Astrocytoma Histologic origin: astrocytes	Rostrotentorial (frontal, periform, temporal lobes); thalamus in higher grade; infratentorial can occur; ventricular contact but do not invade	T1W-mild to moderate hypointense; T2W-moderate hyperintense	Variable; low grade-minimal to mild; higher grade-moderate to marked, nonuniform or peripheral (ring) enhancement	Distinct to indistinct margins; peritumoral edema is variable; high grade tumors may contain hemorrhage; may contain cystic regions
Oligodendroglioma Histologic origin: oligodendrocyte	Usually rostrotentorial (frontal, piriform, temporal lobes); can have surface and ventricular contact, drop metastasis	T1W-moderate hypointense; T2W-hyperintense, marked when mucinous	Variable; low grade-minimal to mild; higher grade-moderate to marked, nonuniform or peripheral (ring) enhancement	Distinct to indistinct margins, globular; tend to have less peritumoral edema than astrocytomas; high grade tumors may contain hemorrhage; may contain cystic regions
Gliomatosis cerebri Histologic origin: most	Focal or multifocal lesions, spread down white	T1W-iso- to hypointense; T2W-hyperintense;	Minimally or nonenhancing;	Indistinct margins; minimal

astrocytic; oligodendroglial?	matter, periventricular, subpial lesions or diffuse meningeal lesions; histologic origin as oligodendroglial or astrocytic	no detection	meningeal lesions can enhance	peritumoral edema; no mass effect
Medulloblastoma/primitive neuroectodermal tumors (PNETs) Histologic origin: Embryonic neuronal tumor	Medulloblastoma-cerebellum; PNETs-olfactory/ frontoparietal lobes	T1W-iso- to hypointense; T2W-hyperintense	None to mildly heterogeneous; PNETs can have marked enhancement	Distinct to indistinct margins
Ependymoma Histologic origin: ependymal lining cells of ventricular system	Common in lateral, 3rd and 4th ventricles; suprasellar region; less common than CPTs	T1W- hypo- to slight hyperintense; T2W-moderate to hyperintense	Variable; none to marked heterogeneous enhancement	Usually distinct conforming to shape of ventricle; absent to minimal peritumoral edema; may contain cysts or hemorrhage; cause ventriculomegaly
Choroid plexus tumor (CPT) Histologic origin: choroid plexus epithelium	Lateral, 3rd and 4th ventricles and lateral apertures; most occur in 4th ventricle; drop metastasis	T1W-hypo-, iso- or hyperintense; T2W-hyperintense; can appear heterogeneous when hemorrhage	Marked, homogeneous enhancement	Usually distinct conforming to shape of ventricle with invasion into tissue; absent to minimal peritumoral edema; may contain cysts or hemorrhage; cause ventriculomegaly
Tumors of the Meninges (Extra-Axial)				
Meningioma (dogs) Histologic origin: leptomeninges or cells forming arachnoid granulations	Most common in meninges of olfactory bulbs and frontal lobes and then cerebral, cerebellar convexities associated with basilar, tentorial, falcine and suprasellar; can penetrate cribriform plate	T1W-usually isointense, heterogeneous; T2W-hyperintense	Usually marked, homogeneous enhancement, can be heterogeneous	Distinct margins, globoid, dural tail, plaque-like, broad base; peritumoral edema; cysts are common
Meningioma (cats) Histologic origin: leptomeninges or cells forming arachnoid granulations	Most common in meninges of cerebral convexity-parietal common, cerebellum; can be multiple	T1W-iso- to hypointense; T2W- hyperintense; signal void from ossification in tumor and hyperostosis of calvaria	Marked, uniform enhancement; can be heterogeneous	Distinct margins with smooth or irregular borders; peritumoral edema; cysts are common
Granular cell tumor Histologic origin: unknown, meningeal origin is suspected	Plaque-like mass extending along meninges of cerebral convexity and floor, falx, suprasellar	T1W-moderate hyperintense; T2W hyperintense	Marked, homogeneous enhancement; meningeal involvement	Irregular but defined margins, plaque-like; peritumoral edema
Lymphoma and Hematopoietic Tumors				
Lymphoma (primary or metastatic) Histologic origin: B or T cell;	Intra- or extra-axial; primary-rostrotentorial,	T1W-iso- to hypointense; T2W-iso-to hyperintense	Variable; homo- to heterogeneous enhancement;	Indistinct margins; minimal to moderate

Dog-B cell, Cat-B or T cell	suprasellar, often near ventricle; metastatic—often meninges with parenchymal invasion; focal or multifocal		diffuse meningeal enhancement	peritumoral edema
Histiocytic sarcoma Histologic origin: arise from interstitial dendritic cells of meninges	Usually extra-axial but can be intra-axial; restricted to meninges and choroid plexus near olfactory, cerebral convexity, cerebellum; focal or diffuse	T1W-iso- to hypointense; T2W-iso-, hypo- to heterogeneous intensity	Moderate, homo- to heterogeneous enhancement; mild to marked, diffuse meningeal enhancement	Indistinct to distinct margins, dural tail, plaque-like; mild to marked peritumoral edema
Sellar Region Tumors				
Pituitary tumors	Most arise from the adenohypophysis into sellar region (>10 mm)	T1W-isointense; T2W-mild hyperintense	Marked homogeneous enhancement	Distinct margins; mild to moderate peritumoral edema when large; may be cystic or hemorrhagic
Metastatic Tumors				
Metastasis	Usually multifocal lesions; gray-white matter interface cerebrum	T1W-mixed intensity; T2W-mixed intensity	Variable contrast enhancement; peripheral (rim) enhancement	Indistinct margins; marked peritumoral edema; some tumors (e.g., hemangiosarcoma) have hemorrhage and cysts

*Compared to gray matter.

Age, Gender, Breed and Risk Factors

Primary brain tumors typically affect older dogs, with no sex predilection and a median age of 9 years (range, 4 to 13 years); 95% are older than 5 years.[292,293] The median age for dogs with meningiomas, gliomas (astrocytoma, oligodendroglioma) and choroid plexus tumors is reported as 10-14 years, 8 years, and 5-6 years, respectively.[291,293,301,305] Primary brain tumors, particularly gliomas, can be seen in younger dogs.[291,306] The Boxer, Boston Terrier, Golden Retriever, French Bulldog and Rat Terrier have increased risk of primary intracranial neoplasia.[291] Dolichocephalic breeds may be at increased risk for meningiomas, whereas brachycephalic breeds may have increased risk for gliomas.[291,293] Certain breeds were found to be at a significantly increased risk for specific primary intracranial neoplasms, including Golden Retrievers, mixed breed, Miniature Schnauzers, Rat Terriers for meningiomas; English Toy Spaniels, Boston Terriers, French Bulldogs, Boxers, English Bulldogs and Bullmastiffs for gliomas; and Dalmatians and English Setters for choroid plexus neoplasms/ependymomas.[291] Dogs >15 kg had increased risk of meningioma.[291] Doberman Pinschers and Cocker Spaniels were found to have a significantly decreased risk of primary intracranial neoplasms.[291]

Cats with brain tumors are older, with a median age of approximately 12 years old.[294] In feline meningiomas, male cats are affected more than female cats.[294,307] The Domestic Shorthair cat is the most common breed identified.[294] Definitive risk factors for development of brain tumors are unknown for dogs and cats. Genetics may have a role in some breeds of dogs since meningiomas (like in people) have similar phenotypes and may share similar genetic alterations leading to tumorigenesis.[308] The marked breed association of specific tumors such as gliomas with brachycephaly may provide an opportunity to decrease incidence by selective breeding.[291,309] Young cats with mucopolysaccharidosis type I have a high incidence of meningiomas, providing suspicion for a genetic basis.[310] Hormones such as estrogen and progesterone can

influence tumorigenesis.[311,312] Overexpression of vascular endothelial growth factor (VEGF) appears to be common in primary brain tumors of dogs and may correlate with tumor malignancy.[313,314]

Secondary Brain Tumors

Types

Secondary intracranial neoplasia can follow metastasis into the brain parenchyma from a distant primary site or by direct extension from adjacent tissues. Nasal tumors are the most common to spread by direct extension through the cribriform plate.[315-317] Tumor types that invade by direct extension include otic squamous cell carcinoma, pituitary tumors, calvarial tumors (osteochondrosarcomas, chondrosarcoma, multilobular osteochondrosarcomas), and nerve sheath tumors (cranial nerve V tumors). Intracranial metastasis usually occurs by the hematogenous route in dogs, with embolization at the gray-white junction or "watershed" distributions of the intracranial vasculature in the cerebral cortex and cerebellum.[13] Leptomeningeal metastasis can occur when tumor cells enter the arachnoid space hematogenously through leptomeningeal and diploic veins or the choroid plexus, or by perineural spread along peripheral and cranial nerves. Although rare, a diffuse or multifocal infiltration of leptomeninges with carcinoma cells can cause meningeal carcinomatosis.[299,318,319]

Dogs

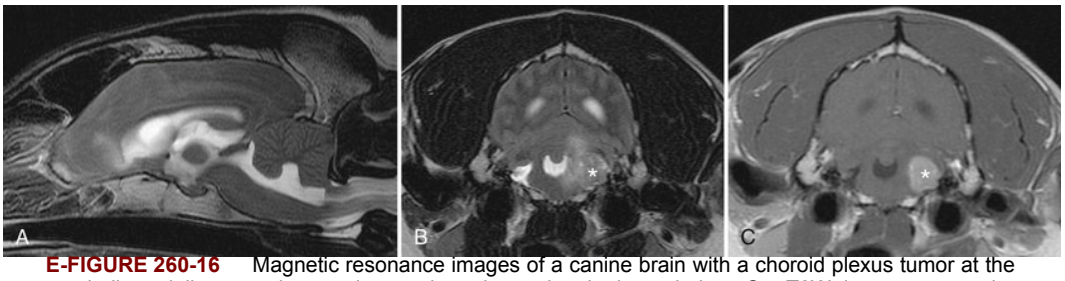
Secondary neoplasia accounts for approximately 50% of all canine intracranial tumors. In two large groups of dogs, hemangiosarcoma (29, 35%), pituitary tumors (11, 25%), lymphoma (12, 20%), metastatic carcinomas (12, 19%) extension of nasal neoplasms (6%), malignant melanoma (3%) and histiocytic sarcoma (3%) were the most common intracranial tumors.[13,291] Nerve sheath tumors (0.9%) and poorly differentiated round cell neoplasms (0.48%) were not common.[291] Metastases more often affect the cerebrum.[13,289] Secondary pituitary tumors may consist of lymphoma, carcinomas, or less commonly histiocytic sarcoma or melanoma.[13,320-322] Imaging for identification of intracranial metastases accounts for increased awareness of some cancers. Use of imaging has led to better treatment regimens for many conditions resulting in increased longevity and more time for metastasis to occur. Multifocal distribution of secondary brain tumors occurs in only 30% and concurrent unrelated neoplasms in about 18% of dogs.[13,293]

Cats

Prevalence of secondary intracranial neoplasms in cats is about 22% of brain tumors; the most common are lymphoma and pituitary tumors.[294,295,303,323] Primary renal lymphomas often spread to the CNS and the meninges may be a site for lymphoma.[324] Spread by the hematogenous route (pulmonary adenocarcinoma is most common) in cats is seen in about 6%.[294] Other secondary tumor types in cats include adenocarcinoma, squamous cell carcinoma, fibrosarcoma, malignant fibrous histiocytoma, sarcoma, and hemangiosarcoma.[294]

Clinical Signs

Clinical signs reflect the location of the intracranial tumor. Regardless of the tissue origin, focal intracranial neoplasms cause typical signs in dogs due to compression of surrounding brain tissue by the expanding mass or peritumoral edema compromising blood flow or obstructive hydrocephalus (E-Figure 260-16). Intracranial tumors may cause brain vasogenic edema, preferentially distributed in peritumoral extracellular space of white matter. As a condition progresses, clinical signs may evolve and reflect further damage due to rising intracranial pressure that causes shifts in intracranial contents. Additional damage and clinical signs can result from expansion of the tumor into nonneural tissues, such as the nasal cavity, periorbita, or the surrounding calvarium. Common neurologic signs observed in animals with brain tumors include altered mentation (e.g., obtundation, stupor, coma), seizures, ataxia, circling, and behavioral changes. Seizure (45%-51%) is most common, but circling (23%), ataxia (21%), and head tilt (13%) occur.[292,293] Dogs with intracranial neoplasia that are at higher risk for seizures from tumors that affect the frontal lobe, enhance markedly with gadolinium or cause subfalcine and subtentorial herniation.[325] Brain neoplasia should be considered as a disease differential when a dog has its first seizure after 4 years of age.[292]



E-FIGURE 260-16 Magnetic resonance images of a canine brain with a choroid plexus tumor at the cerebellomedullary pontine angle causing obstructive hydrocephalus. On T2W images, note the enlargement of the entire ventricular system **(A)** and the hyperintense mass (asterisk) at the right cerebellomedullary pontine angle **(B)** causing mass effect and edema of the medulla. On the T1W image **(C)** after intravenous gadolinium contrast administration, note the homogeneous hyperintensity of the mass (asterisk).

Clinical signs in cats are similar but often are vague or nonspecific with anorexia and lethargy being most common. In 160 cats, their most common neurologic signs were altered mentation (26%), circling (22.5%) and seizures (22.5%).[294] Cats with nonspecific neurologic signs were common (21%).[294] Behavioral changes were noted in 81% of 121 cats with meningioma.[307]

Diagnosis

Baseline Testing

When intracranial neoplasia is suspected, neuroimaging is of fundamental value, but when used alone may only prioritize a differential diagnosis. CBC, biochemical analysis, and urinalysis may be useful for identifying underlying metabolic, inflammatory, or toxic disorders that can mimic intracranial neoplasm. Thoracic and abdominal radiography and abdominal ultrasound (US) are useful screening tools to rule out metastatic disease and comorbidities that may alter treatment plans.[326] In a retrospective study of 177 dogs with secondary intracranial neoplasm, 76% had pulmonary metastasis on post-mortem examination and 39% had evidence of metastatic disease on thoracic radiography.[13] US examination of the abdomen should be included in the evaluation of any dog with CNS signs.[14]

Cross-Sectional Imaging

Cross-sectional imaging with MRI or CT is usually needed for tentative diagnosis and for identifying an area for acquisition of tissue. Biopsy requires special equipment or surgery. CT abnormalities in intracranial neoplasia consist of multifocal or focal distributions, mass effect associated with edema and neoplastic mass and ventricular asymmetry. Lesions may be difficult to detect with CT if located in the caudal fossa due to interference by the surrounding petrous temporal bone or a lack of contrast enhancement. CT is necessary for radiation planning because bony structure radiation attenuation is used in calculations.

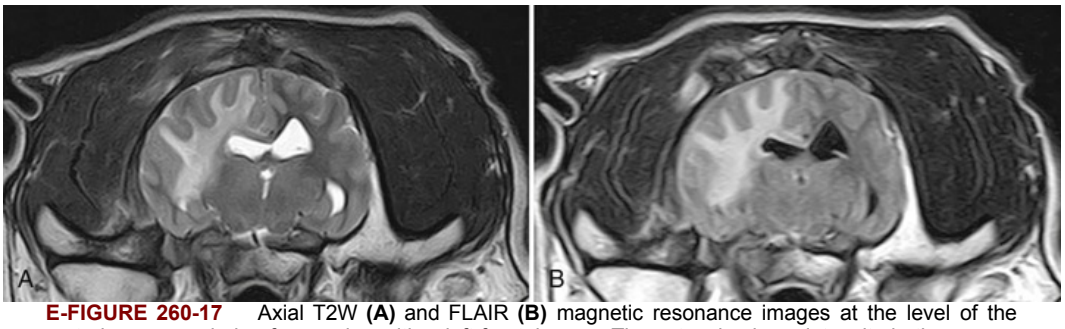
MRI Scans Are Preferred

MRI is the preferred technique for antemortem diagnosis of intracranial neoplasms. Image acquisition in multiple planes is especially useful for surgical planning. MRI can provide detail regarding tumor size, margination, tissue properties and anatomic location. MRI scans may identify secondary pathologic effects (e.g., edema, obstructive hydrocephalus) caused by a tumor.[17,289] Extra-axial masses arise from outside the brain (e.g., meninges, calvaria, ventricles) and intra-axial from within brain parenchyma. MRI features of intracranial neoplasms are often used to prioritize the differential diagnosis.[17-19,288,289,305,327] MRI patterns have been described for extra-axial meningeal and ventricular masses, intra-axial enhancing lesions, intra-axial mildly or nonenhancing lesions, and multifocal lesions in dogs. Features of each may provide suspicion for a particular tumor type (see Table 260-9).[288]

Primary Brain Tumor MRI

Based on MRI scans, the majority of primary brain neoplasms are solitary. Meningiomas, gliomas, and choroid plexus tumors can be multifocal.[293,305,311,328-332] Brain tumors are often hypo- to isointense on T1W imaging and hyperintense on T2W imaging. Mass effect (midline shift, distortion of ventricles and adjacent parenchyma and brain herniations) may be identified. Mass effect can also be caused by peritumoral edema that tends to follow the white matter (corona radiata) and is evident by hyperintensity on T2W and FLAIR

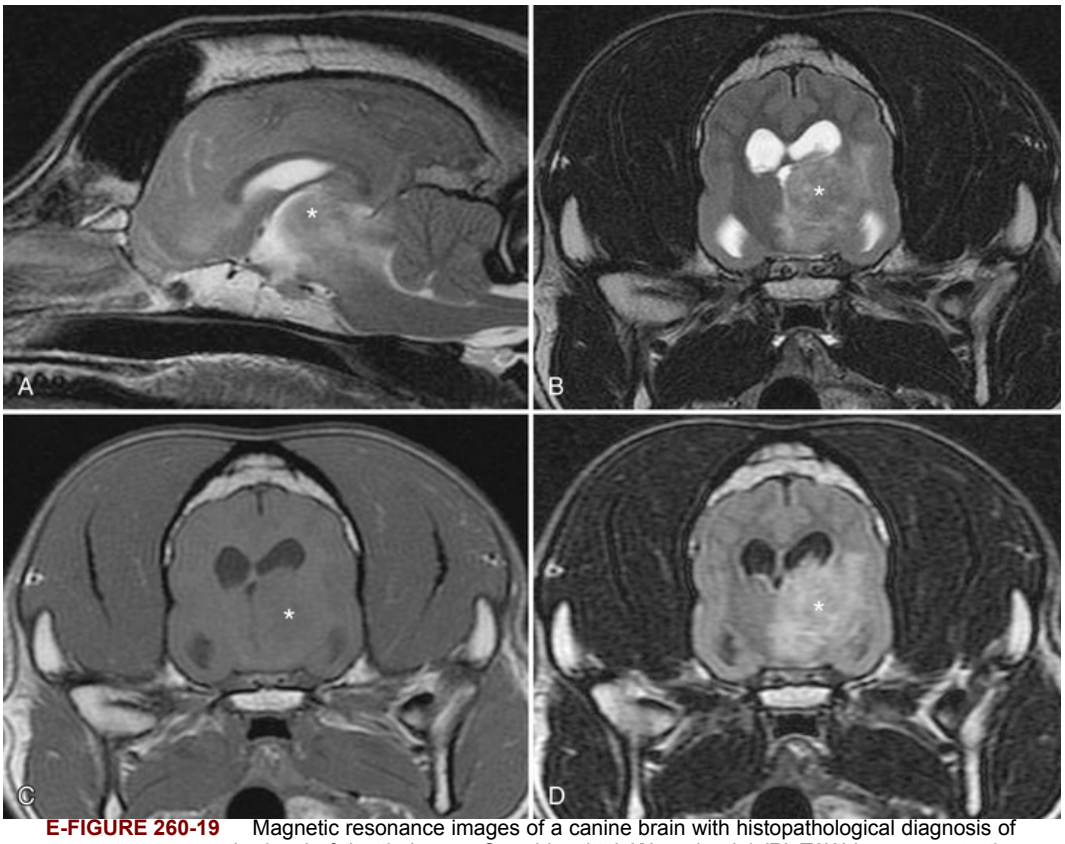
images (E-Figure 260-17). Diffuse edema is reported in 52% of canine meningiomas.[305] Most meningeal masses (e.g., meningioma, histiocytic sarcoma, granular cell tumor, meningeal carcinomatosis, lymphoma) tend to have broad-base dural contact and sometimes a "dural tail" sign.[288,289,329,333,334] A distinct border with the neuroparenchyma helps in distinguishing meningioma from extra-axial meningioma.[305] However, smaller granulomas and other intradural masses could have similar locations, a dural tail, marked and homogeneous contrast enhancement, perilesional edema and T2-hyperintensity.[293,305,323,329,335] As intra-axial masses, gliomas, including oligodendroglioma and astrocytoma vary widely in their appearance on MRI and may be confused with an embolus or inflammatory disease.[289,336] Tumor margins often appear indistinct on MRI.[337,338] There are no MRI features that reliably distinguish astrocytoma from oligodendroglioma.[338]



E-FIGURE 260-17 Axial T2W **(A)** and FLAIR **(B)** magnetic resonance images at the level of the rostral mesencephalon from a dog with a left frontal mass. The extensive hyperintensity in the corona radiata both on T2W and FLAIR images is consistent with high protein fluid content suggestive of vasogenic edema. Note the signal null in the lateral ventricles, which represents the low protein content of CSF. A mass effect is also recognized by deviation of the falx cerebri to the right and compression of the left lateral ventricle.

Many primary brain tumors on MRI demonstrate contrast enhancement after gadolinium-based contrast agents are given.[13,17,19,288,289,293,301,305,323] Contrast enhancement, well-defined margins, and regular shape are key features of neoplasia on MRI as compared with inflammatory or vascular diseases.[19,339] Peripheral ring contrast enhancement is a nonspecific finding consistent with central necrosis associated with neoplastic and nonneoplastic brain diseases.[17,288,289,340] Since the pachymeninges lie outside the BBB, most tumors (e.g., meningioma, histiocytic sarcoma, granular cell tumor, meningeal carcinomatosis, lymphoma) and granulomas that arise from this area will contrast enhance (E-Figure 260-18).[299,305,334,341-344] Of the ventricular masses, choroid plexus tumors tend to strongly contrast enhance,[301] whereas enhancement of ependymomas is more variable.[335,345] The characteristic contrast enhancement of gliomas on MRI is that of a diffuse, variable or ring-like enhancing mass compared to hypointense to isointense on pre-contrast T1W images (E-Figure 260-19).[288,293,337] This type of enhancement pattern can overlap with MRI features of intra-axial lymphoma and granuloma.[19,293,294,335] Low-grade gliomas tend to have mild to no enhancement more commonly than high-grade gliomas.[337,338] Gliomas that are classified as high-grade on histopathology tend to have moderate or marked enhancement after IV contrast administration.[293,337,338,346] However, minimal to no contrast enhancement is an imaging characteristic of gliomatosis cerebri.[347]

E-FIGURE 260-18 Magnetic resonance images of a canine brain with a histopathologically diagnosed meningioma (asterisk) at the level of the right frontal lobe. Note the broad-base proximity to the dura, heterogeneous intensity on the mid-sagittal **(A)** and axial **(B)** T2W images. Compared to the isointensity on the pre-contrast axial T1W images **(C),** the mass has a homogeneously hyperintense and well-demarcated enhancement pattern after gadolinium contrast administration on T1W images **(D).**

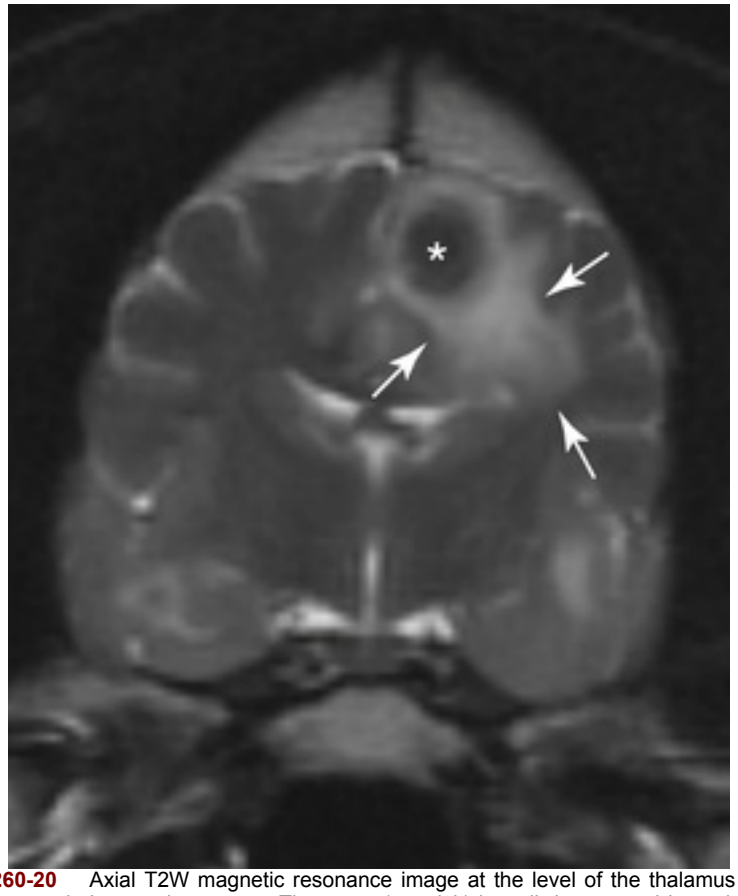


E-FIGURE 260-19 Magnetic resonance images of a canine brain with histopathological diagnosis of an astrocytoma at the level of the thalamus. On midsagittal **(A)** and axial **(B)** T2W images, note the intra-axial location, and heterogeneous hyperintensity with presumed peritumoral edema extending into

the midbrain and right corona radiata. Compared to the isointensity on pre-contrast T1W images **(C),** the enhancement pattern of the mass is heterogeneous and poorly demarcated **(D)**.

Metastatic Tumor MRI

Metastatic tumors on MRI are usually multifocal lesions in the brain parenchyma or meninges.[13,17,288] Multiple small mass lesions are usually present although solitary lesions can occur. Hematogenous metastatic brain tumors on MRI appear as ovoid to spherical lesions at the gray-white matter interface, while embolism is likely to occur in the cortical arterioles (E-Figure 260-20). Other characteristic MRI features of metastatic CNS tumors include multiple hyperintense lesions on T2W images surrounded by marked edema and variably contrast enhance or have peripheral enhancement on post-contrast T1W images.[13,17,288]



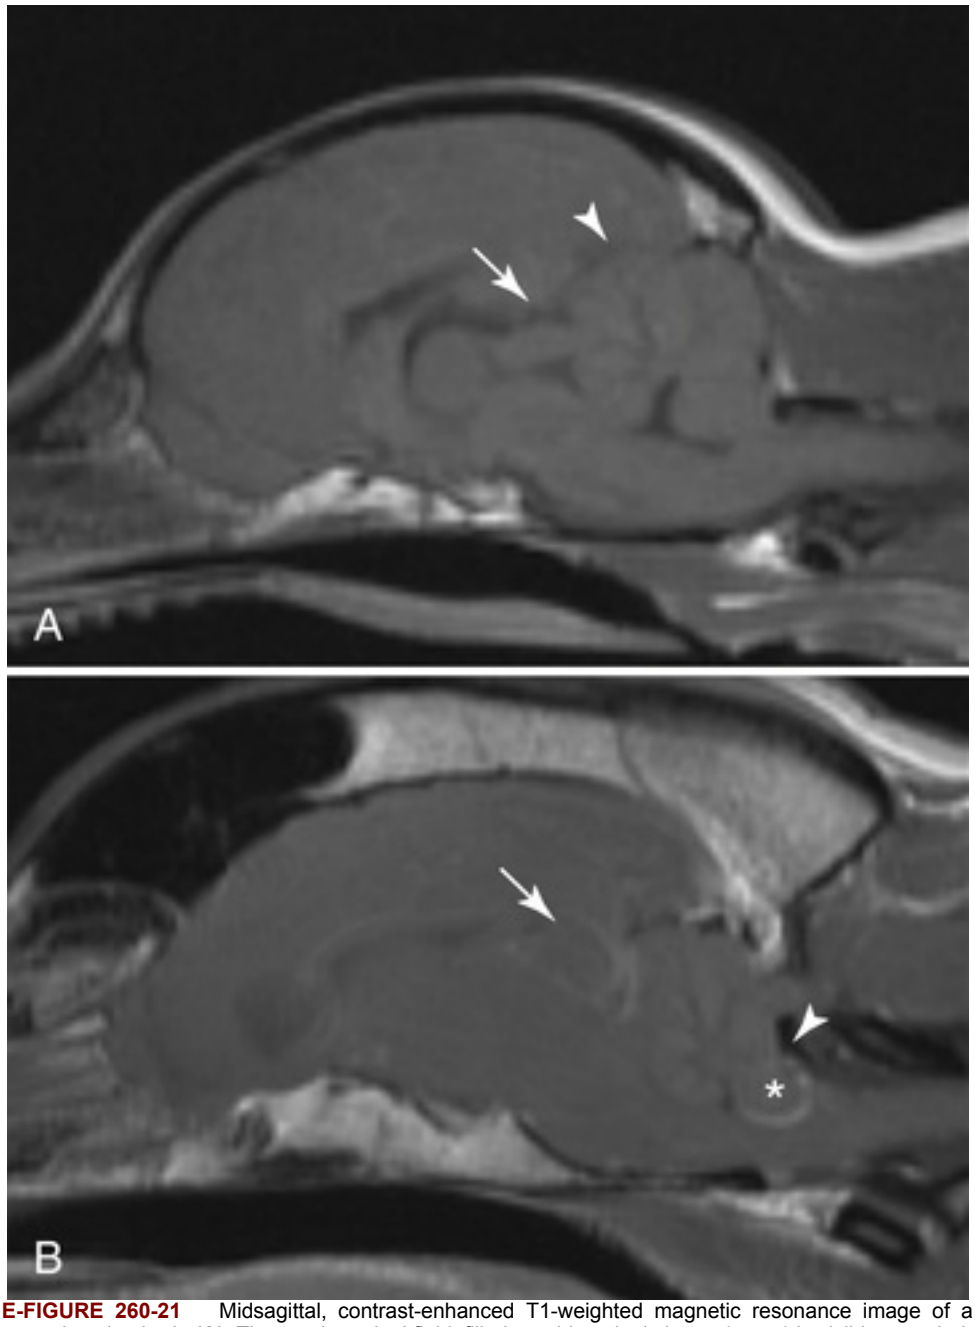
E-FIGURE 260-20 Axial T2W magnetic resonance image at the level of the thalamus of a canine brain with metastatic hemangiosarcoma. The mass (asterisk) is well demarcated by a ring-pattern of edema that has extended (arrows) into the adjacent white matter.

Other Imaging Aids

Metabolic and physiologic MRI techniques, combined with structural data gleaned from traditional MRI or CT, are more commonly used for identification and monitoring intracranial neoplasms and other CNS diseases.[286,348] Specifically, positron emission tomography (PET) using 2-deoxy-2 [^{18}F] fluoro-D-glucose (FDG), which reflects increased glucose metabolism in brain tumors is gaining use for defining the best areas to biopsy.[23,24] Diffusion-weighted imaging based on the ADC image and MRS have been described in brain tumors of dogs but lacked specificity in determining the histological type of intracranial disease.[349] Metabolite alterations using MRS have been used to differentiate inflammatory from neoplastic lesions; neoplastic lesions tend to have lower N-acetylaspartate (NAA) and higher choline concentrations.[350]

Cerebrospinal Fluid Analysis

Analysis of CSF can aid in diagnosis and ruling out overt inflammatory disease and may be beneficial as a screening test (see ch. 115).[351,352] Collection of CSF should be avoided due to risk of herniation when increased intracranial pressure is suspected based on clinical signs and imaging (deviation of the falx cerebri, compression of the ventricles or quadrigeminal cistern, or obstructive hydrocephalus) (E-Figure 260-21). Increased protein concentration and a normal to mild increase in total nucleated cell count (albuminocytologic disassociation) are typical for an intracranial neoplasm.[353-355] Choroid plexus tumors are associated with the most marked elevations in CSF total protein, and in others, CSF may have increased white blood cell numbers, increased total protein, but cytology is usually a mixed nonspecific cell pleocytosis.[293,353,354,356] Similar findings are reported for cats.[294,357] Rarely, neoplastic cells can be found in CSF in association with neoplasms in close proximity to the ventricular system or meninges such as choroid plexus tumor, lymphoma, glioma, ependymoma, neurocytoma, and histiocytic sarcoma.[293,301,333,358-361] CSF protein composition can be further defined by semiquantitative electrophoretic techniques and abnormalities have been reported to be useful in identification of inflammatory, neoplastic and degenerative disease.[43,352] Studies defining biomarkers from dogs with brain neoplasms (matrix metalloproteases [MMP], uric acid, fibrinolytic activity) for determining tumor burden and type have limitations in specificity and sensitivity.[362-365]



E-FIGURE 260-21 Midsagittal, contrast-enhanced T1-weighted magnetic resonance image of a normal canine brain **(A)**. The cerebrospinal fluid–filled quadrigeminal cistern (arrow) is visible as a dark area below the osseous tentorium (arrowhead). With increased intracranial pressure due to a forebrain mass **(B),** herniation under the tentorium (arrow) has compressed the quadrigeminal cistern. Herniation of the cerebellum (asterisk) through the foramen magnum (arrowhead) is also compressing the medulla, usually the terminal event of herniation. Note also the rim of enhancement around the herniated tissues.

Brain Biopsy and Histopathology

Development of improved imaging techniques permits a higher degree of lesion definition from anatomic and pathologic characteristics. Brain biopsy is particularly useful when lesions are small, deep-seated, or in a surgically inaccessible area. Choice of biopsy site depends on the suspected diagnosis and lesion extent. Tissue heterogeneity on imaging should be taken into account by adequate sampling of different areas, including the interface between tumor and adjacent brain. Sampling areas of necrosis is to be avoided as it is usually unrewarding. Diagnostic yield is considered highest when biopsy targets include both the noncontrast- (necrotic) and contrast-enhancing areas of the tumor.[366] Tru-cut biopsy is considered more

reliable than fine needle aspirates in determining the specific type of tumor.[366] Cytologic evaluation of brain tumor crush preparations can be performed within minutes of biopsy collection.[37] Diagnostic yield is generally >90% for neoplastic lesions.[286] Early studies of brain biopsy report morbidity and mortality rates ranging from 7 to 27%.[25,28]

Definitive diagnosis of intracranial neoplasia and of tumor subtype and grade is by histologic examination of tissue.[52,53] Immunohistochemistry is being used to more accurately identify cell phenotype using cell-specific antigenic markers to further classify intracranial neoplasms.[290] Molecular and genetic characterization of neoplasia is becoming more common in veterinary neuropathology and neuro-oncology.[286,313,367,368]

Treatment

Goals

Goals for treatment of brain tumors are complete tumor removal or size reduction and control of secondary effects (edema, increased intracranial pressure).[286,287] Treatment options depend on tumor type and location, onset of clinical signs, costs, and associated morbidity/mortality.[286,287] Treatment guidelines for specific types of brain tumors consist of palliative and definitive therapies. Surgical resection and fractionated radiotherapy are the common definitive methods used to treat canine and feline brain tumors. Other contemporary therapeutic advancements for brain tumor in animals include stereotactic radiosurgery, convection enhanced delivery and immunotherapy.[287]

Palliative Therapy

Palliative therapy consists of controlling tumor-caused secondary effects and minimizing clinical signs. For animals with brain tumors, palliative therapy has focused on controlling vasogenic edema and seizures. Corticosteroid treatment counters the secondary effects of peritumoral edema and obstructive hydrocephalus and reduces intracranial pressure. Anti-inflammatory doses of corticosteroids may be used and adjusted on clinical response. Osmotherapy such as mannitol is useful to control acute increases in intracranial pressure.[369] Mannitol is most widely used at a 25% solution administered as an IV bolus (0.5 to 2 g/kg). Furosemide (0.7 mg/kg IV) may have a synergistic effect in rapidly reducing vasogenic edema.[370] Single doses have brief effect and may need to be repeated. Clinical signs of mass-associated ventricular obstruction may be ameliorated with a ventricular shunting procedure.[204] Antiepileptic drug therapy for acute (e.g., diazepam) and maintenance seizure control is indicated for tumor-associated seizures.

Surgery

Surgery alone can be curative when complete resection is achieved, but is often limited by anatomy and extent of disease. Surgery can achieve cytoreduction, yield a definitive diagnosis, and provide prognostic information for adjunctive treatment planning. Craniectomy can relieve signs due to secondary increases in intracranial pressure.[371] Criteria for successful surgery include that the tumor mass is solitary, noninvasive, located near the brain surface in the cerebral hemisphere, and removal will cause minimal neurologic impairment. Surgery has been most common for forebrain meningiomas, but carries a poorer prognosis in dogs than in cats because they are more invasive and often atypical in dogs.[328,372-375] Dogs with surgically excised meningiomas have had a median survival of about 7 months while the median survival in cats is about 36 months.[307,328,372,373] Surgical treatment incorporating ultrasonic aspiration and endoscopic techniques has increased access to tumors located deep within the brain parenchyma.[35,374] Irreversible electroporation (IRE) is a novel nonthermal tissue ablation technique that involves electrodes and delivery of electrical pulses.[376] Safe and feasible use of IRE delivered stereotactically with a NanoKnife system was reported for treating canine gliomas.[377]

Radiation Therapy

Radiation therapy has become a mainstay in management of malignant and benign CNS tumors in animals. Radiation therapy can be delivered in multiple treatments (fractionated radiotherapy) or in a single treatment (radiosurgery) (see ch. 340).[286,287] Fractionated radiotherapy is beneficial in the treatment of brain tumors as a sole therapy or as an adjuvant to surgical resection.[328,378,379] Studies investigating presumptively diagnosed

brain tumor varieties in dogs with fractionated radiotherapy reported median survival times that ranged from 5 to 24 months.[378-383] When censoring death from causes unrelated to the brain tumor and using survival based on deaths attributable to worsening of neurologic signs, a median overall survival time was 39 months for radiotherapy alone on extra-axial, intra-axial and pituitary brain tumors combined.[378] Radiation as the sole therapy has produced median survival times of 11.5 to 19 months in dogs with a histologic diagnosis of meningioma.[378,379]

Recurrent deterioration of neurologic signs due to either recurrent disease or necrosis is usually the cause of death or reason for euthanasia of dogs with brain tumors treated with radiation.[328,378-380] The risk of CNS necrosis increases as the radiation dose increases.[384] Acute adverse effects of radiation include cerebral edema linked to BBB disturbance, which may result in demyelination and responds to corticosteroid therapy.[385,386] Delayed complications include focal CNS radiation necrosis and severe vascular lesions.[385] As technology has continued to evolve, computer generated treatment plans and more accurate methods for patient positioning have contributed to better dose homogeneity and reduced toxicosis to normal brain tissue.[378,387-389] Three-dimensional conformal radiation therapy has shown a median survival of 19 months in treated dogs with meningioma, which was increased to 30 months when censoring patients that died of causes unrelated to meningioma.[330] At a few veterinary centers, stereotactic radiosurgery (e.g., linear accelerator, GammaKnife, CyberKnife) for brain tumors is being used to administer a single large radiation dose to a defined target. Stereotactic radiosurgery involves use of convergent ionizing radiation to intersect at the treatment target. A single-dose therapy session delivers a precise high dose (>10 gray) causing significant vascular damage and hypoxia to tumor tissue while sparing surrounding normal tissue. Meningiomas have been the most commonly reported tumor treated by stereotactic radiosurgery. Median survival time in dogs was 13.3 months for all brain tumors and for meningiomas.[390,391] Thus, radiosurgery alone has shown promise in the treatment of brain tumors in dogs with fewer acute adverse effects than conventional radiation therapy.

Chemotherapy

Systemically administered chemotherapeutics for treatment of brain tumors in veterinary medicine is primarily anecdotal. The BBB has been considered a major hindrance to the use of chemotherapy for brain tumors, even if it can be iatrogenically disrupted with mannitol administration prior to administration of agents.[392] Hydroxyurea has been advocated as chemotherapy in dogs with meningioma.[393] Intrathecal cytosine arabinoside and methotrexate have been evaluated for short-term safety in dogs with CNS disease, including neoplasia.[394] A recent study failed to demonstrate a difference in median survival in dogs with brain tumors treated with palliative prednisone and AEDs compared with those that received palliative therapy and lomustine.[395]

Novel Therapies

The recognition of canine brain tumors as a translational disease model has created collaborative opportunities for novel treatment methods.[286,287] Convection-enhanced delivery (CED) circumvents the BBB, resulting in high intratumoral drug concentrations with minimal systemic toxicosis. The technique involves targeted local delivery of macromolecules by bulk flow using low pressure microinfusion with specifically designed catheters. In dogs with gliomas, CED has been performed as a single therapeutic modality prior to and after surgical resection.[396] Use of CED in delivery of liposomal CPT-11 and cetuximab bioconjugated magnetic iron oxide nanoparticles has been shown to have efficacy in canine gliomas.[397,398] During CED, infusions can be monitored with real-time MRI and gadolinium based tracers.[287,399]

Immunotherapies, in oncology, consist of using the host immune response to kill tumors (see ch. 341). In active immunotherapy, patients are treated with a combination of tumor antigens or antigen-presenting cells with a stimulatory agent such as a cytokine or immunoadjuvant that is often combined with another definitive therapy.[287] This combination immunotherapy has been used in dogs with brain tumors.[400,401] In these studies, it was demonstrated that vaccines induced antibodies systemically and locally at the tumor site.

Prognosis and Survival

Except for feline and canine meningiomas, the prognosis for other brain tumor types is quite variable. Survival times for gliomas after imaging diagnosis tend to be short with a median <80 days.[338] The prognosis for dogs with palliative-treated brain tumors is poor. Dogs with brain tumors definitively diagnosed at necropsy had a median survival of 2 months after diagnosis with brain imaging.[402] Longer survival times may occur depending on tumor size, type, location, severity of clinical signs and owner decision to continue therapy. Supratentorial tumors tend to have a longer median survival time compared to infratentorial tumors.[402] Metastatic brain tumors have a median duration of clinical signs to death of 21 days.[13]

Prognostic conclusions from definitive therapies of brain tumors in animals are limited by small case numbers, retrospective study design, lack of definitive histopathologic diagnoses and lack of easily monitored objective criteria.[286,287] Median survival times for all tumor types reported in dogs after surgery alone vary from 2 to 7 months.[328,380] Usually within the first 30 days after surgery, animals with infratentorial tumors are at a significantly higher risk of mortality compared with those with supratentorial tumors.[403] A common devastating perioperative complication is aspiration pneumonia (see ch. 242). As previously described in dogs with brain tumors, surgery combined with radiation therapy resulted in the longest survival times. Median survival times for dogs with brain meningiomas treated by combination surgical excision and radiation therapy have been reported between 11 and 28 months in previous studies.[311,328,379,381] Since cats have meningiomas that can be completely removed by surgery, their overall survival prognosis is better than dogs. A recent large retrospective study of meningiomas after surgical excision reported a median survival time of 37 months (95% confidence interval of 28-54 months).[307]

Goals of molecular characterization of canine brain tumors have been directed toward obtaining information regarding prognosis. Aberrant expression of tumor-specific genes, receptors, cytokines and cellular proteins have been identified in canine and feline brain tumors, including progesterone receptors, proliferating cell nuclear antigen, vascular endothelial growth factor (VEGF) and a proliferative marker Ki-67.[312,313,404-407] Progesterone receptors have been identified in canine meningiomas and loss of receptors may be associated with higher tumor proliferative fractions, which may indirectly affect prognosis.[311,312] A positive association may exist between degree of malignancy and an angiogenic factor, VEGF[312,406] in canine meningiomas but may not correlate with outcome.[405] In dogs, tumors with a high proliferative fraction index measured by immunohistochemical techniques to detect proliferating cell nuclear antigen have been associated with lower survival rates.[311,408] The increased recognition of epidemiologic, neuropathologic, molecular biologic and genetic similarities between canine and human brain tumors will continue to drive the use of canine brain tumors as translational disease models.[286,287,396,409]

Idiopathic Epilepsy

Consensus Statements

In 2014, the International Veterinary Epilepsy Task Force (IVETF) was founded and it developed a series of consensus reports based on published understanding of epilepsy.[410] The consensus reports focused on definition, classification, terminology, breeds, diagnosis, treatment, outcome measures of therapeutic trials, neuroimaging and neuropathology.[410-417] In 2015, an ACVIM Small Animal Consensus Statement was established to focus on canine seizure management based on literature and complementary clinical expertise.[418] Both consensus statements provide a platform for ongoing and future research of epilepsy in veterinary medicine that will improve our understanding of epilepsy and its management.[410,418]

Primary and Syndromic Epilepsy

Definitions

Epileptic seizures are defined as transient signs due to abnormal excessive or synchronous neuronal activity in the brain. Epilepsy refers to at least 2 unprovoked seizures >24 hours apart (also see ch. 35).[419,420] The term idiopathic means a disease of unknown cause, but to be meaningful, the term must clearly define an entity.[421] In people, many epilepsies previously classified as "idiopathic" have been associated with specific mutations. This led to the recommendation that the prior International League Against Epilepsy (ILAE) classification

system of idiopathic, symptomatic and cryptogenic be replaced with genetic, structural/metabolic, and unknown.[422] Until the genetics of epilepsy in animals is better defined, however, there is still utility in using the well-recognized term idiopathic epilepsy (IE) for pets in whom a structural or metabolic cause of the seizures has not been identified.[411,423]

Incidence

The incidence of epilepsy from all causes in dogs has been estimated at 0.62-0.75%, comparable to the estimated incidence in people (0.22-4.1%).[424-426] Most dogs with epilepsy have idiopathic disease, whereas only 0-22% of epileptic cats have idiopathic disease.[427-430] Male dogs are more commonly affected than females at a ratio of about 1.4 : 1 while no sex bias has been found in cats.[424,425,430,431] The majority of epileptic dogs have their first seizure between 1 and 5 years of age and those are more likely to be diagnosed as idiopathic. About one-third of dogs 1-5 years of age are diagnosed with a structural or metabolic seizure cause. Dogs of any age may not have a cause for their seizure identified.[431-435] The median age of onset of idiopathic epilepsy in cats was 3.8 years in one study while each cat with familial epilepsy had its first seizure when <1 year of age.[430,436] Epileptic dogs are more likely to be diagnosed as idiopathic if the time between the first and second seizures is >4 weeks.[431] Seizures in IE can be either generalized or focal in onset, even when a genetic cause is suspected.[8,9,431,437-441]

Cause

There is strong evidence that IE is genetic in many dog breeds. The prevalence of epilepsy is significantly greater in purebred dogs versus mixed-breed dogs.[442] Offspring of an epileptic dogs have a significantly greater chance of having seizures and an earlier age of onset.[434] Specific genetic studies in numerous breeds show a genetic basis with an incidence of up to 33% in some breeds.[9,434,435,437-439,441,443-456] Where calculated, heritability runs as high as 0.87, suggesting a significant role of genetics in the risk of epilepsy. In contrast, only one family of cats with genetic epilepsy has been reported.[436] In spite of this strong evidence for a genetic cause, the association of specific genetic variants with epilepsy in most breeds has remained elusive.[457]

Specific mutations have been identified in a number of diseases where recurrent seizures are a part of a broader syndrome. For example, the progressive myoclonic epilepsies have other progressive neurologic signs.[458] In dogs, mutations have been identified in the malin gene *(EPM2b* or *NHCLRC1)* in Dachshunds with Lafora disease and in several of the neuronal ceroid lipofuscinosis genes associated with progressive myoclonic epilepsy (*TPP1* and *PPT1* genes in Dachshunds) or other seizure syndrome (*CLN5* in Border Collies, *CLN8* in cattle dogs and English Setter, and *ATP13A2* in Tibetan Terriers) (see Table 260-7).[278-283,459,460] In all these diseases, other signs such as ataxia, blindness or cognitive decline are also present. Other examples of syndromic epilepsy would include mutations in ion channels such as the potassium channel *KCNJ10* in spinocerebellar ataxia with myokymia and seizures in Jack Russell Terriers[96] or mutations in transcription factors *ATF2* in neonatal encephalopathy with seizures in Standard Poodles.[239]

The only mutation associated with IE in dogs is in the *LGI2* gene in Lagotto Romagnolo dogs with remitting focal epilepsy.[461] Variants in the *ADAM23* gene have been linked with an increased risk of seizures in Belgian Shepherd dogs.[462] *LGI2* and *ADAM23* form part of a pre-synaptic, voltage-gated potassium channel complex, and antibodies against this complex have been demonstrated in cats with temporal lobe epilepsy.[463,464] These cats show evidence of hippocampal necrosis, which would classify them as structural/metabolic seizures, but they illustrate that there can be causes of IE other than genetic predispositions.

Diagnosis Using IVETF Criteria

Traditionally, the clinical diagnosis of IE is one of exclusion following diagnostic testing for causes of reactive seizures and structural epilepsy. The IVETF established a three-tier system of confidence criteria for the diagnosis of idiopathic epilepsy.[413] Tier I confidence for the diagnosis of IE is based on a history of two or more unprovoked epileptic seizures occurring at least 24 hours apart, first noted between 6 months and 6 years of age, unremarkable interictal physical and neurologic examinations, and no significant abnormalities on minimum database bloodwork and urinalysis. Tier II confidence for the diagnosis of IE is based on tier I factors plus unremarkable fasting and post-prandial bile acids, MRI of the brain and CSF analysis. Tier III

confidence level is based on tier I and II factors plus identification of EEG abnormalities characteristic for seizure. Use of advanced imaging and CSF were preferable but not essential for the diagnosis of IE. The IVETF recommends performing brain MRI and CSF analysis after exclusion of reactive seizures in dogs with one of the following: (1) age at epileptic seizure onset <6 months or >6 years; (2) interictal neurologic abnormalities consistent with intracranial localization; (3) status epilepticus or cluster seizure; and (4) previous diagnosis of IE and drug resistance to a single AED titrated to highest tolerable dosage.[413]

Imaging and CSF Analysis

Epileptic seizure activity, itself, can cause changes on MRI scans and in the CSF. Brain histopathology of epileptic dogs and cats can reveal evidence of neuronal injury and loss in susceptible brain areas, such as piriform/temporal lobes, cingulate gyrus, hippocampus and cerebral cortex.[465-468] Signal changes on MRI can be localized unilaterally or bilaterally in those susceptible brain areas and are characterized by varying degrees of hyperintensity on T2W, FLAIR and post-contrast T1W imaging (E-Figure 260-22).[467,469] These signal changes have been shown to partially or completely resolve on repeated MRI 10-16 weeks later after seizure control, indicating vasogenic or cytotoxic edema due to seizure activity.[467] Hippocampal atrophy also can be a component of MRI findings in dogs and cats with chronic epilepsy.[436,470] If MRI abnormalities are compatible with seizure-associated changes, the IVETF recommends repeating the MRI 16 weeks after seizure control.[413] CSF abnormalities reflected sometimes by a mild pleocytosis with an increased protein concentration can occur as a result of epileptic seizure activity.[471] The longer the time interval after the seizure, the lower the CSF white blood cell count.[471] If CSF abnormalities are present, infectious disease should be ruled out; it has been recommended to repeat the CSF analysis following a seizure-free interval.[413]

E-FIGURE 260-22 Midsagittal **(A)** and axial T2-weighted magnetic resonance images at the level of the thalamus **(B)** and caudal midbrain **(C)** from a dog with idiopathic epilepsy 24 hours after cluster seizures. Note the hyperintensity in the cingulate gyrus (arrowheads) and in the temporal lobes and hippocampus (asterisks), indicating cytotoxic and vasogenic edema.

Treatment

Treatment Goals

The goals of therapy are to decrease seizure frequency, severity and duration with few acceptable side-effects and no adverse effects, while taking into account that complete elimination of seizures is not a realistic goal in dogs. Use of antiepileptic drugs (AEDs) has been the mainstay of therapy for epilepsy in dogs and cats. However, lack of uniform and scientifically based guidelines on AED treatment has posed challenges in appropriate decision-making. When deciding on AED therapy, clinicians should follow a treatment approach taking into account: (1) when to start AED treatment; (2) selecting the most appropriate AED and dosage; (3) monitoring the AED and adjusting treatment; (4) knowing when to add or change AED; and (5) promoting owner compliance.[414,472-475]

Antiepileptic Drug Therapy Initiation

The decision to start AED treatment is based on a number of factors, including etiology, risk of recurrence, seizure type and tolerability.[475] Clinicians should also consider the general health of the pet, owner lifestyle, financial limitations, and ability to comply with any proposed regimen.[472] In people, there is no benefit to starting AED therapy after a single unprovoked seizure, but there is evidence to support early seizure control after a second.[476-478] In dogs, long-term seizure management is thought to be most successful if AED therapy is initiated soon after onset, especially in dogs with frequent seizures and in breeds known to have severe epilepsy.[437,438,479,480] To summarize, the IVETF and ACVIM consensus statements recommend initiation of

long-term treatment in animals with epilepsy when any one of the following criteria is present: (1) identifiable structural lesion or prior history of brain disease or injury; (2) acute repetitive seizures (status epilepticus) has occurred; (3) interictal period is < 6 months (i.e., 2 or more seizures within 6 month period); (4) prolonged, severe or unusual post-ictal periods; and (5) epileptic seizure frequency and/or duration is increasing and/or seizure severity is worse over three interictal periods.[414,418]

Overview of Medical Choices

A variety of AEDs can be used for management of epileptic dogs and cats, but no evidence-based guidelines are available to aid in choosing a first-line AED for long-term management of seizure control in dogs and cats. Most seizures in dogs with IE can be controlled with monotherapy. After the first systematic review in veterinary medicine to evaluate drug efficacy in treatment of IE, most data are derived from retrospective studies and open-label trials.[481] A meta-analysis of three randomized controlled drug trials on epileptic dogs revealed that 30% of dogs experienced a 50% or greater reduction in seizures with placebo, a consideration when evaluating retrospective or open-label studies, especially those that involve a small number of animals, as reported results might be overstated.[482] Due to ethical issues of a placebo-controlled study, which are of relevance to epileptic dogs and their owners, there is general consensus that clinical trials of AEDs in veterinary patients should be conducted in a controlled, blinded and randomized manner in order to achieve a high level of evidence and to adjust for the placebo effects.[415,481]

In principle, administration of a single AED is preferred because it avoids drug-to-drug interactions and improves owner compliance. Other factors to consider when choosing an AED include mechanism of action, efficacy, adverse effects, potential drug interactions, frequency of administration based on pharmacokinetic properties and cost.[472] Mechanisms of action for many AEDs include increase in inhibitory effects of the GABA-activated chloride channels, modulation of membrane associated cation (sodium and calcium) channels, and reduction in excitatory neurotransmission. The most commonly used AEDs in veterinary medicine mechanistically enhance inhibition in the brain.[475] In general, AEDs are initiated at the low end of the dosage range and then tailored to individual needs based on seizure control, adverse effects and serum drug concentrations. A number of AEDs with improved tolerability, fewer side-effects, and fewer drug-drug interactions have been developed for treating people with epilepsy and several (e.g., levetiracetam, zonisamide, gabapentin, pregabalin) have been used in dogs and cats. Currently, these drugs are being used as first-line AED or as add-on in dogs with refractory epilepsy; however, efficacies for either use still remain to be established. Table 35-2 (ch. 35) lists the commonly used AEDs with reported adverse effects in the treatment of seizures in dogs and cats. Other current reviews exist on properties and usage recommendations of AEDs in dogs and cats.[414,418,472,475]

Until recently, phenobarbital (PB) and potassium bromide (KBr) were the first-choice sole AEDs for long-term treatment of IE in dogs based on their history, availability, and cost.[483-486] The meta-analysis review of AED efficacy reported a better level of evidence supporting use of oral PB as compared with oral KBr.[481] In a randomized clinical trial comparing PB to KBr as first-line AEDs in dogs with presumptive IE, 85% of dogs given PB became seizure-free for 6 months compared with 52% of dogs given KBr, and PB was better tolerated.[486] In 2013, imepitoin was approved in Europe as a first-line AED in dogs with IE, based on randomized controlled trials that demonstrated antiepileptic drug efficacy, high tolerability and safety. The evidence for recommending use of imepitoin as sole AED in dogs with epileptic seizures is good.[481,487-489] In a randomized controlled study, the efficacy of imepitoin was similar to PB, with fewer side-effects.[489] The ACVIM consensus panel provides high recommendation and established treatment efficacy for PB and imepitoin as first-line AEDs in dogs with IE.[418]

Therapeutic Monitoring

Once AED therapy is started, it is important to systematically monitor seizure control, systemic drug effects, and serum drug concentrations with goals of seizure control with minimal adverse effects.[472] Epilepsy management depends on accurate owner observation when assessing efficacy of therapy.[472] Owners should be instructed to maintain a logbook to document seizure occurrences and changes in medication administration. Objectives of monitoring serum concentrations include determining: effective drug levels after therapy initiation; if drug failure is due to pharmacokinetic factors (metabolic tolerance) or pharmacodynamic factors (functional tolerance) regarding a change of drugs; if treatment failure is due to poor compliance or inadequate drug level; prevent toxic effects from occurring; and aid with

individualization of therapy.[418] Measurement of drug concentrations takes place after establishment of a steady-state concentration based on 5 elimination half-lives. Peak and trough levels are recommended for drugs with short elimination half-lives and when seizures are not well controlled.[490] Serum drug concentrations are available for some medications to determine whether or not the target range has been reached. A 20% or greater drop in the trough serum concentration is often an indicator of poor administration compliance.[475] Therapeutic serum concentrations are based on studies evaluating the concentration at which the majority (population) of dogs with IE experience seizure control. However, few AEDs (i.e., PB, KBr) in veterinary medicine have established therapeutic concentrations and dose adjustments are based on the seizure control, serum drug concentrations, and side effects. It is important to have regular assessment of serum concentrations even at times when seizures are well controlled in order to monitor for toxic levels, especially for drugs with a narrow therapeutic window (i.e., PB and KBr), to monitor for serum concentration fluctuations and to have awareness when there is a need to make changes in therapy (see ch. 35).

Combination Therapies

Not all epileptic patients can be controlled with a single AED and such patients may require add-on medications for seizure control. Approximately 30% of dogs with IE require two or more AEDs to control seizures.[481,483,484] Moreover, approximately half of all epileptic dogs are able to maintain a seizure-free status without experiencing adverse effects from the medication.[491] Before initiating a second drug, sufficient time must be allotted to determine effects of the first drug and to assure that adequate serum concentrations have been achieved before assuming lack of efficacy. A drug should not be considered a failure until maximum dosage or target serum concentrations have been attained or unacceptable side effects or adverse effects occur.

Refractory Epilepsy

The term refractory or drug-resistant epilepsy is utilized in veterinary medicine to describe a condition in which an animal with epilepsy fails to attain satisfactory seizure control or suffers intolerable side-effects despite appropriate therapy with conventional AEDs.[473,474] Although drug resistance is a serious problem for some dogs with IE, it is less frequent in cats. Factors for refractory IE can be related to three variables: disease-related, drug-related and patient-related issues.[475] Disease-related factors are attributed to underlying brain disease such as cortical malformation, prior traumatic brain injury or another active disease process. Drug-related mechanisms include metabolic or functional tolerance, known as pharmaco- or drug resistance, which has two theories on pathogenesis: the target hypothesis which proposes genetic or disease-related alterations in cellular targets of AEDs and the transporter hypothesis which postulates altered transport of drugs across the BBB.[492,493] Metabolic tolerance occurs when increasing the drug dosage does not result in a parallel increase in serum drug concentration. As the genetics of canine and feline epilepsy become better understood, patient-related issues may become more relevant with respect to treatment response.[412] Evidence for predicting pharmacoresistance in dogs is limited, although seizure density (multiple seizures within a short time period) was an influential predictor of pharmacoresistance.[494]

Criteria for decision-making on starting a second or third AED are lacking in veterinary medicine. Several factors should be considered when deciding on a second AED: selecting an AED with a different mechanism of action, minimizing drug-drug interactions, limiting additive toxicity, determining risk versus benefit of polytherapy, and effects on quality of life for the pet and pet owner.[418] The ACVIM consensus panel recommended PB, KBr, levetiracetam, zonisamide, and imepitoin (Europe) be considered for drug resistant epileptics.[418,473,485,495-499] The only published clinical trial in cats with refractory epilepsy evaluated the use of levetiracetam; 7/10 cats had a favorable response to treatment and tolerated the drug well.[500]

Prognosis

Based on a consensus by the IVETF, *seizure freedom* is the primary treatment goal in the therapeutic management of canine and feline epilepsy.[415] Seizure freedom was defined as extending the interseizure interval to three times longer than the pretreatment interval after a minimum of 3 months of therapy. Partial therapeutic success is defined as preventing cluster seizures or status epilepticus, relevant reduction of seizure frequency while considering the pretreatment seizure frequency and reduction in seizure severity.[415] Evaluation of treatment efficacy of AEDs has often been assessed by the proportion of dogs in a study population that had a reduction in seizure frequency. When >50% reduction in seizure frequency is used as an

outcome measure, about two-thirds of dogs achieved this goal.[494] Factors associated with reduction in seizures included female gender, neutering, no history of cluster seizures and older age at onset. In people, factors associated with remaining seizure free include no structural brain lesion, short duration of epilepsy, few seizures before pharmacologic control and AED monotherapy.[478]

Dogs and cats with epilepsy can experience debilitating recurrent epileptic seizures, which can lead to behavior changes, other clinical effects and reduced quality of life.[501,502] Moreover, the quality of life is also impacted for a pet owner of an epileptic pet.[503-505] In one study, 60% of owners reported that their dog's epilepsy had a negative impact on their quality of life.[501] Several studies have shown a normal life expectancy for dogs with idiopathic epilepsy while others have shown up to a 2-year decrease in life expectancy.[444,501,506,507] A median survival time of 1.5 years for canine epilepsy after diagnosis has been reported in a large cohort study of epileptic dogs.[424] This same study found that breeds kept solely for companionship lived longer after diagnosis than those with dual purpose, such as hunting and working breeds.[424] The breeds least likely to go into remission or have a >50% in seizure reduction were the Border Collie, German Shepherd Dog and Staffordshire Terrier.[494] Many pets are euthanized because of the severity of seizures or because of severe drug-induced side-effects.[485,501,508]

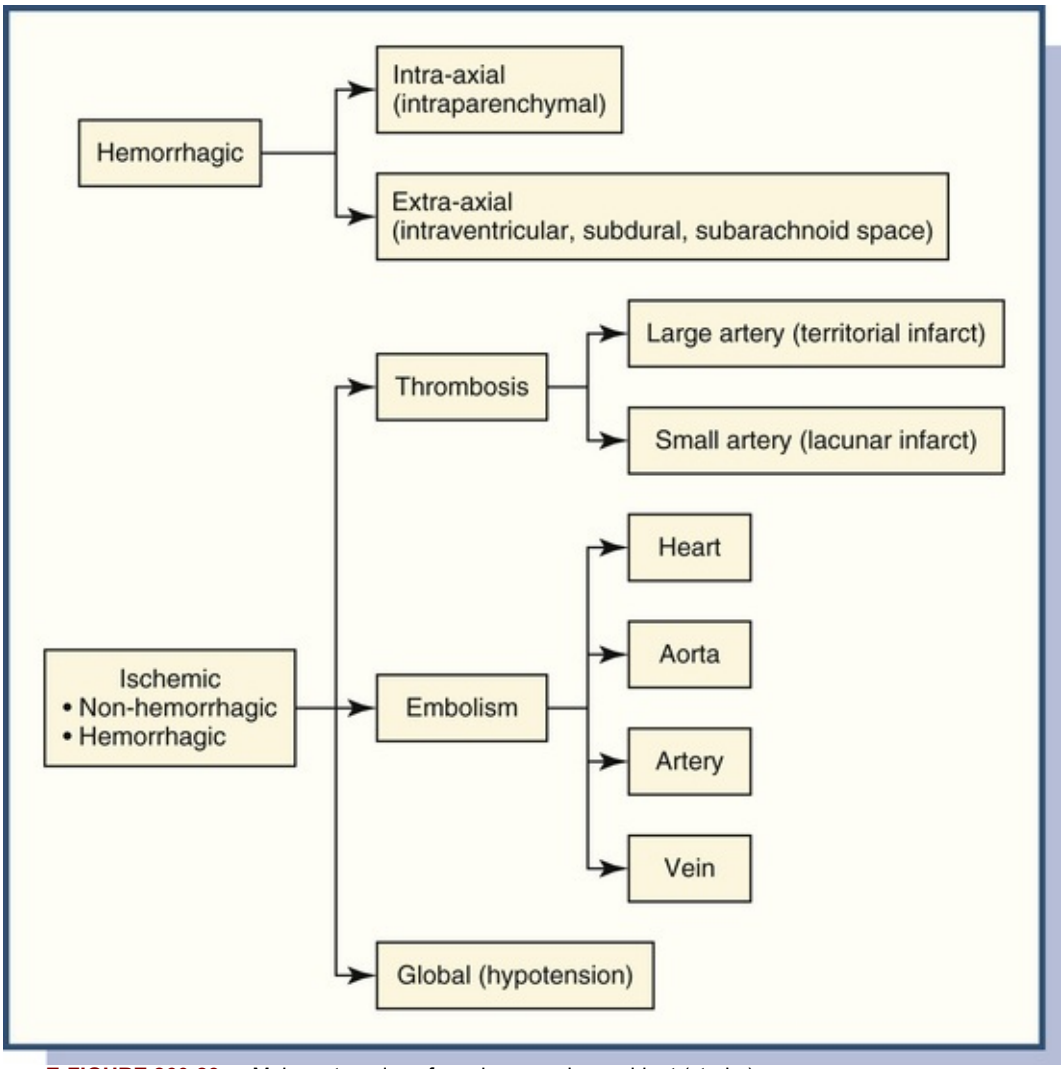
Risk factors for euthanasia include younger age of onset, high initial seizure frequency, poor seizure control, and episodes of status epilepticus.[437,479,506,507] Approximately 40-60% of dogs with epilepsy have one or more episodes of cluster seizures or status epilepticus and a mean lifespan of 8 years compared to 11 years for those with epilepsy and no status epilepticus.[428,507-510] Dogs that have had cluster seizures are significantly less likely to achieve remission with any AED treatment.[494] Though life expectancy of the pet may not be affected, the odds of an epileptic going into complete remission and not requiring ongoing therapy are low: 6-8% in dogs[438,479,501] and 17% in cats.[430] Thus, epilepsy in companion animals usually requires lifelong therapy and commitment from the owner. A balance between quality of life and therapeutic success is often key for an owner's commitment to the pet's therapy.[503]

Although AED treatment should be considered lifelong, discontinuation of AEDs may be considered in pets with seizure remission. The decision to gradually taper the dosage of AED should be on an individual basis, but seizure remission of at least 1 to 2 years is advised.[414,474] There is little information on seizure recurrence and owners must be aware that seizures could recur anytime. It is advised to decrease the AED dosage by 20% or less on a monthly basis.[414] Only in the case of life-threatening adverse effects should the AED be immediately discontinued. In this situation, the animal is under close observation and an AED that has a different metabolism is simultaneously administered as a loading dose.

Vascular Brain Disease

Classification

The high metabolic demand of brain tissue necessitates adequate blood supply. Reduced blood supply causes lack of oxygen and/or glucose, leading to neuronal ischemia and death. Cerebrovascular disease is defined as any abnormality of the brain resulting from a pathologic process affecting its blood supply.[511] Vascular diseases of the brain may result from excessive blood flow through the cerebral vasculature (hypertension), rupture of vasculature (bleed) or a reduction of blood flow (infarction).[53,175] Cerebrovascular accident (CVA), also known as stroke, is the clinical manifestation of cerebrovascular disease resulting from brain ischemia *(ischemic stroke)* and less commonly brain hemorrhage (*hemorrhagic stroke;* E-Figure 260-23).



E-FIGURE 260-23 Major categories of cerebrovascular accident (stroke).

Clinical signs must be present for ≥24 hours to be considered a stroke.[512] If signs of a CVA resolve within 24 hours, the term used is *transient ischemic attack*. *Global ischemia* refers to hypoxia/anoxia of the entire brain and bilaterally symmetrical death in selectively vulnerable neuronal populations (e.g., cerebral cortex, hippocampus, cerebellar cortex, basal nuclei and thalamus).[53]

Brain infarction can result from disruption of the vasculature leading to a hemorrhagic infarction or by vascular occlusion causing ischemic infarction.[513] A thrombus or embolus causes a focal occlusion but, less commonly, it can be multifocal. Ischemic infarcts that have secondary hemorrhage are termed *hemorrhagic infarcts*, whereas when hemorrhage is not present, infarcts are termed *nonhemorrhagic infarcts*. Based on size of the vessel, infarcts can be a consequence of small vessel disease, which gives rise to lacunar infarcts, or of large vessel disease, which gives rise to a territorial infarct. Territorial infarcts tend to occur in the cerebellum and cerebrum. Nontraumatic hemorrhagic stroke follows rupture of a brain vessel and development of a hematoma. Hemorrhage can be localized as intra-axial in the brain parenchyma or extra-axial such as in the intraventricular, subdural or subarachnoid space and CSF.[514] Subarachnoid hemorrhage can produce cerebral vasospasm, a temporary constriction of an intracranial artery causing transient regional ischemia. Vasospasm is difficult to determine clinically in animals but has been associated with subarachnoid hemorrhage in dogs.[515]

Pathophysiology

Ischemic Stroke

An infarct is an area of compromised brain parenchyma that is the result of focal vascular occlusion by

thrombosis or embolism. In thromboembolic-related stroke, the occlusion is due to an embolic source (septic, parasitic, metastatic, atherosclerotic) that has traveled from another vascular bed or from the heart.[512,516] The area of infarcted brain consists of an ischemic core with permanent loss of blood flow and irreversible neuronal injury surrounded by a penumbra, where blood flow is decreased but still-viable neurons are at risk for irreversible injury. Therapy is targeted at reversing this pathologic process as in 4-6 hours the ischemic cascade and vasogenic edema may progress within the penumbra and continue over 24-48 hours.[512,516]

Nonhemorrhagic ischemic infarcts are the most common CVA recognized in dogs.[517,518] Common sites for ischemic stroke in dogs include the cerebellum, striatocapsular region, and thalamus.[517-521] No underlying antemortem cause is detected for about 50% of dog CVAs.[522] No age or sex related factor has been identified and incidence is unknown.[512] Cavalier King Charles Spaniels and Greyhounds appear overrepresented.[517,518,522] Greyhounds appear more predisposed to ischemic stroke than all other breeds combined, with hypertension a possible contributing factor.[523] Cerebellar territorial infarcts are more likely in small breed dogs, especially in Cavalier King Charles Spaniels, and lacunar thalamic/midbrain infarcts occur more often in large breed dogs.[518,522] Miniature Schnauzers may be at increased risk possibly related to hyperlipidemia.[524]

Various etiologies have been associated with ischemic stroke in dogs and cats, including sepsis, atherosclerosis associated with primary hypothyroidism and Miniature Schnauzers with primary hyperlipidemia, aberrant parasite migration, thromboembolic disease, and neoplasia.[512-529] Diseases that predispose to nonhemorrhagic ischemic stroke include metabolic disorders (hypothyroidism, pheochromocytoma, hypertension) or hypercoagulopathy (diabetes mellitus, hyperadrenocorticism, renal disease, protein-losing nephropathy).[512-531] Hemorrhagic brain infarcts may follow venous thrombosis or vascular damage with leakage of blood when reperfusion occurs in focal ischemia.[53] Various conditions underlie hemorrhagic ischemic stroke (coagulopathy, hypertension, sepsis, inflammation, and metastasis (hemangiosarcoma).[512,531,532]

Hemorrhagic Stroke

Bleeding can injure the neighboring tissues by interrupting vital pathways, by exerting local pressure on surrounding brain structures and by causing ischemia of adjacent tissues. Hematomas may be large enough to increase intracranial pressure, causing shift and herniation of brain tissue. Nontraumatic intracranial hemorrhage results from blood vessel rupture or bleeding disorder and may be primary or secondary. Multiple hemorrhages may indicate bleeding disorder, toxin, trauma or metastatic vascular tumors.[53] Incidence of hemorrhagic stroke in dogs and cats is unknown. Intracranial hemorrhage occurs most commonly secondary to head trauma.[514] In a study of 75 dogs with nontraumatic intracranial hemorrhage, lesions were intraparenchymal (n = 72), subdural (n = 2) or intraventricular (n = 1); 33 of the dogs had a concurrent condition including *Angiostrongylus vasorum* infection, hypertension, metastatic hemangiosarcoma, chronic kidney disease, hyperadrenocorticism, intracranial lymphoma, meningothelial meningioma, sepsis and hypothyroidism.[533] Bleeding disorder associated with *A. vasorum* infection likely predisposes to intracranial hemorrhage.[534] Concurrent conditions most commonly associated with multiple lesions <5 mm (cerebral microbleeds) were endocrinopathies and hypertension.[533] Pituitary adenoma infarction or hemorrhage (pituitary apoplexy) can cause sudden onset seizures, behavior changes or vision loss.[535]

Less is known about CVAs in cats but hemorrhagic and ischemic strokes have been reported.[532] Feline ischemic encephalopathy, a cerebral infarction syndrome, usually involves the middle cerebral artery. Some cases have been associated with aberrant migration of *Cuterebra* spp. larvae into the brain.[528,536] Since not all have obvious vascular lesions, vasospasm may be the result of hemorrhage in the subarachnoid space caused by the migrating larva or the results of a larval produced toxin.[196] Hemorrhagic infarcts should be suspected in cats with liver disease and central vestibular signs.[532]

Global Ischemia

Global brain ischemia is a differential in dogs and cats with peracute neurologic dysfunction after anesthesia or post-cardiopulmonary resuscitation.[537,538] Watershed infarction develops when cerebral blood flow is lowered below the point of compensation by cerebral autoregulatory mechanisms, causing widespread

bilateral brain dysfunction. Use of ketamine and the brachycephalic breeds predispose for global ischemia.[537] Use of mouth gags in cats has been associated as a potential risk factor for development of cerebral ischemia, hearing loss and blindness.[538] If the mouth is opened maximally, blood flow through the maxillary arteries is occluded in some cats.[539,540] Additional findings suggest that vision and hearing deficits might not only be the results of reduced perfusion to the brain, but could also result from disrupted blood flow directly to the retina or inner ear.[539] Smaller mouth gags were not associated with abnormalities on retinal function tests or MRI angiography and still provided sufficient opening while minimizing the risks of reductions in maxillary artery blood flow.[541]

Clinical Signs

Onset of neurologic signs is peracute to acute and usually nonprogressive after 24 hours.[512] Common signs noted by owners include altered mentation, hemiparesis, seizures and vestibular dysfunction. Neurologic deficits in dogs with CVAs usually have a focal anatomic localization and reflect the site and lesion extension of the vascular insult.[512,517,521,522,531,542] Infarction of a specific brain region is associated with specific clinical signs (i.e., forebrain, thalamus, midbrain, pons, medulla, cerebellum).[517,542] In 38 dogs with brain infarctions, locations involved were the cerebrum (29%), thalamus/midbrain (21%), cerebellum (47%) and multifocal in 7%. Ischemic stroke in 27 dogs involved the middle cerebral artery in 70% of dogs.[542]

Motor dysfunction and general proprioceptive ataxia were reported in 78%, including signs of sensory hemi-neglect and contralateral motor deficits as a result of middle cerebral artery infarction. One study reported seizures in 50% of dogs after ischemic stroke,[542] but another study reported seizures in only 1 dog. Onset of ischemic stroke is usually acute to peracute. Typically, deterioration occurs after the insult, presumably due to edema, but then becomes static or improves after the first 24 hours. In hemorrhagic stroke, often the territory affected involves more than one artery and secondary signs ensue from increased intracranial pressure. If the hemorrhage is associated with mass effect, deterioration may be a result of edema formation or hematoma enlargement.

Diagnosis

Initially, other acute brain diseases such as metabolic, neoplastic, inflammatory and trauma must be considered. It is important to determine presence of underlying extraneural disorders (Figure 260-24). Dogs and cats with ischemic and hemorrhagic stroke should be evaluated for hypertension, endocrine disease, renal disease, cardiac disease and metastatic disease.[522,530] Along with physical (see ch. 2) and neurologic (see ch. 259) examinations, a retinal examination (see ch. 11) should be considered and changes may reveal evidence of tortuous vessels suggestive of hypertension (see ch. 157) and hemorrhage that may suggest a bleeding disorder or hypertension. A CBC allows identification of abnormal red blood cell indices or platelet abnormalities. Serum biochemistry profile and urinalysis should be used to evaluate for hypercoagulability or other underlying systemic disease. Specific coagulation testing is recommended (see ch. 196). Serial blood pressure monitoring can detect underlying hypertension (se ch. 99). Hypertensive encephalopathy can be observed with acute (>30 mm Hg from resting level) or sustained (>180 mm Hg) increases in systolic arterial blood pressure (see ch. 157).[543] Other adjunctive testing includes thoracic, abdominal and cardiac imaging, and endocrine testing for adrenal (see ch. 306) and thyroid (see ch. 299) diseases.

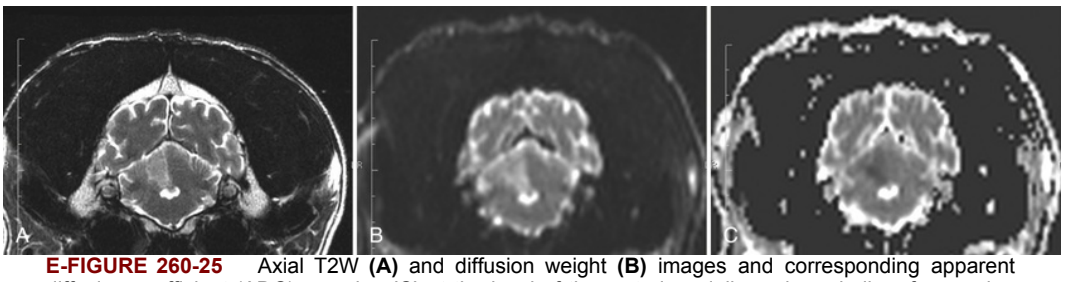
Definitive diagnosis of stroke requires histology via biopsy or necropsy. Imaging studies are necessary to make a presumptive diagnosis, determine the lesion extent and distinguish between ischemic and hemorrhagic stroke.[512,531] Moreover, recognizing infarction and/or hemorrhage assists with appropriate patient management. CT images are frequently normal during the acute phase of ischemia; thus, a diagnosis relies on exclusion of other mimicking diseases. Early signs of ischemic injury on CT include parenchymal hypodensity, loss of gray-white matter distinction, subtle effacement of cortical sulci and local mass effect from edema.[512,531] MRI is considered more sensitive than CT for detecting acute ischemic lesions.[513] Characteristic MR imaging findings associated with ischemic infarction include well demarcated, wedge-shaped lesions, with minimal mass effect. The intra-axial lesion is hyperintense on T2W and FLAIR sequences and hypointense on T1W sequences with minimal enhancement.[336,513,517] Lesion distribution should correlate with its loss of territorial arterial supply.[336,517,518,542] Chronic CVA lesions tend to weakly contrast enhance for days after onset,[517,518,531,544] which can be confused with neoplasia and inflammation.[19,336]

Difficulty in differentiating acute from chronic ischemic lesions using MRI can be overcome with functional MRI techniques. Diffusion weighted imaging (DWI) complements other conventional MR sequences with its sensitivity to cytotoxic edema, especially in early ischemia, and in assessing temporal evolution in acute versus chronic ischemic stroke.[513,545] Tissue contrast on DWI reflects Brownian motion of water molecules. Peracute (hours to 4 days) ischemic infarction appears as hyperintense on DWI that corresponds with

hypointensity on ADC maps, consistent with cytotoxic edema and reduced Brownian motion of water molecules (E-Figure 260-25). With time vasogenic edema develops and on DWI and corresponding ADC mapping, the signal becomes hyperintense as the diffusion becomes higher due to increased extracellular water. MR angiography (MRA) can be useful for identify underlying vascular occlusion or malformation.



E-FIGURE 260-25 Axial T2W **(A)** and diffusion weight **(B)** images and corresponding apparent diffusion coefficient (ADC) mapping **(C)** at the level of the rostral medulla and cerebellum from a dog with an ischemic infarct in the left cerebellar hemisphere. Note the wedge-shaped hyperintensity on the T2W image **(A)** and the hyperintensity on the diffusion weighted image. The lesion appears hypointense on ADC mapping, indicating restricted diffusion associated with cytotoxic edema after a hyperacute ischemic injury. (Courtesy Fred A. Wininger, Veterinary Surgical Specialist, St Louis, MO.)

Recognition of hemorrhage is important in diagnosis and appropriate management. CT is considered highly sensitive for detection of acute hemorrhage, which appears hyperdense due to attenuation of X-rays by the globin portion of hemoglobin (Table 260-10). Over days to weeks, hematomas eventually become isodense with variable contrast enhancement. On MRI, acute and subacute hemorrhagic lesions often are associated with surrounding vasogenic edema, which appears as hyperintense on T2W and FLAIR sequences. There are distinct stages of MRI appearance of intracranial hemorrhage lesions due to RBC breakdown and various forms of hemoglobin that create various patterns of signal intensities on defined sequences (see Table 260-10).[546-548] Gradient-echo sequences (T2*) are recommended for visualization of hemorrhage. The T2*W sequence takes advantage of the magnetic properties of hemosiderin, oxy-, deoxy-, and methemoglobin to identify areas of blood product accumulation and temporal evolution of intracranial hemorrhage. The paramagnetic properties of deoxyhemoglobin in acute hemorrhage cause a susceptibility artifact on T2*W, which is visualized as a signal void (dark; E-Figure 260-26). Sometimes the T2*W sequence can improve conspicuity of microbleeds (<4 mm) that are not readily seen on a T2W sequence.[549]

TABLE 260-10

Timing of Hemorrhage and MRI/CT Description

	<24 HOURS	1-3 DAYS	>3 DAYS	>7 DAYS	>1 MONTH
Clinical Stage	Hyperacute	Acute	Early subacute	Subacute to chronic	Chronic
State of Hemoglobin (Hb)	OxyHb	DeoxyHb	MetHb	MetHb	Hemosiderin and ferritin
Cellular Location in RBCs	Intra	Intra	Intra	Extra	—
T1W Signal Intensity	Iso	Iso to hypo	Hyper	Hyper	Iso to hypo
T2W/FLAIR Signal Intensity	Slightly hyper	Hypo	Hypo	Hyper	Hypo
T2* (GRE) Signal Intensity Loss (Signal Void)	Present (rim)	Present	Present	Present	Present
CT Density	Hyper	Hyper	Hyper	Iso	Iso to hypo

GRE, Gradient echo; *RBC*, red blood cell.

E-FIGURE 260-26 Magnetic resonance images at the level of the thalamus of a canine brain with cerebrovascular disease. Axial T2W image **(A)** shows a demarcated area of hypointensity in the corona radiata (arrow). On T2*W **(B)** of the same area, a signal void is recognized along with additional other smaller focal lesions (arrowheads) of signal void that were not conspicuous on T2W imaging. The lesion was T1-hypointense **(C)** with no contrast enhancement **(D).**

Treatment

Management of CVAs is largely supportive: controlling seizures and intracranial pressure, and treating any underlying cause such as vasculitis or hypertension.[512] After an ischemic stroke, recovery often occurs within several weeks with supportive care. Treatment includes correcting of physiologic abnormalities, minimizing effects of the ischemic cascade and improving cerebral blood flow. Based on development of the penumbra in human stroke patients, the "window of opportunity" for instituting these therapies is within 6 hours.[516]

Principles of acute treatment for stroke include monitoring of vital parameters (airway, breathing, circulation), intracranial stabilization and investigating underlying causes. Intracranial stabilization focuses on reducing cerebral edema, optimizing cerebral blood flow and if indicated, removal of the space-occupying hematoma. Cerebral perfusion is optimized with management of systemic blood pressure and elevated intracranial pressure. In hemorrhagic stroke, benefits likely outweigh the risks when considering administration of an osmotic agent, such as mannitol. Thrombolytic agents (i.e., tissue plasminogen activator, streptokinase) during acute treatment are infrequently used because of expense, rarity of blood clots associated with infarction in dogs and cats, and failure to administer these agents within the 6 hour window.[512,516] Although unproven to be beneficial, long-term antithrombotics (e.g., aspirin) may be considered in thromboembolic disease to reduce risk of another infarction. Long-term, the patient should be serially monitored for signs of recurrence of stroke and progression of the underlying condition.

Prognosis

Prognosis depends on the type and localization of the CVA, severity of neurologic dysfunction, occurrence of deterioration or complications and the underlying cause.[522] Survival studies of CVAs are difficult because dogs often have severe neurologic signs that prompt owners to elect euthanasia. In ischemic stroke, most

dogs recover within weeks after onset of signs.[517,518,522] In a study of 20 dogs with ischemic stroke, prognosis was good if they survived the initial 30 days post-stroke, but there is risk of recurrence.[550] Recurrence has been based on a repeated episode of acute neurologic dysfunction.[522,542] Dogs with a concurrent medical condition causing ischemic stroke have shorter survival times than dogs with no identified underlying condition.[522] In a study of 75 dogs with nontraumatic intracranial hemorrhage, 61% had a good to excellent long-term outcome.[533] However, hemorrhagic stroke in the cerebellum is associated with higher mortality.[518] Identification of hypertension in dogs with nontraumatic intracranial hemorrhage is a poor prognostic indicator.[533] In dogs with intracranial hemorrhage and multiple lesions >5 mm, *A. vasorum* (see ch. 242) was the only concurrent condition with a good outcome.[533]

CHAPTER 261

Inflammatory, Infectious, and Other Multifocal Brain Diseases

Chelsie Estey, Curtis W. Dewey

Client Information Sheet: Granulomatous Meningoencephalitis

Disorders of the brain in which the neurologic examination reveals multifocal or diffuse involvement are relatively common in clinical practice. Multifocal or diffuse involvement of the brain refers to clinical evidence that more than one functional division of the brain is affected by a disease process. For example, a dog with both forebrain and cerebellar dysfunction would be considered to have multifocal or diffuse involvement of the brain. Whether to call a neurologic localization multifocal or diffuse is somewhat a matter of semantics, but *diffuse* suggests a more generalized and symmetric constellation of deficits, whereas *multifocal* connotes a more asymmetric group of abnormalities. There are several implications of multifocal/diffuse localization in a patient with signs of encephalopathy; for example, the type of disorder more likely to present with such a neurolocalization. In general, inflammatory disorders, metabolic disorders, multifocal/metastatic neoplasia and toxins are highest on the differential diagnosis list for dogs and cats with multifocal/diffuse encephalopathy. However, it is important to note that these implications are sometimes inaccurate. Patients with metabolic or toxic disorders causing brain disease are more likely to exhibit symmetric neurologic deficits (i.e., resulting from a diffuse encephalopathy), but this is not an absolute. The clinician should be aware that focal brain lesions can lead to multifocal signs of encephalopathy due to several mechanisms: (1) an extensive mass that invades more than one region of the brain; (2) edema surrounding a focal mass, producing a mass effect; (3) obstruction by a brain lesion of normal cerebrospinal fluid (CSF) flow, leading to accumulations of ventricular CSF (e.g., obstructive hydrocephalus associated with a caudal fossa lesion); and (4) lesions affecting one area of the brain that has influence over a separate region of the brain (e.g., flocculonodular lobe or caudal cerebellar peduncle).

This chapter reviews salient clinical features of the more common multifocal/diffuse brain disorders encountered in dogs and cats. Disorders that commonly lead to multifocal/diffuse brain dysfunction are summarized according to the DAMNIT (*d*egenerative, *a*nomalous, *m*etabolic, *n*eoplastic, *n*utritional, *i*nflammatory [noninfectious], *i*nfectious, *t*oxins, *t*rauma) scheme in Box 261-1. Not all of these disorders are discussed in detail, and some are not discussed at all because they appear elsewhere in this textbook. Emphasis is placed on the noninfectious inflammatory brain disorders of dogs due to their frequent occurrence in clinical practice and propensity to cause multifocal brain dysfunction.

Box 261-1

Disorders That May Cause Multifocal or Diffuse Brain Dysfunction

Degenerative

Lysosomal storage disease* (also see ch. 260)
Cognitive dysfunction syndrome (also see ch. 263)
Leukodystrophy/spongy degeneration (also see ch. 260)
Neuronal vacuolation and spinocerebellar degeneration in Rottweilers and Boxer dogs

Anomalous

Caudal occipital malformation syndrome (also see ch. 260)
Intracranial arachnoid cyst

Congenital hydrocephalus (also see ch. 260)
Neuronal migration disorders
Atlanto-occipital overlap
Dandy-Walker syndrome (also see ch. 260)

Metabolic

Hepatic encephalopathy (also see ch. 281 and 284)
Hypoglycemic encephalopathy (also see ch. 303)
Electrolyte-associated encephalopathy
Endocrine-related encephalopathy (e.g., hypothyroidism [see ch. 299], hyperthyroidism [see ch. 301])
Renal-associated encephalopathy (also see ch. 322)
Kernicterus
Mitochondrial encephalopathy
Organic acidurias

Neoplastic

Primary brain tumors (also see ch. 260)
Metastatic/multifocal brain tumors (e.g., lymphoma; also see ch. 260)

Nutritional

Thiamine deficiency (see ch. 12)
Cobalamin deficiency (Border Collies) (also see ch. 292)

Inflammatory, Noninfectious

Granulomatous meningoencephalomyelitis
Necrotizing encephalitis
Eosinophilic meningoencephalitis

Infectious

Bacterial
Fungal
Viral
Rickettsial
Protozoal
Verminous
Hydrocephalus with periventricular encephalitis

Toxins

Bromethalin (see ch. 152)
Marijuana (see ch. 154)
Metaldehyde (see ch. 152)
Tricyclic antidepressants (see ch. 153)
Brunfelsia (see ch. 155)
Lead
Methylxanthine overdose
Nicotine (see ch. 155)
Salt intoxication (paintballs; see ch. 13 and 152)

Trauma (see **ch. 148**)

Intracranial hemorrhage
Edema
Diffuse axonal injury

*These disorders can also be considered metabolic in nature.

Inflammatory, Noninfectious Disorders of the Brain

The terminology associated with these disorders can be confusing. An important concept to remember is that these terms are based upon histopathologic descriptions, rather than known etiologies. In addition, it has been estimated that approximately one-third of all inflammatory canine brain disorders do not achieve a specific diagnosis. The two most commonly recognized disorders in this disease category are granulomatous meningoencephalomyelitis (GME) and necrotizing encephalitis (NE). Necrotizing encephalitis is often subdivided into two forms: necrotizing meningoencephalitis (NME) and necrotizing leukoencephalitis (NLE). The authors have encountered a number of patients with features of both GME and NE. Because of this phenomenon and the lack of specific identifiable causes for these disorders, the "umbrella" term *meningoencephalitis of unknown etiology* (MUE) has been suggested.[1] Although such a term does have some clinical utility, clinical features and response to therapy do tend to differ between "classic" GME and NE cases. Because of this, the authors feel it is important to consider these as separate clinical entities when it is possible to use clinical and/or diagnostic information to help differentiate between the two disease processes.

Granulomatous Meningoencephalomyelitis

This is a common and enigmatic idiopathic inflammatory disease of the central nervous system (CNS) in dogs and is considered extremely rare in cats. GME is diagnosed definitively via histologic features, typified by perivascular infiltrates of primarily mononuclear cells (lymphocytes, macrophages, and plasma cells) in the brain and/or spinal cord. Characteristic perivascular cellular infiltrates of GME both define the disease syndrome and are responsible for the observed neurologic deficits. The underlying cause of this disease remains a mystery, but it is widely believed that GME is an autoimmune disorder, specifically a delayed-type (T cell–mediated) hypersensitivity reaction. Lesions predominate in the white matter. Autoantibodies directed against astrocytes have been demonstrated in GME cases, further supporting the suspicion that this is an autoimmune brain disorder. It is, however, unclear whether these anti-astrocytic antibodies represent a primary or secondary immune response. Recent polymerase chain reaction (PCR) studies have failed to detect viral genetic material in brain tissue from dogs with GME. There are three recognized clinical forms of GME: focal, multifocal (disseminated), and ocular. The ocular form is the least common form. In the experience of the authors, multifocal GME is the most common form of the disorder.

GME can affect any breed of dog of any age and either sex. However, young to middle-aged (median age of 5 years) female dogs of small breeds (e.g., Poodles, Terriers) appear to be predisposed. Seizures, cerebellovestibular dysfunction, and cervical hyperesthesia are common features of multifocal GME. Patients with GME may occasionally be febrile upon presentation. There are reports of biopsy-confirmed cases of GME in dogs, but the vast majority of confirmed GME cases have been diagnosed at necropsy. A presumptive antemortem diagnosis of GME is based upon characteristic signalment and historical and clinical findings in addition to results of diagnostic testing. CSF evaluation (see ch. 115) usually provides the most important information in the antemortem diagnosis of GME. A mainly mononuclear pleocytosis, with a variable percentage of neutrophils and elevated protein level, is typical of GME. Results of imaging studies are highly variable in dogs with GME. In most cases, however, computed tomography/magnetic resonance (CT/MR) images of the brain in GME patients show solitary or (more commonly) multiple (Figure 261-1) lesions, or they may reveal areas of contrast enhancement with indistinct margins.

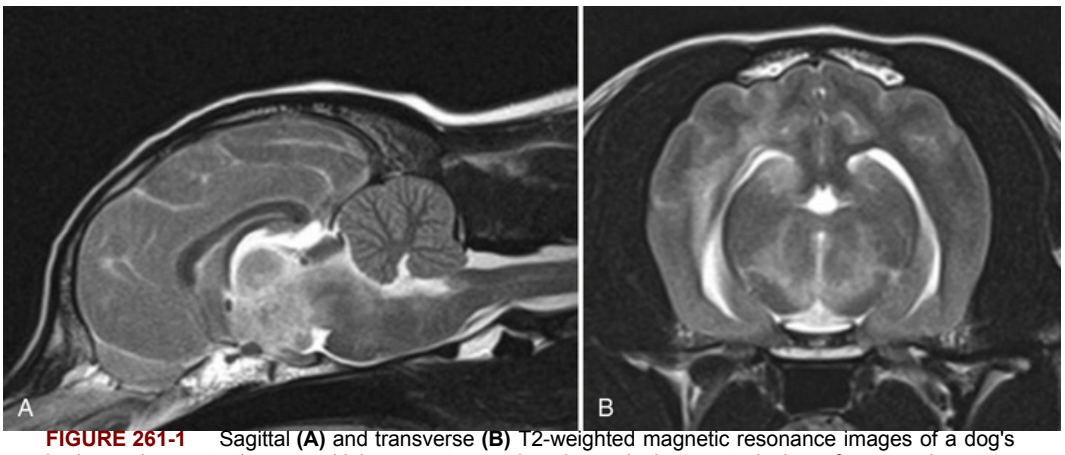

FIGURE 261-1 Sagittal **(A)** and transverse **(B)** T2-weighted magnetic resonance images of a dog's brain, demonstrating multiple contrast-enhancing lesions typical of granulomatous

meningoencephalomyelitis.

Immunosuppressive glucocorticoid therapy (e.g., oral prednisone, 1 to 2 mg/kg q 12 h; also see ch. 165) has long been considered the standard treatment protocol for GME, despite a high rate of clinical failure. The dosage may be slowly reduced over time if the patient exhibits a clinical response to treatment. However, GME patients typically require lifelong immunosuppressive therapy. The prognosis for GME remains guarded, but has improved dramatically in recent years, due to new treatment protocols for the disease. In one study, the median survival time of dogs with multifocal GME treated with glucocorticoid therapy was 8 days.[2] Several alternative immunosuppressive drugs have been evaluated as adjunctive treatment options for GME patients. The three most promising drug options include procarbazine, cytosine arabinoside, and cyclosporine.[3-6] Survival times exceeding 12 months have been reported for each of these three drugs. In addition, the use of these drugs appears to allow for successive decreases in glucocorticoid dosages, thereby minimizing adverse side effects associated with steroid use. Procarbazine is an antineoplastic drug that crosses the blood-brain barrier (BBB) and has some specificity for T cells. The cytotoxic effects of procarbazine are thought to be primarily via methylation of DNA bases. In one study of presumptive GME dogs, the use of procarbazine as an adjunct to prednisone was associated with a median survival time of 14 months, regardless of the clinical form of GME (the majority were multifocal). The dosage used by the authors is 25 mg/m^2 PO q 24 h. Myelosuppression is the most likely adverse effect, although hemorrhagic gastroenteritis may also occur. A complete blood count (CBC) should be checked weekly for the first month, then monthly thereafter to monitor for myelosuppression.[3] Cytosine arabinoside is a synthetic nucleoside analog that crosses the BBB. This drug inserts itself into DNA molecules after enzymatic activation, causing premature chain termination in mitotically active cells. The protocol used for dogs with GME is a continuous rate IV infusion (CRI) (400 mg/m^2) administered over 24 hours. The IV CRI is the authors' preferred route of administration since the steady state achieved via this route may allow for a more prolonged exposure of cytarabine at cytotoxic levels in plasma.[7] A subcutaneous injection of 50 mg/m^2 q 12 h for 2 subsequent days is less effective than the CRI due to the cell-cycle–specific nature of this medication. Drug administration should be repeated initially every 3 weeks, with the interval gradually extending over time. The drug should be diluted 2 : 1 with sterile saline (to prevent tissue irritation) prior to injection, and gloves should be worn when handling cytosine arabinoside. Because myelosuppression is a potential side effect of this drug, a CBC should be checked weekly for the first month and a CBC and serum biochemistry profile should be checked prior to every subsequent treatment. Myelosuppression appears to be very infrequent with this protocol. In one report of 10 dogs with noninfectious encephalitis of undetermined etiology, cytosine arabinoside treatment was associated with a median survival time of approximately 1.5 years. In two of these dogs, tertiary treatment (procarbazine, leflunomide) was also administered.[4] Cyclosporine (cyclosporine A) is a lipophilic peptide that does not readily cross the BBB. Despite this, it is thought that the drug may become trapped in endothelial cells in the CNS, and that the inflammatory nature of GME may allow more cyclosporine to cross the BBB than would occur in the absence of inflammation. The mode of action of cyclosporine is blocking of transcription of genes in activated T cells that lead to the production of inflammatory cytokines. There have been several clinical reports of cyclosporine use in the treatment of GME in dogs; the drug appears to be successful, with a median survival time of 2.5 years in one report of 10 dogs.[5] Several dosage regimens have been suggested. The authors use 3 to 5 mg/kg PO q 12 h. Reported side effects attributable to cyclosporine use in dogs include vomiting, diarrhea, anorexia, weight loss, gingival hyperplasia, papillomatosis, hypertrichosis, and excessive shedding.[5] There has been one report describing the use of leflunomide, a pyrimidine analogue, for noninfectious inflammatory brain disease in three dogs. The dogs responded favorably to leflunomide and were still alive more than 12 months after starting therapy.[8] The specific inflammatory brain disease(s) affecting these dogs were not determined in this report. In recent years, the authors have been combining the three newer drugs to treat suspected GME patients, most commonly using prednisone, cyclosporine and cytosine arabinoside. Results are preliminary, but responses have been favorable and side effects minimal.

Necrotizing Encephalitis

This disease subcategory includes NME and NLE. As with GME, these are suspected to be autoimmune disorders. Both necrotizing disorders are similar in that they are characterized by multiple cavitary necrotic nonsuppurative inflammatory brain lesions that involve both gray and white matter (Figure 261-2). In NME, these lesions are typically found in the cerebrum, with consistent meningeal involvement. Extensive cerebral

cavitations with a loss of demarcation between gray and white matter are often found in NME images. NLE exhibits similar lesions that often involve the brainstem in addition to the cerebrum, with less consistent involvement of the meninges and cerebral cortex (i.e., mainly white matter). Early reports of these disorders in predisposed breeds led to the terms *Pug encephalitis* or *Pug/Maltese encephalitis* for NME and *Yorkshire Terrier encephalitis* for NLE. Pug and Maltese dogs are commonly affected by NME, but other breeds have been reported with this disorder, including Chihuahua, Shih Tzu, Pekingese, Papillion, Yorkshire Terrier, Coton de Tulear, Brussels Griffon and Staffordshire Terrier mixed breed dog.[9,10] Yorkshire Terriers seem to be the most common breed afflicted by NLE, but this disease may also affect other small-breed dogs, such as the French Bulldog. It is very possible that NME and NLE represent variants of the same disease process. It is expected that more breeds will be reported with idiopathic NE. PCR tests have failed to identify viral DNA associated with these disorders. As with GME, the necrotic lesions observed on brain histopathology both account for the clinical signs of dysfunction and define the disease syndrome.

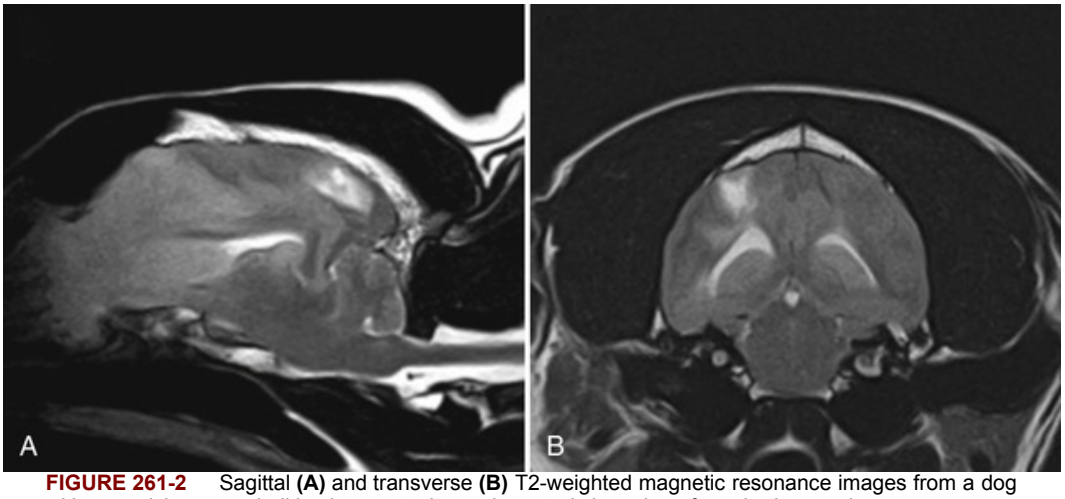

FIGURE 261-2 Sagittal **(A)** and transverse **(B)** T2-weighted magnetic resonance images from a dog with necrotizing encephalitis, demonstrating a characteristic region of cerebral necrosis.

NE tends to occur in young, small-breed dogs, but a wide age range has been reported. Clinical signs (see ch. 259) typically correspond to the distribution of brain lesions. Seizure activity is frequent with NE, often being the primary clinical complaint. Pug and Maltese dogs with NME have varying ages at presentation—between 6 months and 7 years. The onset and progression of clinical signs of neurologic dysfunction may be acute (disease course of 2 weeks or less) or chronic (disease course of 4 to 6 months). Clinical signs of forebrain dysfunction (seizures, circling, obtunded mental status, visual deficits with normal pupillary light reflexes, head-pressing, etc.) predominate. Neck pain is a common feature and may be due to the meningitis and/or forebrain disease. Yorkshire Terriers with NLE have been reported between the ages of 1 and 10 years. These dogs commonly display a chronic, progressive worsening of neurologic dysfunction over several months. In addition to clinical signs of forebrain dysfunction and neck pain, Yorkshire Terriers with NLE often show clinical signs of brainstem dysfunction (e.g., central vestibular disease). The definitive diagnosis of NE is based upon characteristic histopathologic brain lesions observed at necropsy. A tentative diagnosis is based primarily upon signalment, history, and findings of the neurologic examination. Bloodwork results are characteristically normal. CSF findings (see ch. 115) are often abnormal; most commonly, a predominantly or exclusively mononuclear pleocytosis with elevated protein levels is found. The mononuclear cells in NME are usually primarily lymphocytic, whereas a mixture of lymphocytes and monocytes is usually seen in the CSF of NLE patients. MRI and CT findings have been described in several cases of NE. Lesions on MRI are usually isointense or hypointense on T1-weighted images, hyperintense on T2-weighted and FLAIR images, and inconsistently and nonuniformly contrast enhancing. Asymmetric ventricular dilation and areas of hypointensity in the brain (corresponding to malacic brain parenchyma), sometimes appearing continuous with the lateral ventricles, are consistent findings.

Treatment of suspected NE patients with glucocorticoids and anticonvulsant drugs (if seizures are occurring) should be attempted but often has little to no appreciable clinical effect. The prognosis for NME is poor to grave. The majority of dogs die or are euthanized due to progressive neurologic dysfunction within 6 months of onset of neurologic deficits. The same drug protocols used in recent years for GME have been

suggested for use in cases of NE. Due to lower case numbers compared with GME, as well as lack of distinction in some reports between GME and NE, it is unclear whether these drugs are effective for NE or not. In the authors' experience, procarbazine does not appear to be as effective in suspected NE cases, as compared with GME cases. The prognosis for this group of disorders remains poor. The authors and colleagues have had anecdotal success treating several suspected NME patients with mycophenolate mofetil (see ch. 165).

Eosinophilic Meningoencephalitis

Eosinophilic meningoencephalitis (EME) is an uncommonly diagnosed cause of canine intracranial disease. It is characterized primarily by meningeal inflammation and an eosinophilic pleocytosis with a greater than 10% eosinophil count in the cerebrospinal fluid (CSF) of affected animals, independent of circulating blood eosinophil levels. In veterinary medicine, EME is frequently idiopathic in nature, although infectious EME can be caused by agents such as *Cryptococcus neoformans* (see ch. 231), *Neospora caninum* (see ch. 221), and *Baylisascaris procyonis* (see ch. 210). In one retrospective study, an infectious cause for EME was only identified in 17% of cases, while 70% were determined to be idiopathic.[11] In contrast to other canine encephalitides, such as granulomatous meningoencephalitis and necrotizing meningo- and leukoencephalitis, to which toy and small-breed dogs are predisposed, idiopathic EME is most commonly diagnosed in larger breeds. Specifically, the Rottweiler, Golden Retriever and Belgian Tervuren appear over-represented for this condition.[12-14] Idiopathic EME has been reported to occur in only a handful of small-breed dogs, including the Yorkshire Terrier, Beagle, Pug dog and Miniature Pinscher. A diagnosis can be made based on clinical findings, MRI appearance and an eosinophilic pleocytosis on CSF analysis (see ch. 115). A wide range of MRI appearances is seen in canine idiopathic EME, including normal scans.[11] The same drug protocols used for treatment of GME and NE have also been used with success by the authors.

Greyhound Nonsuppurative Meningoencephalitis

Greyhound nonsuppurative meningoencephalitis is a breed-associated disorder with a unique lesion distribution. This disease process affects young Greyhounds that are typically less than 12 months of age. A genetic risk factor is assumed because the disease has been shown in siblings and a causative infectious agent has yet to be identified. An association between dog leukocyte antigen class II haplotype and Greyhound meningoencephalitis has been found.[15] Reported clinical signs are varied and can include forebrain signs (mentation and behavior changes, blindness) and brainstem signs (head tilt, circling, ataxia).[16] MRI abnormalities show a predilection for the rostroventral portions of the cerebrum, particularly the olfactory lobes and bulbs.[17] Histopathologic examination reveals severe gliosis and gemistocytosis with mononuclear cell perivascular cuffing in the caudate nucleus and cortical gray matter of the cerebrum and in the periventricular gray matter of the rostral portion of the brainstem. Milder lesions are also found in the molecular layer of the cerebellum, the caudal brainstem, and the cranial cervical spinal cord.[18]

Infectious Disorders of the Brain

Infections of the brain may result in neurologic dysfunction by producing a mass effect (i.e., organized abscess) or release of toxins and inflammatory mediators. A major cause of neurologic deficits is thought to be the secondary inflammatory response induced by the organisms. Infectious brain disorders are far less commonly encountered in dogs and cats compared with noninfectious disorders. However, the dogmatic assumption that these disorders are rare, combined with the often rapid clinical progression of such diseases, may place an affected patient at undue risk of not receiving timely and appropriate therapy. This is, of course, a specific concern for those infectious diseases that may respond to antimicrobial agents. In some cases, surgical decompression and brain abscess or granuloma removal may also be indicated on an emergency basis.

Bacterial Meningoencephalitis

Bacteria can gain access to the brain via the hematogenous route or by extension of infection from a neighboring focus (e.g., extension of otitis interna). The BBB and absence of a lymphatic system in the CNS help protect it from microbial invasion. However, once an infectious agent has successfully breached the BBB, the immunologically privileged nature of the CNS represents an advantage to the invading organism and a

detriment to the host. Commonly implicated organisms in canine and feline bacterial meningoencephalitis include *Staphylococcus* and *Streptococcus* species, *Pasteurella multocida* (especially cats), *Actinomyces* and *Nocardia* species, as well as anaerobes (e.g., *Bacteroides, Peptostreptococcus, Fusobacterium, Eubacterium*). In one report of canine bacterial meningoencephalitis, the most common causative organisms were *Escherichia coli, Streptococcus* species, and *Klebsiella* species. Gram-negative infections were most common, and single-versus multiple-organism infections were equally likely.[19]

Dogs and cats of any age, breed, or sex may develop bacterial meningoencephalitis, but it is more common in young to middle-aged animals (e.g., 1 to 7 years). Clinical signs of neurologic dysfunction are often acute and rapidly progressive. Fever and cervical hyperesthesia are considered classical features of bacterial meningoencephalitis but may not be evident. A tentative diagnosis of bacterial meningoencephalitis is based upon historical and clinical data, as well as results of laboratory tests. A positive response to antibiotic drugs also supports the diagnosis. CBC results may indicate a systemic inflammatory response, but this is often not the case. Abnormalities on serum chemistry profiles (e.g., elevated ALT and SAP levels, hypoglycemia, hyperglycemia) are apparent in the majority of cases. Advanced imaging (CT, MRI) may be helpful in diagnosing mass lesions (Figure 261-3) or obstructive hydrocephalus. The most valuable information is obtained from CSF analysis (see ch. 115), which is usually abnormal. With acute bacterial meningoencephalitis, a suppurative CSF pattern, often with degenerate and toxic-appearing neutrophils, is common. Protein levels are also often elevated. The presence of intracellular bacteria in the CSF sample confirms the diagnosis. Extracellular bacteria may represent causative agents but may also be contaminants. Positive CSF, blood, and/or urine culture results also support the diagnosis of bacterial meningoencephalitis, but these are often falsely negative (see ch. 221).

FIGURE 261-3 Axial T1-weighted (with contrast) brain magnetic resonance image of a cat with a cerebral abscess. (Reprinted with permission from Dewey CW: Encephalopathies: disorders of the brain. In Dewey CW, editor: *A practical guide to canine and feline neurology*, ed 2, Hoboken, NJ, 2008, Wiley-Blackwell.)

Antibiotic treatment of bacterial meningoencephalitis is ideally based upon culture/sensitivity results of the causative organism. Because this is often not obtainable, antibiotic therapy is often based on Gram stain results of organisms seen on CSF analysis, or on the most likely pathogen(s), if organisms are not observed. Appropriate antibiotics for bacterial meningoencephalitis should ideally be bactericidal, have a low-level protein binding, and be able to cross the BBB. Intravenous therapy is recommended for at least the initial 3 to 5 days of therapy. High intravenous dosages of ampicillin (e.g., 22 mg/kg q 6 h) have been recommended as an appropriate therapeutic choice for most cases of canine and feline bacterial meningoencephalitis.

Ampicillin crosses the inflamed BBB relatively well and is bactericidal. If a Gram-negative infection is suspected or confirmed, enrofloxacin (e.g., 10 mg/kg IV q 12 h in dogs) or a third-generation cephalosporin (e.g., cefotaxime at 25-50 mg/kg IV q 8 h) are good choices. Metronidazole (10 mg/kg IV slowly q 8 h) is an excellent antibiotic choice for most anaerobic infections. Intravenous metronidazole should be administered over 30 to 40 minutes because rapid infusion can lead to hypotension.

In severe cases of bacterial meningoencephalitis, it may be prudent to institute combination antimicrobial therapy while awaiting CSF laboratory results (Gram stain, culture results). Based on information concerning causative agents in canine bacterial meningoencephalitis, inclusion of antibiotics with strong activity against Gram-negative bacteria is highly recommended. Once a positive response to intravenous antibiotic therapy is achieved, the patient can be switched to oral therapy. Trimethoprim-sulfonamide (15 mg/kg PO q 12 h) is broad and bactericidal, and it readily penetrates the BBB, even when the BBB is not inflamed. Oral formulations of enrofloxacin and metronidazole are also available. Recommendations for the length of oral antibiotic therapy vary. Discontinuation of antibiotic therapy is ideally based both on clinical signs as well as normal follow-up CSF tap results. However, the latter-mentioned information is often not available. Antibiotic therapy should be administered for 10 to 14 days after resolution of clinical signs of disease. Glucocorticoid use in the face of infection is theoretically contraindicated, but there is evidence that transient (maximum of 4 days), anti-inflammatory doses of glucocorticoids improve outcomes in people with bacterial meningitis.[9] Such therapy should be considered for dogs and cats with this disorder. If CT or MR imaging localizes a surgically accessible abscess, surgical intervention may play an important role in the management of bacterial meningoencephalitis. Unfortunately, there are no reports describing large groups of dogs or cats treated appropriately for confirmed bacterial meningoencephalitis.

The sparse information available suggests a poor prognosis overall. Similar to human bacterial CNS infections, the key to successfully treating dogs and cats with bacterial meningoencephalitis is early diagnosis and rapid, aggressive therapy.

Fungal Meningoencephalitis

There is a wide variety of fungal organisms that may invade the CNS, including *Cryptococcus* (see ch. 231), *Coccidioides* (see ch. 232), *Blastomyces* (see ch. 233), *Histoplasma* (see ch. 233), *Aspergillus* (see ch. 234 and 235), and the phaeohyphomycoses (e.g., *Cladosporium*; see ch. 236). *Cryptococcus neoformans* is by far the most common fungal organism associated with meningoencephalitis in dogs and cats. Meningoencephalitis due to coccidioidomycosis has been reported in 36 dogs.[20] Fungal disease is typically contracted by dogs and cats via inhalation of fungal spores. Infection of the CNS can occur via local extension (e.g., nasal/frontal sinus) or hematogenously. Similar to bacterial meningoencephalitis, dogs and cats with fungal meningoencephalitis are often young to middle-aged. Although clinical signs of neurologic dysfunction may be acute in onset and rapidly progressive, fungal meningoencephalitis is often characterized by slow progression (weeks to months) of neurologic dysfunction, often preceded by a period of nonspecific illness (e.g., lethargy, anorexia). Clinical evidence of extraneural fungal infection is common in cases of fungal meningoencephalitis. With cryptococcosis, extraneural infection around the head region (eyes, nasal and frontal sinuses) is most likely. With coccidioidomycosis, initial infection of the pulmonary system is typical.

The diagnosis of fungal meningoencephalitis is based upon identifying the presence of a fungal organism in a patient displaying signs of encephalopathy. Finding a fungal organism in an extraneural site in a patient with brain dysfunction is strong evidence for fungal meningoencephalitis. Brain imaging (preferably MRI) is likely to demonstrate intraaxial lesions that strongly contrast enhance (Figure 261-4). These fungal granulomas often have evidence of substantial perilesional edema. Identifying the organism in a CSF sample is the strongest evidence to support the diagnosis, and this is more likely to occur with *Cryptococcus* infections than with other fungal infections (see ch. 115). Special stains are available to help identify specific fungi on cytology specimens. CNS fungal infections typically cause a mixed-cell pleocytosis with elevation of protein on CSF examination. The nature of the pleocytosis is highly variable but usually includes a large proportion of both mononuclear cells as well as neutrophils, typical of a granulomatous disease. In the report of dogs with intracranial coccidioidomycosis, mononuclear pleocytosis was most commonly demonstrated, followed by mixed-cell pleocytosis. Eosinophils may also constitute a large proportion of CSF white blood cells in fungal meningoencephalitis patients. Testing of CSF and/or serum for antibodies to fungal antigens can also be performed. These tests are very reliable for *Cryptococcus*, *Coccidioides*, and *Blastomyces* infections, less so for *Aspergillus* infections, and unreliable for *Histoplasma* infections. No such tests are available for the phaeohyphomycoses. The various fungi can also be cultured from bodily fluids, using special growth media; this can be hazardous to human health in the case of blastomycosis, coccidioidomycosis and histoplasmosis.

Bloodwork abnormalities are variable and nonspecific. Fungal elements may be identifiable in urine samples. Ophthalmic examination may show evidence of inflammatory disease (e.g., uveitis, chorioretinitis; see ch. 11). Pulmonary lesions may be identifiable in some cases (e.g., *Histoplasma, Blastomyces, Coccidioides*) on thoracic radiographs. Cats with suspected or confirmed fungal meningoencephalitis should be tested for feline leukemia virus (see ch. 223) and feline immunodeficiency virus (FIV; see ch. 222).

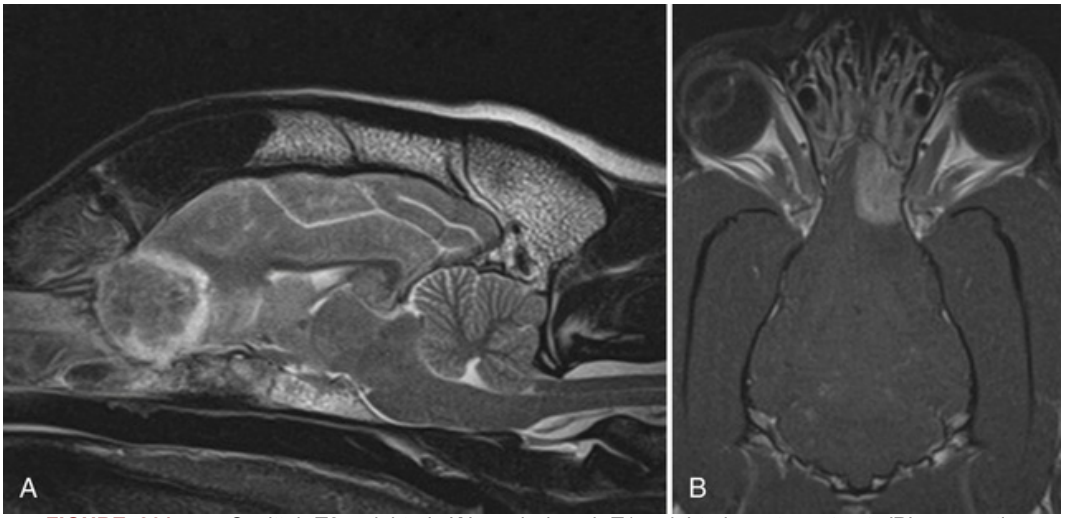

FIGURE 261-4 Sagittal T2-weighted **(A)** and dorsal T1-weighted post contrast **(B)** magnetic resonance images of a dog with a cryptococcal granuloma.

Treatment and prognosis for canine and feline fungal meningoencephalitis are poorly defined. Although antifungal drugs constitute the mainstay of treatment for these cases, surgical removal/debulking of large intracranial granulomas may sometimes be indicated. Similar to bacterial meningoencephalitis, data describing large numbers of dogs and cats with CNS fungal disease treated with appropriate antifungal agents are lacking. Meningoencephalitis caused by *Aspergillus* or phaeohyphomycosis species is likely to be fatal. Few antifungal drugs are able to cross the BBB effectively, even when inflamed. Flucytosine (5-fluorocytosine) and the triazole drug fluconazole are two antifungal drugs that readily cross the BBB. There are several reports of sustained remissions or cures in CNS cryptococcosis patients treated with drug combinations that included flucytosine and/or the newer triazole drugs (itraconazole and fluconazole). Flucytosine use alone may lead to the development of drug resistance. In a report of 36 dogs with intracranial coccidioidomycosis, 84% of dogs improved or resolved with fluconazole therapy.[20] Once clinical signs of disease are controlled, most patients with fungal meningoencephalitis will require long-term antifungal therapy (months). In the author's experience, fluconazole therapy for fungal meningoencephalitis cases may need to be very prolonged. In the report of 36 dogs with coccidioidomycosis meningoencephalitis, the minimum treatment time was one year.[20] The decision of when to discontinue antifungal therapy should be based upon clinical signs, repeat CSF results, and CSF/serum titers for the organism (if appropriate). Because fluconazole penetrates the BBB well and itraconazole does not, fluconazole for CNS fungal infection is the preferred antifungal agent (5 mg/kg PO q 12 h). The main drawback of fluconazole use is the high cost of the drug. Although controversial, it may be beneficial to administer low dosages of oral prednisone (e.g., 0.5 mg/kg q 12 h) in the early treatment period (1 to 2 weeks), in order to combat perilesional edema.

Viral Meningoencephalitis

The most frequently encountered viral infections of the brain in dogs and cats in clinical practice are canine distemper (paramyxovirus; see ch. 228) virus and feline infectious peritonitis (FIP-coronavirus; see ch. 224) virus, respectively. Other, less common causes of viral meningoencephalitides include rabies virus (dogs and cats; see ch. 226), FIV (a lentivirus; see ch. 222), canine herpesvirus (see ch. 228), feline parvovirus (panleukopenia virus; see ch. 225), feline Borna disease virus (BDV; see ch. 270), pseudorabies (dogs and cats, caused by a porcine herpesvirus; see ch. 228), and West Nile virus (a mosquito-borne flavivirus; see ch. 228). CNS involvement is rarely reported in association with canine adenovirus (infectious canine hepatitis virus), canine parainfluenza virus (also a paramyxovirus), and canine parvovirus. There are multiple routes of viral

infection, but inhalation is most common. Rabies is typically contracted via bite wounds from infected animals, and pseudorabies from ingestion of infected raw pork meat. FIV may be spread via bite wounds. Viruses can damage brain parenchyma via both direct (e.g., cytolytic) and indirect (e.g., immune-mediated) effects. Some viruses have a predilection for neuronal and glial cells and are termed "neurotropic." Such viruses include the causative agents of canine distemper, rabies, pseudorabies, and feline Borna disease.

As with other CNS infectious diseases, affected animals are often young to middle-aged. Viral CNS infections typically run an acute to subacute course but may be peracute (e.g., pseudorabies) or insidious (FIP) in onset and progression. Clinical signs of multifocal encephalopathy are common. Extraneural signs (e.g., fever, ophthalmic disease, respiratory disease) of viral infections may or may not be present. In canine distemper meningoencephalitis, historical or clinical evidence of gastrointestinal and/or respiratory disease prior to or concurrent with neurologic dysfunction are classic findings supportive of the diagnosis. Hyperkeratosis, or "hard pad," affecting the footpads and/or planum nasale is another classic yet inconsistent indicator of canine distemper infection. Other extraneural manifestations of distemper virus infection in dogs include mucopurulent conjunctivitis, mucopurulent rhinitis, and chorioretinitis (see ch. 11). Extraneural involvement can be either nonexistent or subclinical and therefore may not be appreciated. Myoclonus (repetitive, rhythmic muscular contraction) involving one or more limbs and/or muscles of the head is a relatively specific and common clinical finding in canine CNS distemper infection (see ch. 31). Myoclonus is thought to be due to abnormal pacemaker activity in neurons damaged by the virus. "Chewing gum fits"—rhythmic jaw movements displayed by some dogs with CNS distemper—may represent a form of myoclonus or focal seizure activity. FIP (coronavirus) infection of the CNS is typically associated with the noneffusive form of the disease. Historical and clinical signs of systemic disease (e.g., fever, weight loss) are common in cats with coronavirus meningoencephalitis. Multifocal encephalopathy is common, often with brainstem and cerebellar dysfunction.

A poor to nonexistent vaccination history in an acutely encephalopathic dog or cat with possible exposure to wildlife or other nonvaccinated dogs or cats should alert the clinician to consider rabies (see ch. 226). The typical "furious" and "paralytic" forms of rabies have been described. The furious form is more common in cats and is characterized by apprehension and aggression, suggesting primarily forebrain dysfunction. The paralytic form, encountered more frequently in dogs, is characterized by lower motor neuron dysfunction of brainstem nuclei, leading to a dropped jaw (cranial nerve [CN] V) and swallowing difficulty with attendant ptyalism (CNs IX to XI). Respiratory difficulty and gait abnormalities may also be apparent. Focal and/or generalized seizure activity may occur with either form of rabies. Dogs and cats with rabies may present with a wide variety of clinical signs of neurologic dysfunction, and the previously mentioned forms of rabies should be viewed as very rough guidelines.

Diagnosis of viral meningoencephalitis is usually made at necropsy. Identification of causative virus in brain parenchyma through various methods (e.g., visualizing inclusion bodies, immunocytochemistry, viral isolation) and the appearance of characteristic histologic patterns (e.g., pyogranulomas in FIP, demyelinating brainstem lesions in canine distemper) help confirm a diagnosis of a specific viral-induced encephalopathy. In the case of an unvaccinated dog or cat that has died or was euthanized because of brain disease (of recent onset) and has had exposure to people (especially bite wounds), examination of the brain (e.g., direct fluorescent antibody test) for rabies is mandatory. The antemortem diagnosis of viral meningoencephalitis is often difficult and relies on combining characteristic historical and clinical findings with several diagnostic tests. Specific and reliable diagnostic tests for viral meningoencephalitis are lacking. Intuitively, identifying the presence of a viral agent in a patient displaying encephalopathic signs would support that virus as being the causative factor. However, identifying virus or viral antigen in body tissues or fluids is usually unsuccessful. The indirect fluorescent antibody test for canine distemper, usually performed on conjunctival scrapings, buffy coat smears, and/or urine sediment, may produce too many false-negative and false-positive results to be of much clinical use. Identification of circulating antibody against various viruses in the blood and CSF can be readily accomplished. Because the patient may have been exposed naturally or intentionally (vaccination) to a suspect viral pathogen in the past, a positive serum antibody titer often has little clinical meaning. Similarly, in a patient previously immunized for a specific viral disease, demonstrating a positive titer in the CSF for that viral agent has little meaning. If the BBB is disrupted for any reason, the serum antibodies can passively move to the CSF. Demonstrating a gradient of titers (i.e., CSF titer for an antiviral antibody higher than the serum titer) is more definitive evidence of that virus as the causative agent.

More recently, the use of a one-step, reverse transcriptase-polymerase chain reaction (RT-PCR) test to amplify canine distemper virus–specific RNA products in serum and CSF has been described. This PCR procedure appears to be a specific antemortem test for canine distemper virus infection. The authors have had a number of positive RT-PCR results for coronavirus from CSF procured from cats with suspected or proven

neurologic FIP. The sensitivity and specificity of RT-PCR for CSF in neurologic FIP are currently unknown, but it is likely that this test is sensitive but not specific for neurologic FIP. Some basic laboratory tests may provide supportive evidence for specific viral infections, if abnormal. Lymphopenia may occur with canine distemper infections (see ch. 228), and hyperglobulinemia is common with FIP infections (see ch. 224). Ophthalmic examination may provide valuable clinical evidence in some diseases (e.g., hyperreflective retinal lesions in canine distemper; see ch. 11).

CSF values are often abnormal with viral meningoencephalitis. Immature dogs with distemper affecting primarily gray matter may have normal CSF results. The characteristic CSF analysis results of a patient with CNS viral disease consist of predominantly mononuclear (lymphocytic) pleocytosis with elevated protein. The exception to this rule is CSF from FIP patients. The coronavirus tends to induce an intense immune response in this disease, and the predominant cell type in FIP meningoencephalitis is usually the neutrophil, with variable numbers of lymphocytes and macrophages (a pyogranulomatous response). CSF IgG titers to feline coronavirus are probably not diagnostically useful.

Advanced imaging (CT/MRI) may demonstrate brain lesions (e.g., contrast-enhancing regions of inflammatory foci) in some cases of viral meningoencephalitis. Although brain imaging is unlikely to reveal specific characteristic abnormalities in most cases, it may be useful to rule out other diseases (e.g., intracranial intraarachnoid cysts in young dogs and cats). Hydrocephalus may be a common sequela to FIP meningoencephalitis that can be appreciated on a CT or MR image. Periventricular contrast enhancement has also been described in MR brain images of cats with FIP meningoencephalitis. Cats with confirmed FIP meningoencephalitis may have normal MR brain images.

There are no effective antiviral agents available for viral meningoencephalitis, and the prognosis for these diseases is generally poor to grave for survival. Rabies and pseudorabies are rapidly progressive and invariably fatal (often from respiratory failure) within 1 week and 48 hours of the onset of clinical signs, respectively. FIP typically progresses over several weeks and is also invariably fatal. Most dogs with CNS distemper infections die or are euthanized due to progressive neurologic dysfunction. However, clinical signs of disease may remain static or improve in some dogs, and survival is possible with proper nursing care. Anti-inflammatory doses of prednisone are often prescribed to lessen the secondary effects of viral infection on CNS tissue in these cases. FIV-associated encephalopathy appears to have a chronic course without progression of clinical signs in many cases.

Other Infectious Diseases

Other infectious organisms that may lead to multifocal encephalopathy in dogs and cats include rickettsial (e.g., ehrlichiosis, Rocky Mountain spotted fever [RMSF] in dogs; see ch. 218), protozoal (e.g., *Toxoplasma* in dogs and cats, *Neospora* in dogs; see ch. 221), and verminous (e.g., *Cuterebra* in cats) agents. *Toxoplasma gondii* and *Neospora caninum* are protozoal agents known to occasionally cause meningoencephalitis in dogs. *Toxoplasma* has also been reported to cause meningoencephalitis in cats. Experimental infection of cats with *Neospora* may lead to meningoencephalitis, but no naturally occurring cases have been reported. Canine and feline meningoencephalitis due to an organism that appears to be *Sarcocystis* has also been reported.

For rickettsial and protozoal infections, antemortem diagnosis is usually based upon serologic testing for the presence of the offending organism (i.e., rising antibody titers), in conjunction with other supporting evidence (e.g., thrombocytopenia in a dog with RMSF infection). Unfortunately, diagnosis of verminous meningoencephalitis requires identification of the parasite, which is often not possible. Advanced imaging (preferably MRI) may demonstrate contrast-enhancing brain lesions with these infections, and CSF results are likely to be abnormal. Varying distributions of cell types have been reported for CSF analyses from patients with these infectious disorders.

Drugs used to treat dogs with rickettsial meningoencephalitis include doxycycline, chloramphenicol, and enrofloxacin. Clindamycin or sulfonamides combined with trimethoprim or pyrimethamine are recommended for protozoal meningoencephalitis. In suspected cases of CNS cuterebriasis in cats, ivermectin treatment is recommended. These cats should be pretreated with diphenhydramine and glucocorticoids in order to ameliorate allergic reactions to dead and dying intracranial larvae. In addition, it is recommended to treat these cats for 2 weeks with antibiotics (e.g., amoxicillin/clavulanic acid) after ivermectin treatment, to minimize the likelihood of secondary bacterial meningoencephalitis.

Degenerative and Anomalous Disorders of the Brain (see also ch. 260)

Degenerative brain disorders that may cause multifocal or diffuse encephalopathy are numerous and include

lysosomal storage diseases, mitochondrial encephalopathies, and organic acidurias. These categories of degenerative diseases comprise a wide variety of inherited (primarily autosomal recessive) abnormalities, which have in common the intracellular accumulation of one or more products of an interrupted degradative metabolic pathway. The metabolic defect is responsible for the development of intracranial disease, typically via an accumulation of by-product(s) that will lead to cellular dysfunction, presumably due to cellular swelling, a toxic effect of the accumulated material(s), or both. In general, diagnosis of these diseases requires either identifying the specific enzymatic defect, an accumulation or storage product, and/or a defective gene responsible for the abnormality. At present, treatments are limited for these disorders and the prognosis is often guarded to poor. There are a number of anomalous brain disorders that can lead to multifocal or diffuse clinical signs of brain dysfunction. These include caudal occipital malformation syndrome (COMS, also known as *Chiari type I malformation* and *occipital bone hypoplasia*), intracranial arachnoid cysts, and congenital hydrocephalus. These disorders are best diagnosed with MR imaging and treated with a combination of surgical and medical management (Figure 261-5).

CHAPTER 262

Sleep Disorders

Brian M. Zanghi

Client Information Sheet: Sleep Disorders of Dogs and Cats

Sleep is a complex physiological process driven by an active neurobehavioral state maintained by the central nervous system. Ultimately, sleep plays an essential restorative function for both physical and cognitive purposes, and is an indispensable function of a healthy life. Naturally occurring sleep disorders are relatively uncommon in cats and dogs. In all types of sleep disorders, the condition can vary from subtle to severe, but may also indicate another underlying neurological disease. Having some familiarity with both normal and abnormal sleep will assist in diagnosing sleep-associated abnormalities.

Normal Sleep

Sleep is not a passive resting state, but is a dynamic physiology that is controlled by very active neurological processes.[1] Peak hours of "normal" locomotor activity or sleep in healthy cats and dogs are influenced by feeding frequency,[2-4] age,[2,3,5] housing (indoor and/or outdoor),[6] and daily schedule of the pet-owner.[7,8] In addition, activity during wakefulness, and rest during periods of sleep, can be influenced by many other factors including environmental light, temperature, presence of other animals, and/or hunger. Therefore, considering a pet's home environment, age, feeding pattern, and owner's schedule will assist in assessing the individual pet's "normal" sleep pattern and influencing factors, and thus assist in evaluating an intrinsic sleep disorder or extrinsic sleep disturbance prior to conducting a more thorough diagnostic evaluation.

The chronobiology and characteristics of sleep have been well documented in humans and rodents over the past several decades.[9-15] In addition, an understanding of the normal characteristics of electroencephalography (EEG)-measured sleep in dogs[16-19] and cats[20-23] exists. Normal sleep consists of rapid eye movement (REM) and non-REM (or slow wave sleep; SWS) sleep states, which all mammalian species experience. The process of sleep begins with transition into SWS, followed by REM sleep, then a brief state of wakefulness before re-entering the cycle and re-initiating SWS.[16,18] SWS stages and REM sleep are best determined by polysomnography (PSG) that allows for the simultaneous generation of EEG, electro-oculogram (EOG), and/or electromyography (EMG) data, that are summarized to generate a hypnogram (Figure 262-1). Although PSG is considered to be the "gold standard" in determining sleep/wake status, it is difficult to conduct in a normal clinical setting because it is time consuming, expensive, and requires attachment of multiple electrodes in a manner that prevents dislodgement. Consequently, PSG is largely limited to experimental use and not offered clinically.

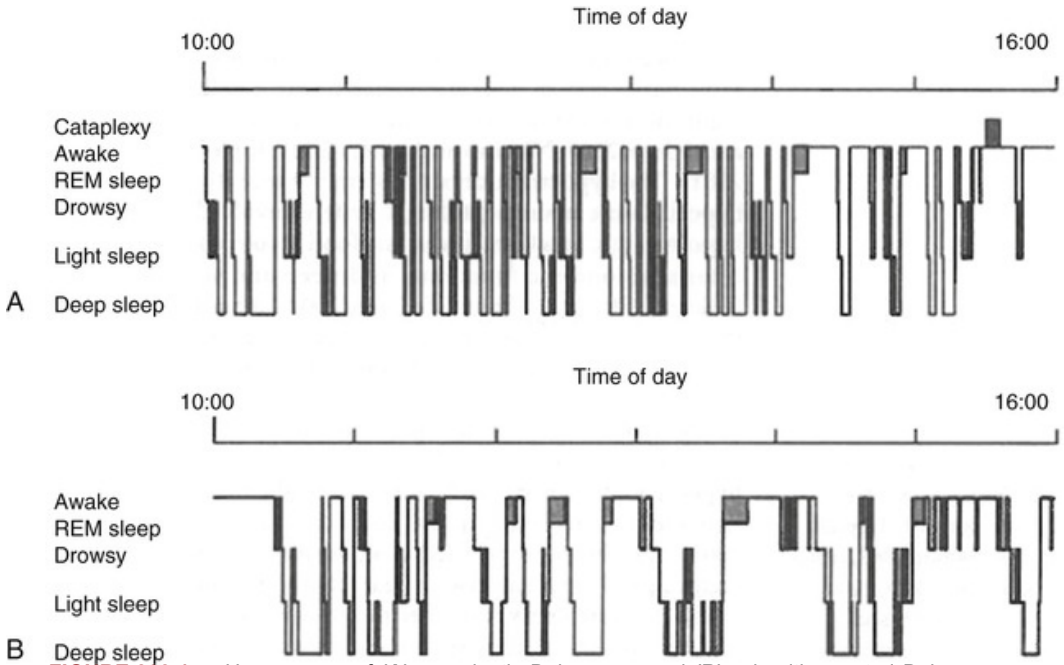

FIGURE 262-1 Hypnograms of **(A)** narcoleptic Dobermann and **(B)** a healthy control Dobermann. The recordings were carried out by cortical electroencephalography (EEG) and neck muscle electromyography (EMG) monitoring with chronically implanted electrodes (Shelton and coworkers, 1995). Sleep was scored on the basis of the EEG and EMG signals and each 30-second period was classified as wake, drowsy, light sleep, deep sleep, or rapid eye movement (REM) sleep (or cataplexy for the narcoleptic dog). (Used with permission from Tonokura M, Fujita K, Nishino S: Review of pathophysiology and clinical management of narcolepsy in dogs. *Vet Rec* 161:375-380, 2007.)

The relative proportions of different sleep and wake states observed in kennel-housed dogs are generally similar across multiple studies.[16-19] Wakefulness of adult dogs predominates during the day, comprising 7-8 hours of the 12-hour day[19,24] compared to ≈5 hours during the night. In contrast to dogs, cats housed with 12-hour light/dark cycles exhibit typical nocturnal behavior (awake/drowsy state 42% of light phase versus 53% during the dark phase).[23]

Geriatric Changes in Sleep and Circadian Rhythm

As in humans,[25,26] age-related changes in PSG-measured sleep/wake rhythms occur in the dog,[27] and awareness by dog-owners that activity declines with advancing age has been reported.[28-30] Senior dogs (>9 years) can experience lower locomotor activity, more daytime sleep, decreased REM sleep, fragmented sleep during the day (more naps, not longer naps), and increased night-time PSG-wakefulness.[3,27,31] However, it is undefined if night-time sleep disruptions reported by pet-owners are related to increased night-time PSG-wakefulness or are a symptom of other age-related behavioral/physical change.

Age-related sleep changes in people are linked to circadian rhythm disruptions,[25,26,32,33] which is also linked to cognitive dysfunction, such as in Alzheimer's patients, who experience significantly more daytime sleep, disrupted nocturnal sleep,[34] and exaggerated hyper- and hypoactivity.[35,36] Cognitively impaired dogs[31] also experienced a delay in peak activity (circadian rhythm shift), but in the absence of cognitive dysfunction, this does not appear to occur as a consequence of advanced age.[2] The relationship between advanced age, behavioral sleep/activity patterns, and cognitive impairment has only been initially explored in dogs.[31,37,38] In addition, age-related (9-15 years old) hyperactivity appears associated with a progression of multiple cognitive domain dysfunction,[31,37] but not single domain,[38] and if severe, may be best treated through addressing the underlying cognitive impairment. (See ch. 263, cognitive dysfunction syndrome [CDS] in dogs).

Diagnostic Approach

Sleep disorders are either primary or secondary. Secondary sleep disorders may result from encephalitis,

intracranial masses, trauma, drug administration, or other disease processes. In addition to a thorough history, physical and neurologic examination (see ch. 2 and 259), an owner video of the event is invaluable if it occurs during sleep, since most animals will not relax enough to sleep at the veterinarian's office. Information about the time of onset of the event after sleep, duration, and whether the animal can be roused from it will help the veterinarian determine whether this is likely to be a sleep disorder. The possibility of a true seizure must be ruled out, since most animals have the onset of epileptic seizures during sleep. Conversely, a sleep disorder should be considered a possibility in an animal treated for suspected epilepsy with minimal or no response to appropriate doses of anticonvulsant medication.

Systemic screening with blood work and radiographs of the thorax and abdomen or abdominal ultrasound will rule out other diseases. Abnormalities on neurologic examination should increase suspicion for primary CNS disease, but intracranial imaging with magnetic resonance imaging (MRI) and cerebrospinal fluid (CSF) analysis are necessary to rule out structural brain disease or infectious or inflammatory disease. If intracranial disease is identified in a patient with a sleep disorder, treatment of the primary disease should be attempted, if possible, prior to any specific treatment of the sleep disorder, as it may be secondary to underlying brain disease.

REM Sleep Behavior Disorder

During REM sleep, normal inhibition of motor neurons causes most muscles to become atonic. Exceptions exist with minor and/or random contractile activity of diaphragm, intercostals and small distal muscles of the face, paws, larynx and tail.[39-42] This localized muscular activity results in the hallmark twitching of the eyes, as well as face, larynx, and paws, with minor coordinated contraction sometimes leading to a paddling of all four limbs (paddling not in cats)[39,41] representing a "dreaming" state. In REM Sleep Behavior Disorder (RBD), no muscle atonia is present and significant coordinated movement occurs. Movements often result in violent limb movements,[39,41,43] but can also present as chewing and teeth grinding, biting at air or bedding, and/or attacking the owner or another dog.[43]

In people, the diagnosis of suspected RBD is based on both clinical and PSG criteria,[44] which requires (1) the PSG-determined REM sleep without atonia, (2) documented PSG abnormality during REM sleep (elevated EMG tone and/or excessive phasic limb twitching), and (3) absence of an EEG epileptiform activity during REM sleep. Because of the rarity of RBD in veterinary medicine, little need exists to use PSG in cases with suspected RBD. Therefore, the diagnosis of RBD in the majority of veterinary cases has relied on (1) a description of the clinical signs that are characteristic of RBD behaviors and (2) examination of video recordings of the sleep events.

Reports provided by pet-owners revealed that in 93% of RBD dogs (13 of 14 cases) the RBD events were unsuccessfully treated with melatonin, gabapentin, diazepam, diphenhydramine, acepromazine, clonazepam, or phenobarbital.[41,43] However, dose and frequency of these medication treatments were not reported by clients during the study review survey.[43] Potassium bromide (44 mg/kg/day) decreased the severity and frequency of client reported RBD events in 78% of the dogs (11 of 14 cases).[43] In addition, longer-term (6-month) reduction of RBD episode severity during night-time sleep was observed with clomipramine starting at 1 mg/kg PO q 12 h and progressively increasing dosage to 4 mg/kg PO q 12 h by 12 weeks.[45]

Sleep-Disordered Breathing or Sleep Apnea

Sleep apnea is a common problem in humans. The characteristics of sleep-disordered breathing (SDB) include normal arterial oxygen saturation when awake, but disordered respiration and episodes of oxygen desaturation when asleep, particularly in REM sleep, frequently causing awakening. Hypersomnolence, or excessive daytime sleepiness, is also present, likely a result of continually interrupted sleep. The brachycephalic conformation has anatomic features (stenotic nares, elongated soft palate, hypoplastic trachea) that will increase upper airway resistance and can cause an obstructive breathing pattern (see ch. 238). Clinically, the respiration of a brachycephalic dog can be exacerbated by excitement or exertion (increased passage of air), or when the pharyngeal region is relaxed (anesthesia, sedation, sleep).

The English Bulldog has been proposed as a natural model of SDB. Bulldogs demonstrated marked oxygen desaturation in REM sleep, paradoxical breathing patterns (unsynchronized thoracic and abdominal movements), and awakening from events of apnea.[46,47] These dogs also fell asleep faster than control dogs, suggesting hypersomnolence. Clinical improvement of the hypersomnolence was noted in one dog in which upper airway surgery was performed to alleviate clinical signs.[46] Bulldogs were also used to evaluate

effectiveness of various experimental drug therapies with serotonergics.[48-50]

Narcolepsy (Narcolepsy-Cataplexy)

Narcolepsy occurs in animals and humans, and is a chronic sleep disorder of neurological origin characterized in dogs by excessive daytime sleepiness and/or very pronounced cataplexic attacks (sudden loss of muscle tone). Because affected dogs share very similar clinical characteristics to humans with narcolepsy/cataplexy, a great deal of research has been conducted with affected dogs to determine the underlying pathology, which has facilitated criteria for positive diagnosis of primary narcolepsy for both animals and humans.

Forms of Primary Narcolepsy and Pathophysiology

Primary canine narcolepsy exists as familial or sporadic, and is estimated to have a very low prevalence in dogs (less than 0.2%).[51] The sporadic form is the most common and has been observed in over 17 breeds[51,52] with initial onset occurring over a wide range of ages (7 weeks to 7 years). For familial affected dogs, onset occurs before 6 months of age[53,54] and is a result of a mutation in the hypocretin-receptor-2 gene *(Hcrtr 2)* that is heritable through classic Mendelian genetics. Etiology of both forms is associated with a deficit in hypocretin neurotransmission.[52,55]

Clinical Signs of Narcolepsy

The diagnosis of narcolepsy in dogs is mainly focused on the occurrence of cataplexy that can manifest as a mild loss of skeletal muscle tone or muscle weakness, likely observed as a buckling of both hind legs and possibly accompanied by a drooping of the neck. In mild conditions, the dog may appear drowsy or struggling to resist "sleepiness," whereas more severe attacks can be a complete paralysis and collapse lasting from a few seconds to a few minutes. Excessive salivation and incontinence are not observed during a cataplectic attack, as in seizures. Because narcolepsy is a sleep disorder, dogs experiencing prolonged cataplectic attacks may experience characteristics of REM sleep. Following a cataplectic attack, dogs will get up and resume normal activity, or possibly go into normal sleep.

Diagnosis

For proper diagnosis, it is important to rule out cataplectic attacks resulting from other episodic disturbances like seizures or syncope.[56] Owner-reported information about previous attacks and age of onset is also helpful to evaluate how and when the attacks occur.

Because cataplectic attacks can be triggered by positive emotional experiences, an attack can be elicited by engaging play or being offered a favorite food reward. Therefore, cataplexy can be clinically assessed by using the food-elicited cataplexy test (FECT).[57] However, if the dog is nervous during the examination it may not exhibit the attacks, thus in-home testing with video recording would be beneficial. Video clips of typical cataplexy attacks and FECT are included (Videos 262-1 and 262-2), as well as available online through the Stanford School of Medicine, Center for Narcolepsy website at http://med.stanford.edu/psychiatry/narcolepsy (2014).

Measuring the concentration of hypocretin-1 peptide (<80 pg/mL; normal = 250 to 350 pg/mL) in the CSF is the most specific and sensitive diagnostic tool for diagnosing the sporadic form of narcolepsy.[55] Cases with the familial form that results from a mutation in *Hcrtr 2* receptor gene have "normal" CSF hypocretin concentrations, and thus does not exclude a diagnosis of narcolepsy.[55]

If a mild form of narcolepsy/cataplexy is suspected, a drug challenge may be useful for diagnosing dogs and is well tolerated. Increased cholinergic activity for triggering REM sleep has been established[57] and centrally active acetylcholinesterase inhibitors (physostigmine salicylate; 0.025-0.1 mg/kg IV) increase the frequency of cataplectic attacks within 15 min in narcoleptic dogs, but have no effect on normal, non-narcoleptic dogs. Starting with the lower dosage range is recommended because of possible adverse effects of salivation and diarrhea.

Treatment and Prognosis

The treatment of narcolepsy in animals is aimed primarily at reducing the frequency and duration of cataplectic attacks. Dogs with mild to moderate cataplectic attacks may be best treated by avoiding the inciting cause, thus limiting the play experiences or behaviors that trigger a cataplectic episode. For multiple-dog households, feeding narcoleptic dogs in a separate location and/or time from other dogs may reduce episodes. Efficacy at reducing, but not curing, cataplectic episodes has been demonstrated with both a change in routine and oral administration of various drugs (Table 262-1). Activation of the adrenergic systems that inhibits cataplexy is the main form of treatment.[57] Recording the frequency of cataplectic attacks and the time to finish a meal when attacks occur is useful for judging the efficacy of the treatment and daily dosage.

TABLE 262-1

Anticataplectic Drugs for Treating Narcolepsy in Dogs

DRUG TYPE	COMPOUND	DAILY DOSAGE (mg/kg PO)	HALF-LIFE (hours)	SIDE EFFECTS (class)	COMMENTS	REFERENCES
Tricyclic antidepressant	Imipramine	1.5-3	5-30	Vomiting, anorexia, lethargy, diarrhea, anticholinergic, antihistaminergic	Care should be taken if the dog has epilepsy	57-59
	Clomipramine	3-6	15-60			57
	Desipramine	3 twice daily	10-30			57, 61
Serotonin/noradrenaline uptake inhibitor	Venlafaxine	6-12	4*	No anticholinergic side effects		62
Alpha-2 adrenergic antagonist	Yohimbine	0.045 twice daily†	<1	Seizures, excitement, muscle tremor, ptyalism		61

*Active metabolite is O-desmethylvenlafaxine, which has an 11 hour half-life.

†Tolerance may develop and clinical signs are moderately well controlled with altering monthly regimen between yohimbine and desipramine.

Canine narcolepsy is neither progressive nor life-threatening, but requires proper care by the pet-owner throughout the life of the pet. The pet's quality of life can be maintained with understanding by the pet-owner about the disease so that provisions can be made to the pet's environment to improve safety. Care should include the use of unbreakable food bowls, elevated water bowl (possibly at shoulder level) should the pet experience a cataplectic attack near the bowl or while drinking, and possibly also restricting access to stairs.

CHAPTER 263

Cognitive Dysfunction in Aged Dogs and Cats

Gary Landsberg

Client Information Sheet: Cognitive Dysfunction in Aged Dogs and Cats

Advanced age in dogs and cats can be associated with a variety of behavioral changes, including an increase in, or the onset of, fears, phobias and anxiety, increasing irritability and aggression, repetitive disorders, night waking and vocalization, and housesoiling.[1,2] Such signs are consistent with manifestations of pathologic brain aging. However, some of these behaviors instead can be attributable to underlying medical conditions (including other neurologic disorders) and some can be due to primary behavior problems arising from changes in the household. In addition, senior pets can be more stressed and less able to adapt to change than younger ones. Therefore, to determine whether such clinical signs are related to pathologic brain aging, these other medical and behavioral causes first must be ruled out (see ch. 9).

Clinical Signs

Cognitive dysfunction syndrome (CDS) is a neurodegenerative disorder of senior dogs and cats that is characterized by behavioral changes in an array of domains, which are believed to be cognitively based, and is associated with the development of distinct patterns of brain lesions. CDS is not an inevitable consequence of aging in dogs and cats, and individual differences are more likely the rule than the exception. Some aged animals show only mild behavioral signs, while others develop severe or multiple signs, which can include a decline in awareness, altered response to stimuli, and deficits in learning and memory, all of which can disrupt normal function and dramatically reduce quality of life. Clinical signs of CDS in dogs have been described by the acronym DISHA, which refers to *D*isorientation, altered *I*nteractions with owners or other pets, *S*leep-wake cycle alterations, *H*ousesoiling, and *A*ctivity changes (which might be increased, repetitive, or reduced).[1-4] Additional signs also can include: increasing agitation and anxiety; altered responsiveness to stimuli (i.e., heightened or reduced); altered interest in appetite and/or self-hygiene (i.e., increased or reduced); and decreased ability to perform previously trained commands or tasks. This same constellation of signs also applies to CDS in cats, although prevalence of individual signs can differ.[5,6]

Early detection and intervention might slow further decline, prevent complications, increase longevity, and address the pet's welfare. Signs of CDS often go unreported because veterinarians might not solicit the necessary information and because pet owners can consider the behavioral signs insignificant or untreatable.

The prevalence of CDS has been assessed in a number of survey-based studies. In one, ≈48% of owners of 150 dogs reported that their senior dogs (≥7 years old) exhibited at least one clinical sign of CDS. However, only 17% of these owners reported these signs to their veterinarians (proprietary data, 1999, Pfizer Animal Health). In another study, 180 owners of aged dogs with no identifiable medical problems reported at least one sign consistent with CDS in 28% (aged 11-12 years) to 68% (aged 15-16 years) of dogs.[4] Prevalences of 22.5%[7] and of 5% (10-12 year old dogs) to 41% (dogs >14 years of age) have been reported more recently.[7,8] While overall prevalence was 14.2% (68/479) in the latter study, a diagnosis of CDS was made in only 1.9% (9/479) of all dogs or 13% (9/68) of affected dogs.[8] Further, CDS is a progressive disease with prevalence and severity increasing with age.[7,9] In some studies, females and neutered males have been reported to be more affected than males and intact dogs, respectively.[7,10] However, while females might live longer if spayed, a longer lifespan was not associated with neutering in males, except in giant breeds, which are less likely to reach an age at which CDS would become a clinical concern.[11,12] In a study of cats >11 years old, 35% were diagnosed with CDS (28% of 95 cats aged 11-15 years and 50% of 46 cats >15 years old).[5,6]

The high prevalence and underdiagnosis of CDS make it essential for veterinarians and staff to inform

clients of the importance of reporting these signs for early identification of CDS. Veterinarians should be proactive in asking owners if there has been any change in behavior or any signs that might be indicative of CDS. A behavioral questionnaire should include questions eliciting information about (a) disorientation or confusion, (b) decreased interest in social interactions (e.g., petting, play), (c) altered sleep/waking at night, (d) housesoiling, (e) repetitive activities such as pacing or circling, (f) a decrease in activity or apathy about feeding or self-hygiene, (g) increasing anxiety or irritability, (h) altered response to stimuli (sights, sounds, odors) and (i) decreased responsiveness to previously learned commands.

Laboratory Studies

Questionnaire-based tools used for identifying cats and dogs with CDS provide evidence of global brain dysfunction, but are likely to be insensitive to early and subtle changes in learning and memory associated with pathologic brain aging.[1,5,13] Cognitive dysfunction is most accurately evaluated with the use of neuropsychological tests designed to provide quantitative measures of cognitive function using a standardized test apparatus (Toronto General Testing Apparatus; Figure 263-1). These tests are systematic, standardized, objective, and provide a quantitative measure of age-related cognitive decline.[14-18] In fact, while signs of CDS might not be recognized until ≥11 years of age, neuropsychological tests can identify age-related deficits in learning and memory in dogs and cats as early as 6 years of age.[8,15,18,19] Similarly, functional changes in the neurons of the caudate nucleus result in impairments in information processing in cats as young as 6 years of age.[19] Several cognitive functions assayed with these laboratory-based tasks are also likely to be contributors to the clinical signs that might be noted by pet owners.[20,21] Although these tests generally are too lengthy and complex to be applicable for clinical use, recently researchers have demonstrated that these tasks might be used in a clinical environment to identify cognitive deficits in pet dogs.[22-25]

FIGURE 263-1 Toronto General Test Apparatus (TGTA). This apparatus and computer software are the feline version of the test apparatus for learning and memory tasks. In the discrimination task, the cat would first learn to displace one of the two objects (e.g., yellow circle), randomly placed in one of the two locations, for a food reward. Once the cat can consistently displace the correct object for food, the food is then placed under the opposite object (blue square) until the cat learns to displace the new object consistently (reversal task). (Photograph used with permission of CanCog Technologies.)

In laboratory studies using a battery of reward-motivated neuropsychological tests, several cognitive

domains or functions can be evaluated independently in aged dogs and cats.[18-26] These tests involve simple learning problems such as discrimination tasks in which the animal is presented with two objects that are different in appearance, and one is associated with a food reward (see Figure 263-1 and Video 263-1). Aged dogs and cats can learn these problems, and may not differ from younger animals in rate of learning.[17,27,28] Once dogs and cats have learned a visual discrimination problem, the object-reward contingency can be switched, such that the previously incorrect object becomes the rewarded object. This is called *reversal learning*, a type of cognitive ability that depends upon the intact function of the prefrontal cortex[27,28] (see Video 263-1). Aged dogs and cats, compared to young counterparts, are impaired in their ability to switch to selecting the previously incorrect object, suggesting a lack of ability to modify learned behaviors.[17,26-28] Other behavioral changes that are likely to be associated with prefrontal cortex dysfunction include stereotypical behaviors (such as pacing); changes in personality, including increasing fearfulness, irritability, or aggression; and an inability to inhibit previously learned behaviors (e.g., housesoiling).

The aging process also can affect memory significantly. Spatial memory is measured by the ability of dogs to remember where they last obtained a hidden food reward and is compromised in a subset of aged animals[14-18,26,29,30] (Figure 263-2). Functionally, this type of memory impairment can present clinically in companion animals as disorientation, wandering, and getting lost. Dogs also show age-dependent impairments in their ability to recognize objects seen previously.[14] This type of dysfunction may be reflected in decreased recognition of familiar people or animals. In a laboratory study evaluating feline performance in a holeboard task, aging did not significantly affect spatial learning but memory errors were increased.[30]

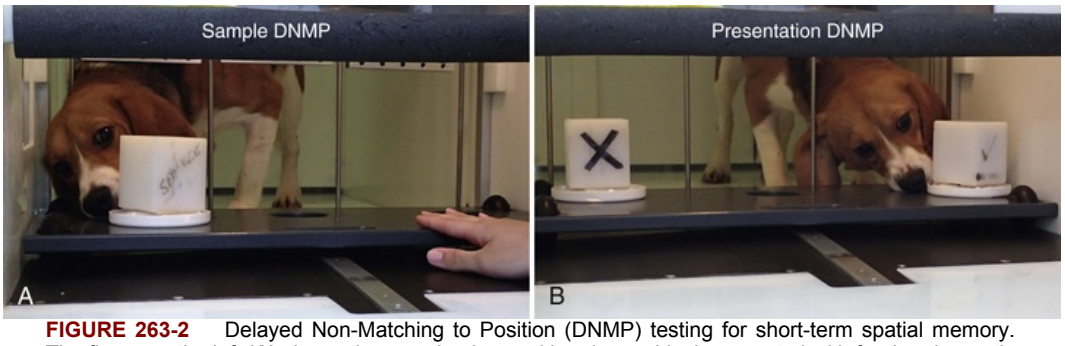

FIGURE 263-2 Delayed Non-Matching to Position (DNMP) testing for short-term spatial memory. The figure on the left **(A)** shows the sample phase with only one block presented with food underneath. The object is withdrawn and this is followed by the presentation phase. During this phase, two identical objects then are displayed, with the non-matching object covering the food. In the figure on the right **(B),** food is located under the new (right) object. Memory can be assessed by increasing the delay between withdrawing the initial object (sample) and offering the two objects (presentation). (Photograph used with permission of CanCog Technologies.)

Age-related behavioral differences also have been demonstrated in reactivity tests.[20,21,31] The curiosity test, for example, allows dogs to examine and play with a variety of toys to assess an animal's reaction and attention to objects. In this 10-minute test, young dogs show significantly more exploration and contact with novel objects than do old dogs, with cognitively impaired aged dogs showing the least object contact.[21] Further, cognitively impaired aged dogs show higher levels of locomotion than do their age-matched unimpaired peers, which could be linked to stereotypy or wandering behavior.[21,31] Measures of exploratory behavior might be more amenable to clinical assessment because they require brief testing sessions and a small test area, suggesting that they may be a useful clinical screen for aged animals with CDS.[21,31]

Neurobiologic Basis

Gross morphologic changes in the aging canine brain include decreased brain mass particularly in the frontal cortex, increased ventricular volume, and meningeal thickening.[27,32] Additional changes can include accumulation of lipofuscin, emergence of apoptic bodies, neuroaxonal degeneration, a reduction in neurons, and demyelination.[32-34]

Aged dogs show neuron loss in the hippocampus, a brain region that plays a critical role in memory.[35] Interestingly, providing aged dogs with behavioral enrichment (outdoor walks, social interaction, play toys,

cognitive training) can lead to maintenance of hippocampal neurons.[35] Aged dogs also lose their ability to generate new hippocampal neurons (i.e., neurogenesis), which is linked to a loss of learning and memory ability.[36] Magnetic resonance spectroscopy studies also have identified an age-related decline in neuronal health.[37]

Aged cats also demonstrate cerebral atrophy, neuronal loss, widening of the sulci, a decrease in gray and white matter volumes, and increased lateral ventricular volumes, although these may not be as marked as in the dog.[6,19,38-40] Changes in the pyriform lobe could be associated with cognitive decline, and a reduction in cerebellar Purkinje cells might be associated with information processing and motor deficits.[5,6,38,40]

At the biochemical level, several changes have been reported in canine aging, including a reduction in cholinergic function and oxidative damage; feline aging is associated with marked atrophy of the cholinergic system in the locus coeruleus.[39-45] The role of oxidative damage is supported by the finding that a diet rich in antioxidants and mitochondrial cofactors can significantly improve cognitive function in aged dogs and cats.[18,46]

Amyloid-beta (A-beta) accumulation in the human brain is one of the earliest pathologic features in the development of Alzheimer's disease and is thought to precede synaptic and neuronal dysfunction, neuronal loss, brain atrophy, and symptoms.[47] The A-beta change in dogs is strikingly similar to that seen in human Alzheimer's disease patients in its peptide sequence, temporal distribution, and biochemistry,[48,49] and cognitive impairment in dogs is correlated with increased A-beta deposition (Figure 263-3).[35,50,51] By contrast, cats >10 years old demonstrate more diffuse A-beta plaques and predominantly a shorter species of the protein.[7,9,48,51-54] Although some studies in cats demonstrate an association between CDS and A-beta lesions, others do not.[51,53,54] In contrast to human Alzheimer's patients, neither dogs nor cats demonstrate neurofibrillary tangles, although hyperphosphorylated tau is reported in both species and it could represent pre-tangle abnormalities.[53-56] Cerebrovascular and perivascular changes, including A-beta accumulation, and periventricular microhemorrhage, or infarcts, also can cause some of the clinical signs associated with cognitive dysfunction in senior pets[2,6,27,32,34,48,50,51,53] (see Figure 263-3). Vascular A-beta may contribute to cerebral hypoperfusion.[57]

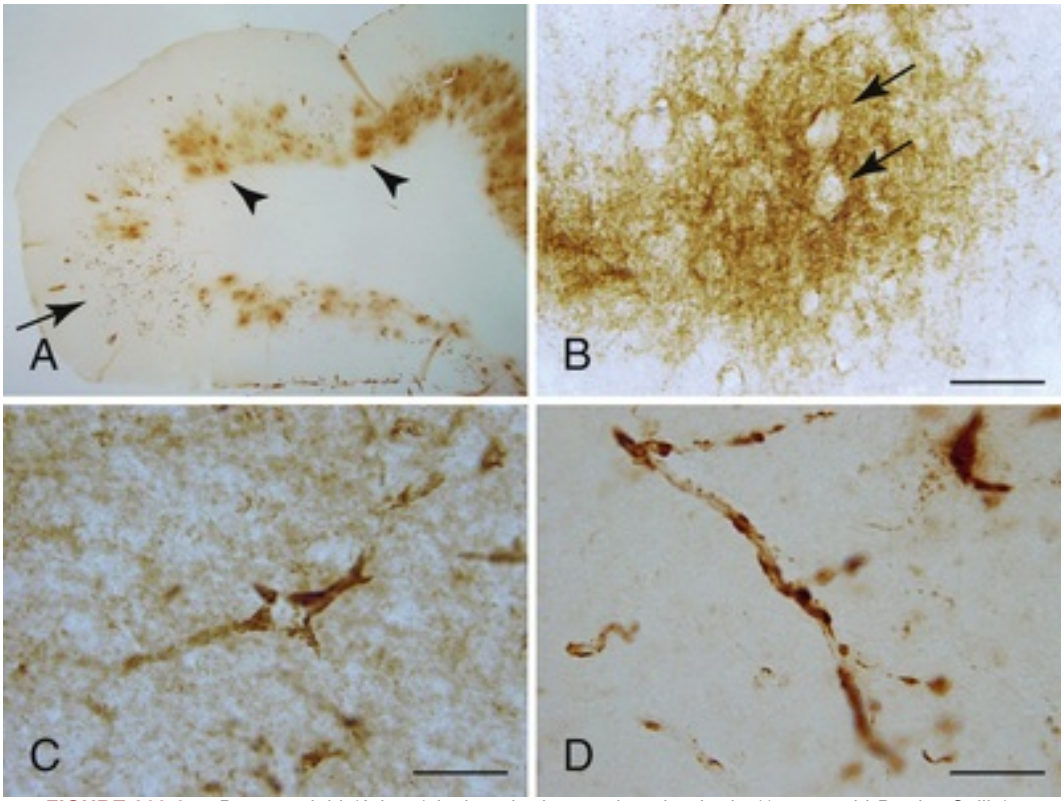

FIGURE 263-3 Beta-amyloid (A-beta) lesions in the aged canine brain (15-year-old Border Collie). **A,** A-beta accumulates extensively in the temporal cortex as both diffuse deposits (arrowheads) or in

the cerebrovasculature (arrow). **B,** A higher magnification of a diffuse A-beta plaque shows small fibrils accumulating in the space between neurons (arrows). **C,** A-beta also can be observed on the membranes of neurons. **D,** Blood vessels within the parenchyma of the brain also can accumulate A-beta. All sections immunostained with anti-Abeta1-42 antibody. Bars in **B-D** = 20 microns. (Brain tissue kindly provided by Carolyn Wilki.)

Treatment Options

Diet, drugs or supplements all might be effective in improving signs and slowing the progress of CDS. Canine studies have demonstrated that mental stimulation in the form of training, play, exercise, and use of manipulation toys can help to maintain quality of life as well as cognitive function, but are most effective together with an appropriate nutritional base.[58,59] This is consistent with studies in humans in which education, and brain and physical exercise, have been found to delay the onset of dementia.

Currently there is one pharmaceutical in North America, selegiline (Anipryl, Zoetis Animal Health), that is approved for the treatment of CDS in aged dogs. Selegiline hydrochloride is a selective reversible monoamine oxidase B inhibitor, which was found to significantly improve cognitive signs in aged dogs.[60,61] In the canine brain, selegiline increases 2-phenylethylamine, a neuromodulator that enhances dopamine and catecholamine function. Its metabolites l-amphetamine and l-methamphetamine could further enhance cognitive function and improve behavior. Selegiline also might contribute to a decrease in free radical load in the brain.

Propentofylline, a xanthine derivative, is licensed in Europe and Australia for the treatment of dullness, lethargy, and depressed demeanor in old dogs. It could increase blood flow and inhibit platelet aggregation and thrombus formation. In a laboratory trial with aged Beagle dogs, it had no effect on behavioral activity.[62]

Since the elderly are particularly susceptible to the effects of anticholinergic drugs, it is prudent to avoid medications with anticholinergic effects in such patients.[41] In fact, drugs or natural products that enhance cholinergic transmission might have potential benefits for improving signs of CDS in dogs and cats, but more research is required to find safe and effective drugs and dosages.[63]

No drugs are approved for treatment of CDS in cats; however, both selegiline and propentofylline have been reported anecdotally to be useful.[1,5,6]

Another therapeutic strategy for cognitive dysfunction in dogs, cats, and humans is diets and natural supplements that might reduce the risk factors that contribute to brain aging and cognitive decline. It is likely that an integrative approach is required to achieve and maintain brain health, such as diets supplemented with polyunsaturated fatty acids, antioxidants, and mitochondrial co-factors.[64-66] Two veterinary therapeutic diets that have been developed for the management of CDS have been demonstrated in laboratory studies to improve learning and memory in dogs. A diet from Hills Pet Nutrition (Canine b/d) is supplemented with fatty acids, antioxidants (vitamins C and E, beta carotene, selenium, flavonoids, carotenoids), and dl-alpha-lipoic acid and l-carnitine to enhance mitochondrial function.[58,59,67] When the diet was combined with environmental enrichment, the greatest level of improvement was achieved.[58,59] In a clinical trial, significant effects were obtained from the diet alone.[68] A diet from Nestle Purina Research (Purina Pro Plan Bright Minds) is supplemented with botanic oils containing medium chain triglycerides to provide ketone bodies as an alternate source of energy for aging neurons.[69] A dietary supplement from Nestle Purina (not yet commercially available) with antioxidants, (vitamins E and C, and selenium), arginine, B vitamins, and fish oil significantly improved learning and memory tasks in cats aged 5.5 to 8.7 years.[18]

A number of nutritional supplements also might be effective in the management of CDS based on laboratory and/or clinical studies. Senilife (CEVA Animal Health), which contains phosphatidylserine (a membrane phospholipid) and *Gingko biloba,* vitamins E and B6, and resveratrol, is labeled for both dogs and cats but only has been evaluated in canine studies to date.[70,71] Activait (Vet Plus Ltd), which contains phosphatidylserine, omega-3 fatty acids, vitamins E and C, l-carnitine, alpha-lipoic acid, coenzyme Q, and selenium, has been evaluated in a canine clinical trial.[72] A feline product also is available with alpha-lipoic acid removed. S-adenosyl-l-methionine (Novifit, Virbac Animal Health) might help to maintain cell membrane fluidity and receptor function, regulate neurotransmitter levels, and increase production of glutathione.[73,74] Apoaequorin (Neutricks, Neutricks, LLC), is a calcium-buffering protein found in jellyfish that improved learning and attention in dogs in laboratory trials.[75] Immunotherapy has also been evaluated in aged dogs, involving the vaccination of aged animals against the A-beta protein. Although the study was not successful in reversing cognitive deficits, this approach might have future treatment potential.[76]

CHAPTER 264

Cranial Neuropathies

John Henry Rossmeisl Jr.

Client Information Sheet: Cranial Neuropathies

The term cranial neuropathy refers to any condition that causes dysfunction of a cranial nerve (CN) anywhere along its anatomic course.[1] Cranial neuropathies most often affect a single CN (mononeuropathy), but can involve multiple CNs, or appear in association with generalized polyneuropathies.[2-5] A thorough neurologic examination is necessary (see ch. 259) to correctly localize the level of CN dysfunction, with particular emphasis on identification of involvement of the central or peripheral components of the affected CN in order to best formulate differential diagnoses and a management plan (Table 264-1).[1] For example, identification of deficits involving two or more CNs usually indicates the lesion involves the anatomic region in which the nerves are in close proximity, as would be the case for signs of Horner's syndrome, facial paresis, and peripheral vestibular dysfunction caused by disease of the middle and inner ear.[6] Common etiologies of cranial neuropathies include degenerative, idiopathic, inflammatory, metabolic, and neoplastic diseases.[1-6] By convention, an idiopathic cranial neuropathy is diagnosed only following exclusion of structural and metabolic causes of disease with the propensity to affect the dysfunctional CN, which can be challenging in the living patient. Idiopathic mononeuropathies affect CNs more frequently than other peripheral nerves, and many of these idiopathic cranial neuropathic syndromes are self-limiting.[2,3,5]

TABLE 264-1

Cranial Nerves: Names, Functions, and Manifestations of Dysfunction

NUMBER	NAME	MAJOR FUNCTIONS	CLINICAL SIGNS OF DISEASE
I	Olfactory	Smell	Inability to smell
II	Optic	Vision	Blindness
III	Oculomotor	Movement of the eye and constriction of the pupil	Abnormal eye position, pupil size, or pupil reactivity to light
IV	Trochlear	Movement of the eye	Abnormal eye position
V	Trigeminal	Sensation to the eye and face, movement of the jaw	Rubbing or pawing of the face Loss of muscle mass on the head Dropped jaw—flaccid inability to close the mouth
VI	Abducent	Movement of the eye	Abnormal eye position
VII	Facial	Movement of facial muscles Taste Tear and saliva production	Drooping of the ear or cheek, deviation of the nose, drooling Dry eye
VIII	Vestibulocochlear	Balance and hearing	Abnormal head position, abnormal eye movements, vertigo Deafness
IX	Glossopharyngeal	Sensation and movement of throat muscles Taste	Difficulty eating or swallowing
X	Vagus	Movement of throat muscles	Loss of voice, coughing, regurgitating

XI	Accessory	Movement of neck and shoulder muscles	Difficult to appreciate in small animals
XII	Hypoglossal	Movement of the tongue	Tongue deviation or paralysis, difficulty eating

Optic Nerve (Cn II)—Optic Neuritis

Optic neuritis is characterized by an acute onset of vision loss, which is typically bilateral and associated with mydriatic and unresponsive pupils (see ch. 11).[7] Frequently, there are visible changes in the posterior segment of the eye, such as optic disc swelling (Figure 264-1), vascular congestion, hemorrhage, and peripapillary neuroretinitis, although the ophthalmic examination can be normal in cases of retrobulbar disease.[7,8] If optic disc swelling is visible, differential diagnoses include papilledema or optic nerve edema that can accompany uveitis or glaucoma. These conditions usually can be differentiated based on the collective findings of the clinical examination.[7] Papilledema is non-inflammatory disc edema resulting from intracranial hypertension that does not cause acute vision loss.

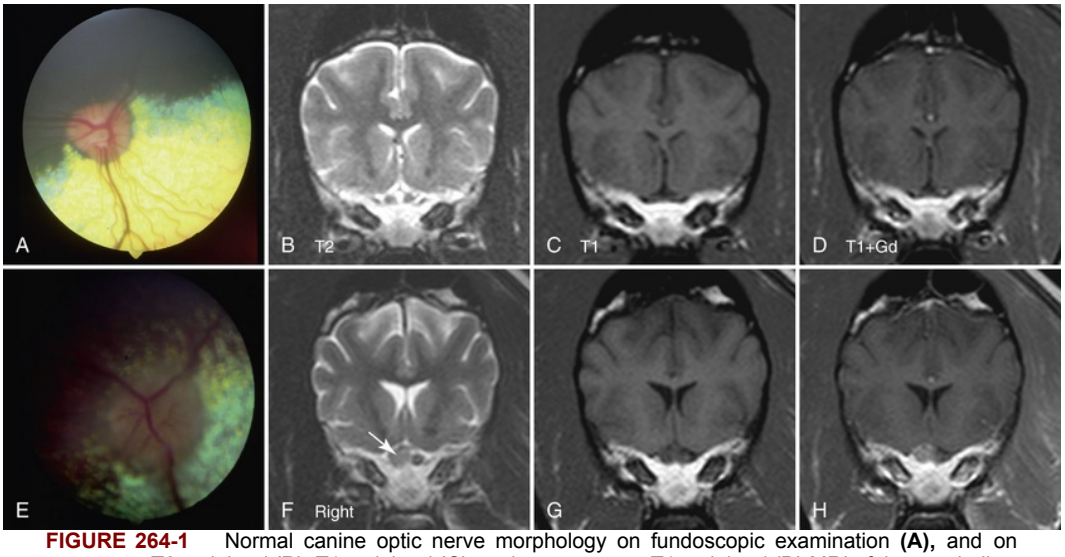

FIGURE 264-1 Normal canine optic nerve morphology on fundoscopic examination **(A),** and on transverse T2-weighted **(B),** T1-weighted **(C),** and post-contrast T1-weighted **(D)** MRI of the retrobulbar region. Optic neuritis associated with fundoscopic evidence of a swollen optic disc **(E),** caused by optic nerve astrocytoma, which appears as unilateral enlargement of the right optic nerve on transverse MRI **(F** [arrow], **G, H).**

Potential etiologies of optic neuritis include infectious (e.g., canine distemper viral, mycotic, and protozoal) and immune-mediated (e.g., granulomatous meningoencephalitis) meningoencephalitides, and neoplasms (see Figure 264-1) that infiltrate or compress (e.g., meningioma, glioma, pituitary tumors) the optic nerves or chiasm.[7-10] Thus, magnetic resonance imaging (MRI) examinations of the brain (see ch. 260 and 261), cerebrospinal fluid analysis (see ch. 115), and serologic assays are diagnostics recommended in cases of optic neuritis.[8-10] The management of meningoencephalitis is reviewed in ch. 261. Electroretinography (ERG) is normal in patients with optic neuritis. In many dogs with optic neuritis, no underlying cause is identified, the disease is presumed to be idiopathic, and systemic therapy with immunosuppressive dosages of prednisone is attempted (see ch. 165).[7] In dogs, sudden acquired retinal degeneration syndrome (SARDS) is another cause of bilateral acute blindness associated with mydriatic pupils.[10,11] However, many dogs with SARDS will have sluggish and incomplete pupillary light reflexes, the fundic examination is initially normal, and the ERG will be extinguished.[10,11] The prognosis for complete visual recovery with optic neuritis is guarded to poor.[7]

Oculomotor (CN III), Trochlear (CN IV), And Abducent (CN VI) Nerves

Collectively, these nerves innervate the extraocular muscles. They participate in ocular position and coordinated and conjugate movement of the eyes, along with the vestibular and cervical proprioceptive systems.[12] The parasympathetic portion of CN III is responsible for pupillary constriction. Clinical signs of

dysfunction of these nerves or their associated vestibular projections include strabismus, abnormal physiological nystagmus due to external ophthalmoplegia, pathological nystagmus if the lesion involves the vestibular system, and internal ophthalmoplegia (i.e., a mydriatic and fixed pupil) if the lesion affects the parasympathetic portion of CN III.[12-14]

Cavernous sinus (CSS) and orbital fissure (OFS) syndromes are defined by clinical dysfunction of two or more of the following CNs: III, IV, and VI, and the ophthalmic or maxillary branches of CN V.[13,14] The axons of these CNs course in intimate anatomic association with each other along the floor of the skull adjacent to the cavernous sinus prior to exiting the skull through the orbital fissure. Clinical signs frequently observed with these syndromes include external and internal ophthalmoplegia, reduced corneal sensitivity, neurotrophic keratitis, and ptosis.[13,14] Differentiation of CSS from OFS requires demonstration of the anatomic level of the lesion with diagnostic imaging. The most common causes of CSS and OFS are primary or metastatic neoplasms, although infectious causes have been reported, particularly in cats.[13,14]

Trigeminal Nerve (CN V)—Trigeminal Neuropathy

The trigeminal nerve consists of three primary branches that provide sensation to the face (i.e., ophthalmic, maxillary, and mandibular nerves) and motor function to the muscles of mastication (i.e., mandibular nerve).[1,2] Common clinical presentations of trigeminal mononeuropathies involve mandibular motor dysfunction; cases of isolated trigeminal sensory dysfunction are rare.[15] The first is an acute onset of a flaccid bilateral paresis of the mandibular nerves resulting in a dropped jaw and inability to close the mouth (Video 264-1).[2] This clinical presentation can result from disorders affecting mechanical jaw function (e.g., temporomandibular joint fracture or avulsion), diseases resulting in pain associated with jaw movement (e.g., masticatory muscle myositis, retrobulbar mass lesions), and inflammatory (e.g., *Neospora, Toxoplasma, Cryptococcus,* rabies), idiopathic, or neoplastic (e.g., hematopoietic neoplasia, nerve sheath tumor [NST]) trigeminal nerve lesions.[2,16-18] Animals with clinical signs limited to an acutely dropped jaw usually have disease of the peripheral portions of the trigeminal nerve, because a bilateral lesion in the pontine trigeminal motor nuclei would be expected to be associated with additional and severe clinical signs of pontomedullary syndrome, which often include central vestibular dysfunction, a depressed level of consciousness, and/or CN VI-XII deficits.[1]

Idiopathic trigeminal neuritis (ITN) is the most common cause of dropped jaw in dogs (see Video 264-1). ITN mainly impairs masticatory muscle motor function, although trigeminal sensory deficits can accompany ITN in approximately one-third of dogs, and concurrent facial nerve paralysis, masticatory muscle atrophy, or Horner's syndrome occasionally also can be observed.[2] Treatment includes supportive care with assisted feeding (see ch. 82). Affected dogs usually recover within 2-4 weeks. MRI of the brain of animals with trigeminal neuropathy provides the best, non-invasive method to differentiate etiologies of trigeminal neuropathy. On MRI, both normal and abnormal trigeminal nerves will demonstrate contrast enhancement.[19] ITN may be associated with normal nerve signal characteristics and morphology, or diffusely enlarged and T2-hyperintense nerves.[20]

Another presentation of trigeminal neuropathy is an acute onset of unilateral, and often severe, atrophy of the muscles of mastication ipsilateral to the dysfunctional mandibular nerve. Trigeminal NST are a common etiology of unilateral neurogenic masticatory muscle atrophy (Figure 264-2).[20] Facial hypalgesia or paresthesia, manifesting as facial rubbing, itching, or pain, in addition to Horner's syndrome, also can be seen. NST are locally invasive and slow to metastasize. Treatment options for NST include surgical debulking, radiotherapy, or supportive care with glucocorticoids.[20,21] The prognosis is guarded, although a median overall survival of 881 days was reported in 4 dogs with trigeminal NST treated with stereotactic radiosurgery.[21]

Transverse **(B)** and left parasagittal **(C)** post-contrast T1-weighted MRI demonstrating lobular, contrast-enhancing extra-axial mass involving the trigeminal nerve resulting in mesencephalic compression and loss of muscle mass (**B;** left temporalis).

Facial Nerve (CN VII)—Facial Neuropathy/Paralysis

Facial paralysis is characterized by an acute inability to close the palpebral fissure, a drooping of the ear and lip and drooling on the affected side.[1] Causes of peripheral facial nerve paralysis include otitis media-interna, iatrogenic surgical injury (e.g., bulla osteotomy), idiopathic disease, metabolic disease (e.g., hypothyroidism), otic neoplasms, trauma, and sulfonamide hypersensitivity.[3,6,22,23] Due to the close anatomic relationships of the vestibulocochlear and facial nerves in both the medulla and petrous temporal bone, vestibular signs can accompany both peripheral and central (e.g., neoplasia, meningoencephalitis) etiologies of facial paralysis.[6,24] Facial paresis also can be a feature of generalized neuropathies or neuromuscular diseases, such as acute canine polyradiculoneuritis, tick paralysis, and myasthenia gravis.[25-27] Facial paralysis is reported to be idiopathic in 75% of dogs and 25% of cats with facial neuropathy.[3] Approximately 60% of cases of idiopathic disease present with unilateral signs and 40% with bilateral signs (Video 264-2).[28] Idiopathic facial paralysis is commonly associated with various segments of facial nerve enhancement on MRI examinations.[28,29] Spontaneous recovery from idiopathic facial nerve paralysis is possible. In dogs, contrast enhancement of the nerve on MRI can provide prognostic information, with one study indicating that recovery of facial nerve function is less likely to occur or may be prolonged in cases demonstrating enhancement.[29] Animals that recover usually do so within 3 to 8 weeks.[3,29]

Vestibulocochlear Nerve (CN VIII)

The vestibular branch of CN VIII participates in maintenance of balance and posture, and disorders affecting the vestibular system are reviewed in ch. 265.[1,12] Dysfunction of the cochlear branch results in deafness that can be classified as conductive (e.g., otitis externa/media) or sensorineural in origin.[30] The most common cause of deafness is congenital hereditary sensorineural associated with a white coat color and the piebald and merle genes.[30,31] In dogs and cats, acquired sensorineural deafness can occur secondary to progressive age-related cochlear degeneration (i.e., presbycusis) or ototoxic drug therapy (e.g., aminoglycosides).[30] Deafness is diagnosed via brainstem auditory evoked response testing.[30,31]

Glossopharyngeal (CN IX), Vagus, (CN X), And Accessory (CN XI) Nerves —Dysphagia, Megaesophagus, and Laryngeal Paralysis

The glossopharyngeal, vagus, and accessory nerves are important for function of the pharynx, larynx, and esophagus.[1] In the dysphagic patient, it is important to differentiate neurogenic prehensile problems that imply dysfunction of the jaw (CN V), lips (CN VII) and/or tongue (CN XII) from neurogenic deglutition problems. Prehensile and oropharyngeal dysphagic disorders can be identified with a physical examination, including observation of eating, while characterization and diagnosis of disorders of the pharyngeal, cricopharyngeal, and/or esophageal phases of swallowing often requires diagnostic imaging examinations

including contrast radiography or videofluoroscopy (see ch. 38).[32] Dysphagia can be associated with clinical signs of gagging, coughing after drinking or eating, pharyngeal accumulation of saliva or food, and an abnormal gag reflex. Neurologic diseases that commonly cause dysphagia include primary myopathies (see ch. 354), polyneuropathies (see ch. 268), neuromuscular junctional disorders (e.g., myasthenia gravis, botulism; see ch. 269), and caudal brainstem lesions (e.g., encephalitis and neoplasia; see ch. 260 and 261).[25,27,33,34]

The esophagus is innervated by the vagus and internal branch of the accessory nerves.[1] Megaesophagus is characterized by generalized dilation and abnormal peristalsis of the esophagus (see ch. 273).[35,36] Regurgitation is the primary clinical sign observed, and secondary aspiration pneumonia is common (see ch. 242). Megaesophagus is more common in dogs than in cats, and can be congenital or acquired, although most canine cases are acquired and idiopathic.[35] Although megaesophagus can be identified readily with thoracic radiography, a thorough history and ancillary diagnostics are required to establish the etiology.[32] Acquired megaesophagus can be caused by polyneuropathies, polymyopathies, myasthenia gravis, endocrinopathies (e.g., hypoadrenocorticism, hypothyroidism), intoxications (e.g., lead, organophosphate, thallium), that must be ruled out to make a diagnosis of idiopathic megaesophagus.[25,27,32,33,35-40] Treatment is directed at the underlying cause, when present, and various assisted feeding procedures (e.g., Bailey chair, gastrostomy tube). The prognosis associated with megaesophagus is highly variable and dependent on the underlying etiology (see ch. 273).[35-39]

The larynx is innervated by branches of the vagus nerve.[1] The recurrent laryngeal nerve innervates the abductor muscles of the larynx. Lesions affecting the recurrent laryngeal nerve can result in dysphonia, inspiratory stridor, and respiratory distress.[4] Congenital laryngeal paralysis has been described in several breeds.[25,41,42] Acquired laryngeal paralysis has been associated with metabolic disease (e.g., hypothyroidism), trauma to the recurrent laryngeal nerve, neoplasia (e.g., squamous cell carcinoma, thyroid carcinoma), intoxications (e.g., lead), and brainstem disease (e.g., neoplasia, encephalitis).[25,42-44] In older, large-breed dogs, laryngeal paralysis is often the initial clinical manifestation of a progressive, degenerative polyneuropathy (see ch. 239).[4,25,42]

Horner's Syndrome

Horner's syndrome (HS) results from lesions affecting any portion of the three-neuron oculosympathetic pathway.[5,45] Clinical signs consist of miosis, ptosis, protrusion of the third eyelid, and enophthalmos. First order (i.e., upper motor neuron or central) neurons originate in the rostral brainstem, travel down the cervical spinal cord to synapse on second order (i.e., preganglionic) neurons, which have their cell bodies in the T1-T3 spinal segments. Second order axons course up the vagosympathetic trunk to synapse on third order (i.e., post-ganglionic) neurons in the cranial cervical ganglion, which then project to the eye and adnexa.[5,46] Topical phenylephrine testing can aid in lesion localization along this pathway.[5] Observation of mydriasis within 20 minutes of the application of phenylephrine indicates a post-ganglionic lesion, whereas mydriasis occurring after 20 minutes suggests a pre-ganglionic lesion.[5] HS can be caused by degenerative, inflammatory, ischemic, metabolic, neoplastic, or traumatic lesions at any site in the oculosympathetic system, although in the majority of HS cases no etiology is found and the condition is presumptively idiopathic.[5,46] Golden Retrievers are predisposed to developing idiopathic HS.[45,46] Recent data indicate idiopathic HS is post-ganglionic in the majority of cases, which contradicts results of earlier reports.[45,46] Idiopathic HS is mainly an aesthetic problem, as vision is not impaired unless the problem is bilateral, and the condition will resolve in many dogs within 3-4 months.[45,46]

CHAPTER 265

Vestibular Disease

Veronique Sammut

Client Information Sheet: Vestibular Disease

Head tilt and nystagmus are clinical manifestations of vestibular diseases and are a common neurologic problem in small animals. Patients with vestibular diseases can have a dramatic clinical presentation. Vestibular dysfunction can originate from the peripheral or central vestibular system.

Functional Neuroanatomy

The vestibular system is the sensory system responsible for maintaining the head and body posture, balance, and tone in relation to gravitational forces and movement. It is divided into peripheral and central components (Figure 265-1). The peripheral vestibular system is located primarily in the petrosal portion of the temporal bone and includes the membranous labyrinth and the vestibular portion of the vestibulocochlear nerve (cranial nerve [CN] VIII). The membranous labyrinth is a series of fluid-filled structures consisting of three semicircular canals, the utricle, and the saccule, which are responsible for the vestibular function.

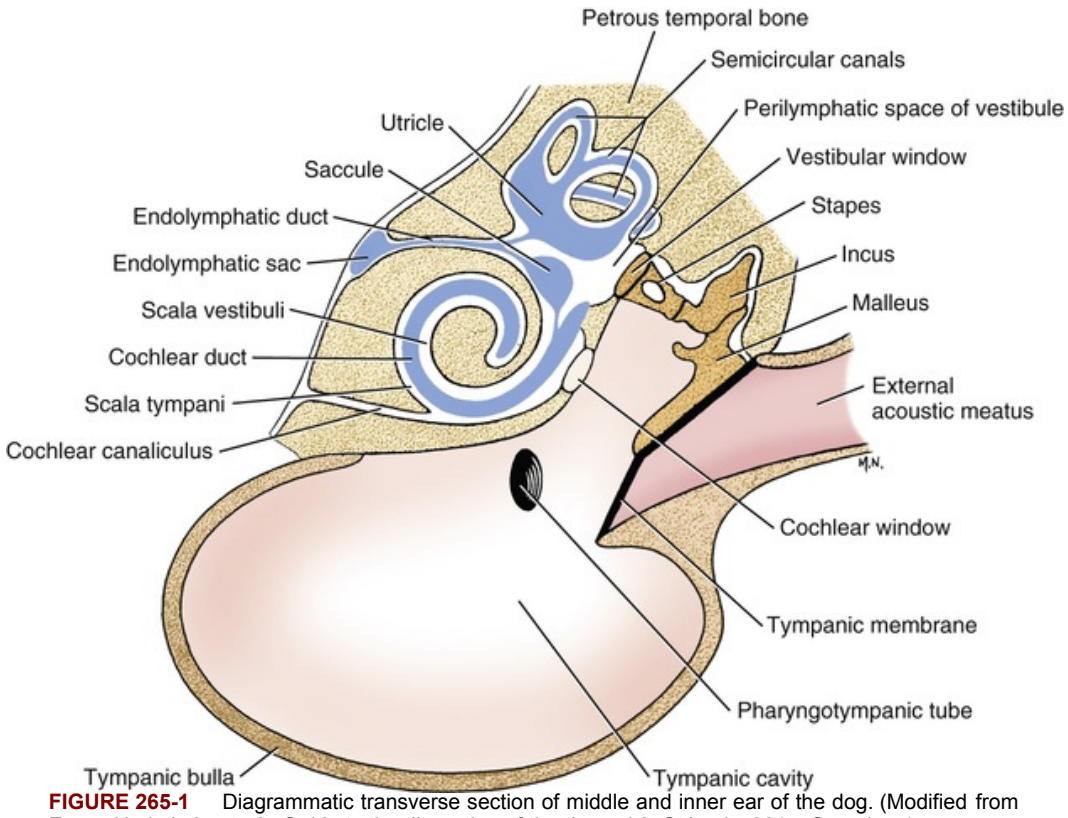

FIGURE 265-1 Diagrammatic transverse section of middle and inner ear of the dog. (Modified from Evans H, de Lahunta A: *Guide to the dissection of the dog,* ed 8, St Louis, 2017, Saunders.)

The central vestibular components include the four pairs of vestibular nuclei adjacent to the wall of the

fourth ventricle on the dorsal part of the pons and medulla, and the fastigial nucleus and flocculonodular lobe of the cerebellum. From CN VIII, some axons synapse in one of the vestibular nuclei, whereas others will ascend directly to the cerebellum via the caudal cerebellar peduncle. Most axons from the vestibular nuclei project to the spinal cord via the ipsilateral lateral vestibulospinal tract to influence extensor tone by facilitation on the ipsilateral extensor muscles and inhibition on the ipsilateral flexor muscles and to the medial longitudinal fasciculus (MLF) which synapses in the nuclei of CN III, IV, and VI, to adjust the position of the eyes in relation to the position and movement of the head. A few axons will project to the vomiting center in the reticular formation of the medulla (playing a role in motion sickness), whereas others will ascend to the cerebral cortex (forebrain) for conscious perception of position via a relay through the thalamic nuclei. For this reason, vestibular disease can sometimes be seen with thalamic lesions. The cerebellum provides an inhibitory effect on the vestibular nuclei, preventing excessive extensor tone.

Clinical Signs

A vestibular lesion will cause a lack of facilitation of the extensor muscles on one side, leading to imbalance with the normal side "pushing" the body and head toward the abnormal side. Because most disease processes are unilateral or asymmetrical, loss of balance and head tilt to one side is usually seen. However, bilateral involvement is possible as well.

Head Tilt

A head tilt is the most common and most consistent sign of a unilateral or asymmetrical vestibular disorder. It is characterized by a rotation of the head on the median plane bringing one ear lower than the other. It is important to differentiate a head tilt from a head turn or torticolli from a forebrain lesion, in which both ears and eyes are parallel to the ground but the nose is turned toward one side of the body. Patients with bilateral vestibular involvement may not have a head tilt unless one side is more affected than the other but tend to have wide head excursions from side to side. With cerebellar involvement, the head may be tilted to the opposite side of the lesion (see Paradoxical Syndrome).

Vestibular Ataxia

Vestibular ataxia is characterized by a wide-based stance and loss of balance on the side of the lesion. The head and body can sway and the animal will often lean, fall, or even roll to one side. The animal may walk in circles (vestibular circling) and the circles are typically erratic and of small diameter (Video 265-1). This must be differentiated from compulsive circling secondary to a forebrain lesion where the circles are typically large, regular and nicely shaped. The presence of paresis and/or general proprioceptive (GP) deficits indicates a central lesion affecting the descending motor pathways and the ascending proprioceptive tracts. However, evaluation of GP can be difficult initially if the patient is severely affected.

With bilateral disturbance, the animal will typically stand crouched and low to the ground and may lose balance on both sides.

Nystagmus

Nystagmus is a rhythmic, involuntary movement of the eyes. It can have equal movement on both sides (pendular nystagmus) or most commonly has a fast phase and a slow phase (jerk nystagmus). It can be physiologic or pathologic. By convention, the direction of the nystagmus is described in regards to its fast phase and can further be characterized as horizontal, vertical, or rotary.

Pendular nystagmus is not a sign of vestibular dysfunction and is mainly recognized in Siamese, Himalayan, Birman, and crosses of these breeds.

Physiologic

Physiologic nystagmus is the conjugated eye movement occurring during head movement in order to stabilize images on the retina. It can be elicited in normal patients with movement of the head from side to side (oculovestibular reflex). In vestibular diseases, the physiologic nystagmus may be reduced in both eyes when the head is turned toward the side of the lesion. In cases of bilateral involvement, the physiologic (and pathologic) nystagmus may be completely absent because of lack of vestibular activation on both sides.

Pathologic

Pathologic nystagmus is frequently, but not always, present in vestibular disease. It can be spontaneous, which occurs when the head is in the normal position, or positional, which is visible only when the head is placed in an unusual position (e.g., in complete extension or with the animal in dorsal recumbency). The pathologic nystagmus is described by the orientation of the plane in which the eyeballs are moving (vertical, rotary or horizontal) and, by convention, by the direction of the fast phase (left or right) (Videos 265-2 and 265-3). With vestibular disturbance, the eyes will tend to "drift" in the direction of the lesion (slow phase) and will quickly reset to their original position through a brainstem reflex (fast phase). This makes the fast phase of the nystagmus away from the lesion. Spontaneous nystagmus is often present in acute lesions and can disappear within a few days because of central compensation. For this reason, and because the presence of pathologic nystagmus (either spontaneous or positional) is always abnormal and indicative of vestibular disease, it is important to attempt to elicit positional nystagmus.

In peripheral vestibular disease, the pathologic nystagmus can be horizontal or rotary and the fast phase is always away from the lesion. In central disease the pathologic nystagmus can be in any plane (including vertical), can change direction with different positions of the head, and the fast phase can be toward the lesion. Therefore, identification of a vertical nystagmus or a nystagmus with the fast phase toward the lesion is an indication of central involvement. However, caution should be exerted when labeling a patient with central disease based on vertical nystagmus alone since it is easy to confound nystagmus with a slight rotary component with vertical nystagmus. One comparative clinical study also suggested that the number of beats of the resting nystagmus was significantly higher in peripheral vs. central disease. A resting nystagmus rate of more than 66 beats per minute was found to be very specific (95%) and sensitive (85%) of peripheral disease.[2]

Strabismus

Vestibular strabismus is characterized by a ventral deviation of the ocular globe on the side of the lesion when the head is in extension (positional strabismus). However, the eye can move normally from side to side because there is no paralysis of any of the extraocular muscles. This type of strabismus can be seen with a peripheral or central vestibular lesion.

Cranial Nerve Deficits

Although not exactly part of the vestibular syndrome, other CN deficits can be seen along with vestibular signs. In the brainstem, the facial nerve (CN VII) is close to the vestibulocochlear nerve and travels close to the inner ear as well. For this reason, facial nerve paralysis may be noticed with both peripheral and central diseases. The sympathetic innervation of the eye also travels close to the inner ear and Horner's syndrome can occur from peripheral disease but is seen rarely in central diseases. Any other CN involvement indicates a central origin of the disease.

Nausea and Vomiting

Nausea and vomiting are frequently seen with vestibular disease and can be related to motion sickness or the result of a problem in the pathways between the vestibular nuclei and the vomiting center in the brainstem. Nausea and vomiting can be seen with both peripheral and central diseases, although vomiting might be more common with peripheral diseases.[1]

Change in Mentation

Patients with vestibular disease are often very anxious and quite disoriented by the lack of balance. However, this should be differentiated from central depression or obtundation, which indicates brainstem involvement. Some degree of mental depression usually occurs with central diseases because the vestibular nuclei are in close proximity to the diffuse ascending reticular activating system (ARAS) responsible for normal alertness.

Paradoxical Syndrome

The cerebellum is inhibitory to the ipsilateral vestibular nuclei. With a lack of inhibition from a cerebellar lesion, the vestibular nuclei will appear "hyper" on that side. This will cause excess in extensor tone on the

side of the lesion, which will "push" the head and the body on the other side. This causes the head to be tilted away from the lesion. The side of the lesion can be identified by the presence of concomitant deficits (ipsilateral GP deficit, paresis, hypermetria, or CN deficits).

Paradoxical vestibular syndrome can be seen with lesions in the flocculonodular lobe of the cerebellum, the caudal cerebellar peduncle, and the rostral and medial vestibular nuclei in the medulla.[3]

Neurolocalization

The most important aspect in evaluating a patient with vestibular disease is to localize the lesion to either the peripheral vestibular system or to a central origin (Table 265-1). A good history, physical examination, and careful and thorough neurologic examination are essential (see ch. 1, 2, and 259).

TABLE 265-1

Clinical Signs Associated with Peripheral and Central Diseases

CLINICAL SIGNS	PERIPHERAL	CENTRAL
Nystagmus	Horizontal or rotary Fast phase away from the lesion	Horizontal, rotary, or vertical Fast phase away or toward the lesion
Positional strabismus	Possible	Possible, real strabismus also possible (from CN III, IV, VI)
Cranial nerve (CN) deficits	CN VII only (except in case of polyneuropathy)	Any CN possible (mostly CN V to XII)
Horner's syndrome	Possible	Rare
Mental status	Alert, may be anxious or disoriented	Altered May be obtunded, stuporous, comatose, and disoriented
General proprioception deficit and/or paresis	No	Possible, usually ipsilateral
Hypermetria	No	Possible if cerebellar lesion (ipsilateral)

To diagnose central involvement, identification of deficits that cannot be attributed to the peripheral components such as GP deficits, paresis, altered mentation or CN deficits (other than CN VII) is necessary. The presence of vertical nystagmus without rotary component or of nystagmus with the fast phase toward the lesion is also suggestive of a central involvement. The presence of Horner's syndrome suggests a lesion in the middle/inner ear. Although it may seem like a straightforward distinction between peripheral and central diseases, clinical signs often overlap.

Diagnostic Procedures

In the assessment of peripheral vestibular diseases, diagnostic tests should include an otoscopic examination (ideally under sedation or anesthesia), imaging of the tympanic bullae with radiographs or ideally, advanced imaging (computed tomography [CT] or magnetic resonance imaging [MRI]), myringotomy for cytology (see ch. 33, 85, and 259) and culture, and thyroid evaluation. CT is more sensitive than radiographs even with otitis media (84% vs. 75%, respectively) but MRI has even greater sensitivity and can detect otitis interna as well.[53]

Diagnosis of central diseases (Figure 265-2) often requires advanced imaging of the brain with CT or MRI, cerebrospinal fluid (CSF) analysis, and titers for infectious diseases. MRI is preferred over CT because it provides better soft tissue details and because the bone-hardening artifact in CT renders the evaluation of the vestibular component in the caudal fossa more difficult. MRI also allows visualization of the inner ear structures as well as CSF, meninges and brain parenchyma (Figure 265-3).[4] Other potentially useful diagnostic procedures include a fundic examination to evaluate for lesions of chorioretinitis or retinal hemorrhages (ch. 11) and a brainstem auditory evoked response (BAER) test because the latter also evaluates the brainstem component of hearing.

SUPPORTIVE Treatment and Compensation in Vestibular Diseases

The central vestibular system has a great potential of compensation for even extremely severe vestibular signs. Patients with vestibular disease will benefit from general therapy aimed at reducing some clinical signs such as vomiting and motion sickness. Promoting normal activity and physical therapy will also speed up the recovery in most cases. Correction of the vestibular deficits by the central nervous system (CNS) requires that the patient move in order to provide the somatosensory feedbacks necessary for compensation.

Antiemetics and fluid therapy (ch. 39 and 129) might be necessary if the patient is vomiting and/or dehydrated. Meclizine (12.5 to 25 mg per pet PO q 24 h) has antiemetics and antivertigo properties.[5] It likely helps through its weak antihistamine, CNS depressant properties and anticholinergic effects. Maropitant (1 mg/kg SC q 24 h or 2-8 mg/kg PO q 24 h in dogs and 1 mg/kg PO q 24 h in cats) is a neurokinin-1 inhibitor, which blocks the action of substance P to the final common pathway in the emetic center in the brain. However, maropitant does not seem to possess any antivertigo effect and therefore, meclizine might be beneficial even in conjunction with maropitant.

Peripheral Vestibular Diseases

Otitis Interna/Media

Otitis interna/media (OIM) is a common cause of peripheral vestibular disease in dogs and cats (Video 265-4). Facial nerve involvement and Horner's syndrome are often present as well. The etiology is most commonly an extension of otitis externa in dogs, but an ascending infection from the nasopharynx (via the Eustachian tube) seems more common in cats.[8] Hematogenous spread is also possible. The most common bacteria are *Staphylococcus* species, *Streptococcus, Pseudomonas, Proteus,* and the yeast *Malassezia pachydermatis.* The diagnosis is usually made by otoscopic examination, imaging of the bullae, and myringotomy for culture and sensitivity. The entire eardrum might not be visualized with standard otoscopy and an intact tympanic membrane does not rule out a diagnosis of OIM. If material is present in the middle ear, samples should be obtained if possible for cytology and culture. Radiographs are normal in up to 25% to 33% of confirmed cases, whereas CT results are falsely negative in about 17%.[9,10] Treatment of OIM consists of antibiotic therapy based on the results of the culture and sensitivity for a minimum of 4 to 6 weeks. In the absence of a culture, an antibiotic effective against the most common causative organisms with good boney penetration should be chosen (e.g., amoxicillin/clavulanate or a fluoroquinolone) (ch. 161 and 162). In some cases, a bulla osteotomy may be required in order to control the infection or to confirm the diagnosis. The prognosis is good for resolution of the infection.[12] However, a mild permanent head tilt is possible and the damage on the facial nerve may be irreversible. Occasionally, the infection can extend into the cranial cavity causing an otogenic meningoencephalitis, epidural empyema or a brain abscess which can be life threatening (Figure 265-4). Treatment should be aggressive and consists of surgical drainage of the tympanic cavity with antibiotic therapy but the prognosis is usually favorable.[6,11]

FIGURE 265-4 Transverse T1-weighted magnetic resonance image of the brain of a dog at the level of the tympanic bullae following administration of gadolinium–DTPA. The right bulla is filled with isointense material and there is contrast enhancement in the brainstem at the same level. The diagnosis of middle/inner ear infection was confirmed in surgery.

Nasopharyngeal Polyps

Nasopharyngeal polyps are pedunculated growths resulting from chronic inflammation (see ch. 238). In cats, they may be congenital.[13] They originate from the auditory tube, the nasopharynx, or the lining of the tympanic bulla. Young cats between 1 and 5 years old are most commonly affected, but this can occur in dogs as well (Figure 265-5).[15] In addition to causing signs of middle/inner ear disease, they can cause upper respiratory signs (sneezing, stridor) or pharyngeal signs (gagging, dysphagia). Treatment involves removal of the polyp. This can be done by a simple traction-avulsion, but recurrence is possible in 30% to 50% of cases.[13,14] When there is middle ear involvement, a bulla osteotomy is often necessary to prevent recurrence. A recent retrospective study of per-endoscopic trans-tympanic traction of polyps in 37 cats suggested a resolution in 94% of cases with fewer complications than bulla osteotomy and simple traction (8% vs. 57-81% vs. 43%, respectively).[54]

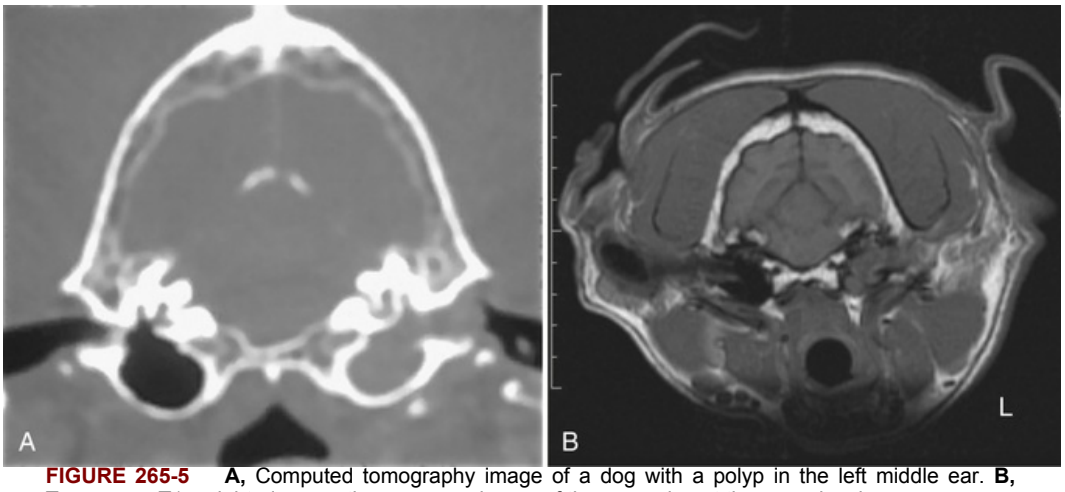

FIGURE 265-5 **A,** Computed tomography image of a dog with a polyp in the left middle ear. **B,** Transverse T1-weighted magnetic resonance image of the same dog at the same level.

Idiopathic Vestibular Disease

This is a common condition seen in cats of all ages and in older dogs, which is why it is sometimes called "old dog vestibular disease" or "canine geriatric vestibular disease."[16,17] The condition is characterized by an acute or peracute onset of peripheral vestibular signs. Unilateral signs are more common but bilateral disease is sometimes seen, especially in cats. It can easily be misinterpreted as a stroke or a seizure. The vestibular signs can be mild but are usually quite severe to the extent that the patient is severely incapacitated, making a complete neurologic examination difficult initially. Nausea and vomiting are common as well as anxiety but there is no sign of central involvement or middle ear disease (i.e., no facial paralysis or Horner's syndrome). The etiology is unknown but could be an abnormality in the endolymph flow. In cats, the condition is more common in the northeastern part of the United States and Canada in the summer and early fall and may be caused by the migration of small *Cuterebra* larvae through the ear canal.[18] A similar presentation is seen in the southeastern part of the United States in cats ingesting the tail of the blue tail lizard.[1,19] The diagnosis is one of exclusion and most patients improve significantly within 72 hours, although complete recovery may take 2 to 3 weeks. Treatment is directed toward the nausea and vomiting and supportive care only. Despite the often dramatic presentation, the prognosis is very good but mild residual deficits are possible. Treatment directed toward *Cuterebra* in cats is usually neither necessary nor recommended.

Hypothyroidism

Vestibular disease secondary to hypothyroidism is mainly recognized in middle-aged to older dogs (see ch. 299).[20] The vestibular signs are usually mild to moderate and can be unilateral or bilateral and may result from a deficit in energy metabolism with disturbance in axonal transport and possible segmental demyelination.[21] There may be concomitant facial nerve involvement and the patient may be lethargic, which makes differentiation from central disease difficult.[22] Definitive diagnosis is made with thyroid testing and resolution or improvement of the clinical signs is expected within 2 months of adequate thyroid hormone supplementation.

Ototoxicosis and Iatrogenic Trauma

A list of ototoxic agents has been compiled mainly from extrapolation from the human literature or from anecdotal reports. These include aminoglycosides, loop diuretics, chlorhexidine and cisplatin.[23,24] Among those, aminoglycosides (mostly streptomycin) and chlorhexidine are probably most common. Because of the potential for ototoxicosis, these should never be used topically if the tympanic membrane cannot be visualized.

Iatrogenic trauma during ear cleaning is probably more common than true ototoxicosis. Iatrogenic rupture of the tympanic membrane during ear cleaning will allow entry of material in the bulla which can lead to a severe inflammatory otitis media.[8,26] Facial nerve paralysis and/or Horner's syndrome can be seen

concomitantly.

Others

Congenital

Congenital unilateral vestibular disease has been reported in a few dog breeds including German Shepherds, English Cocker Spaniels, Dobermans, and Smooth Haired Fox Terriers and cat breeds including Siamese, Burmese, and Tonkinese.[25,27-29] Bilateral congenital disease has been reported in Akitas and Beagles.[25] The etiology can be either a malformation or degeneration of the inner ear structures. Clinical signs are usually noticed when the animal first starts to ambulate and include vestibular ataxia and head tilt unless the condition is bilateral. Pathologic nystagmus is usually not a feature of the condition but some patients also have hearing impairment. There is no treatment but the vestibular signs usually improve because of compensation.

Neoplasia

Tumors of the ear canal or middle ear are not common and tend to be aggressive, especially in cats. They include ceruminous gland adenocarcinoma, squamous cell carcinoma, fibrosarcoma, osteosarcoma or chondrosarcoma, and lymphoma (cats mainly). Overall, most of these tend to have a very guarded to poor prognosis.

Because of the proximity of the trigeminal nerve (CN V) to the CN VIII, dogs with a trigeminal nerve–sheath tumor can present with vestibular signs.

Central Vestibular Diseases

Any disease process that can affect the brain has the potential to cause a vestibular syndrome. However, some conditions and diseases tend to affect the vestibular components preferentially.

Inflammatory Diseases

Inflammatory diseases of the brain (encephalitis), either infectious or noninfectious, can affect any part of the CNS and often produce multifocal signs. They are a common cause of vestibular disturbance. Some diseases tend to cause vestibular signs more often and are discussed briefly here. The reader is referred to ch. 261 for a more complete discussion of inflammatory diseases.

Infectious Diseases

Canine distemper virus commonly causes cerebellar and vestibular signs, which can progress to tetraparesis. In older dogs, systemic signs and myoclonus are often lacking, making the diagnosis difficult.[30,31] The diagnosis can be made by direct immunofluorescence assay (IFA) of a conjunctival scraping or CSF, but this is often unrewarding in chronic cases. Polymerase chain reaction (PCR) analysis of either urine or CSF has proven most useful in the antemortem diagnosis of CNS distemper.[30,32] There is no specific treatment and the prognosis is guarded to poor. However, some dogs may recover although residual neurological deficits are common (see ch. 228).

In cats, vestibular signs can be seen with feline infectious peritonitis (FIP). Neurologic signs are reported in one fourth to one third of cats with the dry form of FIP.[33] Cats affected are often younger than 3 years old and from multiple-cat homes or shelters. The FIP virus induces a pyogranulomatous and immune complex–mediated vasculitis. Antemortem diagnosis is difficult. The prognosis is poor, and the disease is usually fatal (see ch. 224).

Rocky Mountain spotted fever (RMSF) and ehrlichiosis are reported to cause neurologic signs in about 40% and 20% of cases, respectively, and vestibular dysfunction is a common manifestation especially for RMSF.[7,34] The presence of typical laboratory findings (thrombocytopenia, anemia, leukocytosis) should raise the suspicion of these diseases even if there is no history of tick exposure.[31,35] Fungal diseases, in particular cryptococcosis, can lead to vestibular dysfunction. Bacterial diseases are rare and mainly result from extension of middle ear diseases. *Toxoplasma gondii* infection in dogs and cats and *Neospora caninum* in dogs can also be seen. Rabies has been reported to cause rapidly progressive vestibular signs (see ch. 226 and 231).[31,36-40]

Noninfectious Diseases

Noninfectious inflammatory diseases of the brain are also called meningoencephalitis of unknown etiology (MUE) or steroid-responsive encephalitis (see ch. 261). These diseases affect dogs and much less commonly cats. Included in these are the granulomatous meningoencephalitis (GME) and some breed-specific encephalitides (e.g., necrotizing leukoencephalitis of Yorkshire Terriers, necrotizing encephalitis of Pugs), which carry a guarded to poor prognosis. Clinical signs may be acute or insidious and signs are usually progressive. Definitive diagnosis requires histopathology (see ch. 261), but a presumptive diagnosis can be made based on the results of advanced imaging (CT or ideally MRI), CSF analysis, and negative titers for infectious diseases. Treatment consists of steroids (e.g., prednisone 1 to 2 mg/kg/day PO) along with other immunosuppressive drugs (e.g., cytosine arabinoside, lomustine, procarbazine, cyclosporine) or radiation therapy. Most patients improve with therapy but relapses are common. The prognosis is guarded but extremely variable and with aggressive therapy, it is now considered better than previously reported.

Neoplasia

Primary or secondary tumors can affect the brainstem and cerebellum. They are a common cause of central vestibular disorders. The reader is referred to ch. 260 for a more detailed discussion on brain tumors. The most common primary tumors affecting the vestibular components of the CNS in dogs are meningioma, nerve-sheath tumor of the trigeminal nerve (affecting the brainstem or CN VIII by extension), and choroid plexus tumor in the fourth ventricle. In cats, meningioma and lymphoma are most often diagnosed. Clinical signs can be acute or insidious and the condition is usually progressive over a period of weeks to months (Video 265-5). Diagnosis requires advanced imaging of the brain (CT or ideally MRI). CSF analysis might be useful in attempting to rule out the possibility of inflammatory diseases but is seldom diagnostic of a tumor process (Figure 265-6). Treatment can be palliative with glucocorticosteroids or directed toward the tumor process (surgical excision, chemotherapy, radiation therapy). The prognosis is usually guarded to poor.

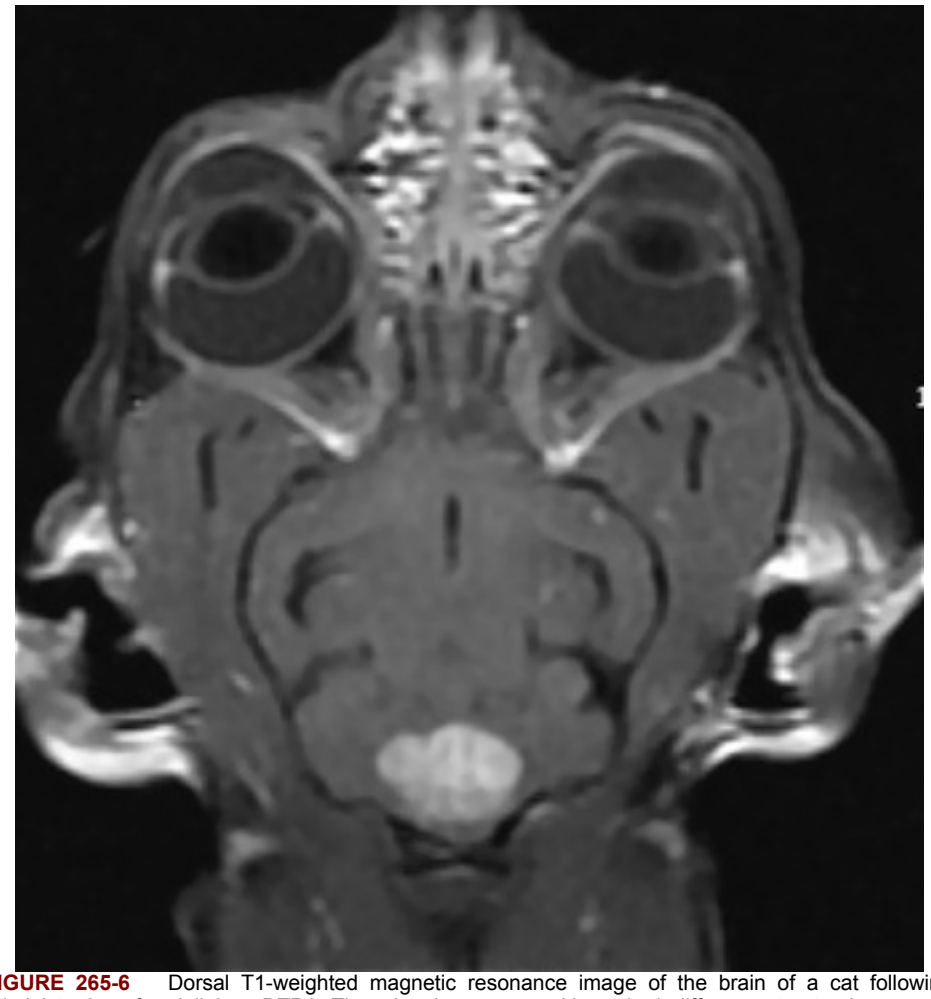

FIGURE 265-6 Dorsal T1-weighted magnetic resonance image of the brain of a cat following administration of gadolinium–DTPA. There is a large mass with marked, diffuse contrast enhancement in the cerebellum. The presumptive diagnosis was a primary brain tumor. However, *Cryptococcus* organisms were identified on cerebrospinal fluid analysis and the cat responded to fluconazole.

Vascular

A cerebrovascular accident (CVA) or stroke is characterized by a sudden onset of nonprogressive focal signs of brain dysfunction (see ch. 260). It occurs when the blood flow to a region of the brain is obstructed by an infarct (thrombus or embolism), a hemorrhage, or an arterial spasm and may result in death of brain tissue. It was previously believed to be uncommon in dogs and cats but is now recognized with increased frequency with the use of MRI.[41,42] The most common location for CVA in dogs is the cerebellum, in areas supplied by the rostral cerebellar artery.[42] Most CVA result from nonhemorrhagic infarcts but a hemorrhagic component is present in some cases.[43] The etiology of the CVA cannot be determined in many cases.[45] However, concurrent medical conditions such as chronic renal failure or hyperadrenocorticism are present in a little more than 50% of cases. Cats with hemorrhagic infarcts often have a liver pathology and/or nephritis. The diagnosis is made with the history (peracute onset of nonprogressive neurological deficits) and MRI findings. Typical MRI findings include a well-defined lesion with sharp demarcation that is hyperintense in T2-weighted images and fluid-attenuated inversion recovery (FLAIR) sequences and has minimal to no mass effect (Figure 265-7) and minimal peripheral or no contrast enhancement. The sensitivity and specificity of MRI in the diagnosis of CVA is improved with the use of newer functional studies like the diffusion-weighted imaging, but its use is not widely available in veterinary medicine.[42] Gradient echo images (T2* or T2-GRE) are helpful in identifying hemorrhagic infarcts, as hemorrhages will appear hypointense on this sequence no matter the age of the hemorrhage. Evaluation of coagulation can be helpful in the diagnosis of hemorrhagic infarcts. Thromboelastography (TEG), which evaluates clot formation and lysis, can detect a hypercoagulable state. Unfortunately, this test has very limited availability at this time. If a hypercoagulable state is confirmed

or suspected, treatment with clopidogrel (1-3 mg/kg PO q 24 h), an ADP-receptor antagonist, can help reduce platelet aggregation.

FIGURE 265-7 Transverse fluid-attenuated inversion recovery magnetic resonance image of the brain of a dog. There is a well-defined hyperintense lesion with sharp demarcation and no mass effect in the cerebellum compatible with a vascular accident (rostral cerebellar artery).

Treatment is mainly supportive and attention should be made to ensure good hydration, blood pressure, and oxygenation (Video 265-6). The prognosis is guarded to good, but dogs with a concurrent disease have a shorter survival and an increased risk of relapse.[44] A retrospective study of 23 dogs with ischemic stroke reported a mortality rate of 23% within 30 days but a mean survival of 505 days.[55] Sometimes, episodes of paroxysmal neurologic events are seen prior to the presentation (sometimes described as seizures because of their short duration) and these could represent transient ischemic attacks (TIAs).[42] TIAs are episodes of brief, focal neurologic deficit secondary to embolism, vascular constriction, or spasms that resolve within 24 hours with most of them resolving within minutes to few hours.[46] In humans, TIAs precede cerebellar infarcts in 26% to 41% of cases. TIAs are poorly recognized and understood in veterinary medicine.

Toxicosis

Metronidazole toxicity in dogs causes acute to subacute bilateral central vestibular signs usually accompanied by cerebellar signs (intention tremors, hypermetria) (Video 265-7). Resting or positional vertical nystagmus is a common finding. Anorexia and vomiting often precede the vestibular signs. The exact mechanism of toxicity is unknown but metronidazole seems to interact with the GABA receptors in the cerebellum and vestibular nuclei. Toxicosis is usually seen with daily administration of more than 60 mg/kg/day for 3 to 14 days but has been reported in dogs receiving as little as 33 mg/kg/day.[47] Recovery usually occurs in 1 to 2 weeks after stopping the metronidazole with supportive care. The addition of diazepam (0.5 mg/kg IV followed by 0.5 mg/kg PO q 8 h) to the treatment fastens the recovery to about 1 to 3 days because of its effect on GABA receptors.[47] In cats, metronidazole toxicosis tends to cause forebrain disturbance (seizures,

blindness, ataxia) instead of vestibular signs.[48]

Others

Thiamine Deficiency

Thiamine (vitamin B_1) deficiency causes bilateral necrosis and hemorrhage in susceptible brain nuclei (also see ch. 12). In cats, the vestibular and ocular nuclei are often affected, leading to vestibular signs and dilated, unresponsive pupils, often with profound ventroflexion of the head and neck. Thiamine deficiency can occur in patients fed a diet rich in thiaminase (raw fish) or canned food subjected to excessive heat (>100° C or 212° F).[50] Sulfur dioxide used as a preservative can destroy thiamine in food. Diagnosis is based on history, typical MRI findings and blood thiamine level.[57] Treatment consists of thiamine administration (12.5 to 50 mg per patient per day, IM, SC, or PO) and the prognosis is usually good if the disease is recognized and treated rapidly.

Anomaly

Some malformations and congenital anomalies can cause vestibular signs. Among those, the caudal occipital malformation syndrome common in Cavalier King Charles Spaniels and sometimes seen in other small-breed dogs is probably the most common. An arachnoid cyst, especially in the quadrigeminal cistern, can also cause cerebellar deficits.

Trauma

Head trauma can cause vestibular signs because of cerebellar and/or brainstem involvement. If the brainstem is affected, obtundation and even stupor or coma is likely. The prognosis for head trauma is fair for a cerebellar lesion and very guarded with brainstem involvement.

Degenerative Diseases

Storage disease, abiotrophy, and cerebellar hypoplasia among others can cause vestibular signs. These diseases are usually progressive and the prognosis is guarded to poor.

Postanesthetic Vestibular Syndrome in Cats

The author and other veterinarians from the province of Quebec, Canada, have seen and reported cases of acute vestibular syndrome following anesthesia in young cats. In a retrospective study, 18 cases have been evaluated over a period of 4 years.[51] In this study, 90% of the cats were between 3 and 6 months with 72% being between 3 and 4 months. These cats recovered normally from the anesthesia with no observed deficits and the vestibular signs appeared 2 to 24 hours after the recovery. Most cats were alert, although salivation and nausea were occasionally reported. No ear cleaning was performed during the procedure in any of the cats. Recovery took 48 hours to 10 weeks with the vast majority being back to normal within a week. The cause of the condition is unknown and no anesthetic complications were reported in any of the cases. Not a single drug or combination of drugs or technique was identified to be common to every case (Video 265-9).

Episodic

Episodic vestibular disturbance is sometimes seen, mostly in dogs (Video 265-8). The episodes may last a few seconds to a few minutes and are characterized by a head tilt, loss of balance, and nystagmus. In some patients, the episodes seem to be induced by excitement or certain activities or movements. The etiology of these "vestibular episodes" is probably varied. Some cases may represent TIAs, while others are likely secondary to hypertensive encephalopathy and therefore, serial blood pressure evaluations should be considered in these cases. Hypertensive encephalopathy has been reported with both acute and sustained elevation in systolic blood pressure (see ch. 99 and 157). The clinical signs are often reversible with normalization of the blood pressure.[56] However, the etiology remains undetermined in many cases despite an extensive diagnostic workup. It is possible that some seizures may present with vestibular signs. In humans, temporal lobe epilepsy can cause dizziness and vertigo.[52] Two conditions tend to cause episodic vestibular disturbance in humans: benign paroxysmal positional vertigo (BPPV) and Meniere's disease. With BPPV, the episodes are usually triggered by certain head positions. They last a few seconds and the condition can

resolve in a few months.[52] Although these conditions have not been reported in veterinary medicine, the episodic vestibular syndrome could represent one of these.

CHAPTER 266

Spinal Cord Diseases

Congenital (Developmental), Inflammatory, and Degenerative Disorders

Ronaldo Casimiro da Costa, Simon R. Platt

Client Information Sheets:
Intervertebral Disc Disease in Dogs
Wobbler Syndrome

Cervical Spondylomyelopathy

Etiology and Pathogenesis

Cervical spondylomyelopathy (CSM) is the most common disease of the cervical vertebral column of large- and giant-breed dogs. Fifteen names have been used to describe this disease (wobbler syndrome, cervical vertebral instability, cervical malformation-malarticulation syndrome, among others) reflecting the limited understanding of the disease's pathogenesis.[1-4]

The cause of CSM remains unresolved. Genetic, congenital, body conformation, and nutritional factors have been proposed; however, both body conformation and nutrition do not appear to be significant.[5,6] Current evidence supports a congenital etiology with a genetic basis. This has been documented in Dobermans as an autosomal dominant trait with variable penetrance.[7]

There are two forms of CSM, which despite some degree of overlap, can be broadly divided into osseous-associated compression and disc-associated compression.[1,8,9] Disc-associated compression typically is seen in middle-aged large-breed dogs (mostly Dobermans). It is caused by intervertebral disc protrusion with or without hypertrophy of the dorsal longitudinal ligament or ligamentum flavum (Figure 266-1, *A*). The vast majority of these compressions affect the C5-6 and C6-7 discs. The pathophysiology of the osseous form is different. This form is seen predominantly in young adult giant-breed dogs, especially Great Danes. Giant breeds usually have spinal cord compression secondary to proliferation of the vertebral arch (dorsally), articular processes (dorsolaterally), or articular processes and pedicles (laterally) (Figure 266-1, *B*). The cause of the compression appears to be a combination of vertebral malformation and osteoarthritic-osteoarthrotic changes affecting the articular processes.[1]

FIGURE 266-1 **A:** Disc-associated cervical spondylomyelopathy. *Top:* Ventral spinal cord compression and nerve root compression at C5-6 caused by intervertebral disc protrusion. Dorsally, hypertrophy of the ligamentum flavum causes mild spinal cord compression. **a,** Transverse section at the level of the C4-5 disc region showing normal spinal cord and vertebral canal. **b,** Ventral compression at the C5-6 region caused by intervertebral disc protrusion and hypertrophy of the dorsal longitudinal ligament and ligamentum flavum (leading to mild dorsal compression). **c,** Asymmetric intervertebral disc protrusion at C6-7 causing spinal cord and nerve root compression. **B:** Osseous cervical spondylomyelopathy. **a,** Severe dorsolateral spinal cord compression at C2-3 caused by osseous malformation and osteoarthritic changes. **b,** Normal C3-4 disc region. **c,** Bilateral compression at C4-5 caused by osteoarthritic changes and medial proliferation of the facets resulting in absolute vertebral canal stenosis and foraminal stenosis, which lead to spinal cord and nerve root compression, respectively. *Bottom:* Dorsal spinal cord compression at C3-4 caused by lamina malformation and hypertrophy of the ligamentum flavum. Osteoarthritic changes also are shown at C2-3. (From da Costa RC: Cervical spondylomyelopathy (wobbler syndrome) in dogs. *Vet Clin North Am Small Anim Pract* 40(5):881-913, 2010.)

Clinical Findings

Dogs with CSM will typically present with a longstanding history of chronic and progressive gait deficits affecting mainly the pelvic limbs. The main neurological abnormality is proprioceptive ataxia leading to a "wobbly" gait (thus the name "wobblers"), along with variable degrees of weakness affecting the pelvic limbs or all four limbs. Since most lesions are located in the caudal cervical region, many dogs present with the so-called "two-engine gait," where the thoracic limb gait can appear choppy and short-strided, whereas the pelvic limb gait is often wide-based (abducted), with a longer stride length, and markedly uncoordinated (Video 266-1). Postural reaction deficits (proprioceptive positioning deficits) are usually seen, but may not be evident in those with a chronic history despite the presence of proprioceptive ataxia, thus reinforcing the importance of a careful gait evaluation (see ch. 259). Spinal reflexes in the thoracic limbs will usually reveal decreased flexor (withdrawal) reflex with normal to increased extensor tone. The pelvic limb reflexes will be normal to increased. Palpation of the cervical spine may reveal pain; however, cervical hyperesthesia is not a prominent feature of this disease. Forceful manipulations of the cervical spine are unnecessary and can lead to severe neurologic decompensation.

Diagnosis

Definitive diagnosis should be made using advanced imaging (computed tomography [CT] or magnetic resonance imaging [MRI]) or myelography. Survey radiographs cannot be used as the only criteria for diagnosis. Radiographs can be used as a screening test to rule out other differential diagnoses and for a presumptive diagnosis. Radiographic findings seen in the disc-associated form are primarily changes in the shape of the vertebral body, narrowing of the intervertebral disc space, and vertebral canal stenosis. Osteoarthritic, sclerotic changes of the articular processes are the radiographic hallmarks in giant-breed dogs with osseous compressions, and can be seen on lateral and ventrodorsal projections.[10] Myelography is no longer the method of choice to diagnose CSM. It can be used if CT and MRI are not available. CT is a rapid test that allows visualization of transverse sections of the cervical spine. It has to be combined with myelography to identify the exact location of the compressive lesion(s). It provides superior visualization of the direction and severity of the spinal cord compression compared with myelography.[11] MRI is the gold standard test for diagnostic evaluation and has been shown to be superior to myelography and complementary to CT.[12-14] The main advantage of MRI is that it detects spinal cord signal changes (seen in approximately 50% of affected dogs), allowing precise identification of the site(s) most severely affected.[15]

Treatment

Ideally the *natural history* of a disease should be understood so that treatment recommendations and prognosis can be based on this knowledge. Unfortunately, the natural history of CSM has not been defined. It appears that the disease progresses slowly in many dogs with both forms of CSM.[4,16] The two broad options for treatment are medical (conservative) or surgical. Conservative management is a viable option for many dogs, primarily those giant-breed dogs with multiple compressive lesions affecting the lateral aspect of the spinal cord. It may also be appropriate to start dogs on medical management initially to evaluate the improvement obtained with it, and to give owners the opportunity to decide on surgery. The response to medical management can be used to indirectly evaluate the degree of reversibility of spinal cord lesions. The most important component of medical management is exercise restriction to minimize the dynamic component of spinal cord injury.[1,17] Dogs can be leash-walked, but free, unsupervised activity is strongly discouraged. A body harness should be worn instead of a neck collar. Corticosteroids appear to benefit dogs with CSM, and anti-inflammatory dosages of prednisone often are used (0.5 to 1 mg/kg PO q 12 to 24 h) progressively tapering it over the course of 2 to 4 weeks. Proposed mechanisms of actions for corticosteroids are reduction of vasogenic edema, protection from glutamate toxicity, and reduction of neuronal and oligodendroglial apoptosis.[18-20] Surviving demyelinated axons may also remyelinate with treatment. Due to the possibility of gastrointestinal complications, omeprazole or famotidine is often used in conjunction with corticosteroid therapy. Approximately 50% of dogs improve with medical management.[16,21-23]

Surgery is generally assumed to represent the treatment of choice for most dogs with CSM.[2,24] Because most affected dogs have spinal cord compression, decompressing the spinal cord in theory provides the definitive treatment. It is important, however, to consider several factors such as severity of neurological signs, type and severity of compressive lesion(s), response (or lack of response) to medical management,

short- and long-term expectations of the owner, and presence of other concurrent neurological, orthopedic, systemic or cardiac diseases such as dilated cardiomyopathy that would affect the long-term outcome. This is also one of the most controversial topics regarding this disease. Twenty-seven surgical techniques have been proposed to treat CSM.[24,25] They can be broadly divided into direct decompression (e.g., ventral slot or dorsal laminectomy), indirect decompression (e.g., distraction techniques with polymethyl methacrylate plug), and motion-preserving techniques (disc replacement).[24-28] Currently no technique is clearly superior. Approximately 70-80% of dogs improve with surgical treatment, although many deteriorate 2-3 years after surgery. Extensive discussion on surgical options is beyond the scope of this chapter.

Degenerative Lumbosacral Stenosis

Etiology and Pathogenesis

Degenerative lumbosacral stenosis is a common disease of adult large-breed dogs. Several terms have been used to describe it, such as cauda equina syndrome, cauda equina compression, lumbosacral stenosis or disease, lumbosacral instability, and degenerative lumbosacral stenosis.[29-31] These terms all encompass a syndrome characterized by stenosis (narrowing) of the lumbosacral region frequently caused by intervertebral disc protrusion (Figure 266-2). The basic pathophysiology involves chronic progressive intervertebral disc degeneration, with subsequent protrusion of the L7-S1 intervertebral disc into the vertebral canal along with proliferation of the soft tissues surrounding the cauda equina, such as hypertrophy of the interarcuate ligament (ligamentum flavum), the joint capsule, and epidural fibrosis.[29,32,33]

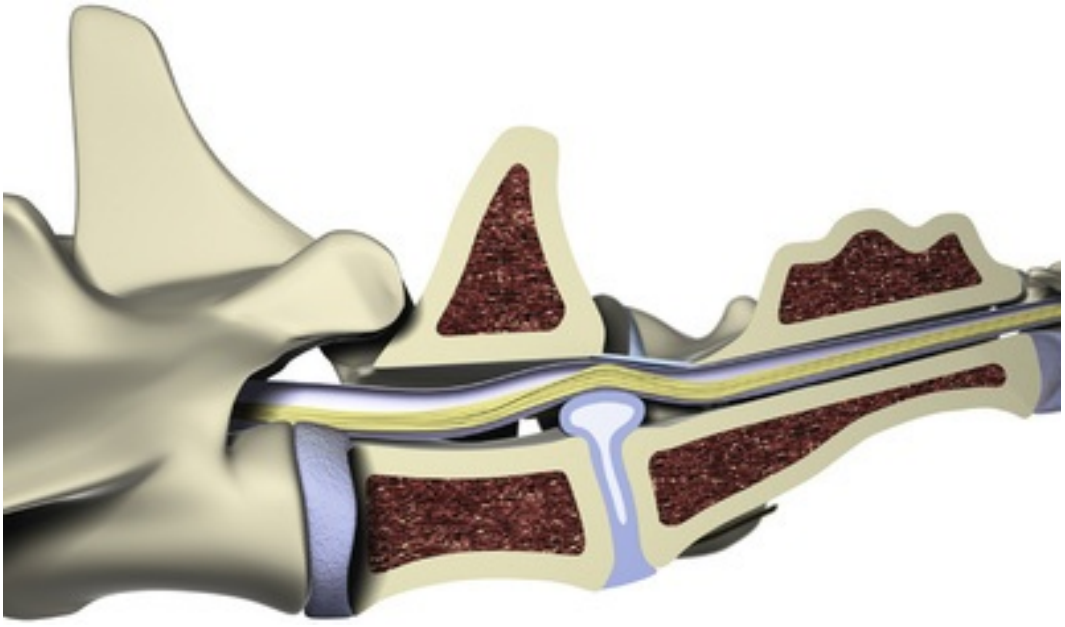

FIGURE 266-2 Schematic illustration of intervertebral disc protrusion at L7-S1 compressing the cauda equina. (From Dewey CW, da Costa RC: *Practical guide to canine and feline neurology*, ed 3, Ames, IA, 2015, Wiley.)

The specific causes for the high incidence of this degenerative process in the lumbosacral region are unknown. A genetic basis was proposed recently in German Shepherds.[34] It appears that the presence of transitional vertebrae or sacral osteochondrosis at the lumbosacral junction in German Shepherd Dogs as well as other large-breed dogs is associated with development of degenerative lumbosacral stenosis.[34-37] German Shepherds have also been shown to have vertebral canal stenosis and a higher step between L7-S1 compared to other breeds.[34]

Clinical Signs

The signs reflect compression of the spinal nerves and nerve roots at the lumbosacral region. The main

clinical sign is lumbosacral pain. Patients will come with a history suggestive of pain, such as difficulty or reluctance to sit, jump, go up stairs and lameness. Careful palpation of the lumbosacral area, including lordosing the caudal spine while pressing on the lumbosacral area, elevation of the tail, or rectal palpation, should cause pain. It is important to always perform rectal examination in these dogs as neoplasms in the pelvic canal can extend dorsally, causing signs of cauda equina dysfunction.[29]

Gait examination of affected dogs reveals pelvic limb weakness (without proprioceptive ataxia), and often a "stiff" gait. In some cases, the only sign is uni- or bilateral lameness, which can be misinterpreted as a sign of orthopedic disease. Many large dogs also have concurrent orthopedic diseases, highlighting the importance of a good neurologic evaluation (see ch. 259) and spinal palpation. Most dogs will have deficits on proprioceptive positioning tests of the pelvic limbs, with a decreased flexor reflex (primarily poor hock flexion), and a normal patellar reflex (sometimes with "pseudohyperreflexia"). In the latter stages of the disease, patients may show urinary and/or fecal incontinence.

Diagnosis

Diagnosis of degenerative lumbosacral stenosis is based upon signalment (mostly middle-aged to older large-breed dogs), historical and clinical findings, and results of imaging tests of the lumbosacral region. Radiographic examination should always be the initial imaging test. It is rarely diagnostic by itself, but can be used to rule out discospondylitis, osseous spinal neoplasms and traumatic lesions. Common radiographic findings are collapse of the intervertebral disc space, sclerosis of the vertebral endplates, malalignment of the sacrum with the L7 vertebra, narrowing of the cranial foramina of the sacrum, and spondylosis.

A number of procedures have been proposed to definitively diagnose degenerative lumbosacral stenosis, but it is clear that CT and MRI (primarily MRI) provide the most detailed structural information regarding the cauda equina, including information concerning the L7-S1 intervertebral foramina and L7 nerve roots.[32,38-43] It is important to bear in mind that clinically normal dogs (mainly older dogs) can have compression of the lumbosacral region without associated clinical signs, and that the degree of cauda equina compression seen on imaging does not correlate with presence of disease or its severity.[42,44] This is one of the challenges associated with the diagnosis of lumbosacral stenosis.[45]

Treatment

Treatment of the patient with degenerative lumbosacral stenosis may be non-surgical or surgical. Treatment decisions are based primarily on severity of clinical signs, age of the patient, and concurrent diseases (neurologic and non-neurologic). Non-surgical therapy consists of enforced rest initially for a few weeks, followed by a period of regular short walks to maintain muscle mass. Additionally, anti-inflammatory medication (either non-steroidal drugs or prednisone, not both; see ch. 164), analgesics (such as gabapentin; see ch. 126, 166, and 356), and body weight reduction (see ch. 176) are recommended.[29,33] Non-surgical or conservative treatment is a reasonable initial option, primarily in older patients with multiple orthopedic or systemic diseases. A recent retrospective study evaluated the short- and long-term follow-up of 31 dogs treated medically, and found a successful outcome in 55% of cases (17 out 31 dogs).[46] Epidural steroids are a popular therapeutic approach in people for lumbar and lumbosacral disc herniations compressing nerve roots.[47] A retrospective study evaluated the use of fluoroscopic-guided epidural steroid injections and found an improved outcome in 79% of dogs.[48]

Surgical treatment is elected when the patient's signs are severe or refractory to medical management. Surgery usually consists of a dorsal laminectomy over the L7-S1 interspace, often combined with removal of hypertrophied soft tissue. Lateral extension of the decompression (facetectomy) may be necessary depending on the lesion. Stabilization may also be necessary in some cases. In cases of lateralized foraminal stenosis, as opposed to vertebral canal stenosis, foraminotomy (surgical enlargement of the foramen) may need to be performed.[49] The prognosis for functional recovery from this disorder is generally good to excellent with surgical intervention. Successful outcomes after surgery range from 66.7% to 95% of cases.[50-52] Surgical treatment is less successful in dogs with fecal or urinary incontinence, with a report indicating failure of resolution of incontinence in 55% to 87% of cases.[29,33,50-52]

Extradural Synovial Cysts

Etiology and Pathogenesis

Extradural synovial cysts (ESC) or extradural intraspinal cysts are cysts arising from periarticular joint tissue. They can be divided into two cyst types: synovial and ganglion cysts. Synovial cysts have a synovial lining containing fluid, and ganglion cysts contain myxoid material with no specific lining. These are pathological differences that may indeed reflect different stages of the same disease.[53] Considering that both types of cysts occur in close proximity with the intervertebral joints, the term *juxtafacet cysts* has been coined to encompass both cysts.[53] The pathophysiology of these cysts is not well established. It is thought that degeneration of the zygapophyseal joint (osteoarthritic changes) causes protrusion of the synovial membrane through defects of the joint capsule. Protrusion of the synovial membrane will cause the formation of a para-articular cavity filled with synovial fluid, which leads to extradural compressions.[53,54] Other proposed mechanisms are proliferation of pluripotent mesenchymal cells, myxoid degeneration with cyst formation in collagen tissue, and increased production of hyaluronic acid by fibroblasts.[54] Some of the affected dogs with lumbosacral cysts had transitional vertebrae, and this may be a risk factor.[55]

Clinical Findings

The clinical signs of synovial cysts will reflect their location in the vertebral column, with the two most frequent locations being the lumbosacral and cervical regions. Clinical signs of cervical cysts are those of a cervical myelopathy with proprioceptive ataxia and tetraparesis, whereas pelvic limb lameness or weakness, with or without pain on palpation, can be seen with lumbosacral cysts.[54,55]

Diagnosis

The majority of reported dogs with lumbosacral/caudal lumbar synovial cysts were large-breed, middle-aged or older dogs (median age 8 years).[53] Cervical synovial cysts are relatively common in association with the osseous form of CSM in young, giant-breed dogs.[3,56,57] Two MRI studies indicate that they occur in 20% of dogs with CSM.[3,56,57]

Diagnosis of synovial cysts is best done with MRI (Figure 266-3). In human beings, MRI is reported to have a sensitivity of 90% for the diagnosis of ESC, compared with 70% with CT.[58] Both soft tissue and bone windows have to be used to increase accuracy of CT to detect these cysts. MRI in dogs reveals the cysts as well-circumscribed extradural masses on one or both sides of the vertebral canal. They are hyperintense in T2-weighted images, with variable characteristics on T1-weighted images.[55,56,59] Radiographic changes are non-specific and will only indicate degenerative joint disease in the affected sites. Myelographic changes may be suggestive but are not diagnostic. Changes in the lateral projection are dorsal extradural compression(s), and in the ventrodorsal view, uni- or bilateral axial compressions.[54] Cerebrospinal fluid (CSF) typically reveals albuminocytologic dissociation but mild mononuclear pleocytosis may also be seen.[53,54]

FIGURE 266-3 Extradural synovial cyst in a Great Dane with the osseous form of cervical spondylomyelopathy (arrow).

Treatment

Treatment of these cysts is typically surgical, many times done at the same time as the decompressive surgery (dorsal laminectomy) for CSM or degenerative lumbosacral stenosis. In humans, however, many of these cysts are asymptomatic, and in many cases may be incidental findings.[60] The same may be true for dogs. Therefore, attempting medical management with activity restriction and anti-inflammatories is recommended initially. All reported cases of surgical treatment of synovial cysts had positive outcomes.[53]

Spinal Arachnoid Diverticula (Cysts)

Etiology and Pathogenesis

Spinal arachnoid diverticula are focal dilations of the subarachnoid space, which can lead to a progressive, compressive myelopathy. These diverticula were previously called arachnoid cysts, but this is a misnomer because they are not closed epithelial lined cavities.[53,61,62] They have also been called intra-arachnoid or subarachnoid cysts, meningeal cysts, leptomeningeal cysts, and pseudocysts.[63-65] Currently, it appears that these diverticula are being recognized more frequently with the widespread use of MRI. In people, cyst-like structures of the meninges have been classified into three types, with type III (intradural forms) best fitting the diverticula described in dogs.[53,61]

The etiology of these cysts is not fully understood. A recent report indicated a genetic predisposition in Pugs.[62] It appears that a congenital etiology is likely in the cases seen in young dogs. Other proposed causes are the presence of concurrent diseases. A large, recent case series indicated that 21.3% of dogs had concurrent diseases (e.g., intervertebral disc disease, vertebral malformations, myelitis) in close proximity with the diverticula, which might have influenced their development.[66]

Two recent studies reviewed 215 cases of arachnoid diverticula.[53,66] These studies revealed that approximately 55% of these diverticula occur in the cervical region, whereas 45% are seen in the thoracolumbar region. The most common specific sites were C2 and C3, and T9 to T13. Large-breed dogs have

a predilection for cervical diverticula, whereas small-breed dogs have a tendency to have thoracolumbar diverticula.[53,66] Approximately 88% of the diverticula appear to be located in the dorsal aspect of the spinal cord, 8% in the ventral region, and the remainder in the lateral or circumferential regions.

Clinical Signs

Clinical signs reflect the location of the myelopathy. This disease is primarily characterized by proprioceptive ataxia with various degrees of tetraparesis or paraparesis, without obvious spinal pain. Some dogs with cervical diverticula will display more severe signs in the thoracic limbs, suggesting an intramedullary lesion. A common feature is a severely spastic gait in the thoracic limbs, giving the appearance of "pseudo-hypermetria."[67] Spinal hyperpathia is not a prominent sign, but has been reported in 18.9% of dogs in a large case series (although a good proportion of dogs had concurrent diseases, thus making it difficult to know the exact source of pain).[66] Urinary and fecal incontinence have been reported in approximately 8% of dogs, primarily with thoracolumbar diverticula.

Diagnosis

Two breeds are overrepresented: Rottweilers and Pugs. French Bulldogs are also predisposed to thoracolumbar diverticula. Overall, a male predisposition is clear, with a male-to-female ratio ranging from 2 : 1 to 3 : 1 in large case series. Median age of affected dogs is 2.5 years, ranging from 2.5 months to 13 years. Pugs tend to be affected at an older age (median 59 months).[53,66]

Myelography, CT-myelography or MRI are required to diagnose this disorder (Figure 266-4). Myelography and post-myelographic CT demonstrate these diverticula as contrast-filled teardrop shaped expansions of the subarachnoid space.[53,63] It may also reveal a block of the subarachnoid contrast column without filling of the subarachnoid diverticula. MRI is generally considered the imaging modality of choice to evaluate these diverticula because it also allows assessment of the spinal cord parenchyma and detection of comorbidities, such as syringohydromyelia. It is important to use MR myelogram sequences (heavy T2-weighted images) to facilitate visualization of the diverticulum.[68] CSF analysis is typically normal in the majority of cases. Approximately 20% of dogs show albuminocytologic dissociation and 10% can show mild mononuclear pleocytosis.[53,63]

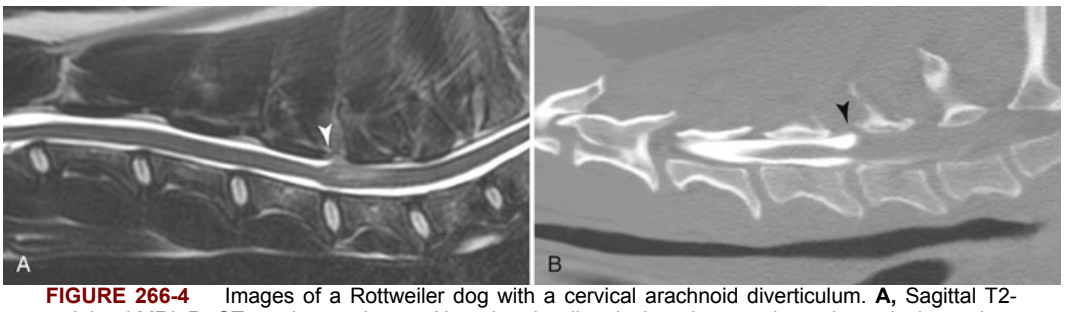

FIGURE 266-4 Images of a Rottweiler dog with a cervical arachnoid diverticulum. **A,** Sagittal T2-weighted MRI. **B,** CT-myelogram image. Note that the diverticulum does not have the typical tear-drop appearance on MRI (white arrowhead). CT-myelography facilitates visualization (black arrowhead) and confirmation. (From Dewey CW, da Costa RC: *Practical guide to canine and feline neurology*, ed 3, Ames, IA, 2015, Wiley.)

Treatment

Medical management (i.e., glucocorticoid therapy) may be attempted initially. In a few cases the signs can be managed for long periods and the disease appears to become stable. Surgical management is typically the treatment of choice. Surgical techniques described involved fenestration with durotomy or durectomy, and marsupialization of the diverticulum. In cases where vertebral instability may be present, stabilization is recommended. From the limited data available, surgical treatment of spinal arachnoid cysts appears to have a good prognosis. It appears that 65-80% of cases have good outcomes.[53,65] It is not clear how many dogs have recurrence because the follow-up of reported cases is variable, but it appears that at least 10-20% of cases have

recurrence of signs. Factors associated with a better outcome were age (younger than 3 years) and duration of clinical signs (less than 4 months).[65]

Spondylosis Deformans

Etiology and Pathogenesis

Spondylosis is a very common degenerative process of the vertebral column, with essentially no clinical significance by itself.[69] It is characterized by the formation of exostoses or bone proliferations around the ventral (and sometimes lateral) vertebral endplate margins, which could result in a bony bridge between adjacent vertebrae.[70] This is a non-inflammatory condition believed to be associated with degenerative changes in the annulus fibrosus of the intervertebral discs in an effort to stabilize the disc region. Osteophytes vary from small spurs to bone bridges across the disc space, leaving at least part of the ventral surface of the vertebral body unaffected. A recent retrospective study of 2041 dogs found spondylosis in 367 (18.1%) of dogs.[70] Spondylosis commonly affects the thoracic, lumbar and lumbosacral regions.

Clinical Signs

It is very tempting to attribute signs of spinal cord disease such as paresis, paralysis or proprioceptive ataxia to spondylosis but such association has never been documented (in spite of the high prevalence of spondylosis). A study suggested that spondylosis may predispose dogs to adjacent segment disease, making them susceptible to the development of intervertebral disc protrusion (type II) in the segments cranial or caudal to the fused disc spaces.[71] Thus, the presence of neurologic deficits should indicate the possibility of concurrent neurologic diseases. The only sign reported to occur in working dogs is a reduction of activity level secondary to the diminished flexibility of the vertebral column.[70] Nerve root compression (leading to pain and lameness) has been documented in dogs with diffuse idiopathic skeletal hyperostosis. It is possible that it could also occur rarely in cases of spondylosis with severe lateralized bony proliferation causing intervertebral foraminal stenosis.[72]

Diagnosis

Spondylosis can be seen in adult animals of various sizes and ages, but is more prominent in middle-aged to older, medium- to giant-breed dogs. Boxers, German Shepherds and Flat-Coated Retrievers seem to be primarily predisposed.[70,73] Diagnosis is established based on the radiographic appearance of vertebral osteophytes arising from the periphery of the endplate, along with sclerotic endplates, and preservation of central portion of the vertebral bodies.[70] It is important to differentiate spondylosis from discospondylitis and disseminated idiopathic skeletal hyperostosis (DISH). As previously stated, spondylosis by itself does not cause neurological signs, so in patients with obvious neurologic signs, further diagnostic work-up with myelography, CT, MRI and CSF is recommended to definitively diagnose the cause of signs (see ch. 115).

Treatment

Spondylosis has no clinical significance in the vast majority of dogs, and treatment is not necessary.[69] In the cases where it can be documented to cause nerve root compression, treatment with analgesics such as gabapentin or surgical decompression of nerve roots may be necessary.[72]

Disseminated Idiopathic Skeletal Hyperostosis (DISH)

Etiology and Pathogenesis

DISH is a systemic disorder characterized by fibrocartilaginous proliferation followed by endochondral ossification within soft tissues of the axial and appendicular skeleton. Ossification of DISH appears to affect an area rather than specific anatomic structures. DISH in dogs is mostly characterized by generalized new bone formation that appears as flowing ossification along the ventral and lateral aspects of the vertebral column.[70]

Initially thought to be a rare condition, a recent report described DISH in 78 dogs (3.8% of 20,141 dogs). Among these 78 dogs, 53 (67.9%) also had spondylosis. The most common locations for DISH were T6-T10

and L2-L6 vertebral regions.[70]

Clinical Signs

Similar to spondylosis, DISH is typically a radiographic finding with little clinical significance. It can cause spinal stiffness and limited performance in working dogs.[70] Spinal pain may be seen, although is probably quite uncommon. It has been shown to cause foraminal stenosis leading to pain and pelvic limb lameness (nerve root signature).[72] As DISH can predispose dogs to adjacent segment disease, any dog with clear neurologic deficits should be thoroughly investigated.[67]

Diagnosis

DISH is seen primarily in older (mean age 8 years), large-breed dogs, with Boxers being overrepresented. The characteristic radiographic appearance is "flowing" ossification primarily at the ventrolateral aspect of the vertebral column, extending for at least four contiguous vertebrae (Figure 266-5).[70,74] The osseous proliferation does not invade the vertebral canal and as such does not cause spinal cord compression or neurologic deficits. There may also be ossification of the interspinous ligaments dorsally, which might be quite extensive.[75,76] It is important to differentiate DISH from spondylosis deformans.[70] Lesions of spondylosis typically spare at least part of the ventral surfaces of adjacent vertebral bodies, and that is the most important radiographic difference with DISH.

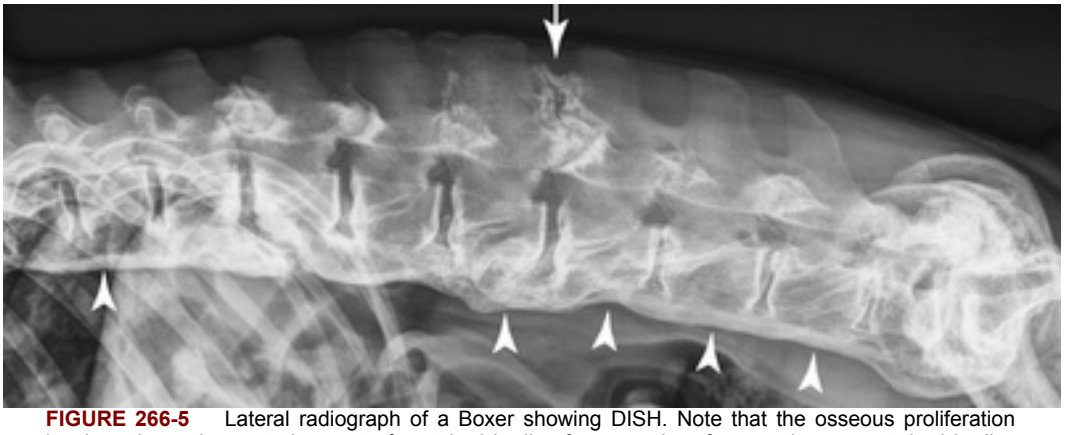

FIGURE 266-5 Lateral radiograph of a Boxer showing DISH. Note that the osseous proliferation involves the entire ventral aspect of vertebral bodies for more than four contiguous vertebral bodies (arrowheads). Osseous proliferation is also seen in the dorsal aspect of the vertebral column at L3-4 (arrow).

An MRI study revealed the signal intensity of the proliferative bone lesions to be of equal intensity to the vertebral bone marrow (on both T1- and T2-weighted sequences). In contrast, in dogs with spondylosis, the signal from osteophytes was hypointense compared to the bone marrow signal on both T1- and T2-weighted images.[77]

Treatment

Similar to spondylosis, the vast majority of dogs with DISH do not display signs secondary to the disease's bone proliferation. If nerve root compression is documented as the source of pain, treatment with analgesics or surgical decompression of nerve roots may be necessary.[72]

Degenerative Myelopathy

Etiology and Pathogenesis

Degenerative myelopathy is a degenerative disease that affects primarily the thoracolumbar spinal cord of medium- to large-breed dogs.[78,79] It has also been called degenerative radiculomyelopathy because of nerve

root involvement.[80]

Immunologic, inflammatory, metabolic, nutritional, oxidative stress, excitotoxic and genetic mechanisms have been explored as underlying the pathogenesis of degenerative myelopathy (DM).[79,81-87] Definitive causal evidence is lacking for most of these mechanisms. An incompletely penetrant autosomal mode of inheritance has been proposed after the identification of a mutation in the superoxide dismutase 1 *(SOD1)* gene in some affected dogs.[85] Familial degenerative myelopathy has been reported in Boxers and Rhodesian Ridgebacks.

Degenerative myelopathy is a primary central axonopathy restricted to the spinal cord that begins in the thoracic spinal cord and ascends and descends along the spinal cord. Axon and myelin degeneration of the spinal cord occurs in all funiculi but primarily in the dorsal aspect of the lateral funiculi and dorsal funiculi. Hence the lesion description is best denoted as a segmental degeneration of the axon and associated myelin rather than Wallerian degeneration.[88,89]

Clinical Signs

The clinical signs are those of chronic thoracolumbar (T3-L3) myelopathy (Video 266-2). Signs start with mild proprioceptive ataxia and paraparesis that slowly progresses, leading to more severe paresis until dogs are non-ambulatory. This progression usually takes 6-12 months in large-breed dogs.[78,79] Lack of spinal hyperesthesia is a typical feature and greatly assists in the differential diagnosis with other compressive myelopathies that occur in older large-breed dogs (such as intervertebral disc protrusion and spinal neoplasia). Proprioceptive deficits are commonly seen in the early disease stages. Spinal reflexes in the pelvic limbs are typically normal to hyperreflexive. Decreased to absent patellar reflexes are found in approximately 10%-15% of patients. This does not necessarily indicate a lower motor neuron lesion, but instead may reflect selective damage to dorsal (sensory) lumbar nerve roots in these dogs. The extensor tone of these dogs is always increased in the earlier phase of the disease, which suggests that the patellar areflexia or hyporeflexia is a sensory, rather than lower motor neuron disturbance. The disease relentlessly progresses, and if the dogs are kept alive it will progress to involve the lumbar and cervical spinal cord regions, as well as the brainstem, causing lower motor neuron deficits, tetraparesis and eventually dysphonia and dysphagia.

Diagnosis

Several large breeds of dogs can be affected with degenerative myelopathy but German Shepherds and Boxers are the most commonly affected breeds. Age of onset of neurologic signs is usually 5 years or older with a mean age of 9 years in large dog breeds. The mean age of affected Pembroke Welsh Corgis was 11.2 years in one study.[84] There appears to be a female predominance (1.6:1) for the disease in Corgis but not in other breeds.[79]

The diagnosis is based primarily on the exclusion of other myelopathies. Spinal imaging (myelogram, MRI, CT) is typically normal, but some dogs may have concurrent mild disc protrusions. The clinician must then consider the duration of clinical signs as well as the findings of the neurological examination to determine the significance of these lesions. MRI is the imaging modality of choice to ensure that all other differentials are ruled out, including intramedullary lesions such as neoplasms.[90] Patients with degenerative myelopathy typically have normal CSF results, or increased protein levels with a normal cell count.[84] A DNA test based on the *SOD1* mutation is commercially available. Dogs that are homozygous for the mutation are at risk for developing DM and will contribute one chromosome with the mutant allele to all of their offspring. The heterozygotes are DM carriers that are unlikely to develop clinical DM but could pass on a chromosome with the mutant allele to half of their offspring.[78] Corticosteroids can be used to assist in the differential diagnosis of this disease. Corticosteroids will typically lead to improvement in dogs with chronic compressive myelopathies (such as intervertebral disc protrusion) but will not benefit dogs with degenerative myelopathy. This strategy might be useful to convince pet owners to pursue advance imaging.[67]

Treatment

No pharmacological therapy has been shown to alter the course of degenerative myelopathy. Vitamin supplementation, glucocorticoid administration, aminocaproic acid, and *N*-acetylcysteine have all been used, but none of these medications showed beneficial effects.[91] The only treatment that has been shown to alter the

long-term course of the disease is physical therapy (see ch. 355).[92] In one retrospective study, dogs with confirmed and suspected degenerative myelopathy had controlled physical therapy, including walking, passive range of motion of the pelvic limbs, massage of pelvic limb and paraspinal muscles, and hydrotherapy. Dogs that were treated with a more intense physical therapy regimen had a mean survival time of 255 days, compared with dogs receiving a moderate regimen (130 days) or no physical therapy (55 days).[92] The long-term prognosis is poor, and most dogs are euthanized due to severe pelvic limb dysfunction within 6-12 months. In the study of Pembroke Welsh Corgis, the average time from diagnosis to death was 1.25 years.[93]

Intervertebral Disc Disease (IVDD)

Etiology and Pathogenesis

The intervertebral discs are interposed in every intervertebral space (except between C1 and C2), uniting the bodies of the adjacent vertebrae.[94,95] Each intervertebral disc consists of an outer laminated fibrous ring (annulus fibrosus) and a central, amorphous, gelatinous center (nucleus pulposus).[96] The nucleus pulposus is highly hydrated gelatinous mesodermal remnant of the notochord.[95] Chondrodystrophic breeds show progressive collagenation and calcification in the nucleus pulposus and inner annulus fibrosus at an early age.[95] The annulus fibrosus consists of bands of parallel fibers that run obliquely from one vertebral body to the next. They provide a means for the transmission of stresses and strains that are required by all lateral and upward movements.[96]

Intervertebral disc degeneration or disease leads to extrusion or protrusion (both termed *herniation*) of disc material into the spinal canal resulting in clinical signs due to spinal cord compression and/or contusion.[94,97] The pathophysiology of the resulting spinal cord injury, which has been well described elsewhere,[97] doesn't always explain the degree of associated neurological dysfunction.[98] IVDD is classified as Hansen type I and type II.[99] Type I IVDD is herniation of the nucleus pulposus through the annular fibers and extrusion of nuclear material into the spinal canal. It is typically associated with chondroid disc degeneration but sometimes a hydrated nucleus pulposus extrusion can be responsible for spinal cord dysfunction.[100,101] The disc extrudes through the dorsal annulus causing ventral, ventrolateral or circumferential compression of the spinal cord. Type I IVDD typically affects chondrodystrophic breeds and has an acute onset. However, large non-chondrodystrophic breeds of dog such as the Doberman Pinscher and Labrador Retriever, may also be affected,[102] particularly when subsequent to trauma.[103] Congenital vertebral malformations result in early degeneration of adjacent intervertebral discs,[104] although clinical disc disease at these sites may not be as common as elsewhere in the spinal column.[105] Long backs, miniaturization and being overweight also increases the risk of type I IVDD.[106] Hansen type II IVDD is annular protrusion caused by shifting of central nuclear material and is commonly associated with fibroid disc degeneration. The annulus fibrosus slowly protrudes into the spinal canal to cause spinal cord compression. The chronic compression can lead to focal ischemic and other microvascular derangements of the spinal cord. Type II IVDD usually occurs at the mobile points of the spinal column and is more common in older, non-chondrodystrophic breeds of dog. It is not uncommon to identify multiple affected disc spaces. Chronic spinal instability may be an underlying predisposition to type II IVDD.

Cervical Disc Disease

Clinical Findings

Most dogs with cervical disc disease, which accounts for 14% to 25% of intervertebral disc disorders in dogs,[107,108] have disc extrusion rather than protrusion.[109] Chondrodystrophoid and other small breeds are at the greatest risk. Dachshunds, Toy Poodles and Beagles have been documented to account for the majority of cases[110]; however, large-breed dogs such as Labrador Retrievers, Dalmatians and Dobermans can be affected with cervical disc extrusions, accounting for up to 24% of all cases.[94,109,111,112] Most affected dogs are between 4 and 8 years of age when they present with clinical signs with a mean age ranging from 6.3 years to 8.6 years; it is extremely rare for dogs less than 2 years of age to be affected.[109-113] Males and females are evenly affected.[110] When large-breed dogs are affected by acute or chronic cervical disc disease, an underlying concurrent malformation and/or instability as part of a CSM syndrome should always be considered (see

CSM section). Most cases of cervical disc disease in chondrodystrophoid dogs occur in the cranial cervical spine, with 80% affecting C2-C4 spaces and 44%-59% affecting C2-C3 alone[107,108]; however, most large-breed dogs are affected at the C6-C7 intervertebral disc space and most protrusions versus extrusions are more caudally located.[109,113]

Approximately 45% of dogs with cervical disc extrusion will have an acute onset of signs, with 55% experiencing a slower onset of signs, whether the dogs are large non-chondrodystrophoid or small breeds.[109] The predominant clinical sign is neck pain, which can be seen in up to 60% of dogs with no neurological deficits and nearly 90% of affected dogs overall.[109,114] Neck pain, evident from the animal's posture or from palpation of the spine and muscles of the neck, can be extreme, unremitting and refractory to medication, which is apparently less likely with hydrated nucleus pulposus extrusions than with other disc-related disease.[101] Nerve "root signature" is another frequent finding with cervical disc disease and can be seen in 22-50% of dogs.[108,114] Neurological deficits may be restricted to one thoracic limb or the animal may show hemiparesis, tetraparesis or even tetraplegia with hypoventilation. Ambulatory tetraparesis is seen in up to 42% of dogs and 11-22% exhibit non-ambulatory tetraparesis.[109,114,115] Tetraplegia is uncommon and has been described in 2-7% of cases.[109] Neurological deficits are more common with lesions at C4-C5 to C6-C7 inclusive, which may reflect the greater degree of space in the cranial vertebral canal compared to more caudally.[116] The reduction or loss of thoracic limb reflexes usually implies a C6-T2 spinal cord lesion; however, 36% of dogs with reduced to absent thoracic limb reflexes actually have a C1-C5 spinal cord lesion.[112]

Diagnosis

Survey radiographs can help to rule out discospondylitis, neoplasia and anatomic malformations, which may be considerations given the clinical signs.[117] Although radiographic signs such as narrowing of the intervertebral disc space and dorsal displacement of mineralized disc material may be highly suggestive of disc extrusion, myelography, CT or MRI is essential for a definitive diagnosis.[117] The overall accuracy rate for correct identification of the site(s) of disc extrusion with radiography is 35%.[117] CSF analysis should be considered to rule out inflammatory disease (see ch. 115). Deviation of the ventral contrast column is the most common myelographic finding of cervical disc disease; oblique views can help with lateralized or foraminal localizations.[118,119] CT performed after myelography can provide more detailed information on the localization of the compressive lesion (Figure 266-6), particularly for lateralized discs and intradural discs.[120,121] MRI is the best method for evaluation of the cervical spinal cord and provides a safe and non-invasive method for obtaining high-resolution images (see Figure 266-6).[122,123] This imaging modality can provide detailed information on the structure of the intervertebral discs and spinal cord and may help with prognosis.[124,125]

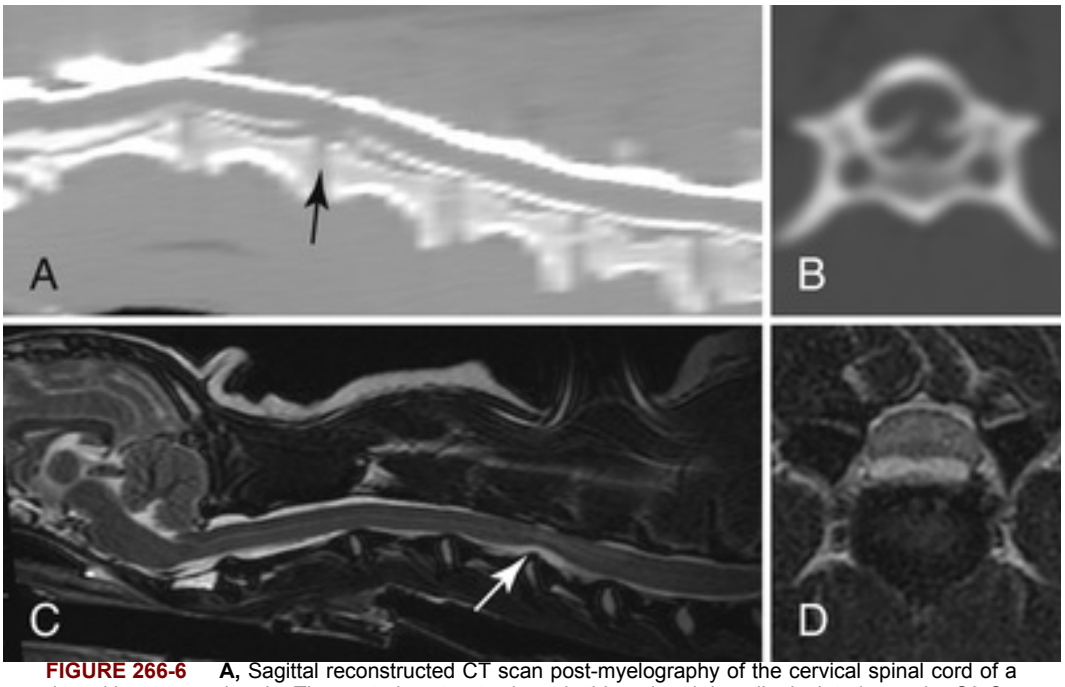

FIGURE 266-6 **A,** Sagittal reconstructed CT scan post-myelography of the cervical spinal cord of a dog with acute neck pain. The ventral contrast column is thinned and dorsally deviated over the C3-C4 disc space (arrow) due to a disc extrusion (type I disease). **B,** The transverse CT-myelographic image at the level of the C3-C4 disc space confirms ventral cord compression. **C,** A sagittal T2-weighted MRI of the cervical spinal cord of a dog with acute tetraparesis. Ventral cord compression can be identified above the C4-C5 disc space due to a hyperintense lesion (arrow). **D,** A transverse T2-weighted MRI at the C4-C5 disc space confirms that the cord is ventrally compressed by a hyperintense structure, which is compatible with acute hydrated nucleus pulposus extrusion.

Treatment

Strict cage rest for 4-6 weeks is the most important aspect of a conservative approach to cervical disc disease. This can be followed by restricted and gradual incremental exercise over the next month using a body harness rather than a collar and leash. The protracted period of rest enables resolution of the inflammation and stabilization of the ruptured disc by fibrosis, preventing further herniation.[94] The use of anti-inflammatory medications such as corticosteroids or non-steroidal analgesics can be recommended for a few days to accompany the rest (see ch. 164). Analgesic medications may be necessary in some dogs in addition or in place of the anti-inflammatory medications (see ch. 126, 166, and 356). The use of acupuncture in dogs with cervical disc disease has been described and was reported to be associated with an initial recovery in 69% of cases (see ch. 356).[126] Muscle relaxants such as diazepam and methocarbamol are useful adjunctive medications in dogs with neck pain related to disc disease. Signs of nerve root involvement such as nerve root signature, or foraminal herniation identified on advanced imaging, may be treated with gabapentin (10-20 mg/kg PO q 8 h). Recurrence rates of 33-36% or more have been reported with conservative approaches.[126-128] A study evaluating 88 dogs with conservatively managed presumptive cervical intervertebral disc herniation found that 49% of cases had a successful outcome, 33% recurred and 18% had therapeutic failure.[128] More chronic disease duration and more severe neurological deficits may result in less success when managed conservatively, as is the case with thoracolumbar disc disease.[128]

The decision to treat surgically is often based on multiple factors. Pertinent criteria include neurological severity, chronicity, whether the signs represent a recurrence, response to medical treatment, systemic health of the patient and owner finances. Symptomatic patients can be divided into three groups: group I, first episode involving neck pain only; group II, repeated episodes of neck pain only; and group III, neck pain and concurrent neurological deficits.[94] Medical therapy can often be recommended for group I dogs. Surgical decompression is most appropriate for group II dogs and is necessary for group III dogs.

When treated with ventral slot decompression alone, complete recovery is observed in up to 90% of dogs at 1 month and 98% of dogs at 12 months following surgery.[114] Long-term follow-up (6 months to 4 years) for ventral slot decompression for caudal cervical disc protrusion in large-breed dogs revealed only a 66%

success rate, and it was concluded that dynamic compressive lesions may need a stabilization procedure.[129] The recurrence rate following surgery for cervical disc disease has been suggested to be approximately 5 to 10%, with a mean time to recurrence being 91 days for all dogs.[109,127] Several significant adverse events have been reported in up to 10% of dogs undergoing ventral slot surgery, which include deterioration in neurologic status, respiratory difficulty, intraoperative hemorrhage and persistent pain.[130]

Thoracolumbar Disc Disease

Clinical Findings

Hansen type I IVDD most commonly occurs within the thoracolumbar region of chondrodystrophic breeds. The thoracolumbar junction (T12-T13 to L1-L2) accounts for the highest incidence of all disc lesions.[131] The incidence of thoracolumbar IVDD progressively decreases from T12-T13 caudally. The most common site for Hansen type I IVDD in large, non-chondrodystrophic breeds is the interspace between L1 and L2[102]; however, German Shepherd Dogs particularly can be affected by discs between T1-T5.[132,133] Onset of neurological signs may be peracute (<1 hour), acute (<24 hours) or gradual (>24 hours). Dogs presenting with peracute or acute thoracolumbar disc extrusions may manifest clinical signs of spinal shock or Schiff-Sherrington postures.[131] These indicate acute and severe spinal cord injury but do not determine prognosis. The degree of neurological dysfunction is variable and affects prognosis. Clinical signs vary from spinal hyperesthesia only to paraplegia with or without pain perception. The incidence rate of focal and ascending/descending myelomalacia has been reported to be as high as 10% in dogs with acute thoracolumbar IVDD and loss of nociception[131,134,135]; the risk of developing this condition may be higher in certain breeds such as French Bulldogs.[105] Severe neurologic dysfunction function is also not an uncommon scenario with acute non-compressive nucleus pulposus extrusions (Hansen type III IVDD, traumatic disc extrusion, high-velocity low-volume disc extrusion) where the extruded nucleus spreads along the epidural space and may completely surround or penetrate the dura mater (Figure 266-7).[136,137] Clinically significant intervertebral disc extrusion has been reported in cats <5 years of age but is more common in middle-aged to older cats.[138,139] Clinical signs due to disc disease in cats may reflect a painful transverse myelopathy at any region of the spinal cord but the probability of clinically significant disc extrusion seems to be higher in the thoracolumbar and lumbar area. Onset of type I IVDD in cats is usually acute.[138]

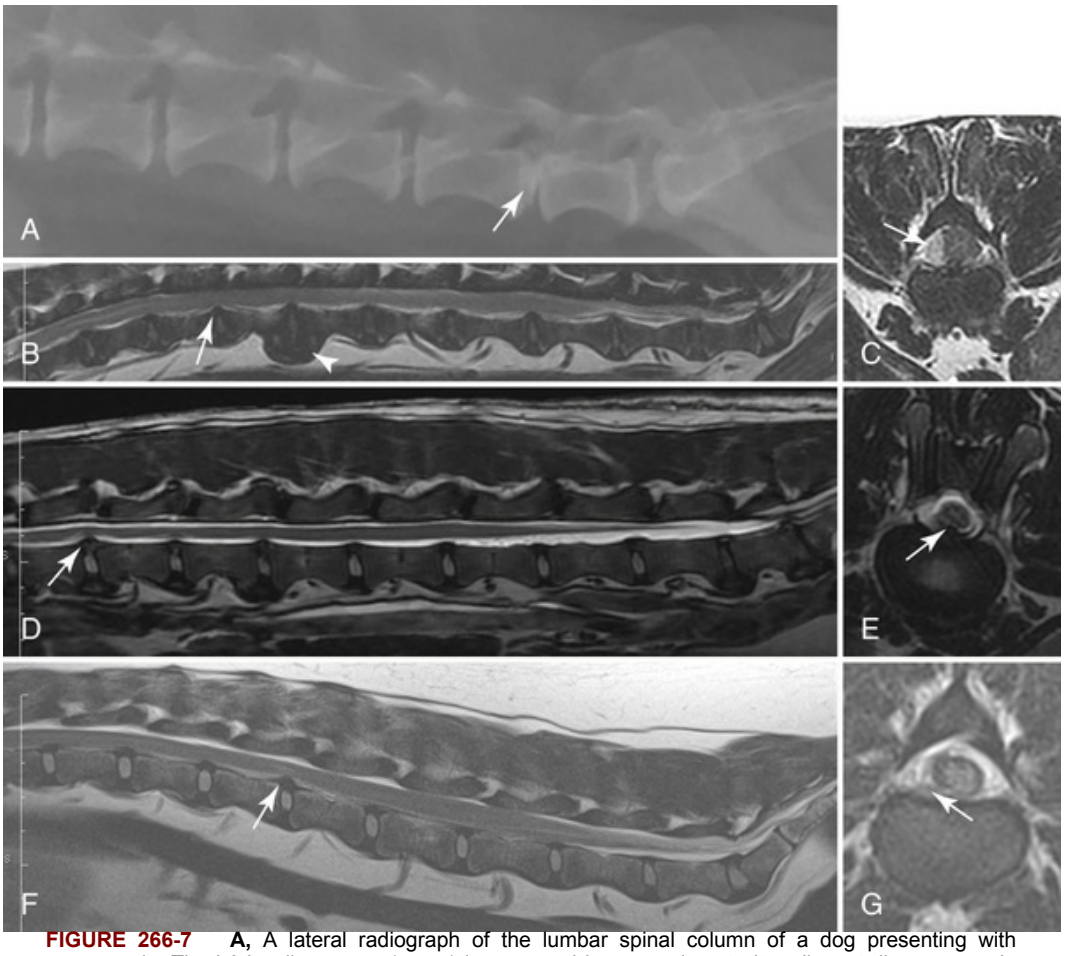

FIGURE 266-7 **A,** A lateral radiograph of the lumbar spinal column of a dog presenting with paraparesis. The L6-L7 disc space (arrow) is narrowed in comparison to its adjacent disc spaces. In addition, the disc appears calcified *in situ* and there is opacity in the intervertebral foramen. All of these characteristics are compatible with intervertebral disc extrusion at this site. **B,** A T2-weighted sagittal MRI of the thoracolumbar spinal column of a dog with acute onset back pain and paraparesis. There is moderate ventral vertebral body bridging spondylosis at L1-L2 (arrowhead). In addition, there is mild ventral deviation of the spinal cord at T13-L1 (arrow), which is not convincing of a lesion that would require surgery. However, marked lateral cord compression can be seen at this site (arrow) on the transverse T2-weighted MRI **(C),** which was due to an acute disc extrusion. **D,** A T2-weighted sagittal MRI of the thoracolumbar spinal column of a large-breed dog with mild paraparesis and ataxia. Ventral cord deviation can be identified at T12-T13 due to annular protrusion compatible with a type II disc lesion. The mild cord deviation can be seen on the transverse T2-weighted MRI **(E),** due to the ventrolateral annular protrusion (arrow). In **(F)** a sagittal T2-weighted MRI of a large-breed dog with acute paralysis again reveals a mild lesion ventral to the cord at L2-L3 (arrow) which appears to be similar to Figure 266-2, *D*. However on transverse T2-weighted imaging at this site **(G),** abnormal signal is present within the epidural pace (arrow) and the cord appears heterogeneously hyperintense. The lesion inside the cord was due to an acute non-compressive nucleus extrusion, often itself associated with trauma.

Diagnosis

The initial diagnosis of thoracolumbar IVDD is obtained from the signalment, history and neurological examination. Survey spinal radiography can help to determine the diagnosis and site of a thoracolumbar disc extrusion if radiographic signs are well-defined and consistent with neuroanatomical localization (see Figure 266-7).[140,141] Studies of dogs with surgically confirmed thoracolumbar IVDD showed that when identifying the site of disc extrusion, survey radiography had an accuracy of 68-72%; but the percentage accuracy was higher with myelography.[131] Longitudinal lesion localization by myelography for thoracolumbar IVDD varies in accuracy from 40% to 97%, but is usually close to 90%.[131] CT or MRI are used alone or as an adjunct to myelography to more completely delineate lateralization of extruded disc material and lesion extent.[97] CT alone has been shown to be more accurate than myelography at identifying the major site of disc herniation and has the advantage of being a more rapid test with fewer side effects than myelography.[142,143] Mineralized

disc material and acute hemorrhage can be identified in the vertebral canal using non-contrast-enhanced CT. Acutely extruded disc material typically is recognized as a heterogeneous hyper-attenuating extradural mass compressing the spinal cord,[144,145] and chronically extruded disc material has a more homogeneous hyper-attenuating appearance. MRI provides a more sensitive technique in recognition of spinal cord pathology, e.g., edema and hemorrhage and three-dimensional delineation of the spinal cord compression allowing for an accurate surgical approach and determining the extent of surgical decompression required (see Figure 266-7).[146] MRI is considered the best method for early recognition of *in situ* disc degeneration based on a decrease in signal intensity within the nucleus pulposus on T2-weighted images and for determining localization and extent of extruded disc material within the epidural space.[147,148] MRI has also been demonstrated to be superior for the assessment of recurrent IVDD.[149]

Treatment

Indications for non-surgical treatment of thoracolumbar IVDD include a first-time incident of spinal pain only, mild to moderate paraparesis and the financial constraints of the client. The latter is the only reason for non-surgical treatment of a recumbent patient, which should always be considered a surgical candidate. Dogs can be managed with strict cage rest for 4-6 weeks combined with pain relief using anti-inflammatory drugs, opioids and muscle relaxants (see ch. 356). Acupuncture also has been advocated as a treatment for pain management. Dogs should be monitored closely for deterioration of neurological status. If pain persists or the neurological status worsens, surgical management is recommended. Studies have shown that recovery rates in non-ambulatory dogs are lower and recurrence rates higher following conservative rather than surgical treatment. Success rates for conservative management of ambulatory dogs with pain only or mild paresis range from 82% to 100%.[131] More recent retrospective studies of conservatively managed dogs with thoracolumbar disc disease documented 30% to 50% recurrence rates in dogs with minimally affected ambulatory status.[131,150] Recurrence of spinal pain in dogs with thoracolumbar IVDD that are conservatively managed usually occurs within 6 months to 1 year from onset of the initial clinical signs. Indications for surgical management of thoracolumbar IVDD include spinal pain or paresis unresponsive to medical therapy, recurrence or progression of clinical signs, paraplegia with intact pain perception and paraplegia without pain perception for <24-48 hours. Prolonged loss of pain perception (>48 hours) carries a poor prognosis and owners should be made aware of this prior to surgery. Surgery includes spinal cord decompression by removal of extruded disc material. Differences in recovery rates of non-ambulatory dogs vary according to the severity of neurological dysfunction (neurological grade), time interval from initial clinical signs to surgery and speed of onset of signs.[131] In ambulatory dogs, an increasing degree of deficits pre-operatively is significantly associated with longer recovery times.[151] Administration of corticosteroids or high-dose methylprednisolone sodium succinate appears to not improve outcome in dogs undergoing surgery for intervertebral disc extrusion but instead has been associated with higher prevalence of gastrointestinal and urinary tract complications, increased hospital stay and owner expense.[97,150] Pain perception is considered the most important prognostic indicator for a functional recovery. In general, the majority of dogs with intact pain perception have an excellent prognosis particularly if treated surgically.[152] Dogs with loss of pain perception for more than 24-48 hours prior to surgery have a poorer prognosis for return of function. A study of 87 dogs with loss of deep pain perception reported 58% of the animals regained deep pain perception and the ability to walk.[134] In general, the prognosis is poor if pain perception does not return within 2 to 4 weeks from time of surgery.[131,134,135] Recurrence of clinical signs after decompressive surgery in dogs with thoracolumbar IVDD is a common clinical entity with incidence rates reported from 2% to 42%.[131] The time for recurrence usually occurs between 1 month and 2 years after surgery. Recurrence of clinical signs within 1 month after surgery is likely related to the original herniated disc space; later recurrence of longer than 1 month after surgery is caused by a disc herniation at a site distinct from the initial extrusion.[131]

Atlantoaxial Instability

Etiology and Pathogenesis

Atlantoaxial (AA) joint instability leads to compression and concussion of the cervical spinal cord resulting from displacement of the vertebrae (subluxation) into the vertebral canal[153]; atlantoaxial subluxation results from a ligamentous and/or osseous abnormality between the atlas (first cervical vertebra) and the axis (second cervical vertebra). The axis has a cranioventral peglike projection called the dens or odontoid process. The

dens lies within the vertebral foramen of the atlas, held down by the transverse ligament, which prevents its movement into the spinal canal but still allows rotational movement. The dens is also attached to the foramen magnum by the apical ligament and to the occipital condyles by bilateral alar ligaments. There is also a dorsal atlantoaxial ligament joining the dorsal arch of the atlas and the craniodorsal spine of the axis.

Atlantoaxial subluxation was first reported in dogs in 1967.[154] Since this time, several congenital and developmental deformities of the AA joint have been documented to cause instability of the vertebral column predisposing to AA subluxation particularly in young, small-breed dogs.[155-158] Possible congenital or developmental anomalies of the AA joint include dysplasia (34% of dogs), hypoplasia or aplasia (46% of dogs), dorsal angulation, and separation of the dens, as well as absence of the transverse ligament.[155,156,159,160] Any abnormality of the dens will predispose to instability of the AA joint due to its important role in the normal stability of this joint; however, up to approximately 24% of dogs with AA subluxation will have a normal dens.[160]

Small breeds of dogs including Yorkshire Terriers, Chihuahuas, miniature Poodles, Pomeranians, and Pekingese are most often affected by the congenital and developmental anomalies that predispose to AA instability and potential subluxation.[159,161,162] This is mainly because the dens is prone to maldevelopment in miniature breeds due to aberrations of physeal growth plate closure. However, atlantoaxial subluxation due to congenital vertebral anomalies has also been reported in large-breed dogs.[163,164] Atlantoaxial subluxation due to congenital vertebral anomalies in cats is very rare.[165-167] Traumatic AA subluxation can occur in any breed and age of dog. Traumatic AA subluxation results from forceful over-flexion of the head, which may tear the ligaments or cause a fracture of the dens or dorsal arch of the axis.[159] Considerable impact may be required to cause such injuries in a normal AA joint and so many times even traumatic AA luxations are associated with an underlying congenital defect and instability of the joint.[159,160]

Clinical Findings

Neck pain is the most common sign associated with AA subluxation, being seen in most dogs with traumatic lesions and 30-60% of dogs with congenital lesions.[159,160,162,168] The associated neurological deficits (see ch. 259) are determined by the degree of damage present in the spinal cord following both the concussion and residual compression. The neurological deficits can range from mild postural reaction abnormalities (56%) to tetraplegia (10%); overall, gait dysfunction has been reported in up to 94% of dogs.[160,168,169] These deficits can appear asymmetrical in addition to appearing worse in either the pelvic limbs or the thoracic limbs. In the rare cases which present with tetraplegia, progression of the clinical signs to a state of clinical respiratory compromise and even arrest is possible.[159]

Diagnosis

Atlantoaxial subluxation can be diagnosed from survey radiographs of the cervical spine although extreme care must be taken when restraining and moving dogs in which this disease is suspected. On lateral radiographs, an increased space can be seen between the dorsal lamina of the atlas and the dorsal spinous process of the axis (Figure 266-8).[153] In severe cases, malalignment of the bodies of the atlas and axis is clearly visible. The presence and size of the dens can be evaluated most accurately on ventrodorsal views; this can also be evaluated well on oblique radiographs.[170] These views are preferable to open mouth views, which place the patient at severe risk of spinal cord trauma. If there is no evidence of subluxation on the lateral views, the neck can be carefully flexed to see if there is instability (the space between the dorsal lamina of the atlas and the dorsal spinous process of the axis should be evaluated). It is preferable to do this with fluoroscopy so that the movement can be monitored to prevent accidental iatrogenic subluxation; this can provide a rapid diagnosis in a conscious dog. CT and MRI can add vital information, which helps with decision making regarding treatment of the individual patient.[171-173] CT can assist with identification of dens conformation, dens or vertebral fracture presence and surgical implant placing.[171,173] Three-dimensional CT reconstruction of the AA joint can add an extra level of understanding to the diagnosis which can assist with surgical decision making. An MRI can provide additional information regarding spinal cord pathology such as hemorrhage or edema and syringohydromyelia that might be important for prognosis (see Figure 266-8).[173,174]

FIGURE 266-8 **A,** A lateral radiograph of the cervical vertebral column of an 11-month-old Yorkshire Terrier, which presented with tetraparesis and neck pain. Dorsal subluxation of C2 with respect to C1 causes an increased space between the dorsal lamina of C1 and dorsal arch of C2. **B,** A ventrodorsal radiograph of the cervical vertebral column of the dog in Figure 266-3, *A*. The joint space between the first and second cervical vertebrae is enlarged and there is no evidence of a dens, a predisposing factor for atlantoaxial subluxation. **C,** A sagittal T2-weighted MRI of the cervical vertebral column of a dog with atlantoaxial subluxation identifies the spinal cord compression associated with the vertebral lesion and an enlarged atlantoaxial joint space (arrow). **D,** A lateral postoperative radiograph of a dog with surgical fixation of the atlantoaxial joint using transarticular pins, vertebral body screws and methylmethacrylate cement.

Treatment

The goal of conservative treatment is to stabilize the AA joint while the ligamentous structures heal.[161] Non-surgical treatment of AA subluxation, including strict cage confinement for 6 weeks, analgesia and a rigid cervical brace, has been successful in some patients; however, non-surgical or conservative approaches are likely to result in recurrent or progressive clinical signs.[161,175,176] The splint must immobilize the AA junction and so the entire wrap must come over the head cranial to the ears and go back to the level of the chest. Complications associated with the use of a splint and neck wrap include recurrence of disease, corneal ulcers, migration of the splint to become ineffective, moist dermatitis and decubital ulcers, hyperthermia, respiratory compromise (dyspnea, aspiration), anorexia, otitis externa and the accumulation of food between the splint and mandible.[161] A good long-term outcome has been documented in 10 of 26 (38%) cases managed conservatively.[161,175,176] Dogs that were affected for less than 30 days were significantly more likely to have a good long-term outcome when managed conservatively, compared with dogs affected >30 days.[161] The goal of surgical treatment is to stabilize the AA joint, thereby preventing further spinal cord damage (see Figure 266-8). Although the surgery will by design reduce the compressive component of the disease, it will not

address any underlying parenchymal disease resulting from the concussion associated with this disease. Surgery should be considered in all dogs as it holds the potential to fuse the AA joint permanently and reduces the chance of catastrophic recurrence. Perioperative mortality rate associated with AA fixation has been reported to be between 10-30%.[160,162] Risk factors affecting surgical outcome in dogs have been identified.[160] Age of onset (<24 months) was significantly associated with greater odds of a successful first surgery and final outcome.[160] Duration (<10 months) and severity of clinical signs was significantly associated with greater odds of a successful final outcome[160]; despite the guarded prognosis for dogs with severe neurological deficits, many dogs that are unable to walk before surgery have a good outcome.[162] Whether a dorsal or ventral procedure is performed does not seem to change the odds of a successful outcome.[160]

Congenital Spinal Column Malformations

Incidental, congenital malformations of the vertebrae are described commonly in several dog breeds such as the Bulldog, and occasionally in cats.[177-179] The defects may be associated with structural abnormalities of the spinal cord, both of which may arise during embryonic or fetal development. Embryonic developmental abnormalities primarily affect formation of the vertebral bodies (e.g., butterfly and hemivertebra predominantly causing scoliosis) while fetal anomalies are more commonly segmentation defects (e.g., block vertebrae and centrum defects predominantly causing kyphosis), but there can be cross-over.[178] Survey radiographs can often detect a vertebral anomaly but advanced imaging such as MRI is necessary to evaluate for associated spinal cord compression or concurrent disease (Figure 266-9). A modified human radiographic classification scheme has been proposed to assist in describing these anomalies,[180,181] while the degree of radiographically calculated spinal curvature has been shown to be associated with the presence of neurological deficits.[182,183] Three-dimensional CT reconstructions can assist with a greater understanding of the vertebral anomaly present in the individual case and in humans CT serves to help classify the underlying anomaly (see Figure 266-9).[178,184]

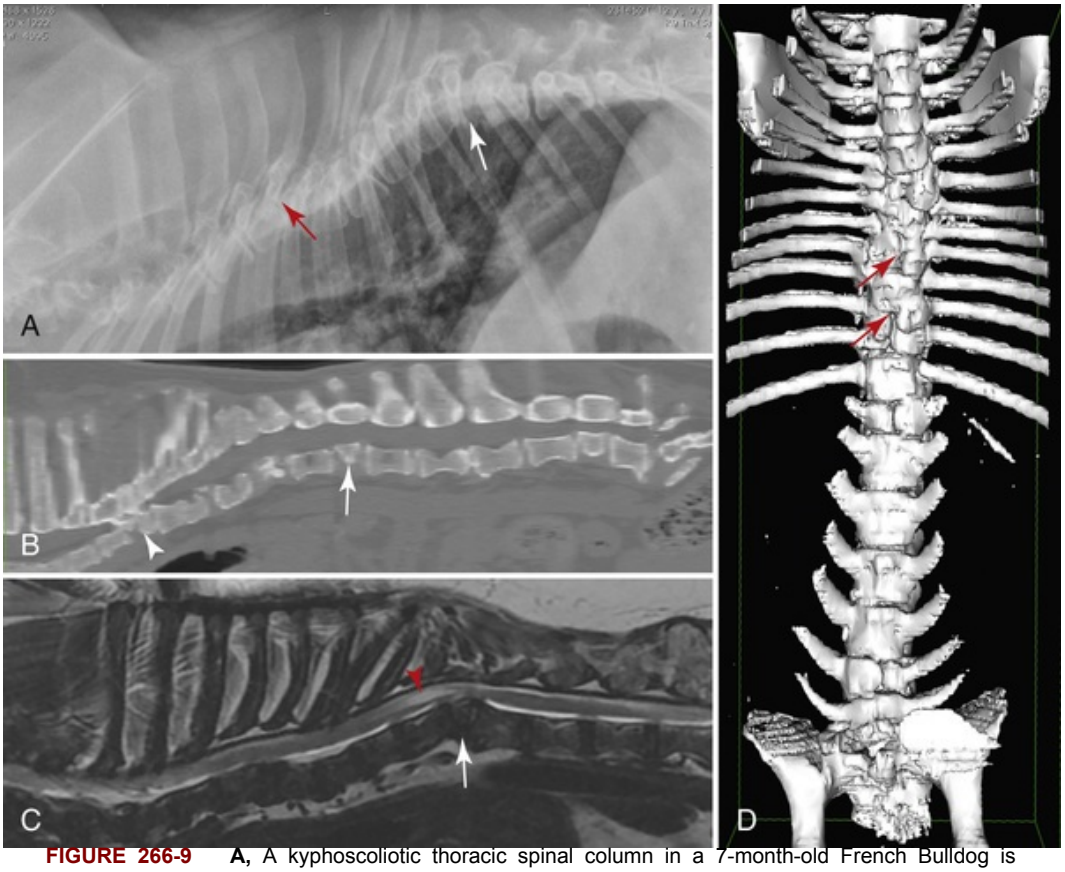

FIGURE 266-9 **A,** A kyphoscoliotic thoracic spinal column in a 7-month-old French Bulldog is

demonstrated on this lateral radiograph, which is due to the vertebral malformations present. The most severe vertebral body abnormalities, compatible with centrum hypoplasia, can be seen to be affecting T10 (white arrow) and T5 (red arrow). **B,** A sagittal CT scan of the thoracolumbar vertebral column of a different French Bulldog makes it easier to discern the shape of the vertebral bodies and infer how they may be affecting the spinal canal. The anomaly affecting L1 (arrow) does not seem to be associated with canal stenosis. The anomalies affecting the cranial thoracic vertebral column (arrowhead) are associated with a significant stenosis. **C,** A sagittal T2-weighted MRI of the thoracolumbar vertebral column of a Pug Dog demonstrates the effect that a vertebral body anomaly (arrow) associated stenosis has on the spinal cord causing compression and a syrinx (red arrowhead) cranial to the lesion. **D,** A three-dimensional reconstructed CT scan of the vertebral column of a French Bulldog helps to identify multiple vertebral body anomalies (arrows).

Butterfly Vertebrae

So named because of their ventrodorsal appearance on a radiograph, they result from failure of formation of the ventral and central portions of the vertebral body.[178,185] These anomalies are most often seen in brachycephalic, screw-tailed breeds and although are often clinically insignificant, they may result in deviation of the column.[178]

Hemivertebrae

These anomalies arise due to the failure of one sagittal half of the vertebra to develop, possibly due to congenital absence of vascularization, and result in a laterally wedged vertebra and scoliotic angulation.[178] They are most commonly described in French and English Bulldogs and Boston Terriers, although other breeds can be affected.[183] They are thought to be heritable in English Bulldogs, Yorkshire Terriers and German Shorthaired Pointers as an autosomal recessive abnormality.[186] Most affected vertebrae are located between T5-T9 but they could arise in any location.[183,187] Hemivertebrae are not associated with severe canal stenosis; spinal cord compression, however, results more from associated kyphosis and subluxation.[183] In addition, at the site of the anomaly it is not uncommon to find concurrent disc herniation and/or an arachnoid diverticulum, both of which could be responsible for neurological signs. Although hemivertebrae may be clinically insignificant, when they are associated with clinical signs, the signs are referable to their neuroanatomical location and occur at a very young age or late into adulthood.[183,187] Surgical realignment and stabilization rather than a dorsal laminectomy alone has been advised in clinical cases with the prognosis being good to guarded.[183,188]

Centrum Hypoplasia

Centrum hypoplasia or aplasia results in variable (bilateral or unilateral) loss of the vertebral body, resulting in a degree of scoliosis.[178] The degree of spinal column deviation that results is related to the severity of the defect and the number of vertebrae affected. This defect is said to be distinct from a hemivertebra, albeit potentially appearing similar on a radiograph and resulting from the same hypothetical etiologies in the same screw-tailed breeds. Although these defects are present at birth, associated clinical signs may not be apparent until 10 months of age,[189] at which time they can appear acute or chronic in onset; clinical signs at a later stage in life may be due to an association with a concurrent condition such as disc disease.[178]

Block Vertebrae

This defect results from partial or total fusion of two vertebrae at any point. They may be associated with angulation of the spinal column, atlantoaxial subluxation and or disc disease.[158,190]

Articular Facet Aplasia

Abnormalities of the articular process or facet of the vertebrae may result from dysgenesis of the two neural arch ossification centers or abnormal development of secondary ossification centers.[191] Frequently located between T1-T9 and asymptomatic, they have been occasionally reported caudal to this region and associated with vertebral canal stenosis.[191-193]

Transitional Vertebrae

Found at the junction between two structural divisions of the spinal column (e.g., thoracolumbar and lumbosacral), transitional vertebrae are congenital vertebral anomalies that share characteristics of both divisions. The most common abnormality is the presence or absence of a costa or transverse process, often asymptomatic and described in both dogs and cats.[178] Similar to block vertebrae, these anomalies can be associated with disc disease, which has been well described at the lumbosacral junction in German Shepherd Dogs.[194-196]

Meningomyelitis

Meningomyelitis is defined as inflammation of the spinal cord parenchyma and surrounding meninges. It is relatively uncommon for it to be present without encephalitis; a retrospective review of 220 dogs with inflammatory central nervous system (CNS) diseases revealed that only 41 had focal spinal cord involvement.[197] Canine distemper virus (see ch. 228) and protozoa (see ch. 221) have been the most commonly identified infectious causes, while steroid-responsive meningitis-arteritis is often the most frequently recognized probable non-infectious inflammatory disease process.[197] Rickettsiae, fungi, bacteria, helminths and meningitides of unknown etiology (MUE) such as granulomatous meningoencephalomyelitis are other reported causes of meningomyelitis in dogs.[198-204] However, in many cases the underlying disease process remains undetermined. A review of 28 dogs with meningomyelitis revealed that MUE was the most common diagnosis and that hound and toy breed dogs less than or equal to 3 years of age had a 13 times higher odds of meningomyelitis compared with other breeds.[205]

The clinical signs associated with meningomyelitis reflect the region of the CNS involved and can include paraspinal hyperesthesia, general proprioceptive ataxia and limb paresis or paralysis. Definitive diagnosis of inflammatory CNS disease requires histopathology but can be presumptively diagnosed using a combination of CSF analysis (see ch. 115), advanced imaging and infectious disease testing (see ch. 207). The prognosis is presumed to be specific to the underlying disease process and severity of clinical signs.[205] For a more detailed description of inflammatory CNS diseases, the reader is referred to ch. 261.

Steroid-Responsive Meningitis-Arteritis (SRMA)

Etiology and Pathogenesis

An immunological cause of this disease is suspected, resulting in a vasculitis, although no specific trigger factors have been identified.[206,207] Notably, increased levels of CSF and serum immunoglobulin A (IgA), increased CSF and blood B-cell/T-cell ratios, and CSF interleukin (IL)-6 and IL-8 levels are all thought to be compatible with immune system stimulation.[208-210] High CD11a expression on polymorphonuclear cells appears to be an important factor in the pathogenesis of SRMA and may be involved in the enhanced passage of neutrophils into the subarachnoid space, leading to meningitis and clinical signs.[211] Matrix metalloproteinase (MMP)-2 seems to also be involved in the neutrophilic invasion into the subarachnoid space.[212] Involvement of such molecular markers provides a potential therapeutic target. With chronic progression of the lesions, rupture and hemorrhage of the weakened vasculature may be present accompanied by thickened leptomeninges with less severe inflammation.

Clinical Findings

SRMA, also termed necrotizing vasculitis, juvenile polyarteritis syndrome, corticosteroid-responsive meningitis/meningomyelitis, aseptic suppurative meningitis, panarteritis and pain syndrome, is reported in Beagles, Bernese Mountain Dogs, Boxers, German Shorthaired Pointers, Border Collies, Jack Russell Terriers, Weimaraners and Nova Scotia Duck Tolling Retrievers,[207,213,214] but is noted and probably occurs in other medium to large dog breeds. Affected dogs are often young adults (8-18 months old) but may be of any age, and are usually febrile and hyperesthetic, with cervical rigidity and anorexia. Neurological deficits can be seen in the chronic form of this disease and rarely severe motor dysfunction may result from spontaneous bleeding into the subarachnoid space.[213] Some dogs (up to 46%) with immune-mediated polyarthritis (see ch. 203), especially Bernese Mountain Dogs, Boxers and Akitas, may show similar clinical signs to dogs with SRMA and have concurrent meningitis (see ch. 261).[215]

Diagnosis

A marked peripheral neutrophilia with a left shift may be seen at the time of the clinical signs. CSF (see ch. 115) often reveals a marked neutrophilic pleocytosis and protein elevation; cell counts of >100 cells/mcL are common. Neutrophils are non-degenerative, unlike bacterial meningitis. In the majority of dogs with either acute or chronic disease, there are elevations of IgA levels in the CSF and the serum, although this is not specific for this disease. IgA CSF concentrations are significantly higher in dogs with SRMA compared to other disease categories, with the exception of inflammatory CNS disease, and so are considered nonspecific. The sensitivity for IgA concentrations in serum and CSF was 91% with a specificity of only 78% when evaluated in 311 dogs with SRMA.[216] C-reactive protein (CRP) is the primary major canine acute phase protein (APP) and has been shown to be immediately responsive to both inflammation and its resolution; other APPs include serum amyloid-A (SAA), haptoglobin and alpha-1-acid glycoprotein (AGP). Serum CRP has been shown to be significantly higher in dogs with SRMA in comparison to dogs with other neurological diseases.[217] Results of a recent study of 9 dogs with SRMA demonstrated a significant increase of all serum APPs above normal concentrations, which all decreased, apart from haptoglobin, in response to corticosteroid treatment.[218] Serum CRP and SAA were also found to be consistently elevated in all patients exhibiting signs consistent with a relapse during treatment in the presence of normal CSF and leucograms. However, much like IgA, elevations of CRP are considered to be nonspecific, are elevated in sepsis, and so can only be used as a supportive diagnostic test.[219]

Treatment

The prognosis can be good if dogs are treated early and aggressively with immunosuppressive doses of corticosteroids (see ch. 165), with up to 80% of cases going into a long-term remission.[220,221] Infectious diseases should be ruled out before this treatment is initiated. The treatment is long-term, and has been reported to be required for over 2 years in some dogs; however, after this time, serum and CSF IgA levels were still elevated in some dogs so these titers are not considered valuable for disease monitoring.[221] Monitoring of CSF cell count in dogs with this condition is a sensitive indicator of success of treatment. In refractory cases or in patients having steroid-related side-effects, alternative immunomodulation therapy should be considered, such as azathioprine.

Discospondylitis

Etiology and Pathogenesis

Discospondylitis is due to infection of the intervertebral disc and adjacent vertebral endplates; if the infection is confined to the vertebral body, it is called vertebral osteomyelitis or spondylitis.[222] Coagulase-positive *Staphylococcus* spp. (*S. pseudintermedius* or *S. aureus*) is the most common etiological agent associated with canine discospondylitis[213]; other less commonly identified organisms include *Streptococcus* spp., *Escherichia coli, Actinomyces* spp. and *Brucella canis,* as well as *Aspergillus* spp. Young German Shepherd bitches seem to be predisposed to aspergillosis (see ch. 234),[223] whereas young Basset Hounds contract discospondylitis due to systemic tuberculosis (see ch. 212).[224] Hematogenous spread from distant foci of infection (urogenital tract, skin, dental disease), penetrating wounds, surgery,[225] or plant material migration can cause direct infection of the disc space or vertebrae, the latter of which is usually seen at the level of L2-4 at the insertion of the diaphragmatic crus. The most commonly affected sites are L7-S1, caudal cervical, mid-thoracic, and thoracolumbar spine.[213] The infection is usually slowly progressive but can result in acute signs due to secondary pathological vertebral fractures and intervertebral disc disease. An association with empyema has been documented in several dogs, which may represent an extension of the disease and should be considered when selecting diagnostic tests and/or when dealing with a refractory case.[226-228]

Clinical Findings

Spinal pain is the most common initial clinical sign in this disease, which is most frequently seen in large intact male young to middle-aged dogs.[229] With proliferation of inflammatory tissue, compression of neural tissue can lead to ataxia, paresis and occasionally paralysis dependent on where the lesion is located. Approximately 30% of dogs have signs of systemic illness such as fever and weight loss.

Diagnosis

Hematological changes are usually not present unless there are concurrent conditions such as endocarditis (see ch. 251). Urine cytology may reveal bacterial or fungal agents (see ch. 72). Blood and urine cultures should be performed in all suspected cases and are positive in up to 75% and 50% of cases, respectively (see ch. 207).[213,222] Ideally these should be performed prior to initiating antibiotic therapy. Serology for brucellosis should also be performed, especially in view of its zoonotic potential (see ch. 213); this has been reported to be positive in up to 10% of cases. Definitive diagnosis is usually made with spinal radiographs (Figure 266-10), although radiographic change may not be evident in the first 2-4 weeks of infection. The most commonly affected site is L7-S1, but other frequently affected sites include the caudal cervical/cranial thoracic vertebrae and the thoracolumbar junction. As this can be a multifocal disease, the entire spine should be radiographed. Radiographic evidence of disease includes narrowing of the disc space, accompanied by subtle irregularity of both endplates through to gross lysis and osseous proliferation of the adjacent vertebral bone and even fractures. Radiography can also be used to monitor the response to treatment or the progression of the disease,[230] although clinical progression is equally important, as radiographic change can lag behind clinical improvement. Myelography used to be recommended in patients with substantial neurological deficits to rule out concurrent disc disease and subluxation affecting the neural tissue; however, this should be reserved for when neither CT nor MRI is available. A study of 27 dogs with discospondylitis found that contrast-enhanced radiographs revealed only a 5% median cord compression in the dogs that was not related to clinical signs or outcome.[231] CT can identify subtle endplate erosion and paravertebral soft-tissue swelling more readily than radiography. Post-myelogram CT clearly defines compression of the neural tissues by infected tissues, as does MRI. Discospondylitis appears to have increased signal intensity on T2-weighted images and decreased signal intensity on T1-weighted images, changes also seen in the paravertebral tissues in all cases.[232,233] Contrast enhancement was seen in the endplates of affected vertebrae in 15 of 17 (88%) of sites in one study as was endplate erosion and T2-hypointense bone marrow. MRI can also highlight the inflammation in the surrounding muscles (see Figure 266-10).

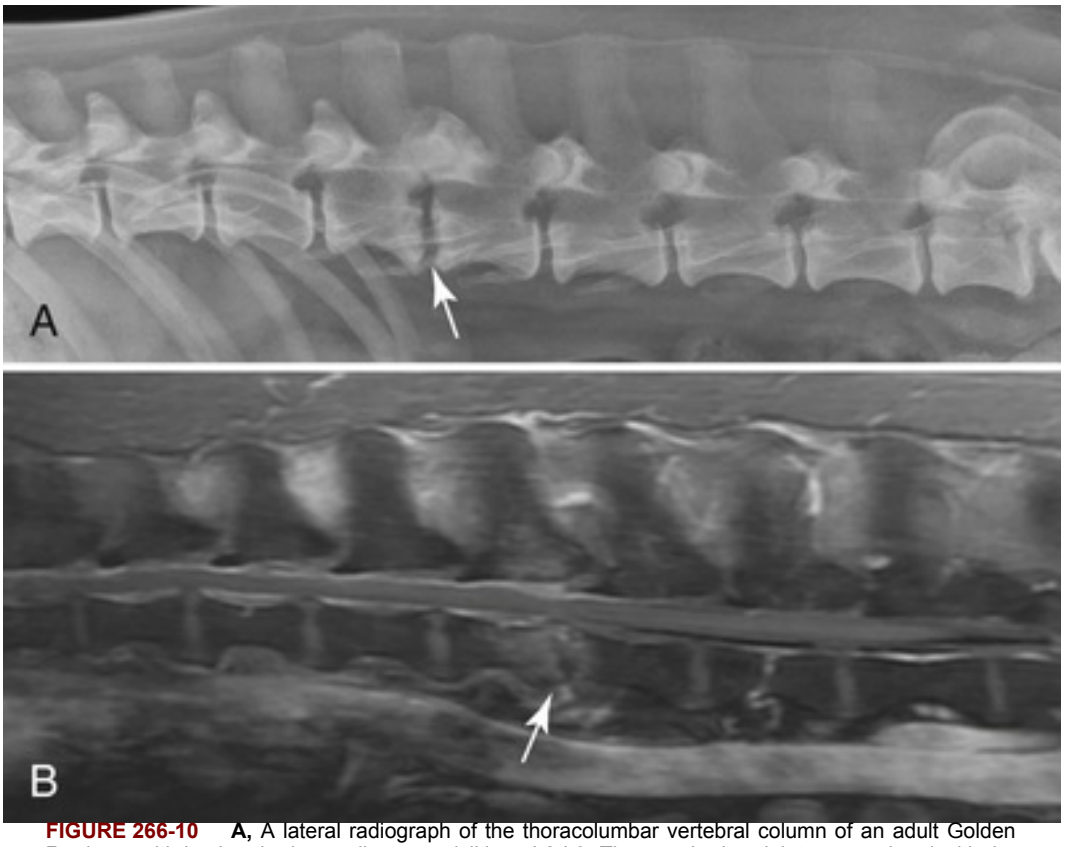

FIGURE 266-10 **A,** A lateral radiograph of the thoracolumbar vertebral column of an adult Golden Retriever with back pain due to discospondylitis at L2-L3. The vertebral endplates associated with the L2-L3 intervertebral disc space (arrow) are irregular due to lysis and osseous proliferation. **B,** A sagittal T1-weighted post-contrast MRI of the thoracolumbar vertebral column depicted in Figure 266-5, *A*

reveals contrast uptake (hyperintensity) within the vertebral body and dorsal spinous process of L1 and associated with the endplates of L1 and L2 (arrow). Soft-tissue proliferation and spread of infection into the epidural space secondary to the discospondylitis is associated with a slight narrowing of the spinal cord above the disc space.

Treatment

The initial treatment of discospondylitis consists of antibiotics (potentiated amoxicillin or cephalexin), cage rest and analgesics. Intravenous antibiotics should be considered if severe neurological compromise or signs of sepsis are present; otherwise, oral antibiotics are acceptable. However quickly the patient improves, continuation of the antibiotics for 8-16 weeks is recommended, although one study evaluating 513 cases noted a mean duration of treatment as 54 weeks.[213,222,229] Resolution of clinical signs, such as pain and fever, should be expected within 5 days of initiating therapy; however, complete neurological resolution may take 2-3 months. Residual deficits may remain, but persistent pain indicates an active disease, and these patients should be treated with an additional antibiotic and considered for further diagnostics as they may have a potential fungal infection or surgical lesion. Discospondylitis associated with *Aspergillus* spp. has been treated with itraconazole (5 mg/kg of body weight, PO, q 24 h) although long-term reports of success are lacking with the belief being that chronic recurrence and progression is likely (see ch. 234). The prognosis for this disease is generally very good unless the etiology is fungal, there are multiple lesions, vertebral fracture or subluxation occurs or there is endocarditis; the potential for recurrence should be considered, especially if brucellosis has been diagnosed or an underlying immunosuppressive condition is present.

CHAPTER 267

Spinal Cord Diseases

Traumatic, Vascular, and Neoplastic Disorders

Nicholas Jeffery

Client Information Sheet: Fibrocartilaginous Embolization

Mechanisms of Spinal Cord Dysfunction

Traumatic, vascular and neoplastic disorders may seem unrelated, but each causes spinal cord dysfunction primarily by impairing blood flow. Acute impact trauma and vascular interruption cause instantaneous compromise of blood flow that triggers a secondary series of autodestructive events within the spinal cord, forming a sharp contrast to the slow, progressive, compression of blood vessels and attenuation of circulation generally associated with neoplastic lesions. Pure impact injury may cause little immediate damage to the spinal cord, such as a few severed axons and focal hemorrhage, but this cannot be used to predict the severity of subsequent destructive events.[1]

Functional consequences of impact injury usually arise because trauma initiates a cascade of molecular reactions culminating in severe microcirculatory impairment that causes cellular apoptosis, tissue necrosis and progressive damage over 3-7 days.[2,3] Almost complete cross-sectional destruction can occur, although the extent of damage is clearly related to severity of the initial injury.[4,5] Extent of injury is mediated in large part by inflammatory mediators. The loss of circulation leads to secondary consequences caused by lack of oxygen and lack of glucose. Ultimately, the depolarization of neurons and axons allows accumulation of calcium as a key secondary messenger that will activate many autodestructive enzymes, notably calpains, caspases and xanthine oxidase.[2] Similar events follow primary vascular lesions, but usually with more limited spatial effects because affected vessels are often of narrow diameter with small regions of distribution. They also differ in that external trauma can be associated with prolonged compression. For example, displaced vertebral fractures may further compromise blood flow.

The mechanisms underlying the tissue destruction associated with chronic compression of the spinal cord are less well understood. There is evidence of impaired microcirculation.[6,7] Neoplastic lesions usually cause progressive compression of the spinal cord over a period of weeks to months. Initially, blood flow remains sufficient to preserve adequate spinal cord function but, eventually, a "tipping point" is reached, at which the compression becomes too severe to allow compensation and clinical signs then rapidly progress.

Diagnosis of Spinal Cord Lesions

Introduction

The initial approach to nervous system disease is to attempt to localize the problem using the physical neurologic examination (see ch. 259). With this information, one can then consider the possible causes of a lesion at that site in the context of the signalment and history. The rate of onset and degree of progression or regression of clinical signs is important. This approach is used for localizing traumatic, vascular or neoplastic spinal cord diseases. Crucially, either traumatic or neoplastic disease can be associated with spinal pain without evidence of neurologic deficits. In such cases, careful observation and gentle palpation may aid in localizing the lesion site, although observations can be misleading in anxious or stoic animals. Sometimes an accurate assessment can be assisted by in-clinic observation during a period of 24 hours or longer.

History

Listening carefully and evaluating owner observations can be critically important for developing an "index of suspicion" for specific types of spinal cord lesions. Historical and signalment information are crucial.[8] In people, it has been estimated that ≈80% of diagnoses are derived from history alone, although the species aspect of "signalment" is a given in humans.[9]

Differential Diagnosis

In general, traumatic lesions may have few differential diagnoses. Clinical signs in pets with vascular lesions are usually highly obvious.

Diagnostic Testing

Most traumatic, vascular and neoplastic diseases require imaging to confirm localization and suggest an etiology, although the precise diagnosis is usually dependent upon histologic examination. Inflammatory disease can be identified using cerebrospinal fluid (CSF) analysis, but it is rare for this to be a reasonable first diagnostic test because of associated risks (e.g., exacerbated hemorrhage, spread of tumor cells) and images are often required to aid interpretation of the results. For instance, raised CSF protein is a non-specific finding that is commonly, but not invariably, associated with spinal cord compression.[10,11] Radiography and computed tomography (CT) are excellent modalities for diagnosing lesions affecting vertebrae but provide poor detail of the spinal cord itself. Magnetic resonance imaging (MRI) scans are preferred for diagnosis of spinal cord lesions and MRI can also be used in detecting ligamentous injuries. MRI has the drawback of providing relatively poor bone detail, and can be expensive and time-consuming. CT and MRI scans can be regarded as complementary, but in veterinary medicine one is often selected dependent on whether the lesion is suspected to be bony or soft-tissue (especially affecting the spinal cord). This decision is usually made bearing in mind the nature of the inciting injury (e.g., external trauma), the severity of the lesion, the need to diagnose a lesion for subsequent surgical intervention and whether the animal shows evidence of pain (which tends to suggest skeletal involvement). Animals in which a vascular lesion is suspected would be initially imaged with MRI because such lesions are not visible using other modalities (Table 267-1).

TABLE 267-1

Ability of Imaging Modalities to Detect Lesions of the Spinal Cord and Vertebral Column

LESION TYPE	RADIOGRAPHS	CT	MRI
Traumatic			
Fracture-luxation	+	++	+
Disc extrusion	−	±	++
Vascular (any type)	−	−	++
Neoplasia			
Extradural	±	±	++
Intradural/extramedullary	−	−	++
Intramedullary	−	−	++

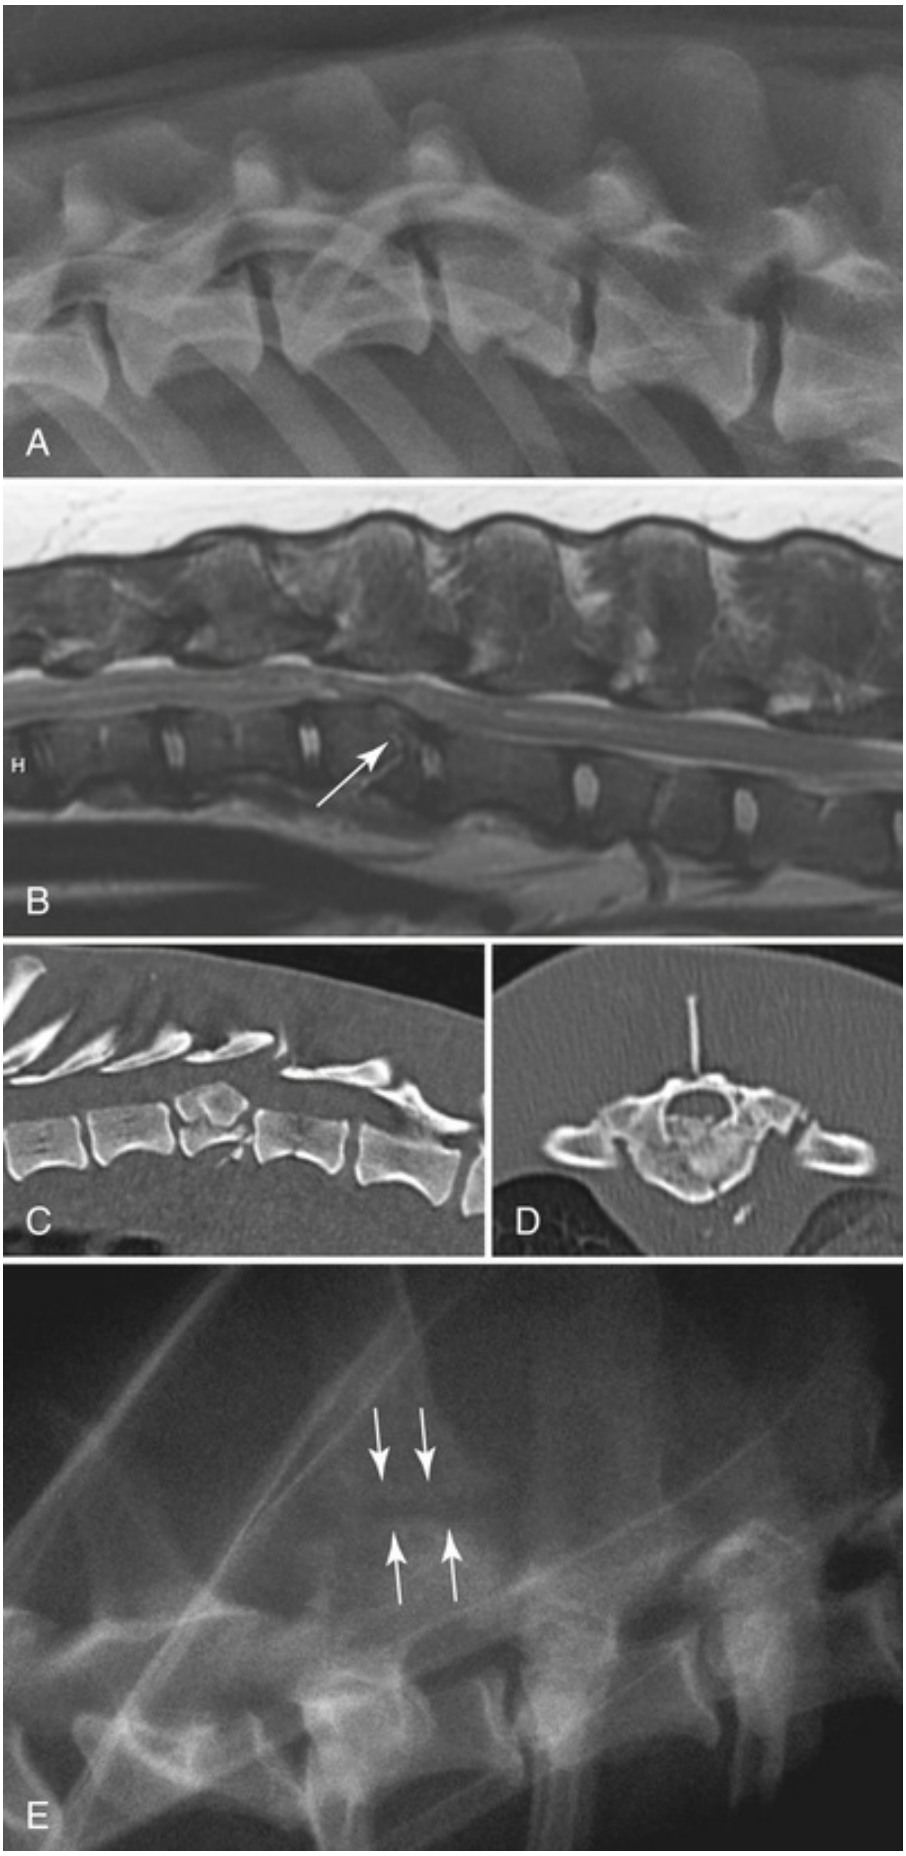
CT, Computed tomography; *MRI*, magnetic resonance imaging.

Treatment

Overview

Categories of disease in this chapter have extremely varied etiologies and prognoses. For instance, traumatic lesions may require demanding surgical stabilization (e.g., unstable fracture-luxations; Figure 267-1), but conservative (e.g., stable fractures) or non-specific (e.g., peracute disc extrusion) supportive care, such as cage rest, is sometimes recommended. Primary vascular lesions that cause spinal cord damage are generally not

responsive to therapy by the time affected animals are diagnosed. This does not imply a hopeless prognosis because many injuries are incomplete and those animals recover function as inflammation resolves and plastic alterations in circuitry supervene.[12] Neoplastic lesions also show extreme variability in prognosis; some cases are hopeless with or without treatment (e.g., disseminated metastases of hemangiosarcoma), whereas other affected animals may be expected to live for several years (e.g., multiple myeloma[13]).



A
B
C
D
E

FIGURE 267-1 Thoracolumbar vertebral fracture-luxations frequently cause instability that threatens spinal cord integrity and often requires surgical stabilization. **A,** Fracture of caudal aspect of L1 vertebra clearly visible using radiography alone. **B,** T2-weighted sagittal MRI scan also shows the fracture (arrow) and reveals detail of the spinal cord injury. **C,** Sagittal reconstructed CT scan reveals excellent detail of a T13 vertebral fracture in another dog. **D,** Corresponding transverse CT image reveals the extent of vertebral canal compromise associated with this "burst" fracture, probably resulting from compression along the long axis of the vertebral column. **E,** Pathological fracture of the spinous process of T1 vertebra (arrows). This lesion did not cause neurologic deficits but was associated with severe pain.

Corticosteroids

The role of corticosteroid therapy in traumatic and vascular spinal cord lesions is a source of persistent controversy.[14] For decades, physicians and veterinarians have used corticosteroids, often at high dosages, to reduce the functional and pathologic consequences of acute spinal cord insults. Despite the positive effects of corticosteroids that are sometimes reported in laboratory research, positive results have not been duplicated in clinical studies.[15] Initial reports on the use of high-dose methylprednisolone sodium succinate in human spinal cord injury suggested a benefit,[16] but this has since been disputed and the current consensus is that corticosteroids are not helpful in ameliorating acute spinal cord insults.[17] Further, corticosteroid use is detrimental in head trauma, perhaps because it reduces muscle mass and is immunosuppressive.[18]

However, corticosteroids often have a dramatic alleviating effect on the neurologic deficits associated with (prolonged) central nervous system (CNS) compression by reducing blood vessel permeability and reducing edema in the vicinity of the compressive lesion.[14] Although this can be helpful from the perspective of an owner and the pet, steroids may obscure both functional and imaging information. Indiscriminate corticosteroid administration can also expose animals to an unnecessary risk of detrimental side effects such as immunosuppression.

Traumatic Diseases

Signalment and History

No specific signalment need be associated with traumatic injury, but it is well-recognized that young, especially male, animals tend to be overrepresented. The history may be of greatest value in raising suspicion of traumatic lesions. There is almost always an acute onset of clinical signs and often the traumatic event has been witnessed. The exceptions are few, but animals that sustain vertebral fracture-luxations occasionally do not exhibit neurologic signs immediately after the incident but, with time, vertebrae in the affected region may become displaced, producing signs of neurologic deterioration and pain. This seems to be particularly prevalent in association with lesions of the upper cervical region, specifically the atlanto-axial region, and at L7/S1 (although lesions at this level do not affect the spinal cord). Although external trauma causing symptomatic spinal lesions is usually severe, some animals develop signs of spinal cord injury after what was considered minor trauma; e.g., dogs with congenital atlanto-axial subluxation who develop clinical signs after trivial trauma, such as hitting their head on the underside of furniture when rising from recumbency.

Presentation and Immediate Management

Vehicular impact or falls from height are the most common causes of vertebral column traumatic lesions that cause obvious neurologic deficits. However, some pets only have signs of poorly localized pain. Importantly, some animals may present in circulatory shock so that neurologic examination is not immediately reliable because poor CNS perfusion can cause temporary neurologic deficits. For this reason, it is imperative to re-examine affected animals at frequent intervals to determine whether neurologic status is changing. When first examined, it may be tempting to attend to striking neurologic injuries first, but it is important to prioritize treatment according to the ABC (airway, breathing, circulation) system (see ch. 147).[19] On the other hand, it is crucial to be cognizant of the possibility of neurologic injury, specifically fracture-luxation. This is especially true of animals that have nonspecific pain, because careless handling can lead to inadvertent further injury. It is important not to move animals more than absolutely needed if presented recumbent after major external trauma. It is often sensible to take radiographs of the vertebral column at an early stage, even sometimes prior to full neurologic examination, so as to identify sites which may be at risk of iatrogenic injury. In animals in which a single spinal fracture-luxation has been identified, it is essential to consider the possibility that there

could be additional lesions in the vertebral column which may not be producing such obvious clinical signs.[20] Therefore, it is frequently prudent to obtain radiographs or, better still, CT images, of the entire vertebral column.

Diagnostic Testing

For almost all pets known to have suffered trauma, imaging results are a critical decision-maker. Thoracic radiographs are always indicated because pneumothorax (see ch. 149 and 244) and pulmonary hemorrhage (see ch. 149 and 242) are common. Plain radiographs of the vertebral column function best as "rule-in" rather than "rule-out" tests, because many traumatic lesions, even those affecting the vertebrae or, indeed, the vertebral canal itself, can be overlooked. CT is indicated in animals in which a lesion of the skeletal structures is still suspected—for instance those exhibiting severe spinal pain despite negative findings on radiography. However, some traumatic lesions may not be apparent despite use of CT. MRI scans are excellent for detecting traumatic lesions within the spinal cord, although they provide less precise definition of bone contours.

Specific Diseases

Differential Diagnosis

Traumatic lesions have few differential diagnoses, particularly if the trauma was observed. Trauma should also be considered as a possible explanation for any animal with acute clinical signs indicative of spinal cord injury, whose major differential diagnoses are intervertebral disc herniation or vascular lesions of the spinal cord. Although inflammatory disease can theoretically cause acute clinical signs, it is not common for them to develop as quickly as occurs after trauma. Trauma may be overlooked as a possible cause, especially in animals with acute signs of lethargy or obtundation (which may indicate pain).

Vertebral Fracture-Luxation

The most commonly observed result of external trauma is fracture or luxation of vertebrae.[21] Unless such lesions affect the vertebral canal they will not cause clinical signs indicative of *spinal cord* injury (although spinal *nerves* may be affected). All patients exhibit pain. In most cases, subluxation is caused by part of a vertebra fracturing, but there can be simple subluxations resulting from ligamentous injury alone, most notably in the cranial cervical region (Figure 267-2). Treatment of vertebral fracture-luxations depends largely upon the severity of the clinical signs, an estimate of "stability," and lesion location.[21] It is critical to determine if the "deep pain" response is intact, because this provides the most accurate prognostic information (see ch. 259). It is important to remember that animals in circulatory shock may have temporarily dulled pain responses.

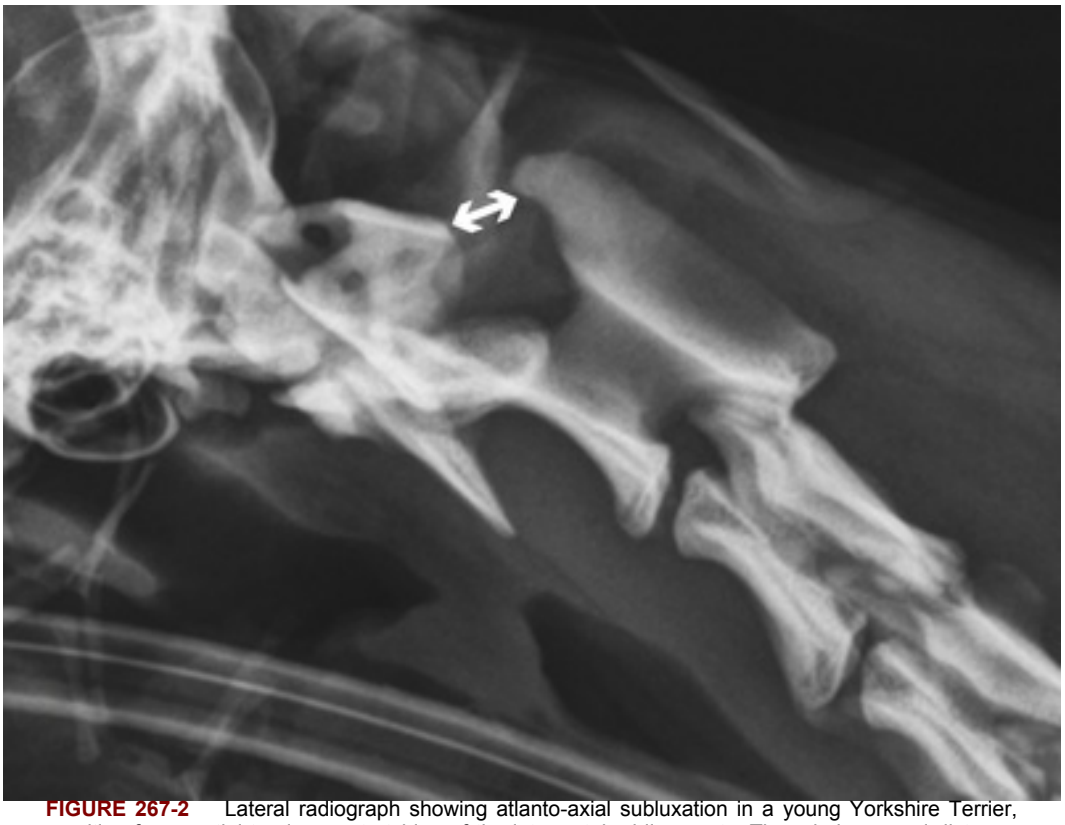


FIGURE 267-2 Lateral radiograph showing atlanto-axial subluxation in a young Yorkshire Terrier, resulting from partial tearing or stretching of the intervertebral ligaments. There is increased distance between the arch of the atlas and the cranial tip of the spinous process of the axis (arrows). This sign must be interpreted with caution because it can also be observed to some extent in apparently normal dogs.

Treatment options for spinal fracture-luxations can vary greatly. For instance, ambulatory animals displaying mild neurologic deficits in the pelvic limbs associated with inherently stable fractures of the thoracic vertebrae may not require surgical intervention and may recover with simple restriction of exercise while the lesion heals. In contrast, an animal with paraplegia (but intact pain sensation) caused by a fracture of a lumbar vertebral body would be a good candidate for surgical stabilization. Treatment of vertebral fracture-luxations is the subject of many reviews.[21] Decision-making can be aided by thinking of the vertebral column as a series of three sagittal columns running through its entire length. If two of the three columns are interrupted by the lesion it suggests instability, providing a strong indication for internal fixation. The magnitude of subluxation at the injury site is not often a good guide to prognosis because the position of the skeletal elements during imaging may not adequately reflect the extent of motion during the injury process.

Traumatic Disc Extrusion

Occasionally, animals (especially dogs) that have suffered external trauma to the vertebral column will have signs of severe spinal cord injury yet no obvious evidence of vertebral fracture-luxation. In some, there will be apparent intervertebral disc space narrowing. With use of MRI, many of these patients can be demonstrated to have collapsed disc spaces associated with escape and dorsally-directed extrusion of the nucleus pulposus.[22,23] Almost invariably, this disc extrusion is not of a diseased nucleus, as commonly occurs in type I disc herniation in chondrodystrophic dogs (see ch. 266). Rather, the escape of a normal nucleus is via an annulus that has been torn.[24] Forceful extrusion of a small volume of nucleus creates a spinal cord lesion due to a contusion that does not cause persistent compression (Figure 267-3). Clinical signs are often lateralized because the disc herniates to one side of the midline dorsal longitudinal ligament. Signs may resemble those of fibrocartilaginous embolism (FCE). Postmortem examination of such cases has suggested that the extruded nucleus may sometimes actually pass through the spinal cord substance.[25] The resultant spinal cord lesion cannot be seen on images other than MRI.

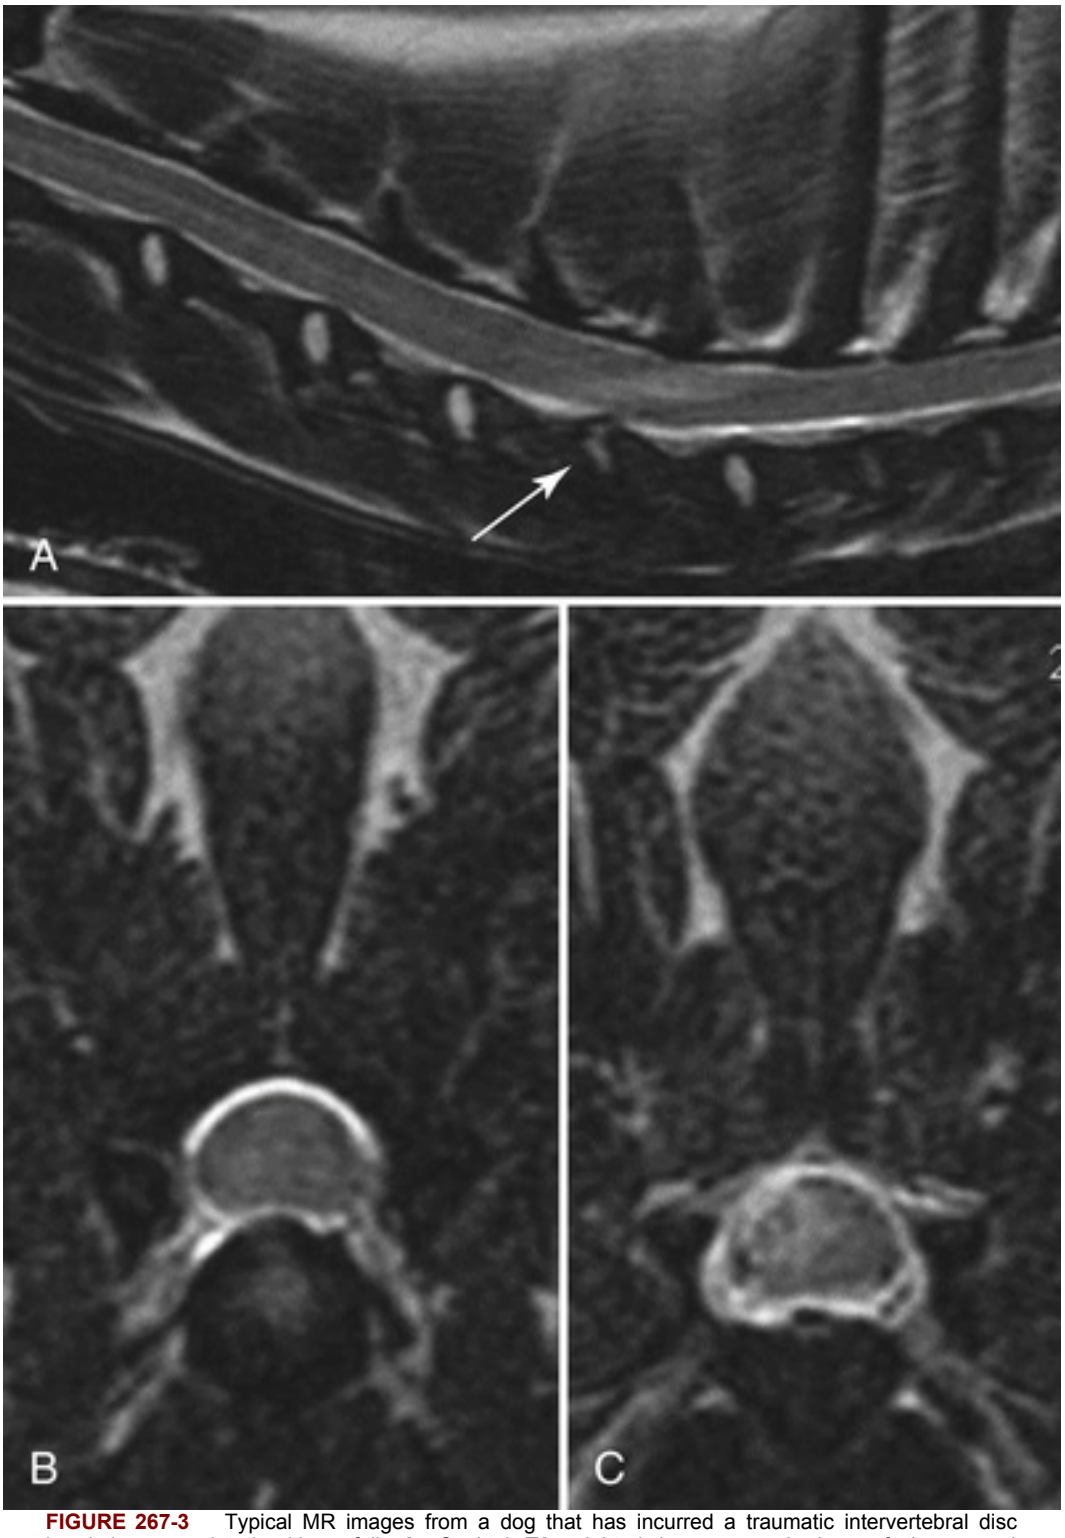

FIGURE 267-3 Typical MR images from a dog that has incurred a traumatic intervertebral disc herniation associated with a fall. **A,** Sagittal T2-weighted image reveals loss of the normal hyperintensity of the nucleus of the intervertebral disc between C6 and C7 vertebrae (arrow), plus hyperintensity of the immediately adjacent spinal cord, suggestive of edema. **B,** Transverse T2-weighted image at the mid-portion of the C6 vertebra illustrates normal intensity of spinal cord parenchyma. **C,** Transverse T2-weighted image at the mid-portion of the C7 vertebral body reveals abnormal hyperintensity within the spinal cord.

Microchip Trauma

There are several reports of inadvertent introduction of identifying microchips into the spinal canal.[25a]

Reports suggest that very small dogs might be at heightened risk for this type of injury, which can occur immediately following implantation or develop after properly placed microchips migrate.[26,27]

Prognosis

The prognosis for traumatic lesions of the spinal cord is, of course, dependent upon the severity of injury, but is often surprisingly good. The best available prognostic indicator remains "deep pain" sensation. When it is present, most animals will (eventually) recover enough locomotor ability to live normal, or near-normal, lives. Animals with cervical lesions almost always retain deep pain sensation—those that don't, usually die of respiratory compromise.[28] Loss of deep pain sensation after external thoracolumbar trauma is indicative of an extremely guarded prognosis, at best. Few such pets recover to walk again. Animals with thoracolumbar injury and intact pain sensation usually recover remarkably good function.

Recovery after serious traumatic spinal cord injury can be a long process—animals will frequently require at least 10 days before demonstrating *ANY* change at all. Full recovery may take three months or more. After severe spinal cord injury, a "scar" develops within the spinal cord consisting mainly of astrocytic processes and a secreted proteoglycan matrix. Both can inhibit axonal regeneration.[29] More familiar fibroblastic scarring can also develop in the subarachnoid space and impair CSF flow. The end result of such scarring may lead to accumulation of fluid within the spinal cord, sometimes sufficiently severe to be recognized as syringomyelia (see ch. 266). These secondary lesions may give rise to pain syndromes in people that are uncommonly recognized in dogs and cats. Loss of fecal continence may occur (see ch. 42).[30]

Vascular Diseases

Introduction

A wide range of circulatory disorders could lead to spinal cord dysfunction. This includes any cause of reduced blood pressure (see ch. 159). However, other clinical signs are likely to predominate in conditions (e.g., heart failure) severe enough to cause such systemic circulatory disturbances. Nevertheless, it may be prudent to measure blood pressure in cases with no obvious cause for spinal cord dysfunction (see ch. 99). Signs associated with aortic thrombosis (see ch. 256), peripheral nerve disease (see ch. 268) or muscle diseases (see ch. 354) also may be consistent with spinal cord disease. Blood pressure measurement may provide a straightforward rule-in/rule-out test.[31] Similarly, systemic diseases that affect blood clotting (see ch. 197), including both hypercoagulable states such as hyperadrenocorticism and hypocoagulable states such as thrombocytopenia, might cause spinal cord lesions and should be considered during physical examination (see ch. 196). Most pets with spinal cord damage due to a vascular lesion have a regionally-specific disease, and those are discussed below.

Signalment

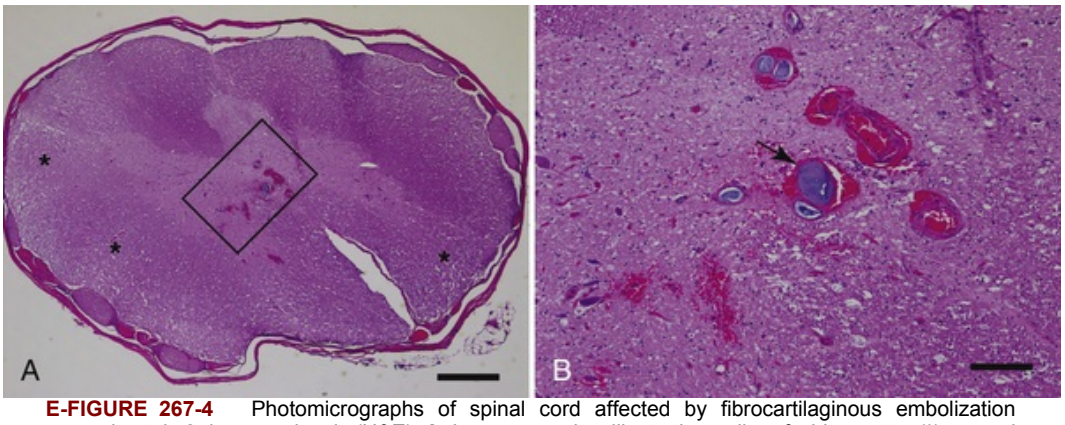
Spinal cord vascular lesions are, in general, more common in middle-aged to older animals. Fibrocartilaginous embolization, specifically, occurs more commonly in non-chondrodystrophic breeds and, perhaps, the Miniature Schnauzer is at increased risk.[32] In general, signalment is not especially suggestive of this specific type of lesion and, indeed, spinal infarctions have been documented in animals that are relatively young.[33]

History

Vascular-origin spinal cord lesions have an instantaneous onset, during which the animal may exhibit signs of pain. Most often, the animal is exercising and then suddenly cries out or simply collapses and is already neurologically impaired.[34] By the time the animal is seen by the veterinarian, there is usually no evidence of pain (but beware of anxious and stoic patients; see ch. 126). Over the course of several subsequent days (if the animal is not seen for that long) there is often gradual regression of neurologic signs. Animals with vascular lesions of the spinal cord are not thought to show pain when examined after a delay. This history, especially combined with other typical signs, can be so characteristic of vascular lesions they are almost pathognomonic.

Presentation

Spinal cord vascular lesions frequently have a highly stereotypical presentation. The underlying cause can be obstruction of the vasculature (thrombosis or embolism); rupture of a (often abnormal) blood vessel is less common. In either case, the vessel is usually small, and signs are almost always strongly lateralized. Therefore, the typical presentation is a peracute onset of neurologic signs which are often highly lateralized (Video 267-1). However, alternative presentations do occur; for instance, animals in which the ventral spinal artery is compromised will show evidence of severe bilateral disease. The typical progression after the immediate presentation is of gradual recovery of lost function. The rapidity of recovery depends on the precise localization and severity of the lesion. Animals with lesions that do not affect the lower motor neurons (which lie within the C5-T2 and L4-S3 spinal cord segments) typically will recover rapidly if the lesion is insufficiently severe to cause loss of deep pain sensation. The occasional animal with an extremely severe vascular lesion usually does not survive. At necropsy, severe or widespread thrombosis is usually identified (E-Figure 267-4). Animals in which the lower motor neuron regions are affected are especially at risk for needing prolonged recovery time or failure to recover.



E-FIGURE 267-4 Photomicrographs of spinal cord affected by fibrocartilaginous embolization approximately 2 days previously (H&E). **A,** Low-power view illustrating pallor of white matter (*) caused by widespread axonal destruction. Scale bar = 500 microns. **B,** High-power view of the region contained within the box in **A,** illustrating chondroid material obstructing the lumen of several arteries (example is arrowed). Scale bar = 100 microns. (Photomicrograph courtesy Dr. Jodi Smith, College of Veterinary Medicine, Iowa State University.)

Differential Diagnosis

Typical signs of vascular lesions are highly suggestive of the etiology. Nevertheless, intervertebral disc herniation (see ch. 266) and traumatic spinal cord injury should be considered. Each differential diagnosis requires MRI scanning to confirm the etiology.

Diagnostic Testing

Apparent lack of spinal pain, plus the stereotypical lateralization, often strongly suggests a vascular origin. Such a suspicion leads to an MRI scan as the only modality that can reveal disease within the spinal cord parenchyma. Other imaging modalities cannot rule out this diagnosis. Only if there is doubt about other diagnoses is it worth using other imaging modalities.

Specific Diseases

Fibrocartilaginous Embolism (FCE)

This condition is well described in the veterinary literature and can occur in dogs or cats. The inciting lesion is an occlusion of the spinal cord arterial supply by chondroid material that obliterates the vessel lumen. This causes the equivalent of a "stroke" in the spinal cord. The dependent spinal cord region after infarction is devitalized and non-functional immediately. It later becomes necrotic.[35] In the hours following the initial insult, edema may accumulate within the surrounding spinal cord parenchyma, leading to mild worsening of clinical signs that may be visible to the owner and veterinarian. The source of the chondroid material is not known. It has been suggested that it is derived from an intervertebral disc (nucleus) and then ends up in the

arterial supply.[36] However, there are no satisfactory explanations for the eventual location of the material. Alternative explanations include blood vessel walls undergoing chondroid metaplasia with that material ending up either detaching and lodging further downstream or, perhaps, inducing a thrombus at the original site.

FCE is suspected in animals which exhibit typical clinical signs with the typical lesion observed on MRI scan, but definitive diagnosis can only be made at postmortem examination. Classic FCE lesions are small, often localized to one quadrant of the spinal cord, hyperintense to normal gray matter on T2-weighted scans, and iso- or hypointense on T1-weighted scans.[37] However, many dogs suspected of having FCE display large regions of hyperintensity on T2-weighted and STIR MRI scans (Figure 267-5).[38] Since many recover naturally, the diagnosis is not definitively confirmed and the precise nature of the lesion remains speculative. For this reason, the term *ischemic myelopathy* is sometimes used to more accurately reflect the lack of a precise diagnosis.[39] Before widespread access to MRI, FCE was suspected in a larger proportion of cases. With use of MRI, some cases have been shown to have one of several types of peracute intervertebral disc herniation (see Figure 267-3; see ch. 266). Most dogs suspected of having FCE exhibit mild to moderately severe, lateralized signs that show considerable improvement within a period of about 48 hours. Others, however, can have devastating functional deficits from which spontaneous improvement cannot occur. Of course, the only lesions that are definitively diagnosed are those (unusual) cases that are found at postmortem examination, therefore providing a possibly biased view of the nature of the disease. Risk factors for this condition are not established but it may be prudent to analyze the clotting status of affected animals (see ch. 196).

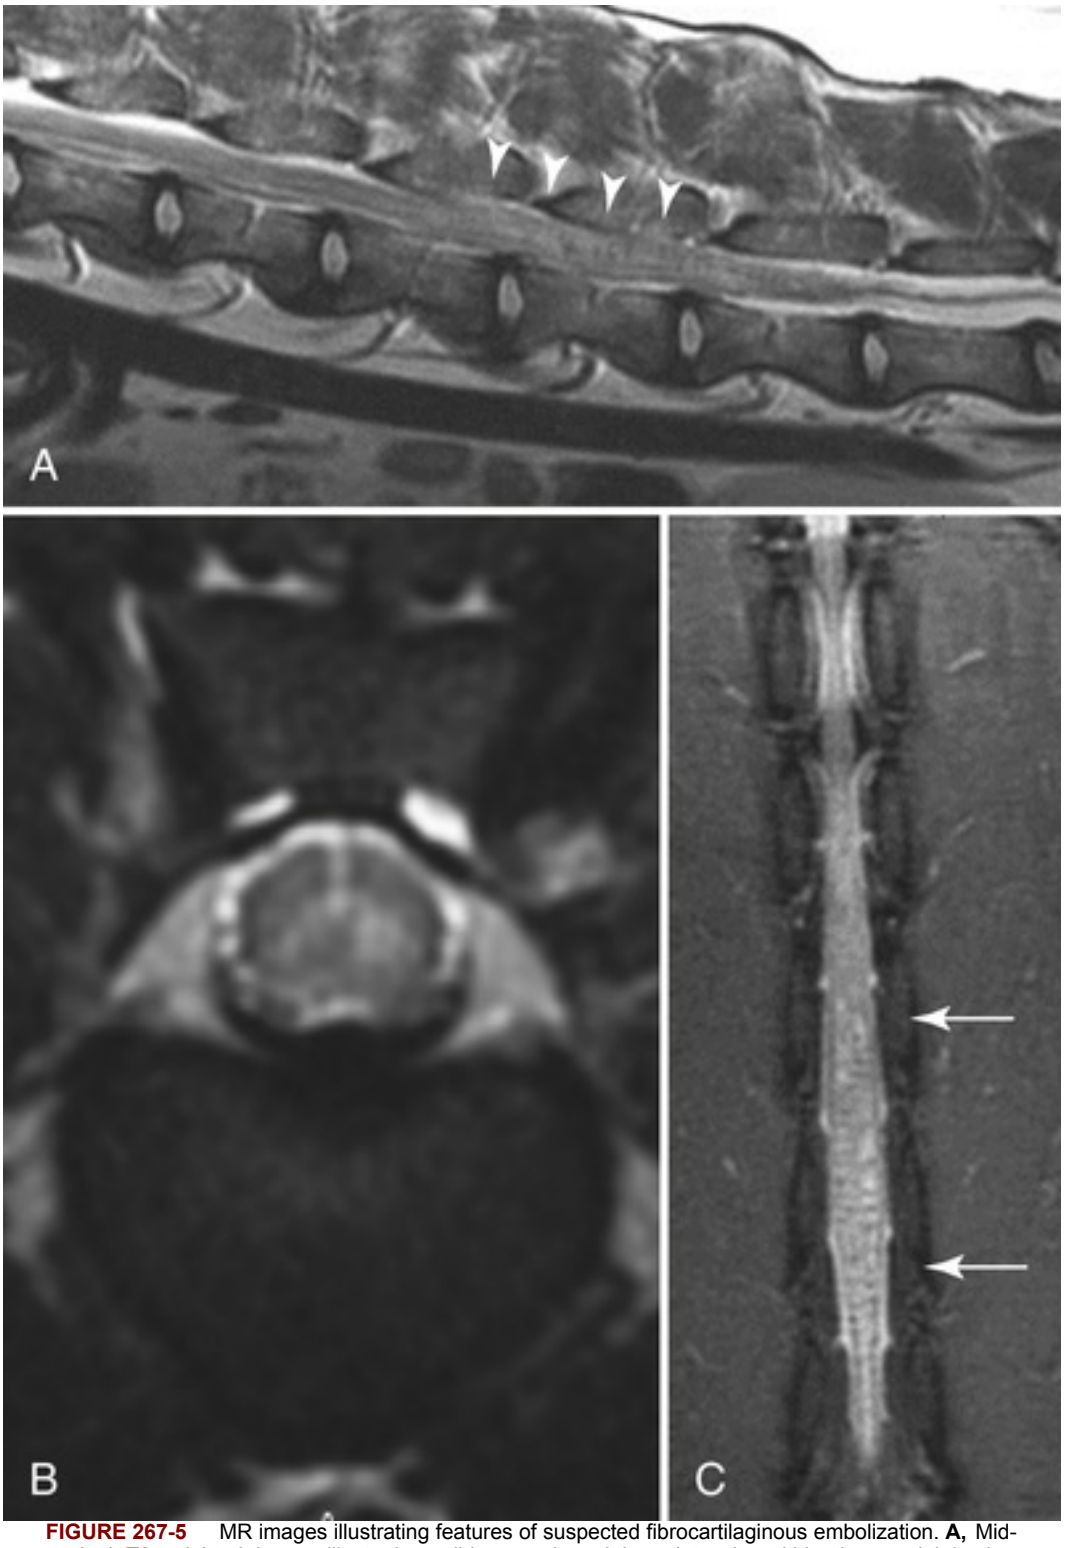


FIGURE 267-5 MR images illustrating features of suspected fibrocartilaginous embolization. **A,** Mid-sagittal T2-weighted image illustrating mild parenchymal hyperintensity within the caudal lumbar vertebrae (arrowheads). Note the normal size, shape and intensity of the intervertebral disc nuclei, indicating that disc herniation is not a likely cause. **B,** Transverse T2-weighted image at mid-lesion level illustrating asymmetric hyperintensity of the gray matter. **C,** Dorsal STIR image of the caudal lumbar region. This scan sequence is often sensitive to vascular lesions and reveals characteristic patchy parenchymal hyperintensity (see region between arrows).

Prognosis is dependent on severity and location of the initial lesion. In general, animals with lesions in the T3-L3 or C1-C5 regions of the spinal cord have a good prognosis if their deep pain sensation is intact (see ch. 259). Animals that have lost deep pain or that have large lesions affecting the spinal cord intumescences (i.e.,

C6-T2 or L4-S3) have a more guarded prognosis because there is less scope for plastic responses to ameliorate the functional deficits if those gray matter regions have been destroyed. Lesions that affect the sacral spinal cord can be particularly troublesome because fecal and/or urinary incontinence are common and difficult-to-manage long-term issues. No treatment is required but, similar to the prognosis for traumatic lesions, a period of up to three months or more must be allowed to appreciate the full extent of recovery.

Blood Vessel Rupture/Hematomyelia

A small number of cases with a hematoma within the substance of the spinal cord have been reported.[40] Many of these cases have been young animals and the assumption has been that the hematoma developed because of rupture of an anomalous vessel. Indeed, anomalous vessels have been described within the spinal cord in some cases, supporting this assumption. Risk factors for this condition are not known but it would be presumed to occur more frequently during periods of raised systemic blood pressure, although this has not been documented. Trauma has not been associated with this condition. Although one might expect such lesions to occur acutely, there is evidence in many that bleeding accumulates over a period of several weeks. The severity of clinical signs varies considerably. The definitively diagnosed cases have tended to be quite severe, but this might reflect the implicit need for diagnosis in such cases.

Diagnosis of this intraparenchymal lesion relies on MR imaging. Blood accumulations in the spinal cord undergo a series of changes in imaging characteristics over time, which can aid in identifying its duration. However, changes can be unreliable and vary considerably depending upon the field strength of the magnet and various other factors (e.g., precise timing of image acquisitions).[41] Small hematomas within the spinal cord are suspected fairly frequently, but when associated with relatively mild clinical signs that have developed acutely, the affected animals are often treated conservatively. Thus, a definitive diagnosis is not achieved because they often recover uneventfully. Severely affected cases that have large intraparenchymal masses require emergency surgical intervention. If left unchecked, the expanding hematoma will cause progressive damage to the spinal cord that may cause irreversible clinical deficits. Surgical intervention aims to drain the hematoma via incision through the pia and superficial parts of the spinal cord parenchyma.[40] Anomalous blood vessels can be identified and biopsied if present. The prognosis for surgical treatment depends mainly upon the severity of the clinical signs.

Extradural Hematoma

Extradural hematomas are commonly found in association with acute disc herniations and occasionally with disorders of hemostasis. Rarely, dogs are presented with acute or chronic progressive neurologic signs, often associated with pain, for which the underlying cause is an idiopathic hematoma.[42] Surgical decompression is associated with a good to excellent prognosis. It is important to recognize that such patients exist, because the imaging appearance is also consistent with extradural neoplasia, which has a far worse prognosis.

Vascular Anomalies

Vascular anomalies are often incriminated in the development of intraparenchymal hemorrhage.[43] They can also sometimes form mass lesions which can be detected on MRI scans and might be candidates for surgical removal.[44]

Systemic Disease Associated with Bleeding and Thrombosis Into the Spinal Cord

Bleeding into the spinal cord parenchyma may also arise from systemic disease that causes hypocoagulable states. Disorders of blood clotting, such as hemophilia, are rare causes of spinal lesions in dogs (see ch. 197).[45] However, there are various clotting disorders that can be associated with spinal dysfunction, including von Willebrand disease and, rarely, immune-mediated thrombocytopenia (see ch. 201).[46,47] Vascular fragility associated with inflammation (vasculitis) can also be a cause of hemorrhage into or around the spinal cord. Recognized causes in dogs include *Angiostrongylus vasorum* infection (see ch. 242) and leishmaniasis (see ch. 221).[48-50] Conversely, vasculitis can also lead to spinal cord lesions by causing thrombosis rather than hemorrhage.[51]

Neoplastic Lesions

Signalment

Neoplastic lesions of the spinal cord or vertebral column have definite breed associations. Large dogs are more susceptible to osteosarcoma, a common spinal tumor.[52,53] Golden Retrievers in the United States are thought to be at risk for hemangiosarcoma, another common spinal neoplasm.[52] Older age (≈4 years old for giant dogs) is a recognized risk factor for any neoplastic condition, although younger dogs (often ≈12 months old) are susceptible to nephroblastoma, an intramedullary spinal tumor.[54] Age should not be used as a rule-out for neoplastic disease. Nephroblastoma may be more common in German Shepherd Dogs, although not all studies concur.[53-55] Lymphoma is a common spinal lesion in cats and dogs (see ch. 344). It is the leading cause of spinal lesions in adult cats.[56] Metastatic lesions of the spinal cord occur occasionally,[57] so it is worth considering that possibility during the clinical examination, especially in cachexic animals.

History

Animals with neoplastic disease commonly have an insidious onset of clinical signs, as the lesion gradually enlarges. However, some animals with spinal tumors have an acute onset of clinical signs. This can arise through two main mechanisms: (1) development of pathologic fracture, in which a progressively weakened bone finally fractures and causes immediate spinal cord injury; and (2) acute vascular injury associated with tumor embolization or with compression and thrombosis associated with prolonged or excessive pressure. Thus, it is important to consider the possibility of a tumor in any older dog that has evidence of spinal cord dysfunction, even if the onset is acute.

Presentation

Most animals bearing spinal neoplasms have a slow onset of progressive neurologic deficits and spinal pain. However, clinical signs vary depending on the nature of the tumor. Extradural neoplasia is typically painful, probably because it distorts the spinal cord meninges or nerves, or because of damage to the skeletal elements. Lesions inside the dura are not typically associated with signs of pain until the later stages, but some recent data on intramedullary lesions suggest this may not be accurate.[57] Rate of tumor growth is highly variable. Similar tumors may grow differently depending on the spinal cord site, although the progression of signs can be misleading because lesions may become quite large before any clinical signs are noted (Figure 267-6). On the whole, clinical signs associated with intradural lesions progress slowly, and some animals may have clinical signs for many months or even years prior to presentation.[58] On the other hand, animals that have clinical signs associated with extradural lesions typically show rapid (days to weeks) progression.

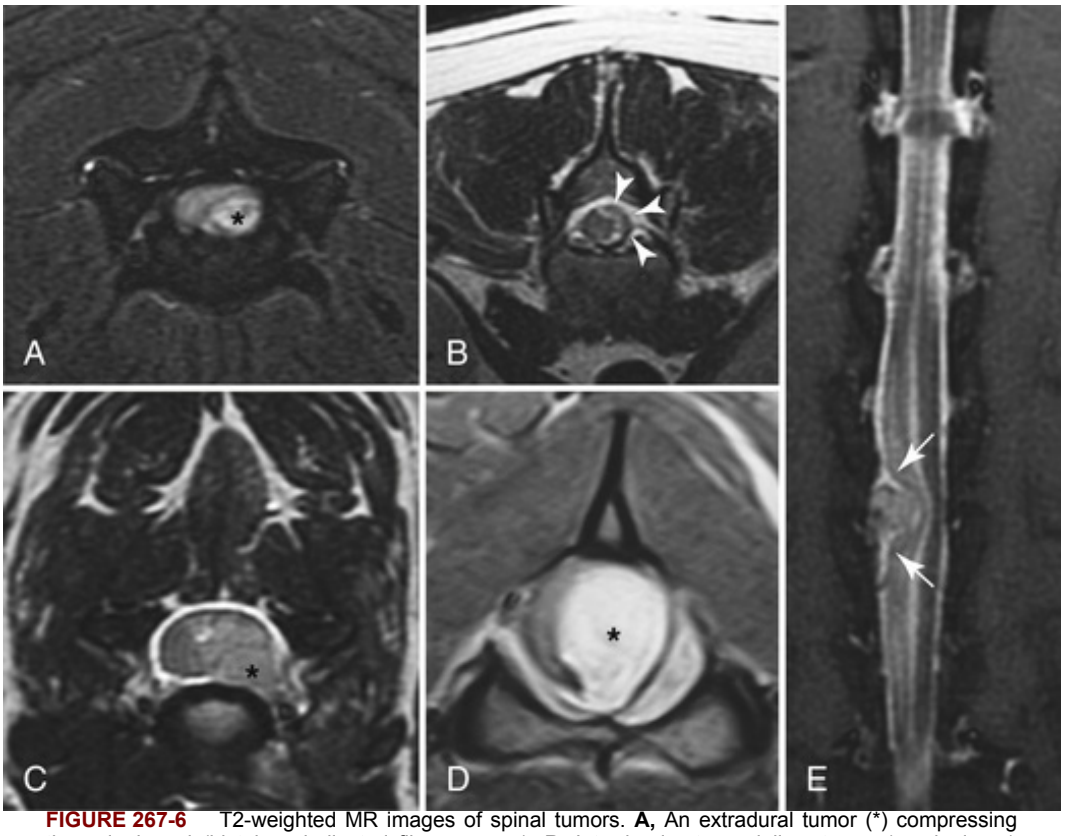

FIGURE 267-6 T2-weighted MR images of spinal tumors. **A,** An extradural tumor (*) compressing the spinal cord (histology indicated fibrosarcoma). **B,** Intradural-extramedullary tumor (meningioma) (arrowheads). **C,** Nerve sheath tumor (intradural-extramedullary to intramedullary) (*). **D,** This large extradural tumor (*) was diagnosed in a dog that was ambulatory at the time of presentation. **E,** Cervical meningioma illustrating the typical "golf tee" appearance created by the surrounding CSF (arrows).

Differential Diagnosis

Chronic progressive spinal cord dysfunction is most often associated with neoplasia or chronic disc herniations (usually type II). However, there is a reasonably wide possible differential diagnosis that would also include inflammatory or infectious diseases such as discospondylitis and meningoencephalomyelitis of unknown origin.[60] In older animals, degenerative diseases are often a consideration, most notably degenerative myelopathy, especially in corgis and German Shepherd Dogs[61] (see ch. 266). Congenital,[62] post-traumatic or adhesion-associated syringomyelia (accumulation of fluid within the spinal cord parenchyma) can produce similar clinical signs in some cases, especially in small dogs.[30] In addition, there are many non-neoplastic masses or anomalies that can be associated with gradually progressive spinal cord progression and neural deficits, such as dermoid sinus, calcinosis circumscripta, hematomas (see above), cartilaginous exostosis, lipoma, bony proliferation associated with inborn errors of metabolism, and poorly-classified disorders such as meningioangiomatosis.[63-68] This wide differential diagnosis list, including many benign lesions, implies the need for precise diagnosis to avoid assumptions of poor prognosis. For animals with acute spinal cord dysfunction the main differential diagnosis is acute disc herniation (even in large-breed dogs) and the traumatic and vascular lesions discussed above. Many, but not all, cases of acute spinal cord injury associated with neoplastic lesions exhibit signs of pain.

Diagnostic Testing

As for most conditions of the central nervous system, after a lesion has been localized, the usual next diagnostic step is to image the affected area. Frequently it is helpful to commence with radiographs, because a reasonable proportion of affected animals will have lesions of the skeletal elements that can be identified (see Figure 267-1). However, it is important to recognize that only a proportion of spinal neoplasia will cause sufficient bone loss or bone proliferation to be recognizable on plain radiographs. Lesions within the dura

usually will not change bone density and not even all epidural neoplasia is associated with bone change. Therefore, radiography is a good "rule-in" but poor "rule-out" test. The next step is usually an MRI scan (see Figure 267-6). MRI is excellent for detecting lesions, regardless of location outside or within the spinal cord parenchyma. CT is limited to detection of radio-opaque lesions or those that cause changes in bone density, although this can be extremely useful for specific lesion types (Figure 267-7).

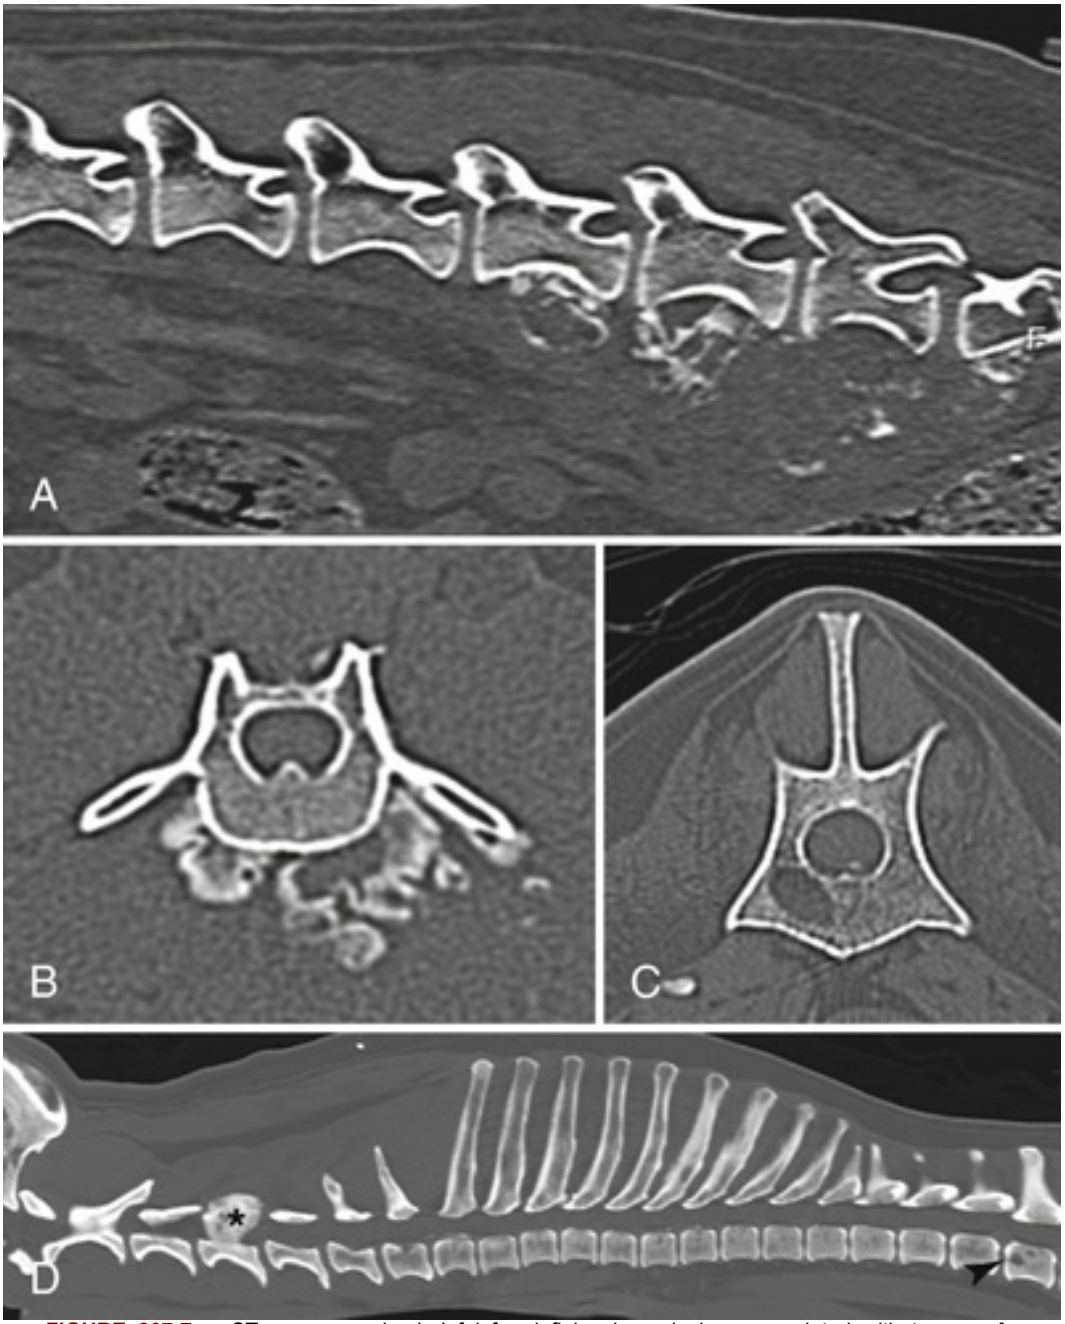

FIGURE 267-7 CT scans can be helpful for defining bone lesions associated with tumors. **A,** Sagittal reconstructed image illustrating extensive bone proliferation along the ventral aspect of the caudal lumbar vertebrae, associated with a metastatic prostatic tumor. **B,** Transverse image of the same lesion. **C,** Transverse image illustrating a lytic lesion within the L2 vertebral body caused by multiple myeloma. **D,** Sagittal reconstructed CT image illustrating a primary lesion in the C4 vertebra (*) and suspected metastatic lesion in the L1 vertebral body (arrowhead).

Specific Diseases

Overview

Neoplastic disease of the spinal cord is best categorized according to the location of the lesion in relation to the meninges surrounding the cord. Thus the clinical (and pathologic) divisions are extradural, intradural/extramedullary and intramedullary. Of these, the most common are thought to be extradural, with intradural/extramedullary types probably being the next most common.[53,58,59]

Extradural Tumors

These lesions lie within the epidural space, normally filled by fat. In line with their site of origin, neoplasms arising here usually are tumors of bone or various types of soft-tissue sarcoma, such as osteosarcoma, hemangiosarcoma, fibrosarcoma, lymphoma, liposarcoma, and multiple myeloma. Rare benign tumors in this location include lipomas.[66] Most epidural tumors are malignant and often cause secondary bone damage leading to bone weakening and, commonly, pathological fractures. Many such cancers (e.g., hemangiosarcoma, osteosarcoma) have metastasized by the time of diagnosis and it is common to observe metastatic lesions at other sites in the skeleton or within the lungs (see Figure 267-7). Importantly, many dogs affected by extradural spinal neoplasia appear to experience considerable pain, which can aid in suspecting these types of lesions versus other tumor types described below.

Intradural/Extramedullary Tumors

These are lesions of tissue that lines or projects through the subarachnoid space, such as the meninges and nerve roots. Both meningiomas and nerve sheath tumors tend to be slow-growing, producing clinical signs over a period of months to years.[58] Nerve sheath tumors appear to be more common at spinal cord intumescences, although this may also reflect the greater likelihood of diagnosis of lesions at sites that cause lameness. Meningiomas can occur at any site but appear to be especially common at the C1/C2 space in dogs, with a possible predisposition in Boxer dogs. Although both nerve sheath tumors and meningiomas are generally regarded as relatively benign histologically, each typically invades locally into normal tissue and can be difficult to excise in their entirety. Some nerve sheath tumors appear to be associated with neuropathic pain syndromes, including generalized depression and behavior changes.[58]

Intramedullary Tumors

These tumors are not common.[57] They arise from elements of the neuropil, such as glial cells (of various types) and (rarely) the neurons. Common tumor types in this category include astrocytoma and ependymoma. They can vary considerably in their histologic behavior: some are well-circumscribed by a capsule and can be excised, while others are highly invasive and aggressive. Typically they have a slowly progressive course over a period of several months. Nephroblastoma is an example of a neoplasm found in this compartment, although it may also cross into the extramedullary/intradural space. This tumor appears to develop close to the thoracolumbar junction of juvenile dogs as a consequence of an error during embryogenesis, in which a small number of kidney progenitor cells are incorporated into the developing neural tube and later become neoplastic.[55] This type of tumor often has a benign histologic phenotype but can be locally invasive.

Diagnosis of Spinal Tumor Type

Bearing in mind the extreme variability in tumor behavior and, therefore, prognosis, it is highly desirable to be able to make a specific diagnosis without traditional open surgery. Analysis of CSF may also be of assistance occasionally, in that cancer cells may exfoliate into the fluid and be detected or, alternatively, the fluid may reveal evidence of an infectious condition (see ch. 115).[69,70] Blood and/or bone marrow aspirate analysis (see ch. 92) may be helpful in some cases, such as those with suspected multiple myeloma (see ch. 344).[13] Similarly, it may be useful to obtain aspirates from enlarged lymph nodes to identify cases of multifocal lymphoma or lung aspirates from lesions suspected to be metastases. If a mass lesion has been identified on images, it may be possible to obtain biopsy samples from within or outside the spinal cord parenchyma without open surgery.[71,72] Ultrasound, fluoroscopic or CT-guided biopsies can be obtained using needles, TruCut biopsy tools or Jamshidi needles. There are obvious and serious potential hazards. For lesions within the spinal cord itself, it may be possible to place a needle into the spinal cord and obtain biopsy through judicious aspiration.[71] Such biopsies may be useful to rule out other differential diagnoses such as fungal granulomas or benign mass lesions. Despite a multitude of methods, it can be difficult to diagnose

cancer percutaneously unless it exfoliates easily. Most spinal tumors are suspected on imaging but not confirmed until histology is performed. Extradural masses should not be assumed to be neoplastic because affected animals may be inappropriately euthanatized.

Treatment and Prognosis

Neoplastic disease affecting the spinal cord has a wide range of treatments and prognoses, depending upon the nature of the lesion. For instance, meningiomas can often be surgically excised, although they will frequently regrow over a period of months to years. Nerve sheath tumors can theoretically be excised in their entirety but, because they often are close to the spinal cord and require large margins for total excision, this is rarely achieved when they lie within the spinal canal. Nevertheless, long-term (>12 month) disease-free interval can be achieved by surgical resection alone. Some other neoplastic lesions have a hopeless prognosis, such as hemangiosarcoma that has already metastasized. Others have an intermediate prognosis and may occasionally be responsive to chemotherapy (e.g., multiple myeloma).[13] Although radiation-induced myelitis is a potentially devastating sequel to radiotherapy directed at the spinal cord, careful planning can produce gratifying outcomes.[73,74] Radiotherapy is most notably an option for adjuvant therapy for cases in which there is recurrence of a previously excised tumor, or in which there has been incomplete primary extirpation.[55]

In general, the prognosis for most epidural tumors is poor, mainly because they are often malignant and may well have already metastasized at the time of diagnosis. Surgical debulking can provide rapid and effective relief of compression, which is often associated with rapid recovery of much lost function. Unfortunately the results, especially for sarcomas, are often short-lived, with recurrence of clinical signs within a few weeks to months. Intradural/extramedullary tumors are amenable to surgical excision and this is the major treatment modality. The outcome can be quite gratifying for meningiomas, because they are frequently slow-growing and the clinical signs can be alleviated for ≈12 months. In contrast nerve sheath tumors tend to have a worse prognosis because of the difficulty in removing the tumor in its entirety. Intramedullary tumors often are of benign types and may even be encapsulated, meaning that they can potentially be excised. This of course entails incising the spinal cord parenchyma and using microdissection techniques, but the results can be quite gratifying,[55,75] although recurrence of clinical signs has been reported in some of the (very small) number of cases reported in the veterinary literature.

CHAPTER 268

Peripheral Neuropathies

Christopher L. Mariani

Client Information Sheet: Peripheral Neuropathies

The peripheral nervous system (PNS) includes all nerve structures outside the central nervous system (CNS; i.e., the brain and spinal cord). The PNS is comprised of motor nerve fibers innervating skeletal muscle, sensory nerve fibers carrying touch, pain and proprioceptive position information from the skin, joints and muscles, afferent fibers carrying special sense information (e.g., auditory and vestibular systems), and autonomic fibers innervating the thoracic and abdominal viscera as well as other structures (e.g., salivary glands, irises, baroreceptors). The autonomic system is further divided into the sympathetic and parasympathetic systems. Peripheral nerve fibers may arise from the ventral horn of the spinal cord, exiting via the ventral root (motor and sympathetic fibers), from the dorsal root ganglion adjacent to the spinal cord, entering the cord via the dorsal root (sensory fibers), or from the brainstem or adjacent ganglia (motor and parasympathetic fibers), entering or exiting in cranial nerves. Although some nerves carry purely motor or sensory information, most nerves are comprised of a combination of motor and sensory fibers. A neuropathy refers to peripheral nerve disease (either spinal or cranial nerves [see ch. 264]) while polyneuropathies affect multiple peripheral nerves, often in a diffuse manner.

Clinical Signs

Most recognized peripheral nerve disorders in veterinary medicine have a clinical presentation dominated by dysfunction of the motor nerves, although sensory and autonomic signs are seen with some conditions. Characteristic clinical signs include paresis, hypotonia, muscle atrophy, and depressed or absent segmental spinal reflexes (Video 268-1). The paresis may involve all limbs, or may manifest as paraparesis, and often results in a short-strided gait. Dysphonia, dysphagia, inspiratory stridor, megaesophagus, and reduced or absent gag and palpebral reflexes may be seen due to involvement of the recurrent laryngeal, glossopharyngeal, vagus and facial nerves (see ch. 259).[1-3] Disorders of the neuromuscular junction (see ch. 269) and muscle (see ch. 354) can result in many of the same signs, and can be difficult to distinguish from peripheral nerve disease based on clinical examination alone. Signs of sensory dysfunction include ataxia, loss of proprioceptive positioning, reduced or absent spinal reflexes and paresthesia or anesthesia, potentially resulting in self-mutilation. Autonomic dysfunction may result in vomiting or regurgitation, diarrhea, ileus, urinary retention, incontinence, impaired lacrimation and salivation, and pupillary dysfunction. These disorders may exhibit acute and progressive, or occasionally episodic signs, but more often display a chronic, progressive course.

Diagnostic Plan

A complete blood count, serum biochemical evaluation and urinalysis are indicated to identify metabolic disorders responsible for nerve dysfunction (e.g., diabetes mellitus, hypothyroidism), comorbid disease, and to assess the suitability of patients for general anesthesia. Additional metabolic testing, including thyroid evaluation (see ch. 299-302) and serum fructosamine (see ch. 304 and 305), may also be considered. Serum creatine kinase (see ch. 66), carnitine, and pre- and post-exercise pyruvate, lactate (see ch. 70), and blood gas evaluation (see ch. 128) may be useful to identify certain muscle disorders. Imaging of the thoracic and abdominal cavities is often indicated to identify neoplastic disease. Serum titers or polymerase chain reaction (PCR)–based testing for infectious disease (see ch. 207), such as toxoplasmosis or neosporosis (see ch. 221), may also be appropriate.

More advanced diagnostic imaging (magnetic resonance imaging [MRI] or computed tomography [CT]) is occasionally useful to demonstrate neoplastic, inflammatory or other disease processes affecting specific nerves or nerve roots, or for diseases also displaying CNS lesions. However, these modalities typically play a larger role in ruling out other disorders on the differential diagnosis list. Similarly, cerebrospinal fluid (CSF) evaluation (see ch. 115) is most useful to eliminate other disease processes, but is occasionally abnormal in peripheral nerve disorders involving the nerve roots or those with both CNS and PNS involvement.

The most useful diagnostic tests for peripheral nerve disorders are electrodiagnostics (see ch. 117) and histopathology of muscle and nerve biopsies (see ch. 116). Electrodiagnostic testing includes electromyography (EMG), motor and sensory nerve conduction velocities (MNCV, SNCV), F wave evaluation, cord dorsum potentials, H reflex evaluation, magnetic stimulation and brainstem auditory evoked response (BAER).[4,5] Together, EMG and MNCV are useful to confirm dysfunction of the neuromuscular system, to differentiate peripheral nerve disease from muscle disease, and to distinguish axonal disease from demyelination. F wave evaluation allows investigation of the proximal nerve and ventral nerve roots, while SNCV and cord dorsum testing evaluates sensory nerves and dorsal nerve roots. However, electrodiagnostic testing rarely allows the diagnosis of a specific etiology. Histopathologic examinations of muscle and nerve biopsies are helpful to confirm and further define abnormalities detected with electrodiagnostic testing and are more likely to identify a specific etiology.[6,7] Electrophysiologic testing and muscle and nerve biopsy are described in more detail elsewhere (see ch. 116 and 117). Specific tests for autonomic dysfunction may also be useful to identify animals with involvement of this part of the nervous system.[8,9]

Degenerative Disorders

There are several degenerative neuropathic disorders that affect specific breeds of dog and cat and thus, appear to be heritable in nature. These disorders are quite rare, and a detailed discussion is beyond the scope of this chapter. The reader is referred to more comprehensive reviews of this topic.[10-16]

Metabolic Disorders

Diabetes Mellitus

Diabetic neuropathy is one of the most common causes of peripheral nerve dysfunction in human patients,[17] but appears to occur with much less frequency in veterinary medicine. Clinical signs are primarily noted in cats (see ch. 305) while overt disease is rarely recognized in dogs (see ch. 304). The pathophysiology of diabetic neuropathy has been intensely studied, with a number of causative theories proposed.[18-20] Clinical signs include paraparesis, progressing in some cases to tetraparesis, pelvic limb ataxia (see Video 305-2), difficulty in jumping, reduced postural reactions and segmental spinal reflexes, and distal muscle atrophy.[12,18-24] A plantigrade stance is frequently seen in cats (see Video 305-3). Although poorly recognized, sensory nerve dysfunction resulting in paresthesias, hyperesthesia and irritability likely occurs with some frequency in this disorder.[12,19,22,23,25] Cranial nerve and autonomic signs are common in humans, but are rarely reported in animals.[19,26] However, subclinical nerve dysfunction appears to occur with some frequency.[27-30]

The diagnosis is strongly suspected with demonstration of hyperglycemia and glucosuria in an animal with consistent clinical signs. Serum fructosamine may also be of some utility, as neuropathy is more common in poorly regulated patients. Electrodiagnostic testing may reveal spontaneous activity within affected muscles with reduced motor and sensory nerve conduction velocities, although these changes may be subtle and patchy.[12,18,21,24,26,28] However, consistent abnormalities are detectable in MNCV, SNCV, F wave and cord dorsum evaluation, even when EMG abnormalities are subtle or absent.[22] Evidence of conduction block has also been noted in dogs.[28] Together, these findings suggest that demyelination predominates over axonal changes, which is supported by histopathology of muscle and nerve biopsies,[22,27,31] although at least one report documents the contribution of axonal injury to the disease process.[23] Microscopic and ultrastructural evidence of perineurial abnormalities and microvascular lesions has also been documented in diabetic dogs and cats.[32,33]

Therapy is primarily directed at control of the underlying diabetic disorder, and improved glycemic control typically results in improvement or resolution of signs.[18,20,21] There are few reports of additional therapy in veterinary medicine. Acetyl-L-carnitine has multiple potential beneficial mechanisms of action, and has

demonstrated efficacy in experimental models and human patients.[34] It has been used in cats with diabetic neuropathy with anecdotal success.[35] The author has noted dramatic improvement of signs in some feline patients after antioxidant therapy with vitamin E and N-acetylcysteine.

Hypothyroidism

Signs of neuromuscular dysfunction have been frequently associated with hypothyroidism in both canine and human patients (see ch. 299).[18,20,36,37] The underlying pathophysiology of this association remains poorly characterized but potentially involves both peripheral nerve and muscle. Thyroid hormone deficiency appears to lead to both axonal damage and demyelination, based on electrophysiological studies.[36-39] Accumulation of glycosaminoglycans and glycogen within Schwann cells may be responsible for cellular dysfunction and resultant demyelinating change. There is also experimental evidence of a role for thyroid hormone in microtubule assembly and normal axonal transport, which may result in axonopathies when impaired.[18] Altered sodium-potassium ATPase activity, with impaired axonal transport, is another potential mechanism.[39-41] In human patients, mononeuropathies (particularly carpal tunnel syndrome) are common, and are attributed to mucinous deposits in the soft tissue structures causing a compressive neuropathy.[42] It has been suggested that a similar process may be responsible for the compression of cranial nerves in veterinary patients.[18]

Animals may present with paresis or rarely lameness involving a single limb, two limbs or all four limbs.[41,43,44] Cranial nerve deficits, including facial paresis, vestibular signs and trigeminal nerve dysfunction are frequently recognized, are often unilateral, and commonly affect multiple nerves (see ch. 264).[18,45-48] These signs may occur secondary to a peripheral neuropathy, or in other cases may be related to CNS involvement.[49] An association has also been made between hypothyroidism and both megaesophagus (see ch. 273) and laryngeal paralysis (see ch. 239),[41,50] although a causal role is tenuous and remains to be proven.[45,51-53] Affected animals may or may not have classical clinical signs such as lethargy, weight gain, alopecia, and seborrhea. Complete blood count and serum biochemistry profile may show a mild nonregenerative anemia, hypercholesterolemia, or an elevated creatine kinase level. The diagnosis is confirmed by the demonstration of a reduced free and total serum thyroxine (T_4) level with an elevated thyroid stimulating hormone level (see ch. 299).[54] Analysis of CSF may show an increased protein without concurrent pleocytosis.[40,46] Electrophysiological testing shows denervation potentials on EMG, with reductions in MNCV and SNCV.[41,43,44] BAERs may also be abnormal.[41,46] Muscle biopsy shows type I and II fiber atrophy consistent with neuropathic change, or a selective type II fiber atrophy suggestive of a myopathy. Nerve biopsy may show mixed changes characteristic of both axonal degeneration and demyelination.[12,15,41,43] In many cases, the diagnosis is partly based on the administration of levothyroxine and demonstration of a clinical response, which often begins within several days and is complete by 3-8 weeks.[45] Cranial nerve deficits, megaesophagus and laryngeal paralysis may be less likely to improve.[18,41,45,50]

Neoplastic Disorders

Peripheral nerve dysfunction due to neoplasia may result from compression of nerve tissue due to a nerve or nerve sheath tumor,[55-57] from adjacent neoplastic tissue,[58-62] or may occur as a paraneoplastic process. Nerve sheath tumors frequently display malignant characteristics, based on histopathology and their tendency to be locally invasive, growing proximally up nerves or nerve roots.[15,56,63-67] These tumors may occur in any small animal patient (Video 268-2), although they are most common in large-breed dogs and are rare in cats.[57,65,66,68] They commonly arise from the brachial plexus. Lameness and muscle atrophy are the most common and often the only clinical signs for extended periods before additional signs such as paresis, postural reaction or reflex deficits occur.[56,57,65,66,69] The tumor may eventually invade the spinal cord, leading to ataxia, paresis, and postural reaction deficits caudal to the site of invasion. Pain may be elicited with manipulation of the limb or with palpation of the axilla or inguinal region.[56] Horner's syndrome may be present with involvement of the caudal brachial plexus.[56,69] Trigeminal nerve sheath tumors are the most common cranial nerve neoplasms and typically lead to unilateral masticatory muscle atrophy.[70] Tumors involving other cranial nerves are seen less frequently.[71,72]

Diagnosis of peripheral nerve sheath tumors can be challenging. Occasionally, a mass may be palpated in the axilla or via the rectum.[73] MRI or CT may allow visualization of the tumor in many cases.[58,70,74-80] Ultrasonography can also be useful, and can facilitate fine needle aspiration or biopsy of identifiable mass lesions.[58,71,81-85] An EMG examination may be helpful in demonstrating denervation potentials, supporting a neuropathic process in lame patients without an obvious orthopedic cause.[56,65,73] Definitive therapy for peripheral nerve sheath tumors consists of surgical removal of the neoplasm, which can be very difficult. Although tumors involving distal portions of peripheral nerves may be completely resectable, most tumors involve the brachial or lumbar plexus and associated nerve roots.[77,86-89] Surgical intervention for these tumors typically requires amputation of the affected limb, and definitive removal may require laminectomy with sectioning of the nerve roots as close to the spinal cord as possible. Despite such aggressive therapy, many tumors recur, as they have a tendency to grow proximally and invade multiple nerve roots.[56,87] Surgical removal of trigeminal nerve sheath tumors has been reported.[70] Other neoplasms that may involve peripheral nerves include sarcomas,[58,61] carcinomas,[60] and round cell tumors.[59,80,90-94] Lymphoma and other round cell neoplasms may involve single or, in many cases, multiple nerves or nerve roots, leading to focal or multifocal signs.[80,90-93,95,96]

Paraneoplastic Neuropathy

A polyneuropathy associated with cancer in a remote location has been described in a number of dogs and a cat (see ch. 352). This syndrome has been reported most frequently with insulinoma (see ch. 303),[97-104] although a variety of other tumors has also been implicated.[12,105-112] The mechanism of disease is suspected to be primarily immune-mediated, due to antigen mimicry, wherein the immune system generates a response to antigens present within the neoplasm that are shared with the peripheral nerves.[113,114] In patients with insulinoma, hypoglycemia has also been suggested to have a causative role. Sensory, motor and autonomic neuropathies have been described in humans,[115] but motor signs have predominated in veterinary reports. Although infrequently reported, electrophysiological or histological evidence of peripheral nerve dysfunction is present in a large proportion of animals with cancer, and this condition is likely an underrecognized cause of weakness in these patients.[97,116,117] A substantial number of circulating autoantibodies have been associated with specific neoplasms in human patients with paraneoplastic polyneuropathies, often predating the diagnosis through conventional means.[113,114,118] Such autoantibodies have not yet been identified in veterinary patients. Diagnosis consists of documenting appropriate clinical signs (e.g., paresis, hyporeflexia, muscle atrophy), electrophysiologic changes and muscle and nerve biopsy results in an animal with an identified neoplasm, while eliminating other potential etiologies.

Dramatic improvement or resolution of clinical signs has been documented after surgical excision or other therapy for the cancer.[98,102,105,108,119,120] As the underlying mechanism is likely immune-mediated, immunomodulatory therapy has been utilized in human patients, including corticosteroids, plasma exchange, intravenous immunoglobulin, and other immunosuppressive drugs. Such therapy may be ineffective in resolving the neurologic signs if neuronal destruction has already occurred, although stabilization of signs may be seen.[113,121] Immunomodulatory therapy has been infrequently reported in veterinary patients, although dramatic improvement after corticosteroid therapy has been documented in a dog with insulinoma.[98]

Infectious and Inflammatory Disorders

Protozoal Polyradiculoneuritis

Neosporosis has emerged as an important cause of neuromuscular disease in dogs (see ch. 221).[122-124] The responsible protozoal organism, *Neospora caninum*, was first identified in 1988, and the canine species was confirmed to be a definitive host in 1998.[125-129] Many cases of protozoal polyradiculoneuritis previously attributed to *Toxoplasma gondii* were likely caused by *N. caninum*.[123,124,130] These organisms can be distinguished with immunohistochemistry, and occasionally with careful study of cyst structure with light or electron microscopy.[122,131] Both *T. gondii* and *N. caninum* display a predilection for nervous tissue, and can invade peripheral nerves, muscle and the CNS. Clinical signs include paresis involving one or multiple limbs, muscle atrophy, reduced muscle tone, muscle pain, postural reaction deficits, and reduced or absent

segmental spinal reflexes.[132,133] Cranial nerve signs such as head tilt, dysphagia, and tongue paresis have occasionally been reported.[132] A classical presentation of *N. caninum* infection is paraparesis in young puppies, which progressively leads to a non-ambulatory state characterized by rigid extension of the pelvic limbs associated with muscle contractures.[122,134-136] These dogs are infected transplacentally, and 25% or more of puppies from such litters may show clinical signs.[124,130,133,137] Ingestion of raw meat appears to be a risk factor for both *T. gondii* and *N. caninum* infection.[124,133,138]

Serological tests are available for *T. gondii* and *N. caninum* but must be interpreted with care, as exposed animals may seroconvert in the absence of clinical disease.[122,138-141] Paired acute and convalescent titers and evaluation of IgM levels (for *T. gondii*) may help in distinguishing infected from merely exposed animals.[133] However, serum titers for *N. caninum* rarely exceed 1 : 800 in clinically unaffected dogs.[132,139] PCR tests have been developed for these organisms and are now available from a number of laboratories.[142-144] EMG typically shows spontaneous activity in affected limb muscles. Analysis of CSF may show a mixed cell or nonsuppurative pleocytosis with protein elevation.[123,124] Muscle and nerve biopsies often show evidence of inflammatory cell infiltrates and may show protozoal organisms in some cases.[145]

Clindamycin remains the treatment of choice for *T. gondii* infection in both dogs and cats, although other drugs, including sulfonamides, pyrimethamine, doxycycline, and minocycline have some efficacy.[133] For *N. caninum*, therapy with clindamycin or potentiated sulfonamide drugs, with or without pyrimethamine, is often effective and can result in complete resolution of signs.[132,146,147] However, some patients progress in the face of such therapy, and significant improvement is very unlikely if muscle contractures have occurred.[136,148]

Acute Polyradiculoneuritis

Acute polyradiculoneuritis can be seen in both dogs and cats and causes an acute, ascending, flaccid tetraparesis (Video 268-3). Clinical signs typically progress rapidly over several days, although progression may continue for up to 10 days.[18,149-152] Although the pelvic limbs are usually involved first, with subsequent involvement of the thoracic limbs, the latter may be primarily or exclusively involved in rare cases. Severe cases progress to involve the cranial nerves and respiratory musculature, leading to hypoventilation. Segmental spinal reflexes are reduced to absent, but sensation remains intact, and many animals appear hyperesthetic. This disorder was first recognized in dogs approximately 7-10 days after contact with a raccoon and was originally termed coonhound paralysis. However, identical signs are seen in animals without raccoon exposure, and although other precipitating causes such as vaccination or infection may be identified, in many cases the trigger is unknown.[151-153] The evidence strongly suggests that this is an immune-mediated disease with similarities to Guillain-Barré syndrome (GBS) in humans, resulting from shared antigen between the inciting stimulus and peripheral nervous tissue.[18] Inflammatory cell infiltrates occur in and around peripheral nerves and particularly involve the ventral nerve roots.[18,149-151,154] Recently, circulating anti-GM2 ganglioside antibodies have been detected in a subset of dogs with acute polyradiculoneuritis.[155]

The diagnosis is suspected based on characteristic clinical signs, disease course, and potential history of an inciting cause. The main differential diagnoses are tick paralysis, botulism, elapid envenomation, and fulminant myasthenia gravis, which are all diseases of the neuromuscular junction (see ch. 269). Electrophysiologic testing can be helpful in distinguishing acute polyradiculoneuritis from these other diseases (see ch. 117). Spontaneous activity is seen on EMG examination, which may be detectable 1-2 days after disease onset.[156,157] Abnormalities on motor nerve conduction studies include reduced compound muscle action potential (CMAP) amplitudes and temporal dispersion with prolonged CMAP latencies.[4,156] Motor and sensory nerve conduction velocities are relatively preserved. F wave evaluation is particularly sensitive in detection of this condition due to involvement of the ventral nerve roots, and reveals increased F wave latencies, abnormal F ratios or completely absent F waves.[18,156] Analysis of CSF collected from the lumbar cistern (see ch. 115) may reveal an increased protein concentration without pleocytosis.[18] Therapy is mainly supportive in nature, and most animals will recover if given sufficient time (Video 268-4).[151,152] However, recovery time is variable, and may take a few weeks or up to 6 months in rare cases.[18,158] Patients with respiratory muscle involvement may require mechanical ventilation.[159] Despite the immune-mediated nature of the disease, corticosteroid therapy has not been shown to be beneficial, worsens muscle atrophy and

may predispose patients to secondary infections.[149] A recent study suggested that administration of human intravenous immunoglobulin might shorten the recovery time in dogs with acute polyradiculoneuritis,[160] although this and other immunomodulatory therapies such as plasmapheresis require further study in veterinary patients.

Brachial Plexus Neuritis

Brachial plexus neuritis is a rare condition, with only a few case reports in the veterinary literature.[88,161-165] Reported clinical signs include lameness, paresis, muscle atrophy, depressed segmental spinal reflexes, and sensory impairment exclusively affecting the thoracic limbs, typically with a bilateral but asymmetric distribution. Spontaneous activity is noted on EMG, while nerve conduction may be normal or slightly prolonged. Analysis of CSF may also be normal or may show a mild lymphocytic pleocytosis and protein elevation.[164] Diagnostic imaging, particularly MRI, may show thickened nerves and nerve roots suggestive of this condition, but histopathology may be required to differentiate neuritis from neoplastic infiltration of the nerves.[15,88,164] A response to glucocorticoids has been noted in some cases,[164,165] and spontaneous remissions, although often protracted, have been described.[15,158] The cause of this syndrome is uncertain, but an immune-mediated mechanism is likely.

Chronic Inflammatory Demyelinating Polyneuropathy

Chronic inflammatory neuropathies characterized by demyelination have been described in both dogs and cats using a number of terms, including chronic inflammatory demyelinating polyneuropathy (CIDP), chronic relapsing neuropathy, acquired demyelinating neuropathy, and chronic demyelinating polyradiculoneuritis.[14,18,158,166,167] Parallels have been drawn to the human disease, also termed CIDP.[167,168] The underlying etiology is unknown, but is suspected to be immune-mediated based on endoneurial mononuclear inflammatory cell infiltrates, IgG antibody immunostaining of myelin, the absence of detectable infectious agents, and a positive response to corticosteroid administration.[15,18,158,166] Demyelination is the predominant pathologic finding on examination of nerve biopsies, with axonal degeneration seen less frequently.[15,158] Inflammatory cell infiltrates have a patchy distribution and may not be appreciated in biopsy samples. Skeletal muscle biopsies may show fiber size variation, consistent with denervation.[166,169,170] Clinical signs usually develop insidiously and are slowly progressive, typically involving the pelvic limbs first and then the thoracic limbs.[167] Monoparesis is a less frequent initial manifestation. Some patients display a relapsing-remitting course[167,169,170] and acute onset of signs has also been described.[171] Clinical signs consist of various degrees of paresis, exercise intolerance, muscle wasting, reduced segmental spinal reflexes, and occasionally muscle tremors, lameness, ventroflexion of the neck, facial paralysis, dysphonia, megaesophagus, and laryngeal paralysis (Video 268-5).[15,167,169,170] EMG may be normal or may show patchy spontaneous activity, but MNCV is consistently decreased, often with evidence of conduction block (see ch. 117).[18,167,169,170] Many animals respond to corticosteroid administration at immunosuppressive dosages, although this response is incomplete in some animals.[18,158,167,169] Additional immunosuppressive regimens have not been well studied in veterinary patients, although intravenous immunoglobulin, plasma exchange, azathioprine, cyclophosphamide, and other immunomodulatory drugs have been recommended for human patients.[168,172]

Sensory Polyganglioradiculoneuritis

An inflammatory neuropathy preferentially affecting the sensory nerves, nerve roots and dorsal root ganglia has been described in various breeds of dog from 1.5-9 years of age.[149,173-176] The underlying cause of the condition is unknown, although infectious (viral), immune-mediated, and toxic etiologies have been suggested.[173,176] Similar sensory nerve involvement has been seen with some toxins, including mercury, doxorubicin and the administration of large amounts of pyridoxine (vitamin B_6).[158,177,178] There is a mononuclear inflammatory cell infiltrate into the sensory nerve structures and occasionally into autonomic ganglia predominated by CD3+ lymphocytes.[15,173-176] Clinical signs consist of ataxia, reduced to absent proprioception and segmental spinal reflexes (particularly the patellar reflex), and hypalgesia of the face, trunk or limbs.[149] Dysphagia, regurgitation, megaesophagus, anisocoria, and self-mutilation have been

reported in some cases.[149,173,175] Acute and chronic clinical courses have been noted, and the condition is typically progressive. Limb muscle mass, tone and strength is preserved, although masticatory muscle atrophy has been reported in some cases, and is attributed to damage to motor fibers as they pass through the trigeminal ganglion.[15] EMG and MNCV are typically normal, although SNCV is abnormal and may not be recordable.[173] CSF analysis is usually normal.[173] Histological changes characterized by axonal degeneration may be noted with a nerve biopsy, although care should be taken to biopsy a sensory or mixed function nerve (e.g., caudal cutaneous antebrachial nerve or caudal cutaneous sural nerve).[6,7,179] Inflammatory infiltrates may not be noted unless a dorsal root ganglion is biopsied. Muscle biopsy is usually normal. As the disease is inflammatory and suspected to be immune-mediated, immunosuppressive therapy with corticosteroids and other drugs has been attempted, but has not been successfully reported to date.[158,173] A similar condition has been described in a young cat.[180]

Traumatic Disorders

Trauma to peripheral nerves can occur secondary to a variety of insults, including blunt trauma, laceration injuries (e.g., animal bites, knife wounds), stretching or tearing injuries (e.g., automobile accidents), compression from fractures or swollen compartmentalized tissue, or iatrogenic injury (e.g., injection site injury or surgical trauma). Several terminologies and grading systems have been developed to describe the degree of nerve injury based on disruption of the myelin sheath, axon and supporting tissue.[158,181] The most common injuries are those involving the brachial plexus secondary to a motor vehicle accident (Video 268-6),[165,181] the sciatic nerve secondary to trauma or iatrogenic injury,[181-187] and the caudal nerves secondary to traction injury of the tail.[181,188-190] Femoral nerve dysfunction is also being increasingly recognized secondary to trauma involving the iliopsoas muscle in dogs.[191-193]

The main clinical signs are varying degrees of paresis and disuse of the limb or tail, impaired postural reactions and reflex function, pain with ambulation or limb manipulation and possibly impaired sensation.[181,184,186] The diagnosis is usually obvious based on history and examination. However, assessment of the severity of the injury may be aided with EMG to document denervation or nerve conduction studies to document the presence or absence of conduction past the injured site (see ch. 117).[69,181,183,194-196] Ultrasonography, CT or MRI may be useful in documenting nerve or muscle trauma associated with the injury.[191-193,197,198] Therapy typically centers on supportive care and rehabilitation including passive range of motion, massage and other physiotherapy exercises to help to maintain muscle and joint integrity while awaiting recovery (see ch. 355). Removal of compressive bone fragments or implants is indicated, if present. Some animals may traumatize limbs due to dragging during ambulation or by self-mutilation, and covering the limb with a bandage or bootie may help to avoid this complication.[199] Other potentially useful interventions include analgesics and medications to modulate paresthesias (e.g., gabapentin, pregabalin) and orthotics or braces for limb support.[199-203] Although rarely employed, techniques to surgically reattach partially or fully severed peripheral nerves and the use of nerve grafts have been described in small animals.[184,204-208] Recovery is dependent on the integrity of the endoneurial structures as well as the distance required to re-innervate the target, as axonal regeneration occurs at a rate of approximately 1-2 millimeters per day.[181] A loss of sensation in the limb or tail distal to the injury usually indicates a poor prognosis, although ideally 4-6 weeks should be allowed for potential recovery. Ultimately amputation of the limb or tail is often necessary.

Toxic Disorders

Several toxins, pharmaceuticals and other agents have been reported to cause peripheral neuropathies in small animals, although these are infrequently seen and documented. Such substances include heavy metals (e.g., mercury, thallium, lead), antibiotics (e.g., lasalocid, nitrofurantoin, salinomycin), pesticides (e.g., organophosphates), organic solvents and chemicals (e.g., acrylamide, hexacarbons), vitamins (e.g., pyridoxine), and antineoplastic drugs (e.g., vincristine, vinblastine, cisplatin).[15,18,120,177,178,209-218]

Autonomic Neuropathies

Dysautonomia refers to generalized dysfunction of the autonomic nervous system, and is seen in several

veterinary species.[219-223] Detailed discussion of this condition is beyond the scope of this chapter, and interested readers are referred to more comprehensive reviews of the topic.[9,219,224,225] Autonomic dysfunction can also occur as part of a more generalized peripheral neuropathy, which has been well documented in human patients with a variety of conditions including diabetes mellitus, paraneoplastic polyneuropathy, Guillain-Barré syndrome, and toxic neuropathies.[115,226,227] Reports of such autonomic involvement are infrequent in the veterinary literature, but this component of the disease process may be under-recognized.[26,104,225,228] Selective autonomic lesions have been reported in dogs with myenteric ganglionitis presenting with diarrhea or megacolon,[229,230] a dog with pupillotonia and several cats with Pourfour du Petit syndrome presenting with unilateral mydriasis,[231,232] and are frequently seen in animals with Horner's syndrome or oculomotor nerve lesions due to neoplastic, inflammatory, traumatic, or idiopathic causes.[233]

Miscellaneous Idiopathic Neuropathies

Distal denervating disease is an idiopathic canine polyneuropathy with primarily axonal involvement that affects motor nerves in a distal distribution and usually spontaneously improves in 4-6 weeks.[158,234,235] Other axonopathies with a similar distal distribution, but with chronic, unremitting courses, have also been described and termed distal symmetrical polyneuropathy or chronic axonal degeneration.[18,158,236] Idiopathic neuropathies affecting the trigeminal, facial and vestibular nerves are frequently recognized.[47,158,237-241] Whereas dysfunction of the trigeminal and vestibular nerves is typically self-limiting with spontaneous improvement, facial nerve paralysis often fails to improve, and requires long-term management. Idiopathic laryngeal paralysis occurring in older dogs is likely one manifestation of a more generalized peripheral neuropathy and Labrador Retrievers are overrepresented in reports of this condition (see ch. 239).[242-244]

CHAPTER 269

Neuromuscular Junction Disorders

Sarah A. Moore, Christopher L. Mariani

Client Information Sheet: Myasthenia Gravis

Introduction

Definitions

The neuromuscular junction (NMJ) is composed of the pre-synaptic motor nerve terminal, synaptic cleft and post-synaptic muscle end plate (Figure 269-1). It provides unidirectional communication between axon terminal of the motor nerve and the muscle via the neurotransmitter acetylcholine (ACh). The NMJ is one of several components of the motor unit, and patients with disease of the NMJ present with clinical signs consistent with lower motor neuron (LMN) disease (see ch. 268).

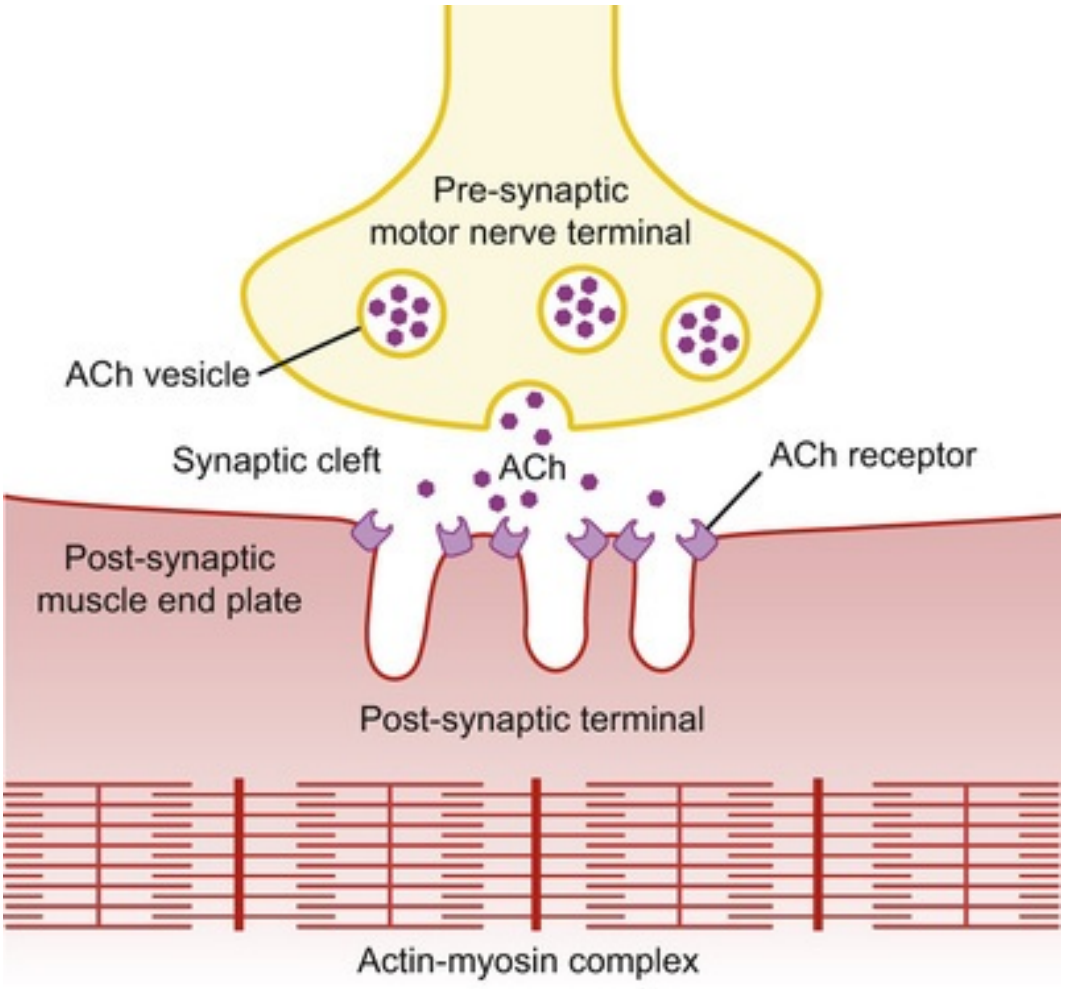

FIGURE 269-1 Schematic representation of the neuromuscular junction. (Reproduced with

permission from The Ohio State University.)

Function

Action potentials originating within the ventral horn motor neurons of the spinal cord are propagated down peripheral motor nerve fibers. Flattened processes of the motor nerve endings (the *pre-synaptic terminal*) form a small indentation in skeletal muscle fibers, called the *synaptic cleft*. A thickened portion of the muscle fiber membrane adjacent to the synaptic cleft constitutes the *post-synaptic terminal*. The pre-synaptic terminal contains a large store of ACh-containing vesicles which are released into the synaptic cleft in response to depolarization of the pre-synaptic nerve terminal. Calcium, an important co-factor in this process, facilitates fusion of ACh vesicles to the pre-synaptic membrane and subsequent exocytosis of ACh into the NMJ. ACh diffuses across the synaptic cleft to bind to ACh receptors (AChR) on the post-synaptic muscle membrane to ultimately result in muscle fiber contraction. Free ACh that persists within the synaptic cleft is broken down by the enzyme acetylcholinesterase (AChE) (see Figure 269-1). In normally-functioning motor units, there is an excess of available ACh and AChR. The muscle membrane potentials produced by nerve depolarization also greatly exceed what is required for muscle fiber contraction. This is known as the *safety factor* of neuromuscular transmission.

Clinical Signs

Disorders affecting the NMJ can be classified as pre-synaptic or post-synaptic in nature. They result from inability to release ACh from the pre-synaptic terminal into the synaptic cleft, or from inability of the post-synaptic muscle membrane to respond to ACh. Either disorder results in impaired neuromuscular transmission. Clinical manifestations of impaired neuromuscular transmission are typically symmetrical in nature, and may include acute tetraparesis or tetraplegia, chronic static or progressive tetraparesis, or episodic weakness that is exacerbated by activity. Pets with clinical signs referable to the NMJ have paresis that is accompanied by decreased muscle tone (flaccid paresis) and they may not be able to hold their head up due to weakness of the cervical musculature. They may also have decreased segmental spinal reflexes, cranial nerve deficits, or autonomic signs. The presence of the latter three abnormalities is disease- and severity-dependent. Patients with disease of the NMJ generally have normal sensory function and a normal level of consciousness.

Pre-Synaptic Diseases of the Neuromuscular Junction

Tick Paralysis

Tick paralysis is most commonly associated with exposure to ticks of *Dermacentor* sp. or *Ixodes* sp.[1,2] Clinical signs of tick paralysis result from a neurotoxin produced in the large salivary glands of female ticks. This neurotoxin is released into circulation after the tick attaches and feeds for several days. The exact cellular mechanism of this salivary neurotoxin has not been defined but it appears to interfere with ACh release from the pre-synaptic nerve terminal via a calcium-mediated mechanism.[1,3,4] Tick paralysis does not cause abnormalities on the complete blood count (CBC), serum biochemical tests, diagnostic imaging, or cerebrospinal fluid (CSF) evaluation.[5] Electrodiagnostic procedures are not typically performed. Clinical signs are present when an engorged tick is attached, and resolve when the offending tick is removed. Diagnosis is presumptive in most cases and is based on identification and removal of an engorged tick (see Video 211-1 in ch. 211).

In North America, *Dermacentor* ticks are most commonly associated with tick paralysis.[1] Dogs are commonly affected, while cats appear resistant. Clinical signs begin 5-9 days after tick attachment.[6] Dogs with tick paralysis have an acute, rapidly progressive, ascending flaccid paresis that can progress to tetraplegia over 12-72 hours. Segmental spinal reflexes are severely diminished to absent in all four limbs, and muscle tone is decreased.[5,7-9] Cranial nerve deficits are uncommon in dogs from North America, but mild facial and masticatory muscle weakness and dysphonia are occasionally observed.[7] Autonomic, sensory, and sphincter abnormalities do not occur in dogs with American tick paralysis. In severe cases, respiratory paralysis may necessitate mechanical ventilation and death due to hypoventilation can occur. Removal of the offending tick results in dramatic improvement in signs, usually within hours.

In Australia tick paralysis is far more severe, and is most often caused by *Ixodes* sp. ticks. Cats as well as

dogs may be affected.[3,6-8] Similar to American tick paralysis, dogs and cats with Australian tick paralysis have an acute, rapidly progressive ascending flaccid paresis that can progress to tetraplegia in hours. Autonomic dysfunction, urinary dysfunction, and congestive heart failure due to diastolic dysfunction can occur.[5,7,8,10] Pupillary dilation is common in cats and often observed in advanced canine cases.[6] Affected animals may develop pulmonary edema, aspiration pneumonia, and progressive hypoventilation.[5,8,10] Unilateral cranial nerve deficits and Horner's syndrome have also been reported.[11] Unlike American tick paralysis, pets with Australian tick paralysis may continue to decline for several days after tick removal.[12]

Tick removal in conjunction with supportive care is the primary treatment for both American and Australian tick paralysis. Pets should be searched carefully for ticks, which may necessitate clipping the hair. Examining the ear canals, perineum, mouth, nasal cavities, and interdigital spaces is also important. If a tick cannot be found, topical acaricides may be applied. In Australian tick paralysis, phenoxybenzamine and acepromazine may be used to treat autonomic signs.[7,8,13] Glucocorticoids are not routinely used to treat tick paralysis, and antibiotic therapy is not helpful.[7,9]

Botulism

Botulism is an acute diffuse lower motor neuron condition resulting from exposure to neurotoxins produced by the bacterium *Clostridium botulinum,* a Gram-positive anaerobe ubiquitous in soil, water, and the gastrointestinal (GI) tracts of mammals and fish. Most pets develop botulism by ingesting the pre-formed botulinum neurotoxin in spoiled or uncooked meat, although rarely botulinum toxin may be produced *in vivo* after liver or GI infection. This latter scenario is referred to as toxico-infection. Eight different types of botulinum toxin have been identified, but the most common in dogs is botulinum neurotoxin type-C (BoNT-C).[15-18] Naturally occurring botulism is extremely rare in cats, but has been reported with BoNT-C.[19]

Botulinum toxin blocks release of ACh at the pre-synaptic terminal of skeletal muscle and cholinergic autonomic synapsis by irreversible enzymatic cleavage of Soluble N-ethylmaleimide-sensitive factor activating protein receptor (SNARE) proteins.[6,15,20,21] SNARE proteins are essential for "docking" synaptic ACh vesicles to pre-synaptic membranes, allowing release of ACh into the synaptic cleft. Impaired ACh release causes an acute onset of progressive tetraparesis accompanied by autonomic signs such as ileus, tachy- or bradycardia, mydriasis, and urinary retention. Cranial nerve deficits such as a decreased palpebral reflex, megaesophagus, and diminished pupillary light reflexes are also common.[15,16,22] The rate of development and severity of clinical signs is dependent on the quantity of toxin ingested, with signs occurring within hours to as long as 6 days after ingestion of contaminated food.[8,10]

A diagnosis of botulism can be made by demonstrating BoNT in blood, feces, stomach contents, or food source of an affected animal. Historically, the gold standard for diagnosing botulism was the mouse inoculation test: instilling a patient sample into the peritoneal cavity of a mouse and observing development of clinical signs.[15,16] In reality, a clinical diagnosis of botulism is often presumptive based on history and clinical examination. Routine bloodwork will not show abnormalities. Electrodiagnostic testing can confirm botulism poisoning by demonstrating incremental increases in compound muscle action potentials (CMAP) with stimulation at high rates.[18] This finding is present in about 60% of adult humans with botulism, but has not been described in the dog.[23]

Treatment for botulism is primarily supportive in nature. Antibiotics are not generally indicated but may be considered if toxico-infection is a possibility or if other indications such as aspiration pneumonia are present. Certain antibiotics such as aminoglycosides and ampicillin may potentiate neuromuscular blockade and should be avoided.[24] Although the administration of antitoxin has been recommended, most available products do not contain antibodies against BoNT-C and are therefore not useful for dogs.[15,22] Antitoxins cannot bind toxin after it has entered nerve terminals, but they may be effective in binding circulating toxin and in partly halting the progression of disease.[15,20] If given, a test injection should be performed, as these products are of equine origin, and anaphylactic reactions are possible (see ch. 137).[20] Recovery from botulism occurs spontaneously over 1 to 4 weeks and the prognosis for most animals is excellent if they can be adequately supported.[8,15]

Elapid Snake Envenomation (see ch. 156)

Elapid snakes include the eastern *(Micrurus fulvius)* and Texas *(Micrurus tener)* coral snakes in North America,

the tiger *(Notechis scutatus)*, brown (*Pseudonaja* spp.) and red-bellied black snakes *(Pseudechis porphyriacus)* in Australia, and a variety from other continents, including cobras, kraits, and mambas.[25-29] Unlike crotalids, elapid snakes have short, rigid, immovable fangs, and an obvious puncture wound may not be present in envenomated animals.[25] Depending on the snake, the venom causes either a postsynaptic nondepolarizing neuromuscular blockade by tightly binding to AChR on the postsynaptic membrane, or it causes a presynaptic inhibition of ACh release.[25,27,30]

Clinical signs occur within hours of envenomation and include flaccid tetraparesis or tetraplegia, hypotonia, reduced or absent segmental spinal reflexes, and hypoventilation.[25-32] Pelvic limb ataxia may also be a prominent clinical sign in some cases.[33-35] Cranial nerve signs—ptyalism, dysphagia, dysphonia, and facial paresis or paralysis—are frequently observed.[28,31,32] Urine discoloration due to hemoglobinuria or myoglobinuria is seen in many dogs, but not as frequently in cats.[26,32,33] This can be useful in diagnosis, as it is not a feature of other NMJ or peripheral nerve diseases. Other abnormalities noted include vomiting, depression, hypotension, hypothermia, bleeding secondary to coagulopathies, and ventricular arrhythmias.[27,31-35] Diagnosis of elapid snake envenomation is typically presumptive, based on clinical signs and history. A CBC may show decreased hematocrit, spherocytosis, and erythrocyte "burring."[32]

Treatment is mainly supportive. The use of a pressure bandage at the site of envenomation can help to prevent circulation of venom through the lymphatics.[27] Fluid diuresis should be considered if hemoglobinuria or myoglobinuria is present (see ch. 129). The administration of antivenin has been advocated and may be beneficial in preventing or reducing the severity of clinical signs.[25,26,29,33-36] Equine-based products carry risks of anaphylaxis, and test injections should be considered. A variety of antivenins is available in Australia and other countries. North American supplies of coral snake antivenin are no longer being manufactured. However, cross-protection with tiger snake and Mexican coral snake antivenins occurs, and this product is used routinely with good results by some clinicians.[37-39] Most animals make a full recovery within 1 to 2 weeks with adequate supportive care.[29,31-33,39]

Post-Synaptic Diseases of the Neuromuscular Junction

Acquired Myasthenia Gravis (MG)

Pathogenesis and Breed Predispositions

Acquired myasthenia gravis (MG) is an autoimmune disorder characterized by production of autoantibodies against nicotinic AChR on the post-synaptic muscle terminal.[40-42] These autoantibodies lead to complement-mediated destruction of the AChR, reduced numbers of functional receptors, and a diminished ability of the muscle to respond to ACh released into the synaptic cleft.[43-47] The result is skeletal muscle weakness that is often exacerbated by activity. There is a bimodal age distribution for developing acquired MG. Dogs are usually <4 or >9 years of age.[44,48,49] Breeds overrepresented include Akitas, German Shorthaired Pointers, Chihuahuas, German Shepherds, Golden Retrievers, and Newfoundlands.[6,50-52] Acquired MG is less common in cats, but predilections for Abyssinian, Somali, and other pure breeds are reported.[48,53,54] Acquired MG can present in one of three forms, the most common being "generalized," but focal and severe fulminant forms are reported.[48]

Generalized MG

Patients with generalized MG generally have a normal neurologic examination at rest (see ch. 259). However, during a bout of exercise or activity-induced weakness, they demonstrate a choppy, stilted gait first noted in the pelvic limbs.[44] If continued activity is encouraged, thoracic limb involvement will become apparent. Some pets demonstrate a diminished or fatigable palpebral reflex, although not consistently present. Segmental spinal reflexes are typically normal. Signs of pharyngeal or laryngeal dysfunction which can manifest as ptyalism (due to difficulty swallowing; see ch. 36) and/or dysphonia are variably present.[44,48] Dogs with generalized MG often have concurrent megaesophagus and a history of regurgitation (see ch. 39 and 273). In cats, megaesophagus is less often noted.[53] Ventroflexion of the neck due to weakness of the cervical muscles is more common in cats than in dogs.[48,54-56]

Fulminant and Focal Forms of MG

Patients with fulminant MG have sudden and rapidly progressive severe diffuse weakness that does not improve with rest. Their condition progresses quickly to nonambulatory tetraparesis and lateral recumbency.[6] Spinal reflexes may be preserved or diminished.[6] Frequent regurgitation of large fluid volumes associated with megaesophagus is typical and aspiration pneumonia common (see ch. 242 and 360).[40] Additional signs include respiratory muscle weakness and urine retention. The prevalence of fulminant myasthenia has been reported to be 16% in dogs and 15% in cats. Thymoma has been associated with the development of this form of the disease in both species.[42,55,57-63]

Focal MG presents as weakness of an isolated muscle group, most commonly the ocular, facial, esophageal, pharyngeal, or laryngeal muscles. Generalized weakness is not observed in these pets and typical presenting complaints include regurgitation, dysphagia, dysphonia, or strabismus.[44,49,64]

Associated Conditions

Several diseases have been associated with MG in dogs and cats. These include thymoma, hypothyroidism, hypoadrenocorticism, polymyositis, and masticatory myositis.[42,63,65,66] In hyperthyroid cats, an association between acquired MG and methimazole treatment has been reported, which resolves with discontinuing the medication.[53,67,68]

Diagnosis

No change on routine CBC or serum biochemistries is pathognomonic for MG. Evidence of inflammation is common in pets with aspiration pneumonia. These tests are valuable in screening for metabolic causes of neuromuscular weakness (hypocalcemia, hypothyroidism, hyperadrenocorticism) and to assess creatinine kinase as an indicator of polymyositis (see ch. 66).[69] Thoracic radiographs or thoracic CT should be obtained to document presence or absence of thymoma and to screen for secondary aspiration pneumonia. Contrast swallowing studies can be used to assess dysphagic pets (see ch. 273), but are contraindicated in megaesophagus and regurgitation. Abdominal ultrasound may also be considered to rule out paraneoplastic causes of acquired MG in older patients (see ch. 88).[70-73]

The gold standard for diagnosis of acquired generalized MG in veterinary patients is demonstration of anti-AChR autoantibodies in serum.[69,73,74] While some cross-reactivity between species does occur, autoantibodies against the AChR are relatively species-specific. For this reason, it is essential to use a canine- or feline-specific assay system.[69] Antibody levels are highly variable between patients and do not correlate well with severity of clinical signs; however, within a specific patient, a decrease in antibody levels correlates well with improvement in clinical signs and can be followed to assess remission of disease.[69] It has been suggested that measurement of species-specific anti-AChR autoantibodies will detect approximately 98% of dogs with generalized acquired MG.[69] Antibodies are reported in a smaller percentage of dogs with focal MG. Antibody titers may be negative early in the course of disease and can be impacted by administration of corticosteroids prior to measurement.[75] Retesting is suggested in patients where either scenario is suspected. A small number of patients may have true seronegative acquired MG. In these cases, a diagnosis can be confirmed by documenting decrements in CMAP in response to repetitive nerve stimulation, and by normalization of limb muscle weakness after anticholinesterase therapy.[75]

Administration of the short-acting anticholinesterase drug edrophonium can be used diagnostically to assess improvements in muscle strength, gait, or the ability to swallow.[42] This drug inhibits AChE, allowing more ACh to remain in the NMJ, thereby improving neuromuscular transmission. Animals will often show improvement within seconds of receiving the drug (Video 269-1). The effect lasts for several minutes, followed by a return of clinical signs. It should be noted that improvement following edrophonium administration is not completely specific to MG, as some animals with other forms of neuromuscular weakness can also show improvement.[43,73,76] In addition, not all animals with MG will improve with edrophonium.[43,73,77] Precipitation of a cholinergic crisis is possible by overstimulation of AChR, leading to aggravation of weakness, salivation, tremors, vomiting, bradycardia, bronchoconstriction, and respiratory distress. Animals must be monitored closely after edrophonium administration. Atropine and equipment to provide intubation and respiratory support must be available and ready for use if necessary.

Long-Term Treatment

Long-term treatment for animals with acquired MG targets two goals: (1) increasing the amount of ACh

available within the synaptic cleft to counteract the deficiency in AChR numbers and (2) reducing autoantibodies produced against the AChR. Anticholinesterase drugs such as pyridostigmine bromide (oral) or neostigmine (IM) are the mainstays of therapy, working by inhibiting AChE so that ACh has a longer duration of action within synaptic clefts.[8,42,78,79] These medications must be carefully titrated to effect. Neostigmine is generally only used in hospitalized patients that are unable to take medications by mouth such as those in acute crisis or with profound and frequent regurgitation. Both medications have a narrow therapeutic window, and significant side effects such as bradycardia, hypersalivation, vomiting, diarrhea, muscle cramping, and weakness can occur.[79] This can be problematic, as the clinical signs associated with excessive anticholinergic drug administration may be difficult to distinguish from those of uncontrolled MG.

Immunosuppressive drugs such as cyclosporine, mycophenalate mofetil (MMF), and azathioprine are also frequently used in the treatment of acquired MG to reduce the levels of circulating autoantibodies by targeting the adaptive immune response while sparing innate immunity and neutrophil function (see ch. 165).[78,80-83] MMF was once the favored immunosuppressive drug for MG based on the human experience; however, a recent study comparing pyridostigmine plus MMF and pyridostigmine alone showed no difference in survival time or remission rates.[83]

Corticosteroids can also be effective in the treatment of MG (see ch. 165), but should be used with caution in patients with aspiration pneumonia (see ch. 242 and 360). Corticosteroids can potentiate muscle weakness and exacerbate clinical signs in some patients, and a gradual increase in steroid dosage is recommended to help avoid this complication.[41,57,73,75,77,78] Other strategies for immunomodulation may also be employed in patients with MG, including therapeutic plasma exchange and IV immune globulin (IVIG).[84-86] Neither technique has been thoroughly evaluated in a large number of dogs with MG, although there is some evidence to support their utility in this and other immune-mediated diseases.[86-91] A long-term spontaneous remission rate as high as 88% has been reported for dogs with non-paraneoplastic causes of acquired MG.[92]

Congenital Myasethenia Gravis

Presumed congenital MG, or myasthenic syndrome, has been reported in Jack Russell Terriers, Smooth Fox Terriers, Springer Spaniels, Samoyeds, smooth-haired Miniature Dachshunds, Gammel Dansk Hønsehund (GDH) dogs, mixed-breed dogs, and cats.[54,93-104] A deficiency of AChR is assumed in most breeds and has been documented in Jack Russell Terriers, Springer Spaniels, and Miniature Dachshunds.[101,105] The disease often affects multiple animals within the same litter and usually becomes evident after 6 to 9 weeks of age. Generalized limb and cervical muscle weakness that worsens with activity is common. Megaesophagus may or may not be present.[98,101] The GDH dogs are unusual because the condition begins at about 4 months of age and is relatively unresponsive to AChE-blocking drugs.[102,106] These dogs are thought to have a pre-synaptic defect in neuromuscular transmission.[106,107] An autosomal-recessive mode inheritance has been demonstrated in Smooth Fox Terriers, Jack Russell Terriers, and GDH dogs.[94,97,108]

A definitive diagnosis of congenital MG can be made by quantification of AChR in a muscle biopsy (see ch. 116), although such testing is not readily available.[101,105] Pyridostigmine or neostigmine are cornerstones of therapy and often cause improvement. However, the long-term response to therapy is variable, and reports in most breeds describe death or euthanasia of affected animals due to difficulty in controlling clinical signs.[98,99] Exceptions to this are congenital MG in Miniature Dachshunds, which spontaneously resolved by 6 months of age, and GDH dogs who remain stable with mild clinical signs.[101,102]

Other

Exercise-Induced Collapse of Labrador Retrievers

Although not a disease of the NMJ, exercise-induced collapse of Laborador Retrievers (EIC) causes fatigue and flaccid para- or tetraparesis during or after strenuous activity. Examination findings are normal at rest. Ataxia, pelvic limb weakness, and collapse develop in association with intense or prolonged field training, hunting, or vigorous play. Clinical signs may progress to involve the thoracic limbs if the animal continues activity. Recovery occurs with rest, and most dogs are clinically normal within 30 minutes; however, severe episodes can result in death.[109-111]

The condition is heritable in Labradors, associated with an autosomal recessively inherited mutation (Arg256Leu) in the gene encoding for the protein dynamin 1 (DNM1).[109,110] The dynamin gene family

encodes for a group of enzymes that maintain synaptic vesicle function during sustained neurotransmission (e.g., during intense physical activity).[109,112] Specifically, DNM1 is expressed at synaptic terminal membranes within the central nervous system and is important in the recycling of synaptic vesicles during high-frequency neurological stimulation. A collapse phenotype is also recognized in other breeds, but association between collapse and the Arg256Leu mutation in variable.[112]

Dogs with DNM1-associated EIC (d-EIC) typically experience their first episode of collapse before 2 years of age.[111] Loss of the patellar reflex is common during an episode, and dogs maintain normal mental status.[111,113] Hyperthermia and elevated plasma lactate often develop during an episode, but are not distinct from what is observed in normal exercising dogs.[113] Serum lactate/pyruvate ratios are normal in dogs with EIC both at rest and during exercise, and muscle biopsies are unremarkable.[113] A genetic test for the *Arg256Leu DNM1* mutation is now commercially available to assist in diagnosis. While there is no cure for EIC, affected dogs have an excellent prognosis if they refrain from intense physical activity known to trigger episodes.[113]

CHAPTER 270

Unique Feline Neurologic Disorders

Elsa Beltran, Luisa De Risio

Client Information Sheet: Feline Cerebellar Hypoplasia

Central Nervous System (CNS) Diseases

Congenital Malformations

Feline Panleukopenia

Cerebellar hypoplasia caused by perinatal infection with the feline panleukopenia virus (FPV) is the most common diffuse cerebellar disorder in cats.[1] Exposure to FPV during the last 3 weeks of gestation or the first 3 weeks of life may induce destruction of the dividing external germinal layer and cause granuloprival cerebellar hypoplasia in kittens (see also ch. 225).[2,3] Fetal infections before the last 3 weeks of gestation can result in hydranencephaly.[4,5] Vaccination with a modified-live FPV vaccine during pregnancy can result in clinically affected kittens.[5] Clinical signs include cerebellar ataxia, intention tremor, menace response deficits, and nystagmus (Video 270-1). The clinical signs usually remain stable or even improve over time, as some compensation is possible. There are no specific diagnostic tests. Advanced imaging, in particular magnetic resonance imaging (MRI), can reveal cerebellar atrophy. Cerebrospinal fluid (CSF) analysis usually is normal. There is no treatment but these cats may have a good quality of life when their environment is modified to accommodate their disabilities (see online Client Information Sheet). Prevention can be achieved by vaccination of queens before pregnancy.

Inborn Errors of Metabolism

Few are reported uniquely in cats, and these typically also affect the peripheral nervous system (PNS) (Table 270-1).

TABLE 270-1

Inherited Unique Feline CNS and Neuromuscular Diseases

DISEASES, AFFECTED BREED(S), AGE OF ONSET, AND SEX INHERITANCE PATTERN	CLINICAL SIGNS	DIAGNOSTIC TESTS	TREATMENT AND PROGNOSIS
Mannosidosis (alpha-mannosidase deficiency)[74-77] • DSH, DLH, Persian • 7-15 m.o. • AR	Progressive cerebellar dysfunction, abnormal behavior, lethargy, corneal and lens opacification	Genetic test	No treatment Poor prognosis
Glycogen storage disease type IV[78,79] • Norwegian Forest Cat • 5 m.o.	Generalized muscle tremors and weakness that progresses to tetraplegia (PNS and CNS involvement)	Genetic test	No treatment Poor prognosis. Death around 12 m.o.

• AR			
Niemann-Pick disease type A[80-82] • Siamese and Balinese cats • 2-5 m.o., males and females • AR	Progressive tetraparesis, palmi- and plantigrade stance, decreased spinal reflexes	EMG: spontaneous activity Reduced MNCV Enzyme assay in leukocytes and cultured fibroblasts (decreased sphingomyelinase activity)	No treatment Poor prognosis Death around 10 m.o.
Hypokalemic periodic polymyopathy[83-85] • Burmese and Burmese-related breeds • 2 m.o. to 2 y.o., males and females • AR	Episodic and acute onset of passive ventroflexion of the neck, myalgia, head bobbing, stiff gait, weakness. Normal between episodes.	Intermittent hypokalemia (<3.0 mmol/L) and elevated CK Genetic test available	Oral potassium supplementation May improve with time
Muscular dystrophy associated with alpha-dystroglycan deficiency[86,87] • Sphynx and Devon Rex cats • 3-23 w.o., males and females • AR	Inability to jump, passive ventroflexion of the neck, difficulty swallowing, dorsal protrusion of the scapulae, crouching gait, fatigability after short periods of activity	CK: mild to normal values EMG: mild spontaneous activity RNS at 1-3 Hz shows decremental response Muscle biopsy	No treatment Slow progression or can stabilize Death due to aspiration/laryngospasm possible
Polyneuropathy associated with primary hyperchylomicronemia[88,89] • DSH, DLH, Himalaya, Persian, Siamese • 4-8 w.o., females and males • AR	Progressive, focal/multifocal, asymmetric mononeuropathy due to lipid granulomas compressing the peripheral nerves	Reduced LPL activity Mutation in LPL characterized	Low-fat diet could resolve the peripheral neuropathy
Primary hyperoxaluria (L-glyceric aciduria)[90] • DSH • 5-9 m.o., females and males • Suspected AR	Acute onset, weakness, tetraparesis, decreased spinal reflexes, decreased nociception, and abdominal pain	Urine analysis (L-glyceric aciduria) Kidney disease, uremia	Poor prognosis due to acute kidney injury and uremia
Axonal polyneuropathy[91] • Snowshoe cats • 3-6 m.o., males • Suspected inherited	Insidious onset, slightly progressive, intermittent pelvic limb weakness with decreased withdrawal reflex bilaterally	EMG spontaneous activity Reduced MNCV Muscle and nerve biopsies	Supportive treatment Stabilization within 6-12 months, with tendency for remission
Central and peripheral distal axonopathy[92] • Birman cats • 10 w.o., females • Suspect inherited	Slowly progressive palmigrade stance with adduction of the hocks. Hypermetric gait and paraparesis.	EMG: spontaneous activity Reduced MNCV Muscle and nerve biopsies	Supportive treatment Prognosis unknown

AR, Autosomal recessive; *CK*, serum creatine kinase concentration; *CNS*, central nervous system; *DLH*, domestic longhair; *DSH*, domestic shorthair; *EMG*, electromyography; *LPL*, lipoprotein lipase; *m.o.*, months old; *MNCV*, motor nerve conduction velocity; *PNS*, peripheral nervous system; *RNS*, repetitive supramaximal nerve stimulation; *w.o.*, weeks old; *y.o.*, years old.

Prion Disease

Feline spongiform encephalopathy (FSE) is a prion-induced disease affecting the Felidae family.[6-8] Experimental

studies suggest that FSE is caused by the same agent that causes bovine spongiform encephalopathy (BSE) in cattle and new variant Creutzfeldt-Jakob disease in humans.[6,7] Cats are believed to contract the disease by ingestion of BSE-contaminated food. To date, FSE has only been reported in Europe. A recent experimental study demonstrated that chronic wasting disease (transmissible spongiform encephalopathy of mule deer, white-tailed deer, elk, and moose) can be transmitted to the domestic cat, thus raising the issue of potential cervid-to-feline transmission.[9] Clinical disease presents in adult cats and is characterized by chronic progressive clinical signs (from weeks to months), including abnormal behavior, ataxia, muscle tremors, hypersalivation, dilated and unresponsive pupils and hyperesthesia. The diagnosis is based on histopathologic evaluation of the brain.[7,8,10-12] There is no current treatment and the disease is progressive and fatal.

Infectious and Noninfectious Inflammatory CNS Diseases

Viral CNS Diseases

Feline Infectious Peritonitis (FIP)

Feline infectious peritonitis (FIP) is the most common infectious CNS disease in cats.[13-15] Up to 33% of FIP cases show neurological signs, and all three forms (effusive [wet], non-effusive [dry], and mixed) have been associated with CNS involvement; however, the non-effusive form is the most common (see also ch. 224).[14,16,17] FIP usually is seen in purebred cats from multi-cat environments, typically <4 years of age.[14,18-20] The neurologic signs reflect the area of CNS involvement, which often includes the caudal fossa (cerebellum, pons, and medulla oblongata).[17,21] Neurological signs can present alone or in conjunction with systemic signs.[16,18,19] Ophthalmic lesions (iritis, anterior uveitis, and keratitis) have been reported in up to 53% of cases with neurologic FIP (see ch. 11).[16,18,21] The most common neurologic signs are altered mental status, menace response deficits, vestibular syndrome, seizures, ataxia, and paresis (Video 270-2).[16,18,21-25] Seizures occur in up to 33% of cats with neurologic FIP and have been associated with a poor prognosis.[21,24] FIP is the single most common cause of myelopathy in cats younger than 2 years of age (Video 270-3).[23] The general diagnostic evaluation for FIP is described in ch. 224. Current antemortem diagnostic tests for neurologic FIP aim to exclude other conditions that could cause a similar clinical presentation but cannot directly confirm the diagnosis. Advanced imaging findings include obstructive hydrocephalus, ventricular dilation and periventricular, ependymal and meningeal contrast enhancement reflecting the superficial and ventricular nature of the FIP lesions in the CNS (Figure 270-1).[15,18] However, up to 37% of cats with histologically-confirmed neurologic FIP can have normal MRI results.[15] CSF collection should be performed after ruling out the possibility of increased intracranial pressure (ICP), ideally by MRI, because high ICP can increase the morbidity and mortality associated with this procedure in cats with neurologic FIP (see ch. 115).[15,21,26] The most common CSF findings are protein concentration > 2 g/L (>200 mg/dL) and nucleated cell count > 100 cells/mcL with a neutrophilic pleocytosis.[14,16,21,27] Elevated protein concentration in the CSF could cause increased viscosity and therefore CSF may not flow adequately during collection. Coronavirus antibodies have little diagnostic value as negative serum titers or titers <1:400 have been reported in cats with neurologic FIP.[14,18,21] CSF coronavirus antibodies (IgG) are not necessarily more sensitive than serum antibodies.[17] The use of albumin quotient and IgG index has failed to identify a protein pattern specific for neurologic FIP, indicating that disturbance of blood-CSF barrier function and intrathecal IgG synthesis is not a common feature of FIP.[28] A strongly positive reverse-transcriptase polymerase chain reaction (RT-PCR) in CSF supports the diagnosis. However, some cats with histologically-confirmed neurologic FIP have negative RT-PCR.[18] Immunohistochemistry has been used successfully in one cat to identify FIP-infected macrophages in CSF; nonetheless, further studies are needed to assess its sensitivity and specificity.[29] Definitive diagnosis requires a combination of gross and histopathological examination with the demonstration of viral antigen in postmortem CNS samples. There is still no cure nor reliable prevention of FIP (see ch. 224). The prognosis for cats with neurologic FIP is poor: The median survival time has been reported as 6.5 days (range 2 to 330 days) and 21 days (range 7 to 150 days) in two studies.[16,21]

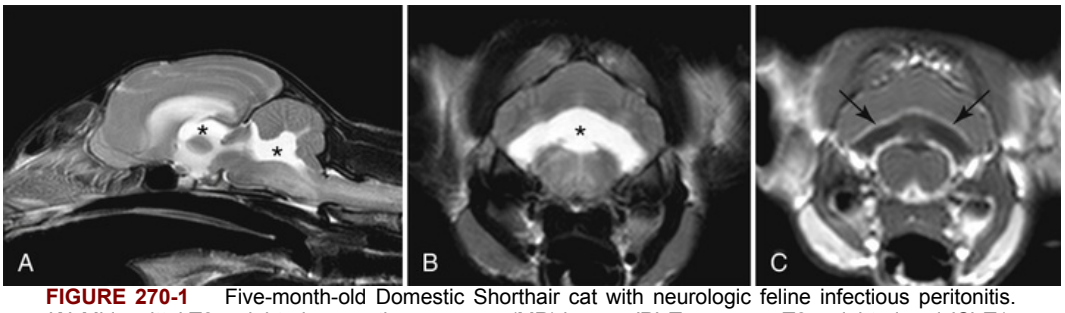

FIGURE 270-1 Five-month-old Domestic Shorthair cat with neurologic feline infectious peritonitis. **(A)** Midsagittal T2-weighted magnetic resonance (MR) image, **(B)** Transverse T2-weighted and **(C)** T1-weighted post contrast MR images at the level of the 4th ventricle showing severe dilation of the ventricular system (asterisks) with marked periventricular enhancement (arrows) after contrast administration.

Feline Immunodeficiency Virus (FIV)

Feline immunodeficiency virus (FIV) is a neurotropic retrovirus that causes acquired immune deficiency syndrome, which can result in opportunistic CNS infections and neoplasms (lymphoma). FIV shares many characteristics with human immunodeficiency virus (HIV) and has been used as an animal model for understanding the neuropathogenesis of HIV (see ch. 222). However, neurologic signs in naturally-infected cats are very uncommon.[30-32] Neurologic signs (insidious onset and progressive course) include abnormal behavior, followed by facial twitching, ataxia, seizures, sleep disorders, and intention tremors.[32,33] Slight elevations in nucleated cell count (mononuclear pleocytosis) and total protein concentration have been reported in CSF.[34] In experimentally-infected cats, MRI showed cortical atrophy and mild ventricular dilation, white matter changes, and increased apparent diffusion coefficients in the white matter, gray matter, and basal nuclei.[35,36] Positive serologic test results and a positive PCR on serum and CSF can support the diagnosis. Treatment is focused on managing opportunistic CNS infections. The prognosis is poor; however, some cats remain asymptomatic for many years.[37]

Feline Leukemia Virus (see ch. 223)

Feline leukemia virus (FeLV) has been associated with a chronic degenerative myelopathy in adult and geriatric cats.[38] There is no breed or sex predilection, and the onset of clinical signs is insidious, with a slowly progressive course. Neurological signs include abnormal behavior, vocalization, hyperesthesia, and paraparesis progressing to paraplegia with urinary incontinence.[38] MRI (brain and spinal cord) and CSF analysis are normal. Positive serologic test results and a positive PCR on serum and CSF can support the diagnosis. This disease is uncommon, and therefore, other concomitant diseases should be considered for FeLV-infected cats with myelopathy. The prognosis is poor and the treatment is supportive.

Feline Borna Disease Virus

Feline staggering disease refers to a meningoencephalomyelitis caused by a negative-stranded RNA virus, Borna disease virus (BDV). It has been reported mainly in Europe but also occurs in other parts of the world, including Asia and Australia.[39-43] The probable reservoirs are birds and rodents; therefore, young adult outdoors cats from rural areas are at increased risk.[44] The most common neurologic signs include unsteady, "staggering" gait (ataxia) and postural reaction deficits followed by abnormal behavior and absent or decreased menace response.[44] Advanced imaging findings usually are unremarkable. CSF can be abnormal in 50-60% of infected cats (mononuclear pleocytosis with increased total protein concentration).[44] Serologic titers and real time RT-PCR in serum and CSF can support but not confirm the diagnosis.[44,45] The disease is progressive, and despite supportive treatment, the majority of affected cats die or are euthanized during the first month after the onset of clinical signs.[44,46]

Parasitic CNS Disease

Gurltia Paralysans

Gurltia paralysans is a neurotropic metastrongylid nematode of domestic cats in South America.[47-51] The life

cycle of *G. paralysans* is unknown. Adult worms and eggs can be found in the thoracolumbar and lumbosacral spinal cord parenchyma and leptomeningeal veins causing chronic and slowly progressive meningomyelitis (feline gurltiosis). There is no breed or sex predilection and young adult cats from rural or periurban areas are generally affected. Clinical signs include pelvic limb proprioceptive ataxia, paraparesis, paraplegia, lumbosacral hyperesthesia, fecal or urinary incontinence and/or tail paralysis (Video 270-4). CT-myelography and MRI show diffuse enlargement of the thoracolumbar and lumbosacral spinal cord.[48] CSF mononuclear pleocytosis has been reported in up to 55% of affected cats.[48] An antemortem presumptive diagnosis of feline gurltiosis is based on neurological signs, epidemiological factors, and the exclusion of other causes of feline myelopathies.[48-51] No larvae or parasite eggs are found on fecal examination. The definitive diagnosis is based on histopathology via detection of adults of *G. paralysans* in the spinal cord (Figure 270-2). PCR of serum and CSF samples is being evaluated as a possible diagnostic tool for *G. paralysans* infection in domestic cats.[52] There is no treatment and the prognosis is poor.

FIGURE 270-2 Pathologic lesions associated with *Gurltia paralysans* infection in an adult cat. **A,** Lumbar spinal cord segments showing marked vascular congestion (asterisk). **B,** Histological section from the spinal cord showing parasite sections inside the vasculature (arrows) within the subarachnoid space and spinal cord parenchyma. (Images courtesy Dr. Marcelo Gomez.)

CNS Disorders of Unknown Origin

Feline hippocampal necrosis (FHN) is a seizure disorder characterized by epileptic events (generalized seizures and/or focal seizures with orofacial involvement) and interictal abnormal behavior.[53-56] There is no breed or sex predilection.[56-61] The age of presentation ranges from 3 months to 14 years of age.[56-58,61,62] The onset of clinical signs is acute with a rapid progression. The seizures have a tendency to become recurrent within days or weeks of onset.[54,56] Two major groups of FHN should be considered: primary or idiopathic FHN, which appears to be the direct cause of the seizures, and secondary FHN, which appears as a consequence of ongoing seizure activity due to a precipitating hippocampal or extrahippocampal forebrain disease (autoimmune feline limbic encephalitis, neoplasia).[54,56,59,60,63] Definitive diagnosis is made histopathologically; however, MRI findings can confirm hippocampal lesions (Figure 270-3).[56] Treatment consists of antiepileptic medications. Immunosuppressive medication also has been recommended in suspected cases of autoimmune feline limbic encephalitis.[56,61,63] The prognosis generally is poor, as the majority of cats become antiepileptic medication-resistant during the acute phase of the disease; however if this phase is overcome, the long-term outcome can be favorable.[54,57,60,61,63]

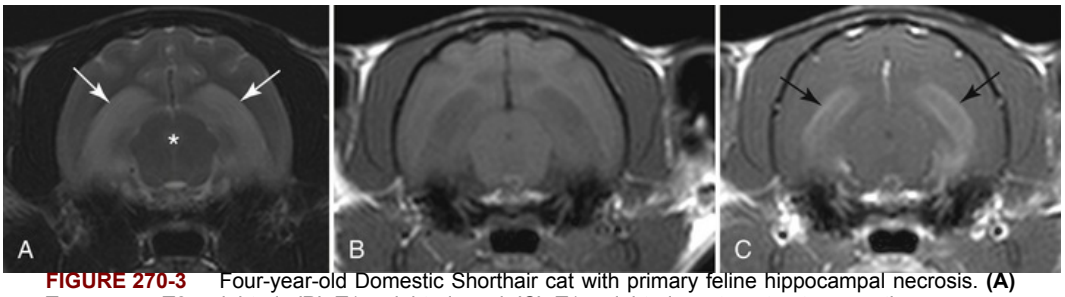

FIGURE 270-3 Four-year-old Domestic Shorthair cat with primary feline hippocampal necrosis. **(A)** Transverse T2-weighted, **(B)** T1-weighted, and **(C)** T1-weighted post-contrast magnetic resonance (MR) images at the level of the mesencephalic aqueduct (**A,** asterisk). There is moderate bilateral hyperintensity on T2-weighted images (**A,** white arrows) and hypointensity to normal gray matter on T1-weighted images of the hippocampal formation **(B).** There is marked enhancement of the hippocampus (**C,** black arrows) on T1-weighted images after contrast administration.

Slowly progressive lymphohistiocytic meningoencephalomyelitis is characterized by a late onset (mean of 9 years old) and slow progression (mean of 11 months).[64] There is no sex or breed predilection and all the reported cases were outdoor cats (active hunters living in northeast Scotland). Neurological signs include an obtunded or disoriented mental status, spastic gait, stiff and extended tail posture, decreased to absent postural reactions in all four limbs, and decreased to absent menace response bilaterally (Video 270-5 ▶). Advanced imaging can show brain atrophy. CSF analysis was normal in one tested cat. Definitive diagnosis is based on histopathologic analysis of brain tissue.[64] The suggested possible causative agents include an infective or environmental immunogenic trigger. There is no treatment and the prognosis is poor.[64]

Feline polioencephalomyelitis is a subacute to chronic nonsuppurative encephalomyelitis with a predominance of pathological changes in the gray matter, mainly affecting the medulla oblongata and the spinal cord.[65,66] Pathological findings are highly suggestive of a viral agent. There is no breed or sex predilection and cats of any age can be affected. The disease is considered rare (prevalence of 1% in cats with myelopathy).[23] Clinical signs include ataxia, paresis, and decreased postural reactions in all four limbs.[65-68] The diagnosis is based on histopathologic analysis of tissue.[65,66,69] There is no treatment, and prognosis can be favorable when neurological signs are mild and non-progressive.[67]

Neuromuscular System Diseases

Inherited Neuromuscular Diseases

Inherited neuromuscular diseases are rare, slowly progressive, and they predominantly affect young kittens (see Table 270-1).

Acquired Neuromuscular Diseases

Motor Polyneuropathy of Unknown Origin in Young Cats

Recurrent or progressive motor polyneuropathy has been reported to affect young cats from 3 to 44 months of age, mainly Bengals (but any breed or sex can be affected).[70,71] Clinical signs include generalized weakness (recurrent or progressive), palmigrade and plantigrade posture, ventroflexion of the neck, and decreased to absent spinal reflexes.[70,71] The diagnosis is based on electrodiagnostic testing (see ch. 117) and histopathologic assessment of muscle and nerve biopsies. Treatment is supportive and the prognosis varies from poor to excellent, which highlights the possible different etiologies.[70,71]

Specific Paroxysmal Disorders of Unknown Origin

Feline orofacial pain syndrome (FOPS) is a pain disorder characterized by acute behavioral signs of oral discomfort with or without tongue mutilation. It is prevalent in Burmese cats; however, cats of any breed, sex or age can be affected.[72,73] FOPS has been hypothesized to be analogous to trigeminal neuralgia in humans. Clinical signs include paroxysmal events of acute onset of exaggerated licking, chewing movements and pawing at the mouth, usually confined to one side of the oral cavity and lips (Video 270-6 ▶). The events last from 5 minutes to 2 hours and the cat typically can be distracted from it. Neurological examination findings

are normal. The diagnosis is based on ruling out other possible causes of oral pain or trigeminal nerve dysfunction. Oral lesions and environmental stress can precipitate these episodes. Some cats can be resistant to traditional analgesics including gabapentin.[73] Adjuvant antiepileptic medications (phenobarbital) could help to control the allodynia effect and environmental stress should be limited.[73] Occasionally, life-long therapy is required; however, remission has been reported in up to 45% of affected cats.[73]

Chapter 278 Rectoanal Disease
Chapter 279 Peritonitis

CHAPTER 271

Laboratory Evaluation of the Gastrointestinal Tract

Jörg M. Steiner

Client Information Sheet: Laboratory Evaluation of the Gastrointestinal Tract

Introduction

Signs of gastrointestinal disease are very common in both dogs and cats, but definitive diagnosis can be challenging. There are a wide range of laboratory tests that can help assess patients with suspected gastrointestinal disease. Depending on the clinical signs the patient is presented with (e.g., diarrhea [see ch. 40], vomiting [see ch. 39], weight loss [see ch. 19]), a specific systematic approach should be taken to rule in/out the various causes of the clinical signs. Regardless of the clinical sign(s) observed, the primary goals of the clinician should be (1) to rule out secondary causes of gastrointestinal signs initially, (2) to rule out common causes of gastrointestinal disease before ruling out rare causes, and (3) to use less-invasive and more affordable diagnostic tools before reaching for more-invasive and more expensive ones.

Cytologic evaluation of fine needle aspirates (see ch. 89) or tumor impressions (see ch. 93) and histopathological evaluation of endoscopically- (see ch. 113), laparoscopically- (see ch. 91), or surgically-collected biopsy specimens also belong to the laboratory diagnostic modalities that are important in arriving at a definitive diagnosis, and they are discussed elsewhere (see Section V).

Laboratory Evaluation for Specific Etiologies

Myasthenia Gravis

Megaesophagus describes a loss of motility of the esophagus that leads to an extension of the esophageal diameter, regurgitation, and in many cases aspiration pneumonia. In many patients the underlying cause of megaesophagus cannot be determined, but some patients have a localized form of myasthenia gravis, which can be diagnosed by demonstrating antibodies against acetylcholine receptors in serum from affected dogs, a test which is both highly sensitive and specific for this disease (see ch. 269).[1]

Laboratory Tools to Diagnose Enteropathogens

Helicobacter-Like Organisms

The actual pathogenetic impact of infections with *Helicobacter*-like organisms in dogs and cats is not completely understood. Many healthy dogs and cats show evidence of *Helicobacter*-like organisms in the stomach.[2] However, there is a group of dogs and cats that have evidence of chronic gastritis (i.e., clinical signs of chronic vomiting), have no other identifiable cause of these clinical signs, have evidence of *Helicobacter*-like organisms in the stomach, and respond to triple or quadruple therapy designed for the treatment of *Helicobacter pylori* infections in humans. The presence of *Helicobacter*-like organisms in the gastric mucosa can be determined by using special stains (e.g., Warthin-Starry stain), PCR, or fluorescent *in situ* hybridization (see ch. 275).[3] The organism can also be identified indirectly by a urease test on a gastric biopsy or by ^{13}C-urea blood or urine tests, the latter of which are however currently not commercially available for use in dogs or cats.[3,4]

Parvovirosis

In clinical practice, an in-house ELISA that detects CPV-2 antigen in feces is currently the most frequently used test for parvovirosis in dogs. This test can however be falsely positive in dogs that have recently been

vaccinated.[5] CPV-2 can also be diagnosed by PCR, which is associated with a higher sensitivity, but of course is less optimal in patients with severe peracute disease (see ch. 225).[5]

Salmonella spp.

Salmonella spp. can be harbored by both dogs and cats for a long period of time without causing clinical signs (see ch. 220).[6,7] However, there are dogs and cats that have acute or chronic diarrhea that are positive for *Salmonella* in the feces. Identification of *Salmonella* spp. organisms has traditionally been achieved by specifically culturing for *Salmonella* spp., followed by susceptibility testing. However, in many patients the organism is not consistently shed in the feces (see ch. 40 and 220). Also, *Salmonella* spp. can be diagnosed by an enrichment culture followed by PCR or by a direct PCR.

Pathogenic *Campylobacter* spp.

While there are many different *Campylobacter* spp. that have been identified in the intestinal tract of dogs and cats, only a limited number of these organisms, namely *C. jejuni* and *C. coli,* have been associated with diarrhea (see ch. 40 and 220).[8] These subspecies can be specifically diagnosed by PCR.

Clostridium difficile and *perfringens*

Clostridium difficile has been associated with diarrhea in both dogs and cats (see ch. 220).[9-11] The virulence of *C. difficile* is associated with the presence of genes that encode for various toxins, most notably toxin A (an enterotoxin) and toxin B (a cytotoxin), which can both be detected by ELISA, but positive results do not always correlate with the disease.[9,11]

Clostridium perfringens has commonly been associated with diarrhea in both dogs and cats. The main virulence factor is the *Clostridium perfringens* enterotoxin (CPE), which has been shown to induce mucosal damage, increase intestinal permeability, and reduce water absorption, thus leading to diarrhea.[12] Bacterial culture of feces for *C. perfringens* has little diagnostic value, as *C. perfringens* is a commensal organism that can be detected in up to 80% of fecal samples from dogs and cats.[9,11] Microscopic examination of fecal smears and enumeration of fecal endospores also is not useful for the diagnosis of *C. perfringens*-associated diarrhea.[11,13] The current recommendation for diagnosis of *C. perfringens*-associated diarrhea is the detection of *C. perfringens* enterotoxin by ELISA, but a positive result does not definitively prove a cause-effect relationship.[12]

FISH for Enteroinvasive *E. Coli*

Histiocytic ulcerative colitis is a severe form of colitis that has traditionally most commonly affected Boxer dogs, but it can also be seen in dogs of other breeds (see ch. 40 and 277).[14] Diagnosis is based on histopathologic findings of histiocytic ulcerative colitis on a colonic biopsy sample and the detection of an enteroinvasive *E. coli* by fluorescent *in situ* hybridization.[14,15] This test is based on using a genetic probe directed against a specific section of the DNA of this organism that has been fluorescently labeled.[15] Finding fluorescently labeled organisms in the colonic mucosa confirms the presence of the organism and the disease (see ch. 133 and 277).

Laboratory Tools to Diagnose Endoparasites (see ch. 81)

Fecal Smear

A fecal smear can be used to identify protozoal infections, most commonly *Giardia lamblia* in either dogs or cats or *Tritrichomonas foetus* in cats. However, the sensitivity of a fecal smear for the diagnosis of either infection is rather low and a negative fecal smear does not rule out an infection with a protozoal organism.[16,17] Occasionally, other parasitic infections (e.g., whipworms) can be detected by direct fecal smear evaluation.

Fecal Flotation

Fecal flotation is a great tool for the detection of ova from a wide variety of helminths and *Giardia* cysts in either dogs or cats. There are advanced flotation techniques (i.e., centrifugal flotation, zinc sulfate flotation) that increase the sensitivity of this tool.[18]

Immunofluorescence for *Giardia* and *Cryptosporidium*

Immunofluorescence is an excellent diagnostic technique for the detection of *Giardia* spp. and *Cryptosporidium* spp. in both dogs and cats (see ch. 210 and 221).[19,20] Immunofluorescence uses fluorescently labeled antibodies directed against specific antigens of those protozoal organisms to differentiate these organisms from other fecal matter (Figure 271-1).

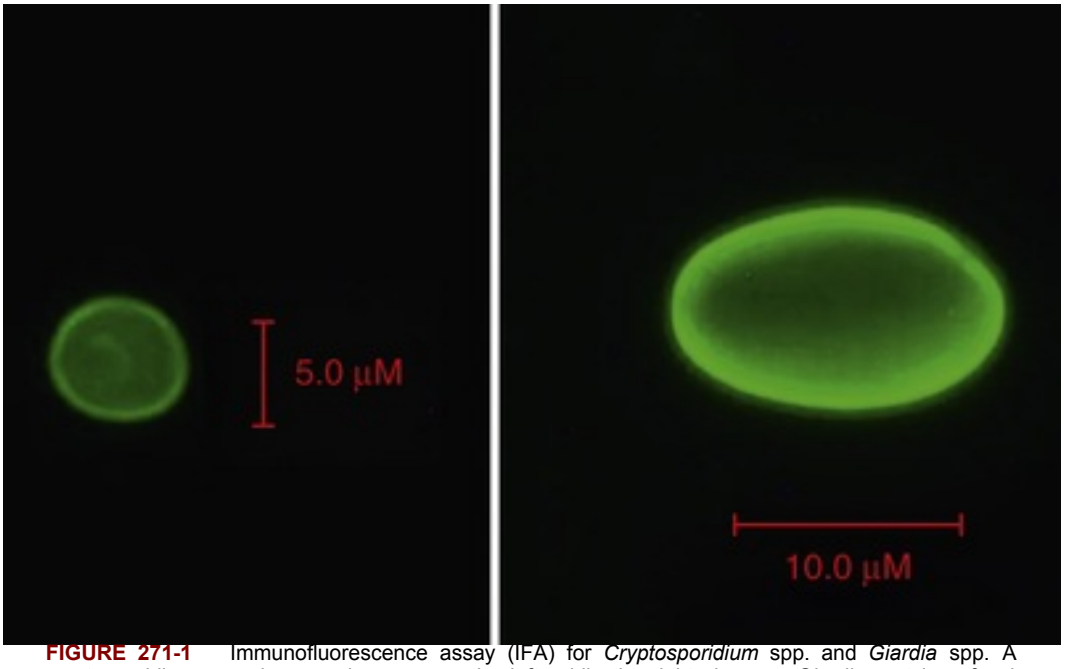

FIGURE 271-1 Immunofluorescence assay (IFA) for *Cryptosporidium* spp. and *Giardia* spp. A cryptosporidium organism can be seen on the left, while the right shows a *Giardia* cyst in a fecal sample from a dog (Magnification ×1000). (Reprinted from The GI Lab Newsletter, Suchodolski, "Update on the diagnosis of enteropathogens," page 3, © 2012, with permission from the Gastrointestinal Laboratory.)

ELISAs for *Giardia lamblia*

There are ELISAs for the detection of antigens from *Giardia* in fecal samples. These ELISAs have been shown to be highly sensitive for the presence of *Giardia,* but the specificity is lower than with immunofluorescence, especially in patients that have recently been treated.[20,21]

PCR for *Tritrichomonas foetus*

Tritrichomonas foetus is one of the most important protozoal infections in cats. In general, *T. foetus* can be diagnosed by direct fecal smear, culture-pouch, or PCR, but only PCR affords an acceptable sensitivity.[22,23] Many laboratories offer PCR testing for this organism. However, there is no generalized standard and some laboratories use real-time PCR while other labs use a more traditional nested PCR. Thus the minimum number of organisms detectable per gram of feces could vary quite dramatically between laboratories. Some cats shed the organism intermittently and a colonic flush (https://www.youtube.com/watch?v=JMfZ9M80V8E) may afford the highest sensitivity.

PCR for *Heterobilharzia americana*

Heterobilharzia americana is a trematode that causes schistosomiasis in dogs and has mainly been described in some areas of Texas and Louisiana. The trematode egg can be identified by sodium chloride sedimentation, which is only performed upon special request. A PCR-based assay for the detection of DNA from the eggs of this organism in feces is available and has been shown to be more sensitive than sodium chloride sedimentation.[24]

Laboratory Tools to Assess Intestinal Function and Disease

Serum Folate Concentration

Folate is a water-soluble B-vitamin (vitamin B_9) that is plentiful in most commercial pet foods. However, folate in the diet is mostly supplied as folate polyglutamate, which cannot be readily absorbed. In the proximal small intestine, folate polyglutamate is deconjugated by folate deconjugase and the resulting folate monoglutamate is absorbed by specific folate carriers in the proximal small intestine (Figure 271-2 and Video 271-1).[25,26] In patients with proximal small intestinal disease, both folate deconjugase and folate carriers can be destroyed, leading to folate malabsorption in patients with severe disease. If the condition is chronic, folate body stores can become depleted and serum folate concentration decreases. The same is true in patients with diffuse small intestinal disease, as long as the proximal small intestine is involved in the disease process.[27,28] Many bacterial species synthesize folate and it is believed that an increased number of certain bacterial species (i.e., small intestinal dysbiosis) can lead to significant increases in serum folate concentrations.[29]

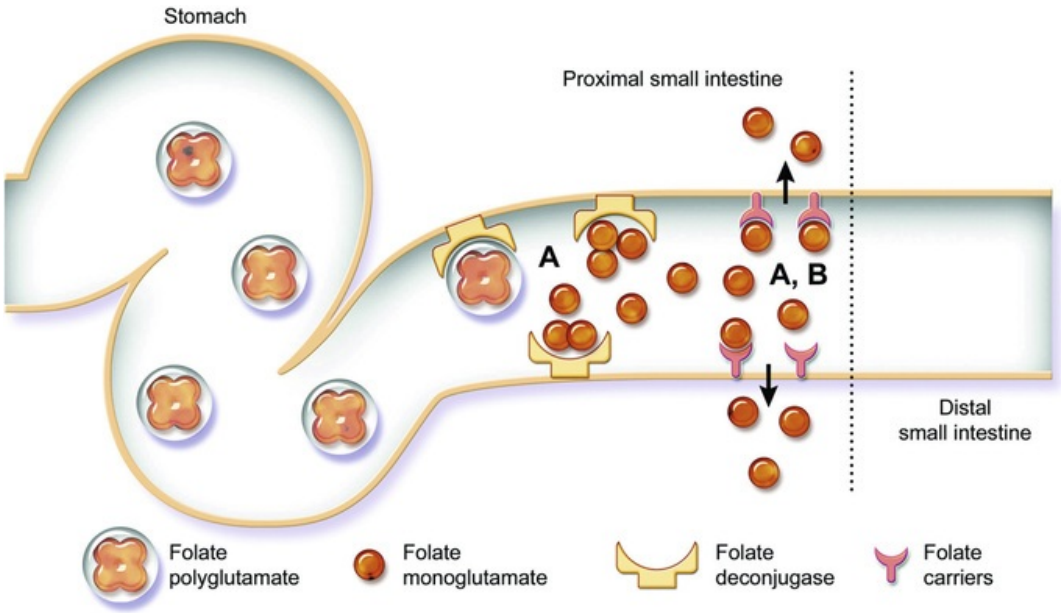

FIGURE 271-2 Folate absorption. Dietary folate enters the gastrointestinal tract predominantly as folate polyglutamate. Folate deconjugase, a brush border enzyme in the cranial small intestine, deconjugates folate polyglutamate to folate monoglutamate. Specific folate carriers on enterocytes located in the cranial small intestine absorb folate monoglutamate. Both the deconjugase and folate carrier molecules are only localized in the cranial small intestine and there is no appreciable absorption of folate in the distal small intestine or the colon. (Reprinted from Clinical Techniques in Small Animal Practice, 18(4): Suchodolski and Steiner, "Laboratory assessment of gastrointestinal function," page 208, © 2003, with permission from Elsevier.)

Serum Cobalamin Concentration

Cobalamin (vitamin B_{12}) is a water-soluble vitamin that is plentiful in most commercial pet foods and dietary deficiencies are thus not very common. However, owners who feed their pets exclusively vegetarian or vegan diets that are not fortified with cobalamin may inadvertently cause cobalamin deficiency in their pets. Dietary cobalamin is bound to animal-based dietary protein and cannot be absorbed. In the stomach dietary protein is digested by pepsin and HCl and cobalamin is released. The free cobalamin is immediately bound by R-protein, which is a cobalamin transporter protein that is synthesized by the gastric mucosa. In the small intestine, R-protein is digested by pancreatic proteases and the free cobalamin is bound by intrinsic factor (Figure 271-3 and Video 271-2).[30] In dogs and cats the vast majority of intrinsic factor is secreted by the exocrine pancreas.[31-33] This is different from humans where the majority of intrinsic factor is secreted by the gastric mucosa.[34] Complexed intrinsic factor/cobalamin is absorbed by specific receptors in the ileum (see Figure 271-3 and Video 271-2).[33] Distal small intestinal disease, if severe, will lead to destruction of cobalamin receptors in the ileum, leading to cobalamin malabsorption. Cobalamin malabsorption will ultimately lead to

depletion of cobalamin body stores and cobalamin deficiency. Diffuse small intestinal disease can also lead to cobalamin malabsorption if the ileum is involved in the disease process.[29,35-39] Exocrine pancreatic insufficiency also commonly leads to cobalamin deficiency.[40,41] Finally, some patients with small intestinal dysbiosis have a decreased serum cobalamin concentration as some intestinal bacteria may compete for the cobalamin available (see ch. 277).[42]

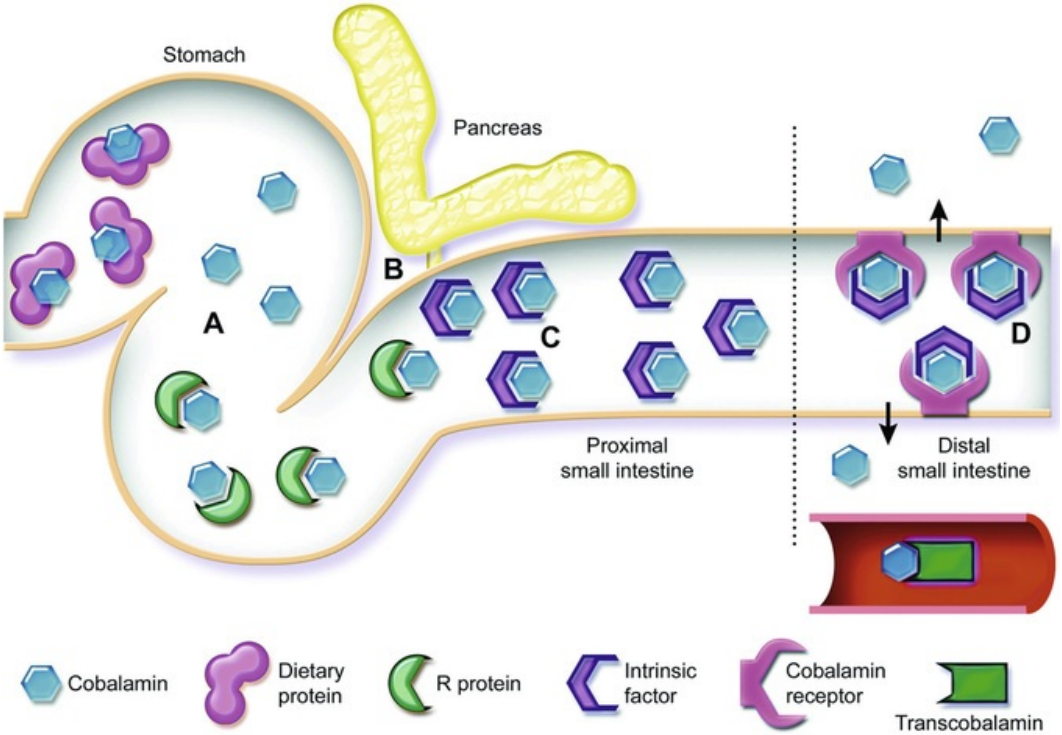

FIGURE 271-3 Cobalamin absorption. Dietary cobalamin is bound to dietary protein. In the stomach, pepsin and hydrochloric acid degrade the dietary protein, releasing cobalamin **(A).** The cobalamin is immediately bound by R-protein, which is produced by the gastric mucosa. In the duodenum, pancreatic proteinases digest the R-protein, releasing cobalamin. Free cobalamin in the duodenum is bound by intrinsic factor **(B).** In dogs and cats intrinsic factor is mostly produced by the exocrine pancreas. Cobalamin remains bound to intrinsic factor during passage through the cranial small intestine **(C).** In the distal small intestine the cobalamin/intrinsic factor complexes are taken up by specific receptors found only on enterocytes in the ileum **(D),** the enterocytes process the intrinsic factor/cobalamin complex and release cobalamin into circulation, where a final set of binding proteins (transcobalamins) complex the vitamin and carry it to the cells. Fecal Alpha$_1$-Proteinase Inhibitor Concentration

Many gastrointestinal disorders, if severe, can be associated with gastrointestinal protein loss. Alpha$_1$-proteinase inhibitor (alpha$_1$-PI) is synthesized in the liver and inhibits a variety of different proteinases.[43] Alpha$_1$-proteinase inhibitor has a molecular mass of approximately 60,000 Da, which is similar to that of albumin. Thus, when gastrointestinal disease is severe enough to be associated with gastrointestinal loss of albumin, alpha$_1$-PI is lost at approximately the same rate (Figure 271-4).[44] In contrast to albumin, alpha$_1$-PI is not hydrolyzed by digestive and bacterial proteinases in the gastrointestinal lumen.[44] Therefore, fecal alpha$_1$-PI concentration can be used as an estimate for gastrointestinal protein-loss.[45,46] Clinically, fecal alpha$_1$-PI concentration should be evaluated in dogs with hypoalbuminemia that do not have clinical signs of gastrointestinal disease and where an extra-gastrointestinal source of protein loss cannot be identified. Also, dogs belonging to a breed that is associated with a high prevalence of protein-losing enteropathy (e.g., Norwegian Lundehund, Soft Coated Wheaten Terrier, Yorkshire Terrier) that don't have any clinical signs of gastrointestinal disease, but are intended for breeding, should be tested.[45]

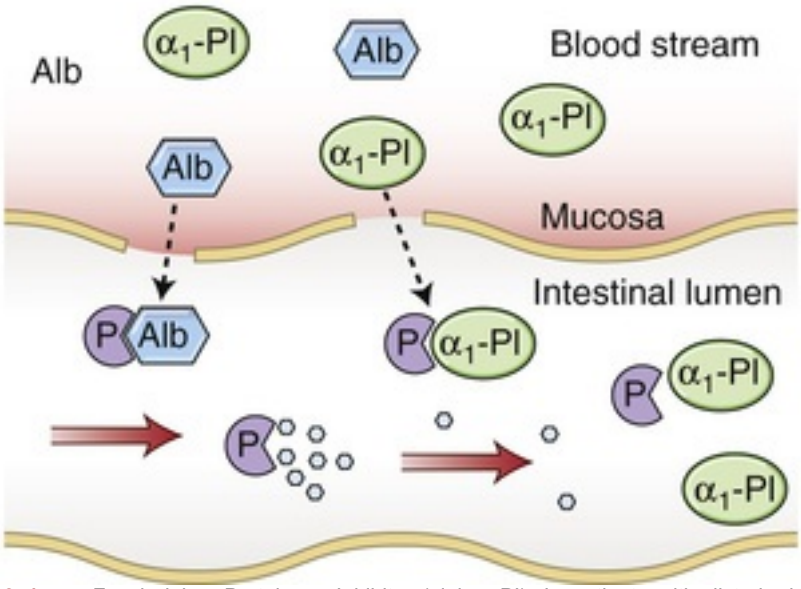

FIGURE 271-4 Fecal alpha$_1$-Proteinase Inhibitor (alpha$_1$-PI). In patients with disturbed mucosal integrity, plasma proteins can be lost into the intestinal lumen. Unlike albumin, which is degraded by digestive and bacterial proteases, alpha$_1$-PI is resistant to proteolytic degradation and can survive intestinal transit. Therefore, alpha$_1$-PI can be measured in feces using an immunoassay. (Reprinted from Veterinary Clinics of North America: Small Animal Practice, 41: Berghoff and Steiner, "Laboratory tests for the diagnosis and management of chronic canine and feline enteropathies," page 321, © 2011, with permission from Elsevier.)

Serum C-Reactive Protein Concentration

C-reactive protein (CRP) is an acute phase reactant that is receiving increasing interest for the assessment of dogs with a variety of inflammatory diseases. C-reactive protein has been reported to be increased in dogs with idiopathic inflammatory bowel disease (IBD), and has also been shown to correlate well with the IBD clinical disease activity index.[47-49] Thus, the greatest clinical utility of this test is for monitoring the response to treatment in dogs with IBD, as effective dietary or medical therapy will be associated with a decrease in serum CRP concentration.[48] A variety of assays for the measurement of CRP in serum are available, but unfortunately not all of them provide reliable results.[50]

Gastrointestinal Permeability Testing

One important property of the gastrointestinal wall is to provide a barrier function against the loss of plasma proteins and against uncontrolled uptake of harmful substances from the gastrointestinal lumen. During intestinal disease the gut wall becomes more leaky and gastrointestinal permeability testing can be used to assess the barrier function. Traditionally, the uptake and/or differential uptake of simple sugars, such as lactulose, rhamnose, and/or lactulose has been used to assess gastrointestinal permeability.[51,52] However, at the moment no assays for routine assessment of gastrointestinal permeability are available. In recent years iohexol has been explored as a new marker for intestinal permeability, but further studies are needed before this test can be suggested for routine use.[53]

Serum or Fecal Concentrations of Inflammatory Markers

Several markers for assessment of gastrointestinal inflammation have recently been described. Calprotectin and S100A12 are markers for neutrophilic inflammation and have been shown to be increased in both serum and feces in some dogs with IBD.[54,55] Methylhistamine is a stable marker of mast cell degranulation, and increased serum and fecal methylhistamine concentrations have been described in some dogs with IBD.[56] Brominated tyrosine is a marker of eosinophil activity and increased serum concentrations have been described in some dogs with IBD.[57] Much more research will be needed before the clinical utility of these markers can be definitively established, but it is an attractive speculation that in the future it may be possible to assess the specific types of inflammatory cells involved in a specific patient with suspected IBD without

intestinal biopsies and determine the optimal therapeutic approach based on a panel of these markers.

Gastrointestinal Endocrinology

The gastrointestinal tract is likely the biggest endocrine organ of the body, yet very little is known about diseases that can occur because of an imbalance of gastrointestinal hormones.[58] Many gastrointestinal hormones cannot even be reliably measured and others show complex cyclical concentrations that make interpretation of a single measurement very difficult. There are validated assays for the measurement of insulin and gastrin in dogs and cats and for the measurement of CCK and motilin in dogs. Measurement of serum gastrin concentration has been shown to be useful for the diagnosis of gastrinoma, but none of the other assays currently play a role in everyday clinical practice.[59,60]

CHAPTER 272

Oral and Salivary Gland Disorders

Alexander M. Reiter, Maria M. Soltero-Rivera

Client Information Sheet: Oral and Salivary Gland Disorders

This chapter will provide information on the importance of recognizing normal anatomical findings of the oral cavity often confused with pathologic lesions. Perioperative considerations are raised, and the judicious use of antibiotics is discussed. Common oral and salivary gland disorders are reviewed, with a focus on their non-surgical management.

Normal Structures Often Confused With Pathologic Lesions

It is not uncommon that dentists and oral surgeons are consulted because of the presence of a normal anatomical finding that could be unpaired and might look larger than expected or is colored differently compared to surrounding tissues (Figure 272-1). The incisive papilla is a rounded eminence of hard palate mucosa situated on the midline caudal to the maxillary first incisors. Occasionally, the papilla may be more or less pigmented compared to surrounding mucosa and then confused with pathologic lesions.

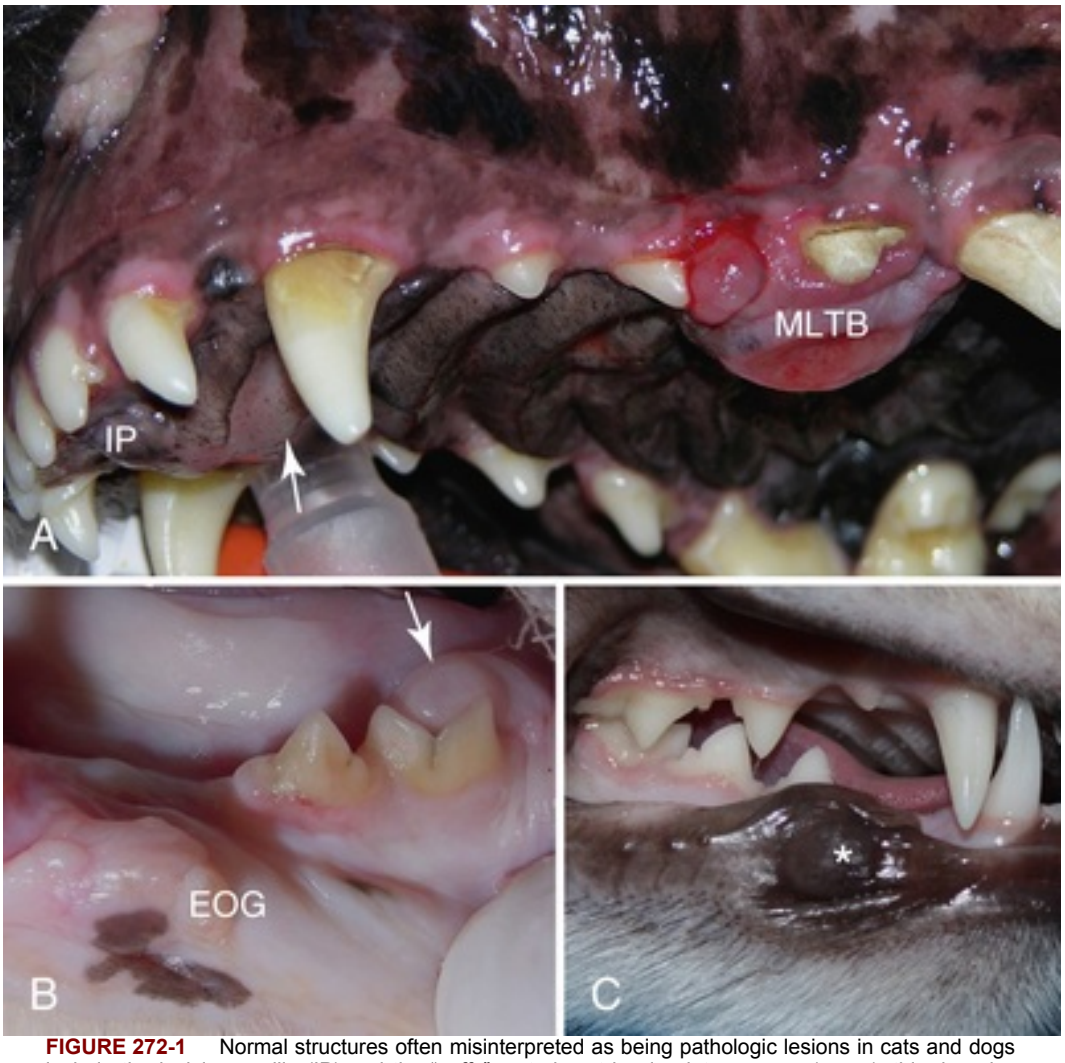

FIGURE 272-1 Normal structures often misinterpreted as being pathologic lesions in cats and dogs include the incisive papilla (IP) and the "puffy" rostralmost hard palate mucosa (arrow); this dog also was diagnosed with a multilobular tumor of bone (MLTB) in its left upper jaw **(A).** The lingual molar gland (arrow) is a small salivary gland situated lingual to the mandibular first molar tooth in the cat; this cat also was diagnosed with eosinophilic granuloma (EOG) at the lower lip margin **(B).** A strong frenulum-like attachment (asterisk) is situated immediately caudal to the mandibular canine tooth in normal cats and dogs **(C).** (Copyright Alexander M. Reiter.)

The mucosa of the most rostral hard palate often appears "puffy," as though sitting on a cushion of air. When a finger presses into this mucosa, it typically feels soft, giving way to the pressure exerted. The apparent swelling returns as soon as the finger is removed. This is normal and due to the presence of an extensive, fine arterial plexus resulting from profuse branching and anastomosing of the major palatine arteries overlying the palatine fissures.

Cats and dogs have four pairs of major salivary glands (parotid, zygomatic, mandibular, and sublingual). Scattered glandular tissue is present submucosally in the lips, the tongue, soft palate, and pharyngeal walls. Cats, but not dogs, have a small gland situated lingually to each mandibular first molar tooth. This lingual molar gland appears as a soft mucosal bulge and should not be confused with an abnormal swelling.

Cats and dogs have very discrete median mucosal folds (frenula) that connect the upper and lower lips to the jaws in the midline. A much stronger and more obvious frenulum-like attachment is situated immediately caudal to each mandibular canine tooth. This lateral lip frenulum sometimes can be more pigmented on one side, giving rise to concern about the presence of a neoplasm.

Oral pigmentation most commonly is associated with melanin produced by melanocytes. While these cells can be involved in the development of pigmented lesions in the mouth, oral mucosa usually shows various presentations of normal pigmentation. Pigmentations suspicious of early malignant melanoma lesions are often slightly raised, whereas normal pigmentation does not alter the mucosal surface.

Perioperative Considerations

Mouth Speculum

Prolonged, wide mouth opening has been reported to reduce maxillary artery blood flow, potentially resulting in temporary or permanent blindness post-anesthesia and/or other neurological deficits in cats.[1] Placing mouth gags and wedge props aids in visualization and allows for access to tissues deep in the oral cavity, pharynx, and larynx. However, the duration of wide mouth opening should be minimized to reduce the risk of masticatory muscle strain and injury to the temporomandibular joints. The wider the mouth of a cat is opened, the tighter the lip and cheek become and the more difficult it will be to deflect these tissues to accomplish procedures such as dental cleaning or tooth extraction. Placing 30 mm or 20 mm plastic gags between maxillary and mandibular canines enables adequate mouth opening for these procedures in cats.[2] Postanesthetic deafness has been reported in dogs and cats following dental and ear cleaning procedures. Geriatric patients could be more prone, and vestibular function also can be compromised. However, this may be temporary, and animals might recover.[3]

Endotracheal Tube Cuff Inflation

In an adult cat, a clinically airtight seal can be obtained by filling the endotracheal tube cuff with 1.6 ± 0.7 mL of air. Overinflation of the cuff can result in tracheal rupture in cats, and this complication has been reported mostly in association with anesthetized dental procedures. Various other causes have been hypothesized, including iatrogenic trauma from endotracheal tube movement during oral manipulations and turning over of the patient.[4] Clinical signs associated with tracheal rupture include palpable evidence of subcutaneous emphysema, coughing, gagging, dyspnea, anorexia, and fever (see ch. 241).

Manipulation of Oral and Adjacent Structures

Overzealous pharyngeal packing, tongue manipulation, excessive elevation of the alveolar mucosa on the lingual aspects of the mandibles and other iatrogenic complications can result in oral edema, which could exacerbate already existing tissue swelling in patients with oral inflammation or trauma.[5] When severe enough, breathing could be compromised during recovery from anesthesia, and such patients could benefit from a single injection of dexamethasone (0.1-0.2 mg/kg IV) at the end of the procedure. The tongue also can be wrapped with a gauze sponge soaked with a hypertonic solution prior to extubation. It is never wrong to be prepared for the potential need of performing an emergency tracheostomy. Gauze sponges used for pharyngeal packing should be counted for safe and complete retrieval at the end of the procedure. Small gauze sponges can have the potential to be displaced into the esophagus. The throat of each patient should be thoroughly inspected with the help of a laryngoscope prior to extubation to ensure that all foreign material has been removed.

Excessive ventral pulling of the tongue in the cat prior to intubation can puncture the sublingual mucosa or mucosa on the underside of the tongue by a very pointed mandibular canine tooth. Owners of dogs with severe periodontal disease should be warned about an increased risk of mandibular fracture, which can occur during relatively routine manipulation (when opening the mouth for intubation, placing a mouth prop or gag, and during tooth extraction). This emphasizes the importance of preoperative dental radiography to determine the health of the jaw bone.

Regular application of eye lubricant or taping the eyelids closed during anesthesia helps prevent corneal injury.[6]

Hypo- and Hyperthermia

Prevention of hypothermia of the patient is of particular importance when water is used for cooling dental power instruments or to rinse debris from the mouth (see ch. 49).[7] Conversely, hyperthermia also is a concern, especially in cats when opiates like hydromorphone, with or without gas anesthesia, ketamine, or both, are used.[8] Cats with postoperative hyperthermia often respond favorably to intravenous fluid administration, removal of blankets in the cage, mechanical cooling methods such as a fan and ice packs, and application of rubbing alcohol to footpads (see ch. 134).

Oral Bleeding and Hemostasis

Severe oral bleeding can be due to injury of larger blood vessels, bleeding dyscrasias (e.g., von Willebrand disease), lingual or palatal injury, oral inflammation, soft tissue trauma, oral neoplasia, or jaw fracture. Intravascular volume replacement is accomplished with crystalloids, colloids and/or blood products.[9] Diffuse bleeding from nasal mucosa (e.g., after maxillectomy or palate surgery) can be stopped by irrigation with a mixture (0.05-0.1 mL/kg in cats; 0.1-0.2 mL/kg in dogs) of 0.25 mL phenylephrine 1% and 50 mL lidocaine 2%,[10] vessel ligation, bone wax, fibrin sealants, and many others.

Subcutaneous or Submucosal Emphysema

Emphysema sometimes occurs after use of air-driven equipment, or blowing air or air/water spray into submucosal tissues, particularly after deep dissection of large mucoperiosteal flaps. In the lower jaw, it is usually subcutaneous, as the air migrates to the intermandibular space and from there to the ventrolateral aspects of the face; submucosal emphysema can happen in either the upper or lower jaw. Emphysema usually resolves within a few days. It can be reduced or prevented effectively with gentle digital pressure applied to the sutured flap for a few minutes to evacuate air bubbles and provide an adhesive seal between soft tissue and bone. Blowing air or air/water spray into alveolar sockets and onto denuded bone or bleeding tissues can cause air emboli and is strongly discouraged.[11]

Incisional Dehiscence

Dehiscence of oral surgical sites usually is a result of tension on suture lines. Other causes include infection or necrosis of hard and/or soft tissues when the surgery was excessively traumatic and/or caused loss of vascular supply to the tissues. Oral wounds may be treated by means of resuturing, or they are left to granulate and epithelialize. Any oral wound that does not seem to be healing for 7 days or longer following surgery should be biopsied to rule out the possibility of neoplasia.

Judicious Use of Antibiotics

The possible transfer of antibiotic-resistant bacteria from cats and dogs to humans recently has been acknowledged as a potential threat to public health,[12,13] and antimicrobial drugs must be used appropriately (see ch. 209). Systemic antibiotics can have a broader range of activity than do topical antibiotics, and can reach all periodontal tissues, but they only achieve a low local concentration. Antibiotics such as amoxicillin-clavulanate (14 mg/kg PO q 12 h), clindamycin hydrochloride (11 mg/kg PO q 12 h) and, for severe osteomyelitis in dogs, metronidazole (30 mg/kg PO q 24 h × 10 days, then 10 mg/kg PO q 24 h × 20 days, in addition to radical surgical debridement) are the drugs of choice against the common periodontopathogens isolated in dogs. When using low-dosage doxycycline (1-2 mg/kg PO q 12 h), the medication's anti-inflammatory features are considered rather than its antibacterial effects. Local application of doxycycline (8.5%) or clindamycin (2%) gel into cleaned periodontal pockets deeper than 4 mm has the advantage of delivering a very high local concentration of drug and results in favorable clinical outcome in dogs.[14,15]

Temporary bacteremia secondary to an oral condition occurs daily in patients with periodontal disease and has been described in cats and dogs during and after dental cleaning and tooth extraction. This is usually short-lived in healthy animals, as the bacteria are eliminated by the host's immune system. Therefore, the expected bacteremia is not an indication for the perioperative use of systemic antibiotics in the otherwise healthy patient. Systemic infection as a result of poorly performed tooth extraction has been reported only anecdotally.[16] Antibiotics could be required in select patients with preexisting conditions that might worsen during or after the dental or oral surgical procedure (e.g., hyperadrenocorticism, diabetes mellitus, renal and hepatic disease, and oncologic patients undergoing chemotherapy). The drug of choice is intravenous ampicillin (22 mg/kg; when working in the mouth only) or cefazolin (20 mg/kg; when the skin outside the mouth is included in the surgery) given at induction and repeated every 2-4 hours during the procedure. In addition to bacteremia in pets with periodontal disease, there is a chronic release of inflammatory mediators, immune complexes, and bacterial and cellular degradation by-products into blood and lymph vessels that can produce direct or immune-mediated distant organ lesions. The systemic effects of periodontal disease are well-documented in humans (heart disease and stroke, diabetes, respiratory disease, and increased risk of premature delivery and low birth weight infants) and are being increasingly investigated in dogs and cats.[17,18]

Oral Inflammation

Most dogs and cats have some degree of periodontal disease. Gingivitis is inflammation of the gingiva, and periodontitis is inflammation of the gingiva, periodontal ligament, alveolar bone, and cementum (Figure 272-2). Periodontopathogens in dental plaque cause periodontal disease, but the host's reaction to bacteria and their toxins also plays a role in inflammatory tissue destruction (gingival recession, attachment loss, periodontal pocketing, alveolar bone resorption, tooth mobility, and tooth loss). Affected teeth are professionally scaled and polished under anesthesia, and various periodontal therapy and surgery options (including extraction) exist. Use of antibiotics for treatment of periodontal disease is not recommended.

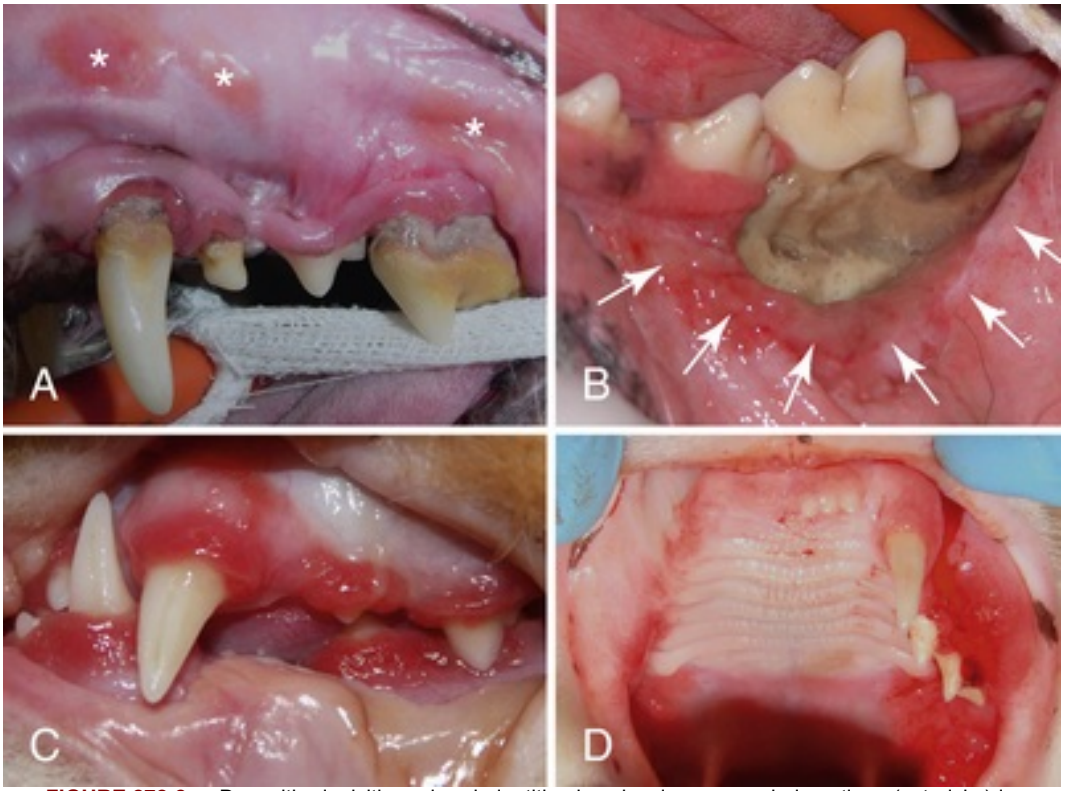

FIGURE 272-2 Dog with gingivitis and periodontitis also showing mucosal ulcerations (asterisks) in the labial and buccal mucosa that contacts the plaque-laden teeth of the left upper jaw **(A).** Dog with idiopathic osteomyelitis and osteonecrosis of the left mandible surrounded by ulceronecrotic oral mucosa (arrows) **(B).** Adolescent cat with juvenile hyperplastic gingivitis **(C).** Adult cat with stomatitis; note that the teeth of the left maxillary quadrant had previously been extracted, resulting in reduction of oral inflammation on that side of the mouth **(D).** (Copyright Alexander M. Reiter.)

Contact Ulcers

In dogs, inflammation beyond periodontal disease tends to be located in oral mucosa facing plaque-laden tooth surfaces. Such lesions commonly are referred to "kissing ulcers" or "contact ulcers." Young adult to middle-aged Cocker Spaniels, Labrador Retrievers, Standard Poodles, Scottish Terrier, Maltese, and Dachshunds sometimes present with severe osteomyelitis and adjacent cellulitis (exposed infected, inflamed, and necrotic bone and tooth roots surrounded by ulceronecrotic oral mucosa) that make them lethargic, febrile, and unwilling to eat and drink due to oral pain. Some of them also have otitis externa, lip fold dermatitis, and pododermatitis. Treatment involves partial- or full-mouth tooth extraction; tissue debridement; pain control; anti-inflammatory, antiseptic, and antibiotic therapy; and nutritional support.[19]

Juvenile Hyperplastic Gingivitis

Juvenile hyperplastic gingivitis can be found in immature, adolescent, and young adult cats that present with enlarged and inflamed gingiva (other oral mucosae are not affected) mostly around their maxillary and

mandibular cheek teeth. Certain medications (e.g., calcium channel blockers, cyclosporines) also can cause gingival hyperplasia. Careful gingivectomy and gingivoplasty should be performed (including histological examination of suspicious lesions), followed by professional dental cleaning. The owners are encouraged to perform daily tooth brushing with an azithromycin-containing dentifrice (8.5%). Azithromycin previously has been shown to reduce the occurrence of gingival enlargement in dogs.[20]

Pyogenic Granuloma

Pyogenic granuloma is a benign ulceroproliferative lesion in cats, resulting from the maxillary fourth premolar tooth traumatizing the gingiva, alveolar and buccal mucosa adjacent to a present or missing mandibular first molar tooth. Surgical excision of the mass plus blunting or extraction of the involved tooth or teeth is the treatment of choice.[21]

Stomatitis

Stomatitis in adult cats usually manifests as inflammation of the mucosal linings of the caudal oral cavity lateral to the palatoglossal folds, extending rostrally into gingiva, alveolar mucosa, buccal and labial mucosa, sublingual mucosa, and occasionally also the ventral and dorsal tongue surface. The etiology is not clear, but feline calicivirus (FCV) and feline herpesvirus-1 (FHV-1) have been implicated (see ch. 229).[22] History and clinical signs of cats with stomatitis include inappetence, weight loss, oral, nasal and ocular discharge, regional lymphadenopathy, and signs of oral pain. In severe cases, the inflamed oral tissues become proliferative and ulcerated, and bleed spontaneously. Various degrees of periodontal disease and tooth resorption can be present. An increase in serum total protein usually is due to elevated gamma globulin concentrations. A biopsy specimen should be obtained to rule out neoplasia or other causes of oral inflammation. A multimodal treatment approach is required, using a combination of surgical and medical therapies. Pain management is imperative (see ch. 356). Plaque control is achieved with professional dental cleaning, topical and systemic antimicrobial therapy, and tooth extraction. Partial and full-mouth tooth extraction still is the gold standard for treatment of feline stomatitis.[23] Corticosteroids often are required to decrease inflammation, reduce pain, and stimulate appetite. Some cats can benefit from periodic subcutaneous or intramuscular injections of methylprednisolone acetate (Depo-Medrol) (4 mg/kg). Others do well with prednisolone ointment (1 mg/kg per 0.1 mL q 12-24 h) that is applied to the pinna of the ears. Cyclosporine (e.g., Neoral) can be useful (starting at 2.5 mg/kg PO q 12 h for 6 weeks before judging effectiveness; monitoring kidney values; whole-blood cyclosporine levels > 300 ng/mL have been associated with significant improvement of oral inflammation). Clinical improvement of stomatitis also was reported with bovine lactoferrin (250 mg PO q 24 h). Low-dosage doxycycline (1 mg/kg PO q 24 h) and interferon omega (5 MU are diluted and divided as necessary to submucosally inject all inflamed areas; the remaining 5 MU are injected into a 100 mL bag of sodium chloride and frozen in ten 10 mL aliquots; the client gives 1 mL PO q 24 h for 100 days; the 10 mL fraction in use is refrigerated and the other aliquots are kept frozen until needed) also have been suggested as medical treatment options for cats with stomatitis.[24] Laser surgery (to remove proliferative tissue and ablate inflamed mucosa) may be used as an adjunct in patients with refractory stomatitis not responding to extractions and medical therapy.[25]

Eosinophilic Granuloma Complex

Eosinophilic granuloma complex includes several conditions of the oral mucosa (dogs and cats) and lips and skin (cats) that are characterized by an eosinophilic infiltrate histopathologically.[26] Lesions are more common in young adult female cats and male dogs. Suggested causes include ectoparasites and other insects, environmental allergens, or dietary hypersensitivity. Clinical signs depend on the location of the lesion, and include dysphagia, ptyalism, and inappetence. In cats, the condition manifests either as nodules (speckled with small, dense, white or yellowish areas) at the dorsal and lateral tongue surfaces, hard and soft palate, palatoglossal folds, and chin, or as well-demarcated ulcers (raised edges surrounding an ulcerated surface) on the upper lip and philtrum (occasionally also the lower lip). In dogs, single or multiple (often confluent) ulcerated lesions can be present on the soft palate and lateral pharyngeal mucosa (typically in Cavalier King Charles Spaniels), or raised, irregular, ulcerated lesions with well-demarcated edges are located on the lateral or ventral tongue (primarily in Siberian Huskies and Alaskan Malamutes). Biopsy with histopathologic evaluation is warranted to rule out differential diagnoses (such as squamous cell carcinoma, lymphoma, and

other skin diseases). In addition to eliminating the underlying cause, the treatment of choice is prednisone or prednisolone (1-2 mg/kg PO q 12 h initially, then tapered to the lowest effective dose) or periodic methylprednisolone acetate injections (4 mg/kg SC or IM). Amoxicillin-clavulanate (14 mg/kg PO q 12 h) also may be attempted. Surgical excision of affected areas rarely is recommended. Untreated lesions can result in major soft tissue loss (upper lip) and oronasal communication (hard palate).[26]

Autoimmune Oral Conditions

Autoimmune diseases causing skin lesions in dogs and cats also can occur at the mucocutaneous junction areas surrounding the mouth and the oral mucosa inside the mouth (lupus erythematosus with autoantibody production against tissue and nuclear proteins; see ch. 204 and 205). Occasionally, they are wholly contained within the oral cavity, as with pemphigus vulgaris and bullous pemphigoid with autoantibody production against specific squamous epithelial structures, or mucous membrane pemphigoid with autoantibody production against tissue proteins. Contrary to stomatitis in cats and contact ulceration in dogs, the hard palate mucosa can be affected. Biopsy of the leading edge of a lesion when an intact blister is not found could be sufficient. Storing the samples in Michel's solution is recommended by some pathologists to preserve tissue antigenicity at ambient temperatures.[27]

Bullae undergo different stages, from bleb (vesicle) formation, to erosion, to ulceration. Vesicles are characteristic, but they might no longer be present at the time of diagnosis and be replaced by scales, crusts, erosions and ulcers. The causative lesion in pemphigus vulgaris is suprabasilar (intercellular clefting) with formation of acanthocytes. The causative lesion in bullous pemphigoid is subepidermal without formation of acanthocytes. Laminin 5 and 6, collagen XVII, and integrin alpha-6/beta-4 have been implicated as autoantigens in mucous membrane pemphigoid in dogs, but only laminin 5 has been recognized in the cat. Treatment approaches are described in ch. 204 and 205.

Hypersensitivity and Metabolic Oral Conditions

Erythema Multiforme and Toxic Epidermal Necrolysis

Erythema multiforme possibly is mediated by deposition of immune complexes in the superficial capillaries of the skin and less often the oral mucosa as a result of an infection or drug exposure.[28,29] Toxic epidermal necrolysis is characterized by full-thickness coagulative necrosis with minimal dermal inflammation[30]; it is an extreme form of drug reaction (see ch. 169), with the animal being depressed, febrile, and inappetent. The underlying cause must preferably be eliminated (e.g., cessation of using a particular drug). Anti-inflammatory, immunosuppressive or immunomodulating therapy is instituted together with nursing care.

Uremia results from retention of uremic wastes after rapid decline in renal function[31] (see ch. 322). A sharp odor of ammonia is present in the breath (see ch. 36), and oral ulcerations occur, especially at the labial and buccal mucosa, lateral margins of the tongue, lateral lip frenula, and lip commissures. Uremic vasculitis and thrombosis can lead to necrosis and sloughing of the mucosa. In severe cases, this may lead to sloughing of the tip of the tongue. The lesions often are painful, contributing to the anorexia already observed in pets with kidney disease. Any condition (e.g., leptospirosis, diabetes mellitus, etc.) that can produce a hypercoagulable state can lead to thrombi formation and subsequent sloughing of the affected areas.[32] Treatment is supportive, until the inciting cause can be removed or resolved, and includes pain management (such as buprenorphine 0.01 mg/kg q 8-12 h, IV), bypassing the mouth with supplemental enteral or parenteral nutrition (see ch. 82), and use of gastric protectants (sucralfate 0.5-1 g PO q 4-6 h). Topical mouthwashes, such as a mixture of diphenhydramine, sucralfate or aluminum and magnesium hydroxide (Maalox, Novartis), and lidocaine can provide some local pain control. Diluted (0.12%) chlorhexidine rinse helps prevent secondary infection of necrotic areas.[31]

Oral Foreign Body

Penetrating foreign bodies can create deep and contaminated wounds in the sublingual area, palatoglossal fold, soft palate, palatine tonsil, floor of the orbit, or pharyngeal wall.[33] They also can be lodged across the hard palate between maxillary cheek teeth (e.g., a wooden stick), entrapped in oral mucosa (e.g., burdock and foxtails) or caught around the tongue and saw their way into the lingual frenulum (e.g., a needle with thread). Affected pets show halitosis, decreased appetite and water intake, pawing at the face, swelling in the intermandibular or neck region, sinus tracts, drooling of clear or blood-tinged saliva, and retching, gagging or

vomiting. Ultrasound, computed tomography, and magnetic resonance imaging are more helpful than radiographs in pinpointing a hidden foreign body's location.[9] Management requires surgical exploration, foreign body removal, wound cleansing and, if appropriate, drain placement and suturing. Microbial sampling is performed and empirical antibiotic therapy is instituted prior to availability of culture and sensitivity results. Intraoral wounds often are closed to prevent entrapment of food, hair, and other debris. If the intraoral point of entry has healed by the time the patient presents with clinical signs, the surgical approach is chosen based on diagnostic findings to determine the most direct and safest route for foreign body retrieval.[9]

Oral Burns (Figure 272-3)

Electric injury usually occurs in young animals that chew on power cords.[24] Life-threatening complications are related to neurogenic pulmonary edema or smoke inhalation (see ch. 242). Affected tissues typically include the lips, cheeks, oral mucosa, tongue, and palate. More extensive burns also affect teeth and bones. The patient initially is stabilized if noncardiogenic pulmonary edema has occurred, then is managed conservatively (wound lavage) at first. Later, once necrotic tissue is evident, conservative debridement may be initiated. Tongue necrosis can cause a large piece of tissue to slough off. Palate necrosis can cause an oronasal defect.

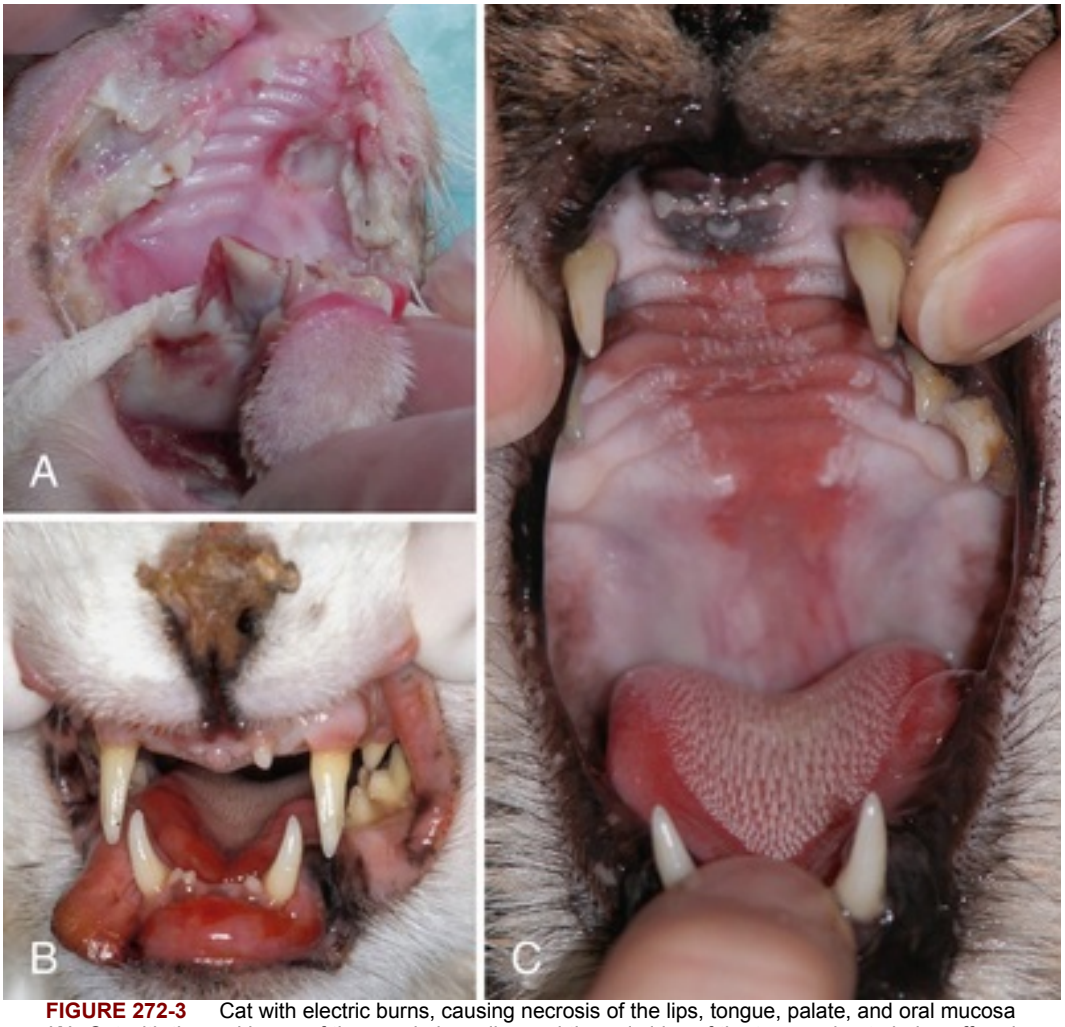

FIGURE 272-3 Cat with electric burns, causing necrosis of the lips, tongue, palate, and oral mucosa **(A).** Cat with thermal burns of the nasal plane, lips and tip and sides of the tongue due to being offered microwaved food **(B).** Cat with chemical burns, resulting in acute-onset erosions of the tip and sides of the tongue and the palate **(C).** (Copyright Alexander M. Reiter.)

Thermal burns resulting from exposure to hot items sometimes are seen on the nasal plane, lips, labial

mucosa, tongue and palate. Owners are advised not to overheat food and liquids when they attempt to make them more palatable in patients with inappetence. Chemical burns present as acute ulcers covered by necrotic debris from exposure to household cleaning products, phenolic compounds, essential oils (e.g., potpourri), heavy metal (thallium), or plant toxins (i.e., *Dieffenbachia*). Initial therapy for thermal and chemical burns is lavage with lactated Ringer's solution, followed by conservative management. The haircoat of an affected pet should be cleansed if there is suspicion that it contains residuals of the agent responsible for a chemical burn.[24]

Masticatory Muscle Myositis

Masticatory muscle myositis (MMM) is an autoimmune disease affecting the temporal, masseter, and medial and lateral pterygoid muscles in dogs (see also ch. 354). Large-breed, young-adult to middle-aged dogs appear to be affected most commonly.[34] An acute stage (painful muscle swelling/inflammation) typically lasts for 2-3 weeks, followed by a latent stage (apparently healthy animal) which is then followed by a chronic stage (muscle atrophy) or a recurrent acute stage. Dogs with acute MMM have a history of decreased activity, lethargy, reluctance to eat, and signs of pain on yawning or when prehending treats and toys. Dogs with chronic MMM usually are bright and alert, but they show progressive atrophy of the masticatory muscles. The acutely affected dog can show fever, regional lymphadenopathy, swelling of temporal and masseter muscles (painful on palpation) and exophthalmos. The dog resists opening of the mouth or is unable to open the mouth fully. The chronically affected dog can show atrophy of masticatory muscles, enophthalmos, and inability to open the mouth fully. Muscle swelling/atrophy can be asymmetric.[34]

The temporal, masseter, and medial and lateral pterygoid muscles possess 2M fibers that differ from the common type 2C fibers of other skeletal muscles. In this disease, autoantibodies target the unique myosin component of type 2M fibers, resulting in muscle inflammation, necrosis, and phagocytosis. A definitive diagnosis of MMM can be made if antibodies against type 2M fibers are identified in serum and/or immune complexes detected in biopsied muscle samples.[35] A serum type 2M fiber antibody titer of <1 : 100 is negative, 1 : 100 is borderline, and >1 : 100 is positive.

Computed tomography (CT) aids in ruling out most differentials of MMM, allows guided fine-needle aspiration of surgically inaccessible pterygoid muscles, shows changes in size (larger due to edema or inflammation; smaller due to atrophy, necrosis or fibrosis), pre-contrast tissue attenuation (hypoattenuated due to edema) and heterogeneous contrast enhancement (due to inflammation) in affected muscles, and the presence of regional lymphadenopathy.[35]

Muscle biopsies are taken from areas of temporal or masseter muscles that show the most obvious contrast enhancement on CT. A 0.5 to 1 cm-diameter specimen of muscle tissue is excised, enveloped in a dry or minimally moistened gauze sponge, and placed into a water-tight container (e.g., a 10 mL red top tube) (see ch. 116). The sample is kept cool and shipped overnight (Comparative Neuromuscular Laboratory, University of California, San Diego, USA or Institut fuer Neuropathologie, Universitaet Duesseldorf, Duesseldorf, Germany). Particular attention should be paid to complete wound closure, because corticosteroids will delay connective tissue healing.[36] Corticosteroid therapy should not be started prior to blood collection and muscle sampling. A dexamethasone injection (1 mg/kg IV once after muscle biopsy) is helpful in the immediate reduction of inflammation in dogs with acute MMM. The patient is discharged with prednisone (1-2 mg/kg PO q 12 h), usually resulting in rapid improvement of clinical signs (reduction of pain and signs of systemic illness, as well as visible improvement of mouth opening, 1-2 days after start of corticosteroid therapy). After 2 to 3 weeks, the dosage can be decreased to 1 mg/kg PO q 24 h for another 3 to 4 weeks before it is slowly tapered to the lowest possible alternate-day effective dosage over a period of 8-12 months. Dogs unable to receive corticosteroids, unresponsive to corticosteroids alone, or showing unacceptable side effects in response to corticosteroids might benefit from administration of azathioprine (1-2 mg/kg PO q 24 h). Follow-up examinations should take place 2 weeks and 1, 2, 6, 9 and 12 months after initiation of corticosteroid therapy and once every 6 to 12 months thereafter, focusing on body weight, degree of muscle atrophy, pain on head palpation, and range of opening the mouth (which is measured with a ruler between the incisal edges of the maxillary and mandibular incisors). Periodic antibody titer tests are important prior to decreasing prednisone dosages, particularly when the dosage already is very low (e.g., 0.1-0.2 mg/kg PO q 48 h). In dogs with relapses, treatment should be reinstituted at the maximum prednisone dosage and slowly tapered to the lowest possible alternate-day effective dosage.[34]

Salivary Gland Conditions

Sialocele (extravasation of saliva into submucosal or subcutaneous spaces) requires surgical treatment, and the reader is referred to surgery textbooks for information on diagnosis and treatment.[37,38]

Sialadenitis, an inflammation of a salivary gland, is seen in middle-aged to older dogs. The zygomatic salivary gland is affected most commonly, and the dog can present with a painful swelling in the orbital/retrobulbar area with exophthalmos. Clinical signs include malaise, inappetence, lymphadenopathy, fever, signs of pain on retropulsion of the eye through the closed eyelid and on opening the mouth, dysphagia, and mucopurulent discharge at the duct opening in the mouth. The soft palate can have an asymmetric appearance from an enlarged, inflamed zygomatic gland. Sialoliths can be a contributing factor. Computed tomography and magnetic resonance imaging should be considered to rule out differential diagnoses. Fine-needle aspiration and cytological evaluation of the zygomatic salivary gland (through the oral mucosa) and regional lymph nodes (see ch. 95), bacterial culture and sensitivity testing (if infection is suspected), and three-view thoracic radiographs (if neoplasia is suspected) may be performed. A definitive diagnosis of sialadenitis requires an incisional biopsy and histopathological evaluation. Intraoral drainage to alleviate mucopurulent fluid accumulation and associated pressure causing discomfort may be attempted. Medical treatment includes management of pain (if present; see ch. 126 and 356) and use of antibiotics (based on culture and sensitivity results of the fluid/tissue aspirate), nonsteroidal anti-inflammatory drugs (NSAIDs), and anti-inflammatory dosages of corticosteroids (see ch. 164).[39]

Sialadenosis is a non-inflammatory enlargement of a salivary gland without obvious cytological or histological abnormalities. *Necrotizing sialometaplasia* (salivary gland necrosis or infarction) is a painful enlargement of a salivary gland with squamous metaplasia of the salivary gland ducts and lobules and lobular ischemic necrosis. Sialadenosis and necrotizing sialometaplasia mostly occur in young adult to middle-aged, small breed dogs. History and clinical signs are less severe with sialadenosis (weight loss, reluctance to exercise, snorting, lip smacking, nasal discharge, hypersalivation, inappetence, depression, retching, and gulping). In addition to those, dogs with necrotizing sialometaplasia often show gagging, regurgitation, chronic vomiting, coughing, tachypnea, dyspnea, reverse sneezing, and abdominal respiratory efforts. Dogs are sensitive on palpation of the pharyngeal region, show signs of pain associated with opening the mouth, and are depressed, nauseated, and anorexic. A neurogenic pathogenetic mechanism is suspected to correlate with abnormalities of the vagus nerve, and conditions associated with necrotizing sialometaplasia include esophageal disorders. In addition to pain management, similar diagnostic and therapeutic attempts as for sialadenitis should be performed. Oral phenobarbital administration (1-2 mg/kg PO q 12 h) has resulted in dramatic improvement in some cases, providing support for a neurogenic mechanism.[39]

Non-Neoplastic Jaw Bone Disorders

Craniomandibular osteopathy is characterized by woven bone proliferation at the body of the mandible, temporomandibular joint, and the tympanic bulla bilaterally in smaller dog breeds. A thickening of the calvarium, tentorium cerebelli, and extremities can be observed.[40] The dog may show signs of pain, unwillingness or inability to fully open the mouth, and reluctance to eat. Hyperthermia can be present, and neurological signs occasionally can be seen. Treatment consists of anti-inflammatory drugs (NSAIDs or corticosteroids; see ch. 164), analgesic drugs (see ch. 126 and 356), and nutritional support (see ch. 82).

Calvarial hyperostosis, primarily seen in young Bullmastiffs, is characterized by irregular, progressive bony proliferation and thickening of the cortical bone of the calvarium. It manifests as a smooth thickening of calvarial bones, making it different from the irregular thickening seen in craniomandibular osteopathy. Clinical signs include painful swelling of the skull, exophthalmos, fever, and lymphadenopathy. In most cases it is self-limiting.[41]

Fibrous osteodystrophy results from a congenital condition associated with primary hyperparathyroidism and nutritional or renal secondary hyperparathyroidism (see ch. 297).[42] There is generalized osteopenia with more pronounced manifestation in the jaw bones, causing tooth mobility, facial swelling, thickened rubbery jaws, and ulcerated oral mucosa. Radiographs display marked, diffuse decrease of bone density, loss of normal trabecular bone structure as well as loss of lamina dura. The teeth usually do not appear to be demineralized and rarely undergo resorption. The prognosis is very poor, except for cases of nutritional secondary hyperparathyroidism that may be treated by feeding an appropriately formulated diet.

Benign Oral Tumors

Papillomas are viral-induced, cauliflower-like whitish lesions at mucous membranes and mucocutaneous

junctions of the mouth in dogs less than one year of age (see ch. 228). They often resolve spontaneously in 1-3 months, unless the patient is immunocompromised; ruling out lymphoma is particularly important in older dogs presenting with severe oral papillomatosis.

Peripheral odontogenic fibromas are mixed odontogenic tumors (common in dogs, rare in cats) and often are located in the gingiva near the incisor, canine, or premolar teeth.[43] The ossifying type (previously called ossifying epulis) is distinguished from the fibromatous type (previously called fibromatous epulis) by its content of varying amounts of bone or dental hard tissue within the tumor's soft tissue. These tumors are excised together with extraction of the involved tooth and thorough curettage of the alveolus. Biopsy will distinguish these tumors from gingival hyperplasia (Figure 272-4).

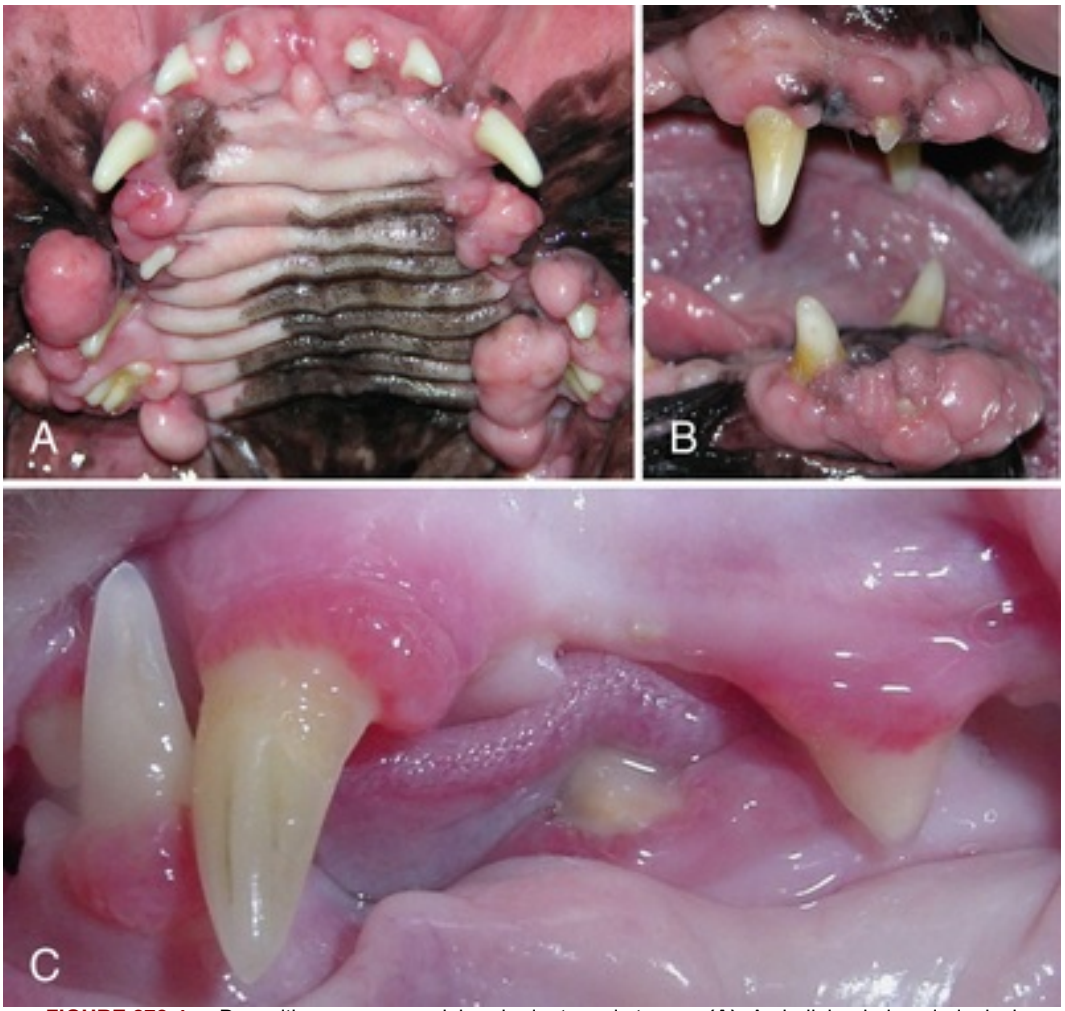

FIGURE 272-4 Dog with numerous peripheral odontogenic tumors **(A).** Amlodipine-induced gingival hyperplasia in a dog **(B).** Cyclosporine-induced gingival hyperplasia in a cat **(C).** (Copyright Alexander M. Reiter.)

Ameloblastomas are epithelial odontogenic tumors. The canine acanthomatous ameloblastoma (previously called acanthomatous epulis) is a locally-invasive tumor causing bone lysis around tooth roots and cystic changes. However, despite this locally aggressive behavior, it does not metastasize and is therefore considered to be benign.[43] Externally, it often has a rough, cauliflower-like surface and sometimes can be similar in appearance to squamous cell carcinoma. It occurs most commonly in the incisor and canine tooth area of the lower or upper jaw, and less commonly in the carnassial tooth area of the lower or upper jaw.

Odontomas are not true neoplasms but, rather, a conglomerate of disorganized, normal tissue cells. Enamel, dentin, cementum, and small tooth-like structures can compose the mass. Lesions with characteristics resembling normal teeth are considered compound odontomas, whereas complex odontomas have a more disorganized arrangement.[44]

Other benign oral tumors that are less common include the cementoma, giant cell granuloma, feline inductive odontogenic tumor, amyloid-producing odontogenic tumor, plasma cell tumor, osteoma, and lipoma.

Malignant Oral Tumors

Malignant melanoma usually occurs in older dogs with oral pigmentation, and it is very rare in cats (see ch. 345). The tumor is pigmented or nonpigmented (amelanotic), often grows rapidly and invades bone early. The tumor surface usually is ulcerated and foul-smelling because of necrosis caused by the lesion outgrowing its blood supply. Typical locations are the gingiva, palate, dorsal surface of the tongue, and mucosal surface and mucocutaneous junctions of the lips and cheeks. Regional and distant metastasis is common at the time of diagnosis.[45]

Nontonsillar *squamous cell carcinoma* typically is a tumor of older cats and dogs, but papillary squamous cell carcinoma also can occur in adolescent and young adult dogs. The tumors most often are found on the gingiva as proliferative and ulcerated lesions and less often on the mucosa of the lips, cheeks, tongue and sublingual area. Bone invasion is common for gingival lesions. If occurring on the upper jaw in cats, the tumor can be less protuberant, while bone invasion is more severe. Use of flea collars, eating canned tuna and canned cat food, and exposure to environmental tobacco smoke have been identified as risk factors for squamous cell carcinoma in cats.[46] Metastasis to regional lymph nodes is common, while distant metastasis can occur late in the disease process. Recent studies of cats with squamous cell carcinoma suggest a rate of metastasis to the mandibular lymph nodes of >30%.[47] Tonsillar and lingual squamous cell carcinoma in dogs are highly metastatic. See ch. 345 for treatment and prognostic information on squamous cell carcinoma.

Fibrosarcoma is the second most common malignant oral tumor in cats and the third most common in dogs. It tends to occur in young adult to middle-aged large-breed dogs and older smaller dogs, affecting the gingiva, lip/cheek mucosa, or the hard and soft palate. Often, it appears as a protuberant, ulcerated lesion. Occasionally, it can arise from the lateral surface of the incisive bone and maxilla, presenting a slowly enlarging, firm mass at the muzzle. Fibrosarcomas are highly invasive. Regional and distant metastasis are less common compared to malignant melanoma and squamous cell carcinoma. Low-grade fibrosarcomas appear benign histologically but are malignant biologically.[48] See ch. 348 for treatment and prognostic information on fibrosarcoma.

Osteosarcoma affects the mandible and, less often, the maxilla, often manifesting as a fleshy, ulcerative or necrotic oral mass with extensive radiographic evidence of bone invasion (bone lysis rather than hard tissue proliferation). Regional and distant metastasis seem to be less common than for limb osteosarcoma.[49] Multilobular tumor of bone is a less aggressive variant of osteosarcoma, manifesting as a hard, well-circumscribed, non-ulcerated mass on the maxilla, palate, ramus of the mandible, zygomatic arch, and calvarium. It appears radiographically as a combination of mineralized and non-mineralized tissue ("popcorn ball" appearance). See ch. 348 for treatment and prognostic information on osteosarcoma.

Peripheral nerve sheath tumors sometimes are misdiagnosed as fibrosarcoma. They tend to grow along major nerves (i.e., infraorbital nerve, inferior alveolar nerve, major palatine nerve) of the face, upper and lower jaw, and palate (see ch. 268).

Other less common, malignant lesions include hemangiosarcoma, lymphoma, mast cell tumor, and anaplastic or undifferentiated tumors.

Approach to Evaluating Oral Masses

The TNM (tumor, node, metastasis) system aids in describing the clinical extent (staging) of neoplastic disease through evaluation of the primary tumor, regional lymph nodes, and distant sites of possible metastasis.[50] Three-view thoracic radiography (and occasionally also an abdominal ultrasound if there is a reason to suspect intraabdominal disease) should be performed prior to placing an oral tumor patient under anesthesia, particularly when a malignant oral lesion is suspected. However, metastatic lesions sized <5 mm in diameter might not be visible on radiographs. Conversely, inclusion of the thorax during computed tomography of the head (to evaluate the primary tumor) and neck (to evaluate lymph nodes) can allow for detection of metastatic lesions <2 mm in diameter.[51] The use of conventional or digital dental radiographs (in particular with size 4 dental films or phosphor plates) is superior to standard medical radiography in the evaluation of quality and extent of bony lesions of upper and lower jaws.

A biopsy preferably is obtained from an area that can be included in the definitive resection. Areas of necrotic tissue can be present in rapidly growing tumors, and such tissue is not helpful diagnostically; viable

tissue should be included in the biopsy sample. Cytological sampling can be performed in the awake or sedated patient. Fine-needle techniques are useful for lesions that exfoliate well, and sampling often is performed with a 22-gauge needle by means of a needle biopsy ("woodpecker method") or needle aspiration (see ch. 93 and 95). Palpation of lymph nodes is neither sensitive nor specific for detecting regional lymph node metastasis.[52] Therefore, cytological examination of lymph node needle biopsies and aspirates should be performed, and this can be adequate for diagnosing metastatic melanoma and squamous cell carcinoma but is less satisfactory for other oral tumors. Impression smears and scrapings obtained from the surface of an epithelialized or ulcerated tumor have no diagnostic value. Impression smears and scrapings can be of much greater value if obtained from the cut surface of an excised tumor (see ch. 86 and 87).

Histological sampling requires general anesthesia and microscopic examination of a formalin-fixed specimen. This is more accurate than cytological sampling. Rongeurs are ideal for bone samples and scalpel blades for incisional and excisional soft tissue sampling. Tissue-damaging instrumentation (e.g., electrocautery) must not be used during the sampling procedure so that a diagnosis is not obscured. Multiple samples should be obtained. Hemostasis is achieved with digital pressure, and biopsy sites of more deeply invading tumors are sutured. For adequate fixation, the specimen is placed in 10% buffered formalin at 1 part tissue to 10 parts fixative. Parotid, mandibular, and medial and lateral retropharyngeal lymph nodes preferably should be evaluated histologically after excision (see ch. 95). A negative lymph node biopsy, however, does not preclude the possibility of regional metastasis, which can occur along perineural or vascular routes, or metastasis to other, less-accessible lymph nodes. If cytological or histological results do not match the clinical findings, a second, deeper, and larger specimen is obtained. A mucosal flap could be raised to access deeper tissue for tumors that are covered by a layer of variably-thick normal tissue.

Outcome and Conclusion

Client communication is extremely important prior to embarking on an involved oral surgical procedure. In general, home care in the immediate postoperative period, long-term home oral hygiene, and the need for periodic reexaminations should be discussed with every client. Considering that general anesthesia is required to assess any dental and oral lesions fully and to perform treatment as needed, the risk of perioperative complications also should be discussed. Additionally, some of the diseases discussed in this chapter require medical treatment for the rest of the patient's life or surgical procedures that could lead to a change in the patient's esthetic appearance or functionality.

A diagnosis of a malignant or locally aggressive oral tumor should lead to an in-depth discussion about the biological behavior of the tumor, possibility of intraoperative complications, expectations in terms of quality of life for the pet, life expectancy after the procedure, life expectancy if surgery is not performed, and non-surgical treatment alternatives (such as radiation therapy, immunotherapy, and chemotherapy). Collaboration with medical and radiation oncologists is helpful to allow the veterinarian and client make an informed decision that fits the pet and its family.

CHAPTER 273

Diseases of the Pharynx and Esophagus

Stanley Leon Marks

Client Information Sheet: Megaesophagus in Dogs and Cats

Normal Anatomy and Function

The oral cavity, oropharynx, and esophagus can be thought of as a series of expanding and contracting chambers, divided by muscular sphincters. Propulsion of a bolus through this part of the alimentary tract is the result of positive pressure developed behind the bolus, as well as a vacuum or negative pressure developed in front. Any disturbance in the functional or anatomical elements or coordination of this system can result in abnormal transfer of a bolus from the oral cavity to the stomach, resulting in dysphagia (difficulty swallowing). Dysphagia is relatively common in dogs and the list of possible causes is extensive (Box 273-1). Dysphagia is far less common in cats with the exception of structural causes of oropharyngeal dysphagia (OPD) associated with oral tumors, ulcers, and gingivostomatitis.

Box 273-1

Causes of Oropharyngeal and Esophageal Dysphagia in Dogs

Central Nervous System

Cerebrovascular accident
Brainstem tumor

Iatrogenic

Antihistamines
Anticholinergics
Phenothiazines
Chemotherapy
Postsurgical muscular or neurogenic
Radiation
Ingestion of a corrosive substance
Antibiotics (clindamycin, doxycycline)
Nonsteroidal anti-inflammatory drugs

Infectious/Inflammatory

Esophagitis
Botulism
Tetanus
Candidiasis
Rabies
Abscess
Calicivirus infection (cats)
Rhinotracheitis virus infection (cats)

Metabolic

Hyperadrenocorticism

Hypoadrenocorticism
Hypothyroidism (not an important cause in dogs)
Thyrotoxicosis-associated myopathy (people)

Myopathic/Neuropathic

Peripheral neuropathies
Inflammatory myopathies (infectious, immune-mediated, pre-neoplastic)
Dermatomyositis
Muscular dystrophies
Myasthenia gravis
Megaesophagus

Structural

Oropharyngeal or esophageal neoplasia
Cricopharyngeal bar
Proximal esophageal webs
Esophageal tumors
Esophageal stricture
Esophageal fistula
Esophageal diverticulum
Vascular ring anomaly
Foreign body
Congenital anomaly (cleft palate, diverticula)
Hiatal hernia
Gastroesophageal reflux
Gastroesophageal intussusception

The swallowing mechanism is complex, involving 31 pairs of striated muscles and five cranial nerves with nuclei in the brainstem (sensory and motor fibers of the trigeminal, facial, glossopharyngeal, and vagus nerves, and motor fibers of the hypoglossal nerve), and the swallowing center in the reticular formation of the brainstem. The normal swallowing reflex is a four-phase process: oral preparatory, oral, pharyngeal, and esophageal phases.[1] The esophagus transports the bolus from the pharynx into the stomach. The outer coat of esophageal loose connective tissue, the adventitia, is present in the cervical portion but is largely replaced by serosa in the thorax. In dogs, the muscularis of the esophagus is entirely striated from the cricopharyngeus muscle to the gastroesophageal junction. In cats, the striated muscle is replaced by smooth muscle in about one-third of the esophagus. The inner esophageal wall consists of submucosa and mucosa, divided by fenestrated muscularis mucosae, more prominent in the thoracic esophagus. The submucosa contains blood vessels, nerves, and glands. The mucosa is composed of keratinized, stratified squamous epithelium. Innervation of the striated muscle of the esophagus in dogs and cats is provided by special visceral efferent neurons from the bilateral nucleus ambiguus in the medulla oblongata. Axons are carried in the vagus nerves and distributed with the pharyngoesophageal and recurrent laryngeal nerves, and the vagal trunks. The smooth muscle innervations in cats arise from the rostral bilateral nucleus ambiguus via general visceral efferents, and are also distributed via the branches of the bilateral vagus nerve.

Phases of Swallowing

Oral Preparatory, Oral, and Pharyngeal Phases

The *oral preparatory phase* is voluntary and begins as food or liquid enters the mouth. Mastication and lubrication of food are hallmarks of this phase, as the bolus is modified and prepared for swallowing. Abnormalities of the oral preparatory phase are associated with dental disease (see ch. 272), xerostomia, and weakness of the lips (cranial nerves V and VII), tongue (cranial nerve XII), and cheeks (cranial nerves V and VII) (see ch. 264). The *oral phase* consists of the muscular events responsible for movement of the bolus from the tongue to the pharynx, and is facilitated by the tongue, jaw, and hyoid muscle movements. The *pharyngeal phase* begins as the bolus reaches the tonsils, and begins with elevation of the soft palate to prevent the bolus from entering the nasopharynx, elevation and forward movement of the larynx and hyoid, retroflexion of the epiglottis and closure of the vocal folds to close the entrance into the larynx. Then, there is synchronized

contraction of the middle and inferior constrictor muscles of the pharynx together with relaxation of the cricopharyngeus muscle that makes up much of the upper esophageal sphincter (UES). This allows passage of the bolus into the esophagus (Figure 273-1). Respiration is briefly halted (apneic moment) during the pharyngeal phase.[2]

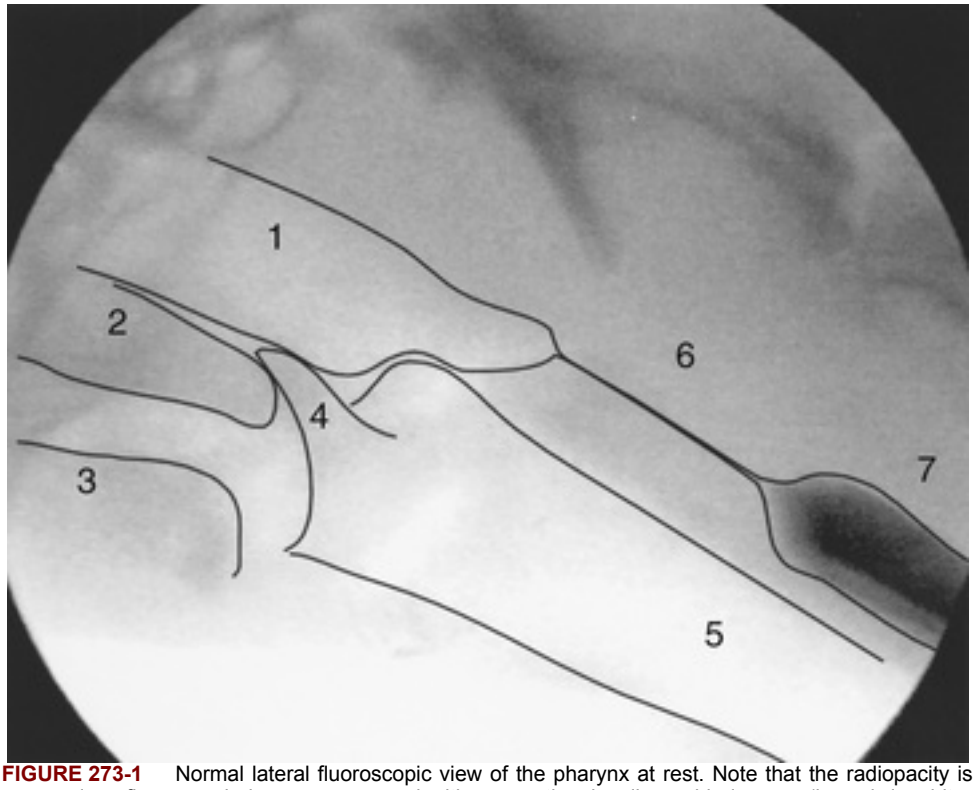

FIGURE 273-1 Normal lateral fluoroscopic view of the pharynx at rest. Note that the radiopacity is reversed on fluoroscopic images compared with conventional radiographic images (i.e., air is white, bone is black). 1. Nasopharynx; 2. Soft palate; 3. Base of tongue; 4. Epiglottis; 5. Trachea; 6. Upper esophageal sphincter; 7. Proximal esophagus with barium in the lumen. (From Pollard RE, Marks SL, Davidson A, et al: Quantitative videofluoroscopic evaluation of pharyngeal function in the dog. *Vet Radiol Ultrasound* 41[5]:409–412, 2000.)

Abnormalities of the pharyngeal phase of swallowing include pharyngeal weakness due to neuropathies or myopathies, pharyngeal tumors or foreign bodies, or obstruction of the UES secondary to hypertrophy of the cricopharyngeus muscle. Synchrony between constriction of the pharyngeal muscles and relaxation of the cricopharyngeus muscle is essential to allow passage of the bolus into the esophagus. Despite the myriad causes of OPD, the pathophysiologic end results fall into one of two inter-related categories: (1) abnormalities of bolus transfer or (2) abnormalities of airway protection. Abnormalities of bolus transfer can be further grouped into those caused by (a) oropharyngeal pump failure (pharyngeal weakness); (b) oropharyngeal and pharyngo-UES asynchrony (neuropathies); and (c) pharyngeal outflow obstruction (cricopharyngeal achalasia, tumors of the pharynx, foreign bodies).

Esophageal Phase

The *esophageal phase* is involuntary, beginning with relaxation of the UES and movement of the bolus into the esophagus. Sensory feedback likely plays a role in regulating the speed and intensity of peristaltic waves, depending on bolus characteristics. Swallow-induced peristalsis is primary peristalsis. Secondary peristalsis occurs in response to distension of the esophageal lumen by a bolus that has failed to be propelled into the stomach. Relaxation of the LES in advance of the propagated pressures permits food to empty into the stomach and once the bolus passes, the LES contracts to prevent reflux of gastric contents into the esophagus.

Diagnostic Approach

Signs

The diagnosis of disorders affecting the oropharyngeal phase of swallowing can be extremely challenging. A history of repetitive swallowing, gagging, and retching associated with meals, nasal regurgitation with meals, swallow-related coughing, food falling from the mouth during swallowing, and recurrent pneumonia should cause suspicion of OPD (Figure 273-2). OPD can cause transient apnea and syncope in some dogs. In contrast, animals with esophageal dysphagia are typically less challenging to diagnose, although some have concurrent disease of the pharynx and esophagus. The hallmark signs of esophageal dysphagia include regurgitation (solids or liquids), odynophagia (painful swallowing), repeated swallowing attempts, and excessive salivation. *Regurgitation of food or water is the most consistent sign of esophageal disease and must be differentiated from the signs of OPD or vomiting.* Pharyngeal or esophageal disease may be part of a systemic disease in animals manifesting signs of dysphagia only, underscoring the importance of a comprehensive systemic evaluation. The assessment of dogs and cats with signs of pharyngeal or esophageal dysphagia include a review of signalment, medication history and asking about any recent anesthesia (Box 273-2). Physical (prefeeding assessment) and neurologic examinations and assessing laboratory tests are valuable before watching swallowing and using imaging studies and endoscopic evaluations.

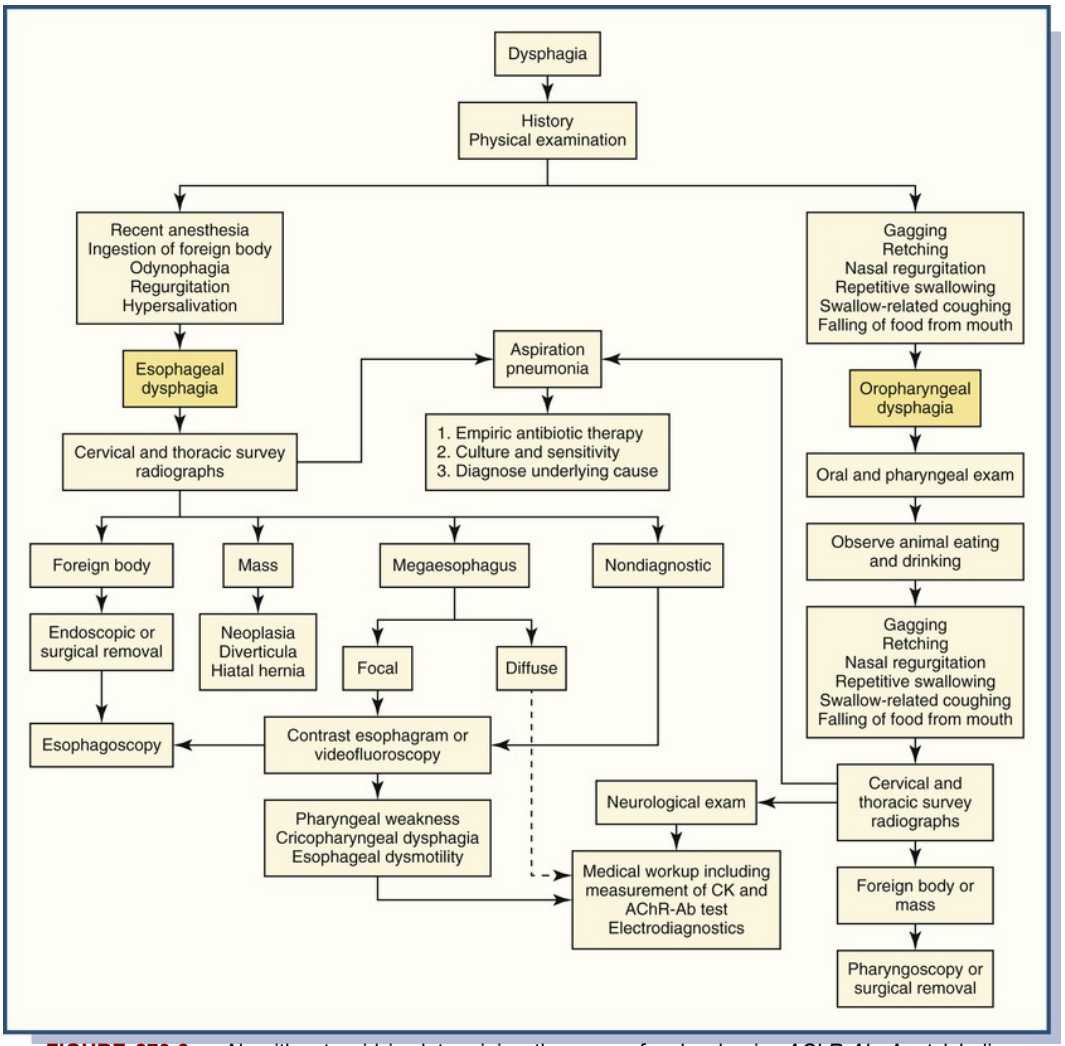

FIGURE 273-2 Algorithm to aid in determining the cause for dysphagia. *AChR-Ab,* Acetylcholine receptor antibody; *CK,* creatine kinase.

Box 273-2

History-Based Evaluation of the Dysphagic Animal

Age of onset?
Sudden onset or gradual onset?
Dysphagia while eating or between meals?
Difficulty with solids or liquids or both?
Intermittent or progressive dysphagia?
Temporal pattern of dysphagia (oropharyngeal dysphagia occurs within seconds following swallowing)
History of coughing?
History of medication administration?
History of dysphonia?
Recent general anesthesia?
History of odynophagia?

Signalment

Causes of OPD in puppies include cleft palate, cricopharyngeal dysphagia, muscular dystrophy, and pharyngeal weakness. Breeds with a hereditary predisposition or high incidence of OPD include the Golden Retriever (pharyngeal weakness),[3] Cocker and Springer Spaniels (cricopharyngeal dysphagia), Bouvier des Flandres and Cavalier King Charles Spaniel (muscular dystrophy)[4] and Boxer and Newfoundland (inflammatory myopathy). Large-breed dogs are predisposed to masticatory muscle disorders. A familial predisposition for congenital megaesophagus has been suggested in the Great Dane, German Shepherd, Labrador Retriever, Irish Setter, Chinese Shar-Pei, Newfoundland, Miniature Schnauzer, and Fox Terrier breeds.[5] Congenital megaesophagus is rare in cats, although Siamese are predisposed. Acquired idiopathic megaesophagus is more commonly recognized in large breed dogs.

Physical and Neurologic Examination

Physical examination of the dysphagic animal includes careful examination of the oropharynx, using sedation or anesthesia if necessary, to help rule out dental disease, foreign bodies, cleft palate, glossal abnormalities, and oropharyngeal tumors. The pharynx and neck should be palpated carefully for masses, asymmetry, or pain and the chest auscultated carefully for evidence of aspiration pneumonia. Evaluation of cranial nerves should include assessment of the tongue, jaw tone, and ability to abduct the arytenoid cartilages with inspiration. Complete physical (see ch. 2) and neurologic (see ch. 259) examinations may reveal evidence of a generalized neuromuscular disorder: muscle atrophy, stiffness, decreased or absent spinal reflexes. The gag reflex should be evaluated by placing a finger in the pharynx; however, presence or absence of a gag reflex does not indicate efficacy of pharyngeal swallowing nor adequacy of deglutitive airway protection.[6]

Observation of Eating and Drinking

The importance of carefully observing the dysphagic animal while eating (kibble and canned food) and drinking cannot be overemphasized. Observations help localize the problem to the oral cavity, pharynx, or esophagus. Dogs with an abnormal oral phase of swallowing typically have difficulty with prehension or aboral transport of a bolus to the tongue base, and these disorders often can be diagnosed by watching the animal eat. OPDs affecting the pharyngeal phase of swallowing can be diagnostically challenging. These dogs often have non-specific signs: gagging, retching, and multiple swallowing attempts before a bolus is moved successfully into the proximal esophagus (Video 273-1). These pets often have abnormal transport of a bolus from the oropharynx to the hypopharynx or from the hypopharynx to the proximal esophagus. Cricopharyngeal dysphagia, with signs similar to those seen with pharyngeal disorders, causes abnormal bolus transport through the UES. Dogs with megaesophagus, esophageal strictures or esophagitis can exhibit evidence of odynophagia and regurgitation seconds to minutes following bolus swallowing.

Laboratory Testing

Comprehensive laboratory testing is warranted in animals with OPD and esophageal dysphagia to provide a minimum neuromuscular data set. Testing should include a complete blood count (CBC), serum chemistry panel (including creatine kinase [CK] and electrolyte concentrations), urinalysis, evaluation of thyroid

function (see ch. 299), and acetylcholine receptor (AChR) antibody titer for acquired myasthenia gravis (see ch. 269). Persistently elevated CK concentrations (2,000-20,000 IU/L) could indicate generalized myositis, whereas marked CK increases (>20,000 IU/L) are more suggestive of necrotizing or dystrophic myopathy (see ch. 354). Normal CK concentrations do not rule out myopathy, particularly when focal (masticatory muscle myositis; see ch. 272) or chronic. Acquired myasthenia gravis is an important neuromuscular cause of OPD causing pharyngeal, esophageal, and/or laryngeal weakness without clinically detectable muscle weakness in the extremities. Pharyngeal weakness as the only clinical sign of myasthenia gravis has been described in 1% of affected dogs.[7] The acetylcholine (AChR) antibody test should be performed in all pets with acquired dysphagia. The gold standard for the diagnosis of acquired myasthenia gravis remains the demonstration of serum autoantibodies against native AChR by immunoprecipitation RIA. Within individuals, AChR antibody levels correlate with disease severity, but antibody levels between patients are highly variable and do not correlate well with severity. This test is not useful for congenital dysphagia in which an immune basis is unlikely.

Cervical and Thoracic Radiography

The pharynx of healthy animals is air filled and easily seen on radiographs. The size of the air-filled space can be decreased by inflammation/edema, neoplasia, or elongation of the soft palate and it can appear increased with pharyngeal or UES dysfunction, chronic respiratory (inspiratory) disease, or chronic severe megaesophagus. The normal esophagus is not visible on survey radiographs except after aerophagia due to excitement, nausea, dyspnea, or anesthesia.

Videofluoroscopic Swallow Study

Contrast videofluoroscopy involves real-time images of the animal swallowing liquid barium or barium-soaked kibble and is one of the most important procedures for assessing the functional integrity of the swallow reflex (see Figures 273-1 and 273-2). Fluoroscopic swallow studies usually involve assessment of 5 swallows of 5-10 mL of liquid barium (60% weight per volume), 5 swallows of canned food and 5 swallows of kibble soaked in barium. Videofluoroscopy is used to determine the sequence of events that make up a swallow and to time these events in relation to one another. Movement of certain anatomic structures can be measured in relation to a fixed point to assess function further. Swallowing events that occur out of sequence, at inappropriate times, or with reduced vigor can cause significant morbidity.

Positioning is not standardized for videofluoroscopy. Alterations in body position (sternal versus lateral recumbency) do not appear to affect measuring pharyngeal constriction ratios or the timing of swallowing in healthy dogs. However, cervical esophageal transit is significantly delayed when dogs are in lateral recumbency.[8] Thus, retaining liquid or kibble boluses in the cervical esophagus may not be considered abnormal when ill dogs are in lateral recumbency during imaging. Swallow studies on dogs in sternal recumbency are significantly more likely to result in generation of primary peristaltic waves for both liquid and kibble boluses.

The timing of the swallow can be determined easily when the swallow video is viewed frame by frame with each frame representing 1/30 of a second in the National Television System Committee (NTSC) system (analog television system used in the United States). The starting point is the frame in which the epiglottis closes over the larynx. The frames are counted until observation of maximal pharyngeal contraction, opening and closing of the UES. The swallow is considered complete when the epiglottis is observed to reopen, usually after 5 or 6 frames in healthy dogs.[9] A contrast videofluoroscopy method for quantifying pharyngeal contractility in dogs has been described.[10] The pharyngeal constriction ratio (PCR) is calculated by dividing the pharyngeal area at maximum contraction by the pharyngeal area at rest. As pharyngeal contractility diminishes, the ratio approaches 1.[10] This simple procedure provides important information regarding the strength of pharyngeal contraction in dysphagic dogs.

Laryngoscopy, Pharyngoscopy, and Esophagoscopy

Thorough laryngeal examination (see ch. 239) is important in all animals with OPD and esophageal dysphagia to rule out laryngeal paralysis associated with a polyneuropathy (see ch. 268). Geriatric large-breed dogs may develop progressive generalized neuropathy with associated pharyngeal weakness, OPD, and esophageal dysmotility.[11] Pharyngoscopy and esophagoscopy provide information about these areas, but both procedures are of limited diagnostic utility for evaluating functional disorders in anesthetized animals.

Esophagoscopy is helpful for diagnosing esophagitis, esophageal strictures (that can be missed on barium swallow studies), and hiatal hernias (see ch. 113).

Electrodiagnostic Testing

Electrodiagnostic evaluation, including electromyography and measurement of motor and sensory nerve conduction velocities, does not provide a specific diagnosis in most cases but can supply important information as to the severity, distribution, and character of a myopathic or neuropathic disease process and assist in selecting the optimal anatomic site for biopsy (see ch. 117). Electrodiagnostic testing should include the pharyngeal muscles and tongue. Health status must be considered because these procedures are performed under general anesthesia.

Muscle and Nerve Biopsies

Muscle and nerve biopsies usually are integral to reaching a specific diagnosis (see ch. 116). Muscle biopsies should be collected early in the course of an evaluation in animals with suspected neuromuscular disease before fibrosis and myofiber loss is extensive but after a negative serum AChR antibody titer has been obtained. If onset of clinical signs is recent and the antibody titer is 0.3 to 0.6 nmoL/L, retesting 4-6 weeks later may be of value, as a significant number of dogs with early clinical signs can have antibody titers in the "gray zone" at initial testing. In dogs with suspected myopathic disease, muscle biopsies are usually obtained from large muscles (the vastus lateralis or the triceps). Biopsies of pharyngeal and cricopharyngeal muscles should be obtained in dogs with OPD.[12] The thin frontalis muscle lies directly under the skin and is commonly biopsied instead of the temporalis muscle in dogs with suspected masticatory muscle myositis (MMM; see ch. 272). The frontalis muscle is not affected in MMM and, if biopsied by mistake, a diagnosis of MMM may be missed.[12] Incise and retract the frontalis muscle and the thick fascia that lies underneath the frontalis and directly over the temporalis muscle to expose the temporalis muscle for biopsy (see ch. 116). Wrap muscle specimens (0.5 × 0.5 × 1.0 cm) in saline dampened (not dripping wet) gauze sponges and place into a dry watertight container and keep cold until shipped. A second smaller biopsy specimen from next to the original biopsy should be placed in 10% buffered formalin. All specimens with cold packs are shipped overnight so the samples arrive at the laboratory within 24-36 h of collection (see ch. 354). Muscle biopsies must remain cold to optimize the condition of the specimens.

Magnetic Resonance Imaging (MRI) and Computed Tomography (CT) Scans

MRI and CT imaging of the head and neck have been used to diagnose inflammatory myopathies, particularly MMM in dogs.[13] Imaging can be used for selecting muscle biopsy sites. Common findings include changes in size (atrophy or swelling) of all masticatory muscles except the digastricus and a predominantly inhomogeneous contrast enhancement seen in the temporalis, masseter, and pterygoid muscles.[13] MRI may also detect neoplasia.

Esophageal Manometry

Esophageal manometry allows the pressures in the esophageal lumen and sphincters to be measured to assess neuromuscular activity. Manometry involves high-resolution (HRM), with up to 36 pressure sensors.[14] Advances in computer processing allow objective pressure data to be presented in real time as a compact, visually intuitive "spatiotemporal plot" of esophageal pressure activity assessing the forces that drive food and fluid from the pharynx to the stomach. This diagnostic test can be employed in fully awake dogs and provides a sensitive functional assessment of the UES, esophagus, and LES.[14]

Esophageal pH/Impedance Testing

Esophageal pH/impedance testing is used to evaluate acid and non-acid reflux in animals with suspected gastroesophageal reflux (GER), unexplained esophagitis, or hiatal hernias. Clinicians have several choices when selecting esophageal pH probes. The catheter-free Bravo pH Monitoring System from Medtronic is the first catheter-free system used to measure esophageal pH in people suspected of having GER. This is revolutionizing esophageal pH testing, because it allows people to maintain their diet and activities during

testing. This system is an alternative to the traditional pH trans-nasal pH catheter that can cause discomfort and is easily dislodged in dogs and cats. The main disadvantages of the Bravo system are that it only records esophageal pH and does not utilize impedance technology that allows more accurate measurement of both acid and non-acid reflux events. Esophageal pH testing has been utilized in awake and anesthetized dogs in an effort to identify risk factors for GER and/or the effects of prokinetic agents on GER.[15,16]

Disorders of the Pharynx

Pharyngitis

Anatomy, Causes, Signs

The pharynx is divided into three regions: nasopharynx, oropharynx, and laryngopharynx. Clinical manifestations vary depending on location and extent of the inflammation, etiology, and involvement of adjacent structures. Pharyngeal inflammation can occur from foreign bodies, obstructive masses (nasopharyngeal polyps, lymphoma, squamous cell carcinoma), infectious disease, ingestion of caustic or irritating substances, and as an extension of stomatitis, rhinitis, or sinusitis. The most common clinical manifestations include dysphonia, snoring, gagging, coughing, dysphagia, hyporexia, and hypersalivation. Tonsillitis is often recognized in association with pharyngitis.

Diagnosis and Treatment

History and oral examination are usually sufficient to confirm this diagnosis, although a comprehensive oral exam under sedation or rhinoscopy with retroflex nasopharyngoscopy may be necessary in select cases. Survey radiographs of the cervical region might be unrewarding unless a radiodense foreign body or pharyngitis secondary to extrapharyngeal disease is present. Removal or treatment of the primary cause is essential. Analgesics, topical antimicrobial rinses, systemic antimicrobials, hydration and nutritional support are important. Nasopharyngeal inflammatory polyps in cats with normal bulla may be removed by traction avulsion. Nasopharyngeal stenosis can be treated by balloon dilation under general anesthesia.

Pharyngeal Weakness

Anatomy, Causes, Signs

Oropharyngeal pump failure (pharyngeal weakness) is a disruption in coordinated transport of food and water from the oropharynx to the hypopharynx, or from the hypopharynx into the esophagus. Pharyngeal weakness can occur secondary to morphologic abnormalities (infection, inflammation, trauma, neoplasia, obstruction to the UES [cricopharyngeal achalasia]) or from functional (neuromuscular disease) causes. Specific neuromuscular disorders that should be considered include myasthenia gravis, muscular dystrophy, polymyositis, hypothyroidism, and cranial nerve neuropathy. Clinical signs commonly include dysphonia, gagging, dysphagia, repeated swallowing attempts of a single bolus, and coughing.

Diagnosis and Treatment

Survey thoracic and cervical radiographs should be obtained in all dogs before completing a videofluoroscopic swallow study. Fluoroscopy can demonstrate absence of aboral pharyngeal contraction, incomplete bolus transport, and occasional nasopharyngeal reflux of barium. Fluoroscopy is pivotal for differentiating pharyngeal weakness from cricopharyngeal dysphagia. A systemic workup (CK level, AChR antibody titer, thyroid hormone testing, electrodiagnostics) is warranted in an effort to rule out systemic disease and an underlying neuropathy or myopathy (see Figures 273-2 and 273-3). Therapy of pharyngeal weakness secondary to underlying neuromuscular disease is mostly palliative, particularly when an underlying cause cannot be identified, and includes enteral nutritional support, alterations in diet and water consistency, and elevated feedings. Dogs with myasthenia gravis should be managed with acetylcholinesterase inhibitors (e.g., pyridostigmine, 1 to 3 mg/kg PO q 8-12 h). Glucocorticoids (e.g., 1 to 2 mg/kg prednisolone or equivalent PO q 12 h with gradual taper over the course of 10-12 weeks depending on response) or cyclosporine (5 mg/kg PO q 12-24 h for 10-12 weeks) are utilized to manage inflammatory polymyopathies (see ch. 354 and 360), and thyroid replacement therapy should be attempted in animals with documented hypothyroidism (see ch. 299).

Disorders of the Esophagus

Cricopharyngeal Dysphagia

Definition and Clinical Signs

Cricopharyngeal dysphagia is a congenital or acquired neuromuscular disorder of the UES characterized by failure of the UES to relax *(achalasia)* or a lack of coordination between UES relaxation and pharyngeal contraction *(asynchrony).* Affected dogs have abnormal transport of bolus from the hypopharynx to the proximal esophagus. Cricopharyngeal asynchrony is essentially a "pump problem" whereby the weak pharyngeal muscles are unable to propel the bolus through the UES. The etiology of neither condition is determined, although preliminary studies are supportive of an underlying focal neuropathy. Affected animals demonstrate progressive dysphagia (typically worse when drinking water) at the time of, or shortly after, weaning. Clinical signs are characterized by repeated attempts to swallow, gagging, retching, and nasal regurgitation (see Video 273-1). The clinical signs of dogs with cricopharyngeal achalasia are indistinguishable from cricopharyngeal asynchrony. Physical examination may reveal evidence of aspiration pneumonia (coughing, moist crackles on auscultation, fever).

Diagnosis and Treatment

Dogs suspected of having cricopharyngeal dysphagia should be thoroughly evaluated prior to surgical intervention to ensure that systemic disorders (myopathies [see ch. 354], polyneuropathies [see ch. 259 and 268]) have been ruled out with AChR antibody titers, CK level (see ch. 66), electromyography (EMG; see ch. 117), and muscle biopsy (see ch. 116). In addition, ensure that aspiration pneumonia is properly managed (see Figure 273-1).[17] Thoracic radiographs help rule out structural causes of dysphagia (foreign body, mass); however, a videofluoroscopic swallow study is the diagnostic procedure of choice (Video 273-2). Most affected dogs with cricopharyngeal achalasia have a prominent thickened cricopharyngeus muscle (cricopharyngeal "bar") visible on videofluoroscopy or endoscopy causing severe obstruction to propulsion of the bolus through the UES (Figure 273-4 and E-Figure 273-5). Static contrast radiographs may demonstrate

barium retention in the pharynx or aspiration into the trachea; however, static studies do not allow the functional integrity of the UES or the coordinated contraction of the pharynx and relaxation of the UES to be evaluated.

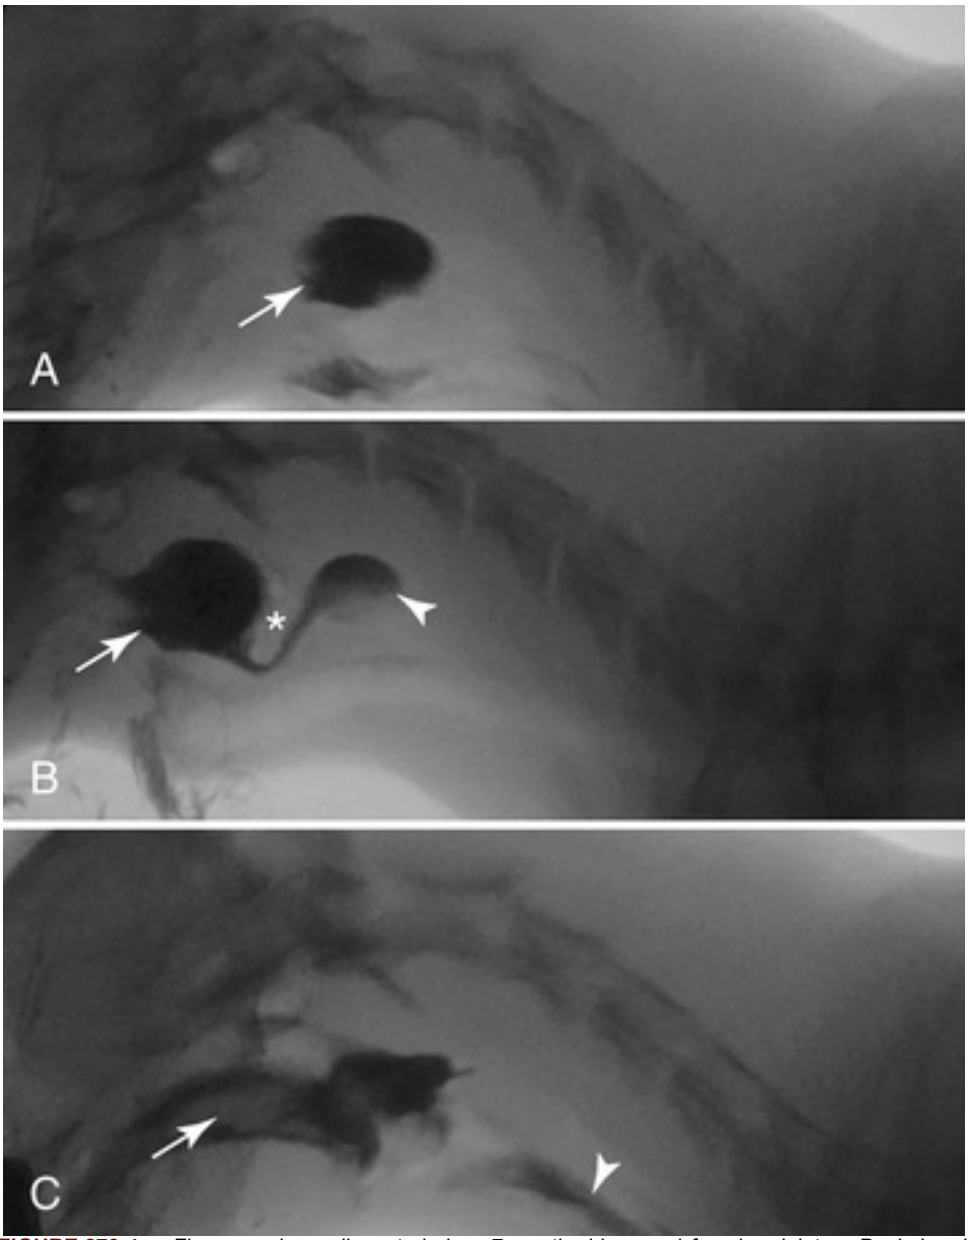

FIGURE 273-4 Fluoroscopic swallow study in a 7-month-old spayed female miniature Dachshund with severe dysphagia secondary to cricopharyngeal achalasia. **A,** The pharynx (arrow) is filled with liquid barium; **B,** hypertrophied cricopharyngeus muscle (cricopharyngeal "bar") (asterisk) obstructing the movement of the bolus from the pharynx (arrow) into the proximal esophagus (arrowhead). Notice the attenuated column of barium being squeezed through the narrow opening of the upper esophageal sphincter (UES); **C,** retrograde movement of liquid barium into the oropharynx (arrow) caused by obstruction of the proximal esophageal sphincter, and subsequent aspiration of barium into the trachea (arrowhead). (From Marks SL: Oropharyngeal dysphagia. In Bonagura JD, Twedt DC: *Kirk's current veterinary therapy XV,* St Louis, 2014, Saunders.)

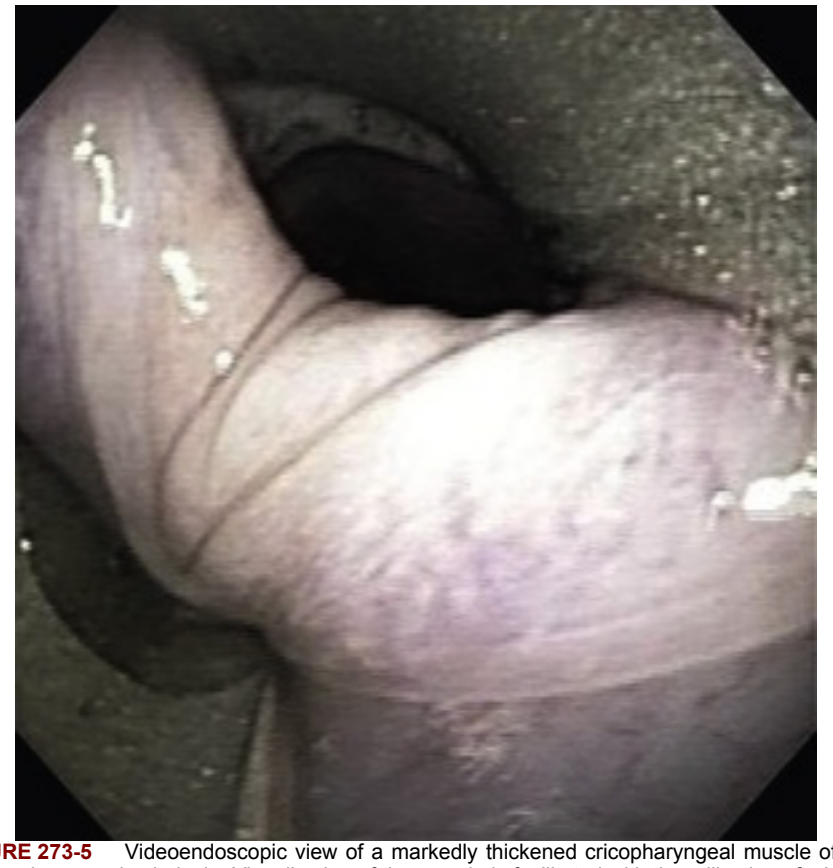
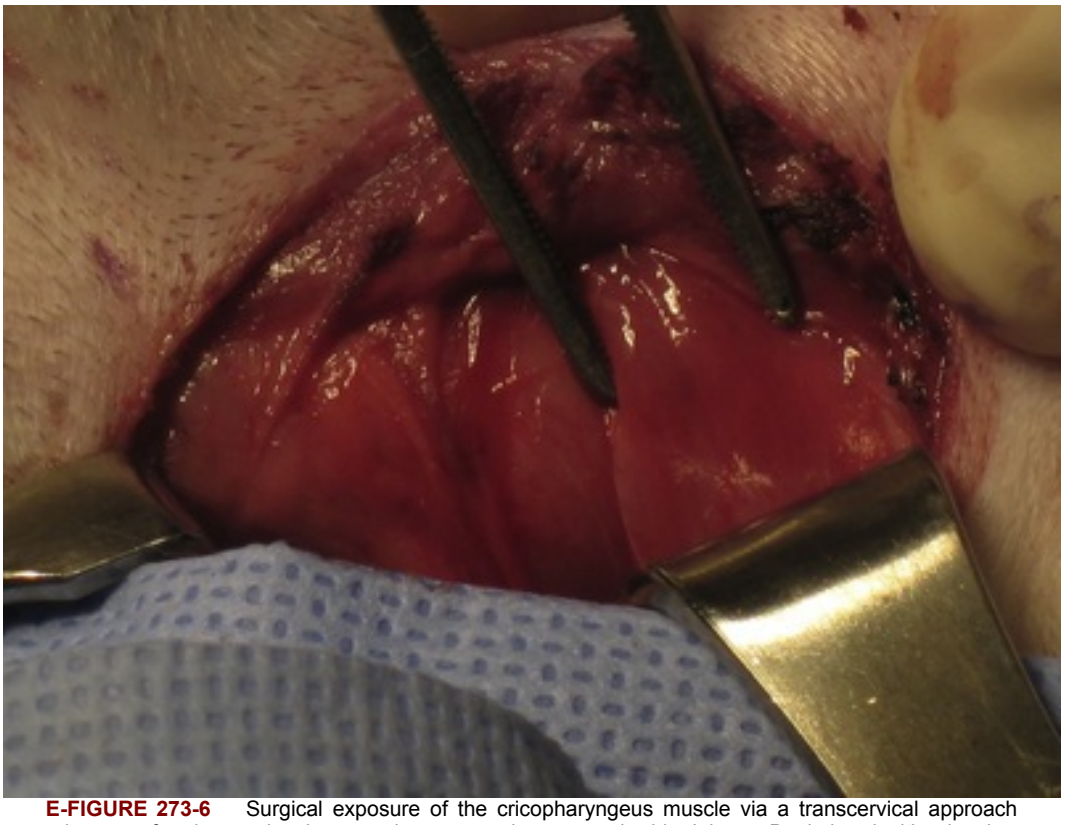


E-FIGURE 273-5 Videoendoscopic view of a markedly thickened cricopharyngeal muscle of a dog with cricopharyngeal achalasia. Visualization of the muscle is facilitated with the utilization of a Weerda distending diverticuloscope that has been placed in the dog's hypopharynx transorally.

Definitive treatment for cricopharyngeal achalasia involves surgical myotomy or myectomy of the cricopharyngeal muscle (E-Figure 273-6). The cricopharyngeal and thyropharyngeal muscles are approached by standard ventral midline with 180° rotation of the larynx on its longitudinal axis or via a lateral approach with 90° rotation of the larynx.[18] Cricopharyngeal myotomy involves transecting the cricopharyngeal muscle to the level of the pharyngeal mucosa. A closed endoscopic CO_2 laser cricopharyngeal myotomy is being increasingly utilized in people and dogs, with reduced anesthesia time and morbidity compared with the more traditional transcervical cricopharyngeal myotomy.[19]



E-FIGURE 273-6 Surgical exposure of the cricopharyngeus muscle via a transcervical approach prior to performing a cricopharyngeal myectomy in a 5-month-old miniature Dachshund with cricopharyngeal achalasia.

There is less compelling evidence for surgical myectomy of dogs with cricopharyngeal asynchrony; however, one report documented successful bilateral cricopharyngeal myectomy to manage an 8-month-old mixed breed dog with cricopharyngeal asynchrony after initially failing standard unilateral cricopharyngeal myectomy.[20]

A less invasive procedure for the temporary resolution of cricopharyngeal achalasia involves the injection of botulinum toxin into the cricopharyngeus muscle.[21] Botulinum toxin A (BTA), a neurotoxin synthesized from the bacillus *Clostridium botulinum,* acts at the presynaptic cholinergic nerve terminals to block the release of acetylcholine. In a dose-related manner, it weakens contraction when injected into the target muscle and has been successfully used in people and dogs for the temporary management of esophageal achalasia. The toxin is reconstituted shortly before injection with 0.9% sterile saline to a concentration of 25 units/mL and is injected into the cricopharyngeus muscle in 3 sites (10 units per site) using a transbronchial needle. The limited duration of botulinum toxin's effect (about 3-4 months) can be used to help screen dogs that might benefit from a permanent surgical myectomy, because animals that respond favorably to the toxin should do well with surgical myectomy. An effort to identify the optimal consistency of food and water (adding commercial food thickeners such as "Thick-It") for these dogs can be helpful. Some succumb to repeated bouts of aspiration pneumonia and malnutrition. Enteral feeding via a PEG tube is a viable alternative; however, silent aspiration and pneumonia can occur despite the advent of enteral feeding devices.

Esophagitis

Anatomy, Cause, Clinical Signs

Esophagitis is an acute or chronic inflammatory disorder of the esophageal mucosa that occasionally involves the underlying submucosa and muscularis. It may result from a variety of causes, including ingestion of caustic agents, chronic vomiting, esophageal foreign bodies, embrittled nasoesophageal or esophagostomy feeding tubes and gastroesophageal reflux associated with general anesthesia or hiatal hernia. Orally administered doxycycline and clindamycin have caused "pill-induced" esophagitis, particularly in cats.[22] Gastroesophageal reflux during anesthesia preceded development of benign esophageal stricture in 46-65% of cases and represents the most common cause of high-grade esophagitis and stricture formation in dogs.[23]

Relaxation of the LES is mediated by non-adrenergic non-cholinergic pathways and has been shown to occur with the administration of commonly utilized injectable pre-anesthetic and inhalant anesthetic agents.[24,25] The prolonged exposure of the esophageal mucosa to acid is an important cause of esophagitis and potential stricture formation, particularly when pH is <4.0 as the proteolytic pH range for the conversion of pepsinogen to pepsin is between 1.5 and 3.5.[26] In addition, esophagitis decreases LES tone, which leads to more reflux and mucosal inflammation. Disturbances in esophageal motility may occur as a sequela of esophagitis, regardless of cause. The clinical signs of esophagitis are dependent on the severity of inflammation, extent of esophageal involvement, and type of injury. Animals with mild inflammation may exhibit no clinical signs, whereas animals with moderate-to-severe esophagitis may exhibit signs of anorexia, dysphagia, odynophagia, regurgitation, and hypersalivation. Coughing may be observed with concurrent aspiration pneumonia.

Diagnosis and Treatment

Results of CBC, serum biochemistry, and urinalysis are usually unremarkable, and the esophagus appears normal on survey thoracic radiographs. Aspiration pneumonia may be evident in the dependent areas of lung. Segmental or diffuse esophageal dilatation may be seen with severe mucosal inflammation. Videofluoroscopy may confirm irregular esophageal surface, esophageal dysmotility (Video 273-3), or stricture formation (see Figure 273-3). Definitive diagnosis of esophagitis requires endoscopy and esophageal biopsy; however, presumptive diagnosis is often made from the appearance of the esophageal mucosa: erythema and a granular surface with areas of ulceration and active bleeding (Figure 273-7). Mild esophagitis may appear normal on endoscopic examination and mucosal biopsy is necessary to confirm the diagnosis. Lesions are usually most evident in the distal esophagus, adjacent to and including the LES.

FIGURE 273-7 Severe esophagitis characterized by severe erythema, ulceration, and a granular mucosa in a 3-year-old Labrador Retriever secondary to gastroesophageal reflux during an anesthesia procedure.

Mild esophagitis usually resolves with minimal treatment other than feeding smaller-sized fat-restricted meals frequently to enhance gastric emptying and minimize GER. Animals with moderate to severe

esophagitis or those exhibiting signs of dysphagia, regurgitation, salivation, or anorexia should be managed with gastric acid suppressants and prokinetics. The benefits of proton pump inhibitors (PPIs) such as omeprazole in people with moderate to severe GER are documented and several studies have shown the superior acid suppressive effects of PPIs compared to the H2-receptor antagonists (famotidine, ranitidine).[27,28] The PPIs are administered orally or IV (1 to 1.5 mg/kg q 12 h) and should be gradually tapered over 7-10 days if used for more than 2 weeks. The diffusion-barrier drug sucralfate can be administered as a suspension (0.5 to 1 g PO three times a day) for managing reflux esophagitis. It binds to eroded mucosa and provides effective barrier protection against refluxed barrier contents. Prokinetic agents such as cisapride (0.5 mg/kg PO q 8-12 h) or metoclopramide (0.2 to 0.4 mg/kg SC or IV as a bolus injection q 8 h, or at 1 to 2 mg/kg/24 h as an IV constant rate infusion [CRI]) can be used to increase LES pressure and enhance gastric emptying. Cisapride is a more potent prokinetic than metoclopramide and is more effective at reducing GER in dogs.[14] Broad-spectrum antibiotics are recommended for animals with aspiration pneumonia (see ch. 242). The duration of therapy varies depending on the severity of the esophagitis and clinical signs, but ranges from 5-7 days (mild cases) to 2 to 3 weeks (moderate to severe esophagitis). A combination of cisapride, sucralfate, and omeprazole is an effective combination for the management of severe esophagitis caused by persistent vomiting, GER, or foreign body induced trauma.

Esophageal Stricture

Definition, Anatomy, Clinical Signs

Esophageal stricture, an abnormal narrowing of the esophageal lumen, is most commonly caused by GER during general anesthesia, chemical injury from swallowed substances, esophageal foreign bodies, esophageal surgery, and intraluminal or extraluminal mass lesions (neoplasia or abscess). Cats are particularly susceptible to doxycycline and clindamycin-associated esophagitis and subsequent esophageal stricture.[22] GER during general anesthesia has been reported to have preceded stricture in up to 65% of cases. Clinical signs are seen about 7-8 days post-anesthesia.[29] The incidence of GER in dogs during anesthesia varies from 16-55%, and occurs secondary to a decrease in LES pressure induced by a variety of anesthetic agents, including atropine, morphine, acepromazine, thiopentol, xylazine, and isoflurane.[24,25] Damage to the muscularis layer of the esophagus is associated with fibroblastic proliferation and contraction leading to stricture formation. The clinical signs, progressive regurgitation and dysphagia, are related to the severity and extent of the stricture. Early clinical signs might include a subtle "hard swallow" for a few days that can be easily missed by owners. Progressive clinical signs include dysphagia, odynophagia, regurgitation, salivation, anorexia, coughing, and weight loss.

Diagnosis and Dilation Treatment

Diagnosis of esophageal stricture is often suggested by the history and confirmed with contrast radiographs using liquid barium or barium mixed with canned food (esophagram) or via videofluoroscopic swallow studies (see Figure 273-2 and E-Figure 273-8). Contrast radiographs are helpful for determining the number, location, and length of strictures. Esophagoscopy, the definitive diagnostic procedure, is helpful for differentiating benign from malignant strictures and facilitates balloon-dilation (Figure 273-9). Mechanical dilation of the stricture is best accomplished using balloon dilation or bougienage. The theoretical advantage of balloon dilation (Figure 273-10) is that the forces applied to the stricture are a radial stretch, in contrast to the longitudinal forces applied with the rigid bougienage instrument. However, a retrospective case series in 20 dogs and 8 cats with benign esophageal strictures that underwent bougienage treatment suggested that this procedure was safe and effective for most dogs and cats with benign esophageal strictures, with outcomes similar to balloon dilation.[30] Balloon dilators are available in various diameters (up to 20 mm) and lengths (3 to 8 cm), are made of a rigid plastic material that can withstand a relatively high pressure (up to 147 psi), and are manufactured to either pass through the biopsy channel of the endoscope or alongside the endoscope with the use of a guidewire. If a guidewire is used, it is passed through the channel of the endoscope (or imaged with fluoroscopy) and advanced beyond the stricture into the stomach or caudal esophagus. The scope is removed as the guidewire is advanced through the channel, thus leaving the guidewire near its original position. The balloon catheter is then passed over the guidewire (with the balloon deflated) until it is positioned within the stricture. The position of the balloon is visualized through the endoscope or via fluoroscopy. An inflating device that has a manometric pressure gauge is attached to the balloon and the pressure is slowly increased to the pressure specified by the manufacturer. The balloon is kept inflated for 60-90 seconds and then deflated. Sequentially increasing pressures are applied to dilate the

stricture in 1-2 mm increments without causing excessive tearing or bleeding (Figure 273-11). The procedure is repeated 3-5 days later in an effort to maximally dilate the stricture.

FIGURE 273-9 Esophageal stricture viewed endoscopically prior to balloon dilation. The distance between the tips of the wings of the biopsy forceps measures 5 mm and can be used to measure the diameter of the small stricture.

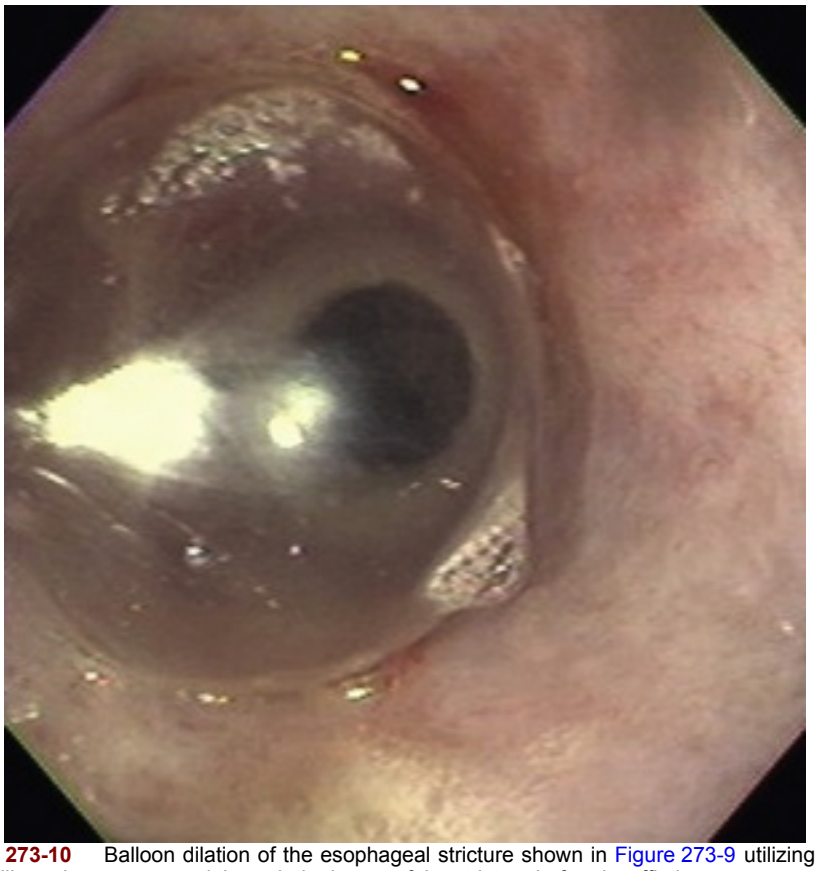


FIGURE 273-10 Balloon dilation of the esophageal stricture shown in Figure 273-9 utilizing a CRE balloon dilator that was passed through the lumen of the stricture before insufflation.

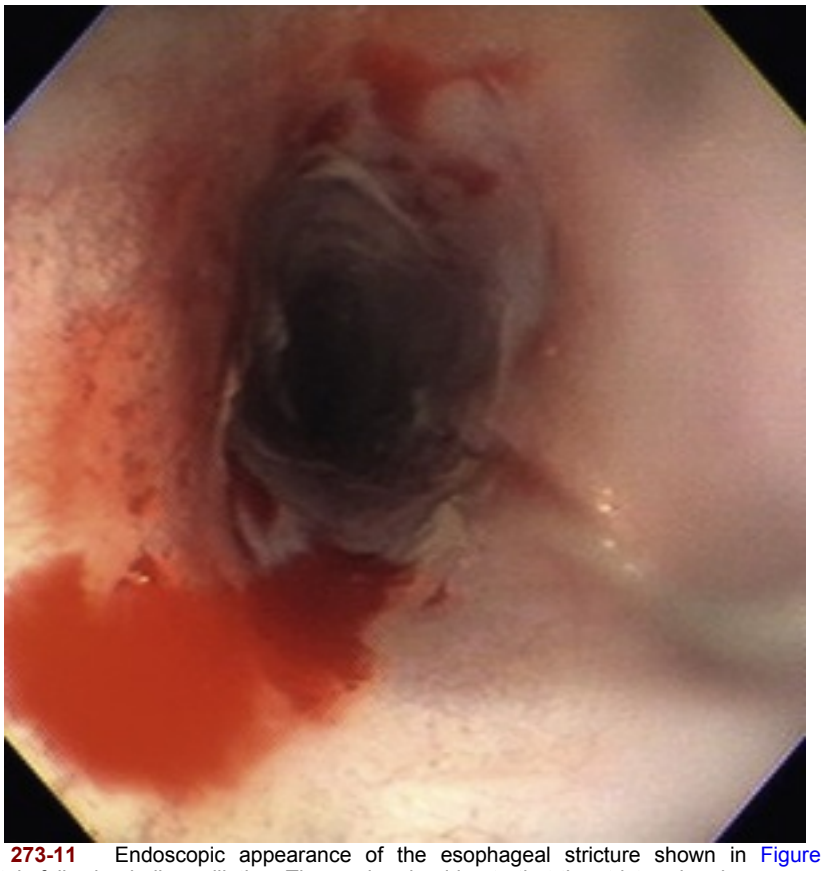

FIGURE 273-11 Endoscopic appearance of the esophageal stricture shown in Figure 273-9 immediately following balloon dilation. The reader should note that the stricture has been successfully broken down; however, the bleeding secondary to the tearing of the stricture at the 7 o'clock position precludes further dilation during this procedure.

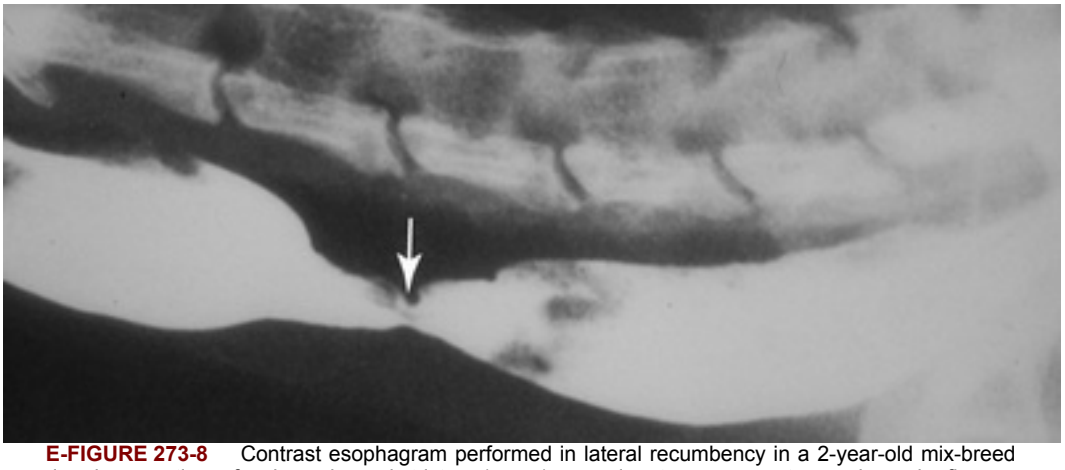


E-FIGURE 273-8 Contrast esophagram performed in lateral recumbency in a 2-year-old mix-breed dog documenting a focal esophageal stricture (arrow) secondary to severe gastroesophageal reflux.

Transendoscopic Triamcinolone

The transendoscopic administration of triamcinolone into the submucosa of the stricture site using a four-quadrant approach before the balloon dilation procedure has been associated with a reduced rate of re-stricture formation.[31,32] Approximately 2.5 mg triamcinolone per quadrant is injected using a transbronchial aspiration needle that can be threaded down the biopsy channel of the endoscope. The steroid is generally used for the first 2-3 dilation procedures. Topical mitomycin C (5 mg of mitomycin C using a soaked gauze

sponge that is placed endoscopically at the stricture site for approximately 5 minutes) has also been shown to be beneficial for preventing restricture.[33] The site is rinsed with 60 mL of water after removing the sponge. Continued medical therapy is warranted following balloon dilation using the same medications and dietary alterations as discussed for esophagitis.

Intraluminal Stents

Intraluminal stents can be used in animals that have failed balloon dilation or those with recurrent strictures (see ch. 123).[34] Stents are available both uncovered and covered with polypropylene to prevent growth of tissue within the stent. Available stent materials include Nitinol (nickel plus titanium), Elgiloy (cobalt, nickel, plus chromium), stainless steel, polyester plastic/silicone, or a biodegradable stent (e.g., PDS). Stent selection is based on stricture location, length, and need for removing the stent. Once deployed, stents must be anchored in place or they quickly migrate into the stomach. Stents can be secured using a suturing device (GI Stitch, Pare Surgical) designed to function in a double channel endoscope.

Esophageal Foreign Bodies

Definition and Clinical Signs

Foreign bodies are a common cause of dysphagia in dogs, but less common in cats. The most common esophageal foreign bodies in dogs are bones, fish-hooks (E-Figure 273-12), needles, and sticks, whereas play toys are more commonly seen in cats. Foreign bodies typically lodge at points of minimal esophageal distension: thoracic inlet, heart base, or at the diaphragmatic hiatus. Mucosal abrasion, ulceration, and perforation may occur with sharp or angular objects that are lodged intraluminally.

Severity of esophageal damage and resulting signs are dependent on the foreign body size, shape, edges, and the duration of obstruction. In some cases, the owner observes foreign body ingestion. Onset of clinical signs is often related to degree of esophageal obstruction and type of foreign body ingested. Animals with smaller foreign bodies with a smooth surface causing incomplete obstruction may have had signs for days to weeks' duration, whereas complete obstruction causes acute dysphagia, regurgitation, odynophagia, gagging, and excessive salivation.

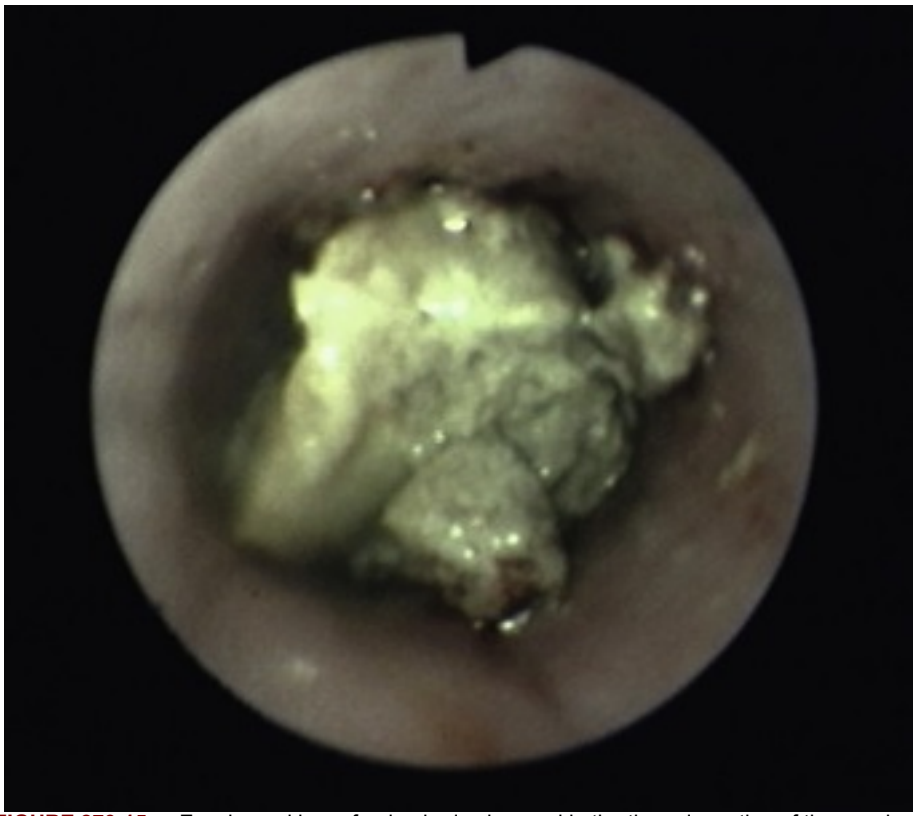
Diagnosis and Treatment

Physical examination is variable, ranging from unremarkable to halitosis (tissue necrosis), fever and lethargy. Bone foreign bodies can occasionally be palpated if they become lodged in the cervical esophagus. Definitive diagnosis usually requires radiography. Radiodense foreign bodies can be detected with survey radiography (E-Figures 273-12 and 273-13), but identifying radiolucent foreign bodies requires an esophagram. Survey radiographs are indispensable for detection of aspiration pneumonia or esophageal perforation (pneumomediastinum, emphysema, or mediastinitis; Figure 273-14). A water-soluble positive-contrast agent (iohexol, Gastrografin [diatrizoate]) should be used rather than barium sulfate if esophageal perforation is suspected. Esophagoscopy can be performed to confirm the diagnosis and assess secondary mucosal damage (E-Figure 273-15).

FIGURE 273-14 Orthogonal projections of the cervical neck performed in a 9-month-old Border Collie that was observed playing with a stick that got stuck in the dog's esophagus. A large volume of free gas (emphysema) is seen dorsal to the pharynx dissecting between the retropharyngeal planes, extending caudally into the thoracic inlet and the cranial mediastinum (pneumomediastinum). No radiographic foreign bodies were identified during the study and endoscopic evaluation of the esophagus was recommended.

E-FIGURE 273-12 Survey thoracic radiograph (lateral view) performed in an adult mix-breed dog showing a fish-hook lodged in the cervical esophagus.

E-FIGURE 273-13 Survey thoracic radiograph (lateral view) performed in a 2-year Doberman Pinscher showing a bone foreign body lodged in the cervical esophagus. The bone was ultimately removed transorally using rongeurs with minimal damage to the esophageal mucosa and no delayed stricture formation.



E-FIGURE 273-15 Esophageal bone foreign body observed in the thoracic portion of the esophagus in a 4-year Golden Retriever. The foreign body was ultimately removed using a rigid sigmoidoscope and esophageal foreign body forceps to grasp the foreign body and pull it into the lumen of the sigmoidoscope.

Esophageal foreign bodies should be removed promptly because retention increases risk of esophageal mucosal damage, ulceration, and perforation. Foreign bodies in the proximal esophagus or large bones may be removed with a rigid sigmoidoscope, whereas more distal foreign bodies beyond the reach of a rigid scope should be removed using a flexible endoscope. Large forceps passed through the lumen of the rigid endoscope are used to grasp the foreign body and pull it into the endoscope for safe removal. Distal esophageal foreign bodies can be pushed into the stomach for removal by gastrotomy if not removed through the mouth. Smaller foreign bodies are best removed with a flexible endoscope and basket, biopsy forceps, or snare retrieving forceps. Fish-hooks that are lodged in the proximal to mid-esophagus can be dislodged with the distal end of a rigid endoscope by inserting the open end of the scope between the shaft and hook portion and pushing aborally. Once dislodged from the mucosa, the fish-hook can be pulled into the lumen of the rigid endoscope for safe removal. A flexible endoscope can be used to remove fish-hooks that are lodged beyond the reach of a rigid endoscope.

Animals with esophageal necrosis or ulceration should be fasted for 24-48 hours after foreign body removal. A gastrostomy tube (see ch. 82) can be inserted during foreign body removal in animals with severe esophagitis or necrosis to temporarily bypass the esophagus during feedings. Specific therapy for esophagitis should include sucralfate suspensions and proton pump inhibitors for 7-10 days following removal of the foreign body. Broad-spectrum antibiotics are warranted in animals with severe ulceration or small perforations. Esophagotomy is indicated if endoscopy fails to remove the foreign body; however, it is preferable to attempt to push the foreign body into the stomach for removal via gastrotomy. Surgery is also indicated to repair larger esophageal perforations.

Vascular Ring Anomalies

See Box 273-3.

Box 273-3

Vascular Ring Anomalies

Definitions and Prevalence

Vascular ring anomalies are congenital malformations of the major arteries of the heart that entrap the intrathoracic esophagus and cause esophageal obstruction. Persistent right aortic arch (PRAA) is the most common vascular ring anomaly in dogs and cats and occurs when the embryonic right aortic arch (rather than the left fourth aortic arch) becomes the functional adult aorta. Circular compression of the esophagus occurs by the aorta on the right, the ligamentum arteriosum dorsolaterally on the left, the pulmonary trunk on the left, and the heart base ventrally. This anomaly is considered to be a familial disorder with evidence of a hereditary basis in German Shepherds and Irish Setters.[35] Other less common vascular anomalies include persistent right or left subclavian arteries, double aortic arch, persistent right dorsal aorta, left aortic arch with right ligamentum arteriosum, and aberrant intercostal arteries.

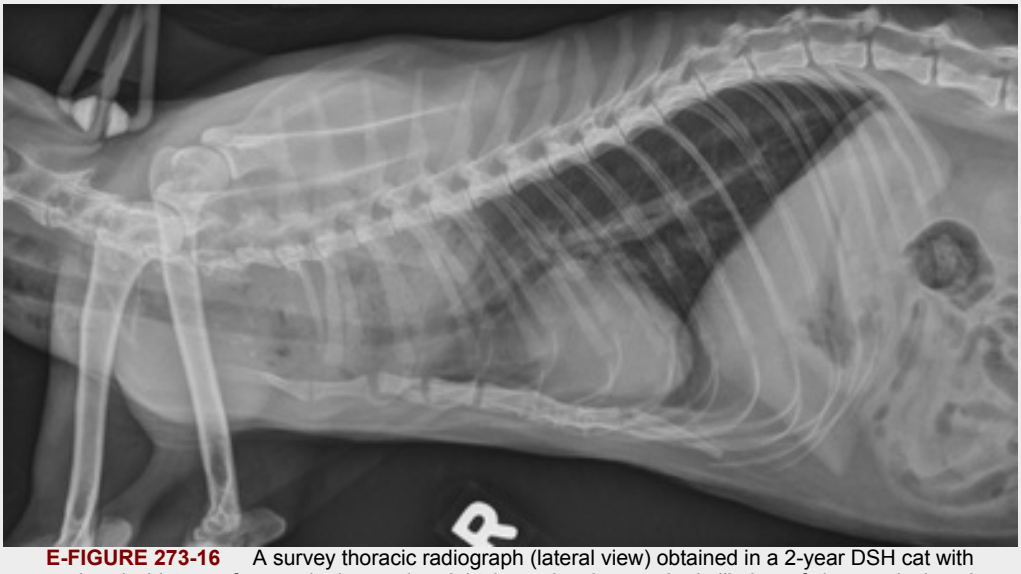
Clinical Signs

Affected puppies and kittens usually present for regurgitation of solid foods at the time of weaning (see ch. 39). Weight loss with failure to thrive despite a good appetite is commonly observed. The presence of a moist cough, dyspnea, and fever suggest aspiration pneumonia (see ch. 242). Physical examination often reveals a thin, stunted animal that is otherwise normal. Occasionally, a dilated esophagus can be observed or palpated in the cervical region.

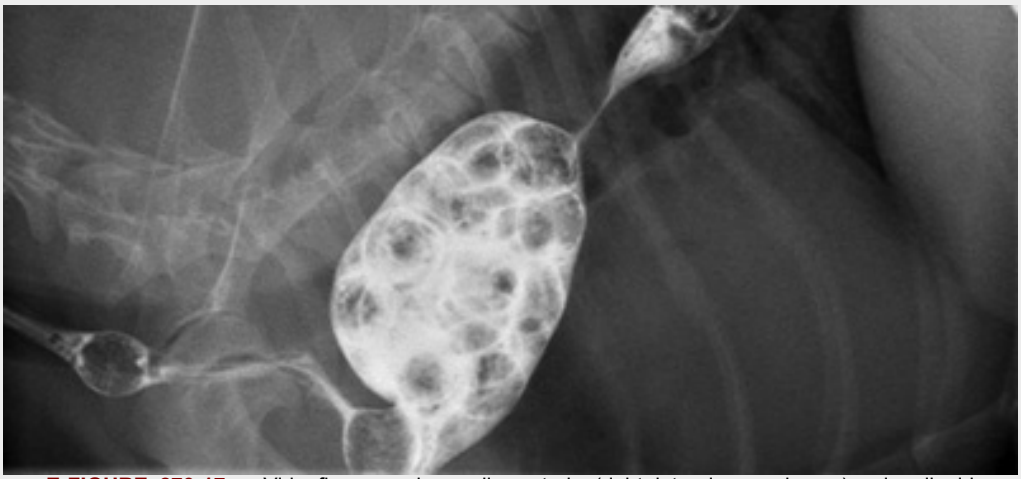
Diagnosis

Vascular ring anomalies should be differentiated from other causes of regurgitation in young animals, such as congenital megaesophagus, esophageal foreign body, and esophageal stricture (see Figure 273-3). The signalment and a compatible history of regurgitation precipitated during weaning are highly supportive of a vascular ring anomaly. Survey thoracic radiographs usually demonstrate esophageal body dilation cranial to the base of the heart (E-Figure 273-16). Focal leftward deviation of the trachea near the cranial border of the heart in dorsoventral or ventrodorsal radiographs is a reliable sign of

PRAA in young dogs.[36] An esophagram may be performed to confirm the location of esophageal obstruction and the severity of esophageal distension (E-Figure 273-17). Esophagoscopy (see ch. 113) can help differentiate an intraluminal stricture from extraluminal compression (E-Figure 273-18). Strictures appear as distinct intraluminal fibrous rings that remain static when viewed endoscopically, whereas rhythmic pulsations of the major arteries compressing the esophagus externally are observed with a vascular ring anomaly. In addition, vascular ring anomalies occur at the base of the heart, whereas intraluminal strictures can occur in any segment of the esophageal body and are more common in adult animals.



E-FIGURE 273-16 A survey thoracic radiograph (lateral view) obtained in a 2-year DSH cat with a chronic history of regurgitation and weight loss showing marked dilation of the cervical and cranial thoracic esophagus, which is filled with heterogenous soft tissue and gas opaque contents as well as multifocal mineral opacities. The trachea exhibits ventral and rightward deviation in the cranial thorax, and the cardiac silhouette appears mildly enlarged. The primary differentials for this cat included vascular ring anomaly (extraluminal obstruction) or esophageal stricture (intramural obstruction).

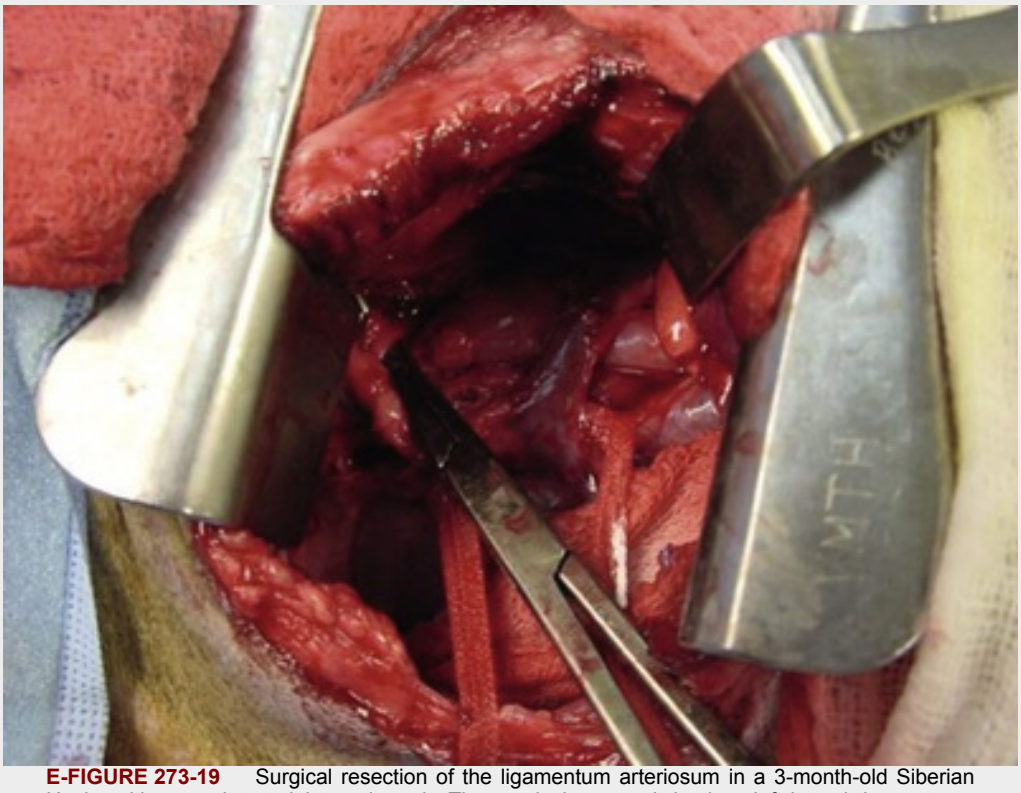


E-FIGURE 273-17 Videofluoroscopic swallow study (right lateral recumbency) using liquid barium mixed with kibble in a 3-year-old miniature Dachshund with a chronic history of regurgitation immediately following the ingestion of food. The dog had no difficulty swallowing water. Barium moved normally through the proximal esophagus but was seen to collect within a distended region of esophagus within the cranial thorax at the level of the first few ribs. The esophagus distal to the distension appears narrowed over the heart base and the trachea was noted to deviate on the dorsoventral view. Thoracic CT confirmed the presence of a vascular ring anomaly.

E-FIGURE 273-18 Esophagoscopy procedure in a 3-month-old Siberian Husky with a diagnosis of a vascular ring anomaly. The reader should note the circumferential narrowing of the esophagus over the base of the dog's heart; the mucosa appears smooth and normal in color in contrast to an intramural stricture in which the mucosa is typically erythematous, granular, and ulcerated and usually has a fibrous band in the strictured region visible on esophagoscopy.

Treatment

Definitive therapy for PRAA is surgical ligation and transection of the ligamentum arteriosum via a left intercostal approach (E-Figure 273-19). During surgery, areas of peri-esophageal fibrosis should be reduced and the strictured site should be dilated with a balloon dilation catheter. Animals with severe debilitation from malnutrition will require enteral nutritional support via gastrostomy tube feedings prior to surgery (see ch. 82). Aspiration pneumonia should be effectively treated with broad-spectrum antibiotics (see ch. 242). Significant clinical improvement usually follows corrective surgery in most patients (>90%); however, esophageal hypomotility and regurgitation may persist, particularly in those animals that have a delay in their surgery. Affected animals may benefit from elevated feedings as described for idiopathic megaesophagus. Unfortunately, there are no drugs to improve motility of esophageal striated muscle.



E-FIGURE 273-19 Surgical resection of the ligamentum arteriosum in a 3-month-old Siberian Husky with a persistent right aortic arch. The surgical approach is via a left lateral thoracotomy between the fourth and fifth ribs.

Esophageal Neoplasia

See Box 273-4.

Box 273-4

Esophageal Neoplasia

Definitions and Prevalence

Tumors of the esophagus are relatively rare, accounting for < 0.5% of all cancers in the dog and cat.[37] Tumors may be of primary esophageal, peri-esophageal, or metastatic origin. Esophageal fibrosarcoma and osteosarcoma are the most common malignant tumors in dogs, developing from malignant transformation of esophageal granulomas associated with *Spirocerca lupi* infection.[38,39] Squamous cell carcinoma is the most commonly diagnosed primary esophageal tumor in cats. Other less commonly reported primary esophageal tumors in the dog and cat include leiomyo(sarco)mas (E-Figure 273-20), adenocarcinomas, and undifferentiated carcinomas. Peri-esophageal tumors arising from regional lymph nodes, thyroid, thymus, and heart base cause local esophageal invasion, direct mechanical obstruction, or both. Metastatic lesions (thyroid, pulmonary, and gastric carcinomas) commonly involve the esophagus but are associated with clinical signs of esophageal disease less frequently.

E-FIGURE 273-20 Esophageal leiomyoma viewed via esophagoscopy in a 9-year-old German Shepherd; the mass was causing partial obstruction of the lower esophageal sphincter and subsequent regurgitation following ingestion of meals.

Clinical Signs

Clinical signs develop gradually and reflect progressive esophageal obstruction. The most common clinical signs include regurgitation, dysphagia, odynophagia, ptyalism, and weight loss. Animals with metastatic disease may have general debilitation, anorexia, and signs of pulmonary involvement such as dyspnea and coughing. Physical examination may reveal emaciation, although some peri-esophageal and esophageal tumors involving the cervical esophagus may be palpable.

Diagnosis

Survey thoracic radiographs may be normal or may reveal variable esophageal dilatation, an intraluminal mass, or evidence of a peri-esophageal lesion displacing the esophagus. The lungs should be evaluated for aspiration pneumonia and metastasis. An esophagram usually confirms the presence of an intraluminal mass or obstructive lesion. Esophagoscopy with mucosal biopsy and exfoliative cytology or histopathology is required for definitive diagnosis of esophageal neoplasia. Small pinch biopsies obtained via endoscopy may be superficial and non-representative of the tumor and a double-bite technique should be performed to maximize the diagnostic yield.

Treatment

Chemotherapy, surgical resection, and radiation therapy represent the primary modalities for treatment of malignant esophageal neoplasia; however, radiation therapy may be complicated by acute and chronic injury to adjacent mediastinal structures, while surgical resection is complicated by limited surgical exposure, tension on the anastomosis, and the risk of stricture formation post-operatively. Lymphoma may be managed with chemotherapy (see ch. 344). Slow-growing benign esophageal neoplasms (e.g., leiomyoma) generally have a favorable prognosis with complete surgical resection.[40] Esophageal granulomas associated with *Spirocerca lupi* can be managed with doramectin administered at a dosage of 200 mcg/kg SC at 14-day intervals for three treatments[38] or 500 mcg/kg of the injectable doramectin solution administered orally once a day for 6 weeks. This regimen is repeated for an additional 6 weeks

in dogs exhibiting any evidence of granuloma formation detected via esophagoscopy.[39]

Esophageal Diverticula

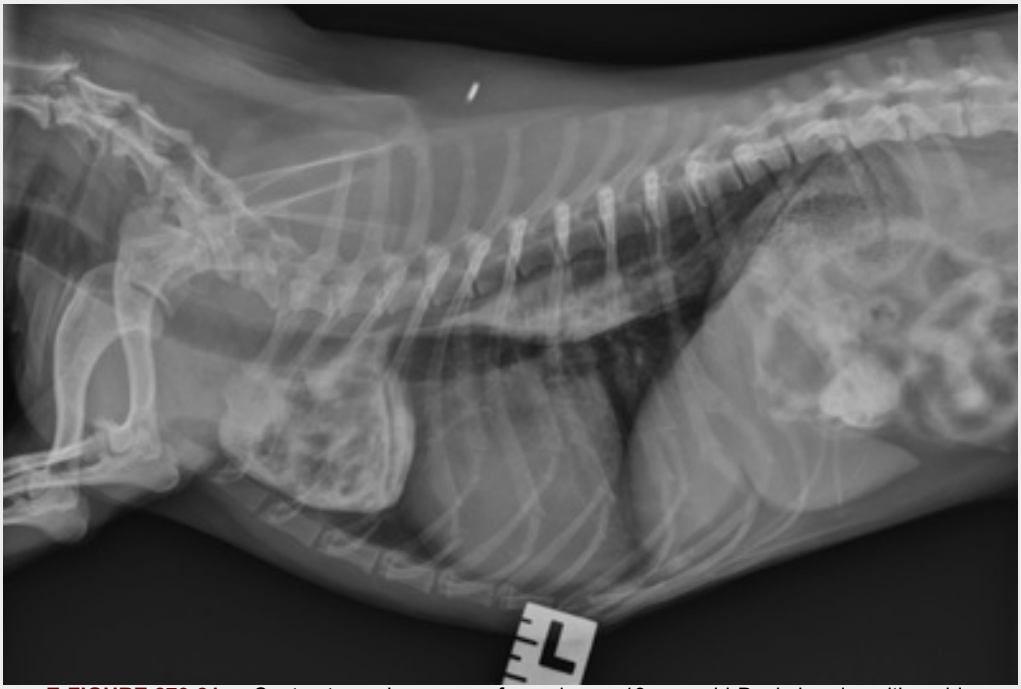
See Box 273-5.

Box 273-5

Esophageal Diverticulum

Definitions and Prevalence

Esophageal diverticula are circumscribed sacculations of the esophageal wall that affect esophageal motility. Congenital diverticula occur secondary to abnormalities in embryological development that permit herniation of the esophageal mucosa through a defect in the muscularis. Acquired diverticula are subdivided into pulsion or traction forms. Pulsion diverticula develop in association with increases in intraluminal pressure secondary to obstruction (stricture or foreign body) or altered motility (E-Figure 273-21).[41] Pulsion diverticula can develop secondary to obstruction from vascular ring anomalies. Traction diverticula result from peri-esophageal inflammation and fibrosis. Adhesions to adjacent tissue (e.g., lung, bronchus, lymph node) distort the esophageal lumen and create sacculations. The development of an abscess from migration of a foreign body (e.g., grass awn migration) is a common cause of traction diverticula in the western United States. The accumulation of ingesta (impaction) within diverticula leads to esophagitis, mechanical obstruction (seen with large diverticula), and esophageal dysmotility.



E-FIGURE 273-21 Contrast esophagram performed on a 13-year-old Dachshund positioned in left lateral recumbency showing a large esophageal diverticulum at the thoracic inlet and irregular filling of the ventral esophagus cranial to the cardiac silhouette. A persistent narrowing (stricture) of the esophageal lumen caudal to the diverticulum was observed. Esophagoscopy of the diverticulum revealed a large amount of blood-tinged fluid in the diverticulum with kibble and a partially chewed raw hide.

Clinical Signs

The clinical signs of esophageal diverticula are similar to many of the other esophageal disorders and

include regurgitation, odynophagia, and retching. Diverticula can occasionally be an incidental finding in animals with no associated clinical signs. Weakening of the muscularis can occur in rare cases, resulting in perforation of the diverticulum with leakage of food and fluid into the mediastinum and signs of sepsis and respiratory distress.

Diagnosis

Survey thoracic radiographs may reveal an air-filled or soft-tissue opacity adjacent to or involving the esophagus (E-Figure 273-22); however, contrast radiography is necessary to differentiate an esophageal diverticulum from a peri-esophageal, mediastinal, or pulmonary mass. Esophagoscopy (see ch. 113) will confirm the diagnosis, although it may be necessary to suction food and fluid to visualize the diverticulum. Diverticula should not be confused with the normal esophageal redundancy seen in young brachycephalic breeds, Bulldogs and Chinese Shar-Peis. Other differentials for epiphrenic diverticula include hiatal hernia and gastro-esophageal intussusception.

E-FIGURE 273-22 Right lateral survey thoracic radiograph of a 4-year-old Dachshund with a chronic history of regurgitation showing a diffusely dilated esophagus (megaesophagus) throughout the cervical and thoracic regions. There is a large, redundant area of esophagus (diverticulum) at the thoracic inlet that contains some mineral opacity material. There is an alveolar pattern in the left cranial and right middle lung lobes and patchy interstitial to alveolar infiltrates in the left caudal lung lobe. There is poor peritoneal detail due to lack of fat.

Treatment

Diverticulectomy is the preferred therapy, particularly for large diverticula that are a continuous cause of esophageal impaction. Small diverticula in subclinical patients may be left alone or managed medically with smaller-sized, upright feedings of a liquid or semiliquid diet to minimize impaction of ingesta in the diverticulum. Traction diverticula are often managed with broad-spectrum antibiotics, whereas pulsion diverticula are treated for their specific underlying cause (stricture, foreign body, esophagitis). Most cases warrant a guarded prognosis because corrective surgery can induce stricture formation and because segmental hypomotility may persist after surgery.

Esophageal Fistula

See Box 273-6.

Box 273-6

Esophageal Fistula

An esophageal fistula is an abnormal communicating tract between the esophagus and adjacent structures. Most esophageal fistulae involve the lungs or airway structures (e.g., esophagopulmonary, esophagotracheal, and esophagobronchial fistulae; see ch. 242). Both congenital and acquired fistulae have been described, although both forms are rare in the dog and cat.[42,43] Congenital fistulae are rare and result from incomplete separation of the tracheobronchial tree from the digestive tract, from which it is formed during embryological development. Cairn Terriers appear to be predisposed to congenital esophageal fistulae. Acquired esophageal fistulae are usually associated with retained esophageal foreign bodies, especially bones and grass awns that cause esophageal perforation and leakage of esophageal contents into adjacent tissues. Healing leads to development of a communicating tract with resultant airway contamination from esophageal contents. Other less common causes of esophageal fistulae include trauma and neoplasia.

Clinical Signs

Clinical signs are primarily related to the respiratory system and include coughing and dyspnea. Coughing after drinking is a common presenting sign. Regurgitation, dysphagia, lethargy, anorexia, fever, and weight loss are less commonly observed.

Diagnosis

Survey thoracic radiographs usually reveal a localized alveolar, bronchial, or interstitial lung pattern or a combination of these patterns. The right caudal and middle lung lobes in dogs and the left caudal and accessory lobes in cats are most commonly affected.[42,43] Radiopaque foreign bodies may be observed in the esophagus; however, an esophagram is required for definitive diagnosis of esophageal-airway communication. Use of iodinated contrast agents should be avoided because they are hyperosmolar and chemically irritating to the lung. Esophagoscopy or bronchoscopy are of limited value in confirming small fistulae.

Treatment

Surgical excision of the fistula with closure of the esophageal defect is required. Lobectomy of the affected lung lobe may be necessary as a result of pulmonary consolidation or foreign material contained within the airways. Postsurgical therapy includes esophageal rest for 48-72 hours and administration of broad-spectrum antibiotics for infection based on culture and susceptibility testing of involved tissues. A good prognosis is given to animals after successful surgery. The prognosis is guarded if severe complications such as severe pleural effusion, pneumonia, or pulmonary abscessation are present.

Megaesophagus and Esophageal Hypomotility

Congenital Megaesophagus

Megaesophagus, the most common cause of regurgitation in dogs, is characterized by focal or diffuse esophageal dilation and concurrent esophageal dysmotility. Megaesophagus can be a congenital condition or acquired. The acquired form is more common and can be idiopathic or secondary to a recognized disease. Congenital idiopathic megaesophagus is characterized by generalized hypomotility and dilation of the esophagus, causing regurgitation and failure to thrive in puppies shortly after weaning. Familial predisposition has been suggested in the Irish Setter, Great Dane, German Shepherd, Labrador Retriever, Chinese Shar-Pei, Newfoundland, Miniature Schnauzer, and Fox Terrier breeds. Congenital megaesophagus in cats is rare, but Siamese cats may be predisposed. The pathogenesis of the congenital form is poorly understood but may involve a defect in vagal afferent innervation of the esophagus.[44,45]

Acquired Secondary Megaesophagus (ASM)

The underlying cause of ASM is unknown, but a defect in afferent neural response to esophageal distension, similar to congential megaesophagus, is suspected.[46] Myasthenia gravis accounts for 25-30% of ASM in dogs,[47,48] and may involve the esophagus only (focal myasthenia gravis) or, more commonly, involves esophagus and peripheral muscles (see ch. 269). ASM has also been associated with hypoadrenocorticism (see

ch. 309), lupus myositis (see ch. 205), polymyopathies (see ch. 354), polyneuropathies (see ch. 268), dysautonomia, lead poisoning, and severe forms of esophagitis. Dysautonomia, a generalized autonomic neuropathy in which megaesophagus and esophageal hypomotility are consistent findings, is more frequently recognized in cats and is attributed to degenerative lesions involving autonomic ganglia.[49] Other causes of segmental or diffuse esophageal hypomotility include foreign bodies, stricture, vascular ring anomalies, and esophagitis.

Clinical Signs and Diagnosis

Regurgitation is the most frequent clinical sign associated with megaesophagus. Considerable variability exists in the frequency and timing of regurgitation episodes after meal ingestion. Puppies with congenital megaesophagus often begin regurgitating when weaned to solid foods. Affected animals may suffer from malnutrition and aspiration pneumonia (see ch. 242). Additional signs depend on the underlying cause of megaesophagus, and include muscle pain and stiff gait (polymyositis), generalized weakness, exercise intolerance (neuromuscular disease), and GI signs (lead toxicosis, hypoadrenocorticism).

Megaesophagus should be suspected in any animal with a history of regurgitation (see ch. 39). Survey radiographs of the neck and thorax will be diagnostic for most cases of megaesophagus (see Figures 273-2 and 273-23), although contrast radiography (esophagram) can be considered if survey radiographs are equivocal to help exclude a foreign body cause of megaesophagus or to evaluate esophageal motility. Survey radiographs may reveal alveolar opacities consistent with aspiration pneumonia. Routine hematology, serum biochemistry, and urinalysis should be performed to screen for causes of ASM. An AChR antibody titer for acquired MG should be done, even in the absence of generalized muscle weakness, because MG can cause focal megaesophagus. The test should be repeated 4-8 weeks later in all dogs with an initial titer in the "gray-zone" (0.3-0.6 nmol/L), particularly when the onset of megaesophagus has been deemed to be acute in nature. A resting cortisol or ACTH stimulation test should be considered to help rule out hypoadrenocorticism. Additional diagnostic procedures that should be based on the individual case presentation include esophagoscopy (see ch. 113), electromyography, nerve conduction velocity (see ch. 117), and muscle and nerve biopsy (see ch. 116). A clear association with hypothyroidism has not been proven and a low total T4 concentration is more consistent with euthyroid sick syndrome (see ch. 299).

FIGURE 273-23 Right lateral survey thoracic radiograph of a 3-year-old Viszla with a 3-week history

of regurgitation, ptyalism, and dysphonia. The esophagus is diffusely gas-distended and there are ventral interstitial to alveolar infiltrates within the left cranial and right middle lung lobes consistent with aspiration pneumonia. The dog was diagnosed with focal myasthenia gravis and had complete resolution of the megaesophagus and associated clinical signs following administration of pyridostigmine.

Treatment

Animals with ASM should be differentiated from those with acquired idiopathic megaesophagus and their underlying disorder treated (E-Table 273-1). Treatment of idiopathic megaesophagus and those acquired forms that fail to respond to specific medical therapy is supportive and symptomatic. The clinician should recommend small, frequent meals from an elevated or upright position (e.g., Bailey chair) to assist passage of ingesta into the stomach. Food consistency should be varied (liquid, canned meatballs or kibble) to determine which types of food are best tolerated. Severely malnourished animals or animals suffering repeated bouts of aspiration pneumonia should have a temporary or permanent gastrostomy tube placed for enteral nutritional support (see ch. 82). Gastrostomy tube feeding reduces risk of aspiration pneumonia; however, dogs with megaesophagus can still aspirate saliva or ingesta refluxed from the stomach into the esophagus. Broad-spectrum antibiotics should be considered in aspiration pneumonia (see ch. 242). Clients should be counseled that recurrent pneumonia is a common problem necessitating prompt detection and treatment for long-term success.

E-TABLE 273-1

Diagnosis and Treatment of Megaesophagus

CAUSE	DIAGNOSTIC TEST	TREATMENT
Neuromuscular Disease		
Idiopathic	Diagnosis of exclusion	Small, frequent, elevated feedings, alter diet consistency, consider gastrostomy feeding tube in select cases with intractable aspiration
Myasthenia gravis (see ch. 269)	AChR antibody titer, edrophonium response (difficult to assess if only acquired secondary megaesophagus), ± EMG	Pyridostigmine (1-3 mg/kg PO q 12 h; ± prednisone (1-2 mg/kg PO, SC q 12 h)
Systemic lupus erythematosus (see ch. 204)	ANA, skin biopsy	Prednisone (1-2 mg/kg PO, SC q 12 h)
Polymyopathy (see ch. 354)	CK, muscle biopsy, EMG	Prednisone (1-2 mg/kg PO, SC q 12 h) or Cyclosporine 5 mg/kg q 12-24 h
Glycogen storage disease (type II) (see ch. 260)	Muscle or liver biopsy, urine metabolic screening	Supportive care
Dermatomyositis (see ch. 10)	Skin and muscle biopsy	Prednisone (1-2 mg/kg PO q 12 h)
Dysautonomia	Clinical signs	Supportive care
Distemper (see ch. 228)	CSF tap, distemper titer, conjunctival scrape	Supportive care
Tetanus (see ch. 214)	Clinical signs, EMG, serum toxin assay	Supportive care, disinfect site of infection
Esophageal Obstruction		
Neoplasia	Contrast radiography, esophagoscopy and biopsy	Surgical resection, chemotherapy
Vascular ring anomaly	Survey or contrast radiography; CT scan	Surgical correction
Stricture	Esophagram, esophagoscopy	Balloon dilatation, topical triamcinolone

Foreign body	Survey or contrast radiography, esophagoscopy	Endoscopic retrieval, occasionally surgical removal
Toxicoses		
Lead	Hematology, blood lead concentration	Chelation with calcium EDTA
Organophosphate (see ch. 152)	Whole blood cholinesterase activity	Gastric lavage, atropine (0.2 mg/kg SC once), pralidoxime chloride (10-15 mg/kg slow IV), supportive care
Miscellaneous		
Hypoadrenocorticism	ACTH stimulation test	Prednisone (0.1 mg/kg PO q 12 h), fludrocortisone (0.01 mg/kg PO q 12 h) or desoxycorticosterone pivalate (DOCP) at 2 mg/kg (Percorten IM and Zycortal SC) q 25 days initially (dosage is altered based on clinical and electrolyte response)
Hiatal hernia	Contrast radiography, esophagoscopy	Surgical correction for long-term resolution. Medical management (cisapride, omeprazole, sucralfate) can be considered in milder cases or to manage associated esophagitis.
Hypothyroidism (see ch. 309)	Clinical and dermatological findings, thyroid panel, hypercholesterolemia, non-regenerative anemia	Levothyroxine 0.022 mg/kg PO q 12-24 h
Gastric dilatation-volvulus (see ch. 275)	Survey radiography	Surgical correction, supportive care
Esophagitis	Clinical signs, Esophagoscopy (dysmotility may be detected on fluoroscopy)	Sucralfate (0.5-1 g slurry PO q 8 h), Omeprazole 1-1.5 mg/kg PO or IV q 12 h Cisapride 0.5 mg/kg PO q 8-12 h
Thymoma (see ch. 344)	Survey radiography, thymic aspirate	Surgical resection

ACTH, Adrenocorticotropic hormone; *ANA*, antinuclear antibody; *CK*, creatine kinase; *CSF*, cerebrospinal fluid; *CT*, computed tomography; *EDTA*, ethylenediaminetetraacetic acid; *EMG*, electromyography.

Modified from Jergens A. In Ettinger SJ, Feldman EC: *Textbook of veterinary internal medicine*, ed 7, St Louis, 2010, Saunders.

Prokinetic drugs are currently of unproven benefit in the management of idiopathic megaesophagus in dogs. Both metoclopramide and cisapride are smooth muscle prokinetic agents that have no effect on esophageal striated muscle, and could exacerbate clinical signs. Cisapride may be a useful prokinetic agent in cats with distal esophageal motility disturbances affecting the smooth muscle component of the feline esophagus.

Affected animals should be reevaluated at 1- to 2-month intervals to monitor disease progression. Thoracic radiographs should be repeated to assess esophageal dilatation and aspiration pneumonia. Some animals with congenital megaesophagus improve over months with diligent supportive care. The prognosis with acquired idiopathic megaesophagus is generally poor. These animals usually succumb to repeated episodes of aspiration pneumonia or are euthanized because of their irreversible disease. Animals with ASM may respond to resolution of the underlying cause. The prognosis in dogs with megaesophagus caused by acquired MG is favorable, with approximately 50% of dogs responding to supportive therapy.[47]

Hiatal Hernia

Definitions and Incidence

Hiatal hernia is defined as any protrusion of abdominal contents (most commonly a portion of stomach) through the esophageal hiatus of the diaphragm into the thoracic cavity in the presence of an intact phrenico-esophageal ligament. Three types of hiatal hernias have been recognized in dogs and cats: Type I is the sliding hiatal hernia, in which the abdominal segment of the esophagus and parts of the stomach are displaced cranially through the esophageal hiatus. In Type II, the paraesophageal hiatal hernia, the abdominal segment of esophagus and lower esophageal sphincter remain in a fixed position but a portion of the stomach herniates into the mediastinum alongside the thoracic esophagus.[50,51] One case of a type IV esophageal hiatal

hernia has been reported in which the liver, stomach, and small intestine were displaced into the thorax.[52] Type I sliding hiatal hernia is the most common form and may occur as a congenital or acquired lesion in the dog and cat.

Congenital sliding hiatal hernias have been documented in brachycephalic breeds: Chinese Shar-Pei, Chow Chow, English Bulldogs, French Bulldogs, Pugs, and Boston Terriers.[53] Affected animals develop clinical signs shortly after weaning. Acquired hiatal hernia may occur in any dog or cat and may result from sudden increases in intra-abdominal pressure secondary to trauma (via damage to diaphragmatic nerves and muscles resulting in hiatal laxity) or respiratory distress (caused by increased negative intrathoracic pressure seen with intermittent airway obstruction [laryngeal paralysis]). Regardless of cause, hiatal herniation reduces LES pressure and leads to gastroesophageal reflux, esophagitis, and segmental or diffuse esophageal hypomotility.

Clinical Signs and Diagnosis

The most common clinical signs are intermittent regurgitation, vomiting, and hypersalivation, often precipitated by excitement or exercise. The persistent reflux of gastric juice can cause secondary esophagitis with signs of odynophagia. Dyspnea and coughing may occur with severe herniation or aspiration pneumonia. Survey thoracic radiographs should be obtained in all dogs with suspected hiatal hernia and may reveal a caudodorsal, gas-filled, intrathoracic soft-tissue opacity (Figure 273-24). Varying degrees of esophageal dilatation and alveolar opacities consistent with aspiration pneumonia may also be observed. Survey radiographs are relatively insensitive for diagnosing hiatal hernia and a dynamic barium procedure (videofluoroscopy) is far more likely to identify intermittent herniation of the stomach and can allow assessment of esophageal motility (see Video 273-3 and Figures 273-3 and 273-25). A normal videofluoroscopic swallow study does not rule out a hiatal hernia because the problem occurs intermittently and could be missed. Esophagoscopy can be used to diagnose sliding hiatal hernia when the apparent separation between the squamocolumnar junction and the diaphragmatic impression is greater than 2 cm using a J-maneuver.[54] Esophagoscopy is also used to look for evidence of esophagitis. High-resolution manometry (HRM) is a non-invasive tool that can be used for diagnosing hiatal hernias in people and animals.

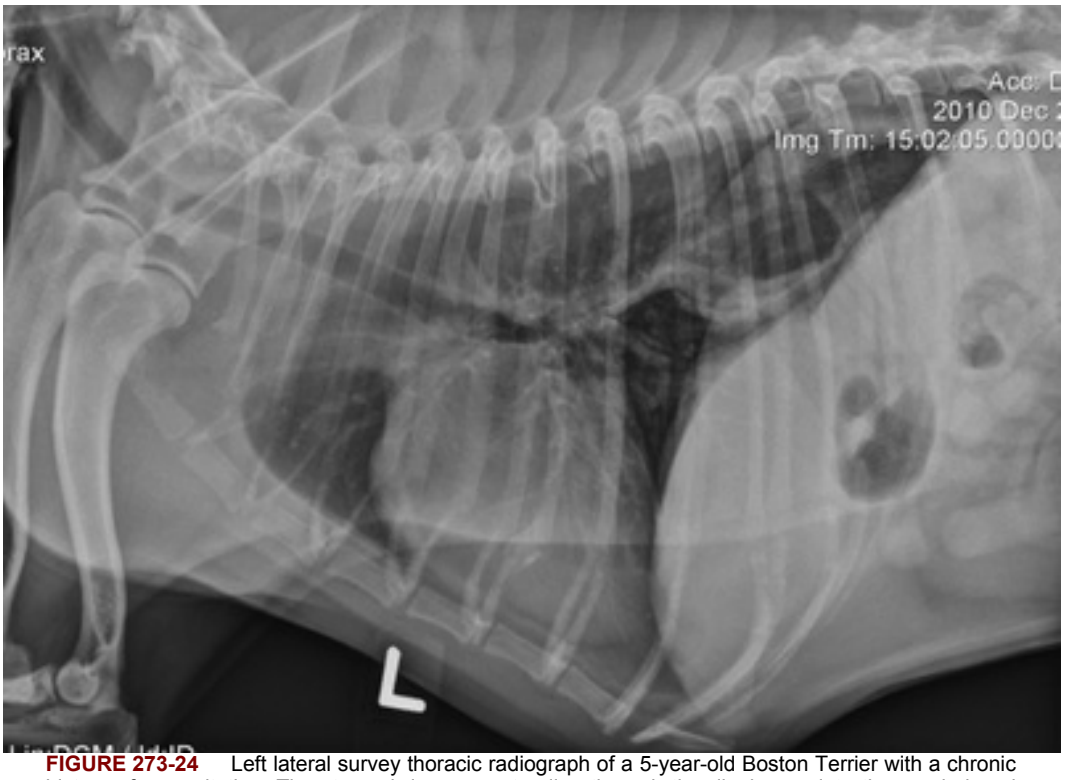


FIGURE 273-24 Left lateral survey thoracic radiograph of a 5-year-old Boston Terrier with a chronic history of regurgitation. The stomach is seen extending through the diaphragm into the craniodorsal thorax on the left lateral projection. It then returns to a more normal location on subsequent projections. These findings are highly supportive of a sliding hiatal hernia.

FIGURE 273-25 Contrast videofluoroscopic swallow study in a 5-year-old Boston Terrier with a chronic history of regurgitation documenting severe gastroesophageal reflux in association with a sliding (type I) hiatal hernia.

Treatment

A sliding hiatal hernia is not always associated with clinical signs, particularly when acquired. Medical therapy should be implemented in animals with clinical signs of severe gastroesophageal reflux (GER), esophagitis, and regurgitation before surgical intervention. Proton pump inhibitors such as omeprazole are superior acid suppressants compared to H2-receptor antagonists and should be administered with sucralfate suspension to afford greater mucosal cytoprotection. Drugs that increase LES tone (cisapride or metoclopramide) can be given with PPIs and sucralfate. Animals failing medical management may benefit from reconstructive surgery, especially for large congenital hiatal hernias. Normal hiatal anatomy can be restored by diaphragmatic crural apposition, esophagopexy, and left fundic tube gastropexy techniques.[40,42] Consideration for surgical management of brachycephalic syndrome in affected dogs with concurrent hiatal hernia is also important because the upper airway obstruction creates an increased negative intrathoracic pressure which can exacerbate herniation. The prognosis for most dogs following surgical correction is generally favorable, although persistent regurgitation is recognized in dogs with concurrent esophageal motility disturbances.

Gastroesophageal Reflux (GER)

Definition and Clinical Signs

GER is associated with reflux of gastric or intestinal fluids or ingesta into the esophagus secondary to the loss of integrity of the gastroesophageal barrier (Figure 273-26). The consequences of GER include varying degrees of esophagitis resulting from prolonged contact of gastric acid, pepsin, trypsin, bile salts and duodenal bicarbonate with the esophageal mucosa. Gastric acid alone produces mild esophagitis; however, the combination of gastric acid with pepsin or trypsin can cause severe esophagitis. The most common causes of GER in dogs and cats include hiatal hernia, general anesthesia induced reductions of LES pressure, chronic vomiting causing a weakening of LES tone, and gastric atony causing GER. The clinical signs of GER are similar to those of esophagitis, and may include regurgitation, hypersalivation, odynophagia, and anorexia. Animals that reflux into their mouth can be seen lip-smacking, panting, or exhibiting a "hard-swallow" immediately following these episodes. Nocturnal reflux occurs more commonly in people and animals because of transient relaxations of the LES during sleep and the loss of the swallow reflex.

FIGURE 273-26 Esophagoscopy performed in a 5-year-old Boston Terrier with a chronic history of regurgitation secondary to a sliding (type I) hiatal hernia. The reader should notice the flaccid lower esophageal sphincter and evidence of gastroesophageal reflux. The esophageal mucosa at the 9-11 o'clock position appears erythematous secondary to esophagitis.

Diagnosis and Treatment

Diagnosis of GER is suspected on the history (nocturnal panting, hard-swallowing, and lip-smacking), recent general anesthesia, or history of chronic vomiting. Videofluoroscopy may demonstrate intermittent GER; however, intermittent episodes of GER may be observed in animals with normal esophageal function. Esophagoscopy is a useful procedure for documenting mucosal inflammation associated with the GER. Esophageal pH/impedance testing is useful for diagnosing acid and non-acid reflux in people and dogs with suspected GER, unexplained esophagitis, or hiatal hernias (see section: Esophageal pH/Impedance Testing).

Medical therapy is aimed at administering acid suppressants (proton pump inhibitors), diffusion barriers (sucralfate), and prokinetic agents (cisapride, metoclopramide). Cisapride is a superior prokinetic agent to metoclopramide and has been documented to tighten LES tone and enhance gastric emptying in dogs. Animals should be fed a fat-restricted diet because dietary fat delays gastric emptying and can reduce LES pressure. In people with severe GER, anti-reflux surgery is commonly performed laparoscopically and is aimed at reinforcing and repairing the defective barrier through plication of the gastric fundus.[55] Endoscopic anti-reflux therapies are currently being utilized in people, although clinical trials in dogs are lacking.

CHAPTER 274

Host-Microbiota Interactions in Gastrointestinal Health and Disease

Albert Earl Jergens

Introduction

The gastrointestinal (GI) tract is colonized with a complex community of bacteria, archaea, fungi, protozoa, and viruses that promote immune system development and contribute to host health.[1,2] The total microbial load in the intestines is estimated to range from 10^{12} to 10^{14} organisms, which is approximately 10 times the number of host cells. The pool of microbes inhabiting the gut is known as the intestinal *microbiota* and their collective genomes as the intestinal *microbiome.* These bacteria exert a conditioning effect on intestinal homeostasis by delivering regulatory signals to the epithelium and instructing mucosal immune responses. This habitat is separated from the intestinal milieu by a single layer of epithelial cells and contains hundreds of different bacterial species. The paucity of bacteria in the stomach and proximal small intestine is due to acid, bile, and pancreatic secretions, which kill most ingested bacteria, and because of propulsive motor activity in the distal small intestine, which impedes stable bacterial colonization. However, bacterial density dramatically increases in the distal small bowel and in the large intestine increases to 10^{11}-10^{12} bacteria/g of luminal contents. A large proportion of the fecal mass consists of bacteria (around 60% of fecal solids).[3]

Major functions of the intestinal microbiota that contribute to maintenance of GI health include metabolic activities that cultivate energy and nutrients, important trophic effects on intestinal epithelia and immune structure/function, and protection of the colonized host against invasion by pathogenic microbes (Figure 274-1). Gut microbiota might also be an essential factor in specific pathologic disorders including inflammatory bowel disease, "small intestinal bacterial overgrowth" (SIBO), and infectious causes for gastroenteritis. Furthermore, pro-/prebiotics and synbiotics and fecal microbiota transplantation (FMT) may have a role in the prevention or treatment of some gastrointestinal diseases.

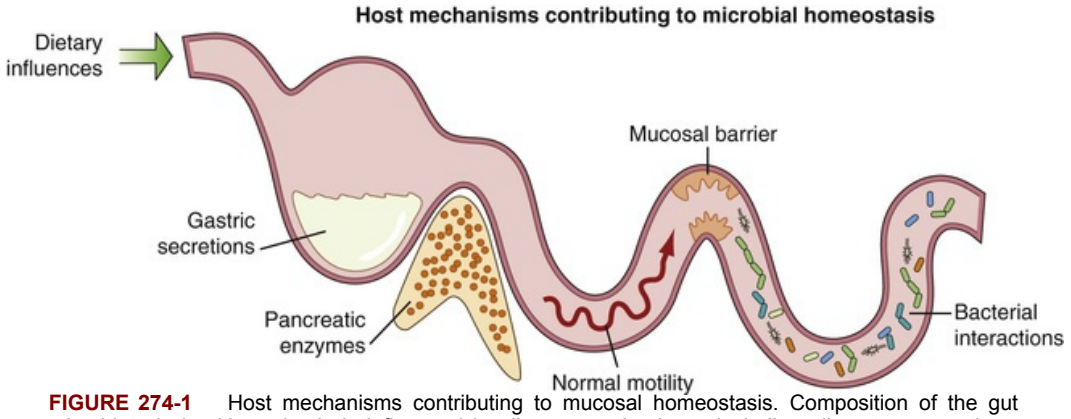

FIGURE 274-1 Host mechanisms contributing to mucosal homeostasis. Composition of the gut microbiota in healthy animals is influenced by diverse mechanisms, including alimentary secretions, gastrointestinal motility, mucosal barrier integrity, the gut-associated lymphoid tissue, and bacterial interactions.

Composition of the Microbiota in Healthy Animals

Colonization of the GI tract starts immediately after birth and occurs within a few days. Commensal bacteria appear to be acquired by opportunistic colonization by particular species as a result of random environmental encounters. These "first chance" bacteria can modulate expression of genes in host epithelial cells and create a favorable habitat for themselves while preventing growth of other bacteria introduced later. Contemporary culture-independent quantitative analyses of the fecal microbiota have shown that anaerobic bacteria outnumber aerobic bacteria by a factor of 100-1000.[1,2] These molecular techniques that focus on the 16S ribosomal RNA (rRNA) genes, which are common to all bacteria but whose precise sequences vary between species, can be used for identifying and classifying bacteria. Examples of this technology include the development of molecular probes for DNA microarrays, high throughput genomic sequencing (i.e., Illumina platform) for microbial abundance, fluorescence *in situ* hybridization (FISH) techniques to assess spatial distributions of mucosal microbiota, and gene chips that identify and enumerate specific bacterial species. Greater than 99% of the human gut microbiota is composed of species within 4 bacterial divisions: *Firmicutes, Bacteriodetes, Proteobacteria,* and *Actinobacteria.*[1,2,4] While the composition of the microbiota within adult humans appears to be relatively stable over time, there is a remarkable degree of inter-individual variation.

It is now realized that the composition of gut flora in healthy dogs and cats is distinctly different. Using traditional bacterial culture, healthy cats have been shown to have a large number of total and anaerobic bacteria in the proximal small intestine.[5,6] The most commonly isolated anaerobic bacteria comprised the genera *Bacteroides, Clostridia, Eubacteria,* and *Fusobacteria,* while *Pasteurella* spp. were the predominant aerobic species. A separate study showed that the canine duodenal microflora typically harbors a bacterial count $>10^5$ CFUs/mL of duodenal juice; however, significantly higher counts have been observed in some breeds and in dogs with no signs of intestinal tract disease.[7,8] Next-generation sequencing studies of the 16S rRNA gene have further defined the canine and feline microbiome, which on higher phylogenetic levels resembles the microbiome of humans and other mammals. On average, 10 different bacterial phyla have been identified in the healthy gut of dogs and cats, with *Firmicutes, Bacteroidetes, Proteobacteria, Fusobacteria,* and *Actinobacteria* comprising the majority of microbes found in feces.[9,10] Importantly, emerging studies now indicate that dietary intake also plays a pivotal role, potentially even greater than host genetics, in shaping intestinal microbial ecology.[11]

Investigation of the canine and feline metagenomes (i.e., shotgun sequencing of genomic DNA) has now provided recent and valuable insight into the functional capacity of the microbiota (Figure 274-2).[12,13] In spite of differences in the microbial populations of dogs and cats, the functional capabilities of these species appear to be highly conserved.

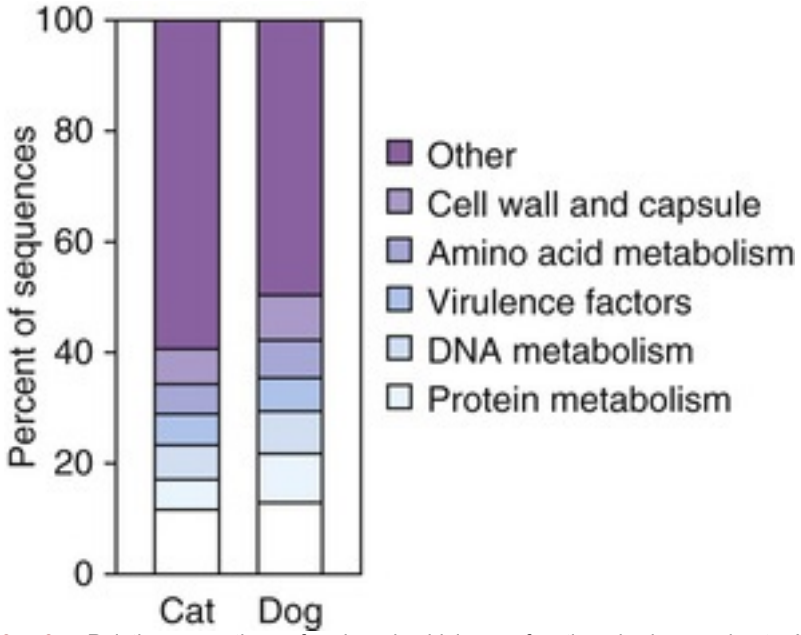

FIGURE 274-2 Relative proportions of major microbial gene functions in dogs and cats. Note that the functional capacity of the microbiota is quite similar between these mammalian species despite variation in their microbial populations. (From Honneffer JB, Minamoto Y, Suchodolski JS: Microbiota alterations in acute and chronic gastrointestinal inflammation of cats and dogs. *World J Gastroenterol*

Physiologic Microbial-Host Interactions

Comparative studies of germ-free and conventionally colonized animals have provided important information about the effect of the gut microbial community on host physiologic mechanisms and disease.

Metabolic Functions

A major metabolic function of the colonic microbiota is the fermentation of non-digestible dietary residues into short-chain fatty acids (SCFA) including acetate, propionate, and butyrate.[14] Butyrate is consumed almost completely by the colonic epithelium, where it serves as a major source of energy for colonocytes. Gene diversity within the microbial community provides the necessary enzymes and biochemical pathways for this purpose and that are distinct from the host's own resources. The outcomes of this complex metabolic activity are recovery of metabolic injury and absorbable substrates for the host, while supplying energy and nutrition for bacterial growth and proliferation. These resident bacteria can break down dietary carcinogens; synthesize biotin, folate, and vitamin K; metabolize bile salts; and assist in the absorption of calcium, magnesium, and iron.[15,16] Colonization increases glucose uptake in the gut, whereas germ-free mice require a greater caloric intake to maintain a normal body weight. It has been proposed that an individual's gut microbiota has a specific metabolic efficiency and differences in microbial composition might regulate energy storage and predispose to obesity in adults.[17]

Trophic and Protective Effects to Epithelium

Enteric bacteria confer numerous and diverse structural and protective effects on the intestinal epithelium.[1,2] Bacterial-induced expression of host genes influences nutrient uptake, metabolism, angiogenesis, mucosal barrier integrity, and the development of the enteric nervous system. Ligands from resident bacteria influence the normal development and function of mucosal immunity.[18,19] These indigenous bacteria educate the mucosal immune system and modulate the fine-tuning/regulation of T-cell repertoires and T-helper cell type 1 (Th1)/Th2 cytokine profiles. Along the epithelium, resident enteric bacteria form a natural barrier (biofilm) against colonization by exogenous microbes. Colonization resistance to pathogenic microbes involves numerous mechanisms including displacement, competition for nutrients and epithelial binding sites, and the production of antimicrobial substances such as lactic acids and bacteriocins.[20] It is noteworthy that the exposure of colonic epithelial cell lines with bacterial ligands enhances ZO-1-associated intestinal barrier integrity.[21]

Host-Microbiota “Cross-Talk” at the Mucosal Surface

Maintenance of mucosal homeostasis requires precise interpretation of the microenvironment to distinguish commensal bacteria from pathogenic microorganisms. Disruption of these processes might lead to inappropriate host immune responses and subsequent intestinal mucosal injury. The interaction between gut-associated lymphoid tissue and microbiota early in life appears to be crucial for appropriate development of complex mucosal and systemic immunoregulatory circuits. Various types of immunosensory cells actively sample commensal bacteria, pathogens, and other luminal antigens. These cells include surface enterocytes, M cells, and dendritic cells (DCs). Surface enterocytes are interconnected by tight junctions and are covered in mucus that promotes antigenic exclusion. They sense danger signals within the luminal microenvironment and respond by secreting defensins, immunoglobulin A, chemokines, and cytokines, which initiate and direct innate and adaptive immune responses.[1,22,23] M cells, which are specialized epithelial cells that overlie lymphoid follicles, sample luminal antigens and deliver their products to DCs and other antigen-presenting cells. Dendritic cells provide further immune surveillance via direct sampling of gut contents by either entering or extending dendrites between surface enterocytes.[24] Furthermore, DCs can ingest and retain live commensal bacteria and transport them to mesenteric lymph nodes, where immune responses to these bacteria might be produced locally.[25] Accordingly, the access of commensal bacteria to the internal host environment is prevented.

Mucosal Recognition of Bacteria

Immunosensory cells must rapidly recognize detrimental pathogenic microbes in the lumen to initiate controlled immune responses but maintain hyporesponsiveness to harmless commensal bacteria (i.e., oral tolerance). This discriminatory process largely is mediated by two major host pattern-recognition receptor (PRR) systems: the family of Toll-like receptors (TLRs) and the nucleotide-binding oligomerization domain (NOD1 and NOD2) molecules.[26] The TLRs comprise a class of transmembrane PRRs that play a key role in microbial recognition, induction of antimicrobial genes, and the control of adaptive immune responses. The NODs are a structurally distinct family of intracellular PRRs that exert antimicrobial activity and prevent pathogenic invasion. Both TLRs and NODs are widely expressed on various cell types of the GI mucosa and participate in host defense against microbial pathogens through: (1) recognition of molecular patterns present on pathogens; (2) expression at the interface with the "environment" of the GI tract; (3) induction of secretion of pro- and anti-inflammatory cytokines and chemokines that link to adaptive immunity; and (4) induction of antimicrobial effector pathways.[23] Thus, TLRs expressed by both non-epithelial cell types (e.g., macrophages, DC) and intestinal epithelial cells (e.g., TLR4 by LPS, and TLR5 by bacterial flagellin) play key functional roles in epithelial cell signaling of innate immune defense.[27]

Different TLRs selectively recognize different PRRs (i.e., each TLR binds specific "molecular signatures" of different classes of microorganisms) and initiates signaling through conserved pathways such as NFkB and mitogen-activated protein kinases (MAPK) signal transduction pathways.[4,26] These downstream effects involve transcriptional activation of genes encoding pro- and anti-inflammatory cytokines and chemokines as well as induction of co-stimulatory molecules.[28] In the healthy gut, TLR/NOD signaling promotes host defense and tissue repair responses, thereby maintaining mucosal as well as commensal homeostasis. This programmed response creates a chemotactic gradient for the entry of neutrophils, monocytes, and T-lymphocytes into the mucosa, which facilitates the clearance of invading pathogens. Conversely, intestinal disease can develop when commensal and/or mucosal homeostasis is/are impaired due to specific genetic (e.g., NOD2/CARD15 mutation in Crohn's disease) or environmental (e.g., dietary constituents, pathogenic infection, use of nonsteroidal anti-inflammatory drugs) triggers.[4,26,29] Therefore, bacterial mis-recognition and mucosal intolerance through aberrant TLR/NOD signaling stimulate exaggerated pro-inflammatory responses, leading to chronic inflammation via cytokine and chemokine production in genetically susceptible hosts.

Microbial Perturbations and Enteric Disease

Idiopathic Inflammatory Bowel Disease

Inflammatory bowel disease is a chronic, immunologically mediated intestinal disorder resulting from the complex interactions between environmental and immunologic factors in genetically susceptible hosts (see ch. 276).[30-32] There is abundant evidence that commensal bacteria are involved in the pathogenesis of human IBD and experimental colitis in animal models. Direct interaction of commensal microflora with the intestinal mucosa stimulates inflammatory activity of the gut lesions in human IBD.[4,30,33] Intestinal lesions also occur in anatomic regions of greatest luminal bacteria concentrations, such as the colon.[34] Flagellin derived from commensal bacteria has been identified as a dominant antigen in humans and dogs, suggesting that TLR5-dependent recognition of flagellin plays a role in immune responses to commensal microbiota observed in IBD.[35] Furthermore, mutations of NOD 2/CARD15 have been strongly associated with the development of Crohn's disease, implicating a role for PRR dysfunction and impaired bacterial sensing in IBD.[4,26,29] Animal models also suggest that the resident microbiota is a causative factor of IBD. In numerous different animal models, colitis and immune activation fail to develop in the absence of commensal bacteria.[1,2,4,30] Multiple animal models also respond to antibiotic therapy for their disease. Moreover, it has been shown that different bacterial species can cause different disease phenotypes in a single host, and that different bacterial species can provide the dominant stimuli for disease expression.[36]

Both clinical and research data indicate that resident microbiota likely play a pivotal role in driving the inflammatory process of companion animal IBD. A role for luminal bacteria is strongly suggested by observations that therapeutic levels of metronidazole and tylosin attenuate clinical disease in cats and dogs, respectively.[32,37] In separate studies, increased lamina propria myeloid/histiocyte antigen-positive macrophages,[38] upregulated epithelial MHC class II molecule expression,[39] and increased antibody reactivity

to components of the normal indigenous bacterial flora[40] have been associated with chronic intestinal inflammation of feline IBD. Furthermore, the numbers of mucosally associated *Enterobacteriaceae* have correlated with abnormalities in duodenal histology, upregulated mucosal cytokine mRNA, and the number of clinical signs in cats with IBD.[41] In separate studies, dogs with IBD have shown distinctly different duodenal microbial communities compared with healthy dogs,[42] and bacteria-responsive TLR2, 4, and 9 were upregulated in the inflamed duodenal and colonic mucosa of diseased dogs.[43] This might lead to increased inflammation through interaction with the commensal bacteria. Granulomatous colitis (GC, formerly histiocytic ulcerative colitis) in dogs now has been recognized to be associated with adherent/invasive *E. coli* (AIEC), wherein affected dogs respond to fluoroquinolone antimicrobial therapy.[44] Detailed phylogenetic studies have confirmed striking similarities between AIEC isolates obtained from Boxer dogs with GC and AIEC isolates derived from ileal tissues of humans with Crohn's disease.[45]

Antibiotic Responsive Diarrhea

Perturbations in the intestinal microbiota and/or dysregulated host responses to its components can cause chronic signs of diarrhea and weight loss (see ch. 276). Canine "small intestinal bacterial overgrowth" (SIBO) traditionally is defined on the basis of increased numbers of total or obligate anaerobic bacteria in duodenal juice, but controversy exists as to which bacterial quantities constitute normal.[46] While the numerical limits of bacteria found within asymptomatic dogs can vary (see above), there is general consensus that SIBO can occur secondary to exocrine pancreatic insufficiency, impaired clearance of bacteria (e.g., intestinal obstruction, motility disorder), or morphologic injury to the mucosa (e.g., infiltrative mucosal disease).[47] Little is known about the etiology of idiopathic SIBO in dogs and the term antibiotic-responsive diarrhea (ARD) has been proposed for antibiotic-responsive enteropathies without an underlying cause.[48,49]

Increased numbers of intestinal bacteria (i.e., SIBO) could cause malabsorption and diarrhea through: (1) competition for nutrients—the bacterial binding of cobalamin which impairs its intestinal absorption; (2) bacterial metabolism of nutrients into secretory products (e.g., hydroxylated fatty acids, deconjugated bile salts) that promote colonic secretions; and (3) biochemical injury to the intestinal brush border, which decreases enzyme activity.[49] Antibiotic-responsive diarrhea can develop secondary to disrupted barrier function, aberrant mucosal immunity, or qualitative changes in the enteric bacterial flora. Studies show that dogs with ARD can have selective IgA deficiency (German Shepherd breed) and increased mucosal CD4+ T cells and IgA plasma cells, which might reflect an underlying immunologic pathogenesis.[50] The microbiota present in ARD generally consists of a mixed population of commensal aerobes and anaerobes that normally inhabit the intestine.

Diagnostic criteria for differentiating SIBO from ARD remain ill-defined. Thorough diagnostic evaluations to eliminate other causes for GI signs should be performed. Due to the limitations of traditional quantitative bacteriology, indirect tests for SIBO/ARD, such as serum folate, cobalamin, and unconjugated bile acids concentrations, have been designed but are unreliable.[46,47] The current diagnostic test of choice for idiopathic ARD is remission of clinical signs following an antibiotic trial.

Infectious Gastroenteritis

Enteropathogenic bacteria can cause diarrhea in young and adult dogs and cats (see ch. 220). The bacteria most frequently incriminated in causing enterocolitis include *Clostridium perfringens, Clostridium difficile, Campylobacter* spp., pathogenic *E. coli,* and *Salmonella* spp.[51] The true prevalence of bacterially mediated diarrhea is confounded by the presence of many of these organisms existing as components of the normal intestinal flora. Nevertheless, diarrhea attributable to perturbation in the intestinal microbiota can result from microbe proliferation, enterotoxin production, and/or mucosal invasion. Information regarding the pathogenesis of *C. perfringens*-associated diarrhea is limited but the mechanism likely involves enterotoxigenic commensal isolates.[51] Administration of antimicrobials prior to admission, and administration of immunosuppressive drugs during hospitalization, were risk factors for hospital-associated colonization with *C. difficile* in one study.[52] Infection with *C. jejuni* is enhanced in crowded, unsanitary environments where its production of cytotoxin and heat-labile toxin promotes mucosal inflammation and fluid secretion, respectively. Much remains to be learned about the role of *Helicobacter* spp. infection in canine and feline chronic gastritis. Studies completed to date indicate that *Helicobacter* spp. are highly prevalent in healthy and sick dogs and cats, and that there is no simple relationship between infection and disease.[53,54]

Probiotics, Prebiotics, and Synbiotics

Bacteria can be used for improving GI health. ***Probiotics*** are living microorganisms that, upon ingestion in sufficient numbers, impart health benefits beyond those of inherent basic nutrition.[55] Lactobacilli and bifidobacteria have been the most commonly used human probiotics, but multi-strain cocktails (e.g., VSL#3), *E. coli* Nissle 1917, and nonbacterial *Saccharomyces boulardii* also have been used for their probiotic effects.[56,57] Probiotic bacteria confer measurable host benefits, including the ability to improve epithelial barrier function, modulate the mucosal immune system, and alter the intestinal microbiota (Figure 274-3). ***Prebiotics*** are non-digestible dietary carbohydrates—lactosucrose, fructo-oligosaccharides (FOS), psyllium, bran—that stimulate the growth and metabolism of endogenous enteric protective bacteria upon consumption.[58] Beneficial effects of prebiotics also are associated with the production of SCFA due to fermentation by colonic bacteria. ***Synbiotics*** are combinations of probiotics and prebiotics that are an emerging therapeutic modality. Increasing evidence supports a therapeutic role for probiotics, prebiotics, and synbiotics in GI diseases of humans, including infectious diarrhea, *H. pylori* infection, irritable bowel syndrome, lactase deficiency, and some forms of IBD.[1,2,59]

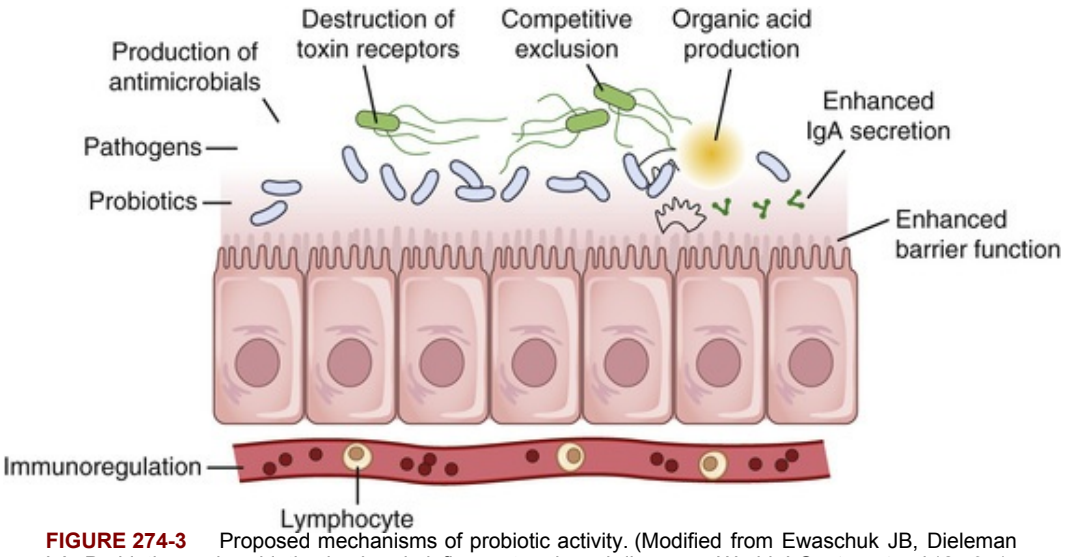

FIGURE 274-3 Proposed mechanisms of probiotic activity. (Modified from Ewaschuk JB, Dieleman LA: Probiotics and prebiotics in chronic inflammatory bowel diseases. *World J Gastroenterol* 12:5941-5950, 2006.)

Scientific studies have investigated the effects of dietary supplementation with prebiotics on the bacterial flora in healthy dogs and cats. In one study, FOS supplemented at 0.75% dry matter produced qualitative and quantitative changes in the fecal flora of healthy cats.[60] Compared with samples from cats fed a basal diet, increased numbers of lactobacilli and *Bacteroides* spp., and decreased numbers of *E. coli,* were associated with the FOS diet. However, bacteriologic examination of the duodenal juice in these same cats showed wide variation in the composition of the duodenal flora, across sampling periods, which was not affected by FOS supplementation.[61] Moreover, healthy Beagle dogs fed a 1% FOS diet in a 3-month trial showed inconsistent fecal excretion of *Lactobacillus* spp. and *Bifidobacterium* spp.[62]

There are only few reports on the use of probiotic bacteria in dogs and cats. Recent *in vitro* studies have confirmed the capacity of a lyophilized probiotic cocktail (e.g., three different *Lactobacillus* spp. strains) to modulate the expression of regulatory versus pro-inflammatory cytokines in dogs with chronic enteropathies.[63] However, a clinical trial using this same probiotic cocktail fed to dogs with food-responsive diarrhea failed to induce consistent patterns of regulatory (e.g., beneficial) cytokine expression despite obvious clinical improvement.[64] One commercially manufactured probiotic (FortiFlora—*Enterococcus faecium* SF68, Nestle Purina) is reported to be of potential benefit in controlling diarrhea and enhancing immune responses in dogs and cats.[65] More recently, human probiotic VSL#3 was shown to enhance clinical remission and reduce histopathologic inflammation in IBD dogs when administered continuously for 8 weeks.[66]

Fecal Microbiota Transplantation

Fecal microbiota transplantation (FMT) describes "the infusion of a fecal suspension from a healthy individual into the GI tract of an individual with colonic disease."[67] The rationale behind FMT includes the reintroduction of a complete, stable microbial community aimed at repairing or replacing the disrupted native microbiota to correct an underlying imbalance. It is assumed that microbiota repair eradicates or hinders pathogens, which could be causing specific GI disease, such as *Clostridium difficile* infection (CDI) colitis in humans.[67,68] Emerging evidence now implicates the intestinal microbiota in the pathogenesis of other non-GI disorders, including obesity, diabetes mellitus, autism, myasthenia gravis, and rheumatoid arthritis in human patients.

Only very sparse clinical data describe the use of FMT to treat chronic GI disease in dogs and cats, including CDI and idiopathic IBD. Formal practice guidelines for performing FMT currently are being designed but should include (1) the clinical indications for use of FMT, (2) proper donor screening procedures, (3) fecal material preparation, and (4) the possible routes of FMT administration (Table 274-1).[67] The link between the intestinal microbiota and GI health is now obvious, and physiologic manipulation of the intestinal microbiota represents an exciting therapeutic strategy for preventing and treating chronic GI inflammation.

TABLE 274-1

Practical Considerations for Fecal Microbiota Transplantation (FMT)

PARAMETER	CONSIDERATION
Donor selection	Breed—GI disease susceptible? Vaccination history Diagnostic screening for infectious agents Recent history of antibiotic use
Recipient preparation	Role of diet? Perform bowel lavage? Perform antibiotic trial prior to FMT?
Donor sample storage	Fresh versus frozen feces
Type of diluent	Saline versus water versus milk
Volume of stool required	≈60 grams feces in 250-300 mL diluent
Route of administration	Nasogastric/enteric versus colonoscopy

Practical guidelines for FMT are under review and have yet to be designed for dogs, cats, or even humans.

CHAPTER 275

Diseases of the Stomach

Kenneth W. Simpson

Functional Anatomy and Physiology

Overview

The stomach's main function is to act as a reservoir that controls the size and rate of passage of ingesta into the small intestine. The stomach also initiates the digestion of protein and fat and facilitates the absorption of vitamins and minerals.

Anatomically the stomach is composed of four regions: the cardia, fundus, body, and antrum (Figure 275-1). The fundus and body expand to accommodate ingesta. The antrum is thick and muscular and grinds food into small particles that are titrated into the duodenum. The lower esophageal sphincter prevents reflux of ingesta into the esophagus, and the pyloric sphincter controls efflux into the duodenum.

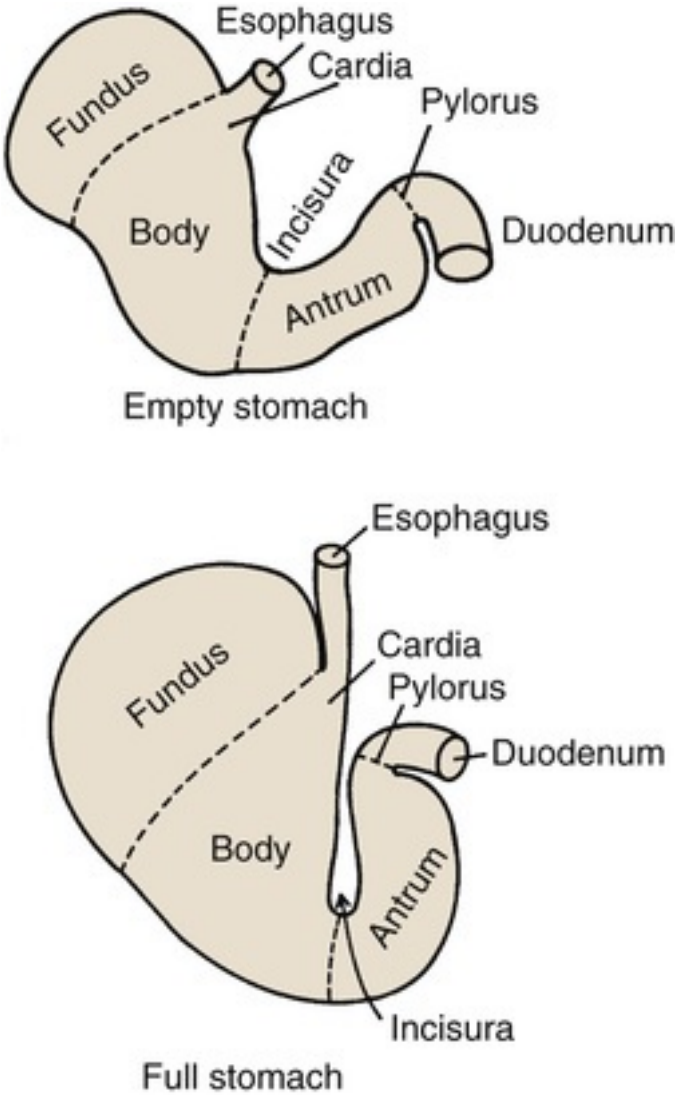

FIGURE 275-1 Gastric anatomy of the empty and full stomach. (From Guilford WG, Strombeck DR: Gastric structure and function. In Guilford WG et al, editors: *Strombeck's small animal gastroenterology*, ed 3, Philadelphia, 1996, Saunders, p 239.)

The gastric wall has three layers: the mucosa, muscularis, and serosa. The mucosa has a superficial epithelium, gastric glands, and an innermost layer of smooth muscle, with fine structure and function varying depending on the gastric region. The mucosa in the cardia and pylorus is thinner and less glandular than in the fundus and body. The mucosa of the body contains mucous neck cells (pepsinogen A, gastric lipase), parietal cells (acid, pepsinogen A, intrinsic factor), and chief cells (pepsinogen A; Figure 275-2).[1-3] A variety of neuroendocrine cells involved with the secretion of gastric acid are interspersed between the glands. The predominant cells are enterochromaffin-like and somatostatin-producing cells in the fundus with gastrin and somatostatin-producing cells in the antrum. Localized small aggregates of lymphoid tissues are observed at the base of the gastric glands. Intertwined among gastric glands is a rich network of blood vessels, lymphatics, and nerves. Beneath the submucosa are two layers of smooth muscle that run perpendicular to each other. The serosa is the outermost layer.

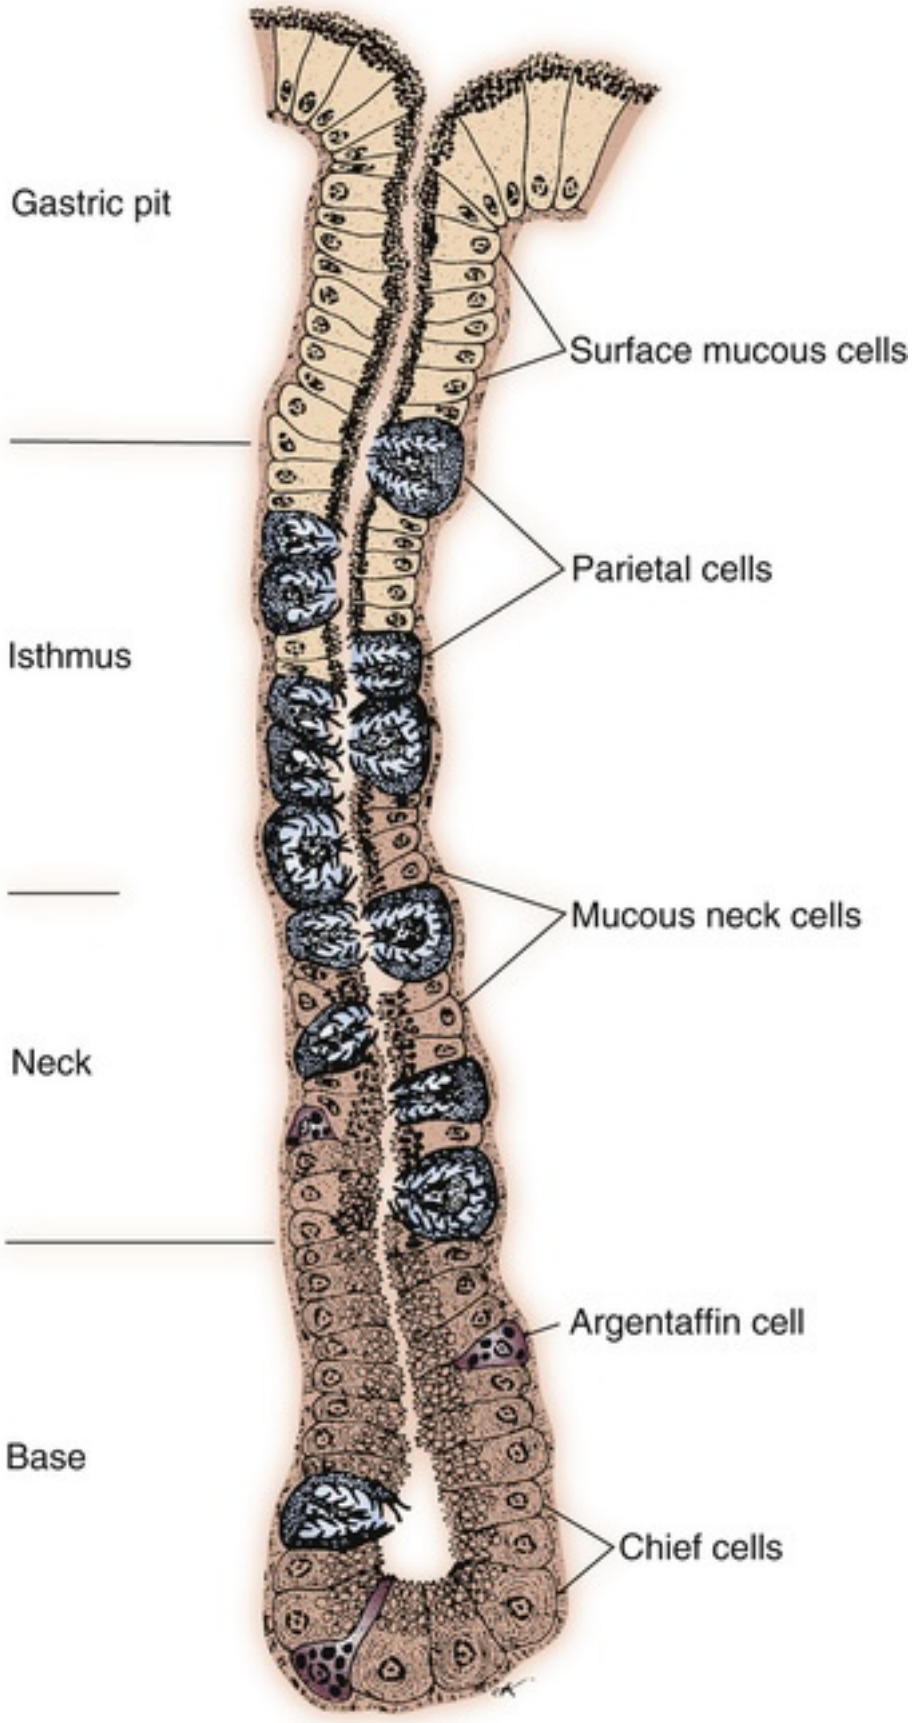

FIGURE 275-2 Histologic appearance of the fundic mucosa. (© Kenneth W. Simpson.)

Regulation of Acid Secretion

Acid secretion is regulated by a variety of neurochemical and neurohumoral stimuli.[4,5] Luminal peptides, digested protein, acetylcholine, and gastrin-releasing peptide stimulate gastrin secretion from G cells and effect histamine release from enterochromaffin-like cells (Figure 275-3). Histamine release from mast cells and binding of acetylcholine and gastrin to parietal cells also contribute to secretion. Somatostatin, released in response to gastric pH levels below 3, decreases gastrin, histamine, and acid secretion.

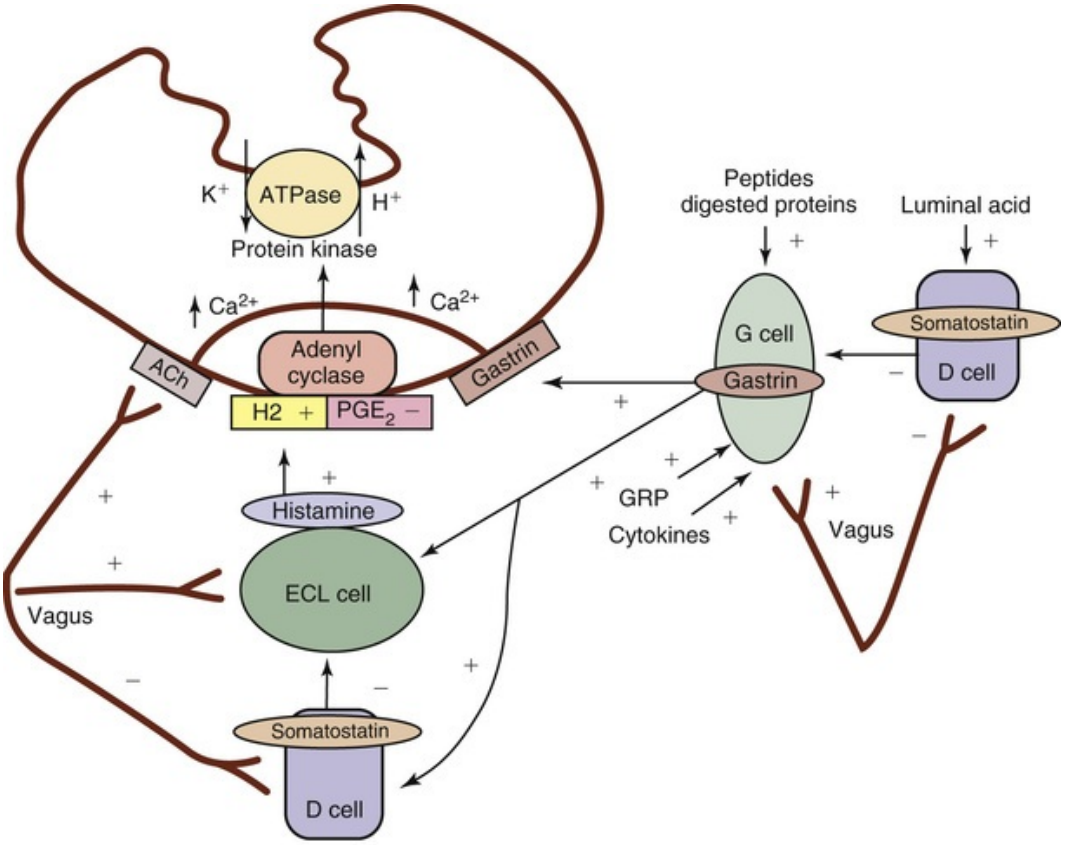

FIGURE 275-3 Regulation of acid secretion. *ACh*, Acetylcholine receptor; *ECL*, enterochromaffin-like cell; *GRP*, gastrin-releasing peptide; *H2*, histamine H2 receptor; *PGE*, prostaglandin E_2 receptor. (Modified from Simpson KW: In DiBartola SP, editor: *Fluid, electrolyte, and acid-base disorders in small animal practice*, ed 4, Philadelphia, 2012, Saunders.)

Unstimulated acid secretion in dogs and cats is minimal (in dogs, <0.04 mmol/kg$^{0.75}$/h)[6] and H^+/K^+-ATPase, "the acid pump," is present in tubulovesicles within the cytoplasm of parietal cells.[7] In the stimulated state, H^+/K^+-ATPase and KCl transporters are incorporated into the parietal cell canalicular membrane; hydrogen ions, derived from the ionization of water within the parietal cells, are transported into the gastric lumen in exchange for K by H^+/K^+-ATPase. Potassium and chloride transporters in the canalicular membrane enable luminal transfer of potassium and chloride. OH^- combines with CO_2, catalyzed by carbonic anhydrase, to form HCO_3^-, which diffuses into the blood (the "alkaline tide"). Stimulation results in a rapid increase in fluid and hydrogen ion secretion, with pH rapidly declining to around 1. The concentrations of K^+ (10 to 20 mmol/L) and Cl^- (approximately 120 to 160 mmol/L) in gastric juice are higher than in plasma.

The stomach is protected from gastric acid by a functional unit known as the *gastric mucosal barrier* (GMB).[8-10] The GMB comprises tightly opposed epithelial cells coated with a layer of bicarbonate-rich mucus and an abundant mucosal blood supply that delivers bicarbonate, oxygen, and nutrients. Local production of

prostaglandins (PGE_2) is important in modulating blood flow, bicarbonate secretion, and epithelial cell renewal. When damage occurs, epithelial cells rapidly migrate over superficial mucosal defects aided by the local production of growth factors such as EGF (epidermal growth factor).

Gastric Motility

Normal gastric motility is the result of the organized interaction of smooth muscle with neural and hormonal stimuli. The rate of gastric emptying is determined by the difference in pressure between the stomach and the duodenum and the resistance to flow across the pylorus. Liquids are expelled more rapidly than solids, and the rate of expulsion of liquids increases with volume. The rate of expulsion of solids depends on caloric density. In dogs, digestible solids <2 mm in size are emptied into the duodenum. Gastric emptying is modulated via intestinal osmoreceptors and chemoreceptors. Carbohydrates, amino acids, and especially fats, retard gastric emptying. The release of cholecystokinin (CCK) in response to fatty acids and amino acids, such as tryptophan, is one factor that slows gastric emptying. Large, undigestible solids are expelled from the stomach in the fasted state by phase III of the migrating motility complex in response to the release of motilin.

Digestion and Assimilation of Nutrients

The stomach has a limited role in the digestion of proteins, fats, and micronutrients. Pepsin, which digests proteins, is secreted as pepsinogen in response to acetylcholine and histamine in tandem with gastric acid. Dog gastric lipase, which digests fat, is secreted in response to pentagastrin, histamine, prostaglandin E_2, and secretin and parallels the secretion of gastric mucus. Although pepsin is active only at acid pH, dog gastric lipase remains active in the small intestine and constitutes up to 30% of total lipase secreted over a 3-hour period.[11] Although gastric lipase and pepsin are not essential for the assimilation of dietary fat and protein, the entry of peptides and fatty acids into the small intestine likely helps to coordinate gastric emptying and pancreatic secretion. Intrinsic factor, necessary for cobalamin (vitamin B_{12}) absorption, is produced by parietal cells and cells at the base of antral glands in the dog but not the cat.[1,12] The importance of gastric intrinsic factor secretion is questionable, as the pancreas is the major site of secretion in both dogs and cats. Gastric acidity may also have an effect on the availability of minerals such as iron and calcium.

Gastric Flora

The concept of gastric contents being sterile was altered when the gastric bacterium *Helicobacter pylori* was isolated from the stomach of people in 1983.[13] The stomach in dogs and cats also harbors a diverse spectrum of large, spiral, acid-tolerant *Helicobacter* species and a variety of aerobes and anaerobes that may play a role in development of gastritis or even cancer (see Chronic Gastritis). A mixed flora of aerobes and anaerobes (approximately 10^6 to 10^7 CFU/mL) is established soon after birth in dogs and colonization with *Helicobacter* spp., which are likely acquired from the dam, has been documented as early as 6 weeks of age.[14] *Helicobacter* spp. are adapted to life in an acid environment and produce urease that catalyzes the formation of ammonia from urea to buffer gastric acidity. Other bacterial species cultured from the canine stomach *(Proteus, Streptococcus, Lactobacillus)* may transiently increase after a meal or after coprophagia.[15] The application of contemporary molecular methods for identifying bacteria has demonstrated the majority of the sequences in healthy Beagle stomachs belong to Proteobacteria (99.6%) with only a few Firmicutes (0.3%). The Proteobacteria included the genus *Helicobacter* (98.6%) in gastric biopsies, consistent with previous *in situ* based analyses.[15-18] Acid secretion and gastric emptying likely regulate much of this transient flora, and bacteria may proliferate in the event of gastric acid hyposecretion due to glandular atrophy or pharmacologic inhibition. Pyrosequencing of 16S rRNA gene amplicons (V1-V3 region) revealed a decrease in *Helicobacter* spp. during omeprazole administration (median 92% of sequences during administration compared to >98% before and after administration; $P = 0.0336$), which was accompanied by higher proportions of Firmicutes and Fusobacteria. Fluorescence in situ hybridization (FISH) confirmed this decrease in gastric *Helicobacter* ($P < 0.0001$) and showed an increase in total bacteria in the duodenum ($P = 0.0033$) during omeprazole administration.[15] From a diagnostic standpoint, it is important to realize that bacteria such as *Escherichia coli* and *Proteus* spp. produce urease that can lead to a false positive test result for *Helicobacter* spp.

Clinical Evaluation of Diseases of the Stomach

Overview

Gastric disease is usually the result of inflammation, ulceration, neoplasia, or obstruction. It manifests clinically as vomiting (see ch. 39), hematemesis, melena (see ch. 41), retching, burping, hypersalivation, abdominal distension (see ch. 17), abdominal pain, or weight loss (see ch. 19). The clinical approach can be simplified by considering gastric diseases as a group of clinical syndromes based on the combination of etiology, pathology, and clinical presentation (Table 275-1). Because a large and varied group of nongastric disorders can cause similar clinical signs, a systematic approach is essential to determine whether primary gastric disease is the cause. The diagnostic approach initially focuses on historical and physical findings, with clinicopathologic testing and diagnostic imaging employed in patients with systemic involvement or chronic signs (Figure 275-4).

TABLE 275-1

Diseases of the Stomach

CLINICAL SYNDROME	PREDOMINANT FEATURES
Acute gastritis	Sudden onset of vomiting
Ulceration or erosion	Vomiting, hematemesis, melena, ± anemia
Gastric dilatation/volvulus	Nonproductive retching, abdominal distension, tachycardia
Chronic gastritis	Chronic vomiting of food or bile
Delayed gastric emptying	Acute to chronic vomiting more than 8-10 hours after feeding
Neoplasia	Chronic vomiting, weight loss, ± anemia

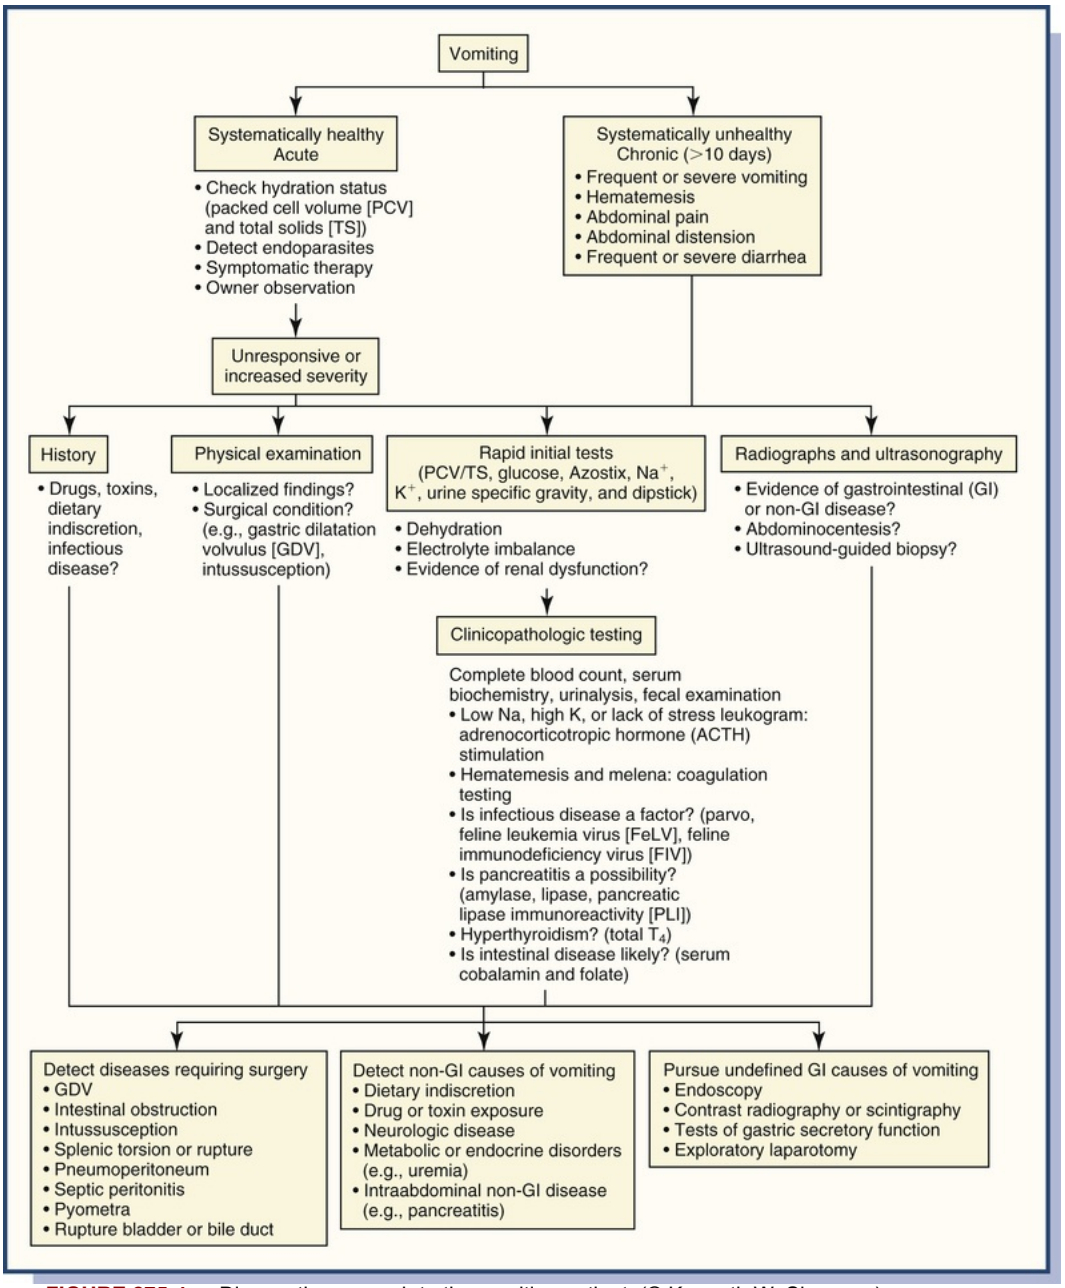

FIGURE 275-4 Diagnostic approach to the vomiting patient. (© Kenneth W. Simpson.)

Signalment, History, and Physical Examination

Age and breed can be helpful in diagnosis of certain gastric disorders. Young dogs are more likely to ingest foreign bodies or to suffer from outflow obstruction caused by *Pythium insidiosum*, whereas gastric cancer is typically encountered in much older dogs and cats. Gastric dilatation and volvulus are typically encountered in giant breeds and dogs with deep chests, such as Great Danes and Irish Setters. There are also breed predispositions to hypertrophic gastropathy (Drentse Patrijshond, Basenji, Shih Tzu), atrophic gastritis (Lundehund), and gastric cancer (e.g., Belgian Shepherd, Rough Collie, Staffordshire Bull Terrier, Beagle, Lundehund). Vomiting is the principal clinical sign of gastric disease (see Table 275-1) and a major objective of the history is to distinguish vomiting from regurgitation (active abdominal effort, presence of bile; see ch. 39). One should attempt to obtain information regarding duration, frequency, contents, color, progression, and relation to eating. Where vomiting cannot be adequately distinguished from regurgitation, it is important to observe episodes. One should request that the owner video episodes at home. Where regurgitation remains a possibility, a video will help. Also, thoracic radiographs can be used to detect esophageal dilatation or

obstruction.

A thorough review of the environment, including whether the animal lives indoors or outdoors, in a single or multi-animal household, with access to foreign bodies, toxins or medications, the vaccination status, body systems (attitude, mentation, presence of polyuria, polydipsia, weight loss, diarrhea, coughing, sneezing, exercise tolerance), past medical history, and physical examination all help to discriminate nongastric from gastric causes of vomiting. Physical examination is often unremarkable in pets with primary gastric disease. Abdominal distension may be detected in animals with gastric dilatation/gastric dilatation and volvulus (GD/GDV) or delayed gastric emptying. Abnormal perfusion, hydration status, temperature, respiratory rate, mucosal pallor, and abdominal pain often accompany diseases such as GD/GDV, gastric outflow obstruction, ulceration, and perforation. Historical and physical findings are integrated to determine whether the patient is systemically well or unwell, and clinical signs may be acute, chronic, mild, or severe (see Figure 275-4).

Non-productive vomiting, retching, and abdominal distension in deep-chested, large-breed dogs are frequently associated with GD/GDV, which requires rapid diagnosis and treatment (see ch. 143 and 144). The presence of fresh or digested blood ("coffee grounds") in vomitus, with or without melena, raises the possibility of gastric ulcers or erosions. Vomiting of food >8-10 hours after ingestion suggests delayed gastric emptying, requiring discrimination of gastric outflow obstruction from defective gastric propulsion. Weight loss is infrequently associated with gastric disease but can accompany cancer, fungal infections, outflow obstruction, and gastropathies that are part of a more generalized disease process, such as Basenji and Lundehund gastroenteropathy. If vomiting is acute and the animal is systemically well, with no historical or physical "red flags," further diagnostic testing is often postponed in favor of symptomatic therapy. If the pet is systemically unwell or has significant historical or physical abnormalities, the emphasis is on efficiently identifying conditions that require surgical intervention, such as gastric dilatation and septic peritonitis, and ruling out nongastrointestinal causes of vomiting before proceeding to more specialized or invasive diagnostic procedures aimed at detecting primary gastric and intestinal disorders (see Figure 275-4).

Clinicopathologic Testing

Clinicopathologic testing helps to differentiate primary gastrointestinal (GI) disease from non-GI disease and to ascertain the metabolic consequences of GI disease (see ch. 39). Blood and urine samples should be obtained prior to treatment. In sick pets, rapid evaluation of microhematocrit (PCV), total solids (TS), blood glucose, blood urea nitrogen (BUN), urine specific gravity, glucose, ketones and protein, and plasma concentrations of sodium (Na) and potassium (K) help detect life-threatening diseases: e.g., renal failure (azotemia, isosthenuria; see ch. 322 and 324) and hypoadrenocorticism (see ch. 309), and to guide initial therapy pending more definitive testing.

Abnormalities in complete blood count (CBC) are infrequent with primary gastric disease. Hemoconcentration as a consequence of dehydration or shock frequently accompanies GDV, gastric perforation, or gastric obstruction. The combination of a hematocrit level greater than 55% and normal or decreased protein concentrations is encountered in dogs with hemorrhagic gastroenteritis, which has recently been associated with the proliferation of *Clostridium* spp. and the elaboration of a necrotizing toxin, netF (see ch. 276).[19,20] Anemia, RBC microcytosis, and thrombocytosis may be present in dogs with chronic gastric bleeding. Drentse Patrijshond dogs can have familial stomatocytosis-hypertrophic gastritis. Basophilic stippling of red cells suggests lead toxicosis. Biochemical abnormalities in primary gastric disease are usually restricted to alterations in electrolytes and acid-base balance, pre-renal increases in creatinine and BUN, and occasionally hypoproteinemia.

Vomiting of gastric and intestinal contents usually involves the loss of chloride (Cl), K, Na, and bicarbonate-containing fluid. Dehydration is variably accompanied by decreases in Na, K, and Cl.[21,22] Determination of acid-base status by assessing total CO_2 or venous blood gas analysis enables recognition of metabolic acidosis or alkalosis (see ch. 128). Metabolic acidosis is generally more common than metabolic alkalosis in dogs with GI disease.[21] Where the gastric outflow tract or proximal duodenum is obstructed, the loss of Cl may exceed that of bicarbonate, with decreases in Cl and K, and alkalosis.[21-23] The metabolic alkalosis is enhanced by retained HCO_3^- due to volume, K and Cl depletion.[24] The net effect is a preferential conservation of volume at the expense of the extracellular pH. The renal reabsorption of almost all filtered bicarbonate and the exchange of sodium for hydrogen in the distal tubule promote an acid urine pH despite an extracellular alkalemia ("paradoxical aciduria").[24,25] Metabolic alkalosis in patients with GI signs is not invariably associated with outflow obstruction and has been encountered in dogs with parvovirus enteritis and acute pancreatitis.[26] Diseases characterized by acid hypersecretion, such as gastrinoma, may also be

associated with metabolic alkalosis and aciduria. Basal gastric acid secretion in two dogs with gastrin-producing tumors (1.7 and 2.7 mmol/h/kg$^{0.75}$ HCl) was maximal in the unstimulated state.[21] In this situation, hypochloremia, hypokalemia, metabolic alkalosis, and dehydration are likely due to the hypersecretion of gastric acid and its loss in vomitus.[27] Venous blood gases and plasma osmolality are often determined in animals suspected of ethylene glycol ingestion, with the findings of metabolic acidosis and a high osmolal gap (calculated by subtracting calculated from measured osmolality) supportive of ingestion (see ch. 152).

Elevated BUN in the absence of elevated creatinine is consistent with gastric bleeding. Low albumin may be detected in Basenji or Lundehund dogs with protein-losing gastroenteropathy, dogs with pythiosis, and dogs or cats with gastric neoplasia. Increased globulin concentrations have been observed in Basenji gastroenteropathy, *Pythium* infection, and gastric plasmacytoma. Elevations in creatinine, urea, calcium (Ca), K, glucose, liver enzymes, bilirubin, cholesterol, triglycerides, and globulin and decreases in Na, Ca, urea, or albumin frequently herald non-GI causes of vomiting.

Urine should be evaluated for specific gravity, pH, glucose, casts, crystals, and bacteria. Thorough urinalysis is important; for example, white cell casts in the urine may be the only evidence that pyelonephritis is the cause of vomiting (see ch. 72). Coagulation testing is indicated in patients with melena or hematemesis to detect underlying coagulopathies and in those with acute abdomen to detect disseminated intravascular coagulopathy (DIC; see ch. 196). Infectious diseases associated with vomiting and diarrhea require fecal examination for diagnosing *Giardia,* endoparasites, *Salmonella* spp., *Campylobacter* spp., and parvovirus (ELISA) or serologic testing (feline leukemia virus [FeLV], feline immunodeficiency virus). Additional tests to confirm hypoadrenocorticism (ACTH stimulation), liver dysfunction (pre- and post-prandial bile acids), hyperthyroidism (T_4), pancreatitis (ultrasound and various tests [see ch. 289-291]), and intestinal disease (serum cobalamin and folate; see ch. 276). In dogs with GDV, assessing serum lactate (see ch. 70 and 144) at the time of admission and its response to therapy may help in determining prognosis and need for aggressive therapy.[28-30]

Imaging

Abdominal Radiography

Survey radiographs are the test of choice when initially evaluating gastric disease, vomiting, or abdominal pain. Radiographs provide information on gastric position and contents that may help to identify GD/GDV, foreign bodies, and gastric outflow obstruction. They also enable evaluating the size and shape of the liver, kidneys, and spleen as well as aiding in detection of intussusception, peritonitis, pneumoperitoneum, and changes suggestive of pancreatitis. Contrast radiographs may provide further information when survey radiographs are inconclusive. However, the combination of ultrasonography (US) and endoscopy is generally more effective for detecting obstructive, inflammatory, and neoplastic GI disorders than contrast radiographs. Use of contrast radiography is often limited to investigating delayed gastric emptying associated with defective propulsion or "functional" intestinal disorders.[31]

Abdominal Ultrasound (US), Contrast Studies, Fluoroscopy

US can be employed to evaluate gastric wall thickness, wall layering and gastric emptying (see ch. 88). US is less accurate than endoscopy for the detection of gastric neoplasia, particularly lymphoma, but it can increase suspicion of gastric lesions and facilitate detection of non-gastric lesions in pets with signs of GI disease.[32,33] When US and endoscopy are not available, distension of the stomach with air (negative contrast) may reveal gastric thickening, masses, or foreign bodies. Positive contrast with barium sulfate can provide further information and is also used to evaluate patency of the gastric outflow tract. The combination of fluoroscopy and positive contrast is helpful for evaluating pyloric patency and gastric emptying. In the absence of endoscopy and US, contrast radiography can be followed by surgical biopsy to achieve a definitive diagnosis.

Endoscopy

Endoscopy (see ch. 113) enables direct visualization and biopsy of the stomach and duodenum and is the best method for diagnosing primary gastric inflammation, ulceration, or neoplasia; removing small foreign bodies; and evaluating patients prior to quantification of gastric emptying. It does not provide good information on submucosal lesions or functional disorders. With mural thickening or gastric masses, endoscopic biopsies are often not deep enough to obtain target tissue and surgical biopsy is required. Recent advances in endoscopic

imaging such as confocal endomicroscopy and chromoendoscopy may help distinguish chronic inflammation from neoplasia.[34] Equipment, its care, techniques, and photographs of a wide range of GI lesions are presented in ch. 83 and 113.[35,36]

The requirement for general anesthesia frequently precludes use of upper GI endoscopy in unstable pets with signs of gastric disease (e.g., hematemesis). The advent of wireless capsule endoscopy has revolutionized non-invasive imaging of the human upper GI tract. Preliminary studies in dogs show it is useful for identifying mucosal lesions in the gastric fundus, pylorus, and small intestine associated with parasitism or gastrointestinal bleeding.[37-39]

Evaluation of Gastric Emptying

Procedures and tools used to evaluate gastric emptying include barium contrast (liquid or mixed with food), barium-impregnated polyspheres, nuclear scintigraphy, the ^{13}C-octanoate and ^{13}C-acetate breath tests, and wireless motility and endoscopy capsules.[37,40-44] Tests of gastric emptying are often used to confirm a suspicion of delayed gastric emptying in patients with normal or equivocal survey radiographs. They are also used where gastric outflow obstruction and obvious causes of defective propulsion have been ruled out prior to and after prokinetic drugs. The limitations and benefits of these approaches are discussed under Delayed Gastric Emptying and Motility Disorders.

Gastric Secretory Testing

Gastric secretory testing is primarily performed in patients with esophagitis, GI ulceration, mucosal hypertrophy, or copious amounts of gastric fluid when acid hypersecretion is suspected. In its simplest form, fasting gastric pH and serum gastrin are measured to determine whether acid hypersecretion is likely (see ch. 273). Anti-secretory therapy should be discontinued for 48 hours prior to testing. Renal and hepatic dysfunction must be ruled out, as either condition can cause increases in circulating gastrin concentrations. The broad range of fasting, unstimulated gastric pH in dogs and cats (pH 1 to 8) makes definitive statements regarding acid production difficult. However, the presence of a gastric pH of <3 with concurrent increases in serum gastrin concentrations rules out the possibility of achlorhydria or mast cell tumor and raises the possibility of gastrinoma.[27] Dogs with mast cell tumors and hyperhistaminemia-induced acid hypersecretion have low serum gastrin concentrations. Dogs with achlorhydria likely have increased gastrin concentrations but a gastric pH >3.[45] Measurement of serum gastrin concentrations after IV infusion of secretin or Ca is used to further investigate the possibility of exogenous gastrin production by pancreatic tumors (gastrinomas; Zollinger-Ellison syndrome; see ch. 310). Basenji dogs with gastroenteropathy and diarrhea have been reported to have enhanced gastrin release in response to secretin stimulation without evidence of gastrinoma.[46] Provocative testing of gastric acid secretion with pentagastrin or bombesin stimulation may be performed to detect achlorhydria in patients with atrophic gastritis, or elevated serum gastrin and gastric pH >3, to determine if achlorhydria is contributing. Pentagastrin-stimulated acid secretion in dogs reaches a peak of 28 mL/kg$^{0.75}$/h, 4.1 mmol HCl/kg$^{0.75}$/h, 0.34 mmol K^+/kg$^{0.75}$/h, and 0.09 Na^+ mmol/kg$^{0.75}$/h.[6] Sedation with oxymorphone and acepromazine is an alternative to anesthesia for secretion studies in dogs.[28] In cats, acid output (mean ± SD) in response to pentagastrin (8 mcg/kg/h) ranges from pH 0.9 to 1.1, with secretion rates (median values) of 1.2 mmol/15 min to 1.4 ± 0.5 mmol/15 min in conscious cats and 1.2 (0.6 to 2.7) mmol/kg$^{0.75}$/h in anesthetized cats.[47] The development of telemetric pH systems may facilitate the non-invasive evaluation of gastric pH in dogs suspected of hypo- and hyper-secretion of gastric acid.[48,49]

Acute Gastritis

Definitions

Acute gastritis is the term applied to the syndrome marked by vomiting of sudden onset presumed to be due to a gastric mucosal insult or inflammation (Box 275-1). In most pets the cause is inferred from the history, such as dietary indiscretion; the diagnosis is rarely confirmed by biopsy, and treatment is symptomatic and supportive (see ch. 39). Animals with acute gastritis associated with drug intoxication, foreign body ingestion, or metabolic disorders frequently have hematemesis, melena, concurrent diarrhea, or other signs of systemic illness, requiring a thorough diagnostic approach to determine the cause and provide optimal care. There is little evidence to support a role of viral infections (parvovirus, distemper, infectious canine hepatitis) in acute

gastritis.

Box 275-1

Causes of Acute Gastritis

Dietary indiscretion or intolerance (nonallergic and allergic)
Foreign bodies (bones, toys, hairballs)
Drugs and toxins (nonsteroidal anti-inflammatory drugs, corticosteroids, heavy metals, antibiotics, plants, cleaners, bleach)
Systemic disease (uremia, liver disease, hypoadrenocorticism)
Parasites (*Ollulanus, Physaloptera* spp.)
Bacteria (bacterial toxins, *Helicobacter*)
Viruses

Clinical Findings and Diagnosis

Vomiting of sudden onset is the principal clinical sign of acute gastritis. In some instances it is accompanied by hematemesis or melena and variable degrees of systemic illness. The history may reveal access to or ingestion of spoiled food, garbage, toxins, medications, or foreign bodies. Signs of toxicosis may be evident, such as jaundice and pallor with zinc ingestion, salivation or defecation with organophosphate toxicosis or mushroom ingestion, and salivation and oral ulceration with chemical ingestion. A diagnosis of acute gastritis is usually based on these clinical findings and response to symptomatic treatment. A specific diagnosis may be sought if the pet had access to foreign objects or toxins, is systemically unwell, or has hematemesis, melena, or vomiting that fails to respond to symptomatic therapy, or other signs of more serious disease. Laboratory testing in most animals with primary acute gastritis reflects mild dehydration and is often not performed in the absence of a suspicion of more serious disease. Abdominal radiographs can be taken to detect foreign objects or GI obstruction. Further diagnostics, such as ultrasonography and endoscopy, are rarely indicated; most animals with simple gastritis respond to symptomatic therapy.

Treatment

Fluid Therapy

Fluid given orally, in small amounts, little and often, can be given to pets who are vomiting, with the volume increasing as vomiting subsides. Giving SC isotonic balanced electrolyte solutions may be sufficient to correct mild fluid deficits (<5%) but is insufficient for moderate to severe dehydration. Pets requiring IV fluids (see ch. 129) should undergo a more extensive diagnostic evaluation.

Dietary Restriction and Modification

When vomiting is acute, oral intake is discontinued for at least 24 hours. Small amounts of a liquid diet can be offered despite vomiting to maintain GI barrier function and to determine whether vomiting has resolved. A homemade non-spicy, fat-restricted, bland diet (e.g., boiled chicken and rice, low-fat cottage cheese, and rice [1 : 3]) or a commercial fat-restricted, rice-based diet can then be introduced, giving little and often with a gradual transition made back to a normal diet over a week or so.

Protectants/Adsorbents

Bismuth subsalicylate, kaolin-pectin, activated charcoal and magnesium, and aluminum- and barium-containing products are often administered to pets with acute vomiting or diarrhea to bind bacteria and their toxins and to coat the GI mucosa. These agents are probably safer and more efficacious than antibiotics or motility modifiers in acute gastroenteritis. Bismuth subsalicylate (Pepto-Bismol 1 mL/5 kg PO q 8 h), bismuth subcitrate, kaolin-pectin (1 to 2 mL/kg PO q 8 h), and sucralfate (0.25 to 1 g PO q 8 h) are often employed. Acid-reducing drugs such as H2-receptor antagonists can be administered but are usually reserved for those with signs of gastric erosion or ulceration (melena, hematemesis) or persistent gastritis as described below. In general, antiemetics should not be given to pets with acute gastritis to avoid masking response to therapy. Patients who continue to vomit require further investigation.

Prognosis

The prognosis for uncomplicated acute gastritis is usually complete recovery.

Gastric Erosion and Ulceration

Definitions and Causes

Gastric erosions and ulcers are associated with a number of primary gastric and non-gastric disorders (Table 275-2). Clinical signs range in duration and severity, from acute to chronic and from mild to life threatening. The pathomechanisms underlying gastric damage can be broadly attributed to impairment of the GMB (defined above) through direct injury, interference with gastroprotective prostaglandins (PGE_2), mucous or bicarbonate, decreased blood flow, and hypersecretion of gastric acid. Perhaps the most predictable cause for gastric erosion and ulceration is use of a nonsteroidal anti-inflammatory drug (NSAID) or a glucocorticoid, either alone or in combination with intervertebral disc disease.[50] NSAIDs cause direct mucosal damage and may interfere with prostaglandin synthesis.[9] Flunixin meglumine, aspirin, and ibuprofen cause gastric erosions and ulcers in healthy dogs (Figure 275-5).[51] Giving anti-inflammatory agents is also considered a significant risk for gastric perforation in dogs and cats.[52,53] High doses of glucocorticoids alone, such as dexamethasone and methylprednisolone, have caused gastric erosions, but the mechanisms by which they induce damage are not clear.[60] Unlike NSAIDs, their effects are not ameliorated by PGE_2 analogs.[61]

TABLE 275-2

Association of Gastric Ulceration and Erosion with Specific Diseases

GASTRIC PROBLEM	RELATED DISEASES
Metabolic/Endocrine	Hypoadrenocorticism, uremia, liver disease, mastocytosis, DIC, hypergastrinemia and other APUDomas
Inflammatory	Gastritis
Neoplastic	Leiomyoma, adenocarcinoma, lymphoma
Drug-induced	Nonsteroidal and steroidal anti-inflammatories
Hypotension	Shock, sepsis
Idiopathic	Stress, spinal surgery, exercise-induced (sled dogs)

DIC, Disseminated intravascular coagulopathy.

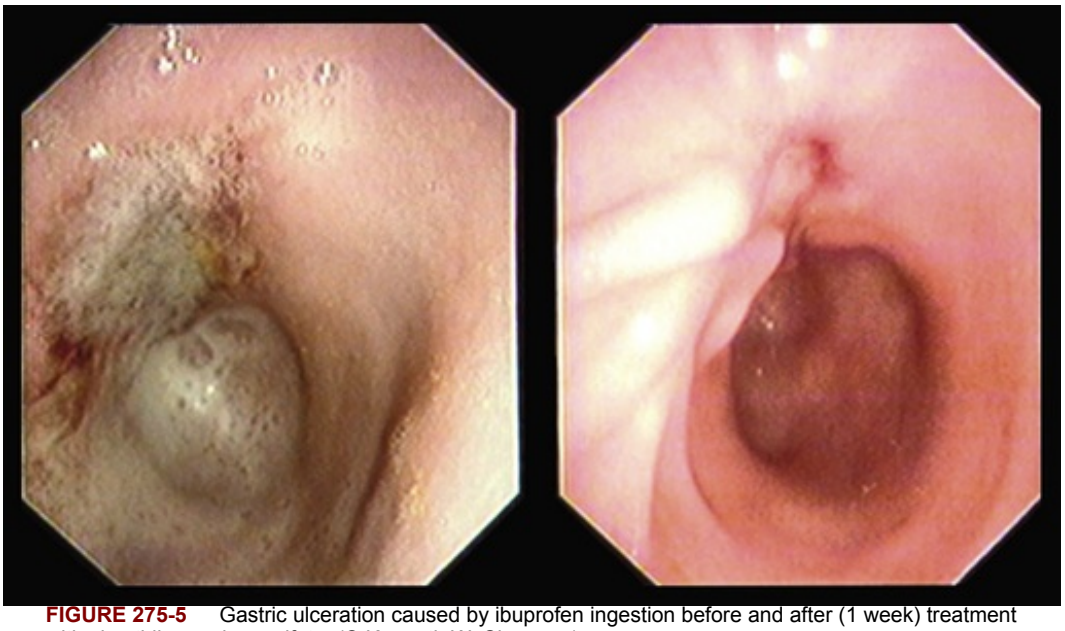

FIGURE 275-5 Gastric ulceration caused by ibuprofen ingestion before and after (1 week) treatment with cimetidine and sucralfate. (© Kenneth W. Simpson.)

To circumvent toxicosis caused by the inhibition of "friendly prostaglandins" (PGE_2), drugs that preferentially block "inducible" cyclooxygenase (COX-2) have been developed. These COX-2 selective agents (e.g., carprofen, meloxicam, deracoxib, etodolac) are less ulcerogenic in dogs.[54,55] However, even COX-2 selective drugs such as meloxicam and deracoxib are ulcerogenic, especially in combination with dexamethasone or other NSAIDs, have been associated with gastric perforation, and their safety in ill pets has not been determined.[51,56-59]

Hypersecretion of gastric acid in response to histamine release from mast cell tumors and gastrin from gastrinomas are clear causes of gastroduodenal ulceration and esophagitis in dogs and cats. Uremia, hepatic failure, hypoadrenocorticism, and hypotension are frequently proposed as risk factors for gastric erosion or ulceration, although few details have been published on pathogenesis, frequency, or severity of gastric damage in these conditions. In a recent study of dogs with chronic kidney disease (CKD), ulceration was present in only 1 of 28 dogs. The predominant findings in these dogs were mucosal edema, vasculopathy, and mineralization that correlated to the degree of azotemia and calcium phosphorus product.[62,63] Similar findings have also been observed in cats with CKD.[63] Sled dogs in the Iditarod race are prone to develop gastric erosions and ulcers (see ch. 173).[64,65] This finding is similar to exercising humans and horses in whom the pathogenesis is not understood but is responsive to acid suppression. Erosions and ulcers are also a sequela of gastric cancer and gastritis and are discussed in this chapter.

Clinical Findings

Vomiting, hematemesis, and melena may be present in patients with gastric erosions or ulcers. Pale mucous membranes, abdominal pain, weakness, inappetence, hypersalivation (potentially associated with esophagitis as a consequence of gastric acid hypersecretion; see ch. 273), and evidence of circulatory compromise are more variably present. Access to toxins and drugs, particularly NSAIDs, should be determined. Testing is directed at identifying current consequences and diseases associated with gastric erosions and ulcers (see Table 275-2). The CBC may reveal anemia that is initially regenerative but can progress to become microcytic, hypochromic, and minimally regenerative. When accompanied by thrombocytosis and decreased iron saturation or low serum ferritin, these findings are characteristic of chronic bleeding and iron deficiency (see ch. 57, 198, and 199). Eosinophilia and lack of a stress leukogram in dogs is consistent with hypoadrenocorticism, dietary allergy (see ch. 186), eosinophilic gastroenteritis, mastocytosis (see ch. 349), or a hypereosinophilic syndrome. A neutrophilic leukocytosis and a left shift may indicate inflammation or possible gastric perforation. Examination of a buffy coat smear may help to detect mastocytosis.

Biochemistry and urinalysis may reveal findings consistent with dehydration (azotemia and hypersthenuria), kidney disease (azotemia and isosthenuria), hepatic disease (increased liver enzymes or

bilirubin; decreased cholesterol, albumin, or BUN), or hypoadrenocorticism (i.e., hyponatremia and/or hyperkalemia). It will also identify electrolyte and acid-base abnormalities associated with vomiting and GI ulceration. The presence of a metabolic alkalosis, hypochloremia, hypokalemia, and acidic urine is consistent with upper GI obstruction (physical or functional) or a hypersecretory state. Testing should be performed to detect abnormalities in primary and secondary hemostasis that may be associated with GI bleeding. Serum gastrin and histamine concentrations can be evaluated where acid hypersecretion is suspected as a cause of ulceration.

Diagnosis

Diagnostic Imaging

Plain radiographs are not usually helpful in diagnosing gastric erosions or ulcers but may help rule out other causes of vomiting, such as foreign bodies, peritonitis, and gastric perforation. Contrast radiographs may reveal filling defects but do not allow detailed mucosal evaluation or sampling. Ultrasonography (see ch. 88) can be used to evaluate the gastric wall for thickening associated with ulcers or masses and also helps to rule out non-gastric causes of vomiting. The information provided by radiography and ultrasound is complementary to endoscopic evaluation, the diagnostic test of choice (Figure 275-6).

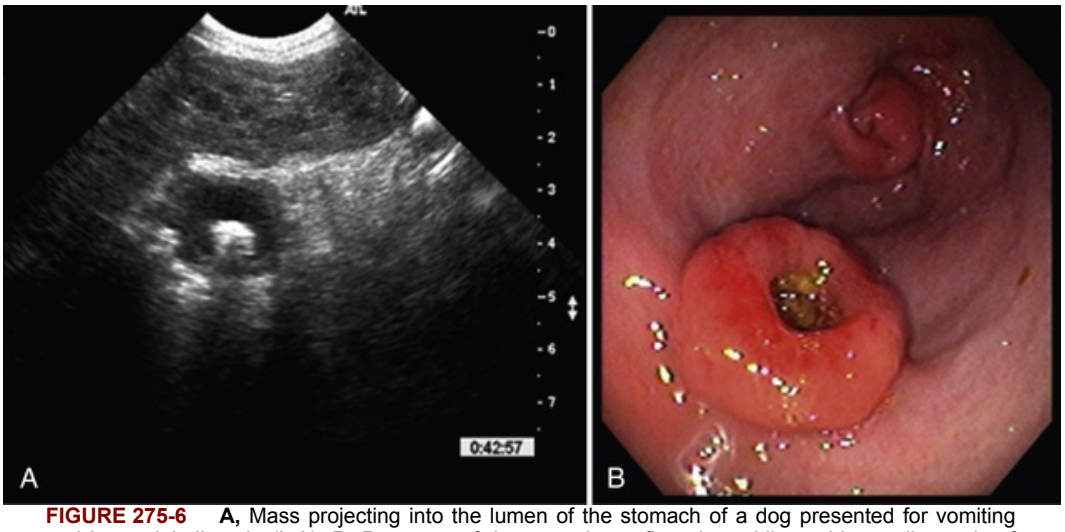

FIGURE 275-6 **A,** Mass projecting into the lumen of the stomach of a dog presented for vomiting and hyperglobulinemia (IgA). **B,** Presence of the mass is confirmed, enabling a biopsy diagnosis of gastric plasmacytoma. (© Kenneth W. Simpson.)

Endoscopy

Endoscopy allows direct evaluation of gastric mucosa and its sampling (see ch. 113). NSAID-associated ulcers tend to be found in the antrum and are not usually associated with marked mucosal thickening or irregular edges (see Figure 275-5). This contrasts with ulcerated tumors that frequently have thickened edges and surrounding mucosa (Figure 275-7). Ulcers should be biopsied at the periphery to avoid perforation. Endoscopically obtained biopsies are not ideal for diagnosing infiltrative gastric neoplasia, but several biopsies from the same site can be taken to enable sampling of deeper tissue. Endoscopic-guided fine needle aspirates that use a needle and tubing in the biopsy channel can also be used to sample deep lesions. Even with this approach, the diagnosis may be missed and surgical biopsy may be required for a definitive diagnosis.

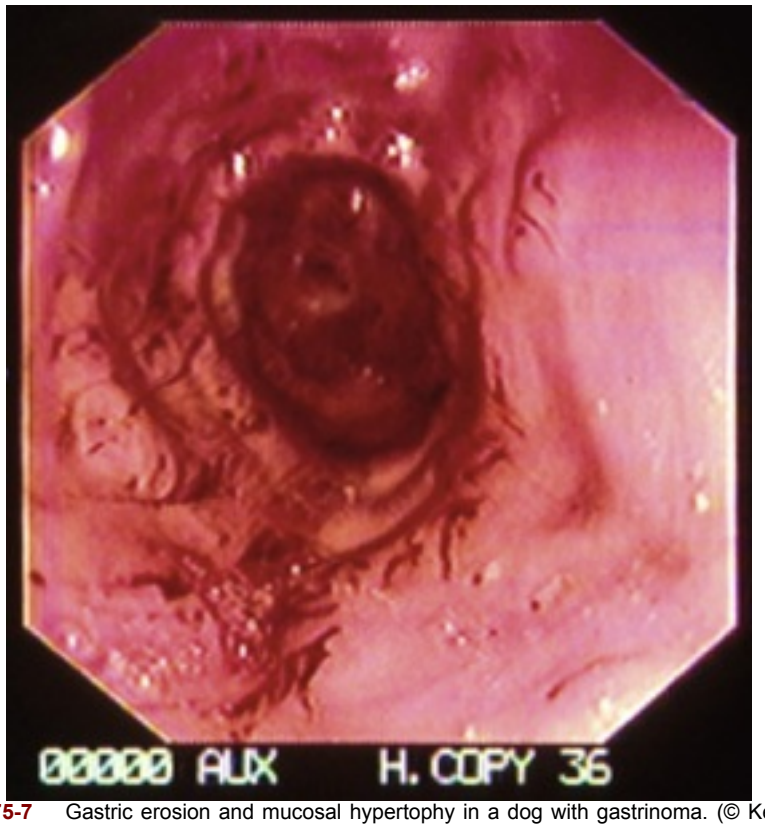

FIGURE 275-7 Gastric erosion and mucosal hypertophy in a dog with gastrinoma. (© Kenneth W. Simpson.)

pH and Serum Gastrin

The combination of mucosal erosion or ulceration, antral mucosal hypertrophy, copious gastric juice, and esophagitis is highly suggestive of gastric hypersecretion (see Figure 275-7). It is prudent to measure gastric pH and serum gastrin in pets with gastric erosion or ulceration not associated with drugs or gastric tumors. Dogs with mast cell tumors and hyperhistaminemia-induced acid hypersecretion have low serum gastrin concentrations.[27] Finding a combination of gastric pH <3 and increased serum gastrin concentrations should prompt further investigation for gastrinoma by secretin stimulation test, US (liver and pancreas), and pentertreotide scintigraphy.[27] The utility of capsule based pH monitoring and endoscopy in detecting gastric acid hypersecretion and associated mucosal abnormalities has not been determined in the clinical setting. The administration of omeprazole or famotidine (both at 1 mg/kg PO q 24 h) to control acid secretion can increase serum gastrin, from 37.2 ng/L to 71.3 ± 19 and 65.5 ± 39.52 ng/L, respectively, within 3 to 7 days.[66] Increased serum gastrin induced by short-term antacid therapy resolved after a 7 day withdrawal period.[66,67] Omeprazole (1.1 mg/kg PO q 12 h for 15 days) has been associated with dramatic increases in gastrin, from a median baseline of 10.0 ng/L (range: 10.0-27.0) to a maximum median of 379.5 ng/L (range: 49.9-566.0) at day 9 of treatment. Serum gastrin remained significantly increased above baseline values from day 6 to day 15 of the treatment, but declined to pre-treatment within three days of cessation.[67]

Treatment

Overview

Treatment of gastric erosions and ulcers is directed at the underlying cause. One should address abnormalities in hydration (see ch. 129), perfusion, electrolytes and/or acid-base (see ch. 128). Blood transfusion may be indicated (see ch. 130). Additional support of the GMB is via enhanced mucosal protection, cytoprotection and decreasing gastric acid secretion. Where vomiting is persistent, antiemetics (see ch. 39) may help to reduce fluid loss, discomfort, and the risk of esophagitis (see ch. 273).

Fluid Therapy

The rate of fluid administration (see ch. 129) depends on the presence or absence of shock (see ch. 127), the degree of dehydration, and the presence of diseases (e.g., cardiac or renal), which predispose to volume overload. Patients with a history of vomiting who are mildly dehydrated are usually responsive to crystalloids (e.g., LRS or 0.9% NaCl) at a rate that will provide maintenance requirements as well as replace deficits and ongoing losses. Potassium depletion is often a consequence of prolonged vomiting or anorexia, and most polyionic replacement fluids contain only small amounts. Therefore KCl is added to parenteral fluids on the basis of serum levels. Central venous pressure monitoring (see ch. 76) and evaluation of urine output (see ch. 322) are necessary in patients with severe GI disease, particularly those complicated by third-space losses of fluid into the gut or peritoneum. Patients in shock require more aggressive support (see ch. 127, 129, and 144).

Reducing Acid Secretion

Pharmacologic inhibition of acid secretion (see Figure 275-3) can be effected by blocking H2 (cimetidine, ranitidine, famotidine), gastrin (proglumide), and acetylcholine (atropine, pirenzipine) receptors and by inhibiting adenyl cyclase (PGE analogs) and H^+/K^+-ATPase (e.g., omeprazole).[68] Long-acting somatostatin analogs, such as octreotide, directly decrease the secretion of gastrin and gastric acid. Decreasing gastric acid secretion with an H2-receptor antagonist has been shown to promote mucosal healing in dogs with a variety of experimentally induced ulcers and erosions (see Figure 275-5). Famotidine is attractive, as it does not inhibit P450 enzymes and can be given once daily. The additional prokinetic activity of ranitidine or nizatidine (mediated by anticholinesterase activity) may make them good choices in cases of delayed gastric emptying associated with defective propulsion.[40] In patients with severe or persistent gastric ulceration refractory to H2 antagonists, more complete inhibition of gastric acid secretion can be achieved with an H^+/K^+-ATPase inhibitor, such as omeprazole (1 mg/kg PO q 24 h [dogs]). Omeprazole is the initial drug of choice in patients with acid hypersecretion secondary to mast cell tumors and gastrinoma (Zollinger-Ellison syndrome). Omeprazole has been shown to have few long-term side effects in dogs (0.7-1 mg/kg PO q 24 h), but it should be used with caution in pets with liver disease and must be reviewed for interactions with drugs such as cisapride. At higher dosages (1.1 mg/kg PO q 12 h) omeprazole has been associated with significant hypergastrinemia and gastric dysbiosis.[67] Sled dogs given omeprazole for exercise-associated gastric hemorrhage had significantly reduced gastric severity scores as compared to placebo. However, the drug caused an increased frequency of diarrhea (omeprazole 54%, placebo 21%).[64] Further investigation is needed on the role of this drug for athletes with gastric ulcers.[64] The combination of omeprazole and the long-acting somatostatin analog octreotide effectively reduced vomiting in a dog with gastrinoma (octreotide 2 to 20 mcg/kg SC q 8 h).[69] Octreotide can also be employed to rapidly decrease gastric acid secretion in pets discovered to have large ulcers at endoscopy, and it has been used to control gastric bleeding in people. Sustained release octreotide acetate (5 mg/IM q 4 weeks) transiently suppressed gastrin secretion in a Shiba Inu with gastrinoma.[70]

Providing Mucosal Protection

The PGE_2 analog misoprostol protects against NSAID-induced gastric erosions in dogs at dosages that do not inhibit acid secretion (3 to 5 mcg/kg PO q 8 h) and may be given to dogs receiving chronic NSAIDs for arthritis.[71,72] The main side effect of misoprostol is diarrhea, and it should not be given to pregnant animals. The mucosal protectant polyaluminum sucrose sulfate (sucralfate) binds to areas denuded of mucosal epithelium, regardless of the underlying cause, and is useful for treating gastric erosions, ulcers, and esophagitis. Sucralfate can be given to patients receiving injectable antacids, but it may compromise absorption of other oral medications and is probably best separated from these by several hours. In contrast to the efficacy of misoprostol and H2 antagonists in preventing NSAID-induced erosions, the prophylactic administration of various combinations of misoprostol, cimetidine, and omeprazole have not been shown to prevent gastric erosions in dogs, with or without intervertebral disc disease, receiving high-dose glucocorticoids.[60,73,74] However, these drugs may speed healing of their gastric lesions. Sucralfate is probably the drug of choice for treating GI ulceration in pets receiving high dosages of glucocorticoids, because it is effective regardless of whether or not acid is causing or delaying healing.

Mast cell tumors (see ch. 349) are also worth considering separately, as gastric ulceration is a frequent and severe complication. Mast cell tumors are thought to cause vomiting via the central effects of histamine on the chemoreceptor trigger zone (CRTZ) and the peripheral effects of histamine on gastric acid secretion, with resultant hyperacidity and ulceration. Treatment of mastocytosis with H1 and H2 histamine antagonists (e.g.,

diphenhydramine and famotidine) should reduce the central and peripheral effects of histamine. Corticosteroids are used to decrease tumor burden. Where acid hypersecretion is present or is suspected, it is likely best managed with proton-pump inhibitors (e.g., omeprazole 1 mg/kg PO q 24 h). Somatostatin analogs may also be useful for controlling refractory gastric acid hypersecretion (e.g., octreotide 2 to 20 mcg/kg SC q 8 h, or octreotide acetate 0.5 mg/kg q 4 weeks).[27,70]

Antiemetics

Antiemetics (see ch. 39) can be used when vomiting is severe and compromising fluid and/or electrolyte balance or causing discomfort.[68] Antiemetics commonly used in dogs include metoclopramide, which antagonizes D_2-dopaminergic and $5HT_3$-serotonergic receptors and has cholinergic effects on smooth muscle (1 mg/kg/24 h CRI IV); phenothiazine derivatives, such as chlorpromazine and prochlorperazine, which are antagonists of $alpha_1$- and $alpha_2$-adrenergic, H1 and H2-histaminergic, and D_2-dopaminergic receptors in the vomiting center and CRTZ; ondansetron (0.5 mg/kg IV), which antagonizes peripheral $5HT_3$ receptors; and maropitant (1 mg/kg IV q 24 h, or 2 mg/kg PO q 24 h, not more than 5 days), which antagonizes neurokinin-1 receptors. Comparing these antiemetics indicates greater efficacy of maropitant and ondansetron for controlling peripheral vomiting induced by ipecac than metoclopramide or chlorpromazine and similar efficacy of maropitant, chlorpromazine, and metoclopramide for controlling centrally mediated vomiting induced by apomorphine.[75] Maropitant has been associated with histologic evidence of bone marrow hypoplasia in puppies and should not be used in dogs <8 weeks or cats <16 weeks of age. Maropitant at 1 mg/kg was effective in preventing xylazine and motion-induced emesis in cats and reduced vomiting (1.1 mg/kg PO daily for 2 weeks) in cats with chronic kidney disease.[76,77] Nonselective cholinergic receptor antagonists such as atropine, scopolamine, aminopentamide, and isopropamide are generally avoided, as they may cause ileus, delayed gastric emptying, and dry mouth.

Antibiotics and Analgesia

Prophylactic antibiotic cover (e.g., cephalosporins, ampicillin) may be warranted for animals in shock with major GI barrier dysfunction. Leukopenia, neutrophilia, fever, and bloody stools are additional indications for prophylactic antibiotics in animals with vomiting or diarrhea. Initial choices in these situations include ampicillin or a cephalosporin (effective against Gram-positive and some Gram-negative and anaerobic bacteria), which can be combined with an aminoglycoside (effective against Gram-negative aerobes) when sepsis is present and hydration status is adequate (see ch. 161). Enrofloxacin is a suitable alternative to an aminoglycoside in skeletally mature patients at risk of nephrotoxicosis from an aminoglycoside. Analgesia can be provided using opioids like buprenorphine (0.0075 to 0.01 mg/kg, IM). Recent studies indicate that the anti-emetic maropitant has analgesic properties during laparoscopic visceral stimulation, but the analagesic effects in other situations remains to be determined.[78] Surgery may be required when the cause of ulceration is unclear or to resect large, non-healing ulcers or those about to perforate. Pyloric perforation has been associated with NSAIDs and mortality rates (about 64%) are similar to perforation at other sites in the GI tract.[52]

Gastric Dilatation and Volvulus

Definitions and Pathogenesis

Gastric dilatation (GD) and gastric dilatation and volvulus (GDV) are characterized by the stomach being dramatically distended with air (see ch. 143 and 144). With volvulus, the stomach twists about its axis, moving dorsally and left of the fundus. Both GD and GDV cause caudal caval obstruction and impair venous return to the heart, resulting in hypovolemic shock that can be exacerbated by devitalization of the gastric wall, splenic torsion or avulsion, congestion of the abdominal viscera, endotoxic shock, and DIC.

No single cause of GD or GDV has been identified. Large-breed dogs with deep chests—such as Akita, Bloodhound, Collie, Great Dane, Irish Setter, Irish Wolfhound, Newfoundland, Rottweiler, Saint Bernard, Standard Poodle, and Weimaraner—are at greater risk. Cumulative incidence of GDV has been estimated at 6% for large-breed and giant-breed dogs. The lifetime risk is influenced by breed, ranging from 3.9% for Rottweilers to 39% in Great Danes.[79] In large-and giant-breed dogs, factors significantly associated with an increased risk of GDV include increasing age, having a first-degree relative with a history of GDV, eating fast, once-daily feeding, a raised feeding bowl, and aerophagia.[80,81] The personality of the dog may also have an

impact, as happier dogs have a decreased incidence.[48] Prior splenectomy does not appear to increase the risk for GDV.[82] Analysis of gastric gas in GD/GDV has been interpreted to support aerophagia as the cause of distension, with dilatation explained by an inability to eructate or empty air into the intestines.[83] However, a recent study found CO_2 composition ranged from 13 to 20%, with one dog having an H2 concentration of 29%.[84] Because the CO_2 content of atmospheric air is less than 1%, these findings suggest that the gaseous gastric distention in GDV is not the result of aerophagia.[84] Likely sources of gas include bacterial fermentation of diet but the specific dietary and microbial factors remain to be determined.[84] Studies in dogs with GDV recovering from gastropexy suggest that abnormal electrical activity and gastric emptying may also be related to the development of GD.[85] The interrelationship of volvulus and gastric distension is unclear, although the length of the hepatogastric ligament may facilitate torsion.

Diagnostic Features

A history of nonproductive retching, salivation, abdominal distention, weakness, or collapse raises the possibility of gastric dilatation or volvulus, particularly in large-breed and deep-chested dogs. Physical findings usually include abdominal distension and tympany, tachycardia, and mucosal pallor. Hypothermia, depression, and coma may be seen when shock is severe. Cardiac arrhythmias, such as ventricular premature beats or ventricular tachycardia, may be detected on the initial examination or may develop up to 72 hours after presentation (see ch. 127 and 144). Radiography is usually performed after fluid support and decompression and helps to distinguish simple dilatation from dilatation and volvulus. Right and left lateral recumbent views are usually required. Dilatation is associated with gas distension, and on a right lateral position, air is present in the fundus (Figure 275-8). With volvulus the pylorus moves dorsally and left, and the stomach is compartmentalized. On a right lateral radiograph, the fundus is viewed as a large ventral compartment with the smaller, gas-filled pylorus located dorsally and separated from the fundus by a band of soft tissue, forming the "Popeye's arm" sign (Figure 275-9). Loss of abdominal contrast may indicate gastric rupture or bleeding from avulsed splenic vessels, whereas increased contrast due to pneumoperitoneum suggests gastric rupture.

Clinicopathologic Findings

Hematologic changes are often restricted to an increase in hematocrit. A variety of acid-base and electrolyte disturbances has been observed in dogs with GDV (see ch. 128).[86,87] Metabolic acidosis and hypokalemia were the most common abnormalities in one study and occurred in 15 and 16 of 57 dogs, respectively.[86] Metabolic acidosis is likely due to tissue hypoperfusion, anaerobic metabolism, and the accumulation of lactic acid (see ch. 70).[86] Metabolic alkalosis may also occur and may be related to the sequestration of gastric acid or vomiting.[86] Measurement of plasma lactate at the time of admission and its response to therapy (>43-50% decrease within 12 h is a good finding) may help in determining the presence of gastric necrosis, prognosis and need for aggressive therapy.[28-30] Respiratory acidosis and alkalosis have been variably observed and reflect hypoventilation or hyperventilation, respectively. The variable nature of acid-base and electrolyte abnormalities in dogs with GDV indicates that fluid therapy should be individualized on the basis of blood gas and electrolyte measurements. Monitoring and correction of acid-base abnormalities are important, because they may predispose to cardiac arrhythmias and muscle weakness. Coagulation abnormalities are usually consistent with DIC (thrombocytopenia, increased D-dimer or FDPs, reduced ATIII, prolongation of the APTT; see ch. 196).

Treatment

Fluids (see ch. 127) and gastric decompression (see ch. 112) are most important.

Fluid Support

Fluid therapy has traditionally consisted of shock doses of LRS (60 to 90 mL/kg/h) given via large-bore catheters into the cephalic or jugular veins (see ch. 127 and 129). Experimental studies comparing crystalloids (60 mL/kg, followed by 0.9% NaCl 20 mL/kg/h) with hypertonic saline (7% NaCl in 6% dextran, 5 mL/kg, followed by 0.9% NaCl 20 mL/kg/h) in dogs with GDV-induced shock indicate that hypertonic saline maintains better myocardial performance, higher heart rate, and lower systemic vascular resistance.[88] The resuscitative dose of hypertonic saline was delivered in 5 to 10 minutes versus an hour for crystalloids. Fluid

therapy should be aggressively monitored by frequent measurement of blood pressure, heart rate, PCV, and total solids and urine output. Potassium and bicarbonate are best administered on the basis of blood gas and electrolyte measurements. Hypokalemia is common after fluid therapy, and 30 to 40 mEq KCl/L should be added to fluids after the initial shock dose, while ensuring that the maximum KCl infusion rate of 0.5 mEq/kg/h is not exceeded (see ch. 324).

Gastric Decompression

Decompression can be performed by orogastric intubation with a well-lubricated stomach tube (see ch. 112), or a 16-g catheter can be used to trocarize the stomach (see ch. 144). Oral decompression can also be performed after trocarization. Decompression should be maintained until surgery. Sedation with butorphanol (0.5 mg/kg IV) or oxymorphone (0.1 mg/kg IV) and diazepam (0.1 mg/kg slow IV) may be necessary to pass a stomach tube.

Adjunct Therapy for Endotoxic Shock and Reperfusion Injury

Adjunct therapy frequently includes prednisolone sodium succinate (10 mg/kg IV) or dexamethasone sodium phosphate for shock and broad-spectrum antibiotics, such as a cephalosporin in combination with a fluroquinolone, to circumvent bacterial translocation and endotoxemia (see ch. 127). Some clinicians advocate flunixin meglumine for endotoxic shock, but the author does not. The administration of agents to decrease lipid peroxidation (U70046F) and chelate iron (desferroxamine) has decreased mortality attributed to reperfusion injury in dogs with experimental GDV.[89,90] These agents are best given before reperfusion occurs, that is, prior to untwisting a torsion.

Cardiac Arrhythmias

Cardiac arrhythmias (e.g., ventricular premature complexes, ventricular tachycardia) are relatively frequent (about 40% of dogs) and may or may not contribute to mortality.[91-94] Arrhythmias can develop up to 72 hours after presentation and are considered a consequence of electrolyte, acid-base, and hemostatic abnormalities, as well as reperfusion injury (see ch. 141 and 248). Arrhythmias should be treated if associated with weakness, syncope, or heart rates >150 beats per minute. Arrhythmias are managed by correcting underlying acid-base, electrolyte, and hemostatic disturbances and administering lidocaine either as a bolus (1 to 2 mg/kg IV) or continuously (up to 50 to 75 mcg/kg/min) and procainamide (10 mg/kg IM q 6 h and then orally if effective) when arrhythmias are persistent (see ch. 141 and 248). It is important that plasma concentrations of K^+ and Mg^{2+} be normalized to enable effective antiarrhythmic therapy. It has been reported that dogs with GDV treated at presentation with lidocaine (2 mg/kg, IV bolus) followed by constant rate infusion (CRI) of 0.05 mg/kg/min IV for 24 h had decreased frequency of arrhythmias, acute kidney injury, and duration of hospitalization.[95]

Surgery

The aims of surgery are to reposition the stomach and spleen and to perform a gastropexy to enable short-term decompression and prevent recurrence. Surgery can be complicated by gastric necrosis, which requires partial gastrectomy, and avulsion or torsion of the spleen, which may require resection or removal.

Prognosis

Mortality rates for dogs with GDV is about 10-15%.[93,94] Dogs with gastric necrosis, gastric resection, splenectomy, pre- or post-operative cardiac arrhythmias, and longer times from presentation until surgery have a higher mortality rate, reaching >30% in some studies.[7,91,93,94] Measurement of plasma lactate at admission (>6 to 9 mmol/L; see ch. 70) and its response to therapy (>43-50% decrease within 12 h is considered a good sign) may help in determining the presence of gastric necrosis, prognosis and need for aggressive therapy (see ch. 127 and 144).[28-30]

Prophylaxis

The recurrence rate of GD/GDV has been estimated at 11% over 3 years in one study, with median survival of 547 days for dogs that had a gastropexy versus 188 days for dogs without.[58] Prophylactic gastropexy in Great Danes, Irish Setters, Rottweilers, Standard Poodles, and Weimaraners reduced mortality from as little as 2.2-

fold in Rottweilers to as much as 29.6-fold in Great Danes.[79] Two recent studies evaluating the effect of prophylactic incisional gastropexy found it completely prevented GDV, with GD reported in 5-11% of 101 cases.[96,97]

Chronic Gastritis

Prevalence and Definitions

Gastritis is common in dogs, with 35% of dogs investigated for chronic vomiting and 26% to 48% of asymptomatic dogs affected.[98,99] The prevalence in cats has not been determined. Diagnosis of chronic gastritis is based on histologic examination of gastric biopsies and is usually sub-classified according to histopathological changes and etiology.

Histopathologic Features of Gastritis

Gastritis in dogs and cats is usually classified according to the nature of the predominant cellular infiltrate (eosinophilic, lymphocytic, plasmacytic, granulomatous, lymphoid follicular), the presence of architectural abnormalities (atrophy, hypertrophy, fibrosis, edema, ulceration, metaplasia), and their subjective severity (mild, moderate, severe). A standardized visual grading scheme has been proposed by Happonen and colleagues and has been adapted for pathologists (Figure 275-10).[99,100] The most common form of gastritis in dogs and cats is mild to moderate superficial lymphoplasmacytic gastritis with concomitant lymphoid follicle hyperplasia (Figure 275-11).[101] Eosinophilic, granulomatous, atrophic, and hyperplastic gastritis are less common.

Etiology

Overview of the Inflammatory Condition

Despite the high prevalence of gastritis, an underlying cause is rarely identified. In the absence of systemic disease, ulcerogenic or irritant drugs, gastric foreign objects, parasites (*Physaloptera* and *Ollulanus* spp.), and in rare instances fungal infections (*Pythium insidiosum, Histoplasma* spp.), gastritis is usually attributed to dietary allergy or intolerance, occult parasitism, a reaction to bacterial antigens, or unknown pathogens. Treatment is often empirical but can serve to define the cause of gastritis, such as diet responsive (see ch. 178), antibiotic responsive, steroid responsive, or parasitic.

Although the basis of the immunologic response in canine and feline gastritis is unknown, recent studies in experimental animals have shed light on the immunologic environment in the GI tract to reveal a complex interplay between GI microflora, the epithelium, immune effector cells (e.g., lymphocytes and macrophages), and soluble mediators (e.g., chemokines and cytokines).[100,102] In health, this system avoids active inflammation by antigen exclusion and induced immune tolerance. The development of intestinal inflammation in mice lacking the cytokines interleukin (IL)-10, transforming growth factor-beta (TGF-beta), or IL-2 indicates their central importance in damping down mucosal inflammation. In murine models, GI inflammation only develops in the presence of indigenous intestinal microflora, leading to the hypothesis that spontaneous mucosal inflammation may be the result of a loss of tolerance to indigenous GI microflora. The role of these mechanisms in outbred species, such as the dog and cat, remains to be determined, but clearly loss of tolerance to bacterial or dietary antigens should be considered.

The role of epithelial cells in the inflammatory response is being elucidated, with gram-negative or pathogenic bacteria inducing proinflammatory cytokine (e.g., IL-8, IL-1-beta) secretion from epithelial cells, whereas commensal or bacteria such as *Streptococcus faecium* or *Lactobacillus* spp. induce the production of the immunomodulatory cytokines TGF-beta or IL-10.[63] The proinflammatory cytokines produced by epithelial cells are modulated by the production of IL-10 from macrophages and potentially by the epithelial cells themselves.[103] In this context, dogs with lymphoplasmacytic gastritis of undetermined etiology showed a correlation between the expression of the immunomodulatory cytokine IL-10 and proinflammatory cytokines (IFN-alpha, IL-1-beta, IL-8).[16] Simultaneous expression of IL-10 and IFN-alpha mRNA has also been observed

in the intestines of Beagles, in the lamina propria cells and the intestinal epithelium, despite luminal bacterial flora that were more numerous than in control dogs.[104] Thus it is tempting to visualize a "homeostatic loop" consisting of proinflammatory stimuli and responses countered by immunomodulation and repair, with an imbalance in either of these arms manifested as gastritis.

Role of Pathogens

The importance of unknown pathogens in development of inflammation in the mucosa is best demonstrated by the gastric *H. pylori,* a Gram-negative bacterium that chronically infects more than half of all people worldwide.[13] This infection is characterized by infiltration of polymorphonuclear and mononuclear cells and upregulation of proinflammatory cytokines and the chemokine IL-8. Mucosal T cells in infected individuals are polarized toward production of interferon-gamma (IFN-gamma), rather than IL-4 or IL-5, indicating a strong bias toward a Th1 type response.[105,106] Sustained gastric inflammatory and immune responses to infection appears to be pivotal for the development of peptic ulcers and gastric cancer in people.

Helicobacter Prevalence

There is a high prevalence of gastric *Helicobacter* spp. infection in 67% to 100% of healthy pet dogs, 74% to 90% of vomiting dogs, 100% of laboratory Beagles and 40% to 100% of healthy and sick cats.[107-109] Dogs and cats are colonized by a variety of large spiral organisms (5 to 12 microns; Figure 275-12). In cats from Switzerland, the United States, and Germany, *H. heilmannii* is the predominant species, with *H. bizzozeronii* and *H. felis* being much less frequent. Cats can also be colonized by *H. pylori* (2 to 5 microns), but infection has been limited to a closed colony of laboratory cats.[110] In dogs from Finland, Switzerland, the United States, and Denmark, *H. bizzozeronii* and *H. salomonis* are most common, followed by *H. heilmannii* and *H. felis; H. bilis* and *Flexispira rappini* have also been described. These gastric *Helicobacter* spp. are distinct from enterohepatic *Helicobacter* spp. that colonize the distal small intestine and colon.[18] Ownership of dogs and cats has been correlated with an increased risk of infection of *H. heilmannii* in people.[111] Recent studies clearly confirm that dogs and cats harbor *H. heilmannii,* but the subtypes of *H. heilmannii* present in dogs and cats, types 2 and 4, are of minor importance in people (about 15% of cases), who are predominantly colonized by *H. heilmannii* type 1—the predominant *Helicobacter* spp. in pigs.[17] The transmission of a variety of non-*H.pylori Helicobacter* spp., including *H. felis, H. salomonis, H. bizzozeronii,* from animals and pets to man appears more common than was initially appreciated.[112]

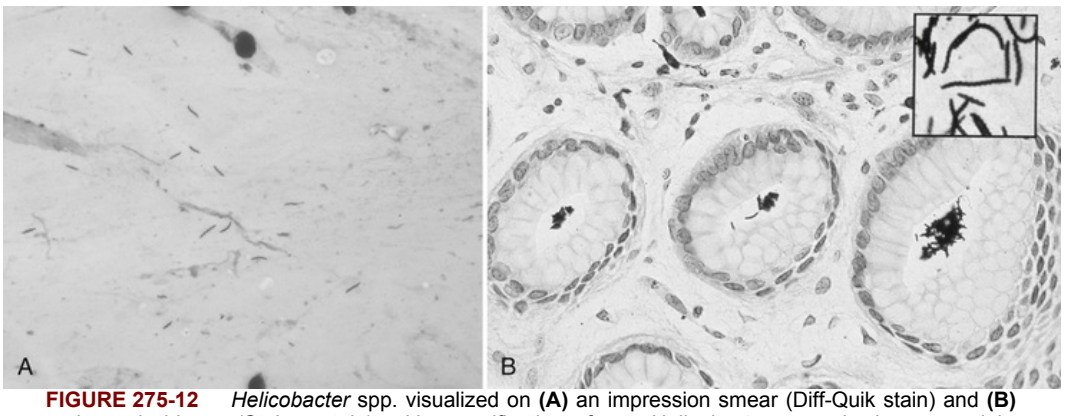

FIGURE 275-12 *Helicobacter* spp. visualized on **(A)** an impression smear (Diff-Quik stain) and **(B)** endoscopic biopsy (Steiner stain), with magnification of one *Helicobacter* group in the upper right corner. (© Kenneth W. Simpson.)

Helicobacter Treatment

The effect of eradicating *Helicobacter* spp. on gastritis and clinical signs in people, the main form of evidence supporting the pathogenic role of *H. pylori,* has not been thoroughly investigated in dogs or cats. An uncontrolled treatment trial of dogs and cats with gastritis and *Helicobacter* spp. infection showed that clinical signs in 57 of 63 dogs and cats responded to a combination of metronidazole, amoxicillin, and famotidine. 14 of 19 animals re-endoscoped had resolution of gastritis and no evidence of *Helicobacter* spp. in gastric

biopsies.[113] A controlled trial of amoxicillin, metronidaziole, and bismuth ± famotidine in 24 dogs found a similar decrease in vomiting (86.4%) but only 43% clearance of *Helicobacter* at 6 months.[114] This study also found that gastritis scores in dogs that were *Helicobacter* negative at 6 months decreased, whereas those in *Helicobacter*-positive dogs increased. The reason for the much higher apparent recrudescence or reinfection rate in dogs and cats than people (1% to 2% per year observed after treatment of *H. pylori*) has not been determined. With such limited information from eradication trials, most current knowledge about the pathogenicity of *Helicobacter* spp. for dogs and cats comes from the evaluation of animals with and without infections and clinical signs and a small number of experimental infections.

The large *Helicobacter* species found in dogs and cats do not attach to the epithelium but colonize the superficial mucous and gastric glands, particularly of the fundus and cardia, and may also be observed intracellularly.[107,109] Degeneration of gastric glands with vacuolation, pyknosis, and necrosis of parietal cells is more common in infected than uninfected animals. Inflammation is generally mononuclear in nature and ranges from mild to moderate in severity. Gastric lymphoid hyperplasia is common and can be extensive in dogs and cats infected with *Helicobacter* spp., particularly when full-thickness gastric biopsies are evaluated. In addition to this local gastric immune response, a systemic response characterized by increased circulating anti-*Helicobacter* IgG has been detected in sera from naturally infected dogs and cats. However, the gastritis observed in dogs and cats infected with large spiral bacteria is generally less severe than observed in *H. pylori*–infected humans. Gastrointestinal ulcers, gastric neoplasia, or changes in serum gastrin or acid secretion have not been associated with *Helicobacter* spp. infection in dogs or cats.

Differences between people, dogs, and cats may be attributed to differences in the virulence of the infecting *Helicobacter* spp. or in the host response. Studies that address this issue indicate that *H. pylori* evokes a more severe proinflammatory cytokine and cellular response in dogs and cats than natural or experimental infection with large *Helicobacter* spp.[110,115] The limited mucosal inflammatory response and absence of clinical signs in most dogs and cats infected with non–*H. pylori Helicobacter* spp., despite significant antigenic stimulation proved by seroconversion and lymphoid follicle hyperplasia, suggests that large gastric *Helicobacter* spp. are more commensal than pathogenic. It is interesting to speculate that it is the loss of tolerance to gastric *Helicobacter* spp., rather than the innate pathogenicity of these bacteria, that explains the development of gastritis and clinical signs in some dogs and cats.

Clinical Findings

The major clinical sign of chronic gastritis is vomiting of food or bile. Decreased appetite, weight loss, melena, or hematemesis is variably encountered. The concurrent presence of dermatologic and GI signs raises the likelihood of dietary sensitivity.[116] Dietary practices and access to toxins, medications, and foreign bodies should be thoroughly reviewed. Signalment is important, as it may increase the probability that chronic gastritis is the cause of vomiting. Hypertrophy of the fundic mucosa is frequently associated with a severe enteropathy in Basenjis and with stomatocytosis, hemolytic anemia, icterus, and polyneuropathy in Drentse Patrijshonds.[117,118] Hypertrophy of the pyloric mucosa is observed in small, brachycephalic dogs such as the Lhasa Apso, associated with gastric outflow obstruction (see Delayed Gastric Emptying and Motility Disorders, below). Atrophy of the gastric mucosa that may progress to adenocarcinoma has been reported in Lundehunds with protein-losing gastroenteropathy.[119] Young, large-breed male dogs in the Gulf states of the United States may have granulomatous gastritis caused by *Pythium* spp. with infection more prevalent in fall, winter, and spring.[120] Physical examination is often unremarkable. Abdominal distension may be related to delayed gastric emptying caused by obstruction or defective propulsion. Abdominal masses, lymphadenopathy, or ocular changes may be encountered in dogs with gastric fungal infections.

Diagnosis

Laboratory Testing

A biochemical profile, CBC, urinalysis, and T_4 (for cats >5 years old) should be performed as a basic screening for metabolic, endocrine, infectious, and other non-GI causes of vomiting, as well as for the acid-base and electrolyte changes associated with vomiting, outflow obstruction, or acid hypersecretion. Test results are often normal in pets with chronic gastritis. Eosinophilia may prompt the consideration of gastritis associated with dietary hypersensitivity, endoparasites, or mast cell tumors. Hyperglobulinemia and hypoalbuminemia may be present in Basenjis with gastropathy or enteropathy or in dogs with gastric pythiosis. Panhypoproteinemia is a feature of gastroenteropathy in Lundehunds, moderate to severe generalized

inflammatory bowel disease, GI lymphoma, and GI histoplasmosis. More specific testing, such as an ACTH stimulation test or serology for *Pythium insidiosum,* is performed based on the results of these initial tests. Determination of food-specific IgE has not been shown to be useful in the diagnosis of dietary sensitivity in dogs or cats. The utility of noninvasive tests, such as serum pepsinogen and gastric permeability to sucrose, used to diagnose gastritis in people has not been determined in dogs and cats.

Imaging

Abdominal radiographs are frequently normal in dogs and cats with gastritis. Gastric distention or delayed gastric emptying (food retained more than 12 hours after a meal) may be noted. Contrast radiography may reveal ulcers or thickening of the gastric rugae or wall but has largely been superseded by the combination of ultrasonography (US) for detection of mural abnormalities and endoscopy to observe and sample the gastric mucosa.[31]

Endoscopy

Endoscopic examination (see ch. 113) enables the visualization of foreign bodies, erosion, ulceration, hemorrhage, rugal thickening, lymphoid follicle hyperplasia (evident as mucosal pock marks), increased mucus or fluid (clear or bile stained), and increased or decreased mucosal friability (see ch. 113). Discrete focal or multifocal mucosal nodules may be observed with *Ollulanus* spp. infection. Gastric phycomycosis can be associated with irregular masses in the pyloric outflow tract and may prompt serologic testing by ELISA, Western blotting, and culture of fresh gastric biopsies. Parasites such as *Physaloptera* spp. may be observed as 1- to 4-cm long worms. Excess bile-stained fluid is suggestive of duodenogastric reflux-associated gastritis, whereas excess clear fluid may indicate hypersecretion of gastric acid. Gastric fluid can be aspirated for cytology (*Helicobacter* spp., parasite ova or larvae) and pH measurement. Impression smears of gastric biopsies are an effective way of identifying *Helicobacter* spp. (5- to 12-micron spirals) and are more sensitive than the biopsy urease test (*Helicobacter* spp. produce urease; see Figure 275-12, *A*). Serum gastrin should be measured if unexplained gastric erosions, ulcers, fluid accumulation, or mucosal hypertrophy is seen.

Dribbling of Antigens and Biopsy

The endoscopic procedure of dribbling dietary antigens onto the gastric mucosa to ascertain the presence of food allergy has not been useful in dogs or cats: It is highly subjective, detects only immediate hypersensitivity, and does not correlate with the results of dietary elimination trials.[116] The stomach should be biopsied even when it looks grossly normal (usually three biopsies from each region: pylorus, fundus, and cardia). Thickened rugae may require multiple biopsies and a full-thickness biopsy is often required to differentiate gastritis from neoplasia or fungal infection and to diagnose submucosal or muscular hypertrophy. The results of gastric US can help predict these possibilities and complement the endoscopic findings (see Figure 275-6).

Gastric sections should be stained with H&E for evaluation of cellularity and architecture and modified Steiner stain for gastric spiral bacteria (see Figure 275-12, *B*). Further special stains, such as Gomori's methenamine silver, are indicated if pyogranulomatous inflammation is present, to detect fungi. Masson's trichrome can be used to highlight gastric fibrosis, whereas sirius red and alcian blue help to reveal eosinophils and mast cells, respectively. Immunocytochemistry can be employed to help distinguish lymphoma from severe lymphocytic gastritis. Mucin staining has been performed in Lundehunds with gastric atrophy and showed an abnormal presence of mucous neck cells and pseudopyloric metaplasia.[121]

Biopsy findings are often used to guide treatment. For example, mild lymphoplasmacytic gastritis may be treated with a change in diet, whereas moderate lymphoplasmacytic gastritis without *Helicobacter* spp. infection, that fails to respond to diet change, may benefit from treatment with corticosteroids. Because the histologic evaluation of gastric biopsies is not uniform among pathologists, even when a standardized scoring scheme is used (see Figure 275-10), the prudent clinician should carefully review histologic sections to get a feel for the pathologist's interpretation.[16] Even with optimum evaluation, similar histologic changes can be observed in patients with different underlying etiologies, so well-structured treatment trials often form the basis of an etiologic diagnosis.

Treatment

Treatment of gastritis initially centers on the detection and treatment of underlying metabolic disorders and the removal of drugs, toxins, foreign bodies, parasites, and fungal infections.

Parasitic Gastritis

Ollulanus Tricuspis

Ollulanus tricuspis is a microscopic worm (0.7 to 1 mm long, 0.04 mm wide) that infects feline stomachs. Its predominant cat-to-cat transmission is through ingestion of vomitus. It can also undergo internal autoinfection, with worm burdens reaching up to 11,000 per stomach. Mucosal abnormalities range from none to rugal hyperplasia and nodular (2 to 3 mm) gastritis. Histologic findings include lymphoplasmacytic infiltrates, lymphoid follicular hyperplasia, fibrosis, and up to 100/hpf globular leukocytes. *Ollulanus* spp. are not detected by fecal examination and require evaluation of gastric juice, vomitus, or histologic sections for larvae or worms. Gastric lavage and xylazine-induced emesis have been described to aid diagnosis. Treatment with fenbendazole (10 mg/kg PO q 24 h 2d) may be effective.

Physaloptera spp.

Physaloptera spp. are about 2- to 6-cm long worms that are sporadically detected in the stomachs of dogs and cats. *Physaloptera rara* are most commonly described and appear to be primarily a parasite of coyotes. Diagnosis is difficult as worm burden is often low and the eggs are transparent and difficult to see in sugar flotation. Treatment with pyrantel pamoate (5 mg/kg PO: dogs, single dose; cats, two doses, 14 days apart) may be effective. Control of infection may be difficult due to the ingestion of intermediate hosts, such as cockroaches and beetles, and paratenic hosts, such as lizards and hedgehogs. Given the difficult diagnosis of *Ollulanus* and *Physaloptera* spp., empirical therapy with an anthelmintic such as fenbendazole may be warranted in dogs and cats with unexplained gastritis.

Other Parasites

Gastric infection with *Gnathostoma* spp. (cats), *Spirocerca* spp. (dogs), and *Aonchotheca* spp. (cats) has been associated with gastric nodules that have been treated by surgical resection of affected gastric tissue.[122]

Gastric Pythiosis

The presence of transmural thickening of the gastric outflow tract (Figure 275-13) and histology that indicates pyogranulomatous inflammation raise the possibility of infection with fungi such as *Pythium insidiosum* (see ch. 236).[120] Special staining (Gomori's methenamine silver), culture, serology, and PCR of infected tissues can be used to help confirm the diagnosis. Treatment consists of aggressive surgical resection combined with itraconazole (10 mg/kg PO q 24 h) and terbinafine (5 to 10 mg/kg PO q 24 h) for 2 to 3 months postsurgery. ELISA titers of pretreatment and posttreatment samples may show a marked drop during successful treatment, and drugs can be stopped. Medical therapy is continued for another 2 to 3 months if titers remain elevated. The prognosis is poor, as <25% of afflicted animals are cured with medical therapy alone.[120,123]

Helicobacter-Associated Gastritis

The general lack of knowledge of the pathogenicity of gastric *Helicobacter* spp. has meant that veterinarians are faced with the dilemma of either treating or ignoring spiral bacteria observed in biopsies from patients with chronic vomiting and gastritis. In light of their pathogenicity in humans, ferrets, cheetahs, and mice, it would seem prudent that eradication of gastric *Helicobacter* spp. be attempted prior to initiating treatment with immunosuppressive agents to control gastritis. However, this must be decided on an individual basis. For example, in the patient with a lymphoplasmacytic infiltrate of the stomach and small intestine with a concomitant gastric *Helicobacter* spp. infection, should one treat for inflammatory bowel disease, *Helicobacter,* or both?

The author recommends treating only symptomatic patients that have biopsy-confirmed *Helicobacter* spp. infection *and* gastritis. Current treatment protocols are based on those found to be effective in humans infected with *H. pylori.* An uncontrolled treatment trial of dogs and cats with gastritis and *Helicobacter* spp. infection showed that clinical signs in 90% of 63 dogs and cats responded to treatment with a combination of metronidazole, amoxicillin, and famotidine, and that 74% of 19 animals reendoscoped had no evidence of *Helicobacter* spp. in gastric biopsies.[113] A recent controlled trial of amoxicillin (15 mg/kg PO q 12 h for 14 days), metronidazole (10 mg/kg PO q 12 h for 14 days) and bismuth ± famotidine in 24 dogs found a similar decrease in vomiting (86.4%) and reduced gastritis scores in dogs that were *Helicobacter* negative at 6 months. The use of famotidine did not improve resolution of clinical signs or eradication of *Helicobacter.* Unfortunately, only 43% of dogs were free from *Helicobacter* at 6 months,[114] which echoes the results of controlled studies in asymptomatic *Helicobacter*-infected dogs and cats. Treatment combinations evaluated in these asymptomatic animals include (1) amoxicillin (20 mg/kg PO q 12 h for 14 days), metronidazole (20 mg/kg PO q 12 h for 14 days), and famotidine (0.5 mg/kg PO q 12 h for 14 days) in dogs;[124] (2) clarithromycin (30 mg PO q 12 h for 4 days), metronidazole (30 mg PO q 12 h for 4 days), ranitidine (10 mg PO q 12 h for 4 days), and bismuth (20 mg PO q 12 h for 4 days; CMRB) in *H. heilmannii*–infected cats;[125] and (3) azithromycin (30 mg PO q 24 h for 4 days), tinidazole (100 mg PO q 24 h for 4 days), ranitidine (20 mg PO q 24 h for 4 days), and bismuth (40 mg PO q 24 h for 4 days; ATRB) in *H. heilmannii*–infected cats.[125] Re-evaluation of infection status at 3 days (dogs) or 10 days (cats) after treatment revealed 6 of 8 dogs, 11 of 11

CMRB-treated cats, and 4 of 6 ATRB-treated cats to be *Helicobacter*-free on the basis of histology and urease testing (dogs) or ^{13}C-urea breath test (dogs and cats).[125,126] However, at 28 days (dogs) or 42 days (cats) after completing antimicrobial therapy, 8 of 8 dogs, 4 of 11 cats that received CMRB, and 5 of 6 cats that received ATRB were found to be reinfected. A transient effect of combination therapy (amoxicillin 20 mg/kg PO q 8 h for 21 days, metronidazole 20 mg/kg PO q 8 h for 21 days, and omeprazole 0.7 mg PO q 24 h for 21 days) on bacterial colonization has also been observed in 6 cats with *H. pylori* infection.

Further analysis of gastric biopsies from asymptomatic infected dogs and cats and *H. pylori*–infected cats using PCR and *Helicobacter*-specific primers revealed persistence of *Helicobacter* DNA in gastric biopsies that appeared negative on histology and urease testing.[127] These studies suggest that antibiotic regimens that are effective against *H. pylori* in people may only cause transient suppression, rather than eradication, of gastric *Helicobacter* spp. in dogs and cats.

A recent study that gave metronidazole (11 to 15 mg/kg PO q 12 h), amoxicillin (22 mg/kg PO q 12 h), and bismuth subsalicylate (0.22 mL/kg PO q 8 h) to five *Helicobacter*–infected animals (three dogs and two cats) for 21 days documented resolution of vomiting and long-term eradication of *Helicobacter* (9 to 38 months) in all animals.[128] The author has employed the combination of amoxicillin (20 mg/kg PO q 12 h), clarithromycin (7.5 mg/kg PO q 12 h), and metronidazole (10 mg/kg PO q 12 h) for 14 days to successfully eradicate *H. pylori* infection in cats. A similar combination of antibiotics plus omeprazole transiently suppressed *Helicobacter* in 4/13 asymptomatic adult stray cats.[127] These studies suggest that a longer duration of treatment (21 days) or the use of antibiotics that can eradicate intracellular *Helicobacter* (clarithromycin) can improve eradication, but further studies are required before clear guidelines regarding the treatment of gastric *Helicobacter* spp. in dogs and cats can be made.

Chronic Gastritis of Unknown Cause

Lymphocytic-plasmacytic gastritis of unknown cause is common in dogs and cats. It may be associated with similar infiltrates in the intestines.[101] Cats with lymphoplasmacytic gastritis and enteritis should also be evaluated for the presence of concurrent pancreatic and biliary disease, "triaditis."[129] The cellular infiltrate varies widely in severity, and it may be accompanied by mucosal atrophy or fibrosis and less commonly by hyperplasia. Patients with mild lymphoplasmacytic gastritis that lack follicular hyperplasia and evidence of HLO are initially treated with diet. The diet is usually restricted in antigens to which the patient has been previously exposed, such as a lamb-based diet if the patient has previously been fed chicken and beef, or it contains hydrolyzed proteins (usually chicken or soy) that may be less allergenic than intact proteins. Many of these diets are also high in carbohydrates and restricted in fat, which facilitates gastric emptying, and they may contain other substances, such as menhaden fish oil or antioxidants that may alter inflammation. The test diet is fed exclusively for a period of about 2 weeks, and vomiting episodes are recorded.[116] If signs improve, a challenge with the original diet is required to confirm a diagnosis of food intolerance. The introduction of a specific dietary component, such as beef, to the test diet is required to confirm dietary sensitivity. If vomiting is unresponsive, the patient may be placed on a different diet for another 2 weeks, usually the limit of client tolerance, or the patient may be started on prednisolone (1 to 2 mg/kg/day PO, tapered to every other day at the lowest dosage that maintains remission over 8 to 12 weeks).

Patients with moderate to severe lymphoplasmacytic gastritis that are HLO-free may be started on a combination of a test diet and prednisolone. If patients go into remission, they are maintained on the test diet while prednisolone is tapered and discontinued if possible. Antacids and mucosal protectants are added to the therapeutic regimen if ulcers or erosion are detected at endoscopy or if hematemesis or melena are noted. If gastritis is unresponsive to diet, prednisolone, and antacids, additional immunosuppression may be indicated, but this is not often required. Gastric biopsies should be carefully re-evaluated for evidence of lymphoma. In dogs, immunosuppression is usually increased with azathioprine (2 mg/kg PO q 24 h for 5d, then q 48 h on alternating days with prednisolone). Chlorambucil is a safer alternative to azathioprine in cats (PO) and has been successfully employed in the management of inflammatory bowel disease and small-cell lymphoma (see below). Prokinetic agents such as metoclopramide, cisapride, and erythromycin can be used as an adjunct where delayed gastric emptying is present. These are discussed below.

Diffuse eosinophilic gastritis of undefined etiology is usually approached in a similar fashion to lymphoplasmacytic gastritis. The presence of eosinophilia, dermatologic changes, and eosinophilic infiltrates may be even more suggestive of dietary sensitivity. In cats, it should be determined whether it is part of a hypereosinophilic syndrome. Treatment for occult parasites, dietary trials, and immunosuppression can be carried out as described above. Focal eosinophilic granulomas can be associated with parasites or fungal

infection that should be excluded prior to immunosuppression with corticosteroids.

Atrophic Gastritis

See E-Box 275-2.

E-Box 275-2

Atrophic Gastritis

Atrophic gastritis in dogs and cats is often associated with a marked cellular infiltrate (see Figure 275-10). In people, atrophy is associated with *Helicobacter* spp. infection, inflammation, and immune-mediated destruction.[130] Gastric disease is often not discovered until the patient presents with pernicious anemia secondary to cobalamin deficiency caused by a lack of gastric intrinsic factor. In people, atrophic gastritis, intestinal metaplasia of the gastric mucosa, hypergastrinemia, and hypochlorhydria are thought to precede the development of gastric cancer.[131] The host inflammatory response is also thought to contribute to the development of atrophy. Proinflammatory IL-1-beta and IL-10 gene polymorphisms in people are associated with increased inflammation, gastric atrophy, hypochlorhydria, and gastric cancer.[132,133]

Atrophic gastritis has been infrequently described in dogs and cats but does share some similarities with people. Atrophic gastritis characterized by reduction in parietal cells and hyperplasia of neuroendocrine cells has been associated with gastric adenocarcinoma in Lundehunds.[134] Some of the adenocarcinomas displayed enterochromaffin-like cell differentiation, suggesting that hypergastrinemia secondary to fundic atrophy may be important in carcinogenesis. In dogs with lymphoplasmacytic gastritis of undetermined cause, gastric atrophy correlates with the expression of mRNA for IL-1-beta and IL-10 and the presence of neutrophils.[16] However, with the exception of the Lundehund, clear evidence that gastritis progresses to atrophy and gastric cancer in dogs or cats[135] and the role of *Helicobacter* spp. or antigastric antibodies in the development of atrophy in dogs and cats remain to be determined.

In contrast to humans, dogs and cats with atrophic gastritis have not been reported to develop cobalamin deficiency. This is likely because the pancreas, rather than the stomach, is the main source of intrinsic factor in these species. Achlorhydria has been described in dogs and may enable the proliferation of bacteria in the stomach and upper small intestine, although this has not been proven. The use of omeprazole at doses of 1.1 mg/kg PO q 12 h has been associated with hypergastrinemia and dysbiosis of the gastric microflora.[15] The treatment of atrophic gastritis has received limited attention, but *Helicobacter* spp. eradication and immunosuppression have been effective in subsets of people.

Hypertrophic Gastritis

See E-Box 275-3.

E-Box 275-3

Hypertrophic Gastritis

Hypertrophy in the fundic mucosa is uncommon and is often part of breed-specific gastropathies or other gastroenteropathies (see Figure 275-13). Concurrent hypergastrinemia should prompt consideration of underlying hepatic or renal disease, achlorhydria, or gastrin-producing tumors, which should be pursued appropriately. Basenji gastroenteropathy is variably associated with fasting hypergastrinemia and exaggerated secretin-stimulated gastrin, and anecdotal reports suggest that affected Basenjis may respond to antimicrobial therapy. Antral hypertrophy of brachycephalic dogs causes outflow obstruction and is treated with surgery (see later).

Delayed Gastric Emptying and Motility Disorders

Definitions

Disorders of gastric motility can disrupt the storage and mixing of food and its expulsion into the duodenum.[40] Normal gastric motility is the result of the organized interaction of smooth muscle, neural, and hormonal stimuli. Delayed gastric emptying is the most commonly recognized manifestation of gastric motility disorders. Rapid gastric emptying and motility disorders associated with retrograde transit of bile or ingesta are less well defined. Delayed gastric emptying is caused by outflow obstruction or defective propulsion (Box 275-4) and is usually suspected when a pet vomits food at least 8 and often 10 to 16 hours after a meal.

Box 275-4

Causes of Delayed Gastric Emptying

Outflow Obstruction

Congenital stenosis
Foreign bodies
Hypertrophy of pyloric mucosa
Granuloma
Polyps
Neoplasia
Extra-gastric masses

Defective Propulsion

Gastric disorders
Gastritis
Ulcers
Neoplasia
Gastroenteritis
Peritonitis
Pancreatitis
Metabolic (hypokalemia, hypocalcemia, hypoadrenocorticism)
Nervous inhibition (trauma, pain, stress)
Dysautonomia
Gastric dilatation and volvulus
Surgery
Drugs (anticholinergics, narcotics)
Idiopathic

Signalment, History, Physical Examination

Vomiting food 8 to 10 hours after ingestion is the most common sign. Vomiting may be projectile with pyloric stenosis. Abdominal distension, weight loss, melena, abdominal discomfort, distension, bloating, and anorexia are more variably present. Signalment and history may be helpful in prioritizing diagnoses. Vomiting noted at weaning raises the possibility of pyloric stenosis. Access to foreign bodies, bones, and medications is of obvious relevance to outflow obstruction. Brachycephalic, middle-aged, small-breed dogs such as Shih Tzus seem predisposed to a syndrome of vomiting secondary to pyloric outflow obstruction caused by hypertrophy of the pyloric mucosa and/or muscularis.[136,137] Gastric neoplasia is usually detected in older animals with weight loss, hematemesis, and pallor. Gastric pythiosis (see ch. 336) is more prevalent in young large-breed dogs in the Gulf states of the United States. Large-breed, deep-chested dogs are more prone to GDV that may have an underlying problem with gastric emptying (see GD/GDV above). A thorough physical examination is performed to detect causes of vomiting: string foreign bodies; intestinal masses or thickenings; non-GI causes, including thyroid (nodules in cats), liver (jaundice, hepatomegaly), or kidney disease (abnormal on palpation); and the systemic effects of vomiting, such as dehydration and weakness.

Laboratory Assessments

Hematology (CBC), serum biochemistry, urinalysis, fecal analysis (parasites [see ch. 81], parvovirus [see ch. 225]), and serology (FeLV; see ch. 223) are employed to detect non-GI causes of vomiting or delayed gastric emptying and to determine the consequences of vomiting. Laboratory findings vary depending on the severity of vomiting, completeness of pyloric obstruction, and the presence of disorders associated with blood loss or inflammation. The CBC is often normal, but anemia may accompany gastric ulcers or neoplasia. Hyperglobulinemia may be present where outflow obstruction is secondary to fungal granuloma. The presence of hypochloremia, hypokalemia, and metabolic alkalosis, with or without aciduria, should increase suspicion of an upper GI obstruction or potential hypersecretion of gastric acid.

Diagnosis: Imaging, Endoscopy, Gastric pH Testing, Scintigraphic Techniques

Radiographs are essential for diagnosing retention of food or fluid in the stomach longer than 8 hours after a meal and to detect extra-gastric disorders such as peritonitis (see ch. 279). US (see ch. 88) may detect mural thickening or irregularity of the stomach suggestive of neoplasia, granuloma, hypertrophy, a radiolucent foreign object, or detect non-gastric causes of delayed emptying, e.g., pancreatitis. Contrast radiography can be used to detect mural abnormalities and to confirm suspicion of gastric obstruction when plain radiographs are inconclusive (Figure 275-14).

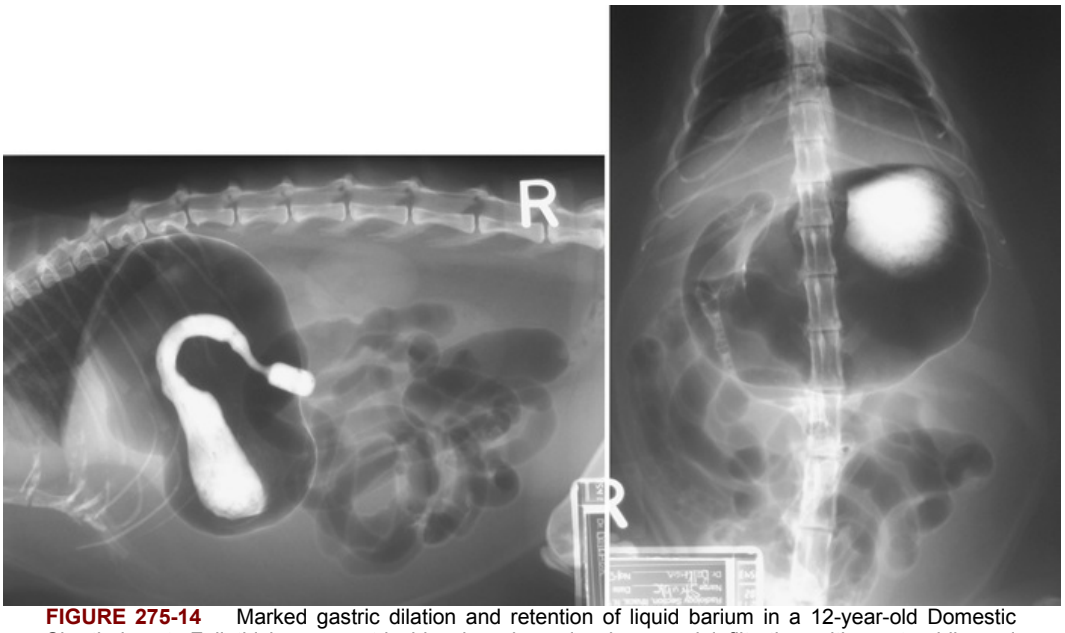

FIGURE 275-14 Marked gastric dilation and retention of liquid barium in a 12-year-old Domestic Shorthair cat. Full thickness gastric biopsies showed submucosal infiltration with neutrophils and lymphocytes. (Courtesy Cornell University. © Kenneth W. Simpson.)

Endoscopy (see ch. 113) is usually favored over radiographic procedures for confirming gastric outflow obstruction or gastric/duodenal causes of decreased propulsion (e.g., ulcers, gastritis; see Figure 275-13). Endoscopy can be hampered by recent administration of barium, so it is often performed first. Endoscopic biopsy is limited to the superficial mucosa, and surgical biopsy is frequently required to achieve a definitive diagnosis of granulomatous, neoplastic, or hypertrophic conditions. Measurement of gastric pH and serum gastrin can help to differentiate idiopathic hypertrophic pylorogastropathy from hypertrophy associated with hypergastrinemia. Pancreatic polypeptide-producing tumors may also be associated with mucosal hypertrophy.

More sophisticated procedures can be used to directly evaluate gastric emptying, motility, and to optimize prokinetic therapy (E-Table 275-3).[40,41] These include barium contrast (liquid or mixed with food), barium-impregnated polyspheres, sonography, nuclear scintigraphy, the ^{13}C-octanoate and ^{13}C-acetate breath tests, and wireless motility capsules.[40-44,49] Radiographic contrast procedures are readily available but are hampered by the wide variability in emptying times for barium in liquid or meal form. Giving barium-impregnated polyspheres is a simplified contrast procedure suited to routine clinical practice, requires far

fewer radiographs than a traditional barium series, and test performance/interpretation are standardized. Its utility in pets remains to be determined. Ultrasound can be useful for detecting gastric wall abnormalities and measuring contractile activity, with standardized measurement of a motility index considered comparable to ^{13}C-octanoate.[138]

E-TABLE 275-3

Review of Methods for Assessment of the Rate of Gastric Emptying in the Dog and Cat[41]

GASTRIC HALF METHOD	SPECIES	TEST MEAL	N	EMPTYING TIME ($T_{1/2}$)*
Radioscintigraphy	Dog	Eggs, starch + glucose	27	66 min (median), 45-227 min (95% CI)
		Beef baby food + kibble	6	4.9 ± 1.96 h (mean ± sd)
		Liver	4	About 2 h
		Canned dog food + egg	6 (18 tests)	172 ± 17 min (mean ± se)
		Canned dog food + egg	7 (14 tests)	285 ± 34 min (mean ± sd); 294 ± 39 min (mean ± sd)
		Canned dog food	6	77 min (mean)
	Cat	Dry cat food	10	2.47 ± 0.71 h (mean ± sd)
		Liver + cream	6 (15 tests)	163 ± 11 min (mean ± se)
		Canned cat food	20	2.69 ± 0.25 h (mean ± sd)
		Dry cat food	20	3.86 ± 0.24 h (mean ± sd)
		Eggs	10	330 min (median), 210-769 min (range)
Radiography		Dry dog food + radiopaque solids	10	3.5 h (median), 1-6 h (range)
		Canned dog food + egg + BIPS	6 (18 tests)	Small BIPS = 416 ± 81 min (mean ± se)
	Dog	Canned dog food + BIPS	20	Small BIPS = 6.05 ± 2.99 h (mean ± sd)
				Large BIPS = 7.11 ± 3.60 h (mean ± sd)
		Kibble + BIPS	8	Small BIPS = 8.29 ± 1.62 h (70% of dogs ± se)
				Large BIPS = 29.21 ± 18.31 h (70% of dogs ± se)
		Kibble + liquid barium	9 (27 tests)	Total gastric emptying time = 7-15 h (range)
		Kibble + liquid barium	4	Total gastric emptying time = 7.6 ± 1.98 h (mean ± se)
	Cat	Canned cat food + BIPS	10	Small BIPS = 6.43 ± 2.59 h (mean ± sd)
				Large BIPS = 7.49 ± 4.09 h (mean ± sd)
		Canned cat food + BIPS	6	Small BIPS = 7.7 h (median), 3.5-10.9 h (range)
				Large BIPS = 8.1 h (median), 5-19.6 h (range)
		Canned cat food + BIPS	10	Small BIPS = 5.36 h (median)
				Large BIPS = 6.31 h (median)
		Cat food + liquid barium	8	Gastric emptying time = 11.6 ± 0.9 h (mean ± sd)
Gastric emptying	Cat	Canned cat food	6	Peak 13C-excretion = 56.7 ± 9.8 min (mean ± sd)
Breath test	Dog	Bread, egg + margarine	6 (18 tests)	3.43 ± 0.50 h (mean ± sd)

*Gastric emptying rate is expressed as gastric half emptying time unless otherwise stated.

BIPS, Barium-impregnated polyspheres.

Reproduced with permission from Wyse CA, McLellan J, Dickie AM, et al: A review of methods for assessment of the rate of gastric emptying in the dog and cat: 1898-2002. *J Vet Intern Med* 17:609, 2003.

Scintigraphic techniques have traditionally been considered the most accurate way to evaluate emptying, but these involve radioactivity and are restricted to specialized facilities. Tests employing non-radioactive ^{13}C-octanoate and ^{13}C-acetate have been evaluated in people and dogs and have been found to reflect gastric emptying (the values are longer than scintigraphy as ^{13}C-substrates have to be absorbed and metabolized before $^{13}CO_2$ is liberated). Wireless capsule telemetry has recently been shown to provide accurate measurement of gastric emptying, with mean coefficients of variation (8%) similar to those of scintigraphy (11%), with emptying times considerably longer than scintigraphy.[43,44] Wireless capsule endoscopy enables simultaneous visualization of the pyloric outflow tract and measurement of gastric emptying time.[37]

Treatment

Direct Management

Treatment of gastric-emptying disorders is directed at the underlying cause. Gastric ulcers, erosions, and inflammation should be investigated and managed medically, as described. Foreign bodies should be removed either endoscopically or surgically. Pyloric stenosis, polyps, and hypertrophic gastropathy that is not associated with hypergastrinemia are managed surgically. When hypertrophic gastropathy, ulcers or erosions, or excessive gastric juice are encountered at endoscopy, IV H2-antagonists can be given during the procedure to try to prevent postoperative perforation or esophagitis. Neoplasia, polyps, and granulomas may require extensive gastric resection and Billroth procedures.

Dietary Modifications

Dietary modification to facilitate gastric emptying may be beneficial regardless of cause. Small amounts of semiliquid, protein- and fat-restricted diets fed at frequent intervals may facilitate emptying, such as an "intestinal-disease diet" blended with water and mixed with an equal volume of boiled rice (see ch. 178).

Medications

No controlled trials in dogs and cats have evaluated the efficacy of different prokinetics in different disease states, and treatment is usually based on a best guess/least harmful basis. Where true prokinetic activity is required, cisapride and erythromycin appear to be the most efficacious.[40] Treatment trials with prokinetics should probably be structured to last between 5 and 10 days to determine benefit. A diary of clinical signs and the objective assessment of gastric emptying using the tests described above, before and after therapy, helps to optimize treatment. Combination therapy, such as erythromycin and cisapride, is not recommended due to the potential for adverse drug interactions (see ch. 169). The prognosis for patients with delayed gastric emptying depends on the cause. A suspected motility disorder characterized by duodenogastric reflux is thought to account for the *bilious vomiting syndrome.* Affected dogs usually vomit early in the morning, and remission may be achieved by feeding the animal late at night. Prokinetic agents may also be employed.

In nonobstructive situations, gastric emptying may be enhanced and duodenogastric reflux inhibited by prokinetic agents such as metoclopramide, cisapride, erythromycin, or ranitidine.[40,68,139] The choice of prokinetic depends on whether a central antiemetic effect is required, as with metoclopramide, or a combined antacid prokinetic (ranitidine) is indicated, or if treatment with one agent has been ineffective or has caused adverse effects, such as behavioral changes with metoclopramide. In addition to its prokinetic activity in the stomach and upper GI tract, metoclopramide (0.2 to 0.5 mg/kg PO SC q 8 h) has central antiemetic properties and is an initial choice in patients with underlying metabolic diseases associated with vomiting and delayed gastric emptying. However, metoclopramide may only facilitate the emptying of liquids and is less effective in promoting organized gastroduodenal and intestinal motility than cisapride. Cisapride (0.1 to 0.5 mg/kg PO q 8 h) has no central antiemetic effects, is generally more potent in promotion of the gastric emptying of solids than metoclopramide, has more drug interactions, and its availability is limited. Erythromycin (dog: 0.5 to 1 mg/kg PO q 8 h, between meals) releases motilin, acts at motilin receptors, and mimics phase III of the interdigestive migrating myoelectric complex, promoting the emptying of solids. Nizatidine and ranitidine (0.5-1 mg/kg PO q 8 h) have prokinetic activity in experimental dogs attributed to an organophosphate-like

effect.[140] Ranitidine hydrochloride (75 mg PO q 12 h) was recently found to have no effect on gastric emptying time evaluated by wireless motility capsule.[43]

Gastric Neoplasia

Overview

Gastric tumors represent <1% of all reported canine and feline neoplasms.[141] Malignant tumors are more common than benign and most types of gastric neoplasms have been reported to occur more frequently in males, except adenomas.[142] Gastric malignancies reported are leiomyosarcoma, lymphoma (see ch. 344), fibrosarcoma, rare anaplastic sarcoma, and gastric extramedullary plasmacytoma (Table 275-4).

TABLE 275-4

Characteristics of Gastric Neoplasia in Dogs

TUMOR	MOST COMMON LOCATION	MEDIAN AGE (YEARS)	REPORTED BREED PREDISPOSITION
Adenocarcinoma	Pyloric antrum, lesser curvature	10	Belgian Shepherd Rough Collie Staffordshire Bull Terrier Lundehund Bouvier Groenendael Standard Poodle Norwegian Elkhound
Leiomyoma	Cardia	16	Beagle
Leiomyosarcoma		7	None
Lymphoma	Diffuse	10	None

Benign Tumors

Benign tumors of the stomach include leiomyomas and, less frequently, adenomatous polyps. Canine gastric leiomyomas are seen in old dogs, median age 16 years, with some identified incidentally at necropsy or when seen for GI bleeding and microcytic anemia (Figure 275-15). Adenomatous polyps are rare in dogs but have been reported as either raised, sessile, or pedunculated single or multiple growths in the stomach, usually in the terminal pyloric antrum. Although most are discovered incidentally, they may also cause signs of GI upset with vomiting (Figure 275-16). In humans, adenomatous polyps are generally regarded as possible premalignant lesions, and changes considered focally malignant have been found in dogs. Benign GI neoplasia in the cat occurs at a much lower frequency than in the dog, although up to 36% of all GI neoplasms are reported to be benign.

Malignant Tumors

Adenocarcinoma

Malignant adenocarcinoma is the most common gastric neoplasm in dogs, accounting for 47-72% of all canine gastric malignancies.[143-146] Gastric adenocarcinoma is extremely rare in cats. The peak age of dogs with gastric carcinomas has been reported to be from 10 to 12 years with a range of 3 to 13 and an average age of 9 to 10 years. A breed predilection for gastric carcinoma in related Belgian Shepherds, Rough Collies, and Staffordshire Bull Terriers has been suggested, although some studies show no significant breed predilections. The Norwegian Canine Cancer Register indicates that Tervuren/Belgian Shepherd, Bouvier des Flandres, Groenendael, Collie, Standard Poodle, and Norwegian Elkhound had a significantly increased risk of developing gastric carcinoma.[141] Males were more likely to be affected than females. Lundehunds with atrophic gastritis seem overrepresented, and gastric atrophy and inflammation may precede tumorigenesis as it does in humans.[134]

Gastric carcinomas of dogs occur most commonly in the lesser curvature and pyloric region as annular or stenosing lesions, and metastasis is frequent with involvement of lymph nodes, lungs, and liver (Figure 275-17). Carcinomas can be further divided into three morphologic patterns of distribution: (1) diffusely infiltrating, nonulcerating lesions that involve most of the stomach and are consistent with the "leather bottle" appearance described in humans; (2) localized, raised, thickened plaque usually containing a raised, excavating central ulcer; and (3) raised, polypoid, sessile lesion projecting into the lumen of the stomach. Two histologic types of gastric carcinoma have been described in people: (1) *diffuse* and (2) *intestinal* or *tubular.* The diffuse type consists of widespread random infiltrates of neoplastic cells dispersed between stromal elements of the gastric wall. The intestinal type is characterized by a tubular, glandular structure. The diffuse type is more common in dogs.

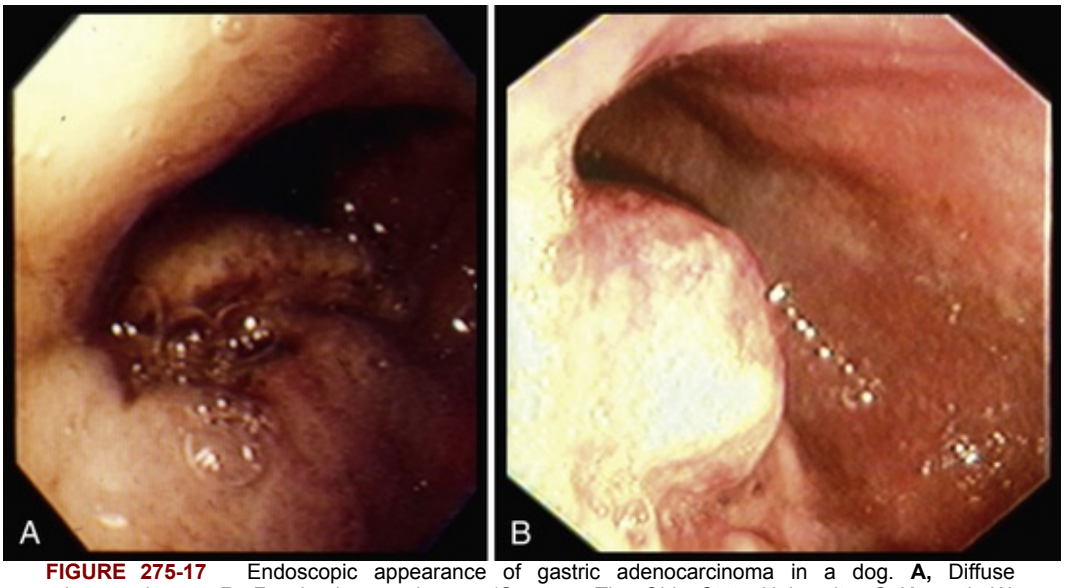

FIGURE 275-17 Endoscopic appearance of gastric adenocarcinoma in a dog. **A,** Diffuse adenocarcinoma. **B,** Focal adenocarcinoma. (Courtesy The Ohio State University. © Kenneth W. Simpson.)

Lymphoma

The most common GI neoplasm in both cats and dogs is lymphoma. In canine lymphoma originating in the gastric submucosa, the process may be described as diffuse or nodular, with the diffuse infiltrate being more common (Figure 275-18). Involvement of the liver, regional lymph nodes, small intestine, and bone marrow is common. Feline gastric lymphoma is not associated with FeLV infection and has been categorized as large cell or small cell, with small-cell lymphoma being more localized to the GI tract and carrying a much better prognosis than large-cell lymphoma.[147,148] In both dogs and cats, lymphocytic-plasmacytic inflammation has been found to precede or coexist with gastric lymphoma. It has been suggested that lymphocytic-plasmacytic inflammation is a prelymphomatous change in the GI tract. The development of gastric lymphoma in response to chronic antigenic stimulation and inflammation is exemplified by gastric MALT lymphoma in people with *H. pylori*–associated gastritis.

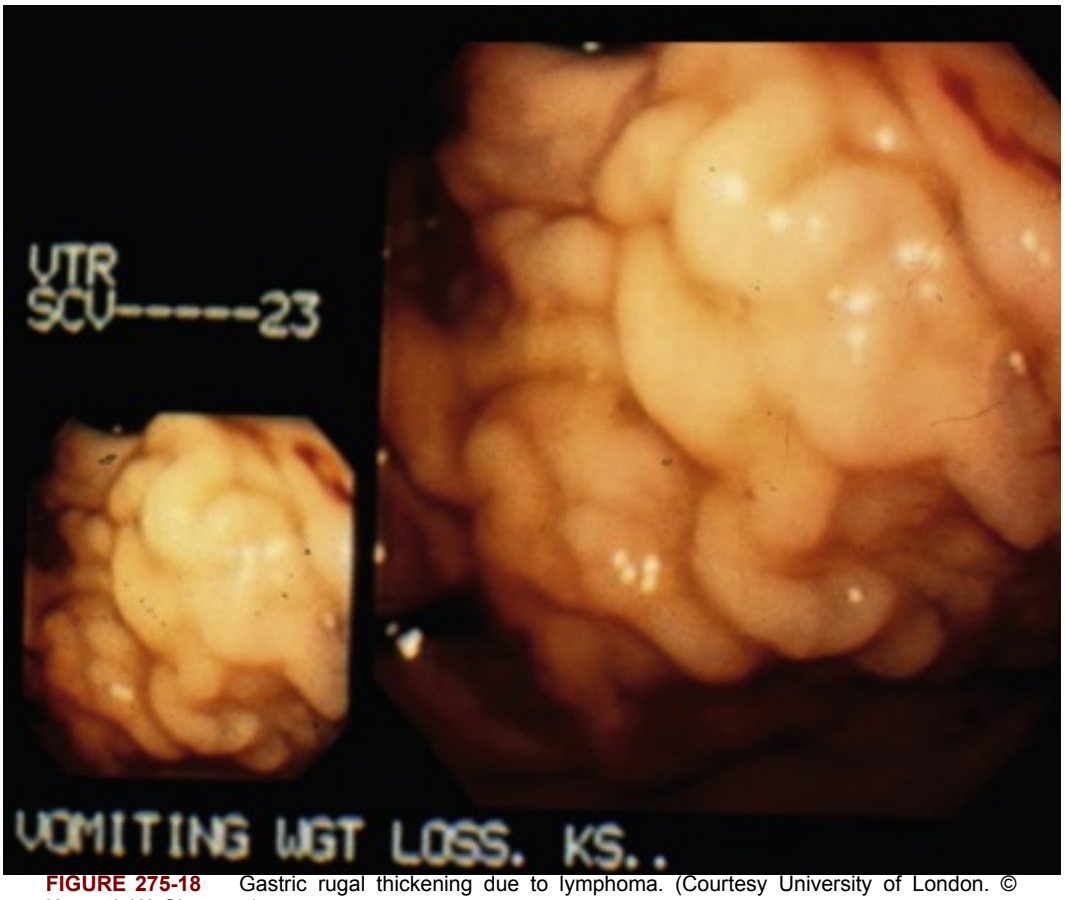

FIGURE 275-18 Gastric rugal thickening due to lymphoma. (Courtesy University of London. © Kenneth W. Simpson.)

Leiomyosarcoma

Leiomyosarcomas are slow growing tumors of smooth-muscle origin. The median age of affected dogs is >10 years. Intestinal leiomyosarcoma has been found to be more common in females and a predilection was reported in the German Shepherd breed. However, neither breed nor sex predilection has been reported for gastric leiomyosarcoma.[149] In one study, dogs with leiomyosarcoma of the spleen, stomach, small intestine, and cecum were grouped together with 79% showing no evidence of metastases at surgery and 64% surviving longer than 2 weeks.[149] Invasion of the gastric wall by leiomyosarcomas and lymphoma is often diffuse. These tumors may cause ulceration grossly resembling adenocarcinomas, or they may appear as discrete masses. The median survival of these dogs was 10 months (range: 1 month to 7 years). Of the stomach/small intestine group, 29% died of leiomyosarcoma eventually. Leiomyosarcoma and leiomyoma have been associated with paraneoplastic hypoglycemia and seizures, presumed due to the production of insulin-like growth factors (see ch. 352).[150]

Clinical Findings

The most common clinical signs associated with gastric neoplasia are chronic vomiting, weight loss, anorexia, diarrhea, and hematemesis, melena, or pallor if ulceration is present. Some dogs have abdominal pain or a distended abdomen. With GI lymphoma, onset of signs is often insidious, gradually increases in severity, and becomes refractory to symptomatic treatment.

Diagnosis

Survey radiographs may be completely normal or may suggest focal gastric wall thickening, an abdominal mass, evidence of peritonitis, splenomegaly, hepatomegaly, or lymphadenopathy. Spontaneous gastrointestinal perforation in cats has been associated with lymphoma.[151] US may reveal mural thickening or

irregularities that may indicate that lesions may be more submucosal or muscular than superficial. Lymphadenopathy or regional metasasis may be evident. US can be employed to evaluate gastric wall thickness and layering, and gastric emptying. US is less accurate than endoscopy for detecting gastric neoplasia, particularly lymphoma, but it can increase suspicion of a gastric lesion and facilitate detection of non-gastric lesions in pets with signs of GI disease.[32,33]

Gastroscopy (see ch. 113) is able to efficiently detect most gastric tumors and has largely replaced contrast radiography. Lymphoma is seen as a diffuse, smooth, or cobblestone-like thickening of the rugae with a mucosa that is pink or white and may have scattered petechial or ecchymotic hemorrhages. Gastric carcinomas tend to be focal, dark pink to red masses that may appear slightly pedunculated. Discolored purple to black areas indicate hemorrhage, whereas yellow to brown foci often represent necrotic ulcers. Some lesions are submucosal and one may gain the impression that something is indenting the stomach, or the wall seems less distensible or thick. Wireless capsule endoscopy may facilitate non-invasive detection of gastric neoplasia.

Several biopsy samples should be taken from suspicious areas, and masses should be biopsied multiple times in the same place to get deeper into tissue, as gastric tumors may have superficial necrosis, inflammation, and ulceration, areas that should be avoided when taking biopsies. Focusing at the periphery helps avoid perforation. Surgical biopsies should be taken where the gross endoscopic appearance does not match the histologic diagnosis, such as a large, focal gastric mass with an endoscopic biopsy result of lymphoplasmacytic gastritis. When endoscopy is not available, contrast radiography may be useful with features of gastric neoplasia, including thickening of the gastric wall, filling defects and derangement of normal rugal pattern, and delayed gastric emptying with retention and irregular pooling of barium. Surgery is then performed to sample the affected area.

Treatment

Except for lymphoma (see ch. 344), surgery is the most common form of treatment for gastric cancer. Resection may be curative if the affected area is localized, or if the tumor is benign. If a widespread area is involved, a partial gastrectomy or antrectomy followed by gastroduodenostomy (Billroth I) may be attempted. However, many patients are at a late stage of disease, and the lesions are often too extensive to resect. Gastric adenocarcinoma often metastasizes, and regional lymph nodes and liver should be inspected and biopsied. Even with surgery, the prognosis for malignant gastric neoplasia is poor, with most pets dying within 6 months from recurrent or metastatic disease. Leiomyosarcoma is an exception and carries a good to excellent prognosis if the mass is surgically resectable. Even if gross metastasis is evident at surgery, a favorable outcome may be achieved, because the tumor is slow growing. Survival in dogs with stomach, small intestinal, splenic, and cecal leiomyosarcoma ranges from 0 to 47 months after surgery, and the median survival is 12.5 months.[149]

GI lymphoma has a poor prognosis in dogs.[152] In cats the prognosis depends on whether the tumor is low or high grade, epitheliotrophic or transmural.[153] Small-T-cell lymphomas (typically epitheliotrophic) achieve substantial remission when treated with chlorambucil and prednisolone.[147,148] Large-cell lymphoma (B or T) is treated with combination cyclical chemotherapy and carries a much poorer prognosis.

CHAPTER 276

Diseases of the Small Intestine

Edward James Hall, Michael J. Day

Client Information Sheets:
Inflammatory Bowel Disease
Giardia Infection

The conflicting functions of the small intestine (SI), namely nutrient digestion and absorption versus protection of the body from environmental threats, make it the largest and most complex immunologic organ in the body, as well as the main digestive organ. In previous editions of this textbook, the SI diseases chapter initially focused on diseases related to disturbances of its digestive function, and later, on diseases associated with the mucosal immune system.[1,2] The last edition then highlighted how the third major component of the SI, the *microbiome* (formerly the *enteric flora*), interacts with the mucosal immune system as part of the integrated function of the organ.[3] It has now become apparent that the microbiome is important not only in intestinal health but also in disease (see ch. 274). Dysbiosis is a disturbance of the normal microbiome and is involved in intestinal inflammation and even carcinogenesis and death.[4-7] This has led to the emergence of novel therapies such as probiotics, fecal microbial transplants and stem cell therapy for chronic enteropathies.[8-13] Even more remarkable, it is now recognized that the microbiome can affect the whole animal; the gut-brain axis involves two-way communication, with increasing evidence that the microbiome can affect behavior and cognitive function, a phenomenon which will undoubtedly be explored more in future editions.[14-20] But even with our current, improved understanding of its three main elements—mucosa, mucosal immune system, and microbiome—the clinician is better able to understand and treat many SI diseases.

The cardinal sign of these diseases is diarrhea, a significant increase in the frequency, fluidity, or volume of feces (see ch. 40). Yet diarrhea can be a manifestation of disease elsewhere in the gastrointestinal (GI) tract or in other organ systems (Box 276-1). Conversely, diarrhea is not present in all cases of SI disease, and there are many other signs of SI dysfunction, some of which are nonspecific (Box 276-2).

Box 276-1

Causes of Diarrhea

Gastrointestinal Disease

- Diffuse GI disease (e.g., inflammation or lymphoma)
- Gastric disease
  - Achlorhydria*
  - Dumping syndromes*
- Intestinal disease
  - Diet-related (e.g., food poisoning, gluttony, sudden change of diet, toxins)
  - Primary small intestinal disease
    - Dietary
    - Dysbiosis
    - Infectious
    - Inflammatory
    - Neoplastic
    - Toxic

- Primary large intestinal disease (see ch. 277)

Non-gastrointestinal Disease

- Pancreatic disease
  - Exocrine pancreatic insufficiency‡
  - Pancreatitis (acute, chronic)
  - Pancreatic carcinoma‡
  - APUDomas (gastrinoma causing Zollinger-Ellison syndrome)*
- Liver disease
  - Hepatocellular failure
  - Intrahepatic and extrahepatic cholestasis
- Endocrine disease
  - Classical hypoadrenocorticism‡ (see ch. 309)
  - Atypical hypoadrenocorticism‡ (see ch. 309)
  - Hyperthyroidism† (see ch. 301)
  - Hypothyroidism‡ (see ch. 299)
- Renal disease
  - Uremia (see ch. 322)
  - Nephrotic syndrome‡ (see ch. 325)
- Polysystemic infection (e.g., distemper, leptospirosis, infectious canine hepatitis in dogs; FIP, FeLV, FIV in cats)
- Miscellaneous
  - Toxemias (e.g., pyometra, peritonitis)
  - Portal hypertension and right heart failure
  - Autoimmune disease
  - Metastatic neoplasia
  - Various toxins and drugs

APUD, Amine precursor uptake and decarboxylation tumor; *FeLV*, feline leukemia virus; *FIP*, feline infectious peritonitis; *FIV*, feline immunodeficiency virus.

*Rare conditions.
‡Rare in cats only.
†Rare in dogs only.

Box 276-2

Clinical Signs of Small Intestinal Disease

Cardinal Sign

- Diarrhea
  - Increase in frequency, volume, and consistency of stool

Other Signs

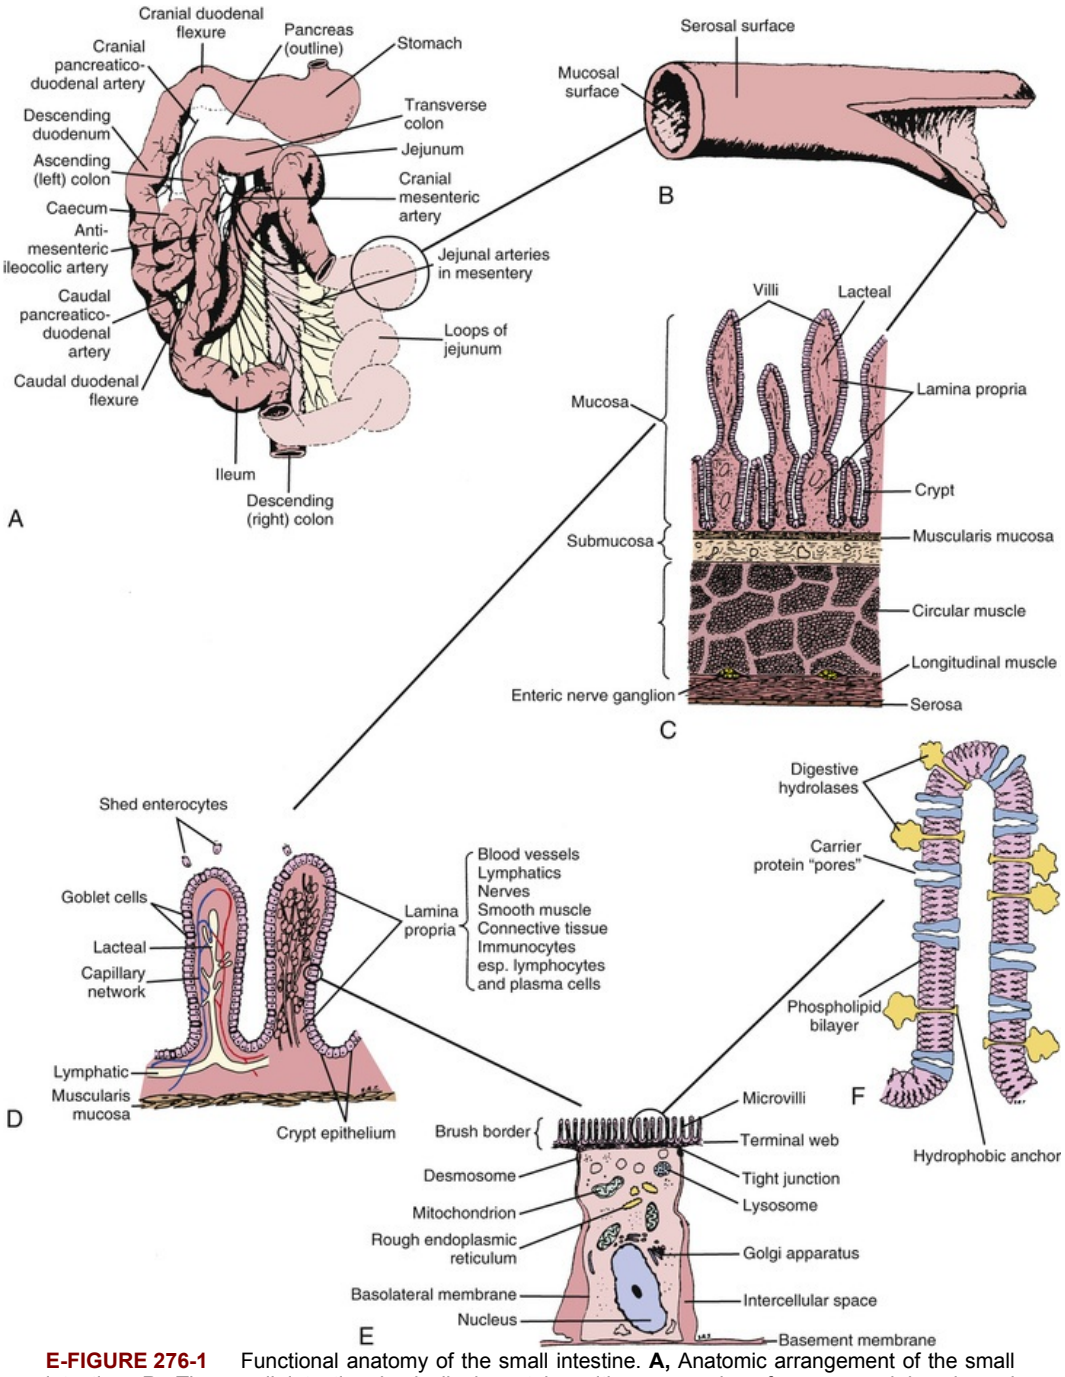
- Vomiting
- Weight loss and/or failure to thrive/stunting
- Hematemesis
- Melena
- Altered appetite
  - Inappetence/dysorexia
  - Anorexia
  - Polyphagia
  - Coprophagia
  - Pica
- Abdominal discomfort, pain

- Abdominal distension: ascites
- Peripheral edema
- Borborygmi and flatus
- Halitosis
- Dehydration
- Polydipsia (compensatory)
- Shock

Functional Anatomy of the Small Intestine

Normal Structure[21-33]

The SI begins at the pylorus of the stomach and ends at the ileocolic valve, being divided arbitrarily into three segments: the duodenum proximally, where the common bile duct and one or more pancreatic ducts enter, then the jejunum, and finally the ileum (E-Figure 276-1, *A*). Blood is supplied by branches of the celiac and cranial mesenteric arteries, and it drains to the liver via the portal vein. Lacteals in the villi drain to mesenteric lymphatic vessels that pass to the cisterna chyli. The autonomic innervation of the SI is from the vagus and splanchnic neves.



E-FIGURE 276-1 Functional anatomy of the small intestine. **A,** Anatomic arrangement of the small intestine. **B,** The small intestine basically is a tube with a serosal surface covered by visceral peritoneum and an inner absorptive and digestive surface, the mucosa. **C,** Beneath the outer serosa, longitudinal and circular muscle layers produce peristaltic and segmental contractions for propelling and mixing the luminal contents. The submucosa is rich in blood and lymphatic vessels. The mucosa comprises the thin muscularis mucosa, the lamina propria, and the columnar epithelium; it is thrown into folds and is covered by fingerlike villi to increase the digestive and absorptive surface area. **D,** Enterocytes, which are shed from the villus tip but are continually replaced through division of crypt cells, are the site of nutrient digestion and absorption. Goblet cells secrete protective mucus. Water-soluble nutrients pass into the rich capillary network of the lamina propria, and fat is passed as chylomicrons into the lacteals. Immunocytes in the lamina propria are involved in maintaining tolerance to luminal antigens. **E,** The luminal membrane of the enterocyte is thrown into processes called microvilli, which increase the luminal surface area. Tight junctions between enterocytes maintain epithelial integrity. Absorbed nutrients are passed from the enterocyte into the intercellular space for distribution to the body. **F,** A schematic representation of a microvillus showing digestive hydrolases anchored in the phospholipid cell membrane and protruding into the intestinal lumen. Carrier proteins in the membrane are believed to act as "pores," shuttling nutrients across the membrane by means of conformational changes in their structure often induced by sodium influx at the expense of energy utilization through Na/K ATPase on the basolateral membrane. (From Hall EJ: Small intestinal disease. In Gorman NT, editor: *Canine medicine and therapeutics,* ed 4, Oxford, 1998, Blackwell Science, p

488.)

The SI is, in essence, a tube ultimately connected to the external environment via the mouth and anus with a basic cross-sectional structure of serosa, muscularis (outer longitudinal and inner circular muscle layers), submucosa, and mucosa around the lumen (E-Figure 276-1, *B*). The inner, mucosal layer is the most important clinically and is responsible for secretory, absorptive, and barrier functions (E-Figure 276-1, *C*). It varies in thickness along the SI, being thinnest distally, and comprises the epithelium and the underlying lamina propria, which contain components of the mucosal immune system. The mucosa is modified by gross folds and finger-like processes, the villi, covered by an epithelial layer of enterocytes and goblet cells that increase its surface area many hundred-fold.

A villus and its feeder crypts comprise the functional unit of the SI (E-Figure 276-1, *D*). Crypt cells are the site of intestinal secretion, and they continually produce undifferentiated epithelial cells. Most develop as enterocytes as they migrate from crypt to villus tip, where they ultimately are shed after approximately three days. Differentiated enterocytes undertake digestive and absorptive processes through digestive enzymes and carrier proteins expressed on the luminal cell membrane, the microvillar membrane (MVM), also called the *brush border* because of its microscopic appearance (E-Figure 276-1, *E* and *F*).

Normal Function[34-38]

Enterocyte function is geared towards production of brush-border proteins for the digestion, absorption, and transfer of simple nutrients and water from the lumen to the blood and lymphatics. Glutamine derived from food is the major energy source for enterocytes, explaining the decline in villus structure and epithelial barrier and immune functions during starvation.

Digestion[39,40]

Major dietary constituents must be hydrolyzed into simple molecules to be transported across the mucosa. This is largely achieved within the SI by bile salt emulsification and luminal enzymatic hydrolysis: the SI merely provides the optimum environment in terms of temperature, pH, and mixing with bile salts and pancreatic digestive enzymes. Only terminal hydrolysis of carbohydrates and proteins is performed by MVM enzymes.

Absorption[41-52]

Simple sugars, amino acids, and oligopeptides are absorbed by active or facilitated carrier-mediated transport; the products of fat digestion and fat-soluble vitamins (A, D, E, and K) are absorbed by passive diffusion into lacteals. Endocytosis of peptides by the adult SI is of no nutritional significance, but neonatal absorption of intact colostral antibodies is crucial.

The absorption of folic acid and vitamin B_{12} is complex (Figure 276-2, *A*) and important clinically because their malabsorption could help determine the site and severity of intestinal disease (Figure 276-2, *B*). Folic acid is absorbed in the proximal SI, while cobalamin (vitamin B_{12}), bound to intrinsic factor, is absorbed in the ileum. Cats and dogs have less capacity to store cobalamin than do humans; cats also lack the binding protein transcobalamin I and rapidly lose cobalamin through enterohepatic recycling. Thus, severe cobalamin malabsorption can deplete cobalamin stores in cats within a month.

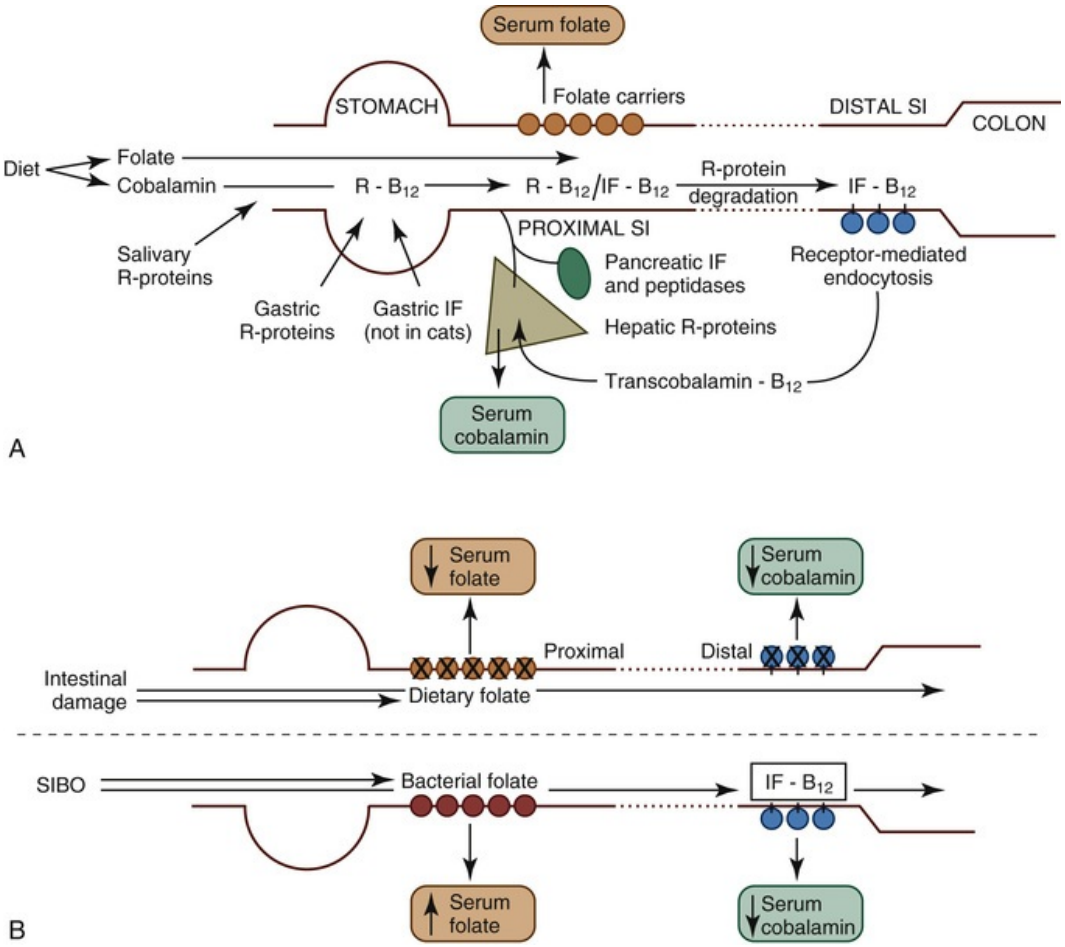


FIGURE 276-2 Diagrammatic representation of the absorption of folate and cobalamin. **A,** In normal intestine, folate is absorbed in the proximal SI by means of carrier-mediated diffusion. Dietary cobalamin initially is protected from digestion by R-proteins and then is absorbed in the ileum through receptor-mediated endocytosis, when bound to intrinsic factor. **B,** In diseased intestine, proximal and distal mucosal damage causes folate and cobalamin malabsorption, respectively. Reduced serum folate and/or cobalamin is/are markers for proximal and/or distal SI damage. Classically, small intestinal bacterial overgrowth (SIBO) causes increased folate uptake because of bacterial folate synthesis and decreased cobalamin uptake because of bacterial incorporation. However, these changes are poorly sensitive and cannot be used for making a diagnosis: they do not correlate with antibiotic-responsiveness. *IF,* Intrinsic factor; *SI,* small intestine.

Motility[53-70]

Slow wave, segmental, and peristaltic contractions of the SI are generated by the coordinated contraction of longitudinal and circular smooth muscle in response to spontaneous electrical activity: interstitial cells of Cajal are the pacemaker cells. Intestinal motility in the fasted state in dogs is characterized by a three-phase cycle: a *quiescent* phase, then *minor contractile activity,* followed by short *migrating myoelectric* (motor) *complexes* (MMCs) that sweep away indigestible material. The MMC "intestinal housekeeper" wave is induced by the hormone motilin, and it can be replicated by low dosages of erythromycin stimulating the motilin receptor. Segmental contractions slow intestinal transit and ensure mixing and digestion of nutrients, until peristalsis propels the ingesta onward. The duration and pattern of contractile activity in the fed state are determined by the nature of the diet, with unabsorbed fats and fiber prolonging activity.

Absorption and Secretion of Water and Electrolytes[71]

The pathophysiology of diarrhea is detailed in ch. 40. Diarrhea is a result of an imbalance between the net amount of fluid and electrolytes secreted and absorbed. Net absorption occurs in health, but the fluxes through the intestine are massive (≈2 liters a day in a 20-kg dog) and net losses result in both diarrhea and severe dehydration. Colonic absorption is important, as it can help compensate for net SI losses, but diarrhea will occur if its reserve capacity is overwhelmed (see ch. 277).

Small Intestinal Microbiome[72-74]

Normal Microbial Population[75-114]

The microbiome comprises bacteria, protozoa, fungi, and viruses, and it is an integral part of the healthy SI. It affects many aspects of SI function—villus size, enterocyte turnover, brush border enzyme turnover, and motility—and the presence of a stable microbiome is important for the development and ongoing balance of the mucosal and systemic immune systems, and for preventing colonization by pathogens. In intestinal disease, the diversity of the bacterial component of the microbiome is reduced and there is a shift to potentially harmful species, while the viral component (the virome) is diversified.

The bacterial flora is the largest component of the microbiome, and it comprises a diverse mixture of aerobic, anaerobic, and facultatively anaerobic bacteria, with more than 200 species present in any individual animal's SI. Many organisms in the microbiome are unculturable, but molecular fingerprinting techniques, using high-throughput 16S rRNA sequencing, can now identify them. The healthy microbiome is relatively resistant to environmental changes but can be modified, both positively and negatively, by dietary changes, antibiotic use, and even lifestyle. Although the effects of antibiotic therapy on the flora often are clinically mild and self-limiting, persistent changes in the microbiome do occur, and therefore, the indiscriminate use of antibiotics in diarrhea is ill-advised, especially as it can also enhance antibiotic resistance; fatal post-antibiotic salmonellosis has been recorded in cats.

Bacterial numbers increase from duodenum to colon: factors maintaining this aboral gradient are luminal patency, motility, substrate availability, bacteriostatic and bactericidal secretions (gastric acid, bile, goblet cell and pancreatic secretions), and an intact ileocolic valve. Quantitative bacterial analysis performed on samples of undiluted intestinal juice from the proximal SI has revealed bacterial counts in healthy dogs and cats ranging from 10^2 to 10^8 colony-forming units (CFUs) of total bacteria/mL. These numbers reach considerably higher than the $<10^5$ CFU/mL reported in healthy humans but which, historically, were extrapolated incorrectly to dogs.

Bacterial-Mucosal Interactions[115-133]

Interactions between bacteria and the mucosa normally are mediated by epithelial surface receptors that are part of the innate immune system. The epithelium uses pattern recognition receptors (PRRs) to recognize conserved elements of bacterial structure (see ch. 274). Originally referred to as "pathogen-associated molecular patterns" (PAMPs) expressed by potentially pathogenic organisms, the alternative terminology "microbe-associated molecular patterns" (MAMPs) encompasses the concept of interaction with normal commensal organisms in addition to pathogens (Figure 276-3).

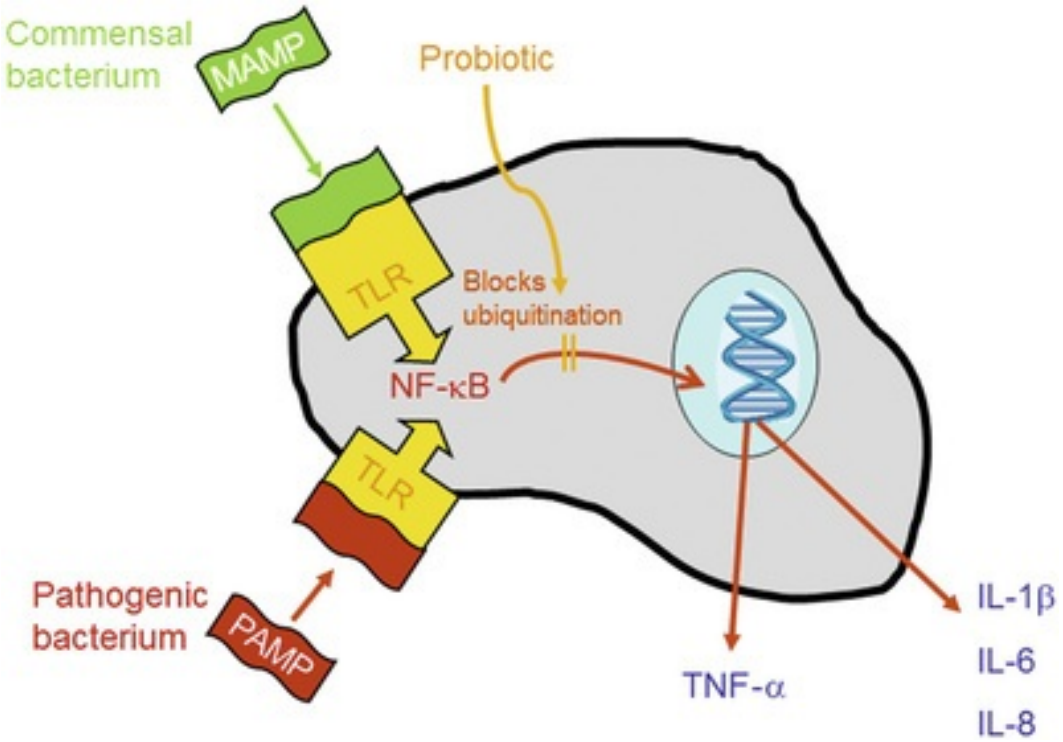

FIGURE 276-3 Recognition of commensal and invading bacteria by mucosal-associated lymphoid tissue. Toll-like receptors (TLRs) are found on endothelial cells, monocytes, macrophages and dendritic cells of the intestinal mucosal-associated lymphoid tissue (MALT), as well as the basolateral surface of enterocytes. The TLRs recognize microbe-associated molecular patterns (MAMPs) expressed by all bacteria and stimulate, via intracellular signalling, the production of the nuclear transcription factor NF-kappa-B. When the cell is exposed to a pathogen-associated molecular pattern (PAMP), NF-kappa-B is ubiquitinated and it can then activate the transcription of the mRNA encoding proinflammatory cytokines such as tumor necrosis factor (TNF-alpha) and various interleukins (ILs), triggering the inflammatory cascade. However, when stimulated by commensal or probiotic organisms, the ubiquitination of NF-kappa-B is blocked. The mechanism of how commensals and pathogens are differentiated is not known.

The enterocyte PRRs include a range of Toll-like receptors (TLRs) and nucleotide oligomerization domain-like receptors (NODs) that can be expressed on the surface membrane or within cytoplasmic compartments. Examples of these molecules include TLR2and TLR4, which, respectively, recognize lipopeptides and lipopolysaccharide found in Gram-negative bacteria; TLR5, which recognizes the bacterial flagella protein (flagellin); and NOD2, which recognizes bacterial lipopolysaccharide.

Gastrointestinal Immune System

The SI mucosa has a general barrier function (E-Box 276-3) and must remain "tolerant" of harmless antigens, such as commensal bacteria and food, while being able to generate a protective immune response against pathogens. The default response of the SI immune system is tolerance, and this is expressed not only within the intestinal tract; tolerance responses at other mucosal surfaces and within the systemic immune system can be induced from interactions within the intestinal tract. Intestinal tolerance responses can be driven by specific subsets of tolerogenic antigen-presenting cells (APCs) that induce antigen-specific regulatory T cells (Tregs) that mediate these effects. Particular elements of the microbiome appear to be responsible for amplifying and maintaining Treg activity to prevent local and systemic immune-mediated diseases.

E-Box 276-3

Components of the Intestinal Mucosal Barrier

- Protein denaturation by gastric acid
- Proteolysis by enzymes and bacteria
- Antimicrobial peptides (e.g., defensins)

- Clearance of waste by peristalsis
- Unstirred water layer
- Surface mucus layer
- Secretory IgA
- Enterocyte microvillus membrane
- Epithelial tight junctions
- Transepithelial electrochemical potential
- Epithelial repair factors (e.g., epidermal growth factor, trefoil peptides)
- Mucosal-associated lymphoid tissue

Functional Anatomy of the Mucosal Immune System[134-138]

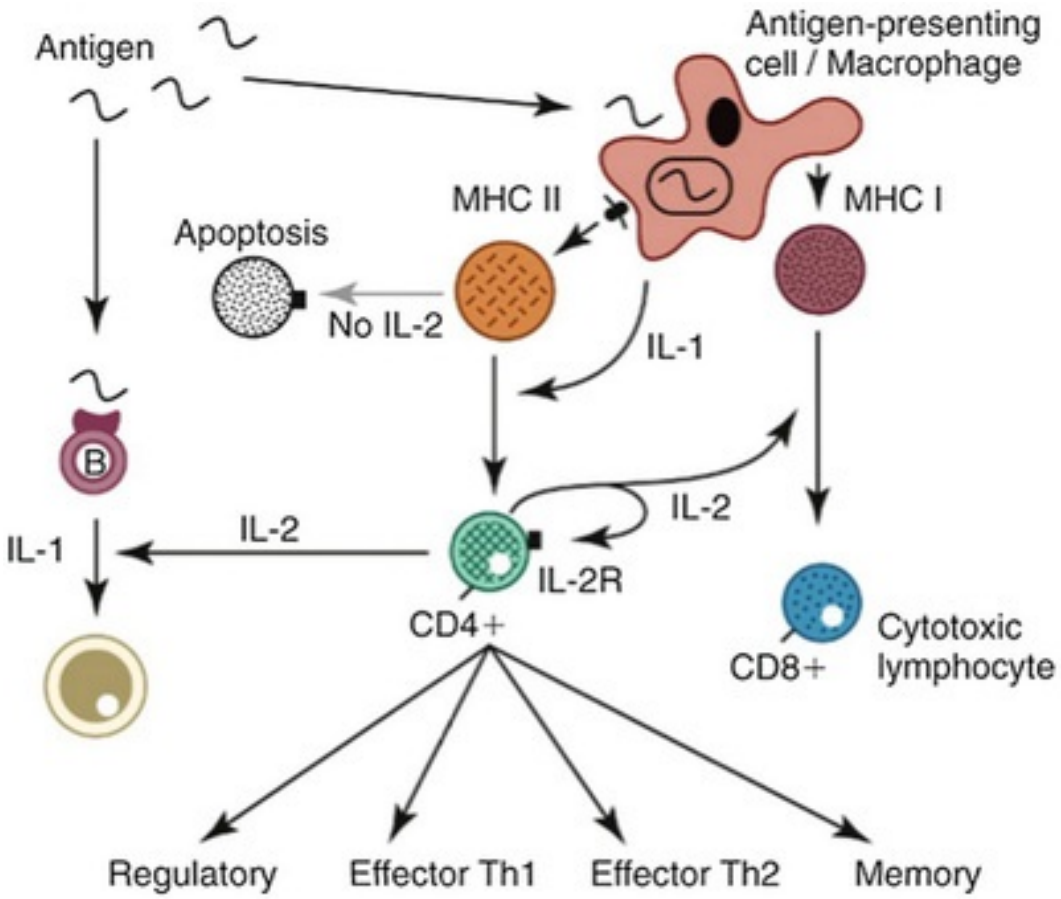
The mucosa-associated lymphoid tissue (MALT) occurs at internal body surfaces; in the intestine, it is termed *gut-associated lymphoid tissue* (GALT) and consists of inductive and effector sites. Inductive sites comprise Peyer's patches (PPs), isolated lymphoid follicles, and the mesenteric lymph nodes (MLNs), whereas effector sites comprise the intestinal lamina propria (LP) and epithelium. Such a distinction is not absolute, however, and the functions of these different sites overlap. The LP consists of a matrix of connective tissue with a prominent mixed, but predominantly lymphoplasmacytic, immune cell component. A large intraepithelial lymphocyte (IEL) population also exists in between enterocytes.

Cells and Molecules of the Mucosal Immune System

Lymphocytes[139-157]

B lymphocytes are present in the follicular region of PPs and the mesenteric lymph nodes. The LP is endowed with a large population of plasma cells, the terminal differentiation stage of an activated B cell. They are predominantly located in the peri-cryptal LP, and most are committed to the production of immunoglobulin (Ig) A. Intestinal T lymphocytes mostly have a T-cell receptor (TCR) formed of an alpha and beta chain and mainly are located within the LP and organized lymphoid tissues; some are IELs. An evolutionarily older T-cell population expressing a TCR comprised of a gamma and delta chain also exists, and these largely are IELs. Because of their location, these cells are considered a primitive first-line defense against pathogens.

T lymphocytes can be subdivided further on the basis of expression of CD4 and CD8 molecules. CD4 T cells (classical "helper" T cells) recognize antigenic peptide presented by major histocompatibility complex class II (MHC II) molecules on APCs, whereas CD8 T cells (usually cytotoxic cells) are MHC class I restricted (E-Figure 276-4). In the canine LP, T cells are most numerous in the upper villus regions and are mostly of the alpha-beta-TCR, CD4 phenotype. However, in the feline LP, CD8 T cells outnumber the CD4 population. There are several functional subsets of the Th population, and these will be described below. Additionally, several subsets of "innate lymphoid cells," which have lymphoid morphology but do not carry classic lymphocyte receptor molecules (see below), now are recognized. Most LP lymphocytes are highly differentiated, which implies that they receive continuous antigenic and mitogenic stimulation, probably from the endogenous microbiome.



E-FIGURE 276-4 Activation of mucosal $CD4^+$ T cells. Antigen presentation in association with major histocompatibility complex (MHC) class II molecules activates mucosal $CD4^+$ T cells. The result is either clonal expansion into memory and effector cells or apoptosis, depending on the synthesis of interleukin-2 receptor (IL-2R) and IL-2. $CD8^+$ T cells are activated by antigen presentation in association with MHC class I molecules and, under the influence of $CD4^+$ T cell–derived cytokines, develop into intraepithelial lymphocytes. Gamma-delta-T cells also form a part of the intraepithelial cell compartment.

Dendritic Cells[118,158-166]

Dendritic cells (DCs) function predominantly as APCs and can be found in both inductive (PP) and effector (LP) tissues. Follicular dendritic cells store antigen to provide continued stimulation to memory B cells. DCs also are prominent in the villus lamina propria, where their main function is antigen sampling. These DCs often are located immediately beneath the enterocyte layer and are able to extend cytoplasmic processes (dendrites) between enterocytes and into the intestinal lumen to sample antigen. In inductive sites, they are responsible for generating active immune responses and tolerogenesis. In rodents, the lamina propria DCs responsible for each of these effects are defined by expression of the CD103 molecule, with those inducing inflammatory responses being $CD103^-$ and those inducing Treg-mediated tolerance being $CD103^+$.

Other Immune Cells[143,145,167-170]

Macrophages are present in the PP and LP, and their functions include phagocytosis, antigen presentation, and immunoregulation. They secrete cytokines, chemokines, and inflammatory mediators, including tumor necrosis factor-alpha (TNF-alpha), eicosanoids, and leukotrienes. Neutrophils are present in small numbers normally, although their numbers increase with mucosal inflammation. Both mast cells (MCs) and eosinophils can be found in the normal LP and can actively produce chemical mediators of inflammation (e.g., histamine, heparin, eicosanoids, and cytokines). Mast cells express the high-affinity IgE receptor (Fc-epsilon-RI), which can bind IgE, causing MC degranulation and release of its inflammatory mediators. In dogs, eosinophils are a prominent population in the LP, especially in the crypts. Eosinophils can have

proinflammatory roles, especially in allergic processes, because they are a rich source of proinflammatory mediators, cytokines, and chemokines. Triangular cross-talk can occur among eosinophils, MCs, and T cells.

Enterocytes[167,171-174]

Enterocytes have important immune functions. First, they exclude antigen. Second, they express surface TLRs, which interact with the enteric flora. Third, they can present antigen through expression of MHC II. In dogs, MHC II is expressed constitutively by enterocytes, but this molecule largely is absent from enterocytes of cats, although it is upregulated in inflammation. Fourth, enterocytes can produce inflammatory mediators, chemokines, and cytokines.

Enteric Neurons[175,176]

Enteric neurons can release immunoactive neuropeptides including substance P, which can cause neurogenic inflammation via neurokinin (NK) receptors. Bidirectional communication also can exist, in which release of mediators by immune cells (e.g., mast cells) can generate axon reflexes and thereby modulate intestinal motility, secretion, and absorption.

Cytokines[177-187]

A large array of cytokines is produced by cells in the SI, and these molecules can be grouped into proinflammatory, immunoregulatory, and chemokinetic types. Different CD4 Th-cell populations have different patterns of cytokine secretion and can differentially regulate distinct arms of the immune system (i.e., humoral and cell-mediated). *In vitro*, two principal populations of $CD4^+$ T cells exist. T helper 1 (Th1) cells produce interleukin-2 (IL-2) and interferon-gamma (IFN-gamma) and mediate cellular immunity involving activation of CD8 cytotoxic T cells and macrophages, classically in response to infection with intracellular pathogens or to cancer. T helper 2 (Th2) cells produce IL-4, IL-5, IL-6 and IL-13 and function to promote B-cell activation and differentiation to antibody-secreting plasma cells. Th2 cells mediate the "immunoglobulin class switch" during B-cell activation, which in the SI is primarily to IgA or IgG. Th17 cells are characterized by production of IL-17, and they function in inflammatory responses, including having a key role in the pathogenesis of inflammatory enteropathies.

Other populations have down-regulatory functions. Th3 cells producing TGF-beta have been identified as effectors of classical "oral tolerance," but the $CD25^+$ $Foxp3^+$ Treg cell (producing IL-10 as a signature cytokine) is the more important "suppressor" population in terms of local intestinal or distant systemic tolerance. Many other cell types also can produce cytokines, and it is the overall local cytokine "milieu" that determines the predominant type of immune response.

The polarized roles of these classical T-cell subsets are mirrored by the complementary activities of recently identified "innate lymphoid cells" (ILCs). Group 1 ILCs, which include the natural killer (NK) cells, produce IFN-gamma akin to Th1 cells. Group 2 ILCs produce IL-5 and IL-13, paralleling the effects of Th2 cells. Group 3 ILCs produce IL-17 and IL-22 and can be either proinflammatory (as for Th17 cells) or in some circumstances have a protective, antiinflammatory effect.

Homing of Lymphocytes in Gut-Associated Lymphoid Tissue[143,149,188-191]

Lymphocytes traffic between inductive and effector sites. Homing pathways are mediated by leukocyte-endothelial interactions through differential expression of "homing receptors" on the surface of the leukocyte interacting with endothelial "vascular addressins." The most important interaction for mucosal lymphocytes occurs between $alpha_4/beta_7$ on the lymphocyte and mucosal addressin cell adhesion molecule-1 (MAdCAM-1) on the endothelial cell. A final factor important to the homing of lymphocytes is the production of chemokines and their receptors. The chemokine milieu of a particular tissue determines which T-helper cell types and other immune cell subsets are recruited from the circulating blood into the tissue.

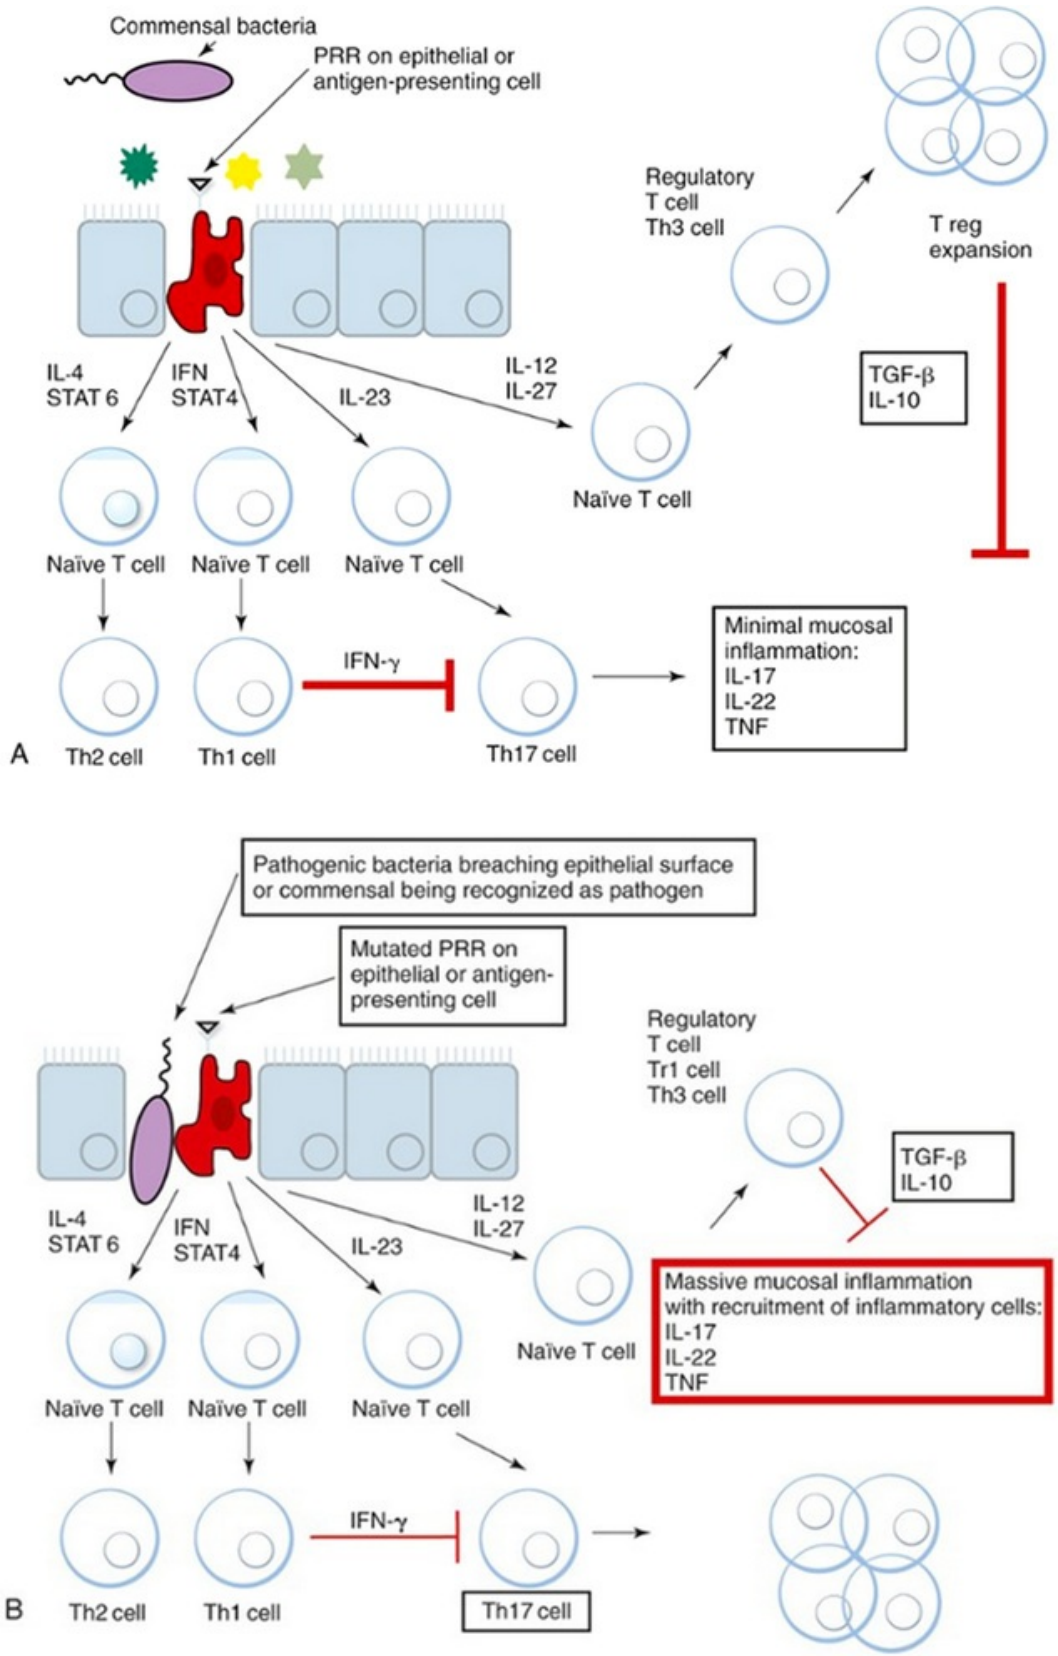
Innate Immune Responses of the SI[192-194]

The innate immune defenses of the SI largely have been described above and include factors such as peristaltic movement, the presence of the intestinal microbiome, the mucus layer and the enterocyte barrier, and the presence and function of innate immune cells (e.g., DCs, macrophages, granulocytes, ILCs and gamma-delta-TCR-expressing IELs). Although poorly defined in the dog and cat, the production of cathelecidin-related antimicrobial peptides (i.e., defensins) by enterocytes (and particularly by cryptal Paneth

cells) is of major importance in other species.

Acquired Immune Responses of Gut-Associated Lymphoid Tissue

Acquired immune responses develop after a series of steps involving antigen uptake, presentation to naïve lymphocytes, costimulation by helper cells, clonal proliferation and differentiation, homing to effector sites, and performance of effector functions (E-Figure 276-5, *A*). The specific mechanisms involved are described in detail elsewhere, but some features unique to the GALT are described here.



E-FIGURE 276-5 A hypothetical model of oral tolerance to commensals and development of inflammatory bowel disease (IBD). **A,** In the healthy intestine, antigen-presenting cells (APCs) continuously sample antigens from the lumen through pattern recognition receptors of microbe-associated molecular patterns (MAMPs) expressed by all bacteria. Depending on both the nature of the antigen and the route by which it is presented (e.g., bacterial, invasive), the APCs drive an adaptive immune response in the appropriate direction. When commensal bacteria are encountered, naïve T cells preferentially differentiate into T-regulatory cells (Treg and Th3), whereas pathogenic bacteria

induce differentiation to Th17 cells to produce proinflammatory interleukin (IL)-17 and IL-22. With exposure to viruses, naïve T cells preferentially differentiate into Th1 cells, which produce cytokines including interferon-gamma (IFN-gamma), thereby recruiting macrophages to kill intracellular viruses and inhibit Th17 differentiation. Parasitic infections drive differentiation to Th2 cells, which recruit eosinophils, basophils, and mast cells to kill or expel the parasite. **B,** In the case of IBD, one or all of 3 factors (dysbiosis, abnormal mucosal permeability, and mutations/polymorphisms in PRRs) lead(s) to the abnormal recognition of commensal bacteria as pathogens, inducing a Th17 response. Proinflammatory cytokines (IL-17, IL-22 and TNF) induce inflammation and epithelial cell injury, allowing more commensal bacterial antigen into the mucosa, such that counterregulation by Tregs fails, and IBD is established. *IFN-gamma,* Interferon gamma; *IL,* interleukin; *PRR,* pattern recognition receptor; *STAT,* signal transducer and activator of transcription protein; *TGF-beta,* transforming growth factor–beta; *Th,* T helper cell; *TNF,* tumor necrosis factor; *Treg,* regulatory T cell.

Antigen Uptake and Presentation[161]

Uptake of particulate antigen occurs through the microfold (M) cells located within the epithelial covering of PPs. M cells transfer luminal antigen to DCs and macrophages within these lymphoid tissues. These APCs process and present antigen to lymphocytes in the context of MHC II molecules (see E-Figure 276-4). Soluble antigens can be absorbed via enterocytes and presented to T cells, and direct luminal antigen sampling by DCs has been described above.

T- and B-Cell Responses[181,195-198]

The role of Th1 and Th17 cells in cytotoxic and inflammatory responses in the intestinal mucosa, and the role of Treg cells in local and systemic tolerance, have been discussed above.

B cells recognize intact conformational antigenic epitopes via their surface membrane B-cell receptor (Ig) (signal 1) and require T cell "help" in the form of direct intercellular molecular interaction (signal 2) and the provision of Th2 cytokine acting on a B-cell cytokine receptor (signal 3). The B-cell "immunoglobulin class switch" enables the differential production of IgA, IgE, or IgG antibodies in response to different classes of antigen. After class switching, B cells undergo further expansion, then traffic to effector sites to differentiate into plasma cells.

IgA synthesis predominates in the healthy intestinal mucosa. Plasma cells in the lamina propria release dimeric IgA molecules, two monomers linked by the joining (J) chain. Dimeric IgA is captured by the polymeric immunoglobulin receptor (pIgR) expressed on the basolateral surface of enterocytes. The complex of receptor and IgA passes through the enterocyte and is delivered across the MVM. On the luminal surface, the pIgR is cleaved to form the secretory component (SC), which remains associated with pIgA, protecting it from enzymatic degradation in the intestinal lumen. The main function of secretory IgA (SIgA) is immune exclusion; that is, to bind its respective antigen and neutralize it. This helps maintain tolerance and protects the mucosa from antigen invasion. Deficiency of SIgA could predispose to intestinal disease.

Responses to parasites involve Th2-determined production of IgE that binds to the Fc-epsilon-RI on mucosal mast cells. When subsequently exposed to antigen, MC degranulation occurs, initiating a local inflammatory reaction, recruitment of tissue eosinophils, and enhanced goblet cell production of mucus. These various effector mechanisms can lead to death of larval forms within the mucosa or expulsion of luminal parasites. Inappropriate IgE responses also can be generated, providing a proposed mechanism for food allergy via a classic type I hypersensitivity response.

Mucosal Tolerance[199-203]

The above descriptions relate to specific immune responses to pathogens, but such responses are the exception rather than the rule, and the default mucosal response to antigens is tolerance. This is not surprising, given that the majority of luminal antigens are derived from innocent dietary components and commensal microflora. Generation of active immune responses to such ubiquitous molecules could be both wasteful and potentially harmful because it could lead to uncontrolled inflammation. Although the mechanisms by which mucosal tolerance actually occurs have been well characterized, the fundamental question of what prompts GALT tolerance or an immune response remains unresolved.

Mucosal tolerance can result either from anergy/deletion (apoptosis) of antigen-specific T cells or from active suppression by antigen-specific suppressor cells. The $CD4^+$ alpha/beta T-cell subsets that mediate active suppression either produce downregulatory cytokines (e.g., TGF-beta, IL-10 or IL-17) or achieve their effect through cell-to-cell interactions (e.g., through CD25, IL-2 receptor). However, any cell capable of producing similar cytokine profiles could play a role and, therefore, tolerance could arise from the effects of $CD8^+$ T cells, macrophages, stromal cells, and enterocytes. Furthermore, because TGF-beta and IL-10 also are

important in IgA production, generation of mucosal tolerance likely occurs in parallel to specific IgA responses, which helps to maintain tolerance through immune exclusion.

Consequences of Inappropriate Immune Activation in the SI[124,132,204-226]

In healthy individuals, the intestinal immune system is maintained in a complex homeostatic balance with a dominant tolerogenic setting. Many of the diseases discussed in this chapter arise when this homeostasis is disturbed by multifactorial influences, including genetic factors, barrier dysfunction and dysbiosis, leading to inappropriate exposure to luminal antigen, induction of tissue inflammation, and alteration in the balance between immune effector and regulatory cells in the mucosa.

If the inappropriate antigenic challenge is contained, the mucosa enters a repair phase, and the normal "tolerogenic" environment returns. However, if the danger persists, either because the mucosal barrier remains breached and/or the pathogenic insult continues unabated, or because of an inherent abnormality in the GALT, a state of chronic inflammation ensues. Inflammation causes increased expression of MHC II molecules and activation of both lymphocytes and endothelial cells, altering the expression of vascular addressins. Enhanced expression of MAdCAM-1 leads to increased recruitment of specific mucosal lymphocytes, whereas expression of other addressins (e.g., E-selectin, P-selectin and peripheral node addressin) can lead to recruitment of a broader range of immunocyte specificities. Extracellular proteolysis by matrix metalloproteinases can lead to architectural changes. Thus, chronic inflammation ultimately leads to histopathologic changes, which are likely to be similar regardless of inciting cause. Furthermore, it has been hypothesized that chronic stimulation of lymphocytes in genetically predisposed patients could ultimately result in expansion of a malignant clone of T-lymphocytes and mucosal lymphoma.

Pathophysiologic Mechanisms in Intestinal Disease

A number of potential pathophysiologic mechanisms can lead to dysfunction of the SI, and one or more of the following can be present in any one specific SI disease.

Luminal Disturbance[227-232]

Lack of pancreatic enzymes in exocrine pancreatic insufficiency (EPI; see ch. 292), or increased destruction of enzymes by acid hypersecretion (e.g., Zollinger-Ellison syndrome; see ch. 275), or bacterial overgrowth, results in failure of digestion. *Dysbiosis* is a better term than overgrowth to describe the disturbance of the normal microbiome that can occur following infection, antibiotic usage, sudden dietary change, or due to underlying mucosal immunoincompetence or inflammation. Some bacteria compete for nutrients and produce metabolites (e.g., deconjugated bile salts, hydroxylated fatty acids) that can stimulate intestinal secretion. Interruption of normal enterohepatic circulation and lack of bile salts result in fat malabsorption. Bile salt deficiency can be caused by marked hepatic dysfunction, bile duct obstruction, bacterial deconjugation, or ileal disease.

Brush Border Membrane Disease[40,47,48,52,233-254]

Primary brush border membrane diseases are biochemical abnormalities that occur in the absence of structural damage. Lack of a key digestive enzyme leads to maldigestion/malabsorption, osmotic diarrhea, and weight loss. Sucrase-isomaltase deficiency is recognized in humans, but it has not yet been described in dogs or cats. Lactase deficiency in man either can be a congenital failure to express the enzyme due to a genetic mutation, or downregulation of expression in adults. Congenital lactase deficiency has not been reported in dogs and cats, but a relative deficiency does occur, particularly in adult cats, as expression is reduced after weaning. Congenital lack of brush border aminopeptidase N has been described in dogs but has no clinical significance as other peptidases compensate.

The mechanism of cobalamin deficiency commonly seen in Chinese Shar-Peis with intestinal disease has not been elucidated yet, but defects in cobalamin–intrinsic factor uptake in the ileum can be due to a mutation in the receptor molecule cubilin. The genetic mutations causing selective cobalamin malabsorption, also known as Imerslund-Gräsbeck syndrome, have been identified in Australian Shepherds, Beagles, Collies, and Giant Schnauzers. All the mutations result in cobalamin deficiency with consequent methylmalonic aciduria and a constellation of clinical signs including one or more of inappetence, failure to thrive, liver degeneration, hepatoencephalopathy, neutropenia, anemia, and proteinuria. Diarrhea can be a feature, as cobalamin-deficient diets result in histologic abnormalities in, and dysfunction of, the SI.

Surgical resection of the ileum (e.g., due to irreducible ileocolic intussusception) and disease affecting the distal SI cause both bile salt and cobalamin malabsorption. However, a congenital deficiency of the ileal bile salt transporter reported in humans, and a cause of severe diarrhea, has not yet been reported in dogs or cats.

Microvillar Membrane Damage[255-260]

The MVM is obviously damaged when overt histologic villus damage can be seen, but even without light microscopic changes, massive impairment of mucosal function can occur if the microvilli are damaged. Such damage is seen with enteropathic *E. coli* infection, carrageenan gum, or lectins, which cause a loss of brush border enzymes and carriers and surface area. Bacterial overgrowth is associated with subtle but specific damage to the membrane, as anaerobes are very effective at degrading membrane glycoproteins and releasing brush border enzymes.

Enterocyte Dysfunction[261,262]

Damage to enterocytes by bacterial toxins but without histologic damage still can interfere with enterocyte function, as well as cause subcellular loss of brush border proteins. Malnutrition and ischemia also impair function and increase epithelial permeability. Abetalipoproteinemia in humans is a failure of transcellular lipid transport resulting in abnormal lipid accumulation within enterocytes. Although this condition has not yet been reported in dogs and cats, the weight loss drug dirlopatide acts by blocking microsomal triglyceride transfer protein within enterocytes and hence fat absorption; diarrhea is a common and predictable side effect of this drug.

Epithelial Barrier Disruption[263-272]

Epithelial integrity is crucial in maintaining oral tolerance and excluding pathogens. In the experimental N-cadherin dominant negative chimeric mouse, where epithelial integrity is disrupted because of a lack of expression of the normal E-cadherin in tight junctions, intestinal inflammation is restricted to regions of the gut where the mutant gene is expressed. In other animal models, malnutrition results in both villus atrophy and increased transepithelial macromolecular absorption, abnormal mucin, and reduced IgA secretion. Natural causes of decreased barrier function include luminal aggressive factors and endogenous inflammatory mediators (E-Box 276-4). Barrier damage can lead to entry of antigens, subsequent allergic and/or inflammatory reactions, and even translocation of bacteria into the circulation. Nonsteroidal anti-inflammatory drugs (NSAIDs) damage the barrier, increasing intestinal permeability, but the presence of soluble fiber (e.g., pectin) is protective. Norepinephrine, which is naturally increased by stress, alters enterocyte tight junction permeability, permitting invasion by *Campylobacter* and recruitment of neutrophils through the induction of IL-8. Leakage of protein-rich tissue fluid in the opposite direction is also of clinical significance, causing a protein-losing enteropathy (PLE).

E-Box 276-4

Examples of Agents That Can Damage the Mucosal Barrier

Luminal Aggressive Factors

- Drugs
  - Cytotoxic drugs
  - Ethanol
  - Nonsteroidal anti-inflammatory drugs
- Endotoxin
- Enteric infections
- Radiation

Endogenous Factors

- Bile salts
- Malnutrition (anorexia, malabsorption)
- Ischemia
- Reperfusion injury

- Nitric oxide
- Remote inflammatory disease and burns

Intestinal Inflammation

- Interferon-gamma
- Mast cell mediators (e.g., histamine, bradykinin)
- Neutrophil migration

Intestinal Neoplasia Leading to Ulceration

- Infiltration causing ischemia
- Crowding out of normal cells

Villus Atrophy[270,273]

Villus atrophy causes loss of intestinal surface area and results in fat malabsorption. Also, carrier-mediated uptake of protein digestion products and of carbohydrate is rate-limited because there are finite numbers of nutrient transporters. Atrophy is caused either by a decrease in the production of enterocytes or an increase in the rate of enterocyte loss. If enterocyte loss outpaces increased proliferation, villus atrophy will result, but if the initiating cause can be removed, the atrophy is completely reversible. However, a persistently increased rate of enterocyte loss can result in a compensatory increase in the crypt cell proliferation rate, such that if the cell loss is matched by the increased proliferation, villus height does not actually decrease. Yet a significant functional effect still occurs because mature enterocytes are replaced by immature, suboptimally functioning enterocytes.

Infectious agents that damage enterocytes can infect the villus tip (e.g., rotavirus) or midvillus (e.g., coronavirus), causing cell loss and a mild to moderate diarrhea. Cytotoxic drugs (e.g., vincristine) and parvovirus infection, which cause crypt arrest and destruction, respectively, can be devastating, causing complete villus and crypt collapse and severe diarrhea. Assuming some stem cells survive the insult, regeneration is possible, but it is likely to take several days.

Disordered Motility[274-282]

Alterations of intestinal motility as a primary cause of SI dysfunction in dogs and cats are poorly characterized. Irritable bowel syndrome (IBS) is a functional disorder with primary changes in motility. Secondary motility alterations occur with intestinal obstruction, pseudo-obstruction, adynamic ileus, or inflammatory and infectious enteropathies. Rapid waves of contractions can be caused by SI ischemia and by enterotoxigenic bacteria. In malabsorption, unabsorbed solutes retain fluid osmotically, causing intestinal distension and reflex hypermotility. Hyperthyroidism in cats decreases transit time and causes diarrhea.

In most instances, however, diarrhea actually is associated with intestinal hypomotility or ileus. Adynamic ileus is a transient and reversible functional obstruction of the intestine with a number of causes (Box 276-5). In enteric viral infections, for example, ileus is common, promoting further diarrhea as stasis allows bacterial fermentation. Postoperative ileus is caused by a combination of surgically induced inflammation and sympathetic inhibition, potentially complicated by peritonitis, opioid administration, or both. Malabsorption leads to the presence of undigested food in the ileum and colon, inhibiting intestinal motility through neurohormonal pathways, and can delay gastric emptying. Hypomotility and constipation are expected with hypothyroidism, but occasionally, antibiotic-responsive diarrhea is found.

Box 276-5

Potential Causes of Ileus

Functional

- Abdominal surgery
- Ischemia
- Irritable bowel syndrome (mixed diarrhea/constipation)

Inflammatory

- Pancreatitis
- Parvovirus

- Peritonitis

Metabolic

- Diabetes mellitus
- Endotoxemia
- Hypokalemia
- Hypocalcemia/hypomagnesemia
- Uremia

Neuromuscular

- Anticholinergic and opioid drugs
- Dysautonomia
- Visceral myopathy
- Visceral neuropathy

Physical

- Intestinal obstruction
  - Foreign body
  - Intussusception
  - Masses—neoplasia, granuloma
  - Mechanical—torsion, volvulus, incarceration, adhesions
- Overdistention by aerophagia

Mucosal Inflammation[283-286]

Inflammation is a cellular and vascular response to a number of inciting causes, including infection, ischemia, trauma, toxins, neoplasia, and immune-mediated reactions. Indeed, anything that disrupts the mucosal barrier is likely to trigger inflammation and tissue damage through the upregulation of matrix metalloproteinases.

Experimental models of GI inflammation in genetically engineered rodents have allowed better understanding of the pathogenesis of mucosal inflammation and the mechanisms that trigger it. Various disruptions of the mucosal immune system can lead to chronic inflammatory responses that are histologically similar. The disruptions can be induced in one of three ways: through disruption of the endogenous microflora, through interference with the mucosal barrier, or through dysregulation of the mucosal immune system. Whether there is mucosal barrier disruption or immune system dysregulation, the presence of an enteric flora is essential for the expression of inflammation. This suggests that healthy individuals are tolerant to their own intestinal microflora, but in patients with idiopathic inflammatory bowel disease (IBD), tolerance is broken (E-Figure 276-5, *B*).

Hypersensitivity[287,288]

Sensitization of a patient to a dietary antigen can provoke an IgE-mediated allergic reaction when the animal is next exposed. The release of numerous mast cell mediators can have generalized systemic effects such as anaphylaxis, remote effects such as pruritus and urticaria, or only local effects on the intestine, inducing rapid changes in absorption and secretion, mucus secretion, epithelial and endothelial permeability, and gut motility.

Neoplasia

Diffuse tumors that infiltrate the mucosa, such as lymphoma, cause SI dysfunction. Malignant cells simply can obstruct blood and lymphatic flow, but enterocyte function is likely to be impaired or the mucosa might show villus atrophy or be ulcerated because of ischemia. Solitary tumors can cause dysfunction, probably through the effects of partial obstruction, with stasis of ingesta and secondary bacterial overgrowth. More typically, solid tumors are associated with signs such as intestinal obstruction, bleeding, and cancer-associated cachexia. Peritonitis can occur if the integrity of the bowel wall is compromised. Cutaneous mast cell tumors can cause histamine-mediated gastric acid hypersecretion leading to gastroduodenal ulceration and even perforation.

Nutrient Delivery Failure[289,290]

After absorption, nutrients are transported via blood and lymph, but only intestinal lymphatic diseases are well described in animals. Primary lymphatic dilatation and dysfunction (lymphangiectasia) that causes malabsorption can be idiopathic or can be associated with lymphangitis. Secondary lymphangiectasia is seen with any condition causing lymphatic obstruction.

Congenital Abnormalities[291-302]

Intestinal stenosis, atresia, nonrotation, and random duplications of segments of both SI and large intestine (LI) in dogs and cats are reported. Duplications are cystlike lesions that rarely cause clinical signs unless they cause an obstruction. Blind-ending diverticula may predispose to foreign body entrapment, bacterial overgrowth, GI bleeding or perforation. Cystic vitelline ducts can occur with umbilical leakage of SI contents if there is a persistent *ductus omphaloentericus.* Arteriovenous fistulae can cause SI hemorrhage.

Clinical Features of Small Intestinal Disease

Diarrhea[303-305]

The cardinal sign of SI dysfunction is diarrhea, which is a significant increase in the frequency, fluidity, or volume of feces caused by an increase in fecal water and/or solid content. Yet it must be remembered that diseases of other organs can cause diarrhea, or that the absence of recognizable diarrhea does not preclude the possibility of significant SI disease; other signs can occur (see Box 276-2).

Diarrhea can be classified in several ways (Box 276-6). These categories are not mutually exclusive, and they allow the problem to be viewed from different perspectives, facilitating the diagnostic approach and the choice of appropriate treatment. A mechanistic approach helps an understanding of why overt diarrhea develops. Most SI diseases have a component of osmotic diarrhea, but even in a situation as simple as lactase deficiency, mixed mechanisms occur (Figure 276-6). Malabsorption typically causes osmotic diarrhea, but bacterial fermentation of unabsorbed solutes can complicate it; fecal pH often is low because of the production of volatile fatty acids, and some products (e.g., hydroxylated fatty acids, unconjugated bile acids) cause colonic secretion. For this reason, signs of LI diarrhea frequently accompany prolonged SI disease. Permeability diarrhea is due to inflammation or neoplastic infiltration causing exudation, and secretory diarrhea is caused by chemical or bacterial toxins (Box 276-7).

Box 276-6

Classification Schemes for Diarrhea

Anatomic
- Extraintestinal
- Small intestinal
- Large intestinal
- Diffuse

Causal
- Exocrine pancreatic insufficiency, salmonellosis, lymphoma, other

Clinical
- Nonfatal, mild, self-limiting
- Protein-losing
- Severe, potentially fatal
- Multisystemic

Etiologic
- Bacterial
- Dietary
- Idiopathic
- Neoplastic
- Parasitic

- Viral

Mechanistic

- Dysmotility
- Osmotic
- Secretory
- Permeability (exudative)
- Mixed

Pathophysiologic

- Allergic
- Biochemical
- Infectious/inflammatory
- Neoplastic
- Vascular/lymphatic

Temporal

- Acute
- Chronic

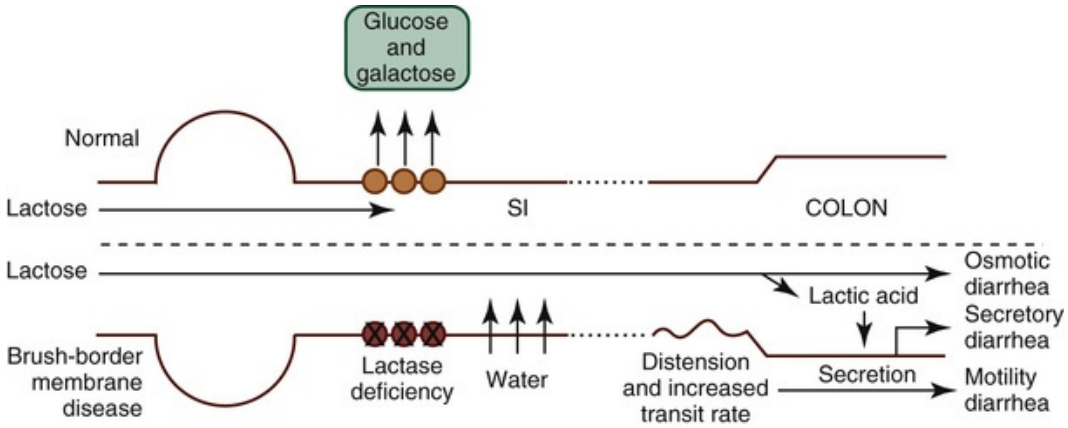


FIGURE 276-6 Lactase deficiency. Diagrammatic representation of the mechanisms of diarrhea caused by lactase deficiency. Absence of the brush border enzyme lactase leads to maldigestion and malabsorption, osmotic diarrrhea, and more rapid transit because of distension with water. Bacterial fermentation of undigested lactose to lactic acid stimulates colonic secretion.

Box 276-7

Causes of Secretory Diarrhea

- Bacterial enterotoxins and endotoxins (e.g., *Clostridium perfringens, Escherichia coli, Salmonella* spp.)
- Hydroxylated fatty acids from bacterial fermentation
- Unconjugated bile acids from bacterial fermentation
- *Giardia* infection
- Stimulant laxatives (e.g., castor oil, dioctyl sodium sulfosuccinate, bisacodyl)
- Cardiac glycosides
- Amine precursor uptake and decarboxylation (APUD) neoplasms (excess vasoactive intestinal polypeptide, serotonin, prostaglandins, substance P)
- Intestinal inflammation

Malabsorption[306-309]

Failure of food assimilation sometimes is classified as either a primary failure to digest (maldigestion) or a primary failure to absorb (malabsorption). However, such a distinction is misleading because failure of absorption is an inevitable consequence of failure to digest. The preferred use of the term malabsorption is to describe defective absorption of a dietary constituent resulting from interference with the digestive and/or absorptive processing of that molecule. The site of the primary abnormality can be found in the luminal, mucosal, or transport phases (Table 276-1). The clinical manifestations of malabsorption—namely diarrhea, weight loss, and altered appetite (polyphagia, coprophagia, pica)—largely are a result of the lack of nutrient uptake and the losses in feces. The reserve capacity of the distal SI and colon can prevent overt diarrhea despite extensive malabsorption and weight loss. Polydipsia is an unusual and peculiar manifestation of excessive appetite. Animals often are systemically healthy but losing weight despite an increased appetite unless an underlying neoplastic or a severe inflammatory condition is present. Only when the patient is severely malnourished or develops hypoproteinemia does he or she appear ill.

TABLE 276-1

Pathophysiologic Mechanisms of Malabsorption

MECHANISM	EXAMPLE
Luminal Phase	
Dysmotility	
Rapid intestinal transit	Hyperthyroidism
Defective Substrate Hydrolysis	
Enzyme inactivation	Gastric hypersection
Lack of pancreatic enzymes	Exocrine pancreatic insufficiency
Impaired release of CCK, secretin	Impairment of pancreatic secretion due to severe small intestine disease
Fat maldigestion	
Decreased bile salt delivery	Cholestatic liver disease, biliary obstruction
Increased bile salt loss	Ileal disease
Bile salt deconjugation	Bacterial overgrowth
Fatty acid hydroxylation	Bacterial overgrowth
Cobalamin Malabsorption	
Intrinsic factor deficiency	Exocrine pancreatic insufficiency
Cobalamin receptor deficiency	Inherited selective cobalamin deficiency (Imerslund-Gräsbeck syndrome)
Competition for cobalamin	Bacterial overgrowth
Mucosal Phase	
Brush Border Enzyme Deficiency	
Congenital	Trehalase (cats) Aminopeptidase N (Beagle)
Acquired	Relative lactase deficiency
Brush Border Transport Protein Deficiency	
Congenital/inherited	Inherited selective cobalamin deficiency
Acquired	Secondary to diffuse SI disease
Enterocyte Defects	
Enterocyte processing defects	Abetalipoproteinemia,* microvillus inclusion disease,* dirlopatide administration
Reduction in surface area	Villus atrophy
Immature enterocytes	Increased enterocyte turnover
Mucosal Inflammation	Inflammatory bowel disease

Transport Phase	
Lymphatic Obstruction	
Primary	Lymphangiectasia
Secondary	Obstruction caused by neoplasia, infection, or inflammation
Vascular Compromise	
Vasculitis	Infection, immune-mediated
Portal hypertension	Hepatopathy, right heart failure, cardiac tamponade

*Human condition, not yet reported in dogs or cats.

CCK, Cholecystokinin.

Melena[310]

The presence of dark, tarry, oxidized blood in feces, a condition called *melena*, reflects either swallowed blood or generalized or localized GI bleeding proximal to the LI (Table 276-2; see ch. 41). It is estimated that the loss of 350 to 500 mg/kg of hemoglobin into the GI tract is required for melena to be visible. As a caveat, medication with ferrous sulfate or bismuth suspensions (e.g., Pepto-Bismol) can also impart a black color to the feces. On the complete blood count, the presence of microcytosis, especially with thrombocytosis, suggests iron deficiency secondary to chronic blood loss. On a serum biochemical profile, an increased blood urea to creatinine ratio (from bacterial digestion of blood) provides supportive evidence. Hypoproteinemia can indicate blood loss or a PLE.

TABLE 276-2

Causes of Melena

Mechanism	Source
Bleeding disorders	Thrombocytopenia, thrombocytopathy, factor deficiencies, DIC
Swallowing of blood	Oral, nasal, pharyngeal, esophageal or pulmonary
Gastrointestinal erosion/ulceration	
Metabolic	Uremia, liver disease
Inflammatory	Gastritis/ulcer, enteritis, HGE
Neoplastic	Leiomyoma, GIST, adenocarcinoma, lymphoma
Paraneoplastic	Mastocytosis, hypergastrinemia (gastrinoma)
Vascular	A-V fistula, aneurysm, angiodysplasia
Ischemia	Hypovolemic shock, hypoadrenocorticism, thrombosis/infarction, reperfusion
Drug-induced	Nonsteroidal anti-inflammatory agents and glucocorticoids
Sharp foreign objects	

A-V, Arteriovenous; *DIC*, disseminated intravascular coagulation; *GIST*, gastrointestinal stromal tumor; *HGE*, hemorrhagic gastroenteritis.

Protein-Losing Enteropathy[289,290,311-315]

When SI disease is severe enough for protein leakage into the gut lumen to exceed plasma protein synthesis, hypoproteinemia develops. Chronic diarrhea associated with panhypoproteinemia usually requires intestinal biopsy to define the cause of the PLE (Table 276-3). Lymphangiectasia, alimentary lymphoma, and IBD are the three most common underlying diseases, although histoplasmosis and pythiosis must be considered in endemic areas. Nonintestinal diseases causing ascites through portal hypertension usually cause ascites before diarrhea. Hypoproteinemia associated with GI disease is much less common in cats than in dogs and, when it occurs, most often is related to GI lymphoma; it results in ascites infrequently in cats.

TABLE 276-3

Protein-Losing Enteropathies

Causes	Examples
Inflammation	Lymphocytic-plasmacytic, eosinophilic, granulomatous
Lymphangiectasia	Primary lymphatic disorder, venous hypertension (e.g., right heart failure, hepatic cirrhosis)
Neoplasia	Lymphoma
Infectious	Parvovirus, salmonellosis, histoplasmosis, phycomycosis
Gastrointestinal hemorrhage	HGE, neoplasia, ulceration
Endoparasites	*Giardia, Ancylostoma* spp.
Structural	Intussusception

HGE, Hemorrhagic gastroenteritis.

Clinical signs associated with PLE include weight loss, diarrhea, vomiting, peripheral edema, ascites, and pleural effusion. Loss of muscle mass frequently is a predominant feature, but diarrhea is not invariably present, particularly with lymphangiectasia and focal intestinal neoplasia, where it can be absent. Physical findings can include pitting edema, ascites, emaciation, thickened intestines, and melena. Thromboembolism secondary to hypoproteinemia is a feature of some cases of PLE because affected patients are hypercoagulable (see ch. 197).

Borborygmi and Flatulence[316]

Borborygmi are abdominal rumbling noises caused by the propulsion of gas in the stomach and through the intestines. Swallowed air and bacterial fermentation of ingesta are the main causes of borborygmi and flatulence and often result in an offensive odor. Feeding a diet that is highly digestible, with a low fiber content (e.g., cottage cheese and rice in a 1:2 ratio), leaves little material in the intestine for bacterial fermentation, and feeding charcoal biscuits can confer a symptomatic benefit in some cases. If borborygmi or flatulence continue despite dietary modification or addition of adsorbents, the animal could be excessively aerophagic or might have malabsorption, especially if diarrhea or weight loss also is present, and investigations for an underlying SI disease should be performed.

Weight Loss or Failure to Thrive

General causes of weight loss are reduced nutrient intake, increased nutrient loss, or increased catabolism (see ch. 19). The history should reveal whether the type and amount of diet fed is adequate and whether anorexia, dysphagia, or vomiting is a potential cause. Weight loss or failure to thrive accompanied by diarrhea often is a feature of malabsorption, and the diagnostic approach is the same as for chronic diarrhea. However, diarrhea does not invariably accompany malabsorption causing weight loss because colonic reserve absorptive capacity can remove the excess water from the feces.

Diagnosis of Small Intestinal Disease

Diagnostic Approach[317-322]

Diarrhea

Most cases of diarrhea are acute, nonfatal, and self-limiting and require only general supportive care and not a specific diagnosis. However, some cases do need definitive diagnosis and management as they can become life-threatening and/or have an infective potential for other animals and/or represent a zoonotic risk. If clinically significant hypovolemia or dehydration is present, fluid and electrolyte deficits must be addressed simultaneously with the diagnostic effort, but the extent of diagnostic investigations required varies. Investigations are necessary if diarrhea is hemorrhagic, accompanied by systemic signs, or unresponsive to nonspecific supportive treatment. By definition, chronic diarrhea is not self-limiting, and an etiologic diagnosis usually is required to allow specific treatment. Diagnostic approaches to acute and chronic diarrhea are discussed in ch. 40 and are outlined in Figures 276-7 and 276-8, respectively.

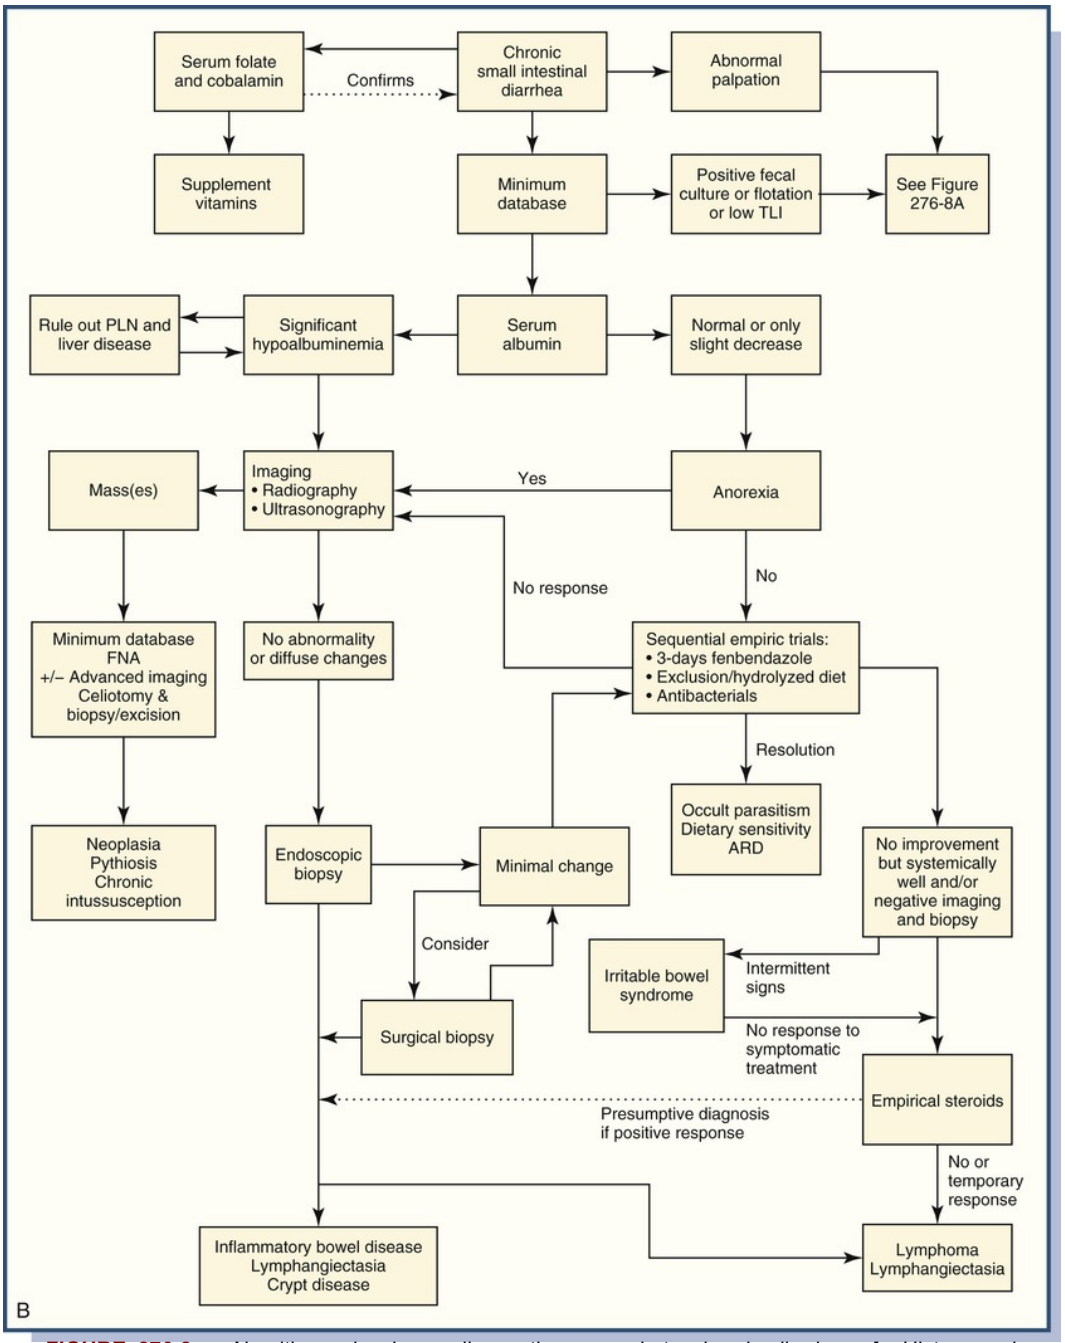

FIGURE 276-8 Algorithms showing a diagnostic approach to chronic diarrhea. **A,** History and physical examination will usually identify a SI problem, but failure of specific therapy for a suspected LI problem should also make the clinician consider SI disease. Abnormal serum folate and cobalamin concentrations can provide more evidence of SI disease and are an indication to supplement. A minimum database can provide evidence of systemic disease, leading the investigation away from the SI, and basal cortisol (or ACTH stimulation test) in dogs and serum T4 in older cats usually are indicated. Abnormal abdominal palpation is an indication for abdominal imaging, but a minimum database of a complete blood count (CBC) and serum biochemistry profile should be performed before investigations that are more invasive. Trypsin-like immunoreactivity (TLI) probably should be measured in all canine cases without abnormalities on abdominal palpation, as the signs of exocrine pancreatic insufficiency are not always typical and serum folate/cobalamin concentrations can be altered. Fecal examination will identify gastrointestinal parasites and pathogenic bacteria, but they could be coincidental findings. **B,** The path taken for further investigations of cases with unremarkable abdominal palpation depends on the serum albumin concentration and the patient's appetite. If albumin is not substantially decreased and the patient is systemically well and eating, sequential empirical trials with fenbendazole, an exclusion or hydrolyzed diet, and with antibacterials such as metronidazole can be undertaken before considering intestinal biopsy. Imaging and endoscopic biopsy are indicated if the patient has evidence of a protein-losing enteropathy or is anorexic. If biopsy results are unremarkable, then surgical biopsy can be considered or empirical trials with glucocorticoids started. *ACTH stim*, Adrenocorticotropic hormone stimulation test; *ARD,* antibiotic-responsive diarrhea; *CBC,* complete blood count; *FeLV*, feline leukemia virus; *FIV*, feline immunodeficiency virus; *FNA*, fine-needle

aspirate; *PLI*, pancreatic lipase immunoreactivity; *PLN*, protein-losing nephropathy; *SIBO*, small intestinal bacterial overgrowth; *TLI*, trypsin-like immunoreactivity.

The aim of the diagnostic approach is to eliminate extraintestinal diseases from consideration and to differentiate SI from LI disease (Table 276-4). The history (Box 276-8 and ch. 1), breed susceptibility (E-Table 276-5), and physical examination (Table 276-6 and ch. 2) are crucial steps toward reaching a diagnosis, and in some cases they can be all that is required. A rectal examination should be performed to confirm diarrhea, identify any unsuspected melena, and obtain samples for rectal cytologic and fecal examinations.

TABLE 276-4

Clinical Signs Associated with Small-Bowel and Large-Bowel Disease

SIGNS	SMALL INTESTINAL DISEASE	LARGE INTESTINAL DISEASE
Feces		
Stool volume	Large	Small
Mucus	Rare	Common
Blood (if present)	Melena	Fresh blood
Fat	Sometimes	Absent
Color	Variable	Normal
Undigested food	Occasionally	Absent
Defecation		
Tenesmus	Rare	Common
Frequency	Two to three times a day	More than three times a day
Urgency	Uncommon	Common
Other Signs		
Vomiting	Sometimes	Uncommon
Gas	Sometimes	Absent
Weight loss	Common	Rare

Box 276-8

Historical Information Useful in the Diagnosis of Small Intestinal Disease

Patient Information

- Age
- Gender
- Species and breed (see E-Table 276-5)

Environmental History

- Indoor versus outdoor
- Free roaming
- Scavenging
- Exposure to parasites
- Contact with infected animals
- Recent change of environment
- Endemic disease area

Past Medical History

- Vaccination status

- Worming status
- Previous abdominal surgery
- Previous excision of cutaneous mast cell tumor
- Drug history

Clinical Signs

- Duration
- Frequency
- Severity
  - Altered appetite
  - Presence of blood
  - Weight loss
- Progression
  - Order of appearance
  - Continuous or intermittent in nature
  - Length of sign-free intervals
- Other signs (e.g., vomiting, ascites)
- Factors that improve or worsen signs (e.g., treatments, diets)

TABLE 276-6

Physical Findings in Animals with Signs of a Small Intestinal Disorder

FINDINGS	INTERPRETATION
General	Rule out other systemic disease
Oropharynx	
Mucous membranes	Hydration status, cardiovascular status, anemia, icterus
Tongue	Linear foreign body
Cervical region	
Thyroid gland	Thyroid nodule (hyperthyroidism)
Abdominal palpation	Effusions, masses, bunching of intestinal loops, foreign bodies, abnormal accumulations of ingesta, associated pain, feces, lymphadenopathy, other systemic disease
Abdominal auscultation	Ileus, borborygmi
Rectal examination	
Digital examination	Masses, foreign bodies, hemostatic disorders, dehydration
Collection of stool sample	Laboratory analysis, identification of melena
Rectal mucosal scrape	Cytology
Cutaneous examination	
Poor coat condition, scale	Malnutrition
Pruritus	Food hypersensitivity
Facial pruritus	Food hypersensitivity
Pedal pruritus	Food hypersensitivity, *Uncinaria stenocephala* infection (larval migration)

E-TABLE 276-5

Some Suspected and Confirmed Breed Susceptibilities to Small Intestinal Disease in Dogs

BREED	CONDITION
Basenji	LPE (also called IPSID)
Beagle	Selective cobalamin malabsorption, aminopeptidase N deficiency
Border Collie	Selective cobalamin malabsorption
German Shepherd Dog	Idiopathic ARD; IBD (lymphoplasmacytic, eosinophilic)
Giant Schnauzer	Selective cobalamin malabsorption
Irish Setter	Gluten-sensitive enteropathy
Lundehund	Lymphangiectasia
Retrievers	Dietary allergy
Rottweiler	Susceptibility to parvovirus, lymphangiectasia
Soft-coated Wheaten Terrier	Protein-losing enteropathy/nephropathy
Chinese Shar-Pei	LPE, cobalamin deficiency
Toy breeds	HGE
West Highland White	Dietary allergy
Yorkshire Terrier	Lymphangiectasia

ARD, Antibiotic-responsive diarrhea; *HGE*, Hemorrhagic gastroenteritis diarrhea; *IPSID*, Immunoproliferative small intestinal disease; *IBD*, Inflammatory bowel disease; *LPE*, Lymphocytic-plasmacytic enteritis.

Preliminary investigations also can include collection of baseline data through a complete blood count (CBC), serum biochemistry profile, urinalysis, and fecal examination. This can identify cases of hypoadrenocorticism, but an abnormal serum sodium to potassium ratio sometimes is seen in primary SI disease, notably salmonellosis and whipworm infection. Diagnostic imaging could be indicated, especially if a disease requiring surgical intervention is suspected from the history and/or physical examination findings (see "Surgical Intestinal Disorders," below). Further investigations in cases of chronic diarrhea include exclusion of EPI, indirect tests of intestinal function (e.g., serum folate and cobalamin) and damage (e.g., fecal alpha$_1$-protease inhibitor, fecal calprotectin) and, ultimately, direct inspection of the SI by endoscopy or surgery with histologic examination of biopsies, but they are rarely necessary in acute disease.

Melena[310,323-334]

The general approach to melena is to rule out generalized bleeding diatheses, ingestion of blood from other lesions (e.g., oral masses), toxicoses (e.g., NSAIDs), and underlying metabolic disorders (e.g., hypoadrenocorticism) before pursuing primary GI causes. Ultrasonography is particularly useful for detecting GI masses and thickening. The next step is endoscopy to identify gastric or duodenal bleeding. Enteroscopy and videocapsule endoscopy can be used for localizing a more distal bleeding site but rarely are available. If the source of GI bleeding still is undetermined, tagged red cell scintigraphy or angiography can be considered, but ultimately exploratory laparotomy can be indicated.

Protein-Losing Enteropathy[289,290,312,314,335-338]

The identification of a PLE is based on finding hypoalbuminemia. Usually in patients with PLE, the serum concentrations of both albumin and globulin are reduced. However, exceptions are hyperglobulinemia with hypoalbuminemia found in both histoplasmosis and immunoproliferative SI disease of the Basenji and occasionally in severe IBD and in alimentary lymphoma. PLE causing substantial hypoalbuminemia is rare in cats, but dog breeds that appear to be predisposed to PLE are the Basenji, Lundehund, Rottweiler, Soft-coated Wheaten Terrier, Yorkshire Terrier, and Chinese Shar-Pei. The breed raises the suspicion in a hypoproteinemic dog even if diarrhea is absent, but renal and hepatic causes of hypoalbuminemia should be eliminated by assay of serum bile acids and urinary protein loss (i.e., urine protein to creatinine ratio), respectively, with the caveat that concurrent PLE and protein-losing nephropathy is seen in Soft-coated

Wheaten Terriers. Hypocholesterolemia and lymphopenia are common in PLE, and ionized hypocalcemia and hypomagnesemia can occur. Measurement of increased fecal alpha$_1$-protease inhibitor can be a sensitive test for PLE before significant hypoalbuminemia develops.

Survey abdominal radiographs are unhelpful in patients with PLE and ascites because of the loss of radiographic contrast, but ultrasound scans can reveal intestinal thickening and/or mesenteric lymphadenopathy, as well as abdominal effusion. Thoracic radiographs can show pleural effusion, metastatic neoplasia, or changes consistent with histoplasmosis. Although intestinal function tests may confirm the presence of malabsorption, they rarely provide a definitive diagnosis and intestinal biopsy is more useful. Because many intestinal causes of PLE are diffuse, endoscopy is the safer way to obtain biopsies, but surgical biopsy could be required to obtain a definitive diagnosis for transmural lymphoma and lymphangiectasia (E-Box 276-9).

E-Box 276-9

Relative Advantages of Endoscopic and Surgical Intestinal Biopsy

Endoscopy

- Advantages
  - Minimally invasive
  - Allows visualization and biopsy of focal lesions
  - Permits multiple biopsies
  - Minimal risk
  - Allows steroids to be started early; no convalescence
- Disadvantages
  - Requires general anesthesia
  - Small risk of perforation
  - Permits reliable access only to duodenum:
    - Proximal jejunum only accessible in cats and small dogs
    - Distal ileum only accessible via colonoscopy
  - Produces only small, superficial (and potentially crushed) biopsies
    - Could miss lymphangiectasia, lymphoma
  - Requires expensive equipment
  - Technically demanding

Laparotomy

- Advantages
  - Allows biopsy of multiple sites
  - Permits large, full-thickness biopsies
  - Allows inspection and biopsy of other abdominal organs
  - Offers potential for corrective surgery
- Disadvantages
  - Requires general anesthesia
  - Surgical risk
  - Postsurgical risk of dehiscence
  - Requires convalescence
  - Requires delay before steroids can be started

Laboratory Examination

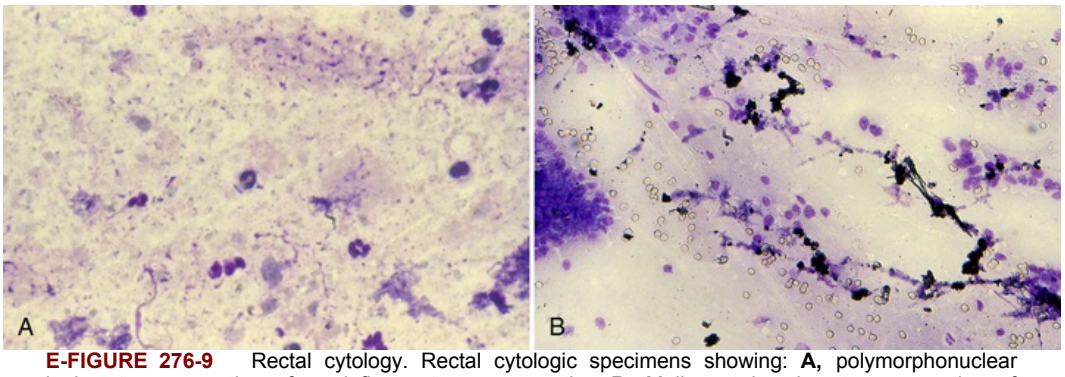
Minimum Database

Preliminary investigations include a complete blood count, serum biochemistry profile, and urinalysis.

Rectal Cytology

At the end of the rectal examination, the gloved finger is rolled on a microscope slide and the smear is stained (E-Figure 276-9). Although the result often is negative or at best more representative of LI disease, an increased number of neutrophils can be suggestive of a bacterial problem, indicating the need for fecal

culture. Fungal elements also can be identified. The test is fast and simple, but in all cases confirmatory tests are indicated.



E-FIGURE 276-9 Rectal cytology. Rectal cytologic specimens showing: **A,** polymorphonuclear leukocytes suggestive of an inflammatory enteropathy. **B,** Malignant lymphocytes suggestive of alimentary lymphoma.

Fecal Examinations

Fecal examinations are an important part of the investigation of SI disease (see ch. 81). Tests such as quantification of fecal fat excretion are unsuitable for practice, and bacterial culture is sometimes of questionable value, but identification of parasites is important.

Direct Smear

Staining of smears for undigested starch granules (Lugol's iodine), fat globules (Sudan stain), and muscle fibers (Wright's or Diff Quik stain) can indicate malabsorption, but findings are nonspecific. The presence of fungal elements and sporulating clostridia is of uncertain significance, but rectal cytology can be helpful to identify an associated neutrophilic inflammation. Very fresh, unstained wet mounts can be used for observing motile protozoal trophozoites. Enterotoxin production by *Clostridium perfringens* is a potential cause of diarrhea; however, the presence of a large number of clostridial endospores (more than 5 per oil immersion field) on Diff Quik–stained smears is no longer considered a reliable indicator, whereas a positive fecal enterotoxin assay (enzyme-linked immunosorbent assay [ELISA]) or reverse passive latex agglutination) is more likely to be significant.

Fecal Concentration Methods[339-345]

For the detection of most intestinal parasites, fecal concentration methods are most rewarding (Figure 276-10; see ch. 81). Examination of three fecal samples by zinc sulfate flotation is recommended to detect *Giardia* oocysts. A direct smear, sedimentation, or the Baermann technique can identify larvae of *Strongyloides* spp.

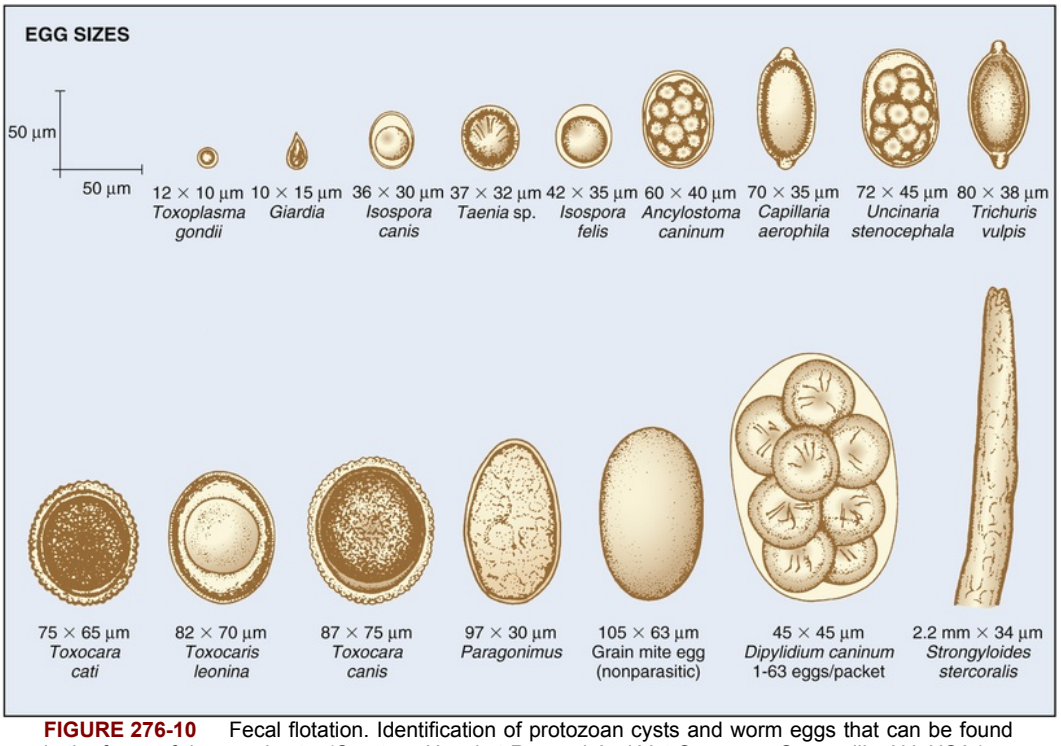


FIGURE 276-10 Fecal flotation. Identification of protozoan cysts and worm eggs that can be found in the feces of dogs and cats. (Courtesy Hoechst-Roussel-Agri Vet Company, Somerville, NJ, USA.)

Antigen Tests[342,346-348]

Copro-antigen tests of feces can be used to detect cestode, trematode and nematode infections, but antigen tests most frequently are used for detecting protozoal or viral infections. Commercially available, point-of care ELISAs can be used for detecting *Giardia* (see ch. 221) and canine parvovirus (see ch. 225) antigen in feces.

Immunofluorescence[348,349]

Imunofluorescent antibody staining of fecal smears is considered one of the most sensitive methods for detecting *Giardia* and *Cryptosporidium* (see ch. 221).

Routine Bacterial Culture[350,351]

Attempting to grow all bacterial species present in a fecal sample is of little value, especially as the fecal flora does not necessarily reflect the SI flora, and many species are unculturable. However, targeted identification of potential pathogens could be helpful. Culture of feces is indicated in animals with hemorrhagic diarrhea or fever, or with an inflammatory leukogram, or with neutrophils on rectal cytology. Identification of *Salmonella* spp., *Campylobacter jejuni,* and *Clostridium difficile* can be helpful, although the significance of a positive isolate should be interpreted in light of the clinical history because these organisms can be present in feces from clinically healthy animals. Feces can be cultured for fungi, such as *Histoplasma capsulatum,* but isolation is difficult and slow.

Fecal Polymerase Chain Reactions (PCR)[352-362]

Although PCR of fecal material can be difficult because of the presence of inhibitors of the reaction, by using specific primers and adequate controls, bacteria and parasites in fecal samples can be identified. PCR potentially is more sensitive than bacterial culture as live organisms need not be present, and speciation also is possible. However, PCR more often is used for classifying organisms after they have been cultured; *E. coli* can be cultured from most fecal samples, but only certain strains are pathogenic, and PCR probes are able to detect molecular pathogenicity genes. PCR is the method of choice for the diagnosis of *Tritrichomonas* infection in cats (see ch. 221 and 277).

Molecular Fingerprinting[72,74,85,104,108,228,363,364]

Many intestinal bacteria are unculturable *in vitro* and can only be identified by gene sequencing of bacterial 16S rRNA. This method is used for looking at the pattern of the flora in intestinal fluid, biopsies, and feces in a population and is unlikely to be helpful in individual patients.

Virologic Examination[365-368]

Viral diarrhea usually is acute and self-limiting and does not require a positive diagnosis. Electron microscopy can be used for identifying characteristic viral particles such as rotavirus, coronavirus, and parvovirus. Fecal ELISA and PCR tests for parvovirus are also available.

Occult Blood[310,369-371]

This test is used for identifying intestinal bleeding from ulcerated mucosa and benign or malignant tumors before melena is seen, but it does not help localize the source. Unfortunately, most assays nonspecifically test for any hemoglobin and are very sensitive, reacting with any dietary meat, as well as patient blood. Therefore the patient must be fed a meat-free or hydrolyzed diet for at least 72 hours for a positive result to have any significance. Immunological tests are too sensitive and they detect hemoglobin from healthy dogs.

Alpha$_1$-Protease Inhibitor[315,372-382]

This test assays the presence in feces of alpha$_1$-protease inhibitor (alpha$_1$-PI), a naturally occurring endogenous serum protein that is resistant to bacterial degradation in the intestinal lumen. It appears to be of value for the diagnosis of PLE, correlating with historical testing by fecal radioactive ^{51}chromium-labeled albumin excretion. It appears to be a more sensitive marker than measurement of serum albumin for the detection of early disease. To improve diagnostic accuracy, three fresh fecal samples should be evaluated. The assay is valid only if used on fecal samples collected after voluntary evacuation because abrasion of the colonic wall during digital evacuation is enough to elevate fecal alpha$_1$-PI concentrations.

Fecal Calprotectin[383-389]

The assay of fecal calprotectin is a proven marker of intestinal inflammation in human IBD, as the molecule that is identified is released with neutrophil elastase activity. A dog-specific assay has been developed, and increased fecal concentrations tend to correlate with intestinal inflammation and the degree of histologic change, but not necessarily with clinical signs.

3-Bromotyrosine and N-Methylhistamine[390-392]

The 3-bromotyrosine molecule (3-BrY) is a stable product of eosinophil peroxidase, and its serum concentration can serve as a marker of eosinophil activation. However, preliminary studies indicate it could be increased in any form of IBD and not just eosinophilic enteritis. Urinary and fecal N-methylhistamine concentrations are poor markers for mast cell activation or clinical disease activity in dogs with chronic enteropathies.

Serum Folate and Cobalamin Concentrations[52,234,237-239,242,377,393-410]

The assay of serum folate and cobalamin concentrations often is performed on the same serum sample taken for the TLI test. This assay has limited value in the diagnosis of specific SI diseases and is *not* recommended for the diagnosis of bacterial overgrowth. Subnormal folate and cobalamin concentrations are primarily markers of GI disease (see Figure 276-2), but also indicators of the need to supplement. Hypercobalaminemia has no significance in dogs or cats with GI disease and could be due to supplementation, but it has been associated with hepatic and neoplastic disease in cats.

Special Indirect Tests[411-414]

In cases of malabsorption, intestinal biopsy usually is necessary to obtain a definitive diagnosis. However, EPI should be ruled out before biopsy because signs of malabsorption are nonspecific and do not permit differentiation of cause. Thus, serum trypsin-like immunoreactivity (TLI) measurement must be performed in all cases (see ch. 292). It also is well recognized that biopsies from up to 50% of patients are considered normal by light microscopy. Therefore, usually before biopsy, a number of indirect tests can be performed to assess for intestinal damage, altered permeability, and dysfunction, although their sensitivity and specificity limit their utility.

Tests of Intestinal Absorption[415-419]

Tests of intestinal function assessing the mediated absorption of numerous substrates—such as lactose, glucose, starch, triglyceride, and vitamin A—are no longer performed because of a lack of sensitivity and specificity. Even the D-xylose test has been abandoned because it is too insensitive in dogs and is nondiscriminatory in cats. The differential absorption of two sugars—xylose/3-O-methyl-D-glucose—eliminates the nonmucosal effects that blight the xylose test, but this assay has not entered routine practice.

Intestinal Permeability[266,416,420-449]

Intestinal permeability is an index of mucosal integrity, and it is assessed by measuring unmediated uptake of nondigestible, nonmetabolizable probe markers in plasma and/or urine. The permeability probe chromium[51]-labeled ethylenediamine tetra-acetic acid (^{51}Cr-EDTA) was used in original studies, but being a gamma-emitter limited its safe use. The lactulose/rhamnose test has become the standard test of SI permeability. Recently, iohexol has been shown to be a useful probe marker, because it is safe and its assay is commercially available. In IBD, there are reductions in E-cadherin and alpha-catenin, which are integral to tight junction structure and function. Consequently intestinal permeability is increased by villus atrophy or epithelial damage or both. NSAIDs also increase intestinal permeability.

Tests for Protein-Losing Enteropathy[315,450,451]

Historically, intestinal protein loss has been detected by measuring the fecal loss of radiolabeled molecules such as ^{51}Cr-labeled albumin and ^{67}Cu-labeled ceruloplasmin. These tests are unpleasant to perform and potentially hazardous and have been discarded, although they remain the standard by which other tests, such as fecal alpha$_1$-PI, are judged.

Breath Tests[405,452-467]

Breath tests are used for assessing bacterial metabolism in the GI tract. Bacteria synthesize a gas, which is absorbed and excreted in breath. Breath hydrogen tests have been used most extensively because mammalian cells cannot produce hydrogen, and therefore any that is measured must be bacterial in origin. Such tests potentially can assess carbohydrate malabsorption, bacterial colonization of the SI, and oro-cecal transit time, but are not widely used.

Unconjugated Bile Salts[468-472]

The hypothesis behind the serum unconjugated bile acids (SUBA) test was that some SI bacterial species can deconjugate bile acids. Unconjugated bile acids then are absorbed passively by the SI and do not undergo enterohepatic recycling. Therefore, in theory, increases in SI bacterial activity might result in an increase in SUBAs. However, results do not correlate with the diagnosis, partly because there is a significant postprandial increase in SUBA in healthy dogs, and the test is no longer recommended.

Miscellaneous Tests of Bacterial Activity[460,472-479]

Several tests for intestinal bacterial metabolites have been devised to detect bacterial metabolic activity, bacterial overgrowth, or to assess oro-cecal transit time. These include the nitrosonaphthol test, urinary indican excretion, serum D-lactate, and bacterial release of sulfapyridine from sulfasalazine or p-amino benzoic acid (PABA) from a bile salt conjugate (PABA-UDCA). Evaluation of the volatile gases emitted by feces can give a profile that is characteristic of specific infections. However, none of these tests is used widely in companion animals.

Indirect Assessment of Intestinal Motility[458,460,479-491]

Intestinal transit time can be assessed directly by barium studies with and without food, ultrasonography (including pulsed-wave Doppler), and scintigraphy. Recording of myoelectrical activity *in vivo* is not practicable in clinical practice, although peristaltic pressure can be measured with the SMART capsule. Indirect assessments of intestinal motility include breath hydrogen following carbohydrate administration, and visual (carmine red dye, chromic oxide) or chemical markers (sulfasalazine, acetaminophen, nitrofurantoin, PABA-UDCA) given orally. Results are variable, and often the methodologies do not correlate well. Many are technically difficult, and the composition of the test diet and stress affect transit rates as much as disease does.

Diagnostic Imaging[492-496]

Historically, imaging of the intestinal tract was limited to plain and contrast radiographs, and now it is complemented by ultrasonography and flexible endoscopy. Scintigraphy, computed tomography (CT), and magnetic resonance imaging (MRI) now are rapidly being adopted, and "virtual endoscopy" by helical CT is becoming available.

Plain Radiography[483,497-503]

Survey, plain radiographs are most useful in the investigation of primary vomiting, diarrhea associated with vomiting, evidence of abdominal pain, and palpable abnormalities. Diagnostic yield is improved if both lateral views are taken in addition to an orthogonal view, although a single lateral radiograph may be all that is required if radiography is combined with ultrasonography. Generally the aim is the detection of (acute) surgical disease (foreign bodies, free peritoneal gas, intestinal displacement, masses, obstructions), decreased serosal detail, and ileus (E-Table 276-7).

E-TABLE 276-7

Helpful Survey Abdominal Radiographic Findings in Patients with Intestinal Disease

FINDINGS	INTERPRETATION
Radiopaque foreign bodies	Visible on survey films
Ileus	Either adynamic/paralytic or obstructive (see Box 276-5)
Abnormal soft tissue shadow	Abdominal mass
Displacement of viscera	Abdominal mass, enlargement of intraperitoneal or retroperitoneal organ, rupture, or hernia
Bunching of intestine	Excess intraabdominal fat, large mass, adhesions, linear foreign body
Bowel wall thickness*	Edema, infiltrative (inflammatory, neoplastic) disease
Bowel wall irregularity*	Enteritis, neoplasia, ulcers
Loss of serosal detail	Emaciation and immaturity, peritoneal effusion (ascites in hypoproteinemia and/or portal hypertension, peritonitis, carcinomatosis)

*Requires contrast.

Ileus is an abnormal dilation of an immotile segment of intestine, and the differential diagnosis depends on whether it is localized or generalized and whether an accumulation of gas or fluid is present (Box 276-10). Interpretation should be cautious if the patient has been treated with drugs that can affect the GI tract. Comparisons of the degree of intestinal dilation to bony landmarks to determine if there is an obstruction are not always helpful, and the usefulness of plain radiographs in malabsorption is minimal, especially if ascites is present, as all detail is obscured by fluid.

Box 276-10

Differential Diagnosis of Ileus

Gas Ileus

- Generalized
  - Aerophagia
  - Enteritis
  - Generalized peritonitis
  - Smooth muscle paralyzing drugs (e.g., atropine)
- Localized
  - Disruption of mesenteric arterial supply

- Early-stage bowel obstruction
- Localized peritonitis (e.g., pancreatitis)

Fluid Ileus

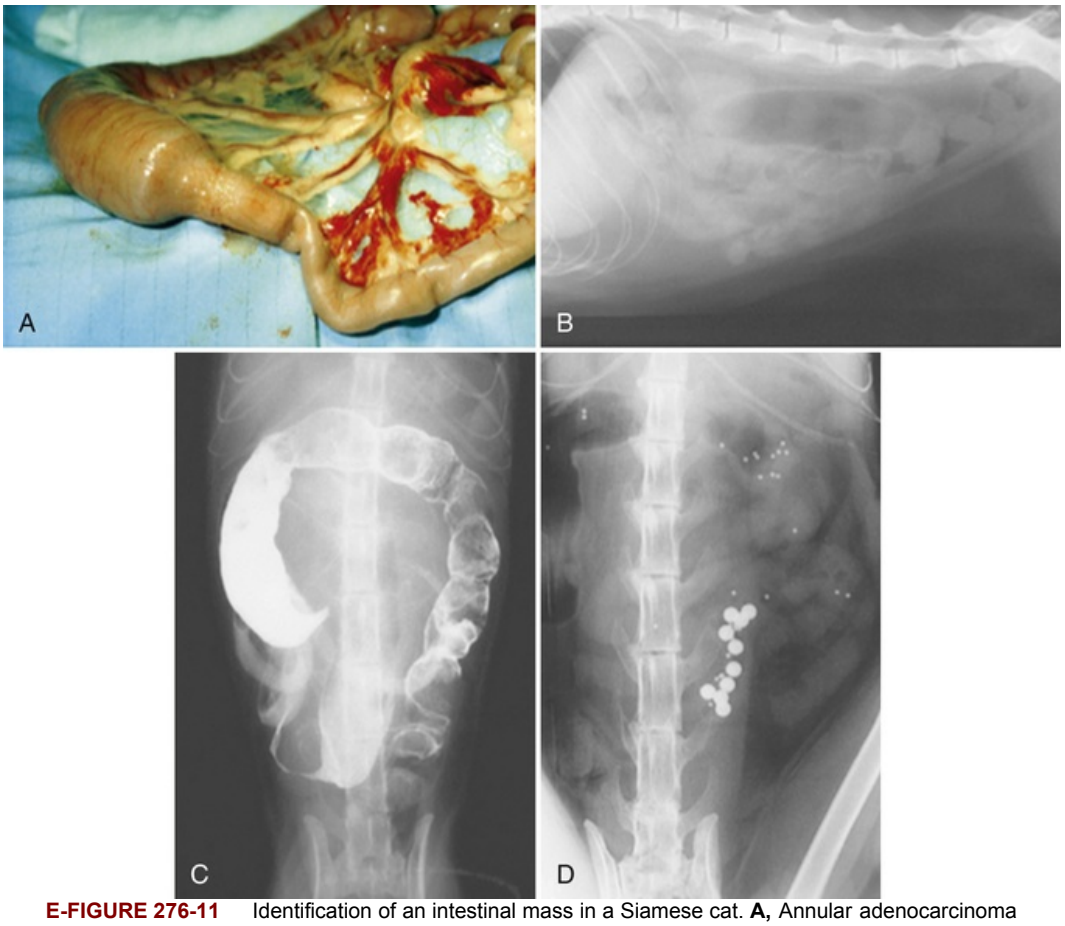
- Generalized
  - Enteritis
  - Diffuse intestinal neoplasia
- Localized
  - Foreign body
  - Intussusception or other mechanical obstruction (e.g., incarceration)
  - Tumor causing obstruction

Contrast Radiography

Since the introduction of abdominal ultrasonography and endoscopy, contrast radiographic studies have had limited value in the assessment of SI disease, but they remain useful for gastroesophageal disease (see ch. 273).

Follow-Through Examinations[504-506]

Studies using microfine barium suspensions can identify ulcers and irregular mucosal detail and could confirm the presence of radiolucent foreign bodies but are insensitive for identifying mural masses and partial obstructions and rarely provide more information than a good-quality survey films (E-Figure 276-11). Administration of barium can delay endoscopy for at least 24 hours. If perforation is suspected, an iodine-based contrast is used. Enteroclysis (deposition of contrast directly into the stomach or intestine via orogastric or orointestinal intubation, for optimal distension) provided more information but is technically demanding and has not been adopted. Although contrast studies allow assessment of the intestinal transit rate of the contrast agent, this is not physiologic and does not correlate closely to movement of ingesta assessed by the gold standard of scintigraphy. Furthermore, evidence of dysmotility provides no etiologic information.



E-FIGURE 276-11 Identification of an intestinal mass in a Siamese cat. **A,** Annular adenocarcinoma in the ileum demonstrated at laparotomy. **B,** Prior plain lateral radiograph showing a dilated loop of bowel associated with this caudal abdominal mass. **C,** Ventrodorsal radiograph after oral administration of barium suspension showing a dilated loop of small intestine on the midline, colonic filling, and narrowing of the intestinal lumen at the site of the mass. **D,** Ventrodorsal radiograph after oral administration of barium-impregnated polyethylene spheres (BIPS) showing accumulation of the larger markers at the site of the partial obstruction caused by the mass. (Courtesy A. H. Sparkes.)

Barium-Impregnated Polyethylene Spheres (BIPS)[491,507-510]

BIPS are solid-phase radiopaque markers that provide information on gastric emptying, intestinal transit, and obstructive disorders (see E-Figure 276-11). Given that the transit time of BIPS is highly variable, their use for transit studies is limited and they are most helpful in the detection of partial obstructions.

Ultrasonography[494,511-562]

Abdominal ultrasound examination of the SI is now a routine part of the investigation of SI disease (see ch. 88 and 89), although its diagnostic utility in chronic diarrhea has been questioned. A conventional examination can detect loss of layering of the SI wall, ulceration, mucosal heterogeneity and striations, evidence of fibrosis, peristalsis, ileus, luminal contents and foreign bodies and can be used for measuring SI wall thickness. Ultrasonography has greater sensitivity than radiography and excellent specificity for the detection of lesions such as intussusceptions, masses, both radiopaque and radiolucent foreign bodies, and intestinal wall thickening and lymphadenopathy in chronic inflammatory, inflammatory, lymphatic, and neoplastic enteropathies (Figure 276-12); even Peyer's patches and sites of previous intestinal surgery can be identified with the appropriate equipment and operator expertise. The development of endoscopic ultrasound now is allowing the mucosal wall and adjacent viscera to be examined in even more detail.

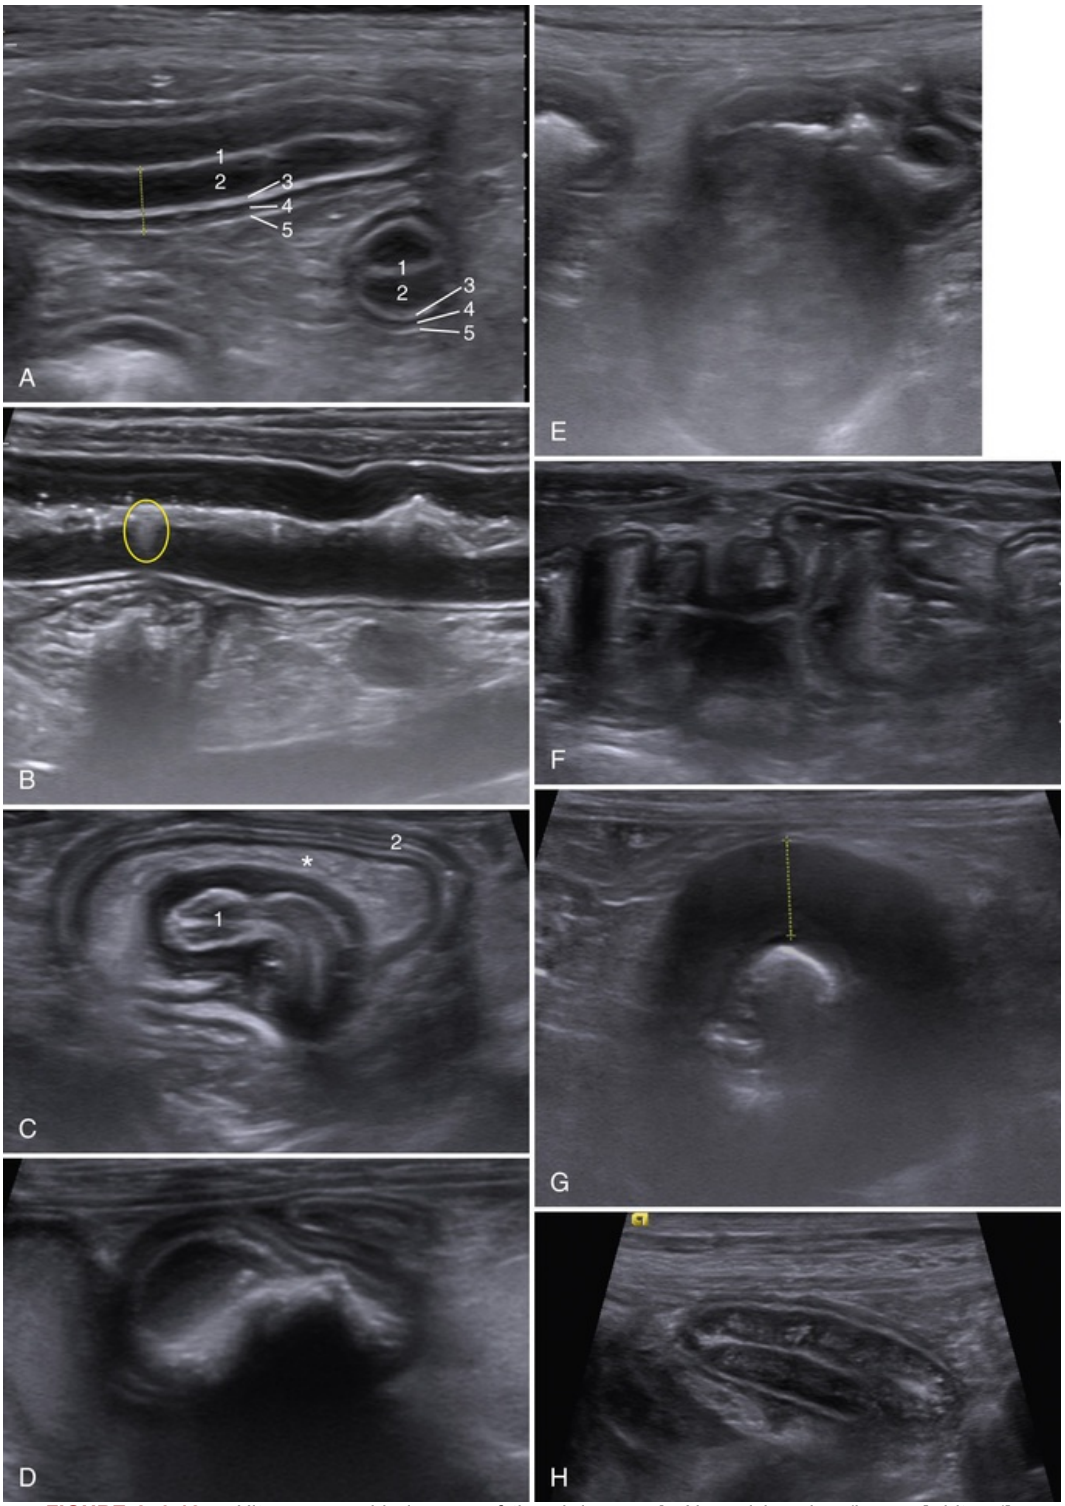


FIGURE 276-12 Ultrasonographic images of the abdomen. **A,** Normal layering (lumen [white; *1*]; mucosa [black; *2*]; submucosa [white; *3*]; muscularis [black; *4*]; serosa [white; *5*]) of loops of jejunum in both longitudinal and transverse section in a dog. **B,** Longitudinal section of canine duodenum with normal layering and a Peyer's patch indenting the mucosa (circled); note that the duodenum is straighter and has a thicker wall than the jejunum. **C,** An intussusception with the classic double-walled structure; the intussusceptum *(1)* is surrounded by ingesta (asterisk) in the intussuscipiens *(2)*. **D,** An intestinal foreign body with acoustic shadowing. **E,** An eccentric mass lesion that would be amenable to fine-needle aspirates or Tru-Cut biopsy. **F,** A linear foreign body with plication of the intestinal loops. **G,** Thickened intestinal wall with loss of layering caused by lymphoma. **H,** Heterogeneous, hyperechoic mottling and striation in the mucosa of a dog with lymphangiectasia (see Figure 276-14, *H*). (Images courtesy Chris Warren-Smith, Langford Veterinary Services.)

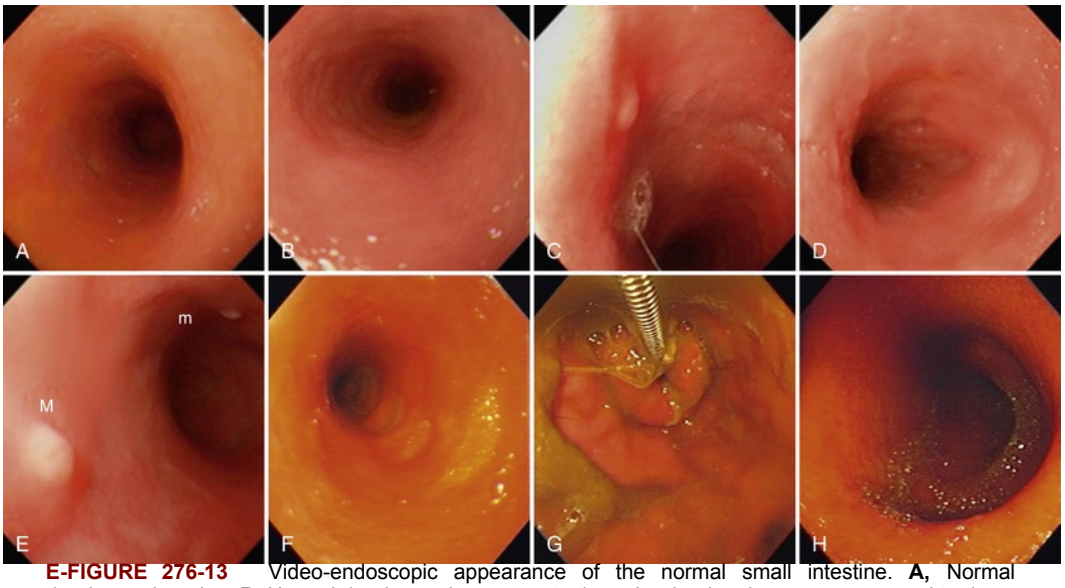
Values for normal SI wall thickness have been reported for dogs and cats; thickness decreases from 5-6 mm proximally to 4-5 mm distally but also depends on body size, with the thickest wall being seen in the largest dogs. Intussusceptions usually are recognized in the transverse plane as multiple concentric rings and longitudinally as a thick, multilayered segment. Disruption of the normal five-layered sonographic appearance (mucosal surface, mucosa, submucosa, muscularis, serosa) is typical of neoplasia, whereas wall thickening also can result from other infiltrative disorders and edema, although a thickened muscularis has been associated with lymphoma in cats. Mucosal heterogeneity can be indicative of inflammation or crypt abscessation. Striations reflect lymphatic dilation; administration of corn oil before the examination can improve their identification, although the specificity of the finding is reduced. High-frequency ultrasound can differentiate mucosal lymphoid aggregates. Ultrasound-guided fine-needle aspiration of masses or grossly thickened walls for cytologic examination is possible, and needle biopsy can be possible with larger lesions.

Endoscopy[325,326,331,480,563-586]

Endoscopy allows visualization of the SI mucosa and collection of multiple tissue samples without the need for invasive surgery and the risk of surgical biopsy; complications of bacteremia or perforation are rare. Optimal, well-maintained endoscopic equipment and operator experience are more important than pharmacologic manipulation in achieving successful SI intubation (see ch. 83 and 113). The proximal SI is viewed during gastroduodenoscopy (E-Figure 276-13 and Video 276-1), and the ileum can be sampled by passing the endoscope retrograde through the ileocolic valve during colonoscopy. Therefore only the midjejunum cannot be examined satisfactorily by routine endoscopy. However, given that most cases of malabsorption involve diffuse disease, this limitation might not be significant, although discordance between the findings of paired duodenal and ileal biopsies means that ideally both sites should be sampled.



E-FIGURE 276-13 Video-endoscopic appearance of the normal small intestine. **A,** Normal duodenum in a dog. **B,** Normal duodenum in a cat; note the paler duodenal mucosa compared to dogs. **C,** The major duodenal papilla in the duodenum of the dog is the site of entry of the common bile duct and major pancreatic duct. **D,** Peyer's patches (lymphoid aggregates) in the duodenum appear as pale oval depressions along the antimesenteric border of the descending duodenum. **E,** The minor duodenal papilla (m) is seen in some but not all dogs, distal to the major duodenal papilla (M) and approximately 100 degrees clockwise from it. **F,** Normal canine duodenum with a line of Peyer's patches. **G,** Blind biopsy of the ileum achieved by passing biopsy forceps through the ileocolic valve via colonoscopy. **H,** Normal ileum viewed by successful passage of the endoscope through the ileocolic valve; the mucosa is thinner than in the duodenum and appears more granular due to the presence of multiple small lymphoid follicles. (**A-E,** Reprinted with permission from Lhermette P, Sobel D, editors: *BSAVA manual of canine and feline endoscopy and endosurgery*, Quedgely, Gloucester, England, 2008, BSAVA Publications.)

Currently, flexible endoscopy is the standard diagnostic method, but emerging technologies include capsule endoscopy, enteroscopy, double-balloon endoscopy and confocal endomicroscopy. Enteroscopy uses a much longer, thinner endoscope (with or without a guiding oversleeve) and/or advancement balloons and

could allow examination of most of the jejunum, as does a videoendoscopy capsule that passes from mouth to anus and transmits images by telemetry. The SMART capsule allows collection of physiologic data (pH, pressure) by telemetry but no images. Confocal endomicroscopy allows evaluation of cellular morphology in the SI and the potential for early detection of epithelial dysplasia and neoplasia.

Abnormal findings on gross endoscopic examination include mucosal granularity and friability, erosions/ulcers, retained food, mass lesions, and hyperemia/erythema (Figure 276-14). A milky-white exudate and/or dilated lymphatics is/are suggestive of lymphangiectasia, and the presence of intraluminal parasites can be diagnostic in some cases (Video 276-2), but identification of roundworms usually is an incidental finding. A simple qualitative endoscopic scoring system for IBD has been developed (Table 276-8). However, none of these characteristics is pathognomonic for particular disease conditions, and gross findings frequently do not correlate with histopathological results.

FIGURE 276-14 Examples of endoscopic duodenal lesions. **A,** Incidental finding of an isolated *Toxocara* worm in the duodenum of a cat. **B,** Proximal duodenal ulcer (arrow) in a cat with lymphoplasmacytic enteritis presented because of hematemesis. (Courtesy Natasha Hetzel.) **C,** Mild inflammatory bowel disease: lymphoplasmacytic enteritis; note the irregularity and the major duodenal papilla at approximately 7 o'clock. **D,** Severe inflammatory bowel disease: lymphoplasmacytic enteritis; note the marked granularity, even involving Peyer's patches. **E,** Marked crypt abscessation associated with protein-losing enteropathy in a Chihuahua. (Courtesy Jenny Reeve.) **F,** Inflammatory bowel disease: bleeding associated with eosinophilic enteritis. **G,** Severe inflammatory bowel disease: eosinophilic enteritis. **H,** Lymphangiectasia; note the multiple dilated lacteals containing white lymph.

TABLE 276-8

Quantitative Assessment of Endoscopic Mucosal Appearance

APPEARANCE	SCORE	DESCRIPTION
Friability	0	Absent
	1	Mild bleeding to touch
	2	Marked bleeding to touch
Granularity	0	Normal texture
	1	Texture increased
	2	Markedly increased texture
Erosions	0	Absent
	1	Only few erosions

	2	Diffuse erosions
Lymphatic dilatation	0	Absent
	1	Focal–multifocal white foci
	2	Diffuse white foci

Maximum enteroscopy score = 8.

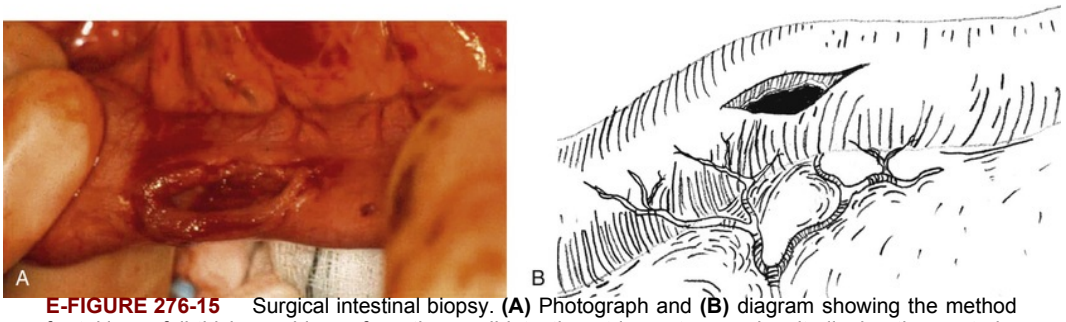
Duodenal Juice[103,469,587-591]

Duodenal juice can be collected during duodenoscopy through a sterile polyethylene tube passed down the biopsy channel or by needle aspiration through the intestinal wall at laparotomy. However, collection of sufficient sample without blood and tissue contamination can be difficult. The sample can be examined for *Giardia* trophozoites, although this has not proven reliable in diagnosis. Alternatively, quantitative and qualitative aerobic and anaerobic cultures can be performed. This was considered the gold standard for diagnosis of bacterial overgrowth, but there are major problems in interpretation and results do not aid in decision-making for cases of GI disease. Therefore, routine bacterial culture of duodenal juice is not recommended.

Intestinal Biopsy[565,577,592-608]

In most cases of acute diarrhea, a tissue diagnosis is not needed, and intestinal biopsy is rarely performed. However, in chronic diarrhea a definitive diagnosis often depends on histologic examination of intestinal tissue, although this does have major limitations. Biopsy specimens are collected either endoscopically or surgically (i.e., laparotomy or laparoscopy).

At laparotomy, full-thickness biopsies usually are taken from at least three sites: the duodenum, the jejunum, and the ileum (E-Figure 276-15). However, the risk of dehiscence after surgical biopsy can be substantial, especially if the patient is malnourished and/or hypoproteinemic, the tissue is neoplastic, or the surgeon inexperienced. Administration of plasma reduces the oncotic effects of hypoproteinemia, but the effect is only transient and only worthwhile to provide oncotic support during the perioperative period; it will not help wound healing.



E-FIGURE 276-15 Surgical intestinal biopsy. **(A)** Photograph and **(B)** diagram showing the method for taking a full-thickness biopsy from the small intestine at laparotomy; a longitudinal antimesenteric, elliptical incision is made and is then closed transversely to prevent stricture formation. (Reprinted with permission from Hall E, Williams D, Simpson J, editors: *BSAVA manual of canine and feline gastroenterology*, ed 2, Quedgely, Gloucester, England, 2005, BSAVA Publications. Part B, Drawn by Ellen Williams and reproduced with her permission.)

The reduced risk of endoscopic biopsy to the patient compared with surgery is balanced by a number of drawbacks (see E-Box 276-9), and the client should always be warned prior to endoscopic biopsy that surgical biopsy might ultimately be required for definitive diagnosis. The duodenum, and proximal jejunum, if possible, are biopsied routinely, and ileal biopsies can be obtained via colonoscopy. It is best practice to perform endoscopic biopsy before contemplating surgery unless there is evidence that the disease is beyond the reach of the endoscope. The surgical option is preferred if there is any possibility of extraintestinal disease or focal intestinal lesions. The size and quality of endoscopic biopsies depends not just on the equipment available but also the pressure exerted by the forceps, which is in part dependent on the operator's experience

and how the biopsies are processed. Biopsies should always be taken, even in the absence of gross abnormalities, because microscopic changes can be present. Multiple specimens (six or more) should be collected because the size of the specimens, crush artifacts, and fragmentation can make interpretation difficult (Figure 276-16).

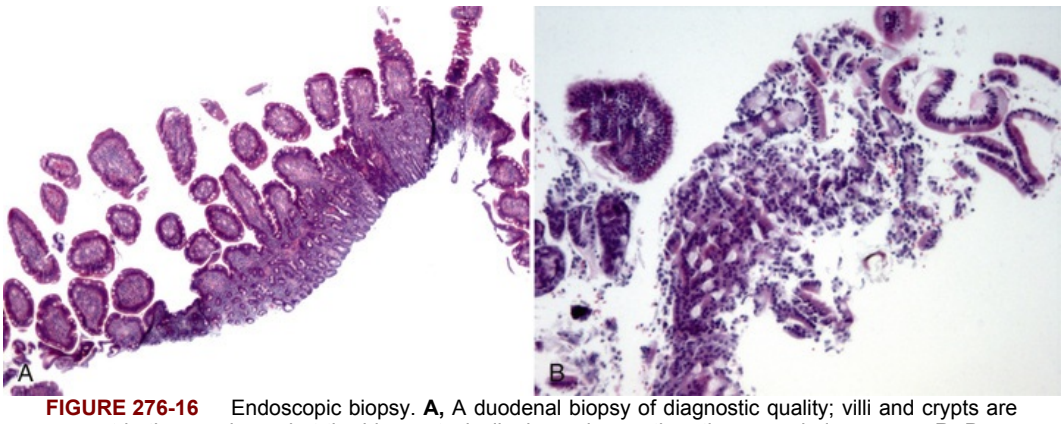


FIGURE 276-16 Endoscopic biopsy. **A,** A duodenal biopsy of diagnostic quality; villi and crypts are present in the specimen, but the biopsy, typically, is no deeper than the muscularis mucosa. **B,** Poor-quality endoscopic biopsy; the tissue is traumatized and disrupted; it is not suitable for making a diagnosis. (Reprinted with permission from Hall E, Williams D, Simpson J, editors: *BSAVA manual of canine and feline gastroenterology,* ed 2, Quedgely, Gloucester, England, 2005, BSAVA Publications.)

Examination of Biopsies[604,609-616]

Histopathology

Although histopathologic assessment of intestinal biopsies remains the supposed gold standard for diagnosis of intestinal disease, it has marked limitations. Many biopsy specimens can be normal by light microscopy, which suggests that many diseases have a functional rather than a morphologic cause (Box 276-11) or that sampling or interpretation problems have occurred. Agreement between histopathologists often is poor, especially when examining endoscopic biopsies, and a standardized approach is required (E-Box 276-12). In one study, some histopathologists made a diagnosis of lymphoma after assessing tissues from healthy dogs, and there was only reasonable agreement between five independent pathologists in about half of the samples examined. Histopathologic scoring schemes and standardized criteria have been suggested by the World Small Animal Veterinary Association (WSAVA) GI Standardization Group as a means of improving agreement. However, Group members also have shown that the experience of the endoscopist, as well as simply the quality and number of biopsies and the quality of processing and staining, all can influence the reliability of the histologic interpretation. As expected, the better the quality of the biopsies, the fewer that are needed to reliably detect architectural changes (i.e., size, depth, and integrity) but more specimens are needed to identify deeper (cryptal) lesions. Ileal biopsies are more likely to show histopathologic changes than are duodenal biopsies. Therefore, the primary clinician should always interpret endoscopic biopsy results cautiously and in light of the clinical presentation; results should be questioned if the tissue diagnosis does not fit the clinical picture or if the response to apparently appropriate therapy is poor. In some cases, repeat biopsy (e.g., by exploratory laparotomy) might be required.

Box 276-11

Causes of Chronic Diarrhea for Which Small Intestinal Biopsy Results Can Be Normal*

- ARD, SIBO
- Brush border membrane disease (e.g., hypolactasia)
- Dietary indiscretion
- Food intolerance
- Intestinal sclerosis (if biopsies are not full-thickness)

- Motility disorder/irritable bowel syndrome
- Patchy mucosal disease not sampled
- Toxigenic/secretory diarrhea
- Type I hypersensitivity to food (if dog is starved before biopsy)
- Undiagnosed EPI or colonic or systemic disease

ARD, Antibiotic-responsive diarrhea; *EPI,* exocrine pancreatic insufficiency; *SIBO,* small intestinal bacterial overgrowth.

*Detection of histologic abnormalities depends on the size and quality of the biopsy, the quality of processing, and the expertise of the pathologist.

E-Box 276-12

WSAVA GI Standardization Group's Histologic Scoring System for Grading Intestinal Inflammation in Endoscopic Biopsies*

Morphologic Features

- Villus stunting
- Epithelial injury
- Crypt distension
- Lacteal dilation
- Mucosal fibrosis

Cellularity in Lamina Propria

- Intraepithelial lymphocytes
- Lymphocytes and plasma cells
- Eosinophils
- Neutrophils
- Other cells

All features graded as normal/mild/moderate/severe.

Cytology[617-620]

Cytologic examination of endoscopic biopsy squash preparations or mucosal brushings only are an adjunct to histopathologic examination. Impression smears show the best correlation with histological findings and are most useful for neoplastic masses.

Alternative Examinations[144,621-635]

Other biopsy examinations available include electron microscopy; biochemical assay of brush border enzymes with subcellular fractionation; immunocytochemical characterization of B cells, T cells, and their subsets (e.g., CD4 and CD8 cells) and MHC expression by immunohistochemistry and flow cytometry; cytokine mRNA expression; and assessment of T-cell clonality. These are largely research tools. Fluorescent *in situ* hybridization (FISH) allows identification of organisms in tissues and their spatial arrangement.

Acute Small Intestinal Disease

Diagnosis[320,636-639]

Potential causes of acute diarrhea are listed in Table 276-9, but whether an absolute diagnosis is pursued or

whether supportive, empirical therapy is instituted is a clinical and sometimes economic judgment. Patients that are bright, alert, and not dehydrated might require no further investigation because signs often are self-limiting.

TABLE 276-9

Causes of Acute Diarrhea

CAUSES	EXAMPLES
Anatomic	Intussusception
Dietary	Hypersensitivity (allergy), intolerance, sudden diet change, food poisoning (poor quality, spoiled foods/bacterial)
Infectious	
Bacterial	*Salmonella, Campylobacter jejuni, Clostridium* spp. (?) and *Escherichia coli* (?)
Parasites*	
Helminths	*Ancylostoma caninum, Trichuris vulpis*
Protozoa	Coccidia, *Giardia* spp., *Tritrichomonas foetus*
Viral	
Mild	Adenovirus, Coronavirus, Norovirus, Rotavirus May or may not be FeLV/FIV related
Severe	Parvovirus, Paramyxovirus (distemper)
Metabolic	Hypoadrenocorticism
Toxic	Food or other sources
Pancreatic	Acute pancreatitis

*Often start acutely but become chronic if not treated.

FeLV, feline leukemia virus; *FIV*, feline immunodeficiency virus.

The diagnostic approach to acute diarrhea is discussed in ch. 40 and summarized in Figure 276-7. Nonintestinal causes such as pancreatitis or hypoadrenocorticism are ruled out before focusing on the SI. Further investigation of acute diarrhea is indicated if the patient is dull or depressed, febrile, dehydrated, tachycardic or bradycardic; or has abdominal discomfort, melena, bloody mucoid stools, or frequent vomiting; or has obvious physical abnormalities (e.g., intestinal masses, thickening, or plication) localizing the problem to the SI, and diagnostic imaging (Figure 276-17), noninvasive biopsy, or surgery can define the cause; or has systemic abnormalities as defined by a minimum database and other clinicopathologic tests; or has not responded to general, nonspecific therapy.

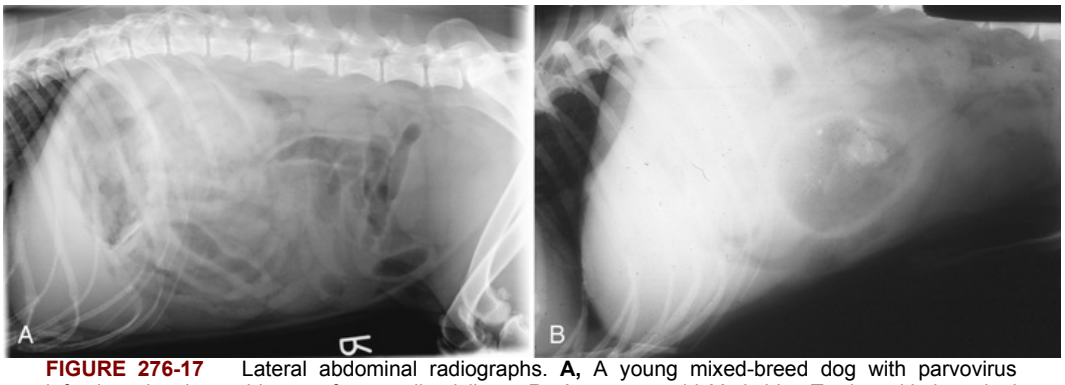

FIGURE 276-17 Lateral abdominal radiographs. **A,** A young mixed-breed dog with parvovirus infection showing evidence of generalized ileus. **B,** A ten-year-old Yorkshire Terrier with intestinal obstruction due to an annular adenocarcinoma. Note the dilated bowel loop proximal to the mass, and the gravel sign (i.e., accumulation of material proximal to the mass).

Treatment of Acute Diarrhea[640-644]

The initial management of acute diarrhea is nonspecific and supportive and is chosen on the basis of clinical findings, especially the presence of dehydration, while the results of the initial database and any further tests are pending. Administration of antiemetics is indicated if the patient is vomiting and an intestinal obstruction has been ruled out. It is important that the patient regularly be reevaluated to monitor the response to therapy and to detect any new criteria of concern that might arise.

Fluid Therapy[645-652]

Oral fluid and electrolyte replacement therapy could be sufficient if acute diarrhea is associated with insignificant or only mild dehydration and if vomiting is infrequent or absent. Solutions containing glucose and electrolytes—sometimes with added glycine, glutamine or peptides (e.g., rice water)—are used, as they promote the osmotic uptake of water (see ch. 189). The inclusion of glutamine, a nutrient utilized preferentially by enterocytes, could promote recovery and decrease bacterial translocation. However, when diarrhea is accompanied by significant vomiting or dehydration, parenteral fluids should be administered, and at a rate that replaces deficits, supplies maintenance needs and compensates for ongoing losses (see ch. 129). Patients with marked hypovolemia require more intensive support. Antiemetics can be beneficial to reduce fluid loss and patient discomfort but could mask signs of intestinal obstruction. The type of fluid and requirement for potassium supplementation is best judged by performing a minimum database and blood gas analysis. Parenteral fluids are best given intravenously; the intraosseous route can be used if venous access is unavailable (see ch. 77), but subcutaneous fluids are unlikely to be adequate.

Diet[644,648,649,653-658]

Current recommendations regarding the role of diet in the treatment of acute diarrhea largely are based on common sense, anecdotal evidence, and extrapolation from management guidelines for treating humans. Best practice generally is considered to be withholding food for 24 to 48 hours to "rest" the gut and then feeding a bland diet, given little and often, for 3 to 5 days. Thereafter, the original diet is gradually reintroduced. Common choices of a bland, fat-restricted diet for dogs are boiled rice with either boiled chicken or white fish or low-fat cottage cheese. Cats have a lower tolerance to dietary starch and could benefit from a diet with a higher protein and fat content. Little attention need be paid to the overall nutritional adequacy of home-prepared bland diets when fed in the short term. Commercial veterinary GI diets are available and more convenient.

The dogma of "intestinal rest" for dogs and cats has been challenged by studies that demonstrate that feeding human infants during infectious, secretory diarrhea promotes recovery and strengthens mucosal immunity. There is some evidence in dogs that feeding speeds recovery from hemorrhagic gastroenteritis (HGE). However, in general, secretory diarrhea is less common in dogs and cats compared to infants, the resultant increased volumes of diarrhea (although over a shorter period) could be cosmetically unacceptable, and the presence of vomiting can preclude this approach anyway.

Theoretically, any intestinal disease can predispose the animal to the development of a food sensitivity. Therefore, feeding of a novel protein source during these periods may preclude the development of sensitivity to the staple diet. However, evidence for this concept of feeding a "sacrificial protein" is circumstantial.

Protectants and Adsorbents[659,660]

Bismuth subsalicylate, kaolin, montmorillonite (a refined form of smectite clay or kaolin), pectin, activated charcoal and magnesium, and aluminum- and barium-containing products often are administered in acute diarrhea to bind bacteria and their toxins and to protect the intestinal mucosa. They also bind water and could be antisecretory. Therapy should not exceed three days if there is no improvement.

Motility- and Secretion-Modifying Agents[661-669]

Anticholinergics and opiates or opioids (loperamide, diphenoxylate) often are used for the nonspecific management of acute diarrhea, but anticholinergic agents can potentiate ileus and are not recommended. Opioid analgesics were thought to exert their effects by stimulating segmental motility, thereby slowing transit, but they actually act mainly by decreasing intestinal secretion and promoting absorption. They are indicated in short-term supportive management of acute diarrhea in dogs; they are contraindicated in cases involving obstruction or an infectious etiology. Loperamide can have central nervous system side effects in

collies and other dogs with the multidrug resistance (MDR-1) gene mutation. Antimuscarinic drugs such as hyoscine (butylscopolamine) generally are not recommended, as they can produce a paralyzed, nonfunctional SI, can predispose to intussusception, and can cause intoxication. However, in mild cases of acute gastroenteritis, their antispasmodic effect could help relieve colic-type pain.

Antimicrobial Therapy[670-675]

Antimicrobials frequently are prescribed for acute diarrhea but are only truly indicated in animals with SI disease with a confirmed bacterial or protozoal infection. The current consensus is that they also are indicated when a widespread breach of intestinal barrier integrity is suspected from evidence of hemorrhagic diarrhea when, consequently, the patient is at risk of sepsis. However, there is no benefit if the patient is not bacteremic or showing signs of sepsis. Leukopenia, neutrophilia with left shift, fever, the presence of blood in the feces, and shock all are potential indications for prophylactic antibiotics in animals with diarrhea. Initial choices in these situations include clavulanate-potentiated amoxicillin or a cephalosporin (effective against Gram-positive and some Gram-negative and anaerobic bacteria). If systemic translocation of enteric bacteria is suspected, antimicrobials effective against anaerobic organisms (e.g., metronidazole or clindamycin) and "difficult" Gram-negative aerobes (e.g., an aminoglycoside or a fluoroquinolone) are indicated. Potentially nephrotoxic aminoglycosides, such as gentamicin, should not be given until the patient is volume-expanded. Intravenous quinolones have been shown to reach therapeutic concentrations in the canine gut lumen and can be effective against enterococci and *E. coli*.

Prebiotics and Probiotics (Synbiotics)[10,676-729]

Prebiotics are selective substrates used by a limited number of "beneficial" microbial species, which therefore cause alterations in the luminal microflora. The most frequently used prebiotics are nondigestible carbohydrates, such as lactulose, inulin, fructo-oligosaccharides (FOS) and mannan-oligosaccharides (MOS), and immunomodulators such as lactoferrin. Their use combined with probiotics is designed to encourage the growth of organism and is termed *synbiosis;* they might also have an effect on the immune system.

Probiotics are defined as "orally administered living organisms that exert health benefits beyond those of basic nutrition." However, what constitutes enteric health is poorly defined, and which features of probiotic activity are beneficial is not clear. For example, probiotics that increase IgA secretion might indicate improved immune exclusion but, conversely, might indicate poorer mucosal barrier function.

In addition to direct antagonistic properties against pathogenic bacteria, probiotics modulate mucosal immune responses (e.g., they can induce Treg cells) and can alter intestinal permeability. There is evidence that the positive effect of probiotics is species-specific and is present only while the probiotic is administered continuously. The traditional practice of feeding live yogurt as a way of repopulating the intestine with beneficial lactobacilli after an acute GI upset or antibiotics is unlikely to work, but probiotics are now available for use in dogs and cats. There is growing evidence of some efficacy in acute diarrhea, and probiotics are a more responsible therapeutic choice than blanket antimicrobial administration in first-opinion cases of gastroenteritis.

Etiologies of Acute Diarrhea[730-732]

In many cases of primary SI disease causing acute diarrhea, an etiologic agent is not identified. The lack of a definitive diagnosis commonly is seen in humans with HGE who survive, and while academically unsatisfying, the lack of a specific diagnosis in dogs and cats does not matter if the problem resolves, does not recur, and does not pose a risk to others. A number of etiologic mechanisms has been described.

Acute Diarrhea Induced by Diet, Drugs, or Toxins[320,733]

Acute, self-limiting diarrhea in dogs most commonly is associated with rapid diet change, dietary indiscretion, dietary intolerance, hypersensitivity, or food poisoning. The history can allow an educated, presumptive diagnosis to be made. However, the exact cause rarely is determined. Sudden diet change quite commonly causes diarrhea, perhaps because it alters the microbiome. Ingestion of drugs (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs] or antibacterials) or toxins (e.g., insecticides) also can cause vomiting and diarrhea. The prognosis usually is excellent, and only if the diarrhea does not resolve or the patient's condition deteriorates is further investigation necessary.

Hemorrhagic Gastroenteritis (HGE)[644,674,675,734-749]

There are numerous potential causes of bloody vomiting and diarrhea, but *hemorrhagic gastroenteritis* (HGE) is the name that was given to a syndrome in dogs characterized by acute hemorrhagic diarrhea accompanied by marked hemoconcentration. This condition has recently been renamed acute hemorrhagic diarrhea syndrome (AHDS), but not all reported cases have the characteristic hemoconcentration. The cause of the syndrome is unknown, but the current hypothesis is that it is a consequence of *C. perfringens* enterotoxin production, although that has been refuted. Dysbiosis is present, but it is not clear whether that is a cause or an effect. Indeed, HGE could represent a diet-related type 1 hypersensitivity reaction, as recurrence is noted in some dogs, suggesting repeated exposure to an inciting cause.

Clinical Findings

Small-breed dogs and especially Miniature Schnauzers are affected most frequently, but HGE can affect large breeds too. Dogs present with acute hemorrhagic malodorous diarrhea, sometimes (but not always) preceded by vomiting. Fever is unusual, but depressed mentation and abdominal discomfort are common. The onset can be peracute and can be associated with marked fluid shifts into the SI, leading to severe hypovolemic shock even before classical signs of dehydration (i.e., increased skin tenting) appear (see ch. 127).

Diagnosis

Direct evidence of clostridial invasion has been shown in endoscopic biopsies but rarely is obtained, as endoscopic examination is not normally indicated. Instead, a presumptive diagnosis of HGE is made on the basis of appropriate clinical findings associated with a packed cell volume (PCV) > 60%. Serum total protein concentration often is normal or not as high as would be expected relative to the PCV, probably because of intestinal plasma loss. Radiographs can demonstrate evidence of ileus. The absence of leukopenia and the marked hemoconcentration help distinguish HGE from parvovirus infection, but pancreatitis (see ch. 290) and hypoadrenocorticism (see ch. 309) need to be ruled out.

Treatment

Intravenous crystalloids are essential (see ch. 129); some patients become hypoproteinemic and then require plasma (see ch. 130). Parenteral antibiotics often are administered because of the possible clostridial infection and the high risk of sepsis but might not be necessary and do increase the risk of inducing resistance in the microbiome (see ch. 161). Clinical improvement usually is noted within a few hours, though the diarrhea can take several days to resolve. Once the patient is in the recovery phase, standard supportive therapy for acute diarrhea can be instigated. The prognosis for most animals with HGE is good, although recurrence can occur, but if HGE is complicated by severe hypoproteinemia or sepsis, the prognosis is more guarded.

Infectious and Parasitic Causes[750-753]

Diarrhea caused by infectious and parasitic agents is considered common in animals that are young, immunologically naïve or immunocompromised, housed in large numbers, or housed in unsanitary conditions. Parvovirus (see ch. 225), *Giardia* (see ch. 221), *Tritrichomonas* (see ch. 221), *Salmonella* (see ch. 220), *Campylobacter* spp. (see ch. 220), hookworms, and whipworms (see below) can be significant causes of diarrhea. The importance of coronavirus, *C. perfringens,* and *E. coli* as causes of diarrhea has yet to be defined. Trematodes (flukes) are rare in dog and cats and more likely to cause liver disease, as well as carrying *Neorickettsia* (salmon poisoning; see ch. 218). Intestinal myiasis is a very rare problem.

A zoonotic potential exists for many of these infections, and good hygiene precautions always should be adopted. Specific SI infections are discussed later. Most viral enteritides of dogs and cats cause an acute and usually self-limiting diarrhea, although severe cases in young or immunocompromised patients can be fatal.

Chronic Small Intestinal Disease

Etiologies of Chronic Diarrhea

In many cases of primary SI disease causing chronic diarrhea, mucosal inflammation is present but an etiologic agent is not identified. This situation has been termed *chronic enteropathy,* as it encompasses diet-, antibiotic-, and steroid-responsive diseases. Steroid-responsive disease has been equated with idiopathic IBD, although there are several histologic variations (i.e., lymphoplasmacytic, eosinophilic, neutrophilic, granulomatous) suggesting that even true IBD is not a single disease entity. Known causes of intestinal inflammation include parasites (especially *Giardia*; see ch. 221), bacterial infection (see ch. 220), and food allergy (see below), and only idiopathic inflammation should be termed IBD. Other causes of primary chronic

diarrhea include lymphangiectasia and lymphoma, and structural abnormalities (e.g., chronic intussusception).

Characterization[754-759]

Chronic enteropathies historically have been defined by their histologic appearance. This criterion provides little information as to their etiology, and indeed many cases have no obvious histologic changes. So, more recently, chronic enteropathies have been defined by their response to empirical treatments trialled sequentially. Food-, antibiotic-, and corticosteroid-responsive disease have been compared to dietary sensitivity, bacterial disease, or idiopathic IBD, respectively. Risk-benefit analysis of intestinal biopsy suggests that pursuing a histologic diagnosis before parasiticide treatment and diet and antibiotic trials might not be worthwhile if the patient is still eating and has no evidence of a PLE, and particularly if it is a young animal. Findings of intestinal inflammation still require empiricial trials to be performed in order to reach a presumptive diagnosis, and the response to treatment and the prognosis in older cats is similar whether they have IBD or alimentary lymphoma.

Management of Chronic Inflammatory Enteropathies[760]

If a specific histologic diagnosis is made (e.g., lymphangiectasia, lymphoma), specific treatments can be used. However, in many circumstances there is intestinal inflammation with no identifiable cause because of a lack of specific histopathologic changes. In such cases, it is appropriate to perform empirical treatments sequentially. It is logical and safest to treat with parasiticides first to try to identify occult parasitism, before pursuing a diet trial, followed by an antibacterial trial, before finally attempting immunosuppression. Thus a three-day course of fenbendazole is the most appropriate trial initially, in order to identify or rule out giardiasis and helminthiasis (see ch. 163).

Dietary Management[103,591,654,655,761-778]

Dietary management is a very important treatment modality in the general management of chronic enteropathies (see ch. 178), and anorexia has adverse effects on the immune system. The ideal diet is highly digestible, moderately fat-restricted, lactose free, gluten-free, not markedly hypertonic, nutritionally balanced, and palatable. Hydrolyzed diets are a potential alternative (see below). Feeding the daily nutritional requirement in divided meals (usually between two and four) reduces the load on a compromised intestine. Feeding more frequently is unnecessary because gastric emptying imposes natural trickle-feeding of the SI. Inclusion of moderately fermentable fiber (e.g., psyllium, ispaghula) is known to promote colonic health, and soluble fiber also promotes SI health, but fiber can delay intestinal transit and excess fiber can be contraindicated. Prebiotic supplements such as FOS and MOS alter the fecal flora, but their effect on the SI flora is limited.

Raw meat diets or biologically appropriate foods (BARFs) are currently fashionable, and anecdotal claims of their success in managing chronic enteropathies are made. The concern, however, is that of microbiological safety, as they can be contaminated with *Salmonella, Campylobacter* and *Toxoplasma,* none of which is adequately destroyed by freezing (see ch. 192).

Antibacterials

Antibacterials are indicated for specific conditions in which a bacterial pathogen has been documented, in the treatment of ARD or secondary SIBO, and in other chronic enteropathies, such as IBD, in which modulation of the flora may be desirable. Tylosin, metronidazole, or oxytetracycline is commonly used, but any beneficial effects could go beyond their antibacterial activity, with potential effects on the mucosal immune system (see ch. 161).

Immunosuppression[779]

Immunosuppressive drugs are indicated when evidence of mucosal inflammation is present and no underlying cause is found. However, given the potential for adverse side effects, the diagnosis should be reviewed before institution of such therapy, especially if it was made on the basis of endoscopic biopsy alone, as these are notoriously unreliable. Glucocorticoids are the preferred first choice for immunosuppression, as they are generally effective and have the positive side effect of increasing appetite. However, if such steroids are ineffective or side effects are unacceptable, then other agents, such as azathioprine, chlorambucil, methotrexate, cyclosporine, or mycophenolate, can be used for their steroid-sparing effect (see ch. 165).

Vitamin Supplementation[408,780-783]

Low serum concentrations of folate and cobalamin can be found in cases of malabsorption causing chronic diarrhea and have diagnostic utility. The clinical significance of reduced serum folate is uncertain, and the value of supplementation is unproven. However, hypocobalaminemia is associated with a poorer prognosis. Significant metabolic changes occur with cobalamin deficiency, with accumulation of homocysteine and methylmalonic acid, which can lead to hyperammonemia. The acidemia can cause inappetence, loss of condition, and worsening of the intestinal disease. Cobalamin therefore should be supplemented: weekly parenteral injections are continued for at least 4 weeks and until serum concentrations are high.

Probiotics[718,784]

Most reports of probiotic use in animals concern the treatment of acute diarrhea (see also ch. 167). One report indicated that a symbiotic produced a reduction in feline chronic diarrhea, but there was no evidence for *Enterococcus faecium* SF68 clearing chronic infections such as *Giardia* from dogs.

Adjunctive Treatments[785-787]

Prokinetic agents such as metoclopramide, cisapride, or mosapride could improve well-being and appetite by overcoming the nausea associated with ileus. Mirtazapine often is given to improve appetite, but it also has a prokinetic effect. Loperamide and diphenoxylate slow intestinal transit and reduce the frequency of diarrhea but mostly are useful as cosmetic agents to reduce the likelihood of inappropriate passage of diarrhea. Antidiarrheals such as absorbents and fiber offer general, nonspecific treatment.

Alternative Treatments[788-797]

Acupuncture has been shown to stimulate SI motility, and various herbal preparations (e.g., agrimony, arrowroot, blueberries, chamomile, elm bark, neem bark, and marsh mallow *[Althaea officinalis]*) are recommended for the management of chronic enteropathies. Some bind water, like kaolin, whereas others contain molecules that reduce intestinal secretion. However, there are no blinded, placebo-controlled studies to support their use. Bovine lactoferrin has been proposed as a way of boosting the innate immune system, but there is no positive evidence, and homeopathic remedies have no scientific basis. Beta-1,3/1,6-D-glucan, beta-hydroxy-beta-methyl-butyrate and levamisole have been shown to reduce SI inflammation in IBD, with glucan being the most effective and most rapid in onset. Generic and autogenous enterovaccines have been trialled, but with no proof of efficacy so far.

Management of a PLE

Colloid support or plasma transfusion (see ch. 130) may be indicated during the perioperative period when collecting biopsy specimens but are ineffective at maintaining colloid osmotic pressure in the long term. Diuretics may reduce ascites; spironolactone may be safer (i.e., potassium-sparing and less drastic) and ultimately more effective than furosemide. Specific treatments are discussed later.

Viral Enteritides

Several viral infections of dogs and cats can cause enteritis as an important component of their clinical syndromes. The following are covered in detail in their respective chapters: canine parvovirus infection[365-368,653,798-912] (see ch. 225), feline parvovirus infection/panleukopenia[807,913-926] (see ch. 225), canine and feline coronavirus infections[802,927-955] (see ch. 224), feline immunodeficiency virus[956,957] (see ch. 222), and feline leukemia virus[958] (see ch. 223). Other viruses of generally lower prevalence also can cause enteritis.[959-977] Rotaviruses can infect dogs and cats, but infection usually is so transient that no signs are recognized. Norovirus has been isolated from cats and dogs with enteritis, and there also is serological evidence of widespread infection. A torovirus-like agent has been isolated from the feces of cats afflicted with a characteristic syndrome of chronic diarrhea and third eyelid prolapse, but a clear association with clinical signs was not demonstrated. Circovirus has been isolated from dogs with diarrhea and vasculitis. Bocavirus is a small, nonenveloped virus with a linear ssDNA genome and is a member of the Parvoviridae. Canine strains of bocavirus (minute virus of canines) have been incriminated in causing enteritis in puppies, and a fatal infection was associated with a novel strain, canine bocavirus 2. Many other novel enteric viruses such as Astroviruses (Mamastrovirus 1 and 2), Kobuvirus and Sakobuvirus have been identified, but their pathogenic

roles remain to be elucidated.

Bacterial Enteritides (also see ch. 220)

Relevance of Bacterial Isolation[943,978-982]

Potentially enteroinvasive bacteria, such as *Campylobacter jejuni*, *Salmonella* spp., and *Escherichia coli*, can be pathogenic in dogs and cats and be associated with acute diarrhea. The incidence of infection is greatest in young, kenneled animals and immunocompromised patients, and coinfections probably are common. However, these organisms also can be isolated from healthy animals and from those with chronic diarrhea, so confusion exists about their significance when isolated. Although these organisms still present a zoonotic risk, and care should be taken with pets owned by immunocompromised patients or families with young children (see ch. 210), attempting to eradicate the organisms with antibiotics when the animal is showing no clinical signs can be unhelpful and unnecessary and even could induce a carrier state.

Campylobacter spp.[263,980,983-1020]

Campylobacter organisms (see ch. 220) can be found in the feces of up to 100% of healthy and diarrheic dogs and cats at some point in their lives; eating chicken is a major risk factor for infection. *Campylobacter jejuni*, *C. coli*, *C. helveticus*, *C. lari* and *C. upsaliensis*, identified by molecular analysis of the 16S ribosomal RNA, all have been detected. In humans, all *Campylobacter* species are considered pathogenic, but their presence in the feces of healthy animals begs the question of whether they are pathogenic in dogs and cats. *Campylobacter* organisms attach to intestinal epithelial cells and, under the correct conditions, can invade and cause an ulcerative enterocolitis. Pathogenicity of *C. jejuni* in chickens has been shown to be related to its ability to invade when exposed to norepinephrine and to recruit neutrophils to an inflammatory process. *In vitro* studies using epithelial cell lines have demonstrated activation of NF-kappa-B and production of neutrophil chemokine IL-8 and the ability to induce neutrophil migration via the bacterial production of chemotactic n-formyl peptides.

There is experimental evidence that *C. jejuni* causes enterocolitis in dogs, but it appears to be at its most pathogenic when there is a viral coinfection. *C. coli* infection has been associated with kitten diarrhea and neutrophilic enteritis. It is possible that the most common isolate from dogs, *C. upsaliensis*, is a commensal because longitudinal studies show that it persists in healthy dogs. Thus, many *Campylobacter* infections are asymptomatic, with reported carriage rates in healthy dogs and cats ≥50%; kennelled and younger animals have the highest isolation rates. Clinical signs could depend on the number and species of *Campylobacter* infecting an animal and the animal's condition and can vary widely from mild to severe enterocolitis, with clinical signs of watery, mucoid, or hemorrhagic diarrhea accompanied by vomiting, tenesmus, fever, and anorexia and severe dehydration. Younger animals, with less-developed immune systems and less renal concentrating capability to withstand dehydration, are more likely to be more severely affected.

Diagnosis

The presence of slender, seagull-shaped bacteria on a stained fecal smear yields a presumptive diagnosis. The organism is fragile *in vitro*, and culture of fresh fecal samples, or PCR, is recommended to avoid false negatives. Speciation by biochemical testing of cultured organisms is unreliable, and PCR is preferred.

Treatment[1021]

Whether treatment is necessary depends on the *Campylobacter* species identified, the health status of the pet, and the severity of clinical signs if present. In healthy animals, antimicrobial therapy should be reserved for cases where there could be contact with immunocompromised humans, although the zoonotic risk is small if normal hygiene precautions are taken (see ch. 210). Erythromycin is an effective treatment in dogs and cats (dogs: 20 mg/kg PO q 8 h; cats: 10 mg/kg PO q 8 h), reducing shedding within 48 hours when administered to dogs, but it can cause vomiting. Tylosin and clindamycin are alternatives if antimicrobial therapy is deemed necessary. The organism usually is sensitive to fluoroquinolones, but it is hard to justify their use to eliminate an organism that could either be a commensal or only produces self-limiting signs. Resistance to antibiotics has been reported. Multiple post-treatment cultures to document eradication of *C. jejuni* have been recommended, but unless speciation by PCR is available, this may not be a sensible approach.

Prognosis

The prognosis for recovery usually is good, but persistent colonization, especially by *C. upsaliensis,* may occur.

Salmonella spp.[990,1022-1058]

Salmonella organisms (also see ch. 220) have a zoonotic potential (see ch. 210) and can cause significant clinical signs, although this is unusual and occurs most frequently in young, parasitized, kenneled, or immunocompromised animals. Subclinical carriage is seen more frequently, and *Salmonella* bacteria have been isolated from the feces of up to 30% of healthy dogs and 18% of healthy cats. Isolation rates of ≈2% are reported more commonly, unless the animal is coprophagic or eating raw meat (BARF diets). Rates of *Salmonella* contamination of BARF diets of up to 20% have been reported. Human infection from dogs, cats and their food can occur.

Clinical Findings[1036,1059-1061]

Four scenarios can follow infection: transient subclinical carriage, acute gastroenteritis, bacteremia and endotoxemia, or a carrier state. If infection causes acute diarrhea, the diarrhea ranges from mild to severe and bloody, as well as causing anorexia, fever, abdominal pain, and vomiting. Invasion and then translocation from the gut lumen can result in septicemia, endotoxemia, disseminated intravascular coagulation, and death in susceptible animals (see ch. 132). The receptor for invasion is the cystic fibrosis transmembrane conductance regulator (CFTR) protein expressed by enterocytes, but its expression is modulated by commensal bacteria. Cats with *Salmonella* infection can show only vague signs (e.g., fever, leukocytosis, and conjunctivitis) and no GI signs. A seasonal, acute, febrile illness and diarrhea, known as "songbird fever," has been reported in cats in Mediterranean countries after ingestion of migrating songbirds carrying *S. typhimurium.*

Diagnosis[318,321,354,1062]

Diagnosis is based on the isolation of *Salmonella* organisms from feces, or from blood in septicemic patients, either by cuture on selective media or by PCR. Clinicopathologic features are nonspecific: hyperkalemia and hyponatremia (pseudo-hypoadrenocorticism) can occur.

Treatment[1063]

Antibiotic treatment can promote bacterial resistance and a carrier state, so it is not recommended when *Salmonella* bacteria are isolated from healthy infected animals or stable animals with just diarrhea. In animals with severe hemorrhagic diarrhea, marked depression, shock, persistent fever, or sepsis, parenteral antibiotics need to be given. The choice of antibiotic should be governed by sensitivity testing when possible, but fluoroquinolones appear to be effective against many *Salmonella* spp. and are least likely to induce a carrier state. Therapy should be given for 10 days initially, but prolonged therapy can be required. The feces should be recultured on several occasions to ensure that the infection has been eliminated. However, invading organisms can be seen in SI biopsies by FISH, even when stool culture is negative.

Prognosis

The prognosis for diarrhea associated with *Salmonella* infection in most cases is good. A guarded prognosis should be given in patients with septicemia. Negative prognostic indicators include peracute onset, high fever (>40° C [>104° F]), hypothermia, severe hemorrhagic diarrhea, degenerative left shift, and hypoglycemia.

Clostridium spp.

C. perfringens has been associated with HGE (AHDS; see above and ch. 220). The same organism and *C. difficile* can be part of the resident microflora of dogs but also can cause colitis-like signs (see ch. 277).

Escherichia coli[351,358,1057,1064-1080]

E. coli can be an important cause of acute diarrhea, although the organism often is part of a mixed infection with other pathogens such as parvovirus, while some isolates can cause chronic diarrhea (see ch. 220). Many *E. coli* strains are commensals, but in others, chromosomal and/or plasmid genes encode for pathogenicity mechanisms. Enterotoxigenic, enteropathic (attaching and effacing), and enterohemorrhagic *E. coli* (ETEC, EPEC and EHEC, respectively) can cause both acute and chronic diarrhea. EHECs also have been associated

with hemolytic uremic syndrome, and attaching and invasive *E. coli* (AIEC) with granulomatous colitis (see ch. 277).

ETECs cause SI disease primarily by producing heat-stable and heat-labile toxins that stimulate excess secretion by the SI, whereas EHECs have a tropism for the large intestine (see ch. 277). EPECs, which cause attaching and effacing damage to intestinal epithelial microvilli (Figure 276-18) through intimin expression by the *eae* gene, can damage both the SI and LI. Fatal EPEC infection has been reported in a kitten and an adult cat in which attaching and effacing lesions were found in the ileum and colon. Death of puppies with EPEC infection is believed to be more common, but often there is a mixed infection with distemper virus, parvovirus, and pathogenic protozoa contributing.

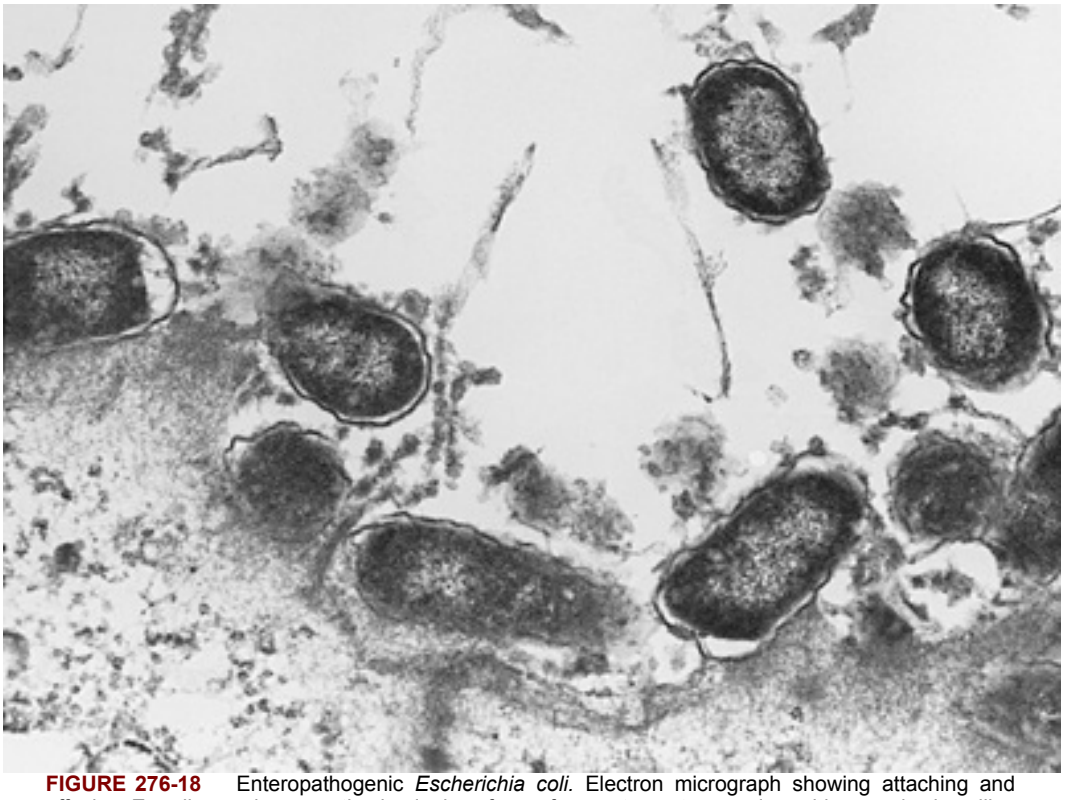

FIGURE 276-18 Enteropathogenic *Escherichia coli.* Electron micrograph showing attaching and effacing *E. coli* organisms on the luminal surface of an enterocyte, causing widespread microvillus damage. (Courtesy R. J. Higgins and G. R. Pearson.)

Identification of pathogenic strains requires specialized assays, such as bioassays for toxins or PCR probes for identification of pathogenicity markers, but even isolation of organisms carrying pathogenic genes does not prove causation. Conventionally, treatment consists of appropriate antibiotics; vaccination and oral immunoglobulins are unproven alternatives that at least do not induce resistance.

Enteroadherent Organisms[1081-1085]

As well as *E. coli*, adherent organisms such as *Streptococcus* spp. have been reported to cause chronic diarrhea in dogs, and *Enterococcus hirae* has been isolated from kittens.

Yersinia pseudotuberculosis[216,1086-1088]

Yersinia pseudotuberculosis can be ingested when cats eat infected rodents or birds. The bacteria infect the GI tract, liver, and lymph nodes, causing marked weight loss, diarrhea, anorexia, lethargy, jaundice, and mesenteric lymphadenopathy. Susceptibility in humans is related to NOD expression. Treatment may be attempted with oxytetracycline or trimethoprim-sulfa, but the disease usually is progressive and fatal. *Yersinia enterocolitica* is predominantly a LI pathogen (see ch. 277).

Tuberculosis[1089]

In dogs and cats, *Mycobacterium* spp. cause multisystemic, granulomatous infections that occasionally involve the GI tract (see ch. 212). Cats can develop SI infection with *M. bovis* from drinking infected cow's milk but more commonly have cutaneous or pulmonary infections. A granulomatous enterocolitis with mesenteric lymphadenopathy associated with *M. avium* infection was reported in five Basset hounds.

Miscellaneous Bacteria[1090-1099]

Many GI bacteria may be opportunistic pathogens or part of a mixed infection, but occasionally clinical signs are related directly to a specific organism, such as *Shigella. Clostridium piliforme* (formerly *Bacillus piliformis*) is a rare infection causing Tyzzer's disease, an acute, fatal diarrhea in puppies and kittens for which no effective treatment has been described. *Providencia alcalifaciens* was reported to cause primary bacterial enteritis in three dogs. *Anaerobiospirillum* has been associated with ileocolitis in cats, but the spirochetes *Brachyspira pilosicoli* and *Serpulina pilosicoli*, although pathogenic and zoonotic, are more likely to cause colitis (see ch. 277).

Rickettsial Diarrhea (Salmon Poisoning; see ch. 218)[1100-1112]

Neorickettsia helminthoeca and *Neorickettsia elokominica* are found in the metacercariae of the fluke *Nanophyetus salmonicola,* which is present in salmon in the western regions of the Cascade Mountains from northern California to central Washington and in Brazil. About a week after ingestion of infected salmon by dogs (and coyotes), the rickettsiae emerge from the mature fluke and cause a disease characterized by high fever, hemorrhagic gastroenteritis, vomiting, lethargy, anorexia, polydipsia, oculonasal discharge, and peripheral lymphadenopathy. Mortality is extremely high in untreated patients. The diagnosis is based on a history of ingestion of raw fish in an endemic area, the detection of operculated fluke eggs in feces, and the presence of intracytoplasmic inclusion bodies in macrophages from lymph node aspirates. Oxytetracycline (7 mg/kg IV q 8 h) is the treatment of choice, and it should be continued for at least 5 days. The trematode vector is eradicated with praziquantel.

Algal Infections[1113-1121]

Toxic algae can lead to acute gastroenteritis and death. Blue-green algal blooms can synthesize an anticholinesterase that induces vomiting, diarrhea, ataxia, and rapid death in dogs that drink contaminated water. *Prototheca* spp. are achlorophyllous algae that cause protothecosis. Typically a cutaneous infection in cats, in dogs it can involve the intestine and the CNS. Fatal disseminated disease affecting the SI has been reported, but LI disease is more common (see ch. 277).

Fungal Infections

Pathogenicity[85,109,1122-1131]

Low numbers of fungi are found in the normal intestinal microbiome by routine culture, but more are identified by molecular fingerprinting techniques. They are generally not considered pathogenic. Increased numbers of fungi can be found in idiopathic IBD, but it is unclear whether this is cause or effect, although empirical benefit of nystatin administration has been reported in intractable diarrhea cases, suggesting a role for fungi. The yeast *Cyniclomyces guttulatus* has been isolated from dogs and cats with chronic diarrhea but is found more frequently in the feces of healthy animals, and probably is not significant unless found in massive numbers. However, under the right circumstances such as immunosuppression, fungi can invade the intestinal mucosa and even disseminate throughout the body. Intestinal aspergillosis (see ch. 234 and 235), mucormycosis (see ch. 236), and cryptococcosis (see ch. 231) occur occasionally, but the incidence of fungal infections varies worldwide; some are ubiquitous (e.g., candidiasis,[840,1130,1132] zygomycosis[1124,1160-1165]; see ch. 236), and some are localized to specific geoclimatic regions (e.g., histoplasmosis[1166-1169]; see ch. 233). Primary intestinal infection with the aquatic oomycete *Pythium* spp. (pythiosis) is by far the most common phycomycosis (i.e., an infection with a poorly septate mold).[1133-1159] GI involvement can be extensive and severe; pythiosis is discussed in ch. 236.

Helminths

Importance[1170-1178]

Helminth infestation is common in dogs and cats (E-Box 276-13). Most infect the SI; *Trichuris* whipworms are a LI infection (see ch. 277). Some species are pathogenic, especially when present in large numbers, others are nonpathogenic except in puppies and kittens but may predispose to other diseases, and some are zoonotic. Regular anthelminthic treatment therefore is important for the health of young animals (see ch. 163) and the protection of humans (see ch. 210). A number of anthelmintics is available (e.g., benzimidazoles [albendazole, fenbendazole, febantel, flubendazole, mebendazole, oxfendazole, thiabendazole], milbemycin oxime, moxidectin, niclosamide, piperazine, pyrantel, selamectin), although their availability can vary geographically.

E-Box 276-13

Intestinal Metazoan Parasites of Dogs and Cats

Helminths

- Roundworms
  - Canine
    - *Toxocara canis*
    - *Toxascaris leonina*
    - *Baylisascaris procyonis*
    - *Strongyloides stercoralis* (rare)
  - Feline
    - *Toxocara cati*
    - *Toxascaris leonina*
    - *Strongyloides* spp. (rare)
- Hookworms
  - Canine
    - *Ancylostoma caninum*
    - *Ancylostoma brasiliense*
    - *Uncinaria stenocephala*
  - Feline
    - *Ancylostoma tubaeforme*
    - *Ancylostoma brasiliense*
    - *Uncinaria stenocephala* (rare)
- Whipworms
  - Canine
    - *Trichuris vulpis*
  - Feline
    - *Trichuris felis*

Cestodes

- Canine
  - *Dipylidium caninum*
  - *Taenia* spp. *(T. crassiceps, T. hydatigena, T. multiceps, T. pisiformis, T. serialis)*
  - *Echinococcus granulosus*
  - *Echinococcus multilocularis*
  - *Diphyllobothrium latum*
  - *Spirometra* spp.
- Feline
  - *Dipylidium caninum*
  - *Taenia taeniaeformis*
  - *Echincoccus multilocularis*
  - *Diphyllobothrium latum*
  - *Spirometra* spp.

Trematodes

- Canine
  - *Nanophyteus salmincola* (carries *Neorickettsia* spp.)

- *Heterobilharzia americana* (mesenteric and hepatic veins)

- Feline
  - *Nanophyteus salmincola*
  - *Platynosomum fastosum* (biliary tree)

Protozoa

- Canine
  - *Giardia*
  - *Cryptosporidium*
  - *Prototheca*
- Feline
  - *Giardia*
  - *Cryptosporidium*
  - *Toxoplasma*
  - *Tritrichomonas*—large intestine

Roundworms[996,1179-1211]

Roundworms are ubiquitous in dogs and cats, with numerous studies showing geographical variations in prevalence, dependent on ownership, economics, and deworming practices. Typically, *Toxocara canis* is found in dogs and *Toxocara cati (T. mystax)* in cats. *Toxascaris leonina* is found less commonly in both dogs and cats. *Baylisascaris procyonis,* the ascarid of racoons, occasionally infects dogs.

Epidemiology[1208,1212-1221]

Adult dogs and cats can be infected by *Toxocara* spp. through ingestion of embryonated eggs or ingestion of paratenic hosts, such as rodents. However, puppies and kittens more commonly are infected because the major route of infection is transplacental transmission for *T. canis* and trans-mammary transmission for both *T. canis* and *T. cati.* Migrating juvenile *T. canis* can cause hepatic, pulmonary, and occasionally ocular damage. The adult nematodes live in the SI.

Clinical Findings[1222,1223]

Roundworms cause disease most often in young animals, and signs of heavy infestation are diarrhea, weight loss, or failure to thrive. A poor haircoat and a potbelly may be evident in puppies or kittens. Intestinal obstruction and rupture have been described in very severe infestations.

Diagnosis[341,342,345,1224]

Almost all puppies can be presumed to have *T. canis* infection. The diagnosis can be confirmed by fecal flotation (see Figure 276-10 and ch. 81) or occasionally on endoscopy (see Figure 276-14, *A*).

Treatment[1213,1225-1235]

A wide range of anthelmintics is effective against roundworms, and any adverse reactions usually are mild or not reported (see ch. 163). Treatment should be repeated at 2- to 3-week intervals in affected animals.

Public Health Concerns[1189,1221,1236-1246]

Infection of humans by *Toxocara* is by ingestion of ova, which, when first shed, are unembryonated and not infective (see also ch. 210). Progression to the embryonated L3 stage is required for infection, so fresh feces are not a zoonotic risk because embryonation takes from two to seven weeks. Humans can be infected by accidental ingestion of contaminated soil or food, or contact with eggs adherent to the animal's coat. *T. canis* presents a substantial public health problem as it can cause visceral, ocular, and neural *larva migrans,* while up to 30% of people are seropositive, indicating exposure. Rates of infection and soil contamination vary widely depending on socioeconomic factors, geography and climate, but children are at greatest risk because of geophagia and pica. Risk is increased threefold if the person owns a dog and fivefold if he or she owns more than one dog.

Young animals should be routinely dewormed at 2, 4, 6, 8, 12, and 16 weeks of age and then at a minimum of 6-month intervals to protect the public, but there are concerns that the lack of antigenic stimulation

provided by endoparasites affects immunocompetence. *T. canis* can be controlled by administering to pregnant bitches either fenbendazole 50 mg/kg PO q 24 h from day 40 of gestation to 2 days after whelping, or two doses of moxidectin.

Strongyloides sp.[1179,1219,1247-1252]

Strongyloides tumefaciens is a parasite of the LI (see ch. 277), but *S. stercoralis* is a small nematode that can cause hemorrhagic enteritis in young puppies. Infective larvae are ingested, transmitted through the dam's milk or through penetration of the skin and, after migration through the lung, they mature in the SI. Fecal evaluation using the Baermann technique or demonstration of motile first-stage larvae in smears of fresh feces (see Figure 276-10) helps differentiate larvae from *Angiostrongylus, Oslerus,* and mature hookworms. Infection can be treated with thiabendazole or possibly fenbendazole or ivermectin (see ch. 163).

Hookworms[1216,1253-1263]

Ancylostoma spp. infections are most common in tropical and subtropical regions and are important zoonoses, causing cutaneous *larva migrans* (see ch. 210). Hookworms have a direct life cycle, and infection can be acquired prenatally, during lactation (not in cats), by ingesting larvae, by migration of larvae through the skin, and by ingestion of a paratenic small rodent host.

Ancylostoma caninum is the most important hookworm of dogs, and it is associated with blood loss and hemorrhagic enteritis. *Ancylostoma braziliense* occurs in dogs in the southern United States and in cats. *Ancylostoma tubaeforme* is the most common hookworm in cats but is rarer and less pathogenic. *Uncinaria stenocephala* is the hookworm of dogs in western Europe, and it does occur in the northern United States and in Canada. Infection most commonly is reported in kennelled dogs, particularly Greyhounds, and very rarely in cats.

Clinical Findings

Diarrhea, vomiting, dehydration, and poor growth are common in puppies with *A. caninum* infection. Weakness and pallor reflect extensive blood loss, and the infection can cause a rapid, potentially fatal anemia or chronic iron deficiency anemia. *U. stenocephala* does not cause anemia, but severe infestations can be associated with diarrhea. Interdigital skin penetration and larval migration of *U. stenocephala* causes pedal pruritus.

Diagnosis[341,342,357,1224,1264,1265]

The diagnosis is made by demonstrating ova in feces (see Figure 276-10 and ch. 81). Hookworms can be seen on endoscopy (see Video 276-2), but infection should be diagnosed or empirically treated before embarking on such a procedure.

Treatment[1225,1264,1266-1269]

For *Ancylostoma* infection in anemic puppies, pyrantel pamoate has been suggested as the treatment of choice because it acts very rapidly and is comparatively safe (see ch. 163). Anemic puppies could require blood transfusion (see ch. 130) and supportive care. Monthly administration of milbemycin or ivermectin plus pyrantel pamoate has been approved for the prevention or control of hookworm in dogs.

Tapeworms[1225,1236,1270-1274]

Dipylidium caninum is the most common tapeworm infecting dogs and cats in the United States and Europe, with fleas as its intermediate host. Usually, there are no clinical signs except motile "rice grains" (proglottids) visible in the perineal area or on feces. Heavy infestations of *D. caninum* only rarely are associated with diarrhea, weight loss, and failure to thrive. A diagnosis of *D. caninum* infection is confirmed by demonstrating characteristic egg capsules, contained in proglottids, obtained from the perineal area or feces (see Figure 276-10).

Various *Taenia* spp. tapeworms are common in dogs and cats, with cattle, sheep, goats, and rabbits the most common intermediate hosts. Dogs are definitive hosts of the small tapeworm *Echinococcus granulosus sensu stricto;* humans and sheep are intermediate hosts. Infection occurs through ingestion of infected raw meat, and sheepdogs typically are infected by ingestion of sheep carcasses. *E. granulosus* infection is not associated with clinical signs in dogs but is an important zoonosis, causing hydatid disease. *Echinococcus multilocularis*

can be carried by dogs and also is an important zoonosis. *Mesocestoides* spp. very rarely causes intestinal disease (PLE), but occasionally causes intraperitoneal infection. The cat is the definitive host of *Spirometra* spp., which rarely causes intestinal signs.

D. caninum, *Echinococcus* spp. and *Taenia* spp. are best controlled by routine administration of praziquantel (alternatives include dichlorophen, epsiprantel, or niclosamide; see ch. 163). Treatment of *D. caninum* infection also involves adequate flea control.

Protozoa

Coccidia generally are considered to be minor pathogens in dogs and cats, causing disease in young or immunosuppressed patients, but *Giardia* infection can be clinically significant. The trichomonads *(Tritrichomonas foetus, Pentatrichomonas hominis, Balantidium coli* and *Entamoeba histolytica)* are colonic inhabitants (see ch. 277).

Isospora spp.[1275-1288]

Isospora spp. (syn, *Cystisospora*) are the most common coccidial parasites of dogs *(I. canis, I. ohioensis)* and cats *(I. felis, I. rivolta).* Transmission occurs by ingestion of ova or paratenic hosts. Sporozoites are liberated in the SI and enter cells to begin development. The prepatent period ranges from 4 to 11 days, depending on the species. Infection with *Isospora* organisms commonly produces no clinical signs. Puppies and kittens kept in unhygienic conditions or immunosuppressed animals can develop heavy infestations, which can be associated with diarrhea that is often mucoid but sometimes bloody. Concurrent infectious agents are common and clinically can be more significant.

Isospora oocysts are found on direct examination of a fecal smear or by flotation. The infection often is self-limiting, but sulfadimethoxine or trimethoprim-sulfa can be used when clinical signs warrant treatment. Coccidiostats, such as toltrazuril and diclazuril, when available, are preferred (see ch. 163 and E-Table 276-10). The prognosis for recovery is good.

E-TABLE 276-10

Oral Treatments for Coccidiosis in Dogs (D) and Cats (C)

DRUG	DOSAGE (SPECIES)
Amprolium	300 to 400 mg (total) q 24 h for 5 days (D); or 110-200 mg (total) q 24 h for 7-12 days (D); or 60-100 mg/kg q 24 h for 7 days; or 1.5 tbsp (23 mL)/gal (sole water source) not to exceed 10 days (D)
Sulfonamides	
Sulfadimethoxine	50-60 mg/kg q 24 h for 5-20 days (D, C)
Sulfadimethoxine/amprolium	150 mg/kg of amprolium and 25 mg/kg of sulfadimethoxine q 24 h for 14 days (D)
Sulfadimethoxine/ormetoprim	55 mg/kg of sulfadimethoxine and 11 mg/kg of ormetaprim q 24 h for 7-23 days (D)
Sulfaguanidine	150 or 200 mg/kg q 24 h for 6 days (D, C); or 100-200 mg/kg q 8 h for 5 days (D, C)
Trimethoprim/sulfonamide	Dosage/duration depends on sulfa; 30-60 mg/kg trimethoprim q 24 h for 6 days in animals > 4 kg; or 15-30 mg/kg trimethoprim q 24 h for 6 days in animals <4 kg
Furazolidone	8-20 mg/kg q 12-24 h for 5 days (D, C)
Quinacrine	10 mg/kg q 24 h for 5 days (C)
Toltrazuril	10-30 mg/kg q 24 h for 1-3 days (D)
Diclazuril	25 mg/kg q 24 h for 1 day (C)
Ponazuril	20 mg/kg q 24 h for 1-3 days (D, C)

Companion Animal Parasite Council Guidelines. Available at: http://www.capcvet.org/capc-recommendations/coccidia/. Accessed August 15, 2016.

Cryptosporidium spp.[349,359,360,844,1287-1322]

The taxonomy of this genus is changing as new molecular genetic information emerges, and these organisms are no longer considered closely related to coccidia. *Cryptosporidium parvum*, a clinically significant pathogen in humans and calves, is now recognized not to be a single species. Over twenty *C. parvum* genotypes have been identified, and they include cat and dog "species," sometimes termed *C. canis* and *C. felis*, respectively (see ch. 221). Dogs can transmit the cattle and murine genotypes to humans, but specific cat and dog genotypes are likely to be zoonotic only to immunocompromised humans (see ch. 210).

C. parvum is an obligate intracellular parasite, with transmission occurring by the fecal-oral route. Infection can be asymptomatic but has been associated with self-limiting diarrhea in cats and rarely in dogs, and with severe hemorrhagic diarrhea in immunocompromised animals and animals with coinfections. Infection is most common in young animals, often with concurrent parasitic infections, but prevalence varies with geography as well. Cats shed more frequently than do dogs, and excretion can be reactivated by corticosteroid administration or surgical stress.

Diagnosis[347,349,359,1307,1315,1323-1325]

Cryptosporidial oocysts are extremely small (approximately 1/10 the size of *Isospora* oocysts) and must be identified by fecal flotation and oil immersion microscopy, direct immunofluorescence and modified acid-fast staining of fecal smears, enzyme immunoassay techniques, or PCR. Organisms can be recognized in intestinal biopsies.

Treatment[1291,1298,1326-1329]

Paromomycin was reported to be effective against *Cryptosporidium* organisms in a cat. However, the drug's efficacy is probably poor and it can cause acute kidney injury and uremia. Tylosin and azithromycin can be tried, but positive effects might be due to treatment of other infectious agents. Nitazoxanide could prove to be as effective as it is in humans but, fortunately, the disease is usually self-limiting in immunocompetent animals and needs no specific treatment.

Giardia sp.

Epidemiology[361,990,1031,1032,1183,1190,1293,1301,1314,1316,1319,1320,1330-1369]

Giardia sp. can infect both dogs and cats (see ch. 221). Previously named *G. lamblia*, molecular epidemiologic studies indicate there are seven genotypes (A-G), but that common assemblages infecting dogs (C and D *[G. canis]*) and cats (F *[G. felis]*) are not those typically found in human infections (A *[G. duodenalis]* and B *[G. enterica]*). Cats and dogs can harbor the zoonotic assemblage A; assemblage B has been found in dogs but not cats.

The parasite usually is transmitted via the fecal-oral route. Ingested oocysts excyst in the upper SI, and trophozoites attach to the intestinal mucosa from the duodenum to the ileum. After multiplication of trophozoites, oocysts are passed in the feces 1-2 weeks after infection.

Prevalence[356,1183,1199,1200,1203,1204,1209,1210,1219,1287,1321,1364,1370-1392]

The prevalence of infection in canine studies depends on geography, diagnostic method, and the age and health status of the animal, ranging from <2% to 100% in kennels. Cats are less commonly infected.

Clinical Findings[1363,1393-1397]

Most infections are asymptomatic, but signs can range from mild, self-limiting, acute diarrhea to severe or chronic small bowel diarrhea associated with weight loss.

Diagnosis[340,342-344,348,412,590,1307,1315,1382,1398-1406]

Giardia organisms can be seen on the surface of intestinal biopsies, but sensitivity is poor as they may be lost during processing; goblet cell numbers are often increased. Infection can also be diagnosed by demonstration of motile trophozoites in duodenal juice or a very fresh fecal smear. Identification of oocysts in feces by zinc sulfate flotation is preferred, but oocyst shedding occurs intermittently, so three fecal analyses within five days are needed for 95% sensitivity (see ch. 81). *Giardia* antigen also can be detected by means of fecal ELISA tests (SNAP *Giardia* Antigen Test Kit, Prospect T *Giardia* Microplate Assay), which have 95% specificity but sensitivities of ≈90% (see ch. 221). This may be the preferred method compared to zinc sulfate flotation performed by an inexperienced technician. Fecal IFA and PCR also are available.

Treatment[714,718,1328,1332,1407-1428]

Metronidazole 25 mg/kg PO q 12 h for 5 days was the drug most commonly used to treat *Giardia* infection in small animals. Ronidazole can be used, but it has side effects. Metronidazole eliminates *Giardia* infection in approximately two thirds of cases, but it can cause neurologic side effects at these high dosages, especially in cats. Efficacy can be increased by supplementing metronidazole with silymarin. Fenbendazole (50 mg/kg PO q 12 h for 3-5 days) generally eliminates *Giardia* infection and can be combined with metronidazole to resolve clinical signs and cyst shedding. Albendazole is not recommended as it is associated with bone marrow toxicosis. The efficacy of febantel (in a combination product with praziquantel and pyrantel) is debated, but nitazoxanide is likely to be effective and secnidazole only needs to be administered once. Decontamination of the patient's coat by bathing and the patient's environment by steam cleaning or cleaning with quaternary ammonium compounds is advised to prevent reinfection. *Giardia* vaccines are no longer available, and administration of probiotics has shown no benefit in clearing infection.

Prognosis

The prognosis is usually good, but some patients might require several treatments to eliminate infection because reinfection is a common problem. Reactivation of latent infection by corticosteroid administration also has been reported.

Adverse Reactions to Food

An adverse reaction to food is a repeatable, deleterious response to a dietary component. It may be a manifestation of either an immunologic reaction to a dietary antigen (i.e., a true food allergy) or a nonimmunologic reaction (i.e., an intolerance). Although food allergy and intolerance differ in their etiopathogeneses, the clinical signs are similar, and the approach to treatment—exclusion of the offending food component—is the same. Food intolerance can be associated with a single ingredient of a prepared food, such as lactose or a preservative, which can be present in immunologically unrelated foods. Conversely, confirmed allergy to a specific food can impart allergy to related foods. In humans, food intolerance is diagnosed more frequently than is hypersensitivity, but its true prevalence in small animals is unknown.

Exclusion diet trials are required to diagnose both food allergy and intolerance but do not distinguish between them.

Food Allergy (Hypersensitivity)[287,288,1429-1437] (see ch. 10, 186, and 191)

Pruritic skin disease is the most commonly reported manifestation of food allergy, but the true prevalence of food allergic intestinal disease is uncertain because no easy, reliable, indirect tests are available, and even a positive response to an exclusion diet is not absolute proof. This is because other causes of GI signs can respond, for nonallergic reasons, to dietary manipulation (Box 276-14). The management of food allergy is simple—feed any food that does not contain the allergen—but the difficulty lies in the initial recognition that food allergy is present, and then the identification of the food(s) that must be excluded (also see ch. 186).

Box 276-14

Conditions That Can Improve Clinically in Response to Dietary Modification

- Chronic gastritis
- Exocrine pancreatic insufficiency
- Food allergy
- Food intolerance
- Gastric emptying disorders
- Gastroesophageal reflux
- Inflammatory bowel disease
- Lymphangiectasia
- Nutritionally inadequate diet
- Pancreatitis

- Portosystemic shunt
- Small intestinal bacterial overgrowth

Mechanisms[1438-1454]

Current hypotheses of food allergy propose one or a combination of mechanisms that lead to breakdown of oral tolerance: an inadequate mucosal barrier, abnormal microbiome, abnormal presentation of dietary antigens to the mucosal immune system, or immune system dysregulation. Such hypotheses could explain both a genetic susceptibility to allergy and its development after a primary GI insult that damages the mucosal barrier, such as viral enteritis, which can damage both the immune system and the mucosal barrier. Active immune responses, rather than tolerance, then can occur directed toward bystander antigens (i.e., sensitization to dietary antigen) and involve a variety of mechanisms, including type I (IgE-mediated, immediate), type III (immune-complex mediated), and type IV (delayed hypersensitivity) reactions. Modulation of the response also depends on the composition of the microbiome. A contemporaneous association between ingestion of a particular food and the onset of signs is suggestive of a type I reaction. In mixed or delayed reactions, the inevitable delay between food ingestion and onset of signs obscures any causative link, particularly if repeated ingestion causes chronic disease.

Clinical Signs[1455-1460]

Clinical signs of food allergy generally involve the skin or the GI tract (Box 276-15); simultaneous skin and GI signs can occur but have been reported infrequently. Systemic signs (anorexia, lethargy) are recorded rarely, and urticaria-angioedema and even anaphylaxis seem rare (see ch. 137). Signs such as abnormal behavior and asthma are largely anedcdotal, but abnormal licking of surfaces (e.g., concrete) has been reported to resolve with the introduction of an exclusion diet (see ch. 9). The major sign of food-allergic skin disease is pruritus; other skin lesions, with the exception of eosinophilic complexes in cats, arise through self-trauma and secondary pyoderma. Signs of food-allergic GI disease are not pathognomonic and include vomiting, diarrhea, abdominal pain, flatulence, borborygmi, and weight loss or failure to thrive (E-Figure 276-19).

Box 276-15

Clinical Signs Recognized as Manifestations of Food Allergy

Systemic Signs
- Anorexia
- Lethargy
- Peripheral lymphadenopathy (cats)
- Urticaria-angioedema
- Anaphylaxis

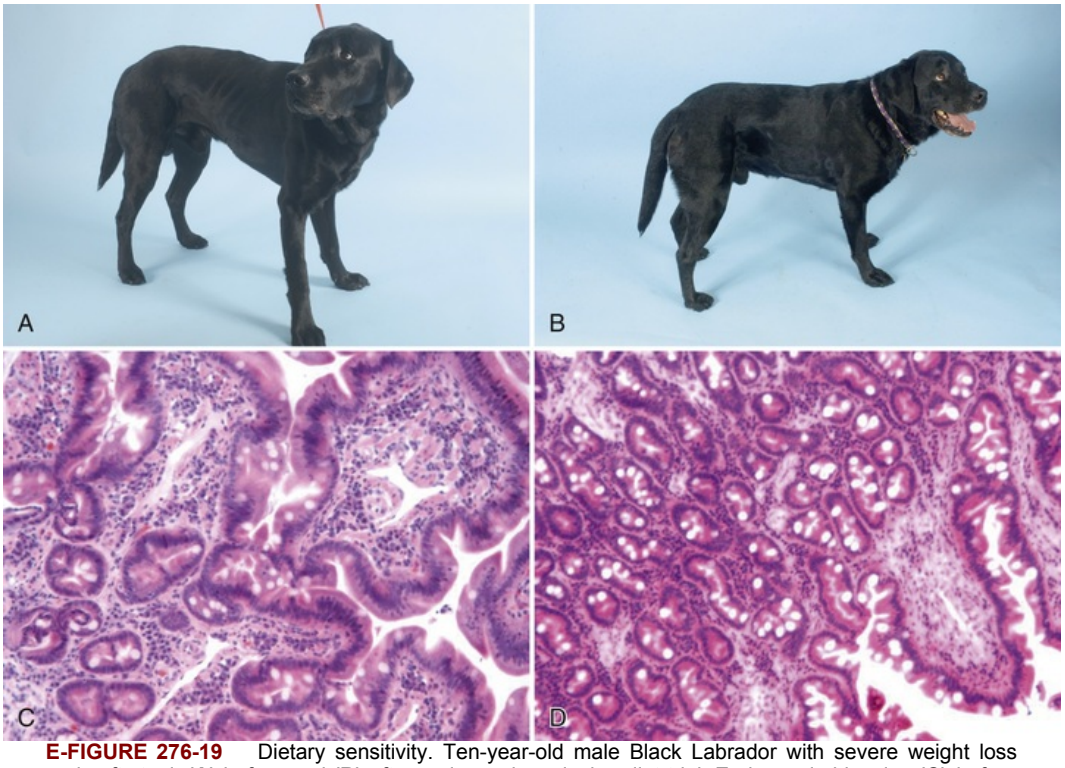
Cutaneous Signs
- Primary papules
- Erythroderma
- Pruritus and self-trauma
  - Secondary pyoderma
  - Scaling
- Otitis externa
- Miliary dermatitis (cats)
- Eosinophilic granuloma complex (cats)

Gastrointestinal Signs
- Abdominal discomfort/pain or "colic"
- Vomiting
- Hematemesis
- Diarrhea
- Small intestinal–like signs
- Colitis-like signs

- Altered appetite
  - Licking surfaces
  - Pica
  - Weight loss and/or stunting

Not Proven

- Asthma
- Behavioral changes
- Lameness



E-FIGURE 276-19 Dietary sensitivity. Ten-year-old male Black Labrador with severe weight loss and soft stool, **(A)** before and **(B)** after a six-week exclusion diet trial. Endoscopic biopsies **(C)** before the trial showing lymphoplasmcytic enteritis and **(D)** resolution of the inflammation after the trial.

Diagnostic Approach[443,525,759,1461-1464]

After negative preliminary investigations (minimum database, fecal examination, imaging) and a fenbendazole trial, the diagnosis of dietary sensitivity is made by the response to dietary manipulation. Although detailed analysis of intestinal biopsies from dogs with food-responsive disease showed a tendency for an increase in mucosal eosinophils, a diet trial is recommended, either before intestinal biopsy in patients that are eating and not hypoproteinemic or after a biopsy that reveals intestinal inflammation. Clinical signs should resolve on exclusion of the offending dietary component and return with rechallenge with the original food. Objective criteria by which to judge such a response are lacking: monitoring changes in intestinal permeability or mesenteric arterial blood flow patterns by Doppler ultrasonography are not specific enough, and even repeat biopsy does not necessarily show resolution of any histologic changes, although this may be because they take longer than the improvement of clinical signs. A positive clinical response to an exclusion diet can reflect an allergy or intolerance, or occur by chance, and confirmation of the diagnosis of either allergy or intolerance requires rechallenge, but many clients refuse.

Serologic Tests[1465-1477]

Attempts have been made to devise tests for food allergy that avoid diet trials, but unfortunately, none in veterinary medicine is reliable. Food-specific serum IgE and/or IgG can be measured *in vitro*, but critical

appraisal suggests these tests are unhelpful because discrepancies between laboratories exist and results do not correlate with a patient's response to an exclusion diet trial. Intradermal skin testing and patch testing also have proven unreliable in the diagnosis of food-allergic GI disease. Gastroscopic food sensitivity testing (GFST), in which dietary antigens are instilled directly onto the gastric mucosa, theoretically should give results that are more specific in cases presenting with GI signs. However, correlation between GFST and clinical challenge trials is poor. Using the colonic mucosa as the testing surface (colonoscopic allergen provocation [COLAP] testing) could be more reproducible but has not been adopted widely.

Exclusion Diet Trial[1478-1482]

The principle of an exclusion (elimination) diet is to feed dietary components to which the animal has not previously, or at least recently, been exposed (see ch. 186). This diet should be the sole source of nutrition during the trial. Complete owner compliance is essential, and all treats and supplements must be withheld. Options for exclusion diets include home-prepared diets, single-source protein diets, and hydrolyzed protein diets. Home-cooked diets have been preferred to commercial diets because of reports of relapse when patients are switched to an equivalent commercial diet, and food analyses have shown undeclared proteins in some commercial diets. However, many clinicians recommend the use of a commercial diet initially because convenience improves compliance.

In single-source protein diets, the food contains only one protein source and one carbohydrate source. If a home-cooked diet is used, it is unlikely to be nutritionally balanced, but this is not generally important for the short duration of the trial. However, baby foods, although convenient, are not suitable for cats because they are relatively taurine deficient and often contain onion powder that can cause Heinz body anemia. Lamb or chicken with rice have been the standard choices, but given the increased diversity of pet foods, the patient might already have been exposed to these components and, therefore, they are not always appropriate. Thus, more esoteric food sources have become a requirement. An alternative to home-prepared diets is use of a commercial exclusion diet, and a wide range is now available, containing different sources of protein (e.g., chicken, soy, salmon, catfish, venison, or duck) and carbohydrate (e.g., rice, corn [maize], tapioca, or potato).

Hydrolyzed protein diets,[763,1483-1491] which usually are based on either chicken or soy protein, are an alternative exclusion diet and now are widely available. In principle, the hydrolytic process splits proteins into components of a molecular weight below that which would be expected to elicit an immune response. To completely abolish all antigenicity, peptides need to be less than 1 kD in size, but at that size they almost invariably have a bitter taste; only one anallergenic diet, based on feather protein and containing only peptides < 1 kD, is available. At the size achieved in the majority of hydrolyzed diets (7-10 kD), proteins still are potentially antigenic but are too small to be able to cross-link IgE molecules on mast cells, and type I reactions are abolished; however, type IV reactions still are possible. Hydrolyzed diets also are substantially more expensive to produce than are standard exclusion diets, and both palatability and owner compliance can be problematic. Nevertheless, such diets currently are the easiest way to guarantee the feeding of novel antigens, and this approach has become the preferred method for many clinicians. Studies have suggested a significant beneficial effect of such diets, and they appear to have an advantage over traditional single-source protein exclusion diets. However, lack of histologic resolution after a successful trial could indicate that the patient actually has idiopathic IBD, and the clinical improvement simply is due to feeding a more digestible diet.

A standardized protocol for diet trials has not been established, and the optimum duration for an exclusion diet trial is unknown.[1432] Three weeks has been chosen arbitrarily, but at least six weeks could be preferable, particularly if a partial response is seen by three weeks. Indeed, cases of food-allergic skin disease might require up to ten weeks to respond, probably because antigen translocated to the skin and stored in dendritic cells needs to be eliminated. Food-allergic GI disease often responds quicker such that it is, fortunately, rarely necessary to feed the exclusion diet for this length of time because it can become difficult to maintain patient and/or owner compliance. Challenge and provocation tests usually are conducted for up to 14 days but are concluded earlier if signs recur on two consecutive days.

1. Exclusion phase. The exclusion diet is fed as the sole source of food for a minimum of three weeks.
2. Challenge phase. Once remission is achieved, the animal should be challenged with the original diet to demonstrate relapse and confirm the diagnosis. Some animals might not relapse, perhaps because the mucosal barrier has been restored and further reactions are prevented. However, some clients refuse challenge, particularly if relapse is likely to bring recurrence of diarrhea.
3. Rescue and provocation phases. After relapse during the challenge phase, for clients who are willing, a series of provocation tests can be performed to identify the offending food(s). Remission is regained by "rescue" with the original exclusion diet, and single foodstuffs are then introduced sequentially. If there

is no relapse, the food is identified as "safe," and the next food is tested; if there is a relapse, rescue is repeated and the food is identified as "unsafe."

4. Maintenance phase. When all the offending foods have been identified, or at least sufficient safe ones have been recognized to permit the choice of a regular diet, the animal is maintained on a safe standard diet. Subsequent to the food trial, most animals can be maintained on one of the available antigen-limited diets.

Treatment[1492]

Treatment is simple once a diagnosis has been made: avoidance of the offending food prevents the occurrence of signs. Proprietary diets often are more suitable as maintenance diets and are preferred over home-prepared meals because they are nutritionally balanced. Continuing a hydrolyzed diet is an expensive alternative. Peptide immunotherapy is used in humans but is not yet available for animals.

Food Intolerance[1433,1434]

Gluttony, scavenging, and food poisoning are common and may be considered examples of food intolerance. However, they tend to be isolated, acute incidents. In contrast, true food intolerances are repeatable, but they can be predictable or unpredictable. Predictable intolerances occur in any animal after ingestion of a contaminated foodstuff or after consumption of a recognized toxin or excessive amounts of food. In contrast, unpredictable food intolerances, although repeatable in a susceptible individual, are idiosyncratic reactions. Reasons for idiosyncrasies include differences, genetically based or otherwise, in intestinal enzyme activities, intestinal permeability, postabsorption metabolism, mast cell stability, and in the microbiome.

Mechanisms

Most of the suggested mechanisms of food intolerance are extrapolated from humans and might or might not be valid for dogs and cats.

Food Poisoning

Food poisoning is most likely in dogs that scavenge and is caused by the presence of a toxin in food, or by its contamination with toxin-producing organisms, or infection by organisms that have multiplied in the food and subsequently cause acute GI signs, such as campylobacteriosis.

Pharmacologic Intolerances

Such intolerances result from the presence of pharmacologically active compounds (e.g., chocolate poisoning with methylxanthines). In humans, intolerances can result from naturally occurring compounds—vasoactive amines, cardiac glycosides, plant alkaloids, and fungal hallucinogens and tremorgens—or substances produced by intestinal bacterial metabolism.

Pseudo-Allergic Mechanisms[1493,1494]

These adverse reactions are histamine-mediated but arise from nonimmunologic mechanisms. A high histamine concentration can be present naturally in some foods, such as tuna, mackerel, and some commercial dog foods, or because of histamine-producing *Proteus* or *Klebsiella* organisms contaminating foods, such as cheese or canned fish. Some foods, such as shellfish, strawberries, and some food additives, such as tartrazine, can cause histamine release from mast cells without IgE mediation. This mechanism is well documented in humans, but not in small animals.

Metabolic Reactions[40,252,1495]

Such reactions are poorly documented in small animals. Carbohydrate malabsorption and intolerance can be features of a number of intestinal diseases, whereas specific intolerance to lactose can be associated with lactase deficiency. At weaning, activities of lactase decline, especially in cats, and animals can become lactose intolerant if fed excess milk. If an animal has underlying SI disease, dairy products should be avoided as marginal lactase activities will be reduced even further. However, allergy to bovine milk proteins or previously subclinical intestinal disease could also explain adverse reactions to milk.

Clinical Signs[1496]

The clinical signs of food intolerance include vomiting, diarrhea, and signs of abdominal discomfort.

However, pruritus and even anaphylaxis are possible if histamine release is involved. Behavioral problems (see ch. 9) can be diet-responsive through nonimmunologic mechanisms.

Diagnosis

The only reliable means of diagnosing food intolerance is by monitoring the response to a diet trial. Again, such trials do not define the exact pathogenetic mechanism involved. The results of serologic food allergy testing are irrelevant.

Gluten-Sensitive Enteropathy (GSE)[623,1497-1510]

Intestinal disease caused by dietary wheat gluten has been demonstrated in Irish Setters. Affected Setters typically are presented for veterinary attention due to poor weight gain and chronic intermittent diarrhea after weaning. However, the age of the dog when gluten is introduced and the dosage both affect expression of the disease, with some dogs becoming asymptomatic later in life.

The condition resembles gluten sensitivity (celiac disease) in humans, although clinical signs and mucosal atrophy are less marked. Celiac disease shows a clear genetic predisposition and, in Irish Setters, GSE is a familial condition with an autosomal recessive mode of inheritance. However, unlike human celiac disease, there is no relationship with major histocompatibility genes *DQA* and *DQB*, and the pathogenesis is different. GSE can affect other dog breeds but has not been reported in cats. Gluten sensitivity has been suggested in Soft-Coated Wheaten Terriers with PLE and protein-losing nephropathy.

Pathogenesis[430,1511-1524]

The pathogenesis of Irish Setter GSE remains incompletely characterized. Ingested wheat protein, gluten, either is directly toxic to the intestinal mucosa or induces an adverse immune reaction. In contrast to celiac disease, where there is cross-reactivity between gluten peptides and tissue transglutaminase, T-cell and immunoglobulin responses to gluten or mucosal antigens are not noted in Irish Setters. However, involvement of the immune system is suggested by the fact that increased lamina propria $CD4^+$ T-cell populations and decreased $CD8^+$ populations do occur. Clinical signs and histologic and biochemical changes resolve on a wheat-/gluten-free diet and relapse when gluten-containing diets are reintroduced. Abnormal mucosal permeability precedes the development of disease in affected Irish Setters, implying that an abnormality in the mucosal barrier could permit abnormal entry of gluten peptide.

Diagnosis[1498,1502,1525]

Histologic changes show partial villus atrophy and intraepithelial lymphocyte infiltration, with a variable lamina propria infiltrate. These changes and the clinical signs resolve when a gluten-free diet is fed, and relapse on wheat and gluten challenge.

Treatment

Successful treatment depends on the exclusion of gluten from the diet. Proprietary gluten-free food (i.e., lacking wheat, barley, or rye) is recommended.

Small Intestinal Bacterial Overgrowth (SIBO) and Idiopathic Antibiotic-Responsive Diarrhea (ARD)

Definitions[255,469,1526-1538]

True small intestinal bacterial overgrowth (SIBO) is defined by an increase in the absolute number of bacteria in the upper SI during the fasted state. The normal bacterial population of the SI is controlled by a number of mechanisms, and overgrowth is the uncontrolled proliferation of these bacteria rather than a specific infection. In human medicine, primary SIBO as a cause of diarrhea and irritable bowel syndrome remains controversial, but it is accepted that it does occur secondary to disorders that interfere with normal control mechanisms (Box 276-16). Historically, the term *idiopathic SIBO* was used to describe an antibiotic-responsive condition of large-breed dogs, especially German Shepherd Dogs, for which no underlying cause could be found, and where overgrowth was claimed. A positive response to a range of antibiotics usually is seen, but an enteropathy responsive only to tylosin has been reported. However, given concerns regarding whether a true increase in bacterial numbers exists in idiopathic canine cases, the alternative name of antibiotic-

responsive diarrhea (ARD) has been adopted, whereas SIBO is best considered a clinical sign or a secondary pathogenetic mechanism. Although cats might feasibly suffer from secondary SIBO, an idiopathic antibiotic-responsive condition similar to that seen in dogs has not been documented, except that the efficacy of metronidazole in mild IBD sometimes is noted.

Box 276-16

Causes of Secondary Small Intestinal Bacterial Overgrowth

Abnormal Anatomic Structure
- Blind loop (congenital or surgically induced)
- Surgical resection of ileocolic valve

Achlorhydria
- Acid blockers, especially proton pump inhibitors
- Spontaneous (atrophic gastritis)

Exocrine Pancreatic Insufficiency

Motility Disorder
- Functional
- Hypothyroidism
- Intestinal pseudo-obstruction

Mucosal Disease
- Chronic giardiasis
- Dietary sensitivity
- Inflammatory bowel disease (cause or effect?)
- Occult primary pathogens

Partial Intestinal Obstruction
- Chronic intussusception
- Stricture
- Tumor

The upper limit for normal duodenal bacterial numbers (reported as the number of colony-forming units cultured per milliliter [CFU/mL] of duodenal juice) in humans is $<10^5$ total or $<10^4$ anaerobic CFU/mL. That number was incorrectly extrapolated to dogs, and subsequent studies have demonstrated that a total count $\geq 10^5$ CFU/mL commonly is found in asymptomatic dogs. Therefore, although a true SIBO could exist secondary to conditions equivalent to those in humans, the premise of defining the idiopathic, antibiotic-responsive disease as SIBO, based on the original numeric cutoff, is flawed. In this chapter, cases with a documented underlying cause are defined as secondary SIBO, and the term *idiopathic ARD* is used for idiopathic antibiotic-responsive conditions.

Etiology and Pathogenesis[255,1539-1541]

Idiopathic ARD[255,760,1542-1562]

Several hypotheses as to the cause of idiopathic ARD exist. Originally, they were based on the belief that a true SIBO was present. Mechanisms allowing true SIBO, such as abnormal SI motility, are not proven in dogs or cats. Achlorhydria secondary to omeprazole treatment does qualitatively alter the microbiome in dogs, but this does not correlate with disease. More recent hypotheses focus on host-bacterial interactions.

Another hypothesized mechanism is secretory IgA (SIgA) deficiency. Studies that have documented low serum IgA concentrations are irrelevant, as mucosal SIgA secretion does not reflect serum concentrations. An absolute deficiency of fecal IgA in German Shepherd Dogs associated with EPEC infection has been demonstrated once but has not been reproduced by others. Yet a secondary SIgA deficiency in the German Shepherd Dog breed could exist, explaining decreased IgA production by intestinal biopsies cultured *in vitro,* despite increased numbers of mucosal IgA^+ plasma cells. The cause of this deficiency is not clear, but a complex defect is likely, involving abnormalities either in the production and release of IgA from the plasma

cell or in the pathway of translocation of IgA across the epithelium during secretion. Yet no abnormalities in J-chain or pIgR expression have been found. German Shepherd Dogs do possess a specific variant of the IgHA gene, and four mutations in the code for the hinge region of the IgA heavy chain could affect the efficacy of the molecule or its susceptibility to proteolysis. Yet all German Shepherd Dogs, irrespective of health status, are the same variant, C, and this finding is probably merely a breed-specific phenomenon.

Dogs with ARD have increased lamina propria $CD4^+$ T cells and increased expression of certain cytokines, suggesting immune dysregulation. Hypermethylation of genes controlling IgA switching has been shown in IBD and is associated with decreased mucosal IgA expression and perhaps a loss of tolerance toward endogenous bacteria. Alternatively, a polymorphism in TLR-5, the receptor for bacterial flagellin, is suspected in German Shepherd Dogs with perianal fistulae and ARD. Such a hypothesis is supported by the fact that antibacterials lead to resolution of clinical signs and decreased cytokine expression, but not to a decline in bacterial numbers. The fact that the most effective antibacterials also are those with immune-modulating properties (e.g., oxytetracycline, metronidazole, tylosin) could also support this hypothesis. Furthermore, there is anecdotal evidence that some German Shepherd Dogs affected by ARD in younger life go on to develop IBD later. An alternative hypothesis is that an unidentified pathogen is involved; candidates include intestinal *Helicobacter* spp. or enteropathogenic *E. coli.* The predisposition of German Shepherd Dogs to ARD could then be explained by infection in the perinatal period and/or genetic susceptibility to infection as a result of MHC II or TLR polymorphisms.

A true increase in bacterial numbers in the SI could cause malabsorption and diarrhea through several mechanisms: competition for nutrients; production of nutrients to create products that provoke diarrhea (e.g., deconjugated bile salts and hydroxylated fatty acids); and/or direct damage to the mucosal brush border. However, these mechanisms might not be relevant in idiopathic ARD because there is no increase in numbers, although reversible changes in brush border enzyme activity are seen in dogs responding to antibiotics.

Secondary SIBO[232,1563-1565]

True SIBO can occur secondary to (1) diseases that result in excess substrate in the intestinal lumen, (2) diseases that affect the clearance of bacteria, or (3) morphologic or functional derangement of the mucosa (see Box 276-16).

Clinical Presentation

Idiopathic Antibiotic-Responsive Diarrhea

Idiopathic ARD most commonly is recognized in young German Shepherd Dogs, although cases have been reported in other large dog breeds (but not in cats). The flora present is comprised predominantly of either aerobic or anaerobic bacteria, but it tends to be a mixed population with staphylococci, streptococci, coliforms, enterococci, and corynebacteria, and anaerobes such as bacteroids, fusobacteria, and clostridia. These bacteria generally are commensals found normally in the oropharynx, SI, and LI. Culture of fecal bacteria cannot be correlated with the SI bacterial flora and cannot be used for making a diagnosis of this condition.

Affected dogs most frequently show signs of chronic intermittent diarrhea accompanied by weight loss and/or stunted growth, and often associated with excessive intestinal gas production manifested as borborygmi and flatus. However, vomiting and signs of colitis are reported, and occasionally dogs are stunted in their growth yet do not have overt diarrhea. Appetite is variable; most affected dogs have polyphagia, pica, and/or coprophagia, but a few are anorectic, perhaps associated with acquired cobalamin deficiency. A positive response to antibiotics is expected, and the condition could deteriorate if corticosteroids are given. The major differential diagnoses are EPI and IBD, both of which are common in the breed.

Secondary SIBO

SIBO can occur secondary to numerous primary conditions (see Box 276-16), but clinical signs firstly relate to the underlying condition. When SIBO develops secondary to a partial obstruction or focal dysmotility, bacterial numbers can exceed 10^9 CFU/mL. However, signs of secondary SIBO also can be seen and are indistinguishable from those of idiopathic ARD, with diarrhea predominating. Clinical signs can be intermittent because recurrent diarrhea can temporarily flush out the overgrowth. Using the historical numeric cutoff of 10^5 CFU/mL total bacteria, secondary SIBO was considered common in chronic enteropathies. In reality, these numbers were normal, and true secondary SIBO is uncommon, with the

exception of SIBO secondary to EPI. An increase in SI bacterial numbers has been documented in experimentally induced EPI, and bacterial numbers decrease upon treatment of EPI with enzyme replacement. Therefore, in many cases, the SIBO itself is of no significance. However, a proportion of naturally occurring EPI cases responds suboptimally to pancreatic enzyme supplementation alone and might require concurrent antibiotic therapy. Given that the majority of dogs affected with EPI are German Shepherd Dogs, it is not clear whether this is the result of secondary SIBO or of concurrent idiopathic ARD.

Diagnosis[588,1528,1532,1566,1567]

The diagnosis of SIBO and ARD is controversial. In all cases, it is critical that a thorough investigation be conducted to eliminate causes of secondary SIBO before the patient is treated with antibacterials. Systemic disorders should be ruled out with a minimum database, EPI eliminated by serum TLI assay (see ch. 290), and diagnostic imaging performed to identify partial intestinal obstructions (see ch. 88). Fecal examination for parasitic and known bacterial pathogens is mandatory (see ch. 81).

Quantitative aerobic and anaerobic culture of duodenal juice was the gold standard for the diagnosis of SIBO but is no longer recommended for the reasons described above. This overdiagnosis of SIBO probably explains why it was reported in 50% of dogs with chronic intestinal disease. Culture of endoscopic biopsies has not been shown to be helpful.

Indirect Tests for SIBO/ARD

Indirect tests include serum biochemical markers and breath hydrogen analysis.

Serum Folate and Cobalamin Concentrations[405,469,1568-1570]

Bacteria can synthesize folate and prevent cobalamin absorption. Therefore, SIBO is predicted to be associated with an increased serum folate concentration or a decreased cobalamin concentration, or both, as seen in humans with secondary SIBO. Yet studies have demonstrated that these tests are of limited value in the diagnosis of idiopathic ARD. This poor performance could be related to dietary factors, the presence of concurrent disease, or the use of drugs that alter serum vitamin concentrations, or simply that bacterial numbers are not necessarily increased. Any alterations of serum folate and cobalamin noted in EPI could reflect pancreatic dysfunction rather than secondary SIBO. Although these tests often are the only tests available to practitioners, they generally are unhelpful in the diagnosis of idiopathic ARD and are not recommended.

Serum Unconjugated Bile Acids[469,470]

A preliminary study in dogs suggested that serum unconjugated bile acid (SUBA) concentrations increased in SIBO due to bacterial deconjugation of bile salts. However, later studies demonstrated that SUBA concentrations were neither sensitive nor specific for diagnosis of idiopathic ARD.

Other Biochemical Tests[473]

Measurement of increased amounts of a bacterial product made either naturally (e.g., urinary indican, p-nitrosonaphthol) or after oral administration of a test substance (e.g., sulfapyridine, PABA) could diagnose SIBO, but these tests have been unreliable.

Breath Hydrogen Excretion[1571]

Bacterial fermentation in the intestinal tract releases hydrogen, which, after systemic absorption, is exhaled and can be measured in breath samples. Theoretically, SIBO would result in a high resting breath hydrogen concentration and/or an early (or double) hydrogen excretion peak after ingestion of a test meal. However, increased breath hydrogen concentrations also can be seen with carbohydrate malabsorption or decreased orocecal transit time, and the lack of specificity means the test largely has been abandoned.

Intestinal Permeability[1572-1574]

Intestinal permeability can be abnormal in SIBO and can improve after antibiotic treatment. However, such findings are not pathognomonic for either secondary SIBO or idiopathic ARD and are not readily available in practice.

Lack of Histologic Changes on Intestinal Biopsy

Intestinal biopsies most often are histologically normal or demonstrate only subtle abnormalities in ARD. However, such findings cannot be diagnostic because other conditions yield similar results, and such findings have been described as "minimal change enteropathy."

Empiric Response to Antibiotics

Currently, the definitive diagnostic test for idiopathic ARD is, logically, the response to empirical therapy. However, a clinical response to antibacterials is not specific and indeed can be seen with IBD, infectious diarrhea, and even a range of nonenteric diseases such as portovascular anomalies. Furthermore, response to antibiotic therapy does not discriminate idiopathic ARD from secondary SIBO, and ARD is only a valid diagnosis after thorough diagnostic investigations have eliminated other possible causes.

Identification of Idiopathic ARD[469]

Both direct and indirect tests advocated for diagnosing idiopathic SIBO are of limited value. Therefore, the only available diagnostic test for ARD is response to an antibacterial trial. However, such a diagnostic process is appropriate only after thorough diagnostic investigations have eliminated all other causes of antibacterial responsiveness. In conclusion, four suggested criteria for a diagnosis of idiopathic ARD are (1) a positive clinical response to an antibiotic trial; (2) relapse of signs upon withdrawal of antibiotics; (3) remission on reintroduction of antibiotics; and (4) elimination of other causes based on the results of other diagnostic tests and histopathologic assessment.

Identification of Secondary SIBO

Although numerous tests are available to document true overgrowth, in practice it is more important to identify the underlying cause.

Treatment

Idiopathic ARD[75,102,107,1529-1531,1539,1545,1575-1579]

Antibacterials

No cure is available for idiopathic ARD, but signs can be controlled with antibiotics. A broad-spectrum antibacterial is indicated; suitable choices include oxytetracycline (10-20 mg/kg PO q 8 h), metronidazole (10-15 mg/kg PO q 12 h), and tylosin (20 mg/kg PO q 8-12 h). Oxytetracycline (OTC) is cheap but is not universally available. It can be given with food because systemic absorption is not required, but it cannot be used before permanent tooth eruption because it causes staining of tooth enamel. Some authors have criticized its use because it is associated with rapid development of plasmid-mediated antibiotic resistance. However, given that long-term efficacy is maintained in most cases, OTC might not be acting through its antibacterial properties, especially as it does not significantly reduce SI bacterial numbers. Rather, it could provide selective pressure on the intestinal flora, encouraging the establishment of less harmful bacteria, in the same way that tylosin has been shown to increase fecal lactobacilli and enterococci. Alternatively, OTC might exert immunomodulatory effects, which has been suggested for this antibiotic group and other antibacterials commonly used for treating ARD, namely metronidazole and tylosin. OTC has been shown to exert an effect on MVM enzyme activity, but it is not known whether this is through inhibition of microbial activity.

Whichever antibacterial is chosen, a 4- to 6-week course is given initially, although the antibiotic is changed after 2 weeks if the response has been suboptimal. In some cases premature cessation of treatment can lead to relapse, and prolonged therapy often is necessary. In some animals a delayed relapse occurs several months after cessation of antibiotics, and such cases require either repeated courses or indefinite therapy. Efficacy often is maintained despite a reduction in dosage or dosage frequency: once-daily antibacterials can maintain control of signs, and tylosin at 5 mg/kg has been shown to be as effective as the standard 20 mg/kg dosage. Dogs can also "outgrow" the problem with age, either as a result of a decrease in caloric intake or because of developing maturity of the mucosal immune system. In view of the public health concerns over prolonged use of antibiotics, it is appropriate to periodically stop treatment to determine whether it is still required.

Ancillary Treatments[79,103,591,773,775-777,1577,1580,1581]

Dietary manipulation can be a useful adjunctive treatment for both idiopathic ARD and secondary SIBO (see ch. 178). A highly digestible, low-fat diet is desired, to reduce the substrate available for bacterial use. Addition of FOS has been advocated to reduce SI bacterial numbers, although evidence of efficacy is

conflicting, with the greatest effect seen in the colonic flora. Probiotic use has not been assessed thoroughly in ARD. Finally, if low serum cobalamin concentrations occur, parenteral cobalamin therapy is warranted.

Secondary SIBO

Although antibacterial therapy improves clinical signs, appropriate treatment for the underlying condition is preferable. For EPI, pancreatic enzyme supplementation can reduce bacterial numbers because exogenous proteases have antibacterial properties (see ch. 290).

Inflammatory Bowel Disease

Definition[754,757,760,1544,1582-1592]

Inflammatory bowel disease (IBD) is a collective term that describes disorders of the GI tract characterized by persistent or recurrent GI signs and histologic evidence of intestinal inflammation. The disease bears little resemblance clinically or histologically to IBD (Crohn's disease and ulcerative colitis) of humans but might share the same etiology. However, the indiscriminate use of the term *IBD* is unhelpful, as several diseases are associated with chronic intestinal inflammation (Box 276-17), whereas, by definition, the cause of IBD is idiopathic. Variations in the histologic appearance of the inflammation suggest that idiopathic IBD is not a single disease entity (Figure 276-20), and the nomenclature merely reflects the anatomic distribution and the predominant cell type present. The inflammation can be confined to the SI or there can be diffuse gastroenterocolitis. Lymphocytic-plasmacytic enteritis (LPE) is the most common histologic form reported; eosinophilic enteritis (EE) and eosinophilic gastroenteritis (EGE) are less common; and granulomatous enteritis is rare. Underlying neutrophilic infiltration is a feature of early human IBD, and neutrophilic enteritis sometimes is seen in cats and rarely in dogs.

Box 276-17

Causes of Chronic Small Bowel Inflammation

Chronic Infection

- *Giardia* sp.
- *Histoplasma* sp.
- *Toxoplasma* sp.
- *Mycobacterium* sp.
- Protothecosis
- Pythiosis
- Pathogenic bacteria (*Campylobacter, Salmonella* spp., pathogenic *Escherichia coli*)

Food Allergy

Small Bowel Inflammation Associated with Other Primary Gastrointestinal Diseases

- Lymphoma
- Lymphangiectasia

Idiopathic Causes

- Lymphocytic-plasmacytic enteritis (LPE)
- Eosinophilic gastroenterocolitis (EGE)
- Granulomatous enteritis (same as regional enteritis?)
- Neutrophilic enteritis (possibly secondary to bacterial invasion)

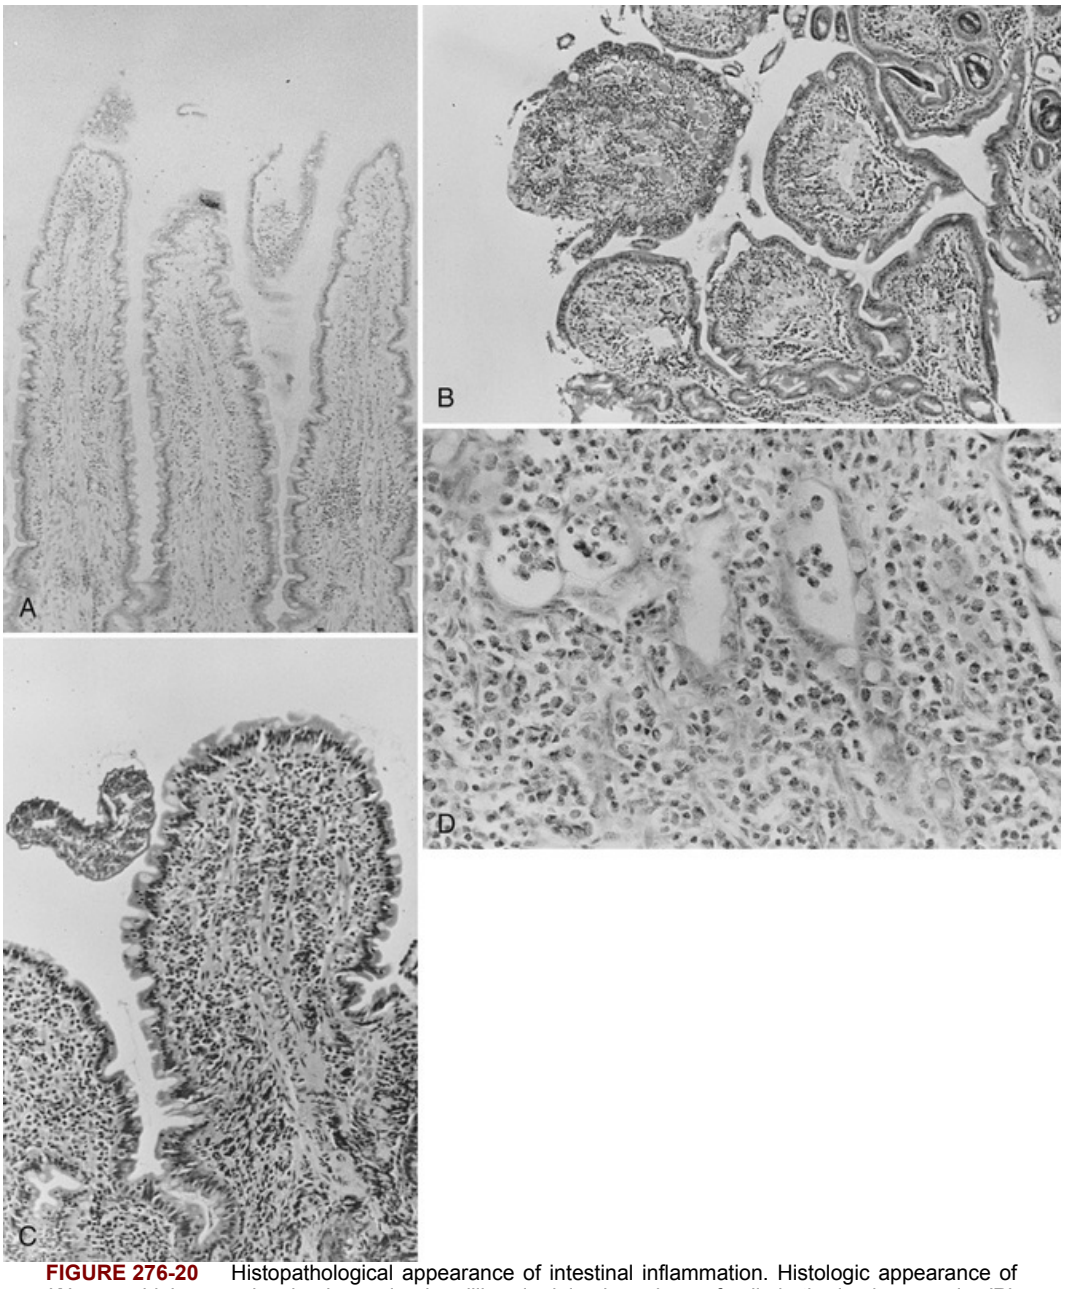


FIGURE 276-20 Histopathological appearance of intestinal inflammation. Histologic appearance of **(A)** normal jejunum, showing long, slender villi and minimal numbers of cells in the lamina propria; **(B)** idiopathic lymphoplasmacytic enteritis in a Dachshund, showing stunted villi and a lymphoplasmacytic infiltrate; **(C)** lymphoplasmacytic intestinal inflammation associated with *Strongyloides* infection (a worm is visible in the section on the mucosal surface); and **(D)** eosinophilic enteritis in a German Shepherd Dog, showing massive infiltration of the crypt area with eosinophils. (Courtesy G. R. Pearson.)

Clinical Presentation[780,1592-1602]

Idiopathic IBD is a common cause of chronic vomiting and diarrhea in dogs and cats, but its true incidence is unknown. In reality, it is probably overdiagnosed because of the relative ease of obtaining endoscopic biopsies and the difficulties in interpretation of such small histopathologic specimens, plus the failure to eliminate other causes of mucosal inflammation. No apparent gender predisposition occurs, but in both dogs and cats, IBD appears to develop most commonly in middle-aged animals, with intermittent signs sometimes seen at an earlier age. Although IBD potentially can occur in any animal, certain breed predispositions are recognized (see E-Table 276-5) and characteristic patterns of disease can be seen in specific breeds. In cats an association called *triaditis* exists between IBD, lymphocytic cholangitis, and chronic pancreatitis (see ch. 283).

Vomiting and diarrhea are the most common clinical signs in IBD, but an individual case can show some or all of the signs listed in Box 276-18. Sometimes an obvious precipitating event (e.g., stress, dietary change, acute gastroenteritis) is present in the history, but clinical signs can wax and wane spontaneously. The nature of signs crudely correlates with the region of the GI tract affected: vomiting is more common if gastric or upper SI inflammation is present; in cats, vomiting often is the predominant sign of SI IBD; weight loss is associated with SI disease; and LI-type diarrhea can be the result of primary colonic inflammation or can occur secondary to prolonged SI diarrhea (see ch. 277). The presence of blood in the vomit or diarrhea generally is associated with more severe disease and particularly EE/EGE. Severe IBD also is associated with weight loss and PLE, with consequent hypoproteinemia and ascites. Appetite is variable; polyphagia can be present in the face of significant weight loss, whereas anorexia typically occurs with severe inflammation. Eating grass can be increased in IBD but generally is considered a mechanism for inducing vomiting in a nauseated animal. Milder inflammation might not affect appetite, although signs of postprandial pain can be significant even without other signs.

Box 276-18

Clinical Signs Associated with Inflammatory Bowel Disease

- Vomiting
  - Bile
  - Food
  - With or without hair in cats
  - With or without grass in dogs
  - Blood (hematemesis)
- Small intestinal–type diarrhea
  - Large volume
  - Watery
  - Melena
- Thickened bowel loops
- Large intestinal–type diarrhea (see ch. 277)
  - Hematochezia
  - Mucoid stool
  - Frequency and tenesmus
- Abdominal discomfort/pain
- Excessive borborygmi and flatus
- Weight loss
- Altered appetite
  - Polyphagia
  - Decreased appetite/anorexia
  - Eating grass
- Hypoproteinemia
  - Ascites
  - Subcutaneous edema
  - Pleural effusion

Etiology and Pathogenesis[125,149-151,183-186,204-207,225,266,282-285,434,1545,1603-1658]

The underlying etiology of small animal IBD is unknown, but comparisons have been made with human IBD. In this regard, the breakdown of immunologic tolerance to luminal antigens (bacteria and dietary components) is thought to be critical, perhaps resulting from disruption of the mucosal barrier, dysregulation of the immune system, or disturbances in the microbiome, with upregulation of TLRs. Intestinal growth factors such as trefoil peptides from goblet cells and epidermal growth factor could be downregulated in IBD, inhibiting mucosal repair.

Antigens derived from the endogenous microflora are likely to be important in disease pathogenesis, and a potential role for diet-related factors is suggested by the clinical benefit of dietary therapy in some cases of IBD. Autoimmune enteropathy is a rare condition in humans that resembles LPE somewhat (i.e., villus blunting, mononuclear cell infiltrate, and crypt abscesses). However, there is no evidence for autoimmunity in small animal IBD.

Undiagnosed infection as a cause of SI inflammation remains an alternative possibility, considering the relatively recent identification of attaching and invading *E. coli* in granulomatous colitis of Boxers, a condition previously considered to be a manifestation of idiopathic IBD. Toxoplasmosis has been associated with SI inflammation (see ch. 221), and a PCR study identified *Mycobacterium avium* subspecies *paratuberculosis* in about 20% of presumed idiopathic IBD cases (see ch. 212). The presence of yeasts in the SI, the presence of anti-*Saccharomyces* antibodies in some cases of IBD, and anecdotal reports of improvement with oral nystatin suggest yeasts might sometimes be involved in IBD.

Genetic factors are likely to contribute to the pathogenesis of IBD, and in humans the strongest associations are with genes of the human MHC (human leukocyte antigen [HLA]). Furthermore, some human patients with Crohn's disease have a mutation in the *NOD2-CARD15* gene. This gene's product detects bacterial lipopolysaccharide and can activate the proinflammatory transcription factor NF-kappa-B. Such a link could explain the development of aberrant immune responses to bacteria in certain individuals. Genetic polymorphisms in either *NOD2* or TLRs have been shown in certain dog breeds. For example, single nucleotide polymorphisms (*snp*s) in exon 3 of the *NOD2* gene occur in German Shepherd Dogs with IBD, but not in other breeds and *snp*s also are recognized in genes encoding TLR4 and TLR5 in affected dogs of this breed. Upregulation of TLRs has been demonstrated in IBD. This could be an epiphenomenon associated with inflammation but could infer hyperresponsiveness of TLRs to luminal bacteria.

Diagnosis[609,1659-1661]

Intestinal biopsy is necessary for a diagnosis of intestinal inflammation, but the diagnosis of idiopathic IBD should be limited to cases in which histologic evidence of inflammation is found *without* an obvious underlying cause. All other etiologies, including infectious, diet-responsive, and antibacterial-responsive conditions, must be excluded. Therefore, before intestinal biopsy is undertaken, laboratory evaluation and diagnostic imaging are performed. Such tests cannot prove inflammation is idiopathic, but they can help eliminate known causes of intestinal inflammation and the possibility of anatomic intestinal disease (e.g., tumor, intussusception) or extraintestinal disease (e.g., pancreatitis). Furthermore, by determining whether focal or diffuse intestinal disease is present, the clinician can choose the most appropriate method of intestinal biopsy.

Complete Blood Count[1662]

Occasionally neutrophilia, with or without a left shift, is noted. Eosinophilia could suggest EE/EGE, but it is neither pathognomonic nor invariably present. Anemia can reflect chronic inflammation or chronic blood loss. Thrombocytopenia is seen in <3% of cases, but thrombocytosis often is noted with chronic GI bleeding.

Serum Biochemistry Profile[780]

No pathognomonic changes are seen in IBD, but diseases of other organ systems should be recognized and excluded. In addition, hypocholesterolemia suggesting malabsorption, hypocalcemia, and hypomagnesemia also can be found. Hypoalbuminemia and hypoglobulinemia are characteristic of PLE, and hypoalbuminemia correlates with a poorer prognosis. Intestinal inflammation in dogs can cause a "reactive hepatopathy," with mild elevations in serum activities of liver enzymes. In contrast, because of their shorter half-lives in cats, increases in serum activities of liver enzymes in this species are more likely to be the result of primary liver disease.

Fecal Examination[374,384,1660]

Fecal examination is important for eliminating other causes of mucosal inflammation, such as hookworms and whipworms, *Giardia,* and bacterial pathogens (see ch. 81). Given the potential for occult *Giardia* infection, empirical treatment is recommended in all cases (see above). Increased fecal alpha$_1$-PI concentrations would be expected in IBD as a marker of intestinal protein loss even before hypoproteinemia develops, and fecal calprotectin concentration should be increased if there is inflammation.

Serum Vitamin Concentrations[50,234,395,401,402,780,783,1663-1665]

Hypovitaminosis D can occur in IBD and can be associated with ionized hypocalcemia. Uptake of folate and cobalamin potentially are reduced by intestinal malabsorption, and therefore, SI inflammation can result in subnormal serum folate (proximal inflammation) or cobalamin (distal inflammation) concentrations, or both (diffuse inflammation). The degree of hypocobalaminemia in IBD correlates with the degree of histologic damage and a poorer prognosis. Although cobalamin deficiency is not pathognomonic for IBD, it does require therapeutic correction as it has systemic metabolic consequences (see ch. 292). Anecdotal evidence suggests that cobalamin-deficient cats with IBD require parenteral supplementation to respond optimally to immunosuppression.

Diagnostic Imaging[498,524-529,551,556,561,1666]

Information from imaging, together with specific clinical signs, allows the clinician to choose the most appropriate biopsy method. Plain radiographs can be useful for detecting anatomic SI disease but generally are unremarkable in IBD, and contrast studies rarely add further specific information. Ultrasonographic examination can document focal or diffuse disease and/or whether other organs are affected and is superior to radiography for identifying SI disease. It permits evaluation of intestinal wall thickness and can document mesenteric lymphadenopathy, while ultrasound-guided fine-needle aspiration (FNA) can provide samples for cytologic analysis (see ch. 89 and 93). However, increased intestinal wall thickness is not a feature of all cases of canine idiopathic IBD and is not pathognomonic. Mucosal heterogeneity is consistent with inflammation or crypt abscessation, while striations are indicative of lymphatic dilatation.

Intestinal Biopsy[144,565,570,571,577,581,603,604,609-616,1544,1590,1596,1667-1672]

Intestinal biopsy is necessary to document intestinal inflammation, which is essential for a diagnosis of IBD. Endoscopy is the safest method of biopsy (see E-Box 276-9), but it has limitations: samples are superficial and can be small and crushed, while histopathologic interpretation is prone to disparity both between pathologists, but also with the gross endoscopic appearance. An endoscopic scoring system has been published by the WSAVA GI Standardization Group to try to obtain reliability in the subjective assessment of mucosal erythema, irregularity, and friability,[609] similar to a standardized histologic grading system for SI and LI IBD in dogs and cats. These guidelines are not a numerical system for counting features and "scoring" intestinal inflammation, nor a weighted scale. Rather, the guidelines are a template that allow objective comparisons of individual findings to a reference point. They are intended to allow comparative, prospective studies to identify which changes are important in the histologic definition of IBD and thereby understand the correlation between clinical and histologic severity. A simplified model only assesses villus atrophy, epithelial injury, IELs, crypt changes, and LP infiltrate.

Endoscopic SI biopsies (see ch. 113) only can be collected from the proximal segment of the SI unless ileoscopy via colonic intubation is also performed (see E-Box 276-9). However, ileal biopsies appear to give a higher diagnostic yield. In some cases, full-thickness surgical biopsy is necessary, although the procedure is more invasive and dehiscence can be problematic, especially if severe hypoproteinemia is present. Laparotomy might be more suitable for cats, given the tendency for multiorgan involvement (i.e., triaditis). Histopathologic assessment of biopsy material remains the gold standard for the diagnosis of intestinal inflammation, and the pattern of histopathologic change dictates the name of the IBD type present. However, the limitations of histopathologic interpretation of intestinal biopsies are recognized: the quality of specimens can vary, agreement between pathologists is poor, and differentiation between normal specimens and mild LPE, and between severe LPE and lymphoma, can be difficult. Histologic grading schemes have been suggested, and standardized criteria have been produced and should be adopted. Importantly, mucosal inflammation on endoscopic biopsies is described broadly, emphasizing both architectural changes and the number of inflammatory cells in the LP (see E-Box 276-12). This approach considers that increased cellularity merely could be a reactive response, equivalent to enlargement of a draining lymph node, and that evidence

of mucosal damage also is necessary to confirm inflammation.

IBD Activity Indices[524,780,1673-1678]

Clinical activity indices aid quantification of the severity of IBD and show some correlation with ultrasound findings. They help researchers assess the response to treatment and compare studies, and allow practitioners to make a prognosis by comparison to published studies. The Canine IBD Activity Index (Table 276-11) correlates with histological severity and serum concentrations of acute phase proteins, such as C-reactive protein. Measuring trends in acute phase proteins also might be useful in monitoring response to treatment. The Canine Chronic Enteropathy Clinical Activity Index is a modification that includes serum albumin concentration and the presence of ascites and pruritus, but it remains to be independently evaluated.

TABLE 276-11

Indices for the Objective Assessment of Disease Severity in Inflammatory Bowel Disease

FEATURE	CIBDAI	SCORE	CCECAI	SCORE	FCEAI	SCORE
Attitude/activity	Normal	0	Normal	0	Normal	0
	Slight decrease	1	Slight decrease	1	Slight decrease	1
	Moderate decrease	2	Moderate decrease	2	Moderate decrease	2
	Severe decrease	3	Severe decrease	3	Severe decrease	3
Appetite	Normal	0	Normal	0	Normal	0
	Slight decrease	1	Slight decrease	1	Slight decrease	1
	Moderate decrease	2	Moderate decrease	2	Moderate decrease	2
	Severe decrease	3	Severe decrease	3	Severe decrease	3
Vomiting	None	0	None	0	None	0
	Mild (once/week)	1	Mild (once/week)	1	Mild (once/week)	1
	Moderate (2-3/week)	2	Moderate (2-3/week)	2	Moderate (2-3/week)	2
	Severe (>3/week	3	Severe (>3/week	3	Severe (>3/week)	3
Stool consistency	Normal	0	Normal	0	Normal	0
	Slightly soft, fecal blood, mucus or both	1	Slightly soft, fecal blood, mucus or both	1	Slightly soft, fecal blood, mucus or both	1
	Very soft feces	2	Very soft feces	2	Very soft feces	2
	Watery diarrhea	3	Watery diarrhea	3	Watery diarrhea	3
Stool frequency	Normal	0	Normal	0	Normal	0

	Mild IBD	4-5	Mild IBD	4-5	Mild IBD	4-5
	Moderate IBD	6-8	Moderate IBD	6-8	Moderate IBD	6-8
	Severe IBD	≥9	Severe IBD	≥9	Severe IBD	≥9

ALT/ALP, Alanine aminotransferase/alkaline phosphatase; *CIBDAI*, Canine Inflammatory Bowel Disease Activity Index; *CCECAI*, Canine Chronic Enteropathy Clinical Activity Index; *FCEAI*, Feline Chronic Enteropathy Activity Index; *IBD*, inflammatory bowel disease.

To convert serum albumin concentration to mg/dL, divide the value in g/L by 10.

Other Diagnostic Investigations[108,384,420,434,618-627,633,1603,1679-1692]

Given the limitations of histopathology, other diagnostic modalities can be required. Cytologic examination is likely to be less sensitive or specific, but immunohistochemistry or flow cytometry can be used for analyzing immune cell subsets and RT-PCR to measure cytokine mRNA expression. However, such techniques are labor intensive, poorly standardized and unlikely to be generally available in the foreseeable future. The presence of perinuclear antineutrophilic cytoplasmic antibodies (pANCA), increased serum acute phase proteins, altered GI hormone concentrations, increased intestinal permeability, increased serum 3-BrY concentration, and fecal excretion of calprotectin can be useful markers of intestinal inflammation. Immunohistochemical evaluation of T- and B-cell markers and PCR for antigen receptor rearrangement (PARR) clonality testing to distinguish lymphoma from severe IBD also is of potential value, but clonal rearrangement also is seen in some patients with IBD.

Treatment[1631,1693-1696]

Whatever the histologic type of IBD, treatment usually involves a combination of dietary modification with antibacterial and/or immunosuppressive therapy. Objective information on efficacy is limited, and most recommendations are based on clinical experience. A staged approach to therapy is recommended whenever possible; sequential treatment trials of parasiticides, an exclusion diet, and antibacterials are tried to rule out known causes of inflammation before immunosuppressive medication is used. Mild cases frequently respond to a diet change and/or metronidazole, especially in cats. However, in some cases, clinical signs or mucosal inflammation are so severe that early intervention with immunosuppression is essential. If clinical signs are intermittent, the owners should keep a diary to track signs and activity, which can provide more objective comparisons.

Dietary Modification[658,1485,1697-1701]

An easily digestible diet that decreases intestinal antigenic load and reduces mucosal inflammation is indicated for patients with IBD (see ch. 178). Traditionally, antigen-limited diets based on a highly digestible,

single-source protein preparation have been recommended, eliminating the possibility of an adverse food reaction as the cause of GI inflammation. Such an exclusion diet trial is recommended in all cases where there is not a PLE and the patient is eating; most clients are happy to try this first, given concerns over the side effects of drug therapy.

Well-cooked rice is the preferred carbohydrate source because of its high digestibility, but potato, corn starch, and tapioca also are gluten-free. Fat restriction reduces clinical signs associated with fat malabsorption. Modification of the n3:n6 fatty acid ratio also can modulate the inflammatory response and could have some benefit both in treatment and in maintenance of remission. Supplementation with folate and cobalamin is indicated if serum concentrations are subnormal, although it is not yet clear whether cobalamin must be supplemented parenterally or whether oral supplementation produces a physiologic effect.

Exclusion diets also can help resolve any secondary sensitivities to dietary components that could have arisen following disruption of the mucosal barrier. Then, after the inflammation has resolved, the usual diet often can be reintroduced without the risk of an acquired sensitivity. More recently, hydrolyzed diets have been used in IBD with reportedly greater success, even in patients that have failed a trial with an antigen-limited exclusion diet. However, histologic improvement in mucosal cellularity has not been apparent, despite resolution of clinical signs. Downregulation of some proinflammatory cytokine mRNAs has been shown; therefore, the response to a hydrolyzed diet could indicate (1) simply that the hydrolyzed diet is so digestible that even a diseased SI can cope with it or (2) the IBD is in remission or even cured, but histologic improvement in cellularity takes longer than does the improvement in clinical signs. The latter explanation perhaps mirrors what happens to a draining lymph node after the primary infection is eliminated.

Antibacterial Therapy[691,1702-1708]

Treatment with antimicrobials can be justified in IBD, partly to treat any secondary SIBO and partly because of the importance of bacterial antigens in the pathogenesis of IBD. However, the only controlled study showed no benefit to giving metronidazole with prednisolone. Fluoroquinolones and metronidazole often are used in human IBD, and metronidazole is the preferred drug for small animals. The efficacy of metronidazole, especially in feline IBD, might not be related just to its antibacterial activity because it could exert immunomodulatory effects on cell-mediated immunity. Other antibacterials (e.g., oxytetracycline, tylosin) can also have immunomodulatory effects and some efficacy.

Immunosuppressive Drugs

The most important treatment modality in idiopathic IBD is immunosuppression, although this should be used only as a last resort (see ch. 165). In human IBD, glucocorticoids and thiopurines (e.g., azathioprine, 6-mercaptopurine) are used most widely.

Glucocorticoids[1702,1709-1711]

In dogs, glucocorticoids are used most frequently, and prednisone, prednisolone, and methylprednisolone are the drugs of choice. Dexamethasone should perhaps be avoided, because in rodents it, and not prednisolone, is deleterious to brush border enzyme expression. Budesonide is used on occasion; it is most popular for feline IBD.

Prednisolone/Prednisone

An initial dosage of 1-2 mg/kg PO q 12 h (i.e., 2-4 mg/kg/day) is indicated for 2-4 weeks; in severe IBD, it can be administered parenterally because oral absorption might be poor. The dosage then is tapered slowly over the subsequent weeks to months. Step-downs usually are performed every 3-4 weeks; the exact timings and amounts of dosage reductions are based on clinical response versus the tolerability of side effects, the convenience of tablet size, and reexamination availability. In dogs, signs of iatrogenic hyperadrenocorticism are common initially but most, except muscle atrophy, are transient and resolve as the dosage is reduced. Typically the first taper is from 1-2 mg/kg q 12 h to 1-2 mg/kg q 24 h; subsequent tapers usually are a halving of the dosage. In some cases, therapy can be completely withdrawn or at least reduced to a low dosage given every 48 hours.

Budesonide[1712-1717]

This is an enteric-coated, locally active corticosteroid, 90% of which is destroyed during its first pass through the liver. It is used for maintaining remission in human ileal Crohn's disease with minimal hypothalamic-pituitary-adrenal suppression. It is an attractive alternative in cats with IBD and diabetes mellitus secondary

to chronic pancreatitis and is relatively cheap in cats and small dogs. However, adrenal suppression has been documented in dogs and a steroid-hepatopathy can develop. A preliminary study showed apparent efficacy in dogs and cats, but a more recent study showed no benefit over prednisolone in canine IBD in terms of remission and side effect rates. Limited information is published on the use of this drug with very wide dosage ranges being suggested, but an initial daily oral dose of 1 mg per cat and 1/2/3 mg per small/medium/large dog is used most often.

Cytotoxic Drugs[1693,1718-1728]

If clinical signs of IBD recur consistently when the corticosteroid dosage is tapered, cytotoxic drugs can be added to provide a steroid-sparing effect. In dogs, azathioprine (2 mg/kg PO q 24 h) commonly is used in combination with predniso(lo)ne when the initial response to therapy is poor or when corticosteroid side effects are marked. However, azathioprine can have a delayed onset of activity (up to 3 weeks) and, given its myelosuppressive potential, regular monitoring of the CBC is necessary. Toxicosis can partly relate to a lack of thiopurine s-methyltransferase (TPMT) in individual dogs. The complete absence of TPMT in cats means that only low dosages of azathioprine are needed and it is not recommended unless reformulation is available. Chlorambucil (2 to 6 mg/m^2 PO q 24 h until remission, followed by tapering) with prednisolone probably is a better choice in cats. Similarly in dogs, a chlorambucil-prednisolone combination has been shown to be more effective than a prednisolone-azathioprine combination.

Other immunosuppressive drugs sometimes are used. Methotrexate is effective in the treatment of human Crohn's disease, but it is not widely used in dogs as it often causes diarrhea in this species. Cyclophosphamide has few advantages over azathioprine and is rarely used. The efficacy of mycophenolate mofetil in small animal IBD is unknown, but it is not very successful as a sole therapy in human IBD. However, cyclosporine has shown a predictably promising effect, given its T lymphocyte–specific activity and efficacy in canine perianal fistula treatment. Unfortunately, it is expensive, and studies in human IBD have shown variable efficacy and toxicity. Steroid resistance correlates with induction of P-glycoprotein expression; while this would be expected to confer resistance to cyclosporine also, response to cyclosporine in 11/14 dogs with steroid-resistant enteropathy has been reported.

Prebiotics and Probiotics[686,688,694,703,1650,1706,1729-1736]

Modulation of the enteric flora with probiotics or prebiotics could have benefits in targeting the pathogenesis of IBD; both can reduce intestinal inflammation in mouse models of IBD. Placebo-controlled probiotic trials in human IBD patients have shown promising results, and early trials in canine and feline IBD have shown modulation of the mucosal immune system and some clinical efficacy. Most effect has been seen with the Probiotic VSL#3 strains, but more targeted species-specific probiotics are needed.

Novel Therapies for IBD[8-13,690,1724,1737-1749]

Novel drug therapies increasingly are used in human IBD to target the underlying disease process more precisely. These therapies include new immunosuppressive drugs, monoclonal antibody therapy, cytokines, and transcription factors. Drugs that target TNF-alpha (e.g., thalidomide, oxpentifylline) are used in human IBD and could be suitable for the treatment of canine IBD because of the importance of this cytokine in the pathogenesis of this disease. Anti-TNF-alpha monoclonal antibody therapy is used in severe cases of human IBD. In the future, species-specific monoclonal antibodies might be used for treating canine and feline IBD, just as oclacitinib (Apoquel) is used in atopic dermatitis.

Fecal microbiota transplantation (FMT) was developed to treat humans with *Clostridium difficile* infection but is now being trialed for the treatment of Crohn's disease. Preliminary reports of success in treating canine IBD by FMT are appearing. Successful stem cell therapy in feline chronic enteropathy has been claimed, but objective assessment of success was lacking. Whole intestinal transplant has been performed in experimental pigs and in humans, but not dogs or cats.

Response to Treatment and Prognosis[317,780,1659,1677,1750-1758]

There is a perception that the treatment of canine idiopathic IBD with corticosteroids usually is successful and that full remission is the most likely outcome. This notion is not supported by critical evaluation of the literature; reported positive responses to parasiticides, dietary therapy, or antimicrobials alone suggest that some reported success were never truly idiopathic IBD. A negative outcome in dogs has been associated with more severe disease (as assessed clinically, endoscopically, or histologically), suspected concurrent pancreatic

disease indicated by high pancreatic lipase immunoreactivity, hypocobalaminemia, and hypoalbuminemia. P-glycoprotein expression and the differential expression of TLR-2 and TLR-4 also are predictive of response to treatment. It is not clear whether the correlation with hypoalbuminemia simply reflects disease severity or a greater likelihood of death from thromboembolic disease, since antithrombin (58 kDa) and albumin (70 kDa) are similar-size molecules.

The response to treatment in feline IBD appears better, and more often, remission is prolonged; metronidazole as a sole therapy in milder cases can be successful, and cats are more resistant to the metabolic effects of chronic corticosteroid usage. Prolonged survival also has been seen with simple prednisolone and chlorambucil therapy.

One surprising finding has been that clinical improvement is not necessarily accompanied by histologic improvement. This could reflect the difficulty in assessing intestinal inflammation histologically, but such discordance also is seen in human Crohn's disease, where histologic remission is slower than clinical remission. In some canine cases, an initially good response is followed by relapse that is refractory to further treatment, and a euthanasia rate of 10-20% often is reported. Failure to maintain remission could indicate development of corticosteroid resistance through P-glycoprotein expression, an initial misdiagnosis of alimentary lymphoma, or transformation of chronic inflammation into lymphoma.

Lymphocytic-Plasmacytic Enteritis[1759-1767]

Lymphocytic-plasmacytic enteritis (LPE) is the most common histologic manifestation of intestinal inflammation, characterized by a mucosal infiltrate of lymphocytes and plasma cells associated with mucosal architectural changes (see Figure 276-20). However, there are many other causes of lymphocytic-plasmacytic SI infiltration (see Box 276-18), including enteropathogens, bacteria, and *Toxoplasma.* All such underlying causes must be excluded before a diagnosis of idiopathic LPE is confirmed. LPE is prevalent in a number of pedigree dog and purebred cats, and in dogs it often causes a PLE. LPE typically affects older animals; it is rare (but not impossible) in individuals < 2 years of age.

Etiopathogenesis[629,1524,1656,1768]

Alterations in immune cell populations in canine LPE include increases in lamina propria T cells (especially $CD4^+$ cells), IgG^+ plasma cells, macrophages, and granulocytes, ranging in severity from mild to severe infiltration. Various nonspecific alterations in cytokine and chemokine gene expression between animals with IBD and normals have been shown both by gene array and mRNA expression. Increased concentrations of acute-phase proteins (e.g., C-reactive protein), which normalize after treatment, indicate an inflammatory response. Mucosal fibrosis can occur, especially in cats. There are changes in matrix metalloproteinase expression in LPE, and the fibrosis can be recognizable ultrasonographically.

Clinical Signs[1762]

Signs of LPE including chronic diarrhea and weight loss are not pathognomonic. Chronic vomiting can be the predominant sign, especially in cats.

Diagnosis

The approach to the diagnosis of LPE is the same as for any chronic enteropathy, although a definitive diagnosis ultimately depends on histolopathologic documentation of increased numbers of lymphocytes and plasma cells in association with architectural changes but no identifiable underlying cause (see ch. 113). Complete or partial villus atrophy can be present, with villus fusion and crypt abscessation in severe cases. The distinction between severe LPE and alimentary lymphoma can be difficult, and differences can exist between endoscopic biopsies and postmortem specimens from the same patient. Such discrepancies can occur because the two conditions may be present concurrently, because chronic intestinal inflammation ultimately can result in malignant transformation or because low-grade lymphoma could initially have been misdiagnosed.

Treatment and Prognosis

The treatment of and prognosis for LPE is that outlined above for idiopathic IBD.

Eosinophilic Enteritis[1172,1769-1772]

Eosinophilic enteritis (EE) is reported to be the second most common form of idiopathic IBD. Frequently, it also involves the stomach (eosinophilic gastroenteritis, EGE) and/or colon. Diffuse disease is most common, but segmental EE has been reported in dogs, and in cats, feline sclerosing eosinophilic fibroplasia could be a variant of EE. Histologically, variable mucosal architectural disturbances (e.g., villus atrophy) are present, with a mixed infiltrate of inflammatory cells in which eosinophils predominate. As with LPE, diagnostic criteria vary among pathologists; some define EE purely based on subjective increases in mucosal eosinophil numbers, whereas others apply stricter criteria (eosinophils must predominate in the lamina propria). Another criterion is the presence of eosinophils between epithelial cells of the villus and crypt, which suggests transepithelial migration. Nevertheless, the number of mucosal eosinophils can vary markedly in normal dogs, and therefore, this condition could be overdiagnosed. As with other forms of IBD, a diagnosis of idiopathic EE should be made only after other causes of eosinophilic inflammation, such as parasitism and food-responsive enteropathy, have been eliminated.

Clinical Signs[1772-1775]

EE can be seen in dogs and cats of any breed and age, although is most common in younger adult animals. Boxers and Dobermans might be predisposed, and an increased incidence in German Shepherd Dogs has been suggested. EE and EGE also can be associated with systemic eosinophilic disorders in both cats and dogs. The clinical signs reported, which depend on the area of GI tract involved, include vomiting, SI diarrhea, and LI diarrhea. Mucosal erosion/ulceration and hemorrhage may occur more frequently in EE than in other forms of IBD (see Figure 276-14, *F* and *G*); therefore, hematemesis, melena, or hematochezia can be seen. Severe EE has been associated with PLE and, rarely, spontaneous perforation of the GI tract.

Etiopathogenesis[1172,1222,1256,1776-1778]

An eosinophilic mucosal infiltrate can be related to dietary sensitivity, endoparasitism, visceral *larva migrans* or be idiopathic. Zoonotic infection with *A. caninum* has been associated with human EGE. The eosinophil infiltration is likely to be the result of local and systemic production of cytokines and chemokines, such as IL-5, and members of the eotaxin family. These mediators may be produced by the Th2 subset of $CD4^+$ T cells. Eosinophil infiltration also is seen as a paraneoplastic effect of mast cell tumors and, sometimes, lymphoma.

Diagnosis[1779]

The diagnosis of EE ultimately is made by histopathologic assessment of intestinal biopsies (see ch. 113) in conjunction with exclusion of parasites and food hypersensitivity. Eosinophilia is neither invariably present nor pathognomonic for EE because it also can occur with parasitism, hypoadrenocorticism, allergic cutaneous or respiratory disease, lymphoma, and mast cell neoplasia. Thickened bowel loops can be palpated in some affected cats, and thickening confirmed by ultrasound.

Treatment

Given that eosinophilic mucosal infiltrates can be related to endoparasitic diseases, empirical treatment with fenbendazole always is advisable. Subsequent to this, an exclusion diet trial should be instigated to eliminate the possibility of dietary sensitivity before immunosuppressive therapy is considered. The prognosis in idiopathic EE is guarded, even with a good initial response to treatment, because recurrence is common.

Feline Sclerosing Eosinophilic Fibroplasia[545,1161,1780-1785]

This histological variant of IBD probably represents an unusual manifestation of EE in cats. Fibrosis of the feline intestinal wall could be driven by chronic inflammation, as it is also reported in intestinal phycomycosis, and mast cell tumors. The idiopathic condition occurs most often in middle-aged cats and Ragdolls. Clinical signs of vomiting and diarrhea are common, and intestinal masses in the duodenum and ileum can be palpable. Histologically, an eosinophil infiltrate is interspersed with fibroblasts and bands of collagen. Bacteria are found within lesions in about half of cases, but reported cases tend to respond to prednisolone.

Neutrophilic Enteritis[634,1544,1786]

Although neutrophils are present in the normal intestinal mucosa, and they are the first cells to infiltrate the mucosa in human Crohn's patients when the disease comes out of remission, neutrophilic enteritis is rare in

dogs and only slightly more common in cats. Traditionally, when a predominance of neutrophils was found in the intestinal mucosa on biopsy, empirical treatment with antibiotics rather than immunosuppression was recommended first, as concerns existed about a potentially infectious cause. Recent studies using FISH justify this approach, as there appears to be an association between neutrophilic enteritis in cats and invasion by *Campylobacter coli,* and with *C. jejuni* and *Salmonella* in dogs.

Granulomatous Enteritis[1787-1792]

Granulomatous enteritis is a rare form of SI IBD characterized by mucosal infiltration with macrophages, resulting in the formation of granulomas. The distribution of inflammation can be patchy. This condition probably is the same as "regional enteritis," in which ileal granulomas have been reported. Granulomatous colitis is associated with an attaching and invading *E. coli* (see ch. 277). In cats, a pyogranulomatous transmural inflammation has been associated with FIPV infection (see ch. 224).

Proliferative Enteritis[1793-1796]

Proliferative enteritis is characterized by segmental mucosal hypertrophy of the intestine. Although many species can be affected, the condition is most common in pigs. The condition is rare in dogs. There have been suggestions of an underlying infectious etiology, and *Lawsonia intracellularis* has been implicated in some cases of canine IBD. Other infectious agents with a proposed link are *Campylobacter* spp. and *Chlamydia.*

Breed-Specific Forms of Inflammatory Bowel Disease[1797]

Idiopathic IBD is recognized in all pedigree breeds of dogs and mixed breeds, but certain pure breeds can be overrepresented. In some, such as the German Shepherd Dog, in which both LPE and EE are common, the assumption is still that they are affected by the same conditions as other dogs. Similarly, Siamese cats are predisposed to LPE. Yet while the same etiopathogenesis of intestinal inflammation could exist in all dogs, there might be underlying, breed-related genetic/immune dysfunctions that increase the risk of disease. In German Shepherd Dogs, *snp*s in the genes encoding TLRs show polymorphisms, suggesting a genetic basis. Rottweilers, Yorkshire Terriers, and Lundehunds are predisposed to intestinal inflammation, but it is usually associated with dilated lacteals and they generally are classified as having primary lymphangiectasia. Other breeds of dog, however, also are prone to idiopathic intestinal inflammation, but features of their condition suggest they do not have the universally recognized form of IBD.

Basenji Enteropathy[1666,1798-1805]

A severe, hereditary form of LPE is well characterized in Basenjis, although the mode of inheritance is unclear. It has been likened to immunoproliferative small intestinal disease (IPSID) in humans because both conditions involve intense intestinal inflammation. However, IPSID is associated with a gammopathy (alpha heavy chain disease) and a predisposition to lymphoma. Affected Basenjis often have hyperglobulinemia but not alpha heavy-chain disease, although they could be predisposed to lymphoma. The intestinal lesions are characterized by increases in $CD4^+$ and $CD8^+$ T cells.

Signs of chronic intractable diarrhea and emaciation are most common and usually progressive; spontaneous intestinal perforation can occur. Lymphocytic-plasmacytic gastritis, with hypergastrinemia and mucosal hyperplasia, can be seen in addition to the enteropathy. PLE with hypoalbuminemia often occurs, although ascites is less common. The approach to diagnosis is the same as for idiopathic IBD and ultimately depends on histopathologic examination of biopsy specimens (see ch. 113). Treatment generally is unsuccessful, with most dogs dying within months of diagnosis. However, early, intensive combination treatment with prednisolone, antibiotics, and dietary modification has achieved remission in some cases.

Familial Protein-Losing Enteropathy and Protein-Losing Nephropathy in Soft-Coated Wheaten Terriers[1504,1509,1679,1680,1754,1806-1810]

A clinical syndrome unique to Soft-Coated Wheaten Terriers has been characterized. Affected dogs present with signs of PLE, protein-losing nephropathy (PLN), or both (also see ch. 325). A genetic basis is likely, as pedigree analysis has demonstrated a common male ancestor, and mutations in the *NPHS1* and *KIRREL2* genes have been found in dogs with the PLN. The disease probably is immune-mediated, given the presence of inflammatory cell infiltration in the SI. A potential role for food hypersensitivity has been suggested because affected dogs have demonstrated adverse reactions during provocative food trials and alterations in

antigen-specific fecal IgE concentrations.

Signs of PLE tend to develop at a younger age than signs of PLN. Clinical signs of the PLE can include vomiting, diarrhea, weight loss, and pleural and peritoneal effusions. Occasionally, thromboembolic disease can occur. Preliminary laboratory investigations, as in most dogs with PLE, demonstrate panhypoproteinemia and hypocholesterolemia. In contrast, hypoalbuminemia (without hypoglobulinemia), hypercholesterolemia, proteinuria, and ultimately azotemia are seen if only PLN has developed. A positive pANCA test could be predictive of the disease. Intestinal biopsy reveals evidence of inflammation, villus blunting, and epithelial erosions. The treatment for PLE/PLN is similar to that described for idiopathic IBD, but the prognosis is usually poorer.

Lymphoplasmacytic Enteritis and Cobalamin Deficiency in Chinese Shar-Peis[400,1811-1815]

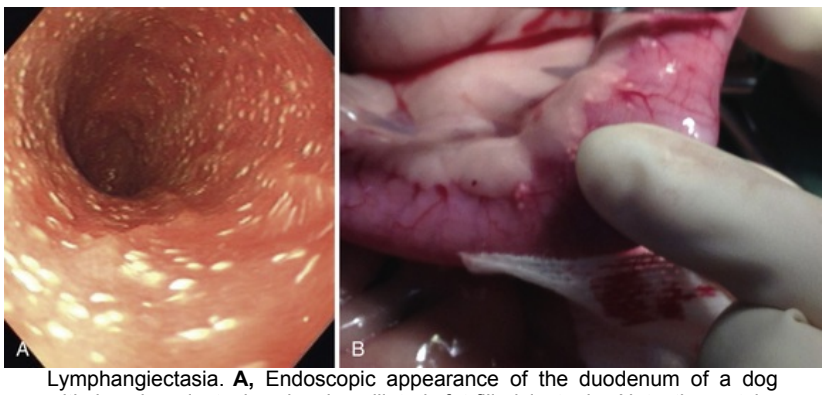
This breed is recognized as being predisposed to lymphoplasmacytic enteritis, and often, there is an associated, severe hypocobalaminemia. A genetic cause is suspected but unproven, and no link to Shar-Pei fever/amyloidosis has been shown; indeed this could just represent IBD.

Lymphangiectasia

Definition and Cause[290,336-338,1816-1839]

Intestinal lymphangiectasia is characterized by marked dilation and dysfunction of intestinal lymphatics. Abnormal lacteals rupture, and protein-rich lymph leaks from villi into the intestinal lumen, a PLE that ultimately causes hypoproteinemia. Concurrent loss of lymphocytes can lead to immunodeficiency, and affected dogs then can be at risk of inflammatory or neoplastic disease; the Lundehund, which has an inherited form of the disease, is predisposed to gastritis and gastric carcinoma, for example. Lymphangiectasia can be a primary disorder or it can develop secondary to lymphatic obstruction. Primary lymphangiectasia usually is limited to the intestine, although it can be part of a more widespread lymphatic abnormality involving, for example, chylothorax. Lymphangiectasia often is considered congenital, although clinical signs are not usually present from birth. Lymphangiectasia has not been described in cats.

Mucosal inflammation and lipogranulomatous lymphangitis sometimes are reported in association with lymphangiectasia, and some authors consider this condition to be a variant of idiopathic IBD. However, the lymphatic abnormalities predominate and involve the full intestinal wall thickness, whereas in most cases of idiopathic IBD only mild lacteal dilatation is seen (Figure 276-21). It is not clear what the primary event is: leakage of lymph could cause inflammation and granuloma formation, or lymphangitis could cause lymphatic obstruction. The development of associated lipogranulomatous lymphangitis, superimposed on the congenital abnormalities, could be one reason for late onset and progression. The disease most commonly is seen in small terrier breeds (e.g., Yorkshire, Maltese), Rottweilers and the Norwegian Lundehund (E-Figure 276-22).



Lymphangiectasia. **A,** Endoscopic appearance of the duodenum of a dog with lymphangiectasia, showing dilated, fat-filled lacteals. Note the patchy nature of the changes. **B,** Appearance of lipogranulomatous lymphangitis in a dog with lymphangiectasia at celiotomy. Note the white spots on the mesenteric side of the jejunal serosa. (Courtesy Sophie Tyler.)

C, Histologic appearance of a jejunal biopsy from a Jack Russell Terrier with a protein-losing enteropathy, in which markedly dilated lacteals are consistent with a diagnosis of lymphangiectasia. **D,** Histologic appearance of a jejunal biopsy from a retriever with moderate lymphoplasmacytic enteritis and mild secondary dilation of the lacteals.

FIGURE 276-21

E-FIGURE 276-22 Lundehunds. Normal Lundehund (right) and one affected with lymphangiectasia (left), showing abdominal distension caused by ascites secondary to severe hypoalbuminemia. (Courtesy D. A. Williams.)

Secondary lymphangiectasia is caused by intestinal lymphatic obstruction. Underlying causes include (1) infiltration or obstruction of lymphatics by an inflammatory, fibrosing, or neoplastic process; (2) possibly obstruction of the thoracic duct; and (3) right heart failure due to congestive heart failure or cardiac tamponade.

History and Clinical Signs[1840-1847]

The clinical manifestations of lymphangiectasia largely are attributable to the effects of the enteric loss of lymph and consequent hypoproteinemia. Other intestinal functions remain intact, and hypoproteinemia even can be present without diarrhea. Diarrhea, steatorrhea, profound weight loss, and polyphagia are more typical, and vomiting, lethargy, and anorexia are seen occasionally. Signs can be insidious in onset and have an intermittent or fluctuating pattern. Ascites or subcutaneous edema can develop secondary to hypoalbuminemia; ascitic fluid usually is a pure transudate, but if right heart failure causes secondary lymphangiectasia, a modified transudate develops through portal hypertension. Chylous ascites can occur if the cisterna chyli is abnormal or abdominal lymphatics are obstructed by abdominal neoplasia such as a pheochromocytoma. Lymphangiectasia has been associated with granulomatous hepatopathy and, in Lundehunds, with chronic gastritis and gastric carcinoma.

Diagnosis[338,550,556,1845-1851]

Given that lymph is rich in lipoproteins and lymphocytes, laboratory analysis often shows panhypoproteinemia, hypocholesterolemia, and lymphopenia due to leakage of lymph. Hypomagnesemia and ionized hypocalcemia have been reported; the latter suggests vitamin D and calcium malabsorption, and intestinal loss of vitamin D binding protein could be involved. PLE can be documented by measuring fecal concentrations of $alpha_1$-PI. In affected Lundehunds, high fecal $alpha_1$-PI excretion occurs before changes in serum proteins.

Hyperechoic mucosal striations are recognized in this condition, but the specificity of this ultrasonographic change is not known. Gross findings at endoscopy include the presence of a milky white exudate and white lipid droplets or prominent mucosal blebs, which likely are the result of villus tip distension with chyle (see Figures 276-14, *H* and 276-20, *A*). Endoscopic biopsies can be supportive of the diagnosis, but full-thickness biopsies could be required to make a definitive diagnosis. Endoscopic biopsies can be too superficial, or the disease can be patchy and potentially missed. At exploratory laparotomy, most dogs show gross abnormalities, including thickened small intestine, dilated lymphatics (in the mesentery and intestinal serosa), and occasionally, adhesions. Mesenteric lymph nodes also can be enlarged, and yellow-white nodular masses (1 to 3 mm in diameter) often are observed in and around the mesenteric and serosal lymphatics (see Figure 276-21, *B*). These nodules are lipogranulomas, consisting of accumulations of lipid-laden macrophages; they seem to result from perilymphatic extravasation of chyle or are associated with a lymphangitis.

The definitive diagnosis of lymphangiectasia depends on intestinal biopsy, and some pathologists believe that full-thickness biopsies are necessary for a reliable diagnosis. However, there are risks involved with exploratory surgery in malnourished and hypoproteinemic dogs. Characteristic histopathologic changes include "ballooning dilatation" of lymphatics in both the mucosa and the submucosa. True lymphangiectasia must be distinguished both from normal postprandial dilation of lacteals and from the secondary lacteal dilatation occasionally noted with IBD (see Figure 276-21, *C* and *D*).

Treatment[1693,1852,1853]

Secondary lymphangiectasia is managed by specific treatment of underlying disease, such as pericardiocentesis or pericardectomy for cardiac tamponade (see ch. 102). The aim of treatment of primary lymphangiectasia is to decrease the enteric loss of protein and resolve associated inflammation to halt diarrhea, while controlling any edema or effusions. Dietary manipulation and glucocorticoids are the most important treatments.

Anti-inflammatory dosages of glucocorticoids (prednisolone 0.5-1 mg/kg PO q 12 h and then tapered) can be beneficial in some cases, especially if associated lymphangitis, lipogranulomas, and/or a lymphocytic-plasmacytic infiltrate is/are present in the lamina propria. Unfortunately, not all cases respond to such therapy. The use of antimicrobials (tylosin, metronidazole) has not shown any obvious benefit. Diuretics are indicated in the management of effusions, and combinations of diuretics are preferred (e.g., furosemide and spironolactone).

The ideal diet for cases of lymphangiectasia is fat-restricted, calorie-dense, and highly digestible, with claims it could be curative even if prednisolone is ineffective, as long as it is instituted before lipogranulomas develop. Weight-reduction diets, although low in fat, are inappropriate, because patients require a high energy-content diet; fat-restricted GI diets are preferred. Previously, administration of medium chain triglycerides (MCT) was recommended because these lipids were thought to be absorbed directly into the portal blood. However, this theory has been contradicted, and because MCT oil is not very palatable, its use is no longer recommended. Supplementation with fat-soluble vitamins is advised. Cyclosporine treatment could be effective, but there is confusion whether such cases are actually IBD with secondary lymphatic dilation or true lymphangiectasia.

The response to treatment is unpredictable, but cessation of clinical signs can occur spontaneously or be achieved temporarily with treatment, with remissions of months to several years. However, the overall long-term prognosis is poor, and patients almost invariably succumb ultimately to severe malnutrition, incapacitating effusions, and intractable diarrhea.

"Crypt Disease"[1854,1855]

The most common causes of PLE are lymphoma, IBD, and lymphangiectasia. However, there are reports of PLE associated with intestinal crypt lesions without evidence of neoplasia, lymphangiectasia, or substantial inflammation. A low frequency of crypt abscessation is seen in normal tissue, as several crypts form one crypt-villus unit, but increased numbers of crypt lesions have been associated with PLE. Superficial endoscopic biopsies could miss such cryptal lesions. Deeper biopsies show either abscessation (see Figure 276-14, *E*) or large numbers of dilated crypts filled with mucus, sloughed epithelial cells, and/or inflammatory cells. The underlying etiology of such lesions is not known. Response to therapy with antibacterials and immunosuppressive medication is variable; some dogs deteriorate suddenly and can die from thromboembolic disease.

Small Intestinal Neoplasia

Spectrum of Disease[1856-1865]

Lymphoma, adenocarcinomas, and mast cell tumors are the most common GI tumors in cats, with lymphoma predominating, whereas adenocarcinomas, smooth muscle, and other stromal cell tumors are more common in dogs. Intestinal fibrosarcoma (dogs), hemangiosarcoma (cats), schwannoma, neuroendocrine tumors, carcinoid, and plasma cell tumors are rare. Clinical signs usually include weight loss if the tumor is malignant, but a range of other signs can be seen including anorexia, diarrhea, melena, vomiting, abdominal discomfort, abdominal effusion, and anemia. Other rarer consequences of intestinal neoplasia include intussusception, intestinal perforation, and paraneoplastic effects. Ultrasonographic loss of wall layering is highly predictive, indicating a fifty-fold increase in the likelihood of neoplasia. Cytologic examinations of fine-needle aspirates only show ≈70% agreement with histologic evaluation. Diagnosis is based on finding a mass or thickened bowel loops on abdominal palpation and/or imaging, with definitive diagnosis ultimately requiring biopsy.

Intestinal Lymphoma[6,7,1866-1877]

Alimentary lymphoma (AL) is characterized by mucosal, submucosal, and/or epithelial infiltration by

neoplastic lymphocytes, invading the intestine in either a diffuse or a focal manner (Figure 276-23 and E-Figure 276-24). Focal infiltration can be nodular, plaquelike, or circumferential, but a diffuse distribution is most common. Focal forms can cause obstruction, while diffuse infiltration results in malabsorption and often a PLE in dogs. Microscopically, the neoplastic cells can infiltrate the epithelium (i.e., epitheliotropic) or lamina propria extending into the deeper, muscular layers and mesenteric lymph nodes. Most affected cats test negative for the feline leukemia virus (FeLV) at the time of diagnosis, and AL has become the most common form of lymphoma in cats following the decline of FeLV infection. AL can arise by mutation in promoter and/or suppressor genes or perhaps by progression from LPE. Chronic antigenic stimulation could lead to the selection of a malignant clone, and there is evidence of upregulation of IL-6 in both feline IBD and AL. Chronic antigenic stimulation in genetically predisposed patients might stimulate transformation to, and selection of, malignant T cells and progression to low-grade AL, as has been seen in humans with MALT gastric lymphomas associated with *Helicobacter* infection. AL often is associated with changes in the spatial distribution of the microbiome, although this is most likely an effect, not the cause, of AL. A broader discussion of lymphoma is presented in ch. 344.

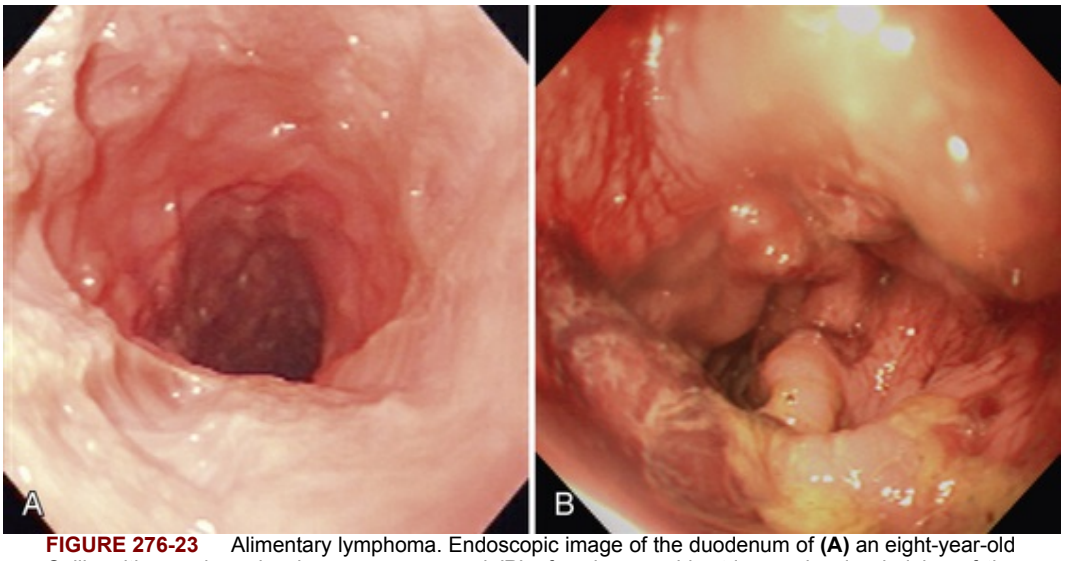


FIGURE 276-23 Alimentary lymphoma. Endoscopic image of the duodenum of **(A)** an eight-year-old Collie with very irregular, lumpy mucosa, and **(B)** of a six-year-old retriever, showing bulging of the mucosa caused by diffuse infiltration. Biopsy is required to confirm the cause of these changes as lymphoma. Clinical Findings[1877-1890]

Middle-aged or older dogs are most commonly affected by AL. Weight loss, chronic diarrhea, and progressive inappetence are common features; vomiting, hematemesis and melena also can be noted. Diffusely thickened intestines, intestinal mass lesions, mesenteric lymphadenopathy, and evidence of abdominal pain can be found on abdominal palpation. Concurrent hepatosplenomegaly and generalized lymphadenopathy are suggestive of multicentric lymphoma or an alimentary form involving the liver. Rarely, there is associated leukemia. Signs due to hypoproteinemia can develop if diffuse AL results in a PLE. Common clinical signs in cats with AL are vomiting (65%), diarrhea (52%), weight loss (46%) and palpable masses.

Complications[1025,1891,1892]

As well as the expected problems of malabsorption and PLE, AL can cause intestinal perforation with consequent peritonitis. Involvement of other sites (spleen, pancreas) can occur. Secondary infection by *Salmonella* and femoral arterial thrombosis have been reported.

Clinical Pathologic Findings[50,1665,1771,1778,1893-1898]

Anemia, characterized as either normocytic-normochromic nonregenerative or microcytic and hypochromic, usually is either anemia of chronic disease or chronic blood loss anemia, but a secondary Coombs'-positive anemia sometimes occurs. Neutrophilia can be evident, and occasionally paraneoplastic hypereosinophilia is found. Most affected cats are FeLV-negative. Routine biochemistry tests in dogs with AL can reveal panhypoproteinemia in animals with diffuse lymphoma causing a PLE, although B-cell AL occasionally can cause hyperglobulinemia via a monoclonal gammopathy. A PLE causing marked hypoproteinemia is unusual in feline AL. Reductions in serum folate or cobalamin concentrations can be the result of malabsorption, SIBO secondary to intestinal obstruction, or consumption of folic acid by tumor cells. Hypovitaminosis D can occur in AL.

Imaging[519,553,1880,1895,1899-1904]

Ultrasonography can demonstrate diffuse or focal intestinal wall thickening, loss of intestinal wall layering, and mesenteric lymphadenopathy (see ch. 88); it also facilitates fine-needle aspiration of mass lesions and gross thickening (see ch. 89). In cats, thickening of the muscularis mucosa is suggestive of AL: a muscularis to submucosa ratio >1 is indicative of an abnormal bowel segment but is not pathognomonic, as it also can be caused by foreign body obstruction and chronic enteropathies. Mesenteric lymphadenopathy also is not discriminatory. Endoscopically, abnormalities due to IBD or lymphoma cannot be reliably distinguished visually, and biopsies should always be taken for histopathologic analysis (Figures 276-12, *G* and 276-23).

Intestinal Biopsy[517,577,604,605,610,617,1905]

Full-thickness biopsy material is preferable to endoscopic pinch biopsies, which could miss the lesion or simply demonstrate adjacent LPE. This is, in part, related to the limited size and depth of endoscopic biopsies, but it also reflects the tendency of AL to occur predominantly more distally in the SI. Thus, endoscopic biopsies might be less sensitive than surgical biopsies unless ileoscopy is performed. Full-thickness biopsies give the most reliable diagnosis when neoplastic lymphocytes can be visualized infiltrating intestinal muscle layers. However, exploratory laparotomy is a risky procedure because many patients are severely debilitated and hypoproteinemic, and subjectively, healing of any intestinal incision is likely to be impaired by the neoplastic infiltration of normal connective tissue. Samples for cytologic evaluation can be collected at endoscopy by cytology brush or squash preparation, or by percutaneous fine-needle aspiration under ultrasound guidance, but in most cases intestinal biopsy is required. Percutaneous, ultrasound-guided biopsy of thickened SI and enlarged mesenteric lymph nodes sometimes is possible.

Histologic Findings

Routine Histopathology[1906-1911]

Although histopathologic assessment of biopsy material is the gold standard for diagnosis of AL, differentiation from severe LPE can be difficult, especially in endoscopic biopsies. Concurrent infiltration with eosinophils can occur and potentially cause misdiagnosis as a mast cell tumor. Further phenotyping can be required for a definitive diagnosis and could provide prognostic information.

Phenotyping[627,633,1682,1686,1906-1920]

Immunohistochemistry, flow cytometry, and assessment of T-cell clonality by PCR analysis of T- and B-cell receptor gene rearrangements improve the accuracy of diagnosis (see ch. 334). These molecular techniques allow a more accurate distinction of lymphoma from LPE and also classification of the lymphocyte lineage. Immunohistochemistry could aid in the diagnosis if all lymphocytes are found to be of a single lineage. B- and T-cell primary ALs have been reported in differing proportions, and clearly the original belief that all AL was always B cell in origin is incorrect.

Most recent research has been into feline AL, which seems to be increasing in incidence. Clinically, three main forms have been defined and all affect older cats (10-13 years) that are generally FeLV-negative. Intermediate- to high-grade AL often presents as a focal intestinal mass (sometimes with extraintestinal involvement). These are T- or B-cell tumors with a median survival time of 7-10 months following multiagent chemotherapy. Low-grade AL presents as diffuse intestinal thickening (sometimes with an intestinal mass and mesenteric lymph node involvement). These are mostly T-cell tumors with a median survival time of 19-29 months following chemotherapy with prednisolone and chlorambucil. Large granular lymphocyte lymphomas present as a focal intestinal mass (sometimes with extraintestinal involvement). These are mostly T-cell tumors (with immunohistochemical expression of granzyme B); median survival time is only 17 days after multiagent chemotherapy.

Pathologists have classified feline ALs using alternative terminology based on the human WHO classification as (1) mucosal T-cell lymphoma of small to intermediate cell type with involvement of the epithelium and lamina propria, (2) transmural T-cell lymphoma of large cell type that can show epitheliotropism and is most often a large granular lymphocyte lymphoma and (3) transmural B-cell lymphoma of large B-cell type.

Treatment and Prognosis[1884,1894,1903,1915,1921-1933]

Dogs with diffuse alimentary AL occasionally respond to multiagent chemotherapy (see ch. 344), but most respond poorly; and in those that do respond, there is a risk of intestinal perforation. The poor response is unlike canine multicentric lymphoma or lymphoma restricted to the canine rectum (see ch. 277). In contrast, the prognosis in cats is more favorable: some attain prolonged remission. Cell lineage appears to be important in determining the response to treatment and prognosis in cats: (1) mucosal T-cell lymphoma of small to intermediate cell type has long median survival time of 29 months, (2) transmural T-cell lymphoma of large cell type has a short median survival time of 1.5 months, and (3) transmural B-cell lymphoma has a median survival time of 3.5 months. Now, there is evidence that the first type (small cell) is increasing in incidence and fortunately has a much better prognosis than intermediate- and high-grade lymphomas. Good responses to combination chemotherapy have been reported, either with standard multidrug protocols or with an "oral-only" regimen (e.g., prednisolone and chlorambucil) for the small cell form. The latter treatment is well tolerated and could be particularly applicable to cases in which the differentiation between low-grade AL and LPE is uncertain, as the treatment is also applicable to severe IBD. Abdominal radiation therapy has been used as a rescue therapy.

Extramedullary Plasmacytoma[1934-1938]

These are rare tumors in the GI tract, and they occur mostly in the stomach or LI; they are sometimes found in the SI. They can be associated with a monoclonal gammopathy, but this has also been found in plasmacytic gastroenterocolitis.

Intestinal Adenoma and Adenocarcinoma[1857,1939-1954]

In dogs, both adenoma and adenocarcinoma are found more commonly in the LI than in the SI; the opposite is true in cats. In the canine SI, carcinoma has a predilection for the duodenum, whereas the jejunum and ileum are affected more commonly in cats (see E-Figure 276-11). Adenocarcinoma is most common in older dogs (mean age: 9 years) and cats (mean age: 11 years). Adenomas can be polypoid, whereas carcinomas are

more likely to grow as plaques or annular, stenotic lesions. Feline intestinal adenocarcinoma is more common than is adenoma, and Siamese cats might be over-represented, but adenomatous polyps are also seen in the feline SI. There is no known association with retrovirus infection in cats, and there is variable p53 expression in dogs.

Clinical Findings and Diagnosis[546,547,1862,1941,1950-1955]

Adenocarcinomata are locally infiltrative and can extend to the serosa and mesentery, and metastasize to local lymph nodes and/or the peritoneal cavity as well as hematogenously. Consequently, clinical signs relate to partial obstruction, or peritonitis when perforation has occurred, or intracelomic carcinomatosis. Abdominal palpation can reveal focal thickening of the intestine. Melena and anemia can be present if significant ulceration has occurred; the anemia usually is strongly regenerative but can become hypochromic and microcytic because of iron deficiency. Diagnostic imaging can delineate a mass lesion and ultrasound-guided FNAs can be helpful, although definitive diagnosis usually requires percutaneous (Tru-Cut) or surgical biopsy (see ch. 89).

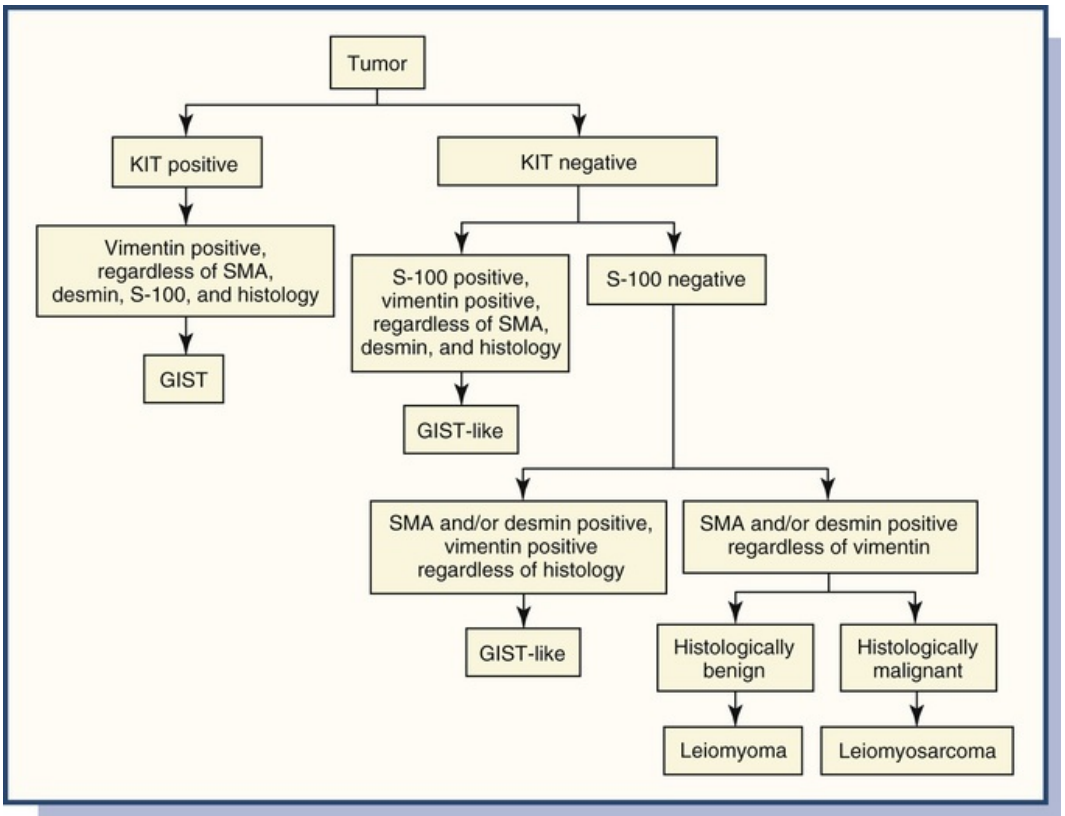
Treatment and Prognosis[1945,1956-1962]

Surgical resection is the treatment of choice. However, the prognosis usually is grave because tumors almost invariably have metastasized at the time of diagnosis. Remission times from surgery of up to 2 years have been reported, but survival time is often <6 months. For dogs, a median survival time of 10 months, with one- and two-year survival rates of 40.5% and 33.1%, respectively, are reported. Survival times are significantly shorter for dogs with histological evidence of metastasis at the time of surgery (median, 3.0 months) than for dogs with none (median, 15.0 months). Metastatic spread commonly involves local lymph nodes and the liver, as well as carcinomatosis, with metastasis to the testes, skin and other organs also reported. COX-2 expression has been documented in canine but not feline intestinal epithelial tumors and is a potential therapeutic target; standard adjunctive chemotherapy has not been demonstrated to be effective.

Smooth Muscle and Stromal Cell Tumors[1963-1981]

Smooth muscle tumors of the SI (leiomyoma and leiomyosarcoma) are an uncommon intestinal tumor of older dogs (average age: 10 years) and are rare in cats. The anatomical site in dogs typically is the jejunum or cecum, whereas in cats they are almost exclusively in the SI. The tumors often are nodular on the antimesenteric border. The histologic distinction between benign and malignant tumors is difficult, but metastatic spread of leiomyosarcoma to liver and local lymph nodes is uncommon anyway. The other tumor within this spectrum is the GI stromal tumor (GIST), which is histologically similar, but which arises from interstitial cells of Cajal.

The distinction of smooth muscle tumors from GISTs is by their differing expression of CD molecules such as CD34 and c-KIT (CD 117) and smooth muscle (vimentin, desmin, alpha-smooth muscle actin [SMA]) and neurogenic (S100, NSE, and synaptophysin) markers. Typically, smooth muscle tumors express SMA but are negative for the c-KIT (CD117) marker. Uncontrolled expression of c-KIT, a receptor tyrosine kinase, is an important marker of GISTs. Tumors otherwise resembling GISTs but showing no c-KIT expression are classified as GIST-like (E-Figure 276-25).



E-FIGURE 276-25 Classification of intestinal smooth muscle and stromal cell tumors. *GIST*, Gastrointestinal stromal tumor; *SMA*, alpha-smooth muscle actin. (Adapted from C. P. H. J. Maas: A new look in intestinal smooth muscle tumors: clinical histologic and immunohistochemical aspects for reclassification. Proceedings of the 18th Annual ECVIM Congress, Ghent, Belgium, 2008.)

Diagnosis[1982-1990]

Clinical Signs

Clinical presentation can vary and can include vomiting, diarrhea, anorexia, polyuria, polydipsia, melena, acute collapse, and weight loss. Many of these signs are the result of local tumor effects (i.e., obstruction, intussusception), acute bleeding, or iron-deficiency anemia. However, paraneoplastic effects are reported, especially hypoglycemia as a result of production of an insulin-like growth factor II–like peptide. Other paraneoplastic syndromes associated with leiomyosarcomas include erythrocytosis, due to the elaboration of an erythropoietin-like molecule, and nephrogenic diabetes insipidus (see ch. 352).

Laboratory Tests

Findings such as erythrocytosis or hypoglycemia reflect the consequences of direct or paraneoplastic effects, but test results can be unremarkable. Iron-deficiency anemia can develop without any overt GI signs due to chronic occult blood loss.

Diagnostic Imaging

Radiographs and especially ultrasound can aid the identification of a mass lesion (see ch. 88), and upper GI endoscopy can confirm the presence of a lesion if it is within reach and disrupting the mucosa (see ch. 113). However, pinch biopsies often are too superficial, and exploratory laparotomy is the technique of choice both for diagnosis and treatment.

Treatment and Prognosis[1991,1992]

The treatment of choice is surgical excision, and the prognosis is excellent for leiomyomas. Leiomyosarcomas are slow to grow and metastasize, and if surgical resection is complete the prognosis is good, with median survival times of 21 months. Prognosis is affected by gross, histologic, and immunohistochemical features such as tumor size, tumor location, mitotic index, AgNOR score, and Ki67 labeling. Even if metastasis is

evident at the time of surgery, the prognosis is reasonable, with prolonged survival reported in some cases. There appear to be no differences in prognosis for GISTs compared with smooth muscle tumors. In humans, the tyrosine kinase inhibitor imatinib prolongs survival in unresectable GISTs; clinical trials of masitinib and toceranib for canine GISTs are ongoing.

Amine Precursor Uptake and Decarboxylation Tumors[1993-1996]

Functional neuroendocrine, so-called amine precursor uptake and decarboxylation tumors (APUDomas)—vasoactive intestinal peptide tumors (VIPomas), pancreatic polypeptide tumors (PPomas)—have yet to be adequately described in dogs and cats. A functional carcinoid, with increased serum 5HT levels, has been described.

Other GI Neoplasms[1776,1781,1857-1861,1943,1952,1993,1994,1997-2012]

Rare tumors such as fibrosarcoma, osteosarcoma, schwannoma and nonfunctional carcinoid tend to be focally invasive and usually cause clinical signs similar to those of intestinal adenocarcinoma. Intestinal mast cell tumors tend to behave more like AL, but in cats they can be admixed with a marked fibrotic reaction and are described as feline sclerosing alimentary mast cell tumors (see above). Histiocytic sarcoma can infiltrate the SI and cause severe malabsorption. Hemangioma of the SI is very rare; hemangiosarcoma also rarely arises in the SI, but it does so more commonly in cats, wherein the signs often relate to hemorrhage and occasionally to mesenteric thrombosis. Intestinal melanoma is very rare. Hamartomatous polyps in dogs and adenomatous polyps affecting the SI in middle-aged cats can cause vomiting, hematemesis, or melena. However, chronic, occult blood loss can occur, and animals can present with iron-deficiency anemia. Ganglioneuromatosis is a very rare benign proliferation of ganglion and glial cells; in most species it occurs between muscle and submucosal layers, but a mucosal lesion that was successfully resected has been reported in a dog.

Other Small Intestinal Disorders

Adynamic Ileus and Intestinal Pseudo-Obstruction

Definition and Clinical Presentation[63,274-278,483,484,2013-2036]

Adynamic ileus is a common sequel to a variety of primary GI problems—abdominal surgery, parvoviral enteritis, pancreatitis, peritonitis, hypokalemia—and dysautonomia (see Boxes 276-5 and 276-10). Postoperative ileus can occur after any abdominal surgery. It is caused by a combination of local inflammation, increased inhibitory sympathetic tone, and often, the use of opioid analgesics. It is of clinical significance because it increases morbidity and prolongs hospitalization.

Dysautonomia often shows multiorgan involvement, affecting pupillary function, salivation, and bladder function, as well as gastroesophageal and intestinal motility. An epidemic in UK cats in the 1980s (so-called Key-Gaskell syndrome) waned, perhaps due to withdrawal of a potentially toxic but unidentified dietary component, but sporadic cases still are seen worldwide in both dogs and cats.

The term *intestinal pseudo-obstruction* describes a condition in which patients show clinical evidence consistent with an obstruction, but no mechanical cause can be found. The condition has been associated with both visceral neuropathies and myopathies in humans, and such causes can occur in small animals. There are many single case reports in the literature in dogs, but very few in cats. Most cases are associated with idiopathic leiomyositis and sclerosing enteropathy, with fibrosis and a mononuclear cell infiltrate of the tunica muscularis. Smooth muscle alpha-actin deficiency has been described in one Bengal cat, and feline intestinal pseudo-obstruction also can be secondary to intestinal lymphoma.

Management[490,2022,2037-2048]

After the possibility of mechanical obstruction has been eliminated, management of both adynamic ileus and intestinal pseudo-obstruction is aimed at identifying any underlying cause and providing specific treatment. Nonspecific therapy to stimulate intestinal motility also is indicated. Suitable prokinetic agents include the 5-HT_4 receptor agonists cisapride or mosapride, the D_2 dopaminergic antagonist metoclopramide, acetylcholinesterase inhibitors such as acotiamide, and motilin-like drugs such as erythromycin. In dogs and cats, cisapride appears to be the most effective agent, but it is no longer available in many countries because of human toxicosis. Antibacterials also can be appropriate, given the probability of secondary SIBO. Feeding is beneficial in humans, and nutritional support can be continued indefinitely, although vomiting and constipation or diarrhea usually continue. Unfortunately, most cases of idiopathic pseudo-obstruction reported in the veterinary literature have responded poorly to therapy, and the prognosis is grave; just one case responding to immunosuppressive dosages of corticosteroids combined with prokinetics has been reported.

Surgical Intestinal Disorders

Intestinal Obstruction[499,501,503,523,2049-2094]

Intestinal obstruction can be the result of extraluminal, intramural, or intraluminal lesions and can be classified as acute or chronic, partial or complete, and simple or strangulated. Most intraluminal obstructions are caused by a variety of foreign objects; radiolucent objects (socks, peach pits, corn cobs) can be the hardest to identify. Intramural causes of obstruction include intestinal neoplasia, parasites (rarely), hematomas (which are believed to occur spontaneously), granulomas (e.g., focal FIP, phycomycosis, embedded hair), and strictures (e.g., after foreign body impaction or surgery). Extraluminal causes include entrapment by hernias, mesenteric tears, congenital and acquired adhesions, and intussusceptions.

Most cases of SI obstruction can be identified on plain abdominal radiographs (see Figure 276-17). A dilated bowel >1.6× the height of the body of L5 at its narrowest point has been considered highly predictive of SI obstructions, but the value of such formulae is debated. Linear foreign bodies cause bunching of the SI and a characteristic pattern of comma-shaped gas bubbles. Ultrasonography is useful in detecting radiolucent foreign bodies, intussusceptions, and intramural obstructions, but intestinal gas accumulation can obscure the lesion.

The prognosis for surgical cure depends on the cause of the obstruction, the presence of perforation and peritonitis, the viability of the remaining intestine, and the severity of any associated metabolic abnormalities. Recovery is aided by a rapid return to enteral nutrition. The outcome is likely to be favorable with simple foreign bodies, but it is guarded for linear foreign bodies as it is likely that there are multiple perforations,

and it is grave for animals with volvulus or metastatic intestinal neoplasia. The patient is at risk of developing short bowel syndrome if an extensive length of SI must be resected (see below).

Intussusception[1858,1997,2095-2138]

The most common extraluminal cause of obstruction is intussusception, and ileo-colic intussusception is the most common anatomical variant. In severe cases the *intussusceptum* can migrate through the *intussuscipiens* and out through the anus, where it can be mistaken for a rectal prolapse. Retrograde, midjejunal and double intussusceptions are reported, whereas duodenogastric intussusceptions are rare and can cause vomiting and shock, although they could be reducible by endoscopy (Figure 276-26). Younger animals are more likely to develop intussusceptions, especially after a case of gastroenteritis or after intestinal surgery, and Maine Coon cats could be predisposed. Increased risk exists after experimental renal surgery, toxicoses affecting intestinal motility, congenital hypothyroidism, and postparturient queens. Neoplasia is the more frequent cause in middle-aged and older animals, with the mass acting as a nidus for the in-folding of the SI. Intussusceptions have also been associated with acute kidney injury due to leptospirosis.

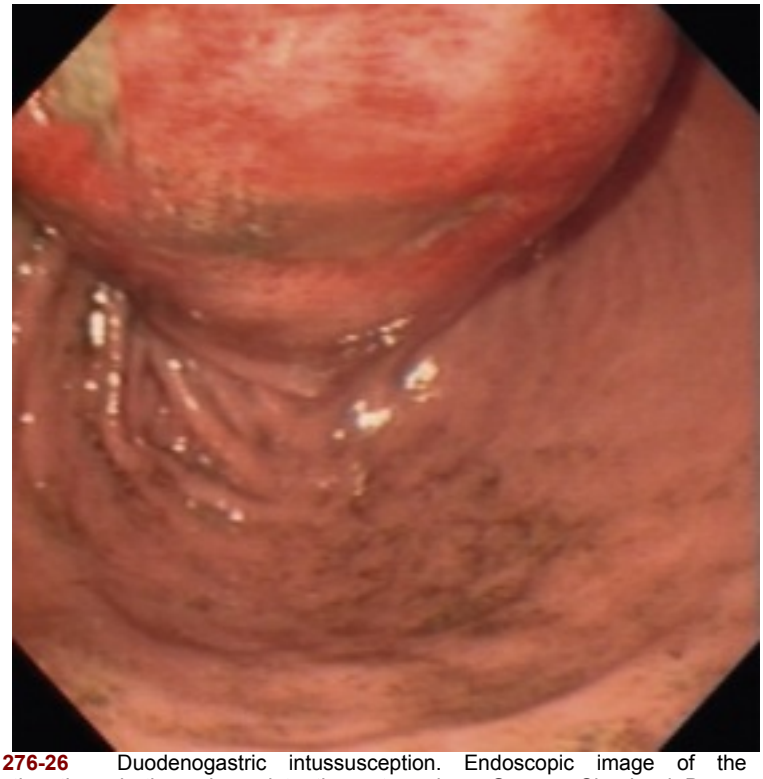


FIGURE 276-26 Duodenogastric intussusception. Endoscopic image of the duodenum intussuscepting through the pylorus into the antrum in a German Shepherd Dog presented for evaluation of vomiting.

The diagnosis of an intussusception is made via a combination of history, palpation of a "sausage-shaped" abdominal mass, radiographic evidence of a mass and SI obstruction, and ultrasonographic demonstration of a characteristic double-walled structure (Figure 276-12, *C*). Transient, clinically silent intussusceptions and spontaneous reductions after obstruction have been reported, but in most clinically affected cases, surgical correction is required. This can involve simple reduction or actual resection of the affected region with end-to-end anastomosis. Recurrence is a recognized risk and can in part be related to damage to the enteric nerves in the region. Rather than paralyze the SI postoperatively with antimuscarinic drugs, a rapid return to feeding and normalization of intestinal motility are recommended. Enteroplication can be performed to try to prevent recurrence, but it carries risks of perforation, entrapment, and stricture.

Intestinal Strangulation[558,2066,2139-2146]

Strangulation can occur if loops of bowel are incarcerated in umbilical or inguinal hernias; an internal hernia through a surgically-induced defect in the mesentery; omental, mesenteric or duodenocolic ligament tears; or

entrapment by adhesions following pubic bone fracture, or intraabdominal lipomas. As well as causing obstruction, intestinal ischemia is likely with the risk of reperfusion injury following surgical correction, or perforation if not corrected.

Intestinal Volvulus[2070,2110,2147-2156]

In this condition, the intestines rotate around the mesenteric axis, compromising the cranial mesenteric artery, and consequential complete vascular obstruction can lead to infarction. The typical radiographic finding is marked gas distension of much of the small intestine. Confirmation is made at surgery, and the possibility of euthanasia on the operating table should be discussed with the owner if laparotomy reveals diffuse intestinal ischemia and necrosis. Reports are sporadic and fortunately rare, as the prognosis is grave.

Intestinal Perforation[2068,2071,2157-2179]

SI perforation leading to septic peritonitis is caused most frequently by NSAID administration, ingestion of linear foreign bodies, and ingestion of sharp nondigestible objects (e.g., cocktail sticks, needles) or if the diagnosis of any SI foreign body has been delayed. Perforation by sharp bone fragments is reported rarely and might not be as much of a risk as the public has been led to believe; bones are softened by, and even dissolved in, gastric acid. Ingestion of multiple magnets has been associated with perforation, presumably because of necrosis of the bowel wall between two objects attracted magnetically. Traumatic avulsion of a mesenteric vessel will lead to ischemia and delayed perforation of the relevant intestinal segment. Tumors and fungal granulomas can perforate, and islands of heterotopic gastric mucosa in the SI also are prone to ulceration and even perforation.

Short Bowel Syndrome[2180-2191]

Short bowel syndrome (SBS) refers to the situation that occurs when large lengths of the SI (more than two thirds) are absent because of resection or, rarely, a congenital anomaly. Cases of SBS are mercifully rare in cats and dogs, as the option of euthanasia for severe cases exists and much information on management has been extrapolated from human GI surgery.

Clinical Signs

Clinical signs (e.g., diarrhea) are a result of insufficient functional mass of SI for assimilation of nutrients and electrolytes. In some cases, SBS can occur transiently after resection because adaptive hyperplasia in the remaining intestine can lead to subsequent clinical improvement. The degree of malabsorption depends on the length of intestine resected; in dogs, experimental studies suggest that removal of up to 85% of the intestine can be tolerated. The site of resection also is important: removal of the ileo-colic valve predisposes to ascending bacterial colonization. Massive resection also precipitates changes in GI hormones, leading to hypergastrinemia and increased acid secretion.

Diagnosis

The diagnosis of SBS usually is based on a history of intestinal resection with consequent diarrhea and weight loss. If a congenital lesion is suspected, contrast radiography can demonstrate the shortened SI length.

Treatment[2192-2195]

After massive resection, intensive parenteral fluid therapy (see ch. 129) and parenteral nutrition (see ch. 189) should be instigated. Oral feeding is restricted but not withheld completely because the presence of food, bile, and pancreatic secretions in the gut are important stimuli for intestinal adaptation. An isotonic, oligomeric, fat-restricted liquid diet can be fed initially, with a gradual transition first to a polymeric liquid diet and then to an easily assimilated, fat- and fiber-restricted diet. Malabsorption of fat- and water-soluble vitamins and minerals also can occur, and dietary or parenteral supplementation could be required. Parenteral cobalamin supplementation is essential if the ileum has been resected. H2-receptor antagonists or proton pump inhibitors can be used in the postoperative period to counteract possible hypergastrinemia. Antimicrobial agents can be necessary if the ileocecocolic junction has been resected or if secondary SIBO is suspected. If the response to diet and antibiotics is poor, antisecretory agents (loperamide, diphenoxylate, or octreotide) could be required. Bile salt binding resin (e.g., cholestyramine) might help reduce colonic secretion caused by bile salts malabsorbed after ileal resection; ursodeoxycholic acid has been shown to enhance intestinal adaptation in a feline surgical model.

Prognosis[1742]

The prognosis depends on the amount of SI left and response to therapy. Some animals undergo remarkable adaptive hyperplasia and can return to a normal diet, whereas others never respond adequately. Complications of human SBS include gallstones, oxalate uroliths, and D-lactic acidosis. In refractory cases, experimental surgical GI modifications to slow intestinal transit and increase absorptive area have been described; reconstruction, regeneration, or intestinal transplantation might be feasible in the future.

Irritable Bowel Syndrome

Definition and Diagnosis[2196-2198]

Irritable bowel syndrome (IBS) is characterized by recurrent, usually acute, episodes of abdominal pain, borborygmi, and diarrhea but which more commonly causes signs of LI dysfunction (see ch. 277). Disordered intestinal motility can be of primary importance (Box 276-19) because in the absence of morphologic changes, a functional disorder is considered the cause of this enigmatic problem.

Box 276-19

Potential Causes of Irritable Bowel Syndrome

- Primary motility disorders
- Psychosomatic disorders
- Undiagnosed food intolerance
- Undiagnosed inflammatory disease
- Visceral hyperalgesia

CHAPTER 277

Diseases of the Large Intestine

Edward James Hall

Client Information Sheets:
Chronic Colitis
Granulomatous Colitis

Normal Structure and Function

Grossly, the canine and feline large intestine (LI) are simple tubular structures, comprising the colon, a small cecal diverticulum, and the rectum. However, they play a critical role in the control of fluid homeostasis, the host's interaction with the intestinal microbiome, and the storage and regulated evacuation of fecal material. Disorders of the LI are common in dogs and cats, and may cause either diarrhea or constipation and, if ulceration is present, the passage of fresh blood (*hematochezia*; see ch. 41). Importantly, most LI disorders, although usually not fatal, can have a significant effect on the patient's quality of life (QOL); children with chronic LI disease are recognized to have a very poor QOL,[1] and the distress caused to dogs, cats and their owners by LI disease is often evident in veterinary practice,[2] although QOL is not easily quantified.

Structure

Macroscopic Anatomy[3-8]

Anatomically, the tubular LI continues from the distal small intestine (SI), beginning at the ileocolic sphincter and ending at the anus, and is composed of three anatomically distinct sections: the cecum, the colon, and the rectum (Figure 277-1, *A*). The colonic section comprises three poorly delineated segments (right, transverse and left colon) demarcated by flexures which are not very pronounced, especially in cats where the transverse colon is also very short. The colon is supported on a loose mesentery, the mesocolon, so that its position on lateral radiographs may be in the dorsal or mid-abdomen.

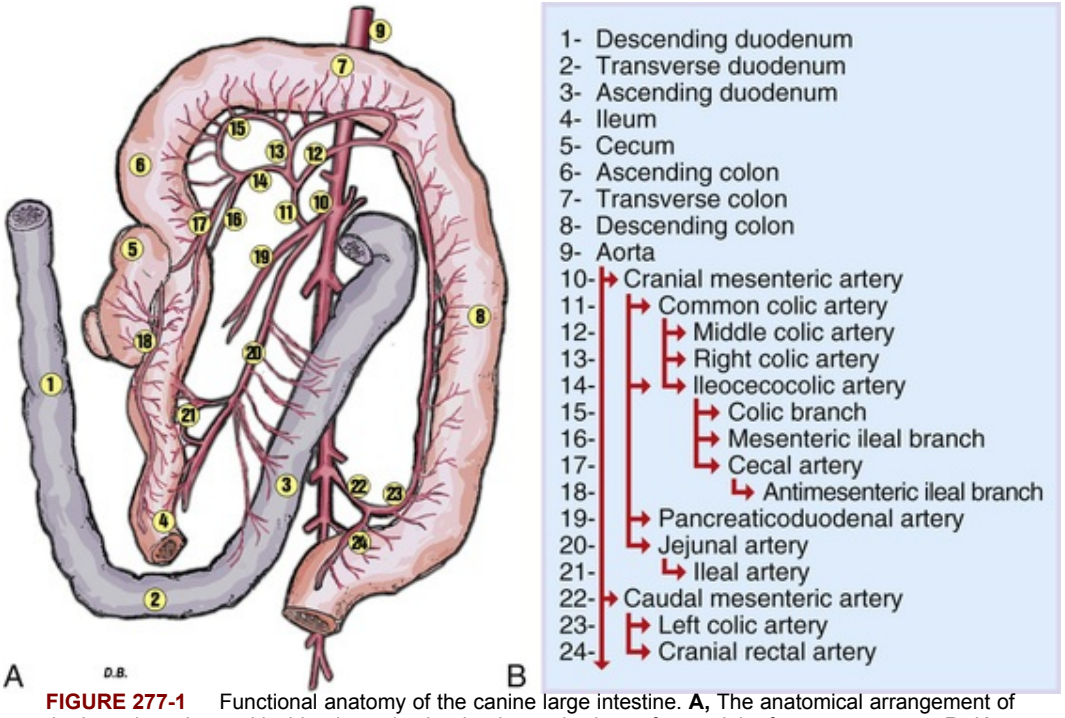

FIGURE 277-1 Functional anatomy of the canine large intestine. **A,** The anatomical arrangement of the large intestine and its blood supply; the duodenum is shown for spatial reference purposes. **B,** Key: Schematic representation of the sections of large intestine, and the divisions of its arterial blood supply. (Adapted and redrawn from Lecoindre P, Gaschen F, Monnet E, editors: *Canine and feline gastroenterology*, France, 2010, Wolters Kluwer.)

The gross structure of the colon is relatively simple with no longitudinal bands of muscle (taeniae), as seen in the human colon and, normally, no sacculations (haustra). The diameter of the colonic lumen is variable depending on the volume of gas and feces within, but it is generally twice the diameter of the SI. On average the LI is 60 to 75 cm long in dogs (range 25 to 90 cm), and ranges from 20 to 45 cm in cats. In both dogs and cats it contributes 20 to 25 per cent of the total (small and large) intestinal length.

Ileocolic Sphincter

The ileocolic papilla can be visualized during flexible colonoscopy: in dogs it appears endoscopically as a raised, mushroom-like protuberance (Figure 277-2, *A* and E-Figure 277-3), but in cats it is often quite flattened and slit-like. It is a sphincter through which liquid ileal contents periodically enter, and adjacent to it is the ceco-colic orifice, which leads into a blind-ending cecum.

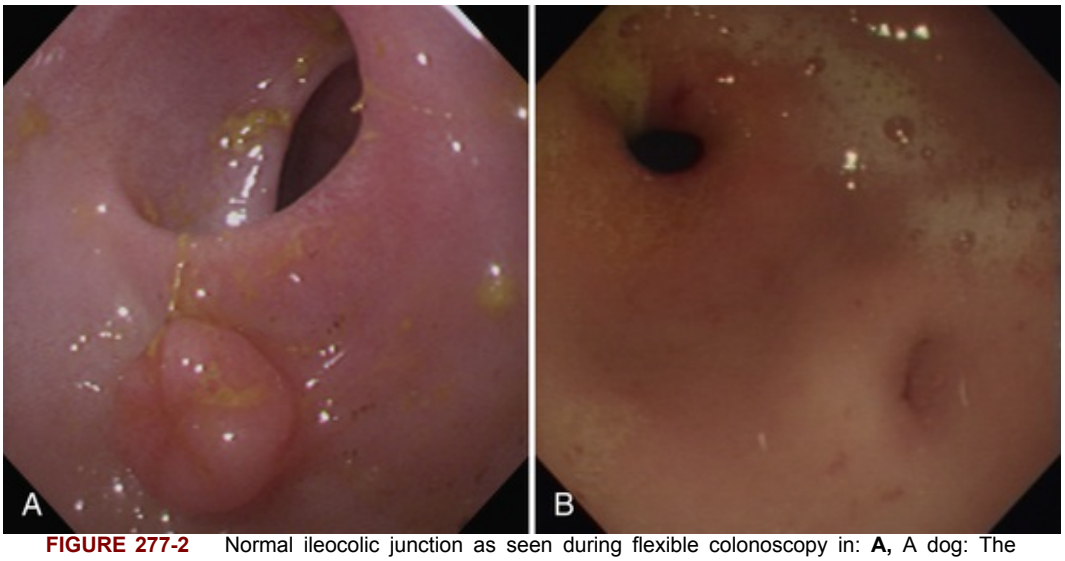

FIGURE 277-2 Normal ileocolic junction as seen during flexible colonoscopy in: **A,** A dog: The

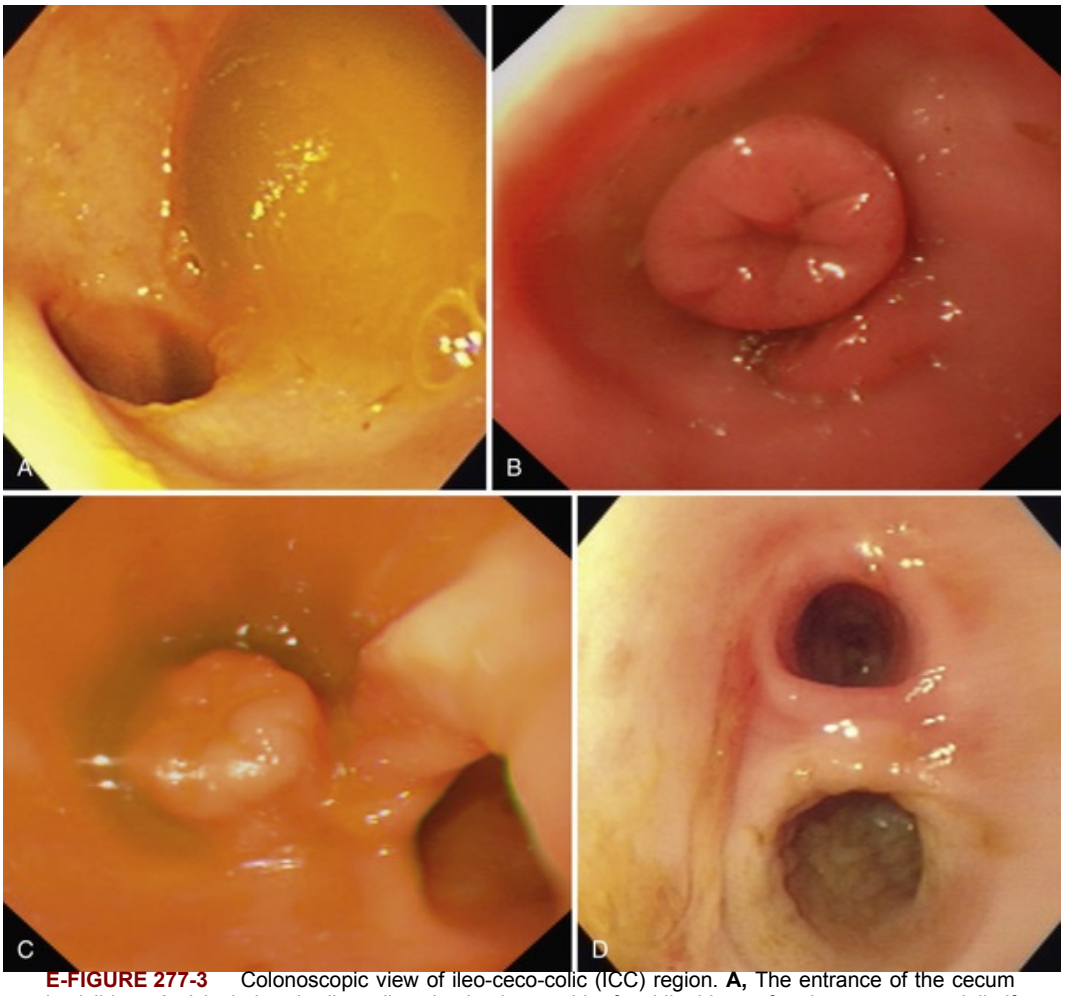
mushroom-shaped ileocolic papilla is seen below the cecal orifice. **B,** A cat: The ileocolic papilla is much flatter and the cecum much smaller and shorter than in dogs.



E-FIGURE 277-3 Colonoscopic view of ileo-ceco-colic (ICC) region. **A,** The entrance of the cecum is visible at 8 o'clock, but the ileocolic valve is obscured by fecal liquid, as often happens, especially if cleansing has been inadequate. **B,** The ICC region is clear of material and the mushroom shaped IC papilla, with a central lumen, is visible. The cecal orifice is obscured by the flattened papilla. **C,** The ileocolic (IC) papilla is visible, with the adjacent cecum spiraling away from it. **D,** The ICC region in a dog after successful ileoscopy. Both the IC (uppermost) and cecal orifices are wide open, with thickening due to their respective sphincter muscles being visible.

Cecum

The cecum is a diverticulum arising from the proximal colon; the ceco-colic orifice is separate from the ileocolic papilla, and has its own sphincter muscle (see E-Figure 277-3, *D*). It lies approximately midway between the right flank and median plane, ventral to the duodenum at the level of the 3rd and 4th lumbar vertebrae, separated from it by the greater omentum. The canine cecum ranges from 8 to 30 cm in length and is sigmoid, spiraling towards its rounded, blind end. Ventrally it is attached to the antimesenteric border of the ileum. The cecum in cats is less twisted and is shorter (2 to 4 cm) and narrower, making endoscopic intubation difficult.

Proximal Colon

The colon runs cranially from the ileo-colic papilla as the *ascending* or *right* colon, which is the shortest colonic segment in dogs; the cecal appendage arises in the proximal right colon no more than 1 cm from the ileocolic papilla. The colon then turns at the *right colic* or *hepatic* flexure to pass across the body as the *transverse* colon, adjacent to the greater curvature of the stomach and left limb of the pancreas, and cranial to the root of the

mesentery. The right and transverse colon together are functionally considered the *proximal colon.*

Distal Colon

The transverse colon turns caudally in the cranial abdomen at the *left colic* or *splenic* flexure, becoming the *left* or *descending* colon, which is considered functionally to be the *distal colon.* The left colon is the longest colonic segment, and passes caudad past the ventromedial border of the left kidney and ventral to the sublumbar musculature and lymph nodes. At the level of the pelvic brim it becomes the rectum.

Rectum

The rectum is generally considered to be totally within the pelvic canal, starting where the cranial rectal artery enters and terminating at the anal canal. It is 4 to 6 cm long and 3 to 4 cm wide in average-sized dogs, and its middle portion is slightly wider, forming a rudimentary bulb. It normally lies midway between the sacrum and floor of the pelvis on lateral radiographs. Like the colon, it also has a smooth surface with no indentations. However, only the cranial half is covered in peritoneum; the distal half is retroperitoneal. The mucosa forms transverse folds which smooth out when the rectum is distended. The anatomy of the recto-anal region is described in ch. 278.

Blood Supply[9]

The cranial and caudal mesenteric arteries supply blood to the LI, and the pattern of distribution is important when planning any surgical resection (see Figure 277-1, *B*). The cranial mesenteric artery supplies the cecum and ascending colon via the ileo-ceco-colic and right colic branches respectively, and the transverse colon via the middle colic artery which anastomoses with the right and left colic arteries. The caudal mesenteric artery supplies the left colic artery which runs cranially along the left colon to anastomose with the middle colic artery, and caudally to anastomose with the cranial rectal artery. The rectum is supplied by the middle and caudal rectal arteries as well as the cranial rectal artery. Of these, the cranial rectal artery supplies the majority of the blood to both the terminal colon and rectum, and ideally should be preserved during any colonic/rectal resection. The veins of the colon all terminate in the portal vein, although veins from the retroperitoneal rectal segment can pass to the caudal vena cava.

Lymphatics[10,11]

Lymph from the colon drains to segmental (right, middle, and left) colic lymph nodes associated with the roots of the cranial and caudal mesenteric arteries. The number of nodes varies from one to nine, with an average of four. This is of importance in the surgical planning of any LI resection, although collateral drainage is established quite quickly.

Innervation[12-14]

The vagus nerve provides parasympathetic innervation to the proximal colon, whilst the pelvic nerves supply the distal colon. Sympathetic nerves arise from the paravertebral ganglia and follow the mesenteric arteries and lumbar splanchnic nerves to the LI. The intestines also contain an intramural nervous system, which is located between the longitudinal and circular muscle layers, and in the submucosa. Parasympathetic pre-ganglionic fibers and sympathetic post-ganglionic fibers synapse on cell bodies and dendrites of the intrinsic nervous system. Reflex pathways control colonic wall movement, water and electrolyte secretion, and local blood flow.

Microscopic Anatomy[7,8,15-37]

Histologically, the LI resembles the structure of the SI (see ch. 276), comprising four layers: mucosa, submucosa, muscularis, and serosa (Figure 277-4).

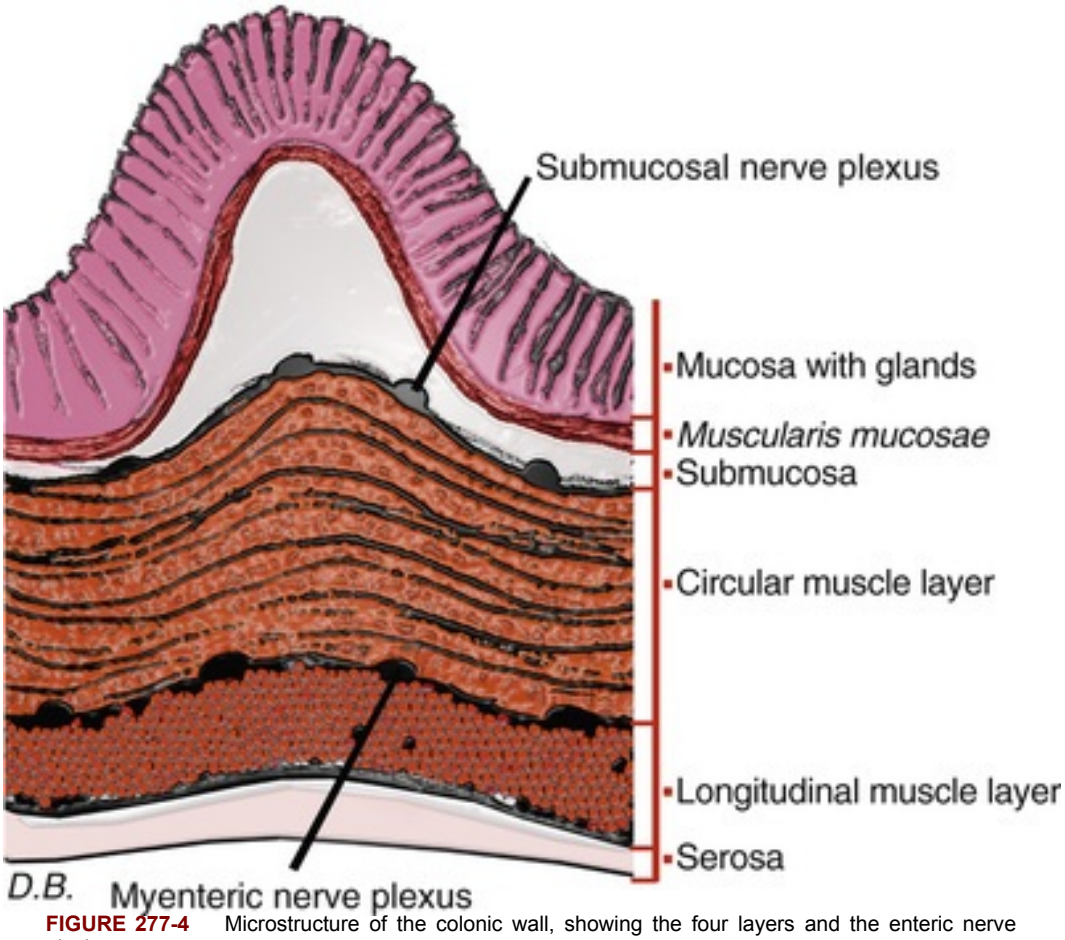


FIGURE 277-4 Microstructure of the colonic wall, showing the four layers and the enteric nerve plexi.

Mucosa

In comparison to the microscopic structure of the SI, the LI is a flat surface with no villi and the epithelial colonocytes expressing fewer microvilli, but there are many more mucus-secreting goblet cells (Figure 277-5).

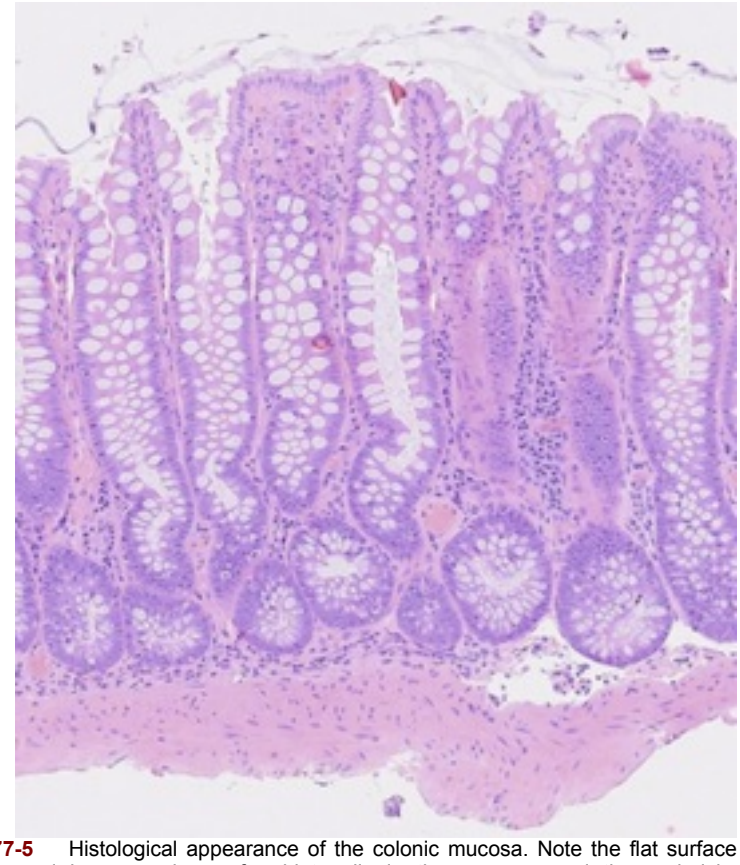

FIGURE 277-5 Histological appearance of the colonic mucosa. Note the flat surface with mucus, deep crypts and large numbers of goblet cells in the mucosa, and the underlying muscularis mucosae. (Image courtesy Michael Day, University of Bristol.)

Epithelium

Numerous straight, tubular crypts (≈500 microns long) are present in the colon, extending through almost the entire thickness of the mucosa. These crypts produce the epithelial, mucus-producing, and endocrine cells. Cells at the base of crypts continually divide and proliferate, migrating to the top of the epithelium as they mature: the cell turnover is slower than in the SI (four to seven compared to three days), but is affected by growth hormone (GH) with GH receptors up-regulated during colonic repair. As colonocytes migrate upwards, they differentiate and mature into epithelial cells, goblet cells, or endocrine cells. Ultimately these cells undergo apoptosis and slough into the lumen.

The flat absorptive surface is lined by a single layer of columnar cells lying on a basement membrane and interspersed with goblet cells (10 to 25 goblet cells per 100 epithelial cells). Goblet cells are important in the LI as they produce mucus that inhibits bacterial invasion as well as lubricating the passage of feces. The endocrine cells secrete somatostatin, polypeptide P, insulin-like growth factors, and glucagon-like peptides. Intraepithelial lymphocytes consist predominantly of the CD8+ T cell subtype.

Lamina Propria

The colonic intraepithelial lymphocytes migrate from the lamina propria (LP), which contains the various components of the mucosal immune system resembling those found in the LP of the SI (see ch. 276), namely mostly lymphocytes and plasma cells, with mast cells, macrophages, eosinophils and neutrophils present in lower numbers. Colonic LP lymphocytes are predominantly CD4+ T cells and IgA-secreting B cells and plasma cells. The overall structure of the mucosal immune system and the gut-associated lymphoid tissue (GALT) is described in more detail in ch. 274 and 276. The other cellular elements of the colonic LP include fibroblasts and enteric neurons which interact with both immune cells and the colonocytes.

Muscularis Mucosae

The innermost layer of the mucosa is separated from the submucosa by the thin layer of the *muscularis mucosae*.

Submucosa

The submucosa of the colon resembles that of the SI: it contains numerous blood and lymph vessels, and dense extracellular matrix sparsely infiltrated by fibroblasts and immune cells, with unmyelinated nerve fibers and ganglion cells forming the submucosal (Meissner's) plexus. The interstitial cells of Cajal are located on the submucosal surface of the circular smooth muscle, and play a dual role as smooth muscle pacemaker cells and as mediators of neuromuscular transmission in the colon. The submucosa is folded, and stretches and flattens when the colon is distended with gas or feces.

Muscularis

The colonic smooth muscle is composed of inner circular and outer longitudinal muscle layers, with the myenteric (Auerbach's) plexus interposed.

Serosa

This layer is composed of mesothelial cells covering the portions of the LI found within the peritoneal cavity. Its serous secretion lubricates and reduces friction caused by intestinal movements.

Function

The interaction of the microflora with colonic immune cells is an important part of the mucosal immune system (see ch. 274). However, the major functions of the colon are (1) the absorption of water and electrolytes from the proximal colon to produce feces of a suitable consistency, and (2) their storage in the distal colon and rectum to allow evacuation at an appropriate time through the coordinated process of defecation.

The LI is not primarily a digestive organ, but microbial fermentation of undigested material occurs within it, with usage by colonocytes of the short chain fatty acids (SCFAs) produced. Curiously, the canine colonic mucosa has also been shown to have the ability to transport amino acids and simple sugars but, except in neonates, it probably has no significant nutritional role compared with SI uptake.[38] However, it may form part of the adaptive mechanism seen in short bowel syndrome.

Absorption and Secretion of Water and Electrolytes[39-49]

The healthy LI has a large absorptive capacity and is able to absorb up to 90 per cent of the water entering the colon in order to produce feces of an acceptable consistency. Indeed it has some reserve capacity that can absorb increased amounts if some SI diarrhea enters the colon, but is overwhelmed if larger volumes of ileal content enter. In LI disease, the colon has a reduced capacity, which also leads to diarrhea.

Water is absorbed by passive osmosis following the active absorption of sodium, which largely occurs in the proximal colon. Absorption of sodium from, and secretion of potassium into the colonic lumen is also moderated by aldosterone and glucocorticoids, which stimulate the activity of the Na^+/K^+-ATPase pump. Sodium uptake is not linked to glucose absorption in the LI, and glucose-containing oral rehydration fluids are of no value in managing diarrhea of colonic origin.

Potassium is absorbed via a K^+/H^+ exchange transporter, but can be actively secreted in the distal colon. These mechanisms complement the control of potassium homeostasis by the kidneys. Chloride absorption follows the electrochemical gradient maintained by active sodium absorption, and by chloride-bicarbonate exchange. The colonic pH is more acidic than the SI, and is maintained by the exchange of sodium and potassium against bicarbonate and chloride: bicarbonate also neutralizes organic acids produced by luminal bacteria.

Mucus[50-55]

Colonic mucus is a mixture of high molecular weight glycoproteins or mucins produced by goblet cells and exfoliated epithelial cells. Mucin secretion is dependent on chloride secretion via the cystic fibrosis transmembrane regulator (CFTR), and exocytosis. Mucus is produced not only as a lubricant, thereby facilitating defecation, but also to protect the mucosa from damage. Pathogens and enterotoxins can be bound by mucus before they reach the epithelium as it acts as a physical barrier, but goblet cells also secrete antibacterial molecules and growth and repair factors, such as trefoil factors. Deficiencies in the mucus layer can predispose to or potentiate intestinal inflammation with increased amounts of mucus secreted in colitis or after parasympathetic stimulation.

Motility[13]

In order to perform its primary functions of water and electrolyte absorption in the proximal colon and the storage and control of defecation in the distal colon and rectum, LI motility and its coordination by the enteric nervous system are complex but crucial. A congenital lack of enteric ganglia in a section of the distal colon and rectum of children causes Hirschsprung disease.[86] The affected section requires surgical resection, but the condition has only ever been described in one cat and never in dogs.[87]

The inherent, spontaneous, contractile ability of normal colonic smooth muscle is influenced by the enteric nervous system and a range of transmitters including cholecystokinin, neurotensin, somatostatin, serotonin and substance P, as well as acetylcholine and epinephrine/norepinephrine from the autonomic nervous system.

There are regional differences in colonic motility patterns to facilitate the differing functions of the proximal and distal colon. In the proximal colon, smooth muscle tone together with electrical slow-wave activity, called rhythmic phasic contractions (RPCs), allow mixing of content and absorption of water. This function is enhanced by retrograde giant contractions (RGCs) initiated in the transverse colon and propagated towards the cecum, causing antiperistalsis. In the distal colon, migrating spike bursts and powerful giant migrating contractions (GMCs) propel the feces towards the rectum and help to expel them.

The sympathetic nervous system acts primarily to restrict progression of contents towards the rectum by inhibiting the activity of the enteric neurons that control motility and by relaxing the non-sphincter muscles and contracting the sphincters. Sympathetic activation also suppresses the secretion of water and electrolytes in the colonic lumen. Thus, sympathetic activity acts to reduce the need to defecate, which is appropriate during a "fight or flight" situation.

The control of defecation is discussed in detail in ch. 278. Briefly, it is a reflex that can be moderated by conscious processes so that in health it occurs at an appropriate time and place. The defecation reflex may be triggered by ingestion of a meal (gastrocolic reflex) as well as distension of the distal colon and rectum. Stimulation of the reflex causes contraction of colonic and rectal smooth muscle, usually commencing with GMCs, and relaxation of the anal sphincter at the same time as the patient adopts the required posture. Voluntary contraction of the anal sphincter can temporarily inhibit defecation, but ultimately the urge may overcome this control. In the diseased LI, the threshold for the urge to defecate is reduced, and so the animal typically defecates after only a small amount of fecal matter has accumulated in the rectum, and it continues to strain unproductively (fecal tenesmus) as it still has the urge although no rectal contents remain to be passed. Difficulty or pain on defecation (dyschezia) is a sign of recto-anal disease (see ch. 42 and 278).

Colonic Microbiome[43,88-106]

The colonic microbiome has essential functions interacting with the mucosal immune system, providing energy for utilization by colonocytes, and synthesizing amino acids and vitamins (see ch. 274). The colon harbors the highest concentration of bacteria in the gut, with up to 10^{12} organisms per gram of feces, representing ≈50% of fecal dry matter. In addition, fungal elements and some protozoa are normally present.

The bacterial species within an individual healthy animal's microbiome is relatively stable, but is influenced by age, breed, geographic locale, housing conditions, coprophagy and diet, and is altered in inflammatory conditions. Each individual animal has a unique bacterial flora, although each tends to have related organisms within each class that occupies a specific ecological niche within the LI. Historically, the composition of the colonic microflora, based on routine culture of feces, was believed to be mainly anaerobic bacteria, with species such as *Bifidobacterium, Bacteroides,* and *Clostridium* dominating, and with few aerobic bacteria, such as lactobacilli, enterobacteriaceae, and streptococci in dogs. Approximately equal numbers of aerobic and anaerobic bacteria were found in cat feces. However, most bacteria in the LI cannot be cultured *in vitro,* and up to 70% could represent unknown species. Using high throughput 16S rRNA gene sequencing, it is now possible to identify almost all bacterial DNA in the feces. Fusobacteriales are most abundant in the colon (≈33% of all identified clones), followed by Bacteroidales (≈30%) and Clostridiales of the cluster XIVa (≈26%). It has been shown that bacterial diversity in the gastrointestinal (GI) tract increases towards the colon in healthy dogs, and is depressed by the administration of antibiotics.

The colonic microflora metabolizes carbohydrates, proteins, and lipids into the SCFAs acetate, propionate, and butyrate, with byproducts of hydrogen, methane, sulfa compounds and carbon dioxide. Fermentable fiber which is not digested by the SI is a major substrate for the bacteria. The SCFAs produced by the bacteria are metabolized by colonocytes and provide an important energy supply to the LI epithelium. SCFAs also promote proliferation and differentiation of colonocytes, stimulate water and electrolyte absorption, and modify colonic motility. In addition, butyrate produced by commensal bacteria can induce anti-inflammatory cytokines such as interleukin (IL)-10.

The normal colonic bacterial microflora has an important function in mediating protection against pathogenic bacteria through a variety of mechanisms including competition for substrates and for mucin binding sites. Chronic intestinal inflammation is linked to alterations in composition of the bacterial population, and feeding of a fiber-free diet has been shown to induce colitis.

Immune Surveillance[7,23,107-112]

The healthy mucosal immune system in the gut evolves to be tolerant of food antigens and commensals, but remains able to respond rapidly to pathogenic microbes. The functional anatomy of the gut-associated lymphoid tissue (GALT) is described in detail in ch. 274 and 276. In the LI, it consists of inductive sites including lymphoid follicles in both the colon and rectum plus the colonic lymph nodes, and effector sites within the LP. So-called microfold (M) cells are particularly abundant in the epithelium overlying the lymphoid follicles in the LI which contain dendritic cells (DCs). The DCs in the LP have the important role of continuously sampling antigens from the lumen by extending dendrites between the epithelial cells, then activating various different immune cells of the adaptive immune system (T cells and B cells) as described in ch. 276. In addition, intestinal epithelial cells can act as non-professional antigen-presenting cells by continuously sampling antigens from the intestinal lumen and presenting them to LP cells through expression of major histocompatibility complex (MHC) II, as well as producing cytokines that will influence immune responses in the LP.

The innate immune system—comprised mainly of epithelial cells, macrophages, and DCs—appears to determine the ensuing immune response. Dysregulation of the balance between tolerance and inflammation can contribute to development of disease. Intestinal epithelial cells also constantly recognize commensals by their binding to toll-like receptors (TLRs). In the presence of commensals, and in normal intestinal homeostasis, a balance between effector and regulatory subpopulations of T cells is maintained through a tightly controlled cytokine network (see ch. 276).

Diagnostic Evaluation

The diagnostic investigation of colonic disease is guided by information obtained from the history and physical examination, absence of any signs of systemic illness, and whether the disease is acute or chronic or has occurred previously as this affects the differential diagnosis list (see Box 277-2). Logical diagnostic approaches to large bowel diarrhea, hematochezia and constipation are shown in Figure 277-6.

Box 277-2

Differential Diagnoses to Consider in Cats with Chronic Constipation[50]

Neuromuscular Dysfunction

Colonic smooth muscle: idiopathic megacolon, aging
Spinal cord disease: lumbosacral disease, cauda equina syndrome, sacral spinal cord deformities (Manx cat)
Hypogastric or pelvic nerve disorders: traumatic injury, malignancy, dysautonomia
Submucosal or myenteric plexus neuropathy: dysautonomia, aging

Mechanical Obstruction

Intraluminal: foreign material, neoplasia, rectal diverticula, perineal hernia, anorectal strictures
Intramural: neoplasia
Extraluminal: pelvic fractures, neoplasia

Inflammation

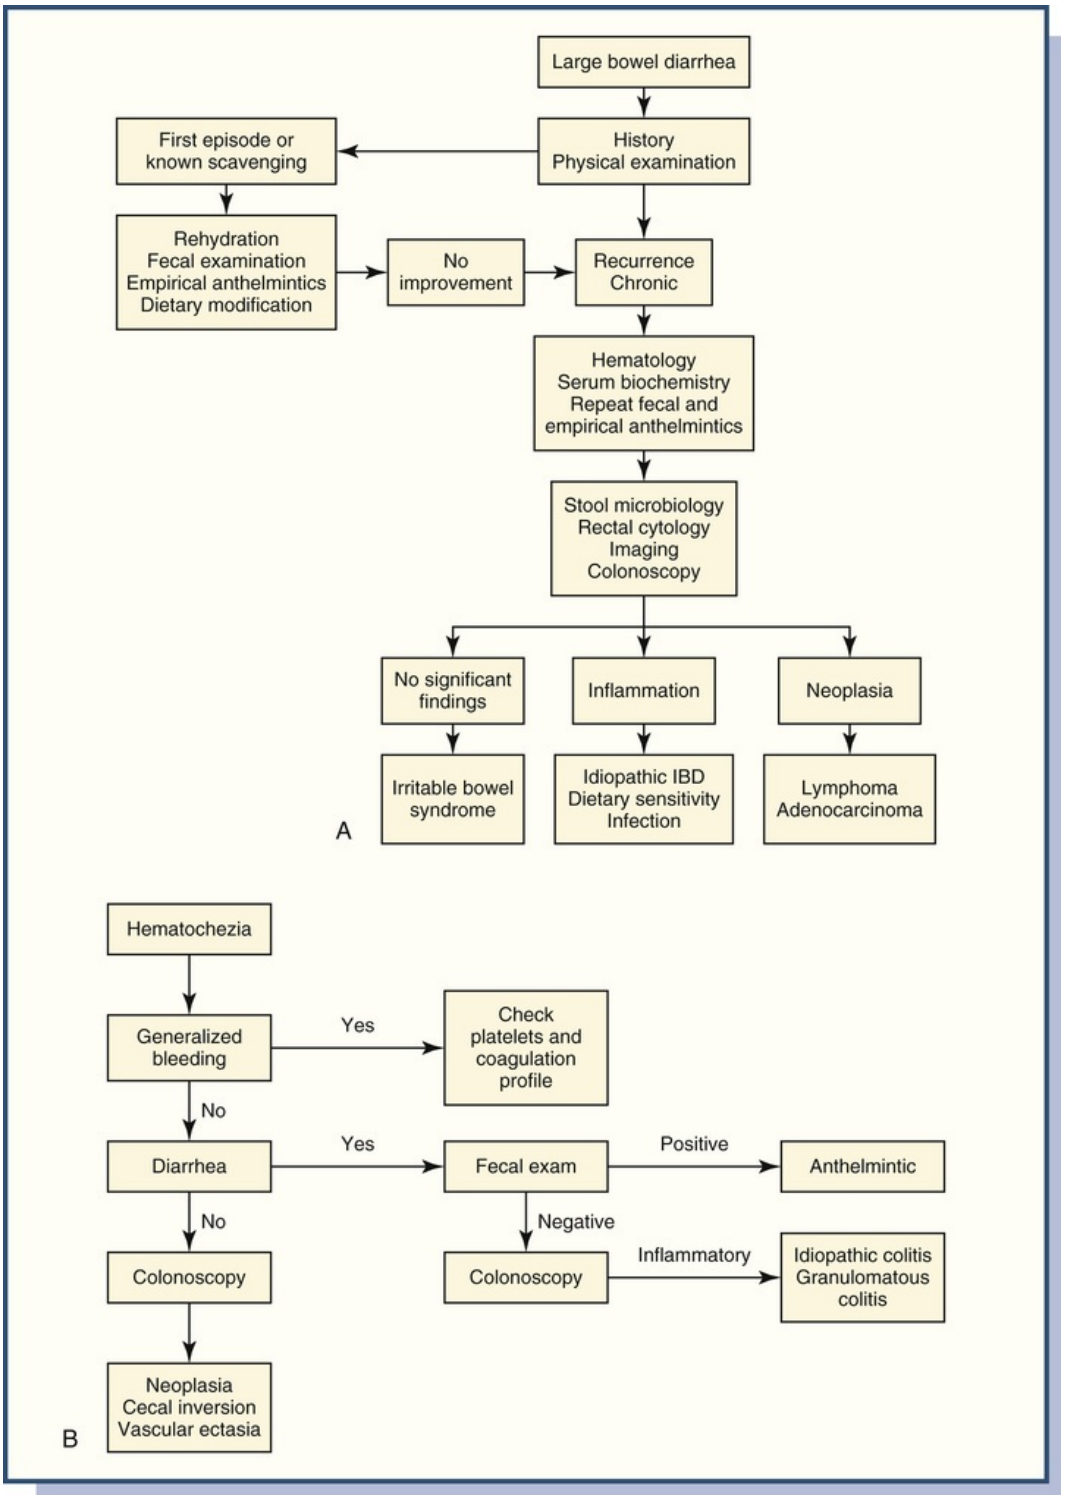
Perianal fistula, proctitis, anal sac abscess, anorectal foreign bodies, perianal bite wounds

Metabolic and Endocrine

Metabolic: dehydration, hypokalemia, hypercalcemia
Endocrine: hypothyroidism, obesity, nutritional secondary hyperparathyroidism

Environmental and Behavioral

Soiled litter box, inactivity, hospitalization, change in environment



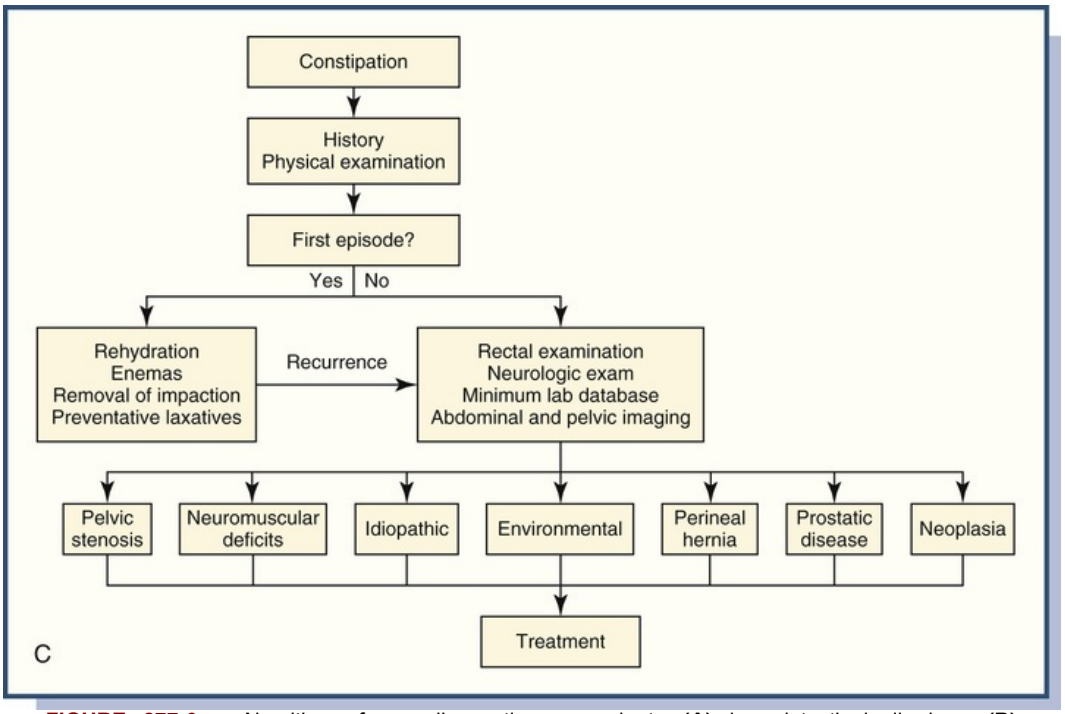


FIGURE 277-6 Algorithms for a diagnostic approach to **(A)** large-intestinal diarrhea, **(B)** hematochezia, and **(C)** constipation. *IBD*, Inflammatory bowel disease.

History

Dogs and cats with LI disease are usually presented for diarrhea, constipation, and/or hematochezia. Standard questions include those about the animal's diet, environment, travel history, vaccination, parasiticide treatments, concurrent medical diseases and any problems in in-contact animals. Weight loss is not a feature of LI disease except with advanced neoplastic conditions, or when the owner tries to control diarrhea by restricting food intake.

The owner should be specifically questioned about the pet's fecal consistency and character, and the frequency of defecation. Some historical findings, such as the presence of mucus in the feces (Figure 277-7), urgency, increased frequency, with or without hematochezia, and tenesmus after defecation are typical of LI diarrhea (Table 277-1). The presence of hematochezia indicates LI ulceration, and once a generalized bleeding problem has been ruled out, is suggestive of severe inflammation, *Ancylostoma* hookworm and *Trichuris* whipworm infection, intussusception or neoplasia.

FIGURE 277-7 Hematochezia. **A,** Fecal material from a dog with severe colitis. Note the fresh blood and mucus, passed in multiple small volumes suggesting increased frequency and tenesmus. **B,** Hematochezia in a dog with severe colitis.

TABLE 277-1

Clinical Signs Associated with Large Bowel Diarrhea

SIGNS	FREQUENCY
Weight loss	Uncommon
Vomiting	Uncommon
Flatulence	Unusual
Defecation frequency	Marked increased in frequency
Fecal volume	Normal to mild decrease
Urgency	Usually present
Tenesmus	Usually present
Mucus in feces	Frequently present
Hematochezia	Often present
Abnormal stool color (e.g., green)	Rare
Melena	Absent
Steatorrhea	Absent

Constipation refers to reduced or absent defecation for several days to weeks. Sequelae include dehydration, weight loss, abdominal pain, and mild to moderate mesenteric lymphadenopathy. Tenesmus is also seen in constipation, but typically no feces are produced. However, occasionally the owner may report that the pet produces a few drops of fecal liquid that they may mistake for diarrhea, as secretions ooze past the impacted feces. Environmental factors (e.g., hospitalization, dirty cat litter) and dehydration which may predispose to constipation may be determined during history taking.

Clinical scoring schemes (the Canine and Feline Inflammatory Bowel Disease Activity Indices [CIBDAI, FIBDAI] and Canine Chronic Enteropathy Clinical Activity Index (CCECAI) and Feline Chronic Enteropathy Activity Index (FCEAI) have been published in an attempt to correlate clinical signs to disease outcomes.[113-115] Such scoring makes monitoring before and after treatment more objective and allows for comparisons of clinical severity between studies (see ch. 276). Young dogs with mild severity scores for colitis have been shown to respond well to elimination diets alone and have the best outcomes.

Physical Examination

Routine physical examination of dogs and cats with LI diarrhea may reveal no abnormalities. Attention should be given to findings such as pyrexia (cecal or colonic perforation, fungal infections) or uveitis (protothecosis, lymphoma, feline infectious peritonitis). Careful abdominal palpation is required to identify abdominal pain (colitis, colonic neoplasia, perforation), abdominal masses (colonic neoplasia, granulomatous colitis, ceco-colic or ileo-colic intussusception), SI thickening (concurrent SI inflammation or lymphoma), mesenteric lymphadenopathy (colitis, lymphoma, disseminated fungal diseases), and hepatosplenomegaly (lymphoma, disseminated fungal diseases).

Constipation is the second most common sign in patients presenting with underlying colonic disease, and is usually obvious on abdominal palpation or rectal examination. Although environmental factors may predispose to constipation, emphasis should be placed on finding underlying causes such as abdominal masses (neoplasia, prostatomegaly), abdominal pain (foreign bodies, colonic perforation), painful defecation (anal furunculosis/perianal fistulae, anal sac abscessation), autonomic neuropathy (dysautonomia), hindlimb paresis (spinal cord lesions), pelvic fractures, and perineal hernias.

In all cases of suspected LI disease, a digital rectal examination is mandatory, although this may require general anesthesia in cats and very small dogs. Recto-anal lesions such as anal sac abnormalities, perineal hernia, strictures, and rectal polyps and other rectal neoplasms should be palpable, and prostatic disease can be simultaneously evaluated as a cause of constipation (see ch. 111 and 337). Palpable irregularities of the colonic mucosa are suggestive of inflammatory or neoplastic infiltrations. At the end of the examination, rectal cytology can be performed by smearing the gloved finger on a microscope slide and staining with Diff-Quik or Wright's stain. A fecal sample can also be collected, and previously unrecognized diarrhea or hematochezia identified.

Laboratory Investigations[116,117]

Minimum Database

Routine laboratory analyses that include a complete blood count (CBC, serum biochemistry profile, and urinalysis are indicated in most cases of chronic colonic disease, but may be unnecessary in mild, acute disease. There are no pathognomonic hematologic or serum biochemical changes in patients with LI disease, but abnormal results can provide diagnostic clues. Abnormalities associated with colonic signs and their potential differential diagnoses are listed in Table 277-2.

TABLE 277-2

Abnormalities Associated with Colonic Disease and Their Potential Causes

FINDING	POTENTIAL CAUSE
Mild to moderate non-regenerative anemia	Chronic disease
Regenerative anemia (hypochromic, microcytic iron-deficiency if chronic bleeding)	Blood loss • Hookworms and whipworms • Intussusception and cecal inversion • Colitis • Neoplasia • Vascular ectasia
Leukocytosis	• Inflammation • Infection • Neoplasia
Eosinophilia	• Parasitism • Hypoadrenocorticism • Mast cell tumor • Hypereosinophilic syndrome • Paraneoplastic (lymphoma, anal sac adenocarcinoma, etc.)
Hypoalbuminemia	• Bleeding • Negative acute phase reaction • Concurrent protein-losing enteropathy
Hyperglobulinemia	• Feline infectious peritonitis • Intestinal inflammation • Neoplasia
Hypercalcemia	• Neoplasia • Fungal granulomas • *Heterobilharzia* infection
Hypoglycemia	• Leiomyosarcoma • GI stromal tumor (GIST) • Large abdominal tumor
Hyponatremia and concurrent hyperkalemia	• Hypoadrenocorticism • Salmonellosis • *Trichuris* infection

There are no pathognomonic laboratory changes in patients with colonic disease, but abnormal results can provide diagnostic clues.

Additional Laboratory Tests

Even in the absence of signs typical of SI disease, serum cobalamin and folate concentrations should be measured in animals with presumed colonic disease (see ch. 276). Low serum cobalamin concentrations indicate disease affecting the distal SI, even when the clinical presentation is more typical of colitis: indeed, persistent SI diarrhea could be the cause of colonic inflammation. Ileal biopsies, obtained via colonoscopy (see ch. 113), are indicated if serum cobalamin is abnormal.

Extension of pancreatic inflammation can also cause inflammation of the adjacent regions of the colon and signs of colitis. Thus, pancreatic lipase immunoreactivity (PLI) measurement may be indicated if there is any

suspicion of pancreatitis (see ch. 290 and 291). Similarly, depending on the index of suspicion, serologic tests for fungal disease could be indicated (see ch. 233 and 236).

In cats with chronic colitis or constipation, feline leukemia virus (FeLV; see ch. 223) and FIV (see ch. 222) testing should be performed, and serum thyroxine measured if there is diarrhea in an older cat (see ch. 301).

Fecal Examination[118-128]

Fecal parasitology (see ch. 81), including direct smears and zinc sulfate flotation, should be completed in all animals before colonoscopy, and empirical administration of broad-spectrum parasiticides may also be trialled first, especially in areas where *Trichuris* infection is endemic. Although primarily a SI parasite, *Giardia* organisms may also be involved in colitis and can be identified, not only by fecal flotation, but by an immunochromatographic test (Witness, SNAP) or by immunofluorescent staining (see ch. 221).

There are several methods for detecting *Tritrichomonas* infection in cats.[129,130] Infection may be identified in a fresh fecal sample: a drop of fresh diarrhea is mixed with a drop of warm saline on a slide, cover-slipped and examined under the ×40 microscope objective. Progressively motile trophozoites may be observed, but the test is quite insensitive. More sensitive are the InPouch culture system or polymerase chain reaction (PCR), for which a diarrheic sample is required, and for which a high colonic flush may be performed. Contamination of the sample with cat litter should be avoided as it may inhibit the PCR reaction.

Fecal bacterial culture is generally performed in dogs and cats with chronic colitis.[119,131-136] Colonic inflammation may be associated with infection by *Campylobacter* spp., *Clostridium perfringens* and *C. difficile*, *Salmonella* spp., and possibly *Yersinia* spp. However, these organisms can also be found in the stool of healthy animals, positive cultures must be interpreted in light of other clinical findings, and sometimes trial therapy will more effectively identify such infections. PCRs for a number of these organisms are now available and may be more sensitive as they do not require live organisms to be present, especially as *Campylobacter* spp. are quite fragile and soon die in *ex vivo* samples.

Quantitative culture of bacteria from the colon is not recommended, as the number of cultivable bacterial species in the colon is estimated to encompass only about 30% of the total microbiome. There is little information available on the specific microbiome abnormalities in the colon of dogs and cats with colitis, but it is likely that composition will be altered specifically for different diseases, as has been shown to be the case in humans with Crohn's disease or colonic cancer, and cats with inflammatory bowel disease (IBD).[137]

Cytology[138,139]

Cytology can be performed after digital rectal examination, by using a gloved finger or a cotton-tipped applicator to wipe the rectum, or by using cytology brushes endoscopically during colonoscopy (E-Figure 277-8). Typically, bacteria and debris predominate, but occasionally causative agents can be identified including fungal elements, neoplastic cells, or inflammatory cells such as lymphocytes, eosinophils, or neutrophils (Figure 277-9 and E-Figure 277-10).

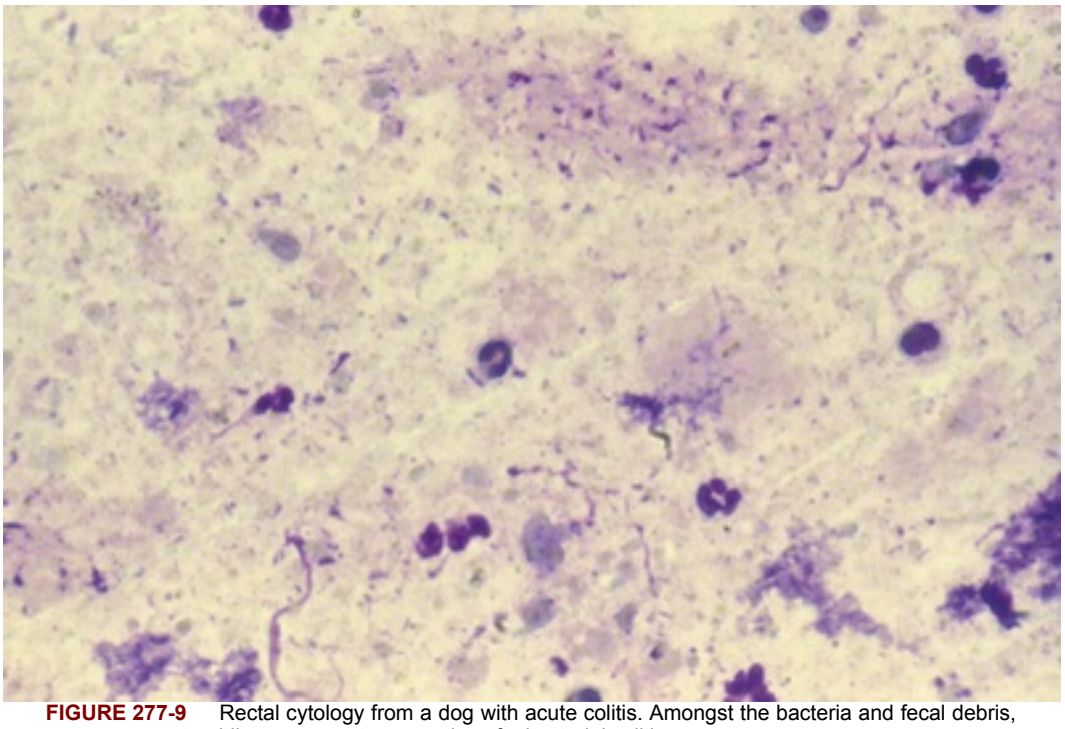

FIGURE 277-9 Rectal cytology from a dog with acute colitis. Amongst the bacteria and fecal debris, numerous neutrophils are present, suggestive of a bacterial colitis.

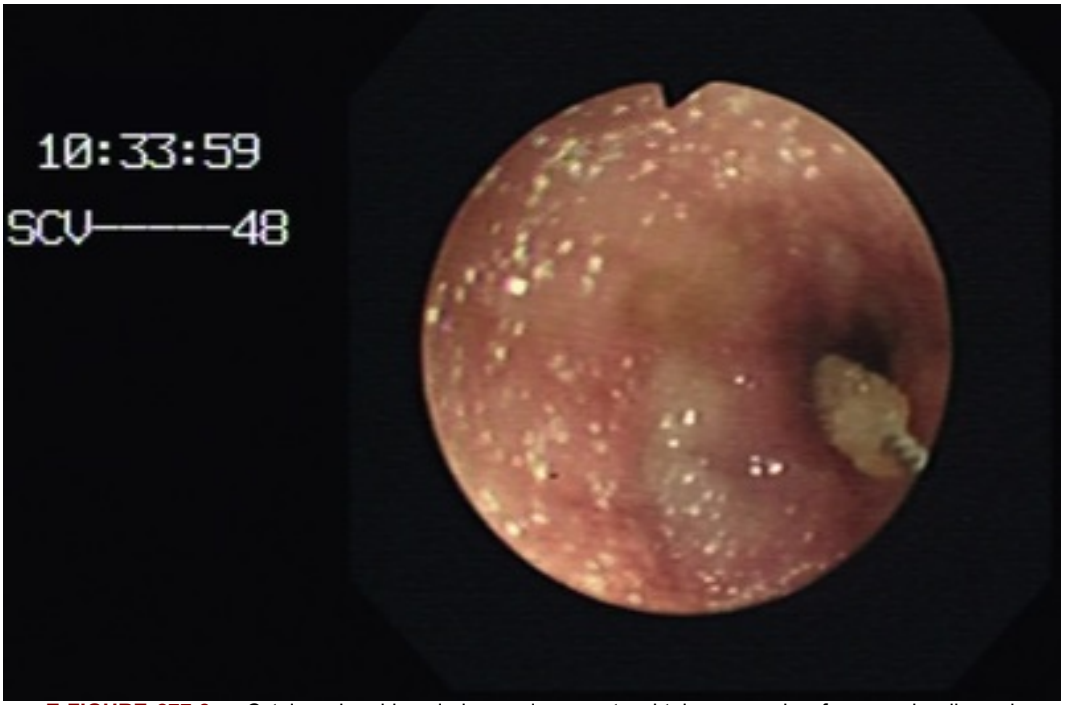
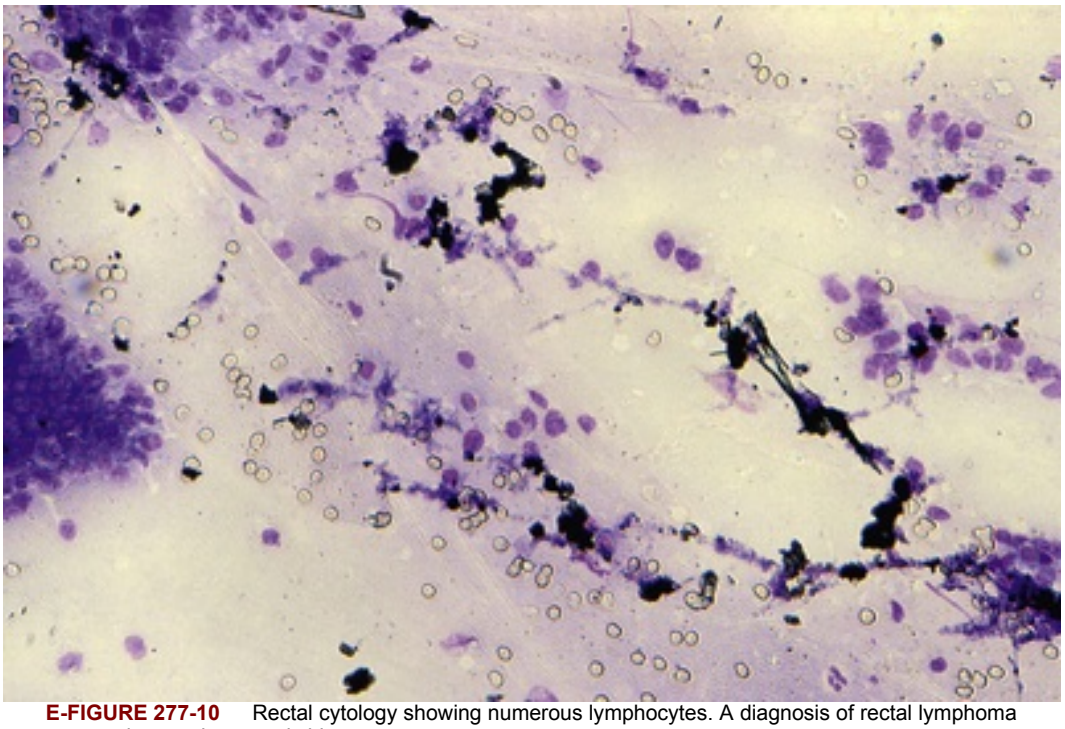


E-FIGURE 277-8 Cytology brushing during endoscopy to obtain a sample of mucosal cells and adherent bacteria.



E-FIGURE 277-10 Rectal cytology showing numerous lymphocytes. A diagnosis of rectal lymphoma was made on colonoscopic biopsy.

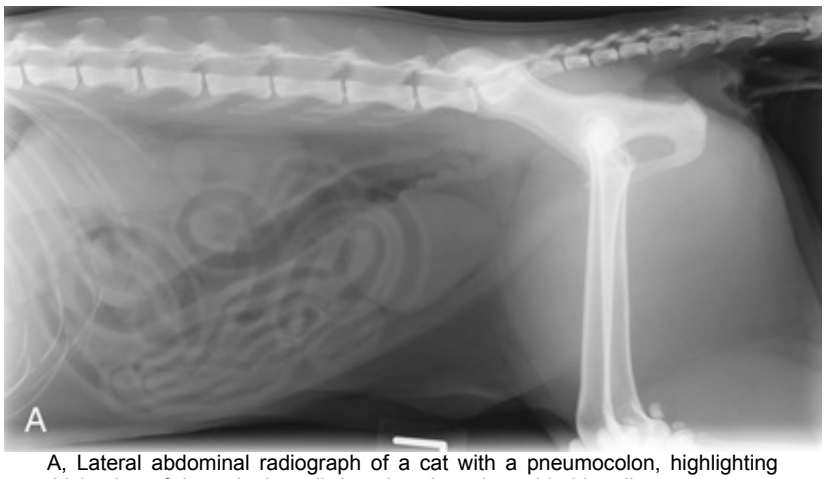
Imaging

Plain lateral and ventrodorsal radiographs of the abdomen and pelvic region can be useful in patients with hematochezia, dyschezia or suspected constipation, potentially identifying obstructions and megacolon, and confirming constipation; they are less likely to be helpful in patients with LI diarrhea, whereas ultrasonography may be more useful.

Radiography[140-144]

Survey radiographs may identify radiopaque foreign bodies, fecal impaction and extra-luminal causes of obstruction such as pelvic canal stenosis or prostatomegaly. Discrete masses in the colon are only likely to be detected if there is luminal gas to highlight them but sublumbar lymphadenopathy may give a clue to metastatic disease.

Sometimes it may be difficult to differentiate between gas-filled SI and colon and therefore to detect a SI obstruction. A negative contrast colonogram, insufflating with air when the colon is empty, may help in determining which structure on the radiograph is the colon, as well as potentially highlighting colonic wall thickening and masses (Figure 277-11). Thus a pneumocolonogram can be helpful, although it may preclude performing ultrasonography immediately afterwards because the gas interferes with the ultrasound. Colonic torsion is rare but may be identified radiographically by gaseous distension and displacement of the colon within the abdomen.[145-149]



A, Lateral abdominal radiograph of a cat with a pneumocolon, highlighting thickening of the colonic wall dorsal to the urinary bladder. (Image courtesy Virginie Barberet, University of Bristol.)

B, Lateral abdominal radiograph of a dog with a colonic adenomatous polyp in the pelvic region. The mass has been visualized by insufflation of the colon with air before taking the radiograph.

FIGURE 277-11

Pneumatosis coli, a form of *pneumatosis cystoides intestinalis,* is a very rare manifestation of colonic disease in live animals, although a recognized feature in post-mortem specimens following putrefaction. Free gas is visualized within the colonic wall below the submucosa or serosa. It can be associated with colitis or colonic neoplasia, or may be idiopathic and resolve spontaneously.[150-155]

Radiographs taken after a positive contrast follow-through study will eventually show barium in the colon and lesions may occasionally be identified (Figure 277-12). However, filling is often incomplete, and a barium enema is more likely to show problems such as intussusception, cecal inversion, and stricture. However, barium enemas, and especially double contrast studies,[144] are rarely performed nowadays unless

colonoscopy is unavailable. Positive contrast studies are unpleasant to perform, and prone to artifact as retained feces may mimic a filling defect caused by mass, also the normal narrowing of the colon at the pelvic brim is sometimes misinterpreted as a stricture.

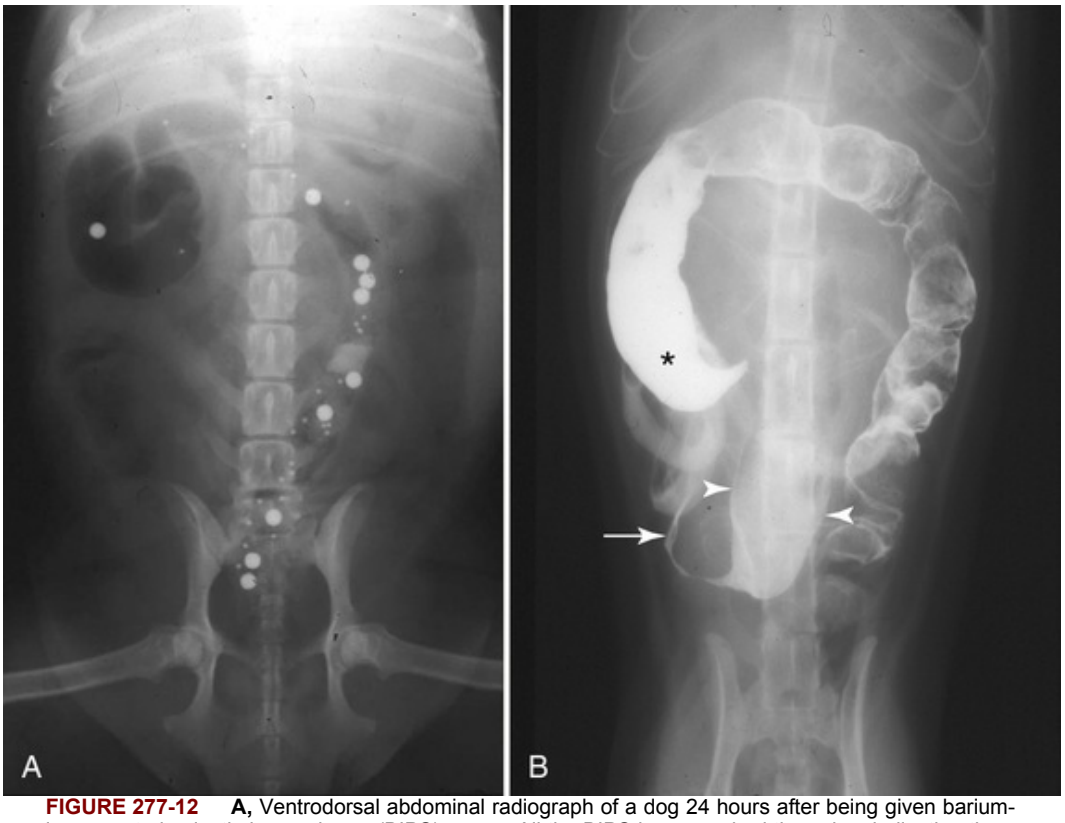


FIGURE 277-12 **A,** Ventrodorsal abdominal radiograph of a dog 24 hours after being given barium-impregnated polyethylene spheres (BIPS) *per os*. All the BIPS have reached the colon, indicating there are no partial obstructions preventing their passage. Gas fills the coiled cecum and proximal colon; fecal material is present in the distal colon. **B,** Ventrodorsal abdominal radiograph of a Siamese cat 24 hours after the oral administration of barium suspension. Barium fills the pointed cecum and the colon (asterisk), but a dilated small intestinal loop (arrowheads) is seen connected to the proximal colon by a thin streak of barium (arrow). This "apple core" sign is consistent with an ileal mass, and a carcinoma was confirmed at surgery.

Advanced imaging of the LI is possible,[156-159] and is especially useful for imaging the LI within the pelvic canal. "Virtual endoscopy" using helical CT has been developed in humans to identify colonic polyps and carcinomas, although it may not be as sensitive as colonoscopy.

Ultrasonography[143,160-169]

Using abdominal ultrasound, the ileum, ileocecal junction, cecum, and ascending, transverse, and descending colon can all potentially be identified (see ch. 88). A perineal approach is indicated if abnormalities are suspected in the intrapelvic LI.

If distended, a normal colon should have three layers and a thickness of ≤2 mm. An undistended colon may give an appearance of wall thickening, but the presence of air in the lumen can make it difficult to assess the whole organ. In colitis, there are often no radiographic or ultrasonographic findings or just diffuse thickening of the mucosa; focal infiltration and intramural masses are more suggestive of LI neoplasia.

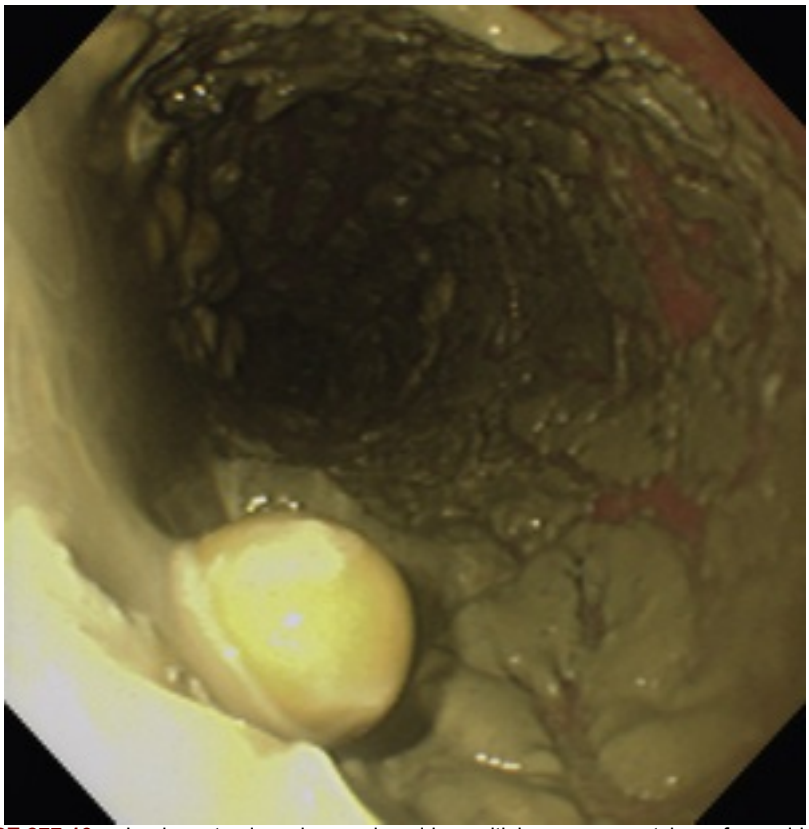
Colonoscopy[170]

Colonoscopy is indicated in patients with LI diarrhea and/or hematochezia, and occasionally in constipated patients after the LI has been emptied (see ch. 113). Hollow rigid endoscopes can be used to view the rectum and descending colon, but the view is limited, and the proximal colon cannot be examined. Flexible endoscopy is the method of choice for visualizing the entire colon and for obtaining mucosal biopsies. Concurrent ileoscopy is recommended unless a significant lesion that explains all of the clinical signs is found

in the LI. Surgery to obtain full-thickness colonic biopsies is not recommended because of the risks of wound dehiscence and septic peritonitis.

Preparation[171-175]

Successful colonoscopy depends on adequate cleansing of the colon (E-Figure 277-13). Dogs and cats should ideally be fasted for 36 to 48 hours before the procedure, and if multiple enemas are to be used, then large volume (each 30 mL/kg), high enemas are needed to provide adequate cleansing. Warm water alone is used for enemas and can be delivered using either an enema bucket or a Higginson pump (see ch. 114). Soap or laxatives, often used in managing constipated patients, should be avoided when preparing the patient for colonoscopy as they may induce histological changes in the colonic mucosa. Phosphate enemas may cause potentially fatal hyperphosphatemia in cats and small dogs.



E-FIGURE 277-13 Inadequate cleansing produced by multiple enemas; patches of mucoid diarrhea are stuck to the colonic surface, obscuring the view.

The most thorough cleansing is produced by the administration of an oral lavage solution which is a potent osmotic laxative. Polyethylene glycol (PEG) solutions, made isotonic with added electrolytes, are preferred (e.g., Colyte R, Golytely, and Klean-Prep). As these solutions have an unpleasant, soapy taste or have fruit flavoring added for human palatability, only a very few canine patients will drink them voluntarily. They, therefore, have to be administered by stomach tube in dogs or by naso-esophageal tube in cats the day before the procedure (see ch. 112). Instillation into the airways must be avoided as fatal inhalation pneumonia has been recorded. A large volume (25 to 30 mL/kg PO twice and preferably three times) has to be administered approximately 2 hours apart. Smaller volume, oral, osmotic laxatives, such as sodium phosphate, have been shown to produce poorer cleansing, and may induce abdominal cramping and vomiting. Warm water enemas are then administered the next day before the procedure, or whilst the animal is under anesthesia, until the LI is clean.

Examination

A complete colonoscopic examination includes visualization of the entire colon up to the ileocolic junction (Video 277-1 and ch. 113). Whenever possible, the cecum and ileum should be examined and biopsied as

well. The patient is positioned in left lateral recumbency, to allow insufflation of the proximal colon. After suctioning and washing out any remaining fecal material, the endoscope is advanced around the flexures until the ileocolic papilla is identified. In large dogs, the endoscope can also be retroflexed to allow better examination of the rectum (Figure 277-14, *A*) as it often fails to remain inflated during flexible endoscopy because air leaks through the anus even if an assistant tries to clamp it shut. Indeed, rigid endoscopy with a proctoscope is a better method for examining the rectal mucosa.

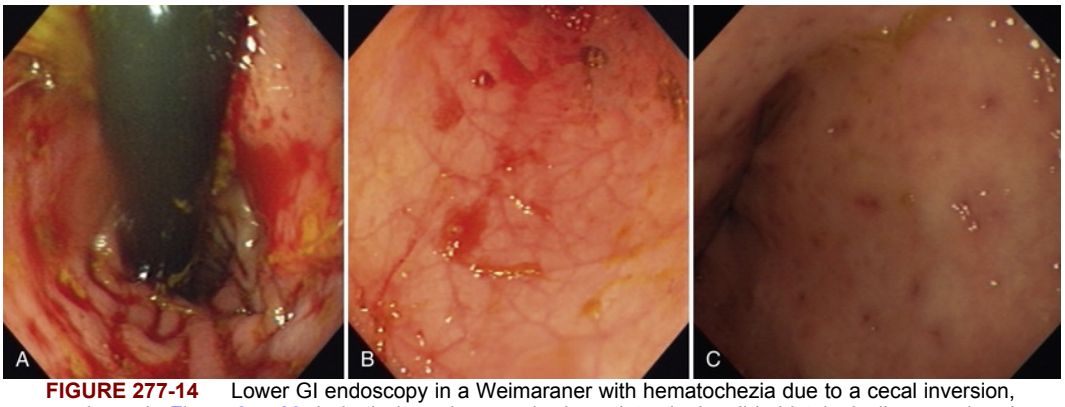


FIGURE 277-14 Lower GI endoscopy in a Weimaraner with hematochezia due to a cecal inversion, as shown in Figure 277-23. In both these images the large intestinal wall is histologically normal and the presence of luminal blood is due to bleeding from the more proximal cecal inversion. **A,** Retroflexed view of distal colon and rectum. **B,** Normal transverse colon, showing submucosal vessels. **C,** Multiple lymphoid follicles visible in the rectal mucosa of a German Shepherd.

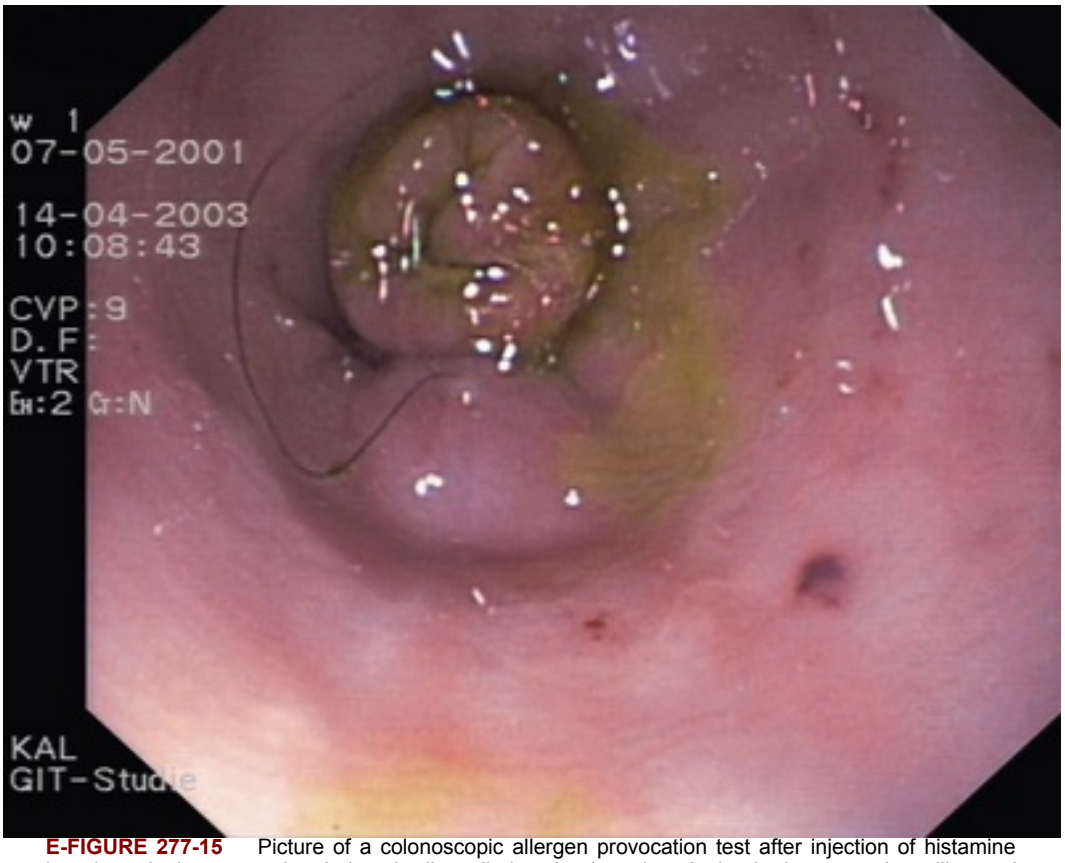
The normal colonic mucosa should appear pink, smooth, and glistening, and the submucosal vessels should be visible (Figure 277-14, *B*); loss of visualisation of the submucosal vessels suggests the mucosa is infiltrated and thickened, but biopsies are needed for confirmation. In the rectum, multiple small dark spots in the mucosa are lymphoid follicles (Figure 277-14, *C*).

Biopsies should be taken from diseased, normal appearing and transitional zone areas for histologic examination. If all the mucosa appears normal, six to eight biopsies from the descending, transverse, and ascending colon each should still be collected. The number and quality of biopsies taken during endoscopy are crucial to obtain an accurate histologic diagnosis. In addition, using the largest possible biopsy forceps (≥2.8 mm diameter) and using disposable biopsy forceps can help in obtaining the best quality endoscopic biopsies.

Other Endoscopic Techniques[176-178]

As well as being used to make a histologic diagnosis, colonoscopy can also be used both for advanced diagnostic testing and therapeutically (e.g., polypectomy, stricture dilatation), although these are rare indications in dogs and cats. If electrosurgery is performed to remove polyps, the colon should be insufflated with carbon dioxide to avoid a potentially explosive mixture of gases.

The colonoscopic allergen provocation (COLAP) test has been developed to identify antigens associated with food allergy or food intolerance, and has been used successfully in dogs but not cats.[179] Briefly, a sheathed sclerotherapy needle is advanced through the colonoscope, and antigen solutions, histamine (positive control) or saline (negative control) are injected into the colonic mucosa in a clock-face pattern around the ileocolic junction. A positive reaction is a demarcated swelling with edema, and hyperemia at the injection site 1 to 2 minutes after injection of the antigen (E-Figure 277-15). Thus, this reaction can be assessed directly on the colonic mucosa more easily than via gastroscopic food sensitivity testing.[180,181] However, false positives and negatives are possible, and COLAP does not appear to work in cats. Furthermore, the COLAP test is only helpful if the clinical signs in food-allergic dogs are caused by an immediate type I hypersensitivity reaction. Therefore, COLAP testing is very rarely used, even in tertiary referral centers.



E-FIGURE 277-15 Picture of a colonoscopic allergen provocation test after injection of histamine into the colonic mucosa just below the ileocolic junction in a dog. A clearly demarcated swelling and hyperemia can be seen.

Inflammatory Diseases

Inflammation of the LI is generally diffuse and simply termed *colitis*, but inflammation of specific regions is identified by the specific names of *typhlitis* (cecum), *colitis* (colon) and *proctitis* (rectum). Isolated typhlitis has been seen in association with impaction and fecolith formation.[182] Whipworm infection is much more common, although more often associated with generalized LI inflammation. Colitis is seen more frequently in dogs compared to cats, and may be acute or chronic.

Acute Colitis[183,184]

Acute colitis is, by definition, sudden in onset and is usually self-limiting. The condition is usually diagnosed on the basis of the characteristic clinical signs of mucoid diarrhea, hematochezia due to the inflammation and increased frequency and tenesmus due to altered colonic motility (see Figure 277-7). Often the cause is never identified, but there are many potential infectious causes (bacteria, protozoa, helminths), and known infectious causes of acute colitis are described later.

Acute colitis in dogs often follows dietary indiscretion although the exact cause is rarely identified. Carrageenan is a mucopolysaccharide extracted from seaweed added to some cat foods to form gels and is an ingredient of many processed human foodstuffs, and it has been suggested to be a cause of acute colitis in dogs stealing cat food. It may damage colonocytes and has been associated with colonic ulceration and neoplasia in rodent models. Traumatic colitis is caused by the inappropriate ingestion of bones, sand or sharp indigestible particles from so-called indestructible nylon bones and toys.

Management of acute colitis is largely supportive and nonspecific, as most cases are self-limiting. Withholding food temporarily and dietary modification (low fat, highly digestible diets) may be all that is required. Kaolin-based antidiarrheals may bind bacterial toxins and produce firmer stool. Diphenoxylate or loperamide can reduce the tenesmus that the patient and owner find most distressing. Antibiotics seem rarely indicated, but empirical treatment with metronidazole is often reported to be effective; a fashion for using trimethoprim-sulfa to treat colitis has thankfully passed. Yet reports of successful treatment with

metronidazole are rarely controlled studies, and it may be that the administration of probiotics or a placebo would be equally effective. Acute colitis that fails to respond becomes chronic colitis.

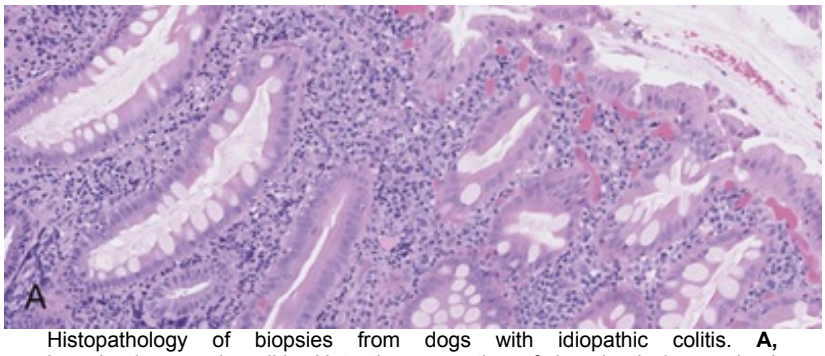
Idiopathic Chronic Colitis

Definition[185-191]

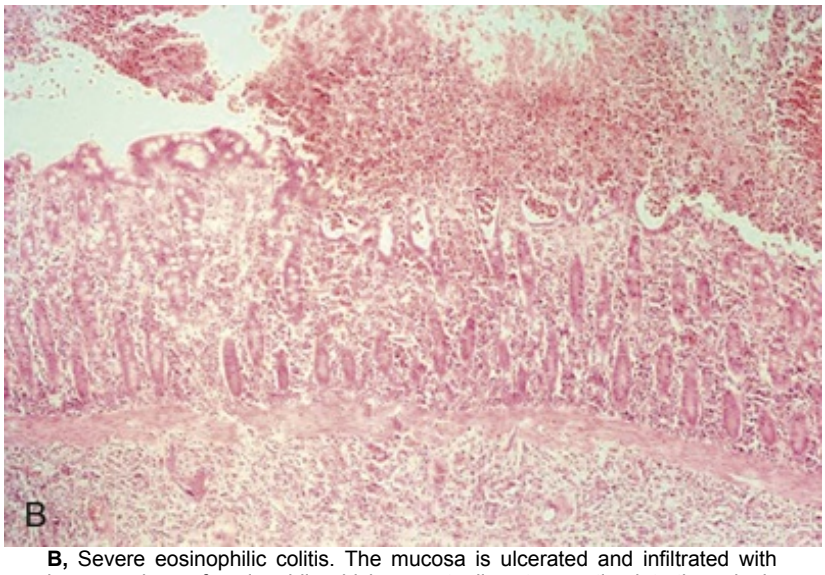
Idiopathic inflammatory bowel disease (IBD) is a disorder affecting the GI tract of dogs and cats where no cause for the inflammation can be identified. It can be classified on the basis of the region of the GI tract affected, and on clinical and histopathological criteria. Clinically, IBD is diagnosed in animals with chronic (>3 weeks in duration) GI signs including anorexia, vomiting, diarrhea and weight loss for which no other known cause can be identified.

If the colon is involved in IBD, the major sign is diarrhea, and typically with mucus, hematochezia, urgency, frequency and tenesmus. Affected animals fail to respond to symptomatic treatment with diet, parasiticides, or antibiotics.

In addition to this empirical elimination process, the histopathologic evaluation of the intestinal biopsies allows classification based on the type of inflammatory cell infiltrating the mucosa (Figure 277-16): such cells found in the colonic mucosa include lymphocytes and/or plasma cells (lymphocytic-plasmacytic colitis), eosinophils (eosinophilic colitis), neutrophils (neutrophilic or suppurative colitis), or macrophages (granulomatous colitis); or more often a combination thereof, but with one predominant cell type. Little is known as to why the predominant cell type differs in the lymphoplasmacytic and eosinophilic forms of colitis but it is often suggested, with little evidence, that eosinophilic disease is more likely a result of an immune reaction to food antigens. Differences in response of the histologic types to treatment are also poorly documented. Neutrophilic GI inflammation is often assumed to reflect a bacterial cause, and campylobacters are known to attract neutrophils, and so antibiotics are usually prescribed before immunosuppression.



Histopathology of biopsies from dogs with idiopathic colitis. **A,** Lymphoplasmacytic colitis. Note the separation of the glands by a mixed population of inflammatory cells, in which the predominant cells are lymphocytes and plasma cells. (Image courtesy Michael Day, University of Bristol.)



B, Severe eosinophilic colitis. The mucosa is ulcerated and infiltrated with large numbers of eosinophils which are actually extravasating into the colonic lumen. (Image courtesy Geoff Pearson, University of Bristol.)

FIGURE 277-16

The inflammatory process may affect the entire GI tract (gastro-entero-colitis), but can involve solely the colon (colitis), when the suggestion is that the prognosis is better. Idiopathic colitis is discussed here, but the whole spectrum of IBD is discussed in detail in ch. 276.

Pathophysiology and Mechanisms of Disease[192-203]

In people, IBD encompasses two main disorders: Crohn's disease is characterized by a transmural granulomatous or pyogranulomatous inflammation and can occur anywhere in the GI tract although is usually centered on the ileum; ulcerative colitis (UC) is restricted to the colon and is characterized by a more superficial, neutrophilic inflammation restricted to the mucosa. The exact pathogenesis of IBD in small animals has not been elucidated, but studies of human IBD and mouse models of colitis have led to the current hypothesis that there is a loss of immune tolerance to luminal bacteria and/or food antigens leading to an inflammatory response.

Recent studies performed in dogs and cats suggest a similar molecular pathogenetic process, potentially including a defective mucosal barrier, an abnormal immune system, and changes in the microbiome. Genetic predispositions to, and mechanisms involved in intestinal inflammation are discussed in detail in ch. 276, and are not repeated here as, at present, there is no evidence that there are significant differences between SI and LI IBD. Indeed, most IBD is either diffuse, involving both regions, or limited to the SI; in the author's experience isolated idiopathic colitis is unusual. Previous reports of colitis may not have recognized SI involvement because of the predominance of colitis-like signs and therefore failure to biopsy the SI. However, why there may be variations in the regional distribution of the inflammation, and whether the SI and LI forms have different etiologies, are unknown.

Immune Responses[204]

Several studies performed in dogs and cats have investigated the inflammatory process associated with colitis. Early studies focused on the description of the predominant inflammatory cell types found, and both T lymphocytes and B lymphocytes, as well as IgG-positive plasma cells, appear to be increased in the inflamed colonic mucosa of dogs with IBD. More recently, using quantitative reverse-transcriptase PCR (qRT-PCR), cytokine mRNA expression has been evaluated in colonic mucosal biopsies. In human IBD, Crohn's disease (Th1 and Th17) and UC (Th2) show distinct cytokine profiles, but results regarding the nature of the specific cytokine pattern seen in dogs with IBD are conflicting. In one study, the prevailing cytokine mRNA expression pattern in dogs was that of a Th1 immune response. However, the accuracy of these results has since been questioned: for example, the more reliable qRT-PCR showed a lack of difference in duodenal mucosal cytokine mRNA expression comparing healthy and diseased dogs. Colonic cytokine mRNA expression has not been re-investigated using qRT-PCR, and it is prudent not to overinterpret results from the

initial study. Cytokines of the IL-17 type may be important in canine and feline IBD, and were not investigated originally. No published data regarding cytokine expression in cats with colitis exist.

Effects of Inflammation on Colonic Function[205-207]

As described earlier, the main functions of the colon are the absorption of water and electrolytes (proximal colon) and storage of feces (distal colon). Colonic inflammation can disrupt these functions in many ways. Colitis may decrease the total absorptive capacity of the mucosa through loss of functional colonocytes, increased permeability, and disturbance of sodium and chloride transport. Additionally, colitis has direct effects on colonic motility, decreasing non-propulsive motility, explained by disturbances of the circular colonic smooth-muscle cells, and increasing giant migrating contractions (GMCs), resulting in frequent defecation and tenesmus. The inflammation may impair calcium mobilization, change the expression of key signaling molecules for excitation-contraction coupling, inhibit muscarinic signaling, and increase transcription of nuclear factor kappa B (NF-kappa B), a key step in causing inflammation. Finally, absorptive and motility disorders may change the composition of the luminal commensal microbiome that plays an important role in the maintenance of colonic function, thereby contributing to further deterioration.

Influence of Diet[208]

Food allergy has been associated with intestinal inflammation, but complete resolution would be expected in response to an appropriate exclusion diet (see ch. 178, 186, and 276). However, food antigens probably do not play a direct role in the pathogenesis of human IBD, but various dietary components can exert either deleterious or beneficial effects on the intestinal microbiome and the mucosa and thereby modify the mucosal inflammatory process. The effects of dietary antigens in IBD have not been studied in detail in dogs or cats, but dietary treatment is viewed as an integral component of therapy. A large proportion of dogs and cats with colitis responds clinically to dietary therapy alone (E-Table 277-3), although histological resolution usually does not occur.

E-TABLE 277-3

Efficacy of Various Dietary Treatments for Chronic Colitis in Dogs and Cats Based on Published Case Series

SOURCE	NUMBER OF ANIMALS	TREATMENT EVALUATED	SUCCESS RATE
Cats			
Nelson et al, 1984	6 cats	Homemade D (boiled lamb and rice) then switched to highly digestible commercial D. SS × 3 weeks in 1 cat with NR to commercial diet.	CR in 6 cats fed homemade D. Rec in 2 cats when switched to highly digestible diet. Both controlled with homemade diets, 1 required SS for 3 weeks.
Dennis et al, 1993	13 cats available for follow-up	F (high F diet or addition of F to diet) in 8 of 10 cats with CR or PR, highly digestible D in 2/7. CR cats received T and/or P initially that was then d/c. All cats with CR maintained on D alone. Cats with PR on P or SS as needed.	CR in 7 cats within 6-50 mo. PR in 3 cats. No change in one cat. Two cats with severe disease were euthanized without treatment.
Dogs			
Nelson et al, 1988	13 dogs	D, initially homemade (cottage cheese and rice), followed by commercial novel antigen or low residue diet. No medication.	CR to homemade diet in all dogs within 3 days to 6 weeks. Rec in 2/13 after switch to commercial novel antigen or low-residue diet. Rec in 9/11 after exposure to pretreatment diet.
Simpson et al, 1994	11 dogs	D (commercial restricted antigen), initially SS in 9 dogs, d/c after resp of clinical signs. No F supplementation.	SS could be d/c after 1 mo in 3/9, 2 mo in 8/9 but had to be resumed in 1 dog. Improvement in stool consistency, fecal mucus, and fecal blood but not in frequency of defecation in all dogs.

Leib, 2000	27 dogs available for follow-up	F (psyllium) added to various commercial or homemade (low-fat, low-residue, or novel protein) D.	Response excellent in 17, very good in 6, good in 3, and poor in 1 dog. Fiber could be d/c in 5/11 dogs, and special diet could be d/c in 5/7 dogs.
Allenspach et al, 2007	30 dogs	D (commercial novel antigen), P if NR to D after 10 days.	CR in 28, NR or PR in 2. No data about resp to P in these 2 dogs.

CR, Complete remission; *D*, diet; *d/c*, discontinued; *F*, fiber; *NR*, no response; *P*, prednisone; *PR*, partial remission; *rec*, recurrence; *resp*, response; *SS*, sulfasalazine; *T*, tylosin.

Hydrolyzed diets are now recognized as being efficacious in many cases of IBD that previously would have been treated by immunosuppression. However, follow-up biopsies often do not show histologic resolution despite the cessation of clinical signs. It is currently unknown whether this reflects the need to wait longer for histologic changes to resolve, or whether the highly digestible diet is merely masking the functional deficiencies of an inflamed gut.

Clinical Examination and History

Dogs with all forms of IBD tend to be middle-aged (median age of 6.5 years with a wide age range) whilst in cats with lymphocytic-plasmacytic colitis, the mean age of onset of clinical signs is similar (median 5.2 years, range 0.5 to 10 years). A predilection for certain dog breeds (e.g., German Shepherd, Shar Pei) is recognized and has been suggested for purebred cats, but with no sex predilection in either species reported.

Signs of chronic colitis are characterized by large-bowel diarrhea with frequent defecation of small volumes of soft to watery stool, often mixed with mucus and/or fresh blood. Urgency to defecate and tenesmus after defecation are often noticed, but vomiting is less frequent than in SI IBD. Abdominal pain, weight loss, anorexia, and lethargy may occur during episodes in severely affected animals, or in those with concurrent gastric and/or SI involvement.

A clinical scoring system to objectively grade the severity of disease in any pet with colitis is recommended in order to monitor treatment response as well as make comparative studies possible.[113-115] Young dogs with mild severity scores and colitis have been shown to respond well to elimination diets alone and have the best outcomes.

Physical Examination

Most dogs and cats with idiopathic colitis are in good general condition, except with severe disease, as their nutritional status is unchanged unless the owner imposes food restriction to try to control the diarrhea. If there is no SI involvement, abdominal palpation is often unrewarding, but it should be performed to rule out intussusception or neoplasia affecting the colon. Digital rectal examination may be painful due to anal and rectal inflammation associated with colitis. Anal furunculosis/perianal fistula (see ch. 278) is also seen in association with colitis in German Shepherd dogs.[209-212] The rectum may feel empty, or it may contain blood, mucus, and/or diarrheic stool. An abnormal, irregular surface of the rectal wall may be noticeable on rectal palpation.

Laboratory Investigation

Serum biochemistry, CBC, and urinalysis results are not usually significantly abnormal in dogs and cats with idiopathic colitis. This may be different in animals with generalized GI inflammation which includes the SI, where leukocytosis with neutrophilia and left shift, hypoproteinemia with hypoalbuminemia and hypoglobulinemia, and sometimes mildly to moderately increased liver enzyme activities can be present (see ch. 276). C-reactive protein (CRP) may be elevated but it is a non-specific marker that is increased in many diseases causing inflammation, and results in dogs and cats with severe IBD are inconsistent. The precise clinical relevance of serum markers of autoimmunity, such as perinuclear antineutrophil cytoplasmic antibodies (pANCA), still remains to be determined in dogs with IBD.[213-219]

A parasitological exam (see ch. 81) may identify parasite infection, such as *Trichuris*, causing colitis, but even in the absence of a positive identification, empirical treatment with fenbendazole (50 mg/kg PO daily for 3 days) is recommended to eliminate most GI helminths and protozoa. Cytological exam of rectal scrapings can reveal the presence of *Histoplasma capsulatum* (see ch. 233); neutrophils, a sign of inflammation (see Figure 277-9); or increased numbers of curved or gull-wing bacilli or gram-positive rods, perhaps indicative of *Campylobacter* infection or *Clostridium perfringens*, although identifying bacterial species on the basis of

morphology is inaccurate (see ch. 220). Usually, diagnostic imaging with radiographs and ultrasonography is not helpful in cats and dogs with colitis, unless there are masses or focal lesions visible, or if the disease extends to the SI. Thickening of the colonic wall may be found on abdominal ultrasound examination, but its absence is more useful for ruling out neoplasia.

Endoscopic Biopsy

When results indicate the possibility of LI IBD, a definitive diagnosis is best achieved with colonoscopy (Figure 277-17; see Video 277-1; see ch. 113). This should be preceded by gastroduodenoscopy in animals with suspected concurrent SI involvement. Flexible colonoscopy allows full visualization of the LI, and it is often possible to biopsy the ileum as well. Histopathologic examination allows neoplastic processes to be ruled out and differentiation between the various types of colonic inflammation.

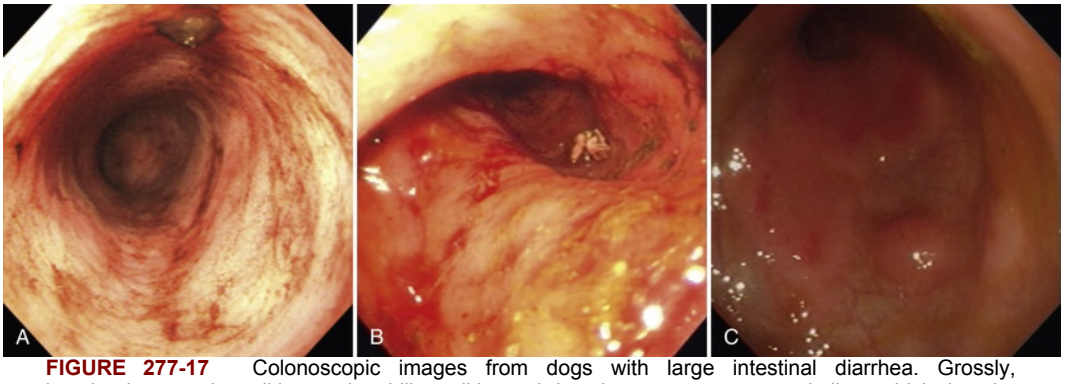


FIGURE 277-17 Colonoscopic images from dogs with large intestinal diarrhea. Grossly, lymphoplasmacytic colitis, eosinophilic colitis and lymphoma can appear similar, which is why endoscopic biopsies must be collected. **A,** Descending colon of a German Shepherd with moderate lymphoplasmacytic colitis. **B,** Descending colon and left colic flexure in a Black Labrador with moderate eosinophilic colitis. Submucosal vessels are obscured by the thickened, inflamed mucosa, which is irregular and ulcerated with spontaneous bleeding. **C,** Terminal colon of Siberian Husky with diffuse, nodular, alimentary lymphoma. Areas of grossly normal mucosa showing submucosal vessels are interspersed with thickened, almost nodular areas of tumor infiltration.

Lymphoplasmacytic colitis is the histologic form most frequently described with eosinophilic colitis being less common (see Figure 277-17). Pyogranulomatous colitis is uncommon and is associated with proliferative masses of several millimeters to centimeters in size visible during colonoscopy or palpable *per rectum:* affected dogs have severe clinical signs. Suppurative (neutrophilic) colitis has been reported as a probable variant of IBD in cats and often responds to the empiric treatment of colitis; there is emerging evidence that this may be due to a specific bacterial infection, as organisms are seen in the tissues using fluorescence *in situ* hybridization (FISH) techniques. Granulomatous colitis (GC) is described in detail in a separate section, as it is no longer considered to be part of idiopathic IBD.

Unfortunately, concordance among pathologists on the interpretation of intestinal biopsy samples submitted for histopathologic assessment is often lacking because, ultimately, it is a subjective assessment and complicated by artifacts caused by the quality of sampling, the processing and the staining techniques. A standardized histologic grading system for SI and LI IBD in dogs and cats, based on pictorial and written descriptions of pathological changes, has been published by the World Small Animal Veterinary Association (WSAVA) GI Standardization Group.[220] It took a broad approach to describing inflammatory changes in the mucosa of endoscopic biopsies, emphasizing both architectural changes and the number of inflammatory cells in the LP (Box 277-1). Controversially, it deliberately omitted evaluation of goblet cell numbers as an indicator of colitis because of a view that goblet cells that had already discharged their mucin content could be overlooked. This view has been challenged, and future schemes need to assess its value in accurately identifying colitis. However, there has been a general misunderstanding of what the WSAVA guidelines were supposed to achieve. It is not a numerical scoring system adding points for each feature, by which intestinal inflammation can then be graded. It is merely a template such that everyone can be confident that different pathologists all mean the same thing when describing a change as mild/moderate/severe. It is not a weighted scale and so a cumulative score may be irrelevant as we do not yet know which of the features examined are the most significant. The guidelines were published in order to allow comparative, prospective studies to analyze which changes are important in the histologic definition of IBD and thereby understand the

correlation between clinical and histologic severity.

Box 277-1

Histologic Scoring System for Objective Reporting of Colonic Inflammation in Dogs and Cats

Features to Assess and Score from Normal, Mild, Moderate, to Marked

Morphological Features

Surface epithelial injury
Crypt hyperplasia
Crypt dilation/distortion
Fibrosis/atrophy

Inflammation

Lamina propria lymphocytes and plasma cells
Lamina propria eosinophils
Lamina propria neutrophils
Lamina propria macrophages

Modified from Day MJ, Bilzer T, Mansell J, et al: Histopathological standards for the diagnosis of gastrointestinal inflammation in endoscopic biopsy samples from the dog and cat: a report from the World Small Animal Veterinary Association Gastrointestinal Standardization Group. *J Comp Pathol* 138(Suppl 1):S1-S43, 2008. Author note: Goblet cell numbers were excluded.

Treatment and Management

It is important to know whether a patient has idiopathic colitis or whether there is an underlying cause, and whether it is part of more generalized IBD, as the treatments differ. A patient presenting with signs of colitis but with abnormalities of serum folate and cobalamin concentrations almost inevitably has SI disease as well. Therefore, ideally, SI biopsies (obtained by upper GI endoscopy and ileoscopy) should also be collected rather than just performing colonoscopic biopsy when colitis is suspected.

Once known causes of colitis have been ruled out, a presumptive diagnosis of idiopathic colitis can be made and empirical treatment based on dietary modification and medications with minimal side effects started. Again, ideally, a precise diagnosis based on histological examination of colonic biopsies should be achieved before the use of glucocorticoids as they can have side effects and mask conditions if further diagnostic tests are then required. However, pragmatically, empirical glucocorticoid therapy may be attempted if other treatments fail. A histologic diagnosis is mandatory before the use of other immunosuppressive drugs, as they can have potentially permanent and even fatal side effects.

Dietary Management[43,221-223]

Diets recommended for pets with chronic colitis include exclusion diets based on highly digestible, low-residue diets or on a novel, single protein or hydrolyzed protein diet (see E-Table 277-3). If successful, most dogs and cats with colitis will have responded to such a diet change within two weeks.

Additional insoluble, dietary fiber may reduce nutrient digestibility but can have a beneficial, symptomatic effect in colitis partly through modification of colonic motility. Alternatively, psyllium is a soluble, indigestible fiber derived from the seed of *Plantago ovata* that is often recommended in the management of colitis. It has great water-holding capacity and forms gels with water, thereby contributing to improved fecal consistency. Psyllium has been shown to be efficacious in the treatment of chronic idiopathic colitis in dogs when added to a highly digestible diet. An initial daily dosage ranging from half a tablespoon for toy breeds to three tablespoons for large dogs is added to each meal, and the dosage is then adjusted to effect.

Fermentable fiber is soluble fiber that resists digestion in the SI and is then metabolized by colonic bacteria. The addition of such fiber has proven adjunctive benefit in clinical studies of canine and feline chronic colitis, and it is often added to commercial pet foods; examples include not only psyllium, but also beet pulp, fructo-oligosaccharides (FOSs), inulin, and mannanoligosaccharides (MOSs). Fermentable fibers are metabolized to SCFAs by the LI bacteria and provide a source of energy for colonocytes, and when this fiber is absent from the diet the structure of the intestinal epithelium becomes abnormal and diarrhea can occur. Acacia gum, and

alpha-glucan butyrogenic (a resistant starch synthesized from 1,4-alpha-D-glucans with polymer chain lengths of 10±35 glucose units) are good substrates for the production of SCFAs and are often found in combination products with probiotics, kaolin and other anti-diarrheals. As well as providing an energy source to colonocytes, the known beneficial effects of fermentable fiber include colonocyte proliferation through increased blood flow to the colonic mucosa and promotion of epithelial cell differentiation into fully functional colonocytes. Additionally, FOSs and MOSs are prebiotics and may influence the composition of the LI microbiome. In cats, they were reported to increase colonic fecal concentrations of *Bacteroides* and *Lactobacillus* spp. and to decrease those of *E. coli* and *C. perfringens.*

Probiotics[224-231]

Probiotics are live microorganisms that are beneficial to the host GI tract (see ch. 167). No clinical study has been able to document convincingly positive effects of probiotics in dogs and cats with chronic GI diseases, even though *in vitro* experiments and studies in canine and feline acute gastroenteritis and in human patients indicate potential benefits. The probiotic organism *Enterococcus faecium* (SF68) has been safely administered to the canine GI tract, and it has been shown to increase fecal IgA content and circulating mature B cells in young puppies. It has been suggested that this probiotic may be useful in the prevention or treatment of canine GI disease. Whilst there is emerging experimental evidence that probiotics do exert an effect on gut permeability and the mucosal immune response, until more studies prove clinical efficacy, veterinarians should probably view product claims with some skepticism.

Adjunctive Therapies

MPS Protect is a mucopolysaccharide also found in some combination anti-diarrheal products, and which theoretically enhances protective colonic mucus production. Herbal remedies have been shown to offer some protection to damage by nonsteroidals.[232,233] There is owner-derived data that homeopathy is effective in approximately two thirds of dogs with diarrhea, but no controlled studies prove any benefit.[234]

Fecal Microbial Transplant[235-240]

Transferring an inoculum of feces from a healthy patient to one with GI disease is becoming an accepted treatment of resistant *Clostridium difficile* infection in human patients, and is being applied in IBD. The concept has been extrapolated to the treatment of canine IBD with anecdotal reports of success so far. As the transplanted material is given in a retention enema, it is perhaps best suited to treating colitis. However, until more studies have been done, it cannot be recommended, particularly as how to screen for and choose healthy donors is debated.

Drug Therapy

Pharmacologic intervention (Table 277-4) is required if dietary and adjunctive therapy (probiotic, etc.) fails to control clinical signs or, in severe cases, may be initiated simultaneously with dietary modification.

TABLE 277-4

Pharmaceutical Therapy of Large-Bowel Inflammation

DRUG CATEGORY AND NAME	DOSAGE RECOMMENDATION	INDICATION
Antimicrobials		
Enrofloxacin	5 mg/kg PO q 24 h (D) for 4-8 weeks; culture and sensitivity for *Escherichia coli* recommended before starting treatment	GC
Metronidazole	10-15 mg/kg PO q 12 h (D, C) to q 8 h (D) For metronidazole benzoate, increase above dosage by approximately 50%	Acute and chronic colitis
Anti-Inflammatory Drugs		
Sulfasalazine	10-30 mg/kg PO q 8 h for 4-6 weeks, max 1 g total dose (D)	Colonic IBD refractory to diet

	5-12.5 mg/kg PO q 8 h for 2-4 weeks (C) Administer with food. Slowly decrease in 10- to 14-day steps to q 12 h, then half the dose q 12 h, then once daily. Regularly measure tear production.	and metronidazole
Olsalazine	5-15 mg/kg PO q 8 h for 4-6 weeks, max 1 g total dose (D) 2.5-7.5 mg/kg PO q 8 h for 2-4 weeks (C)	
Immunosuppressive Drugs		
Prednisone (prednisolone)	1-2 mg/kg PO q 12 h for 10-14 days, then slowly taper over several weeks	Colonic IBD refractory to diet and antibiotics
Azathioprine	Starting dosage: 2 mg/kg PO q 24 h (D) for 2 weeks, then 2 mg/kg every other day for 2-4 weeks, then 1 mg/kg PO every other day May take 2-4 weeks to have full effect	Steroid-refractory colonic IBD
Chlorambucil	Cats >4 kg: 2 mg per cat PO every other day for 2-4 weeks then tapered to the lowest effective dose (2 mg/kg per cat PO every 3-4 days) Cats <4 kg are started at 2 mg/kg per cat PO every third day	Refractory or severe feline IBD; combined with prednisolone
Cyclosporine	5 mg/kg PO q 24 h (D) for 10 weeks	Steroid-refractory chronic colonic IBD

C, Cat; *D*, dog; *GC*, granulomatous colitis; *IBD*, inflammatory bowel disease.

Metronidazole[241-245]

Among the antimicrobials, metronidazole is frequently used in dogs and cats with colitis. Besides its antimicrobial effects against obligate anaerobic bacteria, metronidazole is also effective against *Giardia,* although at standard antibacterial doses (i.e., 10 mg/kg) it only suppresses and does not eliminate infection. Furthermore, metronidazole has been shown to have immunomodulatory effects: it has been shown to be genotoxic to feline lymphocytes, and it affects various steps in innate and adaptive sequences of the immune response. It is used in dogs and cats with colitis to modify the intestinal flora, decreasing obligate anaerobes and inflammation. It is unpalatable, especially in cats, but other side effects are quite rare and include vomiting and diarrhea. Hepatotoxicosis and neurotoxicosis occur at higher dosages.

5-Amino Salicylic Acid

5-amino salicylic acid [5-ASA or mesalamine (mesalazine)] is a nonsteroidal anti-inflammatory drug molecule effective in the treatment of UC in human patients. The native molecule is potentially nephrotoxic if absorbed by the SI, so it is only available as an enteric-coated preparation that is dissolved by the acidic colonic pH, and as a foam enema. The safety of the enteric-coated preparation has not been established in dogs and cats and it is not recommended, whilst enema preparations are unlikely to be suitable. Therefore it is administered to dogs and cats as a pro-drug.

Sulfasalazine (Azulfidine, Salazopyrin) is a pro-drug consisting of 5-ASA linked by an azo bond to sulfapyridine.[223,246,247] It is administered orally, and the pro-drug reaches the distal SI and colon unchanged. There, the bacteria break the azo bond and liberate both molecules. 5-ASA exerts its anti-inflammatory effects directly on the colonic mucosa, inhibiting prostaglandin and leukotriene synthesis. The sulfapyridine is in essence a carrier molecule and is not thought to have therapeutic effect before being absorbed and eliminated by liver metabolism and urinary excretion. The main adverse effect of sulfasalazine is keratoconjunctivitis sicca (KCS); although the exact mechanism of action is unknown, sulfasalazine may damage the lacrimal glands. Early detection with immediate discontinuation of treatment is necessary to prevent the onset of irreversible KCS. Therefore, tear production must be measured at regular intervals in all dogs receiving sulfasalazine. Vomiting can occur and can be prevented if the drug is administered with food, but acute pancreatitis has been recorded as a side effect. Other pro-drugs with the same mechanism of action are available.

Olsalazine (Dipentum) consists of two molecules of 5-ASA linked by an azo bond. As two 5-ASA molecules are released for each olsalazine molecule administered, the dosage is 50% of the sulfasalazine drug. It was hoped that this would eliminate the risk of KCS, but it has still been reported, although more rarely.

Balsalazide is another pro-drug (4-aminobenzoyl-beta-alanine-mesalamine) with 5-ASA bound to an inert carrier, but its safety and efficacy in dogs and cats have not been demonstrated and it cannot be recommended.

Glucocorticoids

Glucocorticoids are used as a second line of treatment for dogs with colonic IBD that is refractory to dietary modification, metronidazole and sulfasalazine (see ch. 164 and 165). Due to the side effects, immunosuppressive dosages of prednisone are ideally reserved for patients that have histologically confirmed colitis and where underlying causes have been ruled out. As side effects tend to be fewer and less severe in cats, and because they may not tolerate three times daily medication with sulfasalazine, and are more susceptible to mesalamine toxicosis, glucocorticoids are a treatment option often considered earlier in cats than in dogs with colitis. Budesonide, which is 90 per cent metabolized via first-pass through the liver, is used in some cases of generalized IBD, but there are no reports of its success in isolated idiopathic colitis.

Cytotoxic Agents

Cytotoxic agents may be used as steroid-sparing agents to treat all forms of IBD, and are not specifically used for idiopathic colitis (see ch. 276). Due to potential side effects and financial considerations, they should be reserved for animals with documented colonic inflammatory disease that show no response to any other treatment. *Chlorambucil* has been used successfully in dogs and in cats with IBD. *Azathioprine* has been recommended for dogs with IBD refractory to immunosuppressive doses of corticosteroids. It is rarely effective as a single agent and should instead be used as adjunctive therapy as it has a significant steroid-sparing effect in canine IBD, although it may take several weeks for azathioprine to become maximally effective. Doses of 2 mg/kg orally every 24 hours in dogs and 0.3 mg/kg orally every 48 hours in cats have

been used with some success in IBD. It is cytotoxic and tablets must not be broken. Therefore, reformulation is needed to produce tablets of an appropriate size for cats and small dogs.

Cyclosporine

Cyclosporine (ciclosporin) reduces IL-2 production in T cells and therefore renders them more susceptible to apoptosis (see ch. 165). Its efficacy at a dosage of 5 mg/kg PO q 24 h for 10 weeks has been reported in 9 of 14 dogs with IBD that were steroid-resistant but none specifically had idiopathic colitis alone.[248-250]

Prognosis

The prognosis for colonic IBD depends on the response to treatment as well as on the initial disease severity. Young dogs that responded well to treatment with an elimination diet alone had a good prognosis, with most in remission within a year. Older dogs with severe disease and those which need steroids to control their clinical signs carry a much poorer prognosis.[113]

Granulomatous Colitis[251-292]

Definition

Formerly known as histiocytic ulcerative colitis (HUC), granulomatous colitis (GC) was for many years considered a form of idiopathic IBD, but is now recognized to be associated with an intracellular *E. coli* infection. It occurs most frequently in young Boxer dogs but is being seen with increasing frequency in French Bulldogs as the breed gains popularity. It has also been described occasionally in other breeds, such as Mastiffs, Alaskan Malamutes, and English Bulldogs, and in one cat. Since being described 50 years ago, the condition has been recognized worldwide, although currently it is most common in the United States and Australia, with rare sporadic reports in Europe. The disease is restricted almost exclusively to the colon, although cases with SI involvement have been noted, and it causes severe signs of colitis with mucoid diarrhea, hematochezia, urgency, and tenesmus. The condition is characterized histopathologically by the presence of macrophages full of Periodic-Acid-Schiff (PAS)-positive-staining material underlying an ulcerated colonic mucosa. Attempts to treat the condition with therapies used for idiopathic colitis (e.g., metronidazole, sulfasalazine, glucocorticoids) failed, and historically the severity of the disease almost inevitably led to the euthanasia of the patient.

Etiopathogenesis

The cause of canine GC has been debated for decades, although its occurrence in clusters and within certain kennels and presence of the PAS-positive material within macrophages suggested an infectious etiology. Early electron microscopic studies demonstrated so-called residual bodies resembling bacteria-like organisms in granules within PAS-positive macrophages. Specific infectious agents, such as mycobacteria, mycoplasmas, *Chlamydia,* and rickettsias have all been proposed to cause GC; attempts to reproduce the disease by infecting dogs with *Mycoplasma* spp. failed. In immunohistochemical studies, GC lesions are characterized by increased numbers of CD3-positive cells, IgG-positive plasma cells, and MHC class II–positive cells, which merely demonstrate an inflammatory response. Alternatively, the marked breed restriction of GC, with most of the affected dogs in the first report of HUC in 1965 being traced back to a single ancestor, suggests a genetic predisposition.

More recently, two independent studies reported simultaneously successful remission and likely cure following prolonged treatment with enrofloxacin.[256,263] A total of 12 cases were described and each showed a dramatic response to treatment with enrofloxacin (5 mg/kg PO q 24 h for 4 to 8 weeks) or a combination protocol with enrofloxacin, amoxicillin (20 mg/kg PO q 12 h), and metronidazole (10 to 15 mg/kg PO q 12 h). The reported response to enrofloxacin was dramatic, with all dogs responding within three to twelve days of initiating therapy, and several dogs being disease-free following a four- to six-week course of therapy. Some dogs apparently needed treatment for much longer than six weeks. Five dogs were re-biopsied when they were in clinical remission after completion of the antibiotic treatment. A dramatic improvement in the histologic lesions was evident in all, with disappearance of PAS-positive macrophages in three dogs and a marked reduction in the number of macrophages in the other two dogs.

The success of enrofloxacin treatment in GC obviously resurrected the question of an infectious etiology. Using FISH, large numbers of coccobacilli were found in the colonic mucosa in Boxer dogs affected with GC

but not in histologically normal tissues or in the mucosa of dogs with other types of colitis.[275,276,282] Further studies identified the bacteria to be an *E. coli* localized in the intracellular compartment of the PAS-positive macrophages, which when co-cultured with epithelial cells and macrophages, revealed specific adherent and invasive properties. Indeed, the *E. coli* variant associated with GC has a phenotype that is similar to the adhesive and invasive behavior displayed by adherent and invading *E. coli* (AIEC) isolated from chronic urinary tract infections in women and bovine endometritis.[293] Similar *E. coli* have been associated with Crohn's disease in people, which has a similar granulomatous histologic appearance. AIECs replicate within the phagolysosomes of macrophages, provoking a granulomatous lesion rather than being cleared. These findings support the hypothesis that genetics play an underlying role in the infection that causes GC. People with Crohn's disease have polymorphisms in certain pattern recognition receptors (PRRs) of the innate immune system, such as NOD2 (nucleotide-binding oligomerisation domain receptor 2), linking a genetic defect in innate immunity with functional disease.[294] It was hypothesized that similar defects in PRRs could be present in GC as an underlying genetic predisposition, due to the preponderance of cases in young Boxer dogs. Confirmation and identification of mutations in PRRs, such as toll-like receptors (TLRs) or NODs, in Boxers with GC is still lacking. However, a defect in neutrophil killing activity has been identified, and this seems the most likely reason why the AIEC infection is not cleared.

Evaluation of the Patient

History and Physical Examination

The onset of disease is usually before 2 years of age. Clinical signs are those of severe, chronic, LI inflammation and include diarrhea, hematochezia, increased frequency of defecation, tenesmus, and presence of excessive mucus in the feces. Physical examination findings are normal in many dogs with GC, however weight loss and inappetence may be seen in severe cases (E-Figure 277-18). Fresh blood and mucus are found upon rectal examination.

E-FIGURE 277-18 A Boxer with granulomatous colitis. Note the marked weight loss.

Investigations

The diagnostic approach to dogs with GC is the same as described for idiopathic colitis. CBC, serum biochemistry, and urinalysis are necessary to exclude any extra-GI diseases. Parasitological examination of fecal samples and fecal culture should be performed (see ch. 81 and 221). An ultrasound exam of the abdomen (see ch. 88) may reveal a diffusely thickened colonic mucosa; however, in many dogs, no abnormalities are detected. Typically, colonoscopy reveals sites of severe colonic hemorrhage and ulceration interspersed with stretches of more normal-appearing mucosa (Figure 277-19). Biopsies should be taken from ulcerated and more normal mucosa, and from transition zones.

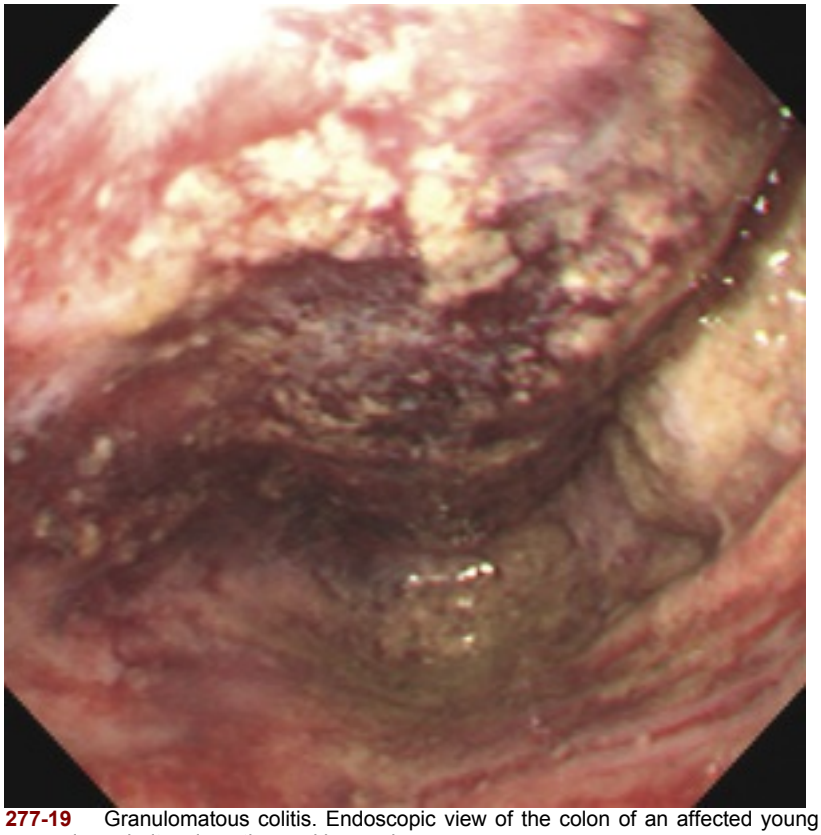

FIGURE 277-19 Granulomatous colitis. Endoscopic view of the colon of an affected young Boxer, showing severe irregularity, ulceration and hemorrhage.

Early lesions can consist of a mixed inflammatory infiltrate in the LP just below a degenerative epithelium. With increasing chronicity and severity, the ulceration worsens, with widespread loss of the epithelial surface and goblet cells. Below, there is severe infiltration of the LP and submucosa by neutrophils, macrophages, lymphocytes, plasma cells, and mast cells, representing a mixed inflammatory response, perhaps reflecting secondary invasion by luminal bacteria. Accumulation of large PAS-positive macrophages is virtually pathognomonic for GC. Fluorescence *in situ* hybridization (FISH) performed on biopsies demonstrates the presence of *E. coli* within the tissue. PAS-staining and FISH remain the best ways to confirm the diagnosis and distinguish GC from idiopathic lymphoplasmacytic colitis, which is seen more commonly even in Boxers.

Treatment and Management

The prognosis for HUC was considered to be grave when management consisted of various combinations of dietary management and anti-inflammatory or immunosuppressive treatment with sulfasalazine, prednisolone, and azathioprine (see above, section on chronic colitis). Inevitably these strategies were not successful, and most affected dogs were euthanized because they were refractory to treatment. The revelation of the success of enrofloxacin treatment has reversed the prognosis, and cure is possible. However, resistance to enrofloxacin has now developed, perhaps because of its inappropriate use in Boxers with colitis due to other causes, and some AIECs isolated from GC are now only sensitive to amikacin.[274]

Infection

GI infections can cause colonic inflammation and acute or chronic colitis. They are common in dogs and cats but most affect either the SI primarily or both the SI and LI together either sequentially or concurrently. Acute gastro-enterocolitis typically starts with inappetence, vomiting and SI-type diarrhea before signs of colitis (hematochezia, mucus, urgency tenesmus) occur, presumably reflecting the passage of the infectious agent down the GI tract. Infectious agents that primarily target the LI are described here.

There are no viral infections that solely affect the LI, although one uncommon manifestation of feline infectious peritonitis (FIP) is a pyogranulomatous mass at the ileo-ceco-colic area, causing either diarrhea or obstruction.[295-297] Information on parvovirus, enteric coronavirus and other viral diseases causing a generalized GI infection can be found in ch. 224, 225, 228, and 276. Similarly a number of causes of bacterial gastro-enterocolitis are discussed in more detail in the preceding chapter and ch. 220. Specific LI infections are mainly protozoa and metazoan parasites that presumably occupy an ecological niche which makes the LI their predilection site for infection.

Bacteria[298-300,320]

Enteropathogens such as *Campylobacter, Escherichia coli, Salmonella,* and *Yersinia* typically infect the SI, but may also cause colitis. Here again, the difficulty is that isolation does not prove causation, and these organisms can be found in the feces of clinically healthy animals. An attaching and invading *E.coli* is associated with granulomatous colitis in Boxer dogs (see above).

Anaerobiospirillum[301,302]

A small, Gram-negative, spiral bacterium, *Anaerobiospirillum* spp. can be isolated from the feces of dogs and cats. There are, however, reports of acute ulcerative or necrotizing ileocolitis in cats associated with this organism. It can be demonstrated within the crypts of biopsies stained with Giemsa or Steiner stains, or by PCR. There is no treatment published.

Brachyspira pilosicoli[303-309]

This organism is a spirochete and the cause of swine dysentery; it may be pathogenic in dogs. Massive infection with signs of acute colitis have been described in dogs kept in colonies with poor hygienic conditions.

Campylobacter spp[131,132,141,299,310-314]

Campylobacters are Gram-negative, motile, spiral-shaped bacteria that are often found in feces, even feces from healthy animals, and whether they are pathogenic in dogs and cats is debated (see ch. 220). They typically cause small intestinal disease, and are discussed in detail in ch. 276. However, there are reports of *Campylobacter* causing enterocolitis and isolated colitis.

Clostridium difficile[119,133,315-328]

A Gram-positive, anaerobic, spore-forming bacillus, *C. difficile* is a significant nosocomial pathogen in humans (see ch. 210 and 220). *C. difficile* produces two major toxins, A (an enterotoxin) and B (a cytotoxin), which can cause fatal pseudomembranous colitis in hospitalized human patients given antibiotics. In the human intestine, the toxins cause loss of epithelial integrity and cell death through glycosylation and inactivation of guanosine triphosphatases, resulting in F-actin depolymerization. They also cause inflammation by stimulating the production of prostaglandins and substance P, and mast cell degranulation. Their effect on canine intestinal epithelium is unknown, and pseudomembranous colitis after antibiotic therapy is not reliably documented in dogs. Indeed, isolation of the organism in diarrheic dogs is most commonly associated with both SI and LI signs.

The organism can be cultured from the feces of up to 40% of both healthy and diarrheic dogs, although its toxins are more frequently found in dogs with diarrhea. It is also reported to be present in the feces of over 90% of neonatal dogs with no clinical signs. Thus, it is difficult to prove a causal relationship between the presence of enterotoxin and disease in dogs, although the organism has been incriminated as a cause of nosocomial infection and diarrhea. Metronidazole (10 mg/kg PO q 8-12 h) is an effective treatment, as antibacterial resistance appears to be rare in canine isolates.

Clostridium perfringens[320,321,328-345]

This Gram-positive, anaerobic, spore-forming bacillus causes food poisoning in humans, and has been incriminated as a cause of canine acute colitis and hemorrhagic gastroenteritis (HGE). However, it is often present in the healthy canine LI, with recorded isolation rates of up to 80%. It can produce Type A toxins including major toxin A and an enterotoxin, also called *Clostridium perfringens enterotoxin (CPE). C. perfringens* organisms producing type A toxins have been associated with acute and often hemorrhagic enterocolitis in dogs, especially in kennels and under boarding conditions. The CPE can stimulate intestinal secretion and initiate apoptosis, but *C. perfringens* may also carry other virulence factors such as beta$_2$ toxin.

Historically, the secretion of CPE was associated with sporulation of the organism when environmental conditions were right, supposedly leading to diarrhea. This was often linked to the stress of hospitalization or kenneling, or a sudden dietary change, possibly causing a change in the colonic pH, with mucoid diarrhea typically occurring one to five days after admission, and typically responding to metronidazole or the addition of dietary fiber. Finding five sporulating organisms per high power field in a fecal smear was considered diagnostic. However, sporulation has now been shown not to correlate with CPE production, and since approximately 15% of healthy dogs can also harbor CPE-producing *C. perfringens,* its pathogenicity is not confirmed.

Isolation of *C. perfringens* by fecal culture is insufficient to prove it is the cause of colitis, but immunoassays are available to detect CPE in feces. PCR is also available for the detection of the *cpe* gene. Yet the clinical value of all of these tests is questionable, as CPE is detected with similar frequency in feces from healthy dogs.

C. perfringens is susceptible to metronidazole (8 to 15 mg/kg PO q 8-12 h) and also to amoxicillin, erythromycin and tylosin; resistance to tetracyclines is common. The prognosis is good, and supportive treatment alone, with the addition of dietary fiber or probiotics, is sometimes just as successful as antibiotic treatment, raising the question of whether antibiotics are indicated.[341] However, whether *C. perfringens* is actually a cause of colitis is debated, although emerging evidence indicates it does cause HGE. Recent studies demonstrate the presence of *C. perfringens* in the intestinal mucosa of dogs with HGE, but there is no association with CPE production.[330]

Escherichia coli[346-356]

E. coli is found in the GI tract of nearly all dogs and most cats, and is likely to be a commensal unless it carries specific plasmid genes that encode for pathogenic mechanisms. Some isolates typically cause SI disease primarily, e.g., enterotoxigenic *E. coli* (ETEC), which produces heat-stable and heat-labile toxins that stimulate excess secretion by the SI (see ch. 220 and 276). Others can damage both the SI and LI, e.g., enteropathic *E. coli* (EPEC), which causes attaching and effacing damage to intestinal epithelial microvilli through intimin expression by the *eae* gene. Fatal EPEC infection has been reported in a kitten and an adult cat in which attaching and effacing lesions were found in the ileum and colon. Death of puppies with EPEC infection is believed to be more common, but often there is a mixed infection with distemper, parvovirus and pathogenic protozoa contributing.

Some *E. coli* isolates, such as enterohemorrhagic *E. coli* (EHEC) have a tropism for the LI. Although non-invasive, EHECs produce Shiga-like toxins (verocytotoxin, cytotoxic necrotizing factors 1 and 2) that kill colonocytes by inhibition of protein synthesis, leading to edema, submucosal hemorrhage, arteritis and arteriolar thrombosis in the colon, and hence hemorrhagic diarrhea. Isolation rates range up to 15% of healthy dogs and 5% of healthy cats.

The EHEC of the serotype O157:H7, a commensal of cattle, also produces a toxin that causes potentially fatal, hemolytic uremic syndrome in humans. Although O157:H7 has been isolated from the feces of healthy dogs, there is no conclusive evidence of hemolytic uremic syndrome in the species, although it can be produced experimentally by IV injection of shiga-like toxin. The organism has also been associated with "Alabama rot," where ulcerative skin lesions and acute kidney injury occur.[357] Other serotypes are isolated more commonly at rates of up to 25% in Greyhounds, presumed to be because they are often fed raw meat. Verocytotoxin-producing *E. coli* are found more commonly in cats with diarrhea than healthy cats.

As the pathogenicity of any *E. coli* depends on which genes it carries, simple isolation by routine culture is meaningless, and PCR is needed to identify the gene or genes that encode for pathogenicity. Even then, identification does not necessarily equate with causation, as the organism may be present in healthy animals, and so attempts to vaccinate dogs against *E. coli* are speculative.

Enterohepatic *Helicobacter* spp.[358]

Gastric *Helicobacter* are well known, although their pathogenic potential in dogs and cats is still debated. However, enterohepatic helicobacters have also been identified and possibly incriminated in feline chlolangitis. Recently an association between the presence of *Helicobacter* organisms in colonic crypts and superficial mucus and histologic evidence of colitis in dogs and cats has been identified. However, a lack of proof of Koch's postulates so far, means we do not yet know their significance in the etiology of supposedly idiopathic colitis.

Salmonella spp.[356,359-388]

Salmonella organisms, most commonly *S. typhimurium* in dogs and cats, are a potential zoonotic risk. They attach to epithelial cells and M cells in the SI and LI, and can cause enterocolitis. Infection is fortunately generally quite uncommon (<2%), but fecal isolation rate is similar in healthy and diarrheic patients, ranging from one to 36% of all dogs, and one to 18% of healthy cats. The higher isolation rates reported are generally associated with feeding raw food, rawhide chews, and improperly cooked meat. Further information on the pathophysiology, clinical presentation, treatment and prognosis are discussed in ch. 220 and 276.

Yersinia enterocolitica[389-391]

Y. enterocolitica is a motile, Gram-negative coccobacillus, which can be isolated from the feces of clinically healthy dogs and cats. It has also, rarely, been associated with abdominal discomfort and/or bloody diarrhea, and in man, infection has been correlated with polymorphisms of CARD15/NOD2, a bacterial pattern recognition molecule in the innate immune system.[392]

Algae

Prototheca spp.[393-406]

Prototheca spp. are achlorophyllous algae which can cause protothecosis in dogs, cats and humans. *Prototheca zopfii* is typically associated with GI and disseminated disease in young dogs, and *Prototheca wickerhamii* with cutaneous infections in dogs and cats. The algae live in animal waste and sewage-contaminated food, soil, and water, and impaired host cellular immunity seems to play a role in infection and in disease dissemination. Primary colonic infection is followed by endosporulation and dissemination to other tissues.

Most dogs with disseminated disease have signs of intermittent or prolonged bloody diarrhea. Ocular and neurological signs often accompany the signs of colitis, and distemper should be included on the differential diagnosis list. Diagnosis is made by cytology of rectal or colonic scrapings and/or histology of affected tissues, showing the capsulated organisms. Culture from affected tissues is readily performed and allows species differentiation. Treatment of disseminated protothecosis with varying combinations of amphotericin B and itraconazole (see ch. 162) has been attempted but only slows progression; the ultimate outcome is invariably fatal.

Fungi

Systemic fungal infections, which may infect the GI tract, occur in certain geographic areas, and are described in detail elsewhere: *Histoplasma* (see ch. 233) typically affects the LI; *Aspergillus* (see ch. 234 and 235) can cause GI infection in immunosuppressed patients, and has been seen during cyclosporine therapy; and Oomycetes such as *Pythium insidiosum* and zygomycetes (see ch. 236) can infect the GI tract (phycomycosis).

Histoplasma capsulatum[407-409]

H. capsulatum is a dimorphic fungus whose free-living mycelial stage grows in warm, moist, nitrogen-rich soil contaminated with bat or bird droppings. In the United States, it mainly occurs along the Ohio, Mississippi, and Missouri rivers. Fungal spores are inhaled and then disseminated by macrophages to the GI tract and other organs; it is suspected that direct infection of the GI tract after ingestion, without pulmonary involvement, may also occur. Granulomatous inflammatory reactions with ulceration and blood loss occur in the GI tract and cause the typical clinical signs.

The organism causes chronic LI diarrhea in young dogs and cats: common signs include tenesmus, hematochezia, and mucus in the feces. Dogs may also show pyrexia, anorexia, vomiting, and weight loss. The SI can also be affected, with signs of weight loss and sometimes protein-losing enteropathy. Colonoscopy reveals severe granulomatous inflammation.

Histoplasma organisms are most reliably diagnosed within macrophages on cytologic smears from rectal

scrapings or cytology brush samples obtained during colonoscopy. Alternatively, lymph node aspirates, or histologic samples can be used for diagnosis. Fungal stains, such as PAS and Gomori's methenamine silver stains can help demonstrate the organisms in fixed tissues.

Supportive treatment with dietary modification, antibiotics, antidiarrheals and 5-aminosalicylates may provide some relief from signs, but definitive treatment is with itraconazole at 10 mg/kg PO q 24 h for 4 to 6 months. Treatment must be continued for at least 2 to 3 months beyond the resolution of clinical signs. The prognosis seems fair in dogs and cats.

Pythium insidiosum[410-412]

Pythium insidiosum, an aquatic organism belonging to the class Oomycetes, causes pythiosis. Large-breed male dogs, used as hunting dogs, are most commonly affected, as the organism lives in warm swamp water. Endemic areas are the Gulf Coast region of the United States, but the disease has been diagnosed as far north as Virginia and as far west as California.

The organism has a predilection for the skin and/or the GI tract, and if the GI tract is affected, upper GI obstruction is seen most commonly due to severe infiltration of the GI wall. Sometimes, the colon is affected as well, resulting in large-intestinal diarrhea. Further information on the diagnosis and treatment can be found in ch. 236 and 276.

Protozoa

The GI tract is host to a number of commensal protozoal organisms that form part of the normal microbiome, but some species are considered enteropathogens (see ch. 221). Most, such as coccidia [*Cryptosporidium, Cystoisospora* (formerly *Isospora*)] and *Giardia* are considered SI infections, but some *(Tritrichomonas)* are clearly LI pathogens. The significance of the presence of other protozoa, such *Balantidium* and *Pentatrichomonas,* is uncertain.

Balantidium coli[413-418]

The primary hosts of this ciliated parasite are pigs and non-human primates. Infection is reported rarely in dogs, and is typically associated with access to swine. *Balantidium coli* supposedly causes ulcerative colitis in dogs, with typical clinical signs of LI diarrhea, and extrapolating from human infection, treatment with tetracyclines or metronidazole should be effective. However, co-infection with *Trichuris vulpis* in reported cases confuses the significance of the organism's presence, especially as treatment of the helminth infection alone can resolve the signs.

Entamoeba histolytica[419,420]

Primarily an intestinal parasite in people and non-human primates, *Entamoeba histolytica* causes amoebic dysentery. Although amoebiasis is generally a mild disease in dogs and cats and the organism can also be found in healthy dogs and cats, one report describes severe colitis in a dog and a cat. The organism lives in the colon or attaches to the colonic wall, rarely disseminating to other organs. The rare cases described had signs of acute LI diarrhea, hematochezia, and tenesmus. The route of infection in pets is generally from humans, which raises important public health considerations if it is diagnosed in a pet. Diagnosis is best made by direct fecal smears. Eradication is achieved with metronidazole at 30 mg/kg PO q 12 h for 3 weeks; monitoring for neurotoxicosis is indicated.

Giardia intestinalis (lamblia)[421]

Giardia intestinalis infection of dogs and cats can cause clinical signs suggestive of colitis, but it is generally considered to be a SI infection. The highest concentration of organisms is found in the duodenum of dogs and the ileum of cats (see ch. 221 and 276).

Pentatrichomonas hominis[422-428]

This flagellate protozoan is generally considered a commensal in dogs, and is most important because it may be mistaken for *Giardia* in fresh fecal preparations. However, some suspicion exists that it can cause colitis, especially in kittens, although concurrent infections usually complicate the picture, and, at worst, it may only be an opportunistic pathogen.

Tritrichomonas foetus[129,130,423,425,426,429-451]

This protozoan is of emerging importance as a cause of persistent diarrhea in cats. It primarily colonizes the LI and causes chronic colitis; anal irritation and fecal incontinence can also be features of infection. Although primarily a feline enteropathogen, it was reported in breeding bitches in France, but was not found in a survey of 215 French puppies.[424] *Tritrichomonas foetus* is a flagellate protozoan similar in size and shape to *Giardia,* but it only exists in the trophozoite form. It is an important pathogen in cattle, causing infertility and abortion, but venereal transmission does not appear to be important in cats; transmission in cats occurs directly via the orofecal route.

Clinical Presentation

Cats of any age, breed or sex can be infected but infection most frequently occurs in young (<1 year old), pedigree cats in crowded catteries, rehoming centers, or multi-cat households. The prevalence in symptomatic cats in the UK has been estimated to be 20% healthy cats, but can be up to 31%. Persistent infection is most common and, although signs may spontaneously resolve, infection may remain latent and cats may suffer recrudescence when stressed. It is, therefore, most appropriate to look for the organism in kittens and younger cats with diarrhea, especially if from the right environment, and also older cats with recurrent colitis-like signs. Indeed, infection of any cat is possible and it should not be considered an infection restricted to pedigree cats. Furthermore, cats that are unresponsive to treatment for *Giardia* infection should be tested in case of misdiagnosis.

Waxing and waning large-bowel diarrhea, with mucus or fresh blood in foul-smelling feces are typical. Infected cats may have semi-formed feces, and exhibit fecal incontinence, and an edematous, painful anus. The cats may appear otherwise healthy. Clinical signs depend on the immune response of the host, the endogenous microflora, the pathogenicity of the parasite strain, and co-infections such as *Giardia.* Infected cats should also be tested for underlying FeLV and FIV infection.

Diagnosis

The organism may be identified on colonic biopsy, but it is preferable to make a diagnosis of a *T. foetus* infection by examination of feces (see ch. 81). There are several methods available, but none is 100% sensitive and antibiotic usage in the previous seven days may cause false negatives. Repeat testing should be considered where there is a high index of suspicion and yet a negative result; false negative results are more likely if formed feces are examined, and test sensitivities can be improved by only examining diarrheic samples. High colonic washings provide the best sample; the saline washings are centrifuged or allowed to settle and the sediment submitted for examination.

Methods of diagnosis include identification of motile organisms in a direct wet mount. Very fresh samples kept warm and then examined within minutes must be used, but even then the sensitivity is reported as only 14%. Specificity can also be low if the organism is misdiagnosed as *Giardia* spp. or *Pentatrichomonas. T. foetus* organisms have a characteristic forwardly progressive, jerky motion with an undulating membrane and three anterior flagellae (see ch. 207 and Video 207-1), whereas *Giardia* organisms have a slow tumbling motion.

The organism can be cultured using a commercially available culture system Feline In Pouch TF (Biomed Diagnostics), originally developed for the diagnosis of bovine venereal infection. Although more sensitive than direct smear examination, the method is laborious and the diagnosis potentially delayed as results can only be considered negative when there is no growth after 12 days.

PCR analysis of feces is relatively quick and is the most sensitive method of detecting *T. foetus:* as few as 10 organisms per gram of feces can be detected. The PCR is based on the conserved internal transcribed spacer region and the 5.8S rRNA gene. Ideally, fresh feces should be tested, but if there is a delay between collection and submission, the feces can be kept refrigerated for up to a week, although sensitivity declines with time. Quantitative PCR allows measurement of the number of organisms present, and can be used to monitor the response to treatment. Again sensitivity is improved by sampling diarrhea or colonic washings, and samples should not include cat litter, which can contain inhibitors of the PCR reaction.

Treatment

Only ronidazole (30 to 50 mg/kg PO q 12 h for 2 weeks) has been shown to be effective in treating cats with *T. foetus* infection. However, neurological side effects have been reported although they do disappear after discontinuing therapy, and clinical signs may resolve without treatment within 9 months of the onset of diarrhea. Relapses are common and can be provoked by diet change, medical treatment, travel, and stress. The disease has a fair long-term prognosis for spontaneous resolution.

Helminths

Heterobilharzia americana[452-460]

Schistosomiasis in dogs is caused by *Heterobilharzia americana,* a fluke parasite that produces acute or chronic LI diarrhea. Raccoons are the most important reservoir hosts, but others include mice, nutria, and rabbits. Canine infection is restricted to the southeastern and Gulf Coast areas of the United States. The *H. americana* life cycle involves at least one intermediate host, typically snails. The cercariae from the snail penetrate the dog's skin and migrate through the lung and the liver. The parasites mature in the liver and lay eggs in the terminal mesenteric venules. Ova then migrate through the bowel wall by releasing proteolytic enzymes and cause severe granulomatous inflammation at the site of penetration. Some ova do not reach the gut lumen and may be disseminated to the liver, pancreas and lungs, where they cause more granulomatous lesions that may result in liver failure.

Clinical signs include vomiting, LI diarrhea, and hematochezia. Serum biochemistry may reveal decreased serum albumin and increased globulin concentrations, and increased liver enzymes are often seen. In addition, granulomas may cause hypercalcemia. Diagnosis is confirmed by identifying eggs on direct fecal smears or saline flotation, or by tissue biopsy from the liver or intestines. An ELISA is available for occult infections. A combination protocol of fenbendazole with praziquantel is an effective therapy. The prognosis is good in acute cases but guarded to poor with longstanding disease involving the liver, where cirrhosis is often present.

Strongyloides tumefaciens[461,462]

Strongyloides spp. are uncommon parasites in dogs and typically infect the SI. *S. tumefaciens,* a feline threadworm, is a rare infection seen mainly in the Gulf Coast of the United States and in tropical areas. Infective larvae penetrate the skin or oral/esophageal mucosa and travel to the lungs. Larvae break into alveoli and are coughed up and swallowed. Adult parasites are exclusively parthogenetic females which burrow and persist in the colonic submucosa in epithelial-lined cavities with a luminal pore, and cause endoscopically visible nodules that may coalesce to form adenomatous masses. Embryonated ova or larvae are present in the feces. Infected cats may be asymptomatic, but the parasite may cause intractable diarrhea in young cats. Treatment with fenbendazole (50 mg/kg PO q 24 h for 5 days) is effective and the prognosis is good.

Trichuris spp.[463-470]

Whipworm infection is quite common in dogs in temperate and subtropical regions of the world and can cause acute or chronic signs of LI diarrhea. Infected dogs can be asymptomatic, or they may have mucoid feces, hematochezia, and tenesmus. *T. vulpis* is a common infection in dogs (and other canids) but is very rare in cats; *T. campanula* and *T. serrata* sporadically infect cats in Australia, the West Indies and Asia. *T. vulpis* has a direct life cycle; it is transmitted via the orofecal route, and eggs hatch in the host's SI where the larvae remain for 2-10 days after burrowing into the mucosa. The larvae then emerge and migrate to the colon, where they latch on to the mucosa; their predilection sites are the cecum and proximal colon, where their thin anterior portion burrows into the mucosa causing a localized granulomatous reaction, and occasionally may even stimulate a cecal inversion. The pre-patent period is 70-110 days, and adult worms live up to 18 months.

Clinical signs depend on the nature of the host's immune response, the nutritional status of the host, its environment, and the presence of other GI parasites. Signs and the degree of bleeding increase with the severity of the worm burden, and may include abdominal pain, vomiting, inappetence and weight loss in addition to the more common signs of diarrhea and hematochezia. On biochemistry profile, some dogs may show evidence of hyperkalemia and hyponatremia, mimicking hypoadrenocorticism, but they have a normal response to ACTH stimulation. Eosinophilia and anemia may be present, but the diagnosis is made by identifying the thick-walled, barrel-shaped eggs with two polar plugs on fecal flotation (see ch. 81). However, false negatives can occur as eggs are shed intermittently, and empirical treatment despite a negative fecal is recommended in endemic areas before colonoscopy is performed to investigate colitis, although the free posterior end of the whipworm will be seen if colonoscopy is performed. Commonly used parasiticides effective against *T. vulpis* include fenbendazole, pyrantel pamoate, febantel, moxidectin, and milbemycin oxime (see ch. 163). Due to a long pre-patent period (70 to 107 days), treatment should be repeated at three weeks and again at three months. Re-infection is likely in dogs living in contaminated environments as the ova are quite resistant, and heartworm prophylaxis with milbemycin oxime may help control infection.

Hematochezia

The presence of fresh blood in feces is indicative of LI bleeding. Hematochezia in association with mucoid diarrhea, urgency and tenesmus is most suggestive of colitis (see above), but the presence of blood without diarrhea and/or with dyschezia is more indicative of a focal, bleeding lesion, assuming a generalized bleeding problem has been ruled out. The diagnostic approach to hematochezia is outlined in Figure 277-6, *B*.

LI Neoplasia[471]

Tumors of the LI are associated with signs of mucosal ulceration and/or obstruction, such as hematochezia, tenesmus, and dyschezia. LI tumors are actually more common than tumors of the stomach and SI in dogs, and the mean age of dogs affected is usually 7 to 11 years; the mean age of cats affected with LI neoplasia is 12.5 years. Most canine colonic tumors are malignant, with adenocarcinoma followed by lymphoma being the most common. Most LI adenocarcinomas develop in the descending colon and rectum, with German Shepherds, Collies and West Highland White Terriers over-represented. Leiomyosarcomas of the LI are found more frequently in the cecum. Benign neoplasms such as adenomas and leiomyomas are much less common than malignant tumors in the canine LI although adenomatous polyps are relatively common. In the feline LI, surprisingly, the adenocarcinoma is more common (46%) than lymphoma (41%), whilst mast cell tumors (9%) are also seen (see ch. 349).

Colorectal Adenocarcinoma[472-481]

Canine intestinal adenocarcinomas are found most commonly in the distal colon and rectum, and can cause mechanical obstruction leading to dyschezia and ultimately constipation with unproductive straining. Observant owners may recognize that their dog is passing progressively deformed feces that are being squeezed past the tumor as it gradually narrows the lumen. Ulceration of the tumor surface leads to hematochezia, even if the fecal consistency is normal, and blood may be seen streaked on the surface. Diarrhea is less of a feature unless the obstruction and tumor invasion cause inflammation, fluid secretion, or malabsorption of water and salts. Local tumor invasion occurs at a relatively slow rate with canine colorectal adenocarcinoma, and metastasis to distant sites is uncommon. Devitalization and necrosis of the tumor can lead to spontaneous perforation and septic peritonitis; dogs may be moribund with fever, lethargy, anorexia, vomiting, abdominal pain, and collapse.

The most common sites of colonic adenocarcinoma in cats are the descending colon (39%) and the ileocolic region (28%), although exclusively ileal adenocarcinomas are more common, with a predisposition in older Siamese cats. Hematochezia, rather than obstruction and constipation, is the most likely sign in cats as the tumor tends to be proximal. Unlike in dogs, feline colonic tumors have a high rate (>60%) of local metastasis, which is associated with decreased survival time.

Diagnosis

Canine colorectal adenocarcinomas are palpable in about 70% of cases. Narrowing of the rectal lumen found on digital rectal examination is suggestive of neoplasia, as benign strictures are very rare. Proximal colonic and cecal lesions are not as readily apparent, although more than 50% of cats with colonic masses do have a palpable abdominal mass. Survey and contrast radiographic and ultrasonographic studies have been used with varying levels of success in the diagnosis of canine and feline colonic neoplasia. Annular stenotic lesions associated with adenocarcinoma of the colon may appear as proximal colonic dilation on survey radiographs. Radiographic contrast material more precisely outlines the narrowing of the lumen at the site of the tumor, but contrast studies have largely been superseded by ultrasonography, which is useful in evaluating mural lesions and lymphadenopathy; ultrasonography was reported to be useful in localizing about 84% of feline colonic neoplasia. CT has not been sufficiently evaluated for reasonable comparison to be made with ultrasonography but is likely to be more sensitive as luminal gas does not interfere.

Flexible colonoscopy with mucosal biopsy is the preferred method for the definitive diagnosis for colonic adenocarcinoma (Figure 277-20, Video 277-2; see ch. 113). Endoscopic abnormalities may include masses, spontaneous bleeding, increased friability, ulceration, and circumferential luminal narrowing. Multiple biopsy specimens should always be obtained from diseased tissue, adjacent healthy tissue, and the transition zone between these areas; the pathologist has a much better chance of diagnosing and staging the disease by evaluating non-necrotic tissue.

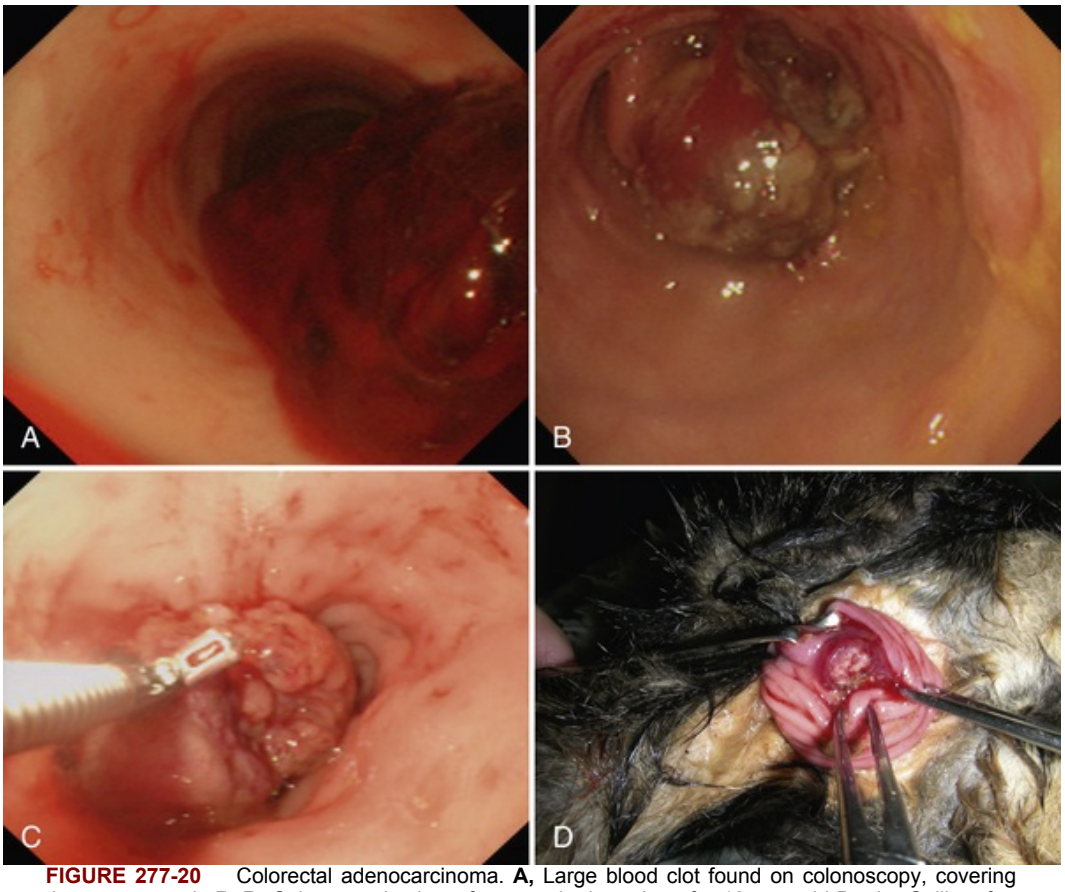

FIGURE 277-20 Colorectal adenocarcinoma. **A,** Large blood clot found on colonoscopy, covering the mass seen in **B. B,** Colonoscopic view of a mass in the colon of a 12-year-old Border Collie, after the blood clot has been removed. **C,** Endoscopic biopsy of a colonic adenocarcinoma in a 10-year-old West Highland White Terrier that had been exhibiting episodes of constipation. **D,** Adenocarcinoma in the rectum of a 12-year-old cat visualized by gradual progressive eversion of the rectum using tissue forceps.

Treatment

The most suitable treatment modality depends on anatomic location, and the presence and extent of metastases. Complete surgical excision is the recommended treatment for focal adenocarcinomas but access to intrapelvic masses may require splitting the pelvis, and may require an often aesthetically and functionally unsatisfactory endo-rectal pull-through procedure. Dogs with colorectal adenocarcinomas generally have a particularly poor prognosis with a median survival time (MST) of only 1.6 months, although in one study dogs having mass resection survived an average of 7 months longer than dogs that just had a biopsy. Radiation therapy has been used inconsistently to palliate recurrent adenocarcinomas, but post-radiation peritonitis and perforation have been reported. Cyclooxygenase 2 (COX-2) upregulation may contribute to the growth characteristics of some tumors, and selective COX-2 inhibitors (e.g., piroxicam, meloxicam) may therefore be useful although, ultimately, euthanasia is indicated.

Feline colonic adenocarcinoma is a locally invasive, highly metastatic tumor that is most often treated with wide surgical excision (subtotal colectomy) and systemic chemotherapy either with or without nonsteroidal anti-inflammatory medications. In one retrospective study, the outcome of subtotal colectomy and adjuvant carboplatin in 18 cats was assessed: the median disease-free interval was 251 days (range, 37-528 days) and the MST was 269 days (range, 40-533 days). Negative prognostic factors included nodal and distant metastasis (178 versus 328 days and 200 versus 340 days, respectively). Thus, subtotal colectomy and adjuvant carboplatin is a safe and potentially effective treatment for cats with colonic adenocarcinoma, with a longer survival time than those receiving mass resection only (MST of 138 days versus 68 days).

Adenomatous Colo-rectal Polyp[157,162,177,178,482-494]

Benign polyps sometimes occur in the terminal colon and rectum of mature dogs, and are recognized by the passage of fresh blood and clots on the surface of feces. Occasionally mistaken for colitis, the key feature is

that diarrhea is not present. Miniature Dachshunds are reported to be overrepresented, and in the author's experience, Cocker Spaniels and Shetland Sheepdogs appear predisposed. A familial adenomatous polyposis is recognized in humans. Malignant transformation of adenomatous polyps to carcinoma *in situ* and invasive adenocarcinoma is a real threat in human patients and has been demonstrated in dogs, although in most cases the polyp remains benign.

The diagnosis can usually be made on rectal palpation, where a mobile mass on a stalk can be felt. However, the tissue can be so soft that it is difficult to recognize the mass in a conscious dog, although copious bleeding occurs. Rectal examination should therefore be repeated once the animal is prepared and anesthetized for colonoscopy. It may be possible to exteriorize the polyp through the anal sphincter if it is in the terminal rectum, or view it with an anal speculum or proctoscope. Indeed, it may be missed by flexible endoscopy because the tip of the endoscope is inserted beyond the lesion before visualization is possible (Figure 277-21, Video 277-3).

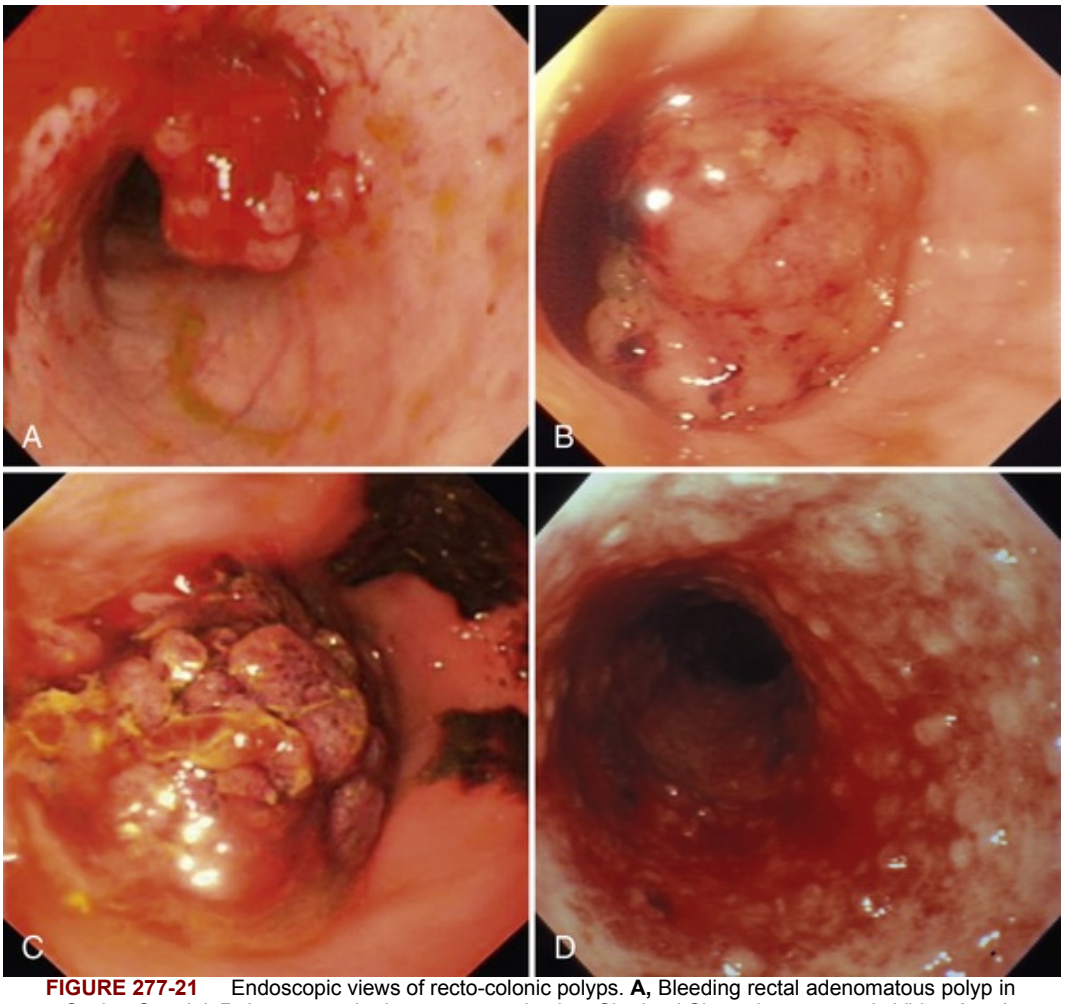

FIGURE 277-21 Endoscopic views of recto-colonic polyps. **A,** Bleeding rectal adenomatous polyp in a Cocker Spaniel. **B,** Large rectal adenomatous polyp in a Shetland Sheepdog as seen in Video 277-3. **C,** Colonic adenomatous polyp in a dog. **D,** Pseudo-polyposis in a Jack Russell Terrier.

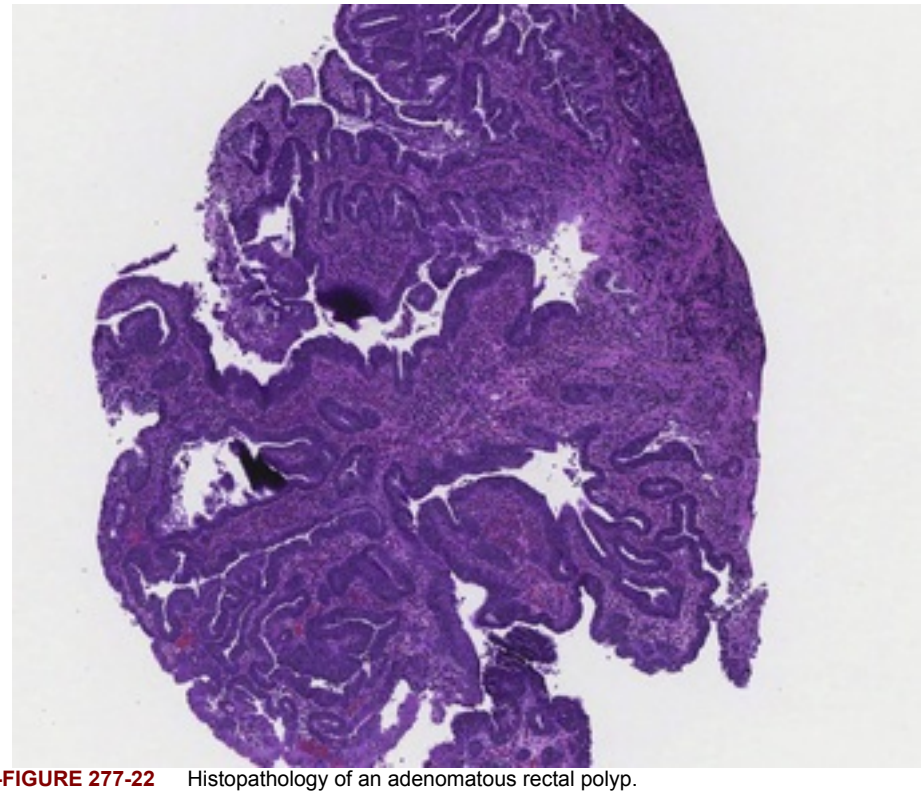
Sometimes, digital rectal manipulation of the polyp results in the mass being accidentally removed, but the stalk remains and the polyp soon regrows and hematochezia recommences. Similarly, removal above a transfixation ligature in the stalk may allow recurrence. Gentle eversion of the rectal mucosa using Allis forceps and submucosal resection of the base of the polyp's stalk is curative. For polyps in the distal colon and proximal rectum, removal with a polypectomy snare and with a resectoscope has been reported. Alternatively, resection via laparotomy is possible for colonic polyps. Multiple polyps have been treated with polypectomy and argon plasma coagulation.

Histology may indicate a benign or inflammatory polyp (E-Figure 277-22), an adenoma or even a carcinoma *in situ*. Pseudopolyposis is a very rare condition wherein multiple nodules are found in the colon (see Figure

277-21, *D*). They are not true polyps as they do not have a stalk. They are treated with glucocorticoids.



E-FIGURE 277-22 Histopathology of an adenomatous rectal polyp.

Alimentary Lymphoma[481,495-501]

Alimentary lymphoma is generally a diffuse disease affecting the SI with or without involvement of the LI, and it can produce a variety of signs including anorexia, vomiting, diarrhea, melena, hematochezia and weight loss. It is emerging as the most common form of lymphoma in cats. In dogs, it is potentially a cause of a protein-losing enteropathy if it involves the SI but it is uncommon compared to multicentric disease in dogs. Rectal lymphoma in dogs is a subset of the condition, where the disease is restricted anatomically, and which responds well to combination chemotherapy. All other forms of canine alimentary lymphoma either respond very poorly to chemotherapy, or tumor lysis leads to intestinal perforation and septic peritonitis; remission is very rare.

Transabdominal fine needle aspiration (see ch. 89), peritoneal fluid cytology, and endoscopic exfoliative cytology may be useful in the diagnosis of lymphoma, but histology may be required for a definitive diagnosis.

Common clinical signs in cats with alimentary lymphoma are vomiting (65%), diarrhea (52%), weight loss (46%) and palpable masses. Most affected cats are FeLV-negative, and most colonic lymphomas in cats are B cell in origin. Combination chemotherapy (prednisone, vincristine, cyclophosphamide) has been used to treat colonic lymphoma.

Other Tumors[483,502-520]

Leiomyosarcoma have a predilection site for the canine cecum. GI stromal tumors (GISTs), which arise from the interstitial cells of Cajal, are very similar clinically and previously could not be distinguished. Indeed 42% of 50 tumors reported as leiomyosarcoma were shown to be GISTs by immunohistochemistry, detecting expression of desmin, smooth muscle actin and c-kit markers (see ch. 276). Smooth muscle tumors have been associated with hypoglycemia and the associated clinical signs of muscular weakness and seizure activity due to the release of an insulin-like factor, and erythrocytosis due to the release of erythropoietin. The prognosis for leiomyomas is generally favorable.

Extramedullary plasmacytomas are a rare tumor of the GI tract but can occur in the colon and rectum.

Functional plasmacytomas secrete a single class of immunoglobulin, and affected animals may go on to develop hyperviscosity syndrome (e.g., retinal bleeding, epistaxis). Plasmacytomas may be managed with adjuvant chemotherapy (e.g., prednisone, melphalan) after surgical excision.

A variety of other mesenchymal tumors can occur in the LI: neurofibrosarcoma, fibrosarcoma, ganglioneuroma, and hemangiosarcoma, with the last more common in the GI tract of cats than dogs.

Ceco-Colic Intussusception (Cecal Inversion)[521-524]

Invagination of the cecum into the colon is abnormal and initially may occur intermittently. However, ultimately, it will become trapped by the sphincter at the ceco-colic orifice. Impairment of venous drainage then leads to mucosal sloughing and intraluminal bleeding. Diarrhea is not a consistent finding, but fresh blood and clots may be seen partially mixed with feces. Dogs may show signs of abdominal discomfort, and the intussusception may be palpable. The lesion may be visible with radiography, with or without barium contrast or with ultrasonography, but a definitive diagnosis is made by flexible colonoscopy (Figure 277-23, *A*) when a bleeding protuberance is seen adjacent to the ileocolic papilla.

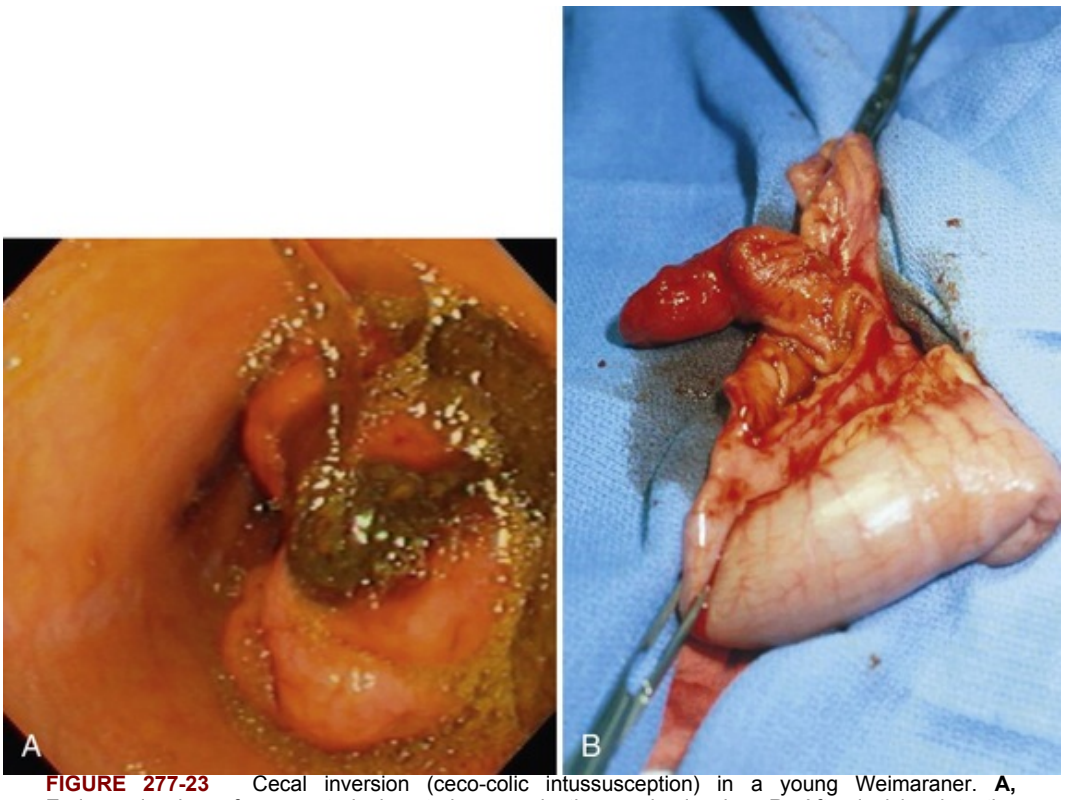


FIGURE 277-23 Cecal inversion (ceco-colic intussusception) in a young Weimaraner. **A,** Endoscopic view of an everted ulcerated cecum in the proximal colon. **B,** After incision into the proximal colon, the hemorrhagic everted cecum is exposed and can be removed by typhlectomy. (Images courtesy Alasdair Hotston-Moore.)

This unusual condition is reported exclusively in dogs, and is presumed to be rare in cats because they have a much shorter, less mobile cecum. *Trichuris* infection is claimed to predispose dogs to this condition, but it can be seen in dogs after diarrhea due to other causes. Treatment is by typhlectomy (Figure 277-23, *B*).

Colonic Vascular Ectasia (Angiodysplasia)[525-529]

There are a few case reports of angiodysplasia in the colon or rectum of young dogs. The vascular ectasia lesion(s) often bleed(s) profusely, leading to marked hematochezia, with patients sometimes needing blood transfusions. Diagnosis is made by colonoscopy when areas of coalescing, tortuous mucosal blood vessels are observed. It may be treated successfully by surgical excision of the affected region, but it can be challenging to detect the lesion at surgery from the serosal surface, and multiple surgeries may still be unsuccessful. Laser ablation and electrocoagulation may also be tried. However, in some cases the condition can affect much of

the colon and rather than perform subtotal colectomy, there are reports of successful management with estrogens.

Visceral Myopathy and Cecal Impaction[530]

A case of cecal impaction associated with visceral myopathy and intestinal pseudo-obstruction has been reported (see ch. 276).

Colonic Perforation[170,472,531-534]

Colono-rectal perforations are rare, but can be caused by trauma (e.g., pelvic fractures, over-vigorous colonic biopsy) and irradiation, or by insertion of a thermometer or other foreign objects. Perforation may also occur after neurogenic colonic ulceration.

Neurogenic Colonic Ulceration[535-537]

Very rarely, colonic ulcers develop in patients with acute intervertebral disc disease or after spinal surgery. They tend to occur in the proximal colon, especially at the left colic flexure. The mechanism is poorly understood, and is complicated by the fact that many of these patients are also treated with glucocorticoids. Localized ischemia and increased intraluminal pressure of neurogenic origin are thought to be involved, with glucocorticoids reducing mucin production and impairing healing. Initially, colonic ulceration will cause hematochezia, but eventually may lead to perforation and septic peritonitis. The prognosis is poor.

Diseases Causing Obstruction

Neoplasia of the LI is the most common cause of LI obstruction (see above). Other non-neoplastic, intramural processes such as intussusception, hematoma, and fibrosing stricture can potentially cause obstruction; FIP granuloma and phycomycosis (see above) should be included in the differential diagnosis list. Linear and nonlinear foreign bodies, and compression by an enlarged prostate, can also cause intraluminal and extraluminal obstruction respectively.

Intussusception[165,168,258,538-558]

An intussusception is an invagination of one segment of the GI tract *(intussusceptum)* into the lumen of the adjoining segment *(intussuscipiens).* Enterocolic intussusceptions account for the majority of cases reported and can be divided into three types: ceco-colic (or cecal inversion; see above), ileo-colic, and the very rare ileo-cecal. Of the three forms of entero-colic intussusception, the ileo-colic intussusception is the one most frequently encountered in practice and the one that most likely causes obstruction. Predisposing factors include intestinal parasitism, viral enteritis, foreign bodies, and masses, and can follow an episode of acute diarrhea. However, many ileo-colic intussusceptions are seen in young animals and appear idiopathic with a suggestion that there is underlying intestinal muscular incoordination because the enteric nervous system is not fully developed. Intussusceptions in older animals usually develop around a lesion such as a tumor or causes of focal peritonitis (e.g., perforation, wound dehiscence).

Pathophysiology

Invagination followed by intussusception of the ileum into the colon results in luminal obstruction and distension of the bowel segment proximal to the intussusception. Because the mesentery and blood supply are included in the invaginating segment, vascular compromise can occur, which initially leads to edema and intramural hemorrhage and eventually to ischemia and necrosis of the bowel.

Clinical Examination

Clinical signs of ileo-colic intussusception are intermittent vomiting, progressive loss of appetite, mucoid bloody diarrhea, and a palpable, cylinder-shaped mass in the cranial abdomen; abdominal pain is not a consistent finding. Most cases are acute, but chronic intussusception is possible when affected animals may eventually succumb to the effects of anorexia or blood loss rather than dehydration (Figure 227-24, *A* and *B*).

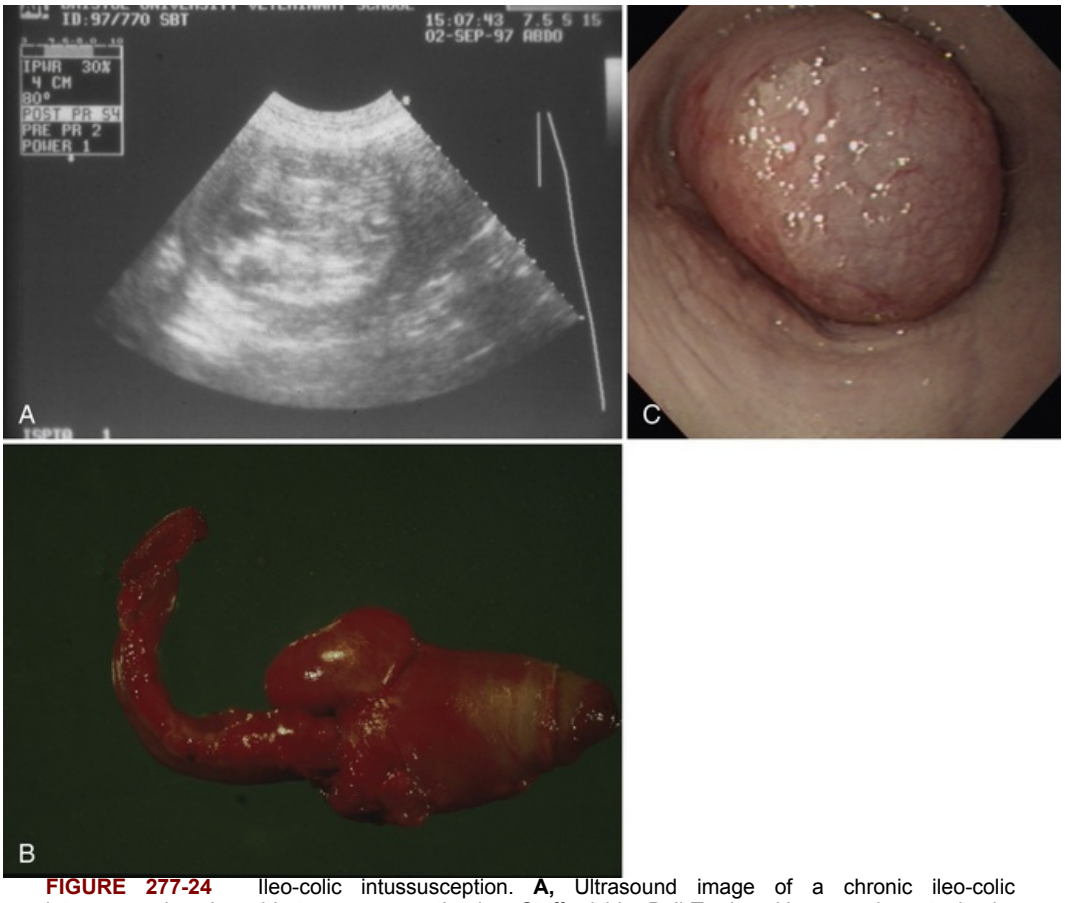

FIGURE 277-24 Ileo-colic intussusception. **A,** Ultrasound image of a chronic ileo-colic intussusception viewed in transverse section in a Staffordshire Bull Terrier with severe hematochezia. The normal double layering is not evident as the lesion has been present for 10 days and adhesions have developed between the intussusceptum and intussuscipiens. **B,** Ileocecocolic region resected from the dog in **A. C,** Endoscopic appearance of an early ileo-colic intussusception in a mix-breed dog.

Diagnosis

With some ileo-colic intussusceptions, the intussusceptum may eventually protrude through the anus, and must be differentiated from a rectal prolapse. A blunt probe passed between the protruding segment and the anal sphincter is indicative: if the probe can be passed cranial to the pubis without reaching a fornix, then the protruding bowel is the apex of an intussusception. Survey abdominal radiographic findings may be suspicious for intussusception, but abdominal ultrasonography is the preferred method of diagnosis. The appearance of a target-like mass consisting of two or more hyperechoic and hypoechoic concentric rings in transverse section, or multiple hyperechoic and hypoechoic parallel lines in longitudinal section, is virtually pathognomonic. Colonoscopy is rarely indicated, but if performed the intussusceptum may be visualized (Figure 277-24, *C*).

Treatment and Prognosis

Surgical management of ileo-colic intussusception involves either reduction or resection and anastomosis. If possible, the ileo-ceco-colic region is preserved to reduce reflux and fecal contamination of the ileum. Short bowel syndrome will occur if large lengths of the SI have to be resected (see ch. 276). The most common complications after surgery are recurrence, dehiscence and peritonitis, ileus, and intestinal obstruction. The recurrence rate in dogs is reported to be between 11% and 20%, and is most likely if there is any leakage at the anastomosis site causing a localized peritonitis. Historical attempts to prevent recurrence by administration of hyoscine to induce ileus may actually have an increased risk, and an early return to enteral nutrition and hopefully normal motility is now recommended. If recurrence occurs, surgical enteroplication of intestinal loops can be performed.

Stricture[176,472,477,559-562]

A benign LI stricture is rare in dogs and cats, and a suspicion of underlying neoplasia should always be considered, unless there is a history of previous LI surgery or foreign body impaction that could have caused a hematoma or ulceration with subsequent fibrosis. Inflammatory strictures have been reported in cats. Non-accidental injury must also be considered as potential cause. Constipation proximal to the stricture will occur, and treatment is by balloon dilatation or stenting.

Foreign Body

If an intestinal foreign body causes an obstruction, it is most likely to occur in the SI. Only occasionally do foreign bodies obstruct the colon as they first have to pass the much narrower SI and ileocolic sphincter.

Irritable Bowel Syndrome[1,563-568]

In human patients, irritable bowel syndrome (IBS) is a multifactorial, functional disorder of the GI tract, and is characterized by waxing and waning abdominal pain in association with diarrhea and/or constipation. Underlying psychological problems may predispose, and patients may have heightened awareness of GI motility, but IBS can also follow acute bacterial gastroenteritis, when the enteric nervous system remains disrupted for many months. The condition can be managed with central analgesics such as tricyclic antidepressants or selective serotonin reuptake inhibitors in addition to psychological interventions.

An idiopathic LI diarrheal syndrome has been characterized in dogs and has been likened to human IBS, yet whilst mucoid diarrhea and tenesmus predominate over constipation, hematochezia may occur. However, there are strict definitions (Rome III criteria) for diagnosing IBS in people, and hematochezia must not be present. Thus, it is not clear that dogs truly suffer IBS. Yet all investigations in dogs with this syndrome are negative for bacterial and other pathogens, histologic evidence of colitis, and colonic neoplasia, and the term chronic idiopathic large-bowel diarrhea has been used instead. Dogs affected with this syndrome may respond to the feeding of a highly digestible diet supplemented with soluble fiber. Anxiolytics (e.g., Librax [chlordiazepoxide with clidinium bromide, an antimuscarinic]) and antispasmodics (e.g., hyoscine, mebeverine, peppermint oil) are also reported to have some efficacy, although there is a suspicion of a strong placebo effect on the owner; this reduces the stress in the dog, which may actually be the cause or at least exacerbate the problem.

Constipation

Constipation and obstipation are manifestations of the same problem but of differing severity. Constipation is defined as infrequent or difficult evacuation of feces but does not necessarily imply a permanent loss of function; patients may suffer from one or two episodes of constipation without further progression. Intractable constipation that has become refractory to cure or control is referred to as obstipation and therefore implies a permanent loss of function. A patient is assumed to be obstipated only after several consecutive treatment failures. Dilated megacolon is the end stage of colonic dysfunction, whatever the cause (also see ch. 42).

Constipated animals typically show dyschezia: repeated unsuccessful attempts to defecate or pain on defecation, although sometimes liquid fecal material oozes out. With obstipation and megacolon, the patient may give up attempts to defecate, but eventually becomes unwell with vomiting, anorexia and dehydration. Megacolon develops through two pathologic mechanisms: dilation and hypertrophy. Hypertrophic megacolon develops as a consequence of obstructive lesions (e.g., malunion of pelvic fractures, tumors, foreign bodies). Hypertrophic megacolon due to pelvic constriction may be reversible with early pelvic osteotomy, or it may progress to irreversible dilated megacolon if appropriate therapy is not instituted. Dilated megacolon may occur secondary to electrolyte abnormalities, neuromuscular disorders or be idiopathic.

There are several factors that can predispose to constipation (see Figure 276-6, *C*; ch. 42) and hospitalized cats are particularly at risk because of lack of activity, unwillingness to defecate whilst kenneled, tendency to develop dehydration and hypokalemia when unwell, and the administration of opioid analgesics. Specific causes such as pelvic fracture and tail-pull neurological injuries are also more common in cats. Prostatomegaly in intact male dogs, and perineal hernia in bitches are more common reasons for constipation in dogs, which are also predisposed by eating bones.

A review of published cases suggests that 96 per cent of cases of obstipation in cats are accounted for by

idiopathic megacolon (62%), pelvic canal stenosis (23%), nerve injury (6%), or Manx sacral spinal cord deformity (5%). A smaller number of cases is accounted for by complications of colopexy (1%) and colonic neoplasia (1%); colonic hypoganglionosis or aganglionosis was suspected, but not proven, in another 2% of cases. Endocrine factors (e.g., obesity, hypothyroidism) were cited in several cases but were not necessarily implicated as part of the pathogenesis of megacolon. Thus the majority of cases are idiopathic, orthopedic or neurologic in origin.

Diagnosis

Constipation and obstipation are usually readily identified by abdominal palpation.

A complete neurologic examination should be performed with special emphasis on caudal spinal cord function, to identify spinal cord injury, pelvic nerve trauma, and Manx sacral spinal cord deformity (see ch. 259). Cats with constipation due to dysautonomia may have other signs of autonomic nervous system failure, such as urinary retention, regurgitation due to megaesophagus, mydriasis, decreased lacrimation, prolapse of the nictitating membrane, and bradycardia.

Digital rectal examination should be performed carefully, and always under sedation or anesthesia in cats. Pelvic fracture malunion may be detected and it may also identify foreign bodies, rectal diverticula, strictures, inflammation, or neoplasia.

Although patients are unlikely to have significant changes in laboratory data, a CBC and serum biochemistry profile should be performed in all patients with obstipation and megacolon where a physical cause cannot be found. Metabolic causes of constipation, such as dehydration, hypokalemia, and hypercalcemia may be detected. Basal serum thyroxine concentration and other thyroid function tests should also be considered in animals with recurrent constipation and other signs consistent with hypothyroidism.

Radiographs should be performed to characterize the severity of colonic impaction and to identify predisposing factors, such as intraluminal radiopaque foreign material (e.g., bone chips), intraluminal or extraluminal mass lesions, pelvic fractures, and spinal abnormalities (Figure 277-25). Extraluminal mass lesions may be further evaluated by abdominal ultrasonography and guided biopsy, whereas intraluminal mass lesions are best evaluated by endoscopy after the fecal material has been cleaned out (see ch. 114).

FIGURE 277-25 Lateral abdominal radiograph of cat with severe constipation due to idiopathic megacolon.

Treatment[45,171,175,569-577]

The specific therapeutic plan will depend upon the severity of constipation and the underlying cause. First episodes of constipation are often transient and resolve without therapy; hospitalized cats should be kept hydrated and fed a fiber-containing diet. Mild to moderate or recurrent episodes of constipation may be managed, often on an outpatient basis, with dietary modification, warm water enemas, oral or suppository laxatives, colonic prokinetic agents, or a combination of these therapies (see ch. 114). Severe cases of constipation usually require brief periods of hospitalization to correct dehydration and metabolic abnormalities and to evacuate impacted feces using water enemas, manual extraction of retained feces, or both. Follow-up therapy in such cats is directed at correcting predisposing factors and preventing recurrence. Subtotal colectomy will become necessary in cats suffering from obstipation or idiopathic dilated megacolon.

Removal of Impacted Feces

This may be accomplished through the use of suppositories, oral laxatives, enemas, rectal suppositories, or manual extraction.

Rectal Suppositories

Rectal suppositories may contain dioctyl sodium sulfosuccinate (DSS), an emollient laxative also called docusate; glycerol (syn. glycerin[e]), a lubricant laxative; or bisacodyl, a stimulant laxative. Their use requires a compliant pet and pet owner, but they can be used alone or in conjunction with oral laxative therapy as a first-line treatment, or as a way of preventing recurrence.

Laxatives

Laxatives promote evacuation of the bowel by stimulation of fluid and electrolyte transport and/or propulsive motility. Many products are available and most are bulk-forming laxatives containing dietary fiber supplements derived from cereal grains, wheat bran, or psyllium. Fiber supplemented diets are available commercially, or the pet owner may wish to add psyllium, wheat bran or pumpkin to canned food.

Emollient Laxatives

Emollient laxatives are anionic detergents that increase the miscibility of water and lipid in digesta, thereby enhancing lipid absorption and impairing water absorption. Docusate or DSS is available in oral and enema forms. Dioctyl calcium or potassium sulfosuccinate are alternatives in some countries.

Lubricant Laxatives

Lubricant laxatives include mineral oil ("liquid paraffin"), petrolatum (petroleum jelly) and a more palatable combination of white paraffin and beeswax (Katalax). The lubricating properties of these agents impede colonic water absorption and ease fecal passage. These effects are usually moderate and, in general, lubricants are only beneficial in mild constipation. Mineral oil use should probably be limited to rectal administration because of the risk of lipoid aspiration pneumonia with oral administration, especially in depressed or debilitated cats as it is tasteless and may be inhaled rather than swallowed. White paraffin products are more easily administered by cat owners, as they only need to be smeared on the cat on a site where it can be licked off.

Hyperosmotic Laxatives

Hyperosmotic laxatives consist of the poorly absorbed polysaccharides (lactose, lactulose, lactitol), magnesium salts (citrate, hydroxide, sulfate), and oral colonic cleansers such as hypertonic sodium phosphate and PEGs (see preparation for colonoscopy). Lactulose and PEGs are the most effective agents in this group. The organic acids produced from lactulose fermentation stimulate colonic fluid secretion and propulsive motility. Lactulose administered at an oral dosage of 0.5 mL/kg every 8 to 12 hours should consistently produce soft feces in cats. Many cats with recurrent or chronic constipation have been well managed with this regimen, but mild cases may be managed with just the addition of milk to the diet.

Stimulant Laxatives

Stimulant laxatives—bisacodyl, danthron (codanthramer), phenolphthalein, castor oil, cascara, and senna—are a diverse group of agents that stimulate propulsive colonic motility. Bisacodyl, for example, stimulates nitric oxide-mediated epithelial cell secretion and myenteric neuronal depolarization. Diarrhea results from the combined effect of increased mucosal secretion and colonic propulsion. Bisacodyl (at a dosage of 5 mg orally, every 24 hours) is the most effective stimulant laxative in the cat. Lubiprostane is a newer laxative

developed for people, which increases colonic secretion by stimulating chloride channels. Its use in animals has not been reported.

Enemas

Enemas may be required for moderate or severe episodes of constipation. Either warm tap water (5 to 10 mL/kg) or enema solutions including warm isotonic saline (5 to 10 mL/kg), DSS (5 to 10 mL/cat), mineral oil (5 to 10 mL/cat), or lactulose (5 to 10 mL/cat) can be used. They should all be administered slowly via a well-lubricated rubber catheter or feeding tube from an enema bucket or using a Higginson pump so that excessive pressure is not applied (see ch. 114). Enemas containing sodium phosphate are contraindicated in cats and small dogs because of their propensity for inducing fatal hypernatremia, hyperphosphatemia, and hypocalcemia.

Manual Extraction

Manual extraction of impacted feces is required for cases unresponsive to laxatives or enemas. Warm water or saline is infused into the colon, while the fecal mass is gently massaged by abdominal palpation. Digital extraction of feces from the rectum is then performed. It is often advisable to evacuate all of the fecal mass over a period of several days to reduce the risks of prolonged anesthesia and risk of perforation of a stretched and devitalized colonic wall. "Spoon" devices to evacuate the feces should only be used with great caution.

Preventative Therapy[477,578]

Once impacted feces have been cleared, it is important to institute measures to prevent recurrence. Any underlying cause should be corrected if possible (e.g., pelvic osteotomy, stricture dilatation or stenting [see ch. 123], castration to reduce prostatomegaly), and any predisposing factors such as dehydration, lack of exercise, over-feeding, etc., avoided. Feeding a diet with added fiber and/or milk are simple but often effective strategies, but in some cases, pharmacologic intervention is still required.

Colonic Prokinetic Agents[71-73,567,579-595]

In vitro studies have shown that cisapride stimulates feline colonic smooth muscle contraction. Although this has not yet been conclusively shown *in vivo,* a large body of anecdotal experience suggests that cisapride is effective in stimulating colonic propulsive motility in mild to moderate idiopathic feline constipation. Longstanding obstipation and megacolon cases are not likely to respond. Unfortunately, cisapride was withdrawn from many drug markets in 2000 after reports of cardiac side effects (prolonged QT) and sudden death in people. Ranitidine and nizatidine were suggested as alternatives, as they have prokinetic activity *in vitro* stimulating cholinergic activity, but experience indicates they are not very effective *in vivo.*

Tegaserod, a potent partial agonist at 5-HT_4 receptors and a weak agonist at 5-HT_{1D} receptors, was developed as it had definite prokinetic effects in the canine colon, but again it has been withdrawn because of prolongation of the QT interval. Prucalopride is related to cisapride with a similar prokinetic activity but no cardiac effects and is now available in Europe. It is a potent 5-HT4 receptor agonist that stimulates GMCs and defecation in dogs and cats. The related mosapride has no activity in the colon, and is as ineffective as metoclopramide in stimulating colonic motility.

Acotiamide facilitates muscarinic acetylcholine activity and has been shown to stimulate post-prandial gastroduodenal and colonic activity in dogs at a dosage of 30 mg/kg and has been approved (Acofide) for use in human patients in Asia. High dosages of mirtazapine have also been shown to accelerate gastric emptying and colonic transit, in addition to the better known appetite stimulant and anti-nausea effects. Finally intra-colonic installation of capsaicin, the ingredient of chilies, stimulates colonic motility and defecation, but when given orally slows SI transit.

Prognosis

Many animals can have one or two episodes of constipation without further recurrence, although others may progress to complete colonic failure. Cats with mild to moderate constipation generally respond to conservative medical management with dietary modification, emollient or hyperosmotic laxatives, and colonic prokinetic agents. Early use of colonic prokinetic agents, in addition to one or more laxative agents, is likely to prevent the progression of constipation to obstipation and megacolon in these cats, which otherwise eventually require colectomy.

Feline Idiopathic Megacolon[143,596-602]

Idiopathic megacolon is most commonly observed in middle-aged (mean: 5.8 years) male (70%) domestic shorthair (46%), domestic longhair (15%), or Siamese (12%) cats. Affected cats usually have reduced, absent, or painful defecation for a period of time ranging from days to weeks or months. Cats may be observed making multiple, unproductive attempts to defecate in the litter box, or just sitting in the litter box for prolonged periods of time. Colonic impaction is a consistent physical examination finding in affected cats. Other findings will depend upon the severity and chronicity of the obstipation and megacolon, and include dehydration, weight loss, debilitation, abdominal pain, and mild to moderate mesenteric lymphadenopathy.

The etiopathogenesis of idiopathic megacolon is incompletely understood but affected cats have permanent loss of colonic structure and function. Medical therapy (laxatives, prokinetics) may be effective initially, but most affected cats eventually require colectomy. The pathogenesis of idiopathic dilated megacolon appears to involve functional disturbances in colonic smooth muscle. The lesion may begin in the descending colon and progress to involve the ascending colon over time. *In vitro* studies show that colonic smooth muscle obtained from cats suffering from idiopathic dilated megacolon undergoing colectomy develops less isometric stress in response to neurotransmitters (acetylcholine, substance P, cholecystokinin), membrane depolarization (KCl), or electrical field stimulation when compared with healthy controls.

Subtotal colectomy should be considered in cats that are refractory to medical therapy.[603-611] Cats have a generally favorable prognosis for recovery after colectomy, especially if the ileocolic valve is preserved, although mild to moderate diarrhea may persist for weeks to months postoperatively in some cases.
