
Physical assessments of tissue perfusion on the first examination include mucous membrane color, capillary refill time, and pulse rate and quality (Figure 147-3; also see ch. 2 and 127).

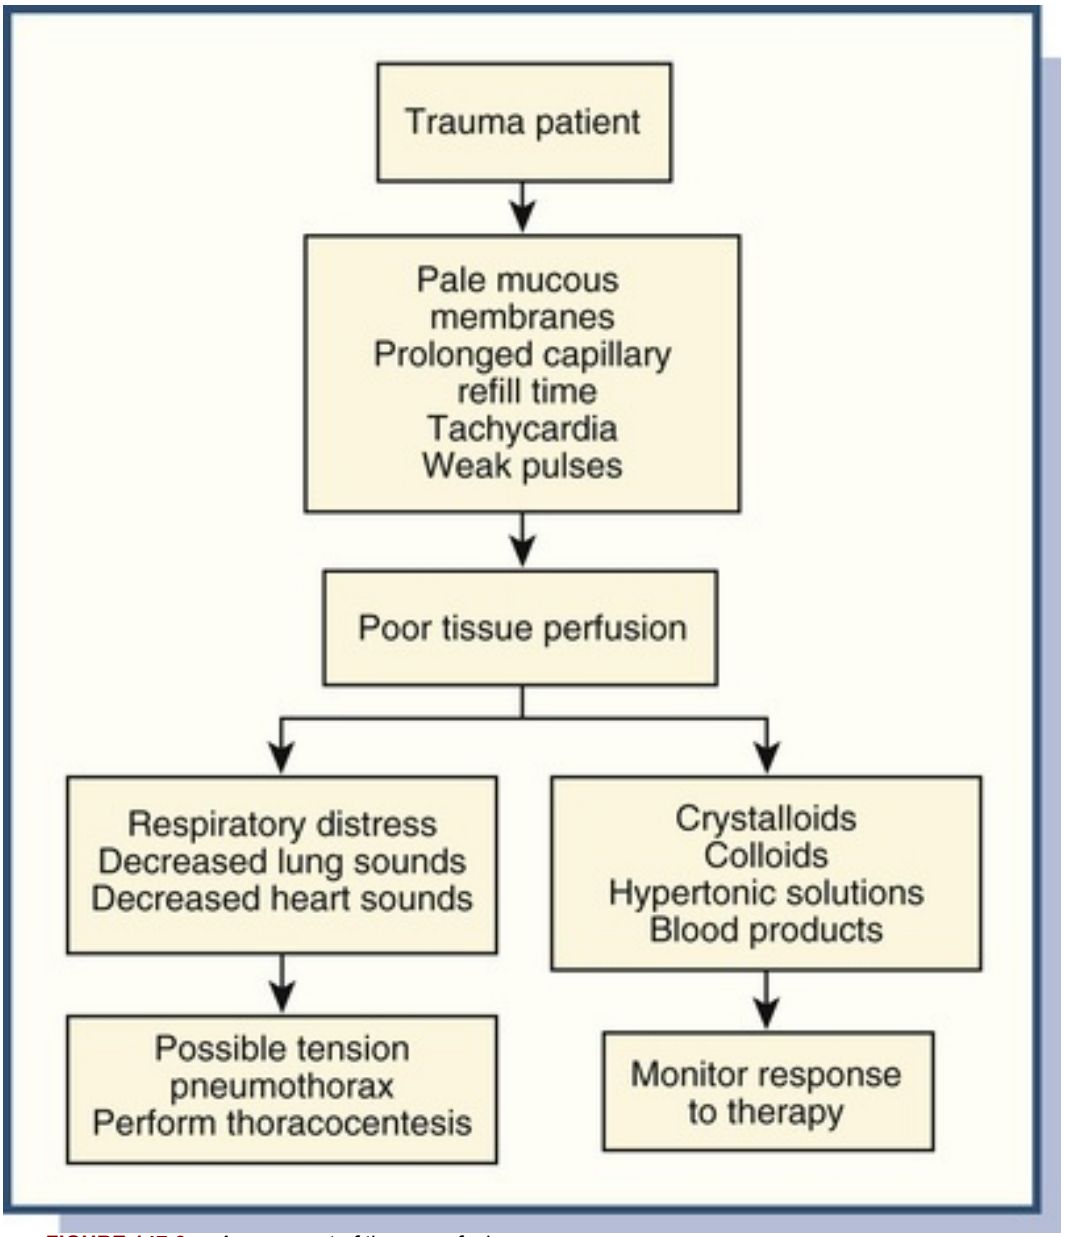

FIGURE 147-3 Assessment of tissue perfusion.

The arterial blood pressure should be measured directly or indirectly by Doppler or oscillometric techniques when possible (see ch. 99). Measurement of blood lactate or central venous oxygen saturation are objective assessments of adequacy of tissue perfusion with the former being more practical (see ch. 70). The most common clinical signs indicative of poor tissue perfusion are pale or gray mucous membranes, a prolonged capillary refill time, a rapid heart rate, and weak pulses. The most common cause of poor tissue perfusion after a traumatic event is hypovolemia secondary to hemorrhage.

Administration of a balanced electrolyte solution at a rate of 90 mL/kg body weight/hr in the dog (40 to 60 mL/kg body weight/hr in the cat) is indicated with physical evidence of poor tissue perfusion (see ch. 129). Two separate, large-bore, intravenous catheters may be required in large dogs (i.e., body weight exceeding 20 to 30 kg). Mucous membrane color, capillary refill time, pulse quality, heart rate, and blood pressure (if available) should be assessed continuously and the intravenous fluid rate adjusted as perfusion parameters improve or worsen. In most uncomplicated situations, improvement in tissue perfusion often is seen by the time one half of a vascular volume of fluid (45 mL/kg in the dog, 20 to 30 mL/kg in the cat) has been administered. As mentioned above, aggressive fluid therapy should be applied cautiously to animals known or suspected of having pulmonary contusions.

If clinical perfusion parameters or the blood pressure has not significantly improved after this volume of

fluid has been administered, an investigation into causes of nonresponsive cardiovascular shock should be pursued. Such causes include ongoing intravascular volume loss (most commonly due to ongoing hemorrhage) or, less commonly, cardiogenic causes, such as arrhythmias, pericardial effusion, myocardial depression or failure, electrolyte abnormalities, decreased venous return (e.g., tension pneumothorax), or ischemic organs. The peritoneal space is the most common location of substantial hemorrhage that can lead to hypovolemia and can be easily detected by abdominal focused assessment with sonography (AFAST, see ch. 143). Less common locations are the pleural space (see ch. 149) and retroperitoneal space (see ch. 88), external hemorrhage, and hemorrhage into the muscles surrounding the femur (see ch. 135).

Abdominal binding may help control ongoing intra-abdominal hemorrhage. However, this is no substitute for adequate intravascular volume supplementation. In human beings, some physicians advocate delayed resuscitation. In animals with severe hemorrhage, the fluid of choice is whole blood, packed red blood cells and plasma, hemoglobin substitutes (e.g., Oxyglobin), and/or colloid supplementation, such as hydroxyethyl starch or dextran 70 (see ch. 129 and 130). Hypertonic solutions can be considered after head trauma if a dog or cat is hypovolemic (see ch. 148) or if an animal appears to be in severe hypovolemic shock and may die before an adequate amount of balanced electrolyte solution can be administered (see ch. 127). Limited volume resuscitation in dogs with spontaneous hemoabdomen has been shown to provide more rapid hemodynamic stabilization compared to conventional crystalloid resuscitation, though further studies are warranted before this therapy can become standard.

Traumatized animals are physiologically dynamic and should be continuously monitored until physiologic parameters are stable. Close monitoring of cardiovascular and respiratory trends allows early detection of problems, before they become life threatening.

Central Nervous System and Urinary Tract

The central nervous system (CNS) (brain and spinal cord) and the renal system are two other organ systems that should be assessed and supported as priorities (see ch. 148 and 150). Compromise of either of these systems can result in irreversible damage. After the initial assessment and treatment of the cardiovascular and respiratory systems, the clinician should complete a thorough neurologic examination, including assessment of mentation and of cranial nerve and spinal cord function (see ch. 259). The results of such an evaluation establish a baseline for further monitoring and therapy. Brain dysfunction may be a result of poor oxygen delivery, direct tissue damage, intracranial hemorrhage, cerebral edema, ischemia, and/or increased intracranial pressure. Therapeutic considerations with head trauma and brain dysfunction include optimization of tissue perfusion, administration of mannitol (0.5 to 1.5 g/kg given intravenously), mild elevation of the head (30 degree from horizontal tilt board with head at the higher end, avoiding flexion of the neck and occlusion of the jugular veins), and maintenance of oxygenation (see ch. 148). Spinal cord assessment should include palpation of the spine and assessment of spinal function, including voluntary motor movement, conscious proprioception, ambulation, spinal reflexes, and pain sensation.

Neurologic function should always be evaluated in light of how well the central nervous system is perfused. In most animals, head trauma is obvious. However, those with severely compromised perfusion may have severely depressed mentation, as well as diminished pain sensation. The mentation and sensation abnormalities may normalize with correction of the poor tissue perfusion.

Manifestations of urinary tract injury or dysfunction may not be immediately evident and may not be detected until several hours of continuous monitoring have passed (see ch. 150). Potential renal/urologic system abnormalities include direct kidney damage (e.g., contusions, hematomas, avulsion), ureteral rupture, bladder rupture, and urethral trauma. Any animal that has been traumatized may have experienced renal/urologic system trauma. Serial assessment of the blood urea nitrogen, creatinine, and serum potassium concentrations, as well as of urine output, should be considered (see ch. 105 and 106). It should be remembered that animals with a ruptured urinary bladder might still urinate. Ureteral rupture may result in urine accumulation in the retroperitoneal space, a situation in which abdominocentesis fails to obtain fluid. Abdominal radiographs, abdominal ultrasound scans, and intravenous contrast studies may be necessary to diagnose ureteral rupture. If free abdominal fluid is present, it should be analyzed for the creatinine and potassium concentrations, which should be compared to the concentrations in peripheral blood. If the abdominal fluid is urine, its creatinine and potassium concentrations are higher than those of blood.

Secondary Survey

After assessment of tissue oxygen delivery, CNS function, and renal function, a full physical examination

should be performed (see ch. 2). Limb function should be evaluated and should include palpation of the entire appendicular and axial skeletal system as well as assessment of the animal's ability to support weight and ambulate. The eyes and oropharyngeal area should be examined for evidence of trauma. The mouth should be manually opened and closed to assess for malocclusion, pain, or crepitus. The roof of the mouth should be checked for split palate, a common finding in cats that have fallen from heights. A rectal examination should be performed, and attention should be paid to palpation of the pelvic canal for fractures or instability and evidence of blood in the rectum. The skin should be thoroughly examined for lacerations, abrasions, and bruising.

Monitoring

After the initial assessment, all the above systems should be monitored for at least 24 to 48 hours, despite how well the animal looks when first examined. In general, if problems are going to occur, they usually occur within this time frame. The intensity and duration of the monitoring should be proportional to the degree of compromise. Owners should also be warned that rarely, complications might arise several days later. For example, clinical signs of a ruptured gallbladder are not often manifested until several days after the traumatic injury. Assessment of tissue oxygen delivery should be performed at presentation and treated appropriately. Assessment should also include the CNS and renal/urologic systems, as well as the musculoskeletal, cutaneous, and peripheral nervous systems. A global approach, with emphasis on the most life-threatening conditions first, optimizes the outcome.

CHAPTER 148

Head Trauma

Eileen Kenney

Traumatic brain injury (TBI) is a significant cause of morbidity and mortality in veterinary patients, with etiologies including motor vehicle accidents, crush injuries, human or animal attacks, falls, and gunshot or other penetrating wounds.[1-3] The severity of brain injury can be quite variable, ranging from minor deficits to life-threatening neurologic impairments. An understanding of the pathophysiology of TBI, along with appropriate and rapid management of the injured patient, is critical to maximize survival and a functional recovery.

Pathophysiology

The pathophysiology of TBI involves both primary and secondary neuronal injury. Primary injury occurs at the moment of the initial trauma from mechanical damage to the brain parenchyma. Primary injury is broadly classified as focal or diffuse, and can be further defined based on the location and type of injury. Types of primary injuries include concussions, contusions, lacerations, diffuse axonal injury, and vascular disruption.

Secondary injury occurs hours to days subsequent to the trauma from a variety of processes that cause continued neuronal damage. Mechanisms of secondary injury include: ischemia, ATP depletion, failure of ionic homeostasis, glutamate excitotoxicity, free radical production, vasogenic and cytotoxic cerebral edema, mitochondrial dysfunction, cerebral lactic acidosis, inflammatory mediator release, activation of the coagulation cascade, and apoptotic and necrotic cell death. Systemic contributions to secondary brain injury include hypotension, hypoxemia, hypoglycemia, hyperglycemia, hypocapnia, hypercapnia, hyperthermia, acid-base disturbances, and electrolyte abnormalities. Intracranial contributions include intracranial hypertension, compromise of the blood brain barrier (BBB), hematoma formation, cerebral edema, infection, vasospasm, and seizures. Prevention and management of secondary injury are the main treatment goals for patients with TBI.

In the healthy brain, cerebral autoregulation maintains a constant cerebral blood flow (CBF) through changes in cerebral vascular resistance (CVR), with the relationship CBF = CPP/CVR. The cerebral perfusion pressure (CPP) is determined by the mean arterial pressure (MAP) minus intracranial pressure (ICP), or CPP = MAP − ICP. Given that normal ICP is generally low (5-14 mm Hg in dogs and cats),[4,5] CPP is mainly dependent upon MAP. Autoregulation can maintain CBF over a MAP range of 50-150 mm Hg, but above and below this limit, CBF becomes pressure-dependent. In TBI, cerebral autoregulation may be compromised regionally or globally, such that even small decreases in CPP (from either a decrease in MAP or increase in ICP) can lead to decreased CBF, causing cerebral ischemia.

ICP is dictated by three components within the skull: the brain parenchyma, arterial and venous blood, and cerebrospinal fluid (CSF). Intracranial compliance normally maintains these components in a balanced dynamic equilibrium by shifting fluids in the brain vasculature and CSF pathways. When TBI occurs, the limits of intracranial compliance can be overwhelmed due to hemorrhage or edema, leading to increased ICP, decreased CPP, and cerebral ischemia. The Cushing reflex, or cerebral ischemic response, is triggered by a severe acute increase in ICP which causes systemic hypertension in order to maintain a normal CPP, along with a vagally induced reflex bradycardia. This response signifies potentially life-threatening intracranial hypertension with imminent brain herniation, and should be treated immediately.

Patient Assessment and Diagnostics

Patients presenting for trauma are often in hypovolemic shock and/or respiratory distress, having sustained multisystemic injuries that impair systemic perfusion, oxygenation, and mentation (see ch. 127). Initial assessment should focus on treating imminently life-threatening abnormalities such as hemoabdomen,

pneumothorax, pulmonary contusions, and upper airway trauma (see ch. 147). Once normovolemia and appropriate oxygenation and ventilation are established, a secondary assessment of additional injuries and neurological evaluation can occur. An abbreviated neurologic examination should be done before analgesic administration to allow accurate assessment, and should focus on level of consciousness, motor ability, and brainstem reflexes (pupil size, pupillary light response, and oculocephalic reflex). Patients should be graded using the Modified Glasgow Coma Scale (MGCS), which provides an estimate of prognosis (Table 148-1; Video 148-1).[2] A more detailed neurologic examination can be performed (see ch. 259) once treatment for neurological stabilization has been initiated.

TABLE 148-1

Modified Glasgow Coma Scale

LEVEL OF CONSCIOUSNESS
6: Occasional periods of alertness and responsive to environment
5: Depression or delirium, capable of responding but response may be inappropriate
4: Semicomatose, responsive to visual stimuli
3: Semicomatose, responsive to auditory stimuli
2: Semicomatose, responsive only to repeated noxious stimuli
1: Comatose, unresponsive to repeated noxious stimuli
MOTOR ACTIVITY
6: Normal gait, normal spinal reflexes
5: Hemiparesis, tetraparesis, or decerebrate rigidity
4: Recumbent, intermittent extensor rigidity
3: Recumbent, constant extensor rigidity
2: Recumbent, constant extensor rigidity with opisthotonus
1: Recumbent, hypotonia of muscles, depressed or absent spinal reflexes
BRAINSTEM REFLEXES
6: Normal pupillary light reflexes and oculocephalic reflexes
5: Slow pupillary light reflexes and normal to reduced oculocephalic reflexes
4: Bilateral unresponsive miosis with normal to reduced oculocephalic reflexes
3: Pinpoint pupils with reduced to absent oculocephalic reflexes
2: Unilateral, unresponsive mydriasis with reduced to absent oculocephalic reflexes
1: Bilateral, unresponsive mydriasis with reduced to absent oculocephalic reflexes

MGCS SCORE	PROGNOSIS
3-8	Grave
9-14	Guarded
15-18	Good

Quick assessment blood work should include a packed cell volume and total solids to assess for hemorrhage, blood glucose to assess the severity of injury, and blood gas and lactate to assess acid-base status, ventilation, and perfusion (see ch. 70, 75, and 128). Electrolyte and renal values should also be obtained before initiating treatment to assess for derangements that could preclude administration of medications. Sampling from the jugular vein should be avoided as temporary occlusion of this vessel could rapidly increase ICP.[6]

Skull radiography can be used to screen for calvarial fractures, but will not otherwise provide clinically useful information about brain injury. Advanced intracranial imaging is indicated if the patient fails to

respond to aggressive medical therapy or neurologically deteriorates. Computed tomography is the modality of choice in the acute setting, due to its rapid scan time and ability to identify intracranial hemorrhage, cerebral edema, cerebral herniation, and fractures.[7,8] Beyond the acute setting, magnetic resonance imaging is indicated in more stable patients that fail to respond to medical therapy due to its higher sensitivity for contusions, diffuse axonal injury, subdural and epidural hematomas,[9-11] and the fact that it can provide prognostic information in dogs.[3]

Treatment

Before initiating therapy directed at lowering ICP, it is essential that hypoxemia, hypovolemia, and blood loss anemia are treated to endpoint resuscitation parameters to minimize secondary brain injury caused by shock (see ch. 127 and 129). The MAP should be maintained ≥80 mm Hg in order to maintain CPP. Oxygen supplementation is recommended during the initial stabilization and should be continued if needed to maintain a SpO_2 > 97% or a PaO_2 > 90 mm Hg (see ch. 131). The patient should tolerate the method of oxygen supplementation, since coughing, sneezing, struggling and anxiety may transiently increase ICP. If the patient is hypoventilating, resulting hypercapnia will cause cerebral vasodilation, which increases CBF and ICP. If $PaCO_2$ cannot be maintained within the normal range (35-45 mm Hg), or if PaO_2 is below 80 mm Hg despite oxygen supplementation, endotracheal intubation with mechanical ventilation is required.

Once the patient's cardiovascular and respiratory systems have been addressed, neurological stabilization can ensue by administering hyperosmolar agents to decrease ICP (Figure 148-1). Mannitol is an osmotic diuretic with an immediate plasma volume expansion effect, which improves CBF while causing a reflex vasoconstriction that decreases ICP. In addition, mannitol may scavenge free radicals and its rheologic effects improve microcirculation.[12,13] Mannitol is administered as a slow bolus over 15-20 minutes at dosages from 0.25 to 1 g/kg. Administration of mannitol is contraindicated in hypovolemic patients due to its diuretic effect causing further volume contraction and thus worsening CPP. An alternative choice is hypertonic saline, especially in hypovolemic patients, since it expands plasma volume while decreasing ICP via osmotic mobilization of water across the BBB. Hypertonic saline also improves microcirculation, decreases excitotoxicity, and modulates the inflammatory response.[14,15] It is administered at a dosage of 3 to 5 mL/kg of 7.5% NaCl in dogs (2 to 3 mL/kg in cats) over 3-5 minutes. Co-administration of hypertonic saline with 2 to 3 mL/kg of an artificial colloid has also been demonstrated to be effective at lowering ICP.[16,17] Elevating the head to a 30° angle reduces ICP by facilitating venous drainage from the brain.[18] Care should be taken to avoid obstructing the jugular veins with constrictive wraps, jugular catheters, or excessively bending the neck. Corticosteroids were historically advocated for treatment of TBI, but have been associated with increased mortality and are now contraindicated.[19] The administration of furosemide has also not been shown to be beneficial and may worsen hypovolemia, so is not recommended.[20] Hyperglycemia is associated with increased mortality rates in humans with TBI,[21] whereas in animals the degree of hyperglycemia is associated with the severity of TBI but not outcome.[1] Glycemic control is an active area of research in humans with TBI, but further studies are needed to advocate its use in veterinary patients.[22,23]

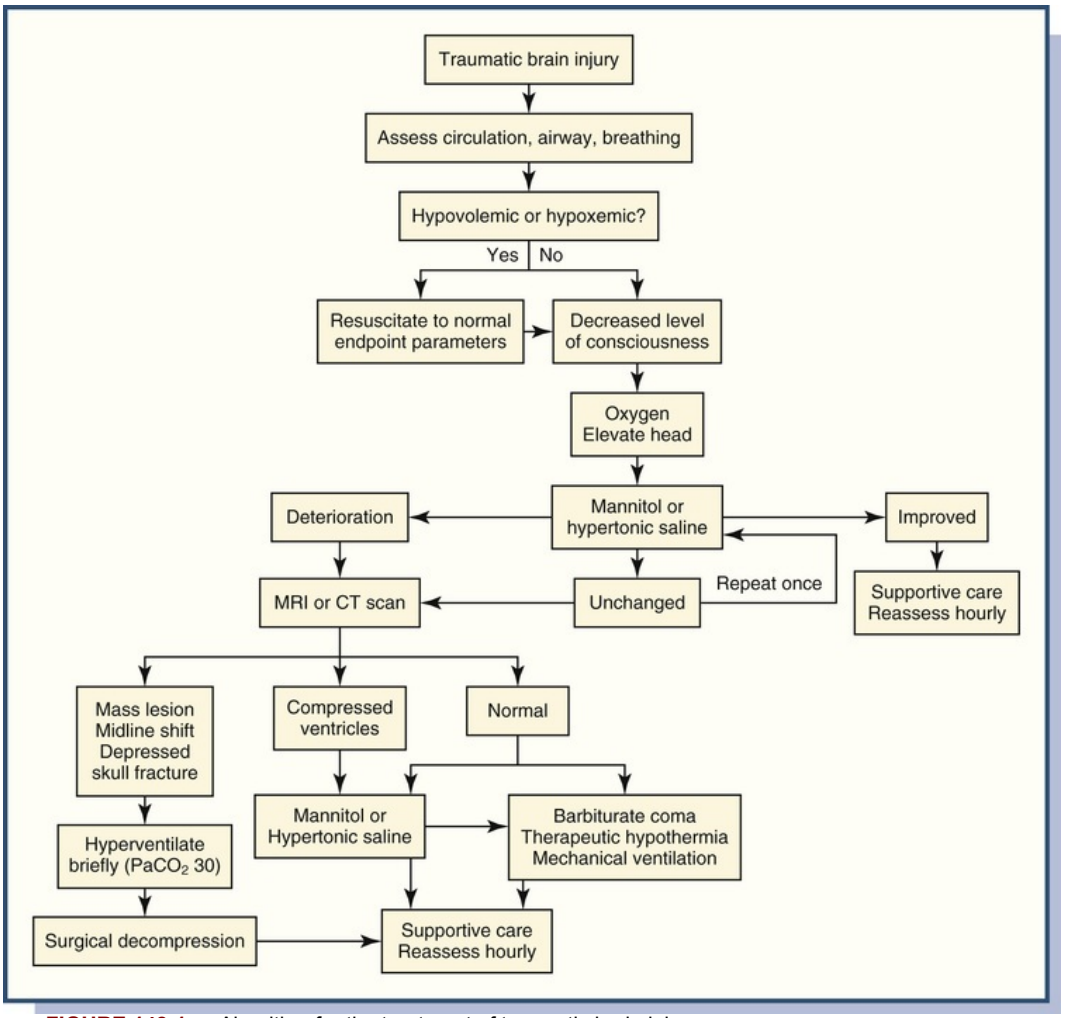

FIGURE 148-1 Algorithm for the treatment of traumatic brain injury.

Other beneficial therapies include therapeutic moderate hypothermia which is utilized in humans and animals to decrease the cerebral metabolic rate, inhibit release of glutamate and inflammatory cytokines, and decrease ICP via reflex vasoconstriction.[24-26] Induction of a barbiturate coma can be used to decrease the cerebral metabolic rate and decrease seizure activity.[26] Use of hyperbaric oxygen therapy in TBI (see ch. 84) has been shown to decrease ICP, secondary brain damage, and improve cerebral oxygenation without an increase in inflammatory markers.[27,28] Decompressive craniectomy with durotomy is effective at decreasing ICP in dogs,[29] and may be indicated with open or depressed skull fractures, ongoing hemorrhage, contaminated foreign body or hematoma removal, and declining neurologic status despite aggressive medical therapy. Patients suffering an acute neurologic deterioration can be hyperventilated to a $PaCO_2$ not less than 30 mm Hg while additional medical or surgical stabilization is initiated. Hyperventilation should be brief, since the resulting cerebral vasoconstriction not only decreases cerebral blood volume and ICP, but globally decreases CBF and perpetuates ischemia.[30]

After initial fluid resuscitation, continued fluid therapy is required to account for maintenance needs, deficits, and ongoing losses. Fluid restriction should be avoided as it places the patient at risk for a negative fluid balance, which is shown to worsen patient outcome.[31] A hypermetabolic and catabolic state occurs after TBI, increasing the demand for energy substrates.[32] Decreased and delayed nutritional support is associated with a worse neurologic outcome and increased mortality, so institution of nutritional support within 48 hours post-injury is recommended.[33,34] Analgesia is often indicated but must be balanced with preservation of blood pressure and ventilation, and should ideally not impede neurologic re-assessment. Opioid agonists administered as a CRI are preferred since they can be titrated to effect and are easily reversible. In-hospital seizures have been reported in 10-28% of dogs after TBI,[3,35,36] so anticonvulsant medication (levetiracetam or phenobarbital) should be administered during the recovery period if seizures are noted (see ch. 35 and 136).

Nursing care should provide clean dry bedding, frequent turning, and physical therapy to prevent urine scalding, pressure sores, and limb contracture.

Patient Monitoring

Cardiovascular, respiratory, and neurologic status should be reassessed hourly to evaluate treatment efficacy and to assess for deterioration. Blood pressure, $PaCO_2$ or $ETCO_2$ (if intubated), and PaO_2 or SpO_2 should be monitored to ensure systemic stability. Serial monitoring of the initial blood work values is essential since dramatic changes can occur due to therapy or changing patient status. Serial MGCS scores should be recorded as an objective assessment of changes in neurologic status. ICP monitoring is frequently employed in human hospitals to guide therapy when ICP exceeds 20 mm Hg, rather than relying on gross neurologic signs. Methods of monitoring ICP have been described in cats and dogs, but are not widely used or available.[4,5]

The animal can be discharged when neurologic signs have improved or plateaued and the patient is able to maintain hydration and nutritional requirements (voluntarily or with a feeding tube). Neurologic recovery may be complete, but owners should be prepared that residual deficits may persist. Dogs and cats have a remarkable ability to compensate for loss of cerebral tissue, so it is important to not reach hasty prognostic conclusions based on initial appearance.[37]

CHAPTER 149

Thoracic Trauma

Elizabeth Rozanski

Trauma, including thoracic trauma, is a common presenting complaint in small animal emergency medicine. The basic tenets of emergency medicine focus on the primary survey of the patient, including evaluation and stabilization of the major body systems (heart, brain, lungs) and then the secondary survey with complete patient evaluation (Figure 149-1). The focus of this chapter is on thoracic trauma. The interested reader is also directed to the Veterinary Committee on Trauma (VetCOT) at https://sites.google.com/a/umn.edu/vetcot/home. The purpose of this chapter is to provide an overview of the approach to the thoracic trauma patient, with a specific focus on pulmonary injury. However, it is important to evaluate the entire patient, rather than to just focus on the thoracic cavity.

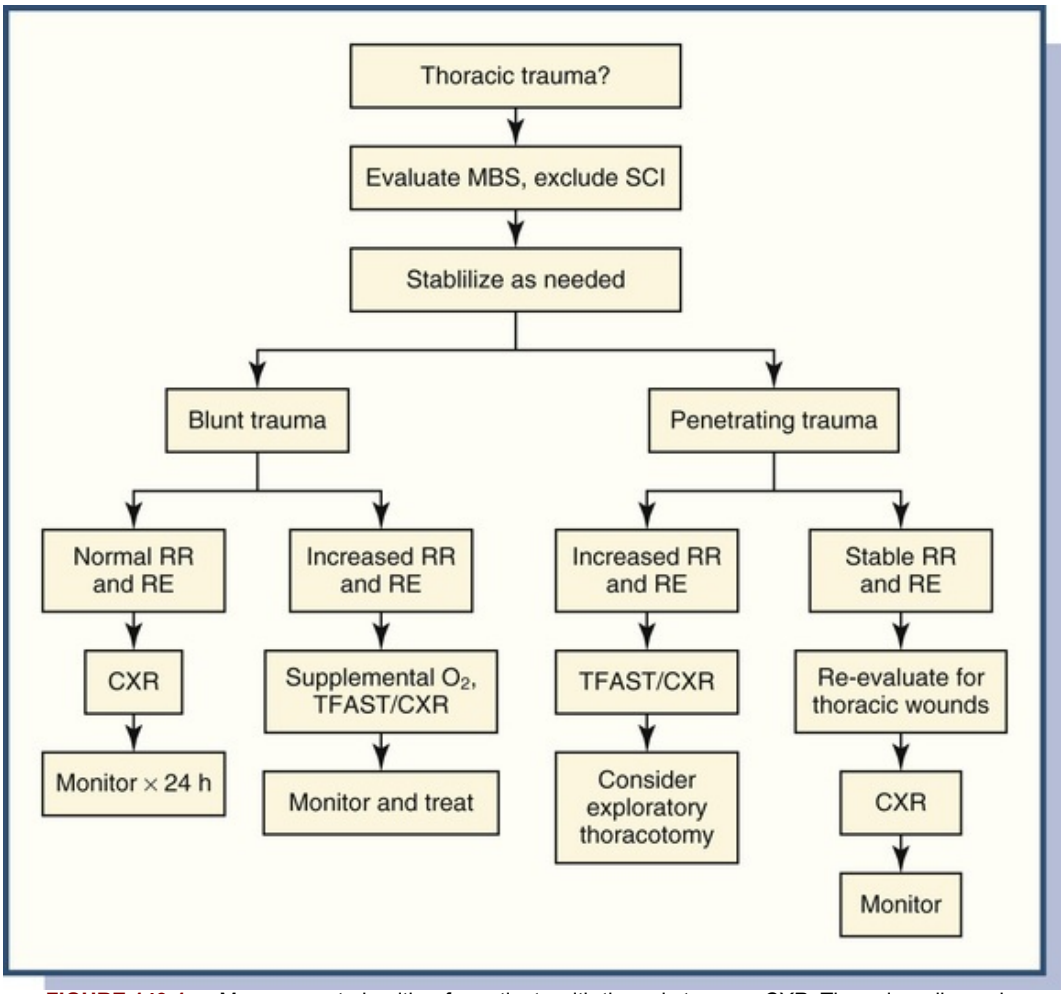

FIGURE 149-1 Management algorithm for patients with thoracic trauma. *CXR,* Thoracic radiograph; *MBS,* major body systems, namely the heart, brain and lungs; *RE,* respiratory effort; *RR,* respiratory rate; *SCI,* spinal cord injury; *TFAST,* focused sonography for trauma—thoracic.

Mechanism of Injury

Trauma can be divided loosely into blunt (e.g., hit by car [HBC]) and penetrating trauma (e.g., bite wound). It is helpful to know the mechanism of injury if possible; however, owners are notorious for misidentification of the circumstances surrounding trauma, such as the speed of the car or the breed of an attacking dog. It is helpful to ask if the patient walked away from the accident using all four limbs, and if the patient lost consciousness at the scene. In rabies-endemic areas, the vaccine status of the victim and the attacker should be established.

Initial Assessment and Stabilization

By nature, trauma cases present on an emergency basis. Each case should be evaluated immediately for life-threatening injuries. With the recent growth of 24-hour veterinary hospitals, each practice should develop policies on which cases should be hospitalized for ongoing care at the primary care veterinary clinic, and which cases should be referred for more specialized care. These policies will reflect geographic constraints and individual practice philosophy. Any pre-existing patient history is helpful, but is unremarkable in most trauma patients, who tend to be younger and healthy. Clinicians are advised to be aware of the possibility of non-accidental injury, consistent with abuse.

Initial assessment focuses on the cardiovascular, neurologic, and respiratory systems. Evidence of cardiovascular compromise includes tachycardia and weak pulses. Hypotension is uncommon but is a crucial finding if detected (see ch. 99 and 159). The shock index (heart rate/blood pressure) has been described as a method of identifying shock in patients with more subtle abnormalities and can be useful if blood pressure is recorded routinely.[1] Treatment of cardiovascular dysfunction revolves around volume resuscitation, most commonly with intravenous crystalloid infusions or blood transfusions (see ch. 129 and 130). Recently, synthetic colloids have been falling in popularity, and the indications for the use of colloids in the resuscitation of traumatized patients are now considered limited.[2] Neurologic dysfunction includes traumatic brain injury, spine cord injury, and peripheral nerve damage, such as brachial plexus avulsion (see ch. 148, 267, and 268). Treatment of neurological dysfunction is dependent on the type of damage; for example, animals with thoracic trauma also can have vertebral fractures or luxations (Video 149-1). Pulmonary dysfunction is recognized by labored ventilation, or by short and shallow respiration, and most commonly is caused by pulmonary contusions or pneumothorax.

Point of Care Blood Tests

Initial testing is useful to evaluate the *presenting* packed cell volume, total solids, and lactate level. Other laboratory testing (complete blood count, serum biochemistry profile, urinalysis) can be indicated on an individual patient basis and is especially important in older patients, those with co-morbidities, or when large surgical procedures are planned (e.g., fracture repair). In general, laboratory testing will document increased liver enzyme concentrations associated with blunt hepatic trauma with little clinical significance. In dogs in particular, marked splenic contraction can result in a normal or near normal hematocrit at presentation, even with severe hemorrhage. However, the total solids (total protein) concentrations will fall, providing a useful clue of blood loss. Total solids concentrations <6 g/dL (<60 g/L) warrant further evaluation, especially if coupled with persistent tachycardia (or bradycardia in cats). Occasionally, pre-existing chronic diseases can be the cause of hypoproteinemia, but the safest approach is to assume hemorrhage when a low total solids concentration is detected at presentation.

Lactate is generated most commonly as a marker of anaerobic metabolism (type A) and can be used to help confirm hypovolemia when elevated (>2.0 mmol/L). Lactate clearance, or the rate of fall of lactate during initial treatment, is also emerging as a useful tool for monitoring response to therapy (see ch. 70).

FAST Scan

Point-of-care thoracic ultrasonography is very useful in trauma. Boysen and colleagues initially introduced the concept of focused assessment with sonography for trauma (FAST) scanning in veterinary medicine, and since that time, multiple studies have documented its utility.[3,4] Following the initial patient survey, and institution of resuscitative measures, a standardized approach with ultrasound will help identify free fluid or air more quickly and easily than with radiographs. FAST involves a limited use of ultrasound to primarily answer the question "Is there fluid or not?" and is not designed to evaluate the entire cavity being scanned.

The clinician should learn specific sites to scan and record these in the medical record. TFAST refers to screening the thorax for free air (traumatic pneumothorax), pleural or pericardial effusion, and pulmonary infiltrates. Pneumothorax is identified by the loss of the glide sign (Video 149-2). Sonographically, it is harder to appreciate pneumothorax than pleural effusion. Ultrasound also is used for identifying "lung rockets" which signify pulmonary infiltrates, consistent with pulmonary contusions.[4] It is essential to recall that in trauma patients, large volumes of pleural effusion are more likely to result in signs of hypovolemia than in respiratory embarrassment because pleural effusion in trauma is typically frank blood, although injury-associated urothorax and bilothorax rarely have been reported.

The focus of this chapter is on thoracic injuries seen in trauma. However, upper airway injuries can occur in conjunction with thoracic trauma and are discussed first.

Upper Airway

The most severe injuries in the upper airway occur in conjunction with bite wounds. Bite wounds to the neck can affect any of the soft tissues in the neck, notably the jugular veins, carotid arteries, esophagus, or trachea. Tracheal damage can result in subcutaneous emphysema or pneumomediastinum.[5] In our practice, we have also identified dogs with damage to the recurrent laryngeal nerves, resulting in laryngeal paralysis. Treatment of tracheal injuries includes primary repair with closure of the defect, or in some cases of a presumed small tear, simple observation (Figure 149-2). Laryngeal paralysis can require surgical palliation with arytenoid lateralization while laryngeal collapse can require a permanent tracheostomy.

FIGURE 149-2 A severe bite wound to the neck in a Corgi. Extensive tracheal damage was present.

Pulmonary Contusions

Pulmonary contusion occurs when blunt thoracic trauma causes alveoli to fill with blood and fluid (inflammation). Although comprehensive data are not available, pulmonary contusion probably occurs in a large percentage of animals with thoracic trauma. Damage to the lung parenchyma develops from capillary injury and subsequent leakage of blood into the interstitium. This hemorrhage triggers an inflammatory response, and results in the influx of inflammatory cells. Pulmonary contusions decrease lung compliance and alter gas exchange, causing hypoxemia and possibly hypercarbia in severe cases. Decreased lung compliance means a higher inspiratory pressure is needed to result in the same tidal volume. Animals typically compensate for reduced compliance with more rapid respiration.

Pulmonary contusions can be suspected clinically by tachypnea and increased respiratory effort. They may be confirmed radiographically as interstitial to alveolar infiltrates. Location is consistent with the site of injury. TFAST may also be used to identify lung rockets, or evidence of lung edema.[4] Computed tomography, while uncommonly performed in veterinary patients with acute trauma, would also confirm pulmonary contusions. Due to influx of inflammatory cells and edema, pulmonary contusions typically will worsen radiographically over the first 12-36 hours. However, radiographs may be taken at any point after the patient is assessed as stable enough for radiographs. Follow-up radiographs are rarely taken if the patient is recovering as predicted, and radiographic clearance is likely to take up to a week.

Therapy for pulmonary contusions is supportive and can include oxygen supplementation (see ch. 131) and fluid therapy as needed to maintain adequate circulating volume (see ch. 127). Large volumes of intravenous crystalloids should be avoided when possible, since they can magnify lung injury by contributing to volume overload and extravasation of lung water. Synthetic colloidal therapy has not been evaluated formally in animals with pulmonary contusions.[2] In people, recommendations are for adequate fluid resuscitation, but with efforts to avoid volume overload. Most dogs with pulmonary contusions show marked improvement in 2-3 days and recover completely in less than one week.

Complicated pulmonary contusions are uncommon, but include the development of pneumonia or acute respiratory distress syndrome (ARDS). Pneumonia is very rare in dogs with pulmonary contusions, despite the perception of blood being a good medium for bacterial growth. Dogs with traumatic pneumocysts can have an increased incidence of subsequent infections.[6,7] Antibiotics should be avoided in isolated pulmonary contusions. Diuretics are not indicated in pulmonary contusions, and there is no role for glucocorticoids. Analgesics may be considered, because pulmonary contusions imply concurrent, substantial chest wall and pleural damage, which are painful. Furthermore, untreated thoracic pain can limit deep breathing, which then promotes atelectasis and worsens lung function.

Pneumothorax

Pneumothorax refers to free air within the pleural space (Figure 149-3). In traumatic pneumothorax, free air reaches the pleural space either from outside the patient due to chest wall damage (typically a bite wound) and/or via air leakage from the pulmonary parenchyma (e.g., lung laceration). A lacerated lung will leak air into the pleural space down the pressure gradient, with some air going into the pleural space during each inspiration. Damaged lung will also bleed. Radiographs, TFAST scanning, thoracocentesis, or possibly auscultation will identify pneumothorax. Auscultation of dogs with pneumothorax can be misleading if respiratory sounds are louder than average due to concurrent pulmonary contusions, or in a thin, smooth-coated dog (e.g., Greyhound) versus an over-conditioned Labrador. In some emergency practices, dogs showing respiratory distress undergo thoracocentesis before radiography, based on the history of trauma and the increased respiratory effort. There is little risk of harm associated with a negative needle thoracocentesis. TFAST, showing the absence of the normal "glide" sign, is diagnostic of pneumothorax. Video 149-2 shows an ultrasound of a normal dog, showing the typical glide sign.

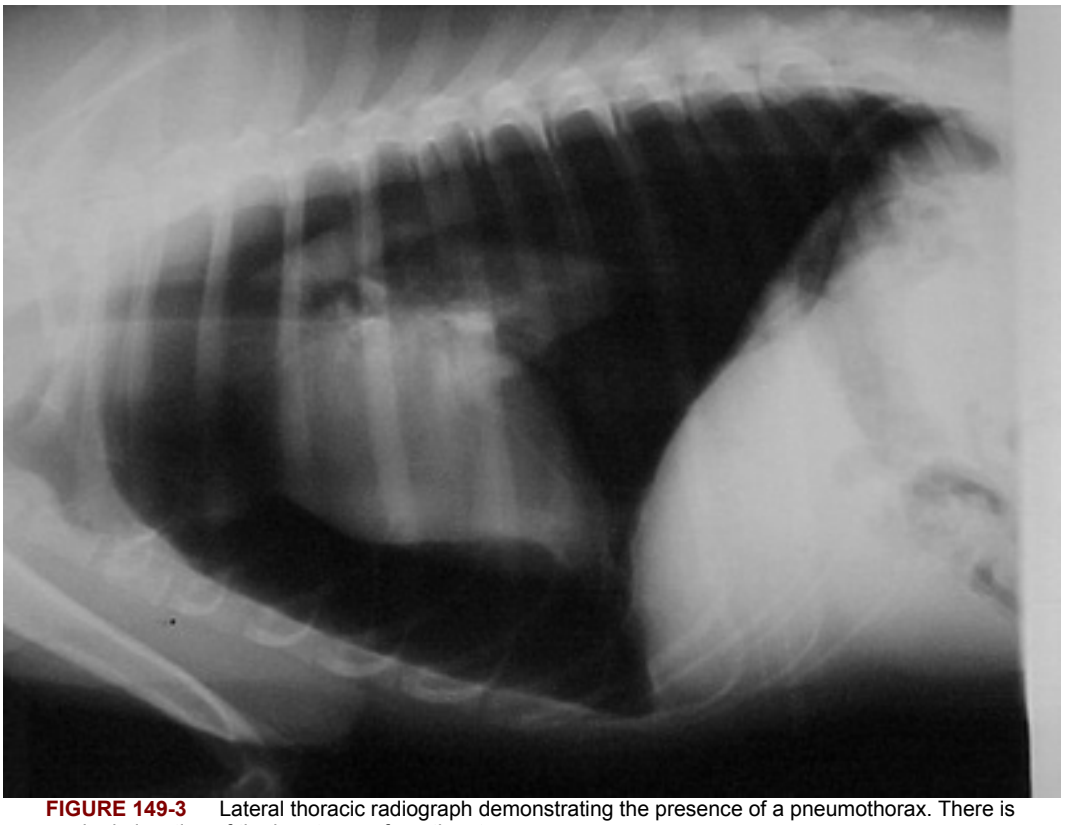

FIGURE 149-3 Lateral thoracic radiograph demonstrating the presence of a pneumothorax. There is marked elevation of the heart away from the sternum.

Approximately 25-30 mL/kg of air generally needs to be removed to provide significant improvement to respiratory status (see ch. 102). Thoracocentesis for pneumothorax is performed as for pleural effusion at the 7-9th intercostal space; some clinicians elect to enter more dorsally to try to remove more air, or the patient can be placed in lateral recumbency (if comfortably tolerated) and the centesis performed at the high point of the thorax, midway between dorsal and ventral midlines. Occasionally, a thoracostomy tube is required to provide either continuous or intermittent chest drainage (see ch. 100). Generally, a dog is considered a candidate for a chest tube if it requires >3 needle thoracocenteses in <12-18 hours, or if no end-point is reached during thoracocentesis. Animals typically will breathe with a restrictive pattern (short shallow breaths) with pneumothorax, but this might not be apparent in all cases (see ch. 139). Surgical therapy for traumatic pneumothorax can be warranted, especially with penetrating wounds (clean and debride damaged tissue, remove or repair ongoing leak). For blunt trauma (HBC), surgical intervention is rarely required, and spontaneous healing usually occurs within a few days. Use of a continuous suction device to keep the lung parenchyma inflated and avoid the cyclic inflation/collapse cycle associated with intermittent suction may facilitate healing (Video 149-3).

Hemothorax

Hemothorax is another possible sequela of thoracic trauma. Pleural effusion can develop from blood loss from damaged pulmonary parenchyma, or damage to the soft tissue structures; small arteries and veins may also bleed. It is unlikely that a patient suffering damage to a large vessel (vena cava or aorta) would survive long enough to reach the hospital unless there was a clot covering most of the damaged vessel and it was subsequently dislodged. The impact of hemothorax is more likely from hypovolemia associated with the blood loss, than from pleural effusion. Hemothorax usually is a presumptive diagnosis after identification of pleural effusion on chest radiographs from a trauma patient. Treatment is supportive, including rest and transfusions. Autotransfusion could be considered in blunt trauma patients, as the blood is unlikely to be contaminated. Typically, thoracocentesis may be avoided unless otherwise indicated by concurrent pneumothorax. Interestingly, in people, evacuation of hemothorax is advised to prevent the development of adhesions; hemothorax in dogs and cats appears to be better tolerated and does not require removal unless there is another indication. Surgical exploration is a last resort and would most likely be associated with

massive hemorrhage. If surgical exploration is entertained, preparations should be made for massive transfusion, and vascular clamps should be available.

Rib Fractures

Rib fractures are common in the patient with thoracic trauma. Rib fractures appear to be painful, particularly on inspiration. Individual fractured ribs do not typically affect lung function, but reflect a severe injury to the chest. Animals with rib fractures almost invariably have associated pulmonary contusions. Radiographic identification of rib fractures can be straightforward, but often requires careful assessment of two or more orthogonal views. Pain can decrease ventilatory efforts and coughing, which, by promoting atelectasis, could be associated with the development of pneumonia. Therapy for rib fractures typically is conservative and includes pain management (typically opioids and local blocks). Nonsteroidal anti-inflammatory agents may be considered if the patient is otherwise eating and drinking, and has normal renal function.

If two or more adjacent ribs are fractured at two or more sites on each rib, an unstable piece or "flail segment" can be formed, termed a flail chest.[8] This flail segment moves paradoxically with respiration, meaning when the patient inspires, the segment moves inward. Flail segments occasionally can be confused with intercostal muscle tears, which are simple muscle lacerations between the ribs that also show paradoxical movement during inspiration; the absence of rib fractures in a patient showing these signs is consistent with intercostal muscle tear. Intercostal muscle tears are particularly common in bite wounds, and can be located some distance from the site of the puncture wound due to the mobility of the skin (Video 149-4). Various methods of stabilization have been described for flail chest; however, the underlying contusions often are the principal detriment to lung function and therefore, supportive care is adequate. If animals undergo exploratory thoracotomy for other reasons, such as bite wounds, torn intercostal muscles should be re-apposed, and fractured ribs may be approximated. Figure 149-4 shows a reconstructed computed tomographic (CT) scan of a dog with multiple rib fractures associated with severe vehicular trauma.

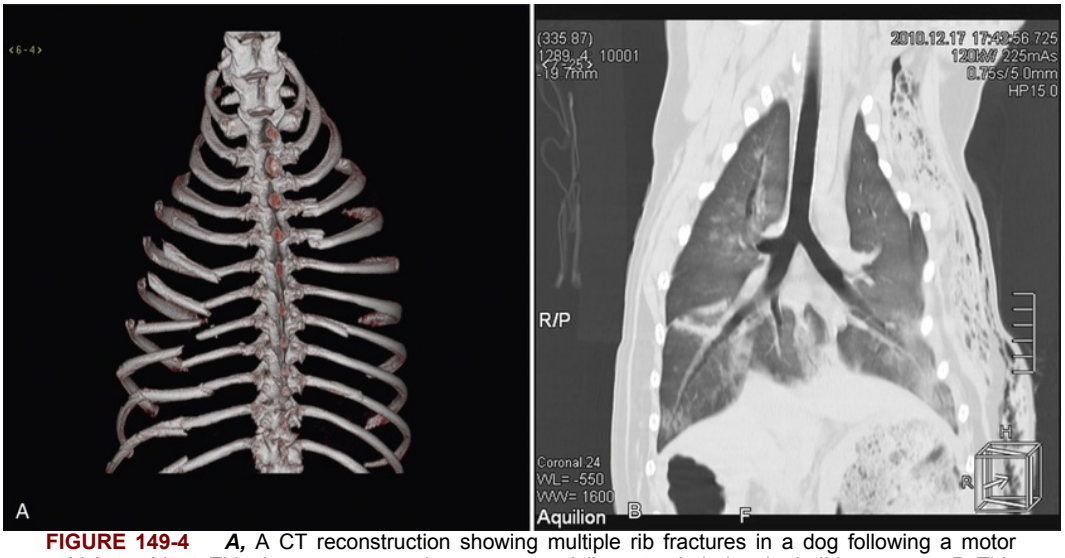

FIGURE 149-4 ***A,*** A CT reconstruction showing multiple rib fractures in a dog following a motor vehicle accident. This dog was run over by an express delivery truck during the holiday season. ***B,*** This image of the same dog shows areas of increased pulmonary opacity consistent with pulmonary contusions.

Diaphragmatic Hernia

Diaphragmatic hernias can also occur in animals with significant thoracic injuries but are less common than sometimes believed. The diagnosis usually is based on thoracic radiographs (Figure 149-5) (see ch. 245). In some cases, it can be hard to visualize on survey radiographs and advanced imaging such as ultrasonography or CT is required (Figure 149-6). The timing of surgery can be important for a successful outcome. Surgery should be undertaken promptly, ideally within 12-24 hours of the injury. In some cases, more urgent surgical repair is required, such as if the stomach is in the thoracic cavity, because the stomach can distend with air

and severely compromise ventilation. If undetected at the time of injury, chronic diaphragmatic hernia can become much harder to repair due to the formation of adhesions within the thoracic cavity.

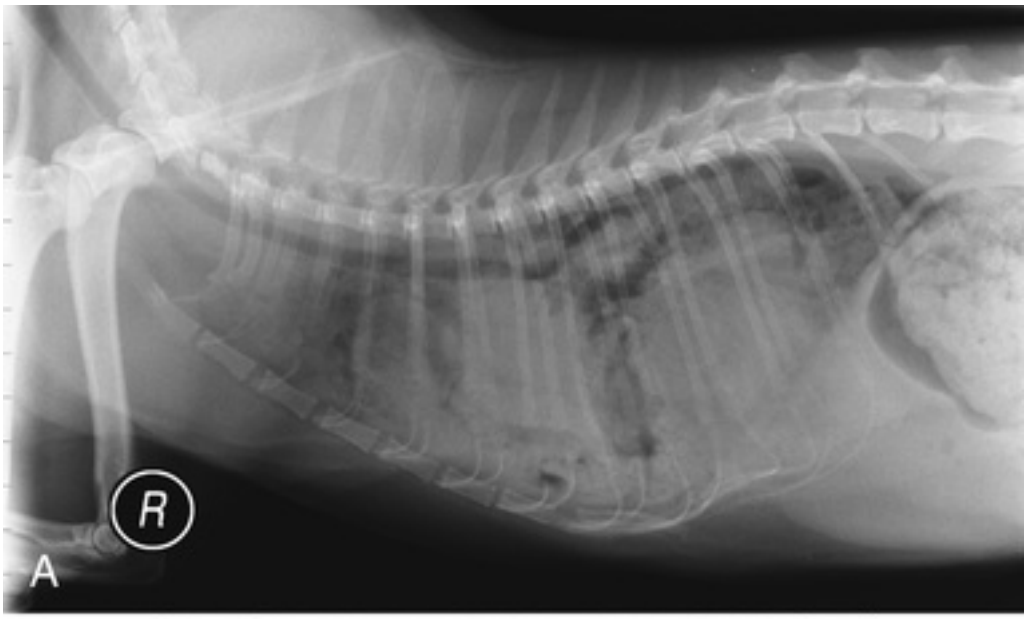

FIGURE 149-5 Lateral **(A)** and ventrodorsal **(B)** radiograph of a cat with a diaphragmatic hernia. Note the presence of bowel loops within the thoracic cavity.

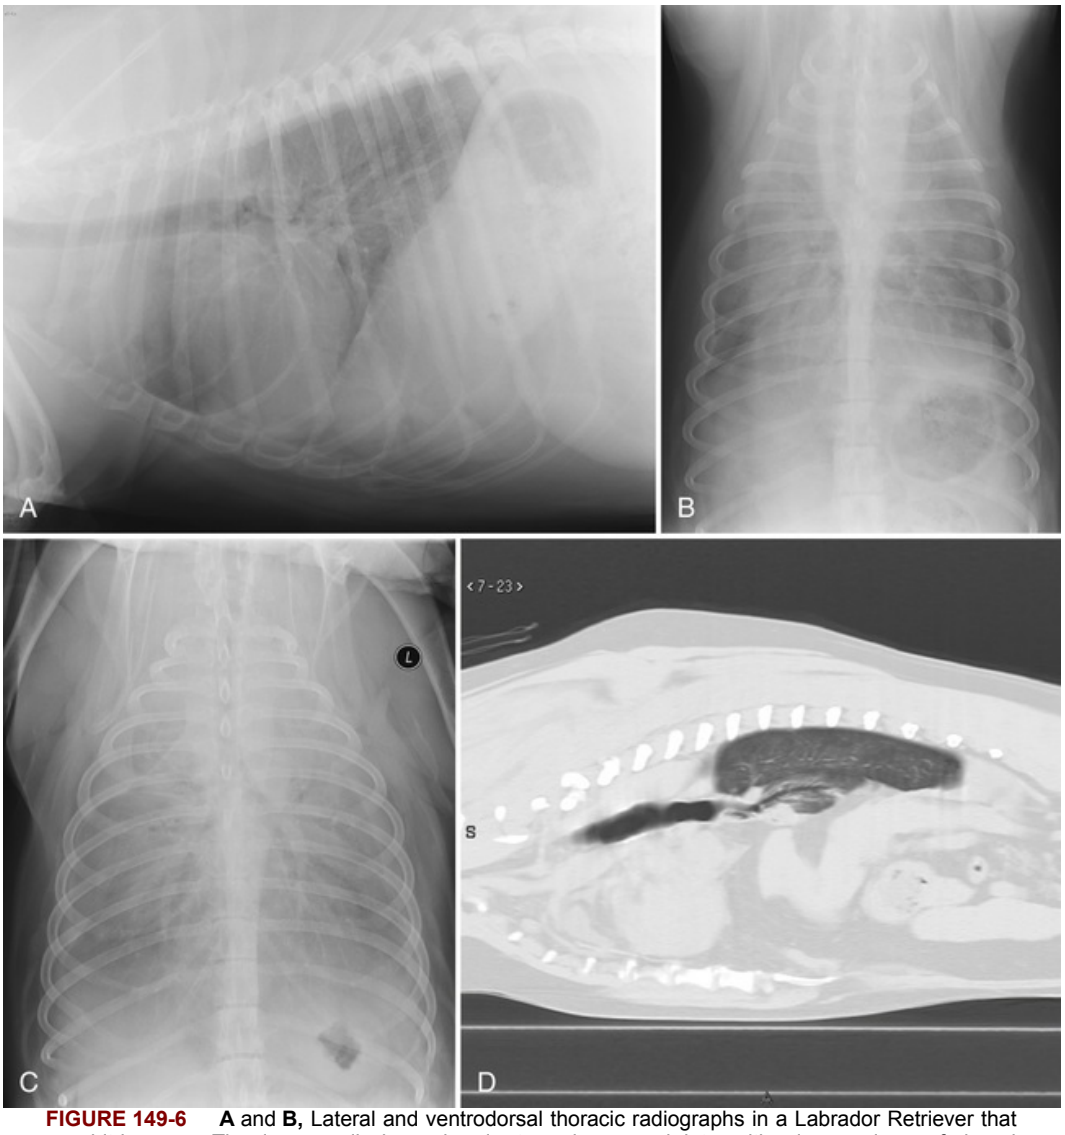

FIGURE 149-6 **A** and **B,** Lateral and ventrodorsal thoracic radiographs in a Labrador Retriever that was hit by a car. The dog was discharged and returned one week later with a large volume of pleural effusion **(C),** and on CT scan, a diaphragmatic hernia was identified **(D).**

In the patient with an acute diaphragmatic hernia, associated injuries can also play a significant role in deciding the time of surgery. Safe anesthetic techniques include rapid intubation and positive pressure ventilation from the time of entry into the abdominal cavity until the integrity of the diaphragm is restored. It can be helpful to tilt the surgery table so the patient's head is raised, to prevent migration of the abdominal contents into the thoracic cavity. As in all trauma patients, all efforts should be made to limit anesthesia and surgery time.

Cardiac Injury

Cardiac arrhythmias are common following trauma in dogs and are generally self-limiting (see ch. 141 and 248). Serum cardiac troponin elevations, consistent with myocardial damage, are common although they are rarely evaluated. Valvular damage or even acquired Gerbode defects have been reported in dogs with blunt trauma.[9,10]

Positive Pressure Ventilation (PPV)

In rare cases, PPV may be used in dogs or cats with pulmonary contusions or flail chest.[11] PPV is useful for eliminating hypoventilation associated with pain or chest wall instability and for improving oxygenation by delivery of positive end-expiratory pressure (PEEP). PEEP will recruit alveolar units, and permit ventilation with lower inspired oxygen concentrations. This can be useful to limit the potential for oxygen toxicosis (see ch. 244). Mechanical ventilation may be considered in patients with evidence of hypoxemia or persistent respiratory distress unresponsive to supplemental oxygen. When mechanically ventilated, dogs with pulmonary contusions, and possibly cats, are prone to the development of ARDS, and consideration should be given for a conservative, low-tidal-volume, low-peak-inspiratory-pressure, moderate-PEEP approach if possible.

Summary

Most dogs and cats with traumatic thoracic injuries recover uneventfully from their injuries with no lasting complications. The standard course is for the patient to look worse for the first 24 hours after presentation and then to make relatively rapid recovery. Successful management includes appropriate identification of injuries and well-timed interventions.

CHAPTER 150

Urinary Tract Trauma

Amy M. Koenigshof

Urinary tract injury is common following trauma and, in veterinary medicine, frequently is caused by vehicular trauma. However, other types of blunt and penetrating trauma also can lead to injury of the urinary tract.[1] Trauma to the urinary tract can range from contusions and hematuria to full-thickness lacerations or avulsions. Delayed identification of urinary tract trauma can increase morbidity and mortality, so careful evaluation of the urinary system following trauma is essential.[1]

Patient Stabilization

Following trauma, patients often present with injuries to more than one body system. A thorough exam should be performed and the most life-threatening injuries identified and treated first (see ch. 147).

Uroperitoneum

Diagnosing Uroperitoneum

The reported incidence of uroperitoneum following trauma is 0.8-39%.[2-7] In particular, patients with pelvic fracture have a higher incidence of urinary trauma (up to 39%).[2] Uroperitoneum can occur from rupture of the bladder due to increased intravesical pressure, laceration from a fracture, or from a penetrating wound.[1,8] Male dogs are thought to be at an increased risk for rupturing the bladder due to increased intravesical pressure because the longer urethra does not allow for rapid expulsion of urine at the time of trauma.[1,9] Disruption of the proximal urethra or avulsion of the distal ureters also can result in uroperitoneum. Avulsion of the proximal ureters or disruption of the renal pelvis results in uroretroperitoneum if the retroperitoneum is intact; however, if it was disrupted during trauma, these injuries also can cause uroperitoneum.

Uroperitoneum should be suspected in patients presenting with a painful abdomen following trauma. In addition, patients presenting with bradycardia 2-3 days after trauma should be carefully evaluated for hyperkalemia from uroperitoneum. The presence of a palpable bladder or observation of freely voided urine does not rule out uroperitoneum.[1,8,10] If uroperitoneum is suspected, several diagnostic imaging techniques can be considered for initial patient evaluation (Figure 150-1). Abdominal radiographs are useful to evaluate a patient for urinary tract trauma. Loss of detail in the peritoneal cavity or retroperitoneum may be indicative of free fluid in the peritoneal cavity or retroperitoneal space. In addition, avulsion of a kidney can be noted radiographically. Visualization of a urinary bladder on radiographs does not confirm an intact bladder or urinary tract.[1]

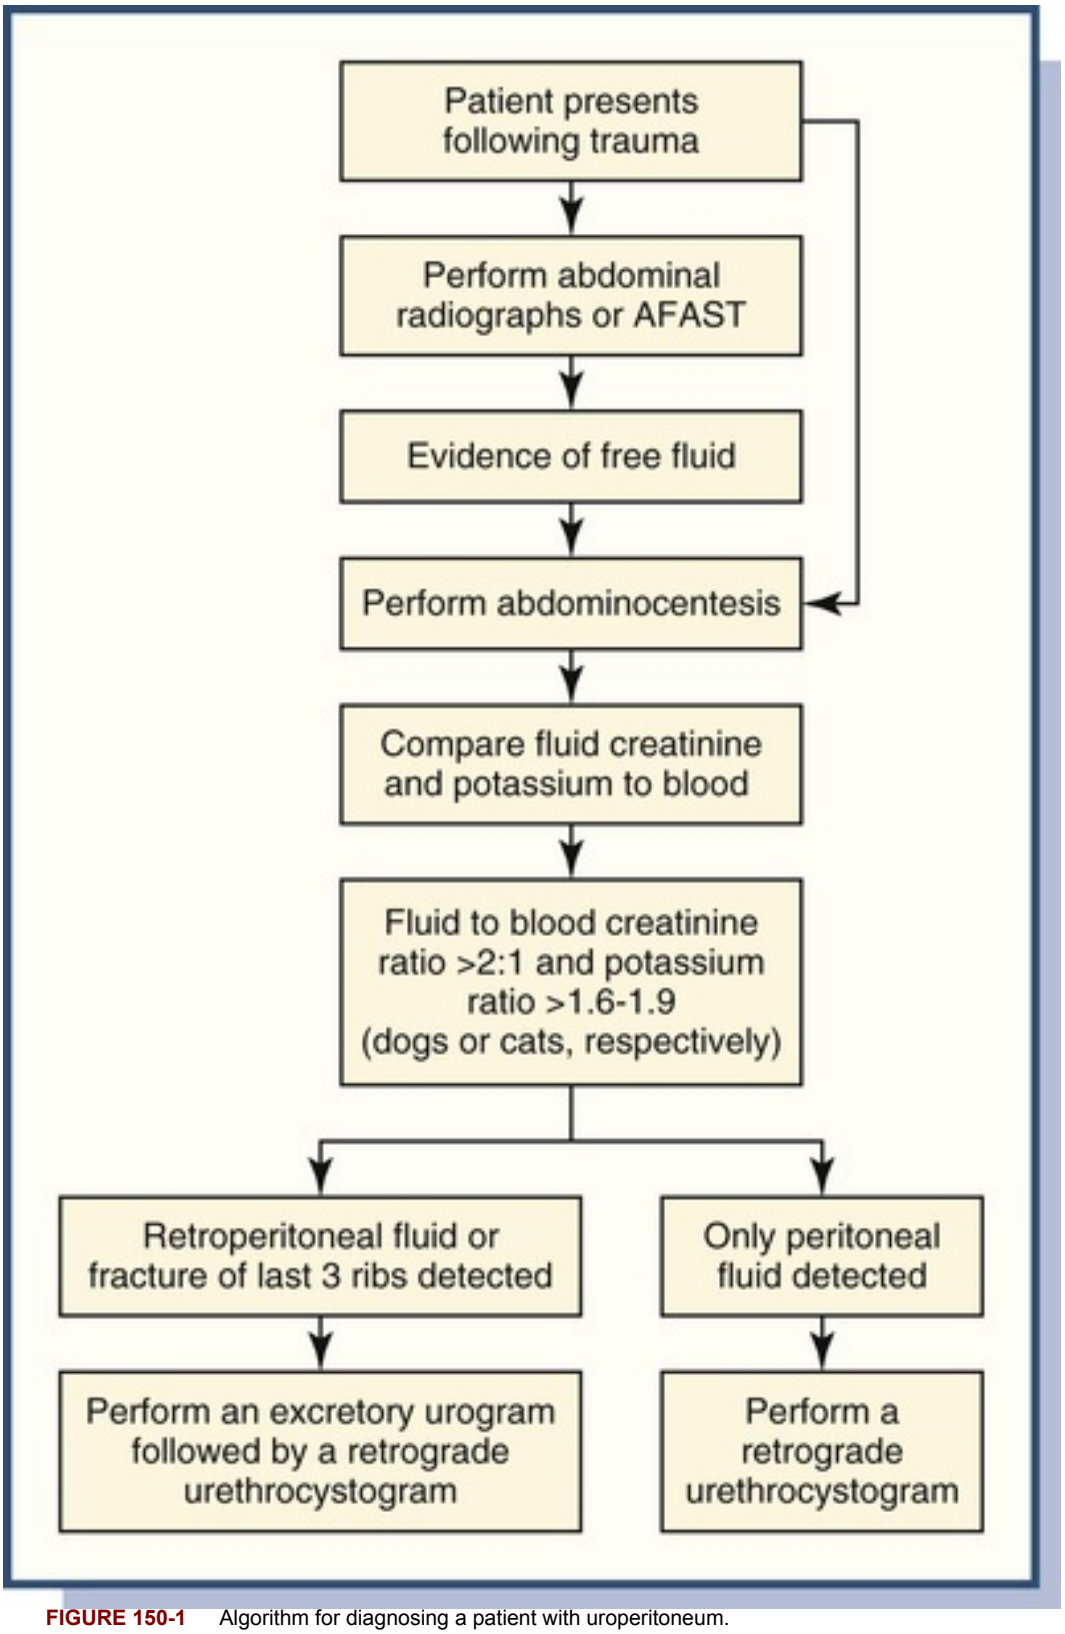

FIGURE 150-1 Algorithm for diagnosing a patient with uroperitoneum.

In addition to radiographs, an abdominal focused assessment with sonography for trauma (AFAST) can be used to identify free fluid in the abdomen or retroperitoneal space (see ch. 143).[5,11] Following the identification of free fluid in the abdomen, ultrasound-guided or blind abdominocentesis can be performed. If ultrasonography is not available, a four quadrant abdominocentesis can be performed to evaluate the patient for free fluid (see ch. 90). Once abdominal effusion has been collected, comparisons between the abdominal

fluid and blood concentrations of creatinine and potassium can be made to help rule in or out uroperitoneum.[8] In cats, abdominal fluid that has at least 1.9 times the concentration of potassium when compared to blood and at least 2 times the concentration of creatinine when compared to blood is consistent with uroperitoneum.[8,12,13] In dogs, abdominal fluid that has at least 1.6 times the concentration of potassium when compared to blood and at least 2 times the concentration of creatinine when compared to blood is consistent with uroperitoneum.[8,12] Urea nitrogen is not as useful for identifying the presence of uroperitoneum because it is a small, non-charged particle that easily moves across membranes.[8]

After confirming the presence of uroperitoneum or uroretroperitoneum, the location of the disruption to the urinary tract should be identified. The most common source of urine leakage is the bladder, followed by the urethra. Ureteral avulsion or rupture of the renal pelvis or parenchyma is uncommon, due to the mobility of the ureters and the protection that the spine, ribs and dorsal body musculature provide to the kidneys.[1] If the patient has uroperitoneum but no evidence of fluid in the retroperitoneal space, a positive contrast retrograde urethrocystogram can be performed to identify the source of the leak. If the patient has either only uroretroperitoneum or fluid in both the peritoneal and retroperitoneal spaces, or if there is fracture of the spine or last 3 ribs, an excretory urogram should be completed first to identify involvement of the kidneys or ureters.[1,8] This should be followed with a positive contrast retrograde urethrocystogram to evaluate for disruption of the urethra or bladder.

Additional Diagnostics for Peritoneal Effusion

Besides measuring creatinine and potassium levels to identify patients with uroperitoneum, additional diagnostics should be considered to further evaluate the fluid.[14] If the fluid is red, a packed cell volume and total protein should be measured to identify concurrent hemorrhage. Cytology should be performed to look for concurrent sepsis, either from a previously existing urinary tract infection or from a concurrent injury (e.g., bowel rupture).[1] Glucose and lactate measurements can also help identify concurrent sepsis. Glucose measurements that are at least 20 mg/dL (1.1 mmol) lower in the abdominal fluid than the blood and lactate measurements that are at least 2 mmol/L higher in the abdominal fluid than in the blood are supportive of, but not diagnostic for, a septic abdomen.[15]

Treatment of Uroperitoneum

Following patient stabilization, the patient's injuries should be prioritized and the most life-threatening injuries should be addressed first. If the patient has significant serum electrolyte derangements from the presence of uroperitoneum, correction of the electrolyte abnormalities should occur prior to anesthesia for any surgical procedures.[16] Life-threatening hyperkalemia leading to bradycardia and electrocardiographic changes such as a prolonged P-R interval, absent P waves, and/or wide bizarre QRS complexes (see ch. 68) should be treated with slow intravenous administration of 10% calcium gluconate (0.5-1.5 mL/kg IV).[1] Administration of crystalloids for volume expansion will help lower potassium concentrations through dilution. Establishing drainage of the urine through temporary placement of a peritoneal drain also can help lower potassium levels (see ch. 90).[8] Peritoneal drainage catheters can be placed using aseptic technique and local anesthesia. Ideally, a dialysis catheter is used for the peritoneal drainage catheter because the presence of multiple fenestrations reduces the chances of obstruction of the catheter. Alternatively, a soft tube drain such as a chest tube (see ch. 100) can be used as a peritoneal drain[17]; additional fenestrations should be created in the tube to reduce the risk of obstruction. A urinary catheter can be placed at the same time to allow drainage of any urine in the bladder (see ch. 105 and 106). If the patient is severely compromised, the peritoneal drainage catheter can be used for peritoneal dialysis until the patient is stable for anesthesia (see ch. 109).[1] Following patient stabilization, treatment is based on the location of urine leakage.

Urinary Bladder Rupture

For patients with urinary bladder rupture, following patient stabilization, an abdominal exploratory laparotomy should be performed and the defect in the bladder identified and corrected.[1,16] Necrotic tissue must be debrided; if a large portion of the bladder needs to be resected, the bladder can be closed over a cystotomy tube.[17]

Urethral Rupture

Many small urethral defects can be managed with placement of a urinary catheter during hospitalization for 7-10 days, while allowing the urethra to heal by second intention.[18,19] A retrograde urethrocystogram should be repeated at this time to ensure the urethra is healed. If a defect is still present, a catheter can be placed again for another 2-3 days followed by repeated imaging. Tears that are close to the bladder or that do not heal by second intention may need to be surgically repaired. Large defects or transection of the urethra requires primary surgical repair.[19]

Ureteral Avulsion or Disruption of the Renal Pelvis

Traumatic ureteral avulsions or disruption of the renal pelvis are uncommon.[10,20] Prompt surgical repair of ureteral avulsions is recommended in human medicine.[1,16] If reimplantation into the bladder or primary repair is not possible (see ch. 124), a ureteronephrectomy could be required.[10]

Subcutaneous Leakage of Urine

Trauma to the distal urethra can result in leakage of urine into the subcutaneous tissue of the hindlimbs and perineal region. This leads to extensive cellulitis and tissue necrosis; fistulas can form if the condition is left untreated.[8] Diagnosis and treatment are the same as described above for urethral trauma leading to uroperitoneum.

Injuries to the Vasculature of the Kidney

Injuries to the vasculature of the kidney can result in life-threatening hemorrhage. Patient stabilization should focus on volume resuscitation and blood transfusions as needed. For patients with ongoing hemorrhage, surgical exploration of the abdomen is warranted and ureteronephrectomy is often performed.[21]

Contusions of the Bladder

The true incidence of bladder contusion is unknown. Hematuria may be the only clinical sign and it may go unnoticed if patients' urinary habits are not closely monitored following trauma.[2] While no treatment is needed specifically for bladder contusions, they should prompt the clinician to look for other more serious concurrent urinary tract injuries.

Herniation of the Bladder

Traumatic body wall defects can lead to herniation of the bladder.[22] These are most commonly caused by bite wounds, and surgical intervention is required.[22] Other rare hernias of the bladder have been described, such as herniation of the bladder through a rectal tear caused by pelvic fractures.[23]

Summary

The prognosis for animals with urinary tract trauma is largely dependent on concurrent injuries.[6] Rapid recognition and treatment of all injuries is key to improving outcome in trauma patients.

CHAPTER 151

Toxin Exposure Therapy/Decontamination

Camille DeClementi

On presentation, all patients exposed to toxicants should be stabilized prior to attempts at administration of antidotal medications (Table 151-1) or patient decontamination.[1] Stabilization refers to correction of life-threatening disorders that can be hemodynamic (e.g., systemic hypotension [see ch. 127 and 159] or cardiac arrhythmias [see ch. 141 and 248]), respiratory (e.g., respiratory distress [see ch. 28, 131, and 139]), neurologic (e.g., seizures [see ch. 35, 136, and 260]), or immunologic (e.g., anaphylaxis [see ch. 137]). Once the patient is stable, decontamination of the patient should then be considered to prevent systemic absorption of the toxicant. The exposure circumstances, such as species involved, time since exposure, chemical nature of the toxicant, and amount ingested, will determine the appropriate method of patient decontamination. The clinician has multiple options for patient decontamination including dilution, induction of emesis, gastric lavage, and the use of adsorbents and cathartics. In many cases, the best treatment plan will include more than one of these methods.

TABLE 151-1

Antidotal Therapies[10,12]

ANTIDOTAL MEDICATION	TOXICANT INDICATIONS	DOSAGE AND COMMENTS
Acepromazine	Amphetamines	• Dog: 0.02-0.1 mg/kg IV, IM, SC. • Can cause hypotension.
Atipamezole (Antisedan)	Amitraz	• Dog: 50 mcg/kg IM. • Reverses the CNS depression, bradycardia, GI stasis, and hyperglycemia associated with amitraz toxicosis. • In cases of ingestion of an amitraz collar, atipamezole may need to be repeated until the collar is removed from the GI tract.
Atropine	Carbamates, organophosphates (OPs)	• Dog/cat: 0.2 mg/kg, ¼ of the dose given IV and the remainder IM or SC. • Used for countering muscarinic effects (SLUDDE: salivation, lacrimation, urinary incontinence, diarrhea, dyspnea, emesis). • For suspected cases, a test dose of 0.02 mg/kg can be given. If this dose results in mydriasis and tachycardia, the patient has NOT been poisoned by a carbamate or OP.
Cyproheptadine (Periactin)	Selective serotonin reuptake inhibitors (SSRIs) 5-hydroxytryptophan (5-HTP) Baclofen	• Dog: 1.1 mg/kg PO or per rectum up to every 8 hours if effective. • Used for countering serotonin syndrome (hyperthermia, tremors, seizures, ataxia, excitation, depression, hyperesthesia, GI distress).
Digoxin immune fab (Digibind)	Digoxin Cardiac glycoside-containing plants *Bufo* toad	• Dog: 1-2 vials slow IV administration (over 30 minutes). • Patient is expected to improve rapidly within 20-90 minutes. • Monitor for hypokalemia and hypersensitivity.

Ethanol	Ethylene glycol	• Details provided in ch. 152: Box 152-2. • Causes severe respiratory and CNS depression, and metabolic acidosis. • In cats, treatment must be started within 3 hours of exposure or prognosis is grave.
Flumazenil (Romazicon)	Benzodiazepines	• Dog/cat: 0.01-0.02 mg/kg IV. • Has a short half-life so may need to be repeated. • Reserved for cases of severe CNS and respiratory depression.
Fomepizole (4MP, 4-methylpyrrazole)	Ethylene glycol	• Dog: initial dose of 20 mg/kg IV, then subsequent doses at 12 and 24 hours with 15 mg/kg and 36 hours with 5 mg/kg. • Cat: initial dose of 125 mg/kg IV, then subsequent doses at 12, 24 and 36 hours with 31.25 mg/kg. May cause CNS depression. • In cats, treatment must be started within 3 hours of exposure or prognosis is grave.
Intralipid emulsion (ILE)	Bupivacaine Verapamil Propranolol Clomipramine Lidocaine Moxidectin	• Dog/cat: using a 20% solution, initial bolus of 1.5 mL/kg slowly IV, then CRI of 0.25 mL/kg/min IV for 30-60 minutes. • Can be useful in intoxications with other lipid-soluble toxicants including ivermectin, cholecalciferol, amlodipine, baclofen, diltiazem, marijuana, permethrin, bupropion, trazodone, barbiturates, and tricyclic antidepressants.
Methocarbamol (Robaxin)	Permethrin Metaldehyde Strychnine Tremorgenic mycotoxins	• Dog/cat: 55-220 mg/kg slow IV or PO. Total dosage should not exceed 330 mg/kg/day. • Can be useful in other intoxications causing severe tremors.
Naloxone (Narcan)	Opioids	• Dog: 0.04 mg/kg IV, IM, SC. • Cat: 0.02-0.04 mg/kg IV. • Used for reversing respiratory and CNS depression. Does not reverse GI effects.
N-acetylcysteine (NAC)	Acetaminophen	• Dog/cat: use a 5% solution; loading dose of 140 mg/kg PO or IV, then 70 mg/kg PO or IV every 6 hours for 7 treatments. • Can cause oral mucosal ulceration if not diluted to 5% solution.
Pamidronate (Aredia)	Cholecalciferol (vitamin D_3) Vitamin D_3 analogs Calcipotriene (Dovonex)	• Dog: 1.3-2 mg/kg slow IV. • Should not mix with calcium-containing IV fluids. • Most effective if given within 24-36 hours of exposure.
Pralidoxime (2-PAM)	Organophosphates (OPs)	• Dog/cat: 20 mg/kg q 8-12 h. Initial dose IM or slow IV. Subsequent doses given IM or SC. • Used for countering nicotinic effects (tremors, muscle weakness). • Works best when used in combination with atropine.
Vitamin K_1	Anticoagulant rodenticides Warfarin	• Dog/cat: 1.5-2.5 mg/kg PO q 12 h. • Oral route preferred. • Should be given with a fatty meal to enhance absorption.
Yohimbine (Yobine)	Amitraz	• Dog: 0.1 mg/kg IV. • Has a short half-life so may need to be repeated.

CNS, Central nervous system; *CRI*, constant rate infusion; *GI*, gastrointestinal; *IM*, intramuscular; *IV*, intravenous; *PO*, per os.

Dilution using a small amount of water or milk is recommended in cases where the patient has ingested an irritant or corrosive material. A dosage of 2-6 mL/kg is suggested, which for an average-sized cat, would be approximately only 1-2 teaspoons.[1] Giving only a small amount is important, since using excessive amounts could lead to vomiting and re-exposure of the esophagus to the damaging material.[2] Dilution is not appropriate in patients who are at an increased risk for aspiration, including those who are actively seizuring or obtunded.[2] Dilution with dairy products, such as milk, yogurt, and cottage cheese, has been useful in cases of oral irritation following ingestion of plants containing insoluble calcium oxalate crystals (e.g., *Philodendron* species).[3]

Emetics generally empty 40-60% of the stomach contents and are usually most effective if used within 2-3

hours after ingestion of a toxicant.[2,4] If the substance ingested could coalesce to form a bezoar in the stomach, emesis can be effective later than 3 hours after the ingestion. Chocolate and chewable medications are examples of products which may form bezoars.[5] Feeding a small moist meal before inducing vomiting can increase the likelihood of adequate emesis (Video 151-1).

Induction of emesis is *contraindicated* with ingestion of corrosive agents including alkalis and acids, due to the risk of caustic effects on the esophageal and oral mucosa. Emesis is also not recommended after petroleum distillate ingestion due to the risk of aspiration.

The clinician must take into account, when deciding whether to induce emesis, any pre-existing conditions of the patient that can cause vomiting to be hazardous; these include severe cardiac disease (risk of vagally-mediated syncope) or seizure disorder (risk of aspiration). In all instances, the attending veterinarian must carefully weigh the benefits of emesis against the risks. Emesis may not be needed if the animal has already vomited, and it is not appropriate if the animal is already exhibiting clinical signs such as coma, seizures, or recumbency, which make emesis hazardous. Additionally, if the patient has ingested a stimulant and is already agitated, the additional stimulation of vomiting could lead to seizures.[2]

Hydrogen peroxide (3% concentration), apomorphine hydrochloride, and xylazine hydrochloride are commonly used emetics in the veterinary clinical setting. Data from the ASPCA Animal Poison Control Center (APCC) toxicology database indicate that 3% hydrogen peroxide and apomorphine are effective emetics in dogs. Induction of emesis, with either hydrogen peroxide (2.2 mL/kg PO once; can repeat once) or apomorphine (0.03 mg/kg IV; or 0.04 mg/kg IM [least preferred]; or ¼ to ½ tablet crushed and dissolved with a few drops of saline in a syringe [without a needle] and instilled in the conjunctival sac, then rinsed free with saline after vomiting has occurred) was successful in 92% of dogs. Hydrogen peroxide can be repeated if vomiting does not occur within 20 minutes. No significant adverse effects were reported in dogs after such use.[6] Apomorphine is poorly effective as an emetic in cats and using it in cats is controversial. Xylazine (0.44 mg/kg IM [can reverse with yohimbine 0.1 mg/kg slow IV after vomiting is complete]) is an effective emetic in only 42% of cats.[7] Some clinicians are also using dexmedetomidine (40 mcg/kg IM, reversed with 0.4 mg/kg atipamezole IM after vomiting is complete) as an emetic in cats.[7]

Gastric lavage can be considered in cases where emesis is contraindicated, is not possible, or has been unsuccessful (see ch. 112).

Adsorbents may be utilized instead of, or in addition to, emetics and gastric lavage, to prevent systemic absorption of a toxicant. These agents act by adsorbing to a toxicant in the gastrointestinal (GI) tract and facilitating its excretion in the feces.[2] Activated charcoal is the most commonly used adsorbent. In asymptomatic patients, activated charcoal can be given with an oral dosing syringe, or can be offered to the patient in a bowl mixed with a small amount of canned food or chicken broth. In symptomatic patients, activated charcoal is administered via an orogastric tube while the patient is under general anesthesia (see ch. 112).

Repeated doses of activated charcoal should be considered if the ingested toxicant is known to undergo enterohepatic recirculation. In enterohepatic recirculation, the toxicant is carried to the liver by the portal circulation after absorption from the GI tract. Once in the liver, the toxicant enters the bile and is excreted into the GI tract where it is again available for absorption. Examples of toxicants known to undergo this type of recycling include most nonsteroidal anti-inflammatory drugs, marijuana, and digoxin. When repeated doses are indicated, half the original dosage should be given at 4- to 8-hour intervals.[8]

Administration of activated charcoal does carry some risks and it does not bind all compounds equally. Some chemicals that are not bound effectively include alcohols, fertilizers, petroleum distillates, most heavy metals, iodides, nitrates, nitrites, sodium chloride, and chlorate. Activated charcoal should not be given to animals that have ingested caustic materials since it is unlikely to bind these materials, can be additionally irritating to the mucosal surfaces, and can make visualization of oral and esophageal burns difficult.[9]

Activated charcoal administration carries a substantial risk of aspiration. The prognosis is poor for a patient that aspirates activated charcoal; therefore, proper placement of a stomach tube and a protected airway are required in symptomatic patients. Constipation can occur and black bowel movements are expected, making it difficult to determine if melena is present. If the activated charcoal resides within the GI tract for an extended period of time, it can release the toxicant. It is for this reason that activated charcoal is frequently administered with a cathartic. Many commercially-available preparations contain a cathartic like sorbitol.

Hypernatremia is another possible adverse effect of activated charcoal administration. The mechanism for hypernatremia is attributed to a water shift from the intracellular and extracellular spaces into the GI tract as

a result of the osmotic pull of the activated charcoal product.[7] The APCC has received reports of high serum sodium concentrations following activated charcoal administration in dogs. Hypernatremia appears to be reported more often in small dogs receiving multiple doses of activated charcoal, but it has also been reported in large dogs and in cases receiving only a single dose. Furthermore, unlike human case reports, high serum sodium concentrations also have been noted in cases where no cathartic was present in the charcoal.[10] With activated charcoal–associated hypernatremia, the APCC has found that administration of a warm water enema is effective at lowering the serum sodium and controlling the resultant central nervous system (CNS) effects.[10]

Cathartics enhance elimination of substances, including administered activated charcoal, by promoting their movement through the GI tract. Activated charcoal only binds to toxicants by weak chemical forces, so without cathartics, the bound toxicant can eventually be released and reabsorbed.[2] When used with activated charcoal, the cathartic is given immediately following, or mixed with, the charcoal. Cathartics are *contraindicated* if the animal is dehydrated, has diarrhea, if ileus is present, or if intestinal obstruction or perforation is possible.[8]

There are bulk, osmotic, and lubricant cathartics. The most commonly used bulk cathartic is psyllium hydrophilic mucilloid (e.g., Metamucil). Another bulking cathartic that can be used in dogs and cats is unspiced canned pumpkin. Osmotic cathartics have limited absorption from the GI tract so they are able to draw water into the GI lumen, thereby increasing the fluid volume and stimulating motility to hasten expulsion in the feces. Sorbitol is the most commonly used osmotic cathartic; it is the cathartic of choice and frequently is combined with activated charcoal in commercially prepared charcoal products. Of the lubricant cathartics, mineral oil is the most often used. Mineral oil is not recommended following activated charcoal administration as the mineral oil can render the charcoal less effective.[9,11] Since all cathartics alter the water balance in the GI tract, serum electrolyte abnormalities, especially hypernatremia, are a potential risk when using them. Hydration status should be monitored frequently and fluids administered, intravenously or via an enema, as needed.

CHAPTER 152

Chemical Toxicoses

Justine A. Lee

According to the ASPCA Animal Poison Control Center (APCC), approximately 150,000 animals are exposed to a variety of toxicants in the United States each year. Approximately 40% of the calls to the ASPCA APCC[a] comprise exposures to human and veterinary medications, with the remaining exposures occurring secondary to a variety of toxic foods, insecticides, rodenticides, plants, household products, herbicides, cleaning products, lawn and garden products, and miscellaneous toxicants. Ch. 13 presents ways of differentiating intoxications from nontoxicologic illness when a history is lacking. In this chapter, a review of some of the most common—or most deadly—chemical toxicants will be discussed.

Rodenticides

One of the top 10 toxicants affecting dogs are rodenticides. Due to U.S. Environmental Protection Agency (EPA) regulations that were mandated in 2011, second-generation anticoagulant rodenticides (ACR) such as brodifacoum and bromadiolone are being removed from the U.S. market. As a result, antidotal therapy (e.g., vitamin K_1) will be less frequently required; instead, the use of non-anticoagulant rodenticides, notably bromethalin and cholecalciferol, have become more prominent as active ingredients.

Bromethalin

Bromethalin, a neurotoxic rodenticide, works by uncoupling oxidative phosphorylation in the brain and liver mitochondria.[1] This results in decreased adenosine triphosphate (ATP) production, which affects cellular sodium and potassium pumps; as a result, lipid peroxidation occurs, resulting in sodium accumulation within the cell.[1] Edema of the central nervous system (CNS) can result.[1] Bromethalin is *not* an anticoagulant rodenticide and should *not* be treated with vitamin K_1 as an antidote. It is sold under several popular brand names: Assault, Tomcat Mole Killer, Talpirid, Real Kill, Clout, Fastrac, Vengeance, etc.

Bromethalin has a narrow margin of safety. In dogs, the LD_{50} of bromethalin is 2.38-3.65 mg/kg, with a minimum lethal dosage being 2.5 mg/kg (corresponding to 120 grams [4 ounces] of typical 0.01% bait consumed by a 5 kg dog).[1] A typical, otherwise healthy 5 kg dog would only need to ingest approximately 12 grams (or 0.4 ounces) to develop clinical signs. Cats are more sensitive to the effects of bromethalin, and the LD_{50} is markedly lower (0.54 mg/kg).[1] Clinical signs are dosage-dependent, and the onset of clinical signs depends on the amount ingested. Typically, with acute ingestion, signs can be seen within 2-24 hours.[1] Clinical signs of CNS stimulation or depression, abnormal behavior, ataxia, hyperesthesia, seizures, and coma can be seen.[1] Other common signs include paresis, hindlimb paralysis, anisocoria, nystagmus, changes in the pupillary light reflex, and tremors.[1] Treatment includes early decontamination of the patient, prevention of cerebral edema, and supportive care. With recent ingestion in an asymptomatic patient, the use of appropriate decontamination (e.g., emesis induction, gastric lavage [Video 152-1], activated charcoal; see ch. 151) is warranted. As bromethalin undergoes enterohepatic recirculation, the use of multiple oral doses of activated charcoal (without a cathartic) is recommended (e.g., q 6 h for 24 h). Patients should be monitored for signs of neurotoxicosis. The use of intravenous (IV) fluid therapy (see ch. 129), oxygen support (see ch. 131), head elevation in recumbent patients, mannitol (to decrease cerebral edema; see ch. 148), anticonvulsant therapy (see ch. 35 and 136), and thermoregulation is warranted, as needed. The use of corticosteroids to decrease intracranial pressure is no longer recommended; rather, mannitol is preferred. With bromethalin toxicosis, the prognosis varies depending on the amount ingested and the severity of clinical signs. In general, the prognosis is fair to excellent with appropriate decontamination of the patient and treatment *prior* to

development of clinical signs. With persistent seizures or paralytic syndrome, the prognosis is poorer.

Phosphides

Phosphide rodenticides result in the production of phosphine gas. When zinc phosphide combines with gastric acid or moisture (or the presence of food), liberated phosphine gas is absorbed rapidly across the gastric mucosa and is distributed systemically, where it exerts its toxic effect. Phosphine gas is considered a corrosive and a direct irritant to the gastrointestinal (GI) tract. While this rodenticide has not grown in popularity compared to others (e.g., ACR, bromethalin, etc.), veterinarians must be aware of this rodenticide as it carries a public health risk to pet owners and veterinary staff.

Phosphide rodenticides have been used since the 1930s and are still available on the market.[3] Aluminum phosphide, a pelleted product, is used as a fumigant in grain storage. Zinc phosphide, which is more readily used, is labeled to kill mice, rats, squirrels, voles, nutria, muskrats, gophers and other vermin.[3] Zinc phosphide is available as a 2-10% concentration, and comes as powder, paste, pellet or tablet formulations.[3] Commercially available zinc phosphide products are sold under popular names such as Sweeney's Poison Peanut Mole, Gopha-Rid, Zinc-Tox, ZP, Arrex, Gopha-Rid, Gopher Bait II, etc.[2] Formulations of phosphides have a malodorous, unique odor similar to rotten garlic, fish or acetylene.[2]

The toxic dosage of zinc phosphide in dogs is approximately 20-40 mg/kg, but up to 300 mg/kg on empty stomachs.[3] In a patient suspected of zinc phosphide toxicosis, the administration of food (e.g., bread, milk, etc.) is contraindicated, as it triggers gastric acid secretion, promoting hydrolysis and further production of phosphine gas.[3] With zinc phosphide toxicosis, clinical signs can be seen within 15 minutes to 4 hours of ingestion; while rare, death has been reported within 3-48 hours.[3] Clinical signs include severe GI (e.g., vomiting, bloat, abdominal pain, hematemesis, melena), CNS (e.g., tremor, seizures, death), and rarely, cardiopulmonary signs (e.g., pulmonary edema, tachypnea, pleural effusion) or other organ dysfunction.[3]

Zinc phosphide carries a public health risk. Emesis—whether intentionally induced or occurring due to clinical signs—can result in secondary exposure of phosphine gas to the pet owner or the veterinary professional. In humans, clinical signs of nausea and difficulty breathing have been reported. To minimize these risks, emesis induction should always be performed in a well-ventilated area (e.g., opening the car window if the patient vomits or inducing emesis outside). Pet owners should be appropriately educated on the risks of toxic gas exposure to themselves. Pet owners should be informed *not* to feed their pet to prevent further production of phosphine gas. In addition, the administration of an antacid (e.g., aluminum hydroxide, milk of magnesia) prior to emesis induction or veterinary attention can help decrease the production of phosphine gas. With recent ingestion in an asymptomatic patient, the use of emesis induction (following antacid administration) and one dose of activated charcoal with a cathartic is warranted to minimize toxic effects of zinc phosphide. Supportive care, including antiemetic therapy, IV fluid therapy, and gastric protectants, is warranted. With treatment, the prognosis is excellent with supportive care.[2]

Cholecalciferol

Cholecalciferol, the chemical name for vitamin D_3, is one of the most deadly rodenticides to pets. Ingestion of toxic levels of cholecalciferol can result in severe hypercalcemia and hyperphosphatemia, with secondary acute kidney injury (AKI) developing from dystrophic mineralization of soft tissue, especially the kidneys (see ch. 322). Other common sources of vitamin D_3 include over-the-counter (OTC) or prescription vitamins (typically found in a calcium/vitamin D_3 combination) and psoriasis creams (in the form of calcipotriene). Cholecalciferol-containing rodenticides have a very narrow margin of safety, and only a minute amount of rodenticide needs to be ingested before clinical toxicosis occurs. In dogs, the LD_{50} is 85 mg/kg (based on the rodenticide concentration of 0.075%)[4]; however, dosages as low as >0.1-0.5 mg/kg can result in clinical signs and hypercalcemia, respectively (i.e., a 30 kg dog would only need to ingest approximately 1 ounce [30 grams] to develop clinical signs of toxicosis).[4]

Typically, clinical signs of toxicosis do not develop for 1-3 days, until the patient has already developed overt manifestations of AKI.[4] Azotemia can develop as early as 12-36 hours following toxic ingestion. Clinical signs and clinicopathologic findings (see ch. 69) include polyuria and polydipsia, weakness, lethargy, anorexia, vomiting, generalized malaise, uremic halitosis, dehydration, hypercalcemia, hyperphosphatemia, azotemia, melena, hemorrhagic diarrhea, weight loss, and death.[4]

With cholecalciferol toxicosis, intensive treatment is imperative due to the narrow margin of safety. Treatment should include thorough decontamination (e.g., emesis induction, gastric lavage, charcoal administration; see ch. 112 and 151). As cholecalciferol undergoes enterohepatic recirculation, the administration of multiple oral doses of activated charcoal (without a cathartic) is warranted (e.g., q 6 h × 24 h). Additional treatment includes the aggressive use of IV 0.9% saline fluid diuresis to promote calciuresis, serum calcium concentration monitoring, GI support (e.g., antiemetics, H2 blockers, sucralfate, phosphate binders, etc.), and the use of medications to increase calciuresis (e.g., prednisone, furosemide) and prevent hypercalcemia (e.g., pamidronate, calcitonin). Treatment often is expensive, and requires hospitalization for an extended period of time (e.g., 2-7 days). In hypercalcemic patients, oral therapy (e.g., furosemide, prednisone) often needs to be continued for several weeks following discharge from the hospital. Frequent monitoring of renal parameters and electrolytes is imperative. Serum calcium, phosphorus, blood urea nitrogen, creatinine, and ionized calcium should be evaluated every 12-24 hours during hospitalization, and then every 2-3 days thereafter for the next 2-4 weeks. This will allow the clinician to titrate drug therapy judiciously, and to ensure that the patient does not continue to develop hypercalcemia or azotemia. Even with intensive decontamination and therapy, chronic kidney disease (CKD) can be a secondary sequela. The prognosis for this rodenticide is poor once clinical signs and azotemia develop due to the risk of CKD.

Anticoagulants

First- and second-generation ACR inhibit vitamin K epoxide reductase, resulting in inactivation of clotting factors II, VII, IX, and X. First-generation rodenticides (e.g., warfarin, pindone)[5] initially were replaced by more potent, longer-lasting second-generation ACR (e.g., brodifacoum, bromadiolone, diphacinone, chlorophacinone, etc.).[5] However, the removal of second-generation ACR from the U.S. market was mandated by the U.S. EPA in 2011. While this will take several years to enact, veterinarians will be seeing fewer ACR cases as a result.

It is important to note that the margin of safety and LD_{50} vary between each ACR; some have very narrow margins of safety (e.g., brodifacoum), while some have very wide margins of safety (e.g., bromadiolone). When in doubt, the toxic dosage should be calculated, or the rodenticide company directly contacted (which offer a free, 24/7 medical support line for assistance) to determine if a toxic dose has been ingested. Likewise, the ASPCA APCC can be consulted for life-saving assistance. Finally, it is worth keeping in mind that species differences exist; cats are much more resistant to the effects of ACR compared to dogs, and rarely develop toxicosis from ACR.

	CANINE[5] LD_{50}	FELINE[5] LD_{50}
Difethialone:	4 mg/kg	>16 mg/kg
Brodifacoum:	0.25-2.5 mg/kg	25 mg/kg
Bromadiolone:	11-20 mg/kg	>25 mg/kg
Diphacinone:	3-7.5 mg/kg	>15 mg/kg

When a toxic ingestion of ACR has occurred, prolongation in coagulation factors (prothrombin [PT] or activated partial thromboplastin time [aPTT]) is not observed or measurable for 36-48 hours, based on the half-life of factor VII. Clinical signs typically do not develop for 3-5 days. Clinical signs are due to clotting factor depletion, resulting in generalized hemorrhage secondary to hypocoaguability. The most common clinical signs include lethargy, exercise intolerance, inappetence, pallor, dyspnea, coughing, and hemoptysis. Hemoabdomen, hemothorax, and pericardial effusion also can occur. Rarer clinical signs include gingival bleeding, epistaxis, ecchymoses, petechiae, hematuria, bleeding into the subcutaneous space or joint space, or melena.[5]

Optimal management depends on clinician preference and on the pet owner's commitment to follow up. Ideally, with recent ingestion, the patient should be decontaminated, if appropriate, and have a baseline PT measured at 36-48 hours post-ingestion. If PT is prolonged at that time, initiation of vitamin K_1 2.5-5 mg/kg PO q 24h for 7 (first generation) to 30 (second generation) days is warranted, with rechecking of PT 2-3 days after discontinuation of vitamin K_1. When client compliance is of concern, routine administration of vitamin K_1 therapy for 30 days is warranted. For patients with clinical bleeding or coagulopathy, treatment should include vitamin K_1 therapy; plasma transfusions; intensive care; oxygen therapy; and monitoring of PT 2-3

days after discontinuation of therapy with vitamin K_1.

Veterinary professionals often make errors when it comes to the medical management of ACR intoxication cases. While it is often appropriate to decontaminate a patient with emesis induction and activated charcoal administration, with non-toxic ingestions (based on the LD_{10}), this is often unnecessary (unless the patient is neonatal, geriatric, has an underlying hepatopathy, or has previously ingested an ACR). Also, the administration of a "one-time," parenteral injection of vitamin K_1 at the time of decontamination is unnecessary and potentially detrimental. As factor VII has the shortest half-life, PT will be the first blood test to be prolonged with ACR ingestion, 36-48 hours post-ingestion. Testing *prior* to this time is typically unnecessary (unless the patient has been chronically ingesting an ACR over several days). By administering a "one-time shot" of vitamin K_1, the clinician can cause the patient's PT to be briefly normal at 36-48 hours, followed by coagulopathy and clinical bleeding days later (3-5 days, instead of 2 days).

Insecticides

Certain insecticides carry a wide margin of safety (e.g., pyrethrins, pyrethroids), while those with a narrower margin of safety (e.g., carbamates, organophosphates) have been predominantly removed from the market due to the severity of clinical signs seen with accidental or intentional poisonings.

Pyrethrins and Pyrethroids

Pyrethrins and their synthetic derivative, pyrethroids, commonly are found in household insect sprays and insecticides (e.g., permethrin, cypermethrin, cyphenothrin, etc.). Due to cats' altered liver glucuronidation metabolism, they are markedly more sensitive to pyrethrins than are dogs. While a precise toxic dosage for cats is not well established, products containing >5-10% concentration of pyrethrins can lead to systemic toxicosis. Products such as household insect sprays, topical flea sprays, and shampoos typically contain <1% of pyrethrins; toxicosis due to exposure to these diluted products is unlikely. However, higher concentration products such as canine spot-on pyrethrin/pyrethroid-based insecticides (which typically contain a 40-60% pyrethrin concentration) are extremely toxic to cats. Clinical signs of pyrethrin toxicosis in cats include GI (e.g., hypersalivation, vomiting, nausea), CNS (e.g., disorientation, weakness, hyperexcitability, tremors, seizures) and respiratory signs (e.g., tachypnea, dyspnea).[6]

Treatment in cats with systemic signs of pyrethrin toxicosis include dermal decontamination with a liquid, degreasing dish soap (e.g., Dawn, Palmolive) once the patient has been stabilized. Tremors should be treated with parenterally administered methocarbamol (e.g., 22-220 mg/kg, IV PRN to effect), a centrally acting muscle relaxant.[6] While oral or rectal methocarbamol administration can be considered, it has a very slow onset of action via these routes. Tremors generally are less responsive to benzodiazepines (e.g., diazepam) compared to methocarbamol. Seizures can be controlled with anticonvulsants or general gas anesthesia (see ch. 136). Supportive care including fluid therapy, thermoregulation, and blood glucose monitoring are imperative. Signs can persist for 1-3 days, depending on the patient.[6] The prognosis is excellent with intensive dermal decontamination and treatment.

In dogs, systemic toxicosis or allergic sensitivity is rare; rather, clinical signs of paresthesia can be seen at the area of application. Paresthesia, which is characterized by a stinging or tingling sensation to the skin, can cause secondary pruritus or trauma to the site. The use of dermal decontamination and topical vitamin E ointment are recommended; antihistamines and corticosteroids generally are not of benefit.

Carbamates and Organophosphates

The use of carbamates and organophosphates (OPs) as insecticides has fallen out of favor, due to the narrow margin of safety and severity of clinical signs with intoxications. The EPA has removed many of the more dangerous insecticides from the market, such that pyrethrins and pyrethroids have grown in popularity concomitantly. However, some older products (particularly rose or plant fertilizer/insecticide combination products) may still contain dangerous carbamates or OPs. Carbamates and OPs competitively inhibit acetylcholinesterase and pseudocholinesterase, resulting in excess acetylcholine accumulation and hence, clinical "SLUDGE" signs (e.g., salivation, lacrimation, urination, defecation, GI upset, emesis).[6]

Different carbamate and OP preparations can have varying levels of toxicity, depending on the active ingredient. Clinical signs include severe GI (e.g., hypersalivation, vomiting, diarrhea), cardiovascular (e.g., tachycardia, bradycardia, pallor, shock), CNS (e.g., agitation, sedation, mydriasis or miosis, tremors, seizures,

coma), and respiratory signs (e.g., tachypnea, dyspnea, cyanosis—secondary to voluminous bronchial secretions or secondary aspiration pneumonia). Intensive decontamination (e.g., gastric lavage with an inflated endotracheal tube in place [see Video 152-1; ch. 112], administration of activated charcoal with a cathartic), IV fluid therapy, antiemetics (e.g., maropitant), muscle relaxants (e.g., methocarbamol), anticonvulsants (e.g., phenobarbital, diazepam, levetiracetam), thermoregulation, electrocardiogram and blood pressure monitoring, and supportive care are indicated. Most importantly, proactive use of the antidotes atropine or 2-PAM (which is rarely available) is warranted (see ch. 151).[6] The anticholinergic effect of atropine counters the direct clinical signs of this toxicosis, and typically high dosages are warranted (e.g., 0.1-0.5 mg/kg, IV, IM PRN).

Household Products

Many household products are ingested accidentally by dogs and less commonly, by cats (Box 152-1). In general, the prognosis for household product toxicosis is good to excellent with appropriate decontamination of the patient and supportive care.

Box 152-1

Common Household Products Affecting Dogs and Cats

Alpha Lipoic Acid (ALA)

Commonly used as a human supplement for diabetes mellitus. Narrow margin of safety in dogs and cats; cats are thought to be more sensitive. Toxic dosage warranting decontamination: >5 mg/kg (cats), >50 mg/kg (dogs). Clinical signs: GI (e.g., hypersalivation, vomiting), CNS (e.g., ataxia, tremors, seizures, etc.), AKI and hepatotoxicosis can be seen. Treatment includes dextrose supplementation, blood glucose monitoring, fluid therapy, antiemetics, anticonvulsants, hepatoprotectants (e.g., SAMe, n-acetylcysteine, etc.).

Silica Gel Packs

Rarely result in toxicosis due to wide margin of safety. Rare risk of constipation or foreign body obstruction with massive ingestions in small-size patients.

Food Oxidizer Packs (Commonly Found in Food Product Bags or Containers)

Rarely result in toxicosis. These packages contain iron, where the powder is often black or brown in color and magnetized. Rare risks of iron toxicosis if ingestion by small-size patients. Treatment for iron toxicosis includes antacid therapy (e.g., milk of magnesia), supportive care, monitoring blood iron levels, and potentially chelation (in severe cases). Activated charcoal is not warranted (does not bind reliably to heavy metals).

Amitraz

A formamidine pesticide found in tick collars. Amitraz is a monoamine oxidase inhibitor and an alpha-adrenergic agonist. Toxicosis occurs when the collar is accidentally ingested, resulting in GI absorption. Lethal dosage is 100 mg/kg (dogs, PO), although toxic doses as low as 10-20 mg/kg have been reported. Clinical signs include CNS (e.g., ataxia, sedation, mydriasis, hypothermia, coma), cardiac (e.g., bradycardia, tachycardia), and GI (e.g., vomiting, diarrhea) signs. Treatment includes appropriate decontamination of the patient, removal of the collar from the GI tract (e.g., via endoscopy), alpha-2-antagonists (e.g., yohimbine or atipamezole), and supportive care.

Insect Bait Stations

Typically contain abamectin, hydramethylnon, or fipronil. Rarely toxic due to low-concentration of active ingredients. Rarely, plastic container can result in foreign body obstruction. Treatment is rarely indicated unless the dog has the ABCB1 gene mutation (MDR-1 polymorphism).

Batteries

Several types of batteries: acid dry cell, alkaline dry cell, disk-shaped, lithium. Corrosive injury or current-induced injury potentially can result in GI perforation. Clinical signs of dysphagia, anorexia, tachypnea, abdominal pain, and fever can be seen. Treatment should be aimed at radiographic

confirmation of ingestion, removal (e.g., endoscopy, surgery), antacids, and supportive care.

Diethylene Glycol (DEG)

Used as an industrial solvent for canned cooking fuels, hydraulic fluid, lubrication, and brake fluid. With DEG toxicosis, calcium oxalate crystalluria is *not* observed; however, DEG can result in severe kidney injury. Clinical signs of CNS (e.g., depression, coma), GI (e.g., vomiting), renal (e.g., azotemia) dysfunction can be seen. Treatment and prognosis are similar to those of ethylene glycol.

Paintballs

Paintballs contain polyethylene glycol, sorbitol, glycerin, gelatin, and other ingredients that can result in free water loss and secondary, severe hypernatremia. GI (e.g., vomiting, diarrhea) and CNS signs can be seen (secondary to hypernatremia), including ataxia, tremors, head pressing, seizures, etc. Treatment is aimed at rapidly reducing blood sodium levels with IV fluids; antiemetics, electrolyte monitoring, anticonvulsants, and supportive care also are indicated. The use of activated charcoal is contraindicated with this toxicant.

Tea Tree *(Melaleuca)* Oil

Toxicosis has been reported in dogs and cats when concentrated (100%) oil is used as a holistic remedy. Clinical signs of CNS depression, weakness, ataxia, hypothermia, and muscle tremors can be seen within 1-2 hours after application. Rarely, coma, increased serum liver enzyme activities, dermal or oral irritation, or cardiorespiratory effects can occur (more often in cats). Treatment is aimed at dermal and oral decontamination (e.g., multiple doses of activated charcoal), fluid support, thermoregulation, clinicopathologic monitoring, and supportive care.

Liquid Potpourri

Contains essential oils. Only noted to result in toxicosis in cats, not dogs. Due to their altered glucuronidation, cats are very sensitive to cationic detergents and essential oils. Can result in severe chemical burns in the mouth, along with dermal and ocular irritation. Rarely, CNS depression, pulmonary edema, seizures, and hepatopathy can be seen in cats. Treatment includes oral and dermal decontamination, analgesics, antacids, fluid therapy, clinicopathologic monitoring, and supportive care.

Metaldehyde

Commonly-used pesticide for controlling snails and slugs; often used in the northwestern United States. Less commonly seen as a toxicant in the past few years due to replacement with the safer ingredient, iron phosphate. Metaldehyde toxicosis can result in GI (e.g., vomiting, diarrhea), CNS (e.g., tremors, seizures, secondary hyperthermia), and miscellaneous signs (e.g., DIC, hepatopathy). Treatment aimed at decontamination (e.g., gastric lavage, activated charcoal administration), antiemetic therapy, muscle relaxants, anticonvulsants, muscle relaxants, thermoregulation and supportive care.

Plant Food and Fertilizers

Wide margin of safety; contain natural elements (e.g., nitrogen, phosphorus, potassium). Clinical signs of GI disturbance with direct ingestions from the bag in moderate to large amounts. Treatment includes antiemetic therapy, fluid therapy, and supportive care.

Organic Meal Fertilizers

By-products from the meatpacking industry used as a soil amendment, typically made of bone, blood, feather, fish, etc. Very palatable to dogs. Clinical manifestations include GI signs (e.g., hypersalivation, abdominal distension, vomiting, bloody diarrhea), metabolic (e.g., pancreatitis), and rare risk of foreign body obstruction. Treatment is aimed at emesis induction, fluid therapy, antiemetics, bland diet, and supportive care.

Compost (e.g., moldy food)

Presence of tremorgenic mycotoxins (e.g., penitrem A and roquefortine), which interfere with the release of neurotransmitter amino acids. Clinical signs can be seen within 2-4 hours of ingestion and include GI (e.g., hypersalivation, vomiting, diarrhea, distended abdomen) and CNS signs (e.g., agitation, hyperesthesia, ataxia, muscle tremors, seizures, and secondary hyperthermia). Treatment should be aimed at decontamination of the patient, muscle relaxants, antiemetics, anticonvulsants, fluid therapy, thermoregulation, and supportive care.

Cocoa Mulch

Rarely seen as a toxicant, but can result in secondary theobromine toxicosis. Clinical signs of methylxanthine toxicosis can be seen (e.g., GI, cardiac, CNS). Treatment is aimed at decontamination (e.g., emesis induction, charcoal administration), fluid therapy, anti-emetics, sedation, anxiolytics, beta-blocker therapy, anticonvulsants, and supportive care.

De-Icing Salts

High concentrations of salt mixtures (e.g., sodium chloride, calcium chloride, potassium chloride, magnesium chloride hexahydrate, etc.), which is mildly toxic to dogs when exposed. Typical toxicosis due to dermal exposure (e.g., licking fur off snow-covered sidewalk). Rarely, more severe clinical signs can be seen if directly ingested from the bag. Clinical signs include GI (e.g., vomiting, diarrhea) signs; rarely, electrolyte abnormalities can be seen (e.g., hypernatremia), typically associated with large ingestions. Treatment includes IV fluid therapy, electrolyte monitoring, antiemetics, and supportive care. The use of charcoal is not recommended with salt toxicosis.

AKI, Acute kidney injury; *CNS,* central nervous system; *DIC,* disseminated intravascular coagulation; *GI,* gastrointestinal.

Household Cleaners

Most household surface cleaners are generally benign, and when ingested directly from the bottle, may result in minor GI signs. However, certain concentrated cleaners can be highly toxic or corrosive. Household bleach, which typically contains 3-6% sodium hypochlorite, is a GI irritant, but "ultra" bleach, which typically contains a 5-10% sodium hypochlorite and 0.2-2% sodium hydroxide, can be corrosive, resulting in severe esophageal or upper GI damage. Concentrated lye products, toilet bowl cleaners, and oven cleaners also are corrosive, and immediate flushing of the mouth with tap water for 10-15 minutes should be performed prior to the veterinary visit to minimize tissue injury. On presentation to a veterinary clinic, additional oral flushing should be continued. The use of antacids, a bland soft diet, and analgesics (e.g., tramadol) may be warranted.

Detergents

Most detergents result in direct irritation to the oropharynx, esophagus and GI tract, particularly in cats. Ingestion of hand soaps, shampoos, cleaners, or laundry products can cause hypersalivation, vomiting, anorexia, and oral ulceration. Treatment is based on supportive care (e.g., flushing mouth out, antacid therapy, nutritional support, etc.).

Xylitol

Xylitol is a natural sweetener found in small quantities in certain fruit. Xylitol has gained popularity because it is sugar-free, and it is often found in diabetic snacks, foods, baked foods, mouthwashes, toothpastes, chewing gum, mints, candies, and chewable multivitamins.[7] Sugarless products, particularly those with xylitol listed within the first 3 to 5 ingredients, can result in severe toxicosis within 15-30 minutes of ingestion. Ingestion of xylitol results in an insulin spike in non-primate species, resulting in severe hypoglycemia. Many pieces of candy and gum (e.g., Orbit, Trident, Ice Breakers) contain xylitol ranging in amounts, on average, from 2 mg to 1 g/piece (with a typical piece containing 120-170 mg). Unfortunately, xylitol content is considered proprietary information by some companies, and sources or amounts are not disclosed for all products. With xylitol toxicosis, it is imperative to calculate whether a toxic dose has been ingested whenever possible. Doses >0.1 g/kg are considered toxic and result in profound, sudden hypoglycemia from stimulation of insulin secretion.[7] Higher dosages (>0.5 g/kg) of xylitol have been associated with acute hepatic necrosis.[7] Clinical signs of xylitol toxicosis include lethargy, weakness, vomiting, collapse, anorexia, generalized malaise, tremors, and seizures (from hypoglycemia).[7] When hepatotoxic doses are ingested, clinical signs and clinicopathologic findings can include icterus, diarrhea, melena, hypoglycemia, increased liver enzymes, hypoalbuminemia, hypocholesterolemia, and decreased blood urea nitrogen.

When a patient is presented after ingesting a toxic amount of xylitol, the clinician should measure a blood glucose concentration immediately upon presentation; if the patient is hypoglycemic, a bolus of 1 mL/kg of 50% dextrose, diluted with 0.9% NaCl (in a 1 : 3 ratio of dextrose : NaCl) should be given IV over 1-2 minutes. Emesis induction should not be performed until the patient is euglycemic. Activated charcoal does *not*

reliably bind well to xylitol, and its administration is not routinely recommended for xylitol toxicosis. Hypoglycemic patients should be hospitalized for IV fluid therapy [supplemented with dextrose (2.5-5%, CRI, IV)] for approximately 12-24 hours, and blood glucose concentrations should be measured every 1-4 hours. For patients ingesting a hepatotoxic amount of xylitol, the use of hepatoprotectants (e.g., SAMe, n-acetylcysteine), antiemetics, and supportive care (including frequent liver enzyme monitoring) are warranted (see ch. 286).

Garage Toxicants

Hydrocarbons

Hydrocarbons consist of chemicals containing a hydrogen and carbon group as their main constituents. Examples include liquid fuels such as kerosene, engine oil, tiki-torch fuels, gasoline, diesel fuels, paint solvents, wood stains, wood strippers, liquid lighter fluids, and asphalt/roofing tar. These often are referred to as "petroleum distillates" based on their viscosity, carbon chain length, and lipid solubility. It is *contraindicated* to induce emesis after hydrocarbon ingestion due to the risks of aspiration pneumonia; due to the low viscosity of hydrocarbons, these compounds are more easily aspirated, resulting in respiratory injury and secondary infection. In general, hydrocarbons are GI tract irritants, but also can be irritants to the respiratory system (if inhaled), eyes, and skin. Clinical signs can include nausea/vomiting, tachypnea, and dermal or ophthalmic irritation. Typically, GI irritation is self-limiting. Patients should be treated with antiemetic therapy (e.g., maropitant), fluid therapy (e.g., SC or IV), fasting (no food per os), and a bland diet. Patients demonstrating any coughing, retching, or tachypnea post-ingestion should have thoracic radiographs performed to rule out aspiration pneumonia, for which treatment is supportive (e.g., oxygen therapy, fluid therapy, appropriate broad-spectrum antibiotic therapy, nebulization and coupage; see ch. 242).

Windshield Wiper Fluid (Methanol)

Most windshield wiper fluids are made up of water and methanol; however, certain types designed for extreme cold weather may contain ethylene glycol (EG), ethylene glycol monobutyl ether (EGME), ethanol, isopropyl alcohol, ammonia, or even hydrocarbons (e.g., liquefied petroleum gas). Methanol (methyl alcohol) can result in toxicosis in dogs, but does not result in the retinal toxicosis and blindness as seen with humans. When methanol is metabolized (via alcohol dehydrogenase), it creates formaldehyde, which is rapidly oxidized by aldehyde dehydrogenase to formic acid.[8,9] This is then metabolized to carbon dioxide and water in non-primate species, whereas in primates, formic acid accumulates because of low tissue levels of folate, leading to acidosis and ocular toxicosis (blindness).

Clinical signs include CNS (e.g., ataxia, lethargy, sedation), GI (e.g., vomiting, hypersalivation), and respiratory signs (e.g., tachypnea). With methanol toxicosis, decontamination typically is not warranted, as alcohols are rapidly absorbed from the GI tract.[8] Likewise, the administration of activated charcoal is contraindicated, as it does not bind to alcohols reliably. Treatment includes IV fluid therapy, antiemetic therapy, and supportive care. Administration of fomepizole (4-methylpyrazole, 4-MP), the antidote for ethylene glycol (EG) intoxication, is *not* necessary with methanol toxicosis.[9]

Ethylene Glycol

Accidental or malicious poisoning with EG can be seen in veterinary medicine, as the public generally is well aware of the narrow margin of safety with antifreeze. The minimum lethal dose in dogs is approximately 6.6 mL/kg, while in cats it is 1.4 mL/kg.[9] Sources of EG include automotive antifreeze (radiator coolant, which typically contains 95% EG), windshield deicing agents, motor oils, hydraulic brake fluid, paints, solvents, etc.[9] As little as one tablespoon (15 mL) can result in severe AKI in a dog, while as little as 1 teaspoon (5 mL) can result in AKI in feline patients. Ethylene glycol is metabolized by the body to highly poisonous metabolites including glycoaldehyde, glycolic acid, and oxalic acid, which lead to severe AKI secondary to development of calcium oxalate crystalluria.[9] There are three clinical stages with EG toxicosis:

- Stage 1: This occurs within 30 minutes to 12 hours, and looks similar to alcohol poisoning. Ataxia, hypersalivating, vomiting, seizuring, and polyuria/polydipsia are seen.
- Stage 2: This occurs within 12-24 hours post-exposure, and clinical signs seem to "resolve" to the pet owner; however, during this time, severe internal injury is still occurring. Ataxia might seem to improve during this stage, but signs of dehydration, tachycardia, and tachypnea can be seen.

- Stage 3: In cats, this stage occurs 12-24 hours after EG exposure. In dogs, this stage occurs 36-72 hours post-ingestion. During this stage, severe AKI occurs secondary to calcium oxalate crystalluria. Severe anorexia, lethargy, hypersalivation, uremic halitosis, coma, depression, vomiting, and seizures can be seen.

Any patient suspected of EG toxicosis should have an EG blood test, venous blood gas, and urinalysis performed. The diagnosis of EG toxicosis should be based on the combination of clinical suspicion, accurate interpretation of diagnostic testing, clinical signs, and patient history, because false positive results are well-recognized (see below). A positive EG test in a patient with known or suspected exposure can be sufficient to warrant initiating treatment immediately; metabolic acidosis, elevated anion gap, and calcium oxalate crystalluria offer further support, but confer a much worse prognosis if they already exist before treatment has been initiated.[9] Importantly, EG testing is only accurate within approximately the first 24 hours after ingestion, as false negatives can be found thereafter due to complete transformation of EG to its more toxic metabolites, which are not routinely detected on EG tests. On veterinary-specific EG tests, false positive results can occur with other compounds such as propylene glycol (found in many compounds, notably oral activated charcoal products and injectable drugs including diazepam), isopropyl alcohol (at the venipuncture site), sorbitol, mannitol, etc. Currently available veterinary brands for EG testing include Kacey[10] and Catachem[11]; the PRN test is no longer available. Due to the occurrence of false positive results with these tests, the author recommends submitting samples to a neighboring human hospital for quantitative EG levels.

Treatment for EG toxicosis includes antidote therapy (e.g., fomepizole, ethanol), intensive IV fluid therapy, monitoring urine output and clinicopathologic parameters, antiemetic therapy, and supportive care. Fomepizole is an expensive but life-saving antidote that is preferred over ethanol for the treatment of EG toxicosis.[9] While it is no longer being produced for dogs and cats,[12] it can be compounded by certain veterinary pharmacies. The clinician must keep in mind that antidotal therapy needs to be administered quickly: in dogs, within 8-12 hours of exposure, and in cats, within 3 hours of exposure.[9] If fomepizole is not available, ethanol can also be used, as it competes with alcohol dehydrogenase, thereby preventing metabolism of EG into its more toxic metabolites. Adverse effects of CNS depression, drunkenness, metabolic acidosis, hypoglycemia, bradycardia, hypoventilation, and hypothermia can be seen with ethanol treatment. Once a patient has already developed azotemia, the prognosis is generally poor to grave without hemodialysis (see ch. 110). Please see Box 152-2 for antidote dosing information.

Box 152-2

Antidotes for Ethylene Glycol[9]

Fomepizole (e.g., 4-MP, 4-Methylpyrazole)

- Dogs: Loading dose 20 mg/kg IV, followed by 15 mg/kg IV at 12 and 24 h. Give additional 5 mg/kg IV at 36 h. Can continue to use 3 mg/kg IV q 12 h until evidence of metabolic acidosis and clinical signs resolve.
- Cats: Extra-label. Loading dose 125 mg/kg IV, followed by 31.3 mg/kg IV at 12, 24, and 36 h after initial loading dose.
- Potential adverse reactions in dogs and cats include: anaphylaxis following second dose, CNS depression, tachypnea, hypersalivation, trembling, osmotic diuresis.

Ethanol

- Choose a clear, non-flavored, high concentration/proof alcohol (e.g., vodka, grain alcohol, etc.).
- Note: With U.S. alcohol, the alcoholic proof is twice the percentage of alcohol (e.g., 100 proof = 50% ethanol = 500 mg/mL OR 190 proof = 95% alcohol = 950 mg/mL).
  - To calculate how to make a certain percentage alcohol solution, use the formula: $C_1 \times V_1 = C_2 \times V_2$
  - To make a 7% ethanol solution with an 80 proof alcohol (40% alcohol), remove 175 mL from a 1 L bag of saline; add in 175 mL of an 80 proof alcohol back into the bag of saline.
    - $C_1 \times V_1 = C_2 \times V_2$
    - (40)(X) = (7)(1000)
    - X = 175 mL
  - To make a 7% ethanol solution with a 190 proof alcohol (95% alcohol), remove 74 mL from a 1 L bag of saline; add in 74 mL of a 190 proof alcohol back into the bag of saline.

- $C_1 \times V_1 = C_2 \times V_2$
- (95)(X) = (7)(1000)
- X = 74 mL

- There are two IV treatment recommendations for administering ethanol that are published.
  - CRI method: Using a 7% ethanol (70 mg/mL), give 8.6 mL/kg (600 mg/kg) IV once slowly; followed immediately by 1.43 mL/kg/h (100 mg/kg/h), IV, CRI for 24-36 h.
  - Alternative method: Using a 20% ethanol solution (200 mg/mL), give 5.5 mL/kg q 4 h × 5 doses; follow with 5.5 mL/kg q 6 h × 4 more doses.
- Potential adverse reactions in dogs and cats include: severe CNS depression, sedation, bradycardia, hypoventilation, metabolic acidosis, hypothermia, hypoglycemia.

CNS, Central nervous system; *CRI,* constant rate infusion.

Propylene Glycol

Propylene glycol (PG), an odorless, tasteless, and colorless dihydroxy alcohol, is a component of many household products due to its hydroscopic, emollient and humectant properties.[9,13] It often is found in pet-friendly antifreeze fluids, moist pet foods, disinfectants, medications (e.g., injectable diazepam, oral activated charcoal preparations), room deodorants, suntan lotions, cosmetic creams, paints and varnishes, food coloring, lubricants, and more.[9,13] When ingested by animals, PG is metabolized to both D- and L-lactic acid, contributing to metabolic acidosis. PG is absorbed rapidly from the GI tract. While the LD_{50} for dogs is reported to be as low as 9 mL/kg,[9,13] the author clinically rarely sees severe clinical signs from PG ingestion. Doses of 5 g/kg daily can result in hemolytic anemia, reticulocytosis, and hyperbilirubinemia in dogs.[13] In cats, 1.6 g/kg and 8 g/kg of oral PG chronically for 2-4 weeks resulted in dose-related increases in Heinz bodies of 28% and 92%, respectively.[13] Clinical signs of PG toxicosis include CNS depression, narcosis, tachypnea (secondary to metabolic acidosis), muscle twitching (cats), hypotension (cats), cardiovascular collapse, polyuria/polydipsia (secondary to an osmotic diuretic effect), and hematological changes (e.g., hemolytic anemia, Heinz body anemia).[9,13] Treatment is supportive, including fluid therapy to help correct metabolic acidosis, red blood cell morphology monitoring, and rarely, red blood cell transfusions if needed. There is no need for antidotal therapy with PG exposure.[9,13]

Herbicides

The majority of herbicides are considered to be *mildly* toxic to dogs and cats. There are several types of herbicides that are commonly used, including glyphosate (e.g., Roundup), pyridine herbicides, imidazolinone compounds, chlorophenoxy compounds (e.g., 2,4-D), and dicamba (a translocation herbicide similar to chlorophenoxy compounds). Typically, when herbicides are ingested, clinical signs are limited to GI abnormalities (e.g., hypersalivation, vomiting, diarrhea) or dermal irritation.

Glyphosate, an aminophosphonate (non-cholinesterase inhibitor), is a nonselective post-emergent herbicide. Glyphosate has a wide margin of safety in mammals and generally is regarded as nontoxic to mammalian, aquatic, and avian species.[14] It works by interfering directly with the synthesis of amino acids within the plant. When it is ingested in large amounts or directly from the container, clinical signs of hypersalivation, vomiting and diarrhea can be seen; this likely is due to the inactive surfactants found in the liquid formulation.[14] **Pyridine** herbicides (which commonly end with "pyr") include active ingredients such as thiazopyr, dithiopyr, fluroxypyr, triclopyr, etc. These typically are used as sprays to control the growth of broad-leafed weeds. This class of herbicides works by mimicking auxin, a natural hormone that inhibits growth in plants. **Imidazolinone** herbicides also are used for controlling the growth of broad-leafed weeds, and they work by inhibiting acetohydroxy acid synthase (and thereby inhibiting amino acid formation in plants).

2,4-D or chlorophenoxy compounds are some of the most commonly used herbicides, and they include the commonly known Vietnam War chemical Agent Orange. While it has a wide margin of safety in animals, this class has been shown to uncouple oxidative phosphorylation and affect ribonuclease synthesis, resulting in potential CNS affects (e.g., demyelination of peripheral nerves). In experimental studies, dogs developed GI signs and myotonia when given doses of 175 or 220 mg/kg.[14] Clinical signs reported after exposure include GI (e.g., vomiting, diarrhea, signs of abdominal pain) and CNS signs (e.g., myotonia, muscle stiffness, extensor

rigidity).[14,15] While clinical signs rarely are seen in small animal exposures to 2,4-D, the author has concerns about chronic or large exposures due to the mechanism of action. Several published studies have postulated an association with lymphoma and phenoxy herbicides.[14-17] Lastly, **dicamba** (which is related to the chlorophenoxy compounds such as 2,4-D) is a commonly used benzoic acid herbicide that has a wide margin of safety. With all herbicide exposures, treatment is directed towards supportive care. If large amounts are ingested, decontamination of the patient typically is sufficient.

Summary

In general, the prognosis for the poisoned patient is fair to excellent with immediate recognition and treatment. However, a few of these chemical toxicants have a very narrow margin of safety (e.g., OPs, carbamates, ethylene glycol), and intensive therapy is warranted. When in doubt, the clinician should consult the ASPCA Animal Poison Control Center in cases of life-threatening emergencies, or when the mechanism of action, clinical signs, and treatment are not known.

CHAPTER 153

Prescription and Over-the-Counter Drug Toxicoses

Anna G. Brutlag

Client Information Sheet: Prescription and Over-the-Counter Drug Poisonings in Dogs and Cats

Collectively, exposures to human and veterinary prescription and over-the-counter drugs account for approximately 40% of all cases reported to Pet Poison Helpline, a 24/7 veterinary poison control center based out of Minneapolis, Minnesota, serving all of North America.[1] Such exposures most often involve unintentional overdoses (e.g., dog chewing into a bottle of medication) but intentional administration of medication by the pet owner (e.g., giving an ailing cat a liquid children's NSAID) and iatrogenic intoxications also occur.

Calcium Channel Blockers

Calcium channel blockers (CCBs) or calcium channel antagonists, such as amlodipine, diltiazem, and verapamil, are commonly used in both human and veterinary medicine for the treatment of systemic hypertension, cardiac disease including hypertrophic cardiomyopathy, supraventricular tachycardia arrhythmias, and other cardiac issues. In general, CCBs inhibit the transmembrane influx of extracellular calcium through slow or long-lasting (L-type) ion channels primarily located in myocardial and arterial smooth muscle cells. This mechanism results in decreased myocardial contractility, and arterial dilation, with a subsequent decrease in peripheral resistance, blood pressure, and afterload. Slowing conduction in the SA node and reducing AV nodal conduction result in slowing of the cardiac rate, potentially precipitously.

Overdose or intoxication from CCBs results in an exaggeration of therapeutic effects, predominantly sinus bradycardia, bradyarrhythmias (e.g., all degrees of heart block), and hypotension secondary to vasodilation (see ch. 159 and 248). Sinus tachycardia may occur reflexively due to severe hypotension and will typically self-correct if hypotension is resolved. Non-cardiac signs such as vomiting (especially in cats), hypothermia (see ch. 49), central nervous system (CNS) depression, non-cardiogenic pulmonary edema, hypokalemia, hyperglycemia, metabolic acidosis (secondary to hypoperfusion), and increased lactate production can also occur. Rarely, signs of CNS stimulation such as tremors or seizures occur.[2]

Toxic dosages for CCBs in dogs and cats have not been determined and, due to the narrow margin of safety of these agents, most overdoses are considered potentially toxic. Signs of intoxication have been noted at therapeutic dosages in both dogs and cats with additional reported intoxications occurring at 14.5 mg/kg verapamil in a cat and 95-109 mg/kg sustained-release diltiazem in an adult dog.[2,3]

Treatment of CCB intoxication begins with gastrointestinal decontamination if appropriate (see ch. 112 and 151). In any case of potential CCB overdose, close monitoring of heart rate, rhythm, and blood pressure (see ch. 99) should be continued for 12-24 hours after exposure. Symptomatic animals also require laboratory monitoring of electrolytes, blood glucose, acid/base status and lactate (see ch. 70 and 128). Typical first-line agents of treatment include IV crystalloids for hypotension (colloids may also be necessary—see beta-blocker section of this chapter and see ch. 129), atropine for bradycardia (0.02-0.04 mg/kg IV), and calcium gluconate (10% solution, 0.5 to 1.5 mL/kg IV slowly over 5 minutes while monitoring an electrocardiogram [ECG] or as a constant-rate infusion [CRI]; see ch. 298) or calcium chloride (10% solution, 0.1 to 0.5 mL/kg IV slowly over 5 minutes or as a CRI of 0.01 mL/kg/h) to increase transmembrane calcium flow. If the patient is refractory to this suite of therapies, other agents such as intravenous lipid emulsion (ILE) and high-dose insulin (HDI) therapy may be considered.

While the exact mechanism of intravenous lipid emulsion therapy has not been fully elucidated, its beneficial effects are likely to be multifactorial. Current theories include the "lipid sink" theory which postulates that lipophilic agents (i.e., logP > 1.0) are "pulled" from their receptor sites and sequestered in the

lipid compartment of the blood.[4] Additional direct benefit to the myocardium is thought to result from the utilization of free fatty acids as an energy source, an increase in intracellular calcium, an alpha-adrenergic receptor mediated increased vasopressor effect, and the reduction of nitric oxide- and insulin-induced vasodilatation by ILE.[4] The current recommend dosage of ILE is 1.5 mL/kg IV bolus followed immediately with a CRI of 0.25 mL/kg/min until clinical signs resolve or for 30-60 minutes, whichever is shorter. Significant improvement is expected within minutes of ILE administration. If no significant improvement occurs, additional boluses may be administered. The total amount of ILE that can be safely administered is not known and may vary greatly depending on the individual patient, the toxicant, and the severity of clinical signs. In the current human literature, a maximal daily dosing of 8 mL/kg of 20% ILE is recommended but this dosage has been safely exceeded without adverse events in both humans and animals. Experimentally, ILE has been shown to be beneficial in canine verapamil intoxications and is also often utilized in humans with CCB overdoses.[5-7]

High-dose insulin therapy, also referred to as hyperinsulinemia-euglycemia therapy, has also been shown to be successful in treating CCB intoxication in dogs and is currently a first-line agent of care in human medicine CCB overdosage.[7-10] The proposed therapeutic mechanism of HDI is multifactorial and includes enhanced myocardial uptake of glucose, suppression of phosphodiesterase III (increases cAMP leading to increased intracellular calcium influx), and induction of mild hypokalemia resulting in enhanced cardiac inotropy. Administration of HDI requires a central line and concurrent administration of dextrose to support euglycemia (see ch. 76). Prior to beginning treatment, it is important to monitor the blood glucose (BG) concentration and supplement if the BG is <100 mg/dL in dogs or <200 mg/dL in cats. Dosages in veterinary species have not been well established and are still considered novel but typically start with 1 U/kg of regular insulin given as an IV bolus followed by a CRI at 2 U/kg/h.[11] The dosage may be increased by 2 U/kg/h every 10 minutes to a maximum dosage of 10 U/kg/h depending on the response to therapy. Experimentally, measureable inotropic improvement has been seen within 5 minutes after starting HDI.[7] Blood glucose concentrations should be monitored every 10 minutes while titrating the dosage of insulin. A concentrated solution of dextrose, usually greater than 5%, sometimes upwards of 15-30%, is administered concurrently via the central line. When the insulin dosage is stabilized, BG concentrations should be measured every 30-60 minutes and the dextrose dosages adjusted as needed. Additionally, serum potassium concentrations should be monitored hourly. Based on the human literature, it is advisable to keep potassium concentrations in the low therapeutic range but potassium chloride should be administered if the potassium drops below 3.0 mmol/L.[7] When the signs of CCB intoxication have resolved, the insulin dosage can be decreased by 1-2 U/kg/h while continuing to monitor BG and potassium concentrations hourly. Dextrose administration will typically need to be continued for 24 hours following the discontinuation of insulin.[7,11]

Additional therapies for CCB intoxication traditionally include glucagon (50 ng/kg IV bolus followed by a CRI of 10 to 15 ng/kg/min up to 40 ng/kg/min), vasopressors, and temporary pacemakers, although treatment with HDI or ILE is currently preferred.[12] In one reported case, ILE and HDI were successfully used in tandem in a dog that had ingested 79 mg/kg of diltiazem after the patient failed traditional therapies including glucagon.[13]

Beta-Blockers

Beta-blockers (also called beta-receptor antagonists) are frequently used in human medicine for hypertension and other cardiac diseases. As a result of their abundance, accidental exposures, especially by dogs, are commonly reported to Pet Poison Helpline. Although there are no FDA-approved beta-blockers for veterinary use, these agents are used to treat hypertrophic or hypertrophic-obstructive cardiomyopathy in cats and tachydysrhythmias in dogs.

Beta-blockers work primarily by antagonizing beta-adrenergic receptors ($beta_1$ and $beta_2$) and many display specificity for one receptor over the other. For example, atenolol, esmolol, and metoprolol are primarily $beta_1$-selective, whereas carvedilol, propranolol, and sotalol are non-selective beta-blockers. At supratherapeutic dosages, $beta_1$ selectivity may be lost and $beta_2$-blockade can occur. Some agents, such as carvedilol, may also antagonize $alpha_1$ receptors; others, such as propranolol, inhibit fast sodium channels, which create a membrane stabilizing effect, and prolong PR and QRS intervals. $Beta_1$ receptors are located predominately in the myocardium but are also found in the kidney, adipose tissue, eye, and skeletal muscle. Cardiac effects from $beta_1$ antagonism typically result in negative inotropic and chronotropic effects and reduced cardiac output by reducing sinus heart rate and slowing AV conduction. A reduction in blood

pressure and myocardial oxygen demands can also occur. $Beta_2$ receptors are located in bronchial smooth muscle, skeletal muscle, the gastrointestinal tract, pancreas, liver, and blood vessels. Antagonism of these receptors often results in bronchospasm (more likely in animals with concurrent airway disease) and peripheral vasodilation leading to hypotension.

The clinical signs following overdose of beta-blockers can vary slightly depending on the specific agent but often include bradycardia, heart block (first-, second-, or third-degree), reduced cardiac output, hypotension with possible cardiogenic shock, hypoglycemia, and respiratory compromise/bronchospasm. Seizures have also been reported and may be more likely following overdoses of propranolol due to its lipophilicity. Propranolol overdoses may be more likely to result in prolonged PR, QRS, and QT intervals.

Data regarding the toxic dosages of beta-blockers in companion animals are very limited. In general, doses exceeding 2-3 times the therapeutic dosage are considered potentially problematic. In experimental canine studies of propranolol intoxication, IV dosages of 10 mg/kg consistently resulted in severe clinical effects or death.[14]

Treatment for beta-blocker intoxication is fairly similar to that of CCB intoxication and begins with gastrointestinal decontamination, if appropriate (see ch. 112 and 151). In any case of potential beta-blocker poisoning, close monitoring of heart rate, rhythm, and blood pressure (see ch. 99 and 103) should be continued for 12-24 hours after exposure. Symptomatic animals also require laboratory monitoring of electrolytes, and blood glucose, acid/base status and lactate (see ch. 67-70). Typical first-line agents of treatment, similar to CCBs, include IV crystalloids for hypotension (colloids may also be necessary; see ch. 129 and 130), and atropine for bradycardia (0.02-0.04 mg/kg IV). Volume resuscitation with IV crystalloid fluid administration for hypotension is typically dosed at 20 mL/kg for dogs given over 10-15 minutes and 10-15 mL/kg for cats over 10-15 minutes.[11] Boluses may be repeated as needed for stabilization but care should be taken to avoid fluid overload in patients with cardiogenic shock. Additionally, fluid therapy may be ineffective for patients with severe bradycardia and this issue must be concurrently addressed (i.e., atropine administration). Clinical signs consistent with fluid overload include increased respiratory rate/effort, increased lung sounds, decreased pulse oximetry readings, and concomitant blood gas abnormalities. Continuous ECG monitoring to assess conduction and frequent blood pressure monitoring are also recommended (see ch. 99 and 248). As with CCB intoxication, ILE and HDI can be successful therapies and should be considered in severe cases refractory to IV fluids and atropine (for detailed information on ILE and HDI, see CCB section in this chapter).[7,11,15]

Selective Serotonin Reuptake Inhibitors and Others

Prescription antidepressant drugs routinely rank amongst the most commonly prescribed agents in the United States. Additionally, they are commonly used in veterinary medicine for a variety of behavioral disorders including separation anxiety, storm phobias, inappropriate urine marking, stereotypic behaviors, and psychogenic alopecia. While mild adverse effects may be noted at therapeutic doses, severe toxicosis and death may result following overdose, especially if these drugs are ingested along with other drugs with serotonergic properties (such as monoamine oxidase inhibitors or 5-hydroxytryptophan).

Selective serotonin reuptake inhibitors (SSRIs) block the reuptake of serotonin in the presynaptic membrane, which results in an increased concentration of serotonin in the CNS. Common SSRIs include fluoxetine (Prozac), citalopram (Celexa), escitalopram (Lexapro), paroxetine (Paxil), and sertraline (Zoloft), many of which are highly protein-bound and all of which undergo hepatic metabolism.

The range of toxicity varies depending on the drug and species. Cats, as compared to dogs, are more sensitive to SSRIs, necessitating lower therapeutic dosages and exhibiting lower ranges of toxicity.[16] Animals with seizure disorders, or cardiovascular or hepatic impairment may be at greater risk for toxicosis. Small overdoses of SSRIs typically result in sedation or agitation, hypersalivation, vomiting, mydriasis, and tremors. Larger overdoses may cause tremors, seizures, nystagmus, dysphoria, vocalization, aggressive behavior, ataxia, and bradycardia. As the degree of overdose increases, so does the risk for the development of serotonin toxicity (also called serotonin syndrome), a toxidrome characterized by central nervous, autonomic, and neurobehavioral signs. Signs may include muscle rigidity, increased reflexes, tremors, hyperthermia, hypertension, and transient blindness.

Treatment of SSRI overdoses is largely supportive and symptomatic; no specific antidote is available. Appropriate decontamination is recommended. Cyproheptadine (dogs, 1.1 mg/kg; cats, 2-4 mg total dose q 4-6 h, PO or rectally), a serotonin antagonist, is useful in reducing the severity of signs, especially vocalization and dysphoria. Agitation may be treated with acepromazine (0.05-0.2 mg/kg, IV, IM, or SC PRN) or

chlorpromazine (0.5-1 mg/kg, IV or IM PRN). The author prefers IV administration for the first dose due to the more rapid onset of effect. Due to the risk for extreme sedation and hypotension from phenothiazines, it is important to start at the low end of the dosage range and increase as needed. Some animals may require larger dosages than are listed here. For seizures in the absence of serotonin syndrome, benzodiazepines (e.g., diazepam, 0.25-0.5 mg/kg, IV PRN) are effective. In cases of serotonin syndrome, benzodiazepines *may* exacerbate neurologic signs (although they are routinely used in human medicine for this syndrome), so barbiturates (e.g., phenobarbital 3-5 mg/kg repeated q 20 min for 2-3 doses, IV) can be considered instead. Additional treatments include methocarbamol for tremors (55-220 mg/kg, IV slowly and to effect), IV fluids (crystalloids, 1.5-2.5 times maintenance; see ch. 129) for thermal cooling and to maintain hydration and adequate perfusion, and beta-blockers (e.g., propranolol 0.02-0.06 mg/kg, slowly IV) for tachycardia and hypertension if this is not corrected following appropriate sedation.

Overdoses of other antidepressants such as duloxetine (Cymbalta), a serotonin norepinephrine reuptake inhibitor (SNRI), and venlafaxine (Effexor), a bicyclic antidepressant, are clinically similar to SSRI overdoses; however, due to their mechanism of action, these agents have an added element of increased presynaptic concentration of norepinephrine and dopamine (venlafaxine). This may lead to sympathomimetic signs such as mydriasis, tachycardia, hyperthermia, hypertension, etc. Treatment is similar to SSRI overdoses but more focus on sedation may be needed. Extremely high dosages of chlorpromazine (10-18 mg/kg, IV) or acepromazine may be necessary.[16]

Tricyclic Antidepressants

Tricyclic antidepressants (TCAs) are structurally similar to phenothiazines and act on numerous receptors by inhibiting the neuronal reuptake of norepinephrine, serotonin, and dopamine in the CNS. They also have an affinity for muscarinic and histamine H_1 receptors and can cause a sodium and potassium channel blockade to varying degrees. The most common TCAs used in veterinary medicine include amitriptyline and clomipramine (Clomicalm).

In general, TCAs have a very narrow margin of safety with mild adverse effects possible at therapeutic dosages and serious effects possible following minor (2-3×) overdoses. Thus, any overdose should be considered potentially serious. As opposed to SSRIs and SNRIs, TCAs may lead to profound cardiac toxicosis in addition to neurologic signs. Following ingestion, clinical signs may develop within the first few hours and may include severe CNS depression and seizures along with anticholinergic signs such as mydriasis, tachycardia, urinary retention and a slowed GI transit time. Due to the inhibition of fast sodium channels in the cardiac ventricles, slowed depolarization may lead to bradycardia, hypotension, and arrhythmias. Cardiovascular collapse is often the cause of death in domestic animals.

Treatment of acute ingestions consists of appropriate decontamination and aggressive supportive care; no specific antidote is available. Laboratory values, especially venous blood gasses, electrolytes, and blood glucose should be monitored closely (see ch. 61, 66-70, and 128). If hypoglycemia occurs, supplementation is indicated with dextrose at 2.5-5% in IV fluids. Continuous ECG monitoring is recommended to note arrhythmias, widening QRS complexes, and prolonged PR intervals. Administration of IV crystalloids at 1.5-2.5 times maintenance is indicated to correct hypotension and maintain perfusion. Cyproheptadine may be helpful (see SSRI section). If seizures occur, ruling out hypoglycemia is important and, if needed, treatment can be given with diazepam (0.25-0.5 mg/kg, IV PRN) or barbiturates (e.g., phenobarbital 3-5 mg/kg, IV PRN). Phenothiazines should not be used as they may exacerbate the clinical signs. The duration of signs is highly variable (hours to days) and animals should be hospitalized until they are asymptomatic.

Sleep Aids: Benzodiazepines and Non-Benzodiazepine Hypnotics

Benzodiazepines (BZDs) are commonly used as antianxiety agents, anticonvulsants, muscle relaxants, and sedatives/hypnotics. Non-benzodiazepine hypnotics (non-BZDs) are typically used as sleep aids. Although the two groups have different pharmacological profiles, both exert their effects through the inhibitory neurotransmitter gamma-amino butyric acid (GABA) and have similar clinical effects and treatment regimens. Common BZDs used off-label in veterinary medicine include alprazolam (Xanax), diazepam (Valium), lorazepam (Ativan), midazolam (Versed), and zolazepam/tiletamine, a dissociative agent (Telazol). Other BZDs frequently used in human medicine include clonazepam (Klonopin), oxazepam (Serax), and temazepam (Restoril). Common non-BZDs include zolpidem (Ambien), eszopiclone (Lunesta), and zaleplon (Sonata).

Both families of drugs have a relatively wide margin of safety and fatality is not common following a one-

time overdose. Chronic oral use of oral BZDs in cats, however, can result in fulminant hepatic failure and is not recommended (see ch. 286).[17,18] Following ingestion, clinical signs of acute intoxication may develop rapidly (30-60 minutes) and commonly include CNS depression, ataxia, confusion, and/or aggression. Rare signs include hypotension, hypothermia, coma, or seizures. Paradoxically, 40-50% of animals ingesting these agents display stimulation and excitement.[19]

Treatment of acute ingestions consists of appropriate decontamination, supportive care and, if necessary, the reversal agent/antidote flumazenil. The need for treatment is based on the degree of overdose and the severity of signs. In symptomatic animals, body temperature and blood pressure monitoring (see ch. 99) and warming measures or IV crystalloids are indicated as needed to maintain perfusion, treat hypotension, and correct dehydration. In cases of paradoxical stimulation, benzodiazepines should not be given as they may exacerbate the clinical signs. Instead, acepromazine (0.05-0.2 mg/kg, IV, IM or SC PRN) or medetomidine (1-10 mcg/kg, IV, IM or SC PRN) are recommended. The reversal agent flumazenil (0.01 mg/kg, IV to effect PRN) is the antidote for benzodiazepine overdoses but is only recommended or necessary in cases of severe CNS or respiratory depression. It reverses the sedative and muscle relaxant effects within about five minutes and, due to the short half-life, should be repeatedly given as needed.

Phenylpropanolamine

Phenylpropanolamine (PPA) is a sympathomimetic amine that is FDA-approved for the treatment of urinary incontinence secondary to urethral sphincter hypotonus in dogs. Historically, it was used as an over-the-counter weight loss supplement and cold medication for people but was banned by FDA in 2003 due to human safety concerns. Although the exact mechanism of action is not known, it is believed to directly stimulate alpha-adrenergic receptors, which results in the therapeutic effect of smooth muscle contraction in the urethra. The drug is also believed to increase norepinephrine release from presynaptic sites, thereby resulting in indirect stimulation of both alpha- and beta-adrenergic receptors. The drug has a half-life of 3-4 hours (canines) and is largely excreted, unchanged, in the urine within 24 hours.[16]

Mild clinical signs can be seen with therapeutic dosing (1 mg/kg PO q 12 h) so the lowest effective dosage should be selected. In general, dogs ingesting more than 2-3 mg/kg are at risk for mild to moderate intoxication and should be decontaminated and monitored for 8 hours (see ch. 151). The onset of clinical signs can occur as early as 30 minutes following ingestion but is more likely to begin 2-4 hours after ingestion. Reported signs of intoxication are consistent with $alpha_1$, $alpha_2$, and $beta_1$ stimulation such as vasoconstriction, increased cardiac output through positive inotropic and chronotropic effects, agitation, mydriasis, and piloerection. Reported neurological signs include behavioral changes (lethargy, hiding, vocalization), ataxia, nystagmus, hypermetria, muscle tremors (rare) and seizures (rare).[20,21] Gastrointestinal signs such as vomiting and hypersalivation have also been reported and may lead to dehydration.[20] Common cardiovascular signs include hypertension, ventricular tachycardia, and bradycardia (secondary to hypertension; see ch. 248). Erythema of the abdomen and pinna may also occur. Hyperthermia is less common but should be monitored for.

Reported serious effects as a result of PPA overdoses include a 4-year-old Labrador Retriever with a dosage of 56-69 mg/kg developing severe and sustained hypertension resulting in hypertensive retinopathy and elevated cardiac troponin I concentrations (11.7 ng/mL; reference range <0.3 ng/mL) suggestive of myocardial necrosis. Full recovery occurred within 30 days.[22] A 5-year-old Labrador Retriever ingesting approximately 48 mg/kg of PPA also developed probable myocardial necrosis evidenced by cardiac troponin I concentration >40 ng/mL (reference range 0.00-0.07 ng/mL), multiform ventricular tachycardia, and left ventricular dilatation with a focal dyskinetic region in the dorsal interventricular septum with full recovery after 6 months.[21] Death has been reported in a dog ingesting 145 mg/kg of PPA although the cause of death was unable to be determined as no necropsy was performed.[20]

Common laboratory abnormalities following PPA overdoses include azotemia, myoglobinuria, mild hypokalemia, elevated creatinine kinase, and mild to moderate elevations of alkaline phosphatase (ALP) and alanine aminotransferase (ALT) (secondary to muscle damage and possible hepatic hypoperfusion injury). In cases of severe intoxication, the following diagnostics should be considered: ECG and blood pressure monitoring (see ch. 99 and 103), chemistry values including renal parameters and electrolytes, complete blood count (CBC), urinalysis to evaluate renal function and monitor for myoglobinuria (see ch. 72), creatinine kinase, coagulation panel if disseminated intravascular coagulation (DIC) is suspected (see ch. 197), and cardiac troponin I and other biomarkers to monitor for myocardial necrosis/myocardial infarction (see ch. 246).

Following appropriate and timely decontamination, treatment is symptomatic and supportive, as no antidote exists. Sedation is often best achieved with acepromazine (which also causes peripheral vasodilation, therefore lowering blood pressure). The author recommends starting with a dosage of 0.05 mg/kg IV and titrating to effect. Large doses may be necessary in cases of severe intoxication. Butorphanol may also be effective for agitation/hyperactivity. If sedation alone is not sufficient to resolve hypertension, treatment with hydralazine or nitroprusside may be used. Refractory tachycardia can be treated with a $beta_1$ antagonist such as esmolol or propranolol; lidocaine can be used to treat ventricular tachycardia. Tremors may be treated with muscle relaxants (i.e., methocarbamol). Seizures can be treated with benzodiazepines but paradoxical worsening of clinical signs may occur. Therefore, these agents should be used with caution initially. Phenobarbital is also effective for seizures, especially for those refractory to benzodiazepines. Intravenous crystalloid fluid therapy may be beneficial to maintain organ perfusion but should be used judiciously in dogs with suspected or confirmed hypertension. Prognosis is excellent with appropriate treatment.[20]

Veterinary Approved Nsaids

Nonsteroidal anti-inflammatory drugs (NSAIDs) are most commonly used for their antipyretic, anti-inflammatory and analgesic properties, especially in patients with osteoarthritis and post-operative pain. Products FDA-approved for small animal use include carprofen, deracoxib, firocoxib, ketoprofen, meloxicam, robenacoxib, and tepoxalin. At the time this chapter was authored in 2016, NSAIDs such as mavacoxib (long-acting) and tolfenamic acid were not approved for veterinary use in the United States but were approved in foreign markets.

Mechanistically, NSAIDs inhibit the activity of cyclooxygenase (COX, mainly COX-1 and -2), an enzyme that converts arachidonic acid to several prostanoids, including the prostaglandins, the prostacyclins, and thromboxane. Although both COX-1 and -2 have constitutive effects, COX-1 appears to have more desirable physiological effects such as prostaglandin regulation resulting in gastric mucosal production and normal platelet activity, and regulation of renal blood flow. Conversely, COX-2 is responsible for production of inflammatory mediators. Some NSAIDs, such as carprofen, deracoxib, firocoxib, meloxicam and robenacoxib, are COX-2 preferential or selective, meaning they exert greater inhibition over this enzyme than COX-1, thereby giving these drugs a comparatively wider margin of safety compared to drugs with less selective COX inhibition. In contrast, ketoprofen is a nonselective inhibitor of COX enzymes and tepoxalin inhibits COX-1 and -2 as well as lipoxygenase (LOX) enzymes. In spite of greater safety associated with COX-2 inhibitors, this selectivity is lost following overdose, resulting in COX-1 inhibition and consequent adverse or toxic effects.

The most common sequelae of NSAID intoxication are GI erosion or ulceration, especially of the gastric and proximal duodenal regions, and acute kidney injury.[23] Clinical signs of intoxication include vomiting (possible hematemesis), abdominal pain, melena or hematochezia, and diarrhea, which can lead to secondary dehydration. Gastrointestinal perforation and septic peritonitis are the most serious GI effects (see ch. 275 and 279). Acute kidney injury (AKI) typically occurs at dosages greater than those needed to cause GI signs but, in rare cases, has developed in patients lacking GI signs (see ch. 322). Signs of AKI as a result of multifocal renal tubular necrosis include polyuria, polydipsia, anorexia, lethargy, and vomiting. Pale mucous membranes and tachycardia may occur secondary to blood loss from the GI tract, hypovolemia, and poor perfusion. Platelet function can also be inhibited as a result of NSAID exposure.[24] In severe toxicosis, CNS signs such as weakness, ataxia, and seizures can develop (see ch. 35). Hepatic damage may also occur following massive overdoses (see ch. 286). The onset of clinical signs may begin within an hour after ingestion, although toxic effects such as acute kidney injury or GI perforation may take 48-72 hours before being clinically evident.

The toxic dosage of each NSAID varies widely amongst the various agents and is influenced by the species, concurrent use of NSAIDs and other medications (e.g., corticosteroids), underlying disease (especially renal, hepatic, or GI), and, to a lesser extent, breed. For example, Labrador Retrievers may develop idiosyncratic hepatic damage from carprofen more often than other breeds. As a general rule, acute overdoses exceeding 4-5 times the therapeutic dosage in dogs can result in signs of intoxication and require treatment. Even smaller overdoses may put cats at risk for intoxication for most NSAIDs, especially if the drug is not approved for cats or not approved for chronic use in cats.

The goal of treatment for NSAID overdose and intoxication is focused on appropriate decontamination, GI protection, fluid therapy, and other supportive measures. Gastric emptying via the induction of emesis or lavage should be performed in cases of recent exposure to oral products (see ch. 112 and 151). Depending on the extent to which enterohepatic recirculation occurs, decontamination with multiple doses of activated

charcoal may be appropriate. GI protectants such as H_2 antagonists and proton pump inhibitors are warranted for 7-10 days following exposure. Agents such as misoprostol and sucralfate may also be necessary. For large overdoses or serious clinical signs, all of these agents are recommended. Antiemetics such as maropitant are often needed, especially in the early stage of intoxication. In severe cases, blood products may be necessary in case of blood loss due to ulceration (see ch. 130).

Animals exposed to nephrotoxic doses of NSAIDs require additional treatment including IV crystalloid therapy at fluid rates sufficient to ensure excellent renal perfusion (typically, 2-3 × maintenance) for 1-3 days (see ch. 129 and 322). Concurrent monitoring of daily renal parameters and urinalysis should continue for at least 3 days or until values have normalized. Due to extensive protein binding, hemodialysis following NSAID overdose is not likely to be helpful. If there is no indication of nephrotoxic damage within 3-5 days of exposure, it is no longer expected. Additionally, monitoring for hepatic damage following large NSAID overdoses is advisable and hepatoprotectants such as SAMe can be beneficial. Additional prescription and nonprescription medications with potentially toxic effects in dogs and cats are listed in Table 153-1.

TABLE 153-1

Additional Prescription and Over-the-Counter Agents of Toxicological Concern in Small Animals

DRUG NAME	CLASS OF DRUG	MOST COMMON SIGNS OR PRESENTATION	BASIC TREATMENT
5-Fluorouracil (5-FU)	Anti-neoplastic agent, often used topically in people for treatment of actinic keratosis and superficial basal cell carcinomas.	Rapid onset vomiting, grand-mal seizures, tremors, dyspnea, cyanosis. Other: Ataxia, depression, hypersalivation, diarrhea. Protracted seizures lead to increased intracranial pressure, non-cardiogenic pulmonary edema with cardiopulmonary arrest. Death often in <24 hours. If survives initial phase, then bone marrow suppression and GI toxicosis.	No antidote. Multi-modal anti-seizure support including levetiracetam (seizures often refractory to diazepam) and/or general anesthesia; see ch. 35 and 136. IV fluids, anti-emetics, oxygen supplementation (see ch. 131). Close monitoring of ECG, O_2 saturation, blood pressure (see ch. 98, 99, and 103). Mechanical ventilation.
Acetaminophen (e.g., Tylenol)	OTC analgesic, COX-3 inhibitor	Cats more sensitive than dogs. Methemoglobinemia, respiratory distress, cyanosis. Hepatotoxicosis with icterus, hepatic encephalopathy, etc. Facial and paw edema (more common in cats). KCS.	Antidote: N-acetylcysteine (PO or IV). Supportive care: IV fluids, SAMe. Increase O_2 carrying capabilities if needed: Transfuse with pRBCs, whole blood, Oxyglobin. Methylene blue for severe MetHb (use cautiously). Plasma transfusions and Vit K if coagulopathic (liver failure).
Albuterol	Beta-adrenergic agonist	Apprehension, agitation, depression/weakness (often due to hypokalemia). Ventricular arrhythmias, AV block. Possible tremors, vomiting, hypertension, mydriasis, hyperthermia, hyperglycemia. Rare urinary retention.	Supplemental potassium, beta-antagonists for tachycardia, lidocaine for PVCs, continuous ECG and blood pressure monitoring. Anti-emetics PRN. Hyperglycemia usually resolves with IV fluids.
Alpha lipoic acid (thioctic acid)	OTC dietary supplement, often used for diabetes mellitus or cognitive dysfunction.	Signs due to hypoglycemia. Hypersalivation, vomiting, and ataxia. Possible tremors and seizures. Increased liver enzyme 24-72 hours after ingestion; acute kidney injury	IV dextrose, glucose monitoring and diuresis. Hepatoprotectants. Thiamine *may* be helpful.

		may also occur.	
Baclofen; cyclobenzaprine (Amrix, Flexeril)	Centrally-acting skeletal muscle relaxants used orally for the treatment of spasticity resulting from multiple sclerosis and spinal cord injuries/diseases in people.	Vocalization, vomiting, ataxia, disorientation, depression. May progress to recumbency, flaccid paralysis, seizures, or respiratory arrest.	No antidote, supportive care only. IV fluids for perfusion/shock, diazepam for seizures, atropine for bradycardia, cyproheptadine for vocalization. ILE can be considered in severe cases.
Caffeine	Methylxanthine compound (stimulant), common in "energy" and weight loss supplements. Also sold as single-agent tablets, inhalers, and drink augmentations.	Restlessness, hyperactivity, PU/PD, vomiting, urinary incontinence. Tachycardia, hypertension, weakness, ataxia, hyperthermia, cardiac arrhythmias, seizures. Potential electrolyte imbalances.	No antidote, supportive care only. Sedation with acepromazine or chlorpromazine (helps with hypertension), IV fluids for perfusion and excretion, methocarbamol for tremors, diazepam for seizures. Injectable beta-blockers for persistent tachycardia or hypertension. Urinary catheter or frequent voiding to prevent caffeine reabsorption across bladder wall.
Dexmethylphenidate (Focalin); dextroamphetamine/amphetamine (Adderall); dextroamphetamine (Dexedrine); lisdexamfetamine (Vyvanse); methylphenidate (e.g., Concerta, Metadate, Ritalin)	Prescription CNS stimulants, often used to treat ADD/ADHD or narcolepsy.	Restlessness, hyperactivity, pacing, mydriasis, tachycardia, tachypnea, hypertension with potential reflex bradycardia. Possible hyperthermia, head-bobbing, tremors, seizures.	No antidote, supportive care only. Sedation with acepromazine or chlorpromazine (helps with hypertension), IV fluids, methocarbamol for tremors, injectable beta-blockers for tachycardia refractory to sedatives. Cyproheptadine for serotonin syndrome. CAUTION: Diazepam may cause paradoxical effects; use other anti-seizure agents instead.
Pseudoephedrine (Sudafed, Claritin-D, etc.)	OTC sympathomimetic agent used as a decongestant.	See prescription CNS stimulants (Video 153-1).	See prescription CNS stimulants.
Vitamin D_2 (ergocalciferol); vitamin D_3 (cholecalciferol); calcipotriene (Dovonex, Calcitrene, Sorilux); calcitriol (Calcijex, Rocaltrol, Vectical)	OTC and prescription vitamin D and analogues. Sold OTC in very large doses, prescription use for treatment of hypocalcemia (oral) and psoriasis (topical) in people.	Hypercalcemia and hyperphosphatemia resulting in metastatic mineralization. Depression, weakness, anorexia. Vomiting, PU/PD, dehydration due to renal damage, calciuria. GI ulceration (severe cases). Less common: dyspnea, bradycardia, ventricular arrhythmias.	Multi-dose activated charcoal. Pamidronate, saline diuresis, furosemide, prednisone for hypercalcemia. Oral phosphate binders. GI protectants. Close monitoring of electrolytes and renal values. Prolonged treatment for 2-4 weeks is often necessary. See ch. 152.

ADD/ADHD, Attention deficit disorder/attention deficit hyperactivity disorder; *AV*, atrioventricular; *CNS*, central nervous system; *COX-3*, cyclooxygenase-3; *ECG*, electrocardiogram; *GI*, gastrointestinal; *ILE*, intravenous lipid emulsion; *KCS*, keratoconjunctivitis sicca; *MetHb*, methemoglobin; *OTC*, over the counter (nonprescription); *pRBCs*, packed red blood cells; *PRN*, as needed; *PU/PD*, polyuria/polydipsia; *PVC*, premature ventricular complex; *Vit K*, vitamin K.

CHAPTER 154

Recreational Drugs Toxicosis

Safdar A. Khan

Most exposures to recreational or illicit drugs in pets occur in dogs and can be accidental, intentional, or sometimes malicious.[1] Accidental exposures are common in part due to enhanced use of certain prescription drugs (e.g., amphetamines, opiates) in humans, thus increasing the probability of their availability in a pet's environment. Police dogs are at higher risk of exposure because of their ambitious nature and occupation.[2] Recreational drug toxicosis in pets is considered an emergency situation and, because of the illegal nature of most of these substances, owners often provide inaccurate or misleading exposure histories, making the diagnosis difficult. Moreover, to make them more potent, recreational drugs often are adulterated with other pharmacologically active substances, making the diagnosis even more challenging due to multiplicity of clinical signs. Different recreational drugs have different street names that vary from area to area. Therefore, in a suspected case, calling a local police station or animal or human poison control center can help facilitate identification of the illicit substance if the street name of the substance involved is known.

An efficient way to rule in or out a suspected case of recreational drug toxicosis is by using a commonly available human over-the-counter (OTC) drug test kit. These kits are widely available in human pharmacies, inexpensive, and easy to use. They are designed to detect drug metabolites in the urine. These can help identify some of the most commonly available recreational substances such as marijuana (note: delta-9-tetrahydro-cannabinol [THC], not synthetic marijuana; see below), amphetamines, cocaine, opioids, benzodiazepines, barbiturates, and antidepressants. The use of these drug kits has not been validated for dogs or cats, so these kits should be used with caution in veterinary medicine. Irrespective of species of patient, the sensitivities and specificities of these test kits can vary and the results of drug test kits need to be interpreted cautiously. Depending on the timing, and if any concurrent medication has been used in the patient (best results are obtained while no prior medication has been used in the patient before performing the test), these test kits can yield false positive or false negative results. A positive test result therefore should be given credence only when presenting history and clinical signs match the positive test substance. Positive test results may be confirmed by sending appropriate samples to a human or veterinary laboratory. Most human hospitals or emergency clinics and some veterinary diagnostic laboratories offer illicit drug screens and can check for the presence of recreational drugs or their metabolites in different body fluids. The presence of a parent drug or its metabolites in blood or urine can help confirm the exposure in suspect cases. Clinicians should contact these laboratories for appropriate sample collection and shipping instructions and time required for obtaining the results. The longer turnaround time usually limits the use of these central laboratory-based tests to retrospective confirmation (e.g., if toxicosis was uncertain, for preventive reasons involving future re-exposure, and in legal matters).

Prescription Drugs

Amphetamines and Amphetamine-Like Compounds

These drugs are central nervous system (CNS) and cardiovascular system stimulants commonly used in humans for appetite control, narcolepsy, attention deficit disorder, parkinsonism, and some behavioral disorders. Different amphetamine salts are available legally by prescription, either alone or in combination with other amphetamines. Some of the commonly encountered amphetamines or related drugs are benzphetamine, dextroamphetamine, pemoline, methylphenidate, phentermine, diethylpropion, phendimetrazine, methamphetamine, and phenmetrazine. Various street names for illegally sold amphetamines are speed, uppers, dex, bennies, or dexies. Caffeine, ephedrine, and phenylpropanolamine are common adulterants.[1]

Amphetamines are well-absorbed orally, with a peak plasma concentration seen in 1-2 hours. Absorption is

delayed in extended-release formulations, with slower onset of clinical signs but longer duration. Clinical signs can be seen as early as 15 minutes after the exposure or can be delayed for a couple of hours depending on the dose and the formulation.[1]

Amphetamines cause CNS and cardiovascular system excitation due to stimulation and release of norepinephrine, affecting alpha- and beta-adrenergic receptors, as well as catecholamine release centrally in the cerebral cortex, medullary respiratory center, and reticular activating system. The main affected neurotransmitters in the CNS are norepinephrine, dopamine, and serotonin.[1]

Clinical signs of toxicosis are manifestations of sympathomimetic stimulation including hyperactivity, pacing, irritability/hyperesthesia, tremors, head bobbing, and seizures. Other reported signs include hyperthermia, vocalization, tachycardia, cardiac arrhythmias (premature ventricular complexes), systemic hyper- or hypotension, salivation, and mydriasis.[3]

Treatment is aimed at early decontamination of the patient and good supportive care. Induction of emesis at home typically is not recommended because clinical signs are usually apparent by the time toxicosis is suspected; however, emesis induction can be useful in an asymptomatic patient under veterinary supervision (see ch. 151). Gastric lavage followed by activated charcoal with a cathartic could be useful in early cases (see ch. 112).

The preferred way to control CNS excitation is with phenothiazine tranquilizers such as acepromazine (0.05-1 mg/kg IV or IM, administered slow IV when using high dosages; IV route is preferred in patients with severe clinical signs such as circling and head tremor; IM route can be considered for mild cases or when IV catheter cannot be placed; repeat as needed) or chlorpromazine (0.5-1 mg/kg IV or IM; same cautions as with acepromazine above). Alternatively, CNS signs can be controlled with diazepam (0.5-2 mg/kg slow IV [watch for paradoxical hyperexcitation; stop administration if seen and use other alternatives listed here]), barbiturates (e.g., pentobarbital 2-6 mg/kg/hour IV constant rate infusion [CRI] or phenobarbital 5 mg/kg IV q 15-20 min, repeated PRN), or isoflurane inhalant anesthesia with varying success. With repeated use, or when used at high dosages as rapid IV boluses, diazepam in some patients can cause paradoxical hyperresponsiveness (aggravated paddling, vocalization, hyperactivity). For such patients, diazepam should be discontinued and alternative medications should be used for controlling CNS excitation signs. For treating serotonin syndrome signs, cyproheptadine (1.1 mg/kg PO or per rectum) may be tried. Treatment of tachycardia depends on the nature of the tachycardia (sinus versus ventricular; see ch. 141 and 248). In all cases, monitoring of clinical signs, respiratory rate and effort, heart rate and rhythm, body temperature, and serum electrolytes is critical, with treatment provided as needed.[1,4]

Sedative/Hypnotics

Opiates and Opioids

The terms opiates and opioids are used interchangeably in the literature. The term opiate refers to natural alkaloids like codeine or morphine obtained from the poppy plant, whereas opioids are synthetic morphine-like medications. The opioids are used therapeutically for their good analgesic and sedative properties. These drugs also frequently are abused by humans due to opioids' psychoactive properties. The opioids include several legal and illegal synthetic drugs. Morphine and codeine are derived from the poppy plant *(Papaver somniferum).* Oxymorphone and hydromorphone are legal prescription derivatives of morphine; heroin is an illegal derivative. Common synthetic opioids include buprenorphine, butorphanol, fentanyl, hydrocodone, meperidine, methadone, oxycodone, and propoxyphene. Oxycodone, hydrocodone, and fentanyl are perhaps the most commonly abused drugs in this group. When animals are exposed, it is typically through accidental ingestion.

Absorption and onset of clinical signs depend on the specific opioid, formulation, and route of exposure; signs vary depending on species, dosage, and age, as well as the opioid. For example, ingestion of prescribed human fentanyl by dogs is fairly common through the ingestion of either fentanyl lollipops or new or used fentanyl patches. Cats and dogs with the MDR-1 gene mutation can be more sensitive to the effects of opioids. In general, opioids are well-absorbed in the GI tract and are metabolized in the liver. Some undergo extensive first-pass hepatic metabolism and are markedly less potent orally (morphine). Opioids exert their pharmacologic effects by interacting with opiate receptors found in the limbic system, spinal cord, thalamus, hypothalamus, striatum, and midbrain. Each opioid can have agonist, mixed agonist-antagonist, or antagonist interaction(s) at these receptors. Clinical signs in dogs include early mild excitation, ataxia, tachypnea, vomiting, diarrhea, and urination, followed by CNS depression, respiratory depression, hypothermia, hypotension, and death due to respiratory failure. Cats can show excitation, aggressive behavior,

hyperthermia, and mydriasis, but not vomiting.

Treatment includes early decontamination of the patient (see ch. 151), cooling measures for hyperthermia (see ch. 134), and supportive care, and reversal with naloxone (0.02 to 0.04 mg/kg IV, repeated as needed based on monitoring of clinical signs and vital parameters).[5] Diazepam (0.25-1 mg/kg slow IV) for dysphoric-type reactions (vocalization, disorientation, excitation) and cyproheptadine (1.1 mg/kg PO or per rectum) can be used for patients showing signs of the serotonin syndrome. Ingested fentanyl patches (also a foreign body hazard) may require endoscopic removal, surgical removal (very rare), or bulking of the diet to facilitate removal in the stool. Mechanical ventilation could be needed for recumbent patients with severe respiratory depression. Isotonic intravenous fluids for volume expansion (see ch. 129) should be given to patients with severe clinical signs (coma, respiratory depression, hypothermia).

Ketamine

Ketamine, an analog of phencyclidine and a Schedule III controlled substance, is used widely in veterinary medicine and less so in human medicine due to the dysphoric and dissociative effects. Illicit production involves evaporation of ketamine injectable solution to produce powder for sniffing or pills, crystals, and capsules for ingestion. Illegally obtained ketamine is popular on the streets and can be referred to as "special k," "green jet," and "cat valium." Pets are exposed when they drink ketamine-spiked party punch, eat baked goods or marijuana laced with ketamine, or inhale contaminated marijuana smoke. It is also used as an adulterant with some stimulants like ecstasy (methylenedioxymethamphetamine, MDMA).

The onset of action depends on the dosage, species and route of exposure. Oral absorption is limited. At low dosages, it produces mild signs of stimulation and hallucinations lasting for 30-60 minutes. With large dosages, commonly reported clinical signs in dogs and cats include opisthotonos, mydriasis, a blank stare, ataxia, agitation, muscle twitching, and increased muscle tone, all signs that are identical to those noted when the drug is used therapeutically. Severe overdose can cause coma, respiratory depression, hyperthermia, seizures and death.

A presumptive diagnosis of ketamine toxicosis is solely based on evidence or history of exposure and development of characteristic clinical signs. There is no rapid test available to determine the presence or absence of ketamine in the body. The goals of treatment are early decontamination of the patient and supportive care. Mildly affected animals may only require supervision for the development of further clinical signs. Severely affected animals should be kept in a quiet, dark room with little physical restraint. Intravenous fluids and mechanical ventilation support should be provided as needed. Diazepam is effective for control of excitation, hyperactivity, and seizures; phenothiazines are contraindicated.[6]

Street Drugs

Marijuana and Synthetic Marijuana

Marijuana *(Cannabis sativa)*, referred to as "grass," "weed," and "pot," is the most common recreational street drug ingestion in dogs since its legalization in some U.S. states. It remains illegal at the federal level. Several cannabinoids are present in the plant resin but THC is considered the most active and main psychoactive agent. THC is highly lipophilic and distributes to brain and other fatty tissues following absorption. With oral ingestion, there is a substantial first-pass effect. The concentration of THC in a marijuana plant can vary from 1-8%, although some genetically-modified plants can contain higher concentrations. Most ingestions by pets are accidental, due to eating home-grown plants, marijuana cigarettes, or marijuana-containing baked goods. Occasionally, pets are deliberately poisoned by people blowing smoke into their face to see what happens, or who feed marijuana to a pet with therapeutic intent. Fortunately, marijuana has a wide margin of safety and death is rarely reported.

The onset of action depends on the route and dosage: clinical signs can develop within 6-12 minutes after inhaling smoke and 30-60 minutes after ingestion. The main clinical signs in dogs are CNS depression, disorientation, ataxia, glassy eyes, mydriasis, recumbency, hypothermia, bradycardia, and behavioral changes.[7] Urinary dribbling/incontinence frequently is reported in dogs. In cats, a commonly described behavioral change is "fly-biting." Other less frequent signs include vomiting or diarrhea associated with gastrointestinal (GI) irritation; stupor; and seizures.

Synthetic marijuana contains synthetic cannabinoids (SCs). It refers to a wide variety of herbal mixtures that were initially synthesized in the early 1960s to investigate therapeutic properties and to also study cannabinoid receptor physiology. In the 2000s, different SCs were produced commercially and sold over the Internet, on the street, and in head shops under several popular brand names such as "K2," "Spice," "Herbal

incense," "Cloud 9," "Mojo," "fake weed," "Yucatan," "Fire," "Skunk," "Moon Rocks" and many others. The use of SC has become a large public health concern in humans due to its unpredictable toxicity and abuse potential. In addition to their psychoactive properties, SCs have gained popularity because these are considered natural and legal, are cheaper and easier to produce, and are undetectable on routine drug screens. Different products often contain more than 1 structure or form of SCs leading to extensive variation in concentration and toxicosis potential.[8]

Similar to natural cannabinoids (THC) in terms of properties, SCs have psychoactive effects when ingested or smoked. The psychoactive effects of both SCs and THC are achieved through binding to the cannabinoid receptor types 1 and 2. The cannabinoid receptors are found mainly in the CNS but are also found in various peripheral tissues including lungs, liver, and kidneys.[8]

SCs are more potent, unpredictable, and more toxic, and in humans, are associated with higher rates of hospital admissions compared to natural cannabis. This enhanced toxicity is due to SCs being known as full cannabinoid receptor agonists, whereas THC is a partial cannabinoid receptor 1 agonist; therefore, SCs bind to the cannabinoid receptors with a higher affinity than does THC. Significant differences in toxicity within SCs could be due to different chemical structures and variable concentration in different formulations, possibly having additive or synergistic effect with each other. These products can also contain unknown contaminants.[8]

Most intoxications are acute and occur in dogs (and occasionally cats) mainly due to accidental ingestion of SC products available in the pet's environment. Like human cases, toxicosis in dogs and cats is variable and unpredictable, and depends on factors like dosage and concentration of SC in the product. In general, these cases are more serious in terms of severity and duration of clinical signs and can be life-threatening, in contrast to natural marijuana toxicosis cases. Commonly reported clinical signs of synthetic marijuana intoxication are severe coma, recumbency, disorientation, hypothermia, seizures, and death.

The diagnosis of SC toxicosis in veterinary patients mainly is based on history of exposure and presence of characteristic clinical signs. There have been more than 20 SC structures identified and more are being characterized. Due to this variability, and differences between SC and THC structures, SCs are not detected in routine drug screens, i.e., OTC illicit drug test kits. Some human clinical or toxicology laboratories can identify SCs in urine, blood, vomitus, and the source (different brands) at increased cost.[8] However, this option for identifying SC might not be useful for treatment due to long turnaround time (up to several days).

Treatment of both SC and natural marijuana toxicosis is primarily the provision of supportive care. Animals with mild intoxications often require confinement and monitoring for a few hours. SC cases with marked clinical signs may require fluid therapy, monitoring of body temperature, respiratory rate, and heart rate for several days. Diazepam (0.5-1 mg/kg IV; repeat as needed) can help reduce agitation, excitation, and seizures. Mechanical ventilation support could be necessary for comatose patients. Renal parameters should be monitored as acute kidney injury has been reported in humans in association with SC toxicosis. Asymptomatic dogs ingesting large amounts of plants or baked goods can benefit from early induction of emesis (see ch. 151); those with CNS depression should have gastric lavage (see ch. 112) followed by administration of activated charcoal with a cathartic (see ch. 151).

Cocaine

Cocaine, an alkaloid obtained from *Erythroxylon coca*, is the most widely abused human street drug and is second only to marijuana in animal abuse potential. Cocaine hydrochloride, the powdered form, is referred to as "coke," "nose candy," and "blow." Cocaine can further be processed into the free alkaloid referred to as "crack," "crank," "ice," and "crystal." Both forms are highly toxic to animals, whether they inhale smoke, inhale the powder, or ingest a plastic bag of cocaine that then ruptures in the GI tract.

Cocaine is rapidly absorbed across all mucosal surfaces including the nose, mouth, GI tract, and respiratory alveoli. Clinical signs can be seen within minutes but vary depending on route, tolerance, and presence of adulterants. Clinical signs of amphetamine and cocaine toxicosis are similar (CNS excitation) and difficult to differentiate clinically. These signs include excitement, agitation, pacing, hyperesthesia, tremor, and seizures. Non-febrile hyperthermia secondary to cocaine-induced heat production can be life threatening (see ch. 134).[9] Other associated signs can include tachycardia, hypertension, arrhythmias, mydriasis, respiratory arrest, and death.

Induction of emesis is not recommended due to rapid absorption and potential for seizures. Gastric lavage can be effective but caution needs to be taken in police dogs or "pack dogs" (dogs fed sealed bags of cocaine as a method of illicit drug transport) so the bags do not rupture. Body temperature must be monitored

closely, and early and intensive cooling measures undertaken when necessary. Acepromazine or chlorpromazine can be used successfully to control muscle tremors and associated hyperthermia, while diazepam or barbiturates can be used successfully to control seizures/CNS excitation (see routes and dosages, above). Propranolol or other beta-blockers (e.g., esmolol) can be effective in treating persistent and rapid sinus tachycardia (see ch. 141 and 248). Dogs with marked hyperthermia should be watched closely for disseminated intravascular coagulation (see ch. 134). All symptomatic patients should be treated intensively with intravenous fluids. Mechanical ventilation may be necessary in dogs with severe respiratory depression.

Heroin

Diacetyl morphine, or heroin, is a synthetic opioid. Common street names are "brown," "horse," "black," "smack," or "H." It is used mostly by IV injection but sometimes is smoked or snorted. Dogs are most often poisoned when used as "pack dogs" or "drug mules" for the illegal movement of heroin. In this context, heroin-filled sealed plastic bags either are fed to the dogs or are surgically inserted into the peritoneal cavity. Extreme care needs to be taken when these products are removed surgically so they are not ruptured. Treatment is similar to opioids toxicosis (above).

Club Drugs

Club drugs or "designer drugs" are synthetic drugs that have become increasingly popular in the past 10 years. Common club drugs include GHB (gamma hydroxybutanoic acid), flunitrazepam, and designer amphetamines such as MDMA/"ecstasy," 4MA, MDEA, and others. GHB and flunitrazepam are often referred to as the "date rape" drugs. There are few reports of accidental animal ingestion.

GHB is a synthetic derivative of GABA that occurs normally in the body. Street names for GHB include "liquid x," "liquid ecstasy," and "scoop." Effects occur within 15-30 minutes after ingestion and usually last only several hours, although signs have persisted for over 8 hours in some humans.[10] Clinical signs are similar to those of benzodiazepine overdose and include severe CNS depression/lethargy, coma, hypotonia, tremors, loss of consciousness, hypothermia, and respiratory depression. The aim of treatment is early decontamination of asymptomatic patients and provision of good supportive care. Emesis at home is contraindicated due to rapid onset of neurologic signs. The short duration of action can limit further treatment.

Flunitrazepam, a prescription benzodiazepine drug, is available in most countries but not in the United States. The blue-colored tablets are referred to as "roofies," "Rohypnol," "Mexican valium," and "rope." Clinical signs in humans occur 20-30 minutes after ingestion and last up to 12 hours. The most common signs include confusion, sedation, amnesia, muscle relaxation, and hallucinations.[11] Treatment with flumazenil, a specific benzodiazepine antagonist, has been successful in humans. The dosage for flumazenil in dogs and cats is 0.01 mg/kg IV, repeated in 1-3 hours if needed. For dyskinesia and extrapyramidal reactions (paddling, vocalization) diphenhydramine (1-2 mg/kg IM) can be given. Diazepam should not be used for controlling paradoxical hyperactivity reaction; instead, low dosages of acepromazine (0.02 mg/kg IV) can be used.

MDMA, or 3,4-methylenedioxymethamphetamine, or "Ecstasy," is also called "lover's speed," "roll," and "disco biscuits." Structurally similar to amphetamine, it has both hallucinogenic and amphetamine-like properties. In dogs, clinical signs can develop as early as 45 minutes and persist for up to 8 hours.[12] Signs are dose-dependent and include hyperactivity, pacing, head tremor, mydriasis, hyperthermia, seizures, and death. Patients with marked, persistent hyperthermia are at increased risk of developing disseminated intravascular coagulation followed by multiple organ failure (especially affecting the liver and kidneys; see ch. 132 and 197). Treatment is similar to treatment for amphetamine toxicosis (above).

Hallucinogens

Lysergic acid diethylamide (LSD, *Lysergsäure-diethylamid*) is a powerful, synthetic hallucinogen. Street names include "purple acid," "cubes," and "dots." LSD is rapidly absorbed orally with signs occurring within 90 minutes and persisting for up to 12 hours. Clinical signs include abnormal mentation associated with hallucinations and euphoria; disorientation; and ataxia. Cats exposed to LSD have developed bizarre postures, yawning, head twitching, body shaking, compulsive scratching, and abnormal movements.[13] Treatment is aimed at providing good supportive care and includes keeping the animal in a dark, quiet room, minimizing stimulation, and providing adequate sedation. Diazepam and haloperidol have been used successfully in humans and may be helpful in animals.

Phencyclidine, a synthetic drug similar to ketamine, is referred to as "angel dust," "rocket fuel," and "love boat." Strictly speaking, phencyclidine and ketamine are classified as dissociative anesthetics and not as hallucinogens. Clinical signs of toxicosis include coma, seizures, muscle rigidity, and systemic hypo- or hypertension. Treatment mainly involves supportive care.

CHAPTER 155

Plant Intoxications

David C. Dorman

Client Information Sheet: Plant Poisonings

Overview

Ingestion of plants by small companion animals and children is a very common occurrence. For example, the National Capital Poison Center reported that in 2013, plant and mushroom exposures accounted for approximately 3% of all calls involving children under the age of six.[1] The American Association of Poison Control Centers received more than 46,000 reports of poisoning in 2013 due to plant exposure with approximately 12.8% due to unknown plants.[2] Plant exposures account for approximately 2 to 13% of all companion animal poisonings handled by poison centers.[3-5] Certain classes of plants (e.g., oxalate-containing plants, lilies) often make animal poison control center "top ten" lists of dog and cat poisons.[6-8] Most cases involving companion animals relate to accidental ingestion of ornamental household plants rather than wild plants.[3] Information concerning plant hazards doesn't always reach the consumer; for example, despite nearly two decades of veterinary experience with lily intoxications in cats, only 27% of cat owners surveyed in one study were aware of the hazards these plants pose to cats.[9] Thus, client education is a critical component of case management (Figure 155-1). Exposures can also occur through the ingestion of table scraps and other foods, plant extract-based medications, potpourri and other plant containing products, and plant-derived products (most notably tobacco or nicotine). Garlic is even sometimes intentionally given to dogs as a health supplement. Cats are often at greater risk than dogs, presumably because they more frequently chew on plant leaves. In general, the incidence of plant exposure is highest amongst juvenile animals and likely reflects their inquisitive nature.

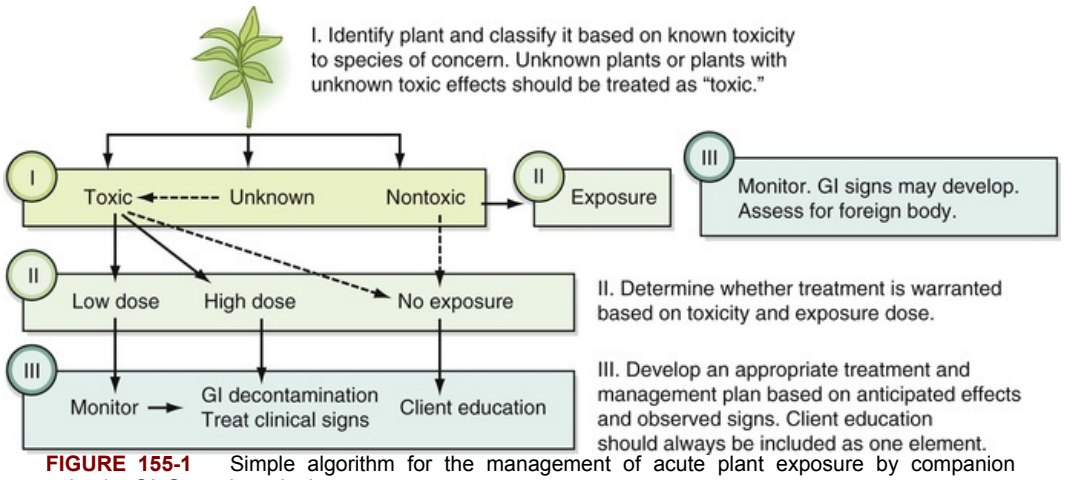

FIGURE 155-1 Simple algorithm for the management of acute plant exposure by companion animals. *GI*, Gastrointestinal.

Veterinary management of plant exposures (see Figure 155-1), including a decision to treat an animal, can be complicated by a number of factors. A significant problem in dealing with plant exposure questions involves the correct identification of the plant. Most plants found in the home or garden have several trivial

or common names and different species may share the same common name (e.g., *Sansevieria* spp. and *Dieffenbachia* spp. are sometimes referred to as "mother-in-laws tongue"). The trivial "lily" or "fern" names are commonly applied to plants from different scientific genera or even families, many of which are not true lilies or ferns. Reliable plant toxicity data for the particular species of interest (e.g., dog, cat, pet bird) are also often lacking (see Table 155-1 for toxicity data for plants discussed in this chapter). Toxicity is also often dependent on the variety, part, growth stage or condition of the plant.[10] In many cases, an owner cannot reliably estimate the exposure dose (e.g., cats frequently tend to nibble whereas dogs often chew and sometimes destroy an entire plant) or deduce when an exposure may have occurred. Species differences in the systemic toxicity of a plant may also occur. For example, the cat appears to display a unique susceptibility to several members of the *Lilium* species of plants while domesticated dogs appear more sensitive to the toxic effects of grapes and raisins. A variety of on-line and iPhone based resources with plant photographs, toxicity, and clinical signs data are readily available to veterinarians and their clients.[11,12]

TABLE 155-1

Toxic Principles and Toxicity Data for Several Common Poisonous Plants of Concern for Small Animal Veterinarians

TOXIC PRINCIPLE	SCIENTIFIC NAMES	COMMON NAMES	VETERINARY SPECIES AFFECTED	ORGAN SYSTEMS AFFECTED	TOXIC DOSAGE
Calcium oxalates (soluble)	*Dieffenbachia* spp. *Zantedeschia aethiopica* *Philodendron* spp. *Schefflera* spp. *Spathiphyllum* spp. *Syngonium podophyllum*	Dieffenbachia, dumbcane Calla lily Philodendron Umbrella plant Peace lily Arrowhead vine	Dog Cat Bird	Gastrointestinal Renal (rare)	Variable
Unknown, aqueous soluble	*Lilium longiflorum* *Lilium tigrinum* or *lancifolium* *Lilium speciosum* *Hemerocallis dumortieri* and *H. fulva*	Easter lily Tiger lily Japanese showy lily "Day" lily	Cat	Gastrointestinal Renal	<1 leaf[24]
Delta-9-tetrahydrocannabinol (THC)	*Cannabis sativa*	Marijuana, kush, hashish	Dog Cat (uncommon) Others	Gastrointestinal Central nervous	Minimal lethal oral dosage in the dog is approximately 3 g/kg.
Azoxyglycosides (e.g., cycasin, neocycasins)	*Cycas revolute* *Zamia* spp.	False sago palm Coontie, Florida arrowroot	Dog Cat (uncommon) Others	Gastrointestinal Liver	1-2 seeds
Andromedotoxin (grayanotoxin)	*Rhododendron* spp.	Rhododendron and azalea	Dog Cat	Gastrointestinal Cardiovascular	2 to 3 leaves
Ricin	*Ricinus communis*	Castor bean	Dog Cat Others	Gastrointestinal	Minimal lethal dose = 1 bean
Abrin	*Abrus precatorius*	Precatory bean	Dog Cat	Gastrointestinal	Minimal lethal dose = 1 bean

			Others		
Various alkaloids including lycorine and narcissine	*Amaryllis* spp. *Narcissus* spp. *Tulip* spp. *Hyacinth orientalis*	Amaryllis Daffodil, jonquil, and narcissus Tulip Hyacinth	Cat Dog Others	Gastrointestinal Central nervous	Oral LD_{50} of isolated lycorine in dogs is approximately 40 mg/kg. The lycorine content in some plant species ranges from 0.097-0.529%.100
Unknown	*Macadamia integrifolia* *Macadamia tetraphylla*	Macadamia nut	Dog	Gastrointestinal Central nervous	Minimum toxic dose 2.2 g/kg69
Methyl and prop(en)-ylcysteine sulfoxides	*Allium cepa* *Allium sativum* *Allium schoenoprasm*	Onion Garlic Chives	Cat Dog	Hemolysis	Variable. Toxicosis was experimentally induced in small dogs at 30 g/kg.78 The toxic dosage has been found to be as low as 5 g/kg in cats and 15 g/kg in dogs.79
Unknown	*Vitis vinifera*	Grapes, raisins, currants	Dog	Renal	0.32 to 0.65 oz/kg. In dogs that develop acute kidney injury, the lowest toxic doses reported are 19.6 g/kg (0.7 oz/kg) of grapes and 2.8 g/kg (0.1 oz/kg) of raisins. The ingested dose does not appear to correlate with the degree of renal damage.
Nicotine	*Nicotiana tabacum* *Nicotiana rustica*	Cultivated tobacco Wild (Indian) tobacco	Dog Cat Others	Nervous Respiratory	Minimal oral lethal dose in dogs and cats is approximately 10 mg/kg.

Diagnosis of plant poisoning generally requires an evaluation of exposure conditions, medical history, and health status. Physical evidence of exposure is also a critical diagnostic indicator (e.g., damaged plant materials, plant remnants in vomitus). On occasion, some analytical chemical methods are available to confirm the presence of plant toxins in gastrointestinal contents, blood, or urine. Animals consuming so-called nontoxic plants may develop vomiting, diarrhea, and other gastrointestinal signs. Irrespective of the plant's innate toxicity, animals ingesting plants are at risk for possible complications associated with a foreign body.[13,14] In some recent (<2 hour) high-dose toxic plant exposures, decontamination of the gastrointestinal tract using species-appropriate emetics and oral activated charcoal (1-2 g/kg) combined with a cathartic is often recommended for asymptomatic animals (see ch. 151). Unless otherwise noted, these decontamination methods are considered applicable to all of the plants discussed in this chapter. Symptomatic and supportive measures are also warranted in affected animals. On occasion, the exposure is significant enough that surgical removal may be required.[13,14] Few plants have effective antidotes. Fortunately, most plant exposures in companion animals result in minimal exposures and often do not constitute a medical emergency. However, a relatively small number of garden and ornamental plants do cause an emergency. This chapter discusses hazards and medical management associated with several garden and ornamental plants that are extremely common or are associated with life-threatening toxic syndromes.

Oxalate-Containing Plants

Plants containing calcium oxalate are one of the most frequent causes of plant poisoning of dogs and cats in the United States.[5] Most oxalate-containing plants of concern to small animal veterinary practitioners (see Table 155-1) contain an insoluble calcium oxalate salt that is arranged in crystallized raphides bundles within

widely-distributed idioblast cells.[15] All parts of the dieffenbachia plant are toxic, with the stem being the most toxic portion of the plant.[16] The raphides are "ejected" from the idioblast upon chewing or contact and may become embedded in exposed tissues. Calcium oxalate and its crystals result in mechanical and inflammatory injury to the skin and mucous membranes.[14,15,17-19] Plant proteolytic enzymes may also contribute to the local inflammation by promoting the release of kinin and histamine from affected cells.[19,20]

The majority of exposures do not result in serious adverse effects. Clinical signs are generally acute (within a few hours) and are often manifested by a local mucosal inflammatory response. Common clinical signs include pain, hypersalivation, variable degrees of oral and peri-oral mucosal edema (tongue, lips, palate, pharyngeal areas), and local pruritus. Animals will often paw at the muzzle or exhibit smacking or swallowing motions. Ingestion is unlikely to result in systemic effects unless very large amounts of plant material have been ingested. Higher-dosage exposures may result in vomiting, dysphagia, dyspnea, abdominal pain on palpation, vocalizing, diarrhea, and hemorrhagic gastritis or enteritis. Most cases resolve with conservative management within 12 to 24 hours, while more significant ingestions may require more aggressive intervention over several days.

Treatments include gastrointestinal decontamination (see ch. 112) and symptomatic and supportive care. Rinsing the oral cavity with water or milk to assist removal of insoluble oxalate crystals is also recommended.[14] Respiratory distress requiring advanced life support, and death due to severe upper airway obstruction, have been reported in humans and animals.[15,18,19,21] Prognosis is generally very good in dogs and cats, and rarely does a life-threatening situation develop.

Liliaceae

Many types of ornamental lilies (see Table 155-1) have been associated with kidney injury in cats.[9,22-24] Poisoning in cats has been associated with the ingestion of flowers, leaves, or plant stems[22-24] and may be associated with an unknown aqueous soluble toxin.[22]

The toxic syndrome is often biphasic. Initially, affected cats frequently (>70% of affected cats) develop increased salivation and moderate to severe vomiting within minutes to hours after ingestion.[25] Vomiting generally subsides after 6 to 12 hours, however, it may recur 24 to 72 hours post-ingestion. The second phase of the clinical syndrome is characterized by oliguric to anuric renal failure, anorexia, central nervous system (CNS) depression, dehydration, and hypothermia. Abdominal (kidney) pain is often present and may be due to swelling and tenderness of the kidneys.[26] Renal damage with polyuria may occur as early as 12 hours after ingestion. Clinical pathology usually reveals moderate to marked increases in serum creatinine, blood urea nitrogen (BUN), phosphorus, and potassium.[27] Serum glucose may reflect a moderate to marked decrease, while liver enzymes may be normal to moderately elevated. Urinalysis generally reveals numerous casts, proteinuria, glucosuria, and isosthenuria (see ch. 72).[22,27] On occasion birefringent crystals, most likely attributable to decreased excretion of oxalates, will also be observed.[27] The most prominent histologic finding is severe necrosis of the proximal convoluted tubules with the basement membranes remaining intact.[22] In addition to the acute gastrointestinal and delayed nephrotoxic effects, approximately 36% of cats exposed to day lilies develop ataxia, depression, tremors, seizures, head pressing, and other neurological signs.[25] Other signs that have been reported include facial and paw edema and dyspnea.

Frequent monitoring of renal function and aggressive clinical intervention have been shown to be effective early in the course of the toxic syndrome.[9] Cats that are decontaminated (oral activated charcoal and cathartic) within hours of clinical onset and undergo aggressive fluid diuresis for a minimum of 24 hours often experience successful recovery (see ch. 112 and 129).[9] Conversely, delays of 18 to 24 hours before intervention are reported to result in renal shutdown and death or euthanasia by 3 to 6 days post-ingestion.

Marijuana *(Cannabis sativa)*

Marijuana (see Table 155-1 and see ch. 154) is a coarse, rough-stemmed annual with opposite or alternate, mostly palmately-compound leaves. This plant was formerly cultivated for fiber production and may be found growing naturally along roadsides, railroads, and pastures. The majority of exposures of concern to veterinarians involve the ingestion of fresh or dried plant material or food products that have been adulterated with marijuana.[28] Companion animal exposure to this plant is considered common.[29] Several states have passed marijuana legalization legislation, which has resulted in increased sales and higher

exposure rates in children and dogs.[30,31] Marijuana contains delta[9]-tetrahydrocannabinol (THC) and other cannabinoids, which interact with brain cannabinoid type 1 (CB1) receptors that form part of the endocannabinoid system. In laboratory animals, agonist interactions with the CB1 receptor result in hypothermia, analgesia, cataplexy, and locomotor suppression—this cluster of signs has been termed the cannabinoid tetrad.[32,33] The amount of THC found in the leaves, stem, flowers and buds vary with plant variety, sex of plant, geographic location, and growing season. Marijuana potency is usually expressed in percent THC by weight—fresh plants can contain up to 1-6% THC while hashish contains as much as 40% THC.[34,35] The most common reported clinical signs of marijuana toxicosis in dogs include ataxia and CNS depression, which is often prolonged for several days.[28,30] Other common clinical signs include mydriasis, increased sensitivity to motion or sound, hyperesthesia, ptyalism, tremors, and urinary incontinence.[10,28,30,36] Less frequent signs can include coma, tremors, tachycardia, or more commonly, bradycardia.

The treatment of marijuana toxicosis relies on gastrointestinal tract decontamination (emetics, activated charcoal and a saline cathartic; see ch. 112) and symptomatic and supportive care.[28] The antiemetic properties of marijuana may limit the effectiveness of certain emetic drugs but these may still be tried before the onset of sedation or ataxia. Because THC is highly lipid-soluble, recent efforts have included the use of intralipid therapy to help reduce the severity and duration of clinical signs (see ch. 153).[28] Dogs with moderate to severe CNS stimulation can be treated with diazepam (0.25-0.5 mg/kg, IV) or chlorpromazine (0.5-1 mg/kg IV).[28] Assisted respiration may be required if significant respiratory depression occurs. Full recovery may require several days to occur in marijuana-poisoned dogs. THC can be detected in plasma or urine in laboratories that are equipped to perform the test.

Cycadales (Cycads)

Several tropical cycads (see Table 155-1) are grown as an ornamental in the subtropical United States. These plants contain azoxyglycosides, which after ingestion are hydrolyzed by intestinal microflora to a hepatotoxic and carcinogenic aglycone (methylazoxymethanol).[37] Cycad amino acids may be involved in the neurologic form of the syndrome.[38,39]

Gastrointestinal and hepatic effects characterize the toxic syndrome seen in dogs.[40] The onset of clinical signs following cycad ingestion can be variable (15 minutes to 3 days) and usually results in vomiting (± hematemesis).[10,40] Less frequent (<50% of cases) signs include CNS depression, diarrhea (± blood), anorexia, and neurological signs including weakness, ataxia, proprioceptive deficits, coma or seizures.[10,40,41] In severe intoxications, persistent vomiting, generalized icterus, generalized subcutaneous ecchymotic hemorrhage, ascites, pulmonary hemorrhage, and congestion may be expected over a 96 hour time period. Serum chemical changes consistent with hepatic injury are frequently seen and include elevated blood levels of alanine aminotransferase, bilirubin, and alkaline phosphatase as well as hypoalbuminemia and prolonged prothrombin (PT) or partial thromboplastin (PTT) times (see ch. 286).[10,40-42] Alterations in white blood cell counts and thrombocytopenia are also frequently (>25%) seen in affected dogs.[10,40] Elevated levels of ammonia and BUN have also been reported.[41] Case fatality rates in excess of 50% have been reported.[40] Acute histopathologic changes can include centrilobular hepatocellular necrosis accompanied by variable amounts of neutrophilic infiltration and hemorrhage.[40,43] One published canine case involving *Zamia floridana* showed microscopic evidence of mild cerebellar nerve fiber degeneration, which may account for some of the observed neurologic effects.[43]

Depending on the amount of plant material ingested, activated charcoal should be re-administered once or twice at 3- to 4-hour intervals.[40] Asymptomatic patients that are successfully decontaminated should be observed for a minimum of 24 hours for evidence of digestive upset, and for the passage of charcoal and or consumed vegetation. Symptomatic animals should be rapidly and carefully assessed and treated for cardiovascular effects (including disseminated intravascular coagulation) as well as respiratory, and neurologic function. Treatment is largely symptomatic and supportive.

Rhododendrons

The Heath, or *Ericaceae*, family includes important ornamentals found throughout the temperate regions of the world. Several members of this plant family are extremely toxic with the ingestion of as little as two or three leaves producing serious intoxication in a dog or cat. One of the more important members of the family

are *Rhododendron* (rhododendron, azalea) species. The stems, leaves, flowers, and nectar contain various derivatives of the toxic parent compound grayanotoxin. Labrador tea includes the dried leaves of *Rhododendron groenlandicum* and represents another possible exposure source.[44] Grayanotoxin intoxication in people is also related to the consumption of honey ("mad honey disease") contaminated with *Rhododendron* nectar.[45,46] Grayanotoxin binds to sodium channels thereby maintaining excitable cell membranes in a state of depolarization.[47] These plants also accumulate high levels of tannins, flavonoids, or phenolic glycosides. These latter compounds are considered most responsible for the significant gastrointestinal effects following ingestion. Grayanotoxin poisoning in veterinary medicine occurs most frequently in livestock and is uncommon in companion animals.[48]

Most of our knowledge regarding grayanotoxin poisoning is derived from the human clinical literature. Clinical signs in animals following *Rhododendron* ingestion generally occur within 2 to 6 hours. Vomiting and diarrhea are acute (can occur within minutes), moderate to severe, and may be protracted and may occasionally be hemorrhagic. Abdominal pain, tenesmus, vocalization, CNS depression, skeletal muscle weakness, dyspnea, tachypnea, hypotension, pulmonary edema, and positive inotropic effects are commonly described.[49] Convulsions, collapse, and cardiopulmonary arrest may also occur. Cardiovascular effects (arrhythmias, hypotension, and shock) may be life-threatening and should be anticipated and monitored very closely.[47] Increased vagal stimulation may contribute to clinical bradycardia; however, tachyarrhythmias may also be noted.[46,47,50] Cardiorespiratory arrest is thought to occur due to sustained grayanotoxin-induced depolarization of the myocardium.

Unless otherwise indicated, vomiting should be induced if it has not occurred spontaneously, followed by gastrointestinal decontamination using oral activated charcoal and a cathartic (see ch. 112). Management depends heavily upon symptomatic care including appropriate use of antiarrhythmic drugs to control cardiovascular effects (see ch. 248). It is noteworthy that several cases of *Rhododendron* ingestion with large numbers of nearly intact leaves required emergency gastrotomy.[51] A rapid liquid chromatography mass spectrometry method has been developed for the quantitative determination of grayanotoxins in gastrointestinal contents and urine.[52]

Castor Bean and Precatory Bean

Castor bean *(Ricinus communi)* and precatory bean *(Abrus precatorius)* are among the most toxic plants. The castor bean is readily recognized by its large lobed leaves and spiny seedpods. Castor bean and precatory bean contain the toxalbumins ricin and abrin, respectively. Castor bean seeds and oil have been used as a laxative and for the treatment of certain other diseases.[53] Castor bean seed hulls are used as mulch and fertilizer while the cake meal residue has been used as a livestock feed supplement.[53] Exposure to these castor bean-based fertilizers and soil conditioners has been implicated in poisonings in domesticated dogs.[54,55]

Ricin consists of a neutral A-chain (32 kDa) bound by a disulfide bond to an acidic B-chain (34 kDa).[56] The B-subunit binds to glycoproteins on the surface of epithelial cells, enabling the A-subunit to enter the cell via receptor-mediated endocytosis.[57] This subunit inactivates ribosomal RNA, thereby inhibiting protein synthesis, which ultimately leads to cell death. All parts of the plants are toxic; indeed, seeds can contain 5% ricin. The seeds of these plants have a tough coat requiring mastication to release the ricin molecule. Toxalbumins are poorly absorbed from the digestive tract[58]; however, even very small absorbed doses can be lethal. Depending upon the exposure dose, the onset and progression of clinical effects can vary between peracute (within 2-4 hours) to delayed (by ≥24 hours). Most commonly, there is a 12- to 24-hour quiescent period followed by the development of severe hemorrhagic gastroenteritis. Systemic delivery of ricin can result in delayed (2 to 5 days) cytotoxic effects on the CNS, kidney, liver, and adrenal glands.[55,59,60] Clinical signs may include hyperthermia, colic, nausea, vomiting, dehydration, leukopenia, hemolysis, hemorrhagic diarrhea, hemoglobinuria, kidney failure, progressing to terminal seizures and death.[54,55,59,60] Lesions can include severe hemorrhagic to necrotizing gastroenteritis, necrosis of lymphoid organs, and multifocal renal tubular degeneration and necrosis.[55,60]

Management of the asymptomatic animal includes induced emesis, followed by gastric lavage and/or activated charcoal plus a small amount (50% of normal dose) of a suitable cathartic (see ch. 112 and 151).[59,61] Shock doses of intravenous fluids and additional digestive system support should be used as indicated by the patient's condition (see ch. 129). Baseline serum chemistries and a complete blood count, with daily reassessment through recovery, are recommended. Confirmation of ricin exposure in veterinary cases has

depended on analytic chemical detection of the biomarker ricinine in gastrointestinal content, liver and kidneys.[55,60] A variety of ELISA-based approaches has also been developed for the detection of ricin in biological samples.[62]

Iris, Amaryllis, and Related Bulbs

The iris (*Iris* sp.) contains irritant resins including irisin, iridin, and irigenin in its bulb. Other toxic ornamental bulbs include amaryllis, daffodil, jonquil, narcissus, tulip, and hyacinth. The toxic constituents in these plants are not well understood although several of these plants contain lycorine, narcissine, and other alkaloids.[63] In general, all parts of these plants are considered toxic.[64] Lycorine is a potent emetic with an incompletely understood pharmacologic mode of action. Lycorine interactions at the neurokinin-1 (NK_1) and to a lesser extent 5-hydroxytryptamine 3 ($5\text{-}HT_3$) receptors are thought to be involved in lycorine-induced emesis in dogs.[65] Lycorine-induced emesis follows the pharmacokinetics of this alkaloid.[66] Lycorine has an elimination half-life in the dog of <1 hour following parenteral administration, which coincides with vomiting.[66] Most poisonings in dogs occur when bulbs are planted, while cats may occasionally ingest leaf and stem materials.[67] Ingestion of the bulb itself may result in severe gastroenteritis, vomiting, tremors, seizures, hypothermia, bradycardia, and hypotension.[64,67] Treatment of intoxications with these plants is strictly symptomatic and supportive, relying primarily on gastrointestinal tract decontamination with emetics (unless vomiting has already occurred) and oral activated charcoal and cathartics (see ch. 112 and 151).

Toxic Foods

Natural plant foods that are toxic to companion animals include macadamia nuts, onion, garlic, chives, grapes, and raisins.[68] Macadamia nut ingestion by dogs is associated with an acute toxic syndrome that generally develops within 1 to 12 hours after ingestion.[68,69] Initial clinical signs often include weakness, CNS depression, vomiting, ataxia, tremors, decreased conscious proprioception, and hyperthermia, while some animals develop hindlimb weakness resulting in recumbency.[68,69] The most noteworthy clinical pathologic change seen is a marked increase in serum lipase that can persist for several days.[69]

Onion, garlic, and chive bulbs, bulblets, flowers, and stems—including dehydrated, powdered, and cooked materials—are toxic and may induce hemolysis in dogs and cats.[68,70,71] These plants contain sulfoxides that can be broken down into N-propyl disulfide. N-propyl disulfide causes oxidative damage to hemoglobin and erythrocyte membranes, resulting in the formation of methemoglobin, Heinz bodies, and eccentrocytes, which then lead to intravascular hemolysis and anemia.[68,72] Cats may be more sensitive to the toxic effects of onions and related plant species because of differences in their hemoglobin that result in an increased sensitivity to oxidative damage.[68] Certain breeds of dogs (such as Japanese Shiba and Japanese Akita) have a low-sodium and high-potassium phenotype due to an active Na-K pump found in the mature red blood cell membrane.[73] These breeds are thought to be more sensitive to oxidant-induced hemolysis and may be at greater risk for *Allium* intoxication.[73,74] In all species studied, hemolysis is associated with Heinz body production.[71,75-77] The initial appearance of Heinz bodies may often be observed within 6 to 24 hours after ingestion. Methemoglobinemia may also be clinically significant in occasional cases, especially where the ingested dose is relatively high.

Clinical signs associated with ingestion of these hemolytic plants include vomiting, diarrhea, and increased salivation.[68,78,79] Clinical signs may not develop for 1 to 5 days and often emerge as hematologic changes begin. Other clinical signs can include pale mucous membranes, weakness, ataxia, anorexia, depression, tachypnea, and tachycardia secondary to anemia. Icterus and hemoglobinuria may be seen secondary to intravascular hemolysis.[68] Hematologic alterations include decreased packed cell volume, hematocrit, and hemoglobin concentration. Increased reticulocyte counts and neutrophilic leukocytosis may be seen in response to the anemia. Clinical chemistry changes include hyperbilirubinemia and increased blood urea nitrogen level caused by transient nephrosis.[68,79]

Ingestion of raw fruit, fruitcakes, mince pies, chocolate bars, malt loaf, scones and snack bars containing grapes, raisins, and related fruits by dogs has been linked with acute kidney injury (see ch. 322). At this time, the toxin and mode of action remain poorly characterized. Clinical signs usually appear within 4 to 6 hours after ingestion. Animals that remain asymptomatic one to two days after exposure are not expected to

develop clinical signs.[68,80] The most common signs seen include vomiting (often present within 2 hours of ingestion), lethargy, anorexia, CNS depression, and diarrhea.[81,82] Severely affected dogs often develop evidence of impaired renal function (azotemia, proteinuria, glucosuria, hematuria, and crystalluria) within 24 to 72 hours of exposure.[80,82] Reduced urine output, ataxia, and weakness are associated with a negative outcome or poor prognosis.[83] Additional clinical chemistry changes including increased serum phosphorus, amylase, glucose, alanine aminotransferase, and alkaline phosphatase concentrations have been reported.[80,82] Blood chemistry values, including renal values, should be periodically monitored for 72 hours following ingestion. Tubular degeneration and necrosis of the kidneys may follow. Acute tubular necrosis of the proximal convoluted tubules with or without mineralization has been reported.[80,84]

Management of an animal with suspected macadamia nut, onion, grape or other toxic food exposure depends on the animal's initial presentation and the agent. Decontamination by emesis, followed by oral administration of activated charcoal with a cathartic, is generally used in all asymptomatic animals with recent toxic food ingestion (see ch. 151). No specific antidotes exist, so most treatment plans depend heavily on symptomatic and supportive care. There are a few additional measures that can be considered for the following agents:

- Onions (and related plants): Ascorbic acid (30 mg/kg PO) has been recommended for the prevention and control of Heinz body anemia and methemoglobinemia.[68,79] Intravenous fluids are recommended to correct dehydration from vomiting and promote diuresis to reduce the potential for hemoglobin nephrosis. The packed cell volume (PCV) should be monitored daily for 5 to 7 days. If anemia becomes severe, transfusions with whole blood or packed red blood cells may be needed (see ch. 130).[68,79] Antioxidants have not been shown to be beneficial.[77]
- Grapes (and related plants): Fluid diuresis for the first 48 hours may help reduce the severity of acute kidney injury.[80] Medications such as furosemide, dopamine, or mannitol can be used in anuric renal failure. Hemodialysis or peritoneal dialysis may be of benefit if available (see ch. 109 and 110).[85]

Tobacco

Sources of tobacco include cigarettes and chewing (smokeless) tobacco. Processed tobacco contains a complex mixture of naturally derived plant products as well as a variety of flavoring and other additives.[86] A description of these components is beyond the scope of the present chapter; instead, the main focus will relate to nicotine toxicity. Plant strain, geographical locale, growing conditions, and other factors contribute to the highly variable nicotine content in tobacco.[87] Individual, commercially-processed United States cigarettes contain approximately 9 to 30 mg nicotine.[10,87] The recent emergence of so-called electronic cigarettes has led to an increase in pediatric human and animal exposures to nicotine.[88,89] These cylindrical devices hold a fluid-filled ("e-liquid" or "e-juice") cartridge containing a liquid solution with up to 80 mg/mL of nicotine.[90] Other constituents found in the liquid include glycerol, propylene glycol, and ethylene glycol.[91] Several over-the-counter nicotine-based 2 or 4 mg polacrilex chewing gums and replacement transdermal patches are available in the United States as nicotine replacement therapy used in smoking cessation. Nicotine polacrilex is a resin complex of nicotine and polacrilin, which is a cation-exchange resin prepared from methacrylic acid and divinylbenzene. The gum may also contain sorbitol as a sweetener and buffering agents to enhance buccal absorption of nicotine. The rate of release of nicotine from the resin complex in chewing gum is variable and depends on the vigor and duration of chewing. Nicotine transdermal patches typically contain 8.3 to 114 mg of the free alkaloid. All patches have significant residues of nicotine (2 to 83 mg) even after 24 hours of application. Some patches consist of a drug reservoir containing nicotine in an ethylene-vinyl acetate copolymer matrix that delivers the drug via a rate-controlling polyethylene membrane. Nicotine can be absorbed from these patches (and other products) following ingestion.[92] Most nicotine gum and transdermal patch formulations are buffered to alkaline pH to facilitate the nicotine absorption through cell membranes.[93] Peak blood nicotine concentrations are often reached within minutes following the ingestion of tobacco or nicotine, making gastrointestinal decontamination more difficult.[89,93]

Nicotine is a cholinergic (nicotinic) receptor agonist that exhibits both stimulant (low-dose) and depressant (high-dose) effects in the peripheral nervous system and CNS.[94] Nicotine's cardiovascular and neurologic effects are usually dose dependent. For example, low dosages of nicotine induce central or peripheral nervous system stimulation with arousal and an increase in heart rate or blood pressure. At high dosages, nicotine

causes ganglionic blockade resulting in bradycardia, hypotension, and depressed mental status.[95] Nicotine is quite toxic (the minimal oral lethal dosage in dogs and cats is approximately 10 mg/kg), and the toxic effects develop rapidly after ingestion.[92,96] Minimal toxic dosages in companion animals are incompletely understood; however, in children, poisoning can occur after ingestion of 1 mg of nicotine per kilogram of body weight.[97] Nicotine-induced clinical effects may include muscle tremors, hypertension, tachycardia, tachypnea, vomiting, hypersalivation, CNS depression or excitation, mydriasis, ataxia, weakness, seizures, and death from respiratory paralysis.[10,89]

Management of nicotine overdose generally involves gastric decontamination followed by symptomatic and supportive therapy (see ch. 151).[89,98] If vomiting has not occurred following an acute ingestion of nicotine, the stomach should be emptied immediately by inducing emesis or by gastric lavage. Activated charcoal and a saline cathartic should be given immediately following gastric emptying. Activated charcoal should be given every 6 to 8 hours following ingestion of transdermal patches because delayed nicotine release may occur. Vigorous intravenous fluid support and additional therapy should be instituted if hypotension or cardiovascular collapse occurs. Seizures should be treated with standard anticonvulsants such as diazepam (see ch. 136). Atropine may be given for bradycardia, excessive bronchoconstriction, or diarrhea. Assisted pulmonary ventilation may be necessary for the management of respiratory paralysis. Nicotine can be detected in gastrointestinal contents, serum, and urine.[99]

CHAPTER 156

Venomous Bites and Stings (Zootoxicoses)

Michael Peterson

Client Information Sheet: Pit Viper Bite

Snake Bite: Pit Vipers

Pit vipers, the largest group of venomous snakes in the United States, are involved in an estimated 150,000 bites of dogs and cats annually, approximately 99% of all venomous snakebites.[1] In North America, there are three genera of pit vipers: rattlesnakes (*Crotalus* and *Sistrurus* sp.), copperheads, and cottonmouth water moccasins (*Agkistrodon* sp.; E-Figure 156-1). Pit vipers control the amount of venom they inject depending upon the situation. Initial defensive strikes are often nonenvenomating. Offensive bites deliver a controlled amount of venom, and agonal bites deliver the entire venom load. The severity of any pit viper bite is related to the volume of venom injected, its toxicity and location. Location influences rate of venom uptake. Toxicity of rattlesnake venom varies greatly among individuals and species (Table 156-1). Traditionally, pit vipers were believed to have hemotoxic venoms, but many rattlesnake species and several subspecies have venom with potent neurotoxic components. Some may only have neurotoxic venom (E-Box 156-1).[2-4] The primary purpose of the venom is not to kill but rather immobilize the prey and predigest its tissues.

TABLE 156-1

Venom Yields of Selected North American Snakes

SNAKE SPECIES	DRY WEIGHT (MG VENOM)	LD_{50} IV (MICE)
Eastern diamondback *(Crotalus adamanteus)*	200-850	1.68
Western diamondback *(Crotalus atrox)*	175-800	2.18
Mojave rattlesnake *(Crotalus scutulatus)*	75-150	0.23
Eastern coral snake *(Micrurus fulvius)*	2-20	0.28
Cottonmouth *(Agkistrodon piscivorus)*	90-170	4.17
Copperhead *(Agkistrodon contortrix)*	45-75	10.92

E-FIGURE 156-1 Pit viper skull with retractable front fangs. Note secondary and tertiary fangs. (Courtesy Arizona Desert Museum, Tucson, AZ. In Peterson ME: Snake bite: pit vipers. *Clin Tech Small Anim Pract* 21[4]:174-182, 2006.)

E-Box 156-1

Species of Rattlesnakes with Populations Containing Neurotoxins in Venom

Crotalus durissus durissus
Crotalus durissus terrificus var. *cumanensis*
Crotalus horridus atricaudatus
Crotalus Lepidus klauberi
Crotalus mitchellii mitchellii
Crotalus tigris
Crotalus vegrandis
Crotalus viridis abyssus
Crotalus viridis concolor
Crotalus scutulatus scutulatus (venom A)
Crotalus scutulatus salvini
Crotalus catenatus catenatus

Onset of clinical signs after envenomation may be delayed for several hours. In humans, 49% of all severe envenomations are later graded as nonenvenomating or mild. Every pit viper envenomation is different. The victim's body mass, bite location, post-bite excitability, and use of medication affects severity. The snake affects the severity by its species, size, reason for striking, and degree of venom regeneration since last use (Table 156-2). Life-threatening envenomation may occur with no local clinical signs other than the puncture wounds. Severity of local signs may not reflect systemic severity. Local tissue reactions to pit viper envenomation include puncture wounds, which may bleed or swell. Additionally, ecchymoses and petechiae may develop. Fang marks do not indicate that envenomation has occurred, only that a bite has taken place

(Box 156-2). Systemic signs include pain, weakness, dizziness, nausea, muscle fasciculations, regional lymphadenopathy, altered respiratory rate, salivation, cyanosis, proteinuria, bleeding, obtundation and convulsions. Abnormal clotting times, decreased hemoglobin, echinocytosis of red blood cells (RBCs), hypotension, and thrombocytopenia have been seen.

TABLE 156-2

Variables Affecting the Severity of Envenomation

VICTIM	SNAKE
Body mass	Species
Bite location	Size
Time to medical facility	Age of snake
Type of first aid applied	Motivation for bite
Concurrent medications?	Time since last venom use?
	Time of year?

Box 156-2

Common Signs of Envenomation

Pain
Swelling
Ecchymosis
Weakness
Sloughing tissue
Shock
Punctures
Nausea

Severe hypotension follows fluid loss from the vascular space into the subcutis and pooling of blood within "shock organs" (i.e., hepatosplanchnic [dogs] or pulmonary vascular bed [cats]). Clotting abnormalities largely depend upon the species of snake. Bleeding disorders range from direct blockage or inactivation of various factors in the patient's clotting cascade to destruction of megakaryocytes in the circulation and bone marrow. Approximately 60% of patients develop a bleeding disorder, usually consisting of hypofibrinogenemia, prolonged clotting times, and thrombocytopenia (30% of victims). Some venoms lyse mature clots. The "snakebite scoring system" (Box 156-3) has been proven useful for monitoring severity and progression of the clinical syndrome, providing an accurate means of quantifying the patient's condition.[5] Patients should be scored on entry, and 6, 12, and 24 hours after admission.

Box 156-3

Snakebite Severity Score Sheet

Snakebite Severity Score

Pulmonary System

0 Signs within normal limits
1 Minimal—slight dyspnea
2 Moderate—respiratory compromise, tachypnea, use of accessory muscles
3 Severe—cyanosis, air hunger, extreme tachypnea, respiratory insufficiency or respiratory arrest from any cause

Cardiovascular System

0 Signs within normal limits
1 Minimal—tachycardia, general weakness, benign dysrhythmia, hypertension
2 Moderate—tachycardia, hypotension (but tarsal pulse still palpable)
3 Severe—extreme tachycardia, hypotension (non-palpable tarsal pulse or systolic blood pressure < 80 mm Hg), malignant dysrhythmia or cardiac arrest

Local Wound

0 Signs within normal limits
1 Minimal—pain, swelling, ecchymosis, erythema limited to bite site
2 Moderate—pain, swelling, ecchymosis, erythema involves less than half of extremity and may be spreading slowly
3 Severe—pain, swelling, ecchymosis, erythema involves most or all of one extremity and is spreading rapidly
4 Very severe—pain, swelling, ecchymosis, erythema extends beyond affected extremity, or significant tissue slough

Gastrointestinal System

0 Signs within normal limits
1 Minimal—abdominal pain, tenesmus
2 Moderate—vomiting, diarrhea
3 Severe—repetitive vomiting, diarrhea, or hematemesis

Hematological System

0 Signs within normal limits
1 Minimal—coagulation parameters slightly abnormal, PT <20 sec, PTT <50 sec, platelets 100,000-150,000/mm^3
2 Moderate—coagulation parameters abnormal, PT 20-50 sec, PTT 50-75 sec, platelets 50,000-100,000/mm^3
3 Severe—coagulation parameters abnormal, PT 50-100 sec, PTT 75-100 sec, platelets 20,000-50,000/mm^3
4 Very Severe—coagulation parameters markedly abnormal with bleeding present or the threat of spontaneous bleeding, including PT unmeasurable, PTT unmeasurable, platelets <20,000/mm^3

Central Nervous System

0 Signs within normal limits
1 Minimal—apprehension

3 Severe—lethargy, seizures, coma

Total Score Possible 0 to 20

PT, Prothrombin time; *PTT,* partial thromboplastin time.

A complete blood count with differential, including platelet count and red cell morphology evaluation, should be obtained. Echinocytosis of RBCs has been reported in 89% of dogs post-envenomation: marked type III echinocytosis (95-100% of mature RBCs affected) in 18/28 dogs (64%) and moderate echinocytosis (15-30% of mature RBCs affected) in 7/28 dogs (25%) in one study.[6] But, pets lacking this abnormality may still have been envenomated. A serum biochemistry panel, serum electrolytes, and coagulation profile should be obtained. This should include activated clotting time, prothrombin time, partial thromboplastin time, fibrinogen, and fibrin degradation products. Urinalysis with macro- and microscopic evaluations including free protein and hemoglobin-myoglobin should be performed. Testing should be repeated as indicated to monitor syndrome progression and effectiveness of therapy. Circumferential measurements of the affected body part at, above, and below the bite site at intervals aid in monitoring progression of swelling secondary to many pit viper bites.

Although many first-aid measures have been advocated for pit viper bite victims, none has been shown to prevent morbidity or mortality.[7] Recommendations are to keep the patient calm and quickly transport the patient to a medical facility to be hospitalized and monitored closely for a minimum of 8 hours. A mainstay of treatment is IV fluids to maintain volume support and combat shock (see ch. 127 and 129). The only proven specific therapy against pit viper envenomation is IV administration of a polyvalent pit viper antivenom effective against North American pit viper venoms (Table 156-3). Coagulation defects, fluid losses, changes in

neurologic status, cardiac conduction abnormalities, and the necrotizing effect of venom can be dramatically reversed when antivenom treatment is initiated appropriately. Coagulopathies have been corrected in both human and veterinary patients if treated within 96 hours of envenomation. Proper reconstitution of lyophilized antivenom is demonstrated in the companion electronic version of this text (Video 156-1). Skin testing prior to administration is unreliable and not advocated.

TABLE 156-3

Antivenoms for Treatment of North American Pit Viper Envenomations

	DONOR SOURCE	BINDING PROTEIN	LYOPHILIZED	IMMUNIZING VENOMS
Boehringer-Ingelheim	Equine	IgG	Yes	Western diamondback rattlesnake Eastern diamondback rattlesnake Fer-de-lance* South American rattlesnake*
BTG Crofab	Ovine	Fab1	Yes	Western diamondback rattlesnake Eastern diamondback rattlesnake Mojave rattlesnake Water moccasin
Venomvet	Equine	Fab2	No	Fer-de-lance* South American rattlesnake* Lance head
Bioclon Antivipmyn	Equine	Fab2	Yes	South American rattlesnake* Fer-de-lance*
Polyvet	Equine	IgG	No	Central American rattlesnake Fer-de-lance*

*May be from different regions of South and Central America.

Antivenom should be diluted in normal saline (100-250 mL) and administered slowly IV for the first few minutes to assess for allergic reactions manifested as facial pruritus, emesis, and hyperemia of ear pinna (see ch. 130 and 137). If no adverse reactions are noted after 5 minutes, the antivenom infusion rate can be increased. If a reaction occurs, stop the infusion, continue IV fluids and treat the patient with diphenhydramine (1 mg/kg IV). Since most reactions are infusion-rate-related, once the patient stabilizes antivenom, administration can be resumed at a slower rate. If the reaction recurs, stop the infusion. Ideally, patients receive their total dose within ½ hour. A single antivenom vial usually suffices; however, some patients will require administration of multiple vials (E-Box 156-4). Patients with severe thrombocytopenia are at risk of recurrence within a week, generally not as severe as the initial condition, and should have daily thrombocyte counts performed. Pain management often is necessary with antivenom administration, and some patients may require further therapy (see ch. 126). Fentanyl is preferred as an IV continuous rate infusion (loading dose 2 mcg/kg, then 2-10 mcg/kg/h). Morphine should be avoided due to its histamine-releasing activity, which may be confused with the onset of anaphylaxis. Corticosteroids and nonsteroidal anti-inflammatory drugs should not be used. Since there has been no definition of a "protective" titer and no canine or feline challenge studies, use of the rattlesnake vaccine is not endorsed.

Indications for Additional Antivenom Administration

Evidence of Progression of Envenomation Syndrome

Quantifiable increase in swelling
Worsening laboratory values
Decreased mental status

Worsening coagulation defects
Severity score increasing

Coral Snakes

Sonoran coral snake envenomation is not clinically relevant, but the Eastern, Texas, and the South Florida coral snakes are dangerous.[8,9] North American coral snakes have a black snout and distinct encircling color bands of black, yellow and red (E-Figure 156-2). They have short fixed fangs and need to hold and chew to deliver venom (E-Figure 156-3).[10] These snakes can be aggressive if disturbed, delivering a pugnacious bite. Venom uptake can be delayed for hours and may take a week or longer to clear the body. The venom is neurotoxic, inducing a non-depolarizing postsynaptic neuromuscular blockade (a curare-like syndrome) with little local tissue reaction. Dogs exhibit acute central nervous system depression, emesis, excessive salivation, quadriplegia with decreased spinal reflexes in all limbs, and respiratory paralysis. Additionally, hemolysis, anemia, hemoglobinuria, and morphologic alterations of red blood cells may become manifest.[11] Cats exhibit acute ascending flaccid quadriplegia, central nervous system depression, reduced nociception, anisocoria, absence of spinal reflexes in all four limbs, hypothermia, and loss of the cutaneous trunci reflex.[12] Hemolysis and hemoglobinuria have not been observed in cats.

E-FIGURE 156-2 Coral snake coloration: black, yellow, red fully encircling bands. (Courtesy Arizona and Poison Drug Information Center, Tucson, AZ.)

E-FIGURE 156-3 Small fixed front fangs. (Courtesy Arizona Poison and Drug Information Center, Tucson, AZ.)

Coral-snake-bitten pets should be transported to a veterinary facility capable of 24-hour critical care and assisted ventilation. An elastic compression bandage, firmly encompassing the bitten limb, will delay venom uptake and should not be removed until antivenom has been administered.[12,13] A bitten pet should be hospitalized for at least 48 hours of continuous monitoring (extreme vigilance) and supportive care that includes managing paralysis and preventing aspiration pneumonia. Any evidence of respiratory distress should be aggressively addressed and endotracheal intubation considered. The only definitive treatment is administration of coral snake antivenom, no longer made in the United States. Studies have shown crossreactivity with either Australian Tiger snake *(Notechis scutatus)* or the Mexican coral snake (Micrurus) antivenoms (may be available at a local zoo).[11,14] Other South and Central American antivenoms do not cross-react with U.S. coral snake venom. Early IV antivenom administration is most effective. Once clinical signs of coral snake envenomation become manifest, they progress with alarming rapidity and are extremely difficult to reverse. The initial recommended antivenom dose is one to two vials, but additional vials maybe required. If antivenom is not available or if administration is delayed, supportive care includes respiratory support. Assisted mechanical ventilation can be used but may have to be employed for up to 48 to 72 hours.

Brown Spider Envenomation

At least 5 species of *Loxosceles* spiders indigenous to the United States (Figure 156-4) have been associated with necrotic arachnidism: *L. reclusa, L. refuscens, L. arizonica, L. unicolor,* and *L. laeta*.[15] These spiders are commonly called "violin spiders," because of the violin-shaped marking on the cephalothorax, with the neck of the violin pointing toward the abdomen (Figure 156-5). Many dermonecrotic lesions are commonly incorrectly diagnosed as brown recluse bites, as up to 60% of the diagnoses are made in geographic regions of the country which do not have indigenous *Loxosceles* spider populations. The long list of differential diagnoses include burns to decubital ulcers. It is important to note that in humans, the primary misdiagnosis is MRSA. A single bite can inflict a lethal envenomation. Male spiders of equivalent size generate half the venom volume of females. Larger mature spiders have more venom. Their venom has eight major and four

minor electrophoretic bands, with sphingomyelinase D recognized as the primary dermonecrotic factor.[16] It binds to cell membranes and chemotactically induces polymorphonecular leukocyte infiltration. The toxin depletes serum hemolytic complement, prolongs activated partial thromboplastin time, and depletes clotting factors VIII, IX, XI, and XII.[17] The venom induces rapid coagulation and occlusion of small capillaries, causing subsequent tissue necrosis. When C-reactive protein and calcium are available, sphingomyelinase D has a direct hemolytic effect. In the presence of amyloid protein, calcium-dependent platelet aggregation can occur, leading to activation of the prostaglandin cascade. The venom releases body lipid fragments into circulation, which subsequently act both as emboli and as inflammatory mediators. The victim's immune response to the venom ultimately determines the severity of the ensuing lesions.[17] Histologically, lesions resemble Arthus and Shwartzman phenomena.

FIGURE 156-5 Violin marking on cephalothorax of *Loxosceles* spider. (Courtesy Bill Banner, MD, PhD.)

Early clinical diagnosis is difficult since lesions initially appear mild.[4] The ensuing bite severity is determined by the quantity of venom injected, the bite site, and the victim's immune status.[15] Dogs and cats are not often examined before lesions are well-developed with necrosis. Human bite victims describe a mild stinging sensation lasting as long as 8 hours. Subsequent pruritus and soreness develop as vasoconstriction causes local ischemia. Edema follows with development of a classic "bulls-eye lesion" (an erythematous area surrounding a pale ischemic region with a dark necrotic center as the lesion matures). Lesion margins may progress unevenly as gravity pulls venom ventrally, leaving an eccentric lesion with the original center located dorsally. Hemorrhagic bulla may develop within 24-72 hours with a maturing eschar (decubitus ulcer) below. If pets do not disturb the eschar, it usually sloughs within 2 to 5 weeks, leaving an indolent ulcer that does not usually penetrate into the muscle below. Lesions in adipose tissue can be extensive. Healing is slow, and these ulcers may persist for months, leaving a deep scar.

Systemic signs are less common but can be life-threatening. The most common condition is a Coombs' negative hemolytic anemia with significant hemoglobinuria, usually developing within 24 hours of envenomation and persisting for up to one week. Other early-onset clinical signs include fever, arthralgia, vomiting, weakness, and a maculopapular rash. Pets may have a leukocytosis, thrombocytopenia, or disseminated intravascular coagulation (DIC) (see ch. 197). Systemic reaction is not proportionally related to the local reaction or vice versa.[15]

There is no specific antidote. Treatment plans are directed at one or two possible syndromes, local cutaneous lesions, and systemic manifestations of envenomation. The use of the antibiotic and leukocyte inhibitor dapsone (4,4′,-diaminodiphenylsulfone) has been advocated in the past but subsequently has failed to prove clinical efficacy. Surgical excision is not encouraged. Lesions are treated as open wounds with several cleanings daily with Burrow's solution. Some debridement may be necessary. Broad spectrum antibiotics may be indicated. One or two atmospheres of hyperbaric oxygen twice daily for 3 to 4 days may be benefical.[18]

Systemic signs of *Loxosceles* envenomation are potentially fatal and should be treated aggressively. Patients exhibiting signs should be hospitalized for close observation. Anti-inflammatory, antipyretic, and analgesic agents can be useful. Compounds that affect clotting should be avoided. Systemic corticosteroids have a protective effect on red cell membranes, thereby inhibiting hemolysis. Their use should be limited to the first few days of the syndrome and, in the case of prednisolone, should be administered at a rate of 0.5-1 mg/kg/day. Coagulation defects are treated as indicated (see ch. 135). Hospitalization and IV fluid therapy may be indicated to maintain hydration and renal function (see ch. 129).

Black Widow Spider

Female *Latrodectus* spiders are capable of life-threatening envenomation. They are shiny black and globose with an hourglass red/orange marking on the abdomen. Immature females are beige, brown, and reddish which changes to black as they mature, with the hourglass marking becoming more prominent (Figures 156-6 and 156-7). They control the amount of venom injected and a single bite is capable of delivering a lethal dose of venom to pets. Venom promotes calcium-independent release of neurotransmitters (acetylcholine, norepinephrine and others) down concentration gradients and inhibits their subsequent reuptake.[19] Acetylcholine, noradrenaline, dopamine, glutamate, and encephalin systems are all susceptible to the toxin.[19]

FIGURE 156-6 Immature black widow spider; note the paler coloration. (Courtesy Arizona Poison and Drug Information Center, Tucson, AZ.)

FIGURE 156-7 Mature female black widow spider with egg sac. (Courtesy Arizona Poison and Drug Information Center, Tucson, AZ.)

Local signs are generally absent, and systemic manifestations usually occur during the first 8 hours post-envenomation. The condition is extremely painful in moderate to severe envenomations. Progressive muscle pain and generalized muscle cramping is common, especially of the chest, abdomen, and lumbar regions. Abdominal rigidity without tenderness is a hallmark sign. Systemic hypertension and tachycardia are common.[20] Cats are extremely susceptible to the venom. Marked signs of paralysis may occur early. Severe pain is manifested by loud vocalizations. Excessive salivation, restlessness, vomiting, and diarrhea may occur. Muscular tremors, cramping, ataxia, and inability to stand precede complete paralysis.

Bitten pets should be hospitalized for at least 48 hours. Treatment is administration of specific antivenom, usually supplied in a lyophilized state and reconstituted rapidly with 2 mL of supplied diluent.[21] Antivenom should be diluted into less than 20 mL fluids and given by slow IV infusion, as previously described. A single vial is usually sufficient to resolve the clinical syndrome within 30 minutes. Care should be taken with administration of IV fluids since most patients are hypertensive. Complete recovery may take weeks.

Chapter 159 Systemic Hypotension

CHAPTER 157

Pathophysiology and Clinical Manifestations of Systemic Hypertension

Serge Chalhoub, Douglas Palma

Pathophysiology of Systemic Hypertension

The product of cardiac output and total peripheral resistance equals systemic blood pressure (BP). Cardiac output is determined by heart rate and stroke volume. Counterregulatory mechanisms normally exist to counteract sustained elevations in BP. Systemic hypertension (SH) is defined as a persistent pathologic elevation in systemic arterial BP, more importantly recognized with sustained elevations in systolic BP. A complex interaction between systems, including the kidneys, nervous system, vasculature, and heart, can lead to altered BP control (Figure 157-1).[1] Guidelines for identification and evaluation of SH have been devised on the basis of probability of target-organ damage (TOD) secondary to SH, and recommended monitoring and therapy guidelines have been established.[2] These guidelines do not take into account interbreed differences, sex, body condition score, age, and other health factors potentially affecting BP.

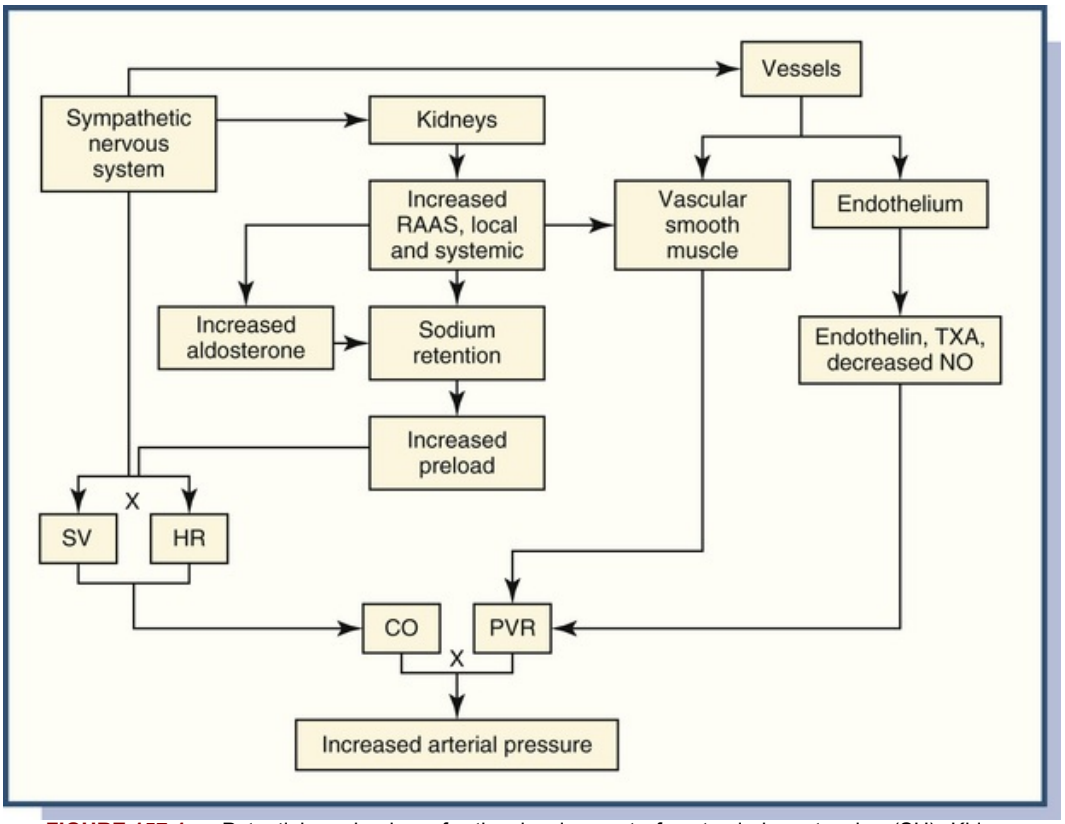

FIGURE 157-1 Potential mechanisms for the development of systemic hypertension (SH). Kidney disease is likely the most common cause of SH in cats and dogs. Increased sympathetic system activation, vascular smooth muscle abnormalities, and endothelial disease are other known mechanisms. *CO,* Cardiac output; *HR,* heart rate; *NO,* nitric oxide; *PVR,* peripheral vascular resistance; *RAAS,* renin angiotensin aldosterone system; *SV,* stroke volume; *TXA,* thromboxane. (Modified from Syme H: Hypertension in small animal kidney disease. *Vet Clin Small*

SH can be divided into two broad categories: secondary hypertension and idiopathic hypertension. Secondary hypertension is induced by clinical disease or medications. Idiopathic hypertension occurs in absence of a readily identifiable cause based on clinical investigations. Secondary hypertension is much more common in cats and dogs, whereas the reverse is true in humans, in whom idiopathic hypertension traditionally is called "essential" hypertension.

Conditions Commonly Associated With Hypertension

Signalment

SH is more common in older male dogs than in females.[3] Recent evidence suggests that both healthy cats and cats with CKD show a significant increase in BP with increasing age, and there also is a correlation with increased heart rate.[4] The cause of SH with increased age is likely multifactorial and unclear at this time.

No relationship exists between breed and BP in cats[5]; however, certain interbreed variations likely exist in dogs. Greyhounds seem to have an average systolic BP that is 10-20 mm Hg higher than in other dogs[2]; however, a recent study of BP in retired racing Greyhounds identified a significant white-coat effect (systolic and mean BP, and heart rate, were significantly lower at home than in-hospital).[6]

Obesity (see ch. 176 and 359)

There appears to be either a small, or no, correlation between obesity and SH in dogs. In obese dogs, SH might be more related to other diseases such as kidney disease, cardiac diseases, and endocrinopathies, but not gonadal status.[5,7,8] In cats, no studies correlate gender, breed, and body weight with increased SH risk.[9] Unlike in dogs and cats, obesity is a major risk factor for the development of SH in humans.[10]

Kidney Disease (see ch. 322-328)

The most common cause of SH in dogs and cats is kidney disease. 65-100% of cats that present with SH and TOD have evidence of reduced kidney function.[9,11,12] The prevalence of SH in cats with CKD varies between 20% and 65%,[9,11-13] and contrary to humans, prevalence does not seem to increase with increased severity of CKD.[13] With CKD, pathophysiology likely is multifactorial and involves systemic renin-angiotensin-aldosterone system (RAAS) activation (Figure 157-2), impaired sodium (Na^+) excretion, increased intravascular volume, sympathetic stimulation, structural arterial changes, endothelial dysfunction, lack of local nitric oxide (NO) to mediate vasodilation, increased production of vascular endothelin, and likely oxidative stress with increased reactive oxygen species production (see Figure 157-1).[9,14,15] Decreased Na^+ excretion in early kidney disease could be the result of defective collecting duct Na^+ handling because decreased Na^+ filtration should lead to compensating decreased tubular Na^+ reabsorption at this stage.[1] No consistent associations among plasma aldosterone or renin concentrations, SH, and feline CKD have been reported.[9,16-18]

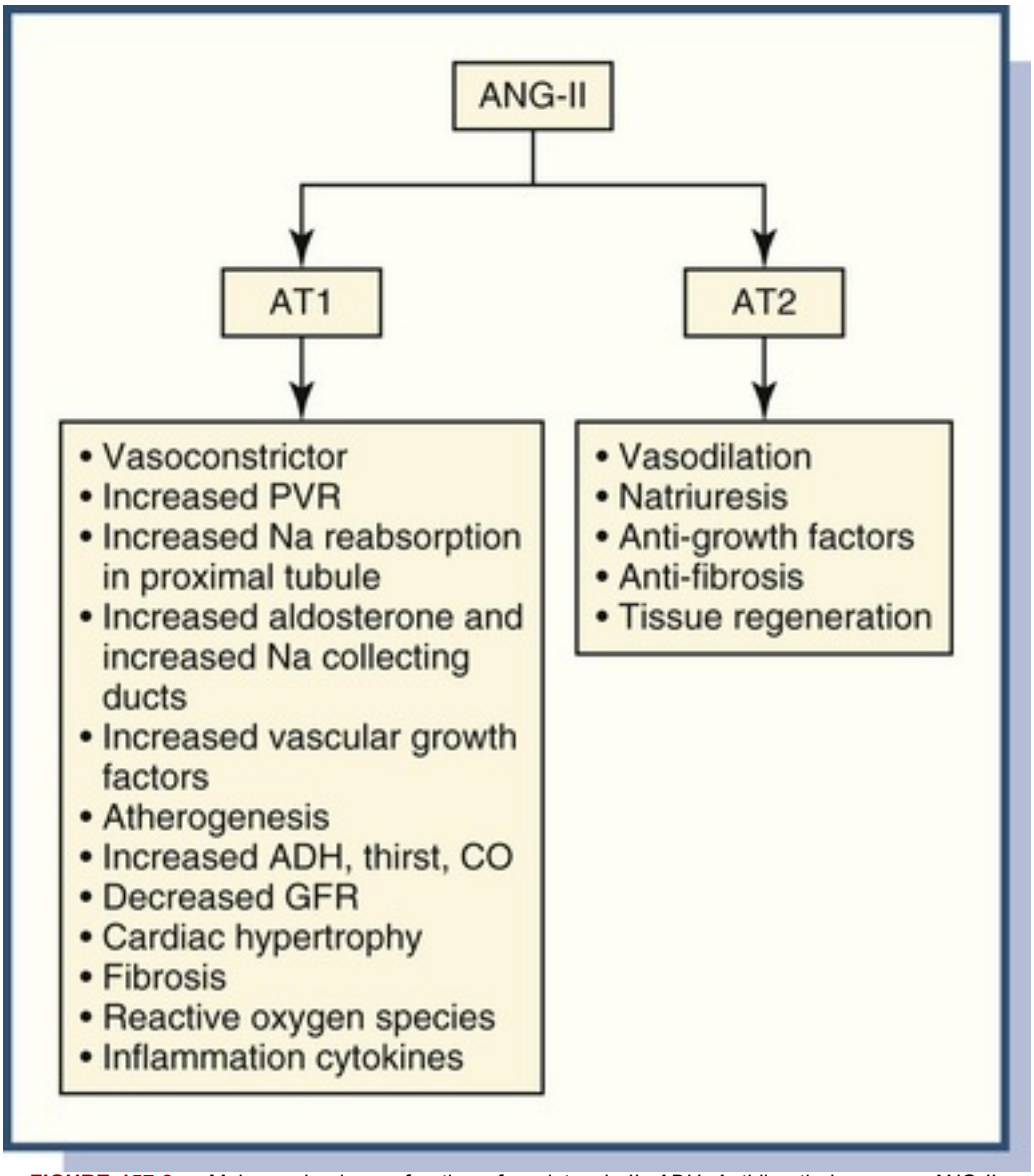

FIGURE 157-2 Main mechanisms of action of angiotensin-II. *ADH,* Antidiuretic hormone; *ANG-II,* angiotensin-II; *AT1,* angiotensin-II receptor, type 1; *AT2,* angiotensin-II receptor, type 2; *CO,* cardiac output; *GFR,* glomerular filtration rate; *PVR,* peripheral vascular resistance.

Angiotensin II also is produced locally, in the renal parenchyma, and intrarenal RAAS likely contributes to and maintains SH in human CKD patients. This promotes glomerular hypertension, worsens proteinuria, leads to oxidative damage, and ends in renal fibrosis.[19-22] Systemic RAAS concentration therefore might not reflect intrarenal RAAS. Systemic aldosterone concentrations are higher in cats with CKD, indicating that elevated aldosterone can contribute to SH and is independent of RAAS. SH in these cats did not respond to treatment with angiotensin converting enzyme (ACE) inhibitors and plasma renin activity was found to be low to normal.[16,17] The pathogenesis of SH in cats could be associated with increased vascular tone, more so than in dogs and humans, and could explain their dramatic response to treatment with calcium channel blockers.[1,23]

Endothelial dysfunction likely is involved in the pathogenesis of SH in human CKD patients. Plasma asymmetric dimethylarginine (ADMA) and symmetric dimethylarginine (SDMA) both affect NO production and action, and circulating concentrations are increased in cats with CKD; levels also correlate with plasma creatinine. However, ADMA concentrations do not seem to be associated with SH, nor is there a correlation between circulating ADMA concentration and cats with TOD. In addition, no difference has been found in plasma ADMA concentrations between normotensive nonazotemic cats and hypertension nonazotemic cats.[1,13]

Proteinuria is an independent variable that is significantly associated with survival in cats with CKD and also in cats with all causes of SH.[23] Protein loss through the glomerulus and tubules likely stimulates the production of inflammatory mediators and cytokines, leading to glomerular hypertension, glomerular sclerosis, and renal fibrosis.[9] With protein-losing nephropathies, SH likely is the result of immune-complex deposition in the glomeruli and subsequent proteinuria and local vascular changes. SH prevalence seems higher in dogs with glomerular disease than in dogs with other forms of CKD.[24,25] SH is prevalent in dogs with leishmaniasis, with 61.5% of dogs with glomerular disease secondary to leishmaniasis developing SH (see ch. 221).[25]

SH occurs with acute kidney injury frequently (see ch. 322), as well as with the use of erythropoiesis-stimulating agents and feline kidney transplants.[26-29] Cats with polycystic kidney disease do not have a high prevalence of SH.[30]

Hyperadrenocorticism (see ch. 306 and 307)

SH is reported in 59-86% of all cases of hyperadrenocorticism in dogs, with those having unilateral adrenal tumors having a higher prevalence of SH.[31,32] In humans with hyperadrenocorticism, SH is suspected to occur secondary to increased intrinsic mineralocorticoid activity, activation of RAAS, and glucocorticoid-induced suppression of vasodilatory mechanisms such as NO production. However, there exists no clear evidence of decreased NO or increased aldosterone concentrations in dogs with hyperadrenocorticism. Many dogs remain hypertensive even after the diagnosis and treatment of hyperadrenocorticism.[31,32]

Adrenal Tumors (see ch. 308 and 311)

SH is common in cats with adrenal tumors, with unilateral cortical tumors such as carcinoma being more prevalent. In these cases, SH has not been found to be associated with survival, and most hypertensive cats return to normal BP after surgical therapy.[33] SH in cats with primary hyperaldosteronism is likely secondary to excess circulating aldosterone and its effects on renal Na^+ reabsorption. Increased Na^+ retention leads to increased intravascular volume and increased potassium secretion.[9] Aldosterone also causes vasoconstriction and increased peripheral vascular resistance, and it increases the effect of the sympathetic nervous system.[9,32] The majority of cats (>90%) with primary hyperaldosteronism have SH as defined by a systolic BP > 180 mm Hg, with SH resolving in all cats in whom BP was measured post-operatively.[9,32,34,35]

Pheochromocytoma is considered uncommon in dogs and rare in cats. Increased catecholamine secretion leads to excessive stimulation of alpha- and beta-adrenergic receptors, causing sustained or paroxysmal SH. At least half of affected dogs have SH at some point, and variable, paroxysmal SH also is possible.[32,36,37]

Hyperthyroidism (see ch. 301 and 302)

Excessive thyroxine in humans will cause a substantial decrease in systemic vascular resistance (SVR), followed by a decrease in diastolic BP. This in turn causes a reflexive increase in cardiac output. In the kidneys, decreased SVR stimulates the activation of RAAS, leading to increased BP. More importantly, thyroid hormones also increase sensitivity to catecholamines, thereby increasing cardiac inotropy and chronotropy.[9,32,38]

The prevalence of SH in cats with hyperthyroidism was once considered to be 5-23% and hyperthyroidism a major risk factor for SH and TOD.[9,32,39-41] However, recent evidence points to a much lower prevalence than previously thought,[42] and studies evaluating cats with TOD such as retinopathy indicate very few cats were hyperthyroid and severe SH seems rare. In dogs, hyperthyroidism is rare but it can occur; SH has been reported secondary to thyroid gland adenocarcinoma, with subsequent return to normal BP after carcinoma therapy.[43]

Diabetes Mellitus (DM) (see ch. 304 and 305)

SH is common in human DM patients, and nephropathy secondary to DM is thought to be the main factor for the development of SH in human type 1 diabetics. In human type 2 DM, a wider range of metabolic syndrome factors (obesity, insulin resistance, hyperlipidemia) could be implicated.[32,44] Loss of insulin can lead to decreased endogenous vasodilatory effects via altered NO generation, increased Na^+ and water retention,

increased intracellular calcium concentrations leading to increased vascular smooth muscle tone, proliferation of vascular smooth muscle, and sympathetic system stimulation.[32,45]

SH occurs in about one third of humans with type 1 DM and in >50% of type 2 DM patients.[46,47] SH is recognized in 35%-46% of acute spontaneous DM in dogs as well as in longitudinal studies.[47,48] However, no associations between hypertension, proteinuria, and retinopathy with time of DM diagnosis or degree of glycemic control have been found, and systolic BP tends to be <160 mm Hg in most diabetic dogs. In diabetic dogs with SH, the elevation in BP usually is mild.[47] Interestingly, recent evidence indicates that BP does not increase significantly over the course of the disease in dogs, suggesting the effect of DM on BP occurs early on.[47] This contrasts with previous evidence that indicated an increase in prevalence with duration of disease.[48] In cats, SH may only occur in a very small percentage of diabetics.[32,49]

Cardiovascular Disease and Diet (see ch. 183)

SH causes cardiovascular changes in cats and dogs, but contrary to the analogous situation in humans, cardiac disease does not seem to produce SH in cats or dogs (see discussion below).[50] There is no known association between high salt diets and the development of SH in cats.[51]

White-Coat Hypertension

White-coat hypertension is defined as a transient increase in systemic BP in the hospital setting compared to the patient's normal setting, and is likely secondary to activation of the sympathetic nervous system by environmental stimuli. White-coat hypertension is recognized in cats and dogs. Evidence is contradictory on whether cats acclimate, and return to normal BP, faster than do dogs.[6,52] In retired racing Greyhounds, adaptation and acclimation might not occur until after many hours or days.[6]

Idiopathic Hypertension

Idiopathic hypertension is quite rare in dogs. In cats, reports indicate 13-20% of hypertensives are idiopathic.[2,9,12,23] However, this could be an overrepresentation, as other diseases such as early CKD may have been overlooked in retrospective studies. When compared to a population of normotensive nonazotemic geriatric cats, cats with SH have had a significantly higher plasma creatinine concentration (but still considered nonazotemic) and lower urine specific gravity.[53] The development of renal biomarkers that are more sensitive might change the prevalence of idiopathic hypertension in cats as earlier stages of kidney disease are recognized in hypertensive cats that previously would have been classified as idiopathic.

Clinical Manifestations of Hypertension

SH can result in both mechanical and functional alterations in vasculature that can lead to the development of TOD.[54,55] Independent risk factors for TOD exist in people and likely do in our patients as well, including neurohormonal alterations, metabolic or inflammatory factors, and patient factors (obesity, diet).[54-57] Changes in the vasculature transmit elevated pressures to tissue, or induce local ischemia. The most common organs affected include the eyes, brain, kidneys, and heart. The magnitude of BP elevation, variability over 24 hours, and speed of development influence TOD in people.[58] Little information exists in animals regarding the development of TOD and magnitude of BP elevation, but it has been suggested that blood pressure be reduced to a systolic BP of 150 mm Hg and a diastolic BP < 95 mm Hg.[2]

Ocular Manifestations

The most common site of TOD is the eye, with the posterior segment most commonly affected (see ch. 11). As BP exceeds retinal autoregulation, a hypertensive choroidopathy/retinopathy leads to the breakdown of the blood-retinal barrier and altered vessel diameter, reducing retinal/choroidal perfusion.[59,60] Hypertensive retinal lesions are common in geriatric feline patients and were reported in 16% of cats >8 years old in one study.[61] Prevalence is unknown in dogs. Common ocular lesions caused by SH include: partial to complete retinal detachment, hemorrhage, multifocal edema, retinal vessel tortuosity, retinal perivascular edema, papilledema, optic nerve atrophy, and vitreal hemorrhage (Figure 157-3, *A* and *B*).[2,12,62,63] Tortuosity of the

retinal vasculature occurs in small animals but might be less distinct than in people.[3,63-65] Changes to the anterior chamber occur less frequently and generally are manifested as hyphema and/or iris hemorrhage.[12,64,66] Extraocular manifestations are rare; retrobulbar bleeding has been reported in a cat.[67] Secondary ocular manifestations include retinal degeneration and glaucoma.[12,68]

Note the retinal vasculature as it appears in the non-detached (non-blurry; lower right) region and detached (blurry; center and upper) region. **B,** Hypertensive retinopathy characterized by multifocal retinal hemorrhages on fundic examination. **C,** Ultrasound image of hypertensive retinopathy; retinal detachment with subretinal hemorrhage. Arrowheads indicate detached retina. (**A** and **B,** Courtesy Dr. Alexandra van der Woerdt; **C,** Courtesy The Animal Medical Center.)

Vascular Manifestations

SH can cause a vasculopathy that is characterized by endothelial dysfunction and remodeling of arteries (i.e., arteriosclerosis, arteriosclerotic stenosis) (Figure 157-4).[69] The end result is reduced dilation capability of the resistance vasculature. Vascular changes are less common in dogs and cats relative to people. However, arteriosclerosis has been described in cats.[9,11] Rarely, aortic dissections can occur in dogs and cats (Figure 157-5).[70,71] Vascular remodeling characterized by intimal thickening, fibrosis, and degeneration of the extracellular matrix results in tearing of the tunica intima. Increased intraluminal pressures and pulsatile flow promote formation of a "dissection" between the two layers.[72] Aortic dissections can rupture and/or cause visceral ischemia.

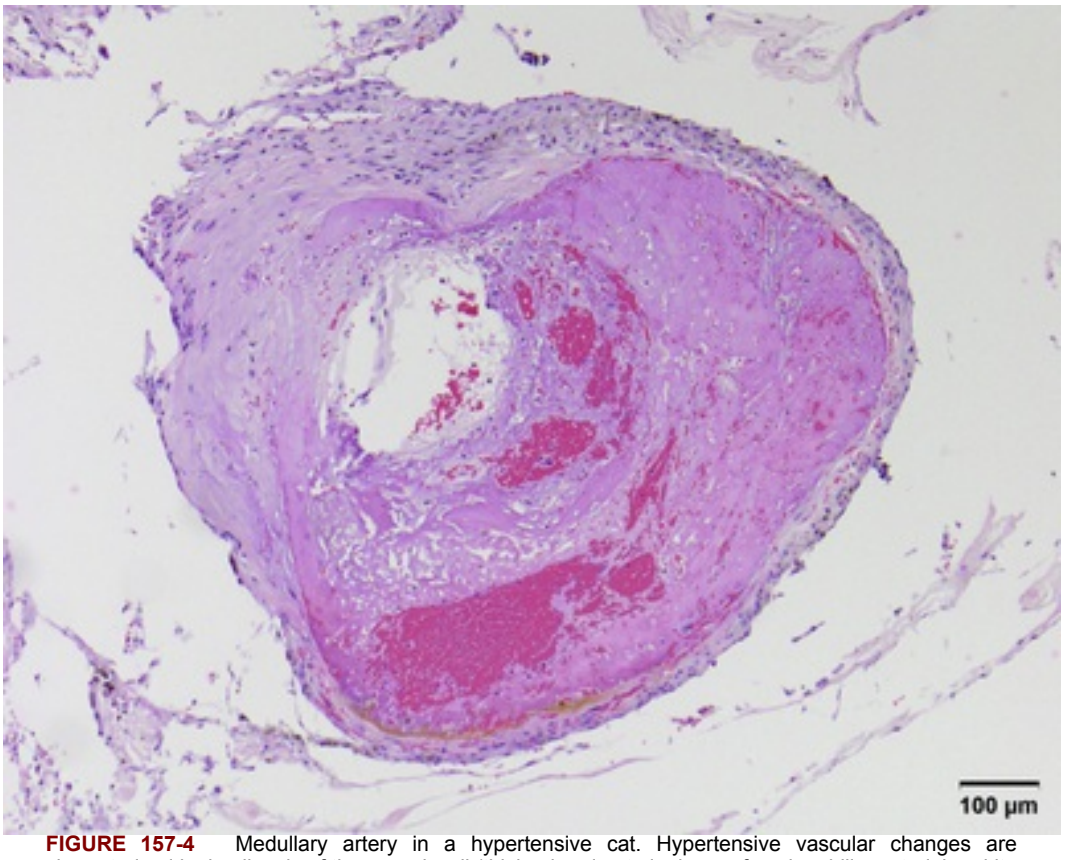

FIGURE 157-4 Medullary artery in a hypertensive cat. Hypertensive vascular changes are characterized by hyalinosis of the vessel wall (thickening due to leakage of eosinophilic material and its deposition in the vessel wall resulting in a hyaline appearance) or as hyperplastic arteriosclerosis (thickening of the vessel wall due to concentric hyperplasia of spindloid cells). Both can be seen in this image. The abnormal vessel is markedly distended by a large thrombus. (Courtesy Taryn Donovan, The Animal Medical Center.)

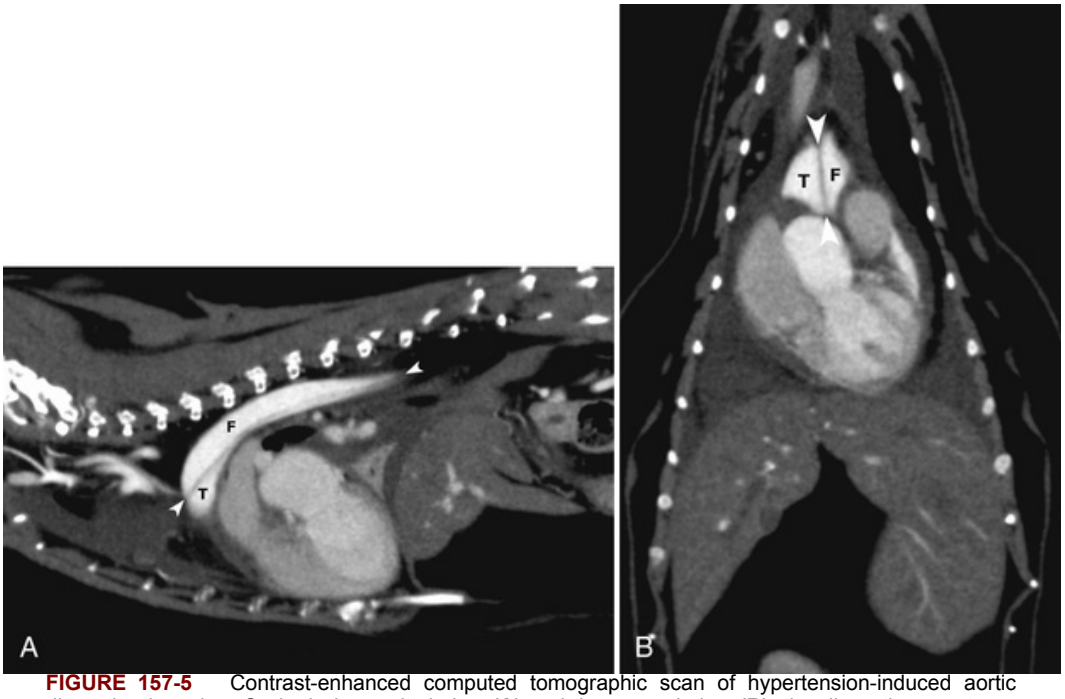

FIGURE 157-5 Contrast-enhanced computed tomographic scan of hypertension-induced aortic dissection in a dog. On both the sagittal view **(A)** and the coronal view **(B),** the dissection creates a false lumen (F) and a true lumen (T), separated by the dissected aortic endothelium (hypointense line;

arrowheads). (Courtesy The Animal Medical Center.)

Cardiac Manifestations

SH can result in both functional and structural cardiac changes.[69] The most common structural change is left ventricular concentric hypertrophy (LVH) in response to increased wall tension (pressure overload). Hypertrophy occurs in an effort to normalize wall stress and preserve left ventricular (LV) chamber function.[73] LVH is non-linearly correlated with SH in cats, with a reported prevalence of 74-85%.[74,75] Left ventricular free wall and interventricular septum thicknesses are significantly different from age-matched controls without SH.[11] Structural alterations occur in experimental models and in 5-91.4% of dogs with spontaneously occurring SH, depending on echocardiographic criteria.[25,76,77] Many patients have limited structural changes and are asymptomatic.[50,78-80] Additional structural alterations can include: aortic root dilation, aortic insufficiency and, potentially, ruptured chordae tendineae.[81]

Remodeling of the coronary vasculature can lead to reduced coronary blood flow reserve. However, direct coronary remodeling is less common in our patients compared to humans. Studies in dogs have documented changes in coronary autoregulation and blood flow distribution independent of vasculopathy.[69] This could predispose to cardiac ischemic injury at lower blood pressures.[82] Reduced coronary reserve has been documented in dogs, increasing their susceptibility to mortality when coronary arterial flow is disrupted.[83,84] Coronary density is further complicated by ventricular hypertrophy. In people, decreased coronary circulation can manifest as angina, a condition not characterized in animals to date.

SH also can induce functional cardiac alterations.[85,86] Hypertensive diastolic dysfunction occurs in people and animals.[79,87] LV relaxation is slowed but overall LV stiffness or rate at which LV stiffness changes with changes in volume is unchanged. Additionally, increases in LV systolic and arterial stiffness exacerbate load-dependent relaxation.[87] Alterations in relaxation frequently precede hypertrophy and fibrosis; however, they also can contribute to these processes.[80,88,89] Echocardiographic features of diastolic dysfunction can include: reversal of the mitral valve E wave (early diastolic filling) to A wave (atrial contraction) ratio, and alterations in tissue Doppler imaging.[80,88,90] Systolic dysfunction, manifested as a reduced velocity of myocardial shortening, stress-corrected mid-wall shortening, and longitudinal LV free wall systolic velocities and gradients, have been observed.[80,88] However, ejection fraction often is normal and other systolic parameters (end-systolic elastance, end-systolic elastance/LV mass, and preload recruitable stroke work) are increased. Additionally, afterload enhancement of systolic performance is maintained. Some of these changes could be contribute to fibrosis, hypertrophy and diastolic dysfunction (Figure 157-6).[87]

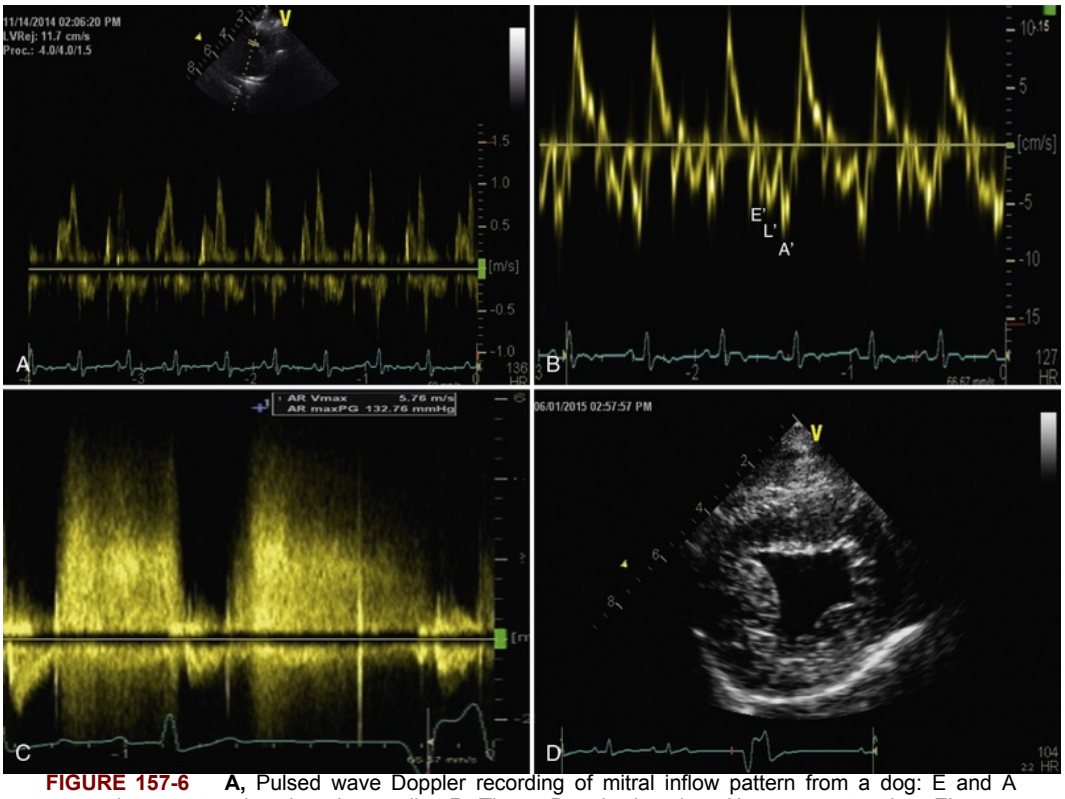

FIGURE 157-6 **A,** Pulsed wave Doppler recording of mitral inflow pattern from a dog: E and A reversal; supports relaxation abnormality. **B,** Tissue Doppler imaging: A' wave greater than E' wave; relaxation abnormality. Mid-diastolic L' wave consistent with diastolic dysfunction. **C,** Continuous wave Doppler; elevated peak aortic regurgitation velocity; consistent with high diastolic BP. **D,** Concentric left ventricular hypertrophy. (Courtesy Dennis Trafney, The Animal Medical Center.)

Both morphologic and functional changes secondary to SH can result in cardiac electrical instability. Ventricular and supraventricular arrhythmias are described in people but are less well characterized in small animals with SH.[91-93] This could be more common in dogs with pheochromocytoma, as catecholamines can contribute independently to arrhythmogenicity: idioventricular rhythms, premature atrial and ventricular contractions, and complete AV block have been documented.[94,95] Hypertension in patients with valvular heart disease can contribute to increased regurgitant volume and decreased stroke volume.

Renal Manifestations

SH can induce a hypertensive nephrosclerosis characterized by glomerulosclerosis, medial thickening of the arteriolar wall, and intimal fibrosis. Due to the common coexistence of hypertension and kidney disease, cause and effect have been questioned, as mentioned before. Additionally, treatment of hypertension could mitigate vascular changes histologically. A reduction in glomerular blood flow from preglomerular arterial narrowing and resultant ischemic injury may contribute. However, glomerular hypertension and hyperfiltration from preglomerular vasodilation also likely occur.[1] Activation of the RAAS could be a key player in the development of hypertensive nephropathy in animals, as has been suggested in people.[73,96,97]

SH also contributes to disease progression in patients with CKD,[97] and hypertension control is directly associated with outcome. SH is linearly associated with death and likelihood of uremic crises in dogs with renal disease.[98] Additionally, SH was correlated directly with histopathological and laboratory evidence of glomerular disease in leishmaniasis in one study, supporting the effect of SH on CKD progression.[99] Experimental canine renal models have shown reduced glomerular injury with ACEI and calcium channel blocker treatment, supporting the association between BP and renal disease progression.[100-102] In cats, glomerulosclerotic changes are slightly more common in hypertensive patients; however, SH has not been correlated directly with increased mortality.[103] The direct association between SH and proteinuria, an independent predictor of renal disease progression, makes correlations between spontaneous (especially proteinuric) kidney disease and SH difficult. Additionally, effective BP control limits the ability to determine

its independent role in disease progression. Blood pressure control in people can delay progression of renal disease/mortality, with some forms benefiting from even aggressive BP targets.[104-108]

Nervous System Manifestations

The nervous system also is affected by SH, with hypertensive encephalopathy being the most common clinical manifestation (Figure 157-7; also see ch. 12). Loss of autoregulation leads to an altered blood-brain barrier and development of vasogenic edema in acute SH. In chronic SH, a rightward shift in the range of blood pressure needed to maintain constant cerebral blood flow occurs. This can lead to changes in the cerebral vasculature, resulting in loss of regulatory tone and changes to vessel walls, potentially leading to hypoperfusion and stroke.[11,98,109,110] Secondary vasoconstriction also can induce ischemia and lead to edema.[11,98,109,110] Hypertensive encephalopathy has a predilection for white matter and predominantly occurs within the cerebrum (parietal and occipital lobes), although it can occur anywhere in the brain. Clinical signs include seizures, altered mentation, blindness, vestibular or cerebellar ataxia and pathologic nystagmus.[111] Cerebellar herniation has been reported in some patients.[110]

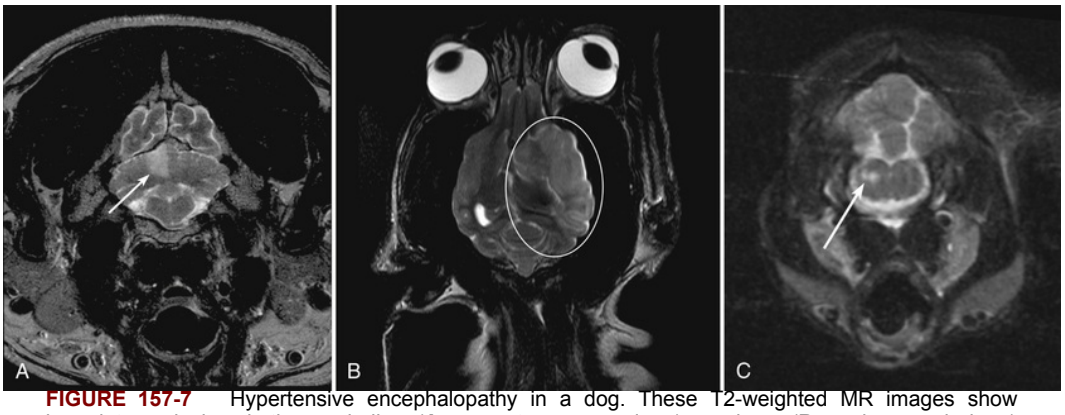

FIGURE 157-7 Hypertensive encephalopathy in a dog. These T2-weighted MR images show hyperintense lesions in the cerebellum (**A,** *arrow;* transverse plane), cerebrum (**B,** *oval;* coronal plane) and medulla (**C,** *arrow;* transverse plane). (Courtesy The Animal Medical Center.)

The spinal cord also is susceptible to SH injury. Ischemic myelopathy secondary to ventral spinal cord white matter ischemia is seen in cats (Figure 157-8). Histopathologic vascular changes (hyalinization, aneurysmal dilation, and/or thrombosis) may be seen.[112] Most cats present acutely, with paresis/plegia and/or cervical ventroflexion. All spinal segments can be affected, but there is a predilection for C1-C5 and most commonly C2 or C3.[113] Intramedullary hyperintense (T2) and isointense > hypointense (T1) lesions are seen on magnetic resonance imaging.[114] Independently, ischemic myelopathy related to perivascular calcification and thrombosis can occur in cats and be associated with myelomalacia.[115,116]

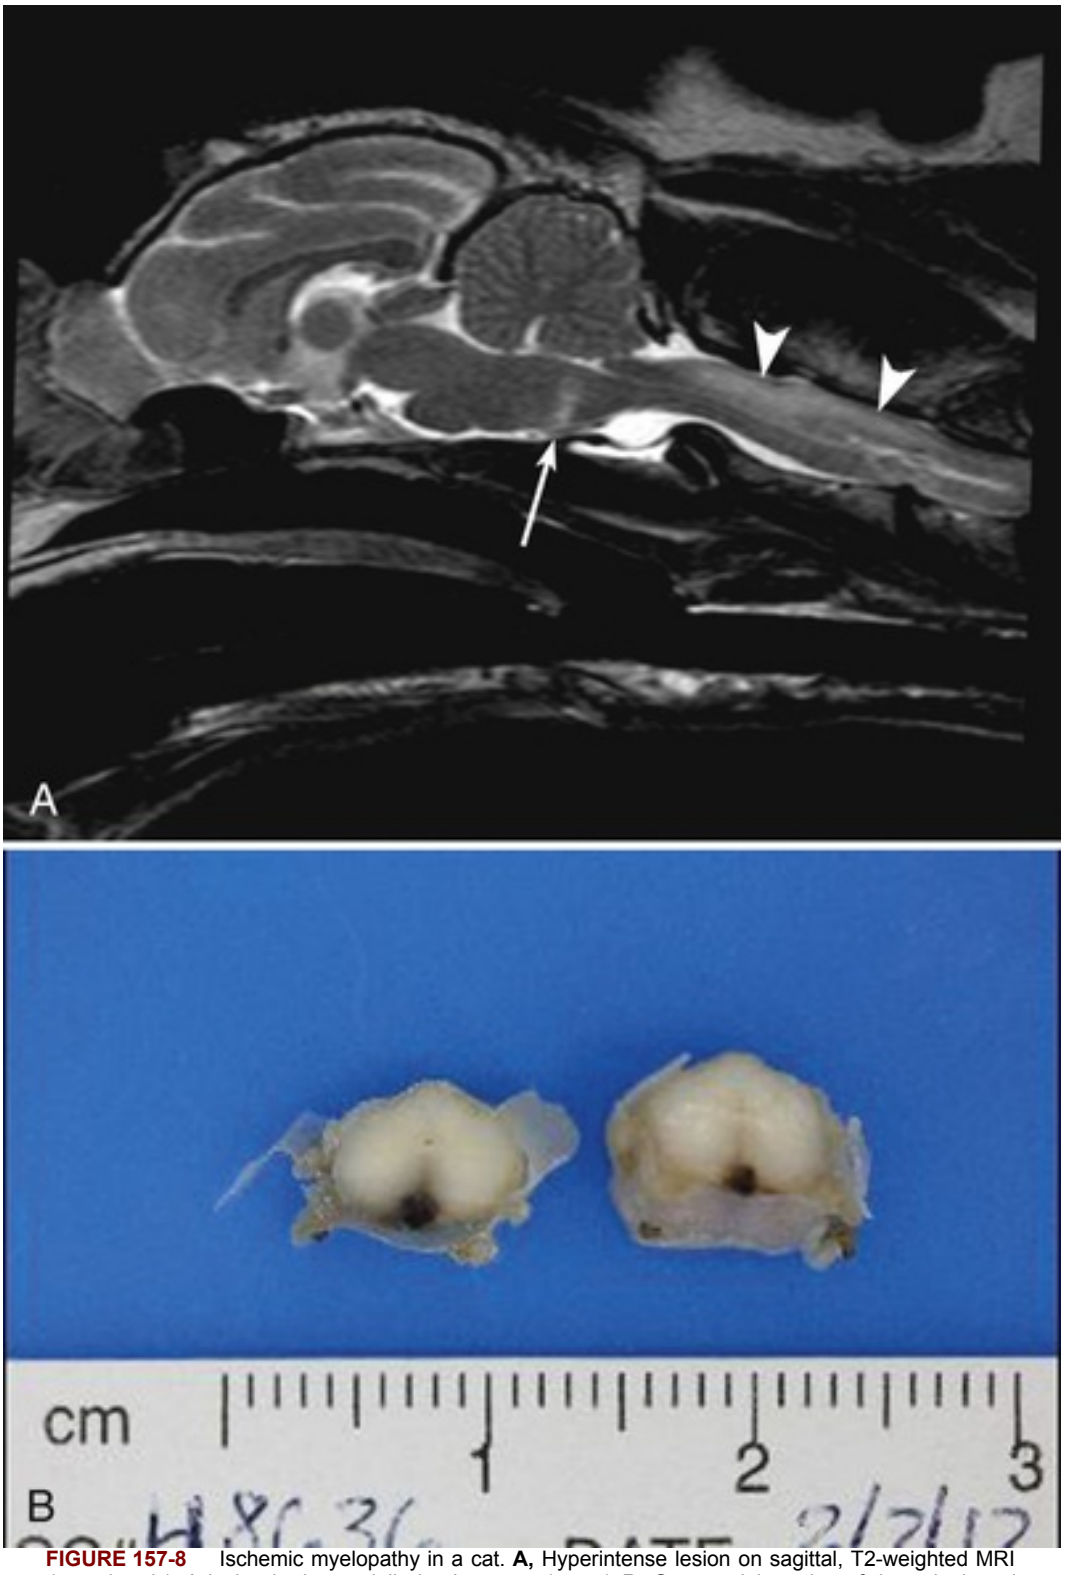

FIGURE 157-8 Ischemic myelopathy in a cat. **A,** Hyperintense lesion on sagittal, T2-weighted MRI *(arrowheads)*. A lesion in the medulla is also seen *(arrow)*. **B,** Gross axial section of the spinal cord demonstrating aneurysmal dilation of vessels. (Courtesy The Animal Medical Center.)

Neurodegenerative conditions in people can be exacerbated by hypertension.[117] Cognitive dysfunction (Figure 157-9), a neurodegenerative condition of small animals, shares pathologic similarities to Alzheimer's disease in humans (see ch. 263).[118] SH is a risk factor for and contributes to progression in Alzheimer's disease, potentially through impaired vascular repair mechanisms.[119]

FIGURE 157-9 Diffuse cerebral cortical atrophy in a dog on MRI (transverse plane), consistent with cognitive dysfunction. (Courtesy The Animal Medical Center.)

Cerebral amyloid angiopathy has been reported in geriatric cats and dogs and has been associated with vascular dementia in people.[120-122] Additionally, ischemic infarcts and/or hemorrhages might be more common in patients with cerebral amyloid angiopathy when hypertension is present.[123-129] Antihypertensive therapy can slow the progression of cognitive dysfunction and reduce the incidence of stroke in people.[130,131]

Epistaxis

SH has been suggested to cause epistaxis in small animals. The association in people has been questioned. Additionally, retrospective reviews of epistaxis in dogs and cats have shown, at best, a rare occurrence and questionable association overall.[11,132-134] Concurrent hypertension can complicate management of epistaxis.[135]

CHAPTER 158

Treatment of Systemic Hypertension

Dan G. Ohad

Client Information Sheet: Treatment of Systemic Hypertension

Systemic hypertension (SHT), even when severe and persistent, may not be associated with clinical signs. Hypertension needs to be controlled once recognized, even if not associated with any apparent clinical signs of secondary "target organ disease" (TOD). To maximize quality and quantity of life, one of the goals of SHT management is amelioration of clinical signs, if present. Overt clinical signs associated with hypertension might include acute blindness (due to retinal or intraocular hemorrhage, retinal detachment or degeneration), neurological signs (such as recumbency, seizure activity, mentation alteration, or vestibular signs), epistaxis, and (rarely) congestive heart failure (where there is severe left-sided heart disease, or circulatory volume overload) following excessive intravenous fluid administration (see ch. 157).[1-3]

Another treatment goal is to slow the progression (if present) or minimize the risk of SHT-related TOD, if not yet present, before it ever develops. This is important as the risk of TOD increases with increasing blood pressure (BP), and vice versa (Table 158-1, Figure 158-1).[4] The prognosis for dogs with chronic kidney disease (CKD) and cats with hyperthyroidism has been shown to be worse with concomitant, uncontrolled SHT.[5,6]

TABLE 158-1

Classification of Hypertension on the Basis of Risk for Target Organ Damage[4]

RISK CATEGORIES	SYSTOLIC BP (mm Hg)	DIASTOLIC BP (mm Hg)	RISK FOR TARGET ORGAN DAMAGE
I	<150	<95	Minimal
II	150-159	95-99	Mild
III	160-179	100-119	Moderate
IV	≥180	≥120	Severe

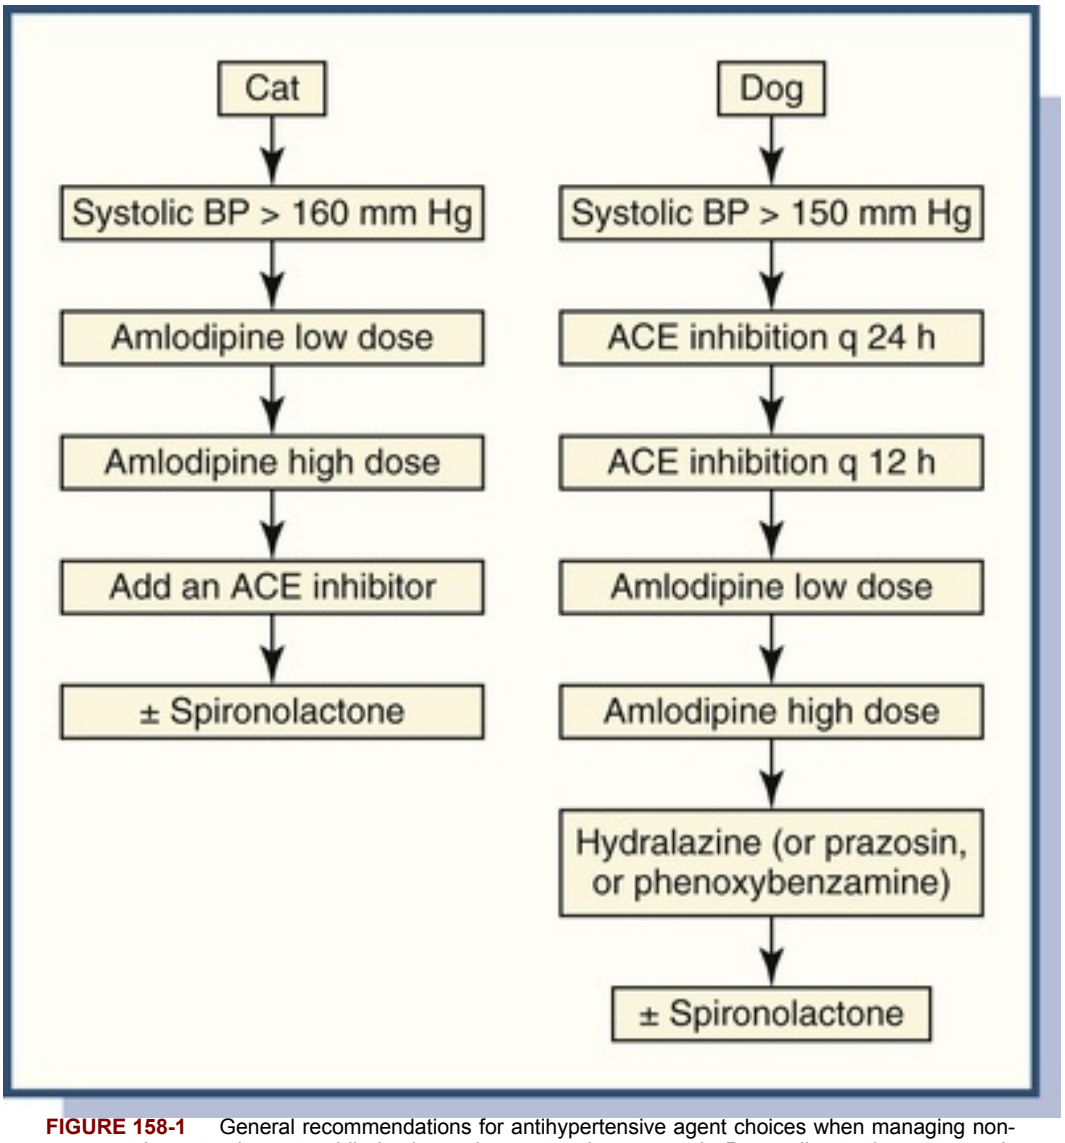

FIGURE 158-1 General recommendations for antihypertensive agent choices when managing non-emergent hypertensive pets while implementing a stepwise approach. Proceeding to the next step is an escalation in treatment, which should be considered when SHT is inadequately controlled. See Table 158-2 and reference #4 for more details.

Systemic hypertension, whether primary (rarely) or secondary (more commonly), is often progressive. In many patients, it remains clinically silent throughout most of the disease course, and yet, often requires lifelong therapy. This may be challenging to justify when communicating the need for chronic therapy to the unsuspecting owner.[4] The fact that control does not mean cure further increases this challenge. The pathogenesis of SHT is multi-factorial and its diagnosis can be elusive. Prior to the onset of lifelong, potentially harmful pharmacotherapy for SHT, its presence, severity, and triggers, if identifiable, should be established. This is attempted based on some or all of the following measures: (1) Multiple BP measurements per examination, repeated on several (at least two) separate occasions, to ascertain SHT persistency (see ch. 99). To minimize over- or underestimation of SHT severity, and to avoid misidentifying trends of change in BP values, every effort should be made to consistently use the exact same measuring instruments, limb-of-choice, and technique, each and every time BP measurements are repeated.[7] This is performed while minimizing auditory and visual stimuli that can trigger a sympathetic-tone mediated, transient, reactive elevation of BP, potentially leading to overestimation of BP values (a "white-coat effect") and to unnecessary side effects or even treatment-related toxicosis. (2) Seeking evidence of ongoing, or of a high risk of, TOD. (3) Ruling out (or controlling, as needed) other conditions that might trigger or contribute to SHT, and that can occasionally be adequately controlled while minimizing the dosage of antihypertensive agents (Table 158-2). While such background conditions are often chronic and incurable, they may account for up to 80% of

hypertensive patients. Control, unfortunately, does not always adequately reduce BP values.[4] These conditions might include any, or even several of the following: renal disease, hyperadrenocorticism, diabetes mellitus, pheochromocytoma, feline hyperthyroidism, primary hyperaldosteronism, obesity, and, rarely, canine hypothyroidism (see ch. 157).[1,4,8,9] (4) Discontinuation or at least a decrease in dosage and/or frequency of drugs that can inadvertently increase systemic BP (e.g., corticosteroids, erythropoietin, or phenylpropanolamine) should be considered.[4]

TABLE 158-2

Dosing Recommendations for Antihypertensive Agents in Alphabetical Order

AGENT	CANINE DOSAGE	REFERENCES	FELINE DOSAGE	REFERENCES
Acepromazine (phenothiazine)	0.05-0.1 mg/kg **SC or IV**	11	0.05-0.1 mg/kg SC or IV	11
	0.5-2 mg/kg PO q 8 h	4	0.5-2 mg/kg PO q 8 h	4
Amlodipine (dihydropyridine calcium channel blocker)	0.0625-0.25 mg/kg PO q 24 h	74	0.125-0.25 mg/kg PO q 24 h	47, 49, 56
	0.05-0.1 mg/kg PO q 24 h	34	0.13-0.3 mg/kg PO q 24 h	11
	0.1-0.25 mg/kg PO q 24 h	4	0.625-1.25 mg/cat PO q 24 h	11, 15, 34
	0.1-0.4 mg/kg PO q 24 h	11, 15	0.1-0.5 mg/kg PO q 24 h	4
Atenolol (cardioselective, beta-1 adrenergic blocker)	0.25-1 mg/kg PO q 24-12 h	11, 15, 74	2 mg/kg PO q 24-12 h	11
	0.25-1 mg/kg PO q 12 h	4	6.25-12.5 mg/cat PO q 24-12 h	11, 15, 34, 74
	1 mg/kg PO q 24-12 h	34	6.25-12.5 mg/cat PO q 12 h	4
Benazepril (ACE inhibitor)	0.25-0.33 mg/kg PO q 24 h	74	0.25 mg/kg PO q 24 h	74
	0.25-0.5 mg/kg PO q 24 h	11	0.25-0.5 mg/kg PO q 24 h	11
	0.25-0.5 mg/kg PO q 24-12 h	15, 34	0.25-0.5 mg/kg PO q 24-12 h	34
	0.5 mg/kg PO q 24-12 h	4	0.5 mg/kg PO q 12 h	4
			0.5-1 mg/kg PO q 24-12 h	15, 47, 56
Enalapril (ACE inhibitor)	0.25-0.5 mg/kg PO q 24-12 h	11	0.25 mg/kg PO q 24 h	74
	0.5 mg/kg PO q 24-12 h	4, 74	0.5 mg/kg PO q 24 h	4
	0.5-1 mg/kg PO q 24-12 h	15, 34	0.25-0.5 mg/kg PO q 24-12 h	11, 15, 34
Hydralazine (direct arteriolar dilator)	0.5-2 mg/kg PO q 12 h	4	1-2.5 mg/cat **SC**	15
	0.5-3 mg/kg PO q 12 h	11	2.5 mg/cat PO q 24-12 h	4
	0.5-3 mg/kg PO q 12-8 h	4, 15, 74	2.5-5 mg/cat PO q 24-12 h	11
	0.2 mg/kg **IV or IM** q 2 h, PRN	4	2.5-5 mg/cat PO q 12 h	74
			0.2 mg/kg **IV or IM** q 2 h, PRN	4
Phenoxybenzamine (alpha-1 adrenergic blocker)	0.25-2.5 mg/kg PO q 12 h	15	Not recommended	11
	0.25 mg/kg PO q 12-8 h or 0.5 mg/kg PO q 24 h	4	Not recommended 2.5 mg/cat PO q 12-8 h or 0.5 mg/cat PO q 24 h	15 4
	0.25-1 mg/kg PO q 12 h	74		
	0.25-1.5 mg/kg PO q 12-8 h	11	2.5-5 mg/cat PO q 24-12 h	74
Prazosin (alpha-1 adrenergic blocker)	0.5-2 mg/dog PO q 12 h	15, 34	Not recommended	11
	0.5-2 mg/dog PO q 12-8 h	11, 74	Not recommended	34
	0.5-2 mg/kg q 12-8 h	4	Not recommended	15
			0.25-0.5 mg/cat PO q 24 h	4
			0.5-1 mg/cat PO q 12-8 h	74

Propranolol (non-cardioselective beta-adrenergic blocker)	2.5-10 mg/dog PO q 12-8 h	34	2.5-5 mg/cat PO q 12-8 h	34, 74
	0.2-1 mg/kg PO q 12-8 h	74	2.5-5 mg/cat PO q 8 h	4
	0.2-1 mg/kg PO q 8 h	4		
Ramipril (ACE inhibitor)	0.125 mg/kg PO q 24 h	15	0.125 mg/kg PO q 24 h	11, 15
	0.125-0.25 mg/kg PO q 24 h	11	0.125-0.25 mg/kg PO q 24 h	47, 56
	0.125 mg/kg PO q 12 h	74	0.5 mg/kg PO q 24 h	74
Sodium nitroprusside (nitrate vasodilator)	1-5 mcg/kg/min IV CRI	53	1-2 mcg/kg/min IV CRI	74
	1-7 mcg/kg/min IV CRI	74	≥0.5 mcg/kg/min IV CRI	53
Spironolactone (aldosterone antagonist diuretic)	1-2 mg/kg PO q 12 h	4, 15, 34	1 mg/kg PO q 12 h	34
	1-4 mg/kg PO q 24-12 h	74	1-2 mg/kg PO q 12 h	4, 15,
			1-4 mg/kg PO q 24-12 h	74

When a dosage range is given, treatment is usually initiated at the low end of the range and titrated upward to effect. Boldface font is precautionary, indicating parenteral routes and dosages for drugs that can be given either orally or parenterally.

ACE, Angiotensin converting enzyme; *CRI*, constant rate infusion; *h*, hour; *IV*, intravenous; *PO*, orally; *PRN*, as needed; *q*, every; *SC*, subcutaneously.

Sustained SHT can involve autoregulatory vasoconstriction in vascular beds that depend on capillary pressure more than they depend on capillary flow, including the myocardium, the brain and retina, and the kidneys.[10] Such vascular beds may consequently develop arteriolar medial hypertrophy, tissue ischemia, microscopic infarcts, and hemorrhage (e.g., in the brain or retina).[11] If SHT is caused by persistent exposure to volume overload, left-sided congestive heart failure can develop in susceptible cardiac patients (see ch. 246). When SHT is caused by an elevated systemic vascular resistance, rather than by fluid volume expansion, the left cardiac ventricle (LV) is forced to contract against a persistently elevated resistance (afterload). This leads not only to a persistently elevated force of LV contraction, but also to compensatory left ventricular concentric hypertrophy, teleologically "aimed at" decreasing oxygen consumption by LV cardiomyocytes.[10] Similarly, if CKD is involved in triggering SHT, the kidneys may also lose their autoregulatory capabilities, normally used to cope with elevated BP and to prevent its transmission into the glomeruli, further exacerbating the already preset renal injury.[12] The choice of a treatment strategy, therefore, should ideally be individually tailored and based on previously gathered knowledge about ongoing comorbidities and the underlying mechanism(s) responsible for the development of SHT in each given patient (see below).

Changes in lifestyle may be considered for companion animals with mild-to-moderate SHT without evidence of TOD, prior or in parallel to the onset of pharmacotherapy. Reducing body weight has been recommended in obese, hypertensive pets,[8] although this recommendation has been recently challenged.[13] As an extrapolation from human medicine, reduction of dietary sodium intake has been advocated in the past,[14] but has not proven beneficial to hypertensive pets.[15] It may, in fact, carry some risks such as volume depletion, leading to reduced renal perfusion with resultant exacerbation of ongoing renal disease, if present. Another possible, and likely more important risk is the activation of the renin-angiotensin-aldosterone system (RAAS) with resultant kaliuresis and hypokalemia, and even exacerbation of SHT.[15-19] If dietary sodium reduction is recommended for other, non-related reasons, it should therefore be achieved gradually and in combination with, rather than as a surrogate for, antihypertensive pharmacotherapy.[20] Avoiding excessive sodium intake, on the other hand, does benefit SHT patients.[4] In renal hypertensive pets, the common practice of avoiding excessive dietary protein intake is considered more important than aggressively limiting dietary sodium intake. Avoiding excessive dietary sodium while arteriolar vasodilators or beta-receptor antagonists are being administered might negate those compensatory hypertensive effects mediated by sodium retention and extracellular fluid volume expansion.[21] Despite such compensatory effects, beta-receptor antagonists also have the potential to reduce BP not only in patients with hyperthyroidism, but also in those with renal hypertension, by decreasing heart rate and stroke volume, as well as by inhibiting the release of renin.[15] Hypertensive pets with pheochromocytoma, too, should receive beta-receptor antagonists, when already receiving phenoxybenzamine (see ch. 311).[22]

Among the diseases associated with secondary SHT, kidney disease is one of the most common underlying etiologies in both dogs and cats (see ch. 157 and 324).[4] When managing a dog or a cat with kidney disease and SHT, gradual and consistent reduction of BP should be the goal, and choices of antihypertensive agents

should be based on the known or suspected underlying mechanism behind SHT. For example, if SHT is thought to involve an elevated serum renin concentration, drugs that interrupt the RAAS such as angiotensin converting enzyme inhibitors (ACEi), or angiotensin receptor blockers (ARBs) should be thought of as a priority. Agents from both groups, however, should not be co-administered if other combination therapies perform better. Nevertheless, ACEi are not highly potent antihypertensive agents and are therefore not expected to control severe SHT when used as a sole therapy. Beta-adrenergic antagonists, renin antagonists, or centrally acting alpha-2-receptor agonists may theoretically be considered in such patients instead of ACEi or ARBs, but are not typically used as first line antihypertensive medications. If, instead of RAAS activation, excessive serum sodium and/or fluid volume-mediated SHT is present, diuretic agents, an alpha-1-receptor antagonist, or a dihydropyridine calcium channel blocker might be more effective and should be prioritized.[15] The latter, in fact, is usually the treatment of choice in severe feline SHT and is often combined with ACEi in hypertensive dogs (see Figure 158-1 and Table 158-2).

Sympathetic nervous system-mediated increases in heart rate and aldosterone-mediated sodium and water retention may moderate the BP-controlling effect of systemic arteriolar vasodilation. Thus, hypertensive patients with kidney disease that are refractory to treatment and therefore need polypharmacy may benefit the most from a combination of antihypertensive mechanisms (which may sometimes also aid in controlling each other's side-effects), e.g., interference with the RAAS while at the same time achieving relaxation of vascular smooth muscle via calcium channel blockade, along with reduction of sodium and fluid volume, rather than from a combination of two different agents belonging to the very same group.

An intricate interplay between multiple organ systems (heart, kidneys, hormonal and autonomic nervous systems) regulates BP, and an imbalance might readily develop between their relative contributions to maintenance of a steady state, in response to silently and subtly progressive disease, or to otherwise changing circumstances. Therefore, even normotensive patients should be regularly reevaluated at 1-3 month intervals, or even more frequently until SHT is controlled. Reevaluation is used to assess BP and renal function, and to make appropriate dose and administration frequency adjustments, so as to achieve and ascertain long-term stability.[1,4] One example of this principle is the gradual loss of muscle mass and lean body weight occurring in some patients with CKD, necessitating decreased dosages of antihypertensive agents unless BP has progressively increased.

In hypertensive cats, physical examination should include evaluation for a thyroid nodule "slip" along with serum biochemistry including thyroxine concentration. Evaluating a bilateral funduscopic examination (see ch. 11), a neurological assessment (see ch. 12 and 259), kidney function evaluation (see ch. 321), careful thoracic auscultation (an intermittent gallop rhythm, an arrhythmia, or a murmur; see ch. 55), and NTproBNP testing (see ch. 246) should all be considered. Relevant findings warrant further evaluation and treatment as addressed in the appropriate chapters in this textbook (see above and ch. 157).[4,23-25]

Treating Canine SHT

Controlling spontaneously-occurring SHT in dogs is reportedly challenging, and may often require multi-drug therapy (see Figure 158-1 and Table 158-2).[1,5] Regardless of the initially documented magnitude of BP, it has been recommended to target a systolic BP of 140-150 mm Hg, when possible, while avoiding systemic hypotension (BP < 110-120/60 mm Hg).[1,4] A target diastolic BP of ≤95-100 mm Hg has also been suggested, if tolerated.[4,11] In stable hypertensive dogs, staged pharmacotherapy has been suggested by some investigators, starting with a once or twice daily administration of ACEi (see Figure 158-1).[20] Many clinicians choose an agent of the ACEi family as the first line of therapy for dogs with CKD-related SHT, not because of its proven efficacy in BP reduction but rather because of its ability to reduce proteinuria (urinary protein-to-creatinine ratio, or UP/C ≥ 0.5 for dogs) in proteinuric kidney disease, as this effect is associated with a lower progression rate in glomerulonephritis, hereditary nephritis, and CKD.[26-28] This also makes intuitive sense as progressive SHT, when transmitted through renal arteries into glomerular afferent arterioles, contributes to proteinuria development and exacerbation, which, in turn, is associated with decreased survival rates.[5,29,30] However, despite evidence of reduced glomerular capillary pressure and reduced histopathological scores of glomerular and tubular injury following ACE inhibition in dogs with experimentally-induced kidney disease, systemic BP values in these dogs were only slightly reduced.[31]

Systolic BP is expected to decrease by up to about 10%, once a new steady state is achieved following the onset of chronic ACE inhibition, which may be all that is needed in dogs with mild SHT.[1] However, if SHT is moderate or severe, or if BP is not sufficiently controlled with ACEi monotherapy, the second generation,

dihydropyridine-type, voltage-dependent calcium channel blocker amlodipine besylate is often co-administered on a once-a-day basis. Due to the long elimination half-life of amlodipine, the once daily administration interval is typically enough to reduce calcium influx into vascular smooth muscle cells and, thereby, to sufficiently relax systemic arteriolar vessels and decrease total peripheral resistance and systemic BP for many hours, in both dogs and cats.[11,32-37] The degree, progression rate, and duration of vasodilation, as well as the timing of its offset following oral amlodipine therapy have all been shown to be dose-dependent, at least in rodents.[38] Binding of amlodipine to vascular smooth muscle L-type calcium channel receptors is slow. Onset of action, therefore, is slow too, which is beneficial in minimizing acute hypotension and resultant reflex tachycardia from activation of vascular baroreceptors. Similarly, the duration of the BP reduction effect is long as well. Hence, the choice of amlodipine besylate is also typically made because amlodipine is associated with less reflex tachycardia than other arteriolar dilators, such as hydralazine.[1] The co-administration of an ACEi and amlodipine might not only provide for (modest) additive BP-reducing effects, but also for treatment safety, as the former helps to blunt the RAAS stimulation (and resultant proteinuria) potentially triggered by the latter.[1,39] Mild and possibly tolerable elevation (0.5 mg/dL, 50 mmol/L, or 10-20%) of serum creatinine is sometimes to be expected following initiation of ACEi therapy,[4,11] but acute azotemia is considered rare in otherwise well-hydrated patients.[40-44] Such elevation, even if mild and seemingly tolerable at first, is considered by some as evidence of acute kidney injury with potential risks, which should, and can be avoided by staged pharmacotherapy as elaborated above.[20] Caution should therefore be exercised, especially in patients with advanced CKD or in those that are prone to dehydration. Glomerular filtration rate may decrease following ACE inhibition, especially in dehydrated or hypovolemic animals. Although single nephron studies have shown that this is not necessarily the case in pets with CKD,[31,41] one has to keep in mind that ACEi, too, can be directly nephrotoxic at very high (70×) dosages, and/or when administered to severely volume-depleted animals, or if co-administered with other nephrotoxic agents such as aminoglycosides or nonsteroidal anti-inflammatory drugs.[11,44]

If combination therapy is still insufficient to control SHT in a dog, the amlodipine dosage is successively increased, based on repeated BP measurements (meticulously repeating the same measurement technique and circumstances whenever possible). In hypertensive pets with no evidence of TOD and when a hypertensive crisis is ruled out (see below), such repeated BP measurements are performed every one to two weeks, until satisfactory BP control is achieved or until reaching the highest recommended amlodipine dosage. Owner understanding of, and compliance with, the dosing schedule should be confirmed prior to increasing amlodipine dosage even further, which allows at least one or two weeks of maximal amlodipine dosage to ascertain that a new steady state has been achieved. Measurement of BP prior to making the decision of increasing the dosage even further, should ideally be made about 12 hours post-amlodipine dose, so as to avoid an underestimation of its performance, based on too early a measurement.[1] Treated patients should be monitored closely for hypotension (e.g., BP values of ≤120/60 mm Hg, accompanied by weakness, syncope or sinus tachycardia) and for azotemia.[4] If even this extreme measure is inadequate for achieving satisfactory BP control, hydralazine, prazosin, or phenoxybenzamine may be considered in addition to amlodipine besylate, although clinical studies in spontaneously hypertensive dogs have yet to support these recommendations. Diuretics should only be used to treat SHT in over-hydrated patients, while exercising extreme caution in animals with CKD that are already prone to dehydration and acute decompensation of the disease. One has to weigh the risks versus the benefits of empirical combination therapy and adopt a conservative approach in terms of dosage and administration frequency, when facing reflex tachycardia and/or hypotension in any patient. If the clinician does not feel experienced enough with using any of the latter agents, using them while the patient is hospitalized for 1-3 days, during which serum biochemistry, hydration status, appetite, BP and heart rate can be monitored, is encouraged.

A cardioselective beta-adrenergic antagonist such as atenolol can be added to control reflex tachycardia resulting from highly potent arteriolar vasodilators, especially if reflex tachycardia is thought to contribute to inadequate BP control. On the other hand, as reflex tachycardia is thought to develop as a compensatory reaction to iatrogenic excessive hypotension, one should exercise extra caution and avoid negating such tachycardia too aggressively. Non-cardioselective beta-receptor antagonists such as propranolol, might, in fact, counteract their own systemic BP-lowering effects by negating arteriolar dilation in vascular beds of skeletal muscle throughout the body. This specific vascular bed comprises a large enough portion of the systemic circulation to compromise the efficacy of antihypertensive therapy, or at least increase total peripheral resistance and systemic afterload.[45] Moreover, beta-receptor antagonists as monotherapy have not been shown to be very effective in the treatment of hypertension in hyperthyroid cats,[46] and might therefore

prove to be a less-than-ideal monotherapy choice in dogs as well.

Treating Feline SHT

A systolic BP of <160, and preferably 140 mm Hg if tolerated, has been recommended as a target value for treated hypertensive cats, while avoiding hypotension.[47] A decrease of as much as 30 to 60 mm Hg in systolic BP can often be achieved upon reaching a steady state based on a once daily dosing regimen of the second-generation calcium channel antagonist amlodipine besylate.[15,35,36,48] In a recent randomized, double-blind, placebo-controlled clinical trial, systolic BP either decreased by at least 15% or to <150 mm Hg in over 60% of 34 hypertensive cats receiving amlodipine at 0.125 to 0.25 mg/kg once daily for up to 28 days, while only 18% of the 27 placebo-treated cats reached these same endpoints.[49] Due to the long (53 hours) elimination half-life of amlodipine in cats,[50] a once-daily administration interval is not only convenient but is also considered safe and effective,[49] other than a rarely documented risk of mild hypokalemia or hypochloremia, both of which should, therefore, be periodically ruled out. Due to the potential of SHT to be silently progressive, BP should ideally be measured about every 6 to 8 weeks, at least until steady BP values are repeatedly documented to be within target range, at which time re-evaluation can be carried out up to every 3 months.[4,51] It has been estimated that amlodipine-treated cats have nearly 8 times greater odds of treatment success than placebo-treated cats.[49] This agent has been shown to be sufficient to prevent the development of hypertensive encephalopathy and ongoing ocular damage, and to stabilize, or even reverse, compensatory concentric cardiac hypertrophy in cats with SHT.[23,52] An initial amlodipine dosage of 0.125 mg/kg once daily has been recommended, following which steady state of plasma concentration is achieved in about 14 days in healthy cats.[50] This initial dosage can therefore be doubled, if needed, within 2 weeks. In cats with CKD associated with SHT, it can even be quadrupled (gradually over 4-8 more weeks) with only minimally negative chronotropic or inotropic effects, should insufficient performance be demonstrated, and prior to being stepped up by a multi-drug administration strategy (see Figure 158-1).[20,47] Feline CKD does not require amlodipine dosage reduction since it undergoes hepatic metabolism and its pharmacokinetic profile, therefore, should not be affected by this condition.[49,53] Calcium channel blockers, however, have not been shown to increase life expectancy in hypertensive cats.[48,54] Nevertheless, they do carry the potential of improving quality of life of such cats, including the maintenance of appetite level and body weight,[35,47,48] which might indirectly increase life expectancy, for example, when decisions around euthanasia are being considered. Dihydropyridine calcium channel antagonists, such as amlodipine besylate, can also act directly to reduce secretion of aldosterone by the adrenal cortex, which may add yet another mechanism by which they contribute to BP reduction in hypertensive cats.[55] This specific effect can theoretically be intensified by the addition of an aldosterone antagonist, such as spironolactone. In contrast, despite some preliminary evidence of normalization of BP values in about 40% of cats treated with ramipril,[56] generally using an ACEi agent as monotherapy has not been shown to be effective enough in controlling severe feline SHT.[1,3,41,48,57-59] As amlodipine besylate preferentially dilates the afferent renal arterioles, it might trigger an elevation of the intra-glomerular pressure in cats with severe, CKD-related SHT, when systemic BP is insufficiently reduced. However, amlodipine usually is able to sufficiently lower systemic BP enough to avoid transmission of SHT into the glomeruli, despite its preferential dilation of the afferent glomerular arterioles.[54] In patients where such transmission cannot be avoided, proteinuria (UP/C ≥ 0.4 for cats) can still be triggered or exacerbated despite adequate control of SHT. Persistent proteinuria, in turn, might promote glomerular and tubular damage, resulting in worsening kidney disease,[60,61] and even decrease survival.[5,54] This is where an addition of ACEi agent administered once daily can theoretically be beneficial, as these agents trigger preferential dilation of the efferent glomerular arterioles, thereby assisting the control of intra-glomerular pressure. Such co-therapy may prove important in proteinuric cats with CKD and renal hypertension, as proteinuria in this population is associated with reduced survival rates.[54] The goal should be reduction of the UP/C to the non-proteinuric range, or at least by 50% of baseline if abolishing proteinuria is impossible. Nevertheless, a small pilot study of hypertensive cats with CKD, comparing benazepril and amlodipine co-therapy to amlodipine monotherapy, did not support this theory.[62] Conversely, when amlodipine administration is successful in substantially reducing BP, it is shown to actually reduce, rather than exacerbate, proteinuria.[15] Until such controversies are resolved by more data, seeking evidence of and reducing proteinuria should probably be considered as highly important goals when managing cats with CKD and renal hypertension.[63]

Due to the potent anti-vasospastic effects of amlodipine, it should not be administered to hypertensive cats

if they also have moderate-to-severe aortic stenosis or left ventricular outflow tract obstructive disease, so as to avoid exacerbation of the trans-obstruction systolic pressure gradient, which may deteriorate their hemodynamic and clinical stability.[64] Similarly, amlodipine therapy is to be avoided when treating pets with myocardial failure, cardiogenic shock, severe bradyarrhythmia, or severe hepatic failure, and caution should be exercised when administered to those concomitantly treated with antifungal azoles, as some of these may trigger negative inotropic effects under certain circumstances, at least in people and dogs.[65-67] In addition, some azoles may also increase the plasma concentration of amlodipine by affecting hepatic/intestinal enzyme CYP3A4 metabolism.[68]

Similar to ACEi monotherapy, the use of beta-adrenergic antagonists or spironolactone as monotherapy for feline SHT has been so far disappointing.[46,57,69] However, cardio-selective beta-adrenergic antagonists can still be useful when attempting to reduce SHT secondary to feline hyperthyroidism, when administered prior to or following the onset of therapy for hyperthyroidism, simultaneously with amlodipine.[1]

Cats with systolic BP > 180 mm Hg prior to the onset of treatment for hyperthyroidism are likely to remain hypertensive after becoming euthyroid. However, even when hyperthyroid cats are normotensive prior to treatment, monitoring of BP values should probably be periodically performed for at least 6 months following reaching euthyroidism.[70] Only then can antihypertensive therapy be gradually weaned off while still consistently monitoring systemic BP values, as SHT can actually be exacerbated or even triggered *de novo* following thyrotoxicosis resolution. This phenomenon is thought to result from an "unmasking" effect of such resolution on an underlying, and previously occult CKD along with renal hypertension. When this is the case, antihypertensive therapy should be adjusted accordingly and maintained long-term, as needed.[6]

Treating a Hypertensive Crisis

Evidence of TOD along with a repeatedly documented systolic BP > 160 mm Hg justifies emergent intervention (Figure 158-2). If TOD is shown and SHT values are >180/120 mm Hg, emergent therapy should be administered based on even a single BP measurement session.[4] The need of continuous aggressive therapy, however, should be re-evaluated once BP values are shown to decrease to target levels and there is evidence of TOD improvement. Conversely, if no evidence of TOD is present and systolic BP is <200 mm Hg, urgent, rather than emergent therapy is indicated.[1] This means that BP reduction should be carried out in a more controlled and gradual manner, so as to avoid reaching mean BP values that are considered physiological in normotensive pets, but might be too low for sustaining adequate cerebral perfusion in those that have been chronically hypertensive up until that point in time.[34,71-73] As with other non-emergent cases, and in light of the above risk associated with too rapid and/or too extreme a decrease in BP values, at least one week should be allowed for a steady state to be achieved, prior to deciding on dosage titration.[1]

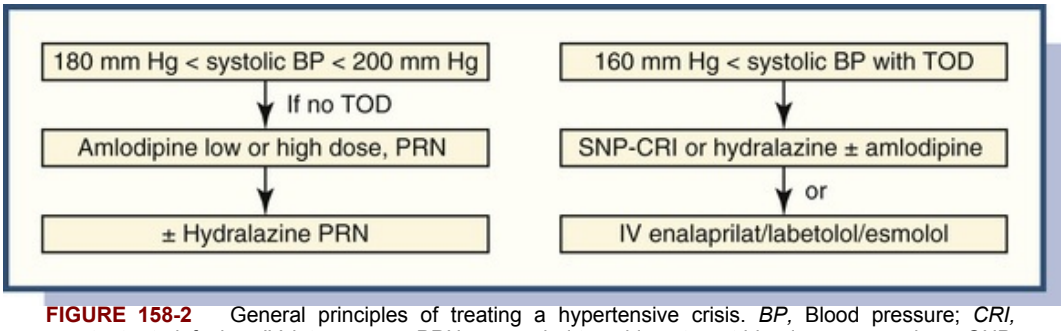

FIGURE 158-2 General principles of treating a hypertensive crisis. *BP*, Blood pressure; *CRI*, constant rate infusion; *IV*, intravenous; *PRN*, as needed to achieve target blood pressure values; *SNP*, sodium nitroprusside; *TOD*, target organ damage.

For emergent patients, constant rate intravenous infusion of sodium nitroprusside (SNP) is a good choice in experienced hands, as it can reach target BP values both rapidly and in a titratable fashion.[1] Moreover, the short plasma elimination half-life of SNP makes its choice a relatively safe one, as long as heart rate and BP can be frequently (i.e., at least hourly), reliably, and consistently documented throughout hospitalization. This is advised to avoid inadvertently reaching excessively low BP values, which might jeopardize pressure-dependent vascular beds such as the renal, cerebral and coronary circulation, an important consideration in

patients with renal disease and in geriatric patients in general. Other adverse effects associated with too rapid, or too extreme a decrease of BP should be looked for. These include reflex tachycardia with weakness, syncope, and even organ failure.[11,34] If SNP is unavailable or deemed too labor-intensive a drug to choose, oral or parenteral[4] hydralazine can serve as a reasonable alternative because of its high potency. However, because it cannot be constantly infused and therefore cannot be abruptly discontinued when needed,[32,53] it is a potentially less safe choice. When combined with amlodipine, oral hydralazine can reduce BP by about 25% over several hours.[1] A high oral dosage of amlodipine can sometimes be a potent enough single-agent alternative to control a hypertensive crisis in cats. Alternative parenterally administered agents, if available, include enalaprilat (0.2 mg/kg IV, repeated q 1-2 h as needed), labetolol (0.25 mg/kg IV over 2 minutes, repeated up to a total dose of 3.75 mg/kg and followed by a constant rate infusion of 25 mg/kg/min), and esmolol (at a 50-75 mg/kg/min constant rate infusion).[4] Note that any parenterally administered antihypertensive agent warrants continuous BP monitoring using a direct, intra-arterial catheter (see ch. 75 and 99). Oral amlodipine besylate can be carefully added once BP values start decreasing, if not yet administered up until this point. High dosages may be employed if necessary, with caution.[4] Once new BP values are stabilized with no intervention-related complications, and oral pharmacotherapy can be maintained with no adverse reactions, discharge from hospitalization can be considered, and a follow-up BP measurement should be scheduled in 1-3 days.[4] In clinically and hemodynamically stabilized patients, BP re-evaluation should be performed 7-10 days later, and then every 1 to 3 or 4 months, depending on the initial extent of SHT during the crisis, on the previously documented rate of TOD progression, and on stability and magnitude of BP values following resolution of the crisis (i.e., the higher they are, the more frequent the re-evaluation).[20]

CHAPTER 159

Systemic Hypotension

Lori S. Waddell

Arterial blood pressure is measured as systolic, diastolic, and mean. Systolic and diastolic pressures correspond to the phases of the cardiac cycle. Mean arterial pressure (MAP) can be calculated using the equation

$$\text{MAP} = \text{Diastolic} + [(\text{Systolic} - \text{Diastolic})/3]$$

and it is the most important value when considering perfusion of tissues. *Systemic hypotension* is defined as a systolic arterial blood pressure < 80 mm Hg and/or MAP < 60 mm Hg in either dogs or cats.

Causes of systemic hypotension include decreased preload to the heart, decreased vascular tone, and cardiac dysfunction. Untreated hypotension can lead to shock from inadequate tissue perfusion and oxygen delivery to the tissues. Treatment of systemic hypotension should consist of identifying and correcting the underlying problem. Recognition and treatment of systemic hypotension are essential to prevent the development of refractory shock, organ failure, and death (Figure 159-1).

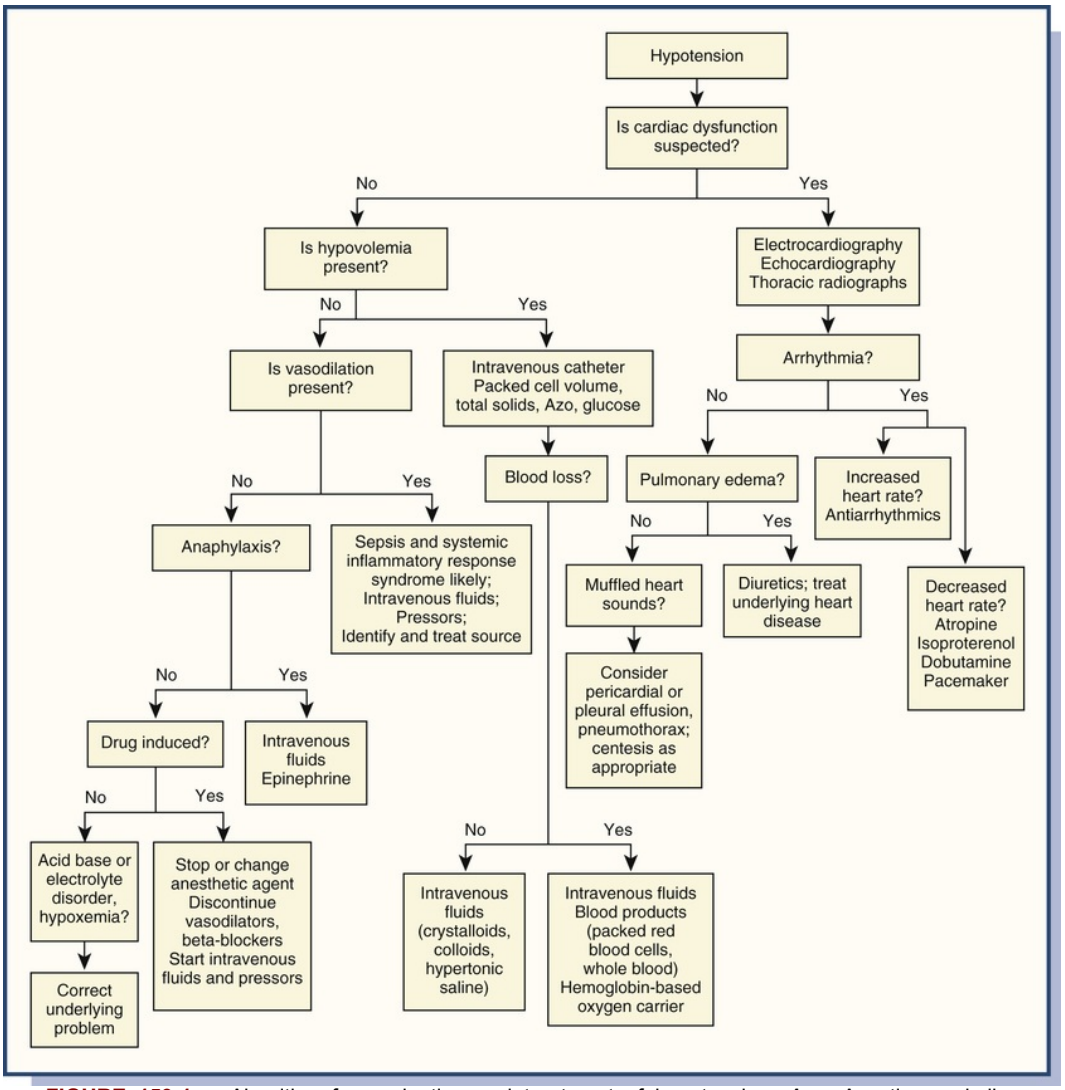

FIGURE 159-1 Algorithm for evaluation and treatment of hypotension. *Azo*, Azostix or similar measurement or blood urea nitrogen.

Blood pressure provides a measurement of tissue perfusion. The two are not equivalent, but blood pressure monitoring is the simplest means of obtaining an objective measurement (see ch. 99). Subjective measures of tissue perfusion are obtained by physical examination; they include pulse quality, mucous membrane color, capillary refill time (CRT), temperature of extremities, and heart rate and rhythm. Combined with blood pressure monitoring, evaluation of these parameters provides the basis for a more accurate assessment of tissue perfusion. A normal blood pressure does not necessarily mean that the tissues are adequately perfused, as blood pressure may be maintained with severe peripheral vasoconstriction with or without increased cardiac output.

Clinical Manifestations

The clinical signs associated with systemic hypotension depend on the severity and cause of the condition. In dogs, hypotension usually is associated with a reflex sinus tachycardia, bounding to weak pulses, pale mucous membranes, slow CRT (>2 seconds), mental dullness, and weakness (Video 159-1). If the underlying cause is sepsis, the mucous membranes can be injected or red with a rapid CRT (<2 seconds; see Video 144-1). Cardiac causes of systemic hypotension can alter the clinical picture, with arrhythmias, weak and irregular pulses, and even severe bradycardia possible. Hypotensive cats also usually have sinus tachycardia, poor pulse quality, pale mucous membranes, slow CRT, mental dullness, and weakness. However, unlike dogs, cats with sepsis or systemic inflammatory response syndrome (SIRS) often have bradycardia rather than tachycardia and rarely have injected mucous membranes. In both species, systemic

hypotension often is associated with decreased urine output, hyperventilation, hypothermia, and cool extremities.

Inability to palpate pulses peripherally can be useful in assessing blood pressure. When the metatarsal pulse is palpable, the systolic blood pressure is >70-80 mm Hg. Although measurement of blood pressure confirms the presence of systemic hypotension, the diagnosis can be made on physical examination findings alone.

Pathogenesis

Systemic arterial blood pressure (ABP) is dependent on cardiac output (CO) and systemic vascular resistance (SVR) (Figure 159-2):

$$ABP = CO \times SVR$$

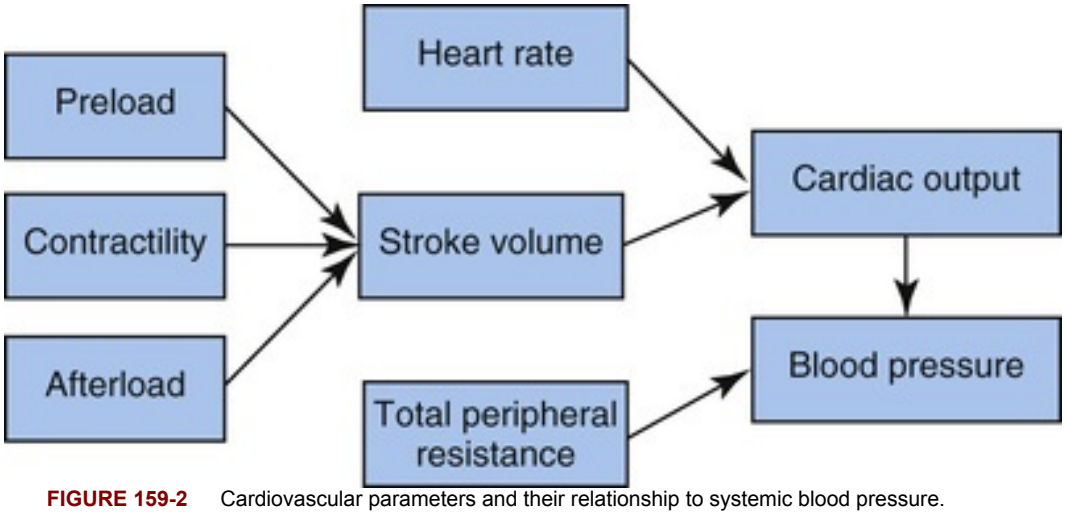

FIGURE 159-2 Cardiovascular parameters and their relationship to systemic blood pressure.

Cardiac output is determined by heart rate, cardiac contractility, preload, and afterload. The three main causes of systemic hypotension are decreased preload, decreased cardiac function, and decreased arterial tone (Box 159-1). These may occur individually or in combination.

Box 159-1

Causes of Systemic Hypotension

Decreased Preload

Hypovolemia

Blood loss
Gastrointestinal losses
Polyuria
Hypoadrenocorticism
Effusions or other third spacing of fluid
Burns
Heatstroke

Decreased Venous Return

Cardiac tamponade
Constrictive pericarditis
Severe pneumothorax
Positive pressure ventilation

Gastric dilation and volvulus
Heartworm disease (caval syndrome)

Decreased Cardiac Function

Cardiomyopathy
Adult-onset valvular disease
Congenital heart disease
Bradyarrhythmias
Tachyarrhythmias
Serum electrolyte abnormalities
Acid-base disturbances
Severe hypoxemia
Sepsis/systemic inflammatory response syndrome (SIRS)

Decreased Vascular Tone

Sepsis/SIRS
Anaphylaxis
Neurogenic
Drug-induced (anesthetic agent, vasodilators [e.g., beta-blockers, calcium channel blockers])
Electrolyte abnormalities
Acid-base disturbances
Severe hypoxemia

Systemic arterial blood pressure is maintained via neural, hormonal, and local mechanisms. Smooth muscle in blood vessel walls is innervated by fibers from the sympathetic nervous system. Activation of this system results in vasoconstriction of vessels in tissue beds with the exception of skeletal muscle, where it causes vasodilation. Sympathetic innervation of cardiac muscle causes increased heart rate and contractility. Sympathetic stimulation occurs when the vasomotor center, located in the medulla oblongata, is activated. Hypovolemia and systemic hypotension can lead to activation of the vasomotor center due to the baroreceptors in the carotid sinuses and aortic body sensing a lack of stretch, and the stretch receptors in the atria and pulmonary artery sensing a lack of distension and atrial filling. The vasomotor center also is activated by local hypoxia or hypercapnia causing stimulation of the chemoreceptors in the carotid sinus and aortic bodies, although this mechanism is less important than the baroreceptor reflex.

Hypotension also causes release of antidiuretic hormone (ADH, vasopressin) and adrenocorticotropic hormone (ACTH) from the pituitary, as well as release of catecholamines (norepinephrine and epinephrine) and cortisol from the adrenal glands. Increased concentrations of these hormones stimulate an increase in heart rate, vasoconstriction, and water retention by the kidneys. Simultaneously, the macula densa in the glomeruli is affected, and the renin-angiotensin-aldosterone system is activated, resulting in sodium retention by the kidneys and further vasoconstriction. These mechanisms serve to increase blood volume by means of sodium and water retention and to preferentially perfuse the brain and heart while decreasing perfusion to the skin, muscles, and abdominal organs, including the kidneys. Recognition and treatment of hypotension are essential to prevent the development of refractory shock and organ failure (see ch. 127). Acute kidney injury and oliguria/anuria are among the most common consequences of systemic hypotension (see ch. 322), but others include decreased coronary artery perfusion due to the increased heart rate, increased risk of bacterial translocation from the gastrointestinal tract (see ch. 274), impaired hepatic function (see ch. 285 and 286), and activation of the coagulation cascade (see ch. 197).

In addition to the mechanisms listed above, there are several other important effectors of blood pressure and vascular tone. Activation of the arachidonic acid cascade leads to production of prostacyclin and thromboxane A_2. Prostacyclin causes vasodilation, but thromboxane A_2 causes vasoconstriction. Nitric oxide (NO), produced by endothelial cells via nitric oxide synthase, is an important regulator of vascular tone, resulting in vasodilation. There are two types of nitric oxide synthase: the constitutive form and the inducible form. In sepsis and SIRS, there is a tremendous increase in NO production from inducible NO synthase, which is activated by a variety of inflammatory mediators including interleukin-1 (IL-1), IL-2, IL-6, and tumor necrosis factor. This overproduction of NO, coupled with depletion of vasopressin, downregulation of catecholamine receptors, and disruption of vascular smooth muscle calcium metabolism, can result in vasoplegia, severe hypotension, and refractory shock.

Hypovolemia results in decreased cardiac output secondary to decreased venous return to the heart. This,

in turn, results in decreased preload. Moderate to severe hypovolemia must be present to affect blood pressure due to the normal compensatory actions that occur, including increased heart rate to maintain cardiac output and increased peripheral vascular resistance secondary to vasoconstriction. The compensatory mechanisms maintain adequate blood pressure until >20-25% of the intravascular volume has been depleted. Hypovolemia can occur with blood loss or increased fluid losses secondary to vomiting, diarrhea, polyuria, or third-spacing of fluid.

Restriction of cardiac filling can also result in decreased stroke volume, decreased cardiac output, and systemic hypotension. Pericardial effusion with tamponade and restrictive pericarditis can result in systemic hypotension by this mechanism. Severe pneumothorax and positive pressure ventilation can also reduce venous return to the heart. Hypertrophic cardiomyopathy in cats reduces left ventricular volume, thereby reducing stroke volume and, therefore, cardiac output.

Bradyarrhythmias can affect blood pressure by reducing cardiac output, especially when the heart rate is extremely slow (see ch. 141). Although pulse quality can be normal or strong in a dog or cat with bradyarrhythmia, cardiac output can be drastically reduced by the infrequency of heartbeats. This low cardiac output can be severe enough to cause syncopal episodes secondary to hypotension and decreased perfusion of the brain (see ch. 30). Tachyarrhythmias can result in systemic hypotension by reducing cardiac preload. At extremely rapid heart rates, filling of the heart chambers is limited by the shortened duration of diastole. This can result in reduced cardiac output despite an increased heart rate because at pathologically high heart rates, the reduction in diastolic filling time is disproportionately more severe than any benefit gained by the higher heart rate. Also, coronary perfusion occurs during diastole, so at rapid rates, cardiac perfusion can be markedly decreased and can worsen the cardiac arrhythmia further (i.e., more rapid and/or refractory to treatment) (see ch. 248).

Decreased cardiac output also can occur due to cardiac disorders characterized by systolic dysfunction and/or valvular regurgitation. Dilated cardiomyopathy is characterized by reduced stroke volume and reduced cardiac output caused by decreased myocardial contractility (see ch. 252). Valvular incompetence, resulting in regurgitant flow, also can lead to decreased stroke volume if compensatory increases in systolic function, and eccentric hypertrophy, have not occurred (see ch. 251). Other causes of decreased cardiac systolic function include myocarditis, myocardial infarction, myocardial depression secondary to sepsis, SIRS, anesthetic drugs, beta-blockers, calcium channel blockers, and acid-base and electrolyte abnormalities.

Decreased systemic vascular resistance can also cause hypotension. Common causes of vasodilation are sepsis/SIRS (see ch. 132); anaphylaxis (see ch. 137); anesthesia; use of vasodilators, including beta-blockers and calcium channel blockers; electrolyte abnormalities; and acid-base disturbances (see ch. 128). Many of these mechanisms also affect myocardial contractility, resulting in systemic hypotension mediated by decreased cardiac output and vasodilation simultaneously.

Measurement of Blood Pressure

Blood pressure monitoring can be divided into two main types: noninvasive and invasive methods (see ch. 99). Noninvasive methods are most commonly used, and in dogs and cats usually consist of either an oscillometric system (Cardell Monitor, Sharn Veterinary, Tampa, FL) or Doppler methods (Parks Electronics, Aloha, OR). Invasive blood pressure monitoring is performed by direct arterial pressure measurement via placement of an arterial catheter and connection to a pressure transducer (see ch. 75); it is considered the gold standard of blood pressure monitoring.

Treatment

It is essential that initial treatment of systemic hypotension always be aimed at correction of the underlying physiologic problem: decreased preload, cardiac dysfunction, or peripheral vasodilation. Differentiation of cardiac and noncardiac causes of systemic hypotension is a critical first step (see Figure 159-1). If the animal is hypovolemic, intravenous fluids and/or blood products should be administered until euvolemia has been attained (see ch. 129 and 130). If hypovolemia is severe enough to cause hypotension, a shock bolus should be given. The standard shock dosages of isotonic crystalloids are 60 to 90 mL/kg for dogs and 45 to 60 mL/kg for cats. If colloids are indicated in place of crystalloids, approximately one fourth of the crystalloid dose should be given. Hypertonic saline (5% to 7.5%) is a rapid intravascular volume expander and can be used when immediate fluid resuscitation is needed. The dosage for hypertonic saline is 5 mL/kg given over 5-10 minutes for dogs and 3 to 4 mL/kg given over the same time period for cats. After administration of hypertonic saline, it is essential to follow with one-third to one-half of a shock bolus of isotonic crystalloids to provide continued

intravascular volume expansion and to replenish the interstitial space. If hypovolemia occurs secondary to blood loss, blood products, such as whole blood or packed red blood cells, or a hemoglobin-based oxygen-carrying solution, might need to be administered to provide adequate oxygen-carrying capacity.

If the volume status is unknown or if there are concerns about overloading the animal with intravenous fluids, a central venous catheter can be placed for central venous pressure (CVP) monitoring (see ch. 76). A low CVP (<0 cm H_2O) indicates hypovolemia due to fluid loss or vasodilation secondary to decreased peripheral resistance. A high CVP (>10 cm H_2O) indicates intravascular volume overload, right-sided heart failure, or increased pulmonary vascular resistance (afterload). If the significance of a low to normal CVP reading is questionable, a small test bolus of fluids can be given. A rapid bolus of 10-15 mL/kg of crystalloid or 3-5 mL/kg of colloid is used. It is important to remember that the vascular bed is a compliant system, able to accommodate changes in volume with minimal changes in pressure. If the animal has a low CVP due to hypovolemia, the CVP will show either no change or a transient rise toward normal followed by a rapid decrease. The MAP also increases transiently. A bolus given to a dog or cat that is euvolemic usually causes a small increase in the CVP of 2 to 4 cm H_2O with a return to baseline within 15 minutes. A large increase (greater than 4 cm H_2O) followed by a slow return to baseline (longer than 30 minutes) is seen with hypervolemia or reduced cardiac compliance.

If the animal remains hypotensive once euvolemia has been achieved, the use of pressors should be considered. Commonly used pressors for treating vasodilation include dopamine (5-15 mcg/kg/min), epinephrine (0.05-1 mcg/kg/min), norepinephrine (0.1-1 mcg/kg/min), or phenylephrine (0.5-5 mcg/kg/min), administered for their alpha-agonist effects, as constant-rate IV infusions. Only phenylephrine is a pure alpha-agonist; the others have varying degrees of beta effects in addition to their alpha effects. Vasopressin (0.5-5 mU/kg/min) also can be used in cases with vasodilatory shock and may be especially useful in cases of sepsis/SIRS as the vessels can become refractory to catecholamines. These drugs need to be titrated to effect, requiring frequent blood pressure monitoring (see ch. 99). They should never be used in place of adequate volume expansion, because most patients with hypovolemic shock already have compensatory vasoconstriction.

Cardiac causes of hypotension must be addressed on a case-by-case basis. With tachyarrhythmias, the cause should be corrected when possible and antiarrhythmic therapy should be administered if necessary (see ch. 248). Bradyarrhythmias may respond to medical therapy or may require placement of a pacemaker (see ch. 249). Obstruction of cardiac filling by pericardial effusion or severe pneumothorax should be addressed by appropriate centesis. Positive inotropes such as dobutamine (5-15 mcg/kg/min), which is predominately a beta-agonist, can be administered as a constant rate infusion when decreased cardiac contractility is suspected.

Diagnostic Plan

Diagnosis of the underlying cause of severe systemic hypotension must often wait until after therapy has been initiated due to the critical nature of such hypotension. History and physical examination abnormalities often can help in the determination of a tentative diagnosis, allowing therapy to be started (see ch. 2). Initial diagnostics in an unstable hypotensive dog or cat should include measurements of packed cell volume, total solids, blood glucose, and an estimate of the blood urea nitrogen level (e.g., Azostix, Bayer Corporation, Elkhart, IN). Serum electrolyte concentrations (see ch. 67-69), acid-base status (see ch. 128), and serum lactate concentration (see ch. 70) also can be helpful. Depending on the clinical signs, an electrocardiogram (see ch. 103), abdominal and thoracic radiographs, abdominal ultrasound exam (see ch. 88 and 143), echocardiogram (see ch. 104), CVP measurement (see ch. 76), and pulse oximetry determinations (see ch. 98), and arterial blood gas analysis (see ch. 75 and 128), can be useful. A complete blood count, serum biochemistry profile, and urinalysis (see ch. 72) also should be performed. If indicated by a suspicion of hypoadrenocorticism, an ACTH stimulation test should be completed (see ch. 309). If sepsis is suspected, blood and urine cultures should be done unless the source of sepsis can be directly cultured, and broad-spectrum antibiotics should be initiated as soon as possible (see ch. 132).

CHAPTER 160

Principles of Drug Disposition and Pharmacokinetics

Butch KuKanich

Pharmacokinetics describes the absorption, distribution, metabolism and elimination of drugs. For example, morphine is rapidly absorbed into the plasma from the injection site following intramuscular administration in dogs. Morphine distributes throughout the body, including the central nervous system where it elicits its analgesic effects. Morphine is metabolized primarily to the inactive metabolite morphine-3-glucuronide, ending its pharmacologic effect and the inactive metabolite is primarily eliminated in the urine. In contrast to dogs, cats metabolize morphine primarily to morphine-3-sulfate, demonstrating a species-specific difference in morphine metabolism. Although the pharmacokinetics of some drugs is similar between species, similarities should not be assumed.

Absorption

Drug absorption from the site of administration needs to occur for any extravascular dose, assuming systemic effects are desired. Per os (PO)/oral, intramuscular (IM), subcutaneous (SC), transdermal (TD) and transmucosal (TM) drug administration are the most common routes of delivery in dogs and cats. Drug administration by an esophagostomy or jejunostomy tube (see ch. 82) is expected to have very similar absorption to PO administration for most drugs.

Drug absorption can occur by passive diffusion (through lipid membranes or aqueous pores and capillary fenestrations) or through transporters such as anionic, cationic, and amino acid transporters among many others. Diffusion is directly proportional to surface area and drug gradient, and lipid diffusion is directly proportional to the drug's lipophilicity and directly inversely proportional to the thickness of the membrane. Drug absorption by diffusion is not saturable, with higher doses resulting in proportionally greater drug absorption. However, absorption by transporters can be saturated, resulting in decreased rate or extent of absorption with higher doses (less than proportional) as seen with gabapentin in dogs.[1]

Bioavailability is most often referred to as the extent or fraction of drug absorbed after extravascular administration, but also includes the rate of absorption. For the context of this chapter, bioavailability will refer to the extent of drug absorption. Numerous factors can result in incomplete bioavailability. Intramuscular and subcutaneous bioavailability can be decreased by tissue sequestration at the injection site due to tissue binding, granuloma, scarring, etc.; degradation or metabolism at the injection site; incomplete release from pharmaceutic formulation; or inadequate blood flow to site of administration (e.g., shock or inadvertent injection into connective tissue).

Oral drug bioavailability may be decreased due to drug degradation or instability (e.g., acid hydrolysis in the stomach), pre-systemic metabolism, gastrointestinal (GI) motility dysfunction (ileus or hypermotility), binding to ingesta or drugs or the inability to cross the intestinal mucosal cellular membrane due to low lipid solubility, drug ionization or lack of or saturation of appropriate transporters. Oral bioavailability can also be decreased by transporters such as the p-glycoprotein (p-gp) efflux pump effluxing drug that was absorbed back into the intestinal lumen.[2]

Oral drug administration is commonly used in veterinary patients. Tablets, capsules, suspensions, and solutions can all be administered PO. Solid dosage forms must first disintegrate in the gastrointestinal fluid and then dissolve into solution prior to drug absorption. Some drugs are poorly soluble in the GI tract (e.g., itraconazole) and have low bioavailability. Solid dosage forms may be formulated to alter the rate of disintegration or dissolution to decrease rate of absorption (extended release) or target disintegration for a specific part of the GI tract (delayed release). Most of these delayed- or extended-release formulations are designed specifically for people and may not be effective or consistent in dogs and cats due to differences in

GI anatomy and physiology. Delayed or extended release formulas may result in immediate release in dogs and cats or may be passed through the GI tract without release, resulting in little drug absorption. Therefore, unless specific data are available on delayed- or extended-release formulations in dogs and cats, their use is cautioned.

The primary site of drug absorption following PO administration is the small intestine (duodenum and jejunum and to a lesser extent ileum). The large surface area for diffusion and presence of active transporters facilitates absorption of drugs from the intestinal tract. Metabolizing enzymes (both Phase I and Phase II, see metabolism) are also present in the intestine, which can metabolize absorbed drugs before the drugs enter the vasculature, thereby decreasing oral bioavailability.[3] Drugs absorbed from the intestine enter the portal circulation, which carries the drugs directly to the liver. As the drugs pass through the liver they are again exposed to drug metabolizing enzymes (Phase I and Phase II) that can decrease systemic drug exposure. The sum of intestinal and hepatic presystemic metabolism is referred to as first-pass metabolism. It is important to note that the majority of drug absorbed from the rectum and large intestine in dogs and cats also enters the portal circulation; therefore, in contrast to humans, rectal drug administration in dogs and cats does little to decrease first-pass drug metabolism and subsequently results in similar bioavailability, at best, as oral administration.[4,5]

Intramuscular and subcutaneous drug administration deposits drug in the interstitial fluid in the musculature or subcutaneous space, which communicates with the plasma compartment by pores and fenestrations within the capillaries. Therefore, drugs with low lipophilicity like aminoglycosides can still be absorbed without diffusion through cell membranes. First-pass metabolism and its effects on bioavailability are avoided for IM and SC injections. Drugs administered IM or SC as suspensions (solid particles suspended in a liquid) must first dissolve prior to absorption. Some suspension formulations may provide prolonged dosage intervals due to delayed absorption (e.g., procaine penicillin G, methylprednisolone acetate), but not all suspensions provide sustained effects. Drugs administered IM or SC as solutions may result in more rapid absorption compared to suspensions, assuming they are small drug molecules capable of diffusion into the vasculature, but some extended release formulations are solutions (buprenorphine injection, Simbadol). Therefore, the individual formulation pharmacokinetics should be evaluated prior to establishing a patient's dosage.

Pain may occur on injection due to tonicity, inflammation (often delayed by hours), and preservatives such as benzyl alcohol, solvents or due to the active ingredient itself. Acidic or alkaline solutions may result in pain as well, which is the reason adding pH neutralizers to decrease pain is sometimes recommended (e.g., adding sodium bicarbonate to lidocaine or fentanyl extravascular injections). Sterile or aseptic techniques are desired for IM and SC drug administration, as introduction of bacteria or foreign material can result in abscesses, cellulitis and even septicemia in extreme cases. Subcutaneous injections may have decreased and erratic absorption due to dehydration, hypotension, hypothermia and obesity. In patients with dehydration, hypotension, hypothermia and obesity, IM injections are preferred as they are less affected by these conditions.

Transdermal and transmucosal administration avoids first-pass metabolism and may result in greater bioavailability than oral administration. Transdermal drug administration may also result in a depot effect due to sequestration in the stratum corneum. Drugs have to be very lipophilic and un-ionized to undergo TD and TM absorption, which limits the number of drugs available for these routes. It is important to note that very few drugs sold as compounded pluronic lecithin organogel (PLO) formulations actually undergo transdermal absorption and most should be avoided. Compounded drugs are not required to demonstrate safety or efficacy (see Bioequivalence, Generic Drugs and Compounded Drugs). Some transdermal PLO methimazole formulations are effective in some, but not all, cats with hyperthyroidism and some studies suggest phenobarbital and amlodipine have some absorption in cats, but clinical efficacy has not been reported for the latter in PLO formulations (see ch. 168).

Distribution

Drug distribution is dependent on many factors including drug lipophilicity, regional blood flow, anatomic barriers, and plasma protein binding. Drug lipophilicity is a measure of the drug's solubility in lipids. Drugs that are poorly soluble in lipids (low lipophilicity) do not have the ability to reach intracellular targets and tend to have restricted distribution. For example, aminoglycosides are poorly lipophilic and as a result are ineffective for intracellular infections and infections in tissues such as the brain and prostate, due to their inability to diffuse across lipid membranes.

Highly perfused tissues are those that have a high blood-flow-to-tissue-mass ratio (E-Table 160-1). Highly

perfused tissues have faster equilibration between plasma and tissue concentrations and as a result may equilibrate at higher drug concentrations than tissues that are not highly perfused (Figure 160-1). For example, fentanyl brain concentrations equilibrate more rapidly and at higher plasma concentrations after IV injection than less highly perfused tissues such as muscle. As fentanyl continues to distribute into the anatomically large volumes of muscle (in addition to metabolism), the plasma concentrations decrease below the central nervous system (CNS) concentrations. This results in fentanyl diffusing out of the CNS, decreasing CNS fentanyl concentrations and subsequently loss of central opioid effects. Therefore, the loss of central opioid effects of fentanyl is due in part to drug redistribution from the CNS to the plasma.

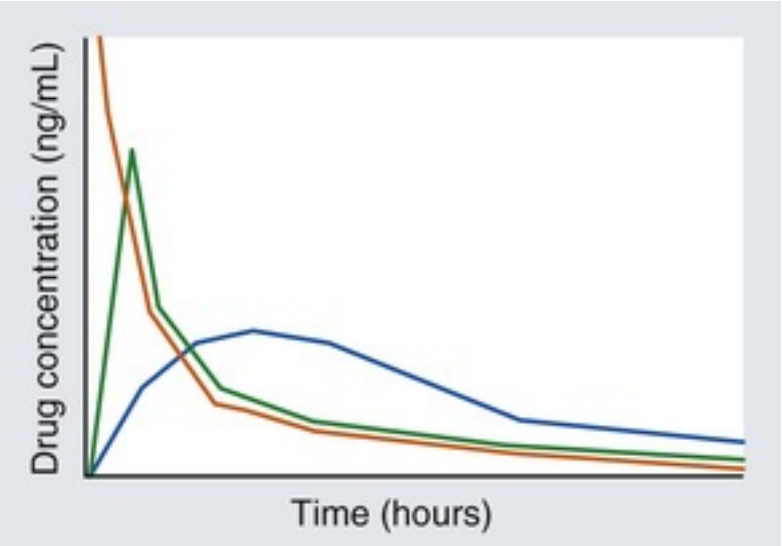

FIGURE 160-1 Theoretical drug concentration versus time profile of IV fentanyl. The red line represents plasma drug concentration, the green line represents CNS fentanyl concentration and the blue line represents muscle drug concentration. Fentanyl is lipophilic and rapidly diffuses into the highly perfused CNS and equilibrates to high plasma concentrations. However, less well perfused tissues such as muscle equilibrate later and at lower drug concentrations. The loss of CNS (analgesic) effects of fentanyl is due in part to fentanyl redistributing from the CNS back into the plasma in addition to metabolism.

E-TABLE 160-1

Examples of Anatomic Locations That Have Different Regional Blood Flows per Gram of Tissue

HIGH PERFUSION	INTERMEDIATE PERFUSION	LOW PERFUSION
Brain	Muscle	Adipose tissue
Kidneys	Skin	Bone
Liver	Gastrointestinal tract	
Heart		
Lungs		
Endocrine glands		

Anatomic barriers can decrease drug distribution into certain tissues for drugs that are not highly lipophilic. The blood-brain barrier consists of a physical barrier including glial cells, which decrease drug penetration into the CNS. Physiologic barriers including efflux proteins such as the p-gp efflux pumps remove drug that penetrates the CNS by pumping the drug back into the vasculature, decreasing CNS drug concentrations. Animals affected by p-gp mutations or receiving p-gp inhibitors can have increased drug concentration in the CNS, resulting in more pronounced central effects of drugs that are p-gp substrates. Examples of drugs that may have increased CNS concentrations with decreased p-gp efflux pump activity

include ivermectin (resulting in ivermectin toxicosis at therapeutic dosages) and loperamide (resulting in pronounced central opioid effects, including sedation) among others. Ivermectin toxicosis in "normal" animals with functional p-gp can occur from drug interactions with a p-gp inhibitor such as spinosad.

The blood-prostate, blood-bronchus and blood-ocular barriers also decrease drug penetration into those tissues. Drugs with high lipophilicity are needed to penetrate these tissues as well. Other anatomic barriers occur in tissues such as the mammary gland, testes, placenta and synovium, but in general are less effective barriers to drug penetration.

Drugs that are highly bound to plasma proteins may have restricted distribution, as the protein-drug complex is too big to diffuse out of the plasma. For example, cefovecin is highly protein-bound, resulting in a low fraction of cefovecin distributing into the tissues at the location of infection.[6] However, it is important to note that plasma protein binding is reversible and there is always some free drug available that can diffuse out of the vasculature. Therefore, some drugs that have high protein binding can still distribute throughout the body. For example, buprenorphine is highly protein-bound in dogs, but it distributes well into the CNS producing central opioid effects.[7] Many references still caution against using multiple highly protein-bound drugs concurrently due to protein binding interactions, but the likelihood of a true interaction is minimal. For a protein-binding interaction to occur, the drugs would have to be administered IV, have a low therapeutic index, and undergo rapid hepatic metabolism.

Metabolism

Drug metabolism results in chemical changes to the drug molecule to enhance renal or biliary elimination. Drug metabolism occurs due to enzymes that catalyze changes in the drug molecule, changing the drug into a molecule (metabolite) that is more readily eliminated by renal or biliary mechanisms. A drug may not undergo metabolism (e.g., gentamicin, which is eliminated as intact drug in the urine or doxycycline, which is eliminated as intact drug in the bile). A drug may undergo a single metabolic process (e.g., morphine, primarily metabolized to morphine-3-glucuronide in dogs, which is eliminated in the urine). A drug may also undergo multiple metabolism processes (diazepam in dogs metabolized to temazepam, followed by temazepam metabolized to oxazepam followed by oxazepam metabolized to oxazepam-glucuronide, which is then eliminated in the urine).

Metabolism does not always inactivate a drug. For example, tramadol is metabolized to the metabolite O-desmethyltramadol in cats, increasing the mu opioid effects by approximately 200 times compared to tramadol. Metabolism may also be different in different species. For example approximately 60% of codeine is metabolized to morphine in humans, but <1% of codeine is metabolized to morphine in dogs and cats with codeine-6-glucuronide being the major metabolite in dogs, but norcodeine the major metabolite in cats.[8]

There are two primary metabolism pathways, Phase I (metabolic) and Phase II (conjugation) reactions. Phase I, metabolic reactions (oxidation, reduction, hydrolysis, and hydration), are catalyzed by different enzymes. Cytochrome P450 (CYP) enzymes are a major group of enzymes commonly involved in Phase I drug metabolism. Cytochrome P450 enzymes are classified into families (>40% amino acid homology) designated with a number, followed by subfamilies (>55% amino acid homology) designated with a letter, and the specific enzyme is finally labeled with a number. For example, dogs have CYP3A12 and CYP3A26 enzymes and humans have CYP3A4 enzymes which have >55% homology, but are different enzymes. Different enzymes may have different specificities for substrates and inhibitors, but some overlap may occur. For example, methadone is metabolized by CYP2B11 in dogs, but diazepam is metabolized by both CYP2B11 and CYP3A12/26 in dogs.

Species similarities and differences occur in CYP substrate and inhibitor specificity. For example, similar metabolism of midazolam occurs by the canine CYP3A12/26 and human CYP3A4 and methadone is metabolized by canine CYP2B11 and human CYP2B6 orthologs. Similarly, ketoconazole inhibits the CYP3A enzyme orthologs in dogs and humans. However, species/ortholog differences also occur. For example, chloramphenicol inhibits CYP2B11 in dogs, but in humans chloramphenicol primarily inhibits CYP2C19, not CYP2B6 (the human CY2B ortholog).

Species similarities and differences in metabolite formation can also occur. For example, methadone is primarily metabolized to EDDP (2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine) in humans by CYP2B6, but EDDP is not a major metabolite in dogs, which metabolize methadone by CYP2B11.[9] Tramadol is primarily metabolized to the inactive metabolite n-desmethyltramadol in dogs, but to the active metabolite O-desmethyltramadol in cats.[10] The difference in primary metabolites formed may be due to the relative amounts of the different CYP isoforms (e.g., cats may have a larger amount of CYP2D than dogs, which form

the active metabolite, but dogs have a relatively larger amount of CYP2B11 and CYP3A isoforms, which form the inactive metabolite). Different affinities of the drugs and enzymes, or lack of certain enzymes can also contribute to species differences in drug metabolism.

Phase I metabolism enzymes can be inhibited or induced, producing clinically relevant drug interactions. Clinically relevant drug interactions due to CYP inhibition are relatively specific and more likely to occur when a drug is a substrate for a specific CYP (not metabolized by multiple CYPs) and has a low therapeutic index. Clinically relevant drug interactions due to CYP induction typically occur due to increase in CYP content (more metabolizing enzymes) resulting in more rapid drug metabolism (E-Table 160-2).

E-TABLE 160-2

Examples of Drug Interactions in Dogs and Cats

SUBSTRATE	Inhibitor/Inducer	CLINICAL EFFECT
Phenobarbital, pentobarbital, propofol, methadone	Chloramphenicol	Phenobarbital toxicosis, prolonged effects of pentobarbital, propofol, and methadone
Theophylline	Enrofloxacin (and other fluoroquinolones)	Theophylline toxicosis
Cyclosporine	Ketoconazole, fluconazole	Increased cyclosporine effects or decreased cyclosporine dosage
Midazolam	Ketoconazole	Prolonged sedative effects of midazolam
Chloramphenicol, diazepam, theophylline, digoxin, levetiracetam, glucocorticoids	Phenobarbital	Decreased substrate efficacy
Phenobarbital	Phenobarbital	Decrease plasma concentrations over time resulting in decreased efficacy if dosage not adjusted
Phenytoin	Phenytoin	Poor efficacy due to rapid elimination

Phase II metabolism pathways are conjugation reactions that add an endogenous substrate to the drug molecule, resulting in a metabolite with larger size and decreased lipophilicity. The Phase II metabolite can then be eliminated by glomerular filtration, renal excretion, or biliary excretion. Glucuronidation, sulfation, acetylation and amino acid conjugation reactions are the most common Phase II metabolism pathways. Specific enzymes are associated with each type of conjugation reaction and there are often subtypes within each reaction. Drug interactions involving induction or inhibition of conjugation enzymes are not well characterized in animals and are thought to be rare.

Species-specific differences in conjugation reactions have been identified. For example, uridine diphosphate glucuronosyltransferase (UGT) is the enzyme family catalyzing glucuronide conjugation, with UGT1A6, 1A7, 1A9, 1A11 and 2B31 present in dogs. Cats are deficient in UGT1A6 and 1A9, which results in decreased or alternate conjugation of some conjugation substrates, including acetaminophen and morphine.[11] The lack of glucuronide conjugation of acetaminophen results in large amounts of acetaminophen undergoing Phase I metabolism, resulting in reactive metabolites and acetaminophen toxicosis in cats even at low (subtherapeutic) acetaminophen dosages. In contrast, the lack of morphine glucuronidation in cats is clinically "irrelevant" as no reactive morphine metabolites are formed and morphine is rapidly eliminated in cats by sulfate conjugation, with a similar elimination half-life in dogs and cats.

Dogs lack N-acetyltransferase enzymes and as such are deficient in forming acetyl conjugates. Clinical effects of the deficiency include lack of N-acetyl procainamide (NAPA) metabolite formation of procainamide, a Class I antiarrhythmic (sodium channel antagonist).[12] The NAPA metabolite is a Class III antiarrhythmic (potassium channel antagonist); therefore, the antiarrhythmic effects of procainamide in dogs are different (Class I effects only) compared to other species (Class I and III antiarrhythmic effects). Sulfonamide metabolism in most species also involves acetylation reactions, but the acetylation deficiency in dogs may contribute to an increased risk of sulfonamide hypersensitivity reactions due to metabolism by other pathways to reactive metabolites.[13]

Drug metabolism (both Phase I and Phase II) may be decreased with hepatic disease, but the extent of decreased drug metabolism may not be proportional to the extent of disease. There are little data evaluating the pharmacokinetics or metabolism of drugs in animals with naturally-occurring liver disease; therefore,

specific recommendations on dosage adjustments are not available. If single parenteral doses or PO doses of drugs with a high oral bioavailability are administered, the maximum drug effect will be similar, but the duration of effect may be markedly longer. However, multiple doses may result in greater than expected drug accumulation due to a prolonged terminal half-life, resulting in dose-dependent adverse effects (see Half-life). Drugs with low oral bioavailability may result in concentration-dependent adverse effects, even with a single dose, due to less first-pass metabolism and a higher PO bioavailability due to the liver disease. The best option for animals with hepatic disease would be choosing a drug with a similar effect, but that undergoes renal elimination (e.g., choosing atenolol instead of propranolol to decrease sinus tachycardia). Another option is to use a drug with therapeutic drug monitoring (TDM) available and adjusting the dose based on plasma concentrations (e.g., theophylline to manage bronchitis), but progression of disease may result in unpredictable changes in plasma concentrations if TDM is not done regularly. Adjusting the dosage based on clinical response is another option, but this option would be limited to drugs with a high therapeutic index and in which responses can be readily monitored (e.g., oral codeine without acetaminophen in a dog with liver impairment and osteoarthritis).

Other metabolism enzymes are present, but contribute less commonly to drug metabolism. Plasma esterases metabolize remifentanil. Xanthine oxidase metabolizes and inactivates 6-mercaptopurine, an azathioprine active metabolite. Ethylene glycol and ethanol are metabolized by alcohol dehydrogenase.

Elimination

Elimination includes the removal of the drug and drug metabolites from the body (E-Table 160-3). Some drugs are not metabolized and as such are primarily eliminated as unchanged drug (e.g., gentamicin undergoing renal elimination by glomerular filtration). Some drugs are eliminated as both intact drug and drug metabolites (e.g., codeine eliminated in the urine as codeine and norcodeine in cats). Other drugs, such as propofol, may be almost completely metabolized prior to elimination and eliminated primarily as metabolites.

E-TABLE 160-3

Factors That Enhance or Decrease Drug Elimination from the Body in Healthy Animals

ENHANCE DRUG ELIMINATION	DECREASE DRUG ELIMINATION
Metabolism, hepatic—Phase I	Renal tubular reabsorption—active transporters
Metabolism, hepatic—Phase II	Renal tubular reabsorption—passive diffusion
Metabolism, hepatic—other	Enterohepatic recycling
Metabolism, extrahepatic	
Biliary excretion	
Glomerular filtration	
Active renal tubular excretion	
Other elimination (e.g., respiratory)	

Renal elimination of drugs and drug metabolites can occur by glomerular filtration and renal tubular secretion. However, renal tubular reabsorption can also occur, decreasing elimination due to drug being reabsorbed from the urine and back into systemic circulation. Approximately 25% of cardiac output goes to the kidneys and as such, renal elimination can be highly efficient. Glomerular filtration is essentially a method of ultrafiltration in which proteins and cells are retained in the vasculature and a portion of the plasma fluid enters the urine through the glomeruli. Protein-bound drugs tend to be retained in the vasculature and as such, highly-protein bound drugs may have slow elimination by glomerular filtration. For example, cefovecin is >95% bound to plasma proteins and persists for weeks after a single administration. Glomerular filtration is not saturable and increases in dosage or drug concentration result in proportional increases in renal elimination by glomerular filtration. Glomerular filtration is dependent on renal blood pressure and plasma oncotic pressure. Therefore, renal hypotension may decrease glomerular filtration and drug elimination or conversely hypoproteinemia may increase renal drug elimination by glomerular filtration.

Drugs may also be actively eliminated in the urine in the renal tubules by transporters. Weak acid (organic

anion transporters; OAT) and weak base transporters (organic cation transporters; OCT) are most associated with renal excretion but other transporters such as the p-glycoprotein efflux pump are also present. Penicillin and other beta-lactams are classic substrates of OAT and cimetidine is the classic substrate of OCT renal excretion. Since these are transporters, they are subject to saturation and competition with the classic example of probenecid (a weak acid) competing with penicillin G (a weak acid) excretion, resulting in decreased elimination of penicillin and prolonged dosing intervals.

Drugs and metabolites can also undergo active renal tubular reabsorption and diffusion from the tubules back into the plasma with a net effect of decreasing drug elimination. Similar to active renal tubular secretion, active tubular reabsorption can be saturated and competition for reabsorption can occur, decreasing reabsorption. Renal tubular reabsorption also occurs by diffusion and undergoes similar principles as any drug movement by diffusion. The rate of diffusion could be decreased (enhancing elimination) by increasing urine flow through fluid diuresis or altering the urine pH. For example, phenobarbital is a weak acid; therefore, alkalinizing the urine results in phenobarbital ionization, which prevents it from diffusing out of the renal tubules back into the vasculature and produces significantly increased phenobarbital elimination in dogs fed a urinary alkalinizing diet compared to dogs fed an acidifying diet (also known as ion trapping).[14] Urinary acidification (for drugs or toxins that are weak bases) and urinary alkalinization (for drugs or toxins that are weak acids) are strategies to help enhance elimination of drugs and toxins that undergo passive renal tubular reabsorption.

Drugs or diseases that result in decreased renal function are expected to result in near-proportional decreases in renal drug elimination. For example, the renal elimination of amikacin will decrease proportionally as glomerular filtration rate decreases and is significantly decreased before changes in urine specific gravity or azotemia are noted. The best strategies for drug choices in an animal with renal dysfunction are to choose a drug eliminated by hepatic metabolism (e.g., marbofloxacin instead of enrofloxacin) or choosing a drug with a higher therapeutic index (e.g., amoxicillin with clavulanate instead of enrofloxacin).

Biliary excretion occurs through active transporters, including OAT and OCT as well as neutral and heavy metal transporters, p-glycoprotein and other active transporters. Drugs and metabolites eliminated by biliary excretion tend to be larger molecules, including some drugs (e.g., doxycycline) and drug metabolites. Once excreted through the bile into the intestine, the drugs and drug metabolites can be eliminated in the feces. However, there are situations in which drug-conjugate (Phase II) metabolites secreted in bile are deconjugated by intestinal flora, resulting in liberation of free drug that has the potential for reabsorption (i.e., enterohepatic recycling). Enterohepatic recycling is the rationale for multiple doses of activated charcoal following some drug or toxin exposures. The activated charcoal can bind the drug conjugates and deconjugated drug preventing, reabsorption and enhancing elimination.

Other mechanisms of drug elimination exist. Respiratory elimination of most inhalant anesthetics occurs by diffusion through the lungs and elimination in exhaled air. Some drug elimination can occur in milk through lactation, but in companion animals is not typically a substantial route of elimination. However, drug elimination in the milk can result in clinically relevant drug exposure to nursing animals. Rifampin can be eliminated in tears, which is a clinically irrelevant elimination route, but can produce red discoloration of tears as an effect that may be alarming to clients.

Pharmacokinetic Parameters

Pharmacokinetic parameters are often determined from studies using a small number of healthy animals, often of the same breed, and typically young adults. For example, the pharmacokinetics of oral gabapentin are described with 6 healthy Greyhound dogs aged 1.5-3 years.[1] The means and ranges are then reported. The pharmacokinetics are typically well described in that specific group of animals, but may not describe the range seen in dogs of all ages, all breeds, and the effects of health, gender, or neutering are not described. Therefore, extrapolation from a small study to a specific patient should be done with the understanding that every dog is not an "average" dog. More recently, population pharmacokinetic studies are being performed in veterinary species in which large numbers of animals are included of various breeds, ages and health statuses to better describe the variability in a population that more accurately represents the target population to be treated. Additionally, as described in the preceding section, numerous factors could alter the pharmacokinetics in a clinical patient, including drug interactions and disease states.

Half-Life

The half-life is a commonly referred-to pharmacokinetic term, most often referring to the terminal half-life which is the half-life of the terminal portion of a plasma-time profile. The terminal half-life describes the amount of time it takes for plasma concentrations to decrease by half (50%). The terminal half-life may be the elimination half-life (the amount of time it takes to eliminate 50% of drug), but may not be, as factors other than elimination can affect the terminal slope.

The terminal half-life is useful for many clinical applications. The obvious utility is to estimate how long drug exposure will persist after administration. The terminal portion of the plasma versus time curve most often decreases in logarithmic decay, in which a fixed portion of drug concentration is decreased per unit time. This is the reason many plasma profiles are presented with a logarithmic drug concentration scale. For example, the plasma concentrations of morphine in dogs and cats decrease by approximately one half every hour. Based on these assumptions, after 3 half-lives (or 3 hours in this case) plasma concentrations will decrease by ≈88%; by 5 half-lives, plasma concentrations will decrease by ≈97%; and by 7 half-lives (or 7 hours in this case), plasma concentrations will decrease by ≈99% (E-Table 160-4).

E-TABLE 160-4

Predicted Percent Changes in Drug Concentrations and Steady State Plasma Concentrations Based on the Number of Half-Lives Elapsed

NUMBER OF HALF-LIVES	% OF ORIGINAL CONCENTRATION	% DECREASE IN ORIGINAL CONCENTRATION	% OF STEADY STATE DRUG CONCENTRATION
0	100	0	0
1	50	50	50
2	25	75	75
3	12.5	87.5	87.5
4	6.25	93.75	93.75
5	3.125	96.875	96.875
6	1.563	98.438	98.438
7	0.781	99.219	99.219
8	0.391	99.609	99.609
9	0.195	99.805	99.805
10	0.098	99.902	99.902

The terminal half-life can be applied to other clinical situations. For example, the duration of a dose of 0.5 mg/kg IM morphine in dogs is about 4 hours. If the dose is doubled to 1 mg/kg IM, then the duration of effect is increased by 1 half-life (1 hour in the case of morphine) since the extra amount will be eliminated in 1 half-life. Doubling the dose does not double the duration of effect, but typically extends it by 1 half-life. However, doubling the dose does double the C_{MAX} (see below) and may markedly increase adverse effects such as morphine-induced sedation. As another example, a dog ingested a bottle of meloxicam in the morning and the owner brings you the dog in the evening. How long will it take for plasma concentrations to decrease in the dog? Meloxicam has a terminal half-life ≈24 hours in dogs; therefore, in 5 days (120 hours) the plasma concentration will decrease by ≈97% from time of presentation and in 7 days, the plasma concentration will decrease by ≈99%. Therefore you may recommend hospitalization and fluid therapy for 5-7 days to minimize renal adverse effects.

The terminal half-life is also an important parameter to predict the amount of time it takes to reach steady state plasma concentrations with multiple doses or drug infusions (see E-Table 160-4). Drugs are often administered for multiple doses. If the second dose is administered prior to complete drug elimination from the first dose, then there will be some additive effects of the first and second dose on the plasma drug concentrations and increases in plasma drug concentrations will continue with subsequent doses until steady state plasma concentrations are reached. Steady state occurs when no further increases in drug concentration occur with continued dosing (i.e., the plasma drug versus concentration curve plateaus) (Figure 160-2). The time to reach steady state can be predicted knowing the terminal half-life, with the amount of time it takes to reach 97% of steady state plasma concentrations being 5 half-lives (see E-Table 160-4). For example,

meloxicam has a terminal half-life of 24 hours; therefore, ≈97% of the steady state plasma concentration will be achieved in 5 half-lives, 120 hours (5 days).

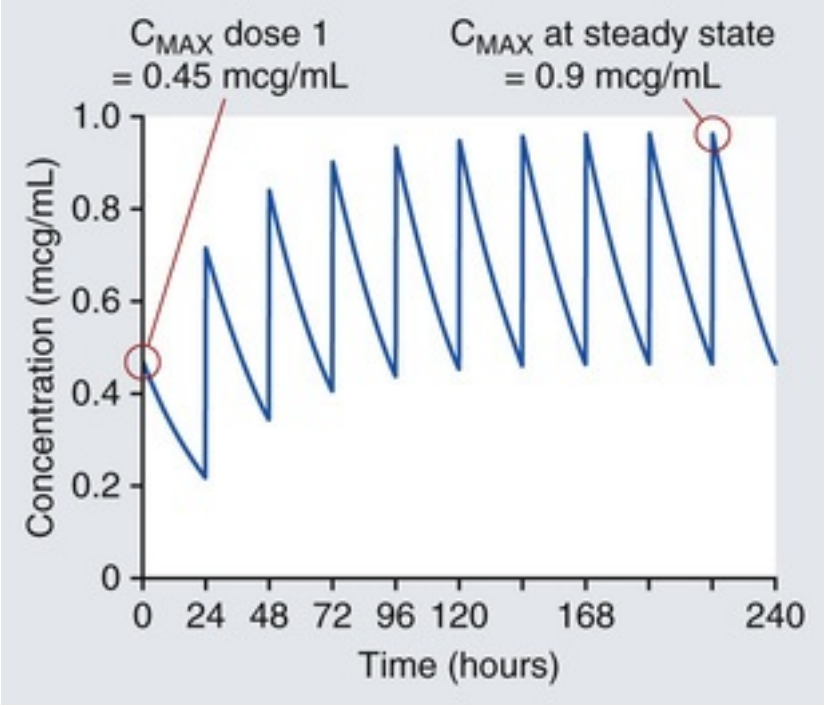

FIGURE 160-2 Steady state plasma concentrations and the extent of drug accumulation can be predicted based on the terminal half-life and dosing interval.

The extent of drug accumulation can also be estimated knowing the terminal half-life and dosing interval (E-Table 160-5; see also Figure 160-2). If the dosing interval is much shorter than the half-life, then extensive accumulation can occur, since the subsequent dose is administered prior to substantial decreases in plasma concentration. If the dosing interval equals the half-life, then a 2-fold increase in plasma concentrations between the first dose and steady state plasma concentrations is predicted. Finally, when the dosing interval is ≥5 times the terminal half-life, then minimal accumulation (<5%) will occur between the first dose and steady state plasma concentrations as the majority of the previous dose will be eliminated prior to the administration of the subsequent dose.

E-TABLE 160-5

Predicted Accumulation and Fluctuation of Peak and Trough Concentrations for Multiple Doses Based on Terminal Half-Life and Dosing Interval

DOSING INTERVAL (HOURS)	HALF-LIFE (HOURS)	HALF-LIFE: DOSING INTERVAL	PREDICTED EXTENT OF ACCUMULATION	FLUCTUATION OF PEAK AND TROUGH PLASMA CONCENTRATIONS
CRI	24	N/A	N/A	N/A
6	24	1 : 4	6.29 ×	1.2 ×
12	24	1 : 2	3.41 ×	1.4 ×
24	24	1 : 1	2.00 ×	2 ×
48	24	2 : 1	1.33 ×	4 ×
72	24	3 : 1	1.14 ×	8 ×
96	24	4 : 1	1.07 ×	16 ×
120	24	5 : 1	1.03 ×	32 ×

For a drug with a half-life of 24 hours administered every 6 hours (a dosing interval to half-life ratio of 1:4), a 6.29-fold accumulation is predicted between the first dose and steady state. Conversely, a drug dosage with a dosing interval:half-life of 5:1 will have minimal drug accumulation between the first dose and steady state plasma concentrations, as most of the drug will be eliminated prior to the next dose being administered. Drugs administered as a constant rate infusion (CRI) will have no fluctuations in plasma drug concentrations, but as the dosing interval increases, the fluctuations in peak and trough concentrations, increase with a 32-fold difference between peak and trough concentrations if the dosing interval:half-life is 5:1.

The fluctuation between peak and trough plasma concentrations can also be predicted by assessing the dosing interval and half-life. A constant rate infusion has essentially no fluctuations in plasma concentrations (at steady state) because the dosing interval is infinitesimally smaller than the half-life for any drug. However, as the dosing interval gets closer to, then exceeds, the terminal half-life, the fluctuations between peak and trough concentration will increase (see E-Table 160-5). Large fluctuations in peak and trough concentrations may be desirable (e.g., gentamicin to reduce risk of renal toxicosis) or minimal fluctuations may be desirable (e.g., morphine infusion to maintain analgesia, but minimize dose-dependent effects such as sedation).

Clearance

The plasma clearance is a measurement of the ability of the animal to remove drug from the plasma through metabolism or elimination. Plasma clearance is the sum of hepatic, renal and other mechanisms of metabolism and elimination. Plasma clearance predicts the steady state plasma concentrations (or average plasma concentrations) for a given dose rate with the following equation:

$$\text{Dose rate} = \text{plasma clearance} \times \text{average plasma concentration}$$

Therefore, if you know the plasma clearance, the dose rate needed to achieve a targeted mean (or steady state) plasma concentration can be calculated. Many pharmacokinetic studies are available for drugs used in veterinary medicine with the clearance reported in most of the studies. For example, the published mean plasma clearance of IV ceftriaxone in dogs is 3.61 mL/min/kg.[15] Therefore, if you wanted to achieve an 8 mcg/mL mean (steady state) plasma concentration, you could calculate the dose rate:

$$\text{Dose rate} = \text{plasma clearance} \times \text{average plasma concentration}$$

$$\text{Dose rate} = 3.61\ \text{mL/min/kg} \times 8\ \text{mcg/mL}$$

$$\text{Dose rate} = 28.88\ \text{mcg/min/kg}$$

$$\text{Dose rate} = 1733\ \text{mcg/h/kg} = 1.73\ \text{mg/h/kg}$$

It is important to remember that the time to reach steady state is still predicted by the terminal half-life, which is 0.9 hours for ceftriaxone. It would take approximately 4.5 hours to reach steady state plasma concentrations for an IV constant rate infusion of ceftriaxone. It is also important to note that the specific animal treated may not have the "average" clearance and as such the dose may need to be adjusted based on other factors such as renal dysfunction or fluid diuresis. If a drug is administered by a route other than IV, then the bioavailability (F) must be included in the equation as follows:

$$\text{Dose rate} = (\text{plasma clearance} \times \text{average plasma concentration}) \,/\, F$$

Volume of Distribution

The volume of distribution is a measure of the dilution of a drug into the body after administration. There are numerous ways to calculate and express volumes of distribution, but they are beyond the scope of this chapter. The primary utility of the volume of distribution is to calculate the loading dose needed to achieve a targeted plasma concentration with the following equation:

$$\text{Dose} = \text{volume of distribution} \times \text{plasma concentration}$$

Loading doses are important for drugs with a long terminal half-life and when you want to immediately achieve an effective plasma drug concentration. For example, you desire to immediately achieve a plasma ceftriaxone concentration of 8 mcg/mL (you do not want to wait 4.5 hours to reach steady state). Ceftriaxone has a mean volume of distribution of 277 mL/kg. A dose can be calculated as an IV bolus to immediately achieve 8 mcg/mL; then the CRI can be started to maintain 8 mcg/mL. The loading dose is calculated by:

$$\text{Dose} = \text{volume of distribution} \times \text{plasma concentration}$$

$$\text{Dose} = 277\ \text{mL/kg} \times 8\ \text{mcg/mL}$$

$$\text{Dose} = 2216\ \text{mcg/kg} = 2.2\ \text{mg/kg}$$

Therefore, an IV bolus of 2.2 mg/kg would immediately achieve a plasma concentration of 8 mcg/mL, combined with an IV infusion of 1.73 mg/h/kg to maintain 8 mcg/mL.

Maximum Plasma Concentration and Time to Maximum Plasma Concentration

The maximum plasma concentration (C_{MAX}) is the highest (peak) plasma concentration achieved after drug administration following extravascular administration (Figure 160-3). The C_{MAX} is often correlated with drug toxicity (e.g., propofol-induced cardiac depression) or efficacy (e.g., aminoglycoside antimicrobial effects). Other drugs may be correlated with maintaining minimum plasma concentrations (e.g., opioids) or achieving a targeted area under the curve. The C_{MAX} for most drugs is directly proportional to the dosage (e.g., doubling the dosage doubles the C_{MAX}, halving the dosage halves the C_{MAX}), but of course there are some exceptions, such as less-than-proportional increases in gabapentin C_{MAX} with increasing dosage due to saturation of active transporter-mediated absorption in the intestine.[1] The time of the C_{MAX} is abbreviated as T_{MAX}. The T_{MAX} is typically unchanged by dosage (e.g., if the dosage is doubled, the T_{MAX} is unchanged), but there are some exceptions.

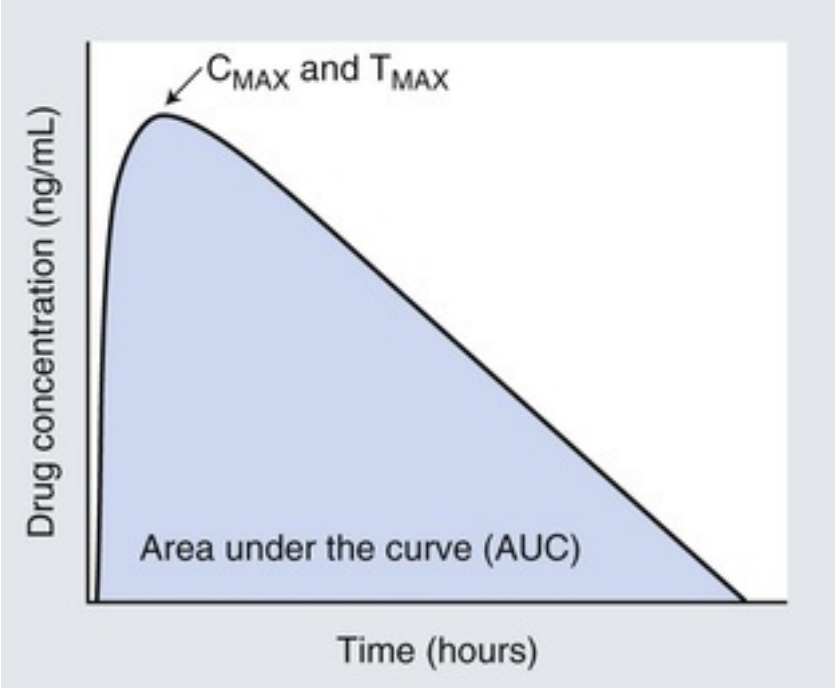

FIGURE 160-3 The maximum plasma concentration (C_{MAX}), time to C_{MAX} (T_{MAX}) and area under the curve (AUC) for a generalized plasma profile.

Area Under the Curve

The area under the curve (AUC) is a measure of total drug exposure and encompasses both the plasma concentrations and the length of time the plasma concentrations persist (see Figure 160-3). The AUC is often correlated with efficacy (e.g., fluoroquinolone clinical cures) or toxicosis (e.g., aminoglycoside-induced kidney injury). The AUC for most drugs is directly proportional to dosage (e.g., doubling the dosage doubles the AUC). Decreased elimination due to disease or drug interactions results in directly proportional effects on AUC (e.g., if the half-life of gentamicin doubles due to renal insufficiency then the AUC doubles). Similarly, increased elimination results in directly proportional decreases in AUC (if the half-life of phenobarbital is halved due to CYP induction, then the AUC is halved).

Bioequivalence, Generic Drugs and Compounded Drugs

Regulatory approval (e.g., Food and Drug Administration [FDA], European Medicines Agency [EMA], et al.) of generic drugs often uses bioequivalence studies and generic drugs may not be required to undergo more extensive safety and efficacy studies that the pioneer products underwent. Generic products must have the same drug and drug content as the pioneer product, be bioequivalent, be manufactured in inspected facilities and demonstrate stability in the dosage form. However, the inactive ingredients can be different.

Bioequivalence studies are pharmacokinetic studies, with the C_{MAX} and AUC being the pivotal parameters assessed. The assumption is that a similar C_{MAX} and AUC will produce a similar drug exposure over time and subsequently similar efficacy and safety. There are specific statistical parameters that must be met for bioequivalence studies. The 90% confidence interval of the mean (CI) for log-transformed data of the generic drug must be 80-125% of the pioneer product for both the C_{MAX} and AUC. The 90% CI is a measure of statistical variability interpreted as having a 90% confidence that the true mean would fall within that range, if the bioequivalence studies were repeated numerous times. For example, a bioequivalent formulation of enrofloxacin is approved by the FDA for dogs. The bioequivalence studies demonstrated a mean AUC of 10963 hr × ng/mL for the generic product compared to 10931 hr × ng/mL for the pioneer product with a 90% CI range of 98.9-103.8% of the pioneer product. The mean C_{MAX} of the generic product was 2811 ng/mL compared to 2785 ng/mL of the pioneer with a 90% CI range of 94.5-107.4% of the pioneer product; therefore, this product was approved as a bioequivalent.

Compounding is the practice of using FDA approved drugs to make a formulation or strength that is not

currently available for a specific patient (see ch. 168). Compounding from bulk ingredients or active pharmaceutical ingredients (API) is not considered by the FDA as legitimate drug compounding, but drug manufacturing and is illegal in the USA. Compounding just to decrease cost is not considered a legitimate reason for choosing a compounded formulation when an approved formulation is available.[16] In contrast to generic drugs, compounded drugs are not required to contain the same drug content, drug form, or have stability and bioequivalence data. In the United States, the state boards of pharmacy have the primary regulatory authority over compounding pharmacies. Since compounded drugs do not undergo bioequivalence assessment, there should be no expectation of similar safety, adverse effects and efficacy as an approved drug. Compounded drugs have been recalled due to poor quality control. For example, routine random testing of compounded drugs (human and veterinary) between 2006 and 2015 by the Missouri State Board of Pharmacy found 13-25% of tested drugs failed to have the correct drug content. The range of content in the failing drugs was as low as 3% to as high 225% of the stated content.[17] Recalls by the FDA for lack of sterility and endotoxin assurance for "sterile" compounded drugs from numerous compounding pharmacies have been conducted.[18,19] Additionally, deaths in animals have occurred due to incorrect compounding practices resulting in incorrect drug content.[20] Therefore, use of compounded drugs in lieu of available FDA-approved drugs increases the risk of adverse effects, including the lack of efficacy, and increases the risk of malpractice and civil lawsuits. Client education, describing the risks and limitations of compounded drugs, is critical when compounded drugs are prescribed. Additional information on veterinary compounding is available in ch. 168, and the American Veterinary Medical Association has a Veterinary Compounding Policy with further details on legitimate compounding practices.[16]

CHAPTER 161

Antibacterial Drug Therapy

Mark G. Papich

Overview

Antimicrobial therapy is one of the most important therapies performed by small animal veterinarians. Skin/soft tissue infections, urinary tract infections, respiratory infections, blood-borne infections, and post-surgical infections are just some examples that require primary antibiotic therapy. In addition, our small animal patients present with a variety of diseases involving various body systems. Bacterial infections are often secondary to the primary problem and these patients also require antimicrobial therapy. More than ever, veterinarians are under pressure to use antimicrobial agents prudently. Virtually all practicing veterinarians have encountered multi-drug antimicrobial resistance. These strains of bacteria can present significant therapeutic challenges as well as potential public health risks. This chapter will discuss the essential principles of effective and prudent antimicrobial therapy in order to optimize treatment and decrease risks from resistant organisms.

Principles of Therapy

Every veterinarian should ask simple and basic questions before starting antimicrobial therapy (Box 161-1). The factors listed in Box 161-1 emphasize the activity of the drug, achieving adequate concentrations at the site of infection and considerations of drug safety.

Box 161-1

Important Factors to Consider When Starting Antimicrobial Therapy

- Activity of the drug: susceptibility: Will the empirical selection of a drug be active against the pathogen?
- Penetration: Will the drug adequately penetrate the tissue to reach the site of infection?
- Local factors that affect drug activity: Are there any local factors that will affect antimicrobial activity? Such factors can include low pH, anaerobic environment, cellular debris and pus, and compromised blood flow.
- Pharmacokinetic-Pharmacodynamic (PK-PD) factors: Is it possible to deliver a dosage and frequency of administration that are optimal to ensure the proper PK-PD exposure?
- Convenience of dosage regimen: Can the pet owner adequately administer this medication to the pet and achieve the desired compliance?
- Drug safety: Will the drug be safe in this patient? Does the patient have organ disease (liver disease, kidney disease); is the patient young, old, or pregnant?

Selecting a Drug That Is Active Against the Organism

Most of the time, veterinarians will start antimicrobial treatment before a culture and susceptibility test is obtained. In order to begin this treatment, veterinarians should have confidence that their empirical selection will produce the desired results. The first step is to consider the bacteria most likely present at the site of infection. This is accomplished by considering the most common commensal bacteria, opportunistic bacteria, and those most likely to invade the tissue. For example, *Staphylococcus pseudintermedius* is the most common

isolate from the skin of dogs, *Escherichia coli* is the most common urinary tract isolate in dogs and cats, and the respiratory tract can be infected with a mixed population. Clinicians should consider the likelihood of a pathogen infecting a tissue or the aid of other tests. Simple diagnostic tests such as cytologic examination of infected material can be helpful to identify the probable pathogen. If the bacteria are accurately identified, antibiotic selection is simplified because the susceptibility pattern of many organisms is predictable. Initial empirical treatment can begin with—but not be limited to—agents listed in Table 161-1.

TABLE 161-1

Probable Bacterial Susceptibility Based on Wild-Type Strains

ORGANISM	LOCATION	SUSCEPTIBLE TO
Streptococcus species (but not *Enterococcus*)	Respiratory infections, wound infections	Penicillin and penicillin derivatives (amoxicillin, ampicillin)
Pasteurella multocida	Wound infections, bite wounds, post-surgical wounds, respiratory tract, pyothorax	Penicillins, tetracyclines, trimethoprim-sulfonamides, cephalosporins*
Staphylococcus species, particularly *Staph. pseudintermedius*	Skin infections, wound infections, urinary tract infections, bone infections, discospondylitis	Beta-lactamase resistant beta-lactams (e.g., a cephalosporin), or a drug combined with a beta-lactamase inhibitor (e.g., Clavamox). Also generally susceptible to trimethoprim-sulfonamides and clindamycin.*
Anaerobic bacteria: *Clostridium, Peptostreptococcus, Actinomyces, Fusobacterium, or Bacteroides* (including those of the *Bacteroides fragilis* group)	Oral infections, pyothorax, penetrating wound infections. Abdominal infections (peritonitis) usually contain Gram-negative bacilli anaerobes (e.g., *Bacteroides* spp.).	Amoxicillin + beta-lactamase inhibitor (Clavamox), chloramphenicol, metronidazole, clindamycin, or a second-generation cephalosporin: cefoxitin
Enterobacteriaceae: Escherichia coli, Klebsiella pneumoniae, Enterobacter species	Urinary tract infections, pneumonia, sepsis, abdominal infections, and opportunistic pathogens in wound infections	With high drug concentrations in the urine, they may be susceptible to amoxicillin, amoxicillin-clavulanate, and trimethoprim-sulfonamides, and cephalosporins. In non-urinary tract infections, they may be susceptible to cefazolin, cefpodoxime, fluoroquinolones, aminoglycosides, penicillin-beta-lactamase inhibitors (piperacillin-tazobactam), and carbapenems.
Gram-negative non-fermenters: *Pseudomonas aeruginosa*	Chronic wound infections, otitis infections (chronic), urinary tract infections	Fluoroquinolones, ceftazidime, aminoglycosides, carbapenems, penicillin-beta-lactamase inhibitors (piperacillin-tazobactam)
Methicillin-resistant *Staphylococcus* (e.g., methicillin-resistant *Staph. pseudintermedius*)	Skin infections, pyoderma, bone and joint infections, urinary tract infections	These strains are resistant to all beta-lactam antibiotics, and often to fluoroquinolones, clindamycin, and trimethoprim-sulfonamides. Some strains are susceptible to rifampin, chloramphenicol, and tetracyclines (confirm with susceptibility test).
Enterococci *(Enterococcus faecium, Enterococcus faecalis)*	Urinary tract infections, biliary and abdominal infections. Can be identified in some infections, but are not always responsible for disease.	Wild-type strains can be susceptible to penicillins (amoxicillin, ampicillin, amoxicillin-clavulanate). If resistant to penicillins, a susceptibility test should be used to select the appropriate treatment.

*Fluoroquinolones (enrofloxacin, marbofloxacin, pradofloxacin, orbifloxacin) also may be active against these organisms, but are often not used as first-choice empirical treatment.

Treatment for wild-type strains of *Staphylococcus pseudintermedius, Pasteurella* species, and *Streptococcus* species can be accomplished with the administration of drugs that are common in our veterinary practices (see Table 161-1). Treatment for the Gram-negative enteric bacterial infections can be initiated with a fluoroquinolone (enrofloxacin, ciprofloxacin, marbofloxacin, pradofloxacin, or orbifloxacin), an extended-spectrum cephalosporin (ceftazidime, cefotaxime, cefpodoxime proxetil), or an aminoglycoside (gentamicin,

amikacin). However, if initial treatment is not effective, guidance from a susceptibility test is advised. For *Pseudomonas aeruginosa,* methicillin-resistant *Staphylococcus,* or *Enterococcus* spp., a susceptibility test is always advised because these organisms can have unpredictable susceptibility and the drugs to which they may be susceptible may not be familiar to veterinarians.

If anaerobic bacteria are suspected (for example, *Clostridium, Fusobacterium, Prevotella, Actinomyces,* or *Porphyromonas*), predictable results can be attained by administering a penicillin, chloramphenicol, metronidazole, clindamycin, amoxicillin-clavulanic acid, or one of the second-generation cephalosporins (cephamycins). Metronidazole is consistently highly active against anaerobes including *B. fragilis*. The activity of first-generation cephalosporins, trimethoprim-sulfonamides/ormetoprim-sulfonamides, or fluoroquinolones for an anaerobic infection is unpredictable. If the anaerobe is from the *Bacteroides fragilis* group, resistance may be more of a problem because they produce a beta-lactamase that may inactivate first generation cephalosporins and ampicillin/amoxicillin and some *Bacteroides* spp. may also be resistant to clindamycin.

Empirical Selection of Antibacterial Drugs

Empirical treatment of common infections in animals described above can be accomplished by selecting the antimicrobial agent with a high likelihood of success for the suspected clinical infection. Many guidelines have appeared in published proceedings, review papers, consensus documents, and textbooks. But when empirical treatment fails, or when resistance is suspected, a culture and susceptibility test is needed to guide therapy. The empirical choice for initial treatment is based on the assumption that the infection is not complicated and the infection is caused by wild-type bacteria. Wild-type strains of bacteria are those that have an absence of acquired and mutational resistance mechanisms, whereas non-wild-type strains of bacteria are those that have the presence of an acquired or mutational resistance mechanism to the drug in question. Wild-type strains may include bacteria that have inherent resistance to antimicrobials. For example, wild-type anaerobic bacteria are inherently resistant to aminoglycosides by virtue of a lack of an oxygen-dependent drug entry to the bacteria. Gram-negative bacteria of the *Enterobacteriaceae* and *Pseudomonas aeruginosa* are inherently resistant to macrolide antibiotics.

Susceptibility Testing

Culture and antimicrobial susceptibility testing (AST) will provide the best guidance for drug selection when susceptibility is not known, or if the seriousness of the infection warrants an accurate selection. These advantages notwithstanding, it is also understood that even when an agent is selected from the "susceptible" category, treatment may not always be successful. The prediction of whether the bacteria will, or will not, respond to treatment is commonly referred to as the "90/60 rule."[1] The 90/60 rule was derived from the observation that, in general, bacteria treated with antimicrobials to which the strain is sensitive will have a favorable therapeutic response in approximately 90% of the patients. On the other hand, when the bacteria isolate is resistant to the antimicrobial administered, despite the susceptibility result, approximately 60% of patients will respond to therapy. In veterinary medicine, we have no data to confirm or challenge the 90/60 rule.

The most important information for the clinician is simply which drugs have an "S" and which ones have an "R." These are the results that guide their treatment. For the test to be reliable, the laboratory should use the standards for interpretation available from the Clinical and Laboratory Standards Institute—CLSI.[2]

The most common test used by commercial laboratories is to directly measure the minimum inhibitory concentration (MIC) of an organism with an antimicrobial dilution test. Zone inhibition (also known as the Kirby-Bauer test) also is performed but provides only qualitative information. The MIC dilution test is performed by inoculating the wells of a plate with the bacterial culture and dilutions of antibiotics are arranged across the rows. The test is usually performed in modern laboratories using high-throughput plates, but individual tubes or plates can be used for dilution tests also. The MIC is not a measure of efficacy, but instead it is simply an *in vitro* measurement of drug activity and bacterial susceptibility. The lower the MIC value, the more susceptible the isolate is to that drug. The MICs are determined using serial two-fold dilutions of drug to which is added a standardized inoculum that is incubated for a prescribed time. Concentrations are always listed in mcg/mL. For example, if one were to start at a concentration of 256 mcg/mL, the MIC dilution series would be as follows: 128, 64, 32, 16, 8, 4, 2, 1, 0.5, 0.25, 0.12, 0.06 mcg/mL, etc. (Log_2 dilutions). If, for example, bacterial growth occurs at a dilution of 0.12 mcg/mL for a specific drug, but not at 0.25 mcg/mL and above, the MIC is determined to be 0.25 mcg/mL. The MIC dilution test is only

semi-quantitative because there are gaps between each dilution. Realistically, the true MIC lies somewhere between these values, but the MIC is recorded as the highest value. In some laboratories, other methods to measure the MIC are being used such as the Etest (epsilometer test) from bioMérieux, Inc. The Etest is a quantitative technique which measures the MIC by direct measurement of bacterial growth along a concentration gradient of the antibiotic contained in a test strip.

This MIC frequently is expressed as MIC_{50} or MIC_{90}, which is the MIC that inhibits 50% or 90% of the bacteria, respectively. It is sometimes cited in error that the MIC_{50} and MIC_{90} are the average concentrations for 50% and 90% efficacy. These values should not be confused with clinical efficacy (see below).

Interpretation of Susceptibility Tests

Resistance and susceptibility are determined by comparing the organism's MIC to the drug's breakpoint (also known as interpretive category). After a laboratory determines an MIC, it may use the CLSI "SIR" classification for breakpoints (S, susceptible; I, intermediate, or R, resistant). In practice, if the MIC for the bacterial isolate falls in the susceptible category, there is a greater likelihood of successful treatment (cure) than if the isolate were classified as resistant. It does not ensure success; drug failure is still possible owing to other drug or patient factors (for example, immune status, immaturity, or severe illness that compromises the action of antibacterial drugs), and interactions. If the MIC is in the resistant category, clinical failure is more likely because of specific resistance mechanisms or inadequate drug concentrations in the patient. However, a patient with a competent immune system may sometimes eradicate an infection even when the isolate is resistant to the drug in the MIC test.

The intermediate category is intended as a buffer zone between susceptible and resistant strains. This category reflects the possibility of error when an isolate has an MIC that borders between susceptible and resistant. If the MIC value is in the intermediate category, therapy with this drug at the usual standard dosage is discouraged because there is a good likelihood that drug concentrations may be inadequate for a cure. However, successful therapy is possible when drug concentrates at certain sites—in urine, or as the result of topical therapy, for example—or at dosages higher than the minimum effective dosage listed on the label. Prescribing guidelines for some antimicrobials allow for an increase in dosage when susceptibility testing identifies an organism in the intermediate range of susceptibility. For example, fluoroquinolone antimicrobials have been approved with a dosage range that allows increases in dosages when susceptibility testing identifies an organism in the intermediate range ("I") of susceptibility. In these cases, higher drug concentrations make a cure possible if the clinician is able to safely increase the dosage above the minimum labeled dosage. For the example of enrofloxacin in dogs, this would be equivalent to a dosage of 10 to 20 mg/kg/day, rather than the minimum dosage of 5 mg/kg/day.

MIC data should not be used in isolation, but by coupling the MIC from a laboratory report with CLSI breakpoints and other important information such as the virulence of the bacteria and the pharmacology of the antibiotics being considered, the clinician can make a more informed selection of an antibacterial drug.

Tissue Penetration of Antibiotics

The susceptibility interpretation and pharmacokinetic-pharmacodynamic (PK-PD) criteria are based on plasma/serum concentrations. No tissue-specific interpretation can be provided that accounts for differences in drug distribution among tissues. For example, even though it is anticipated that many antibiotics concentrate in the urine, which may be beneficial for treating a urinary tract infection, the susceptibility interpretation is based on achieving adequate concentrations in the blood. There are two exceptions to this because amoxicillin and amoxicillin-clavulanate interpretations allow for high concentrations in urine.

Urinary Tract Infections

For uncomplicated urinary tract infections, high urine antibacterial drug concentrations may be sufficient to achieve a cure.[3] However, this assumption does not hold up when treating a complicated infection, an infection in a patient with dilute urine (e.g., chronic kidney disease) or when other structures are involved such as the layers of the bladder mucosa, kidney, or prostate. In these cases, high urine concentrations alone are not sufficient. In these instances, it is the tissue concentration—which is correlated to the plasma concentration—that will be predictive of a bacteriologic cure.[4]

Drug Penetration to Other Tissues

A frequent mistake in MIC interpretation is to compare the MIC with published tissue concentrations that are derived from whole-tissue homogenized samples. Tissue concentration data are often published by pharmaceutical companies in their product information. These concentrations may be misleading because they may either underestimate or overestimate (depending on the drug's affinity for intracellular sites) the true drug concentration at the site of infection. For most tissues, antibiotic drug concentrations in the serum or plasma approximate the drug concentration in the extracellular space (interstitial fluid). This is because there is no barrier that impedes drug diffusion from the vascular compartment to extracellular tissue fluid.[5] There is really no such thing as "good penetration" and "poor penetration" when referring to most drugs in most tissues. Pores (fenestrations) or micro-channels in the endothelium of capillaries are large enough to allow drug molecules to pass through unless the drug is restricted by protein binding in the blood. Tissues lacking pores or channels may inhibit penetration of some drugs (see below).

If adequate drug concentrations can be achieved in plasma, it is unlikely that a barrier in the tissue will prevent drug diffusion to the site of infection as long as the tissue has an adequate blood supply. Clinicians should be concerned when treating tissues that have poor or impaired blood supply. Drug diffusion into an abscess or granulation tissue is sometimes a problem because in these conditions, drug penetration relies on simple diffusion and the site of infection lacks adequate blood supply. In an abscess, there may not be a physical barrier to diffusion—that is, there is no impenetrable membrane—but low drug concentrations are attained in the abscess, or drug concentrations are slow to accumulate.

Tissue Barriers

In some tissues a lipid membrane (such as tight junctions on capillaries) presents a barrier to drug diffusion. In these instances, a drug must be sufficiently lipid-soluble, or be actively carried across the membrane, in order to reach effective concentrations in tissues. These tissues include: the central nervous system, eye, and prostate. A functional membrane pump (p-glycoprotein) also contributes to the barrier. There also is a barrier between plasma and bronchial epithelium (blood:bronchus barrier). This limits the penetration of some drugs into the bronchial secretions and epithelial lining fluid (ELF) of the airways. However, in the event of treating pneumonia, this barrier is largely broken down and drug concentrations in extracellular fluids can diffuse to pneumonic areas of the lung.[6] If the blood-bronchus barrier is intact, it is difficult to predict the extent of penetration for veterinary antimicrobials. Macrolide antibiotics (e.g., azithromycin) concentrate in these fluids; but their spectrum of activity is limited. The extent of penetration for other classes of antibacterial drugs used in veterinary patients has not been adequately studied. Most of the agents are likely to produce concentrations in these fluids that are lower than the plasma/serum concentration.

Local Factors That Affect Antibiotic Effectiveness

Local tissue factors may decrease antimicrobial effectiveness. For example, pus and necrotic debris may bind and inactivate vancomycin or aminoglycoside antibiotics (gentamicin or amikacin), decreasing their effectiveness. Cellular material also can decrease the activity of topical agents such as polymyxin B. Foreign material in a wound (such as surgical implants or plant material) can protect bacteria from antibiotics and phagocytosis by forming a biofilm (glycocalyx) at the site of infection. Cellular debris and infected tissue can inhibit the action of trimethoprim-sulfonamide combinations through the secretion of thymidine and para-aminobenzoic acid, both known to be inhibitors of the action of these drugs. This may explain why trimethoprim-sulfonamide combinations have not been effective in some infected tissues, particularly anaerobic infections. Cations can adversely affect the activity of antimicrobials at the site of infection. Two important drug groups diminished in activity by cations such as Mg^{2+}, Al^{3+}, Fe^{3+}, and Ca^{2+} are fluoroquinolones and aminoglycosides. (Cations such as magnesium, iron, and aluminum also can inhibit oral absorption of fluoroquinolones.)

An acidic environment of infected tissue may decrease the effectiveness of clindamycin, erythromycin, fluoroquinolones, and aminoglycosides. Penicillins and tetracycline activity are not affected as much by tissue pH, but hemoglobin at the site of infection will decrease the activity of these drugs. An anaerobic environment decreases the effectiveness of aminoglycosides because oxygen is necessary for drug penetration into bacteria.

As mentioned previously, an adequate blood flow is necessary to deliver an antibiotic to the site of infection. Effective antibacterial drug concentrations may not be attained in tissues that are poorly

vascularized (e.g., extremities during shock, sequestered bone fragments, and cardiac valves).

Pharmacokinetic-Pharmacodynamic (PK-PD) Principles (also see ch. 160)

The use of exposure relationships and PK-PD principles for evaluation of antimicrobial compounds has become common in the veterinary literature. Practically all pharmacokinetic papers on antimicrobials published in the last few years in veterinary journals discuss the features of the pharmacokinetics in light of the pharmacodynamics of the drug and how this relates to rational dosage regimens.

PK-PD Terminology

Frequently-used parameters include the time above MIC, peak plasma concentration to MIC ratio, and area-under-the-curve to MIC ratio. There have been important attempts to standardize the terminology for PK-PD indices in antibiotic therapy.[7,8] Shown in Figure 161-1 are some terms used to describe the shape of the plasma concentration versus time profile. The C_{MAX} is simply the maximum plasma concentration (peak) attained during a dosing interval. The C_{MAX} is related to the MIC by the C_{MAX}:MIC ratio. The AUC is the total area-under-the-curve. The AUC for a 24-hour period is related to the MIC value by the AUC: MIC ratio. Also shown in Figure 161-1 is the relationship of time to MIC measured in hours (T > MIC). The value reported is the percent time during a 24-hour interval that the concentration is above the MIC.

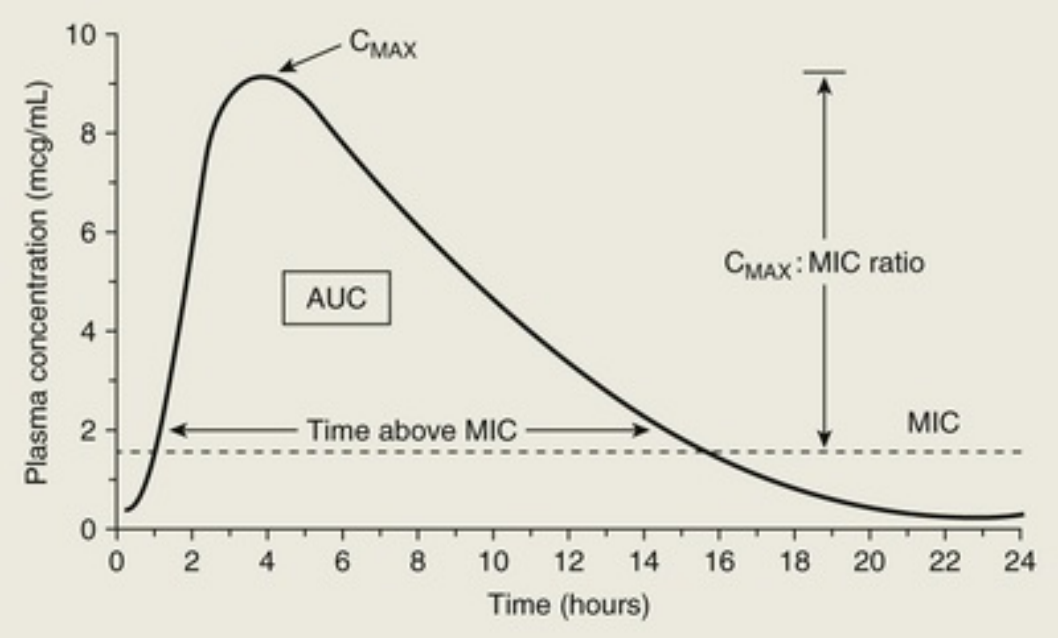

FIGURE 161-1 Plasma concentration vs. time profile illustrating the principal pharmacokinetic-pharmacodynamic relationships for antimicrobial therapy.

As discussed above in the Tissue Penetration section, these parameters refer to the plasma/serum drug concentration. It is preferred to use the protein unbound fraction *(fu)* to differentiate total drug concentrations from the unbound, pharmacologically active concentrations. The unbound drug concentration in plasma theoretically is in equilibrium with the unbound concentration in tissue fluid. Tests performed *in vitro* (susceptibility tests) do not use protein in the media. If the PK-PD indices do not use the unbound fraction, they can overestimate the drug's activity.

Optimizing Dosage Regimens with PK-PD Principles

Pharmacokinetic-pharmacodynamic relationships of antibiotics attempt to explain how these factors can correlate with clinical outcome. Although these concepts were originally derived from laboratory animals, the

principles apply to other species as well and can predict clinical outcomes in veterinary patients.[9]

Aminoglycosides

Aminoglycosides (e.g., gentamicin, or amikacin) are concentration-dependent bactericidal drugs; therefore, the higher the drug concentration, the greater the bactericidal effect. An optimal bactericidal effect occurs if a high enough dosage is administered to produce a peak of 8-10× the MIC. This can be accomplished by administering a single dose once daily. Regimens using this strategy are at least as effective, and perhaps less nephrotoxic, than lower dosages administered more frequently.[10,11] Our current regimens in veterinary medicine employ this strategy.[12] The single daily dose is usually calculated from the drug's volume of distribution (VD). Protein binding here is irrelevant because these drugs are essentially unbound.

Fluoroquinolones

Fluoroquinolones are concentration-dependent antimicrobials. Either the C_{MAX}:MIC ratio or the AUC:MIC has been used to predict antibacterial success, but in recent years the AUC/MIC ratio has become the preferred index. Most experts agree that an AUC:MIC ratio greater than 100-125 has been associated with a cure. There is evidence that for some clinical situations, AUC:MIC ratios as low as 30-55 are adequate for a cure, because studies in which a ratio above 125 was cited involved critically ill human patients or immunocompromised laboratory animals.

To attain the same PK-PD target with fluoroquinolones, treatment of some bacteria may require higher doses. For example, a low dosage is adequate for susceptible organisms with low MIC, such as *E. coli* or *Pasteurella* spp. On the other hand, *Staphylococcus* species typically have a higher MIC and may require slightly higher dosages. To achieve the necessary concentration for bacteria such as *Pseudomonas aeruginosa*, which usually has the highest MIC among susceptible bacteria, the highest dosage in a range is recommended. Bacteria such as enterococci and anaerobes are more resistant. Even at high dosages, a sufficient peak concentration or AUC:MIC ratio will be difficult to achieve for these organisms using currently available veterinary drugs (pradofloxacin is an exception because it has activity against anaerobic bacteria).

Beta-Lactam Antibiotics

Beta-lactam antibiotics such as penicillins, potentiated-aminopenicillins (e.g., amoxicillin plus clavulanate, piperacillin-tazobactam), and cephalosporins are bactericidal but their action may be slower than other bactericidal drugs, and generally a post-antibiotic effect (PAE) is not observed. Therefore, the concentration should be kept above the MIC as long as possible during the dosing interval (T > MIC) for the optimal bactericidal effect.[13] Dosage regimens for the beta-lactam antibiotics should consider these pharmacodynamic relationships. Therefore, for treating a Gram-negative infection, especially a serious one, some regimens for penicillins and cephalosporins require administration 3 to 4 times per day. Some long-acting formulations of penicillin have been developed to prolong plasma concentrations (for example, procaine- and benzathine-penicillin) but these formulations rarely produce plasma concentrations above the MIC for Gram-negative bacilli. Some of the third-generation cephalosporins have long half-lives and less frequent regimens have been used for these drugs (for example, cefpodoxime proxetil, and cefovecin). (The long half-life for ceftriaxone in people does not occur in animals because of differences in drug protein binding.)

Gram-positive organisms are more susceptible to the beta-lactams than are Gram-negative bacteria. Additionally, since the MICs are lower for Gram-positive bacteria, and antibacterial effects occur at concentrations below the MIC (post-antibiotic effect or PAE), longer dose intervals may be possible for infections caused by Gram-positive as compared to Gram-negative bacteria. For example, cephalexin and amoxicillin-clavulanate have been used successfully to treat staphylococcal infections when administered only once daily (although twice-daily administration is recommended to obtain maximum response).

The optimal duration of plasma concentrations above the MIC has varied among studies, but a general assumption is that the drug concentration should be above the MIC for at least 40-50% of the dosing interval.[13] This may vary depending on the immune competence of the animal and specific drug class. The carbapenem class of drugs (for example, imipenem and meropenem) is used with increasing popularity in small animal practice. These drugs are more bactericidal than penicillins and cephalosporins and the T > MIC for successful therapy may be less for these drugs than other beta-lactams (for example, 30% of the dose interval).

Other Time-Dependent Drugs

Many of the other drugs we include in the time-dependent group have post-antibiotic effects and are evaluated using an AUC/MIC ratio, rather than T > MIC. These include the macrolides, tetracycline, clindamycin, and chloramphenicol. These drugs are usually considered bacteriostatic in activity, but the lines between bactericidal and bacteriostatic drugs have become a bit blurred because it can vary with dose and among pathogens. Drugs such as tetracyclines, macrolides (erythromycin and derivatives), sulfonamides, lincosamides (lincomycin and clindamycin), and chloramphenicol derivatives have traditionally been considered bacteriostatic, but under some conditions of dosing can have bactericidal activity.

Most of the drugs grouped under this heading must be administered frequently to achieve this goal, unless they have long half-lives. For some of the drugs in this group, administration two or three times daily may be necessary.

CHAPTER 162

Antifungal and Antiviral Therapy

Mark G. Papich

Overview

Antifungal and antiviral drugs are used to treat both primary and secondary infections in dogs and cats. Safe and effective antifungal drugs can be vital in treating serious systemic fungal disease as well as skin infections caused by dermatophytes or yeasts. Some dogs and cats have greater risk of developing fungal infection if immunosuppressed, receiving anti-cancer drugs, undergoing radiation therapy, or being given corticosteroids chronically. Since there are few antifungal or antiviral drugs approved for use in dogs and cats, veterinarians have used human-label and experimental drugs to manage such infections, relying on published evidence of efficacy, safety and dosing.

In contrast to antibacterial drugs (see ch. 161), the relationship between plasma drug concentrations and clinical effectiveness has not been established for antifungal and antiviral drugs. Some guidance on the pharmacokinetic-pharmacodynamic (PK-PD) criteria for antifungal drugs is available from treated humans.[1,2] Susceptibility testing is rarely performed on isolated pathogens for antifungal or antiviral agents. Standards, rarely used in veterinary medicine, are available for testing and reporting antifungal and a small number of antiviral drug susceptibilities from the Clinical and Laboratory Standards Institute (CLSI).[3-5]

Antifungal Drugs

Dermatophyte Infections (Box 162-1)

Isolated dermatophyte lesions caused by *Microsporum* spp. or by *Trichophyton* spp. in dogs and cats are usually treated with topical ointments, creams or solutions that can be applied to the skin without concern for systemic effects unless the pet is consuming quantities by licking. Systemic therapies include griseofulvin (Fulvicin), azole antifungal agents, and terbinafine. Included with dermatophyte infections are yeast infections caused by *Malassezia pachydermatis* that most often affect the external ear, but also can occur on the skin. *Malassezia* dermatitis can be treated with topical products, but systemic drugs (e.g., azoles) also have been used.

Box 162-1

Drugs for Treating Dermatophyte Infections in Dogs and Cats

Topical (Creams, Ointments, Solutions)

- Enilconazole (Clinafarm)
- Miconazole (Conofite)
- Clotrimazole (Lotrim)
- Terbinafine (Lamisil)

Systemic Drugs (Oral Products)

- Griseofulvin (Fulvicin)
- Ketoconazole (Nizoral)
- Itraconazole (Sporanox)
- Fluconazole (Diflucan)
- Terbinafine (Lamisil)

Systemic Infections (Table 162-1 and Box 162-1)

The most serious diseases treated with antifungal agents are the systemic mycoses, including the filamentous fungi such as *Aspergillus* spp. (see ch. 234 and 235), *Fusarium* spp., and *Penicillium* spp. and opportunistic fungi such as *Histoplasma capsulatum* (see ch. 233), *Blastomyces dermatitidis* (see ch. 233), *Coccidioides immitis* (see ch. 232), *Cryptococcus neoformans* (see ch. 231), and *Candida* spp. (see ch. 236).

TABLE 162-1

Selected Antifungal Drugs Used in Companion Animals

DRUG	BRAND NAME	FORMULATIONS	DOSING PROTOCOL	COMMENTS
Griseofulvin	Fulvicin	125 and 250 mg capsules, 125, 250, and 500 mg tablets, and oral syrup 125 mg/mL	Dosage has ranged from 22 mg/kg to 110 mg/kg per day. Most common dosage is approximately 50 mg/kg per day.	Administer with food. Do not administer to pregnant cats. Rarely used compared to the azoles and topical products. Consult older references for more information on griseofulvin.
Ketoconazole	Nizoral and generic	200 mg tablets	Dermatophytosis in cats: 10 mg/kg/day. Candidiasis: 10 mg/kg/day for 6 to 8 weeks. Blastomycosis, histoplasmosis, cryptococcosis and coccidioidomycosis: 10 to 20 mg/kg q 12 h. *Malassezia* dermatitis in dogs: dosages of 5-10 mg/kg/day have been recommended. CNS infections (*Cryptococcus* in cats) 10 to 15 mg/kg per day.	Availability has diminished in recent years. Administer with food. Monitor liver enzymes in treated patients. Adverse effects such as suppression of endocrine synthesis, anorexia, vomiting, and hepatic injury are more common than with other systemic azoles. Ketoconazole will inhibit a large range of drug-metabolizing enzymes and p-glycoprotein.
Itraconazole	Sporanox, and generic	100 mg capsules and 10 mg/mL cherry flavored solution	In cats, dosages for dermatophytes have ranged from 10 mg/kg q 24 h to 3 mg/kg q 24 h. For *Cryptococcus* in cats, 8.5 mg/kg per day has been used. Pulse dosing for dermatophytes in cats has used a dosage of 10 mg/kg q 24 h, for 28 days, followed by pulse dosing of one week on, one week off. In dogs, 5 mg/kg per day is usually sufficient. Pulse dosing has been used in which it was administered 5 mg/kg per day for 2 days per week × 3 weeks.	Itraconazole oral capsules should be administered with food; however, itraconazole oral solution can be administered with or without food. Although drug interactions are less likely than with ketoconazole, hepatic enzyme inhibition is possible. Adverse effects are less common than for ketoconazole, but are still possible.
Fluconazole	Diflucan, and generic	50, 100, 150, 200 mg tablets. 10 and 40 mg/mL oral suspension, and injectable solution.	Cryptococcosis in cats: 100 mg/cat/day in one or two divided doses, or 2.5-5 mg/kg once a day. In dogs, the dosage is 10-12 mg/kg/day PO.	Fluconazole is more water-soluble and better absorbed orally than other azole antifungal drugs. The limitation for fluconazole is that it is less active against many fungi compared to other azole antifungal agents.
Voriconazole	Vfend	50 mg or 200 mg tablet, oral suspension	Cats: loading dose of 5 mg/kg PO, followed by 2.5 mg/kg q 48 h. Dogs: 6 mg/kg, per day, PO.	Dosage in cats has not been confirmed through safety or efficacy studies. Administration to cats may cause

		(40 mg/mL) and an intravenous formulation		miosis, neurotoxicosis, and salivation. Safety and efficacy have not been studied in dogs. Hepatic injury is possible and liver enzymes should be monitored during treatment. Like other azoles, it should not be used in pregnancy.
Posaconazole	Noxafil	Oral suspension (40 mg/mL), delayed-release tablet (100 mg), and injectable solution	Cats: 15 mg/kg loading dose, followed by 7.5 mg/kg PO q 24 h. Dogs: 5 mg/kg q 48 h of delayed release tablet, or 10 mg/kg per day of oral suspension.	Dosage in dogs and cats is based on preliminary studies and has not been tested for safety or efficacy.
Terbinafine	Lamisil	1% topical cream (available over the counter) and 125 and 250 mg tablets	Dogs: 30-35 mg/kg PO q 24 h. Cats: 30 mg/kg per day, or ¼ tablet for small cats (62.5 mg), ½ tablet for medium size cats (125 mg) and one tablet for large cats (250 mg), all administered once daily.	Terbinafine has been used in some clinical studies in dogs and cats with mixed results. The dosage is much higher than in people. Some studies have reported efficacy for dermatophyte treatment; other studies have reported limited efficacy.
Amphotericin B	Fungizone	50 mg injectable vial	Pretreatment with 0.9% sodium chloride followed by infusion of 0.5 mg/kg in 5% dextrose over 4-6 hours IV q 48 h; a test dose of 0.25 mg/kg is sometimes recommended	Kidney injury is a serious limitation to therapy. Vomiting, nausea, fever, and phlebitis also can occur with IV infusions.
Liposomal Amphotericin B	Abelcet	Unspecified	2-3 mg/kg IV 3 times per week diluted in 5% dextrose to a concentration of 1 mg/mL for a total of 9-12 treatments (cumulative dosage of 24-27 mg/kg)	The liposomal formulation of Abelcet has been the most frequently used in veterinary medicine. Its use is limited by the high expense.

Amphotericin B

Background

Amphotericin B (Fungizone) is a polyene macrolide antibiotic with antifungal activity effective in treating serious systemic fungal infections. Its use, however, is associated with a high incidence of adverse effects, requiring careful administration and patient monitoring. Amphotericin B is active against *Blastomyces dermatitidis, Histoplasma, Cryptococcus, Coccidioides, Candida, Aspergillus,* as well as *Leishmania* (see ch. 221).

Clinical Use and Administration

Amphotericin B is poorly absorbed from the gastrointestinal (GI) tract; therefore, it is usually administered via IV infusion. Acute kidney injury (AKI; see ch. 322) is the most severe adverse effect and the most common cause for discontinuing therapy before the goal in total dosage has been administered. Early reversible AKI is seen with each daily dose, but permanent damage is related to the total cumulative dosage. Risk of AKI can be reduced by pre-treating each patient with IV saline and administering the drug slowly (over 4-6 hours). Renal function must be closely monitored at least once daily during treatment (SDMA? see ch. 322 and 324), realizing that the amphotericin B may need to be discontinued if persistent azotemia is identified. Other amphotericin B side-effects include vomiting, tremors, pyrexia, and anorexia. These adverse effects may be associated with each daily treatment and can usually be somewhat alleviated with anti-histamines, nonsteroidal anti-inflammatory drugs (NSAIDs), and/or antiemetics.

Liposomal Formulations *(Box 162-2)*

These lipid and cholesteryl formulations of amphotericin B are commonly used in people, but experience is limited in veterinary medicine due to cost. The advantage over traditional formulations is that these forms can be given at higher doses with greater efficacy and less toxicity.[6] Dosages achieved with lipid complex formulations of amphotericin B have been >3 mg/kg body weight (BW) as compared to 0.25 to 0.5 mg/kg of the conventional formulation. Decreased toxicity is attributed to a selective transfer of the lipid complex amphotericin B, releasing the drug directly to the fungal cell membrane, sparing mammalian tissues. Reduced drug concentrations in the kidneys and diminished release of inflammatory cytokines from amphotericin lipid complexes, as compared with conventional formulations, also may help reduce the frequency of adverse reactions.

Box 162-2

Amphotericin B Formulations

- Amphotericin B deoxycholate (conventional formulation)
- Amphotericin B lipid complex (ABLC, Abelcet), a suspension of amphotericin B complexed with two phospholipids. The most extensively evaluated in dogs, shown in one study to be safe and effective in dogs at a cumulative dosage of 8-12 mg/kg.
- Amphotericin B cholesteryl sulfate complex (Amphotec). This is a colloidal dispersion, also called ABCD (amphotericin B colloidal dispersion).
- Liposomal complex of amphotericin B encapsulated in a lipid bilayer (L-AmB, AmBisome)

Azole Antifungal Drugs (see Box 162-1)

Overview

The azole antifungal drugs are the most efficacious oral systemic drugs used in people and animals. Common features shared by the azoles are their high lipophilicity and poor solubility. Their poor solubility limits GI absorption unless the medication is administered with food to stimulate stomach acids to aid in lipid dissolution. Antacids, histamine H-2 blocking drugs (e.g., famotidine), and proton pump inhibitors (e.g., omeprazole) can decrease GI absorption. Azole drugs are not good candidates for compounding because manipulation affects solubility (Figure 162-1).

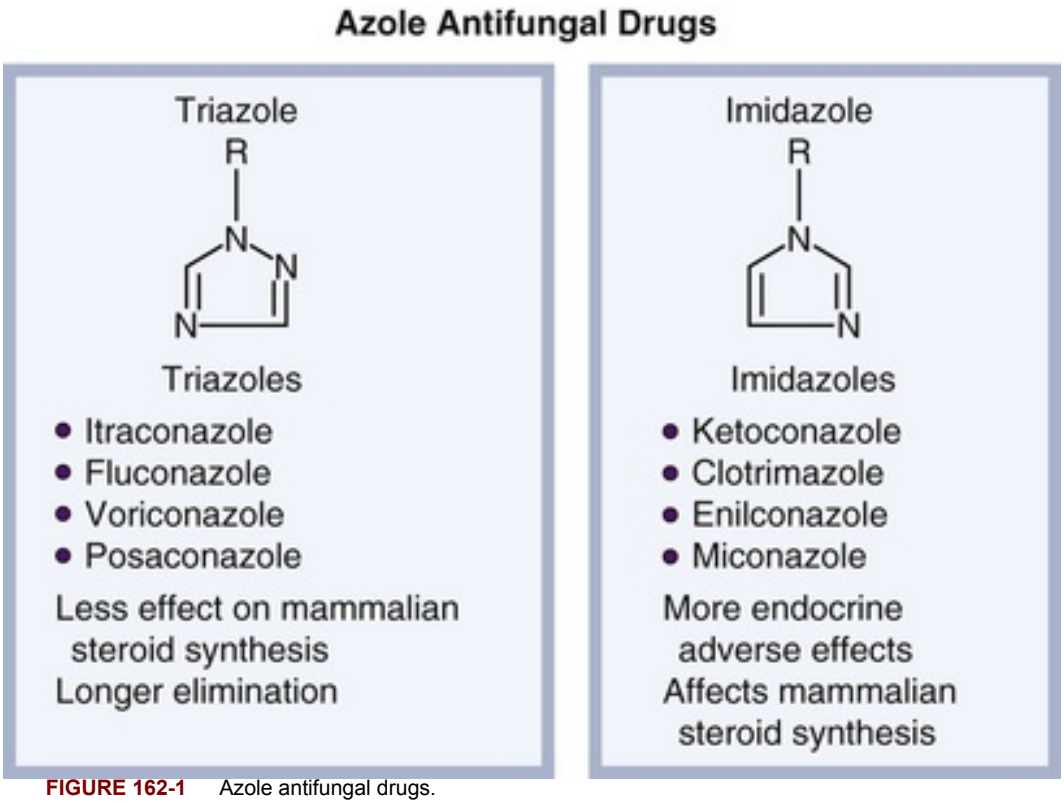

FIGURE 162-1 Azole antifungal drugs.

Ketoconazole

Ketoconazole is one of the first azoles administered systemically for fungal infections in animals. Ketoconazole has a wide spectrum of activity that includes yeast (e.g., *Malassezia pachydermatis*), systemic fungi, and dermatophytes. Although ketoconazole is seldom used in people because of adverse effects and drug interactions, it remains an important and cost-effective antifungal agent for use in animals. Common adverse effects in animals (nausea, anorexia, vomiting) are usually dose-related and may be diminished by decreasing the dosage, dividing the total dose into smaller doses, and/or administering each dose with food. Ketoconazole inhibits synthesis of steroid hormones via inhibition of cytochrome P-450 enzymes, most notably cortisol and testosterone. Although this may be a side-effect of therapy, it has been employed for the temporary management of hyperadrenocorticism in dogs and as an anti-androgen.[7,8] Hepatic enzyme activities may increase with therapy (especially alkaline phosphatase and alanine aminotransferase) and hepatotoxicosis has been reported. The hepatotoxicosis is most likely an idiosyncratic reaction (unpredictable) but it may be more common at higher dosages (see ch. 169). They should not be used in pets with evidence of hepatic disease nor in pregnant animals because fetal death may occur.

Ketoconazole is one of the most potent inhibitors of hepatic and intestinal microsomal enzymes (cytochrome P450 enzymes), potentially altering metabolism and/or elimination of other drugs being given. It also is an inhibitor of the MDR membrane pump, also known as p-glycoprotein (p-gp), involved in drug penetration across intestinal, blood-brain barrier, and other tissues. For example, if ketoconazole is administered with cyclosporine, cyclosporine concentrations are increased 2- to 3-fold in dogs.

Itraconazole *(see Figure 162-1)*

Itraconazole is an azole of the triazole group. Triazoles and imidazoles have antifungal mechanisms of action that are similar. Itraconazole is one of the most widely employed triazoles in animals, used for systemic or cutaneous fungal infections. It is more potent than ketoconazole (5 to 100 times more active), has fewer side effects, and does not cause adverse endocrine effects because triazoles lack affinity for some cytochrome P-450 enzymes in animals. The commercial formulation (Sporanox) is available in capsules and as an oral liquid. The oral solution is better absorbed in cats than the capsule by approximately 3-fold, but, it can be difficult to administer to cats because of its taste. The granules in the capsules or the solution may be added to food for convenience, but granules should not be crushed. Itraconazole is insoluble and is not absorbed well unless

administered as the commercial formulation. Bioequivalence studies in dogs have shown that compounded formulations are not sufficiently absorbed in cats or dogs.[9]

The long half-life of itraconazole in cats (18-24 hours) allows once per day or every-other-day dosing. While some studies report no adverse effects, idiosyncratic liver injury has been reported despite every-other-day administration. In dogs, itraconazole has been used in treating blastomycosis, other systemic fungal infections, dermatophytoses, and *Malassezia pachydermatis* dermatitis. Protocols have been described using pulse or intermittent dosing, involving administration 2 or 3 days per week.

Itraconazole is better tolerated in dogs and cats than is ketoconazole, but it may still produce adverse reactions. Since some reactions (anorexia, vomiting) are dose-related, one is advised to lower the dosage if observed. Hepatopathy is reported in as many as 10% of treated dogs.[10] Liver enzyme activities may increase in 10-15% of treated dogs and hepatic toxicosis in cats may be an idiosyncratic reaction. Itraconazole causes only mild inhibition of cytochrome P-450 enzymes but if given concurrently, concentrations of cyclosporine, digoxin, and/or cisapride increase. Itraconazole also inhibits p-gp, which may cause concentrations of other drugs to increase.

Fluconazole

Because of its availability as an inexpensive generic drug, veterinary use of fluconazole is common. While better tolerated than the other azoles, fluconazole is not as active against dermatophytes, *Blastomyces,* or *Histoplasma*. Fluconazole has good activity against *Coccidioides* spp. and *Cryptococcus neoformans.* Cats with cryptococcosis have been successfully treated with fluconazole. It has been used to treat dermatophytes, yeast infections, as well as some systemic fungal infections in dogs. Fluconazole is more water-soluble than the other azoles, with unique pharmacokinetic characteristics. It is absorbed well regardless of other potential interfering factors.

Voriconazole

Voriconazole (Vfend) is a triazole similar to itraconazole and fluconazole. It has become a valuable drug for humans, especially those with disseminated aspergillosis. Its use in animals has been limited but dosages for mammals and birds are being developed. The advantage of voriconazole is its excellent activity against yeasts, dermatophytes, and some filamentous fungi. Voriconazole is similar in structure to fluconazole, but has much better activity against several species of molds, including *Aspergillus* spp. and *Fusarium* spp (see ch. 234 and 235).

Experimental use of voriconazole in dogs has shown rapid and complete absorption of the drug after oral administration, a short terminal half-life, and induced metabolism (lowering blood concentrations after repeated dosing). These factors may limit its long-term use in dogs. There is concern regarding neurotoxicosis in cats. Since the drug has a long half-life in cats (over 40 hours as compared with about 3 hours in dogs) it may accumulate to toxic concentrations if administered daily. Dosages listed in Table 162-1 are based on preliminary pharmacokinetic studies, while safety and efficacy studies have not yet been reported.

Posaconazole

Posaconazole (Noxafil) is similar to itraconazole, with a slightly different spectrum of activity. It is used in people primarily for *Aspergillus* and *Candida* infections. It is also active against dermatophytes, *Histoplasma capsulatum, Blastomyces dermatitidis, Coccidioides immitis,* and *Cryptococcus neoformans*. In contrast to other azoles, posaconazole also has activity against Mucorales (formerly called Zygomycetes: *Mucor* and *Rhizopus*; see ch. 236). Use of posaconazole in animals has been limited to a few case reports in cats and pharmacokinetic studies in dogs and cats. It was well-tolerated in short-term studies in dogs and cats.

Antiviral Drugs (Box 162-3)

Overview

Systemic antiviral drugs have rarely been used in veterinary medicine. Antiviral topical ointments are most commonly used in pets for viral ophthalmic conditions, particularly feline herpes infection. Systemic treatment of viral diseases in dogs and cats has not been thoroughly evaluated, pharmacokinetic information is incomplete, and dosing protocols are mostly anecdotal. Treatment of viral diseases in dogs and cats primarily relies on supportive care together with prevention and treatment of secondary bacterial infections. *Antiviral chemotherapy does not eliminate the virus in infected dogs and cats.*

Box 162-3

Antiviral Drugs

- Zidovudine (AZT): Has produced some benefit in cats with feline immunodeficiency virus infection, but is less effective for cats with feline leukemia virus infection. High dosages have caused adverse effects in cats.
- Stavudine (d4T)
- Didanosine (ddI)
- Zalcitabine (ddC)
- Lamivudine (3TC)
- Suramin
- Foscarnet
- Ribavirin
- Plerixafor
- Famcyclovir: Has produced improvement when administered to cats with feline herpesvirus-1 (FHV-1).

For some diseases, such as feline leukemia virus infections (FeLV), immunomodulators (e.g., acemannan, interferon omega, bacterins) and other products purported to act as "immune stimulants" have little documented evidence of efficacy (see ch. 223). Unfortunately, the terms "immunomodulation" and "immune stimulation" are poorly defined. There is some evidence that interferon-omega may improve survival in cats infected with FeLV, but other evidence is lacking. Use of drugs to stimulate the immune system may seem counterproductive for some diseases (e.g., feline infectious peritonitis [FIP]) because the clinical signs are a result of an immune-mediated process.

For some diseases, the use of antiviral drugs developed for people has resulted in failure or toxicosis. For example, treatment of FIP has been disappointing. Ribavirin should theoretically be effective because of *in vitro* activity, but it failed in clinical trials and resulted in toxicosis. Larger controlled studies using feline interferon have not shown significant benefit. No antiviral or immunomodulatory drug has been shown to substantially affect the outcome of FIP (see ch. 224).

Feline Immunodeficiency Virus and Feline Leukemia Virus

Management of retrovirus-infected cats (feline immunodeficiency virus [FIV] or FeLV) with antiviral drugs has been disappointing (see ch. 222 and 223). No available drug eliminates either virus from infected cats and few controlled studies have been conducted on drug effectiveness. Several drugs have been investigated but few are promising. Among the drugs listed in Box 162-3, some have *in vitro* activity but in each case the agent may not have been investigated sufficiently *in vivo,* or it failed in clinical trials, or the adverse side-effects make use contraindicated.[12]

Zidovudine (AZT) has activity *in vitro* against both FeLV and FIV by inhibiting replication of the virus. This drug is a nucleoside analog that blocks reverse transcriptase of retroviruses. In clinical studies in FIV-infected cats, using dosages of 5-10 mg/kg q 12 h, SC or PO, zidovudine had clinical benefit, improved quality of life, and decreased virus load. But cats with FeLV had no significant improvement after therapy with zidovudine, while high dosages suppressed the bone marrow.

Feline Herpesvirus-1

Systemic treatment with antiviral drugs has been justified in treating feline herpesvirus-1 infections (FHV-1). Agents evaluated for efficacy have been used in people to treat herpes simplex type-1 virus infection. Some drugs have been investigated, such as acyclovir, valaciclovir and ribavirin, but these have either been ineffective, toxic to cats, or both. Penciclovir has been shown to have good *in vitro* activity against FHV-1, but is not well absorbed.[13] However, the pro-drug of penciclovir, famciclovir, is converted to the active compound via de-acetylation in the intestine and liver. Administration of the pro-drug substantially improves bioavailability and, once absorbed, penciclovir is converted in a step-wise process to the triphosphate inhibiting viral DNA polymerase to inhibit viral replication.

Early studies with oral administration of famciclovir at 62.5 mg per cat failed to produce adequate blood

concentrations of penciclovir to be consistently effective.[14] Higher dosages of 125 mg or more, q 8-12 h, are now recommended based on clinical observations.[15] Despite some promising results from the use of famciclovir for skin and ocular lesions, cats with upper respiratory disease caused by FHV-1 or feline calicivirus (FCV) are usually not treated with these agents (see ch. 229). These cats are managed with supportive care and administration of antibiotics for secondary bacterial infections (see ch. 161).

CHAPTER 163

Antiparasitic Therapy

Byron L. Blagburn, Jane D. Mount

Client Information Sheet: Antiparasitic Therapy

The goals of parasiticide therapy are to reduce or eliminate signs of disease and to remove the causative parasite(s). Antiparasitic agents must be safe, effective, and convenient to use.[1] Additional considerations are spectrum of activity (types of parasites that are eliminated), formulation, sex and age of the target animal, other concurrent health problems, pregnancy and nursing, product approval or off-label use, ease of acquiring the parasiticide, and other current parasite control strategies such as heartworm prevention and flea and tick control. Given the spectrum of parasites in companion animals, and complexity of the parasiticide market, selection of antiparasitic products can be difficult.[2,3]

Accuracy of Diagnosis

Selection of the appropriate parasiticide is dependent on an accurate diagnosis.[4,5] Intestinal parasites and those that are found in the lungs, hepatobiliary system and other organs that open to or communicate with the gastrointestinal tract are usually passage stages that are recovered from feces. These parasites are usually confirmed by properly conducted fecal examination (see ch. 81).[4] Current prevention strategies (heartworms, intestinal parasites) rely less on an initial diagnosis than on the historical risk of parasitic infection. Available products are intended to provide protection against major internal parasites while improving compliance.[1]

Target Animal and Formulation

The spectrum of activity, dosage, and route of administration of antiparasitic drugs are usually developed and approved with specific hosts in mind. To assume that products that are approved for one host species can be used safely and effectively in other hosts is an assumption that could result in either lack of effectiveness or toxicosis. Topical products are often developed and marketed for both dogs and cats, but they are particularly useful in cats because of the difficulty (and safety) of administering oral or injectable products to cats. Also, products are designed to release the active ingredient at a rate that will provide efficacy and safety over the approved period. Using the same product in an alternative species could result in a shorter or longer duration of activity. Formulations of some parasiticides may be the same for more than one host species, but weight ranges in the different animals are often different. For example, some product package sizes may be duplicated for both dogs and cats. It is necessary to remind the client that this is true for only certain product sizes. Even then, the weight ranges covered by the same product package will likely be different for the dog and cat.

Spectrum of Activity

Foremost in our considerations of which parasiticide to select is whether it is label-approved for the target parasite, or if its efficacy is supported by legitimate published research data.[1] Antiparasitic drugs are available as single active ingredients or as combinations of active ingredients. Those with a single ingredient are often effective against several internal parasites. Combining more than one active ingredient in a product usually increases the spectrum of activity against internal parasites and may add external parasites to the label. When common internal parasites (i.e., *Toxocara canis, Ancylostoma* spp., and/or *Trichuris vulpis*) are the targets, several broad spectrum agents that are available as oral, topical and injectable products can be used. Deciding among them is dependent on factors discussed in other sections of this chapter. When heartworm

prevention is needed, the spectrum of available products changes further. Another consideration is whether the goal is to eliminate existing parasites or to prevent additional infections, or both. These are important points because concentrations of the active ingredients(s) often determine the level of efficacy achieved and whether efficacy is against mature or immature stages. Clearly, the landscape of antiparasitic drugs is complex. Consider the following. Examples of single entity broad-spectrum agents are pyrantel pamoate, fenbendazole, milbemycin oxime, moxidectin, praziquantel, epsiprantel, and selamectin. Dual broad-spectrum actives include pyrantel pamoate/praziquantel, ivermectin/pyrantel pamoate, milbemycin oxime/praziquantel, milbemycin oxime/lufenuron, milbemycin oxime/spinosad, and emodepside/praziquantel. A combination of three active ingredients further broadens the spectrum of the formulation. Examples are milbemycin oxime/lufenuron/praziquantel, ivermectin/pyrantel pamoate/praziquantel, and fenbantel/pyrantel pamoate/praziquantel.[1] We must also consider the use of antiparasitic drugs that have not gained regulatory approval, but are often used safely and effectively against problem parasites. Examples are metronidazole, secnidazole, ponazuril and ronidazole, just to mention a few.[1]

Effectiveness

Efficacy of parasiticides is a must when removal of target parasites and elimination of disease are the goals. To reach the market, approved parasiticides must be effective enough to eliminate the majority of the target parasites. Regulatory approval usually requires the removal of 90% of the parasites from treated animals compared to non-treated controls.[6] Heartworm preventives are the only exception. Heartworm preventive products must be 100% effective after either experimental or natural infection (see ch. 255). Interestingly, melarsomine dihydrochloride, the only approved heartworm adulticide, must achieve a high level of efficacy (usually >90%) but is not required to be 100% effective. Many parasiticides that are not approved for specific parasites are used successfully based on either published data or testimony that supports their efficacies. The authors strongly recommend that approved parasiticides are used when possible. Antiparasitic drugs that are not approved should be researched thoroughly and used in a manner consistent with available published data.

Strategic Versus Preventive Parasite Control

The selection and frequency of use of parasiticides will depend on the intended result. Animals that present with acute parasitism caused by parasites confirmed by appropriate and reliable diagnostic tests should be treated with antiparasitic drugs that eliminate the parasites. Additional treatments with other therapeutic agents as well as supportive therapy may also be necessary, depending on the presence of concurrent disease and the condition of the animal. The difference between antiparasitics with therapeutic effects and those with preventive effects is often one of dosage and frequency of administration. Therapeutic products that are administered to eliminate established infections are often administered once or twice at a higher dosage. Preventive products are usually administered at intervals (i.e., monthly or every 6 months). Products used in therapeutic strategies usually are administered at a higher dosage than preventive products. However, this is not always the case. Migrating stages of parasites (i.e., *Toxocara, Ancylostoma*) may require higher dosages of parasiticides and longer treatment regimens. Reasons are not always clear, but are likely due to lower metabolic rates of these stages and the greater difficulty in getting adequate amounts of parasiticide to the parasite's migratory sites. Some parasiticides are both therapeutic and preventive at the same dosage, but this is usually a unique situation involving treatment of one parasite and prevention of another. Examples are the products that eliminate adult intestinal parasites while preventing heartworm infections. In many of these cases, the heartworm preventive dosage is higher than necessary because heartworm is not the dose-limiting parasite. Clearly, understanding both the parasites and the target stages is important in applying preventive or therapeutic strategies successfully.[7]

Environmental Considerations

The environment in which animals are housed as well as their numbers and ages can affect the kinds and intensity of parasitic infections. These variables, alone or in combination, will determine the selection and use of antiparasitic drugs. Treatment and control of parasites in dogs in kennels and cats in catteries presents a different problem than individual pets in households. The same is true of animals in shelters and animal control facilities. Multi-pet households, including homes for fostered pets, may require strategies that are

similar to kennels and catteries. The difficulty in these situations is delivering proper therapies to many individuals in the same environment. Also, the variation in ages and sizes of animals makes population treatments in food or water more difficult. As mentioned above, environmental variables often result in different populations and intensities of parasites in each animal. This requires collection of individual specimens such as feces or urine from each animal. Products approved for application to food or water are lacking. Some parasiticides, such as amprolium for treatment of coccidiosis in dogs, can be added to water, but most cannot. Consequently, animals must be handled individually. Many off-label products are used in these situations. When using products and formulations intended for other host species, it is necessary to understand concentrations of formulations, dosages required for effective use, potential toxicoses, and proper storage.[1]

Compounded Parasiticides

It is common in today's veterinary practice to have some parasiticides reformulated by pharmacists for easier dosage calculations and more convenient product administration. These usually are products that are not approved for routine use, but for which there is a body of evidence that indicates that the active ingredients can be effective if dosages are calculated properly and the entire dose is administered to the target animal. These formulations often have not undergone evaluation for stability over time, or pharmacologic analysis in target animals to ensure that blood levels are achieved that are comparable to approved products or to other formulations for which research has been performed. Veterinarians should always consult with pharmacists about available information on a compounded parasiticide. Actually, the same arguments could be made against using parasiticides from other host species that contain the same or similar active ingredients. Differences in concentration and rates of absorption, distribution and elimination could result in lack of efficacy or unexpected adverse events. In summary, it is best to use formulations that are approved for the target parasite and host species.[8] If alternative products are considered, it is prudent to obtain as much information about them as possible before use.

Reproductive Status of the Host

Many antiparasitic drugs carry a disclaimer for use in pregnant or nursing animals, or more correctly that their safety in pregnant or nursing animals has not been determined. This does not necessarily indicate that they are unsafe. In most cases, it means that sufficient data on reproductive safety are not available to allow a label claim. It is the opinion of the authors that it is best to avoid the use of products in pregnant animals when such products have not been evaluated for reproductive safety. That said, a decision to proceed with therapy using a non-approved product could be justified depending on the severity of parasitism and the prognosis of the animal's recovery without therapeutic intervention.

Repeat Treatments

We are often asked whether additional treatments are necessary following a single therapeutic treatment for parasites. The necessity to retreat is determined by improvement of clinical signs and reduction in stages recovered at post-treatment examinations. A few considerations will help determine if additional treatments are necessary. Animals less than 6 months of age often have migrating stages of parasites that may not be eliminated by the selected antiparasitic agent. Therefore, choosing the correct retreatment interval requires knowledge of the parasite's life cycle. Parasites with longer endogenous cycles (i.e., longer period of migration in the host) would probably require a longer interval between the first and subsequent treatments. Also an initial high number of parasites present before the first treatment may leave a residual burden of parasites that would require additional treatments. It is important to keep in mind that this is also determined by the effectiveness of the parasiticide. A general rule of thumb for most parasites is that if retreatment is necessary, an interval of 1 to 2 weeks should suffice. Treatment efficacy should be the main factor on which decision to retreat is based.

Resistance to Antiparasitic Drugs

Resistance to antiparasitic drugs has been documented for important animal parasites.[9,10] Many view the development of resistance as an indication that subsequent use of these drugs will provide little or no benefit in preventing parasitic disease. Although this may be true for some parasites of livestock and horses, it has

not proven true for companion animal parasites. Resistance has been identified for some field strains of heartworm and rarely for some common intestinal parasites. However, in the majority of cases, antiparasitic drugs remain effective and beneficial to companion animals. There are several things that can be done to deter the development of resistance. First, use approved products at their label doses and according to their approved regimens. Underdosing and use of products at treatment intervals that are too frequent may lead to resistance development. Always monitor the efficacy of antiparasitic drugs by performing post-treatment tests, or at the very least, annual tests. Avoid the use of off-label products unless sufficient research supports that treatments are effective at eliminating the parasite. If a product appears to lose its efficacy, retreat with a product from a different chemical group. The most important aspect of resistance management is to monitor the effectiveness of antiparasitic drugs by regular fecal examination or other appropriate tests.

CHAPTER 164

Anti-Inflammatory Therapy

Shauna Blois, Karol A. Mathews

Glucocorticoids and nonsteroidal anti-inflammatory agents (NSAIAs) are commonly used classes of drugs that provide potent anti-inflammatory actions to treat a variety of conditions. The major anti-inflammatory actions of these drug classes include suppression of pro-inflammatory cytokines and other mediators. Glucocorticoids are less specific in their actions compared to NSAIAs, influencing metabolic and immune system functions. Pharmacology, clinical indications, and adverse effects of each drug class are discussed below.

Pharmacology and Clinical Indications for Glucocorticoids

Glucocorticoids enter cells largely through passive diffusion and bind to cytosolic receptors. Receptor number and type vary between tissues. Upon binding, receptors rapidly move into the nucleus where they exert molecular effects. At the level of the nucleus, glucocorticoids influence gene regulation and other transcription factors.[1,2] All types of inflammation, including those arising from infectious, traumatic, hypersensitivity or other immune response, and neoplastic etiologies, can be impacted by glucocorticoids. The inflammatory process is mediated by proinflammatory transcription factors, which in turn produce mediators of inflammation. Glucocorticoids exert anti-inflammatory actions by switching off the genes encoding for cytokines, chemokines, and other mediators of inflammation including adhesion molecules, inflammatory peptides, and mediator receptors. Glucocorticoids decrease movement and activity of white blood cells and fibroblasts, as well as inhibiting expression of cyclooxygenase (COX)-2, cytokines, cellular adhesion factors, complement components, and histamine release (Box 164-1). Many of the anti-inflammatory actions of glucocorticoids also suppress the immune system, especially cell-mediated immunity, and inhibit wound healing. While glucocorticoids can be effective in the treatment of unwanted inflammation, they can suppress the necessary protective responses to infection and healing. Synthetic glucocorticoid drugs are derivatives of endogenously produced cortisol. Modifications of the molecular structure lead to enhanced or diminished glucocorticoid, mineralocorticoid and other properties of synthetic steroid preparations. In addition to potent anti-inflammatory actions, glucocorticoids have widespread actions on metabolic functions (see Box 164-1).

Box 164-1

Selected Actions of Glucocorticoids

Anti-Inflammatory Effects

- Suppression of pro-inflammatory cytokines and chemokines (e.g., interleukin [IL]-1, IL-2, IL-6, IL-8, tumor necrosis factor [TNF]-alpha)
- Decreased expression of endothelial cellular adhesion molecules (e.g., intercellular adhesion molecule [ICAM]-1, E-selectin)
- Diminished inflammatory enzyme activity (e.g., cyclooxygenase [COX]-2, phospholipase [PL] A_2)
- Suppression of T-cell proliferation
- Inhibition of mononuclear phagocytosis and of chemotaxis
- Apoptosis of activated lymphocytes
- Induction of anti-inflammatory cytokines (e.g., IL-10, transforming growth factor [TGF]-beta)
- Stabilization of lysosomal membranes

Hematopoietic Effects

- Increase in circulating neutrophils, monocytes
- Decrease in circulating lymphocytes, eosinophils
- Sequestration of lymphocytes; involution of lymphoid tissue
- Increase in circulating red blood cells, platelets

Metabolic Effects

- Increase in hepatic gluconeogenesis
- Increase in protein catabolism
- Mobilization of free fatty acids
- Antagonism of insulin activity

Endocrine Effects

- Suppression of adrenocorticotropic hormone production
- Decrease in thyroid stimulating hormone and thyroid hormone production

Neurologic and Muscular Effects

- Behavior change
- Muscle weakness and atrophy

Renal Effects

- Increase in glomerular filtration rate
- Inhibition of antidiuretic response in renal tubules
- Proteinuria
- Retention of water, sodium, and chloride
- Excretion of potassium and calcium

Miscellaneous Effects

- Stimulation of appetite
- Increase in bone resorption
- Antioxidant action
- Inhibition of fibroblast proliferation and collagen activity

Synthetic glucocorticoids can be administered systemically (orally or via intramuscular, subcutaneous, or intravenous injection) or locally (e.g., topical skin ointment or aerosol delivery). Synthetic glucocorticoids vary in their glucocorticoid (anti-inflammatory) and mineralocorticoid activity and duration of hypothalamic-pituitary-adrenal axis (HPAA) suppression they exert. Clinicians must be aware of the equivalent dosage range between preparations (Table 164-1). Depot or repositol preparations are not recommended for routine use due to the chronic HPAA suppression, unpredictable blood concentrations, and inability to withdraw therapy associated with such products.

TABLE 164-1

Pharmacologic Properties of Selected Glucocorticoids

	RELATIVE GLUCOCORTICOID (ANTI-INFLAMMATORY ACTION) POTENCY	RELATIVE MINERALOCORTICOID POTENCY	EQUIVALENT DOSAGE (mg)*	DURATION OF ACTION IN HOURS (HUMANS)
Short-Acting				
Cortisol	1	1	20	<12
Hydrocortisone	1	0.8-1	20	<12
Intermediate-Acting				

Prednisone/Prednisolone	3.5-5	0.3-0.8	5-6	12-36
Methylprednisolone	5	0-0.5	4-5	12-36
Triamcinolone	3-5	0	4	24-48
Long-Acting				
Dexamethasone	25-30	0	0.7-0.8	>48
Betamethasone	25-40	0	0.6-0.8	>48

*Typical anti-inflammatory dosage for a 5-10 kg dog (based on glucocorticoid effect).

Effects of glucocorticoids are dosage-dependent, and can vary among species. Dosages should be titrated to maximize therapeutic benefit while minimizing adverse effects. Prednisone, prednisolone, and dexamethasone are commonly used systemic glucocorticoids in dogs. Prednisolone is preferred over prednisone for use in cats, due to its superior pharmacokinetics in this species.[3] Cats might be more resistant to the effects of glucocorticoids and require relatively higher dosages than dogs.[4] However, cats also are more sensitive to serious glucocorticoid adverse effects such as diabetes and congestive heart failure.[5,6] Unfortunately, scientific evidence for glucocorticoid dosing regimens in dogs and cats is lacking. A common initial anti-inflammatory dosage of predniso(lo)ne is 0.5-1 mg/kg/day (dogs) or 1-2 mg/kg/day (cats). In comparison, a physiologic dosage of predniso(lo)ne generally is considered to be 0.1-0.3 mg/kg/day; recommended immunosuppressive dosages range from 2-4 mg/kg/day in dogs and 2-8 mg/kg/day in cats.

Several considerations should be weighed when choosing among the many options for anti-inflammatory glucocorticoid therapy, including desired rapidity of onset, site of activity, and duration of treatment. In cases when rapid onset of activity is needed (e.g., respiratory inflammation leading to airway obstruction), injectable succinate or phosphate salts of glucocorticoids are recommended. More commonly, anti-inflammatory glucocorticoid therapy is needed for days to months. Intermediate-acting products allow for easy dose scheduling. Topical or local application of glucocorticoids can inhibit regional inflammation, while minimizing adverse systemic effects. Common sites of local glucocorticoid therapy include the respiratory and gastrointestinal (GI) tracts, skin, and eyes.

Inhaled glucocorticoids commonly are used for treating inflammatory airway diseases such as chronic bronchitis and allergic airway disease (see ch. 97 and 241). Inhaled fluticasone, budesonide, and beclomethasone are reported to have minimal systemic adverse effects compared to oral glucocorticoids, although HPAA suppression occurs in some veterinary patients.[7-9]

Oral budesonide has a high rate of first-pass hepatic metabolism in humans, enabling its use as a topical treatment for GI disease with fewer adverse effects than systemic glucocorticoids.[10] Similarly, oral budesonide is efficacious in the treatment of inflammatory GI diseases in dogs.[11-13] However, budesonide suppresses the HPAA in dogs and can cause adverse effects at a similar rate as prednisone in dogs with inflammatory bowel disease.[12,13]

Topical glucocorticoids can be used for treatment of atopic dermatitis and other inflammatory skin conditions, adjunct to other efforts aimed at controlling or eliminating the predisposing causes (e.g., ectoparasite control, hyposensitization for allergy-mediated conditions).[14] Long-term use of topical glucocorticoids can lead to significant systemic absorption, especially when dermal barriers are not intact.

Topical ocular glucocorticoids (e.g., 1% prednisolone acetate or 0.1% dexamethasone solutions) achieve good intraocular penetration and provide potent anti-inflammatory action to treat uveitis and other ocular inflammatory conditions, in the absence of corneal ulceration.[15] Frequency of therapy can be titrated to effect (every 1-8 hours).

Adverse Effects and Contraindications for the Use of Glucocorticoids

Adverse effects of glucocorticoid therapy result frequently from prolonged use of high dosages. Exogenous glucocorticoids can suppress the HPAA and cause iatrogenic hyperadrenocorticism. Clinical signs are similar to pituitary and adrenal-dependent hyperadrenocorticism, including polyuria, polydipsia, pendulous abdomen, and dermatologic changes (see ch. 306 and 307).[16,17] Secondary infections, especially urinary tract infections and pyoderma, can result from prolonged glucocorticoid therapy.[16,18] Other adverse effects include muscle wasting, weakness, ligament rupture, obesity, hypercoagulability, insulin resistance and diabetes.[5,19] Glucocorticoid administration can cause a wide range of GI effects, from subclinical gastric mucosal injury to

GI ulceration and perforation at high dosages.[20,21]

Glucocorticoids cause insulin resistance and elevate blood glucose levels; therefore, they should be used sparingly if at all in patients with diabetes mellitus. Due to the immunosuppressive actions of glucocorticoids, their use is relatively contraindicated during infection. However, treatment of some infectious diseases benefits from adjunct glucocorticoid therapy to reduce inflammation or modulate the immune response, when combined with appropriate antimicrobials (e.g., *Malassezia* otitis or *Mycoplasma haemofelis*) (see ch. 360). Glucocorticoids should not be used concurrently with NSAIA therapy due to the increased risk of GI ulceration. Because glucocorticoids may affect cardiac muscle function and cause water retention, cautious use is recommended in patients with heart disease as congestive heart failure is a potential risk, especially in cats.[6] Topical ocular glucocorticoids should not be used in patients with corneal ulceration or infection, as ulcers can worsen and stromal melting can occur.

Nonsteroidal Anti-Inflammatory Analgesics

Nonsteroidal anti-inflammatory analgesics (NSAIAs) are a group of pharmaceutical agents that possess both analgesic and anti-inflammatory properties. The NSAIAs are frequently used in human and veterinary medicine to relieve mild, moderate, or severe pain. The efficacy of many NSAIAs can be superior to that of butorphanol or buprenorphine, and superior or equal to the pure mu agonist opioids (oxymorphone, morphine, hydromorphone, meperidine) in managing soft tissue and orthopedic postoperative pain.[22-36] When used in combination with opioids, NSAIAs appear to confer synergism and can require reduced dosing of the opioid in mild to moderate, but not in severe, pain states. The NSAIAs concentrate in inflamed joints and tissues, likely contributing to duration of effect which varies between 12 and 24 hours.[37] The duration and efficacy of NSAIAs makes them ideal for treating acute[22-36] and chronic pain[38-49] in veterinary patients; however, due to their potential for harmful adverse effects, patient and NSAIA selection must be considered prior to administration (see ch. 126 and 356). Dosage calculations for any NSAIA must be based on the patient's ideal body weight and not on actual weight in overweight/obese patients (Table 164-2). Many veterinary publications review the clinical use of NSAIAs in great depth with extensive citations of original studies,[50-60] including a critical review of published studies.[50]

TABLE 164-2

Indications and Dosing Regimen for NSAIA Administration Based on Ideal Body Weight

DRUG	INDICATION	SPECIES, DOSAGE, ROUTE	FREQUENCY
Ketoprofen	Surgical pain	**Dogs** ≤ 2 mg/kg, IV, SC, IM, PO **Cats** ≤ 2 mg/kg, SC **Dogs and cats** ≤ 1 mg/kg	Once postoperative Once postoperative Repeat q 24 h
	Chronic pain	**Dogs and cats** ≤ 2 mg/kg, PO ≤ 1 mg/kg	Once Repeat q 24 h
Meloxicam	Surgical pain	**Dogs** ≤ 0.2 mg/kg IV, SC ≤ 0.1 mg/kg IV, SC, PO	Once Repeat q 24 h
	Chronic pain	**Dogs** ≤ 0.2 mg/kg PO ≤ 0.1 mg/kg PO	Once Repeat q 24 h
	Surgical pain	**Cats** ≤ 0.2 mg/kg SC, PO ≤ 0.05 mg/kg SC, PO, lean weight	Once Daily × 2-3 days
	Chronic pain	**Cats** ≤ 0.05 mg/kg SC, PO, lean weight. Titrate reduction to comfort ≈0.025 mg/kg ASAP.	Once daily Daily or 3-5 × weekly
Carprofen	Surgical pain	**Dogs** ≤ 4 mg/kg, IV, SC ≤ 2.2 mg/kg PO	Once upon induction Repeat q 12-24 h PRN
		Cats ≤ 2 mg/kg SC, lean weight	Once upon induction
	Chronic pain	**Dogs** ≤ 2.2 mg/kg PO	q 12-24 h
Etodolac	Chronic pain	**Dogs** ≤ 10-15 mg/kg PO	Once daily

Deracoxib	Perioperative pain Chronic pain	**Dogs** 3 mg/kg PO **Dogs** 1-2 mg/kg PO	Once daily × ≤7 days Once daily
Firocoxib	Chronic pain	**Dogs** 5 mg/kg PO	Once daily
Tepoxalin*	Chronic pain	**Dogs** 10 mg/kg PO	Once daily
Tolfenamic acid	Acute and chronic pain	**Cats and dogs** ≤ 4 mg/kg SC, PO	Once daily for 3 days. 4 days off. Repeat the cycle.
Flunixin meglumine	Pyrexia	**Dogs and cats** 0.25 mg/kg SC	Once
	Ophthalmic procedures	**Dogs and cats** 0.25-1 mg/kg SC	q 12-24 h PRN for 1 or 2 treatments
Ketorolac	Surgical pain	**Dogs** 0.3-0.5 mg/kg IV, IM	q 8-12 h for 1-2 treatments
		Cats 0.25 mg/kg IM	Once only
	Panosteitis	**Dogs** 10 mg/**DOG** ≥ 30 kg, PO 5 mg/**DOG** > 20 kg < 30 kg, PO	Once daily for 2-3 days
Piroxicam	Inflammation of the lower urinary tract	**Dogs** 0.3 mg/kg PO	q 24 h for 2 treatments, then q 48 h
Acetaminophen	Acute or chronic pain	**Dogs only** 15 mg/kg PO	q 8 h
Aspirin	Acute or chronic pain	**Dogs** 10 mg/kg PO	q 12 h

*Not available in North America.

ASAP, As soon as possible; *PRN*, as needed.

The indications proposed here assume there are no contraindications to their use. A more in-depth discussion on general considerations, indications, and adverse effects is available in the previous edition of this textbook.[99]

Pharmacology and Clinical Indications for Nsaias

Cyclooxygenase enzymes oxidize arachidonic acid to various eicosanoids and related compounds, or prostanoids[61] (Figure 164-1). Nonsteroidal anti-inflammatory analgesics are, with varying differences, inhibitors of COX-1, COX-2, both, or COX-3, resulting in reduced prostaglandin (PG) synthesis. In addition to the peripheral action, a significant part of the NSAIAs' antinociceptive effect is exerted at the spinal cord and supraspinal levels where both COX-1 and COX-2 isoenzymes are nociceptive transmitters independent of inflammation.[62-68] This action, in addition to pain relief, could account for the observed overall well-being and improved appetite of patients receiving injectable NSAIAs for relief of acute pain (personal observations). COX-1 can be induced in inflammatory states and is increased approximately twofold or threefold in tissue injury, and can also generate PGs at sites of inflammation (e.g., joints). It is present within the central nervous system, and is active in transmission of pain, especially visceral nociception. COX-1 also is a constitutive enzyme (i.e., functions in tissues continuously, noninducible) that ultimately converts arachidonic acid into the prostanoids (thromboxanes, prostacyclin, and prostaglandins [PGE_2, PGF_2, and PGD_2]) involved in many homeostatic functions.[67]

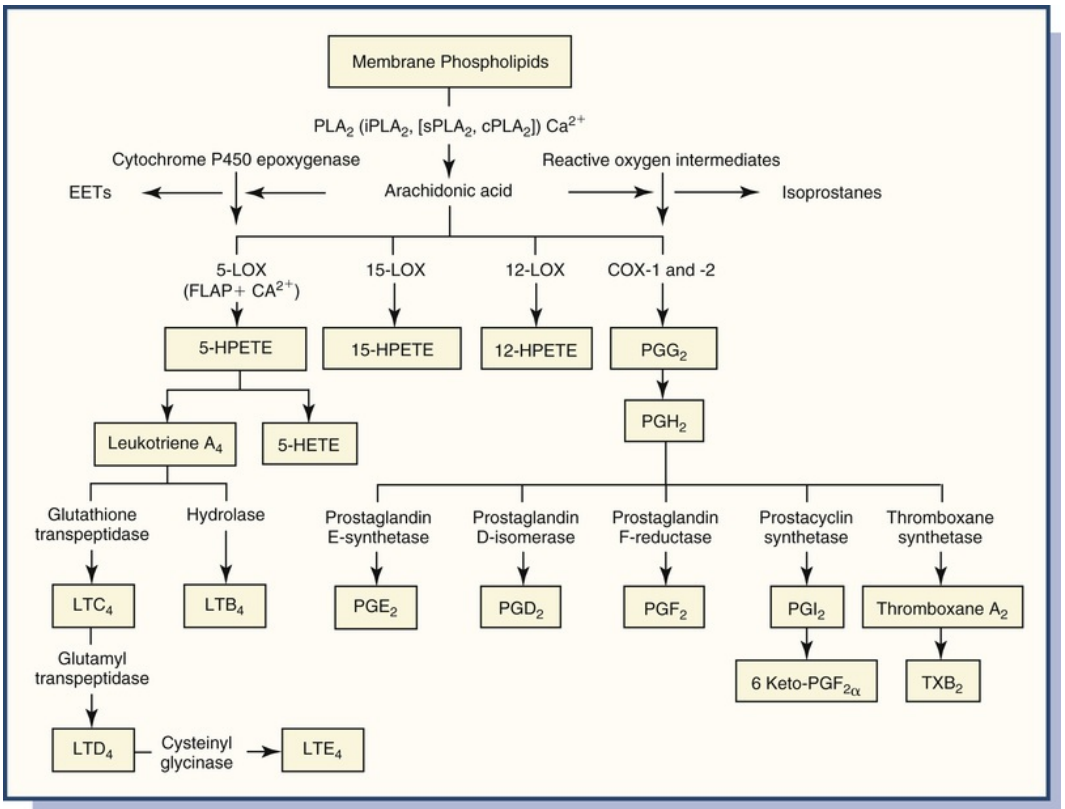

FIGURE 164-1 The arachidonic acid cascade. *COX,* Cyclooxygenase; *EETs,* epoxy-eicosatrienoic acids; *FLAP,* 5-lipoxygenase-activating protein; *HETE,* hydroxyeicosatetraenoic acid; *HPETE,* hydroperoxyeicosatetraenoic acid; *LOX,* lipoxygenase; *LT,* leukotriene; *PG,* prostaglandin; *PLA_2,* phospholipase A_2; *TXB_2,* thromboxane B_2.

Cyclooxygenase-2 also is inducible and synthesized by macrophages and inflammatory cells, potentially increasing by twentyfold over baseline, especially in injured tissue and inflammatory conditions such as osteoarthritis.[63] The increased COX levels increase prostanoid production, where these compounds serve as mediators of inflammation and amplifiers of nociceptive input and transmission in both the peripheral and central nervous systems.[63] By this mechanism, COX-2 is responsible for a substantial amount of pain and hyperalgesia experienced after tissue injury. As COX-2 appears to play an important role in nociceptive transmission, medications that prevent COX-2 activity and spare the constitutive COX-1 functions should be effective, with potentially fewer adverse effects, in the management of pain. Based on these findings, emphasis is placed on COX-1 versus COX-2 activity of NSAIAs, with respect to safety and efficacy; however, it is important to note that COX-2 also has important constitutive functions,[47,48] and the notion of a "good versus bad COX" is misleading. The discovery of COX-3, characterized as being generated from COX-1, is expressed in the brain and brain microvasculature in dogs and has been proposed to be a target of the analgesic/antipyretics acetaminophen and metamizole (Dipyrone).[67,70,71] Currently, the presence of COX-3 appears to be restricted to dogs. Both acetaminophen and metamizole have minimal effect on COX-1 and COX-2[67] and frequently are used for reducing fever in animals with few GI or renal adverse effects. Acetaminophen and metamizole are toxic to cats. The COX-3 isoenzyme is more sensitive to NSAIAs that are analgesic and antipyretic but have low anti-inflammatory activity. As the COX-3 isoenzyme genetic profile is derived from the COX-1 gene, this suggests that the COX-1 gene plays an integral role in pain and/or fever depending on the physiologic context.[65]

Prostaglandins, especially those derived from COX-1, are ubiquitous throughout the body and they regulate many functions such as vascular and bronchial smooth muscle tone and fluid balance, to name a few. Prostaglandins exert a negative feedback effect on cyclic adenosine monophosphate (cAMP) with potential perturbations in many physiologic functions. As an example, renal water reabsorption depends on the action of antidiuretic hormone (ADH), which is mediated by cAMP; inhibition of prostaglandin synthesis could lead to increased levels of cAMP with a potential for enhanced ADH activity. Urine volume can be decreased through this mechanism but without renal injury.[67,72,73] In the inhibition of COX-2 activity when managing

pain, the COX-2 enzyme has some important constitutive functions: there is a protective role for COX-2 in maintenance of GI integrity and ulcer healing.[74] In addition, there is constitutive activity associated with nerve, brain, ovarian, and uterine function and bone metabolism.[72,75] COX-2 has constitutive functions in the kidney, which differ from those of COX-1. COX-2 is important in nephron maturation.[73,76] The canine kidney is not fully mature until 3 weeks after birth, nor is it optimally functional until 6 weeks after birth[76]; continual administration of an NSAIA during this time, or to the bitch prior to birth or during lactation, can cause a permanent nephropathy. Most important is the dual role of the PGs as inflammatory and anti-inflammatory mediators, where COX-2–derived PGs also function in resolution of inflammation.[68,71,77]

On the other hand, COX metabolites have been implicated in functional and structural alterations in glomerular and tubulointerstitial inflammatory disease.[73] Because COX-2 expression also is increased in glomerulonephritides such as lupus nephritis, it is possible that COX-2 inhibitors could alter the natural history of glomerular inflammatory lesions.[73] COX-2–derived metabolite production is regulated and localized to the structures in the kidney that play an essential role in renal blood flow associated with renin activity and fluid-electrolyte homeostasis.[52,73,78] COX-2 is glucocorticoid-sensitive, in that it is reduced following administration of glucocorticoids, which could partially explain the anti-inflammatory and analgesic effects of this class of medications. Of interest, in addition to the COX-2 role in inflammation, aberrantly upregulated COX-2 expression is increasingly implicated in the pathogenesis of Alzheimer's disease and possibly other neurologic conditions and a number of epithelial cell carcinomas, including those affecting the colon, esophagus, breast, and skin.[79,80] The COX-2 inhibitors are being researched as potential anticarcinogenic agents. A good review of the "Coxibs" is available; the background and pharmacology of the Coxibs are reviewed elsewhere.[68,79,81]

Most NSAIAs that inhibit COX have been shown to result in diversion of arachidonate to the 5-lipoxygenase (5-LOX) pathway (see Figure 164-1). This results in an excessive production of leukotrienes (LT), which have been implicated in many pathologic states, including hyperalgesia and the creation of NSAIA-induced ulcers.[67,82,83] Leukotrienes are the products of the 5-LOX cascade, where arachidonic acid is converted by a two-step mechanism into the conjugated triene epoxide leukotriene (LTA_4), the most biologically important intermediate LT.[68,83-85] LTA_4 subsequently is metabolized to LTB_4 and LTC_4. An LTD_4 also is recognized. Cells known to express 5-LOX include circulating neutrophils, monocytes, basophils, eosinophils, tissue macrophages, and mast cells. These cells release LTA_4 and participate in transcellular biosynthesis of either LTC_4 or LTB_4.[86] As with the prostanoids, it is impossible to list all the activities of the LTs as these are also dependent on organ involvement. An in-depth discussion of dual inhibitors is available elsewhere.[60,68,87-89]

Associated with the use of NSAIAs is the risk of perturbation of the constitutive functions of COX-1 and COX-2 potentially resulting in organ dysfunction. Depending on the NSAIA selected, primary plug formation of platelets, modulation of vascular tone of all organs (the kidney and gastric mucosa being of specific importance), cytoprotective functions on the gastric mucosa, healing of intestinal mucosa, smooth muscle contraction, and regulation of body temperature all will be affected.[67,72] However, in this regard not all NSAIAs are created equal, as the COX-1, COX-2, and COX-3 enzymes variably control these functions. Some NSAIAs inhibit both COX-1 and COX-2 (aspirin, phenylbutazone, ketoprofen [Anafen], ketorolac [Toradol], flunixin meglumine [Banamine, Schering-Plough]); while others preferentially can inhibit COX-2 and be weak inhibitors of COX-1 (meloxicam [Metacam], carprofen [Rimadyl], etodolac [Etogesic], vedaprofen [Quadrisol-5], tolfenamic acid [Tolfedine]). Others selectively inhibit COX-2 (deracoxib [Deramaxx], firocoxib [Previcox], robenacoxib [Onsior],[90-92] cimicoxib [Cimalgex]),[93] while still others, such as acetaminophen and metamizole, can weakly inhibit both COX-1 and COX-2 but have greater inhibition of COX-3. Metamizole has been used for postoperative analgesia following ovariohysterectomy in dogs.[94]

Tepoxalin (Zubrin) is a dual COX/lipoxygenase (LOX) inhibitor that is reported to reduce concentrations of COX-1, COX-2, and 5-LOX to some degree in dogs.[95] Licofelone, a new true dual inhibitor being evaluated in people and dogs, could have greater GI safety than other NSAIAs.[96]

Adverse Effects and Contraindications for the Use of Nsaias

As a group, NSAIAs are not reversible; it is, therefore, imperative that the general health of the patient be considered prior to prescribing NSAIAs. Where the large animal formulations of an NSAIA exist, it is not

advised to dilute or estimate a dose for a cat or dog as a very small volume can easily result in serious overdose. Doses should be calculated based on the ideal weight of a patient (see Table 164-2). Anecdotal incidents of single, accidental, large overdoses have been observed with no long-term adverse effects; however, short-term, gastric protection and intravenous (IV) fluids to support renal function are advised with high overdoses. Relative overdose resulting in acute kidney injury also has been observed in obese patients when the dosage was based on true weight rather than ideal weight. Cats and dogs are more susceptible than are people to the adverse effects of NSAIA administration; therefore, the reported safety of any NSAIA approved for the human patient should not be assumed to be so in the veterinary patient and the drug should not be prescribed. Cats are even more of a concern than dogs as the potential for toxicosis with certain NSAIAs is greater than for other species due to their limited ability to glucuronidate NSAIAs, resulting in a prolonged duration of effect.[59] There are many potential interactions between NSAIAs and other medications, many of which are contraindicated during NSAIA use.[97]

Based on the many important physiologic functions the prostanoids perform, one can appreciate the potential perturbation of normal homeostatic functions with administration of NSAIAs. The recommended dosages for the various NSAIAs rarely compromise these functions; however, should a patient be in a prostaglandin-dependent state, administration of NSAIAs frequently results in adverse effects (see ch. 126 and 356). However, even in normal states, the NSAIAs may result in GI, renal, or hepatic abnormalities, or rarely a coagulopathy (predominantly COX-1 NSAIAs) in the genetically predisposed individual. While the incidence of GI signs could be reduced with COX-2–specific targeted NSAIAs, adverse effects can still occur. Cyclooxygenase-2 expression has been identified in the duodenum of dogs, which increased significantly following 3 days of aspirin (10 mg/kg q 12 h) when compared with effects of carprofen and deracoxib at recommended dosages.[98] Upregulation of COX-2 has been identified in the duodenum in response to mucosal erosion/injury, performing an integral role in the daily healing process.[98] Nonsteroidal anti-inflammatory analgesics should not be administered to patients with acute kidney injury or uremia, hepatic insufficiency, dehydration, hypotension, conditions associated with low "effective circulating volume" (e.g., congestive heart failure, ascites), bleeding disorders (e.g., factor deficiencies, thrombocytopenia, von Willebrand disease), concurrent use of any other NSAIAs or glucocorticoids, evidence of gastric erosion (vomiting with or without the presence of "coffee ground" material, melena), spinal injury upon presentation (including herniated intervertebral disc, especially since many of these patients receive glucocorticoids with medical or surgical management). NSAIAs should never be administered to patients in shock, trauma cases upon presentation, or where hemorrhage is evident (e.g., epistaxis, hemangiosarcoma, head trauma). Patients with severe or poorly controlled asthma, or other moderate to severe pulmonary disease, can deteriorate with COX-1–inhibiting NSAIAs, especially aspirin. NSAIAs may have adverse effects on the reproductive tract and fetus, as they can block prostaglandin activity, resulting in cessation of labor, premature closure of the ductus arteriosus in the fetus, and disruption of fetal circulation.[73] As COX-2 induction is necessary for ovulation and subsequent implantation of the embryo,[73] NSAIAs should be avoided in breeding females during this stage of the reproductive cycle. For specific details on reported adverse effects associated with NSAIA administration in dogs and cats, the reader is referred to published reviews on this topic.[29-39] Due diligence on behalf of the veterinarian will reduce the potential for harm.

FDA Newly-Approved Drug

The EP4 receptor, one of the four PGE_2 receptors, has a primary function of mediating the PGE_2-elicited sensitization of sensory neurons and PGE_2-elicited inflammation resulting in inflammatory pain. Piprants are prostaglandin receptor antagonists (PRA), a new class of analgesic agents. The EP4 receptor has been associated with osteoarthritis (OA) in rodents, dogs and cats.[100] Grapiprant (Galliprant, Aratana Therapeutics), an EP4 PGE_2 receptor antagonist, has recently been approved for OA in dogs. In a field study, grapiprant 2 mg/kg q 24 h improved pain scores when compared to placebo (48.1% vs. 31.3%). Based on the specific receptor target, grapiprant was well tolerated with occasional vomiting (17% of dogs) throughout the 28 day study.[101] However, long-term studies are required to further assess safety. In the interim, appropriate patient selection and monitoring, as with other NSAIDs, is advised. Studies in cats are under way.

CHAPTER 165

Immunosuppressive Therapy

Todd M. Archer

Immune-mediated diseases are diverse and they range from those that are very organ-specific to those that are systemic. The central therapy for these diseases includes halting ongoing damage by the immune system and can include nonspecific immunosuppression as well as utilization of medications to target specific parts of the immune system; this includes specific phases of the cell cycle and specific enzymes needed for sustained activity of the immune system. In dogs, glucocorticoids commonly are used in addition to another immunosuppressive agent, as dogs are very susceptible to the side-effects of glucocorticoids and can respond favorably to other immunosuppressive medications. In cats, initial immunosuppressive therapy often only includes glucocorticoids, as cats are not as susceptible to their clinically significant side-effects. More options for immunosuppressive medications are now available for small animal patients than ever before. Unfortunately, large controlled prospective clinical studies evaluating these drugs for specific canine and feline immune-mediated diseases are lacking; therefore, making specific recommendations for certain diseases can be challenging. The subject of concurrent infection in patients requiring immunosuppression is discussed in ch. 360.

Glucocorticoids

Glucocorticoids remain as a mainstay of immunosuppression in small animal medicine. Their physiological effects come from interactions with glucocorticoid receptors in the cytosol of the cells of the body. Glucocorticoids enter cells by passive diffusion and interact with these receptors, creating a conformational change and subsequent release of an activated complex that translocates to the nucleus. In the nucleus, this activated complex recognizes and associates with short DNA sequences called glucocorticoid-responsive elements.[1,2] This interaction then modulates gene transcription, with the formation of targeted proteins either being up- or downregulated. Glucocorticoids also can interact with plasma membranes to create cellular responses.

The mechanism of action of glucocorticoids is multifaceted, and includes effects on both the humoral and cell-mediated arms of immunity. Some of these actions include inhibition of production and release of cytokines (interleukin [IL]-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-10, tumor necrosis factor alpha [TNF-alpha], gamma interferon [IFN-gamma]), chemokines, adhesion molecules, and other mediators of inflammation; impaired macrophage activity through influence on both expression and function of macrophage Fc receptors; decreased macrophage antigen processing and presentation to T helper cells; impaired complement function; decreased antibody binding; inhibition of antibody production; reduction in the numbers of lymphocytes; and decreased migration of inflammatory cells from the bloodstream into tissues.[1,3,4]

Many formulations of glucocorticoids are available. The most commonly used include prednisone and prednisolone. Prednisone is a prodrug that is metabolized to prednisolone. In cats, higher plasma concentrations are achieved with orally administered prednisolone as compared to orally administered prednisone; thus, prednisolone is preferred over prednisone in this species.[5-7] Dexamethasone is an oral and injectable glucocorticoid that is approximately 7 times as potent as prednisolone and prednisone. Additional information on various glucocorticoid types and formulations, and dosage information for specific diseases, can be found in ch. 164 and disease-specific chapters, respectively.

Cyclosporine

Cyclosporine is a potent immunosuppressive agent increasingly being used for the treatment of inflammatory and immune-mediated diseases in dogs and cats. Cyclosporine, a molecule derived from the soil fungus *Tolypocladium inflatum*, was originally developed for renal transplant use in human medicine. It is now a

cornerstone medication in human transplantation medicine. Cyclosporine's primary mechanism of action is the inhibition of calcineurin and the subsequent inhibition of T-lymphocyte function. Once cyclosporine is in the cytosol of cells, it complexes with cyclophilin. This complex has a high affinity for calcineurin, causing an inhibition of calcium-stimulated phosphatase in calcineurin. This inhibited dephosphorylation step does not allow for activation of NFAT (nuclear factor of activated T-cells) which is needed for the nuclear transcription of genes coding for several important cytokines. Ultimately, cytokine production, most notably IL-2, is inhibited. IL-2 plays a key role in the activation and proliferation of T-lymphocytes, and thus its inhibition leads to reduced T-cell function and a blunting of the immune response.[8]

Cyclosporine is a lipophilic molecule that must be solubilized before administration. Two formulations exist for cyclosporine: a vegetable-oil preparation that mainly is of historic interest, and an ultramicronized formulation. The vegetable-oil formulation (Sandimmune) was associated with significant intraindividual and interindividual variations in blood drug concentrations and thus is not recommended for use in clinical veterinary patients.[8] The newer ultramicronized formulation forms a microemulsion upon contact with aqueous fluids, resulting in an increased bioavailability and more predictable absorption. The current United States Food and Drug Administration (FDA)-approved oral veterinary product for dogs and cats is an ultramicronized formulation, Atopica.

Cyclosporine's pharmacokinetic behavior can be complex, and can depend on a number of variables. After oral administration, cyclosporine is absorbed in the small intestine. Food has been shown to decrease the oral absorption of cyclosporine in dogs but not cats; therefore, recommendations exist to administer cyclosporine 2 hours before or after feeding in dogs.[8] Peak cyclosporine concentrations generally occur 2 hours after oral administration, with blood levels then rapidly decreasing over the remainder of the dosing interval. Metabolism mainly occurs in the liver by the cytochrome P450 or CYP enzyme pathway, creating a number of cyclosporine metabolites. A number of medications can influence this metabolism, and thus can increase or decrease cyclosporine blood concentrations. In dogs, the most frequently used medication used concurrently with cyclosporine therapy to purposefully decrease the cyclosporine daily requirements is ketoconazole. Studies of the treatment of perianal fistulas in large breed dogs have shown that significantly decreased daily cyclosporine dosages maintain blood cyclosporine concentrations when ketoconazole is coadministered[9,10]; this strategy for lowering the daily cyclosporine requirements is only beneficial if ketoconazole is appropriately priced. Cyclosporine metabolites mainly are excreted though the biliary system.

To monitor the effectiveness of therapy when using cyclosporine, two options exist: therapeutic drug monitoring and pharmacodynamic evaluation. Evaluation of blood cyclosporine concentrations can be an important tool to help facilitate successful therapeutic management. The intent is to establish and maintain a patient's therapeutic range in order to help avoid toxicosis or therapeutic failure. Whole blood is the preferred sample for measuring cyclosporine blood concentrations, with sampling recommendations including measuring both a peak (2 hours after dosing) and trough (just prior to drug administration) sample.[8] Reference intervals for cyclosporine blood concentrations are specific to each laboratory performing the assay, and decisions on monitoring and on implementing dosage changes should be made in consultation with the laboratory performing the test.

Pharmacodynamic monitoring utilizes assays that measure one or more biomarkers. This approach offers a more individualized approach when cyclosporine blood concentrations do not correlate well with clinical response. In dogs, this has been explored experimentally, with a validated PCR assay emerging.[11] Through this type of testing, individual responses to cytokine suppression were shown to be different in dogs receiving the same dosage of cyclosporine and in dogs having the same cyclosporine blood concentrations.[12] This PCR pharmacodynamic assay, which measures IL-2 and IFN-gamma, is now available to practitioners.

Adverse effects can occur in patients receiving cyclosporine. In dogs and cats, the most common side-effects are gastrointestinal (e.g., vomiting, diarrhea, anorexia).[8] Other side-effects in dogs include lethargy, gingival hyperplasia, hirsutism, coat shedding, cutaneous papillomatosis, and footpad hyperkeratosis.[8] Adverse effects seen in cats can include lethargy, behavioral disorders (hiding, hyperactivity, aggression), hypersalivation, gingival hyperplasia, ocular discharge, and sneezing/rhinitis.[a] In both cats and dogs, long-term administration can result in secondary infections. Hepatotoxicosis and nephrotoxicosis are rare potential complications in dogs and cats; they have not been reported reliably in the veterinary literature.[8,13] Cyclosporine administration has been associated with the emergence of neoplasia, particularly lymphoma in dogs and cats.[8,13] Cyclosporine administration, unlike other immunosuppressive medications, has not been associated with myelosuppression and neutropenia.[8]

Cyclosporine's clinical use has expanded well past transplantation medicine. The veterinary formulation

(Atopica) is approved for the treatment of atopic dermatitis in dogs and allergic dermatitis in cats. With the ultramicronized formulation of cyclosporine as treatment for dogs with non-life-threatening diseases such as skin diseases or mild inflammatory bowel disease, cyclosporine therapy often is started at a lower dosage (e.g., 5 mg/kg PO q 24 h or q 12 h) and the dosage titrated upward as needed, based on clinical efficacy. Cyclosporine blood concentrations often are not measured in these cases because of a lack of correlation of blood concentrations and clinical efficacy. Generally, response to therapy dictates the adequacy of dosage. For the treatment of severe immune-mediated diseases in dogs, the ultramicronized formulation of cyclosporine is administered at a higher dosage. The initial starting dosage often is 5-10 mg/kg PO q 12 h, with therapeutic drug monitoring and/or pharmacodynamic testing strongly recommended to adjust the dosage and ensure adequate immunosuppression with fewest side-effects. To obtain immunosuppression in cats, the ultramicronized formulation of cyclosporine often is initiated at a dosage of 3-5 mg/kg PO q 12 h.[13,14]

Azathioprine

Azathioprine is a purine analogue affecting both the humoral and cell-mediated arms of the immune system, suppressing lymphocyte activation and proliferation as well as macrophage function. The main target is cell-mediated immunity, specifically lymphocytes, because of their lack of a salvage pathway for synthesis of purines.[4,15] Azathioprine's active metabolite, 6-mercaptopurine, resembles adenine and guanine, and is alternately inserted during the S-phase of cell division.[16] This interference with purine synthesis causes ribonucleic acid miscoding, leading to disruption of RNA and DNA synthesis and mitosis.[4] Chromosome breaks can also occur secondary to incorporation into nucleic acids.

The metabolism of azathioprine to 6-mercaptopurine occurs in the liver.[16] Thiopurine methyltransferase (TPMT), xanthine oxidase, and hypoxanthine-guanine phosphoribosyltransferase are the enzymes responsible for the further metabolism of 6-mercaptopurine, resulting in inactive metabolites or active intracellular metabolites (6-thioguanine nucleotides).[4,16,17] Variations in the activity of TPMT in human patients affect clinical outcome: low TPMT activity is associated with a higher incidence of toxic effects, and high TPMT activity is associated with a decrease in effect of azathioprine.[16,17] Breed variations have been documented in dogs, with Giant Schnauzers having lower TPMT activity and Alaskan Malamutes having higher activity compared to other breeds.[17] Caution and a reduced dosage should be considered in canine patients concurrently receiving allopurinol, a xanthine oxidase inhibitor, concurrently with azathioprine, as this could allow increased intracellular concentrations of the active metabolites to occur.[14]

In dogs, azathioprine initially is administered at a dosage of 2 mg/kg PO q 24 h, often in combination with immunosuppressive dosages of glucocorticoids.[2,13,14] This drug is *not* recommended in cats because they are very prone to the myelosuppressive effects of azathioprine due to their low species-specific concentrations of TPMT.[4,15,18] Azathioprine has been used in dogs for treatment of immune-mediated thrombocytopenia (see ch. 201), immune-mediated hemolytic anemia (see ch. 198), autoimmune skin diseases (see ch. 204), chronic hepatitis (see ch. 282), inflammatory bowel disease (see ch. 276), immune-mediated glomerular disease (see ch. 325), systemic lupus erythematosus (see ch. 205), immune-mediated polyarthritis (see ch. 203), perianal fistula (see ch. 278), myasthenia gravis (see ch. 269), meningoencephalomyelitis of undetermined etiology (see ch. 261), as well as part of canine transplantation protocols (see ch. 323).[3,13,15,17,19] Retrospective studies support its use in the treatment of these diseases but prospective controlled studies are lacking.

Adverse effects in dogs associated with the use of azathioprine include gastrointestinal complications (anorexia, vomiting, diarrhea), myelosuppression (leukopenia, anemia, and/or thrombocytopenia), hepatotoxicosis, poor hair growth, secondary infections, and acute pancreatitis.[4,14,15,17,20] Azathioprine-induced myelosuppression and hepatotoxicosis are idiosyncratic, non-dose–dependent drug reactions that typically are reversible once the drug is withdrawn. Regular monitoring of blood counts and serum biochemical profiles should occur during azathioprine therapy to identify such drug reactions early and allow for drug discontinuation should they occur.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) is the prodrug of mycophenolic acid (MPA), which is the active immunosuppressive molecule.[21,22] MPA induces its immunosuppressive effects by inhibiting inosine monophosphate dehydrogenase (IMPDH), an enzyme necessary in the *de novo* cellular pathway for purine synthesis. This action inhibits both B- and T-cell proliferation and clonal expansion, suppresses B-cell

antibody formation, and induces apoptosis of activated T-cells, thus affecting both humoral and cell-mediated responses.[21-25] MPA also downregulates expression of adhesion molecules, which decreases the recruitment of lymphocytes and monocytes out of circulation and into sites of chronic inflammation.[22-24] MPA inhibits IMPDH in a selective, reversible, and non-competitive manner. Two isoforms of IMPDH exist, with type 1 existing in most cells and type 2 existing in activated lymphocytes.[25-27] MMF has a 5-fold greater affinity for the type 2 IMPDH isoform.[5,21,23,25-27] MPA specifically inhibits lymphocyte proliferation during the S phase of the cell cycle, due to depletion of guanosine and deoxyguanosine nucleotides.[1] Lymphocytes also are preferentially targeted because they are dependent on the *de novo* pathway for purine synthesis and cannot use the salvage pathway for purine synthesis as other cell lines can.[27]

After oral administration, MMF is rapidly absorbed and completely de-esterfied into MPA.[22,27] The peak MPA blood concentration (Cmax) occurs 1-2 hours after oral administration of MMF.[23] MPA then undergoes hepatic glucuronidation to form mycophenolic acid glucuronide (MPAG), an inactive metabolite.[22] Most of MPA and MPAG circulate systemically, bound to albumin. Part of the MPAG is excreted into the biliary system, with presumed deglucuronidation of MPAG to MPA by the gut flora. Subsequent enterohepatic recirculation and absorption also occurs, explaining the secondary plasma MPA peak seen in dogs 4-12 hours after oral administration of MMF.[22,28] Over 90% of an orally administered dose of MMF is excreted in the urine, mostly as MPAG.[22,23] A small percentage of MPAG is excreted in the feces.[22,29]

Prospective, randomized, double-blinded clinical trials in human transplant recipients treated with a combination of MMF, cyclosporine, and glucocorticoids have demonstrated reductions in rejection episodes and improvement in patient and graft survival.[23] Initially, MMF was used in dogs as part of a protocol to control renal transplant rejection[30]; now, it also is being used for the treatment of various immune-mediated and inflammatory diseases in dogs and cats.[24-27,31-33]

Currently, no MMF products are approved for veterinary use. However, MMF is available as oral and parenteral human products. MMF recently has become much more affordable in the United States. While an early pharmacodynamic study in dogs suggested oral administration every 8 hours, this dosing strategy has not entered common clinical usage.[34] Dosage recommendations for dogs range from 10-40 mg/kg/day PO either given once daily or divided and given twice or three times a day, with many protocols recommending 10 mg/kg PO q 12 h.[3,14,24,31] In cats, dosage recommendations include 10 mg/kg PO q 12 h.[14,25] MMF is thought to have a rapid onset of action, occurring within 2 to 4 hours after dosing.[2,5] In dogs, it often is used as part of a combination protocol, although in one case series of five dogs with immune-mediated thrombocytopenia, MMF monotherapy at a median dosage of 8.5 mg/kg PO q 12 h was associated with complete remission of disease.[31]

Adverse effects of MMF in people include gastrointestinal upset, susceptibility to infection, increased risk of lymphoma, allergic reactions, teratogenic effects, headache, hypertension, peripheral edema, cough, confusion, tremor, and bone marrow suppression (leukopenia, thrombocytopenia, and anemia).[14,23] Based on limited veterinary studies, side-effects in dogs primarily include gastrointestinal complications (inappetence, vomiting, diarrhea, inflammation/ulceration), weight loss, lethargy, papillomatosis, and allergic reactions.[14,32] In a study of 5 dogs with immune-mediated hemolytic anemia receiving MMF 10-15 mg/kg PO q 8 h, the authors concluded that the level of gastrointestinal toxicosis they observed could not justify its use with this dosing regimen, despite achieving remission in four of five dogs.[32] Myelosuppression and hepatotoxicosis have not been documented, although monitoring of complete blood counts should be considered in dogs receiving MMF until more is known about its use in this species. As with any immunosuppressive medication, monitoring for secondary infections should take place.

Leflunomide

In veterinary medicine, leflunomide initially was investigated in canine transplant medicine.[35,36] Gregory and colleagues described its use in a variety of immune-mediated diseases and inflammatory diseases in dogs, with promising initial results.[37] Until recently, it could be cost prohibitive, but now the reasonably priced generic formulation is leading to increasingly frequent use in small animal medicine.

Leflunomide is a prodrug that is metabolized by the intestinal mucosa and liver to its active metabolite, A77 1726 (or teriflunomide).[5,38] Its main mechanism of action is the reversible inhibition of dihydro-orotate dehydrogenase, an enzyme needed for the *de novo* synthesis of pyrimidines.[5,37,39] Lymphocytes are

particularly targeted due to the lack of a salvage pathway for pyrimidines.[5] Effects include inhibition of B- and T-cell proliferation, suppressed production of immunoglobulin, and impaired leukocyte adhesion.[37,39,40] It also causes tyrosine kinase-mediated inhibition of cytokine and growth factors[5,37,41] and has an inhibitory effect on the replication of feline herpesvirus-1 in feline kidney cell cultures.[42]

In humans, leflunomide is used for treating rheumatoid arthritis, Crohn's disease, systemic lupus erythematosus, and is used in the management of transplant recipients.[5] In veterinary medicine, information on leflunomide use in dogs and cats is similar to that seen with MMF, being limited and including single case reports or small retrospective studies. Leflunomide has been investigated in dogs for the treatment of glucocorticoid-resistant immune-mediated hemolytic anemia (see ch. 198), Evans's syndrome (see ch. 198), immune-mediated thrombocytopenia (see ch. 201), immune-mediated polyarthritis (see ch. 203), pemphigus foliaceus (see ch. 204), systemic histiocytosis (see ch. 350), and nonsuppurative encephalitis/meningomyelitis (see ch. 261).[37,39,41] In cats, it has been described in the treatment of feline rheumatoid arthritis.[43]

Reported side-effects in humans include gastrointestinal upset, myelosuppression, secondary infections, headaches, interstitial lung disease, hepatotoxicosis, skin rashes, alopecia, and toxic epidermal necrolysis.[39] Reported side-effects in dogs include vomiting, diarrhea, inappetence, bone marrow suppression, and lethargy.[5]

The current initial dosing range in dogs is 2-6 mg/kg PO q 24 h, with many clinicians beginning at 4 mg/kg PO q 24 h.[13,14,40,44] In cats, the initial starting dosage often is 2 mg/kg PO q 24 h (or often 10 mg total dose PO q 24 h).[13,14,43] The dosage can be adjusted based on the patient's response to therapy as well as through the measurement of blood concentrations. Current recommendations regarding blood concentrations include measuring trough concentrations and targeting 20 mcg/mL to maintain a desired therapeutic effect,[13,40,44] with testing available through the Auburn University Veterinary Clinical Pharmacology Laboratory.

Tetracycline and Niacinamide

This combination of medications is used mainly for treating immune-mediated dermatopathies. It is discussed further in ch. 204.

Alkylating Agents

Alkylating agents mainly are used in antineoplastic chemotherapy protocols in small animal medicine, but they have also been investigated for their use in the treatment of immune-mediated diseases. The drug in this category that has been used most commonly for immunosuppression is chlorambucil. The mechanism of action for alkylating agents is cross-linking DNA, thus interfering with DNA replication and RNA transcription.[1,4,45] These compounds are toxic to both resting and rapidly dividing cells, particularly proliferating lymphocytes, and thus affect both humoral and cell-mediated immunity.

Chlorambucil is a cell-cycle–nonspecific alkylating agent that is cytotoxic.[5] It has a high oral bioavailability and is highly protein-bound. Once in circulation, chlorambucil is metabolized by the liver to its active metabolite, phenylacetic acid.[1,5] Phenylacetic acid then is metabolized further to inactive compounds that are excreted in the feces and urine. Side-effects with its use in dogs and cats mainly can involve gastrointestinal upset (vomiting, diarrhea, anorexia), myelosuppression, and alopecia.[1,5,14] In cats, neurological side-effects have been noted, including facial twitching, myoclonus, and seizures.[1,5,14]

Chlorambucil has been evaluated in dogs and cats for adjunctive therapy of several immune-mediated diseases, including canine and feline pemphigus foliaceus (see ch. 204), feline eosinophilic complex, and feline immune-mediated hemolytic anemia (see ch. 198), immune-mediated thrombocytopenia (see ch. 201), and inflammatory bowel disease (see ch. 276).[1,5,14,15] Different protocols exist for the various diseases, with chlorambucil often either administered q 48-72 h, or given q 24 h for 4 consecutive days, repeated every 3 weeks. Unfortunately, strong evidence for its use through controlled prospective trials is lacking.

Cyclophosphamide is a pro-drug that is metabolized by the liver, mainly to two metabolites, 4-hydroxycyclophosphamide and acrolein.[45] 4-hydroxycyclophosphamide is thought to confer the anti-tumor and immunosuppressive activity of cyclophosphamide while acrolein is thought to induce bladder toxicosis with the resultant possibility of sterile hemorrhagic cystitis.[45] Because it has many clinically significant possible side-effects and there are many other safer and effective therapeutic options in dogs and cats, the author does *not* recommend cyclophosphamide for treatment of immune-mediated diseases in dogs and cats.

It is now mainly saved for specific indications in treating cancer.

Applications and Clinical Decision-Making

For spontaneously occurring immune-mediated diseases, initial therapy often commences with glucocorticoid therapy because of its broad efficacy and low cost. In cats, due to an ability to tolerate glucocorticoid therapy without major side-effects, glucocorticoids often are used as a sole therapy. In dogs with severe, life-threatening diseases, such as immune-mediated hemolytic anemia or immune-mediated thrombocytopenia, the author often begins glucocorticoid therapy with another immunosuppressive medication such as azathioprine, cyclosporine, or mycophenolate mofetil. Which other immunosuppressive medication to consider adding to the therapy is often influenced by cost, potential side-effects, and ability to appropriately dose the medication (see ch. 360 for a review of concurrent immune suppression and infection in the same patient). The reason for beginning a second immunosuppressive medication initially in dogs with life-threatening immune-mediated diseases is twofold: to try to suppress the immune system using 2 drugs with differing mechanisms of action, and to decrease glucocorticoid therapy as soon as possible, because dogs can be very susceptible to the side-effects of high-dosage glucocorticoids. In dogs with milder or non-life-threatening immune-mediated diseases, glucocorticoids as a sole therapy can be considered.

If efficacy has been demonstrated for a specific disease using non-glucocorticoid immunosuppression (such as cyclosporine therapy for canine atopic dermatitis), then a sole non-glucocorticoid therapy should be considered as the initial treatment.

If the treatment is effective and well-tolerated, therapy is tapered slowly (often a 25% dosage reduction in only one medication every 3-4 weeks based on clinical response to therapy) to find the lowest effective dosage of medication(s) needed to maintain disease remission. When more than one immunosuppressive medication is being used, the drug which causes the most side-effects and/or is the most expensive usually is decreased first. In dogs, this often means that the glucocorticoid therapy is tapered first because of overt side-effects seen by the owners. Once glucocorticoids are reduced in dosage enough to minimize or eliminate these side-effects, then the other immunosuppressive medication (if one is being used) can be slowly tapered in a similar fashion. Weaning to the lowest effective dosage to maintain disease remission can take months to occur, and in some patients, eventually it is possible to discontinue all medications. If glucocorticoid therapy is used as a sole therapy and substantial side-effects are encountered or the treatment is not successful, then the addition of another immunosuppressive medication in addition to glucocorticoids (or as a replacement for glucocorticoids altogether) should be considered.

CHAPTER 166

Analgesic Therapy

Kristen Messenger

The International Association for the Study of Pain defines pain as "an unpleasant sensory or emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[1] Pain can be challenging to diagnose and treat appropriately in small animal medicine due to deficiencies in pain recognition, limited availability of analgesic options, and side-effects of drugs. However, pain assessment and management of clinically apparent or suspected pain is a vital component of patient care. Ch. 126 and 356 review the pathophysiology of acute and chronic pain and its consequences.

Many companion animal diseases present with a painful component that should be treated with appropriate analgesics. When potentially painful diagnostics, such as tissue biopsies, are performed, pre-emptive analgesia should be administered as a component of the sedative or anesthetic plan for the patient. For patients suffering from either severe acute or chronic pain, such as that associated with pancreatitis, multimodal analgesia improves patient comfort. Multimodal analgesia provides a means to treat different steps in the pain pathway to maximize analgesic effects, while at the same time often minimizing overall doses and side-effects of individual drugs.[2] Importantly, the clinician must remember that individual animals will have differing responses to analgesic therapy and therefore repeated pain assessments on the patient are a critical aspect of treatment.

This chapter summarizes basic clinical pharmacology of commonly utilized analgesic drugs in dogs and cats, with the exception of nonsteroidal anti-inflammatory drugs (NSAIDs). For more detailed information on the drugs discussed here, the reader is referred to several other sources[3,4] and ch. 126, 164, and 356. NSAIDs should be included in pain management protocols unless there are specific contraindications to these drugs.

Opioids

The opioids are considered the drugs of choice for treating moderate to severe pain in dogs and cats.[2] The opioids are either naturally-occurring chemicals derived from the poppy plant, or synthetic compounds. These drugs exert their analgesic effects primarily via the mu opioid receptor, although agonist activity at the kappa receptor also results in mild to moderate analgesia. All of the opioid receptors are G-protein coupled receptors, and are located in many tissues in the body. The analgesic responses are primarily via the receptors located in the central nervous system (CNS; brain and spinal cord), although opioids administered into joints provide local effects as well.[5] Analgesic effects are ultimately due to decreases in postsynaptic neurotransmitter release as well as hyperpolarization on postsynaptic neurons.[6] The pure mu opioid agonists, such as fentanyl, have a linear dose-response curve, such that dosing can be titrated to the optimal analgesic effects while minimizing adverse effects. There are currently 3 FDA-approved opioids available for use in dogs and cats in the United States: buprenorphine (Simbadol), fentanyl (Recuvyra), and butorphanol (Torbugesic). Several other opioid drugs are used in extralabel fashion in dogs and cats in the United States (Table 166-1). Simbadol was recently FDA-approved for once daily use in cats. It is administered subcutaneously as a high-dose single injection (0.24 mg/kg).[7]

TABLE 166-1

Commonly Used Opioid Dosages in Dogs and Cats

DRUG	INDICATION	SPECIES, DOSE, ROUTE, COMMENTS	FREQUENCY
Full Mu Agonists			

Fentanyl and remifentanil	Moderate to severe pain from any etiology	Dogs and cats: 2-5 mcg/kg IV, following by CRI: 2-10 mcg/kg/h, adjusted as needed. Transdermal patches available for off-label use in dogs and cats. Transdermal liquid (Recuvyra): 2.7 mg/kg dosage **in dogs only.** These drugs can result in clinically significant respiratory depression and bradycardia.	CRI recommended due to short duration of action. Recuvyra approved only for a single administration.
Hydromorphone		Dogs and cats: 0.05-0.2 mg/kg IV, IM. Emesis is common, in particular after IM administration.	Every 2-4 hours as needed
Oxymorphone		Dogs and cats: 0.05-0.1 mg/kg IV, IM	Every 4-6 hours as needed
Morphine		Dogs and cats: 0.1-0.5 mg/kg IM. Do not administer rapidly IV due to histamine release. Emesis is common. Epidural and intra-articular dosage is 0.1 mg/kg of the preservative-free solution.	Every 2-4 hours as needed
Methadone	Moderate pain. Particularly useful for patients where vomiting is a major concern, i.e., increased intracranial pressure, laryngeal paralysis, myasthenia gravis, etc.	Dogs and cats: 0.2-0.6 mg/kg IV, IM	Every 4-6 hours as needed
Partial Mu Receptor Agonists			
Buprenorphine	Moderate to severe pain from any etiology	Dogs: 0.01-0.03 mg/kg IV, IM; 0.04 mg/kg OTM small dogs Cats: 0.02-0.04 mg/kg IV, IM, OTM. *SC route not recommended due to erratic and poor absorption.	Every 4-8 hours as needed
Kappa Receptor Agonists			
Butorphanol	Mild to moderate pain. Particularly useful for patients where vomiting is a major concern, i.e., increased intracranial pressure, laryngeal paralysis, myasthenia gravis, etc.	Dogs and cats: 0.2-0.4 mg/kg IV, IM. As a partial reversal for full mu agonists: 0.01-0.1 mg/kg IV, slowly, to effect.	Every 1-2 hours as needed
Nalbuphine	Mild pain	Dogs and cats: 0.1-0.5 mg/kg IV; 0.25-1 mg/kg SC, IM. Not commonly used in veterinary medicine.	Every 1-2 hours as needed
Miscellaneous			
Tramadol	Mild to moderate pain	Cats only: 2-4 mg/kg. Cats may become aversive to bitter taste.	Every 6 hours as needed

CRI, Constant rate infusion; *IM*, intramuscular; *IV*, intravenous; *OTM*, oral-transmucosal; *SC*, subcutaneous.

For dosage ranges listed, it is common to administer the lower end of the dosage range IV, while higher dosages are administered via extravascular routes.

Routes of Administration

Oral administration of opioids is generally discouraged due to very limited data on efficacy and absorption.[8] Overall, these drugs are cleared by first-pass hepatic metabolism, resulting in very low systemic bioavailability.[8,9] Despite discouraging data on oral absorption, there appear to be anecdotal reports of the successful use of orally-administered opioids. This author discourages their use until more controlled trial data are available. Oral-transmucosal (OTM) administration of certain opioids such as buprenorphine is feasible for cats and small dogs. The bioavailability of OTM buprenorphine is highly variable, with an average value of 40% in both dogs and cats, thus requiring a high dosage of 0.02-0.04 mg/kg.[10-12] There are

reports of OTM dosages as high as 0.12 mg/kg in dogs.[9]

Recuvyra (fentanyl) represents a novel route of opioid administration in dogs: the topical liquid has been specifically formulated for rapid transdermal absorption. Recuvyra avoids some of the general concerns of prescribing opioids in veterinary medicine such as drug diversion by owners, although it does not necessarily avoid accidental owner or pet exposure. Currently an online training program provided by the sponsor (Elanco Animal Health) is required before a veterinarian can order Recuvyra.[13] Recuvyra is not approved for use in cats and there are currently no published studies on the use of this formulation in cats. Until information is available, this product should not be used in cats. The transdermal administration of fentanyl via patches (e.g., Duragesic) is commonly used in dogs and cats, and provides effective analgesia although systemic absorption is highly variable due to differences in skin thickness, blood flow, and composition.[14,15] Transdermal buprenorphine in patch form has been investigated in dogs and cats, although the results were not encouraging in the pain models tested.[16,17]

The epidural and intra-articular administration of preservative-free morphine provides potent regional and local analgesic effects, while avoiding side-effects associated with systemic administration.[14,18] The reader is encouraged to review other resources for epidural and intra-articular administration of analgesics, and to utilize these techniques in practice.[19-21]

Adverse and Side Effects of Opioids

General side- and adverse effects of opioids can include vomiting, nausea, ileus and constipation, urinary retention, bradycardia, respiratory depression, sedation and dysphoria.[18,22,23] Many of these side-effects are drug- and dosage-dependent. In cats, opioid administration has been associated with hyperthermia, which resolves with supportive care or partial reversal.[14,24-26] Additionally, opioids may have negative immunomodulatory effects, which would be most concerning in critically ill patients.[6] Some of the side-effects of the opioids, including dysphoria, are believed to occur through effects at the delta receptor. Certain opioids are associated with fewer side-effects as compared to others. For example, buprenorphine, a partial mu-receptor agonist, has fewer and less severe side-effects than the pure mu-receptor agonists such as fentanyl. These features make buprenorphine more attractive for clinical use in at-risk patients, such as those with increased intracranial pressure where respiratory depression would be a major concern.

The opioids and their effects, both analgesic and adverse, are fully reversible with opioid antagonists such as naloxone (0.01-0.04 mg/kg). Butorphanol can be used to partially reverse full mu agonists such as fentanyl, thereby maintaining some level of analgesia for the animal.

Tramadol

There is little to no evidence to support the use of tramadol to treat pain in dogs, although there is seemingly widespread use of this drug in veterinary medicine.[8,27] Recent pharmacokinetic studies reveal that dogs do not produce the opioid metabolite of tramadol (M1) that is responsible for the analgesic effects experienced in humans.[8] Other pharmacologic effects of tramadol include the inhibition of norepinephrine and serotonin reuptake,[28] and some of the observed effects in dogs may be related to these actions.[27] In the United States, tramadol is now a Schedule IV drug. With the exception of serotonin syndrome, there are few major side- or adverse effects of tramadol administration in dogs. Contraindications to tramadol administration include the concurrent administration of serotonin and/or norepinephrine reuptake inhibitor drugs, monoamine oxidase inhibitors, or tricyclic antidepressants.[8]

Tramadol may be more effective as an analgesic in cats, with dosages of 2-4 mg/kg PO q 6-12 h as needed, providing analgesia in a feline thermal threshold model.[8,29] Dysphoria and excessive salivation (due to the bitter taste) may be observed after administration.[8]

Alpha-2 Adrenoreceptor Agonists

Dexmedetomidine is the only alpha-2 agonist approved for use in dogs and cats in the United States. Dexmedetomidine is the active isomer of the racemic formulation, medetomidine, and has a high selectivity for the alpha-2 receptor as compared to the alpha-1 receptor.[30] The potent analgesic properties of this drug are primarily through actions at the alpha-2 receptors in the brain and spinal cord. In cats, dosages ranging from 5-50 mcg/kg have provided analgesia in thermal antinociceptive models,[31,32] although it is important to

note that these doses all resulted in profound sedation.[31] Clinically recommended dosages are in the range of 1-5 mcg/kg IV, or as a constant rate infusion of 1-3 mcg/kg/h (Table 166-2). The use of dexmedetomidine in dogs and cats should be weighed against the potential adverse and side-effects, of which there are many including emesis, diuresis, sedation, and transient hyperglycemia.[33] Most notably, the negative effects on the cardiovascular system need to be considered, including hypertension followed by hypotension, bradycardia, and arrhythmias.[34-36] The effects of dexmedetomidine are fully reversible with atipamezole, at dosages of approximately 0.1-0.3 mg/kg IM, although lower dosages are often effective.[4]

TABLE 166-2

Drug Dosages for Other Commonly Used Analgesics in Veterinary Medicine

DRUG	INDICATION	SPECIES, DOSE, ROUTE, COMMENTS	FREQUENCY
Dexmedetomidine	Moderate to severe pain from any cause in generally healthy dogs and cats	Dogs and cats: 1-5 mcg/kg IV, or CRI 1-3 mcg/kg/h with close monitoring	Every 1-2 hours as needed
Ketamine	Acute and chronic pain, neuropathic pain, somatic pain	Dogs and cats: 0.12-0.6 mg/kg/h, adjusted as needed based on analgesia or development of side-effects	CRI
Amantadine	Osteoarthritis, chronic pain	Dogs: 3-5 mg/kg PO Cats: 5 mg/kg PO	Every 12-24 hours
Gabapentin	Neuropathic pain, possibly acute pain	Dogs and cats: 10-20 mg/kg PO	Every 6-8 hours
Pamidronate (a bisphosphonate)	Bone pain	Dogs: 1-2 mg/kg IV over 2 hours Cats: 1 mg/kg IV (no reports of analgesic use in cats)	
Lidocaine (systemic administration)	Moderate to severe pain from any cause; caution in patients with neurologic, severe cardiac, or hepatic disease	Dogs only: 1-2 mg/kg IV; CRI 1-3 mg/kg/h. Neurologic signs will develop if toxic doses are administered. Cardiac effects may include arrest.	Bolus once, then CRI

CRI, Constant rate infusion; *IV*, intravenous; *PO*, per os.

N-Methyl-D-Aspartate (NMDA) Antagonists

Ketamine

Ketamine is a dissociative anesthetic drug that is used at sub-anesthetic dosages to treat a variety of acute and chronic pain conditions, including severe pain associated with pancreatitis or surgery (see Table 166-2).[28,37,38] This drug successfully prevents pain pathway remodeling in the dorsal horn of the spinal cord, thereby reducing the likelihood of the development of chronic pain resistant to traditional therapies.[28] Ketamine has cardiostimulatory effects through endogenous norepinephrine release, although these effects have been best documented at anesthetic dosages.[39,40] Ketamine may have some additional analgesic benefits through anti-inflammatory effects, which have been documented in both controlled research and clinical trials.[39,41,42] Ketamine should be administered as a constant rate infusion (CRI) to be most effective, thus requiring frequent observation and hospitalization.[28] Although there are very limited veterinary data, the administration of sub-anesthetic doses of ketamine in dogs and cats is associated with few side-effects or contraindications. The drug is metabolized by the liver to norketamine, which possesses some anesthetic activity. In dogs, norketamine undergoes further metabolism, but in cats a large amount of norketamine is excreted unchanged by the kidneys.[43] Ketamine should be used cautiously in cats with severe kidney injury/disease due to the possibility of drug accumulation and enhanced or prolonged effects secondary to the active metabolite norketamine. High dosages of ketamine may result in dysphoria and hallucination, which can be mitigated by discontinuing or reducing the rate of administration as well as by administration of an appropriate sedative.

Methadone and Dextromethorphan

Both of these drugs have weak activity at the NMDA receptor, and studies in humans suggest that both of these agents possess analgesic activity.[28] There are few veterinary studies demonstrating significant analgesic effects in dogs and cats. Methadone is a pure mu-opioid agonist with other pharmacological mechanisms including inhibition of serotonin and norepinephrine reuptake.[44]

Amantadine

Amantadine is an antiviral agent, but has weak activity at the NMDA-receptor as well as good oral absorption in people.[28] Amantadine appears to be well-absorbed following oral administration in dogs and cats[8,45,46] although plasma concentrations corresponding to analgesic effects are not known. There are reports of the successful use of amantadine as an adjunctive analgesic in dogs and cats, with few to no adverse effects.[45,47,48]

Gabapentin

Gabapentin was originally developed and used as an anti-epileptic drug, but was found to have analgesic benefits in people suffering from certain painful conditions, in particular neuropathic pain[28] and more recently acute postoperative pain.[49,50] Gabapentin is a structural analog of GABA; however, it does not interact with GABA receptors or influence endogenous GABA activity. The primary mechanism of action is currently believed to be via inhibition of voltage-gated calcium channels through binding at the alpha-2-beta subunit on these channels,[51,52] although it has been suggested that gabapentin has activity at a variety of other receptors.[28] The use of gabapentin as an analgesic in veterinary medicine has had mixed results. In dogs, gabapentin at a dosage of 10 mg/kg PO per day was not found to improve pain scores following forelimb amputation,[50] but anecdotally gabapentin is believed to be an effective adjunctive analgesic for chronic or neuropathic pain (see Table 166-2).

Pharmacokinetic studies on gabapentin administration in cats have been reported[53] and simulations using data in these studies have recommended dosage regimens of 3-8 mg/kg PO q 8 h to achieve target plasma concentrations that are considered effective in people.[54] Pharmacodynamic data in cats have shown that gabapentin was not effective in a thermal stimulus model of pain, with the drug achieving plasma concentrations between 1-10 ng/mL following oral administration of 5 and 10 mg/kg.[54]

Bisphosphonates

The bisphosphonates include zoledronic acid, tiludronic acid, and pamidronate. These compounds bind to hydroxyapatite in bone and ultimately reduce bone resorption and destruction through the inhibition of osteoclast activity.[55] There is very limited evidence that bisphosphonates may be beneficial in the treatment of pain-associated osteoarthritis and bone cancers in dogs.[55] These compounds are administered as an intravenous infusion (see Table 166-2). In people, there have been reports of bisphosphonate-associated osteonecrosis and renal toxicosis, although adverse effects of these drugs in dogs and cats are largely unknown.[56,57]

Local Anesthetics

A full discussion on the use of regional and local anesthesia is beyond the scope of this chapter; however, these techniques can be of immense benefit in the management of pain in dogs and cats. For example, a sacrococcygeal epidural can be quickly and safely performed in cats suffering from urethral obstruction in order to provide potent analgesia with little to no systemic adverse effects.[58] A description of local anesthetic techniques and indications can be located in several previously listed resources.[20,21] Lidocaine transdermal patches (Lidoderm) have been investigated in dogs and cats, and although there is systemic uptake of lidocaine, the analgesic benefits are likely minimal.[59,60] However, the systemic administration of lidocaine has been advocated for use as both an analgesic and antiinflammatory in dogs (see Table 166-2), but should not be administered to cats due to risk of toxicosis.[36,61] The *systemic* administration of local anesthetics other than lidocaine is contraindicated due to concerns of neuro- and cardiotoxicosis, and risk of death.

Neurokinin-1 Receptor Antagonists

Maropitant is an NK-1 receptor antagonist that is approved in the United States as an antiemetic in dogs and cats. There is very limited evidence that maropitant may provide analgesia for visceral pain in dogs.[22] At this time, further studies are needed before a general recommendation can be made for the use of this drug as an analgesic.

Adjunctive Analgesics for Chronic Pain and Future Directions

Several "nontraditional" analgesic compounds have been utilized as adjunctive treatments for chronic pain. These drugs include antidepressants belonging in the tricyclic antidepressant or selective serotonin (and norepinephrine) reuptake inhibitor classes.[8] The reader is referred to ch. 126 and 356 for information regarding comprehensive management of pain, and to a recent review article.[8] Researchers and pharmaceutical companies are investigating novel therapeutics to treat pain in dogs and cats. Currently these products are still undergoing trials, but promising therapeutics include monoclonal antibody therapies such as anti-nerve growth factor, which is known as tanezumab in human medicine.[62] Toxins targeting specific nerve fibers and ion channels, such as resiniferatoxin, are still undergoing research although there is growing evidence for the clinical use of this compound in veterinary medicine.[63]

CHAPTER 167

Antioxidants, Nutraceuticals, Probiotics, and Nutritional Supplements

Laura Eirmann

Advances in the understanding of companion animal nutrient requirements and in food science technology allow pet owners to feed complete and balanced diet formulations that meet the animal's nutrient requirements throughout various life stages and often to meet specific needs of an individual. Moving in parallel to these improvements, interest among pet owners regarding the benefits of dietary supplements and nutraceuticals continues to emerge. Although it does not apply to products intended for animals, the Dietary Supplement Health and Education Act (DSHEA) of 1994 defines a dietary supplement as a product (other than tobacco) intended to supplement the diet that bears or contains one or more of the following dietary ingredients: a vitamin, mineral, herb or other botanical, amino acid, dietary substance for use by man to supplement the diet by increasing the total dietary intake or a concentrate, metabolite, constituent, extract, or combination of these ingredients.[1] The National Research Council publication, *Safety of Dietary Supplements for Horses, Dogs, and Cats,* defines an animal dietary supplement as "a substance for oral consumption by horses, dogs, or cats, whether in/on feed or offered separately, intended for specific benefit to the animal by means other than provision of essential nutrients for intended effect on the animal beyond normal nutritional needs, but not including legally defined drugs."[2] There is no legal definition of the term nutraceutical in the United States. It is a portmanteau of "nutrition" and "pharmaceutical" coined by a physician and generally applied to dietary supplements intended for specific therapeutic effects.[3] It is important to recognize that dietary supplements and nutraceuticals are not required to undergo a premarket approval process with the U.S. Food and Drug Administration (FDA) before being sold to the public.

An estimated 10-33% of dogs and cats in the United States are fed a dietary supplement.[2,4,5] However, despite the considerable interest in dietary supplements, knowledge about their efficacy, modes of action, and safety often is lacking. With the myriad products and supplements currently available, veterinarians often are asked by clients to comment on a specific product or to make a recommendation. It is important to obtain an understanding of dietary supplements and to develop a systemic and scientific approach to assess patients and products before making a recommendation. A comprehensive discussion of all dietary supplements is beyond the scope of the chapter. This review, while not exhaustive, will provide a brief overview of the regulatory aspects of dietary supplements marketed for companion animals in the United States and provide guidelines for veterinarians to facilitate accurate assessment and when possible to make sound recommendations supported by studies published in the peer-reviewed scientific literature. A very brief introductory overview of two categories of dietary supplements, antioxidants and probiotics, will be presented.

Regulatory Aspects

Food and drugs for either humans or animals are regulated in the United States under the Federal Food, Drug, and Cosmetic Act (FFDCA) of 1938. Responsibility for enforcing all aspects of the FFDCA that could apply to use in animals rests with the Center for Veterinary Medicine (CVM) of the FDA. The legal distinction between a "food" (an item consumed primarily for taste, aroma, or nutritive value) and "drug" (an item intended to treat or prevent disease or affect structure or function of the body) largely depends on the intended purpose or claims made by the manufacturer or distributor.[3] The DSHEA sets a regulatory framework for dietary supplements marketed for humans that allows a "nutrition support statement" related to "structure-function" claims, but requires a disclaimer that the supplement has not been evaluated by the FDA and that "the product is not intended to diagnose, treat, cure, or prevent any disease."[1] This Act opened

the possibility of certain types of claims (i.e., structure/function claims) to be made without having scientific evidence submitted to the FDA prior to marketing. However, in 1996, the CVM published a notice that the DSHEA does not apply to products intended for use in animals and therefore "dietary supplements for animals are not recognized as a class of products."[6] Under the FFDCA, products marked as dietary supplements for use in animals are classified as either foods or drugs depending on their intended use. For reasons beyond the scope of this chapter, most animal health supplements are considered drugs of low regulatory priority.[7] It behooves the veterinary clinician to understand that some products on the market might not comply with applicable law and could contain unapproved ingredients or make unsubstantiated claims, and that "extralabel" use only applies to approved drugs.[3]

General Guidelines for Dietary Supplement Selection

For legal and ethical reasons, the veterinary clinician must make a critical evaluation before recommending a dietary supplement or nutraceutical. This begins with a complete patient history, including open-ended questioning regarding dietary supplement usage. Up to 70% of human patients do not report supplement use to their physicians.[8,9] Pet owners might not mention these products when asked about medications or could be reluctant to mention alternative therapies not prescribed by the veterinarian. Nevertheless, survey studies report supplement usage ranging from 13-38% for veterinary patients with heart or kidney disease.[10-12] Given the potential for adverse events associated with supplement usage and potential for supplement-drug interactions, this information is critical.

As with any veterinary recommendation, the clinician must first establish an accurate diagnosis. An owner may inquire about a supplement for "joint health" when the patient does not have a condition that warrants this particular supplement. If the veterinarian determines that a particular dietary supplement may be beneficial to the patient, specific product selection is the next step. The acronym PETS has been used for making a product assessment and can be used for assisting discussions with clients about a particular supplement.[13] The key points are summarized as follows:

- Product Quality (P): The manufacturer should be able to provide adequate information about a specific product to assist the veterinarian in assessing product quality. The product must contain an appropriate amount of the substance of interest for both safety and efficacy. Unfortunately, there are examples of products that are mislabeled or do not contain the ingredient listed on the label.[14] The label should be accurate and include information such as a list of ingredients, intended use of the product, adequate directions for use, lot number, expiration date, and manufacturer information. The manufacturer should utilize Good Manufacturing Principles and be willing to provide information regarding quality assurance such as ingredient and final product testing. A specific nutraceutical may require enteric coating, encapsulation, or specific packaging or storage conditions. More detailed questions for manufacturers of nutraceutical products can be found elsewhere.[7] Third party resources may also provide the veterinarian with information regarding a specific product's quality. A non-profit trade organization, the National Animal Supplement Council (www.nasc.cc), offers a voluntary program that provides animal supplement manufacturers with guidelines for product quality assurance, adverse event reporting, and labeling standards. Successful completion of this program allows the member company to display the NASC Quality Seal on their products, website, product literature, and advertisements. Additional third party resources include the U.S. Pharmacopeial Dietary Supplement Verification Program and ConsumerLab.com.
- Efficacy (E): Efficacy, defined as a desired biological response, of any therapy is established by scientific testing. First the compound of interest must be present in a form that is bioavailable to the pet. For example, the oral bioavailability of chondroitin sulfate in dogs increases with decreasing molecular weight.[15] Demonstrating efficacy of a nutraceutical substance requires rigorous and often expensive testing depending on the extent to which claims for a product are being made and the regulatory environment surrounding that substance. Manufacturers should be asked to provide supportive documentation of efficacy. Critical evaluation of studies is required. It is important to ensure the studies were conducted in the target species using the same dosage and form of active ingredient with the same product formulation. The study should be blinded and include an appropriate control group, although it must be recognized that such robust evidence does not always support currently existing recommendations in many aspects of veterinary medicine. Determining if the studies were published in peer-reviewed journals and if the results are applicable to the specific patient being evaluated is also important. Clinicians should be cautious of product support and marketing based solely on testimonials or poorly designed studies.

- Tolerance (T): Tolerance for any nutraceutical or supplement must exist for it to be effective. The treatment plan must be acceptable to the pet owner and patient. For instance, the number of tablets to achieve efficacy and route of administration must be achievable for that client and patient.
- Safety (S): Safety is paramount and must be known before using a dietary supplement. Historical data on usage of certain substances can provide practical information regarding safety. The margin of safety (difference between effective dosage and maximum safe dosage) might or might not be known. Using a particular supplement in the absence of any published safety data in the target species is particularly risky and caution is advised. Safety must be evaluated with regard to the specific patient's medical condition and concurrent treatments. Supplement-drug interactions must be considered. Pet owners are sometimes under the erroneous assumption that "natural" is always "safe." Client education including a discussion of known data, knowledge gaps, and controversies will help enable the owner to make an informed decision.

Select Nutraceuticals of Interest

Antioxidants

Reactive oxygen species (ROS) are ubiquitous and highly reactive in biological systems. They are associated with oxidation-reduction reactions, energy metabolism, biosynthesis, cell signaling, and body defense and detoxification mechanisms. Their reactivity can be beneficial due to oxidative burst reactions and other mechanisms that characterize neutrophil and other inflammatory cell functions. They are produced not only as a result of normal metabolism but also by exposure to environmental stressors including UV radiation, pollutants, and certain chemical agents. When present in excess, oxidative damage and destruction of normal cell membranes and cell function occurs. The ROS are capable of reacting with all biologic molecules including nucleic acids, proteins, carbohydrates, and lipids. Continued oxidative damage is thought to be part of the pathogenesis of many conditions including cancer, degenerative conditions such as arthritis, and the aging process including cognitive decline.

Because of the potential adverse effects of ROS, cell systems utilize numerous antioxidant mechanisms to inhibit oxidative damage and quench the formation of free radicals. These systems include: direct interaction with reducing agents (e.g., vitamin C, glutathione); free radical scavenging (vitamin E, vitamin C, carotenoids, superoxide dismutase); reduction of hydroperoxides (e.g., glutathione peroxidase, catalase); removal of transition metals by protein binding (e.g., ferritin, ceruloplasmin, and other chelators); prevention of reactive oxygen from reaching specific sites; and even repair of oxidative damage.[16]

Because free radicals arising from metabolism or environmental sources interact continuously in biologic systems, the oxidants and antioxidants are in a continual utilization and replenishment cycle that must be balanced to minimize cellular and tissue damage. This makes antioxidant supplementation to augment endogenous antioxidant systems a potential intervention strategy. For instance, decreased hepatic glutathione concentrations have been demonstrated in naturally-occurring liver disease[17] and supplementation with S-adenosylmethionine (SAMe), a glutathione precursor, has been shown to be beneficial to dogs and cats with acetaminophen intoxication.[18,19]

The selection of the correct type, dosage, and/or combination of antioxidants to ameliorate such a complex biological system is challenging. For example, the specific SAMe product utilized in the acetaminophen reports contains 74% of the biologically active SAMe stereoisomer whereas a different SAMe product may contain much less.[20] Certain antioxidants can act as pro-oxidants at certain levels or under certain biological conditions.[21] Some treatment modalities rely on oxidative damage, so supplementation with antioxidants during the specific treatment phase may not be optimal. Therefore, the clinician needs to evaluate the patient, the treatment plan, and the scientific literature regarding safety and efficacy of particular antioxidant or antioxidant combination before making a specific recommendation.

Probiotics

The Food and Agriculture Organization of the United Nations and the World Health Organization define probiotics as "live microorganisms which, when administered in adequate amounts, confer a health benefit on the host."[22] They are often lactic acid bacteria and include strains of *Enterococcus, Streptococcus, Bifidobacterium,* and *Lactobacillus* spp. The mechanism of action is complex and likely multifactorial.[23] This is not surprising given that the microbiota composes 90% of the total cells in the mammalian body. Only recently have newer sequencing and bioinformatics technology provided better insight regarding the vast

numbers and diversity of the intestinal microbiota.[24] This research is uncovering a highly complex, diverse intestinal ecosystem that is unique to the individual and differs along the gastrointestinal tract.[25] A better understanding of the intestinal microbiome, its influence on health and disease within and beyond the gastrointestinal tract, and potential for probiotics to modulate the complex interactions between microbiota and host are areas of active research in human and veterinary medicine. Evidence supports the use of specific probiotic organisms in certain human populations for defined disease conditions including necrotizing enterocolitis, antibiotic-associated diarrhea, and pouchitis with expert panels convening to review the research and provide specific recommendations for probiotic use in humans.[26]

Research elucidating the canine and feline microbiota and the potential benefit of probiotics is ongoing and promising. However, the complexity and current limited data make recommendations challenging. It behooves the clinician to use the same general guidelines and "PETS" approach described above when considering a probiotic for a patient. Commercial products have a large variation in quality control.[23] Assessment of product quality includes evaluating the product label. The label should include a guaranteed analysis stating the number of live probiotic bacteria, a list of the specific genus, species, and strain, and an expiration date.[27] Unfortunately, previous studies have shown that many commercially available products contain labeling errors, including failure to list specific microorganisms, misspellings, and failure to list expected bacterial numbers.[14,28] Furthermore, comparison of actual content versus label claims demonstrated some products did not meet viable organism claims, contained organisms without probiotic effect, or contained potentially pathogenic organisms.[14,28] The veterinarian should select a probiotic from a reputable manufacturer and ask questions regarding product quality, including manufacturing practices and stability studies to ensure the probiotic survives production, storage prior to consumption, and passage through the gastrointestinal tract. Safety is of utmost concern. Safety includes testing for virulence and antibiotic-resistance genes as well as patient tolerance. Caution is advised when considering probiotics in patients with marked intestinal mucosa compromise, or those who are immune-compromised or critically ill.[23] Adverse events associated with any dietary supplement should be reported. Current evidence of efficacy is minimal and at times conflicting but there is a growing body of data in the peer-reviewed literature especially regarding gastrointestinal health[29-37] and immune modulatory effects[38-43] of probiotics in dogs and cats. Study design should be critically evaluated and outcome measures should be relevant to the clinical patient. It is realistic to anticipate that with future scientific research using well-designed placebo-controlled blinded studies with proper sample size and study duration, recommendations will become more refined and targeted to specific probiotic strains that impart a desired biological effect to address specific conditions in a defined cat or dog population.

CHAPTER 168

Compounding Drugs

Ron Johnson, Dinah G. Jordan

One of the greatest challenges to veterinarians can be the availability of appropriate drug dosage forms that enable easier and more accurate dosing of patients and improve owner compliance. Although advances have been made with new drugs and dosage forms approved for veterinary medicine, clearly there remains a need for additional drug formulation options. As such, drugs approved in one animal species are frequently used in another species, including human-approved drugs. Compounded medications have not undergone the rigorous approval process where they are tested for safety, efficacy, and stability. Practitioners must ensure that the administration of compounded drugs to veterinary patients is justifiable, not driven by economics, and is based on meeting an individual patient need that cannot be met by a commercially available, approved product (Box 168-1).

Box 168-1

General Recommendations for the Use of Compounded Medications in Companion Animals

1. The use of compounded veterinary preparations should be based on rational drug therapy determined by a licensed veterinarian within the confines of a valid veterinarian/client/patient relationship.
2. Compounded preparations may be necessary when: (i) a legitimate medical need exists, such as suffering or death resulting from a lack of treating the affected animal, (ii) an appropriate dosage regimen does not exist for the species, size, age, or medical problem of the intended animal or (iii) there is no marketed approved animal or human drug available, whether employed in a labeled or extralabel manner, to treat the condition, or there is reason to believe the approved drugs will not be efficacious or safe in the intended animal.[4]
3. Compounded preparations may be dispensed by a licensed veterinarian for patients within his/her practice. Veterinarians should seek the services of a reputable compounding pharmacy when the complexity of the compounded preparation exceeds the experience, training, equipment and/or facility of the veterinarian.
4. Compounded preparations may be dispensed by a licensed pharmacist for an individual veterinary patient pursuant to valid prescription in accordance with state and federal laws.
5. FDA-approved veterinary and human products should be used for compounding in accordance with AMDUCA whenever commercially available and medically appropriate. In the absence of an appropriate FDA-approved product, APIs should be obtained from a facility registered with the FDA when possible or other reliable source if no FDA-registered site is available. All APIs should be accompanied by a Certificate of Analysis.
6. Compounded drugs dispensed by a veterinarian or pharmacist must be labeled in accordance with the extralabel use provisions of AMDUCA and all applicable state laws and regulations.[3] The required information includes, but is not limited to, patient identification, date dispensed, name of all active ingredients, quantity dispensed, directions for administration, prescriber/pharmacist identification, address of veterinary clinic or pharmacy, auxiliary and caution labels, lot number and beyond-use date. Adequate records of dispensed compounds (including formulas) must be maintained by the dispensing pharmacist or veterinarian.
7. Compounded preparations should be patient-specific and not available for "resale," which implies repackaging and/or relabeling.

8. Veterinarians may legally maintain non-patient-specific "office use" veterinary compounded preparations in some states.
9. The veterinarian should establish objective parameters for monitoring patients, which will indicate whether the compounded medication is clinically effective, subtherapeutic or toxic.[11]
10. The prescribing veterinarian and/or dispensing pharmacist should report any suspected adverse events associated with the use of compounded veterinary preparations.

Veterinary Compounded Drugs: Regulations

Compounding in veterinary medicine remains a topic of regulatory attention and indecision. Compounding is defined by the United States Pharmacopeial Convention as "the preparation, mixing, assembling, altering, packaging, and labeling of a drug, drug-delivery device, or device in accordance with a licensed practitioner's prescription, medication order, or initiative based on the practitioner/patient/pharmacist/compounder relationship in the course of professional practice."[1] While traditional compounding is regulated primarily at the state level, the United States Congress passed the Compounding Quality Act (Title I, Drug Quality and Security Act of 2013), which addressed many compounding issues in human medicine. This statute, however, pertains only to compounding for human patients and does not address regulations for non-human species.[2]

One of the most glaring and controversial issues regarding veterinary compounding is the ability to compound veterinary medications from bulk substances, also referred to as active pharmaceutical ingredients (APIs). The Animal Medicinal Drug Use Clarification Act (AMDUCA) legalized compounding for veterinary patients from approved veterinary and human products with few restrictions for non-food animals.[3,4] The Act, however, did not include language that specifically included compounding from APIs. The Center for Veterinary Medicine, Food and Drug Administration (FDA) has long held the position that this form of compounding for animals is illegal although necessary in some cases.

Veterinarians and pharmacists acknowledge that there are clearly medications for veterinary patients that must be compounded from bulk substances, including, but not limited to potassium bromide, cisapride, metronidazole benzoate suspension, diethylstilbestrol, transdermal formulations, some poison antidotes and drugs that are currently unavailable due to manufacturer backorders or that are no longer commercially available. The legality of veterinary compounding from APIs has been a longstanding debate among pharmacists, veterinarians, veterinary drug manufacturers, and the Center for Veterinary Medicine and has been the subject of lawsuits filed in the U.S. federal court system.[5,6] It seems absurd that medications for human patients can legally be compounded from APIs, but not for non-human species. On the other hand, it is well known that some compounding pharmacies have generated large amounts of unapproved drugs for veterinary use that are largely copies of FDA-approved drugs, and veterinarians have bought them for their clinic inventory. These practices constitute attempts to bypass the drug approval process and can be construed as illegal manufacturing disguised as compounding.

Another compounding issue that warrants regulatory resolution is the need for veterinarians to buy non-patient-specific compounded medications (stock medications) from compounding pharmacies (anticipatory compounding) not only for administration to patients while they are in the clinic, but also for administration after the patient is discharged to avoid interruption of therapy. These medications may be more complex compounds, such as sterile ophthalmic solutions or ointments. Most veterinarians lack pharmacy experience or training and do not have facilities or equipment for compounding beyond simple reformulations of non-sterile medications; therefore, it is rational for a veterinarian to purchase "office use" preparations from a compounding pharmacy. However, while some states allow "office use" compounds, others do not. The dilemma arises when a veterinarian needs to dispense a medication previously compounded by a pharmacy, which would involve relabeling and perhaps repackaging the medication. This practice is deemed "resale," and is not allowed in most states. Note: California and Virginia are, at the time of publication, the only two U.S. states that allow veterinarians to dispense an emergency 72 hour supply of "office use" compounds.[7,8]

These and other unresolved issues in veterinary compounding resulted in the formation of a Task Force on Veterinary Compounding Legislation by the American Veterinary Medical Association in 2014. The Task Force will examine such issues as "maintaining office stock, compounding from bulk ingredients, adverse event reporting, and quality assurance. They will also consider the role that drug shortages and the preservation of the Food and Drug Administration's approval process play in the access to compounded preparations."[9]

Veterinarians should keep up with current regulatory information regarding veterinary compounding as

the regulatory process evolves. Professional veterinary organizations, along with published literature in reputable journals, represent valuable sources of information on compounding for animals that may assist the veterinarian with the complex and often confusing regulatory environment surrounding veterinary compounding.

Understanding Risks Versus Benefits With Compounded Drugs

Pharmaceutical Issues

Compounding by veterinarians and pharmacists is not equivalent to the formulation of commercially manufactured products by appropriately registered manufacturing pharmaceutical firms. Whether by a pharmacist or a veterinarian, compounding must therefore be done only within the compounder's level of experience, training, equipment and facility. A compounded drug must possess adequate purity, potency and demonstrate stability (shelf-life) to maintain acceptable bioavailability (extent of systemic drug absorption) of the active pharmaceutical ingredient, but not produce toxicosis or an ineffective preparation. Vehicles used in the formulation process can alter drug concentration. For example, vitamin/mineral liquids and some forms of molasses that contain iron, although palatable for many pets, are not good choices for compounding vehicles, as they may chelate the active drug ingredient and render it ineffective. Alterations in pH caused by combinations of active and inactive ingredients, when protective tablet coatings are disrupted or liquids are added, can also result in loss of active drug in a formulation. Evidence of potential loss of active drug and instability of compounded formulations includes color changes that can indicate oxidation, separation of product phases or signs of cloudiness or precipitation in liquid dosage forms, or cracking, swelling or release of odors in solid dosage forms.[10] There may also be no visible evidence of deactivation of the drug. Manipulations of the dosage form can also result in contamination of a sterile product meant for injection or affect drug bioavailability through alterations in drug-release rates. In general, the more extensive the manipulation of a drug preparation from its original formulation the greater the chance that drug efficacy will be compromised.

Because drug pharmacokinetics, safety and efficacy have not been determined for most compounded preparations, and are likely not to be, it is important for the veterinarian to establish objective parameters which will indicate whether the compounded preparation is efficacious, subtherapeutic or toxic.[11] Objective parameters can include hematologic or clinical chemistry changes, serum drug levels when drug monitoring is available, and clinical signs and clinical end-points.

While compounding from the finished formulation of an approved drug is recommended whenever possible, there are circumstances in small animal practice that warrant compounding from an API. Approved drugs may not be available commercially due to backorder or withdrawal from the human market, e.g., cisapride for the treatment of gastrointestinal disorders in cats. In other cases, there has never been an approved drug formulation containing the required ingredient, e.g., potassium bromide for seizure control. Finally, approved drug formulations may be unacceptable for veterinary compounding for various reasons. A pet may have an intolerance for an ingredient in the commercial product, such as the xylitol content in some human-approved products when compounding for dogs. Furthermore, excipients in commercial products are not desirable when compounding transdermal medications. When APIs are needed to compound veterinary preparations, it is critical that the ingredient source be known and that all components of the compounded formulation meet either United States Pharmacopeia (USP), National Formulary (NF), Food Chemicals Codex (FCC) standards or another high-quality source such as analytical reagent or certified American Chemical Society, and be obtained from a facility that is registered and inspected by the FDA whenever possible.[12] If such a facility is not an option, the compounder should use professional judgment in locating a reliable source for the needed chemical based on the company's reputation and its willingness to provide a Certificate of Analysis for its chemicals.[12]

Transdermal Delivery of Drugs

Systemic delivery of drugs using the transdermal route is a convenient method of administering some medications to pets, especially feline patients that have an aversion to orally-administered drugs. While some drugs are suitable for this delivery system, others are not for a variety of reasons. First, a medication must be able to cross the skin and be absorbed into the systemic circulation. Absorption of drug via the transdermal route is primarily passive. As such, ideal drug molecules for this route of delivery are low molecular weight (<400 Daltons), lipophilic in nature, and soluble in both water and oil.[13] Although chemical penetration

enhancers such as pluronic lecithin organogel, Lipoderm, and dimethylsulfoxide may be used in formulations to enhance absorption, there are limitations to what can be accomplished with these agents. Based on studies performed in cats, overall systemic bioavailability for transdermal preparations is low, compared to the oral route; and it takes longer for transdermal medications to reach therapeutic blood levels, if at all.[14]

Second, the dosage of the drug is also a consideration in transdermal therapy. The maximum dosage that can be absorbed on the inside pinna of a cat is approximately 25 milligrams due to limited surface area.[14] Larger dosages are not good candidates for transdermal delivery. Generally, drugs that can be considered for transdermal administration are those that meet the criteria above and have a wide margin of safety and objective monitoring parameters. They are also more often effective in chronic therapy versus acute therapy when it is important to rapidly achieve therapeutic blood levels. Drugs that cannot be recommended for transdermal administration include, but are not limited to, those that are locally irritating to the pinna, toxic to humans or other pets in the household, or have a narrow therapeutic index.

Adverse events can also occur in pets whose owners are undergoing compounded transdermal therapy. Canine alopecia secondary to human topical hormone replacement therapy has been documented in the scientific literature and reported clinically.[15] Compounding antibiotics for transdermal delivery is also not recommended because of the potential for developing resistance due to unreliable blood drug levels. Prodrugs that must be activated by gut enzymes cannot be applied transdermally, since they bypass the gastrointestinal tract. The transdermal route of drug delivery provides for several advantages including owner compliance, patient tolerance, ease of administration and most importantly the ability to bypass first-pass metabolism by the liver.[13,16] However, the skin is also capable of metabolizing drugs.

Compounding by the Veterinarian and Pharmacist: Roles and Responsibilities

It is the responsibility of the veterinarian, as the prescriber, to determine the appropriate drug therapy and dosage. When a compounded medication is needed, the prescribing veterinarian must then decide whether to compound the medication in the clinic or seek the services of a compounding pharmacist. In making this decision, veterinarians should consider whether they have adequate training and experience, appropriate equipment and an adequate facility for compounding, and whether they are covered by their liability insurance carrier should there be a problem with the compound that causes harm to the patient. If the veterinarian decides to prescribe or outsource the medication, he/she should use care in choosing a compounding pharmacy. Veterinarians should ask the following questions:

1. **Is the compounding pharmacy accredited by the Pharmaceutical Compounding Accreditation Board (PCAB)?** Accreditation by this body indicates that the pharmacy has successfully completed an inspection by an independent non-profit organization and meets nationally accepted standards for quality assurance, licensure, and staffing. The accredited pharmacy must demonstrate compliance with USP Standards for Compounding (see section titled "What Is USP?").
   If the pharmacy is not PCAB accredited, additional questions should be asked:
   i. **Does the pharmacy have the appropriate licensure in the state where the medication is to be shipped?** Some states also require that the pharmacy staff include a pharmacist licensed in the state where the medication is to be shipped.
   ii. **Does the pharmacy comply with USP guidelines for assigning beyond-use dates?** (See section titled "What Is USP?")
   iii. **Does the pharmacy provide documentation to support any beyond-use date that exceeds USP guidelines?**
2. **Is there a pharmacist on staff that has specific training in veterinary pharmacy?** This question is very important, since compounds designed for human patients may not be safe for use in pets. Some of the organizations that offer training in veterinary pharmacy and/or veterinary compounding are as follows: Society of Veterinary Hospital Pharmacists, American College of Veterinary Pharmacists, International Academy of Compounding Pharmacists, and Professional Compounding Centers of America.

What Is USP?

Primary areas of concern for veterinarians who prescribe compounded medications are formulation, purity and stability. Veterinarians may hear pharmacists cite USP standards when addressing various recommendations or requirements (both legal and ethical) regarding compounded medications, such as

quality control issues or assigning beyond-use dates. The United States Pharmacopeia (USP) is a compendium legally recognized by the Federal Food, Drug, and Cosmetic Act, that contains standards for drugs, including determination of strength, quality and purity. It is published by the United States Pharmacopeial Convention and revised periodically. The compendium also contains standards for compounding sterile (USP <797>) and non-sterile (USP <795>) medications.[12,17] It contains compounded preparations monographs that include formulas (ingredients and quantities), specific directions to correctly compound the particular preparation, packaging and storage information, labeling information, pH, beyond-use dates based on stability studies, and detailed assays (majority of monographs).

Beyond-use dates are an important consideration when compounded medications are prescribed, especially oral liquids and injections. The USP has published guidelines for both sterile and non-sterile compounded medications (see section on Guidelines for Assigning Beyond-Use Dates for Compounded Preparations). Veterinarians should ask compounding pharmacies for documentation to support beyond-use dates that exceed USP guidelines.

In the U.S., compounding is regulated primarily at the state level through the state boards of pharmacy, and most states now include USP guidelines in their pharmacy practice acts, making the standards legally binding in those states.

Guidelines for Assigning Beyond-Use Dates for Compounded Preparations

The USP has developed guidelines for assigning beyond-use dates to compounded preparations. The term "expiration date" is the date beyond which a commercial product should not be used and is assigned by the manufacturer based on analytical testing and defined storage conditions. On the other hand, a "beyond-use date" is the date after which a compounded preparation should not be used and is determined from the date the preparation is compounded. It should be based either on stability information that is applicable to a specific drug formulation or on USP guidelines in the absence of chemical and physical stability data for a specific formulation. See table below.

COMPOUND CLASS	BEYOND-USE-DATING AND STORAGE
Non-sterile, nonaqueous formulations	180 days, controlled room temperature (20-25° C)
Non-sterile, water-containing oral formulations	14 days, controlled cold temperature (2-8° C)
Non-sterile water-containing topical/dermal, mucosal liquids and semi-solid formulations	30 days, controlled room temperature
Sterile compounds* prepared from sterile ingredients	48 hours controlled room temperature, 14 days controlled cold temperature, 45 days frozen (<–10° C)
Sterile compounds* prepared from non-sterile ingredients	24 hours controlled room temperature, 3 days controlled cold temperature, 45 days frozen

*Sterile compounds include the following: Compounded biologics, diagnostics, drugs, nutrients, and radiopharmaceuticals, including but not limited to the following dosage forms that must be sterile when they are administered to patients: aqueous bronchial and nasal inhalations, baths and soaks for live organs and tissues, injections (e.g., colloidal dispersions, emulsions, solutions, and suspensions), irrigations for wounds and body cavities, ophthalmic drops and ointments, and tissue implants.

United States Pharmacopeia General Chapter <795>: Pharmaceutical Compounding—Non-sterile Preparations, USP37/NF32, 2014; United States Pharmacopeia General Chapter <797>: Pharmaceutical Compounding—Sterile Preparations, USP37/NF32, 2014.[12,17]

The compounding of sterile preparations (including ophthalmic preparations, injections) requires strict adherence to the provisions of *USP <797> Pharmaceutical Compounding—Sterile Preparations*.[17] This form of compounding carries a much higher risk for causing harm to the patient if the preparation is contaminated. For sterile compounds assigned beyond-use dating longer than those indicated by USP <797> standards, the pharmacy must conduct its own sterility testing based on sample size requirements defined in *USP Chapter <71> Sterility Tests* using commercially available media.[18] These sterile compounds are quarantined for 14 days while awaiting test results. If a test result is positive, the sample is sent to the microbiology laboratory for identification and speciation of contaminants.

CHAPTER 169

Adverse Drug Reactions

Wayne Stanley Schwark

Client Information Sheet: Adverse Drug Reactions

Overview

Drugs manufactured by pharmaceutical companies are submitted to regulatory agencies for human or veterinary use approval. To gain such approval, every drug must satisfy two key criteria: be efficacious and lack toxicity. Initial studies in the approval process are usually based on experimental protocols or clinical trials on relatively limited numbers of individuals. Following approval, when the drug is being used in huge numbers of individuals, unexpected adverse events not detected during the approval process may become apparent. These adverse events are of two major types: (1) the drug may lack effectiveness in a subset of patients or (2) unpredicted and serious toxic events may be observed. While any drug may have undesirable (or desirable) side effects, the "unexpected toxic effects" are worse than those associated with predictable unwanted actions. For the purposes of this chapter, adverse drug reactions (ADRs) and drug toxicity will be considered synonymous.

In the United States, the Center for Veterinary Medicine (CVM), a division of the Food and Drug Administration, has been compiling adverse drug events submitted by veterinarians, drug manufacturers and animal owners since 1987. This process, whereby drugs are monitored in order to detect, assess, understand and hopefully prevent adverse drug effects is called pharmacovigilance.[1,2] The online resource extends beyond those drugs specifically approved for use in dogs and cats and includes drugs manufactured for people that are used in an extra-label manner and drugs made by compounding pharmacies which have not gone through the approval process.

Limitations of the Reporting System

While the data generated by the CVM program are an excellent resource, there are several difficulties in analyzing the information. It must be emphasized that whenever an adverse experience is reported with a drug, there is no absolute proof that the drug was the causative agent. Multiple reports of a similar array of ADRs provide more credible evidence of a cause-effect relationship. Furthermore, there is no indication of the total number of animals treated with any drug listed. Thus, drugs which are more widely employed will generate a greater incidence of adverse effects based simply on their popularity. There is no information on the underlying disease state being treated or the concomitant use of other drugs which may contribute, through drug interaction or some other manner, to the adverse event. For example, if glucocorticoids were used concurrently with non-steroidal anti-inflammatory drugs (NSAIDs), there would be an increased likelihood of gastrointestinal (GI) toxicosis.

Lack of Efficacy as an Adverse Drug Reaction/Event

Ineffectiveness of a drug in producing the clinical benefit for which it was originally approved constitutes an adverse outcome. Ineffectiveness was cited as the most common (11% of dogs; 10% of cats) negative outcome in the CVM reporting system (Figure 169-1).[3] There are numerous reasons for a drug to "lack efficacy," and some of the more common are discussed here. If a condition was misdiagnosed or inappropriately investigated, the drug may have no benefit. Thus, mycoplasma pneumonia would not be affected by beta-lactam antibacterials since mycoplasma lack the cell wall-active site of penicillins and cephalosporins. However, appropriate use may still result in suboptimal clinical outcomes. The condition being treated may

simply have progressed to the extent that no drug will have beneficial effects. Alternatively, adequate drug quantities may not have been administered as, for example in cats, oral drugs are often difficult to administer and inability to administer a drug will preclude beneficial effects. An appropriate chemotherapeutic agent (e.g., antibacterials) may fail to produce the desired effect because of target organism resistance, an increasingly worrisome issue. Some patients develop a tolerance related to receptor down-regulation to some drugs, as with chronic use of beta-adrenergic agonists in feline asthma. If drug dosage remains unchanged, this will lead to diminished drug effect. Pharmacokinetic factors such as impaired absorption (e.g., an orally administered drug undergoing rapid gastrointestinal transit and decreased absorption due to diarrhea), increased elimination rate (e.g., of a hepatically biotransformed drug in an epileptic dog receiving chronic phenobarbital therapy leading to enzyme induction), interactions with concurrently administered drugs (e.g., sucralfate hinders enrofloxacin absorption from the gut) or pathological or physiological barriers for drug access into abscesses, prostate, brain, eye, etc. may result in insufficient concentrations of a drug being delivered to the desired site.

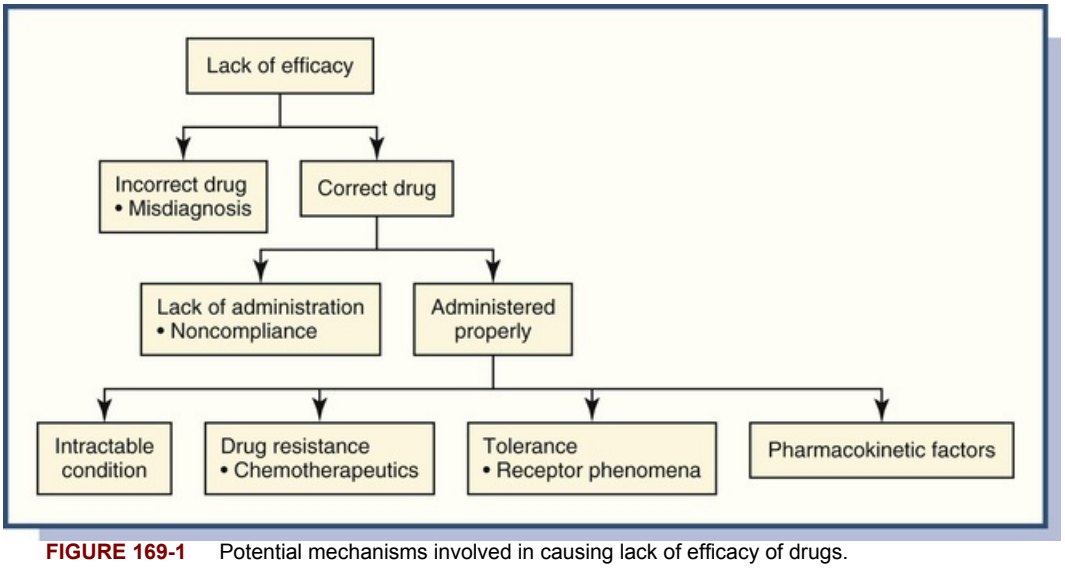

FIGURE 169-1 Potential mechanisms involved in causing lack of efficacy of drugs.

Toxicosis as an Adverse Drug Reaction (ADR)/Event

Overview and Types of ADRs

Toxic ADRs are by far the most common report on the CVM website. The adverse effect may be associated with the drug itself, vehicle-related or due to compounding errors with reformulated drugs (Figure 169-2).[4] Dose-dependent reactions ("Type A") are characterized by an exaggerated expected drug effect and are more likely with low therapeutic index drugs. They may of a physiological (e.g., hypotension with phenothiazine tranquilizers) or a pathological (organ/tissue damage) nature. Drugs with high inherent ADRs (e.g., antineoplastic agents) may not necessarily be reported to regulatory agencies since this is an expected consequence of their mechanism of action. Type B (or bizarre) ADRs, subclassified as being of an idiosyncratic or allergic nature, are unexpected, generally not dose-dependent and initially of unknown mechanism. The cause may become unraveled with further investigation and some are eventually shown to be Type A with a pharmacogenetic origin, e.g., dose-dependent acetaminophen hepatotoxicosis or enrofloxacin-induced blindness in cats.[5,6] Type B ADRs may be catastrophic, causing death, teratogenesis or carcinogenesis.

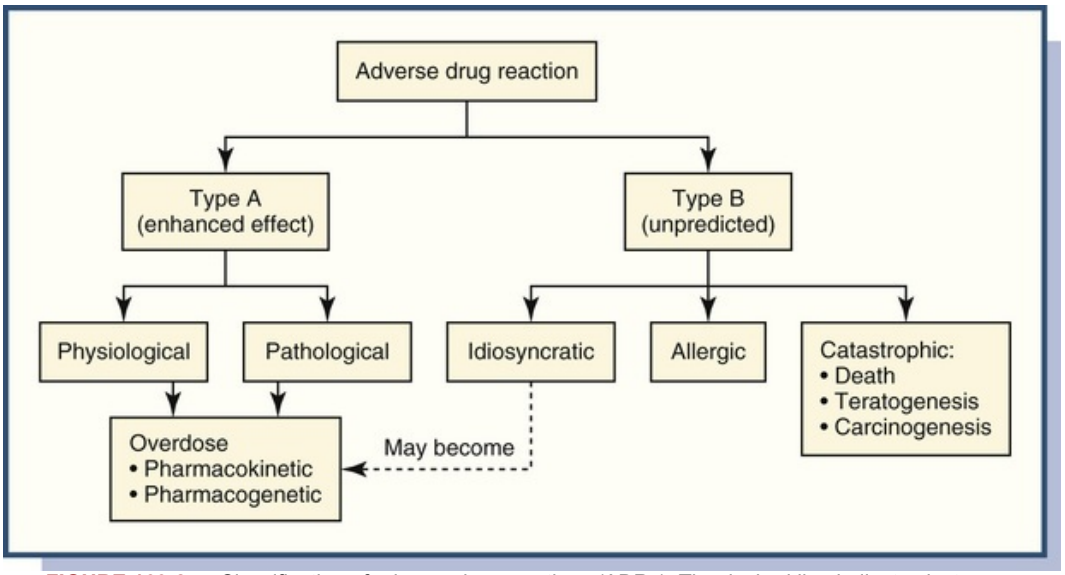

FIGURE 169-2 Classification of adverse drug reactions (ADRs). The dashed line indicates instances where idiosyncratic reactions may eventually be shown to be of a pharmacokinetic/pharmacogenetic nature.

Subclasses of Type A ADRs include those which are delayed in onset (e.g., secondary cancers long after initial chemotherapy for a malignancy) or occur only after withdrawal of a drug following a course of therapy (e.g., iatrogenic hypocortisolism after abrupt cessation of long-term glucocorticoid treatment). Another subclass are toxicoses related to exaggerated drug effects, due to accidental overdose or a reflection of pharmacokinetic anomalies which lead to accumulation of toxic amounts in a tissue. Since liver and kidney are exposed to circulating drugs or their metabolites at greatest levels, these organs are common sites of Type A toxicosis.

Species, Breed, Drug Interaction ADRs

Species or breed differences in drug metabolism can result in enhanced drug effect (e.g., deficient phase 1 metabolism in sight hounds; low glucuronidation capacity in cats). Dysfunction of a key organ involved in drug elimination (liver, kidney) can lead to accumulation of toxic drug levels and warrants dosage adjustment or use of an alternative less reliant on these routes of elimination.[3] Drug interactions, such as one drug inhibiting elimination of a second potentially toxic drug (e.g., enrofloxacin inhibition of theophylline metabolism) is a common cause of toxicosis and becomes more likely as more drugs are given to any patient.[7] Genetic lack of ABCB1 (MDR-1) transporters that prevent exit of drugs from tissue (such as the macrocyclic lactone antiparasitics from the central nervous system) may be a pharmacokinetic/pharmacogenetic anomaly in specific dog breeds (Collie; Table 169-1).[8] Enhanced absorption of phosphate enemas in cats compared to larger species can lead to profound systemic toxicosis, an example of species-specific concerns. Obesity or lean body conformation may affect the volume of distribution or another pharmacokinetic parameter which could lead to over- or underdosing.

TABLE 169-1

Selected Examples of Drugs with Adverse Effects on Different Organ Systems in Dogs and Cats, Particularly Those with Species Predilections

ORGAN SYSTEM/SITUATION	DRUG	TOXIC EFFECTS
Liver	Acetaminophen Phenobarbital (dog) Diazepam (cat)	Hepatocellular necrosis, cirrhosis
Kidney	Aminoglycoside antibiotics	Tubular necrosis
Central nervous system	Avermectin antiparasitics (dog breeds)	CNS depression

	Metronidazole	Seizures, vestibular signs
	Pyrethroid insecticides (cat)	Hyperactivity, seizures
Respiratory	Potassium bromide (cat)	Lower airway disease
	Cisplatin (cat)	Pulmonary edema
Cardiovascular	Anthracycline antineoplastics	Congestive heart failure
Gastrointestinal	NSAIDs	Gastrointestinal ulceration
	Doxycycline (cats, small dogs)	Esophageal strictures
	Anticancer drugs	Gastroenteritis
Skin	Glucocorticoids (dogs)	Bilateral alopecia
Ocular	Sulfonamide antimicrobials (dogs)	Keratoconjunctivitis sicca
Otic	Aminoglycoside antibiotics (dogs)	Deafness; vestibular damage
Hematological	Anticancer drugs Chloramphenicol (cats)	Bone marrow suppression
	Acetaminophen (cats)	Methemoglobinemia
Perinatal	Tetracycline antibiotics	Tooth discoloration/damage
	Fluoroquinolone antimicrobials (dogs)	Arthropathy

Death associated with drug use is the "ultimate toxic consequence." The CVM reporting system indicates a high rate of death associated with oral NSAID use in dogs, possibly a consequence of the GI toxicosis caused by this group of drugs.[2] In cats, the highest death rates were associated with agents used for general anesthesia, attributable to the precarious clinical situations in which these drugs are often employed. Teratogenesis is a rarely reported toxicosis. Suspected or known teratogens are extensively documented in a variety of veterinary resources.[9,10] Griseofulvin, perhaps the most widely recognized teratogen in cats, was not listed as a cause of a single birth defect in the CVM compilation.[2] Mutagenesis and subsequent carcinogenesis following chemotherapy with cytotoxic agents for cancer has been documented in people.[11] There is a paucity of such information in animals, perhaps because of the relatively recent introduction of cancer chemotherapy in dogs and cats. Genotoxicosis has been demonstrated to follow administration of clinically used doses of non-anticancer drugs such as metronidazole. The long-term implications of these concerns are not known.[12]

Organ System ADRs

Extensive compilations of ADRs (many of which were originally classified as idiopathic and with further investigation were shown to be a type A/exaggerated effect) in dogs and cats are available.[9,10,13] Table 169-1 summarizes the widely recognized ADRs in different organ systems with emphasis on those with species predilections. The precise pathogenesis of some ADRs is well-established (e.g., acetaminophen hepatotoxicosis) while others remain obscure (e.g., fluoroquinolone-induced arthropathy in puppies).[14,15] Certain ADRs result in cell damage/death (acetaminophen hepatotoxicosis; aminoglycoside nephrotoxicosis) whereas others cause a readily reversible, quasi-physiological adverse event (ivermectin toxicosis in Collies and other breeds; neurotoxicoses due to metronidazole in dogs and cats or pyrethroid insecticides in cats). Contributory factors may play a role in the development of ADRs. Dehydration and decreased renal blood flow enhance the nephrotoxicosis associated with aminoglycosides and NSAIDs. Increased access to the inner ear of dogs with tympanic membrane rupture increases the likelihood of deafness and vestibular side effects of aminoglycoside-containing otic preparations. The regenerative capacity of the site of a cytotoxic ADR will affect the long-term consequences. Proximal tubular lesions associated with the aminoglycosides or mild hepatocellular insults are usually reversible following withdrawal of the provoking drug. In contrast, retinopathy and blindness associated with fluoroquinolones in cats or tooth damage due to perinatal exposure to tetracycline antibiotics are more likely to be permanent.

Allergic and Hypersensitivity ADRs

Allergic drug reactions are not dosage-related and usually require previous drug exposure. An exception is a

pseudoallergenic/anaphylactoid drug reaction where initial administration may provoke release of mast cell mediators (e.g., histamine) that produce acute anaphylactic-like reactions such as bronchoconstriction and/or hypotension. This is more likely with rapid IV administration of a drug such as morphine. The classical system of Gell and Coombs remains the most widely accepted categorization of drug- (and other allergen) induced hypersensitivity reactions: (1) anaphylaxis; (2) hematological manifestations such as hemolysis or bone marrow damage leading to agranulocytosis and/or thrombocytopenia; (3) antibody mediated; (4) cell-mediated immune damage in tissues such as the skin (skin eruptions, dermatitis, epidermal necrolysis), liver (hepatitis), kidney (glomerulonephritis), vascular sites and articular surfaces. Treatment options for type 1 hypersensitivities (epinephrine, antihistamines, glucocorticoids) are well-established (see ch. 137) whereas those involving types 2, 3, and 4 rely on immune-modulating drugs and supportive measures.

Well-documented examples of drug-induced hypersensitivities in dogs and cats include those involving beta-lactam and sulfonamide antimicrobials, particularly the latter in dogs.[16] The sulfa moiety found in numerous drugs (e.g., antimicrobials, NSAIDs [deracoxib], diuretics [furosemide], drugs for colitis [sulfasalazine], carbonic anhydrase inhibiting antiglaucoma drugs [dichlorphenamide]) preclude their use in pets known to be sensitized to sulfa antimicrobials. There may be cross reactivity between different beta-lactam classes (penicillins, cephalosporins, carbapenems). Documented evidence of hypersensitivity to many others classes of drugs is available for people but not usually for animals. Skin tests or recently developed *in vitro* immunological tests may help to predict the likelihood of allergic ADRs.[16-18]

ADRs in Humans Associated with Veterinary Drugs

The CVM reporting system compiles data on toxic effects associated with use of drugs in veterinary personnel or clients administering drugs to their animals (Table 169-2). Presented data were confined to those drugs where there were at least 100 reports of an adverse effect per drug/route. Exposures were most commonly by the topical (skin) or parenteral (accidental injection) routes. Other reported routes of exposure were orally (accidental/self-medication?—see clomipramine), ophthalmic exposure, or inhalation of volatile drugs. Topical exposure to antiparasitic drugs was by far the most commonly reported route associated with adverse effects. Tilmicosin, a large animal antibiotic with potential for serious toxicosis, including death, in people after accidental self-injection, generated many reports of adverse reactions although none of these was fatal. Preventing exposure of people to any drug administered to animals is critically important and must be explicitly explained, especially when drugs have the potential for profound human toxicosis such as chloramphenicol (rare aplastic anemia in people), misoprostol (abortion in pregnant women) and cytotoxic antineoplastic drugs (mutagenesis/carcinogenesis; teratogenesis).

TABLE 169-2

Veterinary Drugs Commonly Involved in Causing Adverse Effects in Humans Following Inadvertent Exposure (ADRs)

DRUG CLASS	DRUG	ROUTE	MOST COMMON ADVERSE EFFECT (% OF TOTAL ADR)
Antibacterial	Ceftiofur	Parenteral	Injection site pain (35)
	Enrofloxacin	Parenteral	Injection site pain (25)
	Tilmicosin	Oral	Taste abnormality (22)
		Parenteral	Injection site pain (16)
		Topical	Taste abnormality (8)
Antiparasitic	Amitraz	Topical	Rash (25)
	Doramectin	Topical	Nausea (6)
	Imidacloprid/moxidectin	Topical	Nausea (6)
	Ivermectin	Topical	Nausea (8)
	Milbemycin	Oral	Nausea (28)
	Moxidectin	Topical	Nausea (7)

	Selamectin	Topical	Rash (29)
Behavioral	Clomipramine	Oral	Depression/lethargy (33)
Combination	Dexamethasone/neomycin/thiabendazole	Ophthalmic	Eye irritation (59)
Hormone	Altrenogest	Topical	Abnormal menses (20)
	Bovine somatotropin	Parenteral	Injection site pain (26)
NSAID	Carprofen	Ophthalmic	Eye irritation (46)

Based on CVM reports of over 100 ADR per drug/route.

ADR, Adverse drug reaction; *NSAID*, non-steroidal anti-inflammatory drug.

Prevention and Treatment of ADRs

Diligent observation of animals for any ADR once starting a treatment protocol is key to prevention and management. Potential side effects/toxicoses included on package inserts are important information to share with clients if drugs are administered on an outpatient basis. This information may be less readily available with newly released drugs, since novel adverse effects or drug interactions may only become apparent with use. Prophylactic measures (e.g., GI protective drugs in conjunction with NSAID therapy; antinausea medications during cancer chemotherapy; diuresis to allay bladder toxicosis associated with cyclophosphamide) should be considered whenever ADRs are expected. Use of such interventions may not be as readily available or established in dogs and cats as in people (e.g., use of dexrazoxane to prevent doxorubicin cardiotoxicosis).[19]

Investigation of precipitating causes for an ADR may unravel contributing factors, especially with Type A reactions. Special attention to liver and kidney function is warranted, since these organs most dramatically affect pharmacokinetics. Liver or kidney dysfunction could result in drug accumulation to toxic levels. Dose adjustment or elimination of precipitating factors may be sufficient to prevent perpetuation of the toxicosis. If necessary, a drug may be discontinued and substituted with an alternative drug. Particularly in the case of allergic reactions, care must be taken to opt for drugs without the offending chemical moiety.

Nutritional Assessment

Kathryn E. Michel

Client Information Sheets:
Nutritional Assessment of Cats
Nutritional Assessment of Dogs

The purpose of nutritionally assessing a patient is to allow the clinician to answer the question, "Is intervention for this patient necessary?" and to aid the clinician in selecting the most appropriate nutritional intervention for that patient. This simple and rapid process involves evaluating both subjective and objective information regarding the patient, the patient's diet and the patient's feeding management and environment.[1] In addition to aiding in the selection of a suitable diet and feeding management for the patient, nutritional assessment will also help the clinician to anticipate potential problems or complications and to devise strategies to avoid or monitor such developments.

Patient Assessment

In addition to signalment (including life stage and neuter status) and any previous or ongoing medical conditions (including medications), evaluation of body condition is a chief consideration in the assessment of the patient. Although some sophisticated techniques are currently being used in human patients or in a research setting (e.g., multiple-frequency bioelectrical impedance, dual-energy radiographic absorptiometry [DEXA]), they have either not been sufficiently validated in companion animals or do not lend themselves to a clinical setting because of logistic considerations or expense. Body condition scoring (Figures 170-1 and 170-2; Video 170-1) although subjective, is simple to learn, requires no special equipment, and has been shown to be repeatable and consistent among multiple observers.[2] The body condition scoring systems that have been published for companion animals are principally based on characterization of body silhouette and palpation of body fat (see ch. 2). These systems are useful, particularly for identification of patients that have an overweight body condition; however, they may misclassify some malnourished patients. It is important to recognize that catabolism of lean body tissue can occur very rapidly and may account for a disproportionate amount of the body mass lost in sick patients. Although the purpose of adipose tissue is to serve as an energy reserve, no analogous reserve of endogenous protein exists. Because all endogenous protein is serving some function, continuous catabolism will eventually have deleterious consequences for the patient. Therefore, the process of body condition assessment should include not only the standard evaluation of body silhouette and evaluation of adipose tissue as an assessment of energy reserves but also a separate evaluation of muscle mass (i.e., a muscle condition score) as a subjective means of assessing lean tissue status (Video 170-2). This can be accomplished by palpation of skeletal muscle over the axial skeleton and other bony prominences (see also ch. 177).[3]

FIGURE 170-1 Body condition scoring for a dog. (From German A, Holden SL, Morris PJ, et al: Comparison of a bioimpedance monitor with dual-energy x-ray absorptiometry for noninvasive estimation of percentage body fat in dogs. *Am J Vet Res* 71:393-398, 2010; Jeusette I, Greco D, Aquino F, et al: Effect of breed on body composition and comparison between various methods to estimate body composition in dogs. *Res Vet Sci* 88:227-232, 2010; Kealy RD, Lawler DF, Ballam JM, et al: Effects of diet restriction on life span and age-related changes in dogs. *J Am Vet Med Assoc* 220:1315-1320, 2002; Laflamme DP: Development and validation of a body condition score system for dogs. *Canine Pract* 22:10-15, 1997; Global Nutrition Committee Toolkit provided courtesy of the World Small Animal Veterinary Association.)

FIGURE 170-2 Body condition scoring for a cat. Other aspects of the physical examination of a patient that should be taken into consideration include haircoat quality and skin condition (see ch. 10), dental abnormalities or disease (see ch. 272), evidence of peripheral edema or ascites (which may indicate hypoproteinemia; see ch. 17 and 18), and clinical signs that may indicate specific micronutrient deficiencies such as neck ventroflexion or tetany (see ch. 21).

Taking a Diet History

The more information that is available about the patient's diet and feeding management, the better the clinician will be able to assess the adequacy of nutrient intake, the suitability of feeding practices, and the urgency for nutritional intervention. At the core of a dietary history is the careful gathering of information that will give an accurate picture of the foods that the patient consumes. Ideally, the person who is most responsible for feeding the patient should be questioned; however, it is important to find out who else resides in the household or has regular contact with the patient, including other pets. The patient's caregiver should be questioned about all foods that the patient receives (Box 170-1) and asked whether the information reflects what is typical for this pet, whether changes have occurred, and if so, when they happened.

Box 170-1

Information to Be Included in a Diet History

- Commercial pet foods (specific type [brand/formulation/flavor] and daily portion; dry foods should be weighed or measured with an 8-oz [250 mL] measuring cup; canned foods should be measured by can size and portion used)
- Commercial treats (brand, size, and frequency of use)
- Table foods or scraps (detailed information about type of food, portion size, and frequency of use)
- Treats for chewing (e.g., rawhide, pig's ears; size and frequency of use)
- Dietary supplements (brand and daily portion)
- Foods used for medication of the patient (type of food, portion size, and frequency of use)
- Pet's access to garbage
- Pet's ability to scavenge or roam
- Timing, location, and method of feeding and storage of food

In addition to particulars about the patient's diet, the history should also include information regarding appetite, feeding management, documented or perceived changes in bodyweight or condition, level of physical activity, and occurrence of any gastrointestinal (GI) signs. Again, the patient's caregiver should be queried as to whether the information reflects what is typical for this pet or whether (and if so when) changes have occurred. Although it is often the case that a pet owner cannot precisely recount an exact weight change, he or she may have an impression of the period of time over which the change occurred. Rapid weight loss and deterioration in body condition, particularly if associated with muscle wasting, suggests a greater degree of metabolic derangement or reduction in food intake (or both) and greater potential for significant malnutrition than a more gradual loss of weight.

Special Considerations Regarding Assisted Feeding

No definitive tests are available for establishing a patient's nutritional status. However, based on the information gathered from the patient's medical and dietary history and physical examination (as described previously), the clinician should be able to classify broadly the patient as being well nourished, mildly malnourished, or severely malnourished. The decision to intervene with some nutritional support has to balance the anticipated benefits with the potential risks and costs of the proposed intervention. Therefore, the intent of nutritional assessment should not simply be to diagnose inadequate food intake or malnutrition, but

rather to identify patients that are at risk of a poor outcome as a result of their compromised nutritional status. Investigations of human patients have found an increased risk of morbidity and mortality associated with various objective markers of nutritional status including hypoalbuminemia, lymphopenia, and attenuated delayed hypersensitivity reactivity. Other investigators have found that clinical assessment of patients based on a carefully performed history and physical examination, as described previously, has a predictive value similar to that of objective markers of nutritional status such as serum albumin concentration.[4] Furthermore, investigations of the effect of nutritional support on improving clinical outcome suggest that the most significantly malnourished patients are the most likely to show benefit from nutritional support.

There has been only limited investigation of the prognostic value of nutritional assessment in veterinary patients. Admission serum albumin concentration has been shown to correlate with risk of poor clinical outcome in critically ill dogs, and elevation of serum creatine kinase activity has been found to be associated with anorexia in feline patients.[5,6] To date, there have not been any investigations of the prognostic value of subjective nutritional assessment or the impact of nutritional support on clinical outcome in companion animals; however, it is not unreasonable to expect results similar to those found in human patients. Therefore, it is recommended that patients assessed to be significantly malnourished on presentation or that are at risk of becoming significantly malnourished in the course of their illness due to decreased food intake, malassimilation of diet, or metabolic derangement, should be considered candidates for assisted feeding.

Monitoring Nutritional Interventions

Once a dietary recommendation has been made, the patient should be reassessed after an appropriate interval of time. The actual timing of reassessment depends on the severity of the patient's illness and the type of nutritional intervention it has received. One should determine whether the prescribed recommendations are being followed, if problems with diet acceptance or tolerance are seen, if the desired outcomes have been achieved, or if any adverse events associated with the diet or feeding management have occurred. A thorough nutritional assessment at the outset will often identify potential problems or complications and thereby determine what parameters should be monitored in the patient. At the least, bodyweight and condition should be reassessed regularly to ascertain that the patient is maintaining, gaining, or losing weight appropriately.

CHAPTER 171

Neonatal and Pediatric Nutrition

Cecilia Villaverde

Client Information Sheet: Nutrition and Feeding in Growing Animals

Adequate nutrition during the growth period (from birth into adulthood) is very important to ensure an animal achieves the adequate body weight (BW) and size determined by its genetic potential without suffering from nutrient deficiencies or excesses. Puppies and kittens have different nutrient requirements from adults, not only quantitatively but also qualitatively.[1] All essential nutrients are important, but the ones showing more marked differences between growing animals and adults are protein, calcium and phosphorus (required for new tissue formation), and docosahexaenoic acid (DHA). This long chain polyunsaturated omega-3 fatty acid is considered essential for growing animals due to its role in retinal and neural development[2,3] and it has been shown to increase learning performance in puppies.[2,4] Providing DHA directly via marine oils is more efficient than providing its precursor, alpha linolenic acid, due to the limited capacity of dogs and cats to biotransform it.[5]

Nutrient deficiencies and excesses are very rare in puppies and kittens fed commercial diets from reputable manufacturers but can be seen with improperly formulated home-cooked (or raw) diets (see ch. 192); thus, they are not the best choice in growing animals and should be avoided so as to prevent lifelong consequences. Nutrient excesses with implications in skeletal health (calcium, vitamin D, vitamin A) can be seen in growing pets fed a commercial diet plus calcium or other vitamin/mineral supplements. Energy requirements also are higher in growing animals than in adults, especially during the first four months of life,[1] which is why puppy/kitten (or all life-stage) foods usually are more energy dense and digestible than are adult foods. Conversely, pets that are inactive, belong to breeds predisposed to obesity (see ch. 176), or are neutered (see ch. 313) have lower energy requirements than average,[6] which is why the diets have to be carefully evaluated for each patient. Energy requirements expressed as kilocalories of metabolizable energy (ME) per day for puppies can be estimated at 3 times the resting energy requirement (RER; $70 \times BW[kg]^{0.75}$) from weaning to 4 months of age and 2 × RER for the rest of the growth period. For cats, the average daily energy requirement is estimated at 2.5 × RER for the whole period.[7]

Feeding the Newborn

Nursing is the main source of nutrition for newborns. Colostrum (the secretion from the mammary gland during the first few days of lactation) provides nutrients, energy, and passive immunity, and it is very important that newborns receive it within the first 24-72 hours after birth.[8] Adequate nutrition of the mother is very important for sufficient production of quality milk. During lactation, the bitch and queen should eat a nutritionally complete diet formulated and, ideally, one that has undergone feeding trials for reproduction or all life stages. It should have an energy density of at least 4 kilocalories ME per gram of dry matter, which is especially important in large-breed dogs with large litters where the diet can be volume-limiting (i.e., the amount of food the mother would need to consume to have adequate ME is excessive in volume). Large-breed puppy diets usually are not adequate for reproduction due to their reduced energy density. Both food and water have to be available at all times. In newborns, signs like restlessness, continuous vocalization, and failure to grow at an adequate rate signal a maternal health problem, a failure to suckle, or inadequate milk production.[9] BW and body condition score (BCS) should be recorded every 24-48 hours. Puppies should grow 2-4 grams/kg of adult body weight/day and kittens should grow at the very least 10-15 grams per day (average of 100 grams per week).[8-10] If milk production is not adequate, partial or total hand rearing is recommended. Maternal milk is enough as a sole source of nutrients only until weeks 3-4, and solid food

should be introduced at that time (at week 3 for larger breeds and large litters). Despite introducing solids at this time, weaning takes place at weeks 7-9 because early weaning (before week 6) can result in behavioral problems in both species.[11] The bitch's diet, or a growth dry diet, mashed with water (1 part food : 1 part water, by volume) can be used for starting the puppies on solid food at 3-4 weeks of age, although canned puppy/kitten food also is a good choice. For large breeds, using a large-breed puppy diet different from the mother's diet is indicated. Solid food should be introduced slowly and gradually until it is the sole source of nutrition by the time of weaning. Shallow plates can be used so the animals will step on the food and lick their paws, or both the paws and the mouth (never the nose) can be smeared with the gruel. See ch. 315 and 320 for more information on queen and bitch management and newborn care.

Rearing Orphan Puppies and Kittens

Newborns that are orphaned, or whose mother cannot produce enough milk due to disease or to a large litter, have to be completely or partially hand-reared. The mother not only provides nutrition but also warmth, humidity, elimination, sanitation, and security, and all this should be supplied by the care provider as well.[9,10] Regarding nutrition, the best way to rear orphans is to find a foster mother; if this is not possible, milk replacers will be necessary, using either commercial products or home-prepared recipes.[9,12] The latter are not ideal[13] and should be reserved for emergencies, although commercial products are not without problems and a high variability (and deficiencies of nutrients including amino acids, calcium and DHA) has been described among U.S. canine milk replacers.[14] Some of them are very low in energy density (compared to the 1.4 kcal/mL of canine milk). One European study[15] also found issues with nutrient excesses of calcium and vitamin D in canine milk replacers, which could be a risk for fast-growing, large-breed puppies. Thus, it is important to choose a product with at least 1 kcal/mL (reconstituted) and to carefully select the manufacturing company, calling to ask them about their practices and nutritional expertise.[16] Energy requirements of newborn puppies and kittens are estimated at 20-25 kcal/100 g BW.[1] Dividing this by the energy density of the milk replacer will provide the volume per day to provide, divided over several meals per day every 2-4 hours, assuming a stomach capacity of 4 mL/100 g of BW.[8] It is recommended to start slower (50% of energy requirements) the first day to ensure a safer transition. Lower intakes (or formula dilution) also are indicated in cases of diarrhea. Adjustments every 48 hours will be necessary to achieve the desired rate of weight gain. Water requirements are estimated to be 18 mL/100 g body weight/day and additional water should be provided if the milk replacer does not provide it. Strong vital animals can be bottle fed, whereas weak newborns should be tube fed with a 5- to 8-Fr feeding tube,[8,10] placing them horizontally with the head held high to prevent aspiration. Formula should be warmed up to body temperature before use. After feedings, the abdomen should not be overdistended and the perineum has to be massaged with a warm wet cloth or cotton to stimulate elimination. Solid food should be introduced at week 3 as a gruel (puppy/kitten canned or dry food can be mixed with water or with the milk replacer) and slowly increased until weaning. Ch. 320 gives more details about postnatal care.

From Weaning to Adulthood

The puppy/kitten has to be fed a complete and balanced diet formulated for growth (or all life stages). Ideally, the diet is one that has undergone feeding trials, and no nutritional supplements should be part of the regimen. Free-feeding only is indicated for lean puppies and kittens that show an adequate rate of weight gain and a lean BCS (4-5 out of 9). Portion-controlled feeding is recommended for all other animals during growth, particularly for large-breed dogs, obesity-prone breeds, and puppies/kittens that have been neutered. One study[17] found that Labradors kept at a BCS of 4/9 (compared to 6-7/9) from weaning into adulthood and maturity lived longer, with chronic diseases being delayed and appearing at a later age than in their counterparts; thus, keeping puppies lean is extremely important.

Large-breed puppies need special nutritional care[18]: overfeeding can predispose to developmental orthopedic disease and osteoarthritis in adulthood. These dogs should always be fed portion-controlled, aiming for a lean BCS of 4/9, using a specifically formulated, large-breed puppy food. These diets are lower in energy density (to facilitate an adequate energy provision) and also have controlled calcium levels (1-1.5% dry matter), because these puppies have an immature calcium regulation system and are susceptible to excess.[19] Adult foods, a common recommendation for these cases, can result in deficiencies and, depending on the choice, could provide more calcium and energy than desired, and they should not be used in any case.

See ch. 187 for more details on nutrition and orthopedic disease. The puppy/kitten food should be fed until the animal has reached adult body weight and the growth plates have closed (12 months for small- and medium-size dogs and cats; 18-24 months for large- and giant-breed dogs).

Reassessment

A nutritional evaluation (ch. 170) during each visit, and BW and BCS every 2 weeks during the fast growth phase (first six months), are crucial. Evaluation can be done every 3-4 weeks afterwards. BW can be compared to growth curves[20] and BCS should be kept at 4-5/9 (4 for large-breed puppies). The owner has to be taught how to assess BCS[16] and how a healthy lean puppy/kitten should look (see ch. 2 and 170). Adjustments in the calorie allowance can be made by 10% to achieve BW and BCS goals. Switching to a diet that is lower in energy density can help with very hungry puppies or kittens that are not free-fed. Bloodwork is not a very sensitive or specific measure of the nutritional status and both serum biochemistry values (such as calcium, phosphorus, albumin, liver enzymes, lipids) and complete blood cell count can be affected by age in both puppies and kittens,[21,22] and altered values compared to adult reference ranges should not be misconstrued as indicative of malnutrition.

CHAPTER 172

Nutrition for Healthy Adult Dogs

Martha G. Cline

Client Information Sheet: Nutrition for Healthy Adult Dogs

Data from 2012 indicate a population of almost 70 million dogs in approximately 43 million United States households.[1] Caregivers of these dogs generally strive to provide their pets with quality nutrition. Quality nutrition should begin when dogs are young and healthy, not just considered after an illness is identified. "Young adult healthy dogs" can be defined as a group ranging in age from about 1 to 7 years, depending on breed and size. Nutrition should be at the forefront of discussions on preventative medicine between veterinarians and young healthy adult dog caregivers. Nutrition goals during early adulthood should include optimizing health, providing disease prevention, increasing performance, and enhancing longevity.

Dogs as Omnivores

Dogs are members of the order *Carnivora.* The word carnivore describes both the taxonomic group and its feeding behavior. The diverse order *Carnivora* includes true carnivores such as those in the family *Felidae* and herbivores, such as pandas, in the family *Ailuropodinae.* The dog is in the *Carnivora* family, but its metabolism and nutritional needs approach those of omnivores. Unlike true carnivores, dogs have the capability to synthesize taurine, arachidonic acid, and vitamin A from their metabolic precursors in plants: cysteine, linoleic acid, and beta-carotene, respectively.

Domesticated dogs are also adapted to thrive on a starch-rich diet. Genes that play a role in starch digestion—pancreatic amylase *(AMY2B),* maltase-glucoamulase *(MGAM),* and the sodium/glucose cotransporter *(SGLT1)*—demonstrate changes in expression and activity that favor starch digestion in dogs when compared to wolves.[2] The ability to handle a starch-rich diet may have some breed variability, as demonstrated by a wide variation in *AMY2B* activity amongst dog breeds.[3] Like true carnivores, however, dogs possess metabolic characteristics such as an obligation to conjugate bile acids with taurine and an inability to synthesize vitamin D. Dogs are not simply omnivores, but have developed their own metabolism and nutritional requirements as they evolved.

Meeting Energy Requirements

Energy is supplied by the oxidation of fat, carbohydrate, and protein. The energy needs of adult dogs may be supplied by diets with varying ratios of these three macronutrients. About 80% of food consumed by mature dogs is used to provide their energy needs. The remaining dry matter is used to meet requirements for protein, vitamins, and minerals. Excess energy is disposed of by oxidation to produce adenosine triphosphate or stored in the form of adipose tissue. Mature dogs in energy balance convert all available metabolizable energy (ME) from food into heat. The ME value of a food should be known to calculate the amount of food needed to meet energy requirements (see ch. 170, 173, and 174).

Maintenance and resting energy requirements of adult dogs can be estimated using formulas relating ME requirements to body weight (Box 172-1). Because mature dogs have about fiftyfold range in body weight, and because ME requirements per unit of body weight decrease with body weight, formulas generally include some power function of body weight (e.g., body weight raised to three-fourths power). Resting energy requirement (RER) represents the energy needs of a normally-fed animal at rest in a thermoneutral environment. Various life stage factors can be applied to the RER depending on the activity level and neuter status of an adult dog. Typically, RER × 1.4-1.6 is used to determine adult maintenance energy requirements (MER). Meta-analysis of the MER of adult dogs demonstrated average MERs of 142.8 ± 55.3 kcal/kgBW$^{0.75}$/day

with a suggested allometric equation of 81.5 kcal/kgBW$^{0.93}$/day.[4] The energy requirements of adult dogs in this meta-analysis were impacted by husbandry (highest in racing dogs, then working/hunting dogs, and least in pet and kenneled dogs) and neuter status (decreased in neutered animals versus sexually intact) with no effect of gender. The recommended equation for determining the MER of pet dogs is 62.5 kcal/kgBW$^{0.97}$/day.[4]

Box 172-1

Formulas for Estimating the Energy Requirements (ERs) of Adult Dogs Per Day

Resting ERs (exponential equation): 70 × (BW in kg)$^{0.75}$
Resting ERs (linear equation): 70 × (BW in kg) + 30
This equation is not recommended for use in dogs < 2 kg or > 20 kg as it will overestimate energy requirements.
Maintenance ERs (all dogs): 81.5 × (BW in kg)$^{0.93}$
Applies to racing, working, hunting, kenneled, and pet dogs.
Maintenance ERs (pet dogs only): 62 × (BW in kg)$^{0.97}$
BW, Body weight.

Large variation exists in the prediction interval of MER; therefore, formulas should be used only as starting points when determining MER and dogs should be fed to an ideal body condition.[5] A complete diet history (see ch. 170) together with following the dog's weight and body condition score (BCS) over time will help practitioners accurately determine an individual's MER. These equations can be useful clinically to estimate energy requirements, particularly when a complete diet history is not available to estimate energy intake. This includes recommendations for enteral or parenteral nutrition or making recommendations for either body weight loss or gain.

Macronutrients

Protein and Amino Acids

Protein provides both essential amino acids and nitrogen. Nitrogen is required for synthesis of dispensable amino acids, heme, purines, pyrimidines, etc. Essential and dispensable amino acids are required for protein synthesis and are the precursors for various hormones and neurotransmitters. The crude protein requirement represents the dog's nitrogen requirement. Crude protein is defined as the quantity of nitrogen times 6.25. Protein requirements for healthy dogs have been determined using nitrogen balance and endogenous nitrogen excretion. The National Research Council's (NRC) Nutrient Requirements of Dogs and Cats minimum requirement for crude protein in adult dogs is 2.62 g/kgBW$^{0.75}$ or 20 g per 1000 kcal and recommended allowance is 3.82 g/kgBW$^{0.75}$ or 25 g per 1000 kcal (Table 172-1).[6] Minimum protein recommendations by the Association of American Feed Control Officials (AAFCO; 51.4 g per 1000 kcal) are, in part, based on this information and account for changes in processing that can alter protein digestibility or bioavailability.[7] The NRC and AAFCO also set minimum recommendations for amino acids. After the amino acid requirement is met, additional protein is deaminated by the liver. Ketoacids are used for energy or stored as fat or glycogen. By-products of protein catabolism are excreted by the kidneys. The estimated percentage ME to define low, moderate, and high protein diet when comparing commercial pet foods for a dog is provided in Table 172-1.

TABLE 172-1

Comparison of Protein and Fat Levels in Commercial Dog Foods (% Metabolizable Energy [ME])

	NRC MINIMAL REQUIREMENTS	NRC RECOMMENDED REQUIREMENTS	AAFCO MINIMUM REQUIREMENTS	ULTRA-LOW	LOW	MODERATE	HIGH
Crude Protein	7	9	18		<20	20-30	>30

Total Fat		12	12	<20	20-25	25-35	>35

AAFCO, Association of American Feed Control Officials; *NRC*, National Research Council.

%ME calculated using Modified Atwater Factors (3.5 kcal/g protein, 8.5 kcal/g fat).

Essential Fatty Acids

Polyunsaturated fatty acids (PUFAs), linoleic acid (18:2n-6) and alpha-linolenic acid (18:3n-3), must be incorporated into the diets of dogs because dogs lack enzymes to synthesize these fatty acids *de novo*, making them "essential." Dietary fats are not only an excellent source of energy, but they also provide these essential fatty acids (EFAs), depending on the source. EFAs are required to maintain the structure of cell membranes, to allow intestinal absorption of fat-soluble vitamins (A, D, E and K), and they are precursors of eicosanoids including prostaglandins, leukotrienes, and thromboxanes with both paracrine and endocrine activities. The EFA canine requirement is greatest for linoleic acid, whose deficiency results in hyperkeratosis, water loss through the skin, and testicular degeneration. Linoleic acid is incorporated into sphingolipids in the epidermis of the skin, aiding with barrier function and to help maintain skin and coat quality. Dogs need about 1-2% of total calories as linoleic acid to prevent clinical signs of deficiency, though higher levels of total fat in the diet may result in better coat condition. High concentrations of alpha-linolenic acid can be found in some plant oils such as flaxseed oil. Eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3), found in high concentrations in marine oils, have a nutrient requirement in the dog. However, higher dosages of these fatty acids may have a therapeutic effect due to their anti-inflammatory properties.

Fats provide over twice the calories as protein and carbohydrate; therefore, dog food containing high levels of fat will have increased calorie density. Moderate levels of fat generally range from 25-35% ME, with low being <25%, high >35%, and ultra-low fat diets generally considered to contain less than 20% of ME as fat (see Table 172-1). Low-fat diets are recommended for dogs prone to obesity (see ch. 176).

Fiber

While dogs do not have specific nutritional requirements for carbohydrates or fiber, fiber can be added to dog diets to optimize health through various functions, such as promotion of satiety or maintenance of stool quality. Fiber is a poor source of energy; therefore, its inclusion in pet food will decrease energy density, useful when feeding animals prone to obesity. Fiber is expressed on pet food labels as maximum percentage of crude fiber, which reflects the percentage of cellulose (insoluble fiber) in the diet. Total dietary fiber more accurately reflects the fiber content of a pet food by including both soluble and insoluble fibers, with the exception of certain types of fiber such as oligosaccharides (see ch. 190).

Minerals and Vitamins

Adult dogs require the same minerals and vitamins essential to growing puppies (see ch. 171), although the requirements for adult maintenance are sometimes based on our knowledge of nutrient requirements during growth and are less precise. The function and clinical role of minerals and vitamins have been reviewed.[8,9] Vitamin and mineral requirements are published by the NRC and the bioavailability of minerals must be taken into account when formulating diets. The bioavailability of calcium, phosphorus, and magnesium from plant sources is considerably less than that from mineral salts or bone and should be discounted by 50%. Additionally, the bioavailability of copper and zinc from plant sources is also compromised. In contrast, sodium, potassium, and chloride are readily exchangeable, and no adjustments are necessary concerning their source.

Dogs must consume vitamin D as they cannot synthesize it using ultraviolet light.[6,8] The requirement for vitamin E is a function of total PUFA content in a diet. Canine vitamin K requirements are largely met through intestinal synthesis, making dietary supplementation less critical. Choline, although partially synthesized in the liver, is considered an essential vitamin because it supplies labile methyl groups. Choline is a component of the neurotransmitter acetylcholine, promotes lipid transport in the liver as a component of phosphatidylcholine, and plays a role in platelet activation. Deficiency in methyl groups results in accumulation of fat in the liver. Vitamin C is not essential in dog diets as *de novo* synthesis occurs from glucose via the glucuronic acid pathway. There is insufficient evidence to indicate that healthy dogs benefit from additional dietary vitamin C. L-carnitine (a vitamin-like substance), while non-essential, may benefit certain breeds of dogs with a limited capacity to synthesize this nutrient.

General Feeding Recommendations

A complete nutritional assessment should be completed prior to suggesting dietary recommendations (see ch. 170). Following a nutritional assessment, diet selection, energy requirements, feeding amounts, and feeding methods should be determined. Primary goals for feeding a young adult dog include optimizing health, disease prevention, enhancing performance, and promoting longevity. While we expect young adult dogs to be relatively healthy, obesity and periodontal disease commonly begin during this life stage.[10,11] With advancing age, the development of various disease processes such as chronic kidney disease (CKD), osteoarthritis, cancer, and diabetes mellitus may alter various nutritional goals (see ch. 175). When selecting an appropriate diet for one of these conditions, one should always select a diet that has been evaluated for the intended purpose. Calorie restriction to maintain an ideal body weight throughout life is recommended and has been shown to delay onset of clinical signs associated with chronic disease and increase longevity in Labrador Retrievers by nearly two years.[12] Advising owners to feed measured meals using standard measuring devices (8 oz [250 mL] measuring cup) or by weight (grams) rather than *ad libitum* feeding is recommended to aid in the prevention of obesity (see ch. 176).

Guidelines are available to aid pet owners when selecting commercial pet foods (Box 172-2). Selecting a pet food company with a full-time qualified nutritionist is recommended. Appropriate qualifications include PhD in animal nutrition or board certification with either the American College of Veterinary Nutrition (ACVN) or European College of Veterinary Comparative Nutrition (ECVCN). Additionally, a company should be able to provide a complete nutrient profile (typical analysis) of their diets. Ideally, any AAFCO-required nutrient should be provided on an energy basis (grams per 100 kcal or per 1000 kcal or for macronutrients % ME).

Box 172-2

Guidelines for Selecting Commercial Pet Foods

1. Does the pet food company employ qualified nutritionists full-time? Can the company provide their name and qualifications?
2. Who formulated their foods and what are their credentials?
3. Are the diets tested using AAFCO feeding trials or formulated to meet AAFCO nutrient profiles? If the latter is performed, is the diet formulated to meet the nutrient profile or is an analysis of the finished product performed?
4. Where are the diets produced and manufactured?
5. Which specific quality control measures are used to ensure the consistency, quality, and safety of the diet?
6. Can the company provide a complete nutrient analysis beyond the guaranteed analysis of the finished dog or cat food?
7. Does the company perform product research and if so, is this published in peer-reviewed journals?

AAFCO, Association of American Feed Control Officials.

Adapted from World Small Animal Veterinary Association Global Nutrition Committee: Recommendations on selecting pet foods. Available at: http://www.wsava.org/sites/default/files/Recommendations on Selecting Pet Foods.pdf. Accessed January 15, 2015.

Practitioners should advise clients to choose a commercial diet that has passed an AAFCO feeding trial protocol for adult maintenance or all life stages. Diets designated for all life stages are typically higher in fat and more calorie-dense, as they are also intended for growing and reproducing animals. Therefore, not all adult dogs should be fed this type of diet, especially not if they are overweight or prone to obesity. Diets formulated to meet AAFCO requirements meet specific nutrient requirements based on either a calculated nutrient profile or analysis of the finished product. If a diet formulated to meet AAFCO requirements is chosen by a caregiver, determination of nutrients by analysis of the finished product is recommended. This information is typically only available by contacting the manufacturer. Diets formulated to be complete and balanced and demonstrated to be fully adequate in adult dogs through feeding tests are most ideal when selecting a product.

CHAPTER 173

Nutritional Management of the Canine Performance Athlete

Joseph J. Wakshlag

Body Condition and Exercise

Sporting activity often dictates the body condition required for various events. Typically, performance dog owners maintain their dogs at a 4-5/9 body condition score (BCS) when utilizing the 9 point system for evaluation (see ch. 2 and 170).[1] Greyhounds, field trial, hunting and sprinting athletes may benefit from being maintained at a body condition score between 3 and 4/9. Dogs in this condition have ribs easily visualized in shorter-haired dogs, prominent spinous processes and wings of the ilia, but with ample paralumbar musculature that extends between the wings of the ilia so that the sacral spinous processes can be identified, yet do not protrude. Being lean is advantageous for sprinting and intermediate activities (10-30 minutes) that are timed events, for ideal performance (Figure 173-1), and restricted meal feeding particularly on event days. In endurance activities where speed is less important, and there is a greater chance for loss of body condition due to extended activity, a body condition score of 4-5/9 may be ideal to prevent severe weight loss in events such as Foxhound trialing or endurance sled dog racing.[2]

FIGURE 173-1 Appropriate body condition for the canine athlete. Notice the rib cage showing just behind the elbow and the prominent musculature of the shoulder and hind limb. This dog would be considered a 4/9 on the BCS chart.

Energy and Activity

The National Research Council estimates that active pet dogs require roughly 130 × (metabolic body weight [BW] in kg)$^{0.75}$ for maintenance energy requirements (MER, kcal/day). The effects of increasing physical activity have been extensively studied in dogs.[3] Caloric expenditure during exercise is directly related to the distance traveled.[4] For example, agility would be expected to require less caloric expenditure as compared to field trials.

Studies in Greyhounds suggest 150-160 kcals/kg$^{0.75}$ energy expenditure on a daily basis, which is only slightly elevated from active dog maintenance values.[5,6] The distance traveled per day in racing Greyhounds is relatively short. This comparatively high MER for the limited activity may be a reflection of the increased muscle mass of Greyhounds.[6] On the opposite end of the spectrum are endurance sled dogs who expend approximately 1,000 kcals/kg$^{0.75}$ BW per day during long-distance pulling activity, suggesting the average 25 kg sled dog expends approximately 10,000 kilocalories per day.[7,8] This shows the variation in energy need for athletic dogs, making it difficult to adjust feed according to daily activity. Thus, many owners and handlers feed according to body weight and body condition, which is evaluated daily.

Fuel: Fat and Carbohydrate

Exactly which substrates are consumed at which point during exercise is debated, but it is generally thought that initial adenosine triphosphate (ATP) production in muscle is synthesized through a creatine phosphate shuttle for immediate ATP synthesis, but is exhausted within seconds. Glycolysis then kicks in to produce ATP from glucose metabolism to pyruvate, with pyruvate feeding into the citric acid cycle for oxidation of carbohydrate. This is the primary energy source for 30-90 minutes of exercise, particularly if dogs are running hard (50% or greater of their maximal oxygen consumption). Within 10 minutes, the rate of beta-oxidation of fat will increase and reach a threshold within 30 minutes that can supply a majority of the energy needed for exercise. However, this cannot sustain very high levels of activity (above 50% of maximal oxygen consumption) because the beta-oxidation of fat is rate-limiting and can only be oxidized at around 30-40% of the mitochondrial maximal capacity for oxidation (Figure 173-2). Amino acid breakdown is also rate-limiting, but will supply the cells with glucose through gluconeogenesis when glycogen stores have been exhausted.[9-13]

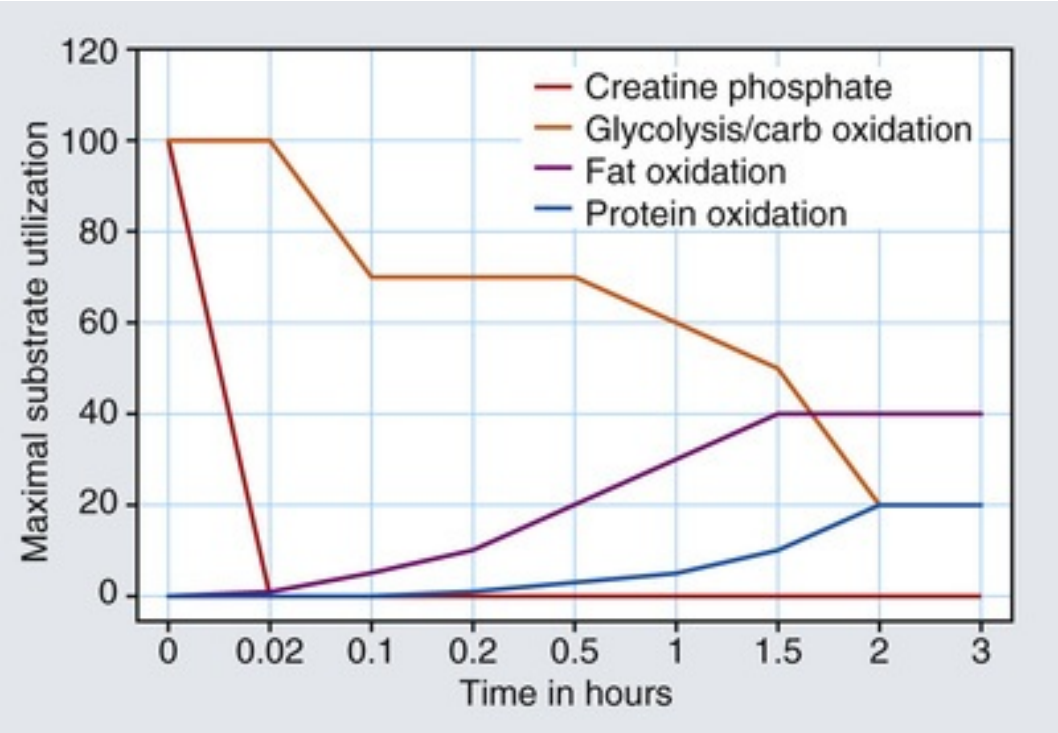

FIGURE 173-2 Substrate utilization and intensity during exercise over an extended period of time.

Carbohydrate oxidation becomes a major source of energy for long-term exercise at greater than 50% of

maximal oxygen consumption (20 minutes to 2 hours) as long as sufficient glycogen is present for glycogenolysis and the rate of conversion of pyruvate to acetyl-CoA is adequate. A recent study in trained endurance dogs suggests that dogs burn glucose at an equal if not greater rate than fat when running at submaximal intensity.[14] Carbohydrate oxidation is the primary fuel for most sprinting and intermediate athletes (less than 20 minutes of exercise) and should not be restricted: up to 50% of the ME as digestible carbohydrate can be utilized successfully in sprinters and 15-30% can be utilized successfully in endurance dogs.[5,6,15]

Fat is a preferred fuel due to the large stores throughout the body; therefore, dietary fat is often seen as a good energy source, with studies suggesting that higher fat and higher protein diets may be advantageous for endurance work.[13,16-20] Diets containing approximately 55 to 70% of ME as fat can provide adequate energy for endurance exercise and this composition is typical of the feed for most endurance athletes.[21,22] Owners and trainers are best advised to introduce fats to the diet slowly, to prevent steatorrhea, which is a common adverse effect from feeding high fat diets too quickly. To get the full benefits of a higher fat ration, it is best to initiate this diet approximately 8-12 weeks before competition to allow for mitochondrial and metabolic adaptation.[23] Excess fat in the diet may require dietary increases in divalent cation nutrients (calcium, iron, zinc, copper and manganese), which may chelate with free fatty acids, thereby reducing their bioavailability.[21]

Fat and Carbohydrates—Special Considerations

Many speculate that fatty acid chain length and saturation affect a variety of issues from inflammation to oxidative stress during exercise, despite very little information regarding optimal dietary fat intakes for canine athletes.[29] Fatty acid composition might also slightly influence detection in scent-trained dogs such as hunting dogs and service dogs. A recent study utilizing corn oil as a source of elevated polyunsaturated fatty acids (linoleic acid) demonstrated slightly improved detection at the lowest scent threshold in scent-trained Labradors.[27] The precise mechanism and magnitude of this effect has not yet been fully elucidated, but elevated polyunsaturated fatty acids may modestly improve performance in dogs that require olfactory acuity as part of their work.

Strategic carbohydrate supplementation can be beneficial for sprinting and intermediate-distance athletes if muscle glycogen is depleted daily, over the course of multiple-day events.[12,30,31] Current recommendations are to provide 1-1.5 grams of maltodextrin supplement for any dog running between five minutes to three hours per day, particularly when expected to perform similarly the following day.

Protein Requirements for the Canine Athlete

There are multiple methods to evaluate dietary protein adequacy, each with its own merits and disadvantages, which are beyond the scope of this chapter. Dietary protein helps maintain muscle integrity and appropriate total protein, albumin and hematocrit. The hematocrit and serum albumin tend to decrease with training and racing, which appears to be a result of an overtraining syndrome[23,24] that may respond in part to increased protein intake. Sled dog studies have postulated that approximately 30% of daily ME (70-80 g protein/Mcal) should come from highly digestible animal-based protein.[22,25] Protein quality and source may also be important, with highly digestible animal based sources being preferable.[26]

Sprinting dogs require less protein for exercise than do endurance athletes, with studies suggesting that 24% of ME may be adequate.[15,25,26] Other working dogs, however, may perform well on lower protein intakes. Scent detection dogs retained normal performance even when fed a high-fat, low-protein diet containing 18% ME.[27] Therefore, the optimal protein requirement for all athletic dogs may be different depending on the intensity of exercise and the specific task. However, there is little detriment associated with a higher protein ration; therefore the recommendation for most athletes is 24% of the ME or above.[21,28]

Electrolytes, Minerals and Vitamins in the Working Canine

As long as a dog is being fed a majority of its calories as a complete and balanced dog food, then electrolyte or mineral deficiencies are unlikely to be a problem. Only in instances where dogs are fed primarily meat and other table foods will there be cause for concern. In fact, one study suggested an increased incidence of gastrointestinal disturbances in dogs when provided a glucose and electrolyte drink.[32] Unlike humans and

horses, dogs cool primarily via panting, which is not associated with the same electrolyte losses as sweating in other species. Therefore, dietary supplements are not necessary, with only extremes such as endurance sled dog racing showing any need for alterations in electrolyte intake, which may be more of a reflection of feeding pattern changes than true need.[33]

Vitamins, if supplied by a complete and balanced pet food, are of little concern since intake is directly correlated to dietary energy needs. Antioxidant vitamins like C and E have received the most attention. Vitamin C is synthesized in dogs through hepatic synthesis from glucose. However, dogs might not synthesize as much as other species.[34] The possibility for limitations in hepatic synthesis combined with observations that serum ascorbic acid concentrations decrease more than 50% after 190 minutes of sled racing have led to suggestions that supplementation may be beneficial.[22] Similarly, vitamin E has been examined in racing sled dogs, with implications of deficiency being associated with performance.[35] Current examination of supplementation of vitamins E and C to racing Greyhounds showed detriment to performance, making any recommendations tenuous at best.[36-39]

Non-Traditional Diets

In the sporting arena more than anywhere else, the feeding of home prepared cooked and raw diets is commonplace. The exact reasons are unclear, but it is often thought that these diets have a higher energy density, since they can often contain more fat, and that digestibility is greater than the average extruded diet.[40,41] Unfortunately, many home prepared rations are not ideally balanced for dogs,[42,43] creating subclinical deficiencies and more importantly, if raw, putting dogs at risk of bacterial or protozoal infection (see ch. 192).[44,45] Though this is not the focus of this chapter, it has already been established by certain governing bodies that certain service dogs cannot be fed raw diets due to the zoonotic risk.[46] For those owners looking for alternatives to traditional kibble and canned diets, a recent study suggests that freeze-dried or pressure-pasteurized foods may be an alternative for those clients, since they rarely test positive for bacterial contaminants.[47]

CHAPTER 174

Nutrition for Healthy Adult Cats

Jennifer Larsen

Client Information Sheet: Nutrition for Healthy Adult Cats

Overview

Cats have unique metabolic and nutritional needs that reflect their evolution as hunters consuming small mammals, birds, reptiles, and insects. Their dietary requirements set them apart from most other species commonly kept as pets. However, precisely defining the optimal intake of every essential nutrient in order to maintain health throughout life is extremely challenging. There is much controversy regarding the "ideal" cat food. Some argue in favor of feeding prey or meat-and-bone-based raw diets. Others recommend feeding only canned (i.e., high-heat-cooked) or dry kibble diets. Regardless, there is little evidence to support the superiority of any particular feeding style. An increasing focus on disease prevention has led to our better appreciating the importance of body condition with an emphasis on obesity prevention. Also, there has been the adoption of feeding management strategies designed to accommodate the needs of specific households and of individual cats.

the Unique Nutritional Physiology of the Healthy Adult Cat

Protein and Specific Amino Acids

Cats have higher dietary protein requirements as compared with dogs, despite similar amino acid needs. Although cats can adapt protein oxidation to manage excess intake, there is limited ability to conserve nitrogen if protein intake is too low.[1] While the amount required is based on protein serving as a source of nitrogen and essential amino acids, it also provides energy. This reliance on glucogenic amino acids as a source of energy may influence the high protein requirement of carnivorous mammals with relatively large, glucose-consuming, brains.[2] Unlike other species, cats require dietary taurine and arginine due to low enzyme activities in those synthetic pathways.

Vitamins

Essential vitamins in cat diets include vitamin D, vitamin A, and niacin. Unlike other species capable of synthesizing vitamin D when the precursor, 7-dehydrocholesterol in skin, is exposed to UV light, a dietary source of vitamin D is essential for cats whose physiology shunts 7-dehydrocholesterol for metabolism to cholesterol.[3] Similarly, cats have a dietary requirement for niacin despite possessing all its necessary synthetic enzymes. The picolinic carboxylase enzyme activity in cats degrades an intermediate in the pathway which would lead to niacin synthesis. Cats also have low conversion efficiency for beta carotene (the plant-based precursor) to be processed to vitamin A. Therefore, the retinol form of vitamin A is required.[4] A dietary source of arachidonic acid is required for cats to reproduce, due to limited activity of the delta-6 desaturase enzyme. Many of the nutritional peculiarities of cats are likely the result of evolutionary adaptations to a carnivorous diet, which lessened the selection pressure to maintain energetically expensive pathways for nutrient synthesis.[5]

Carbohydrate, Fiber, Starch, Sugar

Due to their natural history as hunters, it has been theorized that cats are metabolically inflexible with regard

to the digestion, absorption, and metabolism of dietary carbohydrate. Indeed, specific saccharides, starches, and fibers are not considered nutritionally essential. However, fiber is a beneficial, but often overlooked, component of feline diets (see ch. 190). The potential role of poorly digestible animal tissue as "animal-sourced fiber" in large cats fed only carcasses has been suggested.[6] Digestible carbohydrates are often included in the diets of both dogs and cats as an energy source that allows a decrease in protein content, which may become increasingly important given emerging issues related to environmental concerns and pet food sustainability.[7] Further, there is lack of evidence that consumption of carbohydrate results in adverse effects when supplied in the moderate concentrations typical of commercial pet foods. It has been well documented that cats are able to digest and absorb sugar and starch despite their carnivorous nature. Cats produce several intestinal disaccharidases (including maltase and sucrose) and pancreatic amylase secretion is stimulated by dietary starch.[8-10] Cats have lower amylase activity than dogs, regardless of diet.[9,11] Even so, cats efficiently digest and absorb ground or cooked starch, even when fed at about 30-35% of total energy intake, similar to concentrations found in commercially available diets.[12,13]

In addition to efficient digestion and absorption, healthy adult cats also capably metabolize dietary carbohydrate despite some important physiologic idiosyncrasies. Once absorbed, glucose must be phosphorylated by gluco- or hexokinase prior to entering one of several metabolic pathways, including glycolysis. Cats only produce hepatic hexokinase rather than glucokinase or fructokinase. Interestingly, cats have higher activities of not just hexokinase but of several other glycolytic as well as gluconeogenic enzymes when compared with dogs.[14,15] Hexokinase is inhibited by its primary product, phosphorylated glucose. The limited hepatic uptake of glucose depends on the conversion rate of "trapped" glucose into energy or other compounds. This limit in hexokinase activity, together with the lack of glucokinase and fructokinase, may contribute to urinary losses of monosaccharides when fed in high concentrations (about 20% of energy supplied as sugar).[16,17] However, lower concentrations of carbohydrate (about 13% of energy supplied as sugar) are well accepted and tolerated.[17] Although higher dietary concentrations of glucose or fructose sometimes result in diarrhea, gluco- or fructosuria, blood glucose concentrations are not impacted. Healthy cats do not have persistent hyperglycemia even with an IV glucose bolus.[17,18] Although academically interesting, gluco- or fructosuria is not a clinical problem in healthy cats consuming commercially available diets since they typically do not contain simple sugars. Regardless, insulin response and adaptive enzymatic activity appear to be adequate compensation for the lack of glucokinase under conditions of both typical and supraphysiologic carbohydrate intakes in cats. Overall, in response to varied macronutrient proportions, the cat has the ability to increase glucose or protein oxidation, increase glycogenesis, and increase lipogenesis, which are remarkable given its evolution as a hunting carnivore.[1,19,20]

Determining the Optimal Feline Diet

Overview

The known nutritional needs of cats are summarized by the National Research Council as "minimal requirements" or "adequate intakes" depending on available data, "recommended allowances," and for some nutrients, "safe upper limits."[21] In addition, minimum and, in some instances, maximum concentrations of nutrients for use in commercial cat foods are suggested by the Association of American Feed Control Officials (AAFCO).[22] These Cat Food Nutrient Profiles, guidance for product labeling, and other aspects of pet food manufacturing and marketing as defined in the AAFCO Model Regulations for Pet Food are adopted by many states into official feed control laws.[23] Despite these well-defined resources regarding nutrient needs and the amounts of certain nutrients required in cat foods, exact quantitative information regarding the optimal intake of both micro- and macronutrients for adult cats remains unknown. Many guidelines are extrapolated from data generated using growing kittens, or represent minimal intakes that prevent defined deficiency syndromes rather than characterizing the ideal diet for longevity or other, more global, health parameters.

The Feral Cat Model

Defining the optimal intake of any nutrient in order to maximize both quality and quantity of life is a challenge. The utility of preference studies is thus far limited due to the lack of relevant measurable outcomes. Analysis of natural diets also has limited data, regardless of the known poor health and short lifespan of free-roaming cats. Although longevity data for small wild feline species are lacking, protracted lifespans for these

as well as feral domestic cats are unlikely to approximate those of pet cats. One study demonstrated a high reproductive rate in managed colonies of feral cats but kitten mortality was high, with only 25% surviving to 6 months.[24] Similarly, another study reported a life expectancy <5 years in feral cats due to infection, trauma, and poisoning.[25] Despite these impacts on longevity, the number of free-roaming cats is sustained due to their young age at sexual maturity and reproductive efficiency.[26] The estimated nutritional profile of free-roaming domestic cats has been reported, but association with health and longevity is lacking.[27,28] Since the life expectancy and general health status of most free-roaming cats differs markedly from that desired by most pet owners, it remains unknown if a "natural" approach to feeding cats would support optimal health and longevity. Regardless, avoidance of feeding practices associated with known problems can help promote health and longevity in the pet cat population.

Feeding Management of Cats

Overview, Avoiding Obesity, Effect of Neutering

The most common nutritionally-related disease in pet cats is obesity (see ch. 176). Avoidance of overfeeding is an important goal in feeding healthy cats. Although dietary carbohydrate and the use of dry cat foods have been blamed for increasing obesity risk in cats, the concept has not been supported by epidemiological data or prospective research.[29-32] Rather, dietary fat has clearly been shown to promote overeating that leads to weight gain, likely due to the increased energy density compared to carbohydrate and protein.[31,32] In addition to diet, epidemiological data have demonstrated that neutering is an important risk factor for obesity in cats, especially in males.[33-36] Overweight cats are more likely to suffer from diabetes mellitus, constipation, orthopedic disease, urinary tract disease, hepatic lipidosis, skin disease, and other issues.[29,37,38] As the majority of pet cats have a known risk factor (neuter status) for a disease that is likely to result in potentially significant morbidity (obesity), feeding management strategies aimed at prevention are indicated.

The relationships among food intake, body weight and condition, and energy expenditure after neutering are complex (see ch. 313). It seems clear that cats fed ad libitum after neutering are most likely to gain weight.[39-42] Food continuously available causes greater body weight and body fat percentage after neutering both male and female cats, as compared with cats that have restricted access to food.[43,44] In addition, greater weight gain and body fat accumulation is seen after neutering when fed energy dense diets.[31,32] As such, unrestricted access to food should be actively discouraged for most cats and energy dense foods should be used with caution.

It has been demonstrated that body weight gain can be avoided after neutering provided that food intake is actively limited, although it seems clear that some cats need fairly severe restriction to maintain pre-neutering body weight.[40,45] This underscores the role of food intake and feeding management in cats after neutering. It also supports an individualized approach to determining the necessary amount of restriction. Some cats need a reduction of 30% or more of their pre-neutering dietary intake.[44] Although using diets high in moisture or fiber may be effective in limiting food intake, more active restrictions on food consumption are probably needed.[46,47] Further, given the marked reduction in voluntary activity in queens after neutering, it is possible that encouraging increased activity may help offset the effect of neutering.[44] Thus, less severe food restrictions are required of active cats. In any case, portion-controlled feeding is recommended and regular monitoring of body weight and body condition may be needed to enable adequate and timely adjustments. Weight loss is difficult to achieve and re-gaining lost weight is always a concern.

Maintenance Requirements

Daily energy maintenance requirements of cats, based on absolute body weight, have been reported to be as low as about 30 to as high as about 100 kcal/kg BW.[21] Many factors likely explain these variations. The National Research Council provides different equations for lean versus overweight adult cats which both use metabolic, rather than absolute body weight[21]:

$$\text{Lean cats: } 100\ \text{kcal} \times \text{kg BW}^{0.67}$$

$$\text{Overweight cats: } 130 \text{ kcal} \times \text{kg BW}^{0.4}$$

Many clinical nutritionists use a simpler equation based on a neuter/activity status factor applied to the resting energy requirement (RER) at the current weight[48]:

$$1.0\text{-}1.4 \times \text{RER}$$

where RER = 70 × (current weight in kg)$^{0.75}$. Regardless, any equation used should be seen as a starting point and recommendations for individuals require reassessment and adjustments as needed to maintain an ideal body condition.

Choosing a Commercial Diet

Most cats are fed commercial food with many options for healthy cats encompassing a wide range of prices, marketing approaches, availability, ingredients, and nutritional profiles. This can be a benefit in that there are products to meet the needs and preferences of most cats as well as most owner financial limitations and any philosophical inclinations. However, the wide range of choices can also be overwhelming, confusing and, at times, misleading. The most important information from the pet food label is the nutritional adequacy statement required on pet food labels in states that adopted AAFCO Model Regulations for Pet Food.[22]

The nutritional adequacy statement on the label should state the intended use of the food (species and life stage) and specify whether it carries a complete and balanced claim versus "for intermittent or supplemental feeding only." The label should also disclose how claims are substantiated (passed feeding trials or formulated to contain nutrient concentrations as specified by AAFCO).[22] Neither method of adequacy substantiation is perfect; however, many nutritionists favor the animal feeding trial method as it at least partially accounts for nutrient digestibility and bioavailability and provides proof of adequacy by direct testing *in vivo*. Ideally, commercial pet foods are formulated to meet the AAFCO nutrient profiles by laboratory analysis (not just by calculation) as well as being subjected to and passing appropriate animal feeding trials.

Owner Education

Underestimation of obesity or a general unawareness of body condition is common among cat owners and can contribute to the development of obesity.[35] One study identified owner underestimation of cat body condition as a main variable influencing feline obesity.[30] Owners should be counseled on appropriate body condition for their pet and encouraged to perform regular home body condition scoring.[49,50] Determination of energy needs should be based on prior intake if known; however, the degree of restriction necessary to avoid weight gain is variable and underscores the importance of monitoring and adjustment.

Free feeding is common for cats and, while convenient for many owners, it may contribute to overeating. Free feeding is practiced by about 80% of cat owners, regardless of their pet's body condition and some studies have found no link between feeding practices and the prevalence of obesity.[30,51-54] It is clear that some cats successfully regulate their food intake to maintain an ideal body weight while others tend to overeat and become overweight or obese. In multi-cat households, individual, portion-controlled meal feeding can be an effective, albeit not as convenient, method for ensuring appropriate food intake and body condition.

Collection of diet history information should be done at every veterinary visit and should include not only the main diet used but also amounts and types of any treats and supplements. Monitoring of the pet's body condition score and body weight (see ch. 2), accompanied by any necessary adjustment in the amount and type of food fed, is a critical component in providing recommendations that meet the needs of individual pets. This process starts with a veterinary assessment and should be maintained by both the owner and the veterinary team.[50]

CHAPTER 175

Nutrition in Healthy Geriatric Cats and Dogs

Cecilia Villaverde

Client Information Sheet: Nutrition and Feeding of Senior Pets

Geriatric dogs and cats are an increasing percentage of the pet population in the U.S.[1,2] Older cats can be classified[3] as "mature" from 7 to 10 years of age, "senior" from 11 to 14, and "geriatric" from 14 onwards. For dogs, size affects life span, with smaller breeds living longer than larger breeds.[4] The American Animal Hospital Association's Senior Care Guidelines Task Force[5] has suggested that pets should be considered geriatric when they are in the last 25% of the predicted life span for their species and breed. Aging is a continuum and individuals vary greatly as to their aging process, so any age classification should only be taken as a guide. Larsen and Farcas[6] proposed that an individualized assessment, where aging "milestones" such as joint disease and muscle atrophy are recorded, would be a better measure of aging rather than a cut-off age. This chapter will focus on the nutritional needs of healthy geriatric patients.

Nutrient-Related Changes Associated Wth Aging Pets

Some of the physiological consequences of aging are related to nutrient and energy utilization,[1] since aging can alter gastrointestinal structure and function, which is well described in humans.[7] Canine studies assessing digestibility of macronutrients (and some minerals) show that geriatric dogs have digestion capacities that are similar to those of young adults,[8,9] despite described anatomical[10] and microbiota[11] changes in the gastrointestinal tracts of geriatric dogs (see ch. 274). On the other hand, macronutrient (protein and fat) digestibility is reduced in geriatric cats.[12,13] As for energy, average canine energy requirements decrease with age.[14] Thus, obesity is a main problem in the senior dog population (see ch. 176). However, older dogs also are more likely than adults to be underweight.[15] As for felines, mature cats (>7 years) have decreased energy requirements compared to adults, but geriatric ones (>12-14 years) tend to have increased energy requirements,[16] which can, in part, be related to the lower digestibility of fat and protein and result in undesired weight loss. Average protein requirements also are changed with aging, with an increase in requirements in both dogs[17] and cats.[18] In cats, again, lower protein digestibility can contribute to this increased requirement. Also, lean body mass tends to decrease in older dogs[19] and cats.[20] As for other essential nutrients, such as vitamins and minerals, there are not enough conclusive data to know if these requirements are affected by old age. For this reason, neither the National Research Council[21] nor the Association of American Feed Control Officials has separate, specific requirements for senior pets in their publications addressing nutrient requirements of dogs and cats. Aging changes that are not related to nutrient utilization but that can respond to nutrient modification include brain aging (see ch. 263), joint degeneration (see ch. 187 and 353), and alterations in the immune system (see ch. 194).[1,2,6]

Aging also can result in a change in feeding patterns, sometimes associated with pain secondary to oral or joint problems or to cognitive disorders. Moreover, it has been described in aged people that their sense of taste and smell is altered,[7] which could also happen in our senior patients.

Nutritional Evaluation of the Senior Pet

The goals of feeding geriatric pets are to slow the changes associated with aging, promote well-being and, if at all possible, promote longevity, while keeping a healthy body weight (BW) and body condition score (BCS). Evaluating each patient is critical because not all animals age in the same way. The World Small Animal

Veterinary Association (WSAVA) nutritional guidelines describe how to perform a nutritional evaluation[22] (see ch. 170). Assessment of the patient, diet, and feeding method can identify risk factors that warrant changes in the diet and feeding method. Particularly, for aged patients,[6] it is important to focus on assessing BCS, energy intake, and feeding behavior, ensuring the diet is complete and balanced, and assessing if there are any age-associated alterations that could be addressed with diet, such as muscle atrophy/sarcopenia (see ch. 177), joint disease, cognitive alterations, and changes in palatability of the diet. This assessment will help decide on the feeding plan: how much to feed, the feeding method, and what to feed (choice of diet). In a patient with no known malnutrition risk factors and that is already healthy and lean, changes to the feeding plan might not be necessary. However, if risk factors are present, changes will need to be made to the feeding strategy accordingly.

How Much to Feed

The amount to feed depends on the energy requirement of the pet (maintenance energy requirements, MER). Ideally, MER can be determined from the current energy intake, if the patient's BW is stable. This is sometimes not possible to achieve, due to several reasons such as *ad libitum* feeding, multiple pets, diet variety, and the use of treats. In these cases, MER can be estimated with formulae[21,23,24] (Table 175-1), but the error associated with them is estimated to be 50%[24]; therefore, monitoring and adjusting the energy allowance is necessary. If there is a history of unintended BW loss or the patient has a low BCS, the current energy intake (or the estimated MER) should be increased by 10-20%. If BW does not improve with an increase in energy intake, or the patient won't eat enough, diagnostic tests will be necessary to identify the cause of the problem. Patients that are overweight and otherwise healthy should be considered for a weight loss plan (see ch. 176). Weight management and keeping lean during the pet's lifetime has been associated (in Labrador dogs) with a longer life span and a delay in the appearance of chronic disease, including osteoarthritis.[25] Therefore, keeping lean during growth and adulthood is the most important management strategy to keep a geriatric dog healthy for a longer period of time.

TABLE 175-1

Formulae to Estimate Daily Energy Requirements Adequate for Senior Pets (Expressed as Kilocalories Per Day)

DOGS		CATS	
Inactive pet dogs21	95 × BW0.75	Lean adult cats21	100 × BW0.67
Older active pet dogs21	105 × BW0.75	Obese adult cats21	130 × BW0.4
Obesity-prone adult dogs24	98 × BW0.75	Obesity-prone adult cat24	70 × BW0.75

BW, Body weight (kg).

Once the energy intake has been determined, the daily ration has to be calculated (Figure 175-1). If treats are to be included in the regime, it is recommended that a maximum of 10% of the daily calories be used for unbalanced items (such as treats, table scraps, supplements). In all cases, frequent reassessment and readjustment are necessary. Senior dogs and cats should be weighed at least once a month, using the same scale, to make adjustments up or down by 10%.

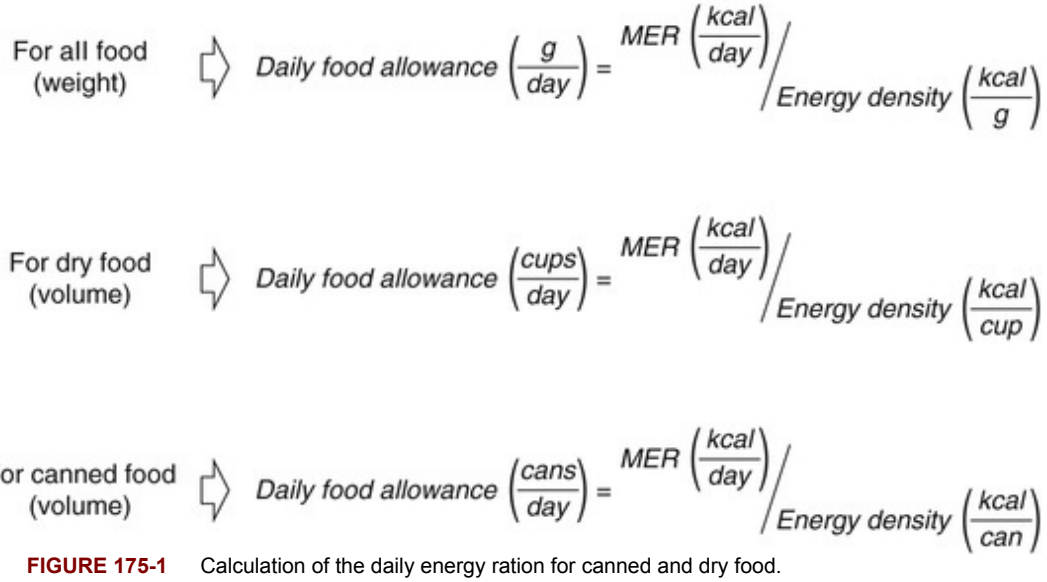

FIGURE 175-1 Calculation of the daily energy ration for canned and dry food.

Feeding Method

Ad libitum feeding, where food is always available, can work well in thin patients and picky eaters. For overweight (or prone to overweight) patients, rationed feeding (where a specific amount of food is fed daily) is the best approach. Diet form also will affect the decision regarding feeding method, since only dry food can be left out all day safely. Rationed feeding can be adequate in most cases, even when weight gain is desired and for picky eaters. This is important in multi-pet households, where different animals have different nutritional needs. Rationed feeding can be done in one or in multiple feedings a day. Multiple feedings have the advantage of both reducing hunger in animals that are energy-restricted and also promoting weight gain in animals that are volume-intolerant or are picky eaters. In thin patients, where the energy allowance should be increased, the options are: feeding *ad libitum*, increasing the volume of each meal, adding one more meal to the schedule, or choosing a more energy-dense diet. The last two are more useful in patients whose intake is volume-limited. Warming the food or using flavor enhancers (such as home-prepared broth) can help bring out the flavor of the food and encourage senior picky eaters to eat (also see ch. 183). In all cases, environmental enrichment, including the feeding method (such as hiding food, using food dispenser toys, etc.), is recommended.[2,6]

Choice of Diet

The diet that is chosen has to be nutritionally complete and be palatable to the specific animal. Senior/mature/geriatric diets are a subset of adult diets because there is no legal definition of what a senior diet is. The nutritional composition of these diets on the market varies widely and reflects the philosophy of each manufacturing company. One study[26] evaluated 37 over-the-counter (OTC) senior canine diets on energy density, protein, fat, fiber, sodium and phosphorus and found huge variations. For this reason, recommending a senior diet for an aging dog or cat is not a useful or precise enough recommendation and the choice of diet has to be tailored to the patient, always considering the current diet. A healthy, lean patient doing well on its current complete adult diet will not necessarily require a diet change. Overweight patients will benefit from therapeutic, nutrient-fortified weight loss diets and a weight loss plan (see ch. 176) while obesity-prone individuals can be either fed less of the current diet or fed an OTC diet higher in fiber and/or lower in fat (thus, lower in energy density). Some senior and light diets will help in the latter case, but the energy density of the particular product of choice has to be compared to the current diet, to ensure the change is made in the correct direction. For thin patients, weight gain can be promoted using diets with higher energy density than the current one (such as kitten/puppy diets, convalescence or performance-type diets, or a variety of OTC adult/senior diets). Regarding nutrient composition, protein is a controversial issue, since there is the mistaken impression that diets higher in protein can cause kidney damage. However, as mentioned above, protein requirements of senior pets are at least as high as those of adults, if not more. Thus,

protein moderation/restriction (less than 20% and 30% protein calories for dogs and cats respectively) provides no benefit and potentially is problematic to senior pets. Appropriate protein content is particularly important in healthy patients showing some degree of muscle mass loss; in such a case, choosing a higher-protein diet than the current one is indicated. If patients have chronic kidney disease and need protein restriction (plus other strategies), they will benefit from therapeutic diets rather than senior OTC diets (see ch. 184). Antioxidants can be useful for the management of age-associated cognitive dysfunction[27,28] and are suggested to improve immune function parameters in dogs[29] and cats[30] (although the clinical significance of the latter is unknown). There are both OTC and therapeutic antioxidant-enriched diets that could potentially help with brain aging (see ch. 263); however, there is a lack of standardized dose-response studies to make a specific (type, combination, and dosage) recommendation at this time. Other nutrients that can help with cognitive dysfunction are long-chain omega-3 polyunsaturated fatty acids (PUFAs) from fish oil and medium chain triglycerides (MCTs). The brain has a high concentration of these omega-3 PUFAs and they are very important for brain development in the young.[31] The data regarding their effects on canine and feline brain aging still are lacking. In one study,[32] middle-aged cats fed a blend of fish oil, B vitamins, antioxidants, and arginine performed better in cognitive tests than control cats did, but it is impossible to separate the effects of the different nutrients. As for MCTs, there are preliminary data in dogs[33] showing that MCTs can help with clinical signs associated with mild cognitive dysfunction and the authors propose that ketone bodies obtained from MCT metabolism provide alternative sources of fuel to the aged brain, which has a reduced glucose oxidation capacity. Some OTC and therapeutic diets contain MCTs (mostly from coconut oil but also from other purified sources). Long-chain omega-3 PUFAs (eicosapentaenoic acid and docosahexaenoic acid) also have been proposed to help reduce clinical signs of joint disease (see ch. 187), although there are no data supporting any nutritional modification to prevent joint disease (as opposed to treating it) except weight management. The use of pre- and probiotics to modify intestinal microbiota (altered during aging[1]) and immune system modification potentially are interesting but data still are lacking. One study[34] in cats showed that long-term feeding of a diet enriched with a blend of chicory root (a prebiotic), antioxidants (vitamin E and carotene) and omega-3 and -6 fatty acids resulted in a longer life and less loss of lean body mass associated with aging compared to the control group, but no difference compared to a group fed the control diet plus only the antioxidants. Even though the results are encouraging, from this study it is impossible to discern each individual nutrient's effects and there are no dose-control studies to give a specific recommendation.

In summary, old age is not a disease, and the feeding plan (diet, amount, method) has to be tailored to the senior patient after a careful nutritional evaluation, since individual variation precludes generic recommendations. Senior pets should be fed a complete and balanced diet for adult dogs or cats (with specific modifications depending on the evaluation), fed in sufficient amounts to maintain an ideal BW and a lean BCS. Adequate weight management from weaning onwards is the best strategy to ensure a healthy geriatric pet. Conditions that cause pain, discomfort, and alterations in cognition should be addressed. The use of antioxidant- and omega-3-PUFA-enriched diets can have positive effects on well-being although no specific recommendations can be made at this time. There are many commercial OTC diets (marketed for both adult and senior pets) that can be used, with different ingredients, processing, and texture to accommodate for palatability preferences. In senior pets with health conditions, specific nutritional management for that specific disease is indicated.

CHAPTER 176

Obesity

Juan José Ramos-Plá

Client Information Sheets:
Owner-Pet Lifestyle Questionnaire
Pet Obesity: Common Questions

Definition

Obesity is defined as excess body fat, to such an extent that it may compromise health.[1] In general, dogs and cats are considered obese when their excess fat exceeds optimal body weight by 15-20%.[2] It has been estimated that 25-40% of pet cats and 25-44% of pet dogs are obese. Some believe these estimates will become progressively more conservative, in parallel with the human condition.[3-7] Animals who remain moderately overweight for years are estimated to have their life expectancy decrease as much as 2.5 years, while suffering from an obesity-related condition.[8]

The most accurate measure of an animal's obesity is quantitative analysis methodology.[2] Dual-energy X-ray absorptiometry (DXA) and % total body water (TBW) are reliable.[9-13] Bioelectrical impedance analysis (BIA) is commonly used in people, although its validity in dogs and cats has yet to be demonstrated.[2] Veterinary clinicians need a simple, quick, and cost-effective means of estimating obesity, such as body condition scoring (BCS) and morphometric measurements (see ch. 2). BCS is widely accepted for assessing levels of body fat subjectively with a combination of visual assessment and palpation over ribs/spine and presence/thickness of abdominal folds (see ch. 170).[14,15] Each animal is classified on a scale of 1 to 5 or 1 to 9 points.[15-18] The 9-point scale, validated with DXA, establishes ideal weight at 5, with each point above or below representing weight gain or loss of approximately 10-15%.[2,16,17,19] *Morphometric measurements* involve estimating BCS of dogs and cats by measuring various body area circumferences. This method has been validated with DXA and should only be used on obese animals.[2]

Etiology

Obesity has a multifactorial etiology that involves genetic and environmental factors (Table 176-1).[20] Although some diseases (hypothyroidism, hyperadrenocorticism, etc.), drugs (glucocorticoids, anticonvulsants, etc.) and rare genetic disorders (especially in humans) may contribute, obesity is almost always caused by more calories being consumed than used over an extended period of time.[7] The hereditary predisposition to obesity is reported in some purebred dogs and cats (Labrador Retriever, Cavalier King Charles Spaniel, Shetland Sheepdog, Cocker Spaniel, Rottweiler, Yorkshire Terrier, Poodle, domestic short-hair and long-hair cats, mixed-breed cats, Manx cats, etc.).[21-23] Some breeds (Greyhound, et al) are resistant or less prone to obesity.[24] Other predisposing factors in dogs include: age of owner, hours of daily exercise, frequency of treats, amount of food intake, consumption of table scraps, body condition of owner and the pet being a spayed female.[5,21,25] In cats, predisposing factors include frequency of feeding, being middle-aged (over 7 years) and being a neutered male.[4,26,27] Neutering affects both dogs and cats because absence of sex hormones reduces metabolic rates.[22,25,28] In particular, neutering female dogs predisposes them to obesity because estrogen has central effects on food intake and energy expenditure by inhibiting the deposit of adipose tissue and controlling the number of adipocytes.[29]

TABLE 176-1

Risk Factors for Obesity

Related to the Animal	*Age:* middle-aged and older (d and c)
	Breed: Labrador Retriever, Cocker Spaniel, Cavalier King Charles Spaniel (d) and domestic short-hair (c)
	Sex: female (d) and male (c)
	Hormone status: spayed or neutered
	Related disorders: hypothyroidism (d), hyperadrenocorticism
Iatrogenic Effects	*Medication:* anticonvulsants, steroids (d and c), etc.
	Surgeries: thyroid gland removal (d), spay/neuter surgery, etc. (see ch. 313)
Related to the Owner	Older or elderly people, overweight/obese, women, high earners, underestimating the problem, overprotective, etc.
Related to Food and Diet	Non-commercial food, canned food, table scraps (d and c), feeding very often, lots of treats (d), free feeding (c)
Related to Lifestyle and Behavior	Living indoors, humanization (d and c), begging for human food (d), inactivity, substitute for human companionship, anxiety, little time to play (c)

c, Cats; *d*, dogs.

Pathophysiology

Adipose tissue is composed of about 50% adipocytes and 50% other cell types (preadipocytes, stem cells, endothelial cells, pericytes, macrophages, fibroblasts, nerve cells).[20,30-33] It was once thought that fat was a metabolically inert energy storage depot, used during extended fasting. It is now appreciated that fat is a complex and active organ.[20,33,34] An excess accumulation of fat leads to being overweight, an increased burden on both joints and the heart, contributing to their degenerative conditions. In addition to adipose tissue, the gastrointestinal and reproductive systems also have hormonal influences on obesity.

Adipose Tissue as an Endocrine Organ

Introduction to Leptin and Adipokines

Adipose tissue is an endocrine organ, not only producing leptin (the OB protein), but substances called adipokines that have local and systemic effects.[20,35-38] The term adipokine encompasses more than 100 biologically active products, including steroid hormones, cytokines, vasoactive amines, regulators of glucose and lipid metabolism, regulators of cardiovascular function, and other biologically active mediators.[30-32,34,36,37] Adipokines are secreted not only by adipocytes but also by other cells within adipose tissue (e.g., macrophages). Although their physiological mechanisms are not completely known, adipokines are generally divided into those which alter inflammation (pro- or anti-inflammatory) and those that affect energy balance by promoting insulin resistance.[34] Along with leptin, dogs and cats have other adipokines: adiponectin, resistin, components of the renin-angiotensin-aldosterone system (RAAS; e.g., angiotensinogen), certain proinflammatory cytokines (interleukins [IL], tumor necrosis factor alpha [TNF-alpha], etc.) and other inflammatory mediators (C-reactive protein [CRP], etc.).[30-32,36,39,40]

Adipokines have local (apocrine) and systemic (endocrine or inflammatory) effects that may differ depending on the animal species and the physical location of the adipose tissue.[30] If fat deposition in adipocytes is limited or altered by lipodystrophy or age, lipid can be deposited in other organs (liver, pancreas, kidneys and muscle), potentially altering function due to lipotoxicity.[41] In humans, as fat builds up in visceral versus SC deposits, risk of insulin resistance, atherosclerosis and diabetes mellitus increases.[42] Leptin, adiponectin and angiotensinogen have been studied in dogs.[30] Resistin, visfatin and apelin have been studied in people and in laboratory animals.

Leptin

Leptin is an anti-obesity hormone mainly synthesized in adipocytes, although small quantities are produced by gastric mucosa, liver, mammary glands and placenta.[30,43] Obese individuals may be relatively resistant to leptin. Plasma concentrations of leptin increase in dogs and cats that have large amounts of body fat and large number of adipocytes. Conversely, leptin concentrations decrease when animals lose weight.[44-47] The primary action of leptin is binding to brain receptors (called OB-R receptors) that suppress appetite and increase energy expenditure, influencing food-related behavior.[48,49] Leptin also stimulates angiogenesis, suppresses apoptosis, acts as a mitogen (which could explain the higher incidence of cancer in obese people), regulates immune and reproductive functions, modulates insulin sensitivity, exerts proinflammatory (mediated by IL-6 and others) and prothrombotic effects, and inhibits adiponectin.[20,30,50] Although it is considered a long-term regulator of body weight, postprandial concentrations of leptin decrease transiently in lean but not obese people.[51] In dogs, there is a transient increase in circulating leptin concentrations after meals, with a postprandial peak 5-8 hours after eating, concentrations being double or triple those seen when the same dogs are fasted.[52] In cats, increased serum leptin concentrations after meals are mild compared with those of fasted animals.[53,54] Most obese animals have serum leptin levels higher than those of thin animals, perhaps due to leptin resistance.[52,55-57] Resistance to or lower sensitivity to leptin may originate in defective leptin receptors or in reduced target tissue signaling, such as hypothalamic neurons.[48,57] In a study of obese dogs, elevated serum leptin concentrations and deficient leptin transport across the blood–brain barrier were observed.[58]

Adiponectin

Adiponectin is an adipokine thought to be synthesized and secreted by mature adipocytes of dogs and cats. In rodents and humans, it may also be synthesized in cardiac muscle.[59-61] Serum adiponectin concentrations are decreased in obese dogs and cats, perhaps as a result of inhibition caused by secretion of inflammatory cytokines.[45,56,59,62,63] The effects of adiponectin vary by target organ. It contributes to increased insulin sensitivity and lower serum glucose concentrations. Liver and muscle triglyceride concentrations as well as inflammatory responses and atherosclerosis are reduced by adiponectin.[30,37,64,65]

Angiotensinogen and the RAAS

Adipose tissue is an important source of angiotensinogen.[30,66,67] The RAAS has a role in adipocyte differentiation and metabolism, as well as in vascular homeostasis, fluid balance and kidney function.[20,30] In humans, rodents, and dogs, adipose tissue can activate the RAAS via angiotensinogen, renin and angiotensin-converting enzyme, resulting in increased concentrations of angiotensin II, vasoconstriction, and aldosterone synthesis. Aldosterone increases renal retention of Na^+, which contributes to hypertension and kidney impairment.[67,68] Alterations in the RAAS may contribute to local inflammation in adipose tissue, allow insulin resistance to progress, stimulate leptin production and reduce adiponectin production.[67,69-71] Although the role of obesity and the RAAS are not completely understood in cardiovascular or kidney conditions in dogs and cats, studies in people and rodents are suggestive.[20]

Resistin

Resistin, synthesized by adipocytes in mice, may have important physiologic effects in dogs and cats.[72,73] In people, resistin is primarily synthesized by macrophages, but is also expressed in adipocytes.[30,74,75] Plasma resistin concentrations are increased in obese people, but the cell receptor has not been identified.[30,76,77] Its secretion pattern is similar to that of leptin: it increases with food intake and plasma concentrations are proportional to percent body fat.[72] It stimulates proinflammatory cytokine production in macrophages, leading to the elevated resistin concentrations associated with atherosclerosis in people.[30] Serum resistin concentrations increase in acute pancreatitis and diabetic ketoacidosis, but not in pituitary-dependent hyperadrenocorticism.[78-80]

Apelin

Secretion of this adipokine primarily by adipocytes in rodents and humans is directly influenced by insulin. Serum apelin and insulin concentrations increase in obese rodents and people, exerting cardioprotective effects via vasodilation, lowering blood pressure, and reducing vasoconstrictive actions of angiotensin II.[81-85]

Visfatin

Visfatin is produced in adipocytes, lymphocytes, bone marrow, the liver and muscle tissue, and is more prevalent in abdominal fat than in subcutaneous fat. It binds to insulin receptors, thereby stimulating the use of glucose by adipocytes and myocytes, suppressing release of glucose from hepatocytes.[86] It also has proinflammatory and regulatory properties with regard to some immune functions.[87]

the Gastrointestinal System as an Endocrine Organ

Overview

Gastrointestinal hormones affect appetite and satiety (see ch. 310). Disorders in the brain–gut axis can lead to weight gain and obesity. Peptides released from the gastrointestinal tract (primarily ghrelin, cholecystokinin and glucagon-like peptide-1 [GLP-1]) affect the hypothalamic and brainstem regulatory centers that control food intake and eating habits.[88]

Ghrelin

Known as the "hunger hormone," ghrelin is synthesized by oxyntic glands within the stomach fundus and is the only known orexigenic hormone.[89] Its acylated active form, produced after fasting, crosses the blood–brain barrier, binding to receptors that stimulate appetite and synthesis of growth hormone.[90,91] Levels of ghrelin increase during overnight fasting and drop to minimum levels approximately one hour after eating.[92-94] Ghrelin concentrations in humans and dogs are decreased in obese individuals and high in those with anorexia. Secretion is also influenced by calorie intake and diet, decreasing less with high-fat diets than with carbohydrate-rich diets.[47,95-99] Ghrelin concentrations decrease less after meals in obese versus lean people.[100]

Cholecystokinin (CCK)

CCK is an anorexigenic hormone secreted by L-cells of the small intestine in response to food intake.[101] It stimulates digestion by increasing pancreatic and biliary secretions, delays gastric emptying and exerts negative feedback on the appetite at a central level (the dorsomedial hypothalamic nucleus and median eminence).[102-106] In lean people, postprandial CCK concentrations increase more quickly, reaching and maintaining higher concentrations than in obese people.[107] Postprandial levels are also higher after high-fat meals.[108] While CCK is considered important with regard to regulating food intake, there is no clear link with obesity.[33]

Glucagon-Like Peptide-1 (GLP-1)

GLP-1 is produced in intestinal L-cells, and to a lesser extent, in the pancreas and hypothalamus.[88,105] Its secretion is stimulated by the presence of food in the small intestine, by glucose and fatty-acid concentrations or by vagus nerve stimulation.[88] It stimulates beta-cell synthesis of insulin and inhibits glucagon secretion in alpha-cells.[105] GLP-1 suppresses appetite in the central nervous system (CNS) via specific receptors and decreases rates of gastric emptying and food absorption.[109,110] GLP-1 concentrations are higher after eating high-fat meals.[111] Postprandial GLP-1 production is lower in obese versus lean people, probably due to elevated glucose and fatty-acid levels associated with obesity.[112-114] By contrast, in dogs obesity is positively associated with GLP-1 concentrations.[40,44]

Obesity and Reproductive Hormones

Sex hormones, particularly estrogens, affect energy balance in both the central and peripheral nervous

systems.[29] In the CNS, they reduce food intake and increase energy expenditure.[115,116] Estrogens regulate lipid and glucose metabolism, inhibit lipogenesis, and determine the number of adipocytes.[29,117,118] Neutering contributes to the development of obesity via direct action on the satiety and metabolism centers as well as indirectly affecting cell metabolism and interaction with hormones such as leptin.[119] The estrogen/obesity relationship has been extensively studied in people but information is limited in dogs or cats (see ch. 313).[33]

Obesity as Chronic Low-Grade Inflammation

Rapid increases in adipocyte numbers beyond their blood supply reduce available oxygen, stimulating synthesis and secretion of cytokines and angiogenic factors that promote vascularization.[120] Expanding adipose tissue, therefore, may result in increased cytokine and proinflammatory mediator concentrations. Also, production of monocyte chemoattractant protein-1 (MCP-1) is enhanced. Attracted macrophages represent a primary source of inflammatory mediators in adipose tissue. This may explain the increased expression of TNF-alpha and IL-6 in obese animals.[34,121-123] Conversely, decreases in adipose tissue are associated with fewer macrophages and lower inflammatory mediator concentrations.[124,125] In addition to a higher number of macrophages, people have been shown to have "proinflammatory" (M1) and "anti-inflammatory" (M2) macrophage imbalances that increase risk of inflammation and metabolic disorders. Obesity, in this context, may represent a chronic proinflammatory disease.[126-128]

TNF-alpha is a cytokine produced by a large variety of cells, including macrophages, mast cells, neurons, fibroblasts and adipocytes.[2] Serum concentrations of TNF-alpha, which is primarily synthesized by macrophages, are higher in obese versus lean dogs and cats.[123,129-132] In addition to its antitumor activity, TNF-alpha affects energy metabolism by blocking insulin-receptor activation, causing insulin resistance.[37,133-135] TNF-alpha is involved in inflammatory processes, autoimmune disorders, septic shock and fever.[136,137]

Interleukins, which participate in metabolic, regenerative and neurological processes, also have roles in obesity-associated inflammation.[138] For example, in the obese, IL-6 is released into portal circulation by visceral adipose tissue, stimulating hepatic triglyceride secretion, reducing hepatic insulin sensitivity, and actively taking part in the inflammation associated with obesity.[20,139] IL-6 serum concentrations increase in humans with type 2 diabetes and metabolic syndrome, being closely linked to excess body mass.[139]

C-reactive protein (CRP) is generated in the liver in response to the presence of IL-6 and TNF-alpha, with an important role in heightening the inflammatory response.[140-143] It is an excellent marker of obesity-associated inflammation and a good predictor for certain cardiovascular diseases and diabetes.[144]

Consequences of Obesity

General Associations

Disorders associated with being overweight due to excess body fat can be either metabolic, mechanical, or both. Metabolic disorders may follow increased production of metabolites by adipose tissue (inflammatory mediators, hormones, etc.), with local, peripheral and central effects. Mechanical disorders follow increased body mass and weight on bones, joints, the cardiovascular system, etc., and are usually slowly progressive. By the time signs appear, many conditions are already chronic and/or advanced. This is one of the most compelling reasons to persuade owners to use suitable preventive medicine: obesity increases the risk of chronic disease, shortens lifespan and diminishes quality of life.

Osteoarthritis

Osteoarthritis may result from metabolic and mechanical phenomena (see ch. 353, 355, and 356). The inflammatory action of leptin, produced in large amounts by excess adipose tissue, is the triggering factor for certain forms of inflammation (osteoarthritis).[145] Increased leptin concentrations in cartilage (chondrocytes) and synovial fluid in the obese are directly related to body mass index (BMI).[146] Together with increases in other cytokines (IL-1-beta, TNF-alpha), leptin may degrade cartilage in part by increasing expression of specific proteolytic enzymes, including matrix metalloproteinases (MMP-1 and MMP-13) and aggrecanases (ADAMTS-4 and ADAMTS-5).[147] In rodents and people, chondrocytes synthesize not only leptin, but also proteoglycans. This link suggests that leptin may have a role in the anabolic activity seen in

osteoarthritis.[146,148] Chondrocytes, stimulated by leptin, synthesize growth factors (e.g., insulin-like growth factor [IGF]-1 and TGF-beta, with short-term enhancement of cartilage repair but long-term stimulation of osteophyte production and osteoarthritis-related signs).[148-153] Mechanical problems stem from being overweight (even in moderate cases) for extended periods of time. Overweight dogs have a shorter average life expectancy and problems associated with osteoarthritis at younger ages when compared with dogs whose weight is within an ideal range.[8] It has been estimated that one-third of lame cats would improve if they attained an optimal BCS.[27]

Insulin Resistance and Type 2 Diabetes Mellitus

Endocrine Pathways

Insulin resistance associated with obesity is one of many predisposing factors for type 2 diabetes mellitus (DM2; see ch. 305).[154,155] Cats are almost 4 times more likely to develop DM2 if overweight.[155,156] Different endocrine, neurologic and inflammatory pathways are altered in the obese and contribute to insulin resistance.[157] *Fatty acid (FA) concentrations* increase in the obese and, with other factors, activate protein kinases that adversely affect key mediators of insulin receptor function.[158] Hormones produced by adipose tissue (leptin, adiponectin, resistin, etc.) play a fundamental role in insulin resistance. Adiponectin concentrations, synthesized by mature adipocytes, decrease in the obese. In experimental animal models, adiponectin disruption worsens insulin resistance.[159] In the liver, adiponectin increases insulin sensitivity and FA oxidation, reducing hepatic glucose secretion.[160] In muscle, adiponectin stimulates use of glucose and FA oxidation and likely the AMP-activated protein kinase (AMPK).[161] Serum resistin concentrations are elevated in obese animal models, causing insulin resistance because they induce expression of the suppressor of cytokine signaling 3 (SOCS-3), a negative regulator of insulin expression.[162-164] Lack of resistin improves glucose homeostasis in experimental animals.[165]

Inflammatory Pathways

Activation of inflammatory pathways in hepatocytes may cause local and systemic insulin resistance.[166,167] The kinase *Jun N-terminal protein kinase 1* (JNK1) is activated by inflammatory stimuli (e.g., TNF-alpha) and has increased liver, muscle and adipose tissue activity in the obese.[168] Activation of JNK1 leads to phosphorylation of IRS-1, which weakens insulin action and facilitates insulin resistance.[169] Concentrations of *IL-6* are directly proportional to obesity, lowering glucose tolerance, increasing insulin resistance, and having predictive value for development of DM2.[170,171] When administered, JNK1 induces hyperglycemia and hyperlipidemia by reducing insulin receptor substrate (IRS), and increasing SOCS-3.[172,173] *TNF-alpha* concentrations are directly proportional to an individual's adipose tissue and insulin resistance.[123] TNF-alpha activates serum kinases that increase the phosphorylation of IRS-1 and IRS-2, converting them into poor substrates for the kinases that activate insulin receptors and increasing their degradation.[174,175] *Retinol binding protein (RBP4)* is produced in liver and adipose tissue. Serum concentrations of RBP4 increase with obesity, causing insulin resistance in animal models and people by inactivating glucose transporter type 4 (GLUT4) in adipose tissue.[176]

Neurologic Mechanisms

The brain processes the concentrations of substances such as leptin, FAs, and insulin for control of appetite and metabolism in relation to energy storage and expenditure.[157,177-179] Insulin and leptin have critical roles in the central control of peripheral glucose metabolism by acting on the hypothalamus and brainstem to reduce hepatic glucose production and increase peripheral utilization.[180] Central administration of leptin decreases insulin resistance in rodents with lipodystrophy and leptin deficiency.[181,182] Both leptin and insulin induce SOCS-3 expression, which actually reduces sensitivity to both.[183]

Dyslipidemias

Serum concentrations of cholesterol and triglycerides in the obese are often increased and they decrease with weight loss.[97,184] Both cholesterol and triglycerides are transported by blood lipoproteins and classified as

very low (VLDL), low (LDL) and high-density (HDL) (see ch. 182).[185] Abnormalities in lipoprotein profiles from obese dogs with insulin resistance are similar to those in people.[184,186] Obese dogs, cats and humans who have insulin resistance have less lipoprotein lipase (LPL) activity and reduced lipolysis.[186,187] There are also increases in circulating concentrations of non-esterified fatty acids (NEFAs) and VLDL.[188,189] Hypercholesterolemia has been associated with eye damage and hypertriglyceridemia with acute pancreatitis in dogs.[190,191]

Cardiovascular Conditions

A link between obesity, metabolic, and hemodynamic disorders is the associated increase in circulatory volume and vascular resistance, contributing to hypertension.[192-194] Increased circulatory volume increases left ventricular (LV) mass with chamber dilation but without wall thickening (eccentric hypertrophy). Increased vascular resistance causes the LV wall to thicken but the chamber does not dilate (concentric hypertrophy).[195,196] Abdominal obesity, more than general obesity, is associated with heart disease in dogs, by worsening cardiac relaxation (diastolic dysfunction) and reducing LV systolic function.[197-199] This has been associated with portal vein thrombosis and myocardial hypoxia.[200,201] In people, while obesity is clearly a predisposing factor for cardiac disease, the prognosis after a diagnosis of heart failure is better in obese or overweight people than those whose body weight is at or below ideal.[202,203] Several explanations have been suggested for this "obesity paradox": (1) cardioprotective effects of some cytokines and hormones synthesized by adipocytes[203,204]; (2) obese patients may manifest cardiovascular signs at earlier stages of the disease than those who are not overweight[203]; (3) the paradox is more likely related to a lack of weight loss than to actual weight gain, given the adverse effects that wasting syndrome causes in people with heart failure.[205] Dogs with heart failure who gained weight had a significantly longer survival than those whose weight remained stable or decreased.[206] In cats, there may be a link between weight and survival.[207]

Kidney Disease

The link between kidney damage and obesity is a combination of hemodynamic factors (including sympathetic nervous system [SNS] and RAAS activation leading to increasing blood pressure), metabolic factors (diabetes), and still to be defined inflammatory factors.[208] Excess ectopic fat storage in the viscera may cause lipotoxicity and a build-up of renal toxic metabolites derived from lipid metabolism (e.g., diacylglycerols and ceramides).[209]

Obesity increases Na^+ reabsorption, extracellular fluid volume and blood pressure.[210,211] Increased blood pressure (BP) and glomerular filtration rates adjust for excess Na^+ reabsorption initially, but chronic hypertension, renal vasodilation, renal hyperfiltration, SNS and RAAS activation, metabolic issues and inflammatory disorders contribute to progressive renal damage.[208] The obese have mild increases in renal and skeletal muscle SNS activity, the effects of which on BP are mediated within the kidneys.[212,213] Leptin, which activates the SNS to exert its central functions of reducing appetite and increasing energy expenditure, also may be important in raising BP in obese individuals.[211,214]

Cancer

Hormones and growth factors produced by adipose tissue, inflammation, and central mechanisms that regulate energy balance may contribute to obesity-related cancers.[215] This link is evident in endometrial, breast and kidney cancers but is less obvious in colorectal, pancreatic and prostate cancers.[216] Insulin and IGF-1 are potentially critical in cancer development. Calorie restriction, which reduces their concentrations, also inhibits carcinogenesis.[217] Leptin has been extensively described as a mediator of colon and breast cancers, as it increases cellular proliferation and transformation and has anti-apoptotic effects.[218-220] By contrast, adiponectin may have anti-cancer effects by reducing insulin/IGF-1 and the production of nuclear factor kappa-B (NF-kappa-B).[221] Adiponectin levels are inversely related to thyroid and breast cancers.[222-224] The link between adiponectin and endometrial cancer is controversial.[225,226] Inflammatory cytokines (TNF-alpha, IL-6, etc.) increase with activation of NF-kappa-B complexes and steroids are possible cancer-obesity links.[227-229]

Respiratory Diseases

Although respiratory syndromes and airway distress associated with obesity have been widely described in human medicine, only anecdotal reports have linked obesity with greater distress in dogs with tracheal collapse or laryngeal paralysis or cats with asthma.[20] Obesity appears to limit airflow during expiration.[230]

Treatment

Overview

Under physiological conditions, an animal's weight tends to remain relatively constant due to a balance between the calories ingested and those utilized. The energy balance is positive when energy input is greater than utilized and negative if use exceeds intake. Physiologic responses to excess input increase energy expenditure.[231] Treatment of obesity focuses on reducing calorie intake and increasing calorie expenditure. Due to variations in energy utilization (basal metabolic rate [BMR]) and types of physical activity, most pets benefit from an individualized approach.[231,232] An assessment should be made to determine the extent to which a dog or cat is overweight/obese. The easiest method in dogs and cats is to combine body weight (BW) and body condition score (BCS) (see ch. 2).[1]

Essentially, treatment for obesity should be based on four points[233]:

a. Initial assessment (patient, owner, environment, type and amount of food)

b. Reduce calorie intake (change diet amount and/or composition, pharmacological aids)

c. Increase energy expenditure (exercise)

d. Monitoring and maintenance of the objectives attained

Initial Assessment

It is essential to start with a complete history and physical examination. Laboratory tests and diagnostic imaging may help rule out associated conditions. Likewise, BW, BCS and muscle condition scoring (MCS) should guide the clinician in estimating ideal weight (see ch. 177).[233-235] As discussed, one should use the 1-9 point BCS with "5" being ideal and each point above indicating a 10-15% increase in body weight above ideal (see ch. 2).[16,17,19]

Once the pet is examined and confirmed to be overweight, the owner can be asked to fill out a questionnaire, such as that in the provided Client Information Sheet, to establish the conditions that may have led to weight gain and the owner's interest in having his/her pet lose weight. The owner is the key to treatment success. Of pets with a BCS >5, 40-50% of their owners did not consider their pets overweight.[235] Owners must understand their roles modifying feeding habits, feeding times, reducing treats, rationing food into one or two meals (no *ad libitum* feeding), avoiding feeding table food, and increasing both frequency and duration of walks and playtime.[233,236]

Reduction of Calorie Intake

Although each pet must be considered individually, one can begin by reducing the quantity of food offered by 20% for a period of one month.[237] If the amount of food is not known or free feeding is done, daily energy requirement for weight loss is usually about 80% of RER, based on the pet's ideal weight, with re-checks every 2-4 weeks (see ch. 170).[235,238-240] Some studies recommend greater restrictions in RER (60%).[241] Resting energy requirements (RER) can be calculated with the following formula:

$$\text{RER in kcal/day} = 70 \times (\text{ideal weight in kg})^{0.75}$$

Although complete fasting might lead to weight loss, this approach is not recommended.[242,243] The only realistic alternative is use of home-made or commercial diets which contain fewer calories, less fat, more protein, and more micronutrients.[7,231] Changing diet composition can reduce the total number of calories and/or modify the sensation of satiety to improve body composition and metabolic expenditure.[231] Weight loss should progress slowly (0.5-2% per week) in dogs and cats.[232,241,244] For adequate dietary protein, dogs

should be given about 5 g/kg of BW and cats about 2.5 g/kg. Choose and weigh diets according to pet preference, perhaps using a scale for extremely small animals.[238]

Changes in Diet Composition

High-Protein Diets

Because the energy utilization rate for protein (77%) is lower than for fat (94%) and carbohydrate (98%), weight-loss diets should be low in calories and high in protein.[245] Thus, a high protein/calorie ratio should be achieved that increases the percentage of fat loss and minimizes the loss of muscle mass.[246,247] A similar effect is achieved with diets high in protein and low in carbohydrates.[248-250] This metabolic effect is related to postprandial energy expenditure for proteins being greater than that for fats and carbohydrates, improving its effect on satiety.[251-253]

High-Fiber Diets

There is no universal agreement regarding effectiveness of high-fiber diets as part of nutritional treatment for obesity in dogs and cats. Although some studies suggest fiber reduces appetite (satiating effect) and improves weight loss in dogs and cats when combined with high protein diets, others describe no such effect.[254-258] Nevertheless, fiber with its low digestibility provides low caloric density that can replace dietary carbohydrate or fat, useful for reducing the total calories given per meal.[34,256] Fermentable fiber may reduce insulin resistance in obese patients.[259,260]

L-Carnitine Supplements

L-carnitine is an amino acid synthesized in the liver and the kidneys from the amino acids lysine and methionine.[1,7] Its effects include nitrogen retention and FA oxidation, which increases lean tissue mass and reduces the total amount of body fat during weight loss.[261-264] In cats, it reduces hepatic fat accumulation and has a protective effect against fasting ketosis.[265,266] Supplementation is particularly important when the pet is unable to synthesize L-carnitine due to insufficient intake of protein and other nutrients.[261]

Conjugated Linoleic Acid

Conjugated linoleic acid (CLA), from the family of isomers of FA derived from linoleic acid, has anti-adipogenic effects, reducing weight and accumulated fat.[7,267] CLA appears to have a greater effect on preventing weight gain after weight loss than on initial weight loss.[268] Most of its effect on changing body mass comes from the attenuating action of its t10,c12 isomer on adipocyte differentiation, inducing apoptosis in adipose tissue in mice.[269,270] Furthermore, CLA inhibits stearoyl-CoA desaturase activity, which limits monounsaturated FA synthesis due to triglyceride synthesis. In humans, dogs and cats, studies on the effectiveness of CLA for weight loss show mixed results.[271-273]

Diacylglycerols (DAG) and Other Dietary Supplements

Diacylglycerols reduce weight, percentage of fat, and serum concentrations of cholesterol and triglycerides.[274] The isomer 1,3-DAG has been described as having a lipid-lowering effect. Diets with added 1,3-DAG reduce diet-induced insulin resistance through skeletal muscle fat oxidation and suppression of hepatic gluconeogenesis.[274-276] *Saponins chitosan* and *pyruvate* have exhibited some anti-obesity activity.[277-281] Extracts of *Garcinia cambogia, chromium picolinate* and *chia seeds (Salvia hispanica)* have not been consistently helpful.[282-286]

Treats

Many owners give treats to their pet to show affection. It is necessary to limit treats to a <10% of total calories.[240]

Pharmacotherapy

Sometimes increased energy expenditure and a change of the animal's dietary habits can be accomplished with the aid of drugs. Anti-obesity drugs may act by reducing appetite and fat absorption or by increasing energy expenditure and thermogenesis.[287]

Lipase Inhibitors

Tetrahydrolipstatin (THL or Orlistat) is a reversible inhibitor of gastric lipase that does not affect amylase, trypsin or chymotrypsin. It is widely used in people together with fat-containing diets to limit calorie intake by inhibiting triglyceride hydrolysis and reducing absorption of monoglycerides and free fatty acids.[288] THL reduces total cholesterol, low-density lipoprotein cholesterol (LDL-C) and blood pressure, thereby reducing insulin resistance and improving blood glucose concentrations.[289-291] Common side effects include gastrointestinal disorders (diarrhea, flatulence, abdominal pain, dyspepsia and abdominal bloating).[292] Isolated episodes of serious liver damage have been described.[293] Patients must be supplemented with fat-soluble vitamins (A, D, E and K), because treatment with THL interferes with their absorption.

Microsomal Triglyceride Transfer Protein (MTP) Inhibitors

These drugs interfere with intestinal fat absorption. They not only reduce fat absorption, but they release factors that reduce appetite. MTP inhibition involves reduced formation of chylomicrons from FAs and proteins in enterocyte cytoplasm.[294] Its main use in weight loss is to decrease appetite. Intracellular fat accumulation caused by MTP inhibition stimulates the release of peptide YY from enterocytes into the circulation.[294] Peptide YY is a peripheral hormone that helps to regulate food intake by suppressing appetite and producing a satiating effect in the hypothalamus and other centers of the brain.[295] Dirlotapide and mitratapide are MTPs currently approved for use in dogs. They have been effective and safe for as long as a year in achieving slow but constant weight loss.[262,296] Side-effects are generally mild, but can include vomiting, diarrhea and altered liver function tests.[297,298] Dirlotapide is given continuously, with dosage adjustments made as weight changes. Mitratapide is administered in 2-3 week courses separated by 2-3 weeks without treatment. It should be accompanied by diet and behavior-modifying techniques.[262] Owner involvement is essential for establishing correct feeding routines and preventing inappropriate behavior to avoid weight gain when drug therapy is discontinued.

Increase in Energy Expenditure

Weight loss is most likely to be achieved with a combination of calorie restriction and increased exercise (see ch. 359). It increases energy expenditure, preserves muscle mass, and improves the human-animal bond.[299-302] In dogs, the number of walks, duration of walks, and playing periods should be increased. Swimming is a low-impact exercise that may help with weight loss. Hydrotherapy and treadmills may be beneficial if osteoarthritis-related diseases exist (see ch. 355).[7,235] In cats, increasing activity may be achieved with specific toys for cats, feeder balls, "circuits" with tunnels and towers to climb, and placing food in different places to encourage activity.[1,7] When possible, allowing cats to spend time outside the home increases activity, enhances calorie utilization and can lead to weight loss. Some owners can provide restricted space outside that prevents a cat from escaping but allows outdoor activity.

Monitoring and Maintenance of the Objectives Attained

It is easier to maintain a suitable weight if the weight loss is gradual rather than rapid, as this makes a rebound effect less likely.[303] Owners should be instructed to adjust the amount of food to the needs of the pet, changing and adapting according to different situations (e.g., increasing or decreasing the time spent doing physical activity), in addition to weighing pets relatively regularly.[240] It is important to help the owner to understand that maintaining the correct weight for a pet may require life-long strategies and periodic re-evaluations. Owner involvement is critically important.

CHAPTER 177

Cachexia and Sarcopenia

Lisa M. Freeman

Cachexia and sarcopenia occur in a variety of chronic diseases and aging, respectively. Although cachexia has been recognized in people for over 2000 years, there is burgeoning interest because of the relatively recent finding of its negative effects on morbidity and mortality. This is spurring development of new drugs to combat cachexia and sarcopenia in people. Veterinary patients will benefit from this research, but greater awareness of these syndromes among the veterinary healthcare team and more research in dogs and cats are needed.

Cachexia

Cachexia is a loss of lean body mass (LBM) which occurs commonly in people and companion animals with a variety of chronic diseases, including congestive heart failure (CHF; see ch. 246), cancer, chronic kidney disease (CKD; see ch. 324), and chronic obstructive pulmonary disease (COPD; see ch. 242), as well as acute illness and injury (see ch. 189).[1] Cachexia and sarcopenia change an animal's normal metabolism such that he or she loses primarily muscle, rather than fat. In healthy animals that lose weight, fat is the primary tissue lost and LBM is preserved. The inflammatory mediators elaborated in disease states (e.g., inflammatory cytokines, catecholamines, cortisol, insulin, glucagon) cause an animal to use amino acids as the primary source of energy and to quickly lose muscle and LBM.[1] Therefore, the hallmark of cachexia is a loss of LBM.

The loss of LBM has direct and deleterious effects on strength, immune function, wound healing, and survival.[1] Many of the effects of cachexia, such as weakness, anorexia, weight loss, and perceived poor quality of life, are major contributing factors to an owner's decision of euthanasia.[2] As a result, cachexia may be even more deleterious for dogs and cats because of the option for euthanasia. These important clinical implications underscore the importance of early identification and effective treatment.

Specific Forms of Cachexia

The hallmark of all forms of cachexia is a loss of LBM, which is most readily evident in the epaxial, gluteal, scapular, or temporal muscles. The epaxial muscles over the thoracic and lumbar region are the sites in which muscle loss can be identified in its earliest stages (Figure 177-1 and ch. 170). Temporal muscle wasting is more variably expressed: In some animals, temporal muscle wasting is apparent at an early stage of disease, whereas in others, moderate to severe muscle wasting is present elsewhere before substantial temporal muscle wasting is apparent. There are some unique features to the different forms of cachexia.

Cardiac Cachexia

Depending upon the definition used, cachexia has been identified in up to half of all people with CHF.[3] In 1 study of dogs, over 50% of dogs with dilated cardiomyopathy (DCM) and CHF had some degree of cachexia.[4] In people, cardiac cachexia, even using relatively insensitive measures, is associated with an increased risk for

death.[5] Cardiac cachexia typically is recognized only after CHF has developed. Cachexia is usually recognized more easily in dogs than in cats, but it likely occurs at similar rates in both species. Dogs with right-sided CHF have more advanced muscle loss compared to dogs with left-sided CHF.[4]

Whereas obesity is a risk factor for development of heart disease in people, obesity actually may confer a protective effect once CHF is present—this is known as the obesity paradox, and it occurs in people, dogs, and cats with CHF.[6-9] The benefit of obesity in CHF is likely due to the lack of cachexia, rather than to the obesity *per se*, given the adverse effects of cachexia. This is due to the increased reserve of LBM in obesity, which can provide a greater reserve during the catabolic state of CHF.

Cancer Cachexia

Over 50% of people with cancer lose weight unintentionally, although the prevalence depends on the type of cancer.[10] Low body condition score (BCS) is uncommon in dogs and cats with cancer (4-5%) and obesity is more common,[11,12] but many animals with cancer have experienced weight loss (69% in one study) or muscle loss (35-91%).[11,13] In addition, results of one study showed that cats with low BCS had a significantly shorter survival time compared to those with a BCS ≥5.[13] This underscores the importance of assessing not only BCS which assesses fat stores (see ch. 2 and 170)[14,15] but also muscle condition score (MCS; see Figure 177-1 below) and changes in body weight in order to detect cancer cachexia.

Renal Cachexia

The prevalence of cachexia in dogs and cats with CKD has not specifically been measured, but subjectively is very common. The obesity paradox also exists in CKD. One retrospective study in dogs with CKD showed that underweight dogs had a significantly shorter survival time compared to both moderate and overweight dogs.[16]

Sarcopenia

Sarcopenia, like cachexia, is characterized by a loss of LBM, but unlike cachexia, sarcopenia is a syndrome that occurs during aging in the *absence* of disease. In people, sarcopenia actually begins around 30 years of age and progresses over time. The loss of LBM in sarcopenia often is accompanied by an increase in fat mass so the total weight may not change (or may even increase), thus masking the sarcopenia. Inflammation, reduced physical activity, decreased concentrations of growth hormone and testosterone, changes in type II muscle fibers, insulin resistance, and decreased protein synthesis all contribute to sarcopenia.[17] Like cachexia, sarcopenia is associated with increased morbidity and mortality.[17] Sarcopenia also occurs in dogs and cats during aging.[18] It is important to note that cachexia and sarcopenia can occur concurrently in an animal—i.e., an elderly dog with CKD may have muscle loss due to both sarcopenia (from aging) and cachexia (secondary to CKD).

Diagnosis of Cachexia and Sarcopenia

Cachexia and sarcopenia are processes and not just end-stage syndromes. It is important not to rely on weight loss to diagnose cachexia and sarcopenia since loss of LBM occurs before weight loss. Waiting until weight loss occurs prevents an early diagnosis. In addition, in sarcopenia and certain types of cachexia (e.g., cardiac cachexia with fluid accumulation), weight loss may be masked by accumulation of water or fat. Another important issue is that the muscle in cachexia and sarcopenia is not only lost in quantity but there are qualitative changes in muscle, such as increased collagen content, altered mitochondrial function, and a shift from type I (oxidative) to type IIb (glycolytic) fibers.[17]

To recognize cachexia and sarcopenia in their earliest stages, when intervention is more likely to be successful, BCS and MCS must be consistently assessed at every visit. The goal for BCS in a healthy dog or cat is 4-5 on a 9-point BCS scale. However, in certain diseases (e.g., CHF, CKD), a slightly higher BCS may be desirable (i.e., a BCS of 6-7/9), although further research is required to make specific recommendations. Even in animals with these diseases, obesity (BCS >7/9) should be avoided.

BCS and MCS differ in that the BCS assesses fat stores, while the MCS specifically evaluates muscle mass.[14,15,19] Evaluation of muscle mass includes visual examination and palpation of the head, scapulae, epaxial muscles over the thoracic and lumbar vertebrae, and pelvic bones (see Figure 177-1 and Video 170-2). BCS and MCS are not directly related because an animal can be obese but still have substantial muscle loss (or

conversely, be very thin but have a normal MCS). Palpation is required for accurately assessing BCS and MCS.

Cachexia should be anticipated in animals with chronic diseases such as CHF, CKD, and cancer, as well as in acutely ill or injured animals in which muscle loss can develop quickly. Routinely evaluating body weight, BCS, and MCS will help to identify muscle loss early, rather than waiting until muscle loss is more advanced, when it may be more difficult to successfully manage. Muscle loss also is likely to occur in aging, even in healthy individuals. Therefore, body weight, BCS, and MCS should be assessed at every visit in geriatric cats and dogs.

In addition to body weight, BCS, and MCS, a complete diet history should be obtained at every visit because this can identify factors that may contribute to muscle loss, such as a nutritionally unbalanced diet or insufficient protein or calorie intake (see below).

Mechanisms of Cachexia and Sarcopenia and Potential Interventions

There are 4 major aspects of the pathophysiology of cachexia: increased energy requirements or decreased nutrient absorption (both most common in CHF), decreased energy intake, and alterations in metabolism. However, it is a highly redundant system, which adds to its complexity but also offers multiple opportunities for targeting muscle loss. Currently, few of these interventions have been studied in companion animals, but the enhanced interest in these syndromes in people will likely lead to the development of products that may have benefits in animals or may spur interest within the veterinary pharmaceutical industry.

Decreased Energy Intake

An important problem in most forms of cachexia is a decreased energy (calorie) intake. For example, reduced food intake is present in 34-84% of dogs and cats with heart disease.[2,20,21] Appetite changes may be secondary to medication side-effects or due to the underlying disease. Absolute food intake may decrease in animals with these diseases, but there also may be altered food preferences, cyclical appetite, and other issues that negatively affect overall food intake. Control of food intake is a complex system, which includes numerous anorexigenic or satiety signals (e.g., adiponectin, serotonin, insulin) and orexigenic signals (e.g., ghrelin, neuropeptide Y, agouti-related protein).[22,23] For example, an imbalance between orexigenic and anorexigenic hormones or a resistance to orexigenic signals can negatively affect appetite. Inflammatory mediators play an important role in this dysregulation, which may provide targets for treatment to increase food intake.

In people, food intake is not only affected by the many orexigenic and anorexigenic factors but also by physiological factors, such as social situation, memory, time of day, fatigue, and depression.[22] The role of these factors in dogs and cats is unknown but such factors could be involved because dogs and cats appear to develop aversions to certain foods, particularly when sick, and this can contribute to decreased food intake.

Potential Interventions

A variety of drugs, such as ghrelin agonists and megestrol acetate, have been (and continue to be) studied to improve food intake in people with reduced appetite. It is unclear whether increasing appetite alone will reverse or even minimize the deleterious effects of cachexia if the weight gained is fat and not LBM. However, appetite stimulation may provide benefit for dogs and cats if increased appetite is viewed by the owner as improving the animal's quality of life (and thus, reducing the likelihood of euthanasia).[2]

Altered Metabolism

Although increased energy requirements, alterations in nutrient absorption, and decreased energy intake all play important roles in the pathogenesis of cachexia and sarcopenia by causing a net calorie deficit, metabolic alterations also are primary factors in this syndrome, including increased production of inflammatory cytokines. Tumor necrosis factor-alpha (TNF) was initially thought to be the major cause of cachexia, and cachexia research throughout the 1990s focused on TNF and other inflammatory cytokines. However, it is now apparent that there are multiple metabolic alterations involved in the pathophysiology of cachexia and that it is a redundant system with multiple pathways triggering the muscle loss. At the core of cachexia and sarcopenia is an imbalance between decreased protein synthesis and increased protein catabolism, resulting in a net loss of lean tissue.

Inflammatory Cytokines and Nuclear Factor Kappa-B

The inflammatory cytokines, especially TNF, interleukin-1-beta (IL-1), and interleukin-6 (IL-6), are primary factors in cachexia because they cause anorexia, increase energy metabolism, and accelerate loss of LBM. This loss of LBM results in large part from the activation of the nuclear factor kappa-B (NF-kappa-B) pathway that, in turn, activates the ubiquitin proteosome pathway. TNF and IL-1 also cause cardiac myocyte hypertrophy and fibrosis and have negative inotropic effects that may contribute to progression of the underlying disease.[24] Inflammatory cytokines also are increased in dogs and cats with CHF.[4,25]

Potential Interventions

Anti-TNF agents (e.g., soluble TNF receptors, TNF antibodies) showed promising results in rodent models and in Phase I and II human clinical trials, but were less successful (or even associated with higher mortality rates) in Phase III clinical trials for CHF. TNF antagonists are now a mainstay in rheumatoid arthritis and Crohn's disease in people, and some studies have shown positive effects both on the underlying disease and on muscle mass, but they are avoided in CHF. The effects of blocking TNF or other inflammatory cytokines in dogs and cats are unknown but their use is challenging given the species-specific nature of these antibodies. A variety of other agents with anti-inflammatory effects, such as thalidomide and pentoxifylline, also is being evaluated in cachexia.

Myostatin

Myostatin is a member of the transforming growth factor-beta superfamily that negatively regulates muscle mass. Exercise decreases myostatin concentrations, allowing muscles to increase in size. Several myostatin mutations have been described in various species in which enlarged musculature is present (e.g., double-muscled cattle breeds, "bully" Whippets).[26,27] Myostatin is increased in animal models and people with CHF.[28,29] A variety of factors, such as TNF and angiotensin II, increases myostatin expression, which can then cause muscle loss in CHF.[30]

Potential Interventions

Studies of myostatin antagonists (e.g., activin receptor type IIB antibodies or decoys, myostatin antibodies) have shown benefits in rodent models of cachexia, and studies currently are underway in people with sarcopenia, COPD, cancer cachexia, and critical illness.[31] A small open-label pilot study using a myostatin antagonist showed increases in muscle mass in some dogs with cardiac cachexia.[32] Exercise also decreases myostatin concentrations and may be of benefit in certain chronic diseases.[33]

Neurohormonal Activation

Neurohormonal activation is another mechanism by which cachexia can occur, in addition to the NF-kappa-B pathway. This is especially likely in CHF in which many neurohormonal alterations occur that can affect myocardial and whole body energy metabolism and protein flux (see ch. 246). Catecholamines and neurohormones (e.g., renin-angiotensin-aldosterone system, epinephrine, cortisol, atrial natriuretic peptide, B-type natriuretic peptide) can increase muscle catabolism.[3]

Potential Interventions

Because of its effects on muscle, neurohormonal blockade may provide benefits other than cardiovascular effects. For example, certain beta-blockers have been shown to decrease protein oxidation and muscle atrophy in a rodent model of CHF,[34] and to reduce cardiac cachexia in people.[35,36]

Reduced Anabolic Signals

Although increased protein catabolism is a major contributor to cachexia, decreased protein synthesis also plays a role in the net loss of lean tissue. Inflammatory mediators, such as TNF, contribute to cachexia by reducing growth hormone and insulin-like growth factor-1 (IGF-1), which are both important for maintaining LBM.

Potential Interventions

Although growth hormone treatment has not been overwhelmingly successful for treating cachexia and has important adverse effects, some promising results have been seen with IGF-1 treatment in rodent models of cachexia.[37,38] IGF-1 mediates most of growth hormone's effects so it may offer an effective method for treatment of cachexia and sarcopenia in the future, either by administration of IGF-1 or through nutritional approaches and resistance training.[39]

Another anabolic agent is testosterone, but its adverse effects limit its use in cachexia and sarcopenia. However, non-steroidal selective androgen receptor modulators (SARMs) are being developed which have anabolic activity primarily in muscle and bone, with minimal androgenic effects in other tissues, thus reducing side-effects. SARMs are being studied for use in various forms of cachexia and sarcopenia in people.

Multifactorial Effects

Both cachexia and sarcopenia appear to have highly redundant mechanisms that make it unlikely that there will be a single agent treatment that will result in complete resolution of the syndromes. Finding therapies that target multiple pathways may, therefore, be useful. As an example, ghrelin is an orexigenic hormone. It also stimulates growth hormone secretion (and thus, IGF-1 production), stimulates neuropeptide Y and agouti-related protein, decreases expression of proopiomelanocortin, attenuates cardiac and renal sympathetic tone, stimulates gastric motility, and has anti-cytokine and anti-inflammatory effects.[40,41] Ghrelin is secreted primarily by the stomach in response to fasting and results in increased food intake. People with CHF appear to have ghrelin resistance because ghrelin concentrations are increased but food intake is decreased, although exogenous ghrelin administration may overcome this ghrelin resistance.[41-44] Ghrelin itself has a short half-life, which limits its use, but ghrelin agonists with longer half-lives have been developed and are being tested in people, dogs, and cats. Results from studies being conducted in people with cachexia due to cancer, CHF, COPD, and CKD show promise for this class of agents.[31,44] Ghrelin agonists for dogs and cats also are being tested in clinical trials for anorexia and weight loss.

Practical Implications for the Non-Pharmacologic Interventions

Until effective pharmacologic interventions for treating cachexia and sarcopenia are available for dogs and cats, these important syndromes still can be addressed in a number of ways. These other aspects of therapy also will continue to be important since, to be most effective, a treatment for cachexia should include 3 key components: (1) an anti-catabolic effect to decrease muscle loss, (2) an anabolic effect to enhance protein synthesis, and (3) adequate substrate to support the first 2 actions (i.e., calories, protein, and other nutrients).[45] Treatments with anabolic effects, for example, will not be effective if there is insufficient substrate (i.e., calories and protein) with which to build muscle. Therefore, careful attention to the nutritional aspects of treatment of cachexia and sarcopenia is critical for success.

Nutrition

Optimizing medical treatment for the underlying disease in animals with chronic conditions commonly associated with cachexia (e.g., CKD, cardiac or hepatic failure, cancer, respiratory disease) is of primary importance. Physical factors (e.g., dental disease, back or joint pain) or environmental factors (e.g., multipet households) that can negatively affect food intake must be investigated and addressed. The diet also should be carefully evaluated for information that can provide relatively easy, practical solutions. A brief nutrition screening should be performed in every patient at every visit, including a diet history, body weight, BCS, and MCS.[14,15] For animals that have risk factors identified from the screening (e.g., animals with medical conditions, geriatric animals, and those with altered BCS or MCS), a more thorough nutrition evaluation is required (see ch. 170). The diet history includes not just the pet food, but also treats, table foods, rawhides or other chews, and foods used to administer medications. Clinicians should ensure that the diet being eaten by the animal is nutritionally complete and balanced. If owners are feeding a homemade diet, it is almost always nutritionally unbalanced (sometimes severely so) unless a board-certified veterinary nutritionist formulated the diet and the owner is carefully following the recipe. Even commercial dog and cat foods may be nutritionally unbalanced if they are made by companies with questionnable quality control or the label states "for intermittent or supplemental use." This phrase is acceptable for veterinary diets that are designed to help manage diseases and are used under a veterinarian's supervision, but over-the-counter diets should always be complete and balanced if fed in any substantial amounts to a pet.

The diet history also may reveal that the diet is unbalanced not because the animal is eating an unbalanced diet, but due to intake of a large proportion of calories from treats, rawhides, or table food. In this situation, even if the main diet is well-balanced, the other foods may be fed in a large enough proportion that the overall diet is unbalanced, which can contribute to weight and muscle loss as well as not being optimal for the underlying disease.

It is important to assess not just the brand of food being fed, but also the specific product and flavor because it may reveal factors that can contribute to cachexia or sarcopenia (or that are not optimal for the underlying disease). For example, animals with CHF should not be fed a renal or otherwise reduced-protein diet unless advanced concurrent CKD is present. Providing at least the AAFCO minimum for protein (4.5 g/100 kcal for dogs and 6.5 g/100 kcal for cats)[46] is important, although higher dietary protein levels may be more optimal if muscle loss is present. Dietary protein restriction does not slow progression of disease in animals with CKD (unless proteinuria is present) and can contribute to muscle loss so should be avoided until more advanced CKD is present. Senior diets are highly variable in terms of their protein content[47] so the individual product (and flavor) must be investigated to ensure it is appropriate for an individual patient. Commercial pet foods also vary widely in calorie density—there are dog and cat foods available on the market now that are >600 kcal/cup or <250 kcal/cup. Therefore, it is important to ensure that undesired weight loss is not simply the result of switching to a lower calorie density food.

Dietary supplement use is important to determine. Animals with diseases are more likely to be receiving supplements,[20,21,48] but owners typically do not volunteer this information unless specifically asked. Dietary supplements may contribute to muscle loss by reducing appetite or by interacting with medications used to treat the underlying disease, thus decreasing their efficacy or increasing the adverse effects of the medications.

This emphasizes the importance of obtaining and evaluating a thorough diet history in animals with cachexia or sarcopenia, and will provide important information needed to optimize the nutritional aspects of a patient's care. Board-certified veterinary nutritionists can be helpful in assisting the busy veterinary clinician by consultations in these situations.[49,50]

Addressing Changes in Appetite

Appetite can be a challenging issue in animals with cachexia and sarcopenia. Complete loss of appetite (anorexia) may not be present but owners often note changes in appetite, such as reductions in food intake (hyporexia), or altered food preferences or "cyclical" appetite (dysrexia). Client communication is important to address decreased or altered food intake. Owners who are prepared for changes in appetite appear better able to deal with these changes effectively. Tips for addressing alterations in appetite are included in Box 177-1.

Box 177-1

Tips for Managing Anorexia, Hyporexia, and Dysrexia in Patients with Cachexia or Sarcopenia

- Assess the patient for optimal medical control of any underlying disease(s).
- Assess the patient for side-effects of medications.
- Ask the owner about dietary supplement use, which could be causing side-effects, or having interactions with medications.
- Feed more frequent but smaller meals.
- Provide multiple diet options so owners can rotate foods if hyporexia or dysrexia occurs.
- Warm the food to body temperature (for cats). Try different temperatures of food for dogs—they may prefer it warmed, at room temperature, or even cold.
- Feed the animal from a different type of dish (e.g., a new food dish or a human dinner plate).
- Feed in a different location in the house.
- Add homemade chicken, beef, or fish broth to the food (even low sodium store-bought broths are too high in sodium).
- For animals with heart failure, add a small amount (1-2 teaspoons) of cooked meat (hamburger, chicken, or fish) to the food. Be sure to instruct the owner not to use any prepared foods, such as

rotisserie chicken, lunchmeats, or canned meats or fish due to their high sodium content. Cats typically prefer meat or fish as a palatability enhancer. Meat or fish also may enhance food intake in dogs, but some dogs prefer sweet flavors as a palatability enhancer (e.g., maple syrup, applesauce, fruit-flavored yogurt). These sweet flavorings also can be used for dogs with other medical conditions (except diabetes).

- Supplement fish oil, which is high in n-3 fatty acids, to reduce inflammatory cytokines. This may have modest benefits for appetite.

Appetite stimulants (e.g., mirtazapine) may benefit some animals with decreased or altered appetite, but it is important to carefully monitor body weight, BCS, MCS, and food intake to ensure adequate calorie intake. Owners (and veterinarians) often are comforted by some food intake, even if it is not sufficient to maintain weight or is not comprised of an optimal nutritional profile (e.g., a cat with CKD that will only eat meat or a high-protein, high-phosphorus commercial food). In animals that continue to lose weight and muscle, a feeding tube should be considered (see ch. 82). Early tube placement typically has a better outcome than waiting until the animal is in end-stage disease with severe weight and muscle loss.

Omega-3 Fatty Acids

Increased dietary long-chain polyunsaturated omega-3 fatty acids, either from a highly enriched diet or through supplements, may have a number of benefits in animals with diseases that predispose them to cachexia or in animals with sarcopenia. Omega-3 fatty acids result in less potent inflammatory mediators (eicosanoids) than do omega-6 fatty acids, and omega-3 fatty acids also decrease TNF and IL-1 production. Omega-3 fatty acid supplementation has been shown to decrease the muscle loss in dogs with CHF and, in some animals, to improve appetite.[4]

The optimal dosage of omega-3 fatty acids has not been determined, but the author currently recommends a dosage of fish oil to provide 40 mg/kg eicosapentaenoic acid (EPA) and 25 mg/kg docosahexaenoic acid (DHA) for animals with any degree of cardiac cachexia. Higher dosages may be recommended for other conditions.[51] Unless the diet is one of a few specially designed therapeutic diets, supplementation will be necessary to achieve this omega-3 fatty acid dosage. When recommending a supplement, it is important to know the exact amount of EPA and DHA in the specific fish oil brand because supplements vary widely. Fish oil supplements with good quality control should be used and they should always contain vitamin E as an antioxidant, but other nutrients should be excluded to avoid toxicoses. Cod liver oil should not be used to provide omega-3 fatty acids at this high dose because it contains high concentrations of vitamins A and D that can result in intoxication. Flaxseed oil or other plant-based omega-3 fatty acids also should be avoided because of metabolic differences that make them inefficient (in dogs) or ineffective (in cats) sources of omega-3 fatty acids for these species.

Exercise

Exercise has been an effective method for helping to maintain muscle mass in people with cachexia and sarcopenia. Both aerobic and resistance exercise are beneficial for minimizing cachexia and sarcopenia in people although resistance exercise appears to be most useful. Exercise may be more challenging in some of the diseases associated with cachexia in dogs (e.g., CHF) and particularly in cats, but exercise such as walking may provide an effective treatment for muscle loss in some diseases and in preventing sarcopenia in aging animals (see ch. 355 and 359).

Summary

Veterinarians should be aware of cachexia and sarcopenia and their negative effects, because earlier diagnosis will provide enhanced opportunities for treatment. New drugs, nutritional approaches, and other treatments to specifically target sarcopenia and cachexia are being developed and are likely to benefit dogs and cats, as well as people. In the meantime, careful nutritional assessment and detailed nutritional recommendations can help to optimize the treatment for patients with these common and deleterious syndromes.

CHAPTER 178

Nutritional Management of Gastrointestinal Disease

Debra L. Zoran

General Guidelines

The gastrointestinal (GI) tract is a complex tubular system primarily responsible for accepting and digesting food, absorbing nutrients and water, and expelling wastes from the body in the form of feces. A proper diet and normally functioning GI tract are integral to the delivery of nutrients, prevention of malnutrition, repair of damaged intestinal epithelium, restoration of normal luminal bacterial populations, promotion of normal GI motility, and maintenance of normal immune function (e.g., both tolerance of and protection from pathogens).[1] Dietary characteristics, such as the amount of food, its form, the frequency of feeding, and the composition of the diet, all have important effects on GI function and can be used for helping to ameliorate signs of disease. Appropriate selection of dietary therapy, tailored to meet the needs of individual, species, and specific to the diagnosis, is an essential component of intestinal recovery and successful management of GI disease.

Traditionally, nutritional management of acute, nonspecific GI disease has included institution of a short-term period of fasting, or alteration of food intake with the general intent to "rest" the gut.[2] Effective treatment of many acute, non–life-threatening GI disturbances includes withholding of food and water for 24 to 36 hours, along with correction of fluid and electrolyte deficits. For example, in acute gastroenteritis due to parvovirus infection where vomiting is a significant problem, a period of nothing *per os* (NPO) for 24-36 hours could be essential for initial therapy to be effective.[3] However, prolonged (i.e., >48 hours) fasting should be avoided, as it can contribute to delayed recovery of intestinal function, development of malnutrition, or lead to problems resulting from a lack of enteral nutrition (e.g., ileus, dysbiosis, bacterial translocation, and reduced digestive function due to villus blunting; see ch. 225).[4] Prolonged fasting also deprives the GI epithelium of its primary metabolic fuel source, glutamine, which is present in chyme and is necessary not only for replacement of the GI mucosal cells lost in normal turnover (every 3 to 5 days) but also for repair of mucosal injury and normal immune function.[5] Thus, a good general rule of thumb for reintroduction of feeding for all dogs and cats with GI disease is to minimize the period of fasting to 12-36 hours, or a maximum of 3 days. Then, a palatable, highly digestible diet is reintroduced gradually—the type of diet can vary for dogs versus cats—depending on the diagnosis, previous diets used, and concurrent diseases. If the dog or cat is unable or unwilling to eat, enteral nutritional support via other means (e.g., nasoesophageal or esophageal feeding tubes; see ch. 82), or other methods of nutritional support (see ch. 189) should be implemented. When indicated, a gradual reintroduction of the original diet, or a more appropriate diet for long-term management, can be given.

Diets Used in GI Disease: Definition and Selection

Selection of a diet for managing dogs or cats with GI disease should be based on several factors: (1) the specific GI disease (if it can be determined), (2) the area of the GI tract affected, (3) any prior diets used in the management of the disease (a dietary history is essential to success in any dietary therapy chosen; see ch. 170), and (4) understanding any other health issues that could influence the diet choice (e.g., pancreatic, endocrine or renal disease). There are several specific characteristics to be considered when selecting a diet for management of GI disease, including the type and amount of protein, carbohydrate (CHO), fat, fiber (type and amount), and digestibility. The foremost consideration in choosing a diet to feed an animal with GI disease is nutrient content and digestibility. If the animal is fed a diet novel in both protein and CHO but the nutrients are not highly digestible or there is too much fat (e.g., especially in cases of protein-losing enteropathy [PLE] in dogs), the malassimilation of those ingredients due to poor digestibility could at the

very least result in no improvement, and at worst, contribute to progression of the clinical signs (e.g., vomiting, diarrhea, flatus, poor appetite, weight loss, or malodorous feces) and, potentially, worsening of the disease itself (e.g., dysbiosis, inflammatory bowel disease [IBD], PLE). Typical commercially available maintenance pet foods have protein and CHO digestibilities ranging from 70% to 85% on a dry matter (DM) basis.[6,7] Less well-known specialty brands or pet foods available from bulk sellers can consist of ingredients with highly variable quality and digestibility. Digestibility information is not required to be available on the pet food label, and typically is only present if the manufacturer wants this information presented. However, it is generally accepted that foods formulated for dietary therapy of GI disease (e.g., highly digestible or enteric diets) ideally should have CHO and protein digestibilities of at least 88% DM.[7,8] Other characteristics of an ideal intestinal diet include: low to moderate levels of fat (15-20% DM in cats or 3-5 g fat/100 kcal consumed, and between 6% and 15% DM in dogs or <3 g fat/100 kcal diet consumed), be lactose- and gluten-free, have no additives, artificial flavoring or coloring, and have reduced amounts of insoluble dietary fiber or other poorly digestible CHO.[9] There are many different, commercially available therapeutic diets, and each formula is unique, and therefore will elicit a different individual response. For example, therapeutic diets are likely to have different protein or CHO sources and varying levels and types of fat (e.g., some formulations contain added omega-3 fatty acids), and some are formulated with ingredients designed to enhance GI health, such as the prebiotic fructo-oligosaccharides (FOS). Although the benefits of feeding any one highly digestible diet could have a variable effect in an individual animal, the benefit of a dietary trial with a highly digestible food (whether it is commercial, homemade or organic or raw) in pets with both acute and chronic GI diseases is widely accepted as important to successful therapy. The hard part is finding which highly digestible diet is the right one for an individual patient based on that animal's individual needs and response to therapy.

Role of Consistency, Frequency, and Meal Size

The amount of food fed should be calculated based on the energy needs of the individual animal and the ability of the GI tract to assimilate different foods. In general, a good rule of thumb for any animal with clinically significant GI disease is “less volume, more frequent, don't try to achieve full-feed.” Although there is ongoing discussion among nutritionists regarding the best method for determining energy requirements of well or sick animals, the goal should be to meet the animal's daily resting energy requirements (RER). One generally accepted equation for determining resting energy requirements (in kcal/day) in neutered or spayed dogs is 70 $(BW_{kg})^{0.75}$ and for castrated or spayed cats 60 $(BW_{kg})^{0.67}$.[6,10] The linear equation $[(BW_{kg}) \times 30] + 70$ is an estimate that is better for animals in the middle of the weight range (20 kg) than it is for those on either end of the scale (<10 kg, >40 kg), but it can be used as a reasonable starting point. Intact animals have a higher RER, but for purposes of feeding sick pets with GI disease, it is best not to overfeed, so use of the RER and not maintenance energy requirements (MER) is suggested.

In most animals with GI disease, small meals (e.g., less than one third of stomach capacity) are recommended several times each day (three to six meals). Feeding small meals reduces gastric acid secretion, reduces gastric distension (which can increase nausea), reduces gastroesophageal reflux, and reduces the risk of vomiting.[2,4] It also increases the mixing and digestion of the food present in the stomach. The feline stomach has a smaller capacity (approximately 60 mL/kg) and is less distensible than the stomach of a dog (capacity is nearly 80 to 90 mL/kg), which has greater capacity due to its distensibility.[4]

In general, liquid diets empty faster from the stomach than do canned foods, and canned foods faster than dry.[6] Therefore, animals with GI disease could benefit from small meals of a canned food, or water added to moisten a dry formula. Commercially available liquid diets primarily have been used in specialized circumstances (e.g., for nasoesophageal or jejunostomy tube feeding) or with certain GI conditions (e.g., esophageal stricture, selected cases of megaesophagus, or gastric outflow disturbances) to reduce the risk of regurgitation or vomiting. However, one disadvantage of liquid diets is that a very large volume of the food is required to meet the caloric needs of a large (>25 kg) dog. Also, if liquid diets are fed too quickly or in large volumes, diarrhea can be induced by too-rapid emptying of the stomach content, which can overwhelm the capacity of the small intestine. A good use of liquid enteral diets is to substitute them for water used for mixing or liquefying a diet for syringe or tube feeding to reduce the caloric dilution.

Diet Composition

A variety of nutritional and non-nutritional diseases affects the GI tract and their treatment can be enhanced by appropriate diet selection, including homemade, organic/holistic, or raw diets. The safe use and

preparation of these alternative diets is discussed in ch. 192. Numerous therapeutic diets are available for treatment of a wide variety of GI diseases in dogs and cats, including highly digestible, novel antigen, hypoallergenic, hydrolyzed protein, or increased fiber content diets. Each of these different dietary options can be used in management of GI disturbances; however, selection of the most appropriate diet requires an understanding of the differences in the nutrient composition of these formulations. Furthermore, specific diets (e.g., homemade or elemental diets) could be required for dietary management of intractable or chronic GI diseases for which commercially available options have not been successful. Examples of these situations can occur in cats with idiopathic chronic diarrhea (requiring a homemade diet with high protein and no carbohydrate to resolve their clinical signs) or dogs with severe PLE due to lymphangiectasia (requiring a homemade diet with extremely low fat content and highly digestible protein to overcome the effects of these patients' inability to digest fat through normal channels). In each of these situations, the clinician may choose to use a non-balanced diet during the 7-10 day trial period, but for therapeutic feeding of the diet for a longer period, a clinical nutritionist or service (e.g., https://secure.balanceit.com) should be consulted to provide a complete and balanced diet.

Protein

Protein in the diet is very important for normal GI tract function.[1,5,11] Dietary protein in the stomach increases lower esophageal sphincter pressure and can be a potent stimulus for secretion of hormones, including gastrin and pancreatic hormones. Protein also decreases (slows) both gastric emptying and intestinal transit.[1,11] However, protein maldigestion due to poor quality protein (low digestibility), lack of digestive enzymes (e.g., exocrine pancreatic insufficiency), or reduced absorptive function (e.g., IBD, dysbiosis, lymphangiectasia/PLE) not only reduces available body protein (for immune function, repair and muscle function), it also has numerous effects on the GI ecosystem. Protein malassimilation can directly impair GI function (including motility and hormone release), normal enterocyte replacement and growth, repair of mucosal injury, and the mucosal immune response.[12,13] In addition, intact protein reaching the distal small intestine and colon increases bacterial ammonia production, alters bacterial numbers, and can alter the bacterial species present (dysbiosis). Change in the bacterial flora can lead to production of abnormal fecal consistency, odor, and flatus initially, and eventually can lead to overt diarrhea due to IBD. More importantly, a change in flora could contribute to development of bacterial enteritis, colitis, or colonic hypersensitivity.[13]

Feeding high-quality protein that is highly digestible is essential in the initial approach to the dietary management of any animal with GI disease. However, in kittens or cats with GI disease, the quantity, quality, and digestibility of protein is one of the most important aspects of nutritional therapy. Due to their shorter GI tract (compared to dogs and other omnivores)[14] and greater need for protein (for maintenance of muscle and amino acid needs),[14,15] cats with GI disease must have high quality, highly digestible protein sources to prevent lean body mass loss, protein malassimilation, and development of dysbiosis. In many situations, this can be achieved by feeding a commercially available, highly digestible, higher protein, lower CHO formula (this includes some of the feline diabetic diets),[16] but in some cats with severe or unresponsive enteropathy, a homemade, lightly cooked, high-protein, no-CHO diet formulated by a nutritionist or nutritional service to be complete and balanced could be required. In the author's experience, this approach has been successful in resolving the clinical signs (vomiting, diarrhea, or weight loss) associated with chronic IBD or dysbiosis in numerous kittens and cats for which antibiotics, immunosuppressive therapy, and a variety of commercially available GI diets had previously failed.

Chronic severe enteropathies of dogs, such as IBD and PLEs, are a group of severe intestinal diseases that can occur as primary enteropathies (e.g., lymphangiectasia) or familial enteropathies (e.g., in Soft-Coated Wheaten Terriers, Basenjis, or Irish Setters). Alternatively, they can occur secondary to infectious, neoplastic, or inflammatory processes that result in inflammation, protein loss (from maldigestion, malabsorption, or leakage across damaged mucosa) and lead to vomiting, diarrhea, appetite changes, and weight loss of varying degrees and severity.[12,13,17] In addition to protein loss, these enteropathies also result in loss of mucosal function, motility disturbances, and loss or disruption of other gut functions.[13,17] Regardless of cause, nutritional therapy is essential in managing chronic enteropathies like IBD and PLE in dogs. In mild forms of either disease, feeding a highly digestible, low-fat diet, in addition to specific therapy for the primary disease, might be sufficient (Table 178-1 illustrates low fat commercial diet options).

TABLE 178-1

Comparison of Dietary Fat Concentrations in Canine Diets

PRESCRIPTION CANINE DIET (dry)	FAT (g/100 kcal)	FAT (% DM)
Hill's i/d	2.5/3.4	7.4/13.9
Hill's z/d	3.4	14.1
Hill's d/d (salmon)	3.6	14.8
Hill's d/d (venison)	4.0	16.3
Hill's w/d	2.8	8.7
Purina EN	3.1	10.5
Purina HA	2.4	8.0
Purina OM	2.8	8.5
Royal Canin Low Fat	1.9	5.0
Royal Canin Hypoallergenic HP	4.7	17.0
Royal Canin Fiber Response	4.8	14.5
Royal Canin Selected Protein PV (pea/venison)	3.2	10.0

DM, Dry matter.

In dogs with severe intestinal disease, such as lymphangiectasia with moderate to marked hypoalbuminemia (serum albumin < 1.5 g/dL), severe inability to digest and absorb fat and protein will occur (see ch. 276). Disease progression can result in subsequent development of GI mucosal edema and further nutrient malassimilation.[17] In these animals, ultra–low-fat diets (fat concentrations <3 g/100 kcal or <10% DM) with a highly digestible protein source to prevent further malassimilation and dysbiosis will be required.[17] In the most severe forms of PLE (albumin < 1.0 g/dL), a combination of parenteral and enteral nutrition could be needed to provide protein for oncotic pressure and help resolve the GI edema until specific immunosuppressive therapy or antibiotic therapy can be put in place to help stabilize the patient.[17,18] Once serum albumin concentrations are >1.5 g/dL, a highly digestible, low-fat commercial diet containing intact protein might be tolerated. However, some dogs with severe chronic enteropathies like PLE could require feeding of ultra–low-fat homemade diets (e.g., non-fat turkey breast, non-fat cottage cheese, egg whites, rice, and cooked potatoes) indefinitely. If a specially formulated diet (either homemade or elemental) is required for management of the disease, a nutritionist should be consulted to ensure the diet recipe is complete and balanced if it will be used for more than 1-2 weeks. There are several elemental diets that may be used as a supplemental diet for dogs with severe GI disease, but the elemental with the lowest fat (≈5%) used most at the author's hospital is Vivonex TEN (Abbott). This is a human product and is not complete and balanced for dogs; however, it can be used as a short-term supplemental diet (see ch. 182). Vivonex (and other human elemental diets) should not be used alone in nutritional support of cats because they do not contain enough protein, essential amino acids (including taurine), or essential fatty acids (e.g., arachidonic acid).

Adverse reactions to food are important causes of signs of GI disease in both dogs and cats (see ch. 191). These clinical disorders generally are classified as immunologic (immune-mediated, e.g., IBD, food allergy/food sensitivity) or non-immunologic (food intolerance or idiosyncratic reactions to food). Diets used for establishing the diagnosis of, or to treat, adverse food reactions should contain: (1) a reduced number of novel protein sources or a protein hydrolysate (no intact proteins, molecular weights <10,000 daltons), (2) highly digestible protein, (3) no food additives; reduced numbers of substances known to cause intolerance (lactose, gluten) or vasoactive substances (e.g., preservatives, antimicrobials, humectants, coloring agents, flavors, flavor enhancers, emulsifying agents, stabilizers, and thickeners), and (4) be nutritionally complete and balanced.[19] The above recommendations can be achieved with a commercial novel protein or hydrolyzed diet or by preparing a homemade elimination diet.

Fats and Fatty Acids

Like protein, dietary fat also has some important direct effects on GI tract physiology and function, including

slowing gastric emptying in dogs and humans but not in cats.[2,4,6] In contrast to the effects of protein, increased levels of dietary fat decrease the tone of the lower esophageal sphincter and could lead to an increased risk of gastroesophageal reflux or vomiting.[6] Therefore, low-fat, highly digestible diets improve gastric emptying in dogs and could reduce vomiting. Undigested fats or fatty acids that reach the distal ileum or colon can increase bacterial fermentation (especially nonbeneficial species), resulting in formation of proinflammatory and prosecretory hydroxy fatty acids, and osmotic diarrhea.[9,17] Furthermore, even though low fat diets are important in the dietary management of many chronic enteropathies of dogs, extremely low levels of dietary fat (or severe disease resulting in poor fat absorption) will lead to a deficiency of essential fatty acids and fat-soluble vitamins, and can have wide ranging impacts on cell function, production of prostaglandins, cholesterol, phospholipids, other cell mediators, and hormones. Dietary fat also is important in pet food as a palatability enhancer—which can create a problem with diet acceptance in some of the low-fat, highly digestible or high-fiber diets.

In general, dietary fat is highly digestible—more so, generally, than CHO or protein—with an average digestibility of fat in commercial foods >85% and as high as 95% in premium diets.[6,7] Therefore, fat malabsorption due to diet source is unusual; however, because digestion and absorption of fat is a complex process requiring multiple steps, malassimilation of fat in dogs with GI disease is common. In commercial, therapeutic, highly digestible diets formulated for dogs with GI disease, a reduced amount of fat, ranging from 4% to 12% DM, or <3-4 g/100 kcal, is present. There is a large variability in fat content in both hypoallergenic and hydrolyzed diets, but higher amounts of fat generally are present because these diets are not formulated for dogs with severe GI diseases (see Table 178-1). The wide variation in dietary fat content can influence response to treatment, especially in dogs with severe enteropathies.

In contrast to dogs, feline diets formulated for GI disease do not have the same reduction in fat content. There are some low-fat diets formulated for cats, but most are weight loss diets or "light" diets formulated to prevent weight gain in adult cats. There is a wide range of fat content in feline intestinal diets, high protein diets, and novel protein diets—but in general, the lowest fat content is about 15-20% (4 g/100 kcal). The reasons for this difference are multiple: (1) There is no current evidence to support a low-fat diet in the therapy of feline intestinal disease (in one recent study the highest fat diet was the most effective),[16] (2) cats have a higher requirement for essential fatty acids, and some fat-soluble vitamins, than dogs do,[14] and (3) most cats will refuse to eat a diet that is too low in fat.

Carbohydrates/Dietary Fiber

There are no requirements for dietary CHO in canine or feline diets; however, dietary CHO is present in pet foods to provide a readily available energy source, to reduce fat or protein content of food, as a source of dietary fiber, and to make the diets more economical to produce. The CHOs present in pet foods primarily are plant starches, such as rice, potato, corn, wheat, and barley, but they also can include a variety of non-grain starches (e.g., legumes and other vegetables).[6] These vary in digestibility, glycemic index (ability to increase blood sugar rapidly), and glycemic load (ability to increase total glucose over time). In diets for dogs with GI disease, the overall quantity of CHO is less important than its digestibility. In cats, an obligate carnivore species, the reduced ability to efficiently digest and metabolize dietary CHO, especially in the presence of GI disease, demands not only the presence of highly digestible CHO but also a greatly reduced quantity.[14] The quantity of CHO also has an impact on other aspects of feline metabolism due to cats' reduced ability to remove glucose from the blood stream following a high glucose meal. This effect does not have an impact on GI disease, but it could have an impact on pancreatic function, so is a relevant concern.[20] Studies in cats with IBD have shown that CHO malabsorption is occurring (detected by the presence of increased breath hydrogen), but is not related to overt changes in clinical signs.[21] Further evidence of CHO intolerance is demonstrated by the resolution of diarrhea in cats and kittens when diets containing high protein/low carbohydrate concentrations are used.

CHO digestibility is determined by its source and by cooking; for example, cooked rice and cracked wheat are highly digestible, whereas uncooked whole corn or potato starch is less digestible.[6] CHO malassimilation can cause osmotic diarrhea, increased intestinal gas (flatus), loss of water and electrolytes, enhanced fermentation of bacteria in both the small intestine and the colon, and overgrowth of pathogenic bacteria. Further, CHO malassimilation contributes to acidification of the colonic luminal environment, which promotes formation of hydroxy fatty acids and other potentially toxic intermediates.[9] White rice is the CHO of choice for most dogs (and is the most commonly used CHO in therapeutic diets), because it is gluten-free,

highly digestible, and nonantigenic.[2,6,7] Other gluten-free CHO sources include potato and tapioca, but they are less digestible than cooked white rice. In short, all commercially available diets formulated for dogs with intestinal disease contain moderately high quantities of highly digestible CHOs.

Another class of CHOs present in some diets are the beta-linked polysaccharides (i.e., those broken down by bacterial enzymes, not mammalian amylases), which include the dietary fibers.[6] Dietary fibers are a large, complex group of CHOs that include starch and non-starch polysaccharides found in plants. They are readily digested by bacterial enzymes but less well digested by mammalian enyzmes.[6] Traditionally, fibers were classified as soluble (highly fermentable) or insoluble (poorly fermented or nonfermentable) based on their digestion by amylase; however, a physiologically relevant classification, based on their activity in the GI tract, currently is recommended (Table 178-2).

TABLE 178-2

Comparison of Fermentable and Nonfermentable Fiber Effects on the Gastrointestinal Tract

EFFECT	SOLUBLE (FERMENTABLE) FIBER (e.g., beet pulp, guar gum, psyllium)	INSOLUBLE (NONFERMENTABLE) FIBER (e.g., cellulose, methylcellulose)
Transit time	No effect on transit in colon, slows transit of ingesta in small intestine	Normalizes transit in the colon by increasing segmentation (mixing) and improving propulsion, appears to increase speed of transit in small bowel
Fecal bulk	Decreased—stool smaller and softer	Increased—stool larger, drier
Bacteria/fermentation	Increases (more fermentation, could support beneficial bacteria such as lactobacilli or bifidobacteria)	Fermentation occurs, but to a very minor extent—minimal change in fecal flora
Water binding	High water binding, forms thick gels, increases fecal water, feces wetter and smaller	Water absorption is efficient—feces can become quite dry if not expelled quickly or if the pet is dehydrated

Fibers are soluble if they form gels in solution (thus attracting water), delay gastric emptying, slow intestinal transit, inhibit absorption of cholesterol and some other nutrients, are poor bulking agents, are highly fermentable in the colon (i.e., increase the numbers of bacteria and increase short chain fatty acids [SCFAs], especially butyrate, an essential colonic fuel source), acidify luminal contents, and stimulate colonic cellular proliferation.[22] Examples of soluble fibers include FOS, pectins, psyllium, oats, barley, guar gum, fruits, and some legumes.[6]

Insoluble fibers do not form gels, have no effect on gastric emptying, increase small intestinal transit and "normalize" colonic (segmentation) transit, have no direct effect on nutrient absorption (except reduced time for digestive action), are good bulking agents (i.e., they dilute colonic contents and thus bind noxious agents in the colon), are fermented less and therefore produce fewer SCFAs, and increase fecal weight.[22] Typical examples of insoluble fibers are cellulose, peanut hulls, wheat and rye fibers (most cereal fibers), and the woody parts of plants (e.g., lignins).[6] Prescription diets containing dietary fiber are used primarily for weight-loss diets, and in treatment of diseases of the colon, with soluble fibers being used for promoting colon health in colitis or other infectious or inflammatory diseases of the colon, and insoluble fibers being used for normalizing motility (e.g., hair or irritant colitis), acting as an adsorptive agent (e.g., colitis due to toxins or bacterial colitis), or in animals prone to constipation that need the propulsive effects of a bulking agent. It should be noted that insoluble fibers acting as bulking agents could worsen constipation or cause recurrence when animals are dehydrated, or when animals have decreased colonic function (obstipation/megacolon).

Nutritional Deficiencies Due to GI Disease

Nutritional deficiencies can occur as a consequence of GI disease (see ch. 192 and 193). Protein and calorie malnutrition is the most common nutritional deficiency in severe or chronic GI disease. A variety of vitamin deficiencies can occur as a result of severe intestinal disease, but deficiencies of B vitamins, especially cobalamin, and of some of the fat-soluble vitamins (E and K), are the most common and clinically important deficiencies recognized in dogs and cats.[13,23] The reader is referred to ch. 276 for more information on

cobalamin and folate therapy in GI disease.

CHAPTER 179

Nutritional Management of Exocrine Pancreatic Disease

Marjorie Chandler

Client Information Sheet: Nutritional Management of Exocrine Pancreatic Disease

Acute Pancreatitis

Nutritional Risk Factors

Nutritional risk factors for acute pancreatitis (see ch. 289 and 290) in dogs include obesity, ingesting table scraps or food from the trash, a high-fat meal, or a high-fat low-protein diet.[1,2] Middle-aged, neutered dogs are considered to be at increased risk; this age and neutering status also has the highest prevalence of overweight and obese dogs.[3,4] Obesity in humans is a risk factor for a poor outcome in severe acute pancreatitis.[5] Obesity causes a low-grade inflammatory state and adipose tissue secretes numerous cytokines from adipocytes and adipose tissue macrophages.[6] Fat necrosis occurs after release of lipolytic enzymes from the damaged pancreas.[5] Fat necrosis promotes leukocyte infiltration of damaged areas, resulting in increased inflammatory mediators. The unsaturated fatty acids generated from lipolysis also contribute to inflammation and necrosis, processes that are worse in obese humans and mice compared to the non-obese.[7]

The increased risk associated with dogs that have scavenged in trash is the likelihood that they have consumed a large amount of fat present in scraps. Dietary fat has an effect on the Toll-like receptor (TLR)-4 present on macrophages, neutrophils, adipocytes and intestine epithelial cells. Activation of TLR-4 causes release of cyclooxygenase-2 derived cytokines and transcription factor NF-kappa-beta, which synthesizes tumor necrosis factor, further enhancing inflammatory responses. TLR-4 can be stimulated by lipopolysaccharide (LPS) endotoxin. There are similarities in LPS endotoxin and saturated long-chain fatty acids. Saturated long-chain fatty acids can stimulate macrophage receptors, similar in potency to LPS endotoxin. The adipocyte receptor is similarly activated by long chain fatty acids, although with less effect than LPS endotoxin.[8]

In >90% of cats with pancreatitis (see ch. 289 and 291), a cause is not identified and dietary risk factors for this condition are not well described.[9] Hyperlipidemia has been associated with feline pancreatitis.[2] Considering the effects of dietary fatty acids and obesity on inflammation and pancreatitis in other species, it is likely that diet has a role. Pancreatitis occurs in some cats fed high fat diets (Steiner J, personal communication, 2014).

Dietary Therapy for Acute Pancreatitis

Background

In the past, dogs and cats with pancreatitis were given nothing orally to decrease stimulation of pancreatic enzyme secretion and "rest" the inflamed pancreas. It is now appreciated that pancreatic inflammation and necrosis are worsened when exocrine activity is suppressed.[10] The intestine also plays a key role in the pathophysiology of acute pancreatitis. Intestinal ischemia, increased permeability and reperfusion injury may contribute to organ failure during pancreatitis. Withholding food promotes intestinal mucosal atrophy, increases rate of enterocyte apoptosis, decreases glutamine and arginine transport, and increases intestinal permeability.[11] Enteral feeding beneficially increases blood flow to the splanchnic circulation (see ch. 82).[8] In dogs with parvovirus, for example, early enteral nutrition hastened clinical improvement and likely

improved gut barrier function.[12]

People and Dogs

In the past 20 years, several trials involving people with acute pancreatitis have demonstrated the attributes of enteral, rather than parenteral, nutrition, including decreased mortality rates.[13,14] In people with pancreatitis, enteral feeding within 48 hours of hospital admission has been shown to be beneficial.[14] Meta-analysis has also shown that nasogastric feeding was not inferior to feeding into the jejunum.[14] Enteral feeding a low-fat diet via esophagostomy tube in dogs with severe acute pancreatitis, within the first 12-24 hours of admission, was well tolerated and resulted in fewer complications when compared with parenteral nutrition.[15] Dogs with pancreatitis are fed very low fat diets (e.g., less than 25 g fat per 1000 kcal), although no significant difference in the degree of pancreatic physiologic response in healthy dogs fed diets with 16% or 5% crude fat (as fed) was reported.[16,17]

Cats

Dietary management for cats with acute pancreatitis has not been well described. Many clinicians find that cats tolerate a higher fat diet than do dogs with pancreatitis. However, excessively high fat foods should probably be avoided.[18] Early placement of a nasogastric or esophagostomy tube (see ch. 82) is important in anorectic cats due to their risk of hepatic lipidosis. In a study of 55 cats with suspected acute pancreatitis, nasogastric tube feeding was well tolerated. Diarrhea and/or vomiting were not common.[19]

Maintenance Diets

It is recommended that obese or hypertriglyceridemic pancreatitis dogs or cats be fed ultra-low fat diets, with fat percentage on a dry matter basis (DMB) ≤10% for dogs and ≤15% for cats. Non-obese dogs and cats without elevated triglycerides may be fed diets with <15% and <25% fat DMB, respectively.[20] While there are commercial dog foods available which meet these criteria, there are fewer cat foods. Some "low calorie" or "senior" diets, which may not contain sufficient calories for an ill cat, are low in fat. Adverse effects have been reported with tube feeding elemental diets to cats, so a better approach may be to use a liquid diet formulated for use in cats if using a nasogastric tube.[18] If esophageal tube feeding is used or the cat has returned to voluntary eating, a diet with moderate fat content may be used (e.g., most commercial adult maintenance diets). In cats, intrinsic factor, a cobalamin (vitamin B_{12}) binding protein that promotes cobalamin absorption in the ileum, is only produced by the pancreas. In dogs it is synthesized in both stomach and pancreas. Many cats with pancreatitis are cobalamin deficient.[21,22] If a deficiency exists, parenteral supplementation is recommended at 250 mcg weekly for six weeks and then monthly.

Chronic Vomiting and Parenteral Feeding

When vomiting is too intractable to allow enteral feeding, peripheral or central parenteral feeding may be an option (see ch. 189). If possible, a small amount of enteral feeding should still be attempted to maintain gut integrity. In humans, the addition of glutamine has been found to reduce length of hospital stay and decrease overall complications in patients with acute pancreatitis given parenteral nutrition.[23]

Omega-3 Fatty Acids

The provision of omega-3 fatty acids to people with acute pancreatitis decreased complications and length of hospital stay.[23] The omega-3 fatty acid docosahexaenoic acid (DHA) affects the pancreatic acinar cell by inhibiting intracellular signalling, reducing amount of inflammatory cytokines generated, and inducing apoptosis instead of necrosis.[8] While saturated fats stimulate TLR-4, omega-3 fish oils inhibit stimulation of this receptor. No studies have been performed in dogs or cats to prove beneficial effects in the treatment of acute pancreatitis; however, fish oils can be useful in the treatment of hypertriglyceridemia and should be considered in pets with this condition as they are at increased risk of pancreatitis. The fish oils DHA and eicosapentaenoic acid (EPA) are recommended for use in cats and dogs over plant sources of omega-3 fatty acids. A recommended dosage of EPA plus DHA (230 to 370 $mg/kg^{0.75}$) has not been studied in dogs or cats with pancreatitis.[24]

Probiotics

Probiotics have been claimed to benefit people with severe acute pancreatitis by stabilizing intestinal barriers and minimizing bacterial translocation which contributes to infection of necrotic tissue.[25,26] They have also been claimed to stimulate host cell production of antimicrobial peptides and produce antimicrobial factors. However, in the PROPATRIA (probiotic prophylaxis in patients with predicted severe acute pancreatitis) trial, there was a higher mortality rate in people given a multi-strain probiotic compared to those given the control.[27] Because of this study, caution has been advised in the use of probiotics in pancreatitis and certainly the multistrain (Ecologic 641) used in this study should be avoided in pancreatitis.[14] A 2014 meta-analysis of the use of probiotics in the treatment pancreatitis found no evidence for probiotics being either harmful or beneficial in preventing infection, length of hospital stay, or mortality.[25] There are no recommendations for use of probiotics in pets with pancreatitis.

Antioxidants

A commonly accepted pathogenesis of pancreatitis begins with an insult to acinar cells followed by a proinflammatory response, which may then progress to a profibrotic response mediated by stellate cells. The level of oxidative stress in severe acute pancreatitis likely determines the severity of any systemic inflammatory response syndrome (SIRS; see ch. 132), duration of disease, and, potentially, risk of death.[8] The balance of pro-oxidants and antioxidants may be factors in resolving inflammation. In people, antioxidant cocktails (e.g., containing selenium, beta carotene, vitamin C and/or vitamin E) have reduced abdominal pain, disease recurrence, chronicity and length of hospital stay.[28-31] Studies of experimental canine pancreatitis have indicated an increase in free oxygen radical generation.[32-35] However, a study on the effects of superoxide dismutase on experimentally induced pancreatitis showed no improvement in serum laboratory findings or survival rates.[36]

Exocrine Pancreatic Insufficiency (EPI)

Overview

In dogs, progressive, immune-mediated pancreatic acinar and ductal atrophy is a common cause of EPI, although chronic pancreatitis may also be a cause.[37] While EPI is less common in cats, it is being diagnosed more commonly.[38] In cats, chronic pancreatitis is thought to be the most common cause of EPI.[22,34] Regardless, EPI is a condition associated with digestive enzyme deficiencies which may result in malassimilation, voluminous stools, steatorrhea, borborygmus, flatulence, and weight loss. While enzymatic therapy is the cornerstone of treatment (see ch. 292), dietary management is also extremely valuable.

Dietary Fat and Types of Diets

Restriction of dietary fat has previously been recommended for treatment of EPI. The rationale for lowering fat intake is that intestinal bacteria metabolize unabsorbed fat to hydroxylated fatty acids, which stimulate secretion of fluids in the distal small intestine and colon, potentially worsening diarrhea. Steatorrhea may also be a feature of EPI and could be worsened by high dietary fat.[39] Low-fat diets (e.g., 12 to 13% of calories as fat) have been recommended for initial treatment of canine EPI. In the only study to date, there was no control group and the dogs continued to do well when switched to a variety of diets later.[40]

In a canine EPI study, feeding a moderate-fat, low-fiber, highly digestible food decreased flatulence, borborygmi, fecal volume and defecation frequency compared to feeding the original diets. No differences were noted in appetite or fecal consistency.[41] In a later study on fat restriction and diet change in dogs with EPI, feeding a low-fat diet (13% of metabolizable energy [ME] as fat) compared to the original diets (14 to 30% calories ME basis) showed no significant difference in severity of signs.[42] A further study compared three diets in dogs with EPI: a high-fat diet (51% fat ME basis), a high-fiber, low-fat diet (22% fat on ME basis), and a moderate-fat, highly digestible diet (30% fat ME basis).[43] No consistent improvement was associated with any diet, and more importantly the response to the diets varied greatly among the dogs.

A low-fat diet may worsen lipase activity, as high-fat and high-protein diets optimized fat absorption when used with supplemented lipase enzymes in experimentally-induced canine EPI.[44] In three German Shepherd Dogs with EPI, feeding a highly digestible rice and soy protein–based hydrolysate diet with a high fat content

(40.8% fat ME basis) improved diarrhea and dermatological abnormalities.[45] When tolerated, a higher fat diet is likely to promote improvement in body condition, which is often poor in animals with EPI. A low-fat diet may not be necessary unless steatorrhea is uncontrollable. The effect of dietary fat on feline EPI has not been reported. In one retrospective study on EPI in 16 cats, 6 cats had received a "prescription diet."[46] Choice of diet appears to depend on the individual patient, as responses to diets vary. In some cases, a diet change may not be needed. Generally a low fiber, highly digestible diet is appropriate, with fat content adjusted as needed.

Medium Chain Triglycerides (MCTs)

Medium chain triglycerides with fatty acid chain lengths of six to twelve carbons have been suggested as a fat source for pets with EPI; however, results of a study looking at three diets (0%, 16% and 35% of total fat as MCTs) suggested that inclusion of MCTs did not improve clinical signs.[47] Moreover, MCTs are associated with poor palatability in dogs and extremely poor palatability in cats.[48,49]

Vitamins and Minerals

Cobalamin deficiency has been reported in many dogs and most cats with EPI.[38,46,50] Cobalamin should be supplemented parenterally if deficient and may need to be given chronically. Fat-soluble vitamins (A, D, E and K) may be deficient when fat is malabsorbed, but they do not necessarily require supplementation. Vitamin K deficiency has been reported in a cat with EPI.[51] If a coagulopathy is present or suspected, administration of vitamin K at 2.5 mg/kg SC q 24 h for two to three days is indicated. Supplementation of excess vitamins A and D can result in toxicosis, whereas vitamin E supplementation is generally safe.[10] There is no information on macro- and trace mineral absorption in dogs and cats with EPI, although one study found lower serum and tissue concentrations of zinc and copper compared to control dogs.[52,53]

CHAPTER 180

Nutritional Management of Hepatobiliary Disease

Craig G. Ruaux

Client Information Sheets:
Nutritional Management of Animals with Liver Disease
Nutritional Management of Animals with Hepatic Encephalopathy

Metabolic Energy and Protein Requirements in Chronic Hepatic Disease

Nutritional interventions in pets with hepatic disease must provide sufficient metabolic energy to meet the needs of the patient, while considering the disease state of the animal. Protein requirements to maintain a positive nitrogen balance may be substantially higher in animals with hepatobiliary disease than in normal dogs.[1] Dietary protein restriction in this group of patients may actually slow recovery. If dietary intake is inadequate, a common problem in patients with liver disease,[2] protein-calorie malnutrition can develop, worsening many of the clinical signs accompanying hepatobiliary disease. The first aim of nutritional support for most animals with hepatic disease should therefore be to ensure adequate caloric intake to meet metabolic energy requirements (see ch. 170 and 177).[3] Normal canine maintenance diets utilizing high-quality, readily digestible protein sources are indicated in most dogs with liver disease, unless overt hepatic encephalopathy is present.

While the actual metabolic energy requirements of animals with hepatic disease are not well defined, clinical experience suggests that most of these patients require at least the same dietary metabolic energy input as healthy, active animals. In cats, the provision of adequate protein intake is even more important to maintain lean body mass. Several amino acids (e.g., taurine, arginine, methionine and cysteine) are either essential in cats or become conditionally essential in disease states featuring decreased voluntary intake (see ch. 174).[4] Bile acids in the cat are exclusively conjugated to taurine[5]; as bile acids are deconjugated by intestinal bacterial activity, there is a constant demand for additional taurine, which must be met either from dietary intake or mobilization of muscle protein.[6] Taurine deficiency can thus develop rapidly in cats with hepatic disease.

Representative major nutrient compositions of diets from several manufacturers that are either directly labeled for use in animals with hepatic disease or recommended by the manufacturer for use in liver disease are summarized in Table 180-1.

TABLE 180-1

Major Nutrient Compositions of Representative Veterinary Prescription Diets with a Labeled Indication for Use in Hepatic Disease or Hepatic Encephalopathy

DIET	PROTEIN (% DM)	PROTEIN (g/100 kcal ME)	FAT (% DM)	CARBOHYDRATE (% DM)	MANUFACTURER RECOMMENDED INDICATIONS
Canine					
Hills l/d Dry	17.8	4.1	24.4	48.5	Liver disease, hepatic encephalopathy, copper storage
Hills l/d Canned	17.6	3.9	24.2	49.3	
Purina NF Kidney Function Dry	15.9	3.6	15.7	62.8	Renal failure, hypertension, early CHF, hepatic disease with encephalopathy

Purina NF Kidney Function Canned	16.5	3.6	27.4	50.4	
Purina EN GastroENteric Formula, Dry	27.5	6.6	13.3	47.7	Hepatic disease not associated with encephalopathy, enteritis, pancreatitis, IBD
Purina EN GastroENteric Formula, Canned	33.9	8.0	15.0	43.9	
Royal Canin HEPATIC Dry	14.0	4.0	14.0	49.0	Hepatic insufficiency, hepatic disease, hepatic encephalopathy, portosystemic shunts, disorders of copper metabolism
Royal Canin HEPATIC Canned	15.0	4.1	28.0	57.0	
Feline					
Hills l/d Dry	29.0	7.0	23.1	37.7	Liver disease, hepatic lipidosis, hepatic encephalopathy
Hills l/d Canned	31.6	6.7	23.2	38.0	
Purina NF Kidney Function Dry	28.5	7.2	12.8	50.6	Renal failure, hypertension, early CHF, hepatic disease with encephalopathy
Purina NF Kidney Function Canned	31.1	6.0	29.5	30.6	
Purina EN GastroENteric Formula, Dry	56.2	12.9	18.4	16.7	Enteritis, diarrhea, gastritis, hepatic lipidosis

CHF, Congestive heart failure; *DM*, dry matter; *IBD*, inflammatory bowel disease; *ME*, metabolizable energy.

Values are rounded to one significant figure. Data and indications obtained from respective company websites or printed materials as of March 2015.

The majority of liver diseases encountered in companion animals do not carry a risk of encephalopathy except in end-stage disease (Table 180-2); thus, the use of "liver" diets with markedly reduced protein content is not recommended for all, or even the majority of, animals with liver disease. Diets with mildly reduced protein content, utilizing a high digestibility protein (such as the renal and hypoallergenic diets listed in Table 180-1), are a preferred choice in most companion animals with liver disease.

TABLE 180-2

Common Canine and Feline Liver Diseases

CANINE	FELINE
Vacuolar hepatopathy Glucocorticoid-induced Diabetes mellitus Chronic illnesses (Pancreatitis, IBD)	Vacuolar hepatopathy Glucocorticoid-induced Diabetes mellitus Chronic illnesses (pancreatitis, IBD) Hepatic lipidosis **(very severe cases may have encephalopathy)**
Infiltrative diseases Acute hepatitis Idiopathic chronic hepatitis Lymphoma	Infiltrative diseases Cholangiohepatitis Lymphoma
Biliary tree diseases Major bile duct obstruction Biliary mucocele	Biliary tree diseases Major bile duct obstruction Cholangitis Neoplasia (biliary carcinoma)
Primary or metastatic neoplasia Metastases of hemangiosarcoma Massive hepatocellular carcinoma	Primary or metastatic neoplasia Hepatocellular carcinoma (rare)

Primary portal vein hypoplasia/microvascular dysplasia	
Cirrhosis	**Cirrhosis**
Portosystemic vascular anomalies	**Portosystemic vascular anomalies**
Juvenile fibrotic disorders (rare)	

Conditions associated with risk of hepatic encephalopathy are in **bold** type. Note that the majority of liver diseases diagnosed in companion animals are not associated with hepatic encephalopathy, except in an end-stage state.

Modified from Center SA: Nutritional support for dogs and cats with hepatobiliary disease. *J Nutr* 128(Suppl 12):2733S-2746S, 1998.

Nutraceuticals in Hepatic Disease

A reasonable definition of the term "nutraceutical" would be a food, food-derived compound, or dietary supplement that is given with the intent to modulate disease or provide health benefits. Many nutraceutical compounds have been suggested as supplements in human beings and animals with hepatic disease[7]; however, within the veterinary literature only two compounds/products, S-adenosylmethionine and silymarin, have received meaningful attention.

S-adenosylmethionine (SAMe) is critical for the synthesis and reduction of glutathione (GSH), which is one of the most important early protection mechanisms within the hepatocyte against oxidant stress.[8-10] SAMe has been assessed prospectively in healthy, untreated cats and in healthy dogs receiving chronic prednisolone therapy.[8,11] Increases in hepatic GSH, with an increase in the ratio of reduced GSH to the oxidized glutathione disulfide (GSSG) form, were noted. In the dog study, however, no protective effect was seen against glucocorticoid-induced vacuolar hepatopathy.[11] In one prospective, randomized, non-blinded trial, dogs receiving lomustine (CCNU) chemotherapy and an S-adenosylmethionine/silymarin combination product* showed less pronounced elevations in liver enzyme activities and were less likely to experience treatment delay than the control group receiving CCNU alone.[12]

Cats are particularly susceptible to acetaminophen-induced hepatotoxicosis, and SAMe would appear to be a rational therapeutic for this condition. Unfortunately, controlled studies of the effect of SAMe therapy on a model of acetaminophen hepatotoxicosis in the cat showed little to no effect.[9] There are very few well-controlled clinical studies assessing the efficacy of SAMe as a therapy for spontaneous chronic liver disease in dogs or cats.[13]

Silymarin has been shown to have potent antioxidant efficacy in several models of oxidant-mediated liver disease.[14] There have been very few well-controlled studies of silymarin use in companion animals with spontaneous disease, with the notable exception of the previously cited study using combined SAMe/silymarin in cancer-bearing dogs receiving CCNU.[12] Meta-analysis of clinical trials using silymarin in human beings reveals little evidence for clinical benefit, except in *Amanita phalloides* mushroom poisoning.[20]

Using a strictly evidence-based approach to medical decision-making, there is relatively little evidence of benefit from any current nutraceutical for management of chronic hepatic disease in dogs and cats.[13] While these products are unlikely to cause harm, and in many cases there are compelling physiological arguments for their possible benefit, accurate diagnosis of the primary liver disease and implementation of therapy directed towards this diagnosis are recommended in preference to empirical therapy with nutraceutical compounds at this time.

Copper-Restricted Diets

Copper (Cu) accumulation hepatopathy is well recognized as an autosomal recessive disorder in the Bedlington Terrier (see ch. 282).[15] In several other breeds there is evidence of excessive Cu accumulation in some liver diseases.[16-18] As Cu can accumulate with cholestasis as well as primary hepatocellular disease, the significance of Cu accumulation as a primary pathological event is less clear in many of these dogs. In the Labrador Retriever, studies suggest that chelation therapy and reduced Cu diets are associated with an improvement in chronic inflammatory liver disease and reduction in liver Cu concentrations in subclinical cases.[19,20]

Animals with hepatic Cu accumulation sufficient to cause overt hepatopathy are best treated with specific therapy using chelating drugs such as d-penicillamine, at least until hepatic Cu content is reduced below toxic levels. Dietary Cu restriction can be useful in the maintenance phase of management for dogs with these

diseases. Typical maintenance canine diets will contain a minimum of 7.3 ppm Cu, while Cu-restricted diets may contain as little as 3 ppm Cu on a dry matter basis.

Additional dietary manipulations to decrease hepatic Cu accumulation include supplementation with ascorbic acid and elemental zinc (Zn). Zn supplementation increases the intestinal expression of metallothionein, an avid metal binding protein within the enterocytes. Metallothionein has a higher affinity for Cu than Zn. Administration of Zn between meals leads to increased metallothionein expression in the enterocytes. Cu in the diet is then bound with high affinity within the mature enterocyte and lost in the feces as the enterocyte is shed.[21] Zinc is given at a loading dosage of 100 mg elemental Zn orally twice weekly for three weeks, followed by a maintenance dosage of 50 mg elemental Zn orally twice weekly. Vomiting and nausea may both occur as side-effects of Zn therapy; administration of the Zn with a small amount of food may reduce these side effects.

Vitamin and Mineral Supplementation

Animals with liver disease often have vitamin and/or mineral deficiencies. Several factors, including reduced voluntary intake, fat malabsorption, reduced gastrointestinal mucosal function and loss of reserve stores in hepatic tissue can all contribute to the development of vitamin and mineral deficiencies.

Water-soluble vitamins such as folic acid, thiamine, cobalamin, niacin and riboflavin are often critical cofactors in enzymatic pathways carried out in hepatic cells. In cats with hepatic lipidosis, deficiencies of these vitamins are common.[22] Administration of multivitamin supplements is cost-effective, simple, and should be included in any nutritional support plan for patients with liver disease.

In the cat, cobalamin malabsorption due to small intestinal disease is commonly documented in association with liver disease.[23] It has previously been thought that cobalamin malabsorption due to intestinal disease could not be overcome by increased dietary supplementation, implying that parenteral therapy is necessary.[24] Recent data, however, suggest that a small, but sufficient, amount of orally administered cobalamin is absorbed in both canine[25] and feline (Toresson L, personal communication, 2015) patients with gastrointestinal disease. Further studies of the efficacy of oral cobalamin supplementation in patients with chronic gastrointestinal and hepatic disease are eagerly awaited.

Some patients (particularly fractious cats and dogs) may still be most effectively treated for their cobalamin deficiency via a parenteral route; this route may also be essential during the initial phase of treatment of some patients where oral intake is reduced or absent. The protocol currently recommended for parenteral cobalamin use in cats with cobalamin deficiency due to intestinal disease is 250 mcg/cat injected subcutaneously, once a week for four weeks, one dose one month (4 weeks) later, then a recheck one month later. Further details of the current parenteral cobalamin dosing schedule and recheck recommendations may be found at http://vetmed.tamu.edu/gilab/research/cobalamin-information and in ch. 292. The concentration of cobalamin in standard injectable multivitamin preparations is insufficient to supply this amount of cobalamin in a reasonable injection volume; the use of pure preparations of cobalamin in addition to multivitamin products is recommended in dogs and cats with documented cobalamin deficiency.

Significant elevations in the plasma concentration of proteins induced by vitamin K antagonism (PIVKA) have been documented both in cats with hepatic lipidosis and cats with cholangiohepatitis associated with inflammatory bowel disease.[26] Vitamin E deficiency reduces cellular defenses against oxidant-mediated damage, and potentially plays a role in copper-associated hepatoxicosis.[27,28] Empirically, regular supplementation of vitamin E, A and D at three- to four-month intervals is recommended in companion animals with long-standing liver disease.

Nutritional Intervention in Hepatic Encephalopathy

Hepatic encephalopathy (HE) results from loss of hepatic detoxification function and subsequent accumulation of encephalotoxins within the systemic circulation and central nervous system.[29] These encephalotoxins may be directly toxic to neurons (i.e., ammonia), or may act as "false" neurotransmitters, interfering with central nervous system function.[29] In human patients, HE is graded via a variety of physiological and neurological scoring systems, most of which refer back to the West Haven Criteria.[29] Under this scoring system, HE is scored from 0 (no encephalopathy) to 4 (hepatic coma). Subtle neurological impairments, equivalent to inattention or mild tremor, are difficult to detect in small animals; therefore, most animals with a diagnosis of HE will fall within the West Haven Criteria scores 2-4. According to a consensus statement of the European Society of Parenteral and Enteral Nutrition, protein restriction is not indicated in

human patients with an HE score of 0-2, as negative protein balance and resultant malnutrition are negative prognostic factors.[2] Protein restriction is indicated in human patients with West Haven Criteria scores of 3-4. Such scores are a strong negative prognostic factor, with most dying within one year.[2] A critically important point, however, is that most animals with liver disease *do not* have this degree of HE. In many veterinary patients with hepatobiliary disease, aggressive protein restriction is counterproductive.

Recommendations for dietary protein content in diets fed to animals with severe HE vary. Most dogs can be managed with diets containing 3-4 g of protein per 100 kcal of diet, while cats require at least 6 to 7 g/100 kcal. It is important to note that the recommendation is for protein proportion within the diet, not for protein intake/kg of animal. Several commercially available diets are formulated to meet these recommendations (see Table 180-1).

The amino acid makeup of the diet used in patients with HE is another area of interest and controversy. It has been suggested that aromatic amino acid (AAA)-rich diets are likely to potentiate HE, the AAAs potentially acting as substrates for the production of encephalotoxins.[1] The molar ratio of AAA to branched-chain amino acids (BCAA) in plasma has been shown to be increased in animals with HE.[1] BCAA are important substrates for gluconeogenesis, and thus, the presence of protein/calorie malnutrition will lead to depletion of these amino acids in the plasma. While these changes in the AAA:BCAA are well documented in veterinary and human patients, their significance as a direct cause of HE rather than as an epiphenomenon is unclear. Experimental studies using dogs with surgically-created portosystemic vascular anomalies found more pronounced HE and higher blood ammonia concentrations in the dogs receiving a low AAA:BCAA diet. However, the dogs receiving this diet ate more than those receiving a high AAA:BCAA diet, resulting in greater total protein intake.[30] Based on meta-analyses of studies in human beings with HE, BCAA supplementation is recommended in patients who develop severe HE scores during enteral nutrition.[2] The situation is less clear with lower grade HE human patients, and by extension most veterinary patients. In most cases, BCAA supplementation is unlikely to lead to a net negative benefit, unless voluntary intake is reduced. Most veterinary prescription diets specifically labeled for hepatic disease are formulated to achieve a higher BCAA content and derive a significant proportion of metabolizable energy from fats and carbohydrates.

Feeding of several small meals throughout the day is often of benefit for animals with overt HE, reducing the total ammonia load following each meal. Other strategies used to control HE in small animals include antibacterial therapy with neomycin or metronidazole and the use of enteric lactulose therapy (oral or via enema) to reduce ammonia production and absorption, respectively, from the gastrointestinal tract (see ch. 281 and 284).

Nutritional Management of Hepatic Lipidosis in Cats

Appropriate nutritional management is absolutely central to successful resolution of hepatic lipidosis (HL) in cats (see ch. 285). Most (>95%) cats with HL have an underlying illness that predisposes the cat to enter a catabolic state.[22] Successful management typically requires addressing this underlying disease process, to allow a return to more normal appetite. In the short term, diligent attention to restoration of a positive caloric balance is necessary.

The feline liver has relatively small glycogen stores, making the cat dependent upon systemic lipolysis and hepatic metabolism of triglycerides relatively soon after the onset of anorexia. The underlying biochemical defects leading to hepatic accumulation of these lipids are complex and not fully understood; however, they do appear to be intrinsically linked to the cat's strictly carnivorous diet.[4,31] Arginine, choline and carnitine supplementation are commonly recommended in the nutritional management of cats with hepatic lipidosis. Cats with hepatic lipidosis fed arginine-deficient diets, even if fed in quantities necessary to supply adequate caloric intake, can rapidly develop severe HE as the urea cycle is compromised.[22] Choline and carnitine are both important in mitochondrial fatty acid transport and packaging of fatty acids into very-low-density lipoproteins for export from the hepatocyte. Thus, deficiency of these trace elements may contribute to lipid accumulation. If the diet used for initial feeding is deficient in arginine, as is the case with most human formulations, this amino acid should be supplemented at a dosage of 250 mg/100 kcal of diet delivered. The author empirically supplements HL cats with arginine, carnitine (250-500 mg/day), and taurine (250-500 mg/day) regardless of the enteral nutrition formula used.[22,32]

Most cats with HL are severely anorectic. Assisted feeding should be implemented as soon as feasible in these patients. Oral forced alimentation is not recommended, because many force-fed cats will develop food aversion. Medical agents for appetite stimulation in cats are variably effective, often ineffective in HL cats,

and may require hepatic detoxification.[33] Early placement of a feeding tube, at the minimum an esophagostomy tube, should be considered the standard of care (see ch. 82). Placement of a large-bore esophagostomy tube (10-14 French) can make feeding easier and allow the use of blenderized diets. Percutaneous, endoscopically-placed gastrostomy (PEG) tubes allow greater movement of the head and neck of the cat (as these areas are not bandaged), allowing the cat to self-groom. If a large bore PEG tube can be placed, owners can easily feed the cat at home. Clinicians experienced in this technique can place a tube in a 10-15 minute anesthetic procedure.

With critically ill cats, where even a short anesthetic procedure to place an esophagostomy tube is felt to carry excessively high risk, initial feeding with a nasoesophageal tube (5-8 French) can be attempted (see ch. 82). However, these tubes are more prone to clogging and failure due to vomiting, regurgitation, or removal by the patient.

Many cats show vitamin K deficiency and elevated PIVKA with HL[26]; administration of subcutaneous vitamin K for 1-2 days before feeding tube placement is recommended for cats with documented coagulopathy. Surgical placement of gastrostomy tubes via celiotomy in cats with hepatic lipidosis is associated with high risk of post-operative morbidity and an unacceptable risk of stomach displacement.[22]

During initial reinstitution of feeding, dramatic and potentially life-threatening electrolyte derangements can occur, particularly in serum potassium (K^+) and phosphate (PO_4^{3-}). These electrolyte derangements should be anticipated when beginning assisted feeding in cats with hepatic lipidosis, and may require aggressive management (see ch. 142 and 305).

Many cats with HL have water-soluble vitamin deficiencies. These are commonly supplemented by admixing multivitamin preparations into IV fluids at a dosage of 1-2 mL/1 L bag. IV fluid bags and lines containing supplemental multivitamins should be protected from light.

Thiamine deficiency is particularly insidious in cats with HL. Both thiamine and K^+ deficiencies can result in obtundation, weakness and neck ventroflexion (see ch. 21). These signs may be misinterpreted as HE, and these abnormalities should be screened for and corrected before instituting low-protein diets for presumed encephalopathy. HE is not a feature of most cases of HL, and use of low-protein diets may be associated with an adverse outcome.[34]

CHAPTER 181

Nutritional Management of Endocrine and Metabolic Diseases

Jennifer Larsen

Client Information Sheet: Nutritional Management of Diabetes Mellitus in Dogs and Cats

Successful management of many endocrine diseases may be facilitated with appropriate nutritional strategies. Most important is diabetes mellitus (DM; see ch. 304 and 305) and, to a lesser extent, feline hyperthyroidism (see ch. 301). Hypothyroidism (see ch. 299 and 300) and hyperadrenocorticism (see ch. 306 and 307), while treated medically, often require consideration of nutritional management for appetite control, weight loss, and controlling secondary hyperlipidemia (see ch. 182).

Nutritional Management of Diabetes Mellitus

Overview

Nutritional management of DM in both dogs and cats includes choosing a diet, meal schedules, consideration of energy requirements, weight management, and addressing any concurrent disease. Concurrent or historical pancreatitis should be considered, especially in dogs (see ch. 290). In either species, identifying and addressing potential underlying causes of insulin resistance, especially obesity (see ch. 176), is critical. The goal of nutritional therapy for DM is to help improve glycemic control in conjunction with insulin therapy and management of other medical problems or other individual factors.[1] Consideration of the individualized nutritional assessment (body weight, body condition score, appetite, diet history, etc.) as well as feeding management issues that may include owner abilities and limitations is warranted in order to provide a customized and effective nutritional plan (see ch. 170). Further, dietary features such as fat and fiber content, energy density, and palatability can each be key.

Nutritional Background for Dogs with DM

Insulin requirement in DM dogs (see ch. 304) is largely determined by dietary factors such as meal timing, meal size, and the rate of glucose absorption from the intestine. Consistency is an important aspect of the feeding schedule. Ideally, the same amount of the same diet is fed at the same time every day. Two or more smaller meals are preferable to one large daily meal, to minimize wide fluctuations in blood glucose. Most DM dogs are fed two equal-sized meals daily, coordinated with twice-a-day insulin injections. A minority of dogs with DM are finicky eaters and may prefer consuming food in small amounts throughout the day. In these pets, consumption of a significant portion of the daily energy requirement (up to 50%) at the time of insulin administration should be encouraged, to provide adequate concentrations of glucose for the administered insulin. Dogs with DM, whether at the time of diagnosis or after excellent response to therapy, are usually always hungry (polyphagic) and meal feeding is rarely an issue. However, diet palatability remains important to ensure adequate intake of energy and other essential nutrients.

Nutritional Background for Cats with DM

Unlike dogs, cats with DM (see ch. 305) do not appear to require strict control of meals, perhaps due to their longer gastric emptying times and absorption of dietary carbohydrates.[2,3] For example, feeding diets containing various starch sources at concentrations similar to those found in commercially available feline diets (approximately 35% dry matter) had only a minor impact on postprandial glucose and insulin responses

in healthy cats; maximum plasma glucose concentrations were 68 to 93 mg/dL several hours after eating.[4] The largest differences between dogs and cats in response to feeding were noted with diets containing cornstarch (38 and 34% dry matter for dogs and cats respectively). Peak blood glucose concentration for dogs was 92 mg/dL 15 minutes after eating. However, 7.2 hours were needed for cats to reach a similar peak value of 93 mg/dL.[4,5] These findings are consistent with data demonstrating that feline glycemic responses to commercial dry diets are not only prolonged (intestinal absorption occurred over 10-12 hours), but are not associated with dietary carbohydrate concentration or carbohydrate digestibility.[6]

Controlling Postprandial Hyperglycemia in Diabetic Dogs and Cats

Introduction

Diet composition characteristics can reduce the magnitude of postprandial hyperglycemia in dogs and cats with DM. These factors include increased fiber and the use of lower amounts of carbohydrate. Both factors probably contribute to the lower "glycemic index" of some foods, with those higher in fiber and/or lower in starch having lower glycemic indices.[7-9] Overall, the glycemic index concept has not yet been validated in either dogs or cats and is not currently used in assessing carbohydrate sources or pet foods. Other strategies to prolong gastric emptying time, such as increased amounts of fat, might be contraindicated in DM due to obesity or to abnormal lipid metabolism and resultant dietary fat intolerance (e.g., pancreatitis or hyperlipidemia).

Dietary Fiber (see ch. 190)

Fiber comprises a varied group of compounds produced by plants, not digestible by mammalian enzymes. Fiber sources are primarily complex carbohydrates (beta-linked chains of sugar molecules) but also include compounds such as lignin, phytates, and waxes. Fiber is usually categorized by its degree of solubility in water and its degree of fermentation by intestinal bacteria. Fiber is not considered nutritionally essential for dogs or cats, but can be a useful adjunct in managing many conditions. The goals of adding fiber to a diet are typically to achieve satisfactory and consistent stool quality, promote satiety, decrease energy density of food, achieve a prebiotic effect (e.g., fermentation by the intestinal microbiota to produce short-chain fatty acids), or to modulate gastric emptying and nutrient absorption.

Various methodologies are utilized to quantitate different fiber fractions within food. Currently, the quantity of crude fiber (CF) is the standard for reporting fiber content of pet foods. This method quantifies some, but not all insoluble fiber as cellulose, hemicellulose, or lignin. However, soluble fiber content is not assessed. In contrast, total dietary fiber (TDF) is reported for human food. TDF simulates enzymatic digestion within the gastrointestinal tract, captures more insoluble fiber than the CF method, and allows for quantification of soluble plus insoluble fiber. Newer TDF methods also separately quantify low-molecular-weight dietary fibers, such as the indigestible oligosaccharides utilized by intestinal microbes. They are included in the World Health Organization's definition of dietary fiber. These distinctions are important given that CF is a poor measure of true fiber concentration (as determined by TDF) in adult maintenance dog foods, in veterinary therapeutic diets formulated for the management of feline DM or obesity, and in those formulated for canine DM, obesity, or fat-responsive conditions.[10-12] The use of CF in pet foods leads to significant challenges in comparing products based on fiber type and concentration, while also overestimating energy content and carbohydrate concentration. One study found that using CF vs. TDF resulted in carbohydrate overestimates as high as 93% in cat diets formulated for DM.[11] As such, conclusions drawn by previous research utilizing CF to estimate fiber and carbohydrate content of diets may not be accurate.

There are few data describing the impact of dietary fiber on managing feline DM. One randomized crossover study investigating the role of insoluble fiber in the treatment of DM cats demonstrated improved glycemic control in 12/16 consuming a diet high in fiber (61 g TDF/Mcal) and in 4/16 cats who consumed a diet low in fiber (11 g TDF/Mcal) but higher in starch.[13] Another study assessing the efficacy of glipizide included unequal groups of cats on commercial diets varying in fiber content (16 fed a high-fiber diet and 4 a low fiber diet); cats on each diet responded to the treatment but the response rate could not be compared due to the study design.[14] The optimal concentration and type of dietary fiber for nutritional management of cats with DM remains unknown.

Insoluble fiber, in particular, appears to be beneficial in DM dogs, although soluble fiber may have a role as well. One study showed lower mean 24-hour and postprandial blood glucose concentrations when dogs were

fed a high fiber diet (mostly insoluble; 56 g TDF/Mcal) compared to baseline values.[15] There is evidence that diets high in insoluble fiber (73 g TDF/Mcal), when compared to high-soluble-fiber (56 g TDF/Mcal) diets, are beneficial in managing canine DM, including lower mean glucose concentrations, lower maximum blood glucose concentrations and lower areas under the blood glucose curve.[16] However, when fiber types were compared in feeding studies of dogs with experimental DM, diets high in either insoluble (cellulose; 70 g TDF/Mcal) or soluble fiber (pectin; 55 g TDF/Mcal) resulted in lower blood glucose concentrations when compared with a lower fiber diet (24 g TDF/Mcal). There was no difference between groups fed the high fiber diets.[17] With regard to the efficacy of moderate fiber concentrations, no benefit for dogs with DM was noted with diets containing 18-20 g TDF/Mcal when they were compared with modestly-low fiber diets containing 14 g TDF/Mcal (mostly insoluble).[18] In summary, if a higher fiber strategy is desired, it appears that the concentration should exceed 55 g TDF/Mcal from an insoluble or mixed fiber source to provide a beneficial effect.

Feline Diabetes Mellitus

Background

There is no consensus regarding specific dietary strategies for cats with DM and little scientific evidence to support promotion of any particular nutritional approach. Almost all the diets used in studies on cats with DM had carbohydrate and fiber content based on inaccurate calculations using CF. This likely contributed to carbohydrate overestimations in tested diets.[11] Further, clinical trials on the effect of commercially available diets differ in many respects. To date, no studies comparing diets for cats with DM have controlled for ingredients, fiber type, fiber concentration, carbohydrate source, or for other macronutrients (fat and protein). While some clinical product testing is useful with regard to comparing the efficacy of specific diets in treating particular diseases, these studies do not provide definitive information on the effect of any particular nutrient on managing feline DM. It is known that dietary factors other than carbohydrate concentration and source have a role in treating cats with DM. For example, one study demonstrated benefits attributable to higher fiber intake.[13]

Carbohydrates

Recent focus on carbohydrate concentrations may be misguided. Arguably, definitions of what constitutes a "low carbohydrate" diet are subjective, although a range of up to 25% carbohydrate on an energy basis has been suggested.[1,19] Also, in the absence of data from cats with DM fed controlled diets with graded concentrations of carbohydrate, dose-response curves to determine the optimal amounts are also lacking. In addition, the inaccurate calculation of carbohydrate concentrations using CF values may result in needless and incorrect elimination of potentially beneficial dietary options.[11] Feline diets marketed as "low carbohydrate" tend to be high in fat and have high energy density, less than ideal for most overweight cats with DM and especially if the restricted amount is not acceptable to the owner or the cat.[11] This may be somewhat ameliorated by the use of higher moisture (canned) diets.[20] It remains unknown whether the effects of a specific diet are maintained long-term and of sufficient magnitude to sustain weight loss and an ideal body condition.

Diet Comparisons

Limited data examining the effect of diet on control of naturally-occurring DM in cats have been published. Several studies involved feeding only one diet during the test period, important for standardization prior to measurement of dependent variables. However, this approach omits dietary control groups and precludes interpretation of any potential response to nutritional factors.[21-25] To our knowledge, only four studies have compared two or more diets in cats with DM. In each study, improvement or remission of the DM was noted for more than one dietary group.[13,14,26,27] Two of these studies demonstrated that most cats benefited from consuming a higher fiber diet, although statistical analysis of response rates was not possible in one study.[14] A third study found improvement when the cats were fed a lower carbohydrate, lower fiber, higher fat diet.[26] The fourth study found no difference in improvement rates between DM cats fed lower carbohydrate diets and those fed "maintenance" diets; this study also reported a median body weight gain in both diet groups.[27] Overall, it appears that improvement or resolution of the diabetic state may be more likely in cats who were obese and who lost body fat, regardless of diet.[22,26] Further investigation into why some cats achieve

remission while some do not, regardless of diet, is necessary to understand the underlying physiology and identify potential targets for dietary and medical therapy.

An Individualized Approach to Nutritional Management of DM

For both dogs and cats, appropriate dietary management of DM depends, in part, on individual factors: body weight, body condition score, weight trends, diet palatability, food acceptance, exercise, and treats. Energy restriction and maintenance of a lean body condition improves glucose tolerance, and increases quality and quantity of life in healthy dogs (see ch. 2 and 170).[28] It is not known if these apply to dogs with DM, but it has been demonstrated that intake of a very high-fat-diet (80% fat calories) by dogs may lead to obesity, impaired central nervous system insulin transport, insulin resistance and reduced ability to synthesize and secrete insulin.[29,30] Preventing or reversing obesity is important for health, longevity, and improved sensitivity to insulin. Therefore, a lean body condition should be a goal for every patient. Diets that are highly energy dense and high in fat would not be appropriate for achieving a lean condition in an overweight pet. Conversely, a lower-energy-density, high fiber diet would not be ideal for a thin diabetic.

For dogs and cats with evidence of fat intolerance (e.g., pancreatitis or hyperlipidemia), clinical experience suggests that reducing dietary fat by at least 50% on an energy basis (% of calories from fat) is effective. Formulation of an appropriate diet requires not only correct interpretation of a detailed diet history, but determination of the amount of fat routinely consumed before the diagnosis of DM was made. Consideration of relevant patient factors, as well as the willingness and ability of the owner to purchase and feed a specific type of diet, are important aspects of assessment and ongoing management. In the absence of the need to address concurrent issues, diet change may not be necessary if the meal schedule is appropriate and the diet balanced. The optimal approach to feeding dogs and cats with DM is one customized to the individual.

Nutritional Management of Insulinoma

See E-Box 181-1.

E-Box 181-1

Insulinoma

Overview

Insulinoma is a tumor that commonly causes clinical signs attributable to hypoglycemia including seizure, collapse, and weakness among others (see ch. 61 and 303). Although clinical trials assessing the efficacy of dietary modification on signs, prognosis, and other outcomes in dogs with insulinoma have not been reported, nutritional strategies can be successfully employed for varying time periods. Insulinomas tend to be relentless in their progression. The goals of nutritional management of dogs with insulinoma include avoidance of prolonged periods of fasting and minimizing large variations in blood glucose concentrations. Feeding management strategies and specific dietary profiles may help achieve these goals through modifying peripheral, hepatic, and normal pancreatic metabolism of nutrients. Dietary simple sugars may stimulate secretion of profound amounts of tumor-derived insulin and must be avoided.

Feeding Management and Nutritional Profile

Dietary factors such as meal timing, meal size, and meal frequency are important to ensure a steady and low to moderate absorption of glucose from the intestine. Feeding several small meals each day, including a last one at bedtime, is indicated. In addition, controlling the amount of digestible carbohydrate (sugars and starches) will contribute to this effect. Moderate fat and protein intake (20-35% of dietary energy for each macronutrient) will help slow stomach emptying and gastrointestinal transit, but attention to the dietary energy density as well as the total daily amount fed is indicated to prevent unwanted weight gain secondary to the anabolic effect of hyperinsulinemia. Fiber, especially soluble fiber, also slows gastrointestinal transit and promotes a more viscous chyme from which absorption of glucose is slowed or reduced. Veterinary therapeutic diets formulated for canine diabetes mellitus incorporate many of these strategies and remain a good option for dogs with insulinoma.

Nutritional Management of Feline Hyperthyroidism (see ch. 301)

Background

Thyroid hormone is integral for growth, development, and metabolism. Selenium and iodine are among the nutrients required for normal thyroid function, even though the quantities needed may appear small (micrograms). Selenoproteins such as type I iodothyronine 5'-deiodinase, which converts T_4 (thyroxine) to T_3 (triiodothyronine), are impacted by the dietary supply of selenium. As in other mammals, cats fed diets low in selenium have increased circulating T_4 and decreased T_3 concentrations, as well as low serum concentrations of selenium and glutathione peroxidase (another selenoprotein).[31] Despite some degree of variability in selenium concentrations in pet foods, deficiencies in cats consuming commercial food are either rare or not recognized.[32] Likewise, selenium toxicosis is unlikely, not described, and studies have shown that cats appear to increase urinary excretion in order to regulate selenium homeostasis at high intakes.[33,34]

Iodine is necessary for synthesis of thyroid hormones T_3 and T_4. Like selenium, the concentration of iodine in pet foods is highly variable.[35-37] There has been speculation that variability and/or extremes in iodine intake may contribute to the pathogenesis of hyperthyroidism. One report found that serum free T_4 concentrations in 10 cats were not affected by chronic and stable intake of high or low (21 vs. 0.11 mg/kg dry matter) iodine-containing diets over a period of 5 months.[38] However, alternating intake levels every 2 weeks over a 12-week period in 2 groups of 8 cats resulted in a significant inverse relationship between iodine intake and serum free T_4 concentration.[39]

Reduction in iodine intake has been a target for dietary modifications aimed at controlling hyperthyroidism in cats, as dietary deficiency in other species reliably results in hypothyroidism. There are limited data on the effect of iodine deficiency in cats. One study reported thyroid gland hyperplasia but lack of other clinical abnormalities in kittens fed a diet low in iodine for several weeks (0.45 mg/kg dry matter).[40] Another study showed no clinical signs of deficiency nor any impact on thyroid hormone concentrations despite achieving a negative iodine balance in adult cats over a period of 9 months (0.46 mg/kg dry matter).[41] The dietary iodine requirement for hyperthyroid cats is unknown; however, low-iodine diets have been explored as a strategy to reduce the synthesis of thyroid hormone in hyperthyroid cats. There are data supporting successful use of an iodine-restricted diet as a treatment for cats with hyperthyroidism. One uncontrolled prospective study assessed a large number of cats with naturally occurring hyperthyroidism; variable numbers of cats had clinical and bloodwork parameters assessed at baseline and at 4 and 8 weeks after consuming an iodine-restricted diet (0.14 and 0.19 mg/kg dry matter basis for canned and dry formulas, respectively).[42] Total T_4 concentrations normalized in 56/88 cats after 4 weeks of consuming the diet, while clinical parameters such as weight loss and poor coat quality were improved in subsets of cats for which these were assessed.[42] Another smaller, blinded, and randomized study demonstrated that 12 hyperthyroid cats fed a diet low in iodine (0.21 and 0.36 mg/kg dry matter for canned and dry formulas, respectively) for 12 weeks had lower total and free T_4 concentrations when compared to 10 cats fed a control maintenance diet (6.34 and 3.01 mg iodine/kg dry matter for canned and dry formulas respectively). 6/12 hyperthyroid cats on the test diet became euthyroid.[43] Creatinine decreased, while urine specific gravity and body weight did not change.[43] Other data, not yet published, used diets with iodine concentrations at levels that induced and maintained euthyroidism in hyperthyroid cats for as long as 3 years.[44-46]

There is one iodine-restricted (0.2 mg/kg dry matter) veterinary therapeutic diet available for management of hyperthyroid cats. While definitive treatment of hyperthyroidism with radioactive iodine therapy or surgical thyroidectomy is still preferred, dietary therapy is an alternative for cats who are not suitable candidates for those procedures. Dietary therapy is also an alternative when use of anti-thyroid medication is not an option. Due to the need for strict and consistent control of the amount of dietary iodine consumed, issues potentially impacting compliance should be considered. Iodine intake from treats, access to other foods, hunting, and some supplements must be avoided. Therefore, dietary therapy may work best for indoor-only, single cat households or for owners who can control intake of individual cats in multi-cat homes.

CHAPTER 182

Dietary and Medical Considerations in Hyperlipidemia

Richard C. Hill

Client Information Sheet: Dietary and Medical Considerations in Hyperlipidemia

The metabolism of lipid by dogs and cats has been the subject of several substantial reviews.[1-5] These reports discuss similarities and important differences in how fat is metabolized among mammals, which limits extrapolation of information from people to dogs and cats. Hyperlipidemia is only encountered sporadically in dogs and cats, except in a few breeds. Recommendations are based, therefore, on a few retrospective case-control studies and anecdotes. Careful monitoring of an individual's response to treatment remains essential.

Fat Metabolism

Triglyceride in food is emulsified by bile acids in the intestine and hydrolyzed by pancreatic lipase into fatty acids and monoacylglycerides, absorbed, and then reassembled into triglycerides in the enterocyte. Bile acids are synthesized from cholesterol in the liver and undergo enterohepatic recycling: they are excreted by the liver and are then reabsorbed in the gut. Triglycerides, cholesterol, cholesterol esters and phospholipids are transported in blood packaged as lipoproteins: as chylomicrons from the intestine, very low density lipoproteins (VLDL) from the liver, or as intermediate density lipoproteins (IDL), low density lipoproteins (LDL) and high density lipoproteins (HDL) (Figure 182-1).

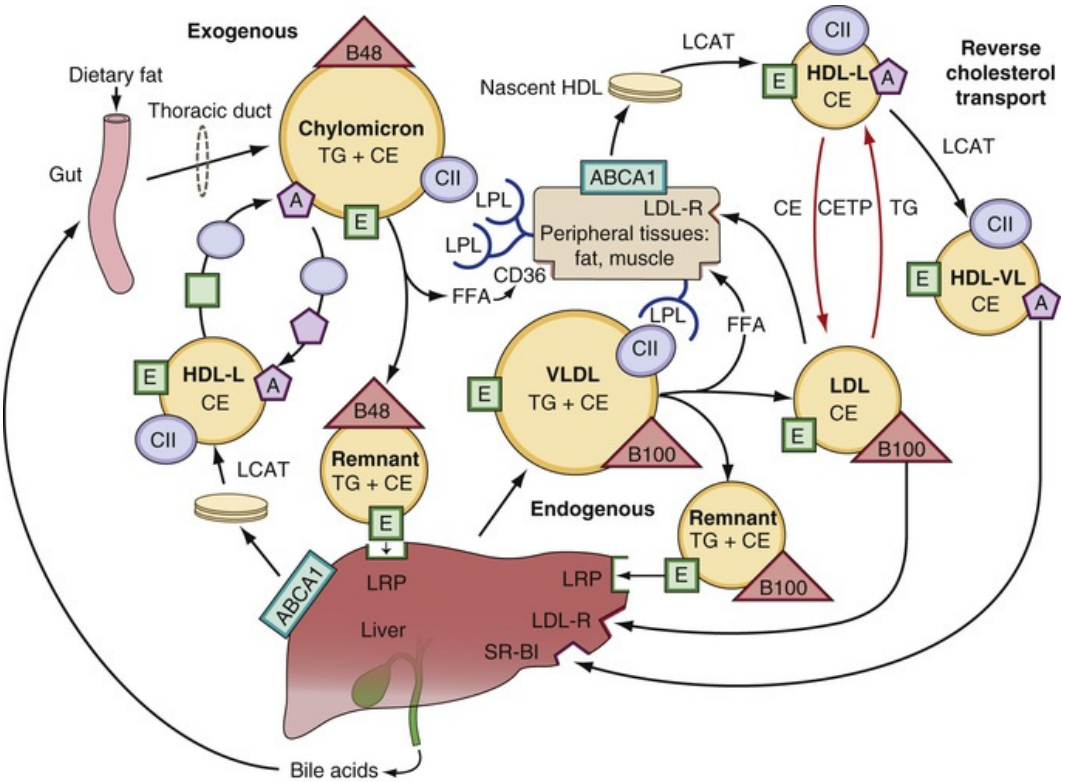

FIGURE 182-1 Exogenous and endogenous lipoprotein metabolism and reverse cholesterol transport involving chylomicrons, very low density lipoproteins (VLDL), low density lipoproteins (LDL), large and very large high density lipoproteins (HDL-L and HDL-VL, respectively). Lipoprotein lipase (LPL) hydrolyzes triglycerides (TG) from lipoproteins containing apoprotein CII (blue oval) and the free fatty acids (FFA) generated are taken up by peripheral tissues mediated by the CD36 scavenger receptor. Apoproteins B (pink triangle) and E (green square) are recognized by the LDL receptor (LDL-R) in liver and peripheral tissues and the LDL receptor-related protein (LRP) receptor in the liver. Nascent HDL are secreted by the ATP-binding cassette, sub-family A member 1 (ABCA1) in many tissues and then accumulate cholesterol esters (CE) by the action of lecithin cholesterol acyl transferase (LCAT). HDL also obtain apoprotein A (purple pentagon) in exchange for apoproteins C and E with chylomicrons. HDL transport cholesterol back to the liver and steroidogenic tissues where CE uptake is mediated by the scavenger receptor B, type I (SR-BI). In some animals, but not dogs, there is an additional method of reverse cholesterol transport (red lines) in which CE are exchanged for TG between HDL and other lipoproteins by the action of cholesterol ester transport protein (CETP).

Healthy dogs and cats have adapted to consuming high fat diets. Sled dogs have been fed a diet containing large amounts of fat with impunity.[6,7] Dogs carry more fatty acids on albumin, have mostly aerobic muscle fibers and are able to metabolize fat at twice the rate of less aerobic species.[8,9] Fecal fat is mostly endogenous.[10,11] Dogs appear to lack cholesterol ester transport protein (CETP), which facilitates transfer of cholesterol from HDL to VLDL and chylomicrons. As a consequence, half their high density lipoproteins (HDL) remain large and reverse cholesterol transport is limited. In people, increased CETP activity has been correlated with post-prandial hyperlipidemia and an increased risk of disease.[12] The risk of atherosclerosis increases in people with low HDL and high LDL concentrations but about 66% of fasting lipoproteins are HDL and 33% are LDL in both dogs and cats, whereas in people, 66% are LDL and 33% are HDL, perhaps explaining why atherosclerosis is rare in dogs and cats.[13]

Risk of Disease Relative to Blood Fat Concentrations

Managing hyperlipidemia is difficult. The decision to treat hyperlipidemia should be dependent on the risk of illness it causes (see ch. 63). For example, obese people with a combination of abnormal blood lipids, insulin resistance, and hypertension have the condition "metabolic syndrome" and are at increased risk of type 2 diabetes mellitus (DM), atherosclerosis, coronary heart disease and stroke. Cut-offs for each component of the syndrome are based on threshold values above which disease becomes more likely.[14] Such cut-offs, based on risk of disease, are not possible in dogs and cats because dogs and cats rarely develop atherosclerosis, cardiac thrombosis, or stroke. An attempt to define metabolic syndrome in dogs using reference range cut-offs for

blood lipid and glucose did not account for disease risk and are, therefore, of limited value.[15]

Insulin resistance has been demonstrated in Miniature Schnauzers with hyperlipidemia and obesity (see ch. 176). It has been associated with insulin resistance and hyperlipidemia in dogs and cats.[16-19] Type 2 DM is common in cats but rare in dogs (see ch. 304 and 305).[20] Type 2 DM has been described and an increased prevalence of DM has been noted in obese dogs, but cause and effect were not established.[21-23] Why some obese cats develop DM is not known. Thus, an association between blood lipid concentrations and an increased risk of DM has not been established for dogs or cats. Atherosclerosis in dogs is usually associated with DM and hypothyroidism but has also been described in dogs without endocrinopathy or hypercholesterolemia.[24] Atherosclerosis has been induced in healthy cats and dogs by feeding diets very high in fat (>60 g/Mcal) and cholesterol (>4 g/Mcal), but serum cholesterol concentrations had to be maintained above 750 mg/dL for >6 months in dogs before atherosclerosis developed.[25-27]

Increased prevalence of other conditions and abnormalities has been described in dogs with hyperlipidemia, but causal relationships have not been established. Therefore, it is unclear whether conditions develop as a result of hyperlipidemia or vice versa. For example, hyperlipidemia is about three times more common in dogs with gallbladder mucocele.[28] Miniature Schnauzers with hyperlipidemia are more likely to have increased serum alkaline phosphatase and alanine aminotransferase activities.[29] However, biliary tract obstruction increases serum cholesterol concentrations four-fold and triglyceride concentrations two-fold.[30,31] Thus, serum alterations may be a consequence or a cause of disease. Proteinuria is increased with triglyceride concentrations in Miniature Schnauzers and was most severe with triglyceride concentrations >400 mg/dL.[32] Nephrotic syndrome is associated with hypercholesterolemia. Dogs with chronic kidney disease (CKD) have increased LDL and decreased HDL concentrations (see ch. 324), but triglyceridemia appears to cause the glomerular damage (see ch. 325).[33]

Hyperlipidemia is about 15 times more common in Miniature Schnauzers who have recovered from pancreatitis as compared to Schnauzers without pancreatitis (see ch. 290), suggesting that dogs with lipid abnormalities are more susceptible to pancreatitis.[34] Hyperlipidemia, however, could be secondary to pancreatitis. Hyperlipidemic Miniature Schnauzers had higher pancreatic lipase immunoreactivity (PLI) concentrations than controls and Schnauzers with cholesterol concentrations above 860 mg/dL were 4.5 times more likely to have a PLI concentration consistent with pancreatitis.[35] High PLI concentrations have also been observed in obese dogs with post-prandial triglyceride concentrations >440 mg/dL, but these dogs did not develop overt signs of clinically important pancreatitis for >4 years. It remains to be determined, therefore, whether fat should be restricted in dogs with high pre- or post-prandial PLI concentrations but no overt pancreatitis. It may be prudent, however, to attempt maintaining near normal lipid concentrations while monitoring for signs of clinical disease when normal concentrations are not achieved. Previous recommendations, to maintain pre-prandial triglyceride concentrations <500 mg/dL, may not be sufficient and concentrations may need to be <400 mg/dL to prevent glomerular injury.[4] Serum cholesterol concentrations should be maintained below about 700 mg/dL to prevent atherosclerosis.

Diagnosis and Monitoring of Hyperlipidemia

Background

Hyperlipidemia is often first suspected on physical examination due to abnormal appearance of the eyes or by assessing the appearance of blood (Figures 182-2 and 182-3). Measurement of pre-prandial serum cholesterol and triglyceride concentrations is currently the standard for diagnosing lipid abnormalities and assessing response to treatment. Triglyceride concentrations increase in normal dogs and cats after a small fatty meal, peak after about 2-4 hours, and return to normal after about 8 hours.[36,37] Recent feeding is the most common explanation for increased serum lipid concentrations and usually does not warrant investigation. It may be sufficient to wait 12 hours after a meal to measure fat concentrations in some dogs, but food can take >12 hours to pass through the small intestine.[38] Triglyceride concentrations may increase more and for a longer duration in obese dogs, dogs receiving phenobarbital, and some Burmese cats.[36,37,39] Thus, it may be necessary to wait for longer than 12 hrs after a meal to measure pre-prandial lipid concentrations. It may also be necessary to measure fat concentrations 4-6 hours after a meal because post-prandial hypertriglyceridemia can occur in patients with normal pre-prandial concentrations.[36,39,40] Reevaluation every 6-8 weeks is recommended to assess response to diet change or alternative treatment.[41]

FIGURE 182-2 Some ophthalmic changes that may be seen secondary to hyperlipidemia. **A,** Lipemic aqueous. **B,** Lipemia retinalis. **C,** Corneal lipodystrophy. **D,** Lipid keratopathy. **E,** Arcus. (Photos provided courtesy Drs. DE Brooks, RD Whitley, KE Plummer, all of the University of Florida.)

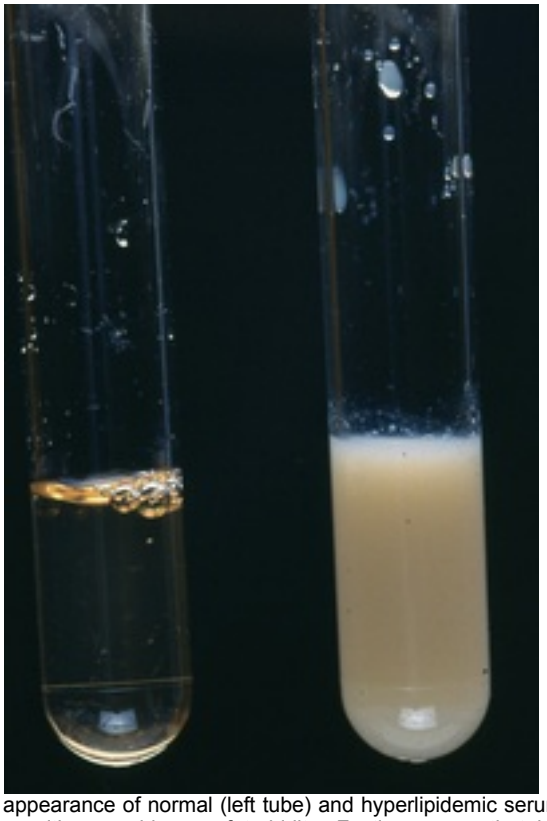

FIGURE 182-3 The appearance of normal (left tube) and hyperlipidemic serum (right tube). Normal serum should be clear, with no evidence of turbidity. Fasting serum that is turbid indicates the

presence of excess lipid in the serum (right tube).

Lipoprotein fractions are measured in people to assess atherosclerosis risk using electrophoresis or ultracentrifugation. If samples from dogs or cats are assessed using a human laboratory, one should be familiar with differences in human and animal lipoproteins (see ch. 63).[1] Lipoproteins responsible for an increase in serum fat concentrations can be better understood by evaluating refrigerated (Figure 182-4) or centrifuged blood (Figure 182-5). Chylomicrons separate as a cream layer, VLDL causes lactescence, and smaller lipoproteins (LDL, HDL) are not visible. Relative increases in triglyceride compared to cholesterol can be informative as chylomicrons and VLDL contain more triglyceride than cholesterol. Distinct lipoprotein fractions can be measured in pets, but their value has not been established.[42]

FIGURE 182-4 Refrigeration test of hyperlipidemic serum. On the left is a fasting hyperlipidemic serum sample from a dog. Following a refrigeration test, a lactescent layer ("cream layer") appears on the top of the serum. This layer is due to increased chylomicron particles present in the serum sample. Note that the serum below the top lactescent layer is also turbid, indicating the presence of other excess lipoproteins.

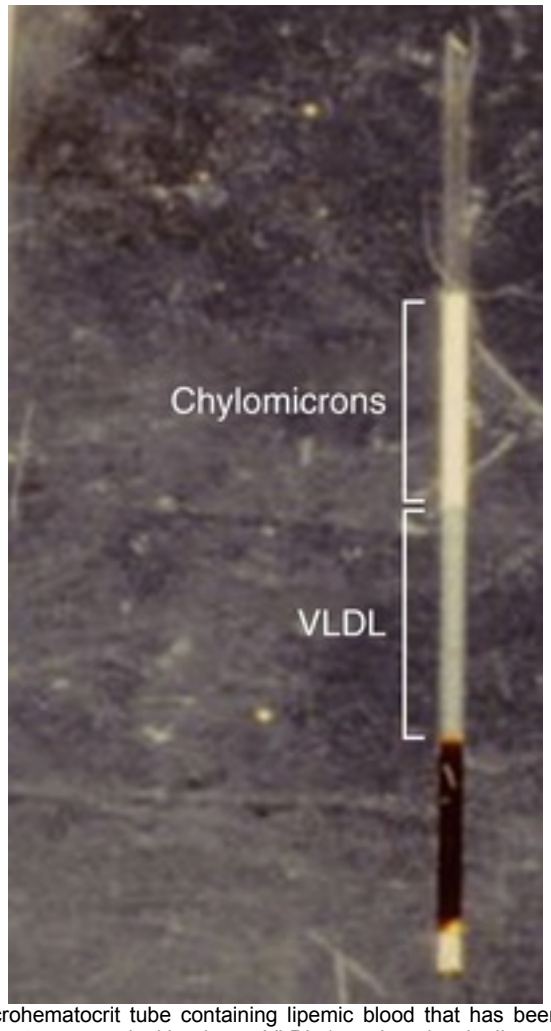

FIGURE 182-5 Microhematocrit tube containing lipemic blood that has been centrifuged. Excess chylomicron causes the top cream-looking layer; VLDL (very low density lipoprotein) causes turbidity (lactescence) below the chylomicron layer.

Secondary Hyperlipidemias

Hyperlipidemia in dogs and cats may occur secondary to feeding a high fat diet (60% ME fat), obesity, certain endocrine diseases (DM, hypothyroidism, hyperadrenocorticism), diestrus, protein loss (nephrotic syndrome), pancreatitis, bile duct obstruction (mucocoele) and certain drugs. Specific treatment of hyperlipidemia in such conditions should not be pursued. Rather, the focus should be on treating the primary condition. Drugs that may be responsible for increased blood lipid concentrations (corticosteroids, phenobarbital, thiazides, beta-blockers with no alpha effect, and estrogens), should be discontinued if possible.[37,43] It has been suggested that dogs and cats with DM be fed low fat diets, but this should not be necessary if abnormalities resolve with treatment and weight loss. Changing the diet of a newly diagnosed diabetic can be detrimental if food aversion develops. Low fat diets may be indicated in obese pets or those with pancreatitis. A new diet should only be introduced once nausea has been medically controlled (see ch. 39). Ovariohysterectomy prevents periodic increased progesterone and lipid concentrations during diestrus.[44] Exercise may decrease triglyceride concentrations.[45] Administration of antioxidants may also benefit obese patients. Green tea extract (0.9 mg/kcal daily) returned plasma triglyceride and VLDL concentrations to normal by stimulating lipoprotein lipase and improving insulin sensitivity by 60% when given to obese dogs fed a high fat diet (47 g fat/Mcal).[46] Each gram of green tea extract contained 36 mg epicatechin, 65 mg epicatechin gallate, 20 mg epigallocatechin and 153 mg epigallocatechin gallate (total: 0.25 mg antioxidant catechins/kcal ME).

Primary Hyperlipidemias

Primary hyperlipidemia has been described in both dogs and cats: hypertriglyceridemia in Miniature Schnauzers and Brittany Spaniels; hypercholesterolemia in Briards, Shelties, Rough Collies, Doberman Pinschers and Rottweillers; increased triglycerides and cholesterol in Beagles. Also, cats with lipoprotein lipase deficiency and, Burmese cats with increased post-prandial but normal fasting triglyceride concentrations may have primary hyperlipidemia. Associated signs can be neurological (seizures and peripheral neuropathy), ophthalmic (lipemia retinalis, lipemic aqueous, corneal dystrophy or keratopathy, and arcus; Figure 182-2), renal (proteinuria), gastrointestinal (vomiting, diarrhea, abdominal pain, pancreatitis), and dermatological (xanthomata).

Dietery Management of Hyperlipidemia

Background

Feeding a low fat diet remains the cornerstone treatment of primary hyperlipidemia. Fat intake is determined by both dietary fat content *and* quantity of food consumed. Thus, it is important to assess fat content relative to the metabolizable energy (ME) of the food as well as the ME required to maintain body condition. Unfortunately, labels are only required to list the guaranteed minimum percent fat as fed. A "low fat" statement on a label is unreliable because the definition of low fat used by the Association of American Feed Control Officials (AAFCO) differs for dry and canned food. An approximate estimate of the fat content relative to ME (g/Mcal) can be obtained by adding 1 to the guaranteed % fat, multiplying that number by 10 and dividing by the kcal ME/g in the diet. It is best, however, to obtain the typical value in g/Mcal ME from the manufacturer. Table 182-1 lists a selection of low and moderate fat diets with published typical fat contents relative to ME.

TABLE 182-1

Fat and Protein Content (g/Mcal ME)[a] of Selected Commercial Foods

MANUFACTURER	BRAND NAME	DRY			CANNED

	mixture 2[f]	20	56	0.3				

[a]Values are typical values reported by the manufacturer in product guides and are dependent on the method by which metabolizable energy (ME) content of the diet was determined. Where manufacturers have used modified Atwater factors to calculate the ME content of digestible but high fiber diets, the fat content relative to ME may be overestimated slightly because using these factors slightly underestimates the ME content of food. Reported values for each diet change over time.

[b]Low fat diets are <25 g fat/Mcal for dogs and <30 g fat/Mcal in cats, but the division between low and moderate is somewhat arbitrary. Restricting energy intake limits fat intake so moderate fat diets containing 25-35 g fat/Mcal ME may provide sufficient fat restriction in animals consuming very few calories such as those undergoing a weight loss program. Higher protein diets (>90 g protein/Mcal) are recommended to maintain lean body mass.

[c]EPA + DHA represents the combined concentration of eicosapentaenoic (EPA) and docosahexaenoic acid (DHA). Diets with more than 1 g EPA and DHA combined/Mcal do not need supplementation with additional fish oil.

[d]Contain medium chain triglycerides.

[e]These higher fat diets are included to show that some diets with a similar name, especially canned diets, are not always similarly low in fat.

[f]Mixture 1 comprises 1 can (250 mL) of CliniCare and 1 sachet of Vivonex Plus diluted to 300 mL. Mixture 2 contains 125 mL of CliniCare with 300 mL of Vivonex.

Commercial foods are reported to contain about 18 to 65 g fat/Mcal ME. Commercial canine therapeutic diets contain the lowest amounts of dietary fat (<25 g fat/Mcal in dog foods and <30 g fat/Mcal in cat foods). There are various inexpensive dry extruded diets and some therapeutic diets designed for weight loss or intestinal disease that contain moderately low amounts of fat (25-35 g fat/Mcal ME). Such diets may lower blood lipid concentrations in obese pets consuming fewer calories to lose weight. Severe fat restriction, however, is often needed. In some instances, it may be of value to formulate a home-cooked diet containing <18 g fat/Mcal. The National Research Council suggested a recommended allowance of 13.8 g fat/Mcal ME based on an adequate intake of 10 g fat/Mcal ME for adult dogs maintaining body condition while consuming about 130 kcal ME/kg body weight $(BW)^{0.75}$ daily.[9] The recommended allowances (g/Mcal ME) for adult dog maintenance are 2.8 for linoleic acid and 0.11 for linolenic acid. The recommended allowance (g/Mcal ME) for adult cats maintaining body condition while consuming 100 kcal ME/kg $BW^{0.67}$ daily was set at 22.5 for fat, 1.4 for linoleic acid and 0.015 for arachidonic acid. A nutritionist should be consulted when formulating home-cooked diets to ensure that enough essential nutrients and fats are included. Minimum fat requirements are not known accurately and may be lower than the recommended allowance in some individuals. How fat requirements change in animals maintaining body condition while consuming fewer than average calories is also not known. Therefore, careful monitoring for signs of fatty acid deficiency (poor hair coat, skin disease, renal compromise, infections, cell fragility, poor wound healing, bruising and reduced neurologic and ophthalmic function) is necessary when feeding very low fat diets.[9]

Low Fat Tube Feeding

In hyperlipidemic patients reluctant to eat, it may be necessary to provide nutritional support with a liquid diet through a nasogastric or jejunal tube or with a blended diet through a wider bore esophageal or gastric tube (see ch. 82). Most liquid diets designed for human beings contain 33 g fat/Mcal and those for dogs and cats contain much more fat. The human liquid amino acid based diet, Vivonex Plus, contains 6 g fat/Mcal and can be mixed with higher fat liquid diets to create an intermediate diet. Vivonex Plus has a pH of about 5 when mixed with water. This is close to the isoelectric point at which casein, found in most liquid diets, precipitates. Thus, it may be necessary to increase the pH of Vivonex Plus solution before it can be mixed with a casein-based diet. This pH correction can be achieved by adding sodium hydroxide (0.5-1 mL of 6N solution) or adding 10-20 mL of 1 mEq/mL (8.4%) sodium bicarbonate to each 300 mL of Vivonex. These liquid mixtures may contain slightly less than the recommended allowance of some essential nutrients, such as calcium, phosphorus, cobalamin, and trace minerals. Nutrient availability is likely to be high, however, so deficiencies are unlikely over the short term.

Low fat commercial diets can be blended with water for administration through a larger bore esophageal or gastric tube. Nevertheless, most commercial low fat foods contain increased amounts of insoluble fiber, which absorbs water. These high fiber foods often have to be diluted with extra water to achieve a suitable consistency for tube feeding, reducing energy density and increasing the volume that must be supplied. A low fat (25 g/Mcal) blended diet of high energy density suitable for administering through a larger bore tube can be obtained by mixing a sachet of Vivonex powder with a 5.5 oz can of kitten food and a small amount of water.

Change the Type of Fat

The type of fat should be changed if a low fat diet fails to adequately resolve hyperlipidemia after 6-8 weeks. Adding fish or krill oil, which naturally contains omega-3 fats, to a diet can lower serum lipid concentrations if given in high dosages.[41] Fish oil and omega-3 fat capsules contain variable amounts and types of omega-3 fats. Dosage recommendations are for eicosapentaenoic acid (EPA) or docosahexaenoic acid (DHA) combined. Other omega-3 fats, such as alpha-linolenic acid, are not converted well to EPA and DHA by dogs and cats. A standard recommendation for dogs is 0.22 g fish oil containing 66 mg of EPA + DHA/kg BW/day. This is equivalent to about 1 mg of EPA + DHA/kcal ME, assuming a 10 kg dog consumes about 120 kcal/kg$^{0.75}$ daily.[41] Some diets already contain 1 g/Mcal of EPA and DHA (see Table 182-1), in which case additional supplementation may be of no benefit. Dosing relative to ME is preferred to dosing on body weight, which provides a disproportionate amount of EPA and DHA to large breed dogs. Slightly lower dosages may be effective in some pets if their breath has a fish smell.[41]

Studies in other species suggest that replacing dietary fat containing long chain fatty acids with medium chain triglycerides may decrease blood triglyceride concentrations but may also increase cholesterol concentrations.[1] Some commercial diets contain medium chain triglycerides (see Table 182-1). Replacing beef tallow or coconut oil (primarily saturated fat) with cotton-seed or safflower oil (primarily unsaturated fat) prevented the development of atherosclerosis or thrombosis in dogs fed high fat diets.[26,47] The role that cholesterol ingestion plays in the management of hyperlipidemic dogs and cats cannot be assessed because the cholesterol content of pet foods is not reported. Nevertheless, as the fat content of a diet decreases, an increasing proportion of fat must be of plant origin to ensure that adequate essential fats are included. Since plant oils contain no cholesterol, its content must decrease with the amount of fat in the diet.

Other Dietary Changes

Other dietary changes have modified serum lipid concentrations in healthy dogs and may improve concentrations in hyperlipidemic animals. For example, adding beet pulp and fructo-oligosaccharides to diets decreased serum triglyceride and cholesterol concentrations in healthy dogs.[48] Higher blood fat concentrations may be tolerated if antioxidants are provided in sufficient quantity to prevent oxidative damage. Administration of 400 IU vitamin E daily prevented endothelial dysfunction and maintained coronary blood flow in 7 kg dogs fed a high fat–high cholesterol diet that induced atherosclerosis.[49] Vitamin E decreased concentrations of the oxidative marker malondialdehyde and tissue cholesterol without altering serum cholesterol concentrations. This dosage of vitamin E (54 IU/kg, 90 IU/kg$^{0.75}$ daily, or 750 IU/Mcal ME assuming consumption of 120 kcal ME/kg$^{0.75}$ daily) is very high and could inhibit absorption of other fat soluble vitamins. Whether lower dosages provide the same effect is not known. The recommended allowances for adult dogs and cats are 7.5 and 10 IU vitamin E/Mcal, respectively. An intermediate dosage

(100 IU/Mcal) is likely to inhibit oxidation without causing undesirable side-effects.

Medical Management of Hyperlipidemia

Background

Any disease or condition that increases lipid concentrations (e.g., obesity or an endocrinopathy) should be treated in dogs with primary hyperlipidemia. Drug therapy should be considered if dietary management fails to reduce serum lipid concentrations adequately. Fibrates can be considered for animals with hypertriglyceridemia and statins for those with hypercholesterolemia. Niacin has potential benefit in animals with either or both hypertriglyceridemia and hypercholesterolemia.

Fibrates

Fibrates, agonists of peroxisome proliferator-activated receptor-alpha, stimulate lipolysis by lipoprotein lipase. They decrease VLDL and LDL concentrations by increasing hepatic uptake. They are not effective for hypercholesterolemia in dogs, as 25 mg/kg of gemfibrozil daily did not decrease cholesterol concentrations.[50] Reported doses of fibrates for dogs and cats are mostly anecdotal; gemfibrozil (Lopid): 10 mg/kg in cats or dogs or 200 mg (range 150-300 mg) q 12 h in dogs; bezafibrate (Bezalip): 4-10 mg/kg q 24 h in dogs. Fenofibrate at a dosage of 10 mg/kg daily reduced pre- and post-prandial serum lipid concentrations about 30% in obese dogs fed a high fat diet.[51] Large amounts of drug/tablet (600 mg in gemfibrozil and 400 mg for bezafibrate) require compounding for small doses. Fenofibrate comes in a range of tablet sizes. Gemfibrozil was tolerated by dogs at dosages up to 150 mg/kg daily for 12 months but liver abnormalities were noted in some given 300 mg/kg daily for 12 months.[52] Side-effects are also relatively uncommon in dogs, rats and people chronically receiving fenofibrate.[51,53] In people, side-effects have included malaise, muscle pain and arthralgia, skin rash, increased liver enzymes and dose-related chronic liver disease, increased creatinine concentrations, hematuria and acute kidney injury. Kidney stones developed in some dogs chronically given fenofibrate and bezafibrate.[53]

Statins

Statins reduce hypercholesterolemia by inhibiting HMGCoA reductase, the rate-limiting enzyme in cholesterol synthesis. Atorvastatin (Lipitor), 2-5 mg/kg daily, lowered total cholesterol proportional to dosage by 15-30% in normal dogs and was well tolerated during a year-long study at dosages ≤10 mg/kg.[54-57] Rosuvastatin (Crestor), 2 mg/kg daily, and pitavastatin (Livalo), 0.4 mg/kg daily, were well tolerated and reduced total cholesterol by 30% in dogs with experimentally induced heart failure.[58,59] Statins should be administered on an empty stomach 30 minutes before feeding.[60]

Niacin

Niacin at a dosage of 2 g/day (≈1 g/Mcal ME) increases HDL and decreases VLDL and LDL in people. Such a high dosage may be toxic to dogs.[9] A much lower dosage (100 mg) has been reported to reduce fat concentrations in dogs but erythema and pruritus have been reported in dogs receiving only 25 to 100 mg.[61]

Inhibitors of Fat Absorption

Calcium forms soaps in the intestinal tract, which have been shown to decrease fat absorption, especially for long chain and saturated fats.[62] Increasing calcium in diets from 1.1 to 3.6% dry matter, for example, may inhibit fat digestibility by about 5%.[62] The consequences of a high calcium intake should be considered on an individual basis. Microsomal transfer protein inhibitors (Dirlotapide [Slentrol], Mitratapide [Yarvitan]) also inhibit fat absorption. These drugs are licensed for short term administration to aid weight loss by inhibiting appetite (see ch. 176).

Inhibition of Cholesterol Absorption

Healthy dogs given cholesterol absorption inhibitors compensated for the loss of biliary cholesterol by increasing hepatic synthesis. Serum cholesterol concentrations decreased 30 to 60% when the absorption

inhibitor ezetimibe (0.007 mg/kg/d) was co-administered to dogs with an HMGCoA inhibitor (5 mg/kg lovastatin, 5 mg/kg fluvastatin, 2.5 mg/kg pravastatin, 1 mg/kg fluvastatin or 1 mg/kg atorvastatin) for 2 weeks.[56,63] Phytosterols and stanol esters also inhibit intestinal absorption of cholesterol and lower LDL cholesterol concentrations in people but not to the same degree as statins. Cholestyramine, 0.7 mg/kg daily, decreased blood cholesterol by 16% in normal dogs by binding bile acids and increasing their fecal excretion.[64] Dosages up to 4 mg/kg have been administered chronically to normal dogs. Chitin, as chitosan, has been proposed to limit fat absorption, but its efficacy is uncertain.

CHAPTER 183

Nutritional Management of Heart Disease

Lisa M. Freeman, John E. Rush

Client Information Sheets:
Tips for Addressing Poor Appetite in Pets with Heart Disease
Safe and Effective Tips for Administering Medications to Dogs and Cats with Heart Disease

The goal of nutrition is no longer just to prevent deficiencies. It is now known that modification of diet is an important part of medical therapy for heart disease. In the 1960s, the main nutritional recommendations for dogs with congestive heart failure (CHF) were to feed a low-sodium diet (for all stages of heart disease), to feed a restricted protein diet, and to provide supplemental B vitamins.[1] Few changes to these recommendations were made until the 1970s, when mention of cardiac cachexia appeared in veterinary medicine[2] and when the question of how early to institute sodium restriction was raised in the 1980s.[3] It was also in the late 1980s that the discovery of the relationship between taurine deficiency and feline dilated cardiomyopathy (DCM) was published.[4] Now, research is beginning to show that nutrition may be able to modulate heart disease, either by slowing the progression, minimizing the number of medications required, improving quality of life or, in rare cases, actually curing the disease. Therefore, nutrition is an important adjunct to medical therapy for animals with heart disease.

The main goals of diet therapy for heart disease are to maintain optimal body weight, to avoid nutritional deficiencies and excesses, and to take advantage of the potential benefits of pharmacologic doses of certain nutrients.

Optimal Weight Maintenance

A key goal for the optimal management of heart disease is to maintain optimal body composition, because body weight, muscle mass, and obesity can significantly impact health.

Cachexia

Cardiac cachexia is the muscle loss commonly seen in patients with CHF (see ch. 177). In one study of dogs with DCM and CHF, more than 50% of patients had some degree of cachexia.[5] The weight loss that occurs in animals with CHF is unlike that seen in a healthy dog or cat that loses weight. In a healthy animal receiving insufficient calories to meet requirements, metabolic adaptations allow fat to be used as the primary fuel source, thus preserving lean body mass. Conversely, the primary fuel source in animals with an acute or chronic disease, including heart disease, is amino acids from muscle; therefore, these animals quickly catabolize lean body mass. Thus the distinguishing feature of cachexia is a loss of lean body mass, which has direct and deleterious effects on strength, immune function, and survival.[6] Cachexia is often mistakenly viewed as an end-stage syndrome manifested by an emaciated dog or cat. In fact, cachexia is a progressive process of muscle loss that can be very subtle initially and can even occur in an obese animal. Recognizing the process of cachexia at an early stage provides better opportunities to manage it effectively.

The loss of lean body mass in cardiac cachexia is a multifactorial process caused by decreases/alterations in appetite, increased energy requirements, and metabolic alterations.[6] Animals with CHF can have anorexia (complete loss of appetite), hyporexia (reduced appetite), or dysrexia (changes in appetite and food preferences). Anorexia is present in 34% to 75% of dogs and cats with clinically significant heart disease.[5,7-9] These alterations in appetite may be secondary to fatigue or medication side-effects.[6] However, inflammatory cytokines, such as tumor necrosis factor-alpha (TNF) and interleukin-1-beta (IL-1), are primary mediators of

cachexia.[6] These inflammatory cytokines directly cause reduced appetite, increase energy requirements, and increase catabolism of lean body mass. TNF and IL-1 also cause cardiac myocyte hypertrophy and fibrosis and have negative inotropic effects.

Cardiac cachexia is typically recognized only after CHF has developed. It is more easily recognized in dogs than in cats and is most often seen in DCM or right-sided CHF. Loss of lean body mass is most readily evident in the epaxial, gluteal, scapular, or temporal muscles. Muscle condition score (along with body condition score (BCS), which assesses an animal fat stores—see ch. 2, 170, and 177) should be assessed at every visit for animals with heart disease.[7] The muscle condition score is categorized as normal, mild muscle loss, moderate muscle loss, or severe muscle loss (Figure 183-1).[8] In addition, a complete diet history should be assessed at every visit as this can identify factors that are contributing to muscle loss (e.g., inadequate calorie or protein intake, nutritionally unbalanced diet).[7] Diet history forms are available[8] or one specifically designed for animals with heart disease can be used (Box 183-1). Nutritional considerations for cardiac cachexia should include management of altered appetite, if present. Nutritional modulation of cytokine production also may be helpful. One method of decreasing the production and effects of cytokines is omega-3 (n-3) polyunsaturated fatty acid (PUFA) supplementation (see below). Supplementation of fish oil, which is high in n-3 fatty acids, can decrease cytokine production in dogs with CHF and improve cachexia.[5] In some but not all dogs with CHF-induced anorexia, fish oil supplementation can improve food intake.[5] In addition, n-3 fatty acid intake has been associated with longer survival in dogs with CHF.[9]

Diet History Form for Animals with Heart Disease

Please answer the following questions about your pet

Today's date: _____

Pet's name: _____ Your name: _____

1. How would you assess your pet's appetite? (mark the point on the line that best represents your pet's appetite)
   Poor **Excellent**
   _____

2. Describe your pet's appetite over the last few weeks? (check all that apply)
   ☐Eats about the same amount as usual ☐Eats less than usual ☐Eats more than usual
   ☐Seems to prefer different foods than usual

3. Over the last few weeks, has your pet (check one)
   ☐Lost weight ☐Gained weight ☐Stayed about the same weight ☐Don't know

4. Please list below the brands and product names (if applicable) and the amount of ALL foods, treats, snack, dental chews, rawhides, and any other food item that your pet currently eats.

Food	Form	Amount	How often?	Fed since
Examples:				
Purina Dog Chow	dry	1½ cups	2x/day	Jan, 2011
Science Diet Adult Gourmet Beef Entree	can	½ large can	1x/day	Jan, 2012
90% lean hamburger	microwaved	3 oz	1x/week	Jan, 2011
Milk Bone medium	dry	1	2x/day	Aug, 2010
Rawhide	dry	2x6" strip	3x/week	Dec, 2011

5. Do you give any dietary supplements to your pet (for example: vitamins, glucosamine, fatty acids, or any other supplements)?
   ☐Yes ☐No If yes, please list which ones and give brands and amounts:

			Brand	Tablet/capsule number, size, and frequency
Taurine	☐Yes	☐No		
Carnitine	☐Yes	☐No		
Antioxidants	☐Yes	☐No		
Multivitamin	☐Yes	☐No		
Fish oil or cod liver oil	☐Yes	☐No		
Coenzyme Q10	☐Yes	☐No		
Other (please list)	☐Yes	☐No		

6. How do you administer pills to your pet?
   ☐I do not give any medications
   ☐I give them without any food
   ☐I put them in my pet's dog/cat food
   ☐I put them in a Pill Pocket or similar product
   ☐I put them in foods (list foods):_____

Information below to be completed by the veterinarian:

Current body weight: _____kg

Ideal body weight: _____kg

Current body condition score: _____/9

Muscle Condition Score: ☐normal muscle ☐mild muscle loss ☐moderate muscle loss ☐severe muscle loss

From Smith FWK Jr, Tilley LP, Oyama MA, et al: *Manual of canine and feline cardiology*, ed 5, St Louis, 2016, Elsevier.

Obesity

Overweight (i.e., over ideal body weight) and obesity (i.e., more than 20% over ideal body weight) are common in the pet population, and can have detrimental effects on health (see ch. 176). Therefore, maintaining an optimal body weight and BCS should be a goal for healthy dogs and cats and for those with asymptomatic heart disease. The effects of obesity are less clear in animals with CHF. Obesity is common even in animals with CHF, with 41% of dogs in one study being overweight or obese at the time of diagnosis of heart failure.[9] Although obesity has some physiologic effects which could be detrimental in CHF, numerous studies in people with CHF have shown that obesity actually is associated with a longer survival time; this is called the "obesity paradox."[10,11] Results of one study of dogs with CHF showed that dogs that gained or maintained weight had a longer survival time than those that lost weight.[9] A study in cats also showed that overweight but not obese body condition was associated with longer survival.[12] This supports the concept that weight loss and particularly muscle loss is very detrimental in CHF and careful attention to body weight, muscle loss, and appetite is of critical importance in animals with heart disease. The authors aim

for a BCS of 4-5/9 for healthy animals and those with asymptomatic heart disease and a BCS of 6-7/9 for those with CHF. A BCS > 7/9 may still have detrimental effects so obesity should be avoided, although the authors typically will not try to initiate a weight loss plan in dogs or cats after the onset of CHF (unless obesity is severe and adversely affecting quality of life). It is important to be aware that cachexia (i.e., muscle loss) can occur even in overweight and obese animals, so monitoring of the muscle condition score at every visit is important.[8] Muscle loss in overweight animals is usually most apparent over the epaxial muscles.[8]

Modulation of Specific Nutrients

Nutritional deficiencies once were a common cause of heart disease in people and probably animals. In cats, taurine deficiency was a common cause of heart disease until as recently as the late 1980s. Identifiable nutritional deficiencies are now uncommon in dogs and cats (unless owners are feeding homemade, vegetarian, or otherwise nutritionally unbalanced diets; see ch. 192) but still could play a role in the etiology of some heart diseases. Nutritional deficiencies also may develop secondary to the disease or its treatment. A new area of nutritional research is that of nutritional pharmacology, the concept that supplementation of certain nutrients may provide benefits above and beyond their known nutritional effects. Therefore, providing higher levels of certain nutrients may be recommended for some animals with heart disease.

Protein and Taurine

Protein

Protein restriction should be avoided in dogs and cats with heart disease because these patients are predisposed to loss of lean body mass. Diets that are low in protein, even if they are designed as cardiac diets, diets designed for renal disease, and "senior diets," are not recommended unless severe renal dysfunction is present. Otherwise, a good quality nutritionally balanced food providing at least the canine (4.5 g/100 kcal) and feline (6.5 g/100 kcal) minimum protein levels according to Association of American Feed Control Officials (AAFCO) is recommended.[13]

Taurine

Taurine is an amino acid found in high levels in the myocardium. Despite knowledge of the role of taurine deficiency in feline DCM, a small number of cats still develop DCM (see ch. 253).[4] Most current cases of feline DCM do not involve taurine deficiency but it should be suspected in all cats with this disorder. A dietary history should be elicited from owners to determine whether the cat has been fed a poor-quality, homemade, vegetarian, or otherwise unbalanced diet. Plasma and whole blood taurine should be measured, and treatment with taurine (125 to 250 mg PO q 12 h) should begin concurrently with medical therapy. If the taurine concentration is found to be normal, taurine supplementation can be discontinued, although some benefits may still be derived from taurine's other effects (see below).

Unlike cats, dogs are thought to be able to synthesize adequate amounts of taurine, which is not considered a requirement in canine diets. Most dogs with DCM do not have taurine deficiency, but low taurine concentrations have been found in some dogs with the disorder.[14-20] The most common breeds in which DCM has been reported to be associated with taurine deficiency are the American Cocker Spaniel, Golden Retriever, Labrador Retriever, Portuguese Water Dog, Saint Bernard, English Setter, and Newfoundland (see ch. 252).[14-20]

Diet appears to play some role in the development of taurine deficiency in dogs as very-low-protein, lamb and rice, and some high-fiber diets have been associated with taurine deficiency, as have been diets low in methionine, but the exact role of diet remains unknown.[16-25] Taurine deficiency also may be the result of increased renal or fecal loss of taurine, higher requirements, or other metabolic defects present in certain breeds.[23-25]

While some dogs with DCM have low circulating taurine concentrations, not all of these respond impressively to taurine supplementation. One small prospective study showed that Cocker Spaniels supplemented with taurine and carnitine had clinical and echocardiographic improvements.[26] It is not known whether the response would be similar with either taurine or carnitine alone. A retrospective study of 12 dogs with taurine deficiency and DCM documented improved cardiac contractility after taurine supplementation.[17] In a study of Portuguese Water Dog puppies, plasma taurine was low in all puppies tested, and DCM was diagnosed in eight of nine puppies.[20] Taurine supplementation was instituted in six of

the puppies, which significantly increased circulating taurine concentrations and cardiac function.[20] Finally, in a study of Beagles fed a low-taurine, very-low-protein diet for 48 months, one dog developed DCM but showed significant improvement in cardiac contractility after supplementation of taurine.[21]

Dogs with DCM and taurine deficiency that do respond to taurine supplementation generally do not have as dramatic a response as do taurine-deficient cats with DCM. Nonetheless, measurement of plasma and whole blood taurine concentrations is warranted in the breeds of dogs with DCM listed above, or in breeds that are not typically associated with the development of DCM (e.g., Border Collie, Dachshund). Taurine concentrations also should be measured in dogs with DCM eating lamb meal and rice-based diets, very-low-protein, vegetarian, or high-fiber diets. Taurine analysis is usually not recommended in typical breeds that develop DCM (e.g., Doberman Pinschers, Boxers). Supplementation with taurine (250 to 1000 mg PO q 8-12 h) is recommended in dogs with documented taurine deficiency, although the exact dosage required for repletion is not known. Some of the potential benefits of taurine in dogs with DCM may be due to pharmacologic effects: taurine is a positive inotrope, has antioxidant effects, and plays an important role in myocardial calcium regulation.

Fat

Fat provides calories and increases the palatability of pet foods but it also can significantly affect immunologic, inflammatory, and hemodynamic parameters. The n-3 fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), are long chain fatty acids in which the first double bond is at the position of the third carbon from the methyl end (vs. the n-6 PUFAs, namely linoleic, gamma-linolenic, and arachidonic, in which the first double bond is at the sixth carbon).[27] This minor chemical difference conveys different structural and functional characteristics to the fatty acid. Plasma membranes normally contain very low concentrations of n-3 fatty acids, but levels can be increased by a food or supplement enriched in n-3 fatty acids. Dogs with CHF have been shown to have plasma fatty acid abnormalities, including decreased concentrations of EPA and DHA compared to normal dogs.[5] In one study of dogs with DCM and CHF, fish oil supplementation normalized these plasma fatty acid abnormalities.[5]

Another potential benefit of n-3 fatty acid supplementation is that breakdown products of the n-3 fatty acids (3- and 5-series eicosanoids) are, in general, less potent inflammatory mediators than eicosanoids derived from n-6 fatty acids (2- and 4-series eicosanoids). This decreases the production of cytokines and other inflammatory mediators, which may minimize cachexia.[5,27] Finally, n-3 fatty acids have antiarrhythmic effects in a variety of species including Boxers with ventricular arrhythmias (see ch. 252).[28] The authors currently recommend a dosage of 40 mg/kg EPA and 25 mg/kg DHA for dogs and cats with reduced/altered food intake or cachexia. This dose also can be used as an adjunct to medical therapy for arrhythmias. Finally, the authors will discuss the possible benefits of n-3 fatty acid supplementation with all owners of dogs or cats with CHF, advising that there may be some benefit to supplementation in all cases of CHF. With the exception of a few specially-designed veterinary diets, most commercial diets do not achieve this level of n-3 fatty acids, so supplementation is usually necessary. The amount of EPA and DHA in individual fish oil supplements varies widely, so it is important to know the exact amount in the brand of supplement recommended. The most common formulation of fish oil, however, is 1-g capsules that contain approximately 180 mg EPA and 120 mg DHA and can be purchased over the counter at most human pharmacies or health food stores. At this concentration, fish oil can be administered at a dose of one capsule per 10 pounds of body weight to achieve the authors' recommended EPA and DHA dosage. Fish oil supplements should contain vitamin E as an antioxidant, but other nutrients should not be included in order to avoid toxicosis. Cod liver oil and flaxseed oil should not be used as sources of n-3 fatty acids.

Minerals

Sodium

Recommendations regarding the degree of dietary sodium restriction, and when sodium restriction should be initiated, continue to evolve for dogs and cats with heart disease. Studies in the 1960s showed that very–low-sodium diets could help to control fluid accumulation in dogs with CHF.[1] Authors in the 1960s and 1970s recommended changing animals to a severely sodium restricted diet when a heart murmur was first detected, even before clinical signs were present. More recently, questions have been raised about severe sodium restriction in asymptomatic heart disease (and even in CHF) due to activation of the renin-angiotensin-aldosterone system.[29,30] One study of dogs with asymptomatic chronic valvular disease (CVD) showed that a

low-sodium diet resulted in increased aldosterone concentrations and heart rate, with no improvement in cardiac size or function.[30] Because of lack of documented benefits and potential adverse effects of severe sodium restriction in asymptomatic disease, the authors recommend only mild sodium restriction (<100 mg/100 kcal) in asymptomatic heart disease (International Small Animal Cardiac Health Council [ISACHC] Stages 1a and 1b). However, this is an opportune time to begin educating the owner about the animal's overall dietary patterns—the pet food, treats, table food, and how medications are administered—as it is generally much easier to institute dietary modifications at this earlier stage, before the animal develops clinical signs of CHF. Most owners are unaware of the sodium content of pet foods and human foods and need very specific instructions regarding appropriate foods and acceptable low-salt treats.[31]

When CHF first arises, additional sodium restriction is recommended (<80 mg sodium/100 kcal). This can be achieved with a veterinary diet designed for animals with early heart disease or with certain other veterinary diets (which may be designed for other disease) or even some over-the-counter diets. The content of sodium and other nutrients, such as protein, potassium, and magnesium, can be found by consulting manufacturers' product guides, by calling the manufacturers, or from reputable websites.[31] Caution is indicated with "senior diets," which often are reduced in protein (which is not recommended for animals with heart disease). Senior diets also vary tremendously in sodium (and other nutrients). In one study of 37 commercial diets marketed for senior dogs, the sodium content ranged from 33-412 mg/100 kcal.[32] Similarly, diets designed for animals with renal disease are usually not recommended, even though they might be low in sodium content, because of the protein restriction (unless proteinuria or advanced renal dysfunction is present). As CHF becomes more severe, more sodium restriction (i.e., <50 mg/100 kcal) may allow lower dosages of diuretics to be used to control clinical signs.[33] There are no commercial veterinary diets marketed specifically for cats with heart disease, but a number of veterinary and over-the-counter diets are reduced in sodium and may meet an individual cat's nutritional needs.[31]

Potassium

Hypokalemia causes muscle weakness and potentiates arrhythmogenesis. In addition, Class I antiarrhythmic drugs (e.g., mexiletine, lidocaine) are relatively ineffective in the face of hypokalemia. Hypokalemia can be precipitated by the use of loop diuretics (e.g., furosemide), thiazide diuretics (e.g., hydrochlorothiazide), or inadequate dietary intake (often associated with anorexia or hyporexia).

Angiotensin-converting enzyme (ACE) inhibitors cause renal potassium sparing, which can result in increased serum potassium and, therefore, some animals develop hyperkalemia. Spironolactone, now used in some dogs with heart disease, is an aldosterone antagonist and a potassium-sparing diuretic. Whereas animals receiving ACE inhibitors or spironolactone can develop hyperkalemia, hyperkalemia severe enough to affect appetite or clinical status is not a common occurrence, unless they are eating a diet that contains high levels of potassium.

Commercial diets vary widely in potassium concentrations. Commercial reduced-sodium diets range from <150 to >300 mg potassium/100 kcal, with an AAFCO minimum of 170 mg/100 kcal for dogs and 150 mg/100 kcal for cats. If hyperkalemia is present in an animal with heart disease, a diet with a lower potassium content should be selected. Conversely, if an animal is hypokalemic, a diet higher in potassium or oral potassium supplementation is indicated. This information can be obtained by contacting manufacturers.

Magnesium

Magnesium plays an important role in normal cardiac function. Alterations in magnesium homeostasis can occur in people and dogs and can have deleterious effects in a variety of cardiovascular conditions including hypertension, coronary artery disease, CHF, and cardiac arrhythmias. Some cardiac drugs, including loop diuretics, are associated with magnesium depletion. Therefore, animals with CHF receiving these medications have the potential to develop hypomagnesemia. Hypomagnesemia can increase the risk of arrhythmias, decrease cardiac contractility, cause muscle weakness, contribute to renal potassium loss, and can potentiate the adverse effects of certain cardiac medications.

Hypomagnesemia has not been a consistent finding in studies of animals with heart disease, but this may be because serum magnesium concentrations are a poor indicator of total body stores.[34] Therefore, normal serum magnesium does not necessarily mean there are adequate total body stores. However, it still can be useful to routinely measure serum magnesium, especially in animals with arrhythmias or those on large doses of diuretics.

Like potassium, magnesium concentrations vary widely in commercial pet foods. Commercial reduced-

sodium diets for dogs can contain between 10 and 50 mg magnesium/100 kcal (AAFCO minimum of 11 mg/100 kcal for dogs and 10 mg/100 kcal for cats). A diet high in magnesium would be indicated for an animal with a low serum magnesium concentration. In some animals with low serum magnesium concentrations, diet adjustment alone will not correct the problem and oral supplementation will be required.

Vitamins

B Vitamins

Thiamine deficiency is known to be a cause of cardiomyopathy in people, but there has been little investigation into the role of B vitamins as a cause of heart disease in dogs and cats. Anorexia and urinary loss of water-soluble vitamins can contribute to low B vitamin concentrations in patients with CHF. In one study of human CHF patients, for example, 33% were thiamine-deficient.[35] As with other nutrients such as potassium, B vitamin deficiencies may have been much more common when furosemide was the primary means of therapy for patients with CHF. Research suggests that vitamins B_6, B_{12}, and folate may be significantly lower in cats with cardiomyopathy than in healthy controls, an effect that appeared to be unrelated to diet or furosemide use.[36,37] Animals with heart disease (at least those receiving diuretics) may have higher B vitamin requirements. Routine supplementation of B vitamins in animals with heart disease on good quality commercial diet is likely unnecessary; however, empirical supplementation may be tried in animals on high dosages of diuretics, especially those with anorexia or hyporexia, or in animals on an unbalanced diet.

Other Nutrients

Carnitine

L-carnitine is concentrated in skeletal and cardiac muscle and is critical for fatty acid metabolism and energy production. Carnitine deficiency is associated with primary myocardial disease in a number of species, and has been described in a family of Boxer dogs.[38] Anecdotal reports exist regarding the efficacy of L-carnitine in canine DCM, but no blinded prospective monotherapy studies have been done so its role in DCM remains unclear. Even if carnitine deficiency is not the inciting cause of DCM, L-carnitine supplementation could be beneficial by improving myocardial energy production. A study of rapid pacing–induced CHF in dogs showed that myocardial concentrations decreased in normal dogs after the onset of CHF;[39] however, effects of supplementation in dogs that do not have a primary deficiency are unknown. There are few side-effects of L-carnitine supplementation but high cost is a deterrent for some owners. We currently discuss the option of L-carnitine supplementation (50 to 100 mg/kg PO q 8 h) to owners of dogs with DCM.

Antioxidants

Much attention has been given to antioxidants for their potential role in the prevention and treatment of human heart diseases. Reactive oxygen species are a byproduct of oxygen metabolism for which the body normally compensates through the production of endogenous antioxidants. An imbalance between oxidant production and antioxidant protection, however, could increase the risk for heart disease. Antioxidants are produced endogenously but also can be supplied exogenously. The major antioxidants include enzymatic antioxidants (e.g., superoxide dismutase, catalase, glutathione peroxidase) and oxidant quenchers (e.g., vitamin C, vitamin E, glutathione, and beta-carotene). Most of the research in human cardiology has been in coronary artery disease, but in dogs with CHF due to either DCM or CVD there is an imbalance between increased oxidant production and reduced antioxidant protection, particularly as the disease becomes more severe and particularly for the fat-soluble vitamins (e.g., vitamin E).[40,41] Supplemental antioxidants are now included in many commercial veterinary diets, including at least one cardiac diet, and can increase circulating antioxidant concentrations and reduce oxidation.[30] However, potential clinical benefits of antioxidant supplementation require additional study.

Coenzyme Q10

Coenzyme Q10, like carnitine, is a cofactor in a number of energy-producing reactions but is also an antioxidant. Studies in people suggest a beneficial effect of this supplement. Possible reasons for the purported benefits of supplementation include correction of a deficiency, improved myocardial metabolic efficiency, or increased antioxidant protection. Although coenzyme Q10 supplementation has anecdotally

been reported to be beneficial in dogs with DCM, controlled prospective studies are necessary to accurately judge the efficacy of this product. One study of experimentally-induced CHF in dogs showed that serum coenzyme Q10 levels were not reduced and that coenzyme Q10 supplementation increased serum, but not myocardial, concentrations.[42] The current recommended dosage in dogs is 30 mg PO q 12 h, although up to 90 mg PO q 12 h has been recommended for large dogs. Further research is needed in dogs with DCM.

Practical Aspects of Feeding the Patient With Heart Disease

There is not a single "best" diet for managing heart disease. It is important to match the nutritional needs of an individual patient to the diet or diets that best suit those needs. Patients with heart disease vary in terms of their clinical signs, laboratory parameters, and food preferences, and these all affect diet selection. For example, animals with asymptomatic heart disease require less severe sodium restriction than animals with CHF. Dogs with cardiac cachexia require a calorically dense diet while an overweight dog without CHF should be fed a calorically restricted diet. Concurrent diseases also influence diet choice and, in one study, were present in approximately 61% of dogs and 56% of cats with heart disease, respectively.[43,44] For example, a cat with hypertrophic cardiomyopathy and a history of struvite urolithiasis would need a diet that is sodium restricted but also one that has nutritional modification to reduce the risk of struvite urolith formation. Finally, laboratory results, such as the presence of moderate to severe azotemia, or alterations in potassium or magnesium, also can affect selection of optimal diet(s).

Performing a nutritional assessment on every patient at every visit can optimize nutritional and medical management (see ch. 170). The nutritional assessment helps to identify whether the current diet could be contributing to the heart disease (e.g., in a dog with DCM eating a vegetarian diet or a cat with CHF eating a diet very high in sodium), if the current diet is optimized for managing the heart disease, and what the animal's and owner's preferences are. In addition, the nutritional assessment identifies all components of the animal's diet that will need to be addressed in making a nutritional plan. Nutritional screening can be done with only a short diet history form and a physical examination, and includes a diet history, body weight, body condition score, muscle condition score, and the knowledge of other medical conditions that also require nutritional modification (e.g., gastrointestinal disease, feline lower urinary tract disease, chronic kidney disease).[7,8] The diet history includes the main pet food being provided (or the home-prepared diet recipe being used, if any), but also treats, table food, dietary supplements, and foods used for medication administration (Box 183-1).

Based on these and other patient parameters, diets can be matched to the individual patient. There currently are several commercial veterinary diets available that are specifically designed for animals with heart disease. Specific characteristics of these foods vary, but they are moderately to severely sodium-restricted, generally contain increased levels of B vitamins, and vary in their protein content; ensuring adequate protein intake is critical. Some cardiac diets also may include increased levels of taurine, carnitine, antioxidants, or n-3 fatty acids. There also are many veterinary diets designed for other diseases or even over-the-counter diets that may have the desirable nutritional profile.[31] Above all, the diet must be palatable enough that the animal will willingly eat it. The authors typically determine several diets that would be appropriate for an individual animal. These diets are offered as choices for the owner and the pet. Having dietary choices is particularly beneficial for more severely affected patients, in which a cyclical or selective loss of appetite is common. A starting goal for calorie recommendations in animals with CHF is 1.0-1.2× resting energy requirements, but adjustment is necessary to maintain ideal body and muscle condition. All diet recommendations should also include discussion of treats, table food, and foods used for medication administration (Box 183-2).[7,8]

Box 183-2

Methods for Administering Medication to Dogs and Cats

1. Teach the owner to pill the animal without using foods.
2. Use a pill administration treat but be sure to check the individual brand for content of sodium and other nutrients of concern for an individual patient. This becomes particularly important the more of these treats per day are used for medication administration.
3. Use a pet piller or pet pill gun.
4. Use a compounded, flavored liquid medication instead of a pill. Note: Compounding may alter the

pharmacokinetics of a drug and be sure to check the sodium content of a compounded product (see ch. 168).

5. Insert medications into appropriate foods, such as the following:
   - Fruit (e.g., banana, orange, melon, berries [not grapes])
   - Low-sodium cheese
   - Low-sodium canned pet food
   - Peanut butter (labeled as "no salt added")
   - Home-cooked meat (without salt); not lunch meats

As mentioned earlier, appetite changes are a common problem in animals with CHF and can contribute to the syndrome of cachexia. Another important problem with reduced appetite is that it may affect survival by influencing an owner's decision to euthanize the pet. In one study of owners of dogs euthanized for CHF, reduced appetite was one of the most common contributing factors to the euthanasia decision.[45] Anorexia, hyporexia, and dysrexia become more common as the heart disease becomes more advanced. Owners often report a variable or cyclical appetite, where the animal will eat one food well for a few days and then refuses it, but will eat a different food well. This dysrexia is common in animals with advanced CHF. Recommendations for managing reduced appetite are listed in Box 183-3. In animals with an acute episode of CHF, avoid changing the diet until the patient is stabilized. Once the animal is home and stabilized on medications, a gradual change to a new diet can be made. Forced dietary changes when the animal is sick or starting new medications may induce food aversions.

Box 183-3

Keys to Managing Anorexia, Hyporexia, and Dysrexia in Patients with Heart Disease

- Assess the patient for optimal medical control of heart failure.
- Assess the patient for side effects of medications (e.g., dehydration, azotemia, hyperkalemia, drug toxicosis).
- Feed more frequent but smaller meals.
- Provide multiple diet options so owners can rotate foods if hyporexia or dysrexia occurs.
- Warm the food to body temperature (for cats). Try different temperatures of food for dogs—they may prefer it warmed, at room temperature, or even cold.
- Feed the animal from a different type of dish (e.g., a new food dish or a human dinner plate).
- Feed in a different location in the house.
- Add homemade chicken, beef, or fish broth to the food (even low sodium store-bought broths are too high in sodium).
- Add a small amount (1-2 teaspoons) of cooked meat (hamburger, chicken, or fish) to the food. Be sure to instruct the owner not to use any prepared foods, such as rotisserie chicken, lunch meats, or canned meats or fish due to their high sodium content. Cats typically prefer meat or fish as a palatability enhancer. Meat or fish also may enhance food intake in dogs, but some dogs prefer sweet flavors as a palatability enhancer (e.g., maple syrup, applesauce, fruit-flavored yogurt).
- Supplement fish oil, which is high in n-3 fatty acids, to reduce inflammatory cytokines. This may have modest benefits for appetite.

In many cases, the desired nutrient modifications can be achieved through diet alone. However, supplementation of certain nutrients may be desirable if they are either not in a particular diet or not at high enough levels to achieve the desired effect. It is important to be aware that dietary supplements currently do not require proof of safety, efficacy, or quality control to be marketed. Therefore, veterinarians should consider recommending specific brands of dietary supplements that bear the logo of the United States Pharmacopeia Dietary Supplement Verification Program, which tests human dietary supplements for ingredients, concentrations, dissolvability, and contaminants. Another good resource is Consumerlab.com, which performs independent testing of dietary supplements (primarily human supplements but also some pet products).

In addition to finding a diet that has the desired nutritional properties and palatability, it also is important to devise an overall dietary plan that meets the owner's expectations. This includes finding a diet that the owner perceives the pet to enjoy, providing acceptable treats, and devising a satisfactory method for administering medications. In one study, over 90% of dogs with heart disease received treats and these treats are often high in sodium.[43] Fewer cats (33%) receive regular treats but this additional source of nutrients also should be addressed with cat owners.[44] In addition, the majority of people administering medications to their dogs use foods as a way to administer the medication,[43] so appropriate methods of medication administration should be provided to owners (see Box 183-2). Only 34% of cat owners use foods to administer medications,[44] but because of the difficulty of this activity in cats, special care should be taken to ensure that the cat owner can be successful and adherent in medication administration. Including information regarding all sources of food from pet food, treats, table food, and medication administration in the overall diet plan is important to achieve success with nutritional modification.

CHAPTER 184

Nutritional Management of Renal Conditions

Joseph W. Bartges

Client Information Sheet: Nutritional Management of Chronic Kidney Disease

Chronic Kidney Disease (CKD)

Chronic kidney disease is common in dogs and cats (see ch. 324) and is characterized by an irreversible decrease in renal function that may stabilize or plateau for periods, but invariably, the condition progresses. Clinical studies of dogs and cats with CKD have demonstrated that dietary modifications can slow disease progression, prolong survival, and improve quality of life.[1-5] The American College of Veterinary Nutrition recommends an assessment of patient, food, and feeding methods (see ch. 170). Then, plans can be developed that include a diet and feeding strategies. Periodically, these should be re-evaluated using this two-step process.[6] Because CKD is progressive, there is no set period for adjustments; this is dictated by the patient's condition.

Two-Step Process in Developing Feeding Recommendations for Dogs and Cats with CKD

Assessment Phase

The Patient

Some dogs and cats with CKD appear healthy while others have changes consistent with chronic disease: an unkempt appearance, poor hair coat, weight loss, and/or muscle wasting. Signs of chronic disease are negative prognostic indicators (see ch. 177).[7,8] Additional signs of uremia may be present, such as gastrointestinal (GI) ulcers or uremic halitosis. The International Renal Interest Society (http://iris-kidney.com/) developed a system for staging severity of dysfunction in dogs and cats with CKD (see ch. 324) based on degree of azotemia, presence of proteinuria and/or hypertension.[9] Some pets with CKD have anorexia and nausea due to retention of uremia toxins, dehydration, biochemical alterations (azotemia, metabolic acidosis, electrolyte imbalances, mineral imbalances), anemia, renal secondary hyperparathyroidism (R2HP), or uremic gastroenteritis.[10,11] Gastric ulcers occur less commonly in dogs and cats than in people; however, many dogs and cats with CKD have gastric lesions that include vascular changes, edema, and hyperacidity due to hypergastrinemia from decreased renal excretion (see ch. 275).[12,13] Administration of maropitant, mirtazapine, or ondansetron may be beneficial in uremic gastroenteritis.[14-18]

The Diet

Energy

Body weight and body condition vary among dogs and cats with CKD. The obese may be prone to systemic arterial hypertension (see ch. 157 and 176), while those that are underweight or cachectic may be prone to medication intolerance, secondary infections, and/or poor quality of life (see ch. 177).[19] Dogs with CKD and poor body condition have shorter life-spans when compared with CKD dogs that are of optimal condition or overweight.[8] Decreased energy intake due to inappetence or advanced renal failure may lead to poor body condition.

Fatty Acids

The average fat content of adult dog and cat foods is about 12% (dry matter basis), containing predominantly n-6 polyunsaturated fatty acids, unless fish oil is added. Cytokines derived from membrane-bound n-6 fatty acids include prostaglandins, thromboxanes, and leukotrienes of the 2- and 4-series. These cytokines are typically pro-inflammatory and vasoactive. In people with CKD and dogs with induced CKD, intra-renal free radical production and antioxidant depletion occur, which may promote CKD progression.[20-22]

Antioxidants

CKD is a pro-oxidant state, beginning early in the condition and progressing as the disease worsens.[22,23] Modification of oxidative stress may have benefit in managing CKD, including improved neutrophil function and decreased DNA damage.[21,24-28]

Water-Soluble Vitamins

Theoretically, water-soluble vitamins are lost at an increased rate in pets with CKD due to their polyuria. No study has documented vitamin loss. One study did not find differences in plasma concentrations of water-soluble vitamins in dogs with CKD.[29]

Electrolytes

Hypokalemia and whole-body potassium (K) depletion occur in 20-30% of cats with CKD (possibly associated with primary hyperaldosteronism in some; see ch. 308 and 324), but are uncommon in dogs (see ch. 68). Hyperkalemia was reported in 13% of 186 cats with CKD.[30] Consequences of hypokalemia include a polymyopathy and secondary weakness, hyporexia, and progression of CKD.[31] Amlodipine may promote hypokalemia in some cats with CKD[32] while enalapril and benazepril may promote hyperkalemia in dogs and cats with CKD.

Serum sodium (Na) concentrations are typically normal in CKD and the interactions between dietary Na, systemic arterial hypertension, and CKD are not completely understood (see ch. 67). High salt intake has not been associated with systemic arterial hypertension in dogs or cats; however, these studies were in healthy animals, animals with induced disease, or those ill for a short time.[32,33] A 2-year study of non-azotemic, aged cats did not show an effect on glomerular filtration rate, blood pressure, or other routine laboratory variables when cats were fed a 3.1 g/Mcal Na diet versus a 1.0 g/Mcal Na diet. In a 3-month crossover study of cats that were healthy, obese, older, or who had IRIS stage 2 CKD, consumption of a 2.9 g/Mcal "high Na" diet increased water intake and urine output in cats, except for those with CKD, when compared with consumption of a 0.9 g/Mcal "low Na" diet.[34] Consumption of the 2.9 g/Mcal Na diet was not associated with increased blood pressure in any group; however, it paralleled increases in serum concentrations of urea nitrogen, creatinine, and phosphorus in all cats. The greatest increases were noted in those with CKD.[34]

Acid-Base Balance

Metabolic acidosis is common in dogs and cats with CKD due to retention of metabolic acids, lactic acid production, electrolyte imbalances, and/or consumption of dietary acids. As renal function declines, capacity to excrete hydrogen ions and reabsorb bicarbonate ions is reduced. Metabolic acidosis may exacerbate hypokalemia, increase muscle catabolism, cause loss of lean mass, disrupt intracellular metabolism, and promote osteodystrophy. Cats appear to adapt to CKD and metabolic acidosis does not appear to occur until later in the course of their disease.[35] Provision of an alkalinizing agent, such as potassium bicarbonate or potassium citrate, to dogs and cats with azotemic CKD has been beneficial.[36,37]

Moisture

Due to the polyuric nature of CKD, dehydration may occur, especially in cats. Canned formulated diets contain 70-80% moisture and dry formulated diets contain 10-12%; therefore, dehydration is more likely to occur in animals consuming a dry formulated diet.

Protein

Azotemia is, by definition, an increase in nitrogenous compounds in the blood, most of which are derived from dietary protein or catabolism of endogenous protein. Formulating a diet that contains reduced quantity, but highly biologically available protein and adequate non-protein calories is based on the premise that reducing non-essential protein results in decreased production of nitrogenous compounds.[38] This may aid in amelioration of clinical signs associated with renal azotemia. Whether reducing dietary protein alters

progression of CKD is less certain.[39-47] Dietary protein restriction does decrease urinary protein excretion and increase serum albumin concentrations in azotemic and nonazotemic dogs with proteinuria.[48,49]

Minerals

Renal secondary hyperparathyroidism (R2HP) occurs commonly in dogs and cats with CKD.[1,50] Deficiencies of calcitriol (vitamin D_3) have been hypothesized to play a pivotal role in development of R2HP, but phosphorus retention also likely has a role.[51] Phosphorous retention and hyperphosphatemia occur early in CKD and play a primary role in R2HP and progression of renal failure. It suppresses fibroblast growth factor 23, which may be integral in progression of chronic kidney disease.[36,41,42,52-56]

The Feeding Method

The most important aspects of nutritionally managing CKD are whether the pet is eating and whether food intake is adequate. Questioning owners as to the volume of food provided, how frequently it is provided, how much of the meal is consumed, and whether the pet has a preference for a certain form of diet is important.

Initiation and Monitoring Phase

Selection of a Diet

The second phase in nutritional planning for pets with CKD is selecting the most appropriate diet and means of providing nutrition. Once the new diet is started, one must monitor and adjust as needed. Several commercial diets are formulated and marketed for feeding dogs or cats with CKD. While these diets are somewhat similar in their components, different ingredients and other nutritional variations exist. Homemade diets should be formulated by certified veterinary nutritionists (E-Box 184-1). While commercial diets tend to be consistent in composition, several studies have shown variability in nutrient content and some imbalances in homemade diets.[57,58]

*This is a partial listing (see ch. 192, Table 192-1).

Energy

Sufficient energy must be provided to maintain body condition and body weight. Thus, sufficient energy is necessary to minimize protein catabolism that can result in malnutrition and exacerbate azotemia and uremia. Caloric requirements for dogs and cats with CKD are not precise, but are likely similar to those of healthy dogs and cats (see ch. 172 and 174).[59] Remember that daily resting caloric requirements are only estimates and individual variability can be significant. Therefore, body weight, body condition, and appetite should be monitored closely and adjustments made as needed.

Cats and dogs with CKD often have periods of partial or complete anorexia causing weight loss and other issues consistent with chronic illness. Therefore, diets that are more calorically dense than maintenance adult foods promote adequate energy intake without requiring the patient to eat a large volume. This can help reduce gastric distention and nausea. Because dietary fat is more calorically dense than protein or carbohydrate, CKD diets are usually higher in fat as compared with maintenance adult foods. Diets formulated for CKD usually contain 12-30% crude fat (dry matter basis). Nausea and anorexia associated with CKD may be due to hypergastrinemia and gastric hyperacidity.[12] Giving histamine-2-receptor antagonists, other antacids, neurokinin-1 inhibitors, or a medication that works via serotonin pathways may be beneficial in CKD.

Fatty Acids

In people, CKD is associated with increased free radical production and antioxidant depletion that may promote disease progression. Dogs fed diets containing 15% fat with fish oil had more sustained glomerular filtration rate (GFR) when compared with dogs fed beef tallow or safflower oil.[60] This benefit has not yet been demonstrated in cats.

Antioxidants

Cats fed a therapeutic diet formulated for managing CKD that was supplemented with vitamin E (742 mg/kg), vitamin C (84 mg/kg) and beta-carotene (2.1 mg/kg) had a significant reduction in oxidative DNA damage.[28] In an unpublished study of 6- to 8-year-old Beagles using the remnant kidney model, dogs were divided into 4 dietary groups: high n-3 fatty acids, high n-3 fatty acids plus antioxidant supplementation, high n-6 fatty acids, and high n-6 fatty acids plus antioxidant supplementation.[21] Specific antioxidants were vitamin E, carotenoids, and lutein (amounts not specified), and dietary total (n-6 + n-3) polyunsaturated fatty acid content was approximately 2.5% (dry matter basis). Results demonstrated independent and additive protective effects of antioxidant therapy and n-3 fatty acids. The rate of decline of GFR was slowed by n-3 fatty acids and the antioxidants; effects were additive and were associated with reduced magnitude of proteinuria, glomerulosclerosis, and interstitial fibrosis.

Water-Soluble Vitamins

Although B-vitamin deficiency has not been demonstrated, many diets formulated for managing CKD contain higher amounts of B-vitamins when compared with adult maintenance diets. B-vitamin supplementation may also stimulate appetite.

Electrolytes

Diets formulated for CKD are typically higher in potassium (K) than adult maintenance foods; K-citrate is used to supply the K and as an alkalinizing agent with a goal of maintaining serum K concentrations in the middle to upper half of the laboratory reference range. If necessary, K can be supplemented orally as gluconate or citrate salts. K-chloride is not recommended because of poor palatability and acidifying nature. K-gluconate (2 to 6 mEq/cat/day) and K-citrate (40-75 mEq/kg/day) can be given orally. The dosage depends on the size of the pet and severity of hypokalemia. Routine low-dosage K supplementation has been recommended for cats with CKD. However, one study failed to demonstrate that K-gluconate (4 mEq/day) improved muscle K stores when compared with Na gluconate.[61] In this study, median muscle K content did increase in the supplemented group to a level approaching that of normal cat muscle, with no significant adverse effects. Based on current data, no recommendation can be made for or against low-dose K supplementation to cats with CKD.

Whether dietary Na content should be restricted with CKD is controversial. In one study, high dietary Na intake in cats with naturally occurring CKD was associated with worsening azotemia.[34] In a separate study of induced CKD in cats, Na restriction was associated with hypokalemia.[32] Thus, salt supplementation and salt restriction must be done cautiously and patients should be monitored. Increased dietary Na may increase urinary Ca excretion, can contribute to ongoing renal damage, and may contribute to formation of Ca oxalate urolithiasis (see ch. 331 and 332).

Acid-Base Balance

Treatment options for managing the metabolic acidosis associated with CKD include dietary modification and alkalinization therapy. Dietary protein is a major source of organic acids; therefore, reduction of dietary protein decreases metabolic acidosis. Diets formulated for CKD usually have less protein and contain K-

citrate, an alkalinizing compound. Oral Na bicarbonate may be used for additional alkalinization. The effects of gastric acids on oral Na bicarbonate are unpredictable; therefore, doses should be individualized. The starting dosage is 8-12 mg/kg PO q 8-12 h. Since many dogs and cats refuse oral Na bicarbonate, an alternative with the advantage of providing K is K-citrate. Starting dosages are about 40-80 mg/kg, PO, q 12 h-q 8 h.

Moisture

Voluntary water intake may be insufficient to maintain hydration, especially in cats. Feeding a canned formulated diet, which contains 70-80% water, does supplement fluid intake. In pets that cannot maintain hydration via voluntary consumption, additional fluids may be administered SC or by a nasogastric, esophagostomy, or gastrostomy feeding tube (see ch. 82 and 324).

Protein

Minimal dietary protein requirements for dogs and cats with CKD are not precisely known. Diets formulated for managing dogs with CKD typically contain 13-18% protein (dry matter basis) and those for cats typically contain 25-32% protein (dry matter basis). To decrease blood concentrations of nitrogen-containing compounds (blood urea nitrogen and creatinine) one can facilitate nitrogen excretion via the GI tract by providing probiotics or soluble fiber (see ch. 167 and 190). New supplements with fiber-like polysaccharides derived from chitin and bacteria are available as phosphate binders and agents that reduce azotemia. Limited data exist as to efficacy, and maximal effect occurs when combined with nutritional therapy.[62-66]

Minerals

Dietary phosphorus restriction decreases the degree of hyperphosphatemia, hyperparathyroidism, and slows progression of CKD in dogs and cats.[3,41,42,52,67] Dietary phosphorus content for management of CKD should be 0.2-0.5% (dry matter basis) while maintaining a Ca : P ratio of 1.1-1.3 : 1. In stage I and II CKD, feeding a phosphorus restricted diet may normalize parathyroid hormone concentrations (see ch. 324).[53,67]

Clinical Studies

Several studies have demonstrated, in part due to dietary management, longer survival times and better quality of life in dogs and cats that have naturally occurring CKD.[1-4] Most studies showed at least a two-fold increase in survival in dogs and cats fed a "renal failure" diet. Diets were most effective with stage II CKD. Efficacy with stage I CKD has not been demonstrated although dogs with stage I CKD and proteinuria benefit from dietary protein restriction.[48]

Selection of Feeding Method

Most dogs and cats with CKD are fed orally; however, nutritional support can be provided using feedings tubes (see ch. 82 and 324).[68] The formulation of the diet, dry versus canned, may be modified to stimulate adequate nutritional intake as well as moisture intake. Feeding canned diets increases moisture intake and may help prevent dehydration. It may also be necessary to modify feeding frequency if animals are unable or unwilling to consume one or two meals per day. Some dogs and cats respond best to 3 or more small meals each day (see ch. 177).

Monitoring Patient Response

Chronic kidney disease is progressive; therefore, monitoring is important. Monitoring of nutritional management of CKD involves body condition score, body weight, appetite, quality of life, and biochemical parameters. Frequency of monitoring should be individualized to the patient and to the stage of disease. Most animals should be monitored every 4 to 6 months in stage I or II CKD and more frequently in stage III and IV, or if CKD is unstable or progressing rapidly (see ch. 324).

CHAPTER 185

Nutritional Management of Lower Urinary Tract Disease

Yann Queau, Vincent C. Biourge

Client Information Sheet: Dietary Management of Urinary Stones

Lower urinary tract disease (LUTD) encompasses a variety of disorders characterized by dysuria, stranguria, pollakiuria, hematuria, periuria and sometimes urethral obstruction. Urolithiasis accounts for 18% and 7-22% of LUTD cases in dogs (see ch. 331)[1] and cats (see ch. 332)[2-5] respectively, while idiopathic cystitis (IC) is predominant in cats, representing approximately two-thirds of cases (see ch. 334).[2-5]

It is crucial that the precise etiology (or the lack thereof in the case of IC) of the LUTD signs be sought for nutritional management to be successful. Collecting dietary history and information on the patient's environment, obtaining quantitative stone analysis, and diagnosing any potential metabolic disorder are essential to guide and optimize dietary treatment.

Urolithiasis

Uroliths are polycrystalline structures that form under certain conditions affecting urinary concentrations of crystalloids, inhibitors or promoters of crystallization, and pH. Relative supersaturation (RSS) is a risk index of crystallization in humans[6] and companion animals.[7] To calculate RSS, urine pH and the concentrations of ten solutes from a representative urine sample are entered in a computer algorithm. RSS defines three levels of urine saturation: *undersaturation* (crystal dissolution, RSS <1), *metastable supersaturation* (neither crystal formation nor dissolution) and *labile supersaturation* (spontaneous crystal formation and growth). To date, RSS is not available in the clinical setting. Urine specific gravity (USG), urine pH, and microscopic evaluation can be performed readily as indirect and imperfect ways of assessing risk of crystal formation. Maintaining USG <1.030 in cats and <1.020 in dogs often is recommended in patients at risk.[8]

General Considerations: Stimulating Diuresis

Whatever the nature of the stone, urine dilution is the paramount strategy for the prevention and/or the dissolution of uroliths. Increased diuresis lowers RSS and stimulates more frequent urination, decreasing the time for crystal aggregation. Using wet diets (dietary moisture > 70%; cans, pouches, trays) is an effective way to enhance water intake and diuresis in dogs and cats.[9-11] In order to bring dietary moisture of dry diets to a comparable level, warm water can be poured onto kibble: adding 1.5 cups of water to 1 cup of kibble yields approximately 80% moisture. Acceptance of such a diet might be a challenge in cats.

An alternative to moisture to stimulate diuresis is sodium chloride supplementation. In a large number of studies, cats and dogs had greater water intake and urine volume, and in most cases lower USG, when fed dry commercial diets with sodium contents >2.5 g/1000 kcal.[11-19] The use of high dietary sodium is subject to controversy. Based on human studies, concerns have been raised regarding renal and cardiac functions, and blood pressure. One study in cats found a reversible increase in creatinine in 4 cats with marginally impaired renal function when fed a diet with a sodium concentration of 2.9 g/1000 kcal.[17] On the contrary, five short[20-23] (1-12 weeks) and two long[18,19,24] (6-24 months) term studies found no effect of a higher sodium intake on renal (including glomerular filtration rate) and cardiac functions. Systemic hypertension was not found in any study. Another potential concern is an increased urinary calcium excretion with high sodium diets.[12,14] However, due to concurrent urine dilution, urine calcium concentration is either unchanged[11,12,14] or

decreased.[15] The urine concentrations of solutes such as oxalate can decrease, thus lowering calcium oxalate (CaOx) RSS.[11,12,15]

Specific Considerations According to Stone Type

A majority of stones occur as pure uroliths, and their specific dietary management is described in this section. Between 5 and 15% may occur as compound or mixed uroliths. In that situation, dietary prevention should be targeting the inner part of the calculus (nidus), which formed first and facilitated the precipitation of the second mineral.

Struvite

Struvite crystals are composed of magnesium, ammonium, and phosphate. They can form in sterile urine (most feline cases; see ch. 332), or secondary to a urinary tract infection (UTI) with urease-producing bacteria (majority, if not all, of canine cases; see ch. 331). Therefore, the goals of dietary management for struvite uroliths depend on the patient's species: prevention and dissolution in cats, and dissolution in dogs. The target is a struvite RSS <1 for undersaturation and 1-2.5 for metastable supersaturation.[7,25]

Promoting urine dilution might help but is less important for struvite than for other uroliths. Urinary pH is the most important factor in the prevention and dissolution of struvite. In alkaline urine, phosphate is in its trivalent state (PO_4^{3-}), making it readily available to form struvite crystals ($NH_4MgPO_4 \cdot 6H_2O$). When urine is acidified, protonation of phosphate (HPO_4^{2-}, $H_2PO_4^-$ or H_3PO_4) decreases its availability. The lower the urine pH, the lower the struvite RSS. However, other factors such as urine dilution and amounts of precursors also influence RSS. The acidification potential of a diet depends on its ingredients and the balance between acidifiers (methionine, calcium or sodium sulfate, calcium or ammonium chloride, etc.) or alkalizers (calcium or sodium carbonate, potassium citrate, etc.). Consumption of small meals throughout the day rather than 1 or 2 large meals blunts the postprandial alkaline tide and is associated with more acidic urine production and less struvite crystalluria.[26] The target urine pH to manage struvite urolithiasis is generally 6.0 to 6.3 (at least for dry diets), to help obtain an RSS <2.5. Excessive chronic acidification increases urinary potassium excretion and can lead to body potassium depletion if dietary potassium is too low.[27,28] It could also promote bone demineralization, although this phenomenon is not supported by studies in cats.[29-31] In dogs, UTI with urease-producing bacteria promotes alkaline urine and ammonia release, thus increasing the risk of struvite formation. In the setting of UTI, acidifying diets cannot significantly decrease urinary pH without the help of antibiotic therapy. There is a direct link between the amounts of precursors of struvite (especially magnesium and phosphorus) in the diet and their excretion in the urine.[32,33] In the absence of urinary pH control, high dietary amounts of those minerals could increase the risk of struvite urolithiasis. Both minerals interact for their absorption. Studies have proven the efficacy of dry and canned commercial diets with controlled amounts of struvite precursors, acidifying and/or diuretic properties, for the dissolution of naturally occurring struvite uroliths in cats.[34-37] In cats, average complete dissolution times varied from 13 to 28 days (range 6-141 days). In dogs, dissolution can take up to 3 months, and protocols must be accompanied by appropriate antibiotic therapy.[38-40]

Calcium Oxalate

To date, calcium oxalate (CaOx) uroliths are not amenable to medical dissolution. The goal of dietary management is to reduce the risk of recurrence. A CaOx RSS between 1-12 corresponds to urine in the metastable supersaturation zone.[25] This can be achieved by stimulating diuresis. Increasing water intake through dietary moisture[9,11,41] or dietary sodium[11-16,41,42] has lowered CaOx RSS in healthy and stone-forming animals in the majority of studies.

The role of dietary precursors in the pathophysiology of CaOx is poorly understood. In a retrospective study, higher dietary moisture, protein, sodium, and potassium were associated with a lower risk of CaOx urolithiasis in cats (see ch. 332).[43] In dogs fed dry and canned diets, the risk of CaOx urolithiasis was higher for dogs that ate diets with the lowest levels of protein, sodium, potassium, calcium, phosphorus, and magnesium (see ch. 331).[42,44,45] Based on current knowledge, prevention of CaOx urolithiasis aims at reducing urinary concentrations of calcium and oxalate. High dietary calcium levels increase its absorption and urinary excretion, leading to higher RSS.[46] However, calcium absorption is affected by dietary phosphorus, magnesium, oxalate, and vitamin D. Oxalate absorption is affected by dietary calcium.[47-49]

Ingredients such as beets, beans, potatoes, and leafy vegetables are high in oxalate concentration but the effect of dietary oxalate on its urinary excretion is variable.[46,50,51] In humans, dietary oxalate can be degraded by intestinal microflora. Endogenous oxalate production, via the metabolism of some sugars (glucose, fructose), amino acids (including hydroxyproline, glycine, serine, etc.), vitamin C, and glycolate also will affect oxalate excretion.[50-52] Deficiency in vitamin B_6 (pyridoxine) leads to increased endogenous production and urinary excretion of oxalate.[53] However, deficiency of this vitamin is very unlikely, and large supplementation does not decrease urinary oxalate concentrations.[54]

In humans, high animal protein diets are associated with metabolic acidosis and hypercalciuria.[55] Therefore, they are considered a risk factor for CaOx urolithiasis. Conversely, high dietary protein appears protective against CaOx in dogs and cats,[43-45] and it leads to increased urine volumes,[56] which can lower concentrations of crystalloids. One study found higher CaOx RSS with increasing dietary protein (35-57% DM) in cats.[57] The differences were very small, however, and probably not biologically relevant. In addition, increasing protein content was not associated with a consistent increase in calcium excretion nor a decrease in urinary pH. Magnesium can form complexes with oxalate. Epidemiological studies found that low dietary magnesium increases the risk of CaOx urolithiasis in cats.[43] However, excessive magnesium supplementation could increase the risk of struvite urolithiasis.

There has been some controversy regarding the effect of urine pH on the risk of CaOx urolithiasis. The increasing prevalence of CaOx stones has been hypothesized to be associated with the general acidification of pet foods in the 1980s and 1990s. Retrospective epidemiological studies have found the urine acidifying potential of a diet (pH <6.25) to be associated with an increased risk of CaOx urolithiasis in cats[43] but not in dogs.[44,45] Chronic metabolic acidosis is believed to promote release of calcium and phosphate from bone, and calciuria,[27] and to decrease urinary citrate, an inhibitor of CaOx crystallization. Studies on the effect of urine pH on CaOx RSS have yielded conflicting results, with one showing higher RSS with lower urine pH despite similar ionized calcium and calciuria,[31] and the other showing no difference in RSS.[58] Potassium citrate often is recommended for decreasing the risk of CaOx urolithiasis by alkalinizing urine and increasing urine citraturia. This strategy has not been supported by one study in dogs, however.[59] In conclusion, the importance of urine pH to manage CaOx remains to be further defined.

Calcium Phosphate

When calcium phosphate uroliths occur as a minor component of calcium oxalate or struvite stones, the management should be directed towards the original urolith (nidus). Pure calcium phosphate stones are associated with metabolic disorders leading to hypercalciuria (e.g., hypercalcemia, hyperparathyroidism; see ch. 297) and/or alkaline urine pH (e.g., renal tubular acidosis; see ch. 326).[60] These uroliths are not amenable to medical dissolution. Treating the underlying cause should be the first step to reduce the risk of recurrence. Diet should promote urine dilution, contain a controlled amount of calcium, phosphorus, and vitamin D, and induce a moderately acidic urine pH.

Urate

Dietary management of urate uroliths focuses primarily on preventing recurrent episodes in susceptible dogs (SLC2A9 mutation, portosystemic shunt) and cats. Medical dissolution only has been reported in Dalmatians (see ch. 326).[61] As for other uroliths, urine dilution by promoting water intake should be the first step. In dogs with uncorrected portosystemic shunts and hepatic encephalopathy, a diet designed for liver disease may be advised (see ch. 284).

Urinary urate results from the catabolism of endogenous or dietary purines. Altering the purine content of the diet is effective to decrease urinary purine metabolite excretion.[62] Very low protein diets have been recommended to reduce 24-hour urinary excretion of uric acid.[63,64] However, the purine content of proteins varies (it is high in organ meats and in fish, for example). By using selected protein sources, severe restriction is not mandatory to achieve low urinary urate concentrations.[62,65] No dietary study has been conducted in cats with urate stones. Diets designed for renal or liver disease, which typically are protein-restricted, currently are recommended. Urate crystals are slightly less soluble in acid urine. Therefore, the diet should not promote acid urine. Finally, allopurinol, which inhibits the conversion of hypoxanthine to uric acid, can be administered to dogs in conjunction with purine-restricted diets to decrease urinary excretion of urate.[66,67]

Xanthine

Xanthine uroliths usually occur secondary to allopurinol use in dogs fed diets high in purines, but also can occur spontaneously. No medical dissolution has been reported. Preventing recurrence of xanthine stones relies on adjustment of allopurinol dosage and a similar but strict dietary strategy as for urate uroliths.

Cystine

Cystine stones can be dissolved, and dietary treatment should be aimed at dissolution and prevention of recurrence (see ch. 331). Again, promoting water intake and urine dilution is of paramount importance. Urinary cystine excretion can be modulated by dietary protein intake, and more specifically methionine and cysteine.[68] Therefore, feeding a diet containing amounts of these essential amino acids close to their minimum requirements is recommended. Most plant protein sources have lower amounts of these sulfur amino acids than do animal proteins. The solubility of cystine is highly dependent on pH, with higher solubility for pH >7.2.[69] Medical treatment with 2-mercaptopropionylglycine (2-MPG) has been successfully used in dogs.[70] In cystinuric dogs, carnitinuria and taurine deficiency have been found[71] and taurine and carnitine are advised to prevent dilated cardiomyopathy, especially if the animal is being fed a diet restricted in their precursor, methionine.

Other

Silica uroliths are uncommon in dogs and cats, and medical dissolution has never been reported. For prevention, emphasis should be put on urine dilution. Preventing pica, avoiding diets high in high-silica plant ingredients (e.g., brown rice or soybean hulls), and offering bottled water in areas with soils high in silica, are recommended. Canned diets, aside from promoting diuresis, typically are lower in vegetable ingredients. The effect of urine pH on silica solubility is unknown.

Practical Implementation of the Dietary Prescription

Prior to dietary prescription, inquiring about the diet history of the patient is important to identify potential dietary risk factors associated with the urolith that is suspected or has been retrieved (see ch. 170). Several commercial prescription diets are available for different uroliths. Wet diets may be preferred for their effect on diuresis. Dry diets with increased sodium or added water are effective alternatives when canned diets are refused. Mixed feeding (dry plus canned) could compromise diuresis; it should be discouraged unless validated by the manufacturer. If homemade diets are chosen, they should be formulated by a veterinary nutritionist and be high in moisture. Treats should not exceed 10% of the daily calories, and should not interfere with the dietary strategy. Fruits and vegetables generally are low in purines. Rawhide chew treats can contain high amounts of oxalate precursors.

Feline Idiopathic Cystitis

Feline idiopathic cystitis (FIC) currently is believed to result from abnormal activation of the stress response system (see ch. 334).[72] Most episodes of FIC are self-limiting within 2-7 days. Treatment is aimed at preventing recurrence using a multimodal approach with environmental enrichment, limitation of social stressors, and improved litterbox management.[73] Diet is part of this multimodal approach. Based on limited evidence, wet diets have been recommended for their effect on diuresis, as diluted urine might be less irritating to the mucosa.[74,75] Oral glycosaminoglycans have been tested, with no benefit.[76,77] A commercial prescription diet decreased the incidence rate of some LUTD signs compared to a control diet differing in several nutrients, although there was no difference in the proportion of relapsing cats over a 1-year period.[78] A casein hydrolyzate (alpha-casozepine), shown to decrease anxiety-related behaviors in cats,[79] might be useful, but studies are needed.

Summary

Diet is a fundamental aspect of the medical management of LUTD in dogs and cats. Promoting water intake and urine dilution is a common management feature regardless of etiology. The management of some uroliths (struvite, urate, cystine) relies strongly on a specific dietary profile. Success of dietary management requires proper identification of the urolith, the management of metabolic disturbances, and owner compliance with feeding the recommended diet.

CHAPTER 186

Nutritional Management of Dermatologic Disease

Manon Paradis

Client Information Sheet: Nutritional Management of Food Allergy

Nutrition has a fundamental role in the prevention and management of several dermatologic disorders.[1-3] This chapter will discuss the following three distinct areas: (1) food hypersensitivity (cutaneous adverse food reaction); (2) nutritional deficiencies; and (3) nutritional supplementation for the management of skin diseases.

Food Hypersensitivity[4-13]

The development of hypersensitivity to one or more food ingredients in the diet can cause skin or gastrointestinal disorders or both.[14,15] Pruritus is the most frequently observed presenting dermatologic sign, which can be accompanied by subsequent self-inflicted lesions (e.g., alopecia, excoriation, erythema). Allergic otitis externa is a common feature of food hypersensitivity in dogs and sometimes is the only clinical manifestation. Food hypersensitivity can mimic other allergic conditions such as atopic dermatitis[16] or flea allergy dermatitis, and the clinical picture can be complicated further by the presence of these disorders concurrently, as well as with secondary pyoderma or *Malassezia* dermatitis. In cats, food hypersensitivity can present as self-inflicted symmetrical alopecia, excoriations (particularly involving the head and neck), miliary dermatitis, and eosinophilic plaques (see ch. 10 and 191).

Diagnosis of Food Hypersensitivity[17-19]

An elimination diet trial, which involves feeding a home-cooked or a commercial "hypoallergenic" diet exclusively, usually for a period of up to 8 to 10 weeks, is the most important and only reliable diagnostic test to diagnose or exclude food hypersensitivity. Other tests such as intradermal skin testing with food antigens, skin patch testing, and measuring food allergen-specific serum IgE concentrations are of no diagnostic value because of their low sensitivity and specificity.[20]

Before considering initiating an elimination diet trial, it is of outmost importance to first exclude ectoparasites (e.g, fleas, lice, *Sarcoptes, Cheyletiella, Otodectes*) and bacterial and yeast infections as potential causes of pruritus. Usually, the food trial is conducted only if residual pruritus persists after parasitic and infectious causes of pruritus have been excluded or controlled.

Feeding the Elimination Diet

The gold standard for diagnosing food hypersensitivity is to feed the patient nothing but a home-cooked elimination diet containing a novel protein and carbohydrate source for up to 8 to 10 weeks. The food ingredients chosen for the elimination diet trial should be based on the known past exposure of the patient to various foods, avoiding dietary protein and carbohydrate sources to which the patient has been exposed. Because ingested animal proteins often are incriminated as the offending allergen and because of possible cross-reactivity among various meat sources, lentils, kidney beans, or other legumes could be a more suitable protein source for home-cooked diet trials in dogs. Conversely, only a novel animal protein source is sometimes used in cats. Usually, it is not recommended to add supplements (e.g., essential fatty acid [EFA], vitamins, minerals) during the elimination trial since they could be potential sources of allergens (e.g., fish oil, gelatin capsule), and because of the fixed duration of the trial. Home-cooked diets, although incomplete and unbalanced, can be used safely for the diagnostic phase in most otherwise healthy adult pets. Commercial "hypoallergenic diets" containing a hydrolyzed or a novel protein source offer convenience and they are

guaranteed to be nutritionally complete and balanced.[21-24] However, they are not as reliable as home-cooked elimination diets: up to 25% failure rates have been reported, due to presence of preservatives, dye, processing agents, only partially hydrolysed proteins, and/or cross-contamination in processing plants with proteins and carbohydrates not even listed on the pet food label.[25] Another frequent reason for failure of dietary trials is lack of client compliance, which can be avoided with adequate client education.

The trial diet should be introduced gradually over a few days. No other food sources should be given (no treats, bones, table scraps, chew toys with flavoring; glucosamine, vitamins, omega-3 EFAs, oral flavored heartworm preventatives,[26] flavored toothpaste, etc.). Improvement of clinical signs usually is observed within 4 weeks but may take up to 12 weeks for complete resolution in some cats (e.g., eosinophilic plaques).

Dietary Provocation Test (Food Challenge)

If resolution or a substantial decrease in pruritus level is observed during the course of the elimination diet trial, the patient must be rechallenged with all the original dietary components at the end of the trial to confirm the diagnosis of food hypersensitivity. This is to ensure that improvement over this length of time was not only coincidental (e.g., change of season, concurrent new treatments). Recurrence of pruritus within 2 weeks (as early as 15 minutes post-ingestion, and usually within one week) should occur in cases of food hypersensitivity. The diagnosis of food hypersensitivity is confirmed only if pruritus relapses upon challenge with the original diet and subsides again on re-introduction of the elimination diet.

Identifying the Offending Dietary Ingredients[27,28]

Normally, this is done once the patient is fed a suitable commercial hypoallergenic diet and the pruritus is in remission. One food ingredient which is most likely to be the cause of food hypersensitivity (e.g., beef, chicken, dairy, wheat, egg, soy, corn) is introduced and given for a period of two weeks or until pruritus is noted. If the patient eats this food item for 2 weeks with no adverse effect, he/she is not allergic to that ingredient and should be able to consume it without a problem. However, if the patient develops clinical signs on a challenge food item, the owner should avoid giving that food item in the future. The patient should then be fed only with the suitable commercial hypoallergenic diet until the signs have resolved before repeating this process with other suspected ingredients.

Long-Term Management of Food Hypersensitivity[17,21,29]

Long-term nutritional management of food hypersensitivity usually relies on feeding the allergic patient with a diet that is palatable, complete and balanced, and that does not contain the offending allergen(s). This is usually accomplished by feeding a commercial "hypoallergenic diet" tolerated by the patient. Occasionally, once the offending food item(s) is/are identified, it is possible to feed a standard commercial diet that the patient tolerates. Home-cooked diets generally are not recommended for long-term maintenance because they are inconvenient for many owners and need to be supplemented to be complete and balanced. If a home-cooked diet is chosen (because of unavailability of a suitable commercial diet or owner's preference) it is essential that the diet be properly balanced (see ch. 192).

Prognosis of Food Hypersensitivity

The prognosis for animals with food hypersensitivity is generally very good if it is possible to achieve strict avoidance of the food item(s) to which the patient has been shown to be allergic. If there is recurrence or recrudescence of pruritus on a maintenance hypoallergenic diet, one must consider lack of long-term compliance, change in the commercial diet formulation, recent sensitization to the novel food item, or a possible recurrence of a bacterial or yeast skin infection or ectoparasite infestation. Conversely, spontaneous resolution of food hypersensitivity is possible, but it is not known how commonly, or when, it might occur.

Nutritional Deficiencies

The skin is a large organ with high nutritional requirements and diet is crucial in providing nutrients to maintain epidermal integrity and optimize skin healing. Many systemic nutrient deficiencies (e.g., protein, EFAs, zinc, vitamin A, vitamin B) can be associated with dermatopathies[30,31]; however, most produce a similar range of dermatologic clinical signs that can become evident only after feeding a deficient diet for several months. Signs usually are nonspecific and include excessive scaling, erythema, alopecia or poor hair

growth, and greasy skin, which can be accompanied by secondary pyoderma and pruritus.

Dermatologic conditions that occur as a result of nutritional deficiencies currently are rare in developed countries because most dogs and cats are fed complete and balanced commercial diets that meet their nutritional needs. Nonetheless, prolonged or inappropriate storage of the diet (e.g., fatty acid [FA] oxidation), and injudicious oversupplementation (e.g., zinc deficiency following excessive calcium supplementation) can be responsible for nutritional deficiencies (see ch. 167). In addition, with the recent trend of feeding unconventional diets (e.g., raw, home-cooked, or vegetarian diets) it is likely that dermatoses associated with incomplete and unbalanced diets will emerge (see ch. 192). When nutritional deficiency is suspected, it is usually recommended to change the diet to one that is well formulated and has been stored properly rather than to attempt to correct a deficiency by adding FAs and vitamins.

Despite the feeding of an adequate diet, nutritional deficiencies occasionally can arise in animals with chronic gastrointestinal disease (e.g., maldigestion and malabsorption), metabolic disease (e.g., superficial necrolytic dermatitis), and genetic factors (e.g., impaired zinc absorption in Siberian Huskies and Alaskan Malamutes).

There are two syndromes of zinc-responsive dermatosis in the dog.[30,32] Syndrome I predominantly is seen in Arctic breeds, and syndrome II is seen in rapidly growing puppies, often fed poor-quality dog food. Both syndromes present with adherent scaling around the mouth, chin, eyes, pinnae, and foot pads. Dogs with syndrome I require oral zinc supplementation (together with dietary correction, where appropriate), while dogs with syndrome II require a better diet.

Superficial necrolytic dermatitis (also called metabolic epidermal necrolysis and hepatocutaneous syndrome) is a rare disease seen in older dogs in which nutritional deficiencies (e.g., hypoaminoacidemia and possibly deficiency in EFA and zinc) are associated with systemic metabolic disturbances often resulting from hepatic disease.[33] Palliative nutritional management (e.g., feeding of egg yolks, zinc, and EFA supplements) or intravenous amino acid infusions can be of some benefit (see ch. 10, 180, and 285).

Nutritional Supplementation for the Management of Skin Diseases

Nutritional supplements given at supraphysiologic levels have been recommended for the management of several skin diseases.[34-37] Much interest has been paid to the therapeutic value of EFA in the management of canine atopic dermatitis.[38-40] High levels of omega-3 (n-3) FA typically are used for controlling inflammation, and omega-6 (n-6) FA to promote a healthy epidermal barrier. Although there is some evidence that supplements containing n-3 FA and diets enriched with n-3 FA do provide some clinical benefits in the management of atopic dermatitis,[34] the magnitude of these benefits still is poorly documented. It is still unknown if alpha-linolenic acid (ALA, from flaxseeds) is as useful as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), both found mainly in cold-water fish. Moreover, there is an ongoing debate as to whether the ratio of n-6 to n-3 FA in food, or an absolute dosage of n-3, is more important in modulating inflammation. Typically, supplementation with EPA 40-50 mg/kg PO q 24 h is recommended. It may take 8-12 weeks to observe a reduction in pruritus (varying from 0 to 40%). Omega-3 treatment often is used in an attempt to reduce the maintenance dosage of glucocorticoid or cyclosporine in atopic dogs (see ch. 164 and 165).[41]

Major pet food companies have formulated prescription diets for the management of canine skin diseases, particularly for atopic dermatitis. Various micronutrients or cofactors are added in addition to high levels of n-3 FA to support the epidermal barrier and immune function. However, their benefits largely are anecdotal, and controlled studies are needed to support these claims. Of note, canine diets specifically formulated to improve joint health and mobility often contain more n-3 FA (e.g., Hill's Prescription Diet j/d Canine Mobility) than those designed for skin health.

Supplements containing n-3 and n-6 FAs (or diets enriched with n-3 and n-6 FAs) also could be of some benefit to dogs with symmetric lupoid onychodystrophy (symmetric lupoid onychitis).[35,42]

Supraphysiologic doses of *natural vitamin A* (800-1,000 IU/kg/day), in lieu of the more expensive synthetic retinoids (e.g., isotretinoin, acitretin), are recommended for the treatment of some cornification disorders such as sebaceous adenitis, ichthyosis, and comedones in hairless canine breeds, as well as in actinic dermatitis, infundibular keratinizing acanthomas, epitheliotropic T-cell lymphoma, and squamous cell carcinoma. Supraphysiologic doses of *niacinamide* (vitamin B_3), usually in combination with tetracycline (or doxycycline) or *vitamin E*, are used for their antiinflammatory and immunostimulatory effects in several immune-mediated skin disorders (e.g., discoid lupus erythematosus, lupoid onychodystrophy, dermatomyositis) with variable effects. Supraphysiologic doses of *zinc* are required in Siberian Husky and Alaskan Malamutes suffering from

zinc-responsive dermatosis syndrome I.

CHAPTER 187

Nutrition-Related Skeletal Disorders

Ronald Jan Corbee

Client Information Sheet: Nutrition-Related Skeletal Disorders

Introduction

Nutrition-related skeletal disorders include conditions related to imbalances of key nutrients (calcium, phosphorus, vitamin A, and vitamin D), as well as imbalances caused by over-nutrition (i.e., obesity aggravates osteoarthritis; see also ch. 176). Nutritional imbalances can affect the skeleton of dogs and cats of any age but are most detrimental in growing animals because of the higher bone turnover rate in young animals. Furthermore, the incidence of developmental orthopedic disease (DOD; including a diverse group of musculoskeletal disorders that occur in growing animals, most commonly fast-growing large- and giant-breed dogs with an adult weight >25 kg) may be enhanced by dietary imbalances. Understanding the role of nutrition in the pathophysiology of these diseases facilitates prevention, diagnosis, and treatment (see ch. 353 for a medical description of skeletal disorders).

Calcium Metabolism

Although more than 99% of total body calcium (Ca) is stored in the skeleton, it is the extracellular fluid (plasma) calcium concentration ($[Ca^{2+}]$) that is critical for a multitude of cellular, contractive, and enzymatic processes (see also ch. 69 and 297). As a result, plasma $[Ca^{2+}]$ is tightly controlled by a complex homeostatic mechanism involving fluxes of calcium between the extracellular fluid and kidney, bone, and gut. Three major hormones—parathyroid hormone (PTH), calcitonin, and 1,25-dihydroxyvitamin D ($1,25[OH]_2D$)—regulate the influx and efflux of calcium.[1] Increased plasma $[Ca^{2+}]$ inhibits PTH secretion and stimulates calcitonin secretion. The primary function of calcitonin is to prevent increased plasma $[Ca^{2+}]$. This will be achieved by the actions of calcitonin: stimulation of Ca transport to cell organelles, storage of Ca in the labile Ca pool of bone, and increased glomerular Ca excretion.[2]

Decreased plasma $[Ca^{2+}]$ stimulates PTH secretion. The primary function of PTH is to increase plasma $[Ca^{2+}]$ to the normal level. This will be achieved by the actions of PTH: increased mobilization of Ca (and P) from bone, increased renal reabsorption of Ca from the glomerular filtrate, increased urinary P excretion, and stimulation of the conversion of 25-hydroxyvitamin D into $1,25[OH]_2D$. The primary function of $1,25[OH]_2D$ is to mineralize newly formed osteoid and cartilage from the growth plate. This will be achieved by the actions of $1,25[OH]_2D$: increased mobilization of Ca (and P) from bone, increased renal reabsorption of Ca (and P) from the glomerular filtrate, increased absorption of Ca (and P) from the gastrointestinal tract, and finally mineralization of newly formed osteoid and cartilage from the growth plate with the released Ca and P. Furthermore, $1,25[OH]_2D$ inhibits PTH secretion, providing the negative feedback mechanism[3,4] (Figure 187-1).

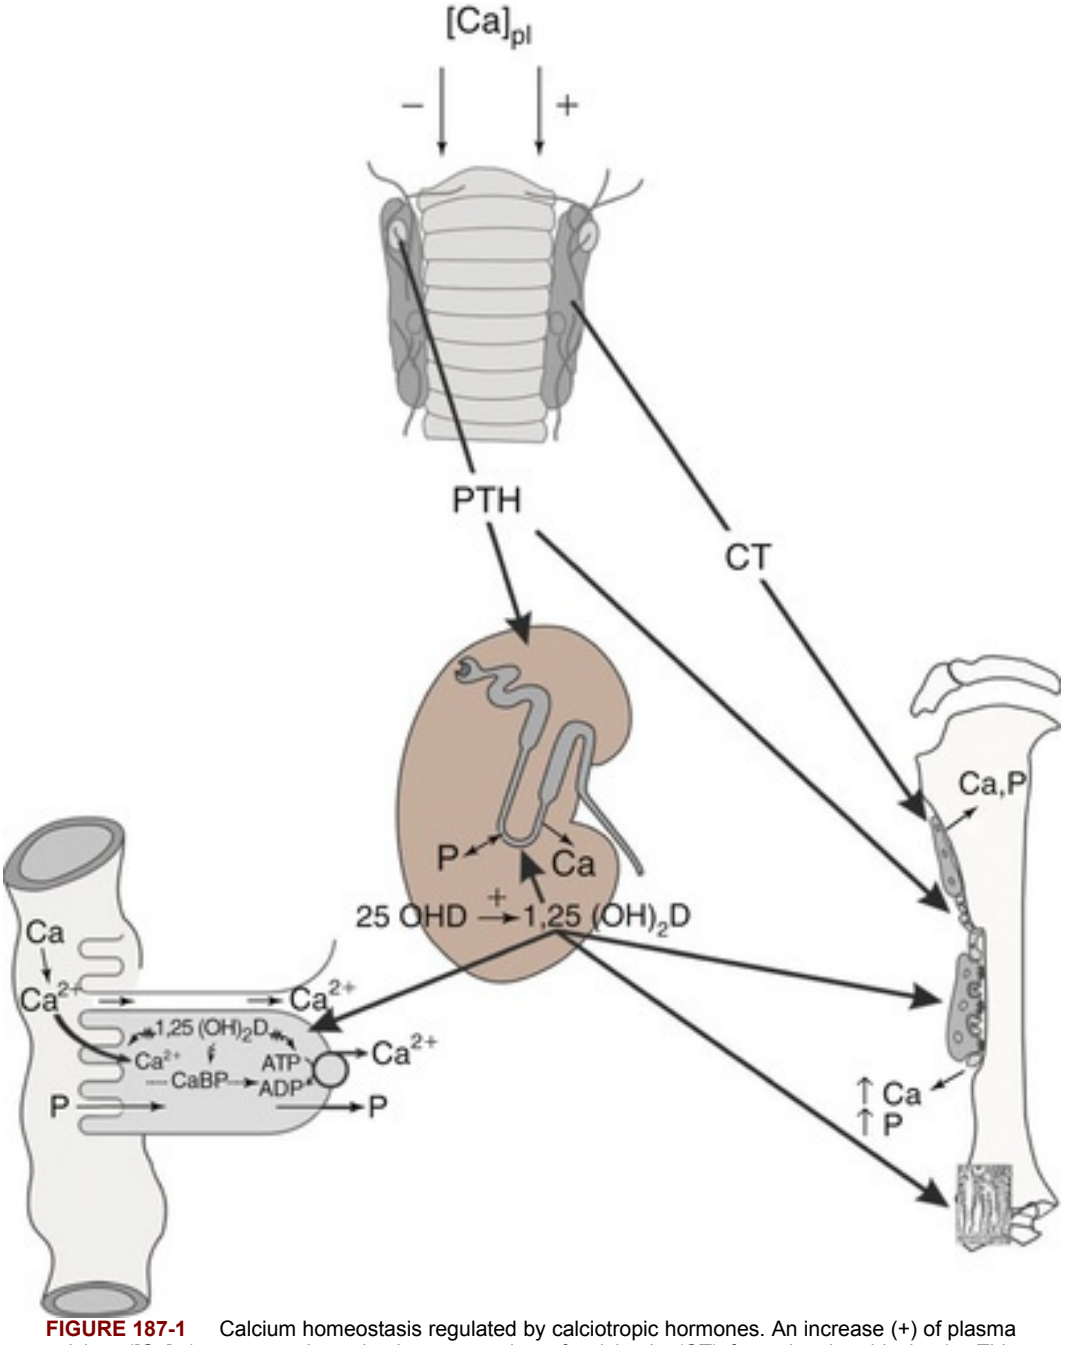

FIGURE 187-1 Calcium homeostasis regulated by calciotropic hormones. An increase (+) of plasma calcium ($[Ca]_{pl}$) concentration stimulates secretion of calcitonin (CT) from the thyroid glands. This enhances renal excretion and inhibits bone resorption of calcium, which in the long term will disturb skeletal remodelling and endochondral ossification. A decrease (−) of $[Ca]_{pl}$ stimulates parathyroid hormone (PTH) secretion from the parathyroid glands, causing (1) shrinkage of osteoblasts, allowing osteoclasts to resorb bone, and (2) increased reabsorption of Ca and excretion of phosphorus (P) and increased formation of $1,25[OH]_2D$ in the kidney. As a result of the latter, active absorption of Ca and P is increased, renal Ca and P reabsorption is increased, and mineralization of newly formed osteoid and cartilage is stimulated.

Nutritional Secondary Hyperparathyroidism

Nutritional secondary hyperparathyroidism occurs when chronic insufficient Ca intake or absorption stimulates continuous PTH secretion.

If increased Ca absorption in the intestine is insufficient to meet daily requirements, Ca will be resorbed at the endosteal surface of the diaphyses and in the areas of cancellous bone. In addition to chronic inadequate

Ca intake, excessive phosphorus (P) intake coupled with inadequate calcium intake may result in nutritional secondary hyperparathyroidism. The excess phosphorus reduces the ionized calcium concentration in serum via mass action equilibrium, resulting in hyper-secretion of PTH. Excessive osteoclasia and pathologic fractures of growing bone are the results of long-term hyperparathyroidism. Mineralization of osteoid and cartilage will be undisturbed, resulting in normal-width growth plates.[5,6]

Clinical and Radiographic Examination

Although animals of any age can be affected, most animals with nutritional secondary hyperparathyroidism are young individuals eating foods deficient in Ca.[7] For example, animals fed improperly formulated homemade foods or all-meat diets may receive insufficient calcium and/or excessive phosphorus (see ch. 192). Clinical signs may include reluctance to move and play, lameness, uncoordinated gait, sternal recumbency, loose teeth, and painful mastication.

Blood calcium concentrations are generally within normal limits although such values can, uncommonly, be decreased. Increases in serum PTH and 1,25$[OH]_2$D concentrations can be detected[4,6] (see Figure 187-1). Radiographs may reveal thin cortices, wide medullary cavities, folding (greenstick) fractures, normal width of growth plates with relatively white metaphyseal borders, as well as compression fractures of cancellous bone of epiphyses and vertebrae[5,6] (E-Figures 187-2 and 187-3).

E-FIGURE 187-2 Radiograph of a 12-week-old kitten with nutritional secondary hyperparathyroidism. Note the fractures in the femur and tibia and the marked generalized osteopenia (thin cortices).

E-FIGURE 187-3 Radiograph of a 12-week-old kitten with nutritional secondary hyperparathyroidism. Close-up of a typical greenstick fracture.

Differential Diagnosis

Rule-outs for radiographic abnormalities and pathologic fractures include nutritional secondary hyperparathyroidism and inborn errors of metabolism that include osteogenesis imperfecta, mucopolysaccharidosis, and other rare diseases (Figure 187-4). Hyperparathyroidism may be primary or secondary (i.e., nutritional or renal). Chronic Ca deficiency may be complicated by vitamin D deficiency if all-meat diets are the sole food source.

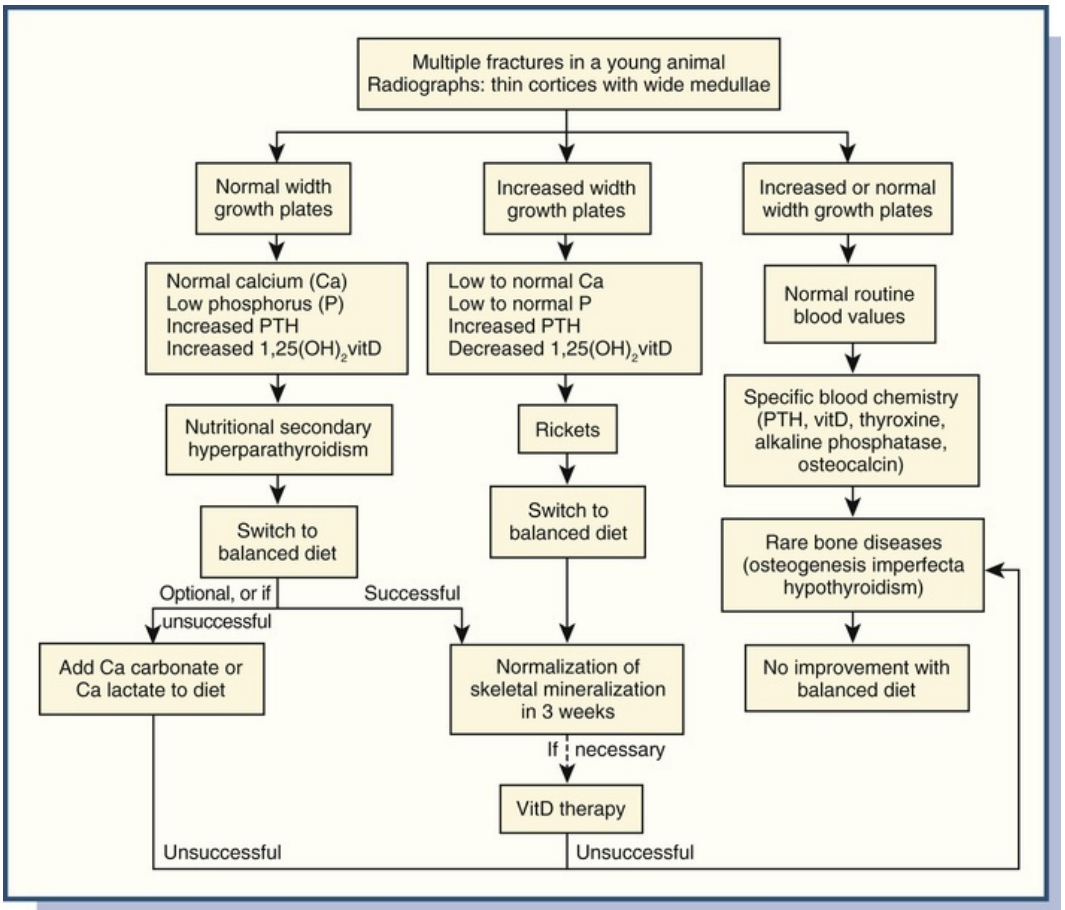

FIGURE 187-4 An algorithm for multiple pathologic fractures in young dogs and cats. *PTH*, Parathyroid hormone; *vitD*, vitamin D.

Therapy

Correction of the diet includes utilizing a commercially available, complete and balanced dog or cat food. The absolute amount of calcium in the food is more important than the calcium-phosphorus ratio in young growing dogs.[8,9] Foods should provide 0.8% to 1.2% dry matter (DM) (or 0.5 to 0.7g/MJ) calcium and the calcium-phosphorus ratio should be kept within physiologic limits (1.1 : 1 to 2 : 1). It is preferred to have the ratio 1.2 : 1.[10] Improved mineralization of the skeleton should be evident in 3 to 4 weeks, because almost 100% of the ingested Ca will be resorbed due to the hyperparathyroid-induced high $1,25[OH]_2D$ levels.[4] During this time it is important to prevent more pathologic fractures, especially of the vertebrae, by reduced handling and cage rest, as the skeleton is too weak for bandages, splints or implants. Non-steroidal anti-inflammatory drugs should be prescribed for proper pain management (see ch. 126, 164, and 356). Supplementing Ca as Ca carbonate or Ca lactate (and not Ca phosphate or bone meal) at 50 mg Ca/kg body weight (BW) may accelerate osteoid mineralization, but correcting the diet is usually sufficient. Corrective osteotomies can be planned, if necessary, after the skeleton is normally mineralized. Even pets with compression fractures of the spinal cord may have a full recovery.

Rickets

Since dogs and cats are not capable of synthesizing vitamin D under the influence of UVB light, they require a source of this essential vitamin (hormone) in their food.[2,5] Vitamin D is absorbed in the small intestine by bile salt–dependent passive diffusion. It is then transported to the liver, where it is hydroxylated into 25-hydroxyvitamin D.[2] A second hydroxylation takes place in the kidney, either to 24,25-dihydroxyvitamin D or to $1,25[OH]_2D$.[2] Both metabolites are necessary for osteoid and cartilage mineralization.[2] Rickets is characterized by defective mineralization of newly formed bone and cartilage as well as metaphyseal

thickening.[5,11] *Rickets* is the term used to describe hypovitaminosis D in young animals; in adults it is referred to as *osteomalacia.* Hypovitaminosis D arises most commonly from inadequate intake of vitamin D, but rickets lesions can also occur secondary to decreased phosphorus intake or by an abnormal calcium-to-phosphorus ratio.[12-14] Additionally, rickets can occur despite normal vitamin D intake if intake of calcium is excessive at an early age (≈3 weeks of life). This causes hypercalcemia, secondary hypoparathyroidism, and tertiary decreased 1,25$[OH]_2$D formation.[6,13]

Clinical and Radiographic Examination

A thorough dietary history is critical. Since commercial pet foods contain 2 to 10 times the Association of American Feed Control Officials (AAFCO) minimum recommended amounts of vitamin D, rickets is generally only seen in animals fed improperly formulated homemade foods such as un-supplemented strict vegetarian foods (see ch. 192). It can also occur in animals with biliary atresia or inborn errors of vitamin D metabolism.[15-19] Radiographs demonstrate thin long-bone cortices and extremely thickened growth plates. Increased growth plate width is not associated with low-calcium/high-phosphorus foods but is a strong indicator of rickets. Despite hyperparathyroidism, plasma $[Ca^{2+}]$ and phosphorus can be normal or low normal. Diagnosis of vitamin D deficiency can be made by measuring the circulating levels of vitamin D metabolites. In rickets, levels of 1,25$[OH]_2$D will be decreased, whereas in nutritional or renal secondary hypoparathyroidism 1,25$[OH]_2$D will be increased.[2,15]

Treatment

Transition to a nutritionally balanced commercial dog or cat food is generally sufficient to resolve rickets. Mineralization of bone cortices, callus, and growth plates will occur within 3 weeks. If the dog or cat fails to respond to a balanced diet, vitamin D therapy can be recommended.

Panosteitis (Enostosis, Eosinophilic Panosteitis)

High Ca intake in young dogs leads to hyperplasia of calcitonin-producing cells in the thyroid gland. This results in reduced osteoclastic activity, which can last even months after an episode of high Ca intake (see Figure 187-1).[20] In immature dogs, a large blood supply to the metaphyseal area (bordering the growth plates) exists. This network of arteriolae receives blood from branches on the periosteal side and the medullary arteries. The latter enter the bone mainly via the nutrient foramen. The direction of efferent blood flow is through the diaphyseal cortex and runs through rigid bone canals. For the widening of these canals in the growing bone, osteoclastic activity is necessary. Due to hypercalcitoninism, the canals cannot be widened, resulting in edema. This edema may also be present underneath the periosteum and thus makes the periosteum painful in response to pressure or muscle activity. So far, no causes other than high Ca intake have been demonstrated.[21]

Clinical and Radiographic Examination

Panosteitis is mainly seen in medium and large-breed dogs (especially German Shepherd Dogs), starting at 6 months of age, with a sudden onset of shifting lameness showing pain reaction on deep palpation of the long bones. Radiographs demonstrate a blurring of the trabecular pattern and well-defined subperiosteal cortical thickening can be noticed (E-Figure 187-5).

E-FIGURE 187-5 Radiograph of a 6-month-old German Shepherd with enostosis/panosteitis. Note the blurring of the trabecular pattern (arrow) and well-defined subperiosteal cortical thickening.

Therapy

Because the disease is self-limiting and is not diagnosed in dogs over 22 months of age, treatment is limited to administration of non-steroidal anti-inflammatory drugs (see ch. 164), and adaptation of the diet. Dietary treatment consists of a reduced Ca intake by feeding a diet that is close to the minimum Ca requirements, and by feeding an amount of food that is necessary to maintain ideal body condition.

Carpal Laxity Syndrome

Carpal laxity syndrome (CLS) describes hypo-extension, hyperextension, or hyperflexion of the carpal joint. It is mostly diagnosed in male, medium- to giant-breed dogs at the age of 10 weeks (mostly 6-12 weeks).[22] Feeding of a deficient diet and/or excessive food intake are thought to be the cause of CLS, as this results in rapid weight gain before adequate bone development, in combination with weakness of the ligaments due to decreased collagen synthesis. This decreased collagen synthesis can be caused by copper deficiency, as copper is incorporated in lysyl-oxidase, which is needed for collagen synthesis.[23] CLS is treated by adjusting the diet to a complete and balanced puppy food being fed in amounts to prevent rapid weight gain, as well as exercise on traction surfaces (sand, grass or carpeting), and swimming, providing good muscle traction[24] (see ch. 353 and 355). In severe cases, bandage, splints, tenotomy and/or arthrodesis are indicated. Usually, CLS is self-limiting.

Developmental Orthopedic Disease

The pathogenesis of DOD in the dog is multifactorial, involving genetic susceptibility, environmental

influences, and nutrition. DOD is a common cause of secondary osteoarthritis and degenerative joint disease (DJD) in dogs. Osteoarthritis is the most commonly diagnosed non-traumatic orthopedic condition in dogs, with an estimated 20% prevalence in adults.[25,26] Canine hip dysplasia and osteochondrosis make up the majority of DOD with a nutrition-related etiology. Specific risk factors for DOD in young dogs include: (1) large or giant breeds (genetics) (>25 kg adult weight), (2) free-choice feeding (management), particularly of high-energy foods (nutrition), and (3) excessive intake of calcium and vitamin D from food, treats, and supplements (nutrition).[27-35] The key nutritional factors that contribute to DOD are excesses of calcium and energy.[29] Excessive calcium intake (and subsequent hypercalcitoninism) results in disturbed endochondral ossification, retained cartilaginous cores, and delayed skeletal maturation.[5] Insufficient calcium intake results in weakening of bones due to insufficient Ca for mineralization. Weakened bones are more prone to trauma and disturbances of endochondral ossification, resulting in DOD (e.g., radius-curvus syndrome, canine hip dysplasia and osteochondrosis). Excessive energy intake promotes both rapid growth and obesity, and (often) also results in increased Ca intake.

Canine Hip Dysplasia

Canine hip dysplasia (CHD) is a polygenic disease with complex inheritance. As such, environmental factors such as nutrition and lifestyle have a profound influence on both its incidence and its severity.[36] Excessive energy intake appears to be paramount to the phenotypic expression of CHD in growing and adult dogs (more information in ch. 353). One long-term study of dogs genetically predisposed to CHD documented that prevalence and severity of osteoarthritis/DJD (the phenotypic expression of CHD) is greater in dogs with body condition scores (BCSs; see ch. 2 and 170) above normal.[37] Over their lifespan, the median age of dogs with radiographic evidence of CHD/osteoarthritis was significantly lower (6 years) in overweight versus normal weight dogs (12 years).[36] Additionally, the mean age at which 50% of the dogs required long-term treatment for clinical signs attributable to osteoarthritis was significantly earlier (10.3 years, $p < 0.01$) in the overweight dogs as compared to the dogs with normal BCSs (13.3 years) (see ch. 176).[38]

Osteochondrosis

Osteochondrosis (OC) is common in young, rapidly growing, warm-blooded, domesticated species and man. In all species, the etiology is considered multifactorial. In dogs, risk factors for OC include age, gender, breed, rapid growth, and nutrient excesses (primarily calcium and energy).[29,30,32,33] All large- and giant-breed dogs are at increased risk for OC. However, Great Dane, Labrador Retriever, Newfoundland, and Rottweiler breeds are at greatest risk.[32] Osteochondrosis is a disruption in endochondral ossification that results in a focal lesion but is considered a systemic disease.[39,40] Osteochondrosis occurs in the physis and/or epiphysis of growth cartilage, most commonly in the shoulder, stifle, hock and elbow. Acute inflammatory joint disease (or DJD) may ensue when the cartilage surface is disrupted and subchondral bone is exposed to synovial fluid. Inflammatory mediators and cartilage fragments are released into the joint (osteochondritis dissecans), which perpetuates the cycle of DJD (see ch. 353).[41,42]

Developmental Orthopedic Disease Treatment

To help prevent DOD in a large- to giant-breed puppy (>25 kg adult weight), it is best to feed a commercial food specific for its unique nutrient requirements. The recommended intake of most nutrients in fast growing, large- and giant-breed puppies is similar to that of other breeds. However, it is important to note that the recommendations are more stringent for energy density, dietary fat, calcium, and the calcium-phosphorus ratio (energy density = 3.5 to 4.1 kcal/g, fat = 8.5% to 17% DM, calcium = 0.8% to 1.2% DM [or 2.0-3.0g/1000 kcal, or 0.5 to 0.7g/MJ], Ca : P from 1.1 : 1 to 2 : 1 with lower end of range [1.2 : 1] preferred). Several commercial foods specifically formulated for fast-growing, large- and giant-breed puppies are available (see also ch. 171). It is important to select a food that is most similar to the key nutritional factor benchmarks. To prevent imbalances and excesses, the addition of vitamin or mineral supplements to balanced foods is not recommended. This is particularly true for calcium, phosphorus, vitamin D, and vitamin A. If a nutritionally adequate growth food is being fed, supplementation is contraindicated. The large- to giant-breed puppy should be fed to maintain a BCS between 4/9 and 5/9 (see Figures 170-1 and 170-2). Dietary deficiencies are of minimal concern in this age of commercial foods specifically prepared for young, growing dogs; the major potential for harm results from excess consumption of energy and calcium. A balanced food fed at an

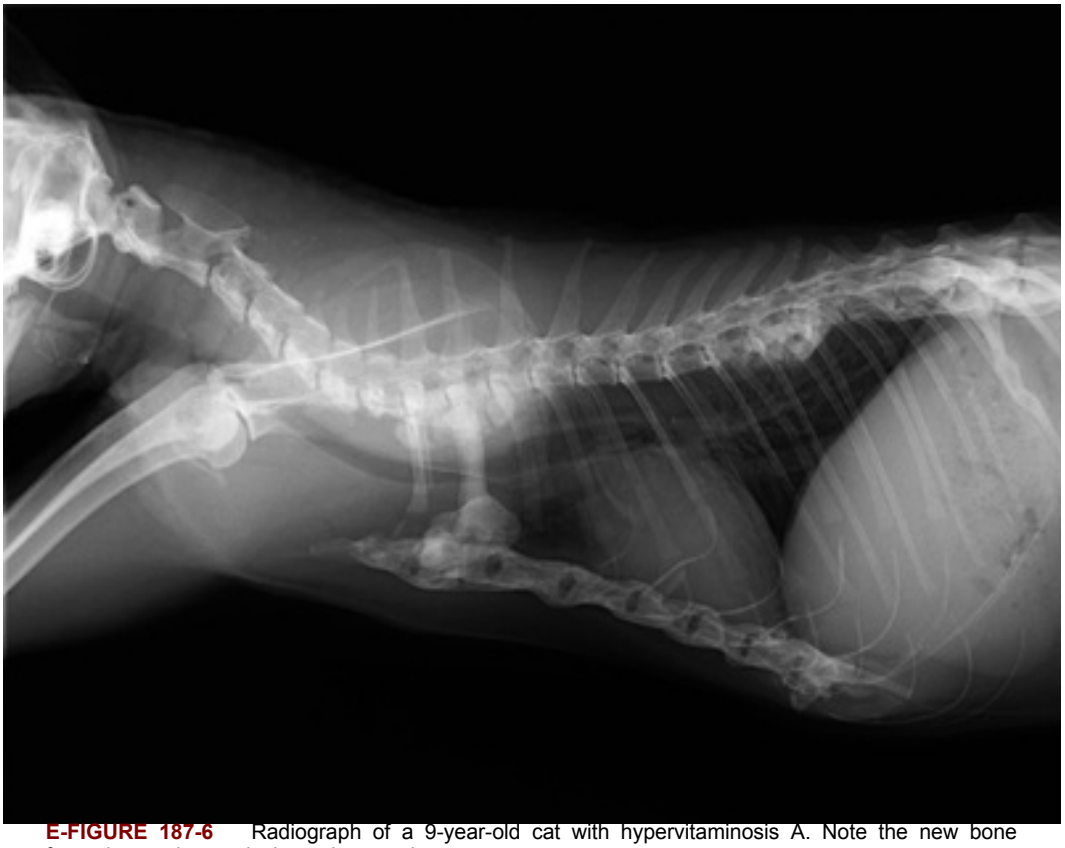
appropriate quantity will help to optimize the conditions of skeletal development and decrease the risk of DOD. When appropriate, surgical correction of underlying conditions should be considered.

Hypervitaminosis A

Vitamin A is needed for terminal differentiation and normal function of osteoblasts and osteoclasts. High vitamin A intake in young animals inhibits chondrogenesis in growth plates and inhibits collagen synthesis in osteoblasts in most species causing "hyena disease" due to premature closure of the growth plates. Because cats are unable to excrete large amounts of retinol and retinyl-esters in the urine, cats are more susceptible to hypervitaminosis A. In older cats, hypervitaminosis A is mentioned as a cause of osteoarthritis.[43]

Clinical and Radiographic Examination

Most cases reporting hypervitaminosis A in cats are due to consumption of large amounts of (pork or beef) liver.[44] In contrast to other species, hypervitaminosis A in cats is characterized by new bone formation without osteolysis, starting at the points of insertion of ligaments, muscles and joint capsules, finally causing ankyloses in vertebrae and large joints which are clearly visible on radiographs (E-Figures 187-6, 187-7, and 187-8). This results in pain, stiffness, and sometimes lameness. Elevated plasma and liver vitamin A concentrations support the diagnosis, as well as characteristic portal-portal bridges, liver fibrosis and swollen hepatic stellate cells seen in liver biopsies.[45]



E-FIGURE 187-6 Radiograph of a 9-year-old cat with hypervitaminosis A. Note the new bone formation on the cervical vertebrae and sternum.

E-FIGURE 187-7 Radiograph of a 14-year-old cat with hypervitaminosis A. Note the new bone formation on the ventral side of the lumbar vertebrae.

E-FIGURE 187-8 Radiograph of a 9-year-old cat with hypervitaminosis A. Note the new bone formation around the hip joint.

Therapy

The ankyloses are irreversible so dietary treatment aims at prevention of further ankyloses by feeding a low vitamin A diet for several weeks followed by a complete and balanced diet for long-term feeding. Supportive treatment consists of administration of nonsteroidal anti-inflammatory drugs (see ch. 164 and 356).

Osteoarthritis Treatment

Once osteoarthritis is diagnosed, the cornerstone of multifaceted therapy is therapeutic nutrition. Nutritional treatment of osteoarthritis should initially focus on weight reduction if the BCS is greater than 5/9 (see ch. 176 and 359). Foods designed for dogs with osteoarthritis should supply age-appropriate nutrition and specific nutrients that may help reduce inflammation and pain, slow the degradation process, complement prescribed medications, and provide tangible improvement in symptoms of osteoarthritis. Clinical studies indicate that nutritional management using a therapeutic food supplemented with n-3 fatty acids helped reduce the clinical signs of osteoarthritis in dogs as noted by pet owners, clinical orthopedic examination, and gait analysis of ground reaction forces.[46-48] Based on these studies, a food designed to aid in the management of osteoarthritis in dogs should provide levels of 0.4% to 1.1% (DM) eicosapentaenoic acid (EPA). Dogs consuming the therapeutic food/supplement should receive an average of 50 to 100 mg EPA/kg body weight (BW) per day. In cats, one study evaluated the effect of a therapeutic diet with EPA, docosahexaenoic acid (DHA), glucosamine, chondroitin sulphate and an extract of green-lipped mussel with naturally occurring osteoarthritis, using clinical signs as well as gait analysis as outcome parameters, demonstrating effectiveness.[49] Another study, performed in client-owned cats with naturally occurring oesteoarthritis, demonstrated effectiveness of an EPA and DHA supplement on clinical signs of osteoarthritis.[50] Based on these studies, a food designed to aid in the management of osteoarthritis in cats should provide levels of 4.5% to 6% (DM) EPA and 1.2% to 3% (DM) DHA. Cats consuming the food/supplement should receive an average of 75 to 100 mg EPA/kg BW per day and 20 to 50 mg DHA/kg BW per day. For other supplements, no clear scientific evidence is currently present. For veterinarians wishing to use glucosamine hydrochloride and chondroitin sulphate, the author suggests a loading dose of 50 mg/kg (body weight) and 40 mg/kg, respectively, followed by a maintenance dosage of 25 mg/kg and 20 mg/kg, respectively. The most recent supplement with promising results in dogs is undenatured type-II collagen from chicken sternum; 10 mg per dog per day demonstrated significant improvement in pain scoring (both observational and by force plate analysis).[51] Apart from dietary treatment, nonsteroidal anti-inflammatory drugs and physical rehabilitation can be prescribed (see ch. 164, 355, and 356). In severe cases, elective surgery may be indicated[52] (Figure 187-9).

CHAPTER 188

Nutritional Management of Cancer

Glenna E. Mauldin

Client Information Sheet: Feeding Your Pet That Has Cancer

Cancer-Associated Malnutrition: Cancer Cachexia

"Cancer cachexia" is the complex form of protein-calorie malnutrition classically associated with the tumor-bearing state. It is common in people and also is described in cats and dogs. A recent consensus statement defines cancer cachexia in people as a multifactorial syndrome characterized by loss of >5% of current body weight, or loss of >2% in cases where there is pre-existing depletion. Affected individuals have ongoing loss of skeletal muscle mass, often with concurrent loss of fat stores. Underlying causative metabolic defects have been identified, although decreased food intake as well as functional abnormalities interfering with food digestion or absorption also can play contributory roles. Progressive development of cachexia occurs through stages, from precachexia to cachexia to refractory cachexia, and it is classified based on the degree of depletion of energy stores and lean body mass combined with the severity of ongoing weight loss.[1]

Cancer cachexia is clinically important because it has an independent and negative effect on prognosis. People, cats, and dogs with cancer and concurrent weight loss have increased morbidity and mortality, and poor quality of life. Depletion of lean body mass leads to decreased muscle mass and to weakness. Altered body composition can change drug pharmacokinetics and pharmacodynamics, increasing treatment-related toxicosis and compromising ability to tolerate aggressive therapy. Overall, and regardless of species, individuals with cancer-associated weight loss have shorter survival compared to weight-stable patients with otherwise identical disease.[2-11]

Cancer cachexia is best conceptualized as a paraneoplastic syndrome where energy metabolism is altered by a pronounced systemic inflammatory response: ultimately, consumed calories are used inefficiently and weight loss occurs.[2,12-14] One of the hallmarks of cancer cachexia is that it cannot be reversed simply by increasing food intake.[15] Various cytokines including tumor necrosis factor-alpha (TNF-alpha) and interleukin-6 (IL-6) are implicated in the underlying mechanism, and distinctive biochemical changes such as glucose intolerance, hyperlactatemia, and increased lipolysis are seen in affected individuals.[12-14] Recent work also suggests that chronic inflammation can cause a phenotypic switch from white adipose tissue to brown fat, leading to increased lipid mobilization and energy expenditure.[16,17]

Weight loss appears to be less common in dogs with cancer than it is in people with cancer.[18,19] Although some of the metabolic changes linked with cancer cachexia have been described in dogs with spontaneous tumors,[20-24] a clear association between these changes, weight loss, and outcome is unproven so far; for instance, the most common cause of hyperlactatemia in tumor-bearing dogs is hypoperfusion rather than cancer cachexia.[25,26] Weight loss is relatively more common in cats with cancer, occurring in ≈50% of animals. As would be expected, it has a negative impact on prognosis.[10,11]

Cancer-Associated Malnutrition: Obesity

Despite the traditional correlation between weight loss and cancer, a relationship between obesity and cancer is now widely recognized. Obese people are predisposed to develop cancers including lymphoma and tumors of the esophagus, colon, endometrium, and breast.[27-30] Increased synthesis of factors such as insulin-like growth factor-1, estrogen, and leptin in obesity are believed to promote malignant transformation by stimulating cellular proliferation, as well as through disruption of cellular differentiation and apoptosis. The systemic inflammatory response associated with obesity also might result in an environment that is

permissive for the induction and progression of tumor.[29-33] Only a few studies have examined the relationship between obesity and cancer in cats or dogs,[34] but based on published surveys, 20-30% of dogs with cancer are likely to be overweight or obese.[18,19] While this does not prove a cause-and-effect relationship, links between development of tumor and obesity as well as historical fat intake have been demonstrated among unspayed female dogs with mammary carcinoma.[35-37]

Obesity has a complex impact on cancer prognosis. In many ways, obese individuals with cancer are more difficult to diagnose and treat than their normal-weight counterparts.[30] Diagnoses tend to be made later in the course of disease: physical examinations are difficult to perform, and accuracy of diagnostic tests such as ultrasonography and cross-sectional imaging is compromised. The metabolism of chemotherapeutics can be altered significantly by obesity, and precise dosing is challenging.[38,39] Radiotherapy is more difficult to deliver because of increased mobility of skin and abdominal viscera, and obscured bony landmarks. Finally, obesity increases the likelihood of some types of surgical complications.[40] Some studies show that overweight people with cancer have shorter survival times and higher all-cause, cancer-specific, and cardiovascular death rates.[41,42] However, other studies reveal that moderately increased body mass confers a paradoxical survival advantage, presumably because of greater availability of energy reserves.[4,43,44]

Feeding Cats and Dogs With Cancer: General Considerations

So-called "cancer diets" often are recommended for cats and dogs with neoplastic disease. Most of these diets share two main features: they are high in fat and low in carbohydrate. One justification for this is that animals with cancer generally are assumed to be at risk for weight loss, which could be addressed by feeding a high-fat, energy-dense diet. In addition, neoplastic cells have a preference for carbohydrates and glycolysis, instead of using fat-derived fuels.[45] Theoretically, then, a high-fat cancer diet preferentially supplies usable energy to a patient with increased needs, and limits the energy available to the tumor.

Although high-fat cancer diets may be appropriate in some cases, a diet change is not necessarily indicated when an animal with cancer is eating a good-quality, well-tolerated diet and already is in optimal body condition. Diet changes actually can be contraindicated in animals eating prescription foods for the management of pre-existing conditions such as kidney disease, pancreatitis, or food allergies. Furthermore, high-fat cancer diets likely will be counterproductive in animals that already are obese at the time of their cancer diagnosis.

Careful nutritional assessment is the best way to determine whether or not an individual cat or dog with cancer might benefit from a change in diet (see Figure 188-1 and ch. 170). This process involves the systematic collection of clinical data evaluating individual nutritional status, and consists of three components: food and food related factors such as current diet plus treats, supplements, and medications; animal and animal-related factors, including signalment, medical history, physical examination findings, body weight and condition score, and diagnostic test results; and finally, owner and feeding management factors. The data collected are integrated into routine patient evaluation, and used for making precise nutritional recommendations. A diet change is indicated if nutritional assessment reveals evidence of disease caused by suboptimal nutrition, or disease where nutrition can be used as adjunct therapy.

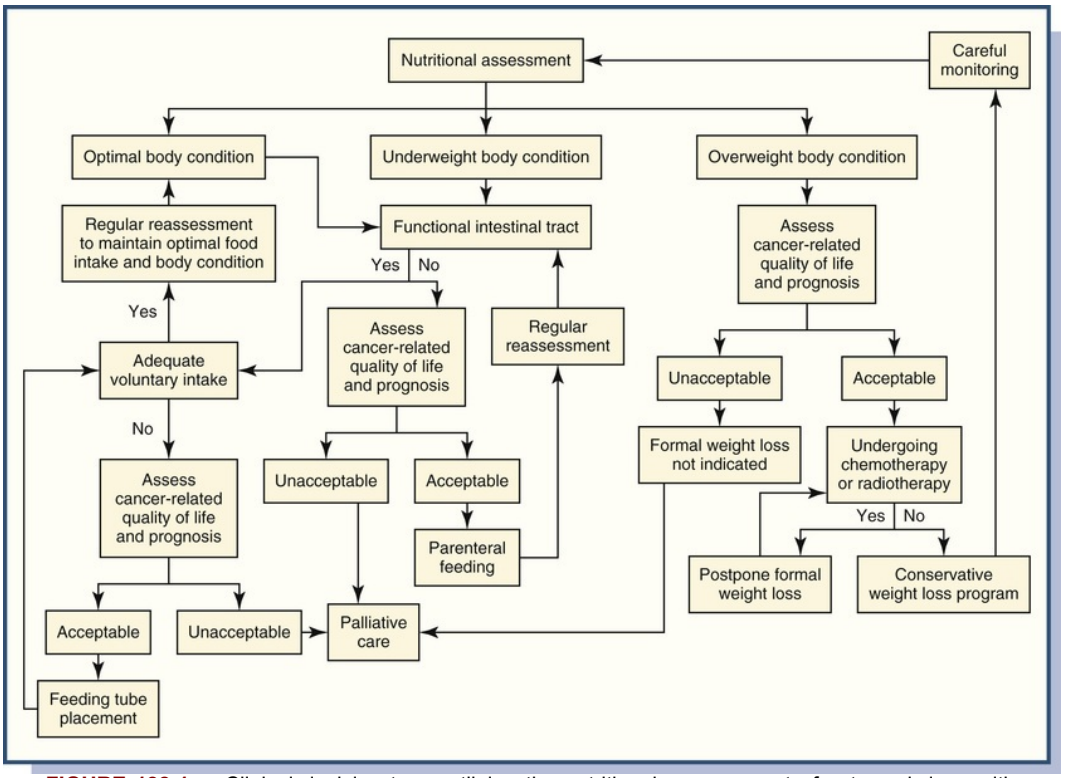

FIGURE 188-1 Clinical decision tree outlining the nutritional management of cats and dogs with cancer. Full nutritional assessments and objective evaluations of the animal's cancer-related quality of life and prognosis must be repeated at regular intervals to ensure that optimal choices are made throughout the course of disease.

If the decision is made to change the diet of a cat or dog with cancer, the first choice always should be a good-quality, commercial ration made by a reputable manufacturer. Over-the-counter products should have clear label claims confirming appropriate testing to prove nutritional adequacy (see ch. 193). Prescription products might not have a label statement of nutritional adequacy, but usually those intended for long-term use have undergone nutritional adequacy testing and this information should be available from the manufacturer. If a home-cooked recipe is followed, it must also be complete and balanced, including added vitamins and minerals.

Once a specific diet has been selected, an appropriate level of intake is calculated. In a self-supportive cat or dog in the home environment, this is based on the estimated maintenance energy requirement (MER). Many different equations can be used for calculating MER; the author uses MER = 110 $(BW_{kg})^{3/4}$ in dogs, and MER = 50 to 80 (BW_{kg}) in cats (varying with activity level). Both of these equations provide an estimate of the number of calories of metabolizable energy needed for daily maintenance. Any new food must be introduced slowly, especially if it is high in fat. Body weight and condition score then are followed through repeated nutritional assessments, moving food intake up or down as indicated to maintain target condition.

Prescription critical care diets often are enriched with nutrients that might be required in greater quantities during illnesses such as cancer, including n-3 (omega-3) fatty acids, branched chain amino acids, arginine, glutamine, and antioxidants; countless other over-the-counter products are promoted for use in cats and dogs with cancer as well. Unfortunately, few studies have evaluated the clinical benefit of such supplements objectively, with the result that indications as well as contraindications must be considered individually on a case-by-case basis. Ideally, before a specific nutritional supplement is recommended or approved for use in a cat or dog with cancer, there should be a clear scientific hypothesis that explains how the product will work; there should be no—or limited—risk of adverse interactions with ongoing cancer therapy; there should be data available from controlled studies investigating the short- and long-term safety of the product when given to cats and dogs; and, there should be some means of ascertaining that the product is of good quality, with consistent concentration, availability of the active ingredient, and lack of contamination.

Feeding Management of Weight-Losing Cats and Dogs With Cancer

Gradual introduction of an energy-dense diet providing 40-60% of calories as fat should be considered for cats and dogs with cancer-associated weight loss, as well as animals at risk for future weight loss. Unless contraindicated by kidney or liver disease, this usually is accompanied by an ample or increased protein intake (from 30 to 50% of calories) to protect existing lean body mass and meet the potentially increased needs of illness.[46] In general, commercial rations fitting the desired profile include performance, puppy and kitten, and prescription critical care diets. A high-fat prescription diet for dogs with cancer also is available (Hill's n/d, Hill's Pet Nutrition, Inc.). MER is calculated as previously described to determine initial food intake, although feeding an increment above MER at the animal's current body weight often will be necessary to prevent or reverse weight loss; once again, a trial and error process with repeated nutritional assessment is used for eventually identifying optimal intake.

Additional strategies beyond a simple diet change can be used for managing weight loss in cats and dogs with cancer. Supplementation with n-3 fatty acids often is recommended, although results in people with cancer are inconsistent: decreased synthesis of pro-inflammatory cytokines and stabilized body condition are reported in some but not all studies.[47-51] Analogous changes in cell membrane fatty acid composition are seen in dogs with increased dietary intake of n-3 fatty acids, which impacts cell membrane eicosanoid production and alters synthesis of cytokines such as IL-1, TNF-alpha, and IL-6.[52] Decreased systemic inflammation in turn could have beneficial effects on cancer cachexia, although this has yet to be proven definitively.[53] Much less information is available regarding the use of n-3 fatty acids in cats compared to dogs[54] but regardless, the appropriate dosage and method of administration for management of cancer-associated weight loss is unknown in either species.

Pharmacologic appetite stimulation is another approach that can be practical and cost-effective in selected cases where voluntary food intake is inadequate. Although progestational agents such as megestrol acetate have a well-established role in treating cancer and cancer-treatment related anorexia in people,[47,55-58] their use is infrequently reported in cats and dogs. Historically, benzodiazepine derivatives and the serotonin antagonist cyproheptadine have been used most often in small animals;[59] more recently, the tetracyclic antidepressant mirtazapine has shown promise, especially in anorectic cats.[59,60] No matter which specific appetite stimulant is chosen, however, careful monitoring of actual food intake is essential. Clinicians must guard against the temptation to postpone more appropriate and efficacious placement of a feeding tube while they await a clinical response to pharmacologic appetite stimulation.

The most aggressive treatment for animals with cancer that are unable to maintain themselves through voluntary food intake is assisted feeding, which usually involves enteral feeding tube placement (see ch. 82). Parenteral feeding may be considered in some cases where intestinal tract dysfunction is very severe (see ch. 189), but increased complications, marginal improvement in nutritional status, and trends toward decreased survival are seen in intravenously fed people with cancer.[61] This is likely to be related at least in part to the compromised gut function and immunity that occurs during parenteral feeding, and a combination of parenteral and enteral feeding should be used whenever possible, rather than parenteral feeding alone, to minimize these potential complications.

Although assisted feeding provides a clear clinical benefit for many cats and dogs with cancer, it also can pose an ethical challenge. When an animal's quality of life is severely compromised and the long-term prognosis is very poor, careful assessment of the expected advantage of assisted feeding is always indicated. Studies in people with terminal cancer show that assisted feeding likely will not improve nutritional or functional status when the expected survival time is very short.[62-65] A frank discussion with the pet owner regarding the realistic value of assisted feeding is an essential part of the decision-making process: it is the veterinarian's responsibility to make certain that assisted feeding is always a humane choice.

Feeding Management of Obese Cats and Dogs With Cancer

The health risks associated with obesity in normal cats and dogs are well-documented.[34] However, the potential benefit of weight loss in an obese animal with cancer must be assessed carefully, especially when the prognosis associated with the underlying neoplastic disease is poor. Weight loss programs can be stressful, labor-intensive and expensive, so the expected cancer-associated survival time must be long enough to justify time and effort needed for weight loss.

The food intake for effective weight loss in otherwise healthy cats and dogs usually is calculated based on the MER at the animal's estimated ideal body weight, and then decreasing that number by 20 to 30% in cats, and 25 to 50% in dogs (see ch. 176). Increments that are more conservative likely are appropriate for many

animals with cancer, and consideration should be given to stopping weight loss at a relatively more overweight body condition than would normally be accepted. Weight loss is contraindicated during critical illness, regardless of the severity of obesity. It is also questionable whether weight loss should be attempted during active anticancer therapy, even when the animal appears clinically stable. Excessive loss of lean body mass during purposeful weight loss could contribute to clinically important complications, including significant loss of muscle and muscle function, reduced performance scores, immunosuppression, and increased risk of cancer treatment-related toxicoses. Ongoing weight loss also can make patient monitoring more difficult, especially in cats: stabilization or reversal of weight loss is a very valuable surrogate marker of remission status in this species.[11]

CHAPTER 189

Critical Care Nutrition

Daniel L. Chan

Overview

Metabolic responses to illness or injury place critically ill animals at high risk for malnutrition and its deleterious effects. These problems include alterations in energy metabolism, compromised immune function, decreased wound healing, and probably a negative impact on overall survival.[1-4] Whereas healthy animals lose primarily fat when they do not receive adequate calories (simple starvation), sick or traumatized patients catabolize lean body mass when they are not provided with sufficient calories (stressed starvation; see ch. 177). Inadequate calorie intake is a common problem in critically ill animals due to anorexia, an inability to eat or tolerate feedings (e.g., vomiting), or decreased absorptive capabilities.[1,4]

Because malnutrition can occur quickly, it is important to provide nutritional support by either enteral or parenteral means if oral intake is inadequate. The goals of nutritional support are either to prevent development of malnutrition or to treat malnutrition. Although unproven in dogs and cats, it is logical to assume that treatment or prevention of malnutrition decreases morbidity and mortality.[1,2,4,5] Whenever possible, oral nutritional support (enteral) should be used because it is safest, most convenient, most physiologically sound, and least expensive. Although enteral nutrition is preferred in critically ill animals, parenteral nutrition (PN) is an established method of providing nutritional support to patients whose gastrointestinal tracts cannot tolerate enteral feedings.[2,3,5-11]

Although the use of PN support has become more common, there remains a perception that this is technically difficult, associated with complications, and limited to university hospitals and referral centers. In reality, PN support can be adopted in many practice settings. Moreover, complications can be reduced substantially with proper management techniques. The goals of this chapter are to outline the identification process of dogs and cats most likely to benefit from PN; to review the process of formulating, implementing, and monitoring parenteral nutritional support; and to discuss how PN can be incorporated into various practice situations.

Nutritional Assessment

The first step in the consideration of nutritional support is appropriate patient assessment. Assessing nutritional status via objective measurements of body composition (e.g., anthropometry, bioelectrical impedance, dual energy x-ray absorptiometry, or serum indicators of malnutrition) is rarely employed in clinical veterinary medicine. Therefore, subjective clinical assessment (see ch. 170) remains paramount in the identification of malnourished animals that require nutritional support, as well as those imminently at risk for malnutrition. Indicators of malnutrition include weight loss, poor hair coat, muscle wasting, signs of inadequate wound healing, hypoalbuminemia, lymphopenia, and coagulopathies. However, these abnormalities are not specific to malnutrition and do not occur early in the process. In addition, fluid shifts can mask weight loss in critically ill patients. Given these limitations, it is crucial to identify early risk factors that can predispose pets to malnutrition (e.g., anorexia of >3 days' duration), serious underlying disease (e.g., trauma, sepsis, peritonitis, pancreatitis, gastrointestinal surgery), or extensive protein losses (e.g., protracted vomiting, diarrhea, protein-losing nephropathies, draining wounds, or burns).

Nutritional assessment also should identify factors that can affect the nutritional plan, such as specific serum electrolyte abnormalities; hyperglycemia, hypertriglyceridemia, or hyperammonemia; or comorbid illnesses, such as renal or hepatic disease. Such findings require adjustments to be made to the formulation of PN and in some cases prompt changing the nutritional plan. Appropriate laboratory analyses (e.g., serum biochemical profile, urinalysis) should be performed in all dogs and cats to assess these parameters.

Goals of Nutritional Support

The goals of nutritional support are to provide for the animal's ongoing needs, prevent or correct deficiencies or imbalances, minimize metabolic derangements, and prevent further catabolism of lean body tissues. Restoration of optimal body condition should not necessarily be the goal of nutritional support in the acute stages of diseases. In severely malnourished dogs and cats, nutritional support is directed toward preservation of lean body tissue and organ function, rather than complete reversal of malnutrition, which is accomplished when the patient becomes convalescent. The necessity for instituting nutritional support is dictated by individual needs and not necessarily by the specific disease. The ultimate purpose of nutritional support is to provide the necessary nutrients and calories until the dog or cat voluntarily consumes an adequate amount of food in its own environment.

The Nutritional Plan

One key to successful nutritional management of critically ill animals lies in the proper diagnosis and treatment of the underlying disease. While an attempt is made to diagnose and treat that underlying illness, a crucial care factor is selection of an appropriate route for nutritional support (Figure 189-1).

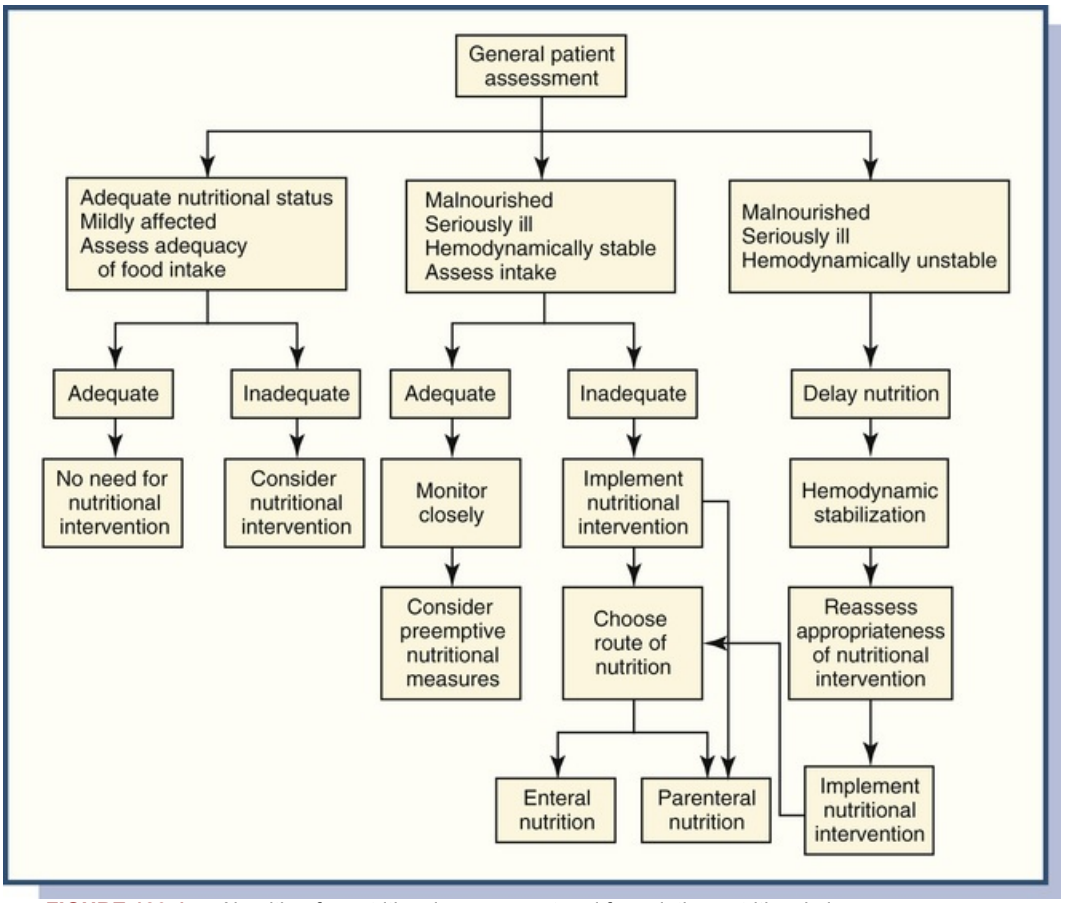

FIGURE 189-1 Algorithm for nutritional assessment and formulating nutritional plan.

Providing nutrition via a functional digestive system is always preferred. Therefore, particular care should be taken to determine whether enteral feedings would be tolerated. Even if only small amounts of enteral nutrition could be tolerated, this route of feeding should be pursued and supplemented with PN only as necessary. The placement of enteral feeding devices is described in ch. 82. Based on the nutritional assessment, anticipated duration of support, and appropriate route of delivery (i.e., enteral or parenteral), a nutritional plan can be formulated.

The first steps of instituting nutritional support include reestablishing proper hydration status, correction of electrolyte or acid-base disturbances, and achieving hemodynamic stability. Commencing nutritional

support before such abnormalities are addressed can increase the risk of complications and, in some cases, further compromise the animal. Implementation of the nutritional plan should be gradual, with an appropriate goal being to reach the target level of nutrient delivery in 48-72 hours.

Calculating Nutritional Requirements

Ideally, nutritional support should provide ample substrates for gluconeogenesis, protein synthesis, and energy necessary to maintain homeostasis. The clinician must ensure that enough calories are being provided to sustain critical physiologic processes (e.g., immune function, wound repair, cell division and cell growth). Therefore, calculating the animal's total energy expenditure is necessary. However, as clinically available direct measurements of energy expenditure in dogs and cats are still in the developmental phase, the use of mathematical formulas is the only practical means of estimating energy requirements. The resting energy requirement (RER) is defined as the number of calories required per day for maintaining homeostasis at rest in a thermoneutral environment while the animal is in a postabsorptive state.[12] While there are several formulas proposed for calculating the RER, a widely used allometric formula that can be applied to both dogs and cats, regardless of body weight, is RER = 70 × (body weight in kg)$^{0.75}$. For animals weighing 2-30 kg, another formula that provides reasonable estimation of the RER is: RER = 30 (body weight in kg) + 70.

Despite the convention of multiplying the RER by an illness factor between 1.0 and 2.0 to account for increases in metabolism associated with different diseases and injuries, less emphasis is being placed now on such subjective and extrapolated factors.[5] The current recommendation is to use more conservative energy estimates (i.e., start with the animal's RER) to avoid overfeeding. Overfeeding can result in metabolic and gastrointestinal complications, hepatic dysfunction, and increased carbon dioxide production.[12] One study demonstrated that use of "illness factors" in calculating energy requirements for cats was strongly associated with the development of hyperglycemia.[13]

As the preservation of lean body mass is a primary goal of nutritional support, close monitoring of body weight, fluid distribution, response or tolerance to feedings, and changes in the underlying condition should dictate whether to increase the number of calories provided in the nutritional plan. Typically, if an animal continues to lose weight on nutritional support, the number of calories provided should be increased by 25% and the plan should be reassessed in a few days. Additional adjustments to the nutritional plan might also include the addition or restriction of electrolytes such as magnesium and potassium, as dictated by serial biochemical profiles.

Nutritional Support

A major advantage of enteral nutrition over PN is superior maintenance of intestinal structure and function. The presence of nutrients within the intestinal lumen elicits trophic effects that mediate mucosal cell proliferation. It has also been proposed that a lack of enteral nutrition contributes to the impairment of mucosal barrier function, which allows for the translocation of intestinal bacteria or endotoxins leading to sepsis and a systemic inflammatory response.

However, in animals unable to tolerate enteral feedings, such as those that are vomiting, regurgitating, or unable to protect their airway, PN should be considered. Inability to tolerate enteral feedings is the only major indication for PN support. Although obtaining enteral access in critically ill animals can be difficult, every effort must be made to ensure that a functional gastrointestinal tract is not bypassed. A more extensive review of enteral nutrition is provided in ch. 82.

Parenteral Nutrition

PN sometimes has been characterized as a technique fraught with complications. In reality, many of the complications attributed to PN in the past might have had more to do with overfeeding or "hyperalimentation," rather than with the route of feeding itself. Although metabolic complications can be associated with PN, these complications generally are mild, have minimal consequences, and rarely require discontinuation of nutritional support. Septic complications associated with PN can be dramatically minimized with careful attention to aseptic technique in the compounding of PN, placement of dedicated PN catheters, and careful monitoring of the catheter site (see ch. 75 and 76).

Types of Parenteral Nutrition

The terminology used for describing the use of PN in veterinary patients has evolved and it is worth reviewing the current nomenclature. Total parenteral nutrition (TPN) previously was defined as the provision of all of the patient's protein, calorie, and micronutrient requirements intravenously, whereas partial parenteral nutrition (PPN) was defined as the provision of only a part of this requirement (typically 40-70% of the energy requirement).[5] More recently, there has been a shift away from describing PN in terms of "meeting energy and nutrient requirements" as they remain largely unknown in animals, and instead, recent recommendations emphasize categorizing PN by the mode of delivery such that PN delivered into a central vein is described as central PN (CPN) and PN delivered into a peripheral vein is described as peripheral PN (PPN).[14]

The lower osmolarity of PPN solutions, as compared to CPN solutions, is achieved by diluting the solution (ideally to less than 800 mOsm/L), which decreases the caloric and protein density but makes it suitable for administration via peripheral veins.

Components of Parenteral Nutrition

PN is formulated as a mixture of a carbohydrate (dextrose), amino acids, and, usually, fat (lipid). Carbohydrate, in the form of dextrose (typically 5% or 50%), can have benefits in addition to acting as a fuel substrate. These potential benefits include stimulation of insulin secretion, reduction of muscle protein catabolism, and inhibition of hepatic glucose output, which can spare muscle protein from being catabolized for gluconeogenesis. However, administration of dextrose or supplementation of maintenance fluids with dextrose as the sole source of calories, in most cases, does not amount to adequate nutritional support and should be discouraged. For example, a 5% dextrose infusion provides only 170 kcal per liter of solution, and would provide less than 25% of the RER for a dog or cat at maintenance fluid rates. Dextrose infusions are more appropriate for the treatment of hypoglycemia rather than for nutritional support.

Crystalline amino acid solutions are an essential component of PN. The importance of supplying amino acids relates to maintenance of positive nitrogen balance and repletion of lean body tissue. This can be vital as critically ill dogs and cats begin to recover from illness. Supplementation of amino acids can support protein synthesis and spare tissue proteins from being catabolized via gluconeogenesis.[8] The most commonly used amino acid solution (Travasol, Clintec Nutrition, Deerfield, IL) contains most of the essential amino acids for dogs and cats. The exception is taurine. However, as PN typically is not used for more than 10 days, the lack of taurine does not become a problem in most circumstances.

Amino acid solutions are available in different concentrations, from 4% to 10%, and the most commonly used is 8.5%. Amino acid solutions also are available with and without electrolytes. Animals with normal serum electrolyte concentrations typically receive amino acid solutions with electrolytes, whereas those with electrolyte disturbances can benefit from amino acid solutions without electrolytes. Special formulations of amino acid solutions containing higher concentrations of the branched chain amino acids are available, although at much greater expense. These solutions originally were thought to be useful in the management of highly catabolic metabolic diseases or when hepatic encephalopathy was present, but studies have not confirmed a clear benefit in overall survival.[15]

Lipid emulsions are the calorically dense component of PN and a source of essential fatty acids. Lipid emulsions are isotonic and are available in 10% to 20% solutions (Intralipid, Clintec Nutrition, Deerfield, IL). These commercially available lipid emulsions are made primarily of soybean and safflower oils. They provide predominantly long-chain polyunsaturated fatty acids that include linoleic, oleic, palmitic, and stearic acids. These solutions are emulsified with egg yolk phospholipids and their tonicity is adjusted with glycerol. The emulsified fat particles are comparable in size to chylomicra and are removed from the circulation via the action of peripheral lipoprotein lipase. A common misconception exists with respect to the use of lipid-containing PN for animals that have pancreatitis. Although hypertriglyceridemia can be a risk factor for pancreatitis, infusions of lipids have not been shown to increase pancreatic secretion nor worsen pancreatitis. Therefore, such therapies are considered safe,[16] except when the serum triglyceride concentration is increased. This would indicate a clear failure of triglyceride clearance. According to the most recent guidelines provided by the American Society of Parenteral and Enteral Nutrition, humans with serum triglyceride concentrations exceeding 400 mg/dL (4.52 mmol/L) should have the lipid proportion in PN markedly reduced or eliminated altogether.[16] Although specific data regarding the maximal, safe level of lipid administration in dogs and cats are not available, it would seem prudent to maintain normal serum triglyceride concentrations.

Another concern regarding use of lipid in PN is its purported immunosuppressive effect. This effect could

develop via impairment of the reticuloendothelial system, particularly when PN solutions containing a high percentage of lipid are used.[9] Despite *in vitro* evidence supporting the notion that lipid infusions also can suppress neutrophil and lymphocyte function, studies have not yet correlated lipid use and increased rates of infectious complications.

Daily vitamin recommendations for dogs and cats receiving PN are extrapolated from established oral nutritional requirements.[5] Multivitamin preparations intended for IV administration provide a convenient and practical means for vitamin supplementation and these can be added to PN solutions. The addition of other parenteral medications to PN admixtures also is possible; however, their compatibility first must be verified. Drugs that are known to be compatible and sometimes are added to PN include heparin, regular insulin, potassium chloride, and metoclopramide. While the addition of insulin to PN often is required in people receiving PN, the hyperglycemia seen in dogs and cats receiving PN does not usually require insulin administration. However, diabetic pets often require adjustments to their insulin regimen when receiving PN. Although a veterinary protocol has been described for the addition of insulin directly to PN, often it is easiest to manage diabetics receiving PN with SC injections of insulin.[2,5]

Parenteral Nutrition Compounding

Based on the nutritional assessment and plan, PN can be formulated according to the worksheets found in Boxes 189-1 and 189-2. For CPN (see Box 189-1), the first step is the calculation of the patient's RER. Protein requirements (grams of protein required per day) then are calculated, taking into consideration factors such as excessive protein loss, severe hepatic disease, or significant kidney disease. Although some recommendations meet all energy requirements with only dextrose and lipids, the protocol listed here also accounts for energy provided by amino acids, and subtracts the calories provided by amino acids from the daily RER to estimate the total nonprotein calories required. Nonprotein calories then are usually provided as a 50 : 50 mixture of lipids and dextrose. This 50 : 50 ratio can be adjusted in cases of persistent hyperglycemia or hypertriglyceridemia (e.g., a higher proportion of calories would be given from lipids in an animal with hyperglycemia). The calories provided from each component (amino acids, lipids, and dextrose) are then divided by their respective caloric densities, and the exact amounts of each component are added to the PN bags in an aseptic fashion. The amount of CPN delivered often will provide less than the daily fluid requirement, and additional fluid can either be added to the PN bag at the time of compounding or be provided as a separate infusion.

Box 189-1

Central Parenteral Nutrition (CPN) Calculations

1. Calculate resting energy requirement (RER)

RER = 70 × (current body weight in kg)0.75	
or for animals weighing between 2 and 30 kg:	
RER = (30 × current body weight in kg) + 70	RER = _____ kcal/day

2. Protein requirements

	CANINE (g/100 kcal)	FELINE (g/100 kcal)
*Standard	4	6
*Reduced (hepatic/renal disease)	2-3	3-4
*Increased (excessive protein losses)	6	7-8

3. Volume of nutrient solutions required
   a. 8.5% amino acid solution = 0.085 g protein/mL

____ g protein required/day ÷ 0.085 g/mL	= ____ mL/day of amino acids

b. Nonprotein calories: The calories supplied by protein (4 kcal/g) are subtracted from the RER to get total nonprotein calories needed.

____ g protein req/day × 4 kcal/g	= ____ kcal provided by protein
RER − kcal provided by protein	= ____ total nonprotein kcal/day required

c. Nonprotein calories are usually provided as a 50 : 50 mixture of lipid and dextrose

*20% lipid solution = 2 kcal/mL	
To supply 50% of nonprotein calories	
____ lipid kcal required ÷ 2 kcal/mL	= ____ mL of lipid
*50% of dextrose solution = 1.7 kcal/mL	
To supply 50% of nonprotein calories	
____ dextrose kcal required ÷ 1.7 kcal/mL	= ____ mL of dextrose

4. Total daily requirements
____ mL of 8.5% amino acid solution
____ mL of 20% lipid
____ mL of 50% dextrose
____ total mL of CPN solution to be administered over 24 h

*Using a common 8.5% amino acid solution containing potassium (i.e., Travasol), CPN made according to this worksheet will provide potassium at higher than maintenance levels. Therefore, it might not be necessary to supplement potassium in any other fluids the patient is receiving. CPN for animals that are hyperkalemic should be formulated using amino acid solutions without electrolytes. Rates of other IV fluids being administered concurrently should be adjusted accordingly.

Box 189-2

Peripheral Parenteral Nutrition (PPN) Calculations

1. Calculate resting energy requirement (RER)

RER = 70 × (current body weight in kg)0.75	
or for animals weighing between 2 and 30 kg:	
RER = (30 × current body weight in kg) + 70	RER = ____ kcal/day

2. Calculate the partial energy requirement (PER)

Plan to supply 70% of the animal's RER with PPN:	PER = RER × 0.7 = ____ kcal/day

3. Proportion of nutrient requirements according to body weight: (Note: For animals ≤3 kg, the formulation will exceed maintenance fluid requirements)
a. Cats and Dogs 3-5 kg:
PER × 0.20 = ____ kcal/day carbohydrate required
PER × 0.20 = ____ kcal/day protein required
PER × 0.60 = ____ kcal/day lipid required
b. Cats and Dogs 6-10 kg:
PER × 0.25 = ____ kcal/day carbohydrate required
PER × 0.25 = ____ kcal/day protein required
PER × 0.50 = ____ kcal/day lipid required
c. Dogs 11-30 kg:
PER × 0.33 = ____ kcal/day carbohydrate required
PER × 0.33 = ____ kcal/day protein required

PER × 0.33 = ____ kcal/day lipids required
d. Dogs >30 kg:
PER × 0.50 = ____ kcal/day carbohydrate required
PER × 0.25 = ____ kcal/day protein required
PER × 0.25 = ____ kcal/day lipid required
4. Volumes of nutrient solutions required:
a. 5% dextrose solution = 0.17 kcal/mL

____ kcal carbohydrate required/day ÷ 0.17 kcal/mL	= ____ mL/day dextrose

b. 8.5% amino acid solution = 0.34 kcal/mL

____ kcal protein required/day ÷ 0.34 kcal/mL	= ____ mL/day amino acids

c. 20% lipid solution = 2 kcal/mL

____ kcal lipid required/day ÷ 2 kcal/mL	= ____ mL/day lipid
	= ____ total mL of PPN to be administered over 24 h

Note: This formulation provides approximately a maintenance fluid rate. Commonly used 8.5% amino acid solutions (i.e., Travasol) with electrolytes contain potassium. For animals ≤35 kg, the PPN solution made according to this worksheet will provide approximately maintenance levels of potassium. For animals >35 kg, the potassium contained in the PPN solution will be lower than maintenance levels. Rates of other IV fluids being concurrently administered should be adjusted accordingly.

For formulation of PPN, Box 189-2 provides a step-by-step protocol in which animals of various sizes can receive 70% of their RER and approximately meet their daily maintenance fluid requirement. In extremely small animals (≤3 kg), the amount of PPN will exceed the maintenance fluid requirement and increase the risk for fluid overload, so volume adjustments are necessary. Also, in animals requiring conservative fluid administration (e.g., congestive heart failure patients), these calculations for PPN might provide excessive fluid volumes. This formulation has been designed so that the proportion of each PN component is dependent on animal weight such that a smaller animal (3-5 kg) will receive proportionally more calories from lipids, compared to a large dog (>30 kg), which would receive more calories in the form of carbohydrates. This allows the resulting formulation to approximate the daily fluid requirement.

Compounding of PN should be done aseptically under a laminar flow hood using a semiautomated, closed-system PN compounder. Regulations implemented by the United States Pharmacopeia in 2004 require strict adherence to sterile compounding of PN solutions.[17] Given these strict conditions, it has become easier to have local human hospitals or human home health care companies (e.g., CORAM–Nourish Nutrition Support Service) compound PN solutions according to protocols outlined in Boxes 189-1 and 189-2 and have the solutions delivered to the practice within hours.

Alternatively, commercial, ready-to-use preparations of glucose or glycerol, amino acids, and lipids are available for IV use (Table 189-1) and clinical experience with such products recently has been published.[18,19] While these ready-to-use preparations are convenient, they provide only 30-50% of caloric requirements when administered at maintenance fluid rates and as a result, they only should be used for interim nutritional support or to supplement low-dosage enteral feedings.[18,19] In practices that do not have access to compounded PN, ready-to-use PN solutions can be a viable option for provision of nutritional support. Some of these products are available in bags with segregated chambers and the solutions are mixed before use by squeezing the bag and breaking the internal seals, yielding an admixture of amino acids, dextrose, and lipids (Video 189-1).

TABLE 189-1

Commercially Available Alternatives to Compounded Parenteral Nutrition

FEATURES	MANUFACTURER

	FEATURES	MANUFACTURER
Clinimix*	2.75% amino acids, 5% dextrose	Clintec Nutrition, Deerfield, IL
Quickmix	2.75% amino acids, 5% dextrose	Clintec Nutrition, Deerfield, IL
ProcalAmine	3% amino acids, 3% glycerol	B. Braun, McGraw Inc., Irvine, CA
Kabiven 5 Peripheral	2.4% amino acids, 6.7% dextrose, 3.5% intralipid	Fresenius Kabi, Bad Homburg, Germany

*Various formulations with different amino acids and dextrose concentrations exist.

Parenteral Nutrition Administration

The administration of any PN requires a dedicated, aseptically placed catheter, used solely for PN administration (see ch. 75, 76, and 77). Most critically ill dogs and cats that receive PN require placement of a new or additional catheter, because PN should not be administered through previously existing catheters placed for reasons other than PN. Long catheters composed of silicone, polyurethane, or tetrafluoroethylene are recommended for use with any type of PN to reduce the risk of thrombophlebitis.[3,5] Multilumen catheters often are recommended for CPN administration. Multilumen catheters can remain in place for long time periods. The non-PN lumens in these catheters can be used for blood sampling, administration of additional fluids, and IV medication administration, and they negate the need for separate catheters placed at other sites.[5,17]

Although placement of multilumen catheters does require more technical skill than conventional jugular catheters, they can be valuable in the treatment of any critically ill animal. The high osmolarity of CPN solutions (often ≈1200 mOsm/L) requires administration through a central venous (jugular) catheter, while PPN solutions can be administered through either a jugular or a peripheral venous catheter. The concern with administering fluids high in osmolarity has been the risk of thrombophlebitis, although this side-effect has not been demonstrated in dogs or cats.

Because of the various metabolic derangements associated with critical illness, PN should be instituted gradually over 48 hours. It is recommended that CPN be started at 50% of the RER on day 1 and then increased to the targeted amount by the second day. In this manner, serum electrolyte, glucose, acid-base status, total fluid requirements, and other parameters can be monitored as CPN is administered. In most cases, PPN can be started without a gradual increase. It is also important to adjust the rates of other fluids being administered concurrently. For both CPN and PPN, the animal's catheter and infusion lines must be handled aseptically at all times to reduce the risk of PN-related infection.

PN should be delivered as a continuous rate infusion over 24 hours via fluid infusion pumps. Inadvertent delivery of massive amounts of PN can result if administration is not properly regulated. Cyclic administration of PN (i.e., alternating PN with other parenteral fluids every 12 hours) also has been described. However, this practice is not recommended, as it circumvents maintenance of a closed system for PN administration and can increase the rate of complications. Once a bag of PN is set up for administration, it should not be disconnected even for walks or diagnostic procedures. The drip regulator can be decreased to an extremely slow rate and can accompany the patient if he or she needs to be moved. Administration of PN through an in-line filter (Air Eliminating Filter, Clintec Nutrition Division, Deerfield, IL) also is recommended; the filter is attached at the time of setup. This setup process is performed daily with each new bag of PN. Each bag should only hold one day's worth of PN, and the accompanying fluid administration sets and in-line filter are changed at the same time using aseptic technique. If using ready-made PN solutions, the recommendation is that the bottle or bag is in use for only 24 hours, and any remaining solution after 24 hours is discarded. However, there are no studies confirming whether this approach is necessary. Discontinuation of PN should be done when the animal resumes consuming an adequate number of calories (i.e., at least 50% of RER). Whereas CPN should be gradually discontinued over a 6- to 12-hour period, PPN can be discontinued abruptly.

Complications

As with any therapy intended for critically ill animals, complications can occur. Complications associated with PN can include mechanical complications of the catheter and lines, thrombophlebitis, metabolic abnormalities, and sepsis. Mechanical complications such as inadvertent catheter removal, catheter occlusion, and line disconnection or breakage probably are not inherently related to PN and likely are no more common

than in any dog or cat with an IV catheter. Metabolic complications are much more likely to be related to PN and include hyperglycemia, hypertriglyceridemia, hyperbilirubinemia, increased alkaline phosphatase activity, azotemia, electrolyte shifts, and hyperammonemia.[2,5,6,10,11,13,14,18,19] The more commonly encountered complications, namely hyperglycemia and hypertriglyceridemia, usually are transient and can be managed effectively without serious consequences. However, one study did demonstrate higher mortality rates in cats receiving PN that developed hyperglycemia within the first 24 hours of PN support.[11] Decreasing the infusion rate for 12-24 hours often is effective, although in some instances reformulation of PN is required. Animals with biochemical changes subsequent to initiation of PN should have more frequent laboratory parameter evaluations.

Septic complications, including catheter-site infection with and without septicemia, have been reported in dogs and cats receiving PN. This complication is uncommon, ranging from 3% to 12% in dogs and cats receiving PN.[2,6,10,11,18] Septic complications can be minimized by strict adherence to established protocols and careful attention to early signs of problems relating to catheter care. Any catheter suspected of causing fever, increase in white blood cell count, or other sign compatible with infection should be removed and cultured.

Monitoring

Given the potential for complications, monitoring of dogs and cats receiving PN is a vital part of nutritional support. This monitoring should be similar to that already in place for any critically ill animal. Careful monitoring of the catheter site is recommended to detect problems early (e.g., signs of inflammation or malposition) and should be done on a daily basis. Catheters should be evaluated for patency, and bandages changed daily. At a minimum, body weight, body temperature, respiratory rate, catheter site, and serum glucose should be evaluated daily. All blood tubes should be inspected for visible lipemia. Monitoring of other parameters (e.g., electrolytes, acid-base status, complete blood count, biochemical profile) also can be indicated. Persistent hyperglycemia, hypertriglyceridemia, or signs of encephalopathy should prompt reevaluation and could necessitate decreasing the rate of infusion or reformulation of PN and serial evaluation of blood work.

Summary

With the growing recognition that nutritional support is an integral part of the therapeutic regimen of many critically ill animals, it is becoming increasingly important for veterinarians to be able to incorporate nutritional support in their practice or to refer these cases to facilities capable of providing such therapy when necessary. Proper identification of dogs and cats most likely to benefit from PN and the ability to formulate, administer, and monitor PN are key factors in ensuring the successful incorporation of parenteral nutritional support in their care.

CHAPTER 190

Nutritional Uses of Fiber

Amy Farcas

Client Information Sheet: Nutritional Uses of Fiber

Dietary fiber (DF) can be utilized in the management of numerous medical conditions and in maintenance of general health. Several properties/attributes usually associated with DF include its water-solubility (soluble DF [SDF] or insoluble DF [IDF]), capacity to be fermented by intestinal microflora, and its energy contribution to a diet.

Considerations Regarding Therapeutic Use of Dietary Fiber

Dietary fiber has long been known to affect seemingly unrelated physical parameters, such as stool quality, metabolism, and immune status. DF is not a single chemical entity but can be viewed as an "umbrella term" under which many types of fiber can be included. Not all DF is expected to have the same effects and certain pairings of DF are understood to result in opposite clinical responses. To complicate matters, many food and feed sources of DF provide mixtures of several DF compounds and the manner in which DF is supplied (as a whole food/feed item or as a purified compound) also affects its action. Historically, it has not been possible to assay DF accurately. Confidence in dietary fiber intake, in terms of quantity and composition, is needed in order to gain useful information from studies reporting response to DF. However, precise measurements are not always available.

Types of Dietary Fiber

DF may be understood, in part, as a concept as much as it is a specific food component. While this may seem unscientific, it is appropriate since DF represents indigestible plant material. Despite being indigestible by mammalian enzymes, some DF may be fermentable by GI microflora. DF represents a group of compounds distinguished on indigestibility and little else. A selection of DF types and sources common to pet food is included in Table 190-1. Within SDFs, there are categories of high-molecular-weight dietary fibers (HMWSDF) composed of >10 sugar molecules and low-molecular-weight dietary fibers (LMWSDF) composed of <10 sugar molecules.

TABLE 190-1

Classification of Dietary Fibers (DF) and DF Sources Based on Water Solubility

FIBER TYPE	IDF/HMWSDF/LMWSDF
Cellulose	IDF
Lignin	IDF
Hemicellulose	Mixed (IDF/HMWSDF)
Psyllium husk	Mixed (IDF/HMWSDF)
Guar gum	HMWSDF
Carrageenan	HMWSDF
Locust bean meal	HMWSDF

Resistant starch	Mixed (HMWSDF/LMWSDF)
Arabinogalactan	HMWSDF
Beet pulp (source of pectin)	HMWSDF
Pullulan	HMWSDF
Chicory (source of inulin/FOS)	LMWSDF
Yeast cell wall (source of MOS)	LMWSDF
Polydextrose	LMWSDF
Gamma-cyclodextrin	LMWSDF

DF, Dietary fiber; *HMWSDF*, high-molecular-weight dietary fibers; *IDF*, insoluble dietary fiber; *LMWSDF*, low-molecular-weight dietary fibers.

Measurement and Reporting of Dietary Fiber in Pet Food

In theory, DF is easily defined as the indigestible plant portion of a diet. However, there is no assay that accurately discriminates food components based on digestibility. In studies measuring DF, the definition of assayed DF invariably changes from "the indigestible plant portion of the diet" to the result of a test specific to that study. Unfortunately, the currently available test that accurately and completely measures all indigestible plant material present in food is costly and not commonly used. While the definitions and methodologies for assaying DF have improved, none is without issues. There are 3 recognized methods for determining DF quantities in pet food (Figure 190-1). The 200-year-old crude fiber (CF) method continues to be used for detecting variable portions of IDF present in food samples. The CF method is both standard and required for pet food labeling in the United States. Another method, inaccurately termed the total dietary fiber (TDF) method, was developed in the 1970s. This assay measures both IDF and HMWSDF. It is the current standard in human food labeling, but it fails to measure the LMWSDF component that has recently been included in the definition of DF. The method fractionates dietary fiber types somewhat and reports results as total (IDF+HMWSDF), IDF, and SDF (actually HMWSDF). This information should be helpful to clinicians attempting to determine potential clinical effects of a diet or diet change in a particular patient. TDF data have been reported for some therapeutic pet foods, but not widely. Recently, a TDF method that also includes LMWSDF has been developed, but veterinary studies using this new assay have yet to be reported.

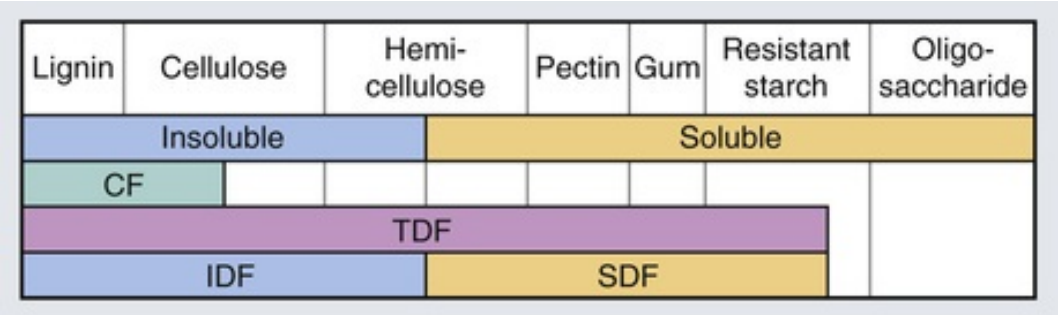

FIGURE 190-1 Simplified comparison of dietary fiber (DF) types to current DF assays. *CF*, Crude fiber; *IDF*, insoluble dietary fiber; *SDF*, soluble dietary fiber; *TDF*, total dietary fiber.

It would be ideal to have the ability to provide DF dosages and to compare responses between studies. However, there have been variables in reporting DF content. Among these variables are whether results were obtained from dry matter (DM) concentrations of experimental diets, whether diets were reported on an as-fed basis or by subject body weight, whether DF was provided as purified substance or whole food item, or whether it was supplemented in addition to a basal diet or incorporated into the basal diet's formulation. Further, there are unavoidable differences in the formulation of basal diets.

Therapeutic Use of Dietary Fiber

Stool Parameters

Perhaps the most widely reported effects of change in DF intake in pets are on stool quantity and quality. This is true for both healthy animals and those with various gastrointestinal conditions. DF affects how ingesta moves through the gastrointestinal (GI) tract, the rate at which nutrients are absorbed, and both structure and water content of feces. IDF tends to create structure for ingesta, but may interfere with nutrient absorption. As the structure adsorbs water, it contributes to larger, "bulkier" stools. This could affect management of anal sac disease, constipation due to functional issues, and soft, non-formed stools. Factors related to stool quality are the primary reason for the addition of an IDF source to most commercial pet food formulations. DF particle size also plays a role.[1,2]

SDF draws water into intestinal content osmotically, creating softer stools with less structure. Such attributes may treat constipation due to nonfunctional causes. Response to the SDF-resistant starch in dog diets varies by breed. Large-breed dogs are more sensitive to development of soft stools with diets that include SDF.[3] Interindividual, as well as interbreed, variability in response to DF supplementation can be expected. Both IDF and SDF increase fecal weight and water content. See Table 190-2 for a summary of DF effects on stools by DF type/source.

TABLE 190-2

Effects of DF on Stool Quality, Fecal Odor Compounds, Fermentation Products, and Microbial Populations

Stool Quality	
Cellulose	Firmer[1,2,24,31,62,63]
Soybean hulls	Firmer[64]
Sugarcane fiber	Firmer[62]
Guar gum	Firmer[37]/no change[65]
Carrageenan	Firmer[37]
Locust bean meal	Firmer[37]
Resistant starch	No change/softer[3]
Beet pulp/pectin	Softer[24,63]
Chicory/inulin/FOS	No change[17,66,67]
Yeast cell wall/MOS	No change[17]
Polydextrose	Softer[68]
Pullulan	Softer[69]
Gamma-cyclodextrin	Firmer[69]
Fecal Odor	
IDF (nonspecific)	Decrease[70]
FOS	Decrease[67]/no change[45]
MOS	Decrease[67]
Fermentation Products	
Cellulose	No change[8,71]
Beet pulp/pectin	Increase total VFA[11,13,63] Increase butyrate[13]
Guar gum	Increase butyrate[72]
Chicory/inulin/FOS	Increase total VFA[73]

	Decrease total VFA[15,74] No change[75] Decrease acetate, propionate[15] Increase butyrate[15] Decrease acetate[15] Decrease acetate, butyrate[74]
Yeast cell wall/MOS	Increase total VFA[73]
Polydextrose	Increase total VFA[68]
Microbial Populations	
Beet pulp/pectin	Increase total bacteria[76] Increase Firmicutes[12,76] Increase Bifidobacter[13,76] Increase Lactobacilli[10,13] Decrease Fusobacteria[12] Increase Proteobacteria[76] Increase *Clostridium perfringens*[10] Increase *E. coli*[10]
Chicory/inulin/FOS	Increase Bifidobacteria[10,13,17,19,74,76,77] Increase Lactobacilli[13,14,19,77] Increase total aerobes[75] Decrease *E. coli*[10,14] Decrease *C. perfringens*[75] No change[15,66,67] No change *Clostridium*[78] No change *E. coli*[78]
Yeast cell wall/MOS	Increase Bifidobacteria[14,17,19] Increase Lactobacilli[16,19] Decrease *E. coli*[17,79] Decrease *C. perfringens*[79] Decrease total aerobes[16,67]
Polydextrose	Decrease *C. perfringens*[68] No change *E. coli*[68] No change Lactobacilli[68] No change Bifidobacteria[68]
Pullulan	Increase Lactobacilli[69]
Gamma-cyclodextrin	Decrease *C. perfringens*[69]
Arabinogalactan	Increase Lactobacilli[58]

DF, Dietary fiber; *FOS*, fructooligosaccharide; *IDF*, insoluble dietary fiber; *MOS*, mannan-oligosaccharide; *VFA*, volatile fatty acids.

Fermentability

Most IDF is not fermentable, in contrast to the typically fermentable SDF (particularly LMWSDF). Psyllium husk is an exception to this generalization because it provides both IDF and non-fermentable SDF.[4] Fermentation of DF by microbes produces the volatile fatty acids (VFA) acetate, propionate and butyrate. Butyrate may be used as an energy source for colonocytes; thus, fermentation of DF increases colonic mass, absorptive capacity, and function.[5] These VFA are also absorbed systemically and can trigger release of

glucagon-like peptide-1 (GLP-1) by intestinal L cells, which contributes to glycemic regulation.[6,7] Blends of fermentable and nonfermentable DF may be used to create specific combinations of improvement in stool quality, in addition to benefits of microbial fermentation.[8] DF is not the only food component with the potential to undergo microbial fermentation. Poorly digestible protein present in digesta also undergoes fermentation by colonic bacteria, contributing to fecal malodor.[9]

Microbiome

The driving force behind DF's effects on fermentation products is its effect on the gut microbiome. Since studies report a high degree of individual variation in this area, variation in response to DF supplementation would also be expected, especially with varied DF dosage.[10-17]

Many studies have evaluated DF's effect on the fecal microbiome (see Table 190-2), but results may not be reflective of changes throughout the GI tract.[18] Few studies have evaluated the effect of DF in more proximal sections of the intestinal tract, but fructooligosaccharide (FOS) and mannan-oligosaccharide (MOS) increase ileal lactobacilli, decrease ileal *Clostridium*, and increase distal colonic total aerobic bacteria.[19,20] Dogs with a clinical diagnosis of small intestinal bacterial overgrowth supplemented with FOS showed fewer aerobic colony-forming units in the duodenum, but no differences in species of small intestinal bacteria.[21]

Mucosa

Given that DF supplementation affects the gastrointestinal microbiome, it is not surprising that changes in mucosal integrity have also been demonstrated. This is particularly true with fermentable DF. Dogs fed fermentable fiber sources such as beet pulp, FOS, or mixtures of these sources had increased small intestinal surface area, intestinal weight, villus height, mucosal mass, and a higher capacity for carrier-mediated glucose uptake as compared with cellulose-supplemented dogs.[22,23] No changes in colon mucosa thickness, crypt area, lamina propria area, goblet cell area, or crypt mean size were demonstrated in cats supplemented with beet pulp, wheat bran, or sugarcane fiber.[24] Inulin supplementation in *Salmonella*-infected puppies decreased the severity of enterocyte sloughing and maintained normal ileal Na^+-dependent glucose transport.[25]

Transit

A delay in intestinal transit may enhance nutrient absorption by increasing contact time between intestinal content, intestinal digestive enzymes, and absorptive surfaces. DF can modulate GI transit time via its physical properties involving water solubility, binding capacity, systemic and local effects on GI motility.[26,27]

In general, SDF increases digesta viscosity, while IDF has minimal effect.[28] Low-viscosity ingesta undergo rapid gastric emptying, whereas higher-viscosity SDF suspensions delay gastric emptying and demonstrate an apparent maximal gastric emptying rate.[29,30] Galactomannan (a LMWSDF) increases frequency and strength of intestinal motility.[29] In cats with chronic constipation, psyllium-enriched diets have improved clinical signs and decreased the need for medical therapy.[30] In dogs, cellulose decreased total intestinal transit time in one study, but both cellulose and corn fiber were reported not to alter transit time in another.[31,32] In cats, a higher-IDF diet did not affect gastric emptying.[33] Oat fiber, tomato pomace, peanut hulls, wheat bran, and guar gum are also reported not to affect GI transit time.[34-36] Studies regarding beet pulp have not provided consistent results.[35,36]

Digestibility

DF is, by definition, indigestible. As such, it may contribute to the formation of viscous ingesta and interact with specific nutrients or dietary components. DF may decrease digestibility by binding or sequestering components from digestive processes. DF may increase digestibility by increasing transit time. Apparent (total tract) digestibility associated with DF may be deceptive, especially with regard to digestibility of protein. The effects of DF, especially fermentable fiber, may also be deceptive when colonic bacterial fermentation processes and products are included in fecal end products evaluated. For these reasons, "apparent digestibility" will be omitted from this discussion. Measuring ileal digestibility largely avoids this issue while providing a clearer assessment of the digestive process alone, without the confounding effects of

colonic fermentation (Table 190-3). DF may affect digestibility of individual diet components, including protein, fat, or minerals, but these generally follow ileal diet digestibility.[15,37] Variability in response is beyond the scope of this chapter.

TABLE 190-3

Effects of DF on Ileal Digestibility of Dietary Dry Matter and/or Organic Matter

Cellulose	Decrease[64] No change[80]
Guar gum	Increase[37]
Locust bean meal	Increase[37]
Carrageenan	Increase[37]
Beet pulp	No change[80]
Chicory/inulin/FOS	Increase[15,75] No change[81]
Yeast cell wall/MOS	Increase[79] Decrease[16]
Pullulan	No change[37]
Gamma-cyclodextrin	No change[37]

DF, Dietary fiber; *FOS*, fructooligosaccharide; *MOS*, mannan-oligosaccharide.

Glucose Metabolism

Some DF have been associated with a "second-meal effect," meaning that DF fed during a first meal will affect the glycemic response to a later glucose meal.[38] Effects of DF on blood glucose, insulin, and GLP-1 concentrations in healthy dogs and cats are summarized in Table 190-4.

TABLE 190-4

Effects of DF Supplementation on Glycemic, Insulinemic, and GLP-1 Response to Meals

Glycemic Response	
Cellulose	No change[23,38,82]
Soybean hulls	No change[38]
IDF (nonspecific)	Decrease[83]
Wheat bran	No change[24]
Soluble corn fiber	Decrease[84-86]
Sugarcane fiber	Decrease[24]
Beet pulp/pectin	Decrease[83,87] No change[23,24,88]
Guar gum	No change[82]
Chicory/inulin/FOS	Decrease[38,87,89] No change[23,88,90]

MOS	Decrease[83]
Pullulan	Decrease[84,85] No change[91]
Insulinemic Response	
Cellulose	No change[82]
Soybean fiber	Decrease[92]
Soluble corn fiber	Decrease[84-86]
Beet pulp/pectin	No change[82,88] Increase[23]
Guar gum	Decrease[88] No change[82]
Chicory/inulin/FOS	No change[88,89] Increase[23]
GLP-1 Response	
Cellulose	No change[23]
Beet pulp/pectin	Increase[23]
Chicory/inulin/FOS	Increase[23]

DF, Dietary fiber; *FOS*, fructooligosaccharide; *GLP-1*, glucagon-like peptide-1; *IDF*, insoluble dietary fiber; *MOS*, mannan-oligosaccharide.

Glycemic and insulinemic responses to DF-containing meals in dogs and cats with diabetes mellitus have been studied. Feeding well-regulated stable diabetic dogs diets classified as high-IDF, high-SDF, or low-DF did not affect insulin dosage. The high-IDF but not the high-SDF or low-DF diet decreased glycemic response to meals and lowered fructosamine concentrations.[39] Of the diets evaluated, however, the high-SDF diet contained less TDF than the high-IDF diet, and the DF in the high-SDF diet was predominantly IDF. Further, neither DF concentration nor composition of the low-DF diet was reported, although the low-DF diet contained both beet pulp and FOS. While the high-IDF diet was associated with improvement in glycemic response as compared with 2 other diets, whether insulin dosage can be attributed strictly to DF type or amount remains unclear. In another study of stable diabetic dogs, guar gum was superior to the control diet alone or to that food with wheat bran added, as assessed by decreased glycemic response to meals.[40] However, the amount and type of DF present in the basal diet were not described. A third study on stable diabetic dogs evaluated 2 diets, one classified as high-IDF and the other low-IDF. Mean fasting and postprandial BG were lower with the high-IDF diet. Most dogs were better regulated with the high-IDF diet, as demonstrated with decreased insulin dosages.[41] In this study, the low-IDF diet contained a moderate amount of DF, which was predominantly IDF. The high-IDF diet had a nearly identical formulation but was supplemented with additional cellulose. The improvement in glycemic control can be interpreted as most dogs responding better clinically to a high, rather than moderate, IDF diet. No interpretation about effects of SDF or a low-DF diet can yet be made. A study of dogs with alloxan-induced diabetes demonstrated that supplementation of cellulose or pectin lowered glycemic response to food.[42] Cats with naturally-acquired diabetes mellitus were fed either high-IDF cellulose-supplemented diets or those described as low-IDF-unsupplemented diets (low in TDF, with TDF composed entirely of IDF). Improved glycemic control was demonstrated in diabetic cats given the high-IDF diet. Most cats were better controlled on the high-IDF diet.[43]

Lipid Metabolism

In addition to potentially affecting digestibility of dietary fat and interfering with enterohepatic recirculation of cholesterol, fermentable DF also may reduce hepatic lipogenesis (Table 190-5; see ch. 182).[44]

TABLE 190-5

Effects of DF Supplementation on Serum Lipid Parameters in Dogs and Cats

Triglycerides	
Flax	No change[93]
Sugarcane fiber	Decrease[24]
Beet pulp/pectin	No change[24] Decrease[87]
Guar gum	Decrease[88]
Chicory/inulin/FOS	No change[88] Decrease[87]
Cholesterol	
Cellulose	Increase[82]
Wheat bran	Increase[24]
Beet pulp/pectin	Decrease[82] No change[24,87]
Guar gum	Decrease[88]
Chicory/inulin/FOS	No change[87]

DF, Dietary fiber; *FOS*, fructooligosaccharide.

Protein/Nitrogen Metabolism

Since feeding fermentable DF promotes colonic bacterial growth involving synthesis of microbial protein from nitrogen, it has been theorized that the feeding of fermentable DF will promote overall loss of nitrogen into stool. FOS, beet pulp, and a blend of SDF fed to dogs increased fecal microbial nitrogen in one study, but no change in fecal nitrogen excretion was seen in cats fed a FOS supplement.[20,45] In these cats, no decrease in serum urea was demonstrated.

Food Intake

Energy derived from absorbed VFA is negligible, yet DF contributes to total volume of food consumed.[46-49] This dilutional effect on energy density, in addition to DF's effects on gastric emptying and on GLP-1, can be beneficial in weight loss programs. In dogs fed IDF-supplemented diets, food intake increased, but calorie intake decreased.[50] Beet pulp and oat fiber increased food and calorie intake in one study of dogs, but peanut hulls, wheat bran, beet pulp or tomato pomace did not affect intake in another.[35,36] Cats supplemented with high concentrations of cellulose decreased their intake with lower levels of supplementation than used in dogs.[51]

Satiety was studied in dogs using an unsupplemented test meal after giving diets supplemented with beet pulp or FOS.[52] Dogs consumed less test meal and less of the supplemented diets. Diets supplemented with IDF, SDF, wheat bran, cellulose, almond shell flour, pea fiber, or lentils and fed to food-restricted dogs in a weight-loss program failed to decrease test meal intake.[53-55] Similar results were obtained with cellulose-fed cats.[51] In dogs, a high-protein, high-TDF diet including cellulose, psyllium husk, beet pulp, and FOS reduced total intake, whereas high-protein or high-TDF diets alone failed to reduce intake.[56]

Beagle puppies fed wheat bran–supplemented diets showed a dose-dependent decline in feed intake, feed and protein efficiency and growth.[57] It should be noted that the concentration of DF at which this effect was seen is quite high and not consistent with commercial pet food. In *Salmonella*-infected puppies, supplementation with inulin or FOS decreased illness-related decline in food intake.[25]

Immune System Effects

Much of the immune system is located in or around the gut. DF also affects parameters related to immune system function.[58] Table 190-6 summarizes effects of DF on white blood cells (WBCs) and immunoglobulins in dogs and cats. Lack of effect on WBC function has also been demonstrated.[59] Supplementation with yeast cell wall in dogs caused decreases in serum concentrations of IgA as well as in saliva and tears.[60] Bitches supplemented with FOS exhibited higher colostrum and milk IgM content without concomitant effect on IgG or IgA. Their puppies showed higher IgM response to *Bordetella* vaccination.[61] A mixture of beet pulp, gum arabic and FOS altered the T-cell composition of gut-associated lymphoid tissue and increased mitogen response in T cells.[59]

TABLE 190-6

Effects of DF on WBC and Immunoglobulin Parameters

WBC Parameters	
Cellulose	No change[13]
Flax	No change[93]
Beet pulp/pectin	No change[13,59]
Chicory/inulin/FOS	No change[13,17,59,67] Decrease lymphocytes[17]
Yeast cell wall/MOS	No change[13,67] Decrease lymphocytes[17] Decrease monocytes[79]
Arabinogalactan (specific forms)	Increase WBC, neutrophils, eosinophils[58]
Immunoglobulins	
Cellulose	No change[13]
Beet pulp/pectin	No change[13]
Chicory/inulin/FOS	No change[13,19,67]
Yeast cell wall/MOS	No change[13,19,67] Increase IgM[60]
Arabinogalactan	No change[58]

DF, Dietary fiber; *FOS*, fructooligosaccharide; *IgM*, immunoglobulin M; *MOS*, mannan-oligosaccharide; *WBC*, white blood cell.

CHAPTER 191

Adverse Reactions to Foods

Allergies versus Intolerance

Jason W. Gagné

Client Information Sheet: Adverse Reactions to Foods

Adverse food reaction (AFR) is an umbrella term that encompasses both food intolerance and food allergy. Both disorders may lead to an abnormal response clinically manifesting as dermatologic and gastrointestinal (GI) signs. Food intolerance encompasses pharmacologic/metabolic reactions, food poisoning/intoxication, and food idiosyncrasy; it has no immunologic basis. Food allergy (also known as food hypersensitivity) is a term reserved for those with clinical signs due to an immunologic reaction (Figure 191-1).

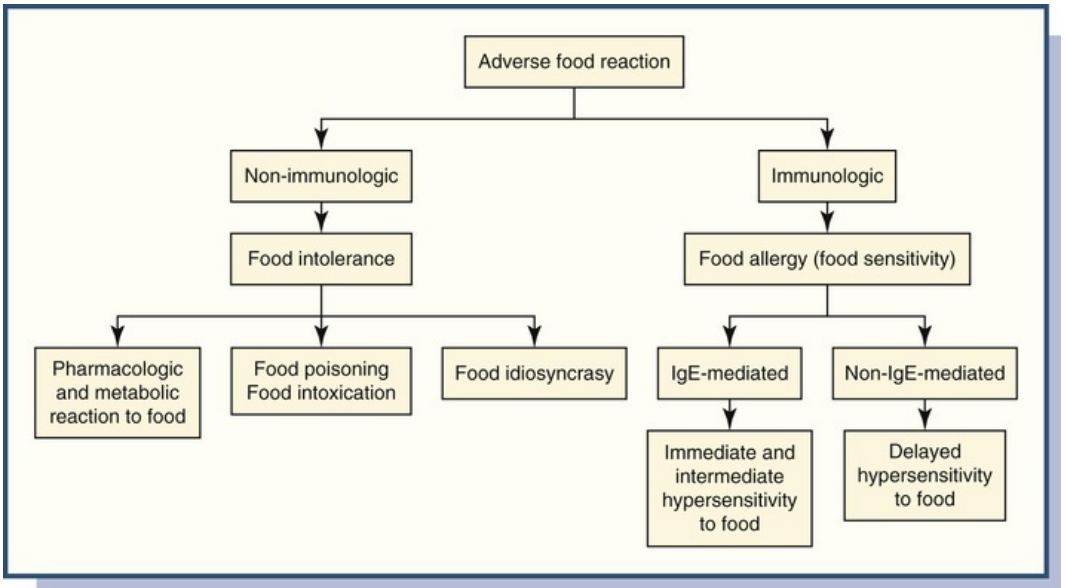

FIGURE 191-1 Classification of adverse reactions to food. *IgE,* Immunoglobulin E. (From Verlinden A, Hesta M, Millet S, et al: Food allergy in dogs and cats: a review. *Crit Rev Food Sci Nutr* 46[3]:259-273, 2006.)

The prevalence of AFR in dogs and cats varies from source to source. Of dogs with nonseasonal pruritic dermatoses, 10-30% are diagnosed as having AFR.[1-6] Of dogs with skin disease, only 1% has been attributed to food allergy.[7,8] Food allergy is the third most common skin allergy behind flea-allergy and atopic dermatitis and accounts for 10-15% of all allergic skin diseases.[9]

The prevalence of AFR in cats is reported to be 1-6% of all feline skin disease and is the third most common hypersensitivity.[10,11] Of dogs and cats diagnosed with food allergy, 15-50% are now recognized to have GI signs.[4,12-14] Additionally, pruritic patients with GI signs are more likely to be diagnosed as food allergic.

Food Intolerance

Since food intolerance has a nonimmunologic etiology, it does not require the stimulation and sensitization of the immune system as documented in food allergy. Therefore, it may occur on a first exposure to a food, "food additive, or substance."

Pharmacologic/metabolic reactions include an array of compounds. This category includes vasoactive and biogenic amines such as histamine found in scombroid fish (mackerel, tuna, skipjack), which may cause adverse reactions within minutes of ingestion. The concentration of histidine available for bacterial conversion to histamine to cause such reactions in unspoiled commercial pet food is low[15,16]; therefore, reactions are more prevalent in raw and spoiled homemade fish diets. The maldigestion with secondary malabsorption that causes an osmotic diarrhea (e.g., lactose intolerance) is an example of a metabolic adverse reaction.[17,18] Undigested lactose is rapidly fermented by small intestinal and colonic bacteria, creating short chain fatty acids, borborygmus, gas, abdominal discomfort, and diarrhea. Lactose activity of puppies drops to 10% at time of weaning compared to at birth.[17] The activity of brush border disaccharidases like lactase may also be decreased by viral infection, fasting, and dietary change.

Food poisoning/intoxication reactions occur in response to ingestion of food containing toxins or microbial contamination. Aflatoxin, a mycotoxin produced by *Aspergillus* spp. commonly found in grains, causes high mortality due to hepatic failure from hepatocellular necrosis (see ch. 286).[19,20] The U.S. Food and Drug Administration has set a maximum level of 20 ppb in human and pet foods,[21] yet dogs and cats are more sensitive to aflatoxin than are other species (rats, sheep, chicken, humans).[22] Therefore, pet food manufacturers set their tolerable levels lower than for human foods and regularly test raw ingredients and finished diets. Strains and toxins of bacteria known to contaminate food and cause acute enteritis in dogs and cats include *Salmonella, Campylobacter,* and *Clostridium* spp. in addition to *Escherichia coli.*

The term food idiosyncrasy is used to describe an abnormal response to food additives and substances such as gelling agents, gums, emulsifiers, preservatives, colors, and humectants. While they have all been implicated as a cause of GI disorders of dogs and cats, minimal evidence exists.[12,23]

Food Allergy

Food allergy is an AFR with an immunologic basis in response to ingestion/absorption of a dietary antigen, usually a dietary protein. The GI tract has a 3-pronged defense to reduce the potential of allergic responses.

The first defense is digestion. Proteins are exposed to various enzymes and compounds, such as pepsin, pH, and pancreatic and intestinal enzymes, which destroy antigenic factors of a protein. A second defense is the inherent functional barrier of the GI tract. One aspect of this is the tight junctions of epithelial cells. Under normal circumstances, only trace amounts (0.002%) of intact proteins will be absorbed, and these small amounts are removed by the reticuloendothelial or Kupffer cells of the liver and mesenteric lymph nodes.[24] In addition, peristalsis, the mucus layer, and secretory IgA found in the lamina propria provide added protection.[25] Lastly, the role of gut-associated lymphoid tissue (GALT) is to distinguish "self" from "nonself," to eliminate those foreign to the body, and to protect components of "self." All dietary antigens are foreign, which speaks to the fascinating ability of the GALT to create an oral tolerance to nutrients while removing pathogens. A compromise in any of these three systems may lead to development of food allergy.

The primary lymphoid tissue where oral tolerance occurs is the microfold (also known as M) cells of the Peyer's patches in the intestinal epithelium. The M cells sample potential antigen and microorganisms from the lumen of the intestine,[26] and oral tolerance occurs with the acceptance of a food antigen through complex interactions of antigen-presenting cells, B cells, dendritic cells, macrophages, and T cells. Alternatively, the process of sensitization and stimulation to a food antigen may occur, resulting in an immunologic response. This response involves antigen-specific lymphocytes and IgE-bearing mast cells leading to inflammation and clinical manifestations of dermatologic and/or GI signs that have been compared to Types I, III, and IV hypersensitivities.[27]

The majority of food allergens that elicit an immune response in humans are water-soluble glycoproteins with molecular weights between 10-70 kDa, which are relatively stable to heat, pH, and digestive enzymes.[28-31] In dogs, all recognized allergic proteins have weighed ≥20 kDa,[32,33] and the most common food allergens are beef, dairy products and wheat. In cats, the most common food allergens are beef, dairy products, and fish.[34] This reflects the most commonly fed ingredients in commercial pet food.

Clinical Features

Dermatologic Responses in Dogs (see also ch. 186)

There are no sex or age predilections for cutaneous disease due to AFR in dogs.[6,8,35,36] The age at which clinical signs have been reported range from 4 months to 14 years,[37] with initial signs reported in those less than 1 year of age in 33-51% of cases. Increased risk has been reported in the following breeds: Boxers, Chinese Shar-Pei, Cocker Spaniels, Collies, Dachshunds, Dalmatians, German Shepherds, Golden Retrievers, Labrador Retrievers, Lhasa Apsos, Miniature Schnauzers, Soft-Coated Wheaten Terriers, Springer Spaniels, and West Highland White Terriers.[6,35,38-40]

Presentation of dogs with AFR occurs on a nonseasonal basis and affected dogs may resemble those presenting with atopic dermatitis. Clinical signs include variable degrees of pruritus that may be generalized or localized to the face, pinnae, and perineal, axillary, inguinal, and paw regions.[6,35,38-40] Secondary bacterial/yeast infections, papules, pustules, epidermal collarettes, and seborrhea may also be observed.[6,8,35,36] Otitis externa has been noted with bacterial and/or *Malassezia* infections. Chronic changes may include hyperpigmentation, lichenification, and alopecia. See Figure 191-2, *A-E* for dermatologic clinical manifestation of canine AFR.

FIGURE 191-2 **A** and **B,** Otitis externa with secondary bacterial and *Malassezia* infection. **C,** Erythematous muzzle. **D,** Erythematous periocular region with scaling of facial region. **E,** Erythematous cervical, axillary, and inguinal regions with secondary bacterial infection. (Images courtesy Dawn Logas, DVM, DACVD, Veterinary Dermatology Center, Maitland, FL.)

Uncommon clinical signs that have been reported include urticaria (hives) characterized by wheals,[41] erythema multiforme,[42] vasculitis,[43] and anaphylaxis (see ch. 137). Angioedema, a localized form, is characterized by edematous swelling of the lips, face, eyelids, ears, conjunctivae, and/or tongue, with or without pruritus. Angioedema may also result from drugs, vaccines, infections, atopic dermatitis, and blood transfusions.

Dermatologic Responses in Cats (see also ch. 186)

There are no sex or age predilections for cutaneous disease due to AFR in cats. The mean age of onset is 4-5 years. The age at which clinical signs have been reported ranges from 6 months to 11 years,[8,44] with 46% of cats experiencing initial signs by the age of 2 in one study.[45] Increased risk has been reported in Siamese, Siamese-cross, and Birman cats.[6]

Clinical signs include nonseasonal, localized or generalized pruritus in 100% of cats with food allergy.[40,45] Pruritus is primarily localized to the head, neck, and ears (which may lead to severe self-trauma) but may spread to the limbs, ventral abdomen, and inguinal region. Alopecia due to "fur-mowing," as well as exfoliative, exudative, and military dermatitis and secondary scaling dermatoses, have been reported. Otitis externa, eosinophilic plaques and ulcers may also develop. Urticaria, angioedema, and conjunctivitis may occur.[44-46]

In cats diagnosed with food allergy, 20-50% have an absolute eosinophilia,[46,47] and 30% have been noted to have a moderate to marked peripheral lymphadenopathy.[37]

Pruritic Threshold

The concept of the pruritic threshold is that each individual dog or cat has a different tolerable level; once it is reached, pruritus develops. The stimuli that cause one to reach or exceed one's threshold include (but are not limited to) ectoparasites, atopic dermatitis, and diet. Regarding ectoparasites and atopic dermatitis, these stimuli may not be present (or may be pharmacologically controlled) at certain times of year and therefore may lower the allergen load to threshold for an individual. This would allow a dog or cat to tolerate a food that he/she could be allergic or intolerant to without experiencing the clinical manifestation of pruritus. This situation would result in food allergy appearing to be seasonal in nature.

It is not uncommon to observe an allergic response that is caused by multiple allergens in the same patient. In dogs, 20-30% of food allergy cases have skin disease including atopic dermatitis and flea allergy.[5,6,38,40] In a study of cats, 35% had concurrent flea allergy.[52] The combination of diseases may hinder diagnosis of food allergy and highlights the importance of diet and dietary history as a means of reducing allergen load to avoid exceeding the pruritic threshold.

Gastrointestinal Responses in Dogs and Cats

There are no sex or age predilections for gastrointestinal disease due to AFR in dogs or cats. Breeds more commonly affected include the Chinese Shar-Pei, German Shepherd, and Irish Setter.[37] Clinical signs may include vomiting, borborygmus, intermittent abdominal pain, and diarrhea (increased frequency, volume, and loosened consistency).[2,5,8,36,44,47]

AFR is included in a vast array of differential diagnoses for GI disease since it can occur in every segment of the GI tract and may present as acute or chronic. Acute onset of AFR is likely food intolerance rather than food allergy.

The well-documented gluten-sensitive enteropathy of Irish Setters appears to be inherited (see ch. 276).[48] Clinical manifestations from gliadin and glutenin (proteins of cereal grains) occur at an early age and are reversible when these dogs are fed a gluten-free diet. This is not the same disease of humans known as celiac disease.[49]

Inflammatory bowel disease (IBD) involves a complex interplay between host genetics, immune status, and microflora. Diet has an effect on quantity and diversity of microflora.[50,51] It is possible that alterations in the

microflora may occur in patients with AFR, which may contribute to development of IBD, but currently the role of AFR is unknown.

Diagnosis

After history (see ch. 1 and 170), physical examination (see ch. 2 and 10), and minimum database (to rule out other causes) have been completed, AFR may be suspected with appropriate clinical signs. A food elimination trial (see ch. 186) is the most important diagnostic tool, although it cannot elucidate the underlying pathogenic mechanism of AFR. A clinical diagnosis is made after resolution of clinical signs on an elimination diet, followed by recrudescence of clinical signs upon reintroduction of the former food after the trial.[27,53] If only GI signs are present, a trial of 2-4 weeks may be sufficient,[23] whereas a trial of 8-12 weeks may be necessary for those with dermatologic signs.[54]

A complete dietary history and owner compliance are of utmost importance. The owner must remove all potential allergens including current diet, flavored medications and toys, treats, food used to administer medications, table scraps and access to other pet food if in a multipet household. Lack of owner compliance has resulted in up to a 33% dropout rate for dogs at referral centers.[2,6,55,56] To increase owner compliance, the elimination diet chosen should be a complete and balanced palatable food for the appropriate life stage, and convenient for the owner to feed. The food chosen should contain a limited number of protein sources that are intact or hydrolyzed, to which the patient has not been exposed previously, and that are highly digestible. For the GI patient, a moderate restriction in fat and a source of fermentable fiber are advised.

Diagnosis by any other means including intradermal skin testing, serology, and gastroscopy should be avoided due to low sensitivity and specificity.[57-62] An outline of how to perform a food elimination-challenge trial may be found in Figure 191-3 and additional infomration is presented in ch. 186.

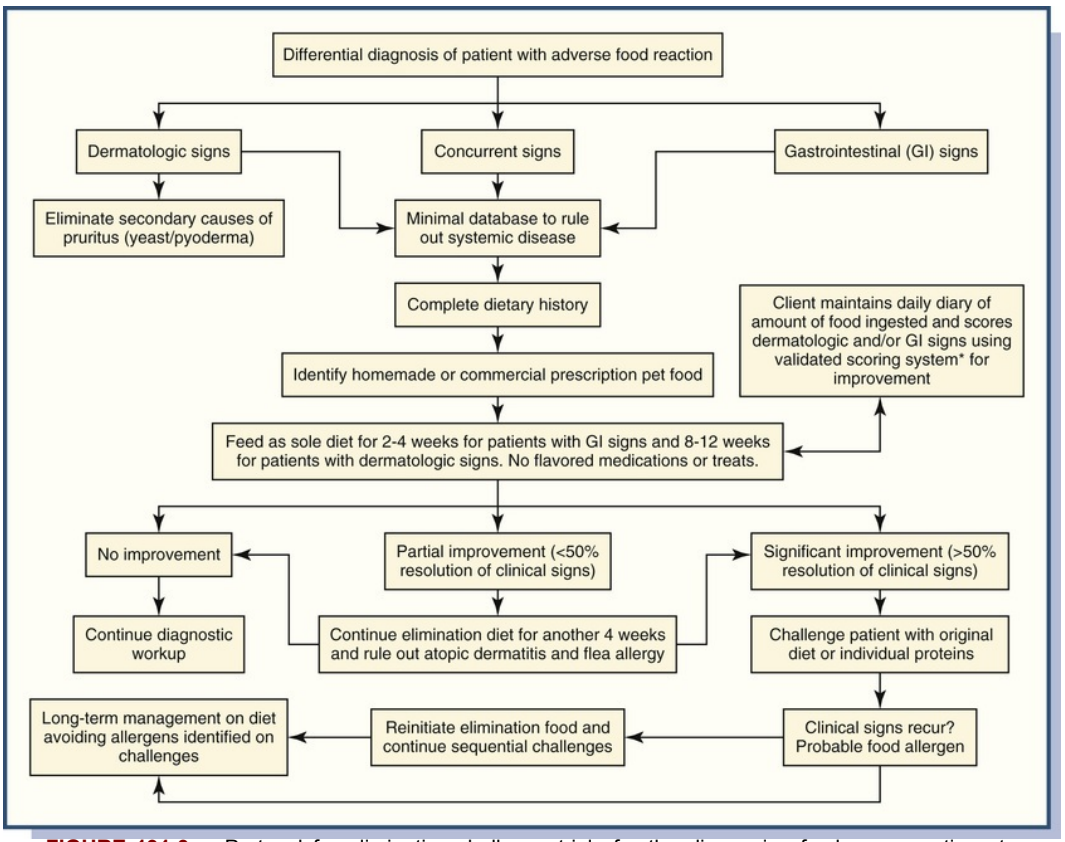

FIGURE 191-3 Protocol for elimination-challenge trials for the diagnosis of adverse reactions to food. Nestlé Purina 2014.)

Homemade Elimination Diets

Homemade diets containing a single protein and carbohydrate source traditionally have been considered the "gold standard" and used as an elimination diet for diagnosis of AFR.[4] This approach is 100% dependent on dietary history, since chosen ingredients are limited to those to which the patient has not been previously exposed. Due to the limited number of ingredients, homemade diets are typically not complete and balanced. They often lack calcium, essential fatty acids, certain vitamins, and other micronutrients, leading to long-term nutritional deficiencies. Previous studies have found that >90% of homemade diet recipes are not complete and balanced according to Association of American Feed Control Officials recommendations.[63,64] If a homemade diet is chosen, the client is encouraged to consult with a board-certified nutritionist (see ch. 192). A list may be found at acvn.org.

Commercial Elimination Diets

This category includes novel protein and hydrolyzed diets. Both options are complete and balanced, convenient for an owner to feed, and do not involve the labor of a homemade diet. If the novel protein diet approach is chosen, dietary history again is critical, and a veterinary prescription diet should be chosen. In a recent study, 75% of over-the-counter (OTC) venison diets were found to contain poultry, soy, and/or beef when analyzed by ELISA.[65] Cross-contamination of common ingredients with those considered novel may occur at various points of manufacturing but is unacceptable. Thus, it is not recommended to use OTC novel protein diets for an elimination diet.

With the expanding variety of "novel proteins" being used OTC, the use of hydrolyzed protein diets has gained popularity. Hydrolysis of a protein results in a reduced molecular weight and altered shape in comparison to the parent protein. The goal is to reduce allergenicity and antigenicity because the hydrolysate is too small to elicit cross-linking of IgE on the mast cell; this therefore prevents degranulation and clinical signs if the AFR is similar to a Type I hypersensitivity. A common misperception is that all hydrolyzed proteins must be less than 10 kDa, when in fact the optimal molecular weight of a protein hydrolysate varies with the type of protein used.[34] In a study of confirmed soy- and corn-allergic dogs, 79% did not experience clinical signs when fed a hydrolyzed soy and cornstarch diet.[66] In a separate study of chicken-allergic dogs, clinical signs improved in 11 of 12 dogs when they were fed a hydrolyzed chicken diet.[67] In a study of canines with naturally occurring chronic small intestinal disease, significantly more dogs were asymptomatic when fed a hydrolyzed diet (as evaluated by the Canine Inflammatory Bowel Disease Activity Index) in comparison to a highly digestible diet.[68]

Treatment

Treatment of AFR entails identifying and avoiding the offending food allergens once identified (see ch. 186). Some dogs and cats may suffer adverse reactions to even trace amounts of an offending food, whereas others may have a higher threshold. Concurrent allergies may influence the threshold level of clinical signs in some animals, in which case pharmacotherapy may be necessary. A complete and balanced diet should be chosen after taking a thorough dietary history. If a homemade diet is chosen, a board-certified nutritionist should be consulted to ensure nutritional adequacy. An attempt should always be made to find an acceptable commercial food that will increase owner compliance. Commercial hydrolyzed diets may be the best practical choice, since relapse is possible if the patient becomes allergic to another protein source, at which point another food trial should be performed.

CHAPTER 192

Unconventional Diets (Homemade, Vegetarian, and Raw)

Sally C. Perea, Sean J. Delaney

Client Information Sheet: Unconventional Diets (Homemade, Vegetarian, and Raw)

Although most pet owners in the United States feed conventional commercial pet foods, there is a growing interest and market for unconventional diets. Unconventional diets include specialty niches such as vegetarian, natural, organic, and a variety of home-prepared raw and cooked diets. Pet owners' motivation for feeding unconventional diets varies, but much of the changing market has been attributed to the humanization of pets and the importance that food plays in the human-animal bond. Some proponents of home-prepared or raw food diets cite benefits such as control over ingredients, avoidance of artificial preservatives, preservation of natural enzymes, and incorporation of phytonutrients.[1] Other reported motives include a desire to pamper, to provide a more wholesome or nutritious diet, for medical benefits, to improve dental health, or to offer a diet that more closely resembles that of wild canids or felids.[1]

Unconventional Commercial Foods

Among pet owners, there is a growing interest in natural food, organic food, and desire to feed pets according to their own philosophy toward food. In addition, pet owners have a higher concern with pet food safety due to recalls, such as the large-scale recall in 2007 associated with melamine and cyanuric acid. These goals and concerns have resulted in greater interest in unconventional foods that may be perceived to have a higher level of quality and safety.[2]

With this growing interest in unconventional foods, a wide spectrum of products has entered the market with nutritional philosophies that have built upon human trends. Many of these new products have grown what has been called the "natural" pet food segment. As defined by the Association of American Feed Control Officials (AAFCO), the term natural includes "a feed or ingredient derived solely from plant, animal or mined sources, either in its unprocessed state or having been subject to physical processing, heat processing, rendering, purification, extraction, hydrolysis, enzymolysis or fermentation, but not having been produced by or subject to a chemically synthetic process and not containing any additives or processing aids that are chemically synthetic except in amounts as might occur unavoidably in good manufacturing practices."[3] Natural pet food products have expanded this regulatory definition by including ingredients that a pet owner would consider "natural," such as fruits, vegetables, and avoiding ingredients that are not recognizable or familiar.[3] The majority of these diet types are designed within the same nutritional parameters of conventional commercial food but offer choices to pet owners seeking to include or avoid specific ingredients based on real or perceived health needs or benefits. Given the limited amount of data in this area, there is an opportunity for further research to better understand natural pet foods and their effects on growth, performance, nutrient availability, digestibility, and other health parameters.

Although nutritional "adequacy" is not a primary concern with most commercial complete and balanced unconventional pet foods, there are some concerns when feeding a vegetarian or vegan diet, particularly to cats. A segment of pet owners has shown interest in feeding vegetarian- and/or vegan-based diets aligned with their dietary philosophies. Unlike pet owners who seek diets that are more natural for their pet, owners feeding vegetarian or vegan foods may be motivated by ethical reasons.[4] Because cats are obligate carnivores, feeding them vegan or vegetarian foods raises concerns regarding essential nutrients. In addition to their higher protein requirement, cats have a unique need for nutrients such as arachidonic acid, niacin, cobalamin, pyridoxine, vitamin A, vitamin D, and some amino acids such as taurine, arginine, methionine, and lysine.

These nutrients can be limited in vegan and vegetarian diets, making it difficult to meet cats' minimum requirements.[5] One study evaluating two commercially available feline vegan diets by laboratory analysis found multiple nutrient deficiencies, including total protein, methionine, taurine, lysine, arginine, arachidonic acid, calcium, phosphorus, vitamin A, pyridoxine, niacin, and cobalamin.[6] This study reinforced concerns that had been raised about feeding cats vegan or vegetarian foods. Cat owners should be alerted to these risks when electing to feed these food types. Pet owners should be encouraged to feed cats a meat-based diet, but in cases where this is not achieved, monitoring blood and plasma amino acid levels is one assessment that can be offered to help to identify potential deficiencies prior to the development of clinical problems. In addition, more regular veterinary exams (at least every 6 months) are also recommended to help identify potential nutrient deficiencies.

Home-Prepared Diets

Overview

A 2008 survey of pet owners in the United States and Australia showed that noncommercial foods (i.e., table scraps, leftovers, or homemade foods) were fed as part of the main diet in 30.6% of dogs and 13.1% of cats.[1] These noncommercial foods comprised at least one quarter of the diet in about 17% of dogs and 6% of cats. Fewer than 3% of pet owners in this survey reported feeding exclusively home-prepared diets, but approximately 7% of dogs received at least half their diet as home-prepared foods.

A more recent study surveying dog breeders suggests that frequency of feeding home-prepared foods may be on the rise, with about 11% feeding exclusively home-prepared diets for all life stages.[7] Home-prepared diets were fed more frequently by Canadian breeders (35.7%), and fed least frequently by breeders in the southern region of the United States (6.3%). The type of diet fed (home-prepared vs. commercial) was significantly associated with breeder trust for all sources of information on nutrition. Breeders who fed home-prepared diets were about 8 times as likely to rate veterinarians as not very trustworthy or not at all trustworthy as sources of nutrition information, compared with those who fed commercial diets. Additionally, breeders feeding home-prepared diets rated nonveterinarian websites, books, or email groups as very trustworthy or somewhat trustworthy sources of nutritional information. The findings in this study support those from a previous study that pet owners feeding unconventional home-prepared diets are seeking alternatives based on perceptions of quality and safety, as well as a mistrust of pet food manufacturers and veterinarians that recommend conventional diets.[2] This underscores the importance of nutritional education for veterinarians and the ability of veterinarians to provide solid nutritional advice to clients, helping to improve trust and compliance with nutritional recommendations.

Nutritional Adequacy of Home-Prepared Diets

One of the primary concerns with feeding home-prepared foods is appropriate nutritional balance and adequacy. Of 54 pet owners feeding their pet at least half of the diet from homemade foods in the 2008 survey, only 16 used a recipe designed for pets. Of these recipes, 8 were from a veterinarian, 3 were obtained from the Internet, and 5 were from other sources.[1] Although the nutritional adequacy of these diets was not evaluated, it raises concerns regarding potential misinformation available to the public regarding home-prepared diets for dogs and cats. Of more concern is the large portion of owners who fed home-prepared foods not designed for pets.

Nutritional inadequacy and/or improper balance are problems that can affect both home-cooked and raw food diets. One study evaluating the nutritional adequacy of homemade pet diets from six published resources (49 maintenance and 36 growth diets) found that 86% had inadequate levels of various minerals, 62% had inadequate levels of various vitamins, and 55% had inadequate protein or essential amino acids.[8] Another study evaluating the nutritional adequacy of 5 raw diets (2 commercial and 3 home-prepared) found that all had essential nutrients below minimum recommended AAFCO levels.[9] In addition to these deficiencies, all 3 home-prepared raw diets had improperly balanced calcium-to-phosphorus (Ca, P) ratios, two had excessive levels of vitamin D, and one had excessive levels of vitamin E.[9]

One study evaluated 200 recipes from a variety of sources, including veterinary textbooks, pet care books for owners, and on-line websites.[10] This study highlighted the concern that most recipes (92%) contained vague or incomplete instructions concerning ingredients, method of preparation, or supplements. Most (89.5%) recipes did not include feeding instructions. Some had large variations in calorie content for different

recipes recommended for the same-size pet. Vague instructions and lack of feeding guidelines can result in highly variable results depending on pet owner interpretation and may lead to inappropriate feeding practices and increased risk for malnutrition. Overall, most recipes (95%) had at least one essential nutrient at concentrations that did not meet NRC or AAFCO guidelines, and many recipes (83.5%) had multiple deficiencies. The most common nutrient deficiencies were zinc, choline, copper, the combination of eicosapentaenoic acid (EPA) plus docosahexaenoic acid (DHA), Ca, vitamin D, and vitamin E. Nine recipes surpassed the safe upper limit for vitamin D, and 6 surpassed safe upper limits for combining EPA and DHA.

Studies evaluating home-prepared recipes for pets with medical conditions, such as renal disease and cancer, have been published.[11,12] Similar to studies evaluating adult maintenance diets, these studies have shown numerous concerns with nutritional inadequacy and highly variable recipe and preparation instructions. Additionally, some key nutrients for the indicated condition, such as P and omega-3 fatty acids for renal management, were above or below recommended levels and may not have been ideally designed to manage the condition.[11] The key conclusion coming out of these studies is that there is an increasing need for veterinarians to counsel clients on the potential risk of feeding home-prepared diets and to encourage clients to consult with board-certified veterinary nutritionists who have experience in formulating diets to ensure optimal nutrition for both maintenance and disease management.

In addition to deficiencies in nutrient profiles, clinical nutrient deficiencies secondary to unbalanced home-prepared foods have been reported.[13-17] Inadequate Ca and improper Ca-to-P ratios are common problems reported in dogs and cats fed unbalanced home-prepared foods.[13,14,16,17] Calcium deficiency, with or without vitamin D deficiency, may cause nutritional secondary hyperparathyroidism (see ch. 69 and 187). Young, growing animals commonly develop long bone abnormalities, while adult animals have been reported to develop bone resorption of the mandible and maxilla, resulting in a rubber jaw syndrome.[13,14,16] One report of a 6-year-old dog fed an unbalanced home-prepared diet for 18 months to manage lymphocytic-plasmacytic enterocolitis documented nutritional secondary hyperparathyroidism, low serum 25-hydroxycholecalciferol concentration, and clinical and computed tomography findings consistent with rubber jaw syndrome.[14] As with many nutritional deficiencies, underlying Ca deficiency is not commonly recognized until stores are significantly depleted. Thus, pets on unbalanced diets may not display clinical signs of underlying nutritional insufficiency. Similarly, many nutrient deficiencies, such as Ca, are not readily apparent on routine blood work because serum concentrations are tightly regulated despite severe dietary deficiencies.

In growing animals, clinical signs of nutritional deficiency will often be more severe and pronounced. An 8-month-old Shetland Sheepdog fed a commercially available muesli-vegetable powder premix combined with raw ground beef over a 4-month period was reported to be thin and abnormally small in stature, with short thoracic limbs relative to the pelvic limbs. This dog had a sudden onset of neck pain, collapse, and inability to rise.[16] Diffuse osteopenia, polyostotic deformities associated with fracture remodeling, and an apparent floating dental arcade were noted on radiographic evaluation. Hypocalcemia, hypophosphatemia, and low vitamin D values were identified. The severity of clinical signs were similar to those of an 8-month-old Saint Bernard fed an unbalanced home-prepared diet due to chicken intolerance whose hypocalcemia resulted in tetanic seizures. This prompted veterinary evaluation and confirmation of nutritional secondary hyperparathyroidism and taurine deficiency.[17] Although taurine is not an essential nutrient for dogs, taurine deficiency–associated dilated cardiomyopathy has been identified in some breeds, including Saint Bernards.[18] These reports highlight the importance of assessing a complete dietary history at all veterinary examinations, particularly in growing animals in which malnutrition can have more severe consequences (see ch. 170).

Evaluating Nutritional Adequacy of Home-Prepared Foods

Chemical nutrient analysis, usually cost-prohibitive, is the ideal method to assess nutrient composition of a home-prepared food. Most diets are assessed with computer-based analysis. A study that utilized both computer-based and chemical nutrient analysis of 15 home-prepared diets showed that computer-based analysis is highly predictive of deficiencies and excesses.[10] However, the study did show that absolute values of specific nutrient concentrations ranged between 0.21-62.1%. This likely reflects variation in nutrient data on individual ingredients, which can vary seasonally and by geographical location. Nutrient profiles of individual ingredients can be obtained from databases, such as the USDA Nutrient Database (E-Table 192-1). However, they only provide an average and actual ingredients used in home-prepared diets likely vary. For this reason, it is recommended that pets fed home-prepared foods be routinely monitored and that dietary reassessments occur on a regular basis. In addition to seasonal and geographical variations, nutrient content of ingredients can vary by cooking methods, cut of meat, and portion of the plant fed. When collecting a diet

history, it is important to include all foods fed, amounts, and cooking methodologies for any home-prepared ingredients. Once the diet history is complete, the pet's diet can be evaluated with the use of computer-based analysis.

Human Foods Nutrient Content Information		
USDA Nutrient Database	www.nal.usda.gov/fnic/foodcomp/search/	

While detailed evaluations should carefully assess the nutritional adequacy and balance of a diet, there are ingredients that can be evaluated quickly (Figure 192-1). One should determine the amount of unbalanced food provided daily. Many pet owners feed small amounts of unbalanced foods that still compromise a diet's nutritional adequacy and balance. Unbalanced foods and treats should provide no more than 10% of total daily caloric intake. When unbalanced foods are added to a complete and balanced diet, nutrient dilution occurs and essential nutrients may fall below minimum requirements. For example, meat is high in P and, when added to a complete and balanced diet, may result in unbalanced Ca:P ratios. Treats may cause the total intake of some components to exceed safe upper limits. For example, liver can be high in some vitamins and minerals, such as vitamin A.

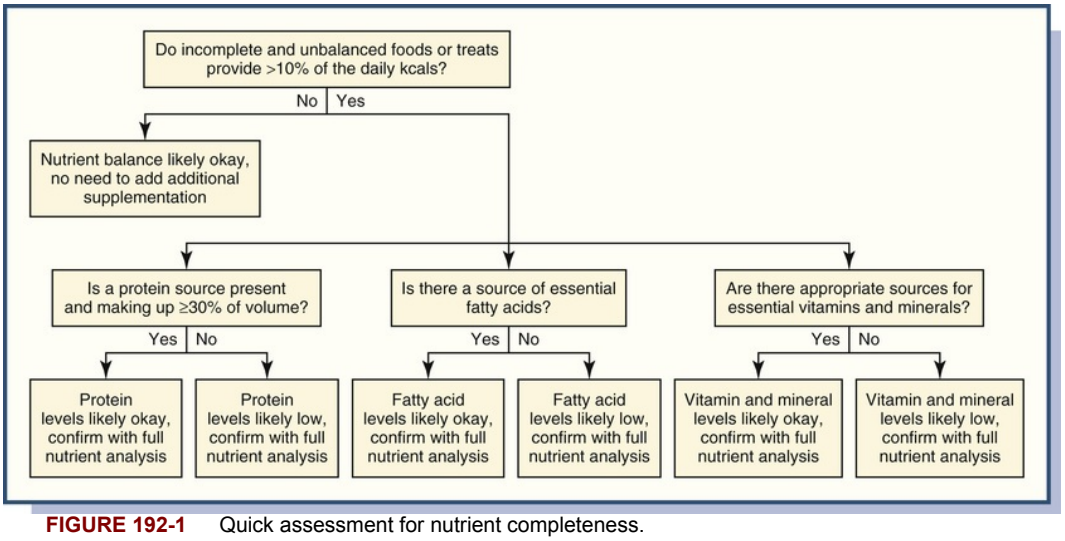

FIGURE 192-1 Quick assessment for nutrient completeness.

If unbalanced foods do provide more than 10% of the total daily caloric intake, they should be assessed for essential nutrients. First, identify the source of protein and essential amino acids, such as meat or a vegetarian (e.g., soy) protein. In general, protein should make up a least one-third of the diet by volume (higher amounts may be required for some vegetarian sources such as legumes). Dogs can generally perform well on vegetarian protein sources, but this is more challenging for cats. Vegetarian protein sources may not have enough sulfur-containing amino acids, such as methionine. Vegetarian protein also lacks arachidonic acid, an essential dietary fatty acid for cats, not dogs. Arachidonic acid, found primarily in animal fat, is difficult to provide in vegetarian diets. However, a recent study in cats demonstrated that feeding high amounts of borage oil, a source of gamma-linolenic acid (GLA), results in arachidonic acid enrichment of red blood cells, suggesting that diets containing high amounts of GLA may be a suitable substitute for preformed arachidonic acid.[19]

In addition to a source of arachidonic acid for cats, both dogs and cats require a source of linoleic acid (18 : 2 n-6). Linoleic acid is important for skin and coat health.[20] Animal fats often provide some linoleic acid, but most diets require additional sources to meet requirements. Vegetable oils (corn oil, walnut oil, canola oil, safflower oil, and soybean oil) can serve as dietary sources of linoleic acid. Of the readily available vegetable oils, corn oil and walnut oil have high concentrations of linoleic acid; therefore, less of these are required to meet minimum requirements and, accordingly, are frequently used by veterinary nutritionists.

Many pet owners like to cook with olive oil and may substitute olive oil for recommended vegetable oils. Olive oil has a high content of monounsaturated fatty acids (MUFAs). Studies in people have shown that MUFAs can help protect against heart disease by controlling low-density lipoprotein (LDL) cholesterol levels ("bad" cholesterol) while raising high-density lipoprotein (HDL) cholesterol levels ("good" cholesterol).[21] Therefore, olive oil is often recommended as part of a healthy diet for humans. However, dogs and cats do not maintain LDLs in circulation, preventing their oxidation and formation of atherosclerotic plaques.[22] Thus, some health benefits promoted for humans do not carry over to dogs and cats. Also, olive oil has low levels of linoleic acid, requiring four to five times the amount of olive oil (compared to corn or walnut oils) to meet requirements, significantly increasing fat content (Table 192-2). Thus, olive oil is avoided or used in combination with other sources of linoleic acid. Coconut oil is suggested and used as a source of medium-chain triglycerides but is a poor source of linoleic acid.

TABLE 192-2

Fatty Acid Contribution of Commonly Supplemented Oil and Fat Sources

				OMEGA-6 FATTY ACIDS		OMEGA-3 FATTY ACIDS		
Ingredient (Quantity) [USDA #]*	Saturated Fat (g)	Total MUFA (g)	Total PUFA (g)	LA	AA	ALA	EPA	DHA

Chicken fat (1 tsp–4.2 g) [04542]	1.27	1.907	0.892	0.832	0.004	0.043	0	0

*Fatty acid compositions acquired from the USDA National Nutrient Database. Nutrient values are expected to have natural variations, and individual sources should be verified.

†Some values approximated from undifferentiated values when n-3 or n-6 differentiation was not reported by the USDA.

AA, Arachidonic acid; *ALA*, alpha-linolenic acid; *DHA*, docosahexaenoic acid; *EPA*, eicosapentaenoic acid; *LA*, linoleic acid; *MUFA*, monounsaturated fatty acids; *PUFA*, polyunsaturated fatty acids; *tsp*, teaspoon; *USDA*, U.S. Department of Agriculture.

Although alpha-linolenic acid (18 : 3 n-3) has not been considered "essential" for dogs and cats, recent studies suggest that providing dietary alpha-linolenic acid provides some benefits for optimal health, especially in growing and reproducing animals.[20] Similarly, DHA is now known to be essential for optimal brain and retinal development in puppies.[23,24] The fatty acid content of commonly supplemented oils and fats are summarized in Table 192-2. Although alpha-linolenic acid can be provided by terrestrial vegetable oil sources (canola or flaxseed oils), algal or fish oil sources must be used to supply dietary long-chain omega-3 fatty acids such as EPA and DHA.

After assessing a home-cooked diet for essential proteins, amino acids, and fatty acids, one should identify the source of essential vitamins and minerals. Many foods contribute to the vitamin and mineral content of a diet, but a supplemental form is generally required to ensure recommended allowances are met. E-Table 192-3 outlines the National Research Council (NRC) recommended allowance of nutrient per 1000-kcal diet for adult dogs, cats, and the nutritional content of an unsupplemented diet consisting of 1/3 roasted chicken breast and 2/3 white long-grain rice. Depending on supplements used, combining multiple supplements may be required to meet all essential needs specific for dogs or cats. Most multivitamin/multimineral supplements designed for people are limited in one or more essential vitamins and trace minerals required to meet canine and feline minimum recommendations. Additional Ca, P, potassium, chloride, iodine, choline, and taurine (for cats) are commonly added to a multivitamin/multimineral supplement. All-in-one veterinary supplements, such as Balance IT (owned in part by author SJD), have been designed to meet nutritional needs of dogs and cats fed home-prepared foods.

E-TABLE 192-3

Comparison of National Research Council (NRC) Nutrient Requirements and Nutrition Composition of an Unbalanced Home-Prepared Chicken & Rice Diet

NUTRIENT	NRC ADULT DOG RECOMMENDED ALLOWANCE PER 1000 kcal	NRC ADULT CAT RECOMMENDED ALLOWANCE PER 1000 kcal	NUTRIENT CONTENT OF 1/3 ROASTED CHICKEN BREAST + 2/3 WHITE RICE*
Crude protein (g)	25	50	81.05

*Nutrient composition of home-prepared formula is based on computer evaluation using nutrient data acquired from the USDA National Nutrient Database. Nutrient values of finished formulas are expected to have natural variations, and individual formulas should be verified.

†Nutrient level below the NRC Recommended Allowance for Adult Maintenance of Dog and/or Cat.

When using a multivitamin/multimineral supplement designed for people, Ca and P are two key minerals that commonly fall short of necessary levels. Ca can be supplemented as Ca carbonate, Ca citrate, or a Ca and P combination such as dibasic or tribasic CaP or bone meal. Commonly, both a Ca-only and CaP supplements

are required to create an appropriate Ca:P ratio. Bone meal is readily available but has fallen out of favor due to concerns of lead contamination. When using Ca supplements designed for people, care should be taken to account for any added vitamin D. This is especially true when used in combination with other vitamin and mineral supplements that already provide vitamin D.

Salts can be used in home-cooked diets to provide additional Na, chloride, potassium, and iodide, including standard iodized salt, which provides Na, chloride, and iodine. Salt substitutes (potassium chloride mixtures) provide no iodine. Lite salt provides a 50 : 50 mixture of iodized salt and salt substitute. Choline, a component of choline phospholipids and a methyl donor for methylation reactions in the body, may need to be added. Other methyl donors, such as methionine, can serve as dietary choline equivalents. Therefore, dietary methionine levels above those required can serve to meet a portion of the choline requirement. However, because methionine can be a limiting amino acid, especially in reduced-protein diets, additional choline supplementation is generally recommended. Common limiting nutrients such as vitamin B_{12} and zinc may be required. Because simply adding higher quantities of the multivitamin/multimineral supplement can push other nutrients beyond safe limits, separate supplements addressing key limiting nutrients may be necessary.

Raw Food Feeding

In addition to potential nutritional inadequacies, feeding raw food carries risk of pathogenic bacterial infection, environmental contamination, and potential gastrointestinal (GI) obstruction by bones. Contamination with pathogenic bacteria in raw pet foods has been well documented.[25-27] Although the number of pets developing illness when fed raw food is unknown, well-documented cases have been reported, including salmonellosis in two cats from the same household fed a raw beef–based diet.[28] One of the 2 cats died after having clinical signs of weight loss, soft stools, and at least a week of anorexia. Tissue cultures taken from the lung, liver, spleen, and kidney at necropsy were shown to be positive for *Salmonella typhimurium.* Samples from the diet were not cultured. The second cat, examined 9 months later, was obtunded and euthanized at the owner's request. Necropsy revealed suppurative pneumonia and enteritis with villous blunting and erosion. Tissue cultures and subtyping revealed *Bordetella bronchiseptica* in the lung and *Salmonella enterica* serotype Newport in both lung and small intestine samples. Samples of the raw ground beef fed to this kitten were subsequently shown to be positive for *S. enterica* serotype Newport confirming the raw meat as the source of infection.

Many of the studies on raw food feeding practices have been conducted in Greyhound racing and breeding facilities, where feeding raw meat is common. One investigation of an outbreak of diarrheal disease and death of young puppies at a Greyhound breeding facility revealed *Salmonella enterica* infections that were traced back to raw beef fed to the dogs.[29] Necropsies revealed *S. enterica* septicemia, enteritis, and colitis. Multiple samples were collected from the facility, and *S. enterica* was recovered from 88 of 133 samples. 57 of 61 fecal samples (93%) were positive, and 75% of raw meat samples being fed were also positive. Other positive samples were collected from the soil, food bowls, water buckets, the kitchen sink, cleaning tools, floor surfaces, and flies. Serotyping of 88 samples positive for *S. enterica* revealed 94.3% Newport, 3.4% Typhimurium, 1.1% Anatum, and 1.1% Uganda serotypes. The Newport serotype was identified in multiple samples of the raw meat, confirming the raw meat as the primary source of the infection. More recently, commercially available raw foods have attempted to mitigate some of these pathogen risks through the use of high hydrostatic pressure processing (also called high-pressure pasteurization). While this process can reduce the total number of pathogens, it does not eliminate them and there is potential for development of bacterial and viral resistance.[30] There is a need for further research in this area to better define the efficacy of this processing method and the implications in terms of overall animal health and risk of pathogenic infections.

Pets not developing clinical illness when fed contaminated raw meat products still introduce a risk to humans and other pets in the environment through shedding of organisms in the feces.[31,32] Children, seniors, and immunosuppressed or immunocompromised individuals are at the greatest risk through environmental contamination. In response to public health concerns, the FDA prepared a set of guidelines for pet owners on the proper handling of raw pet foods to help minimize risk of pathogen cross-contamination.[33] From this guideline, "The FDA does not advocate a raw meat, poultry or seafood diet for pets, but is stepping up its efforts to minimize the risk such foods pose to animal and human health because we understand that some people prefer to feed these types of diets to their pets." This educational approach is also one that should be implemented by veterinarians when discussing raw pet foods with clients. After discussing risks with owners, alternative feeding options that improve safety can be offered. There are many commercially

available cooked pet foods that provide caloric distributions similar to those of raw foods and incorporate similar feeding philosophies such as avoidance of grains, the use of vegetables, the addition of probiotics, and the use of natural preservatives and ingredients. For pet owners who prefer home-made preparations, a complete and balanced home-cooked diet can be suggested as an alternative.

Indications for Home-Cooked Diets

Because commercial food formulations are consistent, complete, and balanced, they are generally preferred over home-prepared foods that are subject to recipe deviations and inconsistencies. Commercial foods that have undergone Association of American Feed Control Officials (AAFCO) feeding tests also have the advantage of demonstrating food performance within a species and nutrient bioavailability. The major advantages of home-cooked diets are that ingredients and nutrients can be tailored to the pet's needs, important for pets with multiple disease conditions that require nutritional approaches not available in a single commercial food.

When selecting the appropriate nutritional management for any patient, the clinician should ask a series of questions: (1) What is the appropriate caloric distribution of macronutrients in this patient's diet? (2) Are there any micronutrients that should be modified to meet this pet's needs? (3) Are there specific ingredients or dietary antigens that must be avoided? and (4) Are there any commercial foods that meet the needs identified in questions 1 to 3? To address the first question, the clinician should consider if modifications to dietary protein, fat, or carbohydrate levels are indicated. If the clinician concludes that more than one of these macronutrients must be reduced or restricted, the commercial food options may be limited. For example, a patient with a history of renal disease and pancreatitis will require both protein and fat restriction. However, most commercially available foods designed for the management of renal disease are moderate to high in fat. The second and third questions consider which micronutrients in the diet should be modified and if any ingredient must be avoided. Again, if multiple disease conditions are present, the required nutrient modifications may not be available in one diet. For example, a cat with a history of struvite urolithiasis and food allergies may not tolerate the ingredients provided by commercially available foods designed for the management of struvite urolithiasis, but foods designed for the management of food allergies may not provide appropriate levels of P and magnesium to address the struvite urolithiasis.

After determining required nutritional modifications, commercial foods should be explored for potential options. There may be cases where a commercial food addresses all the patient's needs. For the example of concurrent renal disease and pancreatitis, currently available foods designed for the management of renal disease should be evaluated for varying fat levels. The questions should then be asked, “What is this patient's fat tolerance?” and “Are there any commercial foods that can meet these needs?” The level of fat restriction required will vary from patient to patient and is generally related to the level of dietary fat that initially contributed to the pancreatitis episode. If the patient was on a high-fat food when pancreatitis developed, the pet may be able to tolerate a moderate fat level provided by a commercially available food designed for the management of renal disease. However, if the patient is sensitive to fat and cannot tolerate moderate fat levels, most, if not all, commercially available options will be eliminated, and home cooking may be the only viable option to address both conditions.

If the choice is made to treat with a home-cooked diet, the next step is to acquire an appropriate and nutritionally balanced home-cooked diet formulation. Consultation with a board-certified veterinary nutritionist will often provide guidance and individual tailoring of a diet to meet the patient's needs (see E-Table 192-1). Other veterinary software programs and published recipes are options available to veterinarians looking for more standardized dietary formulations or recommendations (see E-Table 192-1). Formal consultations and the use of nutrition software are generally preferred to published recipes, as they provide more up-to-date nutritional strategies and can be formulated for the individual pet. Most important, a diet should be complete and balanced for long-term feeding, and developed by a qualified board-certified veterinary nutritionist. As with all veterinary therapeutic diets, regular rechecks are essential to ensure that the dietary therapy is meeting the patient's needs. Most veterinary nutritionists encourage feedback on how the home-cooked diet formulation is working for the patient and can provide reformulations and adjustments to the diet as needed.

CHAPTER 193

Pet Food Safety and Regulatory Aspects of Pet Food

David A. Dzanis

Client Information Sheet: How to Report a Pet Food Complaint

Pet foods tend to receive more than their fair share of blame for any observed adverse health effects in dogs and cats. Historically, pet foods have a good safety record in the United States. In fact, despite their high prevalence and frequency of use in pet-owning households, only 1.7% of reports of poisoning in dogs or cats where the cause was confirmed could be attributed to food.[1] In terms of frequency of occurrence, this is far below that for many other sources of toxins often found in the household, such as drugs, insecticides, plants, rodenticides and cleaning products.

In spite of these statistics, adverse signs in pets are very frequently blamed on the animal's food. The massive pet food recall due to contamination with melamine and melamine analogs in 2007, along with the ongoing issues with chicken jerky treats imported from China, has heightened the public's awareness and concern about pet food safety. Notwithstanding efforts of manufacturers to provide safe and wholesome products, incidents of pet food contamination and subsequent adverse effects can and do occur. In the case of a suspected pet food–borne illness, the veterinarian can be instrumental in helping confirm the cause and, if indicated, reporting the findings to appropriate authorities.

Regulation of Pet Foods

In the United States, pet foods are subject to regulation at both the federal and state levels. The Center for Veterinary Medicine within the U.S. Food and Drug Administration (FDA) has authority over all pet feeds (encompassing complete and balanced foods, treats, nutritional supplements, edible chews and ingredients intended to become incorporated into any of these products) in interstate commerce.[2] This also includes pet products containing meat or poultry ingredients. This is different from regulation of foods intended for human consumption, where meat and poultry products are overseen by an agency within the United States Department of Agriculture (USDA). In addition, many states also enforce regulations for pet foods distributed within their respective jurisdictions, often through adoption of, at least in part, the Association of American Feed Control Officials (AAFCO) Model Bill and Model Regulations for Pet Food and Specialty Pet Food.[3]

Under both the Federal Food, Drug, and Cosmetic Act and similarly worded state laws, a pet food that contains a microbiological, chemical or physical contaminant may be subject to enforcement action as an adulterated food.[2] Especially where exposure to the adulterated product may result in health risks to animals or humans, a recall may be the most effective means of containing the risk in a swift manner. Details of how a recall is conducted are provided elsewhere.[4] Until recently, all recalls were voluntary (i.e., the party responsible for the contamination or other cause of health risk had to agree to participate in the process). There is little incentive for a company to refuse a recall request, as the potential repercussions in terms of legal liability and company/brand reputation may be much more costly in the long term than the costs associated with the recall itself. In the rare cases when that occurred, FDA always had other regulatory recourse. Regardless, the Food Safety Modernization Act of 2011 now provides FDA with mandatory recall authority.[5]

The Veterinarian's Role in Pet Food Safety

Veterinary practitioners are on the “front line” and often in the best position to first detect a possible outbreak of pet food–borne illness. As a matter of course, keeping records of dietary histories for all patients may help expose a pattern if multiple animals show similar signs over a short period of time. Such records also could be very helpful if a recall is announced at a later date.

Due diligence must be done to rule out other potential causes of presenting signs, such as drugs, pesticides, household toxins, and other animals. Still, the possibility of illness stemming from food contamination must remain on the differential diagnosis list until ruled out or when the definitive cause is determined. Unfortunately, the signs of food-borne illness are rarely pathognomonic. Contamination of pet foods with *Salmonella* or other pathogenic enteric organisms may cause gastrointestinal signs (e.g., vomiting, diarrhea), lethargy and fever. Most mycotoxins primarily adversely affect the liver. It was found that the combination of melamine and related compounds (fraudulently added as a component of what was represented as "wheat gluten" in pet foods in 2007) results in formation of crystals in the renal tubules, which can lead to acute nephrotoxicosis.[6] A unique finding in many animals reported to have suffered harm from consumption of China-sourced jerky pet treats is the onset of a Fanconi-like syndrome, characterized by renal insufficiency and glucosuria but without concurrent hyperglucosemia (see ch. 326).[7] Despite years of investigation, no cause has been determined.

When a pet food–borne disease is suspected, as much detail as possible about the food should be recorded (Table 193-1). If some of the information isn't immediately available, the owner should be asked to convey those details by phone as soon as possible. It is advisable to check FDA's Center for Veterinary Medicine web site for any existing notice of recall for any suspected food (click "Recalls" tab on www.fda.gov/cvm).

TABLE 193-1

Information Needed or Helpful in Investigation of a Potential Pet Food–Borne Illness

Food	Type of food (e.g., dry, wet, raw frozen) Type of container (e.g., bag, box, pouch, can, plastic sleeve) Where purchased (e.g., store name and street address, web site address) Date of purchase Appearance of food (e.g., mold, off odor, insect infestation, foreign material) Appearance of container (e.g., torn, wet, dented, open or bulging seams, leaking) How stored (e.g., frozen, refrigerated, transferred to another container)? How handled and prepared? Results of diagnostic testing (e.g., microbial, mycotoxin, chemical), if any
Label	Exact brand, product and variety name Intended use (e.g., puppy, kitten, adult) Manufacturer's or distributor's name and address Package size (net weight or volume) UPC (universal product code, i.e., bar code number) Batch identification (e.g., lot code, best by date, any other markings)
Animal	If multipet household, how many animals affected? Signalment and previous health history Onset and progression of signs relative to time of consumption Other foods, treats, supplements, medications? Results of diagnostic testing, if any Tentative or confirmed diagnosis

Beyond physical examination of the animal and laboratory analysis of appropriate biologic specimens, examination of the suspected food is also prudent. Pet food companies report that even slight changes in odor, color or texture unrelated to any safety concern are frequently the cause for alarm by concerned pet owners. Except for overt moldiness, obvious rancidity or visible inclusion of foreign materials, most incidents of pet food contamination are unlikely to be apparent upon gross inspection. Thus, collection of samples for laboratory analysis may be indicated when the food is suspect. Proper handling of the sample as legal evidence may be critical if there is a possibility of a lawsuit at a later date.[1]

Many veterinary diagnostic laboratories (as well as the laboratories at the state feed control officials offices) can perform the necessary analyses on food samples to help in diagnosis of a food-related illness. As much information as possible with respect to clinical signs, clinical pathology findings, and specifics about the timeframe of events (e.g., time between consumption and onset of illness, course of the disease) may be helpful in determining the likely contaminant and types of analyses to perform. A scribbled "check for poison" on a submission sheet is rarely helpful in detecting the presence of a contaminant.

Even when a pet food is already the subject of a recall, timely reporting of a case of pet food–borne illness

may help curtail a larger outbreak. FDA has established a "Safety Reporting Portal" on its web site where pet owners and veterinarians can report a problem (Table 193-2). There are means provided to contact an FDA consumer complaint coordinator by phone as well. Depending on the nature of the complaint, FDA may follow up with the veterinarian and/or client to obtain more information or to arrange to collect samples of the product. Notification of the state feed control official is also prudent, as they can coordinate efforts with FDA to investigate the report and take action against the pet food if needed.

TABLE 193-2

Reporting Suspected or Confirmed Pet Food Contamination

TO WHOM	HOW TO CONTACT	ALTERNATE CONTACT METHOD
Pet food company	Toll-free "800" telephone number on label	Company web site
FDA	To report electronically, go to "How to report a pet food complaint" on main web page for animal and veterinary products (www.fda.gov/cvm) and follow links to the "Safety Reporting Portal"	To report by phone, go to "How to report a pet food complaint" and follow links to find telephone number for consumer complaint coordinator in appropriate FDA district office
State feed control official (agency varies, but most often in state's department of agriculture)	To find contact information for appropriate state office, go to "Consumers" tag on AAFCO web site (www.aafco.org) and follow links	State government web site (most likely under its "commercial feed" program)

AAFCO, Association of American Feed Control Officials; *FDA*, United Stated Food and Drug Administration.

While not required under the regulations, most pet food labels bear toll-free "800" telephone numbers to be used to report complaints. In fact, the pet food company should be contacted promptly any time a food is suspected to be contaminated, as the firm may be in the best position to recognize an emerging pattern if multiple complaints regarding a product are received.

CHAPTER 194

Immunology and Nutrition

Nick John Cave

Nutrition and Immunity

The interactions between nutrition and immunity are complex and incompletely understood, and there are bidirectional effects between pathogens, immune responses, and nutritional requirements and metabolism (Figure 194-1). Food also contains numerous antigens, which normally stimulate harmless immune responses (oral tolerance) but can elicit harmful hypersensitivities. Nutrition can affect immunity by (1) enhancing or exaggerating, (2) suppressing or limiting, and (3) changing the nature of the response. Any effect can be either good or bad depending upon the specific disease and patient status. Thus, enhancement of an immune response may be desirable for prevention or elimination of infection, or immunity to tumor development, whereas attenuation of an immune response may be beneficial in hypersensitivity diseases, chronic inflammatory disease, or in harmful systemic inflammatory responses. In contrast, immunosuppression during infection can lead to prolonged morbidity or even overwhelming sepsis (see ch. 360). Equally, enhancement of immunity may increase self-damage when there is already excessive or poorly regulated immune activation (e.g., systemic inflammatory response syndrome, hypersensitivity diseases). Clearly then, one diet cannot fit the needs of all. The multiple points where an immune response can be modulated by nutrition are depicted in Figure 194-2.

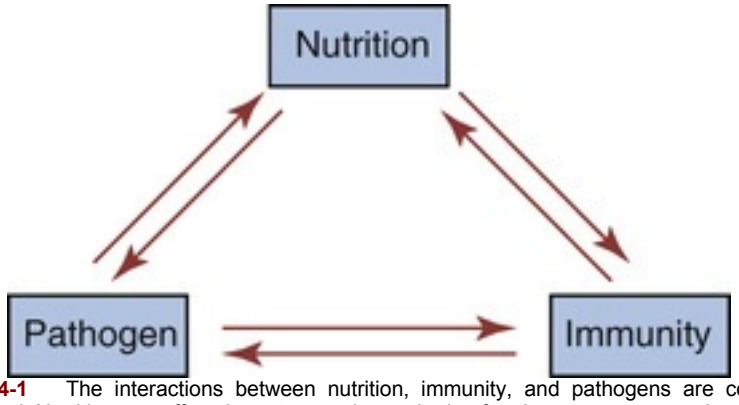

FIGURE 194-1 The interactions between nutrition, immunity, and pathogens are complex and multidirectional. Nutrition can affect the nature and magnitude of an immune response. In turn, immune responses require adequate nutrient supply and alter nutrient delivery to nonimmunological tissues. Diet can also directly modify the microflora and resident opportunistic pathogens, which in turn can influence mucosal pathogens.

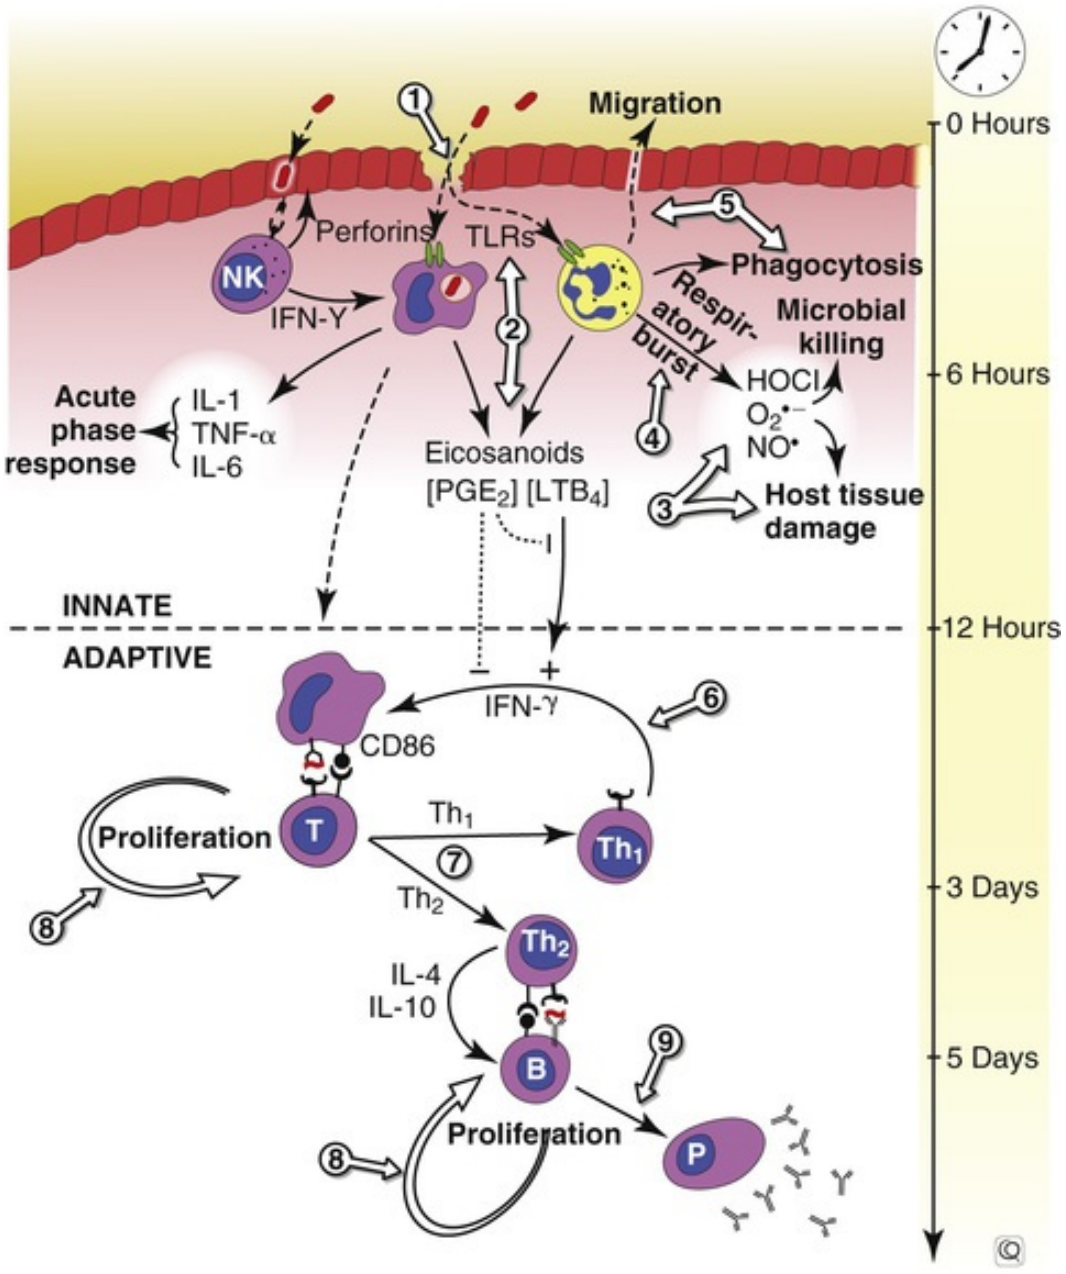

FIGURE 194-2 Schematic to show the multiple points within innate and acquired immune responses that can be modulated by nutrition. (1) Epithelial integrity—vitamin A, protein-energy malnutrition. (2) TLR signaling and eicosanoid production—PUFA. (3) Free radical damage—antioxidants, protein-energy malnutrition. (4) Respiratory burst—antioxidants, arginine, glutamine, genistein, carotenoids, taurine, leptin. (5) Neutrophil migration and phagocytosis—glutamine, genistein, iron, taurine. (6) Th_1 mediated responses—leptin, lutein, genistein. (7) Th_1/Th_2 development—leptin, vitamin E, PUFA. (8) Lymphocyte proliferation—leptin, lutein, genistein, Cu, Zn, B vitamins, glutamine, glucose, antioxidants, PUFA. (9) Immunoglobulin production—lutein, vitamin A, iron, leptin. *B,* B lymphocyte; *IFN,* interferon; *IL,* interleukin; *LT,* leukotriene; *NK,* natural killer; *P,* plasma cell; *PG,* prostaglandin; *PUFA,* polyunsaturated fatty acids; *Th,* T-helper cell; *TLR,* Toll-like receptor; *TNF,* tumor necrosis factor.

Nutritional Requirements for Immunity

Nutritional deficiency can profoundly affect developing leukocytes at any time from *in utero* to throughout life.[1] Table 194-1 lists some of the effects of nutritional deficiencies on immunity. Malnutrition during development can alter the mucosal microbial commensals, impair responses to commensals and pathogens, increase susceptibility to infection, and decrease the ability to clear infecting pathogens. Malnutrition early in

life can produce a lifelong alteration in an animal's immunophenotype.

TABLE 194-1

The Effects of Specific Nutrient Deficiencies on Immunity

NUTRITIONAL DEFICIENCY	IMMUNOLOGICAL DEFECTS	CLINICAL MANIFESTATION
Zinc	Thymic atrophy, lymphopenia, altered T-lymphocyte differentiation, reduced Th1 cytokine production, decreased antibody production	Diarrhea, increased susceptibility to infection from skin commensals
Copper	Lymphopenia, reduced lymphocyte proliferation, increased viral virulence	Neutropenia, anemia
Selenium	Impaired oxidant defense, increased viral virulence	Increased susceptibility to infection, increased organ oxidative damage
Iron	Decreased humoral responses, decreased phagocytosis and respiratory burst, reduced T-lymphocyte proliferation	Anemia, increased susceptibility to infection
Vitamin E	Increased IgE, increased PGE_2 production	Increased atopic disease signs? Increased organ oxidative damage
Vitamin A	Mucosal barrier defects (squamous metaplasia), lymphopenia, depressed antibody production, decreased Th2 responses, depressed neutrophil and macrophage maturation	General increased susceptibility to infection—especially respiratory infections, diarrhea,
Protein	Impaired cell mediated responses, decreased cytokine production,	General increased susceptibility to infection
Protein—energy malnutrition	Thymic atrophy, reduced lymphoid tissue mass (lymph nodes), decreased circulating T-lymphocytes and B-lymphocytes, impaired cell-mediated responses, decreased cytokine production, reduced neutrophil migration	General increased susceptibility to infection from exogenous and endogenous sources, increased morbidity and mortality, diarrhea (villous blunting, chronic enteritis)

IgE, Immunoglobulin E; *PGE2*, prostaglandin E2; *Th1*, T-helper-1 lymphocytes.

At rest, leukocytes utilize both glucose and glutamine for fuel. Following activation of macrophages and neutrophils, or stimulation of lymphocyte proliferation, glucose uptake is dramatically increased and is an essential fuel.[2] Although fatty acids and ketones can be oxidized for ATP production, cellular activation and proliferation of leukocytes do not increase the usage of either.[3,4] Both glutamine and glucose are only partially oxidized, consistent with the need for the cells to survive with low oxygen availability (e.g., in ischemic tissue or unvascularized spaces).[3] In addition to their use as fuel, glucose and glutamine are also used as precursors for nucleotide synthesis by proliferating lymphocytes. Not surprisingly then, low plasma glutamine and glucose concentrations render leukocytes more sensitive to apoptosis and cause immunosuppression.[2,5] The immunosuppressive effect of asparaginase has been shown to be due to its ability to hydrolyze glutamine rather than to the reduction of asparagine.[6] In models of severe sepsis when plasma glutamine is frequently depressed, glutamine supplementation enhances macrophage phagocytosis, helps maintain circulating T lymphocyte numbers, and normalizes lymphocyte function. Predictably, glutamine supplementation of parenteral nutrition solutions has been shown to reduce morbidity in some septic human patients, compared with glutamine-free solutions (see ch. 189).[7]

Several other nutrients affect the nature and magnitude of immune responses. Dietary antioxidants protect leukocytes and host cells against endogenously derived free radical damage and prevent oxidation of lipid within the diet prior to consumption. Intracellular antioxidants in neutrophils and macrophages include taurine, glutathione, ascorbate, and tocopherol. Dietary deficiencies of these can reduce circulating cell numbers and proliferation, whilst dietary enrichment can increase cell activity and antibody production.[8-11] Antioxidants are discussed further in ch. 167.

Normal circulating concentrations of both vitamins A and D are required for optimal leukocyte responses. The vitamin D receptor is expressed in lymphocytes, dendritic cells, and macrophages, and some activated leukocytes produce vitamin D_3. Vitamin D_3 can limit dendritic cell function, alters lymphocyte homing, and

inhibits T cell proliferation, with a bias away from a Th-2 type response.[12] Low vitamin D status is a risk for allergic disease, as well as immune-mediated disease such as multiple sclerosis in humans.[13,14] Vitamin A modulates both innate and acquired immune responses through effects on skin barrier, neutrophils, antibody production, lymphocyte trafficking, T-helper lymphocyte, type 1 or type 2 (Th-1/Th-2) balance, and many regulatory cytokines.[15,16] Canine distemper is rapidly fatal in ferrets fed a vitamin A–deficient diet, but supplementation soon after infection restores protection.[17] Although primary dietary deficiencies of these vitamins are probably rare, chronic intestinal disease in dogs and cats is commonly associated with hypovitaminosis of fat-soluble vitamins and is likely to affect immunity.[18,19]

Effects of Malnutrition on Immunity

Starvation

Malnutrition and simple starvation (see ch. 177) lead to physical and functional defects in the epithelial barriers of the respiratory and intestinal tracts, as well as the dermis. The net result is an increase in susceptibility to infection from both endogenous sources, such as skin and intestinal commensals, and exogenous sources such as hospitals.[8,20]

When mice are fasted for as little as 48 hours, lymphocytes, especially $CD4^+$ T cells, are dramatically reduced in circulation and primary lymphoid tissue.[21] Lymphocytes isolated from fasted mice proliferate less and produce less interleukin (IL)-2 and gamma-IFN. Within 4 days of starvation, otherwise healthy cats have reduced circulating leukocytes, notably $CD4^+$ T cells, which tend to proliferate less.[22] By 7 days of starvation, macrophage phagocytosis is suppressed and antigen presentation impaired.[23] These short-term effects are usually completely reversible upon refeeding.

A principal mediator of the immunosuppressive effects of acute starvation is leptin. The leptin receptor is expressed by neutrophils, macrophages, and lymphocytes, and leptin promotes their development, maturation, activation, and proliferation.[24] As such, leptin is a key regulator of cellular immunity and has a proinflammatory effect on normal and pathological innate and adaptive immune responses. The concentration of leptin drops rapidly during starvation and remains low during prolonged periods of weight loss. Circulating lymphocyte numbers and reduced proliferation responses in fasted rodents correlate with serum leptin concentrations.[25] In an intensive study of the morphometric, inflammatory, metabolic, and endocrine status of hospitalized children with acute severe malnutrition, the marker at the time of admission that best predicted survival was serum leptin.[26] In experimental settings, either leptin administration or recovery of body fat mass restores immune function.[27]

Provision of calories is insufficient to normalize cellular responses, however, and inadequate protein intake severely impairs cell-mediated immunity. Mice fed a protein-deficient diet, which are then infected with influenza, experience higher viral replication, reduced antibody responses, reduced $CD8^+$ T cells, reduced natural killer cell (NK cell) function, and increased mortality, all of which can be abrogated with the introduction of a protein adequate diet.[28,29] The early instigation of nutrition to dogs hospitalized with septic peritonitis shortened hospitalization.[30] Thus, even short-term malnutrition can be detrimental, but restorative feeding can significantly affect outcome in sepsis.

Obesity

In several species including dogs, obesity alters immune responses, which normalize following weight reduction (see ch. 176).[31-33] Reduced NK cell function, altered $CD8^+$:$CD4^+$ lymphocyte ratios, and reduced neutrophil respiratory burst activity have been described.[34] However, obesity is mostly accompanied by an enhanced inflammatory state, characterized by increased circulating inflammatory cytokine concentrations and increased acute phase protein production, which are normalized with weight loss.[35,36] Inflammatory cytokines such as tumor necrosis factor-alpha (TNF-alpha), IL-1, and IL-6, and other inflammatory mediators are produced by activated lymphocytes and macrophages that accumulate within the excessive adipose tissue and from the adipocytes themselves.[37,38] The subclinical low-grade inflammation contributes to peripheral insulin resistance in humans and probably does so in obese dogs and cats. Even within a short period of weight gain in dogs, obesity can increase circulating lymphocyte numbers and proliferative responses and increase serum antibody concentrations.[39] Thus, obesity is a state of enhanced immune activation. Leptin is

again central to the immunological state, but in obesity, leptin excess promotes systemic inflammation and, in people, increases the risk of some autoimmune and allergic diseases.[40]

Effects of Immune Responses on Nutrition

Immune responses can affect the nutritional status of patients. An almost universal finding in significant inflammatory disease is a reduction in food intake, which is mediated in part by the action of IL-1, IL-6, and TNF-alpha on central and peripheral nerves.[41] The fact that anorexia of infection is an almost universal effect in mammals and even insects suggests that it might have a benefit. In support of this notion is the observation that force feeding of anorexic septic mice can increase mortality, and in those that survive, the time to survival is increased.[42] In inflammatory diseases, most cells in the body (especially the liver) are relatively resistant to insulin. This resistance reduces peripheral glucose utilization and preserves blood glucose for essential tissues (brain, erythrocytes, leukocytes). A concurrent increase in cortisol induces lipolysis and muscle proteolysis, increasing the delivery of free fatty acids and amino acids to the liver. Hepatic insulin resistance means that feeding does little to prevent hepatic glucose output, and hyperglycemia results.[43] Therefore, systemic immune activation can result in insulin resistance, increased hepatic glucose production, and hyperglycemia (see ch. 304 and 305).[44] It appears that prevention of hyperglycemia in severe inflammatory disease reduces morbidity and mortality.[45] IL-1, IL-6, and TNF-alpha alter insulin signaling intracellularly causing inappropriate signaling in a diseased state. In addition, insulin-independent cells may experience cellular glucose overload, such as neurons, endothelium, alveoli, vascular smooth muscle, and renal tubule cells. The ensuing cellular dysfunction leads to acute kidney injury, anemia, neuropathy, and immunosuppression.

Sepsis is associated with an increase in nitric oxide (•NO) production by activated macrophages and neutrophils. The production of •NO is limited mostly by the availability of free arginine from which it is synthesized, and increasing available arginine increases the •NO produced by any given inflammatory stimulus.[46] In immunity, •NO has many functions, that range from protective to pathogenic.[47-50] Overall it appears that supplemental arginine, either parenterally or orally administered, enhances the depressed immune response of individuals suffering from trauma, surgery, malnutrition, or infection, presumably through its ability to augment the production of •NO.[51] Although beneficial in some patients, it may also contribute to the disease, especially in systemic inflammatory response syndromes.[51,52] Thus, there may be cases where supplementation with arginine, beyond that provided by a conventional protein source, may be beneficial, whilst in other cases it may be detrimental.[51] This may be particularly true of patients with severe sepsis, compared with patients without sepsis.[53,54]

Effect of Route of Nutrition

In addition to the composition and amount of diet fed, the route of feeding (enteral or parenteral) affects innate and adaptive aspects of immunity.[55] A lack of enteral stimulation leads to decreased intestinal and respiratory tract IgA production and established IgA-mediated antiviral and antibacterial immunity.[56] Increased mucosal permeability and bacterial translocation of luminal bacteria to the mesenteric lymph nodes, liver, and spleen are seen with parenteral nutrition (see ch. 189).[57] A lack of luminal nutrients results in intestinal inflammation.[55,58,59] In human trauma patients, enteral feeding decreases the incidence of pneumonia compared with total parenteral nutrition or starvation by increasing sIgA, hastening elimination of virus.[60,61] Patients without preexisting septic shock who received enteral nutrition had fewer episodes of severe sepsis or septic shock, and the length of stay in the intensive care unit was shorter compared with those given parenteral nutrition.[53]

Recommendations for Feeding in Severe Inflammatory Diseases

Clearly, feeding excessive carbohydrate will exacerbate the hyperglycemia and increase morbidity, whilst feeding excessive fat may promote fatty liver development and liver dysfunction. Until more is known about the responses in dogs and cats, the general recommendations are to instigate nutritional support early, preferably enterally. Complete diets are preferable to simple unbalanced solutions such as glucose or electrolytes, but conservative initial rates of approximately 25% of estimated resting energy requirements are recommended, and any increase should be made only if it is tolerated. Conventional diets that are highly digestible, containing more than 1.5× the minimum protein requirements (to allow for hypocaloric feeding),

are probably adequate. Patients should be monitored for hyperglycemia and hypertriglyceridemia, and the rate of feeding or composition of the diet should be adjusted if either develops.

Nutritional Modulation of Immunity

The most common reason for modifying the diet to affect immunity is to reduce immune-mediated disease. Allergic diseases such as atopic dermatitis (see ch. 186), chronic inflammatory diseases such as osteoarthritis (see ch. 187 and 353), autoimmune disease such as pemphigus (see ch. 204), and idiopathic inflammatory diseases such as inflammatory bowel diseases (see ch. 276) are all amenable to dietary modification. Though rarely sufficient as sole therapy, dietary modification can reduce the dosage of immunosuppressive or antiinflammatory drugs required.

Polyunsaturated Fatty Acids

Dietary polyunsaturated fatty acids (PUFA) can modulate immune responses through several mechanisms.[62-68] The proportions of the 20 carbon n-6 and n-3 PUFA within the phospholipid cell membranes of leukocytes and other cell types is determined by the diet. The n-3 PUFA eicosapentaenoic acid (EPA) competes with the n-6 PUFA arachidonic acid (ARA) as a substrate for cyclooxygenase (COX) and lipoxygenase (LOX), and being less efficiently utilized, EPA reduces eicosanoid production. In addition, EPA-derived eicosanoids function differently and range from antagonistic to equipotent to ARA-derived mediators. However, though complex, the net effect is that n-3–derived eicosanoids are less inflammatory than the n-6 PUFA–derived mediators.

PUFA can also directly affect gene transcription by interacting with the peroxisome proliferator-activated receptors (PPARs), which are a family of cytosolic proteins that, once bound to an appropriate ligand, diffuse into the nucleus and either promote or inhibit gene transcription. PPARs are expressed by macrophages, T cells, B cells, dendritic cells, endothelial cells, and other cell types.[69] Long chain n-3 PUFA are ligands for PPAR-gamma leading to reduced TNF-alpha, IL-6 and IL-1 production by macrophages, and IL-2 production by lymphocytes, and induction of regulatory T cells.[69-72]

Incorporation of EPA in place of ARA in phospholipid membranes alters the physical and structural properties of the cell membranes in lymphocytes, affecting the lipid rafts within which most cell surface receptors are localized. This decreases signal transduction through the T-cell receptor and depresses T-cell activation.[68] Lastly, both EPA and docosahexaenoic acid (DHA) antagonize the interaction between Gram-negative lipopolysaccharide (LPS) and Toll-like receptors, reducing the production of COX, TNF-alpha, IL-1, IL-6, and IL-8 and improving morbidity in severe sepsis.[65,73,74]

So dietary enrichment with n-3 PUFA can have immediate effects on immunity (e.g., antagonism of LPS signaling) but will take several weeks before a maximal response is achieved (i.e., saturation of tissue cell membranes). And although the effects and mechanisms of modulation of eicosanoids by dietary lipid are complex, there is value in the generalization that diets enriched in n-3 PUFA reduce inflammation relative to diets enriched in n-6 PUFA. However, the effect a given diet will have is dependent on many dietary and animal factors, and the reduction of the description of the fat content of a diet to a simple ratio of n-6 to n-3 PUFA provides very limited and potentially misleading information.

Supplementation of a diet with a source of n-3 PUFA will have greatly varying effects depending on the nature of the basal diet and patient. Most commercial diets are highly concentrated in n-6 PUFA, and the addition of a small amount of n-3 PUFA (e.g., as marine fish oil), such as is contained in many veterinary fatty acid supplements, achieves little. The best approach is to start by feeding a diet that is already enriched in EPA and not excessive in ARA. Table 194-2 lists some suitable complete diets enriched in n-3 PUFA. None of the listed diets will produce a maximal immunosuppressive effect, and fish oil can be added to the enriched diet. A recommended total fish oil dosage is 0.2% to 2% of diet by weight per day, or a maximum of 0.4 g EPA/100 kcal, including the n-3 content of the diet.[75] Note that the ratio of EPA to DHA in fish oil varies between 1 : 1 and 3.5 : 1.

Nonnutritive Dietary Compounds

Nonnutritive dietary compounds (see ch. 167) capable of modulating immunity are legion, of which only a few are discussed here. Genistein is an isoflavone compound principally found in plants of the family Leguminosae including soy, clover, and alfalfa.[76] Genistein can interact with estrogen receptors, can inhibit numerous cell cycling cascades by inhibiting tyrosine kinases, and can inhibit cellular proliferation by inhibiting DNA topoisomerase II. This can reduce leukocyte signaling cascades, lymphocyte activation and proliferation, neutrophil activation and superoxide production, bacterial phagocytosis by macrophages, antibody responses, and delayed-type hypersensitivity responses.[77-85] Commercial soy-based diets may contain sufficient genistein to affect mucosal, or even systemic immunity.[86-88] Dietary carotenoids, including beta-carotene and lutein, are incorporated into organelle membranes, especially in the mitochondria or lymphocytes.[89,90] The incorporation of lutein into the diet of cats has been shown to significantly increase cell-mediated and humoral immunity in cats, possibly through localized antioxidant effects.[91]

Immunologic and Hematologic Diseases

Introduction and Drug Therapy

Suliman Al-Ghazlat, Ann E. Hohenhaus

The immune system is vital in protecting the body from internal and external insults. Numerous and complex interactions between the cells and mediators of the immune system must be tightly regulated to maintain a healthy homeostasis. Comprehensive understanding of the basic immunologic mechanisms by which the body mounts and regulates an appropriate immune response is essential to effectively manipulate these mechanisms to prevent or treat undesirable immunological reactions.[1-4] In spite of extensive research over the last few decades, dysregulation of the immune system is still poorly understood but is likely multifactorial. Inappropriate presentation of an autoantigen by an antigen-presenting cell coupled with lack of the immunoregulatory effects of T regulatory cells (Tregs) is thought to be the result of an intricate immunological dysregulation in the innate and/or adaptive immune responses.[1-4] Generally, dysregulation of the immune system causes clinical disease by either excessive activation of Th1 cells and cytotoxic destruction of target tissue or Th2 cells and autoantibody-mediated disease.

Autoimmune/Immune-Mediated Diseases and Immunosuppressive Therapy

Susceptibility to autoimmune diseases is dictated by a complex interaction of genetic determinants and environmental triggers. Recent research has shown that genetic background plays a significant part in predisposing dogs to autoimmune diseases.[5-7] The most significant triggering factors are believed to be infectious agents like rickettsial or viral diseases.[8-10] The pathogenesis of most of immune-mediated hematological diseases is Th2-cells-mediated, resulting in the production of autoantibody that recognizes either a self-antigen or a foreign antigen associated with the red blood cells, platelets and/or white blood cells.[11-14] The resulting sensitization and subsequent destruction of these cells occurs via the complement system, cells of the reticuloendothelial system or both.[11-14] In addition to this section, which focuses on immune-mediated anemia (IMHA) (see ch. 198), immune-mediated thrombocytopenia (IMT) (see ch. 201) and immune-mediated neutropenia (see ch. 202), many other chapters in this book provide additional information on immune diseases, including immunology and nutrition (see ch. 194), polyarthritis (see ch. 203), skin disease (see ch. 204), and systemic lupus erythematosus (see ch. 205). Complementary information on immunosuppressive drugs can be found in the following chapters: 165, 261, 266, 268, 269, 276, 281-283, 323, 325, and 354.

Currently available immunosuppressive therapies act by a variety of different mechanisms, but ultimately they suppress antibody production by lymphocytes and/or suppress the clearance of opsonized cells by macrophages or the complement system.[3-6] Importantly, since the antibody class involved in most cases of canine IMHA is IgG and its half-life is approximately 1 week, therapies directed only at suppression of antibody production are unlikely to improve the outcome in the acute phase of the disease.[11,13] Over the past few decades, great advances have been made in the development of several immunosuppressive agents that are more potent, more selective and less toxic when compared to glucocorticoids (GCs).[13-38] The wide array of new drugs offers the opportunity to use multiple drugs that block different pathways of immune activation while at the same time selecting drug combinations with nonoverlapping toxicity profiles.

Mechanism of Action of Common Immunosuppressive Agents and

Procedures

With few exceptions, such as monoclonal antibodies, drugs used to treat immune-mediated diseases have multiple mechanisms beneficial to the patient with immune disease.

GCs are the most widely used agents in veterinary medicine, and they inhibit multiple mechanisms underlying immune-mediated diseases. The following is a general description of the mechanism of action of the immunosuppressive agents and procedures used in dogs and cats. Additional information about the commonly used drugs in dogs and cats is contained in Table 195-1.

- Regulators of gene expression: The classic examples are GCs (see ch. 165, 201, 261, 266, 268, 276, 281-283, 323, 325, 354, 358, and 360). Recent studies have shown that GCs affect inflammation by other (nongenomic) mechanisms.
- Alkylating agents including cyclophosphamide, procarbazine (see ch. 261) and chlorambucil (see ch. 204, 205, 276, and 325) cross-link DNA helices, preventing their separation and thus the formation of a DNA template.[3,45] These agents are toxic to both resting and dividing cells (particularly proliferating lymphocytes).
- Inhibitors of *de novo* purine synthesis: The first-generation inhibitors are 6-mercaptopurine and azathioprine (see ch. 165, 199, 204, 266, 281, 325, and 354). The second-generation inhibitors are mizoribine and mycophenolate mofetil (MMF) (see ch. 165, 203, 205, 323, 325, and 354). The immunosuppressive effect is achieved through suppression of lymphocyte activation and proliferation, resulting in a reduction in antibody production. These agents are less toxic to resting cells, and therefore they have a narrower spectrum of side effects compared to cyclophosphamide.
- Inhibitors of *de novo* pyrimidine synthesis: Similar to the inhibitors of purine syntheses, these agents work through suppression of lymphocyte proliferation. Leflunomide (see ch. 165, 203, 205, 261, and 323) represents this group.
- Kinase and phosphatases inhibitors: These include cyclosporin A (CsA) (see ch. 165, 198, 204, 261, 268, 276, 278, 281, 282, 323, and 354) and tacrolimus (see ch. 204, 278, and 323), which inhibit kinase cascades and ultimately suppress the activation of transcription of many cytokines vital for the proliferation and maturation of T cells.
- Inhibitors of macrophages: liposomal clodronate is the only drug used in veterinary medicine with primary immunosuppressive effects directed against macrophages.
- Procedural immunomodulation: This category includes splenectomy and plasmapheresis.
- Intravenous human immunoglobulin (see ch. 201) has numerous mechanisms of action, including modulation of expression and function of Fc receptors, interference with activation of B and T cells and complement, and a reduction in immunoglobulin production.
- Monoclonal antibodies: Most of these agents are directed against B-cell antigens. Although developed for the treatment of B-cell lymphoma, rituximab is used to treat immune-mediated disease in humans. It is directed against the B-cell antigen CD20. Recently, two caninized monoclonal antibodies have been approved for the treatment of canine lymphoma: one against CD20 and the other directed at CD52 for the treatment of T cell lymphoma. Use of these monoclonal antibodies in canine immune-mediated disease has not been investigated.

TABLE 195-1

Characteristics of Commonly Used Immunosuppressive Agents

AGENT NAME	CYCLOSPORIN A	AZATHIOPRINE	MYCOPHENOLATE	LEFLUNOMIDE
Mechanism of action	Blocks the transcription of cytokine genes in activated T cells (particularly IL-2)	Competitive purine antagonist	Inhibitor of IMPDH, a key enzyme in *de novo* purine biosynthesis	Inhibitor of DHODH, the rate-limiting enzyme in the *de novo* synthesis of pyrimidines
Routes of administration	Intravenous and oral	Oral	Intravenous and oral	Oral
Side effects	Mild to moderate GIT toxicosis and	Myelosuppression, hepatotoxicosis, pancreatitis	Mild to severe GIT toxicosis. In	Mild to moderate GIT toxicosis, rare neutropenia

	hepatotoxicosis, gingival hyperplasia		people; rare neutropenia and anemia	and anemia at high doses
Dosage and indications	5 mg/kg/day PO for IBD, perianal fistula and atopic dermatitis. 4-7 mg/kg PO q 12 h for IMHA, IMT	2 mg/kg/24 h PO for the first week, then 2 mg/kg/48 h for IMHA, IMT. 50 mg/dog/day PO for perianal fistula.	10 mg/kg PO or IV q 12 h for IMT, IMHA and myasthenia gravis	4 mg/kg/day for IMT, IMHA, IMPA when used alone. 1-2 mg/kg PO daily when used with other agents.

DHODH, Dihydroorotate dehydrogenase; *GIT*, gastrointestinal tract; *IBD*, inflammatory bowel disease; *IMHA*, immune-mediated hemolytic anemia; *IMPA*, immune-mediated polyarthropathy; *IMPDH*, inosine monophosphate dehydrogenase *IMT*, immune-mediated thrombocytopenia.

Practice: Selecting the Immunosuppressive Protocol

Throughout this textbook the reader will find GCs are considered first-line therapy for most immune diseases despite a lack of clinical trial–generated evidence to support their use. GCs are widely available and inexpensive. The adverse event profile of GCs is well known and can be reversed when the drug is discontinued. Also obvious throughout this textbook is the frequent use of azathioprine as the second-line therapy. Ideally, the selection of immune suppressive drugs would be made based on controlled randomized clinical trials. In actuality, drugs to treat immune disease are frequently chosen based on cost, adverse event profile, availability, mechanism of action and clinical judgment. The following general recommendations regarding the choice of immunosuppressive agents are based on the authors' interpretation of the available literature.

Prednisolone is commonly used in cats because of prednisone bioavailability concerns.[39] Due to its negligible mineralocorticoids effects, dexamethasone is the preferred GC type in patients in which water retention is detrimental.[40,41] Anecdotally, if resistance to GCs is suspected, switching to an alternative GC may result in remission again (Table 195-2).[40-42] Risks versus benefits for using GCs in cats with advanced concurrent heart disease or diabetes mellitus (see ch. 358) should be carefully analyzed. The delayed onset of action of azathioprine indicates it should not be the first choice in the management of the acute phase of life-threatening diseases like IMHA and IMT.[43-45] Cyclosporine, leflunomide and MMF appear to have a more rapid onset of action and hence are more appropriate for managing the acute phase of diseases.[25-35] It is also advisable to avoid using azathioprine in patients with concurrent liver disease.[46] Azathioprine is a good choice as a steroid-sparing agent for managing the maintenance phase of the immune-mediated disease, especially in large dogs.[47,52] Due to its gastrointestinal side effects, oral MMF should be avoided in patients with preexisting gastrointestinal disease.[28-31] MMF dosages higher than 10 mg/kg PO q 12 h are associated with significant gastrointestinal toxicosis.[30] The following section offers more information on immunosuppressive therapy for IMHA as an example of the thought process behind the management of acute, life-threatening, immune-mediated disease.

TABLE 195-2

Relative Potency, Water Retention and Half-Life of Glucocorticoids

DRUG	ANTI-INFLAMMATORY POTENCY	MINERALOCORTICOIDS AND WATER RETENTION EFFECTS	BIOLOGIC HALF-LIFE
Hydrocortisone	1	1	8-12 h
Prednisone/prednisolone	4	0.4-0.8	12-36 h
Methylprednisone	5	0.4	12-36 h
Dexamethasone	25	0	35-54 h
Betamethasone	25	0	>48 h
Triamcinolone	5	0	24-48 h

Immunosuppressive Therapy for IMHA

GCs (see ch. 165) are the mainstay of immunosuppressive therapy for IMHA (see ch. 198).[48] At this point there is no compelling evidence to support using a second immunosuppressive agent in the acute phase (the first 1-2 weeks).[48] Most clinicians recommend using a second immunosuppressive agent to maintain remission and prevent relapse while the GC dosage is tapered. Cyclophosphamide is no longer recommended for the treatment of IMHA.[17,47-51] One large retrospective study incorporating azathioprine into its management protocol for canine IMHA suggested an improved survival time when compared to historical controls.[52] Due to the lack of evidence to support the superiority of the more expensive alternatives, the study resulted in a noticeable shift in clinical practice. GCs combined with azathioprine became the most common immunosuppressive protocol used for canine IMHA. Several other retrospective studies described the use of azathioprine for this disease, with conflicting results regarding its effects on patient outcome.[17,45] Nevertheless, the severity and the high mortality of IMHA pressure many clinicians to use other immunosuppressive agents in addition to GCs and the low cost and good tolerability of azathioprine make it an attractive choice. The use of CsA for IMHA is also frequently reported. The cost of CsA, the variability of absorption, side-effects, and the lack of evidence to support its superiority compared to other cheaper alternatives limited its use over the last few years.[18,19,53,54] A few retrospective studies and ample anecdotal data reported the use of MMF and leflunomide for IMHA.[30-32] Both of these agents are theoretically more appropriate than azathioprine for the acute phase of IMHA.[27-32] A small report described the use of splenectomy in the initial management of canine IMHA, with positive results; however, the vast majority of clinicians reserve this therapy for refractory and chronic cases.[55,56] Liposomal clodronate and plasmapheresis are other promising options that require further study.[24,38,57]

In patients lacking negative prognostic factors (bilirubin >5 mg/dL, autoagglutination, hypoalbuminemia and intravascular hemolysis), the authors generally use GCs alone.[58] In dogs at risk for severe GC side-effects (large-breed and overweight dogs), azathioprine or leflunomide is added to allow a rapid GC taper. Due to cost and gastrointestinal side effects, the authors rarely use MMF or CsA for patients without negative prognostic indicators. For patients with one or more negative prognostic indicators, the clinician could consider starting GC therapy combined with a steroid-sparing agent. The authors start either MMF at 10 mg/kg PO or IV q 12 h or leflunomide at 2-4 mg/kg PO daily and adjust the dosage based on clinical response and adverse effects.[31,32] The limited literature on feline IMHA supports the use of GCs as the sole immunosuppressive agent in most cats.[59] Adding a second immunosuppressive agent is recommended for cats at higher risk of serious GC side-effects, such as overweight cats or cats with concurrent cardiac disease. MMF can be used at 10 mg/kg PO or IV q 12 h.[60] CsA is an alternative to MMF; however, CsA can cause further insulin resistance in diabetic or overweight cats.[61]

Patient Monitoring

Dogs and cats receiving immunosuppressive therapy require frequent monitoring, not only to assess treatment success or failure but also to monitor for complications and adverse events. The frequency of monitoring is dynamic and varies with the different diseases and medications used. At least weekly rechecks with physical examinations for the first month of immunosuppressive therapy are essential for detecting side effects such as appetite loss, gain or loss of body weight/body condition score, gastrointestinal ulceration, pyoderma, muscular weakness or cruciate ligament rupture.[18,62-72] Physical examination is also critical to detect an adverse effect common to all immunosuppressive drugs, secondary infections.[65-69] For more information regarding concurrent infections and immune suppression, see ch. 360. Many veterinarians include assessment of quality of life in their evaluation of pets treated for chronic diseases and this assessment would be appropriate in pets with immune-mediated disease. In order to establish appropriate monitoring protocols, clinicians should be familiar with each drug's adverse effects profile (see ch. 165 and 343). Hematologic toxicosis is most commonly seen with cytotoxic agents and nucleotide/nucleoside analogues, necessitating monitoring of a complete blood count at intervals appropriate for the particular drug. In general, cytotoxic agents induce neutropenia and thrombocytopenia between 7 and 21 days following administration. If immunosuppressive drugs (like chlorambucil or azathioprine, for example) are administered continuously, hematologic toxicosis can appear months after initiation of therapy.[63,65] Regular monitoring of a biochemical profile assists in the identification of adverse events such as pancreatitis and hepatopathy from azathioprine, GC-induced diabetes mellitus and cyclosporine-induced renal and hepatic

toxicoses.[18,46,63,64] Urinary tract infection occurs in approximately 30% of dogs treated with CsA and GCs.[66,70] This finding suggests routine urinalysis, culture and sensitivity in dogs treated with CsA and GCs are warranted. Similar data are not available for other immunosuppressive agents, but good clinical judgment suggests monitoring for urinary tract infections would be prudent. In an effort to optimize drug therapy, blood levels of some immunosuppressive agents such as CsA can be monitored and adjusted to achieve adequate immunosuppression without excessive toxicosis (see ch. 165).

CHAPTER 196

Coagulation Testing

Stephanie A. Smith, Maureen McMichael

Laboratory hemostasis testing generally is divided into preanalytical, analytical (the test), and postanalytical (interpretation) phases. The preanalytical phase covers all aspects of preparation of the patient, collection of the sample, processing and storage, labelling, and submission. Hemostasis testing requires stringent attention to detail, particularly during the preanalytical phase, due to variation in interpretation associated with hematocrit, hemolysis, choice of anticoagulant, and fill volume (anticoagulant to whole-blood ratios). Discussions are ongoing in human medicine about the preanalytical phase (i.e., which test do I order for these clinical signs?), and interpretative hemostasis services can assist with all phases[1] (Table 196-1 and Figure 196-1). Common preanalytical mistakes include inappropriate choice of anticoagulant (e.g., underfilling the citrate [powder-blue-top] tube, or using EDTA [lavender-top tube] instead of citrate), incorrect ratio of anticoagulant to blood, cooling or heating of samples, delayed laboratory transport and inappropriate centrifugation speeds. All of these factors can impact interpretation significantly and could lead to inappropriate therapeutic decisions. Strict adherence to sample collection and handling guidelines is essential for proper interpretation of the results.

TABLE 196-1

Tests for Prothrombotic States and Fibrinolysis

Strengths and weaknesses (pros and cons) of the five tests that can be used for assessment of a prothrombotic state.

TEST	SAMPLE SPECIFICS	WHAT IS TESTED	PROS AND CONS
Thromboelastometry, thromboelastography	Citrated whole blood; max holding = 30 minutes; strong activator	Global hemostasis from initial enzyme generation to fibrinolysis	Pro: includes cells in evaluation of clotting Cons: poor reproducibility without a strong tissue factor or contact activator, interpretation difficult in animals with altered Hct, platelets
Thrombin-antithrombin complexes	Citrated plasma	A marker of *in vivo* thrombin activity	Pro: use of plasma eliminates Hct and platelet effects Cons: expensive, must be batched
Calibrated automated thrombography	Citrated plasma PPP or PRP	Assesses thrombin generation *in vitro*	Pros: sensitive indicator of enzyme generation and activity, can assess platelet contribution with PRP Con: not widely available
D-dimers	Citrated plasma	Degradation of insoluble cross-linked fibrin	Pro: Specific for breakdown of cross-linked fibrin (clot breakdown) Con: Not available in all labs
Fibrin[ogen] degradation products	Citrated plasma	Degradation of insoluble cross-linked fibrin, soluble fibrin monomer, fibrinogen	Pros: inexpensive, simple to run Con: Not specific: can indicate lysis of fibrinogen, fibrin, or cross-linked fibrin

Hct, Hematocrit; *PPP*, platelet-poor plasma; *PRP*, platelet-rich plasma.

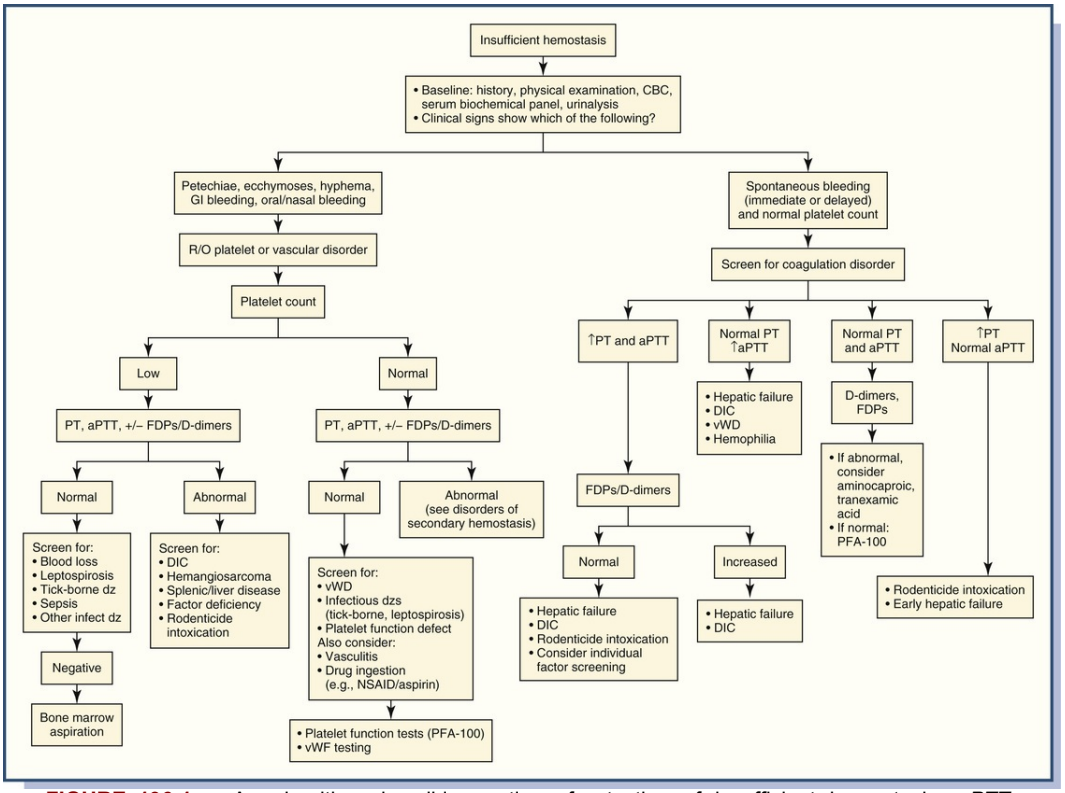

FIGURE 196-1 An algorithm describing options for testing of insufficient hemostasis. *aPTT*, Activated partial thromboplastin time; *CBC*, complete blood count; *DIC*, disseminated intravascular coagulation; *FDP*, fibrin(ogen) degradation products; *infect dz*, infectious diseases; *NSAID*, nonsteroidal anti-inflammatory drug; *PFA*, platelet function analyzer; *PT*, prothrombin time; *R/O*, rule out; *vWD*, von Willebrand disease; *vWF*, von Willebrand factor.

History and Physical Exam

A comprehensive history of a patient with a suspected disorder of hemostasis must include previous bleeding episodes (e.g., associated with ear or tail docking, spay or castration, declawing, loss of deciduous teeth, estrus), the anatomical distribution of bleeding, whether the bleeding was spontaneous or secondary to injury, and whether the bleeding was immediate or delayed. Signalment, breed, age at first episode, travel history, and current medication or toxin exposure should be recorded. Although both congenital and acquired bleeding disorders can cause bleeding anywhere, specific patterns can help to distinguish one bleeding disorder from the other. In general, acquired disorders typically first appear later in life. These patients often have no history of bleeding during previous surgeries (e.g., spay, castration) and could have comorbid conditions. Congenital bleeding disorders often manifest as bleeding episodes associated with challenge to the hemostatic system during youth (e.g., spay, declawing).[2] In patients at risk for thrombosis, essential aspects of the history include predisposing diseases (e.g., hyperadrenocorticism, protein-losing nephropathy, immune-mediated hemolytic anemia [IMHA]), current medications or toxin exposure, and recent interventional procedures (e.g., intravenous catheter placement).[3]

A thorough physical examination is essential, with careful evaluation of the skin, eyes, joints, mucous membranes, urine, and feces for evidence of bleeding (see ch. 135). Disorders affecting the platelet and the vascular wall can include thrombocytopenia, thrombocytopathia, abnormalities of von Willebrand factor (vWF), and vasculitis (see ch. 201). Thrombocytopenia can lead to petechiation if the platelet count is <20,000/mcL, while thrombocytopathia, von Willebrand disease (vWD), and vasculitis more often cause mucosal surface bleeding and bruising.[4,5] Coagulation factor deficiencies or disorders result in ecchymoses, hematomas, and/or muscle, joint, or body cavity bleeding (see ch. 197).[2] In animals at risk for thrombosis, a thorough evaluation of perfusion (e.g., careful palpation of pulses, extremity temperature, mentation, urine output) and the respiratory system are essential. Secondary evaluation of perfusion, to include ultrasound of suspected areas (e.g., distal aorta, femoral vessels, etc.), can be helpful in diagnosing peripheral thromboembolism (see ch. 256). Evaluation of the respiratory system for pulmonary thromboembolism can

reveal an oxygen deficit (tachypnea, pulse oximetry and PaO_2 below accepted range, increased alveolar-arterial gradient; see ch. 128 and 132) with normal thoracic radiographs or mild radiographic changes incongruous with the severity of the clinical signs (e.g., minimal pleural effusion, loss of definition of the pulmonary artery, hyperlucent lung regions; see ch. 243).

Sample Collection and Storage Methods

Ideally, all specimens should be collected prior to therapeutic interventions. Elimination or minimization of preanalytical errors in collection and storage will optimize interpretability of results. Communicating with the laboratory regarding aspects that may affect the test (e.g., hemolysis, icterus, ingestion of a fatty meal) is important. The preanalytical phase recently has been reviewed for veterinary medicine.[6,7] Venipuncture, tube/additive selection, and storage are particularly important. Direct venipuncture into a Vacutainer is the preferred method of collection, as this approach results in less hemolysis than needle and syringe collection.[8,9] Results for prothrombin time (PT), activated partial thromboplastin time (aPTT), and fibrinogen for dogs have been demonstrated to agree clinically between the two collection methods.[10] If using a central line for collection, flushing with heparinized saline followed by removal of at least 3 mL of blood from the catheter before specimen collection will minimize contamination with heparin, saline, or other fluids.[10] The clearance blood may be returned to the patient but will have undergone some degree of contact activation. Immediately following filling, tubes should be inverted 4-6 times.[11] The preferred anticoagulant for complete blood count (CBC) and platelet count is K^+EDTA, a chelating agent that binds calcium.[12] Sodium citrate (3.2%, 1 : 9 ratio citrate to blood) is the anticoagulant of choice for most coagulation assays.[13]

Tests of Platelets and the Vascular Wall

Platelet Count

Thrombocytopenia may be due to decreased platelet production, destruction, loss, or sequestration. Sources of error in automated counts include cells (i.e., microspherocytes, cell fragments) of similar size being counted as platelets, giant platelets being counted as other cells, and agglutination.[14] Manual platelet estimates can be performed by evaluation of a peripheral blood smear using EDTA-anticoagulated blood or fresh samples. An estimate of the count is obtained by multiplying 15×10^3/mcL by the average number of platelets counted from at least 5 oil-immersion fields.

Buccal Mucosal Bleeding Time (BMBT)

The BMBT should only be performed on a patient with a normal platelet count and coagulation panel (see ch. 80).

Cuticle Bleeding Time (CBT)

The CBT test is unpredictable and unreliable, in addition to causing pain. Interpretation is affected by paw movement, which can disturb the forming hemostatic plug. Sedation or anesthesia is often needed, especially if multiple nail cuts are required. The CBT test is not recommended in veterinary patients.

Platelet Function Testing

Options for detection of thrombocytopathia include impedance whole blood platelet aggregometry (WBA), plasma-based light transmission aggregometry, and a commercially available platelet function analyzer (PFA-100). There are also adaptations to thromboelastography/ometry (TE) for testing of thrombocytopathia. Aggregometry techniques, due to cost and requirements for trained personnel, have classically been used for research, but a rapid, automated multiple electrode aggregometry technique (Multiplate) has been developed for WBA with potential for clinical use.[15] The PFA-100 measures time to cessation of whole blood flow (closing time) through a central aperture under high shear conditions. The membrane is coated with collagen and either epinephrine or adenosine-5′-diphosphate (ADP). The collagen/ADP cartridge has a higher sensitivity for canine platelets.[16] Whole blood is collected in sodium citrate and held at room temperature prior to processing.[17] The PFA-100 is easy to use and gives accurate and rapid results that are reproducible.

Platelet aggregation is dependent on platelet number and function, as well as functional vWF.[14] Results can be affected by holding time, anticoagulants, hematocrit and medications.[14,17] The PFA-100 is used as a screening test to detect abnormalities of platelet function but is not specific for any particular disease. A normal PFA-100 closing time result generally rules out a severe platelet function defect or severe vWD, but milder forms of these diseases may still be present. The test had a 95.7% sensitivity and 100% specificity in dogs using the collagen/ADP cartridge in one report.[18]

von Willebrand Factor/von Willebrand Disease

vWD is covered in ch. 201.

Tests of Coagulation

Prothrombin Time (PT)

The PT evaluates the tissue factor pathway (extrinsic; FVII) and the common pathway (FX, FV, prothrombin, fibrinogen; see ch. 197).[19] Citrated plasma is added to $CaCl_2$ and tissue factor in a lipid membrane (thromboplastin); the PT is the time until formation of the first fibrin strands. A prolonged PT (with a normal aPTT) indicates FVII deficiency. Heparin does not generally prolong the PT due to the inclusion of heparin antagonists in commercial PT reagents. Due to the short half-life of FVII, PT prolongation in vitamin K deficiency initially is due to FVII deficiency (not associated with bleeding), but the clinical bleeding occurs with development of prothrombin deficiency.[20]

Activated Partial Thromboplastin Time (aPTT)

The aPTT evaluates the contact pathway (prekallikrein, FXII, FXI); the intrinsic pathway (VIII, IX); and the common pathway (FX, FV, prothrombin, fibrinogen). Note that the only coagulation factors that do not impact the aPTT are FVII and FXIII.[14] Citrated plasma is incubated with a contact activator (e.g., celite, kaolin) and lipids to allow for the generation of FXIIa and FXIa, then recalcified to allow for downstream coagulation steps. The aPTT is the time from recalcification until formation of the first fibrin strands. A prolongation of the aPTT (with a normal PT) is consistent with deficiency of FXII, FXI (hemophilia C), FVIII (hemophilia A), FIX (hemophilia B), or with heparin therapy. Note that FXII deficiency (commonly seen in cats) is a clinically irrelevant incidental finding as it is not associated with clinical bleeding.[21,22]

Conditions associated with prolongation of both the PT and aPTT include anticoagulant rodenticide exposure (vitamin K deficiency), liver disease, disseminated intravascular coagulation (DIC), and hypo- or dysfibrinogenemia.[21]

Activated Clotting Time (ACT)

The ACT is a simple, rapid, inexpensive test that is similar to the aPTT (evaluating all factors except FVII and FXIII) except that it uses whole blood. The tube contains a contact activator, and the platelets in the blood sample provide the lipid surface; note that the ACT therefore can be prolonged with severe thrombocytopenia even when the coagulation cascade is intact.[23] The ACT can screen for rodenticide intoxication, hemophilia, hepatopathy-associated coagulopathies, and DIC.[23] The original ACT tubes (Becton Dickinson) are no longer available. The newer MAX-ACT tube (Helena Laboratories, Beaumont, TX) was designed for use in an automated system. It contains 3 FXII activators (celine, kaolin, glass beads) and a magnet. A manual version of the test (using the tubes alone) has been validated using blood from healthy dogs and cats. The MAX-ACT tube needs to be filled immediately after direct venipuncture (needle and syringe) with 0.5 mL of whole blood, gently tapped to mix the sample without inversion, and placed in a 37° C bath for 30 seconds, then rotated every 5-10 seconds. Visible clot formation is the endpoint. The sensitivity and specificity and validation of its use in animals with clinical bleeding have not been reported. Reported normal values are 66 (range: 55-85) seconds for cats and 71 (range: 55-80) seconds for dogs.[23]

Factor Levels

Concentrations of individual coagulation factors can be measured using specialized modifications of the PT

or aPTT. These tests usually only are available in specialized veterinary laboratories. Factor testing is required to confirm a suspicion of FXII deficiency, or hemophilia A, B, or C, in a patient with a normal PT but prolonged aPTT.[24] The laboratory should be contacted prior to phlebotomy to discuss appropriate sample preparation and testing.

Tests of Fibrinogen and Fibrinolysis

Fibrinogen

Fibrinogen defects can be qualitative (dysfibrinogenemia) or quantitative (hypo- or afibrinogenemia) and either acquired (consumption, decreased hepatic synthesis, or inhibitory antibodies) or congenital. In addition to its role in coagulation, fibrinogen is a strong acute phase reactant in dogs, with increases (hyperfibrinogenemia) occurring during inflammation and infection.[25] The most common assay for detection of fibrinogen activity is the Clauss method, which is coagulation assay based. Low fibrinogen concentrations measured by this method can indicate either hypofibrinogenemia or dysfibrinogenemia.[26] With this method, false decreases can occur due to the presence of anticoagulants, elevations in FDP (fibrin[ogen] degradation product) concentrations, hypoalbuminemia, factor XIII deficiency, or amyloidosis.[27]

Thrombin Time (TT)

In the TT, citrated plasma is made to clot through the addition of thrombin. The TT is the time from recalcification until formation of the first fibrin strands. The TT is an indicator of fibrinogen concentration and/or function. As with the Clauss method, TT results can be increased due to the presence of anticoagulants, elevations in FDPs, hypoalbuminemia, factor XIII deficiency and amyloidosis.[27] Similar to the Clauss method, other factors may falsely prolong the TT.

Fibrin[ogen] Degradation Products (FDPs)

FDPs are created when plasmin lyses fibrinogen, soluble fibrin monomers, insoluble fibrin, and/or cross-linked fibrin. The presence of excess FDPs merely indicates plasmin activity; FDPs are not specific for cross-linked fibrin degradation. FDP concentrations can be increased in a variety of disorders, such as DIC, anticoagulant rodenticide intoxication, hepatic disease, thrombosis, IMHA, neoplasia, pancreatitis, gastric dilation-volvulus, heatstroke, and others.[28,29]

D-dimer

D-dimers are a form of FDP that can only be generated from cross-linked fibrin. Most available assays are immunologic, with no cross-reactivity with fibrinogen or fibrin monomer fragments.[30] Increased D-dimer concentrations indicate thrombin generation, fibrin formation, cross-linking by FXIIIa, and plasmin activity. Because D-dimers have a short half-life, their presence indicates recent (≈5 hours) fibrinolysis.[30] Increased D-dimer concentrations have been reported in dogs with IMHA, liver and renal disease, heart failure, neoplasia, internal hemorrhage, and after surgery.[31] D-dimer assays are commercially available and require a single citrate sample,[30] but not all assays designed for human samples cross-react with animal D-dimers.

Antithrombin (AT) Assay

AT is a member of the serine protease inhibitor (serpin) family. It is an important inhibitor of multiple coagulation enzymes, the most clinically relevant of which are thrombin and FXa. The inhibitory action of AT requires the binding of sulfated proteoglycans (either endothelial cell surface–associated heparans or pharmacologically delivered heparins).[32] Plasma levels of AT can be evaluated via a chromogenic functional assay that measures the *in vitro* ability of AT (provided by the patient sample) to inhibit bovine FXa in the presence of added heparin (both provided by the assay kit). Because many animal AT molecules inhibit bovine FXa with different potency than does human FXa, the degree of inhibition is tested against a standard of pooled normal plasma from the species being tested. The results are then reported as a percentage of normal.[33] AT deficiency is a known risk factor for development of thrombosis. Deficiency can occur due to decreased hepatic production, consumption associated with coagulation activation, or renal or enteric loss.[34-

Indicators of Global Hemostatic Potential and *in Vivo* Hemostasis

New research on the contribution of cells (e.g., platelets, red blood cells) to *in vivo* coagulation highlights the deficiencies of standard coagulation tests, which are performed on platelet-poor plasma (PPP) and are contrived in nature. The following is a general overview of assays that have shown promise in the evaluation of global hemostatic potential and prothrombotic states.

Thromboelastography[ometry] (TE)

Viscoelastic coagulation analyzers, using whole blood, can provide an assessment of global coagulation, from the beginning of clot formation through fibrinolysis. In veterinary medicine, clinical use of viscoelastic technology has been reported in dogs, cats, foals, and adult horses.[37-45] There are, however, substantial limitations to their use, including artifactual data in animals with altered red cell mass.[46,47]

Current point-of-care viscoelastic tests, including the Sonoclot, TEG and ROTEM devices, have been reviewed.[48] The use of the Sonoclot has been reported mostly for equine blood. TEG and ROTEM have been reported in both research and clinical settings with blood from small animals. TE results are not dependent solely on generation of coagulation enzymes but also are impacted by the platelets, red cell mass, and fibrinogen. Abnormalities in these parameters can lead to misinterpretation of TE results.[46,47] Specifically, samples with a higher hematocrit (erythrocytosis) display relatively hypocoagulable tracings while samples with lower hematocrit (anemia) display hypercoagulable tracings, likely due to an artifact of the technology.[45-48] Interpretation of TE, especially in anemic states (e.g., IMHA, hemoabdomen, DIC), may not be possible. Note also that, as with the PT and aPTT, results obtained with TE depend on the activators added to the whole blood sample. The handling conditions applied to the sample can also impact the results obtained; for example, in dogs, longer holding times lead to activation of the contact pathway, and this, or addition of incorrect amounts of tissue factor, or lack of use of a contact activator, can produce results that are erroneous or irrelevant to a patient *in vivo.* Attempts have been made to improve standardization.[49]

Calibrated Automated Thrombogram (CAT)

Thrombin is the central enzyme in hemostasis and thrombosis, but the majority of thrombin is produced after formation of the fibrin clot.[50] The CAT assay evaluates the ability to generate thrombin in real time *in vitro* in response to specific stimuli. It can be used with platelet-poor plasma (PPP) or platelet-rich plasma (PRP) but not whole blood (so the artifact associated with red cell mass that occurs with TE is not a concern). The methodology has been reviewed in detail.[51] CAT sensitively evaluates the contributions of all clotting factors except fibrinogen and FXIII and is sensitive to anticoagulant drugs and direct thrombin inhibitors.[51] Contributions of vWF, hypofibrinogenemia, thrombocytopenia, and antiplatelet drugs can be evaluated using PRP.[52] CAT results have been reported in hypercoagulable states in animals; this is mainly for research, but CAT has potential clinical applications (e.g., drug monitoring).[53,54]

Thrombin-Antithrombin (TAT) ELISA

The half-life of thrombin is extremely short *in vivo,* as it is rapidly inhibited by antithrombin (AT). Consequently, it is not possible to measure the concentration of thrombin directly in plasma. Rather, the concentration of the stable TAT complex is an indirect indicator of thrombin generation *in vivo.* TAT was found to be 97% sensitive for DIC in humans.[55] The commercially available ELISA does cross-react with canine, feline, and equine TAT. An increase in TAT complexes has been reported in Cushing's syndrome, malignant neoplasms, and blastomycosis.[43,56,57] The multi–well plate design and cost generally necessitate batch processing of samples, making this assay impractical for routine clinical use.

Summary

Laboratory evaluation of hemostasis should follow a systematic approach starting with a thorough history and physical exam. General screening tests (platelets, PT, aPTT) should be performed with more specific tests to follow. The location (petechiae, mucosal, venipuncture sites) and timing (intermediate vs. delayed) should

guide the differential diagnoses and consequent testing. Petechiae indicate platelet or vascular disorders (platelet count). Delays in bleeding (e.g., 8-12 hours after surgery) suggest fibrinolytic disorders (TE, FDPs, D-dimers). When a prothrombotic state is suspected, global hemostasis tests (TE value limited with anemia), FDPs, or D-dimers may be indicated. All laboratory tests are dependent on preanalytical variables and need to be interpreted in light of clinical presentation and the results of other diagnostic tests.

CHAPTER 197

Hyper- and Hypocoagulable States

Shauna Blois

Client Information Sheet: Hyper- and Hypocoagulable States

Introduction

The hemostatic system is responsible for controlling hemorrhage while maintaining adequate blood flow. Platelets and plasma coagulation proteins work simultaneously in response to vascular injury and trauma, ultimately generating a thrombin-based blood clot (Figure 197-1). Anticoagulant proteins keep this system in balance by preventing spontaneous generation of clots and eventually lysing formed clots at vascular injury sites.[1] Quantitative and qualitative abnormalities in coagulation process can lead to alterations in normal hemostasis (Box 197-1).

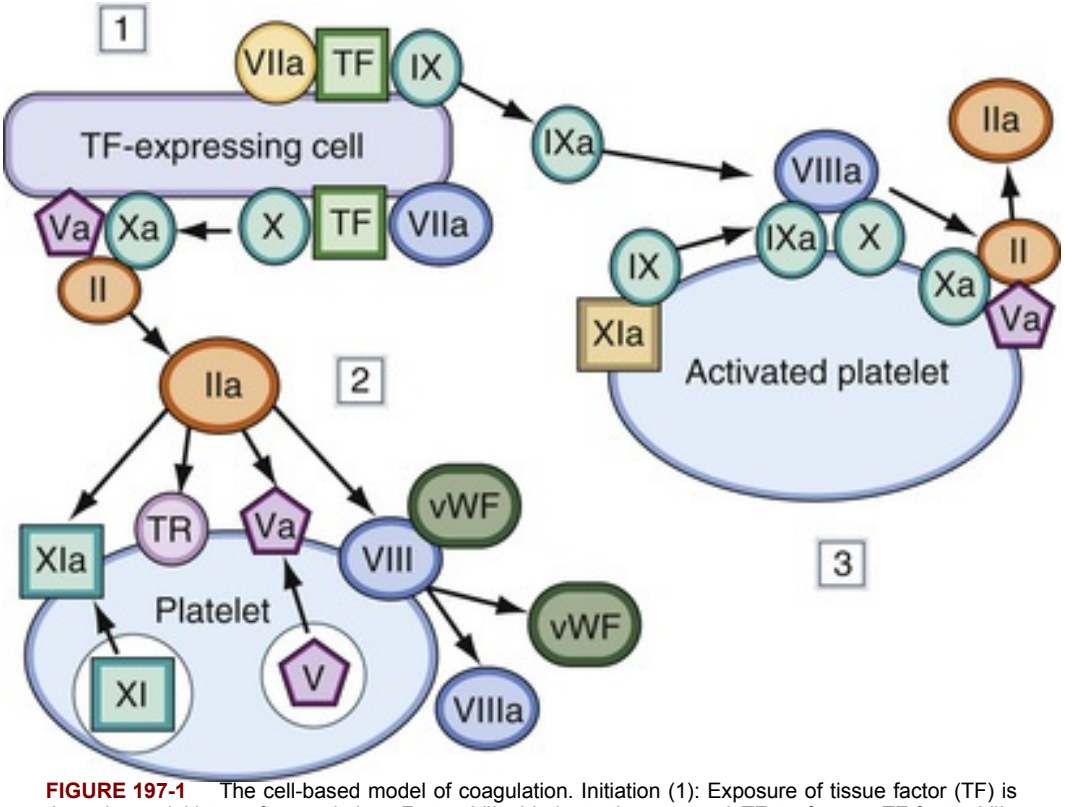

FIGURE 197-1 The cell-based model of coagulation. Initiation (1): Exposure of tissue factor (TF) is the primary initiator of coagulation. Factor VIIa binds to the exposed TF to form a TF-factor VIIa complex. Reactions on the cell surface lead to small amounts of thrombin (factor II) generation. Small amounts of factor IXa diffuse away from the cell surface to activate more platelets or other cells. Amplification (2): The small amount of thrombin generated on the TF-bearing cell surface binds to thrombin receptors (TR) on the surface of platelets. Platelet activation is also facilitated by other stimuli, including von Willebrand factor (vWF) and exposure of collagen in the subendothelial matrix. Upon thrombin binding, platelets undergo morphologic change and release granule contents to further amplify coagulation. Thrombin from the initiation stage activates factor XI and factor V on the platelet surface and liberates vWF from factor VIII to further stimulate platelet activation and aggregation.

Propagation (3): Activated platelets expose ligands to facilitate platelet-platelet interactions and aggregation. Phosphatidylserine is expressed on the surfaces of activated platelets, providing a surface to support the assembly of coagulation factors from the initiation and amplification phases. Factor XIa activates factor IX; factor IXa binds to factor VIIIa to form the tenase complex, leading to activation of factor X. Upon the platelet surface, factor Xa complexes with factor Va, generating a burst of thrombin and converting fibrinogen to fibrin. Fibrin polymerization then forms an insoluble fibrin clot. Roman numerals refer to coagulation factors, "a" denotes activated factor.

Box 197-1

Common Acquired Hemostatic Disturbances in Dogs and Cats

Hypercoagulability

- Immune-mediated hemolytic anemia
- Systemic inflammation
  - Acute pancreatitis
  - Trauma
  - Immune-mediated disease
- Sepsis
- Cardiomyopathy (hypertrophic, restrictive/unclassified, dilated)
- Infective endocarditis
- Heartworm disease
- Protein-losing nephropathy
- Protein-losing enteropathy
- Neoplasia
- Hypothyroidism
- Hyperadrenocorticism
- Corticosteroid therapy
- Diabetes mellitus
- Disseminated intravascular coagulation (initial phase)

Hypocoagulability

- Vitamin K_1 antagonist ingestion (anticoagulant rodenticide)
- Vitamin K_1 deficiency
  - Marked hepatic disease
  - Decreased synthesis by intestinal microflora
  - Severe fat malabsorption (secondary to extrahepatic biliary obstruction, exocrine pancreatic insufficiency, lymphangiectasia)
- Hepatic dysfunction
  - Acute hepatotoxicosis (e.g., *Amanita* ingestion)
  - Cirrhosis
  - Hepatic lipidosis
- Disseminated intravascular coagulation (late phase)
- Acquired anticoagulants (e.g., antiphospholipid antibodies, acquired factor VIII inhibition)
- Neoplasia

Hypercoagulability often is attributed to one or more abnormalities in Virchow's triad: increased coagulability (increased activity of platelets or procoagulant factors, deficiencies of anticoagulant factors, or inhibited fibrinolysis); vascular stasis; and disruption or activation of the vascular endothelium. Thrombosis refers to a blood clot (or thrombus) in a blood vessel occluding blood flow; when a blood clot is dislodged from its origin and travels to a distant site in the circulation, this is referred to as thromboembolism (see ch. 243 and 256). Hypocoagulability can be secondary to decreased platelet or procoagulant activity or excessive fibrinolysis. Such conditions can lead to clinical signs of hemorrhage (see ch. 135).

Hemostatic Testing

Common hemostatic tests include measurement of platelet count, mucosal bleeding times, and coagulation times (e.g., prothrombin time, PT; partial thromboplastin time, PTT; activated clotting time, ACT) (see ch. 196). Activated partial thromboplastin time (aPTT) specifies that the test is potentiated, which was an innovation in test methodology decades ago; today, the test protocol always includes activation, so PTT and aPTT are used interchangeably. Decreased platelet activity can be identified through buccal mucosal bleeding time (see ch. 80), as well as specific platelet function testing (e.g., platelet function analyzer). Prolongation of the PT indicates decreased *in vitro* activity of the extrinsic (factor VII) and common (factors I, II, V, and X) pathways; prolongation of the PTT, the ACT, or both indicates decreased activity of the intrinsic (VIII, IX, XI, XII) and common pathways. Thrombin clot time (TCT) is a direct measure of fibrinogen function (Figure 197-2). In general, PT and/or PTT become(s) prolonged when activity of one or more coagulation factor is/are reduced to <30-50% of normal activity, but this varies depending on the reagents used.[2,3] However, these conventional coagulation tests are insensitive for detection of hypercoagulability.

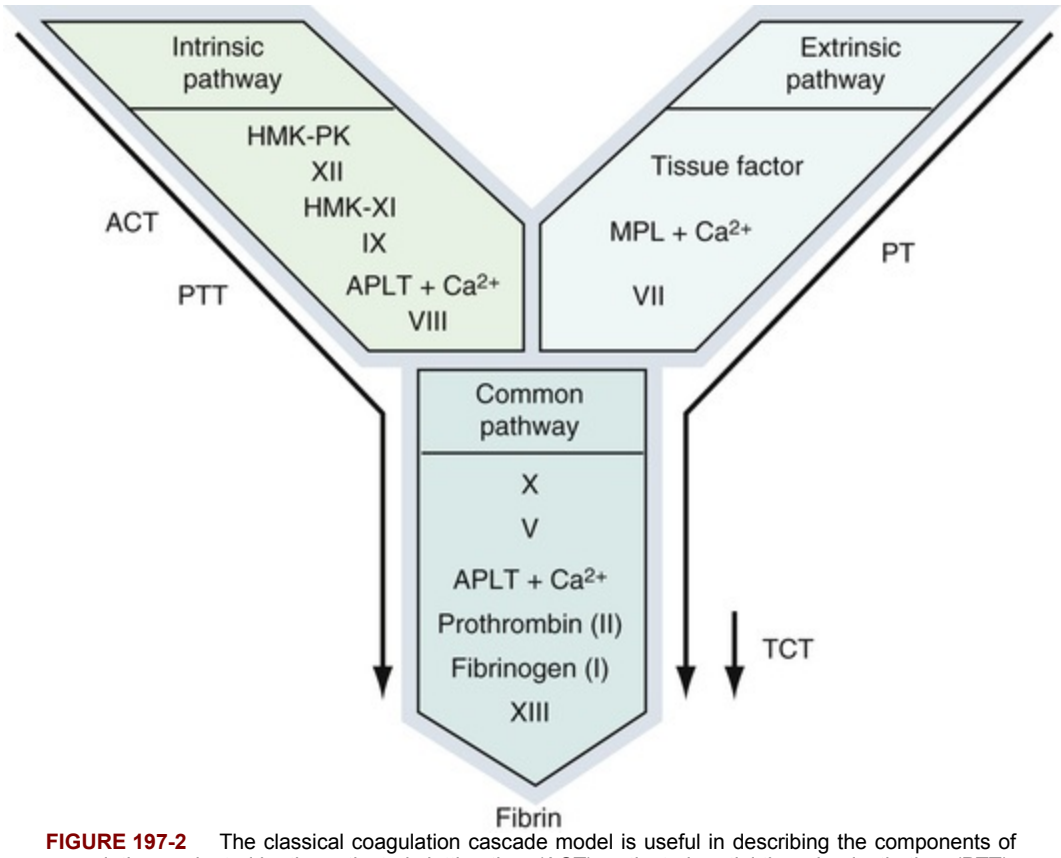

FIGURE 197-2 The classical coagulation cascade model is useful in describing the components of coagulation evaluated by the activated clotting time (ACT), activated partial thromboplastin time (PTT), prothrombin time (PT), and thrombin clotting time (TCT) tests. Roman numerals refer to coagulation factors. *APLT*, Activated platelets; *Ca^{2+}*, calcium ions; *HMK*, high-molecular-weight kininogen; *MPL*, membrane phospholipids; *PK*, prekallikrein.

Viscoelastic testing of hemostasis (thromboelastography, TEG; rotational thromboelastometry, ROTEM) has grown in popularity in veterinary medicine. These whole-blood assays depict clot formation from onset, throughout the process to fibrinolysis. Viscoelastic testing is more likely to correlate with clinical phenotype than is conventional coagulation testing. In one study of dogs, TEG was more sensitive than PT and PTT in detecting hypocoagulability.[4] Viscoelastic testing also is useful in identifying hypercoagulability. However, results of viscoelastic testing can be confounded by several factors. Low hematocrit and hyperfibrinogenemia can produce results consistent with hypercoagulability, while thrombocytopenia can cause results that suggest hypocoagulability.[5,6] Elevated D-dimer concentrations result from lysis of cross-linked fibrin and suggest excessive thrombus formation, but this test has low specificity for thromboembolic disease.[7,8] Thrombin generation assays have been useful in identifying hypocoagulability and could help identify

hypercoagulability.[9,10]

Acquired Hypercoagulable States

Immune-Mediated Hemolytic Anemia

Dogs with immune-mediated hemolytic anemia (IMHA) are prone to thromboembolic disease. Both venous and arterial thromboemboli have been reported in dogs with IMHA, although pulmonary thromboembolism appears to be most common (see ch. 243).

The mortality rate of dogs with IMHA can be up to 80%, with the majority of deaths occurring shortly after diagnosis.[11] Up to half of the deaths are attributed to thromboembolism of major organs, even when preventative anticoagulant therapy is administered.[12,13] Dogs with IMHA usually are hypercoagulable when assessed with viscoelastic testing, although anemia can confound results of these testing methods.[5,14-16] Possible mechanisms of hypercoagulability in IMHA patients include increased platelet reactivity, increased tissue factor expression on monocytes and endothelial cells, exposure of red blood cell membrane phosphatidylserine, circulating procoagulant microparticles, and diminished endogenous anticoagulant activity.[17-20] IMHA creates a systemic inflammatory state in patients, providing further procoagulant stimuli.

Various antiplatelet and anticoagulant treatment strategies are employed to prevent thromboembolic disease in IMHA patients. However, it has been difficult to determine efficacy of these therapies due to lack of controlled studies and difficulty identifying occurrence of thromboembolism in these patients.[20-23]

Cardiac Disease

Hypertrophic cardiomyopathy (HCM) is the most common cause of aortic thromboembolism (ATE) in cats (see ch. 256). The incidence of ATE in HCM cats was reported to be 33% in one study, and reported survival rate of affected cats is approximately 35%.[24,25]

Approximately half of cats with HCM are hypercoagulable.[26] Multiple factors likely contribute to development of hypercoagulability and ATE in cats with HCM. Left atrial enlargement leads to blood stasis and turbulent blood flow. Platelet hyperactivity and endocardial injury also are associated with HCM and could contribute to ATE.[26,27] This complication likely arises after a fragment of thrombus breaks off from the left atrial region and lodges distally, most commonly in the aortic bifurcation.

Prophylactic therapy with anticoagulants or platelet inhibitors is recommended for cats with HCM when high risk of thromboembolism is felt to exist (e.g., a cat with left atrial enlargement that has a history of thromboembolism). Clopidogrel therapy was associated with longer survival times than aspirin in one study of cats with HCM (see ch. 256).[28]

Infective endocarditis and heartworm infection have been associated with thromboembolic disease in dogs.[29] These conditions disrupt normal endothelial integrity and blood flow, promoting development of thromboemboli. Dogs with heartworm disease also have increased platelet reactivity.[30]

Protein-Losing Disorders

Protein-losing nephropathy occurs secondary to glomerular disease (see ch. 325), and it is a common condition in dogs with chronic kidney diseases (see ch. 324). Glomerular damage leads to a protein-losing nephropathy (PLN), whereby low-molecular-weight proteins (albumin, antithrombin) are lost into the urine. Loss of antithrombin appears to be a primary mechanism of thrombosis in PLN patients. Other mechanisms for hypercoagulability in these patients include increased platelet reactivity, hyperfibrinogenemia, and decrease in fibrinolysis.[31,32] The degree of hypercoagulability is not strongly correlated with serum albumin level or antithrombin activity in dogs with PLN.[33]

Dogs with PLN have TEG findings consistent with hypercoagulability.[31,33] PLN is a reported cause of venous and arterial thromboembolic complications in retrospective studies of dogs, and thrombosis has been reported in 14-27% of dogs with PLN.[31,34-36] Hypoalbuminemia might be a marker of thromboembolic risk in patients with PLN, although dogs with normal albumin levels also appear hypercoagulable.[32,33,37]

The prevalence of hypercoagulability also appears high in dogs with protein-losing enteropathy (PLE) based on TEG results, although the reported rate of clinically significant thromboembolic disease is relatively low. Dogs with PLE had marginally low antithrombin levels in one study, a possible mechanism of their

hypercoagulability. However, inflammation itself induces hypercoagulability and therefore the inflammatory condition of these dogs could predispose them to hypercoagulability.[38]

Neoplasia

Coagulation abnormalities frequently are identified in patients with neoplasia, with the majority of these abnormalities being hypercoagulable.[39] Hypercoagulability in patients with neoplasia is hypothesized to be secondary to multiple factors, such as increased soluble or cellular expression of tissue factor, platelet hyperactivity, inflammation, and tumor disruption of vascular endothelium.[40-42] Other risk factors for hemostatic abnormalities in cancer patients are cytotoxic drug therapy and development of disseminated intravascular coagulation (DIC).[35]

Dogs with carcinoma have been shown to be hypercoagulable based on TEG results and have an elevated platelet count and fibrinogen concentration compared to healthy dogs.[43] In a retrospective study, neoplasia was the most common underlying cause identified in dogs with pulmonary thromboembolism (PTE).[35]

Viscoelastic evidence of hypocoagulability was documented in 17% of dogs with neoplasia in one study. Interestingly, all hypocoagulable dogs had metastatic disease.[39] Similarly, prolongation of coagulation times was a common finding in dogs with mammary carcinoma, and it worsened with increasing stage of disease.[44] Cancer patients with hypocoagulability commonly demonstrate thrombocytopenia and prolonged coagulation times. DIC is common in cancer patients, a possible explanation for hypocoagulable tendencies in this population.[45,46] In a large canine study, 20 of 208 dogs (9.6%) presenting with neoplasia were found to have DIC, especially those dogs with hemangiosarcoma, mammary carcinoma, and lung adenocarcinoma.[45]

Therapy of hemostatic abnormalities in cancer patients should target the underlying neoplasm while providing hemostatic support for the patient as needed.

Endocrinopathies

Endocrine diseases appear to increase the risk of thrombosis. Hyperadrenocorticism, hypothyroidism, and diabetes mellitus have been reported as underlying conditions in dogs that develop thrombosis.[35,36,47-49] Furthermore, dogs with hyperadrenocorticism show hypercoagulable tendencies using TEG and other parameters.[50-52] The mechanism of hypercoagulability in dogs with endocrine diseases is unknown. Atherosclerosis has been reported in dogs with hypothyroidism and diabetes mellitus and could be a contributing factor to the hypercoagulable state.[36,53] Therapy for the endocrine disorder is recommended, but hypercoagulability might not resolve with successful therapy.[50] Similar to what is observed with spontaneous hyperadrenocorticism, oral prednisone therapy causes hypercoagulable TEG findings in dogs.[10]

Inflammation and Sepsis

Any disease inducing widespread inflammation, such as acute pancreatitis, sepsis, trauma, and immune-mediated disease, can increase the risk of thrombosis (see ch. 132).[54-57] Inflammation and hemostasis are closely linked processes in the body, and inflammation can induce coagulation via several mechanisms. Systemic bacterial disease was an underlying cause of pulmonary thromboembolism in 20% of dogs in one study.[35]

Proinflammatory cytokines stimulate the production of platelets, and platelet reactivity is enhanced in inflammatory states.[58] Infectious and inflammatory mediators such as endotoxin serve as platelet activators, further increasing platelet activity. Inflammatory cytokines and other mediators increase tissue factor expression on endothelial cells and monocytes, initiating the coagulation via the tissue factor pathway. Anticoagulant activity is diminished in inflammatory states, as is fibrinolysis.[57,59,60] Hypercoagulability associated with systemic inflammatory disorders can progress to DIC. Additionally, hypercoagulability with development of microvascular thrombi is a factor that could contribute to multiple organ dysfunction during sepsis.

Antiplatelet, Anticoagulant, and Thrombolytic Therapy

The most effective methods to treat patients at risk of thromboembolic disease are not well-defined and likely vary depending on the underlying mechanisms. Antiplatelet agents (clopidogrel, low-dose aspirin) and

anticoagulants (warfarin, heparin) are used anecdotally in states of hypercoagulability, but large, prospective, randomized studies investigating efficacy are lacking in many areas. Antiplatelet and anticoagulant therapies do not dissolve existing thrombi but are used for decreasing thrombogenesis and preventing further thrombosis. Reports of systemic and local therapy with tissue plasminogen activator, streptokinase, and urokinase to dissolve existing thrombi are available in the veterinary literature.[61-64] Hemorrhage, reperfusion injury, and embolism are potential adverse effects of thrombolytic therapies. Endovascular stents could be used for treating vascular occlusion (see ch. 122).[62] Multimodal therapy likely is needed to successfully treat patients with severe vascular occlusion secondary to thromboembolic disease.

Acquired Hypocoagulable States

Vitamin K Deficiency

Vitamin K deficiency is one of the most commonly acquired coagulopathies in small animals and it usually is caused by ingestion of vitamin K antagonist rodenticides. Less common causes include decreased vitamin K synthesis from the intestinal microflora and decreased vitamin K absorption.

Vitamin K is an important cofactor in production and activation of the vitamin K–dependent coagulation factors II, VII, IX, and X, and the endogenous anticoagulant proteins C and S. Vitamin K in the reduced form is essential for carboxylation of the glutamic acid residues of these coagulation factors.[65] Anticoagulant rodenticides antagonize vitamin K epoxide reductase, causing rapid depletion of the vitamin K–dependent coagulation factors (Figure 197-3).[66] Factors II, VII, IX, and XI have relatively short half-lives (42, 6.2, 13.9, and 16.5 hours, respectively), and decreased factor levels can be detected shortly after anticoagulant rodenticide ingestion. Dogs and cats consuming rodents intoxicated with anticoagulant rodenticides are unlikely to have coagulopathies result, as the amount of rodenticide within the rodent is small.

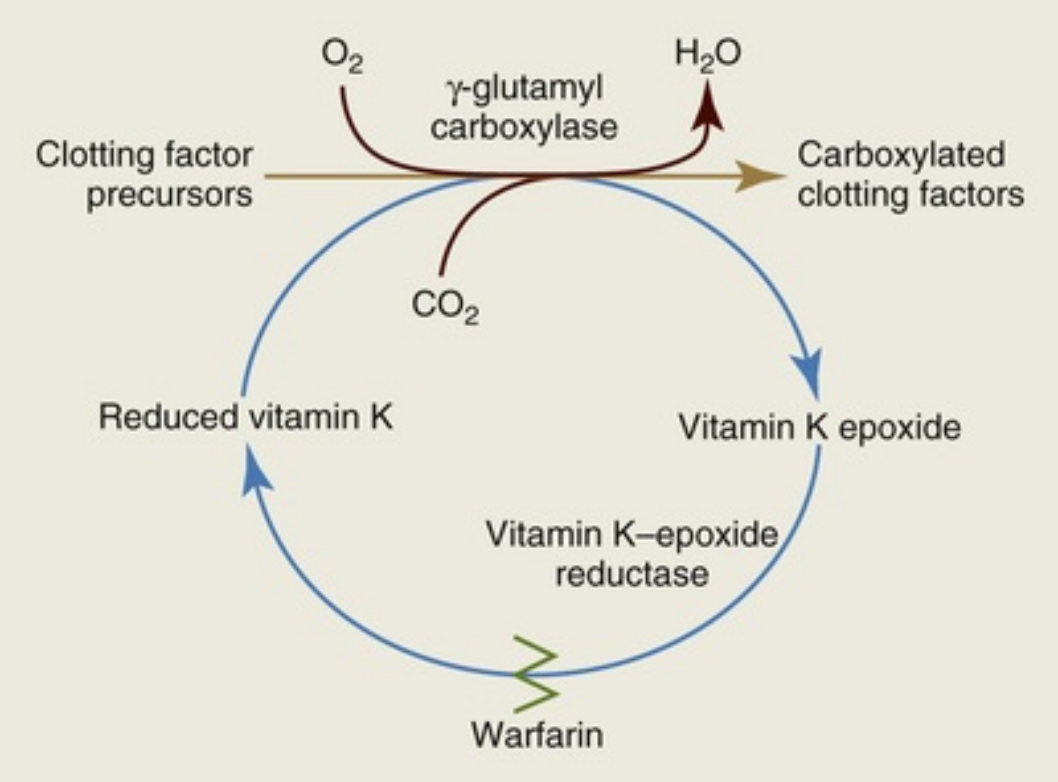

FIGURE 197-3 Vitamin K epoxidase cycle illustrating the carboxylation of clotting factors and the site of warfarin inhibition. (Courtesy Dr. Christian Bédard.)

Clinical signs of bleeding typically are observed 2-5 days after ingestion of anticoagulant rodenticide, and they include epistaxis, melena, hemoptysis, hematochezia, hematoma, ecchymoses, hematuria, and gingival bleeding (see ch. 152). Other clinical signs include dyspnea, coughing, lethargy, collapse, and pallor.[67]

Proteins induced by vitamin K absence/antagonism (PIVKA) levels start to increase within 12 hours of ingestion. PT will be prolonged within 36 to 72 hours, followed by prolongation of PTT and ACT.[67] Blood and serum rodenticide concentrations peak within a few hours of ingestion; liver tissue at necropsy can be used for measuring rodenticide concentration. A point-of-care test is available to detect anticoagulant rodenticide in blood, but it was only useful in detecting warfarin and not second-generation anticoagulant rodenticides in one dog study.[68] A diagnosis of anticoagulant rodenticide intoxication usually is based on consistent history, clinical signs, and coagulation test results.

Following acute ingestion, emetics, adsorbents and cathartics should be given to minimize absorption. Vitamin K_1 (phytonadione) supplementation is recommended. Most commercial anticoagulant rodenticides are second generation (bromadiolone, brodifacoum, and diphacinone) and have a half-life of 5-6 days; therefore, oral vitamin K_1 treatment is recommended for 2-4 weeks (see ch. 152). Prothrombin time typically normalizes 14-36 hours after starting vitamin K_1 therapy.[67] Plasma transfusion quickly will replenish coagulation factors while awaiting the onset of effect of vitamin K_1 therapy, if clinical hemorrhage is significant. Red blood cell transfusion can be necessary in severe hemorrhage cases (see ch. 130). Prothrombin time should be rechecked 36-48 hours after discontinuing vitamin K_1 therapy to ensure normal coagulation status and sufficient treatment duration.

Hepatic Failure

The liver is responsible for synthesizing most pro- and anticoagulant factors, and it plays a central role in hemostasis. Most patients with liver disease have a parallel decline in pro- and anticoagulant proteins, resulting in a relatively balanced hemostatic system *in vivo* in initial disease stages. *In vitro* hemostatic defects (prolonged PT/PTT) commonly are detected in patients with liver disease, but clinical bleeding is uncommon and usually is associated with fulminant or end-stage liver failure.[69-73] Vitamin K deficiency can result from liver disease and it can exacerbate coagulation factor deficiency.

Given the complex and multiple effects that liver disease has on hemostasis, bleeding and/or thrombosis can be consequences. In people with liver failure, the following abnormalities favoring bleeding have been reported: thrombocytopenia, thrombocytopathia, and vessel wall interaction, decreased levels of coagulation factors II, V, VII, IX, X, XI, dysfibrinogenemia, and decreased alpha$_2$-antiplasmin. The following abnormalities favoring thrombosis have been reported: elevated levels of factor VIII and von Willebrand factor and decreased levels of proteins C and S, antithrombin, and plasminogen.[69]

Aside from primary therapy for liver disease (see ch. 281), supportive care in cases of hemorrhage secondary to liver failure can include vitamin K_1 therapy and plasma transfusions.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a systemic activation of coagulation, leading to intravascular fibrin deposition, thrombosis, and organ dysfunction. DIC is a consumptive coagulopathy that can result from many systemic diseases including widespread inflammation, sepsis, and neoplasia.

Tissue factor is a primary mediator of DIC. Normally, tissue factor is not exposed to the circulating blood. However, in states of inflammation and other diseases, proinflammatory cytokines and endotoxins induce tissue factor expression and release. High concentrations of tissue factor can be found on circulating monocytes, endothelial cells, neoplastic cells, microparticles, and other sources. Once in circulation, tissue factor forms a complex with activated factor VII, a potent stimulus for thrombin formation. Excess circulating thrombin cleaves fibrinogen, leaving behind multiple fibrin clots that can lead to microvascular and macrovascular thrombosis. Coagulation inhibitors are consumed in the process, further promoting coagulation. As clots form, platelets become entrapped and thrombocytopenia is identified. Simultaneously, excess circulating thrombin results in the conversion of plasminogen to plasmin, leading to fibrinolysis. Fibrinolysis results in excess amounts of fibrinogen degradation products (FDPs), which have anticoagulant properties, possibly contributing to hemorrhage. Excess plasmin also activates the complement and kinin systems, leading to clinical signs such as shock, hypotension, and increased vascular permeability.[74,75]

During the initial (nonovert, or compensated) stages of DIC, patients are in a hypercoagulable phase. However, procoagulant factors progressively become consumed, leading to a hypocoagulable (overt, or uncompensated) phase. Prolonged coagulation times accompanied by clinical signs of bleeding may be apparent in the hypocoagulable phase. Patients in acute, fulminant DIC present with bleeding; however, in

more chronic forms, patients might show signs only related to the underlying disorder.[74,75]

The diagnosis of DIC can be challenging due to the condition's dynamic nature and considerable variation in coagulation profiles of affected patients. Any animal having experienced prolonged hypotension (see ch. 159), systemic inflammatory response syndrome (see ch. 132), disturbed blood flow to a major organ, or major tissue trauma (see ch. 143 and 147) is at high risk of developing DIC. A combination of clinical and laboratory findings is used for identifying DIC. Typical laboratory findings include prolongation of coagulation times, thrombocytopenia, elevation of fibrinolysis markers (D-dimers and FDPs), hypofibrinogenemia, decreased antithrombin, and signs of red blood cell fragmentation on the blood smear.[74,76] Viscoelastic testing can be used for distinguishing between the various stages of DIC in dogs.[77,78] In one study, the majority of patients suspected to be in DIC were found to have hypercoagulable tracings. In this study, mortality was associated with high D-dimer concentrations, low antithrombin concentrations, and hypocoagulable TEG tracings compared to survivors.[77] Earlier diagnosis of DIC could lead to more prompt intervention, potentially improving survival times. However, viscoelastic test results can be confounded by anemia, thrombocytopenia, and hyperfibrinogenemia, potentially complicating efforts to understand the *in vivo* coagulation status of a patient with DIC.[79]

Treatment of DIC should start by first treating the underlying condition (e.g., antimicrobials for septic patients). Intravenous fluids (see ch. 129) and oxygen therapy (see ch. 131) will promote perfusion and tissue oxygenation. Therapeutic recommendations to address consequences of DIC are controversial. Heparin therapy commonly is used in the hypercoagulable phase of DIC, despite few reports documenting its true benefit.[80] Heparin is an indirect anticoagulant, exerting most of its effect through potentiation of antithrombin activity, which can be diminished in states of DIC. Heparin does not eliminate existing thrombi but could prevent the formation of new thrombi. Use of heparin in veterinary DIC patients has been reported, but optimal dosing regimens are not known.[74,81] Increased morbidity has been reported in people with DIC who receive heparin while actively bleeding; heparin therapy should be avoided in veterinary patients with DIC and evidence of bleeding. Prophylactic plasma transfusion does not show a consistent benefit in humans with DIC, and plasma transfusions usually are recommended only in patients with clinical signs of bleeding.[80] Similarly, fresh frozen plasma or cryoprecipitate therapy (see ch. 130) is recommended in veterinary patients with DIC and signs of bleeding secondary to factor deficiency. Platelet transfusion rarely is indicated in veterinary patients with DIC.[74]

The overall prognosis for DIC is poor and it varies depending on the underlying disorder. Early diagnosis and intervention could lead to improved prognosis.[77]

Acquired Anticoagulants

Spontaneous development of coagulation inhibitors rarely is reported in veterinary patients. Coagulation inhibitors are antibodies (usually IgG) that bind to and inhibit activity of coagulation factor, or cause increased coagulation factor clearance. Acquired anticoagulants can develop secondary to immune-mediated disease, drug reaction, lymphoproliferative disease and other neoplasia, DIC, and following multiple blood transfusions.[82-86] Antiphospholipid protein antibody (i.e., lupus anticoagulant) inhibits interaction between coagulation proteins and cell membranes, causing prolongation of coagulation times such as PTT.[87] Paradoxically, presence of antiphospholipid protein antibodies is associated clinically with thrombosis. Antiphospholipid protein antibodies are reported rarely in veterinary medicine.[88] Development of factor VIII or IX inhibitory antibodies is a reported consequence of multiple transfusions of humans and dogs with hemophilia.[86,89-91]

Clinical signs related to acquired anticoagulants can be absent or can include signs of hemorrhage. Because other aspects of hemostasis might be disrupted, hypercoagulability and thrombosis can be observed concurrently. Coagulation times (PT, PTT) are abnormal depending on which factor(s) is/are affected. A plasma mixing test can be used for supporting a diagnosis of acquired anticoagulant. In this test, various dilutions of patient and control plasma are incubated. If an inhibitor is present, coagulation factor activity in the control plasma will be inhibited and the coagulation test remains abnormal. Confirmatory testing with specific assays can be performed (e.g., Bethesda assay for quantification of factor VIII inhibitor).

General Treatment of Acquired Hypocoagulability

Therapy to address the underlying disorder for hypocoagulability is recommended when possible. Vitamin

K_1 therapy is recommended in anticoagulant rodenticide intoxication cases (see ch. 152) and in liver dysfunction causing coagulopathy (see ch. 281). An initial dose of 2.5-5 mg/kg SC or PO, followed 6-12 hours later with maintenance therapy (0.8-1.7 mg/kg PO q 8 h) can be given. Vitamin K_1 should never be given intravenously as it has been associated with anaphylaxis. Vitamin K_3 therapy is not recommended due to slower onset of action and possible Heinz body formation.

Plasma transfusions can temporarily replenish coagulation factors. Plasma usually is administered at an initial dosage of 10-20 mL/kg (see ch. 130). Fresh frozen plasma contains all coagulation factors and plasma proteins, including the labile coagulation factors (V and VIII). Cryoprecipitate primarily contains factors VIII and XIII, von Willebrand factor, fibrinogen, and fibronectin, at approximately 50-80% of the levels as fresh frozen plasma but in a smaller volume. Cryosupernatant, or cryo-poor plasma, has sufficient quantities of most coagulation factors except for those contained in cryoprecipitate.[92] In comparison, stored plasma contains significantly lower concentrations of factors V and VIII but contains adequate levels of vitamin K-dependent factors and other plasma proteins.[92,93] Either fresh frozen or stored plasma is suitable for replacement of vitamin K-dependent factors, as well as for treatment of other factor deficiencies. Fresh frozen plasma is recommended in patients showing signs of hemorrhage secondary to liver disease or DIC.[94,95]

Hereditary Hypocoagulable States

Scott Syndrome

While Scott syndrome is a defect of procoagulant activity on the platelet surface, it manifests as a coagulopathy because the platelet surface cannot support plasma coagulation protein activity.[96,97] Canine Scott syndrome appears to be an autosomal recessive trait primarily affecting German Shepherd Dogs.[96,98,99] Affected dogs show signs of epistaxis, soft tissue hemorrhage, and surgical hemorrhage; clinical signs can vary in severity.

Scott syndrome is diagnosed by prothrombin consumption assay, or by detecting lack of phosphatidylserine externalized on platelets via flow cytometry. Hemorrhage episodes can be treated with transfusion of platelet products (e.g., cryopreserved platelet-rich plasma), but improvement is only transient.[99]

Hereditary Factor Deficiencies

Single or combined factor deficiencies produce variable clinical signs ranging from asymptomatic states to severe bleeding tendencies. Depending on the deficient factor(s), prolongation of PT and/or PTT is observed (Table 197-1). Measurement of individual coagulation factor activity is required for definitive diagnosis. Genetic testing also is available for some inherited coagulation disorders.

TABLE 197-1

Inherited Coagulation Factor Deficiencies Reported in Dogs and Cats

FACTOR	DEFICIENCY	RESULTS OF ROUTINE SCREENING TESTS
I	Afibrinogenemia; hypofibrinogenemia; dysfibrinogenemia	↑ PT, PTT, ACT ↓ to normal fibrinogen
II	Hypoprothrombinemia	↑ PT, PTT, ACT Normal fibrinogen
VII	Hypoproconvertinemia	↑ PT Normal PTT, ACT, fibrinogen
VIII	Hemophilia A	↑ PTT, ACT Normal PT, fibrinogen
IX	Hemophilia B (Christmas disease)	↑ PTT, ACT Normal PT, fibrinogen
X	Stuart-Prower deficiency	↑ PT, PTT, ACT Normal fibrinogen

XI	Hemophilia C	↑ PTT, ACT Normal PT, fibrinogen
XII	Hageman trait	↑ PTT, ACT Normal PT, fibrinogen
XIII	Factor XIII deficiency	Normal PT, PTT, ACT, fibrinogen
II, VII, IX, and X	Combined vitamin K-dependent factor deficiency	↑ PT, PTT, ACT Normal fibrinogen

ACT, Activated clotting time; *PT*, prothrombin time; *PTT*, partial thromboplastin time.

Hemophilia A and B

Hemophilia A is a deficiency of factor VIII, and hemophilia B is a deficiency of factor IX. Hemophilia A is more common than hemophilia B, and both forms have been documented in dogs and cats.[100-107] Hemophilia A and B are autosomal, X-linked, recessive traits, primarily affecting males while females are carriers.[100] Various genetic mutations are responsible for hemophilia A or B. In some cases, hemophilia within a pedigree can be traced to the original index animal, whereas other cases are suspected to arise from *de novo* mutations.[100,102,108]

Lack of factor VIII or IX inhibits formation of the tenase complex, hindering downstream thrombin generation and blood clot formation. Accordingly, hemorrhage is the principal clinical sign associated with hemophilia A or B, and this hemorrhage typically can manifest as prolonged bleeding after trauma or surgery, subcutaneous or intramuscular hematomas, mucosal bleeding, or lameness due to hemarthrosis.[94,104,106,109]

Hemophilia A or B is suspected in patients with a bleeding diathesis and prolonged PTT or ACT, with a concurrently normal PT. Measurement of coagulation factor activity (FVIII:C or FIX:C) is required for a definitive diagnosis. Normal factor activity levels are 50-150%. Hemophilia is considered mild when the corresponding factor level is ≈6-20%; moderate and marked hemophilia can be defined when factor levels are ≈2-5% and <2%, respectively.[106,110] Severity of factor deficiency correlates with clinical signs in affected people, although additional variables such as function of other hemostatic proteins, the patient's physical condition, and concurrent illness play a role.[111,112] Occurrence of spontaneous bleeding episodes was not significantly different between dogs with mild, moderate, and severe hemophilia A in one study.[106]

Depending on the severity of hemorrhage episodes, transfusion can be used for replacing deficient factors and alleviating short-term bleeding (see ch. 130). While injection of desmopressin temporarily increases circulating factor VIII concentrations in people, the same does not appear to be true in dogs.[113] Prophylactic transfusion might be warranted in patients with hemophilia prior to performing invasive procedures.

The prognosis for dogs and cats with hemophilia appears variable. Severely affected animals likely die at birth. Prognosis did not correlate with degree of factor deficiency in dogs with hemophilia A in one study.[106] Following transfusion, the patient can develop inhibitors to the deficient factor (i.e., factor VIII or IX inhibitors), leading to higher transfusion requirements on subsequent transfusions.[86,90,91] Post-transfusion purpura was reported in a dog with hemophilia A and was successfully treated with corticosteroids.[114] Pedigree analysis and factor activity levels should be analyzed in breeding groups that have given rise to individuals affected by hemophilia. Factor levels often are low-normal in carrier females and can overlap with those of unaffected females, making it difficult to determine carrier status based on factor analysis alone. Lack of clinical signs in carrier or mildly affected animals can lead to propagation of the condition through a pedigree.

Other Inherited Coagulation Factor Deficiencies

Hereditary fibrinogen (factor I) disorders include complete or partial lack of fibrinogen (afibrinogenemia and hypofibrinogenemia, respectively) and qualitative defects in fibrinogen (dysfibrinogenemia).[100,115] Disorders of fibrinogen appear to be uncommon in dogs but have been reported.[100,116-118] Depending on the severity of the disorder, hemorrhage might occur spontaneously or after trauma or surgery. Paradoxically, affected patients also can have thrombosis.[100,115-117] Fibrinogen defects can be suspected when PT, PTT, ACT, and TCT are prolonged; quantitative fibrinogen disorders will have a concurrently decreased fibrinogen concentration. Patients with dysfibrinogenemia typically have normal to low fibrinogen concentrations and

low functional fibrinogen activity (e.g., Clauss test).[117] Due to the uncommon nature of hereditary fibrinogen disorders, more common causes of low fibrinogen concentrations such as DIC or liver disease should be ruled out first.

Other inherited factor deficiencies resulting in hemorrhage have been described, including factor II deficiency in dogs[118]; factor VII deficiency in dogs[107,118-123]; factor X deficiency in dogs[118,124] and cats[125]; factor XI deficiency in dogs[126] and cats[127]; and factor XIII deficiency in a dog.[128]

Feline factor XII deficiency (Hageman trait) is the most common defect of the intrinsic (contact) pathway factors. Cats with factor XII deficiency demonstrate prolonged PTT, but hemorrhage or other clinical signs do not result from this deficiency as *in vivo* clot formation is primarily dependent on factor VII and tissue factor activation.[46,129,130] Concurrent hemophilia A or B has been reported in cats with factor XII deficiency, and it can give rise to clinical signs of hemorrhage.[131,132]

Congenital deficiency of the vitamin K–dependent coagulation factors results from defective gamma-glutamyl carboxylase or vitamin K 2,3-epoxide reductase (VKOR) complex in people. This disorder causes combined factor deficiencies (factors II, VII, IX, and X; anticoagulant proteins C, S, and Z) and results in variable bleeding, as well as skeletal and other developmental disorders in people.[133] A defect in vitamin K gamma-glutamyl carboxylase has been reported in Devon Rex cats, leading to deficiency of vitamin K-dependent coagulation factors and spontaneous bleeding in some affected cats.[134,135] Affected cats have prolonged PT, PTT and ACT, as well as increased PIVKA; factors II, VII, IX, and X activities are diminished. Ingestion of anticoagulant rodenticide should be ruled out prior to pursuing a diagnosis of congenital deficiency of vitamin K–dependent factors. Definitive diagnosis requires hepatic biopsy to identify enzymatic defects.[135] Vitamin K_1 therapy normalizes coagulation factor levels and clinical signs of hemorrhage.[134] Vitamin K–dependent factor deficiency has also been reported in a young Labrador Retriever, although the exact mechanism of deficiency in this case was unknown.[136]

Treatment of Inherited Coagulopathies

Single or combined factor deficiencies can be treated using a plasma product transfusion to temporarily replenish the deficient factor(s) during episodes of hemorrhage (see ch. 130). Plasma dosages are similar to those outlined above for acquired coagulopathies. Fresh frozen plasma can be used for most factor deficiencies, including hemophilia A. Stored plasma lacks factors V and VIII but can be used to treat other factor deficiencies. Cryoprecipitate is suitable for transfusing smaller plasma volumes rich in factors I, VIII, and XIII; cryosupernatant is lacking in those factors but can be used for treating other deficiencies. Factor XII deficiency does not require treatment as it does not result in clinical signs.

CHAPTER 198

Immune-Mediated Hemolytic Anemias and Other Regenerative Anemias

Christine Piek

Client Information Sheet: Immune-Mediated Hemolytic Anemia (IMHA) in Dogs

Definitions and Overview

Anemia is defined as a reduction in circulating red blood cell (RBC) numbers, hematocrit (Ht) and hemoglobin, causing decreased oxygen carrying capacity of the blood (also see ch. 57). Anemia results from diseases causing decreased RBC production, loss of RBCs, destruction of RBCs or some combination thereof. Documentation of adequate erythropoiesis in response to an anemia is instrumental in differentiating those causal categories. Erythropoiesis is part of hematopoiesis and starts with the production of stem cells in the bone marrow (BM) that subsequently differentiate into RBCs, granulocytes, monocytes, platelets and other cells of the immune system. The organ producing RBCs is called the erythron. In the fetus, erythropoiesis is found in the BM and liver.[1,2] After birth, erythropoiesis takes place in the BM and, in anemia, extramedullary erythropoiesis may take place in the liver and spleen. Circulating RBC mass reflects the balance between production and destruction or loss. The hormone erythropoietin is the physiological regulator of RBC production.[2] Increased erythropoietin concentrations induced by renal cortical hypoxia increases proliferation and differentiation of erythroid precursors in a healthy erythron.[2,3]

In the BM, RBC precursors may be identified in so-called erythroblastic islands. Here, erythroblasts at different stages of development closely surround macrophages that provide the necessary iron for hemoglobin production.[3] These erythroid precursors proliferate and differentiate from proerythroblasts into basophilic erythroblasts, polychromatic erythroblasts, orthochromatic erythroblasts, reticulocytes, and finally, into mature RBCs.[3] This process takes about 5-7 days.[4-7] In health, reticulocytes remain in the BM for 2-3 days before being expelled into the bloodstream. Their residual RNA, which distinguishes them from mature RBCs, is gradually lost during the first 24 to 48 hours in the circulation.[6,7] RBCs that retain small clumps of RNA, visible with new methylene blue or brilliant cresyl blue staining, are called aggregate reticulocytes.[5] After an episode of hemolysis or blood loss, aggregate reticulocytes start to appear within 48 hours. In cats, aggregate reticulocytes develop into punctate reticulocytes in which only one to three small RNA clumps are visible before maturing into RBCs. These punctate reticulocytes may remain in circulation for 2-3 weeks.[5]

Recognizing Regenerative Anemia

The number of aggregate reticulocytes may be counted microscopically or with a hematology analyzer per number of circulating RBCs.[5] They may be reported as a percentage or converted to the reticulocyte number per volume of blood.[5] Because reticulocytes are measured as a percentage of circulating RBCs, they may increase in the early response to anemia after blood loss or hemolysis without an increase in actual RBC production. The reticulocyte percentage must be evaluated in association with the corresponding decrease in Ht. This may be done by assessing the corrected reticulocyte percentage, which can be calculated by multiplying the observed reticulocyte count by the patient's Ht, divided by the Ht in health. The latter may be estimated from Ht reference values. Adequate RBC regeneration is present when the corrected reticulocyte percentage is above the reticulocyte reference range.[5] In health, reticulocyte numbers are low, around 1% of circulating RBCs. Therefore, the coefficients of variation for both manual (8-23%) and automated counts (5-8%) are relatively high.[8] This variation should be taken into account when the adequacy of reticulocytosis is

assessed.

It usually takes 2-5 days for reticulocytosis to develop after a hemorrhagic or hemolytic event.[5] Under the influence of erythropoietin, reticulocytes can be prematurely released from the BM, together with late polychromatophilic erythroblasts or so-called normoblasts.[4,5] Immature reticulocytes may be recognized in a blood smear by their relatively large size and polychromatic cytoplasm. Reticulocytosis in these cases merely reflects early BM release, not increased production. This may present a "flattering image" of RBC production but is not a reliable estimate.[5] It has been suggested that these immature reticulocytes require 2 to 3 times longer before becoming mature RBCs.[5]

Determining whether RBC production is appropriate in anemia, likely after blood loss or hemolysis, rests upon the clinician. One must allow sufficient time for the BM to show a regenerative response following acute hemolysis or blood loss and 4-5 days is usually needed for release of new reticulocytes. Cytological and/or histological examination of a BM biopsy may allow assessment of the RBC response earlier (see ch. 92). It is rarely necessary to perform a BM biopsy for the sole purpose of documenting an adequate regenerative response. In many cases a reevaluation of the Ht and reticulocytes after 1-3 days suffices to document the presence of adequate RBC regeneration.

Diagnostic Approach to Regenerative Anemias

Differential Diagnosis

Regenerative anemia is caused by RBC loss, destruction, or both. The differential diagnosis for erythrocyte destruction can be categorized as acquired non-immune hemolytic anemias, hemophagocytic disorders, and the immune-mediated hemolytic anemias (Box 198-1). Acquired non-immune hemolytic anemias include diseases that destroy RBCs due to direct membrane damage, oxidative damage, infections, erythrocyte fragmentation, and conditions that interfere with RBC energy metabolism. Even a detailed differential diagnosis may not be complete. Diseases in which RBC lifespan is shortened but without anemia and some extremely rare diseases have been omitted from this chapter. Successful diagnosis depends on understanding the characteristics and prevalence of the individual conditions in the differential diagnosis as well as having an appreciation for the diagnostic tests that discriminate them. The diagnostic approach (Figure 198-1) utilizes a rational approach in dogs with regenerative anemia that first aims to make optimal use of information available in the history and physical examination. Additional tests further discriminate between the differential diagnoses.

Box 198-1

Differential Diagnosis of Disorders Causing Hemolytic Regenerative Anemia

Acquired Non-Immune Hemolytic Anemias

- Intoxications
  - Venoms such as snake bites,[36-39] bee stings[40,41]
  - Oxidative substances causing Heinz body anemia[43]: zinc,[45-51] acetaminophen (cats),[53,54] methylene blue (cats),[55] onions (dogs)[44,225-227]
- Infections
  - Canine babesiosis[64,66]
  - *Mycoplasma haemofelis*[88,228]
- Red cell fragmentation syndromes[95]
  - Neoplasia (hemangiosarcoma)[95,97]
  - Hemolytic uremic syndrome[99,229,230]
- Hereditary hemolytic anemias
  - Erythrocyte enzyme deficiencies[101,186]
    - Pyruvate kinase deficiency in cats*[231,232] and dogs†[95,233-236]
    - Phosphofructokinase deficiency in dogs‡[26,32,237]
  - Erythrocyte membrane disorders

Stomatocytosis[§25,31,111-113]

Feline hypophosphatemia

In diabetes mellitus, hepatic lipidosis, and enteral alimentation[57-59]

Hemophagocytic Anemias

Hemophagocytic histiosarcoma[¶116,123]

Immune-Mediated Hemolytic Anemias

Idiopathic immune-mediated hemolytic anemia

Secondary immune-mediated hemolytic anemia

Infectious diseases (viral, protozoal, bacterial)

Neoplasia

Medications[187-189]

Penicillins, cephalosporins,[191] sulfonamides,[192,193] methimazole[194,195]

Autoimmune disorders

Idiopathic immune-mediated thrombocytopenia[131,168]

Alloimmune hemolytic anemia

Feline neonatal isoerythrolysis[218]

Incompatible blood transfusions[238,239]

---

[*] Abyssinian, Somali, Domestic Shorthair; PK deficiency-associated single nuclear polymorphisms occur in 12 breeds [231].

[†] Reported breed predisposition: Basenji, Beagle, Cairn Terrier, Chihuahua, Dachshund, Pug, Labrador Retriever, Toy American Eskimo Dog, West Highland White Terrier.

[‡] Reported breed predisposition: English Springer Spaniel, American Cocker Spaniel, Whippet, Wachtelhund.

[§] Reported breed predisposition: Alaskan Malamute, Drentse Patrijshond, Miniature Schnauzer, Standard Schnauzer.

[¶] Reported breed predisposition: Bernese Mountain Dog, Rottweiler, Golden Retriever, Flat-coated Retriever.

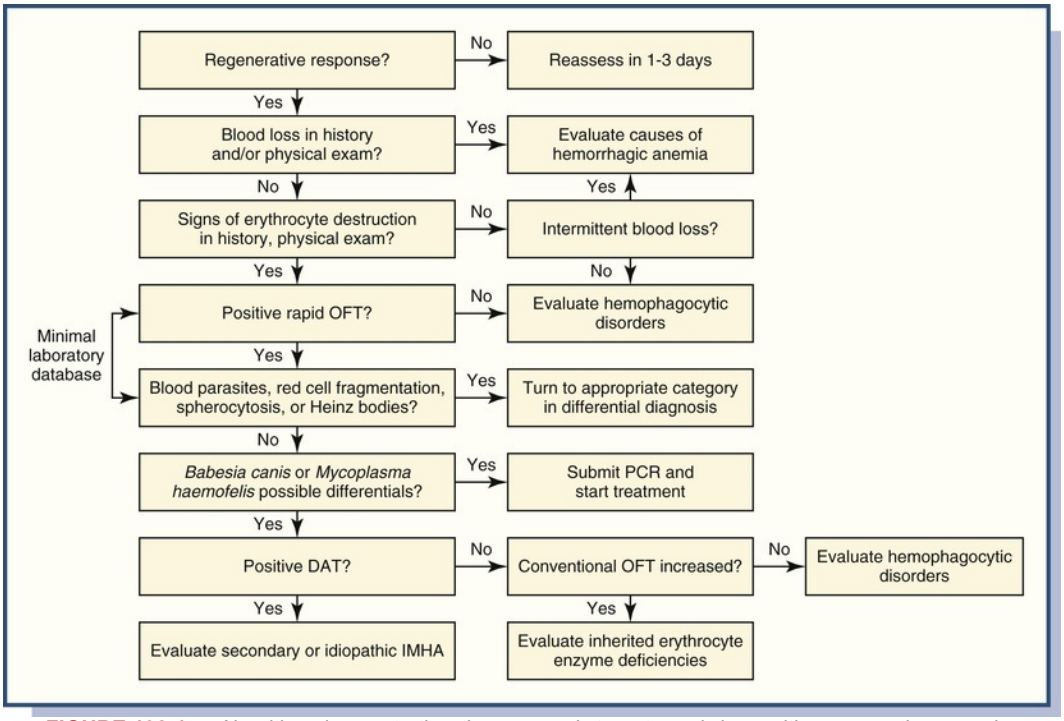

FIGURE 198-1 Algorithm demonstrating the approach to cats and dogs with regenerative anemia. *DAT*, Direct agglutination test; *IMHA*, immune-mediated hemolytic anemia; *OFT*, osmotic fragility test; *PCR*, polymerase chain reaction.

Hemorrhage vs. Hemolysis

The diagnostic pathway starts with differentiating hemorrhagic from hemolytic regenerative anemias. History and physical exam almost always identify external blood loss (see ch. 135). Disorders of abdominal organs, such as neoplasia or amyloidosis, may cause intermittent bleeding that is more difficult to recognize.[9-11] Occult blood loss in the gastrointestinal tract usually begins as a regenerative anemia but ultimately the anemia becomes non-regenerative due to iron deficiency.[12,13] If there is no evidence of blood loss, hemolysis is the next likely explanation for regenerative anemias. Senescent RBCs in health undergo macrophage erythrophagocytosis in the BM, spleen, and liver. In hemolytic diseases, hemolysis may also occur in the intravascular space, causing hemoglobinemia and hemoglobinuria. Clinical signs from hemolysis are usually those of anemia. In severe, acute hemolysis, hypoxemia may cause tissue necrosis and a decrease in hepatic capacity for handling RBCs. In this scenario, icterus may develop. Massive hemoglobin breakdown may result in orange-yellow color of the feces since hemoglobin breakdown products are ultimately excreted via the bile in the duodenum. Hemolysis may be confirmed by the presence of signs such as red urine, yellow feces, and icterus in the history or on the physical exam.

Available Tests

Blood Smears and Rapid Osmotic Fragility Testing

After obtaining a history and physical examination, one should evaluate a blood smear microscopically. In regenerative anemias, macrocytes with polychromasia reflect the degree of reticulocytosis while RBC precursors (e.g., normoblasts) may be seen. Parasites, such as *Babesia* or *Mycoplasma haemofelis,* may be readily identified. In acute anemias, such infections should be excluded by molecular diagnostic testing. One should note presence and numbers of spherocytes. Red cell fragmentation disorders may be detected microscopically, as may Heinz body anemias. Alternatively, the findings on the smear may be indicative of the pathophysiologic route to anemia, such as the finding of microcytes and hypochromasia in iron deficiency anemia.[12,13] The osmotic fragility test (OFT) is of use in discriminating hemolytic from non-hemolytic conditions.[14] Hemolysis can be observed after centrifuging (5 minutes, 2431 × g) RBCs that have first been separated into 2 tubes, one incubated for 5 minutes in 0.9%, the other in 0.55% saline.[14,15] The test is negative if no color difference is observed between the supernatant in the two tubes and positive if the supernatant in the tube with 0.55% saline is obviously more red. A modification includes a negative RBC control (Figure 198-2).

RAPID OSMOTIC FRAGILITY TEST OF ERYTHROCYTES

LABORATORY PROTOCOL

MATERIALS

- 4 clean numbered empty reaction tubes
- 5 mL syringe
- Pasteur's pipette
- Fresh blood sample (EDTA or heparin) of healthy dog or cat as a negative control
- Fresh blood sample (EDTA or heparin) of patient

METHOD

1.
In DOGS: add 0.9% NaCl, (tap) water and (heparin or EDTA) blood in 4 numbered reaction tubes

Tube nr	0.9% NaCl	H_2O	BLOOD NORMAL DOG	BLOOD PATIENT
1	5 mL	--	5 drops	--
2	5 mL	--	--	5 drops
3	3 mL	2 mL	5 drops	--
4	3 mL	2 mL	--	5 drops

In CATS: add 0.9% NaCl, (tap) water and (heparin or EDTA) blood in 4 numbered reaction tubes

Tube nr	0.9% NaCl	H_2O	BLOOD NORMAL CAT	BLOOD PATIENT
1	5.5 mL	--	5 drops	--
2	5.5 mL	--	--	5 drops
3	4 mL	1.5 mL	5 drops	--
4	4 mL	1.5 mL	--	5 drops

2. Mix tubes using vortex
3. Incubate for **5 minutes at room temperature**
4. Centrifuge for 5 minutes at 2431 × g
5. Results:
   Tube 1 and 3 should be clear. Erythrocytes should be intact on bottoms of tubes.
   Tube 2 can be slightly hemolyzed if plasma of patient was already hemolytic.
   Tube 4 will show more hemolysis than tube 2 if osmotic fragility is increased.

FIGURE 198-2 Material needed and protocol to follow for performing a rapid osmotic fragility test of erythrocytes.

Spherocytes and Osmotic Fragility Testing

Immune-mediated hemolytic anemias (IMHAs) are common and often first suspected after noting extensive spherocytosis in blood smears. The identification of spherocytes is subjective, requiring expertise and experience.[15,21] The rapid OFT provides an objective alternative to searching for spherocytes and may be performed as an in-house test, making the results directly available.[14,15] The OFT detects erythrocyte membrane defects and is positive in 85%-100% of dogs with IMHA.[14,15,21] Both the rapid and the conventional OFT may be positive in diseases other than IMHA, however. These include hereditary erythrocyte membrane defects and other diseases affecting erythrocyte membrane stability.[14,22-35]

Direct Agglutination Test (DAT)

Diagnosis of IMHA can be further supported with a positive DAT (Coombs' test) result.[16-20] Starting treatment early in the course of the disease is important, and is one of the determining factors in outcome. Thus, results of diagnostic tests should be available quickly. The conventional DAT offered by most laboratories specializing in veterinary hematology may delay definitive diagnosis of IMHA. Various

alternative DAT techniques have been described that may soon be available for in-house testing.[21] Importantly, DAT results are not influenced by storing samples for a few days, immunosuppression, or transfusions.[21] If the DAT is negative, a diagnosis of alternative conditions should be pursued. A definitive diagnosis of IMHA is based on a positive DAT or spherocytosis. Erythrocyte integrity is not compromised in hemophagocytic disorders and both the OFT and DAT are negative in these conditions. A breed predisposition or the presence of cranial abdominal organomegaly may suggest the presence of a hemophagocytic disorder earlier in the diagnostic pathway.

Differential Diagnosis for Hemolysis

Overview

The differential diagnoses are grouped as acquired non-immune hemolytic, immune-mediated hemolytic, and the hereditary hemolytic disorders (see Box 198-1). Acquired hemolysis may result from direct RBC exposure to chemicals, physical stresses, infection, or may be mediated by antibodies. In hereditary diseases, RBCs may be more susceptible to hemolysis.

Acquired Non-Immune Hemolytic Anemias

Red Cell Toxins

Acquired non-immune hemolytic disorders may result from direct toxicity, such as with snake or bee sting venoms. This may be obvious from the history and physical exam.[36-41] Chemical substances may have an oxidative effect that damages erythrocyte membranes via reactive oxygen species, which denature hemoglobin and result in methemoglobinemia and Heinz body formation. Small numbers of Heinz bodies probably have little consequence, but excessive Heinz body formation increases RBC rigidity, making them susceptible to hemolysis.[42] Heinz bodies stain the same color as RBCs and appear as single masses extending from the more central areas and forming blunt projections from cell membranes.[43] Up to 80% of RBCs from dogs fed onions contained Heinz bodies and up to 6% had eccentrocytes 1-3 days after ingestion.[44] Ingested metal pieces containing zinc may cause Heinz body anemia.[45-51] All 19 dogs in a retrospective case series of dogs with zinc intoxication were anemic and about half had Heinz bodies at presentation.[47] Diagnosis is made by determination of zinc concentrations. Increased numbers of Heinz bodies have been seen in cats with diabetes mellitus, hyperthyroidism, and lymphoma. Hematocrits in these cats were only moderately decreased.[52] Heinz body formation, usually with severe hemolysis, has been reported in acetaminophen and methylene blue toxicosis.[53-55]

Hypophosphatemia

Hypophosphatemia decreases red cell adenosine triphosphate stores, making them susceptible to hemolysis.[56] Severe hypophosphatemia causing hemolytic anemia has been reported almost exclusively in cats with diabetes mellitus, in hepatic lipidosis, and following enteral alimentation.[57-59] It may be diagnosed based on history and plasma inorganic phosphate concentrations.

Red Cell Infections

Background

Infection-associated hemolysis may be due to direct exposure or to products of viral, bacterial or parasitic agents. Babesiosis and feline hemoplasmosis are the two most common infectious diseases that cause hemolysis and regenerative anemias. Feline cytauxzoonosis, most commonly but not exclusively from the Midwestern United States, may cause hemolytic but non-regenerative anemias.[60-63]

Babesiosis

Canine babesiosis is a protozoal tick-borne disease with a worldwide distribution (see ch. 221). The disease may be caused by different *Babesia* species, depending on location.[64-66] *B. gibsoni* infection can follow direct dog-to-dog transmission.[67,68] Feline babesiosis is less common and has mostly been reported from South Africa.[69-71] Regenerative anemia results from acute hemolysis. Intravascular hemolysis is due to direct RBC

damage by intracellular parasitic replication. Depending on the *Babesia* species, hemolysis can be caused by serum hemolytic substances, oxidative damage, or antibody binding to RBCs. Antibody binding stimulates complement activation, spherocyte formation, and increased RBC osmotic fragility.[64,72-76] Extravascular hemolysis may result from increased erythrophagocytosis.[64] Splenic erythrocyte sequestration may contribute to development of anemia.[77,78]

Clinical signs differ between the different *Babesia* species. Nonspecific signs (fever, inappetence, lethargy) may be accompanied by signs of anemia, splenomegaly, icterus, and red urine.[64,79] In most cases, the hemolytic regenerative anemia occurs concurrent with thrombocytopenia.[64,79-81] The DAT may be positive. Antibodies against RBCs have been documented in dogs infected with *B. gibsoni* and *B. vogeli* but not in *B. canis* infections.[64,82-84] The OFT may be increased.[76] Diagnosis, in most acutely ill dogs, is readily confirmed by microscopic examination of a fresh stained blood smear. Capillary blood from the ear tip or toe nail that is concentrated, and stained buffy coat preparations, may have higher levels of parasitemia.[85,86] *Babesia* species appear in the erythrocytes as single or paired, pear shaped, oval, or round parasites measuring around 2-5 microns in diameter. Molecular diagnostic tests have the advantage of higher sensitivity and offer the possibility to differentiate among the different *Babesia* species, even smaller species difficult to identify microscopically.[64] Differentiation of *Babesia* species is relevant since treatment and prognosis may differ. The combination of acute and convalescent antibody titers may also be used to document *Babesia* infection.[64]

Hemotropic *Mycoplasma* Infections

Feline hemotropic *Mycoplasma* infections are erythrocytic bacterial infections that occur worldwide (see ch. 219).[87,88] Among the feline *Mycoplasma* species, *Mycoplasma haemofelis* may cause acute, severe anemia, especially in young cats.[87,88] Prevalence varies widely and may range from 3% to as high as 50%, depending on geographical area and presence of clinical disease or anemia in the population studied.[87,88]

Other feline hemotropic mycoplasmas, *Candidatus Mycoplasma haemominutum* and *Candidatus Mycoplasma turicensis* seldom cause clinical signs.[87,88] Prevalence studies mostly identify chronically infected cats. The absence of a consistent association with anemia in these studies may be due to cats not consistently clearing their infection and becoming long-term carriers, regardless of treatment. Concurrent retroviral infection is a risk factor for hemoplasma infection, which may be due either to immunosuppression or that both infections share similar routes of transmission.[88]

Clinical signs of acute infection include nonspecific signs (lethargy, inappetence, fever) in combination with signs due to anemia. In a minority, icterus may be seen. Chronic infections with *Mycoplasma haemofelis* usually do not cause anemia. Of interest, no significant difference was found in hemoplasma prevalence comparing anemic with non-anemic cats.[89-91] Cats with acute *Mycoplasma haemofelis* infection may have a positive DAT and persistent autoagglutination.[92] Antibodies appear after the onset of anemia.[92] The treatment of choice is doxycycline.[87]

Canine Hemoplasmosis

Canine hemoplasmosis is an extremely uncommon cause of hemolytic anemias and a rare cause of immune-mediated hemolytic anemia in the dog.[93,94]

Red Cell Fragmentation Syndromes

RBC fragmentation syndromes are the consequence of physical trauma to the cells, leading to intravascular hemolysis. Blood smears usually have significant numbers of unusual, triangular, sharply edged, pointy, RBC fragments of variable size and numbers.[95] The cause of the anemia is not always obvious and mechanisms other than hemolysis may contribute.

In microangiopathic hemolytic anemias, RBC fragmentation results from interaction with abnormal vascular endothelium, as in hemangiosarcoma (see ch. 347).[96,97] It may also occur with other cancers, heart failure, glomerulonephritis, and myelofibrosis.[95] Thrombotic microangiopathies begin as microvascular thromboses and cause thrombocytopenia and hemolysis due to RBC fragmentation.[98] In dogs, a hemolytic uremic syndrome has been reported in which renal arterial and arteriolar endothelial lesions induce local thrombi and acute kidney injury.[99] Erythrocyte fragmentation is also seen in disseminated intravascular coagulation when RBCs are damaged due to the multiple venous microthrombi (see ch. 197).[95]

Hereditary Hemolytic Anemias

The hereditary hemolytic anemias are a heterogeneous group of rare diseases (see Box 198-1). Genetic erythrocyte enzyme deficiencies that cause impaired erythrocyte energy metabolism, such as pyruvate kinase deficiency and phosphofructokinase deficiency in dogs, or genetic membrane disorders such as stomatocytosis, are relevant as differential diagnoses in regenerative hemolytic anemias. They should be considered if the OFT is increased and the DAT is negative. As genetic testing becomes more widely available for different, breed-specific mutations, the prevalence of these diseases is expected to decline. Alternatively, enzyme activity may be assessed, but testing is only available in a few research laboratories.[100-102]

Pyruvate kinase deficiencies are autosomal recessive inherited traits that have been reported in several breeds.[100,101] Affected dogs have variable degrees of regenerative anemia.[100,101] Progressive iron overload due to continuous hemolysis may lead to hemosiderosis and liver fibrosis.[103-105] Some dogs, not cats, develop progressive myelofibrosis and sclerosis.[105] In contrast to dogs who are diagnosed young, cats may be older when first diagnosed.[100,101,106] Phosphofructokinase deficiency in dogs is inherited as an autosomal recessive trait.[100,101,107-109] Some dogs have no clinical signs but most have persistent hemolytic anemia exacerbated by sporadic hemolytic crises secondary to exercise-induced hyperventilation alkalemia.[108,110] The rarely seen stomatocytosis is a hereditary disorder of RBCs in which hemolytic anemia is one of the presenting signs.[25,31,111-113] Dogs with hereditary spectrin deficiency have increased osmotic fragility but are not usually anemic.[114]

Feline Hypophosphatemia

Hypophosphatemia inhibits RBC adenosine triphosphate production by interfering with RBC energy metabolism, which results in decreased erythrocyte membrane stability, increased osmotic fragility, susceptibility to oxidative stress, and hemolysis. Hypophosphatemia and hemolysis have been reported in cats with diabetes mellitus, with hepatic lipidosis, and after enteral feeding.[56-58] Hypophosphatemia can follow inadequate intake, shifts from plasma to the intracellular space, gastrointestinal (GI) or renal loss, and has been reported in cats with pancreatitis and GI diseases.[115] Diagnosis is made by measuring plasma phosphate concentrations and treatment involves oral or parenteral replacement.

Hemophagocytic Anemias

Several histiocytic proliferative disorders, or histiocytic sarcomas, have been identified in dogs, but are rare in cats (see ch. 350).[116-122] Predisposed dog breeds are the Bernese Mountain Dog, Rottweiler, Golden Retriever, and Flat-coated Retriever, but the condition has been diagnosed in other breeds.[116,123] Histiocytic sarcomas (HS) are most commonly derived from interstitial dendritic cells and a subgroup of hemophagocytic HS is derived from macrophage cells. The cause of regenerative anemia is erythrophagocytosis, a common concern in hemophagocytic HS. Certain characteristics set hemophagocytic HS apart from other conditions of the HS complex. Pets with hemophagocytic HS do not have mass lesions but erythrophagocytic histiocytes demonstrate infiltrative growth patterns in the spleen, liver, lung, and bone marrow.[116,123] Lymph nodes are less frequently infiltrated.[116,123]

Clinical signs of hemophagocytic HS include vague signs of anorexia, weight loss and lethargy. Many have splenomegaly and hepatomegaly. Laboratory abnormalities include a moderate to severe anemia with abundant reticulocytosis. About half have platelet counts <100,000/microL.[123] The DAT is usually negative. Despite abundant infiltration of organs, the histiocytes usually appear well-differentiated. In general, those within the spleen show more atypia, such as atypical mononuclear and multinuclear giant cells.[116,123] Histiocytes may exhibit phagocytosed RBCs or hemosiderin deposits as evidence of previous erythrophagocytosis.[123] Hemophagocytic HS may be differentiated from other histiocytic proliferative disorders by immunophenotyping for the B-2 integrins CD11/CD18.[123] Rarely, dogs may have hemophagocytic HS from dendritic cell origins.[116,123] Canine hemophagocytic HS has a grave prognosis, with a median survival of only 4 weeks.[123] The anemia caused by hemophagocytic HS may be differentiated from other hemophagocytic syndromes of the BM that typically have non-regenerative anemias and other cytopenias.[124-127]

Immune-Mediated Hemolytic Anemias

IMHAs are due to antibody-mediated RBC destruction and can occur after previous sensitization as in neonatal isoerythrolysis and incompatible blood transfusions. IMHA is most common, however, as an idiopathic autoimmune disease. Autoimmunity may develop in genetically susceptible individuals in whom self-tolerance failure leads to production of functional self-reactive lymphocytes. The onset of the autoimmune disease is thought to follow a random environmental trigger, such as an infection or injury.[128] Integral to the response to one of these triggers is an altered response to self-antigens among the innate and adaptive immune systems.[128]

Idiopathic IMHA is one of the most common immune-mediated diseases of dogs.[102,129-132] In a general veterinary university hospital, the incidence of IMHA diagnoses was estimated as 0.2%.[133] In dogs, familial associations and identification of specific breeds and dog leukocyte antigen (DLA)-haplotypes as risk factors for IMHA suggest a genetic susceptibility.[16,19,134-143] Autoreactive T-cells have been identified in dogs with IMHA as well as in siblings, supporting the hypothesis that DLA-haplotype is indeed a susceptibility locus for IMHA.[144] The risk estimates conferred by breed are, in general, higher than those conferred by DLA-haplotype alone, suggesting that DLA-haplotype is not the sole explanation for the risk on IMHA.[134] The central event in developing IMHA is the loss of self-tolerance towards RBC antigens. As a consequence, antibodies develop to RBCs and cause hemolysis by antibody-mediated erythrophagocytosis, complement-mediated erythrolysis, or both. In dogs with IMHA, the anion-exchange molecule (band 3 protein) and different erythrocyte membrane glycophorins are major target antigens.[145]

Canine Immune-Mediated Hemolytic Anemia

Pathophysiology

Mortality rates in canine idiopathic IMHA have been reported between 21 and 83%, with most fatalities occurring in the first two weeks after diagnosis.[16-20,135,140,146-149] A literature review of studies on canine IMHA suggests that as many as half of the deaths are related to thromboembolism.[19,134,139,150-153] As many as 50% of dogs with idiopathic IMHA have abnormalities in their coagulation parameters consistent with disseminated intravascular coagulation (DIC; see ch. 197).[134] Assessment of platelet activation status and thromboelastography testing indicates that most dogs with IMHA are in a hypercoagulable state at the time of diagnosis.[148,150,154-157]

Several studies using multivariate analyses suggest that icterus, petechiae, increased blood urea nitrogen concentration, prolonged activated partial thromboplastin time (APTT), thrombocytopenia, an inflammatory white cell left shift with monocytosis, and increased concentrations of cytokines involved in macrophage activation are the major determinants imposing an increased death risk.[20,134,138,140,158-162] It has been hypothesized that the hypoxia induced by severe acute anemia causes an inflammatory response, subsequent activation of coagulation, and then liver necrosis and renal failure.[20,134,158,159] Oxygen delivery was impaired in canine isovolemic anemia models at hematocrits <10%, but hypoxia was an identified risk factor in only a few studies on IMHA.[17,138,163,164] This may be explained by the heterogeneity of IMHA patients and because timely blood transfusions modify duration and pathological effects of anemia.[134,158] A pathology study in dogs with IMHA supports the hypothesis that anemia is central to the high mortality risk.[139] Presence of hypoxic necrosis around hepatic central veins was associated with increased white cell counts.[139] Prolonged exposure to increased plasma lactate concentrations caused by anemia increased mortality.[165] In addition, icterus and failing liver function contributing to mortality risk is in agreement with hypoxia as a risk factor.

Clinical Presentation

Signalment

The mean age of dogs with IMHA is 6 years. It is uncommon in dogs under the age of 1 (4% of 222 in one study), but can otherwise occur at any age.[17,18,129,134,135,140,146,160,166] Increased incidences of IMHA have been reported in females, especially when in estrus or during whelping, and in neutered dogs.[16,19,134-137,167]

Signs

Most dogs have non-specific signs: lethargy and loss of appetite. Vomiting and diarrhea has been reported in 15-30% of dogs.[20,134,137,160] The anemia in IMHA usually develops rapidly, as quickly as 3 days, and dogs

may be brought for veterinary care before their BM can mount a response.[134] The physical examination may reveal signs consistent with anemia: tachycardia, tachypnea, rapid heart rate, pale mucous membranes, and a systolic murmur.[18,140] Yellow to orange discoloration of the feces and red urine are consistent with hemolysis.[18,20,134,137,140,160] Red urine is seen in 24-44% of dogs and fever in 46%.[17,18,20,140,149,160] Concurrent thrombocytopenia causing petechiae has been reported in only 2-5% of IMHA cases and may be due to immune-mediated platelet destruction which may be referred to as Evans' syndrome.[18,20,168] Splenomegaly and hepatomegaly is found in up to 40% of cases.[17,18,20,140]

Laboratory Testing

Complete Blood Count

At the time of presentation, most dogs with IMHA have a severe anemia (Ht <12-14%).[17-20,135,137,140,160,166] These results, however, are likely biased toward severely ill dogs, since most IMHA studies are from tertiary referral hospitals. A few dogs have a more chronic form of disease and a higher Ht when first seen.[169] In many dogs, the anemia is not clearly regenerative at the time of diagnosis, with the median corrected reticulocyte counts ranging from 0.9-2.7% in 5 different studies.[17-20,160] Usually, the reticulocyte numbers increase during the first days of hospitalization because adequate time has elapsed for a BM response to begin. An inflammatory leukogram is present in almost all dogs at the time of diagnosis or during the first days of hospitalization.[134,170] Pronounced leukocytosis with a left shift is common and monocytosis is noted in about 50% of IMHA dogs.[17-20,135,137,140,150,160,166,171] Decreased platelet counts are common, with as many as 70% of dogs with IMHA having counts <200,000/mcL. About 40% had platelets counts <100,000/mcL and about 25% have severe thrombocytopenia (<50,000).[17-20,134,137,150]

Coagulation Testing

The prothrombin time (PT) is increased in as many as 50% and the APTT is increased in about 50-60% of dogs with IMHA.[18-20,134,150] This combination, together with thrombocytopenia, is suggestive of DIC (see ch. 197). This conclusion is further supported by the finding of low fibrinogen concentrations in about 20% of dogs, while in many dogs decreased antithrombin (AT), decreased coagulation factor activities, and increased D-dimers and fibrin degradation products are found.[20,150,159] However, one study found fibrinogen concentrations to be increased in 30-90% of dogs, which might be because fibrinogen is secreted during the acute-phase response.[172] Thromboelastography (TEG) tracings in dogs with IMHA are suggestive of hypercoagulability that increases during hospitalization.[157,173,174] Although important, TEG tracings in dogs with severe anemia and hemolysis may not always be reliable.[175-178]

Specific Diagnostic Testing

The diagnosis of IMHA in a dog with hemolytic anemia is made by confirming its immune-mediated pathogenesis. The direct agglutination test (DAT), introduced by the veterinarian Dr. Coombs in 1945, detects erythrocyte-bound immunoglobulins and complement, is species-specific, and is widely available.[179] Several elements of the DAT are essential for reliable results.[21,132,180,181] Erythrocytes are washed several times before performing the test to remove nonspecifically-bound immunoglobulins and plasma proteins that may interfere with the binding of the DAT reagents. The washed erythrocytes are then incubated with the DAT reagent. Agglutination is a positive result. Increasing dilutions of the DAT reagents are added to the erythrocytes to prevent inhibition of agglutination by excess of reagent antibody that may otherwise lead to false negatives. Laboratories traditionally used tubes in performing the DAT but microtiter plates are now commonly employed. Avidity of anti-erythrocyte antibodies may differ at different temperatures and therefore the test may be performed at different temperatures. It has been reported that performing the DAT at 4°C and 37°C as opposed to 22°C improves the quality of the observed agglutination and makes the test easier to read.[15,21,132,182,183] The use of a monovalent DAT in which individual reagents contain anti-IgM, anti-IgG, and anti-complement antibodies reportedly increases sensitivity as compared with using a polyvalent reagent that contains IgG and complement.[184] Positivity for IgM antibodies has been associated with underlying disorders triggering IMHA.[132,184,185]

The sensitivity of the DAT (50-89%) is difficult to assess because no “gold standard” test exists for comparison. It is likely that optimization and standardization of the DAT protocols in laboratories

incorporating the steps discussed above will improve the performance of the DAT.[21] Easily used in-clinic DAT test results correlate well with conventional tube or microtiter assay results.[21,185] DAT's imperfect sensitivity as a diagnostic aid for IMHA may be managed with alternative testing. Spherocytes, from the partial phagocytosis of antibody-coated RBC membranes, are characteristic of IMHA. Spherocytes are not 100% specific, appear as hyperchromatic microcytes in a blood smear, and are seen in 67-94% of dogs diagnosed as having IMHA.[15,17-19,21,132,180,183] Spherocytes may be seen in other hemolytic conditions and in hereditary RBC diseases.[114,186] The presence of spherocytes should be quantified in a standardized manner to avoid false interpretations.

Macroscopic or microscopic agglutinating RBCs are often seen in dogs with IMHA and are suggestive of IMHA (Video 198-1).[16,18,19] Autoagglutination may be caused by proteins other than anti-RBC pathogenic antibodies implicated in IMHA.[21] The degree of autoagglutination and persistence after the first DAT washing step varies. The washing usually causes the agglutinated RBCs to break up.[21] Described protocols that aim to differentiate "true autoagglutination" in IMHA from non-specific agglutination are not validated, not standardized and should not be used (see ch. 130).[21,134]

The OFT can confirm presence of hemolysis but not whether it is immune-mediated. Since the prevalence of hereditary RBC membrane diseases is low and other differentials may be ruled out by history, physical examination, and, if indicated, additional testing, it is fair to use this test to identify IMHA. In the OFT, RBCs are incubated in different saline concentrations (0.10-0.85%), then centrifuged and observed for hemolysis. This protocol has been modified and used for fast in-house OFT using only two saline concentrations (Figure 198-2). Results have been comparable to conventional OFTs in 89-100% of cases.[14,15,21] The increase in osmotic fragility in IMHA may be due to the presence of spherocytes or complement-mediated membrane damage.[14,15] In the Netherlands and Belgium, the rapid OFT is routinely used in the work-up of an IMHA patient.[14,15,20]

Differential Diagnosis

Secondary IMHA develops if antibodies on RBC surfaces occur during or after an infection, neoplasia, administration of some medications or, possibly, vaccination. Secondary IMHA, then, is part of a systemic immune-mediated response.[19,131,146,168,187-195] In 70-80% of dogs diagnosed as having IMHA, no evidence for an underlying trigger is found. These dogs are assigned the diagnosis of idiopathic IMHA.[20,160]

Treatment

Overview

Immunomodulation is the mainstay of treating idiopathic IMHA, to decrease erythrophagocytosis and suppress immunoglobulin production. If the anemia is severe and compromising tissue oxygenation, blood transfusions may be necessary (see ch. 130).[196] Several retrospective studies have found transfusions to be safe.[16,18,19,135] Many treatment protocols using glucocorticoids in combination with other therapies, including immune-suppressive agents, have been described.[16,17,137,140,160,197-204] Treatment of secondary IMHA should be directed at the underlying disorder.

Prednisolone

Conclusions after recent systematic reviews were that no evidence for efficacy of any combined protocol was better than using glucocorticoids alone for idiopathic IMHA.[205] Dosage regimens and related information regarding use of glucocorticoids differ between studies. One retrospective cohort study demonstrated that prednisolone, tapered over about 2 months, controlled IMHA in a large majority of afflicted dogs.[20,160] Their recommended initial oral dosage of prednisolone is 2 mg/kg/day. Dexamethasone (0.2-0.3 mg/kg/day) IV or SC is used when oral medication is not appropriate. Initially, the Ht should be assessed daily and, when it stabilizes, prednisolone is continued at the initial dosage for an additional 3 days, then 1.5 mg/kg/day for 7 days, 1 mg/kg/day for 10 days, and 0.5 mg/kg/day for 14 days. If the dog is continuing to improve, the same dosage is given, but on alternate days for 14 days (7 treatments), and subsequently tapered to 0.25 mg/kg q 48 h for 21 days. Therapy effectiveness should be assessed at visits scheduled 4 and 10 weeks after beginning therapy. If the dog completely recovers, defined as a Ht >36%, the prednisolone protocol should be completed. If relapse is diagnosed, the prednisolone dosage should revert to 2 mg/kg/day. A relapse is

defined as a decrease in Ht after an initial improvement or even complete recovery with Ht >36%. If a dog has improved but the Ht has remained <36%, the duration of each stage of the tapering process should be doubled.

Thromboprophylaxis

Most dogs with IMHA are in a hypercoagulable state and at risk for thromboembolic events. This is the rationale for thromboprophylaxis.[16,149,171,206] A recent review concluded that current evidence is insufficient to provide therapy guidelines regarding thromboprophylaxis in canine idiopathic IMHA.[207]

Prognosis

It is estimated that 65-75% of dogs with IMHA survive the first year.[20,159,160] Most deaths occur in the first 2 weeks after diagnosis (Figure 198-3). Deaths have been attributed to thromboembolism, renal failure, or liver failure.[20,134,158,159] Hemolysis may be difficult to control in some dogs, resulting in need for blood transfusion(s). If intensive in-hospital treatment is successful, the Ht rises into or close to the reference range within 2-3 weeks. These dogs have a high probability of long-term survival. Most dogs will have negative DAT and OFT results by that time.[20,160] Little is known about the incidence of recurrence, but one retrospective case cohort study noted relapses in at least 12% of dogs as many as 5 years after first diagnosis.[208]

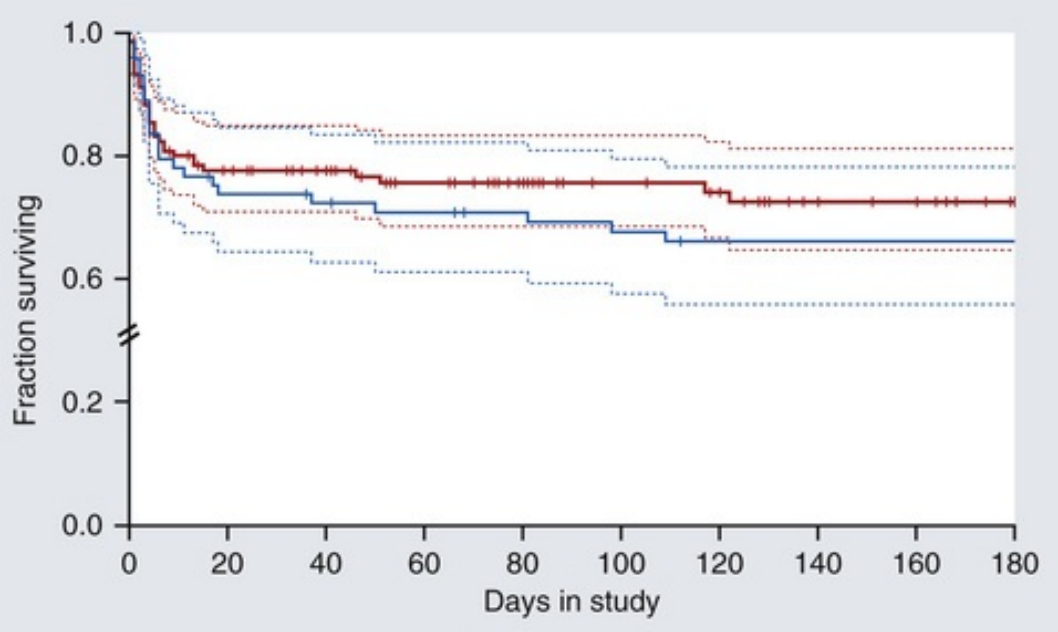

FIGURE 198-3 Estimated Kaplan-Meier survival in dogs with idiopathic IMHA treated with prednisolone alone, or in combination with azathioprine, including 95% confidence intervals (dashed lines). The endpoint was death due to IMHA; other outcomes were censored. All dogs in this study were treated with the same prednisolone protocol as described in detail in the paragraph on canine idiopathic IMHA of this chapter. No statistically significant difference was found for estimated Kaplan-Meier survival times comparing the cohort that received prednisolone only (n = 73, blue) with the cohort that received prednisolone and azathioprine (n = 149, red) acting as a historical control. Side-effects due to azathioprine were noted in 8.1% of dogs.[20,160]

IMHA may be accompanied by severe thrombocytopenia and its impact, when present, is debated.[148,209] Due to lack of access to routine diagnostics for definitive diagnosis of immune-mediated thrombocytopenia, the latter diagnosis often cannot be confirmed. In addition, thrombocytopenia in idiopathic IMHA may be due to DIC, thromboembolism, or their combination. In some dogs with IMHA, their BM is either slow or fails to regenerate RBCs. This may be a so-called non-regenerative IMHA, explained by BM damaged by hypoxia during the initial hemolytic crisis and/or thromboembolism within the BM.[210] Nonregenerative IMHA should be differentiated from pure red cell aplasia (PRCA), since the conditions and responses to

treatment differ (see ch. 199).[211]

Feline IMHA

The paucity of literature on feline IMHA suggests low disease prevalence in cats, but this concept may change. In one study, hemolysis was the cause of anemia in about 10% of 180 anemic cats, many of whom were suspected to have immune-mediated hemolysis.[212] In another study, 20% of 78 cats with anemia had been diagnosed with idiopathic IMHA.[213] Although many features of canine IMHA hold true in cats, there are some differences. The median Ht in cats with IMHA is about 12%.[213] Despite this level of severity, organ failure due to hypoxia or a systemic inflammatory response and hypercoagulability are quite uncommon. In one series, 13 of 19 cats had hyperbilirubinemia, but only 2 had clinical icterus. A slight prerenal azotemia was identified in 6. Only 2 cats had a leukocytosis. At the time of presentation, about half the cats had a regenerative anemia.[213] Severe anemia has been shown to result in volume overload and increased left heart dimensions.[214]

Laboratory diagnosis of feline IMHA can be confirmed with a positive DAT, as in dogs. Increased OFT results may also suggest IMHA.[213] As in dogs, it should be realized that other diseases may increase OFTs.[215] Autoagglutination is present in many cats but not after RBC washings as is required when performing the DAT, and thus does not interfere with results.[215] Spherocytosis in cats is difficult or impossible to assess since their normal RBCs lack the central pallor present in healthy dog RBCs.[102]

Secondary IMHA must be differentiated from idiopathic IMHA. In one study, 36 of 102 DAT-positive cats had idiopathic IMHA.[216] The most common causes of secondary IMHA were infectious diseases: *Mycoplasma haemofelis*, coronavirus, and retroviral infections. Fewer cats had hematopoietic neoplasia and a few had systemic immune-mediated disorders.[216] Since the inclusion criterion was a positive DAT result only, it is possible that mechanisms other than hemolysis contributed to the development of anemia. Persistent absence of a regenerative RBC response may be explained by PRCA.[210,217]

Cats with idiopathic IMHA may be treated with blood transfusions as indicated and glucocorticoids. The same 2-month prednisolone protocol as described for dogs was used in a cohort of cats and resulted in estimated survival times of 75% (Figure 198-4).[216] Also, the mortality rate (about 24%) reported in cats with idiopathic IMHA is similar to that of dogs.[213] It was suggested that about 30% of cats may experience relapse after initial improvement.[213]

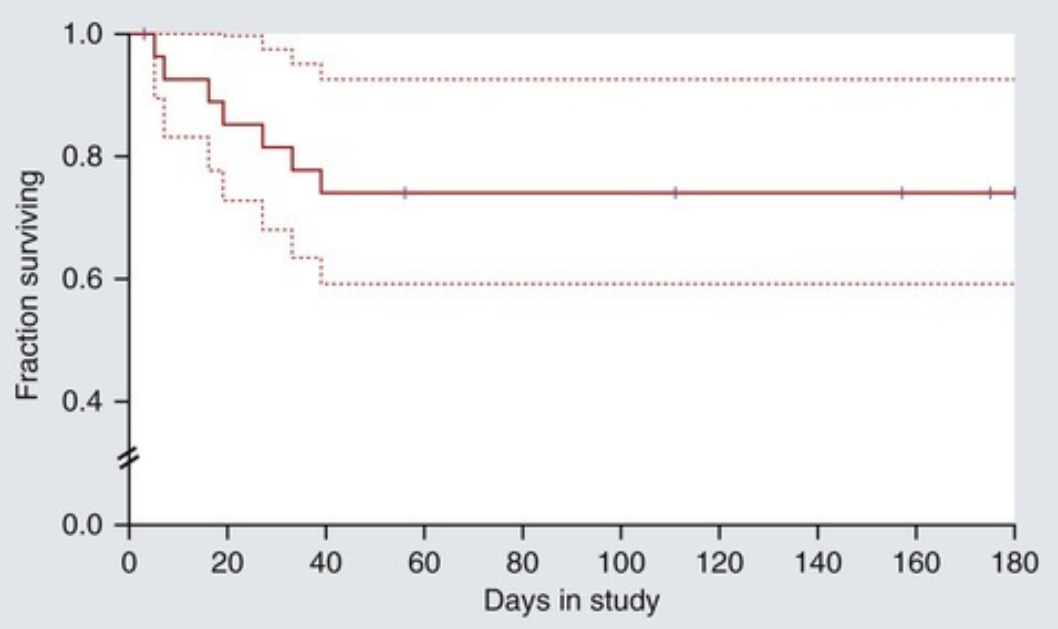

FIGURE 198-4 Estimated Kaplan-Meier survival (solid line) in cats with idiopathic IMHA treated with prednisolone, including 95% confidence intervals (dashed lines). Estimated from the data of a cohort of 30 cats diagnosed with idiopathic IMHA.[216] The endpoint was death due to IMHA; other outcomes were censored. All cats in this study were treated with the prednisolone protocol described in detail in

the paragraph on canine idiopathic IMHA of this chapter.

Feline Alloimmune Hemolysis

Feline alloimmune hemolysis is due to AB blood group incompatibility. Type B cats develop high-titer anti-A antibodies during the first three months of life with hemolyzing and hemagglutinating activity (see ch. 130). These antibodies are the culprit of severe RBC agglutination and destruction in mismatched transfusions and in feline neonatal isoerythrolysis (FNI). FNI occurs when a type A or AB kitten consumes colostrum from a type B cat.[218-221] Signs of hemolytic anemia appear within hours to days and severity is likely determined by the amount of colostrum consumed.[222] The best way to prevent FNI is to avoid incompatible mating. In other cases, kittens should be prevented from suckling incompatible colostrum. In order to prevent transfusion-related hemolysis, cats should always be blood-typed prior to blood transfusion and only AB-matched blood should be given.[221,223,224]

CHAPTER 199

Nonregenerative Anemia

Ann E. Hohenhaus, Sarah Elizabeth Winzelberg

Client Information Sheet: Nonregenerative Anemia

Introduction

Anemia is defined as hematocrit (Hct), hemoglobin concentration ([Hb]) or red blood cell count (RBC) below the laboratory's reference range. In veterinary medicine, Hct is most frequently used to make a diagnosis of anemia. Multiple factors influence the frequency of diagnosis of anemia, including defining anemia as one, two or all three of these parameters outside the reference range as well as the demographics of the patient populations studied and if primary care or referral center populations are evaluated. Despite these distinctions, anemia remains a common clinical problem in veterinary medicine, occurring in approximately 4% of all felines and in as many as 31% of canine patients over the age of eight years.[1,2]

Nonregenerative anemia is the most common form of anemia seen in the cat and dog.[1,3-6] Caution should be used when making a diagnosis of anemia in a cat since Hct, [Hb] and RBC count decrease approximately 25% in cats during general anesthesia.[7] In dogs, the [Hb], Hct, and RBC count results depend on the blood vessel sampled. Arterial blood samples give lower values than venous samples and a spurious diagnosis of nonregenerative anemia could be made if arterial samples are compared to venous sample reference intervals.[8]

Nonregenerative anemia can also be described as anemia with reticulocytopenia because the hallmark of nonregenerative anemia is a reticulocyte count less than 60,000/mcL in dogs and less than 50,000/mcL in cats, although these values vary based on method of reticulocyte enumeration.[9] Automated reticulocyte counts have a smaller coefficient of variation and are more reproducible than manual ones.[10,11] Once hypoxemia occurs, 3-7 days are required for production of reticulocytes; thus, blood loss anemia and hemolytic anemia may initially appear nonregenerative. Consequently, anemia in some patients may not be immediately classifiable as regenerative or nonregenerative. Surrogate measures of regeneration including mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), and red blood cell distribution width are not reliable indicators of regeneration in either dogs or cats.[1,11,12] Observation of polychromasia provides a better estimation of regeneration than do red blood cell indices in dogs.[11,13] Feline reticulocytes occur in at least two forms: punctate and aggregate (see ch. 198). Aggregate reticulocytes are believed to be most important for assessing response to anemia and represent those counted using automated hematology analyzers.

Some automated hematology analyzers have the capacity to measure reticulocyte indices, including those similar to MCV and MCH reported for mature red blood cells. Low reticulocyte hemoglobin content (CHr or CHretic) and reticulocyte mean corpuscular volume (rMCV or MCVretic) have been associated with hematologic and biochemical makers of iron deficiency.[14] Reticulocyte indices may prove useful in the diagnosis of iron deficiency prior to the development of microcytosis and hypochromia.[15] However, changes in reticulocyte indices are not specific for iron deficiency and can also be found in other causes of microcytosis such as portosystemic shunts and breed-associated microcytosis.[16]

A complete understanding of the pathophysiology of nonregenerative anemia, an extensive list of differential diagnoses and a comprehensive diagnostic plan are required to identify the cause and successfully manage patients with nonregenerative anemia (Table 199-1). Determining the cause of nonregenerative anemia is critical to optimal patient management and outcome, as anemia is an important prognostic variable. In dogs with the nonregenerative variant of immune-mediated hemolytic anemia

(IMHA), those infected with *Leishmania infantum,* or diagnosed with lymphoma, anemia predicts outcome.[17-19] Severely anemic cats are less likely to be discharged from the hospital and if anemia is due to chronic kidney disease, cats with anemia have a shorter survival than those without.[3,20]

TABLE 199-1

Differential Diagnoses of Nonregenerative Anemia

MEDULLARY CAUSES	EXTRAMEDULLARY CAUSES

Primary medullary
• Aplastic anemia
• Myelodysplastic syndromes
• Myeloproliferative syndromes
• Dysmyelopoiesis
• Myelophthisis
  • Acute and chronic leukemia
  • Multiple myeloma
• Bone marrow necrosis
Secondary medullary
Infectious:
• Feline leukemia virus (C)
• Feline immunodeficiency virus (C)
• Parvovirus
• Ehrlichiosis
• Sepsis
Drug reactions:
• Antimicrobial agents
• Chemotherapeutic drugs
• Estrogens (D)
• Phenobarbital (D)
• Recombinant human erythropoietin
• Copper deficiency secondary to chelation therapy
Toxins:
• Aflatoxin
Neoplasia:
• Sertoli cell tumor (D)
• Lymphoma
• Histiocytic disease
Congenital:
• Osteosclerosis from pyruvate kinase deficiency (D)
• Cobalamin malabsorption (D)
• Copper deficiency[28] (D)
Immune:
• Nonregenerative variant of IMHA
• Pure red cell aplasia
	Renal
	• Acute kidney injury
	• Chronic kidney disease
	Endocrine
	• Hypoadrenocorticism
	• Hypothyroidism
	Gastrointestinal/Malabsorptive
	• Serum cobalamin deficiency
	Hepatic disease
	Pancreatitis
	Neoplasia
	Iron deficiency
	• Chronic gastrointestinal bleeding (gastrointestinal mass, significant inflammatory bowel disease,[29] vascular ectasia, gastrointestinal parasites)
	• Chronic hematuria (renal hematuria, urogenital mass)
	• Other chronic external losses: dermal mass, high/chronic ectoparasite burden, oropharyngeal bleeding, epistaxis

C, Occurs in cats; *D*, occurs in dogs; *IMHA*, immune-mediated hemolytic anemia.

Clinical Signs and Physical Exam Findings

Clinical signs of anemia are vague in both dogs and cats and are attributable to decreased oxygen delivery to

tissues (Table 199-2). Physical examination reveals findings consistent with a low RBC, [Hb] and Hct: pallor, weakness, and depression. Physical examination will also identify physiologic mechanisms compensating for decreased oxygen delivery such as tachycardia and tachypnea. Thorough physical examination can frequently identify clinical signs of the underlying disease process responsible for anemia.

TABLE 199-2

History and Physical Examination Findings in Dogs and Cats with Anemia[3,21-26]

HISTORY	PHYSICAL EXAMINATION
Lethargy	Pallor
Anorexia	Weakness
Pica (more common in cats)	Depression
Decreased activity	Jaundice
Weight loss	Pyrexia or hypothermia
Drug administration Phenobarbital Estrogen Chloramphenicol	Lymphadenopathy Splenomegaly Hepatomegaly
	Cardiovascular Tachycardia Syncope Heart murmur Gallop
	Respiratory Tachypnea Thromboembolism
	Clinical signs of underlying disease Uremia Coagulopathy Hemoptysis, hematemesis, melena, purpura Endocrinopathy Malabsorption Neoplasia Infection/Sepsis

Characterization of Anemia

To precisely characterize anemia, multiple descriptors of cell size, hemoglobin content and regeneration are required. This characterization of anemia does not provide any indication as to the underlying pathophysiology. Consequently, this chapter categorizes nonregenerative anemia into those caused by bone marrow failure or medullary causes, and secondary or extra-medullary causes. Most cases of blood loss and hemolysis causing anemia (see ch. 198) will become regenerative after a window of time where the bone marrow increases reticulocyte production in response to the anemia (typically 3-7 days). However, certain factors may limit the body's natural response mechanism to produce increased numbers of red blood cells, resulting in nonregenerative hemolytic or blood loss anemia. Causes of these types of nonregenerative anemia include: absolute iron deficiency (as in the case of low-grade chronic bleeding or other blood loss), iron sequestration from chronic inflammation, and decreased erythrocyte half-life or other comorbid conditions that impair the marrow response to a hypoxic trigger. Up to one third of dogs and over 50% of cats with immune-mediated hemolytic anemia may be nonregenerative at the time of diagnosis.[24,27] Additionally, anemia secondary to immune targeting of red blood cell precursors may remain nonregenerative until the patient is adequately immunosuppressed.

Pathogenesis

Many systemic illnesses result in nonregenerative anemia (see Table 199-1) and its pathogenesis is complex and multifactorial (Figure 199-1). Pathologic mechanisms can be typically separated into two main categories: decreased erythrocyte lifespan and decreased or ineffective erythropoiesis.

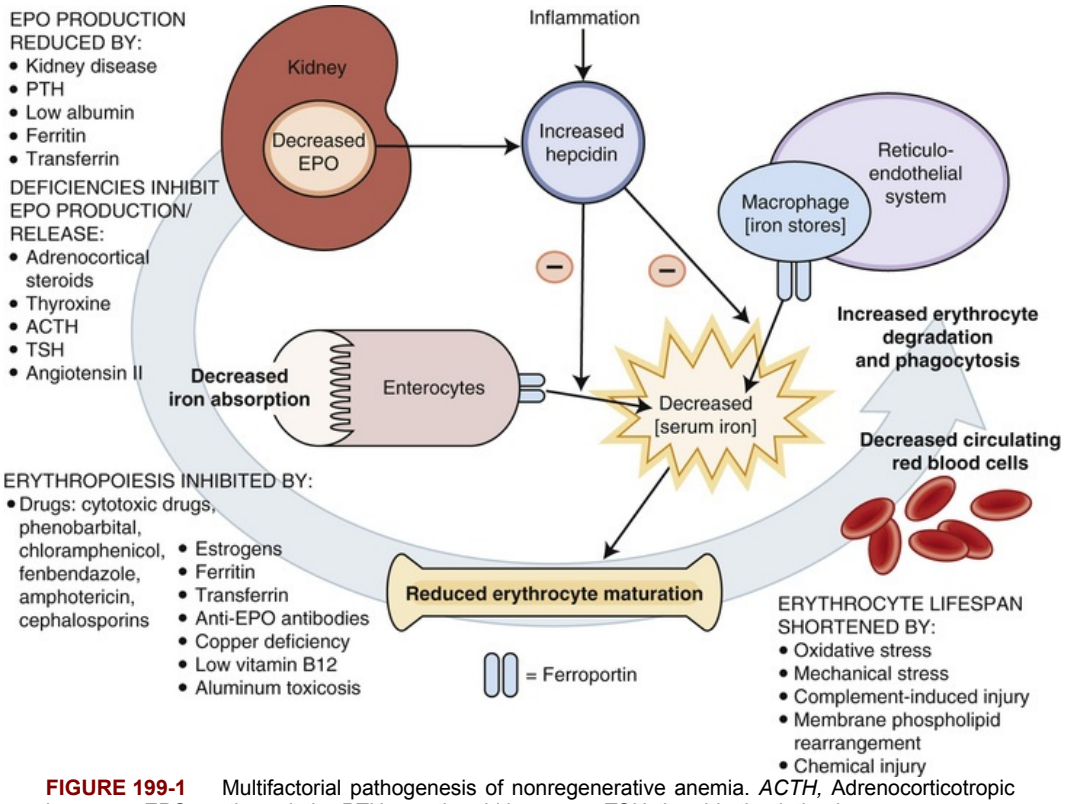

FIGURE 199-1 Multifactorial pathogenesis of nonregenerative anemia. *ACTH*, Adrenocorticotropic hormone; *EPO*, erythropoietin; *PTH*, parathyroid hormone; *TSH*, thyroid-stimulating hormone.

Decreased Erythrocyte Lifespan

The lifespan of a normal red blood cell is 100 days in a healthy dog and 72 days in a healthy cat.[30] During this time, the red blood cell is responsible for oxygen delivery to tissues, and requires maintenance of cellular features of deformability in order to optimize its performance. As the red blood cell ages, numerous biochemical, immunologic and mechanical changes impair its ability to recover from various insults. The accumulation of such injuries triggers the removal of a senescent red blood cell from circulation by the reticuloendothelial system (RES), primarily by mononuclear phagocytic cells within the spleen, liver and lymph nodes. Red blood cell oxidative stress is caused by both endogenous hemoglobin autoxidation and exogenous oxidants that can result in cellular aging and functional impairment, shortening erythrocyte lifespan by triggering removal by the RES.[31] Oxidative stress, mechanical stress, complement-induced injury, rearrangement of membrane phospholipids, contact with cationic proteins released from activated neutrophils, Heinz body formation and hemotropic parasites all alter cytoplasmic viscosity, resulting in impaired deformability and targeting of the red blood cells for early removal from circulation.[32] Similarly, hereditary erythrocyte defects such as membrane protein abnormalities, erythrocyte enzyme deficiencies, hemoglobinopathies and increased osmotic fragility lead to shortened erythrocyte lifespan. Excessive activation of the RES, as seen with certain immune-mediated, infectious, inflammatory and paraneoplastic conditions can also stimulate early removal of red blood cells from circulation. In general, disorders resulting in decreased RBC lifespan cause regenerative anemia in dogs and cats; however, they can also be contributing factors in cases of nonregenerative anemia.

Decreased and Ineffective Erythropoiesis

Erythropoiesis can be decreased due to an absolute or a relative lack of erythropoietin or can be ineffective

secondary to decreased marrow response to erythropoietin. Erythropoietin is produced primarily by the kidney in the peritubular interstitial cells of the inner renal cortex and outer medulla. Renal hypoxia is the main driving factor stimulating erythropoietin synthesis. Renal hypoxia leads to an inhibition of hypoxia-inducible factor 1 (HIF-1) degradation, allowing HIF-1 to bind to hypoxia-response elements of oxygen-regulated genes, leading to an increased production of erythropoietin.[33,34] Erythropoietin production is decreased in both acute and chronic causes of kidney disease, and chronic kidney disease is known to be a common cause of nonregenerative anemia (see ch. 324).[33] The most important extra-renal production site of erythropoietin is the liver, with additional limited production in sites including the brain, vascular endothelial cells, lung, uterus, testis and various solid tumors.[33,35,36] Erythropoietin synthesis from extra-renal tissues cannot be adequately induced to compensate when there is decreased renal production.[35] Hypoxemia does not increase hepatic production of erythropoietin; however, other causes of liver injury can lead to increased erythropoietin production from the liver.[33]

Ineffective erythropoiesis can be secondary to absolute deficiencies in nutrients crucial to hemoglobin biosynthesis and red blood cell maturation or due to a number of different cytokine abnormalities seen in various states of inflammation, commonly designated anemia of chronic disease. In humans, systemic inflammatory states are induced by a number of diseases including infections, autoimmune conditions, malignancies, kidney disease, pancreatitis, diabetes mellitus, cardiac disease, trauma, critical illness, post-surgery, and aging.[37-40] Inflammatory cytokines, such as IL-1, IL-6, TNF-alpha, and interferon-gamma reduce the production of endogenous erythropoietin in the face of hypoxemia, and suppress the erythroid progenitor response to erythropoietin.[38,41] IL-6, in particular, increases the production of hepcidin, an acute phase protein produced by the liver that is responsible for iron homeostasis, resulting in a systemic state of relative iron deficiency. Increased hepcidin levels can also occur secondary to decreased renal clearance and mutations in hepcidin suppressors.[42] Elevated hepcidin levels result in increased cellular internalization and degradation of ferroportin, an integral enterocyte membrane protein responsible for the movement of iron out of the enterocyte and into circulation. The net effect of hepcidin elevation on ferroportin is iron-trapping within the enterocytes, sequestering iron from systemic utilization. Additionally, hepcidin prevents the release of iron stores from macrophages and hepatocytes and blocks luminal intestinal iron absorption. This leads to low blood iron levels and relative systemic iron deficiency.[43] Iron deficiency, whether absolute or secondary to elevations in hepcidin, impairs hemoglobin biosynthesis and causes a blunted erythropoietin response due to reduced erythropoietin sensitivity of progenitor cells in the bone marrow.[43] Copper deficiency is associated with a functional iron deficiency due to decreased hemoglobin synthesis and literature supports that iatrogenic, congenital and nutritional copper deficiencies are an uncommon cause of ineffective erythropoiesis and nonregenerative anemia in the dog.[28,44-46] Deficiencies of vitamin B12 inhibit purine and thymidylate syntheses, impairing DNA synthesis within erythroblasts and causing erythroblast apoptosis.[47] Hypocobalaminemia secondary to hereditary selective cobalamin malabsorption is a cause of nonregenerative, often erythroblastic anemia in the dog.[48-51] While folate deficiency is similarly associated with ineffective erythropoiesis in humans, no documentation of anemia is noted in the veterinary body of literature regarding folate deficiency and anemia. Hypoalbuminemia and elevations in parathyroid hormone, ferritin and transferrin saturation significantly impair the erythropoietic response and can result in ineffective erythropoiesis.[52] Aluminum toxicosis, secondary to chronic high dosages of aluminum hydroxide or other toxic exposure, can result in ineffective erythropoiesis due to interference with erythroid precursor iron utilization and shortened erythrocyte lifespan resulting from morphologic changes to red blood cells.[53] Reports of anemia secondary to aluminum accumulation are limited in veterinary medicine, but are well-documented in human and rodent populations.[53-56] The use of angiotensin-converting enzyme inhibitors can lead to anemia. Although the mechanisms by which this anemia is mediated are not fully elucidated, reduced erythropoietin release as well as ineffective erythropoiesis due to direct drug effects on erythrocyte precursors are suspected.[57,58]

Differentiating iron-deficiency anemia from anemia of inflammation can be difficult and in some cases, both conditions may be driving factors; however, differentiation is essential to selecting the appropriate treatment. Evaluating a variety of iron indices can help distinguish if a component of iron restriction is contributing to the anemia, which helps to guide therapeutic recommendations. Serum iron levels are low in both conditions, and can also be low in dogs with portosystemic shunts.[59] Ferritin, the soluble storage form of iron in tissues, is a positive acute phase protein and in health is a representative measure of total body iron stores. Ferritin levels are classically decreased in iron-deficiency anemia and increased in anemia of

inflammation. However, ferritin can also be increased in acute hepatopathies or hepatic necrosis due to its upregulated production as an acute phase protein or increased release from damaged hepatocytes.[16,44] Transferrin is the main protein in blood that binds and transports iron. In veterinary medicine, transferrin is measured indirectly and reported as total iron binding capacity (TIBC). Transferrin is a negative acute phase protein. Although TIBC levels are typically normal to increased in cases of iron deficiency, concurrent inflammation can hinder interpretation. Elevations in transferrin can also be seen with chronic liver disease or an iron overload state.[60] Iron saturation percentages (serum iron/TIBC) less than 20% can be suggestive of iron deficiency.[60] Because conventional evaluations of MCV and MCHC for microcytosis and hypochromasia are insensitive markers of iron deficiency; reticulocyte indices are better indicators of iron status.[15] Reticulocyte indices have been evaluated in different causes of anemia. While changes in these indices are not specific to dogs with iron deficiency, dogs with decreased reticulocyte hemoglobin concentration (≤26 g/dL) and CHretic (≤20.1 pg), and increased percentage of reticulocytes with low reticulocyte hemoglobin concentration (74%) and low CHretic (>50%) should make the clinician suspicious of a diagnosis of iron-deficient anemia.[16]

Identifying the Underlying Cause of Nonregenerative Anemias

The differential diagnosis list (see Table 199-1 and Box 199-1) for causes of nonregenerative anemia is extensive. Differential diagnoses should be prioritized based on patient signalment, history and presentation. Uncommon causes of nonregenerative anemia should be considered in certain cases. Using an algorithm to guide diagnostic recommendations will help to minimize unnecessary testing while simultaneously maximizing the chances of obtaining a diagnosis (Figure 199-2).

Box 199-1

Uncommon Causes of Nonregenerative Anemia

Medullary Causes

- Primary myelodysplastic syndromes
- Primary myeloproliferative syndromes
  - Chronic granulocytic leukemia
  - Primary myelofibrosis[77]
- Primary dysmyelopoiesis
  - Congenital dyserythropoiesis
    - Springer Spaniel[61]
  - Inherited selective intestinal cobalamin malabsorption (Imerslund-Grasbeck syndrome)[51]
    - Giant Schnauzer
    - Border Collie
    - Beagle
    - Australian Shepherd
- Primary bone marrow necrosis[62]

Extramedullary Causes

- Secondary dysmyelopoiesis
  - Immune hematologic disorders
  - Estrogen-induced aplastic anemia/pancytopenia
    - Exogenous
    - Endogenous Sertoli cell tumor
  - Anticonvulsants
  - Feline retroviral infection[88]
  - Copper deficiency[28,45]
- Secondary myelofibrosis
  - Pyruvate kinase deficiency[63]
  - Feline leukemia virus infection
  - Recombinant human erythropoietin administration

Secondary bone marrow necrosis[62]
  Sepsis
  Neoplasia
  Infection
  Drugs
Myelophthisis

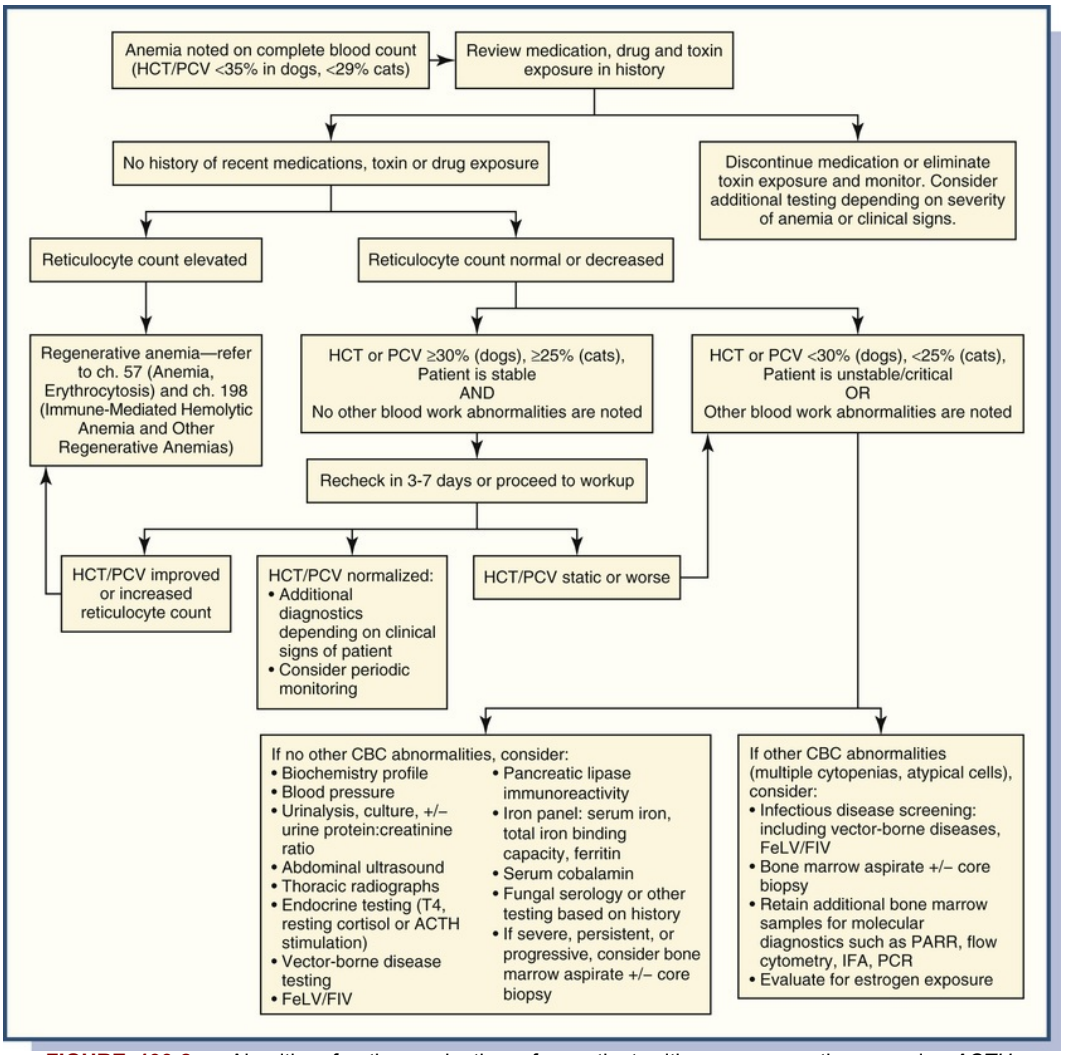

FIGURE 199-2 Algorithm for the evaluation of a patient with nonregenerative anemia. *ACTH,* Adrenocorticotropic hormone; *CBC,* complete blood count; *FeLV,* feline leukemia virus infection; *FIV,* feline immunodeficiency virus infection; *IFA,* indirect fluorescent antibody; *PARR,* PCR for antigen receptor rearrangements; *PCR,* polymerase chain reaction; *T4,* thyroxine.

Bone Marrow Failure as a Cause of Nonregenerative Anemia

Multiple bone marrow disorders produce a nonregenerative anemia (see Table 199-1 and Box 199-1). These include primary medullary disorders: pure red cell aplasia, which may be a more severe form of nonregenerative IMHA, aplastic anemia/pancytopenia, primary myelodysplastic syndromes, primary myeloproliferative disorders, primary dysmyelopoiesis and primary myelofibrosis. Secondary or extramedullary causes of bone marrow failure induce nonregenerative anemia as well, but because these disorders have an extramedullary etiology, treatment targets the primary disorder. Myelophthisis, both primary and secondary, may result in nonregenerative anemia. For more information on tumors causing myelophthisis, see ch. 344, 349, and 350. Pyruvate kinase deficiency and estrogen toxicosis lead to secondary

myelofibrosis and phenobarbital administration causes secondary dysmyelopoiesis. Secondary myelodysplastic syndromes occur in humans as a result of cytotoxic drug therapy or radiation exposure. Their occurrence has not been documented in veterinary patients. For further classification of primary and secondary medullary disorders, see ch. 202.

Diagnosis

The diagnosis of bone marrow failure requires bone marrow aspiration to assess cell morphology and a bone marrow core biopsy to assess cellularity (see ch. 92). When no other cause of a nonregenerative anemia can be identified, bone marrow testing is often the final diagnostic step (see Figure 199-2). Most primary medullary disorders carry a poor prognosis, in part because identification of the underlying molecular defect is lacking in veterinary patients and because, as the least common cause of nonregenerative anemia, their rarity hampers identification of optimal treatment.

Therapeutic Options

Treatments for nonregenerative anemia include symptomatic therapy when needed and identification and treatment of the underlying cause. If patients have clinical signs of anemia, symptomatic therapy by transfusion with packed red blood cells or whole blood may be indicated (see ch. 130). When the anemia is severe, therapeutic options may include supplementation of red blood cell building blocks such as iron and cobalamin as well as targeted use of erythropoiesis-stimulating agents until the bone marrow recovers. For specific treatments of extra-medullary causes of nonregenerative anemia, please review ch. 222 and 223. For regenerative anemia, the reader is referred to ch. 198. For further information on immunosuppressive medications, the reader is referred to ch. 195, 165, and 360.

Symptomatic Therapy

- Transfusion: Although nonregenerative anemia is more common than regenerative anemia, review of the indications for red blood cell transfusion in the dog show transfusion for bone marrow failure is much less common than for blood loss or hemolytic anemia.[64,65] Because of the high frequency of chronic kidney disease in cats, transfusion for nonregenerative anemia is more common than in the dog.[66-68] The low rate of red blood cell transfusion for nonregenerative anemia reflects the moderate degree of anemia present in this condition, its slow onset, adequate compensatory mechanisms and poor prognosis. Certain patients with nonregenerative anemia may receive multiple red blood cell transfusions, increasing the importance of blood typing (see ch. 130) and crossmatching prior to transfusion.[69]

Specific Therapies

- Iron supplementation: Iron supplementation can be administered parenterally or enterally, with parenteral administration being preferable given more reliable absorption, especially if the deficiency is secondary to malabsorption. In dogs receiving iron supplementation, CHretic and MCVretic may be more sensitive to identifying a response in iron body stores.[15] In cases of iron deficiency, parenteral supplementation results in a faster resolution as compared to enteral supplementation when reticulocyte indices are evaluated.[15] Oral supplementation, however, is the least expensive form of supplementation and is also considered the safest. Ferrous sulfate is the most common of the oral supplements, with varied dosing reported in the veterinary literature. The recommended dosage is 100-300 mg/dog per day administered orally (20-60 mg of elemental iron) or 50-100 mg/cat per day administered orally (10-20 mg of elemental iron).[34,70] Side effects with the recommended dosages include gastrointestinal upset, typically mild in nature. Concurrent administration with food may reduce absorption, as does administration with medications that increase gastric pH.[70] Administration of iron may reduce absorption of antibiotics such as fluoroquinolones and tetracyclines and dose spacing should be exercised.[70] Other oral supplements such as ferrous gluconate and ferrous fumarate are available and used for human supplementation. There is less information published regarding dosing of these in veterinary medicine; however, anecdotal information targets the same amount of elemental iron as that with ferrous sulfate administration. A suggested dosage for ferrous gluconate is 16.25 mg/kg/day in cats.[71] Parenteral supplementation includes iron dextran, iron gluconate and iron sucrose. Iron dextran is the most common parenteral supplementation in veterinary medicine. The recommended dosage is 10 mg/kg in

dogs and cats.[70,71] In cats, administration every 3-4 weeks is recommended.[70,71] Administration is recommended to be given intramuscularly, with an increased risk of anaphylactic reaction when given intravenously. It is absorbed slowly via the lymphatic system after injection, with approximately 60% of the drug absorbed within 3 days and up to 90% absorbed after 1-3 weeks.[70] Newer agents without the dextran moiety, such as iron gluconate and iron sucrose, are associated with a lower rate of anaphylactic reactions in humans and can be administered intravenously as well as intramuscularly. One of the newest of the iron-carbohydrate compounds is ferric carboxymaltose, designed to mimic physiologic ferritin.[72] However, data on the use of these newer parenteral iron supplements and intravenous administration are lacking in veterinary populations.[73]

- Erythropoiesis-stimulating agents (ESAs): The use of recombinant human ESAs may be considered in the treatment of nonregenerative anemia. Dogs with a nonregenerative anemia lacking features of primary myelodysplasia respond to the use of ESAs and tend to have a prolonged survival in comparison to dogs with primary myelodysplasia, who typically do not respond to standard therapies.[74] However, ESAs have also been used with positive response in a case of myelodysplastic syndrome with erythroid predominance in a dog.[75] In humans, ESAs are in wide clinical use and are the most commonly used therapy for anemias secondary to myelodysplastic syndromes, despite not being approved by the Food and Drug Administration for this specific use.[76] In dogs with secondary myelofibrosis, the use of ESAs in conjunction with other therapies is associated with a prolonged survival.[77] In humans, these agents are also used to address relative erythropoietin deficiency, as is seen with multiple myeloma and non-Hodgkin's lymphoma.[78]

Several recombinant human erythropoietin products are available on the market including epoetin alfa, epoetin beta and darbepoetin alfa. Significant homology (>80%) between human erythropoietin and canine and feline erythropoietin allows recombinant human products to bind to and interact with erythropoietin receptors in dogs and cats.[79,80] Darbepoetin is hyperglycosylated compared to epoetin, resulting in a circulating half-life that is three times longer than that of epoetin and a reduction in mean clearance time by over 70% (mL/kg × h).[81] The choice of which agent to use should be based on numerous factors. Darbepoetin is only administered once weekly and anecdotally is associated with a reduced risk of pure red cell aplasia secondary to the formation of anti-erythropoietin antibodies as compared to epoetin.[34] In cats, the recommended dosage is 1 mcg/kg SC once weekly initially.[34,82] Once the target PCV is attained, frequency of administration is decreased to every 2-3 weeks with the dosage further adjusted to maintain the PCV within the target range (25-35%).[34] For dogs, the recommended initial dosage in the literature is 0.45 mcg/kg SC once weekly with adjustments accordingly to maintain PCV in target range (37-45%).[70] Epoetin requires administration three times a week, but it may be marginally less expensive than darbepoetin in comparison.[34] The recommended starting dosage in dogs and cats is 100 units/kg subcutaneously three times weekly.[70] Once target PCV is attained, dosing frequency can be reduced to twice weekly as maintenance therapy.[70] Aside from pure red cell aplasia, other side-effects of these agents include hypertension, seizures and iron deficiency.[70] Concurrent monthly parenteral iron supplementation is recommended when ESAs are administered. For epoetin specifically, additional adverse events of local reactions at injection sites (which may be predictive of antibody formation), fever, arthralgia, and mucocutaneous ulcers are also possible.[70]

Treatment of Medullary Causes of Nonregenerative Anemia

Evidence-based treatments for nonregenerative anemia stemming from primary medullary disease are lacking in veterinary medicine. Single case reports and case series predominate in the literature and because multiple classification schemes exist for bone marrow diseases, comparison of treatment outcomes is difficult.

- Glucocorticoids: If, despite the poor prognosis for recovery in pets with bone marrow failure, treatment is pursued, nearly all patients receive initial treatment with immunosuppressive doses of glucocorticoids (see ch. 165). Many dogs with pure red cell aplasia or the nonregenerative variant of immune mediated hemolytic anemia, respond to glucocorticoids with resolution of anemia.[23,83] In other bone marrow disorders, response is more variable.
- Cyclophosphamide: Although most dogs with pure red cell aplasia and the nonregenerative variant of immune mediated hemolytic anemia respond to glucocorticoid immunosuppression, some dogs appear to require additional immunosuppression with cyclophosphamide 50 mg/m^2 PO q 24 h × 4 days, repeated weekly.[23,83] Cyclophosphamide is not currently recommended for the treatment of regenerative immune

mediated hemolytic anemia (see ch. 198).

- Azathioprine: As an alternative to cyclophosphamide, azathioprine (2 mg/kg PO q 24 h × 5 days and then q 48 h) has been recommended for the treatment of pure red cell aplasia and the nonregenerative variant of immune mediated hemolytic anemia.[23]
- Hydroxyurea: Chronic granulocytic leukemia represents an extremely rare primary myeloproliferative disorder in the dog. If treatment is indicated, hydroxyurea 50 mg/kg PO once daily can induce remission.[84,85] If remission is achieved, dosing frequency can be decreased to every 48 to 72 hours. In humans, a chromosomal translocation drives increased production of granulocytes in chronic granulocytic leukemia which can be inhibited by treatment with tyrosine kinase inhibitors. The presence of a similar mutation in dogs with chronic granulocytic leukemia has not been documented.
- Other cytotoxic or immunosuppressive agents: Cytarabine, cyclosporine and combination chemotherapy have been used with variable success to treat myelodysplastic syndromes in feline leukemia virus-positive cats.[89] In humans, cyclosporine coupled with other immunosuppressive agents can induce remission in patients with pure red cell aplasia and certain myelodysplastic syndromes. Evidence for the use of cyclosporine in veterinary patients with pure red cell aplasia and myelodysplastic syndromes is lacking.[86,87]
- Vitamin K2: A preliminary report indicated a vitamin K2 analog (menatetrenone) was beneficial in feline myelodysplastic syndromes when given at a dosage of 2 mg/kg.[89] Menatetrenone promotes cellular differentiation *in vitro*.

New Directions in Therapy

Management of nonregenerative anemia of inflammation using iron and ESAs is ineffective for some patients and there are risks, driving the search for novel therapies targeting the hepcidin-ferroportin axis, including inhibiting hepcidin function with direct hepcidin antagonists, preventing hepcidin transcription with hepcidin production inhibitors (including IL-6 pathway inhibitors and vitamin D), and promoting ferroportin resistance to hepcidin action with ferroportin agonists/stabilizers.[90] As the use of these agents is further explored for humans and their efficacy and safety profiles are established, these novel agents will be considered in veterinary patients to expand our armament of options for long-term management of these challenging cases.

CHAPTER 200

Primary Polycythemia and Erythrocytosis

Ann E. Hohenhaus

Client Information Sheet: Excessive Numbers of Red Blood Cells

Definitions

The term erythrocytosis indicates an increase in red blood cell count, hemoglobin concentration and hematocrit compared to the reference range and is due to either increased red blood cell mass or decreased plasma volume. Increasing reports of breed-specific reference ranges with red blood cell count, hemoglobin concentration and hematocrit greater than the traditional laboratory reference ranges, suggest a diagnosis of erythrocytosis should not be made in a purebred dog until the breed-specific reference range has been reviewed.[1-3] Polycythemia is often considered synonymous with erythrocytosis, but in this chapter, polycythemia will be used with relative, primary, or secondary to indicate the mechanism for the erythrocytosis (Figure 200-1). Relative polycythemia occurs when plasma water is lost without concurrent loss of red blood cells. Primary polycythemia, or in the lexicon of human medicine, polycythemia vera, is a myeloproliferative disorder where production of red blood cells is constitutive and independent of the production of erythropoietin. In primary polycythemia, the negative feedback loop remains intact and the increased number of red blood cells delivers adequate oxygen to the kidney, inhibiting renal erythropoietin production. In humans with primary polycythemia, white blood cell and platelet counts are commonly elevated and 90% of patients have a mutation in the JAK2 gene. The presence of this mutation has become an important diagnostic criterion for polycythemia vera.[4] A JAK2 mutation has been sequenced in a dog with primary polycythemia.[5] Occasionally, cats with primary polycythemia also have thrombocytosis.[6] Secondary polycythemia is either physiologically appropriate, resulting from an increase in erythropoietin production in response to hypoxemia, or physiologically inappropriate, resulting from an increase in erythropoietin production in the absence of hypoxemia. Physiologically inappropriate secondary polycythemia is most commonly due to paraneoplastic production of erythropoietin. Both erythropoietin mRNA and its protein product have been identified in tumors associated with polycythemia.[7,8] A specific subset of physiologically inappropriate secondary polycythemia is hormone-mediated via thyroxine, growth hormone and cortisol, because of the stimulatory effects these hormones have on the production of red blood cells.[9,10]

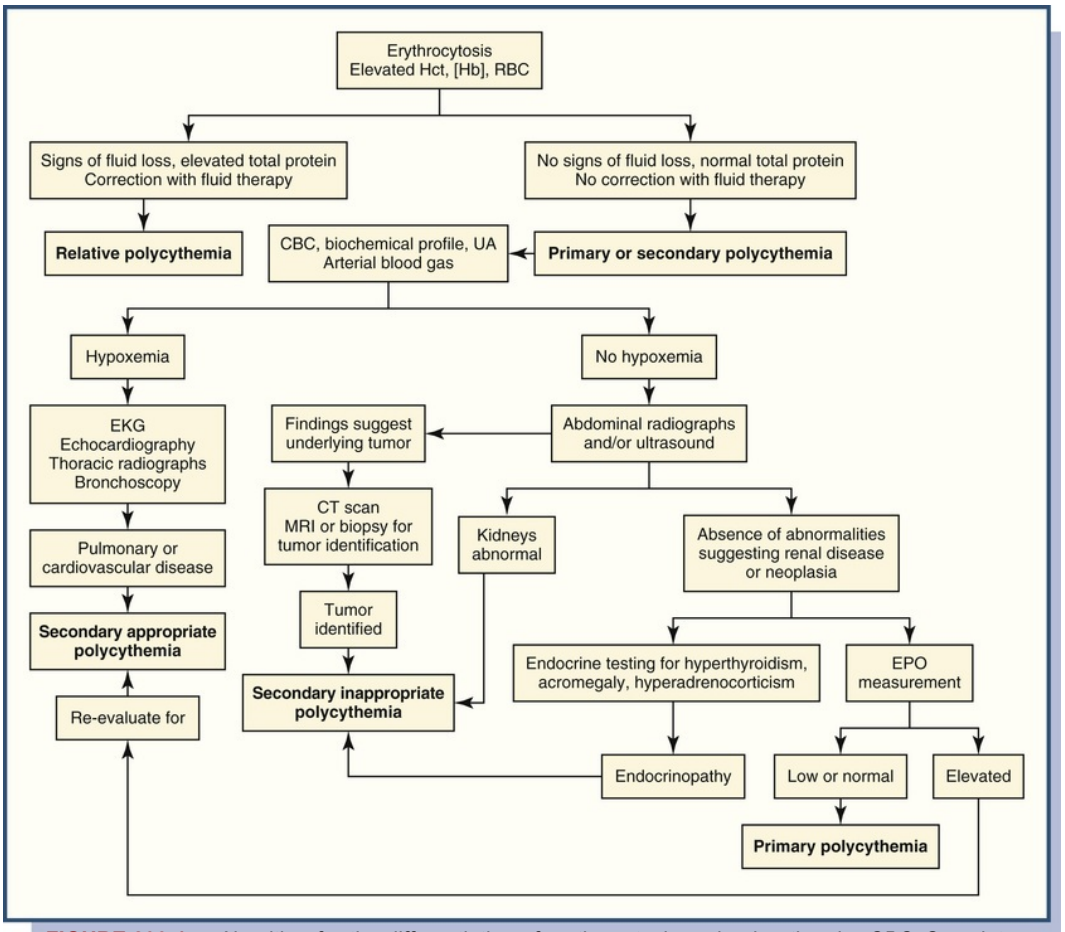

FIGURE 200-1 Algorithm for the differentiation of erythrocytosis and polycythemia. *CBC,* Complete blood count; *CT,* computed tomography; *EKG,* electrocardiogram; *EPO,* erythropoietin; *Hb,* hemoglobin; *Hct,* hematocrit; *RBC,* red blood cell count; *UA,* urinalysis.

Normal Erythropoiesis

Red blood cells, specifically hemoglobin, transport oxygen to tissues. The kidneys serve as the sensor organ for hypoxemia. Renal hypoxia stimulates production of hypoxia inducible factor which in turn stimulates the cortical interstitial fibroblasts to produce erythropoietin.[11] Thyroid hormone directly increases proliferation of erythroid progenitor cells and also enhances hypoxia inducible erythropoietin production.[12] Glucocorticoids synergize with hypoxia inducing factor to stimulate burst forming units—erythroid, cells capable of self renewal.[13] These mechanisms may account for the erythrocytosis seen in patients with hyperthyroidism and hyperadrenocorticism. Growth hormone directly stimulates hematopoiesis or binds to receptors such as those for insulin-like growth factor and prolactin stimulating red blood cell production.[14]

Erythropoiesis in Polycythemia

Control of red blood cell production in polycythemia depends on the type of polycythemia. In relative polycythemia, red blood cell production is not altered. The apparent increase in red blood cells stems from intravascular fluid loss. In secondary polycythemia, the increased red blood cell count results from an increase in erythropoietin in response to hypoxemia in physiologically appropriate polycythemia or an increase in erythropoietin, independent of hypoxemia, often a paraneoplastic process, in physiologically inappropriate polycythemia. Two mechanisms for increased erythropoietin production and subsequent polycythemia secondary to renal disease have been proposed: renal hypoxia as a consequence of the primary disease process and increased or aberrant erythropoietin production by neoplastic cells. The origin of excessive red blood cell production in primary polycythemia is unknown, but a genetic mutation underlies the disease in humans and recent investigations suggest a similar mechanism in dogs.[4,5]

Clinical Signs and Physical Examination Findings in Polycythemia

The clinical signs associated with polycythemia vary, depending on the underlying cause. Hallmarks of relative polycythemia include dehydration and clinical evidence of fluid loss, most commonly from vomiting and/or diarrhea. Excitement, exercise or stress can also result in relative polycythemia. Hyperviscosity and hypervolemia cause clinical signs in both primary and secondary polycythemia, but do not occur in relative polycythemia (Box 200-1). Additionally, dogs and cats with secondary polycythemia may show signs referable to the underlying cardiovascular, renal, respiratory or neoplastic disease (Box 200-2).

Box 200-1

Causes of Clinical Signs and Physical Examination Findings in Primary and Secondary Polycythemia

Hypervolemia

- Ocular manifestations
  - Engorged, tortuous retinal vessels
  - Uveitis[33]
  - Retinal detachment/hemorrhage
  - Glaucoma
- Engorged mucous membranes

Hyperviscosity

Central Nervous System Signs

- Fainting
- Weakness/posterior paresis/ataxia
- Seizures
- Lethargy/depression
- Other central nervous system signs

Unclassified or Multiple Mechanisms

- Hemorrhage
  - Epistaxis
  - Hematochezia
  - Hemorrhagic diarrhea
  - Hematemesis
- Polyuria/polydipsia[34]
- Vomiting
- Diarrhea

Box 200-2

Causes of Secondary Polycythemia

Physiologically Appropriate (Hypoxemia Present)

- Cardiac
  - Right-to-left shunting
    - Patent ductus arteriosus[27,29]
    - Tetralogy of Fallot[35]
    - Persistent truncus arteriosus[36]
- Hematologic
  - Hemoglobinopathy (not reported in animals)
- Respiratory
  - Pulmonary parenchymal disease
  - Pulmonary vascular amyloidosis[37]

High altitude
Obesity
Renal
Lymphoma[38]

Physiologically Inappropriate (Hypoxemia Absent)

Renal
Pyelonephritis[24,39]
Local renal hypoxia
Neoplasia
Nasal fibrosarcoma[40]
Schwannoma[8]
Cecal leiomyosarcoma[7]
Renal cell carcinoma[21,23,26,39,41]
Renal fibrosarcoma[42]
Renal lymphoma[43]

Diagnostic Testing

In dogs and cats identified with erythrocytosis based on results of a complete blood count or a packed cell volume, a point of care hemoglobinometer can be used to accurately confirm elevated hemoglobin.[15] In patients suspected to have relative polycythemia because of obvious fluid loss and elevation of serum total protein concentration, treatment with intravenous fluids and resolution of erythrocytosis confirms the diagnosis.

When erythrocytosis does not resolve with fluid therapy, history, physical examination and diagnostic testing should focus on distinguishing primary from secondary polycythemia. Pet owners should be queried regarding residency in or prolonged travel to a low-oxygen environment as a cause of secondary appropriate polycythemia. Physical examination may reveal organ system abnormalities such as a heart murmur, increased respiratory rate, a tumor or signs consistent with an endocrinopathy. In these patients, diagnostic testing should further evaluate those abnormalities.

Erythrocytosis in the presence of normal arterial oxygen saturation (see ch. 75 and 128) and in the absence of conditions known to be associated with secondary polycythemia is the current diagnostic standard for primary polycythemia in dogs and cats. Since the diagnosis of primary polycythemia is one of exclusion, testing should follow an organized scheme focusing on the respiratory, cardiovascular and renal systems as well as searching for neoplastic causes of polycythemia (see Figure 200-1). Arterial blood gas sampling with arterial oxygen saturation below 92% indicates hypoxemia is present and suggests a secondary physiologically appropriate polycythemia. If metabolic acidosis without hypoxemia is present, the acidosis is most likely the result of increased blood viscosity and sluggish blood flow and could be due to either primary or secondary inappropriate polycythemia.[16] An increase in red blood cell mass can be confirmed using ^{51}Cr labeled autologous erythrocytes, but this is impractical in routine clinical medicine. Thrombocytosis has been reported in association with primary polycythemia in a cat.[6] Primary polycythemia has also been associated with cardiac hypertrophy and a transient glomerulopathy.[17,18]

Erythropoietin Measurement

Measurement of erythropoietin levels cannot substitute for a thorough diagnostic evaluation; however, it will be most helpful in confirming a diagnosis of secondary polycythemia. Arterial oxygen saturation below 92% stimulates the production of erythropoietin in secondary physiologically appropriate polycythemia and paraneoplastic elevation of erythropoietin can be detected in secondary physiologically inappropriate polycythemia. The use of an erythropoietin assay validated for the species being tested is imperative, and the lack of a readily available one limits the clinical utility of erythropoietin measurement. Overlap between the erythropoietin reference range in clinically normal dogs and cats with that found in cases of primary polycythemia means erythropoietin values must be cautiously interpreted.[19,20] Elevated levels of erythropoietin suggest a diagnosis of secondary polycythemia should be strongly considered.

Treatment

The initial goal of treating primary and secondary polycythemia is control of clinical signs through reduction of the hematocrit with phlebotomy. In cases of secondary polycythemia, successful treatment of the underlying cause can resolve the polycythemia without additional therapy.[7,8,21-24] When the primary disease process cannot be corrected, such as in congenital cardiac disease with right to left shunting, management of secondary polycythemia is similar to that of the primary form. Some authors suggest a goal of decreasing the hematocrit to the upper end of the reference range except in patients with cyanotic heart disease, making the target PCV 58-65% (see ch. 250).[25]

Phlebotomy

Rapid reduction of the hematocrit by phlebotomy (15-20 mL/kg) and volume replacement using crystalloids or colloids should be the first line of therapy, although not all patients seem to require fluid replacement.[26-28] Pet and pet owner tolerance of chronic phlebotomy will determine if this treatment can be used as a method of long-term treatment for polycythemia.[28,29] Leeching, a natural form of phlebotomy, has been successfully used to treat primary polycythemia in a cat.[30]

Myelosuppressive Therapy

If phlebotomy is required more than once every four weeks or is difficult due to hyperviscosity, myelosuppressive therapy is indicated. Hydroxyurea is most commonly prescribed. Dosing strategies are empiric: 50 mg/kg q 48 h; 30 mg/kg daily for 7 days followed by a maintenance dosage of 15 mg/kg q 24 h or 12.5 mg/kg q 24 h.[26,27,31] Exact dosage and frequency should be titrated for each individual patient. Chlorambucil has been used in humans with polycythemia vera, but was associated with increased risk of leukemia transformation, limiting its utility. No information regarding its use for primary polycythemia in dogs and cats is available. Radiophosphorus treatment using ^{32}P has proven successful for the treatment of canine polycythemia, but radiological safety issues have made its use uncommon.[32]

Complications of Treatment

Overzealous/chronic phlebotomy can result in iron deficiency, hypoproteinemia, and peripheral edema.[7] Care must be taken when using phlebotomy to control physiologically appropriate secondary polycythemia that balance is maintained between the need to control the clinical signs due to hyperviscosity while still maintaining an adequate number of red blood cells to provide adequate tissue oxygenation. Myelosuppressive therapy may result in leukopenia and thrombocytopenia but these abnormalities are often clinically silent. In humans, thrombosis is the main cause of morbidity and mortality in patients with polycythemia vera. Thrombosis has not been reported as a complication of primary polycythemia in veterinary patients.

Client Information Sheets:
Immune-Mediated Thrombocytopenia
Platelet Function Disorders
Von Willebrand Disease

Primary Hemostasis

Overview

Platelets play a critical role in the initiation, regulation, and localization of hemostasis. The term primary hemostasis refers to the interactions among platelets, von Willebrand factor (VWF), and the vessel wall that culminate in the formation of a platelet plug. These reactions begin with platelets contacting a damaged vessel wall, VWF-mediated adhesion and proceeding through platelet activation, degranulation, aggregation and concluding with development of platelet-dependent procoagulant activity and clot retraction.

Platelet Physiology

Megakaryocytic precursor cells in the bone marrow are programmed, through the action of transcription factors and thrombopoietin, to form platelet-specific organelles and to express platelet cell surface proteins. In the final stages of megakaryocyte maturation, large pseudopodia develop and stretch to form thin proplatelet processes. The processes elongate as platelet organelles move individually over microtubules to the end of the proplatelet, where nascent platelets accumulate. The growing proplatelets branch and form constrictions along their length, giving them a beaded appearance. The entire megakaryocyte is converted into a mass of proplatelets that break away from the megakaryocyte body and fragment into individual platelets. The platelets are released from the marrow and circulate in the vascular compartment as quiescent, nonadhesive, smooth disks. There they act as sentinel cells scanning for sites of vessel damage. Approximately 100 billion platelets are released each day to maintain a peripheral platelet count of 200 million to 500 million cells per milliliter of blood. Platelets have a lifespan of 6 to 10 days in circulation.

Injury to a vessel wall triggers platelet activation within nanoseconds. In the initial step of activation, platelets rapidly transform into adhesive, spiny spheres capable of recognizing and binding to exposed subendothelial matrix components. Surface binding initiates cell-signaling pathways, which then mediate granule secretion. Granule contents include adenine nucleotides, calcium, serotonin, and adhesive proteins such as fibrinogen, VWF, fibronectin, and P-selectin. Secreted compounds accumulate locally, interact with their respective surface receptors, and recruit additional platelets to the site of injury. Large-order platelet aggregates then accumulate and bridge the zone of vascular damage to form a hemostatic plug. Thrombin cleavage of fibrinogen strengthens the platelet plug as a fibrin-platelet meshwork develops.

A subset of collagen and thrombin-activated platelets, termed coated-platelets,[1] scramble phosphatidylserine (PS) from the inner plasma membrane leaflet to the outer platelet membrane surface and release PS-rich microparticles, which act as scaffolding for assembly of highly active tenase and prothrombinase coagulation factor complexes. Expression of platelet procoagulant activity (PCA) greatly amplifies local thrombin and fibrin generation. Contraction of platelet cytoskeletal proteins linked to platelet integrin receptors for fibrin and fibrinogen results in consolidation and subsequent retraction of the growing clot.

Platelet activation requires simultaneous engagement of the platelet membrane surface receptors (Figure 201-1). Species differences in response to platelet stimuli may reflect differences in receptor density and/or subclasses for specific ligands. The endoperoxides prostacyclin (prostaglandin I_2 [PGI_2]), prostaglandin E_2 (PGE_2), and prostaglandin D_2 (PGD_2), which are synthesized by endothelial cells and released into the vascular space, serve as antagonist ligands that react with their respective platelet receptors to dampen platelet reactivity.[2]

Platelet integrins and nonintegrin glycoprotein receptors play a critical role in adhesion (platelet–subendothelial matrix interactions) and aggregation (platelet-platelet association). The alpha-IIb-beta-3 complex ($GPII_b/III_a$) is the most abundant platelet integrin and functions as the activation-dependent receptor for fibrinogen, fibronectin, and VWF. Binding of fibrinogen to this receptor is essential for aggregation and clot retraction.[3] Platelet adhesion to collagen and collagen-induced signaling are supported by collagen's interaction with the integrin receptor alpha-2-beta-1 (GPI_aII_a) and interaction of collagen with platelet GPVI.

Surface receptors, coupled to G proteins, span platelet membranes and transmit signals induced by agonist binding. In platelets, Gq serves as the link for most agonists and is coupled to phospholipase C, which in turn generates diacylglycerol (DAG) and inositol triphosphate, leading to calcium release from the endoplasmic reticulum, protein kinase C and myosin light chain kinase activation, and phosphorylation of platelet-signaling proteins. During activation, phospholipase A_2 releases arachidonic acid from membrane phospholipids. Cyclooxygenase and thromboxane synthetase convert arachidonic acid to the potent agonist thromboxane A_2 (see Figure 201-1).

Platelet–von Willebrand Factor Interaction

Subendothelial collagen fibrils and bound VWF are exposed after vascular endothelial injury. The affinity and strength of the VWF-collagen bond is proportional to VWF multimer size. Collagen-bound VWF displays a conformational change that allows it to interact with the platelet GPIb/V/IX complex. As platelet GPIb contacts and engages with VWF, platelets slowly roll and become activated by interaction with collagen fibrils. VWF then binds to $GPII_b/III_a$ receptors exposed on the surface of activated platelets. Adhesion and aggregation at high shear rates depend on this VWF binding to activate platelet $GPII_b/III_a$.

Clinical Presentation of Primary Hemostatic Disorders

Surface bleeding is a hallmark feature of primary hemostatic disorders. Petechiae, ecchymoses and epistaxis (see ch. 54) are most commonly observed with severe thrombocytopenia (platelet count <30,000/mcL) but may also be noted with a thrombopathia or vasculopathy (see ch. 59 and 135). Von Willebrand disease (VWD) rarely causes petechiae, although ecchymoses may be observed in some dogs with VWD following trauma and surgical procedures. Mucosal surface bleeding (e.g., epistaxis, melena, hematuria) may be severe and lead to blood loss anemia requiring transfusion therapy (see ch. 130). Life-threatening bleeding into the central nervous system or lungs may occur.[4-6] Although cavity bleeding is more commonly associated with disorders of secondary hemostasis (i.e., coagulopathy), hematomas, hemothorax, hemoperitoneum, and hemarthrosis have been reported in dogs with primary hemostatic disorders.[5,7-9] Excessive bleeding following surgery or trauma might be the first indication of a hereditary bleeding disorder, including primary hemostatic defects, coagulopathy (e.g., hemophilia), or excessive fibrinolysis. Repeated episodes of surface bleeding or similar bleeding in related individuals should prompt evaluation for a hereditary primary hemostatic disorder.

Immune-Mediated Thrombocytopenia

Definitions/Pathophysiology

Primary Immune-Mediated Thrombocytopenia (IMT)

IMT is a disorder in which antibodies bind to platelet surfaces resulting in their destruction, leading to severe thrombocytopenia. Primary IMT, also referred to as idiopathic thrombocytopenic purpura (ITP), is an autoimmune disorder in which antibody is directed against platelet surface antigens. Antibodies directed against epitopes on the platelet GPIIb/IIIa, the fibrinogen receptor, have been identified in dogs with primary IMT.[10] In addition, a novel canine model of primary IMT has been developed using a murine monoclonal antibody, 2F9, against canine GPIIb that causes profound, dose-dependent, thrombocytopenia.[11] A detailed review of the immunopathogenesis of primary IMT is beyond the scope of this chapter, but a recent pilot study documented a reduction in regulatory T (Treg) cells, which play an important role in self-tolerance and regulation of immune responses, in the peripheral blood of dogs with primary IMT, suggesting that loss of Tregs might be causally associated with the onset of primary IMT in dogs.[12]

Secondary Immune-Mediated Thrombocytopenia (IMT)

Secondary IMT develops as a result of an antigenic stimulus, typically from a drug, infectious disease, or neoplasia, leading to antibody production. A retrospective, case-control study of 48 dogs with presumptive primary IMT failed to find an association between recent vaccination (within 42 days) and onset of IMT.[13] Any drug has the potential to cause secondary IMT, but antibiotics, including sulfonamides and cephalosporins, are most common.[14-16] There is a single case report of IMT, in combination with immune-mediated hemolytic anemia (IMHA) and neutrophilic dermatitis, in a young dog that was suspected to be an adverse reaction to carprofen.[17] When a medication is administered for the first time, approximately 5 to 7 days of exposure is typically required to produce sensitization and onset of thrombocytopenia, though subsequent re-exposure to the same drug could result in a rapid thrombocytopenia relapse due to the indefinite persistence of antibodies.[18] Infectious agents that have been associated with development of platelet-bound antibody in dogs include: *Anaplasma phagocytophilum*,[7,19] *Babesia* sp.,[5,7,20] *Ehrlichia canis*,[5,7] *Leptospira* sp.,[5,7] and *Leishmania infantum*.[7,21] This suggests that the thrombocytopenia noted with these conditions might be due in part to secondary IMT. Neoplasia can be associated with thrombocytopenia through several mechanisms (e.g., increased platelet consumption secondary to a bleeding tumor or disseminated intravascular coagulation, splenic sequestration, decreased platelet production due to myelophthisis), in addition to secondary IMT. Neoplastic disorders in which platelet-bound antibodies have been documented include lymphoma,[5,7] hemangiosarcoma,[5] and histiocytic sarcoma.[7] Inflammatory diseases, including chronic hepatitis, pancreatitis, and systemic inflammatory response syndrome (SIRS), have also been associated with platelet-bound antibodies in thrombocytopenic dogs.[7] A single dog was reported to have presumptive secondary IMT following massive Africanized bee envenomation.[22]

Diagnostic Evaluation

Thrombocytopenia is a common laboratory abnormality noted in dogs and cats and may be spurious due to traumatic venipuncture and clumping of platelets. If there is no evidence of bleeding, one should repeat a platelet count on a fresh blood sample and evaluate the blood smear for evidence of platelet clumps (see ch. 59). In a retrospective study of 871 dogs with thrombocytopenia (defined as platelet count <150,000/mcL), primary IMT accounted for only 5.6% of the cases, while thrombocytopenia was attributed to neoplasia and infectious/inflammatory disease in 28 and 35% of the dogs, respectively.[8] However, IMT is considered the most common cause of *severe* thrombocytopenia in dogs.

The diagnosis of primary IMT is always presumptive and based on exclusion of known causes of thrombocytopenia and underlying diseases. This necessitates a complete medical history, physical examination, and diagnostic evaluation that may include imaging and infectious disease screening (see ch. 59). The physical examination of dogs with primary IMT frequently reveals evidence of surface bleeding (petechiae, ecchymoses, epistaxis) and, potentially, pallor, splenomegaly, and fever.[5] Severe thrombocytopenia (≤30,000/mcL) is typical[5,7,8,13,23] and might be the only laboratory abnormality noted. In a retrospective study of 48 dogs with presumptive primary IMT, the median platelet count was 1,000/mcL (range 0-39,500/mcL).[13] A platelet count ≤30,000/mcL has been positively correlated with the occurrence of spontaneous bleeding in dogs with IMT.[5] In clinical practice, the diagnosis of primary IMT is typically based on the finding of severe thrombocytopenia, exclusion of underlying disease, and a response to immunosuppressive therapy (see below).

Documentation of platelet-bound antibody further supports a diagnosis of IMT. A flow cytometric assay to detect platelet-bound antibody (also referred to as platelet surface-associated IgG [PSAIgG]) is considered a sensitive but not specific tool for the diagnosis of primary IMT, as the assay does not differentiate platelet autoantibodies from antibodies induced by underlying infection, neoplasia, or drugs.[5,7,8,20] Increased PSAIgG values were detected in 10 of 13 dogs (77%) with primary IMT and all 4 dogs (100%) with secondary IMT due to *Babesia gibsoni* infection.[20] However, a negative platelet-bound antibody test makes a diagnosis of IMT, either primary or secondary, unlikely.[24] EDTA-anticoagulated blood samples are recommended for evaluation of PSAIgG, and the age of the sample is critical, as PSAIgG values have been documented to increase 3- to 7-fold in normal dog blood samples stored for 24-72 hours.[20] Testing for PSAIgG is available through the Clinical Immunology/Flow Cytometry Laboratory at Kansas State University College of Veterinary Medicine. Other platelet parameters, including mean platelet volume (MPV), mean platelet component (MPC), and plateletcrit, have been evaluated in dogs with primary IMT but are unlikely to aid in

making a diagnosis.[7,23,25,26]

Treatment and Outcome

Immunosuppression

Removal of the offending drug or treatment of the underlying disease is essential for resolution of thrombocytopenia in dogs with secondary IMT. Concurrent immunosuppressive therapy may be necessary in some dogs, though it is generally recommended to treat any underlying infectious disease first and reserve immunosuppression for those dogs not responding to antimicrobial therapy. Glucocorticoids are the mainstay of treatment for primary IMT (see ch. 165 and 195). Vincristine and human intravenous immunoglobulin (hIVIG) have been documented to shorten duration of severe thrombocytopenia in dogs with primary IMT compared to prednisone alone.[27-29] In a prospective study of 24 dogs, 12 treated with prednisone alone and 12 treated with prednisone and vincristine (0.02 mg/kg IV once at the time of initial diagnosis of IMT), dogs that received vincristine had a significantly faster increase in platelet count to >40,000/mcL, with a mean response time of 4.9 days compared to 6.8 days for dogs treated with prednisone alone.[27] A subsequent clinical trial comparing prednisone alone (n = 9 dogs) to prednisone plus a single dose of hIVIG (0.5 g/kg) (n = 9 dogs) documented that adjunctive therapy with hIVIG resulted in a shorter time for platelet recovery (median, 3.5 days vs. 7.5 days).[28] Given the expense associated with hIVIG, another group compared the effect of single dose hIVIG (0.5 g/kg) with vincristine (0.02 mg/kg) on platelet recovery time in dogs with primary IMT receiving concurrent corticosteroid therapy; there was no difference between the treatment groups (10 dogs in each group), both having a median platelet recovery time of 2.5 days.[29] It was concluded that vincristine should be the first-line adjunctive treatment for the acute management of canine primary IMT because of its lower cost and ease of administration as compared with hIVIG.[29] Although vincristine, at a single dose of 0.02 mg/kg IV, is generally well tolerated by dogs with primary IMT (no adverse reactions noted in the 22 dogs receiving vincristine in the above studies), there are potential complications, including perivascular sloughing with extravasation. Since the majority of dogs with primary IMT respond to glucocorticoids alone with 7 days,[27,28] adjunctive treatment may not always be necessary. The duration of treatment for dogs with primary IMT varies, but many dogs are managed with tapering dosages of immunosuppressive drugs over 4 to 6 months while monitoring for relapse.[6]

Immunomodulation

Beyond administration of vincristine and hIVIG for management of acute and severe thrombocytopenia, there are no prospective, controlled studies documenting efficacy of adjunctive immunomodulatory agents in treatment of dogs with primary IMT. However, retrospective studies and case series of canine primary IMT report on use of azathioprine,[5,6,13] cyclosporine,[5,6] and mycophenolate mofetil[6] in combination with corticosteroids (with or without vincristine). It is not possible to make conclusions regarding their efficacy, however. There is a case report describing treatment with mycophenolate mofetil (median dosage 8.5 mg/kg PO q 12 h) as a single agent in 5 dogs with presumptive primary IMT in which corticosteroids were considered contraindicated due to chronic nonsteroidal anti-inflammatory drug administration.[30] All 5 dogs achieved a complete remission, with the time for platelet recovery (platelet count >50,000/mcL) ranging from 2 to 6 days and no evidence of relapse during a median follow-up time of 16 months (range 5 to 32 months).[30]

Transfusion Therapy

In addition to immunosuppressive therapy, blood transfusions (see ch. 130) might be required in dogs with IMT and severe mucosal surface bleeding, most commonly into the gastrointestinal (GI) tract. In such cases, packed red blood cell (PRBC) transfusions are indicated to provide additional oxygen-carrying support. Platelet transfusions are uncommonly administered to dogs with IMT due to the belief that transfused platelets are rapidly destroyed following administration. However, in dogs with IMT experiencing uncontrolled or life-threatening bleeding (e.g., suspected bleeding into the brain or lungs), platelet transfusions may provide short-term hemostasis despite a negligible increase in platelet count post-transfusion. In clinical practice, fresh whole blood is the most readily available platelet source, but other options include fresh platelet-rich plasma (PRP) or platelet concentrate (PC) and cryopreserved platelets.

Although not yet commercially available, lyophilized canine platelets may be an option in the future. The safety and feasibility of administering lyophilized canine platelets to dogs with naturally-occurring thrombocytopenia were evaluated in a multicenter, prospective randomized clinical trial in which 37 dogs

(including 27 dogs diagnosed with primary IMT) were enrolled: 22 dogs in the lyophilized platelet group and 15 in the fresh PC group.[31] The mean pre-transfusion platelet counts were ≈17,000/mcL, and the most common clinical signs of bleeding included petechiae, ecchymoses, and GI hemorrhage. The bleeding severity in each group was described as mild to severe. Fresh PC and lyophilized platelets were dosed at approximately 6.6×10^9 and 3.3×10^9 platelets/kg BW, respectively. Evidence of active bleeding was unchanged immediately post-transfusion in 18 of 22 dogs receiving lyophilized platelets and in all dogs receiving fresh PC. Potential adverse reactions to platelet transfusions were noted in 3 dogs in the lyophilized platelet group (one each: fever, sinus tachycardia, and emesis) and 2 dogs in the fresh PC group (1 each: urticaria and emesis). There was no difference between treatment groups in the need for additional PRBC or platelet transfusions, length of hospitalization, hospital discharge rate, or 28-day survival. While the efficacy of lyophilized platelets could not be evaluated, their administration was easy and associated with a low adverse reaction rate.[31]

Prognosis

Dogs with primary IMT have a good prognosis with appropriate treatment and supportive care, including blood transfusions when blood loss anemia is severe. In one retrospective study of 30 dogs, 29 dogs (97%) survived to 14 days after initial presentation, and 27 (93%) dogs survived at least the following 15 to 1684 days (median 220 days); of 19 dogs observed over an extended period (112 to 1684 days; median 340 days), 5 dogs (26%) relapsed with thrombocytopenia between days 19 to 286 (median 66 days).[5] In another retrospective study of 73 dogs with IMT (25% of which tested positive for vector-borne diseases, and, therefore, may have had secondary IMT), 61 dogs (84%) survived to hospital discharge; of 54 dogs that were followed long-term, 5 dogs (9%) had recurrence of their thrombocytopenia, with a median interval to relapse of 1,743 days (range, 735 to 2,555 days).[6] Similarly, in a third study, the in-hospital mortality rate among 48 dogs with primary IMT was 19%, with 77% of dogs (36 of 47) surviving to at least 1 month after discharge and 43% surviving beyond 1 year of discharge.[13]

Concurrent IMT and IMHA in Dogs

Dogs with IMT infrequently have sequential or concurrent IMHA, a condition referred to as Evans' syndrome in humans (see ch. 198). Two retrospective studies have reported on the outcome of dogs with concurrent IMHA and severe thrombocytopenia, with differing conclusions. 21 dogs with concurrent IMHA and severe thrombocytopenia (defined as <50,000/mcL) were identified and 16 (76%) died or were euthanized within 30 days of hospital admission, leading to a conclusion that concurrent IMHA and severe thrombocytopenia is associated with a poor outcome.[32] In contrast, 12 dogs with concurrent IMHA and severe thrombocytopenia (defined as platelet count ≤15,000/mcL) had a mortality rate of 25%, similar to that reported for dogs with IMT or IMHA alone, suggesting that dogs with concurrent IMHA and IMT do not have a worse prognosis.[33] A potential explanation for differences in these 2 studies is the greater likelihood of excluding dogs with disseminated intravascular coagulation (DIC), known to have a poor prognosis, with the more stringent definition of severe thrombocytopenia in the latter study.[33]

Feline IMT

Primary IMT is diagnosed rarely in cats. Two independent case series described primary IMT in 5 and 4 cats during 8- and 5-year periods, respectively.[34,35] Bleeding in cats with primary IMT is similar to that in dogs, with surface bleeding including petechiae (particularly on the pinnae), ecchymoses, epistaxis, gingival bleeding, hematuria, and hemoptysis.[34,35] Platelet-bound antibodies have been documented by a flow cytometric assay in thrombocytopenic cats.[36] Underlying diseases associated with development of platelet-bound antibodies in cats include viral infections (feline leukemia virus, feline immunodeficiency virus, and feline infectious peritonitis), inflammatory disease (fat necrosis), and neoplasia (lymphoma).[36]

Based on the reported 13 cats with primary IMT, the mortality rate was 15% and 11 survived to hospital discharge.[34] While glucocorticoids are the mainstay of treatment of primary IMT in dogs, oral prednisolone was deemed to be effective in only 5 of 9 cats in the two case series.[34,35] Other immunosuppressive agents administered to these cats included dexamethasone, cyclosporine, and chlorambucil, though there are insufficient cases to comment on efficacy.[34,35] In the series with 4 cats, each had a chronic course with frequent relapses noted and long-term immunosuppressive therapy was required for 3 cats that survived to

hospital discharge.[35]

Hereditary Von Willebrand Disease

Definition and Classification

VWD, the most common hereditary bleeding disorder in dogs, is a platelet adhesion disorder resulting from quantitative (types 1 and 3 VWD) or qualitative (type 2 VWD) deficiencies of plasma VWF. Canine VWD is classified according to the concentration and multimeric structure of plasma VWF, as well as clinical severity. Type 1 VWD is characterized by a low plasma VWF concentration, a full array of VWF multimers, and mild to moderate bleeding tendencies. In type 2 VWD, there is a variable reduction in plasma VWF concentration but an absence of the high molecular weight VWF multimers, causing moderate to severe bleeding tendencies. Type 3 VWD is characterized by a complete absence of plasma VWF, resulting in a severe bleeding tendency.

Diagnostic Evaluation

Screening Tests

Mucosal surface bleeding or excessive bleeding following surgery or trauma in a dog with a normal platelet count, prothrombin time (PT), and activated partial thromboplastin time (aPTT) should prompt evaluation for VWD. A screening test that can be performed in clinical practice is a buccal mucosal bleeding time (BMBT) test (see ch. 80), with an abnormal result being specific for primary hemostatic disorders.[37] A prolonged BMBT (>4 minutes) in a dog with a platelet count >100,000/mcL and packed cell volume (PCV) >30% is suggestive of VWD, thrombopathia, or, rarely, a vasculopathy. Because VWD is much more common in the dog than are intrinsic platelet function defects, measurement of plasma VWF antigen (VWF : Ag) concentration is recommended before platelet function testing. The Platelet Function Analyzer (PFA-100, Siemens), a point-of-care instrument that assesses platelet adhesion and aggregation under conditions of high shear forces, is sensitive in identifying dogs with type 1 VWD having plasma VWF : Ag concentrations <35%.[38,39] The PFA-100 measures closure time, that required for full occlusion of a 150-micron aperture in a collagen membrane. If the platelet count is >100,000/mcL and PCV >30%, a prolonged closure time is suggestive of VWD or a thrombopathia.

Quantitative VWF Assay

The laboratory diagnosis of VWD is most often based on measurement of plasma VWF : Ag concentration by an ELISA. The Comparative Coagulation Section of the Animal Health Diagnostic Center at Cornell University is the most widely used laboratory in the United States for VWD testing. Results are reported as % VWF : Ag compared to a pooled canine plasma standard of 100%: normal range = 70-180%, borderline (indeterminate) range = 50-69%, and abnormal range = 0-49%. Blood can be collected into evacuated tubes containing EDTA or sodium citrate (3.2 or 3.8%), with the plasma removed following centrifugation and frozen (≤−20°C) until shipped. Sample hemolysis can cause a spurious decrease in plasma VWF : Ag.[40] In addition, temporal variation in VWF : Ag concentration has been documented within individual healthy dogs, though values typically remain in the same range (i.e., normal, borderline, or abnormal).[40] Ill dogs, particularly those with severe inflammatory disease, such as sepsis, could have an increase in plasma VWF : Ag concentration due to endothelial injury and activation.[41] Plasma VWF : Ag concentration also increases during pregnancy and peaks at parturition in both normal dogs and dogs with type 1 VWD.[42] Therefore, screening for VWD (via measurement of plasma VWF : Ag concentration) should not be performed during illness or pregnancy. Testing of puppies from an age of 3 to 180 days indicated that plasma VWF : Ag concentration remains stable during this period of growth.[40]

DNA Testing

DNA tests are commercially available for canine breeds for which the causative mutations (or what is believed to be the causative mutation) for VWD have been identified (Table 201-1).[43-47] The mode of inheritance for type 2 and type 3 VWD is autosomal recessive. In humans, type 1 VWD inheritance has been controversial. It is transmitted either as an autosomal dominant trait[48] or as a complex multifactorial disorder with interrelated genetic and environmental components.[49] In canine type 1 VWD, evidence for autosomal

dominant[50] or recessive[51] modes of inheritance have been reported. The splice site mutation used to diagnose type 1 VWD segregates as autosomal recessive.[43] Although the literature contains reports of type 2 VWD occurring only in the German Shorthaired Pointer and German Wirehaired Pointer, the same mutation (N883S) has been identified in a Collie and a few Chinese Crested dogs, but no clinical data are available for these other breeds (Loechel R from VetGen, personal communication, March 9, 2015). Since the plasma VWF : Ag concentration of heterozygous carriers for type 2 and type 3 VWD can overlap with the low end of the reference range, DNA testing will more reliably detect carriers and, therefore, be of use to breeders trying to eliminate VWD from their lines.[44,46] Use of a DNA test for type 3 VWD in Dutch Kooiker dogs by their breeding club allowed them to eliminate the splice site mutation at the boundary of exon 16 from all breeding stock within a few years. This required no apparent increased inbreeding or preferential sire usage.[47]

TABLE 201-1

Breeds for Which DNA Testing for VWD Is Available

	Breeds	Mutation
Type 1 VWD	Bernese Mountain Dog, Corgi (Cardigan and Pembroke Welsh), Coton de Tulear, Doberman Pinscher, Dutch Partridge dog, German Pinscher, Goldendoodle, Irish Setter, Kerry Blue Terrier, Manchester Terrier, Papillon, Poodle, Stabyhoun, West Highland Terrier	Ancestral splice site mutation in exon 43 (nucleotide 7437 G→A) [Note: All breeds listed have the same mutation]
Type 2 VWD	German Shorthaired Pointer, German Wirehaired Pointer [Collie, Chinese Crested]	SNP A→G in exon 28 (N883S)
Type 3 VWD	Dutch Kooiker,* Scottish Terrier,** Shetland Sheepdog***	*Splice site mutation at boundary of exon 16 **Base deletion in exon 4 ***Deletion of nucleotide T735

Note: With regard to DNA testing, "affected" refers to dogs that are homozygous for the VWD mutation, and "carrier" refers to dogs that are heterozygous for the VWD mutation. Some breeds designated "affected" (ancestral splice mutation, type 1 VWD) may not exhibit a bleeding tendency. Treatment and breeding decisions should be made after veterinary consultation.

DNA testing for VWD is available through VetGen, Animal Genetics, VetNostic Laboratories, and Paw Print Genetics.

N, Asparagine; *S*, serine; *SNP*, single nucleotide polymorphism.

Qualitative VWF Assays

While measurement of plasma VWF : Ag concentration can be used to detect type 1 or type 3 VWD, the diagnosis of type 2 VWD requires documenting an absence of the high molecular weight multimers of VWF through a functional VWF assay or analysis of the size distribution of multimers using SDS-agarose gel electrophoresis. Since the latter is complex, an ELISA measuring plasma VWF : collagen-binding activity (CBA) is often used to diagnose type 2 VWD.[52] The binding of canine VWF to bovine collagen types I and III used in the ELISA is dependent on the presence of high molecular weight multimers. Therefore, dogs with type 2 VWD have decreased VWF : CBA relative to VWF : Ag. Whereas the ratio of VWF : Ag to VWF : CBA is approximately 1 in normal dogs and dogs with type 1 VWD, the ratio is >2.0 in dogs with type 2 VWD.[52]

Treatment

Background

Medical management of VWD is aimed towards controlling spontaneous (e.g., epistaxis, hematuria) or trauma/surgery-induced bleeding. While dogs with type 2 and type 3 VWD inevitably have a severe bleeding tendency, the phenotype among dogs with type 1 VWD is variable, with some dogs having marked

reductions in plasma VWF : Ag concentration but no apparent bleeding tendency.[53] Therefore, the need for prophylactic treatment, particularly with blood component therapy, should be assessed on a case by case basis.

Desmopressin

Desmopressin acetate (1-deamino-8-D-arginine vasopressin [DDAVP]), a synthetic analogue of the neurohypophyseal hormone vasopressin, has been used to control bleeding in a variety of hemostatic disorders, but most commonly VWD in dogs. While administration of DDAVP to humans with type 1 VWD and clinically normal individuals typically results in a 2- to 5-fold increase in plasma VWF : Ag concentration, the effect of DDAVP is less dramatic in dogs. One hour following administration of DDAVP (1 mcg/kg SC) to 16 Doberman Pinschers with type 1 VWD, mean plasma VWF concentration increased from a baseline of 10% to 17%.[54] Despite the modest increase in plasma VWF : Ag concentration, DDAVP resulted in improved hemostatic function as assessed by the PFA-100 and shortening of the BMBT.[39] It has been proposed that the favorable hemostatic effects of DDAVP may be mediated in part by the appearance of new high molecular weight VWF multimers in the plasma.[55] However, plasma VWF : CBA increased concordantly with plasma VWF : Ag, and plasma VWF multimer analysis revealed proportional increases in band intensity for all multimer sizes 1 hour following administration of DDAVP to Doberman Pinschers with type 1 VWD, suggesting that there is a mechanism other than a preferential increase in high molecular weight VWF multimers resulting in improved primary hemostasis.[54]

DDAVP is available as a sterile solution (4 mcg/mL) for IV administration and a nasal spray (100 mcg/mL) that can be administered SC to dogs. The nasal spray preparation is used more frequently in dogs with VWD due to its lower cost, and a recommended dosage is 1 mcg/kg SC administered not more than once daily due to the risk of water retention and hyponatremia associated with its antidiuretic hormone effects, as well as tachyphylaxis, or a failure to elicit VWF release from the Weibel-Palade bodies in endothelial cells with repeated administration. DDAVP should be administered 30 minutes prior to surgery when used prophylactically to prevent excessive bleeding in dogs with VWD.

Blood Component Therapy

Blood products containing VWF include fresh whole blood, fresh frozen plasma (FFP), and cryoprecipitate (CRYO), the latter representing the blood component of choice to treat bleeding in dogs with VWD. Cryoprecipitate is prepared from FFP and contains a concentrated amount of VWF, FVIII, fibrinogen, fibronectin, and FXIII (see ch. 130). Comparison of administration of FFP (1 unit/15 kg BW, with 1 unit containing 250-300 mL) and CRYO (1 unit/15 kg BW, with 1 unit of CRYO [mean volume of 37 mL/unit] prepared from a 250-300 mL unit of FFP) to Doberman Pinschers with type 1 VWD documented that greater increases in plasma VWF : Ag concentration were achieved with transfusion of CRYO.[56] Based on the pharmacokinetics of VWF assessed in dogs with type 1 VWD after administration of FFP and CRYO, the estimated volume required to reach a target VWF : Ag concentration of 35 U/dL was 49 mL/kg for FFP and 4 mL/kg for CRYO, indicating that CRYO is a more efficient means of managing hemorrhage in dogs with VWD and avoids volume overload.[57]

Guidelines for blood component therapy in the management of bleeding in dogs with VWD include administration of CRYO at a dosage of 1 unit/10 kg (1 unit defined as CRYO prepared from 200-250 mL FFP) or FFP at a dosage of 10-15 mL/kg.[58] Although it is expensive to administer 3 to 4 units of CRYO to a Doberman Pinscher or other large-breed dog in a single transfusion event, this high-dose approach will rapidly increase plasma VWF levels to support platelet adhesion, allowing more rapid control of bleeding. Due to the short half-life of plasma VWF (≈12 hours), CRYO or FFP transfusions may need to be administered every 8-12 hours to control severe bleeding. Blood type- and crossmatch-compatible packed red blood cells should be available when dogs with VWD are undergoing surgery, even when DDAVP and CRYO are administered prophylactically, in the event of excessive blood loss.

Acquired Von Willebrand Syndrome

In people, acquired von Willebrand syndrome (AVWS) is a rare bleeding disorder characterized by structural or functional alterations in VWF caused by lymphoproliferative, myeloproliferative, cardiovascular, autoimmune, or other disorders.[59] Potential mechanisms responsible for the VWF abnormalities depend on the underlying disorder but include clearance due to binding of paraproteins, inhibition of VWF, adsorption

to the surface of platelets, and increased fluid shear stress resulting in increased proteolysis of VWF by ADAMTS13 and depletion of high molecular weight VWF multimers.[59] The latter mechanism is responsible for AVWS noted in humans with mitral regurgitation, ventricular septal defects, and aortic stenosis, with improvement in the AVWS and associated bleeding tendency documented after correcting the cardiac defect.[59,60]

Although not reported to cause bleeding in Cavalier King Charles Spaniels or other dogs, AVWS secondary to myxomatous mitral valve disease and subaortic stenosis has been documented, with a decrease in plasma VWF : Ag concentration and a loss of the high molecular weight VWF multimers.[61,62] Transient AVWS was reported in research dogs given a tetrastarch bolus (40 mL/kg IV over 30 minutes), with a significant decrease in plasma VFW : Ag and VWF : CBA (no change in Ag : CBA ratio) noted up to 2 hours post-infusion but resolved by 4 hours. The clinical significance of this finding is not clear.[63] There is a report of possible AVWS secondary to angiostrongylosis in a young Golden Retriever with cerebral and conjunctival hemorrhage.[64] Although likely uncommon in dogs, AVWS should be considered in cases with new-onset bleeding whenever laboratory findings suggest VWD, particularly in the presence of conditions similar to those reported in humans with AVWS.

Feline Von Willebrand Disease

There are only two reported cases of VWD in cats, both diagnosed with type 3 VWD. A 9-year-old neutered male Himalayan experienced persistent oral hemorrhage following tooth extraction with subsequent spontaneous gingival bleeding.[65] A 1-year-old female domestic longhaired cat developed spontaneous epistaxis, which resolved with FFP transfusion but not DDAVP administration.[66] Although VWD appears to be an uncommon disorder in cats, it should be considered as a differential diagnosis in cats with a bleeding tendency, in the absence of severe thrombocytopenia or coagulopathy (i.e., prolonged prothrombin or activated partial thromboplastin times). As with dogs, a diagnosis of VWD in cats can be confirmed by measurement of plasma VWF : Ag concentration.

Platelet Function Disorders

Hereditary Platelet Dysfunction

Background

Hereditary thrombopathia, or intrinsic platelet dysfunction, is an important and potentially under-recognized cause of spontaneous and post-surgical/trauma bleeding. Several inherited platelet function defects have been identified in dogs and cats (Table 201-2).[67-85] The best characterized disorders are Glanzmann thrombasthenia and calcium-diacylglycerol guanine nucleotide exchange factor I (CalDAG-GEFI) thrombopathia, the latter formerly known as Basset thrombopathia.[67-72] Excellent reviews of the clinical features and molecular characterization of these inherited platelet disorders are available.[73,74]

TABLE 201-2

Hereditary Thrombopathias in Dogs and Cats

Platelet Disorder	Specific Defect	Breeds Affected	Diagnosis
Glanzmann thrombasthenia	Absence or deficiency of the fibrinogen receptor, GPIIb-IIIa	Otterhounds Great Pyrenees	DNA testing*,†,68,69
P2Y12 receptor disorder	Impaired binding of ADP to its platelet receptor	Greater Swiss Mountain Dog	DNA testing*,†,80
CalDAG-GEFI thrombopathia	Signal-transduction disorder preventing change in conformation of GPIIb-IIIa necessary for fibrinogen binding	Basset Hound Spitz	DNA testing*,†,72

		Landseer	
LAD-I variant or LAD-III	Signal transduction disorder due to dysfunctional or missing Kindlin-3, impairing integrin activation	German Shepherd	DNA testing*,†,81
Platelet procoagulant deficiency (Scott syndrome)	Impaired platelet membrane phosphatidylserine (PS) externalization and decreased prothrombinase activity, leading to decreased generation of thrombin	German Shepherd	DNA testing‡
Cyclic hematopoiesis	Associated with cyclic neutropenia and stem cell defect Platelet storage pool disorder (serotonin, ATP, and ADP deficiency); impaired phosphorylation of an intraplatelet protein, preventing platelet activation by collagen, PAF, and thrombin	Gray Collie	DNA testing†,§,82
Chediak-Higashi syndrome	Associated with leukocyte and melanocyte abnormalities Platelet storage pool disorder associated with lack of discernable dense granules and deficiency of ATP, ADP, serotonin, Ca^{2+} and Mg^{2+}	Persian cats	Presence of characteristic granules in leukocytes (blood smear) and melanocytes (skin biopsy)85
Platelet delta-storage pool disease	Platelet dense granule deficiency of ADP	American Cocker Spaniel	Increased platelet ATP : ADP ratio83

Platelet Procoagulant Deficiency (Scott Syndrome)

Research during the past decade has greatly improved our understanding of canine platelet procoagulant deficiency, also known as Scott syndrome, an autosomal recessive disorder identified thus far only in German Shepherds.[75] Characteristics of Scott syndrome platelets include failure to externalize PS, impaired microparticle release and coated-platelet formation, and decreased prothrombinase activity.[76-78] In the absence of PCA, there is insufficient thrombin generation to support fibrin clot maturation and stabilization, resulting in a bleeding tendency. Hemorrhagic events reported for dogs with Scott syndrome include post-surgical, epistaxis, and soft tissue hemorrhage.[79] Interestingly, affected dogs do not develop spontaneous petechiae and ecchymoses that are characteristic of platelet disorders, suggesting that PCA is not required to maintain general capillary integrity but is needed for maintenance of the nasal cavity arterial microvasculature, as evidenced by the profound epistaxis requiring local embolization in some dogs.[79] Recognition of Scott syndrome can be challenging in clinical practice given that results of hemostatic screening tests (e.g., BMBT, PFA-100, thromboelastography, platelet aggregometry) are normal. A simple flow cytometric assay, based on the inability of canine Scott syndrome platelets to externalize PS when stimulated, and DNA testing for the recently identified mutation causing Scott syndrome in German Shepherds, are available at Cornell University.[79a]

P2Y12 Receptor Disorder

A novel P2Y12 receptor gene mutation, a 3 base-pair (CTC) deletion predicted to eliminate serine 173 (173Sdel) from the second loop of the extracellular domain of this ADP receptor, has been identified across 5 generations in a family of Greater Swiss Mountain dogs and associated with postoperative hemorrhage.[80] Spontaneous bleeding is absent to mild in affected dogs; however, severe and life-threatening bleeding requiring platelet transfusions has been observed following ovariohysterectomy. The prevalence of the P2Y12 mutation in the Greater Swiss Mountain dog breed is reported to be about 60%, including heterozygous and homozygous affected dogs (Boudreaux M, personal communication, March 18, 2015).

Acquired Platelet Dysfunction

In vitro platelet function defects have been documented in association with various systemic disorders, including uremia,[86] hepatobiliary disease,[87,88] and paraproteinemia.[89,90] The mechanisms underlying acquired thrombopathias are not well defined and are likely multifactorial. Anemia can be a contributing factor to a bleeding tendency, potentially due to altered rheological properties of the blood limiting contact of platelets with the vessel wall, as well as a decreased source of ADP (from fewer RBCs) to activate platelets.[91] Many drugs (e.g., hydroxyethyl starch,[92-95] nonsteroidal anti-inflammatory drugs,[96,97] cephalosporins[98,99]) have been documented to have an adverse effect on platelet function *in vitro*, though the clinical significance is unclear. However, use of such medications in a patient with a known bleeding tendency should be done with caution. Two drugs that are frequently administered for their anti-platelet activity to patients predisposed to thromboembolic complications include aspirin, an irreversible inhibitor of cyclooxygenase, and clopidogrel, a platelet P2Y12 ADP receptor antagonist (see ch. 198 and 256).

Diagnostic Evaluation

The classic clinical presentation for many hereditary thrombopathias includes spontaneous bleeding in the form of petechiae, ecchymoses, and mucosal surface bleeding, and excessive bleeding following trauma or surgery. This bleeding history, in conjunction with a normal platelet count, PT, aPTT, and plasma VWF : Ag concentration, should prompt diagnostic evaluation for a thrombopathia (Figure 201-2). As for VWD, a BMBT test and PFA-100 can be performed as screening tests for a thrombopathia. For dogs of a breed with a known mutation for a thrombopathia, the diagnosis can be confirmed by DNA testing (see Table 201-2). Special platelet function testing for dogs and cats suspected to have a hereditary thrombopathia includes platelet aggregation studies (optical or impedance), measurement of ATP release, flow cytometry to evaluate the presence of platelet membrane glycoproteins and activation-specific changes (e.g., CAP-1 monoclonal antibody binding to fibrinogen bound to the GPIIb-IIIa complex), and electron microscopy. Platelet function tests require meticulously collected (to prevent platelet activation) and fresh (less than a few hours) blood samples. This makes remote platelet function testing difficult.

Treatment

Dogs and cats with hereditary thrombopathias experiencing severe (e.g., hemoabdomen resulting in anemia following an ovariohysterectomy) or life-threatening bleeding (e.g., pulmonary or central nervous system hemorrhage) require platelet transfusions to control bleeding. In addition, prophylactic platelet transfusions should be considered in patients with a known bleeding tendency and documented thrombopathia undergoing surgery. As discussed, options for platelet transfusions include fresh whole blood, fresh PRP, fresh PC, and cryopreserved PRP/PC (see ch. 130). Canine cryopreserved platelets have been administered to dogs with Scott syndrome prophylactically prior to elective neutering at a median dosage of 5.7×10^9 platelets/kg body weight, as well as in the management of nonsurgical hemorrhage, mainly epistaxis, with apparent efficacy.[79] Since thawed canine cryopreserved platelets have been documented to externalize PS, it has been hypothesized that cryopreserved platelets may provide an advantage to fresh platelets in promoting thrombin generation in dogs with Scott syndrome.[79]

CHAPTER 202

Immune-Mediated and Other Nonneoplastic White Blood Cell Disorders

Jennifer L. Johns

Primary/Congenital White Blood Cell Disorders

Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome is reported in humans and various animal species including Persian cats as a primary immunodeficiency with recurrent neutropenia and neutrophil function defects, along with platelet function defects.[1] In humans, the specific mutation(s) in the CHS1 gene is/are documented; one manifestation of the disorder is partial oculocutaneous albinism that manifests in Persian cats as a blue smoke coat color. Neutrophils, eosinophils, and other cells contain abnormally fused granules. Granulocyte colony-stimulating factor (G-CSF) therapy in cats can partially correct neutrophil function defects, though cats appear less prone to infection than are other species with Chédiak-Higashi syndrome.[2] Birman cat granulation anomaly also causes abnormal neutrophil cytoplasmic granulation that can mimic Chédiak-Higashi syndrome, toxic neutrophil granulation, and mucopolysaccharidosis.[3]

Pelger-Huët Anomaly

Pelger-Huët anomaly is an autosomal dominant disorder causing defective terminal granulocyte maturation (a "laminopathy") and it is described in humans and mammals including dogs[4] and cats.[5] Australian Shepherds are overrepresented, with a 9.8% prevalence in one study, with likely incomplete penetrance of the dominant trait.[6] Granulocytes have hyposegmented nuclei with mature chromatin (Figure 202-1, *A* and *B*). No functional defects have been found in studies of neutrophils from dogs with Pelger-Huët anomaly and it is accepted that immunodeficiency does not occur in this condition.[7] The homozygous state can be embryonic lethal, as reported in a cat and theorized in dogs.[6,8] Pseudo–Pelger-Huët anomaly in cats and dogs can be caused by infections, severe inflammation, myeloid neoplasia (e.g., myelodysplastic syndrome), and drug toxicosis.[8]

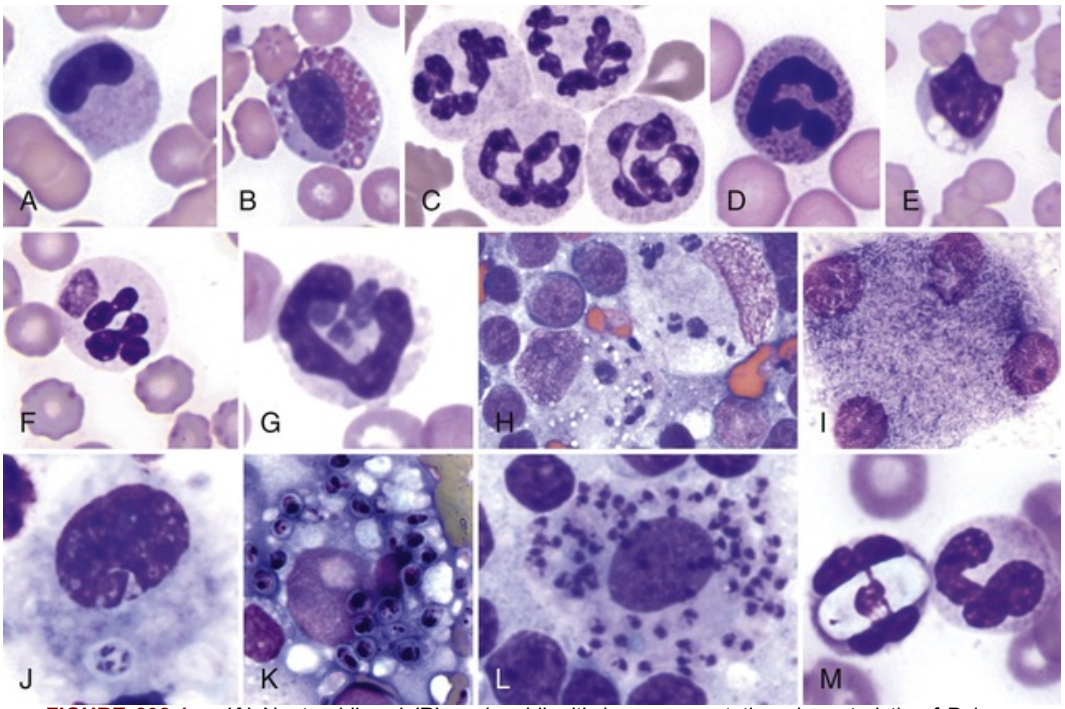

FIGURE 202-1 **(A)** Neutrophil and **(B)** eosinophil with hyposegmentation characteristic of Pelger-Huët anomaly; **(C)** hypersegmented neutrophils in canine leukocyte adhesion deficiency (image courtesy Dr. William Vernau); **(D)** abnormal neutrophil granulation in mucopolysaccharidosis VI; **(E)** abnormal lymphocyte vacuolation in GM2 gangliosidosis; **(F)** neutrophil containing canine distemper virus inclusion; **(G)** neutrophil containing *A. phagocytophilum* morulae; **(H-L)** macrophages containing **(H)** *N. helminthoeca* morulae; **(I)** *Mycobacteria;* **(J)** *P. carinii;* **(K)** *Sporothrix schenkii;* **(L)** *Leishmania;* **(M)** neutrophil containing *Hepatozoon* gamont.

Leukocyte Adhesion Deficiency (LAD)

LADs are due to mutation(s) in leukocyte adhesion proteins and they prevent the normal adherence and migration of white blood cells through luminal endothelium. Type I LAD results from a defect in the beta-2 subunit (also known as CD18) of the heterodimeric integrins and it is described in Irish Setters. The specific mutation was characterized in European Irish Setters[9] and has since been identified in setters in the United States and Australia.[10,11] A clinically similar disease was described in mixed-breed dogs but the mutation described in Irish Setters was not present; CD18 transcription was reduced and additional neutrophil function deficits were described.[12] Marked peripheral neutrophilia with nuclear hypersegmentation (Figure 202-1, *C*) is a typical diagnostic finding in canine LAD, along with absence of neutrophils in tissues. Affected pups initially can present with omphalitis followed by lymphadenopathy, low body weight, and febrile infections.[13] Antibiotic therapy is generally ineffective at prolonging life and most pups succumb or are euthanized by 2-3 months of age.

Trapped Neutrophil Syndrome

Trapped neutrophil syndrome is an autosomal recessive neutropenia in Border Collies, originally described in dogs from Australia and New Zealand. The disorder is characterized by peripheral neutropenia with a degenerative left shift and marked monocytosis, and myeloid hyperplasia in the bone marrow with increased mature neutrophils.[14] Craniofacial development can be abnormal in severely affected animals. Pups with the disorder initially present because of recurrent bacterial or other infections, adverse reaction to vaccination, or because of small size.[15,16] The causative mutation is analogous to that causing Cohen syndrome in human patients, and dogs are one natural model of the human disease.[17]

Pyruvate Kinase Deficiency

Dogs with a congenital pyruvate kinase deficiency (see ch. 198) will develop progressive myelofibrosis and

osteosclerosis of the bone marrow, along with changes in the liver (reviewed in Harvey 2006[18]). These changes are unique to dogs, as cats and humans with pyruvate kinase deficiency do not develop similar bone marrow abnormalities. Progressive myelophthisis leads to bone marrow failure and decreased marrow production of all blood cells. Mechanisms of marrow fibrosis in affected dogs can include iron overload due to hemolytic anemia and excessive intestinal iron absorption, and the effects of prolonged increased erythropoiesis.[19,20]

X-Linked Severe Combined Immunodeficiency (X-SCID)

X-SCID is caused by mutations in the gene encoding the common interleukin-2 receptor (IL-2-R) gamma chain, and is reported in Cardigan Welsh Corgis and Basset Hounds as well as in humans.[21-23] In dogs, the deficiency of the IL-2-R gamma chain primarily affects developing CD4- CD8-thymocytes.[24] Affected pups display stunted growth, develop recurrent and/or chronic infections as maternal antibody protection declines, and rarely survive past four months of age.[25] X-SCID dogs have hypoplastic and dysplastic thymuses, and other lymphoid tissues are hypoplastic or absent. Pups with X-SCID initially have rare peripheral T lymphocytes and increased numbers of B lymphocytes; over time, low numbers of nonfunctional T lymphocytes can appear in circulation.

Autosomal Recessive Severe Combined Immunodeficiency

This severe combined immunodeficiency is characterized by defective recombination events during T- and B-lymphocyte maturation. It is reported in Jack Russell Terriers along with Arabian horses and humans. In dogs, it is caused by a point mutation in the gene encoding the catalytic subunit of DNA-dependent protein kinase.[26,27] Affected pups have severe lymphopenia, decreased serum globulin concentrations due to agammaglobulinemia, and marked lymphoid hypoplasia in the spleen, thymus and other lymphoid tissues.[28] Opportunistic infections and vaccination with modified live virus are frequent causes of death in dogs with this form of SCID.

Cyclic Hematopoiesis in Gray Collies

Also called cyclic neutropenia, this disorder is due to a defect in trafficking of lysosomal membrane proteins and it is reported in gray collie dogs; the gray coat color results from the defect in melanocytes.[29] An insertional mutation in the AP3B1 gene is documented in affected dogs, and it results in cycling of neutrophil and other blood cell counts with an approximately 2-week periodicity.[30,31] The causal mutation, periodicity of cell cycling, presence of hypopigmentation and inheritance (autosomal recessive in dogs) differ from those in the human disorder.[32] Neutrophils in affected dogs are deficient in neutrophil elastase and myeloperoxidase.[33,34] Frequent infections occur in affected dogs and most succumb prior to six months of age. Treatment with recombinant G-CSF eliminated neutropenic episodes but did not correct functional defects in one report.[33]

Common Variable Immunodeficiency

Miniature Dachshunds with *Pneumocystis carinii* pneumonia were found to have lymphocyte function deficits, including hypogammaglobulinemia and absence of B cells in lymph nodes, that resembled those seen in common variable immunodeficiency of humans. Similar immunoglobulin deficiencies were found in Cavalier King Charles Spaniels with *P. carinii* pneumonia.[35,36]

Lysosomal Storage Disorders

Various lysosomal storage disorders are reported in small animals; the most common clinical manifestations are neurologic, but hematologic changes can be seen in some. In dogs and cats, mucopolysaccharidosis type VI (arylsulfatase B deficiency) and type VII (beta-glucuronidase deficiency) can result in abnormal granules in the cytoplasm of neutrophils, monocytes and lymphocytes (Figure 202-1, *D*).[37,38] GM2 gangliosidosis can result in abnormal vacuolation in the cytoplasm of peripheral leukocytes (Figure 202-1, *E*).[39,40]

Secondary/Acquired White Blood Cell Disorders

Immune-Mediated Neutropenia

As with other immune-mediated hematologic diseases, immune-mediated neutropenia (IMN) can be secondary to causes such as tick-borne disease or drug administration, or it can be idiopathic. IMN in small animals can occur in tandem with other immune-mediated disorders, including immune-mediated hemolytic anemia (IMHA; see ch. 198), thrombocytopenia (IMT; see ch. 201) and polyarthritis (see ch. 203).[41,42] A diagnosis of IMN should exclude other causes including acute or overwhelming peripheral demand; decreased production due to hemic neoplasia or other forms of myelophthisis or drug-induced marrow injury; and sequestration due to splenomegaly.[43] Infections, neoplastic diseases, concurrent autoimmune disorders, and drugs are associated with IMN in humans.[44] Anticonvulsants including phenobarbital can induce neutropenia and thrombocytopenia in dogs, as can cephalosporins, and a possible association with ivermectin administration was seen in one case of canine IMN.[43,45,46] Idiopathic IMN was the least common cause of neutropenia in one study (see also ch. 58).[47] Younger age is a risk factor for dogs to develop IMN, and neutrophil counts are significantly lower than in other neutropenic disorders.[48] In a report of pure white cell aplasia in a dog, the patient had absolute granulocytopenia in peripheral blood and absent granulocytic precursors in the bone marrow.[49] Methods to diagnose IMN often require species- and antigen-specific antibodies and are therefore of limited availability in animals. Granulocyte agglutination and immunofluorescence were not considered sensitive for IMN in a study of neutropenic cats.[50] Flow cytometric methods can be used for direct and indirect detection of anti-neutrophil antibodies, and were considered sensitive and specific for the diagnosis of IMN in neutropenic dogs.[51,52] Rapid response to immunosuppressive therapy (e.g., prednisone) is documented in dogs and is considered necessary to confirm the diagnosis of IMN.[41]

Primary Myelodysplastic Syndrome (MDS)

Primary MDSs are clonal disorders arising from mutations within hematopoietic stem and progenitor cells. As clonal (neoplastic) disorders, primary MDSs fall outside of the scope of this chapter but the differentiation between primary MDS and secondary dysmyelopoiesis can be extremely difficult[53]; a brief synopsis is therefore presented here. Nonregenerative anemia is a consistent feature in primary MDS in both dogs and cats (see ch. 199). Feline retroviral infections can cause MDS and dysmyelopoiesis (see ch. 222 and 223).

Evidence of clonality in primary MDS is difficult to obtain in animals and a combination of history, clinical signs, and accurate categorization of hematopathologic abnormalities is needed for diagnosis.[54] Many cases of feline MDS are attributable to feline leukemia virus (FeLV) infection; a clonal origin to FeLV-associated myelodysplasia and acute myeloid leukemia is proven.[55] Primary MDS is rare in dogs, and a clonal origin has not been proven in canine MDS.[56] Microscopic morphologic changes that suggest primary MDS instead of secondary dysmyelopoiesis include increased immature precursors, higher percentages of dysplastic cells, and megaloblastic erythroid precursors.[54,57] Additionally, a history of drug/toxin exposure or concurrent disease can support secondary dysmyelopoiesis instead of primary MDS. Primary MDS is similar to chronic myeloid leukemia; both feature anemia or multiple cytopenias and normal/hypercellular bone marrow with blast cells comprising <30% of all nucleated cells; a key difference is the lack of increased myeloid cells (predominantly mature) in circulation with MDS.[58]

Several classification schemes for MDS in dogs and cats have been proposed. In human medicine, the French-American-British (FAB) working group scheme frequently is used.[59,60] An alternate scheme proposed by the World Health Organization includes molecular genetics.[61] In small animals, the FAB scheme has been modified and applied to consistent disorders.[54] The following is one modified-FAB scheme for classification of primary MDS in small animals.[62]

MDS–Excess Blasts (MDS-EB)

MDS-EB is likely the most common MDS in dogs and it is associated with more severe clinical signs and a poor prognosis on presentation.[63] Neutropenia occurs in this form of primary MDS along with thrombocytopenia and nonregenerative anemia. Increased myeloblasts (up to 20%) and dysplasia of all three cell lines are found in bone marrow.[63,64] Dysplastic changes include asynchronous maturation in all cell lines,

hypersegmented granulocytes, dispersed megakaryocyte nuclei, and erythroid dysplasia as described below for MDS-refractory cytopenia.[53,65] The prognosis for dogs with MDS-EB is poorer than that for other forms of MDS.[57]

MDS-EB affects cats ranging from one year old to advanced age.[66] Studies show that cats with MDS-EB comprise 31%-65% of all cats with primary MDS; cats with secondary dysmyelopoiesis were excluded from these groups.[66-69] In one study, 6 of 13 cats with MDS-EB tested positive for FeLV infection. Other studies found higher percentages of FeLV-positivity; discrepant results could be due to decreasing FeLV prevalence and/or differing prevalence between geographic regions.[66,68,69] Like in dogs, the prognosis for cats with MDS-EB tends to be worse than that for other forms of feline MDS.[66,68]

MDS–Refractory Cytopenia (MDS-RC)

MDS-RC tends to occur in older dogs and has an insidious onset of clinical signs due to progressively worsening nonregenerative anemia. Other cytopenias including neutropenia can occur but are uncommon. Bone marrow can be hypercellular due to erythroid hyperplasia, or normocellular. Erythroid dysplasia including nuclear:cytoplasmic asynchrony, binucleation, and nuclear fragmentation, is a characteristic finding.[63] Rubriblasts can be increased (up to 30% of all nucleated bone marrow cells).[57,58] Descriptions of MDS-RC in cats often include cytopenias and dysplastic changes in multiple blood cell lineages rather than erythroid cells only; it is proposed that such cases represent MDS-RCMD (see below) rather than MDS-RC in this classification scheme.[62,66,68,69]

MDS–Refractory Cytopenia with Multilineage Dysplasia (MDS-RCMD)

MDS-RCMD is defined by dysplasia in at least 2 cell lineages in bone marrow, similar to MDS-EB but without a substantial increase in myeloblasts (<5% myeloblasts for MDS-RCMD). MDS characterized by refractory anemia with sideroblastic differentiation can be included in this category as MDS-RCMD in dogs, as dysplasia occurs in multiple lineages.[62] In cats, experimental infection with FeLV produced hematologic disease resembling MDS-RCMD with cytopenias and dysplasia in multiple cell lines.[70] Several cats with sideroblastic forms of MDS-RCMD are reported.[66,69]

Treatment of Primary MDS

Treatment can be complicated by the difficulty of differentiating primary MDS from secondary dysmyelopoiesis; see Table 202-1 for list of agents used therapeutically.[71-73]

TABLE 202-1

Summary of Treatment Options for Patients with Leukocyte Disorders

DISEASE CATEGORY	NOTES AND RELEVANT CHAPTER REFERENCES
Primary immunodeficiencies	Treatment is unnecessary for asymptomatic Pelger-Huët anomaly. Supportive care for other conditions includes antibiotic therapy as indicted; G-CSF therapy can be useful in neutropenic conditions.33 Curative experimental treatments include gene therapy and bone marrow transplantation.139-141 Also see ch. 360.
Immune-mediated neutropenia	Immunosuppression is indicated but more common causes of neutropenia, particularly infectious disease, should be excluded before starting immunosuppressive therapy. See ch. 165, 195, 198, and 201.
Primary myelodysplastic syndromes	Differentiate from secondary dysmyelopoiesis. Cytotoxic treatment agents for dogs and cats with MDS have included cyclophosphamide, prednisone, cyclosporine, daunorubicin, vincristine, hydroxycarbamide and cytarabine.71-73 Additional therapeutic options include transfusion if indicated (see ch. 130) and erythropoietic agents to support red blood cell production. See ch. 165, 199, 339, 343, and 344.
Secondary dysmyelopoiesis	Eliminate underlying cause if possible. Supportive care can include transfusion, erythropoietin, G-CSF, antibiotics, and/or immunosuppressive therapy.76,142 See ch. 130, 165, and 199.
Myeloproliferative disorders	Treatment is indicated when clinical signs and/or significant cytopenia develops; hydroxyurea is commonly used along with supportive care. See ch. 200 and 344.

Viral infections	Antiviral therapy and/or supportive care varies with specific infection. See ch. 162 and 222-225.
Bacterial, fungal and protozoal infections	Antimicrobial treatment is specific to the infectious agent and/or site(s) of infection. Bacterial infections: See ch. 132, 161, 212, 213, and 218. Fungal infections: See ch. 162 and 231-236. Protozoal infections: See ch. 163 and 221.

G-CSF, Granulocyte colony stimulating factor; *MDS*, myelodysplastic syndrome.

Secondary Myelodysplastic Syndromes

Secondary myelodysplastic syndromes in humans are clonal disorders; mutations are induced by chemotherapeutic agents, toxin exposure, and/or radiation therapy. Dysmegakaryopoiesis and myeloproliferative disorders occur following radiation therapy in dogs, suggesting these syndromes potentially occur in small animals.[68,74,75]

Secondary Dysmyelopoiesis

The most common diseases associated with secondary dysmyelopoiesis (a non-neoplastic disorder) in dogs are IMT and IMHA, myelofibrosis, pure red cell aplasia, and lymphoma; drugs, including chemotherapeutic agents, chloramphenicol, estrogens and phenobarbital; endogenous overproduction of estrogens; heavy metal toxicoses; iron deficiency; adenocarcinoma; and leishmaniasis.[53,56,76,77] Dysplasia can affect one or multiple blood cell lineages, often depending on the underlying etiology. For example, sideroblastic forms of disease are associated with inflammatory disorders and myelofibrosis.[56] Bone marrow cytology alone can be insufficient to distinguish primary MDS from secondary dysmyelopoiesis. Lower percentages of dysplastic cells and non-increased percentages of blast cells are thought to suggest secondary dysmyelopoiesis, although exceptions can include recovery from sepsis or toxic bone marrow injury.[53,54,58,67] Diseases associated with secondary dysmyelopoiesis in cats include immune-mediated hemolytic anemia and thrombocytopenia, pure red cell aplasia, lymphoma, glomerulonephritis, feline infectious peritonitis, and feline immunodeficiency virus (FIV) infection.[66,67,78]

Myeloproliferative Disease (Myeloproliferative Neoplasia)

This category can be difficult to define, as acute leukemias and myelodysplastic syndromes may be included (see ch. 344).[79] The four disease processes listed below are analogous human categories of myeloproliferative neoplasms[80]; evidence of specific genetic mutations in animals is largely lacking.

Polycythemia (Rubra) Vera

Polycythemia vera is a clonal expansion of hematopoietic progenitors (see ch. 200). Leukocytosis and thrombocytosis often occur in addition to erythrocytosis in affected humans, but these abnormalities are rare in animals.

Chronic Granulocytic Leukemia

In humans, chronic granulocytic leukemia is defined by the Philadelphia chromosome translocation. An analogous genetic abnormality is rarely found in small animals, and differentiating chronic granulocytic leukemia from other causes of severe neutrophilic leukocytosis, e.g., paraneoplastic neutrophilia, generally relies on clinical signs, history of concurrent diseases, etc. (see ch. 58 and 352).

Essential Thrombocythemia

Essential thrombocythemia is a clonal disorder primarily affecting megakaryocytes and resulting in platelet overproduction; differentiation from non-neoplastic disorders requires demonstration of the causal genetic mutation and/or use of exclusionary diagnostic schemes.[81] Marked thrombocytosis in dogs and cats usually is due to reactive thrombocytosis (see ch. 59). A few reports appear to describe true essential thrombocythemia based on exclusion of other diagnoses.[82-84]

Primary Myelofibrosis

Primary myelofibrosis in humans is a rare clonal myeloproliferative disease resulting in progressive ablation of marrow space due to fibrosis; extramedullary hematopoiesis can be marked.[85] Confirmation of primary myelofibrosis in humans relies on molecular genetic testing. The occurrence of suspected primary myelofibrosis in all domestic animals is extremely rare,[86] and most cases of myelofibrosis are likely secondary (see below). Several cases of presumptive primary myelofibrosis have been reported in dogs,[87-89] and myelofibrosis without evidence of an underlying disorder has been reported in cats.[67]

Myelophthisis

Myelophthisis, defined as replacement of hematopoietic tissue in bone marrow by abnormal cells or tissue, often is caused by hemic neoplasia. Secondary myelofibrosis is a relatively common, non-neoplastic cause of myelophthisis. In dogs, pyruvate kinase deficiency (see above, see ch. 198) is the most frequently reported cause of secondary myelofibrosis. Other causes in small animals are high-dosage recombinant human erythropoietin, FeLV infection, bone marrow necrosis, infections, and drugs/toxicoses.[90-93] Myelonecrosis is associated with myelofibrosis and marrow ischemia; causes include IMHA, sepsis, hemic neoplasia in bone marrow, and drugs. The specific mechanism linking myelonecrosis and myelofibrosis is unclear.

Myelotoxicosis and Myelosuppression

Due to their high proliferative rate, bone marrow hematopoietic cells are susceptible to injury by numerous drugs, and chemotherapeutic agents are among the most common causes of myelotoxicosis (see ch. 343). Acute myelosuppression also can occur following half-body radiation for canine lymphoma but can be minimized through optimization[94,95]; see "Secondary Dysmyelopoiesis," above, for other drugs and agents of myelotoxicosis.

Viral Infections of Dogs and Cats

Parvovirus Infection

Canine and feline parvoviral infections (see ch. 225) cause bone marrow injury and leukopenia. Neutropenia often is seen in severe canine parvovirus infection but not in all cases; leukopenia was reported in fewer than half of infected dogs on presentation in one case series.[96] 92% of clinically ill dogs and 84% of cats with parvoviral infection had acellular ("complete depopulation of") bone marrow on histologic evaluation in one retrospective study.[97] Treatment with recombinant canine (not human) G-CSF improved total white blood cell counts and neutrophil counts and reduced the duration of hospitalization, but survival times were decreased suggesting potential adverse effects.[98-100]

Distemper and Paramyxovirus Infection

Canine distemper virus (see ch. 228) infects numerous tissues and cells, including lymphoid and other hematopoietic cells. Immunosuppression occurs early in infection and is due to virally mediated lysis of lymphocytes; grossly enlarged lymph nodes and thymic atrophy develop.[101] Secondary lymph node follicles are absent microscopically. Lymphopenia can occur; cytoplasmic (rarely nuclear) viral inclusions can be seen in white blood cells in peripheral blood smears (Figure 202-1, *F*) in early infection.[102] Immunosuppression can be prolonged in some dogs and can exacerbate viral replication and spreading.

Feline Leukemia Virus Infection

In cats, bone marrow suppression frequently is associated with FeLV infection (see ch. 223). Erythroid precursors most commonly are affected but suppression of hematopoiesis can occur in all cell lineages via both direct and indirect/immune-mediated effects. Neutropenia is seen in approximately 50% of cats presenting with FeLV-related illness.[103] Cyclic hematopoiesis has been seen in infected cats.[104] Cats with myelodysplasia and myelofibrosis frequently are FeLV-positive. Myelophthisis due to myelofibrosis and/or other causes, particularly hemic neoplasia, can contribute to decreased leukocyte production.

Feline Immunodeficiency Virus Infection

Acute FIV infection (see ch. 222) can trigger mild leukocyte abnormalities, but substantial changes are variable in any stage of infection. No differences were found between FIV-infected and non-infected cats in

the occurrence of peripheral leukocyte abnormalities in one study[105]; in another, FIV infection increased the odds ratio of neutropenia.[106] Panlymphopenia can occur in acute infection.[107] Viral strain is an important factor: severe neutropenia with lymphocytosis of granular lymphocytes was seen during acute experimental infection with FIV-C-PG.[108] Chronic infection is associated with decreased CD4+:CD8+ T-cell ratios[107] and development of secondary neoplastic and inflammatory disorders.

Feline Infectious Peritonitis

Peripheral blood leukocyte abnormalities, particularly neutrophilia and lymphopenia, are common in feline infectious peritonitis (see ch. 224) but are non-specific. Body cavity effusions usually are modified transudates or exudates with high protein concentrations relative to nucleated cell counts, and mixed inflammatory cell populations of neutrophils, macrophages, and lymphocytes.

Bacterial, Fungal and Protozoal Infections of Dogs and Cats

Rickettsial Infections

In dogs, the rickettsiae that are most often associated with leukocyte abnormalities are *Ehrlichia canis, Ehrlichia chaffeensis, Ehrlichia ewingii, Anaplasma phagocytophilum, Neorickettsia helminthoeca, Neorickettsia risticii* and *Rickettsia rickettsii* (see ch. 218). Natural and/or experimental infections with *E. canis, A. phagocytophilum* and *N. risticii* are reported in cats.[109-112] Acutely, *E. canis* infection can cause neutropenia and/or total leukopenia[113]; bacterial morulae can be found in lymphocytes, monocytes, and macrophages in smears of peripheral blood/buffy coat, bone marrow and lymph node specimens.[114] Severe chronic infection causes pancytopenia and marked panhypocellularity of bone marrow.[115] *E. chaffeensis* is another agent of canine monocytic ehrlichiosis in North America, but hematologic abnormalities are milder and chronic pancytopenia is absent.[116,117] *E. ewingii* and *A. phagocytophilum* cause granulocytic ehrlichiosis and granulocytic anaplasmosis.[118,119] Lymphopenia, neutropenia, eosinopenia, monocytosis and/or total leukopenia are noted in *A. phagocytophilum* infection.[120,121] Morulae of either bacterium can be seen in peripheral blood neutrophils (Figure 202-1, *G*). Neutrophilic polyarthritis can develop in both infections; morulae also can be found in synovial fluid neutrophils.[122] Acute infection with *N. helminthoeca,* the causative agent of salmon poisoning disease in dogs, causes lymphopenia; peripheral and internal lymph nodes are enlarged due to lymphoid reactivity and histiocytic inflammation.[123] Organisms can be found in lymph node cytologic smears stained with Giemsa stain, and vary from irregular inclusions to morulae within macrophages (Figure 202-1, *H*).[124] *Rickettsia rickettsii* natural infection of dogs has been characterized by leukocytosis accompanied by toxic granulation of neutrophils.[125] Experimental infection has produced initial leukopenia progressing to leukocytosis.[126]

Bartonella Infections of Dogs and Cats

Bartonella infections in dogs (see ch. 215) can induce granulomatous inflammation of lymph nodes, heart, liver, and/or other localized sites or systemic inflammation.[127-129] Neutrophilic leukocytosis, monocytosis and eosinophilia occur in *Bartonella vinsonii*-infected dogs.[130] Persistent eosinophilia is seen in some *Bartonella*-infected cats (see ch. 216); neutrophilia can occur with inflammation.[131,132] Lymphoid hyperplasia in lymph nodes and spleen are noted in infected cats, along with pyogranulomatous inflammation in organs.

Mycobacterial Infections

Mycobacterial infections in dogs and cats (see ch. 212) can induce focal or multifocal pyogranulomas or can become disseminated. Cytologic and histopathologic evaluation of lesions often is helpful in diagnosis. Acid-fast stains are required to identify mycobacteria because routine stains "negatively stain" organisms within macrophages (Figure 202-1, *I*).

Fungal Infections

Fungal infections of dogs and cats can cause neutrophilia and monocytosis (see ch. 231-236) as well as pyogranulomatous inflammation in tissues. Some fungal infections, e.g., *Pneumocystis carinii* (Figure 202-1, *J*), are associated with immunodeficiency.[36,133,134] Other fungal pathogens commonly found in macrophages in tissue specimens include *Sporothrix schenckii* (Figure 202-1, *K*), *Histoplasma capsulatum, Blastomyces dermatitidis,*

and *Cryptococcus* spp.

Protozoal Infections

Protozoal infections (see ch. 221) can elicit systemic leukocyte abnormalities, e.g., neutrophilia and eosinophilia. Many protozoa infect leukocytes and can be found on cytologic evaluation of peripheral blood smears and/or tissue aspirates. Intracellular tachyzoites of *Neospora caninum* or *Toxoplasma gondii* can be seen in monocytes or macrophages in samples including airway lavage fluid. *Cytauxzoon felis* schizonts may be found in macrophages in tissue aspirate specimens from infected cats; pancytopenia can occur.[135] *Leishmania* amastigotes are found in macrophages in lymph node and bone marrow aspirates and draining wound impression smears (Figure 202-1, *L*).[136] Marked neutrophilia and monoclonal gammopathy are reported in dogs.[137] Cytologic assessment can be insensitive for detection of *Leishmania* organisms in infected cats.[138] *Hepatozoon* spp. organisms can be seen in blood and tissue leukocytes in infected dogs (Figure 202-1, *M*).

CHAPTER 203

Immune-Mediated Polyarthritis and Other Polyarthritides

Michael Stone

Polyarthropathies are characterized by neutrophilic inflammation of multiple joints. Clinical signs are lameness, stiffness, and/or reluctance to walk, and some patients show signs of systemic illness. The diagnostic evaluation can identify an etiologic agent or other inciting cause, which then warrants specific treatment. A diagnosis of idiopathic, immune-mediated polyarthropathy (IMPA) is made by excluding the presence of known causes of joint inflammation, and a good response occurs with immunosuppressive treatment of IMPA.

Polyarthritis is defined as neutrophilic inflammation of 2 or more joints. Polyarthritis may be divided into infectious, reactive, and primary (idiopathic immune-mediated) etiologies. Primary IMPA is subdivided further into erosive and non-erosive forms (Box 203-1).

Box 203-1

Classification of Polyarthritis

Infectious (rickettsia, bacteria, *Mycoplasma,* L-form bacteria, fungi, viruses [cats])
Secondary to distant immunogenic stimulus ("reactive")
  Non-joint, infectious focus (bacterial, fungal, protozoal, other)
  Non-joint, inflammatory focus (immune-mediated dermatopathy, enteropathy, hepatopathy)
  Drugs (trimethoprim-sulfa, human albumin, other antibiotics)
  Non-joint neoplasia
  Post-vaccinal
Primary immune-mediated polyarthropathy
  Non-erosive
    Systemic lupus erythematosus
    Breed-associated (Shar-Pei, Akita)
    Idiopathic immune-mediated polyarthropathy
  Erosive
    Breed-associated: Greyhound
    Idiopathic
      Rheumatoid arthritis (primarily subchondral bone lysis)
      Periosteal proliferative polyarthritis (cats; prominent periosteal bone proliferation)

General Diagnostic Overview

Typical Features of Idiopathic, Immune-Mediated Polyarthritis

- Involvement of multiple joints, especially if there has been no response to anti-rickettsial treatment. Degenerative arthropathies are differentiated by mononuclear inflammation of synovial fluid (see ch. 353).
- Fever of unknown origin.
- Neutrophilic inflammation in synovial fluid, if only one joint was evaluated (see ch. 74). Differentiation of mono- from polyarthropathies is sometimes difficult by physical examination alone. Unless a monoarthropathy is obviously present (i.e., previous joint surgery or penetrating injury), analysis of synovial fluid from multiple joints is recommended (see ch. 94).

Typical Features of Septic (Bacterial) Arthritis

- Swelling and pain in a joint that has undergone surgery.
- Swelling and pain in a single, large joint (elbow, shoulder, stifle, or hip). Degenerative joint disease predisposes joints to bacterial arthritis from hematogenous spread. Fever, marked pain, and systemic illness suggest infection rather than exacerbation of degenerative joint disease. In contrast, immune-mediated polyarthropathies affect multiple, smaller, and distal joints.
- Lameness in a patient with a history of immunosuppressive therapy, such as with corticosteroids or cyclosporine.
- Lameness in a patient with history of chronic bacterial infection, most frequently of urinary tract or skin origin.

Exclusion of Infectious Agents from the List of Probable Etiologies

- Tick-borne agents (such as *Borrelia burgdorferi, Anaplasma phagocytophilum, Rickettsia ricketsii* and *Ehrlichia canis*) are most easily excluded with a trial of doxycycline or minocycline. Response to anti-rickettsial treatment occurs within 72 hours. Measurement of serologic titers could be helpful, but clinical signs of disease can occur before the development of serum antibodies and therefore, test results can be negative in acutely infected dogs. *A. phagocytophilum, R. rickettsia,* or *E. canis* infection cannot be excluded by a single negative serologic result.
- Dogs with a single swollen and painful joint should be most carefully evaluated for an infectious etiology. Prior surgery greatly increases the likelihood of a bacterial etiology. The sensitivity of bacterial culture of synovial fluid is low; synovial fluid is best subcultured in blood culture medium prior to laboratory submission.[1] Concurrent cultures of blood and urine should be obtained in cases of suspected hematogenous origin.
- Dogs with systemic infections (such as bacterial endocarditis, deep pyoderma, fungal disease, or leishmaniasis) can develop a secondary immune-mediated polyarthropathy. In these cases, synovial fluid culture often is negative, despite an infectious etiology. Evaluation of patients with polyarthropathy can include serologic testing, thoracic radiographs, echocardiography, abdominal ultrasonography, and/or skeletal radiographs.
- Unusual organisms occasionally are identified as the cause of arthritis. Culture of joint fluid might include evaluation for aerobic, anaerobic, mycoplasmal, fungal and L-form agents.
- Bacterial culture of synovial fluid rarely is positive when multiple joints are involved. However, in some patients, one joint is obviously swollen and involvement of other joints is uncertain. In these cases, centesis of multiple joints is warranted (see ch. 94) and fluid from the most obviously affected joint is submitted for culture.
- Locally endemic diseases are considered when making a differential diagnosis list. Systemic fungal diseases are considered in, or after travel to, endemic areas, for example. Serologic titers, microbial cultures in a specialized laboratory, and/or molecular assays could be useful.

Infectious Polyarthropathies

Tick-Borne/Rickettsial

In endemic areas, vector-borne infectious disease is a common cause of inflammatory polyarthritis. *Borrelia burgdorferi* (see ch. 211), *Anaplasma phagocytophilum, Rickettsia rickettsii, Ehrlichia canis, E. ewingii,* and *E. chaffeensis* (see ch. 218) all have been implicated. In areas where tick-borne diseases are endemic, arthrocentesis rarely is indicated in a dog or cat with multiple swollen joints until there has been failure to respond to a 3-5 day course of doxycycline or minocycline.

Leishmaniasis

Leishmaniasis is a chronic systemic disease caused by a protozoal parasite found mainly in South America, Africa, India, and the Mediterranean (see ch. 221).[2] In the United States, visceral disease has been reported in American Foxhounds. Clinical abnormalities develop 3 months to 7 years after infection and typically consist of inappetence, weight loss, muscle atrophy, and cutaneous lesions. Polyarthritis causing lameness and

exercise intolerance is common and joint radiographs can reveal erosive changes. The diagnosis is made when the organisms are identified cytologically, or by serologic or molecular diagnostic testing.

Bacterial

Large joints such as the stifle, hip, shoulder, or elbow are affected most frequently, but any joint can be involved (see ch. 353).[3] Most non-surgical joint infections develop from hematogenous spread but only rarely does bacterial disease simultaneously involve multiple joints. The most common agents are Gram-positive aerobes. When non-surgical bacterial arthritis is suspected, blood and urine should be collected for culture and if positive, additional imaging (echocardiography [see ch. 104], abdominal ultrasonography [see ch. 88]) performed. See "Reactive Arthritis," below.

Mycoplasmal

There are isolated veterinary reports of polyarthritis associated with *Mycoplasma* species: *M. gatae* and *M. felis* have been isolated from cats and *M. spumans* from dogs. Synovial fluid analysis reveals non-degenerate neutrophils. Routine aerobic and anaerobic cultures of joint fluid are negative, and the diagnosis requires isolation in special mycoplasma medium. PCR assays can be more sensitive than culture for detection of *Mycoplasma* species. Doxycycline and fluoroquinolones are active against most *Mycoplasma* isolates.[4]

Bacterial L-Form–Associated Arthritis

A rare syndrome of subcutaneous abscesses with associated polyarthritis has been described in dogs and cats with L-forms of bacteria suspected as the cause. An L-form is a mutant bacterium that has lost its cell wall. Affected cats have swollen, painful joints, and fever. Fistulating subcutaneous wounds can develop over the affected joints. Cultures for aerobic, anaerobic, mycoplasmal, and fungal organisms are negative, and specific L-form media must be used for growing the organism. L-form bacteria are difficult to recognize with a light microscope, but can be identified on electron microscopy. Treatment with doxycycline or a fluoroquinolone should be effective.[5]

Fungal

Systemic fungal diseases (blastomycosis [see ch. 233], histoplasmosis [see ch. 233], coccidioidomycosis [see ch. 232]) can be associated with direct joint involvement. Reactive, immunologically mediated, culture-negative polyarthritis also can occur, and probably is more common than direct involvement of the joint.

Viral

Both calicivirus infections (see ch. 229) and attenuated liver calicivirus vaccines (see ch. 208) have been associated with transient polyarthritis in 6- to 12-week-old kittens. Clinical signs include lameness, stiffness, and fever, with spontaneous improvement in 2-4 days. Synovial fluid analysis reveals a mononuclear pleocytosis.[6]

Polyarthropathies Occurring Secondary to Distant Immunogenic Stimulus ("Reactive")

Animals with reactive polyarthritis can have vague or few clinical signs referable to their underlying disease and be presented only when joint inflammation makes them reluctant to walk.[7] It is important to perform a thorough physical examination of animals with polyarthritis (Video 203-1), to obtain a complete drug history, and to evaluate for evidence of systemic illness. Screening tests (complete blood count [CBC] with manual differential count, serum biochemical profile, serologic testing for endemic infectious diseases, urinalysis, thoracic radiographs, and abdominal ultrasound) often are performed to screen for an underlying cause of polyarthritis.

Non-Joint Infectious Focus (Bacterial, Fungal, Protozoal, Other)

Patients with infection in sites distant from the joints can develop a secondary immune-mediated

polyarthropathy. Endocarditis, discospondylitis, pyometra, bacterial pyoderma/cellulitis, foreign body abscesses, pancreatitis, prostatitis, pyelonephritis, pneumonia, or actinomycosis can represent a source of chronic inflammation, leading to circulation of immune complexes and systemic inflammatory disease. Even though the underlying inflammatory disease is infectious, polyarthritis in these patients is caused by synovial deposition of immune complexes and synovial fluid cultures will be negative. In some cases, such as those with a positive urine culture, it can be difficult to determine whether the infection represents the origin of hematogenous bacterial spread, the inciting source of inflammation, or incidental disease. The low sensitivity of synovial fluid cultures for the detection of infection contributes to this confusion. Heartworm disease, chronic otitis, and severe gingivostomatitis represent common conundra.

Nonjoint, Inflammatory, Noninfectious Focus (Immune-Mediated Skin Disease, Inflammatory Bowel Disease, and Chronic Hepatitis)

This form of reactive arthritis originates with non-infectious antigenic stimuli distant to the joints. In some cases, these diseases may qualify the patient's disease to be categorized as systemic lupus erythematosus (see ch. 205). It can be difficult to establish whether an inflammatory focus is the primary problem and causing a secondary reactive arthropathy, or if both represent manifestations of a single disease process (i.e., systemic lupus erythematosus).

Drugs and Vaccination

Polyarthritis can develop after the administration of any medication, but is most commonly reported with antibiotics (see ch. 169). Polyarthropathy has been described after administration of sulfonamides, vaccines, human albumin, penicillin, cephalexin, lincomycin, erythromycin, phenobarbital, and erythropoietin, although not all are well-described. With sulfonamides, signs of polyarthritis develop 5-20 days after drug exposure and can be associated with fever, thrombocytopenia, hepatopathy, and skin or oral lesions. Doberman Pinschers appear to be predisposed. Improvement occurs within 7 days of drug cessation.[8]

Vaccination represents a potential cause of polyarthritis (see ch. 208); onset within 30 days of vaccine administration is suspicious. Whether vaccination itself represents a risk, or whether immune stimulation triggers the disorder in a patient with a genetic predisposition, remains difficult to determine. Vaccine-triggered, immune-mediated disease can be self-limiting and could respond more favorably than spontaneously arising disease. Dogs with vaccine-induced polyarthropathy have been reported to recover in 1-2 days without immunosuppressive drug therapy.[9]

In 7 healthy dogs given human albumin, 6 developed signs consistent with immune-complex disease (5 of 7 developed lameness).[10] Signs developed 5 to 13 days after administration of human albumin, and in surviving dogs, resolved after 2 to 37 days.

Distant Neoplasia

Polyarthropathy has been associated with carcinomas of tonsillar, mammary, and renal origin; seminoma; Sertoli cell tumor; and leiomyoma. It can be unclear if the cancer is causing polyarthropathy or if it represents a coexisting condition. In cases where neoplasia is the inciting cause, resolution of the neoplastic condition (for example, by surgical removal) would be expected to eliminate polyarthropathy and associated lameness. In many cases, joint pain is responsive to immunosuppressive therapy, even if the primary neoplasm remains untreated.

Primary Immune-Mediated Polyarthropathies

Nonerosive Primary Immune-Mediated Polyarthropathy (IMPA)

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is defined as an immune-mediated polysystemic disorder, often associated with a positive antinuclear antibody titer (see ch. 205). The most common manifestation of SLE is polyarthropathy. Diagnostic testing reveals additional, immune-mediated manifestations such as proteinuria, hemolytic anemia, thrombocytopenia, immune-mediated skin disease, and/or mucocutaneous oral ulcerations (see ch. 204). Treatment of polyarthropathy associated with SLE is the same as for idiopathic IMPA; however, additional attention is given to monitoring for development and/or progression of systemic disease

manifestations.

Breed-Associated

Shar-Pei

Shar-Pei dogs can experience short (12- to 48-hour) recurrent bouts of fever, accompanied by inflammation of joints (especially the hocks, i.e., swollen hock syndrome). This disorder also is known as familial Shar-Pei fever (FSF). Episodes typically are more frequent during the first years of life and become less frequent with age. Nonsteroidal anti-inflammatory drug (NSAID) administration seems helpful during episodes. The major constituent of the thickened skin of Shar-Peis is hyaluronic acid (HA), and HA is overexpressed in Shar-Peis compared with other canine breeds. The extent of hyaluronanosis varies among individual Shar-Peis, although almost all are affected. The administration of corticosteroids decreases cutaneous mucinosis in Shar-Peis, perhaps by decreasing expression of hyaluronan synthase.[11] The role that excessive HA in Shar-Peis plays in FSF needs to be investigated further. Shar-Pei dogs affected with FSF are at risk of developing reactive systemic AA amyloidosis and subsequent kidney or liver failure. Treatment of FSF-affected Shar-Peis with colchicine (0.025-0.03 mg/kg [maximum per dose: 0.6 mg] PO q 12 h) has been recommended. The benefit of long-term colchicine, corticosteroid, or other immunosuppressant administration, however, remains to be published.

Akita

One report has described 8 Akita puppies (<8 months old) with severe polyarthropathy.[12] Only 2 of 8 were responsive to antimicrobial and immunosuppressive therapy. Affected patients were traced back to a common ancestor and this syndrome does not appear to be widespread.

Idiopathic Immune-Mediated Polyarthritis (IMPA)

Once infectious agents and degenerative disease have been excluded, an idiopathic, immune-mediated etiology is presumed.[7,13-16] The cause is felt to be an immune-system dyscrasia, either targeting the joint directly or involving circulating immune complex (Arthus type III) disease. Immunosuppression is associated with rapid clinical response and avoidance of medication-related side-effects is paramount.

Signalment

Idiopathic immune-mediated polyarthritis is most commonly diagnosed in 3- to 7-year-old dogs, although patients have been diagnosed from 6 months to 12 years of age. There is no sex predilection and all breeds can be affected. IMPA is rare in cats; reported cases are young to middle-aged.

Signs

Most cases present with a stiff gait and reluctance to stand and/or walk. Anorexia, weight loss, and peripheral lymphadenopathy can be present. Fever is reported in one half of affected patients. Joint swelling and pain often are detected, but in some cases, these abnormalities are subtle. The carpal and tarsal joints are preferentially affected. Polyarthritis can occur concurrently with meningitis, polymyopathy, dermatopathy, hepatopathy, gastroenteropathy, or as a paraneoplastic syndrome, and physical findings can reflect concurrent disease. IMPA is a common cause of fever of unknown origin (see ch. 48) and the diagnosis cannot be excluded by physical examination findings alone.[17]

Differential diagnoses include tick-borne/rickettsial disease, hematogenous infectious processes (bacterial, fungal, protozoal), meningitis, polymyositis, panosteitis, hypertrophic osteodystrophy, degenerative joint disease, congenital lesions (i.e., elbow dysplasia, osteochondritis dissecans lesions), and trauma.

Diagnostic Testing

In juvenile dogs, it is important to palpate the diaphysis and metaphysis of long bones to differentiate polyarthritis (no signs of pain expected from deep palpation at these locations) from panosteitis or hypertrophic osteodystrophy (see ch. 187 and 353). The oral mucosa should be evaluated for ulceration (suggesting immune-mediated disease, particularly SLE) and the neck palpated and manipulated for signs of resistance or pain consistent with meningitis. Auscultation can reveal a cardiac murmur suggestive of bacterial endocarditis. All joints are evaluated for swelling, pain, range of motion and instability. The carpi and tarsi are preferentially affected and should receive special attention: palpation for evidence of joint effusion, and gentle but firm hyperflexion for signs of pain are indicated (see Video 203-1). Stifle lameness

commonly is associated with cruciate ligament tear, rather than polyarthritis, and careful evaluation must be performed.

Laboratory testing includes a CBC with manual differential, platelet count, serum biochemical profile, and urinalysis. Mild nonregenerative anemia and mild leukocytosis are common. The presence of thrombocytopenia suggests tick-borne or concurrent immune-mediated thrombocytopenia rather than idiopathic disease. Marked elevations of liver enzymes can prompt additional evaluation (bile acids, ultrasonography, and possibly histopathologic examination of a liver biopsy specimen) to assess for hepatopathy as a distant immunogenic stimulus. Proteinuria should prompt evaluation of urinary protein/creatinine ratio and systemic blood pressure (see ch. 99).

The need for imaging is evaluated on an individual basis. Thoracic radiographs, joint radiographs, and abdominal ultrasonography are most useful for patients with advanced age, joint instability, and/or abnormalities on CBC, serum biochemistry profile, or urinalysis. Joint radiographs are clearly indicated in non-responsive cases or in those with joint instability; however, in most cases, at least at the time of initial diagnosis, results are usually uninformative.[18] Erosive arthropathy might not be radiographically visible at the time of initial evaluation and only be detected with repeated assessment (Figure 203-1).

FIGURE 203-1 **A,** Anterioposterior radiograph of a canine tarsal joint, demonstrating extensive subchondral bone destruction, and moderate periarticular soft tissue swelling. These findings are consistent with the diagnosis of erosive arthritis. **B,** Normal canine tarsal joint for comparison.

Antinuclear antibody and rheumatoid factor serologic titers may be evaluated (see ch. 205, and "Erosive Arthropathy," below). The lupus erythematosus prep has low sensitivity. Titers for tick-borne diseases may be performed to help distinguish the cause of polyarthritis; however, in areas where these diseases are endemic, a course of anti-rickettsial antibiotics (doxycycline, minocycline) is always recommended. Because signs of illness can precede development of serum antibodies, acute rickettsial disease cannot be excluded by negative serum titers. Conversely, in endemic areas asymptomatic seroconversion to tick-borne agents is common. Most practically, failure to respond to a 3-5 day course of appropriate antibiotic therapy excludes

the diagnosis of rickettsial disease.

Arthrocentesis is fundamental to the diagnosis of inflammatory joint disorders (see ch. 94). At least four joints (for example, both carpi and both tarsi) are routinely sampled, regardless of physical examination findings. Abnormal synovial fluid can be detected in the absence of either pain or joint swelling. It is common to obtain <0.2 mL of synovial fluid and in many cases only slides for cytologic evaluation can be prepared. Larger volumes allow culture and/or nucleated cell counts; however, slide preparation is sufficient for diagnostic purposes in most cases. The viscosity of synovial fluid is evaluated after its expulsion from the needle. Normal synovial fluid produces a 1-2 cm strand between the needle and slide; abnormal joint fluid loses viscosity and strand formation decreases. Red cell contamination of joint fluid confounds interpretation. Care must be used to avoid surface blood vessels, use gentle technique, and release negative pressure from the syringe prior to removing the needle from within the joint space.

Interpretation of Synovial Fluid Cytology

Degenerative joint disease, trauma, and previous ligament injury are associated with mononuclear inflammation (<10% neutrophils in synovial fluid) whereas immune-mediated and infectious diseases are associated with >10% neutrophils (see ch. 74). Blood contamination alters the differential cell count and makes the interpretation of inflammation less certain. In the presence of marked blood contamination, cytologic results from additional joints, along with comparison to peripheral blood counts, must be utilized.

Treatment (Dogs)

Corticosteroids (prednisone, prednisolone) are highly effective. Prednisone 1-2 mg/kg PO q 24 h is started initially; lower dosages can be effective in less severe cases. High dosages are administered until the disease is in complete remission, defined as resolution of clinical signs as well as laboratory changes that were present initially. After remission is attained, the dosage is tapered, generally by half, for approximately 4 weeks. Reevaluation is performed and if signs of disease are absent (on physical and laboratory evaluation), the dosage is halved again. Tapering is repeated monthly until the animal either relapses or stops medication. The recommended minimum duration of therapy is 4 months. Vaccine- or drug-related cases might not require as long a duration of therapy. If relapse occurs during the taper, the dosage should be increased to the most recently effective dosage.

Combination immunosuppressive therapy with the addition of mycophenolate mofetil often is more effective, and produces fewer adverse effects, than corticosteroid therapy alone (see ch. 165). Prednisone (1 mg/kg PO q 12-24 h) and mycophenolate (10 mg/kg PO q 12 h) are administered in combination. The dosage of prednisone is tapered every 2 weeks while mycophenolate is continued at the same dosage. The goal is to discontinue corticosteroids completely and maintain remission with mycophenolate alone. If, after 2 months, remission is maintained on mycophenolate alone, the dosage is halved for 2 months, and then discontinued. Animals that relapse after discontinuation of mycophenolate are reinduced with a short course of prednisone; mycophenolate (10 mg/kg PO q 12-24 h) is then continued for life. Side-effects of mycophenolate are generally mild (diarrhea) and hematologic side-effects are uncommon.

Inability to control the signs of IMPA using mycophenolate alone may prompt a change of therapy. Mycophenolate is discontinued and leflunomide (2-4 mg/kg PO q 24 h) is administered together with corticosteroids. Corticosteroids are again tapered, with the goal of complete discontinuation. If good control is maintained for several months on leflunomide alone, the dosage may be gradually tapered (2-4 mg/kg PO q 48 h × 3 months, then q 72 h × 3 months, and then discontinued). Relapses are treated with a short course of corticosteroids and the dosage of leflunomide that previously maintained remission. Side-effects of leflunomide generally are mild (anorexia, lethargy, vomiting); however, CBCs and serum levels of liver enzymes should be monitored.

Patients receiving NSAIDs (carprofen, meloxicam, deracoxib, etc.) require special attention. When combined with NSAIDs, corticosteroids are associated with high risk of gastrointestinal ulceration. Therefore, for any transition from NSAIDs to corticosteroids, NSAIDs should be discontinued with a 7-day "washout" period prior to corticosteroid administration. Administration of mycophenolate or leflunomide may begin during this washout period and alternative pain medications (tramadol and/or acetaminophen in the dog) started. After 7 days, corticosteroids may be added if there is a lack of response to initial therapy.

Lack of response or inability to taper corticosteroids may prompt consultation with an internal medicine specialist. Alternative immunosuppressants may include azathioprine, cyclosporine, chlorambucil, or cyclophosphamide.

Treatment (Cats)

Some cats do not respond to prednisone and an alternate corticosteroid (prednisolone, methylprednisolone, triamcinolone, or dexamethasone) needs to be substituted. Chlorambucil may be administered along with corticosteroids for cats that require additional immunosuppression. Chlorambucil is dosed at 15 mg/m^2 PO q 24 h (often 4 mg/cat/day) for 4 days, and the 4-day treatment is repeated every 3 weeks. Alternatively, 2 mg chlorambucil (total dose) may be administered every 2 to 3 days. Potential side-effects can include anorexia and bone marrow suppression. In cats, the dosage of chlorambucil should be tapered before the prednisone is tapered. Treatment with methotrexate and leflunomide also have been described (see "Rheumatoid Arthritis," below).

Follow-Up

The need for and timing of reevaluation are dependent on the clinical response of the patient, requirement for monitoring of concurrent disease, laboratory abnormalities, and avoidance of drug-related side-effects. Since the expected response of idiopathic IMPA cases is good with corticosteroid administration, a lack of response to corticosteroids within 7 days should prompt reevaluation. This should include reconsideration of the diagnosis, assessment of the dosage and proper administration of drugs, and consideration of possible drug-related side-effects.

Previous laboratory abnormalities (anemia, thrombocytopenia, or proteinuria) should be monitored. Rapid resolution of thrombocytopenia, gradual resolution of anemia (most commonly due to anemia of chronic disease with resolution over several weeks) and either slow resolution (months) or stability of proteinuria are expected. Administration of corticosteroids is associated with proteinuria and its effect must be considered. Progressive proteinuria can suggest glomerular injury, and standard treatment for glomerular disease can be warranted in such cases. The skin and urinary tract should be monitored for infection.

Repeated/serial arthrocentesis is not routinely recommended; instead, patients are monitored by clinical evaluation. In selected cases with joint instability or concurrent degenerative change, repeated synovial fluid analysis could be needed to determine if lameness is due to inadequate control of immune-mediated disease. C-reactive protein might represent a serologic marker of clinical response.[19]

Prognosis

A rapid response to immunosuppressant therapy is expected in most (90%) cases. Some patients respond promptly and can be tapered off medication completely. Many others will respond but require some dosage of immunosuppressant to avoid relapse. Some (10%) fail to respond and suffer continued lameness along with progressive joint damage. Many patients suffer side-effects related to corticosteroid therapy effects, especially when long-term administration is needed. Many dogs are euthanized due to these effects and an important goal is avoidance of medication-related harm. Weight gain is a serious problem; many owners are unaware of it and body condition should be carefully monitored (see ch. 2). One successful strategy to decrease glucocorticoid-induced adverse effects is the use of an additional immunosuppressive agent, as described above. Administration of mycophenolate, cyclosporine, or leflunomide is—for most patients—safer than long-term corticosteroid use.

Erosive Immune-Mediated Polyarthropathies

Erosive arthritis is distinguished by the presence of radiographically visible subchondral bone lysis (see Figure 203-1). Destruction of supportive joint ligaments leads to joint instability and luxation.

Breed Associated

A severely erosive polyarthritis has been described in young Greyhounds.[20] A single case suggested *Mycoplasma spumans* as the causative agent; however, *Mycoplasma* was not isolated from two additional Greyhounds. The true cause is unknown and the prognosis is guarded to poor.

Feline Periosteal Proliferative Arthritis

Erosive joint disease in cats includes two syndromes: one showing marked periosteal new bone formation (periosteal proliferative form), and another showing minimal periosteal new bone formation (rheumatoid arthritis).[21] Treatment is as for rheumatoid arthritis (see below).

Rheumatoid Arthritis

In dogs and cats, rheumatoid arthritis (RA) is a rare disorder characterized by inflammation, articular

cartilage loss, erosion of periarticular bone, and joint deformation. Many patients have a positive rheumatoid factor (RF) serologic test result. The cause of RA is unknown and the prognosis guarded. Many patients become severely disabled despite treatment.

Rheumatoid arthritis is suspected by the presence of radiographically visible erosive lesions and/or joint instability. The age at diagnosis in dogs averages 5 years. Approximately 1/3 of cases exhibit fever, lethargy and/or inappetence in addition to lameness.[22] Most dogs demonstrate joint pain, decreased range of motion, and palpable evidence of joint effusion. Joint deformation differentiates these cases from non-erosive polyarthritis. Although by definition RA is a disease that involves the joints, other body systems also can be affected.

Feline RA is very rare. Gradual onset of stiffness with swollen and painful joints is typical. Radiographically, erosive polyarthritis in the cat has been separated into one group with primarily bone lysis (RA) and another with marked periosteal proliferation adjacent to joints (periosteal proliferative polyarthritis). It is unclear if these diseases are separate entities or if they represent different manifestations of the same disease process.

Rheumatoid factor is a collective term for autoantibodies against IgG. These antibodies are thought to play a role in opsonization and elimination of immune complexes. Serum RF levels can be elevated in any inflammatory disease, and the utility of the test is limited by lack of specificity for RA. Approximately 70% of dogs with clinically diagnosed RA are positive for RF; therefore, its absence does not exclude the diagnosis. The concentration of RF, if present, can be useful to follow the course of disease: a decrease in RF concentrations can be associated with effective therapy and an increase with relapse of disease.

Diagnostic testing includes a CBC with manual differential, platelet count, biochemical profile, urinalysis, radiographs of the affected joints and thorax, and synovial fluid analysis. Cats may be tested for feline leukemia virus and feline immunodeficiency virus. Radiographic findings include loss of bone at the epiphyses, narrowing of joint spaces, and irregular joint margins. Erosive mono- or oligoarthropathies prompt synovial fluid culture for bacteria, *Mycoplasma* spp., and if possible, L-form bacteria. Most cases initially are treated with antibiotics pending results of culture. Doxycycline, minocycline, or a fluoroquinolone is the drug of choice.

Immunosuppression is the mainstay of therapy for immune-mediated erosive arthritis. Prednisone and mycophenolate, as described above for treatment of IMPA, are recommended for dogs. Treatment of cats with methotrexate 7.5 mg PO once a week (q 7 days) and leflunomide 10 mg PO q 24 h has been described with marked improvement in 7 of 12 treated cats.[23] When marked clinical improvement occurred, the dosage was decreased to 2.5 mg methotrexate once a week and 10 mg leflunomide every 3-4 days (twice a week). Serious signs of toxicosis were not noted.

Drugs used in humans with RA include the IL-1 antagonist anakinra and the TNF-alpha inhibitors infliximab, adalimumab, certolizumab pegol, golimurnab, and etanercept. There are no published reports of their use in dogs with RA. Adalimumab was used in two dogs with dermatopathy.[24]

Prognosis

RA is a relentlessly progressive disorder and most patients experience joint deterioration over time. Small dogs can fare reasonably well despite obvious joint deformation; larger dogs less well. Pain medications (tramadol, acetaminophen [dogs only], gabapentin, amantadine) often are needed (see ch. 164 and 356). Surgical procedures occasionally can be used for improving joint stability and pain; synovectomy, arthroplasty, joint replacement, and/or arthrodesis can be beneficial in selected patients.[25] Monitoring for side-effects of immunosuppressive medications as well as systemic manifestations of immune-mediated disease is suggested.

CHAPTER 204

Immune-Mediated Dermatologic Disorders

Petra Bizikova

Client Information Sheet: Canine Pemphigus Foliaceus

Immune-mediated dermatoses encompass a broad spectrum of diseases that result from aberrant immune responses damaging skin and/or skin adnexae. Such immune responses can be directed against self-antigens primarily (autoimmune skin diseases; e.g., pemphigus, epidermolysis bullosa acquisita, cutaneous lupus), or against foreign antigens (drugs, viruses, or bacteria), which leads to an immunological reaction that damages the host tissue (secondary immune-mediated diseases; e.g., erythema multiforme, vaccine-induced vasculitis). Based on reported data, primary immune-mediated skin diseases (excluding hypersensitivity) account for <5% of all canine and feline dermatoses.[1-3] Because of their rarity, they often present a diagnostic challenge for clinicians. This chapter provides an overview of the more common autoimmune dermatoses to assist clinicians in a diagnostic process, while the accompanying table includes a more extensive list of diseases (Table 204-1).

Pemphigus Foliaceus (PF)

Pemphigus foliaceus (PF) is the most common autoimmune skin disease of dogs and cats.[4] It is caused by autoantibodies that disrupt desmosomal adhesion between keratinocytes, and induce subcorneal pustules.[5] Desmocollin-1 is a major target autoantigen in canine PF; in cats, target autoantigens remain unknown.[6]

Signalment

Akitas and Chow Chows are predisposed to PF, though PF has been reported in other breeds, such as the English Bulldog, Doberman, Collie, and Australian Sheepdog.[7-10] The mean age of onset is ≈6 years (range: <1-16 years) and there is an equal risk for males and females.[7,8,10,11] In cats, no breed or sex predisposition has been recognized,[8,12] and the median age of onset is ≈5.5 years (range: <1-17 years).[8,12,13]

Clinical Signs

The primary, and diagnostically most valuable, skin lesion characteristic of canine and feline PF is the subcorneal pustule. However, pustules progress rapidly into secondary erosions and crusts, which may represent the only clinical findings during the physical examination. The majority of dogs and cats exhibit initial lesions on the face, particularly on the nasal planum, dorsal aspect of the nose, periocular areas, and the concave pinnae (Figures 204-1 and 204-2).[7,8,12] More than half of patients will progress towards the generalized phenotype involving additional body regions such as the trunk and/or paw pads.[9,10,12] Paw pad lesions are characterized by prominent hyperkeratosis, crusting and fissuring (see Figure 204-1). Pustules occasionally can be found at the margins of the paw pads. In pesticide-triggered PF, a clinical entity described recently in association with flea preventatives such as ProMeris Duo, Certifect, and Vectra 3D, the initial lesion always is present between the dorsal margins of the scapulae, which corresponds to the product application site. In 2/3 of these dogs, lesions can become generalized, and mimic naturally occurring PF both clinically and histologically.[14-16] In cats, ungual folds often are affected, and nipples can be involved (see Figure 204-2).[12] In contrast to other pustular dermatoses such as bacterial pyoderma or pustular dermatophytosis, skin lesions in PF are bilaterally symmetrical.

Diagnostic Approach

Relevant differential diagnoses include other primary pustular dermatoses such as bacterial pyoderma and pustular dermatophytosis. Acantholytic keratinocytes mixed with non-degenerated neutrophils and/or eosinophils on cytologic or histopathologic assessment of specimens raises suspicion of PF; however, acantholysis is not specific for PF and it can be detected with pyoderma or pustular dermatophytosis.[17,18] Therefore, the diagnosis of PF is based on the combination of: (i) skin lesion type and distribution, (ii) exclusion of an infection, and (iii) supportive histopathologic findings.[4] Direct immunofluorescence (IF) or immunohistochemistry (IHC) can be used for demonstrating antikeratinocyte antibodies in skin biopsies of dogs with PF, but results must be interpreted with caution because such antibodies have been detected in skin samples from other dermatoses.[7,8,19-21] Indirect IF demonstrates circulating (serum) antikeratinocyte autoantibodies in up to 84% of tested PF sera depending on the type of substrate utilized.[5,22] Unfortunately, 80% of sera from healthy dogs contain low titers of antikeratinocyte IgGs as well, decreasing the specificity of this test.[5] Finally, anti-desmocollin-1 serologic testing appears to be more specific for PF; however, this test currently is not offered commercially.[6]

Treatment

Historically, the standard of care for treatment of canine and feline PF relied on an immunosuppressive dosage of glucocorticoids (dogs: prednisone or prednisolone 2-6.6 mg/kg PO q 24 h; cats: prednisolone 2-5 mg/kg PO q 24 h or triamcinolone 0.6-2 mg/kg PO q 24 h).[7,8,10,12,23,24] If glucocorticoids alone were unable to provide sufficient resolution of clinical signs and/or if they caused too many side-effects, an additional immunosuppressive drug(s) such as azathioprine (dogs only: 2-2.5 mg/kg PO q 24 h), chlorambucil (0.2 mg/kg PO q 24-48 h) or cyclophosphamide (25 mg/m^2 PO q 24 h) was added.[7,8,10,12,23,25] Recently, cyclosporine at variable dosages (5-18 mg/kg PO q 24 h, with or without ketoconazole co-treatment) has been reported to be of some benefit in management of canine and feline PF.[13,26,27] In addition, treatment with topical glucocorticoids or tacrolimus should be considered in cases with localized skin lesions.

Mucous Membrane Pemphigoid (MMP)

Mucous membrane pemphigoid (MMP) is a subepidermal blistering skin disease recognized in humans, dogs and cats in which autoantibodies target collagen XVII or laminin-332 (laminin 5) of the basement membrane. Although rare, MMP is the most common autoimmune subepidermal blistering dermatosis (AISBD) recognized in veterinary medicine.[28] Because information about feline MMP is limited,[29] the following information pertains to the canine disease.

Signalment

MMP usually is diagnosed in adult dogs (median age 5 years), and males are affected 33% more often than females.[30] It affects a variety of breeds, but German Shepherd dogs are the most common (29%).[30]

Clinical Signs

MMP is a chronic mucosal and mucocutaneous blistering disease with a tendency to form scars (Figure 204-3). Deep erosions and ulcers are the most common lesions, while intact vesicles are seen only rarely. Scarring often is observed in chronic cases. A characteristic of this disease is the remarkable predilection of lesions for the oral cavity, other mucosae (eyes, genitalia, anus), perimucosal areas (mucocutaneous junctions) as well as the nose and concave pinnae. Truly cutaneous, not perimucosal, skin lesions are rare.[30,31]

FIGURE 204-3 Canine autoimmune subepidermal skin diseases. Characteristic skin lesions consistent of deep erosions and ulcers on hard palate and anus **(A, B)** and deep erosions, crusts and scarring on the nasal planum and scrotum **(C, D).** (Photos courtesy Dr. H.L. Tham, case material NCSU.)

Diagnostic Approach

Relevant differential diagnoses include other subepidermal blistering diseases, pemphigus vulgaris and paraneoplastic pemphigus, mucocutaneous lupus erythematosus, and erythema multiforme major (see Table 204-1). Biopsies are required to confirm subepidermal vesiculation with or without inflammation and to rule out differentials. If an intact vesicle cannot be sampled, the edge of a fresh erosion may be the best choice to reveal microscopic blistering. Staining with periodic acid-Schiff (PAS) or for collagen IV can be used for demonstrating that the clefting arises above the lamina densa of the basement membrane zone (BMZ).[31,32] In addition, demonstration of tissue-bound and/or circulating anti-BMZ antibodies, and/or, if available, anti-collagen XII or laminin-332 antibodies, can further assist in the diagnostic process.[31]

Treatment

There is limited information about the treatment and outcome of canine MMP. Tetracycline and niacinamide (250-500 mg of each PO q 8 h) have been shown to be effective, especially in mild cases. If quality of life is impaired, treatment with oral glucocorticoids (e.g., prednisone/prednisolone 1-4 mg/kg PO q 24 h), with or without azathioprine, should be considered. Addition of topical glucocorticoids or tacrolimus is beneficial.[30]

Epidermolysis Bullosa Acquisita (EBA)

The diagnosis of EBA is given to approximately 25% of dogs with AISBD, making it the second most common AISBD in this species.[28] Autoantibodies targeting collagen VII, another BMZ protein, have been uncovered in most affected dogs.[33,34] This disease can occur in the context of classical systemic lupus erythematosus (SLE; see ch. 205), at which point it is recognized as a type-I bullous SLE.[35]

Signalment

EBA affects dogs of various breeds and ages, but more than half of them are young Great Danes. Males are twice as often affected as are females.

Clinical Signs

In contrast to MMP, EBA is a haired-skin–predominant disease with concurrent mucosal lesions. Early lesions present as erythematous and urticarial patches, usually on the face, axillae, abdomen, and inguinal region. They progress rapidly into tense vesicles, which rupture and evolve into widespread, often confluent, sharp-edged ulcerations. Oral epithelial sloughing is a common feature. Skin ulceration is most prominent in areas of friction such as axillae, inguinal region, and paw pads. Lethargy, fever, and anorexia are reported in the

majority of dogs with EBA.[36]

Diagnostic Approach

Relevant differential diagnoses include other AISBD with a skin-predominant phenotype (e.g., bullous pemphigoid), as well as other blistering diseases such as pemphigus vulgaris and paraneoplastic pemphigus, vesicular cutaneous lupus erythematosus, and erythema multiforme major/Stevens-Johnson syndrome (see Table 204-1). Biopsies are required to confirm subepidermal vesiculation containing neutrophils and some eosinophils. Staining with PAS or for collagen IV can be used for demonstrating that, in most cases, the blister arises below the lamina densa of the BMZ.[32] Demonstration of tissue-bound and/or circulating anti-BMZ antibodies, and/or anti-collagen VII antibodies, can further assist in the diagnostic process.

Treatment

The treatment outcome is variable. Approximately 30% of cases are euthanized due to lack of response to treatment. In the rest of the patients, the disease appears to be responsive to standard immunosuppressive treatment with glucocorticoids (e.g., prednisone/prednisolone 2-4 mg/kg PO q 24 h) and/or other immunosuppressive drugs.[36]

Cutaneous Lupus Erythematosus (CLE)

Cutaneous lupus erythematosus (CLE) is subdivided into four disease entities in veterinary medicine (see Table 204-1): vesicular cutaneous lupus (VCLE),[37,38] discoid lupus (DLE), which can be either classic facial or generalized,[1,39,40] exfoliative cutaneous lupus (ECLE),[41] and a newly described mucocutaneous lupus (MCLE).[42] The only form of CLE described in cats is the classic form of DLE.

Discoid lupus erythematosus ("classic" nasal variant) affects dogs and cats.[43,44] In both species, the lesions consist of erythema, depigmentation, and atrophy, often accompanied by erosions and ulcers (Figure 204-4, *A*). Lesions usually are present on the nasal planum and surrounding skin. A favorable response to a wide variety of treatments including tetracyclines and niacinamide has been reported.[45,46] Topical treatment with glucocorticoids or tacrolimus might be of benefit as well.[47]

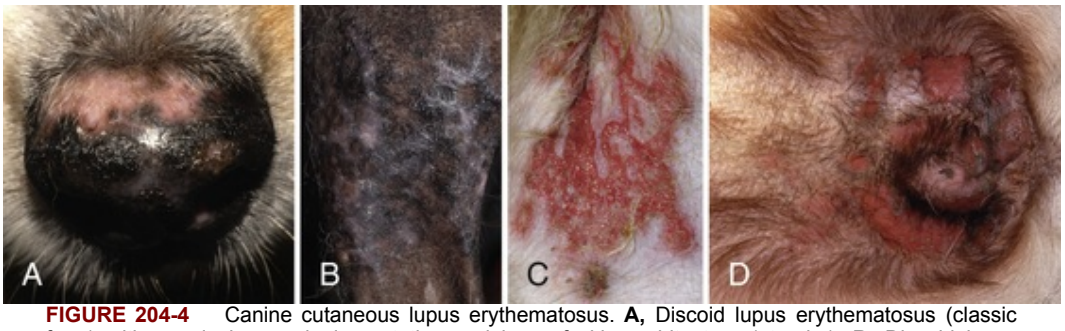

FIGURE 204-4 Canine cutaneous lupus erythematosus. **A,** Discoid lupus erythematosus (classic form) with nasal planum depigmentation and loss of skin architecture (atrophy). **B,** Discoid lupus erythematosus (generalized form) with polycyclic plaques with reticulated hyperpigmentation and central scarring. **C,** Vesicular cutaneous lupus erythematosus with polycyclic erosions and ulceration in the inguinal area. **D,** Mucocutaneous lupus erythematosus with erosions and ulcers affecting the mucocutaneous junction of the vulva and the adjacent haired skin. (**B,** Photo courtesy Dr. U. Oberkirchner, case material NCSU; **D,** Photo courtesy Dr. T. Olivry, case material NCSU.)

Discoid lupus erythematosus (generalized form) has been described in two dogs.[39,40] The main skin lesions consist of hyperpigmented annular plaques with fine scaling, central erosions, and scarring (Figure 204-4, *B*). No progression to systemic lupus erythematosus has been observed in these cases. One of the cases had a favorable response to hydroxychloroquine, while the other was treated successfully with cyclosporine.[39,40]

Vesicular cutaneous lupus erythematosus predominantly affects adult Collies, Shetland Sheepdogs, and their crossbreds. Females outnumber males. Dogs with VCLE present with erythema, flaccid vesicles and ulcers on glabrous skin of the abdomen, axillae, groin and medial thighs. Lesions are sharp-edged annular, polycyclic, or serpiginous (Figure 204-4, *C*). Some patients exhibit ulceration of mucocutaneous junctions, concave

pinnae, and the oral cavity. Skin lesions appear to respond to immunosuppression with orally administered glucocorticoids with or without azathioprine. Oral cyclosporine and topical tacrolimus are effective in some patients.[38,48,49]

Exfoliative cutaneous lupus erythematosus is a hereditary condition of German Shorthaired Pointers.[50] Females outnumber males. The main skin lesions of canine ECLE consist of spontaneous alopecia and scaling, later progressing to erosions. Lesions typically affect the muzzle, pinnae, and trunk. Glomerulonephritis, hematological abnormalities, and systemic signs such as lameness can occur with time, but a positive antinuclear antibody titer has not been reported consistently.[51] Response to therapy is poor. A favorable response might be obtained with high dosages of oral glucocorticoids with azathioprine and/or hydroxychloroquine, though most dogs end up being euthanized.[51]

Mucocutaneous lupus erythematosus predominantly affects German Shepherds, but other breeds can be affected. Females outnumber males. The main skin lesions consist of erosions and ulcers predominantly involving the genital and anal mucocutaneous regions, and spreading to adjacent skin (Figure 204-4, *D*). A favorable response to a wide variety of treatments has been reported, and oral glucocorticoids appear to provide the fastest resolution.[46,52]

CHAPTER 205

Systemic Lupus Erythematosus

Michael Stone

Client Information Sheet: Systemic Lupus Erythematosus

Veterinary patients with systemic lupus erythematosus (SLE) classically demonstrate at least two separate manifestations of autoimmunity in addition to the presence of antinuclear antibody (ANA). However, some patients demonstrate clinical features of multisystemic autoimmunity yet lack serum ANA.

Pathogenesis

Autoimmune disease may be defined as a clinical syndrome caused by activation of the immune system in the absence of an infection or other discernible cause. With SLE, immune system dysregulation leading to immune complex formation is postulated to induce tissue damage (type III hypersensitivity); however, direct antibody-mediated cytotoxicity (type II hypersensitivity) and cell-mediated autoimmunity (type IV hypersensitivity) also occur.

Effectors of SLE

Pathogenic Antibodies

SLE patients produce antibodies directed against a broad range of nuclear, cytoplasmic, and cell membrane molecules. Autoantibodies can cause damage through the formation of immune complexes, opsonization of target cells, and interference with cellular physiology.[1]

Pathogenic Immune Complexes

Immune complexes, formed when antibody meets antigen, are normally removed by the mononuclear phagocyte system. Elevated levels of circulating immune complexes can occur with persistent autoantibody production and/or defective clearance mechanisms. Immune complexes deposit near blood vessels where there is physiologic outflow of fluid, such as glomeruli, synovia, and choroid plexi. Trapped immune complexes activate complement, attract inflammatory cells, and cause tissue damage.[2]

Autoreactive T Cells

T cells can cause direct tissue damage in SLE. Dermatologic and renal lesions have been associated with cytotoxic T cell–mediated damage.[3]

Genetics of SLE

Many genes have been associated with the development of SLE in humans, most encoding proteins involved with immune system function[1]: the major histocompatibility complex, cytokines, antigen receptors, members of cytokine- or antigen-signaling cascades, and others. Protective genes exist that prevent the development of SLE. In dogs, SLE clearly is inherited and experimental colonies of dogs with SLE have been established.[4-6] SLE in dogs has been associated with the allele DLA A7,[7] the DRB1 locus in Nova Scotia Duck Tolling Retrievers,[8] a specific allotype of the fourth component of complement,[9] and decreased serum IgA.[10] A negative (or "protective") association exists with DLA A1 and B5.[7] SLE might occur more frequently in purebred cats, also suggesting genetic influence.[11]

Environmental Factors and SLE

The lower-than-expected rate of SLE concordance among human identical twins demonstrates the importance of environmental triggers.[12] Exposure to UV light causes disease flares in humans with SLE and has been reported in both dogs[5,13] and cats.[14] 90% of SLE cases occur in women, suggesting influence by estrogen and prolactin, or the protective effects of testosterone; gender predilection has not been identified in the dog or cat. Exposure to infectious agents in early life might suppress the development of allergic and autoimmune disorders.[15] It has been suggested that allergy and autoimmune disease are related to decreased exposure to infectious agents during early development, causing inadequate stimulation.[16]

Drugs and SLE

Certain drugs can induce SLE-like disease in humans[17] (Box 205-1), likely different from true SLE. Clinical manifestations of drug-induced lupus in humans include arthritis, serositis, fatigue, malaise, and low-grade fever; nephritis and neurologic disease are rare. The manifestations disappear in most patients within a few weeks of discontinuation of the offending drug, never to reappear unless reexposure occurs.[18] In cats, ANA has occurred with hemolytic anemia and thrombocytopenia (propylthiouracil)[19] or without clinical signs of SLE (methimazole).[20] Hydralazine has been associated with development of ANA in the dog.[21]

Box 205-1

Causes of Drug-Induced SLE in Humans

Allopurinol	Leuprolide acetate	Prazosin
Aminoglutethimide	Lithium	Primidone
Aspirin	Lovastatin	Procainamide
Atenolol	Mephenytoin	Promethazine
Captopril	Methimazole	Propranolol
Carbamazepine	Metoprolol	Propylthiouracil
Chlorpromazine	Mesalazine	Quinidine
Cimetidine	Minocycline	Spironolactone
Clonidine	Minoxidil	Statins (atorvastatin, lovastatin, etc.)
Danazol	Nalidixic acid	Streptomycin
Diphenylhydantoin	Nitrofurantoin	Sulfasalazine
Disopyramide	Penicillamine	Sulfonamides
Enalapril	Penicillin	Tetracycline
Griseofulvin	Phenothiazines	Timolol eye drops
Hydralazine	Phenylbutazone	Valproate
Isoniazid	Phenytoin	
Labetalol	Piroxicam

Infectious Agents and SLE

No infectious agents have been identified that cause SLE. However, it is likely that infections can precipitate the development of clinical signs in patients with the appropriate predisposing genes for SLE. Microbial antigens can initiate autoreactivity through molecular mimicry, polyclonal activation, or the release of previously sequestered antigens.[22] The immunogenicity of autoantigens might be increased by inflammation, explaining why flares of immune-mediated disease can be induced by vaccination or infection. Feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) can induce SLE-like disease in cats, and serum ANA can occur early in FeLV infection.[23] Whether FeLV- or FIV-induced disease is truly similar to SLE is debated.[24] Feline ehrlichial disease has been associated with positive ANA.[2,25]

In summary, the development of clinical signs depends on inheriting an appropriate number of

susceptibility genes to SLE, a lack of protective genes, and an environmental stimulus that sets the whole process into action.

Clinical Findings

The typical age at diagnosis in dogs is 3-7 years, although patients from 6 months to 13 years of age have been reported. Cats have been diagnosed at 1 to 11 years of age.

The clinical signs reported in dogs and cats with SLE are summarized in Table 205-1.

TABLE 205-1

Clinical Signs in Dogs and Cats with Suspected SLE

CLINICAL SIGN	PREVALENCE IN DOGS*	PREVALENCE IN CATS*
Nonerosive polyarthritis	236/302 (78%)	9/25 (36%)
Fever	186/275 (68%)	11/21 (52%)
Renal disorders	167/302 (55%)	10/25 (40%)
Dermatologic lesions	138/302 (46%)	15/25 (60%)
Lymphadenopathy/Splenomegaly	66/175 (38%)	
Leukopenia	54/302 (18%)	
Hemolytic anemia	45/302 (15%)	6/25 (24%)
Thrombocytopenia	40/302 (13%)	2/25 (8%)
Myositis	16/275 (6%)	
CNS disorders	16/302 (5%)	6/25 (24%)
Neuropathy	7/302 (2%)	

*Number of patients affected/number of patients described.

Summarized from references 11, 13, 14, 24, and 26-33.

CNS, Central nervous system.

Lameness due to nonerosive polyarthropathy is the most frequent primary complaint in dogs (see ch. 203). Smaller joints (carpi, tarsi, elbows, stifles) are involved most frequently. Synovial fluid analysis reveals neutrophilic inflammation (>10% neutrophils). In cats, articular signs also are common. Some cats can demonstrate joint swelling and abnormal synovial fluid yet lack signs of lameness.

Fever is reported frequently in both dogs and cats, and it can be either persistent or intermittent (see ch. 48).

In humans, the kidney commonly is involved, with biopsies demonstrating involvement in almost all SLE patients.[34] Renal involvement can be benign and subclinical or progressive and fatal. The earliest manifestation is proteinuria. In dogs with SLE, proteinuria (see ch. 72) and glomerular lesions (see ch. 325) also are frequent. Biopsy can reveal mesangial and/or endothelial hypertrophy, proliferative and/or membranous glomerulonephritis, and sclerotic changes. Proteinuria and/or glomerulonephritis is/are also reported commonly in the cat.

Cutaneous manifestations in dogs can include erythema, scaling, crusting, depigmentation, and alopecia. Lesions can develop in the skin, mucocutaneous junctions, and oral cavity. Preferential localization of lesions can occur in areas poorly protected by the hair coat and be exacerbated by exposure to sunlight. The cutaneous lesions in 25 reported cases in cats have included erythema, ulceration, crusts, and depigmentation of the face, ears, and paws in 7, biopsies consistent with pemphigus foliaceus or plasmacytic pododermatitis in 4, ulcerative stomatitis in 3, and a cornification disorder (seborrheic dermatitis) in one case.

Only rarely is anemia, leukopenia, or thrombocytopenia the presenting feature of human SLE without concomitant problems of the skin, joints, central nervous system (CNS), or cardiopulmonary system. In dogs, although the presence of anemia of chronic inflammation is common, hemolytic anemia is uncommon. Mild thrombocytopenia is noted in some patients, although severe thrombocytopenia can also occur. Leukopenia has been reported. Complement concentrations were decreased in three of eight dogs with suspected SLE in one study.[9] As in dogs, hemolytic anemia is uncommon in cats with SLE and severe thrombocytopenia rare.

Complement levels were decreased in one cat.[11]

Presence of the "lupus anticoagulant" has been reported in dogs and cats.[29,35,36] It is an antibody directed against membrane phospholipids. It causes *in vitro* prolongation of the activated partial thromboplastin time, which explains the name "anticoagulant." Paradoxically, the antibody's effect *in vivo* is to cause platelet activation, hypercoagulability, and thrombosis.

Memory impairment, headache, epilepsy, and personality changes can accompany SLE in humans. CNS involvement without other clinical or laboratory features of SLE is unusual. In cats, reported CNS manifestations have included hyperactivity; twitching of the ears, tail, and hindlimbs; hyperesthesia; vocalization; repetitive licking; neck ventroflexion; and seizures.[10] Polymyositis has been suspected in several dogs and cats, and polyneuritis, characterized by hyperesthesia, has been reported in a dog.[13]

In humans, pulmonary fibrosis, pulmonary embolism, pleural effusion, pericardial effusion, cardiac arrhythmias, and/or myocarditis can occur with SLE. Neutrophilic myocarditis was demonstrated in four dogs with SLE.[28] Subclinical lung changes were noted on thoracic radiographs of one cat,[11] but neither pleuritis nor pericarditis has been observed in cats with SLE.

Diagnosis

Criteria have been developed for the diagnosis of SLE in humans (E-Table 205-2), and these criteria can be modified to apply to veterinary patients (Table 205-3). Veterinary patients with SLE classically demonstrate at least two separate manifestations of autoimmunity along with a positive ANA titer. Patients with three or more separate manifestations of autoimmunity may also be considered to have SLE despite the absence of detectable ANA. The most common syndrome recognized in the dog is immune-mediated polyarthritis, in combination with immune-mediated skin disease, glomerulonephritis, hemolytic anemia and/or thrombocytopenia. Similar signs occur in the cat; however, CNS signs might be more common.

TABLE 205-3

Proposed Criteria for the Diagnosis of SLE

1. ANA	Abnormal ANA titer in the absence of drugs, infectious diseases, or neoplasia known to be associated with its development
2. Cutaneous lesions	Depigmentation, erythema, erosions, ulcerations, crusts, and/or scaling, with biopsy findings consistent with SLE
3. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless
4. Arthritis	Nonerosive, nonseptic arthritis involving two or more peripheral joints
5. Renal disorders	Glomerulonephritis or persistent proteinuria in the absence of urinary tract infection
6. Anemia and/or thrombocytopenia	Hemolytic anemia and/or thrombocytopenia in the absence of offending drugs
7. Leukopenia	Low total white blood cell count
8. Polymyositis or myocarditis	Inflammatory disease of the skeletal or cardiac muscle
9. Serositis	Presence of a nonseptic inflammatory cavity effusion (abdominal, pleural, or pericardial)
10. Neurologic disorders	Seizures, peripheral neuropathy, myopathy, or cranial nerve deficits in the absence of known disorders
11. Antiphospholipid antibodies	Prolongation of activated partial thromboplastin time that fails to correct with a 1 : 1 mixture of patient and normal plasma, in the absence of heparin or fibrin degradation products

ANA, Antinuclear antibody; *SLE*, systemic lupus erythematosus.

*A diagnosis of SLE is established if a patient manifests 3 or more criteria simultaneously or over any period of time.

Adapted from references 28 and 39-42.

E-TABLE 205-2

The American College of Rheumatology Revised Criteria for the Classification of SLE*

CRITERIA	DEFINITION
1. Malar rash	Fixed erythema, flat or raised over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless
5. Arthritis	Nonerosive arthritis involving 2 or more peripheral joints
6. Serositis	a. Pleuritis—pleuritic pain or rub or evidence of pleural effusion OR b. Pericarditis—pericardial effusion
7. Renal disorder	a. Persistent proteinuria OR b. Cellular casts—may be red cell, hemoglobin, granular, tubular or mixed
8. Neurologic disorder	a. Seizures—in the absence of offending drugs or known metabolic derangements or electrolyte imbalance OR b. Psychosis—in the absence of offending drugs or known metabolic derangements or electrolyte imbalance
9. Hematologic disorder	a. Hemolytic anemia—with reticulocytosis OR b. Leukopenia—<4,000/mm^3 on 2 or more occasions OR c. Lymphopenia—<1,500/mm^3 on 2 or more occasions OR d. Thrombocytopenia—<100,000/mm^3 in the absence of offending drugs
10. Immunologic disorder	a. Anti-DNA: antibody to native DNA in abnormal titer OR b. Anti-Sm: presence of antibody to Sm nuclear antigen OR c. Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant, or (3) a false-positive serologic test for syphilis
11. Antinuclear antibody (ANA)	An abnormal titer of ANA at any point in time and in the absence of drugs known to be associated with "drug-induced lupus."

*For the purposes of identifying patients in clinical studies, a person shall be said to have SLE if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.

From Tan, 1982.[38]

Diagnostic testing of suspected SLE patients should include a complete blood count, serum biochemistry profile, urinalysis, imaging, synovial fluid cytology (see ch. 74 and 94), histopathologic examination of the skin (see ch. 86) and/or kidney (see ch. 89), and serum ANA titer. Cats should be tested for feline leukemia virus and feline immunodeficiency virus. Infectious and neoplastic disease must be excluded through imaging, culture of urine, blood and/or synovial fluid, serologic titers for tick-borne and fungal diseases, and therapeutic antibiotic trials. In tick-infested areas, a 3- to 7-day course of doxycycline should be considered prior to concluding the presence of immune-mediated disease.

Immunodiagnostic investigations may include Coombs' testing; screening for platelet autoantibodies and rheumatoid factor; coagulation testing for antiphospholipid antibodies; and testing for serum immunoglobulin, complement, circulating immune complex concentrations and endocrine autoantibodies (i.e., antithyroglobulin). Immunohistologic investigation may include immunohistochemical and immunofluorescence staining.[43]

Biopsies can be supportive but rarely are diagnostic of SLE by themselves. When the skin is biopsied, care should be taken to avoid ulcers or erosions, since an intact epidermis is necessary to substantiate the diagnosis (see ch. 86). Oral biopsy specimens rarely are beneficial, since ulcers, which are inherently not diagnostic, are common in this location. Erythematous areas adjacent to ulcers yield the most useful diagnostic results.[44] Histopathologic findings can reveal an interface dermatitis consisting of a mononuclear cell infiltrate at the epidermal-dermal junction, apoptosis and vacuolar change of the basal keratinocytes, and epidermal-dermal separation.

The diagnosis of SLE in cats is less well defined. In some studies, all cats with positive ANA test results were diagnosed with SLE but whether or not these patients truly had SLE is debatable. Another unanswered question is how to categorize FeLV- or FIV-positive patients: some reports include FeLV-positive cats while others exclude them.[11,24,29-31,45] Because of the possibility of ehrlichial disease, it has been recommended that all cats receive a course of doxycycline before the diagnosis of immune-mediated disease is made.[46]

Specific Testing

Lupus Erythematosus (LE) Cell Test

An LE cell is recognized as a neutrophil that contains phagocytized nuclear material. Because of technical and sensitivity problems, especially regarding subjectivity of interpretation of results (false-negative results are common), the LE cell test has been largely replaced by the more sensitive ANA test.[26,27,47] LE cells rarely can be seen on smears of pericardial, pleural, peritoneal, joint, cerebrospinal and blister fluid and, when present, are highly suggestive of SLE.

Antinuclear Antibodies

Antinuclear antibodies (ANAs) are a heterogeneous population of antibodies directed against various nuclear antigens. Although ANA testing is a cornerstone of the diagnosis of SLE, it has substantial limitations in veterinary medicine. There is no universally accepted protocol for ANA testing used by veterinary laboratories. The result of an ANA test is commonly reported as a serum titer and, sometimes, pattern of nuclear staining. The most commonly observed patterns are speckled or homogenous staining, but there is no clear association between patterns and the nature of clinical disease. A clinically significant titer must be distinguished from low ANA titers that may be present in up to 10% of normal animals and animals with any chronic inflammatory, infectious or neoplastic disease.[48,49]
