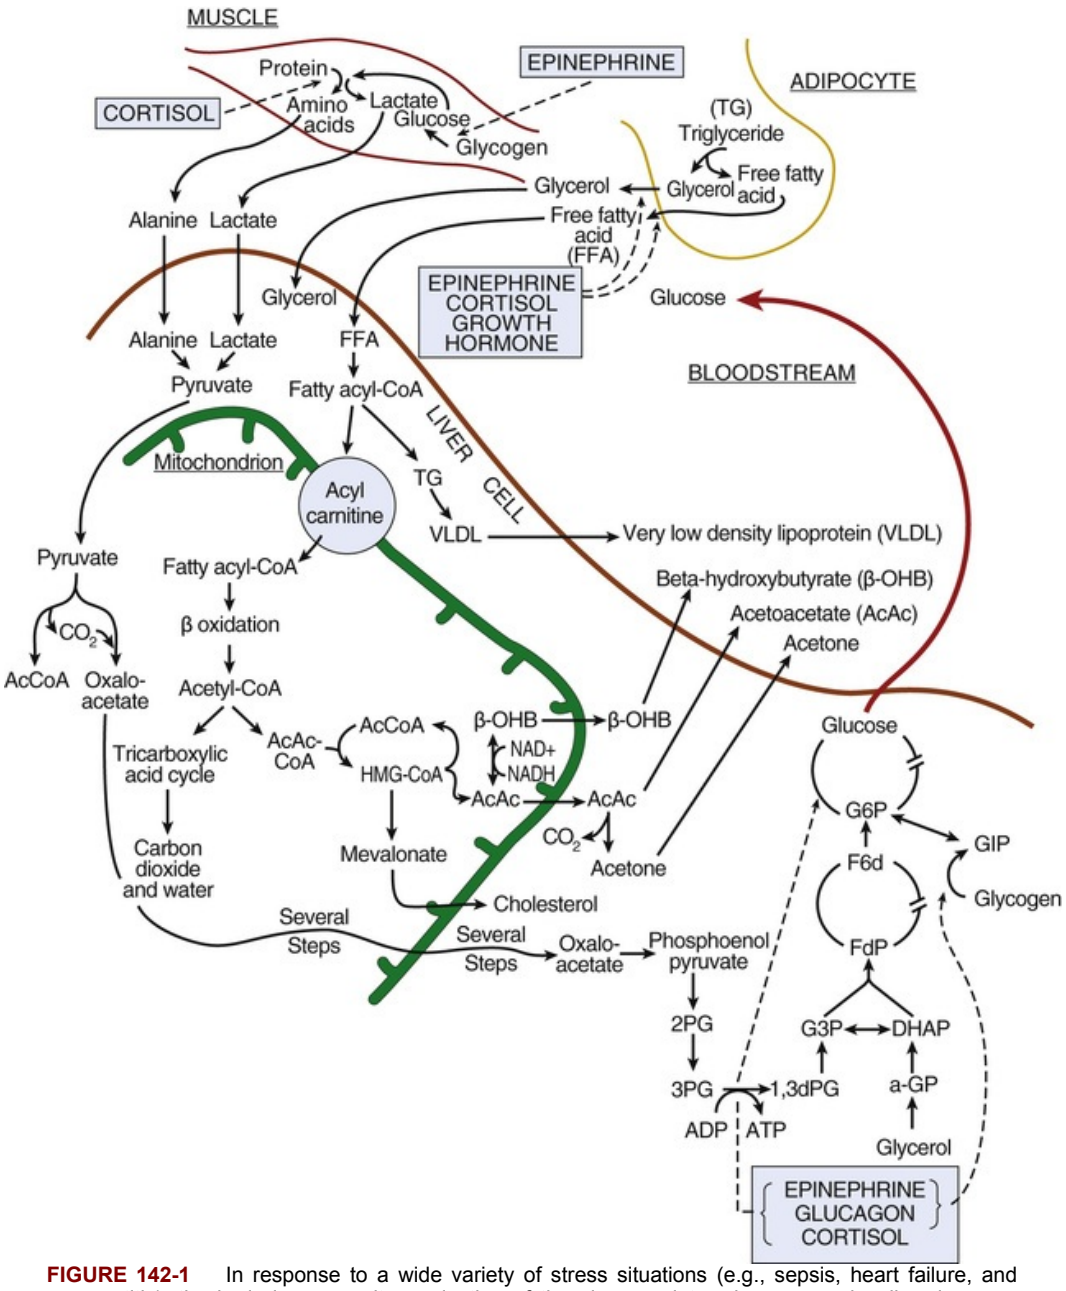

FIGURE 142-1 In response to a wide variety of stress situations (e.g., sepsis, heart failure, and pancreatitis), the body increases its production of the glucoregulatory hormones—insulin, glucagon, epinephrine, cortisol, and growth hormone. In diabetes, the lack of insulin allows the glucogenic effects of the stress hormones to be unopposed in liver, muscle, and adipose tissue. This results in excessive ketone formation, fat and muscle breakdown, and a classic catabolic state. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *DHAP,* dihydroxyacetone phosphate; *GIP,* gastric inhibitory polypeptide; *HMG,* hydroxymethylglutaryl; *NAD+,* nicotinamide adenine dinucleotide; *NADH,* nicotinamide adenine dinucleotide (reduced form). (Adapted from Feldman E, Nelson R: *Canine and feline endocrinology and reproduction,* Philadelphia, 1987, Saunders.)

What distinguishes DKA from uncomplicated DM is the absolute or relative lack of insulin *in combination* with an increase in counterregulatory hormones. GC, cortisol, epinephrine (Epi) and growth hormone (GH) comprise these diabetogenic hormones. They contribute to the pathogenesis by promoting lipolysis and stimulating gluconeogenesis and glycogenolysis. Cortisol increases protein catabolism, providing amino acid precursors for gluconeogenesis.[1] Cortisol and Epi, and to a lesser extent GH, stimulate hormone-sensitive lipase, which mediates the breakdown of triglycerides to glycerol and FFAs in adipose tissue.[15] High Epi and low insulin concentrations reduce peripheral tissue glucose uptake and hyperglycemia develops.[16]

Although DKA and HHS are similar in pathogenesis, ketone production is perhaps minimal or absent in HHS because these patients possess enough insulin to limit lipolysis but not enough to counter hyperglycemia.[13] Other explanations for a lack of ketones include lower FFA concentrations and/or increased portal vein insulin concentrations.[17] Patients with HHS tend to be more dehydrated, less acidemic and may have lower counterregulatory hormone concentrations than those with DKA. HHS patients typically develop "hypernatremic dehydration" as free water losses exceed those of sodium.[7] Glucosuria impairs renal concentrating capacity, exacerbating this water loss. As blood volume decreases, renal perfusion decreases, and the kidneys' capacity to excrete glucose is reduced. This cascade of events can lead to marked hyperglycemia.[18]

Secondary or concurrent diseases are precipitating events that contribute to DKA or HHS by stimulating synthesis and secretion of the stress hormones. In people, the two most common precipitating factors are inadequate insulin dosing and infection.[19] In veterinary patients, acute pancreatitis, urinary tract infection, hyperadrenocorticism, neoplasia, pneumonia, pyelonephritis, and chronic kidney disease (CKD) have been associated with DKA or HHS.[5,20-22] Cats with DM and CKD or congestive heart failure are at increased risk of developing HHS. Cats with HHS are less likely to have pancreatic or hepatic disease as the co-morbid process as compared with DKA cats.[5]

Impaired neutrophil function may explain the increased risk of infection in poorly regulated diabetics.[23] Hyperglycemic states are pro-inflammatory, capable of producing reactive oxygen species.[24-26] Increased concentrations of GH, cortisol, and cytokines (markers of cardiovascular risk and oxidative stress) have been demonstrated in patients with DKA. People in a hyperglycemic crisis may have leukocytosis without obvious infection due to increased pro-inflammatory mediators.[24] Insulin therapy is anti-inflammatory since pro-inflammatory biomarkers decrease with its administration.[27,28]

History and Physical Examination

Some dogs and cats with either DKA or HHS may already be receiving insulin; some are newly diagnosed diabetics; some are yet to be diagnosed and have a recent history of polyuria, polydipsia, and weight loss, but in the day or days preceding veterinary care, owners often note seeing lethargy, partial to complete anorexia, vomiting, diarrhea, and/or generalized weakness.[20] Cats may specifically exhibit posterior paresis secondary to diabetic neuropathy (see ch. 305).[22] Severe metabolic acidosis may result in Kussmaul respirations: a slow and deep breathing pattern, sometimes misinterpreted as respiratory distress.[8] In one study, cats with HHS had been diabetic for a longer time than cats with DKA. Neurologic and respiratory signs are seen more frequently in HHS cats.[5] Physical examination should be complete, as these pets often have concurrent illness. Estimating hydration status and assessing mentation and mucous membrane color is valuable.

Diagnostics

Overview

Any dog or cat suspected of having DKA or HHS should undergo a thorough diagnostic evaluation to assess not only the current condition with regard to DM, but to identify any co-morbid conditions. Minimum testing should include urinalysis (to diagnose DM and presence of ketones), complete blood count (CBC), serum chemistry analysis, serum electrolytes, blood gas, urine culture, abdominal ultrasound, and thoracic radiographs.

Urinalysis and CBC

Urinalysis will be positive for glucose and may be positive for ketones. Urinary tract infections are common.

Bacterial culture of urine should be performed regardless of sediment observations. 20% of dogs with DKA were found to have positive growth on aerobic urine culture despite lack of pyuria (see ch. 72).[20] The hematocrit may be increased secondary to dehydration. Anemia is common in both dogs and cats. Cat red blood cells are susceptible to Heinz body formation and oxidative injury.[29] In one study, 50% of dogs with DKA had nonregenerative anemia, left shift neutrophilia, and thrombocytosis.[20] Leukocytosis is more common in cats.[22,30]

Liver Enzyme Activities, Kidney Testing (see ch. 62 and 65)

In cats, increased hepatic enzyme activities may be seen with concurrent hepatic lipidosis, cholangiohepatitis or pancreatitis. Dogs may have increased alkaline phosphatase activities as well as elevated serum triglyceride and cholesterol concentrations in association with DM, hypercortisolism, or pancreatitis. Increases in serum creatinine and blood urea nitrogen (BUN) concentrations can be due to dehydration; however, some pets have CKD with or without acute kidney injury (AKI). Dogs with HHS and ketones tend to have acute pancreatitis, shorter duration of clinical signs, higher body temperature and higher white blood cell (WBC) counts as compared with those that have HHS without ketones. HHS dogs without ketones tend to be more azotemic with higher osmolalities.[6] The hyperosmolality integral to HHS may cause altered mentation.[31]

Sodium (Na) and Potassium (K) (see ch. 67 and 68)

The combined effects of hyperglycemia, ketonemia, acidosis and many co-morbid processes often causes significant electrolyte derangements in both DKA and HHS. Hyperglycemia-induced osmotic diuresis results in severe fluid and electrolyte losses. Ketones contribute to the solute diuresis via excretion of ketoanions, which obligates urinary cation excretion of Na, K and ammonium salts.[13] Decreases in Na can also follow hyperglycemia, estimated as every 100 mg/dL increase in serum glucose being associated with a 1.6 mmol/L decrease in Na.[16,32,33] This formula may underrepresent the effect on Na.[34] Low Na concentrations can also be seen with hypertriglyceridemia, "pseudohyponatremia." Insulin deficiency also contributes to solute loss as insulin stimulates salt and water reabsorption from both proximal and distal tubules and phosphate from proximal tubules.[13]

Significant hypokalemia is common in DKA. Initially, many DKA patients have normal to slightly elevated serum K concentrations but have severe total body depletion.[16] The acidosis of DKA leads to displacement of K from intracellular stores to the extracellular space in exchange for hydrogen ions.[35] Volume depletion, from lack of intake combined with vomiting, diarrhea and osmotic diuresis, may cause secondary hyperaldosteronism, promoting urinary K excretion.[36] Inter-compartmental K shifts can vary depending on the type of acidosis (mineral vs. organic), by tissue type, and by pH of body fluids.[35] Renal dysfunction, by promoting hyperglycemia and reducing urinary K excretion, contributes to the initially normal or increased K concentrations.[37] Insulin deficiency, by promoting intracellular proteolysis, further impairs K entry into cells. Paradoxically, plasma K concentrations increase initially despite whole body depletion.[1] Magnesium, calcium and phosphorus are also depleted in DKA, mostly as renal losses.[16]

Acid-Base, Ketones

DKA is characterized by metabolic acidosis with an increased anion gap. BHA and AcAc overproduction are key contributors to this acidosis. Both dissociate completely at physiologic pH, resulting in the production of hydrogen ions and ketoanions. The rapid accumulation of hydrogen ions overwhelms the bicarbonate buffering system, resulting in metabolic acidosis. The accumulation of ketoanions is reflected by an increased anion gap. Significant fluid losses and hypovolemia can lead to lactic acidosis, contributing to the metabolic acidosis. Concentrations of acetone, a ketone formed after spontaneous decarboxylation of acetoacetate, are increased in patients with DKA but do not contribute to acidosis because acetone does not dissociate; it is slowly excreted by the lungs and generates the distinctive, "sweet"-smelling breath of DKA.[10] This slow excretion of acetone may result in longer time requirements to correct ketonemia than hyperglycemia.[16,38] Severity of acidosis may be masked in dogs and cats due the metabolic alkalosis associated with vomiting or diarrhea.

The presence of ketones is most commonly assessed using commercially available urine reagent strips. The

methodology utilizes the nitroprusside reaction and a color change to indicate the presence of ketones. These strips measure only AcAc and acetone but the majority of ketone bodies are made up of BHA and AcAc, thus leading to the occasional false negative result. Beta-hydroxybutyrate is formed from AcAc in the presence of hydrogen ions; therefore, the more acidotic the animal, the more BHA is formed.[10] Some patients are significantly dehydrated on presentation with an empty bladder and no urine for assessment. Heparinized plasma can be tested using urine ketone reagent strips. Results correlate with serum concentrations in diabetic dogs and cats.[39,40] Plasma may be more accurate than urine in dehydrated animals since excretion of ketones relies on normal renal perfusion and function. Ketones will be evident in plasma before being detectable in urine.[40] Assays and hand held meters to detect BHA in blood have improved and are considered reliable for diagnosis and monitoring response to therapy; hand held meters are an alternative to using urine ketone tests.[41-47]

Most HHS patients are not acidotic. This reduces cationic exchanges and limits urine electrolyte losses. Unbalanced free water loss eventually leads to profound dehydration masked by preservation of intravascular volume secondary to the hyperosmolar state.[7] HHS patients are reported to have more extensive fluid losses than those with DKA. Severe hyperglycemia can only occur with reduced glomerular filtration rate (GFR) because glucose entering the kidney in excess of the renal threshold should be excreted in the urine. The profound hyperglycemia of HHS then exacerbates the osmotic diuresis.[31] Co-existing disease processes may further decrease fluid intake which, together with losses through diarrhea or vomiting, contribute to the dehydration.

Osmolality

The severity of hyperosmolality can be variable in DKA, but patients with HHS are hyperosmolar by definition. Osmolality is measured by an osmometer that uses the freezing point of a solution to estimate the amount of osmotically active particles. Measurement of osmolality is superior to a calculated osmolality because of the ability to measure volatile substances in a solution.[3] Since most veterinarians do not possess an osmometer, equations have been devised to estimate osmolality. The most commonly used equation, referred to as total calculated osmolality (Osm_T) is: Osm_T (mOsm/kg) = 2 ($Na^+ + K^+$) + Glucose/18 + BUN/2.8.[3] The calculated reference interval ranges from 290-310 mOsm/kg.[48,49] The effective osmolality (Osm_E) is based on the simplified equation: Osm_E = 2 (Na^+) + Glucose/18.[50] Hypertonicity in DKA and HHS patients is due to an increase in concentration of solutes that do not cross the cell membrane (Na and glucose). Urea is not considered an "effective osmole" because it is equally distributed across membranes and its accumulation does not induce an osmotic gradient.[8] Absolute serum ketone concentrations are not routinely measured in DKA but are known to contribute to the osmolality. Measurement of the osmole gap (measured Osm_T − calculated Osm_T) in DKA produces a mean osmolar gap of 29 mOsm/kg, which can decrease to insignificant values within 24 hours of initiating therapy.[51-53] Ketoanions presumably fully dissociate at physiologic pH and therefore do not contribute significantly to tonicity but do contribute to osmolality based on the osmolar gap.[53,54] Hyperosmolality is defined as serum osmolality >320 mOsm/kg in people, >330-350 mOsm/kg in cats, and >325-330 mOsm/kg in dogs.[2-7] Cats with HHS had a median Osm_T of 384 mOsm/kg and median Osm_E of 344.1 mOsm/kg.[5]

With an increase in the osmolality or tonicity of the extracellular fluid, cellular dehydration results as water shifts from the intracellular compartment to the extracellular compartment. The nervous system is the principal organ affected by this shift and neurologic dysfunction (disorientation, ataxia, lethargy, seizures and coma) develops with worsening cellular dehydration. In defense against glucose-induced hypertonicity, neural cells produce osmotically acitve molecules called idiogenic osmoles. Formation of such osmoles occurs over 4-6 hours and should be taken into consideration during management.[55] It has been suggested but not well substantiated that the higher the osmolality, the worse the neurologic signs and risk of cerebral edema.[56-59]

Overview of Management Strategies

Successful treatment of DKA or HHS patients is complex, involving correction of many derangements while anticipating or responding to the various interactions among therapies. Goals of treatment include (1) restoring intravascular volume, (2) resolving dehydration, (3) attending to electrolyte disturbances, (4)

correcting acid-base imbalance, (5) decreasing blood glucose concentrations, (6) ridding the body of detectable ketones, (7) identifying and (8) treating any underlying or co-existing disease. Ideally, patients with DKA or HHS should be hospitalized in a facility that can provide 24-hour biochemical testing, electrolyte testing, and care.

Many DKA and HHS patients are severely hypovolemic, requiring initial fluid resuscitation. Perfusion parameters (heart rate, pulse quality, mentation, mucous membrane color, capillary refill time, blood pressure) should dictate the need for fluid boluses, before rehydration rates are instituted. Insulin is not recommended for hypovolemic animals, as this can cause fluid shifting from the extracellular to the intracellular compartment, worsening the already depleted intravascular volume.[7] Most patients should be rehydrated for several hours before initiating insulin therapy. Close monitoring of perfusion, hydration status and serum electrolytes is critical, regardless of the crystalloid fluid chosen. Fluids contribute to initial decreases in glucose, ketones and counterregulatory hormones by increasing GFR and their excretion.[19]

Fluid Therapy

DKA and HHS

Most commercially available crystalloid solutions are adequate for resuscitation and rehydration (see ch. 129). While the initial fluid of choice has been 0.9% sodium chloride (saline) because most patients are initially hyponatremic, it may cause a temporary hyperchloremic metabolic acidosis, resulting from a loss of bicarbonate rather than gain of organic acid.[19,60,61] Buffered crystalloid solutions have adequate Na content and lactate, acetate, or gluconate to aid in resolving the metabolic acidosis.[62] The saline-induced acidosis is considered temporary and may have serious sequelae.[63,64]

Fluid deficits are calculated based on estimations of dehydration (with % dehydration expressed as a decimal, e.g., 10% = 0.1):

$$\%\ \text{dehydration} \times \text{body weight (kg)} \times 1000\ \text{mL/kg} = \text{mL of fluid deficit}$$

These estimates are subjective, requiring frequent reassessment in the early phases of therapy. Rehydration should take place over a relatively short time (6-24 hours), although speed of replacement depends on the patient's hemodynamic, osmotic, cardiovascular, and neurologic status. Most patients have been hyperglycemic and ketonemic for hours to days, contributing to continued osmotic diuresis. Urine output must continually be assessed when adjusting fluid rates. Rehydration of the HHS patient often requires more conservative fluid therapy than it does in those with DKA because of the combination of severe dehydration and hyperosmolality.

Cerebral Edema

Sudden changes in glucose or Na concentration, affecting the Osm_E, should be avoided. Rapid decreases in Osm_E may lead to fluid shifts from the extracellular to intracellular compartments in the central nervous system (CNS). Water moves from least to most concentrated spaces through semi-permeable membranes. CNS cells may contain the previously discussed idiogenic osmoles, balancing their interior osmolality, initially, to that of the dehydrated extracellular space. Administering IV fluids (extracellular) provides free water, lowering osmolality and promoting flow into cells. This influx of water into brain cells is cerebral edema.

Although it occurs rarely, children and infants with DKA are more prone than adults to developing cerebral edema early in therapy. Cerebral edema occurs in roughly 1% of children with DKA and is associated with a mortality rate of 40-90%.[55] Proposed pathophysiologic mechanisms for cerebral edema remain complicated, with ischemia and reperfusion injury, inflammation, increased blood flow, intracellular osmolyte generation, osmotic "imbalance" and cytotoxins being implicated.[26,57] Additional contributing factors include initial blood glucose concentration, excessive IV fluid administration, persistent hyponatremia despite resolution of hyperglycemia, hypocapnia, acidemia, hyperkalemia, increased BUN/creatinine ratio,

and sodium bicarbonate administration.[55,59,65]

Cerebral edema in DKA is usually noted within 12-24 hours of initiating therapy. Some suggest cerebral edema may precede onset of therapy.[66] Previous studies have associated IV fluid-induced rapid changes in Osm_E with cerebral edema.[67] One current concept is the "cytotoxic theory": osmotic gradients are created by overzealous fluid and insulin dosing.[66] Another concept holds that cerebral edema is vasogenic and independent of fluid therapy. In this context, edema follows increased brain water diffusion coefficients in the acute phases of illness.[68,69] Current recommendations are for initial slow rehydration rates and low insulin dosing to gradually decrease the Osm_E, as should be reflected by decreases in serum glucose and concomitant increases in serum Na.[57,70] Recent investigations in children with DKA compared half-strength saline versus saline, but without clear conclusions.[64,71,72] Since most commercially available isotonic IV solutions are Na-based, deficiencies are addressed with standard IV therapy.

Neurologic Signs

Severe neurologic signs related to increased Osm_E were not observed in either a group of cats with DKA nor another group with HHS, nor were any other complications noted with fluid therapy.[4,5] If neurologic signs are present on presentation, treatment should be more conservative: rehydrate over 24-48 hours and use a lower insulin dosage (Box 142-1). Severely affected patients with altered mentation (obtunded, stuporous or comatose), abnormal cranial nerve reflexes, or seizures should be treated with mannitol (0.5-1.5 g/kg IV over 15-20 minutes).

Box 142-1

Recommended Dosages for Various Conditions in DKA and HHS

Stepwise Treatment for Diabetic Ketoacidosis

1. **Fluid Therapy**
   - Rehydrate over 6-8 hours
   - Place central line (see ch. 76) → repeat electrolytes/PCV/TS
   - After 6-8 hours, start insulin in peripheral line, fluids in central line
   - Fluid rate = 1.5-2× maintenance (due to osmotic diuresis) until glucose "normal"
   - Weigh every 6-8 hours

BG (mg/dL)	FLUID TYPE	DILUTED INSULIN SOLUTIONINFUSION RATE	
		Dog:	**Cat:**
>250	Plasmalyte-A or Norm R	10 mL/h	5 mL/h
200-250	P-lyte + 2.5% dextrose	7 mL/h	3 mL/h
150-200	P-lyte + 2.5% dextrose	5 mL/h	2 mL/h
100-150	P-lyte + 2.5% dextrose	5 mL/h	2 mL/h
<100	P-lyte + 5% dextrose	Stop	Stop

2. **Blood Glucose, Dextrose, Insulin**
   - Regular insulin dosage (add to 250 mL fluid bag):

   Dosage: 2.2 U/kg/day (1.1 U/kg/day if HHS)
   Cats run at half the dog rate (see table, right)
   Change out insulin bag (250 mL bag) every 24 hours
   - Run 50 mL of insulin solution through IV tubing before use
   - Recheck BG every 2-3 hours
   - Repeat PCV/TS every 12 hours (prepare for pRBC transfusion in cats)
3. **Electrolytes**

CHEC

	K EVERY	ADDITIVE	CURRENT VALUES	ADDED TO FLUID	RATE (mL/kg/h)	NOTES
Potassium	8-12 hours	*KCl* 2 mEq K^+/mL	3.6-5.0 mEq/L	20 mEq/L	26	*K^+ Maint = 20-24 mEq/L* At high rates/concentrations, account for K^+ mEq provided by KPhos and fluids
			2.6-3.5 mEq/L	40 mEq/L	12	
			2.1-2.5 mEq/L	60 mEq/L	9	
			<2.0 mEq/L	80 mEq/L	7	
Phosphorus	12 hours	*KPhos* 3 mmol P/mL	1-2 mg/dL	0.03 mmol/kg/h		KPhos = 4.4 mEq K+/mL
			<1.0 mg/dL	0.06-0.12 mmol/kg/h		
Magnesium	8-12 hours	*$MgSO_4$* 4 mEq Mg/mL	<1.2 mg/dL	0.75-2 mEq/kg/***day***		*Put into D5W or saline* For refractory hypokalemia Keep at high rate instead of topping out the K^+ supplementation

4. **Maintenance**
   - Continue on insulin CRI until ketones have resolved and eating/drinking
   - Shut off insulin at noon → at 6 pm: give ¼-½ U/kg NPH SC in dogs, 1 U/cat insulin of choice SC q 12-24 h

From Dr. Brittany H. Perry.

Potassium (K)

Virtually all DKA and HHS dogs and cats are initially hypokalemic. Although serum concentrations can be normal or increased initially, whole body K depletion is typical and needs should be addressed immediately and reassessed frequently until patients are eating, drinking, and no longer receiving IV fluid therapy. Hypokalemia can lead to muscle weakness, cervical ventroflexion in cats, cardiac arrhythmias and respiratory failure, if severe (see ch. 68).[73,74] K supplementation should be initiated once urine production is confirmed. Fluid therapy increases GFR, increases renal K excretion, and alleviates metabolic acidosis. All these factors shift K from the circulation to the intracellular space. Life-threatening hypokalemia ensues. KCl can be added to IV fluids, with the dosage based on serum K concentrations (see Box 142-1). While some sources warn against administering more than 0.5 mEq/kg/h, life-threatening hypokalemia (<2.0 mEq/L) should be treated using 0.5-0.9 mEq/kg/h for the first hour followed by reassessment.[75,76] Insulin therapy should be withheld until K concentrations are >3.5 mEq/L to avoid further loss of K to cells.

Insulin

Initial Considerations

After 4-8 hours of fluid therapy, or when the patient appears to be better hydrated, a central venous catheter should be placed to allow frequent blood sampling without repeated venipuncture (see ch. 76). Insulin therapy should be initiated and glucose levels monitored frequently to adjust insulin dosage accordingly (see Box 142-1). Insulin is essential in managing DKA, in part because no other drug directly turns off ketone synthesis. Insulin decreases ketone body concentrations by inhibiting lipolysis and thereby lowering FFA availability for ketogenesis, by interfering with ketone body production within the liver, and by enhancing peripheral ketone utilization.[77] Although not necessarily ketotic, patients with HHS also need insulin to reduce hyperglycemia in a controlled manner.

Insulin Choices

Regular insulin administered in a constant rate infusion (CRI) is recommended for the initial treatment of critically ill DKA or HHS patients, rather than via IM injections.[21] "Low-dose" regular insulin CRI is considered the standard of care for people with DKA or HHS, with lower mortality rates than seen with repeated IM injections.[1,19] IM insulin should be reserved for uncomplicated cases or those with financial restrictions. IM regular insulin, not administered until patients have been adequately rehydrated with a stable cardiovascular system, is given at dosages of 0.2 U/kg initially and then 0.1 U/kg IM hourly until the blood glucose drops below 250 mg/dL, when insulin is given SC every 6 to 8 hours at dosages of 0.5 to 1 U/kg.[78] Dextrose should be supplemented in the patient's fluids as needed based on the patient's blood glucose level (see Box 142-1 and E-Box 142-2).

Insulin Analogs

The introduction of insulin analogs has resulted in potential alternatives to CRIs. In a small cohort of dogs with DKA, lispro insulin was safe and as effective as regular insulin CRI.[79] Studies in people evaluating SC glargine combined with low-dose regular insulin CRI have noted faster resolution of acidosis, shorter hospital stays, and reduction in rebound hyperglycemia when CRI was stopped.[80,81] Similarly, cats with DKA treated with regular insulin CRI were compared to those given regular insulin CRI combined with IM or SC glargine. The combined insulin group had quicker resolution of hyperglycemia, ketonemia and acid-base status, shorter hospitalization stays, but no advantage to survival.[82] A study of cats with DKA cats given IM and SC glargine shows promise as an alternative to insulin CRI (E-Box 142-2).[83]

E-Box 142-2

Use of Glargine Insulin for Managing Cats with DKA

Glargine can also be used for treatment of diabetic ketoacidosis (DKA) in cats. In one study, 15 cats presenting with DKA were treated with intramuscular glargine (1 IU in 14 cats and 2 IU in one cat), combined with subcutaneous glargine (1-3 IU) in 12 cats. Subcutaneous glargine was continued every 12 hours, with cats receiving 1-3 doses of IM glargine (0.5-1 IU) over the first 22 hours. Subsequent doses of IM glargine were not required in 6 cats, while a second (4 cats) or third dose (5 cats) was required, and cats (3) not receiving subcutaneous glargine on admission required 3 IM doses. All 15 cats survived and were discharged within 5 days of admission on twice daily glargine, and 33% of cats achieved remission within 29 days.

From Marshall R, Rand J, Gunew M, et al: Intramuscular glargine with or without concurrent subcutaneous administration for treatment of feline diabetic ketoacidosis: a preliminary study. *J Vet Emerg Crit Care (San Antonio)* 23:286-290, 2013.

IM or SC Insulin

Critically ill dogs and cats with DKA or HHS often have severe fluid deficiencies. Circulatory compromise in dehydrated patients may hinder or alter delivery of any medication given IM. Unpredictable insulin action could increase risk of hypoglycemia or sudden changes in osmolality. Therefore, patients should be rehydrated adequately before giving IM insulin, with a goal of decreasing glucose concentrations by no more than 50 to 75 mg/dL/h.[84] If the glucose level drops below 250-300 mg/dL and ketones are still present, glucose should be added to the IV solution (see Box 142-1). Once the patient is hydrated and eating, longer acting insulin formulations should be employed.

Serum Phosphate (PO_4) and Magnesium (Mg)

As discussed, serum or plasma K and PO_4 concentrations must be closely monitored, especially after insulin administration begins. Insulin is one of several treatments (IV fluids, sodium bicarbonate as well) that drives K and PO_4 into cells, leaving the vascular space depleted. Clinical signs of hypophosphatemia include muscle weakness and hemolytic anemia. PO_4 can be added to IV fluids in the form of potassium phosphate (KPO_4;

0.03 to 0.12 mmol/kg/h).[85] Alternatively, one-third to one-half of K supplemented can be added as KPO_4 mixed with KCl (see Box 142-1).[78] KPO_4 is reportedly incompatible with lactated Ringer's solution and should be added to balanced, calcium-free, crystalloid fluids.[86] Serum PO_4 concentrations should be monitored at least every 4-6 hours after starting insulin therapy. Serum PO_4 concentrations <1.5 mg/dL may be associated with a risk of intravascular hemolysis.[87]

Magnesium (Mg) is a required cofactor for most adenosine triphosphatases and deficiencies can have detrimental effects on cellular function. For example, low Mg may decrease ATPase activity at the sodium-potassium pump.[89] Magnesium depletion has been correlated with insulin resistance.[90] Hypomagnesemia has been noted in critical illness and DKA.[88] Clinical signs are subtle or non-existent, but low Mg concentrations are associated with refractory hypokalemia, promoting urinary losses. In some patients, serum K concentrations normalize only after Mg replacement.[91,92] Cats tend to be more hypomagnesemic than dogs.[93] Magnesium sulfate is added to the IV fluids and given as a CRI at a dosage of 1 to 2 mEq/kg/day.

Anemias

Many complications encountered in treating DKA or HHS can be prevented or mollified by diligent monitoring and appropriate responses to results. Such monitoring may require repeated blood sampling that can lead to anemia and need for blood transfusions. Cats, having eight reactive sulfhydryl groups on each hemoglobin tetramer, are prone to Heinz body anemia in critical illness and there is evidence to suggest that ketosis can enhance the risk.[29] Acute hemolytic anemia can also contribute to transfusion needs if extracellular PO_4 concentrations drop precipitously with insulin therapy.

Acidosis

The metabolic acidosis of DKA typically resolves with fluid therapy and insulin alone. Sodium bicarbonate, used to help correct the acidosis of DKA, is no longer recommended. The American Diabetes Association does list it as a treatment option for patients with a pH < 7.0 1 hour after onset of fluid therapy, without prospective randomized studies to demonstrate efficacy.[19] Bicarbonate drives K into cells, potentially worsening hypokalemia; shifts the oxyhemoglobin curve to the left, decreasing oxygen release at the tissue level; and can contribute to paradoxical CNS acidosis, fluid overload, lactic acidosis, persistent ketosis and cerebral edema.[1,94,95]

Prognosis

Prognosis in DKA and HHS is largely dependent on the concurrent disease process. Previous retrospective veterinary studies have listed mortality rates ranging from 26-30% for DKA[20-22] and 38-65% for HHS.[5,6] Although mortality rates are lower overall, there is a worse prognosis with HHS compared with DKA in human patients (10-50% vs. 2-10%, respectively).[7,13,19] Regardless of species, without resolution of co-morbid processes, the outcome of DKA or HHS worsens. A recent study showed that the two most important factors predicting mortality in human DKA were severe concurrent illness and blood pH <7.0.[96] The complicated pathogenesis of DKA and HHS creates a considerable medical challenge for the veterinary practitioner. Clients and clinicians should be prepared for the financial, emotional and unpredictable outcome of these diabetic complications.

CHAPTER 143

Acute Abdomen

Søren Boysen

Acute abdomen classically is defined as a sudden onset of severe abdominal pain, evolving in less than a week, and of unclear etiology.[1,2] However, advanced states of shock and/or concurrent decreased mentation (e.g., chemical sedation) can mask an obvious pain response, deferring the diagnosis of acute abdomen until mentation improves, pain worsens, or both. A high index of suspicion in these cases is necessary to identify subtle manifestations of abdominal pain and facilitate early diagnosis and treatment (see ch. 126).

Due to the variety of underlying causes, both medical and surgical, the diagnosis of acute abdomen in small animals is challenging. Clinical signs vary and range from the stable patient with a self-limiting condition to the unstable patient requiring immediate intervention. Additionally, many underlying conditions causing acute abdomen are dynamic and progressive, and can lead to necrosis of abdominal tissues if left untreated.[3] Prompt identification and treatment are essential to decrease the risk of serious complications, including hollow viscus perforation, septic or chemical peritonitis (see ch. 279), and the systemic inflammatory response syndrome (see ch. 132).

The primary objectives in the patient presenting with acute abdomen are to rapidly assess cardiopulmonary status and establish hemodynamic stability, initiate therapy to relieve discomfort (i.e., analgesia), exclude life-threatening surgical conditions, and determine a specific cause.[3] In many cases, emergency surgery is required to further stabilize the patient and correct the underlying cause, making a prompt diagnosis critical.

Pathogenesis

Understanding somatosensory pathways (see ch. 126) helps explain why some patients with acute abdomen caused by disorders such as pancreatitis or peritonitis appear to be in more pain than animals with obstructive gastrointestinal (GI) disorders or organ enlargement.[4] In general, abdominal pain can be classified as visceral or somatic. Most cases of abdominal pain probably are associated with visceral pain receptors.[5] Visceral pain results when nociceptors located in the muscles and mucosa of hollow organs, and in the mesentery and on serosal surfaces of abdominal organs, are stimulated by distension, stretching, vigorous contraction, and ischemia.[5,6] Examples include masses that cause stretching of an organ capsule (e.g., splenic hemangiosarcoma), or thrombosis of the mesenteric artery and subsequent ischemia, inflammation, and cytokine release.[7] Visceral pain tends to be difficult to localize because the afferent nerves of the pathway have fewer nerve endings in the gut, and are primarily mediated by unmyelinated C fibers; these enter the spinal cord bilaterally at several locations, resulting in a dull pain that is more generalized.[8] Inflammation and tissue congestion associated with the inciting disorder can lower the threshold for stimuli, further sensitizing nerve endings, and can secondarily stimulate autonomic nerves, which results in patients also showing signs of nausea and vomiting.[5]

Somatic (parietal) pain receptors tend to be more A-delta fibers and are located principally in the parietal peritoneum, muscle, and skin. These pain receptors typically respond to stretching, tearing, or inflammation, and probably are most active in cases of peritonitis and following surgical procedures. The nerves that convey somatic pain are more numerous, travel within specific spinal nerves that are myelinated, and transmit impulses to specific dorsal root ganglia. Therefore, the pain is more localized, associated with one side or the other, more intense, and more often is described as having a sharp quality.[5] Movement has been shown to aggravate this pain pathway, which often results in the patient remaining still or splinting when walking or during palpation of the abdomen.[5,8]

Localizing abdominal pain can be confounded by referred pain from non-abdominal sites (e.g., intervertebral disc disease, neoplasia). Care must be taken to rule out non-abdominal causes of acute

abdomen. Pain also can be referred from sites outside the abdomen as a result of shared central pathways at the spinal cord level for afferent neurons originating in distant locations.[5,8,9] A common example in people occurs in patients with pneumonia who present with abdominal pain because the distribution of sensory nerves arising from a single spinal nerve ganglion (T9 dermatome) is shared by the lung and the abdomen.[8,9] If an obvious cause of pain cannot be found on workup of the abdomen, thoracic radiographs to rule out referred pain from pleural or lung parenchymal disease have been suggested.[10]

Clinical Signs

The presence of abdominal stretching while in lateral recumbency or the classic "prayer position" should alert the clinician to the possibility of severe acute abdomen (Video 143-1). Subjectively, this often-described abnormality has a low sensitivity and specificity for abdominal pain. Reluctance to move, or a stilted and/or short choppy gait when ambulating, could also reflect abdominal pain.[11,12] Other patients with acute abdominal pain can exhibit excessive salivation due to nausea.[11,12] Although non-specific and variable depending on the underlying cause, signs of vomiting, decreased appetite/anorexia, lethargy, diarrhea, and a distended abdomen often are noted.[11,12]

Differential Diagnosis

Injury to almost any intra-peritoneal organ can cause abdominal pain and an acute abdomen, including hepatic, pancreatic, intestinal, renal, urinary, splenic, and reproductive diseases. In addition, certain disorders of the mesenteric and vascular system also can result in an acute abdomen. Differential diagnoses with key clinical findings and indications for medical or surgical management are included in Box 143-1.

Box 143-1

Differential Diagnoses for the Acute Abdomen

Gastrointestinal System

Foreign body (FB) *(C)*
- Particularly younger animals; linear FBs more frequent in cats. US, radiography often confirmatory. *Surgery required, may be urgent.*

Gastric dilation-volvulus *(C)*
- More common in large-/giant-breed dogs. History of unproductive retching and abdominal distension. Right lateral abdominal radiograph is confirmatory. *Emergency surgery required.*

GI ulceration *(U)*
- History of NSAID ingestion, hematemesis, and/or "coffee grounds" vomitus possible. US and/or endoscopy can be helpful; often diagnosed based on history and response to therapy. *Non-surgical unless refractory to medical management or perforation suspected.*

Gastric or intestinal perforation *(LC)*
- Consider underlying causes (e.g., GI ulcer, foreign body, mass; history of GI surgery if dehiscence). AFAST and abdominocentesis with fluid cytology/ analysis and low effusion glucose level to detect septic effusion. Imaging may identify underlying cause. *Emergency surgery required.*

Gastroenteritis: *Non-surgical*.
- *Bacterial (U)*
  - Consider history of raw food diet, carrion/offal ingestion (see ch. 276).
- *Hemorrhagic gastroenteritis (HGE) (U)*
  - High PCV and normal to low TS in the absence of other diseases are characteristic.
- *Parasitic (U)*
  - More common in younger animals; fecal flotation (see ch. 81).
- *Toxin (C)*
  - Can affect any age patient. History of exposure? (see ch. 13).
- *Viral (C)*
  - Parvoviral enteritis more likely in younger dogs and kittens with suboptimal vaccination history.

Mechanical ileus (obstruction) *(C)*

Consider foreign body; neoplasia in older animals; intussusception in younger animals. Imaging often supportive or conclusive. *Surgery required, may be urgent.*

Functional ileus *(U)*

US often identifies ileus. Fasting/anorexia decreases GI motility. Recent surgery and/or opioids may predispose patients. *Non-surgical.*

Intestinal volvulus *(U)*

More common in large-breed dogs, notably German Shepherds. Severe clinical signs. Abdominal radiography often diagnostic. *Emergency surgery required.*

Intussusception *(LC)*

Younger animals with recent gastroenteritis, abdominal surgery, or opioid Tx overrepresented. US "target lesion" pathognomonic. *Surgery required, may be urgent.*

Ischemia *(U)*

Has been reported following trauma. Angiography, DPL, or surgery often required to confirm the diagnosis. *Surgery required, may be urgent.*

Neoplasia *(U)*

More common in older animals. Imaging to identify masses/lesions. FNA and/or biopsy for diagnosis. *Surgery required, may be urgent.*

Cecal inversion *(U)*

Dogs > cats. History of parasitism or typhlitis possible; US and endoscopy can confirm diagnosis. *Surgery required, may be urgent.*

Obstipation *(U)*

Cats > dogs. History of tenesmus and dry, firm feces on exam. Abdominal palpation and radiography confirmatory. *Non-surgical.*

Colitis, acute *(U)*

Diagnosis based mainly on history, exam, and fecal flotation; US may be helpful. *Non-surgical.*

Hepatobiliary System

Acute hepatitis *(U)*

Toxic, infectious causes (see ch. 282, 283, and 286). Serum liver enzyme levels often very high; US with FNA or Bx generally required for diagnosis. *Non-surgical.*

Hepatic abscess *(U)*

Abdominal radiography/US often identify lesions. FNA for cytology and C&S helpful. Percutaneous drainage with alcoholization has been reported. *Surgery required, may be urgent.*

Hepatic trauma *(U)*

Suspected based on hemoabdomen after trauma, rarely confirmed. *Rarely surgical, may be urgent.*

Hepatic rupture *(U)*

AFAST confirms hemoabdomen but non-localizing. Abdominal US and radiography may identify cause. *May require surgery, may be urgent.*

Hepatobiliary neoplasia *(U)*

Serum liver enzyme levels often high. Masses possible on US; FNA can help identify tumor type: Bx with histopathology confirmatory. *May require surgery, may be urgent.*

Liver lobe torsion *(U)*

More common in large-breed dogs. Serum liver enzyme levels often high. US helpful, particularly with Doppler assessment of hepatic vessels. *Emergency surgery required.*

Biliary obstruction *(U)*

Hyperbilirubinemia. US often diagnostic of obstruction but may not identify underlying cause. *May require surgery, may be urgent.*

Biliary rupture *(U)*

Hyperbilirubinemia. US with FNA of free abdominal fluid (bilirubin concentration: fluid > serum). *Emergency surgery required.*

Cholecystitis *(U)*

High serum liver enzyme concentrations +/− hyperbilirubinemia. Radiography may show gas in biliary tree; US helpful. *May require surgery, particularly if necrotizing (urgent).*

Cholangiohepatitis *(U)*

Cats > dogs. Serum liver enzyme concentrations elevated. US and FNA with cytology/C&S may be helpful. *Non-surgical.*

Cholelithiasis *(U)*

Small-breed dogs overrepresented. High serum liver enzyme concentrations, hyperbilirubinemia. US may detect non-radiopaque choleliths. *May require surgery, may be urgent.*

Gallbladder mucocele *(U)*

Adult/older, smaller breed dogs predisposed, especially Shetland Sheepdogs. High serum liver enzyme concentrations, hyperbilirubinemia. US diagnostic. *May require surgery, may be urgent.*

Pancreatic System

Acute pancreatitis *(C)*

Consider diet-induced, idiopathic, drug-induced, or traumatic. Female Miniature Schnauzers, exposure to garbage, table scraps, or high-fat diet. US, PLI helpful. *Rarely surgical unless abscess, severe necrosis, or neoplasia.*

Pancreatic abscess *(U)*

US and FNA with cytology often helpful. *Surgery required, may be urgent.*

Pancreatic neoplasia *(U)*

US and FNA with cytology helpful; Bx with histopathology may be required. *Surgery required, may be urgent.*

Urinary System

Acute nephritis, pyelonephritis *(U)*

Azotemia with polyuria, oliguria, or anuria typical. US, U/A, and urine C&S most helpful. *Non-surgical.*

Upper urinary tract obstruction (renal, ureteral) *(U)*

Azotemia with polyuria, oliguria/anuria, and hematuria typical. Radiography and US often diagnostic. *May require surgery, may be urgent.*

Lower urinary tract disease (cystic calculi, urethral obstruction) *(C)*

Stranguria, pollakiuria, hematuria common. Urethral obstruction: cats > dogs, males > females; acute azotemia common. Physical exam, history, and response to therapy often diagnostic of urethral obstruction. Radiography and US diagnostic of cystic calculi. *Surgery may be required, may be urgent.*

Trauma-avulsion-rupture *(LC)*

Urinary bladder most commonly ruptured urinary organ, particularly following trauma. Acute azotemia. Uroabdomen often present. US, abdominocentesis with fluid cytology/analysis +/− contrast radiography. *Surgery required, may be urgent.*

Renal artery thrombosis, renal infarct *(U)*

Ultrasonography with Doppler may be helpful. Acute azotemia may be present. *May require surgery, may be urgent.*

Renal neoplasia *(U)*

Acute azotemia common. Lymphoma: bilateral renomegaly +/− CNS metastases typical. *Radiography, US, and Bx may be helpful. May require surgery.*

Reproductive System

Female

Pyometra/uterine rupture *(C)*

Intact female with vulvar discharge and recent heat cycle. Radiography and US strongly supportive. *Emergency surgery required.*

Uterine torsion *(U)*

Intact female. Radiography and US often diagnostic. *Emergency surgery required.*

Uterine neoplasia *(U)*

Intact female. Radiography and US often helpful. *Surgery required.*

Dystocia *(C)*

Pregnancy at term. Physical exam findings often diagnostic. Radiography and US for assessing number and viability of fetuses. *May require surgery, may be urgent.*

Ovarian cyst *(U)*

Intact female. US often identifies lesions. *May require surgery.*

Ovarian neoplasia *(U)*

Uncommon cause of acute abdomen. Intact female. Radiography and ultrasonography often identify masses. *May require surgery.*

Male

Acute prostatitis *(C)*

Common cause of acute abdomen in older, intact male dogs. Rectal, radiography, US often localizing; see ch. 111. *Non-surgical.*

Prostatic abscess *(U)*

Intact older male dogs. Rectal, radiography, US with FNA, cytology, and C&S often diagnostic. *Surgery required, may be urgent.*

Prostatic cysts *(U)*

Intact older male dogs. Rectal, radiography, US with FNA, cytology, and negative C&S often helpful. *Surgery required.*

Prostatic neoplasia *(U)*

Intact older male dogs. Rectal, radiography, US often localizing. Traumatic prostatic wash and/or FNA with cytology and C&S may be required (see ch. 111). *Surgery required.*

Testicular torsion/abscess *(U)*

Intact older male dogs. Physical examination, US may be helpful. *Emergency surgery required.*

Hematopoietic System: Spleen

Splenic neoplasia *(C)*

Typically older dogs. Radiography and US +/− FNA and cytology (depending on vascularity of mass on US). *Surgery required, may be urgent.*

Splenic rupture (mass, trauma) *(C)*

AFAST with fluid FNA and cytology confirms hemoabdomen. Radiography and US +/− FNA and cytology (if minimally vascular splenic mass on US). *Emergency surgery required.*

Splenic torsion *(U)*

Consider in large and deep-chested breeds. US helpful. *Emergency surgery required.*

Splenitis *(U)*

May be diagnosis of exclusion or incidental surgical finding. *May require surgery.*

Splenic abscess *(U)*

US with FNA, cytology, C&S may be helpful. *Surgery required, may be urgent.*

Splenic infarction *(U)*

US with Doppler may be helpful. *Non-surgical.*

Peritoneum and Mesentery

Peritoneum

Septic peritonitis (U)

Consider underlying rupture of hollow viscus or abscess, or intestinal translocation. Shock, sudden collapse common. AFAST and abdominocentesis with fluid cytology: septic effusion, low effusion glucose level. Radiography, US may identify underlying cause. *Emergency surgery required.*

Bile peritonitis (U)

AFAST and abdominocentesis with fluid cytology: bilious effusion. Radiography, US may identify underlying cause. *Emergency surgery required.*

Uroabdomen (LC)

AFAST and abdominocentesis with fluid analysis: free fluid with creatinine > serum creatinine. Contrast radiography, US may identify underlying cause. *May require surgery, may be urgent.*

Viral peritonitis (FIP) (U)

Polysystemic clinical signs, laboratory results (see ch. 224). *Non-surgical.*

Disseminated neoplasia *(U)*

US often identifies lesions. FNA with cytology and/or Bx with histopathology often diagnostic. *May require surgery.*

Pansteatitis *(U)*

Cats > dogs. Fish diets predispose. US may identify diffuse hyperechoic fat. Fat Bx required for diagnosis. *Non-surgical.*

Mesentery

Mesenteric traction: large masses *(U)*

Radiography and US helpful to identify large masses. *Surgery required, may be urgent.*

Mesenteric lymphadenopathy *(U)*

US with FNA and cytology often diagnostic. *May require surgery, may be urgent.*

Mesenteric lymphadenitis *(U)*

US with FNA and cytology often diagnostic. *Non-surgical.*

Adhesions with organ entrapment, internal hernia *(U)*
History of past surgery/surgeries suggestive. US often diagnostic. *Surgery required, may be urgent.*
Retroperitoneal disease *(U)*
Consider abscess, trauma, urine leakage. US often localizing. *May be surgical, may be urgent.*

Vascular

Mesenteric avulsion *(U)*
Doppler US, angiography may be diagnostic. *Emergency surgery required.*
Mesenteric artery thrombosis *(U)*
Doppler US, angiography may be diagnostic. Preoperative diagnosis often difficult. *Emergency surgery required.*
Portal vein thrombosis *(U)*
Ascites, high liver enzyme levels. US with Doppler and angiography often diagnostic. *Often managed medically.*

Abdominal Wall

Trauma: blunt *(C)*
History of trauma and physical exam findings of abdominal wall bruising/injury. *May require surgery.*
Trauma: penetrating *(LC)*
History of trauma and physical exam finding of punctures diagnostic. *Emergency surgery required.*
Abscess *(U)*
Physical exam, US and FNA with cytology and C&S often diagnostic. *Surgery required, may be urgent.*
Strangulated hernia *(U)*
Physical exam, radiography and US often diagnostic. *Emergency surgery required.*
Surgical site dehiscence/infection *(LC)*
History of surgery and physical examination often diagnostic. *Surgery required, may be urgent.*
Neoplasia *(U)*
FNA and cytology and/or histopathology often diagnostic. *May require surgery.*

Referred Pain

IVDD
Back pain, spinal cord signs; imaging to confirm.
Discospondylitis
Back pain, spinal cord signs; lytic vertebral endplate lesions on radiographs.
Spinal neoplasia
Asymmetrical spinal cord signs; imaging to confirm.
Vertebral fracture/luxation
History of trauma; back pain, spinal cord signs; imaging to confirm.
Pelvic trauma
History of trauma; hindlimb lameness/inability to rise; radiographs to confirm.

Note: Common (C), less common (LC), and uncommon (U) refer to whether the disorder is a frequent cause of acute abdomen in small animal practice (not simply the prevalence of the disorder).

AFAST, Abdominal focused assessment with sonography for trauma; *Bx,* biopsy; *C&S,* bacterial culture and sensitivity; *CNS,* central nervous system; *DPL,* diagnostic peritoneal lavage; *FB,* foreign body; *FIP,* feline infectious peritonitis; *FNA,* fine-needle aspirate; *GI,* gastrointestinal; *IVDD,* intervertebral disc disease; *NSAID,* non-steroidal anti-inflammatory drugs; *PCV,* packed cell volume; *PLI,* species-specific pancreatic lipase immunoreactivity test; *TS,* total solids; *Tx,* treatment; *U/A,* urinalysis; *US,* ultrasound.

Modified from the previous edition version created by Jennifer Devey.

Triage

Patients presenting with an acute abdomen generally can be classified into one of four categories: (1) stable patients that do not require surgery and can be managed medically (e.g., stable pancreatitis patient), (2) critically ill patients that do not have a surgical disorder but require rapid stabilization followed by ongoing medical management (e.g., unstable parvovirus patient), (3) urgent patients that require surgery but can be

supported medically to allow further stabilization prior to surgery (e.g., markedly azotemic patient with a ruptured urinary bladder) and (4) critically ill animals that require immediate surgery following rapid stabilization (e.g., gastric dilation and volvulus [GDV] patient).

A rapid triage examination focusing on vital organs (cardiovascular, neurologic, respiratory) is extremely helpful in classifying acute abdomen patients as stable or unstable. The triage exam should be performed at the time of presentation and intensive resuscitative efforts (Airway, Breathing, Circulation) should be initiated in any patient determined to be unstable (see ch. 127 and 140). Once resuscitative efforts have commenced, or if the animal is stable at the time of presentation, a more complete history and examination should be conducted in conjunction with a search for the underlying cause.

History and Signalment

Acute abdominal pain is a cardinal symptom underlying a vast number of possible causes and a detailed history is important to help narrow and prioritize differential diagnoses.[7] However, obtaining a thorough history should be delayed in favor of hemodynamic stabilization if the patient is deemed to be unstable based on the triage examination.

Important information to be gathered includes any possibility of toxin or foreign body exposure. Inadequate vaccination status and exposure to other animals can point toward viral enteritis. The presence of vomiting and diarrhea should be determined, and if present, explored further (see ch. 39 and 40). Projectile vomiting or vomiting soon after eating often is associated with a proximal GI obstruction[10,12] while hematemesis or vomitus with coffee-ground appearance is suggestive of gastric ulceration, neoplasia, or bleeding disorder.[12] Lower intestinal tract obstruction can result in malodorous vomit that smells like feces.[12] Unproductive retching should prompt consideration of GDV. Hematuria, stranguria, dysuria, and pollakiuria indicate a primary or secondary urinary tract problem (see ch. 46 and 47). Altered gait often accompanies abdominal adhesions, prostatic disease, or muscular, skeletal, or spinal cord disease.[10-12] Tenesmus and dry stool suggest obstipation in cats and prostatic disease in dogs (see ch. 42).

Physical and Abdominal Examination

In addition to the general physical examination (see ch. 2), there are important points to consider when evaluating patients with an acute abdomen. The abdomen should be visually inspected for distension, altered contours (e.g., due to hollow organ dilation, abdominal fluid, or organomegaly), obvious masses, bruising/hemorrhage, and lacerations or punctures. It may be necessary to clip the hair to see smaller lesions. The area under the tongue should be assessed for the presence of linear foreign bodies, particularly in vomiting cats. Examination of the vulva can reveal discharge associated with pyometra, while examination of the testes may detect the presence of retained testicles. A rectal examination is recommended to detect the presence of melena, masses, prostatic pain/enlargement, or the presence of uroliths that could be palpable within the pelvic urethra.

Palpation findings that confirm the presence of abdominal pain include the animal crying out or trying to escape or bite, tensing of the abdominal muscles, or shifting from side to side.[10] However, with severe depression or generalized peritonitis, signs of pain might not be evident on the physical examination.[10] Palpation of the abdomen should start with light pressure to evaluate the abdominal wall and superficial structures (e.g., presence of body wall hernia), followed by deeper palpation of the abdominal organs (detections of masses, foreign bodies, organomegaly, etc.). In some patients it might not be possible to perform deep palpation due to associated pain. In this case, analgesics should be given and the patient re-assessed when they have taken effect, although response of the patient can be decreased following analgesics. Pain localization can help narrow the differential diagnosis and help to direct diagnostic testing in some instances; for example, pain on palpation of the retroperitoneal space can suggest upper urinary tract disease, cranial abdominal pain suggests pancreatic, hepatic, gastric and duodenal disorders, and caudal abdominal pain can suggest lower urinary tract or reproductive disorders.[10] The clinical utility of abdominal auscultation and percussion in small animals has not been studied; however, auscultation of abdominal sounds has diagnostic utility in detecting states of ileus (obstructive or paralytic) and the presence of peritonitis in human medicine, despite having poor inter-observer agreement.[13] It is recommended that at least 5 minutes of abdominal auscultation be performed to assess increased or decreased frequency of GI sounds as well as the intensity and pitch of the sounds.[10,13] Absence of gut sounds can reflect ileus, chronic intestinal obstruction, peritonitis, or abdominal effusion while increased gut sounds can reflect acute

obstruction, enteritis, or toxin ingestion.[10,11]

It also should be noted that some animals with spinal or other extra-abdominal injury might show signs of referred pain that must be evaluated carefully to prevent misdiagnosis of an acute abdomen. It is important to check carefully to see if pain is present on palpation of the spine or pelvis in patients with an altered gait, to rule out referred pain.[9,10]

Diagnostic Testing

The clinical signs and examination findings in acute abdomen cases can be non-specific and could overlap with many conditions, which necessitates use of diagnostic laboratory tests and imaging.[8] Concurrent with attempts to stabilize the patient if hemodynamically unstable, cageside emergency diagnostic tests should be started as soon as possible. These tests include the minimum database (packed cell volume [PCV], total solids [TS], glucose, blood urea nitrogen [BUN], lactate [see ch. 70], electrolytes, and an arterial blood gas [ABG; see ch. 75 and 128]), urine specific gravity (see ch. 72), electrocardiogram (ECG; see ch. 103), arterial blood pressure (see ch. 99 and 159), abdominocentesis (see ch. 90), pulse oximetry (see ch. 98), and rapid evaluation of the abdomen with ultrasonography (abdominal focused assessment with sonography for trauma [AFAST; Video 143-2]) and/or diagnostic peritoneal lavage (DPL; see ch. 90). When the patient is stable, and if history, physical examination and emergency cageside tests fail to identify an underlying cause, advanced diagnostic tests including a complete blood count and serum biochemistry profile, abdominal radiography, comprehensive abdominal ultrasonography (see ch. 88), and possibly abdominal computed tomography (CT) or laparoscopy (see ch. 91) should be considered. Blood samples and urine ideally should be collected prior to starting fluid therapy. In some cases, exploratory laparotomy could be required in the absence of a definitive diagnosis, particularly in patients that remain unstable or are rapidly deteriorating once non-surgical disorders have been ruled out.

Minimum Emergency Database

The PCV and TS can alert the clinician to the presence of abdominal hemorrhage, or if both are elevated, suggest dehydration. In acute hemorrhage, it is common to see the TS fall before the PCV falls below the reference interval, and it is recommended to rule out a source of hemorrhage or follow the PCV and TS serially in patients that have a relatively low TS following a traumatic event.[14] A low blood glucose concentration in the patient with an acute abdomen can be reflective of sepsis. A high blood urea nitrogen concentration can be reflective of prerenal, renal or postrenal disease and should be evaluated in conjunction with the physical examination and urine specific gravity. High serum hepatic enzyme concentrations can reflect hepatic or posthepatic causes of acute abdomen. Measurement of blood lactate concentration in conjunction with blood pressure provides an indication of tissue perfusion and can be followed serially to guide resuscitative efforts. The ECG should be followed continuously to evaluate the patient's initial response to resuscitative efforts, to help determine the patient's response to analgesic therapy, and to detect cardiac arrhythmias, which are not uncommon in patients with acute abdominal syndromes secondary to splenic masses, GDV, organ torsions, pancreatitis, pain and trauma (see ch. 141 and 248). Pulse oximetry and ABG analysis, although not specific to cases with acute abdomen, can detect concurrent underlying lung disorders (e.g., aspiration pneumonia secondary to vomiting).

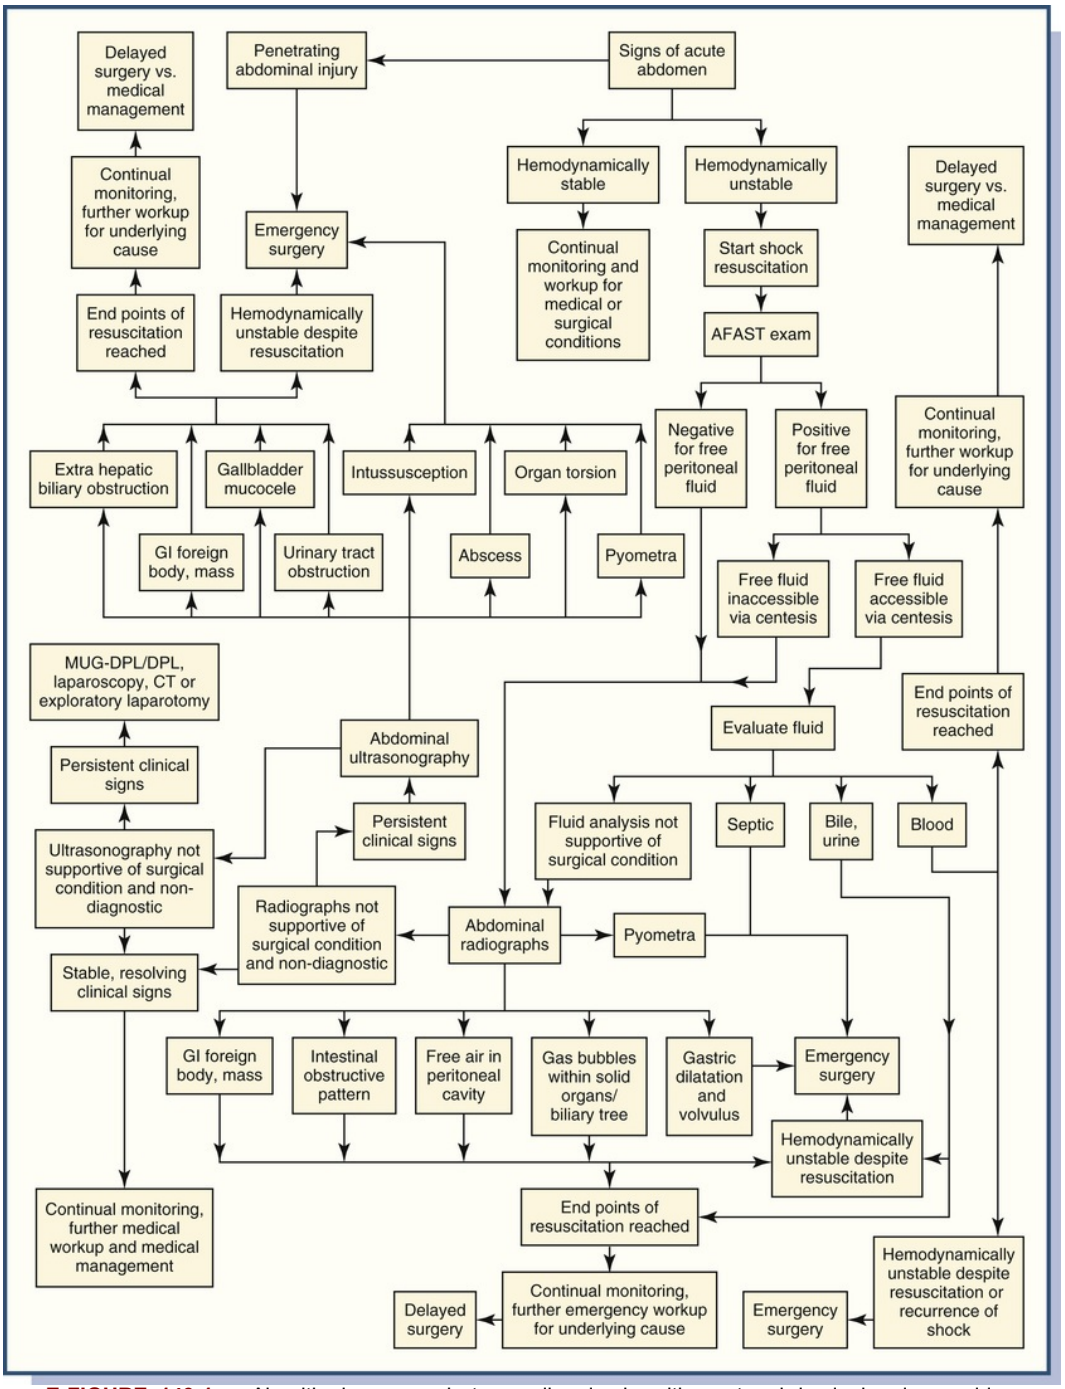
Emergency Ultrasound

Small animal patients presenting with an acute abdomen secondary to trauma should have an AFAST scan performed to detect the presence of free peritoneal fluid, which most often represents hemorrhage, although biliary, intestinal, and urinary tract rupture could also account for posttraumatic free abdominal fluid (see Video 143-2).[14,15] AFAST scans also are indicated in the unstable patient with acute abdomen unrelated to trauma. A study investigating dogs and cats presenting to an emergency service or hospitalized in the intensive care unit found that AFAST exams performed in non-trauma patients identified free peritoneal fluid in 75% of unstable patients compared to only 9% in stable patients.[16] Advantages of AFAST scans to detect the presence of free fluid are that they can be completed in under 5 minutes, require minimal ultrasound training, can be done at the cageside while unstable patients are being resuscitated, and can be repeated as necessary.[14-16] The detection of free peritoneal fluid, concurrent with fluid analysis including cytologic evaluation, can be critical in pursuing prompt surgical intervention. In some cases, free peritoneal fluid will

accumulate in the peritoneum following fluid resuscitation, and serial AFAST exams (repeated in 2-4 hours) can prove valuable in detecting delayed free peritoneal fluid accumulations.[15]

Abdominocentesis and Diagnostic Peritoneal Lavage (see ch. 90)

Abdominocentesis is easy to perform, can be done at the time of initial resuscitation, and is a key diagnostic step in helping determine the need for emergency abdominal surgery (E-Figure 143-1). Abdominocentesis, performed either ultrasound-guided or blind, and combined with fluid analysis and cytologic evaluation, allows for the detection of infection (septic peritonitis), blood (hemoabdomen), urine (uroabdomen), bile (bile peritonitis), or another non-septic effusion (see ch. 74). Abdominocentesis is indicated in acute abdomen patients when there is evidence of abdominal fluid (palpable abdominal fluid wave, loss of detail on radiographs, or detection of fluid with ultrasound), or when an unidentified cause of shock is present and ultrasonography is unavailable.



E-FIGURE 143-1 Algorithmic approach to small animals with acute abdominal pain requiring emergency and delayed surgery. *AFAST,* Abdominal focused assessment with sonography for trauma; *CT,* computed tomography; *DPL,* diagnostic peritoneal lavage; *GI,* gastrointestinal; *MUG-DPL,* modified ultrasound-guided diagnostic peritoneal lavage.

In acute abdomen cases where the underlying cause remains uncertain, and a strong suspicion of septic peritonitis persists, or small quantities of free peritoneal fluid are found that cannot be directly aspirated via centesis, DPL or modified ultrasound-guided DPL (MUG-DPL) should be considered (see ch. 90). Although ultrasonography has replaced DPL in many situations, DPL may still prove valuable in some cases of acute abdomen, including acute mesenteric ischemia.[17] A modification of the DPL technique using ultrasound guidance has been described.[18] Briefly, following ultrasound guidance of a catheter tip within close proximity to free peritoneal fluid, warmed sterile saline in 3-5 mL/kg quantities is allowed to flow through the catheter via gravity until the infused fluid mixes with the existing free peritoneal fluid. A sample can be obtained via the catheter if it becomes continuous with the pre-existing free peritoneal fluid, or alternatively, the catheter

can be removed and ultrasound guided abdominocentesis performed to obtain a sample of the diluted free peritoneal fluid.

Abdominal Radiography and Comprehensive Abdominal Ultrasonography

Survey radiography and ultrasonography are considered the standard imaging modalities for evaluation of the small animal patient with acute abdominal signs.[19] A recent study comparing imaging modalities (radiography, B-mode ultrasonography, contrast-enhanced ultrasonography and contrast-enhanced multi-detector CT) in dogs with acute abdomen found survey radiography and ultrasonography correctly identified cases requiring surgery (intestinal mechanical obstruction, GI perforation, traumatic diaphragmatic hernia, and visceral abscess) 89% of the time.[19] However, given the two imaging modalities have different sensitivities and specificities at detecting different disorders causing an acute abdomen, they should be considered to be complementary. Ultrasonography can be advantageous over radiography in the detection of GI foreign bodies and detection of mechanical ileus.[20,21] Conversely, radiography may be advantageous over ultrasonography in cases with suspected hollow viscus perforation and pneumoperitoneum.[19] Furthermore, the diagnostic imaging test chosen will vary depending on the suspected underlying disease. For example, radiography is preferred to confirm the diagnosis of suspected GDV while ultrasonography is preferred for confirmation of suspected free abdominal fluid as it is more sensitive at detecting small quantities and facilitates ultrasound-guided centesis.[19] Radiographs should be assessed carefully for the presence of free air, fluid, masses, organ position, and focal or diffuse bowel loop distension.[11] See ch. 88 for details on abdominal ultrasonography.

Advanced Imaging

Targeted helical CT is considered the modality of choice for evaluation of acute abdomen in people[22-24] and its use in small animals with acute abdominal signs is likely to increase as it becomes more widely available. Furthermore, awake and minimally sedated contrast-enhanced multi-detector CT protocols using 16-slice technology have been used safely and successfully in the evaluation of canine patients with acute abdominal signs.[25] If radiography and ultrasonography fail to identify a cause and clinical suspicion of an abdominal disorder persists, CT should be considered when available.

Treatment

Once a diagnosis for the cause of acute abdomen is made, therapy should be directed toward that specific cause. However, several therapeutic interventions should be instituted early in the management of an acute abdomen patient, often before a diagnosis can be confirmed. This includes initial stabilization of patients presenting in shock (see ch. 127), analgesia to alleviate abdominal discomfort (see ch. 126), and, when indicated, emergency surgery to prevent deterioration of the patient. Hemodynamic stabilization should be attempted immediately following identification of shock or other forms of hemodynamic instability on triage examination and should be completed prior to anesthesia and surgery to decrease the risk of associated complications (anesthesia-induced vasodilation and hypotension, and further fluid losses and hemorrhage from surgery). There are many analgesics that can be used in patients with acute pain, although opioids often are indicated and should be administered early. While giving opiates to human patients with acute abdominal pain appears to alter the physical examination, the administration of opiates leads to virtually no increase in incorrect management decisions.[26-28] Cardiac arrhythmias should be treated if they result in clinical signs of decreased cardiac output or put the patient at risk of arrest (see ch. 141 and 248). Cases with GI perforation or sepsis should have abdominal fluid or blood samples collected for culture and sensitivity testing prior to antibiotic therapy.[29] Although supportive evidence is lacking in small animals, broad spectrum intravenous antimicrobial coverage should be started within an hour of detecting the presence of sepsis.[29,30] In many cases, the underlying cause of acute abdomen is a life-threatening surgical condition, which requires prompt identification to proceed to surgery.

Deciding if Surgery Is Indicated

A number of underlying conditions causing acute abdomen may require delayed or emergency surgery (see

Box 143-1), and deciding if and when surgery is indicated to prevent patient deterioration is often challenging (see ch. 144). Dealing with such acute emergency patients involves a highly complex decision-making process, which may be simplified with the application of a clinical algorithm (see E-Figure 143-1). In some cases, patients will require emergency surgery based on history and physical examination findings without the benefit of further diagnostic testing, or a confirmed diagnosis. However, attempts should be made to rule out medical causes and to achieve hemodynamic and metabolic stabilization prior to surgery.

CHAPTER 144

Gastrointestinal Emergencies

Amie Koenig

Animals frequently are presented on emergency for evaluation of gastrointestinal (GI) signs including vomiting, diarrhea, and signs of abdominal pain. Any of these can be signs of primary GI or non-GI illness (E-Box 144-1). One of the most important decisions in such situations is whether the animal with a GI emergency can be managed medically or requires surgical intervention. Sometimes the answer to this question is obvious, while other times the question is only answered after careful assessment of history, physical examination, and diagnostic test results (Figure 144-1; also see ch. 143).

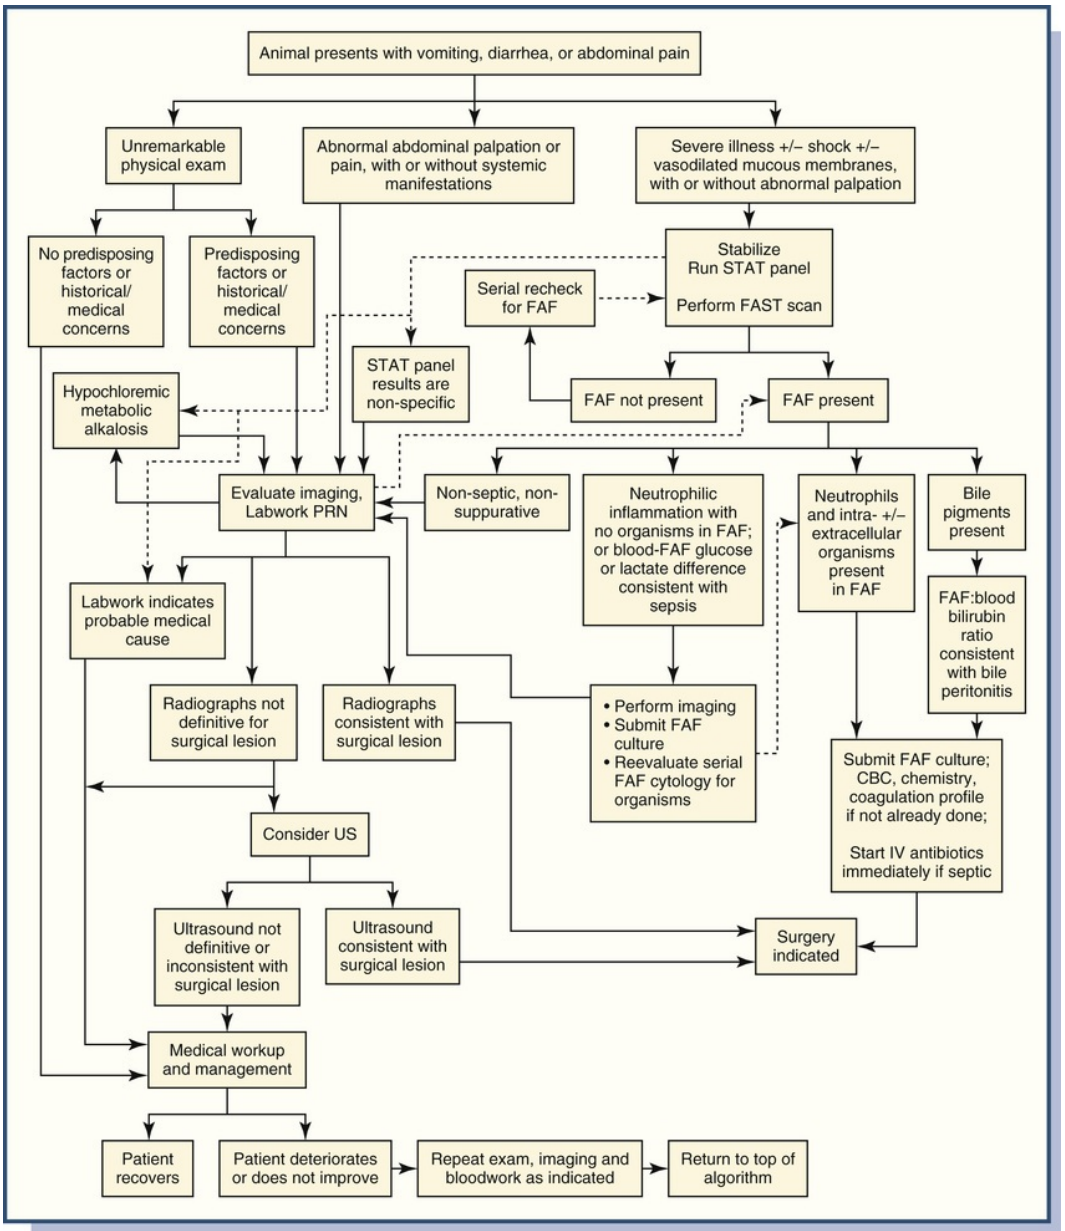

FIGURE 144-1 Algorithm for differentiating a medical from surgical case of gastrointestinal signs. Dotted lines indicate possible courses of action in certain cases. *FAF,* Free abdominal fluid; *FAST,* focused assessment with sonography in trauma, triage, and tracking; *PRN,* as needed; *STAT, statim* (Latin: "immediately"). Dotted lines indicate possible courses of action in certain cases.

E-Box 144-1

Examples of Gastrointestinal and Non-gastrointestinal Causes of Vomiting, Diarrhea, or Abdominal Pain

Gastrointestinal Causes

Infection
- Bacterial (e.g., *Clostridium, Salmonella*)
- Viral (e.g., canine parvovirus, feline panleukopenia virus, canine distemper virus)
- Parasitic (hookworms, roundworms, whipworms)
- Protozoal *(Giardia, Entamoeba, Tritrichomonas)*

Inflammation—inflammatory bowel disease, hemorrhagic gastroenteritis, GI ulceration

Neoplasia—lymphoma, adenocarcinoma, leiomyoma
Obstruction—intussusception, foreign body, GDV, stricture, pyloric hypertrophy
Dietary indiscretion
Functional ileus

Non-gastrointestinal Causes

Cardiovascular/GI hypoxia—Shock of any etiology (especially in the dog), pericardial effusion, GDV, mesenteric torsion, intestinal volvulus, GI thrombosis
Endocrine—hypoadrenocorticism, hyperthyroidism, DKA
Acid-base/electrolyte abnormalities—hypercalcemia
Hepatobiliary—hepatitis, hepatic failure, cholangiohepatitis, cholangitis
Pancreatic—pancreatitis, pancreatic neoplasia
Genitourinary—uremia, pyometra
Nervous system—vestibular disease, increased intracranial pressure or CNS disease affecting CRTZ/emetic center
Toxin/drug reaction—many plants, chemicals, heavy metals, medications, blood products

CNS, Central nervous system; *CRTZ,* chemoreceptor trigger zone; *DKA,* diabetic ketoacidosis; *GDV,* gastric dilation-volvulus; *GI,* gastrointestinal.

Signalment

The first step in evaluating any patient is to review the patient's signalment and a thorough history. Age and breed can help with prioritizing differential diagnoses for GI emergencies. Infectious causes of GI disease are common in younger dogs and cats, as are GI foreign bodies.[1-6] Pancreatitis is more common in toy, terrier, and nonsporting dog breeds while hypoadrenocorticism is seen more commonly in Great Danes, Portuguese Water Dogs, Rottweilers, Standard Poodles, and West Highland White and Wheaten Terriers.[7-10] Certain causes of GI signs or signs of abdominal pain are gender-specific including pyometra, dystocia, uterine torsion, testicular torsion, and prostatitis. Urethral obstruction is more common in males.

History

Information regarding type of GI signs, including vomiting and character of the vomitus, character of any diarrhea, presence of hematemesis, hematochezia or melena, weight loss, and appetite should be gathered. Vomiting should be differentiated from regurgitation, which is more a characteristic of esophageal disorders (see ch. 39). The characteristics of a patient's diarrhea can help identify the segments of the GI tract that could be involved. Urgency, mucus, and frank blood are characteristic of large bowel diarrhea while watery diarrhea, digested blood, and less urgency are more a characteristic of small bowel diarrhea (see ch. 40-42 and 276). Weight loss also is more consistent with small bowel disease. Other signs, such as polyuria and polydipsia, vulvar discharge, or icterus, can point towards non-GI disease.

Onset and duration of illness, progression of clinical signs, and response to any therapy can assist in working through differential diagnoses. Recent antibiotic usage can disrupt GI flora and contribute to development of diarrhea, vomiting, and hyporexia. Duration of clinical signs does not differentiate need for medical versus surgical intervention. As an example, a patient with a foreign body can be presented after months of GI signs and weight loss, or after minimal duration of signs. Waxing and waning GI signs can suggest hypoadrenocorticism.

Vaccination history, diet, and potential exposure to toxins, foreign bodies, or infectious agents also are important. Animals ingesting raw food diets can be at risk for *Salmonella* enteritis or other enteric infections (see ch. 191 and 192).[11-13] Recent dietary indiscretion could lead to gastroenteritis, pancreatitis, or foreign body ingestion and obstruction. Infectious causes can be suggested by recent exposure to other animals such as in dog parks, wilderness, or daycare settings.

Physical Examination

Physical examination of any patient presented on emergency should include both primary and secondary surveys. The primary survey includes evaluation of the cardiovascular, respiratory, and neurologic systems and is aimed at identifying imminently life-threatening abnormalities. The secondary survey, which includes the remainder of a thorough physical examination, follows or accompanies stabilization of abnormalities

identified in the primary survey.

Animals with either surgical or nonsurgical illness can present with similar signs depending on the type, duration, and severity of the underlying disease (see ch. 143). Shock can be hypovolemic, cardiogenic, obstructive, distributive, or metabolic in origin (see ch. 127). Additionally, the GI tract is the shock organ in the dog, and GI signs are a common sequela to shock of any etiology in this species. Hypovolemic shock is common in animals with GI signs due to water losses via vomiting and diarrhea when there is a concurrent inability to either drink or retain water. Signs of compensatory shock include tachycardia, tachypnea, pink mucous membranes with normal or brisk capillary refill time (CRT), normal pulse quality, normal body temperature, normal mentation, and normal blood pressure. Signs of early decompensatory shock include tachycardia (dog or cat) or relative bradycardia (cat), pallor, prolonged CRT, a weak pulse, tachypnea, hypothermia, depressed mentation, and low-normal or low blood pressure. Late decompensatory shock, also called terminal shock, is marked by bradycardia, muddy mucous membranes, markedly prolonged (or absent) CRT, hypothermia, stupor or coma, and extremely low blood pressure, if it can even be measured. Identification of shock should prompt immediate fluid resuscitation with crystalloids +/− colloids, pressors, inotropes, and other treatments as indicated (see ch. 129 and 130). Presence of bright pink to red mucous membranes, especially in the face of shock and hypotension, should prompt careful evaluation for sepsis (Video 144-1). Although there are many other causes of bright red mucous membranes, septic peritonitis should be a top rule-out in an animal with GI signs.

A full physical examination, including careful abdominal palpation, should be performed as part of a secondary survey (see ch. 2). Notable findings can include auscultation of muffled heart sounds in patients with severe hypovolemia but also in patients with pericardial effusion, who often present with concurrent vomiting. Via palpation, it can be possible to localize the source of GI signs to a region of the abdomen or a specific organ based on location of pain or abnormal margination, size, or location of intra-abdominal structures. In cats, diffuse nonspecific abdominal pain has been identified regardless of the site of origin of sepsis.[14] Free abdominal fluid (FAF) can be noted by presence of a fluid wave (see ch. 17).

Specific physical examination findings that suggest a need for surgical intervention include palpation of foreign material within the GI tract, severe small bowel distention, severely distended or tympanic stomach, palpation of a sausage-like intussusception, and identification of a linear foreign body (FB) lodged under the tongue. Only 6% of linear FBs have been reported to be visible under the tongues of dogs.[3] In animals with GI foreign bodies, the object or its subsequent intestinal abnormalities are palpable in 60% and 76% of awake and anesthetized patients, respectively.[1]

Diagnostic Tests

Diagnostic testing might or might not be indicated, and the extent of the workup is based on history and physical examination findings. Bloodwork, survey and advanced imaging, and infectious disease testing are the most commonly performed diagnostic tests for patients presenting with GI emergencies. Abnormalities will depend on the type, duration, and severity of the underlying problem.

Initial Blood Tests

While a routine minimum database (complete blood count, serum biochemistry profile, urinalysis) cannot differentiate a surgical from nonsurgical patient, it can help direct the clinician towards primarily non-GI sources of vomiting and diarrhea, such as liver disease, kidney disease, or hypoadrenocorticism, which are usually treated nonsurgically. Degenerative left shifts, thrombocytopenia, and coagulation abnormalities typically indicate a greater severity of the underlying disease process. Additionally, for those patients ultimately identified as having a surgical lesion, laboratory results can provide prognostic information. For example, preoperative hypoalbuminemia has been associated with an increased risk of mortality or post-operative dehiscence of GI incisions in some, although not all, studies.[15-23] Baseline lactate and delta lactate concentrations (see ch. 70) have been associated with gastric necrosis and mortality in gastric dilation-volvulus (GDV).[24-26]

For unstable, extremely ill, and/or markedly dehydrated patients, cageside diagnostics rapidly deliver information that can impact therapy and outcome. A STAT panel consisting of packed cell volume and total protein, cytology of a stained blood smear, and measurements of blood glucose and venous blood gases with serum electrolyte and lactate concentrations allow assessment of hydration, oxygen carrying capacity, white cell and platelet estimates, glycemic state, electrolyte balance, and oxygen delivery (shock). Metabolic acidosis

can result from shock associated with lactate production or due to ketosis, production of uremic acids or toxins, or hyperchloremia, any of which can be associated with GI signs (see ch. 128). In animals with GI obstruction due to FBs, commonly reported blood gas abnormalities include an elevated bicarbonate (in approximately 75% of patients), hypochloremia (51%), metabolic alkalosis denoted by elevated base excess (≈45%), and hyperlactatemia. Presence of hypochloremic, hypokalemic metabolic alkalosis does not differentiate proximal from distal GI obstruction in dogs.[2]

Analysis of Free Abdominal Fluid

Any FAF should be collected via centesis for evaluation (see ch. 74 and 90). Cytologic indications for immediate surgery include presence of bacteria or bile pigment. Suppurative effusion with no overt bacteria can be seen with early proximal GI (stomach, proximal duodenum) perforation but can also be seen with other causes of peritonitis such as pancreatitis or splenic torsion. Bacterial culture is still considered the gold standard for identification of a septic abdomen; however, culture results are not rapidly available. In the absence of visible organisms on cytologic assessment of fluid, the difference between blood and FAF glucose concentrations on concurrently obtained samples can be suggestive of septic peritonitis. Using measurements obtained on a laboratory biochemical analyzer, a blood glucose concentration >20 mg/dL (>1.1 mmol/L) higher than the FAF glucose concentration was reported to be 100% sensitive and 100% specific for the diagnosis of septic peritoneal effusion in dogs and 86% sensitive and 100% specific in cats.[27] However, measuring a whole blood to FAF difference using a hand-held glucometer results in a large number of false negatives; measuring a plasma-FAF or plasma-FAF supernatant glucose difference on a hand-held glucometer is more sensitive.[28] A lactate concentration that is >2.0 mmol/L higher in FA than in whole blood was reported to be 100% sensitive and specific for a diagnosis of septic peritoneal effusion in dogs.[27]

Fecal Cytology and Infectious Disease Testing

Since intestinal parasitism is such a common cause of GI disease in dogs and cats, a basic fecal flotation is rational for most animals with GI signs. A Romanowsky-stained (e.g., Diff-Quik) cytologic smear of feces and/or of a rectal scraping sometimes can reveal organisms such as *Histoplasma* or *Giardia,* or bacteria consistent with *Clostridium* or *Campylobacter*. A normal, stained smear should show a heterogeneous bacterial population and few red and white blood cells, if any. Potential abnormalities include abundant red cells consistent with hemorrhage, abundant neutrophils consistent with inflammation or infection, macrophages consistent with potential fungal infection, and a bacterial population that lacks diversity, suggesting overgrowth, imbalance, or recent use of antimicrobials. See ch. 81 for more information about fecal examination.

Fecal polymerase chain reaction (PCR) panels for infectious organisms are available from multiple diagnostic laboratories (see ch. 207 and 271). Because some infections tend to occur in certain age groups of animals, different PCR panels may be available for young animals and adults. PCR tests are considered desirable since most are sensitive and specific. However, the tests can also identify nonviable organisms and organisms that are transiting through the GI tract rather than causing disease. As such, in some cases, a positive fecal PCR result will not differentiate true infection from colonization; therefore, PCR testing ideally should be done in animals with compatible clinical signs, rather than as a screening test. For instance, *Salmonella* testing could be indicated in patients with fever, hemorrhagic diarrhea, neutropenia, fecal neutrophils, and possibly an enlarged cecum. A positive fecal *Salmonella* PCR result subsequently should be confirmed with culture and serotyping.

Parvovirus infection should be suspected in very young or unvaccinated dogs and cats with vomiting and watery, hemorrhagic diarrhea with mucosal sloughing. Subclinical disease and peracute disease with sudden death also are possible. Canine parvovirus (CPV) and feline parvovirus (FPV, feline panleukopenia virus) can be identified using cageside antigen test kits.[29] While CPV SNAP test kits are sensitive and specific, a negative test result in a young or unvaccinated animal with compatible clinical signs does not rule out infection. Additional testing with fecal PCR or by repeating cageside ELISA after 24-48 hours should be considered; in cats, FPV antigen might only be detectable in feces for 24-48 hours after infection.[30] Rising convalescent serum titers, viral isolation, and fecal electron microscopy are additional confirmatory methods (see ch. 225).

Imaging

Imaging is a critical component of the diagnostic workup of many patients with GI emergencies. Definitive

imaging modalities must often wait until the patient is stabilized. A FAST scan (focused assessment of sonography in triage, trauma and tracking) can be a valuable point-of-care tool for identifying FAF and other major ultrasonographically visible abnormalities in the critical patient during stabilization (see ch. 143). Ultrasound has been shown to be a more sensitive tool than radiographs for detecting small volumes of FAF.[31] The FAST scan uses four standardized views to attempt to identify FAF in areas where it is most likely to accumulate and easiest to find, namely the diaphragmaticohepatic, splenorenal, cystocolic and hepatorenal views.[32] Serial FAST scans can be used to monitor for FAF that may develop after restoration of vascular volume and improvements in hydration.

Abdominal radiographs are often the first modality utilized for imaging patients with GI disease. There are many radiographic findings that indicate a need for immediate surgery. Dilation and displacement of the stomach ("double bubble") in a right lateral projection is consistent with GDV. Free air in the abdomen in the absence of recent abdominal surgery is most commonly associated with GI tract perforation, although free air can persist in the peritoneal cavity for as long as 2 weeks post-laparotomy. Radiographic signs suggestive of GI obstruction include segmental intestinal dilation and intestinal plication. In the cat, the probability of small intestinal obstruction is >70% if the ratio of the small intestinal diameter (SID) to the dorsoventral height of the cranial endplate of the second lumbar vertebra is >3.0 on a lateral projection. For the dog, a normal ratio of SID to the height of the narrowest point of the L5 vertebral body on a lateral projection is ≤1.6 and there is a >80% probability of obstruction if the ratio is >1.95.[33]

If plain radiography does not identify obstruction or foreign material in an animal with a suspected GI FB, positive or negative contrast can be used. A barium series can be useful in outlining the FB, although it may be vomited prior to reaching the obstruction or retained in the stomach or intestine due to ileus. Gastric foreign material also can be identified using pneumogastrography with either air or a carbonated beverage as the negative contrast medium.[34] Pneumocolonography can be used for distending the colon, to help differentiate it from distended small intestine.

Patients with signs of acute abdomen without significant radiographic abnormalities may need to be evaluated with other modalities such as ultrasound (see ch. 88 and 143). Ultrasound has largely superseded contrast radiography as the preferred method for evaluating patients for potential obstructions or other surgical GI emergencies and has been shown to be better than survey radiography for identifying obstruction when performed by skilled sonographers.[35-37] In one study, obstructed dogs were differentiated from nonobstructed dogs in 70% of cases based on radiographic findings, compared to 97% of cases when based on sonographic findings.[36] In another study of animals with small intestinal obstruction, obstruction was correctly ruled out by ultrasound in 74% of cases and correctly identified in 23% of cases (100% sensitive and 96% specific).[38] Ultrasonographic findings consistent with small intestinal obstruction include intestinal plication, segmental dilation, a jejunal diameter >1.5 cm, and/or identification of the actual obstruction.[36] Ultrasound has a reported sensitivity of as high as 100% for identification of FBs, which are identified by distal acoustic shadowing and surface reflection.[35,37,38]

Ultrasonography also can identify FAF, perforation, free gas, GI wall thickening, loss of GI tract layering, and enlarged lymph nodes that might not be identified with radiography.[35,37] Focal or regional hyperechoic fat, peritoneal effusion or pneumoperitoneum, fluid-filled stomach or intestines, and thickening or loss of GI wall layering are the most common ultrasound findings in dogs and cats with GI tract perforation. Additional reported findings include corrugated or undulating intestine, regional lymphadenopathy, hypomotility, pancreatic changes, presence of a mass or foreign object, gastroduodenal junction "crumpling" and gastric wall mineralization.[39,40]

Additional organ-specific changes consistent with causes of acute abdomen or abdominal pain such as gastroenteritis, pancreatitis, colitis, pyometra, pyelonephritis, splenic or liver lobe torsion, hepatopathy, biliary obstruction, vascular thrombosis, and others also can be identified via ultrasound (see ch. 143).

Management

Identification of a surgical lesion should prompt surgical intervention as soon as possible once the patient is fluid resuscitated and hemodynamically stable. Antibiotic treatment should be initiated immediately upon identification of bacteria within FAF, as early antibiotic therapy has been shown to improve outcome in humans with septic shock.[41] Medical management for vomiting and diarrhea can be as simple as withholding food and water for short periods followed by their slow reinstitution, to in-patient therapy with intensive monitoring. Etiology-specific therapies, such as antiparasitics, antimicrobials, or general supportive care,

including fluid and electrolyte therapy, antiemetics, gastric-acid reducers and nursing care should be included on a case-by-case basis. Good supportive care also should be included as part of the preoperative and postoperative surgical plan.

CHAPTER 145

Hepatic and Splenic Emergencies

Amanda K. Boag

Overview

Dogs and cats seen as emergencies with an underlying hepatic or splenic condition may have a wide variety of clinical signs. As with all emergency patients, a thorough history and physical examination is required to guide the choice of diagnostics and therapeutics. Pets with splenic or liver conditions that become life-threatening usually have hemodynamic instability (hypovolemic, distributive or cardiogenic shock) or neurological signs (coma or seizures). The latter may be seen with hepatic encephalopathy (HE), hypoglycemia or intracranial hemorrhage. Empirical stabilization should be initiated while the diagnostic evaluation is ongoing.

Diagnostic Approach

The clinical signs and historical information associated with hepatic and splenic emergencies can be vague and non-specific; however, most patients seen as emergencies will have evidence of one or more of the following: shock (collapse/weakness; see ch. 21 and 127), icterus (see ch. 53), or neurological signs (see ch. 33, 34, 35, and 259, and Figure 30-1). Historical questions should help identify pre-existing signs (e.g., polyuria and polydipsia [PU/PD], weight loss), access to toxins, and potential for infectious disease. The cardiovascular system examination may suggest the type of shock and helps to prioritize differential diagnoses. For example, the patient likely has hypovolemic shock if there is hemoperitoneum or distributive shock with hepatic abscess. Icterus, if seen, should prompt discrimination of pre-hepatic, hepatic or post-hepatic conditions (see ch. 53).

An initial diagnostic database should include a packed cell volume and total solids (PCV/TS), electrolytes, venous blood gas (see ch. 128), glucose (see ch. 61), lactate (see ch. 70), and blood smear. Clotting tests (prothrombin time and activated partial thromboplastin time) are indicated in emergencies involving the liver or spleen to help identify DIC (disseminated intravascular coagulation) or presence and severity of coagulopathies. Complete blood count (CBC), biochemistry panel, and serum thyroxine (in cats) should be assessed, with attention to indicators of liver function (albumin, blood urea nitrogen [BUN], cholesterol, bilirubin and glucose) and liver enzyme activities. Further laboratory testing may include ammonia concentrations, infectious disease screening, dynamic bile acid testing, pancreatic lipase immunoreactivity and thromboelastography.

A free fluid (FAST) ultrasound (US) scan is the "kennel-side" imaging test of choice in pets suspected of having hepatic or splenic disease (see ch. 143).[1] If free fluid is identified, abdominocentesis should be performed and the fluid analyzed (see ch. 17 and 74). Fluid may be non-clotting blood, a septic or non-septic exudate, chyle, a modified transudate or a transudate. Knowing the nature of fluid is vital for refining any differential list and in determining if surgical intervention is warranted. Evaluation of the bilirubin gradient (i.e., difference in bilirubin from the abdominal fluid as compared with a concurrent serum sample) can confirm biliary tract rupture. If no free fluid is present, US remains valuable for evaluating organ internal architecture, for identification of a mass, and to evaluate vascular flow. US can be integral for diagnosing splenic torsion or portosystemic shunts. Radiographs, while generally not as definitive as US, may aid in identifying free fluid, microhepatica, organ enlargement, or masses involving either liver or spleen. Timing of computed tomography (CT) scans for evaluation of abdominal emergencies in dogs and cats is being evaluated. Focal or diffuse hepatic or splenic abnormalities can be further defined with histologic evaluation of US-guided fine needle aspirates (FNA) or needle core biopsy (see ch. 89). Tissue may also be obtained via laparoscopy or celiotomy (see ch. 91). The sampling technique chosen is based on judging risk versus benefit in each patient, including consideration of coagulation status.[2-4]

Patient Stabilization

Early stabilization protocols of pets severely ill secondary to hepatic or splenic disease commonly include fluid therapy and, less commonly, antiarrhythmic medications for cardiovascular stabilization and/or medications to improve neurological status (see ch. 127, 129, and 141). Blood glucose should be measured as a priority and supplemented if low (see ch. 61). Fluid therapy should be tailored to individual patient needs, based on severity of signs, knowledge of any concurrent disease, initial test results and likely differential diagnoses. Lactate, an objective indicator of shock severity, can be used to help guide therapy (see ch. 70). However, lactate kinetics are altered in some dogs and cats with severe hepatic failure or distributive shock (sepsis).[5,6] Most commonly, IV isotonic crystalloid fluid boluses are used at dosages of 10-40 mL/kg administered quickly (over 15-60 minutes) to improve cardiac output and tissue perfusion. Colloid fluids, hypertonic saline, HBOCs (hemoglobin-based oxygen carriers) and blood products may also be indicated (see ch. 129 and 130). Administration of packed red blood cells may be vital for ensuring adequate oxygen delivery in patients with significant blood loss. Fresh frozen plasma may be useful for pets with a concurrent coagulopathy associated with either acute hepatic failure or DIC (see ch. 197). Electrolyte and acid-base parameters should be assessed and fluid therapy, supplemented as indicated, used in correcting abnormalities. Clotting tests should identify bleeding tendencies that rarely lead to intra-cranial bleeding and neurological signs. Use of fresh frozen plasma (initial recommended dose 20 mL/kg over 4-6 hours) may be beneficial.

The optimal fluid strategy for resuscitating patients in hemorrhagic shock is not well defined, with few studies critically evaluating timing or volume of fluid therapy for patients who are actively bleeding (see ch. 135).[7] Early aggressive fluid resuscitation using "full" shock doses (up to 60-90 mL/kg of isotonic crystalloid or 20 mL/kg of colloid in the dog) is no longer recommended, as it may lead to dilution of clotting factors, increased bleeding, and deleterious effects on cellular metabolism. Current recommendations are to administer fluids in a controlled manner to meet defined end-points, such as a systolic blood pressure of 80-90 mm Hg (see ch. 99).[8] Meta-analyses of studies on people do not suggest any benefit in using colloid over crystalloid fluids.[9] Caution is recommended regarding use of starches due to their potential relationship to acute kidney injury.[10]

Use of hypertonic saline may have beneficial immunomodulatory effects. Evidence in small animals is limited, but results from one study indicated that resuscitation end-points are reached more rapidly when limited-volume fluid resuscitation is used.[11] A small percentage of patients with splenic disease have severe arrhythmias that may lead to cardiogenic shock, identified by an irregular heart rhythm and pulse deficits on the physical examination (see ch. 2, 140, and 141). Such findings should be confirmed by an ECG and appropriate medication given (see ch. 103 and 248).

Patients with severe liver disease may be suffering from HE, whose management should begin with IV fluid therapy and multiple enemas to clear as much stool (and ammonia) from the colon as possible before using oral or rectal lactulose and antibiotics to further reduce the number of ammonia producing bacteria (see ch. 281 and 284).[12] Both hypokalemia and alkalosis can worsen signs of HE. In patients that are actively seizuring, propofol or levetiracetam is recommended (see ch. 136).[13] Although diazepam would be considered routine for most patients with seizures, its use in patients with HE is controversial.[14]

Specific Conditions

Hemoperitoneum

Hemoperitoneum, not always associated with trauma, is a common hepatic/splenic emergency. Depending on severity, patients who bleed into their abdomen can have mild signs of episodic weakness to severe signs of unconsciousness and shock. Pets seen for collapse without a history of trauma may previously have had one or more episodes of weakness, presumably due to less severe bleeding episodes. Dogs in hypovolemic shock have pallor, tachycardia, and changes in pulse quality. They may or may not have abdominal distention but are expected to have reductions in PCV and TS and a metabolic (lactic) acidosis. Hematology and clotting tests may be consistent with DIC. FAST scans demonstrate free fluid, typically non-clotting blood with a PCV similar to that of peripheral blood. Use of abdominal compression bandages may help with stabilization. Cats with hemoperitoneum may have signs of lethargy, anorexia and vomiting.[15]

If one or more cavitated masses is/are visualized with more detailed abdominal US scanning, the most likely diagnosis is hemangiosarcoma although other malignant and benign masses occur (see ch. 206 and

347).[16-18] Surgery is indicated once the patient is stable in the majority of non-traumatic cases and perioperative survival rates are good. Risk factors for death include need for massive transfusions, non-splenic sources of bleeding and development of respiratory signs.[19] Metastasis may be present and thoracic imaging (radiography or CT) is recommended prior to surgery. Risk factors for malignancy are reported to include lower TS and platelet counts and relatively small masses.[16,20] Echocardiography (see ch. 104) to identify right atrial hemangiosarcoma may be performed, although the relationship between right atrial and abdominal hemangiosarcomas is not clear.[21] Pets with traumatic hemoperitoneum often stabilize following fluid therapy, abdominal compression, and/or transfusion therapy. If they remain unstable, surgery should be considered.[22]

Acute Hepatic Failure

Dogs and cats with acute hepatic failure are often seen for collapse, neurological signs (obtundation or seizures) and/or GI signs (see ch. 280). Alternatively, some have acute progression of clinical signs following chronic liver disease. These latter pets are more likely to have a chronic history of weight loss, inappetence, PU/PD, and they may have ascites (secondary to portal hypertension and/or hypoalbuminemia; see ch. 17). Most of these pets are icteric on physical examination (see ch. 2 and 53). Pets with hereditary porto-systemic shunts are not usually jaundiced, but have signs of hepatic dysfunction (particularly HE; see ch. 284). Causes of acute hepatic failure include viral, bacterial and other infectious agents (see ch. 282 and 283), toxicoses (drugs, anesthetic agents, chemicals or biotoxins; see ch. 286), neoplasia (see ch. 287), and metabolic disease (hepatic lipidosis in cats or copper storage disease in dogs, for example; see ch. 285).[12] Sampling of the hepatic parenchyma may be necessary for a definitive diagnosis but is not without risk due to coagulopathies. Prognosis is variable.

Extrahepatic Biliary Disease

Extrahepatic biliary disease includes biliary obstruction (secondary to pancreatitis or less commonly intraluminal obstruction) and biliary rupture (secondary to trauma, cholecystitis or gallbladder infarction; see ch. 53 and 288). Pets with traumatic biliary rupture usually develop signs progressively over a period of 5-7 days and have signs of peritonitis (see ch. 279). Diagnosis is made following the approach previously discussed, with emphasis on imaging and abdominal fluid analysis. Most of these pets benefit from surgery to identify and repair traumatized tissue. Survival rates are reported to be around 70% when a population of dogs with a variety of causes were included, but only 50% when dogs with bile peritonitis were evaluated. Septic bile peritonitis in dogs and cats carries a particularly poor prognosis.[23-26] Some extrahepatic biliary obstructions, such as with pancreatitis, are not usually treated surgically (see ch. 143).

Splenic and Liver Lobe Torsion

Dogs with splenic torsion have signs of acute progressive abdominal disease (see ch. 143 and 206). They may also have ventricular arrhythmias when first examined or during treatment. Large breed, deep chested dogs appear to be at increased risk. Other risk factors are possible.[27] After torsion, the spleen becomes quite prominent on physical examination and radiographs. Abdominal US findings of a hypoechoic pattern within the splenic parenchyma together with decreased venous blood flow is strong support for splenic torsion. Once the patient is stabilized, surgery is indicated to remove the spleen and to perform a gastropexy, if indicated, to reduce risk of subsequent gastric volvulus. Prognosis is good when appropriate resuscitation and management are combined with prompt diagnosis and surgery.

Liver lobe torsion occurs rarely in dogs and cats.[28] Clinical signs and laboratory data are non-specific. A distended abdomen or a palpable abdominal mass can sometimes be detected on physical examination. The diagnosis is confirmed at exploratory laparotomy. The affected liver lobe is resected either manually or with stapling equipment and submitted for histopathologic evaluation.

Hepatic and Splenic Abscesses

Hepatic and splenic abscesses are uncommon (see ch. 143). Clinical signs are typically non-specific.[29,30] On physical examination, patients are often febrile, and exhibit signs of pain and hepato- or splenomegaly on abdominal palpation. Blood test results often reveal leukocytosis, thrombocytopenia, hypoalbuminemia, and

increased liver enzyme activities. Radiography is often unrewarding. The diagnosis is often suspected on abdominal US and confirmed via fine needle aspiration and cytology of the abnormal area or of any abdominal fluid (see ch. 74, 89, and 93). Aerobic and anaerobic culture and sensitivity testing should be performed. The etiology of hepatic and splenic abscesses is debated and probably multifactorial. Hematogenous bacterial spread is one potential cause and possible reservoirs of bacterial infection such as the respiratory system, urinary tract and heart valves should be investigated; radiographic evidence of alveolar infiltrates consistent with pneumonia were found in nearly half the patients.[29] Treatment involves surgical resection of the abscessed liver lobe(s) or splenectomy, long-term antibiotic administration, and periodic US evaluations. US-assisted drainage and alcohol ablation of hepatic abscesses was employed successfully in five dogs and one cat.[31]

Splenic Infarction

Splenic infarction has been rarely diagnosed in dogs. This condition is often associated with altered blood flow and/or coagulopathies, secondary to other diseases. Identification and treatment of the underlying disease(s) is vital for a successful outcome.[32] Splenectomy may be performed but is reserved for those patients with life-threatening complications such as hemoabdomen or sepsis.

CHAPTER 146

Reproductive Emergencies

Luis Miguel Fonte Montenegro, Ana Martins-Bessa

Reproductive Emergencies in Females

Pyometra

Pathophysiology

Pyometra is a severe uterine infection in female dogs and cats currently or recently under the influence of progesterone, i.e., dogs and cats most commonly develop this condition during diestrus.[1,2] Progesterone places female dogs and cats at risk for excessive intrauterine secretions, bacterial growth, inflammation and overwhelming infection. This process, in turn, causes accumulation of purulent exudate within the uterine lumen. About 80% of dogs and cats with pyometra have *Escherichia coli* isolated from uterine content. Most *E. coli* isolates and sensitivity patterns from uterine content are identical to isolates found in urine or blood.[3] Release of bacterial endotoxins, alone, could explain the severe illness, dehydration, and decompensated septic shock that may precede death in dogs with untreated pyometra[3,4] (see ch. 316 for a full discussion).

Clinical Signs and Diagnosis

The severity of clinical signs is related to bacterial endotoxins, on whether the cervix is "open" sufficiently to allow drainage of the purulent uterine content ("open-cervix pyometra"), and how quickly an owner seeks veterinary care after seeing a vaginal discharge or realizing the pet is ill.[4-7] Pets with closed-cervix pyometra do not have the purulent vaginal discharge to alert owners of a problem. Retention of purulent uterine content (an internal abscess) explains the generally more severe clinical signs in pets with closed-cervix pyometra. They may require rapid intervention to prevent overwhelming septic shock and death (see ch. 132).[3,4]

Clinical signs of pyometra include anorexia, lethargy, obtundation, vomiting, polyuria and polydipsia with or without vaginal discharge. Most pets are seen 4-8 weeks after their most recent estrus. Dogs and cats may be brought to the veterinarian on an emergency basis simply because the owner notices a vaginal discharge. A minority of dogs with open cervix pyometra and most with closed cervix pyometra will be seen on emergency basis due to signs of systemic illness. Diagnosis is based on observation of a purulent vaginal discharge (Figure 146-1), palpation of an enlarged uterus, and/or visualization of an enlarged and fluid-filled uterus with imaging (Figure 146-2) in a female who was recently in estrus.[5,8] It is important to be certain the female is not in early-to-mid pregnancy with concurrent vaginitis. This distinction is best accomplished with abdominal ultrasonography (see ch. 88). Review of the complete blood count (CBC), serum biochemical profile and urinalysis can be extremely important for identification of abnormalities associated with pyometra that need attention: renal parameters, serum electrolyte concentrations, acid-base status, blood glucose, or any other issue that may require attention in a critically ill animal (see ch. 316).

FIGURE 146-1 Purulent vaginal discharge can be seen on the hair below the vulva of a bitch with pyometra.

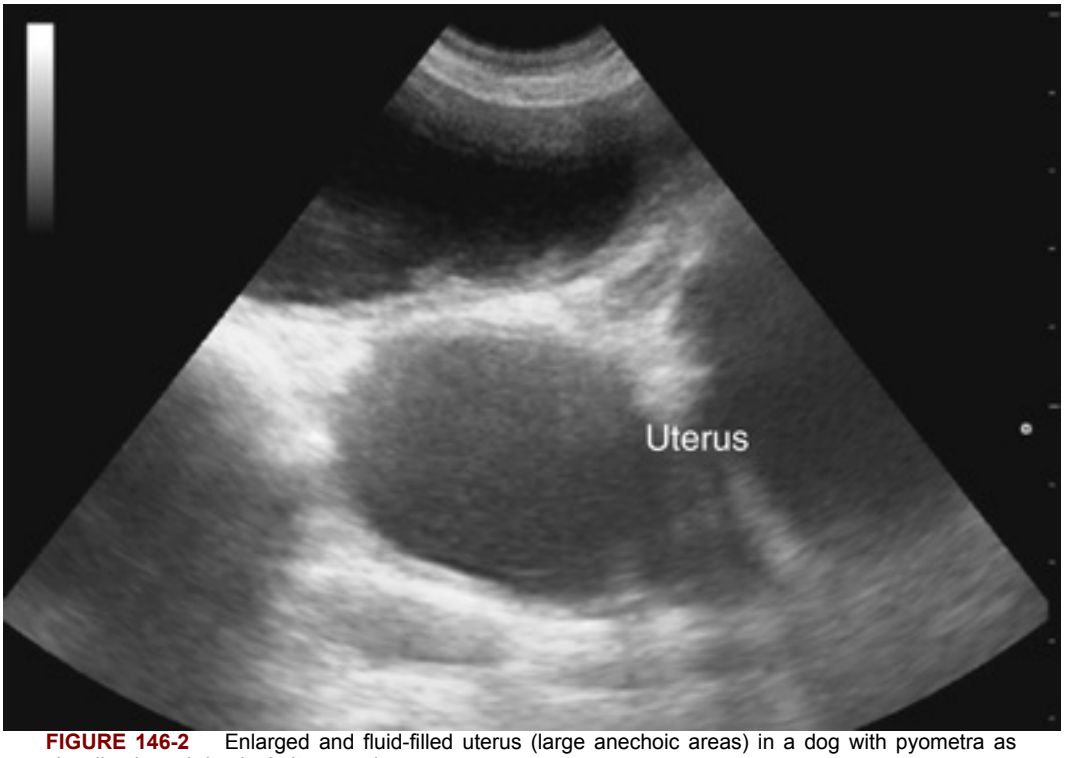

FIGURE 146-2 Enlarged and fluid-filled uterus (large anechoic areas) in a dog with pyometra as visualized on abdominal ultrasound.

Management

Overview

Ovariohysterectomy is considered the only treatment option for seriously ill dogs and cats with pyometra.[4,9] Medical management of pyometra is contraindicated in systemically ill pets[2] (see ch. 316). Surgical removal of the infected uterus results in rapid elimination of bacteria, their endotoxins, and prevents recurrence.[6,10]

Anesthesia and Surgery (Figure 146-3 and Video 146-1)

Anesthesia should be delayed until treatment for hypotension, shock, dehydration, and other serious concerns have been initiated (see ch. 127, 129, 132, and 159). Determining the safest time to begin anesthesia and then surgery may not be obvious. Dire consequences can follow if anesthesia begins before the patient is stable or if one waits too long. Epidural anesthesia is recommended because less general anesthesia will be required for an extremely ill animal. Combining 0.5% ropivacaine with 0.1 mg/kg of morphine is recommended.[11] Ropivacaine is dosed accurately using the formula of 0.1 mL/cm of occipito-coccygeal length (back of the head to the base of the tail).[11,12] Pre-oxygenation is often beneficial. Depending on estimated severity of obtundation, one may consider using fentanyl (3-5 mcg/kg q 20 min) and acepromazine (0.01-0.02 mg/kg) for pre-medication. If the patient is severely depressed, propofol can be used for induction without pre-medication. Anesthesia is typically maintained with isoflurane or sevoflurane, depending on patient stability.[12,13]

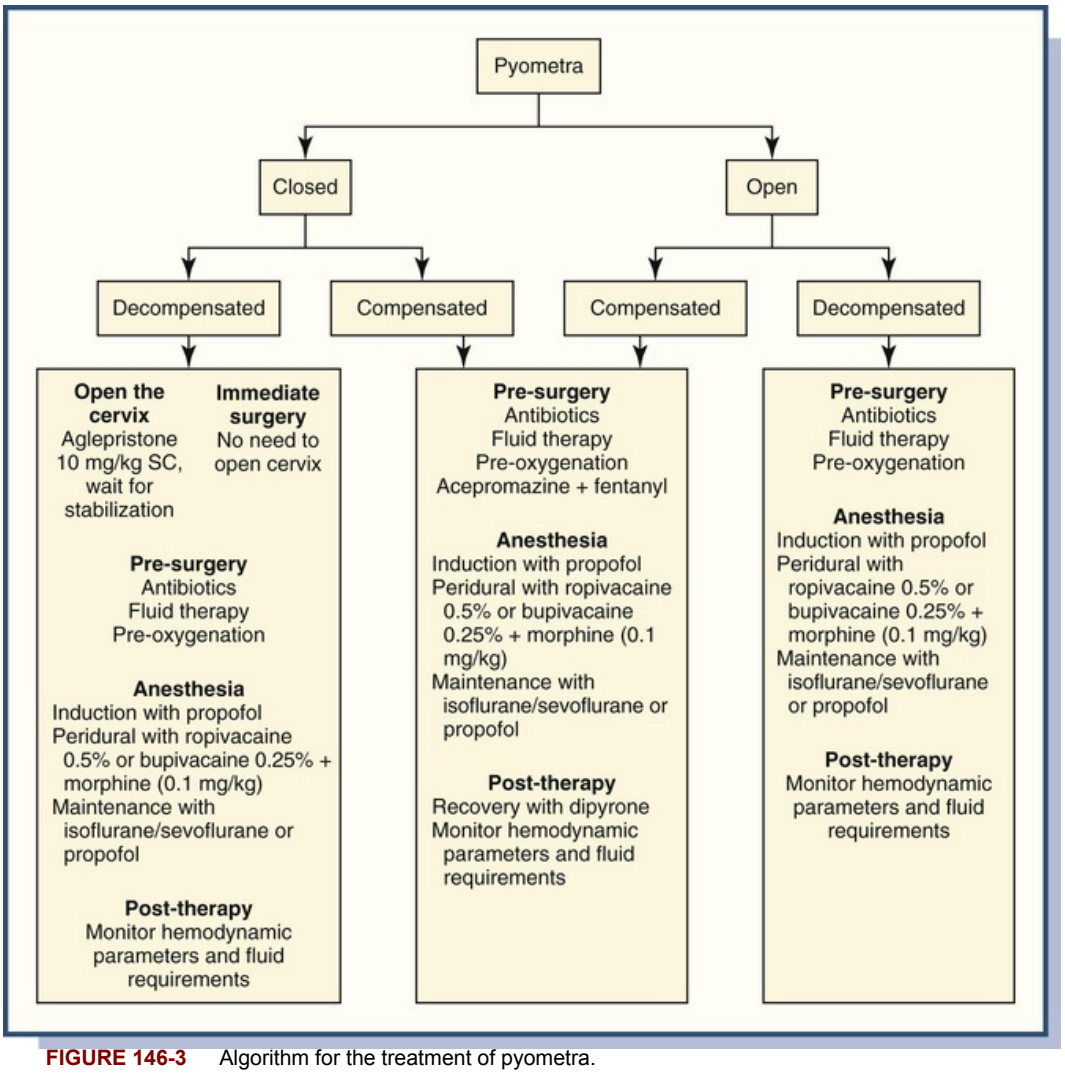

FIGURE 146-3 Algorithm for the treatment of pyometra.

Medical Management

Alterations due to toxemia should be treated as soon as recognized, never forgetting that the infected uterus

must be removed as soon as possible.[5,9,14] White blood cell (WBC) counts can be quite increased in pets with pyometra, but this is an unreliable test that does not necessarily correlate with severity of illness. Normocytic, normochromic, nonregenerative anemia is seen occasionally.[2,5,9] Pets with pyometra may be severely azotemic, uremic, acidotic, and hyper- or hypocalcemic. Serum sodium and potassium concentrations are unpredictable but abnormalities should be addressed. Hypoglycemia, the result of anorexia, vomiting, diarrhea, bacteremia, toxemia, and/or leukocytosis, should be corrected (see ch. 61). However, some pets with pyometra are hyperglycemic. Increases in serum hepatic enzyme activities are common. All these issues underscore the need to identify and treat the many unpredictable problems seen in pets with pyometra.[8] Broad-spectrum antibiotics should be given, IV, prior to surgery. Recommended antibiotics include trimethoprim-sulfonamides, ampicillin, amoxicillin/clavulanic-acid, cephalosporins, enrofloxacin, marbofloxacin and metronidazole.[15,16]

Dystocia

Practical Descriptions

Dystocia is defined as the inability to deliver a fetus through the birth canal[17,18] (Table 146-1).

TABLE 146-1

Causes of Maternal and Fetal Dystocia

MATERNAL ORIGIN	DIAGNOSIS	TREATMENT
Primary uterine inertia	Absent or weak and unproductive contractions	Oxytocin and calcium, usually ineffective. C-section recommended
Narrow birth canal	Radiograph	C-section
Uterine torsion	Ultrasound: not easy to diagnose	C-section
Secondary uterine inertia	Absent or weak and unproductive contractions	Oxytocin and calcium. If after three trials there is no success, C-section recommended
FETAL ORIGIN	**DIAGNOSIS**	**TREATMENT**
Increased fetal size	Radiograph	C-section
Fetal death	Ultrasound	Surgery
Abnormal presentation Abnormal posture	Radiograph	Obstetric manipulation or C-section

C-section, Cesarean section.

The Uterus

Uterine causes of dystocia include uterine weakness or insufficient uterine force to propel the *conceptus* through the birth canal.[19-21] This is the form of dystocia most likely to respond to medical management with oxytocin.

The Pelvis

If the birth canal is too small to allow passage of the *conceptus*, dystocia results. Such a constriction may be a congenitally small pelvic canal size or an acquired defect, such as the sequela to a pelvic fracture. Dystocia may also occur with various breeds that have relatively large heads and shoulders but a small pelvis (Bulldogs, Boston Terriers, etc.). These forms of dystocia require surgical intervention.[21,22]

The Fetus

Occasionally the fetus is too large for the birth canal. The most common explanation for fetal oversize is a single fetus, potentially resulting in a fetus that is too large for the pelvic canal[19,20,23] (see ch. 315). Abnormal

fetal presentation to the pelvic canal causes "relative" oversize. These problems usually require surgical intervention.

Vaginal Vault

A bitch may be examined and found to have a neonate in the vaginal vault. This may be caused by fetal oversize or an undersized pelvis. The vaginal vault itself may be too small, as occurs with a vaginal stricture (see ch. 319). The vaginal band of tissue obstructs fetal passage. This form of dystocia resolves if the stricture can be broken down or incised. Alternatively, cesarean section may be necessary. Vaginal strictures may interfere with natural breeding but may not prevent artificial insemination.

Criteria for Suspecting Dystocia

Diagnosis of dystocia is usually based on owner observation. Those observations also represent the reasons for emergency presentation. Dystocia is considered likely and immediate veterinary consultation or examination is recommended whenever an owner reports one or more of the following in a pregnant dog: (1) 20 to 30 minutes of strong abdominal contractions without successful delivery; (2) after delivering one or more neonates, more than 4 to 6 hours pass without another delivery in a female known or suspected of having additional fetuses; (3) a bitch fails to deliver pups 24 to 36 hours after the rectal temperature was noted to decrease below 99-100° F (≈37° C); (4) a bitch cries and licks or bites at the vulvar area during whelping; (5) a bitch fails to progress to stage II labor after 8 to 12 hours of apparent stage I labor; or (6) a bitch has prolonged gestation, lasting beyond a well-established due date, beyond 70 to 72 days from the first breeding, or beyond 59 days from the first day of diestrus[24] (see ch. 312 and 315).

It is extremely important to remember that "false pregnancy" has been noted to include signs of parturition and a concern of dystocia in a few dogs. It is also possible for an owner to believe that fetuses are present *in utero* when, in reality, an entire litter has been successfully delivered. Thus, one must confirm pregnancy before considering intervention.

History

Ideally, the first step in any emergency is to obtain a thorough history from the care giver (see ch. 1). However, examination of the vaginal area should take precedence to determine whether a fetus is present within the vaginal canal. If no fetus is detected, knowing the patient's age, reproductive history, and previous or current medical conditions may be pivotal. Age, for example, is important because the 2-year-old bitch is less prone to primary uterine inertia than is a 6- or 7-year-old. Heart problems, regardless of age, may worsen during labor. In most cases of suspected dystocia, there is time for obtaining a thorough history, leaving questions regarding this current pregnancy to the end. At that time, one should ascertain if there is an "expected date of whelping" and how this was determined. For example, whelping dates can be rather precisely determined from vaginal cytology, vaginoscopy, or serial serum progesterone concentrations prior to and following breeding (see ch. 312 and 315). Has pregnancy been confirmed? Are the fetuses alive? If yes, when and how was this determined?

Physical Examination

If no fetus is visible or palpated in the vaginal canal, a quick but thorough physical examination should be completed to be certain that contributing problems (e.g., cardiac arrhythmias, dehydration, fever) are not missed (see ch. 2). Sometimes, a concurrent problem is of greater concern. Occasionally, correction of an underlying problem such as hypoglycemia or hypocalcemia simultaneously treats the dystocia. If a bitch is nervous or trembling, the veterinarian must differentiate anxiety, pain, and hypocalcemia (see ch. 298).

The reproductive examination should include careful abdominal palpation, as well as digital examination and assessment of the vaginal vault. If no fetuses are identified *in utero* or in the vaginal vault, the bitch may have completed whelping or she could be in exaggerated clinical pseudopregnancy. The vaginal vault can also be assessed for the presence of strictures, bands, or other defects. One can attempt to determine the presence and strength of uterine contractions by gently stroking the dorsal vaginal wall (Ferguson reflex). Ideally, direct uterine monitoring is used. While less ideal, one can periodically assess the litter via traditional abdominal ultrasonography. One may benefit from knowing the number of fetuses, and their size, position and posture. Pelvic canal anatomy, depth, and width can be estimated with abdominal radiographs. Assessment of fetal viability is critically important and can best be accomplished with a fetal monitor. Fetal heart rates less than 180 bpm, in two measurements less than 10 minutes apart, are evidence of fetal distress potentially due to hypoxia, and this is an indicator for urgent intervention.[20] Fetal heart rate below 130 bpm

are associated with poor survival rate and quick delivery is imperative (Figure 146-4).[17,20]

FIGURE 146-4 Fetal heart rate (196 bpm) as seen with a monitor in a pregnant bitch.

The finding of significant amounts of fresh blood in the vaginal vault can be confusing. The presence of blood may be caused by normal events during whelping, but can also be caused by separation of placental sites, a condition that may be best managed with cesarean section. Other causes of hemorrhage (bleeding disorders, trauma to the vaginal lining, etc.) must always be considered.

Fetus Palpated in the Vaginal Vault

If a fetus is palpated in the vaginal vault, its physical position and viability must be assessed. Digital manipulation and delivery should be attempted. First, one may try to deposit lubricant, using a soft urinary catheter, cranial to the fetus. Then, an attempt can be made at delivery via gentle traction using the limbs, head or mandible of the fetus. Traction is in a caudoventral arc while rotating the fetus's shoulders or pelvis through a dorsoventral plane to help passage through the pelvis.

Uterine and Fetal Monitors

The use of uterine and fetal monitors allows veterinarians to detect the onset of labor and to manage labor with greater accuracy. Such systems for monitoring labor and delivery in the bitch are available.[25-27] The uterine monitoring system consists of a tocodynamometer (sensor) that detects changes in intrauterine and intra-amniotic pressures. The sensor is maintained over the caudolateral abdomen with an elasticized strap. Fetal Doppler cardiac monitoring is performed with a hand-held unit on bitches in lateral recumbency. Directing the Doppler perpendicularly over a fetus causes amplification of fetal heart sounds, distinct from maternal arterial or cardiac sounds.

The canine uterus exhibits characteristic patterns of activity during late gestation and labor, varying in strength and frequency. Owners using such systems may note a concern resulting in their bringing the bitch into the hospital. Such systems are valuable in a hospital (see ch. 315). The two drugs most commonly recommended to treat uterine inertia are calcium and oxytocin. Administration of calcium gluconate increases strength of myometrial contractions. Administration of oxytocin increases the frequency, strength and

duration of contractions. Calcium is recommended when ineffective and weak uterine contractions are detected. Oxytocin is recommended when uterine contractions are less frequent or weaker than expected for the stage of labor and when fetal heart rates are normal. Uterine hyperstimulation with elevated baseline levels of contractility compromising placental blood supply or a uterine obstructive pattern negate use of calcium or oxytocin. Fetal distress is reflected by sustained deceleration of heart rates. Transient accelerations are noted with fetal movement. If fetal stress is evident and response to medication is poor, surgical intervention (cesarean section) may be indicated.

Laboratory Assessments

Timing of veterinary intervention in dystocia patients is important. Premature intervention causes stress, may delay onset of normal parturition, and could place both mother and fetuses at risk.[18,21] Whenever there is uncertainty about gestation length or whether parturition has begun, the serum progesterone (P_4) concentration should be determined. A P_4 concentration below 1-2 ng/mL is required for parturition. A result >2 ng/mL indicates that labor (contractions) have not likely begun.[28] To avoid premature uterine stimulation of parturition or cesarean section, the serum progesterone concentration should be <1 ng/mL. All pets with known dystocia should have blood obtained for a CBC and complete serum biochemical profile. Some results may specifically explain uterine inertia, e.g., decreases in serum calcium, potassium or glucose concentration. Hematocrit decreases progressively throughout gestation due to increases in plasma volume. Values as low as 30% are considered "normal" in the bitch and results as low as 20-25% are "normal" in queens. Results that are significantly lower should be investigated.

Imaging

One of the most valuable tests that a veterinarian can perform on a pet with possible dystocia is abdominal imaging (see Table 146-1). Radiographs can identify or refute the presence of pregnancy. Radiographs are also excellent for locating fetuses and for identifying a malpositioned fetus that is unlikely to be delivered vaginally. Ultrasonography is superb for assessing fetal viability (see ch. 88 and 143). The first condition established by the radiographs is the presence or absence of pregnancy. The non-pregnant bitch either has completed whelping or is pseudopregnant. If pregnancy is confirmed, the veterinarian must ask the following: Are the fetuses viable? How many are present? Where are they? Abdominal auscultation may answer the question of fetal viability if heart beats are heard, but not if heart beats cannot be auscultated. Fetal death is likely if the veterinarian finds on radiographs (1) evidence of collapse of the spinal column, (2) intrafetal gas patterns, (3) overlapping or misalignment of the bones that make up the skull, or (4) fetal positioning not compatible with life. Ultrasonography definitively identifies contracting fetal hearts and is therefore a means of assessing viability if specific fetal monitors are not available. If medical management is being considered without a fetal monitor, ultrasonography should be frequently repeated.

Medical Therapy

Medical treatment should be considered only if there is no evidence of an obstruction.[18,21,29] Parenteral oxytocin, with or without calcium, is commonly employed. Recommended dosages of oxytocin include 0.25-2 IU/dog IM or IV.[22,30] Such dosages increase both strength and duration of uterine contractions.[21,30] Higher dosages are not beneficial and can be detrimental by causing uncoordinated uterine contractions. Doses of oxytocin IM or IV may be repeated two or three times at 30-minute intervals or after each successful birth.

Some bitches who do not respond initially to oxytocin may respond if 10% calcium gluconate is given slowly IV (1 mL/min at 20-40 mg/kg) before or concurrent with any subsequent dose of oxytocin, even if serum calcium concentrations are within reference limits. Calcium solutions should be administered either undiluted or diluted with isotonic fluids. Calcium chloride should not be used. Continuous electrocardiographic monitoring is recommended and calcium discontinued if bradycardia or arrhythmias are detected (see ch. 298). If no fetus is delivered after three doses of oxytocin (± calcium and/or glucose), cesarean section is recommended.

If labor begins and a fetus is delivered after oxytocin, one should wait approximately 30-45 minutes to determine if another dose is indicated for a subsequent neonate. Sometimes a single dose of oxytocin may be sufficient to start parturition, which continues without the need for additional doses. Sometimes one fetus is delivered after each dose. Each additional dose of oxytocin may elicit a weaker response. It is imperative to know, prior to beginning oxytocin, whether or not the mother is pregnant and, if so, the number of fetuses yet to be delivered. Supportive treatment with IV isotonic fluids should be given to maintain or restore

hydration. Dextrose can be administered as a 2.5-5% solution if hypoglycemia is confirmed or suspected. If the female is clinically hypoglycemic, a 0.25 g/kg body weight (BW) bolus can be given.[30]

Anesthesia and Cesarean Section (*Figure 146-5*; Video 146-2)

Epidural anesthesia is recommended for C-section, whenever possible. The aim is to avoid using drugs that can cross the placental-blood barrier and depress or otherwise harm the neonates. After pre-oxygenation, the patient is induced with propofol, allowing the peridural technique to be performed.[31] Lidocaine 2% is recommended as it promotes quick recovery of both proprioception and sensation. This protocol does not interfere with the normal maternal instincts of the bitch towards her new puppies. The dosage of lidocaine is 0.1 mL for each centimeter of occipito-coccygeal length.[12] Anesthesia should be maintained with oxygen and propofol. After all neonates have been delivered, anesthesia can be maintained with isoflurane.[32] C-section anesthesia, surgery and neonatal resuscitation are demonstrated in Video 146-2.

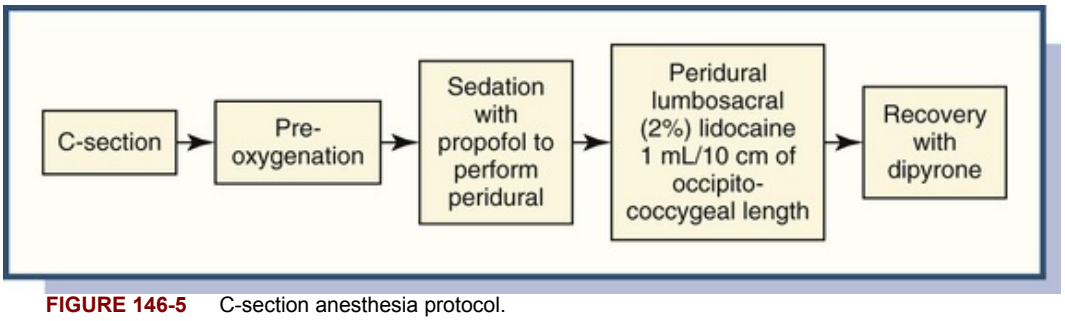

FIGURE 146-5 C-section anesthesia protocol.

Uterine Torsion and Uterine Rupture

Both conditions obstruct the birth canal and are life-threatening conditions. Either can occur late in pregnancy, at the time of parturition, or with pyometra.[23] Some dogs may be suspected of having dystocia. Uterine rupture is a potential side-effect of administering ecbolic drugs such as PGF_2alpha to a patient with closed-cervix pyometra or during labor. Such drugs are dangerous if high doses are used or if the patient is obstructed. In addition to signs typical of dystocia, clinical signs may include abdominal pain, shock, hypothermia, hemorrhagic vaginal discharge, vomiting, and restlessness (see ch. 143). Ultrasonography could show presence of a fluid-filled uterus, fetal stress or death and peritoneal effusion.[20] Exploratory surgery is usually required for definitive diagnosis and treatment.[20] Taking into account the gravity of both situations, quick diagnosis and treatment are essential for survival.[23]

Vaginal Hyperplasia/Vaginal Prolapse

Background and Clinical Features

The vaginal wall of healthy bitches thickens in response to estrogen during proestrus and estrus. An exaggerated response to normal estrogen stimulation may result in a condition frequently called vaginal hyperplasia or vaginal hypertrophy. Such prolapsed vaginal membranes are histologically described as markedly edematous tissue. Protrusion of edematous vaginal tissue through the opening of the vulva will prompt owners to seek veterinary care. Some of these dogs develop urinary obstruction and may be brought to the veterinarian with owner concerns of difficulty or straining to urinate. Vaginal hyperplasia/prolapse is usually seen in younger (<2 to 3 years of age) large-breed bitches in proestrus or estrus. Uncommonly, this condition has been seen in smaller and older dogs. Other owner concerns may include inability or unwillingness to breed or that the male appears unable to penetrate the bitch. Most bitches with vaginal prolapse persistently lick the tissue, but only a small percentage of these have stranguria.

Diagnosis

The diagnosis is straightforward because of the obvious mass protruding from the vulva or a bulging perineum in a young bitch in proestrus or estrus (Figure 146-6). One differential diagnosis for the mass is

clitoral enlargement, usually due to presence of a bone within the clitoris that is a palpably hard, thin, and tubular structure. Benign polyp or a tumor are additional causes for a protruding mass. Polyps are usually small and have a narrow pedicle or base. Tumors are typically irregular in shape, occur in older females, and are not associated with the proestrus or estrus phases of the ovarian cycle. The exception to this rule is transmissible venereal tumor, which most often is identified in bitches that are young and sexually active (see ch. 351).

FIGURE 146-6 Mass protruding from the vulva of a dog with "vaginal hyperplasia."

Vaginal prolapsed tissue is usually relatively large and soft, often reducible. The tissue is in the form of a smooth, rounded mass with folds rising in a wide base from the floor of the vaginal vault. The tissue usually arises cranial to the urethral opening. Less commonly, the vaginal prolapse is more severe and may include the entire circumference of the vaginal wall, in which case the tissue takes on the appearance of a large doughnut (Figure 146-6).

Treatment

Management of vaginal hyperplasia can be difficult. If the bitch can urinate despite the presence of the mass and no necrosis is present, hyperplasia is much less of an emergency. If urination is not possible, an indwelling urethral catheter (see ch. 105 and 106) needs to be placed following identification of the urethral papilla (note the foley catheter in the dog with vaginal hyperplasia in Figure 146-6). Virtually all vaginal prolapses shrink and disappear during diestrus, given enough time. Therefore, initial efforts are directed at keeping the tissue (1) clean with saline washes, (2) lubricated with appropriate jellies, and (3) non-traumatized. One can prevent trauma to exposed vaginal tissue by keeping the bitch indoors on smooth and padded surfaces and by placing an Elizabethan collar around the neck of the bitch to prevent her from causing any self-mutilation. Necrotic tissue requires surgical debridement. Some eversions can be surgically reduced. Decisions regarding ovariohysterectomy should not be made on an emergency basis.

Surgical extirpation of the excess vaginal tissue should be considered only if the vaginal prolapse is associated with an inability to urinate, if it is large and likely to become infected, or if it has recurred in more than one cycle. Surgery can be associated with a great deal of blood loss, can be complicated, and is recommended only if the vaginal tissue is extremely necrotic, if the bitch is unable to urinate, or if compromise of the vascular supply to that tissue, the uterus, or the bladder is suspected.

Hypocalcemia (Eclampsia)

Hypocalcemia is an acute, life-threatening condition that occurs most commonly in small to medium-sized bitches nursing large litters during the first 3 weeks of lactation (see ch. 315).[8,33,34] Eclampsia less often affects queens nursing large litters before weaning and, occasionally, bitches during late gestation. Clinical signs of eclampsia include nervousness, acting anxious, rubbing the muzzle with the paws or the floor, biting at their paws, acting aggressive or any obvious change in behavior, crying as if in pain, panting, hypersalivation, tremors and stiffness (see ch. 298, Video 298-1). Signs may progress to severe hyperthermia, generalized tetany, seizures and death.[8,33] Ionized calcium, the free and biologically active form, is usually <0.6 mmol/L in eclampsia cases. Besides the determination of calcium, a glucose measurement is necessary because signs could be quite similar and both problems could happen concurrently.[33,35,36] Treatment is administration of 10% calcium gluconate (2-20 mL) to effect.[8,34,35] Cardiac auscultation or electrocardiography should be used to identify bradycardia or arrhythmias. If either occurs, calcium administration must stop.[8,34,37] Body temperature should be closely monitored because the hyperthermic dog in tetany may develop hypothermia once calcium has been given and tetany has ceased (see ch. 134).[8,37] The litter should be removed from the mother for 24 hours and fed by bottle. Nursing should be discontinued if hypocalcemia recurs.[8] Calcium supplementation during the remaining period of lactation is recommended (calcium carbonate 100 mg/kg/day).[8]

Reproductive Emergencies in Males

Paraphimosis

Overview

Paraphimosis is the inability to retract the penis into the preputial cavity.[38,39] It is considered a reproductive emergency not due to the severe pain caused by inflammation and tissue swelling, but because it can lead to blood stasis, thrombosis of the corpus spongiosum and necrosis.[8,38,40] Untreated dogs often become severely ill.[38,41] Paraphimosis can be congenital or acquired. Among the conditions encountered are narrow preputial opening, short foreskin, persistent frenulum, preputial constriction secondary to hair entanglement, inability of the preputial muscles to retract the penis, and hypospadias.[40,41] This condition is most commonly seen in young intact males. Transient paraphimosis may follow breeding or masturbation. Treatment is straightforward if no serious tissue trauma is present.[42,43] The primary differential diagnoses are hematoma (vascular thrombosis), chronic urethritis, foreign body, paralysis of the retractor muscle of the penis, penile fracture, chronic priapism (Figure 146-7) and abnormal preputial opening.[39,43,44]

FIGURE 146-7 Boxer with priapism. The penis did not return to its flaccid form following an erection and now cannot be retracted into the penile sheath. This is unlike paraphimosis, the inability for the sheath of the penis to cover the glans penis.

Treatment

The initial approach consists of cleansing the area with a cool saline solution to remove any foreign material.

This can be followed by applying adequate lubricant to all exposed tissue in an effort to ease retraction. One may also use hyperosmotic solutions (50% glucose) or ice packs to reduce inflammation and ease retraction. If the penis is successfully covered by the prepuce, a "purse-string" or "tobacco pouch" suture pattern can be employed, but only for less than a day or two. One may need to catheterize the bladder if stranguria is seen.[40,43,44]

Testicular Torsion

Testicular torsion causes ischemia and necrosis, leading to pain, systemic signs, shock and death.[42,45,46] This condition most commonly involves the retained neoplastic testicle in a cryptorchid male, probably due to the space for torsion to occur within the abdomen.[8] When the testicles are located in the scrotum, the vaginal tunic restricts movement. Therefore, this condition is rare in animals whose testicles are normally positioned.[8,45] Clinical signs are nonspecific and include abdominal pain, "walking on eggshells," abdominal splinting, and lethargy.[42,46]

The diagnosis is based on the physical examination finding of a severely painful abdomen, painful abdominal mass, or simply palpating a mass. These are typically located ventral to the kidney. Abdominal ultrasonography can be quite helpful. However, if hypoechoic and globe-shaped masses are visible within the scrotum, fine needle aspiration and cytology is recommended.[8,42,46] Prognosis depends on the duration of the condition prior to diagnosis. Treatment is removing the abnormal testicle without releasing the torsion.[42,46]

CHAPTER 147

Global Approach to the Trauma Patient

Kenneth J. Drobatz

Trauma is defined as a "wound or injury" caused by an "accident." Severity of injury secondary to any trauma can range from undetectable to fatal. Trauma may affect only one organ system or multiple organ systems, either directly or indirectly. Therefore, a global and thorough approach is required to improve survival and decrease morbidity in traumatized dogs and cats. The initial approach to a critically ill traumatized pet often makes the difference in the eventual outcome. The veterinary staff should be well versed in the evaluation and therapy of a traumatized dog or cat. Initial trauma assessment includes evaluation of tissue oxygen delivery (respiratory and cardiovascular systems), the central nervous system, and the urinary system. This primary survey should be followed by complete examination of all other systems.

Primary Survey

The first goal with a critically injured trauma patient is to optimize oxygen delivery to the tissues. This has been demonstrated to improve outcome in human patients and has been demonstrated recently in dogs with sepsis secondary to pyometra. All initial assessments and therapeutics are oriented toward this goal. Emphasis on early detection and aggressive reversal of impaired tissue perfusion or oxygen delivery improves survival and minimizes multiorgan dysfunction. Oxygen delivery depends on the blood oxygen content and tissue perfusion (Figure 147-1).

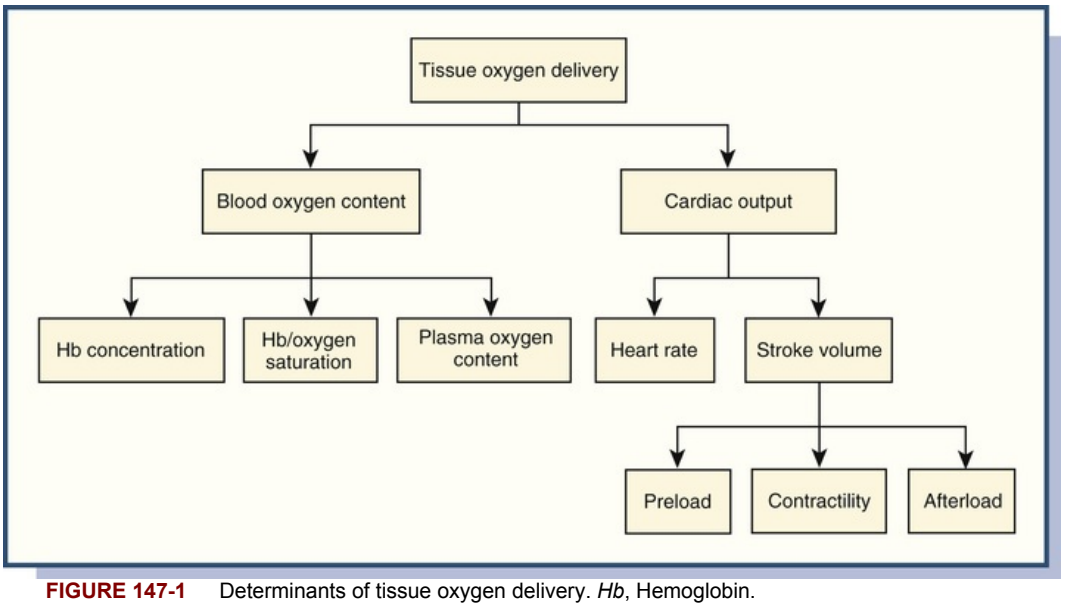

FIGURE 147-1 Determinants of tissue oxygen delivery. *Hb*, Hemoglobin.

Blood Oxygen Content

Maintaining oxygen saturation of hemoglobin through assessment and treatment of respiratory abnormalities is one of the first goals of the critical care team in maintaining oxygen delivery. Pale, cyanotic, or gray mucous membranes; signs of respiratory distress, such as increased respiratory rate and effort, extended head and

neck, open-mouth breathing; loud upper airway sounds and abnormal or diminished breath sounds on auscultation are all potential indicators of inadequate oxygen saturation of hemoglobin. More objective assessments of the oxygenation of blood include pulse oximetry (see ch. 98) and arterial blood gas analysis (see ch. 75 and 128). Thoracic focused assessment with sonography for trauma (TFAST) has been demonstrated to localize or identify pulmonary problems in dogs experiencing trauma (see ch. 149). Supplemental oxygen should be provided to any critically ill traumatized animal until it is proved that oxygen supplementation is not necessary (see ch. 131).

A variety of conditions associated with trauma can result in respiratory distress and decreased oxygenation of hemoglobin (Figure 147-2; also see ch. 28 and 149), but the most common are pneumothorax and pulmonary contusions. In animals suspected of having pleural space disease (decreased lung sounds with signs of respiratory distress), thoracocentesis should be performed even before thoracic radiographs are taken (see ch. 102). If done correctly, benefit far outweighs risk. Tension pneumothorax is rare but represents an acute, life-threatening pleural space abnormality. It is characterized by extreme respiratory distress, poor tissue perfusion and, rarely, a "barrel chest" appearance. Rapid thoracocentesis is immediately indicated. A small incision in the intercostal space may release the air more quickly in animals in which death or collapse is imminent.

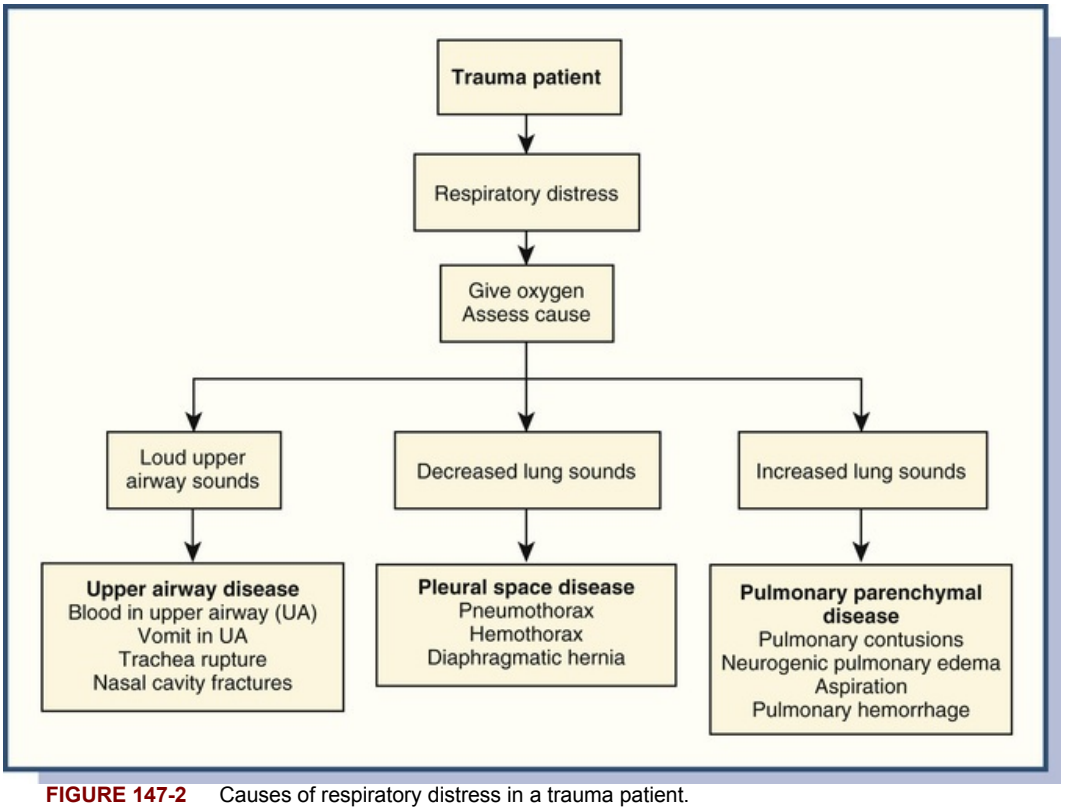

FIGURE 147-2 Causes of respiratory distress in a trauma patient.

Increased bronchovesicular sounds in a traumatized animal are commonly a result of pulmonary contusions (see ch. 242). Pulmonary contusions often worsen before they improve. Intravenous fluid therapy for other conditions should be given with caution in these dogs and cats. There is no specific therapy for pulmonary contusions. Supportive care with oxygen supplementation and pain relief is the mainstay of treatment. Most dogs and cats with pulmonary contusions begin to improve 24 to 36 hours after the initial insult (see ch. 149).

Other respiratory conditions include open chest wounds, flail chest, and rib fractures (see ch. 139). Open chest wounds should be covered and sealed as soon as possible. Once accomplished, the closed pneumothorax should be resolved by thoracocentesis. Treatment of an animal with a flail chest or rib fractures involves oxygen supplementation and pain management. Surgical repair is rarely necessary.

Neurogenic pulmonary edema occurs rarely but is most often associated with severe head trauma (see ch. 148 and 242). This form of pulmonary edema can range from mild to severe enough to require mechanical

ventilation. Most of these pets can be managed successfully with supportive care, such as oxygen supplementation and judicious diuretic therapy. Generally, respiratory problems in animals with neurogenic pulmonary edema caused by head trauma improve substantially within 48 hours, or death ensues due to the severe respiratory compromise.

An adequate amount of hemoglobin in the vascular space is essential to maintenance of tissue oxygen delivery. Decreased hemoglobin content severely limits the oxygen-carrying capacity of the blood and can contribute to decreased tissue oxygen delivery. The packed cell volume (PCV) provides the most rapid estimate of the hemoglobin concentration in a traumatized dog or cat, but it should be interpreted in conjunction with assessment of the vascular volume status (see Tissue Perfusion, below) to get a complete assessment of the total hemoglobin content of the vascular space. Typically, acute blood loss is not reflected by the initial PCV measurement because of splenic contraction in the dog and the length of time it takes for interstitial fluid to shift into the vascular space to dilute the PCV. Initial total solids (TS) and serial measurements of both PCV and TS as intravenous fluids are administered can be more sensitive indicators of acute blood loss (see ch. 135). There is no specific PCV at or below which transfusion is required. Transfusion therapy (see ch. 130) should be based on whether the animal is affected by the decreased hemoglobin content, which is indicated by clinical signs such as pale mucous membranes, tachycardia, tachypnea, bounding or weak pulses, depressed mentation, or cardiac arrhythmias. As with any animal in critical condition, it is best to anticipate and treat problems before they cause physiologic compromise. For example, if the PCV is dropping rapidly, it is best to start a blood transfusion or administer hemoglobin solutions before the hemoglobin content drops to a life-threatening level.
