TEXTBOOK OF VETERINARY INTERNAL MEDICINE

EIGHTH EDITION

STEPHEN J. ETTINGER
EDWARD C. FELDMAN
ETIENNE CÔTÉ

ELSEVIER

Textbook of Veterinary Internal Medicine

DISEASES OF THE DOG AND THE CAT

EIGHTH EDITION

STEPHEN J. ETTINGER, DVM

DACVIM (SMALL ANIMAL INTERNAL MEDICINE AND CARDIOLOGY)
FACC; FAHA; CCRP
Doctor Honoris Causa (University of Veterinary Medicine Bucharest)
VetCorp, Inc.
Los Angeles, California

EDWARD C. FELDMAN, DVM

DACVIM (SMALL ANIMAL INTERNAL MEDICINE)
Emeritus Professor of Small Animal Internal Medicine
University of California, Davis
Davis, California

ETIENNE CÔTÉ, DVM

DACVIM (SMALL ANIMAL INTERNAL MEDICINE AND CARDIOLOGY)
Professor
3M National Teaching Fellow
Department of Companion Animals
Atlantic Veterinary College
University of Prince Edward Island
Charlottetown, PE, Canada

Preface

- About the Cover

Client Information Sheets

Volume 1

Section I The Real Basics of Veterinary Medicine

Chapter 1 The Medical History

- Overview
- The Approach to the Pet Owner
- Requirements for a Thorough History
- The Elements of the History
- Questions for the Vague Clinical Complaint
- References

Chapter 2 The Physical Examination

- Observing the Pet and Meeting the Caretaker
- The Physical Examination Process
- Completing the Physical Examination

Chapter 3 Basic Genetics

Important Genetic Terminology

Dna to Protein

Modes of Inheritance

Dna Evaluation

References

Chapter 4 Clinical Genomics

Important Genetic Terminology

Clinical Genetics

Factors That Impact Clinical Presentation of Familial Disease

Genetic Counseling

Types of Genetic Tests

Pharmacogenetics

References

Chapter 5 Evidence-Based Medicine

References

Chapter 6 Biomedical Statistics

Hypothesis Testing

Statistical Methods

Chapter 7 Euthanasia

References

Section II Differential Diagnosis for Chief Concerns

General

Chapter 8 “Ain't Doing Right”: The Nonspecific Chief Concern of Ill Thrift

Signalment

Medical History

Physical Examination

Diagnostic Tests

Treatment

Ill Thrift That is Not a Sign of Disease

Resolution

Suggested Readings

Chapter 9 Distinguishing Behavioral Disorders from Medical Disorders

Introduction

Behavioral Disorders

Potential Medical Disorders in Dogs

Summary

References

Chapter 10 Dermatologic Manifestations of Systemic Disease

Systemic Diseases Associated with Alopecia

Systemic Diseases With Diffuse Hypotrichosis, Scales and Crusts

Systemic Diseases With Facial and Dorsal Erythema, Alopecia, Scaling and Crusting

Systemic Diseases With Alopecia, Erythema, Scales and Crusts Affecting Face, Legs and Tail; Dermatomyositis (DM)

Systemic Diseases With Alopecia and Shiny Skin of Periocular Region, Ventral Neck, Ventral Abdomen and Legs; Feline Paraneoplastic Alopecia (see ch. 352)

Systemic Diseases With Cutaneous Erythema, Alopecia, Scales and Crusts of Mucocutaneous Junctions and Footpads

Systemic Diseases With Cutaneous Plaques

Systemic Diseases With Cutaneous Nodules

Systemic Diseases With Skin Fragility

Systemic Diseases With Thick Skin

References

Chapter 11 Ophthalmic Manifestations of Systemic Disease

Introduction

Ophthalmic Examination

Orbital Disease

Systemic Hypertension

Metastatic Neoplasia

References

Chapter 12 Neurologic Manifestations of Systemic Disease

Diseases Causing CNS Signs

Diseases Causing PNS Signs

References

Chapter 13 Intoxication versus Acute, Nontoxicologic Illness: Differentiating the Two

Case History

Stabilizing the Patient

Toxicologic Versus Nontoxicologic

Suggested Readings

Chapter 14 Orthopedic Manifestations of Systemic Disease

Diagnostic Approach to Orthopedic Manifestations of Systemic Disease (Figure 14-1)

Other Causes of “Orthopedic Signs”

Diagnostic Testing

References

Chapter 15 Swollen Joints and Joint Pain

Overview and Definitions

Physical Examination

Pathophysiology

Septic Arthritis

Immune-Mediated Polyarthritis

Erosive Polyarthritis

Nonerosive Polyarthritis

Other Causes of Mono- or Polyarthropathies

Arthrocentesis

Joint Fluid Analysis

Additional Testing

References

Chapter 16 Weight Gain

Overview

History

Physical Examination

Diagnostic Approach

References

Chapter 17 Abdominal Enlargement

Differential Diagnoses

Diagnostic Approach

Treatment

References

Chapter 18 Peripheral Edema

Mechanisms of Edema Formation

Diagnosis and Treatment of Edematous Diseases

References

Chapter 19 Weight Loss as a Chief Complaint

Background

History

Physical and Laboratory Findings

Diagnostic Plan

Therapy

References

Chapter 20 Failure to Grow

- Introduction
- Pathophysiology
- Endocrine Causes of Failure to Grow
- Non-Endocrine Causes of Failure to Grow
- Diagnostic Approach (Figure 20-1)
- Treatment
- References

Chapter 21 Weakness

- Specific Mechanisms and Diseases

Chapter 22 Restlessness

- History
- Intoxications and Drugs
- Pain or Discomfort
- Metabolic Encephalopathies
- Primary Intracranial Conditions
- Need for Behaviorist?
- References
- Suggested Readings

Chapter 23 Anorexia

- Definitions and Consequences
- Causes
- Treatment
- References

Chapter 24 Polyphagia

- Physiology and Pathophysiology
- History
- Physical Examination
- Diagnostic Plan
- Management
- Suggested Readings

Chapter 25 Body Odors

- Addressing the Body Odor Issue
- Normal Pet Odors
- Normal Pet with an Obvious Non-Medical Cause
- Primary Medical Condition Resulting in Pet Malodor

References

Cardiorespiratory

Chapter 26 Coughing

Coughing Mechanisms

History

Differential Diagnosis for Coughing

Clinical Assessment

Clinical Investigations

Clinical Management

References

Chapter 27 Sneezing and Nasal Discharge

Clinical Presentations

Diagnostic Approach

Diagnostic Plan

Treatment/Outcome

References

Chapter 28 Tachypnea, Dyspnea, and Respiratory Distress

Pathophysiology

Immediate Assessment and Management of the Dyspneic Patient (see also ch. 131 and 139)

Important Historical Information

Complete Physical Examination

Localization

Further Diagnosis and Therapy

References

Chapter 29 Epistaxis and Hemoptysis

Epistaxis

Hemoptysis

References

Chapter 30 Syncope

Mechanisms and Causes of Syncope

History-Taking

Diagnostic Approach

Summary

References

Neurologic

Chapter 31 Movement Disorders

- Clinical Evaluation
- Spasticity
- Myotonia
- Tetany
- Tetanus
- Paroxysmal Dyskinesia
- Drug-Induced Dyskinesia
- Myokymia and Spinocerebellar Ataxia
- Myoclonus
- Encephalomyelitis
- Dancing Doberman
- Other Abnormal Movements
- References

Chapter 32 Tremors

- Definition
- Pathophysiology of Tremor
- Classification
- Acute Onset Generalized Tremor Syndromes
- Other CNS Inflammatory Disease That May Present with Tremor
- Chronic Onset Generalized Tremor Syndromes
- References

Chapter 33 Ataxia, Paresis, Paralysis

- Ataxia
- Paresis and Paralysis
- Suggested Readings

Chapter 34 Stupor and Coma

- Definitions
- Pathophysiology
- Approach to the Patient with Stupor or Coma
- Diagnostic Plan
- Treatment Goals
- Prognosis
- Suggested Readings

Chapter 35 Seizures

Seizure Classification
Diagnostic Approach
Principles of Therapy
Outcome
References

Gastrointestinal

Chapter 36 Ptyalism and Halitosis
Ptyalism
Halitosis
References

Chapter 37 Gagging
Anatomy and Physiology
History
Clinical Evaluation
References

Chapter 38 Dysphagia
Dysphagia
Regurgitation (also see ch. 39)
References

Chapter 39 Vomiting and Regurgitation
Differentiating Regurgitation From Vomiting
Regurgitation
Vomiting
References

Chapter 40 Diarrhea
Routine Diagnostics
Advanced Diagnostics
Suggested Readings

Chapter 41 Melena and Hematochezia
Melena
Hematochezia
References

Chapter 42 Constipation, Tenesmus, Dyschezia, and Fecal Incontinence

Definitions
Physiology of the Large Intestine
Constipation
Tenesmus and Dyschezia
Fecal Incontinence

Chapter 43 Flatulence
Physiology and Pathophysiology of Flatulence
Pathophysiology
Clinical Presentation and Differential Diagnosis
Investigation
Management
References

Urogenital

Chapter 44 Vulvar and Preputial Discharge
Introduction
Vaginal Discharge
Preputial Discharge
References

Chapter 45 Polyuria and Polydipsia
Introduction
Differential Diagnosis
Primary Polydipsia
Primary Polyuria
Diagnostic Approach
References

Chapter 46 Pollakiuria, Stranguria, and Urinary Incontinence
Definitions
Pathophysiology
Causes of Clinical Signs
Diagnostic Workup (Figure 46-1)
Treatment
References

Chapter 47 Hematuria and Other Conditions Causing Discolored Urine
Overview
Normal Urine

Discolored Urine

References

Section III Differential Diagnosis for Physical Examination Abnormalities

Chapter 48 Fever

Defining Fever, Hyperthermia, and Fever of Unknown Origin

Pathogenesis of Fever

Benefits of Fever

Costs of Fever

Measurement of Temperature

Differential Diagnoses for Fever

Approach to a Fever

Treatment

References

Chapter 49 Hypothermia

Cardiovascular Effects

Respiratory Effects

Neuromuscular Effects

Clinicopathologic Effects (Acid-Base, Coagulation, Electrolytes)

Renal and Metabolic Effects

Treatment

The Use of Hypothermia for Treatment

References

Chapter 50 Pallor

Evaluation

References

Chapter 51 Hyperemia

References

Chapter 52 Cyanosis

Physiology and Pathophysiology

Causes of Central and Peripheral Cyanosis (Box 52-1; see also Figure 52-1)

Evaluation of the Cyanotic Animal

Diagnostic Tests

Treatment

Chapter 53 Jaundice

Pathophysiology

Causes of Jaundice
Clinical Approach (Figure 53-1)
Diagnostic Plan

Chapter 54 Petechiae and Ecchymoses
Pathophysiology
Diagnostic Approach
Treatment
References

Chapter 55 Abnormal Heart Sounds and Heart Murmurs
Transient Heart Sounds
Cardiac Murmurs
Systolic Heart Murmurs
Diastolic Heart Murmurs
Continuous Murmurs
Auscultation and Beyond

Chapter 56 Pulse Alterations
Venous Pulses
References

Section IV Differential Diagnosis for Clinicopathologic Abnormalities

Chapter 57 Anemia, Erythrocytosis
Anemia
Erythrocytosis
References

Chapter 58 Leukopenia, Leukocytosis
Introduction
Leukocytosis
Leukopenia
Approach to Evaluation of Leukocytosis and Leukopenia
References

Chapter 59 Thrombocytopenia, Thrombocytosis
Platelet Life Cycle
Diagnosis of Thrombocytopenia (Figure 59-1)
Classification of Thrombocytopenia (Figures 59-1 and 59-2; also see ch. 201)
Diagnosis of Thrombocytosis (see Figure 59-2)
References

Chapter 60 Hypoproteinemia, Hyperproteinemia

Measurement of Serum and Plasma Protein

Positive and Negative Acute Phase Proteins

Causes of Hypoproteinemia

Causes of Hyperproteinemia

References

Chapter 61 Hypoglycemia, Hyperglycemia

Hypoglycemia

Hyperglycemia

References

Chapter 62 Blood Urea Nitrogen and Creatinine

Introduction and Definitions

Blood Urea Nitrogen

Creatinine

Symmetric Dimethylarginine (Idexx SDMA)

Causes of Azotemia (Increases in BUN and/or Serum Creatinine)

Non-Renal Effects on BUN and Creatinine

References

Chapter 63 Cholesterol, Triglycerides

Introduction and Terminology

Canine Hyperlipidemia

Feline Hyperlipidemia—Species Differences

Hypocholesterolemia and Hypotriglyceridemia

References

Chapter 64 Amylase, Lipase

Dogs

Cats

References

Chapter 65 Liver Enzymes

Clinical Enzymology

Summary

References

Chapter 66 Creatine Kinase

Normal Activity and Tissue Distribution

Effect of Exercise on Serum CK Concentrations

Disorders Causing Increased Serum CK Concentrations (Figure 66-1)

Chapter 67 Sodium, Chloride

Overview

Hypernatremia (Figure 67-1)

Hyponatremia (Figure 67-2)

Hypochloremia (Figure 67-3)

Hyperchloremia

References

Chapter 68 Potassium, Magnesium

Potassium

Magnesium

References

Chapter 69 Calcium, Phosphorus

Calcium Overview

Hypercalcemia in Dogs

Hypercalcemia in Cats

Diagnostic Approach to Hypercalcemia

Hypocalcemia

Phosphorus

References

Chapter 70 Lactate

Introduction

References

Chapter 71 Ammonia

References

Chapter 72 Urinalysis

Overview and Indications

Collection and Care of Urine Samples

Physical Analysis

Chemical Analysis

Microscopic Sediment Examination

Lipids

Other Elements

Other Routine Tests

Non-Routine Tests

References

Chapter 73 Urinary Electrolyte Concentrations

Introduction

Disorders of Sodium (Na^+)

Potassium (K^+) Disorders

References

Chapter 74 Fluid Analysis

Thoracic and Abdominal Cavity Fluid

Joint Fluid

References

Section V Techniques

General

Chapter 75 Venous and Arterial Puncture

Placement of Peripheral Venous Catheters

Arteries: Arterial Puncture

Placement of Arterial Catheters

References

Chapter 76 Jugular Catheterization and Central Venous Pressure Measurement

Placement: Seldinger Technique

Peripherally Inserted Central Catheters

Central Venous Pressure Measurement

Chapter 77 Intraosseous Catheters

Introduction

Contraindications and Possible Complications

Techniques

Equipment

Inserting the Intraosseous Catheter

References

Chapter 78 Constant Rate Infusions

References

Chapter 79 Ear Vein Blood Glucose Monitoring

Capillary Blood Sampling with Conventional Lancet Device

Capillary Blood Sampling with Vacuum Lancing Device

References

Chapter 80 Buccal Mucosal Bleeding Time

Performing a BMBT

Causes of a Prolonged BMBT

References

Chapter 81 Fecal Examination

Collecting and Storing Fecal Specimens

Gross Examination of the Fecal Specimen

Fecal Smear

Fecal Flotation Techniques

Flotation Solutions

Centrifugal Flotation vs. Standing Flotation

Standing Flotation

Centrifugal Flotation

Proper Examination of the Coverslip

Fecal Sedimentation

Baermann Procedure

Fecal Culture for Parasites

Immunologic and Molecular Techniques

Diagnostic Resources

References

Chapter 82 Nasoesophageal, Esophagostomy, Gastrostomy, and Jejunal Tube Placement Techniques

Overview

Enteral Feeding Tube Material and Access Devices

Removal of Esophagostomy, Gastrostomy and PEG-J Tubes

Replacement of Gastrostomy and Esophagostomy Tubes

Complications of Enteral Feeding

References

Chapter 83 Care of Endoscopic Equipment

Overview

Nomenclature

Handling

Instrumentation

“Bedside” Testing and Cleaning (Video 83-1)

Leak Testing (Video 83-2)

Manual Cleaning (Video 83-3)

High-Level Disinfection (Video 83-4)

Endoscope Storage
Documentation
References

Chapter 84 Hyperbaric Medicine
History
Physiology
Indications
Contraindications
Complications
Equipment and Safety
Treatment Protocol (Dive)
Summary
References

Skin

Chapter 85 Otoscopy, Ear Flushing, and Myringotomy
Indications
Equipment
Clinical Anatomy
Otoendoscopic Exam
Deep Ear Cleaning/Aural Flushing
Myringotomy
Complications of Otoendoscopy
References

Chapter 86 Scraping, Fine-Needle Aspiration, and Biopsy of Skin and Subcutaneous Tissues
Skin Scrapings
Getting the Most From a Skin Biopsy (E-Box 86-1)
References

Chapter 87 Cytology of the Skin and Subcutaneous Tissues
Keys to Consider When Submitting or Evaluating Cytologic Samples
Septic Versus Non-Septic Inflammation
Neoplastic Versus Non-Neoplastic Lesions
Benign Versus Malignant Tumors
Types of Neoplastic Lesions
When to Biopsy
References

Abdomen

Chapter 88 Abdominal Ultrasonography

- Ultrasound Physics
- Tissue Characteristics
- Performing the Complete Abdominal Ultrasound Examination (Video 88-1)
- Summary

Chapter 89 Abdominal Ultrasound

- Background
- Indications
- Materials
- Techniques
- Ultrasound-Guided Procedures
- Complications

Chapter 90 Abdominocentesis and Diagnostic Peritoneal Lavage

- Abdominocentesis
- Diagnostic Peritoneal Lavage
- References

Chapter 91 Laparoscopy

- Equipment
- Indications for Laparoscopy
- Technique
- Laparoscopy-Guided Liver Biopsy (Video 91-1)
- Laparoscopic Surgery
- References

General Centesis and Biopsy

Chapter 92 Bone Marrow Aspiration and Biopsy

- Overview
- Materials and Equipment
- Preparation and Site Selection
- Procedure: Bone Marrow Aspiration
- Procedure: Bone Marrow Core Biopsy
- References

Chapter 93 Cytology of Internal Organs

- Background

Indications/Advantages
Disadvantages or Limitations
Complications and Contraindications
Specimen Preparation (see Video 93-1)
Sending Samples to a Laboratory
Cytology of Different Internal Organs

Chapter 94 Arthrocentesis and Arthroscopy
Anatomy and Physiology
Background and Indications
Techniques
Suggested Readings

Chapter 95 Lymph Node Aspiration and Biopsy
Background
Lymph Node Cytology Techniques (Video 95-1)
Lymph Node Cytology Interpretation
References

Chapter 96 Rhinoscopy, Nasal Biopsy, and Nasal Flushing
Rhinoscopy
Nasal Biopsy
Nasal Flushing
References

Respiratory/Cardiovascular

Chapter 97 Respiratory and Inhalant Therapy
Nebulization
Metered Dose Inhaler
Inhaled Chemotherapy and Immunotherapy
References

Chapter 98 Pulse Oximetry
Overview and Basic Principles
Technique of Obtaining a Pulse Oximeter Reading
Interpreting a Pulse Oximeter Reading
References

Chapter 99 Blood Pressure Measurement
Patient Selection

Indications for Blood Pressure Assessment
Hypotension
Choosing a Blood Pressure Measurement Technique
Blood Pressure Measurement Techniques
Suggested Readings

Chapter 100 Chest Tube Placement
Basic Equipment and Types of Thoracostomy Tubes
Techniques
Intermittent Versus Continuous Suction
Troubleshooting Continuous Air Production
Suggested Readings

Chapter 101 Transtracheal Wash and Bronchoscopy
Transtracheal Wash
Endotracheal Wash
Bronchoalveolar Lavage: Blind Technique
Bronchoscopy
References

Chapter 102 Thoracocentesis/Pericardiocentesis
Thoracocentesis
Pericardiocentesis

Chapter 103 Electrocardiography
The Physics of Electrocardiography
Recording the Electrocardiogram
Ambulatory Monitoring
References

Chapter 104 Echocardiography
Principles of Ultrasound Physics¯
Equipment¯
Technical Aspects¯,
The Normal Echocardiogram: Image Acquisition, Standard Views, and Sequence¯,,
Artifacts
Repeatability and Reproducibility in Veterinary Echocardiography
Special Echocardiographic Techniques
Evaluation of Cardiac Structure and Function
Assessment of Global Cardiac Function
References

Renal/Urinary/Prostatic

Chapter 105 Urine Collection

- Background
- Collection Methods
- Sample Management
- References

Chapter 106 Management of Urinary Catheters

- Indications
- Indwelling Urinary Catheter Care
- Personnel
- Monitoring and Care
- Complications
- Catheter-Associated Urinary Tract Infection
- Monitoring “Ins & Outs”
- References

Chapter 107 Unblocking of the Urethra

- Overview
- Patient Management
- Determining the Cause
- Anesthesia
- Unobstructing the Feline Urethra
- Unobstructing the Canine Urethra
- Post-Obstruction Care
- References

Chapter 108 Cystoscopy and Urethroscopy

- Overview
- Equipment
- Patient Preparation and Procedure
- Postoperative Management and Complications
- References

Chapter 109 Peritoneal Dialysis

- Overview
- Preparation
- Procedure
- Complications
- Outcome

References

Chapter 110 Continuous Renal Replacement Therapy/Hemodialysis

Overview

Blood Purification

Intermittent Hemodialysis

Continuous Renal Replacement Therapy

Therapeutic Plasma Exchange

Anticoagulation

Blood Access

Complications

Indications

References

Chapter 111 Prostatic Diagnostic Techniquess

Prostatic Imaging

Prostatic Sample Collection

References

Gastrointestinal

Chapter 112 Gastric Intubation and Lavage

Gastric Intubation

Gastric Lavage

References

Chapter 113 Gastrointestinal Endoscopy

Overview

Equipment

Patient Preparation

Esophagogastroduodenoscopy

Lower GI Endoscopy

Endoscopic Examination and Biopsy

Endoscope Cleaning and Storage

Complications

References

Chapter 114 Enemas and Deobstipation

Enemas and Manual Extraction: When to Use What

Enemas and Manual Extraction: How to Do It (Figure 114-2)

Evaluation of Treatment Success and Long-Term Managment

Summary
References

Neurologic

Chapter 115 Cerebrospinal Fluid Collection, Analysis, and Myelography
Indications and Contraindications for Cerebrospinal Fluid Collection
Myelography
References

Chapter 116 Muscle and Nerve Biopsy
Muscle Biopsy
Nerve Biopsy
Suggested Readings

Chapter 117 Electromyography and Nerve Conduction Velocity
Overview
Electromyography (EMG)
Motor and Sensory Nerve Conduction
References

Reproductive

Chapter 118 Artificial Insemination in the Dog
Overview
AI Techniques in the Dog
References

Chapter 119 Vaginoscopy and Vaginal Cytology in Dogs
Indications
Procedure for Obtaining a Sample
Cell Types Present on Cytology
Cyclic Changes during the Estrous Cycle™ (Table 119-1; Video 119-3)
Other Reproductive Disorders That Vaginal Cytology May Be Helpful in Elucidating
References

Section VI Minimally Invasive Interventional Therapies

Chapter 120 Overview of Interventional Medicine
Introduction
Advantages and Disadvantages

Equipment
IR/IE Instrumentation
Laser
References

Chapter 121 Respiratory Interventional Therapies
Tracheal Collapse
Nasopharyngeal Stenosis
References

Chapter 122 Cardiovascular Interventional Therapies
Preparation for Cardiovascular Catheterization
Right Heart Interventions
Left Heart Interventions
Hybrid Interventions
References

Chapter 123 Gastrointestinal Interventional Therapies
Esophageal Balloon Dilation, Bougienage, and Stenting
GI Polypectomy/Electrocautery
GI Stenting
Endoscopic Retrograde Cholangiography and Biliary Stenting (ERC/BS)
PT(C)E: Percutaneous Transvenous (Coil) Embolization
HAVM
Miscellaneous Hepatobiliary Interventions
References

Chapter 124 Urologic Interventional Therapies
Equipment
Percutaneous Antegrade Urethral Catheterization
Percutaneous Cystostomy Tube Placement
Cystoscopic Basket Retrieval of Lower Urinary Tract Stones
Intracorporeal Lithotripsy of the Lower Urinary Tract
Transvesicular Percutaneous Cystolithotomy (PCCL)
Urethral Stenting
Ultrasound-Guided Endoscopic Laser Ablation of Transitional Cell Carcinoma of the Lower Urinary Tract
Treatment with Urethral Bulking Agents for Sphincter Mechanism Incompetence
Artificial Urethral Sphincter (AUS) Placement
Percutaneous Perineal Access for Canine Rigid Male Cystourethroscopy
Endoscopic Laser Ablation of Vestibulovaginal Remnants (ELA-VR)
Cystoscopic-Guided Laser Ablation of Canine Intramural Ectopic Ureters

Treatment of Nephrolithiasis
Treatment of Benign Ureteral Obstructions
Treatment of Malignant Ureteral Obstructions
Treatment of Idiopathic Renal Hematuria
References

Chapter 125 Neoplastic Interventional Therapies
Palliative Stenting for Malignant Obstructions
Intra-Arterial (IA) Chemotherapy Delivery
Trans-Arterial Embolization (TAE)/Chemoembolization (TACE)
References

Section VII Critical Care

Chapter 126 Pain Physiology, Identification, and Management in the Acute Care Setting
Current Concepts of Pain Physiology
Clinical Pain Taxonomy and Nomenclature
Pain Identification in the Acute Care Setting
Pain Management as a Standard of Practice
Strategies for Acute Pain Management
Adverse Effects of Acute Pain Treatment
References

Chapter 127 Shock
Types of Shock
References

Chapter 128 Acid-Base, Oximetry, and Blood Gas Analysis
Basic Acid-Base Physiology
Acid-Base Disorders
Oxygenation
References

Chapter 129 Crystalloid and Colloid Fluid Therapy
Fluid Distribution and Microvascular Barrier
Fluid Types
Fluid Plans
Monitoring
Complications/Controversies
Albumin
References

Chapter 130 Blood Transfusions, Component Therapy, and Oxygen-Carrying Solutions

Sources of Blood Products

Indications for Transfusion and “Triggers”

Compatibility Testing

Cat Red Cell Antigens

Dog Red Cell Antigens

Non-Red Cell Incompatibilities

Autotransfusion

Administering a Transfusion

Adverse Consequences of Transfusions (Transfusion Reactions)

Acute Immunologic Transfusion Reactions

Delayed and Other Immunologic Transfusion Reactions

Acute Non-Immunologic Transfusion Reactions

Diagnosis and Treatment of Transfusion Reactions

References

Chapter 131 Oxygen Therapy

Indications and Goals of Oxygen Therapy

Techniques

Monitoring

Oxygen Toxicosis and Guidelines for Oxygen Administration

References

Chapter 132 Sepsis and the Systemic Inflammatory Response Syndrome

Pathogenesis

Clinical Aspects

Diagnosis

Treatment

Prognosis

References

Chapter 133 The Endocrine Response to Critical Illness

Overview

Hypothalamic-Pituitary-Adrenal Axis

Hypothalamic-Pituitary-Thyroid Axis

Somatotropic, Gonadal and Lactotropic Axes

References

Chapter 134 Heatstroke

Pathophysiology

Clinical Signs

Laboratory Changes
Treatment
Prognosis
References

Chapter 135 Hemorrhage
References

Chapter 136 Status Epilepticus
References

Chapter 137 Anaphylaxis
Pathogenesis
Clinical Manifestations
Diagnosis
Treatment
References

Chapter 138 Sedation and Anesthesia in Critical Care
Who Deserves Sedation and Anesthesia in the Critical Care Unit?
Drugs for Sedation and Anesthesia
Protocols (Figure 138-1)
Monitoring and Recovery
References

Chapter 139 Initial Evaluation of Respiratory Emergencies
Eight Major Categories of Respiratory Distress
Radiography
Additional Diagnostics
Management
Summary

Chapter 140 Cardiopulmonary Arrest and CPR
Diagnosis of CPA
Initiation of CPR
Basic Life Support
Advanced Life Support
Evaluation of the ECG
ALS Therapy
Open-Chest CPR
Prognosis

References

Chapter 141 Cardiac Emergencies

Heart Failure

Arrhythmias

Cardiac Tamponade

Feline Aortic Thromboembolism

References

Chapter 142 Diabetic Ketoacidosis and Hyperglycemic Hyperosmolar Syndrome

Pathophysiology

History and Physical Examination

Diagnostics

Overview of Management Strategies

Fluid Therapy

Potassium (K)

Insulin

Anemias

Acidosis

Prognosis

References

Chapter 143 Acute Abdomen

Pathogenesis

Clinical Signs

Differential Diagnosis

History and Signalment

Diagnostic Testing

Treatment

References

Chapter 144 Gastrointestinal Emergencies

Signalment

History

Physical Examination

Diagnostic Tests

Management

References

Chapter 145 Hepatic and Splenic Emergencies

Overview

Diagnostic Approach
Patient Stabilization
Specific Conditions
References

Chapter 146 Reproductive Emergencies
Reproductive Emergencies in Females
Reproductive Emergencies in Males
References

Chapter 147 Global Approach to the Trauma Patient
Primary Survey
Secondary Survey
Monitoring

Chapter 148 Head Trauma
Pathophysiology
Patient Assessment and Diagnostics
Treatment
Patient Monitoring
References
Suggested Readings

Chapter 149 Thoracic Trauma
Mechanism of Injury
Initial Assessment and Stabilization
Upper Airway
Pulmonary Contusions
Pneumothorax
Hemothorax
Rib Fractures
Diaphragmatic Hernia
Cardiac Injury
Positive Pressure Ventilation (PPV)
Summary
References

Chapter 150 Urinary Tract Trauma
Patient Stabilization
Uroperitoneum
Injuries to the Vasculature of the Kidney

Contusions of the Bladder
Herniation of the Bladder
Summary
References

Section VIII Toxicology

Chapter 151 Toxin Exposure Therapy/Decontamination
References

Chapter 152 Chemical Toxicoses
Rodenticides
Insecticides
Household Products
Garage Toxicants
Summary
References

Chapter 153 Prescription and Over-the-Counter Drug Toxicoses
Calcium Channel Blockers
Beta-Blockers
Selective Serotonin Reuptake Inhibitors and Others
Tricyclic Antidepressants
Sleep Aids: Benzodiazepines and Non-Benzodiazepine Hypnotics
Phenylpropanolamine
Veterinary Approved Nsaids
References

Chapter 154 Recreational Drugs Toxicosis
Prescription Drugs
Street Drugs
References

Chapter 155 Plant Intoxications
Overview
Oxalate-Containing Plants
Liliaceae
Marijuana *(Cannabis sativa)*
Cycadales (Cycads)
Rhododendrons
Castor Bean and Precatory Bean
Iris, Amaryllis, and Related Bulbs

Toxic Foods
Tobacco
References

Chapter 156 Venomous Bites and Stings (Zootoxicoses)
Snake Bite: Pit Vipers
Coral Snakes
Brown Spider Envenomation
Black Widow Spider
References
Suggested Readings

Section IX Blood Pressure

Chapter 157 Pathophysiology and Clinical Manifestations of Systemic Hypertension
Pathophysiology of Systemic Hypertension
Conditions Commonly Associated With Hypertension
Clinical Manifestations of Hypertension
References

Chapter 158 Treatment of Systemic Hypertension
Treating Canine SHT
Treating Feline SHT
Treating a Hypertensive Crisis
References

Chapter 159 Systemic Hypotension
Clinical Manifestations
Pathogenesis
Measurement of Blood Pressure
Treatment
Diagnostic Plan

Section X Therapeutic Considerations in Medicine and Disease

Chapter 160 Principles of Drug Disposition and Pharmacokinetics
Absorption
Distribution
Metabolism
Elimination
Pharmacokinetic Parameters
Half-Life
Clearance

Volume of Distribution
Maximum Plasma Concentration and Time to Maximum Plasma Concentration
Area Under the Curve
Bioequivalence, Generic Drugs and Compounded Drugs
References

Chapter 161 Antibacterial Drug Therapy
Overview
Principles of Therapy
Susceptibility Testing
Tissue Penetration of Antibiotics
Local Factors That Affect Antibiotic Effectiveness
Pharmacokinetic-Pharmacodynamic (PK-PD) Principles **(also see ch. 160)**
References

Chapter 162 Antifungal and Antiviral Therapy
Overview
Antifungal Drugs
Antiviral Drugs (Box 162-3)
References

Chapter 163 Antiparasitic Therapy
Accuracy of Diagnosis
Target Animal and Formulation
Spectrum of Activity
Effectiveness
Strategic Versus Preventive Parasite Control
Environmental Considerations
Compounded Parasiticides
Reproductive Status of the Host
Repeat Treatments
Resistance to Antiparasitic Drugs
References

Chapter 164 Anti-Inflammatory Therapy
Pharmacology and Clinical Indications for Glucocorticoids
Adverse Effects and Contraindications for the Use of Glucocorticoids
Nonsteroidal Anti-Inflammatory Analgesics
Pharmacology and Clinical Indications for Nsaias
Adverse Effects and Contraindications for the Use of Nsaias
FDA Newly-Approved Drug

References

Chapter 165 Immunosuppressive Therapy

Glucocorticoids

Cyclosporine

Azathioprine

Mycophenolate Mofetil

Leflunomide

Tetracycline and Niacinamide

Alkylating Agents

Applications and Clinical Decision-Making

References

Chapter 166 Analgesic Therapy

Opioids

Alpha-2 Adrenoreceptor Agonists

N-Methyl-D-Aspartate (NMDA) Antagonists

Gabapentin

Bisphosphonates

Local Anesthetics

Neurokinin-1 Receptor Antagonists

Adjunctive Analgesics for Chronic Pain and Future Directions

References

Chapter 167 Antioxidants, Nutraceuticals, Probiotics, and Nutritional Supplements

Regulatory Aspects

General Guidelines for Dietary Supplement Selection

Select Nutraceuticals of Interest

References

Chapter 168 Compounding Drugs

Veterinary Compounded Drugs: Regulations

Understanding Risks Versus Benefits With Compounded Drugs

Compounding by the Veterinarian and Pharmacist: Roles and Responsibilities

References

Chapter 169 Adverse Drug Reactions

Overview

Limitations of the Reporting System

Lack of Efficacy as an Adverse Drug Reaction/Event

Toxicosis as an Adverse Drug Reaction (ADR)/Event

References

Section XI Dietary Considerations of Systemic Problems

Chapter 170 Nutritional Assessment

Patient Assessment

Taking a Diet History

Special Considerations Regarding Assisted Feeding

Section XXII Reproductive Diseases

Chapter 312 Reproductive Endocrinology and Breeding Husbandry of the Bitch
The Reproductive Cycle

Irregular Patterns of Ovarian Cyclicity
Breeding Management
Manipulating the Canine Reproductive Cycle
Estrus Induction
References

Chapter 313 Effect of Spay or Castration on Long-Term Health of Dogs and Cats
Background
Anesthesia and Surgery
Long-Term Health
Benefits
Potential Detriments
Summary
References

Chapter 314 Clinical Feline Reproduction
Seasonality
Puberty
Estrous Cycle
Mating and Ovulation
Pregnancy and Parturition (see ch. 315)
Termination of Pregnancy
Estrous Cycle Abnormalities
Uterine Disorders and Vaginal Tumors
Problems Related to the Mammary Glands
Mating Problems
Conception Failure With Apparently Normal Estrus and Mating
Infertility in the Male Cat
Semen Collection
Artificial Insemination
Pre-Breeding Examination
References

Chapter 315 Pregnancy, Parturition and Periparturient Problems in Dogs and Cats
Semen Peritonitis
Hyperemesis Gravidarum
Vasculitides: Pregnancy Thrombosis
Pregnancy Edema
Pregnancy Loss
Metabolic Conditions
Dystocia

Uterine Disorders
Mammary Disorders: Agalactia, Galactostasis, Mastitis
References

Chapter 316 Pyometra and Cystic Endometrial Hyperplasia
Definition
Epidemiology
Pathophysiology
Clinical Signs and Diagnosis
Treatment
Ovarian Remnant Syndrome
Uterine Stump Pyometra
Prognosis
References

Chapter 317 Other Infectious Causes of Infertility and Subfertility in Dogs and Cats
Introduction
Sample Collection, Type and Site
Pre-Breeding Vaginal Cultures
Vaginal Discharge and Culture
Mycoplasma and *Ureaplasma*
Campylobacter Jejuni
Leptospirosis
Other Bacteria
Viral Pathogens
Protozoal Pathogens
References

Chapter 318 Breeding Soundness Examination and Disorders of Reproduction in Male Dogs
Breeding Soundness Examination
The Prostate (E-Figure 318-10; See Ch. 337)
Puberty, Fertility, and Clinical Disorders
Suggested Readings

Chapter 319 Reproductive Disorders in the Neutered Male or Female Dog
Introduction
Urinary Incontinence in the Ovariectomized Bitch
Chronic Vestibulovaginitis
Estrogen Toxicosis in the Ovariectomized Bitch
Prostatic Adenocarcinoma
Squamous Prostatic Metaplasia

Priapism
References

Chapter 320 Pediatric Care during the Postpartum Period
Definitions
Pre-Partum
The Immediate Post-Partum Period
Assessment and Care of Neonates
Fading Puppy Syndrome
References

Section XXIII Renal Diseases

Chapter 321 Clinical Approach and Laboratory Evaluation of Renal Disease
Introduction
Clinical Approach
Laboratory Diagnostics
Diagnostic Imaging
References

Chapter 322 Acute Kidney Injury
Introduction
Definition and Grading Aki
Etiology
The Four Phases of AKI
Cellular Mechanisms of the Pathophysiology of AKI
Diagnosis
Risk Factors for AKI
Monitoring
Prevention
Treatment
Treatment of Ureteral Obstruction
Treatment of Specific Diseases
Treatment of Uremic Complications
Prognosis
References

Chapter 323 Renal Transplantation
Renal Transplantation in Cats
Renal Transplantation in Dogs
References

Chapter 324 Chronic Kidney Disease

Overview of Chronic Kidney Disease

Clinical Consequences of Chronic Kidney Disease

Diagnostic Evaluation

Staging CKD

Treatment of CKD

Patient Monitoring

References

Chapter 325 Glomerular Diseases

Normal Glomerular Structure and Function

Clinical Findings

Glomerular Diseases

Standard Therapy of Glomerular Disease

Immunosuppressive Treatment of Dogs With Glomerular Disease

Complications of Glomerular Disease

Prognosis

References

Chapter 326 Renal Tubular Diseases

Cystinuria

Carnitinuria

Hyperuricosuria

Hyperxanthinuria

Renal Glucosuria

Fanconi Syndrome

Renal Tubular Acidosis

Nephrogenic Diabetes Insipidus

Evidence of Acute Tubular Injury Using Urine Biomarkers

References

Chapter 327 Pyelonephritis

Introduction

Pathophysiology

Diagnosis (Box 327-2)

Patient Management (Box 327-3)

Follow-Up

Prognosis

References

Chapter 328 Familial and Congenital Renal Diseases of Cats and Dogs

Introduction
Developmental Diseases
Glomerular Diseases
Polycystic Kidney Disease
Tubular Disorders
Miscellaneous Conditions
References

Section XXIV Diseases of the Lower Urinary Tract

Chapter 329 Ureteral Disorders

Anatomy and Physiology of the Ureters
Diagnostic Approach to Diseases of the Ureters
Ureteroliths
Ureteral Obstruction
Ureteral Trauma
Anatomic Abnormalities
References

Chapter 330 Lower Urinary Tract Infections

Introduction
Characteristics of Infection
Diagnosing Urinary Tract Infection
Treatment of Urinary Tract Infection
References

Chapter 331 Lower Urinary Tract Urolithiasis in Dogs

Diagnosis
Predicting Mineral Composition
Urolith Removal
Urolith Prevention (Table 331-3)
References
Suggested Readings

Chapter 332 Lower Urinary Tract Urolithiasis—Feline

Introduction
Purine Urolithiasis (Urate and Xanthine)
Xanthine Urolithiasis
Cystine Urolithiasis
Silica and Mixed Compound Uroliths
Struvite Uroliths
Calcium Oxalate Uroliths

References

Chapter 333 Diseases of Abnormal Micturition

Introduction

Disorders of Storage

Disorders of Emptying

References

Chapter 334 Feline Idiopathic Cystitis

Introduction

Recent Epidemiology

Pathophysiology

Diagnosis (see ch. 46)

Treatment

Summary

References

Chapter 335 Urethral Diseases

Urethral Sphincter Mechanism Incompetence (USMI)

Anatomic Congenital Urethral Disease

Metabolic Urethral Disease—Urethrolithiasis and Feline Matrix-Crystalline Urethral Plugs and Urethral Obstruction

Neoplastic Urethral Disease

Idiopathic Urethral Disease—Reflex Dyssynergia

Inflammatory/Infectious Urethral Disease

Traumatic Urethral Disease

Urethral Stricture

Urethral Foreign Bodies

References

Chapter 336 Congenital Diseases of the Lower Urinary Tract

Anomalies of the Ureterovesical Junction

Anomalies of the Urinary Bladder

Anomalies of the Urethra

References

Chapter 337 Prostatic Diseases

Benign Prostatic Hyperplasia

Acute Bacterial Prostatitis

Prostatic Abscessation

Chronic Bacterial Prostatitis

Paraprostatic Cysts

Prostatic Neoplasia

References

Section XXV Cancer

Chapter 338 The Hallmarks/Origin of Cancer

Cancer Is a Genetic Disease

Tumor Progression and Metastasis

The Cancer Stem Cell Hypothesis

References

Chapter 339 Principles and Practice of Chemotherapy

Tumor Biology in Chemotherapy

Chemotherapy Strategies

Supporting Animals Undergoing Chemotherapy

Evaluating Treatment Response

Safe Chemotherapy Drug Handling

Suggested Readings

Chapter 340 Principles and Practice of Radiation Oncology

Introduction

Basic Principles of Radiation Physics

Biological Principles of Radiation Oncology

Clinical Radiation Therapy

References

Chapter 341 Cancer Immunotherapy

Introduction

Overview of Tumor Immunology

Nonspecific Tumor Immunotherapy

Tumor-Specific Immunotherapy

Challenges for the Future

References

Chapter 342 Molecular Targeted Therapy

Introduction

Toceranib (Palladia)

Masitinib and Imatinib

Management of Adverse Events Associated With Toceranib and Masitinib

Additional Molecular Targets

Summary

References

Chapter 343 Complications of Anticancer Therapy

Introduction

Myelosuppression

Dermatologic Complications

Gastrointestinal Complications

Lethargy

Cardiac Toxicosis

Hepatotoxicosis

Neurologic Toxicosis

Urinary Tract Toxicosis

Hypersensitivity Reactions (see ch. 137)

Specific and Uncommon Toxicoses

References

Chapter 344 Hematopoietic Tumors

Lymphoma

Lymphoid Leukemia

Nonlymphoid Leukemias and Myeloproliferative Disorders

Myeloma-Related Disorders

References

Chapter 345 Tumors of the Skin

General Approach

Epithelial Tumors

Round Cell Tumors

Melanocytic Tumors

References

Chapter 346 Soft-Tissue Sarcomas*

Introduction

Etiology

Initial Clinical Evaluation

Diagnosis

General Treatment Considerations

Management of Canine Soft-Tissue Sarcomas

Canine Soft-Tissue Sarcomas With Unique Clinical Features

Management of Feline Sarcomas

Prevention

References

Chapter 347 Hemangiosarcoma

General Features, Pathology, and Biologic Behavior
History and Clinical Signs
Diagnosis and Staging
Treatment and Prognosis
Summary
References

Chapter 348 Bone and Joint Tumors
Canine Appendicular Osteosarcoma
Canine Appendicular Chondrosarcoma
Canine Appendicular Fibrosarcoma
Canine Appendicular Hemangiosarcoma
Canine Axial Skeletal Tumors
Feline Appendicular Osteosarcoma
Other Feline Appendicular Tumors
Feline Axial Tumors
Metastatic Bone Tumors
Canine Joint Tumors
Feline Joint Tumors
References

Chapter 349 Mast Cell Disease
Canine Mast Cell Tumors
Feline Mast Cell Tumors
References

Chapter 350 Canine and Feline Histiocytic Diseases
Cell Origin and Development
Histiocytic Diseases
References

Chapter 351 Urogenital and Mammary Gland Tumors
Urinary Bladder and Urethra
Kidney Tumors
Prostatic Tumors
Penile, Preputial and Scrotal Tumors
TESTICULAR Tumors
Vaginal and Vulvar Tumors
Uterine Neoplasia
Ovarian Tumors
Mammary Gland Tumors

References

Chapter 352 Paraneoplastic Syndromes

Endocrine-Related Paraneoplastic Syndromes

Hematologic Paraneoplastic Syndromes

Cutaneous ParaneopLastic Syndromes

Gastrointestinal Paraneoplastic Syndromes

Neurologic Paraneoplastic Syndromes

Renal PARANEOPLASTIC SYNDROMES

Miscellaneous Paraneoplastic Syndromes

References

Section XXVI Musculoskeletal Diseases

Chapter 353 Skeletal Disorders in Companion Animals

Causes of Skeletal Disorders

General Consequences of Skeletal Disorders

Surgical Management of Orthopedic Disorders

Non-Surgical Management of Orthopedic Disorders

References

Chapter 354 Muscular Disorders

Clinical Overview

Inflammatory Myopathies

Congenital (Structural) Myopathies

Muscular Dystrophies

Congenital Myasthenic Syndromes

Metabolic and Endocrine Disorders

Channelopathies

References

Chapter 355 Physical Therapy and Rehabilitation

Physical Therapy/Rehabilitation Evaluation

Common Interventions in Physical Therapy/Rehabilitation

Assistive Devices in Rehabilitation (Carts, Slings, Harnesses, Supports, Orthotics, and Prosthetics)

Appendix 355-1

References

Chapter 356 Chronic Pain

Chronic Pain: Pathophysiology

Identification of Chronic Pain and Assessment of Response to Treatment

General Approach to the Chronic Pain Patient

General Approach to Management of Chronic Pain

References

Section XXVII Comorbidities

Chapter 357 Heart Disease and Kidney Disease

Overview

Epidemiology

Pathophysiology

Management of Heart and Kidney Disease

Treatment of Concomitant Conditions

References

Chapter 358 Diabetes Mellitus and Corticosteroid-Responsive Disease

The Dilemma

Corticosteroid Medications

Side Effects and Risks of Steroid Therapy in Diabetes Mellitus

Summary: Important Points When Considering Corticosteroids for Diabetic Dogs or Cats

References

Chapter 359 Comorbidities Associated with Obesity

Obesity's Impact on Respiratory Disease

Obesity's Impact on Cardiovascular Disease

Obesity's Impact on Musculoskeletal and Intervertebral Disk Disease

Urinary Disease

Cancer

Endocrine Disease

Exercise-Limiting Disorders

Summary

References

Chapter 360 Concurrent Infection and Immune Suppression

Infection and Immunosuppressive Drug Use

Immunodeficiency States Not Induced by Immunosuppressive Drugs

TEXTBOOK OF VETERINARY INTERNAL MEDICINE: DISEASES OF THE DOG AND THE CAT, EIGHTH EDITION Two-volume set: 978-0-323-31211-0
Volume 1: 978-0-323-46213-6
Volume 2: 978-0-323-46214-3

Library of Congress Cataloging-in-Publication Data

Names: Ettinger, Stephen J., editor. | Feldman, Edward C., editor. | Côté, Etienne, editor.
Title: Textbook of veterinary internal medicine : diseases of the dog and the cat / [edited by] Stephen J. Ettinger, Edward C. Feldman, Etienne Cote.
Description: Eighth edition. | St. Louis, Missouri : Elsevier, [2017] | Includes bibliographical references and index.
Identifiers: LCCN 2016048596 | ISBN 9780323312110 (two-volume set : hardcover : alk. paper) | ISBN 9780323462136 (volume 1 : hardcover : alk. paper) | ISBN 9780323462143 (volume 2 : hardcover : alk. paper)
Subjects: | MESH: Dog Diseases—diagnosis | Dog Diseases—therapy | Cat Diseases—diagnosis | Cat Diseases—therapy
Classification: LCC SF991 | NLM SF 991 | DDC 636.7/0896—dc23 LC record available at https://lccn.loc.gov/2016048596

Dedication

He who studies medicine without books sails an uncharted sea, but he who studies medicine without patients does not go to sea at all.

Sir William Osler

With love to my wife Pat and my children Ricky, Robbie, Michael, Andrew and Nicole. You remain my inspiration for all that I do.

Steve Ettinger

Los Angeles, CA

Love to Shawn, Rhonda, Shaina, and Rowan who provided me with the time and unconditional support to follow my dreams.

Edward Feldman

Berkeley, CA

To Jen and Hélène, with love and gratitude.

Etienne Côté

Prince Edward Island, Canada

Cardiac Arrhythmias

Section Advisors

Special thanks to the section advisors, who helped provide us with new suggestions for authors and topics for their specific sections.

The Editors

Vanessa R. Barrs BVSc (Hons), PhD, MVetClinStud, FANZCVS (Feline Medicine), GradCertEd
Professor of Feline Medicine and Infectious Diseases
Faculty of Veterinary Science, School of Life and Environmental Sciences
The University of Sydney
Sydney, NSW, Australia
INFECTIOUS DISEASES

Aspergillosis—Feline

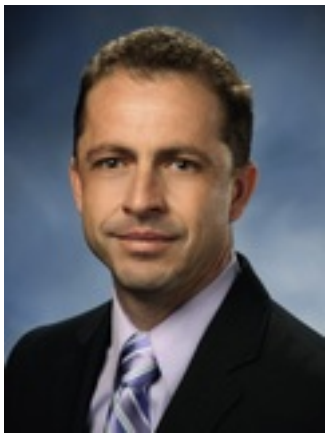
Joseph W. Bartges DVM, PhD, DACVIM (Small Animal Internal Medicine), DACVN
Professor of Medicine and Nutrition

Department of Small Animal Medicine and Surgery
College of Veterinary Medicine
The University of Georgia
Athens, Georgia
DISEASES OF THE LOWER URINARY TRACT

Urine Collection
Management of Urinary Catheters
Nutritional Management of Renal Conditions
Urethral Diseases
Congenital Diseases of the Lower Urinary Tract

Leah A. Cohn DVM, PhD, DACVIM, (Small Animal Internal Medicine)
Professor of Veterinary Medicine
Department of Veterinary Medicine and Surgery
Veterinary Health Center
University of Missouri
Columbia, Missouri
RESPIRATORY DISEASE

Diseases of the Pulmonary Parenchyma



Ronaldo Casimiro da Costa DMV, MSc, PhD, DACVIM (Neurology)
Professor and Service Head, Neurology and Neurosurgery
Veterinary Clinical Sciences
The Ohio State University

Columbus, Ohio
NEUROLOGIC DISEASE

Ataxia, Paresis, Paralysis
Spinal Cord Diseases: Congenital (Developmental), Inflammatory, and Degenerative Disorders

Autumn P. Davidson DVM, MS, DACVIM (Small Animal Internal Medicine)
Clinical Professor
Veterinary Medical Teaching Hospital
School of Veterinary Medicine
University of California, Davis
Davis, California
REPRODUCTIVE DISEASES

Pregnancy, Parturition and Periparturient Problems in Dogs and Cats
Reproductive Disorders in the Neutered Male or Female Dog

Lisa M. Freeman DVM, PhD, DACVN
Professor
Department of Clinical Sciences
Cummings School of Veterinary Medicine
Tufts University
North Grafton, Massachusetts
DIETARY CONSIDERATIONS OF SYSTEMIC PROBLEMS

Cachexia and Sarcopenia
Nutritional Management of Heart Disease

Ann E. Hohenhaus DVM, DACVIM (Oncology and Small Animal Internal Medicine)
Staff Veterinarian
The Animal Medical Center
New York, New York
HEMATOLOGIC AND IMMUNOLOGIC DISEASES

Immunologic and Hematologic Diseases: Introduction and Drug Therapy
Nonregenerative Anemia
Primary Polycythemia and Erythrocytosis

Safdar A. Khan DVM, MS, PhD, DABVT
Senior Director of Toxicology Research
ASPCA Animal Poison Control Center
Adjunct Toxicology Instructor
College of Veterinary Medicine
University of Illinois
Urbana, Illinois
TOXICOLOGY

Intoxication versus Acute, Nontoxicologic Illness: Differentiating the Two
Recreational Drugs Toxicosis

Mark G. Papich DVM, MS, DACVCP
Professor of Clinical Pharmacology
College of Veterinary Medicine
North Carolina State University
Raleigh, North Carolina
THERAPEUTIC CONSIDERATIONS IN MEDICINE AND DISEASE

Antibacterial Drug Therapy
Antifungal and Antiviral Therapy

Jörg M. Steiner med.vet., Dr.med.vet., PhD, DACVIM (Small Animal Internal Medicine), DECVIM-CA, AGAF
Professor and Director
Gastrointestinal Laboratory
Department of Small Animal Clinical Sciences
College of Veterinary Medicine and Biomedical Sciences

Urbana, Illinois

Dermatologic Manifestations of Systemic Disease

Stephan Anthony Carey DVM, PhD, DACVIM (Small Animal Internal Medicine)
Assistant Professor
Department of Small Animal Clinical Sciences, College of Veterinary Medicine
Veterinary Medical Center
Michigan State University
East Lansing, Michigan

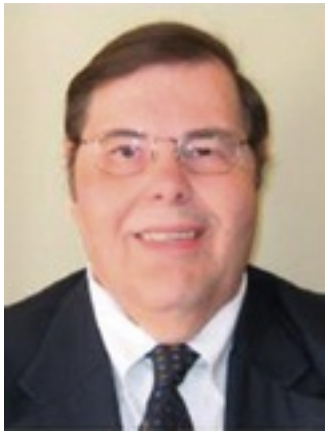
Clinical Evaluation of the Respiratory Tract

Didier-Noël Carlotti Doct-Vét, DECVD †
Clinique Vétérinaire Aquivet, Parc d'Activités
Mermoz, Eysines
Bordeaux, France

Diseases of the Ear

Margret L. Casal Dr.med.vet., PhD, DECAR
Associate Professor of Medical Genetics
School of Veterinary Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

Pediatric Care during the Postpartum Period



James L. Catalfamo MS, PhD
Department of Population Medicine and Diagnostic Sciences
College of Veterinary Medicine
Cornell University
Ithaca, New York

Immune-Mediated Thrombocytopenia, von Willebrand Disease, and Platelet Disorders

Nick John Cave BVSc, MVSc, MANZCVS, PhD, DACVN
Senior Lecturer in Small Animal Medicine and Nutrition
Institute of Veterinary, Animal and Biomedical Sciences
Te Kunenga Ki Pūrehuroa
Massey University
Palmerston North, New Zealand

Immunology and Nutrition

Serge Chalhoub DVM, DACVIM (Small Animal Internal Medicine)
Instructor
Veterinary Clinical and Diagnostic Sciences
Faculty of Veterinary Medicine, University of Calgary
Calgary, Alberta, Canada

Pathophysiology and Clinical Manifestations of Systemic Hypertension

Daniel L. Chan DVM, DACVECC, DECVECC, DACVN, FHEA, MRCVS
Professor of Emergency and Critical Care Medicine and Clinical Nutrition
Clinical Science and Services
The Royal Veterinary College, University of London
North Mymms, Hertfordshire, United Kingdom

Critical Care Nutrition

Marjorie Chandler DVM, MS, MANZCVS, DACVN, DACVIM (Small Animal Internal Medicine), DECVIM-CA, MRCVS
Honorary Senior Lecturer in Small Animal Medicine and Clinical Nutrition
Internal Medicine
University of Edinburgh
Edinburgh, Scotland, United Kingdom;
Clinical Nutritionist
Clinical Nutrition
Vets Now Referrals
Glasgow, Scotland, United Kingdom

Nutritional Management of Exocrine Pancreatic Disease

Valérie Chetboul DVM, PhD, DECVIM-CA (Cardiology)
Professor of Cardiology
Alfort Cardiology Unit (UCA)
Centre Hospitalier Universitaire Vétérinaire d'Alfort (CHUVA)
Ecole Nationale Vétérinaire d'Alfort
Maisons-Alfort, France

Feline Myocardial Diseases

Cécile Clercx DVM, PhD, DECVIM-CA (Internal Medicine)
Professor
Internal Medicine of Companion Animals
Department of Clinical Sciences of Companion Animals and Equids
CVU, Companion Animals Pôle
University of Liège
Liege, Belgium

Diseases of the Trachea and Small Airways

Craig A. Clifford DVM, MS, DACVIM (Oncology)
Director of Clinical Studies
Oncology
Hope Veterinary Specialists
Malvern, Pennsylvania

Complications of Anticancer Therapy
Hemangiosarcoma

Martha G. Cline DVM, DACVN
Clinical Veterinary Nutritionist
Department of Clinical Nutrition
Red Bank Veterinary Hospital
Tinton Falls, New Jersey

Nutrition for Healthy Adult Dogs

Joan R. Coates BS, DVM, MS, DACVIM (Neurology)
Full Professor
Department of Veterinary Medicine and Surgery
Service Leader
Neurology and Neurosurgery Service
Veterinary Health Center (Small Animal Hospital), College of Veterinary Medicine
University of Missouri
Columbia, Missouri

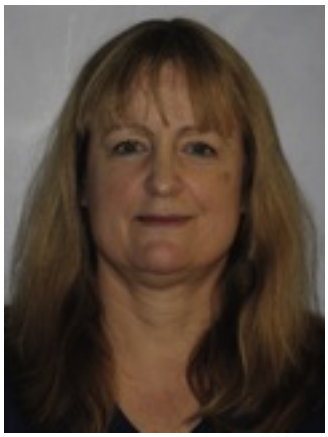
Neurophysiology
Brain Diseases: Degenerative, Anomalous, Metabolic, Neoplasia, Idiopathic Epilepsy, and Vascular

Sarah Cocker DVM
Internal Medicine Resident
Internal Medicine
The Veterinary Specialty Hospital
San Diego, California

Diagnostic Evaluation of the Liver

Ronald Jan Corbee DVM, PhD, DECVCN
Assistant Professor
Clinical Sciences of Companion Animals
Utrecht University, Faculty of Veterinary Medicine
Utrecht, The Netherlands

Nutritional-Related Skeletal Disorders

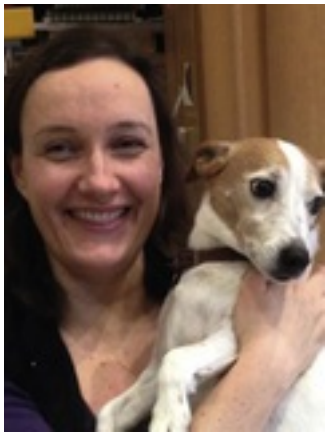


Susan Cox RVT, VTS (Small Animal Internal Medicine)
Small Animal Internal Medicine Technician
Small Animal Internal Medicine Service
William R. Pritchard Veterinary Medical Teaching Hospital
University of California, Davis
Davis, California

Care of Endoscopic Equipment

Sylvie Daminet DVM, PhD, MSc, DECVIM-CA (Internal Medicine), DACVIM (Small Animal Internal Medicine)
Professor
Department of Companion Animals
Faculty of Veterinary Medicine
Ghent University
Merelbeke, Belgium

Polyphagia
Feline Hypothyroidism

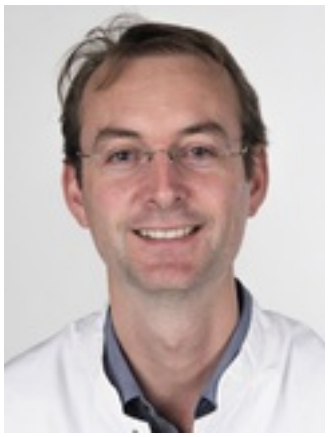


Lucy J. Davison MA, VetMB, PhD, DSAM, DECVIM-CA (Internal Medicine), MRCVS
University Lecturer in Genetics and Small Animal Medicine
Department of Veterinary Medicine
The Queen's Veterinary School Hospital
University of Cambridge
Cambridge, United Kingdom;
Wellcome Trust Veterinary Postdoctoral Fellow
Wellcome Trust Centre for Human Genetics
University of Oxford
Oxford, United Kingdom

Diabetes Mellitus and Corticosteroid-Responsive Disease

Michael J. Day BSc, BVMs (Hons), PhD, DSc, DECVP, FASM, FRCPath, FRCVS
Professor of Veterinary Pathology
School of Veterinary Sciences
University of Bristol
Langford, North Somerset, United Kingdom

Companion Animal Vaccinations
Disease of the Small Intestine

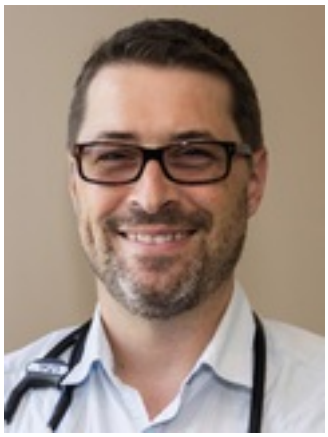


Jeffrey de Gier DVM, PhD, DECAR-CA
Assistant Professor
Department of Clinical Sciences of Companion Animals
Faculty of Veterinary Medicine, Utrecht University
Utrecht, The Netherlands

Vulvar and Preputial Discharge

Armelle de Laforcade DVM, DACVECC
Associate Professor
Department of Clinical Sciences
Tufts Cummings School of Veterinary Medicine
North Grafton, Massachusetts

Hemorrhage



Louis-Philippe de Lorimier DVM, DACVIM (Oncology)
Staff Medical Oncologist
Oncology Service
Centre Vétérinaire Rive-Sud
Brossard, Quebec, Canada

Complications of Anticancer Therapy
Hemangiosarcoma

Luisa De Risio DMV, MRCVS, PhD, DECVN, European and RCVS Recognized Veterinary Specialist in Neurology
Head of Neurology/Neurosurgery
Head of Research-Clinics
Neurology/Neurosurgery Service, Center for Small Animal Studies
Animal Health Trust
Newmarket, Suffolk, United Kingdom

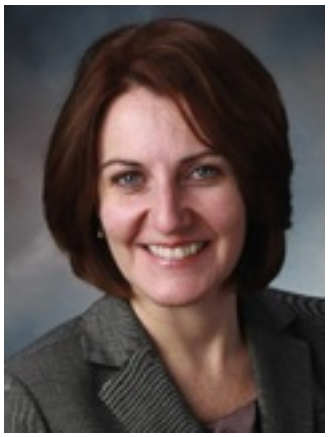
Unique Feline Neurologic Disorders

Hilde de Rooster DVM, MVM, PhD, DECVS
Professor Doctor
Small Animal Medicine and Clinical Biology
Faculty of Veterinary Medicine, Ghent University
Merelbeke, Belgium

Effect of Spay or Castration on Long-Term Health of Dogs and Cats

Jonathan D. Dear DVM, DACVIM (Small Animal Internal Medicine)
Assistant Professor of Clinical Internal Medicine
Medicine & Epidemiology
University of California, Davis
Davis, California

Swollen Joints and Joint Pain
Arthrocentesis and Arthroscopy



Camille DeClementi VMD, DABT, DABVT
Adjunct Instructor
Department of Veterinary Biosciences
University of Illinois, College of Veterinary Medicine
Urbana, Illinois;
Senior Director
Animal Health Sciences
American Society for the Prevention of Animal Cruelty (ASPCA)
New York, New York

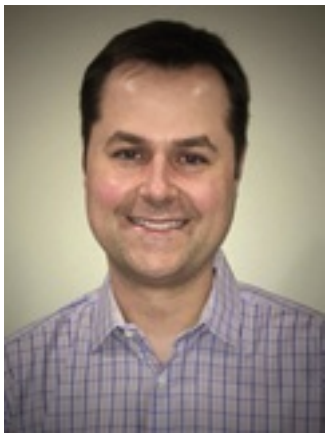
Toxin Exposure Therapy/Decontamination

Amy E. DeClue DVM, MS, DACVIM (Small Animal Internal Medicine)
Associate Professor
College of Veterinary Medicine
University of Missouri
Columbia, Missouri

Leukopenia, Leukocytosis
Sepsis and the Systemic Inflammatory Response Syndrome

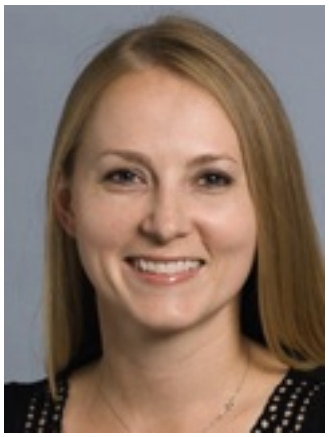
Andrea Dedeaux DVM
Internal Medicine Resident
Department of Veterinary Clinical Sciences
Louisiana State University
Baton Rouge, Louisiana

Blastomycosis and Histoplasmosis



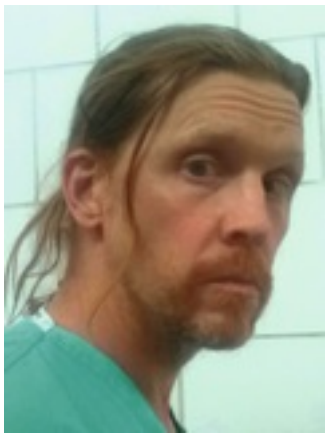
Sean J. Delaney DVM, MS, DACVN
Founder
Balance IT, A DBA of DVM Consulting, Inc.
Davis, California

Unconventional Diets (Homemade, Vegetarian, and Raw)



Ann-Marie Della Maggiore DVM, DACVIM (Small Animal Internal Medicine)
Assistant Professor of Clinical Internal Medicine
School of Veterinary Medicine, Department of Medicine and Epidemiology
University of California, Davis
Davis, California

Potassium, Magnesium



Curtis W. Dewey DVM, MS, DACVIM (Neurology), DACVS
Associate Professor and Section Chief, Neurology/Neurosurgery
Department of Clinical Sciences
Cornell University
Ithaca, New York

Inflammatory, Infectious, and Other Multifocal Brain Diseases

Ryan M. Dickinson BA, DVM, DACVP
Assistant Professor
Department of Veterinary Pathology
Western College of Veterinary Medicine, University of Saskatchewan
Saskatoon, SK, Canada

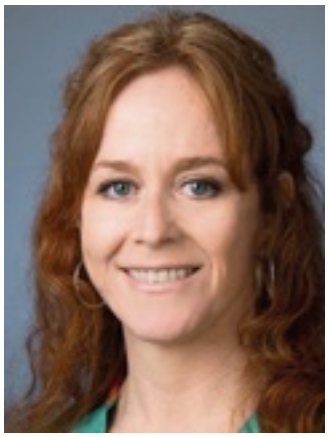
Cytology of the Skin and Subcutaneous Tissues

Pedro Paulo V.P. Diniz DVM, PhD
Associate Professor of Small Animal Internal Medicine
College of Veterinary Medicine
Western University of Health Sciences
Pomona, California

Bartonella—Canine

David C. Dorman DVM, PhD
Professor of Toxicology
Department of Molecular Biomedical Sciences
North Carolina State University
Raleigh, North Carolina

Plant Intoxications



Katie Douthitt RVT
Small Animal Clinic Medicine Services
Veterinary Medicine Teaching Hospital
University of California, Davis
Davis, California

Care of Endoscopic Equipment

Kenneth J. Drobatz DVM, MSCE, DACVIM (Small Animal Internal Medicine), DACVECC
Professor and Section Chief, Critical Care
School of Veterinary Medicine
Director, Emergency Services
Matthew J. Ryan Veterinary Hospital
University of Pennsylvania
Philadelphia, Pennsylvania

Global Approach to the Trauma Patient

Marilyn E. Dunn DMV, MVSc, DACVIM (Small Animal Internal Medicine)
Professor
Department of Clinical Sciences
University of Montreal
St-Hyacinthe, Quebec, Canada

Urologic Interventional Therapies

David A. Dzanis DVM, PhD, DACVN
Chief Executive Officer
Regulatory Discretion, Inc.
Santa Clarita, California

Pet Food Safety and Regulatory Aspects of Pet Food

Melissa L. Edwards DVM, DACVECC, Douglas, Alaska

Hyperbaric Medicine

Laura Eirmann DVM, DACVN
Clinical Nutritionist
Nutrition
Oradell Animal Hospital
Paramus, New Jersey;
Veterinary Communications Manager
Nestlé Purina PetCare
St. Louis, Missouri

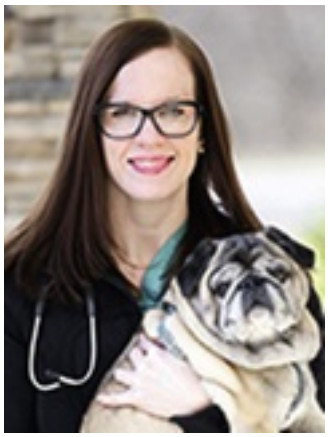
Antioxidants, Nutraceuticals, Probiotics, and Nutritional Supplements

Gary C.W. England BVetMed, PhD, DVetMed, DVR, DVRep, DECAR, DACT, FHEA, FRCVS
Foundation Dean & Professor of Comparative Veterinary Reproduction
School of Veterinary Medicine & Science
University of Nottingham
Loughborough, Leicestershire, United Kingdom

Breeding Soundness Examination and Disorders of Reproduction in Male Dogs

Steven Epstein DVM, DACVECC
Assistant Professor of Clinical Small Animal Emergency and Critical Care
Department of Surgical and Radiological Sciences
University of California, Davis
Davis, California

Urinary Electrolyte Concentrations
Pulse Oximetry

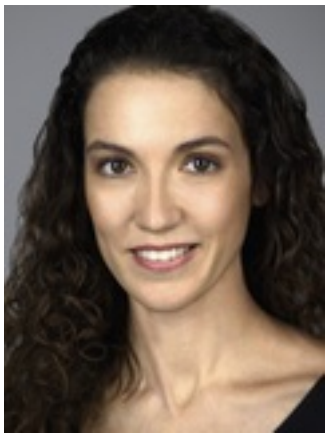


Chelsie Estey MSc, DVM, DACVIM (Neurology)
Neurology/Neurosurgery Service
Upstate Veterinary Specialties
Latham, New York

Inflammatory, Infectious, and Other Multifocal Brian Diseases

Amara H. Estrada DVM, DACVIM (Cardiology)
Associate Professor and Associate Chair for Instruction
Department of Small Animal Clinical Sciences
Director of Teaching Academy
College of Veterinary Medicine
University of Florida
Gainesville, Florida

Cardiac Pacing



Amy Farcas DVM, MS, DACVN
Owner, Veterinary Nutritionist
Veterinary Nutrition Care
San Carlos, California

Nutritional Uses of Fiber

Luca Ferasin DVM, PhD, CertVC, PGCert(HE), DECVIM-CA (Cardiology), GPCert(B&PS), MRCVS
European & RCVS Specialist in Cardiology
CVS Referrals
Cardiology
Lumbry Park Veterinary Specialists
Alton, Hampshire, United Kingdom

Coughing

Deborah M. Fine-Ferreira DVM, MS, DACVIM (Cardiology)
Cardiologist
Ali'i Veterinary Hospital
Kailua-Kona, Hawaii;
Cardiologist
Veterinary Emergency and Referral Center
Honolulu, Hawaii

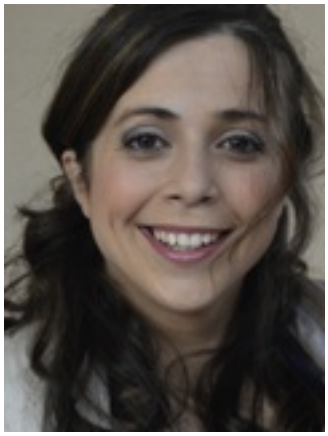
Peripheral Edema

Daniel John Fletcher PhD, DVM, DACVECC
Associate Professor of Emergency and Critical Care
Clinical Sciences
Cornell University College of Veterinary Medicine
Ithaca, New York

Cardiopulmonary Arrest and CPR

Peter Foley MSc, DVM, DACVIM (Small Animal Internal Medicine)
Assistant Professor
Department of Companion Animals
Atlantic Veterinary College
University of Prince Edward Island
Charlottetown, PE, Canada

Constipation, Tenesmus, Dyschezia, and Fecal Incontinence



Yaiza Forcada DVM, PhD, DECVIM-CA (Internal Medicine)
Lecturer in Small Animal Internal Medicine
Clinical Sciences and Services
The Royal Veterinary College
North Mymms, Hertfordshire, United Kingdom

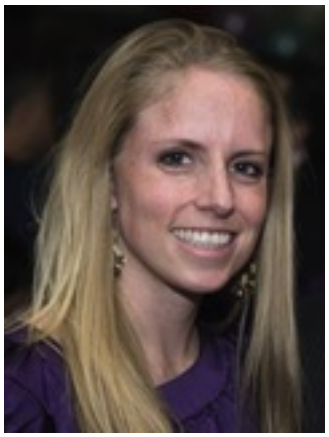
Hypoglycemia, Hyperglycemia

Marnin A. Forman DVM, DACVIM (Small Animal Internal Medicine)
Head of Internal Medicine, Staff Internist
Internal Medicine
Cornell University Veterinary Specialists
Stamford, Connecticut

Anorexia
Feline Inflammatory/Infectious Hepatic Disease

Catharina Linde Forsberg DVM, PhD, DECAR
Professor Emeritus of Small Animal Reproduction
Department of Clinical Sciences, Division of Reproduction
Swedish University of Agricultural Sciences
Private Company
Uppsala, Sweden

Artificial Insemination in the Dog



Amanda Foskett DVM
Resident, Medical Oncology
The Oncology Service, LLCWashington, DC

The Hallmarks/Origin of Cancer

Federico Fracassi DVM, PhD, DECVIM-CA (Internal Medicine)
Professor
Department of Veterinary Medical Sciences
School of Agriculture and Veterinary Medicine
Bologna, Italy

Canine Diabetes Mellitus

Thierry Francey DVM, DACVIM (Small Animal Internal Medicine), DECVIM-CA (Internal Medicine)
Department of Clinical Veterinary Medicine
University of Bern
Bern, Switzerland

Hematuria and Other Conditions Causing Discolored Urine

Diane Frank DVM, DACVB
Professor (Behavioral Medicine)
Clinical Sciences
Université de Montréal
St-Hyacinthe, Quebec, Canada

Distinguishing Behavioral Disorders from Medical Disorders

Angela E. Frimberger BS, VMD, DACVIM (Oncology), MACVSc
Director
Veterinary Oncology Consultants
Wauchope, NSW, Australia

Principles and Practice of Chemotherapy

Jason W. Gagné DVM, DACVN
Senior Manager, Veterinary Technical Marketing
Nestlé Purina PetCare
St. Louis, Missouri

Adverse Reactions to Foods: Allergies versus Intolerance

Sara Galac DVM, PhD
Assistant Professor
Clinical Sciences of Companion Animals
Faculty of Veterinary Medicine, Utrecht University
Utrecht, The Netherlands

Pheochromocytoma

Alex Gallagher DVM, MS, DACVIM (Small Animal Internal Medicine)
Clinical Assistant Professor
Small Animal Clinical Sciences
University of Florida College of Veterinary Medicine
Gainesville, Florida

Vomiting and Regurgitation

Rosalind M. Gaskell BVSc, PhD, MRCVS
Professor (Emeritus) and Honorary Fellow
School of Veterinary Science
University of Liverpool, Leahurst Campus
Neston, Cheshire, United Kingdom

Feline Upper Respiratory Infections
Other Feline Viral Infections

Olivier Gauthier DVM, MSc, PhD
Professor of Small Animal Surgery and Dentistry
Small Animal Surgery
Oniris Nantes-Atlantic College of Veterinary Medicine, Food Science and Engineering
Nantes, France

Diseases of the Ear

James S. Gaynor DVM, MS, DACVAA, DAAPM
Medical Director
Peak Performance Veterinary Group
Breckenridge, Colorado;
Medical Director
Animal Emergency Care Centers
Colorado Springs, Colorado

Sedation and Anesthesia in Critical Care

Alexander James German BVSc, PhD, CertSAM, DECVIM-CA (Internal Medicine), MRCVS
Reader in Small Animal Medicine
Institute of Ageing and Chronic Disease
School of Veterinary Science
University of Liverpool
Neston, Merseyside, United Kingdom

Flatulence

Alireza A. Gorgi DVM, DACVIM (Neurology)
Department Head, Neurology/Neurosurgery
VCA West Coast Specialty & Emergency Animal Hospital
Fountain Valley, California;
Associate Clinical Professor
Western University of Health Sciences College of Veterinary Medicine
Pomona, California

Status Epilepticus

Susan A. Gottlieb BVSc (Hons), BSc(vet), BAppSc, MANZCVS
Veterinarian
The Cat Clinic
Brisbane, Queensland, Australia

Feline Diabetes Mellitus

Peter A. Graham BVMS, PhD, CertVR, DECVCP, MRCVS
Clinical Associate Professor
School of Veterinary Medicine and Science
University of Nottingham
Sutton Bonington, Leicestershire, United Kingdom

Urinalysis

Thomas K. Graves DVM, PhD, DACVIM (Small Animal Internal Medicine)
Dean and Professor
College of Veterinary Medicine
Midwestern University
Glendale, Arizona

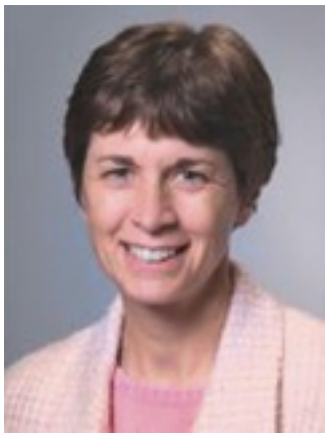
Feline Hyperthyroidism

Amy M. Grooters DVM, DACVIM (Small Animal Internal Medicine)
Professor
Companion Animal Medicine
Louisiana State University
Baton Rouge, Louisiana

Miscellaneous Fungal Infections

Sophie Alexandra Grundy BVSc (Hons), MANZCVS, DACVIM (Small Animal Internal Medicine)
Internal Medicine Consultant
IDEXX Laboratories, Inc.
Westbrook, Maine

Other Infectious Causes of Infertility and Subfertility in Dogs and Cats



Lynn F. Guptill DVM, PhD, DACVIM (Small Animal Internal Medicine)
Associate Professor
Department of Veterinary Clinical Services
Purdue University
West Lafayette, Indiana

Bartonella—Feline

Tim B. Hackett DVM, MS, DACVECC
Professor of Emergency and Critical Care Medicine
Department of Clinical Sciences
Colorado State University
Fort Collins, Colorado

Epistaxis and Hemoptysis
Chest Tube Placement

Jens Häggström DVM, PhD, DECVIM-CA (Cardiology)
Professor
Department of Clinical Sciences
Faculty of Veterinary Medicine and Animal Science
The Swedish University of Agricultural Sciences
Uppsala, Sweden

Adult-Onset Valvular Heart Disease

Edward James Hall MA, VetMB, PhD
Professor of Small Animal Medicine
School of Veterinary Sciences
University of Bristol
Langford, Bristol, United Kingdom

Diseases of the Small Intestine
Diseases of the Large Intestine

Meri F. Hall RVT, LVT, CVT, LATG, VTS (Small Animal Internal Medicine)
Veterinary Technician
Internal Medicine
Veterinary Specialty Hospital
Palm Beach Gardens, Florida

Jugular Catheterization and Central Venous Pressure Measurement

Cathleen A. Hanlon VMD, PhD, DACVPM
Team Lead, Rabies; WHO Collaborating Center Head; OIE Expert (Retired)
Division of High Consequence Pathogens and Pathology
Centers for Disease Control and Prevention
Atlanta, Georgia

Rabies

Katrin Hartmann Dr.med.vet., Dr.habil., DECVIM-CA (Internal Medicine)
Professor
Head of Clinic of Small Animal Medicine
Director of Centre of Clinical Veterinary Medicine
Ludwig-Maximilian-Universitaet
Munich, Germany

Feline Leukemia Virus Infection
Coronavirus Infections (Canine and Feline), Including Feline Infectious Peritonitis

Camilla Heinze DVM, RHD
Dyrlaege Camilla Heinze ApS
Karlslunde, Denmark

Ptyalism and Halitosis

Eric J. Herrgesell DVM, DACVR
Partner
Veterinary Medical Imaging
Sacramento, California

Abdominal Ultrasound: Aspirations and Biopsies

Michael E. Herrtage MA, BVSc, DVSc, DVR, DVD, DSAM, DECVIM-CA (Internal Medicine), DECVDI, MRCVS
Professor of Small Animal Medicine
Department of Veterinary Medicine
University of Cambridge
Cambridge, Cambridgeshire, United Kingdom

Feline Hyperadrenocorticism

Rebecka S. Hess DVM, DACVIM (Small Animal Internal Medicine)
Professor of Internal Medicine
Chief, Section of Medicine
Department of Clinical Studies, Philadelphia
School of Veterinary Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

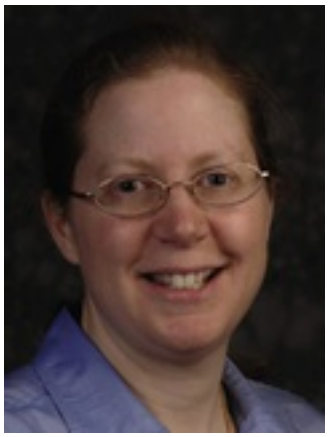
Hypoadrenocorticism

Richard C. Hill MA, VetMB, PhD, DACVIM (Small Animal Internal Medicine), DACVN, MRCVS
Associate Professor
Department of Small Animal Clinical Sciences
University of Florida, College of Veterinary Medicine
Gainesville, Florida

Dietary and Medical Considerations in Hyperlipidemia

Daniel F. Hogan DVM, DACVIM (Cardiology)
Professor, Cardiology
Veterinary Clinical Sciences
College of Veterinary Medicine, Purdue University
West Lafayette, Indiana

Arterial Thromboembolic Disease



Kate Hopper BVSc, PhD, DACVECC
Associate Professor of Small Animal Emergency & Critical Care
Veterinary Surgical and Radiological Sciences
University of California, Davis
Davis, California

Oxygen Therapy

Takuo Ishida DVM, PhD, DJCVP
Medical Director
Akasaka Animal Hospital
Minatoku, Tokyo, Japan;
President
Japanese Board of Veterinary Practitioners
Shibuyaku, Tokyo, Japan

Lymph Node Aspiration and Biopsy

Nicholas Jeffery BVSc, PhD, MSc, DECVN, DECVS, DSAS, FRCVS
Professor, Neurology and Neurosurgery
Veterinary Clinical Sciences
Texas A&M University
College Station, Texas

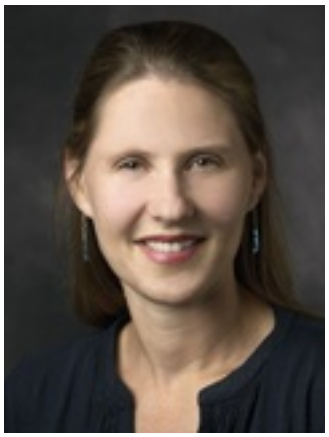
Spinal Cord Diseases: Traumatic, Vascular, and Neoplastic Disorders

Rosanne Jepson BVSc, MVetMed, PhD, DACVIM (Small Animal Internal Medicine), DECVIM-CA (Internal Medicine), FHEA, MRCVS
Lecturer in Small Animal Internal Medicine
Clinical Sciences and Services
Royal Veterinary College
London, United Kingdom

Clinical Approach and Laboratory Evaluation of Renal Disease

Albert Earl Jergens DVM, PhD, DACVIM (Small Animal Internal Medicine)
Professor
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
Iowa State University
Ames, Iowa

Host-Microbiota Interactions in Gastrointestinal Health and Disease



Jennifer L. Johns DVM, PhD, DACVP (Clinical Pathology)
Assistant Professor
Comparative Medicine
Stanford University School of Medicine
Stanford, California

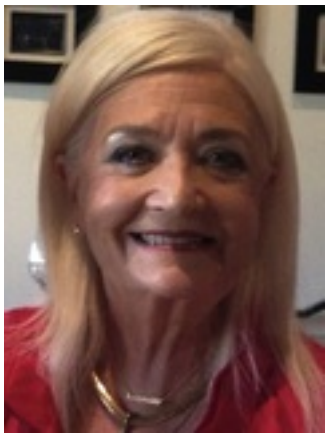
Immune-Mediated and Other Nonneoplastic White Blood Cell Disorders

Andrea N. Johnston DVM, DACVIM (Small Animal Internal Medicine)
Molecular Biology
University of Texas Southwestern Medical Center
Dallas, Texas

Liver Enzymes

Ron Johnson DVM, PhD, DACVCP
Associate Professor
Biomedical Sciences
University of Guelph
Guelph, Ontario, Canada

Compounding Drugs



Dinah G. Jordan BSPh, RPh, PharmD, DICVP
Chief of Pharmacy Services and Clinical Professor, Retired
College of Veterinary Medicine
Mississippi State University
Starkville, Mississippi

Compounding Drugs

Philip H. Kass DVM, MPVM, MS (Statistics), PhD (Epidemiology), DACVPM (Specialty in Epidemiology)
Professor of Analytic Epidemiology
Population Health and Reproduction, School of Veterinary Medicine
University of California, Davis
Davis, California

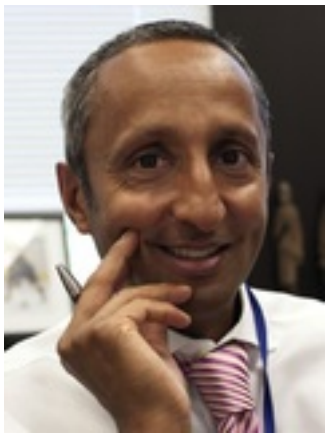
Biomedical Statistics: Selected Topics

Eileen Kenney DVM, DACVECC
Criticalist
Emergency/Critical Care
VCA West Los Angeles Animal Hospital
Los Angeles, California

Head Trauma

Marie E. Kerl DVM, MPH, DACVIM (Small Animal Internal Medicine), DACVECC
Teaching Professor
Veterinary Medicine and Surgery
University of Missouri
Columbia, Missouri

Acid-Base, Oximetry, and Blood Gas Analysis
Renal Tubular Diseases



Chand Khanna DVM, PhD, DACVIM (Oncology), DACVP (Hon)
Chief Science Officer
Ethos Veterinary Health
Woburn, Massachusetts;
The Oncology Service
President
Ethos Discovery
Washington, DC

The Hallmarks/Origin of Cancer

Peter P. Kintzer DVM, DACVIM (Small Animal Internal Medicine)
Field Medical Specialist Manager
CAG Medical Organization
IDEXX Laboratories
Westbrook, Maine

Weight Gain

Karen Lynne Kline DVM, MS, DACVIM (Neurology)
Staff Neurologist
Department of Neurology
VCA Veterinary Specialty Center of Seattle
Lynnwood, Washington

Stupor and Coma

Amie Koenig DVM, DACVIM (Small Animal Internal Medicine), DACVECC
Associate Professor of Emergency and Critical Care
Department of Small Animal Medicine and Surgery
College of Veterinary Medicine, University of Georgia
Athens, Georgia

Gastrointestinal Emergencies

Amy M. Koenigshof DVM, MS, DACVECC
Assistant Professor, Emergency and Critical Care Medicine
Small Animal Clinical Sciences
Michigan State University
East Lansing, Michigan

Urinary Tract Trauma

Hans S. Kooistra DVM, PhD, DECVIM-CA (Internal Medicine)
Associate Professor
Department of Clinical Sciences of Companion Animals
University of Utrecht
Utrecht, The Netherlands

Failure to Grow
Canine Growth Hormone Disorders

Peter Hendrik Kook PD, Dr.med.vet., DACVIM (Small Animal Internal Medicine), DECVIM-CA (Internal Medicine)
Privatdozent
Clinic for Small Animal Internal Medicine
Vetsuisse Faculty, University of Zurich
Zurich, Switzerland

Gagging
Amylase, Lipase

John M. Kruger DVM, PhD, DACVIM (Small Animal Internal Medicine)
Professor, Internal Medicine
Small Animal Clinical Sciences
Michigan State University
East Lansing, Michigan

Congenital Diseases of the Lower Urinary Tract

Butch KuKanich DVM, PhD, DACVCP
Professor of Pharmacology
Department of Anatomy and Physiology
Kansas State University
Manhattan, Kansas

Principles of Drug Disposition and Pharmacokinetics

W. Douglas Kunz MS, DVM
Medical Director
VCA Desert Animal Medical Hospital
Palm Springs, California

Euthanasia

Michelle Anne Kutzler DVM, PhD, DACT
Associate Professor of Companion Animal Industries
Animal and Rangeland Sciences
Oregon State University
Corvallis, Oregon

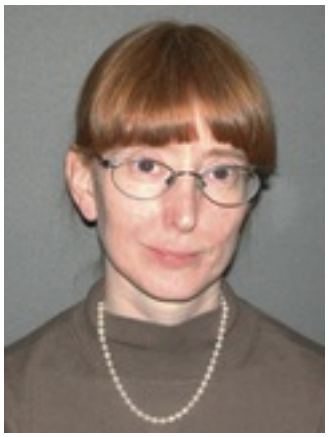
Prostatic Diagnostic Techniques
Prostatic Diseases

Mary Anna Labato DVM, DACVIM (Small Animal Internal Medicine)
Clinical Professor
Section Head, Small Animal Medicine
Department of Clinical Sciences
Staff Veterinarian
Foster Hospital
Cummings School of Veterinary Medicine
Tufts University
North Grafton, Massachusetts

Pollakiuria, Stranguria, and Urinary Incontinence
Continuous Renal Replacement Therapy/Hemodialysis
Lower Urinary Tract Urolithiasis—Feline

Gary Landsberg DVM, DACVB, DECAWBM (Companion Animals)
Veterinary Behaviourist
North Toronto Veterinary Behavior Specialty Clinic
Thornhill, Ontario, Canada;
Vice President, Veterinary Affairs
CanCog Technologies
Toronto, Ontario, Canada

Cognitive Dysfunction in Aged Dogs and Cats



Cathy E. Langston DVM, DACVIM (Small Animal Internal Medicine)
Associate Professor
Veterinary Clinical Sciences
College of Veterinary Medicine
The Ohio State University
Columbus, Ohio

Acute Kidney Injury

Michael R. Lappin DVM, PhD, DACVIM (Small Animal Internal Medicine)
Professor
Department of Clinical Science
College of Veterinary Medicine and Biomedical Sciences
Colorado State University
Fort Collins, Colorado

Laboratory Diagnosis of Infectious Disease
Zoonoses
Protozoal Infections

Jennifer Larsen DVM, PhD, DACVN
Veterinary Medicine, Molecular Biosciences
School of Veterinary Medicine
University of California, Davis
Davis, California

Nutrition for Healthy Adult Cats
Nutritional Management of Endocrine and Metabolic Diseases

Martha Moon Larson DVM, MS, DACVR
Professor
Department of Small Animal Clinical Sciences
Virginia-Maryland College of Veterinary Medicine
Virginia Polytechnic Institute and State University
Blacksburg, Virginia

Diseases of the Mediastinum, Chest Wall, and Diaphragm

Patty Lathan VMD, MS, DACVIM (Small Animal Internal Medicine)
Associate Professor, Small Animal Internal Medicine
Department of Clinical Sciences
Mississippi State University College of Veterinary Medicine
Mississippi State, Mississippi

Hypoparathyroidism

Jessica Lawrence DVM, DACVIM (Oncology), DACVR (Radiation Oncology), MRCVS
Head of Oncology and Senior Lecturer in Oncology
Royal (Dick) School of Veterinary Studies
Easter Bush Campus, University of Edinburgh
Edinburgh, Scotland, United Kingdom;
Associate Professor of Radiation Oncology
Department of Veterinary Clinical Sciences
University of Minnesota, College of Veterinary Medicine
St. Paul, Minnesota

Principles and Practice of Radiation Oncology

Justine A. Lee DACVECC, DABT
VETgirl, LLC
St. Paul, Minnesota

Hypothermia
Chemical Toxicoses

Tekla M. Lee-Fowler DVM, MS, DACVIM (Small Animal Internal Medicine)
Assistant Professor
College of Veterinary Medicine
Auburn University
Auburn, Alabama

Transtracheal Wash and Bronchoscopy

Andrew Lambert Leisewitz BVSc, MMedVet(Med), PhD, DECVIM-CA (Internal Medicine)
Professor
Companion Animal Clinical Studies
University of Pretoria
Pretoria, Gauteng, South Africa

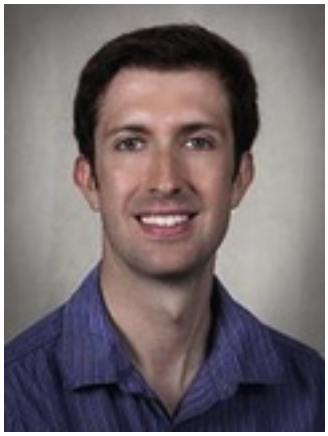
Canine and Feline Parvovirus Infection

David Levine PT, PhD, DPT, DABPTS (Orthopedics), CCRP, Cert. DN
Professor and Walter M. Cline Chair of Excellence in Physical Therapy
Physical Therapy
The University of Tennessee at Chattanooga
Chattanooga, Tennessee

Physical Therapy and Rehabilitation

Julie K. Levy DVM, PhD, DACVIM (Small Animal Internal Medicine)
Professor
Maddie's Shelter Medicine Program
College of Veterinary Medicine
University of Florida
Gainesville, Florida

Feline Leukemia Virus Infection



Jonathan Andrew Lidbury BVMS, MRCVS, PhD, DACVIM (Small Animal Internal Medicine), DECVIM-CA (Internal Medicine)
Assistant Professor of Small Animal Internal Medicine
Gastrointestinal Laboratory Associate Director of Clinical Services
Veterinary Small Animal Clinical Sciences
Texas A&M University
College Station, Texas

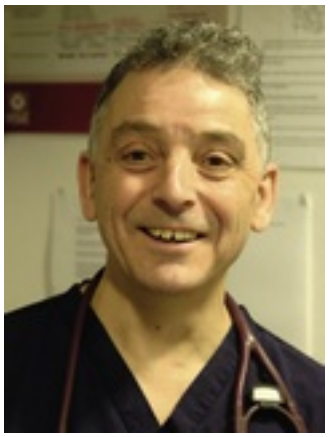
General Principles in the Treatment of Liver Disease

David Lipsitz DVM, DACVIM (Neurology)
Staff Neurologist
Neurology
Veterinary Specialty Hospital of San Diego
San Diego, California

Electromyography and Nerve Conduction Velocity

Julius M. Liptak BVSc, MVetClinStud, FACVSc, DACVS, DECVS
Small Animal Surgeon and Surgical Oncologist
Alta Vista Animal Hospital
Ottawa, Ontario, Canada

Bone and Joint Tumors



Christopher Little BVMS, PhD, DVC, MRCVS
Veterinarian
Barton Veterinary Hospital
Canterbury, Kent, United Kingdom

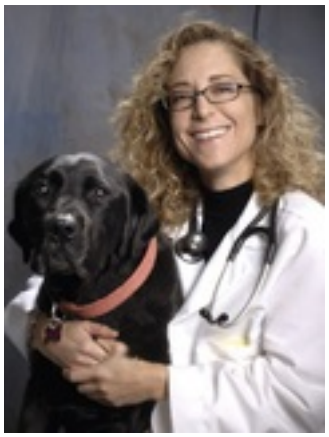
Pulse Alterations

Meryl P. Littman VMD, DACVIM (Small Animal Internal Medicine)
Professor of Medicine
Clinical Studies—Philadelphia
University of Pennsylvania School of Veterinary Medicine
Philadelphia, Pennsylvania

Lyme Disease

Ingrid Ljungvall DVM, PhD
Associate Professor
Department of Clinical Sciences
Swedish University of Agricultural Sciences
Uppsala, Sweden

Adult-Onset Valvular Heart Disease

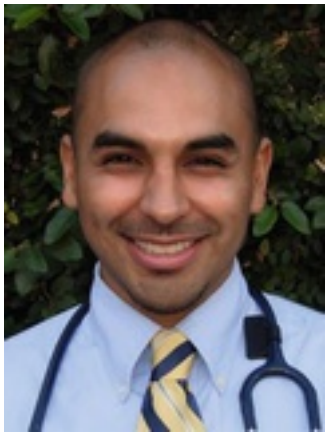


Cheryl London DVM, PhD, DACVIM (Oncology)
Research Professor
Molecular Research Institute, Tufts Medical Center
Cummings School of Veterinary Medicine, Tufts University
Associate Faculty Professor
College of Veterinary Medicine
The Ohio State University
Columbus, Ohio

Molecular Targeted Therapy

Cheryl Lopate MS, DVM, DACT
Co-Owner and Clinical Veterinarian
Reproductive Revolutions
Aurora, Oregon;
Co-Owner and Clinical Veterinarian
Wilsonville Veterinary Clinic
Wilsonville, Oregon

Vaginoscopy and Vaginal Cytology in Dogs
Reproductive Endocrinology and Breeding Husbandry of the Bitch



Julio López DVM, DACVIM (Small Animal Internal Medicine)
Staff Internist
Studio City Animal Hospital
Los Angeles, California

Sneezing and Nasal Discharge
Dysphagia

Jody P. Lulich DVM, PhD, DACVIM (Small Animal Internal Medicine)
Professor
Minnesota Urolith Center
University of Minnesota
St. Paul, Minnesota

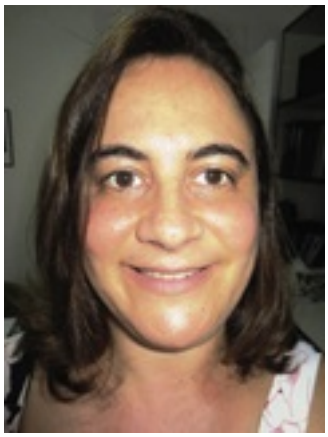
Unblocking of the Urethra
Lower Urinary Tract Urolithiasis in Dogs

Kristin MacDonald DVM, PhD, DACVIM (Cardiology)
Veterinary Cardiologist
VCA Animal Care Center of Sonoma
Rohnert Park, California

Pericardial Diseases

Valerie MacDonald BSc, DVM, DACVIM (Oncology)
Associate Professor
Department of Small Animal Clinical Sciences
Western College of Veterinary Medicine, University of Saskatchewan
Saskatoon, SK, Canada

Bone Marrow Aspiration and Biopsy



Lúcia Daniel Machado da Silva DVM, PhD
Professor
Laboratory of Carnivores Reproduction
Veterinary Faculty
State University of Ceará
Fortaleza, Ceará, Brazil

Breeding Soundness Examination and Disorders of Reproduction in Male Dogs

Catriona M. MacPhail DVM, PhD, DACVS
Associate Professor, Small Animal Surgery
Department of Clinical Sciences
Small Animal Chief Medical Officer
Veterinary Teaching Hospital
Colorado State University
Fort Collins, Colorado

Diseases of the Larynx

Denis J. Marcellin-Little DEDV, DACVS, DECVS
Professor, Orthopedic Surgery
Department of Clinical Sciences
College of Veterinary Medicine, North Carolina State University
Raleigh, North Carolina

Skeletal Disorders in Companion Animals

Christopher L. Mariani DVM, PhD, DACVIM (Neurology)
Associate Professor of Neurology and Neurosurgery
Clinical Sciences
Director, Comparative Neuroimmunology and Neurooncology Laboratory
North Carolina State University
Raleigh, North Carolina

Peripheral Neuropathies
Neuromuscular Junction Disorders

Stanley Leon Marks BVSc, PhD, DACVIM (Small Animal Internal Medicine, Oncology), DACVN
Professor
Department of Medicine and Epidemiology
School of Veterinary Medicine
University of California, Davis
Davis, California

Nasoesophageal, Esophagostomy, Gastrostomy, and Jejunal Tube Placement Techniques
Enteric Bacterial Diseases
Diseases of the Pharynx and Esophagus

Steven L. Marks BVSc, MS, MRCVS, DACVIM (Small Animal Internal Medicine)
Associate Dean and Director of Veterinary Medical Services
North Carolina State University
Raleigh, North Carolina

Constant Rate Infusions

Mike Martin MVB, DVC, MRCVS
Specialist Veterinary Cardiologist
Willows Referral Centre and Referral Service
Shirley, Solihull, West Midlands, United Kingdom

Syncope

Ana Martins-Bessa DVM, PhD
Professor
Department of Veterinary Sciences
Veterinary Teaching Hospital
University of Tras-os-Montes e Alto Douro, UTAD
Vila Real, Portugal

Reproductive Emergencies

Karol A. Mathews DVM, DVSc, DACVECC
Professor Emerita, Emergency & Critical Care Medicine
Department of Clinical Studies
Ontario Veterinary College
University of Guelph
Guelph, Ontario, Canada

Anti-inflammatory Therapy

Glenna E. Mauldin DVM, MS, DACVIM (Oncology), DACVN
Staff Veterinarian in Oncology and Nutrition
Cancer Centre for Animals
Western Veterinary Specialist and Emergency Centre
Clinical Instructor, Distributed Veterinary Learning Community
Faculty of Veterinary Medicine
University of Calgary
Calgary, Alberta, Canada

Nutritional Management of Cancer

Elisa M. Mazzaferro MS, DVM, PhD, DACVECC
Staff Criticalist
Cornell University Veterinary Specialists
Stamford, Connecticut

Heatstroke

Margaret C. McEntee DVM, DACVIM (Oncology), DACVR(RO)
Alexander de Lahunta Chair of Clinical Sciences, Professor of Oncology
Department of Clinical Sciences
College of Veterinary Medicine
Cornell University
Ithaca, New York

Soft-Tissue Sarcomas

Maureen McMichael DVM, DACVECC
Professor
Veterinary Clinical Medicine
University of Illinois
Urbana, Illinois

Coagulation Testing

Carlos Melián DVM, PhD
Director
Department of Veterinary Teaching Hospital
Universidad de Las Palmas de Gran Canaria
Clinica Veterinaria Atlantico
Las Palmas de Gran Canaria, Spain

Hyperadrenocorticism in Dogs

Richard John Mellanby BSc, BVMS, PhD, DSAM, DECVIM-CA (Internal Medicine), MRCVS
Head of Small Animal Medicine
Royal (Dick) School of Veterinary Studies and The Roslin Institute
Hospital for Small Animals
The University of Edinburgh
Easter Bush Veterinary Centre
Midlothian, United Kingdom

Calcium, Phosphorus

Linda Merrill LVT, VTS (AIMVT-Small Animal Internal Medicine & AVTCP-Canine/Feline)
Executive Director
Academy of Internal Medicine for Veterinary Technicians
Seattle Veterinary Associates
Green Lake Animal Hospital
Seattle, Washington

Venous and Arterial Puncture

Kristen Messenger DVM, DACVAA, DACVCP
Assistant Professor of Anesthesiology
Molecular Biomedical Science
North Carolina State University College of Veterinary Medicine
Raleigh, North Carolina

Analgesic Therapy

Kathryn M. Meurs DVM, PhD, DACVIM (Cardiology)
Professor, Clinical Sciences
Associate Dean, Research and Graduate Studies
North Carolina State University College of Veterinary Medicine
Raleigh, North Carolina

Basic Genetics
Clinical Genomics
Myocardial Disease: Canine

Kathryn E. Michel DVM, MS, MSED, DACVN
Professor of Nutrition
Department of Clinical Studies
School of Veterinary Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

Nutritional Assessment

Darryl L. Millis MS, DVM, DACVS, CCRP, DACVSMSR
Professor of Orthopedic Surgery
Small Animal Clinical Sciences
University of Tennessee College of Veterinary Medicine
Knoxville, Tennessee

Physical Therapy and Rehabilitation

Luis Miguel Fonte Montenegro Master's Degree
Clinical Director, Doctor
Surgery
Hospital Veterinário Montenegro
Porto, Portugal

Reproductive Emergencies

Carmel T. Mooney MVB, MPhil, PhD, DECVIM-CA (Internal Medicine), MRCVS
Associate Professor
University Veterinary Hospital
University College Dublin
Belfield, Dublin, Ireland

Canine Hypothyroidism

Antony S. Moore BVSc, MVSc, DACVIM (Oncology)
Veterinary Oncology Consultants
Wauchope, NSW, Australia

Principles and Practice of Chemotherapy

Sarah A. Moore DVM, DACVIM (Neurology)
Associate Professor, Neurology and Neurosurgery
Department of Veterinary Clinical Sciences
The Ohio State University
Columbus, Ohio

Neuromuscular Junction Disorders

Lisa Moses VMD, DACVIM (Small Animal Internal Medicine)
Pain Medicine Service
Angell Animal Medical Center
Fellow in Medical Ethics
Center for Bioethics
Harvard Medical School
Boston, Massachusetts

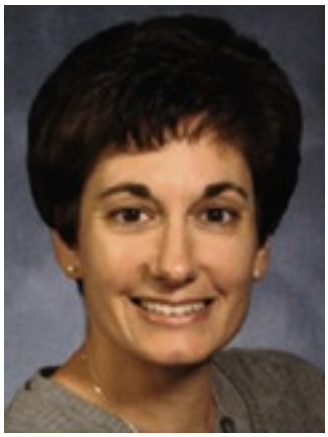
Chronic Pain: Pathophysiology, Identification, and General Management
Pain Physiology, Identification, and Management in the Acute Care Setting

Jane D. Mount MS, PhD
Research Fellow
Pathobiology
Auburn University
Auburn, Alabama

Fecal Examination
Antiparasitic Therapy

Ralf S. Mueller Dr.med.vet., Dr.habil., DACVD, FANZCVSc, DECVD
Professor
Center of Clinical Veterinary Medicine
Clinic of Small Animal Medicine
Ludwig Maximilian University of Munich
Munich, Germany

Scrapings, Fine-Needle Aspiration, and Biopsy of Skin and Subcutaneous Tissues



Karen R. Muñana DVM, MS, DACVIM (Neurology)
Professor, Neurology
Department of Clinical Sciences
North Carolina State University College of Veterinary Medicine
Raleigh, North Carolina

Seizures

Laura A. Nafe DVM, MS, DACVIM (Small Animal Internal Medicine)
Assistant Professor, Small Animal Internal Medicine
Veterinary Clinical Sciences
Oklahoma State University
Stillwater, Oklahoma

Respiratory and Inhalant Therapy

Thandeka Roseann Ngwenyama DVM, DACVECC
Clinical Assistant Professor of Emergency and Critical Care
Veterinary Clinical Sciences
Washington State University
Pullman, Washington

Peritonitis

Brook A. Niemiec DAVDC, DEVDC, Fellow AVD
Chief of Staff
Dentistry
Southern California Veterinarian Dental Specialties & Oral Surgery
Founding Consultant, VetDentalRad.com
President, Practical Veterinary Publishing
Lead Instructor, San Diego Veterinary Dental Training Center
San Diego, California

Ptyalism and Halitosis

Stijn J.M. Niessen DVM, PhD, DECVIM-CA (Internal Medicine), PGCVIM, PGCVetEd, FHEA, MRCVS
Senior Lecturer and Co-Head, Small Animal Internal Medicine
Clinical Science and Services
Director, Feline Diabetic Remission Clinic
Royal Veterinary College
London, United Kingdom;
Research Associate
Diabetes Research Group
Newcastle Medical School
Newcastle-upon-Tyne, Tyne and Wear, United Kingdom;
Consultant, Endocrinology
Veterinary Information Network
Davis, California

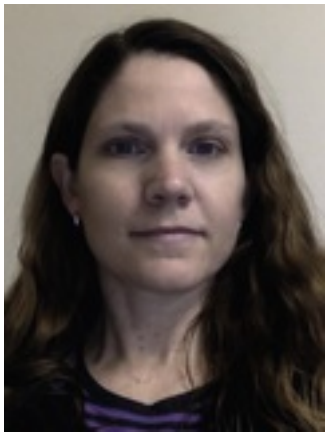
Feline Growth Hormone Disorders

Carolyn R. O'Brien BVSc, MVetClinStud, FANZCVS (Feline Medicine)
PhD Candidate
Faculty of Veterinary and Agricultural Sciences
University of Melbourne
Registered Specialist in Feline Medicine
Melbourne Cat Vets
Parkville, Victoria, Australia

Mycobacterial Infections, Actinomycosis and Nocardiosis

Dennis P. O'Brien DVM, PhD, DACVIM (Neurology)
Chancellor's Chair in Comparative Neurology
Department of Veterinary Medicine & Surgery
University of Missouri
Neurology & Neurosurgery Service
Veterinary Health Center
Columbia, Missouri

Neurophysiology
Brain Diseases: Degenerative, Anomalous, Metabolic, Neoplasia, Idiopathic Epilepsy, and Vascular



Mauria O'Brien DVM, DACVECC
Clinical Associate Professor
Veterinary Clinical Medicine
University of Illinois
Urbana, Illinois

Diabetic Ketoacidosis and Hyperglycemic Hyperosmolar Syndrome

Robert T. O'Brien DVM, MS, ACVR
Department of Veterinary Clinical Medicine
Director of Imaging, Epica Medical Innovations
Staff Radiologist, Oncura Partners Diagnostics, LLC
Nobleboro, Maine

Nonneoplastic Diseases of the Spleen

Gerhard Ulrich Oechtering Dr.med.vet.habil., DECVAA
Professor
Small Animal Department—Ear, Nose and Throat Unit
University of Leipzig
Leipzig, Saxony, Germany

Diseases of the Nose, Sinuses, and Nasopharynx

Dan G. Ohad DVM, PhD, DACVIM (Cardiology), DECVIM-CA (Cardiology)
Clinical Senior Lecturer in Cardiology
Koret School of Veterinary Medicine
Robert H. Smith Faculty of Agriculture, Food and Environment
Hebrew University of Jerusalem
Rehovot, Israel

Pallor
Treatment of Systemic Hypertension

Carl A. Osborne DVM, PhD, DACVIM
Veterinary Clinical Sciences Department
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota

Unblocking of the Urethra
Lower Urinary Urolithiasis in Dogs

M. Lynne O'Sullivan DVM, DVSc, DACVIM (Cardiology)
Associate Professor
Department of Clinical Studies
Ontario Veterinary College, University of Guelph
Guelph, Ontario, Canada

Tachypnea, Dyspnea, and Respiratory Distress

Mark A. Oyama DVM, MSCE, DACVIM (Cardiology)
Professor and Chief, Section of Cardiology
Department of Clinical Studies
University of Pennsylvania
Philadelphia, Pennsylvania

Congenital Heart Disease
Heart Disease and Kidney Disease

Caroline Page BA, VetMB, DACVIM (Small Animal Internal Medicine)
Page Veterinary Consulting
Huntington Beach, California

Rhinoscopy, Nasal Flush, and Nasal Flushing

Carrie A. Palm DVM, DACVIM (Small Animal Internal Medicine)
Assistant Professor
Medicine and Epidemiology
University of California, Davis
Davis, California

Blood Urea Nitrogen and Creatinine

Douglas Palma DVM, DACVIM (Small Animal Internal Medicine)
Staff Internist
Small Animal Internal Medicine
The Animal Medical Center
New York, New York

Pathophysiology and Clinical Manifestations of Systemic Hypertension

Manon Paradis DVM, MVSc, DACVD
Professor of Dermatology
Department of Clinical Sciences
Faculté de Médecine Vétérinaire, University of Montreal
St-Hyacinthe, Québec, Canada

Nutritional Management of Dermatologic Disease

Dominique Peeters DVM, PhD, DECVIM-CA (Internal Medicine)
Professor in Companion Animal Internal Medicine
Equine and Companion Animal Clinical Sciences
University of Liege
Liege, Belgium

Aspergillosis—Canine

Sally C. Perea DVM, MS, DACVN
Clinical Veterinary Nutritionist
Research and Development
Royal Canin, A Division of MARS, Inc.
Lewisburg, Ohio

Unconventional Diets (Homemade, Vegetarian, and Raw)

Dolores Pérez-Alenza DVM, PhD
Professor
Animal Medicine and Surgery
Veterinary School, Complutense University of Madrid
Head of Service
Small Animal Internal Medicine Service, Veterinary Teaching Hospital Complutense
General Secretary, Board Member
AVEPA
Madrid, Spain

Hyperadrenocorticism in Dogs

Michael Peterson DVM, MS
Staff Veterinarian
Reid Veterinary Hospital
Albany, Oregon;
Associate Investigator
Viper Institute
University of Arizona
Tucson, Arizona

Venomous Bites and Stings (Zootoxicosis)

Christine Piek DVM, PhD, DECVIM-CA (Internal Medicine)
Department of Clinical Sciences and Companion Animals
Faculty of Veterinary Medicine, Utrecht University
Utrecht, The Netherlands

Immune-Mediated Hemolytic Anemias and Other Regenerative Anemias

Simon R. Platt BVM&S, MRCVS, DACVIM (Neurology), DECVN
Professor, Neurology and Neurosurgery
Small Animal Medicine and Surgery
College of Veterinary Medicine, University of Georgia
Athens, Georgia

Tetanus and Botulism
Spinal Cord Diseases: Congenital (Developmental), Inflammatory, and Degenerative Disorders

Rachel E. Pollard DVM, PhD, DACVR
Department of Surgical and Radiological Sciences
School of Veterinary Medicine
University of California, Davis
Davis, California

Abdominal Ultrasonography

David James Polzin DVM, PhD, DACVIM (Small Animal Internal Medicine)
Professor and Chief of Internal Medicine
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota

Chronic Kidney Disease

Nathalie Porters DVM, MVM, PhD, DECVS
Professor Doctor
Small Animal Medicine and Clinical Biology
Faculty of Veterinary Medicine, Ghent University
Merelbeke, Belgium

Effect of Spay or Castration on Long-Term Health of Dogs and Cats

Simon Lawrence Priestnall BSc (Hons), BVSc, PhD, PGCert(VetEd), FHEA, DACVP, FRCPath, MRCVS
Associate Professor of Veterinary Anatomic Pathology
Department of Pathology and Pathogen Biology
The Royal Veterinary College
Hatfield, Hertfordshire, United Kingdom

Canine Infectious Respiratory Disease

Robert Prošek DVM, MS, DACVIM (Cardiology), DECVIM-CA (Cardiology)
Adjunct Professor of Cardiology
University of Florida
Gainesville, Florida;
President
Cardiopulmonary Medicine and Interventional Therapy
Florida Veterinary Cardiology
Miami, Florida

Abnormal Heart Sounds and Heart Murmurs
Thoracocentesis/Pericardiocentesis

Yann Queau DVM, DACVN
Research and Clinical Nutritionist
Research and Development Center
Royal Canin
Aimargues, France

Nutritional Management of Lower Urinary Tract Disease

Oriana Raab DVM, MVSc, DACVIM (Small Animal Internal Medicine)
Staff Internist
Internal Medicine
Tufts Veterinary Emergency Treatment and Specialties
Walpole, Massachusetts

Abdominocentesis and Diagnostic Peritoneal Lavage

Alan Radford BVSc, PhD, MRCVS
Reader in Infection Biology
Institute of Infection and Global Health
University of Liverpool
Neston, Cheshire, United Kingdom

Feline Upper Respiratory Infections
Other Feline Viral Infections

Juan José Ramos-Plá DVM, PhD
Associate Professor
Medicine and Surgery
Cardenal Herrera CEU University
Clínica Veterinaria Vinaroz
Valencia, Spain

Obesity

Ian K. Ramsey BVSc, PhD, DSAM, DECVIM-CA (Internal Medicine), FHEA, MRCVS
Professor of Small Animal Medicine
University of Glasgow
Glasgow, Scotland, United Kingdom

Fever
Feline Hyperadrenocorticism

Jacquie Rand BVSc (Hons), DVSc (Guelph), DACVIM (Internal Medicine)
Emeritus Professor
School of Veterinary Science
The University of Queensland
Executive Director and Chief Scientist
Australian Pet Welfare Foundation
Brisbane, Queensland, Australia

Feline Diabetes Mellitus

Kenneth M. Rassnick DVM, DACVIM (Oncology)
Director, Oncology Consultation Service
Veterinary Medical Center of Central New York
Syracuse, New York;
Director, Oncology Consultation Service
Colonial Veterinary Hospital
Ithaca, New York

Tumors of the Skin

Carol R. Reinero DVM, DACVIM (Small Animal Internal Medicine), PhD
Associate Professor
University of Missouri
Columbia, Missouri

Initial Evaluation of Respiratory Emergencies

Alexander M. Reiter Dipl. Tzt, Dr.med.vet., DAVDC, EVDC
Associate Professor of Dentistry and Oral Surgery
Department of Clinical Studies, Philadelphia
School of Veterinary Medicine, University of Pennsylvania
Philadelphia, Pennsylvania

Oral and Salivary Gland Disorders

Keith Richter DVM, MSEL, DACVIM (Small Animal Internal Medicine)
Chief Medical Officer
Ethos Veterinary Health
Staff Internist
Internal Medicine
Veterinary Specialty Hospital of San Diego
San Diego, California

Laparoscopy
Diagnostic Evaluation of the Liver

Teresa M. Rieser VMD, DACVECC
Staff Criticalist
Department of Emergency and Critical Care
VCA West Los Angeles Animal Hospital
Los Angeles, California

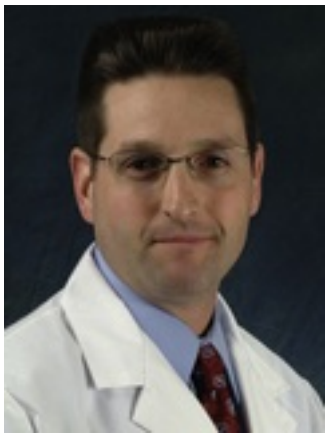
Shock

Stefano Romagnoli DVM, MS, PhD, DECAR
Professor
Animal Medicine, Production and Health
University of Padova
Legnaro, Padova (Veneto), Italy

Reproductive Endocrinology and Breeding Husbandry of the Bitch

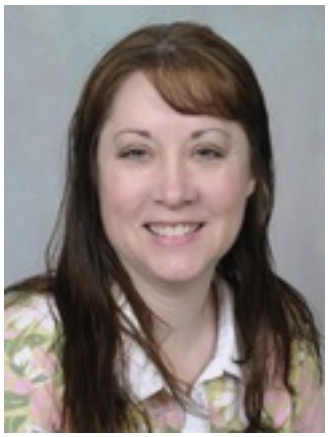
Dan Rosenberg DVM, PhD
Internal Medicine Unit
MICEN VET
Créteil, France

Sodium, Chloride



John Henry Rossmeisl Jr., DVM, MS, DACVIM (Small Animal Internal Medicine and Neurology)
Professor, Neurology and Neurosurgery
Small Animal Clinical Sciences, VA-MD College of Veterinary Medicine
Virginia Tech
Blacksburg, Virginia

Cerebrospinal Fluid Collection, Analysis, and Myelography
Cranial Neuropathies



Elizabeth Rozanski DVM, DACVIM (Small Animal Internal Medicine), DACVECC
Associate Professor of Critical Care
Cummings School of Veterinary Medicine
Tufts University
North Grafton, Massachusetts

Thoracic Trauma
Diseases of the Pleural Space

Craig G. Ruaux BVSc, PhD, MACVSc, DACVIM (Small Animal Internal Medicine)
Associate Professor, Small Animal Medicine
Department of Clinical Sciences
Oregon State University
Corvallis, Oregon

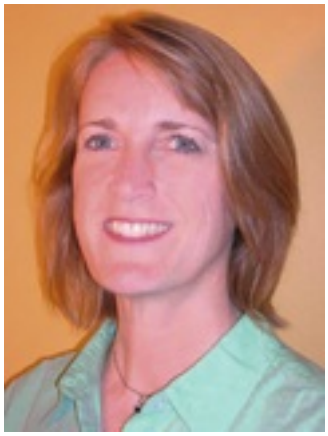
Nutritional Management of Hepatobiliary Disease
Feline Pancreatitis: Diagnosis and Treatment

Clare Rusbridge BVMS, PhD, DECVN, FRCVS
Chief of Neurology
Fitzpatrick Referrals
Eashing, Surrey, United Kingdom;
Reader in Veterinary Neurology
School of Veterinary Medicine
University of Surrey
Guildford, Surrey, United Kingdom

Tremors

John E. Rush DVM, MS, DACVIM (Cardiology), DACVECC
Tufts Cummings School of Veterinary Medicine
North Grafton, Massachusetts

Nutritional Management of Heart Disease



Helena Rylander DVM, DACVIM (Neurology)
Clinical Associate Professor
Department of Medical Sciences
School of Veterinary Medicine
University of Wisconsin
Madison, Wisconsin

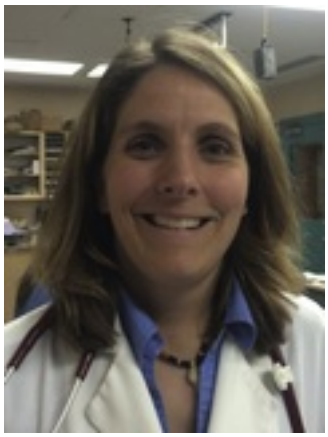
Neurologic Manifestations of Systemic Disease

Veronique Sammut DVM, MS, DACVIM (Neurology)
VCA West Los Angeles
Los Angeles, California

Vestibular Disease

Kari Santoro Beer DVM, DACVECC
Assistant Professor, Emergency and Critical Care Medicine
Department of Small Animal Clinical Sciences
Michigan State University
East Lansing, Michigan

Lactate

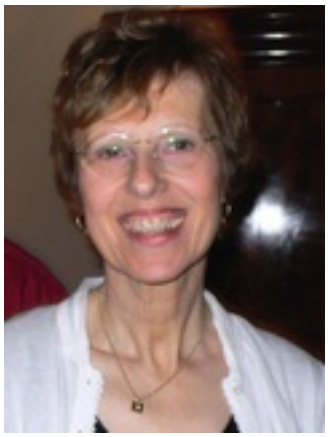


Christine Savidge DVM, DACVIM (Small Animal Internal Medicine)
Assistant Professor, Small Animal Internal Medicine
Department of Companion Animals
University of Prince Edward Island, Atlantic Veterinary College
Charlottetown, PE, Canada

Buccal Mucosal Bleeding Time

Brian A. Scansen DVM, MS, DACVIM (Cardiology)
Associate Professor
Clinical Sciences
Colorado State University
Fort Collins, Colorado

Cardiovascular Interventional Therapies
Venous and Lymphatic Disorders



Auke C. Schaefers-Okkens DVM, PhD, DECAR
Department of Clinical Sciences of Companion Animals (retired)
Faculty of Veterinary Medicine, University of Utrecht
Utrecht, The Netherlands

Vulvar and Preputial Discharge

Michael Schaer DVM, DACVIM (Small Animal Internal Medicine), DCVECC
Emeritus Professor
Adjunct Professor, Emergency and Critical Care Medicine
College of Veterinary Medicine
University of Florida
Gainesville, Florida

The Medical History

Scott J. Schatzberg DVM, PhD, DACVIM (Neurology)
Director of Neurology/Neurosurgery
The Animal Neurology and Imaging Center
Algodones, New Mexico

Neurologic Examination and Neuroanatomic Diagnosis

Thomas Schermerhorn VMD, DACVIM (Small Animal Internal Medicine)
Professor
Department of Clinical Sciences
Kansas State University
Manhattan, Kansas

Weight Loss as a Chief Complaint
Gastrointestinal Endocrinology

Chad W. Schmiedt DVM, DACVS
Associate Professor
Department of Small Animal Medicine and Surgery
University of Georgia
Athens, Georgia

Renal Transplantation

Johan P. Schoeman BVSc, MMedVet, PhD, DSAM, DECVIM-CA (Internal Medicine)
Professor and Head of Department
Department of Companion Animal Clinical Studies
Faculty of Veterinary Science, University of Pretoria
Onderstepoort, Pretoria, South Africa

The Endocrine Response to Critical Illness
Insulin-Secreting Tumors

Simone Schuller Dr.med.vet., DECVIM-CA (Internal Medicine), PhD
Professor
Department of Clinical Veterinary Medicine
Internal Medicine
Small Animal Hospital
Vetsuisse Faculty Bern
Bern, Switzerland

Leptospirosis

Wayne Stanley Schwark DVM, MSc, PhD
Emeritus Professor of Pharmacology
Molecular Medicine
College of Veterinary Medicine, Cornell University
Ithaca, New York

Adverse Drug Reactions

Katherine F. Scollan DVM, DACVIM (Cardiology)
Assistant Professor
College of Veterinary Medicine
Oregon State University
Corvallis, Oregon

Pathophysiology of Heart Failure

Gilad Segev DVM, DECVIM-CA (Internal Medicine)
Senior Lecturer
Koret School of Veterinary Medicine
Hebrew University of Jerusalem
Rehovot, Israel

Familial and Congenital Renal Diseases of Cats and Dogs

Rance K. Sellon DVM, PhD, DACVIM (Small Animal Internal Medicine, Oncology)
Associate Professor
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
Washington State University
Pullman, Washington

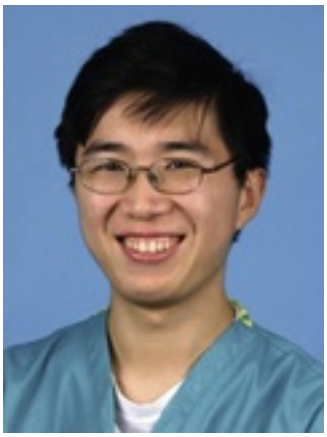
Peritonitis

G. Diane Shelton DVM, PhD, DACVIM (Small Animal Internal Medicine)
Professor
Department of Pathology, School of Medicine
Director, Comparative Neuromuscular Laboratory
University of California, San Diego
La Jolla, California

Muscular Disorders

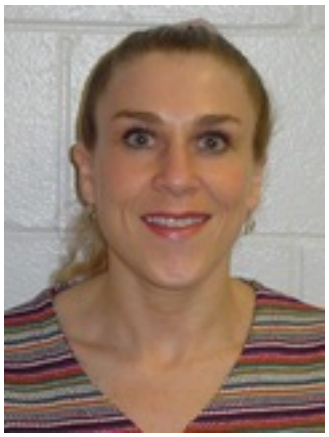
Robert E. Shiel MVB, PhD, DECVIM-CA (Internal Medicine)
Lecturer
Small Animal Medicine Section, School of Veterinary Medicine
University College Dublin
Dublin, Ireland

Polyuria and Polydipsia
Diabetes Insipidus



Andre C. Shih DVM, DACVAA, DACVECC
Associate Professor
Large Animal Clinical Sciences
University of Florida College Veterinary Medicine Anesthesia Service
Gainesville, Florida

Intraosseous Catheters



Deborah C. Silverstein DVM, DACVECC
Associate Professor of Critical Care
University of Pennsylvania
Philadelphia, Pennsylvania

Gastric Intubation and Lavage

Kenneth W. Simpson BVM&S, PhD, DACVIM (Small Animal Internal Medicine), DECVIM-CA (Internal Medicine)
College of Veterinary Medicine
Cornell University
Ithaca, New York

Diseases of the Stomach

D. David Sisson DVM, DACVIM (Cardiology)
Professor Emeritus
Veterinary Clinical Sciences
Oregon State University
Corvallis, Oregon

Pathophysiology of Heart Failure

Barbara J. Skelly MA, VetMB, PhD, CertSAM, DACVIM (Small Animal Internal Medicine), DECVIM-CA (Internal Medicine), MRCVS
University Senior Lecturer in Small Animal Medicine
Department of Veterinary Medicine

Queen's Veterinary School Hospital
University of Cambridge
Cambridge, Cambridgeshire, United Kingdom

Primary Hyperparathyroidism

Stephanie A. Smith DVM, MS
Research Assistant Professor
Department of Biochemistry, School of Molecular and Cellular Biology
Adjunct Clinical Assistant Professor
Department of Veterinary Clinical Medicine, College of Veterinary Medicine
University of Illinois
Urbana, Illinois

Coagulation Testing

David Stephen Sobel DVM, MRCVS
Director of Medicine
Metropolitan Veterinary Consultants
Hanover, New Hampshire;
Clinical Consultant
Elands Veterinary Clinic
Dunton Green, Sevenoaks, United Kingdom

Otoscopy, Ear Flushing, and Myringotomy

Maria M. Soltero-Rivera DVM, DAVDC
Adjunct Assistant Professor
Dentistry and Oral Surgery
Penn Vet—Matthew J. Ryan Veterinary Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania;
Veterinary Specialist
Dentistry and Oral Surgery
VCA San Francisco Veterinary Specialists
San Francisco, California

Oral and Salivary Gland Disorders

Dennis R. Spann DVM, DACVIM (Small Animal Internal Medicine)
Staff Internist
Internal Medicine Department
Sacramento Area Veterinary Internal Medicine
Roseville, California

Leukopenia, Leukocytosis

Thomas Spillmann Dipl.med.vet, Dr.med.vet., DECVIM-CA (Internal Medicine)
Professor of Small Animal Internal Medicine
Department of Equine and Small Animal Medicine
Faculty of Veterinary Medicine, University of Helsinki
Helsinki, Finland

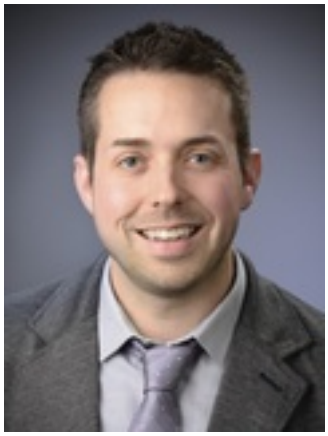
Pancreatitis: Etiology and Pathophysiology

Timothy J. Stein DVM, PhD, DACVIM (Oncology)
Medical Oncologist
Oncology
Austin Veterinary Emergency & Specialty Center
Austin, Texas

Paraneoplastic Syndromes

Rebecca L. Stepien DVM, MS, DACVIM (Cardiology)
Clinical Professor of Cardiology
Department of Medical Sciences
School of Veterinary Medicine
University of Wisconsin—Madison
Madison, Wisconsin

Blood Pressure Measurement



Joshua A. Stern DVM, PhD, DACVIM (Cardiology)
Assistant Professor of Cardiology
Department of Medicine & Epidemiology
University of California, Davis
Davis, California

Basic Genetics
Clinical Genomics
Myocardial Disease: Canine

Tracy Stokol BVSc, PhD, DACVP (Clinical Pathology)
Professor of Clinical Pathology
Department of Population Medicine and Diagnostic Sciences
College of Veterinary Medicine, Cornell University
Ithaca, New York

Anemia, Erythrocytosis
Fluid Analysis: Thoracic, Abdominal, Joint

Michael Stone DVM, DACVIM (Small Animal Internal Medicine)
Clinical Assistant Professor
Department of Clinical Studies
Cummings School of Veterinary Medicine at Tufts University
North Grafton, Massachusetts;
Traveling Ultrasonographer
Veterinary Internal Medicine Mobile Specialists
North Woodstock, Connecticut

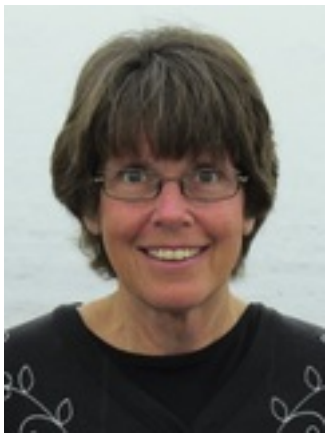
Immune-Mediated Polyarthritis and Other Polyarthritides
Systemic Lupus Erythematosus

Joseph Taboada DVM, DACVIM (Small Animal Internal Medicine)
Professor of Small Animal Internal Medicine and Associate Dean
School of Veterinary Medicine
Louisiana State University
Baton Rouge, Louisiana

Cryptococcosis
Blastomycosis and Histoplasmosis

Séverine Tasker BSc, BVSc (Hons), PhD, DSAM, DECVIM-CA (Internal Medicine), FHEA, MRCVS
Reader in Feline Medicine
The Feline Centre, Langford Veterinary Services
University of Bristol
Bristol, North Somerset, United Kingdom

Fever
Hemotropic Mycoplasmas



Susan M. Taylor DVM, DACVIM (Small Animal Internal Medicine)
Professor
Small Animal Clinical Sciences
Staff Internist
Veterinary Teaching Hospital
Western College of Veterinary Medicine, University of Saskatchewan
Saskatoon, SK, Canada

Creatine Kinase

Karen M. Tefft DVM, MVSc, DACVIM (Small Animal Internal Medicine)
Clinical Assistant Professor
Department of Clinical Sciences
North Carolina State University
Raleigh, North Carolina

Melena and Hematochezia

Douglas H. Thamm VMD, DACVIM (Oncology)
Barbara Cox Anthony Professor of Oncology
Flint Animal Cancer Center, Department of Clinical Sciences
Colorado State University
Fort Collins, Colorado

Mast Cell Disease

William B. Thomas DVM, MS, DACVIM (Neurology)
Professor, Neurology and Neurosurgery
College of Veterinary Medicine
University of Tennessee
Knoxville, Tennessee

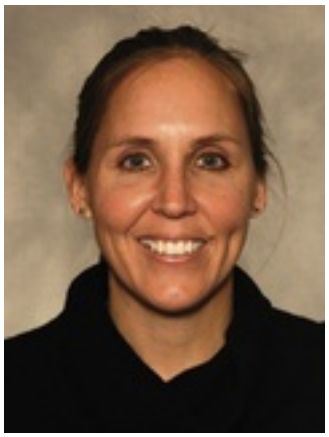
Movement Disorders

Melanie D. Thompson DVM, MVSc, DACVIM (Small Animal Internal Medicine)
Internist
Small Animal Internal Medicine
Advanced Veterinary Care
Salt Lake City, Utah

Ear Vein Blood Glucose Monitoring

Anna Tidholm DVM, PhD, DECVIM-CA (Cardiology)
Associate Professor
Albano Animal Hospital
Danderyd, Sweden

Cyanosis



M. Katherine Tolbert DVM, PhD, DACVIM (Small Animal Internal Medicine)
Assistant Professor
Small Animal Clinical Sciences
University of Tennessee
Knoxville, Tennessee

Gastrointestinal Endoscopy

Lauren A. Trepanier DVM, PhD, DACVIM (Small Animal Internal Medicine), DACVCP
Professor and Director of Clinical Research
Department of Medical Sciences
School of Veterinary Medicine, University of Wisconsin—Madison
Madison, Wisconsin

Toxic Hepatic Diseases

Stefan Unterer Dr.med.vet., Dr. Habil., DECVIM-CA (Internal Medicine)
Oberarzt Innere Medizin
Leiter des Gastroenterologie-Service
Medizinische Kleintierklinik
Ludwig-Maximilians-Universität
Munich, Germany

Enemas and Deobstipation
Rectoanal Disease

Shelly L. Vaden DVM, PhD, DACVIM (Small Animal Internal Medicine)
Professor, Internal Medicine
College of Veterinary Medicine
North Carolina State University
Raleigh, North Carolina

Glomerular Diseases
Heart Disease and Kidney Disease

Thomas Wilhelm Vahlenkamp Dr.med.vet., PhD
Institute of Virology
Center of Infectious Diseases
University of Leipzig
Leipzig, Germany

Canine Distemper and Other Canine Viral Infections

Alexandra van der Woerdt DVM, MS, DACVO, DECVO
Staff Ophthalmologist
The Animal Medical Center
New York, New York

Ophthalmic Manifestations of Systemic Disease

Astrid M. van Dongen DVM, DRNVA
Assistant Professor
Department of Clinical Sciences of Companion Animals—Internal Medicine/Nephrology
Faculty of Veterinary Medicine, Utrecht University
Utrecht, The Netherlands

Pyelonephritis

Lamberto Viadel Bau DVM
Clínica Veterinaria Bau
Buñol, Valencia, Spain

Cytology of Internal Organs

Cecilia Villaverde BVSc, PhD, DACVN, DECVCN
Adjunct Professor
Ciència Animal i dels Aliments
Universitat Autònoma de Barcelona

Department of Small Animal Clinical Sciences
College of Veterinary Medicine and Biomedical Sciences
Texas A&M University
College Station, Texas

Nutritional Management of Gastrointestinal Disease

†Deceased.

Preface

We began the preface to the 7th edition by acknowledging that we had already begun to work on the 8th edition. Little did we realize how this 8th edition was going to evolve, how the publishing field was to change and how the preferences of “junior” and “senior” readers would develop during this relatively brief period. Who would have imagined in 1975 when the first edition came out that at least 7 editions would follow, that figures would have color, that there would be algorithms in almost every chapter, that more than 500 videos would each be available at the click of a mouse (in 1975 a mouse was still a small rodent), and that there would be 360 succinct but complete chapters contributed by 348 authors? More comprehensive internal medicine has been compressed into two volumes that are not significantly different in size from that first edition in 1975. Think of the advances since then! This edition is so different from those that came before that it is truly unique. Now it is a given that the entire textbook is produced both in traditional typeset and in digital format. The reader may choose his/her own preferred format(s). This resource is compatible with desktops/laptops, tablets, and smartphones.

Perhaps the biggest change was adding a third co-editor to assist with every aspect of developing this edition. Etienne Côté has been a friend, a trainee and now a mentor. He has truly helped Ed and Steve bring forth new ideas, enhance the editing process and be part of obtaining new contacts, additional literary input and guidance with digitizing information essential to the intent of the textbook. We thank Etienne for his time, expertise, diligence and never-ending enthusiasm.

The 8th edition brings on major changes. Our greatest pride could be the more than 300 authors who agreed to contribute; or maybe it is the more than 20 countries that our authors call home; or perhaps it rests in the hundreds of original videos and innumerable additional diagrams and other digital media that make this a vibrant book. It could be the true skill of authors, which is revealed in their ability to capture the most important, newest, relevant material for the reader of this textbook—sorting out what matters, and presenting it clearly, without fluff or embellishment. As all will appreciate, it is all these and more.

Previously the book was set up by clinical medicine and then chapters of disease conditions specific to that one system. While this has not changed, what we have emphasized is the cohesion and thoroughness of the material among the sections. Rather than reviewing the table of contents here, we invite the reader to thoroughly peruse the table of contents to see how easy it will be to search the book and how it has been presented so as to mimic the clinical thought process of the reader-practitioner.

The textbook is presented in a manner that reflects clinical veterinary medicine. The very first chapters present the true fundamentals of our professional work. Sections follow on the differential diagnosis for clients' chief concerns and reasons for seeking veterinary care, physical examination abnormalities, and clinicopathologic abnormalities. The latter section is entirely new and it integrates laboratory testing with clinical medicine through detailed differential diagnoses, and explanations of the physiology of different analytes. These are followed by a section that includes virtually all the procedures needed to further clarify or confirm a diagnosis: the core techniques that define veterinary internal medicine, ranging from feeding tube placement and cerebrospinal fluid collection to electromyography and hyperbaric medicine. Another new section consists of 6 chapters on interventional therapies; these urologic, cardiovascular, gastrointestinal, and other procedures are at the forefront of small animal therapeutics today. Disease-specific chapters have been comprehensively updated or rewritten altogether. The book concludes with a new section that acknowledges that diseases do not always exist in isolation. This Comorbidities section identifies pairs of diseases that involve diametrically opposing treatment requirements and make some complex internal medicine cases especially challenging.

All chapters and sections are set up for easy cross-referencing to specific conditions and easy movement from one chapter to another. Figures are set so that the reader can go from one chapter easily to the next, further strengthened by the search function in the digital version of the book. The cross-references in chapters

(which refer the reader to other, pertinent chapters) were implemented by the editors, given their view "from the crow's nest" over the entire book. They are not meant to imply that the chapter's author shares the same viewpoint as that presented in a cross-referenced chapter, but rather to help the reader quickly navigate to relevant, additional information.

Good videos say in a few seconds what would take multiple paragraphs to express less effectively. This edition has an entire library of original, high-quality video clips that embody the notion that ***seeing is believing.*** Each and every video has been carefully chosen by the authors, adapted for learning and teaching and set up with titles and legends that we believe make internal medicine come to life.

Many of the authors have provided client information sheets, which can be found in a subsection of the electronic edition of the book. These are short, easy-to-understand, clinical commentaries describing a condition, diagnostics, and/or treatment options specifically for a disease or procedure. They are available to print out for any client, to supplement discussions regarding a pet's health concern. These aim to help educate a client when there are serious decisions to be made. Then, when clients do go home to consult family, friends or Dr. Google, they will have a reasonable place to begin their search and will have a spelled-out set of information from which further legitimate reading can be accessed.

As a bridge between the print and digital formats, each chapter ends with a QR code for the reference section. Opened, this takes the reader instantly to a separate reference website where each reference is listed for that chapter. Many are linked directly to PubMed, providing the reader access to original source material. In this way, readers can access references quickly and effectively, without having to carry a printed reference section for citations.

The astute reader will note that in the written book there are references to figures and videos that may not appear to be sequentially numbered. This is because all videos and some digital material are presented exclusively in the electronic version, whose numbering is sequential. Some prefer the print edition only but in today's rapidly evolving digital world we believe that the reader should have access, in a digital format, to most every process seen clinically. The saying that "a picture is worth a thousand words" is never more true than it is here. Each reader can view additional photographs and diagrams that can positively impact the management of their own patients. If one hears about a disease once, it is likely to be forgotten, but to see it reinforced with images, videos, and additional graphics provides a greater likelihood for the condition to be remembered and understood.

Because this is a worldwide production, involving authors from 23 countries, we also know that different countries and laboratories utilize upper and lower limits differently or even in different terms for reference ranges. We prefer that laboratory results typical of any condition be reviewed in generalities, suggesting that values may be above, below, or within reference ranges. It is no longer appropriate to provide specific results since each laboratory likely uses different assays and protocols, which invariably cause each reference range to be specific to the laboratory where a test is performed. This approach reflects our desire to meet the needs of readers from around the world.

Traditionally, we provide pictures of the authors in the front matter. The reader, through the author's picture, can recognize anyone who has contributed a chapter to the book. How nice too to see that our authors continue to be thrilled to be part of this effort. We cannot thank them enough for holding to such a short schedule and for keeping their chapters up to date and current, often as close as one month before deadline. Contributing a chapter with a strict page limitation is likely one of the most difficult chores one can impose on an author(s). Condensing scientific material to an advanced level takes a special expertise and our goals have been such that we continue to meet the needs of today's veterinary students, young graduates and practicing veterinarians wanting an encyclopedic effort in small animal medicine. We also thank past authors who contributed content to previous editions and thus added an original layer to the first versions of current chapters.

We are proud of our effort to incorporate outstanding colleagues from so many countries. This book has evolved quickly into an international textbook, published in at least five languages and read in most of the world by veterinarians and students alike. It is with honor, pleasure and a distinct sense of pride that we can offer the reader many of the finest veterinary writers and observers throughout the world. We honor these colleagues and their countries on the inside cover of the book, to signify our belief that this is a one-world, one profession book. In a letter to us about his chapter, one of our contributors, Adrian Boswood, related something that energized us to keep working, when he said, "It is an honor to be able to contribute to your textbook. The book has a reputation that precedes my career and will no doubt also outlive it!" Thank you all

for your well-needed support at such crucial points in the preparation process.

In the past we have not had section editors for this textbook and we have continued this approach into the 8th edition. However, we recognized that there are a growing number of outstanding experts in the profession today. As editors, we cannot know all of these individuals. Thus, we have called upon some of our friends and colleagues to help provide names of potential authors for their specific areas of expertise, and to review the proposed chapter titles as representative of the field. We are most grateful to these colleagues who spent time and effort helping us this way. In some cases, new authors were veterinarians that we knew, but in others we were offered an extensive list of new names, and we are delighted to have been able to call upon them as well to contribute to the book. To our section advisors, we are most appreciative for your assistance. Specifically, we would like to thank Drs. Vanessa Barrs, Joe Bartges, Leah Cohn, Ronaldo da Costa, Autumn Davidson, Lisa Freeman, Ann Hohenhaus, Safdar Khan, Mark Papich, Jörg Steiner, Harriett Syme, Jane Sykes, David Twedt, and David Vail.

As always, the staff at Elsevier has been most helpful in building this new edition of the book from the ground up. We had so many new ideas, so much new material to work with and a huge list of audio-video material, that alone we were overwhelmed. The execution of all this could not have been done without the continued support of Rhoda Howell, Jolynn Gower, Catherine Jackson, David Dipazo, and of course, Penny Rudolph. Thank you so much for your patience and regular input.

To our wives and children, we once again feel the overwhelming desire to remind you how important you are to us. Your support, compassion, and willingness to share this effort means so much to us. We love you so!!! To our colleagues who have been ever so supportive over the years, thank you for your constructive comments as well as your passion for what we have attempted to provide. Your warm welcome, both here at home and wherever we travel, has always been a real joy to us and makes us realize just how much we all communicate in our expanding world of one veterinary medicine.

Sincerely,

Steve Ettinger

About the Cover

Bastet was an Egyptian goddess, and in Greek mythology she is also known as Alluros. She is a protector figure, including protection against illness. To the editors of this textbook her likeness, as shown on this cover, embodies the dignity of the animal.

Bronze statuette, Egypt, Macedonian-Ptolemaic Period (332-330 B.C.E.).

Courtesy of the Metropolitan Museum of Art, New York, NY.

CHAPTER 1

The Medical History

Michael Schaer

Overview

The art of practicing medicine will always begin with two essential components: the history and physical examination. The history is certainly the most important diagnostic aid in medicine and the physical examination is easily second. The history is frequently key in determining cause of an illness, its significance, treatment options and even prognosis. Any clinician who fails to appreciate the value of a thorough history, who does not develop expertise in being able to obtain an owners' complete account of their concerns, or who takes "short cuts," will create an environment for misdiagnosis or errors in therapy. As is true for any individual with *expertise,* practice is critically important. Repetition can improve history-taking skills if coupled with frequent self-assessments. This is an excellent method to avoid repeating errors. One can ask after any difficult diagnosis is confirmed, what questions should have been asked that were not? What did the owner know but was never asked? Could I have changed the formulation of a question to gain better insight? The excellent clinician is an excellent historian and excellent listener. The excellent clinician continuously works to improve his or her skill set.

Obtaining a history is a "process" which should be approached in a methodical manner. This "process" should ensure that no valuable question is forgotten. Thus, the successful clinician has a group of questions consistently asked of every owner. Each question can be expanded or altered as dictated by answers given about the patient by the historian (usually the owner). In some cases, the order of questions may be changed. In other cases, answers provided may stimulate a subsequent set of questions. The clinician should always strive to be an approachable and compassionate listener. One will be well served by having the pet owner calm in order for her or him to provide clear and thoughtful responses. The medical history is a "story" about the patient. The following guidelines should assist with successful procurement of the patient's medical history.

The Approach to the Pet Owner

1. Meeting a client for the first time forms the foundation for any relationship. The adage is true: "You only have one chance to create a first impression." In this scenario, the "you" includes the primary clinician plus all hospital employees, because "the relationship" often begins before the veterinarian ever meets a client. As a client enters your facility and meets the receptionist or any other employee, opinions are formed and trust may or may not begin to be established. Successfully placing a client at ease is much easier when all hospital employees are respected members of the veterinary team with the same goal of providing the best care for a pet and the owner.[1] Owner and pet "needs" must be perceived as having highest priority.
2. Having every client completely comfortable in your presence is desirable but not easily achieved. Remember that with you being a complete stranger, a client may be insecure regarding your trustworthiness in caring for their pet. Many but not all owners prefer a warm, friendly, understanding, patient, and compassionate veterinarian. If an animal arrives in a life-threatening situation, the clinician may speak quickly and even go so far as to remove the pet from the owner in order to provide treatment. Once the patient is stable, the clinician should return to an examination room to obtain the detailed history and begin to build a client-doctor relationship.
3. Your greeting should inform the client who you are and in what capacity you function at the veterinary facility. Every clinician should be well groomed, speak clearly and use an understandable vocabulary.
4. Verify that the owner can understand what is being said or asked. Clearing any form of obstruction between you and the pet owner's ability to understand your questions is extremely important.

5. Verify the patient's age, gender, neuter status, and breed (signalment), even if this information has previously been entered into the medical record. Incorrect data can be misleading and could cause disastrous outcomes in case management. Also, verify vaccination history, routine use of anti-parasite products, as well as all previously and currently used medications.
6. The clinician should determine the relationship between the person to whom one is speaking and the pet. The more familiar an individual is with an animal, the more valuable their information. Next, one can inquire how long the person has "known" this pet. Have they lived in the same home for 12 years or have they been together for 12 days?
7. When seeing an ill pet, the clinician will benefit from knowing when the animal was last "normal." It also may be quite important to understand the owner's definition of "normal."
8. Owners of ill pets may be fearful and anxious. Stress can impair an ability to recall essential historical information. Remember that your patience should be a virtue. It might require you to repeat questions several times. Alternatively, one may inquire about a subject using more than one perspective or more than one question.

Requirements for a Thorough History

Box 1-1 lists the criteria necessary for obtaining a complete history. This box has been modified from a document created for physicians by the American Board of Internal Medicine.[2] It seems obvious for the clinician to always try to ask the key questions pertinent to a specific primary concern or "owner chief concern." However, typical issues caused by one disease will almost always overlap with observations associated with another. Although initial differential diagnoses based on signalment or another factor might steer the examining clinician to a correct diagnosis, it behooves the clinician to avoid "tunnel vision" in situations where another disease process might actually be responsible for the illness (Box 1-2). Owner concerns or initial clinician suspicions are, therefore, always subject to misinterpretation. One objective of the medical history is to obtain an actual "feel" for what is clinically wrong with the animal based on owner-perceived issues. Some clinical signs are difficult to fully understand until either the owner or clinician actually imitates what is being seen or heard. One example is trying to determine if an owner is observing coughing, retching, reversed sneezing, regurgitation, or vomiting. It may be quite valuable to have an owner make a video record of an actual worrisome "event."

Box 1-1

Competence in History-Taking[2]

1. Develop the habit of recording a complete history.
2. Pursue with appropriate thoroughness all historical clues.
3. Establish rapport with the historian in order to obtain accurate information.
4. Adapt language appropriately to ensure communication with the person available.
5. Patiently adapt to clients who provide a disorganized history.
6. Develop a depth of knowledge that permits a thorough exploration of signs related to the patient's problems.
7. Have a depth of knowledge that permits consideration of the various causes that might explain the patient's signs.
8. Understand signs in terms of altered structure and function of the body systems.
9. Approach the history in a logical, directed way to ensure completeness.
10. Follow up medical clues in a directed logical pattern.
11. Organize and record the history completely in a fashion that will be understandable.
12. Be able to integrate signs into a diagnostic hypothesis while obtaining the history.
13. Assess the reliability of the history obtained.
14. Separate irrelevant from relevant information appropriately.

Box 1-2

Essentials for the Complete History

Signalment (age, breed, sex)
Geographic origin and places visited
Prior ownership and location (adopted from pound, found as stray, quality of previous care)
Current environment (indoor or outdoor pet; rural or urban environment; exposure to other animals and potential sources of intoxication)
Diet (raw meat, milk products, fish, commercially prepared, disease-specific or organ-specific diet, ingestion of wild animals)
Prior medical problems (describe illness, medications used, and outcome)
Vaccination and parasite prevention status (history of prior worm infections; prior worming treatments)
Current or "chief" concern or "complaint"
  Last known period of normalcy
  Disease onset—acute or gradual
  Progression and duration
  Intervening signs
  Previous treatments for the current illness and the animal's response
  Present status (weight loss or weight gain, attitude, activity level, appetite status, urination and defecation characteristics, amounts of water intake)

In addition to questions integral to every history, specific clinical abnormalities may have a set of questions designed to help clarify the nature of a medical disorder. The reader is referred to each appropriate section in this text for a more detailed description of the diagnostic approach recommended for various "owner chief concerns" (Section II), "physical examination abnormalities" (Section III), and various "clinicopathologic abnormalities" (Section IV). The focus of this chapter is not to develop a "history" for each condition or concern, but to review the art of asking the right questions.

The Elements of the History

1. *Obtaining the facts.* You will likely obtain the most information by reviewing the history with the person who spends the most time with the patient. Their familiarity with the animal may provide valuable insights. It is the care-giver who has had the best opportunity to have made key observations regarding a concern or illness, i.e., the "chief concern." Sometimes the individual who has brought the pet to the facility is not able to convey the necessary information because of language, handicap, or another issue. This will direct you to attempt identification of the next most knowledgeable source of information. Always verify the patient's signalment as an easy means of beginning a conversation while avoiding misplaced diagnostic and therapeutic pursuits. There are many examples of diagnoses being made after a mistake in the record is identified. It is "best not to assume anything."
2. *Diet and appetite.* Animals with normal appetites are rarely critically ill. Changes in appetite, up or down, are easily and often observed. This reality is the reason that appetite is frequently a cause for concern and may be one of the first observed signs of illness. It may be important to know how much of an increase or decrease in appetite has taken place and over what period of time. Has the change progressively worsened or has it reached some plateau? Changes in appetite often parallel duration of illness. Dietary information is especially important in patients who are cachectic, obese, or who have chronic digestive system complaints. When possible, determine the current diet, duration of providing that food, and all other sources of oral intake. It may be critically important to know if a diet is homemade or a commercially available food. Supplements and "chew toys" may be important.
3. *Drinking, urination, and defecation patterns.* These are 3 daily activities typically observed by owners. As such, they are common areas of concern and frequently represent an "owner chief complaint." Even if an owner's chief concern appears unrelated to water intake, urine output, stool quality, or defecation frequency, having an understanding of the current status of these physical traits will be of general value and may help explain a primary concern. Answers to questions about these matters may provide the clinician with insight regarding the care-giver's observational skills.
   As examples, **polydipsia** can be associated with numerous syndromes while **adipsia** will sometimes be a reason for an animal becoming severely hypernatremic. **Polyuria** can accompany the same syndromes associated with polydipsia while **stranguria** and **dysuria** will usually be associated with lower urinary outflow concerns. Stool quality and frequency of production could provide important information about the pancreas and intestines. High volume, greasy stools in a polyphagic pet who has experienced weight loss or difficulty gaining weight are typical of exocrine pancreatic insufficiency. Frequent watery stools

are associated with small bowel dysfunction. Colonic disease is often characterized by a pet with stable body weight but who has straining (tenesmus), frequency, and the stool may be small in volume while containing blood and/or mucus.

4. *Geographic history.* Knowing the geographic background can provide important information because certain diseases are endemic to specific geographic areas. Clinical diagnosis can escape the clinician who fails to understand the importance of where the pet has traveled or lived.
5. *Describe home environment.* Knowing the conditions of the animal's home is essential. A dog or cat that is allowed to be unattended outdoors might be subjected to various forms of trauma or be exposed to one of several of nature's maladies such as venomous snake encounters, toxic plant ingestion, etc. Behavioral problems can sometimes be traced to changes in the home environment. The addition or loss of a person or another animal from the home may be significant. Remember that pets may be exposed to or consume medications prescribed for people in the home.
6. *The chronology of the sequence of events.* Knowing when the animal was last normal and then being able to trace subsequent events in chronological order may help in understanding a concern. In some cases, this may help categorize the disorder as being either acute (occurring over the past hours or days) or chronic (occurring over a period of two weeks or more). The duration of subacute illnesses lies somewhere in-between.
7. *The initial abnormal signs and their progression.* This information provides the opportunity for the clinician to perceive not only how the illness began, but it furthers the understanding of the disorder by providing important information for how the illness progressed and its effects on the animal. As mentioned, it may allow the clinician to actually get a "feel" for the disease. This can be illustrated in a dog that is examined for initially vomiting a clear watery fluid. If the vomitus then progressed to being bile-colored and if the patient then begins to produce profuse watery brown diarrhea with or without hematochezia, it may be interpreted as gastritis that has progressed to involve the proximal and distal small intestine. The presence of bile provides evidence that the pylorus is probably patent.
8. *Changes in body weight.* Acute disease rarely causes significant weight loss. When weight loss is present in the acute setting, it is usually reflected in dehydration caused by water loss through vomiting and/or diarrhea. Polyuria, if present, will cause dehydration to develop quickly if the animal is not drinking. It is possible for an animal to lose as much as 12 percent of its body weight via water lost through vomiting and diarrhea while retaining muscle mass.
   The chronically ill pet may be brought to the veterinary facility with a "chief concern" of weight gain or weight loss. The hydrated pet with weight loss will have often lost both fat and muscle mass. These more chronic concerns have usually developed over a period of at least 1-2 weeks. Changes in body weight should trigger a number of questions directed at determining duration, changes in environment, diet, appetite, presence of intestinal signs, travel history, water intake and urine output, etc.
9. *Vaccinations and medications.* The owner of every pet should be asked about current, recent and previous medications given. Knowing what vaccinations have been given, when, and where may become valuable. Responses by the pet, positive or negative, to any medications should be noted. This information is not only important to help diagnose the disease, but might also help with its subsequent treatment management. A young dog may have been successfully treated at another hospital with glucocorticoids and parenteral fluids. Later, the dog relapses with the same symptoms after the effects of the treatment dissipated. This treatment history would be classic for adrenocortical insufficiency.
10. *The animal's present condition.* After all of the above information has been obtained, it is helpful to know if the previous treatment(s) has helped. The basic question is whether the animal is doing better, remaining the same, or getting worse.

All of the above information will help the clinician accomplish the clinical mandate of "knowing thy patient."

Questions for the Vague Clinical Complaint

There are occasions when the clinician is presented with a patient where there is virtually no accompanying medical history. Herein lies the formidable challenge of trying to solve the unknown (see ch. 8). The circumstances surrounding this particular situation might involve a stray animal, a pet that is mostly kept out of doors, the person knows little about the pet, or a pet owner is unable to communicate. The recommended approach is to attempt identification of the chief complaint(s) and then to obtain as much as possible of the information described above. If the person accompanying the animal cannot provide this important information, ask to speak with someone who might be able to provide more information. If not possible,

diagnosis will depend on the results of a physical examination, any imaging and/or laboratory test results, and the experience of the clinician.

CHAPTER 2

The Physical Examination

Stephen J. Ettinger, Edward C. Feldman, Etienne Côté

Client Information Sheet: The Physical Examination

The physical examination begins before the veterinarian ever touches the animal. The traditional teachings of look, smell, and listen are as important as ever. Excellent veterinarians avoid making diagnostic decisions driven by laboratory-derived data that bypass the physical examination. This chapter is founded on the concept that veterinarians must bring together data from the history, physical examination, and diagnostic tests to care for an animal in the context of its life—including the expectations the owner envisions for the pet. Algorithms by themselves are of limited value without an excellent history and physical examination.

When possible, the animal's temperature and weight should be recorded before the veterinarian enters the examination room. This provides the nursing staff the chance to communicate with the animal's caretaker, gather pertinent information, note changes in weight, and identify the owner's primary concerns or requests. The veterinarian may review these findings with the owner if there are questions about the history or why the pet is being presented for examination. Unskilled staff should not be doing "TPRs" since mistakes can be made and the veterinarian may lose valuable information such as the anal tone, skin around the perianal region, incorrect weight, etc. Also, skilled technicians know how to talk to the owner and the animal and help to relax rather than frighten the pet.

This is a good time for the staff to record current medications and dosages being administered, prophylactic agents being utilized (e.g., for heartworm, ectoparasites, internal parasites), and herbal or other supplements being administered. The animal's vaccination and reproductive status (i.e., spayed, neutered, or last heat cycle) should be identified in the record. Knowing the current diet being fed can save valuable doctor time and should be recorded. Notation of medications should always be accompanied by the owner's perception of their efficacy, since this information may influence future treatment and prognosis. Nursing staff may also utilize this time to provide valuable client information on subjects the veterinarian may have limited time to discuss. Examples include new vaccine programs, wellness programs, microchipping information, behavior and products to aid in training and health as well as office financial policies.

Always attempt to provide the client with an on-time, efficient examination. Reading material (magazines of interest to a wide variety of clients and their children) should be available if there is a likelihood of the pet's caretaker having to wait. Pet owners should be given an indication of the doctor's schedule and the length of a delay, if any is anticipated. Providing the client with this information can offset frustration, anger, or anxiety. If the hospital has new client brochures or information about hospital services, this is a good time to deliver these and to allow the client to browse through the material. Likewise, appropriate video recordings may be of interest to the client.

Observing the Pet and Meeting the Caretaker

Every veterinarian approaches a pet in his or her own way. With time, it becomes second nature. It is important to develop proper animal handling skills. Clients observe a great deal during this process and may determine long before any recommendations are made just how trusting they will be. Gentle care, compassion, concern, and attention cannot be overemphasized. While already discussed in ch. 1, it is good for the veterinarian to restate the client's concerns because this allows the pet's caretaker to know that you have been listening and are being attentive to them.

The process begins as the veterinarian enters the examination area (Figure 2-1) where the owner and pet are waiting. A friendly greeting and a small but appropriate amount of banter are often appreciated. An occasional client makes it clear that the veterinarian should get down to business. People appreciate being

greeted and particularly like being acknowledged (Figure 2-2). Asking about something unique to an owner assures them that the veterinarian knows who they are and provides a sense of identity. If the case is a referral, noting the distance traveled or offering a kind word about the trip and the referring veterinarian acknowledges the client in an important way. It is not a technique easily taught, and it is not difficult to see whether the veterinarian "gets it" quickly and learns to communicate or simply turns away from such contact.

FIGURE 2-1 When Dr. Ettinger enters the exam room he greets the client and pet. When both are provided the opportunity to feel relaxed, the balance of the examination is likely to be more successful.

FIGURE 2-2 Patient and client in exam room. Comments about the pet or the owner help to break the silence and relieve some of the owner anxiety that likely is associated with the veterinary hospital visit. “That's a nice little comb, where did you get it?”

The importance of letting each client know that the veterinarian cares about him or her and the pet cannot be overemphasized. This must be done in a genuine way, reflected in dialog, attention, body language, and actions. Such a sense of “community” is far more likely to be appreciated and will be recognized as more genuine than superficial attempts like having “We Care” or some other logo stamped on hospital leashes or stationery. Clients value compassion as much as (and often much more than) possession of knowledge. Every successful veterinarian can relate tales about brilliant doctors whom clients dislike! The smartest veterinarian may never have the opportunity to demonstrate his or her skills if concern and caring are not expressed in a way that is meaningful to the client. In fact, clients are likely to be antagonistic toward veterinarians who fail to express compassion. Complaints are likely to be made much more frequently about an arrogant veterinarian than about one who is poorly trained or medically inadequate but friendly and compassionate. Ultimately, an excellent veterinarian approaches the case with both medical skill (which benefits the patient) and personal empathy (which benefits both the patient and the client). Professionals with a disproportionately higher number of malpractice claims may be readily separated from those with fewer claims by evaluation of their examination room attitude.

If there has been a delay, it is paramount that the doctor acknowledges this upon entering the room. The veterinarian should show clients the courtesy of recognizing that they have been waiting. Unnecessary interruptions should be minimized and every hospital should have a policy in this regard. In a large critical care setting, delays and interruptions do occur, but these must be limited. Phone calls should be restricted to those that are professionally relevant or urgent. When such calls interrupt me (SJE) with new clients, I explain that I need to speak with another owner about their hospitalized pet; yet I do try to make it clear that I am focusing on their pet's problems.

A skilled veterinarian understands that no part of the examination is as important as carefully listening to the client. Therefore, adequate time must be allowed for this interaction in an environment that enhances the

process. Examination rooms should be comfortable and inviting. Privacy for clients is necessary, because the situation may be a difficult one for them. Remember, the owner may perceive diagnoses or recommendations that may seem routine or minor to the practicing veterinarian as quite serious and worrisome.

It is important to get the owners' version of the history and not one that has been "dictated" to them. For example, when questioned, the owners may acknowledge that a friend, family member or referring DVM told them about the supposed problem. Further questioning may determine that the owners themselves have not noted any clinical signs that warrant concern (see ch. 1).

Computers today are commonly used for making notations during the history and examination process. Whether the physical exam findings are entered electronically or on paper, it is important to maintain eye contact with the owner as much as possible while recording information. If the owner feels that your computer takes precedence over their impressions, an important component of the examination and history may be lost. Worse, the owner may feel disregarded and dissatisfied. Benefits of computer tablets include their being portable and easily managed in front of the client (Figure 2-3).

FIGURE 2-3 Computer tablets allow the client and the veterinarian to face each other while inputting information. A 2015 paper reports that over 50% of human patients feel neglected while their physician is looking at the computer rather than the patient.

There is no single technique for the examination process. Because this chapter is intended to explain my method of examination, I (SJE) will delineate the regimen I follow, a process learned over decades of experience. When possible, I try to make eye and physical contact with the pet. First, I make a brief attempt at greeting the animal by extending the back of my hand toward its face. For this, cats and smaller dogs can be placed on the examination room table (Figure 2-4, *A* and *B*). Usually, with medium to large dogs, I kneel down on the examination room floor to greet the animal (I [SJE] use a gardener's pad to protect my knees) (Figure 2-5). Of course, some dogs and cats (those that are aggressive [Figure 2-6, *A* and *B*], in cages, or tightly held by the owner) let me know beforehand whether or not they are ready for such a greeting. If not, I bypass the greeting and make a light comment to the owners about the pet not wishing me well ("After all," I say, "who likes going to the doctor?"). This begins a conversation with the owner that acknowledges the

possibility of the pet being fearful and allows the owner(s) to let me know how they feel about the process or about previous veterinary experiences. Frequently it is easier to do the initial examination of the cat while he or she is still in the carrying case if it opens from the top or side (Figure 2-7, *A* and *B*). While not as thorough, it avoids difficulty handling a fractious cat or dog, something the owner does not like to view. Another useful technique is to examine the cat in a blanket-covered basket. This often settles the anxious cat nicely (see Figure 2-7, *C*).

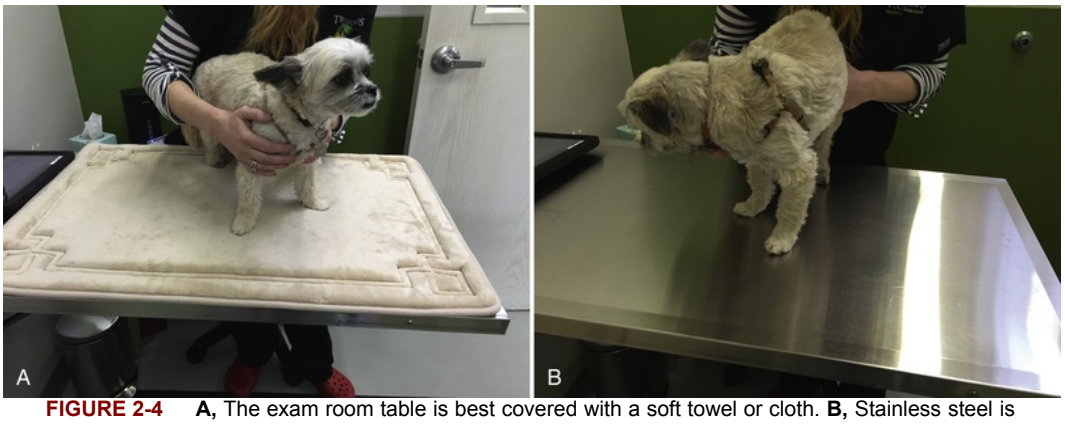

FIGURE 2-4 **A,** The exam room table is best covered with a soft towel or cloth. **B,** Stainless steel is very intimidating, slippery, cold, and unfriendly.

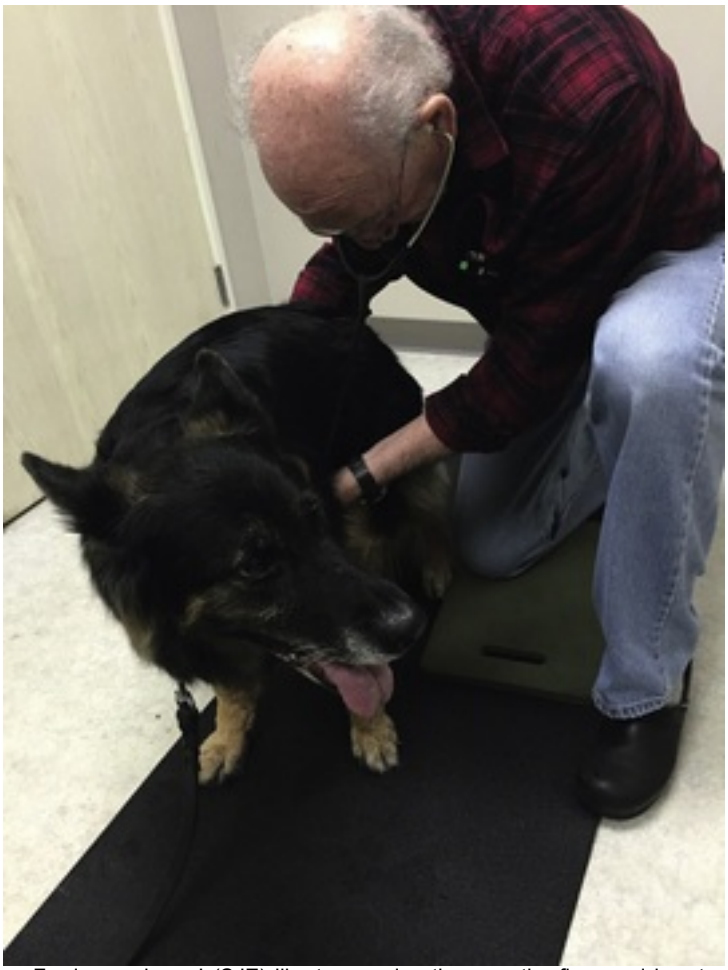

FIGURE 2-5 For larger dogs, I (SJE) like to examine them on the floor and be at eye level with them. I often kneel on a gardener's pad to be more comfortable.

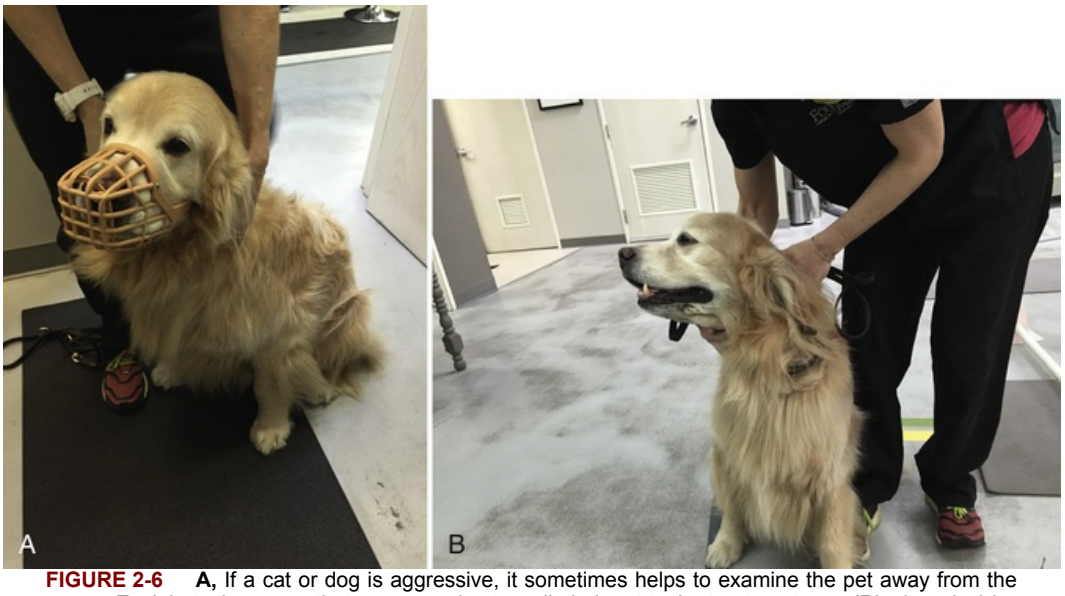

FIGURE 2-6 **A,** If a cat or dog is aggressive, it sometimes helps to examine the pet away from the owner. Explain to the owner that you are going to walk their pet to the treatment area **(B)** where he/she is likely to experience less fear as the animal need not feel that it must protect its owner.

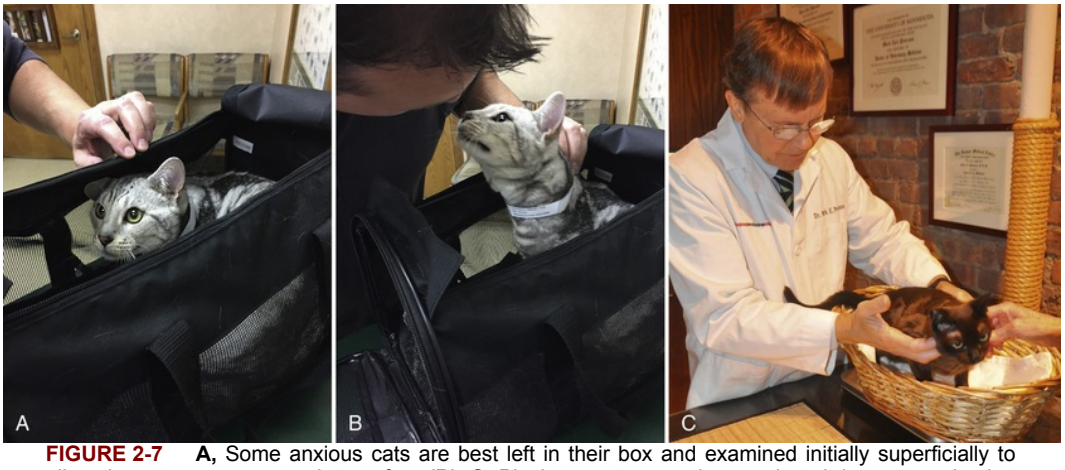

FIGURE 2-7 **A,** Some anxious cats are best left in their box and examined initially superficially to allow them to overcome anxiety or fear **(B). C,** Placing a cat, even those agitated, in an open basket such as this provides enough calming effect that a physical examination can then be completed. (**C** courtesy Mark E. Peterson, DVM, New York.)

Clients often wish to share what they know, think, or understand about their pet's problems. Regardless of how clearly and confidently clients relate their interpretation of their companion's issues, it is essential for the examiner to "go back to square one" in order to provide an objective assessment. Thus, the client's opinion and the veterinarian's analysis may run in parallel. Enough confidence must be placed in the client's story to solidify the trust being developed during this important part of the examination, but the veterinarian must also think independently enough to avoid being led down an incorrect path of deduction. I like to give clients a few minutes to express themselves, regardless of relevance, because what they have to say is likely to be important to the ultimate outcome. For example, clients may refuse to acknowledge how sick the pet is, or they may be worried about "cancer" or may focus on something that may not be pertinent ("can we also clean the anal sacs or trim the toe nails?"). Clients' comments provide valuable insight into their personality, their understanding of veterinary medicine, as well as their concerns and goals. There are different levels of owner commitment to their pet, and this will influence choices they make regarding the pet's care.

Clients may offer information obtained from friends, breeders, or other sources, such as the Internet. They

may wish to have the veterinarian go over this material. A reasonable technique that precludes taking time away from the office call is to acknowledge the request and inform the caretaker that material will be reviewed once the examination and early decision-making processes have been completed. Dr. Google has become a regular but silent partner in the examination room. Dr. Google often will be consulted immediately upon the owner's having access to him/her/it following your examination. If an owner implies: "OK, you are the doctor, so you tell me what is wrong," a different tack then becomes necessary to deal with owners that are more assertive or blunt like this. The approach changes from "tell me what you have observed" to "it appears that your dog (or cat) has been losing weight; tell me, has this been a recent occurrence?" Or, "have you always been able to feel your dog's spine this clearly?" Comments or questions like this may be all that is necessary to have the owners begin talking about their pet.

Not every owner-veterinarian experience is informative. All valuable and relevant acquired facts should be noted in the record. If a client refuses to provide information or begins to verbally attack another individual, the record should be so-noted. The record provides not only a potential legal defense but also a guide to further owner communication.

Clients, who have been dissatisfied with the results of prior care, reasonably object when you prescribe the same medication as the prior DVM did. This suggests that you have not been listening or reading the reports from prior care. This requires careful explanation directly with the owner. See ch. 1 regarding the history concerning drugs given, diet, travel, vaccine history, and other pets in the household, etc.

Inquiring in an unobtrusive manner about the owners' needs and expectations helps define their wishes and permits the veterinarian to provide options from which the owners can choose.

The history and the owner's story are important. These convey to the examiner the owner's perceptions during this initial period of acquaintance or contact. I find that this can be the most useful time of the examination process. I can touch the pet, gently stroke it, observe the quality of the hair coat and skin, determine the hydration status, and generally gain an impression of the animal's health status (e.g., debilitated or well-conditioned, obese or thin, growths or masses) (Videos 2-1A and 2-1B and Figures 2-8 and 2-9). This is also a convenient time to gently examine some pets without the animal being fearful, because a pet may be more aware of its owner's talking than of the veterinarian's gentle palpation. This practice also offers an opportunity to assess the animal's behavior while assuring the client that I am becoming acquainted or reacquainted with their pet. Pets generally seem less fearful while I am at their eye level and when I refer to them by name. Thus, the physical examination begins when the pet enters the examination room and while the history is still being taken.

FIGURE 2-8 Observing the animal from a slight distance also gives the DVM a chance to note other abnormalities—masses, deformities, and difficulty standing or walking. This dog is weak, has plantigrade stance in the rear legs and is uncomfortable standing or walking.

FIGURE 2-9 Observing the dog or cat from a distance allows the DVM to note evidence of an enlarged abdomen (in this case due to ascites) and heavy breathing, which would allow your questioning and examination to move along in a more specific direction.

It is not always possible to begin the examination process during the previously described situation, and I (SJE) do not make a distinct effort to perform every examination this way. If the dog or cat is sitting anxiously (i.e., protectively or in a frightened manner) in the client's lap, I avoid contact and dwell on the pet and the owner's story. Pets often relax during this period and are less fearful of me as time goes by. A truly frightened or fractious animal presents a different situation, which may require use of a muzzle. Before muzzling any dog, it is strongly recommended to attempt an examination away from the owner (see Figure 2-6, *A* and *B*)—for example, while taking a dog to a scale outside the examination room or to an environment that no longer requires the pet to feel protective of the owner. It is important to remember that owners should not be allowed to hold their pets during any examination process that entails a likelihood of injury to anyone, as could occur with a frightened or injured pet. This remains a chronically differing point of view amongst veterinarians (but not insurance companies). Many clients wish to hold their own pet, yet the veterinarian is liable for examination room injuries. Too, the pet is often more likely to be irritable and protective while being so-held. On the other hand, many owners feel uncomfortable not holding their pet. Thus, the examining doctor must use caution, experience, and the cues provided by the owner and the animal to determine the best approach. Most importantly, one must always work to avoid situations likely to result in a bite wound injury to the owner, the veterinarian, or anyone else. When a dog or cat reacts adversely to the veterinarian, it is important to back off slowly, reassess the process, and move forward in a manner that is safe for all involved. Usually the client recognizes the need for this. When the client insists on holding a fractious animal, the veterinarian must step up and identify the need for a safe process to continue, often with the client out of direct sight.

The Physical Examination Process

As previously discussed, the physical examination commences when the veterinarian first sees, smells, and hears the patient. Usually, this takes place in the examination room, where the pet's general appearance, odor, and any irregularities are noted (see Figure 2-8). A severely sick or crisis presentation requires an entirely different approach from that used for a dog or cat presented for a wellness examination or those with a mild or chronic issue. Clients must also be observed and evaluated, since many people are understandably anxious in severe or acute life-threatening situations. Owner anxiety, however, may manifest in a spectrum of

responses (ranging from a quiet, stunned composure to near-hysteria). Skilled veterinarians assess these factors when beginning to talk with an owner. In these and less emotionally charged situations, the veterinarian should assess the owner's state when first approaching the pet. Intense questioning may be inappropriate if the owner feels that the pet needs immediate medical attention. In such situations, it may be wise to advise the client that you are taking the pet to the treatment area so that a more thorough examination may be completed and medications initiated. It is imperative to advise the client that either you or your assistant will be back shortly to brief them on the pet's condition.

While observing the patient, the veterinarian should listen for abnormal breathing sounds or labored respirations, suggesting either respiratory or systemic disorders (see ch. 28 and Video 2-2). The animal's body size and posture also should be observed: for example a plantigrade stance could suggest a neuropathy (Figure 2-10) or a tendon injury (see ch. 354); neck ventroflexion in cats may indicate hypokalemia (see ch. 68) or thiamine deficiency; overweight pets (Figure 2-11) may be overfed, rarely hypothyroid (see ch. 176), or inactive (see ch. 176); thin pets may be sarcopenic, systemically ill, or underfed (Figure 2-12) (see ch. 177). It is true that owners may point out these concerns, but they may misinterpret such changes or may simply not be cognizant of their significance. Dogs and cats with ascites may appear to have gained weight to the owner while in fact they have become rather wasted instead (Figure 2-13 and Video 2-3). In a desire to "wish well" for the pet, the owner sometimes can fail to provide information for fear of its significance. The veterinarian has the responsibility to seek out this information. Examples of owner concerns and signs the veterinarian may observe are presented in ch. 8 through 47 of this textbook. The examination process must not be so quick or expedient as to result in an obvious underlying condition being overlooked. Likewise, an acutely ill patient may require immediate intervention (such as fluids and an IV catheter). This should not be delayed but rather identified in the record as requiring immediate attention and that the balance of the examination will be completed once the pet is stable. This is an early manifestation of triage management being practiced.

FIGURE 2-10 Dog plantigrade in stance (R>L) associated with weakness and pain due to multijoint

osteoarthritis. Right carpal flexion makes the dog ambulate awkwardly and with a limp, suggesting pain.

FIGURE 2-11 Obese dog **(A)** (19.5 kg [42.5 lb]) and cat **(B)** (15.5 kg [34.5 lb]) require an appropriate medical diagnosis first and then nutritional discussion based upon the cause (medical or dietary) of the weight gain. **(C)** 1.6 kg (3.5 lb) weight loss brought this overweight pug down to a healthy weight and resolved most of his respiratory distress without medication and helped him regain a normal walking pattern.

FIGURE 2-12 Cachexia requires a thorough history and medical evaluation to determine if age, disease, or malnutrition is primary to the weight loss. In this case, cardiac cachexia, ascites and chronic dilated cardiomyopathy have been assessed.

FIGURE 2-13 Weight loss associated with sarcopenia (muscle wasting) may be confused with weight gain by the owner, if ascites is present.

If the animal is ambulatory and has a history of a lameness, a neurologic deficit, or weakness, it is essential that the veterinarian watch the animal move (Figure 2-14 and Video 2-4). This may be done before or after the hands-on physical examination process. At some point during this initial phase of the examination, the veterinarian must observe the pet's gait. For dogs, this may require having the pet walk on a surface with adequate traction, preferably with the owner as the handler. Lameness, signs of neurologic deficits, or irregularity in gait and appearance may become critically important to the ultimate diagnosis (Figure 2-15 and Video 2-5). As the physical examination continues, the clinician should attempt to carefully evaluate any specific lameness or suggestion of a localized abnormality (e.g., patella luxation, stifle cranial drawer sign, elbow pain or mass).

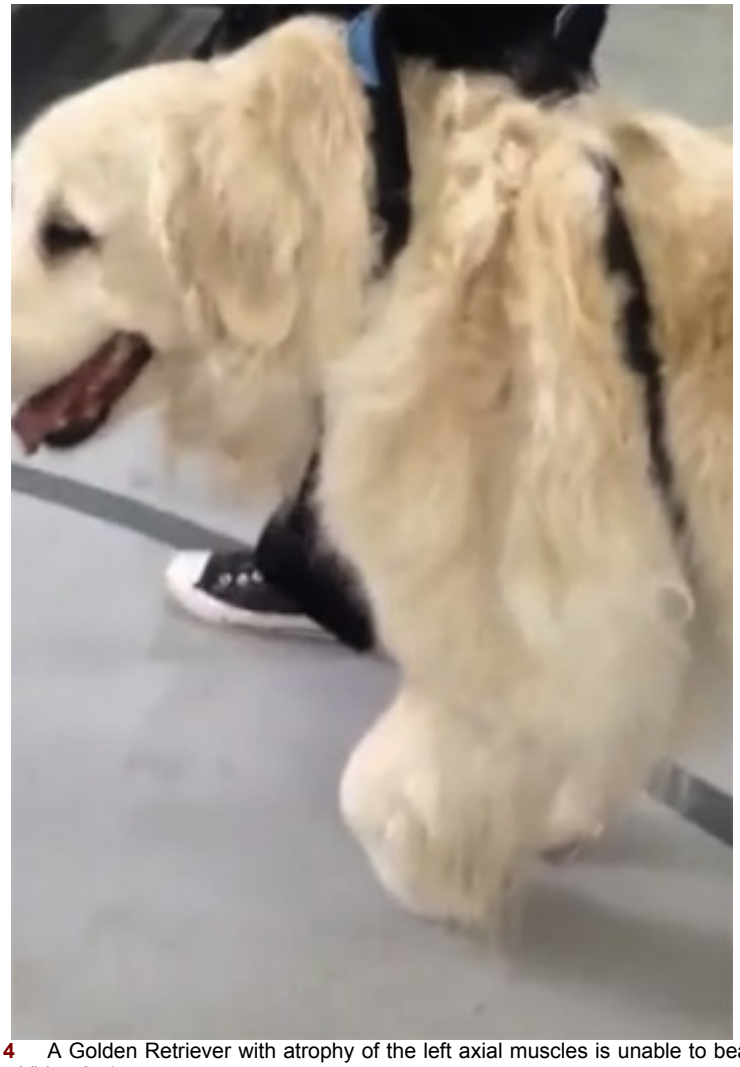

FIGURE 2-14 A Golden Retriever with atrophy of the left axial muscles is unable to bear weight on that limb (see Video 2-4).

FIGURE 2-15 Rhodesian ridgeback presented after treatment by the rDVM for generalized muscle wasting and atrophy, joint swelling, and extremely painful assisted walking. The response to steroid and antibiotic therapy and physical rehabilitation provided this dog with an additional two excellent years of life with only intermittent bouts of lameness. Immune-mediated muscle disease and polyarthritis were assumed to be the cause of this dog's recumbent position at the time of entry to the hospital.

A review of previous examination notes or itemized assessments from the SOAP (Subjective, Objective, Assessment, and Plan—i.e., the entries in the medical record) regarding prior issues can aid in the clinical assessment. For example, comparing the size of a mass with previous findings is something clients appreciate, particularly if the record clearly identifies prior dimensions, appearance, and location. Measurement of lesions with calipers or a ruler is good for review and trend purposes (Figure 2-16). The availability of digital photography makes good use of these tools for the clinician and the client, particularly if digital images can be attached to the medical record (Figure 2-17).

FIGURE 2-16 Measuring skin lesions (or other palpable abnormalities/lesions) provides the client with an opportunity to follow up and can be utilized to compare changes in size, shape, or color to previous examinations. Utilizing handheld devices to photograph such lesions and include them in the medical record is advisable.

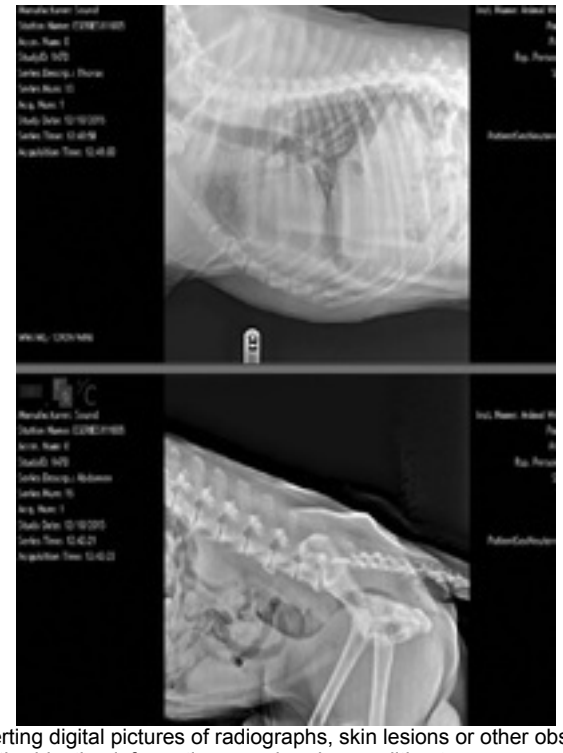

FIGURE 2-17 Inserting digital pictures of radiographs, skin lesions or other observable abnormalities provides the DVM with objective information on prior abnormalities to compare with those observed at the next examination.

Neurologic signs, such as diminished conscious proprioception, diminished muscle tone, limb dragging, or unusual evidence of pain during compression of the muscles or lumbosacral compression, are noted and could require further investigation to point to a diagnosis (Figure 2-18) (see ch. 259). Something can be said for performing the distant or "stand back" examination at this time, which allows the veterinarian to observe breathing patterns or abdominal changes. Note any area that appears extremely painful, since it will provide important clues to the veterinarian and the owner will appreciate your recognition of the nature of the problem.

FIGURE 2-18 Note the conscious proprioceptive deficit in the left rear leg in this dog with degenerative myelopathy. The right rear is similarly affected. This patient will require a thorough orthopedic and neurologic examination to determine the etiology of the proprioceptive deficits.

Every seasoned veterinarian has developed his or her own method of performing the hands-on portion of the physical examination, derived from experience. For example, animals are frightened by a large figure looming overhead and are less anxious when approached at eye level. As stated above (Figure 2-5) I (SJE) prefer to kneel on the examination room floor to perform the physical examination (except for cats and small-medium sized dogs). I find I am better able to perform thoracic auscultation in large breed dogs completely and more thoroughly in this manner (Figure 2-19). Medium-, large-, and giant-breed dogs standing on the floor, rather than the examination table, are almost always more relaxed, making it easier to palpate thoroughly while having a good presence with the pet. Whenever possible, animals should be in the same position (table or floor; standing) each time they are examined.

FIGURE 2-19 Examination of the heart and lungs in my hands (SJE) in a medium- to large-sized dog is best done on the floor, where the animal remains less active and provides a better setting for this critical examination. Others may prefer to do this exam on a table but whatever you choose, use the same technique each time.

After the initial greeting, I (SJE) prefer to stroke the pet to gain a more general knowledge of the overall body status (Videos 2-6 and 2-7). The body condition score is assessed (Figures 2-20 and 2-21), as are hydration status, physical appearance, and hair coat. Cutaneous and subcutaneous masses or areas of concern (size, shape, and appearance) are noted. I then examine the entire torso by touch, gaining a general impression of any specific or general concern. Concerns may include lymph node enlargement, abdominal swelling (fluid, masses, fat, distention, pain), discomfort, and skin or musculoskeletal abnormalities (changes in the hair coat, open wounds, fleas, dirt, ticks, or other abnormalities). Looking for bumps, lumps, or irregularities, I am able to distinguish lymph node changes, evidence of pain or swelling in the joints or limbs (see ch. 15), physical deformities (see ch. 353), and the nature of the femoral pulse. I evaluate the pulse, including its rate, quality, and character (see ch. 56), and listen for irregularities in cardiac sounds while auscultating the heart simultaneously (see ch. 55 and Video 2-12).

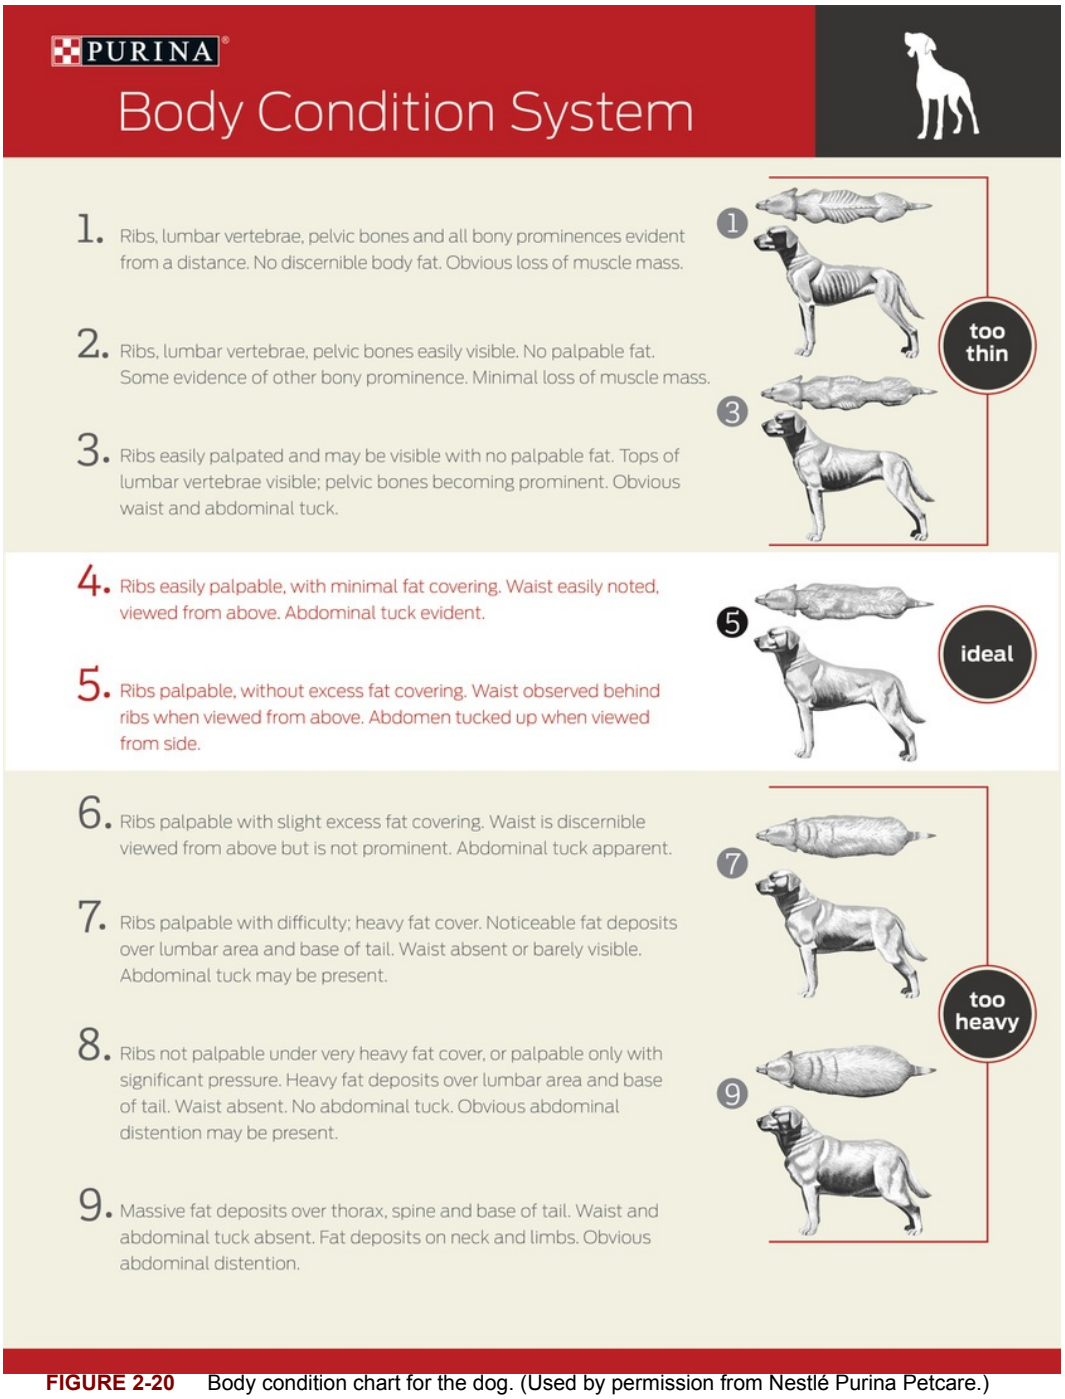

FIGURE 2-20 Body condition chart for the dog. (Used by permission from Nestlé Purina Petcare.)

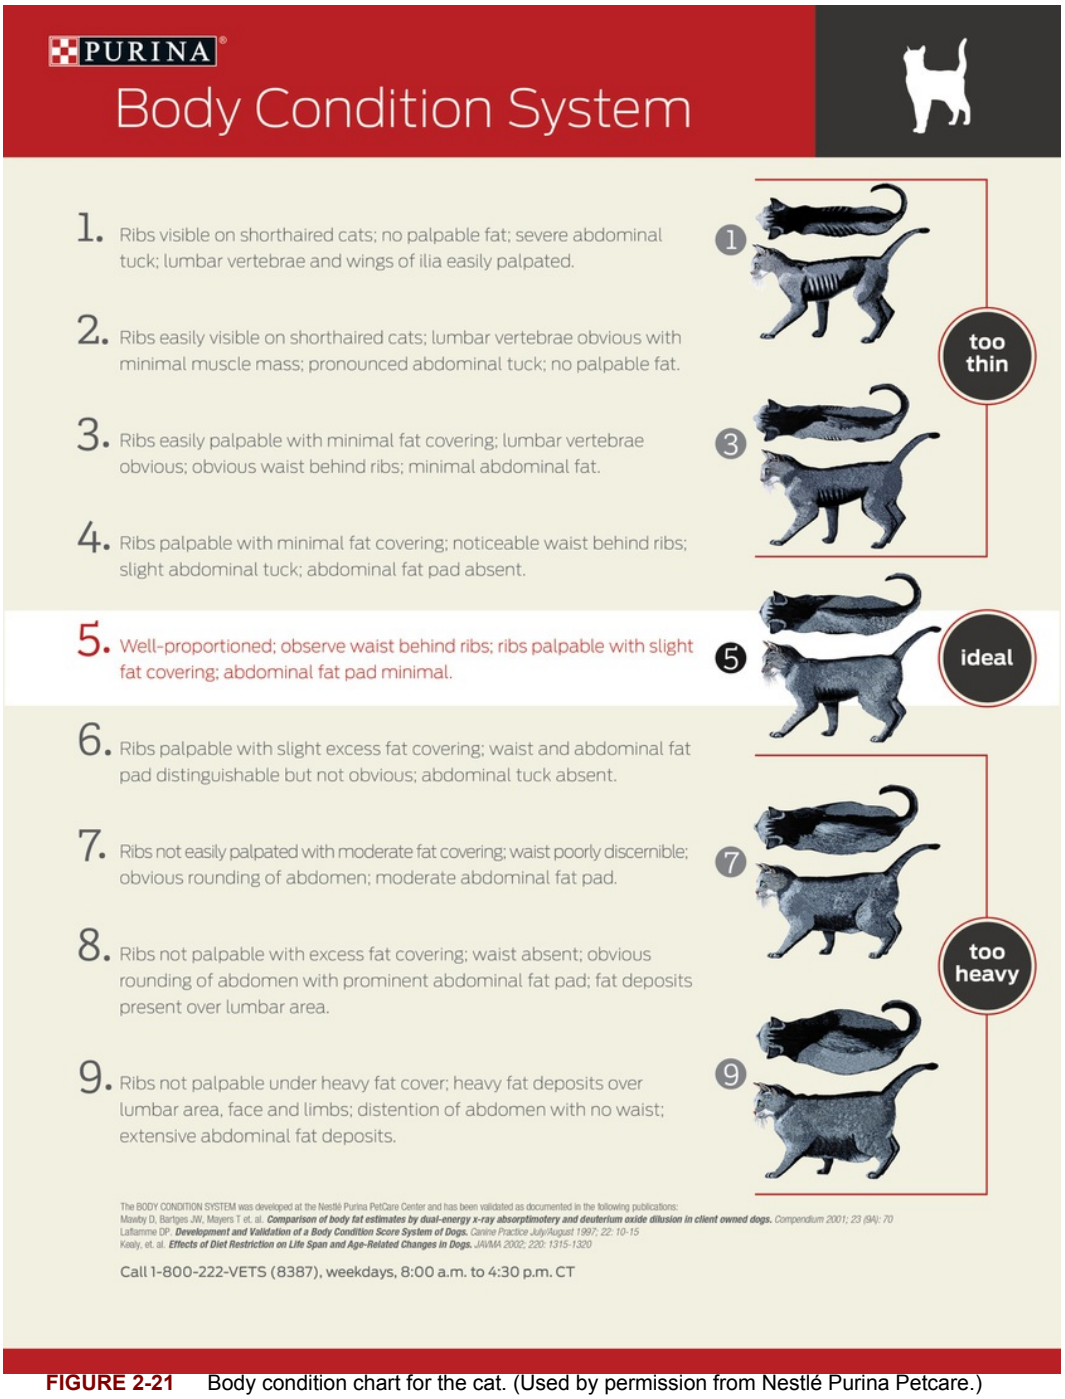

FIGURE 2-21 Body condition chart for the cat. (Used by permission from Nestlé Purina Petcare.)

Swellings in the form of edema or fluid collections are correlated with other changes. Edema is identified as being generalized, localized to one limb or region (ventral thorax, for example), or associated with abdominal fluid. It should be described as: painful, pitting, cold, warm, or oozing (see ch. 15, 17, and 18; Video 2-8).

Specific lameness associated with trauma is identified and may provide an obvious explanation for an owner's concern. However, the veterinarian should not make that assumption without giving reasonable consideration to other possibilities (e.g., a pathologic fracture in a dog with osteosarcoma). I like to run both hands down the animal's body to check for asymmetry in body form.

Skin and coat changes must be evaluated in light of the animal's living arrangements, as established in conversation with the caretaker. Indoor pets should not have foreign body material in their coat (unless some other pets in the household are both indoor and outdoor pets); fleas, flea dirt, ticks, and other ectoparasites should not be present. Hair loss or thinning is a clue to cutaneous or systemic disease and should be noted. Hair loss should be assessed as unilateral or bilateral, patchy or generalized and its full significance should be

identified in the record. Coat changes must also be correlated with other changes that may indicate a systemic illness, such as Cushing's syndrome (see ch. 306 and 307). Areas of skin change should be evaluated and comments made with respect to the potential benefit of skin or hair culture, skin scraping, skin biopsy or allergy testing. Pets that live outdoors are more likely to have ectoparasites, weather-related hair coat changes, or bite wounds. As with the indoor pet, an attempt can be made to find correlations in a skin condition with the owner's concerns or other issues. Recommendations can then be made accordingly. Hair coats with a strong odor of perfume, skunk, oil or smoke could suggest to the examiner possible problems with regard to allergic, skin or lung disease, highly reactive lungs, or an animal that has been in or around a fire with subsequent smoke inhalation (see ch. 25).

My preference (SJE) is to progress during the physical examination from the head toward the tail. First, a generalized evaluation of the hair coat (above) is ascertained. Hydration status, mucous membrane color and capillary venous return should be identified. Pain on dorsiflexion or ventroflexion or lateral movement of the head and neck may be indicative of local discomfort such as cervical disc disease, shoulder muscle spasm or a more distant issue (see ch. 259). The head first should be examined superficially for hair loss, muscle wasting, swelling, or asymmetry. Pay specific attention to the appearance of the mucous membranes (see ch. 50 through 54) (e.g., pallor gives reason to suspect anemia, hypoperfusion, or hypoxemia; muddy in heart failure, pulmonary hypertension and age related primary lung disease; cyanotic with A-V shunting, hypoxemia, intoxication, etc.) (Figures 2-22, 2-23, and 2-24). Note the appearance of the oral cavity, pharynx, lips, gums and teeth (Figures 2-25 and 2-26). Drooling, oral discharge (see ch. 36) or malodor (see ch. 25) should be apparent (see ch. 272). It is important for the veterinarian to speak to the owner about the condition of the pet's teeth and gums; it also is important for the owner to see, if possible, any area of concern in the oral cavity (Figure 2-27).

FIGURE 2-22 Anemic mucous membranes are pale (above) or even white, and associated with a BB-shot or water hammer-like pulse that may also be described as quick to rise and quick to fall.

FIGURE 2-23 Cyanosis in a cat. The blue color of the tongue (and mucous membranes) in this case is associated with a right-to-left–shunting cardiac defect.

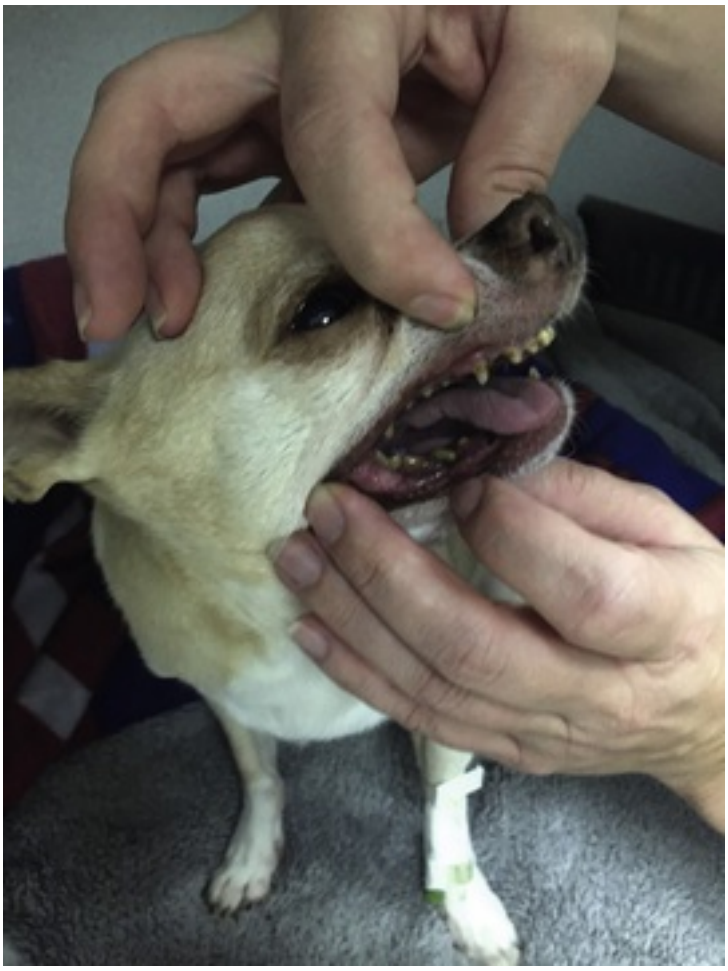

FIGURE 2-24 Ashen (muddy) colored gums and tongue are often associated with heart failure. This pet has long-standing chronic mitral valve disease and is experiencing an episode of recurrent heart failure.

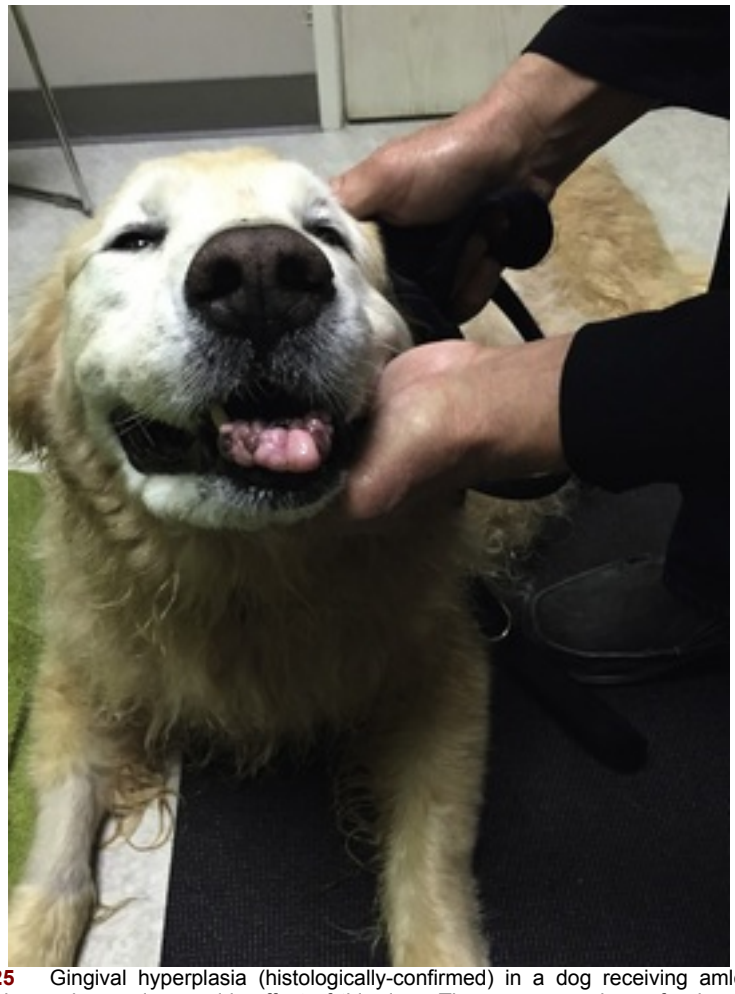

FIGURE 2-25 Gingival hyperplasia (histologically-confirmed) in a dog receiving amlodipine; this change has been observed as a side-effect of this drug. There were no signs of pain or difficulty in prehension of food over many years.

FIGURE 2-26 Chronic dental tartar and gingivitis is common in middle-aged to older dogs and cats and should be identified as a treatable problem. Chronic periodontal disease leads to other medical problems as dogs and cats age and should not be neglected.

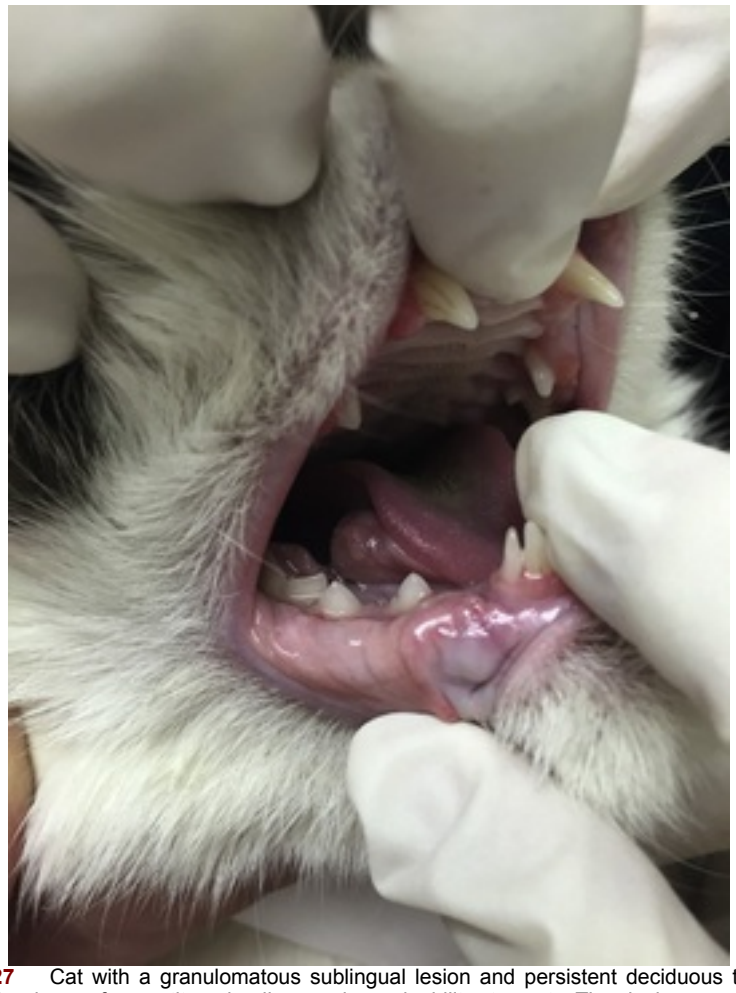

FIGURE 2-27 Cat with a granulomatous sublingual lesion and persistent deciduous teeth initially presented for loss of appetite, drooling and an inability to eat. The lesions were biopsied (pyogranuloma) and the lesions began to regress after removal of much of the affected tissue. One month later the condition extended to the large and small intestines.

Thorough neurologic examinations are not usually a component of the routine physical examination. However, a brief cranial nerve examination should be included during this portion of the examination process. The posture of the head (e.g., head tilt, Figure 2-28), masticatory muscle mass and tone, and the appearance of the eyes may be relevant. Monitoring for superficial and deep changes within the globes and the periorbital region should be assessed. Ophthalmic sensitivity (Figure 2-29), squinting/blepharospasm, or any other evidence of photophobia is noted. Lip and facial skin folds, especially in brachycephalic breeds, may result in inflammation, moist exudate, and a foul odor (Figure 2-30). Any ocular discharge should be described as to color, composition, volume, and whether the discharge is unilateral or bilateral. Tear production is recorded (Schirmer tear testing), as is nasolacrimal duct patency (e.g., note dry, cracked nasal tissue). If nystagmus (Video 2-9), strabismus (Figure 2-31) or other deviations of one or both globes are noted this suggests the need for a more thorough neuro-ophthalmic examination (see ch. 259). Continue the examination while looking for signs of conjunctival color changes or inflammation. Pupillary size, symmetry, and integrity are noted, as is the pupillary light response, both direct and consensual. Sensation in the eyelids and the surrounding tissue is observed as are masses involving the eyelids, noting their size and whether they are irritating the cornea. Corneal lesions should be noted in the record for future comparison, particularly the size, shape and depth of corneal ulcerations.

FIGURE 2-28 Head tilt (right-sided) in a dog with idiopathic vestibular disease, chronic pulmonary hypertension, and mitral valve disease.

FIGURE 2-29 Photophobia in this dog identifies ophthalmic sensitivity associated with blepharospasm in both eyes.

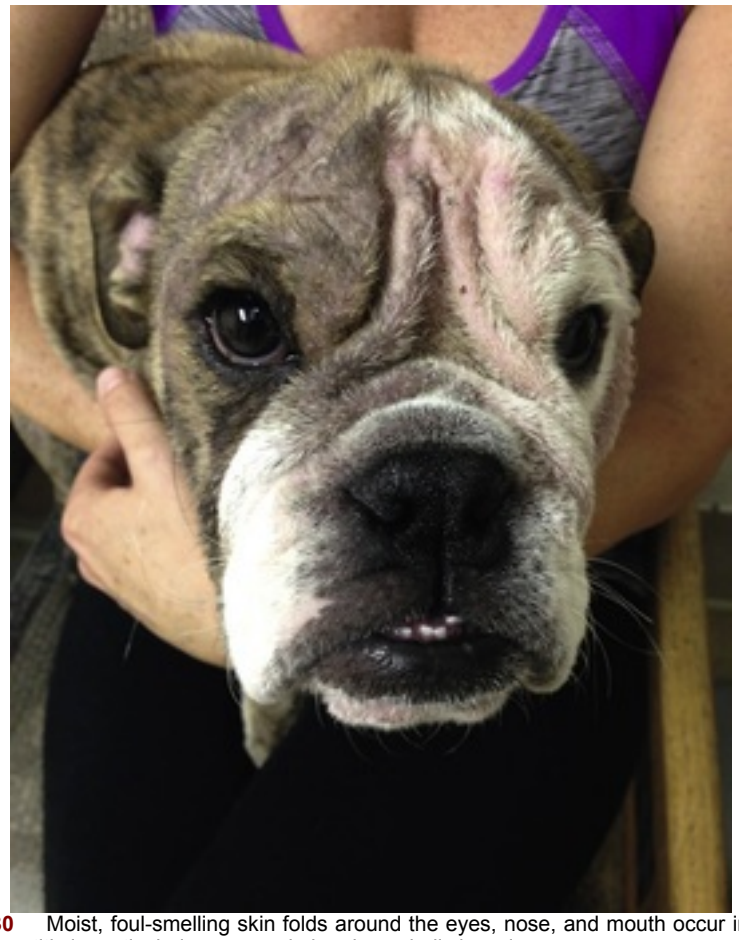

FIGURE 2-30 Moist, foul-smelling skin folds around the eyes, nose, and mouth occur in all breeds. Skin fold dermatitis is particularly common in brachycephalic breeds.

FIGURE 2-31 Strabismus is a deviation of the normal eye position due to one of many disorders of cranial nerves or extraocular muscles. In this case, the ventral strabismus affecting the right eye requires further neuro-ophthalmic examination to identify the etiology.

The appearance of the skull, the muscles of mastication, and the muscles around the head are noted (Figure 2-32). Clients frequently suggest that a mass has developed on the skull, which is in fact the occipital protuberance. This is associated with weight loss as the temporal muscles atrophy, making the external occipital protuberance very obvious (Figure 2-33). In puppies, particularly those with unusually large heads, examination of the fontanelles for hydrocephalus should be part of the examination (Figure 2-34). Enophthalmos can be a sign of periorbital fat loss and may relate to myositis, weight loss, cachexia, or a primary ophthalmic process. Pain, swelling, or heat is identified. More detailed examination of the eyes, including direct and/or indirect ophthalmoscopy, may be completed at this time; or, complete the rest of the physical and then perform a thorough ophthalmic examination. See ch. 11.

FIGURE 2-32 Prominence of the external occipital protuberance associated with temporal muscle atrophy often leads the client to an office visit fearing that the pet has developed a bony lesion on the top of the skull.

FIGURE 2-33 Temporal and masseter muscle atrophy is associated with immune-mediated masticatory myositis chronic corticosteroid administration, as well as aging in older pets. The muscles of mastication and the temporal muscles atrophy. This may cause difficulty chewing, opening the mouth, pain, and enophthalmos. It is important to differentiate the causes of this problem (see ch. 354).

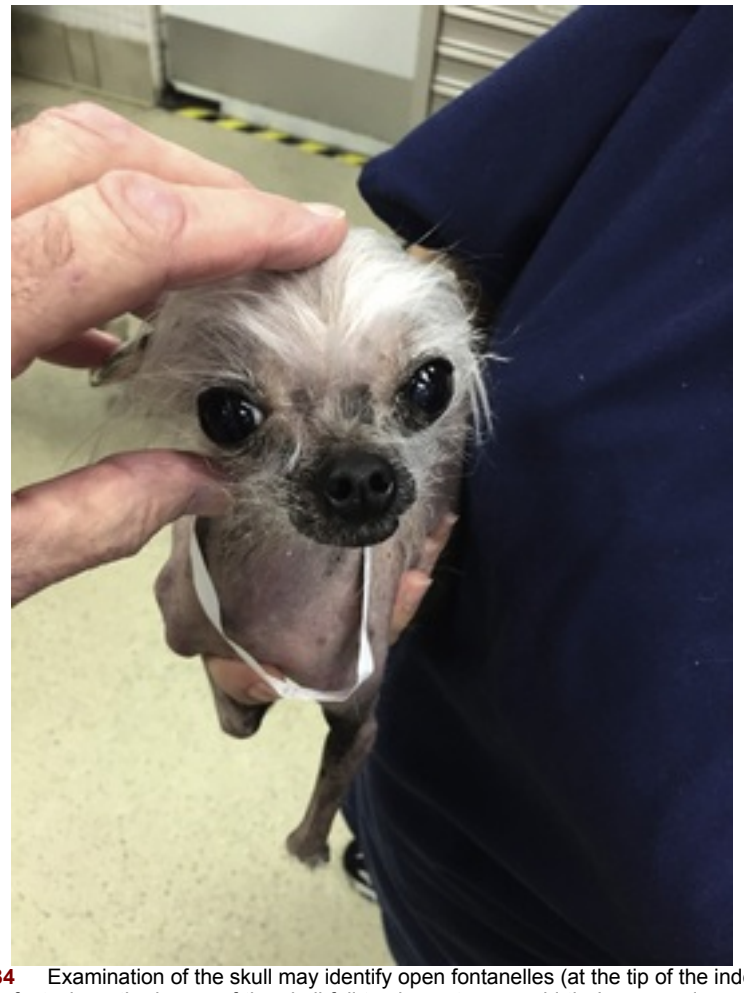

FIGURE 2-34 Examination of the skull may identify open fontanelles (at the tip of the index finger), a congenital defect where the bones of the skull fail to close at or near birth. In young dogs, this may be associated with clinical signs of hydrocephalus. In this 12-year-old Chinese Crested Dog, there were no problems during her lifetime associated with the open fontanelles. She did present for signs of unrelated mitral valvular cardiac disease at a younger age than would normally be expected.

Airflow through the nostrils can be assessed quickly using a stethoscope and contralateral compression of the nares. One may utilize a wisp of cotton in front of each nostril to assess airflow or have the pet breathe onto a metal surface (e.g., a counter top in most examination rooms) or glass microscope slide and observe for fogging as evidence of nostril patency. While seemingly basic, the results of such examinations can be challenging.

Examination of the ears (pinnae and ear canals) is expected by the client and is an important part of every veterinary physical examination (see ch. 237 and Figure 2-35). Presence of ear mites, inflammation, discharge, or abnormal odor is particularly relevant in the new puppy or kitten. In adult dogs, it is more common but by no means absolute to see ear disease in those with long floppy pinnae that cover the ear canal. An owner may report that a pet has difficulty eating or chewing, but the problem may in fact be caused by pain from one or both ear canals (see ch. 237). Discharge, unusual "yeasty" odor, or discoloration of the canal tissue may be noted (Figure 2-36). Owners are likely to notice abnormal conditions of the pinnae (e.g., aural hematoma). Superficial examination of the ear canal can usually be accomplished in the examination room without difficulty, allowing the veterinarian to discuss chronic ear disease with the owners while showing them any abnormality. Otoscopic examination is indicated if there is significant head-shaking or buildup of debris within the ear canal. Video otoscopy is a preferred technique by some veterinarians to show the caregiver changes in the ear canal (see ch. 85 and Video 2-10). Cats likewise are prone to ear disease, particularly when they are outdoor cats or in a household with many cats. Scratching at the ear is likely to leave them with crusts and excoriations at the base of the pinna. Swabs taken from the external ear canal and observed microscopically best identify ear mites and *Malassezia*. Aural hematomas occur in cats but less frequently than in dogs. Careful cleaning of a dirty ear canal is warranted; however, if it is too aggressive, the tympanic

membrane may be affected, leaving the cat with a short-term head tilt. In either dogs or cats presenting with significant disease of the ear canal, sedation may be required to properly clean and evaluate the external ear canal and the tympanic membrane.

FIGURE 2-35 Examination of the pinna is always important, as all forms of ear problems represent a large percentage of daily clinical practice. This is a normal pinna but slightly dirty due to external otitis that required attention (see Figure 2-36).

FIGURE 2-36 The routine physical examination is never complete without looking at the ears and the external ear canal. This dog presented with a "yeasty" odor emanating from his ear canals, along with a waxy moist debris suggesting *Malassezia*, which was confirmed on microscopic examination of a slide swabbed with the debris from the ear canal.

Alignment of the jaw bite (Figure 2-37, *A* and *B*), teeth, and gums should be assessed (see ch. 36). Mucous membrane color, capillary refill time, presence of ulcers, or any discoloration in the oral cavity should be checked. The teeth are examined for calculus, fractures, displacement, or discoloration. Abnormalities, including missing or persistent deciduous teeth, are recorded and mentioned to the owner. Drooping of the tongue to one side suggests a loss of teeth in that part of the mouth (Figure 2-38). Signs of dental wear due to fence biting or rock chewing should be noted, as well as any resulting sensitivity. Gingival hyperplasia, masses, gingivitis, foreign bodies or ulcers may correlate with clinical signs. During the first-time puppy or kitten examination, evaluation for cleft palate or other congenital defects is required. With an uncooperative or fractious animal, examination of the oral cavity can be a daunting procedure. When the pet resists such an examination, removing the pet from the owner often allows a more complete examination without difficulty. Special care is required for aggressive dogs and may require sedation. If drooling or a behavioral change is mentioned, *concern for a rabid patient is always paramount.*

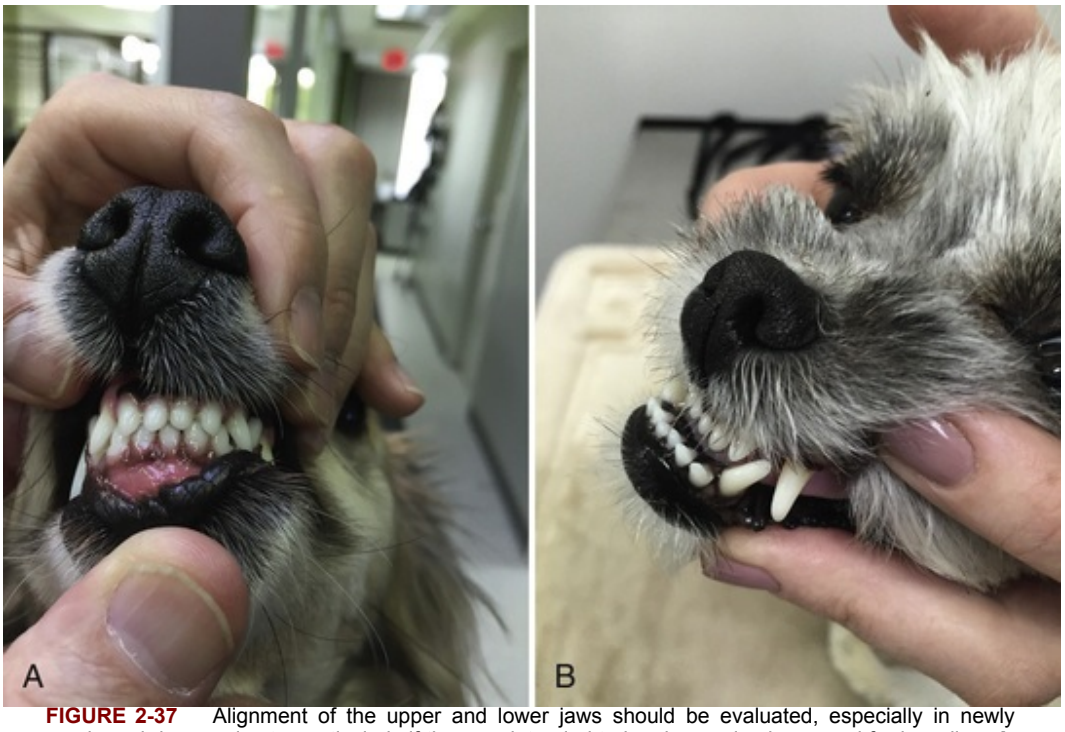

FIGURE 2-37 Alignment of the upper and lower jaws should be evaluated, especially in newly purchased dogs and cats, particularly if they are intended to be show animals or used for breeding. **A,** A normal bite is shown in this young dog, whereas **(B)** this dog has a maxillary brachycephalic bite (prognathism) that is already impeding bone growth and formation. The owner should be made aware of such abnormalities at this time, since in many breeds of dogs and cats, such a condition would eliminate them from being shown.

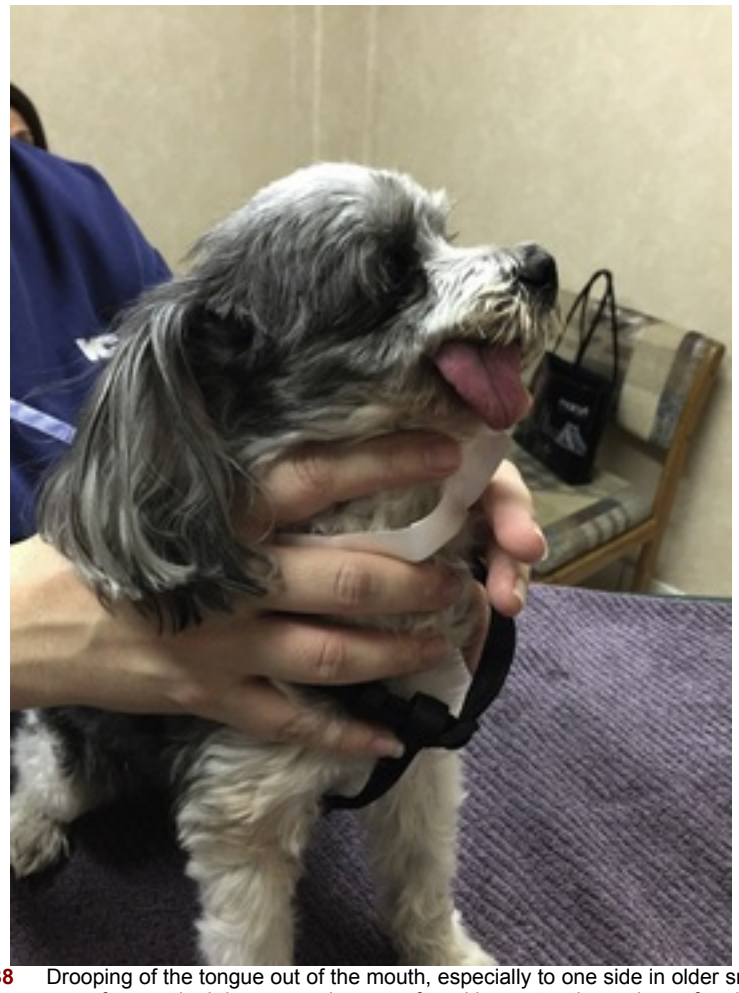

FIGURE 2-38 Drooping of the tongue out of the mouth, especially to one side in older smaller breed dogs and cats, occurs frequently. It is commonly seen after either extraction or loss of major teeth that hold the tongue in place.

Evaluation of the pharyngeal region is limited to external palpation during the physical examination. In some dogs and rarely cats, pressing down on the base of the tongue with an index finger when the animal's mouth is open allows visualization of the tonsils and oropharynx. However, complete visualization is rarely possible. If there is indication of an abnormality in the pharyngeal or laryngeal region, a more thorough examination under sedation may be indicated. The tongue should be elevated (using dorsally directed pressure with the thumb externally, between the mandibles) to assess the sublingual region, such as for masses (see Figure 2-27) in dogs and cats and linear foreign bodies in cats. This type of visualization and assessment of the sublingual area should be a component of every physical examination. The laryngeal region should be checked for sensitivity, pain, or masses or institution of the gag reflex. Detection of visible or palpable deformities and monitoring of the laryngeal apparatus may yet be possible without sedation. Palpation for changes in the salivary glands and the submandibular lymph nodes is important and it is equally important to distinguish between these two organs. Enlargement of the submandibular or sublingual salivary glands is particularly important when there are signs of localized pain or chronic drooling.

Continuing to the ventral cervical region, the veterinarian evaluates for masses, tracheal sensitivity, lymph nodes and the thyroid gland (normal thyroid glands are not usually palpable in dogs and cats). In the cat, noting a "thyroid slip" as the examiner gently moves his/her finger along the trachea just caudal to the thyroid cartilage best identifies an enlarged thyroid. At the thoracic inlet, the clinician palpates for pre-scapular lymph node enlargement, crepitus (subcutaneous air leakage), or masses. Gently palpating the trachea at this time often allows the veterinarian to incite a cough (Video 2-11), which may be the cause for the pet being brought in for an examination (see ch. 241). Asymmetry of the thorax (scapulae, muscles, rib cage, masses, or fat accumulation) should be correlated with signs, as should kyphosis or sternal deformities. Breathing difficulty can be associated with changes in the appearance of the rib cage. Fluid accumulation in the thoracic cavity (see ch. 244), significant pleural or pulmonary disease, and some muscle disturbances may

cause the rib cage to feel or appear abnormal. Congenital thoracic deformities may cause respiratory signs. Peritoneopericardial diaphragmatic hernia (PPDH) (see ch. 254) may be associated with deformities of the xiphoid region of the sternum, such that the examiner can insert a finger into the thoracic cavity and sometimes actually touch the heart (Figure 2-39).

FIGURE 2-39 Lateral radiograph of a cat with a congenital pericardial-peritoneal diaphragmatic hernia (PPDH). Note that the embryonic development at the lower thoracic and abdominal wall failed to close, leaving an opening at the xiphoid where the abdominal contents slip through and into the thoracic cavity. In some cases the examining veterinarian can insert a finger from the caudal ventral xiphoid and push it forward into the thoracic cavity and actually touch the beating heart under the skin.

My preference (SJE) is usually to complete the entire physical examination before auscultating lung and heart sounds (Video 2-12). These portions of the physical examination are described in ch. 55 and 246. When palpating the thorax, the examiner should notice the location of the apex beat of the heart (point of maximal intensity [PMI]). Normally this is over the left fourth to sixth intercostal space at the level of the costochondral junction. Deviations are consistent with cardiac or thoracic cavity issues. Similarly, palpation of a cardiac "thrill" is indicative of an extremely loud heart murmur (higher than grade 4/6). Cardiac thrills should be identified and correlated with the heart sounds and clinical signs. Heart sounds should be identified in terms of rate, rhythm and presence or absence of a murmur, in addition to other abnormal sounds including whoops, clicks, ejection sounds, gallop sounds and splitting of the first and/or second heart sounds (see ch. 55).

Normal lung sounds vary from breed to breed depending upon conformation of the head, neck and thorax of the pet. Normal lung sounds are quiet, non-wheezing, non-crackly inspiratory sounds that are soft, smooth and pure, equal in intensity across the right and left thorax. They are devoid of obstructive sounds, wheezing, or noisy and of unequal sounds of air being pulled into the lungs. Forced open-mouth breathing is not normal except in brachycephalic breeds where they can be very noisy, yet still normal. To some degree it would be correct to say that normal inspiration is usually associated with comfortable inspiratory sounds without tachypnea or dyspnea unless the animal is anxious, hot or excited. They are followed by smooth expiration without undue crackles, wheezing or distinct grunting. Harsh, open-mouth breathing with lower-airway inspiratory stridor, upper airway inspiratory stridor (upper airway obstruction [UAO]) may be typical of chronic lung disease, brachycephalic breathing (Videos 2-13A, 2-13B, and 2-13C) or laryngeal paralysis, especially in larger breeds of dogs (Videos 2-14A and 2-14B). This frightening sound is usually more pronounced with excitement and diminishes as the dog relaxes and quiets down. It can, however, progress to a more advanced state requiring aggressive therapy (see ch. 238, 239, and 241). There are significant

differential diagnoses for UAO (see ch. 238 and 239). Unless laryngeal paralysis is associated with an advanced state, this abnormal respiratory sound is associated with normal gingival mucous membrane and tongue color. Laryngeal paralysis in cats has a very different appearance and sound unique to this species and not at all similar to that of larger breed dogs. It often is not associated with dyspnea but the sounds do bring the client to the veterinarian because of their odd nature.

Progressing caudally to the abdomen, the examiner first should note whether the abdominal wall is pumping rapidly, a possible sign of anxiety, tachypnea, or dyspnea. Tachypnea, dyspnea or abdominal breathing should be observed while standing back from the pet, rather than via auscultation (see ch. 28).

The general appearance of the abdomen should first be assessed. Distended, tucked up, muscular and firm, painful, tense, soft and doughy are all terms used for describing findings from abdominal palpation. Apparent pain should be characterized regarding location and severity. This portion of the examination requires gentle but firm pressure using both hands and moving from dorsal to ventral and cranial to caudal. Adequate palpation includes utilizing ipsilateral fingers in line or touching with thumbs aligned as the abdomen is carefully traversed. This recommendation is important in order to avoid attempting to "hold" a pet in place with thumbs on the spine, where accidental compression in a dog with back pain may be misinterpreted as being abdominal. Some pets do not appreciate abdominal palpation, and may display their displeasure by tensing the abdomen or otherwise avoiding palpation and this should not be mistaken for a pathologic process (Video 2-15).

Examination of the abdomen, as with all other parts of the body, should be performed systematically (Video 2-16). Examine both the abdomen and spinal column independently, before progressing with deeper palpation. This allows the clinician to avoid being misled by apparent sensitivity in one area that is, in fact, derived from another. Assessing the mammary glands and surrounding tissue can be completed during the introductory portion of the physical examination, as noted above, or immediately prior to deeper abdominal palpation. Mammary masses are usually easily palpated but can be confused or mistaken for subcutaneous lesions. Small masses may not be noted unless one dedicates a few moments to carefully assess the area. Moving fingertips up and down the mammary chain on both sides permits the examiner to note discrepancies in the tissue. Likewise, significant enlargement of the sublumbar lymph nodes may be noted. In the male, changes in and around the prepuce may be identified. Preputial discharge (smegma), a small amount of a thin yellowish color that is normal, might not be readily seen unless the pet is placed in lateral recumbency (Figure 2-40). Extruding the penis to appreciate changes in the mucosa or sheath of the penis (Video 2-17) may explain abnormal findings or a history of chronic licking or discharge that the owner may be concerned about and that is normal in most adult male dogs. The presence of the os penis in dogs should allow the penis to be easily and painlessly extruded and evaluated. In the male cat (Video 2-18), evaluation of the penis and its surrounding area is important, particularly in cases of suspected feline lower urinary tract disease. Neutered tomcats have small to no "spines" present on the penis, in contrast to the obvious spines seen in intact tomcats (Figure 2-41).

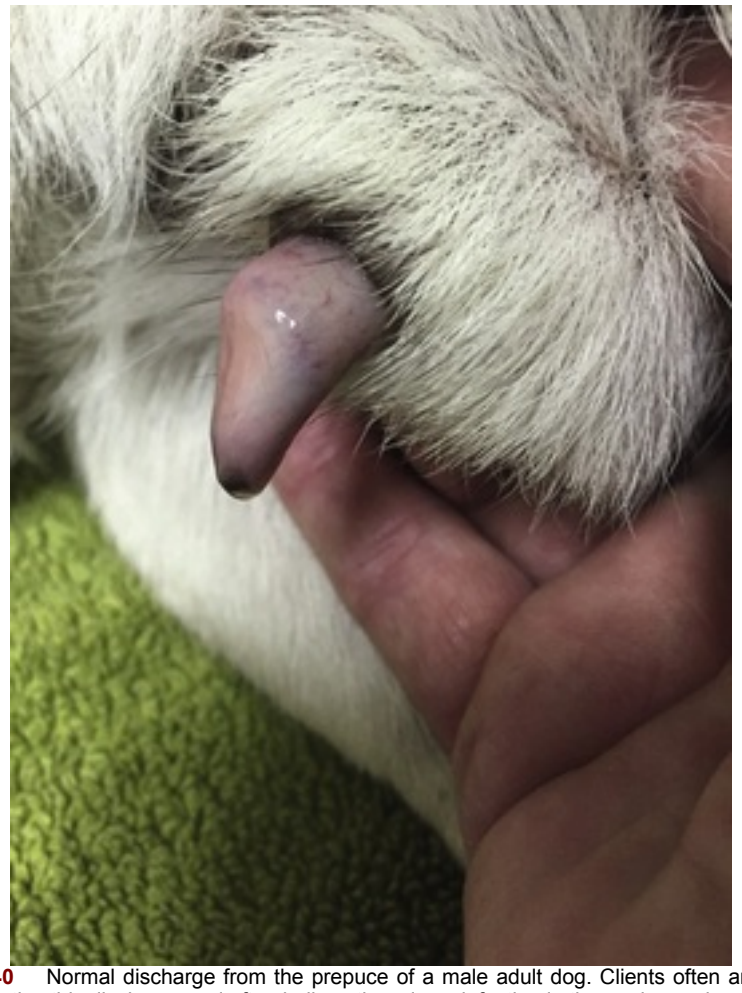

FIGURE 2-40 Normal discharge from the prepuce of a male adult dog. Clients often are disturbed when they notice this discharge and often believe there is an infection in the penis or urinary system.

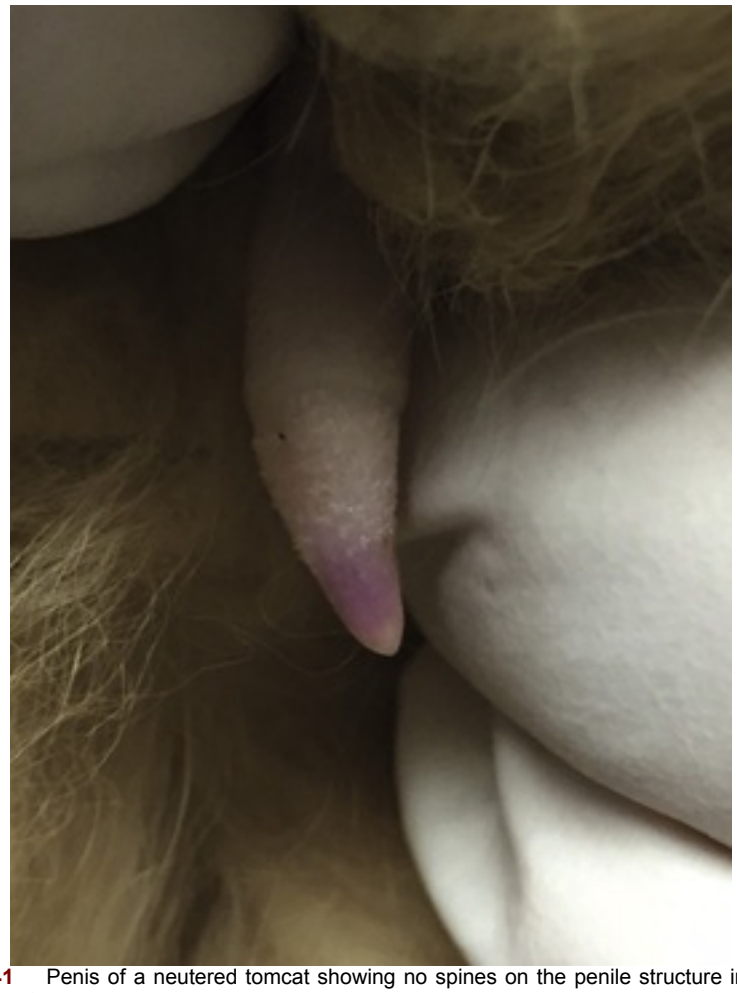

FIGURE 2-41 Penis of a neutered tomcat showing no spines on the penile structure in contrast to an intact tomcat.

Palpation of the abdomen is an individually determined technique. I (SJE) like to examine animals both from behind and from the side. When examining the abdomen from behind, I am able to palpate symmetry, one or both kidneys, and identify mid-abdominal masses (normal or abnormal). Lateral palpation provides another perspective regarding any structure: liver, spleen, bowel, bladder, prostate, etc. Occasionally it is helpful to have an assistant pick up the pet (Figure 2-42) and allow it to stand on the hind legs so that the abdominal viscera or free fluid falls caudally, permitting yet another perspective.

FIGURE 2-42 Lifting the pet up so that the abdominal organs slide to the caudal aspect of the abdomen sometimes allows the examiner to be more thorough in palpation of the abdominal organs or identifying the presence of free abdominal fluid that has collected at the most ventral level.

Distention of the abdominal cavity (see ch. 17) requires attention. In general, there are four major causes of abdominal enlargement: fluid, fat accumulation, muscle laxity, and abdominal organ enlargement (see Figure 2-9). The examination begins with gentle ballottement to determine whether enlargement is likely to be associated with obesity, pregnancy, fluid accumulation, one or more masses, intestinal obstruction, muscle weakness, or poor muscle condition (Cushing's disease, see ch. 306). Correlating the findings of this examination with other history and laboratory tests allows the veterinarian to consider potential causes. It is generally easier to perform a complete abdominal palpation on cats and smaller dogs than on large dogs. In cats, it is frequently possible to palpate the intestines, spleen, both kidneys, and bladder. In larger companion animals this may not be as easily accomplished, but enlargement of abdominal organs, masses, and fluid collection should still be apparent. In cats, palpation of an enlarged spleen often is a sign suggesting mast cell disease, lymphoma, or another neoplastic process. In dogs, a large, irregular splenic margin strongly suggests hemangiosarcoma or hematoma, although other causes of splenomegaly must be considered (see ch. 206 and 347). Differentiation from other abdominal masses can be done initially through the physical examination and later via imaging.

Pain on palpation of the abdomen is a significant finding. Pain requires the clinician to distinguish tensing of the abdomen in a normal frightened patient from referred spinal pain, abdominal pain or generalized pain and discomfort. Pain correlated with abdominal palpation may in fact be referred spinal pain and should not be misinterpreted, which may lead to a misdiagnosis. The acute abdomen needs correlation with laboratory testing and clinical signs. Pain should be localized, if possible, as cranial, mid-abdominal, caudal, or generalized. Palpation for masses and the detection of enlarged viscera comprise an art that is not replaced by more sophisticated, expensive, and complicated tests. Pain in the abdomen is a clear indicator for further testing, such as radiography, sonographic imaging, and laboratory analyses. It also must be correlated with the clinical history. Malaise, failure to move or change position, belching, fever, and nausea may be explained

by abdominal or back pain. In contrast, a fractious cat whose ears are back and whose pupils are dilated, and who seems agitated on palpation may simply be displeased with being examined (Figure 2-43).

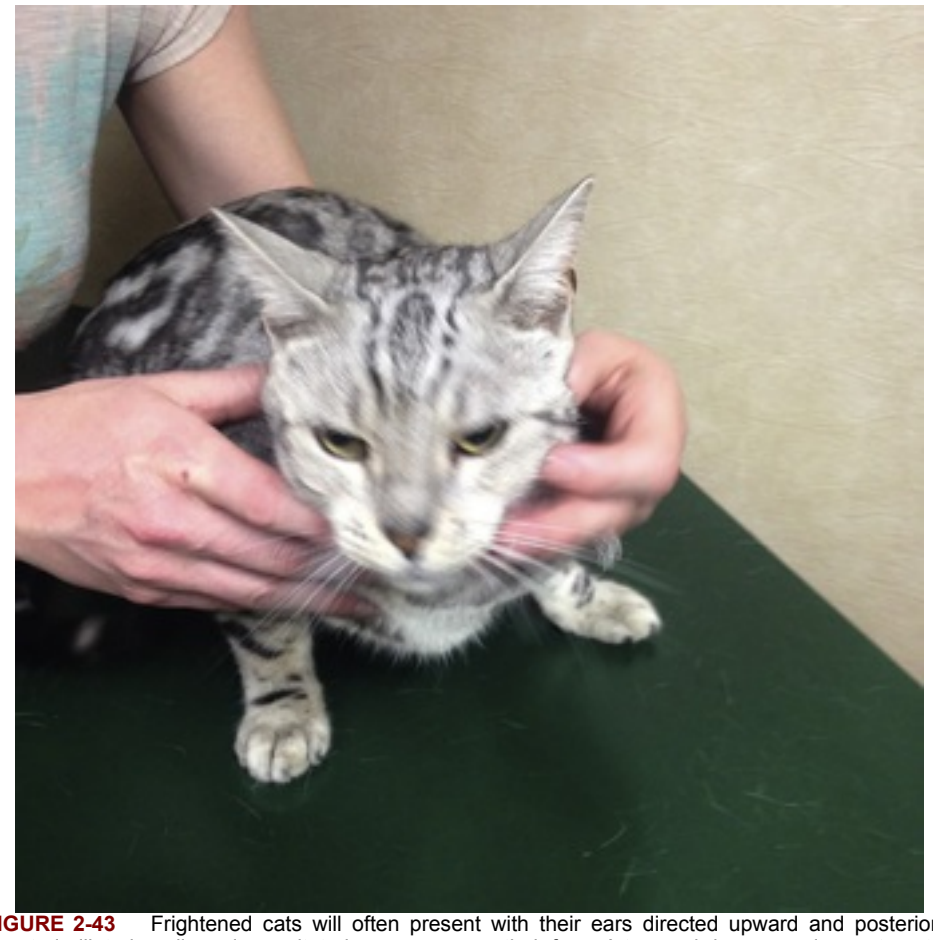

FIGURE 2-43 Frightened cats will often present with their ears directed upward and posteriorly directed, dilated pupils and an agitated appearance on their face. A tense abdomen, and resentment of palpation, should not automatically be interpreted as evidence of abdominal pain in these cases.

Distention of the abdomen must be assessed in the context of owner observations and additional factors. These factors include, but are not limited to: age, breed, gender, neuter status, clinical signs, palpable (balloting) fluid collection, pregnancy, neurologic status, obesity and the presence of masses. Urinary bladder distention should be palpable and defined as normal or distention from abdominal disease or neurological distention (i.e., upper or lower motor neuron). Both kidneys are not always palpable in healthy dogs. Their left kidney is easiest to feel while the right might only be palpable caudally or when it is enlarged or displaced. When bilaterally enlarged, both kidneys in dogs may be palpated. When an otherwise healthy dog is obese, one may not feel either kidney. Both kidneys are usually palpable in cats. The presence of a large or painful prostate in a dog should be noted and correlated with clinical signs. Symmetric enlargement of the fat pads and muscles of the lumbar region ("love handles") are commonly seen in an older pet, particularly if it is gaining weight. The "love handles" are often of concern to the owner in an otherwise normal adult aging dog (Figure 2-44).

FIGURE 2-44 Large fatty deposits, often firm, are noted in many older, overweight dogs and may be confused by the pet's owner as a growth or mass.

Rectal examination is a component of palpating the caudal abdomen and should be part of every physical examination in medium- and large-breed dogs (Figure 2-45). While examining the rectal region and tissue, the clinician should check the animal for evidence of constipation, obstipation, or generally dry, hard stools (see ch. 42). Such problems lead to difficulty defecating. The perianal region should be examined for fecal staining, anal sphincter integrity, masses and, particularly when straining to defecate occurs, for perineal hernia, either unilateral or bilateral. Perineal hernias (Videos 2-19A and 2-19B) are detected by lateral deflection of the index finger immediately after entering the rectum (i.e., no farther than the first or second joint of the inserted finger). If the examiner probes too deeply past that point, this important lesion will be missed. Rectal prolapse must be differentiated from ileocolic intussusception because of different etiologies and treatments. Prolapse is associated with the inability to pass a blunt instrument or digit alongside the everted viscus per rectum beyond the level of the pelvic inlet. Perianal fistulas are readily identified on the physical examination; however, they are often so painful that examination of this area is made difficult without sedation. Perianal masses (Figure 2-46) should be evaluated for changes in size, and appearance. During this portion of the examination, the tail is checked for skin lesions and for pain on rotation and extension/dorsiflexion. Animals experiencing tail pain, and occasionally urinary and/or anal sphincter problems, should be examined with injury to the tail region in mind. Tails that have been caught in doors or pulled aggressively (more common in the cat) can be associated with neurologic problems involving the urinary bladder, anal sphincter, and/or the ability to move the tail.

FIGURE 2-45 Digital rectal examination is regularly performed as part of the physical examination if there is reason to be suspicious of prostatic, colonic, or perianal disease as well as to examine the anal sacs and sphincter. Initial insertion of a gloved, lubricated finger should be gentle and limited to a short insertion to evaluate the anal sacs, rectum and the perianal tissue. Deeper palpation after that is useful for evaluating the colon, prostate gland and occasionally the aortic bifurcation.

FIGURE 2-46 Perianal masses are likely to be painful, irritated and often covered with stool, making them difficult to examine without being gently but well cleaned. This cat presents with an ulcerated mass just ventral and to the right of the anal sphincter.

In older male dogs or when signs suggest lower bowel dysfunction, lower urinary tract problems, prostate concerns, or hind end disorders of an orthopedic or neurologic nature, the findings on rectal palpation gain even greater importance. With the increased use of abdominal sonography, palpation gains value because lesions within the pelvic canal often do not image well. Prostatic abnormalities are likely to be palpated per rectum in all but larger male dogs. Correct palpation of the prostate is done with the index finger of one hand in the rectum while the other hand, externally, is providing dorsocaudal upward pressure at the level of the caudal abdomen to elevate the prostate gland toward the palpating finger. This is especially useful for larger dogs and/or the palpator with a short index finger. A normal rectal examination (see ch. 278) identifies a symmetric, bilobed, nonpainful, rubbery-textured prostate with a median raphe that clearly separates two lobes. Palpation of the surrounding tissue should evoke no pain or irregularity along the canal wall or the bony pelvic structure surrounding the gland. The urethra is a thin, flat tube usually palpable above the pelvic symphysis. A thickened, ropy urethra may be felt in cases of urethritis or transitional cell carcinoma. Rotation of the hand so the palm points dorsally then allows the examiner to palpate the aortic trifurcation and aortic pulse, and may rarely allow the palpation of sacral (sublumbar) lymph nodes if very enlarged. Rotation of the wrist in the other direction (45-90 degrees past midline) is warranted, to identify masses or other abnormalities within the pelvic canal.

With the index finger in the rectum, the examiner palpates the anal sacs at the 4 and 8 o'clock positions to determine whether they are enlarged and if they can be readily expressed. The ease with which these sacs can be expressed and the type of fluid released aids the evaluation for anal sac disease. Many clients worry considerably about “full” anal sacs, and it is important to identify problems if they exist. It could be necessary to alter a diet's fiber content in some dogs to improve natural anal sac compression and expression with each bowel movement. Serious anal sac disease does occur in cats, albeit uncommonly, and expression from outside the anus and rectum is appropriate in small dogs and cats (see Figure 2-45). The rectal tissue should

be neither rough nor painful and no blood should be noted on the examination finger when removed from the anus. Note the presence of mucus or blood specks (red or black) particularly if there are complaints regarding stool appearance at home.

The testicles and scrotum should be examined in the intact male for pain, skin lesions, and variability in testicle size and shape. The scrotum of a neutered male should be examined for masses or ulcerations. The presence of one or no testicles in an intact male is an important diagnostic finding. Retention and/or neoplasia of one or both testicles may correlate with the presenting clinical signs. In the puppy examination, the presence or absence of testicles may indicate a congenital defect and must be identified to the pet owner because the purchase agreement may need to be reviewed. It is important to note the presence of an inguinal (flanker) testicle because showing and breeding would not be allowed and the pet may be infertile. Explanation of such a finding for the new puppy owner is relevant, particularly if the pet was purchased for breeding purposes.

In females, examination of the vulvar region is important in determining the presence of a discharge, the state of estrus, or the presence of skin conditions that may be responsible for licking or irritability of the hind region. Asking questions that relate to the timing of the last or latest heat cycle may elicit insightful information relevant to pseudopregnancy or pyometra. (Remember that not every spayed female has been completely spayed and estrous cycles or stump pyometra remain in the differential diagnosis until proven otherwise.) Vaginal swabs taken to evaluate the state of the mucosa are a quick, easy way to determine the presence of pus or red cells in the canal as well as the hormonal status of the bitch. Examination of the hood region (Video 2-20) may provide a cause for odors and irritation due to the accumulation of mucus or pus. Females usually tolerate gentle digital vaginal palpation, regardless of neuter status or stage of estrous cycle. However, in healthy spayed dogs, vaginal palpation is not a routine component of the physical examination. Some disorders are quite painful, requiring additional restraint or sedation for digital examination. Examination of the mammary glands (Video 2-21) should be thorough, moving up and down both right and left chains probing for masses, irregularities and evidence of enlarged glands. Enlarged glands producing small amounts of fluid may be an indication of a false pregnancy, a near term pregnancy or an infection in that gland. Masses should be noted as to size, shape and texture (Figure 2-47) so that they may be re-examined on the next visit. Hot, ulcerated or rapidly growing masses should be considered for surgical removal.

FIGURE 2-47 Examination of each mammary gland and the entire left and right chains should be completed; note masses, texture, size and any ulceration present. Size and appearance should be noted in the record for comparison at the next health care visit. This firm irregular nodule is measured and noted in the record.

Prior to examining the limbs, particularly in cases of lameness, the examining veterinarian evaluates the mobility and flexibility of the head and neck (see ch. 259 and Videos 2-22A and 2-22B). Particularly in larger breeds of dogs, cervical conditions can cause neck-guarding, failure to thrive, with nondescript signs of acute painful crying, lameness, and malaise. Intermittent or recurrent problems may not be immediately obvious on the physical examination. Dogs that are difficult to examine or animals with acutely painful conditions may be better evaluated utilizing conscious sedation.

Rear leg pain, weakness, and wobbliness may be signs of a musculoskeletal or neurologic disorder, such as cervical disease, thoracolumbar disease, and/or lumbosacral disease. The physical examination should include compression of the tissues along the spinal column and the lumbosacral region (Videos 2-23A, 2-23B, 2-23C, and 2-23D). Sensitivity alone may be inadequate grounds for making a diagnosis and may only point to one of several conditions in the differential diagnosis. Neurologic changes, including postural tone, conscious proprioception deficits, or muscle atrophy, assist the process of evaluating disease states (see ch. 259 and Figure 2-48; see also Video 2-23).

FIGURE 2-48 The patient presents with evidence of pain, difficulty walking and hind limb weakness. His body posture (hunching of the spine—kyphosis) suggests pain in the limbs or back. Deep pain is present, as are patella and toe pad withdrawal reflexes. He is a candidate for a complete neurological and orthopedic examination to establish a differential diagnosis.

Evaluation and examination of the limbs, including bilateral femoral pulses, lymph nodes, joints, footpads, and interdigital regions, can reveal important clues to the presence of medical problems. Joint disease, often silent or less than immediately obvious, is easily overlooked unless specific attention is paid to joint swelling (Figures 2-49 and 2-50) or discomfort. Ch. 353 provides a summary of the orthopedic examination along with figures that demonstrate most common skeletal deformities of concern to the internist. The examiner should flex each of the patient's carpi with moderate pressure to assess for signs of joint pain that would otherwise not be recognized; animals with nonspecific signs, especially suggesting intermittent neck or back pain, may in fact be found to have polyarthritis (see ch. 15 and 203). It is important to observe symptomatic cats out of their carrier, on the floor in a safe, escape-proof room. Many cats will not ambulate in the veterinary clinic and it is good to suggest that the owner video such abnormalities at home when the cat is less inclined to remain static (Video 2-24). Swelling, heat, and pain in one or more joints can explain many signs, including lameness, malaise, and fever. Swelling of the adjacent peripheral subcutaneous tissues provides reason for further evaluation. Claudication, painful or non-weight-bearing lameness directs the examiner to the affected limb. Thorough examination of the limbs for differentiation of warmth, pulses, or swellings may yield a direct clue to the cause of lameness. Embolization is usually associated with pain when the embolism is arterial in contrast to acute paresis with a fibrocartilagenous embolism (FCE). Noting a disparity in the circumference of the joints, muscles of the hindlimb or the presence of atrophy in the shoulders or muscles of the scapula may more readily help to identify the source of the lameness (Figure 2-51).

FIGURE 2-49 Joint swelling may be associated with a single joint or multiple joints. The swollen left tarsal joint carries a multitude of differential diagnoses and should be approached as such unless an obvious cause is identified at the time of the physical examination (see ch. 15). This enlarged joint was firm, cool and only minimally painful on palpation and was associated with chronic arthritis with degenerative joint disease. The discoloration of the hair implies that the dog is chronically licking at his enlarged joint suggesting that sensory discomfort is present.

FIGURE 2-50 Measuring an enlarged joint to compare with the opposite limb may assist in following progression of the disease and also helps to identify to the client the initial disproportionate size of the joint. Client follow-up is more likely to be successful if they recognize the difference in joint size themselves.

FIGURE 2-51 The discrepancy of the size of the left tarsal joint in comparison to the right provides the clinician with more likely evidence as to where the lesion is. Likewise, atrophy of muscle mass on one side of the body compared to the other may be an indication of disuse or underuse because of pain, nerve damage or discomfort.

Deep palpation of the bony tissue provides information relevant to both medical and orthopedic problems. Taking into account the age and health of the animal is relevant, because some diseases are specific to young, growing dogs (panosteitis), whereas others would be expected in older, overweight dogs (cranial cruciate rupture, osteoarthritis, bone cancer) (see ch. 353). Although a general evaluation of the joints is required whenever lameness is present, joint palpation is always performed with the realization that problems may not be recognized without use of conscious sedation or general anesthesia. Cats are usually easier to palpate than dogs, and larger-breed dogs may be difficult to examine without sedation. Prior to sedation and clinical studies it is important to gait the animal to evaluate pain, lameness or proprioceptive deficits at a walk and a trot (see Video 2-5). It may be advantageous to discuss the benefits of sedation or anesthesia with the client for a more thorough physical examination, radiographs or joint tap (arthrocentesis) (see ch. 15 and 94). Palpation of the hips and evaluation for coxofemoral disease must distinguish this from lumbosacral and stifle disorders. Stifle drawer sign and clicking are indications of internal stifle disorders such as cruciate ligament tears, sprains and meniscal tears. The opportunity to evaluate these findings in greater detail may need to be conducted with sedation. When radiographs of a limb are to be taken, the examiner should exercise the benefit of evaluating both limbs to evaluate the significance of the changes noted by comparing symmetry. Some orthopedic problems, including patellar disease in small to mid-size dogs, are usually identified without sedation (see Video 2-22).

No lameness examination is complete without evaluation of the footpads and interdigital regions. It is of paramount importance to examine these tissues carefully for infiltrating problems, foreign bodies, interdigital cysts, tumors, or footpad lesions (Figure 2-52). Lengthy toe nails, sometimes so long that they curl around and re-enter the skin, can be a cause of significant lameness, easily treated by observation and then toe nail trimming.

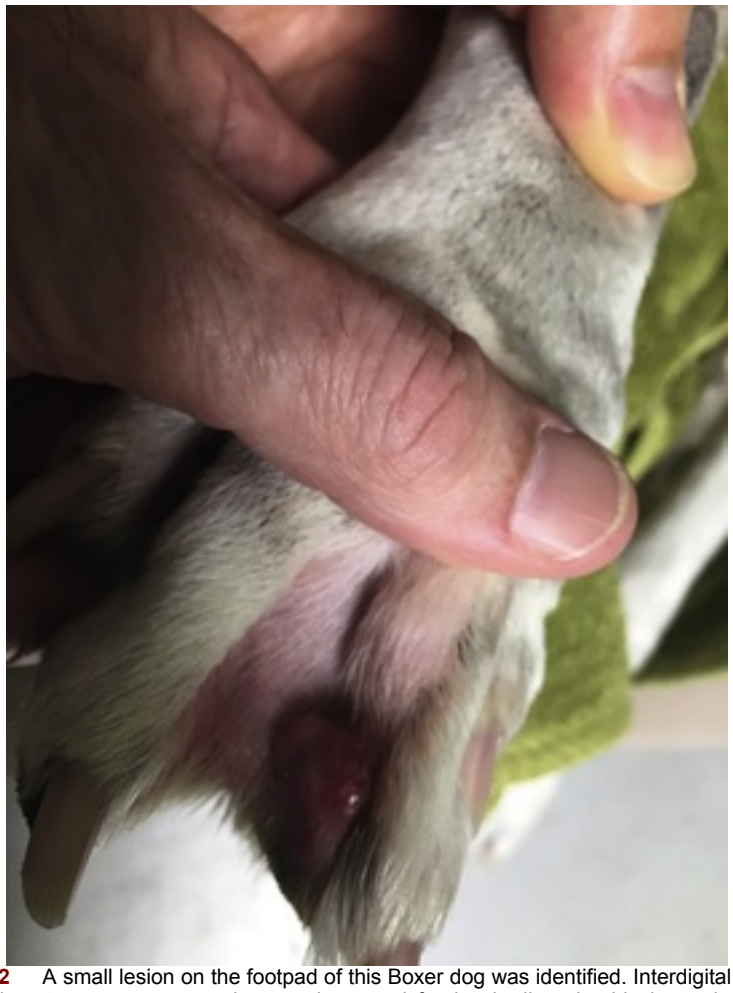

FIGURE 2-52 A small lesion on the footpad of this Boxer dog was identified. Interdigital and footpad cysts, granulomatous masses, neoplasms, ulcers and foreign bodies should always be considered when unidentified lameness is noted.

Completing the Physical Examination

Every hospital has its own set of digital or paper records. This is the time to complete a well-written medical record. The traditional "SOAP" (subjective, objective, assessment and plan) method provides the entire hospital and others with a record of the physical examination, history, findings and the plan for moving forward with the pet's care.

No physical examination is complete until the results are listed in the examination report and an assessment is made of the findings. The veterinarian should identify in the records his or her recommendations for proceeding with the case. It is here that the client or caregiver can once again participate. The veterinarian needs to summarize the findings, note the pertinent points, and identify how care might proceed. Noting the findings alone without recommending a course of action does not complete the process. The examiner should also note in the record, in addition to the subjective and objective findings, the likely rule-outs and tentative clinical assessment. A definitive diagnosis need not be made at this time, but identifying the rule-outs helps to portray a thought process in progress. The owner must be informed of the possible courses of action, the advantages and drawbacks of each, and the estimated cost of such work. If the prognosis is potentially poor or guarded, the examining veterinarian should discuss this with the owner at this point. Clients who fail to "hear" bad news may be very surprised to see that the veterinarian had written the discussion about it in the record one or more times in the course of recordkeeping. From the outset, regularly discussing serious findings with the client ensures better practitioner-client communication. In the plan, the veterinarian should identify the course of action to be followed so that he/she or another DVM may continue the examination process one step at a time if that is how the owner wishes to proceed. From a medical-legal point of view, keeping the client informed and up to date is necessary for maintaining good

doctor-client relations and communication.

CHAPTER 3

Basic Genetics

Kathryn M. Meurs, Joshua A. Stern

Client Information Sheet: Veterinary Genetics: Modes of Inheritance

Canine and feline medical genetics is a rapidly growing field. Both the canine and feline genomes are readily accessible resources and other genetic tools such as DNA extraction, polymerase chain reaction, genome-wide association and whole genome sequencing are now routinely performed for studying both canine and feline genetic diseases. The focus of this chapter will be to provide relevant basic genetic knowledge for the small animal practitioner.

Important Genetic Terminology

Understanding and fully utilizing genetics in veterinary medicine requires knowledge of a few common genetics terms.

Allele—one of a number of different forms of the same gene.
Genotype—the genetic makeup of an individual.
Heterozygous—having two different copies (alleles) of a gene for a specific trait or disease. One of the two is usually the wild type (normal).
Homozygous—having two identical copies of a gene for a specific trait or disease.
Phenotype—the observable characteristics of an animal that result from the interaction of the animal's genetic makeup and the environment. In veterinary medicine we may think of it as an affected or normal phenotype.
Polygenic—a disease or trait caused by the interaction of two or more genes.
Transcription—first step in gene expression when the DNA gets transcribed to RNA.
Translation—second step in gene expression in which RNA becomes decoded to form amino acids.

Dna to Protein

The double helix of DNA is composed of specific sequences of four nucleotides, adenine (A), guanine (G), cytosine (C) and thymine (T), that are arranged to make up both coding and noncoding regions of the genome. The processes that move that sequence of DNA all the way to gene expression include transcription of DNA to RNA and then translation of RNA to the generation of polypeptides and proteins. The processes are complex and transcription and translation errors do occur although there are systems in place that catch and correct many of the errors before an abnormal protein is produced.

Genes are the regions of DNA that code for the production of polypeptides. They contain both coding region (exons) and noncoding regions (introns, untranslated regions). There are also regions that serve to regulate the transcription process. The exons are separated by non-coding intronic regions, which can include areas of regulation called enhancers and silencers. One of the most important areas of regulation is the promoter region, a region at the 5′ end of the gene that helps initiate the transcription process. In the dog and cat, the promoter region of many genes has not yet been fully defined and only a general region can be assumed. Although promoters, introns and untranslated regions all have important functions, at this time, most of the medically relevant DNA variants (mutations) in the genome have been identified in exonic regions. It is very likely that increasingly, disease causative variants will be found in these other regions.

Translation from the RNA to the protein product is aided by ribosomes, which read the RNA (mRNA) as a three-nucleotide codon. Each three-nucleotide codon then codes for the production of a specific amino acid, which is then added into a polypeptide chain to form the protein. The first amino acid that is translated by a ribosome is called the “start” codon and in eukaryotes this almost always produces the amino acid

methionine. The "stop" codon is the codon that signals the end of translation and is typically one of the following codons: TAG, TAA or TGA.

As mentioned above, the DNA replication and transcription system is quite intricate but errors do occur. Many of them are identified and repaired; however, if they are not fixed, an incorrect DNA nucleotide (or in some cases a deletion or insertion) may occur and may result in the translation to an incorrect amino acid. Although the amino acid sequence of a protein is quite specific, some regions of the protein may allow for more variability and the placement of an amino acid of similar size and polarity to the correct amino acid may be very well tolerated. Thus, many DNA errors that result in DNA variant production and a change in the amino acid produced will not impact the individual. However, a DNA variant that codes for an amino acid of a very different size, polarity or other characteristic may greatly alter the protein product produced, impact the cells within the organ of interest and change the phenotype of the animal to that of a genetic disease or disorder. DNA variants that change the amino acid to one of a very different structure, size, or polarity or that result in the development or loss of a stop or start codon are most likely to be of clinical relevance.

Canine Genome

The dog has 38 autosomal chromosome pairs and one pair of sex chromosomes. The sequence of the canine genome was derived from a single female Boxer dog and was first sequenced in 2005.[1] It has coverage of 7.5X plus, meaning that each nucleotide was sequenced 7.5 times on average to determine its identity. The deeper the coverage (higher the number), the more likely the accuracy of the sequence will be. The canine genome is an excellent resource for studying canine genetics; however, since its sequence is based on a single female dog with relatively low coverage (7.5X), additional samples are always evaluated as normal controls when performing genetic studies. The most current version of the canine genome is available for evaluation through searchable websites including the UCSC Genome Browser[2] and the Ensembl Genome Browser.[3]

Feline Genome

The cat has 18 autosomal chromosome pairs and one pair of sex chromosomes. The sequence of the feline genome was derived from an Abyssinian cat from the University of Missouri in 2006.[4] The most recent version is called felcat5 with a 2X coverage.[5] The lower degree of coverage in the cat is indicative of the weaker state of development of the feline genome. The genomic resources for feline studies still lag behind those available for canine genetic research. The most current version of the feline genome is also available for evaluation through searchable websites including the UCSC Genome Browser[5] and the Ensembl Genome Browser.[3]

A unique aspect of the feline genome is its naming system. While canine and human chromosomes are numbered consecutively starting at 1, the feline chromosome numbering system is numbered from A-F as follows: A1, A2, A3, B1, B2, B3, B4, C1, C2, D1, D2, D3, D4, F1 and F2.

Modes of Inheritance

Understanding the mode of inheritance of familial diseases in dogs and cats can provide important clinical information and be used to guide breeding decisions even if a genetic mutation has not yet been identified for a particular disease. Of the identified disorders in which the mode of inheritance is known, the majority are reported to be an autosomal recessive trait.[3] Autosomal recessive traits are not evident unless the individual carries two copies of the disease variant (homozygous). They are often not observed within a family unless two silent carrier parents are inadvertently bred to each other. The high frequency of autosomal recessive traits in companion animal populations likely represents a conscious attempt by pet enthusiasts to breed away from obvious disease traits and demonstrates the complications associated with using this mechanism to attempt to reduce disease in which silent carriers exist.[2]

Determining the mode of inheritance of a disease is ideally performed by prospectively planning breeding experiments and breeding known affected to unaffected animals of known genetic background to study the results of the breeding. However, this type of breeding study is rarely practical since it results in the intentional production of animals with known disease. A simpler approach, which can often give a very good general idea of the mode of inheritance within a particular line of animals, can often be done by careful evaluation of pedigrees as long as the disease status (phenotype) has been accurately determined.

If the mode of inheritance is understood for a disease, a well thought out breeding plan may be developed

which may actually help reduce the frequency of the familial disease even before a mutation has been identified. The most common modes of inheritance in companion animals include autosomal dominant, autosomal recessive, X-linked recessive and polygenic.

Autosomal Recessive

Autosomal recessive traits are carried on autosomal chromosomes and are not evident unless the individual carries two copies of the disease variant (homozygous). Pedigrees of animals with an autosomal recessive trait generally show a pattern where the disease appears to "skip" a generation since the parents can carry the trait but not show the trait if they only have one copy of the disease variant (heterozygous). Males and females should be fairly equally affected (Figure 3-1). Frequently, there will be an example where the mating of two individuals that appear to be clinically normal produces affected offspring. Generally the proportion of affected offspring from the mating of two normal parents (silent carriers) should only equal approximately 25% of all offspring produced. Finally, if two affected animals are bred to each other, all offspring should show the trait.

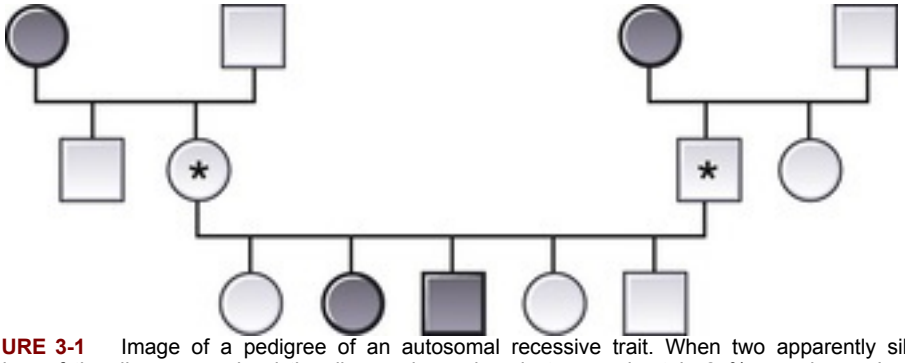

FIGURE 3-1 Image of a pedigree of an autosomal recessive trait. When two apparently silent carriers of the disease are bred the disease is produced at approximately 25% prevalence. In this diagram, circles are females, squares are males. White symbols are unaffected, black are affected. *Indicates a silent carrier of this disease.

They often become clinically apparent within inbred families since the risk of inadvertently breeding two silent carriers of the same trait is increased. If there is a potential likelihood of an autosomal recessive trait within a line, outbreeding to an unrelated family should decrease the risk of breeding to a silent carrier and producing more affected animals.

Autosomal recessive is the most common mode of inheritance identified in cats and dogs.[3] Examples of diseases and disorders that are inherited as autosomal recessive traits in veterinary medicine include nephritis (Alport syndrome) in English Cocker Spaniels, exercise induced collapse in Labrador Retrievers and spinal muscular atrophy in cats.[6-9] Canine cystinuria can be inherited as both an autosomal recessive (Labrador Retriever) and autosomal dominant (Australian Cattle Dog) trait depending on the breed.[10]

Autosomal Dominant

Autosomal dominant traits are also carried on autosomal chromosomes and are clinically evident even when one gene copy possesses the disease variant (heterozygous). Evaluation of pedigrees from affected animals should identify a fairly equal number of affected males and females. Additionally, every affected individual should have at least one affected parent since there are no silent carriers. Animals that show the trait could be either heterozygous or homozygous for the disease variant although generally one cannot tell which one they are by looking at the pedigree (Figure 3-2).

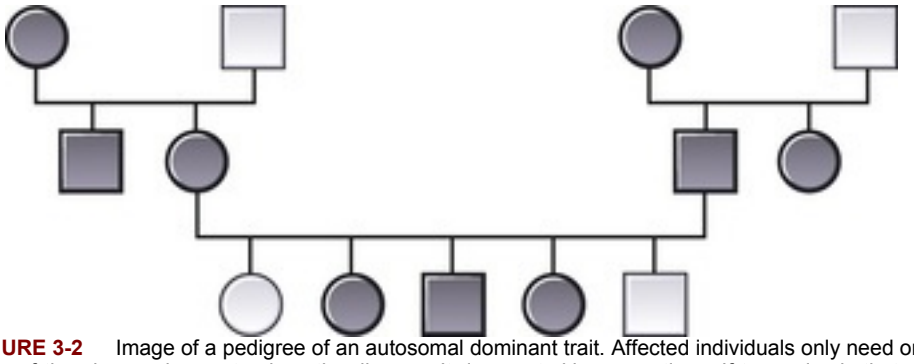

FIGURE 3-2 Image of a pedigree of an autosomal dominant trait. Affected individuals only need one copy of the abnormal gene to show the disease. It does not skip generations. If two animals that are heterozygous for the trait are bred, both affected and unaffected individuals can be produced. In this diagram, circles are females, squares are males. White symbols are unaffected, black are affected.

Examples of diseases and disorders that are inherited as autosomal dominant traits in veterinary medicine include polycystic kidney disease, retinal dystrophy in Abyssinian cats and dilated cardiomyopathy in Doberman Pinschers.[11-13] As mentioned above, canine cystinuria can be inherited as both an autosomal recessive (Labrador Retriever) and autosomal dominant (Australian Cattle Dog) trait depending on the breed.[10]

X-Linked

X-linked traits are carried on the X chromosome. Although X-linked traits can be dominant and demonstrate the trait even if the variant is only carried on one X chromosome, they are almost always recessive in veterinary medicine. X-linked recessive traits are only apparent in females if the disease variant is carried on both X chromosomes. Since the male only has one X chromosome, males will show the trait even if it is on their single X chromosome. Therefore, pedigrees of X-linked recessive traits generally show a predominance of affected males since they only have to have the trait on their single X chromosome. Females are more often silent carriers of disease since they frequently have the abnormal variant on only one of their X chromosomes. Pedigrees of animals with X-linked traits generally show many more affected males than females. Additionally, an affected male crossed with a normal female could produce unaffected females that are silent carriers. Affected males can never pass the disease to their sons since males cannot pass the X chromosome to their sons (Figure 3-3).

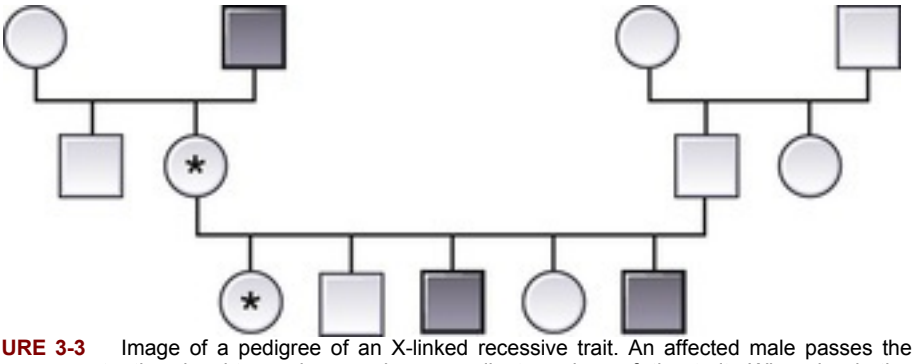

FIGURE 3-3 Image of a pedigree of an X-linked recessive trait. An affected male passes the X chromosome to the daughters who can become silent carriers of the trait. When bred, the X chromosome with the abnormal gene can be passed to some of the male offspring who will show the trait. In this diagram, circles are females, squares are males. White symbols are unaffected, black are affected. *Indicates a silent carrier of this disease.

X-linked traits are much less common in veterinary medicine but an example would include X-linked myotubular myopathy in Rottweilers.[14]

Polygenic

The modes of inheritance described above are generally used to describe diseases, which are thought to be caused by the effect of a single gene (monogenic). However, there are many familial diseases and disorders in veterinary medicine that have been characterized as polygenic, which suggests the impact of at least two genes working together to create the clinical presentation. Polygenic traits are particularly frustrating for both clinicians and geneticists since it is difficult to identify the specific genes of importance and to understand how they work together to create the disease. It is equally complicated to advise breed enthusiasts how they might breed away from a trait that is multifactorial without the risk of breeding away from other positive factors within the breed. The lack of knowledge of the individual genes involved in polygenic diseases makes it very difficult to develop specific breeding recommendations.

An example of a polygenic trait in the dog would be canine hip dysplasia.[15]

Dna Evaluation

Modern technology and increased genetic resources now allow the veterinarian to go beyond the study of pedigrees to that of actual chromosomal and DNA evaluation for their patients. Chromosomal and DNA evaluation of genetic traits can be obtained from a variety of sources including hair, buccal swabs, blood samples (EDTA, heparin), semen straws and tissue samples among others. The sample chosen should be selected based on the clinical evaluation needed. For example, a sample needed for chromosomal evaluation of an animal with infertility issues should include blood samples in heparin and EDTA tubes. A DNA sample needed to test for paternity or for a specific genetic mutation to identify the animal's genotype for a trait generally only requires a small amount of DNA and can come from a hair or buccal sample. DNA samples needed for an individual to participate in a research study for mutation identification requires a large amount of DNA and is best obtained from a blood sample.

CHAPTER 4

Clinical Genomics

Kathryn M. Meurs, Joshua A. Stern

Client Information Sheet: Guidelines for Baseline Recommendations for Genetic Diseases

Canine and feline medical genetics is a rapidly growing field. The first description of a disease-causing mutation in the dog was the identification of a single base pair mutation in the Factor IX gene which resulted in the development of hemophilia in the Cairn Terrier.[1,2] This discovery was made by Evans et al in 1989. In the past 26 years, key mutations have been identified for 186 canine diseases and 49 feline diseases.[3] An additional 104 mendelian diseases have been identified in cats and dogs although the causative mutation(s) have yet to be discovered. Dr. Don Patterson, one of the true fathers of veterinary genetics, suggested that the rapid growth in the importance of clinical genetics in veterinary medicine over the past 20 years was not because of a sudden increase in the development of genetic diseases. Instead, he suggested that the development of antibiotics, anthelmintics, more effective vaccines and improved diets over the past 50 years resulted in a marked reduction in diseases associated with environmental causes.[2] This in association with the increased accessibility of the canine and feline genome and genetic resources for studying genetics in these species has allowed us to begin to utilize clinical genetics as an important part of veterinary medicine. The focus of this chapter will be to provide relevant genetic knowledge for the small animal practitioner.

Important Genetic Terminology

Understanding and fully utilizing genetics in veterinary medicine requires knowledge of basic medical genetic vocabulary.

Allele—one of a number of different forms of the same gene.

Cytogenetics—the study of normal and abnormal chromosomes. Most frequently an assessment of the number or shape of the chromosomes.

Expression—variation in the clinical features of the genetic disorder. Genetic diseases with variable expression may present with variability in severity of disease, even with individuals with the same disease variant.

Genotype—the genetic makeup of an individual.

Heterozygous—having two different copies (alleles) of a gene for a specific trait or disease. One of the two is usually the wild type (normal), but not always.

Homozygous—having two identical copies of a gene for a specific trait or disease.

Karyotyping—evaluation of the number and appearance of chromosomes (Figure 4-1).

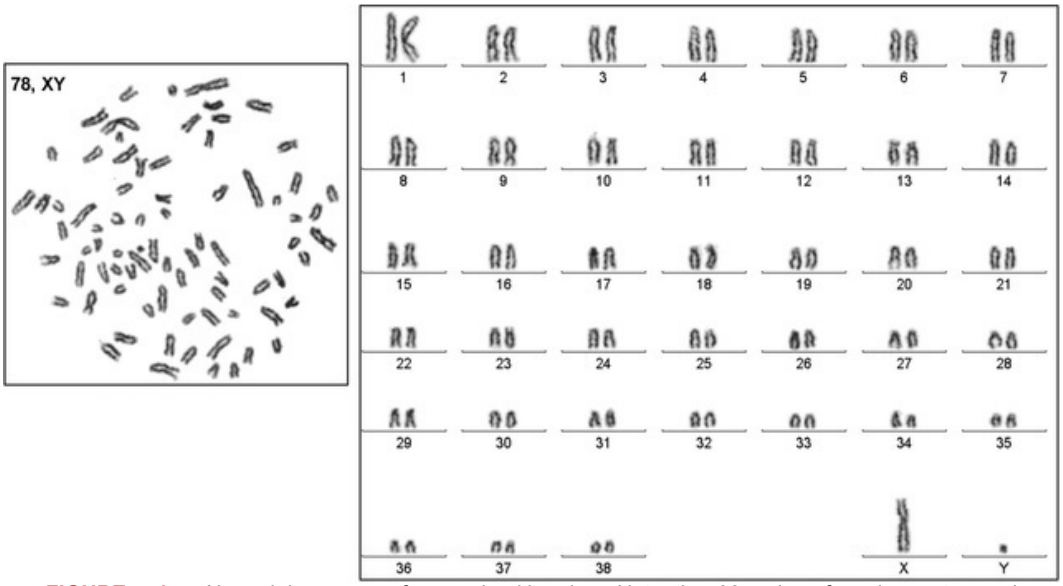

FIGURE 4-1 Normal karyogram from a healthy dog. Note the 38 pairs of canine autosomal chromosomes and the X and Y chromosome.

Missense mutation—a single nucleotide change that results in the formation of a different amino acid than is typically observed.

Nonsense mutation—a single nucleotide change that results in the development of a stop codon, prematurely.

Penetrance—proportion of individuals with a disease gene variant that will develop the disease. If a disease has incomplete penetrance some individuals with the disease gene variant (mutant) will not develop the disease.

Phenotype—the observable characteristics of an animal that result from the interaction of the animal's genetic makeup and the environment. In veterinary medicine we may think of it as an affected or normal phenotype.

Polymorphism—naturally occurring single base pair variants in the DNA sequence that have no adverse effects in the animal and are generally observed in at least 5% of the population.

Wild type—the most common copy (allele) of the gene, typically that found in the normal individuals.

Clinical Genetics

Genetic developmental disorders and diseases typically occur either because of large changes in chromosomal structure (deletions; chromosomal rearrangements) or smaller DNA variants (DNA deletions, insertions or changes).

Cytogenetics

Cytogenetics is the study of normal and abnormal chromosomal number and shapes. A karyotype is number and structural appearance of the chromosomes in a cell. A karyogram is the image of the chromosomes in the cell that allows for the evaluation of the chromosomes to assess chromosomal abnormalities including chromosomal duplications and rearrangements (see Figure 4-1). In human beings, these types of chromosomal changes have been linked to medical issues including cardiac and neurologic birth defects, abnormal sexual development, infertility and miscarriages.[4] Karyotyping has also been used to study neoplastic cells for specific chromosomal abnormalities unique to some forms of cancer.

In veterinary medicine, cytogenetic analysis of the chromosomes has been fairly limited to date. Its widest use has included evaluation of animals with reproductive or neoplastic issues. Chromosomal abnormalities in both dogs and cats have been associated with infertility as well as the development of abnormal external genitalia.[4-6] Evaluation of the feline karyotype in a sterile male tortoise shell cat was performed to identify an extra X chromosome.[7]

Oncologic studies have been using cytogenetic analysis to evaluate neoplastic cells for aberrations in chromosomal number and structure that could be used to improve our understanding of the etiology, prognosis and likelihood of response to treatment in canine neoplasia.[8]

Cytogenetic analysis in canine and feline veterinary medicine at this time is most important for the evaluation of sexual development disorders and should be considered in cases of abnormal sexual development or infertility. However, in the future this technique is likely to have increasing importance in our overall understanding of oncologic issues as well as neurologic and cardiovascular disorders.

Cytogenetic analysis and interpretation can be routinely provided for veterinarians through a number of different diagnostic labs with a small blood sample for a cost of between three and five hundred dollars. Searching for laboratories that perform canine and feline cytogenetic analysis can identify diagnostic laboratories that provide this service.

DNA Variants

Familial diseases and developmental disorders can also develop from genetic variants that occur at the DNA level. This type of DNA variant might include a single base pair change or a small insertion or deletion. However, a significant amount of this type of genetic variation exists normally at the DNA level without causing any specific disease. Polymorphisms are naturally occurring single base pair variants in the DNA sequence that have no adverse effects in the animal and are generally observed in at least 5% of the population. Determining if a DNA variant is a polymorphism or actually causative for the development of a familial disease or disorder can be challenging. Newly discovered DNA variants are typically carefully scrutinized to determine if they have characteristics which could likely lead to an important change in gene function. These might include single base pair variants that lead to the development of a different amino acid (missense mutation) (Figure 4-2) particularly if the amino acid is highly conserved across species, or the creation of a premature stop codon (nonsense mutation). Additional DNA variants that are highly likely to have important functional consequences are the insertion or deletions of additional DNA nucleotides particularly if they are in exonic regions (Figure 4-3).

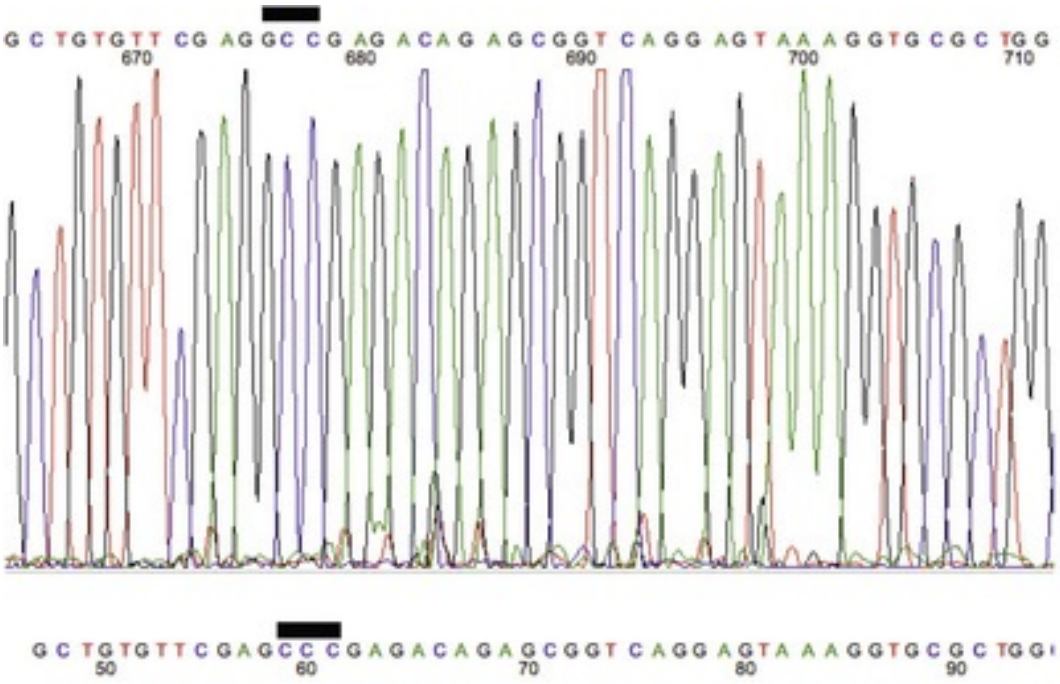

FIGURE 4-2 Missense mutation in a Maine Coon cat with hypertrophic cardiomyopathy. Note that the DNA sequence under the black bar in the top image is GCC, but the sequence under that black bar in the lower image shows the disease variant as CCC. The G has been replaced with a C. This will result in the production of a different amino acid.

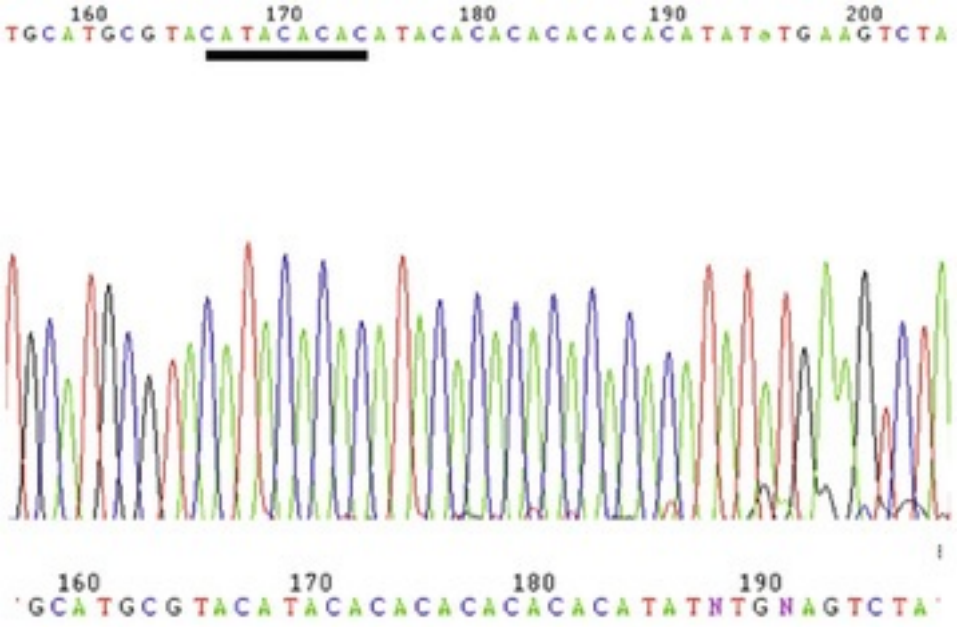

FIGURE 4-3 Deletion mutation in a Boxer dog. The sequence under the black bar in the top image represents a normal dog. In the lower image, the sequence under the bar has been removed and the rest of the DNA sequence has been shifted to the left.

The field of veterinary medical genetics is a rapidly changing field with new disease-causing variations being found on a frequent basis. As new DNA variants are discovered and linked to the development of clinical issues in the canine and feline populations, they are recorded in one or more of several electronic databases that are open-access. Clinicians counseling pet owners about familial diseases are encouraged to visit one of the following databases for the most current information on specific diseases.

1. *Online Mendelian Inheritance in Animals (OMIA)*[3]: The Online Mendelian Inheritance in Animals database is a comprehensive database that includes detailed information on genetic variants of cats, dogs, cattle, pigs, sheep, chickens, horses, goats and a few other species. Information on the DNA variant, evidence for its association to disease and availability of genetic testing are all provided. It serves as an excellent resource for veterinarians who need to do a quick search by disease or breed of dog or cat to identify current information on familial diseases.
2. *Canine Inherited Disorders Database*[9]: The Canine Inherited Disorder Database is more helpful for the pet owner than for veterinarians because it is generally directed at individuals with very little medical training. However, it still provides valuable genetic information on known inherited disease in dogs and it may be a useful resource for referring clients who need additional information on familial disease. This database provides lists of familial canine diseases as well as very brief clinical information on the

more common diseases for the layperson. It is searchable by both breed and disease process. Additionally, it provides general information on familial diseases including basic genetic definitions and recommendations for responsible breeding practices.

3. *Inherited Diseases in Dogs*[10]: This database is also a searchable database with an emphasis on the genetic aspects of the disease. It is intended for someone with a strong genetics background. The genetic data are carefully scrutinized for solid scientific evidence that links a DNA variant to disease.[11]

Factors That Impact Clinical Presentation of Familial Disease

Over 200 genetic mutations (variations, deletions, insertions) have now been associated with the development of clinical disease in the dog and cat.[3] However, it has become increasingly clear that medical genetics in the dog and cat is complicated. Not all individuals with a disease-causing mutation will develop the disease due to incomplete penetrance and not all individuals that develop disease due to a known DNA variant will develop the disease with the same disease severity due to variable expression. Many genetic diseases in animals are inherited with variability in penetrance and expressivity. A trait that is designated as having incomplete penetrance will be one in which less than 100% of individuals with the disease variant (mutation) demonstrate the trait. A trait designated as having variable expressivity is a disease or developmental disorder that has a spectrum of phenotypic expression with some individuals more severely affected than others. For example, some Maine Coon cats with the Maine Coon hypertrophic cardiomyopathy mutation (A31P) may have significant ventricular hypertrophy and develop congestive heart failure while littermates with the same mutation may not even ever show the disease. The Maine Coon mutation has been shown to exhibit incomplete penetrance and variable expressivity.[12] Another example of a disease where incomplete penetrance is thought to play a role in the development of the disease is canine epilepsy, although a genetic mutation has not yet been identified.[13] The mechanisms for the phenomena of variable expressivity and incomplete disease penetrance are poorly understood even in human genetics. It is likely that both environmental and genetic modifiers have an impact on the development of the trait associated with a particular mutation.

Penetrance and genetic expressivity are key concepts for veterinarians to understand and be able to explain to pet owners. They help explain why genetic testing rarely provides a black and white answer to the question of whether an animal should be used for breeding. In many genetic diseases, the presence of a causative mutation does not indicate that the animal will definitely get disease or the severity of the disease. It is very important that pet owners and pet breeders understand that not all individuals that carry a genetic mutation or are the offspring of affected parents will show the disease, or will show it with the same severity. Individuals with the disease variant are generally at increased risk of disease development (based on mode of inheritance), certainly, but are not guaranteed to develop disease. Understanding the limitations as well as the true value of genetic testing will help pet owners maintain confidence in genetic tools.

Genetic Counseling

With the increasing role of genetics in veterinary medicine there is also increasing desire to use this new genetic knowledge to reduce the prevalence of important familial diseases. Once a genetic mutation has been identified and genetic testing becomes available, counseling a pet owner or breeder on how to use the tests is imperative. Although genetic testing represents a great advancement for veterinary medicine, the improper use of genetic tests can be detrimental to the breeds involved. Once a genetic test has been developed, there is often a great desire to test for the causative mutation and remove any animals with the mutation immediately from the breeding pool (gene pool). This may seem initially to be a logical approach but it can have a significant negative impact on the breed overall. Cat and dog breeds are, by definition, closed gene pools. If the mutant gene is found to exist in 30% of a breed's population, which is not an uncommon scenario, a sudden reduction in 30% of the gene pool could dramatically alter the genetic makeup of the breed. Additionally, due to the incomplete penetrance and variable expression noted in many genetic diseases, it should be emphasized that not all animals that have the mutation will develop a clinical form of the disease. These concepts need to be carefully weighed against the ethics of continuing to produce animals that may carry a disease variant and could potentially suffer from the disease. Therefore, guidelines for counseling owners about the results of their genetic tests need to be carefully developed. For an individual animal this information can be used to guide decisions about increased clinical monitoring and could impact recommendations on diet, treatment and even exercise. For the breeding animal, recommendations to continue breeding animals that carry disease variants should be based on many factors including size of the

breed (gene pool), type of disease, risk that the animals produced will develop disease from the mutation (penetrance) and the likely severity (expressivity) of the disease. Finally the positive attributes of the animal that could be passed on and maintained within the gene pool should be considered.

Below are some guidelines for baseline recommendations for counseling owners about genetic diseases.

Genetic Test Results

Negative

This genotype status indicates that the individual animal does not carry any copies of the known disease genetic variant (mutation).

Considerations for the individual animal and breeding population: No special considerations are warranted as this individual should neither develop disease nor have the ability to propagate disease within the population.

Positive Heterozygous

This genotype status indicates that the animal has one copy of the normal gene (wild type) and one copy of the disease genetic variant.

Considerations for the individual animal: If the disease is autosomal recessive, this animal should never develop the disease, and no special considerations are needed. If the disease is autosomal dominant, this animal is at risk of developing disease. In some diseases, heterozygous animals have a more mild form of the disease than do homozygous animals and in some cases (variable penetrance) may never develop disease.[14] However, since this animal carries the disease variant and is at risk of disease development, a patient management strategy that includes annual monitoring for signs of disease and considers dietary, medical or other options that might help prolong the disease free state should be discussed. If the disease is X-linked recessive, a male with the disease variant on his X chromosome is likely to develop disease, but a female with the disease variant on one X chromosome is likely to be a silent carrier of disease.

Considerations for breeding animals: If the disease is autosomal recessive, this animal will not develop disease and can be safely bred to an animal that is negative for the disease variant. This strategy will likely produce both genotype negative and positive heterozygous animals but neither will develop disease. Ideally, a mutation-negative offspring with the desirable traits of the parents could be selected to replace the positive heterozygous parent for future breeding. This would ensure maintenance of genetic diversity within the breed. However, this individual should never be bred to another positive heterozygous animal since they will likely produce positive homozygous animals that will develop the disease.

If the disease is autosomal dominant, a similar strategy for breeding could be considered and one could breed a positive heterozygous animal to a genotype-negative animal. The offspring of this mating (positive heterozygous to a negative) will ideally produce at least some genotype-negative offspring and one of these with the desirable traits of the parents could be selected to replace the positive heterozygous parent in future breedings. This will help maintain the positive attributes of the breed and gradually reduce the prevalence of the disease variant in the breed over a few generations while maintaining breed diversity. However, this breeding will likely also produce a few positive heterozygous animals as well. As such, this strategy does risk producing animals that may eventually suffer from disease. Therefore, this strategy should be considered with regard to the type of disease that may develop in the offspring, the degree (if any) of disease in the positive heterozygous parents since in some diseases a parent with low penetrance of disease may produce low penetrance (healthy) offspring, and the importance of the positive heterozygous animal to the breed. If the animal is an exceptional animal due to personality, health, intelligence or other characteristics, one may be more likely to try this approach once or twice in hopes of producing a genotype-negative replacement animal.

If the disease is X-linked recessive, a male with a disease variant on his X chromosome could be safely bred to a negative female. This will produce both male and female dogs that are clear of disease. The male offspring of this mating will be clear of disease and not carry the disease variant since males cannot pass on their X chromosome to their sons. They will obtain their X chromosome from their genotype-negative mother. Female offspring will also be clear of disease as well since they will only have the disease variant on one chromosome and as a recessive trait, they would need to carry it on both X chromosomes to actually demonstrate the disease. However, importantly, females with a disease variant on one X chromosome will be silent carriers of the trait and can indeed produce clinically affected male dogs even if bred to a negative male. So female offspring resulting from this breeding strategy should not be bred even though they will be clear of disease.

Positive Homozygous

This indicates that the animal has two copies of the disease variant.

Considerations for the individual animal: In autosomal recessive, autosomal dominant and X-linked recessive diseases, positive homozygous animals have the highest risk of developing the disease. A patient management strategy should be developed that may include annual monitoring for signs of disease and consideration to dietary, medical or other options that might help prolong the disease-free state.

Recommendations for breeding animals: Since positive homozygous animals carry two copies of the disease variant, they will certainly pass on the variant even when bred to a genotype-negative animal. This will result in continued presence of the disease variant in the breed. Additionally, since the individual breeding animal is more likely to show the disease, using these animals for breeding may put increased stress on their possible disease states. In general, positive homozygous animals should not be used for breeding.

Types of Genetic Tests

A large number of diagnostic testing laboratories now offer genetic tests for a number of canine and feline diseases. Samples may be submitted in a variety of forms including buccal swabs, blood samples in EDTA, and semen straws, among others. Some labs prefer to send a specific kit for sample collection and others allow samples to be sent directly from the veterinary clinic in a standard EDTA tube. It is important to understand the type of testing performed and its respective sensitivity and specificity. PCR-based sequencing continues to be one of the most accurate methods for testing because it allows the laboratory to actually visualize the animal's DNA sequence and identify the variant. It continues to be slightly more expensive and takes a bit longer than assays that simply amplify the region of the variant and predict the presence or absence of the variant or normal (wild type) sequence based on color or fluorescence.

Importantly, since these canine and feline familial diseases are complicated with issues that include incomplete penetrance, variable expression, closed gene pools and variable phenotypes, it is ideal to use a testing service which is closely linked with the investigators that studied and discovered the disease variants and can provide the most expertise in genetic counseling for pet owners. A reasonable consideration is to identify the report of mutation discovery and contact the corresponding author's laboratory to identify the testing facility of choice.

Pharmacogenetics

Pharmacogenetics is the study of the impact of genetic variation on drug pharmacokinetics and pharmacodynamics, and how the actions and reactions to drugs vary with a patient's genes.[15,16] Pharmacogenetics is frequently viewed as a component of personalized medicine and indicates the personalization of pharmacological therapy to an individual based on their genetic background. A patient's genomic background can influence both a patient's ability to respond to medications as well as the ability to tolerate them without significant side effects. In veterinary medicine, breed-related genetic differences can impact both pharmacokinetics and pharmacodynamics and may suggest the need to alter doses for breed or individual animal variations.[17] Although this is still a fairly new area of clinical genetics, a few well known examples can be discussed.

Cytochrome P450

Cytochrome P450 (CYP) is responsible for the metabolism of a large number of drugs.[16] In human beings, the Cytochrome P450 2D6 (CYP2D6) gene has genetic variations (polymorphisms) that are associated with alterations in drug metabolism. Individuals with a specific genetic variant are considered to be poor metabolizers in comparison to those with the normal (wild type) sequence. Variants have also been identified in the Cytochrome P450 2D15 (CYP2D15) gene in the dog and some dogs have different rates in drug metabolism.[18,19] A genetic deletion in the CYP2D15 gene has been identified and may be associated with the variation in metabolism although this relationship has not yet been well studied.[16] The genetic variation might also be expected to be associated with metabolism of other drugs including propranolol and dextromethorphan.[16]

Thiopurine Methyltransferase

Thiopurine methyltransferase (TPMT) is important for metabolizing a number of cancer and

immunosuppressive agents including azathioprine and 6-mercaptopurine.[20,21] In human beings, genetic variants in this gene are associated with low enzyme activity and can lead to increased toxicoses including bone marrow supression.[16] Genetic variants in this gene have also been identified in both the canine and feline genes.[16,21] In both species, variation of red blood cell TPMT activity was associated with different genetic variants although a specific link to any single variant was not identified. Although the association is not clear enough for a specific clinical application at this time, in the future screening for these variants could possibly be used to determine an individual's activity level of TPMT to determine appropriate dosing.

P-Glycoprotein

For many drugs, plasma and tissue concentrations are very dependent on the activity of a drug transporter.[22] The ABC protein superfamily contains proteins that use ATP to transport substrates across biological membranes.[23] The ABC transporter superfamily transports drug molecules as their substrates. Two examples of this are the P-glycoprotein (P-gp) (encoded by the ABCB1, formerly MDR1, gene) and the breast cancer resistance protein (BCRP) (encoded by the ABCG2 gene).

In 2001, a four base pair deletion was identified in the collie ABCB1 gene that resulted in increased sensitivity to ivermectin.[24] The deletion causes a frame shift mutation that results in the development of a premature stop codon and produces a truncated, non-functional protein. This variant has been estimated to be in approximately 75% of Collies in the United States and 50% of Australian Shepherds. Traditionally thought of as a Collie issue, the mutation has been identified in a wide variety of other breeds including Australian Shepherds, Border Collies, English Shepherds, German Shepherds and Long Haired Whippets.[25] ABCB1 mutant dogs that are homozygous can suffer adverse neurologic signs after even one dose of ivermectin. Variability of ABCB1 expression can also influence pharmacokinetic characteristics of P-gp substrates and many other drugs including digoxin, cyclosporine A, dexamethasone, opioids, fluoroquinolones, beta-adrenergic agonists, loperamide and certain antivirals.[15,16] P-glycoprotein is also known for its role in mediating many chemotherapeutics.[26] Therefore, testing of at-risk breeds for the mutation should be considered before administration of chemotherapeutics including vincristine, doxorubicin and vinblastine.

Pharmacogenetics remains a rapidly growing field with current investigations into the influence of a patient's genetic makeup on response to cardiac medication (ACEI and PDE5a gene reports), chemotherapeutics, anesthetics and anticoagulants.

Clinical genetics is a rapidly growing field of veterinary medicine. It includes both the identification of causative disease mutations as well as the field of pharmacogenetics. The tools and information provided through canine and feline genetics provide exciting new aspects of veterinary medicine.

CHAPTER 5

Evidence-Based Medicine

Steven C. Budsberg

One of the biggest challenges facing today's primary-care veterinary clinicians is staying current in a vast and ever-changing knowledge base and then trying to incorporate this new information into their daily practice routines. Evidence-based veterinary medicine (EBVM) offers a perspective and a set of tools that veterinarians can employ to manage information, facilitate better clinical decision-making, and improve patient care. EBVM represents a shift from opinion-based clinical decision-making to one that is data-based. The critical appraisal of all available information is at the core of EBVM. Modern EBVM is composed of five main elements (Box 5-1)[1] and is defined as *the conscientious, explicit, and judicious use of current best evidence, combined with individual clinical expertise and client/patient preferences and needs, in making decisions about the care of individual patients.*[2]

Box 5-1

The Five Basic Steps of Evidence-Based Veterinary Medicine

1. Converting the need for information (e.g., about prevention, diagnosis, prognosis, therapy, causation) into an answerable question.
2. Tracking down the best evidence with which to answer that question.
3. Critically appraising that evidence for its validity, impact, and applicability.
4. Integrating the critical appraisal with the clinician's expertise and each client/patient's circumstances.
5. Evaluating effectiveness and efficiency in executing steps 1-4 and seeking ways to improve for next time.

As stated above, EBVM has the great potential to improve patient care. Past experience has shown that better outcomes can be achieved with better knowledge. However, as we embark on this new journey, we must be cautious. We must be mindful that the information on which we base our decisions is not always created equal and that misinformation can certainly be worse than no information. It must be constantly remembered that the evidence obtained while practicing the methodologies of EBVM, by itself, does not make a decision, but it can help support decisions regarding patient care (Figure 5-1).

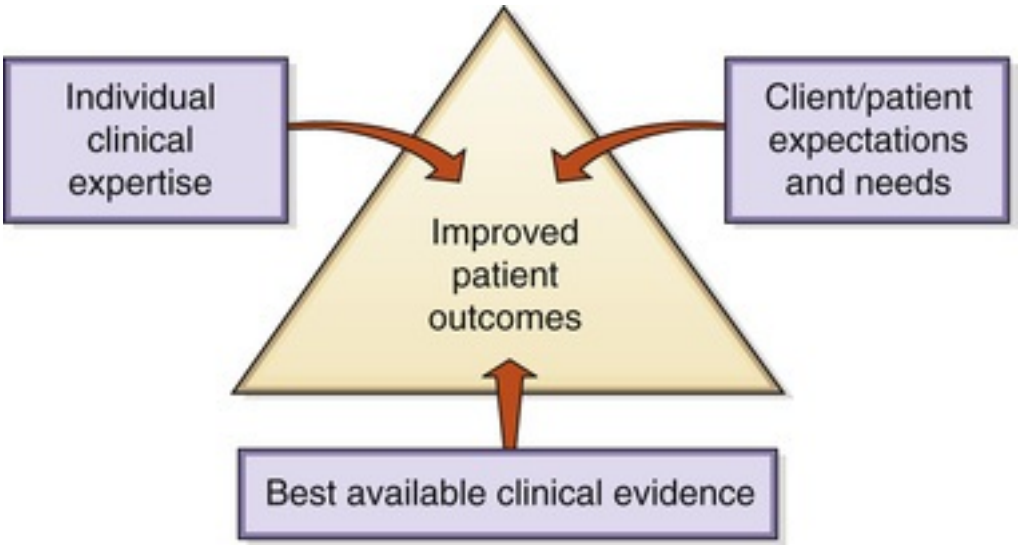

FIGURE 5-1 The optimal decision-making process of EBVM. The best outcome depends on the expertise of the clinician, the best available evidence, and client/patient expectations and needs.[2]

Evidence-based veterinary medicine requires specific skills of the clinician, including efficient literature-searching, and the application of formal rules of evidence in evaluating the clinical literature.[3-5] Let us review the process and show examples of how one begins the practice of EBVM. There are five basic steps employed when teaching or practicing EBVM, as outlined in Box 5-1. However, another popular algorithm is called the five "A." One must **Ask** a question, **Acquire** the evidence, **Appraise** the evidence, **Apply** the evidence to the patient, and finally **Assess** the outcome. This algorithm follows the same fundamental steps described here, presented in a different format, and it has been highlighted in the following example to show how both systems strive for the same information. Remember, EBVM always starts with the patient and thus the process starts as follows:

1. The clinician has a problem/question that arises out of the care of the patient. Next, the clinician must construct a well-developed question derived from the aforementioned problem/question. The question to be asked must be specific to the patient, precise in scope and answerable. Therefore, the first stage of any evidence-based practice process is to **ask** an answerable question. This question forms the foundation for the appropriate searching of the literature and then ultimately the evidence incorporated into the care of that specific patient. A well-formulated question will facilitate the search for evidence and will assist in determining whether the evidence is relevant to the question. An answerable question often takes the format that follows the PICO concept. The acronym translates to:

   P—Populations/Patient/Problem
   How would you describe a group of patients similar to your patient? What are the most important characteristics of the patient? This may include the primary problem, disease, or co-existing conditions.

   I—Intervention(s)
   Which main intervention, prognostic factor, or diagnostic test are you considering? What do you want to do for the patient? Prescribe a drug? Order a test? Recommend a surgical procedure? Which factors may influence the prognosis of the patient? Age? Breed? Sex? Or metabolic status?

   C—Comparison
   What is the main alternative to compare with the intervention you are proposing? Are you trying to decide between two drugs, a drug and no medication, or two diagnostic tests? Remember, your clinical question does not always need a specific comparison.

   O—Outcome
   What are you trying to do for the patient? Relieve or eliminate the signs? Reduce the number of adverse events? Improve function or test scores?

2. Once an answerable question has been created, one must select the appropriate available resource(s) to conduct the search to **acquire** evidence to answer the clinical question. Certainly when starting to search and acquire information, one often turns to the Internet. The most common sites to start with are PubMed (Medline) (www.ncbi.nlm.nih.gov/PubMed) and CAB Direct (www.cabdirect.org or www.cabi.org/publishing-products/online-information-resources/cab-abstracts). However, recently, two newer sites, specific to clinical veterinary medicine, have been developed and are now available and

searchable. BestBETs for Vets (www.bestbetsforvets.org) and VetSRev (www.nottingham.ac.uk/cevm/vetsrev) may vastly improve search capabilities for acquiring the desired information. Other sources of information would include hard copy journals available to the clinician as well as appropriate textbooks and of course information gleaned from lectures, presentations or colleague discussions.[6]

3. With the evidence located and acquired, one must **appraise** that evidence for its validity (strength of data) and applicability (usefulness in clinical practice). This next step involves evaluating the evidence that has been acquired. In essence, one is trying to determine what is the "best evidence" among all the information that has been gathered in the search to use to treat the patient.[7-10] Although the randomized controlled trial is touted as the be-all and end-all of clinical evidence, one can still practice evidence-based medicine without such information. In fact, evidence-based medicine involves using the best available evidence at the time, and what qualifies as "best evidence" differs by clinical question. Therefore, various types of evidence can be used to develop the best treatment plan for a patient, and this evidence is ranked by its strength or level of evidence; the more rigorous the study design, the higher the level of evidence (Figure 5-2). Moreover, this evidence can be synthesized into practice recommendations that are graded according to the strength of the supporting evidence. There are several scales for rating levels of evidence and grading recommendations.[11-16]

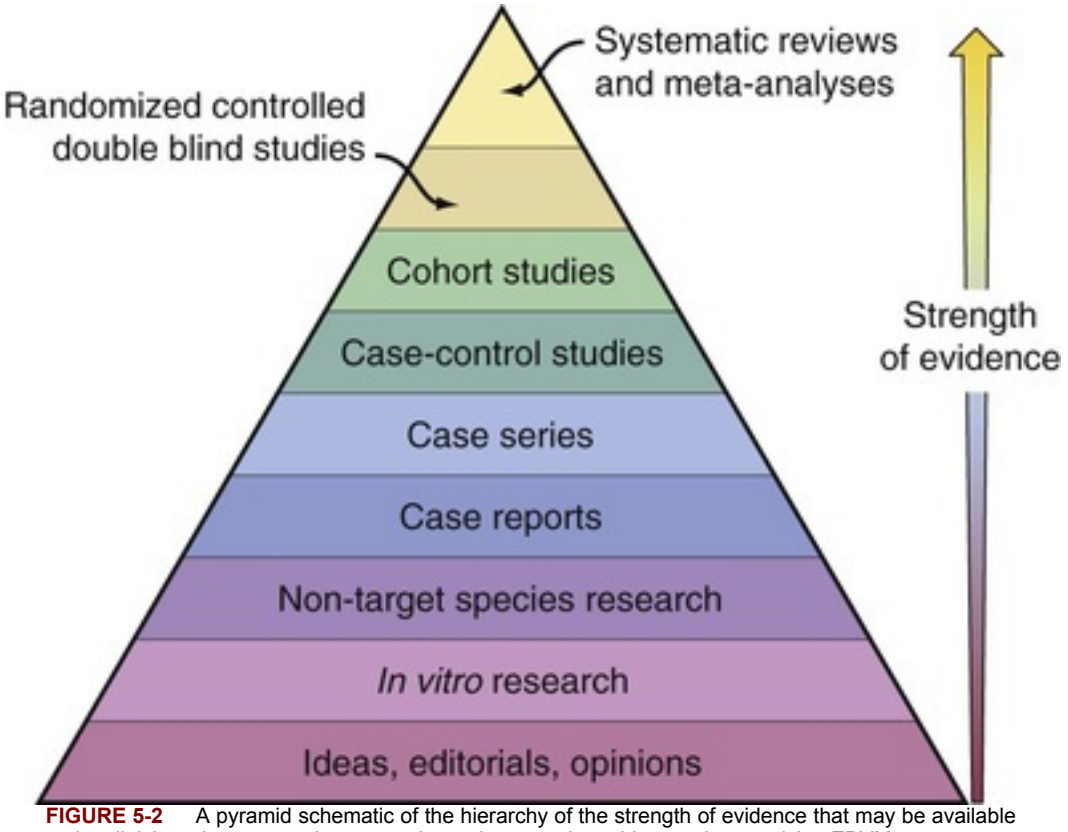

FIGURE 5-2 A pyramid schematic of the hierarchy of the strength of evidence that may be available to the clinician when attempting to acquire and assess the evidence when applying EBVM.

4. Return to the patient—Integrate that evidence with clinical expertise, client/patient needs and **apply** it to that patient in practice.
5. Evaluate your performance with this patient—Critically **assess** the outcome of that decision and the overall benefits to the client/patient.

The goal of EBVM is not to remove the experience of the clinician in treating his or her patients, but to improve clinical decision-making with stronger data. It provides a formal method to generate information that has less bias or error and it can greatly facilitate better clinical decision-making. However, EBVM takes effort and commitment from the clinician. One must learn and be vested in the process as well as the effort needed to complete the search for evidence. Despite the success of EBVM over the last two decades, there

remains wide variation in the implementation of EBVM among clinicians. Additionally, confusion about what EBVM is has led to disagreement, disillusion, and dissent among veterinarians.[5] Many references discuss and reflect on this discord and Table 5-1 outlines some of the misunderstandings and controversies about EBVM.[17-19] Certainly, there are several issues that have slowed the expansion of EBVM, including education on its use by clinicians and the limited student exposure at teaching institutions.[17,20] Yet as progress is made and client/patient outcomes improve through the systematic collation, synthesis, and application of the highest quality evidence available, EBVM will become a potent tool for the primary care veterinarian.

TABLE 5-1

Evidence-Based Veterinary Medicine Issues

OPPONENTS	PROPONENTS
EBVM is "old hat." Clinicians have been using the literature to guide their decisions for a long time. Only the label is new.	The new focus on EBVM "formalizes" that "old hat" process and filters the literature so that decisions are made based on "strongest" evidence available.
EBVM is "cook book medicine." It suggests that decisions are based solely on the evidence, removing or down playing sound clinical judgment.	EBVM should be one part of the process. Decisions must be blended with individual clinical expertise, client/patient needs and when available good evidence.
EBVM is the mindless application of population studies to the treatment of the individual. It takes the results of studies of large groups of animals and tries to apply them to individuals who may have unique circumstances or characteristics, not found in the study groups.	The last step in the EBVM process is to decide whether or not the information and results are applicable to your patient and to discuss the results with the client.
Often there is no randomized controlled trial or "gold standard" in the literature to address the clinical question.	Clinicians might consider the "evidence pyramid" and look for the next best level of evidence. Clinicians need to understand that there may be no good evidence to support clinical judgment.
There is often great difficulty in getting access to the evidence and in conducting effective searches to identify the best evidence.	Tools and information exist to teach clinicians effective searching skills. Additionally there are now reference sites that have already conducted much of the research to give clinicians the information they desire.

CHAPTER 6

Biomedical Statistics

Selected Topics

Philip H. Kass

Science exists as a disciplined, systematic methodology for investigating and understanding the complex world in which we live. The scientific method is, in turn, the series of progressions used for generating knowledge through experimental and nonexperimental inquiries. Central to this method is the postulation of scientific hypotheses for formulating predictions about populations, although they must be falsifiable to be testable. Null hypotheses are examples of falsifiable hypotheses: they typically (but not always) specify the absence of differences, effects, or relationships between comparison groups. Studies in turn generate empirical findings used for testing null hypotheses under certain model assumptions: evidence (data) contravening the veracity of the null hypothesis may be persuasive enough to convince an investigator to seek an alternative explanation and advance a new hypothesis, again subject to later potential refutation.

Hypothesis Testing

Statistical inference is a formalization of the process by which data are reconciled with hypotheses. Under a specified probabilistic model (sampling distribution) framework, it becomes possible to estimate the probability (*P*-value) of obtaining findings that are as much, or more, in conflict with the null hypothesis than findings that would be expected under it. It is important to understand that although ubiquitously reported, the *P*-value is only correct insofar as the model assumptions are correct as well. One common assumption is that population data arise from a normal distribution; another is that individuals are randomized to distinct treatment groups. Small *P*-values therefore do not necessarily correspond to an improbable null hypothesis—they can instead result from one or more erroneous model assumptions, or arise even by chance. Conversely, large *P*-values do not necessarily provide affirmative support for a null hypothesis: the study sample size could have been inadequate for a given contrast (e.g., a difference or effect) between groups, the measure contrasting the groups could have been too small given the sample size, or the model assumptions may be fallacious. Just as important to recognize is that low *P*-values may have no relationship with practical or medical importance, and high *P*-values may mask potentially important findings.

It is sufficient when hypothesis testing to report the model-generated *P*-value. However, it has become common, although far less desirable, to present findings as either $P > 0.05$ or $P \leq 0.05$. The similarly ubiquitous use of statistical "significance" as a proxy for employing $P = 0.05$ as a bright line of demarcation for decision-making is equally undesirable because it reduces a continuous probability distribution from {0 to 1} into two mutually exclusive categories, and attaches a meaning almost effortlessly misconstrued: that "significance" refers to "important" or "real difference," and that "non-significance" corresponds to "unimportant" or "no difference." While firmly ensconced perhaps by no more than habit and rote teaching in the medical literature, its extirpation would come as no loss to readers.

Variability

Intrinsic to hypothesis testing is the measurement of variability in data. The most commonly used (and taught) method of measuring dispersion of observed data is the calculation of sample variance or its square root, the standard deviation. Of the two, the latter is typically preferred for reporting in descriptive studies because it is in the same measurement unit as the reported center of the data distribution (typically the sample mean). A related measure of dispersion, but on an actual calculated statistic instead of observed data, is the standard error. This quantifies the precision surrounding a statistic, such as a sample mean, a

proportion, an odds ratio, and so on (it is, in reality, the standard deviation of the sampling distribution of the statistic). Because the standard error is inversely related to sample size, then usually the larger the study, the more precisely statistics from it can be estimated. Variability of a statistic that cannot be explained by known factors influencing it is known as "random error." While massively large studies have been promoted as scientifically definitive because of their extreme statistical precision, in isolation this is illogical because of another important source of study error.

Validity

When a statistic from a study fails to capture what an investigator is trying to estimate in a population, the statistic is designated as biased. This can arise from a myriad of causes: comparing groups that, if treated exactly the same, would nevertheless have different outcome measurements (confounding bias); selecting or retaining individuals for a study in a way that renders comparisons invalid (selection bias); using incorrect diagnostic or measurement instruments (information bias); and performing improper statistical analyses (specification bias). Such biases, also known as systematic errors, can be present in any sized study; importantly, a large study is no guarantee of the absence of bias, even when random error is negligible or ignorable. Sometimes, the biases introduced in study design or implementation can be rectified in statistical analyses, although these normally require complicated multivariate techniques.

Sample Size and Power

Every inferential study is designed to test one or more hypotheses; with the intent of trying to reject the null form of at least one considered of primary importance, an investigator must enroll a requisite number of individuals to have a reasonable probability of accomplishing this goal. It is a common error for investigators to believe that there is a universal minimum sample size for clinical studies; in reality, every hypothesis test requires a dedicated sample size calculation. Because many studies investigate multiple, and perhaps many, hypotheses (especially those studying potential causal associations between putative risk factors and health outcomes), it is common for an investigator to focus on one or a few key hypotheses, and design a study around testing those. Sample size calculations are intimately related to the principles of hypothesis testing, and are essential in grant and internal review board applications to justify the number of individuals sufficient to find contrasts statistically "significant." Invariably, a sample size calculation requires the specification of a level of significance (alpha), which is the chosen *P*-value below which significance is found (conventionally, if not reflexively, $P = 0.05$ is used), and a level of statistical power (1-beta) that corresponds to the probability of rejecting the null hypothesis when it does not accurately reflect the truth. Ancillary information required for a sample size calculation depends on the statistical test to be used for hypothesis testing. For example, comparing differences in proportions between two groups requires specifying the two proportions the investigator deems worthy of finding significantly different (Figure 6-1). Web-based interactive sample size software is readily available for many kinds of hypothesis tests (e.g., http://www.epibiostat.ucsf.edu/biostat/sampsize.html and http://powerandsamplesize.com).

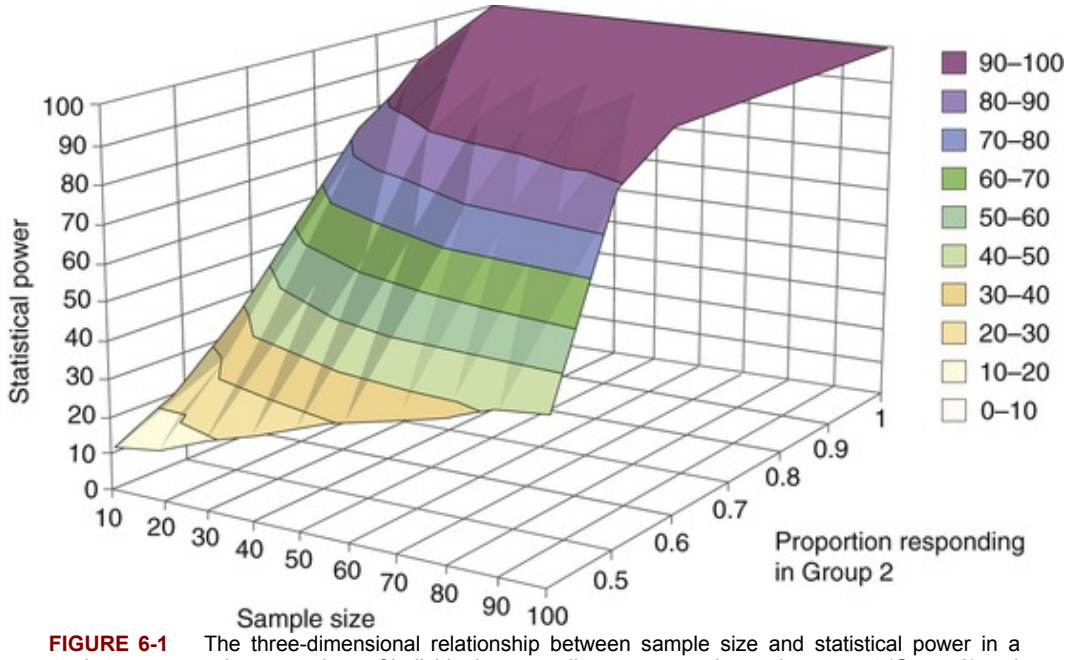

FIGURE 6-1 The three-dimensional relationship between sample size and statistical power in a study to compare the proportions of individuals responding to an experimental treatment (Group 2) and a control treatment (Group 1). The example assumes the proportion of individuals responding to a control treatment in Group 1 is 0.3, and the Type I error probability is 0.05. As the difference in proportions gets larger, statistical power increases because it becomes easier, for a fixed sample size, to find larger differences significant than smaller differences. As the sample size gets larger, statistical power also increases for any fixed difference in proportions.

Another common misunderstanding arises when a study fails to find a statistically significant contrast, and an author is asked to provide the "study power." Such a request is unjustified on two counts. First, as noted above, there is no single "study power"—every null hypothesis has a unique probability of being rejected or not, depending on the factors noted earlier (including sample size). Second, there is no logical reason to perform post-study power calculations because if a hypothesis test was not rejected, by definition the study had insufficient power to reject it, rendering the request tautologous. At best, it could be argued in response that given the magnitude of the contrasts found in a study, a more relevant question would be what sample size should be required in future studies to find such contrasts statistically significant.

Experimental Studies

Controlled clinical research can be broadly divided into experimental and nonexperimental studies, which are distinguished by whether factors of interest, such as treatments, are under the control of the investigator. Both kinds of studies have distinctive advantages (and disadvantages), but it is generally accepted that controlled studies of risk factors of diseases in companion animals are usually nonexperimental, and studies of the effects of interventions or treatments on physiologic responses (including recovery or survival) ideally are experimental. Exceptions to these rules are controversial and should be avoided.

Crossover studies are the most common controlled experimental studies performed in healthy animals, and frequently are used for comparing responses to different treatments (and sometimes dosages within treatments). By doing such studies within rather than between subjects, validity issues arising from endogenous factors that could affect study outcome are obviated because the factors are held constant. This advantage over randomized studies comes at a cost, however, as two critical assumptions must be met. First, the effect of successive treatments must be independent of the effect(s) of earlier treatment(s); i.e., absence of a "carryover" effect. This is often addressed by allowing an appropriate time ("washout") interval between treatments that allows an individual's response to return to a baseline state, and the assumption can be evaluated (though not proven) by comparing baseline (prior to treatment administration) outcome measurements prior to introducing each new treatment. Implicit in this assumption is that the order of treatments should have no effect on outcome. Second, there must be no effect of time on the outcome measurement that operates independently of treatment. Therefore, this study design is best suited to experimental interventions that have rapid onset of effects with transient durations.

The most common controlled experimental studies in companion animal patients are randomized clinical

trials, in which individuals are randomly assigned to different treatments. These studies have superior properties with respect to prevention of confounding bias compared to non-experimental studies because the probability of non-comparability between groups becomes smaller as the number of enrolled individuals increases. Randomization is a constellation of allocation approaches designed to ensure that individuals have equal probabilities of being assigned to a treatment or intervention. The most common approach utilizes random number generation to determine individual-level allocation, and can be modified through stratification (e.g., done separately for females and males or within age categories) and blocking (e.g., performed within non-overlapping sub-intervals of time under study) to ensure that an adequate number of individuals within all covariate categories receive all treatments. However, randomization itself does not guarantee the absence of confounding, especially in small studies prone to random group imbalances in factors affecting outcomes. Although it is common to see groups statistically compared for reassurance of the "success" of randomization with respect to equal distribution of baseline characteristics (age, breed, sex, weight, etc.) or physiologic values, such tests are misleading because of their dependence on sample sizes, and so should not be used for making conclusions about comparability (which can later be addressed as part of a multivariate data analysis). That said, an important advantage of such experimental studies is that the statistical methods used for analyzing them assume randomization of treatment (and other factors, including those unmeasured or unmeasurable), which allows correct estimation of standard deviations, standard errors, and *P*-values even in the presence of confounding.

Intention-to-Treat

The practice of conducting clinical research on patients, especially longitudinally, can be fraught with problems that almost invariably arise, as experienced investigators will attest. Foremost among these is missing data, which transpires for design deviations that include failure of collection, sample mishandling or loss, measurement instrument failure, patient loss to follow-up, and noncompliance (non-adherence) with study protocols. A steadfast design rule prescribing analysis of clinical trial data and recognized by governmental grant agencies is the "intention-to-treat" (ITT) principle: that all randomized study subjects remain members of the treatment group to which they were assigned regardless of what transpires following commencement of the study. All data (regardless of integrity) are retained for analysis, and all individuals are included regardless of whether they successfully complete the study or not (regardless of reason for withdrawal). Underlying this conservative approach is the recognition that violations of study design and protocol that arise in a controlled experimental setting are also likely to arise in clinical (i.e., non-experimental) settings.

An additional analytic strategy that can be used in a supportive role to ITT analyses is the "per-protocol" (PP) or "efficacy subset" approach, which involves willfully excluding patients and observable patient information from the analysis because of flawed or incomplete information obtained during study implementation or after completion. This leads to including only the subset of the original ITT patients to whom the intervention is effectively administered and who remain compliant with protocols. Although this less conservative approach has intuitive appeal, it involves restricting the population eligible for analysis only after study commencement, so the validity advantages intrinsic to randomization are therefore lost with this approach. Concordant results between ITT and PP analyses provide supportive evidence that the protocol violations were unlikely to meaningfully affect the study conclusions.

Confounding by Indication

While randomized clinical trials remain the standard of practice for comparing treatments in patients, nonrandomized approaches (particularly retrospective cohort studies) have been used with hospital-based data to accomplish the same objective. This practice should be strongly discouraged because a clinician's deliberate choice of a treatment can never be assumed to be unrelated to disease severity or patient prognosis. The bias arising from the almost certain differences between groups of patients receiving optional treatments in the absence of random allocation is known as "confounding by indication." Although such retrospective studies may have some value for hypothesis generation, potentially leading to future experimental studies of treatment efficacy, even with statistical control of prognostic indicators their conclusions must be regarded as suspect until confirmed (or refuted) by more appropriate study designs.

Statistical Methods

Scientific hypotheses not only guide the choice of study design, but also the election of the type of data

collected for analysis. Measurements can take on one of several forms that help determine the appropriate analytic approach. These include categorical data that can be subdivided into nominal categories (no natural ordering), ordinal categories (naturally ordered but unequally spaced), interval categories (naturally ordered and equally spaced), and quantitative data that exist on a continuum. Causal hypotheses further allow the dichotomization of "causes" and "effects," which have a direct correspondence with explanatory variables (also called predictors, covariates, and independent variables), and outcome variables (also called dependent variables), respectively. The type of explanatory and outcome data will in turn determine the appropriate statistical test to use. A non-exhaustive assemblage of the most common statistical approaches used in biomedical research is contained in Table 6-1. Software to perform these tests is readily available without requiring programming experience. However, there are several recurrent issues that arise in statistical testing that are important to understand prior to undertaking the actual analyses.

TABLE 6-1

Recommended Statistical Test for Data Commonly Arising in Clinical Settings

OUTCOME DATA TYPE	OUTCOME GROUPING (IF APPLICABLE)	EXPLANATORY VARIABLES	NULL HYPOTHESIS (H_O)	RECOMMENDED STATISTICAL TEST
Continuous (independent data)		Two groups	Means are equal	Student's two-group T-test
			Distributions of data are equal	Wilcoxon-Mann-Whitney test*
		Three or more nominal groups	Means are equal	Analysis of variance
			Distributions of data are equal	Kruskal-Wallis test*
		Three or more ordinal groups	No monotonic relationship	Spearman correlation*
			No ordinal (dose-response) relationship	Jonckheere-Terpstra test*
			No ordinal (dose-response) relationship	Nonparametric trend test*
		Continuous	No linear relationship	Pearson correlation
			No linear relationship	Linear regression
Continuous (time to outcome)	If outcome occurred or not (censored)	Groups	Times to event are equal	Kaplan-Meier survival analysis
		Continuous and/or groups	Times to event are equal	Cox proportional hazards regression
Continuous (correlated data)		Two groups	Paired differences are zero	Paired T-test
			Distributions of paired differences are equal	Wilcoxon signed-rank test*
		Three or more groups	Means are equal	Repeated measures analysis of variance
			Means are equal	Mixed effects analysis of variance
			Distributions of data in matched groups are equal	Friedman test*
		Continuous	No linear relationship	Mixed effects linear regression
Categorical (independent data)	Two groups	Two groups	Proportions are equal	Fisher's exact test*
		Three or more nominal groups	Row and column variables are independent	Pearson chi-square test*
			Row and column variables are independent	Fisher-Freeman-Halton test*

		Three or more ordinal groups	Distributions of data are equal	Kruskal-Wallis test*
		Continuous and/or groups	No association with binary outcome	Logistic regression
	Three or more nominal groups	Two or more nominal groups	Row and column variables are independent	Pearson chi-square test*
		Three or more ordinal groups	Distributions of data are equal	Kruskal-Wallis test*
	Three or more ordinal groups	Two groups	Distributions of data are equal	Wilcoxon-Mann-Whitney test*
		Three or more nominal groups	Distributions of data are equal	Kruskal-Wallis test*
		Three or more ordinal groups	No ordinal (dose-response) relationship	Jonckheere-Terpstra test*

*Indicates a distribution-free test.

Multiple Comparison Adjustment

In every instance where a hypothesis test is performed, an investigator risks making a mistake when calling a finding "statistically significant" and rejecting a correct null hypothesis. When the null hypothesis is in fact correct, this error will occur approximately one out of 20 times when the level of significance is conventionally set to 0.05. Each time a test is performed, however, another opportunity to make mistakes arises, and when many tests are performed, making at least one mistake becomes probable (note that there is an analogy to defining multiple test results as abnormal in chemistry and hematology panels). To lessen the frequency of such errors, the level of significance (alpha) may be divided by the number of tests performed (n), making rejection of a single null hypothesis less likely. This correction, where alpha* = alpha/n, is known as a *Bonferroni adjustment*. For example, if five tests are performed, in order to keep the overall error percent at 0.05, each test should have its own alpha* of 0.01.

Assumption of a Normal Distribution

Many familiar tests assume that data from discrete populations arise from a normal distribution. This holds, for example, within groups compared using Student's two-group T-test and on the differences within pairs using paired T-tests, and can be assessed using normality tests found in software (e.g., Shapiro-Wilk test). For more complex methods, such as analysis of variance and linear regression, the normality assumption applies to model-based "residuals" (observed minus predicted values), and not the dependent variable. Regression diagnostics on the residuals are also available in software to assess this assumption and goodness of statistical model fit.

Small Sample Sizes

When the number of observations is small, tests for normality have low power to detect non-normal distributions, so non-significance should not be interpreted as verification of normality. If investigators either have no *a priori* knowledge that population-based data follow a normal distribution, or have *a priori* belief that the data are non-normal, then analyses relying on statistical tests that do not assume an underlying distributional structure should be employed instead. Such distribution-free tests are collectively called "non-parametric tests" and are noted in Table 6-1. These tests perform nearly as well as other tests that assume normality when sample data arise from a population with normally distributed data, and have superior properties when data are not normally distributed. They are also the methods of choice for analysis of categorical outcome and contingency table data.

CHAPTER 7

Euthanasia

W. Douglas Kunz, Stephen J. Ettinger

As veterinarians, we are very fortunate to be advocates for the well-being of our patients from their first visit to the end-of-life considerations. When we recommend a diagnostic procedure, a surgery, or medication, we are acting for the well-being of the animal under our care. At times, we also must be advocates for the humane demise of our patients. This is a unique position for practitioners of the healing arts. It provides us with certain rights and obligations that no other health care professional has. This is something we as veterinarians deal with daily. Euthanasia takes a toll on our staff and us. This should not be ignored nor should the responsibility of making appropriate decisions regarding euthanasia be dealt with lightly.

We are presented with the request to euthanize a beloved pet for a variety of reasons. These reasons can vary from deterioration of the quality of life to the point that euthanasia is a kind relief from suffering to the cast off pet whose owner is unwilling or unable to find another home for it. Whereas the former is a much easier process for the practice team, as all know that a compassionate service is being performed, the latter can be very difficult because we are in fact being asked to kill a healthy pet. Of course, there are numerous other reasons for euthanasia, such as a severely injured or ill pet whose owner does not have the financial resources for treatment, the pet that has severe, irresolvable behavioral problems, or a puppy born with birth defects that the owner is unwilling to treat or which may not be amenable to intervention. Some veterinarians are asked to provide euthanasia services to a local animal shelter,[1] resulting in a situation that poses other unique considerations.

We also do not know all of the circumstances leading up to the decision on the part of the owner to ask that their pet be put to sleep. Occasionally, the difficult task of euthanasia is requested because the pet is a burden to the owner, affecting the mental and/or physical health of that person or because the owner may have passed away and there is no one to care for the pet that may have some very special needs. The number of excuses, reasons, and simply requests made of the veterinarian for such services seems to grow exponentially daily.

In the course of treating pets, it sometimes becomes necessary to gently suggest to an owner that the time has come for them to consider releasing their beloved pet from a circumstance that no longer provides significant quality of life. Not infrequently, the client will acknowledge this suggestion and indicate that he/she too was thinking this might be appropriate but was afraid the veterinarian would not agree. This has important repercussions upon the ongoing doctor-client relationship. Before such a step is undertaken, it is important to consider the situation. We must be certain that the care the veterinarian is providing is in fact all that is available or requested. Under such circumstances, a second opinion consultation or a referral to a specialist may be in order. It is clearly important to recognize this in advance because the decision to euthanize is not one easily taken and one that is often not forgotten by the client, but rather dwelled upon in some detail. If the client feels that the veterinarian did not judiciously use all of the available resources in his/her community to help this pet, very negative feelings may develop. This could affect the client and the client's decision to return at a later date with another pet. Further, making such a recommendation without consideration of other options also leaves the veterinarian open to question by the client. Should the client decide that this is not the right course and then seek independent review of the case, there can be more serious problems if the animal is subsequently successfully treated after the first veterinarian recommends euthanasia. The veterinarian must recognize, too, what is considered the standard of care for such a problem in that area.

The discussion of euthanasia involves four key factors[2]:

1. Clear communication of the pet's conditions.
2. Assessing the client's feelings and desires, and empathizing with them.
3. Explanation of the process and options associated with euthanasia.

4. Giving grief support and providing outside support resources.

If a pet's condition has deteriorated to the point where the quality of life is poor, how can we best communicate this to the owner? Honest communication describing the professional assessment helps provide the basis for client decision-making. Such a conversation may go as follows: "Robert, Fluffy's heart failure has progressed to a point that medication is no longer effective in maintaining his quality of life. His lungs are being compressed by fluid so that he can't obtain sufficient oxygen for the body to function properly. This is why he is reluctant to lie down." A similar discussion could take place with any medical condition that has impaired the quality of life to the point of suggesting euthanasia. There are schemes[2] to assess the quality of life, but it always is a judgment call based on our knowledge and experience as practitioners of veterinary medicine. Some clients respond immediately and clearly that such an option is not something to be considered. If so, note this directly in the record and proceed with caring for the patient as the owner requests. Decision-making, especially when the veterinarian differs in opinion from the owner, is very difficult. However, it is the choice of the owner and not the veterinarian. Assuming all professional efforts are made to help the pet, then the veterinarian has the responsibility to provide humane care and comfort as best as possible for the pet and the owner. Second opinion referral may also be advisable.

Every client has a different thought process about his or her pet's quality of life. Part of our job is to support the owner's choice.

Reassurance to the client at this point is helpful. Often, agreeing with the client will help. Many clients suggest that the pet is going to heaven, to be with another past pet, to go where things are better. This is not the time or place to differ with the hopes and desires of the owner. It is their pet, their belief system, and their decision. The veterinarian should not be the decision-maker. Often, even suggesting a time period for treatment, say "another day or two to see if this medication will help before we make this difficult choice," may be enough. At times, the client will then ask if it really will make any difference and this can be a time for the veterinarian to offer his/her opinion. Another request that may occur in the office or on the telephone is requesting that euthanasia services be provided at the client's home (see below for a discussion on home euthanasia).

The process of euthanasia in the clinic should be explained along with the option for the client to be present or not. The discussion should include how the client wishes the pet's remains to be handled. Private cremation or burial is an option. In many larger cities, when disposal is requested, it may mean rendering of the body. While this is not something pleasant to discuss, the owner should not be told a lie but rather the facts must be presented. Fees for euthanasia (which can be substantial) and for the disposal of the body should be discussed. Client complaints in this area are not unusual, in part because this occurs during the grieving process and at this stage of the process the client may be angry at what is perceived to be high fees for something that is so unpleasant. It is here that one hears complaints about inappropriate fees, price gouging, or simply, "You are supposed to love pets, but you charged me so much more money than it should have been." Much of this is resolved by advanced discussion and payment. This also allows the client to leave the hospital without having to deal with payment when the bereavement process is so acute.

One area for discussion prior to euthanasia is whether children should participate or be in the room when this is taking place. Of course, ultimately it is the owner's choice; however, often owners will request the opinion of the veterinarian. Generally, our belief is that anyone who cares for the pet and wishes to view the procedure should be there. Occasionally, one of the adults will stay and one will leave, again a personal option. Sometimes the client will ask only to see the pet momentarily after the euthanasia is completed. With respect to the children, we recommend that children too young to really understand the process not be permitted to view the procedure because it may frighten them or make them leery of anything given to them by injection at some later date. On the other hand, young children who love and know their pet, who understand what is happening, and who wish to be with their pet and their parents should be acknowledged and given the privilege of viewing the process and being with their pet. Lying to children about this process is not recommended, and we as veterinarians should not participate in extending an untruth told to them. We want them to understand suffering, humane care, and the role the veterinarian plays in the important human-animal bond process.

If the pet is to be euthanized during the office visit, dealing with the charges and payment should be handled with sensitivity. A possible scenario might be, "While we take Fluffy away for a few minutes to place a catheter in his vein, my nurse has a form for you to sign and she will take care of your bill with you so that you won't have to stop at the desk after we put Fluffy to sleep." If euthanasia will take place at a future visit, fees should be collected prior to entering the exam room on the day of euthanasia. Some[2] have suggested that a dedicated room with soft lighting, candles, and flowers be used for euthanasia. The reality is that in many clinics cramped for space this is not possible. Some method should be in place for alerting staff that a

euthanasia is taking place so that a solemn and sensitive environment is created toward not only the pet's owner and family, but also toward other clients who may be aware of what is to take place. Try to have the staff prepared for the euthanasia and avoid loud noises or laughter on the part of the other hospital personnel when such a serious procedure is being attended to. Often, this simple process is not recognized and causes discontent on the part of the pet's owner. More often, the soft, compassionate staff expressing their true feelings to the client helps to assuage guilt and sadness and allows the process to move along smoothly. If at all possible, set aside a more quiet time of the day for the client to come for this service. It provides the client with a quieter atmosphere and one that is less hectic. If this is anticipated to be a difficult and long, drawn-out process, do not schedule it for the end of the day, when closing the clinic interferes with the client remaining with the patient. Some clients will stay for significant periods of time, causing havoc with the hospital's staff.

The process of the euthanasia itself can be very moving and comforting to the owner if properly prepared. In virtually every case where the client wishes to see and be with the pet, an intravenous catheter should be placed first. Always have saline-filled syringes to check on the patency of the catheter even if it was just placed. Explain to the owner the actual process that you choose to use. Some veterinarians prefer only to use euthanasia solution, others administer the solution after a short acting anesthetic is given, and others prefer to give diazepam or another tranquilizer first to lessen any impact that the pentobarbital solution will have on the central nervous system. The important thing is to explain in detail what will happen, to have an assistant in the room to help hold the pet, and, if the owner wishes to hold the pet as well, to allow them to do so without hampering the process of injecting the euthanasia solution. Infusions, given slowly and efficiently, help the process. Often the pet relaxes quickly, but the veterinarian should continue to administer all of the drugs and should not withhold medication assuming that the pet has died. Not at all unusual is for the pet to continue to breathe for another few moments or for the heart to continue beating. These bodily processes disturb the client and can make them feel distrustful. Some clients believe that veterinarians want to experiment on their pets, and they must be assured that the pet is really dead: that the heart has stopped beating, and that the respirations have ceased. Some clients (rarely) ask to listen with the stethoscope to assure themselves that the pet is dead, and if they do, it certainly behooves the veterinarian to allow that to happen without comment. We prefer at this time to speak softly to those in the room, offer them the opportunity for alone time with their pet, and to quietly leave the room.

Home euthanasia may be requested by the client and should be offered to the client if that is their preference. The veterinarian may not provide this service outside of the hospital and the regular veterinarian may refer the client to someone who does do house call services including euthanasia. Regardless, the consent of the owner should be obtained before any work has commenced. This allows the client to pay full attention to his or her pet and permits the veterinarian to proceed in a professional manner. Arrangements for euthanasia, handling of the remains of the body and other final considerations should be determined prior to taking any activity regarding the procedure. Explanation of what is the plan and how the pet will respond should be undertaken before beginning any drug administration. Collection of fees should be done prior to proceeding, since the owner may be too upset after euthanasia has occurred to consider or discuss fees. Papers that need to be signed should also be completed before proceeding with drug administration.

If the pet is a cat or smaller animal, it is best for the doctor to hold the animal for the initial subcutaneous injection so that the animal will not bite the owner who is likely to be hovering over the pet. Explain to the owner that they will have all the time they need to cuddle or stroke their pet once the sedative takes effect. Usually this occurs after 5-10 minutes and then the animal is in a deep plane of sedation and ready for the final injections. These are given SC, IV or via the intraperitoneal or intrathoracic route depending upon the drugs used, whether there is help available to the veterinarian and the patient's condition. If intravenous drugs are to be used, it is best to shave a small amount of hair at the site of the venous injection. Use of a good quick-release tourniquet is important if the final injection is to be given IV if there is no assistant to help hold off the vein. Every housecall veterinarian has his or her own special combination of drugs used for euthanasia. Frequently dexmedetomidine (Dexdomitor) at 3-5 mcg/kg or tiletamine-zolazepam (Telazol) at 3-5 mg/kg are utilized. Butorphanol may also be administered to provide deep sedation. After 5-10 minutes, when the pet is deeply unconscious, pentobarbital is administered to euthanize the pet.

After the procedure is completed, it is appropriate to express support and sympathy to the client. Ask if they would like a few moments alone with their deceased pet and, if so, withdraw. Explain once again that there may be some muscle twitching which is normal, a deep breath or final expiratory effort may be made, and as the muscles begin to relax the pet might even urinate. Explain that these are normal signs. Also, many owners expect the veterinarian to listen for heart sounds with a stethoscope—they see it daily on TV and in the movies and such a step may be comforting despite the fact that you know the pet died moments ago during the injection process. Some clients express concern that the eyes are not closed; they should be told

that this usually does not occur in people either (again, the TV and movie expectation). Everything should be done with respect for the client. A phone call a few days later to ask how the client is doing is appropriate, as is a sympathy card or a donation to any of the many foundations that accept donations on behalf of a deceased pet. One of our clinics (SE) has sent personalized letters to clients, always with a hand-written note on the letter. Clients return with another pet years later, often expressing the importance of the written note that was personalized.

If, on the follow-up phone call, the client is struggling to cope with the loss, it would be appropriate to refer the client to a grief counsellor. Be prepared by consulting with a local mental health care professional to know what resources are available in your community. If you have mental health care professionals whom you work with, be prepared to offer names to the client. We like to have both psychologists and psychiatrists on our lists and both men and women so that the client may also find comfort in choosing a health care professional. Lengthy discussions regarding the final days, health condition, or laboratory tests often occur with the client who remains unwilling to accept the loss of the pet. While it is more than appropriate to discuss these with the client, record such discussions in the medical record, and be prepared to assist the client in understanding the process. It is also important to recognize when the process goes beyond normal grief and requires professional help. Part of this process is offering to discuss the situation with the client. In the majority of cases this is all that is required. If more is required, be prepared to offer some help but do not allow lengthy discussions to occur if they remain unfruitful and offensive. Offering to continue discussions at a later date, providing written material on the disease process, or even allowing the client to come and review the radiographs and discuss the problem in the office can be helpful. One good method of helping the client is to offer to see them in the office on a no-charge appointment. Have the records, lab tests, and radiographs prepared. Ascertain that the client understands the time limit set for the appointment. Often explaining that your time has elapsed and that you do have another client waiting can make a good ending. Advise the client that if he/she feels that another appointment is necessary, your staff would assist them in making another appointment. Usually there should be a consultation fee for further visits.

Euthanasia can be a difficult time for the pet owner. If the veterinarian and staff are sensitive and caring throughout the process, long-term relationships through multiple pets' lives are often the result. It is of particular importance to help the client not feel guilty over their decision.[3] By implementing and practicing dialogs such as those described above and establishing procedures to empathetically deal with euthanasia, the client and the staff benefit. Role-playing at staff development meetings can be an aid to teach the skill needed for this difficult task. If the staff has been prepared and trained to provide this important service, the process will flow with compassion and professionalism.

One critical component of euthanasia is the method by which the office handles the disposition of the body. More clients are lost to other hospitals here than at any point in the process, other than the lack of professionalism and sensitivity on the part of the veterinarian and staff to the client. It is essential for the hospital to have a well-organized system for determining how the body is to be disposed of. Carefully identifying the body, the pet's name spelled properly, the owner's name spelled properly, and the choices of the owner are incredibly important. Methods for holding the body must also be considered. A hospital should have a time limit during which bodies can be held and the client must be informed of this. Have a limited number of options available to the client, carefully and repeatedly make certain that this is understood, and have the staff do the same with the owner. Then be certain that there is a hospital policy for who handles the body, how it is handled, and what is to become of it. Lost bodies that were intended for private burial and/or cremation cause untold havoc, anxiety, displeasure, and the loss of a client. Such problems simply should not occur when all of the arrangements for euthanasia have been made correctly, fees are discussed and received, and papers requesting euthanasia and handling of the remains of the body are completed in a well-organized facility. Every aspect of this process should also be clearly noted in the medical record and signed by the person acknowledging the decisions being made by the owner. Requests for euthanasia over the phone should be heard by a second member of the staff at the time the phone call occurs and both members of the staff should note this in the record and sign their names for legal purposes.

The process of euthanasia also impacts the veterinary staff. Patients that we have cared for over the years become special to us as well, and we may suffer their loss. Encourage the staff to discuss their feelings and express themselves. This can ward off burnout or compassion fatigue and build the regard for each other as well as team relationships.[4] Staff who have been especially close to the client, the pet, or the medical process may express personal feelings about being present at the time of euthanasia and if possible these feelings should be acknowledged. Similarly, allowing the staff to express their feelings to clients is a wonderful way to let the client know how much everyone cares. A condolence letter or card written by the doctor and the staff is a very important part of closure for all.

Euthanasia represents the end of what may have been a long relationship with a client and his or her pet. During this period, much has been shared in the lives of the family and the veterinary hospital. A good closure is really important to the client and the veterinarian. We were fortunate to have taken care of an important member of the family and to have shared in many experiences. Closure is helpful to all involved and often represents not only closure but also a new beginning. This may be veterinary medicine at its very best!

CHAPTER 8

"Ain't Doing Right": The Nonspecific Chief Concern of Ill Thrift

Stephen J. Ettinger, Edward C. Feldman, Etienne Côté

Ill thrift refers to a vague change in activity level, mental arousal, behavior, or some combination thereof. Often, it is difficult for clients (pet owners, caretakers, family members) to describe it clearly, and they simply can characterize the situation as "He's not himself" or "Ain't doing right" (ADR). Subjectively, it is a common reason for veterinary consultations and it can be caused by a disorder of essentially any organ system.

The hallmark of ill thrift is its nonspecific nature: instead of a discrete clinical sign like coughing or inappetence, ill thrift connotes a poorly defined decrease in vitality. A second characteristic is the wide variability in severity of the underlying cause. Ill thrift can be associated with trivial disorders requiring minimal treatment, or it can be the first manifestation of disorders that progress to life-threatening states. In some cases, it is further complicated by the nature of the concern, the client voicing his or her concern, and the reality of the situation. Usually, these are real concerns, but in other situations they are totally benign processes misidentified by a client with a heightened sense of anxiety. Regardless of the veterinarian's feelings about the concern, it should always be taken seriously and investigated in such a way that the patient's health concern is addressed correctly and the client is guided appropriately.

Virtually any disorder in veterinary internal medicine can cause ill thrift as its clinical expression. The goal of evaluating the patient with ill thrift is foremost to determine severity. When the underlying cause is benign and self-resolving, efforts can focus on exclusion of more serious disorders, on client reassurance, and on monitoring parameters and milestones. When the underlying cause seems likely to be persistently harmful to the patient, the veterinarian's efforts should focus on defining the extent of the problem and on more intensive and immediate intervention.

Since the range of possible diagnoses for ill thrift is vast, the first step necessarily should be a review of the patient's signalment and medical history.

Signalment

Signalment is an important general guide, beginning with the patient's *age*. Young animals are more likely to have ill thrift due to congenital malformations, parasitoses, or ingested foreign bodies or substances, for example. Conversely, mature dogs and cats have a higher prevalence of degenerative diseases and neoplasia. A patient's *somatotype* is important: large-breed dogs have a higher prevalence of osteosarcoma, splenic and cardiac neoplasia, and many other disorders. Small-breed dogs are overrepresented with respect to degenerative/myxomatous mitral valve disease, chronic pancreatitis, and others. Chondrodystrophic breeds have a higher prevalence of intervertebral disc disease, which can manifest with nonspecific signs that a client interprets as not feeling normal. *Gender* has an obvious link to the prevalence of reproductive disorders like pyometra and acute prostatitis, but also to certain disorders like immune-mediated polyarthritis, which has a higher prevalence in females. Any of these disorders first can manifest with vague signs of ill thrift. Importantly, these broad generalizations are nonspecific, and conclusions drawn from a patient's signalment must be kept loose and amenable to change because these guidelines, like the clinical algorithms included in most chapters of this textbook, offer the clinician a starting point and preliminary orientation.

Medical History

A detailed review of the medical history is the next important step. Experience suggests that ill thrift notoriously can trigger suspicions in a client's mind that can be unfounded, such as poisoning by a neighbor, or concerns about infectious disease outbreaks triggered by news headlines. These represent a client's

rationalization of observed signs within the limits of his or her understanding: the immediate environment, the animal's typical behavior, and increasingly, the most readily available information on the Internet. Such interpretations can be useful, or can be misleading, and a skilled veterinarian should consider the client's insistence and convictions with a suitable degree of internal skepticism. Just as importantly, key items of the history could be overlooked by the client and only become apparent on careful questioning. Therefore, the medical history should be explored in a way that is not leading or suggestive, to avoid miscommunication with clients, but in a way that also is thorough and insightful. See ch. 1.

Key aspects of the medical history in patients with ill thrift include:

- Frame of reference. A first-time pet owner might not be familiar with normal interindividual variations in energy and stamina among dogs or cats, whereas an experienced and astute client can identify important, subtle signs that are not even apparent to the veterinarian initially.
- Duration and course. The client should be asked when the pet last was normal, and how the general malaise evolved over time. Medically important ill thrift can be of any duration. If the condition seems to have continued without change for days to weeks or more, two important possibilities should be considered. A chronic disorder could be present, which could be producing obvious physical abnormalities (e.g., morbid obesity, severe osteoarthritis) that might not be as obvious to the client as to the veterinarian and the owner simply feels that the pet "ain't doing right." Alternatively, the client might be misinterpreting the animal's normal state as being abnormal. The latter possibility is more challenging to confirm and generally emerges as a diagnosis of exclusion after completion of diagnostic testing. An important third possibility is a disease that follows a waxing-waning course, and this information must be elicited during the collection of the medical history.
- Exposure, environment, and habits. An adult dog that has never been inquisitive and does not like to mouth objects is unlikely to have ill thrift from intestinal obstruction due to ingestion of a foreign body, for example. Similarly, an indoor cat is unlikely to be exposed to toxic substances that are found outdoors. The client's habits can be informative: dropped (human) medication tablets, missing sewing needles or thread, remodeling of an older home (lead poisoning), the possibility of outdoor exposures (spider bites, plant foreign bodies, encounters with wildlife), use or misuse of nutritional supplements and nontraditional diets and remedies, and a home with a garage (where the animal can have ingested ethylene glycol antifreeze) are examples of important clues.
- Vital functions. The veterinarian should ask about the pet's appetite, and ability to prehend and swallow food; about any changes in elimination of feces and urine; and about change in diet, including dietary indiscretion.

Physical Examination

Together, the findings from the signalment and medical history can allow the clinician to create an initial, often general, differential diagnosis list. In all cases, this information then is refined through interpretation of physical examination findings. The physical exam, which always begins with a hands-off observation of the animal's mentation and gait, is described in detail in ch. 2. The process, and the application of physical examination findings, is as relevant to patients with ill thrift as to patients with any general presenting concern, including a wellness examination.

Diagnostic Tests

Often, a conclusive diagnosis is not reached with signalment, history, and physical exam findings alone. Additional, objective information is available in the form of diagnostic test results. Diagnostic tests provide information on two levels: abnormal results suggest—or conclusively identify—the causative problem, whereas normal results increase the level of reassurance that a serious problem is less likely.

Test selection for patients with ill thrift can be considered according to whether the patient is considered a serious case or a nonserious case. *Serious cases* have one or more of the following characteristics: presence of overt systemic signs that suggest hypovolemia or hemodynamic instability (e.g., poor perfusion, weak/absent pulse, severe cardiac arrhythmia, evidence of dehydration), neurologic compromise (e.g., depressed mentation, locomotor deficits, generalized weakness), respiratory difficulty (e.g., dyspnea, inappropriate tachypnea), or persistent pain (e.g., change in mentation, subdued behavior, guarding). Obvious, externally visible abnormalities such as wounds or spontaneous hemorrhage of course can be evidence of serious disorders, but these specific findings lie outside the realm of ill thrift as a poorly defined, general state of malaise. *Nonserious cases* have none of the characteristics listed above. Specifically, nonserious cases have

normal (or, in the veterinarian's opinion, insignificantly abnormal) physical exam findings for all body systems, notably the cardiovascular, neurologic, and respiratory systems. When the distinction is unclear as to whether a patient is a serious or nonserious case, both the veterinarian's concern and the client's concern (and the client's logistical, financial, and emotional factors) are used for guiding the degree of diagnostic testing to be pursued.

In nonserious cases, basic tests are implemented according to the information obtained in the history and physical examination. A first tier of tests that applies to many situations includes a packed cell volume and total solids, blood glucose, estimation of blood urea nitrogen (e.g., Azostix), urine specific gravity, and a urine dipstick profile. Often, this information and much more can be obtained with the same blood and urine samples, and only a marginally higher cost to the client, via a complete blood count, serum biochemical profile, and complete urinalysis. Clients who make an appointment for their pet to be evaluated for nonspecific malaise should be encouraged to bring a sample of the pet's urine, collected at home in a clean and sealed container. Simple analysis can be performed prior to meeting the client and seeing the patient, which immediately informs the clinician of some important diagnoses (e.g., diabetes mellitus, renal concentrating capacity, various causes of discolored urine). A serum total thyroxine level can be considered for adult cats, and retroviral testing for all cats. A serologic titer for heartworm disease is warranted in endemic areas. Thoracic and/or abdominal radiographs have value if the signalment, history, and physical exam suggest a structural lesion in the thorax or abdomen as the leading differential diagnosis.

In serious cases, these same tests are indicated, and often are followed by a second tier of tests. These additional tests can investigate abnormalities found on the first tier of tests, or they can explore the most likely remaining differential diagnoses given the disorders that have been ruled out by normal results on the first tests. Importantly, serious cases are more likely to produce diagnostic test abnormalities that give a clear direction to the treatment that is necessary.

Depending on the context, including the client's ability and desire to monitor the animal at home, perceived importance of hospitalization for observation, cost of testing, and the client's history of similar situations with other pets, the client may wish to forgo any diagnostic testing and monitor the animal at home. In nonserious cases, such an approach is acceptable, and monitoring typically should involve client assessments of mentation, appetite, ambulation, respiration, digestion, water intake (which the client can measure at home if there is a concern about polydipsia; normal is <100 mL/kg/24 hours in dogs and cats, and usually <80 mL/kg/24 hours), and general responsiveness. Persistent abnormality or worsening of any of these parameters warrants reevaluation and diagnostic testing. The veterinarian should explain to the client both the advantages and the drawbacks of not pursuing testing initially if this direction is chosen. The explanation should be informative without eliciting a sense of guilt in the client, nor the perception of the veterinarian trying to force the client to commit to testing. Importantly, the veterinarian needs to outline how he or she expects the patient's situation to evolve if the problem is self-resolving versus how it is expected to evolve if the problem is worsening. This type of explanation helps the client feel the veterinarian cares, and it empowers the client to pursue tests and treatment with the veterinarian if deterioration occurs, rather than being left with the impression that the veterinarian lost interest because the full array of tests was not pursued. A useful option is to give the client a sheet of paper on hospital letterhead and a broad, written plan, e.g., (1) Exam and history; (2) Blood panel; (3) If not better in 7 days or worse anytime, radiographs (X-rays); (4) If no answers and the problem persists, ultrasound/referral/other; etc. This gives the client a continuum of what could be necessary and the client may then ask for all of it to be done or none of it. A copy in the medical record is useful for continuity if colleagues care for the animal later, and for medicolegal purposes. A follow-up phone call from a staff member in 24-48 hours helps the client understand that the veterinarian cares, and provides early troubleshooting if the problem is worsening.

In serious cases, if the client declines diagnostic testing, the veterinarian needs to provide monitoring guidelines that include indicators of suffering; describe risks that could be posed to the client, including zoonosis, bite wound injuries, and the like, where applicable; and provide recommendations for supportive care.

Treatment

Treatment of patients with ill thrift depends on the inciting cause. When none is found, supportive care can be provided, either by the veterinarian and his or her staff in the hospital or by the client at home. Treatment might need to be implemented sooner, or the patient might be more likely to require hospitalization, in serious compared to nonserious cases.

Ill Thrift That is Not a Sign of Disease

An important element that helps differentiate medically serious from medically nonserious cases of ill thrift is background information that could be affecting the client's perception of the animal's quality of life. The recent loss of another pet or other member of the family, recent illness in the family, forthcoming travel where the pet is being left behind, and other sources of anxiety, tension, and guilt can trigger a heightened level of concern and unjustly raise the perception of ill thrift. This is a common situation in small animal practice and it must neither be overapplied nor discounted too quickly. Without being intrusive, the veterinarian should be mindful of the critical role of these types of circumstances and assess whether the intensity of the client's response might place "overinterpretation of normal signs" on the differential diagnosis, rather than a true medical disorder. "Client overinterpretation," then, becomes a diagnosis of exclusion. A complete physical examination and evaluation according to the serious/nonserious approach described above can identify important problems when they are present, or can be reassuring to the client when results are within normal limits. Follow-up, both to identify emerging disease and to create an atmosphere of support for a concerned client, becomes especially important in this context.

Another example of "relative" ill thrift that can reflect normal variation is the natural decrease in spontaneous activity often associated with aging in an animal with no historical or physical abnormalities to indicate cognitive dysfunction, neurologic disease, or other internal disorder. Often, a client compares a pet to its former self, or to a fellow animal, and identifies "ill thrift" not associated with any existing or emerging disease. Such situations simply can reflect normal maturation and its associated behavioral and physical changes that remain within normal limits. If no abnormalities are present on physical exam or diagnostic tests, or if abnormalities emerge that are considered too mild to explain the client's concern, then having the client videorecord the clinical signs when they occur can be valuable, as can specific laboratory testing guided by the features of the history and physical exam.

Resolution

Follow-through for patients who "ain't doing right" is important. Nonserious cases that fully respond to nonspecific treatment or whose clinical signs simply normalize with time still should be addressed. Veterinarians should request that the client communicate an update to the veterinary hospital staff. Such feedback then needs to be entered in the animal's medical record. This way, the client understands that the veterinarian cares about the patient's outcome and the client bears some of the responsibility for communicating with the veterinary hospital after discharge. Cases that worsen at home instead of improving, or serious cases that are discharged, should be followed more closely, with telephone updates and return visits for reevaluation as dictated by the patient's signs, response to treatment, and perceived severity of the underlying problem. Typically, such deterioration also triggers the emergence of new physical signs that can be more specific, leading to additional diagnostic testing, treatment, and/or referral to a specialist.

CHAPTER 9

Distinguishing Behavioral Disorders from Medical Disorders

Diane Frank

Client Information Sheet: Distinguishing Behavioral Disorders from Medical Disorders

Introduction

Distinguishing behavioral disorders from medical disorders can be challenging. Owners will often report that their animal is ill because of behavioral changes.[1] Behavioral "problems" of animals can be subdivided into undesirable normal behaviors (species-appropriate behaviors that humans dislike) or undesirable abnormal behaviors (behavioral disorder, behavioral illness) (Figure 9-1). *Behavioral disorders* typically have one or several of the following characteristics: (1) the behavior is inappropriate for the context (i.e., one cannot justify the behavior in that situation); (2) the behavioral sequence is altered; (3) the frequency is excessive for the context; (4) the severity and/or duration is excessive for the context; (5) the animal exhibits signs compatible with anxiety in one or several contexts.

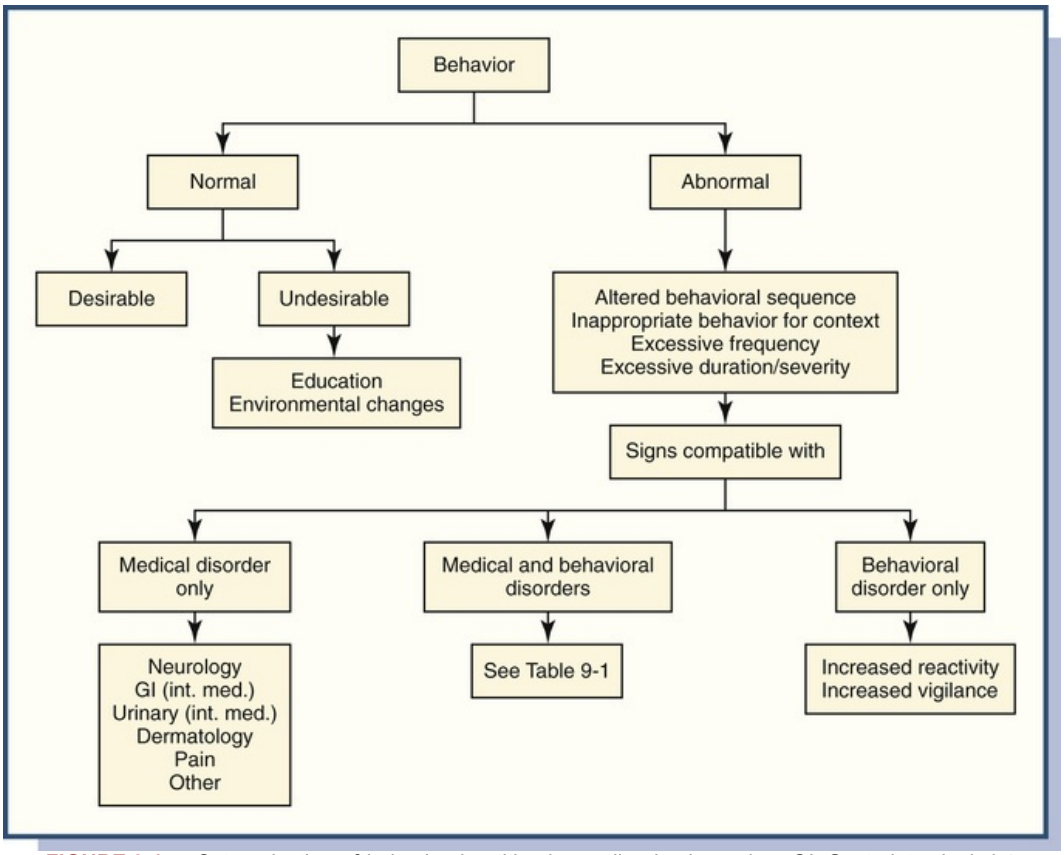

FIGURE 9-1 Categorization of behavioral entities in small animal practice. *GI,* Gastrointestinal; *int. med.,* internal medicine.

Medical disorders or *painful conditions* can have one or several of the following: inappropriate behaviors for the context, altered behavioral sequences, increased frequency and/or duration of behaviors. For example, a dog with a brain tumor could be presented for veterinary care due to sudden-onset aggressive behavior that is not appropriate for the context; a dog or cat that self-mutilates because of pain will have an altered behavior sequence because the animal does not stop the chewing/biting behavior and eventually causes self-injury; and a pruritic cat or dog will lick or groom itself more frequently or for longer periods than normal.

Therefore, certain changes in behavior are nonspecific. Other behavioral changes that can be associated with either medical or behavioral disorders could include appearance of a new behavior (e.g., hiding) or disappearance of a normal behavior (e.g., no longer playing), inappropriate behavior (e.g., aggression "out of the blue"), and changes in frequency and/or duration of normal behaviors.

Truly behavioral disorders ("mental illness") could therefore be defined as behaviors that are inappropriate for the context, have an altered sequence, are excessive in duration and/or frequency, occur in the absence of other identifiable medical disorders, or some combination of these features. It is important to remember that comorbidity of medical and behavioral disorders also occurs, perhaps more often than recognized.

In addition to this overlap of signs for medical and behavioral disorders, many terms used in behavioral medicine as diagnoses are in fact nonspecific signs. Examples could include urine marking, inappropriate elimination, and all of the repetitive behaviors (also called "obsessive compulsive disorders" or "compulsive disorders"), including but not limited to pica, fly-biting, circling, and tail chasing. And finally, signs compatible with anxiety overlap with signs of pain, discomfort or medical conditions.[2] Some examples (Table 9-1) could include restlessness, pacing, vocalizing, panting, licking lips, and repetitive swallowing.

TABLE 9-1

Anxiety Signs Compatible with Behavioral Disorders, Medical Disorders, or Concurrent Medical and Behavioral Disorders

Wandering	✓	✓	✓	Neuro

*Increased reactivity includes signs such as piloerection; long recovery time after an event; propensity to startle easily; appearance of a dog that seems "unable to hear" owner instructions during undesirable behavior (aggression) as opposed to a dog that does not want to obey. See Video 9-5.

†Increased vigilance includes signs such as constant visual scanning; inability to relax; keeping eyes half closed (i.e., the dog is exhausted; different from eyes half closed due to pain/globe retraction). See Video 9-1.

Abd, Abdominal; *Der,* dermatologic disorder; *GI,* gastrointestinal disorder; *Neuro,* neurologic disorder; *Ophtho,* ophthalmic disorder; *Resp,* respiratory disorder.

Behavioral Disorders

Anxiety is a dominant feature of many behavioral disorders and can be an important characteristic for differentiating behavioral from medical disorders. Anxiety is defined as an emotional state associated with adaptive physiological and behavioral responses. Anxiety becomes a disorder when it is exhibited in contextually inappropriate situations or in natural ones but at a level that impairs adaptive responses.[3] Anxiety disorders in companion animals generally are characterized by increased reactivity (heightened arousal)[4] and increased vigilance. The normal dog spends most of its time in a calm, non-vigilant, non-reactive state. The reactive/anxious dog spends most of its time being vigilant (unable to relax even though, in some cases, the dog is totally exhausted) and overly reactive (Video 9-1). An affected dog might startle more easily even at the sound of day-to-day "regular" noises. This dog in specific situations could exhibit piloerection more rapidly and more frequently, could be difficult to interrupt (e.g., the dog "seems unable to hear" the owner), and requires more time to return to "normal" baseline behaviors after an event of inappropriate or undesirable behavior.

Age of Onset of Signs

Behavioral disorders generally are observed in young animals,[5,6] although some exceptions occur. In dogs, behavioral disorders such as redirected aggression, interdog aggression, and impulse-control aggression (formerly called dominance aggression) are reported to commonly occur at social maturity (18-24 months).[7,8] In dogs, anxiety disorders other than aggression often develop in young individuals (e.g., 6 to 18 months) or

at the onset of social maturity.[6] Similarly, in cats, anxiety-related disorders such as intercat aggression or status-related aggression typically appear when the cat reaches social maturity (2-4 years of age).[9] This prevalence by age group can help to raise or lower the likelihood of a behavioral disorder as the cause of clinical signs in an individual patient.

Two studies[10,11] showed that the behaviors of approximately 10% of puppies were significantly different from the behaviors of their peers. One study described puppy behavior in the veterinary clinic.[10] One hundred and two 8- to 16-week-old puppies (46 males, 56 females) that had been adopted at least 1 week prior to evaluation were observed and videorecorded. The evaluation was divided into three different parts: (1) free-floor assessment; (2) physical examination; and (3) specific manipulations. Most puppies (free on the floor) behaved in a similar fashion. They were very active and oriented to the environment (exploring), silent, and not panting. They interacted little with the veterinarian. However, about 10% of puppies were outliers that did not explore, were panting, were vocal (whining or barking), and sought active interaction (jumping up and barking) with the veterinarian.

During the physical examination with pups placed on a table, the "outliers" actively tried to avoid the physical examination, panted, and held their ears drawn back. These "outliers" also licked their lips and yawned during both the physical examination and manipulations on the floor. Many behaviors expressed by the "outliers" were compatible with recognized signs of anxiety such as panting, excessive motor activity (pacing), active avoidance, vocalization, decreased exploration, flattened ear position, lip licking and yawning. This study illustrated that some individuals behave very differently at a young age.

In another study,[11] 32 puppies (16 males and 16 females), ranging in age from 50 to 118 days (mean 82.1 days) were videorecorded at home alone for 60 minutes. The recording process was repeated after 1 and 2 months, yielding a total of 3 recordings per puppy. Puppies were mainly inactive, resting, or sleeping. Vocalization, lip licking, and oral behaviors (chewing, biting, destroying items), which are signs compatible with stress-related/anxious behaviors and tended to cluster together in the dogs of this study, were apparent in 3/32 (10%) of puppies. Although this study did not follow up on all puppies' future behaviors, one of the 3 "anxious" puppies did exhibit separation anxiety as an adult and required treatment. Overall, these findings support the clinical experience of an early-age onset of behavioral disorders. They suggest that careful history-taking can detect signs compatible with anxiety at an early age in puppies, and that such elements in a thorough medical history can be valuable in helping to differentiate behavioral from medical causes of clinical signs.

Potential Medical Disorders in Dogs

Oral Repetitive Behaviors Including Pica, Surface Licking, Fly-Biting, Air Licking, Flank Sucking, and Self-Mutilation

In general, these oral repetitive behaviors are most likely signs of medical disorders in isolation, or possibly with concomitant behavioral conditions. Historically, oral repetitive behaviors were considered almost universally to be of primary behavioral origin, but newer investigations have identified direct causal associations between some of these signs and primary gastrointestinal (GI) and other abdominal disorders. These signs could be heightened by anxiety and coexisting behavioral disorders, but in general, oral repetitive behaviors should carry a broader differential diagnosis than primary behavioral disorders alone.

Pica is defined as the ingestion of non-food items. Owners generally do not distinguish between destruction and pica. If destruction occurs during the owner's absence, the dog should be filmed home alone before diagnosing separation anxiety. One destructive dog tentatively diagnosed with separation anxiety was filmed home alone and slept during the entire duration of the owner's absence. The destruction was associated with pica and the dog also had a history of intermittent diarrhea. Following medical investigation, the dog was diagnosed with inflammatory bowel disease (IBD). With a change in diet and treatment with prednisone, both the diarrhea and pica improved. Whenever the prednisone dosage was decreased, the dog resumed pica. This case illustrates the importance of obtaining GI biopsies when performing surgery for GI foreign body removal in dogs (see ch. 275 and 276), particularly in cases of "repeat offenders," because the foreign body ingestion may be the consequence of primary GI disease; in turn, such GI disease may be escaping detection if it is manifesting through clinical signs that are misinterpreted as being purely behavioral in origin.

Based on preliminary studies and case reports, GI disease can manifest with unusual behavioral signs including excessive licking of surfaces,[12] fly-biting,[13] and star-gazing.[14] In general, there are also other subtle signs of GI disease, such as presence of flatulence, borborygmus, eructation, lip licking, repetitive swallowing,

or drooling, although not always (Videos 9-1, 9-2, 9-3A, 9-3B, 9-4A, 9-4B, 9-4C, 9-5, 9-6A, and 9-6B). Owners will not necessarily report these subtle GI signs unless asked about them specifically.

In a study of dogs licking surfaces (floors, walls, blankets, sofas, etc.) excessively,[12] where patients received concurrent evaluations by a behavioral medicine service and an internal medicine service, 14/19 dogs (74%) had GI disorders including eosinophilic or lymphoplasmatic GI infiltration, delayed gastric emptying, irritable bowel syndrome, chronic pancreatitis, giardiasis, and a gastric foreign body. Mean duration of the "behavior" problem (e.g., how long the dog had been licking surfaces) was 32 months (range 0.08 to 82). Sixteen of the 19 dogs licked surfaces daily. Following treatment for the underlying condition, complete resolution of signs was achieved at 90 days in 53% (9/17) and in 59% (10/17) at 180 days (unpublished results). Three dogs showed both a decrease (more than 50%) in duration and in frequency of licking bouts at 180 days. Therefore, 76% of dogs (13/17) improved significantly clinically over the 6 month follow-up. Of the 5 dogs without GI abnormalities and treated non-specifically (hydrolysed protein diet), two dogs stopped licking by day 90. One of the surface-licking dogs was also air licking (repetitive horizontal tongue movement in and out of the mouth), retching, and closing his eyes partially; endoscopy revealed a 12-inch (30 cm) piece of rope in the stomach, which had been present for an estimated 6 months prior to presentation. Treatment included endoscopic removal of the foreign body and a switch to a hydrolysed protein diet, and both the GI signs (air licking, surface licking, and retching) and the pain-related sign (eyes partially closed)[15] ceased once this treatment was implemented (see Videos 9-6A and 9-6B).

Fly-biting is defined as an activity where the dog appears to be snapping at imaginary flies.[16] In one case series, medical investigation of seven fly-biting dogs[13] revealed that the onset of fly-biting occurred within the wide age range of 6 months to 10 years. At the time of presentation, dogs had exhibited fly-biting from six days to four years. Frequency of bouts varied from once daily to once hourly. Duration of a single bout varied from seconds to one hour. At home, fly-biting was more frequent following feeding in three dogs. The most significant finding was the occurrence of head-raising and neck extension preceding jaw snapping in all dogs. Clinical presentation was similar for all seven dogs. In two cases raising the head and extending the neck occurred more frequently than snapping. Underlying medical abnormalities included gastric and/or duodenal eosinophilic or lymphoplasmacytic infiltration, and delayed gastric emptying. Two dogs had gastroesophageal reflux during endoscopy. One dog had no histological abnormalities but presented a very flaccid and distended stomach on ultrasonographic and endoscopic examination. Medical treatment of the underlying GI disease resulted in complete resolution of fly-biting in 5/6 dogs (within 30 days for 4 dogs, including one dog that had been fly-biting for 2 years). Four dogs also presented behavioral changes compatible with anxiety (pacing, panting, hiding, increased attention seeking) along with the fly-biting episodes. These signs disappeared once the underlying GI disease was treated (see Videos 9-3, 9-4A, and 9-4B).

Some of the repetitive behaviors also labelled as obsessive-compulsive disorders, such as "flank sucking," "self-mutilation," and "checking," could in fact be secondary to somatic or visceral neuropathic pain. Inflammatory bowel disease could, in some cases, be causing anal sac disease.[17] Therefore "checking behaviors" reported in Miniature Schnauzers and "flank sucking" in Dobermans should include GI disease in the differential. These dogs could be experiencing pain or discomfort and are therefore looking repeatedly ("checking") at the hind end or sucking the flank. Similarly, in cats, one case series identified that a majority (16/21 cats; 76%) suspected of having psychogenic alopecia in fact had an underlying medical cause.[18]

Self-mutilation should always alert the veterinarian to the possibility of pain. Pain can be local or neurogenic (see ch. 126 and 356). However, animals should still be assessed for behavioral disorders when pain is suspected. Neuropathic pain often is worsened by stimuli that evoke a sympathetic response, such as the startle response and emotional arousal.[19] Therefore, arousal (increased reactivity often seen in anxiety disorders) can contribute to neuropathic pain.

Summary

- Typically, behavioral disorders are seen in young animals. Dogs suffering from anxiety disorders tend to be more vigilant and reactive.
- For oral repetitive behaviors, owners should always be questioned about more subtle GI signs such as flatulence, borborygmi, eructation, neck extension and stretching, lip licking, tongue flicking, repetitive swallowing, or drooling in addition to more obvious signs such as vomiting, diarrhea, or tenesmus.
- Gastrointestinal biopsies should always be taken when performing surgery for GI foreign body removal in dogs, particularly in cases of "repeat offenders."

- Medical and behavioral disorders may occur concomitantly, and probably more so than is currently recognized. A thorough history of all signs will help to identify these patients as well as address both the medical and behavioral conditions.

CHAPTER 10

Dermatologic Manifestations of Systemic Disease

Karen L. Campbell

Client Information Sheet: Dermatologic Manifestations of Systemic Disease

While not always thought of as "an organ," the skin is, in fact, the body's largest and most visible organ. With an epidermal turnover time of approximately 22 days in dogs, it is also quite "dynamic."[1] Cutaneous markers of internal diseases are common and often indicative of or consistent with specific systemic diseases (E-Table 10-1). Cutaneous signs may be the result of the same etiologic agent or pathogenic process as the systemic condition (bacteria, protozoa, fungal, immune-mediated and neoplastic disorders). Alternatively, signs may be due to hormonal changes, genetic links, or other factors. Recognizing typical cutaneous signs may facilitate diagnosis of an underlying disease process. Skin is easily the most accessible organ for obtaining samples used in cytology, biopsy for histology, culture, and other tests.

E-Table 10-1

Summary of Cutaneous Manifestations of Systemic Diseases

CUTANEOUS LESION(S)	ASSOCIATED SYSTEMIC DISEASE(S)	OTHER FINDINGS	DIAGNOSTIC TESTS
Hypotrichosis/generalized alopecia	Hypercortisolism	Polyuria/polydipsia, hepatomegaly, thin skin, bruising, muscle wasting	Skin scrapings (rule out *Demodex*), DTM culture (rule out dermatophytes), trichogram (rule out color dilute alopecia), hormonal assays (cortisol, ACTH stimulation test, dexamethasone suppression test, ACTH, thyroid hormones, TSH, estradiol, insulin-like growth factor)
	Hypothyroidism	Brittle, faded hairs, pinnal margin alopecia, alopecia of bridge of nose, thickened skin (mucinosis), bradycardia, lethargy	
	Hyperestrogenism	Feminization (gynecomastia, pendulous prepuce), linear preputial erythema	
	Pituitary dwarfism	Small stature, retained deciduous teeth	
Diffuse hypotrichosis with scales and crusts	Feline thymoma-associated exfoliative dermatitis	Waxy debris between digits and in clawfolds	Skin biopsy, thoracic ultrasound, radiograph, CT or MRI
	Cutaneous T-cell lymphoma	± cutaneous plaques or nodules, footpads may also be affected	Skin biopsy, immunohistochemistry
Facial + dorsal alopecia, erythema, scaling,	Leishmaniasis	Weight loss, lethargy, polyarthritis, anemia,	Cytology, skin biopsy, PCR assay, serology

crusting		renal disease, onychogryposis, depigmentation	
	Lupus erythematosus	Polyarthritis, fever, protein-losing enteropathy, anemia, thrombocytopenia	Antinuclear antibody test, Coombs test, skin biopsy
	Exfoliative cutaneous lupus erythematosus (German Shorthaired Pointers)	Polyarthritis, pain, hunched back	Skin biopsy, rule out other differentials
Alopecia, erythema, scaling, crusts affecting face, legs, tail	Dermatomyositis (Collies, Shetland Sheepdogs, others)	Variable dysphagia, abnormal gait and/or megaesophagus	Skin biopsy, muscle biopsy, EMG
Alopecia with shiny skin involving periocular region, ventral neck, ventrum and legs (cat)	Feline paraneoplastic alopecia (pancreatic adenocarcinoma, biliary cholangiocarcinoma, hepatic carcinoma)	Rapid onset, may be pruritic if secondary *Malassezia* dermatitis; Skin is shiny but not fragile	Skin biopsy, abdominal ultrasound, CT, or MRI
Cutaneous erythema, alopecia, scales, crusts of mucocutaneous junctions, ± footpads	Zinc-responsive dermatosis	Most common in Arctic breeds (Alaskan Malamutes, Siberian Huskies), also reported in Pharaoh Hounds	Skin biopsy (parakeratotic hyperkeratosis)
	Lethal acrodermatitis (Bull Terriers)	Autosomal recessive in Bull Terriers, other signs include splayed digits, dysphagia, small stature, secondary infections	Skin biopsy (parakeratotic hyperkeratosis)
	Canine distemper	Also commonly have nasal hyperkeratosis, history of respiratory or neurologic signs	Skin biopsy, immunohistochemistry
	Superficial necrolytic dermatitis (concurrent hepatic disease, diabetes mellitus or pancreatic tumor, e.g., glucagonoma)	Skin lesions may be result of hypoaminoacidemia as consequence of elevated levels of glucagon or hepatic insufficiency	Skin biopsy, serum biochemical profile, serum amino acid levels, abdominal ultrasound
	Erythema multiforme (trigger may be an adverse drug reaction, systemic infection or neoplasia)	Skin lesions are a result of T-cell mediated apoptosis of keratinocytes	Skin biopsy, evaluate history for clues of adverse drug reaction, infection or neoplasia
	Paraneoplastic pemphigus	May also have stomatitis and other lesions; canine cases have been associated with splenic lymphoma and thymoma	Skin biopsy, abdominal ultrasound, thoracic radiographs
	Cutaneous T-cell lymphoma	Wide variety of clinical presentations	Skin biopsy and immunohistochemistry
Cutaneous plaques	Calcinosis cutis—	PU/PD, history of	Skin biopsy, serum biochemical profile,

	hypercortisolism, renal disease, systemic granulomatous disease (blastomycosis)	exogenous or endogenous corticosteroids or progesterone administration; concurrent granulomatous disease or renal disease	review treatment history, history of blastomycosis or other systemic fungal disease
	Xanthomas—hyperlipidemias (familial, diabetes mellitus, hypercortisolism, hyperprogesteronism)	Familial hyperlipidemia has been associated with xanthomas in cats, most cases are secondary to diabetes mellitus, hypercortisolism or hyperprogesteronism	Skin biopsy, serum biochemical profile, serum lipid profile, review history of previous treatments
	Hyperpigmented—papillomavirus associated	May progress to squamous cell carcinomas	Skin biopsy, immunohistochemistry, PCR for papillomavirus
	Eosinophilic—hypersensitivity associated	Cats—associated with flea, food or environmental allergies	Skin biopsy, allergy workup
	Cutaneous T-cell lymphoma	May also have generalized scaling and/or mucocutaneous lesions	Skin biopsy, immunohistochemistry
Cutaneous nodules	Collagenous—nodular dermatofibrosis	Most common in German Shepherd Dogs, concurrent renal cystadenocarcinoma or cystadenoma, also uterine leiomyoma or leiomyosarcoma	Skin biopsy, abdominal ultrasound, CT, MRI
	Sterile nodular panniculitis (SNP)—pancreatic panniculitis	SNP can be associated with pancreatitis or pancreatic neoplasia; cutaneous lesions may ulcerate	Deep skin biopsies (include subcutaneous fat), rule out infectious causes of panniculitis; abdominal ultrasound, pancreatic lipase immunoreactivity
	Infectious—pyogranulomatous nodules may develop in association with blastomycosis, coccidioidomycosis, cryptococcosis, histoplasmosis and aspergillosis	Infectious pyogranulomas usually occur secondary to dissemination of a systemic fungal infection to the skin, less commonly from direct cutaneous inoculation	Cytology and/or biopsy of the skin nodules often results in identification of the organism responsible for the lesions
Skin fragility	Cutaneous asthenia due to abnormal collagen fibril formation	May be associated with joint laxity or hernias	Skin biopsies for histopathology, ultrastructural and/or biochemical evaluation
	Feline acquired skin fragility may develop secondary to hypercortisolism, FIP, or hepatic disease	Skin is fragile and tears easily	Skin biopsy, serum biochemical profile, abdominal ultrasonography

Thick skin	Excessive mucin accumulation results in thickening of the dermis in dogs with hypothyroidism, acromegaly, and is a breed characteristic of Chinese Shar-Pei dogs	Clinical signs of hypothyroidism are highly variable; those of acromegaly include inspiratory stridor and thickening of interdental arcade and thick, hard claws	Thyroid hormones, TSH, evaluation for other diseases, measurement of IGF-1 levels and history are helpful in diagnosis

ACTH, Adrenocorticotropic hormone; *CT*, computed tomography; *DTM*, dermatophyte test medium; *EMG*, electromyography; *FIP*, feline infectious peritonitis; *IGF-1*, insulin-like growth factor-1; *MRI*, magnetic resonance imaging; *PCR*, polymerase chain reaction; *PU/PD*, polyuria/polydipsia; *TSH*, thyroid-stimulating hormone.

Systemic Diseases Associated with Alopecia

Overview

There are numerous differential diagnoses for diffuse hair loss. The classic systemic diseases associated with generalized alopecia are the endocrinopathies: hypothyroidism, hyperadrenocorticism, hyperestrogenism, and pituitary dwarfism. It is always important to rule out other potential causes, including demodicosis, dermatophytosis, bacterial folliculitis, pattern baldness, follicular dysplasias, congenital hypotrichosis, telogen effluvium, color dilution alopecia, sebaceous adenitis, and epitheliotrophic lymphoma.[2]

Hypothyroidism (see ch. 299)

Thyroid hormone is necessary for hair follicles to cycle into the anagen phase. In a hypothyroid animal, hairs remain "in telogen" until shed, resulting in a dull hair coat composed of mature hairs that are not replaced following shedding or shaving. Hair loss commonly first develops over the bridge of the nose, ear pinnae, tail and elbows. The skin may become thickened due to an accumulation of hyaluronic acid in the dermis (mucinosis). Secondary bacterial skin and ear infections are common in hypothyroid dogs.[2]

Hypercortisolism (Hyperadrenocorticism) (see ch. 306 and 307)

The skin is a sensitive indicator of hypercortisolism in dogs with both non-specific (alopecia, secondary infections, poor wound healing) and specific findings (thinning of skin, calcinosis cutis). Early changes include a dull hair coat and alopecia. Over time, many affected dogs develop thin skin. In some, the skin may demonstrate hyperpigmentation, easy bruisability, phlebectasias (dilated blood vessels), striae (pigmented stretch marks), poor wound healing, secondary infections and/or calcinosis cutis.[2]

Hyperestrogenism (see ch. 319)

Hyperestrogenism may develop in female dogs as a result of an estrogen-secreting ovarian neoplasm or follicular cysts. Ovarian cysts in most dogs are clinically silent, being either non-functional or progesterone-secreting. Cutaneous signs of estrogen excess include bilaterally symmetric alopecia, enlarged vulva and nipples, and a history of abnormal estrous cycles. Male dogs may develop hyperestrogenism as a result of an estrogen-secreting testicular tumor, most commonly a Sertoli cell tumor (particularly common in cryptorchid testes). Clinical signs include nipple enlargement, pendulous prepuce, ventral hyperpigmentation, attracting male dogs, and atrophy of the non-neoplastic testicle. Any dog is at risk for iatrogenic hyperestrogenism including a small percentage of the dogs being given estrogen-containing compounds for urinary incontinence. Additionally, iatrogenic estrogenism can occur after contact with or consumption of creams or patches intended for human use. A unique cutaneous manifestation of hyperestrogenism in male dogs is linear preputial dermatosis—a linear, erythematous or hyperpigmented narrow band of skin located between the preputial orifice and the scrotum.[3] A tentative diagnosis may be made based on clinical signs, physical examination, serum estrogen concentrations (variable depending upon which estrogen metabolite is measured), and abdominal or testicular ultrasonography.

Pituitary Dwarfism

Pituitary dwarfism (see ch. 295) has been reported as an autosomal recessive disorder in the German

Shepherd Dog and Karelian Bear Dog. Affected dogs develop a bilaterally symmetric alopecia (E-Figure 10-1), proportionate dwarfism, and delayed eruption of permanent teeth. Clinical signs and low circulating IGF-1 concentrations are consistent with this disorder.[2]

E-FIGURE 10-1 German Shepherd Dog with pituitary dwarfism exhibiting generalized thinning of the hair coat.

Systemic Diseases With Diffuse Hypotrichosis, Scales and Crusts

Feline Thymoma-Associated Exfoliative Dermatitis (see ch. 245)

Skin lesions of erythema, crusting and scaling with alopecia may be the first sign of disease in cats with a thymoma. Secondary infections with *Malassezia* may cause pruritus. Affected cats may later develop coughing, dyspnea, anorexia and/or weight loss. Skin biopsies demonstrate hydropic interface dermatitis with apoptotic keratinocytes. Imaging may demonstrate a mediastinal mass. Surgical removal may be curative.[4,5]

Epitheliotropic/Cutaneous T-Cell Lymphoma (see ch. 344)

Epitheliotropic cutaneous lymphoma can cause erythroderma, alopecia, variable pruritus, scales, crusts, plaques, nodules, leukoderma, mucocutaneous ulcers, and/or depigmented, ulcerated or hyperkeratotic footpads. A few affected animals also have neoplastic lymphocytes in circulation (Sezary syndrome). Diagnosis can usually be confirmed with skin biopsy and immunohistochemistry.[2]

Systemic Diseases With Facial and Dorsal Erythema, Alopecia, Scaling and Crusting

Leishmaniasis (see ch. 221)

Skin lesions have been observed in > 80% of dogs with visceral leishmaniasis, most commonly, silvery white scales over the head, pinnae and limbs and periocular alopecia. Nasodigital hyperkeratosis, onychogryposis

(deformed overgrowth of the nails), paronychia, nasal depigmentation and nodular dermatitis may be present. Systemic signs include lethargy, weight loss, generalized lymphadenopathy, hepatosplenomegaly, muscle wasting, cachexia, fever, epistaxis and lameness. Kidney disease may lead to polyuria and polydipsia. Diagnosis may be confirmed by finding the organism on skin biopsy, polymerase chain reaction (PCR) assay, cultures or serology.[2]

Lupus Erythematosus

Lupus erythematosus is an autoimmune, inflammatory, multisystemic disorder of complex etiologies that may have clinical manifestations restricted to the skin or involve multiple organs (see ch. 205). Discoid lupus erythematosus (DLE) causes skin lesions which are usually restricted to the face, particularly the planum nasale and dorsal surface of the nose. However, severe DLE may involve the nasal turbinates causing epistaxis and the potential for secondary infections.[6] Systemic lupus erythematosus (SLE) is a multisystem disease with variable clinical presentations. Skin lesions are present in 40% to 50% of cases.[7] Skin lesions are usually symmetrical and vary from mild scaling and/or alopecia of the face and dorsum to severe ulcerations. Various other signs may be present depending upon the organ systems affected. Skin biopsy from an affected area should demonstrate hyperkeratosis, epidermal atrophy, basal cell vacuolar degeneration, basement membrane zone thickening and mononuclear cell infiltration at the dermoepidermal interface.[2]

Exfoliative Cutaneous Lupus Erythematosus (ECLE)

ECLE is a familial form of lupus affecting German Shorthaired Pointer dogs.[8,9] Skin lesions are often the first abnormality observed and include excessive scaling and crusting of the muzzle, pinnae and dorsum (E-Figure 10-2). As the disease progresses, some dogs become severely lame and/or develop renal disease. Diagnosis is made on clinical signs and compatible skin biopsy results: hyperkeratosis, epidermal atrophy, basal cell vacuolar degeneration, basement membrane zone thickening and mononuclear cell infiltration at the dermoepidermal interface. Most affected dogs are euthanized before 4 years of age.[8,9] A genome-wide association study identified a SNP allele on canine chromosome 18 that "segregated with the disease."[10]

E-FIGURE 10-2 German Shorthaired Pointer with exfoliative cutaneous lupus erythematosus exhibiting generalized cutaneous scaling.

Systemic Diseases With Alopecia, Erythema, Scales and Crusts Affecting Face, Legs and Tail; Dermatomyositis (DM)

DM is an inflammatory disease affecting skin and/or muscle. In dogs, DM occurs most often in Collies and Shetland Sheepdogs. Skin lesions vary from mild to severe, starting with small focal areas of crusting, scaling and alopecia. The condition most commonly affects the face, lower extremities and tail (E-Figure 10-3). Over time, their skin becomes atrophic. Concurrent muscle involvement may result in dysphagia and gait abnormalities. Affected dogs may develop megaesophagus. The disease is thought to be autosomal dominant with incomplete penetrance in Collies.[11] A study of linkage disequilibrium (LD) mapping in Shelties had evidence of LD linkage to microsatellite marker FH3570 on canine chromosome 35.[12] Gene expression profiles failed to detect any disease-specific autoantibodies.[13] This disorder has also been classified as an ischemic dermatopathy.[14] Diagnosis can be confirmed histologically from affected skin tissue, which usually demonstrates scattered hydropic degeneration of cells in the stratum basale, follicular atrophy, perifollicular fibrosis, mild perivascular to interstitial dermatitis and vasculitis. Histopathology of muscle may demonstrate fiber necrosis and atrophy.[15]

E-FIGURE 10-3 **A,** Shetland Sheepdog puppy with dermatomyositis with alopecia, scaling and crusting of periocular and dorsal nasal skin. **B,** Severe alopecia with scales and crusts on the tail of the Shetland Sheepdog puppy in **A.**

Systemic Diseases With Alopecia and Shiny Skin of Periocular Region, Ventral Neck, Ventral Abdomen and Legs; Feline Paraneoplastic Alopecia (see ch. 352)

Rapid development of extensive alopecia in an older cat may be the first sign of underlying pancreatic or hepatic neoplasia.[16] Hair loss often begins around the eyes and may rapidly progress to the ventral neck, abdomen and legs (Figure 10-4). Hairs epilate easily and the alopecic skin appears shiny but not fragile. Secondary *Malassezia* infections may result in excessive grooming. Some cats also have dry, scaly footpads. Histopathology should demonstrate miniaturization of hair follicles and adnexa with epidermal hyperplasia. Pancreatic adenocarcinoma is most commonly associated with this syndrome. Less frequently, hepatic carcinoma or biliary cholangiocarcinoma has been diagnosed. Pancreatic or hepatic tumors may be identified with imaging or exploratory laparotomy. The prognosis is grave. One cat who improved following surgical removal of a pancreatic adenocarcinoma, relapsed due to metastatic disease.[17]

FIGURE 10-4 Domestic shorthair cat with paraneoplastic alopecia associated with pancreatic adenocarcinoma. Note the distribution of lesions affecting face, legs, neck and ventral abdomen and the shiny texture of the skin.

Systemic Diseases With Cutaneous Erythema, Alopecia, Scales and Crusts of Mucocutaneous Junctions and Footpads

Zinc-Responsive Dermatitis

Skin lesions associated with zinc deficiency or zinc-responsive dermatitis include areas of erythema, alopecia, scales and crusts starting on the face, mucocutaneous junctions, feet and footpads. Other findings may include decreased appetite, weight loss, impaired wound healing and increased susceptibility to secondary infections. Alaskan Malamutes and Siberian Huskies are most often affected, perhaps due to decreased intestinal absorption of zinc.[18,19] Pharaoh Hounds have also been reported to have a severe form of the disease.[20] Diagnosis may be confirmed with histopathology that demonstrates parakeratotic hyperkeratosis in a dog with low serum zinc concentrations and improvement following oral and/or intravenous zinc supplementation.

Lethal Acral Dermatitis/Acrodermatitis

Bull Terriers may be affected by an autosomal recessive condition associated with defective zinc and copper metabolism and altered production of liver proteins. Affected puppies have lighter than normal skin pigmentation and often have difficulty chewing and swallowing. They develop splayed digits in addition to crusting and cracking of their footpads (E-Figure 10-5) and ulcerated crusted lesions on their ear pinnae and mucocutaneous junctions. Foot lesions may progress to onychodystrophy, paronychia and interdigital pyoderma. Systemic signs may include diarrhea and respiratory infections. Most affected dogs succumb to secondary infection before 7 months of age. Diagnosis is tentatively made based on signalment, clinical signs, decreased serum and liver zinc concentrations, and parakeratotic hyperkeratosis on skin histopathology.[21-23]

E-FIGURE 10-5 Left hindleg of 6-week-old Bull Terrier puppy with lethal acrodermatitis. Note the splaying of the digits and hyperkeratosis of the footpads and caudal surface of the leg.

Canine Distemper (see ch. 228)

The classical skin manifestation of canine distemper is "hard pad disease" due to hyperkeratosis of the footpads (and planum nasale). Early in the disease, some affected dogs develop superficial pustules (impetigo). Skin biopsies may show the presence of intracytoplasmic inclusion bodies in keratinocytes. Immunohistochemistry (IHC) may be used to detect canine distemper virus.

Superficial Necrolytic Dermatitis (SND), Metabolic Epidermal Necrosis (MEN), Hepatocutaneous Disease, Necrolytic Migratory Erythema (NME) (see ch. 285)

In people, this condition represents a cutaneous marker for alpha$_2$-glucagon-producing pancreatic islet cell tumors. Skin lesions are caused by degeneration of keratinocytes, resulting in epidermal edema and necrosis. Only a small proportion of dogs with classical lesions of SND, however, have underlying glucagonoma, the majority having had liver disease.[24-26] Degeneration of keratinocytes is believed due to hypoaminoacidemia resulting in inadequate nutrients to maintain a viable epidermis. Lesions begin in areas of high cell turnover including mucocutaneous junctions, face, footpads and pressure points (Figure 10-6). The lesions include crusts and ulcerations with perilesional erythema. Most affected dogs also have a non-regenerative anemia, mild hyperglycemia, increased serum liver enzyme activities and a "honeycomb-appearing" liver on abdominal ultrasonography. Serum amino acid concentrations are decreased. Dogs with pancreatic tumors usually have increased circulating glucagon concentrations.[27] The disease in cats has been associated with pancreatic tumors and chronic liver disease.[28,29] Skin biopsy findings are unique for this syndrome and consist of basal cell hyperplasia, vacuolar degeneration of the stratum spinosum and parakeratotic hyperkeratosis ("blue," "white" and "red" zones). Prognosis is grave, although surgical removal of a pancreatic tumor may be curative in the unlikely scenario that metastasis has not occurred.[30]

A

B

FIGURE 10-6 Doberman Pinscher mixed-breed dog with superficial necrolytic dermatitis associated with liver disease. **A,** Pustules and crusts are present on the ventral thorax, abdomen and limbs. **B,** Ulcerations and crusts of lower leg and footpads of dog in **A. C,** Ulceration and crusting over hock of dog in **A.** Note the intense erythema of the skin adjacent to the crusts.

Paraneoplastic Pemphigus

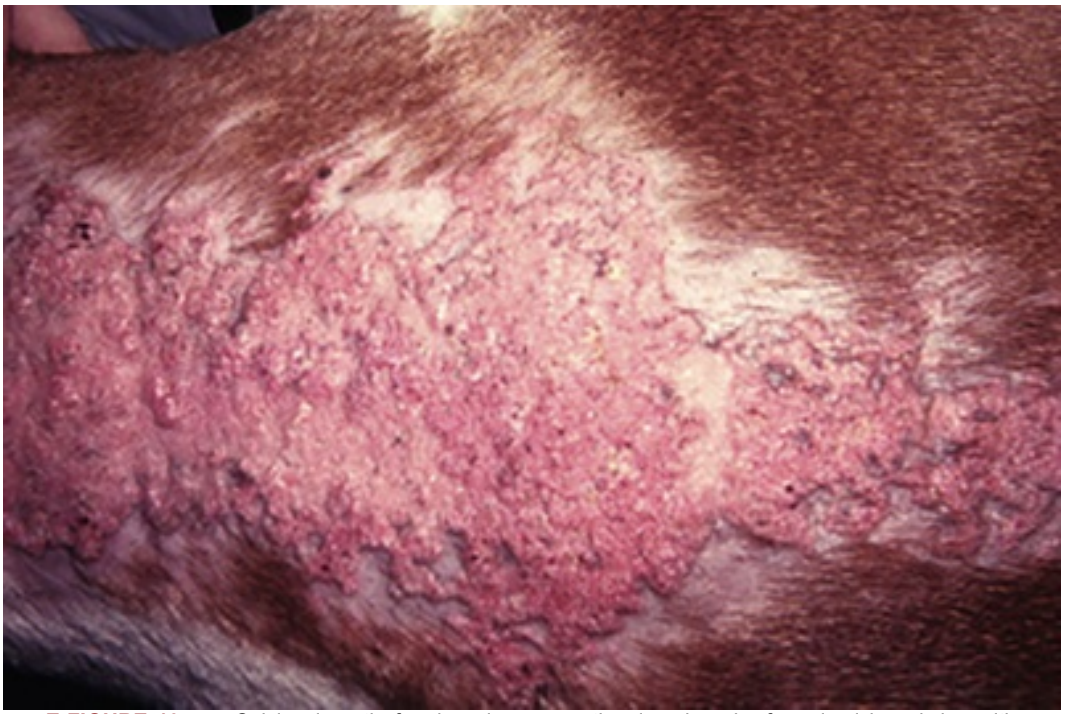
Paraneoplastic pemphigus has been reported in dogs with either thymic lymphoma or splenic sarcoma (see ch. 204 and 352). Autoantibodies in affected dogs have targeted desmoplakin, envoplakin, periplakin, desmoglein 1 and desmoglein 3. Histologically, lesions have features of pemphigus foliaceus (intraepidermal pustules with acantholysis), pemphigus vulgaris (suprabasilar clefts) and erythema multiforme (apoptotic keratinocytes). Prognosis is grave.[31,32]

Systemic Diseases With Cutaneous Plaques

Calcinosis Cutis (see ch. 298 and 306)

Calcinosis cutis appears as granular plaques in the skin (E-Figure 10-7), most commonly over the dorsum or inguinal regions. Microscopically, dermal deposits of apatite crystals are usually identified in association with collagen or elastin fibers. This "metastatic calcification" occurs as a result of excesses in circulating calcium and/or phosphorus in dogs with chronic kidney disease or systemic blastomycosis or paecilomycosis. Dystrophic calcification is thought to occur as a result of alterations to collagen fibers in dogs with hyperadrenocorticism or as a result of inflammatory conditions such as leptospirosis, follicular cysts, foreign body granulomas, interdigital pyoderma, demodicosis or pilomatrixomas. Iatrogenic calcinosis cutis has been associated with percutaneous absorption or injection of calcium-containing products. Calcinosis circumscripta lesions occasionally develop over pressure points or areas of trauma (including the tongue and footpads) of juvenile dogs when serum levels of phosphorus and calcium are increased. Diagnosis is made with

histopathology or after confirming an underlying disorder.[33]



E-FIGURE 10-7 Calcinosis cutis forming plaques on the dorsal neck of a mixed breed dog with iatrogenic hypercortisolism.

Xanthomas

Xanthomas appear as yellow-white papules, nodules or plaques located on the head, limbs, feet or over bony prominences (E-Figure 10-8). The lesions may ulcerate and are often surrounded by erythema. Xanthomas are composed of foamy macrophages and giant cells surrounding deposits of lipid in the dermis. These lesions are cutaneous manifestations of abnormalities in lipid metabolism or may be associated with diets extremely high in fat. Xanthomas develop in cats with hereditary hyperlipoproteinemia and in a small percentage of those with diabetes mellitus, Cushing's syndrome, treated with progestational compounds or fed high-fat foods and treats.[34-37] Diagnosis is based on histopathology or confirmation of an underlying cause of hyperlipidemia.

E-FIGURE 10-8 Xanthomas on the caudal surface of the hindlimbs of a 2-year-old domestic shorthair cat with familial hyperlipidemia.

Hyperpigmented Viral Plaques

Canine viral plaques are an uncommon manifestation of papillomaviral infection in dogs. In contrast to the more common papillomas, viral plaques do not spontaneously resolve. However, most viral plaques remain as small pigmented lesions on the ventral abdomen (E-Figure 10-9) or in the axillary region. The major differential for pigmented viral plaques is canine seborrheic keratosis (SK) which also appear as raised, variably pigmented plaques on the skin of dogs. On occasion, papillomavirus-associated viral plaques progress to squamous cell carcinomas. Histopathology of skin and IHC or PCR for papillomaviruses can be used to distinguish viral plaques from SK.[38,39]

E-FIGURE 10-9 Pigmented viral plaques caused by papillomavirus infection in an 8-month-old Pomeranian dog.

Eosinophilic Plaques

Eosinophilic plaques develop in cats in association with underlying allergies (parasitic, dietary or environmental). Differential diagnoses include mast cell tumor, squamous cell carcinoma, lymphoma and metastatic mammary adenocarcinoma.[2]

Cutaneous Lymphoma—Plaque Form

See previous discussion.

Systemic Diseases With Cutaneous Nodules

Nodular Dermatofibromas

German Shepherds and related dogs have an autosomal dominant genetic disease caused by mutations in the folliculin gene (FLCN) that results in the development of multiple cutaneous nodules as well as multiple renal cysts and cystadenocarcinomas.[40,41] Females may develop uterine leiomyomas and leiomyosarcomas. Skin lesions may develop months or years before renal lesions, although renal cysts or tumors may be identified with imaging by 4 to 5 years of age.

Sterile Nodular Panniculitis (SNP)—Pancreatic Panniculitis Variant

Sterile nodular panniculitis is characterized by sterile subcutaneous inflammatory nodules that may ulcerate and drain a purulent or oily exudate. Lesions often develop in the absence of any concurrent disease or infection; however, pancreatitis and pancreatic tumors have been associated with panniculitis (E-Figure 10-10). Dogs and cats with panniculitis should be evaluated for pancreatic disease.[42-46] Other differential diagnoses for causing nodular panniculitis include foreign bodies, immune-mediated reactions, infection, vitamin E deficiency, serum alpha-1-antitrypsin deficiency, injection reaction, burns and trauma.[47] Minimum database evaluation should include a complete blood count, biochemical profile, pancreatic lipase immunoreactivity screening, abdominal ultrasonography as well as deep cutaneous biopsies for histopathology, culture and PCR evaluations to rule out other causes.

E-FIGURE 10-10 Panniculitis with ulcerations on the back of a dog with pancreatic adenocarcinoma (area has been shaved).

Infectious/Pyogranulomatous Nodules

Cutaneous nodules can develop in animals with blastomycosis, coccidioidomycosis, cryptococcosis, histoplasmosis or aspergillosis. These nodules usually develop as a consequence of hematogenous dissemination of the organism from another site (pulmonary, nasal, gastrointestinal). Less commonly, skin lesions may develop following direct inoculation of fungal organism into the skin. Cytology from impression smears or fine needle aspirates or skin biopsies represent a readily accessible source for organism identification.[2]

Systemic Diseases With Skin Fragility

Cutaneous Asthenia (Ehlers Danlos Syndrome, Dermatosporaxis)

Cutaneous asthenia is a hereditary disease caused by defective connective tissue formation resulting in skin fragility and, in some cases, excess joint laxity, hernias and vascular complications. Several forms occur in animals and humans. The condition in cats is associated with reduced quantities of dermal connective tissue that has shortened and fragmented collagen fibers.[48,50] Clinical signs include hyperextensible skin (E-Figure 10-11) that may tear with minor trauma.[48-50] Dyspnea may occur secondary to diaphragmatic hernia. One affected cat had a perineal hernia.[50] A defect in procollagen peptidase was identified in one cat.[51] Affected dogs have exhibited skin hyperextensibility and fragility, vessel fragility, coxofemoral joint dislocation, medial patellar luxation, subcutaneous hematomas and periodontal disease.[52] Presumptive diagnosis is based on presence of hyperextensible, easily torn skin. Microscopic evaluation of skin biopsies may demonstrate fragmented, shortened, disoriented, eosinophilic collagen fibers. In some cases, ultrastructural or biochemical evaluation is needed to document the collagen abnormalities.[48,51]

E-FIGURE 10-11 Hyperextensibility of the skin of a mixed breed dog with cutaneous asthenia.

Feline Skin Fragility

Acquired skin fragility in cats is most often associated with hyperadrenocorticism, either due to cortisol or sex hormone excess secreted from an adrenal tumor, excess cortisol secretion in pituitary dependent hyperadrenocorticism, or after administration of glucocorticoids or progestational compounds.[53] Affected cats have thin, fragile skin that tears easily (see ch. 307). Skin fragility has been reported in a few cats with feline infectious peritonitis, hepatic lipidosis or hepatic neoplasia.[54-56]

Systemic Diseases With Thick Skin

Mucinosis

The skin may be thicker than normal due to excessive amounts of mucin in the dermis as a breed-associated characteristic of Chinese Shar-Pei dogs or as a result of hypothyroidism.

Acromegaly

Cutaneous changes associated with acromegaly include thickened myxedematous skin with excessive skin folds, hypertrichosis and thick, hard claws. Acromegaly is caused by excessive secretion of growth hormone by a pituitary tumor or is secondary to hyperprogesteronism (see ch. 294-295).

CHAPTER 11

Ophthalmic Manifestations of Systemic Disease

Alexandra van der Woerdt

Client Information Sheets:
Topical Ophthalmic Corticosteroid Medication
Anterior Uveitis/Chorioretinitis
Cataract

Introduction

A thorough ophthalmic examination is an important part of a physical examination in every patient. The clinician has the unique opportunity to directly visualize blood vessels as well as neurologic tissue (the optic nerve) in the fundus of the eye. Abundant blood supply to the iris and choroid make these tissues susceptible to spread of infectious organisms or neoplastic cells to these tissues with inflammation of the iris, ciliary body and choroid as a result. Other parts of the eye may be affected by various systemic diseases as well. This chapter will first describe ophthalmic examination techniques, followed by ocular manifestations of systemic disease in the various parts of the eye.

Ophthalmic Examination

Examination of the anterior segment of the eye is best performed in a clinical setting using a bright light source. A slit lamp biomicroscope is ideal for examination of the anterior segment, as it provides illumination and magnification at the same time (Figure 11-1). The slit lamp function allows further localization of lesions by providing optical cross sections of the anterior segment of the eye. Most penlights are not bright enough for a thorough examination. A Finoff transilluminator will provide a focal bright light beam. Magnification and illumination can be obtained at the same time by using an otoscope. The eyelids are evaluated for function, anatomy and the presence of abnormal ciliae. Normal conjunctiva is thin and has scant blood vessels. Hyperemia and swelling of the conjunctiva (chemosis) are commonly seen abnormalities. A normal cornea has a glossy appearance and is transparent. The anterior chamber is best evaluated for the presence of aqueous flare by focusing a small light beam on the cornea and observing light scattering on proteins and cells in the anterior chamber if present. A normal lens is transparent and located between the iris and the vitreous cavity. The fundus can be examined by either direct or indirect ophthalmoscopy. Direct ophthalmoscopy is easy to learn and the equipment is often readily available (Figure 11-2). It provides high magnification of a small portion of the fundus. Because of the limited size of the area observed in the fundus, relatively large lesions may be easily missed. Indirect ophthalmoscopy is the preferred choice for evaluating a large part of the retina at one time at a relatively low magnification. Equipment needed includes a focal bright light source (such as a Finoff transilluminator) and an indirect viewing lens (see Figure 11-2). Popular lenses include the panretinal 2.2 lens, as well as a 20 or 28 diopter lens. Indirect ophthalmoscopy is a technique that does require practice to master, but the advantages outweigh the disadvantages when compared with direct ophthalmoscopy. The Welch Allyn Panoptic ophthalmoscope combines the ease of use of a direct ophthalmoscope with a relatively large area of the fundus evaluated at one time (Figure 11-3).

FIGURE 11-1 Slit lamp biomicroscope, which provides illumination and magnification when evaluating the anterior segment of the eye.

FIGURE 11-2 A focal bright light source, such as the Finoff transilluminator (right), and an indirect viewing lens (lower left) are used for indirect ophthalmoscopy. The ophthalmoscope head (upper left) is used for direct ophthalmoscopy.

FIGURE 11-3 The Welch Allyn Panoptic ophthalmoscope combines the ease of use of a direct ophthalmoscope with a relatively large area of the fundus evaluated at one time.

Interpretation of Fundus Lesions

One of the most important questions to ask when observing a lesion in the fundus is whether it is an active lesion or an inactive lesion (scar). Inactive lesions are common incidental findings that have little clinical significance. The presence of active fundus lesions may help determine diagnostic plans for current diseases in the patient. Evaluating the color and reflectivity of a lesion in the tapetal area of the fundus can help determine whether a lesion is active or inactive. Focal areas of chorioretinitis over time will result in thinning of the retina, exposing the reflective tapetum to a greater degree than normal. The result is a focal hyperreflective area in the tapetum. If a tapetal lesion involves the retinal pigment epithelium in the deepest part of the retina, focal hyperpigmentation is a common result (Figure 11-4). Clinically this is seen as a hyperreflective lesion with a dark center. When evaluating for the presence of hyperreflectivity, one needs to bear in mind that hyperreflectivity is only seen if the light hits the scar at a perfect angle. If not, the lesion will appear dull and may give the impression of being an active lesion. If the color of the underlying tapetum in an active lesion appears to have changed little compared to the surrounding tapetum, clear fluid is present in the lesion. This can be seen with (early) hypertension and secondary retinal edema. If the color of the underlying tapetum has changed, this indicates the presence of cells in the lesion. This could be either hemorrhage or other cellular infiltrates such as white blood cells or neoplastic cells. Figure 11-5 is a flowchart for evaluating tapetal fundus lesions.

FIGURE 11-4 Multiple hyperreflective lesions are present in the tapetum of this dog. The darkly pigmented center in several of the chorioretinal scars indicates involvement of the retinal pigment epithelium.

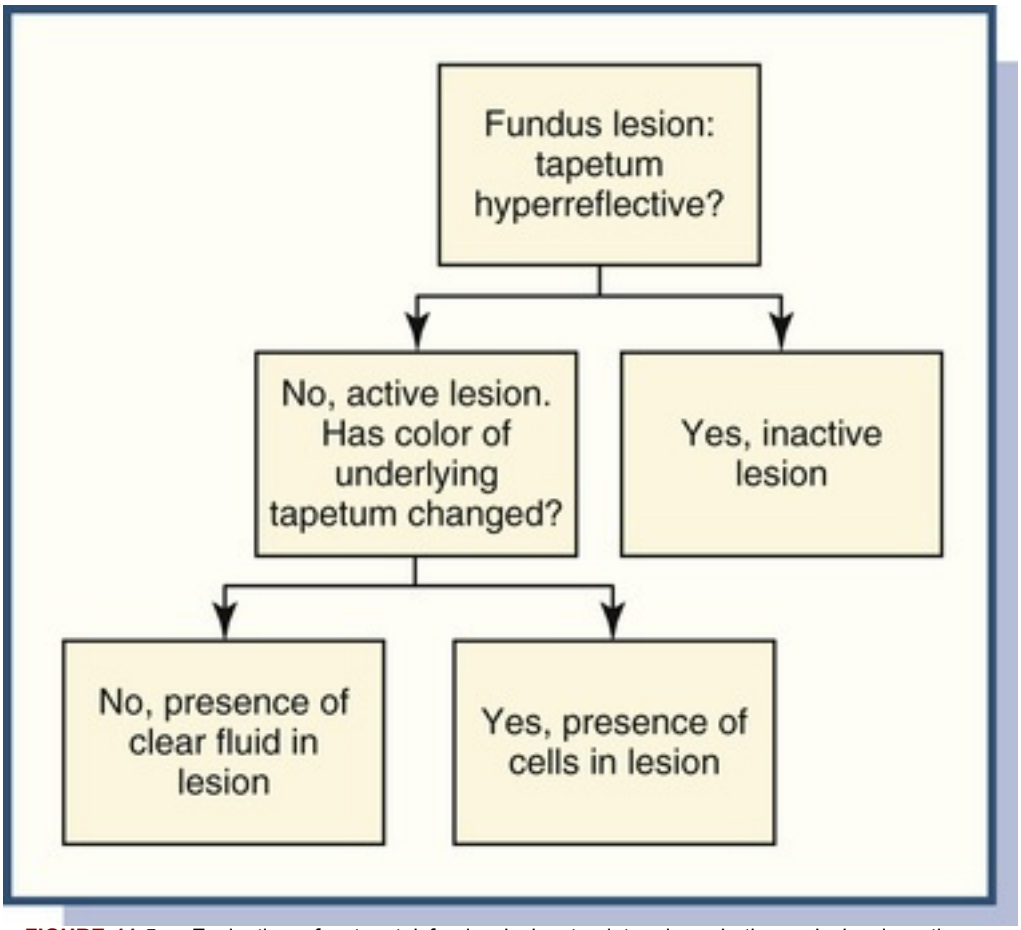

FIGURE 11-5 Evaluation of a tapetal fundus lesion to determine whether a lesion is active or inactive.

Eyelids and Conjunctiva

Blepharitis, inflammation of the eyelids, can be a disease in itself, or be part of a generalized dermatologic problem. The eyelids have numerous meibomian glands, which are an important part of the tear film as they secrete the oily surface part of the tear film. These glands can become impacted and secondary infection with *Staphylococcus* spp. may result in painful, swollen eyelids. Infection with *Demodex* spp. may result in alopecia of the eyelids. Immune-mediated diseases such as uveodermatologic syndrome or pemphigoid diseases may affect the eyelids and the mucocutaneous junctions of the eyelids (ch. 204).[1] Infectious diseases can manifest themselves in the eyelids as well. An example of this is leishmaniasis.[2]

Inflammation of the conjunctiva (conjunctivitis) is common in cats. Hyperemia of the conjunctiva, chemosis, blepharospasm and epiphora are common signs. Infection with feline herpesvirus 1 (FHV-1) is a common cause of conjunctivitis in cats and is often self-limiting in nature. Primary infections with this virus are often associated with upper respiratory signs. Recrudescent infections often involve the eye(s) only. Supportive care with a topical antibiotic ointment three to four times a day is indicated to prevent secondary bacterial infections. In cats with a weak immune system, such as very young cats, older or sick cats, antiviral therapy is often needed to help resolve the clinical signs. This can be either topical (0.5% cidofovir twice a day, or idoxuridine four times a day) or systemic by using famciclovir. The recommended dosage for famciclovir has a broad range from 62.5 mg twice daily by mouth per cat to 90 mg/kg by mouth three times a day. Recent research suggests that a dosage of 40 mg/kg by mouth three times a day may be recommended to treat FHV-1 infections.[3] *Chlamydia felis* is another conjunctival pathogen in cats although less common than FHV-1. Conjunctivitis in dogs is often secondary to a decrease in tear production (keratoconjunctivitis sicca) or systemic allergies. Infectious causes of conjunctivitis such as canine herpesvirus are rare in dogs. Conjunctivitis is a disease in itself without significant other ocular diseases present. This should not be confused with conjunctival hyperemia, which is often a sign of more significant ocular diseases present.

Keratoconjunctivitis Sicca (KCS)

A decrease in tear production is a very common cause of redness, irritation and discharge in dogs. An immune-mediated destruction of the tear gland is the most common cause for KCS in dogs. Many breeds are predisposed, including the English Bulldog, American Cocker Spaniel, Shih Tzu, Lhasa Apso, Cavalier King Charles Spaniel and Pug. Clinical signs include redness and (mucoid) discharge, especially in the morning. In acute KCS, corneal ulceration is common. Measurement of the tear production using a Schirmer tear test is indicated in any dog with a corneal ulcer. The results of the Schirmer tear test should be interpreted with the clinical signs in mind. Tear production in a normal dog's eye is at least 15 mm/min. Surface disease of the eye, such as a corneal ulcer, stimulates tear production and tear production should be much greater than 15 mm/min in an affected eye. Medications can also be a cause of KCS in dogs. Oral sulfonamides have been associated with KCS in dogs, as has the non-steroidal anti-inflammatory drug etodolac.[4,5] Oral antihistamines commonly used in management of atopy in dogs can cause a decrease in tear production as well. Careful monitoring of clinical signs (discharge/redness) and Schirmer tear test results in dogs treated with these medications is indicated.

Special consideration needs to be given to dogs that are sick enough to be hospitalized. A recent study evaluating tear production in dogs admitted to an intensive care unit found a significant decrease in tear production in these dogs.[6] This may predispose to the development of painful corneal ulcerations. Application of lubricating artificial tear ointment several times a day may help prevent surface ocular disease in sick dogs.

KCS is rare in cats and clinical signs are different in cats than in dogs. A transient decrease in tear production is often seen in FHV-1 infection. This decrease may become permanent in some cats. The most common clinical sign of KCS in the author's experience is blepharospasm that is fairly mild but persistent. Mucoid discharge as seen in dogs is not usually present and conjunctival hyperemia is often subtle. Corneal changes such as fibrosis/pigmentation/vascularization are not usually present in KCS in cats. Diagnosis of KCS in cats can be challenging as normal cats can have a low STT reading secondary to stress. Presence of clinical signs in combination with response to therapy (viscous artificial tear solution two to three times a day) often confirms the diagnosis of KCS in cats.

Cornea

A normal cornea is transparent, devoid of blood vessels and pigment, and is in a constant state of dehydration. The cornea receives its nutrition from the aqueous humor and the tear film. The cornea consists of several layers: the epithelium, stroma, Descemet's membrane and endothelium. The corneal endothelium maintains the dehydrated state of the cornea. The stroma is the thickest layer of the cornea. Descemet's membrane has elastic properties and may be seen bulging forward if a corneal ulcer has progressed through the corneal stroma. Multiple different abnormalities can be seen within the cornea. Table 11-1 lists corneal changes and their characteristic appearance. The most common causes of corneal edema include glaucoma, anterior uveitis, corneal ulceration, (anterior) lens luxation, and corneal endothelial cell degeneration. Additional clinical signs of glaucoma include conjunctival and sclera hyperemia, loss of vision, elevated intraocular pressure, and mydriasis. Additional clinical signs of anterior uveitis include conjunctival and scleral hyperemia, presence of aqueous flare and/or cells in the anterior chamber, low intraocular pressure, and miosis. If corneal edema is present, the intraocular pressure should be measured to rule out glaucoma, fluorescein should be applied to the eye to rule out the presence of a corneal ulcer, and careful examination of the anterior segment should be performed to rule out anterior uveitis or lens luxation. The diagnosis of endothelial cell degeneration is made by excluding all other causes of corneal edema.

TABLE 11-1

Corneal Abnormalities and Characteristic Appearance of the Abnormalities

COLOR	LESION	CHARACTERISTICS
White	Fibrosis	Scar tissue. This is usually in the shape and size of the original injury to the cornea. The appearance is smooth, and varies from light grey to a dense grey area. The eye is comfortable.
	Corneal edema	Honeycomb appearance. Corneal edema may be diffuse or focal. Whether or not discomfort is present is determined by the cause of the edema.

	Crystalline infiltrate	Cholesterol/lipid infiltrate: corneal dystrophy is a genetic disorder in some breeds. Lesions are often paracentral in the cornea and may be bilateral. The infiltrate is often well-circumscribed and densely white. The eye is comfortable. This often appears within the first few years of life.
		Cholesterol/lipid infiltrate secondary to systemic disease: This is often located adjacent to the limbus in the periphery of the cornea (arcus lipoides). The eye is comfortable.
		Calcium infiltrate: Corneal degeneration. This is a degenerative disease in older dogs. Calcium spicules are located within the cornea. Their distribution is uneven. The eye is often uncomfortable. Affected areas of the cornea may slough, resulting in corneal ulceration.
	Cellular infiltrate	Abscess formation within the cornea. Significant discomfort is often present as well as vascularization towards the affected area. The affected area may have a yellow-white appearance.
Red	Superficial corneal vessels	Superficial corneal vessels have a branching pattern and are often seen to cross the limbus into the conjunctival vessels. They indicate the presence of superficial corneal disease.
	Deep corneal vessels	Deep corneal vessels originate at the limbus and are straight. They may be 360 degrees around the limbus or in a focal area of the cornea. Deep corneal vessels indicate deep corneal disease or intraocular disease.
	Intrastromal corneal hemorrhage	An intrastromal corneal hemorrhage is a focal bleed between the lamellae of the cornea. It requires the presence of pre-existing corneal vessels. Intrastromal corneal hemorrhages can persist within the cornea for an extended period of time.
Brown	Pigmentation	Secondary to chronic irritation from any source. Examples include chronic entropion, KCS, and abnormal ciliae.
	Pigmentation	Pigmentary keratitis in Pugs. This is a hereditary, progressive pigmentation of the cornea in this breed.
	Corneal sequestrum	Focal brown pigmented spot in the cornea of cats. Brachycephalic breeds are predisposed.

Healing of a corneal ulcer is a rapid process in a young healthy animal with a normal tear production and normal eyelid function and position. It is delayed in older animals, in dogs with KCS and if abnormal eyelid function or position is present. In addition, corneal sensitivity is decreased and wound healing delayed in diabetic dogs.[7]

Iris

The anterior uvea of the eye consists of the iris and ciliary body. Both structures are usually inflamed in anterior uveitis. The ciliary body is continuous with the choroid and inflammation of the anterior uvea is often associated with inflammation of the choroid as well. The uveal tract is a highly vascular area and is often affected by systemic diseases. Inflammation of the uveal tract results in a breakdown of the blood-aqueous barrier. This is clinically visible as aqueous flare when proteins and/or cells enter the aqueous humor. A decrease in production of aqueous humor by the ciliary body in combination with increased resorption through the inflamed uveal tract results in a decrease in intraocular pressure. Spasm of the ciliary body muscles may result in a painful miosis. Other clinical signs seen in anterior uveitis include conjunctival and scleral hyperemia and a decrease in vision or loss of vision if inflammation is severe.

Anterior uveitis has many causes in both dogs and cats.[8] The most common causes in cats include infection with feline leukemia virus, feline immunodeficiency virus, feline infectious peritonitis, *Toxoplasma gondii*, and the various fungal diseases. The role of *Bartonella henselae* in anterior uveitis in cats is still debated. Numerous etiologies exist in dogs and include infectious organisms such as bacterial, fungal, rickettsial, protozoal, parasitic or viral diseases.[9-11] Uveodermatologic disease is an immune-mediated destruction of pigment in the eye and the skin resulting in uveitis and loss of pigmentation in skin and hair.[1] Trauma to the eye may result in uveitis and uveitis can also be the result of ocular diseases such as lens-induced uveitis. A cause may not always be found for anterior uveitis in dogs and cats and symptomatic treatment is indicated in these animals. Treatment of uveitis consists of treatment of the underlying disease if possible as well as treatment of the uveitis itself. Treatment of anterior uveitis consists of topical corticosteroids such as 1% prednisolone acetate or 0.1% dexamethasone solution. The frequency of application depends on severity of the disease. A painful miosis is often present and is best treated with application of topical 1% atropine solution or ointment. The author prefers to avoid using atropine solution in cats, as drainage through the nasolacrimal system may result in profuse salivation. Topical non-steroidal anti-inflammatory medications such as 0.03% flurbiprofen

or 0.1% diclofenac are especially useful if the presence of a corneal ulceration precludes the use of topical corticosteroids. Systemic corticosteroids or other immunosuppressive medications are indicated in treatment of severe anterior uveitis or if the choroid is involved in the disease process as well. Careful monitoring of the intraocular pressure is indicated, as secondary glaucoma may occur in anterior uveitis. This is especially the case if atropine or non-steroidal anti-inflammatory eye medications are used.

Lens

The lens is an avascular structure and abnormalities of the lens are limited to cataract formation and lens luxation. The most common reason for cataract formation in the dog is a hereditary abnormality. The second most common cause is diabetes mellitus in the dog[12] (Figure 11-6). The onset of diabetic cataracts is often very sudden and affected dogs may lose their vision within days to weeks.[13] The high concentration of glucose in the lens is metabolized through aldose reductase into sorbitol which accumulates in the lens. This results in an accumulation of water in the lens with subsequent lens fiber damage and cataract formation. The lens can become much larger than normal (intumescent cataract) and secondary spontaneous lens capsule rupture has been reported in diabetic dogs. The window of opportunity for successful cataract surgery is much shorter in diabetic dogs than in dogs with genetic cataracts and surgery should be performed soon after the onset of cataract formation if possible. Focal cataract formation in the lens can be seen in dogs with hypocalcemia. The most common cause for cataract formation in cats is chronic anterior uveitis. Diabetes mellitus does not cause cataract formation in cats.

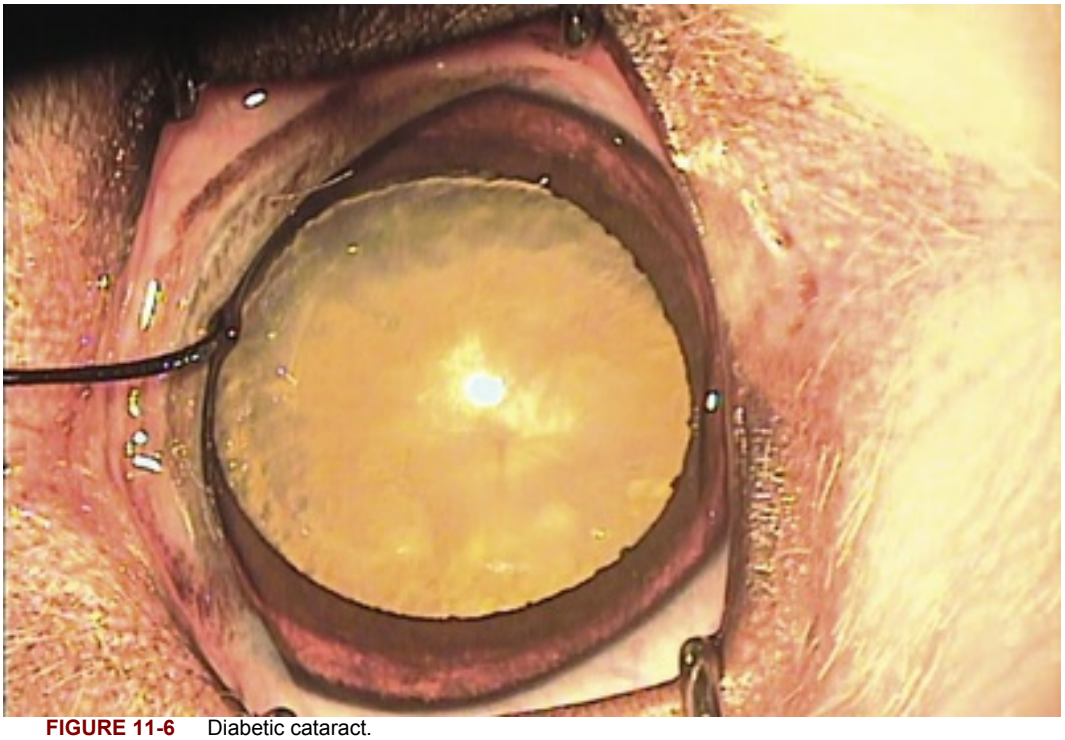

FIGURE 11-6 Diabetic cataract.

Choroid and Retina

It is uncommon for diseases to affect the choroid and/or retina without affecting the anterior uvea as well. The causes for choroiditis, retinitis, and chorioretinitis are similar to the causes for anterior uveitis in dogs and cats. Clinical signs of chorioretinitis may include retinal edema, retinal vascular changes such as tortuosity or vasculitis, intraretinal, preretinal or vitreal hemorrhages, and retinal detachment. Vision may be impaired if changes are severe. Diagnosis and treatment of chorioretinitis is similar to the diagnosis and treatment of anterior uveitis. Topically applied medications, however, are not effective in treating chorioretinitis and systemic treatment is indicated if chorioretinitis is present.

The optic nerve is the only part of the central nervous system that can be observed and evaluated directly.

A normal optic nerve in a dog is variable in size and shape, depending on the amount of myelin present (Figure 11-7). Although there is a large variation in optic nerve size and shape between dogs, the optic nerves in one dog are usually fairly similar in size and shape making comparison between the two eyes a reasonable thing to do. A normal optic nerve in dogs is a combination of white myelin and red blood vessels, resulting in a light pink appearance in most dogs. The edges of a normal optic nerve are well-defined. Edema of the optic nerve and inflammation of the optic nerve can have a similar appearance. The optic nerve is swollen, protruding into the vitreous cavity, the edges are hazy and indistinct, and there may be edema present in the area immediately adjacent to the optic nerve (Figure 11-8). The color of the optic nerve may be much more red than normal. Optic nerve edema may be associated with an increase in intracranial pressure. Evaluation of the optic nerve prior to collection of cerebrospinal fluid is indicated. Vision may not be affected when optic nerve edema is present. Inflammation of the optic nerve (optic neuritis) is usually associated with a mydriatic pupil and loss of vision. Optic neuritis should be considered part of a neurologic disease and appropriate diagnostic workup for neurologic disease is indicated (see ch. 12 and 259).

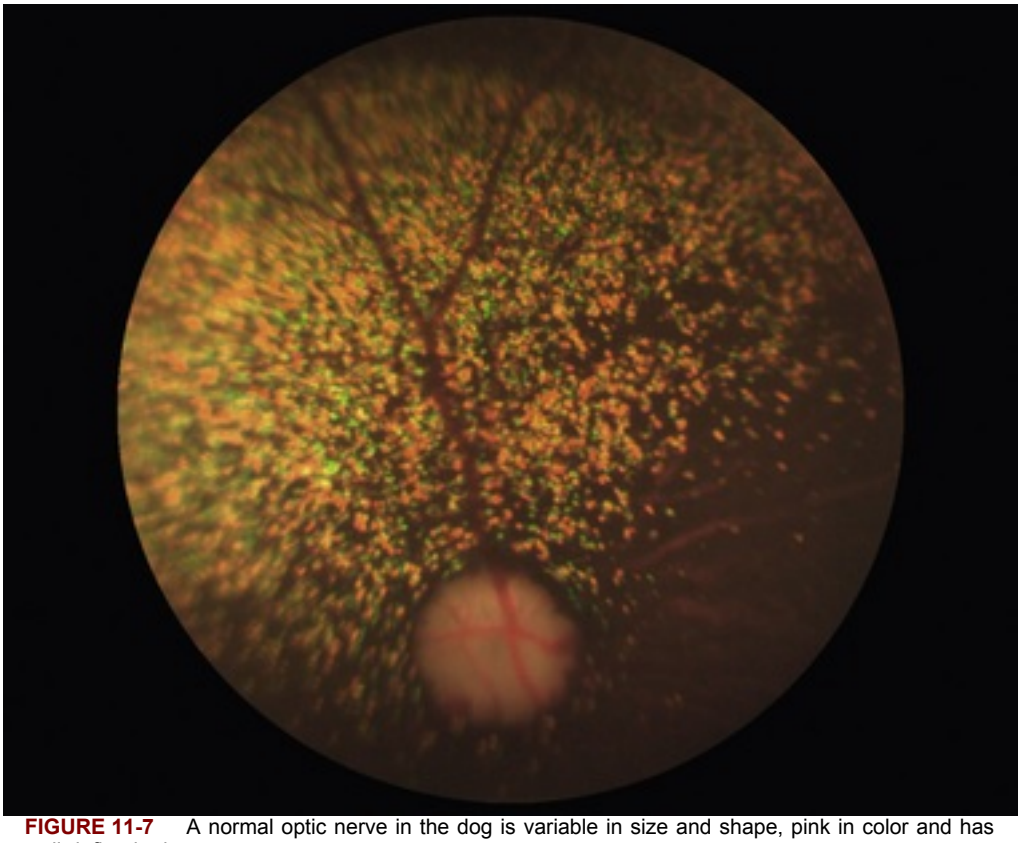

FIGURE 11-7 A normal optic nerve in the dog is variable in size and shape, pink in color and has well-defined edges.

FIGURE 11-8 The optic nerve is swollen, protruding into the vitreous cavity with fluid in the areas adjacent to the optic nerve.

Orbital Disease

Inflammatory or neoplastic diseases of the orbit are often local diseases and not associated with systemic disease. Signs of orbital disease may include exophthalmos, protrusion of the third eyelid, decreased retropulsion of the globe into the orbit, loss of vision and pain upon opening of the mouth. Abscess formation in the orbit of dogs may be associated with dental disease, foreign body penetration through the mouth or conjunctival surfaces, or rarely be a consequence of abscess formation elsewhere in the body. Orbital inflammatory disease often has an acute onset, is very painful, and general malaise is usually present. Masticatory myositis is an immune-mediated inflammation of the masticatory muscles and may result in bilateral painful orbital disease.[14] Diagnosis is confirmed by testing for type 2M fiber specific autoantibodies against masticatory muscle myosin heavy and light chains (see ch. 354). Treatment is aimed at immune suppression and should be long-term to avoid relapse of the disease. Extraocular polymyositis is a disease that is most commonly seen in young Golden Retrievers. Swelling of all extraocular muscles results in bilateral exophthalmos; however, retropulsion in the orbit is normal. The sclera is visible 360 degrees which gives these dogs a distinct look. Diagnosis is confirmed by the presence of enlarged extraocular muscles on computed tomography scan or magnetic resonance imaging. Treatment is aimed at immune suppression.

Orbital neoplasia can be primary orbital neoplasia or secondary from extension from adjacent tissues (most commonly the nasal cavity) or metastatic spread from elsewhere. Orbital neoplasia is usually malignant in both dogs and cats.

Systemic Hypertension

Systemic hypertension may go unnoticed in cats and dogs until loss of vision prompts the owners to bring their cat or dog in for evaluation and treatment. Ocular manifestations of systemic hypertension include hyphema, vitreal hemorrhage, retinal hemorrhage, retinal vascular tortuosity, retinal edema, retinal detachment, and loss of vision[15,16] (Figures 11-9 and 11-10). Secondary to the loss of retinal function, the pupil becomes mydriatic, which is often noted by the owner. Similar clinical signs can be seen in dogs with hyperviscosity syndrome.[17] The reader is referred to ch. 99 and 157-159 for diagnosis and treatment of

systemic hypertension. Multiple blood pressure measurements are sometimes needed to diagnose hypertension. On the other hand, acquiring a single high blood pressure in a stressed cat with a completely normal ocular fundus is unlikely to represent persistent systemic hypertension. Treatment of hypertensive retinopathy consists of treatment of the hypertension. If hyphema is present, use of topical corticosteroids such as 1% prednisolone acetate or 0.1% dexamethasone is indicated two to four times a day. The prognosis for return of vision depends on the ease with which the hypertension can be managed as well as the severity of the ocular abnormalities present. In the author's experience, the presence of significant vitreal or retinal hemorrhages carries a poor prognosis for return of vision. The prognosis for return of vision is much better if retinal edema or detachment is present without the presence of hemorrhages.

FIGURE 11-9 Hypertensive retinopathy in a cat. Focal areas of retinal edema are present.

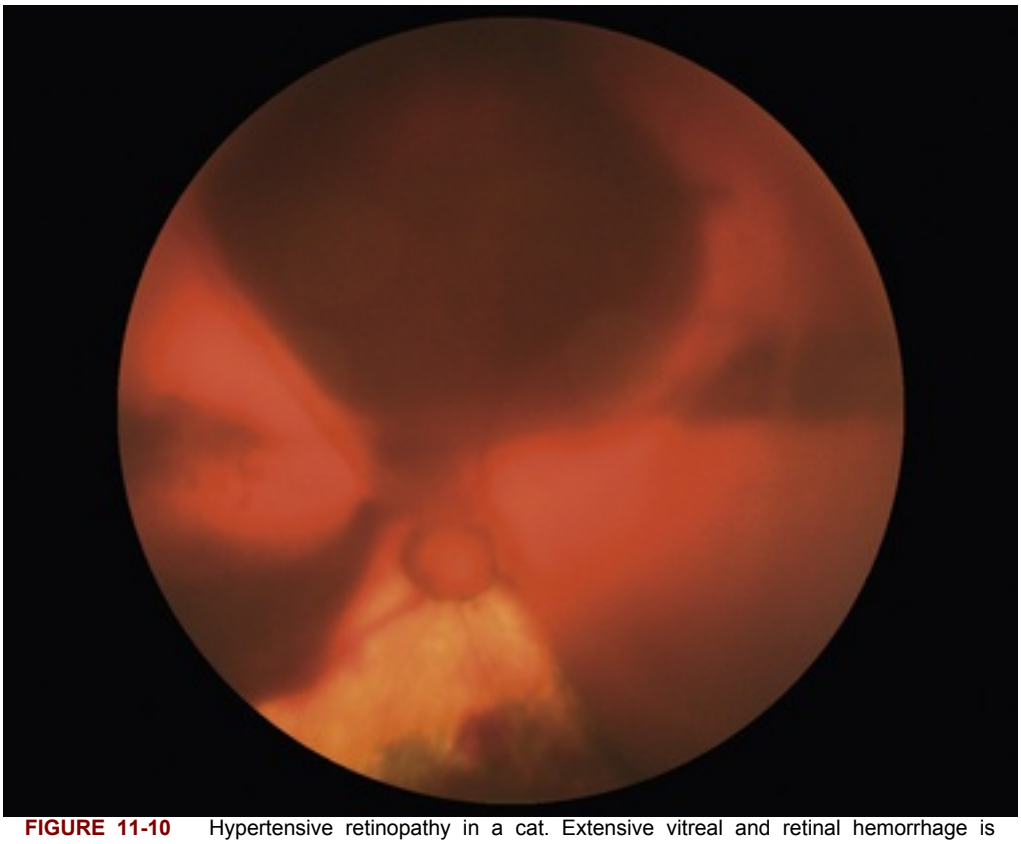

FIGURE 11-10 Hypertensive retinopathy in a cat. Extensive vitreal and retinal hemorrhage is present.

Metastatic Neoplasia

The uvea is a highly vascular structure within the eye that acts as a filter for pathogens and neoplastic cells in the body. Metastatic neoplasia can be seen in the iris and choroid of dogs and cats. The most common metastatic neoplasia found in the iris is lymphoma.[18] Lymphoma (see ch. 344) in the iris of cats is usually a focal pink raised lesion in the iris. Performing an aqueocentesis and submitting the aqueous humor sample for cytospin and cytology may help aid in the diagnosis of lymphoma in cats. Lymphoma in the iris in dogs more commonly manifests itself as an anterior uveitis with or without focal nodules in the iris. Involvement of the uveal tract indicates systemic involvement, especially in dogs. Debate still exists as to whether primary ocular lymphoma without systemic involvement exists in dogs and cats or not.[19] Treatment of ocular lymphoma consists of systemic treatment of the lymphoma. The iris lesions can resolve completely in response to chemotherapeutic agents. Topical corticosteroids are indicated if systemic disease cannot be adequately controlled with chemotherapeutic agents.

CHAPTER 12

Neurologic Manifestations of Systemic Disease

Helena Rylander

Client Information Sheets:
Brain Disorders
Neuromuscular Disorders

A variety of systemic diseases can cause neurologic signs. Findings on history and physical examination may reveal abnormalities that can be associated with a specific systemic disease causing neurologic signs. Neurologic signs may be the only manifestation of systemic disease. The cerebral cortex and the peripheral nervous system (PNS) are areas of the nervous system most susceptible to systemic disease. In addition, white matter, brainstem, and cerebellar signs have been documented secondary to systemic conditions. Specific neurologic signs and lesion localization are discussed in ch. 259.

Diseases Causing CNS Signs

Diseases causing central nervous system (CNS) signs are presented in Table 12-1.

TABLE 12-1

Neurologic Manifestation of Systemic Disease

CENTRAL NERVOUS SYSTEM	PERIPHERAL NERVOUS SYSTEM
Energy Deprivation	**Hypoxemia: Aortic Thromboembolism**
1. Hypoxemia a. Pulmonary disease b. Cardiac failure i. Infarcts ii. Hypoxia iii. Hypertension c. Anesthetic accident d. Vascular i. Hypertension ii. Coagulopathies iii. Vasculitis iv. Hyaline arteriopathy 2. Hypoglycemia a. Insulin-producing neoplasia b. Insulin overdose c. Sepsis 3. Nutritional a. Thiamine deficiency b. Irradiated diet	a. Cardiovascular b. Renal disease c. Hyperadrenocorticism d. Hypothyroidism e. Neoplasia f. Disseminated intravascular coagulation (DIC) g. Sepsis
Metabolic	**Metabolic**
a. Hepatic-encephalopathy b. Uremic encephalopathy c. Hypothyroidism	a. Kidney failure b. Hypothyroidism c. Hyperthyroidism

d. Hyperthyroidism e. Hyperadrenocorticism f. Hypoadrenocorticism	d. Hyperadrenocorticism e. Hypoadrenocorticism f. Diabetes mellitus
Electrolyte Abnormalities	**Electrolyte Abnormalities**
a. Hypercalcemia b. Hypocalcemia c. Hypernatremia d. Hyponatremia e. Hyperkalemia f. Hypokalemia	a. Hypokalemia
Neoplasia	**Neoplasia**
a. Primary b. Metastatic c. Infarcts d. Paraneoplastic syndrome	a. Paraneoplastic syndrome

Hypoxemia from Systemic Disease

Decreased arterial oxygen tension or reduced cerebral blood flow can result in hypoxic encephalopathy. Hypoxemia can occur secondary to an anesthetic accident, hematologic disorders (especially anemia), or cardiovascular and respiratory failure (see ch. 240 and 246). Autoregulatory mechanisms are responsible for providing relatively constant cerebral blood flow despite changes in systemic arterial pressure. Some areas of the brain are more susceptible to energy deprivation or may contain a higher concentration of *N*-methyl-D-aspartate (NMDA) membrane receptors.

Increased release of the excitatory neurotransmitter glutamate in cell injury leads to increased cellular influx of calcium and neuronal death. Global ischemia is associated with bilateral infarcts in the "watershed zones" between areas supplied by major arteries. Changes in blood flow to the brain may occur secondary to hyperviscosity from erythrocytosis (relative or absolute), hypercholesterolemia, hyperlipidemia (familial hyperlipidemia, hyperadrenocorticism, hypothyroidism), immune-mediated disease, sepsis, coagulopathies, and hyperglobulinemia. Hyperviscosity can result in emboli which then cause ischemic infarcts (see ch. 260).[1,2] Clinical signs reflect the area of the brain affected. Recent studies suggest that acute vision loss in cats after a cerebrovascular accident may be due to occlusion of the maxillary arteries and reduced blood flow to the brain, in particular when using a mouth gag.[3] Cytotoxic edema in the white matter can be detected on magnetic resonance imaging (MRI) scans.[4] Treatment consists of attempting to establish normal brain blood flow and oxygenation. Steroids are contraindicated and may cause further damage. Recovery is slow, taking weeks to months. Residual neurologic signs may persist after severe brain injury.

Systemic Hypertension

During a rapid and sustained rise in blood pressure, autoregulatory mechanisms for maintaining blood flow can fail, resulting in hypertensive encephalopathy (see ch. 157). Neurologic signs may occur at a lower blood pressure (170 mm Hg) if hypertension develops rapidly.[5] Common neurologic signs are seizures, ataxia, stupor, and blindness. Postmortem findings may include cerebral edema, caudal displacement of the vermis of the cerebellum, arteriolar hyalinosis, hyperplastic arteriosclerosis, ischemia, and necrosis. Cerebral microhemorrhages, possibly secondary to hypertension, have been reported on both MRI scans and necropsy in dogs.[6] Controlling hypertension in cats after renal transplantation reduces both incidence of seizures and neurologic complication–related deaths.[7] Hyaline arteriopathy in cats secondary to hypertension may result in thrombosis with signs of cervical myelopathy or encephalopathy.[8]

Endocrine/Metabolic Causes

Hepatic Encephalopathy

Hepatic encephalopathy (HE) can be caused by portosystemic shunt (PSS), microvascular dysplasia, idiopathic noncirrhotic portal hypertension, or other causes of liver failure (ch. 280, 281 and 284). Neurologic signs have been reported in about 95% of dogs with PSS.[9,10] The clinical signs may be more obvious after a

meal and tend to wax and wane. Neurologic signs are typical of diffuse cerebral disease and vary from mild (an inability to learn new things and behavioral changes) to more severe (head pressing, blindness, mentation changes and seizures). Brainstem and cerebellar signs have been described.[11] Neurologic signs were more common when the shunts inserted caudal to the liver.[12] One case report describes resolution of generalized neuromuscular weakness and regurgitation after surgical correction of a PSS.[13] MRI scans of dogs with PSS showed hyperintense, non–contrast-enhancing lesions in the lentiform nuclei and widened sulci.[14]

The pathogenesis of HE is not fully understood. Various endogenous toxins (amino acids, ammonia, mercaptans, gamma-aminobutyric acid [GABA], false neurotransmitters) normally cleared by the liver contribute to CNS signs. Hyperammonemia and inflammation predict the presence of hepatic encephalopathy in dogs with PSS.[15] Hyperammonemia, >120 mcmol/L due to urea cycle enzyme deficiency, has been documented in young Irish Wolfhounds without PSS.[16] Increased cerebrospinal fluid concentration of glutamine, quinolinic acid, tryptophan, and tryptophan metabolites have been found in dogs diagnosed with a PSS.[17,18] Activation of GABA receptors by increased levels of endogenous benzodiazepines may contribute to the clinical signs of HE, and a withdrawal effect may cause postsurgical seizures.[19] Hepatic encephalopathy has been successfully treated with flumazenil, a benzodiazepine-receptor antagonist. This also suggests that increased GABAergic tone has a role in the pathogenesis of HE.[20,21] Medically, production and absorption of toxins generated by bacteria in the gastrointestinal tract may be reduced with low-protein diets, antibiotics and/or lactulose.

Seizures may be controlled with potassium bromide (40 to 60 mg/kg PO q 24 h) or levetiracetam (20 mg/kg PO q 8 h) (see ch. 260). Sodium bromide, IV, can rapidly increase serum levels. Phenobarbital (3 to 5 mg/kg PO q 12 h) should be used with caution since it is protein-bound and metabolized by the liver. Benzodiazepine (0.5 mg/kg IV) may prevent postsurgical-withdrawal seizures.[22,23] Surgical correction of congenital PSS carries a better prognosis for postoperative survival and neurologic morbidity if done before 2 years of age according to some, whereas others suggest that the prognosis is similar in dogs >5 years of age.[24,25] Prophylactic antiepileptic therapy may reduce the incidence of postsurgical neurologic signs and seizures.[26-30]

Uremic Encephalopathy

Toxic substances not excreted due to acute kidney injury (AKI; ch. 322) or chronic kidney disease (CKD; ch. 324) can cause signs similar to those of hepatic encephalopathy. Increased concentrations of parathyroid hormone (PTH) and subsequent hypercalcemia may also contribute to uremic encephalopathy. A recent study did not show a significant reduction in serum PTH after treatment with calcitriol in normal cats or those with CKD.[31] Phosphate binders and low phosphate diets aid in minimizing uptake of phosphorus and treating high blood pressure can lower the risk for hypertensive encephalopathy.[31-35]

Hypothyroidism

The only clinical changes in some hypothyroid dogs may consist of acute or chronic progressive central vestibular signs (see ch. 299 and 300). The pathogenesis of hypothyroidism-associated abnormalities is likely multifactorial, and includes atherosclerosis with hypercholesterol-induced or hypertriglyceride-induced microthrombi causing infarcts or transient ischemic attacks, segmental demyelination, dysfunction of metabolic pathways within the brain, and metabolic derangement of neuronal or glial cell populations.[36,37] Intermittent vestibular signs may be seen with transient ischemic attacks. Typically, changes are not detected on MRI scan or on brain histology. Abnormalities may be noted on brain auditory-evoked response (BAER) or electroencephalogram (EEG). Increases in protein content of cerebrospinal fluid may be seen. Thyroid hormone supplementation usually resolves neurologic signs.

Myxedema coma is a rare but life-threatening manifestation of hypothyroidism. Clinical signs include mentation changes due to brain edema, hypothermia without shivering, non-pitting skin edema, and bradycardia. Hyponatremia and hypoventilatory hypoxemia can worsen neurologic status. Treatment consists of adequate ventilation, IV saline, passive correction of hypothermia, and levothyroxine (5 mcg/kg IV q 12 h). This should be followed by oral thyroid supplementation. Clinical improvement, when it occurs, is usually seen within 24 hours. Mortality, however, is high.[38,39]

Congenital hypothyroidism has been described in both dogs and cats. Clinical signs include disproportionate dwarfism, abnormal hair coat, lethargy, a stiff/stilted gait and abnormal mentation. Histologically, hypomyelination is seen in the corpus callosum, corona radiata, pons, pyramids, and the

lateral funiculi of the spinal cord.[40] Recently, a mutation causing congenital hypothyroidism in Tenterfield Terriers was described.[41]

Hyperthyroidism

Cats with hyperthyroidism may show mild CNS signs such as hyperactivity, change in sleep/wake cycle, aggression, or obtundation (ch. 301). Neurologic signs usually improve (and may completely resolve) with treatment.

Hyperadrenocorticism

Direct compression from a pituitary macroadenoma can cause mild to severe neurologic signs (ch. 306). Early clinical signs of macroadenoma include inappetence, mild obtundation, pacing, and disorientation (ch. 306). The condition may progress to more severe obtundation, circling, tetraparesis, ataxia, and seizures. Dogs with clinical signs usually have masses >1.0 to 1.5 cm in greatest diameter. Blindness rarely occurs in dogs and cats. Hyperlipidemia may result in infarcts. Ten of 13 dogs diagnosed with pituitary-dependent hyperadrenocorticism had a visible pituitary tumor at the time of or within a year of diagnosis, and 2 of these dogs developed neurologic signs within one year of diagnosis. Pituitary tumors cause neurologic signs in 15% to 30% of dogs before or after diagnosis and treatment for pituitary-dependent hyperadrenocorticism.[42,43]

Hypoglycemia

The brain neither synthesizes nor stores glucose. It is dependent on blood glucose for cellular metabolism. The brain utilizes ≈100 grams of glucose per day. Persistent hypoglycemia causes vascular constriction and hypoxia. Hypoglycemia can occur in dogs and cats secondary to a variety of conditions, including simple poor nutrition, insulinoma, liver failure, hypoadrenocorticism, nonislet cell tumors producing insulin-like growth factors, large metabolically active tumors (leiomyosarcoma), severe erythrocytosis, and sepsis (ch. 61). Hypoglycemia is a paraneoplastic syndrome (ch. 352).[44-48] It can also be associated with exogenous insulin overdose.

Neurologic signs secondary to hypoglycemia wax and wane with episodes of obtundation, weakness, disorientation, tremors, partial or generalized seizures, blindness, and/or coma. There is no correlation between the severity or frequency of clinical signs, degree of hypoglycemia, and survival time post-treatment. Symptomatic treatment with IV glucose (2 to 4 mL/kg of 50% glucose diluted to 25% concentration) usually quickly reverses neurologic signs. Medical management with prednisone is used to stimulate gluconeogenesis and glycogenolysis. Frequent small meals of high-protein, high-fat, and high–complex-carbohydrate diets can be helpful.

A serum insulin concentration within the midreference range or higher, with a serum glucose concentration <60 mg/dL, is consistent with a diagnosis of insulin-producing tumor (see ch. 303). Surgical removal of insulinoma is ideal, but this is a highly malignant form of cancer. Median survival time in one study of dogs with insulinoma was 196 days with only medical treatment, 785 days with only surgical treatment and 1316 days in dogs treated medically after relapse postsurgery.[46] Diazoxide inhibits insulin secretion, stimulates production of glucose by the liver, and inhibits glucose uptake by the cell. It has been successfully used in dogs but not in cats with insulin-producing tumors.[49] Permanent brain damage from neuronal death may persist despite normalization of blood glucose and insulin concentrations with treatment.[50,51]

Thiamine Deficiency

Thiamine is essential for decarboxylation of pyruvic acid and other alpha-keto acids. Thiamine deficiency causes decreased utilization of pyruvic acid and some amino acids, increased utilization of fats, and aciduria.[52] Thiamine deficiency occurs in cats and dogs fed meat preserved with sulfur dioxide, food low in thiamine due to processing, or thiaminase-containing fish. Histopathologic findings are those of polioencephalomalacia with bilateral symmetrical spongiosis, necrosis, and hemorrhage in the medial vestibular nuclei, caudal colliculi, cerebellar nodulus, and the subcortical grey matter.[53,54] Experimental thiamine deficiency in cats led to learning deficits likely related to lesions in the hippocampal formation.[55] Neurologic signs of thiamine deficiency reflect lesions in the cerebrum and vestibular nuclei. MRI scan lesions are hyperintense on T2-weighted and FLAIR sequences and contrast-enhance after IV gadolinium. Oral supplementation with thiamine (25 to 50 mg total dose q 12 h) usually resolves clinical signs after weeks to months.[54]

Irradiated Diet

Leukoencephalomyelopathy has been described in cat colonies fed irradiated diets in New Zealand and the UK. Cats became ataxic after several months on these diets. Histopathology demonstrated Wallerian degeneration in the brain and spinal cord. The cause of the encephalomyelopathy is unknown, but oxidative stress may play a role. The cats recover when returned to a normal diet.[56,57]

Electrolyte Abnormalities

Hypercalcemia

Hypercalcemia due to primary hyperparathyroidism or secondary to malignant neoplasm rarely has been related to seizures (ch. 69). The mechanism for seizures is poorly understood. Coagulopathies in hypercalcemic dogs have been documented.[58]

Hypocalcemia

Hypocalcemia can be due to any of several conditions, including AKI, CKD, primary hypoparathyroidism, and lactation (eclampsia). See ch. 69. Hypocalcemia causes increased membrane excitability in both muscle and the CNS. This leads to generalized stiffness, lameness, muscle twitching, nervousness, behavior changes, tetany, and seizures (see Video 298-1). Acute treatment consists of IV calcium (0.5 to 1.5 mL/kg 10% calcium gluconate) over 10 to 20 minutes while monitoring the heart rate. Calcium administered too quickly can result in arrhythmias. Long-term care is dependent on managing the underlying condition or administering vitamin D (see ch. 298).[59]

Hypernatremia/Hyponatremia

Severe *hyponatremia* can cause cerebral edema and life-threatening, diffuse encephalopathy.[60] Overaggressive correction of hyponatremia in dogs may also cause cerebral edema with central pontine myelinolysis and loss of oligodendroglial cells. These complications may occur 48 hours to several days after treatment.[61-63] MRI scans of these dogs has shown bilateral symmetrical hyperintense areas on T2-weighted images in the central thalamic nuclei. Correction of hyponatremia should not cause the rise in serum sodium concentration to exceed 10 mEq/L during any 24-hour period, to reduce the likelihood of such lesions. Aggressive IV saline treatment in symptomatic patients with hyponatremia of less than 24-hour duration may be successful without causing neurologic signs.

Hypernatremia, secondary to osmotic shifts in water from brain cells, leads to reduction of brain volume which, in turn, may cause vascular rupture and focal hemorrhage. Severity of neurologic signs appears related to rapid changes in sodium rather than magnitude of hypernatremia. In chronic hypernatremia the brain adapts to hypertonicity by producing idiogenic osmoles, which prevent cellular dehydration. Rapid correction of hypernatremia, however, results in movement of water into cells and subsequent cerebral edema. Mild hypernatremia can be corrected by offering water to animals willing to drink. More severe hypernatremia can be treated with IV hypotonic saline or 5% dextrose in water calculated using the following formula[64]:

$$\text{Free water deficit} = 0.6 \times \text{body weight (kg)} \times [(\text{plasma } Na^+ / 148) - 1]$$

Neoplasia

Neoplasia can cause neurologic signs secondary to direct invasion, metastasis, or ischemic and hemorrhagic infarcts. Diagnosis can be supported with an MRI scan, cerebrospinal fluid (CSF) analysis, or by identifying the primary neoplasia.[2,65] Paraneoplastic syndromes directly affect the CNS (ch. 352). These include hypoglycemia induced by an insulin-producing tumor or hypercalcemia secondary to lymphoma, thymoma, or apocrine adenocarcinoma.[66]

Hyperthermia

The canine brain has an intrinsic thermal resistance. The origin of neurologic dysfunction in dogs and cats with hyperthermia is usually not directly due to increased brain temperature, but from secondary changes such as hepatocellular degeneration, disseminated intravascular coagulation, respiratory alkalosis, or reduction in mean arterial blood pressure. Mentation changes, loss of pupillary light and oculocephalic reflexes, and tetraparesis have been described.[67]

Diseases Causing PNS Signs

Diseases causing peripheral nervous system (PNS) signs are listed in Table 12-1.

Hypoxia

Aortic thromboembolism, although uncommon in dogs and slightly more common in cats, usually occurs secondary to an underlying condition, such as cardiac disease, hyperadrenocorticism, neoplasia, disseminated intravascular coagulation, sepsis, renal disease, atherosclerosis (hypothyroidism et al), or autoimmune hemolytic anemia. Neurologic signs observed by owners may include progressive exercise intolerance with pelvic limb weakness, or more acute symmetric or asymmetric pelvic limb ataxia, paresis, or plegia. Such signs could follow an ischemic myopathy, neuropathy, or myelopathy.[68-70] Cats usually have peracute signs that include tachypnea, hypothermia, paraparesis, or plegia (ch. 256). Underlying causes are cardiomyopathy, hyperthyroidism, and neoplasia.[71]

Metabolic/Endocrine Disorders

Hypothyroidism

Thyroxine (T_4) stimulates mitochondrial respiratory activity, thus facilitating production of adenosine triphosphate (ATP). In hypothyroidism (ch. 299), the associated ATP deficiency impairs Na^+/K^+ pump activity that reduces axonal transport and causes axonal degeneration and demyelination. Myopathy has also been described secondary to hypothyroidism. In rare circumstances, neurologic signs may be the only manifestation of hypothyroidism. Signs include generalized weakness and muscle atrophy. Focal signs include laryngeal paralysis, megaesophagus, facial paralysis, or peripheral vestibular signs. Lameness as the sole clinical sign has been reported in four dogs.[72] Electrodiagnostic abnormalities and histopathologic abnormalities on muscle and nerve biopsies may be detected before clinical signs.[73] Neurologic signs may resolve after several months of thyroid hormone supplementation.[74]

Hyperthyroidism

Feline hyperthyroidism (ch. 301) has been associated with neuromuscular weakness: cervical ventroflexion, a plantigrade stance, and exercise intolerance. Clinical signs may reverse with treatment.

Hyperadrenocorticism

Hyperadrenocorticism (ch. 306) commonly causes muscle weakness. In rare cases, dogs have fibrotic myopathy or polyneuropathy. Clinical signs of fibrotic myopathy may include a stiff and stilted gait, generalized muscle atrophy, and difficulty flexing the limbs (Video 12-1). Clinical signs of polyneuropathy include generalized weakness and muscle atrophy. Diagnosis may be confirmed on electrodiagnostic testing (electromyogram [EMG] and nerve conduction, ch. 117) and biopsy of muscle and nerve (ch. 116). Type II myofiber atrophy is common. In dogs with fibrosis, stiffness may not change or only partially improve with months of treatment.[75,76] Steroid myopathy has also been described secondary to treatment with prednisone.[77,78]

Hypoadrenocorticism

Hypoadrenocorticism (ch. 309) results in episodes of lethargy, weakness, tremors, and collapse. Painful episodes of muscle cramps are extremely rare.[79] Secondary hypoglycemia may contribute to generalized weakness. Treatment with physiologic doses of glucocorticoids (e.g., prednisolone 0.1 mg/kg PO q 24 h) typically results in full clinical recovery.[80,81]

Diabetes Mellitus

Peripheral nerve metabolism is dependent on glucose. Sensorimotor polyneuropathy is a late complication of diabetes mellitus (DM; ch. 304 and 305). Two major theories of pathogenesis involve metabolic derangement and vascular changes.[82] Clinical signs are most prominent in the pelvic limbs with a plantigrade stance, difficulty jumping, postural reaction deficits, decreased tendon reflexes, and muscle atrophy (see ch. 305). Neuropathic signs are much more common in cats than in dogs (Video 12-2). Horner's syndrome has been reported secondary to DM.[83,84] Abnormalities in nerve conduction studies and EMG are found in both thoracic and pelvic limbs. Histopathologic abnormalities include demyelination, splitting and ballooning of the myelin sheath, and axonal injury. Myelin injury is likely associated with microvascular increase in capillary size, increase in capillary lumen diameter, and increased basement membrane thickness.[82,85-87] Permanent deficits, despite control of the DM, are common.

Kidney Disease

Dogs and cats with CKD may have weakness associated with renal secondary hyperparathyroidism, which causes peripheral neuropathy and myopathy. Inositol phosphates, protein kinase C, and cyclic adenosine monophosphate (AMP), among other regulatory enzymes and signal-transducing systems in muscle cells, are directly affected by calcitriol. PTH-mediated uremic myopathy may be reversible when treated with calcitriol. Excess PTH also partially affects motor nerve conduction velocity. Nerve excitability is modulated by calcitriol, which also affects the synthesis of nerve growth factors. Changes can be found on electromyography and nerve conduction studies (ch. 117).

Hypokalemia

Naturally-occurring hypokalemia is uncommon and may follow dietary restrictions (ch. 68). It is most frequently diagnosed in cats with CKD but seems less common in dogs similarly afflicted. Aside from CKD, it is a rare condition secondary to an adrenal tumor causing excess synthesis of aldosterone (primary hyperaldosteronism, Conn's syndrome) or adrenal-dependent hyperadrenocorticism.[88] Hypokalemia alters resting membrane potentials of muscle, resulting in weakness. Neurologic signs, cervical ventroflexion in cats and generalized weakness in both dogs and cats, are nonspecific. Initial treatment requires IV potassium supplementation if seriously ill. Chronic oral administration can alleviate or minimize the condition. However, IV fluids containing potassium may worsen hypokalemia due to increases in vascular volume and through renal losses associated with increased perfusion. Oral administration of 5 to 10 mEq of KCl per day is safe. Dopamine causes a shift of potassium from the intracellular to the extracellular fluid.[89]

Paraneoplastic Syndrome

Paraneoplastic syndromes can cause neurologic signs due to a remote effect of cancer (ch. 352). This may not be caused by direct neoplastic cell invasion of the nervous system. Nor is this condition caused by any other mechanism related to the presence of cancer: coagulopathy, vascular disorder, infection, or metabolic and nutritional deficits. The syndrome can affect both the CNS and the PNS. Neurologic signs can develop months to years before a tumor is detected. The lack of specific diagnostic tests makes the recognition of the syndrome difficult. Pathogenesis may be due to antibodies produced against cells of the nervous system. Removal of the tumor may result in resolution of the neurologic signs. Paraneoplastic syndromes have been documented secondary to insulinoma, adenocarcinoma, cholangiocellular carcinoma, lymphoma, melanoma, myeloma, and thymoma. Thymoma is a common cause of myasthenia gravis in humans and cats and less common in dogs (ch. 269). Neurologic signs can be focal (megaesophagus) or generalized. The myasthenia gravis may improve with removal of the mass; however, megaesophagus signals a poor prognosis.[90-93]

CHAPTER 13

Intoxication versus Acute, Nontoxicologic Illness: Differentiating the Two

Safdar A. Khan

Case History

Upon presentation of an acutely ill animal, a veterinary professional must consider poisoning as a potential cause among the differentials. A complete and thorough case history in this regard is essential for differentiating a poisoning situation from a naturally occurring disease (see ch. 1). Obtaining a clear recent history may sometimes be quite challenging, especially in situations where the pet was unsupervised before the initiation of clinical signs. History questions must include animal signalment (breed, sex, and age) and weight, previous medical history, vaccination history, dietary history (brand; home-made or commercial; if nutritional intoxication is suspected, obtain product label and lot number) and any medications the pet is taking. Initial information about any other animals present in the household, timeline of clinical signs, types of clinical signs reported by the owner, number of affected animals, pet's environment (indoor vs. outdoor; fenced or free roaming), location (urban vs. rural), time of the year (summer vs. winter), recent renovations/updates (construction material; lead in older farms/houses), recent visitors, availability of human medications in the pet's environment (antidepressants, pain killers, stimulants, nutritional supplements), presence or recent use of chemicals (insecticides, herbicides, rodenticides) in the house/yard, information about neighboring animals (outbreaks; illnesses; death) and information about indoor/outdoor plants may help provide clues to the clinician to narrow down the search for a possible cause for the pet's illness. A good case history can help speed up the process of narrowing down a potential cause, eliminate several unnecessary steps, and save time and money.

Stabilizing the Patient

Before obtaining a complete case history, the first goal should be to stabilize the patient and preserve the life of the acutely ill animal irrespective of the cause. Relying too much on specific antidotal treatment may be dangerous. A majority of clinical cases on presentation are treated supportively as only a very few specific antidotes are available or needed for treating specific poisonings. Therefore, on presentation, it is essential to make sure the animal has a patent airway and adequate, effective ventilation (see ch. 139). Heart rate, heart rhythm, and blood pressure should be monitored, and cardiac arrhythmias (see ch. 248) and systemic hypo- or hypertension should be treated as needed (see ch. 158 and 159). Hydration status, serum electrolyte concentrations, and acid-base balance should be checked and abnormalities corrected accordingly (see ch. 67-70 and 127). Central nervous system abnormalities (excitation, depression, seizures) should be identified and treated as required (see ch. 136 and 148), and hypothermia or hyperthermia should be identified and corrected if present (see ch. 48, 49, and 134).

After stabilizing these vital functions, obtain the medical history; then, provide other necessary treatments such as decontamination (administration of activated charcoal, gastric lavage, bathing, dilution; ch. 151), supportive care, and carrying out other diagnostics (e.g., complete blood count, serum biochemistry profile, urinalysis, radiographs, ultrasound) based on the information obtained and on the patient's progress. Collection of samples for toxicologic analyses can be important. Toxicology testing performed in a diagnostic laboratory can be expensive and time-consuming and in most instances, results are not available immediately. Therefore, to rule in or out a suspected cause, commonly used in-house diagnostic tests are likely to be of greater immediate benefit to the patient (whereas toxicologic analyses can be of superior value for group exposures or for cases involving litigation). For example, assessment of prothrombin time or clotting times can be pivotal in anticoagulant poisoning cases. Other samples for toxicologic testing in a diagnostic laboratory include whole blood for heavy metal analysis (lead), blood cholinesterases (organophosphate

poisoning), and presence of pesticides (anticoagulant rodenticides). Serum or plasma can be analyzed for levels of some metals (zinc), drugs, alkaloids, and electrolytes (useful in sodium chloride poisoning or water intoxication). Stomach contents (vomitus; freeze upon collection) can be used for detecting pesticides, metals, baits, alkaloids, and drugs. Urine (chilled or frozen) can be used for some metal analysis, drugs and their metabolites, and alkaloids (strychnine).

Toxicologic Versus Nontoxicologic

Table 13-1 outlines some important toxicologic versus nontoxicologic rule-outs based on clinical abnormalities one must consider in an acutely ill animal. It is important to note that an acutely ill animal with sudden onset of clinical effects may often have multiple major clinical signs/abnormalities present, and that toxicologic problems can trigger nontoxicologic complications (e.g., aspiration pneumonia). The purpose here is to provide an initial guideline for considering toxicologic versus nontoxicologic rule-out in a patient with an uncertain recent history.

TABLE 13-1

Toxicologic versus Nontoxicologic Rule-Outs

MAJOR CLINICAL ABNORMALITY	TOXICOLOGIC RULE-OUTS	NONTOXICOLOGIC RULE-OUTS
CNS abnormalities (excitation and seizures; see also ch. 35)	• Strychnine (rapid onset, rigidity, hyperesthesia, wooden-horse–like stance) • Metaldehyde (hyperthermia, tremors) • Amphetamines or cocaine (ingestion in dogs: sympathomimetic effects and hyperthermia) • Tremorgenic mycotoxins (penitrem A, roquefortine) from eating moldy foods (GI signs, hyperthermia, and tremors) • Cold medications: pseudoephedrine, ephedrine, some antihistamines (sympathomimetic effects, hyperthermia) • Organophosphate or carbamate pesticides (cholinergic crisis; SLUD signs) • Pyrethrin/pyrethroid-type pesticides (especially permethrin in cats: tremors, shaking, ataxia, seizures, GI signs) • Organochlorine pesticides (tremors, shaking, ataxia, seizures) • Chocolate: caffeine, theobromine, methylxanthines (polydipsia, polyuria, GI and CV effects) • Zinc phosphide: mole or gopher baits (GI signs, shaking, dyspnea due to pulmonary edema) • Bromethalin toxicosis: rat or mouse bait (paresis, weakness, ataxia, tremor) • Lead (GI signs, hematologic abnormalities [nucleated RBCs, basophilic stippling, anemia]) • Metronidazole toxicosis (in dogs with repeated use and/or high dosage: nystagmus, ataxia, weakness, paresis, seizures) • Nicotine: tobacco or cigarettes (ingestion in dogs: spontaneous vomiting, tremors, CV effects) • Tricyclic antidepressant toxicosis: amitriptyline, clomipramine, imipramine,	• Trauma/head trauma (outdoor animal, external or internal wounds/injuries) • Meningitis (fever, hyperesthesia, neck stiffness and pain; fundic lesions possible if optic nerve affected) • Hydrocephalus (large, rounded head; divergent strabismus; seizures; brain ultrasound exam possible if open fontanelle) • Intracranial neoplasia (primary or secondary brain tumor; typically older animals; neurologic deficits almost always asymmetrical) • Congenital portosystemic shunts (more common in certain breeds, <6 months of age, small liver) • Rabies (acute behavior changes, excitation, paralysis; endemic region) • Canine distemper (young dogs: history of fever, respiratory, and/or GI signs usually precede CNS signs) • Hypocalcemia or hypercalcemia (hypocalcemic tremor/tetany; hypercalcemia-induced kidney injury can cause uremic signs) • Hypoglycemia (disorientation, ataxia, seizures; serum glucose <60 mg/dL) • Idiopathic epilepsy (dogs 1-5 years of age: diagnosis of exclusion) • Primary or secondary erythrocytosis (causing hyperviscosity), PCV 65% to >80%, brick red mucous membranes • Uremia (secondary to AKI or CKD) • Endotoxemia/septic shock (hemorrhagic GI signs, progressive weakness, abdominal pain)

	nortriptyline (agitation, nervousness, ataxia, CV effects)	
CNS abnormalities (e.g., CNS depression and/or seizures; see also ch. 35)	• Ivermectin, moxidectin and other avermectin toxicosis (ataxia, weakness, depression, tremors, seizures, blindness) • Marijuana ingestion (ataxia, hypothermia, urinary incontinence) • Benzodiazepines ingestion: alprazolam, clonazepam, diazepam, lorazepam (hyporeflexia, ataxia, CNS excitation: paradoxical reaction) • Barbiturate overdose: short-acting or long-acting (coma, hypothermia, weakness, ataxia) • Ethylene glycol (see ch. 322) (ataxia, disorientation, GI signs) • Methanol or ethanol ingestion (GI signs, ataxia, weakness, depression) • Propylene glycol: antifreeze (depression, ataxia, GI signs) • Baclofen or other centrally acting muscle relaxant ingestion in dogs (vocalization, ataxia, disorientation, coma, hypothermia) • Amitraz insecticide exposure (depression, ataxia, CV effects, paralytic ileus)	• Thiamine deficiency in cats (cats fed mainly raw fish diet; ch. 12 and 192) • Polyradiculoneuritis/Coonhound paralysis (ascending flaccid paralysis; often, evidence of muscle pain; occasionally, raccoon exposure within preceding 2 weeks) • Feline infectious peritonitis (blepharospasm due to iritis, fever, weight loss, ataxia, seizures) • Feline leukemia (lymphadenopathy, nonregenerative anemia) • Feline panleukopenia (fever, GI signs, ataxia, neutropenia)
Muscle weakness, paresis, paralysis (see ch. 21 and 269)	• Black widow spider bite (cats: swelling, pain) • 2,4-D and other phenoxy herbicides (dogs: ataxia, weakness, GI signs) • Metronidazole; see Seizures, above • Bromethalin rodenticide; see Seizures, above • Coral snake envenomation (cats: local swelling, pain, puncture wound) • Macadamia nuts ingestion in dogs (weakness, ataxia) • Concentrated tea tree oil exposure: *Melaleuca* oil (both cats and dogs: weakness, ataxia, CNS depression)	• Polyradiculoneuritis/Coonhound paralysis, see above • Botulism (ascending paresis and paralysis; muscles of pharynx can be affected) • Tick paralysis (flaccid ascending paralysis; rapid improvement of signs [<24 hours] after tick removal if North American [*Dermacentor* spp.], longer if Australian [*Ixodes* spp.]) • Aortic thromboembolism (cold extremities, weakness, firm and painful gastrocnemius muscles [cats]) • Profound anemia (measure PCV) • Severe hypokalemia, hyponatremia, hypovolemia, hypo- or hyperthermia (measure parameter) • Degenerative spinal cord diseases (mentation, cranial nerve function intact)
Acute blindness (ch. 11)	• Lead; see Seizures, above • Ivermectin, moxidectin, and other avermectin toxicosis; see Seizures, above • Salt poisoning (in dogs: polydipsia, GI signs, tremors, ataxia, seizures; serum sodium >160 mEq/L is strongly supportive)	• Retinal detachment or hemorrhage (fundic exam; ocular ultrasound) • Glaucoma (measure intraocular pressure) • Trauma (penetrating injury of head, face) • Acute cataract (ophthalmic exam) • Optic neuritis (fundic exam) • Other visual pathway disorders (optic chiasm, optic radiation, occipital cortex) • Sudden acquired retinal degeneration (hyperadrenocorticism-like signs; electroretinogram to confirm)
Acute kidney injury, acute uremia (ch. 322)	• Ethylene glycol toxicosis (ataxia, altered mentation/depression, GI signs; urine may fluoresce with Wood's lamp; azotemia, calcium oxalate monohydrate crystalluria appear after kidney injury has occurred) • Easter lily *(Lilium longiflorum),* tiger lilies *(L. tigrinum, L. lancifolium),* rubrum or Japanese show lilies *(L. speciosum),* day lilies (*Hemerocallis* sp.) ingestion in cats	• Renal infiltration (lymphoma; usually symmetrical nephromegaly; CNS signs common due to brain metastases) • Renal thromboembolism (evidence of peripheral thromboembolism common) • Infectious (pyelonephritis, leptospirosis, Rocky Mountain spotted fever, borreliosis, feline infectious peritonitis: cats) • Urinary tract obstruction (bladder palpation;

	(initially GI signs, azotemia generally 24-72 hours after ingestion) • Cholecalciferol rodenticide and other vitamin D_3 analogs: calcipotriene, calcitriol (initial GI signs, then CV, CNS signs; azotemia; hypercalcemia with hyperphosphatemia differentiates from hypercalcemia of malignancy or hyperparathyroidism) • Grapes and raisins ingestion in dogs (initial GI signs, then azotemia in >24 hours, possible pancreatitis) • NSAIDs: ibuprofen, naproxen, nabumetone, piroxicam, carprofen, diclofenac, ketoprofen, indomethacin, ketorolac, oxaprozin, etodolac, flurbiprofen, sulindac (initially GI signs, azotemia in 24-72 hours after acute ingestions) • Zinc toxicosis; see Acute Hemoglobinemia, below • Melamine and cyanuric acid food contamination (2007 outbreak in the United States, contaminated dog and cat food: crystalluria, azotemia, GI signs)	abdominal ultrasound to evaluate kidneys, ureters) • Chronic kidney disease (end stage) • Ischemic kidney injury and uremia (hypotension, trauma, shock, anaphylaxis, myoglobinuria; urinalysis for renal casts, discoloration) • Amyloidosis (notably Shar-Pei dogs, Abyssinian cats) • Hypercalcemia (lymphadenopathy, hepatosplenomegaly possible with lymphoma, rectal palpation for anal sac mass with anal sac adenocarcinoma; malignancy and primary hyperparathyroidism typically cause concurrent hypophosphatemia) • Transfusion reactions (history)
Acute hepatic injury (ch. 286)	• Mushrooms: *Amanita*-type (delayed onset GI signs [12 hours after ingestion], acute liver injury in 1-3 days) • Blue-green algae: *Microcystis* sp. (exposure to stagnant body of water; acute onset GI signs, hypovolemic shock) • Iron: multivitamin ingestion (GI signs, hypovolemic shock, acute liver injury in 1-2 days) • Sago or cycad palm: *Cycas* sp. (ingestion: GI signs, liver injury in 1-3 days, seizures) • Acetaminophen toxicosis: cats > dogs (methemoglobinemia within a few hours, GI signs, increased liver enzymes in 1-3 days) • Aflatoxicosis (dogs: mostly from contaminated dog food, several outbreaks reported in the United States) • Xylitol; see Hypoglycemia, below • Other drugs (carprofen: GI signs, increased ALT days after starting treatment; corticosteroids: steroid hepatopathy after weeks/months of use; phenobarbital: chronic hepatopathy after months of use)	• Hepatic lipidosis (cats: period of stress, anorexia, obesity) • Hepatic neoplasia (primary or metastatic, acute or gradual; abdominal ultrasound and biopsy to confirm) • Infectious hepatitis (leptospirosis, infectious canine hepatitis, canine herpesvirus, feline cholangiohepatitis, liver abscess, histoplasmosis, coccidioidomycosis, babesiosis, toxoplasmosis, some rickettsial diseases, feline infectious peritonitis; identify other characteristic features of individual diseases) • Septicemia/endotoxemia (vomiting, diarrhea, hypothermia, collapse) • Copper storage (breed: Bedlington Terrier, others) • Heatstroke (high body temperature) • Shock (weak pulse, poor capillary refill time, progressive weakness)
Presence of acute oral lesions/ulcers (ch. 272)	• Acid ingestion (corrosive lesions on lips, gums, tongue, salivation, vomiting, fever) • Alkali ingestion (same as with acid, esophageal perforation more likely) • Cationic detergents: present in several disinfectants (oral burns, salivation, vomiting, fever) • Alkaline battery chewing/ingestion (oral burns, salivation, vomiting) • Potpourri ingestion (cats > dogs: oral burns, salivation, vomiting, tongue	• Uremic stomatitis (uremic halitosis, azotemia, GI signs) • Periodontal disease (associated with dental calculus; gingival lesions) • Trauma (presence of foreign body, recent tooth fracture) • Electrical cord chewing (sharply demarcated ulcers, dyspnea due to noncardiogenic pulmonary edema) • Systemic lupus erythematosus and other autoimmune diseases (lesions are characteristically at the mucocutaneous junction; joint pain, other

	protrusion, fever) • Bleaches: sodium or calcium hypochlorite (bleachlike smell, salivation, vomiting, wheezing, gagging) • Ingestion of phenolic compounds (especially in cats: oral ulcers/lesion may be present, Heinz body anemia and hemolysis may be seen)	systemic signs can be present) • Infectious (feline calicivirus infection, FeLV, FIV, nocardiasis, ulcerative necrotizing stomatitis, *Fusobacterium* spp. infection; identify other characteristic features of individual diseases)
Acute methemoglobinemia, Heinz body anemia, hemolysis or blood loss (anemia) (ch. 198)	• Acetaminophen (chocolate brown-colored mucous membrane within hours, dyspnea) • Naphthalene mothball ingestion (mothball-like odor in the breath, hemolysis) • Onions and garlic toxicosis (hemolysis in 2-3 days, anemia, coffee-colored urine) • Zinc toxicosis (metallic object in the GI tract, gastritis, pancreatitis, hemolysis, hemoglobinuria) • Iron; see Acute Hepatic Injury, above • Anticoagulant rodenticides: brodifacoum, bromadiolone, chlorophacinone, difethialone, diphacinone, pindone, warfarin (lethargy, dyspnea due to pulmonary hemorrhage, persistent bleeding at venipuncture site; increased PT +/- aPTT) • Rattlesnake envenomation (swelling, pain, +/- fang puncture marks in skin; endemic region) • Other drugs (local anesthetic toxicosis [lidocaine, benzocaine, tetracaine, dibucaine]: methemoglobinemia, CV and CNS effects; phenazopyridine and other azo dyes toxicosis [methemoglobinemia, hemoglobinuria])	• Trauma (overt blood loss) • Immune-mediated hemolytic anemia (spherocytosis +/- autoagglutination on blood smear) • Thrombocytopenia (immune-mediated or infectious, uncommonly drug-induced; platelet count) • Chronic kidney disease (smaller kidneys, azotemia, uremic halitosis, oral ulcers) • Infectious (ehrlichiosis, FeLV, hookworms, *Mycoplasma hemofelis*, babesiosis; serologic testing, fecal flotation, blood smear) • Disseminated intravascular coagulation (secondary to shock, neoplasia, septicemia, viral infections, pancreatitis) • Inherited bleeding disorders (von Willebrand disease, factor X deficiency, factor XI deficiency; specific factor analysis needed for confirmation) • Causes of epistaxis (trauma, infectious, nasal polyps, malignant neoplasm, systemic bleeding disorder, systemic hypertension)
Cardiac arrhythmias (ch. 248)	• Foxglove: *Digitalis* sp. (plant ingestion: GI signs, ventricular and/or supraventricular arrhythmias) • Lily of the valley: *Convallaria majalis* (plant ingestion, GI signs, ventricular and/or supraventricular arrhythmias) • Oleander: *Nerium oleander* (GI signs, ventricular and/or supraventricular arrhythmias) • Bufo toads: *Bufo* sp. (endemic region; GI signs, collapse, seizures, sinus tachycardia, ventricular arrhythmias) • Azalea and other *Rhododendron* plants (GI signs, possible cardiac arrhythmias) • Antidepressant toxicosis (CNS signs, anticholinergic effects)	• Automobile trauma (evidence of other injuries) • Gastric dilation and volvulus (abdominal distension, dyspnea, shock; radiographs confirmatory) • Severe anemia (due to any cause of anemia; packed cell volume to confirm) • Severe hypokalemia (due to any cause) • Acidosis (due to any cause) • Hypoxemia (due to any cause) • Primary heart disease (cardiomyopathy, valvular heart disease, congenital heart problems, heartworm infestation: heart murmur, cardiomegaly, and/or evidence of congestive heart failure)
Dyspnea due to pulmonary edema (ch. 242)	• Petroleum distillates: kerosene, gasoline and other hydrocarbons (hydrocarbon smell in the breath, salivation, vomiting, CNS depression, diarrhea, aspiration) • Zinc phosphide (exposure to gopher bait or similar; GI and CNS signs, dyspnea due to noncardiogenic pulmonary edema) • Smoke inhalation (dyspnea, collapse, panting, shock; smell of smoke on fur in	• Cardiogenic (multiple causes of left-sided congestive heart failure) • Noncardiogenic (seizures, head trauma, electrical shock, drowning and near-drowning)

	virtually every case) • Organophosphate or carbamate pesticides (cholinergic crisis, SLUD signs) • Paraquat herbicide (rare; progressive dyspnea, panting, delayed onset after exposure) • Some organic arsenicals (mainly injectable, melarsomine)	
Gastrointestinal signs (vomiting, diarrhea, abdominal pain, drooling) (ch. 36, 39, and 40)	• Garbage poisoning (vomiting, diarrhea, dehydration, abdominal pain) • Chocolate toxicosis (initial stages: polydipsia, polyuria, vomiting, hyperactivity, tachycardia) • Fertilizer ingestion (NPK: vomiting, diarrhea, polydipsia) • NSAID toxicosis (initial stages: GI signs with or without blood in vomitus, diarrhea) • Endotoxins and enterotoxins: staphylococcal, clostridial, *Escherichia coli, Salmonella* (severe GI signs, progressive lethargy, dehydration, hypothermia) • Zinc oxide (diaper rash ointment ingestion in dogs; mild to severe gastritis) • Iron toxicosis; see Acute Hepatic Injury, above • Arsenical herbicides (initial stages: vomiting, abdominal pain, watery diarrhea) • Castor beans: *Ricinus communis* (initial GI signs within several hours) • Insoluble calcium oxalate containing plants: elephant's ear (*Caladium* sp.), dumb cane (*Dieffenbachia* sp.), philodendron (*Philodendron* sp.), peace lily (*Spathiphyllum* sp.) (vomiting, diarrhea, oral swelling, salivation) • Zinc phosphide (GI and CNS signs, pulmonary edema; liver and kidney damage possible)	• Dietary discretion (recent change in diet) • Intestinal parasites (coccidia, roundworms, hookworms) • Foreign body (plastic, wood, metal, cloth, bones; partial or complete obstruction) • Infectious (feline panleukopenia, canine distemper, canine parvovirus, canine coronavirus, infectious canine hepatitis, leptospirosis, salmonellosis) • Gastric dilation/volvulus, intussusception (abdominal distension, pain, dyspnea, shock) • Liver diseases (secondary to gastric ulceration; evaluate serum liver parameters, pre- and postprandial bile acids) • Kidney diseases (uremia secondary to either intrinsic renal disease or post-renal obstruction) • Endocrine disorders (diabetic ketoacidosis, hypoadrenocorticism) • Sudden change in the environment (traveling, weather change, boarding, moving) • Inflammatory bowel disease
Hypernatremia (measured serum sodium >160 mEq/L in dogs and >165 mEq/L in cats)	• Paintball ingestion (dogs: history of paintball ingestion, polydipsia, vomiting, diarrhea, ataxia) • Salt toxicosis (history of inducing emesis with sodium chloride, ingestion of excessive amounts of salt-containing objects [play dough/plasticine] and foods) • Activated charcoal administration (can occur sporadically in some dogs, possibly due to fluid shift) • Sea water ingestion (history of visit to a beach, lack of access to fresh water, swimming)	• Due to pure water loss (nephrogenic diabetes insipidus, heatstroke, fever, burns, no access to water) • Due to hypotonic water loss (severe diarrhea, vomiting, diabetes mellitus, polyuric kidney disease, hypoadrenocorticism)
Hypoglycemia	• Ingestion of xylitol-containing products (dogs; sugar-free gum, sugar-free bakery products, etc.; hypoglycemia within 12 hours; seizures, acute hepatic damage and coagulopathy in 1-3 days) • Ingestion of oral diabetic/hypoglycemic agents (sulfonylureas)	• Insulinoma • Acute hepatic disease, portosystemic shunt • Functional hypoglycemia (idiopathic in neonates, insufficient caloric intake in young puppies and kittens, severe exercise) • Intestinal parasitism • Hypoadrenocorticism • Leiomyosarcoma/smooth muscle tumor

		• Endotoxemia

2,4-D, Dichlorophenoxyacetic acid; *AKI,* acute kidney injury; *ALT,* alanine aminotransferase; *aPTT,* activated partial thromboplastin time; *CKD,* chronic kidney disease; *CNS,* central nervous system; *CV,* cardiovascular; *FeLV,* feline leukemia virus; *FIV,* feline immunodeficiency virus; *GI,* gastrointestinal; *NPK,* nitrogen, phosphorus, potassium; *NSAID,* nonsteroidal antiinflammatory drug; *PCV,* packed cell volume; *PT,* prothrombin time; *RBC,* red blood cell; *SLUD,* salivation, lacrimation, urination, defecation.

CHAPTER 14

Orthopedic Manifestations of Systemic Disease

Bing Yun Zhu

Client Information Sheet: Investigation of Mobility Problems

Dogs and cats of any age may present for lameness, abnormal gait, difficulty rising or more subtle signs such as unwillingness or reduced ability to jump up onto furniture or into a car. It is important to maintain an open mind regarding such signs. A primary orthopedic problem may or may not be the underlying cause of the presenting signs, as there can be many underlying systemic diseases that can cause orthopedic signs. Some medications empirically prescribed can be contraindicated, such as immunosuppressive drugs when there is an underlying infectious condition. Alternatively, some empirical therapies may delay response to later more appropriate treatment. Whenever possible, an accurate diagnosis should precede and direct management.

Diagnostic Approach to Orthopedic Manifestations of Systemic Disease (Figure 14-1)

Signalment

As with any presenting complaint, it is important to first consider patient signalment, as this will impact the likelihood of certain differential diagnoses. Although signalment and presenting complaint alone should not dictate subsequent treatment, this information may aid in listing likely diagnoses by probability. This, in turn, may help selecting tests in an attempt to establish a diagnosis, especially in circumstances where finances are limited. For example, large and giant breed dogs are predisposed to primary orthopedic conditions such as joint dysplasia and degenerative joint diseases. Alternatively, immune-mediated diseases occur more commonly in middle-aged female dogs as compared with cats, in whom primary immune-mediated polyarthropathies are rare.[1] Neoplasia is of higher concern in older pets, while crush injuries may be suspected in nursing puppies or kittens. Males are more likely to develop discospondylitis and any male dog with prostatic disease may appear lame.[2]

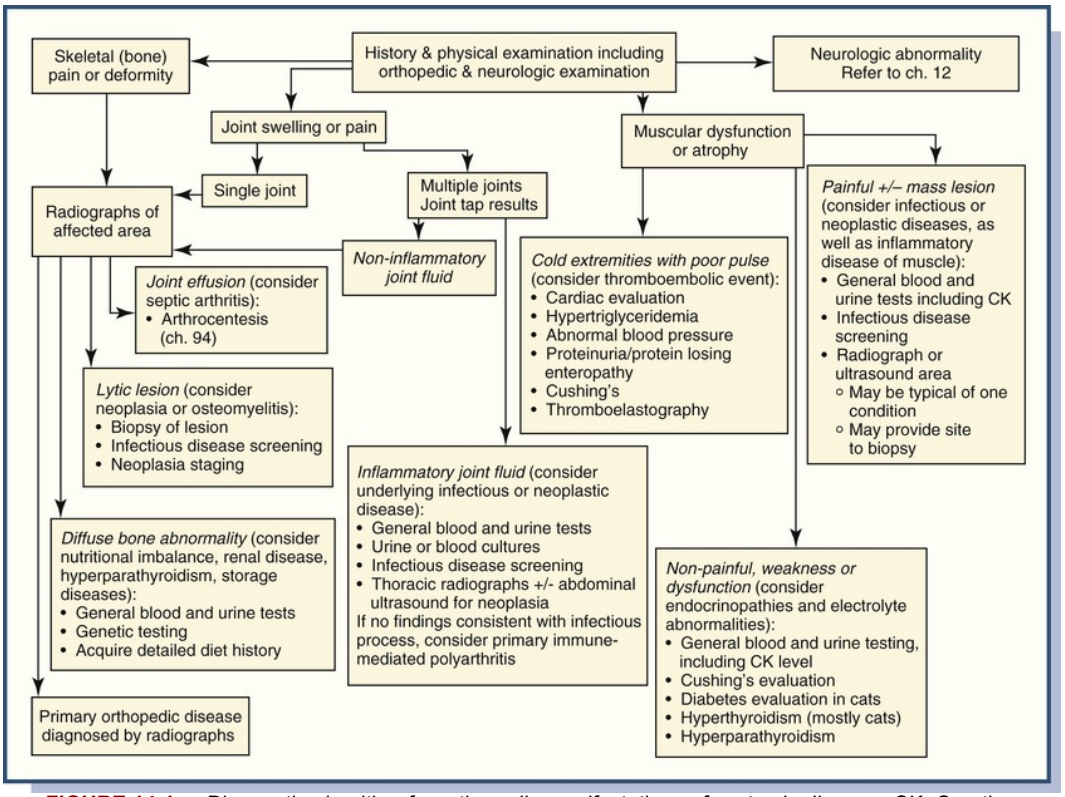

FIGURE 14-1 Diagnostic algorithm for orthopedic manifestations of systemic disease. *CK,* Creatine kinase.

History

Owner observations are extremely valuable. One may inquire about any earlier traumatic episode or ask about issues in littermates or related pets. Review all recent and previous travel because orthopedic signs may be associated with tick borne disease (rickettsial, protozoal, bacterial, spirochete), fungal disease (histoplasmosis, blastomycosis, coccidioidomycosis, cryptococcosis), or leishmaniasis. Seasonality and environment should be considered. Warm weather marks the onset of tick and snake activity. Bites from some can cause rapid-onset paresis and paralysis.

An enquiry into animals' general health should always be undertaken. Cats with recent onset polyuria and polydipsia, weight loss and a plantigrade stance with decreased ability to jump may have diabetic neuropathy. Certain medications may also "trigger" orthopedic signs. Muscle atrophy caused by corticosteroids can reduce a dog's ability to ambulate or jump. Antibiotics such as trimethoprim-sulfur may induce immune-mediated polyarthritis.

Physical Examination

In the scenario of an orthopedic issue, the physical examination should begin when first meeting the pet by carefully observing both ability to rise and gait. Ideally, veterinarians should assess walking and trotting gaits of dogs being led by their owners on a non-slip surface. Cats should be allowed out of their carrier to explore the examination room as the history is taken.

After a thorough general physical examination, a full orthopedic examination should be performed, focusing on palpation of long bones and the vertebral column, including lumbosacral palpation via digital rectal examination. All peripheral joints should be palpated for effusion and manipulated. The clinician should open the jaw to assess the temporomandibular joint. Stifles should be assessed for ligament laxity. Any muscle atrophy should be noted. It is wise to palpate and manipulate non-painful areas in order to gain some patient and owner trust. This also allows the veterinarian to gain insight into a pet's personality and possibly identify pain in areas not suspected as being painful.

Following thorough orthopedic evaluation, a neurological assessment should be performed. At minimum, this should include testing proprioceptive placement reflexes in all four limbs. Any abnormality in

proprioceptive placement, gait, or mentation is an indication for a full neurological examination (see ch. 259). Fundic examination (see ch. 11) may be suggestive of hypertension, fungal disease or another systemic inflammatory or infectious condition.

Differential Diagnoses

One method for remembering many of the possible differentials is to break them down into the main histopathological processes. While these categories are exclusive of other conditions, they provide a starting point in the quest for a diagnosis.

Diseases of Bone

Degeneration, Tissue Injury, and Death

Fractures can be due to trauma or an underlying condition causing weakened bone structure. Bone disease can be focal (such as with infection or neoplasia) or diffuse. Many systemic diseases can lead to diffuse changes in bone. One example is the increased osteoclastic activity associated with excess parathyroid hormone due to primary, nutritional secondary, or renal secondary hyperparathyroidism.[3-6] Disuse osteoporosis begins in a few weeks.[7,8] Osteoporosis has been associated with vitamin D deficiency, whether from inadequate dietary intake or malabsorptive conditions.[9,10]

Inflammation (Infectious or Sterile)

Pain associated with osteomyelitis commonly causes lameness. Severe disease can lead to pathological fractures. Bacterial osteomyelitis can follow hematogenous spread, direct trauma and inoculation, or surgical intervention.[11,12] Fungal causes of osteomyelitis include blastomycosis, systemic aspergillosis, cryptococcosis, histoplasmosis, and coccidioidomycosis.[13] Panosteitis is a disease of medullary adipocytes associated with eosinophilic granular degeneration that affects young, medium- to large- and giant-breed dogs. Clinical signs include lameness, difficulty rising, and pain on palpation of long bones.[14]

Disorders of Cell Growth (Abnormal Growth and Neoplasia)

Disorders of cell growth can be categorized as either deviations in normal growth or those secondary to some cancers. Abnormal growth of bone can cause discomfort when bearing weight or it could cause pain in surrounding tissues. If abnormal bone growth occurs in or near the vertebral column, spinal cord compression can cause paresis or paralysis. Neoplasia of bone can be primary (osteosarcoma, chondrosarcoma, fibrosarcoma, hemangiosarcoma, myeloma) or metastatic.[15] Common cancers that spread to bone include mammary carcinoma, urinary tract carcinomas (including prostate), lymphoma, melanoma and mast cell tumor.[16] Benign neoplasia of bone can also cause lameness. These include osteochondromas, bone cysts and multiple cartilaginous exostoses (see ch. 348).[15,17]

Systemic diseases that can cause abnormal skeletal development in growing dogs and cats include pituitary dwarfism, congenial hypothyroidism, and nutritional imbalances such as hypovitaminosis D (rickets in growing animals), copper deficiency, and calcium or phosphorus deficiencies.[6,17,18] Hypervitaminosis A, in cats fed liver diets, can cause multiple bone exostoses and enthesiophytes, joint laxity, and impingement on nerves causing spinal cord or peripheral nerve and plexus disorders (see ch. 187).[19]

Mucopolysaccharidoses are inherited storage diseases that can cause long bone and/or vertebral column malformations. These conditions can cause changes in gait that often include "crouching," paresis or paralysis.[17,20-22] Clues for the presence of mucopolysaccharidosis are seen in leukocytes as metachromic granules on peripheral blood smears.

Primary diseases of bone development (see ch. 353) include osteogenesis imperfecta and osteochondrodysplasia syndromes. Various skeletal structures are affected, causing signs of lameness and increasing susceptibility to fractures.[17,23] Physeal dysplasia in cats can lead to slipped capital femoral epiphyses.[24,25]

Hypertrophic osteodystrophy is a painful idiopathic disease of young, growing, large-breed dogs affecting the metaphyses of long bones.

Hypertrophic osteopathy may occur secondary to pulmonary neoplasias and systemic infections in adult dogs and cats.[17,26-28]

Vascular Disturbances

Avascular femoral head necrosis is well documented in young small breed dogs, although ischemic necrosis has also been reported in other locations.[29,30] Medullary bone infarcts can occur, but are usually associated with neoplasia or surgical intervention (see ch. 353).[31,32]

Diseases of Joints

Degeneration, Tissue Injury, and Death

Degenerative joint diseases that cause inflammation are common in dogs and cats. Combinations of conformational abnormalities and degenerative changes to ligamentous structures that provide joint stability, such as the cranial cruciate ligament or patella luxation, can precipitate degenerative joint disease. Degenerative arthropathies can also occur secondary to abnormal bone growth, such as in acromegaly.[6]

Inflammation (Infectious or Sterile)

Inflammation in joints may be sterile, or secondary to infectious causes. Septic (bacterial) arthritis is often a result of hematogenous spread or direct traumatic inoculation of bacteria.[33] Single joint effusion, especially of a proximal joint, should raise suspicion for septic arthritis. Other infectious organisms that have been identified in joints include systemic fungi (coccidioidomycosis, blastomycosis, cryptococcosis, sporotrichosis, and aspergillosis), rickettsiae (Rocky Mountain spotted fever, ehrlichiosis, anaplasmosis), spirochetes (Lyme disease), viral (feline calicivirus and coronavirus) and protozoal diseases (leishmaniasis, hepatozoonosis, babesiosis).[13,34] Confirming presence of infectious arthritis is difficult because infected joints often do not "culture positive" and too few organisms may be present for cytologic detection on joint fluid.[34] Blood cultures and serology may be helpful in detecting systemic infectious diseases. Intervertebral spaces can be infected and can cause bacterial or fungal discospondylitis.[2]

Sterile inflammatory joint disease is often immune-mediated, typically affecting multiple distal joints. These can either be erosive (rheumatoid) or the far more common non-erosive (see ch. 203 and 205). Non-erosive, immune-mediated polyarthritis may be an idiopathic, primary auto-immune disorder or it may occur secondary to infectious or neoplastic diseases.[35,36] Drugs such as trimethoprim-sulfur may induce inflammatory polyarthritis. For this reason, a thorough history and screening for underlying disease is important (see ch. 15 and 203).

Disorders of Cell Growth (Abnormal Growth and Neoplasia)

Abnormal growth and conformation of joints can lead to degenerative joint disease. These are described in detail in orthopedic textbooks and include conformational dysplasia of hips and elbows as well as abnormal cartilage development with osteochondrosis.[37] Primary joint tumors that can cause joint deformity include histiocytic sarcoma, synovial cell sarcoma, synovial myxomas as well as fibrosarcoma and chondrosarcoma.[38]

Vascular Disturbance

Primary ischemic joint disease is uncommon. However, secondary coagulopathies can lead to hemarthrosis, an accumulation of blood in the joint space (see ch. 197). This bleeding can be caused by genetic factor deficiencies (such as hemophilia) or acquired (such as by rodenticide intoxication).[39]

Pigmentation and Tissue Deposits

Joint swelling and pain can be associated with systemic amyloidosis, most commonly in Shar-Pei dogs.[40] Amyloid deposits have also been identified within joints.[41] Calcinosis circumscripta is an uncommon syndrome of calcium salt deposition in soft tissue that can affect the joints. This condition may appear idiopathic or secondary to systemic diseases (neoplasia and, rarely, chronic kidney disease [CKD]). In dogs and cats, CKD usually causes calcinosis of footpads, not joints.[42]

Diseases of Muscle

Degeneration, Atrophy or Dysfunction

Distinct from primary muscular dystrophy, muscle atrophy or weakness can be caused by decreased innervation or systemic conditions (see ch. 21). Excess glucocorticoids, whether naturally-occurring or

iatrogenic, often leads to muscle weakness.[6] Catabolism of muscle initiated by hyperthyroidism can cause weakness.[6] Hypokalemia can cause generalized muscle weakness due to altered electrical activity.[43] Hypocalcemia affects nerve and muscular function, leading to rigidity ("tetany") but the patient may be described as weak.[44] Hypercalcemia commonly causes mild weakness.[6] Myolysis can occur secondary to exertion (rhabdomyolysis) or can follow snake envenomation of myolysins. Primary muscular dystrophies have been reported rarely in dogs and cats (see ch. 354).[45,46]

Inflammation (Infectious or Sterile)

Many protozoal infections *(Toxoplasma gondii, Neospora caninum, Hepatozoon canis, Cytauxzoon felis* and *Leishmania)* can cause myositis. Blood tests are available to aid in identifying these infections (see the Infectious Disease section). Microscopic evaluation of muscle biopsy is required for the diagnosis of non-infectious myopathies. Diagnosis may require special analysis for neuromuscular junctionopathies and inflammatory myopathies (see ch. 116 and 354).

Disorders of Cell Growth (Neoplasia)

Muscle tumors that cause changes in mobility are usually large, painful or impacting nerves. Otherwise, muscular neoplasia may only be detected as a palpable non-painful mass. Types of neoplasia that can arise from muscle include varieties of soft tissue sarcoma, hemangiosarcoma, histiocytic sarcoma, and leiomyoma.

Vascular Disturbance

Thromboembolic disease can cause acute, extremely painful, ischemic muscle injury. This can occur in large vessels such as in cats with aortic thromboembolism, or at distal extremities of limbs. Affected limbs will be cold to touch on physical examination and exhibit reduced pulse quality. Search for the cause of hypercoagulability should be undertaken (see ch. 197 and 256).

Diseases of Nerves

It is difficult to break down the various nerve disorders into histopathological processes because many conditions are functional (see ch. 12). Of note, systemic conditions that manifest as changes in mobility include diabetic neuropathy in cats, hypothyroid-associated neuropathies, insulinoma or other neoplasia-induced neuropathy, hypo- and hyperkalemia and hypo- and hypercalcemia.

Other Causes of "Orthopedic Signs"

Conditions unrelated to the musculoskeletal system can cause lameness and/or difficulty rising. Both inflammation and cancer of the prostate can be painful and either can spread to the vertebral column causing discomfort and pain. Disease affecting paw pads such as superficial necrolytic dermatitis and plasma cell pododermatitis can cause lameness.

Diagnostic Testing

After completing a thorough history and physical examination, one should begin to consider most likely differential diagnoses. Clinicians may or may not be suspicious of a specific condition or lesion causing orthopedic signs. Bone and joint disease are often best assessed by radiography. Joint fluid can be obtained for cytology and culture (see ch. 94). If potentially nephrotoxic non-steroidal anti-inflammatory therapy is being considered, kidney function should first be assessed via urine specific gravity and blood for urea nitrogen and/or creatinine.

Complete blood cell count, serum biochemistry profile, urinalysis and urine culture are more strongly indicated in animals exhibiting not only orthopedic signs, but also systemic signs. Those non-specific systemic signs may include lethargy, decreased appetite, fever, lymph node enlargement, vomiting, diarrhea, weight loss, coughing, polyuria and polydipsia. Further diagnostics should be pursued as dictated by radiographic and laboratory findings. This may include specific infectious disease screening, congenital disease testing or investigation of coagulopathies.

CHAPTER 15

Swollen Joints and Joint Pain

Jonathan D. Dear

Client Information Sheet: Swollen Joints and Joint Pain

Overview and Definitions

Lameness and gait abnormalities are common presenting complaints for small animals. In many, signs may be the result of traumatic or developmental orthopedic disease. Others may have neoplastic or infectious bone disease. This chapter focuses on atraumatic inflammatory joint diseases.

A pet with degenerative joint disease (DJD) may appear to an owner to have intermittent or shifting leg lameness. Pets with DJD are generally well and lack signs of systemic disease. Those with inflammatory joint disease, by contrast, are not thought to be lame. Rather, affected pets may be brought to their veterinarian for lethargy or decreased appetite. They often have a fever.[6] The practitioner may be the first individual to detect lameness or joint disease. Inflammatory joint diseases can be subdivided into septic and nonseptic etiologies. Furthermore, arthropathies are often characterized by the number of affected joints: monoarthropathies (single joint) or polyarthropathies (multiple joints).

Physical Examination

Before beginning to develop a differential diagnosis list, a comprehensive physical examination should be performed with particular attention paid to the orthopedic and neurologic examinations. The practitioner should casually observe the patient within the exam room in addition to evaluating gait from a distance (i.e., within a hallway). Different surfaces or speeds may reveal subtle ambulatory disturbances. Some pets who appear "stiff" in an examination room or hospital (particularly cats) may simply be reluctant to move.

Each appendicular joint should be palpated for warmth, effusion and sensitivity. One can progress to assessing flexion, extension and range of motion in those joints. Typically, DJD affects a few joints while immune-mediated and hematogenous arthropathies affect many joints.[10] Distal joints such as the carpus and tarsus are specifically targeted by immune-mediated diseases. The stifle and elbow are affected less commonly.

Pathophysiology

Joints are comprised of two or more articulating bones with articular cartilage, synovium and synovial fluid. Joints are found throughout the body, including along the appendicular skeleton (such as the carpus or stifle) or axial skeleton (such as the vertebral articulations or the temporomandibular joint). In most cases of joint pain or lameness, the appendicular skeleton is predominantly affected.

Due to their vascular anatomy, joints are particularly susceptible to emboli. Emboli to the synovium can be bacteria (as with septic arthritis) or antibody-antigen complexes (as in immune-mediated polyarthritis). Immune-mediated polyarthritis is the most common form of inflammatory joint disease and is generally considered to be a type III hypersensitivity reaction.

The diagnostic approach to joint swelling and pain uses clinical signs, the physical examination, blood tests, radiographs and joint fluid analyses as guides to confirming a diagnosis (Figure 15-1) (see ch. 94).

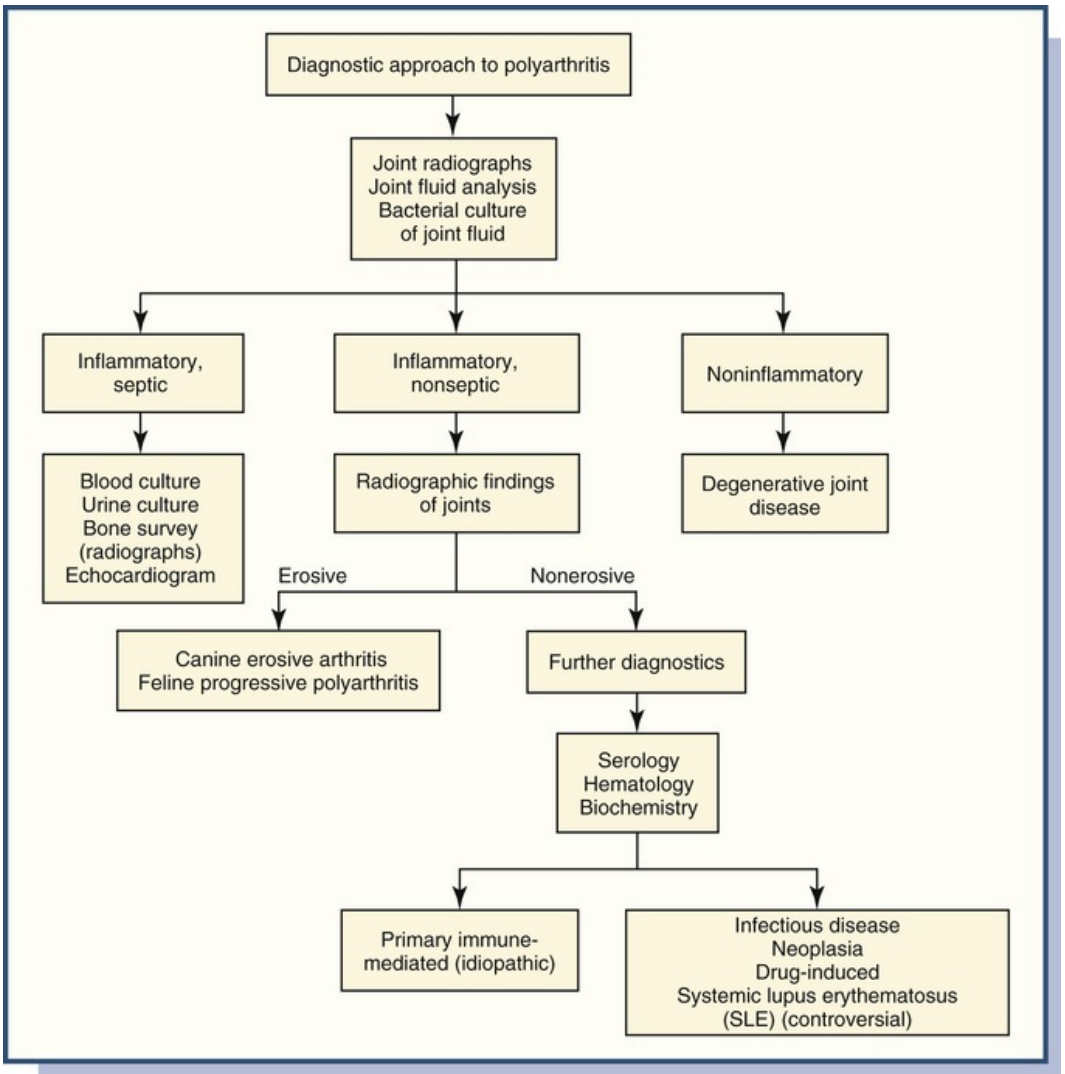

FIGURE 15-1 Algorithm for diagnostic approach to polyarthritis.

Septic Arthritis

Septic arthritis can affect single joints, as with post-operative joint infections, penetrating wounds or foreign bodies. Septic arthritis may affect multiple joints when caused by bacteremia. A septic process should be a top consideration when a single proximal joint is affected (stifle, elbow, shoulder or hip). Recent history of trauma or surgical intervention may lead to the diagnosis of septic inflammation. Neutrophilic inflammation is seen in both septic and immune-mediated arthritis, though degenerative neutrophils or presence of intracellular bacteria suggest infection. Joint culture should be performed when septic inflammation is suspected, though the sensitivity of joint cultures is disappointingly low.

Septic joints should be lavaged and the patient administered appropriate systemic antimicrobials while awaiting joint or other culture results.

Immune-Mediated Polyarthritis

Immune-mediated polyarthritis (IMPA) is the most common form of inflammatory joint disease encountered in small animal patients (see ch. 203 and 205). Patients with IMPA often present for cyclic lethargy (often associated with fever), anorexia, shifting leg lameness, or apparent hyperesthesia. Affected animals are frequently described as appearing to be "walking on eggshells." As with any immune-mediated disease, IMPA can be either primary (autoimmune) or secondary to either endogenous or exogenous triggers. The diagnostic evaluation for immune-mediated disease is discussed in the Additional Testing section, but notable triggers of secondary IMPA include vector-borne disease (specifically *Borrelia burgdorferi*) and

sulfonamide-containing medications (such as trimethoprim-sulfa administration to Doberman Pinschers) (see ch. 211).

Immune-mediated polyarthritides are classified radiographically as either erosive or non-erosive based on assessing bony and cartilaginous lytic and proliferative changes. These categories can be further subdivided based on other diagnostic criteria (see ch. 203 and 353).

Erosive Polyarthritis

Erosive polyarthritis is characterized by progressive osteolysis and proliferation of periarticular joint surfaces. Initially, mild soft tissue swelling and joint effusion may be the only radiographic markers of erosive disease. As the condition progresses, evidence of erosive disease can include decreased opacity of perichondral and subchondral bone, narrowing of the joint space and enthesiophytosis or osteophytosis. In dogs, both septic and rheumatoid arthritis can be erosive. Since radiographic changes are not specific, it is critical to perform joint fluid analysis and culture as aids in differentiating these disorders.

Rheumatoid Arthritis

Rheumatoid arthritis in either dogs or cats is catalyzed by antibody production directed at patient IgA, IgG and IgM—called rheumatoid factor (RF).[1] These antibody complexes circulate and are deposited within synovial tissue, leading to intense inflammatory reactions.[2] Progressive cartilage and bone destruction take place over months to years. In some, the chronic inflammation has been so destructive and poorly responsive to medical therapy that bone deformation and subluxations occur.[10] The underlying cause for development of these autoantibodies is not understood. Though the diagnosis of rheumatoid arthritis in humans follows a rigorous algorithm involving a host of criteria and factors, these criteria have not been established in veterinary medicine. Plasma rheumatoid factor can be measured but is neither sensitive nor specific for this diagnosis (see ch. 195, 203, 205, and 353).

Feline Periosteal Proliferative Polyarthritis

Erosive polyarthropathies are particularly uncommon in cats. Affected cats develop a progressive polyarthropathy and osteopathy that involves periosteal proliferation, subchondral osteolysis, and may progress to ankylosis.[3] Soft tissue edema and joint effusion are typical. This disease appears most frequently in males of any age. Joint fluid cytology reveals aseptic neutrophilic inflammation, though with chronicity, the inflammatory nature may become lymphoplasmacytic. Radiographic features of this disease include intense periosteal proliferation, which may develop a characteristic trabecular pattern, and subchondral bone destruction.[9]

Nonerosive Polyarthritis

Commonly, the inflammation caused by IMPA leads to joint pain and soft tissue swelling without notable or permanent articular destruction of the synovium or cartilaginous interface (see ch. 195, 203, 205, and 353). As a type III hypersensitivity reaction, the disease stems from antibody production directed at chronic antigenic stimulation.[8] However, it is not often possible to identify the source of this antigenic stimulation and the disease is termed *idiopathic polyarthritis*. When identified, inciting causes include neoplasia (particularly hemic neoplasia), chronic infection (such as deep mycoses, diskospondylitis or endocarditis), primary immune disease (such as systemic lupus erythematosus [SLE]) or administration of certain drugs and vaccines.[4]

Patients with nonerosive polyarthritis often are seen for an intermittent, shifting leg lameness or for generalized nonspecific systemic signs such as lethargy and anorexia. Physical exam often reveals fever as well as warmth and effusion involving multiple distal joints. The tissue around affected joints may appear edematous and local lymph nodes may be enlarged as a component of the systemic immune reaction. Though IMPA appears to favor distal joints, other joints such as the temporomandibular joint and vertebral articulations may be affected, leading to the clinical appearance of odynophagia, dysphagia, neck pain or back pain.

Vaccine-induced polyarthritis usually develops within 1-2 weeks of administration and almost always within a month (see ch. 208). This polyarthritis may develop following either initial or booster vaccines. Implicated vaccines include those directed against canine distemper and Lyme. Drug-induced polyarthritis has been reported to occur most often following the administration of sulfonamide-containing drugs (such as

trimethoprim-sulfonamide [TMS]) administered to Doberman Pinschers (see ch. 169).[5,7] The penicillins and cephalosporins have also been implicated. Other causes of nonerosive polyarthritis include juvenile-onset polyarthritis of Akitas and the familial swollen hock syndrome in Chinese Shar-Pei.

Other Causes of Mono- or Polyarthropathies

Hemarthrosis is an uncommon cause for single or multileg lameness. When seen, it may result from thrombocytopenia or other bleeding disorders. Most skeletal system malignancies spare joints, though neoplasia of the synovium or round cell tumors (such as lymphoma or histiocytic sarcoma) can affect the joint and its articulating bone and cartilage (see ch. 308).

Arthrocentesis

Arthrocentesis is the single most important diagnostic aid in patients suspected as having an inflammatory joint disease and can usually be easily performed in most small animals (see ch. 94). Joint aspiration should be performed under heavy sedation or anesthesia using aseptic technique. When immune-mediated disease is suspected, multiple distal joints (carpus and tarsus) should be aspirated and submitted individually for cytology. Remaining samples can be pooled for culture. In pets with suspected monoarthropathy, arthrocentesis of multiple joints can indicate whether single or multiple joints are involved. Synovial fluid viscosity and consistency can be assessed crudely by placing a small drop between the thumb or a glass slide and the index finger (Figure 15-2). Normal joint fluid should be transparent, colorless and string several centimeters when tested in this manner.

FIGURE 15-2 A demonstration of the method to grossly assess joint fluid viscosity. A drop is placed on a glass slide. It is gently touched with a fingertip that is then slowly moved away. The reader should note the strand of viscous fluid typical for normal joint viscosity.

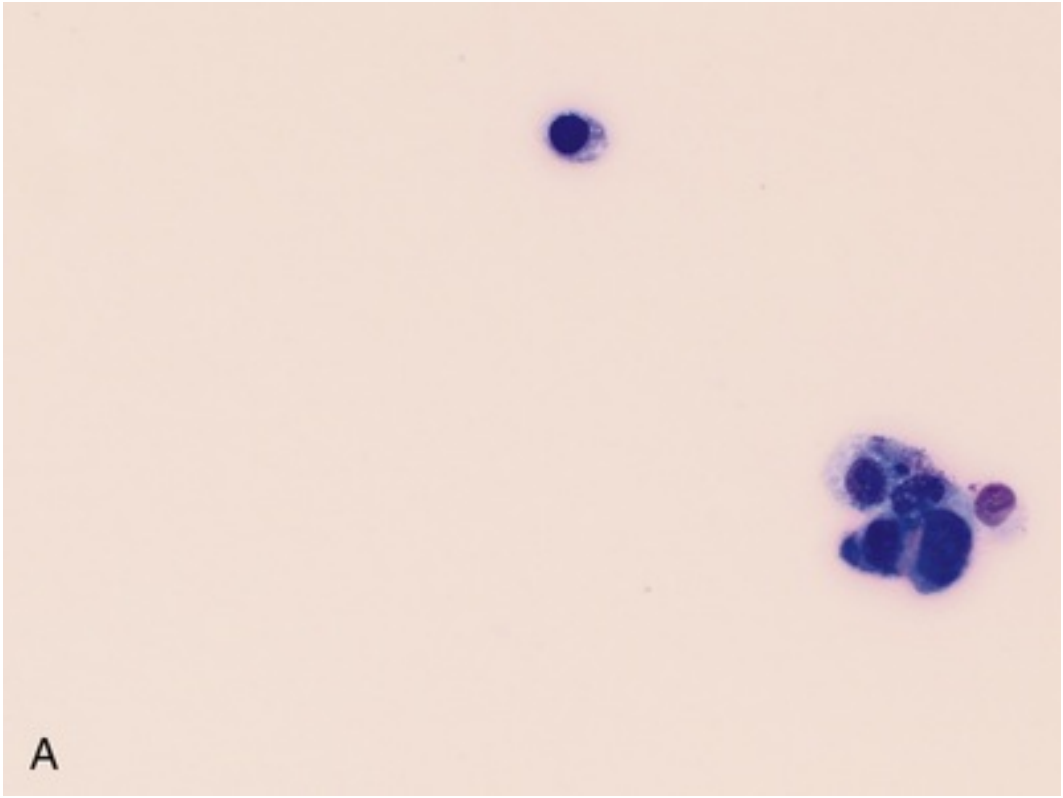
Joint Fluid Analysis

Normal synovial fluid is present in small volumes, clear, viscous, and of low cellularity. A crude test for viscosity can be performed by placing a small drop between the thumb and forefinger allowing the fluid to

string 4-5 cm, as the fingers are pulled apart (see Figure 15-2). Fluid from diseased joints often lacks viscosity and may be turbid or discolored. Samples contaminated with blood from superficial vessels, while entering or withdrawing the needle from the joint, have a small portion of red discoloration.

Normal joint fluid has a relatively small population of large mononuclear cells as "housekeepers." Normal cell counts are less than 3,000 cells per microliter. In IMPA, individual joint cell counts can exceed 50,000 cells per microliter and are primarily nondegenerate neutrophils. Septic joints may be similarly neutrophilic, although the joint fluid often has signs of septic inflammation: degenerate neutrophils, intracellular neutrophils and a positive bacterial culture. In addition to aerobic and anaerobic cultures, *Mycoplasma* culture should be requested for cats with polyarthritis since various species have been associated with a form of septic arthritis that causes nondegenerate joint inflammation (see ch. 219).[11] This organism is difficult to culture using conventional microbiology methods. Ancillary joint fluid testing provides little clinically useful information.

These photomicrographs (Figure 15-3) are of cytology specimens from normal *(A)* and sterile, inflammatory joint fluids *(B).* Normal joint fluid is a relatively acellular, thick, proteinaceous fluid with a small number of large, with rarer small, mononuclear cells (see Figure 15-3). Joint fluid from a dog with immune-mediated polyarthritis contains a larger number of nondegenerate neutrophils and may contain lupus erythematosus (LE) cells (indicated by the arrow in Figure 15-3) in cases of SLE.



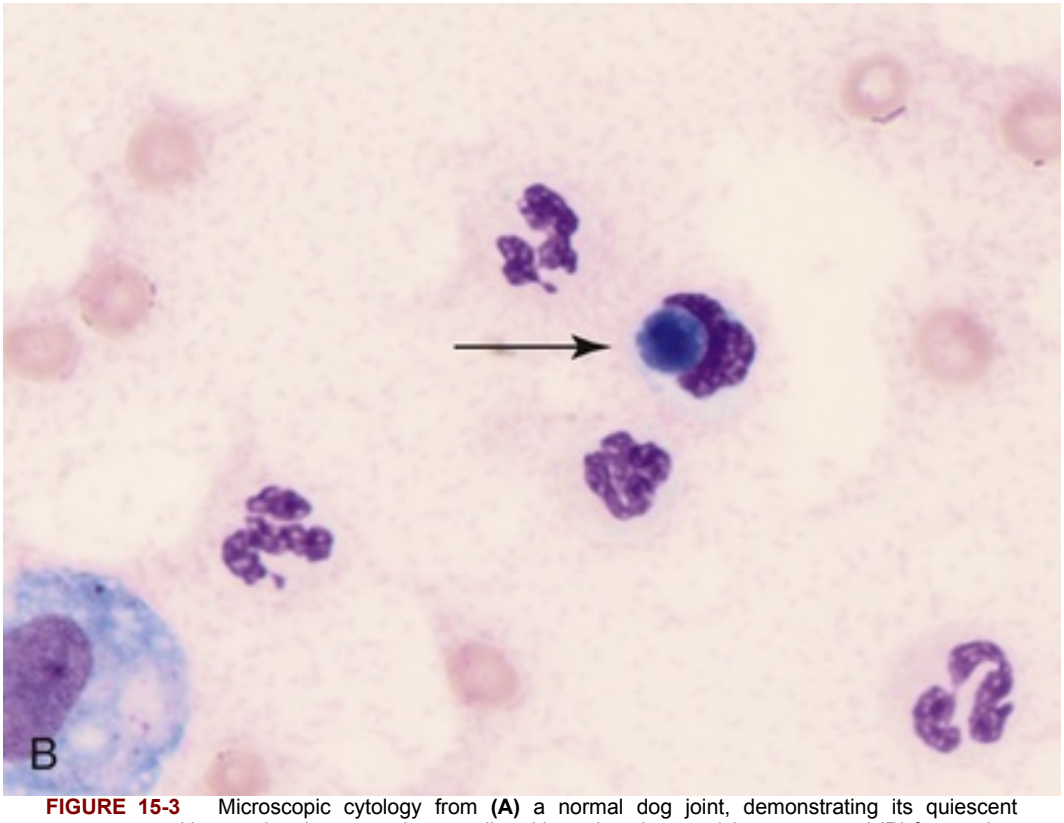


FIGURE 15-3 Microscopic cytology from **(A)** a normal dog joint, demonstrating its quiescent appearance with occasional mononuclear small and large lymphocytes/phagocytes and **(B)** from a dog joint that is sterile but inflamed, demonstrating the high cellularity and influx of neutrophils typical of this condition (arrow). (Courtesy A. Adedeji, DVM, William Pritchard Veterinary Medical Teaching Hospital, UC Davis.)

Additional Testing

Septic arthritis may be suspected in a joint despite there being no clear pathway for introduction of bacteria (i.e., recent orthopedic surgery, trauma or penetrating wound). In such a case, the clinician should investigate the possibility of hematogenous spread of bacteria to the synovium. Specific conditions associated with bacteremia include endocarditis (including *Bartonella* spp.), diskospondylitis, pyelonephritis or prostatitis. Diagnostic imaging and blood or urine cultures should be employed to confirm or deny the presence of these conditions.

Immune-mediated polyarthritis is thought to arise from chronic antigenic stimulation often stemming from chronic infection, inflammation, neoplasia or drug and vaccine exposures. Patients suspected of having immune-mediated polyarthritis should be evaluated for these triggers of immune system activity. This investigation starts with a detailed medical history, paying close attention to the patient's home environment as well as recent travel, medications or vaccination. A thorough physical examination should help identify comorbidities which may relate to current condition and help understand the number of joints involved. Particular attention should be paid to assessing the fundus (ch. 11), thoracic auscultation, axial skeleton palpation, rectal examination, and lymph node size.

A comprehensive medical evaluation helps identify any inciting disease and determine the overall health of the patient prior to initiation of therapy. A complete blood count, serum biochemistry profile, and urinalysis with culture should be performed in all patients. Serologic testing for endemic infectious diseases associated with polyarthritis (such as *Ehrlichia canis, Borrelia burgdorferi, Anaplasma phagocytophilum* or systemic mycoses) should be performed according to the geographic exposure of the patient. When erosive disease is suspected, radiographs of the affected and contralateral joints should be obtained to determine the extent of disease. In order to rule out neoplastic disease and other infectious disease, diagnostic imaging of the thorax and abdomen should be performed. Additional testing such as blood cultures, echocardiogram, vertebral radiographs or cerebrospinal fluid collection and analysis should be considered on a case by case basis.

All cats with polyarthritis should be tested for both feline immunodeficiency virus (FIV) and feline leukemia virus (FeLV). Immunosuppression may play a role in disease development and FeLV has been

implicated in the pathogenesis of periosteal proliferative polyarthritis.

Markers of immune disease such as a Coombs' test, anti-nuclear antibody or rheumatoid factor can bolster the suspicion for immune disease, though both sensitivity and specificity of these tests are controversial. Positive results do not exclude the possibility of secondary disease.

In the absence of other disease inciting polyarthritis, a diagnosis of idiopathic or primary IMPA is reached (see ch. 203). This disease may affect patients individually or along with other immune diseases such as glomerulonephritis or systemic lupus erythematous (ch. 205).

CHAPTER 16

Weight Gain

Peter P. Kintzer

Overview

In canine and feline patients, weight gain is common, both as an historical complaint or a physical examination finding. Generally, pets more than 10% above their ideal body weight are considered significantly overweight and obese when they exceed ideal by greater than 20%.[1] It is important to identify and treat, if possible, any underlying disease state responsible for weight gain. In many cases, however, weight gain is due to a combination of overeating and inadequate exercise. Caloric intake in excess of need leads to weight gain and often obesity. It has been suggested that at least 50% of dogs and cats in the United States can be classified as overweight or obese. It has been suggested that 37% more dogs and 90% more cats were overweight in 2013 as compared with five years earlier. This is important as obesity is not simply an excess amount of adipose tissue, but the condition can be associated with deleterious metabolic and hormonal changes and can affect both longevity and quality of life.[2-4] There are a few clinical conditions that can cause weight gain in dogs and cats. Disorders that result in ascites, pleural effusion and/or edema must be differentiated from those causing a true increase in body tissue mass. Several endocrinopathies may cause weight gain and obesity. Dogs with primary hyperlipidemias may manifest unexplained increases in body weight.

History

A thorough history, including a detailed investigation of diet and lifestyle, is critical in evaluating the patient with weight gain. One needs to determine if the appetite is normal, increased, or decreased. In the majority, weight gain and obesity results from caloric intake in excess of need. In other words, there is a combination of overfeeding and inadequate physical activity. Therefore, it is imperative to obtain a detailed account of caloric intake (including treats, table scraps, etc.), if more than one person in the household feeds the pet, and if there are additional animals whose food could be eaten by the pet in question (see ch. 170). Assessment of exercise level and presence of any orthopedic or neuromuscular disorders is needed. Calculation of the pet's caloric requirements relative to their physical activity allows identification of excess caloric intake as a reason for weight gain. Certain breeds may have a genetic predisposition to weight gain and obesity. Furthermore, individual patients may be more prone to weight gain than others. Lastly, older, less active pets and those with orthopedic problems generally require fewer calories and are at risk of weight gain (see ch. 176).

An increased appetite or polyphagia can lead to weight gain and varying degrees of obesity. Potential underlying factors include drug therapy, certain endocrine disorders and behavioral issues. Certain medications, including corticosteroids, phenobarbital and progestins, can result in polyphagia through stimulation of the appetite center. By stimulating food intake, promoting fat redistribution, and organomegaly, both acromegaly and hyperadrenocorticism usually cause weight gain (see ch. 294, 295, 306, and 307). Behavioral and husbandry issues may play a role (see ch. 176). The ready availability of highly palatable pet food can promote overeating. Boredom and lack of access to physical activity can exacerbate this tendency. Weight gain with a normal or decreased appetite can be seen in association with certain endocrine disorders, including hypothyroidism, as a result of a decreased metabolism (see ch. 299); other historical findings associated with the underlying endocrine disorder are often reported. A careful history to assess for the presence of other clinical signs such as polyuria, polydipsia, lethargy, exercise intolerance, excess panting and cold intolerance among others can provide the clinician with additional clues to an underlying disease condition.

Physical Examination

A complete physical examination is imperative. The clinician can assess a pet for weakness, neuromuscular abnormalities or orthopedic problems. Is such a condition resulting in decreased physical activity and contributing to weight gain? Assessing body weight using an accurate scale is vital, as is an objective determination of body condition using an accepted scoring system (see ch. 2 and 170). It should also be determined if weight gain is due to an increase in adipose tissue or muscle mass. Lean body mass gain can be caused by vigorous exercise as well as anabolic endocrine disorders such as insulinoma in dogs and acromegaly in cats.

There are several physical examination findings that may point the clinician to the underlying cause of the weight gain. Body temperature, capillary refill time, pulse rate and careful auscultation of the heart and lungs may provide clues. The patient should be carefully evaluated for the presence of ascites, pleural effusion and/or edema, which can be caused by cardiac disease, infectious or inflammatory conditions and hypoproteinemic states (such as protein-losing nephropathies and enteropathies). The weight gain associated with these conditions is due to the excess fluid and not a true increase in body mass (see ch. 17 and 18). The skin and hair coat should be carefully examined for abnormalities such as hair thinning or alopecia, seborrheic changes, myxedema, thin skin, hyperpigmentation and comedones, some of which are consistent with conditions like hyperadrenocorticism or hypothyroidism. The abdomen should be carefully palpated for the presence of abdominal masses, abdominal distension and organomegaly. Acromegalic cats frequently have weight gain and organomegaly. The presence of these clinical findings in a diabetic cat, particularly one poorly regulated and/or on higher than typical dosages of insulin, is consistent with concurrent acromegaly (see ch. 294). Patients with hyperadrenocorticism often exhibit hepatomegaly, as well as centripetal fat redistribution and abdominal muscle weakness which can result in a pot-bellied appearance (see ch. 306 and 307). Assessing whether the patient has been neutered is critical (see ch. 313). Neutering has been shown to reduce daily energy requirements (DER) of adult cats by 24-33%. Similar reductions in daily energy requirements have been documented in neutered dogs (see ch. 313 and 319).[5] Reduction in energy requirement is most likely due to a decrease in the basal metabolic rate. An increase in the drive for food and decreased energy expenditure predisposes the patient to weight gain and obesity.

Diagnostic Approach

Figure 16-1 shows an algorithm for a diagnostic approach to weight gain. The presence of fluid retention and large abdominal masses are excluded. Caloric intake in excess of energy requirements is ruled out. Assessment of appetite (polyphagia vs. normal or decreased) will further guide the clinician. A minimum database (complete blood count, serum electrolyte panel and urinalysis) should be performed. The typical laboratory abnormalities of certain endocrine disorders may be observed. The addition of a vector-borne disease screen would be appropriate in certain areas. Depending on the patient, imaging studies may be indicated. Lastly, endocrine testing (e.g., thyroid screening, insulin level, IGF-1 level, ACTH stimulation test, low-dose dexamethasone suppression test) may be appropriate to further assess the causes of weight gain.

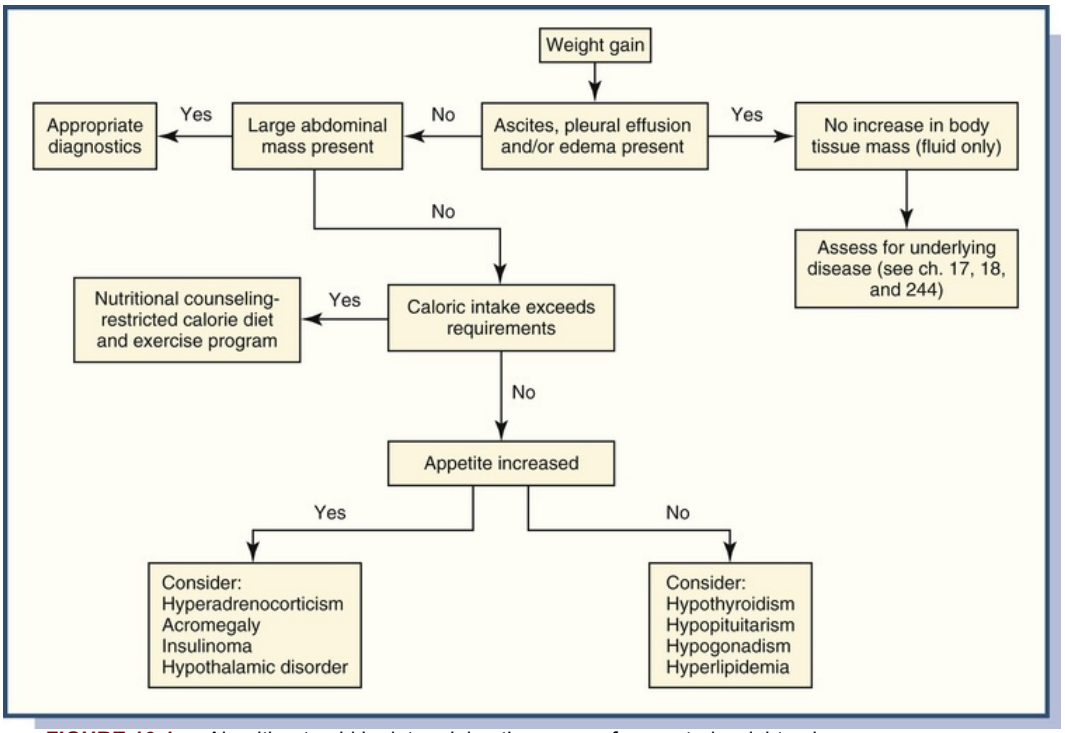

FIGURE 16-1 Algorithm to aid in determining the cause of unwanted weight gain.

CHAPTER 17

Abdominal Enlargement

Julie Walter

Client Information Sheet: Abdominal Enlargement

Enlargement of the abdomen is a common presenting complaint and can be a component of many disease processes. An animal's owners may note abdominal distension or they may describe weight gain, lethargy, weakness, exercise intolerance, increased respiratory rate and effort, decreased appetite, or clinical signs specific to the underlying disease process (e.g., collapse with cardiac tamponade, or retching with gastric dilation/volvulus [GDV]). Some patients with abdominal enlargement require emergency intervention, particularly when it is associated with tachycardia, dyspnea, hypotension, abdominal pain, prolonged capillary refill time (CRT), fever, profound lethargy, and/or weakness (see ch. 143 for more information on the acute abdomen). A thorough history is vital for assessing the need for such emergent intervention and for developing a complete differential diagnosis list. The history should include, but is not limited to: description and duration of clinical signs, the pet's environment, travel history, drug administration and previous medical history. Physical examination findings will vary depending on the etiology and can include: abdominal pain, organomegaly, fluid wave on ballottement of the abdomen, gas distension of the abdomen or gastrointestinal tract, or palpation of a soft tissue mass. Causes of abdominal enlargement can be classified into the following five categories: soft tissue, fluid, gastrointestinal (GI) contents (fluid or feces), gas, and hypotonia of the abdominal musculature (Table 17-1).

TABLE 17-1

Differential Diagnoses for Abdominal Enlargement

SOFT TISSUE	FLUID	GI CONTENTS	GAS	ABDOMINAL MUSCLE HYPOTONIA
Organomegaly (infiltration, congestion, torsion) Fat deposition Neoplasia Granuloma Pregnancy	Effusion (pure transudate, modified transudate, exudate, neoplastic) Cyst Abscess Pyometra Urinary tract outflow obstruction (e.g., hydronephrosis) Ileus (functional or mechanical)	Constipation, obstipation Megacolon Ileus (functional or mechanical) Overeating Heavy intestinal parasite burden (puppies, kittens)	Gastric dilation/volvulus Intestinal or mesenteric torsion GI tract rupture Ileus (functional or mechanical) Iatrogenic (post-surgical) Emphysematous bacterial infections (liver, gallbladder, urinary bladder) Penetrating trauma	Hyperadrenocorticism

Differential Diagnoses[1]

Soft Tissue

Soft tissue structures in the abdomen can cause abdominal enlargement as a result of organomegaly, deposition of fatty tissue (e.g., obesity or lipoma formation), neoplasia, granuloma formation, or pregnancy.

Organomegaly, including hepatomegaly, splenomegaly, renomegaly, and prostatomegaly, can be present secondary to infiltration of the organ (neoplasia), congestion via vascular or lymphatic obstruction, or torsion of the organ (e.g., splenic torsion). Neoplastic processes are common and can be hepatic, splenic, urogenital (renal, urinary bladder, uterine, ovarian or prostatic), GI, adrenal, or pancreatic in origin. More diffuse neoplastic processes, such as lymphoma and carcinomatosis, can produce similar clinical signs. Granuloma formation has also been reported as a cause of abdominal distension and may be seen with parasitic disease (e.g., parasitic larval migrans), fungal infections, or pythiosis (see ch. 236).

Fluid

Fluid accumulation in the abdomen may be within organs, within abscesses or cystic structures, or free in the peritoneal or retroperitoneal spaces. Within organs, fluid accumulation can occur in the GI tract secondary to functional ileus or obstruction; the uterus (e.g., pyometra); the kidneys (e.g., hydronephrosis secondary to ureteral obstruction); and the urinary bladder (e.g., urethral obstruction, disruption of the micturition reflex). Fluid may also be present in abscesses or cystic structures within the kidneys, liver, pancreas or prostate, and cysts can be associated with polycystic kidney disease or liver disease.

Peritoneal and retroperitoneal effusions can be separated into several categories based on gross appearance, protein content, cell counts, and cytologic characteristics (Table 17-2).[2] Identifying effusions by specific gravity as measured with a standard refractometer is often described; however, this approach has not been validated for fluid types other than urine and is not recommended due to interlaboratory variation.[3]

TABLE 17-2

Characteristics of Common Abdominal Effusions

EFFUSION TYPE	GROSS APPEARANCE	TOTAL PROTEIN (g/dL)	NUCLEATED CELL COUNT (cells/mcL)	PREDOMINANT CELL TYPES/CYTOLOGIC FINDINGS
General				
Transudate	Clear; colorless	<2.5	1000-1500	Mesothelial cells (occasional)
Modified transudate	Slightly cloudy; straw-colored	2.5-5.0	>1000, <5000	Mesothelial cells, non-degenerate neutrophils, macrophages, lymphocytes
Exudate	Turbid to opaque; tan, may be blood-tinged	>2.5	>5000	Non-septic: mesothelial cells, non-degenerate neutrophils, macrophages, lymphocytes, occasionally neoplastic cells
				Septic: degenerate neutrophils, intracellular bacteria
Specific				
Blood	Cloudy to opaque; red (clear supernatant after centrifugation)	>3.0, may be = to peripheral blood	>1000, may be = to peripheral blood	Erythrocytes, leukocytes similar to peripheral blood, erythrophagocytosis
Chyle	Opaque; white to pink	>2.5	Variable, <10,000	Small lymphocytes (may be mixed if chronic); fluid [triglyceride] > serum [triglyceride]
Urine	Clear to slightly cloudy; pale yellow to yellow	Variable	>3000	May be septic; fluid [creatinine] > serum [creatinine]
Bile	Clear to cloudy; green to brown	>2.5	>5000	May be septic; presence of bilirubin crystals

Pure Transudates

Pure transudates are characterized by both low cellularity and low total solids, and most commonly occur secondary to decreased oncotic pressure; concurrently increased hydrostatic pressure, and vasculitis, can contribute to the presence of pure transudates. Protein is essential in maintaining appropriate oncotic pressure, with decreased oncotic pressure most commonly resulting from hypoproteinemia (see ch. 60), and

often more specifically hypoalbuminemia. Hypoalbuminemia may be due to loss, which is characteristic of protein-losing nephropathy (see ch. 325), protein-losing enteropathy (see ch. 276), or as a result of weeping of proteinaceous fluid from wounds (e.g., burns). Alternatively, hypoalbuminemia can be due to decreased production, most often as a result of hepatic failure (e.g., cirrhosis) or starvation.

Increased hydrostatic pressure most often leads to modified transudates, but can cause the formation of pure transudates, especially in patients with low-normal or low serum albumin concentrations. High hydrostatic pressure can result from pre-hepatic portal hypertension (e.g., congenital portal vein atresia, extraluminal obstruction such as neoplasia, or intraluminal obstruction such as portal vein thrombosis), intra-hepatic portal hypertension (e.g., pre-sinusoidal disorders such as chronic cholangitis, sinusoidal disorders such as lobular dissecting hepatitis, or post-sinusoidal disorders such as with veno-occlusive disease), or post-hepatic portal hypertension (e.g., right-sided heart failure, or Budd-Chiari syndrome).[4]

Modified Transudates

Modified transudates have nucleated cell counts and total solids concentrations that fall between those of pure transudates and exudates. They may be present due to a variety of causes and therefore can have a multitude of cell types. Decreases in oncotic pressure, increases in hydrostatic pressure, and vasculitis, as previously described with pure transudates, can also result in a modified transudate, typically when the fluid accumulation is chronic. A modified transudate can also be present secondary to neoplastic processes, granulomas, post-surgical or laparoscopic procedures, organ torsion (e.g., splenic, intestinal, or mesenteric), and/or infarction.

Exudates

Exudates are those effusions that have high cellularity and total solids concentrations, with the cellular component consisting primarily of neutrophils and macrophages. Exudates can be divided into non-septic and septic groupings (for peritonitis, see ch. 279). Non-septic exudates are seen in neoplastic processes, pancreatitis, or feline infectious peritonitis (FIP). Septic exudates are most commonly due to perforation of the GI tract, abscess rupture, penetrating injury, or foreign body migration. Rupture of the biliary tree or the urinary tract can result in either a non-septic or septic exudate.

Eosinophilic effusions can present as modified transudates or exudates with a cell population >10% eosinophils. These effusions are most often caused by lymphoma, systemic mast cell tumors, aberrant larval migrans, fungal disease, or disseminated eosinophilic granulomatosis.

Similarly, neoplastic effusions often are considered as a subtype of modified transudates or exudates that contain neoplastic cells. It is important to note that cytologically, normal mesothelial cells can display many criteria of malignancy and therefore can be misinterpreted as neoplastic. For this reason, it is essential that a clinical pathologist perform cytologic evaluations, and even so, definitively confirming or refuting mesothelial neoplasia cytologically can be impossible in some cases.

Blood

Hemorrhagic effusions typically are defined as having a packed cell volume >10%. Thus, cytology of hemorrhagic effusions should closely resemble that of the peripheral blood including red blood cells, neutrophils, and lymphocytes. Unless hemorrhage is peracute, platelets are not typically present and therefore the samples do not readily form a clot. Hemorrhagic effusions are seen most commonly secondary to trauma (e.g., organ rupture, arterial avulsion), neoplasia (e.g., hemangiosarcoma), coagulopathies (e.g., rodenticide intoxication), or in post-surgical patients.

Chyle

Chylous effusions are characterized by high triglyceride concentrations and lower cholesterol concentrations relative to the patient's serum, and variable cell counts. Small lymphocytes usually predominate, but a mixed cell population can be seen with chronicity. Chylous effusions most commonly are associated with disruption of lymphatics (e.g., extraluminal obstruction or rupture) by neoplasia or trauma, or right-sided heart failure. More rarely, lymphangiectasia can be the inciting cause.

Urine

Uroabdomen can result from rupture of one or more structures of the urinary tract (e.g., ureters, urinary bladder, and/or urethra). Urine may accumulate in both the peritoneal and retroperitoneal spaces secondary to trauma or obstruction (e.g., ureteroliths or neoplasia such as transitional cell carcinoma), and may result in

either a non-septic or a septic exudate. The characteristics of the resulting effusion are variable, but a creatinine concentration greater than that of the patient's serum is expected.

Bile

Bilious effusions can be either non-septic or septic exudates, and contain bilirubin crystals. It is worth noting that the concentration of bilirubin in the effusion will be higher than that found in the serum. Bilious effusions are associated with rupture at some level of the biliary system (i.e., the gallbladder, or bile ducts), which may occur secondary to trauma, cholelithiasis or mucocele with subsequent obstruction, neoplasia, or cholecystitis.

Gastrointestinal Contents

An increase in the volume of contents within the GI tract can result in abdominal enlargement. Possible etiologies include overeating, constipation or obstipation, heavy intestinal parasite load in puppies or kittens, functional or mechanical ileus, and megacolon.

Gas

Gas accumulation can cause abdominal distension and may occur within the GI tract, the liver and/or gallbladder, the urinary bladder, or freely in the peritoneal or retroperitoneal spaces. Distension of the GI tract with gas can be seen with gastric dilation, GDV, or mesenteric torsion. Gas accumulation in the GI tract can also be secondary to mechanical and/or functional ileus. Emphysematous bacterial infections can result in gas production within the gallbladder, liver, or urinary bladder. Lastly, free gas in the peritoneal and retroperitoneal spaces may be the result of GI perforation, secondary to gas-producing bacteria in bacterial peritonitis, perforating trauma, or can be iatrogenic in origin after surgical interventions (traditional or laparoscopic).

Abdominal Musculature Hypotonia

Laxity of the abdominal muscles can result in the appearance of abdominal distension, and is most commonly associated with hyperadrenocorticism (see ch. 306 and 307). Hepatomegaly secondary to steroid hepatopathy and redistribution of body fat also contribute to the abdominal enlargement in these patients.

Diagnostic Approach

Due to the number of etiologies causing abdominal enlargement, it is essential that the diagnostic approach be thorough and stepwise (Figure 17-1). It is also important to take into consideration the presentation of the patient, particularly when the clinical signs are consistent with shock (e.g., hypotension, prolonged CRT), which may alter the diagnostic course. After using a thorough history and physical examination to formulate an initial differential diagnosis list, a minimum database (including a complete blood cell count [CBC], serum biochemistry profile and urinalysis) should be obtained. The CBC may reveal changes such as those consistent with sepsis or a bleeding tendency, while the serum biochemistry profile and urinalysis can identify evidence of organ dysfunction that prompts further investigation of a particular body system (e.g., hepatobiliary or urinary tract). Imaging of both the abdominal and thoracic cavities is fundamental and can involve the use of multiple modalities, identifying several abnormalities such as an abdominal mass, cavitary effusions, or cardiomegaly. After the completion of such tests, diagnostic evaluations that are more specific can become necessary and could include abdomino- or thoracocentesis (see ch. 90 and 102, respectively) with fluid evaluation and cytologic examination, fine needle aspiration or biopsy of soft tissues with subsequent cytologic or histopathologic evaluation, echocardiography, or abdominal exploratory laparotomy for organ evaluation and collection of tissue biopsies.

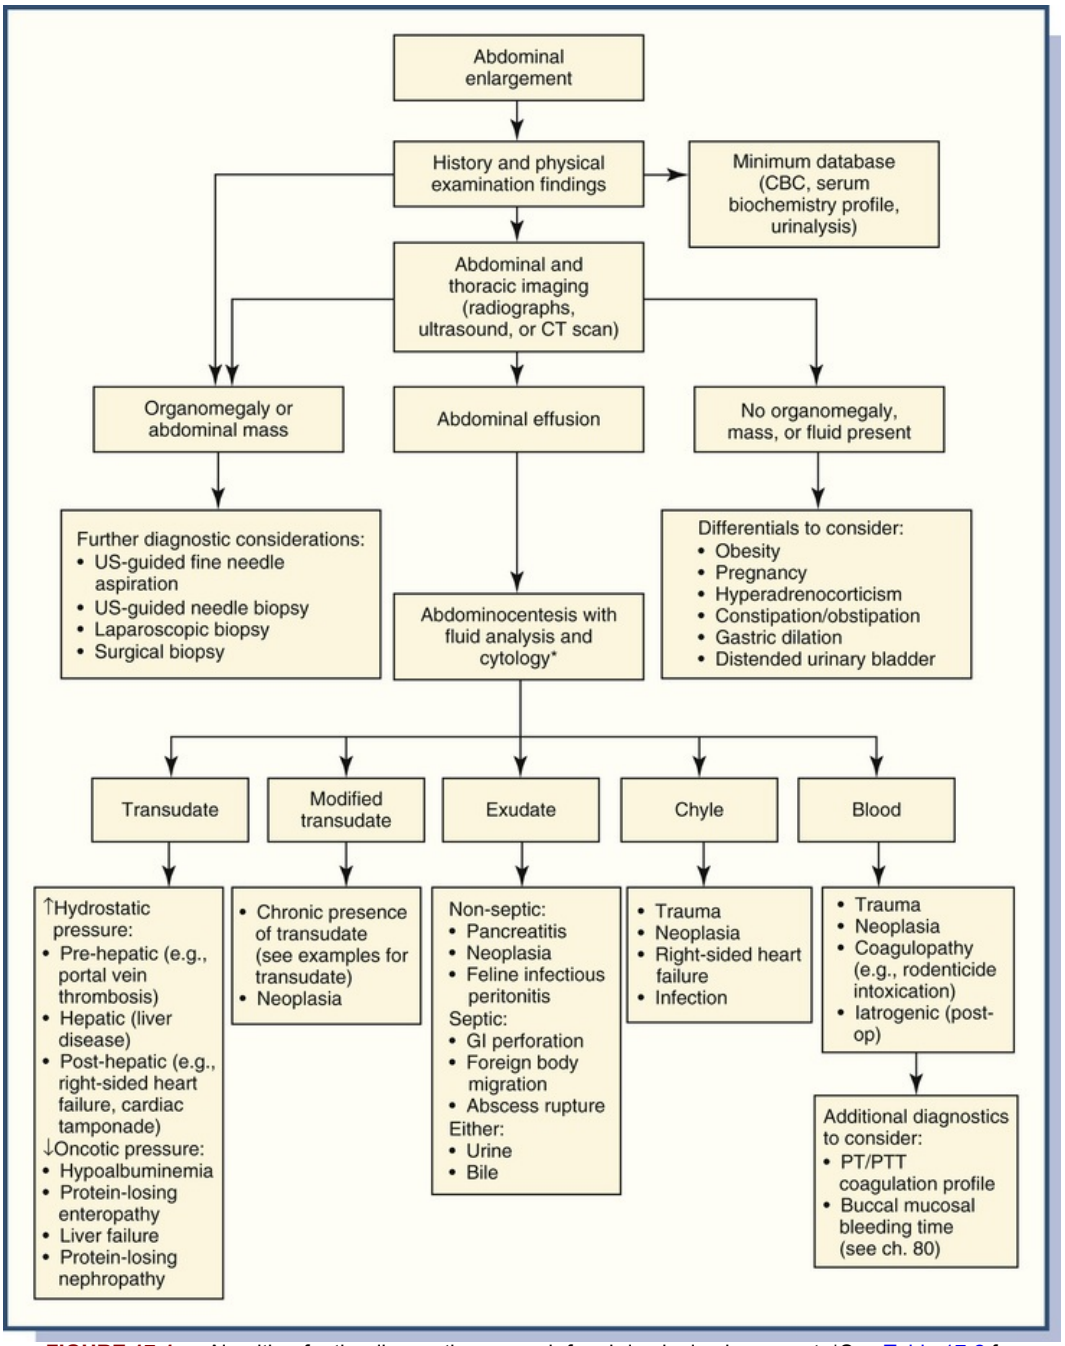

FIGURE 17-1 Algorithm for the diagnostic approach for abdominal enlargement. *See Table 17-2 for characteristics of common effusions. *CBC,* Complete blood count; *PT,* prothrombin time; *PTT,* partial thromboplastin time; *US,* ultrasound.

Treatment

Treatment of abdominal enlargement should be targeted at the underlying cause. This may involve interventions specific to a disease process, such as medical management of hyperadrenocorticism or surgical correction of GDV, or may be palliative in nature, such as therapeutic abdominocentesis in patients with right-sided heart failure. Intra-abdominal pressure measurement may be appropriate in patients with acute increases in abdominal pressure that can result in inadequate regional blood flow and decreased tissue perfusion, culminating in systemic inflammatory response syndrome and multiple organ failure, which is commonly referred to as abdominal compartment syndrome.[5]

CHAPTER 18

Peripheral Edema

Deborah M. Fine-Ferreira

Client Information Sheet: Peripheral Edema

Peripheral edema is the palpable accumulation of fluid within the subepithelial interstitium (Figure 18-1). The interstitial matrix is a dense meshwork composed of proteoglycan filaments, glycoproteins, hyaluronan, collagen, and elastin fibers creating a tissue that is flexible yet remarkably strong.[1,2] There is normally very little free fluid in this compartment, but in disease states, the interstitium is capable of containing a considerable amount of edema. Fluid homeostasis between the intravascular and extravascular compartments is maintained through interplay of the following forces: (1) intravascular hydrostatic pressure, (2) plasma oncotic pressure, (3) extravascular hydrostatic pressure, (4) interstitial oncotic pressure, (5) vascular permeability, and (6) lymphatic function.[3] Classically, Starling's equation describes the relationship between the first 4 of these: $Q = K[(P_{mv} - P_{pmv}) - (p_{mv} - p_{pmv})]$, where Q = net transvascular fluid flow, K = membrane permeability, Pmv = hydrostatic pressure in the microvessels, Ppmv = hydrostatic pressure in the perimicrovascular interstitium, pmv = plasma protein osmotic pressure in the circulation, and ppmv = protein osmotic pressure in the perimicrovascular interstitium. In the cutaneous capillaries, the normal balance of these forces slightly favors the translocation of fluid into the interstitium; however, reabsorption by post-capillary venules and lymphatics maintains normal interstitial fluid volume.[4] There are considerable safety factors built into this system such that a diminution in the function of one factor will be offset by a gain in the function of others, preventing any change in the early stages of disease.

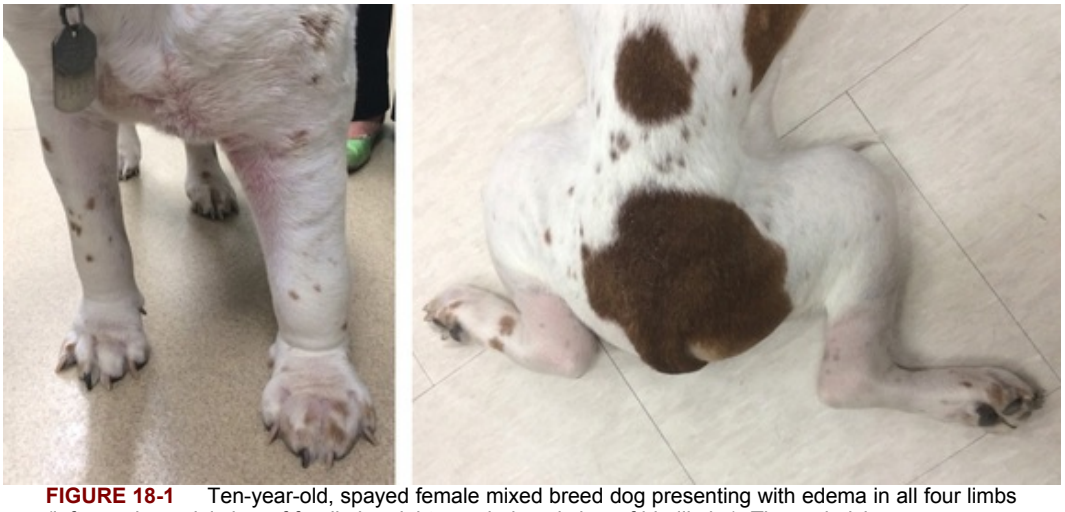

FIGURE 18-1 Ten-year-old, spayed female mixed breed dog presenting with edema in all four limbs (left panel, cranial view of forelimbs; right panel, dorsal view of hindlimbs). The underlying cause was a poorly differentiated widely spread carcinoma. Although all limbs were affected, the left fore- and hindlimbs were much more severely affected than the right. (Courtesy Amy DeClue, University of Missouri.)

Mechanisms of Edema Formation

There are many potential sources of peripheral edema in small animals and certain abnormalities can contribute to the development of edema through more than one mechanism (Box 18-1). Increased intravascular hydrostatic pressure may occur as a localized process, secondary to a mass or trauma to a vascular bed resulting in venous obstruction, or systemically as a generalized process in the setting of plasma volume expansion. Plasma volume expansion ensues from diseases that result in sodium retention via activation of the renin-angiotensin-aldosterone system (e.g., heart failure and chronic kidney disease).[5] In the early stages of these diseases, edema is prevented by a concomitant increase in lymphatic uptake and simultaneous increase in interstitial hydrostatic pressure, which decreases the gradient for fluid movement. However, as the lymphatics ultimately return fluid to the circulatory system, edema is inevitable if the underlying abnormalities progress. Physical examination findings that indicate the presence of plasma volume expansion include distension of the jugular veins and superficial vasculature. This latter finding is particularly obvious in the sparsely haired region of the caudal abdomen. Whereas peripheral edema is a very common manifestation of congestive heart failure in humans, it is rare in small animals. This may be due to differences in fluid homeostasis between species, or simply be a function of increased hydrostatic pressure in the lower limbs of humans (primarily vertically oriented) compared to small animal patients (horizontally oriented).

Box 18-1

General Mechanisms and Specific Causes of Peripheral Edema in Small Animals

Increased Hydrostatic Pressure

- Increased plasma volume
  - Arteriovenous fistula
  - Chronic kidney disease*
  - Right-sided heart failure*
- Venous obstruction
  - Cranial mediastinal mass
  - Caudal abdominal mass
  - Trauma
  - Surgery

Decreased Plasma Oncotic Pressure* (albumin <1.5 – 2.0 g/dL)

- Protein loss
  - Protein-losing enteropathy or glomerulopathy
- Reduced albumin synthesis
  - Liver disease
  - Malnutrition

Increased Capillary Permeability

- Allergic reactions including angioedema
- Inflammation secondary to neoplasia
- Septicemia
- Envenomation
- Burns
- Trauma
- Myxedema

Lymphatic Dysfunction

- Lymph node hypoplasia or aplasia
- Lymph node destruction due to malignancy
- Lymphangiosarcoma

*May cause ascites and/or peripheral edema.

Another potential source of peripheral edema is a decrease in plasma oncotic pressure from either loss of protein[6] (e.g., protein-losing enteropathy or glomerulopathy) or decreased protein synthesis (e.g., hepatic failure, malnutrition).[7,8] Initially, the development of edema in hypoproteinemic states is prevented by a parallel decline in the interstitial oncotic pressure due to decreased albumin entry into the interstitium. This decreases the oncotic gradient between the interstitium and vascular space. Additionally, fluid entry into the interstitium causes a concurrent increase in interstitial hydrostatic pressure, which also opposes the formation of edema. It is important to note that the degree of hypoproteinemia must be quite severe to cause overt edema. Edema is unlikely to develop until albumin falls below 2.0 g/dL unless another process is also occurring.[5] In small animals, hypoproteinemia more commonly manifests as peritoneal effusion (ascites) rather than peripheral edema.

Increased vascular permeability underlies the edematous response to inflammation. These processes include hypersensitivity reactions (e.g., urticaria, angioedema) and sepsis. Vascular permeability is influenced by a myriad of signaling chemicals including inflammatory cytokines, vasodilatory prostaglandins, nitric oxide, bradykinin, and histamine, among others.[5] Increased vascular permeability can also occur due to direct cell damage from mechanical or chemical trauma. Unfortunately, there are no practical clinical methods for measuring increased vascular permeability and thus it must be inferred by other abnormalities such as inflammatory changes on a complete blood count, hyperglobulinemia and hypoalbuminemia on a serum biochemistry panel, and hyper- or hypothermia on physical examination.

Lymphatic abnormalities are another important cause of peripheral edema in small animals.[9] Lymph fluid is high in protein and its presence increases the oncotic gradient within the interstitium, further increasing edema formation. Lymphatic abnormalities can be primary or secondary. Congenital lymphedema is uncommon in dogs and is very rare in cats.[9,10] Affected animals usually show evidence of edema at birth or within the first few weeks of age, though in some instances it may be many months before edema is manifested. The most common presentation in affected animals is hindlimb edema, with one limb usually being more severely affected than the other (Figure 18-2). However, in some instances, all limbs or even the head and ventrum are affected. Patients with congenital lymphedema have small or absent lymph nodes in the affected limbs. The diagnosis may be suspected from the clinical signs and age at presentation, but definitive diagnosis requires lymphatic imaging or biopsy.[11] There are many secondary causes of lymphatic disease, including obstruction or destruction secondary to neoplasia,[12,13] infection, filariasis, surgery, and trauma.

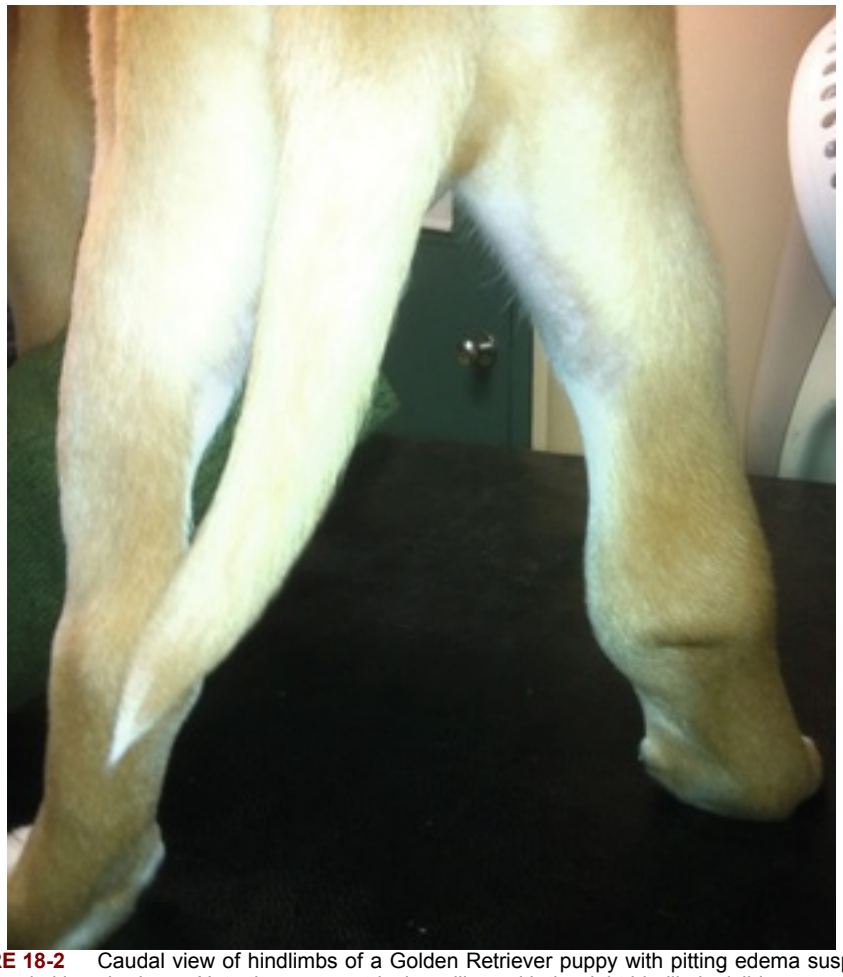

FIGURE 18-2 Caudal view of hindlimbs of a Golden Retriever puppy with pitting edema suspected of congenital lymphedema. Note the asymmetrical swelling, with the right hindlimb visibly more swollen than the left. No abnormalities were found on complete blood count, serum biochemistry panel, or abdominal ultrasonography. (Courtesy Leah Cohn, University of Missouri.)

Myxedema, a manifestation of profound hypothyroidism, results in edema through the combinations of increased capillary leakage of proteins and diminution in lymphatic uptake.[14] This results in non-pitting edema on physical examination, as well as hypothermia, respiratory depression, and bradycardia (see ch. 299).[15,16]

Diagnosis and Treatment of Edematous Diseases

Evaluating the distribution of edema and response to palpation are crucial diagnostic steps in helping to diagnose the underlying cause of the edema (Figure 18-3). Peripheral edema that is diffuse is more likely the result of a systemic inflammatory response (e.g., sepsis, angioedema) or increased plasma volume (e.g., nephrotic syndrome). In contrast, edema that is localized is more commonly the result of venous or lymphatic abnormalities, or possibly an envenomation. Generally, peripheral edema will be most severe in the dependent regions due to gravitational and hydrostatic forces.

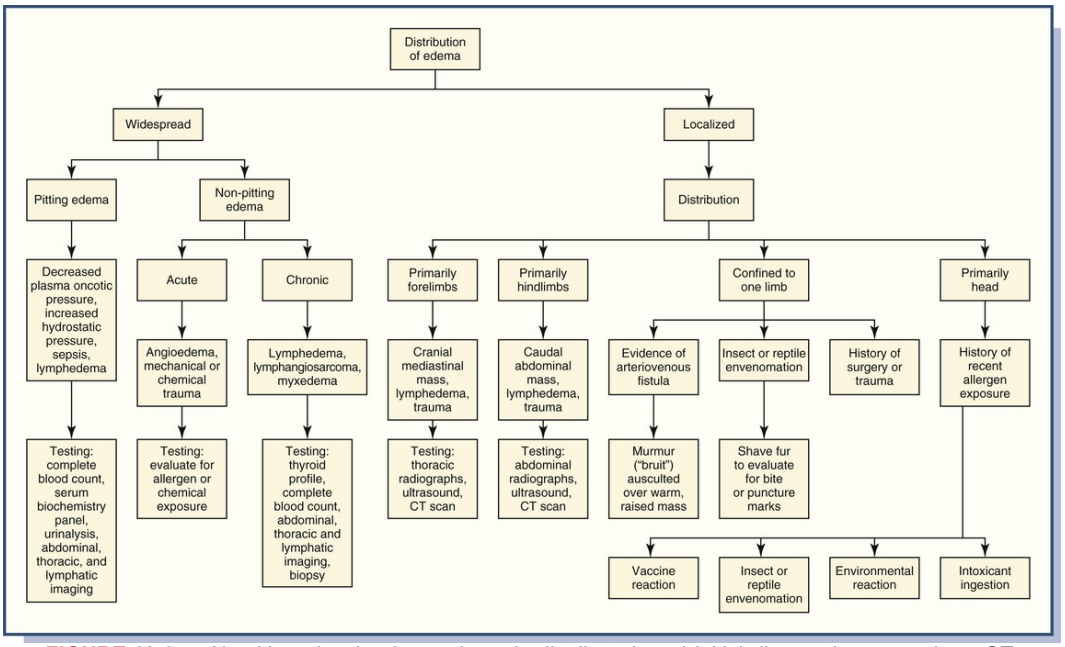

FIGURE 18-3 Algorithm showing how edema is distributed, and initial diagnostic approaches. *CT*, Computed tomography.

Determining if edema is pitting or non-pitting will also help diagnose the cause. Pitting edema is recognized by a persistent depression in the skin after firm pressure is applied (Video 18-1). Mechanistically, pitting edema indicates displacement of fluid within the interstitial space, whereas non-pitting edema indicates intracellular swelling, or interstitial fluid retention with clotted fibrinogen that prevents fluid shifts.[17] In small animal patients, pitting edema is most commonly a manifestation of increased vascular permeability (e.g., inflammation), venous obstruction (e.g., mass, trauma), or lymphatic abnormalities (e.g., obstruction, hypoplasia). Edematous states that are non-pitting include angioedema, post-surgical or traumatic swelling, chronic lymphedema, lymphangiosarcoma, and myxedema. Angioedema is non-pitting due to the process occurring in the deeper layers of the skin below the dermis. Chronic lymphedema will gradually transform into a non-pitting state due to collagen deposition and the development of fibrosis in the affected tissues.[9] Once fibrosis occurs, there is little that can be done therapeutically to resolve the edema.

The diagnostic approach to the edematous patient should be based on history and physical examination findings. Generalized edema warrants a systemic approach including complete blood count, serum biochemistry profile, serum thyroxine concentration, and urinalysis. Diagnostics performed in the presence of edema that is localized to the front or rear limbs should include radiography and ultrasound for ruling out obvious masses and determining if more advanced imaging is indicated.

Direct imaging of lymphatics and lymph nodes requires specialized techniques.[18,19] In the past, lymphangiography via direct lymphatic cannulation was the only method for evaluating lymphatic structure and function. This technique is technically challenging and is rarely performed anymore. Instead, it has been largely supplanted by non-invasive imaging techniques including scintigraphy, computed tomography (CT), magnetic resonance imaging, and positron emission tomography scanning. However, these modalities suffer from limited availability and being relatively expensive to perform.

Therapy for peripheral edema should always be directed at treating the underlying abnormality when possible (e.g., plasma transfusion, surgical removal of an obstructive mass, levothyroxine treatment of myxedema, etc.). In situations where a definitive treatment is not possible, then palliative care can be offered. Except in states of increased hydrostatic pressure, diuretics are relatively contraindicated in edematous states. Although they will initially help decrease the size of a limb in lymphedema, they ultimately increase the progression of disease by concentrating proteins in the interstitium and acting as a draw for further fluid translocation. These patients may benefit from chronic bandaging, surgical palliation, or therapy with rutin, though the latter has not been scientifically evaluated.[11] Efficacy of treatment may be monitored by measuring the circumference of the affected limb before and after performing an intervention in order to objectively assess therapeutic response.[20] In most instances, the finding of peripheral edema confers a

guarded prognosis and owners should be advised that palliation is usually a more realistic goal than a definitive cure.

CHAPTER 19

Weight Loss as a Chief Complaint

Thomas Schermerhorn

Client Information Sheet: Weight Loss

Background

Weight loss may be intentional or unintentional. Intentional weight loss in animals occurs as a result of caloric restriction dictated by a voluntary (or prescribed) dieting program (see ch. 176). Unintentional weight loss, the focus of this chapter, is a frequent clinical complaint and can be associated with serious disease. Maintenance of body weight is a reflection of nutrient intake, absorption, and utilization. These factors may be impacted by age, health status, and environment (diet, food availability, etc.). In people, unintentional loss of ≥5% body weight over 6-12 months warrants investigation.[1] While clinically relevant weight loss has not been defined for dogs and cats, ≈5% is a reasonable benchmark.

The frequency of weight loss as an owner's chief complaint for dogs and cats is unknown. Weight loss is a well-recognized clinical sign in numerous disorders. Weight loss is also common in human illnesses; unintentional weight loss is reported in as many as 65% of geriatric patients.[2] The high prevalence of unintentional weight loss in clinical illness underscores the need to carefully monitor weight in dogs and cats as a part of their general health assessment.

History

Dogs and cats may be brought to a veterinarian with weight loss as a primary or sole complaint. More commonly, it accompanies other signs associated with an underlying condition. Careful history-taking should include questions about appetite, caloric intake, daily exercise, and environment (see ch. 170). Appetite is variable in animals with weight loss and may be reported as reduced, normal, or increased (see ch. 16 and 17). Appetite may be preserved or increased when malnutrition results from starvation, malabsorption, or maldigestion. However, appetite is reduced (hyporexia) or suppressed completely (anorexia) by many systemic illnesses, leading to unintentional weight loss (see ch. 16). When an owner mentions the possibility of weight loss, the dietary history should be carefully reviewed (see ch. 170). This review should include the type and quantity of food offered (including any dietary supplements provided), the possibility that other pets at home might be competing for food, and the pet's appetite. It is important to distinguish those animals that have an appetite but cannot prehend or swallow food from those who have no appetite but can chew and swallow normally (see ch. 272). Diagnostic considerations suggested by various patient history findings are presented in Box 19-1.

Box 19-1

Diagnostic Considerations for Patients with Marked Weight Loss

Dietary History—Inadequate

Starvation
Underfeeding
Poor quality food

Dietary History—Adequate

Environmental/housing factors

Competition for food from other pets
Limited access to food
Oral and dental disease
Impaired use of nutrients
Specific nutrient deficiency
Maldigestion of any cause
Malabsorption of any cause
Diabetes mellitus
Protein-losing disease
  Nephropathy
  Gastroenteropathy
Cardiac disease*
Elevated metabolism
Hyperthyroidism
Chronic fever of any cause*
End-stage renal disease*
Neoplasia*
Chronic infection*
Chronic inflammation of any cause (e.g., immunologic disease*)
  Note: Patients may present with or without a loss of appetite.

*Diseases typically associated with cachexia in humans and animals.

Common mechanisms leading to weight loss include decreased caloric intake, increased metabolic demand, accelerated energy loss, inability to utilize ingested calories, and inappetence. Specific etiologies usually cause weight loss through several mechanisms, each of which may need to be evaluated if weight loss is to be understood and treated. Some cancers can cause weight loss if the tumor mass interferes with food intake or nutrient processing. Some cancers cause severe weight loss via the production of humoral factors that impair metabolism. For example, oral cancer may impede mastication or swallowing while gastrointestinal neoplasia may interfere with digestion and absorption of nutrients or cause nausea, vomiting and/or diarrhea. Some cancers secrete substances that cause anorexia or induce cachexia (see ch. 177).

In humans, gastrointestinal disorders are the leading non-neoplastic cause of unintended weight loss; the same may be true for dogs and cats. Oral and dental diseases, megaesophagus, chronic gastroenteritis, inflammatory bowel disease (IBD), pancreatitis, dysmotility, and other disorders can produce weight loss through a variety of mechanisms that include induction of nausea, inappetence, protein loss, maldigestion and malabsorption.

Several endocrine disorders are associated with weight loss. Hyperthyroidism causes weight loss, in part, due to increases in metabolic rate. Diabetes mellitus, a condition associated with an absolute or relative deficiency of insulin, causes weight loss due to an inability to utilize nutrients. Both these conditions are usually associated with increases in appetite. Other endocrine conditions, such as hypoadrenocorticism and hyperparathyroidism, commonly cause weight loss and are associated with a reduction in appetite.

Chronic bacterial or fungal infection, especially those accompanied by persistent systemic inflammation, are associated with weight loss. Likewise, the persistent systemic inflammation of connective tissue disorders, such as systemic immune-mediated conditions, may cause weight loss through similar mechanisms. Both cardiac and respiratory disorders can lead to an increase in metabolic demands and induce cachexia. Indeed, heart failure caused by chronic valvular disease or cardiomyopathy is a frequent cause of cachexia (cardiac cachexia) in dogs.[3] Uremia secondary to chronic kidney disease (CKD) commonly leads to nausea, gastric ulceration, and vomiting that, in turn, decreases appetite and reduces caloric intake. Some neurological disorders reduce appetite that leads to weight loss. Other neurologic conditions decrease food intake by impairing mastication or swallowing. Some neurologic disorders that impair autonomic function or cause dysmotility may cause gastrointestinal dysfunction and weight loss. Cognitive dysfunction and psychiatric disorders are present in a substantial proportion of people with weight loss but the role of similar neurologic disorders in dogs and cats is unknown.

No standard definition for cachexia exists. In clinical practice, cachexia is the term used to describe the weight loss, loss of muscle, and anorexia that accompany many chronic disease conditions (see ch. 177).[3]

However, cachexia is not simply caused by inadequate nutrient intake. Cachexia and starvation are not equivalent physiologic processes. Two biochemical features distinguish malnutrition caused by cachexia from that caused by starvation.[4] First, unlike starvation, inflammation is a consistent feature of cachexia. Cachexia causes marked activation of the inflammatory cascade, characterized by a pronounced acute phase inflammatory response and excessive production of proinflammatory cytokines such as interleukins (IL-1 and IL-6, among others) and tumor necrosis factor alpha (TNF-alpha).[5] These cytokines stimulate the ubiquitin pathway, a central pathway in protein turnover.[6] Ubiquitin complexes with target cellular proteins and stimulates their metabolism via the proteasome system. Second, cachexia is associated with a rise in resting energy expenditure, which increases as a consequence of altered protein, fat, and carbohydrate metabolism. Loss of body muscle and adipose tissues is marked and an insulin-resistant state may develop. Despite a similar clinical appearance, activation of the ubiquitin-proteasome system and increased energy expenditure are not features of starvation. A diagnosis of cachexia should be considered for any dog or cat with marked weight loss, severe muscle loss, and decreased appetite in the setting of a chronic inflammatory response or cancer.[3] By this definition, cachexia is not a specific diagnosis but a state of disordered metabolism that can be caused by a variety of diseases.

Physical and Laboratory Findings

Weight loss is a clinical sign, not a specific diagnosis. Suspected weight loss should be verified, when possible, by comparing previously recorded body weights with the current status. Owner perception of weight loss may not be accurate. Suboptimal body weight, loss of subcutaneous fat with prominence of underlying skeletal structures, an emaciated appearance, and a low body condition score (BCS) support the suspicion of weight loss (see ch. 2). It must be borne in mind that substantial weight loss may occur without obvious physical changes. Some pets have a normal BCS, despite significant weight loss. Marked loss of body condition is a characteristic finding of severe cachexia in which muscle loss may be disproportionate to fat loss. In many cases, a diagnosis may be apparent after completion of the physical examination. Examples of a "physical examination diagnosis" or "physical examination suspicion" abound. These include, but are not limited to, identifying oral disease, a cervical mass (thyroid tumor?), cardiac arrhythmia, or abdominal mass. If the physical examination fails to identify a concern, a directed physical examination (e.g., detailed neurologic or orthopedic examination) or laboratory examination may be needed to confirm a diagnosis.

Laboratory findings in animals with unintended weight loss are neither specific nor consistent. Test results typically reflect the primary pathologic processes responsible for the weight loss. In cachexia, laboratory findings may show characteristic yet nonspecific changes.[5] Serum protein concentrations vary even in the presence of a systemic inflammatory response. For example, elevated fibrinogen concentrations (as a component of the acute phase response) in humans with neoplasia may be offset by reduced albumin synthesis. Increases in hormone concentrations, such as cortisol and insulin, may be observed in animals with cachexia; these changes may result from or be the cause of cachexia-induced alterations in metabolism. In general, as for other forms of unintended weight loss, the physical and laboratory findings of a patient with cachexia will be representative of the underlying disease rather than specific indicators of cachexia. No compelling reasons exist to perform specific laboratory tests to make a diagnosis of cachexia. Instead, cachexia is largely a clinical diagnosis that is made when appropriate physical findings are present in a dog or cat with a disease associated with a chronic inflammatory response.

Diagnostic Plan

A general algorithm for making a diagnosis of unintended weight loss is shown in Figure 19-1. Unintended weight loss of >5% over a period of less than 12 months in any patient should evoke concern about the possibility of underlying disease. A suitable and tailored diagnostic plan based on physical and laboratory findings should be developed for affected animals. It is important to recognize cachexia because animals with this condition may not respond as expected to therapeutic interventions and nutritional support. In people, a diagnostic work-up may fail to uncover an etiology in as many as 30% of patients with a complaint of unintended weight loss.[1] The proportion of dogs and cats with weight loss that have unrewarding diagnostic evaluations is not known but it is certain to occur.

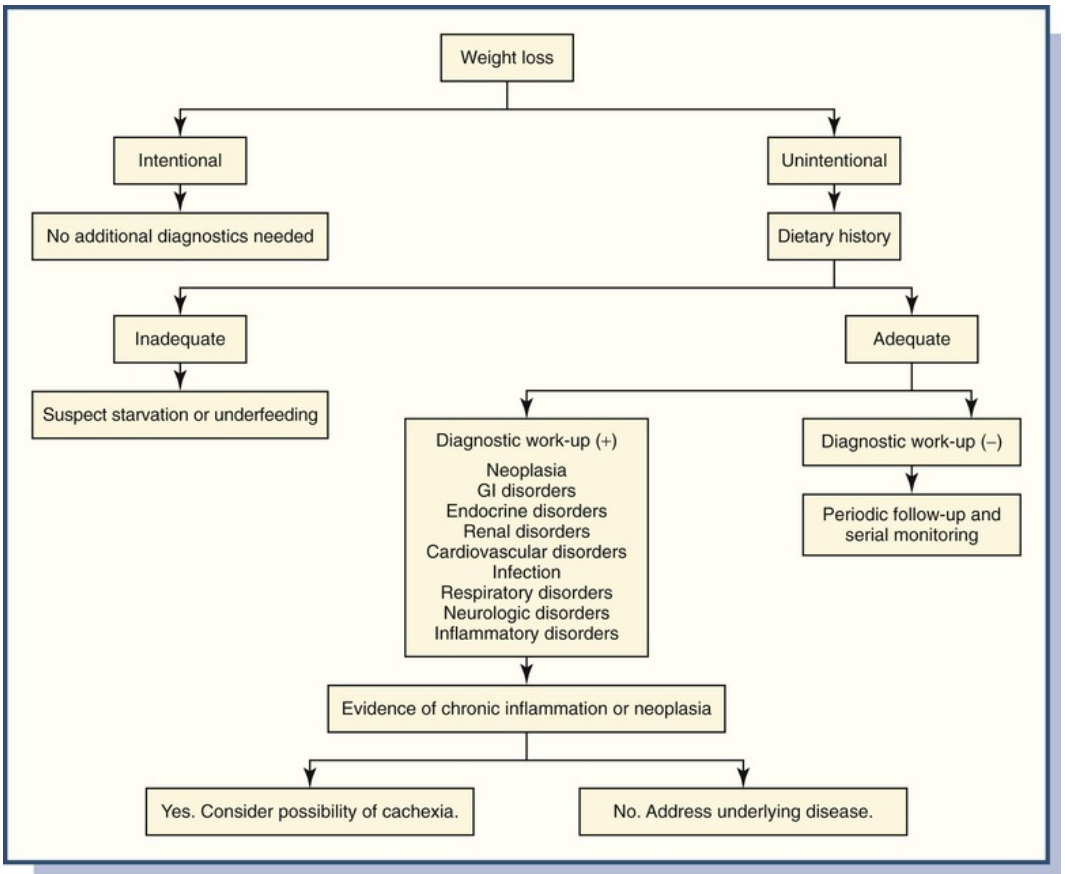

FIGURE 19-1 Algorithm for making a diagnosis of cachexia. +, Testing allowed; −, testing rejected; *GI*, gastrointestinal.

Therapy

Successful therapy or resolution of the primary disorder is the most efficacious means to address unintended weight loss. Therapy will ameliorate or reverse the underlying factors contributing to weight loss and body weight may be restored with nutritional support. When weight loss is due to cachexia, nutritional support remains the cornerstone of specific therapy; however, additional considerations must be given to designing the nutritional plan (see ch. 170). Hypercaloric feeding is intended to supply the dog or cat with sufficient calories to meet increased maintenance caloric needs (because of hypermetabolism), prevent additional weight loss, and promote weight gain. Unfortunately, hypercaloric feeding alone may not be sufficient therapy for animals with true cachexia. People with cachexia who receive hypercaloric feeding gain weight, but the increase in body weight is almost exclusively the result of an increase in adipose tissue without change in lean body mass. Thus, it appears that simple feeding therapy may not be sufficient in all situations to reverse the abnormal protein catabolism that accompanies cachexia. Pharmacologic therapies that have been used for cachexia in humans that may prove useful for the treatment of animals include nutritional supplements (including fish oils), appetite stimulants, anabolic agents, anti-inflammatory drugs, and cytokine inhibitors. Although some of these drugs have been extensively used for other indications in small animals, information is limited about their efficacy when used for cachexia. Specific inhibitors of the ubiquitin system, which inhibit the effects of cachexia at the molecular level, may eventually be developed.

It is less clear which steps should be taken when a patient with weight loss has a non-diagnostic work-up. Cancer is perhaps the most serious diagnosis that clinicians fear may have been missed under these circumstances. While specific information about dogs and cats is lacking, the number of occult neoplasms later diagnosed in humans with weight loss and an unremarkable initial work-up is surprisingly small (<5%). Given the information gleaned from studies of human patients and lacking concerning physical, laboratory or imaging findings, it may be prudent to adopt a wait-and-see strategy when a dog or cat that is presented for weight loss has a negative physical examination and lacks a specific diagnosis after blood, urine, blood pressure and imaging results. Wait-and-see takes a strategy of serial monitoring over time rather than

immediate continued non-directed efforts that might involve more expensive or invasive diagnostics or the pursuit of unlikely diagnoses.

CHAPTER 20

Failure to Grow

Hans S. Kooistra

Client Information Sheet: Failure to Grow

Introduction

Linear growth is a complex process that can easily be disturbed. Young dogs and cats grow rapidly over a relatively short period of time. Linear (vertical) growth primarily occurs during the first 6 to 9 months of life, but can continue in some dogs until about 2 years of age. Growth in long bone length is limited to the growth plates and occurs via the process of endochondral ossification. Linear growth halts when the growth plates close. There is no other species with so much variation in body size as the dog, which may make it difficult to determine whether failure to grow is really a problem.

Failure to grow is defined as not growing at the anticipated rate or to a normal extent. Failure to grow may be an owner's chief concern or may be identified by a veterinarian during routine physical examination. Usually there is good correlation between parental height and that of their offspring. Thus, if possible, the size of the dog with supposed failure to grow should be compared with parental and sibling height. The possibility should be considered that an apparent dwarf may simply be a small individual whose size is within normal biological variation. Alternatively, the individual may be the offspring of an unexpected or unwanted mating with a small sire.

Pathophysiology

Genetic factors play a major role in linear growth, with numerous genes involved in its regulation. After domestication of the dog, selection of such genes by humans has resulted in breeds with a wide variety of body sizes and growth rates. The chondrodystrophic dog breeds are an example of selection by people for the genes that give rise to angular limb formation and short legs. As these breeds have been created intentionally, they are usually not considered as having a problem with failure to grow.

To meet its full genetic potential for growth, any animal must consume sufficient calories and nutrients. Following consumption, food must be digested, absorbed, and the nutrients transported to the necessary tissues and used for metabolic maintenance and growth. The causes of failure to grow can be subdivided into three major groups: (1) inadequate intake of calories and nutrients, (2) metabolic changes associated with increased use of energy, and (3) loss of energy. Because several hormones are important determinants of linear growth, it may be helpful to differentiate endocrine and non-endocrine causes of failure to grow.

Endocrine Causes of Failure to Grow

Growth Hormone and Insulin-Like Growth Factor-1 Deficiency

Growth hormone (GH), originating from the pituitary anterior lobe, plays a central role in the modulation of growth. Hypersecretion of GH at a young age, i.e. juvenile hypersomatotropism, is an important determinant of linear growth.[1] Serial measurements of plasma GH concentrations have revealed that the initial increases documented in Great Dane puppies decrease to adult concentrations by about 6 months of age.[2] In Beagles, GH secretion is increased only until about 7 weeks of age.[1] In Miniature Poodles, GH concentrations do not change significantly with time and values in young animals are within adult reference ranges.[3]

In the total absence of GH, linear growth occurs at about a third to a quarter of the normal rate. Growth hormone deficiency in a young animal affects the growth of almost all tissues, resulting in “proportionate

dwarfism." This means that all body components are equally small.

Although GH has a direct effect on several tissues, the majority of its growth-promoting actions are mediated by insulin-like growth factor-1 (IGF-1). Growth hormone stimulates the synthesis and secretion of IGF-1 by the liver. In the systemic circulation, IGF-1 is bound to carrier proteins, the IGF-binding proteins (IGF-BPs). This binding prolongs the half-life of IGF-1, consistent with its long-term growth-promoting action. This hepatic IGF-1 reaches the target cells via the circulation and stimulates anabolic processes, such as protein synthesis, chondrogenesis, and growth. In addition to its endocrine effects, GH also stimulates local production of IGF-1. Locally synthesized IGF-1 stimulates anabolic processes in a paracrine or autocrine manner. For example, linear growth is largely dependent on local production of IGF-1 in growth plates. In adult dogs, there is a strong correlation between plasma IGF-1 concentration and body size, while basal plasma GH concentrations are quite similar among various breeds. This implies that breed-specific reference ranges must be used to determine whether failure to grow is due to insufficient circulating concentrations of IGF-1.

Juvenile Hypothyroidism

Adequate circulating thyroid hormone concentrations appear to be an absolute prerequisite for normal growth. Total absence of thyroid hormones leads to an almost complete cessation of linear growth. Thyroid hormone exerts direct effects on cell metabolism. In addition, the actions of IGF-1 on cartilage cells are dependent on thyroid hormone. Because skeletal growth strongly depends on thyroid hormones that promote chondrogenesis, in synergy with GH and IGF-1, juvenile hypothyroidism is associated with delayed epiphyseal closure, retarded epiphyseal growth, reduced long bone growth, and disproportionate dwarfism.[4]

Insulin Deficiency (Juvenile Diabetes Mellitus)

Insulin has strong anabolic actions separate from its effects on carbohydrate metabolism. These actions include stimulation of protein synthesis and cell division. Consequently, insulin deficiency, i.e. juvenile diabetes mellitus, is associated with growth retardation. This failure of normal growth, typical of dogs and cats with juvenile diabetes mellitus, is also due to a decrease in insulin-dependent transportation of glucose and fatty acids into muscle and fat cells. Further, glucose is lost in urine.

Glucocorticoid Excess

The catabolic effects of the glucocorticoids are characterized by increased gluconeogenesis, decreased uptake of glucose by muscle and fat cells, increased protein breakdown, and lipolysis. In addition, glucocorticoid excess suppresses pituitary GH secretion. Consequently, long-term administration of glucocorticoids to young growing animals may result in growth retardation.

Gonadal Steroids Excess

Gonadal androgens and estrogens are contributors to linear growth. Prepubertal gonadectomy may result in taller individuals (see ch. 313).[5] Administration of androgens or estrogens at an early age may result in stunted growth due to premature closure of the growth plates.

Other Endocrine Hypofunctions

Hypoadrenocorticism may occur at any age. The Nova Scotia Duck Tolling Retriever is a breed recognized to occasionally develop primary hypoadrenocorticism at an early age. Hypoadrenocorticism is often associated with a decrease in appetite, vomiting and diarrhea. These problems result in reduced nutrient intake, which may give rise to a failure to grow. Hypoparathyroidism may also occur at a young age. Parathyroid hormone (PTH) has an important role in bone metabolism and its deficiency may result in growth retardation. Disorders associated with severe polydipsia, such as central diabetes insipidus, may result in impaired appetite and failure to grow normally.

Non-Endocrine Causes of Failure to Grow

In addition to genotype, another important factor affecting growth is intake of calories and nutrients. Nutritional deprivation severely impairs growth. Selective deficiencies in vitamins or minerals may also cause

abnormalities of growth. The quality and palatability of food should be taken into consideration.

A poor appetite, e.g., due to a systemic disease, may result in less food intake. Oropharyngeal disorders may cause anorexia. Regurgitation or vomiting could result in insufficient nutrients reaching the intestines. A vascular ring anomaly, due to a persistent right aortic arch, should be considered in puppies with stunted growth and chronic regurgitation, especially after weaning. Maldigestion, e.g., due to exocrine pancreatic insufficiency, and malabsorption, e.g., due to an intestinal wall disorder, can result in decreased uptake of nutrients. Intestinal parasites are a frequent cause of inadequate uptake of nutrients in puppies and kittens.

Catabolic processes, such as those associated with inflammatory processes and fever, will result in increased use of energy. Cardiac congenital anomalies and endocarditis may be associated with tachycardia which, in turn, utilizes excess energy, leaving fewer calories for growth. Disorders involving organs that play a central role in metabolism, i.e. the liver and the kidneys, may result in failure to grow. Both congenital renal disorders and acquired kidney disease, e.g., pyelonephritis, can result in stunted growth. Portosystemic shunting resulting in hepatic encephalopathy is the most common liver disorder associated with failure to grow. Hepatitis and glycogen storage diseases have been associated with growth failure. Growth failure in chronically anemic individuals may be associated with impaired oxygen delivery to tissues as well as increased cardiovascular effort. Failure to grow can be associated with glucosuria due to (juvenile) diabetes mellitus or it may follow abnormalities in renal proximal tubules. Persistent proteinuria and protein-losing enteropathies decrease growth potential.

Diagnostic Approach (Figure 20-1)

A detailed history should be obtained regarding the amount, quality and palatability of food consumed. A poor appetite, despite the feeding of a palatable, high-quality food suggests a disorder of the gastrointestinal tract or the presence of systemic disease. Stunted growth in pets with extremely good or ravenous appetites may point to maldigestion, malabsorption or loss of energy. History-taking may also reveal treatment with steroids for an unrelated problem.

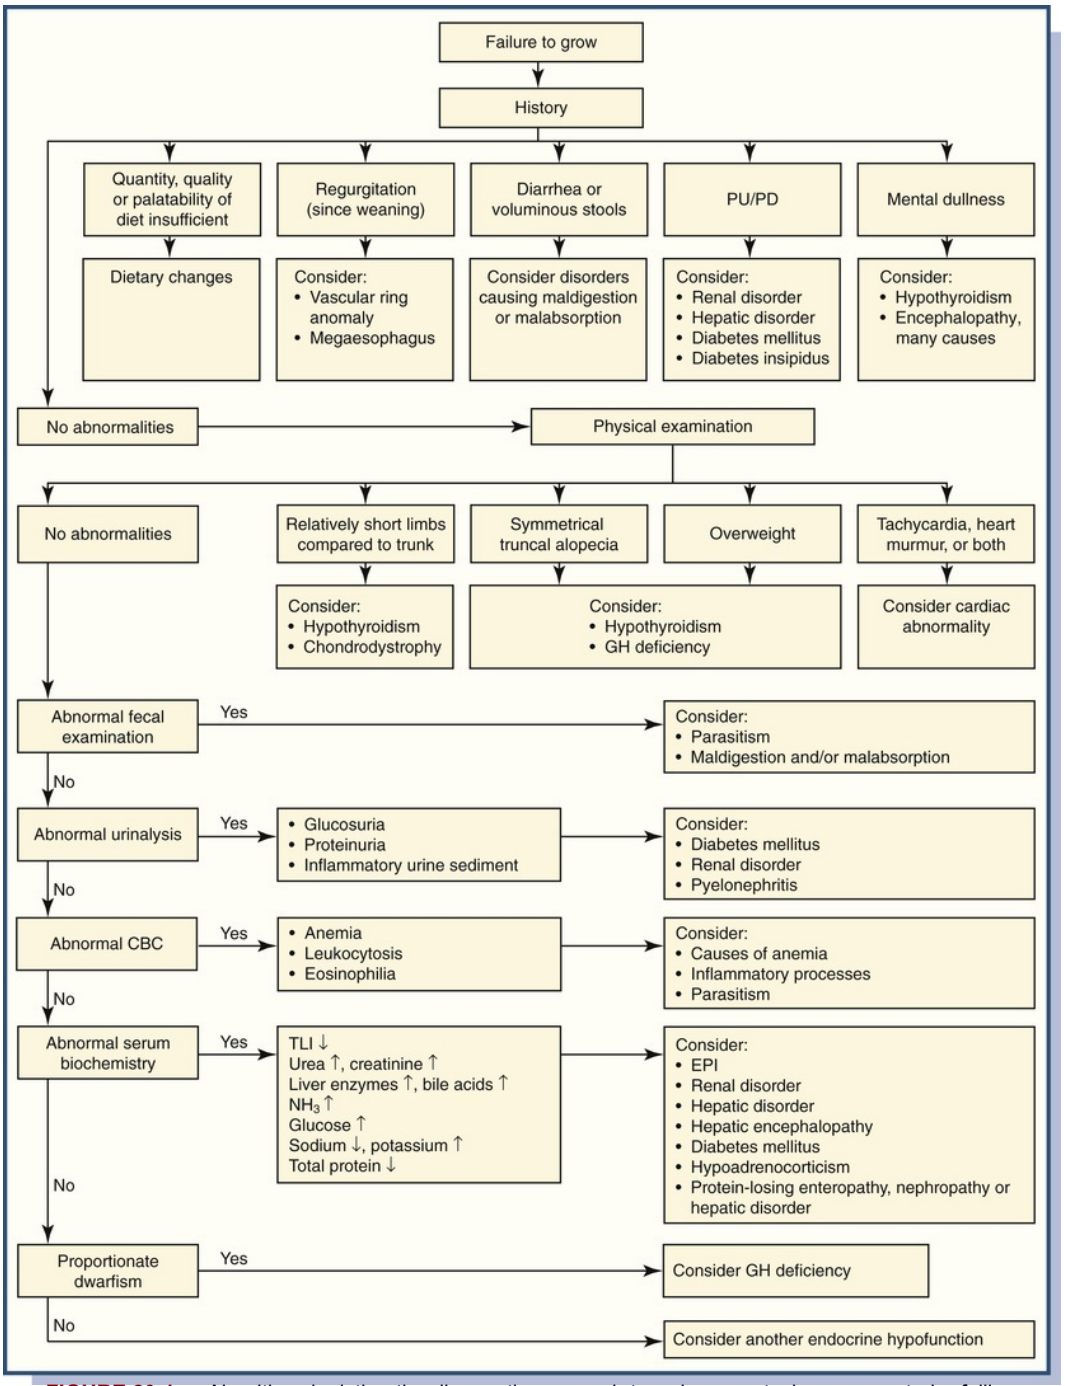

FIGURE 20-1 Algorithm depicting the diagnostic approach to a dog or cat who appears to be failing to grow as expected. *CBC,* Complete blood count; *EPI,* exocrine pancreatic insufficiency; *GH,* growth hormone; *PU/PD,* polyuria/polydipsia; *TLI,* trypsin-like immunoreactivity.

Concurrent clinical signs may help identify an underlying cause for failure to grow. Diarrhea or voluminous stools may point to maldigestion or malabsorption. Polyuria may point to renal disease, hepatic disease, diabetes mellitus, diabetes insipidus or other conditions. Mental dullness may point to hypothyroidism or (hepatic or renal) encephalopathy. Symmetrical truncal alopecia can be seen in dogs with GH deficiency or hypothyroidism. Regurgitation since weaning may point to vascular ring anomaly and megaesophagus.

Body proportions must be carefully evaluated in dogs or cats who fail to grow. Relatively short limbs compared to the trunk suggest either juvenile hypothyroidism or chondrodystrophy. Growth hormone deficiency, in contrast, causes proportionate dwarfism. It is also important to note the ratio of height to weight. An animal with stunted growth that is overweight for its height is more likely to have an endocrine

disorder such as GH deficiency or hypothyroidism. Malnutrition or systemic disorders are more likely to result in underweight animals with stunted growth.

A thorough physical examination is essential in animals with failure to grow, as specific physical findings may point to a specific disorder. For example, dogs with hypothyroidism usually will have a weak pulse or a heart murmur may disclose a cardiac abnormality.

Laboratory evaluations should include multiple fecal examinations for intestinal parasites, e.g., *Giardia*. Fecal examination may also provide information regarding digestion and absorption. Urinalysis may reveal proteinuria, glucosuria or hyposthenuria. Indications for pyelonephritis may be found in the urine sediment. A complete blood count (CBC) should be evaluated for anemia, inflammation or eosinophilia. Remember that puppies and kittens normally have lower red blood cell counts as compared with adults. Eosinophilia may point to parasitism or hypoadrenocorticism. Results of a routine serum biochemistry profile can help to identify renal disease, hepatic disease, diabetes mellitus or hypoadrenocorticism. Decreased serum protein concentrations may point to hepatic disease, protein-losing enteropathy or protein-losing nephropathy. Decreases in serum trypsin-like immunoreactivity (TLI) in a fasted dog confirms exocrine pancreatic insufficiency (EPI). Serum cobalamin and folate concentrations may suggest intestinal abnormalities causing maldigestion and malabsorption.

Specific tests may be required to diagnose endocrine disorders. Growth hormone deficiency can be diagnosed indirectly by measuring and finding low serum IGF-1 concentrations. Absence of a significant increase in circulating GH concentration after IV administration of GH-releasing hormone also implicates GH deficiency. Decreases in serum thyroxine concentration together with increases in thyroid stimulating hormone (TSH) concentration may confirm hypothyroidism. A TSH-stimulation test can be used to secure the diagnosis in dogs whose TSH concentrations are not increased. The diagnosis of hypoadrenocorticism should be based on the results of an adrenocorticotropic hormone (ACTH) stimulation test.

Diagnostic imaging may reveal skeletal abnormalities. Ultrasonography may be helpful to detect structural abnormalities of the internal organs or identify a portosystemic shunt. Biopsy may be needed if gastrointestinal, hepatic or renal disease is suspected.

Treatment

Treatment is dependent on the underlying disorder. Some disorders can be well managed medically, whereas others may require surgical correction. If the underlying disorder is diagnosed and treated early, "catch-up" in growth is usually seen.

CHAPTER 21

Weakness

Fred C. Brewer IV

Weakness or asthenia (lack/loss of or reduced strength) is the clinical manifestation of many disease conditions and consequently, is a common clinical sign (Figure 21-1). In veterinary medicine, the term weakness is often used synonymously with fatigue, lethargy, and exercise intolerance. Weakness is the inability to initiate a task, while fatigue is the inability to continue to perform a task after it has begun. Lethargy is defined by a deficiency in mental or physical alertness or activity, and refers to drowsiness, sluggishness, dullness, or inactivity. Exercise intolerance is defined by the inability to sustain a level of physical exercise expected based on the patient's physical condition. For purposes of this discussion, the term weakness will be used interchangeably to include fatigue, lethargy, and exercise intolerance.

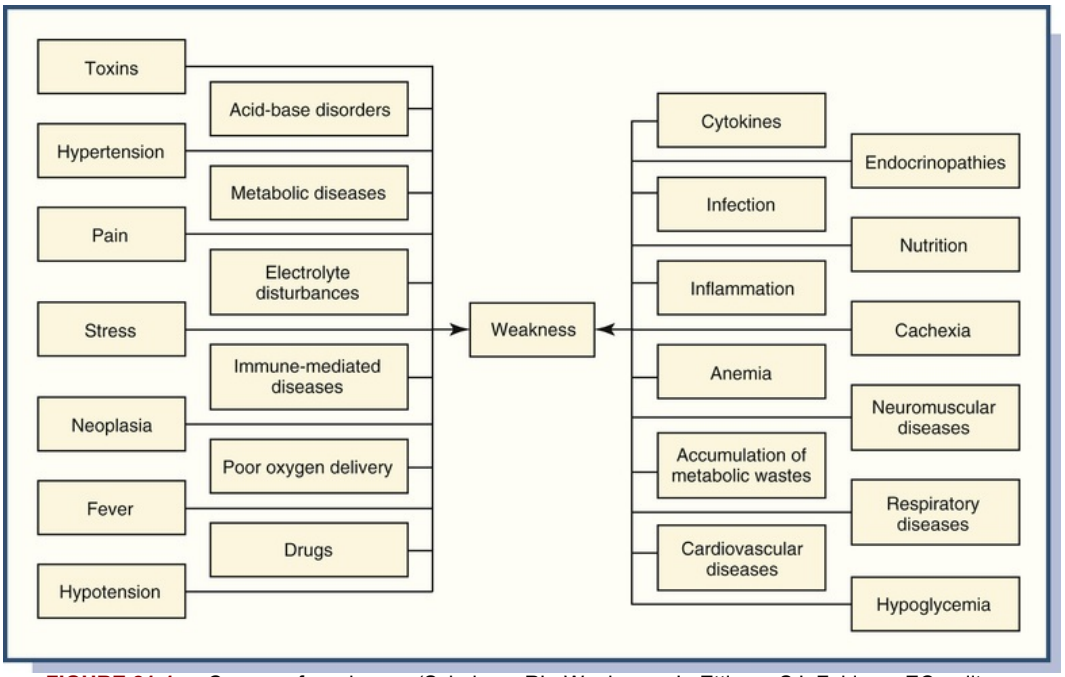

FIGURE 21-1 Causes of weakness. (Schulman RL: Weakness. In Ettinger SJ, Feldman EC, editors: *Textbook of veterinary internal medicine*, ed 7, St Louis, 2010, Elsevier, pp 148-152.)

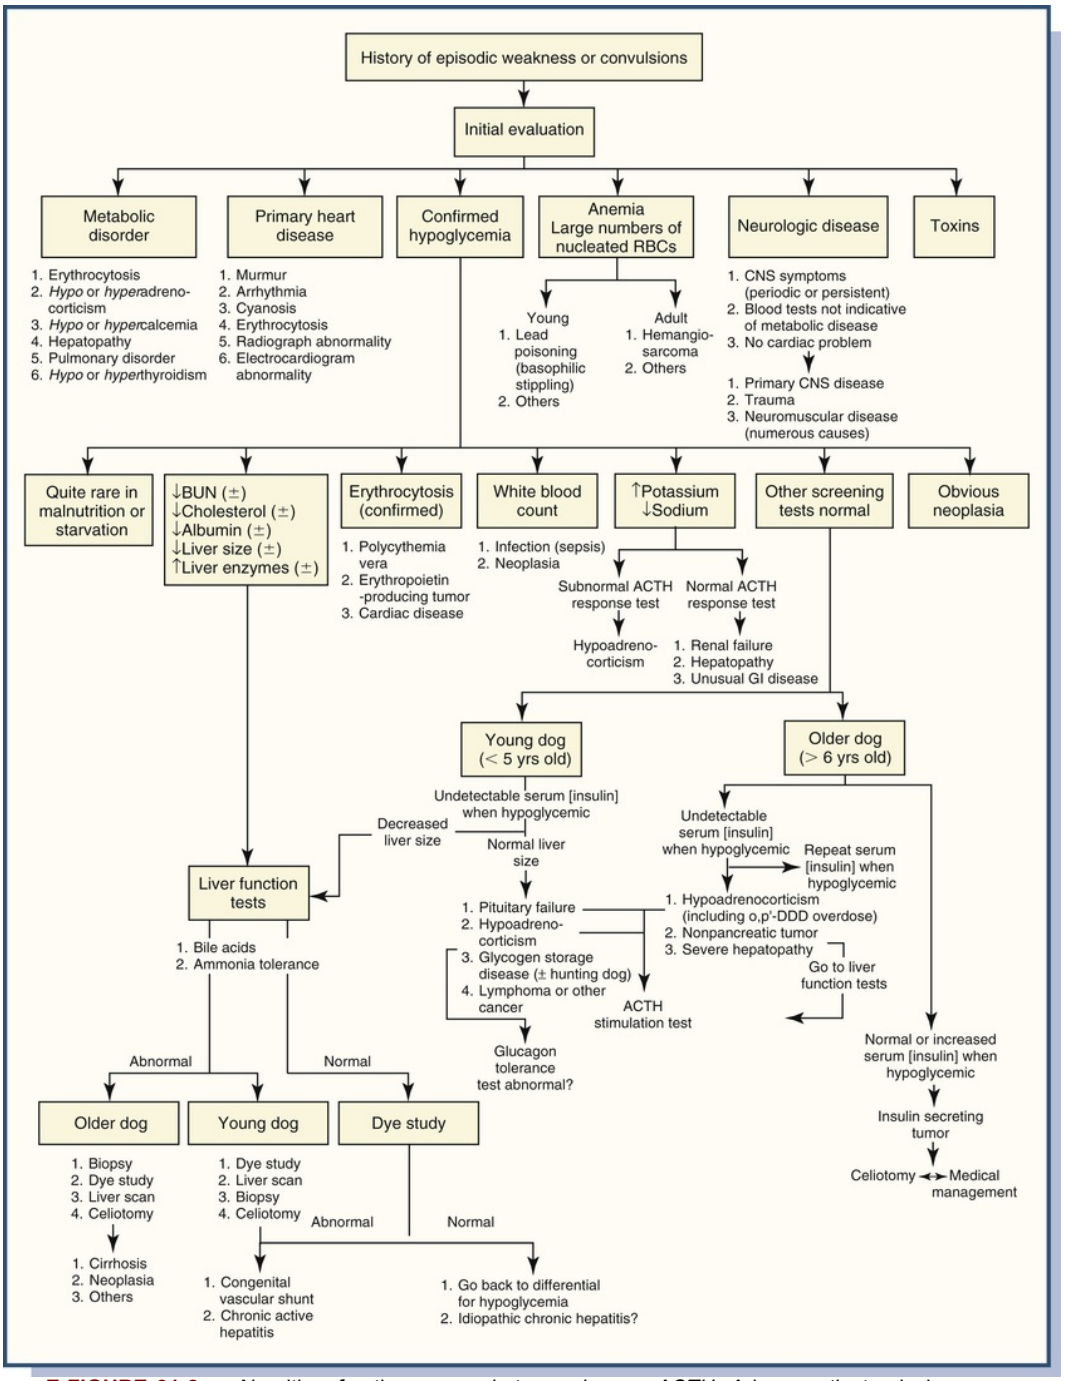
Various degrees of weakness may be difficult to appreciate or accurately quantify in veterinary patients. As a result, the patient presenting with a clinical sign of weakness poses a diagnostic challenge for many clinicians (Video 21-1). Signalment profiling, obtaining an exhaustive history, and performing a thorough physical examination may not result in a definitive diagnosis, but are important steps toward a diagnosis in patients presenting with weakness. Early use of basic diagnostics (blood pressure [BP], complete blood count [CBC], biochemistry) is also important in evaluating causes of weakness.

Evaluating the patient's signalment will aid in prioritizing the differential diagnosis list (E-Figure 21-2). Puppies and kittens are more likely to suffer from dietary indiscretion, toxin exposure, intestinal parasitism, congenital disease, hypoglycemia, or infectious diseases. Geriatric patients may be more likely to suffer from degenerative diseases of the cardiovascular, musculoskeletal, or neurological systems, in addition to endocrine disorders, or neoplastic conditions. In young to middle-aged female dogs, immune-mediated

diseases are more prevalent. Breed predilections for specific diseases must also be considered, some examples of which are arrhythmogenic right ventricular cardiomyopathy in Boxers, hypoadrenocorticism in Standard Poodles, and primary hyperparathyroidism in Keeshonds.



E-FIGURE 21-2 Algorithm for the approach to weakness. *ACTH,* Adrenocorticotropic hormone; *BUN,* blood urea nitrogen; *CBC,* complete blood count; *GI,* gastrointestinal.

Historical information about the pet will provide clues as to the cause of weakness. Questions regarding the time course, severity, associated triggers, concurrent medications, additional symptoms or illnesses, potential exposure to toxins, and travel history will further shorten the list of differentials. For example, a tachypneic and coughing dog with a loud murmur and recent and progressive onset of weakness or exercise intolerance may be in congestive heart failure.

The importance of a thorough physical examination (see ch. 2) cannot be overemphasized. It is the

foundation to all subsequent clinical steps and will determine the use of specific diagnostic tests. Auscultation of the heart and lungs for murmurs, arrhythmias, or abnormal lung sounds will assist in ruling in or out cardiovascular or respiratory disease as a cause for weakness. Pain on palpation and manipulation of joints and long bones may be secondary to underlying orthopedic diseases leading to weakness. A complete neurologic examination (see ch. 259) may reveal neurologic deficits and disorders responsible for weakness. Endocrine disorders may manifest with symmetrical alopecia, cachexia, peripheral neuropathies, or recurrent pyoderma.

Specific Mechanisms and Diseases

Metabolic Diseases

Metabolic disorders encompass a wide range of diseases and are among the most common causes of weakness. Metabolic diseases can cause weakness secondary to major organ failure or from electrolyte derangements, acid base disturbances, accumulation of metabolic wastes, excessive cytokine production, anemia of chronic disease, and nutritional imbalances. Failures of the hepatic or renal system are examples of metabolic diseases that lead to weakness from a multitude of mechanisms.

Electrolyte Disorders (see ch. 67, 68, and 69)

Derangements in electrolyte balances result from many diseases and are commonly the primary cause of weakness. Severe electrolyte disorders can cause muscle weakness and fatigue by affecting the central nervous system and at the cellular level by affecting myocyte membrane potentials. However, mild shifts in electrolyte balances typically do not cause weakness. Significant hypokalemia can occur secondary to many diseases including chronic kidney disease, unregulated diabetes mellitus, excessive diarrhea, endocrinopathies (hyperadrenocorticism), iatrogenic causes (diuretics), and internal shifts (metabolic alkalosis). Hyperkalemia is seen in anuric/oliguric renal failure, urethral obstructions, reperfusion injuries, and hypoadrenocorticism. Hyponatremia is seen in hypoadrenocorticism, diuretic use, gastrointestinal and urinary losses, congestive heart failure, and third spacing. Hypernatremia can be seen in free water loss (vomiting/diarrhea), salt poisoning, and hyperadrenocorticism. Hypocalcemia commonly causes restlessness and excitation, muscle tremors and fasciculations, and seizures. However, between episodes of tetany and seizures, dogs and cats are observed to be weak. Common causes of hypocalcemia include renal failure, primary hypoparathyroidism, eclampsia, and ethylene glycol intoxication. Hypercalcemia can be seen in neoplasia, particularly lymphoma, and also, primary hyperparathyroidism, renal failure, intoxications, and secondary to idiopathic causes (cats). Hypomagnesemia commonly occurs in critically ill pets and is usually secondary to excessive loss. Hypermagnesemia is less common but has been noted in endocrinopathies, renal failure, and iatrogenic causes.

Acid-Base Disorders

Dramatic shifts in acid-base balance can be the result of metabolic or respiratory diseases and result in weakness. Drugs and toxins can also cause acidosis or alkalosis. Most critically ill patients will have an acid-base imbalance (see ch. 128).

Inflammatory Conditions

Inflammatory conditions can be the result of infectious diseases, pancreatitis, neoplasia, hepatitis, burns, trauma, and immune-mediated conditions. Systemic inflammation causes the release of pro-inflammatory cytokines such as interleukin (IL)-1, IL-6, and interferon-alpha, which can directly cause fatigue via central pathways and lead to cachexia. Other mediators, such as tumor necrosis factor (TNF)-alpha and nitric oxide, can depress myocardial contractility and reduce vascular tone, causing systemic hypotension and subsequently weakness. Chronic excessive cytokine production inhibits erythropoiesis leading to anemia and weakness.

Infectious Diseases

Infectious diseases may produce weakness by releasing toxins that lead to a cascade of events resulting in cytokine production, systemic inflammation, acid-base derangements, metabolic disorders, anemia, and a

negative energy balance, all of which worsen the signs of weakness. Bacterial, viral, rickettsial, fungal, parasitic, or protozoal agents can infect organs and body systems, directly and indirectly causing weakness.

Immune-Mediated Diseases

Immune-mediated diseases can affect specific organs or multiple body systems, leading to joint and muscle pain, anemia, renal or hepatic dysfunction, systemic inflammation, or cachexia, all of which lead to weakness, fatigue, or exercise intolerance (see ch. 198 and 201-203). The sole presenting complaint for a dog with immune-mediated polyarthritis may be generalized weakness, which may also be secondary to pain-induced reluctance to move.

Anemia

Anemia is a common laboratory test abnormality in dogs and cats and can cause generalized weakness secondary to poor oxygen delivery to tissues (see ch. 57, 198, and 199). Extensive investigation into the underlying cause for anemia is typically warranted, as multiple organ systems can be involved. Patients with anemia can present with severe clinical signs from shock (peracute blood loss) to more subtle signs of lethargy and weakness (chronic anemia).

Endocrine Disorders

Weakness can be appreciated in most endocrine disorders, including hypoadrenocorticism, hyperadrenocorticism, hypothyroidism, diabetes mellitus, and hyperparathyroidism. Weakness is not a common component of hyperthyroidism. Some endocrine disorders result in electrolyte derangements leading to weakness. Other endocrine disorders may cause muscle wasting, affect blood pressure, or trigger cardiac arrhythmias, all of which may lead to persistent or transient weakness. Neuropathies and myopathies causing weakness may be seen in hyperadrenocorticism, hypothyroidism, diabetes mellitus, and hypoglycemia.

Cardiovascular Disease

A hallmark symptom of cardiovascular disease is exercise intolerance. However, it is typically more apparent in severe stages of heart disease. In a patient with mild cardiovascular disease and weakness, further investigation into the underlying cause may be necessary. Cardiovascular disease can cause weakness from poor cardiac output resulting in reduced oxygen delivery to tissues. The muscle wasting and weakness associated with cardiac cachexia is observed in end-stage disease. Arrhythmias may cause transient weakness. Bacterial endocarditis may cause severe lethargy due to the concurrent septicemia present. Pericardial effusion from various causes may cause sudden and dramatic weakness and collapse.

Blood Pressure

Abnormalities in blood pressure can directly and indirectly cause significant weakness (see ch. 99 and 157-159). Hypotension can directly cause weakness secondary to reduced oxygen delivery to tissues. Hypotension can result from cardiovascular disease (poor cardiac output), decreased preload (hypovolemia, impaired venous return), and decreased vascular tone. Hypertension can indirectly cause weakness by affecting multiple organ systems (kidneys, heart, etc.). Hypertension can result from multiple disease processes such as renal disease, diabetes mellitus, hyperadrenocorticism, hypothyroidism, hepatic disease, and cardiovascular disease.

Respiratory Diseases

Lethargy, fatigue, and exercise intolerance are commonly associated with respiratory diseases and can result from hypoxemia-induced reduction in work capacity of the muscles. Important causes of respiratory disorders include infectious and inflammatory causes; however, neoplasia, toxins, trauma, and hemorrhage can also cause pulmonary disease.

Neurologic Diseases

Brain

Brain diseases can lead to persistent or transient weakness. A more generalized weakness is seen with more severe brain diseases and transient weakness can be observed, for example, after seizure episodes. Causes of brain disease include infectious (viral, bacterial, fungal, rickettsial, or protozoal meningoencephalitis), inflammatory (granulomatous meningoencephalitis), neoplastic (meningioma), congenital/hereditary (hydrocephalus, Chiari-like malformations), metabolic (organic aciduria), and vascular diseases (infarction).

Spinal Cord Disease

Diseases affecting the spinal cord can cause varying degrees of paresis or paralysis that may be interpreted as generalized weakness. Vague generalized signs of weakness are typically appreciated in more chronic and progressive spinal cord diseases. Degenerative diseases, inflammatory conditions, neoplasia, trauma, infectious diseases, and vascular accidents can cause spinal cord problems.

Neuropathies

Diseases that affect peripheral nerves and their neuromuscular transmission are commonly associated with hypotonia, muscle atrophy, and paresis—all of which can manifest as weakness (see ch. 268 and 269). Causes of neuropathies include metabolic disorders (diabetes mellitus), neoplastic disorders (nerve sheath tumors), paraneoplastic causes (insulinomas), infectious disorders *(Toxoplasma gondii),* inflammatory disorders (polyradiculoneuritis), trauma, toxic disorders and drugs (organophosphates, vincristine), autonomic disorders (dysautonomia), and idiopathic causes. Myasthenia gravis may present with constant or episodic weakness after activity that improves with rest.

Myopathies

Disorders of skeletal muscles commonly cause exercise intolerance and generalized weakness (see ch. 354). Causes for weakness with myopathies include generalized or focal muscle atrophy, muscle swelling, myotonia, and pain. Myopathies may result from inflammatory, infectious, metabolic, congenital, immune-mediated, neoplastic, and paraneoplastic causes.

Neoplasia

Many forms of neoplasia are associated with generalized weakness or lethargy. Some cancers cause weakness secondary to cachexia, induced by an overexpression of inflammatory cytokines such as TNF-alpha, which leads to muscle wasting, anorexia, and a negative energy balance. Some tumors may also release specific growth factors and hormones such as parathyroid hormone, insulin or insulin-like growth factors, erythropoietin, estrogen, and steroids that cause or worsen the signs of weakness. Some malignancies can lead to paraneoplastic syndromes that cause peripheral neuropathies causing episodic or constant weakness, as seen in myasthenia gravis (see ch. 269 and 352).

Physical and Psychological Stress

Acute and chronic physical or psychological stress can influence the release of pro-inflammatory cytokines, such as TNF-alpha, IL-1, and IL-6, through activation of both the hypothalamic-pituitary-adrenal axis and sympathetic nervous system with the subsequent release of glucocorticoids and catecholamines. The imbalance of pro-inflammatory and anti-inflammatory cytokines can lead to generalized weakness. Psychological stress in animals is difficult to appreciate but should not be overlooked. Both acute and limited stressors (fireworks, thunderstorms, travel, boarding) and chronic stressors (illness, pain, shift in social status, chronic abuse) can result in vague signs of weakness (see ch. 9). Excessive physical activity or activity beyond the physical or endurance capabilities of an animal may lead to exercise intolerance.

Pain

Acute or chronic pain can result in lethargy, exercise intolerance or weakness. Acute joint, spinal, or bone pain may result in the unwillingness of the animal to move, which may be interpreted as lethargy or weakness. Chronic progressive pain as a form of stress will lead to hyperactivity of the hypothalamic-pituitary-adrenal axis, which can lead to generalized weakness (see ch. 356). Animals experiencing chronic pain may have vague signs of weakness, lethargy, decreased appetite, and depression.

Nutritional Derangements

Nutritional deficiencies may cause generalized weakness and can occur as a primary problem (inadequate diet) or secondary to a chronic disease (malabsorption, decreased intake). Imbalances in nutrition can result in a negative energy balance, reduction in muscle mass and strength, reduction in caloric intake, vitamin and mineral deficiencies, altered glucose homeostasis, dyslipoproteinemias, and electrolyte derangements, all of which cause or exacerbate the signs of weakness (see ch. 170 and 177). Chronic diseases that cause nutritional disorders include neoplasia, endocrinopathies (diabetes mellitus), inherited diseases, and hepatic, renal, gastrointestinal, and pancreatic diseases.

Drugs and Toxins

Many drugs and toxins can cause varying degrees of weakness. An exhaustive history will help provide information regarding possible exposure to toxins or drugs. Medications and toxins that can result in weakness include beta-blockers, anticonvulsants, diuretics, narcotics, antihistamines, antibiotics, chemotherapeutic agents, glucocorticoids, tranquilizers, ethylene glycol, macadamia nuts, xylitol, grape/raisin toxicosis, and marijuana ingestion.

CHAPTER 22

Restlessness

Michael D. Willard

Client Information Sheet: Restlessness

While recognized as an important behavioral problem, restlessness has not received much focused attention by veterinary internists. Hence, this concern has not been as carefully defined or thoroughly discussed in internal medicine circles as have many other "owner chief concerns." Therefore, many veterinarians either do not recognize restlessness when it occurs in a patient, ignore it because they are unsure what to do when it is mentioned, or some may automatically relegate restlessness as a behavior issue (see ch. 9). Restlessness, however, may represent a sign of major, even life-threatening, disease. Thus, not considering medical causes of restlessness may place a patient at unnecessary risk. Granted, it can sometimes be difficult to diagnose the cause of restlessness. However, when uncertain of cause, it may be more appropriate to tell an owner that you have no doubt that the behavior they describe is real, but it can be difficult (and sometimes costly) to ascertain the cause.

History

The first step is to recognize that the patient is restless, and here history is key in detecting and determining its significance. While some clients will use the term "restless," many use words like "agitated," "anxious," "nervous," "pacing," or "uncomfortable." Sometimes owners state that their pet has been recently and constantly "seeking attention." Others indicate that the restlessness is episodic. For example, some dogs with congestive heart failure are described as restless at night, a reflection of respiratory difficulty that an owner may or may not appreciate. Dogs and cats with pleural effusion or pulmonary edema may be restless due to respiratory distress, underscoring the need for careful auscultation and for imaging of the thorax. Dogs with pheochromocytoma have been described as having unpredictable episodes of restlessness. Restlessness in animals who have been placed in a new environment (e.g., caged in a veterinary or boarding facility) is not generally worth pursuing because this is simply recognized as a result of being placed in an unfamiliar environment. Restlessness is much more likely to have medical significance when the owner reports "restlessness" while their pet is in more familiar surroundings.

If the pet has other problems that are both prominent and have more clearly defined rule-outs (e.g., cranial nerve deficits, muscular weakness, vomiting, diarrhea, weight loss, localized pain, etc.), these issues should be the focus of the diagnostic work-up, assuming the patient's restlessness can be readily attributed to the cause of the more typical concerns (Figure 22-1). Placing less significance on this one sign in such cases is likely appropriate, efficient, and cost-effective since restlessness has such a wide range of causes. An example would be restlessness in a cat who is considered a candidate for hyperthyroidism, a problem that is usually easy to diagnose by history (e.g., weight loss despite a ravenous appetite), physical examination (e.g., palpable thyroid nodule), and/or a serum thyroxine measurement.

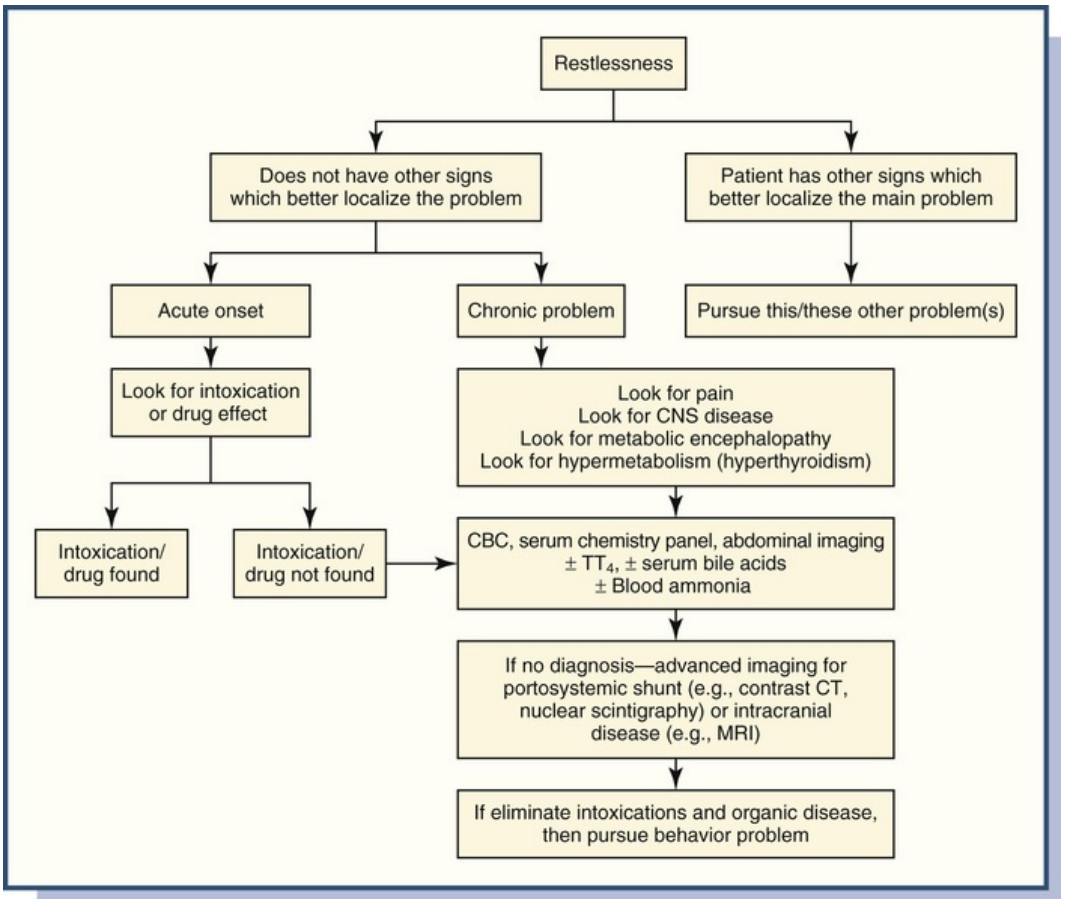


FIGURE 22-1 Suggested diagnostic approach to the problem of restlessness in the dog and cat. *CBC*, Complete blood count; *CNS*, central nervous system; *CT*, computed tomography; *MRI*, magnetic resonance imaging; *TT_4*, total thyroxine.

If restlessness cannot be explained by an obvious "other problem," or if it is the only major complaint with no localizing findings on history or physical examination, then one must attempt to further characterize the observation. Quantify the degree of restlessness (i.e., mild, moderate, severe), how abruptly the restlessness began, how consistent it is (e.g., <10% of the time [episodic?], about half the time, >90% of the time) and whether the restlessness is static, getting better, or becoming worse over time. Are the owners aware of any stimulus that consistently results in the sign?

Intoxications and Drugs

Selected causes of restlessness are listed in Box 22-1 and the general approach to this concern is provided in Figure 22-1. Some causes (e.g., shock, dyspnea) may be identified from the history and/or physical examination because evidence of an underlying illness could be obvious and localizing; these causes will not be discussed further. If no cause is apparent on history and physical examination, then the abruptness of onset is particularly important. If the patient very suddenly became clearly restless, intoxications or drug-induced disease abnormalities are of major consideration. Restlessness can occur before more serious signs of intoxication are noticed.

Box 22-1

Causes of Behavior That Can Be Interpreted as "Restlessness" in the Dog or Cat

Intoxication

Iatrogenic (Drugs)*

Antipsychotics
Tricyclic antidepressants
Selective serotonin reuptake inhibitors
Methylxanthines
Sympathomimetics
Prostaglandins
Opioids
Metoclopramide
Antihistamines (especially cats)
Digoxin
Salicylates
Benzodiazepines (excitatory phase)
Dysphoria (drug-induced)

Various Other Toxic Substances*

Metaldehyde
Pyrethrins
Strychnine
Nicotine
Organophosphates/carbamates
Recreational drugs (cocaine, amphetamine)
Select mycotoxins (especially tremorgens)
Latrodectus envenomation
Bufo toad toxicosis

Normal Behavior

Estrous cycle/mating
Periparturient
Pseudopregnancy
Discomfort
  Pollakiuria
  Tenesmus

Altered Mentation/Encephalopathy

Primary CNS Disease

Epileptic aura (pre-ictal)
Tumors
Inflammation
Rabies/pseudorabies
Canine cognitive dysfunction

Metabolic Encephalopathies

Hepatic encephalopathy
Hypoglycemia
Hypocalcemia

Increased Metabolic Rate

Hyperthyroidism (iatrogenic or spontaneous)

Physiologic Distress

Shock
Transfusion reaction
Anaphylactic reaction
Overhydration (iatrogenic)
Dyspnea
Pheochromocytoma
Overheating
Fever
Pruritus

Emotional Distress

Fear
Stress from altered environment or blindness
Pending natural calamity such as earthquake

Pathologic Behavior

Various causes, including various types of anxiety and projection of the owner's personality on the pet
Pain

CNS, Central nervous system.

*These lists are not meant to be comprehensive; rather, they are lists of some of the more common examples.

Intoxication can result after a patient ingests and/or absorbs a toxic substance such as recreational drugs (e.g., amphetamines,[1] cocaine[2]), metaldehyde,[3] chocolate, tremorgens (i.e., mycotoxins from *Penicillium* spp.), zinc phosphide, being envenomated (e.g., black widow spider bite[4]), etc. (see ch. 152-156). Diagnosing one of these exposures requires some suspicion from the history, physical examination, and, in some cases, appropriate toxicological analysis. Intoxication can also refer to an adverse drug effect (see ch. 169). The classic drug-induced cause of restlessness, in small animal practice, is dogs receiving excess thyroid medication. Pets with diabetes mellitus being treated with excess insulin may exhibit restlessness as a sign of hypoglycemia. Sympathomimetics (e.g., ephedrine, phenylpropanolamine, albuterol), metoclopramide[5] (especially if given as a rapid IV bolus), methylxanthines (e.g., theophylline [especially if given with enrofloxacin, which results in higher blood levels], theobromine, aminophylline, caffeine), atropine, lidocaine (when given IV), and prostaglandins are recognized by most veterinarians as being able to cause restlessness. Drug-induced restlessness can be surprising or unexpected because the most common adverse effect of many drugs is drowsiness or sedation (e.g., antipsychotic drugs, analgesic drugs). However, such agents can have paradoxical effects if they "disinhibit" behaviors. Antihistamines, cyproheptadine, benzodiazepines, buspirone, mirtazapine, haloperidol, phenothiazines (especially perphenazine), amantadine, phenobarbital, levetiracetam, and selegiline can produce such unanticipated behavior. Glucocorticoids are recognized for altering behavior in people and this class of drug can occasionally cause restlessness in dogs. If a drug effect is suspected, the drug should be withdrawn and the patient observed for several days. The reader is directed to ch. 151-156, ch. 169, and to textbooks on toxicology and pharmacology for more information on specific toxins and drugs.

The "serotonin syndrome," in particular, is a potentially fatal intoxication in which restlessness is a prominent finding. Tricyclic antidepressants (TCA) and selective serotonin reuptake inhibitors (SSRI) each can cause restlessness. If such drugs are combined with other medications that increase serotonin (e.g., monoamine oxidase inhibitors [MAOI], such as amitraz), restlessness can result.[6,7] Metoclopramide, s-adenosyl-L-methionine, 5-hydroxytryptophan (a nutritional supplement) and dextromethorphan should be used cautiously or better yet avoided in patients receiving a TCA or an SSRI. St. John's wort, which has been used extensively in complementary medicine, should not be used in conjunction with TCA or SSRI drugs. L-deprenyl, alone, is an MAOI that can cause restlessness.

Pain or Discomfort

Once intoxications and drugs are tentatively eliminated as a cause of restlessness, one should consider pain, discomfort, or encephalopathies as possible explanations. Pain can cause restlessness as an acute or gradual and subacute condition (see ch. 126 and 356). Detecting pain varies from being easy to quite difficult, depending upon cause, how stoic the patient is, and how adept the veterinarian is at physical examination (see ch. 2).[8] Diffuse abdominal pain and generalized muscular discomfort can both be especially difficult to localize. Be sure that the patient is not receiving analgesic or anti-inflammatory drugs that make it difficult to detect and localize pain. If the patient is receiving such drugs, they should be discontinued and the patient re-examined several hours or (in the case of anti-inflammatory drugs) days later. One may need to repeat the physical examination several times before deciding whether or not pain is present. The "feline hyperesthesia syndrome" has numerous causes and can be a diagnostic challenge.[9] A complete blood count (CBC) is indicated because inflammation can be responsible for pain. Readers are referred to ch. 126 and 356, and texts

on pain that deal with these problems in more detail.

Metabolic Encephalopathies

The restlessness associated with encephalopathies may be acute or insidious-and-chronic in onset. Metabolic encephalopathies (i.e., hepatic encephalopathy, hypoglycemia, hypocalcemia) may initially produce restlessness as the only discernable clinical sign to an owner. Hence, a serum biochemistry panel (with the blood preferably taken while the patient is displaying the restlessness) is important. As previously mentioned, hypoglycemia is common among diabetics receiving insulin. Restlessness due to hypoglycemia has been commonly described in patients with insulin-secreting tumors, hepatic failure, or hypoadrenocorticism. Measuring ionized calcium instead of total serum calcium may be advantageous. Abdominal imaging (radiographs ± ultrasound) is typically done at this time because such an evaluation will need to be obtained regardless of serum biochemistry findings. The incidental finding of an adrenal mass in a pet described as having episodic restlessness may be consistent with pheochromocytoma.

While hypoglycemia and hypocalcemia are relatively easy to detect, hepatic encephalopathy can sometimes be difficult to diagnose. Congenital portosystemic shunts (PSS), the major cause of hepatic encephalopathy in dogs and probably cats, can occasionally be a major diagnostic challenge (see ch. 284). Some dogs with congenital PSS may first show signs of encephalopathy when they are 7-12 years of age and have normal serum biochemistry profiles, urinalysis, fasting/post-prandial serum bile acids and resting blood ammonia concentrations. A substantial number of dogs with PSS have a normal-sized liver on abdominal imaging and the shunting vessel or vessels may not be identified even by highly experienced ultrasonographers. Therefore, it is sometimes worth re-measuring serum bile acid and blood ammonia concentrations in patients with undiagnosed restlessness. The ammonia tolerance test is thought by some to be more sensitive for congenital PSS than serum bile acids. Protein C determinations may reveal hepatic insufficiency in some patients who are otherwise not obviously hepatic insufficient. In select cases in which no reason for restlessness can be found after extensive testing, advanced imaging (e.g., contrast abdominal computed tomography [CT], nuclear scintigraphy) may be worth considering.

Primary Intracranial Conditions

Restlessness can be the only sign of primary central nervous system (CNS) disease (see ch. 258-268). Cranial nerve deficits, postural deficits, and seizure activity are absent in some animals afflicted with major CNS disease. Restlessness in these patients may have an acute onset or may develop and progress insidiously. In epileptic animals, restlessness can be a pre-ictal event or even the primary seizure event (see ch. 35 and 260). Advanced imaging with cranial magnetic resonance imaging (MRI) scans is preferred. However, contrast CT may be diagnostic. Cerebrospinal fluid (CSF) analysis may be necessary to aid in confirming a diagnosis in some of these patients. Because of cost, MRI and CSF analysis are often among the last diagnostic tests performed and are done when everything else has seemingly been eliminated.

Need for Behaviorist?

Intoxications, pain/discomfort and altered mentation/encephalopathy are particularly important because they may be caused by diseases that can progress rapidly and cause serious injury or death. Only after these have been considered and tentatively or definitively eliminated should restlessness be attributed to behavior and a behaviorist consulted.

CHAPTER 23

Anorexia

Marnin A. Forman

Client Information Sheet: Loss of Appetite

Anorexia is a common owner concern encountered by veterinarians in small animal practice. Anorexia may be associated with numerous conditions or disease processes. This clinical sign can be both a diagnostic and therapeutic challenge (Figure 23-1), as well as a source of frustration for many owners.

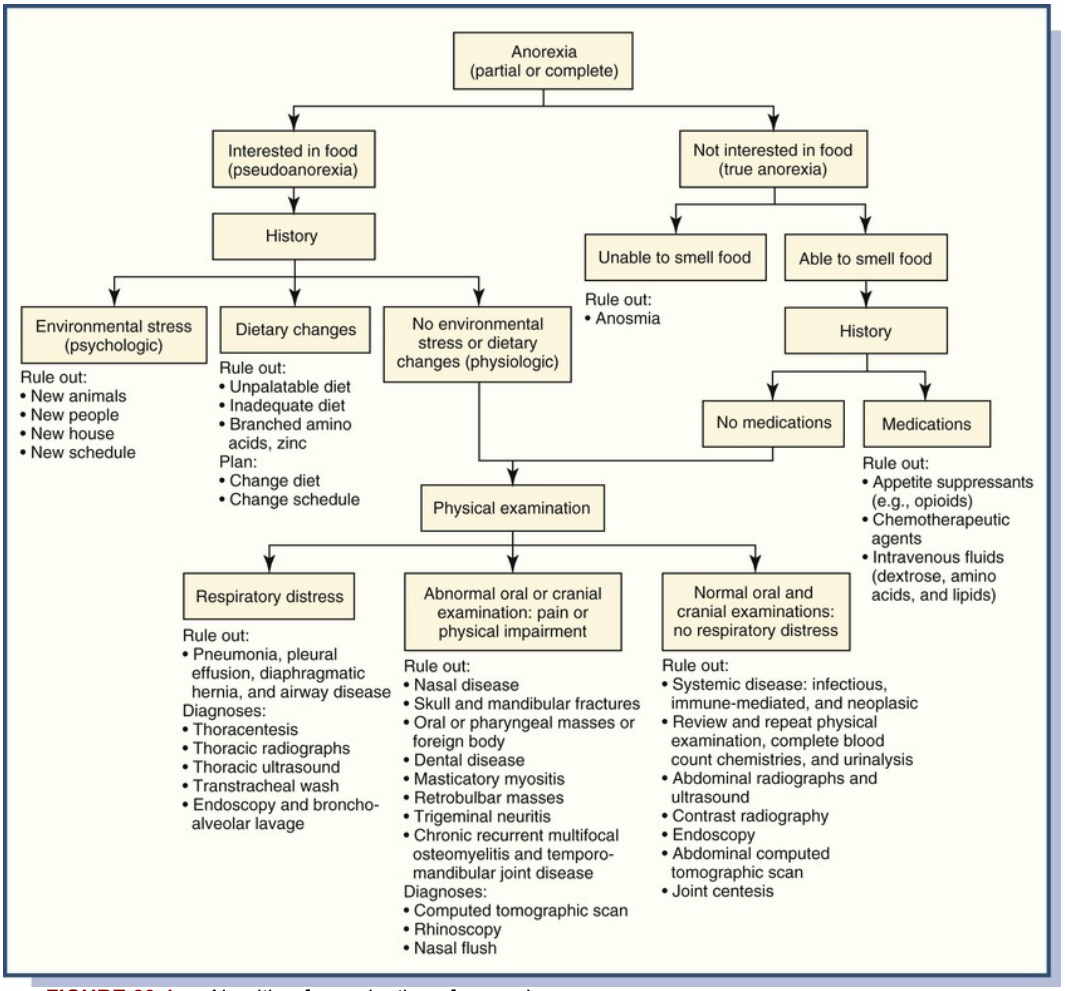

FIGURE 23-1 Algorithm for evaluation of anorexia.

Definitions and Consequences

Anorexia is defined as a lack or loss of appetite for food. The term *hyporexia* has been introduced and may be

a more accurate term to describe a reduction, rather than a complete loss, of appetite.[1] Complicating our understanding of this clinical sign, some disease processes that classically have been described as causing anorexia more accurately produce an inability to eat, rather than a lack of appetite for food. Examples include (there is a myriad of possibilities): (1) severe dental disease; (2) a foreign body in the mouth or pharyngeal area; and (3) an inability to open the mouth due to advanced masticatory myositis.

Considering the challenges in determining and communicating hyporexia vs. anorexia, client-based questionnaires have been evaluated. These questionnaires were evaluated in dogs and cats treated with chemotherapy and focused on two parameters: presence/absence of a normal appetite and the duration of a decreased appetite (1-2 days, 3-5 days, >6 days).[2] It is important to determine the duration of anorexia in an effort to prevent secondary complications. Carbohydrate reserves, such as glycogen, may be exhausted in 3-5 days, resulting in altered metabolism to generate glucose, primarily from fat and some protein, through gluconeogenesis.[1]

Complications of prolonged inadequate nutritional intake are numerous and, for certain disease processes (e.g., feline hepatic lipidosis), can be more serious than the underlying disorder (see ch. 177). Examples of these complications include immune system suppression (decreases in cell-mediated immunity, immunoglobulin synthesis, complement production, and phagocytic activity) and secondary organ dysfunction (decreased hepatic detoxification ability and intestinal alterations).

Causes

Since the causes of anorexia are multiple, an organized diagnostic approach is needed to determine quickly and accurately the causative disorder (Figures 23-1 and 23-2). Obtaining a complete medical, dietary, and environmental history is a critically important first step. Many medications produce anorexia, including antibiotics, antifungals, nonsteroidal anti-inflammatory drugs, narcotic analgesics, chemotherapeutic agents, cardiac glycosides, and diuretics. Identification of nausea, vomiting, labored breathing, or painful behaviors is important. Alterations in diet can lead to, but also can be helpful in treating, anorexia. These may include modifications in flavoring, moisture content, nutrient composition, or feeding location (including physical barriers to eating). Stressful environmental changes, including introduction of new pets and movement to a new household, may cause anorexia.[3]

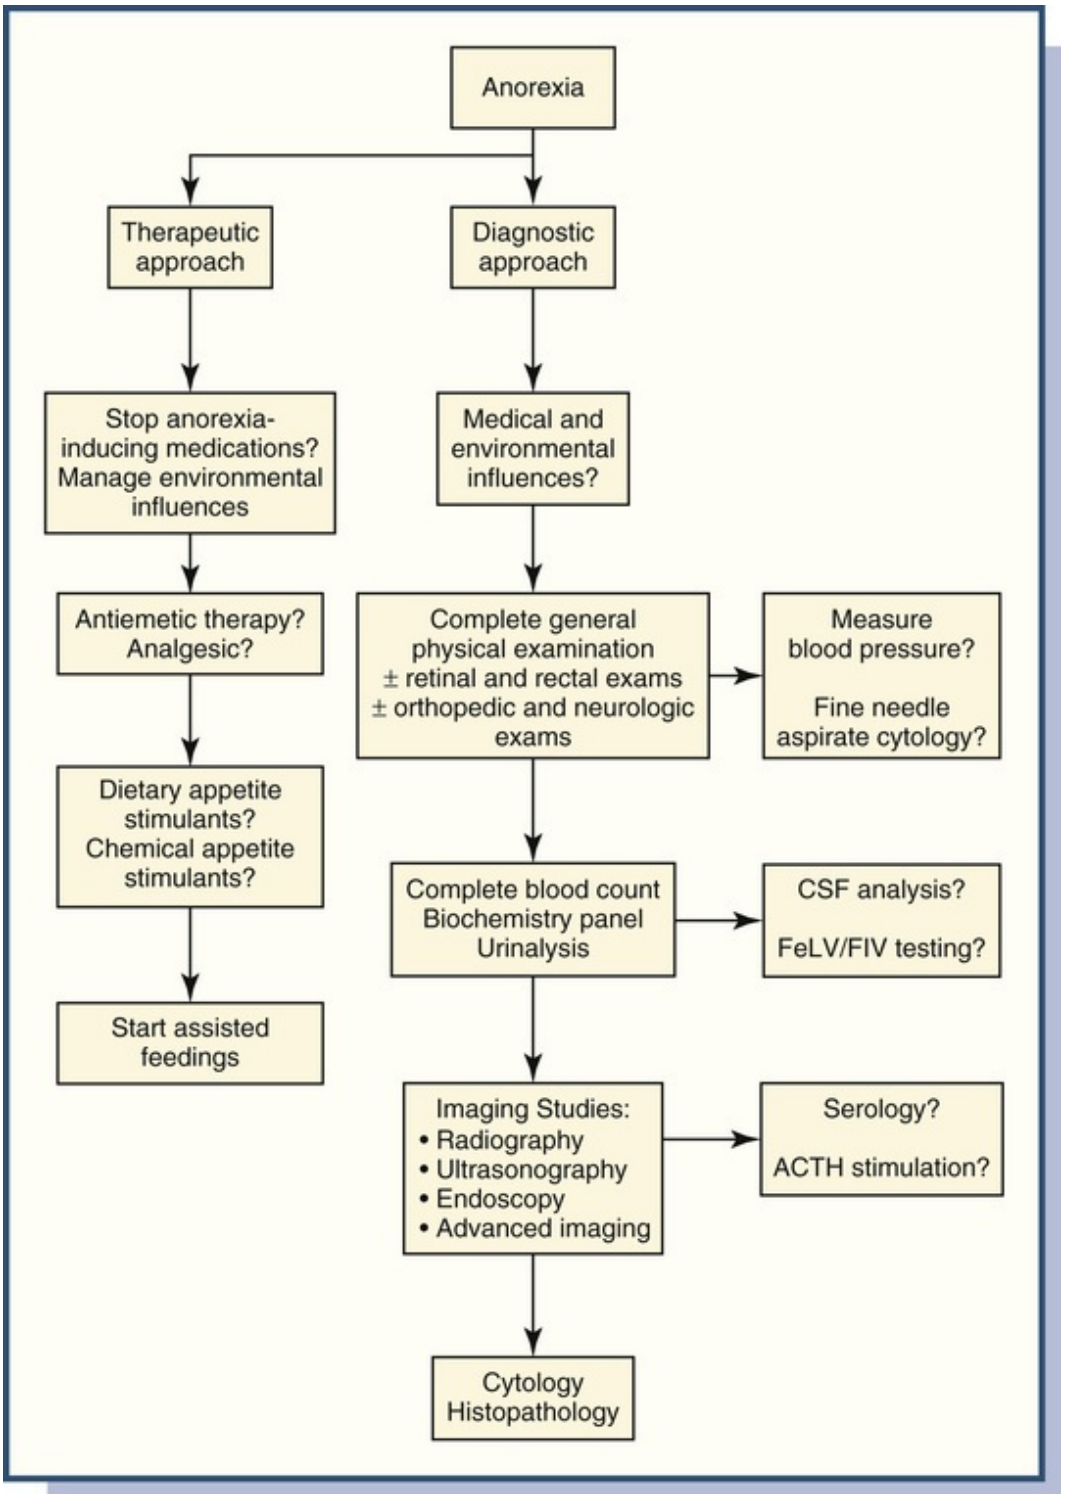

FIGURE 23-2 Therapeutic and diagnostic approach for feline and canine anorexia. *ACTH,* Adrenocorticotropic hormone; *CSF,* cerebrospinal fluid; *FeLV,* feline leukemia virus; *FIV,* feline immunodeficiency virus.

The next step in determining the cause of anorexia is a complete general physical examination, including thorough oral, thoracic, abdominal, rectal, and retinal examinations. In dogs and cats suspected of having anorexia secondary to chronic pain, an orthopedic and neurologic examination should be performed (see ch. 126, 259, 353, and 356). Following these examinations, and in addition to a minimum database (complete blood count [CBC], biochemistry panel, and urinalysis), certain cases require imaging studies (radiography or ultrasonography) or serology. Many causes of anorexia will be identified with these initial evaluations. Additional testing, such as cytology/histopathology, will occasionally be required. It should be understood

that the purpose of the complete history and physical examination is to identify causes of anorexia that would not be obvious from blood, urine, fecal, or imaging examinations. The dog or cat with heart, liver, kidney, or any other major organ dysfunction could develop anorexia acutely or it could progress over a period of time. Unfortunately, a dog or cat with an oral foreign body will likely have similar clinical problems.

Treatment

Therapy of the anorectic dog or cat should always be directed at understanding and treating the underlying cause. These measures may include modification of anorexia-inducing medications or environmental stressors, instituting definitive therapy (e.g., removal of an abscessed tooth), or appropriate utilization of anti-inflammatory, antiemetic or analgesic medications. During the diagnostic workup of an anorexic patient and prior to determination of the causative disorder, chemical and dietary appetite stimulants can be tried. Such stimulants provide only short-term benefit, if any. However, appetite stimulants are useful during the diagnostic workup or prior to implantation of an assisted feeding device, if one becomes necessary (E-Figures 23-3 and 23-4).

E-FIGURE 23-3 Example of prolonged inadequate nutritional intake resulting in marked vitamin deficiencies.

E-FIGURE 23-4 **A,** Example of nasogastric feeding tube. **B,** Example of esophageal feeding tube. **C,** Example of a percutaneous endoscopically placed gastric feeding tube (PEG). **D,** Example of a low-profile (MicKey Low-Profile Gastrostomy Feeding Tube) gastric feeding tube.

Numerous chemical appetite stimulants have been utilized including benzodiazepines (e.g., diazepam [Valium]), cyproheptadine (Periactin), low-dose propofol (Diprivan), mirtazapine (Remeron), and maropitant citrate (Cerenia). Compared to placebo, mirtazapine administration results in an increase in appetite and body weight in cats with chronic kidney disease.[4] Preliminary research suggests maropitant citrate does not significantly improve appetite or result in weight gain in cats with IRIS stage II and III chronic kidney disease.[5] In the author's practice, the most commonly used appetite stimulant is mirtazapine (feline: 1.875 to 3.75 mg total dose PO daily; canine: 3.75 to 30 mg PO daily).[6,7] Adverse side-effects have been detected at the 3.75 mg dosage in cats, including vocalization, agitation, vomiting, ataxia, and restlessness.[8]

Dietary appetite stimulation broadly involves modification of the environment or the type of food offered. Prior to discussing dietary modifications, it is important to consider learned food aversions. This condition involves the association of food with an adverse event (e.g., vomiting) and can lead to avoidance of potentially beneficial diets in the future. Warming, feeding multiple small meals, and the addition of non-nutritive flavors may help prevent the development of learned food aversions to a new diet. Offering a new diet(s) should be avoided in nauseated pets until the nausea is resolved.

A guideline on when to initiate assisted feeding has not been established and often is dependent on patient factors. It is generally indicated when nutritional intake is less than resting energy requirements (RER) = 70 × (body $\text{weight}_{kg}^{0.75}$) for 3 to 5 days. Even with identification of a causative disease process, assisted feeding can be needed during the recovery process for patient support (see ch. 82 and 170, and see E-Figure 23-4).

CHAPTER 24

Polyphagia

Sylvie Daminet

Client Information Sheet: Polyphagia (Increased Appetite)

Polyphagia refers to excessive food consumption and can be classified as physiologic (i.e., increased appetite secondary to expected increased caloric use, such as occurs with lactation or a canine performance athlete [see ch. 171 and 173]), pathologic (i.e., secondary to disease) or drug-induced (e.g., glucocorticoid administration). Polyphagia is almost never the sole clinical sign of a disease. Knowing whether weight gain or weight loss has been observed during the period that the pet has been polyphagic should help in determining cause and in developing a diagnostic plan (see also ch. 16 and 19).

Physiology and Pathophysiology

Food intake is controlled by a variety of factors, including gastrointestinal, environmental, and central nervous system (CNS) phenomena. Within the CNS, key circuits regulating energy homeostasis and food intake originate in the hypothalamus and brainstem. The lateral hypothalamic nuclei represent the "feeding center"; their stimulation causes an animal to eat and their destruction usually results in severe, fatal anorexia. Conversely, the ventromedial hypothalamic nuclei are the "satiety center," as their stimulation causes a refusal to eat even highly appetizing food. Ablation of these cells usually leads to polyphagia and obesity. The feeding center is constantly active unless inhibited by the satiety center (e.g., postprandially). The brainstem serves a secondary coordinating role and the nucleus of the solitary tract and area postrema have minor roles.

In the brain, melanocortin peptides, such as alpha-melanocyte-stimulating hormone (alpha-MSH), and the melanocortin-4 receptor (MC4-R), for which alpha-MSH is the agonist, are extremely important in food intake. Neurons that express pro-opiomelanocortin or coexpress agouti-related protein and neuropeptide Y are also vital to food intake.

Gastrointestinal factors affecting consumption of food include degree of gastric distention, rate of gastric emptying, release of gastric hormones, and absorption of nutrients (fatty acids, glucose, and amino acids) (see ch. 170). Gut hormones may act locally on the gastrointestinal tract and on the CNS. Secretion of insulin, glucagon, cholecystokinin, PYY (a peptide related to neuropeptide Y), and pancreatic peptide causes a decrease in CNS-derived hunger signals. Leptin, a polypeptide released from adipose tissue, may also contribute to a sense of satiety. Ghrelin, a peptide secreted primarily by the stomach, stimulates eating. Serum ghrelin concentrations progressively decrease as a meal is consumed and then progressively increase prior to the next meal. Decreased serum concentrations of glucose, amino acids, or lipid metabolites may cause hunger by stimulating neural centers. Pathologic conditions that affect the CNS can increase hunger despite normal energy stores (primary polyphagia; Box 24-1).

Box 24-1

Differential Diagnosis of Primary Polyphagia

Destruction of satiety center
- Trauma
- Mass lesion (e.g., neoplasia)
- Infection/inflammation

Psychogenic

Stress
Introduction of a more palatable diet

Secondary polyphagia exists when hunger is stimulated by non-neural factors and can be caused by an increased metabolic rate, decreased nutrient supply or certain drugs (Box 24-2). An augmented metabolic rate can be physiologic (e.g., pregnancy) or pathologic (e.g., hyperthyroidism). An inability of cellular response to insulin or an absolute insulin deficiency (diabetes mellitus) results in an inability for cells to utilize glucose. Increasing hunger is the result of an inability for cells to "capture and absorb" this "hidden" sugar. The satiety center is insulin-dependent. In lay terms, the body believes it is dying of hunger despite the blood carrying excessive quantities. Certain diseases (e.g., hyperadrenocorticism and liver disease) lead to polyphagia by unknown mechanisms. Polyphagia can also be caused by certain drugs.

Box 24-2

Differential Diagnosis of Secondary Polyphagia

Physiologically Increased Metabolic Rate
- Cold temperature
- Lactation
- Pregnancy
- Growth
- Increased exercise

Pathologically Increased Metabolic Rate
- Hyperthyroidism
- Infection/neoplasia in early stage

Decreased Energy Supply
- Diabetes mellitus
- Malassimilation syndromes
  - Exocrine pancreatic insufficiency
  - Infiltrative bowel disease
  - Parasites
  - Lymphangiectasia

Decreased Intake
- Megaesophagus (congenital)
- Low-calorie diet
- Hypoglycemia

Unknown
- Hyperadrenocorticism
- Portosystemic shunt/hepatoencephalopathy
- Sudden acquired retinal degeneration syndrome (SARDS)

History

When seeing a pet for polyphagia, one of the clinician's objectives is to assess the possibilities of an owner overfeeding or simple gluttonous behavior. While seemingly straightforward, it is not always obvious. In this context, open questions such as "have you noticed a change in food consumption" will avoid leading the owner. Second, the clinician should establish if a change in body weight has occurred, as this has a major impact on differential diagnosis (Figure 24-1).

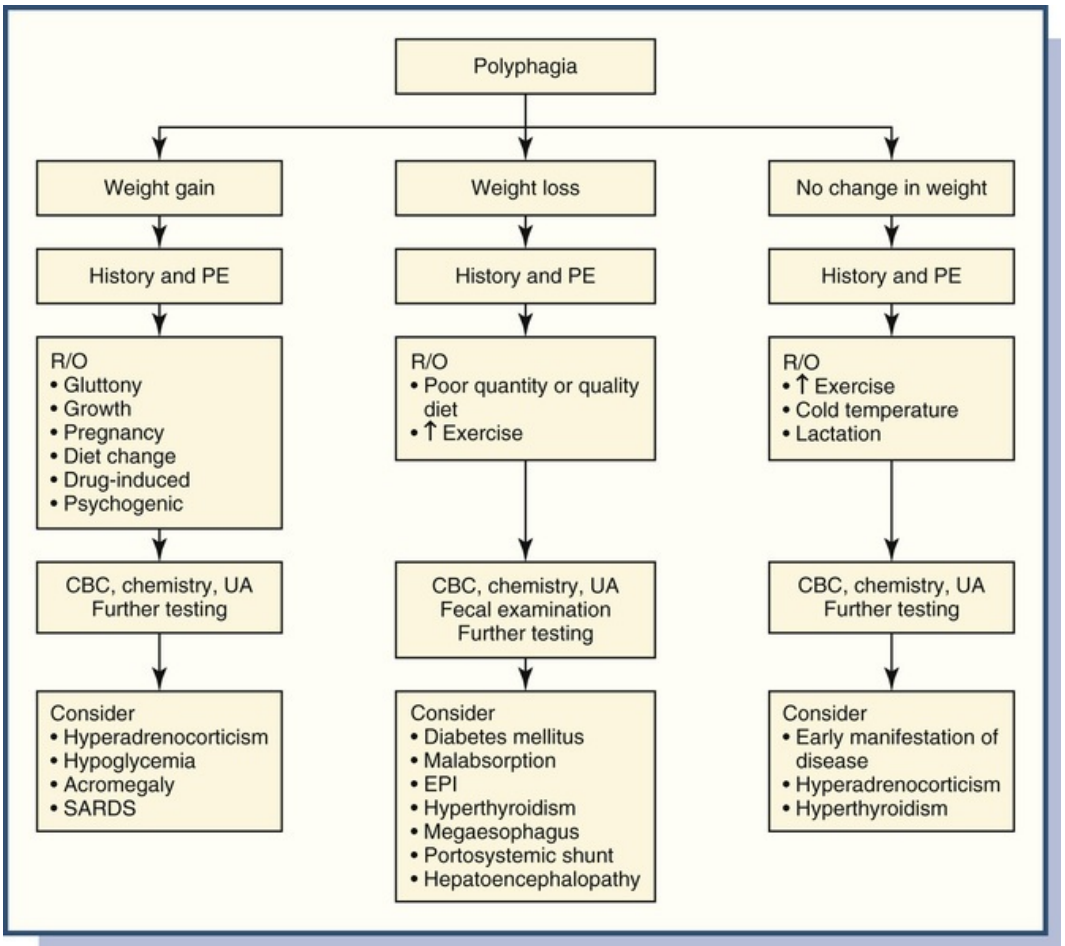

FIGURE 24-1 Algorithm for diagnostic approach to polyphagia. *CBC,* Complete blood count; *EPI,* exocrine pancreatic insufficiency; *PE,* physical examination; *R/O,* rule out; *SARDS,* sudden acquired retinal degeneration syndrome; *UA,* urinalysis.

Primary or drug-induced polyphagia typically results in weight gain. In this scenario, hunger is inappropriately increased and continues each meal despite the pet having consumed an adequate amount of nutrients. Pathologic secondary polyphagia is more commonly associated with weight loss, because the nutrient supply usually does not meet physiologic demands. However, some conditions, such as acromegaly, hypoglycemia caused by an insulinoma, sudden acquired retinal degeneration syndrome (SARDS), and hyperadrenocorticism (HAC), may lead to weight gain. Physiologic polyphagia can result in weight gain (e.g., pregnancy, growth) or weight loss (e.g., lactation, cold environment, increased exercise). Stable weight may be present in the early stages of any of these conditions.

Certain causes of polyphagia may be diagnosed on the basis of the history. Feeding a low-calorie diet, exposure to a cold environment, increased exercise and, for intact females, pregnancy and/or lactation should be ascertained. Polyphagia is commonly associated with phenobarbital or glucocorticoid therapy. Polyphagia has also been observed with other medications (Box 24-3). Psychogenic polyphagia has been noted after introduction of a more palatable diet. Similarly, increased appetite may be a response to a stress, such as introduction of a new pet or child into the household.

Box 24-3

Differential Diagnosis: Drug-Induced Polyphagia

Glucocorticoids
Phenobarbital
Antihistamines
Progestins
Benzodiazepines

Cyproheptadine
Mirtazapine

An animal with primary polyphagia caused by destruction of the satiety center may have a history of trauma or of clinical signs associated with CNS disease (see ch. 259). Depending on the extent of a hypothalamic lesion, upper motor neuron signs may be seen in all four limbs or unilaterally. A midbrain lesion often leads to incessant pacing, circling, and blindness; polyuria/polydipsia (PU/PD) may also be present. Disorders caused by diffuse or multifocal CNS disease may cause other neurological clinical signs.

Historical findings associated with secondary polyphagia can be highly varied. Animals with diabetes mellitus, acromegaly, SARDS, and hyperthyroidism usually have PU/PD. People and cats with HAC do not typically exhibit polyphagia or PU/PD, while these signs are extremely common in dogs with HAC (see ch. 306 and 307). Feline acromegaly is mainly seen in middle-aged to older males, and naturally occurring canine acromegaly is seen almost exclusively in intact bitches under the influence of progesterone (diestrus) (see ch. 294 and 295). In dogs of either sex, progestin administration can lead to acromegaly. Owners of acromegalic pets may note inspiratory stridor or a change in body conformation, such as increased interdental spaces, skin folds, or head size (see ch. 294 and 295). It should also be noted that progestin administration to dogs and cats can increase appetite without causing acromegaly. A multitude of historical details associated with HAC may include abdominal enlargement, persistent panting, failure to regrow hair after clipping, lethargy, and muscle weakness. Animals with SARDS typically have sudden-onset blindness, but PU/PD and polyphagia may precede the blindness. Hyperthyroidism commonly leads to increased activity (rarely depression and lethargy) and gastrointestinal signs (e.g., vomiting and diarrhea) (see ch. 301 and 302).

Hypoglycemia has a number of etiologies. Insulinoma is the most likely to lead to polyphagia, but a few other neoplasms and insulin overdose in any diabetic may also be associated with an increased appetite (see ch. 61 and 303). Dogs and cats with hypoglycemia may exhibit weakness, trembling, ataxia, disorientation and, possibly, grand mal seizures. Malassimilation can be due to a variety of problems, e.g., parasites, exocrine pancreatic insufficiency (EPI), infiltrative bowel disease, and lymphangiectasia (see ch. 276). Each of these conditions may cause large-volume, malodorous, soft stools. EPI is most commonly diagnosed in German Shepherd Dogs <2 years of age (see ch. 292). In older dogs and cats, EPI is rare. When seen, EPI is most commonly associated with chronic pancreatitis. “Infiltrative disease” encompasses processes such as inflammatory, infectious, or neoplastic bowel conditions. Historical details vary according to the underlying disease.

Animals with congenital megaesophagus are often polyphagic, re-eating their regurgitated food (see ch. 273). Although anorexia is more common in animals with a portosystemic shunt (PSS), polyphagia has been reported in as many as 10% of afflicted pets (see ch. 284). Obtundation, vomiting, weight loss, PU/PD, and neurologic signs may also be observed. Polyphagia has been reported rarely with hepatoencephalopathy. With hepatic failure not due to a PSS, icterus is often noticed.

Physical Examination

Physical examination findings in polyphagic animals vary and depend on the underlying condition. With primary polyphagia, neurologic abnormalities such as ataxia and proprioceptive deficits may be present. Complete neurologic and fundic examinations should be performed (see ch. 11 and 259). With acute causes of central blindness, however, the fundus may appear normal.

If unclear from the history, pregnancy may be diagnosed by abdominal palpation and lactation by inspection of the mammary glands. Approximately 80% of cats with hyperthyroidism have a palpable thyroid nodule, and approximately 50% have tachycardia or a gallop rhythm. Hyperthyroidism is much less common in dogs, and they usually have a large palpable cervical mass. Hyperadrenocorticism can have a variety of physical examination findings, including abdominal and hepatic enlargement, muscle wasting, bilaterally symmetric alopecia, cutaneous hyperpigmentation, areas of poor hair regrowth, or calcinosis cutis (see ch. 306). Although animals with HAC may not have weight change, abdominal enlargement may create the impression of weight gain. Physical changes associated with acromegaly include a prominent head, prognathia inferior, stridor, heart murmur and degenerative polyarthropathy. Some acromegalic cats have a normal appearance. In this scenario, assessing photographs of the cat from several years earlier may demonstrate facial changes not otherwise appreciated.

Physical examination in a dog with SARDS may be unremarkable because in the early stages of the disease, the retinas appear normal on examination. Dogs or cats with EPI, insulinoma, megaesophagus, hepatoencephalopathy, or a PSS may have no abnormal physical findings other than changes in weight. In

rare cases, polyneuropathies (especially of the rear legs) are associated with insulinoma. Aspiration pneumonia and chronic cough may accompany megaesophagus. Neurologic abnormalities may be detected in an animal with a PSS, while ascites is uncommon. Neurologic findings associated with hepatoencephalopathy are usually episodic and other examination findings vary with the cause of liver disease. Depending on the cause of malassimilation, the intestines may feel thickened. Lymphangiectasia may lead to ascites.

Other historical and clinical signs are dependent on the cause.

Diagnostic Plan

The first step in diagnosis is to ascertain if there has been a change in body weight (see Figure 24-1). After as many differential diagnoses as possible have been ruled out on the basis of the history and physical examination, further testing may be warranted: complete blood count (CBC), serum biochemistry profile, and urinalysis.

To diagnose primary polyphagia, a complete neurologic examination should be performed and any abnormalities localized (see ch. 259). A cerebrospinal fluid analysis or diagnostic imaging such as computed tomography (CT), or magnetic resonance imaging (MRI) scan, may be necessary. Insulinoma usually can be confirmed by paired blood glucose and insulin serum concentrations when the animal is hypoglycemic (see ch. 303). The diagnosis of SARDS can be made on the basis of appropriate history, physical examination findings, a CBC, biochemistry and urinalysis that rules out other causes, and, if necessary, an electroretinogram (ERG). For dogs or cats suspected of HAC, adrenal testing should aid in confirming or refuting a diagnosis (see ch. 306 and 307). Diagnosis of acromegaly can be difficult because of the lack of a commercial assay for growth hormone, but measurement of insulin-like growth factor-I (IGF-I) may be helpful (see ch. 294 and 295). The history, together with conformational changes if present, can provide evidence of the underlying disease. Most acromegalic cats have insulin-resistant diabetes mellitus, and imaging of the pituitary may reveal the growth hormone–secreting tumor.

Table 24-1 lists common causes of pathologic polyphagia in cats and dogs, including accompanying PU/PD, diarrhea and weight changes. Polyphagia, PU/PD, and weight loss are classic clinical signs for diabetes mellitus and any animal with these clinical signs should have urine and blood assessed for glucose concentrations. Diabetic dogs and cats have glycosuria and persistent hyperglycemia. Another cause of polyphagia, PU/PD, and weight loss is hyperthyroidism, a common condition in older cats but uncommon in dogs. Hyperthyroidism can usually be diagnosed with a single serum thyroxine measurement (see ch. 301 and 302).

TABLE 24-1

Common Causes of Pathologic Polyphagia in Cats and Dogs Including Accompanying PU/PD, Diarrhea and Weight Changes

DISEASE	SPECIES	EXPECTED ACCOMPANYING SIGNS
Diabetes mellitus	cats and dogs	PU/PD, weight loss
Hyperadrenocorticism	dogs > cats	PU/PD, weight gain possible
Hyperthyroidism	cats > dogs	PU/PD, weight loss
Acromegaly	cats > dogs	PU/PD, weight gain
Malabsorption syndromes	cats and dogs	Diarrhea, weight loss
Exocrine pancreatic insufficiency	dogs > cats	Diarrhea, weight loss
Insulinoma	dogs > cats (rare in cats)	Weight gain

PU/PD, Polyuria/polydipsia.

"Malassimilation syndromes" cover a myriad of differential diagnoses (see Box 24-2). Weight loss associated with polyphagia can be caused by intestinal parasitism. If parasites are suspected, fecal examinations and/or therapy with anthelmintics are recommended. If deworming does not resolve the problem, further investigation is needed. Protein-losing enteropathies can be associated with hypoalbuminemia and hypoglobulinemia. Depending on the suspected cause, measurement of serum for

folate, cobalamin or fecal alpha-1 protease inhibitor concentrations may be diagnostic. Abdominal radiography, ultrasonography, and/or biopsy either by endoscopy or exploratory surgery may also be considerations. For verification of EPI, fasted serum trypsin–like immunoreactivity (TLI) should be determined (see ch. 292).

Megaesophagus can be diagnosed with thoracic radiographs. Further testing is necessary to determine cause. Measurement of preprandial and postprandial serum bile acid concentrations can document hepatic dysfunction, but a biopsy may be required to identify the cause. Ultrasonography, CT or a radionuclide scan may be used to visualize a PSS.

If a disease is in the early stages, weight change may not yet have occurred and the list of differentials is more difficult to narrow down. However, a thorough history and physical examination combined with routine CBC, serum biochemistry, urinalysis and fecal parasitology can lead to a direct diagnosis in many conditions.

Management

The management of polyphagia depends on the cause. Physiologic causes of polyphagia are transient. If the condition is drug-induced, polyphagia may be temporary, as is usually seen with anticonvulsants. Psychogenic polyphagia may be corrected by removing the instigating element, if possible, and/or by behavioral therapy.

With pathologic polyphagia, treatment of the underlying disease will resolve the polyphagia in most cases. In some pets, weight management might be necessary, especially if the underlying disease leading to weight gain cannot be effectively treated or if the polyphagia is drug-induced. Small meals and use of low-calorie, high-protein and high-fiber foods can aid in obtaining satiety and prevent obesity. In cases of SARDS, polyphagia usually is self-limiting.

CHAPTER 25

Body Odors

Darren Berger

Client Information Sheet: Common Causes of Body Odor in Dogs and Cats

A classic definition of odor is a perceived sense through olfaction, which is stimulated via volatile chemical compounds and may be interpreted as pleasant or unpleasant. However, many people fail to take into consideration that the situation, a person's culture, and his or her experiences are important factors that determine individual perception of an odor.[1] Besides these contextual references, inter-individual variations in odor sensitivity or thresholds exist. These inter-individual variations have long been observed by olfactory researchers and are influenced by age, sex, personality, cognitive function, and health status.[2-4] These differences in odor threshold, sensitivity and perception are important to comprehend, as clinicians may not be able to detect the malodor that a client is describing or vice versa even when a medical condition is present. A relevant clinical example exists in patients with diabetic ketoacidosis, where only a percentage of people can detect the presence of ketones through olfaction, and those that do may describe the odor differently as either fruity or like nail polish remover. As a result of these differences in perception, many terms are used for describing odors, such as aroma, fragrance, scent, stink, stench, reek, malodor, or essence. Understanding these terms and their connotations can be useful to clinicians in picking up subtle clues from clients regarding possible concerns and in appropriately conveying messages to owners in a delicate or forthright manner.

Addressing the Body Odor Issue

Many factors contribute to the overall odor of an animal. It is important to be aware of the factors that can contribute to the complaint of a malodorous pet so that the clinician can determine if it is the result of a (1) normal pet, (2) a healthy pet with an obvious non-medical cause, or (3) the result of a pet with an underlying disease. Regardless, it is the clinician's duty to either correct the underlying disease process or make the pet's odor more acceptable to the owner. The first step in addressing a patient with a primary complaint of malodor is to obtain a thorough history. Most owners are familiar with the normal odors of their animal. This awareness of the scent of their pets was highlighted by a recent investigation that demonstrated that 89% of participants were able to distinguish their dog's odor from that of another dog.[5] Given this evidence, and clinical experience, many owners are aware of changes in the normal odor associated with their pets, when it occurred, and events that may have been associated with the change. This information is very helpful in differentiating between the various possibilities for a pet's presentation.

Once a thorough history has been acquired, all patients require a complete physical examination, which includes actually smelling the patient from snout to tail to identify if an abnormal odor is present. Many patients that present for abnormal odor will have *Malassezia* dermatitis or an active pyoderma. To help identify these patients, the clinician should pay particular attention to subtle clinical signs and body locations. Clinical signs suggesting a secondary infection is present include: erythema, alopecia, abnormal or excessive exudate, papules, pustules, epidermal collarettes, or excessive scale formation. Specific anatomic locations where meticulous attention should be directed include: the ear canals, skin and facial folds (Figure 25-1), mandibular lip folds (Figure 25-2), around collars, interdigital areas (Figure 25-3) and the perivulvar and perianal regions.

FIGURE 25-1 Facial fold erythema with increased brown keratosebaceous debris secondary to *Malassezia* dermatitis in an English Bulldog, highlighting the importance of separating skin folds when present in a patient who is presented for a complaint of malodor. (Photo courtesy James Noxon, Iowa State University, Ames, IA.)

FIGURE 25-2 Mandibular lip fold erythema, alopecia, and discoloration secondary to bacterial overgrowth in an English Springer Spaniel. This is a common location of secondary infections that is easily overlooked, which results in facial pruritus and the misconception of odor originating from the oral cavity.

FIGURE 25-3 Interdigital erythema with brown discoloration of the fur in a patient with atopic dermatitis and secondary *Malassezia* pododermatitis. The interdigital region is a common location for secondary microbial overgrowth in patients with predisposing conditions that can result in patient malodor.

Normal Pet Odors

Natural body odor is the result of epidermal lipid production, gland secretions (sebaceous, epitrichial, atrichial, ceruminous, and anal sacs) and their decomposition by lipase-producing bacteria into unsaturated and aromatic fatty acids, which produce the perceived unpleasant scent.[6] Glandular density is highest near mucocutaneous junctions, paws, dorsal neck, rump, and specific portions of the tail and these are areas where normal odors predominate.[7] Natural pet odor also is dependent on the species, breed, age, sexual status, and overall health of the individual. Specific examples of a pet's signalment impacting its natural odor include: members of the hound family having a muskier odor; dogs with oilier coats (e.g., Labrador Retrievers) having increased odor; intact male cats compared to their castrated counterparts; animals with excessive skin folds (e.g., Mastiffs); or those that drool excessively, such as St. Bernards and Newfoundlands.[7]

If the pet is deemed healthy with no obvious abnormal odor, client education is required along with management strategies to improve or mask what the client finds offensive. This may require a change in grooming habits or frequencies, shampoo choice, use of conditioners, and fragrance sprays. This would be similar to the approach upon which the entire cosmetic industry is built, and in some cases, it is simply what the client wants. In other circumstances this may not be enough and a second choice of topical agents with different ingredients may be needed, as some owners will find the constituents of products noxious. Finally, diet has been suggested to influence a pet's odor, specifically by proponents of raw dog foods, although studies documenting this are lacking.[8] Despite this, the most common anecdotal report of diet contributing to body odor has been observed with dogs predominantly fed fish-based diets.[9] In cases where no cause can be determined, it may be worth changing the diet to investigate whether alternative ingredients improve the animal's odor.

Normal Pet with an Obvious Non-Medical Cause

The second category encountered is patients who lack a primary medical condition but an obvious cause for

the odor exists. One example would be in patients with long, dense, or corded hair coats that are not maintained or allowed to dry properly. This is seen with dogs that swim frequently, drool excessively, or in animals whose hair coat needs more intensive grooming (e.g., Old English Sheepdogs). In all of these circumstances, client education, improved grooming habits, or shaving the hair coat will eliminate the problem. However, it is important to keep in mind that shaving the hair coat may create a more significant cosmetic issue for some clients.

In other cases, an animal's behavior may be the source of the abnormal odor. This is particularly true with animals that roll in feces or decaying material. These patients require changes in grooming or more frequent bathing similar to that of normal patients without identifiable causes. Other pets may be easily frightened and liberally express their anal sacs. Dietary changes, behavior modification, or surgical excision may be required in these instances. Finally, pets may come across wildlife such as skunks, and as dogs and skunks do not mix, the dog may be sprayed during the encounter. It is important to note that it may take days to weeks to completely eliminate the skunk odor and commercial as well as home remedies are available to address this situation in these patients.[7,9]

Primary Medical Condition Resulting in Pet Malodor

The vast majority of patients presenting with a complaint of body odor are those with a primary medical condition or skin disease. These conditions are outlined in Figure 25-4 and Box 25-1. Thorough historical information, physical examination, and appropriate diagnostics should result in identification of the underlying condition and secondary problems. Detailed discussion and management of these causes are beyond the scope of this chapter. For specific management recommendations of these conditions, the author encourages the reader to refer to other chapters within this textbook, or if required, *Muller & Kirk's Small Animal Dermatology*. Regardless of the cause, targeted therapy against the primary condition and secondary infections present is required to resolve the issue and prevent recurrence.

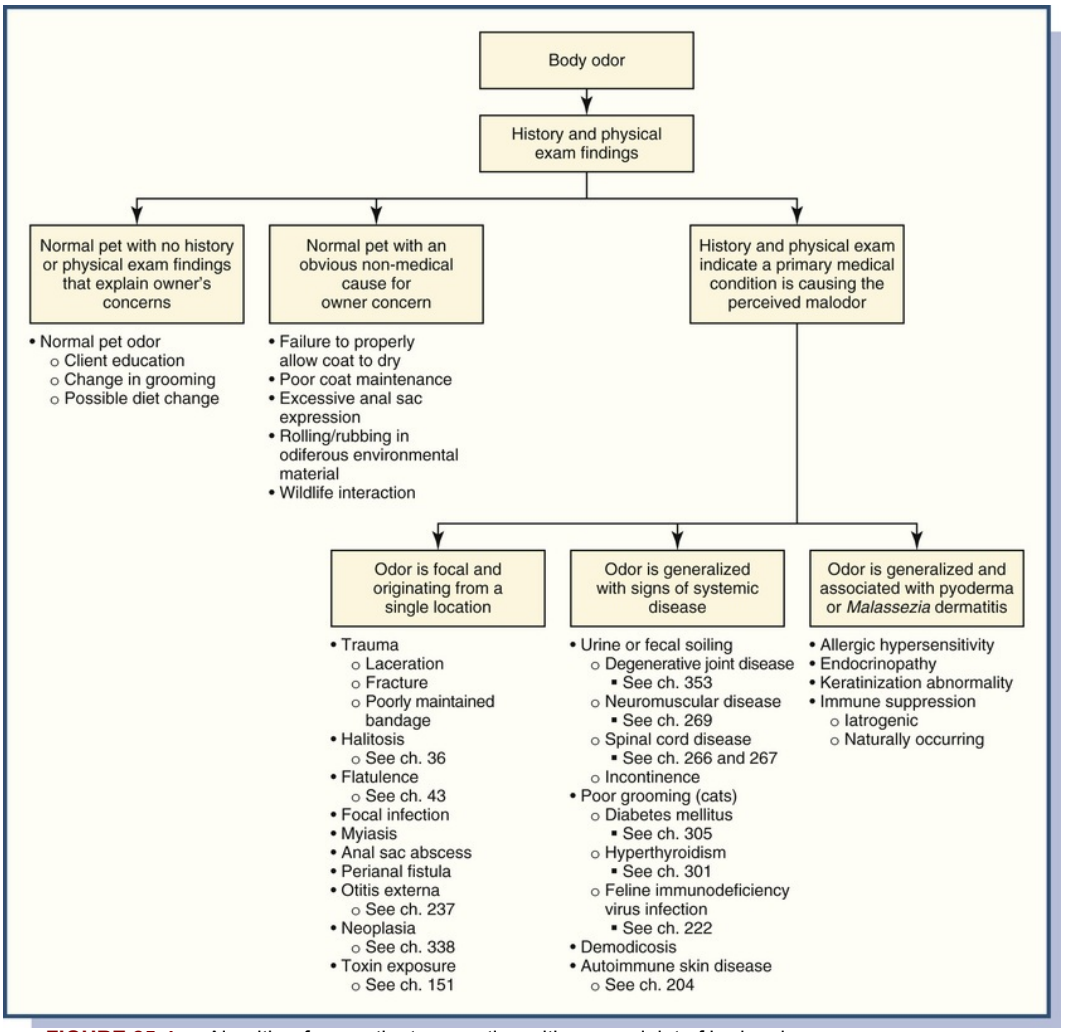

FIGURE 25-4 Algorithm for a patient presenting with a complaint of body odor.

Box 25-1

Common Conditions That Predispose to the Development of Recurrent Secondary Infections Such as Pyoderma, *Malassezia* Dermatitis, and Otitis Externa

Allergic Hypersensitivity

Atopic dermatitis
Cutaneous adverse food reaction
Parasitic hypersensitivity

Endocrinopathy

Hypothyroidism
Hyperadrenocorticism

Keratinization Abnormalities

Primary seborrhea
  American Cocker Spaniel
Feline acne
Ichthyosis
  Golden Retriever, American Bulldog

Miscellaneous Diseases

Sebaceous adenitis
  Standard Poodle, Akita, Vizsla
Feline idiopathic facial dermatitis
  Persian and Himalayan cats

CHAPTER 26

Coughing

Luca Ferasin

Client Information Sheet: Cough

Cough is an important physiological function to preserve the normal health of the respiratory tract, which operates by rapidly expelling harmful substances, such as foreign bodies, excessive mucus, or debris, from the upper airways. However, cough is not only a defensive mechanism. It can also represent an important sign of an underlying disease or even a detrimental symptom when it becomes persistent.[1] Occasionally cough can cause syncope, urinary and fecal incontinence, muscle pain, and exhaustion.[2]

Coughing Mechanisms

The typical coughing reflex (CR) is characterized by an initial deep breath, followed by a rapid and powerful expiratory act against the closed glottis and finally opening of the glottis, closing of the nasopharynx and forceful expiration through the mouth, accompanied by a typical vocalization caused by the vibration of the vocal cords. Cough can be evoked by stimulation of coughing receptors localized in the larynx, trachea, or bronchi, whereas irritation of smaller bronchi, bronchioles, and alveoli does not elicit coughing.[3,4] A second important defensive mechanism, similar to cough, is the expiration reflex (ER). This is induced by stimulation of the vocal cords or trachea and consists of forced expiratory effort against a closed glottis, which is not preceded by a particularly deep inspiration.[4] This reflex is often observed in dogs and sounds like a "huff" sound. The distinction between CR and ER is important since their physiological functions are different. True cough will draw air into the lungs to augment the force of the subsequent expulsive phase, promoting clearance of mucus and foreign material from trachea and bronchi. Conversely, the ER from the larynx will prevent the entry of noxious material into the airways.[2] Therefore, the presence of CR should suggest lower airway disease, such as bronchial disease (Video 26-1), whereas ER is more commonly associated with upper airway irritation (Video 26-2). Finally, the sneezing reflex is also similar to coughing but it is evoked from the nasal mucosa and its expulsion phase occurs mostly through the nose, in order to eliminate the provoking stimulus (see ch. 27).[5,6] Hybrid responses are possible and are characterized by a mixture of coughing and sneezing features (Video 26-3). When these reflexes are ineffective, such as in muscle weakness, laryngeal paralysis, bronchomalacia, and chronic bronchitis, recurrent pneumonia can occur.[2]

History

History alone rarely provides sufficient information to determine the clinical reasons for coughing. Nevertheless, a careful history should include questioning of the duration, characteristics and timing of the cough. Pets' owners often fail to provide a correct terminology or accurate description of the symptom and therefore, audio-video recording of their coughing pet can be invaluable, even when obtained with a mobile phone camera. Very often, the notorious "nocturnal cough" is reported simply because the pet sleeps in the owner's bedroom, while the pet may be unsupervised during the day. Finally, severity of coughing may be perceived differently by different pets' owners, and therefore appropriate questions should be asked once the problem has been identified. Classification of cough based on its duration is rather arbitrary. A cough lasting less than 3 weeks is termed "acute." It usually results from viral upper respiratory tract infection (e.g., kennel cough) and often resolves spontaneously, although post-infective cough can sometimes persists for a longer period of time. A cough present for at least 8 weeks is defined as "chronic" and clinicians should also

recognize an overlap period of between 3 and 8 weeks.[7] Cough can be classified as "productive," "wet" or "chesty" when it is associated with expectoration of large amounts of sputum, often swallowed after coughing. Conversely, a "dry," "honking" or "hacking" cough is characterized by little or no production of phlegm. However, there are substantial overlaps between these two forms. Furthermore, character and timing of a cough are not diagnostically helpful since diagnostic approach and outcome are almost identical, whether the cough is productive or not. A history of hemoptysis (coughing up blood) should prompt urgent investigations since it could be the first clue to the presence of lung tumors, bleeding disorders, pulmonary thromboembolism, heartworm disease, or lungworms. Home environment and animals' habits may also provide useful elements for a successful diagnosis. Indoor pets can be exposed to compounds that could cause coughing, such as dust mites, molds, fireplace ash, dandruff, litter tray dust, sprays, deodorants, and cigarette smoke. Histological bronchial changes have been reported in several animal models following experimental chronic cigarette smoke inhalation, and biochemical evidence of exposure to passive cigarette smoke has been demonstrated both in privately owned dogs and cats.[7-10] History may reveal exposure to boarding kennels, grooming parlors, dog parks and general contact with other dogs in the few days preceding the onset of an acute cough suggesting infectious disease, especially in young unvaccinated animals. Coughing pets living in endemic areas for *Dirofilaria immitis* (heartworm disease), *Angiostrongylus vasorum* (French heartworm) or *Aelurostrongylus abstrusus* (cat lungworm) should be tested for these parasites. Geographical presence of these parasites changes rapidly and it is important to know their potential prevalence in different regions.[11]

Differential Diagnosis for Coughing

Cough is mostly induced by stimuli originating in the airways, with upper airways more frequently involved than lower airways. Dynamic and static airway collapse is one of the most common causes of coughing in dogs and this disorder can affect different portions of the trachea, as well as major bronchi. The condition is mostly associated with weakness of the tracheal or bronchial wall, in isolated tract or extended tracts (i.e., tracheomalacia, bronchomalacia, and tracheobronchomalacia). Dogs affected by airway collapse typically present with a persistent, dry, paroxysmal "honking" cough sometimes associated with varying degree of dyspnea[12,13] (see ch. 241). One of the most common causes of cough in cats is chronic lower airway inflammatory disease, which may originate from multiple etiologic causes. Affected cats commonly present with paroxysmal coughing, which resembles hacking up hairballs and can inadvertently lead to gastrointestinal investigations rather than respiratory workups. Clinical signs can often escalate into bronchospasm associated with severe dyspnea (asthmatic crisis)[14] (see ch. 131, 139, and 241).

Parenchymal conditions, such as pneumonia alone, may not induce cough unless the noxious process extends to the airways (e.g., bronchopneumonia and sputum production). Similarly, converse to inaccurate former reports and opinion, cardiogenic and non-cardiogenic pulmonary edema does not cause coughing.[15,16] This can be easily extrapolated by the fact that cough reflex is not present in the deeper respiratory tract. Patients with pulmonary edema will rather present with tachypnea/dyspnea, although they may occasionally cough if there is concomitant airway irritation or if the amount of fluid in the alveolar space is severe enough to reach higher airways and stimulate coughing receptors, as occasionally observed in large-breed dogs with fulminant pulmonary edema. Cardiomegaly, in particular left atrial enlargement (LAE), is associated with an increased risk of cough in dogs with chronic degenerative mitral valve disease (MMVD), and there is a ten-fold increased risk of coughing if LAE and airway disease coexist.[15] There seems to be a weak association between LAE and airway collapse in dogs with MMVD and therefore underlying airway inflammation might represent the major cause of coughing in such patients.[17]

Gastroesophageal reflux disease (GERD), postnasal drip syndrome (PNDS), and use of angiotensin-converting enzyme inhibitors (ACEi) or beta-blockers are common causes of coughing in people but are only occasionally reported in animals.[18-25] Risk factors for cough are listed in Table 26-1.

Clinical Assessment

The physical examination of the patient with cough may reveal a potential underlying cause. Nasal and ocular discharge accompanied by frequent licking and swallowing could be an indication of PNDS associated with rhinitis and sinusitis. A cough easily elicited by gentle tracheal or thoracic palpation suggests that coughing receptors are already stimulated by an underlying condition where the pathologic stimulus is not sufficient to reach a threshold for continuous coughing (Videos 26-3 and 26-4). Therefore, the widely used concept of "positive tracheal pinch" is incorrect because this maneuver does not provide a "positive/negative" response.[2] Auscultation over the larynx and trachea can reveal stridors or clicks in coughing animals with laryngeal paralysis or tracheal collapse. Thoracic auscultation often reveals stridors, rhonchi, crackles and wheezes, which are suggestive of airway disease at different levels in the respiratory tract. Inspiratory crackles can be present in coughing dogs with chronic interstitial lung disease (ILD), especially in West Highland White Terriers and other terrier breeds.[26] An association between interstitial lung disease and coughing has also been reported in cats.[27] The exact mechanism of cough in ILD is elusive but may be related to up-regulation of lung airway sensory receptors, increased cough sensitivity, and chest wall vibration.[28] Although crackles are commonly reported in the veterinary literature as an indication of alveolar pulmonary edema, the most likely mechanism of crackle generation is sudden airway closing during expiration and sudden airway reopening during inspiration, as happens more commonly in pneumonia and ILD.[29,30] Furthermore, rhonchi associated with bronchial disease can be mistakenly described as crackles by some clinicians. Chest percussion can reveal a horizontal line of dullness consistent with pleural effusion, sometimes associated with cough both in dogs and in cats. Thoracic masses, often responsible for cough by mechanical compression, can sometimes be identified by chest percussion.

Clinical Investigations

Laboratory tests should include differential white cell count, which may reveal neutrophilia in inflammatory diseases or eosinophilia and basophilia in parasitic or fungal infections. Fecal Baermann test should be considered to attempt identification of lungworms. Serological tests are available for detection of *Dirofilaria immitis* and *Angiostrongylus vasorum* and their use is recommended in all coughing animals living in endemic areas. Thoracic radiographs are recommended at an early stage, as a significant abnormality will alter the diagnostic plan and avoid unnecessary investigations. Unfortunately, radiographic examination has a poor sensitivity in identifying dynamic airway collapse, infectious tracheobronchitis, or parasitic infections.[31-33] Bronchoscopy (see ch. 101) can be considered for further evaluation of coughing patients, although diagnostic yield from bronchoscopy in the routine evaluation of chronic cough tends to be low. Bronchoscopy may have a higher diagnostic potential in selected cases, such as inhaled foreign bodies, dynamic or static airway collapse, chronic bronchitis and lungworms. Furthermore, bronchoscopy provides the opportunity for airway sampling by either mucosal biopsy or bronchoalveolar lavage (BAL). Transtracheal wash (TTW) can be considered as an alternative sampling technique, although it provides a lower diagnostic yield. Thoracic computed tomography scanning is becoming widely available in veterinary medicine and this technology allows more accurate diagnoses of diffuse parenchymal lung disease, bronchial disease, and foreign bodies, which may have not been identified on thoracic radiographs. Additional diagnostic investigations may include fluoroscopy, gastrointestinal endoscopy, rhinoscopy, allergy testing, etc. An algorithm for clinical

approach is presented (Figure 26-1).

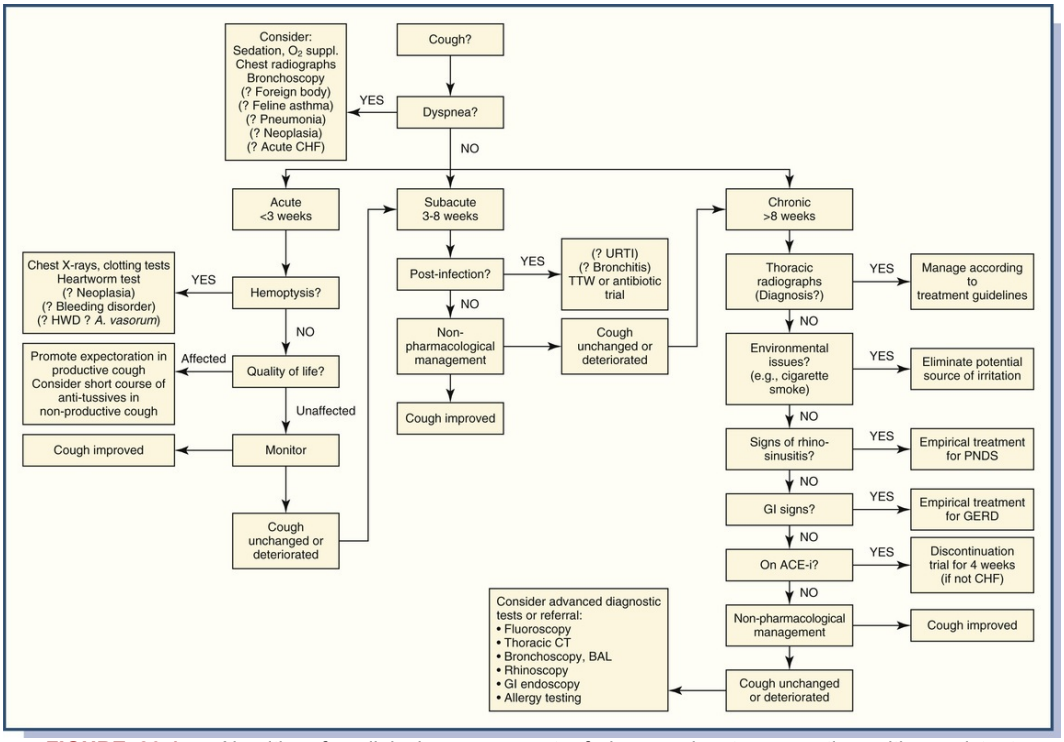

FIGURE 26-1 Algorithm for clinical management of dogs and cats presenting with persistent coughing. *ACE-i*, Angiotensin converting enzyme inhibitors; *BAL*, bronchoalveolar lavage; *CHF*, congestive heart failure; *CT*, computed tomography; *GERD*, gastroesophageal reflux disease; *GI*, gastrointestinal; *HWD*, heartworm disease; *O2 suppl*, oxygen supplementation; *PNDS*, postnasal drip syndrome; *TTW*, transtracheal wash; *URTI*, upper respiratory tract infection.

Clinical Management

Cough alone is seldom a life-threatening condition. However, when it occurs hyper-acutely, it may indicate a serious underlying problem (foreign body inhalation, severe airway obstruction, near-drowning, smoke inhalation, etc.). Cough is a protective mechanism and should not be suppressed. However, incessant coughing may affect the patient's quality of life when it interferes with respiration, eating, drinking, exercise and sleeping. The pet owner's sleeping pattern can also be affected if the dog sleeps in the same room. Cough can also spread infections and, by further irritating the airways, it may initiate a vicious circle of cough-induced cough. Cough suppression should be reserved for use only in the above situations.[2] Ideally, when a primary cause can be identified, removal of the underlying etiology should be considered first (removal of inhaled foreign body, antibiotic treatment in bacterial infections, etc.).

Non-Pharmacological Approach

The initial approach can be empirical and aimed at controlling cough, relieving airway obstruction and reducing the source of irritation, as indicated below:

1. Cigarette smoke, dust, spray cleaners and deodorants should be avoided. Carpets should be vacuumed frequently. Cleaned cotton sheets should be used to cover the pet's bed.
2. Gentle and long walks are more indicated than short intense runs. Light exercise can assist in dislodging bronchial mucus and may help opening small airways.
3. A harness should be worn instead of a collar when the dog is walked on a leash.
4. Weight reduction will improve respiration, exercise capacity, and cardiovascular functions with dramatic results (see ch. 176). Indeed, fat tends to accumulate in the chest and reduce the lung volume. This can cause compression of the airways and stimulate cough.
5. Nebulization favors expectoration from the deeper airways, bronchi, and trachea because it thins the

mucus and lubricates the irritated respiratory tract (see ch. 97). Ultrasound nebulizers are available in many health and beauty shops and they can be activated overnight in the room where the animal sleeps. Repeated coupage may help dislodge some of the deeper secretions.

Pharmacological Approach

If improvement is not observed following empiric interventions, an antitussive approach can be considered, although it should be noted that scientific evidence in dogs and cats is lacking.

Inhaled corticosteroids (ICS) (e.g., fluticasone, beclomethasone, budesonide) act directly on the airway mucosa, reducing local inflammation. Since ICS are minimally absorbed, negligible side effects are expected. ICS are administered using dedicated spacers with mask (see ch. 97).

1. Expectorants (e.g., guaifenesin) work by increasing the volume and reducing the viscosity of airway secretions, therefore improving the efficiency of cough to remove such secretions.
2. Mucolytics (e.g., acetylcysteine, guaifenesin, ambroxol, bromhexine) modify the structure of mucus glycoproteins and reduce mucus viscosity. Their use should be restricted to a few special instances, such as liquefying thick, tenacious, mucopurulent secretions.
3. Cough suppressants (e.g., butorphanol, codeine, hydrocodone, dextromethorphan) are centrally-acting antitussives, which inhibit the cough reflex by acting on the medullary cough center. Most cough suppressants have sedative effects, which might be desirable in painful, persistent cough. The clinical usefulness of dextromethorphan in coughing children has been recently questioned and little information is available about its efficacy in small animals.[34]
4. Bronchodilators (inhaled salbutamol/albuterol, theophylline, aminophylline and terbutaline) relax contracted airways smooth muscle. Therefore, they are only useful during bronchospasm, such as in feline asthma. Inhaled bronchodilators are preferred over systemic medications. Naturally-occurring bronchospasm has not been convincingly demonstrated in dogs.

CHAPTER 27

Sneezing and Nasal Discharge

Julio López

Client Information Sheet: Sneezing and Nasal Discharge

Sneezing is an involuntary, protective reflex that expels air from the lungs through the nose and mouth in a sudden, explosive manner to clear the upper airways. It is triggered when chemical or physical irritants stimulate the subepithelial receptors in the nose. Sneezing or nasal discharge may occur in diseases of the nose, sinuses and nasopharynx (Box 27-1) or may be secondary to lower airway or systemic disease (Box 27-2).

Box 27-1

Nasal and Paranasal Causes of Sneezing and Nasal Discharge

Congenital

Cleft palate
Ciliary dyskinesia
Nasopharyngeal stenosis
Choanal atresia

Inflammatory

Idiopathic lymphocytic-plasmacytic rhinitis
Allergic rhinitis
Nasopharyngeal stenosis
Nasopharyngeal polyp (C)
Polypoid rhinitis
Foreign body

Infectious

Viral

Feline calicivirus (C)
Feline herpesvirus-1 (C)

Bacterial

Mycoplasma spp. (C)
Bordetella bronchiseptica (C)
Pasteurella multocida (D)

Fungal

Aspergillus (D, C)
Penicillium (D)
Rhinosporidium (D, C)
Cryptococcus (C)

Parasitic

Pneumonyssoides caninum (D)
Eucoleus [Capillaria] boehmi (D, C)
Cuterebra sp. (D, C)

Linguatula sp. (D, C)

Neoplastic

Adenocarcinoma
Squamous cell carcinoma
Chondrosarcoma
Osteosarcoma
Fibrosarcoma
Lymphoma
Transmissible venereal tumor
Neuroendocrine carcinoma

Trauma

Blunt or sharp force

Dental Disease

Tooth root abscess
Oronasal fistula

Vascular Malformation

C, Cats; *D,* dogs.

Box 27-2

Systemic Causes of Sneezing and Nasal Discharge

Hemostatic Disorder

Thrombocytopenia
Thrombocytopathia
von Willebrand disease
Coagulation factor deficiency
- Congenital (hemophilia A and B, others)
- Acquired (anticoagulant rodenticide intoxication, disseminated intravascular coagulation [DIC], liver failure)

Vasculitis

Toxic
Inflammatory
Immune-mediated
- Systemic lupus erythematosus

Neoplastic
Infectious
- Ehrlichiosis
- Feline infectious peritonitis
- Rocky Mountain spotted fever
- Leishmaniasis

Hyperviscosity

Multiple myeloma
IgM (Waldenstrom's) macroglobulinemia
Chronic lymphocytic leukemia
Lymphoma
Ehrlichia canis
Feline infectious peritonitis (rare)
Amyloidosis
Plasma cell leukemia

Hypertension

Primary or essential (rare)
Secondary
- Acute or chronic kidney disease
- Pheochromocytoma
- Hyperadrenocorticism
- Hyperthyroidism
- Hypothyroidism
- Acromegaly
- Polycythemia
- Diabetes mellitus
- Overhydration

Infections

Infectious tracheobronchitis
Distemper
Bacterial bronchopneumonia

Clinical Presentations

Most patients with nasal disease will present for evaluation of nasal discharge or sneezing. Signs of caudal nasal cavity disease include stertor, reverse sneezing, excessive swallowing, gagging, coughing, dysphagia, and changes in phonation. Clinical signs are not usually pathognomonic for a particular disease and various ancillary tests are required to reach a diagnosis.

Stertor

This term refers to a snorting/snoring respiratory sound indicating an obstruction to airflow at the nasopharynx that usually resolves with open-mouth breathing. Nasal discharge, mass lesions, and nasopharyngeal swelling can cause it and it is classically heard in brachycephalic breeds due to an elongated soft palate, excessive nasopharyngeal tissue, and airway stenosis (Video 27-5).

Reverse Sneezing

Reverse sneezing is a loud, sometimes violent, inspiratory snoring sound that occurs without warning. Lasting seconds to minutes, it may give clients the impression that respiratory distress is occurring. Irritation of the nasopharyngeal mucosa triggers spasms of the pharyngeal muscles, leading to obstruction of air passage to the larynx and transfer of secretions and foreign material to the oropharynx for swallowing. It is common, and usually of no consequence (Video 27-1). Nasopharyngeal disorders such as a foreign body, the nasal mite *(Pneumonyssoides caninum)*, viral infection, allergic rhinitis or epiglottic entrapment of the soft palate should be investigated when reverse sneezing is new or increases in occurrence.

Nasal Discharge

Location and character of nasal discharge may help formulate a list of differential diagnoses, keeping in mind the tremendous overlap amongst diseases that cause it.[1] Discharge is typically unilateral with foreign bodies, oronasal fistulas, aspergillosis, and neoplasia, and bilateral in inflammatory, infectious, or allergic disease. It is classified as: serous, mucoid, mucopurulent, purulent, sanguineous (containing blood), epistaxis (frank hemorrhage), or food-containing. Nasal discharge may not be noted in nasopharyngeal disease, as secretions tend to be swallowed.

Serous discharge is watery, clear, and can be a normal finding. If excessive, it may be a sign of noninfectious inflammatory disease or a viral upper respiratory tract infection in cats.

Mucopurulent discharge is more viscous and opaque, usually having a white, yellow, or green coloration. Any nasal disease that causes inflammation and secondary bacterial infection can present with this type of discharge, thus making it nonspecific (Video 27-2).

A sanguineous discharge occurs from damaged nasal mucosa and may be brought on by continuous sneezing alone. Significant nasal turbinate destruction or erosion of nasal vascular structures caused by

craniofacial trauma, mycotic infection, or neoplasia, can cause a sanguineous nasal discharge or epistaxis[1] (see Video 27-2). It can also be caused by systemic diseases (hypertension) or hemostatic disorders (thrombocytopenia, thrombocytopathia, vasculitides, or a coagulopathy).[2]

Food material in the nasal cavity suggests a congenital abnormality such as a cleft palate, a dysphagic condition in a young animal, or an oronasal fistula in an older animal.

Diagnostic Approach

Signalment

Young animals are more likely to have congenital or infectious causes of nasal discharge. Conversely, neoplasia and dental disease are more frequent occurrences in older animals. Animals housed together or stressed (shows, shelters, kennels, new home), or those exposed to regional outdoor environments (mycotic infection), are more susceptible to infectious diseases.

Brachycephalic dogs commonly have conformational causes of upper airway disease and less frequently nasal neoplasia, while brachycephalic cats are at increased risk of fungal rhinitis.[3,4] Dolichocephalic breeds are overrepresented with respect to nasal disease, likely related to the greater surface area of their mucous membranes increasing exposure to inhaled irritants and allergens. They also have a higher incidence of fungal rhinitis and nasal tumors.[3]

In cats, nonspecific inflammatory rhinosinusitis is likely the sequela of upper respiratory viruses. They alter normal nasal anatomy and defense mechanisms, causing a predisposition to secondary bacterial infections and an abnormal immune response. Cats with neoplasia are more likely to be older, have dyspnea, or hemorrhagic or unilateral nasal discharge.[5]

History

A thorough history may assist in prioritizing diagnostic tests and treatments. The pet owner should be questioned about attendance at shows/kennels, trauma, travel, outdoor activities (exposure to foxtails/grass awns, fungal organisms) and recent anesthetic procedures (nasopharyngeal gastric reflux, dental extractions) (Videos 27-3 and 27-4).

Another diagnostic aid is the onset of clinical signs (peracute, acute, chronic). Paroxysmal sneezing in a dog that was recently outdoors might indicate a plant-origin nasal foreign body, especially if accompanied by pawing at the face. In contrast, acute sneezing in cats is commonly from a viral etiology. It is less likely from foreign body inhalation due to the smaller opening of the external nares in cats. Nasopharyngeal foreign bodies may occur secondary to vomiting or regurgitation of grass or fur into the nasopharynx. Clients may report reverse sneezing, increased swallowing or gagging (postnasal drip), coughing, or audible breathing noises (stertor) in pets with caudal nasal cavity disease.

Physical Examination

Clinical suspicion of nasal disease can be confirmed by a thorough physical exam, although at times no abnormalities may be noted even though significant disease exists. The nose is examined for the presence of discharge, ulceration/crusting around the nares, depigmentation of the nares (nasal aspergillosis), asymmetry of the nose and/or face (nasal neoplasia, cryptococcosis), and pain over the dorsum of the nose (nasal aspergillosis/neoplasia). Placing a glass slide, a few hairs or a wisp of cotton in front of each nare and noting condensation or movement, respectively, assesses patency of the nasal passages. In a quiet area, listen for nasal stertor while keeping the patient's mouth closed.

A thorough oral exam, usually necessitating anesthesia, is performed as part of a complete evaluation. Mucosal ulceration (feline calicivirus), fractured teeth, oronasal fistula, cleft palate, inability to depress the soft palate or a ventral displacement (nasopharyngeal space-occupying lesion) may be noted. Halitosis may indicate dental disease, oronasal fistula, or a foreign body.

Exophthalmos, prolapse of the nictitans, deformity of the facial bones, or inability to retropulse the eye should lead to suspicion for a retrobulbar mass. Epiphora may be a sign of nasolacrimal duct occlusion. Fundic examination (see ch. 11) may reveal chorioretinitis (neoplastic or infectious diseases) or tortuous retinal vessels, retinal hemorrhages, or retinal detachment (systemic hypertension).

Nasal disease extending beyond the cribriform plate (neoplasia/aspergillosis) may affect the central nervous system and therefore a neurological exam should be performed (see ch. 259).

Primary thoracic diseases may cause secondary nasal signs from secretions coughed into the nasopharynx. Crusting of the nares with the absence of sneezing or nasal discharge suggests keratoconjunctivitis sicca (KCS) or primary dermatoses such as discoid lupus erythematosus.

Epistaxis (see ch. 29) is the most common clinical sign associated with thrombocytopenia. If petechiae, ecchymoses, or melena are noted, a hemostatic disorder should be the primary consideration.

Diagnostic Plan

Using the information gained from the clinical signs, signalment, history, and physical examination, an appropriate systematic diagnostic plan can be formulated (Figure 27-1). Despite thorough evaluation, 36.3% of cases of nasal disease in dogs remain undiagnosed and 23.7% of dogs and 64% of cats are diagnosed with nonspecific rhinitis.[6,7] Likely contributing to these numbers are cases of early neoplasia or foreign bodies, where repeated testing would probably lead to a diagnosis. Testing should also be repeated in patients with chronic rhinosinusitis that have worsening of clinical signs, to investigate the development of a second disease process.

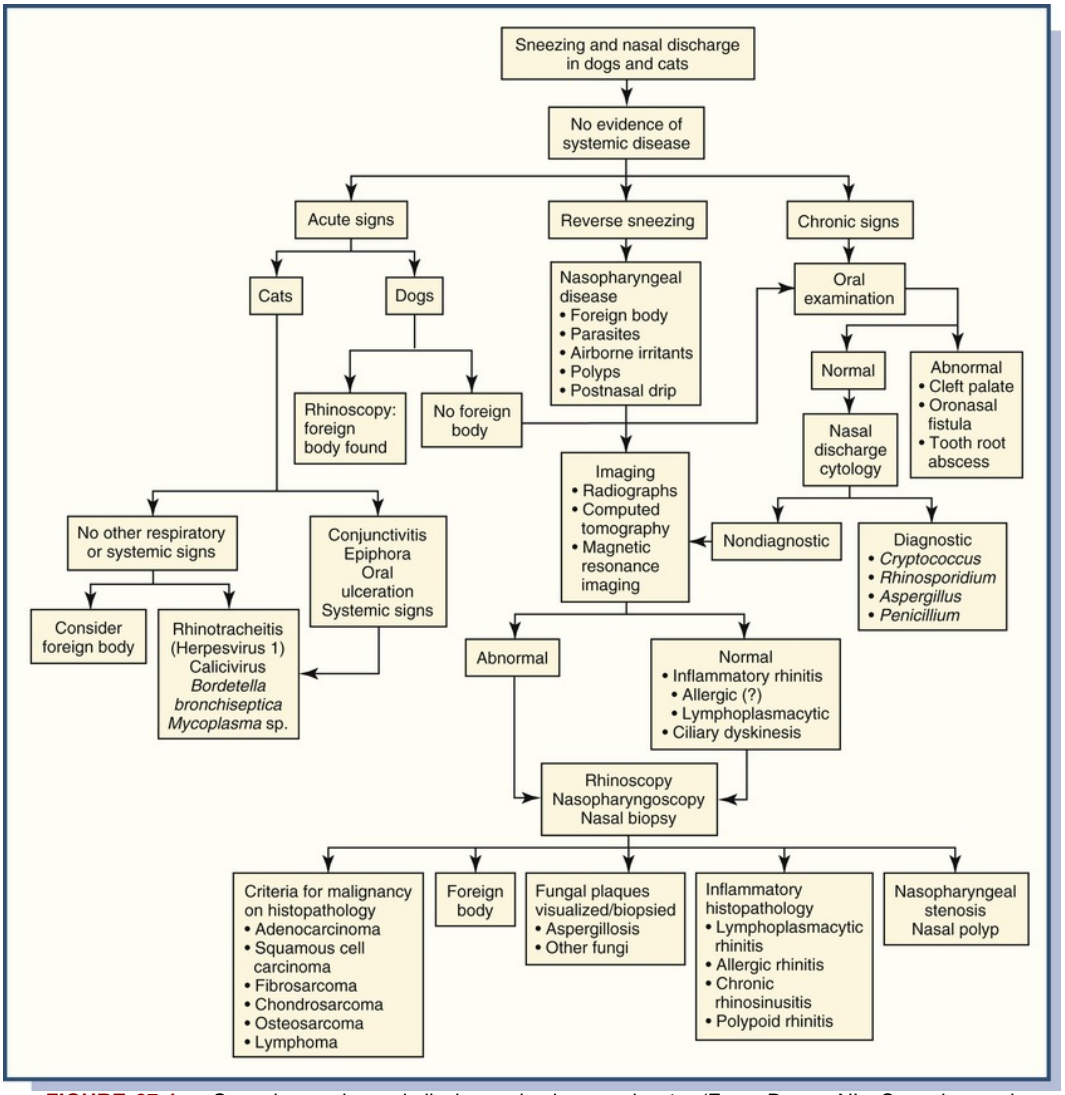

FIGURE 27-1 Sneezing and nasal discharge in dogs and cats. (From Brown NL: Sneezing and nasal discharge. In Ettinger SJ, Feldman EC, editors: *Textbook of veterinary internal medicine*, ed 7, St Louis, 2010, Saunders Elsevier.)

In most cases of nasal disease, complete blood count and chemistry panels are not usually helpful in determining a diagnosis. Despite this, they must be performed to screen for systemic diseases manifesting

with nasal signs and before undergoing diagnostics that require general anesthesia. Cryptococcal serology should be performed in cats. *Aspergillus* serology by agar gel immunodiffusion test may support a diagnosis of fungal rhinitis, as it was shown to be highly specific (98%) but not sensitive (i.e., a negative result does not rule out the disease).[8] Fungal culture as a sole means of diagnosing fungal rhinitis is not recommended due to the possibility of nonclinical transient fungal organisms.[9] Testing for respiratory viruses (feline calicivirus, feline herpesvirus-1) by immunodiffusion, enzyme-linked immunosorbent assay, or polymerase chain reaction is of no use in most situations due to the high prevalence in healthy cats.[10] In cases of epistaxis, a platelet count, coagulation times (prothrombin time, activated partial thromboplastin time) or levels of proteins induced by the antagonism or absence of vitamin K, and blood pressure should be assessed, and, if indicated, a buccal mucosal bleeding time (BMBT) should be performed (see ch. 80 and 99).

Cytology of nasal secretions usually reveals nonspecific inflammation. Occasionally, fungal organisms (*Cryptococcus* sp.), parasitic ova *(Eucoleus boehmi)* or neoplastic cells are noted. Samples obtained by swabbing, brushing, flushing, or impression smears of tissue fragments can be used (see ch. 96 and 240). Facial or nasal swellings and enlarged lymph nodes should be sampled by fine needle aspiration or biopsy (needle core [Tru-Cut] or punch).

Bacterial culture of nasal discharge or the nasal cavity (deep swabbing or biopsy) is generally considered of little value as it commonly yields a mixed growth of normal commensal microflora. Although primary bacterial rhinitis is rare, notable exceptions include *Pasteurella multocida* (dogs), *Bordetella bronchiseptica* (dogs and cats) and *Mycoplasma* spp. (cats).[11,12]

Further assessment beyond these initial steps requires general anesthesia and should begin with an oral examination. If dental disease is suspected, dental radiographs should be acquired. Imaging studies should be obtained before performing dental probing or endoscopic procedures to avoid causing hemorrhage within the nose that will affect visualization. Regardless of the diagnostic method chosen, it cannot be stressed enough that bilateral examination and sampling of the nose should always occur even when unilateral disease is suspected.

Skull Radiographs

Although not the ideal imaging modality when investigating nasal disease, routine radiography may reveal the extent and character of the disease and help direct biopsy sampling. Advantages are that it is widely available and relatively inexpensive. Disadvantages include the need for general anesthesia for proper patient positioning and the inability to detect subtle changes within the nasal cavity. Superimposition of structures or accumulated fluid may obscure abnormalities and can be minimized by obtaining intraoral dorsoventral and/or open-mouth ventrodorsal views, the latter allowing assessment of the cribriform plate. Lateral oblique views and rostrocaudal views allow visualization of the dental arcade and frontal sinuses, respectively.

Rhinitis in dogs and cats, regardless of cause, can have a variable radiographic appearance depending on the chronicity and severity. Destruction of conchae can be a feature of both rhinitis (fungal/other) and neoplasia. This finding along with soft tissue swelling, bony invasion and ipsilateral sinus opacity are more commonly noted in nasal neoplasia.[13,14] In cats, *Cryptococcus neoformans* does not usually cause bony destruction. Radiopaque foreign bodies may be identified. Radiolucent foreign bodies can be localized by the appearance of a soft tissue opacity caused by secondary inflammation and discharge.

Computed Tomography (CT)

In contrast to skull radiographs, CT is much quicker to perform and provides vastly superior, detailed images without the problem of superimposition.[15,16] It also allows for visualization of areas inaccessible by endoscopy, provides guidance for biopsy procurement, and helps plan therapeutic strategies for fungal rhinitis (cribriform plate integrity) or neoplasia (radiation therapy). Disadvantages include availability and the need for general anesthesia, although it is becoming more accessible and, with newer units, sedation may be possible. While cost can be a factor, the superior images obtained may lead to an expedited, cost-effective diagnosis.

Although CT provides a reasonably accurate differentiation between neoplastic and nonneoplastic disease in dogs, confirmation via biopsy should always be performed. Neoplasia is typically associated with a soft tissue density and extensive turbinate destruction, whereas normal to moderate destruction, with or without soft tissue densities, is more typical of inflammatory rhinitis.[17] Fungal rhinitis is associated with extensive turbinate destruction and hyperlucency of the nasal passages.[16,18,19] In cats, features overlap between

nasal neoplasia and fungal rhinitis.[20] Contrast enhancement may differentiate fluid from vascularized soft tissue, although it cannot determine the nature of the lesion.

Magnetic Resonance Imaging (MRI)

Although studies show the ability of MRI to diagnose neoplastic versus inflammatory nasal disease, it is currently not the advanced imaging modality of choice. In dogs with nasal neoplasia or aspergillosis, studies have failed to demonstrate an advantage of MRI over CT.[19,21] The lack of a mass effect was significantly associated with inflammatory disease and a mass effect along with vomer bone lysis, cribriform plate erosion, paranasal bone destruction, and invasion of the mass into the sphenoid sinus or nasopharynx was significantly associated with neoplasia.[22] Disadvantages of MRI include prolonged anesthesia due to the time required to obtain images, the expense, and availability compared to CT. In cases of undiagnosed chronic nasal disease, MRI may be of value.

Rhinoscopy/Nasopharyngoscopy (see ch. 96)

The nasal cavities, nasopharynx, and, in some cases, the frontal sinuses can be directly visualized with endoscopic equipment. The procedures require expertise and moderately expensive equipment. Small rigid or flexible endoscopes provide adequate visualization of the nasal cavities. A flexible endoscope is required for access to the nasopharynx and frontal sinus, although sinuscopy may require trephination.[23] Rigid scopes have better optics and are easier to maneuver, while flexible scopes are associated with less mechanical trauma to the tissue. Nasopharyngoscopy should be performed first, as hemorrhage from rhinoscopy may pool in the nasopharynx and impair visualization.

The procedure can be diagnostic (visualization of fungal plaques, foreign bodies, nasal polyps, mass lesions, nasal mites, nasopharyngeal stenosis) as well as therapeutic (removal of foreign bodies, fungal plaques, flushing/suctioning excessive secretions). It allows for biopsy procurement under direct visualization. Endoscopy was superior to nasal radiographs in achieving a diagnosis in dogs with persistent nasal disease.[24] Evaluation of the choanae correctly identified nasal neoplasia in 26 of 34 animals where biopsies were obtained.[25]

Nasal Biopsy

Several biopsies from each nasal cavity should be procured from all dogs and cats with chronic nasal disease even if etiology appears to be unilateral, is obvious (foreign body), or no apparent lesion is noted. Rhinoscope-guided biopsies are preferred, as visualization ensures that specific lesions are sampled. Blind biopsy techniques can also be used, although in order to avoid inadvertent penetration of the cribriform plate, the clinician should measure the distance from the tip of the nose to the medial canthus of the eye and ensure the biopsy instrument does not pass this distance. A CT can determine the length the biopsy instrument must be advanced to reach the affected area. Biopsies may also be acquired via traumatic nasal flush or via rhinotomy.

Cytology of impression smears from biopsy samples may provide a fast tentative diagnosis.[26] If *Cryptococcus* spp. is detected, serologic testing should be obtained to determine asymptomatic carriage from true infection (positive result) and to help monitor treatment. Hemorrhage (which can be life-threatening) and aspiration of blood are complications that should be expected.

Treatment/Outcome

The diagnosis and treatment of nasal disease can be frustrating for both the veterinarian and pet owner. Despite a systematic and extensive investigation, an etiologic diagnosis remains elusive in many cases. More often, a descriptive diagnosis based on inflammatory infiltrates is provided (nonspecific rhinitis) with management based on symptomatic therapies to alleviate clinical signs. Specific treatments are available for neoplasia, fungal rhinitis, foreign bodies, most congenital abnormalities, parasites, and dental disease. Prior to undergoing an extensive and costly investigation, educating the client of possible outcomes and the potential for lifelong management will help minimize unrealistic expectations and frustration.

CHAPTER 28

Tachypnea, Dyspnea, and Respiratory Distress

M. Lynne O'Sullivan

Client Information Sheet: Tachypnea, Dyspnea, and Respiratory Distress

Dyspnea is used clinically to refer to difficult or labored breathing, though it actually more precisely refers to the conscious sensation of shortness of breath or breathlessness.[1] Respiratory distress is therefore perhaps a more accurate term for what is observed clinically, and implies a certain severity to the situation. Tachypnea refers to increased rate of respiration, which may accompany dyspnea. This should be differentiated from panting, which is rapid breathing without evidence of respiratory distress and which is associated with thermoregulation, anxiety, or pain. Orthopnea refers to dyspnea that is positional, specifically present whenever the patient is not standing or sitting upright.

Pathophysiology

Control of breathing involves the integration of three main elements: 1. Sensors that gather data, and 2. Respiratory control center in the brain that coordinates the data and sends impulses to the 3. Effector muscles (diaphragm and intercostal muscles). The main sensors include central and peripheral chemoreceptors, which are sensitive to changes in arterial carbon dioxide levels and both arterial oxygen and carbon dioxide levels, respectively. Dyspnea is triggered by hypoxemia or hypercarbia (generally PaO_2 < 60 mm Hg or $PaCO_2$ > 50 mm Hg, respectively, depending on duration). Causes of hypoxemia include 1. Decreased fraction of inspired O_2, 2. Hypoventilation, 3. Diffusion impairment, 4. Right-to-left cardiovascular shunt, 5. Ventilation-perfusion (VQ) inequality, and 6. Abnormal hemoglobin. This discussion focuses on disorders resulting in 2, 3, 4, and/or 5. The main causes of hypercarbia include: 1. Hypoventilation, and 2. VQ inequality.[2,3]

Immediate Assessment and Management of the Dyspneic Patient (see also ch. 131 and 139)

Respiratory distress is a common presenting complaint that necessitates immediate evaluation and attention, as respiratory compromise can very rapidly deteriorate to respiratory failure. Since stress and anxiety can contribute to this deterioration, these patients should be handled minimally. Oxygen therapy should be immediately administered via face mask, flow-by, nasal prongs, nasal cannula, hood, or cage. The choice of delivery method necessitates balancing the invasiveness of the technique with the inspired oxygen levels achieved for the given patient's condition and temperament. While oxygen is being administered, much information can be gained from observing the patient at a distance (see ch. 2). It is important to note posture, mental alertness and behavior, and respiratory pattern, including rate, regularity, depth, and effort (degree and timing with the respiratory phase). This information is used for assessing severity and localizing the problem to the upper airways, lower airways, pleural space, or thoracic wall.[3] Breathing patterns may be described as obstructive (slower, deeper breaths) or restrictive (short, rapid, shallow breaths). Obstructive patterns can further be characterized as having more inspiratory effort (suggesting an upper airway disorder) (Video 28-1) or more expiratory effort (suggesting a lower airway disorder) (Figure 28-1; Video 28-2).

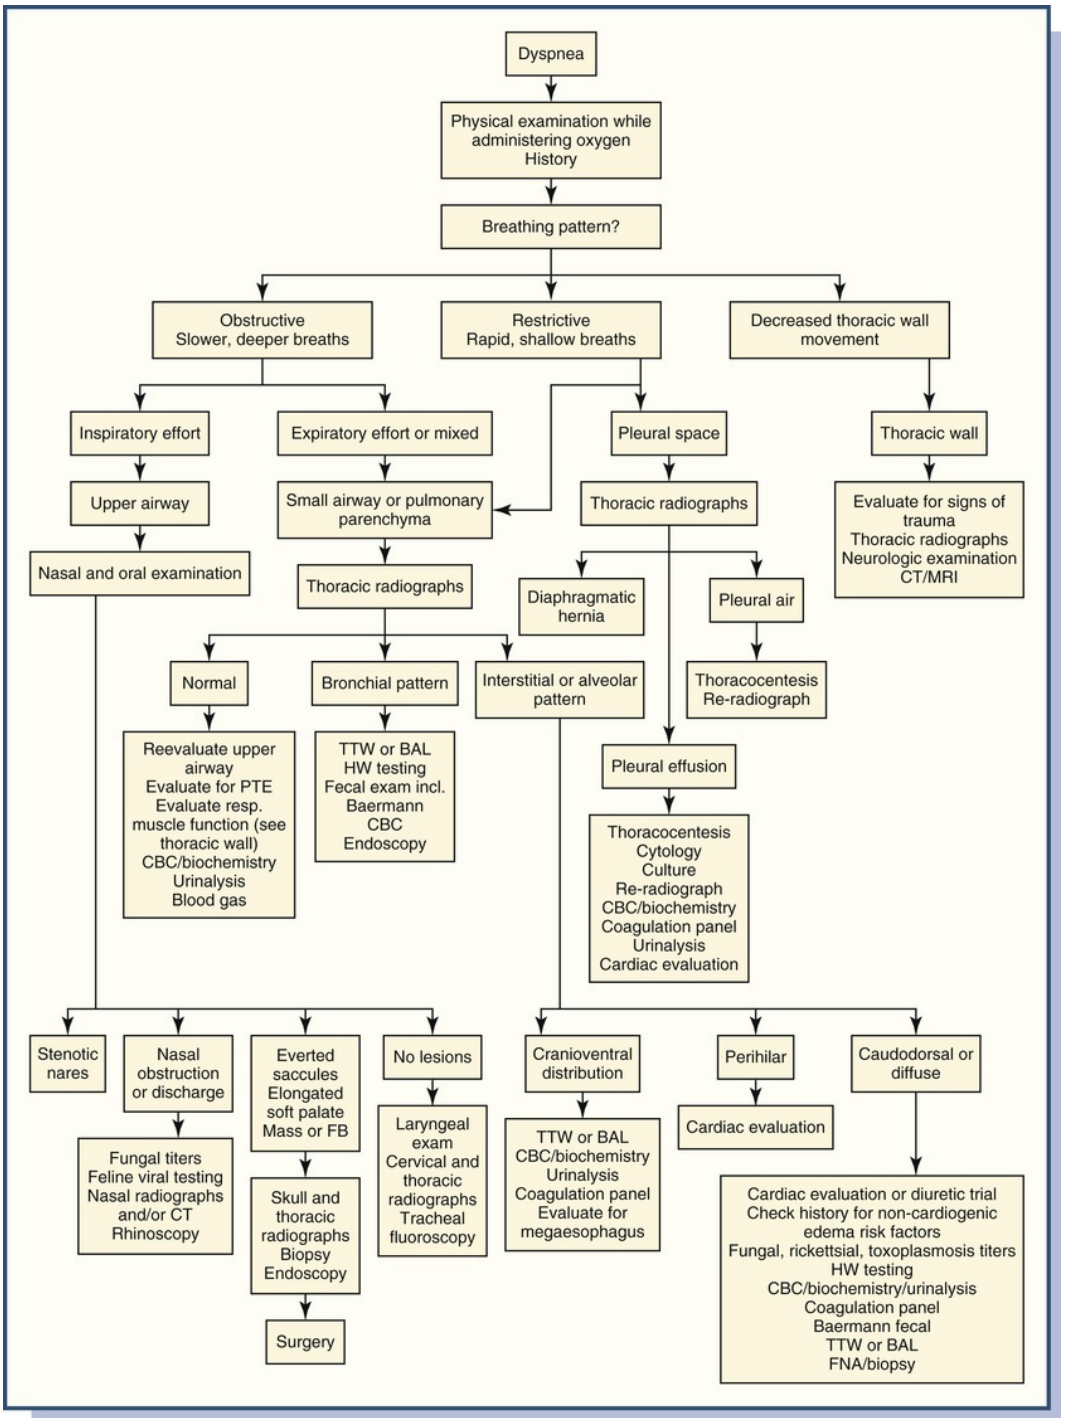

FIGURE 28-1 Algorithm for the approach to the dyspneic patient. *BAL,* Bronchoalveolar lavage; *FNA,* fine needle aspirate; *HW,* heartworm; *TTW,* transtracheal wash.

Markedly hypoxemic animals will appear panicked, often with elbows abducted, head and neck extended, nostrils flared, and with a glazed expression as they are focused on breathing. It is important to promptly recognize upper airway obstruction (exaggerated inspiratory effort with little to no air movement) as sedation and intubation are immediately necessary. Also important to recognize is the paradoxical breathing pattern, which indicates greatly increased work of breathing and respiratory muscle fatigue. During inspiration, the caudal intercostal muscles and ribs are noted to collapse inwards with diaphragmatic contraction and the abdomen is noted to move outward as the cranial abdominal contents are forced backwards (Video 28-3).[1] A thorax that is barrel-shaped or increased in size with expansion of the thoracic wall may indicate tension pneumothorax or marked pleural effusion. Two or more fractures of two or more adjacent ribs may result in flail chest, recognized as a segment of thoracic wall moving in during inspiration and out on expiration.

Some patients will require immediate therapy in addition to oxygen supplementation (see ch. 139). This may include sedation to reduce anxiety and work of breathing or to facilitate intubation. Opioids and benzodiazepines alone or in combination tend to be effective and have a good safety profile.[4] IV access is desirable as soon as safely possible. Cooling may be necessary as patients frequently become hyperthermic from the work of breathing. Techniques include using a fan, cool wet towels, cooled IV fluids, or ice packs in extreme cases. If airway obstruction or imminent respiratory arrest is anticipated, then endotracheal (ET) intubation should be performed. Suction of the ET tube can be helpful therapeutically and diagnostically. Manual or mechanical ventilation may then be instituted if necessary depending on blood gas analysis and work of breathing. If intubation cannot be achieved due to the presence of a physical obstruction, a tracheotomy may be necessary. A red rubber feeding tube or jugular catheter can sometimes be passed beyond the obstruction to deliver oxygen while preparing for a tracheotomy. If a restrictive breathing pattern is noted and either air or fluid is suspected in the pleural space based on auscultation, thoracocentesis should be performed and fluid samples saved for cytologic evaluation and microbial culture (see ch. 102). Readiness of the veterinary team with equipment, drug dosages, and personnel for all of the above are a key part of effective management.

Important Historical Information

Signalment can be very relevant for identifying breed and age predispositions. Examples include brachycephalic breeds like Bulldogs and brachycephalic syndrome (stenotic nares, hypoplastic trachea, elongated soft palate, everted laryngeal saccules), smaller breed dogs like Yorkshire Terriers and Pomeranians and collapsing trachea, older small breed dogs and congestive heart failure due to chronic mitral valve insufficiency (CMVI), older larger breed dogs and laryngeal paralysis, young patients and infectious diseases, West Highland White Terriers and pulmonary fibrosis, young to middle-aged cats and asthma, and middle-aged to older cats and pleural effusion.

Historical information of importance includes the duration and progression of clinical signs, and the presence of concurrent respiratory signs like coughing, wheezing, sneezing, snoring, nasal or ocular discharge, or change in bark or meow. Also of importance is the presence of other systemic signs that may point to involvement of other body systems (weakness, exercise intolerance, collapse, vomiting, regurgitation, seizures) or the presence of known pre-existing disorders (respiratory, cardiac, neuromuscular, metabolic, immune-mediated, inflammatory). Thorough questioning on possible exposure to trauma, toxins, allergens, smoke, other environmental conditions, other dogs, and ticks should be performed.

Complete Physical Examination

Complete and thorough physical examination remains the mainstay of accurate patient assessment and initial diagnosis. As mentioned above, of primary importance is noting the respiratory pattern, including rate, depth, and timing and degree of effort (see Figure 28-1).

During examination of the head, symmetry of the face and nose should be noted, because asymmetry may suggest space-occupying lesions or traumatic injuries. Ocular and nasal discharge may indicate an infectious process, and precautions to avoid spread to other patients +/- isolation protocols may be warranted. Stertor or stridor is indicative of upper airway obstruction (see below). Oral mucous membrane color provides an indication of oxygenation and crude perfusion (cyanosis, pallor). An oral exam for electrocution burn wounds, or obvious mass, foreign body (FB), or blood in the mouth or pharynx is warranted, though a complete exam may not be achievable until the patient is sedated. Light sedation is certainly necessary to properly examine laryngeal function (see Video 28-1). The neck should be palpated for signs of trauma or esophageal FB.

The thorax should be palpated for signs of trauma, rib fractures, or cardiac thrills. In cats, compressibility of the cranial thorax should be assessed, as lack thereof suggests the presence of a cranial thoracic or mediastinal mass. Thoracic auscultation is of central importance. The identification of murmurs, gallops, or arrhythmias on cardiac auscultation supports the presence of cardiac disease that may be responsible for respiratory distress. It is important to recognize, however, that the same geriatric small breed dogs that are predisposed to CMVI may also be predisposed to chronic bronchitis or collapsing trachea; therefore, the presence of a murmur does not automatically indicate the dyspnea is cardiac in origin. Displaced or muffled heart sounds may indicate the presence of a mass or diaphragmatic hernia. Pulmonary auscultation may reveal increased bronchovesicular (BV) sounds as a result of airway narrowing by constriction or secretions causing flow turbulence. Tracheal auscultation should be performed to determine whether the source of increased BV

sounds is indeed the lower airways or referred from the upper airway. Crackles or wheezes may be heard with lower airway disorders. Crackles or rales are discontinuous popping sounds resulting from air bubbling through fluid (not just cardiogenic edema) or from rapid opening of stiff airways. Wheezes are high-pitched continuous musical sounds indicating air movement through very narrowed airways. Decreased to absent lung sounds indicate the presence of something preventing transmission of lung sounds through the thoracic wall. If decreased ventrally, pleural effusion or a space-occupying mass may be present, whereas if decreased dorsally, pneumothorax may be present. Thoracic percussion would tend to yield dullness and increased resonance, respectively, with those two scenarios.

Abdominal palpation should be performed and may reveal discomfort or pain, ascites (suggesting cardiac disease or hypoproteinemia), or distension from aerophagia. Femoral pulse quality may reveal additional information referable to cardiovascular status.

It is important to recognize that in many cases, further diagnostics may not be immediately attainable for the safety of the patient. However, obtaining a good history and physical exam will go a long way in the diagnostic process. When procedures or diagnostics are eventually instituted, they are best done in an interrupted fashion to allow the patient to return to oxygen and to rest.

Localization

Upper Airway (see ch. 239 and 241)

The upper airway is composed of the nasal passages, pharynx, larynx, trachea, and mainstem bronchi. Patients with upper airway obstruction exhibit inspiratory dyspnea characterized by effort during a long inspiratory phase and slower respiratory rate. The exception is intrathoracic tracheal or bronchial collapse, which tends to cause expiratory dyspnea. Patients with upper airway disorders may have noisy stertor (snoring) if there is partial obstruction of the nasal passages or nasopharynx. Differential diagnoses in this case may include stenotic nares, nasal FB, neoplasia, rhinitis (infectious or inflammatory), or nasopharyngeal polyp. Dyspnea may be accompanied by stridor, a harsh high-pitched inspiratory sound, in the case of laryngeal or tracheal obstruction. Common differential diagnoses would include laryngeal paralysis, neoplasia, FB, brachycephalic syndrome, and tracheal collapse. Additional signs with upper respiratory obstruction may include choking, retching, pawing at the face, or a honking cough (in the case of tracheal collapse). Immediate therapeutic priorities in patients with upper airway obstruction include oxygen supplementation, sedation if anxious, ± cooling, ± intubation or tracheotomy, depending on severity. Occasionally, surgical intervention is needed urgently to address laryngeal paralysis, tracheal collapse, or other forms of upper airway obstruction.

Small Airway (see ch. 241)

The small airways include bronchi and bronchioles. Patients with small airway disease typically exhibit expiratory dyspnea, characterized by a shorter inspiratory phase and longer expiratory phase with effort or push, sometimes involving the abdomen. Increased BV sounds, wheezes, or crackles (inspiratory and/or expiratory) may be ausculted. Common differential diagnoses include feline asthma in cats, chronic bronchitis, allergic airway disease, smoke inhalation, and bronchopneumonia.

Pulmonary Parenchyma (see ch. 242)

Disease involving the alveolar ducts and alveoli, pulmonary interstitium, or pulmonary vasculature may result in mixed inspiratory or expiratory dyspnea. Alternatively, these patients may have a restrictive pattern with rapid and shallow breathing if the disease prevents the lungs from fully expanding. Increased BV sounds and often crackles are noted on auscultation. Differential diagnoses may include cardiogenic pulmonary edema, non-cardiogenic pulmonary edema (secondary to strangulation/upper airway obstruction, electrocution, head trauma, post-seizure, vasculitis), pneumonia (viral, bacterial, fungal), hemorrhage, neoplasia, parasitic disease, pulmonary thromboembolism, idiopathic pulmonary fibrosis, the acute respiratory distress syndrome, or pulmonary contusions (trauma). This extensive (yet still incomplete) list of differentials emphasizes the importance of identifying and considering other historical and physical exam data including history or evidence of cardiac disease, history of vomiting or regurgitation to suggest aspiration pneumonia, history of trauma, electrocution, heartworm status, and travel.

Pleural Space (see ch. 244)

Patients with pleural space disease typically have a restrictive breathing pattern characterized by rapid and shallow respirations due to an inability of the lungs to expand. As mentioned above, lung sounds tend to be muffled at least ventrally with pleural effusion and dorsally with pneumothorax. If air or fluid in the pleural spaced is suspected, thoracocentesis should be performed (see ch. 102). Differential diagnoses for pleural space disease include pneumothorax, pyothorax, hemothorax, chylothorax, masses, diaphragmatic hernia, and transudative pleural effusion due to a variety of causes including neoplastic disease, cardiac disease, lung lobe torsion, or hypoproteinemia. As mentioned above, a mass should be suspected in cats with a non-compressible cranial thorax.

Thoracic Wall (see ch. 245)

Patients with disorders of the thoracic wall tend to hypoventilate due to failure of the normal respiratory apparatus. They exhibit respiratory distress in the face of decreased thoracic wall movement, lacking intercostal, diaphragmatic, and abdominal assistance during respiration. They may or may not have signs of trauma. This pattern may be a result of neuromuscular disease (peripheral neuropathies, central disorders, spinal cord disease between C1-C4, phrenic innervation abnormalities) or trauma (rib fractures, flail chest, penetrating wounds). Therapy in these patients typically necessitates intubation and ventilation.

Further Diagnosis and Therapy

Appropriate diagnostic work-up based on this initial assessment is outlined in Figure 28-1. Diagnostics may include thoracic radiography, pleural fluid analysis and culture, oral and laryngeal exam, rhinoscopy, fluoroscopy for tracheal or bronchial collapse, transtracheal wash, bronchoscopy and lavage, computed tomography, and fine needle pulmonary or mass aspirates, among others. Therapy beyond that already described depends on physical examination and diagnostic results. If diagnostics are not available for some time due to stability of the patient, then empirical therapy for the common causes of respiratory distress is often administered, at least as single doses (furosemide for heart failure, bronchodilator and corticosteroid for feline asthma or chronic bronchitis), particularly when there is evidence to support these on history or physical exam.

CHAPTER 29

Epistaxis and Hemoptysis

Tim B. Hackett

Epistaxis

Epistaxis is hemorrhage from the nose due to a variety of etiologies (E-Box 29-1 and Figure 29-1). Knowledge of the animal's environment and signalment can assist in recognition of the source of hemorrhage. Trauma, intranasal transmissible venereal tumors (TVT), and parasitic, rickettsial, and fungal infections are more often seen in dogs and cats allowed outside. Foreign bodies are generally inhaled grasses observed in dogs allowed to roam. While rodenticide ingestion is also associated with roaming, it can also occur in pets kept indoors. Purebred dogs are more commonly affected with immune-mediated diseases, von Willebrand disease (vWD), or congenital coagulation factor deficiencies. Nasal tumors in dogs are more common in older, dolichocephalic animals. Nasopharyngeal polyps occur more often in young cats, while brachycephalic felines are more susceptible to chronic viral respiratory infections.

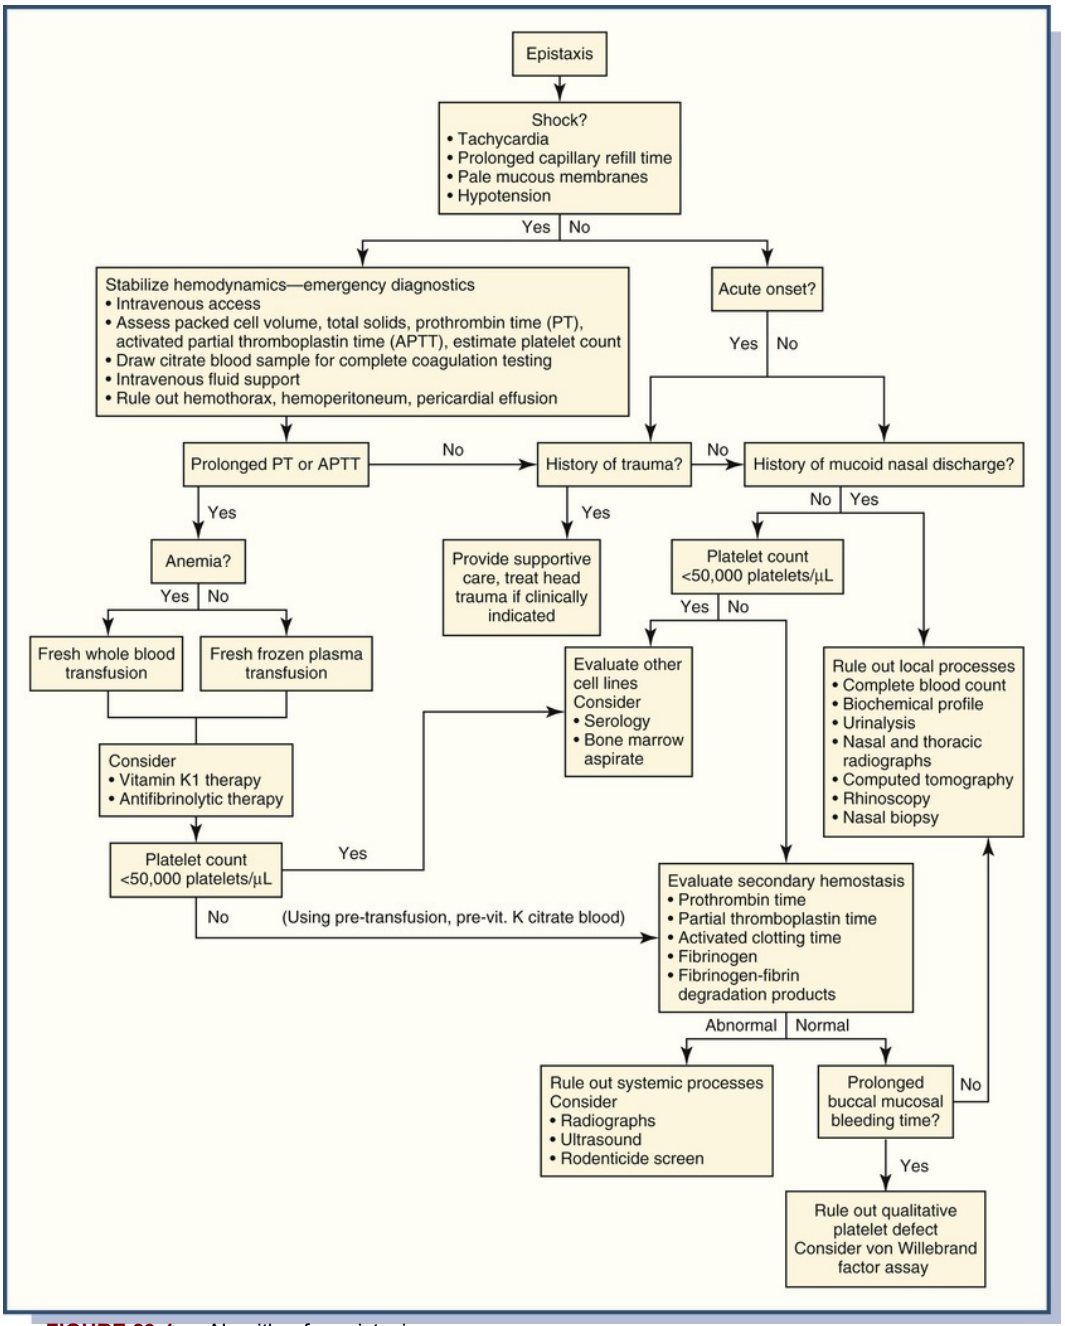

FIGURE 29-1 Algorithm for epistaxis.

E-Box 29-1

Causes of Epistaxis

Extranasal (Systemic) Causes of Epistaxis

Thrombocytopenia (quantitative platelet abnormality)

Decreased production

Infectious: Ehrlichiosis, feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), Rocky Mountain spotted fever, hepatozoonosis, septicemia, endotoxemia, leishmaniasis, *Bartonella* spp. infections

Drugs: Cytotoxic drugs, modified live virus vaccines, estrogens

Neoplasia: Myelophthisis secondary to myeloproliferative or lymphoproliferative diseases

Immune-mediated: Antibodies against megakaryocytes
Other: Bone marrow aplasia, cyclic thrombocytopenia, myelofibrosis, hyperestrogenism (secondary to Sertoli cell and granulosa cell tumors), myelodysplasia, toxins, osteosclerosis, idiopathic
Increased destruction
Immune-mediated: Idiopathic or secondary to drugs, neoplasia, infection
Microangiopathy: Shearing of platelets; associated with hemangiosarcoma
Sequestration
Neoplasia: Large vascular tumors
Splenomegaly or splenic torsion
Hepatomegaly
Increased consumption
Disseminated intravascular coagulopathy (DIC)
Vasculitis: Rocky Mountain spotted fever, endotoxemia, neoplasia, heartworm disease, bacteremia, *Bartonella* spp. infections
Hemorrhage-induced thrombocytopenia
Thrombocytopathia (qualitative platelet defect)
Congenital: von Willebrand disease (vWD), platelet procoagulant activity deficiency in German Shepherd Dogs, Glanzmann's thrombasthenia in Great Pyrenees, Basset Hound thrombopathia
Acquired: vWD (associated with hypothyroidism), uremia, dysproteinemia (associated with multiple myeloma, ehrlichiosis, leishmaniasis), drugs (NSAIDs)
Coagulation factor deficiency
Congenital: Hemophilia A and B, others
Acquired: Anticoagulant rodenticide intoxication, liver failure, DIC
Increased capillary fragility
Hypertension: Primary or secondary to chronic kidney disease, glomerulonephropathies, pheochromocytoma, hyperadrenocorticism, hyperthyroidism, heart disease
Hyperviscosity syndrome: Secondary to multiple myeloma, ehrlichiosis, erythrocytosis (primary or secondary to hypoxia or neoplasia), leukemias
Hyperlipidemia
Thromboembolic disease
Neoplasia invading blood vessels

Intranasal (Localized) Causes of Epistaxis

Trauma
Benign nasal polyps (cats)
Neoplasia
Epithelial: Adenocarcinoma, undifferentiated carcinoma, squamous cell carcinoma
Mesenchymal: Chondrosarcoma, fibrosarcoma, hemangiosarcoma, osteosarcoma, melanoma
Round cell: Lymphoma, transmissible venereal tumor, mast cell tumor
Infection
Fungal: *Cryptococcus, Aspergillus, Penicillium, Rhinosporidium, Exophiala jeanselmei*, phaeohyphomycosis
Parasitic: *Pneumonyssus, Eucoleus, Cuterebra, Linguatula, Capillaria*
Bacterial: Primary *(Bordetella, Pasteurella, Mycoplasma)* or secondary
Viral: Canine infectious tracheobronchitis, canine distemper, feline viral rhinotracheitis, calicivirus
Inflammation
Lymphoplasmacytic: Primary or secondary
Eosinophilic: Allergic rhinitis
Dental disease
Tooth root abscess
Oronasal fistula
Foreign body (FB)
Vascular malformation

A history of bleeding after elective neutering or minor trauma might indicate a congenital coagulation factor deficiency or platelet disorder. Epistaxis from foreign body inhalation is acute in onset and often accompanied by sneezing, agitation and pawing at the face. Foreign objects lodged in the nasal cavity for long periods of time are associated with a cellular and chronic nasal discharge. Patients on vitamin K antagonists

or platelet inhibitors should have those dosages reassessed, along with diet, and concurrent medications. Platelet dysfunction is seen with nonsteroidal anti-inflammatory drug (NSAID) administration. Immune-mediated platelet dysfunction is seen with vaccines and some drugs. Estrogens, phenylbutazone, and many cytotoxic chemotherapy agents can cause thrombocytopenia.

Nasal trauma results in acute-onset bleeding that resolves with supportive measures and does not recur. There are usually other signs of trauma and, due to the proximity of the brain, patients should be closely monitored for evidence of increased intracranial pressure or focal intracranial hemorrhage.

Seasonal epistaxis might be the result of allergic rhinitis. Low humidity, especially change from a humid to dry climate, can dry nasal mucous membranes and result in mild epistaxis. Recurring episodes of epistaxis are seen with oronasal fistulas, fungal and bacterial rhinitis, and nasal tumors. Travel to endemic areas for fungal and rickettsial organisms, such as ehrlichiosis, leishmaniasis, and hepatozoonosis, can help rank differential diagnoses and refine the diagnostic plan.

The initial physical examination should prioritize patient hemodynamics and tissue oxygenation. While emergency diagnostics are indicated to identify specific treatments, the possibility of significant hemorrhage should be assumed since it is difficult to know the volume of blood lost prior to presentation. The patient's heart rate, mucous membrane color, capillary refill time, pulse quality, and blood pressure should be assessed. Coagulopathic patients with epistaxis might also be bleeding into the lungs or other body cavities. Auscultation of the chest can identify intrapleural or intrapulmonary hemorrhage. Muffled heart sounds might indicate hemopericardium. Patients with petechiae, mucosal bleeding, melena, or fundic hemorrhage are likely to have a defect of primary hemostasis (platelets), whereas those with hemarthrosis, hematomas, or bleeding into the chest, lungs, or abdomen are likely to have a defect of secondary hemostasis (coagulation factors).

With any evidence of hypovolemia, vascular access should begin with a peripheral intravenous catheter or intraosseous system (see ch. 75-77). Before beginning fluids, blood samples should be collected for coagulation testing, packed cell volume, complete blood count, blood type, and biochemical profile. Rapid restoration of vascular volume should begin while awaiting results.

Anemic patients showing signs of shock should receive a transfusion of red blood cells. See ch. 130 and 198. Patients with prolonged clotting times should receive a unit of fresh frozen plasma or fresh whole blood. Plasma is always indicated in the presence of clinically significant hemorrhage and an abnormal coagulation profile. The decision to use whole blood should be guided by available component blood products and the need for red blood cells. Blood loss can be minimized by anesthetizing the patient, protecting the airway with a cuffed endotracheal tube, and occluding the nares and oropharynx with appropriately sized Foley catheters to create tamponade (Video 29-1). Arterial embolization with interventional radiology techniques is a viable treatment for intractable epistaxis.[1]

When the patient is stable, inspect the nares and regions above the nasal sinus. Holding a few strands of cotton or a glass slide in front of the nose can assess nasal patency and airflow. Many intranasal diseases, such as nasal tumors, begin with unilateral epistaxis that can become bilateral as the disease progresses and the nasal septum is disrupted. Although bilateral epistaxis might indicate "extranasal" causes such as coagulopathies, hypertension, thrombocytopenia, and thrombocytopathia (a defect in platelet function), this does not always occur.

Ulceration and depigmentation of the nasal planum can be seen with immune-mediated disease, fungal infections, or neoplasia. Asymmetry of the nose is most often associated with neoplasia. Cats with nasal cryptococcosis often have a convexity of the nose referred to as "Roman nose." Polypoid masses extending from the nares are seen with rhinosporidiosis and cryptococcosis.

Careful examination of the mouth for severe dental disease, oronasal fistulas, loose teeth, palate deformity, or masses should be performed. In addition to facial deformities, nasal tumors can extend in other directions, causing hard palate deformity. A fundic examination (see ch. 11) might reveal chorioretinitis with systemic inflammatory diseases, or signs of hypertensive retinopathy such as retinal hemorrhage or retinal edema and detachment (especially in cats). Nasal masses can make retropulsing the globe difficult and can cause epiphora. Regional lymph nodes should be examined and potentially aspirated looking for reactivity, infectious organisms, or metastatic neoplasia. Melena and hematemesis can occur when blood from the nasopharynx is swallowed. Central nervous system (CNS) dysfunction might occur with hyperviscosity syndromes or nasal tumors invading the brain.

Intranasal processes are the most common cause of epistaxis, with nasal tumors the most common cause of epistaxis in older pets. Animals with severe dental disease and/or oronasal fistulas can have nasal discharge or epistaxis. Much less commonly, arteriovenous malformations can rupture, causing severe, acute epistaxis. Primary bacterial rhinitis is uncommon, but usually involves agents ubiquitous to the respiratory tract like

Bordetella, Pasteurella, and *Mycoplasma* spp. Aspergillosis in dogs and nasal cryptococcosis in cats are the most common fungal causes of epistaxis. Cats with upper respiratory infections can develop sneezing, chronic nasal discharge, mucosal damage, and intermittent epistaxis.

Systemic causes of epistaxis most often involve clotting disorders. Primary hemostatic defects (platelet plug formation) include thrombocytopenia or thrombocytopathia. Decreased platelet production, abnormal destruction, sequestration, and increased consumption will lower platelet numbers. Mild, moderate and severe clinical hemorrhage is possible with platelet counts less than 25,000 platelets/mcL, 10,000 platelets/mcL, and 5,000 platelets/mcL, respectively.[2] Spontaneous bleeding is uncommon with platelet counts over 50,000/mcL. Decreased production of platelets occurs secondary to infections, myelophthisic neoplasia, drug reactions, or immune-mediated disorders. Increased destruction of platelets can be immune-mediated or related to microangiopathic changes observed with diseases such as hemangiosarcoma. Sequestration of platelets in the spleen, liver, large vascular tumors, or following rattlesnake envenomation results in a circulating thrombocytopenia. Increased platelet consumption is seen with disseminated intravascular coagulopathy (DIC), vasculitis, and hemorrhage. von Willebrand's disease is the most common cause of primary thrombocytopathia. Secondary thrombocyopathias are more common than hereditary diseases and can occur with NSAID administration, neoplasia, DIC, liver disease, and dysproteinemias such as those seen with ehrlichiosis. Thrombocytopathia can occur with end-stage renal disease due to uremic toxins.[3]

Hemophilia A and B are uncommon congenital coagulopathies that vary in severity. Acquired coagulopathies affecting clotting factors include anticoagulant rodenticide intoxication and decreased coagulation factor production secondary to hepatic failure. Another, less common, systemic cause of epistaxis is increased capillary fragility resulting from hypertension, invasive neoplasia, hyperviscosity syndromes, hyperlipidemia, and thromboembolic disease.

Regenerative anemia indicates a bone marrow response to blood loss. It can take a few days to complete the normal regenerative response to blood loss, making acute hemorrhage appear non-regenerative. A non-regenerative, iron deficiency anemia can also be seen with chronic epistaxis. Schistocytes can be observed with microangiopathic diseases such as hemangiosarcoma and DIC. Leukocytosis occurs with chronic inflammation, infection, or a regenerative marrow response to blood loss. Leukopenia is seen with chronic ehrlichiosis, cytotoxic drug administration, sepsis, and infections such as *Salmonella* and canine parvoviral enteritis. Thrombocytopenia is the result of increased destruction, decreased production, consumption, or sequestration of platelets. A blood smear can assess platelet numbers.

Thrombocytopathia should be investigated if platelet numbers are above 100,000/mcL. Buccal mucosal bleeding time (BMBT) is a useful in-hospital screening test of platelet function (see ch. 80). When abnormal, specific tests such as a von Willebrand's titer are indicated. Coagulation studies, such as partial thromboplastin time (PTT), prothrombin time (PT), and activated clotting time (ACT), should be performed in cases of epistaxis in which thrombocytopathia and severe thrombocytopenia (<10,000/mcL) have been ruled out. If abnormal, a factor-deficiency coagulopathy should be assumed (see ch. 196-197). Further investigation into the cause of the coagulation defect includes testing for anticoagulant rodenticides, evaluation of hepatic and post-hepatic conditions affecting vitamin K production, and testing for specific factor deficiencies. Additional tests for consumptive coagulopathies might include fibrinogen, fibrin degradation products (FDPs), and antithrombin III concentration. Thromboelastography evaluates the efficiency of blood coagulation and can assess factors, such as platelet function, clot strength, and fibrinolysis, that PT, APTT, and ACT tests cannot.[4]

Panhypoproteinemia might develop with chronic blood loss. Hyperglobulinemia is associated with neoplasia or chronic infections. Serum protein electrophoresis can assist in distinguishing between monoclonal or polyclonal gammopathy. Monoclonal gammopathies occur with multiple myeloma, chronic ehrlichiosis, lymphoma, leukemias, and macroglobulinemia. Azotemia is usually seen with uremia-associated vasculitis. Hepatic dysfunction can lead to decreased production of clotting factors and might be evidenced by increased bilirubin and hepatocellular enzymes, or decreased albumin and glucose.

Rickettsial causes of thrombocytopenia, such as ehrlichiosis and Rocky Mountain spotted fever, are diagnosed with serology. *Aspergillus* spp. titers indicate exposure, but correlate poorly with active infection. Latex agglutination tests for *Cryptococcus* spp. capsular antigen are useful for diagnosis and therapeutic monitoring. Feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) tests are indicated in cats with systemic illness.

The goal of imaging in epistaxis is to localize the disease, determine the severity, and guide biopsy procedures. Imaging studies should be performed prior to rhinoscopy and probing bad teeth or oronasal fistulas. Anything causing iatrogenic hemorrhage might complicate interpretation of the images. Nasal

radiographs should include lateral, oblique, open-mouth, ventrodorsal, intraoral, and frontal sinus views. Computed tomography (CT) is superior to radiographs for nasal disease because it allows visualization of bony and soft tissue lesions and it images all areas including turbinates, nasal septum, cribriform plate, and sinuses. Imaging studies should be examined for asymmetry and bone lysis. Contrast enhancement can distinguish tumors from an abscess or mucus accumulation.

Rhinoscopy is performed after coagulopathy has been ruled out with the animal anesthetized and intubated with a cuffed endotracheal tube to prevent aspiration of blood. With the animal in sternal recumbency, the least-affected side is examined first. Thorough evaluation of the oropharynx and oral cavity should be performed. Rigid arthroscopes are the most useful for visualizing the rostral nasal passages. The distance from the medial canthus to the end of the nostril should be marked on the instrument prior to entry into the nose to avoid penetration of the cribriform plate. An otoscope could also be used to view the rostral nasal passages, especially in cases with a foreign body or large tumor. A flexible bronchoscope is best suited to visualize the caudal nasal cavity and nasopharynx. If a rigid scope is used, a spay hook can be employed to retract the soft palate so that structures in the nasopharynx can be viewed with a dental mirror and light source. The entire nasal cavity should be examined for masses, foreign bodies, polyps, and fungal or inflammatory plaques.

Nasal swabs are limited in their utility. The presence of bacteria and even fungal hyphae is not definitive evidence of a primary infectious process. Culture of rostral nasal secretions also has limited value. *Cryptococcus* infections can be diagnosed cytologically using standard stains or India ink because of their characteristic thick, non-staining capsule. Before flushing the nasal cavity or taking biopsies, the cuff of the endotracheal tube should be checked and the oropharynx packed with gauze sponges. Ventroflexing the head and neck and working from below the level of the nose, lavage fluid and blood will come out the nose and mouth protecting the airway. Saline can be flushed through the nares using the rigid scope, a feeding tube, or catheter attached to a large syringe. The liquid recovered should be collected and examined for foreign bodies, accumulations of cellular debris, and even abnormal tissue and parasitic ova. Fluids can also be flushed from the nasopharynx through the nasal passages with a flexible endoscope or large feeding tube. Multiple biopsies should be obtained from suspicious areas identified on rhinoscopy. Complications of rhinoscopy and nasal biopsy include severe hemorrhage, aspiration of blood, and neurologic signs if the rostral brain is damaged.

Primary bacterial rhinitis is rare, but secondary infection is common. Antibiotic treatment might improve clinical signs by resolving secondary infections. If the primary disease is not addressed, it will likely recur. Deep tissue cultures are the most likely to yield primary pathogens in cases with bacterial infection. If a foreign body is too large to remove or if rhinoscopy, flushing, and biopsies fail to aid in diagnosis, exploratory rhinotomy should be considered.

Hemoptysis

Hemoptysis (from Greek *hamia,* "blood" + *ptysis,* "spitting") is the expectoration of blood or bloody mucus from the respiratory tract at or below the larynx (E-Box 29-2). As with epistaxis, environment and signalment can indicate the source of hemorrhage. Animals that roam are susceptible to trauma, rodenticide intoxication, inhalation, and parasitic, rickettsial, and fungal infections. Young animals might be inclined to chew electric cords or play with small objects that could occlude their airway. Older pets are more likely to suffer from mitral insufficiency and primary lung or metastatic neoplasia. Furthermore, fungal and heartworm disease have endemic regions where animals are more likely to be affected.

E-Box 29-2

Causes of Hemoptysis

Pulmonary

Non-cardiogenic pulmonary edema or acute respiratory distress syndrome: Secondary to systemic inflammatory processes and multiple organ failure, airway obstruction, strangulation, electrocution, near drowning, or seizures.

Pulmonary thromboembolism: Secondary to neoplastic, endocrine, cardiac, metabolic disease

Pulmonary hypertension: Secondary to heartworm disease, congenital or acquired cardiac defects that result in shunting of blood

Chronic bronchitis/bronchiectasis
Bacterial and fungal pneumonia
Pulmonary abscess
Canine kennel cough complex:
Viral causes: Canine adenovirus 1 and 2; canine parainfluenza virus; canine respiratory coronavirus; canine reovirus; canine herpesvirus-1; canine influenza virus
Bacterial causes: *Bordetella bronchiseptica; Mycoplasma* spp.
Parasites: *Paragonimus kellicotti, Eucoleus aerophilus* (formerly *Capillaria aerophila*), *Aelurostrongylus abstrusus*
Pulmonary infiltrate with eosinophils (eosinophilic bronchopneumopathy)
Neoplasia: lung: Primary adenocarcinoma, undifferentiated carcinoma, squamous cell carcinoma, chondrosarcoma; metastatic; primary tracheal tumors
Lung lobe torsion

Cardiovascular

Cardiogenic pulmonary edema
Heartworm disease
Arteriovenous fistula
Bacterial endocarditis

Systemic

Coagulopathies: Primary (quantitative or qualitative platelet defects) or secondary hemostatic (factor deficiencies, anticoagulant rodenticide intoxication, disseminated intravascular coagulopathy), abnormalities
Trauma: Pulmonary contusion, tracheal rupture, foreign body
Iatrogenic: Endotracheal intubation, complication of lung biopsy/aspirate, transtracheal wash, or bronchoscopy

Information regarding cardiac and pulmonary abnormalities, medications (including heartworm preventative), toxin exposure, and travel history are essential. Owners should be questioned about the pet's history of exercise intolerance, dyspnea, syncope, and cough. They should be asked about recent trips to a groomer or other potentially stressful events that could trigger non-cardiogenic edema. Since hematemesis can be confused with hemoptysis, a careful history of gastrointestinal problems might be necessary. Recent surgery, trauma, or systemic disease can predispose patients to pulmonary thromboembolism. Prior bleeding episodes suggest coagulopathy. Animals with a history of cough prior to onset of hemoptysis might have chronic disease, such as bronchitis, neoplasia, heartworm disease, or left-sided heart failure. If blood is mixed with inflammatory sputum, more suppurative problems, such as bronchopneumonia or chronic bronchitis, are likely. Pulmonary edema fluid is usually bloody, with a more frothy character, while bright red blood is likely to be active arterial hemorrhage.

As with epistaxis, the initial physical examination should prioritize patient hemodynamics and oxygenation. Small amounts of blood in the lower airways can cause ventilation/perfusion mismatch and significant hypoxemia. Supplemental oxygen is usually indicated especially if mucous membrane color is pale, gray, or cyanotic. If oxygen by face mask, nasal cannula, oxygen hood, or oxygen cage is not sufficient, the patient can be intubated and mechanically ventilated. Hemoptysis secondary to thoracic trauma is indicative of pulmonary contusions. Contusions are best managed with cautious fluid therapy and attention to coagulation function. Auscultation of the airways might reveal fixed stridor over the region of an airway foreign body. Dynamic stridor over the larynx, more pronounced on inspiration, is common with severe laryngeal paralysis. Auscultation of the chest might reveal a regurgitant murmur with mitral insufficiency, moist crackles with pulmonary edema, or a fluid line with pleural effusion.

Vascular access should be established, though fluid therapy should approached cautiously. Pre-treatment blood samples should be collected for coagulation testing, packed cell volume, complete blood count, and biochemical profile. Specific treatment for left-sided heart failure should be instituted if the patient is severely volume overloaded. Diuretics should be used with caution in hypotensive or hypovolemic patients.

Pulmonary edema, secondary to either left heart failure or non-cardiogenic causes, can result in expectoration of blood and pink froth. Non-cardiogenic pulmonary edema is associated with a variety of acutely stressful events, including electrocution, near drowning, airway obstruction (inhaled foreign bodies, strangulation, laryngeal paralysis), and seizures.[5] Platelet defects are less likely to cause hemoptysis, though acquired coagulopathies, like anticoagulant rodenticide intoxication, can present with hemoptysis.

Heartworm disease can cause hemoptysis in dogs and cats. In dogs, exercise after adulticide therapy can result in worm embolization, inflammation of the pulmonary vasculature and parenchyma, and hemoptysis. Parasites, including *Capillaria, Aelurostrongylus,* and *Paragonimus* spp., cause pulmonary lesions that can bleed into airways. Chronic bronchitis (including feline asthma), bronchiectasis, and pulmonary infiltrate with eosinophils (PIE, eosinophilic bronchopneumopathy) can inflame the mucosa, causing bleeding during coughing. Infiltrative bacterial and fungal (*Blastomyces, Histoplasma, Coccidioides* spp.) pneumonia, lung abscesses and invasive neoplasia can all result in hemoptysis. Less common causes of hemoptysis include pulmonary thromboembolism, pulmonary hypertension, ruptured arteriovenous malformations, bacterial endocarditis, and lung lobe torsions.

In addition to the minimum database above, evaluation for systemic disease should include arterial blood gas analysis, urinalysis and three-view thoracic radiographs. The blood gas can help identify hypoxemia and hypoventilation that might require aggressive oxygen support and mechanical ventilation. Proteinuria or a fixed urine specific gravity could suggest renal or endocrine causes of pulmonary thromboembolism. Thoracic radiographs should be carefully evaluated for evidence of cardiac enlargement, pulmonary vascular congestion, pulmonary edema, traumatic rib fractures and contusions, pleural effusion, pneumonia, primary or metastatic neoplasia, foreign objects, and evidence of heartworm disease. If radiographs localize bleeding to one lobe, the patient should be positioned with that side dependent. A heartworm serology should be performed in dogs and cats from endemic areas. An echocardiogram can help characterize cardiogenic pulmonary edema and diagnose pulmonary hypertension. Parenchymal lesions in the lung can require the additional detail of a CT or MRI scan of the thorax.

Pulmonary edema, arterial hemorrhage from an invasive lesion, and traumatic pulmonary contusions are the most serious causes of hemoptysis. Sedation and supplemental oxygen after treating the cause of non-cardiogenic edema is usually sufficient. Cardiogenic edema can be managed with diuretics alone, though severe cases might require additional support (see ch. 242, 243, and 247). Traumatic pulmonary contusions present a therapeutic challenge, as aggressive fluid therapy might exacerbate bleeding. Careful attention to blood pressure, patient temperature, calcium, and pH will help identify other treatable causes of bleeding in the trauma patient. Fortunately, most other causes of hemoptysis are self-limiting with mild sedation and cage rest.

CHAPTER 30

Syncope

Mike Martin

Client Information Sheet: Understanding the Causes of Faints and Fits in Animals

Collapse is a broad, generic term, defined as a sudden loss of postural tone, not necessarily with a loss of consciousness; it may be of any duration. *Syncope* is a subset of collapse that involves a transient loss of consciousness, resulting from insufficient blood flow to the brain. There is an associated reduction in delivery of oxygen and nutrients, which is of short duration and is followed by a recovery to normal.[1] A partial loss of consciousness can result in a brief period of ataxia or stumbling, which is termed *pre-syncope*. It is of paramount importance to differentiate syncope from non-syncopal causes of collapse, particularly neurological causes such as epileptic seizures (also see ch. 35).

The diagnostic rate for animals that present with collapse has been reported as 67% in one study of 743 dogs,[2] which is relatively high, as many animals have abnormalities on physical examination or diagnostic tests that lead to a diagnosis. In this study, there were 153 dogs with undiagnosed collapse of which 42% resolved, 23% continued to collapse, 24% died and 11% were subsequently diagnosed.[2]

If an animal presents in a state of collapse, the opportunity for a physical examination, with a logical approach, during the episode may allow the affected body system to be determined. However, when the animal presents with a history of syncope or non-syncopal collapse and walks into the clinic without clinical signs, then a diagnosis is challenging. In one study of human subjects, the mechanism of syncope remained unexplained in 40% of cases.[3] Additionally, differentiation from an epileptic seizure is difficult; it is estimated that 20% of human patients presenting to a neurology department are subsequently diagnosed with cardiogenic syncope,[4] which is likely to be similar in veterinary medicine.

Mechanisms and Causes of Syncope

It is important to understand the pathophysiological mechanism of syncope so that the relative significance of abnormalities on diagnostic findings is understood and used for directing appropriate treatment (Figure 30-1). Since syncope, by definition, is associated with a transient reduction in blood flow to the brain, then cardiogenic disorders dominate, as a consequence of hypotension associated with cardiac arrhythmias or neurocardiogenic reflexes. It is only by reaching a diagnosis that appropriate treatment can be provided. For example, it may be that patients with intermittent bradyarrhythmias might need pacemaker implantation or those with tachyarrhythmias may require antiarrhythmic therapy.[5]

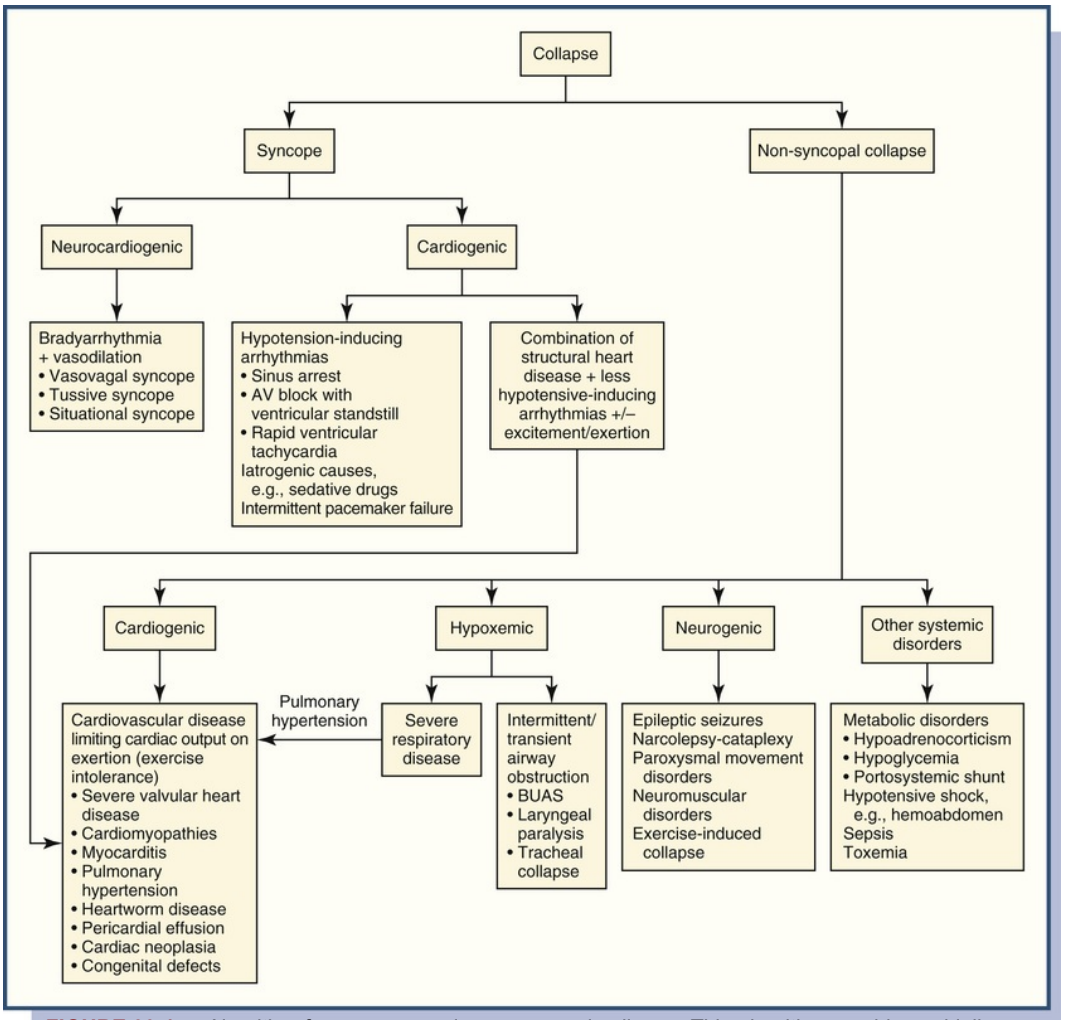

FIGURE 30-1 Algorithm for syncope and non-syncopal collapse. This algorithm provides guidelines for managing animals presenting with syncope and non-syncopal collapse, with the aims of assisting the veterinarian in how to approach this type of case. *BUAS*, Brachycephalic upper airway syndrome.

Cardiogenic Syncope

Cardiogenic syncope occurs when there is intermittent, profound hypotension that results in a marked reduction in blood flow to the brain. It is estimated that blood pressure has to fall by at least 50% before unconsciousness develops,[6] and blood pressure is usually much lower than this during syncope.[7] Therefore, for any arrhythmia to result in this degree of systemic arterial hypotension, it has to be profound and sustained. This requires an arrhythmia that results in asystole, such as sinus arrest or ventricular standstill, or a marked reduction in cardiac output, such as rapid ventricular tachycardia (VT). See ch. 248. Additionally, the duration of a sustained arrhythmia that causes sufficient hypotension to induce syncope has to be a minimum of 10-30 seconds, depending upon the activity level (metabolic demand) of the animal and the presence or absence of structural heart disease.

The most common arrhythmias that cause sufficient hypotension to result in syncope are bradyarrhythmias that result in asystole (for which a pacemaker might be indicated), such as sinus arrest (which might be part of sinus node dysfunction/sick sinus syndrome) or high-grade second-degree, or third-degree, atrioventricular block with periods of ventricular standstill; or tachyarrhythmias that have a marked effect on stroke volume, such as rapid VT (see ch. 248).[8-12] Atrioventricular block is usually evident at the time of examination, although rarely it can occur intermittently, particularly in cats with cardiomyopathy.[13] Sinus arrest or ventricular tachycardia can be intermittent and might only be detected on Holter or cardiac event recordings (Videos 30-1 and 30-3). Ventricular tachycardia does not always produce syncope, although at higher rates there will usually be a degree of hypotension, and it tends to be the more rapid VT that is

associated with syncope. If an arrhythmia is diagnosed, this should prompt further investigations to determine if there is an underlying cause of the arrhythmia such as cardiomyopathy, myocarditis, neoplasia, systemic or metabolic disorders, sepsis, toxemia, shock, or drug-related causes (see ch. 248). In animals fitted with pacemakers, checking for intermittent pacing failure such as lead displacement or high pacing thresholds needs consideration (see ch. 249).

Arrhythmias that produce a lesser degree of hypotension tend to result in episodic weakness rather than syncope. Such arrhythmias might include less-rapid VT or supraventricular tachycardia, or less profound bradyarrhythmias. However, the combination of structural heart disease or pulmonary hypertension (which is severe enough to limit cardiac output) with the addition of these arrhythmias, can result in syncope, particularly following excitement or exertion.[14] Importantly, there are several structural cardiac diseases that are known to be associated with a high incidence of arrhythmia, such as the various cardiomyopathies and myocarditis. Echocardiography is therefore always indicated in animals with syncope.

Neurocardiogenic Syncope

There are many synonyms that describe this type of disorder, including vasovagal syncope and vasodepressor syncope. Neurocardiogenic syncope occurs due to profound hypotension caused by the combination of a profound bradyarrhythmia and reflex vasodilation. It is characterized by sudden autonomic nervous system failure: there is withdrawal of sympathetic tone with abrupt increase in vagal tone,[15] although the exact mechanism remains unclear.[16] The triggering events are variable and determined by which afferent nerve or receptor is stimulated.[17]

Vasovagal syncope is probably the most well-known form of neurocardiogenic syncope in small animals, particularly in young Boxer dogs[2]; the trigger is usually intense excitement such as greeting the owner or play activity, resulting in triggering the neurocardiogenic reflex described above, and syncope. Vasovagal syncope also seems to be exacerbated by concurrent gastrointestinal or abdominal conditions, and syncope may resolve when the abdominal disorder resolves.[18] The presence of structural heart disease such as aortic stenosis or hypertrophic obstructive cardiomyopathy can exacerbate high left ventricular pressures, stimulating ventricular pressure receptors and triggering this neurocardiogenic reflex; this is termed the *Bezold-Jarisch reflex*.[19] This reflex originates in cardiac sensory receptors with non-myelinated vagal afferent C fibers in the left ventricle. When the receptors are stimulated by increased left ventricular pressure, the increased pressure is perceived as hypertension; reflex vasodilation, bradycardia, and syncope result. This reflex is also triggered in animals suffering rapid, severe hemorrhage; vigorous contraction of the left ventricle around a volume-depleted ventricular chamber produces a paradoxical increase in firing of these receptors, resulting in a reflex bradycardia and vasodilation.[19]

It is also well-known that some small breed dogs with degenerative mitral valve disease can present with syncope. The mechanism of the syncope in this setting remains unclear, but includes vasovagal syncope, arrhythmias, and pulmonary hypertension.[20] Situational syncope occurs when the neurocardiogenic reflex is triggered by activities such as coughing (tussive syncope),[21] vomiting, sneezing, micturition, defecating,[22] swallowing, or visceral pain.[1,23] Tussive syncope is common in dogs with either cardiac or respiratory disease; the mechanism remains unclear but may be associated with an increase in intrathoracic pressure during coughing inhibiting venous return or possibly a neurocardiogenic reflex vasodepressor-bradycardia response to cough.[21]

Non-Syncopal Collapse

It is difficult to differentiate syncope from the many causes of non-syncopal collapse that are not in association with a reduction in blood flow to the brain. Conditions to consider would include neurological conditions such as epileptic seizures (ch. 35), narcolepsy (ch. 262), paroxysmal movement disorders (ch. 31), neuromuscular disease (ch. 269) or exercise-induced collapse (EIC).[4,26] Animals with profound hypoxemia, such as those with severe respiratory disease, pulmonary hypertension, or transient upper airway obstructive conditions, can present with intermittent collapse particularly following excitement or exertion.[24-26] Coughing, common with respiratory conditions, can also lead to tussive syncope.[27]

History-Taking

When an animal is presented for evaluation of collapse, it can be very difficult to determine the type of collapse and to differentiate between cardiogenic syncope and seizures. Owners often will recall events in an array of descriptions, misleading analogies, or misunderstood terminology. It is critical that the clinician use analytical questioning to obtain as good an original description of the collapse as possible; this, therefore, also has to be from the person who witnessed the collapse. Differentiation between syncope and non-syncopal collapse is often difficult and therefore keeping an open mind to all causes of transient collapse is prudent. History-taking for collapse is a particularly difficult and challenging task for the clinician, which requires considerable time and experience. Obtaining movies of the animal during a collapse can be invaluable in these situations.

Determining if an animal was unconscious or not, from an owner, is difficult. Additionally, "unconscious" is a symptom, as opposed to a clinical sign. A client is usually unaware that the eyes often remain open when unconscious (or even dead) and this can be misinterpreted as being conscious (their pet was "staring at them"). It is more appropriate to ask questions around how responsive their animal was: did the pet react or move in response to touch or calling? Loss of bladder and/or bowel control with urination or defecation is not only seen with epileptic seizures but can also be seen with cardiogenic syncope (Video 30-2). Animals with cardiogenic syncope are often motionless (sleep-like) with flaccid limb and body tone. However, some that are partially unconscious can flail the limbs (as if struggling to get up), such that this can mimic epileptic seizures; detailed questioning is therefore needed to differentiate semi-conscious "leg-flailing" from repetitive paddling (swimming) movement of the limbs (more suggestive of epileptic seizures). Additionally, dogs with cardiogenic syncope that is prolonged or severe can develop profound cerebral hypoxia which results in a brief period of opisthotonos (forelimbs extended and stiff, with the head and neck extended dorsally), which seems to be uncommon with epileptic seizures (Videos 30-2 and 30-3). Epileptic seizures often are characterized by jaw chopping or chattering of the teeth, and salivation, followed by exhaustion on recovery due to the "exercise" that occurs with an epileptic seizure. Syncope may have a trigger event such as excitement or the onset of exercise, whereas epileptic seizures usually occur at rest or from sleep with no specific trigger, often have a pre-ictal period of anxiety or odd behavior, and also can be associated with facial muscle twitching. Cats can have cardiogenic syncope that mimics brief focal seizures.[28,29] Cardiogenic syncope typically is short in duration and the animal should generally return to normal within a few seconds to up to a minute, although it can be difficult for an owner to reliably recall the duration of time when in a panic. Epileptic seizures can be followed by a post-ictal period of up to hours where the animal may be confused, anxious, or display localizing neurologic signs.

Diagnostic Approach

If abnormalities are found on physical examination, these might identify the body system requiring further investigation. If there is no abnormality found on physical examination, then a meticulous history becomes the most important part of the assessment.

Comprehensive blood work is important (complete blood count and serum biochemistry profile including serum electrolyte and fasted glucose concentrations, and thyroid status); if hemorrhage is suspected, repeated blood tests may be necessary 12-24 hours later to reveal evidence of blood loss. If hypoadrenocorticism is suspected, an adrenocorticotropic hormone stimulation test should be performed.

An electrocardiogram (ECG) is usually indicated, certainly if an arrhythmia is present on physical examination. However, the ECG ideally needs to be performed when the syncopal event occurs, thus documenting if an intermittent arrhythmia was the cause of the syncope or not. Additionally, it is also important to rule out an arrhythmia prior to considering general anesthesia for additional diagnostic investigations such as magnetic resonance imaging of the brain. For these reasons, Holter monitoring has become a key diagnostic test in syncopal animals. It is important when using a Holter monitor that the timing of the event is accurately and reliably recorded, and this is really only reliably achieved by asking the client to press the "event button" on the Holter monitor. Pressing the button at both the start and end of the syncopal event can sometimes be useful (ch. 103). Many animals may not have a syncopal event while the Holter monitor is being worn, so attempts to induce syncope can be encouraged, in view of the importance of reaching a diagnosis so that the correct treatment can be chosen (provided such attempts do not pose undue risk to the patient). From the history, it should be determined if there is a trigger for the syncope, and while this may not be common, if there is, then this behavior or routine can be encouraged in moderation during the Holter recording, once the animal's owner understands the risk to benefit ratio of such an approach and provides informed consent. Holter monitoring typically continues for 24 hours for an arrhythmia count; however, in animals with syncope, the Holter ideally needs to be worn until there is an episode of collapse;

this can take several days, or potentially longer, depending upon the frequency of syncope. In such cases, an external cardiac event recorder also can be a viable option.[9] The limits of duration revolve around what the animal will tolerate, the capacity of the memory card, and battery life. For the majority of cases, the Holter monitor can be worn for 5-7 days. Even if the animal does not collapse within that time, there can be periods of arrhythmia that might be suggestive of the underlying mechanism of syncope.

Insertable loop recorders are implantable event devices that can be placed surgically.[30] Although they are not commonly used in veterinary practice, they provide an alternative option for animals that do not have a syncopal event during Holter monitoring but an arrhythmia is still suspected or important to rule out.

In the majority of cases, echocardiography is indicated to screen for structural heart disease, or for conditions that might be associated with arrhythmias, such as cardiomyopathy (ch. 104). Thoracic radiographs might reveal changes consistent with cardiac or respiratory disease; occasionally, they might be indicative of hypovolemic shock (microcardia, small caudal vena cava, hypovascular lung fields) warranting an investigation for underlying causes, including blood work and abdominal ultrasonography in search of abdominal disease such as hemoabdomen.

If the results of all of the above evaluations are still inconclusive, then the key step remains Holter recording to document if intermittent sustained arrhythmias are the cause of collapse or not; this may need to be repeated a few times, or an event recorder or implantable loop recorder may need to be considered. Alternative options include teaching the client to examine the mucosa for pallor (lips and gums are more reliable than the tongue), or palpating or even ausculting the heart during syncope, although this can be difficult if the duration of syncope is short. Instructing the owner to take a movie of the collapse is particularly useful in providing the opportunity for the clinician to observe the event and decide if this is syncopal or non-syncopal collapse and potentially the body system involved.

The prognosis for patients with syncope depends on the inciting cause. Syncope may indicate a worse prognosis when it is the presenting complaint in Dobermans with DCM[31] or Boxers with ARVC and syncope compared to Boxers with ARVC when the arrhythmia is an incidental finding. Conversely, a chief complaint of syncope is associated with a better prognosis than signs of CHF or ATE in cats with HCM.[32,33]

Summary

Collapse is a broad generic term, defined as a sudden loss of postural tone, but not necessarily with a loss of consciousness. Syncope is a subset of collapse that is characterized by unconsciousness, due to a transient reduction in blood flow to the brain, which is of short duration followed by a rapid recovery to normal. The common causes of syncope are classified as cardiogenic or neurocardiogenic. It is of paramount importance to differentiate syncope from the large number of non-syncopal causes of collapse, particularly epileptic seizures and paroxysmal movement disorders. Cardiovascular conditions dominate the differentials for syncope, most commonly as a consequence of hypotension associated with cardiac disease or neurocardiogenic reflexes. If no abnormality is found on physical examination, then a meticulous history becomes the most important part of the assessment. If diagnostic tests are inconclusive, then the key step is documenting an episode of collapse on Holter recording to rule in/out an intermittent arrhythmia, and this may need to be repeated in some animals. Once a diagnosis is reached, then causes need to be investigated in order to provide appropriate treatment.

CHAPTER 31

Movement Disorders

William B. Thomas

"Movement disorders" are a group of heterogeneous neurologic conditions that result in slow movements (hypokinetic disorders) or abnormal involuntary movements (hyperkinesias). There is no classification system because neuroanatomic lesions or the pathophysiology is not always known. Clinical descriptions provide the best method for categorizing these diverse disorders.

Clinical Evaluation

Clinical evaluation requires a complete history as well as a description of the abnormal movement. The client's objective observations are generally more valuable than their subjective conclusions. For example, a complaint of "tremor" is less precise than reporting "the head suddenly jerks downward every second or so." Encourage clients to videotape episodes. For episodic abnormalities, ask about duration, frequency, progression, and any factor that might precipitate events, such as rest, excitement, or exercise. Is the patient conscious and responsive during episodes? Can the client stop the movement by distracting, petting, or feeding the pet? Past and current medical history, vaccination status, and previous illness, injury or toxin exposure can be important. Have any changes in behavior, gait, or other activity been observed between episodes? Perform a thorough neurologic examination to detect any persistent deficits that might help identify a neuroanatomic lesion (see ch. 259). Based on initial evaluation and differential diagnosis, imaging, electrodiagnostic testing (see ch. 117), or analysis of spinal fluid may be indicated.

Spasticity

Spasticity is an increase in muscle tone due to hyperexcitable muscle stretch (myotatic) reflexes (Video 31-1). Muscle tone is the velocity-dependent resistance of muscle to passive stretch, maintained by intrinsic muscle stiffness and myotatic reflexes mediated by lower motor neurons. Descending upper motor neuron pathways normally attenuate the myotatic reflex. Lesions of the upper motor neuron pathway cause changes in the excitability of motor neurons, interneuronal connections, and local reflex pathways that can lead to hyperexcitable myotatic reflexes and spasticity. The interval between injury and the appearance of spasticity varies from days to months. Once spasticity develops, chronic muscle shortening enhances intrinsic muscle, collagen tissue, and tendon stiffness that can lead to subclinical contractures and exacerbation of spasticity. Increased muscle tone predominates in the antigravity (extensor) muscles, causing a spastic gait characterized by decreased limb flexion. At rest, there is increased resistance to passive limb flexion, exaggerated myotatic reflexes and usually other signs of an upper motor neuron lesion such as paresis and ataxia.

Treatment of spasticity is directed at the underlying lesion, most commonly a chronic spinal cord disease. Physical therapy may be helpful (see ch. 355). It involves strengthening and stretching flexor muscles to maintain normal range of joint motion and minimize contracture. Benzodiazepines such as clorazepate (0.5 to 2 mg/kg PO q 12 h) sometimes help decrease muscle tone. In some patients, spasticity actually aids weight bearing by increasing extensor muscle tone. Thus, dosage should be titrated to avoid weakness.

Myotonia

Myotonia is prolonged contraction or delayed relaxation of a muscle after voluntary or stimulated contraction. Congenital myotonia is well characterized in the Chow Chow and Miniature Schnauzer and occurs sporadically in other dog breeds and domestic cats. Signs are evident by 3 weeks of age and include muscle rigidity (non–velocity-dependent resistance to stretch), difficulty rising, and a stilted gait that improves with movement. Patients may exhibit muscle hypertrophy, dysphagia, or a high-pitched bark. Tapping a muscle

with a reflex hammer causes a dimple. Diagnosis is based on clinical features (Video 31-2). Electromyography (EMG, see ch. 117) is used to confirm myotonia by finding complex repetitive discharges (Video 31-3). In the Miniature Schnauzer, congenital myotonia is caused by a chloride muscle channel mutation for which genetic testing is available. Extended-release procainamide (40 mg/kg PO q 8-12 h) or mexiletine (8.3 mg/kg PO q 8 h) improves the signs.[1]

Acquired myotonia is an uncommon complication of iatrogenic or naturally-occurring hyperadrenocorticism (see ch. 306). Affected dogs show a stilted gait with decreased limb flexion, increased muscle tone, enlargement of proximal limb muscles, percussion myotonia, and EMG evidence of myotonia. Treatment of hyperadrenocorticism partially improves the condition in only a minority, with most having persistent myotonia. Procainamide may be helpful. Myotonia is sometimes a component of other progressive myopathies.

Tetany

Tetany, sustained muscle contraction worsened by stimulation and lessened with relaxation, is a classic result of hypocalcemia (see ch. 69 and 298). Strychnine blocks the inhibitory neurotransmitter glycine causing tetany. A congenital syndrome due to stimulus-induced muscle contractions that resolve with rest has been described in a family of Labrador Retrievers.[2] Voluntary movement or stimulation induces extensor rigidity and apnea, but no alteration in consciousness. Although called "reflex myoclonus," the signs are more consistent with tetany and are similar to hyperexplexia or stiff baby syndrome in children, which is caused by a glycine receptor mutation.

Tetanus

Tetanus is sustained muscle contraction without relaxation. The most common cause is infection with *Clostridium tetani* (see ch. 214). Under anaerobic conditions, the organism produces the toxin tetanospasmin that interferes with release of inhibitory neurotransmitters glycine and gamma-aminobutyric acid. Patients with focal tetanus have sustained contractions in muscles close to the wound, usually the head or a limb. In generalized tetanus, patients suffer generalized muscle rigidity, trismus secondary to masticatory muscle contraction, dysphagia due to pharyngeal muscle involvement, and risus sardonicus resulting from facial muscle involvement (Figure 31-1).

FIGURE 31-1 Risus sardonicus caused by tetanus. The commissures of the lips are drawn caudally and the ears are erect.

Paroxysmal Dyskinesia

Background

Dyskinesia is a general term for various forms of abnormal movement. Paroxysmal dyskinesia is characterized by episodes of abnormal movement in an individual who, between events, is normal in movement and behavior. Clinical manifestations vary and include: (1) dystonia: sustained muscle contractions resulting in twisting and abnormal posture of the face, trunk, or limbs, (2) chorea: rapid, irregular, non-repetitive movements of the face, trunk, or limbs, (3) athetosis: a slow form of chorea characterized by writhing movements that tend to overlap, and (4) ballism or ballismus: a severe form of chorea in which the movements have a violent, flinging quality.

Episodic Falling in Cavalier King Charles Spaniels

This disease is characterized by paroxysmal tetany or increased muscle tone diagnosed in dogs 3 months to 4 years of age. An autosomal recessive mutation in the gene *BCAN*, which encodes a proteoglycan called brevican found primarily in the central nervous system, is a likely cause.[3,4] Episodes are precipitated by excitement, stress, or variable periods of exercise and consist of sustained contraction of limb and trunk muscles, causing the dog to stand rigidly or fall. There is no loss of consciousness. Episodes last seconds to minutes, after which the patient recovers completely. Clients can sometimes interrupt an episode by interacting with the dog. Laboratory and electrodiagnostic testing are normal. Diagnosis is based on clinical features and DNA testing. Clonazepam (0.5 mg/kg PO q 8 h) is useful in minimizing frequency and severity of attacks in some dogs.[5]

Epileptoid Cramping in Border Terriers

The pathophysiology of this syndrome, initially called *Spike's disease,* is not understood. Age of onset varies from several months to 7 years of age. Affected dogs suffer paroxysmal episodes of difficulty walking, stretching, and licking, that progress to difficulty standing, tremor and dystonia of the limbs, head and neck. Episodes are sometimes associated with borborygmus, vomiting and diarrhea. Pets appear healthy between episodes. Since laboratory evaluation, brain magnetic resonance imaging (MRI), and spinal fluid analysis are normal, the diagnosis is based on clinical features. Anti-seizure medication is generally ineffective, but about 50% of afflicted dogs exhibit some improvement after being fed a hypoallergenic diet or a single protein and carbohydrate source diet.[6]

Paroxysmal Dyskinesia in Chinooks

This is an autosomal recessive inherited disorder. Signs generally start by 3 years of age. Episodes are characterized by kicking or flailing (ballism), limb flexion, repetitive limb movements and, occasionally, head tremor. There are neither autonomic signs nor loss of consciousness. Ictal electroencephalographic (EEG) monitoring is normal, suggesting a non-seizure condition.[7] Affected dogs are normal between episodes. Laboratory test results, brain MRI, and spinal fluid analysis are normal. The diagnosis is based on clinical features. Currently, there is no effective treatment.

Scottie Cramp

Scottie cramp is an inherited autosomal recessive condition in Scottish Terriers. An identical syndrome has been reported in related breeds (Cairn, Norwich, West Highland White and Cesky Terriers). Clinical signs become apparent by 6 weeks to 18 months of age. Excitement or exercise induces progressive increase in muscle tone causing lumbar kyphosis and decreased flexion of the pelvic limbs, sometimes severe enough to cause a fall. There is some evidence that the disease is caused by alteration in function of the neurotransmitter serotonin. Laboratory tests, electrodiagnostics, and muscle biopsies are normal. Treatment consists of lifestyle adjustments to avoid precipitating factors and acepromazine maleate (0.1 to 0.75 mg/kg PO q 12 h) or diazepam (0.5 mg/kg PO q 8 h). The disorder is nonprogressive and does not seriously compromise the dog's quality of life.[8]

Episodic Head Tremor

Episodic head tremor occurs in Doberman Pinschers, English Bulldogs, Boxers and, less commonly, other dog breeds.[9,10] The onset varies but is usually in adulthood. Dogs with this condition have paroxysmal vertical or horizontal head tremors. Episodes last from seconds to hours. Dogs are fully conscious and otherwise able to move normally during an episode. In many cases, the episode can be stopped momentarily by distracting the dog, such as by feeding a treat. The frequency of attacks varies from once every few months to multiple times daily. This syndrome is not fully understood, but it generally does not improve with antiseizure medication so it may be a paroxysmal dyskinesia. Diagnostic testing, including laboratory analysis, brain MRI, and spinal fluid analysis are normal. There is no effective treatment. The disorder does not adversely affect quality of life. The condition may naturally resolve. Clients should be assured that their pet does not have a more serious disorder.

Paroxysmal Dyskinesias in Other Breeds

Other paroxysmal dyskinesias have been reported in the Bichon Frise, Boxer, Springer Spaniel and Wheaten Terrier.[11]

Drug-Induced Dyskinesia

In people, dyskinesias are a side-effect of several drugs, most commonly those that antagonize dopamine. Other implicated drugs include metoclopramide, antiseizure drugs, anticholinergics, and antihistamines. Dyskinesia, characterized by contractions of facial, neck, and shoulder muscles, has been reported as an adverse phenobarbital effect in a dog.[12] Drug-induced dyskinesia should be considered in patients that develop movement disorders while taking medication. Signs typically resolve with withdrawal of the offending drug.

Myokymia and Spinocerebellar Ataxia

Myokymia is contraction of small groups of muscle fibers resulting in visible rolling, wormlike undulations. A complex neurologic disease characterized by ataxia, seizures, and episodes of myokymia occurs in Jack Russell, Parson Russell, and Russell Terriers. The cause is a mutation in the gene that encodes glial potassium channels that regulate neuronal excitability by buffering extracellular potassium and facilitating glutamate uptake.[13]

The age of onset is several months to several years. Episodes are often precipitated by excitement or exercise and are sometimes preceded by facial rubbing. There are visible undulating muscle contractions, often more obvious in the proximal limb. These muscle contractions often progress to generalized stiffness and collapse (neuromyotonia). Consciousness is maintained. Afflicted dogs are often anxious, restless, panting and hyperthermic during attacks. Episodes last from a few minutes to several hours. Severe attacks can be fatal. Affected dogs commonly have persistent generalized or pelvic limb ataxia and hypermetria starting at several months of age. Some also develop epilepsy. Laboratory analysis may show mild increases in serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase, and creatine kinase results. Electromyography is normal or shows myokymic discharges (spontaneous activity consisting of regularly occurring high-frequency bursts of 2, 3, or more motor unit action potentials) in muscles showing visible contractions (see ch. 117). Procainamide (10 mg/kg PO q 12 h) or mexiletine (4 mg/kg PO q 12 h) may decrease severity and frequency of attacks. Sedation or general anesthesia is necessary to abort severe attacks.[14]

Myoclonus

Myoclonus is a brief, shock-like contraction of skeletal muscle (see Videos 31-1 and 31-4). Physiological myoclonus occurs in healthy animals and typically causes no disability. Familiar examples are hiccoughs (brief contractions of the diaphragm) and muscle jerks during sleep. The normal "startle response" is a stereotypical myoclonus response to an unexpected sudden stimulus, such as the eyelid blink and brief contraction of head, neck, and limb muscles in response to a loud noise. Epileptic myoclonus is a rare form of seizure that consists of focal or generalized myoclonic jerks. The cause may be idiopathic or underlying brain disease. A genetic disease similar to Lafora's disease in people has been described in several breeds of dog and cat that causes intermittent myoclonic jerks of the head, neck, and thoracic limbs, often in response to visual stimuli.[15] Drug- and toxin-induced myoclonus may follow exposure to chlorambucil, lead, or intrathecal morphine.[16-19] The myoclonus usually resolves after drug withdrawal or treatment of the intoxication.

Encephalomyelitis

Encephalomyelitis caused by canine distemper virus is the most common cause of myoclonus in dogs (see ch. 228; see Videos 31-4 and 31-5). This condition was once called *chorea*, but chorea is a more complex, nonrepetitive, irregularly-timed movement, not the brief, simple muscle jerk of myoclonus. Affected dogs often have other neurologic signs of distemper such as ataxia or weakness, but myoclonus can be the only sign. The muscle contractions are most obvious at rest and can persist during sleep or even general anesthesia, usually occurring rhythmically every 1 to 3 seconds. Rarely, myoclonus is generalized, but more commonly it is restricted to a muscle or a group of muscles innervated by adjacent regions of the spinal cord or brainstem. Limb or jaw muscles are commonly involved, but any skeletal muscle can be affected including the tongue and extraocular muscles. Distemper myoclonus is often refractory to treatment although focal myoclonus is usually not terribly disabling. Procainamide (10 to 20 mg/kg PO q 8 h) may be effective. Other inflammatory diseases of the nervous system can also cause myoclonus in dogs, including granulomatous meningoencephalomyelitis, bacterial encephalitis, protozoal encephalitis, and steroid-responsive meningitis-arteritis.[20]

Dancing Doberman

Dancing Doberman disease is initially characterized by flexion of one pelvic limb when standing (see Video 31-5). Within months, the other pelvic limb becomes affected such that the dog alternately flexes and extends each pelvic limb in a dancing motion. These dogs prefer to sit rather than stand.[21] This disorder is recognized in Doberman Pinschers 6 months to 7 years of age. They may develop an insidiously progressive paraparesis

with decreased proprioception and atrophy of the gastrocnemius muscle. Based on electrodiagnostic testing (see ch. 117) and nerve biopsy (see ch. 116), this may be a peripheral neuropathy with pelvic limb movements related to paresthesias in their paws.

Other Abnormal Movements

Muscle spasms caused by pain, especially intervertebral disk extrusion, can be confused with movement disorders such as myoclonus. Affected animals often suffer intermittent, painful contractions of their paraspinal muscles and may flex one limb. Movement often precipitates an attack. Palpation and manipulation of the spine usually identifies the painful region.

Tremor is a rhythmic oscillation of the body or body part due to alternating contractions of antagonistic muscles (see ch. 32). It occurs with a number of disorders.

Seizures can result in a variety of abnormal movements and are usually recognized by their stereotypic pattern and spontaneous onset (see ch. 35). Seizures are often accompanied by some alteration in consciousness. There may also be autonomic signs, such as urination or salivation. Postictal dysfunction, such as abnormal behavior and ataxia, has been reported.

Normal and abnormal movements can occur during sleep. Important features are that the movements only occur during sleep and the patient can be awakened normally during an episode with no postictal signs.

CHAPTER 32

Tremors

Clare Rusbridge

Client Information Sheet: Idiopathic Generalized Tremor Syndrome (IGTS)/White Shakers

Definition

A tremor is a rhythmical, involuntary, oscillatory movement of a body part produced by alternating contractions of reciprocally innervated muscles.[1,2] Tremor is easy to see but more difficult to categorize and treat[3] and can be confused with other movement disorders such as dystonia (see ch. 31).[4]

Pathophysiology of Tremor

Achieving coordinated movement requires reciprocal innervation (Sherrington's Second Law), i.e., a premotor neuron sends excitatory projections to the motor neurons innervating the agonist muscle group (for example, the joint extensors) and to the inhibitory neuron innervating the motor neuron for the antagonist muscle group (for example, the joint flexors).[5] This reciprocal innervation is controlled by neural circuits in the thalamus, inferior olive nucleus, cerebrum, and cerebellum.[6] Of particular importance is the dentate-rubro-olivary tract, which links the dentate nucleus of the cerebellum with the contralateral red nucleus and the inferior olive nucleus.[7] These circuits with their complex feedback loops are inherently unstable. If neural membrane excitability increases or if inhibition is reduced, then the circuit begins to oscillate. These rhythmic oscillations manifest as tremor.[6]

Neurotransmitters and Tremorlytic Drugs

The cerebellar Purkinje neurons (or cells which synapse on them) are implicated in many tremor syndromes.[6,8] Purkinje cells are inhibitory and GABAergic and influence the outflow of the deep cerebellar nuclei such as the dentate nuclei. Other important neuron groups are the excitatory noradrenergic neurons of the locus coeruleus which synapse and influence the Purkinje cells.[9-11] It is suggested that decreased GABAergic inhibition of deep cerebellar neurons disinhibits their pacemaker activity, resulting in rhythmical activity of the thalamic and thalamocortical circuits.[12,13] Supporting this theory is the observation that many types of tremor respond to drugs that enhance postsynaptic GABA-mediated inhibition, such as phenobarbital and primidone, and/or drugs that have a membrane-stabilizing effect, such as propranolol, gabapentin, and topiramate.[6,8,14,15] Hence, these drugs are the mainstay for treatment of many human tremor conditions (such as essential tremor) and can be of benefit in some veterinary tremor syndromes.[16-18] Parkinsonian tremor is related to basal nuclei dopaminergic degeneration and abnormalities of striatal acetylcholine signaling.[19,20] The mainstay of treatment of human Parkinson's disease are drugs affecting dopaminergic neurotransmission such as L-dopa (increases striatal dopamine), dopamine agonists, and inhibitors of monoamine oxidase (block dopamine degradation).[15] In addition, symptoms are relieved by anticholinergics.[15,19] As conditions comparable to Parkinson's disease are not yet recognized in domestic small animals, use of these drugs for tremor syndromes has not been reported.

Classification

In human medicine, tremor is categorized according to topographical distribution, task- or position-dependence, frequency, and amplitude. Classification was simplified when the Movement Disorder Society

produced a consensus statement.[1] Typical diagnostic aids include tremor electromyographic (EMG) activity (see ch. 117) and computerized tremor analysis with accelerometers attached to body parts.[21] In veterinary medicine, there is no such consensus classification and "borrowing" from the human system has inherent problems because of the absence of diagnostic techniques, because dogs and cats are quadrupeds with weight-bearing forelimbs that cannot be asked to perform a task or hold a non-weight-bearing posture, and because a diagnosis often is made by the patient's subjective description.[1] In addition, it is rare for a tremor syndrome to be associated with a single type of tremor; for example, cerebellar disease is associated with more than an intention tremor. Consequently, it can be easier to consider each tremor syndrome separately. Nevertheless, different tremors have a different etiology and potential management, so it is useful to use a simple classification system. The basic tremor types are resting and action. As the name suggests, resting tremors occur in a body part that is completely supported against gravity without voluntary muscle contraction, whereas action tremors occur with voluntary muscle contraction. Action tremors are subdivided into postural, kinetic (simple, intention, and task) and isometric (Table 32-1).[1,22,23]

TABLE 32-1

Classification and Examples of Tremor Syndromes

TYPE OF TREMOR	FEATURES	EXAMPLE OF UNDERLYING DISORDER
Rest	Tremor when body segment (muscle) is at rest (see Videos 32-2 and 32-11). Demonstrated in a patient lying down and relaxed. More obvious in the distal limb. May be asymmetrical. Resting tremor is uncommon in veterinary medicine but in humans is one of the most important signs of Parkinson's disease and advanced stages of essential tremor.[60] Rule out dystonia where jerky movements may be seen at rest.	Mycotoxicosis
Action		
Postural	Occurs in a body part that assumes a posture against gravity (not standing). Holding the body part against gravity activates load-bearing muscles, which in turn activate tremor. In quadrupeds, most easily assessed in the head. Humans are assessed by being asked to maintain arm and finger posture.	Physiological Postural enhanced physiological (stress, metabolic disease, or intoxications) Cerebellar ataxias (only as part of other cerebellar signs) (see Videos 32-3 and 32-5) Idiopathic generalized tremor syndrome (see Video 32-1)
Kinetic—Simple	Tremor occurs during entire movement trajectory	Cerebellar ataxias Mycotoxicosis Harmaline neurotoxin (rodent model of essential tremor) Idiopathic generalized tremor syndrome (see Video 32-1)
Kinetic—Intention	Tremor progressively increases towards intended target	Cerebellar ataxia (see Videos 32-4 and 32-5)
Kinetic—Task-specific	Only during specific tasks, e.g., writing	No veterinary examples
Isometric	Tremor that occurs during isometric muscle contraction. An isometric muscle contraction, or static exercise, is one in which the muscle fires but there is no movement at a joint or change in length of the muscle. Occurs during voluntary	(senile) Isometric limb tremor (see Video 32-6) Orthostatic tremor in

	muscle contractions against a stationary resistance (e.g., standing).	Great Danes and Scottish Deerhounds (see Video 32-7)
Tremor-like Movement Disorders	Myokymia—rippling muscle contractions Myoclonus—brief, involuntary twitching of a muscle or a group of muscles Dystonia—a sustained involuntary contraction of a group of muscles characterized by a repetitive or patterned pulling or twisting movement	Myokymia—spinocerebellar ataxia with myokymia in the Jack Russell Terrier (see Video 32-9) Myoclonus—post distemper virus encephalitis Cortical myoclonus (cortical tremor) myoclonic jerks associated with epilepsy (see Video 32-8) Dystonia—idiopathic paroxysmal head tremor (see Video 32-10)

Acute Onset Generalized Tremor Syndromes

Physiological and Enhanced Physiological Tremor

Physiological tremor is a barely visible tremor that occurs in healthy individuals. Physiological tremor can be enhanced in certain situations such as loading (muscle fatigue), stress, some drugs and toxins (e.g., caffeine, theobromine, beta-adrenergic agonists), some metabolic diseases (e.g., thyrotoxicosis, hypoglycemia, hypocalcemia) and thermoregulatory shivering.[24]

Mycotoxicosis and Other Tremorgenic Intoxications

Ingestion of tremorgenic mycotoxins can result in acute-onset generalized tremor. Mycotoxins are toxic secondary metabolites produced by fungi and molds, and the most commonly ingested tremorgenic compounds are the *Penicillium* toxins, in particular penitrem A and roquefortine.[25] A whole-body tremor is present at rest and is exacerbated by effort and anxiety. Affected animals may also show mydriasis, vestibular signs, facial myoclonus, generalized seizures, hyperesthesia, hyperthermia, tachycardia and gastrointestinal signs (vomiting, diarrhea, flatulence).[25-27] The most important differential diagnoses are other intoxications including drugs (theobromine, cannabis/marijuana, lysergic acid diethylamide [LSD], cocaine, amphetamines, phenylpropanolamine, pseudoephedrine, cholinesterase inhibitors, ivermectin, methylxanthines) and poisons (permethrin, strychnine, metaldehyde, ethylene glycol, macadamia nuts).[25] In a rodent model, tremorgenic mycotoxins decreased GABAergic inhibitory outflow and increased release of glutamate (excitotoxicity).[26,28-30] Therefore, drugs affecting these targets would seem most appropriate for treatment. However, the tremors often are resistant to treatment with intravenous benzodiazepines,[25] possibly due to intracellular chloride ion accumulation secondary to excitotoxicity.[31] An outline of the management of tremorgenic intoxication is detailed in Figure 32-1. Drugs recommended vary between clinicians and use is often based on anecdotal and personal experience.[25,27,32] The author prefers dexmedetomidine as a first line agent followed, if necessary, by anticonvulsants.[32] Dexmedetomidine is a central alpha-2–adrenoreceptor agonist with a site of action at the locus coeruleus, influencing Purkinje cell and GABAergic output.[10,33,34] Use of the muscle relaxant methocarbamol in cases without seizures is described, but this concerns the intravenous preparation, which is not available in some countries.[35] Mycotoxins are highly lipid soluble, which explains their excellent ability to penetrate the brain,[25] and there is some evidence that using intravenous fat emulsion (i.e., Intralipid 20%) can be effective in management of nervous system toxicosis from lipophilic agents (see ch. 151).[36]

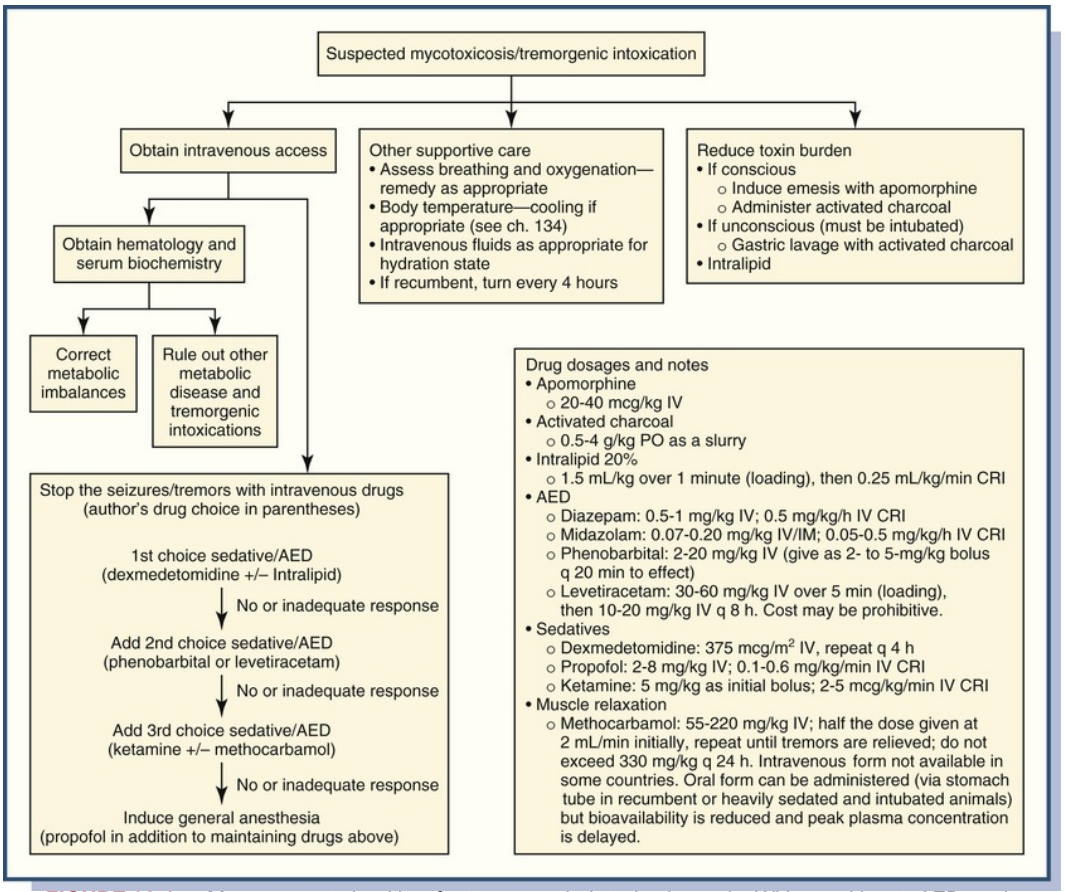

FIGURE 32-1 Management algorithm for tremorgenic intoxication. *+/−*, With or without; *AED,* antiepilepsy drug; *CRI,* constant rate infusion; *h,* hour; *IV,* intravenous; *min,* minute.

Idiopathic Generalized Tremor Syndrome (IGTS)

Patients with IGTS are also referred to as *white shakers*, because of a tendency for this disorder to occur in white breeds like West Highland White Terriers and Maltese dogs. However, IGTS may occur in any dog breed or cross (rarely in large breeds) and is also reported in cats.[37,38] It occurs in young adult dogs; other diseases are more likely in dogs aged 5 years and older. The etiology is undetermined, but histopathological studies and response to immunosuppressive doses of corticosteroids suggest that it is a non-infectious central nervous system (CNS) inflammatory disease. Affected dogs have a whole-body tremor that worsens with anxiety (Videos 32-1 and 32-2). Associated signs include elevated body temperature, hyperesthesia, opsoclonus (ocular tremor), and mild vestibular signs such as head tilt and ataxia. Results of magnetic resonance imaging and cerebrospinal fluid (CSF) analysis can be normal or suggest mild inflammatory change (mononuclear or lymphocytic pleocytosis on CSF analysis). Management is with immunosuppressive dosages of prednisolone starting at 1-2 mg/kg PO q 12-24 h. Some cases may require additional immunosuppressive therapy, such as leflunomide at a starting dosage of 4 mg/kg PO q 24 h. In most cases, the tremor improves in 3-10 days. After the tremor resolves, the corticosteroid dosage is tapered slowly, usually over 6 months or more. The prognosis is good, although relapses can occur and in some patients a low dosage of corticosteroids must be continued for many months. It is important to manage any comorbidities, especially inflammatory bowel disease. Treatment of the tremor with diazepam and/or propranolol in addition to prednisolone is reported.[18]

Other CNS Inflammatory Disease That May Present with Tremor

Any patient with CNS disease that involves the cerebellum or the neural circuits between thalamus, inferior olive nucleus, cerebrum, and cerebellum can present with tremor. However, unlike IGTS, where generalized tremor is the predominant sign, in other CNS inflammatory diseases the tremor occurs in addition to other

neurological signs, like postural deficits. If there is associated meningitis, then pain will be a predominant feature. The most important differential diagnoses for IGTS are granulomatous meningoencephalomyelitis (Video 32-3), necrotizing meningoencephalomyelitis, viral encephalitis (e.g., Aujeszky disease virus[39]) and protozoal encephalitis (Video 32-4).

Chronic Onset Generalized Tremor Syndromes

Cerebellar Tremor

The cerebellum regulates movement by adjusting the output of the descending motor system of the brain. It acts as a "comparator," compensating for errors of movement by comparing intended with actual performance.[40] The hallmark of cerebellar disease is the intention tremor, although many animals with cerebellar disease will also have postural tremor, particularly of the head, and a rhythmic postural sway (truncal tremor) (see Videos 32-3 and 32-5).[41] An intention tremor is an oscillation associated with visually guided movement. It appears during limb and head movement and increases in amplitude with approach of the target (Videos 32-4 and 32-5). In animals, this appears as bobbing action of the head as they go towards an object (e.g., towards food, to eat). There are many causes of cerebellar disease in domestic animals, including spinocerebellar ataxias and other (inherited) degenerative, metabolic, or inflammatory disorders (see ch. 260 and 261).

Disorders of Myelination (Shaker Pups)

Inherited developmental disorders of central myelination can result in the so-called shaker pup syndrome. Affected animals show a gross generalized tremor, particularly when aroused, from approximately 10 days old. Many affected dogs recover with time. The condition is recognized in the Springer Spaniel (autosomal recessive, sex-linked; males have a more severe and fatal phenotype),[42-45] Weimaraner,[46-48] Bernese Mountain Dog,[49] Samoyed,[50] and Siamese cats,[51] but other breeds may be affected. Magnetic resonance imaging of the brain may be useful to make a diagnosis in a non-invasive manner.[52] A differential is a leukoencephalopathy associated with parvovirus infection that has been reported in related Cretan Hound puppies.[53]

Isometric Limb Tremor

An isometric tremor is defined as an involuntary oscillation of one or more body parts during isometric muscle contraction, i.e., when the muscle fires but there is no movement at a joint or change in length of the muscle (e.g., standing).[40] A benign syndrome of pelvic limb tremor is recognized, particularly in older dogs, and has been referred to as a *senile tremor*.[18] Occasionally, the thoracic limbs may be affected. The tremor appears when the dog is standing and disappears during voluntary movement and when the dog is recumbent (Video 32-6). Although the tremor may become more pronounced with time, it does not appear to cause distress or interfere with function; consequently, treatment is not required.

Primary Orthostatic Tremor

A condition described as a primary orthostatic tremor has been detailed in young adult Great Danes and Scottish Deerhounds.[16,17] Tremor with a frequency of 13-16 Hz appears when the dog stands or when moving from one static posture to another (e.g., from standing to sitting, or when posturing to eat, drink or excrete) (Figure 32-2). The tremor disappears on walking and when the dog is recumbent. The condition is progressive over months and years. A distinguishing feature from benign isometric tremor is that the dog appears distressed, and function is compromised. The condition has been compared to primary orthostatic tremor in humans (shaky legs syndrome) which is also characterized by a high frequency tremor (13-18 Hz) predominantly in the limbs and trunk, and triggered during isometric contraction of the limb muscles or during standing.[54] However, there are several differences, most notably that the canine condition has a favorable prognosis as it responds completely or partially to phenobarbital (dosage: 2-3 mg/kg PO q 12 h), often at serum concentrations lower than those required to control seizures. By contrast, the human condition often is poorly responsive to medication.[55] In addition, in humans the tremor is described as fine amplitude rippling that may only be apparent on palpation, auscultation with a stethoscope, or EMG. The diagnosis is

dependent on a subjective feeling of unsteadiness when standing, which is relieved on sitting.[1,55,56] By comparison, in dogs the tremor is visible, gross, and severe (Video 32-7).

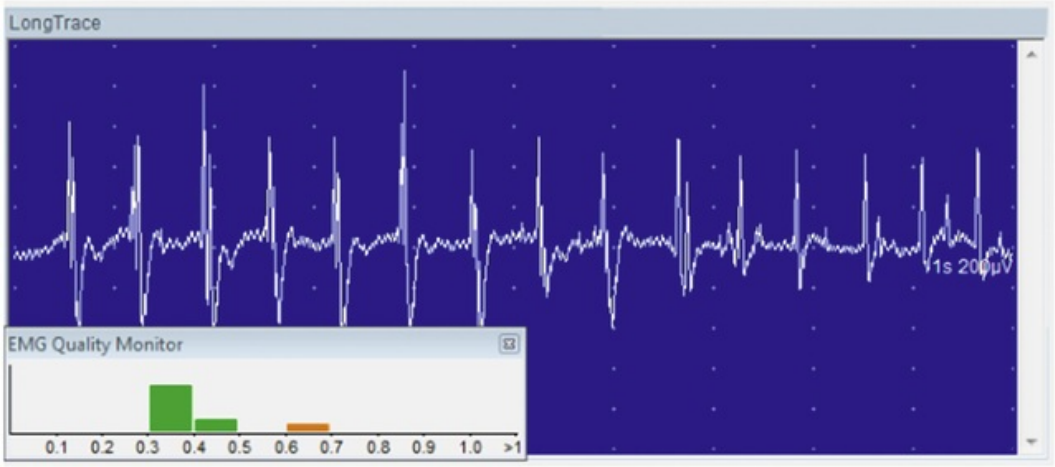

FIGURE 32-2 EMG recording from a 4-year-old male Great Dane with primary orthostatic tremor (see Video 32-7). The dog was conscious and fully weight bearing. The recording demonstrates rapid motor unit action potentials occurring at approximately 16 Hz. (Courtesy Dr. Colin Driver.)

Focal Tremor Disorders

There are many movement disorders that can result in brief, repetitive muscle contractions, which must be distinguished from tremor (see Table 32-1; Videos 32-8 and 32-9).

Idiopathic Paroxysmal Head Tremor

A syndrome characterized by paroxysmal rhythmic head movement is recognized in English Bulldogs (Video 32-10),[57] Dobermans,[58] Boxers, Staffordshire Bull Terriers and others. Affected dogs may have a yes-yes or no-no action. It is very unusual to see both no-no and yes-yes in an individual dog and the direction of movement does not change during an episode.[58] There may be a subtle head tilt (dystonia) and this syndrome may represent a dystonic tremor, i.e., a tremor of a body part affected by dystonia.[4] Paroxysmal episodes vary in duration from a few seconds to several hours and the movement has variable frequency (typical range 4-9 Hz) and amplitude. There is much variation in number of episodes per day and length of time between episodes.[58] Anxiety may be a trigger in some dogs and episodes are more likely (but not exclusively) to occur during rest or sleep.[57] The owners may be able to interrupt mild episodes. The dog remains aware, although may appear anxious, and able to move but may be described as more "stiff" or "floppy."[57] The dog may try to stop the action by pressing its head into an object or its paws. The first episode generally is noted when the dog is a young adult (in one study, the median age was 2 years[57]) and may resolve spontaneously in older animals.[57] Information on treatment is not available. As the condition is self-limiting and there can be many months between episodes, the majority of dogs are untreated.

Tremor Associated with Peripheral Neuropathy

An animal may present with a tremulous limb associated with weakness from a peripheral neuropathy or ventral horn cell (spinal cord) damage (Video 32-11).[10,18] Occasionally the tremor may be disproportionate to the weakness, and in humans it has been suggested that in some demyelinating neuropathies there may be a central component.[59]

CHAPTER 33

Ataxia, Paresis, Paralysis

Ronaldo Casimiro da Costa

Client Information Sheet: Ataxia, Paresis, Paralysis

Ataxia, paresis, and paralysis are clinical signs commonly seen in various diseases of the brain, spine, and peripheral nerves. The main difference between ataxia and paresis is that ataxia affects coordination without affecting strength, while paresis affects only strength. These clinical signs provide fundamental information for lesion localization; it is therefore important to be familiar with their presentation, clinical significance, and main causes. The discussion that follows, combined with the videos and algorithms, aims at assisting the reader achieve this goal.

Ataxia

Ataxia means incoordination. It comes from the Greek word *a taxis,* which means without order or without coordination. It is one of the most important neurologic signs to recognize due to its importance in localizing lesions within the nervous system. Ataxia is an inability for the patient to coordinate the position of its head, trunk, and limbs into space. Ataxia is a sensory, not motor, dysfunction that can only be identified when the patient moves. The type of the ataxia is characterized through a complete neurologic examination (mental status, gait and posture, postural reactions, evaluation of cranial nerves and spinal reflexes, and pain perception). Special attention should be given to the gait and posture. Mild forms of ataxia may be difficult to recognize. The animal's gait should be carefully evaluated in a room large enough to allow the animal to move freely. The animal should also be walked, at a slow pace, toward and away from the examiner in an area with nonslippery floors. Ataxia is mainly a sign of a neurologic disturbance. It is often confused with weakness (discussed below) but they are quite distinct. Systemic conditions can cause ataxia, but more commonly cause weakness without ataxia. Examples of systemic conditions causing ataxia are hypocalcemia causing cerebellar ataxia and thiamine deficiency causing vestibular ataxia.

Types of Ataxia (Figure 33-1)

There are three types of ataxia, namely *proprioceptive, cerebellar,* and *vestibular.* Vestibular ataxia is the easiest to recognize. Vestibular ataxia is characterized predominantly by a head tilt. Usually the side of the head tilt indicates the side of the lesion. Other common signs of vestibular ataxia are leaning, falling, rolling, occasionally circling, strabismus, and nystagmus (see ch. 31 and 265). The severity of vestibular signs depends on a number of factors, but it is usually worse in the acute phase of the disease, while the patient still has spontaneous nystagmus. It is important to differentiate between central and peripheral vestibular disease because the differential diagnoses and prognoses differ greatly. Patients with central vestibular disease have changes in mental status (most commonly somnolence) and deficits in proprioceptive positioning and/or hopping. Nonambulatory tetraparesis is also commonly associated with central disease. Vertical nystagmus or positional nystagmus (one that changes direction when altering the head position) may also be seen. The proprioceptive positioning deficits are ipsilateral to the head tilt, except in cases of paradoxical vestibular syndrome, where proprioceptive deficits are contralateral to the head tilt. Central vestibular signs are associated with rostral medullary lesions (brainstem) or with lesions in the flocculonodular lobe of the cerebellum and are commonly caused by encephalitis or tumors. In peripheral vestibular disease, as the lesion involves the inner ear receptors located outside of the brain (petrosal part of temporal bone), the patient does not display changes in mental status or proprioceptive positioning deficits. The nystagmus is always in the same direction, either horizontal or rotatory, but not vertical. Both central (brainstem) and peripheral (inner ear) vestibular disease is common. It is important to emphasize that idiopathic vestibular disease is always

peripheral. If the patient has signs suggestive of central or paradoxical vestibular disease, further specific neurodiagnostic tests to investigate the brain are warranted. The most frequent causes of vestibular, cerebellar, and proprioceptive ataxias are presented in Box 33-1.

Neoplasia

*Depending on the form of myasthenia gravis.

Cerebellar ataxia is characterized by dysmetria (inability to control the rate and range of stepping movements), which is usually manifested by hypermetria (exaggerated step). It is normally easier to recognize a hypermetric gait in the thoracic limbs. It is important to differentiate this sign from thoracic limb spasticity or hypertonicity, which often accompanies proprioceptive ataxia secondary to cervical myelopathies. Hypermetria is manifested by a prolonged flexion of the step (protraction), while spasticity causes the thoracic limbs to appear rigid or spastic. Other characteristics of cerebellar ataxia are head and whole body tremors, intentional tremors, and wide pelvic limb stance and gait (see ch. 31 and 32). Patients with pure cerebellar ataxia do not display weakness (paresis) or proprioceptive positioning deficits, as they have no involvement of the upper motor neurons or conscious proprioceptive tracts respectively. This can be very useful in distinguishing cerebellar from proprioceptive ataxia. Due to the close anatomic and functional relationships, occasionally patients present with a combination of vestibular and cerebellar ataxia, which indicates a central lesion (Video 33-2).

Proprioceptive ataxia is the type primarily related to spinal cord diseases. This ataxia can be differentiated from vestibular and cerebellar ataxia by the absence of head involvement (tremor or tilt) (Video 33-1).

Proprioceptive ataxia may be seen with brain lesions (brainstem, thalamus, basal nuclei, or cortex) but is much milder, and other brain signs are usually more obvious than the ataxia (somnolence, behavioral changes, cranial nerve involvement, circling, seizures). When evaluating an animal with proprioceptive ataxia, it is important to rule out the influence of any drug (e.g., sedatives) or metabolic disorder (e.g., severe anemia) that may be causing ataxia. As proprioceptive ataxia is commonly associated with spinal cord diseases, this discussion will focus on this aspect. Proprioceptive ataxia is a phenomenon of the spinal cord's white matter, reflecting a dysfunction of the sensory tracts carrying unconscious proprioception (dorsal, ventral, and cranial spinocerebellar tracts, as well as the cuneocerebellar tract). Clinical signs seen with proprioceptive ataxia are truncal sway (wobbliness) and abnormal limb stance and gait such as circumduction, abduction, or adduction with the limbs crossing with each other as the animal walks. Some animals also display a delay in initiating the protraction phase of the gait with a slight hyperflexion of the limb and a longer stride than normal. Proprioceptive ataxia is seen early in the course of compressive

myelopathies, and may or may not be accompanied by proprioceptive positioning deficits (conscious proprioception [CP] deficits or "knuckling"). Usually, patients with spinal cord disease have ataxia associated with proprioceptive deficits; however, dogs with chronic spinal cord disease display ataxia, without CP deficits. This can be explained by the fact that the tracts carrying conscious proprioception (fasciculus gracilis and cuneatus) are different from those involved in unconscious proprioception and responsible for ataxia. It is therefore the gait examination (presence or absence of proprioceptive ataxia) and not the evaluation of proprioception (knuckling) that conclusively defines the involvement of the spinal cord. As the spinal cord lesion worsens, paresis appears (Video 33-5).

Paresis and Paralysis

Paresis means partial loss of motor function, which is usually manifested as weakness. Paralysis (plegia) refers to the complete loss of motor function. The terms *plegia* or *paresis* can be used in association with a prefix to specify which limb(s) are involved. Tetra-, para-, hemi-, or mono-paresis/-plegia refers to involvement of all four limbs, pelvic limbs, ipsilateral limbs, or a single limb, respectively. It is important to make the distinction between ambulatory and nonambulatory paresis and plegia. A "down" dog can have nonambulatory paraparesis and if appropriate treatment is established, dogs with paresis will typically recover faster than those with paralysis (plegia). Paresis and proprioceptive ataxia are common signs in patients with spinal cord diseases (see ch. 266 and 267). The more severe the spinal cord involvement, the weaker the patient becomes, until the point of paralysis. Paresis can be seen with cortical or thalamic lesions, but it is usually mild and always contralateral to the lesion. More severe paresis can be seen with lesions caudal to the midbrain, and in these cases the involvement is ipsilateral. Paresis or paralysis can also be seen with involvement of the peripheral nerves, neuromuscular junction, and muscle. It is important to establish whether the patient has paresis with or without ataxia. Paresis without ataxia indicates that the lesion is located outside of the central nervous system and therefore not affecting the spinal cord. Clinical examples of this presentation are polyneuropathies and polymyopathies, where the patient shows variable degrees of weakness in all four limbs (tetraparesis) but does not have ataxia. A careful evaluation of cranial nerves, postural reactions, and spinal reflexes will assist to establish whether the problem is in the peripheral nerves, neuromuscular junction, or muscle. In a tetraparetic patient, if the reflexes are decreased or absent, a neuropathy or neuritis (e.g., Coonhound paralysis) is likely (Video 33-3). Myopathies cause only mild decrease in spinal reflexes. The clinical approach for a weak patient should first exclude systemic or metabolic causes of weakness. Several systemic conditions can cause weakness. Examples include anemia, metabolic diseases such as hypoadrenocorticism and hypothyroidism, electrolyte imbalances such as hypocalcemia and hypokalemia, cardiovascular diseases such as pericardial effusion or conditions associated with hypotension, and nutritional derangements such as thiamin deficiency. A thorough physical examination along with complete blood count and biochemistry profile may reveal evidence of metabolic or neoplastic diseases, which may cause either neuropathies (e.g., diabetes mellitus in cats [see ch. 305]) or myopathies (e.g., hyperadrenocorticism in dogs [see ch. 306]). Further tests such as a thyroid profile, and a complete cardiac work-up may also be recommended depending on the case.

If the patient is paralyzed, the lesion is within the spinal cord or somewhere along the peripheral nervous system. It is important to localize the spinal lesion as closely as possible to concentrate diagnostic efforts on the affected region. The principles of upper motor neuron (UMN) and lower motor neuron (LMN) are used to localize lesions within the spinal cord (see Figure 33-2). *Upper motor neuron* is a term used to designate a group of motor tracts originating from the brain and terminating within the spinal cord. The most important tracts forming the UMN are the corticospinal, rubrospinal, reticulospinal, and vestibulospinal tracts. Basically, the combined function of the UMN is to facilitate gait in animals, inhibiting extensor muscles of the limbs while facilitating flexor muscles. As such, when the animal has an UMN spinal cord lesion, there is paresis or paralysis with increased extensor tone of the limbs (due to the lack of UMN inhibition). The hallmarks of UMN signs are then paralysis or paresis with increased extensor tone (spasticity or hypertonus), normal to increased spinal reflexes (hyperreflexia), and slowly progressive muscle atrophy from disuse. On the other hand, LMN is formed by a group of neurons that originate in the ventral gray horn of the spinal cord or in a nuclei of the brainstem, to give origin to peripheral or cranial nerves that then innervate the target muscle(s). Lower motor neuron is also known as the final common pathway because any motor activity to be displayed has to go through the LMN. When the patient has a lesion somewhere along the LMN pathway, such as in the spinal cord enlargement (ventral gray horn), nerve roots, spinal nerve, peripheral nerve, or neuromuscular junction, LMN dysfunction occurs. Clinical signs of LMN dysfunction are basically the opposite of those seen with UMN lesions: paresis or paralysis with absent to decreased extensor tone (flaccidity or hypotonus),

decreased or absent spinal reflexes (hyporeflexia or areflexia, respectively), and rapid and severe (neurogenic) muscle atrophy. The presence of UMN or LMN signs dictates the location of the lesion within the spinal cord (Video 33-4).

Clinically, the spinal cord can be divided into four regions, cervical (C1-5), cervicothoracic (C6-T2), thoracolumbar (T3-L3), and lumbosacral (L4-S3). Involvement of all four limbs suggests a lesion at either C1-C5 or C6-T2. Assuming increased tone and reflexes in the pelvic limbs, normal to increased tone and reflexes (UMN signs) in the thoracic limbs indicate a lesion at C1-5, while decreased to absent tone and reflexes (LMN signs) suggest a lesion at C6-T2 (Figure 33-2).

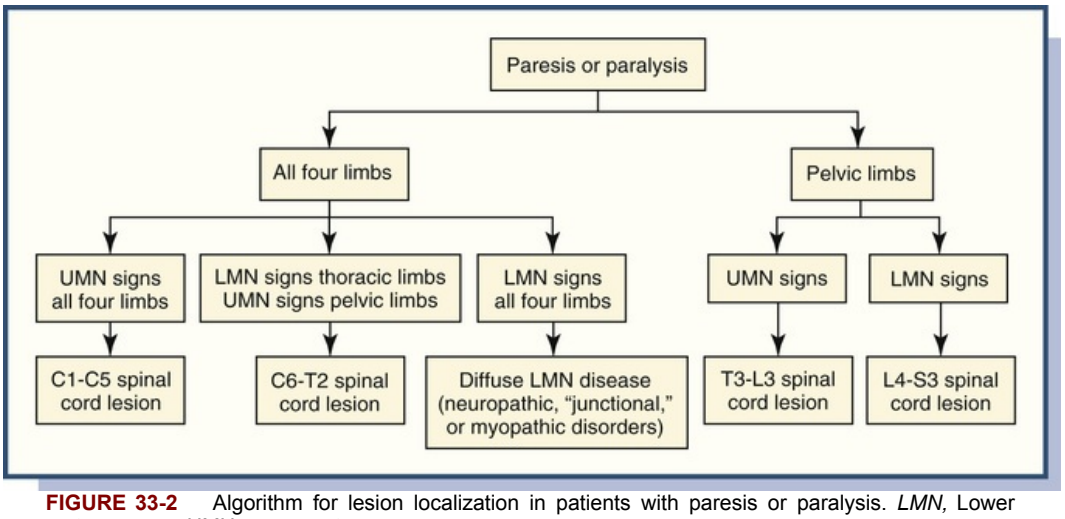

FIGURE 33-2 Algorithm for lesion localization in patients with paresis or paralysis. *LMN*, Lower motor neuron; *UMN*, upper motor neuron.

Paraplegia or paraparesis indicates a lesion caudal to T2. Normal to increased reflexes and muscle tone points to a T3-L3 lesion, the most common site for spinal lesions. More specific lesion localization within the segment T3-L3 can be achieved using the cutaneous trunci reflex and spinal palpation. Decreased tone and reflexes suggests a L4-S3 lesion (see Figure 33-2). It is important to note that the lumbosacral spinal cord segments do not match with their corresponding vertebrae. The entire lumbar enlargement (L4-S3) is located within the vertebrae L4-L5 in most dogs, and L5-L6 in cats. Lesions involving the vertebrae L6, L7, and S1 in dogs affect the nerve roots for the pelvic limbs, perineal region, sphincters and tail (reflecting involvement of sciatic, pudendal, pelvic and caudal nerves). As there is no spinal cord in this region, no proprioceptive ataxia is observed (although proprioceptive positioning deficits may be seen), but paraparesis and pain in the lumbosacral area are present. The flexor and perineal reflexes display signs of LMN. Box 33-1 presents common diagnoses according to lesion localization.

A notable exception exists to the lesion localization within the spinal cord based on the principles of UMN and LMN. It is the so-called Schiff-Sherrington phenomenon that occurs in patients with severe thoracolumbar lesions (T2-L7) damaging the propriospinal tract, which is inhibitory to the extensor muscles of the thoracic limbs. These patients are paraplegic with normal thoracic limb gait, but display, when laterally recumbent, thoracic limb spasticity.

In a paralyzed animal, it is important to establish whether or not nociception (pain perception) is intact. A noxious stimulus such as pinching at one of the toes or at the nail bed should elicit a withdrawal of the limb accompanied by a behavioral response, such as vocalization. If the patient flexes the limb but does not have conscious perception of the painful stimulus, this indicates a severe spinal cord lesion and carries a guarded to poor prognosis, particularly if the patient had an external spinal trauma, is paralyzed for many days, and displays LMN signs.

CHAPTER 34

Stupor and Coma

Karen Lynne Kline

Client Information Sheet: Stupor and Coma

Definitions

Stupor and coma are pathologic abnormalities caused by an interruption in the structural, metabolic, and/or physiologic integrity of the brainstem or cerebral cortex. Stupor is characterized by a state in which the animal appears to be asleep or unconscious but can be aroused by a noxious stimulus. Once the stimulus is withdrawn, however, the animal may lapse back into the sleeplike state. Coma is characterized by a state of unconsciousness from which the animal cannot be aroused even by a noxious stimulus. A strong toe pinch, for example, can elicit a flexion reflex or increased extensor tone but does not cause a behavioral response, such as crying or biting. In either case, prompt action is required to attempt to reverse these signs and correct the underlying cause.

Pathophysiology

Consciousness is maintained by sensory stimuli that act through the ascending reticular activating system (ARAS) on the cerebral cortex. Decreasing levels of consciousness indicate abnormal cerebrocortical function or interference with cortical activation by the ARAS. The cerebral cortex controls the content of consciousness, whereas the brainstem controls the level of consciousness. In a sense, the cerebrum is the light bulb, and the brainstem is the rheostat that regulates its brightness. All sensory pathways have collateral input to the ARAS in the pons and the midbrain, and this information is projected diffusely to the cerebral cortex, where cholinergic synapses communicate constantly with cortical neurons. Balance is maintained between the ARAS and the adrenergic (sleep) system, which projects from the midbrain and diencephalon (thalamus). Signs ranging from hyperexcitability to coma can be observed if imbalance exists between the two systems.

The causes of stupor and coma are numerous. The three most important are (1) increased intracranial pressure, (2) cerebral edema, and (3) herniation of brain tissue. Increased intracranial pressure can occur secondary to an increase in the volume of tissue or fluid (e.g., cerebrospinal fluid, edema, or blood) within the cranial vault; even small shifts in these volumes can have dramatic consequences. Causes of increased intracranial pressure include encephalitis, meningitis, mass lesions (e.g., neoplasia, granulomas, or abscesses), vascular events, traumatic injury, or underlying metabolic disturbances, such as systemic hypertension.

Cerebral edema is an abnormal accumulation of fluid in the brain parenchyma. It is classified into three types: (1) vasogenic, which is most commonly associated with brain masses or stroke and is due to a breakdown in blood-brain barrier integrity; (2) cytotoxic, which is most commonly associated with metabolic disturbances, such as hypoxia and neuroglycopenia, that cause cell or neuronal death; and (3) interstitial, which is most likely associated with hydrocephalus. The end result of progressively increased intracranial pressure and/or cerebral edema is brain herniation.

There are four different types of herniation, two of which can induce stupor or coma: (1) caudal transtentorial herniation, in which portions of the temporal lobe shift ventral to the tentorium cerebelli and cause midbrain compression; and (2) foramen magnum herniation, the most common form, which occurs when the caudal cerebellar vermis moves through the foramen magnum, causing a compression of the displaced cerebellum and the medulla oblongata. In these cases, injury to the respiratory center, descending motor pathway tracts, and cardiovascular centers in the caudal brainstem can lead to irreversible midbrain and cerebral hypoxia and coma (Figure 34-1, *A* and *B*).

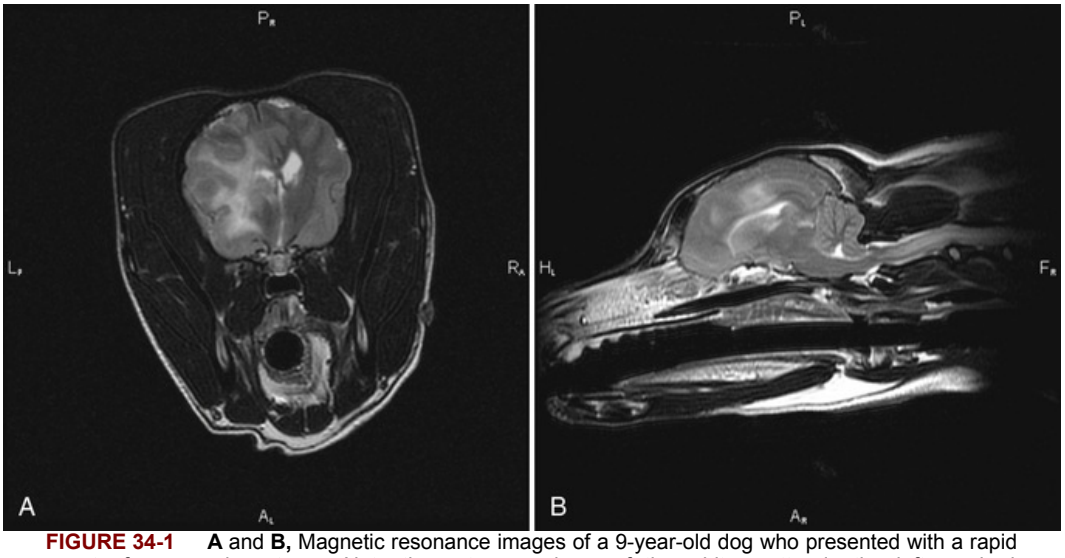

FIGURE 34-1 **A** and **B,** Magnetic resonance images of a 9-year-old dog who presented with a rapid onset of progressive stupor. Note the extreme edema of the white matter in the left cerebral hemisphere as well as the herniation of the cerebellum through the foramen magnum. The dog progressively developed an apneustic breathing pattern indicative of herniation of the brain through the foramen magnum and subsequent compression of the medulla of the brainstem resulting in damage to the respiratory centers. Despite aggressive resuscitation efforts, the dog did not regain consciousness and was euthanized.

Approach to the Patient with Stupor or Coma

After the pet's initial presentation, close attention must be paid to immediate life-threatening injuries and their sequelae, such as hemorrhage, hypoxemia, or shock. The ABCs of critical care medicine—airway, breathing, and cardiovascular status—are paramount. Concurrently, a thorough history, including onset and progression of signs, previous illness or injury, and drug use or toxin exposure, should be ascertained. Thorough physical (see ch. 2) and neurologic (see ch. 259) examinations should be performed, with emphasis placed on the respiratory pattern as well as on cardiac rate and rhythm. Simply observing the patient for a short time can yield considerable information. An anatomic diagnosis can be ascertained on the basis of the following: (1) content of consciousness or mental status and level of consciousness; (2) neuroophthalmic signs (vision, pupil size and symmetry, and ocular movements); (3) alterations in respiratory pattern; and (4) skeletal motor responses. The Modified Small Animal Coma Scale has been used to help distinguish prognostically the extent of the neurologic injury in our patients (see ch. 148). Neurologic function is assessed for each of the three categories (motor activity, brainstem reflexes and level of consciousness) and a grade of 1 to 6 is assigned according to the descriptions for each grade. The total score is the sum of the three category scores. A higher score indicates a better prognosis and a lower score indicates a grave prognosis. Following these trends can improve prognostication, aid the development of treatment protocols, and is essential for patient management (see ch. 148).

Mental Status and Level of Consciousness

Consciousness is maintained by the midbrain ARAS, which acts as a rheostat, projecting diffusely to the cerebral cortex. Consequently, diffuse cerebral disease or midbrain disease can result in stupor, coma, or other alterations in consciousness, such as dementia (see ch. 263). Differentiation between stupor and coma can be achieved with the application of a noxious stimulus, such as a hemostat or needle. Care must be taken to follow trends when evaluating the patient, and hasty prognostication should be avoided. In general, stupor has a better initial prognosis than coma, but exceptions can occur. Other factors include the patient's age, the underlying medical history, and the cause of the alteration in consciousness (Figures 34-2 and 34-3; Videos 34-1 and 34-2).

FIGURE 34-2 Assessment of mentation. Post-operative craniectomy cat with altered mentation secondary to meningioma. Evaluation of the patient for the doll's eye response and oculocephalic responses is imperative in the post-operative craniectomy patient. This cat also had its head elevated and had every-6-hour arterial blood pressure measurements to ensure adequate assessment of neurologic status. Physical therapy was instituted immediately post-operatively to help avoid contracture of the limbs and to aid in patient comfort.

FIGURE 34-3 Magnetic resonance image of a left brainstem meningioma in a dog. This dog presented with dullness and multiple cranial nerve deficits. With lesions in the brainstem, the common presenting complaint will be a change in level of consciousness secondary to injury to the ascending reticular activating system or the rheostat of the central nervous system. The dog also had long tract signs to include hemiparesis and proprioceptive deficits on the same side as the lesion.

Neuroophthalmic Signs

Pupillary Reactions

Pupil size and reactivity to light can be normal in the comatose patient; alterations in these parameters can aid in neurolocalization and prognostication. Integrity of the retinae, optic nerves, and chiasm and of the rostral brainstem is consistent with pupils that are equal in size and that respond well to light and darkness. In general, lesions of the cerebral cortex and thalamus can result in normal or constricted pupils that respond to both darkness and light. Lesions in the brainstem can result in unilateral or bilateral pupillary constriction (pons) or dilation (midbrain), depending on the location. Peripheral lesions involving cranial nerve (CN) III usually result in dilated pupils with normal vision. Pupils that are bilaterally dilated (fixed) and unresponsive to light imply a lesion in the parasympathetic branch of CN III and carry a guarded to grave prognosis.

Ocular Movements

The pathways that mediate ocular movements lie adjacent to the brainstem regions responsible for consciousness, making it clinically useful to evaluate ocular movements in the stuporous or comatose patient. Physiologic nystagmus or conjugate eye movements (the oculocephalic and doll's eye reflexes) are normal and require integrity of CN VIII (vestibulocochlear nerve), the brainstem (vestibular nuclei, medial longitudinal fasciculus), the cerebellum (flocculonodular lobe), and the nuclei of CN III, IV, and VI. Any disruption in this pathway results in pathologic nystagmus (rotary, horizontal, or vertical downbeat). The doll's eye and oculocephalic reflexes are evaluated by moving the head back and forth in a horizontal plane (without moving the head dorsally or ventrally), either quickly, to evaluate the oculocephalic reflex, or slowly, to evaluate the doll's eye reflex. In the normal animal, this movement results in several beats of

horizontal nystagmus (with the fast component toward the direction of the head movement) that stop once the head movement stops. This is consistent with a normal oculocephalic reflex. If the nystagmus continues after the movement stops, if it occurs spontaneously, or if it changes with position, a lesion in the vestibular system is likely to exist. If there is absence of ocular movements in the comatose patient, severe brainstem injury should be suspected, and the prognosis for return to function is guarded to grave. It is important to emphasize that the changes in pupil size can occur suddenly, and an awareness of a sudden change may make the difference between life and death. This is also important to emphasize to the technical staff, as they are many times intimately involved in patient care and will be in charge of following trends. It is important to note that in a patient with seizure activity, the oculocephalic response (mediated through the cerebrum) may be diminished or absent, but the doll's eye reflex should be retained. If the doll's eye or slow phase of ocular movements is lost, this implies a more guarded prognosis and a more significant involvement of the brainstem. It is important to turn the patient on its back to make sure that the character of the nystagmus does not change, as this helps to discern between a central versus peripheral vestibular lesion (Video 34-3).

Alterations in Respiratory Pattern

Severe or progressive brain injury can result in changes in breathing patterns. Cheyne-Stokes respiration is characterized by hyperpnea alternating with apnea and can be an indication of a bilateral cerebral hemisphere or diencephalic lesion. Central neurogenic breathing or hyperventilation is associated with lesions in the midbrain pneumotaxic center, whereas lower pontine and medullary lesions result in apneustic or ataxic (gasping) respirations, respectively. Kussmaul respirations are deeper-than-normal breaths occurring in an otherwise normal pattern. These are typically associated with diabetic ketoacidosis, and the mechanism involves increased ventilation as respiratory compensation for severe metabolic acidosis. When a change in breathing patterns is noted in stuporous or comatose patients, aggressive therapy may need to be instituted to counteract brain herniation. Stimulation of the acupoint GV26 may be helpful in patients that are not breathing well and are in need of further ventilatory support and stimulation. This is done by placing a small-gauge needle at the ventral aspect of the philtrum of the nose and repetitively jabbing the nasal cartilaginous and bony tissue. Monitoring of arterial or venous CO_2 concentrations also is paramount in developing a long-term treatment strategy for the patient with stupor or coma. In cases where the respiratory pattern changes, poor ventilation can ensue and the patient may become hypercapneic and the respiratory drive may be altered. As mentioned previously, monitoring trends and following serial blood CO_2 concentrations is a vital component to patient outcome. It is important to emphasize that the changes in breathing patterns can occur rapidly and should be followed as trends. The importance of serial evaluations is paramount and this should be emphasized to the technical staff as commonly they are monitoring these patients very closely.

Skeletal Motor Responses

The examination of motor function in the stuporous or comatose patient provides valuable localizing information. Trends must be monitored in order to follow the disease course. Injury to the descending motor systems can result in either increased or decreased extensor and flexor tone, depending on where the injury occurs. Involuntary movements, such as twitching or paddling, may indicate seizure activity. Decerebrate posture (all four limbs extended) indicates a lesion in the midbrain or pons and can occur primarily or secondary to cerebrocortical herniation; decerebrate posture indicates that the motor pathways that aid in flexion are damaged and stupor or coma is present. Decerebellate posture (forelimbs extended with alternating hind limb flexion and extension) indicates a rostral cerebellar lesion, and the level of consciousness may not be impaired. Flaccid paralysis due to injury to the descending motor pathways implies a grave prognosis, especially when the patient is stuporous or comatose.

Diagnostic Plan

The causes of stupor and coma are numerous (Figure 34-4). Routine laboratory data (complete blood count [CBC], serum biochemistry profile, urinalysis) can aid in determining a metabolic cause of the alteration in consciousness. Inflammatory, infectious, or toxic agents may cause changes in the CBC, whereas metabolic or endocrine disorders may result in changes in the serum biochemistry results, which could suggest the need for other diagnostic tests, such as evaluation of blood ammonia levels and serum bile acids, adrenocorticotropic hormone (ACTH) stimulation, and thyroid profiles. Chest and abdominal diagnostic imaging (radiographs, ultrasonography) may also be indicated if metastatic, inflammatory, or infectious

disease is suspected. If minimal changes are noted in these parameters, a primary or intracranial cause of stupor or coma should be considered. Noninvasive methods used for determining the cause of intracranial disease include electroencephalography and brainstem auditory-evoked response (BAER). In addition, serial blood pressure monitoring (see ch. 99) is essential to assess for signs of a Cushing's reflex, which occurs when the heart rate decreases and the blood pressure rises to dangerous levels. This can be a sign of increasing intracranial pressure, cerebral edema formation, and herniation. Electroencephalography and BAER are useful for evaluating the integrity of the cerebral cortex and brainstem, respectively, and they can be performed without general anesthesia. Ophthalmic and retinal evaluation may help to determine whether high intracranial pressure or infectious disease is present. Computed tomography and magnetic resonance imaging of the brain are quite useful for confirming the presence and character of intracranial lesions, such as tumors, hydrocephalus, and vascular injuries (see ch. 260 and 261). If the dog or cat is comatose, general anesthesia may not be necessary. Cerebrospinal fluid analysis typically is useful for determining whether the animal has an inflammatory or a neoplastic intracranial process; general anesthesia is required and does carry some risk if high intracranial pressure exists.

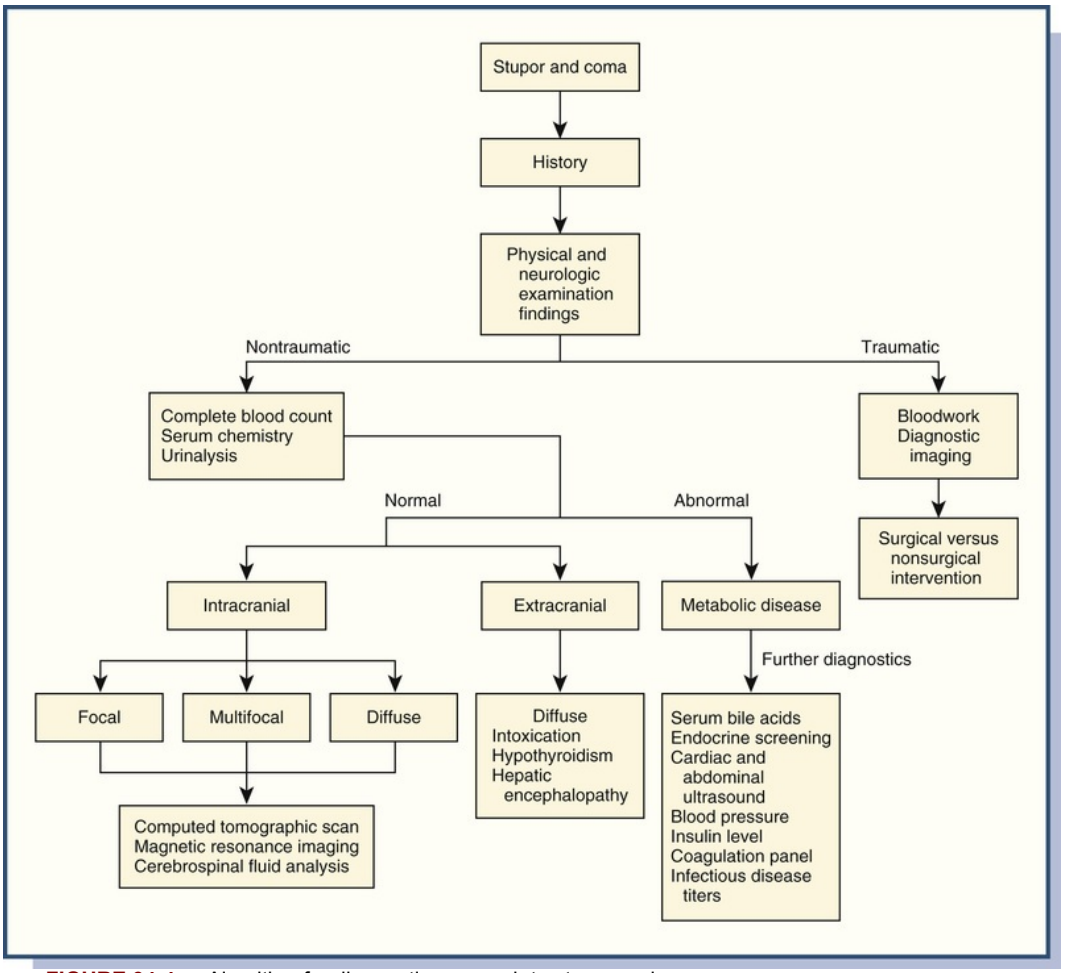

FIGURE 34-4 Algorithm for diagnostic approach to stupor and coma.

Treatment Goals

Most dogs and cats with stupor or coma have life-threatening injuries that require immediate attention. Establishing a patent airway and maintaining respirations and a stable hemodynamic status (in particular, blood pressure and blood CO_2 levels) are critical to stabilization, regardless of the underlying cause of the insult. Blood work should be evaluated, and intravenous administration of fluids, anticonvulsants, osmotic diuretics, and, in some cases, corticosteroids, can be instituted to aid patient stabilization. Elevation of the head may help reduce excessive cerebral blood flow, and body temperature should be monitored

continuously, especially in the case of seizures (see ch. 35). Cerebral edema can be treated using injectable corticosteroids (once the blood pressure has stabilized), osmotic and loop diuretics (mannitol and furosemide, respectively), and hyperventilation. Seizures can be controlled using injectable anticonvulsants such as diazepam, phenobarbital, and pentobarbital. These treatments are discussed in more detail in the chapters on specific brain diseases (see ch. 136, 148, and 260). Intensive nursing care is paramount, including frequent turning (to avoid hypostatic lung congestion), passive range of motion exercises of the limbs, and massage. Bladder evacuation, ocular lubrication, optimal nutrition, and proper bedding are imperative for continued support of the patient and optimization of outcome. Serial neurologic assessments and an assessment of positive and negative trends are essential for accurate prognostication.

Prognosis

The prognosis for animals with stupor or coma depends on the cause of the insult, other underlying disease processes, the location of the injury, the signalment, and the response to therapy. Serial neurologic evaluations that concentrate particularly on the level of consciousness, ocular movements, pupillary size, motor tone, and breathing patterns can guide the practitioner in terms of treatment options and prognostication. Patience is necessary, especially in cases of brain trauma, and trends in improvement or deterioration need to be followed. If the patient survives the immediate injury, sequelae such as seizures, permanent neurologic deficits, and long-term nursing care should be addressed with the client.

CHAPTER 35

Seizures

Karen R. Muñana

Client Information Sheet: Seizures

Seizures are the most common neurologic condition encountered in small animal practice, with an estimated prevalence in a referral hospital population of 1-2% in dogs[1,2] and 2-3.5% in cats.[3,4] Seizures are transient paroxysmal disturbances in brain function that result from an imbalance between excitatory and inhibitory neurotransmission in the brain, and are characterized by hyperexcitability and hypersynchrony. The change in neuronal function can be identified by distinctive epileptiform activity on electroencephalography (EEG), and is typically accompanied by clinical manifestations. Clinical manifestations can be expressed as alterations in consciousness, behavioral changes, involuntary motor activity, and alterations in autonomic nervous system function such as mydriasis, salivation, vomiting, urination, and defecation. Seizures can be preceded by a preictal phase with atypical behavior such as restlessness, attention-seeking, or attempting to hide. The postictal phase immediately follows the seizure, during which an animal can show signs of fatigue, disorientation, restlessness, aggression, ataxia, or blindness. Postictal signs can persist from minutes to days, and the degree of postictal impairment does not necessarily correlate with the severity or duration of the seizure itself.

Seizure Classification

Seizures are classified as either generalized or focal, based on the EEG activity present at the onset of the seizure and the clinical signs that result from the neuronal disturbance. Generalized seizures are characterized by abnormal neuronal activity that originates from both cerebral hemispheres at the onset of the episode, and most often manifest in dogs and cats as symmetric tonic-clonic contractions of somatic muscles, loss of consciousness, and autonomic signs (Videos 35-1 and 35-2). Focal seizures originate within neuronal networks in a discrete region of the cerebrum or thalamus, and can manifest as focal motor activity or behavioral signs (Videos 35-3, 35-4, and 35-5). Focal seizures can secondarily generalize, in which case the seizure event spreads to involve both cerebral hemispheres. Focal seizures are associated with a higher incidence of underlying intracranial disease; therefore, it is important to attempt to discern the type of seizure an animal is having, as this will influence the differential diagnosis and diagnostic plan.

Diagnostic Approach

The general approach to the diagnostic evaluation of an animal with seizures is outlined in Figure 35-1.

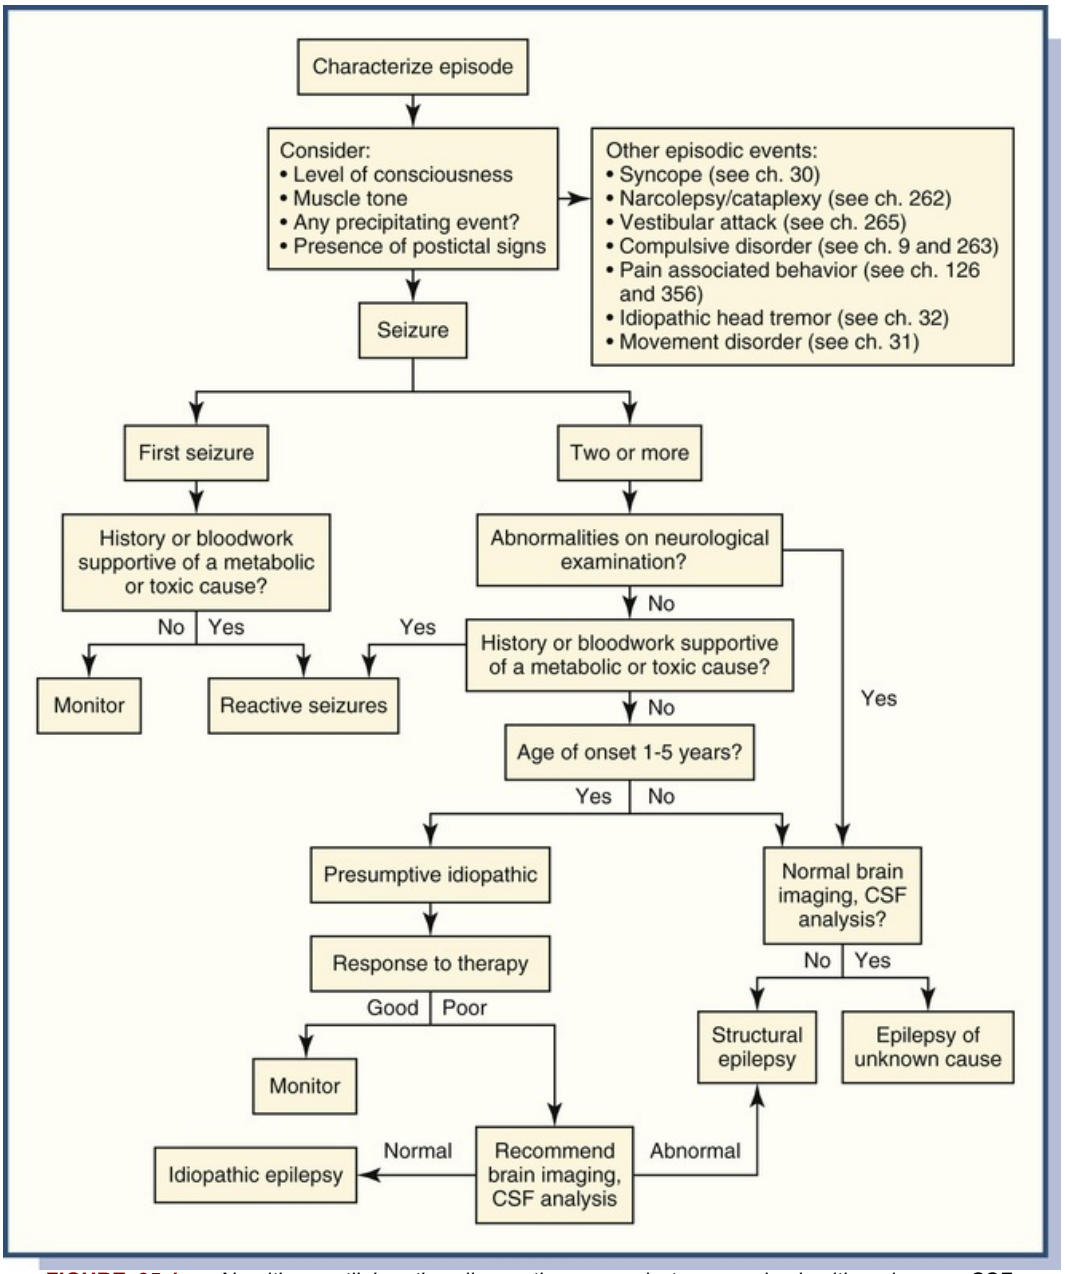

FIGURE 35-1 Algorithm outlining the diagnostic approach to an animal with seizures. *CSF*, Cerebrospinal fluid.

Historical Findings

Seizures, being episodic events, frequently are not witnessed by the veterinarian. Because of this, it is imperative that an accurate description of the episode be obtained from the pet owner to determine whether or not a seizure disorder is considered likely. Disorders that can be confused with seizures include syncope (see ch. 30), narcolepsy/cataplexy (see ch. 262), vestibular attacks (see ch. 265), behavioral disorders (see ch. 9), idiopathic head tremor (see ch. 32) and movement disorders (see ch. 31). If the episode proves difficult to characterize based on the description alone, it can be helpful to have the owner record an episode on video for review.

A thorough history also should be obtained to explore potential causes for the seizures. The owner should be questioned regarding the age of onset, duration and frequency of seizures, whether any events tend to precipitate seizures, any past history of illness or trauma, potential exposure to toxins, vaccination history, and any family history of seizures.

Examination Findings

A general physical examination is useful in evaluating for any evidence of cardiovascular or respiratory disease, as well as any signs of systemic disease that can provide clues as to the underlying cause of seizures. In addition, a complete neurological examination (see ch. 259) should be performed to assess for any signs of forebrain disease, such as changes in mentation or behavior, visual deficits, gait abnormalities, or postural reaction deficits.

Differential Diagnosis

Seizures often are categorized based on etiology (Table 35-1). Reactive seizures result from extracranial causes, in which metabolic (endogenous) or toxic (exogenous) disturbances secondarily impair normal brain function. The term *epilepsy* should be reserved to describe recurrent seizures due to a primary intracranial abnormality. The most common form of epilepsy in dogs is idiopathic epilepsy; this is a disorder characterized by recurrent seizures with no underlying cause other than a presumed genetic predisposition. The analogous condition in humans is now referred to as genetic epilepsy. Idiopathic epilepsy likely is the result of a functional defect at the molecular level, and occurs more frequently in certain breeds of dogs, with a typical onset at 1 to 5 years of age. Structural or symptomatic epilepsy refers to recurrent seizures associated with a congenital or acquired structural lesion in the brain, such as hydrocephalus, encephalitis, cerebrovascular disease, or neoplasia. Epilepsy of unknown cause refers to a condition of recurrent seizures in which genetic epilepsy is determined unlikely based on age of onset or examination findings, but a structural cause is not identified. This has also been referred to as cryptogenic epilepsy or probable symptomatic epilepsy.

TABLE 35-1

Classification and Differential Diagnosis for Seizures in Dogs and Cats

SEIZURE CLASSIFICATION	ETIOLOGICAL CATEGORY	SPECIFIC DISEASES
	Extracranial Causes	
Reactive seizures	Metabolic	Liver disease Renal disease Hypoglycemia Hypocalcemia Sodium imbalance Hyperlipoproteinemia Thiamine deficiency
	Toxic	Heavy metals Pesticides Ethylene glycol Caffeine/methylxanthines Mycotoxins Drugs
	Intracranial Causes	
Structural epilepsy	Degenerative	Neurodegenerative disorders Lysosomal storage disorders
	Anomalous	Hydrocephalus Lissencephaly Cortical malformations
	Neoplastic	Primary Metastatic
	Infectious	Viral Bacterial Protozoal Rickettsial Fungal

		Parasitic
	Inflammatory	Granulomatous meningoencephalitis Necrotizing encephalitis
	Traumatic	Brain trauma
	Vascular	Cerebrovascular disease Hypertension
Idiopathic epilepsy	Genetic	
Epilepsy of unknown cause	Undetermined	No structural cause identified

Diagnostic Plan

As a general rule, the initial diagnostic plan for an animal with seizures should focus on potential extracranial causes. Accordingly, any animal with seizures should have a complete blood count, serum biochemistry profile, urinalysis, and serum bile acid levels measured. If intoxication seems likely based on the history, then specific tests for toxin exposure are recommended (see ch. 152-155). Additional testing for systemic disease might be warranted based on examination and initial laboratory findings. Cats should be evaluated for serologic evidence of infectious disease, including feline immunodeficiency virus (see ch. 222), feline leukemia virus (see ch. 223), toxoplasmosis (see ch. 221), and cryptococcosis (see ch. 231).

If extracranial causes of seizures are excluded, then intracranial disease must be explored. When considering differential diagnoses for intracranial causes, it is often helpful to take into account the likelihood of diseases based on a dog's age at the onset of seizures. In dogs less than 1 year of age, anomalous conditions and infectious etiologies are identified most commonly. Ultrasound of the brain through an open fontanelle can often demonstrate the presence of ventriculomegaly in a patient with hydrocephalus (see ch. 260). Infectious disease testing, particularly in an unvaccinated animal, might lend support for the potential diagnosis of encephalitis. However, cerebrospinal fluid (CSF) analysis is necessary to exclude infectious causes, and advanced imaging of the brain is required to identify most structural abnormalities aside from hydrocephalus.

The most likely intracranial diagnosis in a dog with onset of seizures between 1 and 5 years of age is idiopathic epilepsy. Accordingly, if screening for extracranial causes produces negative results, and the signalment, history, and examination suggest that idiopathic epilepsy is likely, then further diagnostics are not necessary and a presumptive diagnosis can be made. However, if an owner desires a more definitive diagnosis, then brain imaging and CSF analysis are indicated (see ch. 115). In addition, animals in this age group with seizures that prove refractory to treatment should undergo further diagnostic testing to evaluate for structural brain disease.

In dogs with an onset of seizures at >5 years of age, intracranial disorders such as neoplasia and cerebrovascular disease assume a greater prevalence. Serial blood pressure measurements should be performed routinely in these cases (see ch. 99), and if normal, brain imaging and possibly CSF analysis should be recommended.

Since seizures in cats are more commonly associated with an underlying cause,[3,4] it is recommended that cats have advanced imaging and CSF analysis performed to evaluate for an intracranial cause for seizures, regardless of age.

Principles of Therapy

Guidelines for Initiating Treatment

Treatment should be directed at any underlying cause identified in the diagnostic evaluation. This is particularly important if a metabolic cause is identified, as seizures secondary to disorders such as hypoglycemia or hypocalcemia often are refractory to antiepileptic drug (AED) treatment if the primary cause is not addressed.

A decision on whether or not to initiate AED therapy for epilepsy should take into consideration the general health of the patient, as well as the owner's lifestyle, financial limitations and comfort with the proposed treatment plan. In general, the author recommends initiating AED treatment based on the following criteria: (1) seizure frequency of once a month or greater; (2) history of cluster seizures or status epilepticus; (3) seizure or postictal signs that are especially severe; and/or (4) strong desire by the owner to treat the

seizures regardless of the frequency or severity. The final decision on initiating AED therapy should be made on a case-by-case basis after careful consideration of these factors.

Client education is key to the successful management of an epileptic animal. The pet owner should have a clear understanding of the goals and expectations of treatment. The owner should realize that many animals do not become seizure-free with treatment, and adverse effects are common with AED therapy, such that the goal of therapy is to maximize seizure control while minimizing adverse effects to allow for the best quality of life. Furthermore, therapy is lifelong in most instances, and it is imperative that the AED be administered on a regular basis at established treatment intervals. Finally, animals with epilepsy require continuous care, and adjustments to the treatment regimen are likely to be required over time.

In general, therapy with a single AED rather than a combination of drugs is preferred in medical seizure management, as this avoids drug-drug interactions and provides a simpler regimen that may improve compliance.[5] A second drug should not be added until treatment failure has been demonstrated with the first drug, based on continued seizures in the face of maximum dosage or reference range serum concentrations being attained, or the presence of unacceptable adverse effects.

When choosing an AED, factors to consider include the mechanism of action, reported efficacy, potential for adverse effects and drug interactions, frequency of administration, and cost. Pharmacologic properties, dosage recommendations, and potential adverse effects for the AEDs used in dogs and cats are summarized in Table 35-2. A more extensive discussion of treatment options for seizures can be found elsewhere.[6]

TABLE 35-2

Oral Antiepileptic Drugs Used for Treating Seizures in Dogs and Cats

DRUG	SPECIES	RECOMMENDED STARTING DOSAGE	TIME TO STEADY-STATE CONCENTRATION (DAYS)	REPORTED ADVERSE EFFECTS
Phenobarbital	Dog	2.5-3 mg/kg q 12 h	10-14	Sedation, ataxia Polyphagia Polyuria/polydipsia Hepatotoxicosis Bone marrow suppression Hyperexcitability
	Cat	1.5-2.5 mg/kg q 12 h	16	Sedation, ataxia Weight gain Blood dyscrasias
Bromide	Dog	30 mg/kg q 24 h	100-200	Sedation, ataxia Vomiting Polyuria/polydipsia Polyphagia Pancreatitis
	Cat	Not recommended	37	Bronchial asthma Sedation Polydipsia Vomiting Weight gain
Gabapentin	Dog	10-20 mg/kg q 6-8 h	1	Sedation, ataxia
	Cat	5-10 mg/kg q 8-12 h	Not reported	Sedation, ataxia
Zonisamide	Dog	5-10 mg/kg q 12 h	3-4	Sedation, ataxia Loss of appetite
	Cat	5 mg/kg q 12-24 h	7	Sedation, ataxia Anorexia, vomiting, diarrhea
Levetiracetam	Dog/Cat	20 mg/kg q 8 h	1	Sedation, ataxia
Pregabalin	Dog	3-4 mg/kg q 8 h	1-2	Sedation, ataxia

	Cat	1-2 mg/kg q 12 h	Not reported	Sedation, ataxia

Monitoring Response to Therapy

Epilepsy is characteristically a chronic condition, and should be managed accordingly. Ideally, the goal of therapy is seizure remission; however, fewer than half of all epileptic dogs are able to maintain a seizure-free status without experiencing adverse effects associated with medical therapy.[7] Consequently, the primary focus of treatment is to optimize seizure control while minimizing drug-related adverse effects.

The monitoring of treatment response depends to a large extent on accurate owner observation, and owners should be instructed to maintain a calendar to record seizure activity and observed adverse effects and note any deviations in drug administration.

Therapeutic drug monitoring should routinely be performed for drugs such as phenobarbital and bromide that have a more narrow therapeutic index, and for which a reference range has been established. Drug concentrations should be measured once steady state has been achieved after initiation of treatment or dosage adjustment, when seizures persist despite an apparently adequate dosage, or when there are concerns about drug related toxicosis.[8] In addition, drug concentrations should be measured at 6-12 month intervals to screen for any changes in drug disposition over time, and aim to maintain levels within the reference range. Many of the newer AEDs approved for humans that are being utilized in veterinary patients, such as zonisamide and levetiracetam, have wide therapeutic indices such that drug monitoring is not routinely recommended. Furthermore, a reference range for serum concentrations of these drugs has not been established in dogs and cats. Nonetheless, the author finds it helpful to measure trough concentrations in instances where inadequate seizure control is reported, to determine whether a dosage increase might be warranted.

Outcome

The prognosis for an animal with seizures depends on the underlying cause and response to therapy. As would be expected, animals with idiopathic disease have a better prognosis than those with structural epilepsy.[4,9] Breed-related differences in seizure severity have been demonstrated among dogs with idiopathic epilepsy, with certain breeds such the Border Collie,[10,11] Australian Shepherd,[12] and German Shepherd Dog[11] less likely to have good seizure control. Furthermore, cluster seizures and status epilepticus have been shown to negatively influence survival.[9,13] However, many dogs with idiopathic epilepsy can expect a near-normal lifespan,[9,13] and a small percentage of dogs (13-15%) can undergo disease remission and become seizure-free.[9,14]

Ptyalism and Halitosis

Camilla Heinze, Brook A. Niemiec

Client Information Sheets:
Halitosis: Bad Breath in Dogs and Cats
Ptyalism: Drooling in Dogs and Cats

Ptyalism

Saliva is a viscous protein based fluid which flows throughout the mouth, playing an important role in support and maintenance of the health of the oral soft and hard tissues. Among the body's defense mechanisms, saliva works to lubricate and initiate breakdown of ingesta as well as to protect the oral soft tissues.[1] Ptyalism is defined as a pathologic overproduction of saliva, which may occur from a number of disease states.[2] Pseudoptyalism refers to drooling caused by an inability or reluctance to swallow a normal amount of saliva.[3] Excessive salivation, defined as saliva beyond the margin of the lips, is considered to be a normal finding in some breeds of dogs (e.g., Saint Bernard, Dogue de Bordeaux, and Mastiff).[4]

Etiology and Pathogenesis

Saliva is produced in and secreted by the salivary tissues, which are mostly in glands but also occur diffusely throughout the mouth. There are four major pairs of salivary glands in cats and dogs: parotid, zygomatic, mandibular, and sublingual[5] (Figure 36-1). The cat has, in addition, two small, circumscribed glands linguocaudally to each mandibular first molar tooth, which are called the lingual molar glands[6] (E-Figure 36-2).

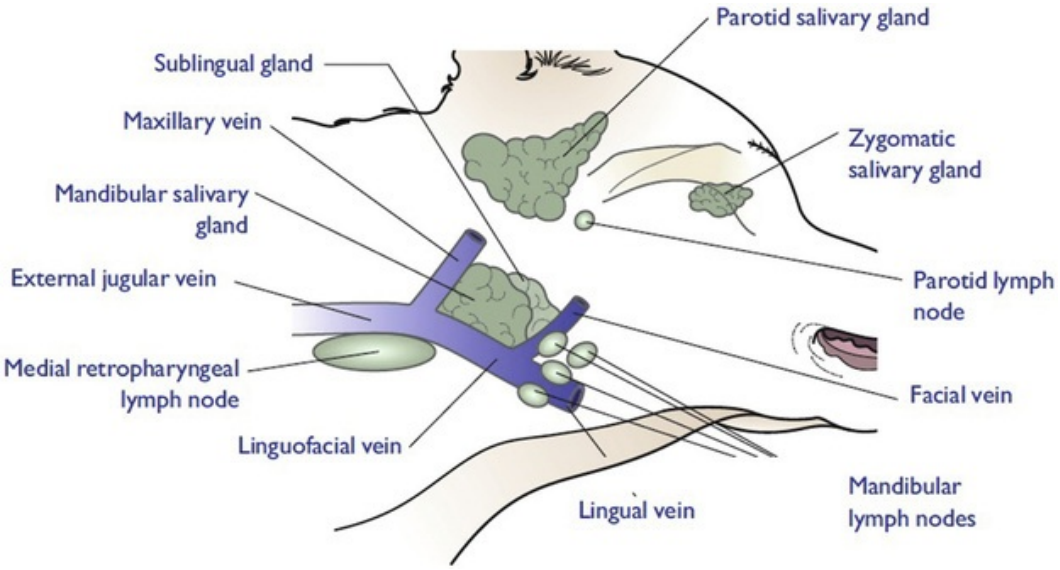

FIGURE 36-1 Scientific drawing of the anatomy of the feline and canine salivary glands. (Previously published in Niemiec BA: *Small animal dental, oral, and maxillofacial disease, a color handbook*, London, 2010, Manson.)

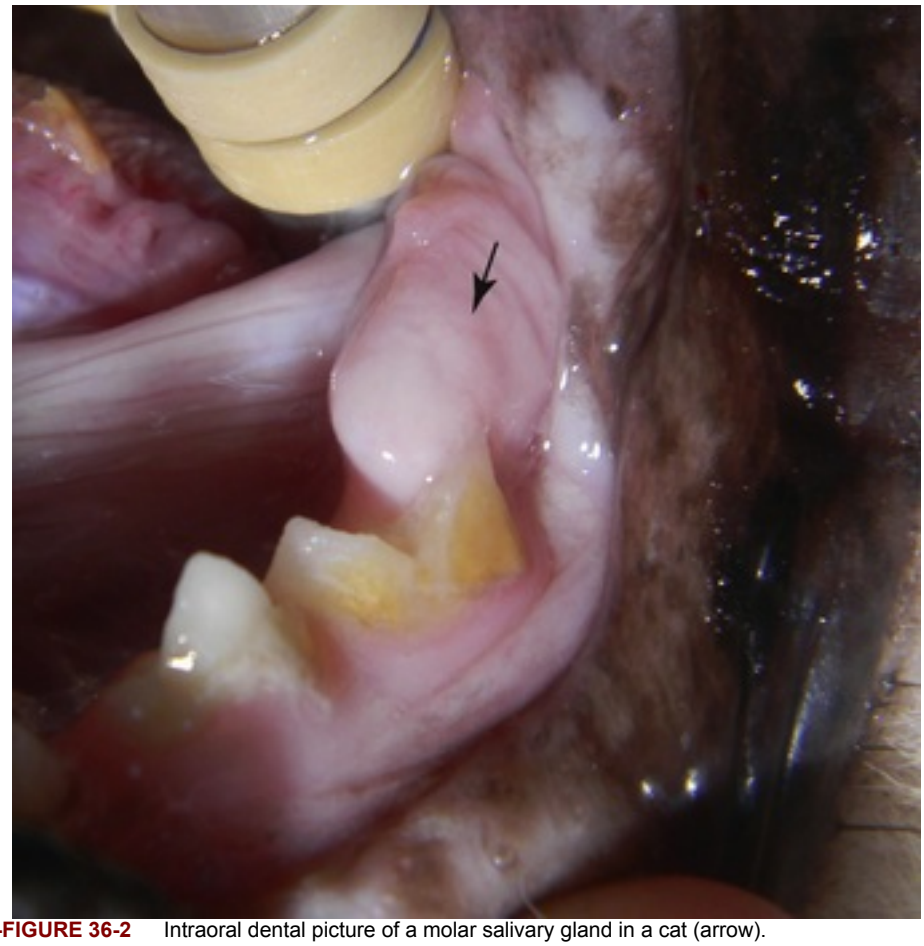


E-FIGURE 36-2 Intraoral dental picture of a molar salivary gland in a cat (arrow).

Parasympathetic postganglionic cholinergic nerve fibers control the rate of the salivary secretion, inducing the formation of large amounts of a low-protein, serous saliva. Sympathetic stimulation promotes saliva flow through muscle contractions at salivary ducts. In this regard, both parasympathetic and sympathetic stimuli result in an increase in salivary gland secretion. The sympathetic nervous system also affects salivary gland secretions indirectly by innervating the blood vessels that supply the glands.

Ptyalism results from an increase in production by one or all of the salivary glands. Pseudoptyalism results from some disruption of the swallowing mechanism, voluntary or involuntary. Often the voluntary disruption is pain-induced, whereas the involuntary is caused by obstruction.

There are numerous causes for hypersalivation, and numerous locations where the inciting cause may originate.[3,4] The inciting cause can originate from the oral cavity, esophagus or alimentary tract, or within the salivary glands themselves. Hypersalivation also can occur due to systemic or neurologic conditions.

Excessive salivation is a common clinical finding in patients with diseases of the oral cavity, and it is usually seen as a consequence of pain, inflammation or obstruction. Trauma patients, such as those with mandibular fractures, may have concurrent disruption in the normal mechanisms of swallowing.

Inability to retain saliva within the mouth due to poor head or lip control, a constantly open mouth, decreased or abnormal tongue mobility, decreased tactile sensation, macroglossia, dental malocclusion and nasal obstruction all lead to ptyalism.

Ingested toxins may have both direct noxious effects on the saliva production, and indirect effects through inflammation of the mucosal surfaces. Intoxicated patients can also be seen with ptyalism caused by the central nausea effect of the toxin.

Primary salivary gland disorders (e.g., necrosis, inflammation and cancer) usually provoke an increase in the secretion of saliva. However, other salivary gland diseases may actually result in a decrease in saliva production.

Neoplasia affecting structures of the oral cavity, oropharynx, or esophagus can disrupt the normal

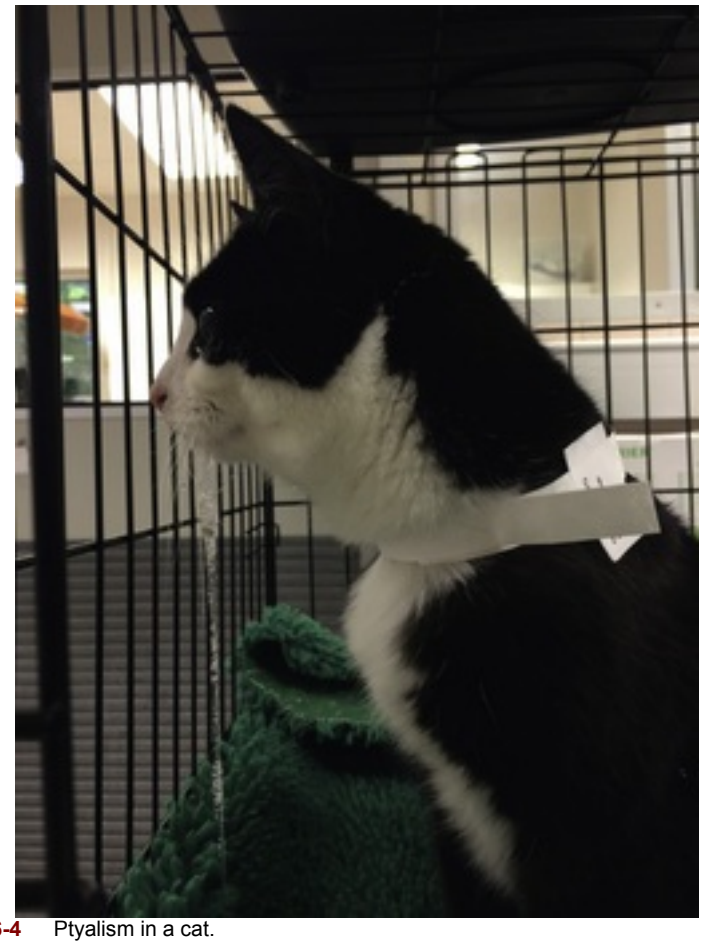
swallowing mechanism and cause pseudoptyalism.

True ptyalism is a common clinical sign with gastrointestinal, metabolic, and systemic diseases, and involves activation of the humoral and neural pathways for nausea and vomiting. Infectious diseases, including viral, bacterial, rickettsial, and protozoal infections, can have direct or indirect effects on saliva production. Central nervous system disorders can either increase salivation or interfere with normal swallowing function.

Clinical Signs[3,4]

The classic appearance is saliva dripping or pouring from the oral cavity (Figure 36-3 and E-Figure 36-4). The drooling may be categorized as mild to severe as well as intermittent to continuous. Clinical signs can occur acutely or be seen as gradual or chronic. The saliva may appear clear or it can be mixed with sanguineous or purulent exudates. Other potential clinical signs such as vomiting, regurgitation, anorexia, oral pain, and oral inflammatory lesions are related to the individual cause.

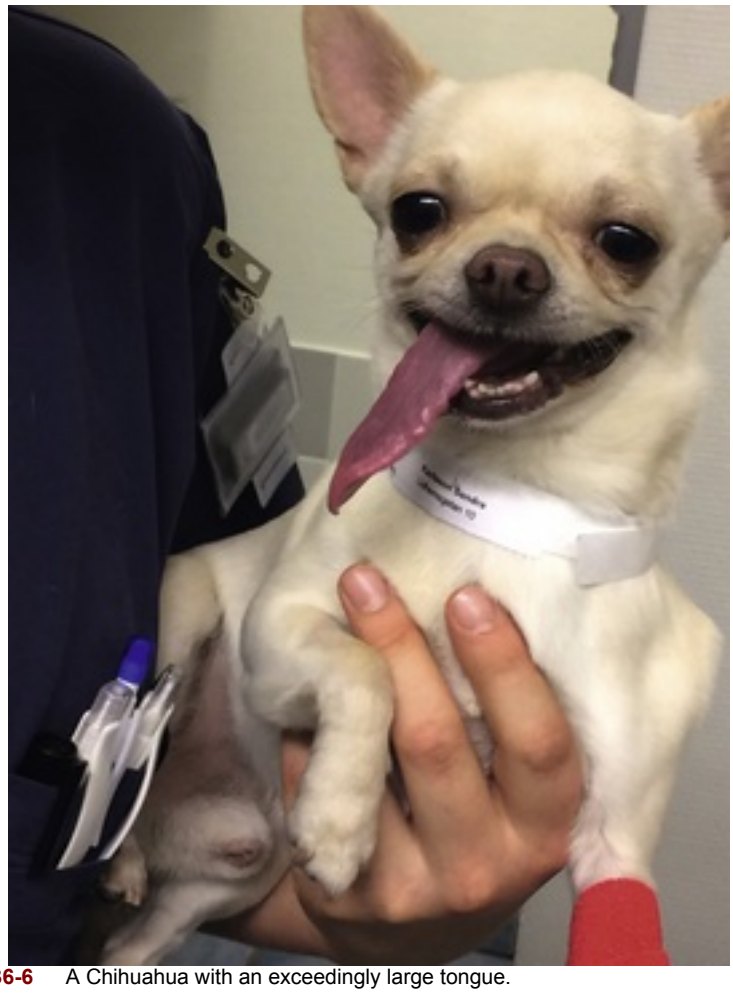
FIGURE 36-3 Ptyalism in a dog.



E-FIGURE 36-4 Ptyalism in a cat.

Differential Diagnoses[3,4] (Figure 36-5)

Neurologic: trigeminal neuropraxia, megaesophagus, facial paralysis, seizures, nausea from vestibular diseases; glossopharyngeal, hypoglossal or vagus nerve lesions that result in the inability to swallow.[7]
Developmental: severe brachygnathism, extensive lip fold, long tongue (E-Figure 36-6).



E-FIGURE 36-6 A Chihuahua with an exceedingly large tongue.

Trauma: soft tissue ulceration or laceration, electrical burn, temporomandibular joint (TMJ) luxation or fracture, mandibular fracture.[8-10]

Postsurgical: anesthesia, mandibulectomy (E-Figure 36-7) glossectomy, and mandibular canine tooth extraction.[11]

E-FIGURE 36-7 Post-operative bilateral rostral mandibulectomy.

Toxic: organophosphates, caustic ingestion, animal venom.[10,12-21]
Drug-induced: opiates, medications with a bitter or unpleasant taste.[22,23]
Behavioral: Pavlovian salivation associated with food, contentment/mood as in cats during purring, pain.
Obstructive: oral or esophageal foreign body, hematoma, seroma, or neoplasia.[8,10]
Metabolic: hepatic encephalopathy, uremia, exocrine pancreatic insufficiency, hyperthermia.[9,24-27]
Gastrointestinal: nausea, hiatal hernia, megaesophagus, gastric dilatation/volvulus, gastric ulcer, esophageal stricture, esophagitis, neoplasia, or foreign body.[28-30]
Infectious: acute calici- or herpesvirus infection, rabies, pseudorabies, tetanus, botulism, upper respiratory infection, candidiasis, severe periodontal disease, spirocercosis.[31-34]
Immune-mediated: chronic ulcerative paradental stomatitis (CUPS) in dogs, caudal stomatitis in cats, pemphigus, bullous pemphigoid, toxic epidermal necrolysis (TEN), masticatory muscle myositis, myasthenia gravis.[9,35-38]
Salivary: sialolith, foreign body, neoplasia, hyperplasia, infarction, sialocele, necrosis, idiopathic.[7,39,40]

FIGURE 36-5 Algorithm for ptyalism. *CBC*, Complete blood count; *CNS*, central nervous system; *CT*, computed tomography; *MR*, magnetic resonance imaging; *UA*, urinalysis.

Diagnostic Steps

The most important initial step is to obtain a complete history and perform a thorough physical exam (see ch. 1 and 2).

History

Establish possible cause, severity, complications and progression of disease. Important areas of the history include: age and mental stage of the patient, chronicity of the condition, associated neurological signs, timing, provoking factors, and estimation of quantity of saliva. Historical questions should include: general history, age, acute vs. chronic clinical signs, other gastrointestinal (GI) signs (e.g., vomiting, diarrhea), toxic exposure, drug administration, or trauma.

Age of the Patient

Young patients are more likely to have toxic exposure, foreign body, acute viral infection, or portosystemic shunts (especially small breed such as Yorkshire Terriers and Maltese; see ch. 284).

Mature patients are more likely to be affected by metabolic, immune-mediated or neoplastic diseases.

Acute versus Gradual or Chronic

Acute onset of significant pseudo- or true ptyalism is most often associated with a virus, toxin, or oral trauma. *Gradual or chronic onset* is more likely to be associated with a metabolic or neoplastic process.

Gastrointestinal Signs

If ptyalism is associated with nausea or vomiting, a GI, systemic, or neurologic problem is more likely. Regurgitation should prompt an esophageal exam, as this is typically associated with an esophageal condition (e.g., megaesophagus) (see ch. 39 and 273). If ptyalism is noted in combination with difficulty eating or quidding, an oral problem should be suspected and a complete oral and maxillofacial exam performed.

Physical Exam

The most important part of the physical exam is a complete oral/maxillofacial/esophageal examination. A thorough oral exam evaluates for infection, neoplasia, fractured/abscessed teeth, periodontal status, trauma, inflammatory/ulcerative disease and foreign bodies.

The clinician should check for sores on the lips or chin, tongue control, swallowing ability, nasal airway obstruction, decreased intraoral sensitivity, and anatomical closure of the mouth. The oral examination should include the sublingual area, as this is a common place for masses and string foreign bodies.

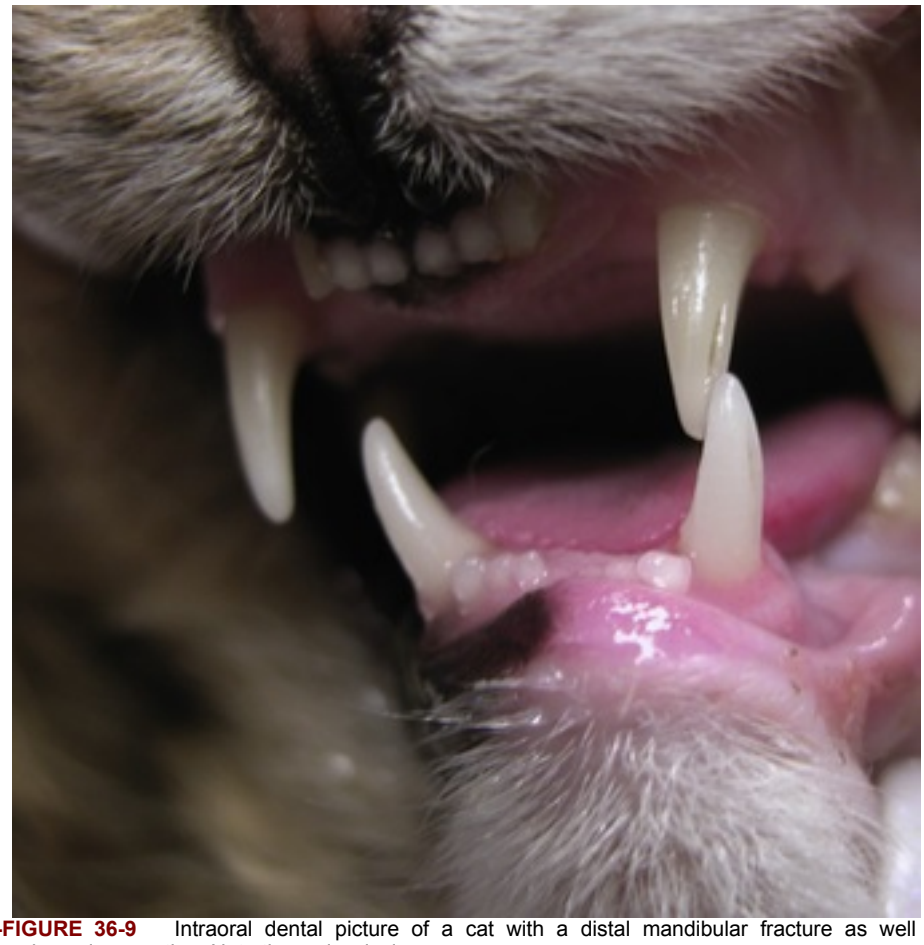
Oral ulcerative inflammatory diseases are typically in advanced stages before ptyalism is induced, and thus in these cases abnormal oral examination findings should be readily seen. These conditions include acute calici- or herpesvirus infection, immune-mediated diseases, caustic ingestion, and uremia.

The saliva itself should be examined for consistency and any additional components (e.g., blood or pus). The severity and frequency of the drooling should be assessed. The hydration status and head posture of the patient should be evaluated.

It is important to note that a complete oral examination is not possible without general anesthesia, and that a minimum database should be obtained prior to the anesthetized exam.

Saliva that has a sanguineous, purulent or fetid component is usually secondary to a problem within the oral cavity, such as: oral infections (such as oronasal fistula [E-Figure 36-8], trauma [E-Figure 36-9], neoplasia [E-Figure 36-10], inflammatory disease [E-Figure 36-11], or uremic ulcers [E-Figure 36-12]).

E-FIGURE 36-8 A large, chronic oronasal fistula in a dog. Dorsal is at the bottom of the image.



E-FIGURE 36-9 Intraoral dental picture of a cat with a distal mandibular fracture as well as symphyseal separation. Note the malocclusion.

E-FIGURE 36-10 Intraoral dental picture of a large oral mass on the maxilla of a dog.

E-FIGURE 36-11 Intraoral dental picture of severe caudal inflammation (especially associated with the mandibular first molars) in a cat.

E-FIGURE 36-12 Uremic ulcers in a cat with advanced renal disease.

A maxillofacial exam should include evaluation for swellings, asymmetry, TMJ luxation, trauma, cranial nerve function, and size and consistency of the salivary glands.

Inability to close the mouth indicates one of the following causes: traumatic (TMJ/mandibular fracture/luxation), neurologic (botulism or trigeminal neuropraxia), or obstructive (neoplastic or foreign body). **Inability to open the mouth** is most commonly associated with: tetanus, craniomandibular osteopathy, masticatory muscle myositis, neoplasia, or TMJ issues. The salivary glands should be systematically evaluated. Enlargement could indicate: infection, sialoliths, or neoplasia.

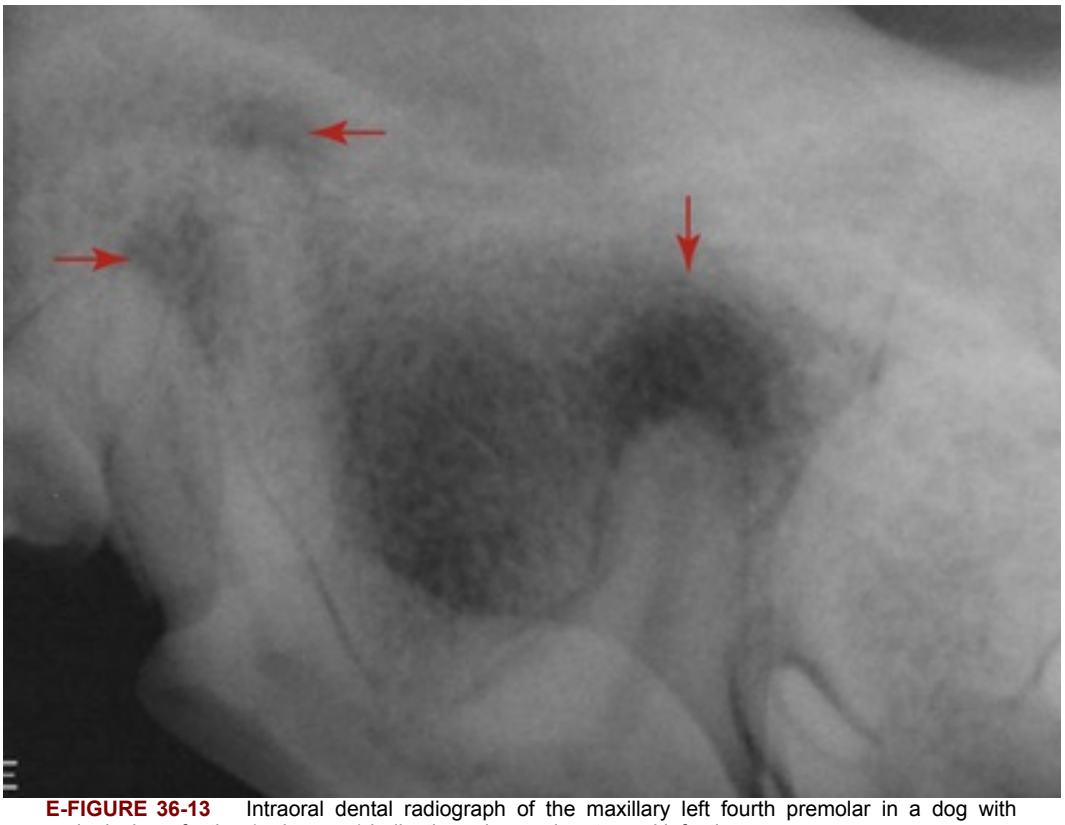
The physical examination of the esophagus is limited to external palpation for masses, pain or foreign bodies. Complete evaluation may require radiographs (+/− contrast), fluoroscopy, computed tomography (CT) scan, and/or endoscopy.

Diagnostic Tests[3,4]

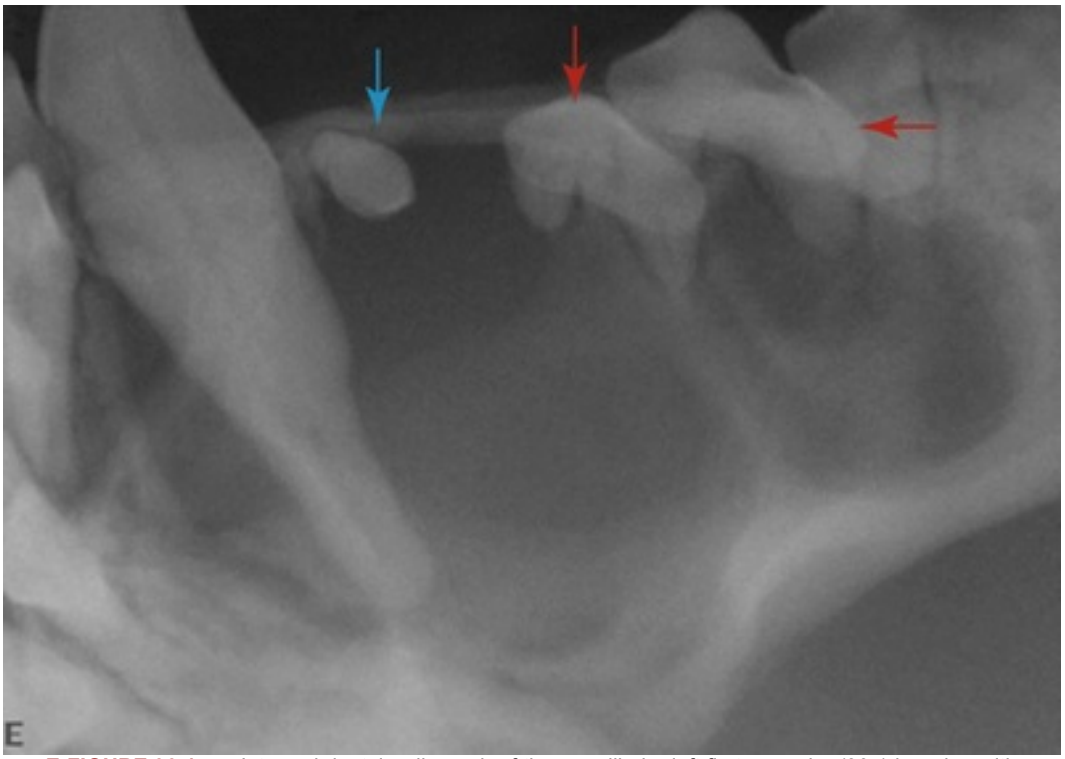
It is important to start initial diagnostic testing with a minimum database including complete blood count/chemistry panel/thyroid level, and urinalysis. This will rule out most of the metabolic causes as well as to verify that there are no blood count or blood chemical abnormalities that would preclude anesthesia for further evaluation.

For oral mucosal changes that are not obviously associated with a toxic or caustic cause or systemic disease (e.g., uremic ulcers), a surgical biopsy should be performed under general anesthesia and submitted for histopathology. When obtaining the tissue sample, ensure that it is representative of and of sufficient size for an accurate assessment. It is worthwhile to note that cytology as well as culture and sensitivity are often insufficient for an accurate assessment of disease processes in the oral cavity.[3,41]

In cases that clinically appear to have an oral cause but the problem cannot be readily identified on oral exam, dental radiographs should be performed. These radiographs may elucidate a subgingival cause such as a tooth root abscess or dentigerous/radicular cyst (E-Figures 36-13 and 36-14). Patients that present with derangements of jaw motion or maxillofacial swellings should be further evaluated with skull radiographs, nuclear scintigraphy, magnetic resonance imaging or CT scan. Finally, tests such as sialography can be of benefit.



E-FIGURE 36-13 Intraoral dental radiograph of the maxillary left fourth premolar in a dog with periapical rarefaction (red arrows) indicating advanced root canal infection.



E-FIGURE 36-14 Intraoral dental radiograph of the mandibular left first premolar (305) in a dog with a large dentigerous cyst. The cyst was created by the impacted first premolar (blue arrow). Note that the teeth are being moved by the cyst (red arrows).

Once oral and maxillofacial causes have been ruled out, further diagnostics are indicated, beginning with thoracic and abdominal radiographs. If the cause of the ptyalism has not been identified at this point, more specific testing should be performed, where indicated, such as upper GI studies, fluoroscopy, and endoscopy (see ch. 113). The clinician may also consider tests for botulism and rabies (see ch. 226 and 214).

Treatment

Treatment is directed at the underlying cause. Examples of treatments of ptyalism can be:

- **Direct toxic exposure** should be treated with dilutional therapy and supportive care.[9,10,42] Water or milk is considered the liquid of choice for dilution (see ch. 151).[43]
- Therapy for **oral inflammatory diseases** should be directed towards reducing the inflammation. This can be accomplished medically with immunosuppressive agents or surgically with periodontal treatment and/or extractions.[9,10,38,44]
- **Oral traumatic diseases** are best treated surgically.[8,10]
- **Portosystemic shunts** can be managed surgically or medically (see ch. 284).
- **Metabolic derangements** are treated as appropriate for the disease process.[9,10]

In case of idiopathic or incurable conditions such as structural or neurologic diseases, treatment is directed at decreasing the flow of saliva and protecting the epidermis in the chronically wet area. If one salivary gland is responsible for the increased production, surgical excision is the treatment of choice.[45,46] Cheiloplasty can be performed to help eliminate excessive drooling caused by lip malformation, mandibulectomy, glossectomy, or neurologic disorders of swallowing.[8] Finally, surgical repositioning of the parotid salivary duct may be effective in controlling the excess salvation.[47]

Decreasing the overall flow of the saliva can be attempted with atropine or glycopyrrolate.[48,49] In cases of idiopathic ptyalism, phenobarbital may be effective.[7] In these cases it is thought that the ptyalism is a form of epilepsy. In human dentistry, injections of biotoxin or ethanolamine oleate (EO) into the salivary glands, as well as radiotherapy, scopolamine via a transdermal patch, and even acupuncture have been investigated options for long-term salivary control.[50-54]

Halitosis

The origin of the term *halitosis* comes from the Latin word *halitus* meaning "breath or exhaled air."[55] Halitosis is defined as an offensive odor of the breath.[56] It is a common problem in companion animals and constitutes a significant psychosociological problem in the companion animal-owner relationship.[57] There is no sex or breed predilection, but the incidence increases with age.[55]

Classification of Halitosis

There is no universally accepted standardization in terminology and classification of halitosis.[58,59]

Genuine halitosis can be sub-classified as physiologic halitosis or pathologic halitosis. Pathologic halitosis means that the breath odor is a sign of a disease or a pathologic condition. Physiologic halitosis covers the situations where the patient has no disease but has a malodor because of putrefaction processes taking place in the oral cavity, most frequently caused by bacterial plaque. An example of physiologic halitosis is what is known in humans as "morning breath." In most cases, physiologic halitosis can be resolved with improved oral home care. This classification of bad breath is considered to be transient, in the sense that its presence comes and goes, as determined by temporary localized conditions in the mouth, and that it can be relatively easily resolved.

The best classification system for veterinary patients is based on etiology which divides halitosis into types based on where the offending molecules originate. This formula is broken into oral, airway, gastroesophageal, blood-borne, and subjective.

Halitosis can also be classified according to the character of the odor[60]: *Sulfurous* is caused by volatile sulfur compounds (VSCs): methyl mercaptan, hydrogen sulfide and dimethyl sulfide. *Fruity* is caused by acetone. *Urine* or *ammoniac* breath is caused by ammonia, dimethyl amine and trimethylamine. *Sweet* smelling breath is often associated with ketones. The degree of halitosis can be measured by a subjective scale from 0 to 3,[61] or

it can be objectively measured using a commercially available sulfide monitor.[62]

Causes of Halitosis

Oral Halitosis

In about 90% of human patients with halitosis, the origin of the problem is within the mouth itself.[63] The list of possible causes of halitosis originating from the oral cavity itself is long; however, by far the most prevalent cause is bacterial growth below the gum line in periodontal pockets created by periodontitis[64-67] (E-Figures 36-15 through 36-17).

E-FIGURE 36-15 Intraoral dental picture of a dog with a significant periodontal pocket between the left mandibular first and second molars (309-10). Note the relative lack of dental calculus and gingival inflammation. Therefore, do not assume that periodontal disease is not present just because the gums appear healthy. An exam under general anesthesia and dental radiographs are always necessary for proper periodontal evaluation.

E-FIGURE 36-16 Intraoral dental picture of a cat with a significant periodontal pocket on the palatal aspect of the left maxillary canine (204).

E-FIGURE 36-17 Advanced periodontal disease with purulent exudate on the left mandible of a dog.

Periodontal disease is generally described in two phases: gingivitis and periodontitis. Gingivitis is the initial, reversible stage of the disease, where the inflammation is confined to the gingiva.[68,69] At this point, there is no inflammation in the periodontal ligament or alveolar bone. The gingival infection is initiated by the plaque bacteria and can be reversed at this stage if a dental prophylaxis is performed and proper home-care maintained.[69] Periodontitis is the later stage of the disease process, which is defined as an inflammatory disease of the supporting structures of the teeth (the periodontal ligament and the alveolar bone) caused by microorganisms.[70] While it is initiated by plaque, the progression of disease is regulated by the patient's immune response.[71] In fact, it is actually the host response that often damages the periodontal tissues.[72-74]

Both gingivitis and periodontitis are initiated when oral bacteria adhere to the teeth in a substance called plaque.[64,65,75-77] Plaque is a biofilm almost entirely made up of oral bacteria contained in a matrix composed of salivary glycoproteins and extracellular polysaccharides.[68,69,73]

Plaque formation begins with the formation of the pellicle. The pellicle is a thin, saliva-derived layer including numerous proteins, enzymes and other molecules that can act as attachment sites for bacteria.[68] This starts forming nanoseconds after a prophylaxis.[15] Plaque is formed when bacteria attach to the pellicle.

Gingivitis is caused by an increase in the overall numbers of bacteria, which are primarily motile Gram-negative rods and anaerobic species.[76] The early colonizers are Gram-positive aerobic and generally minimally pathogenic. However, they promote the growth of the secondary and more periodontopathogenic colonizers, such as *Porphorymonas*. They accomplish this by using oxygen and making products such as lactate, formate, and succinate. The host provides nutrients to the pathogenic species in the form of blood and crevicular fluid.[78]

The whole process of plaque formation takes 24 hours if the plaque is not disturbed, which means that the teeth accumulate plaque **one day** following a complete dental prophylaxis.[68,79] After day 4, the plaque does not grow anymore, but the flora changes from Gram-positive to Gram-negative bacteria. This change in bacterial species is what initiates gingivitis.[80]

In dogs, anaerobes constitute only 25% of the culturable subgingival flora in healthy gingiva, but they become approximately 95% of the flora in dogs with periodontitis.[81] As the virulence of the bacteria increases, so does the effect of bacterial by-products, which elicit inflammation, including chemotoxins, mitogens, antigens, and enzymes such as hyaluronidase, chondroitin sulphate and proteolytic enzymes.[68]

Oral halitosis mainly originates from VSCs, especially hydrogen sulfide (H_2S), methylmercaptan (CH_3SH) and dimethyl sulfide ($(CH_3)_2S$).[82] These compounds typically result from the proteolytic degradation of peptides by oral microorganisms. These peptides are present in the saliva as well as gingival crevicular fluid, interdental plaque, and blood. In addition, they can come from shed epithelium, food debris, and discharge from the nasopharynx. It is interesting that only Gram-negative anaerobic bacteria possess such proteolytic activity. Wherever the location, the common pathophysiology is tissue destruction and putrefaction of amino acids by bacteria. The bacteria associated with gingivitis and periodontitis are almost all Gram-negative anaerobes and are all known to produce VSCs.[65,83-87]

The VSC levels in the mouth correlate positively with the depth of periodontal pocket(s).[67,82,88,89] This is likely due to the fact that deeper pockets will contain more bacteria, including a higher percentage of anaerobic species. The amount of VSCs in breath increases with the number, depth and bleeding tendency of the periodontal pockets.[82,88,89] The VSCs also directly aggravate the periodontitis process. They increase in the permeability of the pockets and mucosal epithelium and expose the underlying connective tissue of the periodontium to the bacterial metabolites.[90] Low oxygen tension in the deep periodontal pockets results in a low pH and activation of the decarboxylation of the amino acids (e.g., lysine, ornithine) to cadaverine and putrescine, both malodorous diamines. Thus, in the presence of gingivitis or periodontitis, VSCs play a prominent role in halitosis; but it is important to remember that not all patients with gingivitis or periodontitis have halitosis and vice versa.

The association between bad breath and periodontal disease in companion animals poses an important issue because halitosis is often the first clinical sign of periodontal disease noticed by the owner. However, it is important to note that halitosis is typically a sign of advanced periodontal disease. Clients should therefore be counselled that halitosis is not normal and that is an indication for professional dental therapy.

Treatment of Periodontal Diseases

There are numerous therapeutic options available for periodontal diseases; however, the basis of periodontal

therapy remains plaque control.[91] The cornerstone of plaque control and the first step for any periodontal therapy is a thorough dental prophylaxis. A complete dental prophylaxis should include the following steps: pre-surgical exam, 0.12% chlorhexidine lavage, supra- and sub-gingival scaling, polishing, sulcal lavage, periodontal probing, oral evaluation, and dental charting, dental radiographs, treatment planning and surgery if necessary.[92]

Pockets with a depth of over 0.5 mm in cats and 3 mm in dogs are pathologic and require a deeper form of cleaning (+/− perioceutic). Teeth with pockets greater than 6 mm deep, furcation exposure level II or III, or mobility, require periodontal flap surgery or extraction to eradicate the infection.

Bacterial plaque colonizes clean tooth surfaces within 24 hours of cleaning.[68,79] Therefore, without a commitment to home care, gingival infection and inflammation quickly recurs.[70,93-96] In addition, with regards to established disease, a recent study found that periodontal pockets become reinfected within 2 weeks of a prophylaxis if home care is not performed.[94] This same study showed that pocket depth returns to pretreatment depths within 6 weeks of therapy. Furthermore, it was found in a human review that professional cleanings were of little value without home care.[97]

Other Oral Causes

There can be other intraoral courses of halitosis; however, these are all much less common than periodontal disease.[98-100] The list of differential diagnoses within the oral cavity is long but contains the following conditions: infections, ulcerations, tumors (E-Figure 36-18) and foreign bodies (E-Figure 36-19).

E-FIGURE 36-18 Large oral mass on the maxillary left of a cat.

E-FIGURE 36-19 Stick foreign body across the palate of a dog.

Owners often misdiagnose malodor caused by intertrigo or skin fold pyoderma as halitosis (see ch. 25).[101] Intertrigo arises from an overgrowth or colonization of skin folds by normal skin bacteria and sometimes yeast. Lip folds are common in brachycephalic breeds, spaniels, and many water dogs and these breeds are often presented due to the smell. The clinical signs are hair loss, redness, and accumulation of debris in the lip folds around the mouth (E-Figure 36-20).

E-FIGURE 36-20 Advanced intertrigo in a Poodle.

Airway

Nose and Sinuses

The nasal and sinus passages can also be the origin of halitosis. The smell typically has a stronger odor when coming from the nose compared to oral infection. Foreign bodies, neoplasia, or even chronic rhinosinusitis can cause nasal halitosis. Breath analysis techniques have not been applied to this condition, but theoretically there are several possible mechanisms of halitosis caused by infection in the nose or sinuses.[102-104]

Tonsils

In the human literature, there is disagreement as to the proportion of halitosis caused by tonsil pathology.[103] Tonsillar diseases which may be associated with halitosis include: chronic caseous tonsillitis, tonsillolithiasis and to a lesser extent peritonsillar abscess, actinomycosis, fungating malignancies and different kinds of tumors.[105]

Bronchi and Lungs

Pulmonary causes include chronic bronchitis and bronchiectasis.[106] Bronchiectasis is the result of chronic airway disease leading to a dilation of the bronchi and a collection of mucus and cell debris within the air passages. It is commonly found in those animals that have been suffering from chronic bronchitis or bronchopneumonia.

Gastroesophageal

Megaesophagus is a disorder of the esophagus characterized by dilation and decreased peristalsis (see ch. 273). Halitosis is a common clinical sign of megaesophagus along with regurgitation, weight loss, and coughing.[107] Halitosis resulting from other extraoral GI disorders is considered to be rare. However, it has been reported among the signs related to *Helicobacter pylori* infections and gastroesophageal reflux disease.[108]

Systemic conditions can also occasionally cause halitosis. The list of systemic differential diagnoses for halitosis includes: diabetes mellitus, renal infection and failure, liver disease, and carcinoma.[87,109] However,

patients suffering from such systemic diseases typically show additional and more diagnostically conclusive signs than halitosis alone.

Diabetes mellitus is a metabolic disorder characterized by a chronic hyperglycemic condition resulting from defects in insulin secretion, insulin action, or both (see ch. 304 and 305).[110,111] The deficiency in or the lack of action of insulin leads to uncontrolled lipolysis and elevated levels of free fatty acids in the plasma. This loss of proper regulation may result in the formation of ketones, used for energy production. A spontaneous breakdown product of the ketones (acetoacetate) is the acetone that is exhaled by the lungs, which gives a distinctive odor to the breath, which has been described as "rotten apples."[106]

Kidney insufficiency (uremia) will lead to increased uric acid levels in the blood, which is exhaled creating ammonium-like breath.[112] This is usually described as a "fish odor."[90] To fully investigate the underlying cause of kidney damage, imaging, blood tests and often renal biopsy are often used.

Liver insufficiency, such as with cirrhosis, will cause ammonium to accumulate in the blood and be exhaled.[113] *Foetor hepaticus* is a peculiar odor to the breath in people with severe liver disease, caused by volatile aromatic substances that accumulate in the blood and urine due to defective hepatic metabolism. It is a late sign in liver failure and is one of the clinical features of hepatic encephalopathy. Malodor caused by end-stage liver disease has a sweet odor, which some describe as that of "dead mice."[106]

CHAPTER 37

Gagging

Peter Hendrik Kook

Client Information Sheet: Gagging

Anatomy and Physiology

The gag reflex is a normal defense mechanism that prevents foreign bodies from entering the trachea, pharynx, or larynx. Gagging comprises brisk and brief elevations of the soft palate together with bilateral contraction of the constrictor muscles of the pharynx resulting in ejection of unwanted, irritating, or toxic material. After intraoral stimulation, afferent fibers of the trigeminal, glossopharyngeal, and vagus nerves pass to the medulla oblongata. From there, efferent impulses give rise to the spasmodic and uncoordinated muscle movement characteristic of gagging. The corresponding center in the medulla oblongata is close to the vomiting, salivating, and cardiac centers, and these structures may be concurrently stimulated during gagging. Furthermore, neural pathways from the gagging center to the cerebral cortex allow the reflex to be modified by higher centers, illustrating why gagging may rarely also be elicited by nontactile sensations such as visual or olfactory stimuli. In small animals, the interpretation of a functioning gag reflex generally is that the neurologic pathways associated with gagging (the above-mentioned cranial nerves and their brainstem connections) are intact. However, in humans the gag reflex is not predictive of pharyngeal swallowing efficiency or aspiration risk because it can be absent in 20 to 40% of normal adults.[1] In dogs, central vagal stimulation can depress the onset of the gag reflex, possibly via blocking of impulses arising in response to pharyngeal stimulation by respiratory afferent impulses conducted through the vagal nerves.[2]

Gagging often occurs together with retching. Retching is an involuntary and futile attempt at vomiting associated with nausea. In retching, the direction of spasmodic and uncoordinated peristalsis is reversed and air is forced over the closed glottis producing a retching sound. It usually occurs post-swallowing and is suggestive of esophageal dysmotility. Ongoing retching usually culminates in the act of vomiting. Gagging, retching, and vomiting may occur separately or together. When they occur together, they are usually in sequence as manifestations of the different events that integrate the vomiting reflex. In contrast to vomiting, gagging and retching do not imply activation of the vomiting reflex. When gagging, retching or vomiting manifest as isolated clinical signs, their significance may differ from the stereotypical picture of vomiting. Gagging typically implies pharyngeal or retropharyngeal dysphagia and describes a patient that is trying to swallow in the presence of a dysfunctional pharyngeal phase of the swallowing process. This results in loss of the food bolus together with coughing or drooling. In addition, gagging tends to result in laryngospasm, particularly in cats. The act of swallowing comprises a series of sequential well-coordinated events that function to transport food and liquids from the oral cavity to the stomach. Deglutition has an oral, pharyngeal, and esophageal phase, and all three phases are involved in the transport of the bolus from the oral cavity to the stomach. The pharyngeal phase of swallowing involves the movement of the bolus from the pharynx to the esophagus. The required sequential contractions are initiated by stimulation of sensory receptors through touch, pressure, and similar action of food on the tongue, faucial pillars, soft palate, uvula, epiglottis, pharyngeal wall, and/or junction between the pharynx and esophagus. The corresponding nerve fibers belong to the maxillary branch of cranial nerves V and IX and to the cranial laryngeal nerve. These afferent pathways carry the information from peripheral receptors to the brainstem and thus evoke contraction of the buccal, tongue, pharyngeal, and esophageal muscles, propelling the food bolus aborally. Particular sensory patterns determine which pharyngeal motor responses will be evoked. Generally, solid boluses are more effective than liquids in stimulating pharyngeal receptors to initiate swallowing, whereas multiple swallowing attempts are sometimes necessary to stimulate deglutition of water, even in healthy animals. Finally, expectoration may be confused with gagging. Expectoration is defined as ejection of airway

and laryngopharyngeal mucus or other material and is not associated with nausea. It usually follows an episode of coughing, for instance in animals with inflammatory airway disease (Video 37-1). Gagging and retching under these circumstances is not associated with swallowing or gastrointestinal disease but rather is a consequence of cardiopulmonary disease usually following an episode of coughing.

History

There are a number of environmental and clinical factors that should be evaluated when a dog or cat is presented because of gagging. These include the occurrence of sneezing, coughing, vomiting, regurgitation, and salivation and changes in appetite, activity level, overall strength, and voice. In addition, environmental factors, the onset, duration, and progression of clinical signs, the potential for foreign body or toxin exposure, and the development of growing animals should be assessed. Vaccination history for rabies is also of interest because the inability to swallow saliva (and food) secondary to lyssavirus-associated laryngeal paralysis may also elicit gagging when intraoral areas known to be ''trigger zones'' such as the base of tongue or palate are stimulated (see ch. 226).

Clinical Evaluation

A physical examination must include thorough evaluation of the oral cavity and oropharynx, palpation of the pharynx, neck, and salivary glands, and assessment of airflow from the nares. Sedation or light anesthesia is usually required for complete examination of the oropharynx and larynx. Ear polyps may cause gagging and should be ruled out by means of an otoscopic examination, particularly in cats. Thoracic auscultation and routine thoracic radiography may also be part of the workup because severe respiratory disease can mimic gagging and retching. Gagging may occur as a sequel to oropharyngeal dysphagia and therefore a neurologic examination is indicated (see ch. 259). Neurologic diseases can damage the neural structures that are involved in the afferent or efferent limbs of the gag reflex; however, most neuromuscular diseases generally tend to weaken pharyngeal function rather than cause pharyngeal spasmodic contractions typically associated with gagging. On the other hand, decreased salivary clearance associated with impaired swallowing may stimulate the gag reflex, and functions mediated by adjacent neuronal structures can concurrently be involved. A complete blood cell count, biochemistry profile, including creatine kinase activity, and urinalysis may be considered to rule out systemic illness. In young breeds of dogs known to have hereditary cobalamin malabsorption, measurement of serum cobalamin concentration may be useful; intermittent impairment of swallowing secondary to stomatodynia and glossitis, which can trigger or mimic gagging, was recently described in canine Imerslund-Graesbeck syndrome.[3] Evaluation of the thyroid function may be helpful in single cases, because cricopharyngeal dysfunction has been reported as the presenting complaint in canine hypothyroidism and was fully reversible with thyroid supplementation.[4]

A list of causes of gagging accompanied by appropriate diagnostic tests is shown in Box 37-1. An algorithm (Figure 37-1) identifies how to workup a gagging dog or cat.

Box 37-1

Differential Diagnosis and Diagnostic Tests for Gagging in Dogs and Cats

I. Nasal sinus
- A. Cleft palate ⇒ oropharyngeal examination
- B. Nasal parasites (*Capillaria, Pneumonyssoides* spp.) ⇒ rostral and retrograde examination of nasal passage, rhinoscopy
- C. Nasal tumors ⇒ same as B plus CT scan/biopsy
- D. Nasal foreign body ⇒ same as B

II. Pharynx (morphologic)
- A. Neoplasia ⇒ oropharyngeal examination, possible CT/MRI scan, fine needle aspiration cytology, core-needle biopsy and histopathology
- B. Foreign body ⇒ oropharyngeal examination, fistulogram, CT/MRI scan
- C. Tonsillitis ⇒ tonsillectomy (rarely the only cause)
- D. Pharyngitis, pharyngeal abscess ⇒ same as A

E. Elongated soft palate ⇒ oropharyngeal examination
F. Nasopharyngeal polyps ⇒ oropharyngeal and nasopharyngeal examination
G. Pharyngeal mucocele ⇒ oropharyngeal examination, fine-needle aspiration cytology
H. Stylohyoid disarticulation ⇒ oropharyngeal examination, pharyngeal radiography or CT scan
I. Cricopharyngeal bar ⇒ videofluoroscopy, manometry

III. Pharynx (functional)

A. Cricopharyngeal achalasia ⇒ videofluoroscopy, manometry
B. Cricopharyngeal dyssynchrony ⇒ videofluoroscopy, manometry
C. Neuromuscular disease
1. Inflammatory ⇒ neurologic examination, EMG, muscle biopsy
2. Degenerative/idiopathic ⇒ same as 1 plus brain imaging
3. Neoplastic ⇒ neurologic examination, CT/MRI scan of brainstem
4. Infectious (rabies, pseudorabies) ⇒ history of exposure, vaccination history, clinical course, histopathology
5. Hypocalcemia ⇒ serum (ionized) calcium concentration

IV. Respiratory tract

A. Upper airway (morphologic)
1. Foreign body ⇒ pharyngeal/laryngeal examination, radiography, CT/MRI scan, endoscopy
2. Neoplasia ⇒ same as 1 plus cytology, histopathology
3. Tracheal collapse ⇒ radiography, fluoroscopy, endoscopy
B. Upper airway (functional)
1. Laryngeal paralysis ⇒ pharyngeal, laryngeal examination
2. Laryngitis ⇒ pharyngeal, laryngeal examination
3. Tracheobronchitis ⇒ radiography, transtracheal aspiration cytology/culture, bronchoscopy
C. Lower airway (functional)
1. Feline chronic bronchial disease ⇒ radiography, bronchoalveolar lavage
2. Canine tracheobronchitis ⇒ history, physical examination, tracheal cytology
3. Fungal pneumonitis ⇒ history, radiography, tracheal and bronchial cytology, fungal antigen testing

V. Esophagus

A. Morphologic
1. Stricture/stenosis ⇒ history, (contrast) radiography, (+/− fluoroscopy), endoscopy
2. Neoplasia ⇒ same as 1
B. Functional
1. Esophagitis ⇒ history, endoscopy, cytology/histopathology
2. Esophageal motility disorder ⇒ same as 1 plus ACh receptor Ab titer, edrophonium response test, EMG, thyroid profile, resting serum cortisol concentration/ACTH stimulation, muscle biopsy

VI. Miscellaneous

A. Salivary gland disease (hypersialosis) ⇒ salivary gland palpation, fine-needle aspiration, treatment trial with phenobarbital

AB, Antibody; *ACh,* acetylcholine; *ACTH,* adrenocorticotropic hormone; *CT,* computed tomography; *EMG,* electromyography; *MRI,* magnetic resonance imaging.

CHAPTER 38

Dysphagia

Julio López

Client Information Sheet: Dysphagia

Dysphagia and regurgitation are clinical signs typically associated with disorders of the oropharynx or esophagus. Careful attention to the history and clinical signs assists the clinician in localizing the dysphagia and differentiating regurgitation from vomiting, which is necessary to formulate an appropriate diagnostic and treatment plan (Figures 38-1 and 38-2) (see ch. 39).

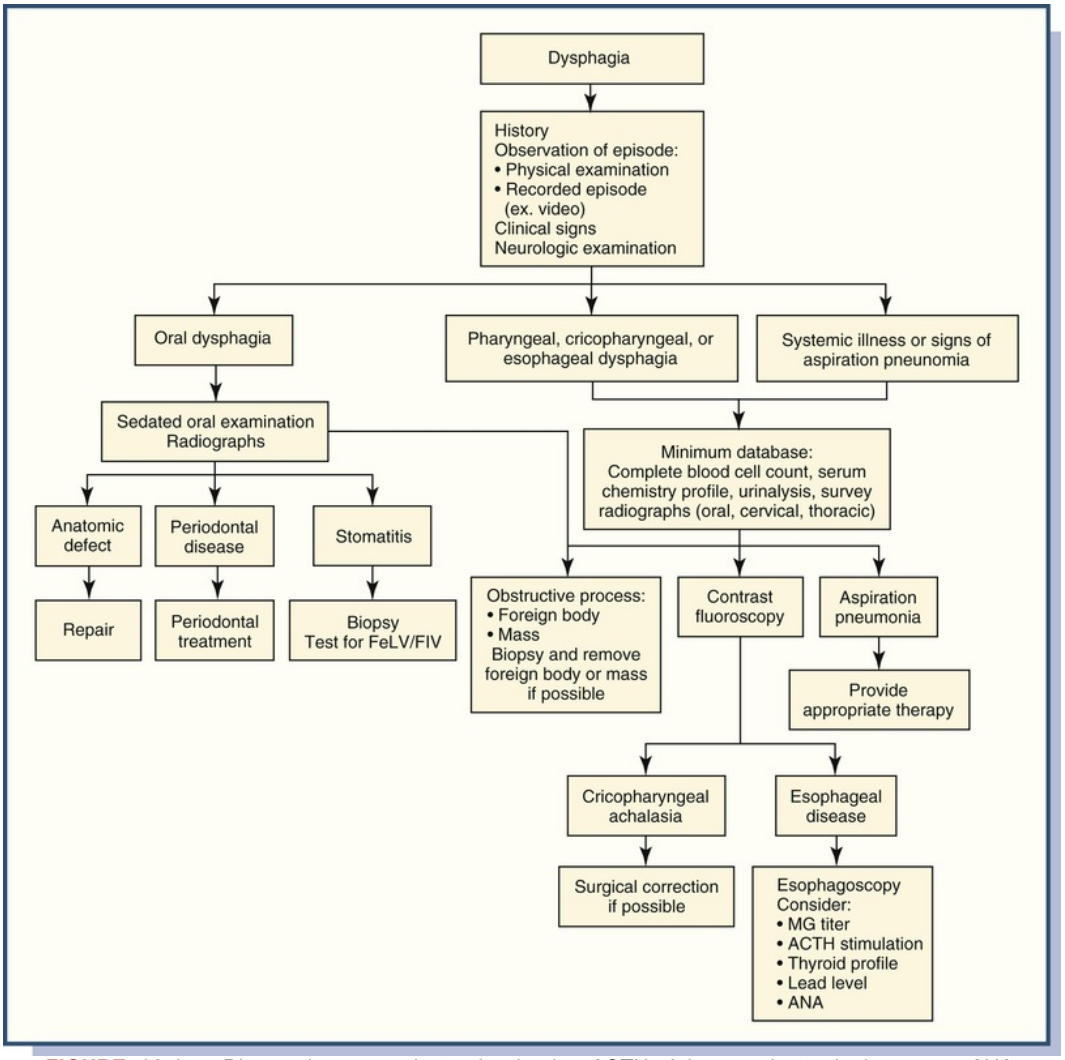

FIGURE 38-1 Diagnostic approach to dysphagia. *ACTH,* Adrenocorticotropic hormone; *ANA,* antinuclear antibody titer; *FeLV,* feline leukemia virus; *FIV,* feline immunodeficiency virus; *MG,* myasthenia gravis (acetylcholine receptor antibody). Louis, 2010, Saunders Elsevier, pp 191-195.)

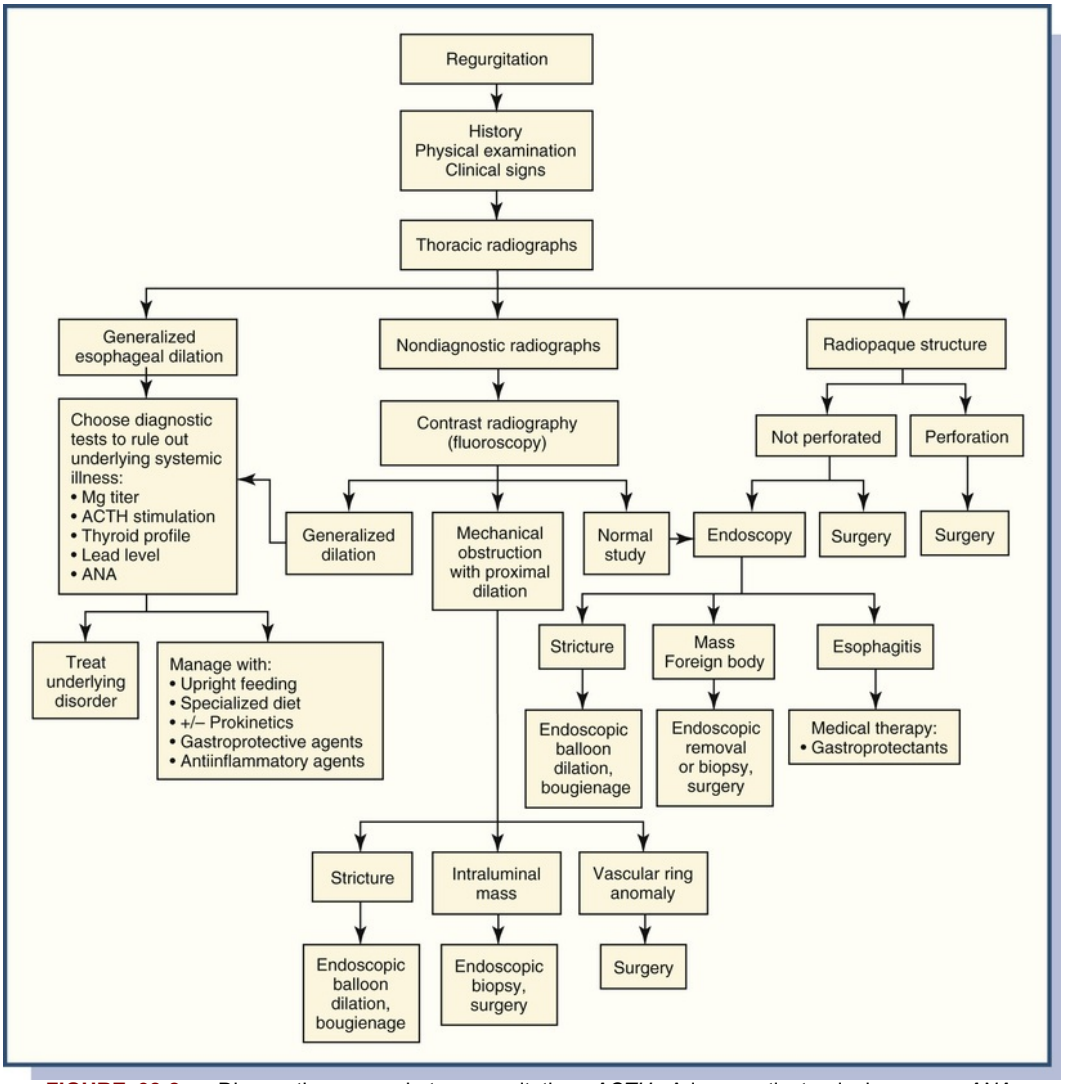

FIGURE 38-2 Diagnostic approach to regurgitation. *ACTH,* Adrenocorticotropic hormone; *ANA,* antinuclear antibody titer. (From Schaefer Woolley C: Dysphagia and regurgitation. In Ettinger SJ, Feldman EC, editors: *Textbook of veterinary internal medicine,* ed 7, St Louis, 2010, Saunders Elsevier, pp 191-195.)

Dysphagia

Dysphagia is defined as difficulty swallowing. The process of swallowing consists of four phases: oral preparatory, oral, pharyngeal, and esophageal.[1] It is essential to observe the animal eating and drinking to assist in localization of the abnormal swallowing phase. The oral phases of dysphagia consist of abnormalities with prehension, mastication, lubrication, and transportation of food from the tongue to the pharynx. Pharyngeal dysphagia occurs when the food bolus cannot be propelled from the oropharynx, through the hypopharynx, and to the proximal esophagus. Cricopharyngeal dysphagia is the abnormal transportation of a bolus through the proximal esophageal sphincter. It is either due to an inadequate or complete lack of opening/relaxation of the upper esophageal sphincter (true cricopharyngeal achalasia) or from abnormal timing of its opening/relaxation (cricopharyngeal asynchrony). Esophageal dysphagia is difficulty in passing a bolus down the esophageal body.

Clinical Signs

Clinical signs are dependent on the location and severity of the swallowing disorder. Oral dysphagia manifests as difficulty prehending or masticating food, or an inability to transport it to the base of the tongue. Pharyngeal dysphagia may present with gagging or retching, and as with cricopharyngeal dysphagia may demonstrate repeated attempts to swallow, excessive head movements, and dropping food from the mouth. Regurgitation is associated with esophageal dysphagia. Coughing may occur in dysphagic animals, both in association with swallowing, or as a sign of aspiration pneumonia, a complication that can occur with any form of dysphagia (see ch. 242).

Signalment

A review of the signalment and age of onset of clinical signs may aid in formulating a differential diagnosis. Congenital defects, such as cricopharyngeal achalasia, are more likely noted in juvenile dogs and may be first observed at weaning. In Golden Retrievers, oropharyngeal dysphagia has been identified as a heritable trait.[2] Hypothyroidism may be considered as a differential diagnosis as well.[3] Mechanical obstruction (foreign bodies) or ingestion of a caustic substance is more likely in young to middle-aged pets. Geriatric pets, or those with chronic signs of disease (weight loss, anorexia), are more likely to have a systemic illness. When other neurologic deficits occur along with dysphagia, a nervous system disease such as a neuropathy, neuromuscular junction disorder, or myopathy is likely (Box 38-1).[4] Cats are less likely to have dysphagia compared to dogs, but when they do, it is usually secondary to a structural abnormality such as an oral tumor, ulcer or stomatitis.

Box 38-1

Causes of Dysphagia

Obstructive Lesion (Anatomic or Mechanical)

Foreign body
Neoplasia
Inflammatory (abscess, polyp, granuloma)
Lymphadenopathy
Sialocele
Lingual frenulum disorder
Cricopharyngeal achalasia/asynchrony
Cleft palate
TMJ disorder
Trauma (fracture, luxation)

Pain

Periodontal (tooth fracture/abscess, periodontitis)
Stomatitis/glossitis/pharyngitis (viral: FeLV/FIV, immune mediated, caustic ingestion)
Traumatic (electric cord burn)
Retrobulbar abscess

Neurologic Disorders

Rabies
CNS disease (brainstem)
Cranial nerve disease (V, VII, IX, X, XII)

Neuromuscular Disorders

Myasthenia gravis
Inflammatory myopathy (masticatory myositis, polymyositis)
Polyradiculitis
Botulism
Tick paralysis
TMJ disease

Endocrine
Hypothyroidism
CNS, Central nervous system; *FeLV*, feline leukemia virus; *FIV*, feline immunodeficiency virus; *TML*, temporomandibular joint.

From Schaefer Woolley C: Dysphagia and regurgitation. In Ettinger SJ, Feldman EC, editors: *Textbook of veterinary internal medicine*, ed 7, St Louis, 2010, Saunders Elsevier, pp 191-195.

Diagnosis

Correctly localizing the source of the dysphagia will require combining observation of the abnormal swallowing along with the signalment, history, clinical signs, and physical exam. A neurological examination should also be performed as it may support a generalized neuromuscular disorder (see ch. 259). The gag reflex should be present in cases of cricopharyngeal dysphagia but may be diminished in pharyngeal dysphagia. As rabies is a differential diagnosis, caution should be taken in any case where there is an index of suspicion for this disease (see ch. 226). A complete oral and laryngeal examination under anesthesia is essential to identify obstructions (foreign body, mass), inflammatory processes (stomatitis, dental disease), or laryngeal paralysis (polyneuropathy).

Survey radiographs of the head, neck and thorax should be obtained, as well as a complete blood count, serum chemistry profile (including creatine kinase and electrolytes), urinalysis, thyroid testing, and acetylcholine receptor antibody titer for myasthenia gravis, which may present as an acquired focal disease.[5] Often, advanced diagnostics such as endoscopy and/or contrast videofluoroscopy motion studies (see Videos 271-1, 271-2, and 271-3) are needed to evaluate the structure and function, respectively, of the anatomic areas involved in the swallowing reflex and allow for a definitive diagnosis (see Figure 38-1).[6]

Treatment

An accurate diagnosis is the key to creating a treatment plan, as surgical intervention of a condition requiring medical treatment will lead to worsening of the dysphagia.[7] When the underlying cause cannot be treated, dietary modifications including changes in food consistency (liquid, solid), meal frequency (smaller, more frequent) and feeding positions (upright) should be attempted until the best fit for that patient is found. If these adjustments do not provide adequate caloric intake, placement of a feeding tube becomes necessary (see ch. 82). Complications, such as aspiration pneumonia, should also be addressed.

Regurgitation (also see ch. 39)

Regurgitation is the passive expulsion of food or fluid from the esophagus due to mechanical, obstructive disease or functional (motility) abnormalities. Clients may incorrectly report their pet is vomiting, a centrally mediated reflex in which gastric or duodenal contents are forcefully expelled, when in fact it is regurgitating. Therefore, careful questioning of the client is paramount in differentiating between the two.

Clinical Signs

With regurgitation, owners may notice the pet lower its head and produce material, or they may report finding fluid or food without having heard the pet. In contrast, vomiting involves retching and abdominal contractions and may be preceded by hypersalivation. Timing and the type or consistency of expelled contents does not help in differentiating regurgitation from vomiting. Regurgitation may occur immediately or hours after feeding, and the contents can vary from undigested to digested food, mucus or a clear, frothy liquid. Bilious material (yellowish-green coloration) is not associated with regurgitation. Sometimes odynophagia (painful swallowing) and ptyalism may be noted. Other systemic signs may include weight loss, polyphagia, weakness and other neurologic abnormalities. If aspiration pneumonia is present, dyspnea, fever and cough may be noted.

Signalment

Megaesophagus is the most commonly reported motility disorder to affect the canine esophagus and is the

most common cause of regurgitation in dogs.[7] There is an increased prevalence for congenital megaesophagus in Labrador Retrievers, Newfoundlands, Chinese Shar-Peis, and for both congenital and acquired forms in Great Danes, German Shepherds, and Irish Setters.[8] Other breeds such as Chinese Shar-Peis, Bouviers des Flandres and terrier breeds can have clinical and non-clinical esophageal motility disorders, without megaesophagus, that may improve or resolve as the esophagus completes maturation.[9] In young-adult, large-breed dogs living in endemic areas, spirocercosis may be a cause of esophageal dysphagia.[10] Recent anesthetic episodes (i.e., spay/neuter, dentistry) and oral medication administration (doxycycline, clindamycin) are the most common cause of esophageal stricture formation and they should not be overlooked as potential causes of regurgitation.[11] Besides stricture formation, anesthesia may also be associated with megaesophagus from esophageal muscle atony secondary to gastroesophageal reflux-induced esophagitis. Idiopathic laryngeal paralysis has also been associated with esophageal dysfunction.[12]

Diagnosis

Physical examination may reveal a thin body condition or a bulging of the neck due to esophageal dilation. Harsh or diminished lung sounds may be noted on thoracic auscultation if aspiration pneumonia is present. A complete neurological examination is necessary to reveal any abnormalities that may occur with diseases such as myasthenia gravis or other neuropathies or myopathies (see Figure 38-2, Box 38-2).

Box 38-2

Causes of Regurgitation

Esophageal Disorders
Megaesophagus (primary or secondary)
Esophagitis
Obstructive (stricture, foreign body, vascular ring anomaly)
Esophageal diverticula

Alimentary Disorder
Pyloric outflow obstruction
Hiatal hernia
Gastric dilatation volvulus

Neurologic Disorder
Central nervous system (brainstem lesion, neoplastic, trauma)
Peripheral neuropathy (lead, thallium, polyradiculitis, polyneuritis)
Dysautonomia

Neuromuscular Disorder
Myasthenia gravis
Botulism
Tetanus
Distemper
Acetylcholinesterase toxicity (organophosphates)

Infectious
Spirocercosis
Pythium insidiosum
Neosporosis

Plain cervical and thoracic radiography is the initial diagnostic step to evaluate for esophageal dilation (focal with stricture or vascular ring anomaly, generalized with megaesophagus), radiopaque structures (foreign body, mass), widening of the mediastinum (thymoma) and for evidence of aspiration pneumonia. A complete blood count, serum chemistry profile, urinalysis, total thyroxine and fecal analysis (see ch. 82) should be obtained. If plain radiographs are not diagnostic, contrast esophagrams, endoscopic examination,

or videofluoroscopic examination (see Videos 271-1, 271-2, and 271-3 and ch. 113) may be necessary. Esophageal retention of any contrast material is abnormal. Other specialized tests including adrenocorticotropic hormone (ACTH) stimulation test (hypoadrenocorticism), complete thyroid profile (hypothyroidism), acetylcholine receptor antibody test (myasthenia gravis), and lead level assay may be needed depending on suspicion for a specific underlying disease process (see Box 38-2).

Treatment

Although treatment of secondary complications such as aspiration pneumonia should be initiated, it is essential to address the underlying disease process for successful therapy. Management of regurgitation while providing adequate nutrition is the primary goal in cases of primary megaesophagus or esophageal dysmotility. Dietary and feeding modifications such as feeding small, frequent high-calorie meals must be made. Trial and error will help determine the right food consistency for each patient as it can vary from chunky food or meatballs to a liquefied diet. If there is difficulty drinking water, adding a tasteless thickening agent can be attempted. Keeping the pet upright during and after feedings, manually or with the aid of a Bailey chair, as well as gentle coupage may help the movement of food down the esophagus. Some patients will require gastrostomy feeding tube placement to achieve adequate caloric intake and reduce regurgitation episodes (see ch. 82). The use of prokinetic drugs (cisapride, metoclopramide) in dogs is controversial, as mechanistically they are likely to be ineffective on their striated esophageal muscle, and may make it more difficult for food to pass into the stomach as they enhance lower esophageal sphincter pressure. Bethanechol may be effective in some dogs.[13] In the cat, cisapride may be a more effective prokinetic agent as it works on the cholinergic neurons of the esophagus.[14] Gastroprotective therapy to decrease stomach acidity (proton pump inhibitors, H2-receptor antagonists), and mucosal protectants (sucralfate) should be instituted in all cases, with the addition of prokinetic agents to increase lower esophageal sphincter tone in cases of primary esophagitis.

CHAPTER 39

Vomiting and Regurgitation

Alex Gallagher

Client Information Sheet: Vomiting and Regurgitation

Vomiting is a common presenting complaint in cats and dogs. While the majority of time the patient is truly vomiting, it may actually be regurgitation in some cases, as owners are often unaware of the difference. The clinician must distinguish between these two clinical signs as the differential diagnoses and diagnostic evaluation are quite different for each.

Differentiating Regurgitation From Vomiting

A complete history and thorough physical examination will usually allow differentiation of regurgitation from vomiting (Table 39-1; Video 39-1). Asking owners to describe the episodes is helpful, as a description of abdominal contractions (retching) or bile in the vomitus is specific for vomiting. In rare instances, bile may be present in regurgitation due to reflux of bile from the stomach into the esophagus prior to regurgitation. Additionally, vomiting is often associated with prodromal signs of nausea such as salivation or lip-smacking. With regurgitation, owners typically report that the animal simply lowers its head and material is expelled.

TABLE 39-1

Clinical Findings Used in the Differentiation of Regurgitation versus Vomiting

CLINICAL SIGN	REGURGITATION	VOMITING
Nausea or salivation	No	Common
Retching	No	Common
Presence of bile	Rare	+/−
Cervical esophageal distension	+/−	No
Amount of material	Any	Any
Time after eating	Variable	Variable
pH	Variable	Variable

Other factors such as timing of the episode in relation to feeding or the amount of material produced are not distinguishing factors. Animals may vomit undigested food or regurgitate digested-appearing food. The pH of the expulsed material has been considered a possible differentiating test. Vomited material is expected to have a low pH and regurgitated material to have a more neutral or high pH. However, some animals may regurgitate stomach contents (such as in reflux esophagitis) and some may vomit bicarbonate-rich fluid refluxed from the duodenum, making pH a poor indicator.

In some instances, the owner may not have witnessed the episode, but only report finding food or fluid on the floor. In other cases, the description of the episodes may not allow obvious distinction. In these cases, the rest of the history and physical examination should be used for determining if vomiting or regurgitation is more likely. As regurgitation is uncommon in cats, episodes can most often be assumed to be vomiting in this species. If possible, having the owner record an episode on video may be helpful. While rare, simultaneous vomiting and regurgitation may be present.

Regurgitation

Regurgitation is the passive expulsion of food, fluid, or other material from the pharynx or esophagus. It must be differentiated from expectoration, which is the expulsion of material from the respiratory tract associated with coughing. Regurgitation may be followed by a terminal retch or gag, which owners may confuse with cough, and regurgitation can lead to aspiration pneumonia resulting in a true cough.

Pathophysiology

The esophagus is a long tubular organ bordered proximally by the upper esophageal sphincter and distally by the lower esophageal sphincter. The muscular composition of the esophagus differs between dogs and cats. In dogs, the esophageal body is fully composed of striated muscle. In the cat, the distal ⅓ to ½ of the esophagus is composed of smooth muscle. In both species, during swallowing, the upper esophageal sphincter relaxes to allow passage of the food or liquid into the proximal esophagus. A primary peristaltic wave is initiated that moves food distally to the stomach. Secondary peristaltic waves are generated as a response to intraluminal distension to clear remaining material. The lower esophageal sphincter relaxes as the food bolus approaches, allowing passage into the stomach. Diseases that result in inflammation, obstruction, or hypomotility in the esophagus interrupt this normal process and can result in regurgitation.

Clinical Signs

The regurgitant may include undigested food, digested food, or clear, frothy fluid. Weight loss and polyphagia may occur due to inadequate nutrition. In some cases, dilation of the cervical esophagus may be apparent. Signs of aspiration pneumonia (see ch. 242) including lethargy, anorexia, cough, or dyspnea may be present. A neurological examination should be performed (see ch. 259) to evaluate for deficits consistent with generalized neuromuscular dysfunction.

Diagnosis

Initial evaluation consists of cervical and thoracic radiographs to assess for generalized (megaesophagus) or focal (vascular ring anomaly, stricture) esophageal dilation, foreign bodies, intra- or extraluminal masses, and aspiration pneumonia (Figure 39-1). Contrast radiography (esophagram) provides further assessment if survey radiographs are non-diagnostic. Use of video fluoroscopy is beneficial to better assess esophageal motility. Endoscopy (see ch. 113) can confirm radiographic findings, provide treatment for foreign bodies or strictures, allow biopsy of mass lesions, and identify esophagitis.

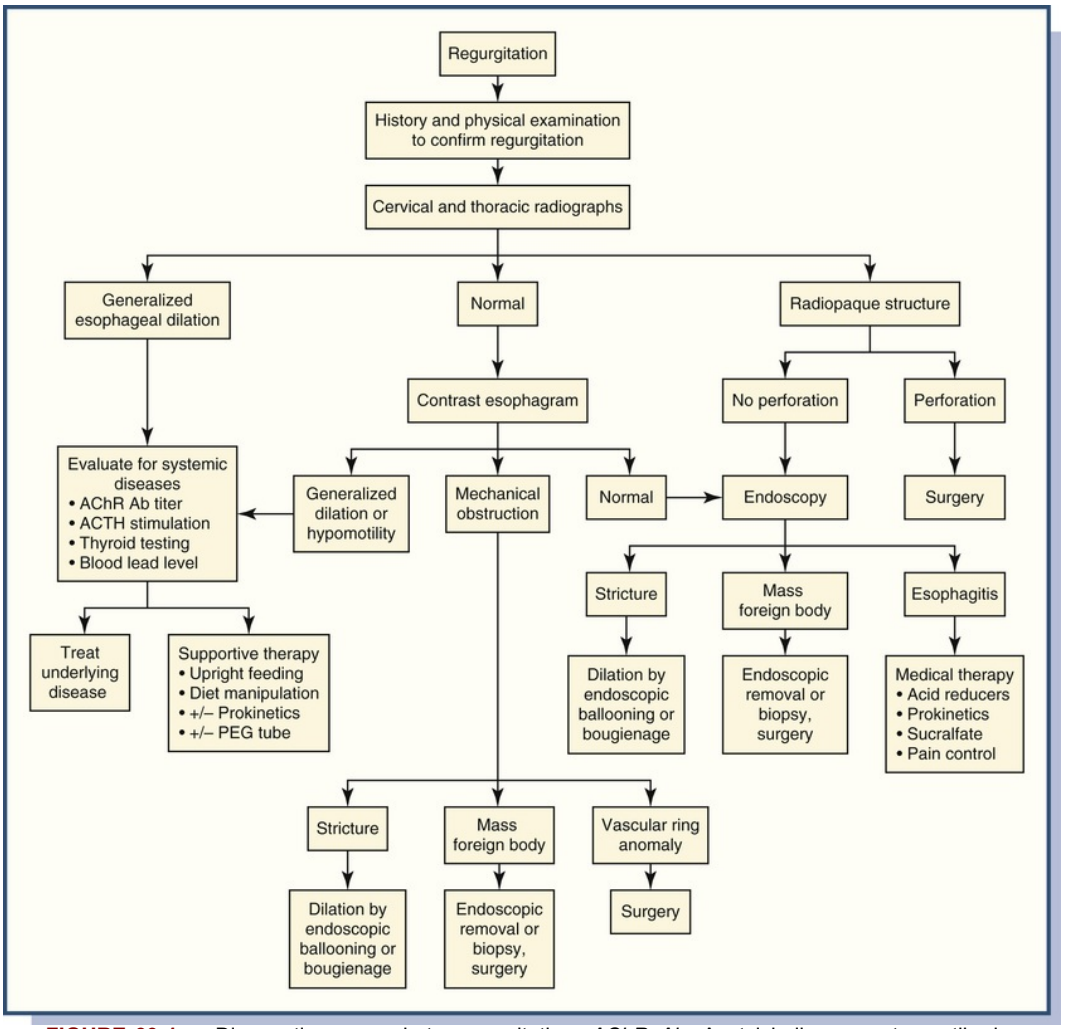

FIGURE 39-1 Diagnostic approach to regurgitation. *AChR Ab,* Acetylcholine receptor antibody; *ACTH,* adrenocorticotropic hormone; *PEG,* percutaneous endoscopic gastrostomy.

A minimum database including complete blood count, serum biochemistry profile, and urinalysis is warranted when systemic illness or megaesophagus is present. Adrenocorticotropic hormone (ACTH) stimulation, thyroid tests, acetylcholine receptor antibody test, and blood lead assay should be considered in cases with megaesophagus or esophageal hypomotility.

Treatment

Specific therapy should be used for any underlying disease as well as aspiration pneumonia if present. Management strategies to reduce frequency of regurgitation are used when primary disease is not identified or is unresponsive to therapy. Dietary management includes small, frequent meals and elevated feeding. Maintaining the patient in an upright position for 5-10 minutes after feeding may allow gravity to help esophageal transit. A Bailey chair can be used for this purpose. Owners should experiment with different food textures such as liquids, gruels, canned, or dry foods to determine which one works best for their pet. If gastroesophageal reflux disease is present, acid reducers and prokinetics may reduce the risk of esophagitis. Cisapride (cats) and bethanechol (dogs) may improve esophageal motility. Increasing the lower esophageal sphincter tone can exacerbate regurgitation in some cases.

Vomiting

Vomiting is one of the most common reasons dogs and cats are presented to a veterinarian for evaluation. It is an active expulsion of ingesta from the stomach and sometimes duodenum through the mouth. In contrast to regurgitation, vomiting involves a centrally mediated reflex with coordinated closure of the nasopharynx and glottis to protect the airway, reducing the risk of aspiration pneumonia. Like regurgitation, it must be

differentiated from expectoration.

Vomiting evolved as protection against the ingestion of toxic or noxious substances, which explains its activation by both neural and humoral stimuli. It is most often associated with primary gastrointestinal (GI) disorders, but may also occur due to non-GI diseases such as metabolic or neurological disorders. Severe or prolonged vomiting can have significant consequences including volume depletion (see ch. 127), acid-base and electrolyte derangements (see ch. 67-70 and 128), aspiration pneumonia (see ch. 242), and esophagitis (see ch. 273).

Pathophysiology

Vomiting is a complex reflex initiated by the emetic center, which is composed of a group of nuclei located in the medulla oblongata of the brainstem (Figure 39-2). Within this area are serotonergic ($5HT_1$) and adrenergic ($alpha_2$) receptors. In addition, neurokinergic (NK_1) receptors are located in the adjacent nucleus tractus solitarii, which can stimulate the emetic center. Activation of these receptors may occur indirectly by humoral pathways via the chemoreceptor trigger zone (CRTZ) or directly through neural pathways from the GI tract, cerebral cortex, or vestibular system.

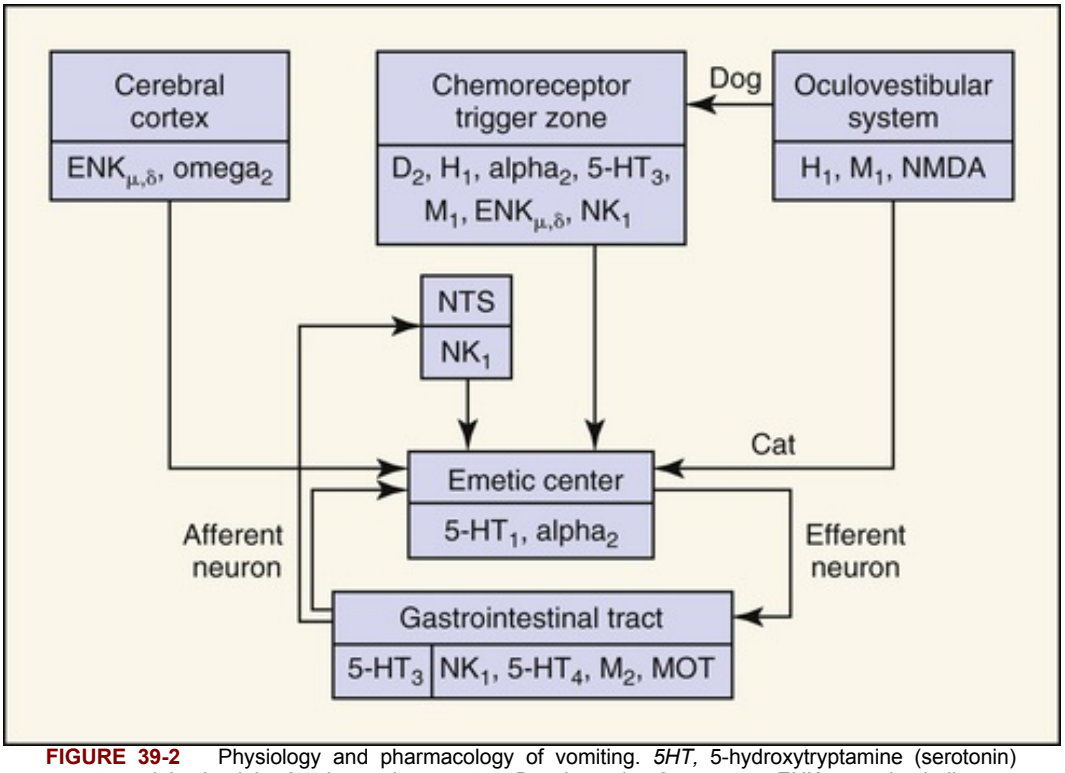

FIGURE 39-2 Physiology and pharmacology of vomiting. *5HT,* 5-hydroxytryptamine (serotonin) receptor; *alpha-2,* alpha-2 adrenergic receptor; *D_2,* dopamine-2 receptor; *$ENK_{\mu,\delta}$,* enkephalin mu, delta receptor; *gamma-2,* benzodiazepine gamma-2 receptor; *H_1,* histamine-1 receptor; *M,* muscarinic cholinergic receptor; *MOT,* motilin receptor; *NK_1,* neurokinin-1 receptor; *NMDA,* N-methyl d-aspartate; *NTS,* nucleus tractus solitarius. (From Washabau RJ, Day MJ: *Canine and feline gastroenterology,* St Louis, 2012, Elsevier, Figure 23-2, p 169.)

The CRTZ is located in the area postrema in the floor of the fourth ventricle and it lacks a blood-brain barrier, allowing it to sample chemical stimuli in the blood. Stimulants include endogenous (uremic or hepatoencephalopathic toxins) and exogenous substances (drugs, toxins). Dopaminergic (D_2), histaminergic (H_1), adrenergic ($alpha_2$), serotonergic ($5HT_3$), cholinergic (M_1), enkephalinergic ($ENK_{\mu,\delta}$), and neurokinergic (NK_1) receptors are present in the CRTZ, but there are species differences (see Figure 39-2). Apomorphine (D_1 and D_2 agonist) is a potent stimulator of emesis in dogs but it has little to no effect in cats, suggesting a lack of D_2 receptors in this species.[1] However, xylazine ($alpha_2$ agonist) is an effective emetic in cats, signifying that $alpha_2$ receptors may be more important.[2] Visceral rather than central $5HT_3$ receptors appear to be more

important in cisplatin-induced emesis in the dog.[3]

Neural stimulation of the emetic center occurs via afferent vagal, sympathetic, vestibular, and cerebrocortical pathways (see Figure 39-2). Gastrointestinal diseases can directly cause vomiting by stimulating release of serotonin from enterochromaffin cells that binds to $5HT_3$ receptors on afferent vagus nerves (dog) or the CRTZ (cat). Vestibular stimulation feeds into the CRTZ before activating the emetic center in the dog, but appears to act directly on the emetic center in the cat.

Clinical Approach

The initial approach starts with a thorough history. A description of the vomiting episodes is essential to differentiate them from coughing or regurgitation. The owner should be asked to describe the frequency, duration, relation to eating or drinking, and the character of the vomitus. Vomiting may be acute or chronic (>1-2 weeks in duration). In some cases, vomiting may be sporadic, making it difficult to determine if it is chronic versus intermittent acute disease. Vomiting food more than 8 hours after ingestion suggests delayed gastric emptying due to either gastric outflow obstruction or gastric hypomotility, while the presence of bile suggests patency of the gastric outflow tract. The presence of either fresh or digested blood ("coffee grounds") indicates GI erosions or ulcers.

A complete dietary history should be obtained, including past and current diets for planning possible diet trials (see ch. 178 and 191). Recent diet changes or opening a new bag or can of food may be the cause of vomiting. Medication history must include asking about drugs, supplements, nutraceuticals, and alternative therapies that could be associated with vomiting. The owner should also be questioned about the animal's possible exposure to toxins or foreign body ingestion. Vaccination status, travel history, and exposure to other animals are important for determining risk of infectious diseases, which are more common in young animals.

Physical examination should start with an overall assessment of patient demeanor (see ch. 2). Oral exam may reveal ulcers associated with uremia or toxin ingestion, or lingual linear foreign bodies (particularly in cats). Icteric mucous membranes suggest liver disease. Cardiac arrhythmias can indicate metabolic derangements or toxin ingestion. The abdomen should be palpated for evidence of pain (pancreatitis, obstruction), effusion (peritonitis), gas distension (obstruction, gastric dilation-volvulus), or organomegaly. Rectal exam may reveal evidence of melena, constipation, or material consistent with foreign body ingestion.

Diagnostic Approach

The diagnostic approach differs based on classification of the vomiting as acute or chronic (Figures 39-3 and 39-4). Acute vomiting with mild clinical signs is often self-resolving. As such, a minimalistic approach is usually appropriate. Fecal examination (see ch. 81) may identify parasitic causes of vomiting. Abdominal radiographs are performed if there is a clinical suspicion of surgical disease (e.g., suspected foreign body ingestion) or if vomiting does not resolve with initial therapy.

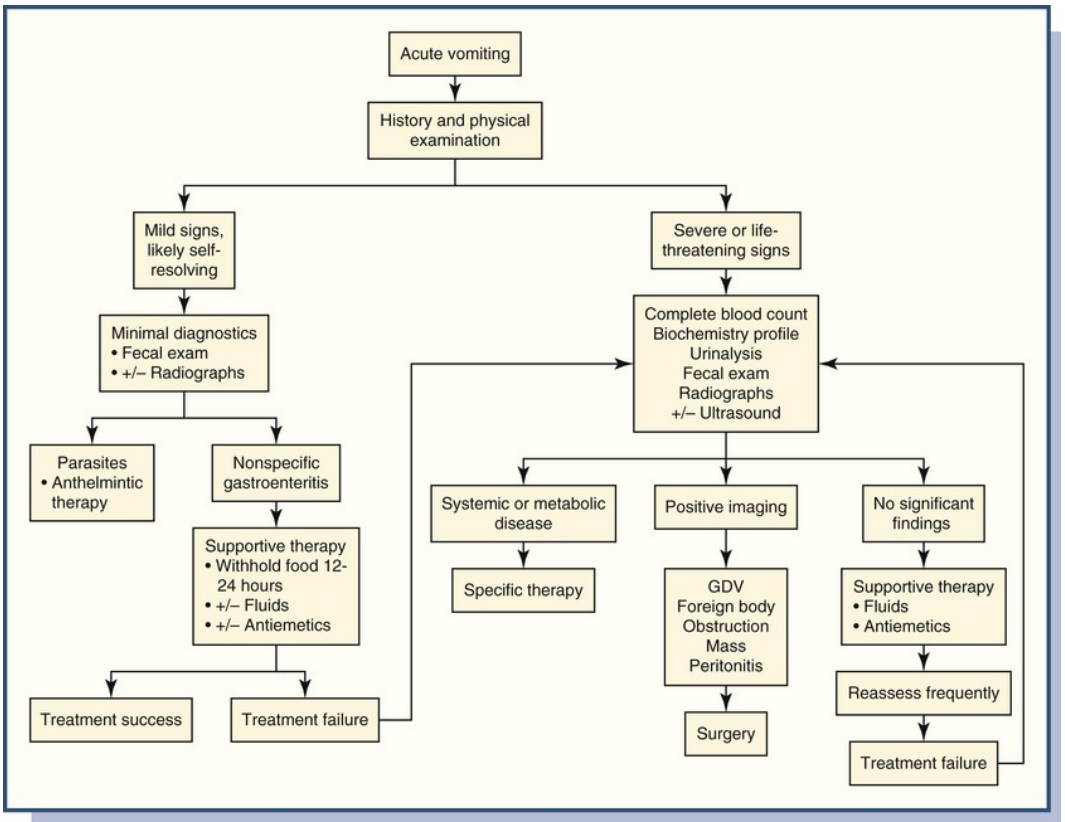

FIGURE 39-3 Algorithm for diagnosis of acute vomiting. *GDV,* Gastric dilation-volvulus.

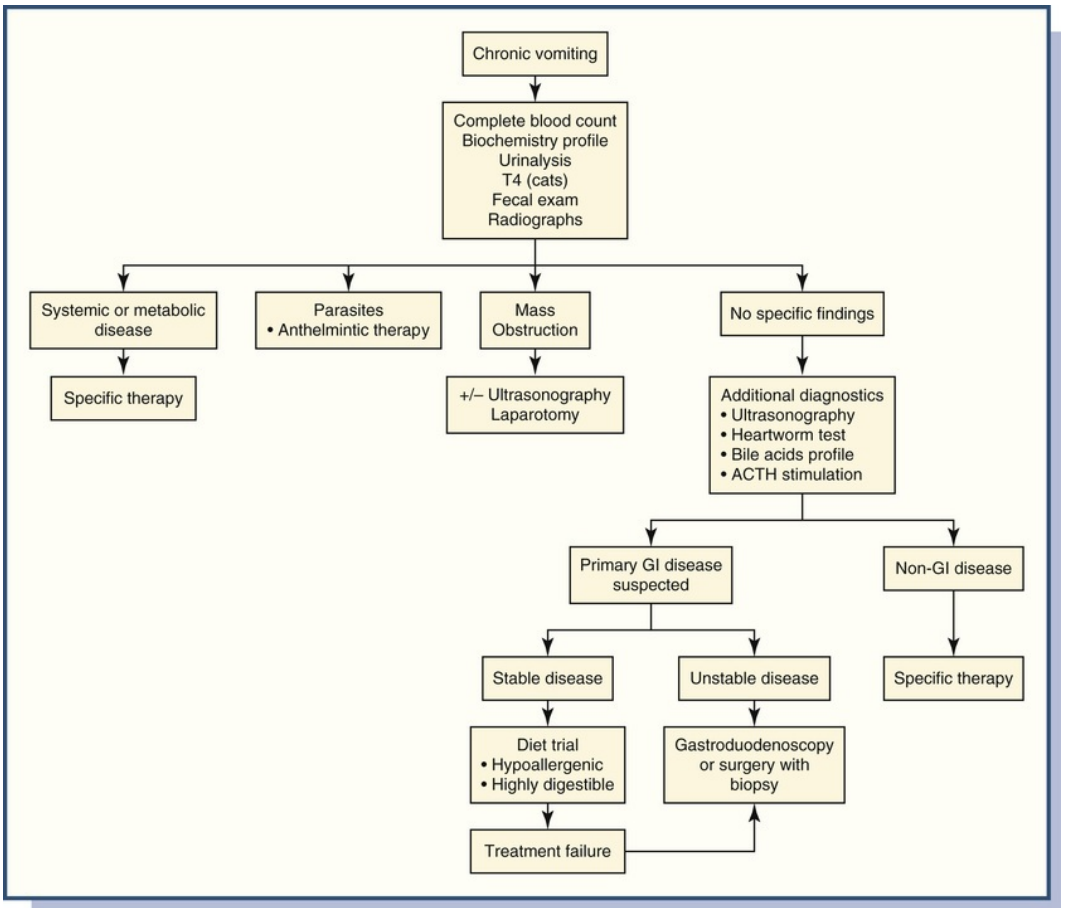

FIGURE 39-4 Algorithm for diagnosis of chronic vomiting. *ACTH*, Adrenocorticotropic hormone; *GI*, gastrointestinal; *T4*, serum thyroxine concentration.

Conversely, severe or life-threatening signs indicate a more thorough evaluation should be done. Complete blood count, serum biochemistry profile, and urinalysis allow identification of systemic or metabolic diseases. Metabolic alkalosis is suggestive of gastric outflow or proximal duodenal obstruction and is often associated with hyponatremia, hypokalemia, and hypochloremia. Abdominal radiographs +/− abdominal ultrasound are used for evaluating for surgical diseases such as foreign body, obstruction, gastric dilation-volvulus, or intussusception.

Chronic vomiting requires further investigation so definitive therapy can be prescribed. Complete blood count, serum biochemistry profile, and urinalysis should be performed. In addition, cats should be tested for feline leukemia and feline immunodeficiency viruses and those over 5 years of age should be evaluated for hyperthyroidism with a serum total T4 assay. If a cause is not found, additional diagnostic testing including ultrasonography, heartworm testing (cats), bile acids profile, pancreatic lipase testing, and ACTH stimulation testing should be considered. If a non-GI cause for the vomiting is not identified with such testing, further evaluation of the GI tract is needed. Contrast radiography may be helpful, particularly if ultrasonography is not available or the stomach is poorly visualized during ultrasonography due to intraluminal gas. Diet trials should be considered in stable animals to exclude diet-responsive disease prior to more invasive testing. Endoscopic or surgical biopsy is required to identify inflammatory disease such as chronic gastritis, *Helicobacter* gastritis, or inflammatory bowel disease (see ch. 113, 275, and 276).

Treatment

Initial treatment should be aimed at the primary disease, which often results in resolution of vomiting (Box 39-1). Acute, self-limiting vomiting usually resolves with fluid replacement and fasting for 12-24 hours. Acute cases with protracted or severe vomiting may benefit from antiemetic therapy (Table 39-2). Caution should be used, as antiemetics may mask underlying disease that has not yet been identified. Chronic cases are best treated by identifying the underlying cause. Antiemetic therapy can be considered for improving comfort and nutrition, and prevent excessive fluid losses.

Box 39-1

Common Causes of Vomiting

Metabolic Diseases

Renal disease
Hepatobiliary disease or failure
Electrolyte derangements
Acid-base derangements
Endotoxemia

Endocrine Diseases

Hypoadrenocorticism
Hyperthyroidism

CHAPTER 40

Diarrhea

Michael D. Willard

Client Information Sheet: Diarrhea

Diarrhea is caused by excess fecal water resulting from decreased intestinal absorption and/or increased intestinal secretion. Small intestinal disease causes diarrhea only if the material exiting the ileum exceeds the absorptive capacity of the colon or causes colonic secretion of water. Thus, while diarrhea means there is intestinal disease, lack of diarrhea does not eliminate substantive small intestinal disease. Many dogs and cats without diarrhea experience severe morbidity or die due to small intestinal disease. In contrast, large intestinal disease commonly causes diarrhea because there is nothing distal to it to absorb water. Patient activity also plays an important role in fecal consistency; active individuals are more likely to defecate more frequently than inactive ones (e.g., those confined to a cage or crate). Thus, a pet that has not had diarrhea while confined to a hospital cage may have diarrhea shortly after going home and resuming normal activity.

Routine Diagnostics

One must first decide if diarrhea is worth the cost or effort to diagnose or treat (Figure 40-1). Examples of diarrhea that should usually be attended to include diarrhea that (1) has a relatively small set of testable differentials, (2) is a predominant problem in the patient, or (3) is likely to cause morbidity or mortality. Diarrhea secondary to non-gastrointestinal (GI) disease is usually (but not invariably) relatively minor, and often there are historical, physical examination findings, laboratory, and/or imaging changes that are more pressing and/or more likely to quickly lead to a diagnosis. Examples of non-GI diseases causing diarrhea include acute pancreatitis, hepatic insufficiency, renal failure, and hypoadrenocorticism. Hyperthyroidism is an important non-GI cause of feline diarrhea.

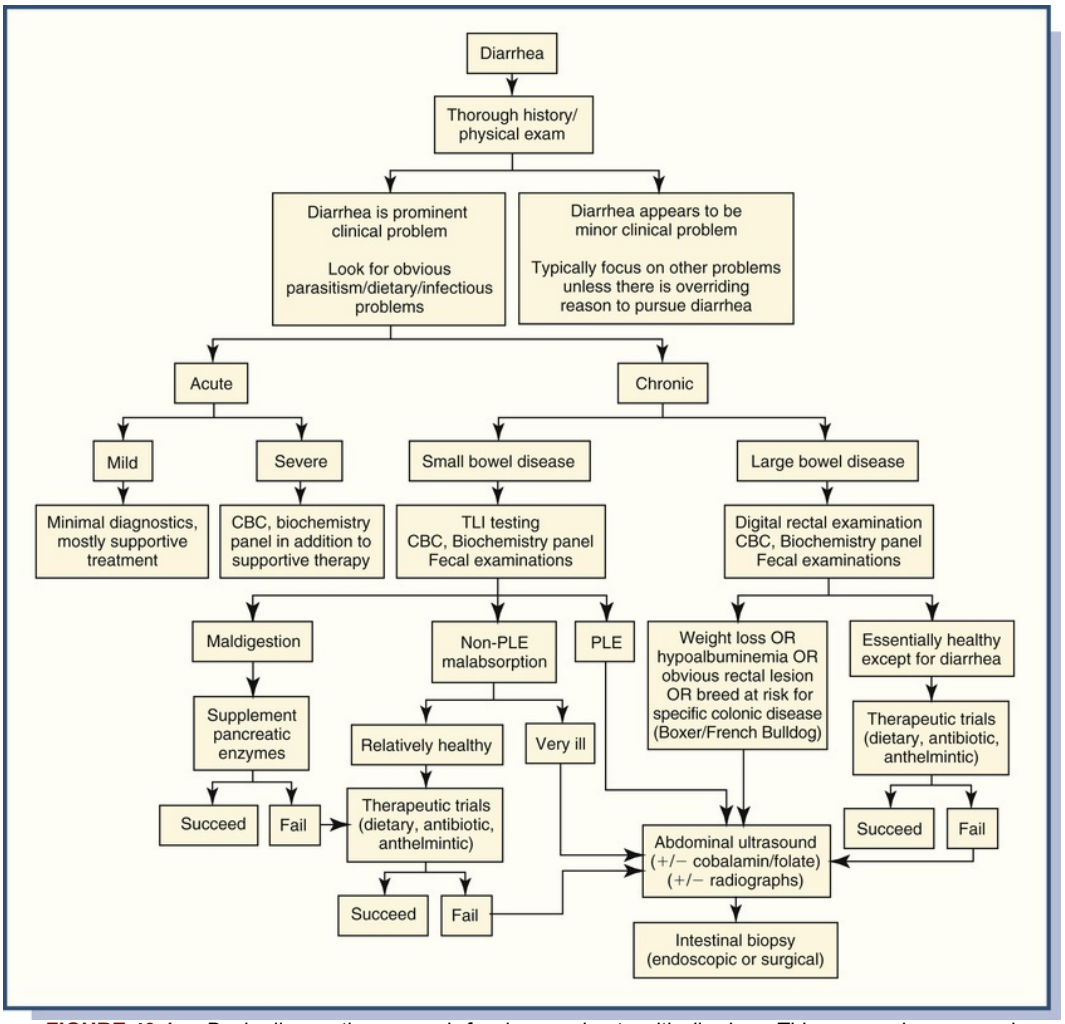

FIGURE 40-1 Basic diagnostic approach for dogs and cats with diarrhea. This approach may need to be modified, based upon specific situations. *CBC*, Complete blood count; *PLE*, protein-losing enteropathy; *TLI*, trypsinlike immunoreactivity.

The clinician should next look for and deal with "obvious" problems (e.g., substantial parasite burdens, poor-quality food, major dietary indiscretion, contagious disease) (ch. 170). Some parasites (e.g., giardiasis) can be difficult to diagnose. Next, one should determine whether diarrhea is acute or chronic. "Acute" means nonepisodic diarrhea occurring for less than 7 to 14 days. These dogs and cats may have diarrhea that is clinically nonthreatening or they may have severe diarrhea that places the patient at risk (e.g., hemorrhagic gastroenteritis; infectious, febrile gastroenteritis such as parvovirus). Most patients with acute, nonthreatening diarrhea spontaneously resolve with symptomatic/supportive therapy (e.g., anthelmintics, dietary change). Diagnostics in these patients are usually limited to fecal examinations and select laboratory tests (e.g., serum electrolytes, packed-cell volume [PCV]). Acute, severe diarrhea capable of causing morbidity/mortality is an indication for at least a complete blood count (CBC) and serum biochemistry panel.

Diarrhea not clearly improving within 14 days is considered chronic. Episodes of diarrhea that occur over 3-4 weeks may also be considered chronic. Chronic diarrhea should be subdivided into large or small bowel disease (ch. 276 and 277). Volume and frequency of bowel movements as well as vomiting are usually not helpful in making this distinction. Weight loss, hematochezia, and fecal mucus are more reliable criteria. Small intestines absorb nutrients; therefore, loss of body weight and/or condition are expected when it is chronically and substantially diseased. Steatorrhea is infrequent and melena distinctly rare in these patients. The large intestine absorbs water and acts as a reservoir for feces until defecation. Therefore, weight loss is unexpected in large bowel disease unless the disease is severe, in which case hematochezia and fecal mucus are typical. Hematochezia and fecal mucus are uncommon when colonic disease is mild to moderate. Tenesmus may occur if the rectal area is affected.

The next decision in patients with chronic small intestinal disease is whether maldigestion (e.g., exocrine pancreatic insufficiency [EPI]) or malabsorption exists. Uncommon in cats, EPI is an important consideration

in dogs (ch. 292). Serum trypsin–like immunoreactivity (TLI) is the most sensitive and specific test for EPI. Once EPI is eliminated, malabsorptive disease is diagnosed by exclusion.

Malabsorptive disease is divided into protein-losing enteropathy (PLE) and non-PLE. This distinction is important because severe hypoalbuminemia is associated with a poor prognosis more often than non-PLE: hence, PLE is usually an indication for a more aggressive diagnostic approach. Protein-losing enteropathy is typically only considered in hypoalbuminemic patients, but PLE is a concern whenever serum albumin concentrations progressively decrease. One must measure serum albumin (serum total protein is inadequate) and one should use the same laboratory for repeat samples so that one can meaningfully compare results. Panhypoproteinemia is neither sensitive nor specific for PLE, especially in areas where hyperglobulinemia is common. Serum albumin concentrations <2.0 g/dL are an indication for hepatic function testing and urinalysis. Eliminating hepatic insufficiency and protein-losing nephropathy in an individual without severe cutaneous disease (severe burns and secondary ulcerations, for example, can cause loss of protein) is consistent with a diagnosis of PLE by exclusion. Fecal alpha-1 protease inhibitor concentrations can be helpful when PLE is suspected but cannot be diagnosed by exclusion; however, there are nuances in performing/interpreting this test. Most PLE and hepatic insufficiency patients are hypocholesterolemic while many protein-losing nephropathy patients are hypercholesterolemic. Imaging, endoscopy, and biopsy are usually desirable in PLE patients, but therapeutic trials (e.g., ultra-low-fat diet for lymphangiectasia) are done if anesthetic risk is too great or client constraints dictate otherwise.

Any GI disease may cause PLE, but the most common causes in adult dogs are probably lymphangiectasia, lymphoma, fungal infections (regional), and inflammatory bowel disease (IBD) (see ch. 276). Lymphangiectasia can be difficult to diagnose unless one is aware of its subtleties. Occult parasitism and chronic intussusception are important in younger dogs. In cats, IBD and lymphoma are the main causes. Other causes include ulcers/erosions, antibiotic-responsive disease, and intestinal crypt lesions.

The major causes of non-PLE malabsorptive disease in dogs are dietary-responsive disease, antibiotic-responsive disease, and parasites (ch. 271, 276, and 277). IBD is often listed as an important cause. A full discussion is beyond the scope of this chapter, but IBD has been overdiagnosed in the past because IBD is not simply a histologic diagnosis. One must find inflammation and eliminate known causes (e.g., diet, parasites, bacteria). In cats, dietary-responsive disease, lymphoma, and IBD appear to be the most common causes, but hyperthyroidism closely mimics primary GI disease.

Advanced Diagnostics

The next step depends upon the patient's clinical condition. If a dog or cat is in relatively good health and not at major risk if a 2- to 3-week therapeutic trial fails, then one may elect to first treat for dietary-responsive, antibiotic-responsive, and/or parasitic disease. The first two diseases generally do not produce pathognomonic histologic lesions. If one cannot take a chance on investing 2 to 3 weeks in a therapeutic trial because of the advanced nature or rapid progression of disease, then aggressive diagnostics are reasonable. Abdominal ultrasound helps detect focal GI lesions that may be aspirated percutaneously (e.g., lymphoma, fungal infection) and may reveal whether GI disease is clearly diffuse or localized outside the reach of an endoscope. Ultrasound is specific but insensitive for GI lesions; absence of ultrasonographic changes does not eliminate serious GI disease.

Intestinal biopsy (surgical or endoscopic) is typically the next step after ultrasound. Faster, safer, and less expensive than surgery, endoscopy often allows one to find and biopsy focal mucosal lesions that cannot be seen from the serosal surface at surgery (see ch. 83 and 113). This ability to direct biopsies to affected areas of the intestinal mucosa enhances the chance to make a histologic diagnosis. Endoscopic biopsies of the ileum can be very important; some diseases (e.g., lymphoma, IBD, lymphangiectasia) may be diagnosed there when they cannot be diagnosed with duodenal samples (even when ultrasonography does not show any obvious difference between the two sites). Endoscopy is typically more than adequate to obtain diagnostic samples if the operator is skilled in taking and submitting biopsies. Endoscopic biopsies should routinely include the full thickness of the intestinal mucosa (with or without muscularis mucosa). If one is not trained in taking high-quality endoscopic samples, it may be better to perform surgical biopsies or refer the patient for endoscopy. Full-thickness intestinal biopsies will not help if they are taken where there is no lesion, a problem encountered if the intestinal disease (including severe intestinal disease) is patchy rather than diffuse. Diseased intestine outside the reach of the endoscope and intestines with dense submucosal infiltrates are indications for surgical biopsy. It is infrequent that diagnosis requires adequate submucosal tissue in small intestinal diseases. Remember, histology is not a good way to diagnose dietary-responsive or antibiotic-responsive enteropathies.

Chronic canine large bowel disease tends to be dietary-responsive, fiber-responsive, so called "clostridial" colitis (i.e., tylosin-responsive), and parasitic. Histoplasmosis, pythiosis and heterobilharziasis are regionally important. Cats tend to have dietary-responsive, clostridial, parasitic (e.g., *Tritrichomonas*), and IBD colitis. Digital rectal examination should be performed in dogs to assess for focal lesions (e.g., polyps) or mucosal thickening. Dogs from endemic areas should generally be treated for whipworms even if fecal examinations do not reveal ova. Giardiasis is a small bowel problem, but clinical signs sometimes mimic large bowel disease. Dogs and cats that are otherwise normal except for diarrhea, have no rectal lesions, and have normal serum albumin concentrations may often be successfully approached with therapeutic trials because: (1) the best way to diagnose dietary-responsive disease, fiber-responsive disease, and tylosin-responsive disease is by therapeutic trial; and (2) these animals are unlikely to worsen rapidly should the trial fail. Patients from areas endemic for histoplasmosis or schistosomiasis and those losing weight or becoming hypoalbuminemic should undergo testing (i.e., abdominal ultrasound, rectal scraping, colonoscopy/biopsy, antigen testing) because of their potential to suddenly become worse. Rectal scraping/cytology is an easy, quick, and specific (albeit insensitive) screening test for colonic histoplasmosis. Urinary antigen testing for histoplasmosis seems reasonably sensitive (see ch. 233). There is also a fecal polymerase chain reaction (PCR) test for *Heterobilharzia*. Colonic biopsy should be done endoscopically; full-thickness colonic incisions have substantial risk of dehiscence and peritonitis. Rigid biopsy forceps typically allow one to obtain large tissue samples with lots of submucosa (especially important in rectal lesions). It is recommended that Boxer dogs and French Bulldogs be biopsied earlier in the course of the workup than other breeds because of their predilection for histiocytic ulcerative colitis.

Abdominal radiographs do not commonly yield valuable information unless they detect an unsuspected radiopaque foreign body. Fecal cultures tend to be a low-yield procedure unless the history strongly suggests contagion. Simply finding "pathogenic" bacteria does not mean that they are responsible for clinical signs. It is critical to contact the laboratory for instructions on collection and submission relative to the specific pathogen(s) being sought. PCR analysis of feces for bacterial antigens can be difficult to interpret, just like fecal cultures.

Measuring serum cobalamin and folate concentrations can be helpful in select dogs and cats (ch. 276). Hypocobalaminemia is relatively specific for small intestinal disease in the dog; however, sensitivity is questionable. Cobalamin and folate determinations are insensitive and nonspecific for canine antibiotic-responsive disease (also called "dysbiosis"). Hypocobalaminemia in an animal with weight loss, but without diarrhea, is strong evidence of small intestinal disease; however, normal values are not helpful. Cobalamin supplementation often clinically benefits hypocobalaminemic cats, and hypocobalaminemia may be prognostic in dogs.

CHAPTER 41

Melena and Hematochezia

Karen M. Tefft

Client Information Sheet: Melena and Hematochezia

Witnessing blood in the stool of their pets is distressing for many owners and can prompt an urgent visit to the veterinarian's office. The presence of blood in the stool may or may not indicate a life-threatening disorder, however. In addition, the source of the blood may not be gastrointestinal (GI) in origin. The veterinarian must localize the source and seriousness of the hemorrhage by careful evaluation of history, physical examination, and diagnostic test findings.

Melena

Definition

Melena refers to the passage of dark-colored to black, tarry stools due to the presence of hematin, which is oxidized hemoglobin (Figure 41-1). While classically this is thought to be due to hemorrhage originating from the small intestine or orad, the amount of time blood spends in the intestinal tract is more important than the site of bleeding. Colonic hemorrhage may present with melena if intestinal motility is decreased.

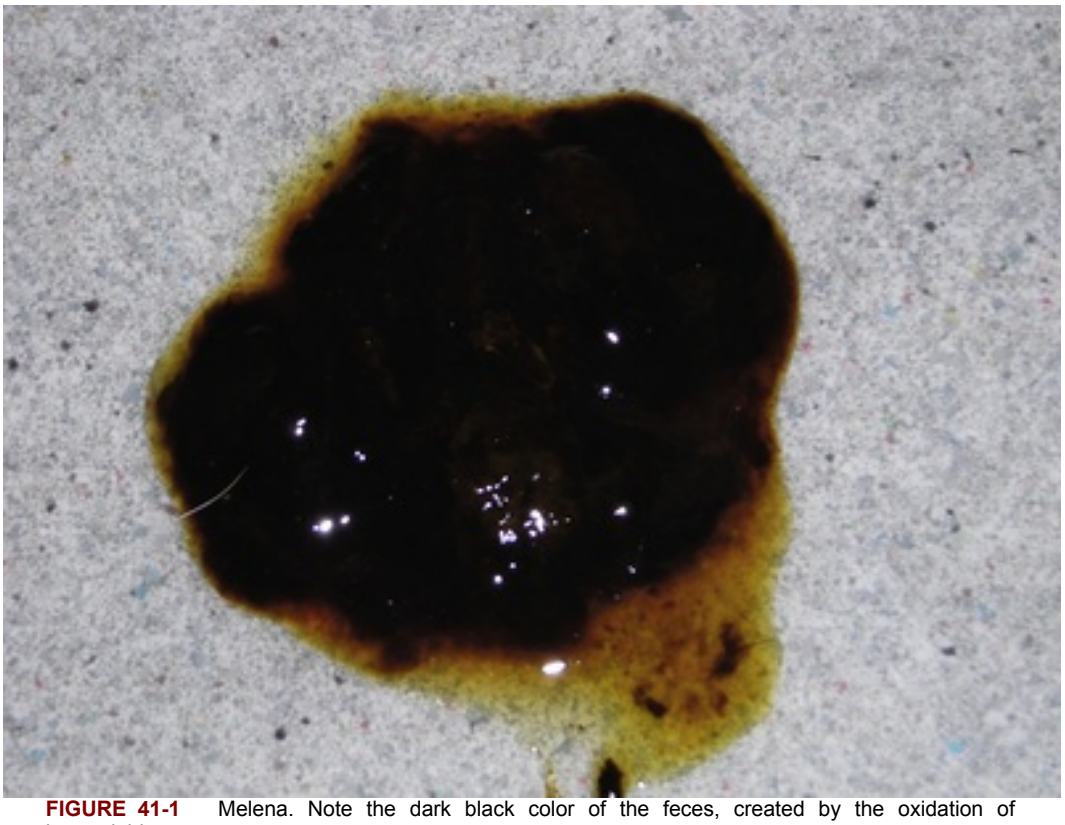

FIGURE 41-1 Melena. Note the dark black color of the feces, created by the oxidation of hemoglobin.

Causes

Sites of hemorrhage to consider in patients with melena include both the upper and lower respiratory tract, where blood from epistaxis or hemoptysis can be swallowed, and the GI tract, including the oral cavity, esophagus, stomach, and small intestine. Rarely, the cecum and colon can also be considered as a source for melena. Melena also can result from blood ingested as part of a raw diet. The absence of melena does not rule out GI bleeding. In humans, it has been experimentally determined that at least 50 to 100 mL of blood must be ingested before melenic stool is appreciated.[1-3] Important mimics of melena that can cause black stool include ingestion of activated charcoal, iron supplements, anti-diarrheal medications containing bismuth, or large quantities of blueberries.

Many diseases have the potential to cause melena (Box 41-1). The majority of these conditions result in GI hemorrhage by directly or indirectly disrupting mucosal barriers to injury.[4] Defense mechanisms utilized by the GI mucosa include an adherent mucus layer, hydrophobic nature of epithelial cells, epithelial secretion of bicarbonate, rapid repair of the epithelial layer by restitution, a high rate of mucosal blood flow, and prostaglandins (see ch. 274-277).

Box 41-1

Causes of Melena

- Ingestion of blood
  - Sinonasal lesions
  - Pulmonary lesions
  - Oral/Pharyngeal lesions
  - Diet
- Inflammatory
  - Esophagitis
  - Gastroenteritis
  - Eosinophilic gastritis
  - Inflammatory bowel disease
- Infectious
  - Bacterial: *Campylobacter, Clostridium, Mycobacterium, Neorickettsia helminthoeca, Salmonella*
  - Fungal/Algal: *Cryptococcus, Histoplasma, Pythium, Prototheca*
  - Parasitic: *Spirocerca, Physaloptera, Ancylostoma, Uncinaria*
  - Viral: parvovirus
- Ischemic/traumatic
  - Hypovolemic shock
  - Thrombosis/infarction
  - Intussusception
  - Volvulus
  - Foreign body
  - Racing sled dogs
- Post-surgical
  - Enterotomy
  - Gastric invagination post-correction of gastric dilation/volvulus
  - Percutaneous endoscopic gastrostomy tube placement
- Drug-induced
  - Corticosteroids
  - Non-steroidal anti-inflammatory drugs
- Neoplastic
  - Adenocarcinoma
  - Gastrointestinal stromal tumor
  - Leiomyoma/leiomyosarcoma
  - Lymphoma
  - Mast cell tumor

Gastrinoma
Vascular
Vascular ectasia/angiodysplasia
Arteriovenous fistula
Metabolic
Hypoadrenocorticism
Uremic kidney disease
Liver disease, particularly with portal hypertension or portosystemic shunt(s)
Pancreatitis
Hypereosinophilic syndrome
Bleeding disorder
Thrombocytopenia
Thrombocytopathia
Disseminated intravascular coagulation
Rodenticide intoxication
Specific factor deficiencies

Clinical Evaluation

History

A careful assessment of the history is the first step in the evaluation of a patient presenting with melena. The clinician should not ask leading questions about the patient's stool color, but instead let the owner use his or her own descriptors. Ideally, the owner can be shown a set of swatches from which to select which color best represents their pet's fecal color, as inconsistencies have been shown in subjective color reporting as compared to selecting a color off a scorecard.[5] The owner should be asked specific questions concerning diet, drug administration, and potential exposure to toxins; the veterinarian uses this information to determine immediately if the owner had administered a bismuth-containing medication or any other compound that can cause black stool. Determining the patient's diet, and specifically whether the animal eats a raw meat diet, or receives liver, spleen, or bones in the food, directly addresses this category of causes of melena.

After ruling out causes of black stool other than respiratory or digestive tract hemorrhage, the focus of the history collection can shift towards these pathologic causes. Clinical signs other than melena, notably exercise intolerance, stridor, coughing or dyspnea, raise the suspicion of respiratory tract disease. Anorexia, regurgitation, vomiting or diarrhea raise suspicion of GI tract disease. The owners should be asked about other instances of observed bleeding; epistaxis or hemoptysis can indicate primary respiratory tract disease and hematemesis can indicate primary GI tract disease. However, the clinician should remain mindful that a systemic bleeding disorder might alternatively be the cause, particularly if hematuria or ecchymosis is reported.

It is important to question the owners specifically about administration of corticosteroids and non-steroidal anti-inflammatory drugs. Both of these classes of drugs reduce the production of protective prostaglandins, leading to gastric mucosal injury. The history should address whether the patient had any opportunity to ingest anticoagulant rodenticides, corrosive compounds or foreign objects. The patient's travel history can suggest the possibility of specific infectious diseases.

Physical Examination

While particular attention should be paid to the respiratory and digestive systems, a thorough physical examination is necessary in the patient with melena (see ch. 2). Inspection of the skin, mucous membranes, and sclera can reveal petechiae or ecchymoses, which can indicate a bleeding disorder or icterus to suggest hepatobiliary disease. A fundic examination (see ch. 11) is important to identify retinal hemorrhages, which can indicate a bleeding disorder, hyperviscosity, or systemic hypertension. Examination of the skin, mucocutaneous junctions, and nail beds can reveal masses, which may indicate mast cell disease. A thorough examination of the nares and oral cavity is warranted, for active hemorrhage or lesions with the potential to bleed. Patients with moderate to severe blood loss can display mucous membrane pallor. Careful auscultation of the lung fields can reveal abnormal sounds supporting the presence of pulmonary disease. Thorough palpation of the abdomen can allow the veterinarian to identify signs of pain, organomegaly, or masses. A digital rectal exam must be included to confirm the presence of melena, to obtain a stool sample for fecal testing, and to assess for mucosal abnormalities and sublumbar lymph node enlargement.

Diagnostic Evaluation

After confirming the presence of melena, the clinician then should move to diagnostic testing to provide objective support for abnormalities detected on physical examination and to begin ruling in and out differential diagnoses (Figure 41-2). The initial diagnostic work-up at a minimum includes a complete blood count (CBC), serum biochemistry panel, urinalysis, prothrombin time, activated partial thromboplastin time, and fecal flotation. Anemia is the most common finding on the CBC of a patient with melena. The anemia can be mild to severe, and a regenerative response may be evident if sufficient time has elapsed since blood loss began and suitable regenerative capacity exists. Chronic, low-grade hemorrhage can result in iron deficiency that ultimately can cause a microcytic, hypochromic, non-regenerative anemia. Thrombocytopenia, if moderate to severe, can be the primary cause of melena. Mild thrombocytopenia likely is a secondary finding resulting from consumption of platelets at the site of acute hemorrhage. Thrombocytosis can be seen with chronic GI hemorrhage. Leukocytes may be decreased in number, within normal range, or increased based on the underlying disease, and a left shift may or may not be present. Eosinophilia can be caused by a variety of diseases that can result in GI hemorrhage, such as parasitism, systemic mycosis, mast cell tumor, eosinophilic gastritis, or hypereosinophilic syndrome. Common abnormalities on the serum biochemistry profile include disproportionately elevated blood urea nitrogen concentration compared to creatinine concentration, and hypoproteinemia. Elevated hepatic enzyme activities or azotemia should raise suspicions for liver or renal disease, respectively. Hyponatremia in conjunction with hyperkalemia should raise suspicion for hypoadrenocorticism, although salmonellosis and whipworm infections can occasionally cause pseudohypoadrenocorticism. A urinalysis is performed for evaluation of concurrent disease, including differentiating causes of azotemia. Prolonged coagulation times will aid in diagnosing cases of rodenticide intoxication or disseminated intravascular coagulation. A fecal flotation can identify parasite ova.

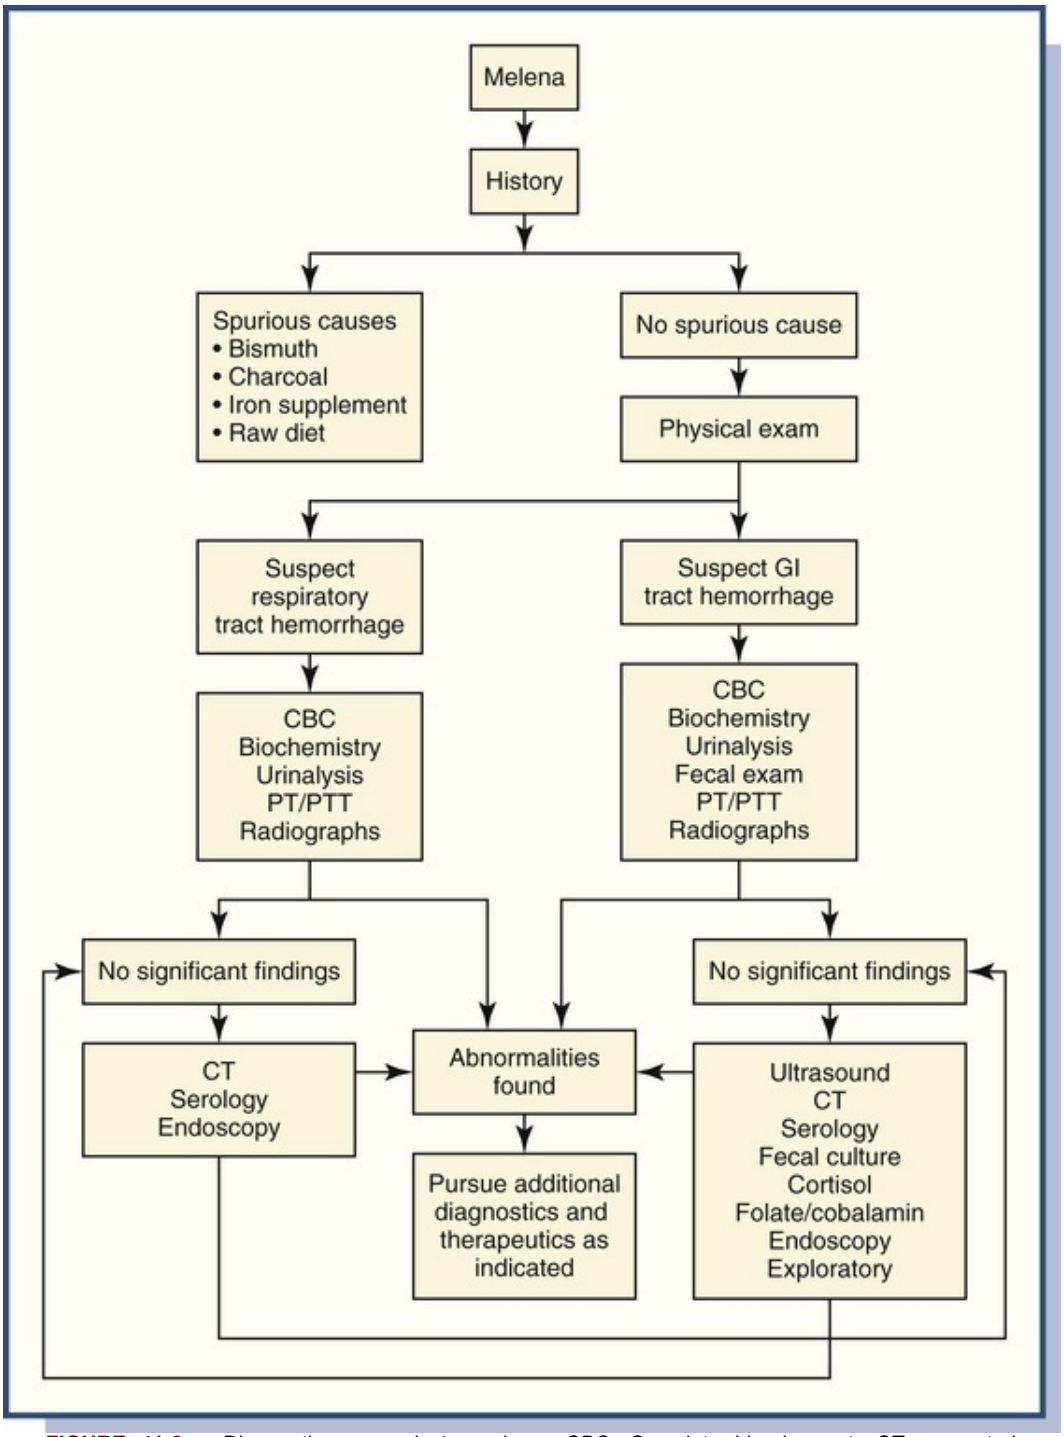

FIGURE 41-2 Diagnostic approach to melena. *CBC,* Complete blood count; *CT,* computed tomography; *PT/PTT,* prothrombin time/partial thromboplastin time.

The next phase of diagnostic testing, which can be performed concurrently with the previously described tests or subsequently, dependent on the owner's finances, includes fecal analysis and imaging. A fecal direct saline preparation and stained cytologic smear can assess for a variety of parasites, enterotoxigenic bacteria, and other organisms. Radiographic imaging of the thorax and abdomen can help further differentiate between respiratory and GI sources of melena. Clearly definable lung patterns likely will be present in cases with hemoptysis. Thoracic radiographs also are useful to screen for metastatic disease if a mass has been palpated in the abdomen. Abdominal radiographic abnormalities can include radiopaque foreign bodies, abnormal size or shape of abdominal organs, mass effects, and abnormal gas and fluid patterns in the GI tract. Abdominal ultrasound is complementary to radiography and can further evaluate for foreign bodies,

abnormal organ architecture, masses, lymphadenopathy, or intussusception.

Definitive diagnosis of the underlying cause of melena often requires advanced diagnostic techniques, which may include specific serologic testing, fecal cultures, computed tomography, rhinoscopy (see ch. 238 and 240), bronchoscopy (see ch. 101), GI endoscopy (see ch. 113), and exploratory laparotomy.

Treatment

Specific treatment for patients presenting with melena will vary dependent on the underlying cause. However, given that GI ulceration is the underlying etiology in most cases of melena, it is reasonable to start therapy that addresses ulceration while a definitive diagnosis is pursued. Pharmaceuticals used in the treatment of GI ulceration work by decreasing intraluminal acidity and promoting mucosal defense mechanisms. Proton-pump inhibitors, synthetic prostaglandin analogues, and sucralfate are commonly used in combination to treat GI ulceration (see ch. 275).

Hematochezia

Definition

Hematochezia refers to the passage of bright-red colored stools due to the presence of hemoglobin (Figure 41-3). While classically this is thought to be due to hemorrhage originating from the colon, the length of time blood spends in the intestinal tract is more important than the site of bleeding. Small intestinal hemorrhage may present with hematochezia if intestinal motility is increased.

FIGURE 41-3 Hematochezia. Note the frank blood in the stool giving the feces a bright red color.

Causes

Some overlap exists between potential causes of melena and hematochezia; however, sites of hemorrhage to typically consider as causes of hematochezia include the cecum, colon, rectum, and anus. Mimics of hematochezia that can cause red stool include ingestion of foods or treats containing red food coloring or large amounts of beets. In addition, owners sometimes mistake bleeding from a perineal bite wound or anal

sac abscess as hematochezia. Many diseases have the potential to cause hematochezia (Box 41-2).

Box 41-2

Causes of Hematochezia

- Unclassified
  - Hemorrhagic gastroenteritis
- Inflammatory
  - Inflammatory bowel disease
  - Histiocytic ulcerative colitis
  - Idiopathic colitis
  - Perianal fistula
  - Mucocutaneous lupus erythematosus
- Infectious
  - Bacterial: *Campylobacter, Clostridium, Mycobacterium, Salmonella*
  - Fungal/Algal: *Cryptococcus, Histoplasma, Pythium, Prototheca*
  - Parasitic: *Ancylostoma, Uncinaria, Trichuris,* coccidia, *Tritrichomonas, Leishmania, Heterobilharzia americana, Entamoeba histolytica*
  - Viral: parvovirus
- Ischemic/traumatic
  - Hypovolemic shock
  - Thrombosis/infarction
  - Intussusception
  - Cecal inversion
  - Volvulus
  - Foreign body
  - Pelvic fracture
  - Rectoanal stricture
  - Racing sled dogs
- Drug-induced
  - Corticosteroids
  - Non-steroidal anti-inflammatory drugs
  - Cytotoxic chemotherapy drugs
- Neoplastic
  - Adenocarcinoma
  - Gastrointestinal stromal tumor
  - Leiomyoma/leiomyosarcoma
  - Lymphoma
  - Plasmacytoma
  - Colorectal polyp
- Vascular
  - Vascular ectasia/angiodysplasia
  - Arteriovenous fistula
- Metabolic
  - Hypoadrenocorticism
  - Uremic kidney disease
  - Liver disease, particularly with portal hypertension or portosystemic shunt(s)
  - Pancreatitis
- Bleeding disorder
  - Thrombocytopenia
  - Thrombocytopathia
  - Disseminated intravascular coagulation
  - Rodenticide intoxication
  - Specific factor deficiencies

Clinical Evaluation

History

The majority of questions for the owner of a patient with melena also apply for hematochezia, with the exception of questions pertaining to the respiratory tract. Additional questions specific to the lower GI tract include inquiring about the patient's bowel habits; i.e., is dyschezia, tenesmus, "scooting," or frequent attempts at defecation producing only small amounts of stool or mucus, present? It is useful to ask if the feces are entirely red or maroon-colored, suggesting a proximal colonic lesion or if they are otherwise normal in color with frank blood only on the surface, suggesting an anorectal lesion. Asking the owner if the patient may have experienced recent stress or an abrupt dietary change or indiscretion is useful, as these are frequent triggers for self-limiting colitis.

Physical Examination

While particular attention should be paid to abdominal and rectal palpation, a thorough physical examination is still necessary in the patient with hematochezia as described for the patient with melena. Thorough palpation of the abdomen is necessary for identifying signs of pain, organomegaly, or masses. A digital rectal exam must be included to confirm the presence of hematochezia, obtain a stool sample for fecal testing, and for assessment of mucosal abnormalities such as masses or strictures, sublumbar lymph node enlargement, pelvic fracture, or other perianal abnormalities such as fistulas or ulceration. The anal sacs should be palpated for the presence of nodules or cellulitis, and expressed for evaluation of their contents. The clinician should be cautious in performing rectal palpation as the underlying disorder may make it painful for the patient.

Diagnostic Evaluation

In a patient presenting with simple, acute hematochezia characterized by blood streaking on the surface of the feces and no other clinical signs or physical examination abnormalities, a fecal flotation and direct saline preparation are the only diagnostic tests initially indicated. Patients with severe hematochezia (i.e., feces that looks like "raspberry jam"), chronic hematochezia, and/or other clinical signs should have a diagnostic work-up as described for patients with melena.

Treatment

Specific treatment for patients presenting with hematochezia will vary dependent on the underlying cause. In a patient presenting with simple, acute hematochezia as described above, empiric treatment with a broad-spectrum anthelmintic, metronidazole, and a bland diet containing soluble fiber is often successful (see ch. 277 and 278).

CHAPTER 42

Constipation, Tenesmus, Dyschezia, and Fecal Incontinence

Peter Foley

Client Information Sheet: Constipation and Straining to Defecate

Definitions

Constipation is defined as infrequent or difficult evacuation of dry, hard feces. *Obstipation* is a severe form of constipation where the feces are so dry and hard, or the constipation is so longstanding, that the animal is no longer able to defecate. Obstipation requires medical intervention. *Tenesmus* is ineffectual and painful straining at defecation or urination. *Dyschezia* is difficult or painful evacuation of feces from the rectum. In contrast to tenesmus, dyschezia is a result of disease of the anal and perianal tissues, whereas tenesmus is a result of disease of the large intestine or lower urinary tract. *Fecal incontinence* is defined as defecation without conscious control.

Physiology of the Large Intestine

The large intestine or colon serves two main functions in the dog and cat: absorption of water and electrolytes, and storage of feces. Absorption of water and electrolytes occurs primarily in the ascending and transverse colon, whereas the descending colon is mostly the site of storage of feces.

At rest, considerable mixing of colonic contents occurs as a result of segmental contractions of the colon. These *haustral contractions* are coordinated contractions of the circular and longitudinal smooth muscle of the colon that result in accumulation of colonic contents in unstimulated segments. This mixing of colonic contents increases exposure of contents to colonic mucosa for maximum water and electrolyte absorption, while slowly propelling the ingesta down the length of the colon.

In addition to haustral contractions, there are periods of intense propulsive activity down the entire length of the colon. These are called *mass movements,* and they serve to propel fecal matter toward the anus in preparation for defecation. Mass movements occur only a few times daily in contrast to the continuous haustral contractions. Mass movements are most common following a meal and are stimulated by the autonomic nervous system. See also ch. 277.

The anal sphincter is composed of two layers: an internal anal sphincter composed of smooth muscle, which is a direct extension of the circular smooth muscle of the rectum, and an external anal sphincter composed of striated muscle. The internal anal sphincter remains contracted most of the time and is the layer most responsible for fecal continence. The internal sphincter receives its parasympathetic nervous supply from the sacral spinal cord segments via the pelvic nerves. Its sympathetic innervation is from the lumbar spinal cord segments via the hypogastric nerves. Sympathetic stimulation results in contraction of the internal anal sphincter, whereas parasympathetic stimulation results in its relaxation. The external anal sphincter is under conscious control and allows the animal to resist and prevent defecation from occurring, but it is important to remember that it is the internal anal sphincter's continuous tone that is most responsible for anal continence. The external anal sphincter is innervated by somatic efferent nerve fibers originating in the cranial sacral spinal cord segments and coursing through the pudendal nerves. See also ch. 278.

As mass movements propel feces into the rectum, the internal anal sphincter is stimulated to relax. This usually results in defecation. The animal assumes a defecation posture, the diaphragm and abdominal muscles contract to increase the intraabdominal pressure, and the external anal sphincter relaxes. The animal has the ability to override the mass movements and relaxation of the internal anal sphincter by maintaining conscious constriction of the external anal sphincter. When defecation is voluntarily prevented, the mass

movements of the colon dissipate after 10 to 30 minutes, the rectum relaxes to accommodate the fecal material, the internal anal sphincter regains its tone, and the urge to defecate dissipates.

Constipation

There are several different disease states that can cause the feces to become dry, hard, and difficult to evacuate (Figure 42-1).

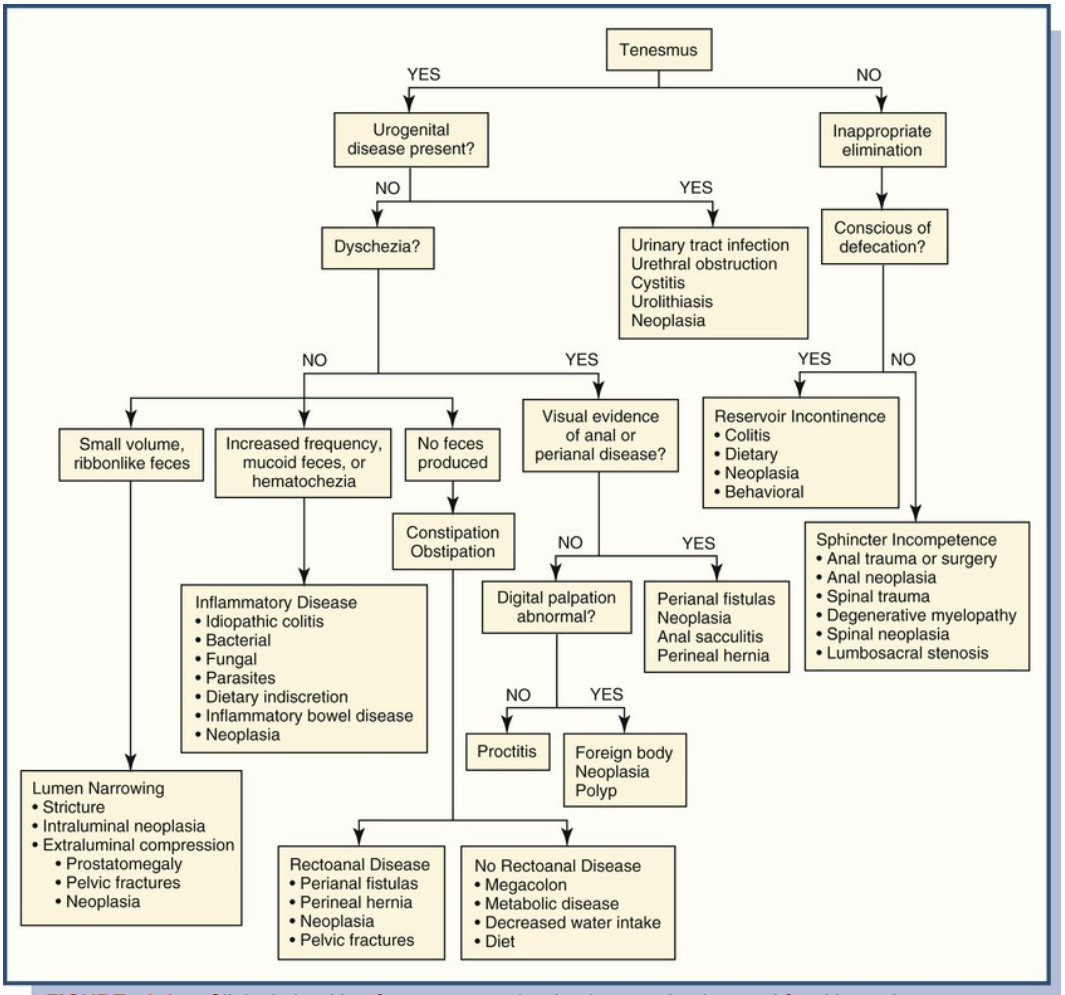

FIGURE 42-1 Clinical algorithm for tenesmus, dyschezia, constipation, and fecal incontinence.

Diets low in fiber or high in indigestible material such as hair or bones can contribute to constipation. Lack of exercise, and weakness, also can be contributing factors to constipation. Good hydration status is essential for normal defecation. Animals who have had restricted access to water or who otherwise experience decreased water intake (e.g., anorexia) commonly experience constipation. Similarly, increased water loss due to polyuria or vomiting also can lead to constipation if there is insufficient water intake to replace lost body water. Colonic or rectal obstruction, either intraluminal (masses or foreign bodies) or extraluminal (mass compressing the colon, pelvic fractures, perineal hernia, pseudocoprostasis [external obstruction from feces-matted hair, preventing defecation]), likewise can inhibit or prevent defecation and result in constipation. Similarly, neurologic abnormalities such as idiopathic megacolon or dysautonomia can result in constipation due to impaired colonic motility (Figure 42-2).

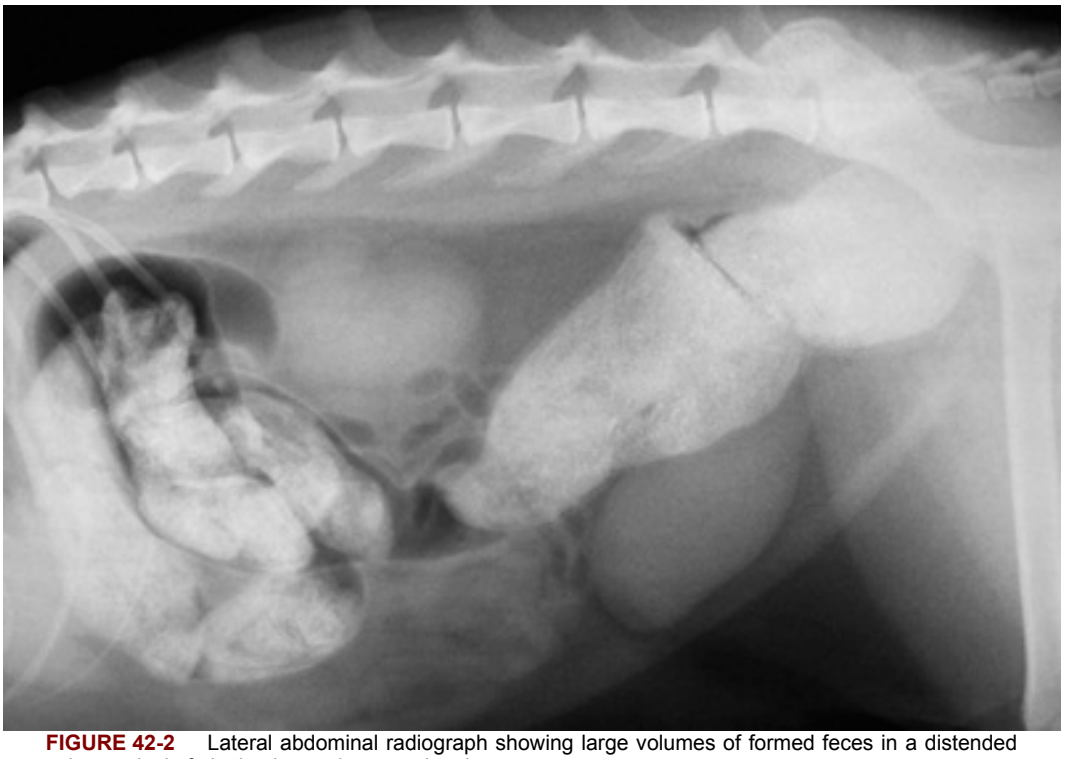

FIGURE 42-2 Lateral abdominal radiograph showing large volumes of formed feces in a distended colon, typical of obstipation and megacolon, in a cat.

History

Information should be gathered on the duration of the signs of constipation and how frequently the animal is attempting to defecate. Dietary details should be collected, including how much fiber is in the diet and whether the animal is consuming substantial quantities of indigestible material such as hair or bones. Anorexia or decreased access to food or water should be determined. A history of previous pelvic trauma or recent abdominal surgery is important because these can be additional contributing factors. Pets with a history of dyspnea can be reluctant to defecate, as straining may worsen their respiratory distress.

Signalment

Constipation can occur in any breed or either sex and at any age. English Bulldogs, Boston Terriers, and Manx cats tend to have an increased incidence of constipation due to possible malformations of the sacral spinal cord (see ch. 266). German Shepherd Dogs are predisposed to perianal fistulas that could result in dyschezia and constipation (see ch. 278). Megacolon tends to occur more commonly in middle-aged male cats. Intact male dogs should be examined closely for prostatomegaly (see ch. 337).

Physical Examination

The entire body should be examined closely for signs of underlying systemic disease that could be causing weakness, anorexia, or increased water loss (e.g., polyuria) that might be contributing to the constipation. Abdominal palpation can reveal a colon distended with hard feces. The anus should be visually inspected for fecal hair mats obstructing the anus (pseudocoprostasis), masses, and perianal fistulas. The rectum and distal colon should be carefully palpated digitally for evidence of hard, dry feces; colonic or rectal masses or foreign bodies; pelvic fractures; enlarged sublumbar lymph nodes; prostatomegaly in the male dog; perianal hernias; and evidence of anal sac disease.

Diagnostic Evaluation

A complete blood count, serum biochemistry profile, and urinalysis are useful in ruling out underlying systemic disease. Abdominal radiographs can confirm colonic distention with feces. In severe cases, the colon

is so distended with feces that the feces are not able to pass through the pelvic canal. Abdominal radiographs can also reveal evidence of colonic masses, foreign bodies, sublumbar lymph node enlargement, prostatomegaly, or pelvic fractures. Abdominal ultrasound may identify intraluminal or extraluminal masses, prostatomegaly, and enlarged lymph nodes. Once feces are evacuated from the colon and rectum, colonoscopy may reveal colonic neoplasia, perineal hernias, diverticula, and strictures.

Tenesmus and Dyschezia

It is important to localize the cause of straining to diseases of either the lower urinary tract or the lower gastrointestinal (GI) tract. Inflammatory and infectious diseases of the lower GI tract, such as inflammatory bowel disease, dietary indiscretion, intestinal parasitism, idiopathic colitis, pythiosis, and bacterial or fungal colitis, can cause irritation and straining at defecation. Obstructions, both intraluminal (colonic neoplasia, foreign bodies, strictures) and extraluminal (pelvic fractures, extraluminal masses, organomegaly), can make defecation difficult and result in tenesmus. Dyschezia results from diseases of the anus and perianal region including anal sacculitis, perianal fistulas, perineal hernia, anal/rectal neoplasia, and pseudocoprostasis.

History

Urination must be evaluated carefully to rule out lower urinary tract disease as a cause of tenesmus. Is the animal able to produce a normal stream of urine? Is there dripping of urine as the animal strains? Is the urine of normal appearance? Details of defecation are likewise important. Are normal feces being passed? Thin, ribbonlike feces, or small amounts of diarrhea, are common with intraluminal or extraluminal obstructions. Excessive grooming of the anal/perianal region is common with disease in that location (Figure 42-3). Sometimes the owners may report the animal turning around and looking at the hind end while attempting to defecate. There may be a history of trauma and pelvic fractures. Cats with tenesmus or dyschezia commonly vocalize or defecate outside the litter box. The timing of tenesmus in relation to defecation may help localize the problem: tenesmus prior to defecation suggests an obstruction, while tenesmus after defecation suggests irritation/inflammation.

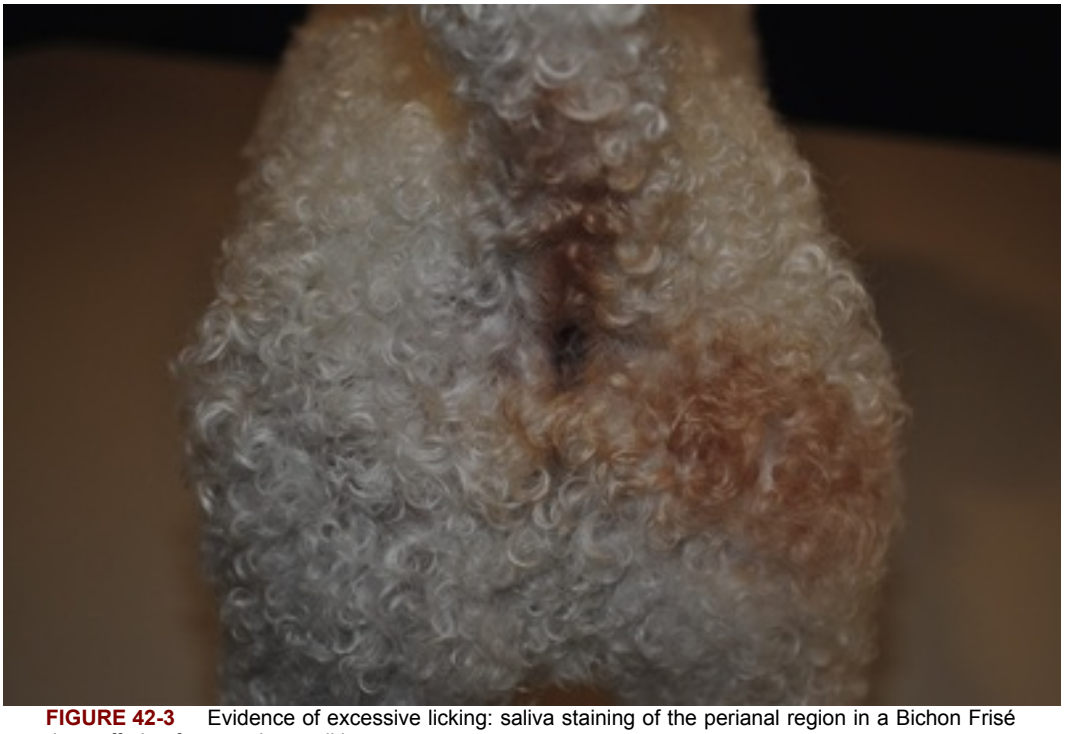

FIGURE 42-3 Evidence of excessive licking: saliva staining of the perianal region in a Bichon Frisé dog suffering from anal sacculitis.

Signalment

Inflammatory diseases are more common in young to middle-aged animals, while neoplasia is more common in older animals. German Shepherd Dogs are predisposed to perianal fistulas. Boxer dogs are predisposed to histiocytic colitis.

Physical Examination

The lower urinary tract should be examined by palpation of the bladder to rule out urethral obstruction (as evidenced by a distended and turgid bladder). The anus and perianal region are best inspected visually to rule out perianal fistulas, evidence of anal sac rupture, and fecal hair mats causing pseudocoprostasis. Digital rectal palpation may sometimes reveal uroliths in the urethra, or prostatomegaly in male dogs. It is also used for identifying rectal masses, perineal hernia, anal sacculitis, sublumbar lymph node enlargement, and pelvic fractures. Rectal palpation also allows for characterization of the feces; absent, scant, or bloody fecal material is consistent with inflammatory disease of the distal GI tract.

Diagnostic Evaluation

A complete blood count, serum biochemistry profile, and urinalysis are helpful in ruling out systemic disease. A fecal flotation can be performed to rule out GI parasites (see ch. 81). Abdominal radiographs and ultrasound are useful in ruling out extraluminal compression of the colon, foreign bodies, pelvic fractures, and colonic masses. Colonoscopy and proctoscopy are useful in identifying colonic masses, foreign bodies, and strictures, once fecal material is evacuated from the colon. Colonic biopsies may be necessary to evaluate the colonic wall for inflammation, infection, or neoplasia.

Fecal Incontinence

Fecal incontinence can be due to damage to the anal sphincter (nonneurogenic sphincter incompetence), disruption of the nervous supply to the anal sphincter (neurogenic incompetence), or reduced capacity or compliance of the rectum (reservoir incontinence). With reservoir incontinence, the animal is aware of the urge to defecate, but conscious control of defecation is overwhelmed by the presence of colorectal disease causing irritation, decreased storage capacity of the rectum, or overwhelming fecal volume. Diseases that can damage the anal sphincter and cause nonneurogenic sphincter incompetence include anal trauma or surgery, anal neoplasia, and damage to the levator ani and coccygeus muscles. Conditions that can result in neurogenic sphincter incompetence include cauda equina syndrome; damage to the pudendal nerve; sacral spinal cord trauma, neoplasia, or compressive lesions; and degenerative myelopathy (see Figure 42-1).

History

The first thing to establish is whether the animal is consciously aware of defecation and is assuming a normal posture to defecate. Conscious awareness of defecation, and the presence of diarrhea, increased frequency of defecation, and mucus or blood in the feces, suggest colorectal disease and reservoir incontinence. It is important to rule out behavioral problems when the animal is consciously defecating in inappropriate locations. With behavioral problems, there is normal posturing to defecate, normal frequency of defecation, and normal consistency of the feces. Often, the location of the defecation in the home is a clue to a behavioral problem. For example, if the dog has been punished previously when defecating inappropriately in the presence of the owner, the dog may seek out locations out of sight of the owner and away from the door outside. Animals with reservoir incontinence often attempt to get outside to defecate, but are unable to retain the feces, and defecate close to the door outside.

A history of recent trauma or perianal surgery may suggest damage to the anal sphincter. With neurogenic sphincter incompetence, other neurologic deficits may be detected, including loss of tail wagging, abnormal tail carriage, hind limb ataxia or weakness, decreased hind limb spinal reflexes, and concurrent urinary incontinence.

Physical Examination

Visual inspection of the anal sphincter may reveal evidence of trauma or mass lesions. Anal tone can be evaluated by the strength of constriction of the sphincter in response to a finger, thermometer, or hemostatic forceps stimulating the sphincter. A digital rectal exam may reveal masses disrupting the sphincter. Evidence of pain on palpating the sacrum or lumbosacral space rectally may occur with lumbosacral stenosis.

Abnormal fecal consistency, with mucus or blood, often is an indication of colorectal disease and reservoir incontinence. Neurologic examination (see ch. 259) can reveal decreased tail tone, hind limb ataxia, decreased hopping and wheelbarrowing, decreased hind limb spinal reflexes, decreased conscious proprioception of the hind limbs, evidence of lumbosacral pain, and loss of urinary bladder tone with many cases of neurogenic sphincter mechanism incompetence as a result of spinal cord disease or damage.

Diagnostic Evaluation

In addition to routine complete blood count, serum biochemistry profile, urinalysis, and caudal abdominal radiographs, additional diagnostic imaging of the caudal spinal cord (epidurogram, myelogram, computed tomography scan, or magnetic resonance imaging) may be required to characterize the nature of disease of the spinal cord if neurogenic causes of sphincter incompetence are suspected based on the history and physical examination.

CHAPTER 43

Flatulence

Alexander James German

Client Information Sheet: Flatulence

"Flatus" refers to gas generated within the gastrointestinal tract, and "flatulence is the act of expelling flatus through the anus." Flatulence is more common in dogs than cats, with a recent unpublished survey reporting an incidence of 10%, a quarter of which experienced daily signs.[1] However, in many instances owners are not concerned and do not seek veterinary attention.

Physiology and Pathophysiology of Flatulence

Passing flatus through the anus is a normal physiological phenomenon in mammalian species including cats and dogs, although volume, frequency, and smell vary. Most gas in flatus is derived from the gastrointestinal tract,[2] with some additional gas diffusing from the bloodstream. Aerophagia can also contribute to flatus, although its significance has been questioned.[3] Whilst rapid food consumption promotes aerophagia in dogs, excessive flatulence is not more frequently reported in dogs described as "greedy."[4] Aerophagia provokes more flatus in dogs with functional alimentary tract abnormalities, and examples include defects in gastro-esophageal sphincter function, eructation, or alimentary gas transit (see ch. 276 and 277).

Flatus comprises a mixture of gases, with >99% lacking odor. Typical gases include oxygen, nitrogen, carbon dioxide, hydrogen and methane. Most such gases are all produced within the gut, as a result of normal mammalian digestion (e.g., carbon dioxide) or microbial fermentation (e.g., methane), though some cases (e.g., nitrogen) arise from environmental air due to aerophagia.[5] A variable volume is produced, largely dependent upon diet composition (especially fermentable fiber), the presence of methane-producing bacteria, and concurrent disease.[6,7] In contrast, odor arises from the trace gas fraction, which is commonly <1% of total flatus volume. The odor-producing compounds in canine flatus include carboxylic acids, phenol, ammonia, hydrogen sulfide, indole, skatole, mercaptans, volatile amines, ketones, alcohols, and short-chain fatty acids.[8] Hydrogen sulfide is most important, but production is highly variable even amongst animals fed the same diet,[8] most probably due to differences in the presence of sulfur-reducing bacteria.[9] Possible sources of sulfur include intestinal mucin, nuts and vegetables, as well as carrageenan (a sulfated polysaccharide). Feeding a "high protein" diet can also increase volatile sulfur compounds and, therefore, odor.[5]

The propulsion of gas in the gastrointestinal tract is an active process which is separate from that of solid and liquid contents.[10,11] Dietary factors influence this process with protein, fat and fiber all slowing transit times, and simple sugars and dietary moisture having no effect.[12,13] Other factors that influence gas transit include physical activity, which increases the speed of gas transit and decreases retention.[11]

Pathophysiology

Since passage of flatus can be a normal physiological phenomenon, owners only present animals to a veterinarian when it is problematic (e.g., excessive volume or odor) or is associated with other clinical signs. Possible causes of excessive flatulence include aerophagia, alimentary tract disease, and diseases affecting other organs. Aerophagia commonly arises from disorders in gastro-esophageal sphincter function, eructation, and alimentary gas transit, with a key example being gastric dilatation volvulus (GDV).[14] Concurrent respiratory system disease might also be responsible, for example, brachycephalic airway syndrome.[15] Where excess flatus results from endogenous gases, it is usually either a byproduct of certain

foods or due to incomplete digestion. Foods commonly implicated are usually of vegetable origin, and contain large amounts of polysaccharides, which provide substrate for the large intestinal microbiota containing fermentable fiber or resistant starch, dairy products (if lactose intolerance is suspected), and other components (e.g., gelling agents such as carrageenan and guar gum in meat products). In humans, flatulence can result from carbohydrate malabsorption, and this is also a common feature in cats with gastrointestinal disease.[16] In a similar manner, dogs and cats that have hypersensitivity or intolerance to specific proteins might demonstrate flatulence, and other gastrointestinal signs if exposed to foods to which they are sensitive. Changes in protein content might alter the smell of flatus, whilst other dietary components can alter gas transit (e.g., dietary fat and fiber). Such changes can prompt an owner to present their dog for flatulence, even though the volume has not changed. Flatulence can occur with various diseases. In humans, a predominance of methane production can also occur in individuals with obesity, constipation, irritable bowel syndrome, and inflammatory bowel disease.[17,18] Lactose intolerance is an occasional cause of flatulence, as a result of gas production from intestinal bacteria utilizing lactose. Finally, certain enteric infections can cause flatulence, most notably infection with *Giardia* sp.,[19] and there is some suggestion that antimicrobial use can provoke flatulence, on account of effects on gastrointestinal microbiota.

Clinical Presentation and Differential Diagnosis

Clinical signs associated with flatulence include excessive flatus volume, unpleasant flatus odor, noise associated with episodes, and abdominal pain or abdominal distension ("bloating"). Patients with flatulence may also have excessive eructation or borborygmi, as well as other alimentary tract signs such as including vomiting, diarrhea, and weight loss.

Differential diagnoses for flatulence include excessive aerophagia, dietary factors, motility disorders, malabsorption, and microbial causes. As discussed above, aerophagia can result from swallowing disorders (e.g., esophageal dysmotility, and megaesophagus), respiratory tract disorders (e.g., those causing dyspnea), and problems relating to feeding behavior (e.g., rapid food ingestion, obsessive compulsive disorders). Dietary causes include excessive fermentation (e.g., due to excessive dietary fermentable fiber) and adverse reactions to food (e.g., hypersensitivity, intolerance, and dietary indiscretion). Motility disorders that cause flatulence include esophageal dysmotility, GDV, dysautonomia, ileus, obstructive intestinal disease (e.g., neoplasia, foreign body, stricture, and adhesions), and "irritable colon syndrome." The most likely causes of malabsorption are exocrine pancreatic insufficiency (EPI) and chronic enteropathies that affect the small intestine (e.g., inflammatory bowel disease, lymphoma). Since giardiasis and antibacterial use can cause flatulence in humans, they are also possible differential diagnoses in companion animals.

Investigation

As mentioned above, flatulence is a normal physiological phenomenon, and one aim of investigations is to determine whether the reported episodes are of significance. Therefore, the extent of the investigations and management should depend upon the individual case. Possible reasons for an owner presenting their dog include flatulence developing in a dog not previously affected, increasing severity of signs (in terms of volume, odor, sound), or concurrence of other clinical signs, perhaps suggesting a significant underlying gastrointestinal disease or disease in another organ. History and physical examination are first used to determine the likelihood of an underlying disease and whether there are any recent changes to diet or management (see ch. 1 and 2 and Figure 43-1). This will enable the clinician to determine if investigations are necessary. Appropriate treatments are used when an underlying disease is identified, while symptomatic therapy (diet, management, medical) can be used at any stage, if an underlying cause is neither suspected nor identified on investigations.

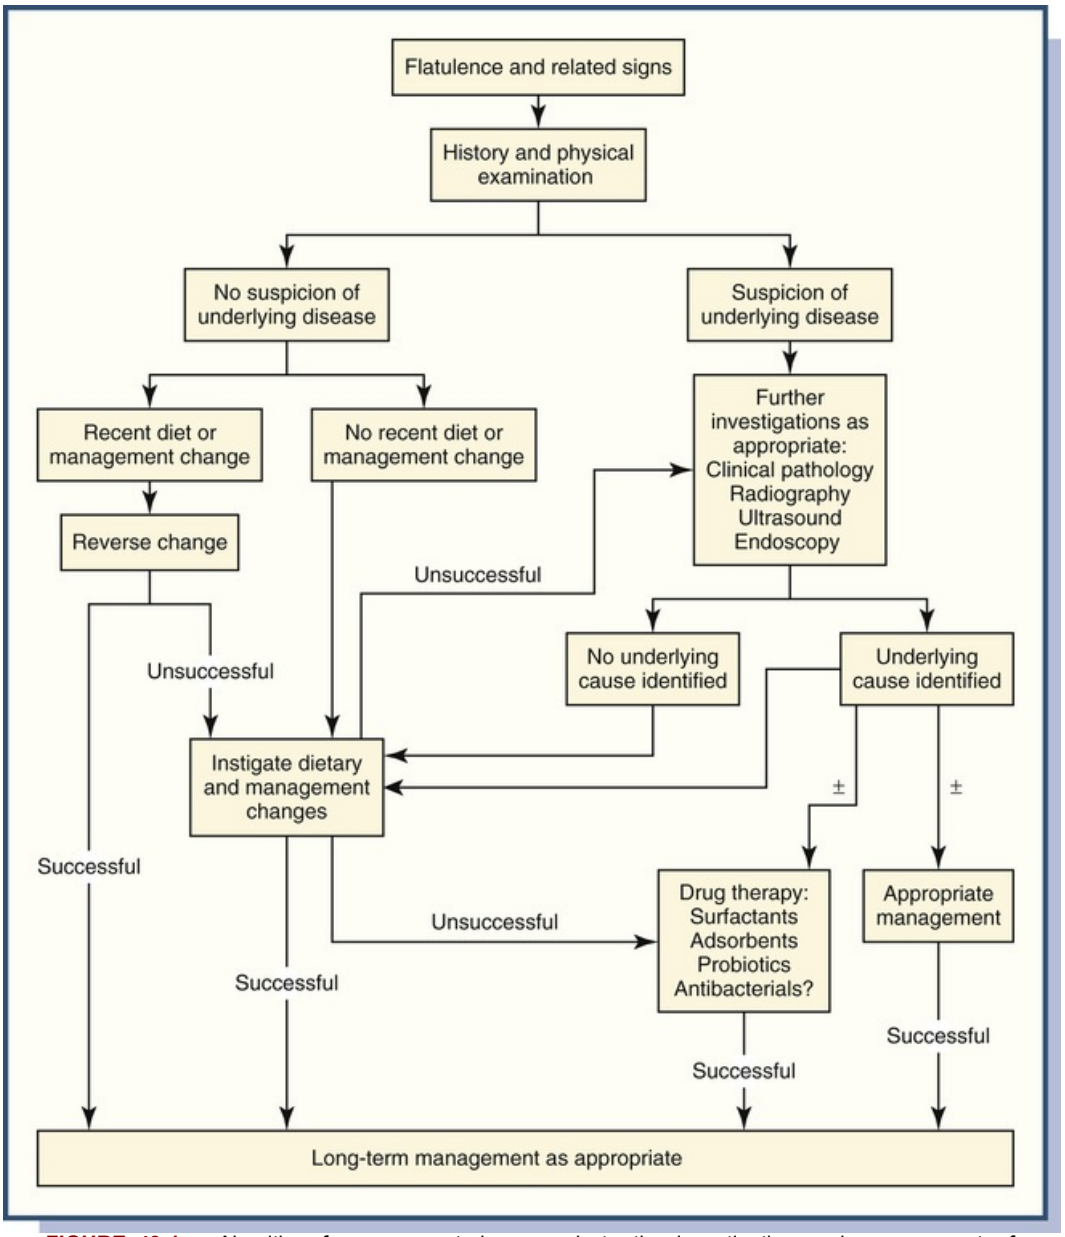

FIGURE 43-1 Algorithm for a suggested approach to the investigation and management of flatulence.

In addition to the medical history, diet history should be gathered, including all food given, timing, amount, and if recent changes have occurred. Both main meal and extras (e.g., supplements, table scraps, treats, or food scavenged) must be recorded. The clinician should also consider diet composition, since many components can cause flatulence (see above), and the possibility of an adverse reaction to food. On physical examination, flatulence, borborygmi, abdominal discomfort, and abdominal distension may be present. Since other signs would not be expected in simple flatulence cases, their presence can suggest an underlying disease (see ch. 178, 179, and 191).

Further investigations are required when underlying disease is suspected, with tests dependent upon the individual case. Routine hematological and serum biochemical analysis, coupled with urinalysis, can give information regarding general systemic health, whilst routine fecal examination may indicate an enteric infection. Measurement of folate and cobalamin can help to confirm malabsorption, whilst trypsin-like immunoreactivity (see ch. 292) can be used to identify EPI. Diagnostic imaging, especially thoracic and abdominal radiography, can show the presence and distribution of gas in the alimentary tract, as well as confirming problems such as megaesophagus or GDV. Finally, although gastrointestinal biopsy is rarely required, it is used when an underlying small intestinal malabsorption is suspected.

Management

Where there is evidence of an underlying disease, specific therapy should be implemented, and examples would include immunosuppressive medication for IBD with concurrent malabsorption, pancreatic enzyme supplementation for EPI, and antiparasitic medication for giardiasis. In such cases, the flatulence should resolve when the underlying disorder is treated, although symptomatic treatment may also be required. Examples of symptomatic therapies for flatulence include dietary management, altering feeding behavior, and medical therapies.

The goal of dietary management is to reduce (e.g., fat, fermentable fiber, gelling agents) or eliminate altogether (e.g., proteins suspected of causing hypersensitivity) the component of the food responsible for signs. The components in different foods should be compared relative to energy content of the food (i.e., g per 1000 kcal) rather than relative to dry matter. When it is not possible to determine the exact offending agent, a highly digestible diet should be chosen, which is reduced in fat and fermentable fiber. An empirical choice for a dog would be a food with less than 30 g/1000 kcal fat and 15 g/1000 kcal crude fiber (<25 g/1000 kcal total dietary fiber). Either a formulated therapeutic diet or a home-prepared diet can be used. The latter does not need to be balanced if fed for ≈7 days (i.e., as a diet challenge), but must be nutritionally balanced when fed long term, ideally by a board-certified clinical nutrition specialist. Generally, it is best to avoid vegetarian diets (given the potential for greater fermentable fiber content) and foods containing lactose. Further, some dry foods have an altered kibble shape and require more chewing, thereby slowing food intake. If an adverse reaction to food is suspected, it is advisable to consider conducting one, or more, exclusion diet trials using either a hydrolyzed or single source protein diet (see Section XI and ch. 191). Trials should last for at least 2 weeks since signs associated with adverse food reactions usually improve within 7-10 days.

Where flatulence is the result of aerophagia, changing the pattern, timing, and method of feeding can sometimes help. Animals that are group fed can be separated to avoid rapid eating through food competition. When rapid intake is a possible cause, interactive feeders (e.g., hollow toy "puzzle" feeders and modified feed bowls) can be used to slow the rate of food intake. Further, giving the daily food ration over a number of meals can help, though evidence of efficacy is mixed with one study suggesting twice daily feeding to be better than once daily,[20] and another study suggesting no effect of change in meal frequency.[4] Finally, increasing physical activity can also be considered since it can increase the rate of intestinal gas transit, and decrease gas retention[11]; indeed, dogs that are exercised frequently are less likely to bloat than sedentary dogs.

Various drugs can symptomatically reduce the volume and/or odor of flatulence, with options including surfactants, adsorbents, antibacterials, and probiotics. Simethicone is a surfactant that is used to treat flatulence in humans; it reduces surface tension causing gas bubbles within the stomach and intestine to coalescence, thereby reducing gas trapping and promoting its passage through the gastrointestinal tract.[21] Empirical use is thought to be safe in cats and dogs, using a scaled-down human dose (e.g., 25-200 mg q 6 h PO).[22] Plant saponins derived from *Yucca schidigera* has been shown to have effects on antimicrobial fermentation.[23] Indeed, extracts of *Yucca schidigera* reduce fecal odor when fed both to dogs and cats.[24-26] Other adsorbents used for symptomatic flatulence management include activated charcoal, bismuth subsalicylate, and zinc-containing compounds (e.g., zinc acetate, zinc sulfate). Bismuth and zinc are divalent cations that bind compounds with a sulfhydryl group (e.g., hydrogen sulfide), whilst activated charcoal has a large internal surface area binding molecules leading to flatulence. Whilst such products are effective,[27] they require frequent dosing, making compliance a possible challenge. Dietary activated charcoal reduces hydrogen sulfide concentrations and odor associated with flatus in dogs.[26] Combination products are also available for veterinary use, and the individual agents are synergistic. For example, a supplement containing *Yucca schidigera* extract, activated charcoal, and zinc acetate significantly decreased hydrogen sulfide content of flatus, when fed to dogs[26]; each component had independent effects, but the combination product was better overall.

In humans, antibacterials are used empirically to manage flatulence. Suitable drugs should be orally administered, effective against anaerobic bacteria, not be systemically absorbed, and be free from side effects. Examples include rifamixin, which is more effective than activated charcoal treating flatulence in humans.[28] Antibacterial therapy can also be considered for dogs with flatulence,[29] but caution is recommended with empirical use long term, given the potential for antimicrobial resistance. If necessary, nonabsorbed antibacterials are preferable, as in humans. Probiotics are a possible alternative given studies suggesting a reduction in severity of flatulence in humans with irritable bowel syndrome.[30] Recent work in dogs has also demonstrated possible efficacy of probiotics for treatment of flatulence in dogs, by decreasing number of

flatulence events, hydrogen sulfide concentration, and odor.[31]

Finally, whilst surgical procedures are not directly used for management of flatulence, prophylactic gastropexy may be required for dogs predisposed to gastric dilatation-volvulus. Rather than eliminating clinical signs, the main aim is to prevent torsion from developing in the future. Nonetheless, some cases of chronic partial torsion manifest with chronic low-grade signs of flatulence and borborygmi. In such cases, prophylactic surgery can also provide long-term relief from clinical signs.

Vulvar and Preputial Discharge

Jeffrey de Gier, Auke C. Schaefers-Okkens

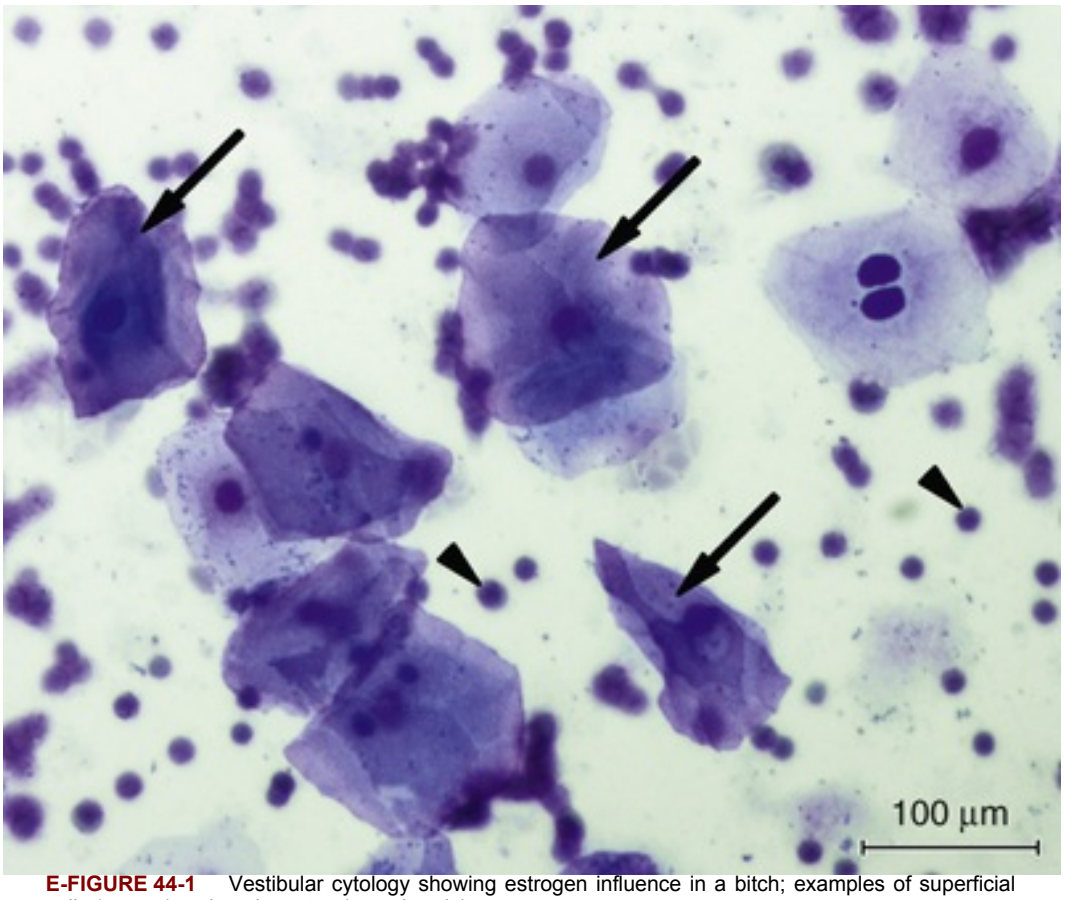
Client Information Sheet: Vulvar Discharge

Introduction

The content of this chapter is devoted to the causes of and clinical approach to non-physiological vaginal or preputial discharge. This discussion will not include disorders of the urological tract and/or perineal pathology, which may cause "pseudovaginal discharge," such as occurs with anal sac abscess or perivulvar dermatitis. Physiological vaginal discharge is commonly observed in the bitch during proestrus, estrus, pregnancy, parturition and the days to weeks following parturition. Discharge is normally seen in some cats during parturition and in the days thereafter. In male dogs, mucopurulent discharge from the prepuce without concomitant clinical signs is often considered physiological or of little consequence.

Vaginal Discharge

In order to make a proper diagnosis, one should begin with a complete history and then perform a thorough physical examination. The following information is important: (a) the pet's age; (b) the nature of the discharge: serosanguineous, mucoid, or mucopurulent? (c) is the animal intact or has an ovariectomy or ovariohysterectomy been previously performed? If intact, when was the last estrus? As the final component of the physical examination, the genital tract should be evaluated with abdominal palpation and, as indicated: digital palpation of the vaginal vault, vaginoscopy, and cytology of the vestibule to evaluate for estrogen influence (see ch. 119) (E-Figure 44-1). The more invasive examinations are usually not done or feasible in awake young animals or cats. Additionally, any of the following may be warranted: laboratory testing to assess for inflammation or bone marrow hypoplasia, endocrine testing of the pituitary-gonadal axis, ultrasonography of structures which are of concern, cytology of a fine needle aspirate or histologic assessment of a tissue sample.[1]



E-FIGURE 44-1 Vestibular cytology showing estrogen influence in a bitch; examples of superficial cells (arrows) and erythrocytes (arrowheads).

Serosanguineous Vaginal Discharge in Intact Bitches and Queens (Figure 44-2)

In young bitches during the first or second estrous period, prolonged estrogen influence or "split heats" are relatively common. Prolonged exposure to estrogen can result in a persistent sanguineous discharge and can be confirmed with vaginal cytology (see E-Figure 44-1) and/or vaginoscopy (Video 44-1) (see ch. 119). This condition is frequently caused by failure to ovulate, as can be demonstrated by persistently low plasma progesterone concentrations. Other causes of prolonged proestrus include cystic ovarian follicles, portosystemic shunt (see ch. 284), or exogenous estrogen influence. In middle-aged or older dogs, the most common cause for prolonged sanguineous discharge is ovarian neoplasia. Such neoplasia can usually be visualized with abdominal ultrasonography or more advanced imaging studies.

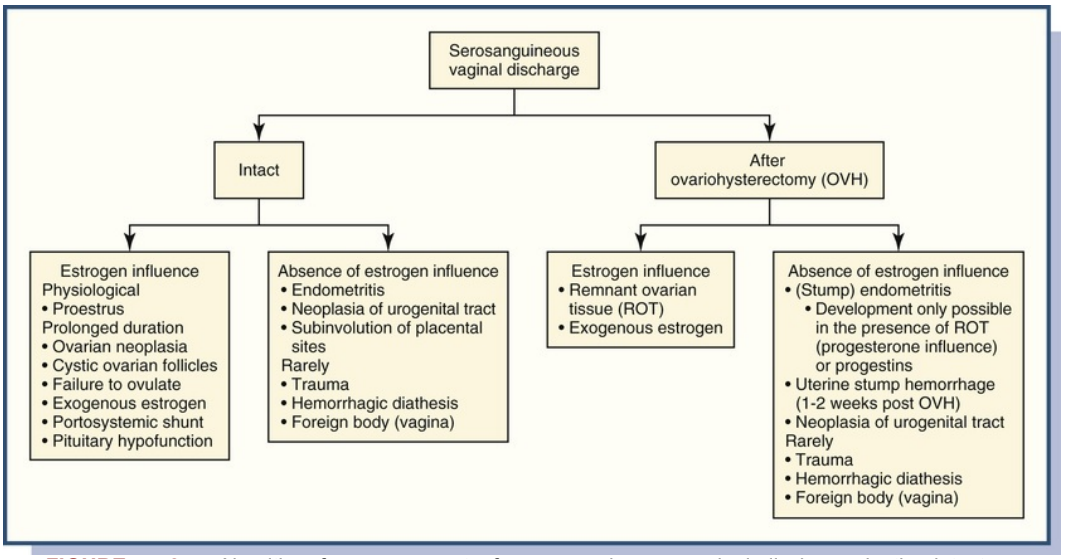


FIGURE 44-2 Algorithm for assessment of serosanguineous vaginal discharge in the intact or ovariectomized bitch based on the presence or absence of estrogen influence.

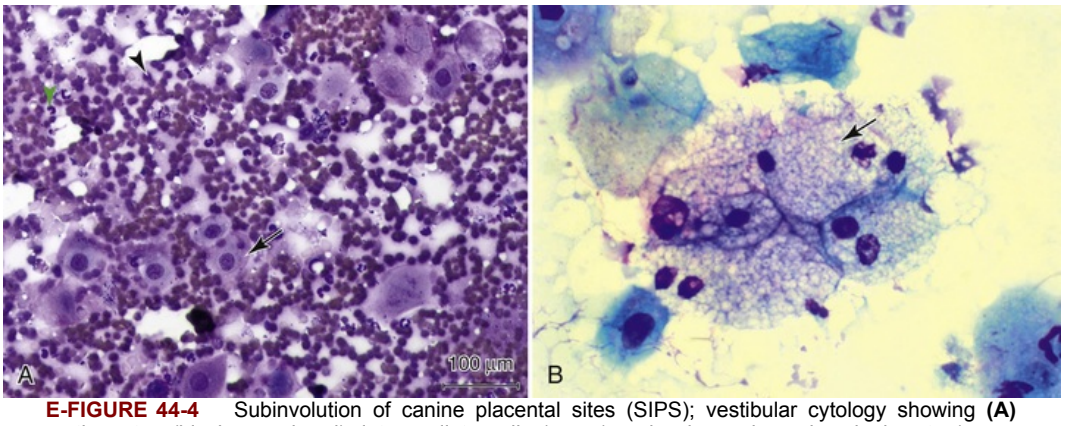
Bloody discharge in the absence of estrogen influence in middle-aged to older intact bitches is most frequently caused by endometritis or neoplasia of the urogenital tract (E-Figure 44-3; Video 44-2; see ch. 316 and 351). In intact bitches, vaginal tumors are often benign (e.g., leiomyoma, fibroma). Cytology or histopathology may be of value before surgical removal of the tumor(s) is attempted.

E-FIGURE 44-3 Vaginoscopy in a bitch showing a small and probably benign tumor (asterisk), protruding into the cranial end of the tubular speculum.

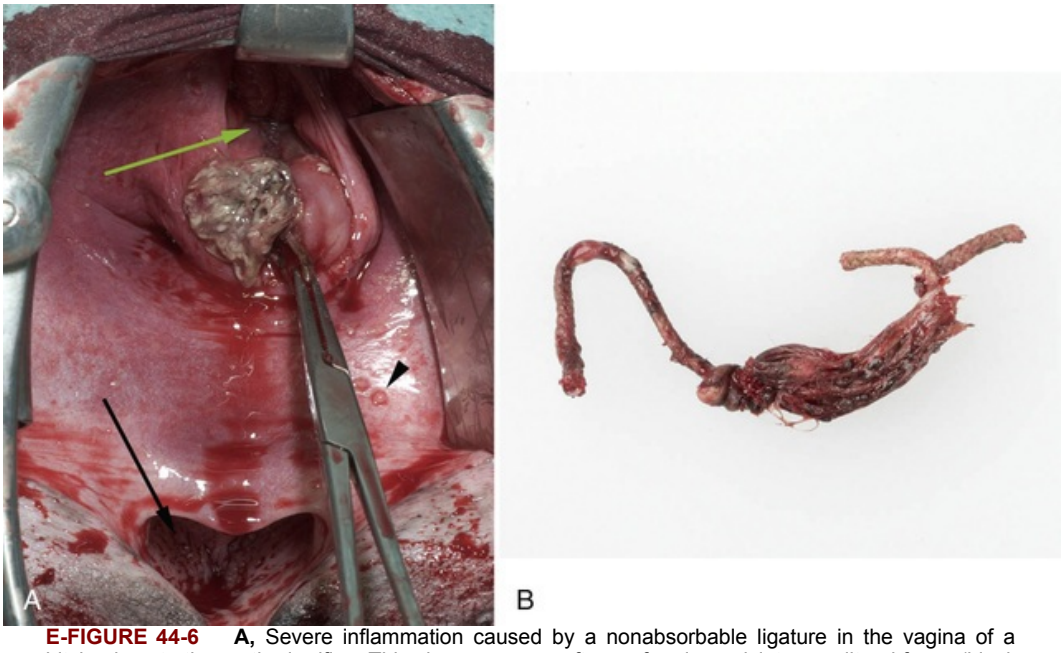
Subinvolution of placental sites (SIPS) is often the cause of prolonged bloody discharge (longer than 2-3 weeks) in bitches after parturition (see ch. 315). These bitches are otherwise healthy. The bloody discharge is

usually obvious on vaginoscopy. The cells seen on vaginal smears include erythrocytes, occasional neutrophils, and vacuolated giant cells (E-Figures 44-4 and 44-5). Placental sites visualized with ultrasonography may appear large. If left untreated the discharge may continue until the next estrus period.[2] In queens, bloody discharge may be caused by endometritis or (partial) abortion. Rarely, bloody discharge in bitches and queens may be due to trauma, hemorrhagic diathesis or a foreign body (E-Figure 44-6).



E-FIGURE 44-4 Subinvolution of canine placental sites (SIPS); vestibular cytology showing **(A)** erythrocytes (black arrowhead), intermediate cells (arrow) and polymorphonuclear leukocyte (green arrowhead) and **(B)** a polynucleated, vacuolated giant cell (arrow).

E-FIGURE 44-5 Vaginoscopic view in a bitch 8 weeks after parturition with subinvolution of placental sites (SIPS). Note the bloody discharge cranial in the vagina.



E-FIGURE 44-6 **A,** Severe inflammation caused by a nonabsorbable ligature in the vagina of a bitch, close to the urethral orifice. This view was seen after performing episiotomy; clitoral fossa (black arrow), possible lymphoid tissue (arrowhead), vagina (green arrow). **B,** Ligature after removal.

Serosanguineous Vaginal Discharge in Bitches and Queens after Ovariectomy (see Figure 44-2)

Serosanguineous discharge due to estrogen influence observed in a previously ovariectomized bitch is usually caused by functional remnant ovarian tissue. The diagnosis is easily made if estrogen influence is confirmed via vulvar swelling, vaginal cytology, vaginoscopy (Video 44-3; see ch. 119) and/or if the plasma progesterone concentration is >2 ng/mL. If no estrogen influence is observed and the plasma progesterone concentration is <2 ng/mL, then a gonadotropin-releasing hormone (GnRH) stimulation test or determination of anti-mullerian hormone concentrations may be necessary to confirm a diagnosis. Determination of basal plasma luteinizing hormone (LH) concentrations, alone, is not reliable due to changes in the hypothalamic-pituitary-ovarian axis after an incomplete ovariectomy.[3-5]

Serosanguineous discharge after ovariectomy may also be caused by long-term administration of estrogens, e.g., estriolum for urinary incontinence.[6] Further causes of bloody discharge after ovariectomy, without the presence of estrogen influence, include stump endometritis due to the administration of progestins, neoplasia of the urogenital tract (more frequently malignant than in intact bitches), or uterine stump hemorrhage in the 1-2 weeks after ovariohysterectomy. Rarely, trauma, hemorrhagic diathesis or a foreign body may cause bloody discharge.

Mucopurulent Vaginal Discharge in Intact Bitches and Queens (Figure 44-7)

Clear to opaque mucous vaginal discharge is sometimes observed physiologically around day 30 of normal pregnancy (E-Figure 44-8). Mucopurulent vaginal discharge in the intact bitch at the onset of diestrus may be physiological as well (E-Figure 44-9). The most common pathological cause of mucopurulent vaginal discharge in the intact bitch after estrus or parturition is endometritis (see ch. 316). The vaginal discharge in association with abortion is often dark green. Additionally, vestibulitis/vaginitis may cause mucopurulent discharge. Primary vaginitis is not seen in the cat.

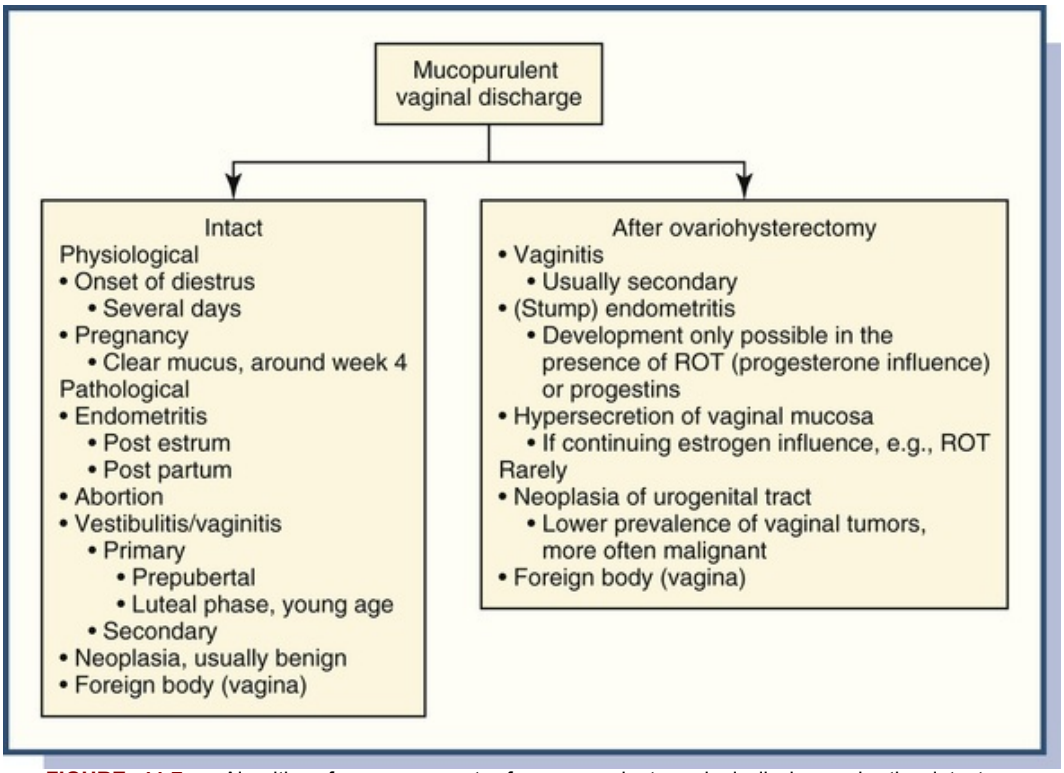


FIGURE 44-7 Algorithm for assessment of mucopurulent vaginal discharge in the intact or ovario(hyster)ectomized (OVH) bitch. *ROT,* Remnant ovarian tissue.

E-FIGURE 44-8 Clear and frequently seen physiological mucous discharge in the bitch around day 30 of pregnancy.

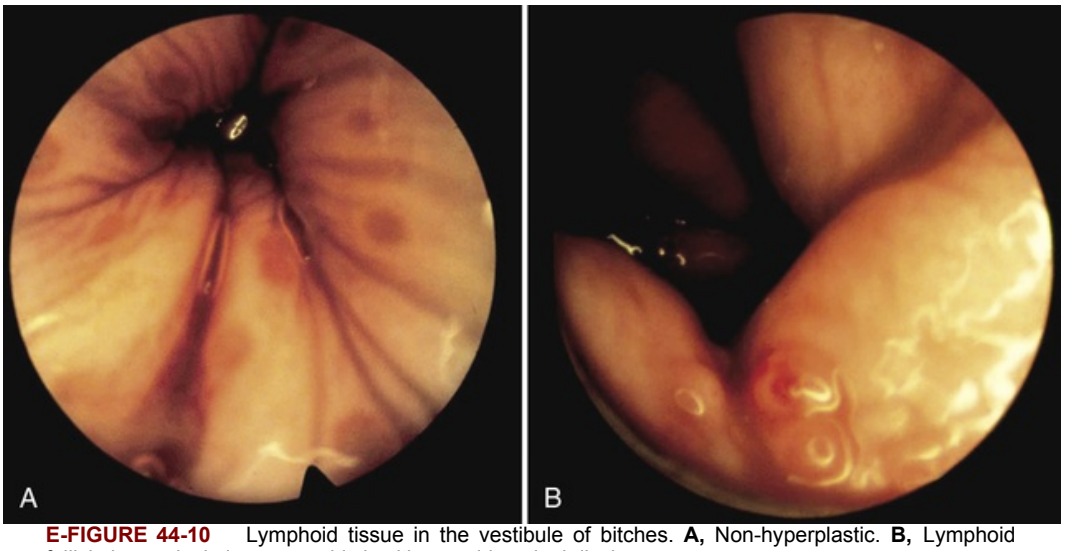
E-FIGURE 44-9 Discharge seen in a bitch at the onset of diestrus a few days after mating. **A,** Visual inspection of the vulva. **B,** Cytology, intermediate cell (black arrow), polymorphonuclear leukocyte (arrowhead).

The etiology of vaginitis and/or vestibulitis may be better understood by reviewing the embryologic development of this anatomic area. The area immediately proximal to the urethral opening is the caudal aspect of the internal genitalia, which fuses during development with the external genitalia. This "fusion"

creates the entire vaginal vault.

Age and the stage of the estrous cycle may be important. Infrequently, inflammation within the vestibule may be due to an infection, e.g., with canine herpesvirus. Hormonal and immunological factors may play a major role in "vaginitis/vestibulitis" in young dogs, whose clinical signs are often restricted to mucous discharge and attractiveness to male dogs.

Prepubertal *"puppy vaginitis"* and *"vaginitis/vestibulitis" after the first or second estrus* are most commonly seen in large and brachycephalic breeds, sometimes as early as 3 months of age. This condition is characterized by a slightly swollen vulva, mucoid white or yellow discharge and/or attraction of male dogs. Vaginoscopy may reveal an exudate, mucosal lesions primarily in the vestibule and concomitant lymphoid follicle hyperplasia (E-Figure 44-10; see ch. 304). Vaginoscopy performed when a normal bitch is in diestrus shows a patchwork of white and red areas. Red areas in these dogs should not be mistaken for inflammation if mucosal lesions are not present (E-Figure 44-11; Video 44-4).



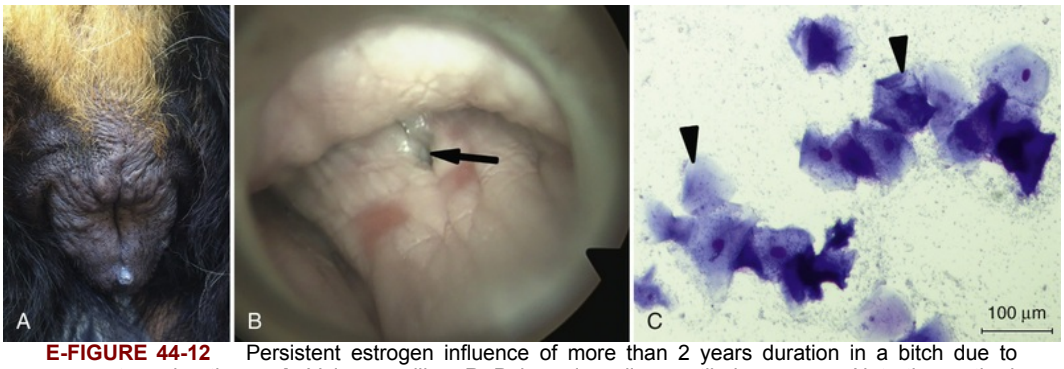
E-FIGURE 44-10 Lymphoid tissue in the vestibule of bitches. **A,** Non-hyperplastic. **B,** Lymphoid follicle hyperplasia in a young bitch with mucoid vaginal discharge.

E-FIGURE 44-11 Vaginoscopic view of vaginal mucosa during diestrus/anestrus in the bitch. Note the red and white areas which are seen in healthy bitches during these stages.

Frequently, the signs in young dogs are self-limiting and disappear after the first estrous cycle or after the second or third luteal phase. Treatment of "puppy vaginitis" prior to the first estrus is not recommended for several reasons. Most drugs, such as local or parenteral antibiotics, will not alleviate signs. Application of locally active ointments or other medications are not well tolerated, especially in prepubertal bitches. Lastly, the general health and fertility of these patients is usually not affected by this condition.

"Vaginitis/vestibulitis" after the first or second estrus may be treated by local application of ointments containing glucocorticoids. If these agents are beneficial in alleviating the signs, it would support an underlying immunological etiology. If vaginal discharge is noted in a patient with concurrent urological problems (e.g., cystitis and/or pyelonephritis), more intensive therapy may be needed (see ch. 330 and 327). Bacterial culture of the vagina usually demonstrates normal flora and is not a test with significant value. However, if antibiotic treatment is being considered, culture and sensitivity testing should be performed. "Vestibulitis/vaginitis" may recur, but the problem is usually self-limiting with the end of the luteal phase or with advancing age.

"Vaginitis in the mature bitch" is usually secondary to other problems such as a foreign body or neoplasia in the vagina. Very rarely, anatomic deformities may lead to accumulation of secretions or urine, leading to inflammation and vaginal discharge. Vestibulitis with discharge may also be caused by urinary incontinence, e.g., after ovariectomy. In addition, vesicles may be temporarily observed along the mucosa of the vestibule if a bitch has a canine herpes infection. Remnant ovarian tissue in a bitch, after hysterectomy, may lead to non-bloody vaginal discharge, mostly of shed superficial cells (E-Figure 44-12; Video 44-5).



E-FIGURE 44-12 Persistent estrogen influence of more than 2 years duration in a bitch due to remnant ovarian tissue. **A,** Vulvar swelling. **B,** Pale and swollen vestibular mucosa. Note the urethral opening (arrow). **C,** Cytology showing erythrocytes and mainly superficial cells (arrowheads).

Mucopurulent Vaginal Discharge in Bitches and Queens after Ovariectomy (see Figure 44-2)

Mucopurulent discharge after ovariectomy without estrogen influence may be caused by neoplasia in the genital tract or it may be seen in dogs with "stump endometritis" due to progesterone secretion from remnant ovarian tissue (E-Figure 44-13) or may follow progestin administration. Progestin administration is always contraindicated after ovariectomy. If, after ovariectomy, cystic endometrial hyperplasia is present in the uterine tissue, and progestins have not been administered, then remnant ovarian tissue is present.

E-FIGURE 44-13 Surgically removed uterine stump showing pyometra due to progesterone influence in a bitch with remnant ovarian tissue.

Preputial Discharge

Preputial discharge may be composed of fluid and cells that originate from the urinary bladder, prostate gland, testicles and epididymides, urethra, and mucosa of the penis and penile sheath. Preputial discharge

may be present in either intact or castrated dogs but is extremely uncommon in tomcats. Rarely, generalized mucosal disease or hemorrhagic diathesis may cause preputial discharge.

Normal discharge in the intact male is characterized by a small amount of grayish-white to yellow mucopurulent material that may be seen at the preputial orifice as moist or dried exudate. Abnormal discharges may be mucopurulent (E-Figure 44-14) or serosanguineous (Figure 44-15).

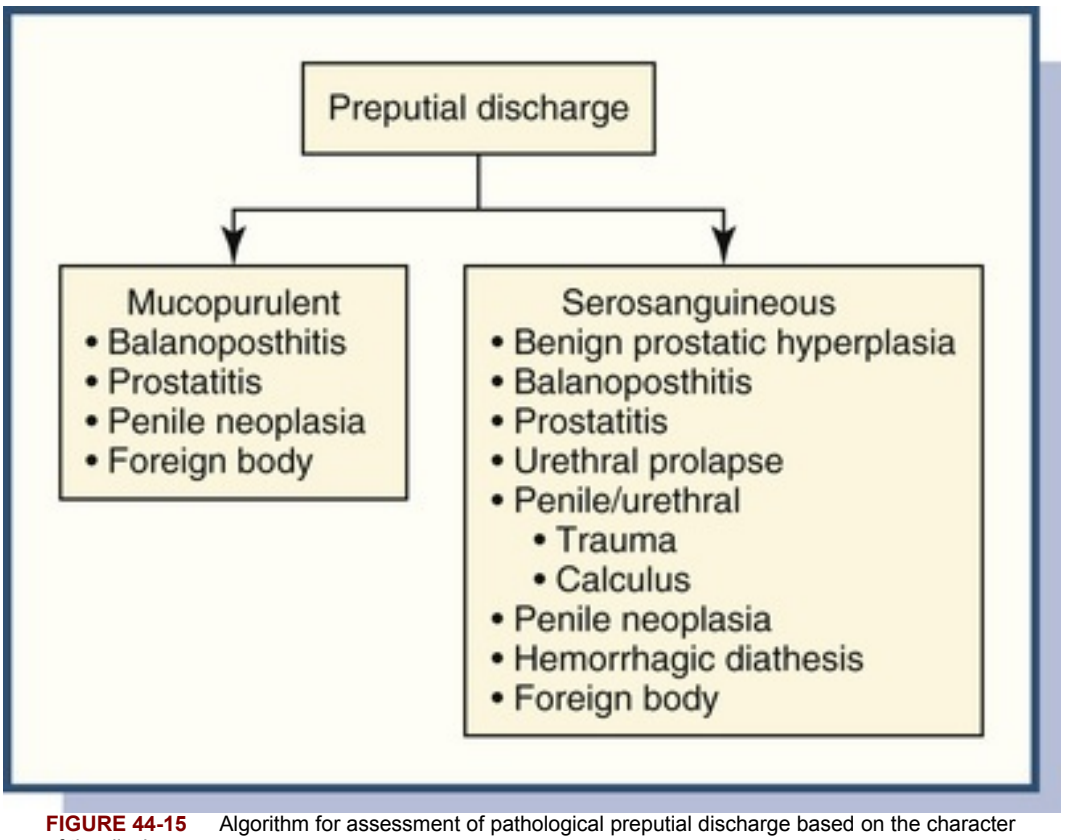


FIGURE 44-15 Algorithm for assessment of pathological preputial discharge based on the character of the discharge.

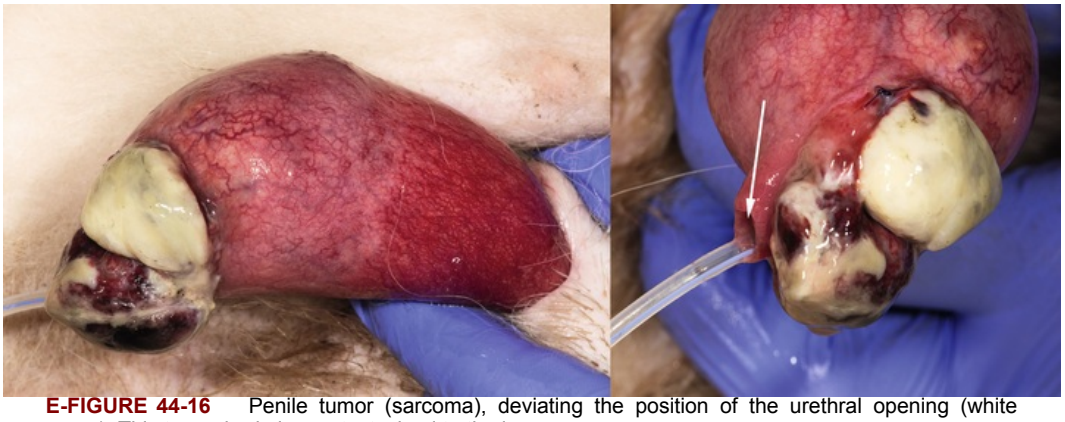
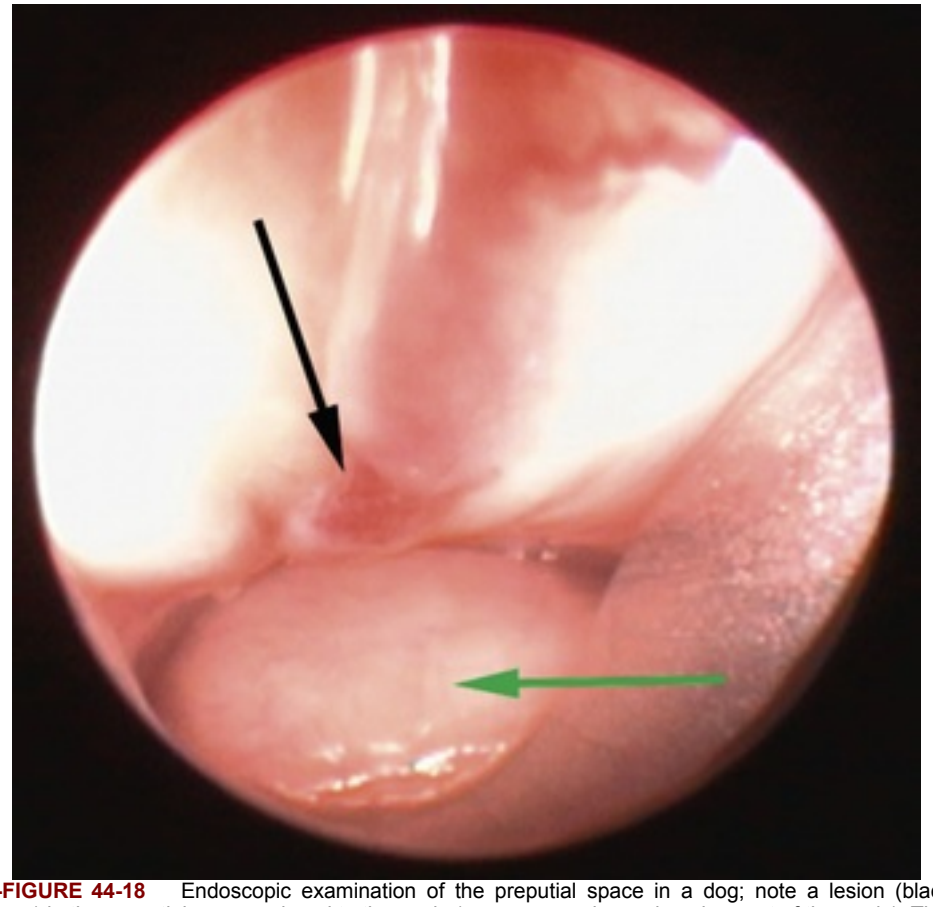
E-FIGURE 44-14 Mucopurulent preputial discharge in a castrated male dog.

It is important to consider age, breed, and reproductive status of the pet. The duration and historical character of the discharge should also be noted. Systemic signs that precede or are associated with preputial discharge may accompany inflammatory conditions, infectious disease, neoplasia, trauma, or exposure to a toxin. Penile tumors are rare (E-Figure 44-16). The prevalence of transmissible venereal tumor varies with geographical location (E-Figure 44-17). A complete physical examination, including the male reproductive tract, should be performed.[7] Digital examination and visual inspection of the preputial space (preputioscopy) may be indicated to assess the entire mucosal surface (E-Figure 44-18).



E-FIGURE 44-16 Penile tumor (sarcoma), deviating the position of the urethral opening (white arrow). This tumor had also metastasized to the lungs.

E-FIGURE 44-17 Transmissible venereal tumor causing bloody preputial discharge in a dog.



E-FIGURE 44-18 Endoscopic examination of the preputial space in a dog; note a lesion (black arrow) in the preputial mucosa dorsal to the penis (green arrow shows dorsal aspect of the penis). This lesion was only visible using endoscopy and not upon extrusion of the penis.

In dogs and cats castrated prior to puberty, the penile tissue may appear less developed. Additionally, in cats it may be more difficult to completely extrude the penis for visualization. Based on the appearance of the preputial discharge, historical information, and physical examination findings, a list of possible diagnoses can be generated (see Figure 44-15).

Further evaluation might include a complete blood count, serum biochemical profile, and urinalysis, as well as imaging of the testicles, prostate, or urinary bladder with ultrasonography. Evaluation of testicular or prostatic secretions may be possible through semen collection or prostatic massage (see ch. 111). Additional diagnostics may include bacterial culture and sensitivity testing, fine needle aspiration, or biopsy.

Testing, as discussed, may lead to a definitive diagnosis. In the absence of definitive findings, the male should be re-evaluated at a later date. Comparison of subsequent findings with the original data may lead to a definitive diagnosis or management plan.

CHAPTER 45

Polyuria and Polydipsia

Robert E. Shiel

Client Information Sheets:
How to Measure Your Pet's Water Intake
Polyuria and Polydipsia: Excess Urine Output and Water Intake

Introduction

Polyuria and polydipsia are common presenting complaints. Polydipsia is generally defined as a water intake greater than 90-100 mL/kg/day in dogs, and greater than 50 mL/kg/day in cats. However, water intake in healthy animals is variable and may be increased by high environmental temperature, exercise and feeding dry diets. Polyuria is defined in both species as urine output greater than 50 mL/kg/day.

Differential Diagnosis

The causes of polyuria and polydipsia are summarized in Box 45-1. Polyuria is caused by excessive intake of water (primary polydipsia) or decreased urinary concentrating ability (primary polyuria).

Box 45-1

Causes of Polyuria and Polydipsia in Dogs and Cats

- Central diabetes insipidus
- Primary nephrogenic diabetes insipidus
- Secondary nephrogenic diabetes insipidus
  - Hyperadrenocorticism
  - Hypoadrenocorticism
  - Hyperthyroidism
  - Hyperaldosteronism
  - Liver disease
  - Pyelonephritis
  - Pyometra/*Escherichia coli* endotoxemia
  - Hypokalemia
  - Hypercalcemia
  - Erythrocytosis
  - Leptospirosis
  - Acromegaly
  - Leiomyosarcoma
  - Drug administration, e.g., glucocorticoids, phenobarbital
- Osmotic
  - Diabetes mellitus
  - Chronic kidney disease
  - Primary renal glycosuria
  - Fanconi syndrome
  - Post-obstructive diuresis
  - Drug administration, e.g., osmotic diuretics

High salt diet
Low renal medullary tonicity
Renal medullary washout
Low protein diet
Other/unknown
Polyuric phase of acute kidney injury
Syndrome of inappropriate ADH secretion
Splenic hemangiosarcoma
Pheochromocytoma

Primary Polydipsia

Primary polydipsia represents a group of disorders in which increased thirst is the primary pathophysiological mechanism. In people, many cases are associated with psychiatric conditions, which have led to the term "psychogenic polydipsia." The cause of primary polydipsia in dogs and cats is not known (idiopathic). Behavioral disorders, altered hypothalamic thirst center function, or inappropriate stimulation of thirst centers by osmoregulatory, neural or hormonal abnormalities are often suspected, but difficult to confirm. Primary polydipsia is proposed to contribute to the polyuria reported in hyperthyroidism and with hepatic failure. An association between primary polydipsia and gastrointestinal disease has been reported in dogs.

Primary Polyuria

Diabetes Insipidus

Arginine vasopressin (AVP, antidiuretic hormone) is the primary hormone responsible for water homeostasis, acting within the renal collecting ducts to increase water permeability and absorption from the tubular lumen. A deficiency in production or lack of response to AVP is associated with an inability to concentrate urine. This results in polyuria and compensatory polydipsia. Central diabetes insipidus is a complete or partial lack of AVP production. It is most commonly idiopathic, but can be associated with neoplasia, inflammation, trauma or developmental structural defects (see ch. 296).

Nephrogenic diabetes insipidus is defined as a complete or partial lack of response to AVP. Primary nephrogenic diabetes insipidus is an extremely rare congenital disorder resulting in severe polyuria and polydipsia at an early age. Secondary nephrogenic diabetes insipidus is the most common cause of polyuria and polydipsia in small animals. Several diseases and some drugs have the capacity to decrease the responsiveness of renal tubules to vasopressin (see Box 45-1). Multiple additional mechanisms may be responsible for the development of polyuria and polydipsia. Interference with the action of AVP is important because it may lead to hyposthenuric, isosthenuric or minimally concentrated urine.

Osmotic Diuresis

The abnormal presence of osmotically active particles in urine impairs the ability of the kidney to reabsorb water. This mechanism is responsible for polyuria in diabetes mellitus, renal tubular disorders (such as primary renal glycosuria and Fanconi syndrome), chronic kidney disease (CKD), post-obstructive diuresis and following administration of some diuretics such as mannitol. In these conditions, solute abnormally present within tubules drives loss of water; therefore, hyposthenuria is not observed. When large quantities of solute are present, urine may be erroneously assessed as adequately concentrated.

Other Mechanisms

Increased intravascular volume and/or pressure reportedly contribute to polyuria observed during the polyuric phase of acute kidney injury (AKI), the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and in some dogs with pheochromocytoma.[1] Chronic polyuria or IV fluid administration can result in renal medullary solute washout and loss of the osmotic gradient necessary for water reabsorption. Similarly, low renal interstitial tonicity and polyuria can develop in dogs fed severely protein-restricted diets. Polyuria has also been described in dogs with splenic hemangiosarcoma, but the mechanism has not been well characterized.[2]

Diagnostic Approach

The investigation of polyuria and polydipsia is usually straightforward if a logical and sequential approach is used (Figure 45-1).

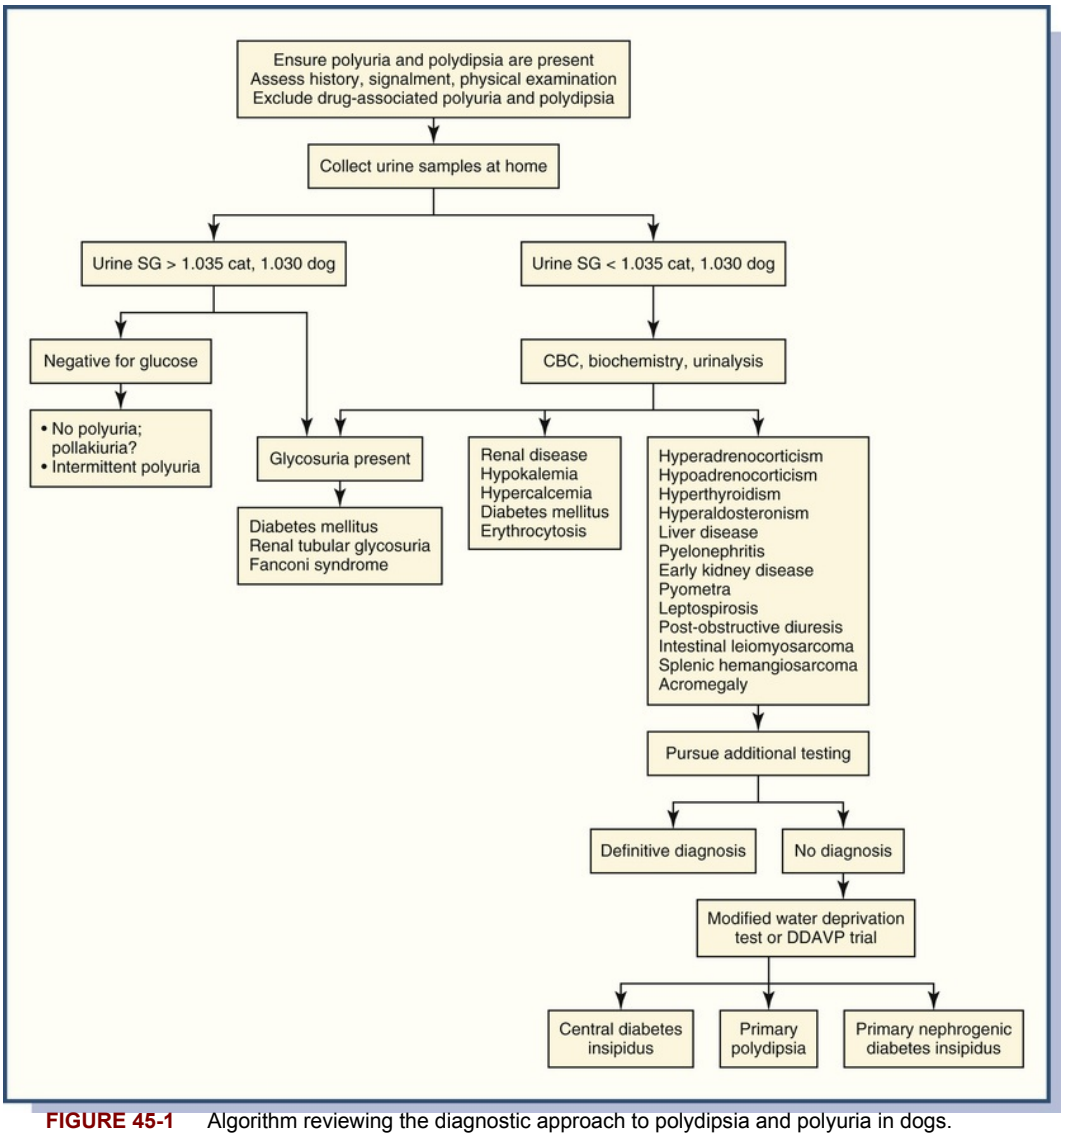

FIGURE 45-1 Algorithm reviewing the diagnostic approach to polydipsia and polyuria in dogs.

Step 1: Ensure Polyuria and Polydipsia Are Present

Before commencing a diagnostic investigation, it is necessary to ensure that polyuria and polydipsia are truly present. A thorough history should be undertaken to distinguish between polyuria, incontinence, nocturia and pollakiuria. Polydipsia without polyuria may be seen in animals with non-urinary water loss, such as diarrhea or excessive panting.

Calculation of water intake during hospitalization is unreliable because "home" drinking patterns may be altered. Measurement at home is possible, but can be difficult in multi-pet households. It is not usually possible to quantify urine volume, although it can be estimated by weighing cat litter in single cat households. Alternatively, the presence of dilute urine is suggestive of polyuria. Urine osmolality is the gold standard measure of concentration but is not widely available. The measurement of urine specific gravity by refractometry is more commonly used. In general, there is good agreement between the two techniques but there is considerable variation between individual refractometers.[3,4] Glycosuria can increase urine specific gravity by approximately 0.004 for each g/dL of glucose in urine. Animals with marked glycosuria may have

specific gravity values consistent with concentrated urine. When measuring osmolality or specific gravity it is essential to ensure free access to water because some animals may retain the ability to concentrate urine when water is withheld.

Unsurprisingly, urine specific gravity values in apparently healthy small animals vary markedly, ranging from 1.006 to 1.050 in dogs and 1.005 to 1.090 in cats.[5,6] In general, urine specific gravity is higher in healthy cats compared to dogs (mean 1.050 in cats versus 1.033 in dogs). In dogs, the specific gravity of morning samples is typically higher than evening samples.[5] One may recommend that an owner collect multiple urine samples at home over several days to determine the ranges of urine specific gravity. In most cases, maintenance of a urine specific gravity greater than 1.030 in dogs and greater than 1.035 in cats is not supportive of polyuria unless due to marked glycosuria, or intermittent polyuria (primary polydipsia or disorders of the regulation of AVP secretion).

Step 2: Signalment, History and Physical Examination

Although unlikely to lead to a definitive diagnosis, breed, age and sex may be useful to refine the differential list for polyuria and polydipsia. For example, hyperthyroidism is common in older cats and pyometra should always be considered in entire females. Primary nephrogenic diabetes insipidus can be excluded unless the animal is very young.

Recently administered drugs should be recorded. Drugs including glucocorticoids, diuretics and phenobarbital cause polyuria and polydipsia in a dose-dependent manner. However, the severity of polyuria in response to drugs can be variable. In particular, polydipsia can be observed at low doses and following topical administration of glucocorticoids. If possible, drugs should be discontinued or the dose reduced prior to additional investigations.

A complete physical examination is essential in all cases. Animals with diseases such as hyperadrenocorticism, hyperthyroidism, pyometra and liver disease may have additional findings that allow rapid refinement of the differential list.

Step 3: Complete Urinalysis

Although urine specific gravity may have been assessed to confirm the presence of polyuria, a complete urinalysis, complete blood count (CBC), and serum biochemistry profile should be performed. Marked hyposthenuria (SG < 1.006) is most commonly due to central diabetes insipidus, primary nephrogenic diabetes insipidus, hyperadrenocorticism, hypercalcemia, primary polydipsia or atypical leptospirosis. The presence of hyposthenuria allows exclusion of CKD and other osmotic causes of polyuria. Identification of glycosuria allows confirmation of diabetes mellitus or renal tubular disease, providing stress hyperglycemia is not present.

The value of performing urine bacterial culture in all animals with polyuria has been questioned.[7,8] However, the sensitivity of urine sediment examination for detection of urinary tract infection is low and the consequences of not identifying infection can be deleterious (see ch. 330).[8] As a result, urine bacterial culture is often recommended early in the investigation of polyuria. This is best performed on urine collected by cystocentesis (see ch. 105).[9,10] Pyelonephritis is a recognized cause of polyuria, and it is common to identify the same pathogen from cystocentesis samples (see ch. 330). Urinary tract infections are common in dogs with either diabetes mellitus or hyperadrenocorticism and in cats with diabetes mellitus, hyperthyroidism or CKD (see ch. 301, 304, 305, 306, and 324).[11,12]

Step 4: CBC, Biochemistry and Electrolyte Assessment

Most animals with hyperadrenocorticism, hyperthyroidism, hyperaldosteronism, liver disease, CKD or pyelonephritis have some changes on physical examination, CBC, serum biochemistry profile and/or serum electrolytes. Results of these blood tests may allow exclusion of erythrocytosis, hypokalemia, hypercalcemia, hypoadrenocorticism, diabetes mellitus and SIADH. CKD as a cause of polyuria can be challenging to confirm. Classically, isosthenuria or minimally concentrated urine is characteristic of renal azotemia and concentrated urine a feature of pre-renal azotemia. However, when polyuria is present, concentration of urine may not be possible despite severe hypovolemia and dehydration. Pre-renal azotemia with "low" urine specific gravity is common in animals with hypoadrenocorticism or hypercalcemia (see ch. 297 and 309). In addition, certain disorders, such as hypercalcemia, hyperthyroidism and hyperaldosteronism, can contribute to the development or progression of kidney disease. Finally, early CKD may be difficult to identify because

polyuria can precede the development of azotemia.

One of the main characteristics of primary polydipsia is the presence of decreased plasma osmolality, a dilutional effect of increased water intake. It is important to ensure free access to water until the time of sampling if plasma osmolality is to be measured. Osmolality is ideally determined from measures of freezing point or "vapor point depression," but this is rarely available in clinical practice. As an alternative, serum osmolality can be estimated based upon the concentrations of the major determinants. The following formula using common units has been shown to be reliable in both cats and dogs even when hyperglycemia or azotemia is present[13,14]:

$$\text{Osmolality (mOsm/kg)} = 2\,((\text{sodium [mEq/L]}) + (\text{glucose [mg/dL]}/18) + (\text{BUN [mg/dL]}/2.8))$$

The presence of low osmolality is supportive of primary polydipsia. Additional investigations are usually performed because primary polydipsia may contribute to the polyuria observed with several diseases including liver disease and hyperthyroidism.

Step 5: Additional Tests

If a definitive diagnosis has not been achieved, the selection of additional tests is largely dependent upon clinical suspicion. Abdominal ultrasonography is often performed because changes may be identified in dogs or cats with adrenal, liver or kidney diseases. It is sensitive for the diagnosis of pyometra, splenic hemangiosarcoma, and intestinal leiomyosarcoma. Although ammonia concentration is reported to be more sensitive than resting bile acid concentration for the diagnosis of a portosystemic shunt, the bile acid stimulation test has been evaluated in a larger range of hepatic diseases, is more widely available and requires less stringent sample handling (see ch. 284).[15]

Testing for hyperadrenocorticism may require ACTH response testing, low dose dexamethasone suppression testing or measurement of the urine cortisol to creatinine ratio. Assessment of thyroid function, initially by measurement of total thyroxine concentration, is indicated in older cats. Pyelocentesis can be performed if pyelonephritis is suspected based upon abdominal imaging or urinalysis results, but a presumptive diagnosis is usually made based upon abdominal imaging and urine culture results. Measurement of glomerular filtration rate is necessary to demonstrate decreased renal function in dogs or cats with early (non-azotemic) renal disease, although the symmetric dimethylarginine (SDMA) blood test may identify CKD earlier in the course of disease than BUN or serum creatinine. Leptospirosis can be confirmed by serum microscopic agglutination or urine polymerase chain reaction tests (see ch. 217). Acromegaly can be investigated by measurement of serum IGF-1 concentration (see ch. 294 and 295). Advanced imaging such as MRI is indicated if brain disease is suspected.

Step 6: Modified Water Deprivation Test or DDAVP Trial

The modified water deprivation test is performed to distinguish between primary polydipsia, central diabetes insipidus and primary nephrogenic diabetes insipidus. It is essential to ensure that all other differential diagnoses have been excluded prior to commencing a modified water deprivation test or DDAVP trial.

The modified water deprivation test is time consuming, labor intensive and associated with a risk of severe hypertonic dehydration, which can be fatal. For these reasons, some authors propose trial therapy with DDAVP as an alternative. Further details relating to these and additional tests are provided in ch. 296.

CHAPTER 46

Pollakiuria, Stranguria, and Urinary Incontinence

Mary Anna Labato

Client Information Sheets:
Pollakiuria, Stranguria, and Urinary Incontinence: Dogs
Pollakiuria, Stranguria, and Urinary Incontinence: Cats

Disorders of urination are quite common and inappropriate urinations are a leading cause of a pet being presented for medical evaluation or worse, resulting in relinquishment of ownership or euthanasia. Differentiation must be made between pollakiuria, stranguria, and urinary incontinence and polyuria (an increased urine volume). The differential diagnosis for these three conditions is often the result of diseases of the lower urinary tract or genital tract.

Definitions

Incontinence is defined as an involuntary escape of urine during the storage phase of the urinary cycle. This can appear clinically in a variety of ways; however, the most common presentation is intermittent or continuous dribbling of urine combined with episodes of normal voiding. Causes of incontinence include urethral sphincter mechanism incompetence, an anatomic abnormality in the termination of the urethra, inability of the bladder to expand in capacity, spasms of the bladder, and nerve damage[1-4] (see ch. 333).

Urge incontinence or detrusor hyperspasticity or instability is defined as spontaneous and uninhibited detrusor contractions (an overactive bladder). It is characterized by involuntary bladder contractions resulting in the frequent voiding of small volumes of urine. This will result in urinary incontinence, although more commonly clinical signs resemble pollakiuria. Most often animals with detrusor hyperspasticity have an underlying cystitis that must be differentiated from a bacterial infection, inflammation, cystic calculi, polypoid cystitis, neoplasia or drugs and is referred to as urge incontinence. Cases in which no underlying cause is determined are referred to as idiopathic detrusor instability.[4,5] The syndrome is commonly seen in cats with cystitis or feline idiopathic cystitis (FIC) (see ch. 330-335).

Pollakiuria is defined as abnormally frequent passage of urine.[6] Common causes are urinary tract infection, inflammatory diseases of the bladder or urethra, polypoid cystitis, cystic calculi, neoplasia or drugs (see ch. 330-335).

Stranguria is defined as a slow and painful discharge of urine produced by spasmodic muscular contraction of the urethra and bladder.[6] This may be described as difficulty in micturition where the owner describes that urine is being passed only drop-by-drop with pain and even tenesmus. The common causes are similar to those of pollakiuria and include urinary tract infection, inflammatory diseases of the bladder or urethra, polypoid cystitis, cystic calculi, and neoplasia (see ch. 330-335).

Dysuria is defined as difficult or painful urinations and is often used as a "catch all" term to describe stranguria or pollakiuria. It is important in obtaining the history and through observation of the animal urinating to distinguish between these conditions.

Pathophysiology

Bladder function is primarily under the influence of smooth muscle. The body of the bladder contains smooth muscle, referred to as the detrusor muscle. The outlet conduit is comprised of the trigone and proximal urethra. The smooth muscle fibers of the detrusor continue into the proximal urethra, forming a functional internal urethral sphincter. The distal urethra is comprised of striated skeletal muscle and functions as an external sphincter.

During the storage phase of micturition, the bladder functions as a low-resistance, high-capacity vessel. The urethra functions as a high-resistance barrier. The reverse is true during the voiding phase. The bladder acts as a muscular pump and the urethra as a low-resistance vessel.

Nervous Control

Nervous control of the bladder and urethra is a combination of autonomic and somatic interactions.

Parasympathetic innervation is supplied to the detrusor by the pelvic nerve, which arises from sacral spinal cord segments S1-S3. Stimulation of the pelvic nerve results in detrusor contraction.

Sympathetic innervation is supplied via the hypogastric nerve, which is composed of preganglionic fibers exiting the lumbar spinal cord at L1-L4 and synapses in the caudal mesenteric ganglion. Sympathetic innervation is supplied to both the detrusor and urethral smooth muscles and characterizes the storage phase of micturition. Alpha-adrenergic fibers synapse in smooth muscle in both the trigone and urethra. Stimulation results in contraction of these muscles and forms a functional internal urethral sphincter. There are also alpha-adrenergic fibers that have a modulating effect on the external urethral sphincter. Beta-adrenergic fibers synapse in the detrusor muscle; stimulation results in relaxation. Somatic innervation is supplied via the pudendal nerve, which arises from sacral spinal cord segments S1-S3, providing stimulation to the striated urethral musculature.

For voluntary control of micturition to occur, there must be integration between the cerebral cortex, pons, and the spinoreticular tract. A second pathway from the cerebral cortex to the sacral nuclei coordinates voluntary sphincter control. Additionally, cerebellar neurons inhibit nervous transmission to the reticulospinal pathways in the pons.

Sensory receptors are located in the bladder mucosa and are numerous at the ureterovesicular junction and in the trigone. Inflammation of the mucosa or bladder contraction may cause pain, an urgency to urinate (even if the bladder volume is small), detrusor spasm, or a "burning" sensation. Sensory receptors in the urethra respond to flow, urethral sensation and traction on the trigone. Inflammation or irritation of the urethra causes pain, burning sensation and spasms of the urethral sphincter. In male dogs, prostatic disease (see ch. 337) usually involves the urethra and bladder, producing dysuria.[7]

Causes of Clinical Signs

Diseases of the lower urinary tract (urethra and bladder) or lower genital tract (prostate or vagina) may result in mucosal irritation or inflammation and result in frequent or painful urinations. Many of the causes of pollakiuria (Box 46-1) and stranguria (Box 46-2) are associated with pyuria, hematuria or both (see ch. 47). Many general disorders such as urolithiasis, urinary tract infections, urethral diseases, prostatic diseases and neoplasia are discussed in more detail in their respective chapters (see ch. 329-332 and 334-337). The main differential diagnosis for urge incontinence (Box 46-3) is cystitis or, in cats, feline idiopathic cystitis (see ch. 333 and 334). Once other causes are ruled out, a diagnosis of detrusor hyperspasticity may be established. This is confirmed by a urethral pressure profile demonstrating the presence of uninhibited detrusor contractions, or response to treatment with an antispasmodic if a urodynamic study is unavailable.

Box 46-1

Causes of Pollakiuria

Infection: bacterial, mycoplasma, viral, fungal, parasitic (bladder, prostate)
Inflammation: polypoid cystitis, pyogranulomatous cystitis, granulomatous urethritis, follicular vaginitis
Urocystolithiasis
Neoplasia (example: transitional cell carcinoma, prostatic adenocarcinoma, vaginal leiomyoma/sarcoma)
Detrusor atony (partial obstruction)
Urethral stricture
Feline idiopathic cystitis (FIC)
Chemical/drugs (example: cyclophosphamide)
Anatomic abnormalities (perineal hernia with retroflexed bladder, spay granuloma or uterine stump disease [infection, mass])
Iatrogenic: urethral irritation secondary to catheterization, palpation, voiding urohydropropulsion, overdistension of bladder secondary to flushing procedures

Box 46-2

Causes of Stranguria

Cystitis: infectious vs. inflammatory
Urethritis: infectious vs. inflammatory
Urocystolithiasis
Vaginitis: follicular (inflammatory) vs. infectious
Neoplasia (urethral: transitional cell carcinoma; prostatic: adenocarcinoma; vagina: leiomyoma/sarcoma)
Prostatic disease: prostatitis, prostatic abscess, neoplasia
Trauma, foreign body
Feline idiopathic cystitis
Ruptured bladder
Urethral stricture

Box 46-3

Causes of Urge Incontinence

Detrusor hyperspasticity (idiopathic)
Cystitis/urethritis: infectious vs. inflammatory
Anatomical abnormality such as ectopic ureter(s)
Pelvic bladder, urethral dysplasia
Neurological abnormality: upper motor neuron bladder
Urethral sphincter mechanism incompetence
Urethral stricture

Diagnostic Workup (Figure 46-1)

A complete history and physical examination are essential to the diagnostic workup for any patient presenting with pollakiuria, stranguria or urge incontinence. This should include the reproductive status; age at neutering; age at the onset of the problem; previous medical problems, especially those involving the urogenital system; previous history of trauma; and an accurate description of the abnormality. How frequent is urination? What is the volume of urine that is being passed? Pollakiuria may be associated with large or small volumes of urine. Is there stranguria, and if so, is any urine being passed? Stranguria is more frequently associated with voiding of small amounts of urine, or the owner may report that a normal volume is ultimately produced after multiple attempts to urinate with small volumes passed each time. If there is incontinence (Figure 46-2), is it continuous or intermittent? Is the animal aware of the incontinence? Does it occur only at rest/asleep or while the animal is awake and moving? Urge incontinence is most frequently associated with spontaneous voiding while the dog or cat is awake. Owners may report it as purposeful voiding.

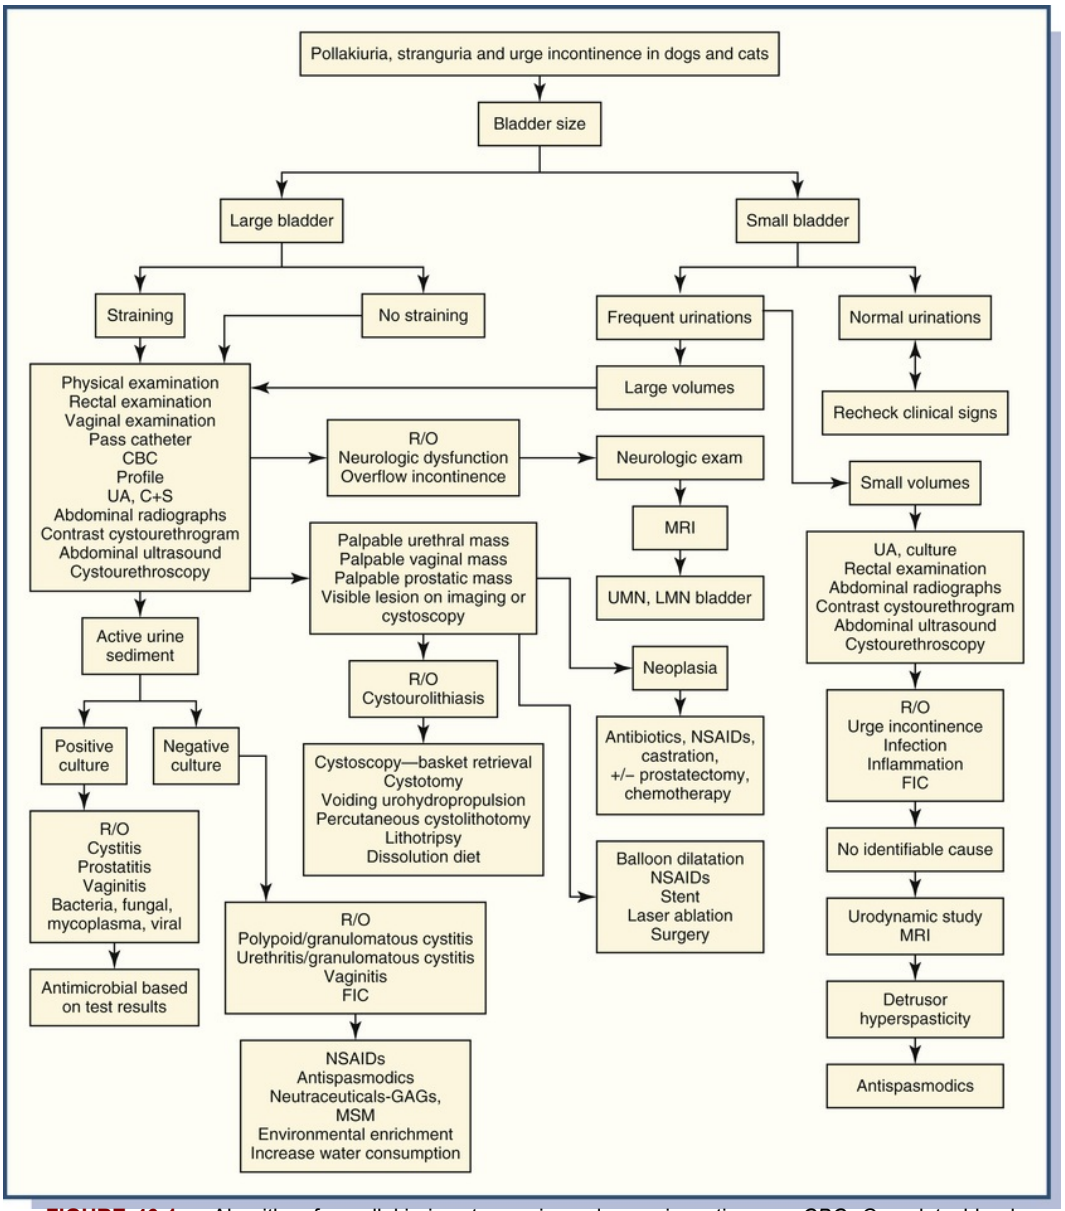

FIGURE 46-1 Algorithm for pollakiuria, stranguria and urge incontinence. *CBC,* Complete blood count; *C+S,* bacterial culture and sensitivity; *FIC,* feline interstitial cystitis; *GAG,* glycosaminoglycan; *LMN,* lower motor neuron; *MRI,* magnetic resonance imaging; *MSM,* methylsulfonylmethane; *NSAID,* nonsteroidal anti-inflammatory drug; *R/O,* rule out; *UA,* urinalysis; *UMN,* upper motor neuron.

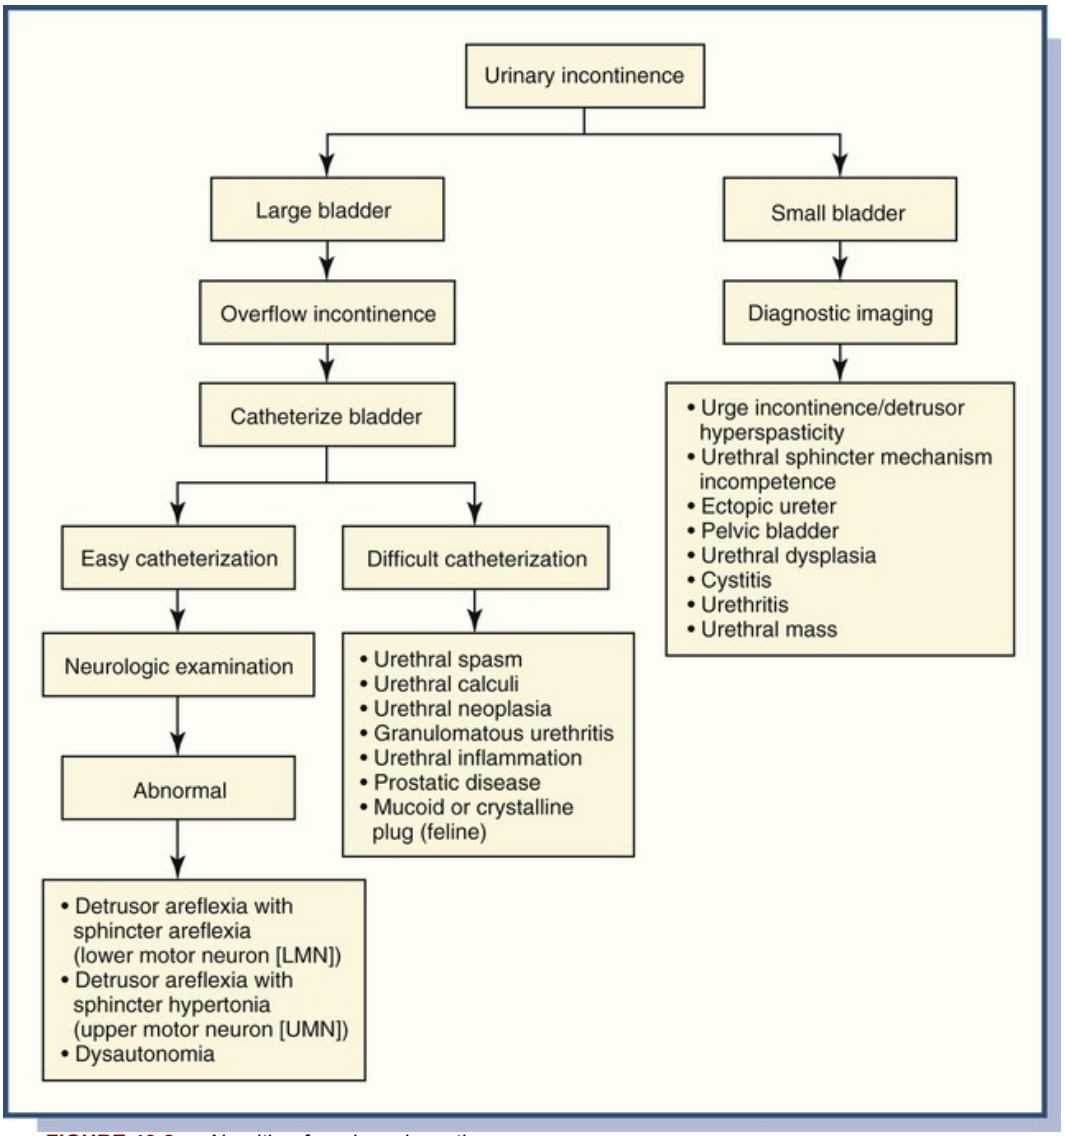

FIGURE 46-2 Algorithm for urinary incontinence.

Complete physical (see ch. 2) and neurologic (see ch. 259) examinations should be performed, with particular attention paid to the urogenital system. The bladder should be palpated carefully before and immediately after voiding to evaluate the extent of distension, tone, and the ease with which the bladder may be expressed manually. Lower motor neuron lesions generally are associated with easy manual expression and reduced sphincter tone. Upper motor neuron lesions generally are associated with difficult manual expression and increased sphincter tone. In the neurologic examination, the innervation of the urogenital system should be evaluated. The perineal reflex evaluates the pudendal nerve. The bulbospongiosus reflex evaluates the integrity of both the pudendal nerve and the sacral spinal segments. Pollakiuria is commonly associated with a moderate to small bladder and with normal to small amounts of urine being passed. Stranguria is commonly associated with a moderate to large bladder if there is a partial obstruction and normal, to moderate to small amounts of urine being passed if the stranguria is associated with infection or inflammation without an obstructive process. With urge incontinence, the bladder is often found to be small on palpation.

A rectal examination should be done to evaluate the prostate gland, pelvic diaphragm, and anal tone. Observe the animal urinating (Video 46-1) to verify the micturition abnormality. The residual urine volume should be measured. The animal is allowed to void until urine is no longer passed, the bladder is catheterized, and the volume of any remaining urine is measured. In a normal animal, the residual volume should not exceed 0.4 mL/kg. Catheterization of the bladder also assesses the patency of the urethra. This will help to rule in or rule out a complete or partial obstruction secondary to calculi, stricture or neoplasia.

Ultimately, a contrast cystourethrogram, ultrasound examination or cystoscopy may need to be performed to further characterize the lesion unless it is the result of a radiopaque calculus.

The diagnostic workup should include a complete blood count and serum chemistry profile to assess the patient's overall health status. Typically, the serum chemistry profile will be normal if there is infection or inflammation within the lower urinary tract. Obstructive lesions in the lower urinary tract may result in azotemia, hyperkalemia and hyperphosphatemia. If there is infection within the upper urinary tract, there may be a concurrent azotemia. A complete blood count may demonstrate a leukocytosis if upper tract infection is present, but not typically with lower tract infection except in cases of acute prostatitis or a prostatic abscess.

A urinalysis is one of the most important tests that can be performed (see ch. 72). Hematuria, pyuria and proteinuria indicate inflammation within the urinary tract. These are nonspecific findings, which may be associated with both infectious and noninfectious processes. It may be possible to visualize bacteria, fungal organisms or parasitic ova while examining the urine sediment. The presence of these organisms, however, may not represent infection. Quantitative urine culture and sensitivity are the definitive way of identifying actual infection. High bacterial numbers in a properly collected sample indicates true infection. Small numbers may indicate contamination.

Crystalluria may be seen in normal patients, those with urolithiasis, or those with disorders unassociated with the urinary tract such as with portosystemic shunts. The presence of crystals in urine sediment must be interpreted cautiously. Urine is best evaluated for the presence of crystals shortly after being obtained. In cats with feline idiopathic cystitis, crystalluria, hematuria and proteinuria occur, while pyuria of any significance is uncommon.[8]

The presence of neoplastic cells in urine sediment indicates the presence of urinary tract neoplasia. However, it may be difficult to diagnose neoplasia based solely on urine sediment examination. Atypical epithelial cells arising from inflammation or extremes in urine pH or osmolality are difficult to differentiate from neoplasia.[8] Cytological examination of prostatic fluid may be helpful in identifying prostatitis, abscess or neoplasia.

Imaging of the urinary tract is especially beneficial in differentiating the various causes of pollakiuria, stranguria and urge incontinence. Survey radiographs are helpful in identifying urocystolithiasis. Contrast radiographs, such as an intravenous pyelogram or double contrast cystourethrogram, may be helpful in determining the presence of calculi or a space-occupying mass, especially those causing a partial obstruction. Abdominal ultrasound is a helpful diagnostic tool, providing the ability to visualize wall thickness, presence or absence of cystouroliths, and soft tissue masses within the bladder or portions of the urethra (see ch. 88). Finally, cystoscopy (Figure 46-3, *A* and *B*) may be used to visualize the urethra, bladder and in females the vagina (see ch. 108). Biopsy and brush cytology may be performed via cystoscopy to help in identifying the underlying cause of the dysuria.

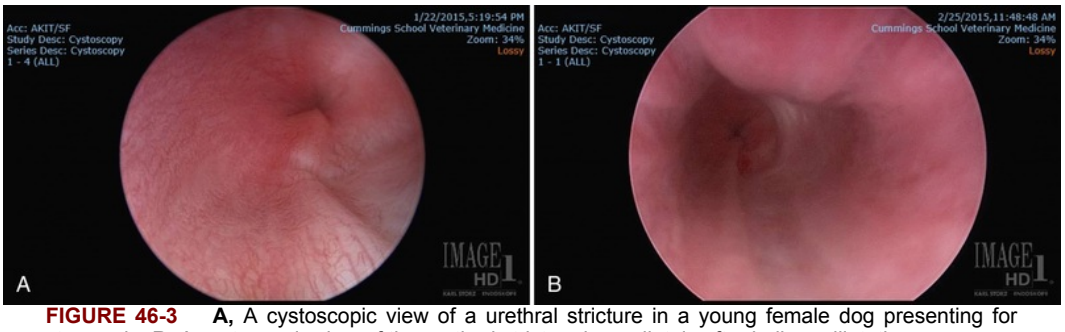

FIGURE 46-3 **A,** A cystoscopic view of a urethral stricture in a young female dog presenting for stranguria. **B,** A cystoscopic view of the urethral stricture immediately after balloon dilatation.

While causes of pollakiuria and stranguria are quite common and often are a relatively easy diagnosis based upon history, signalment, physical exam findings and diagnostic workup, urge incontinence is a diagnosis of exclusion. Urge incontinence may be diagnosed via a good history, observation of the animal urinating, imaging modalities, and urodynamic studies such as a cystometrogram and urethral pressure profile. Causes of an inflammatory cystitis or urethritis must be eliminated as the source of urgency. If it is possible to perform a urodynamic study, uninhibited contractions of the detrusor will confirm detrusor hyperspasticity. Otherwise, response to therapy will be the diagnostic test and treatment of choice.

Treatment

Treatment of pollakiuria, stranguria, and urge incontinence will be dictated by the underlying cause. Treatment in detail will be discussed in later chapters of this book that specifically deal with the underlying etiologies (see ch. 330-335).

Pollakiuria arising from a urinary tract infection is relatively easy to diagnose and treatment with an antibiotic should be based on culture and sensitivity results. If the underlying cause of the pollakiuria is from an inflammatory condition, treatment with anti-inflammatory agent such as a nonsteroidal anti-inflammatory drug and other analgesic agents, such as opioids, may be necessary if there is considerable pain associated with the stranguria. If urocystoliths are the source of the pollakiuria, then a variety of options is available with treatments incorporating antibiotics and dissolution diets, to minimally-invasive procedures such as voiding urohydropropulsion (see ch. 107), or cystoscopy and basket retrieval (see ch. 124), or lithotripsy or surgery. Neoplasia may be treated with chemotherapy, surgery, radiation therapy or a combination of modalities depending upon the type of cancer (see ch. 351). Diseases of the prostate or vagina may be treated with a range of modalities depending upon the underlying cause but may involve medical management (hormonal replacement therapy, hormonal limiting therapy), to medical management of prostatic infections or vaginitis, to surgical interventions (see ch. 44 and 337).

Treatment for the multiple causes of stranguria will range from medical management utilizing antibiotics, antispasmodics, and interventional therapy (laser lithotripsy/ablation, stent placement, cystostomy tubes; see ch. 124) to the management of cancer.

Identifying and then addressing the underlying cause best treats urge incontinence. If the problem is secondary to idiopathic detrusor hyperspasticity, then an antispasmodic agent such as flavoxate hydrochloride, or oxybutynin, tolterodine or dicyclomine is indicated. If the condition is recognized in cats with FIC, then treatments may range from administration of an antispasmodic for the bladder to a smooth muscle relaxant such as prazosin for the proximal urethra and diazepam for the skeletal muscle component of the distal urethra, to pain medication such as buprenorphine, dietary change to a canned food product, increased water consumption, glycosaminoglycans, to environmental enrichment.

CHAPTER 47

Hematuria and Other Conditions Causing Discolored Urine

Thierry Francey

Client Information Sheet: Hematuria and Other Conditions Causing Discolored Urine

Overview

Visual inspection of urine is the first step in a standard urinalysis (see ch. 72) and it aims at evaluating color and turbidity. More than being just a leftover of uroscopy, macroscopic evaluation of urine can provide useful clinical information. Further, abnormal urine color is occasionally recognized by the pet owner and it may represent the only reason for a consultation, especially when the urine is overtly red. Abnormal urine color indicates presence of endogenous or exogenous pigments and is usually associated with a clinical problem. However, significant systemic or urinary tract disease may coexist with normal colored urine. Urine discoloration provides nonspecific information, but it should always prompt the clinician to pursue a thorough history, including questions related to diet, medications, environment, and collection technique. Physical examination is also critically important. We recommend examination of the urogenital areas last, in order to ensure completion of a thorough examination before approaching the "problem area." Laboratory testing is often warranted, including detailed urine sediment examination. Knowledge of urine color may also be important in interpreting dipstick colorimetric test results since discolored urine may interfere with the assays.

Normal Urine

Normal urine is typically transparent and light yellow, yellow, or amber in color. The intensity of the yellow color of normal urine varies primarily with degree of urine concentration or dilution (Figure 47-1, *A*). The yellow color is mainly associated with renal excretion of plasma urochrome, a yellow sulfur-containing oxidation product of a colorless urochromogen. The daily urinary excretion of urochrome is relatively constant and the intensity of urine color provides an estimate of the degree of urine concentration. Highly concentrated urine will thus be amber in color, while dilute urine may be light yellow or almost colorless. Production of urochrome does depend to some extent on the metabolic rate. Increased quantities of urochrome are excreted as a result of fever, catabolism, or starvation. Urochrome may further darken when exposed to light, giving a false impression of highly concentrated urine. Small quantities of the endogenous orange-brown heme degradation pigment urobilin may contribute further to the yellow color of urine. Urobilin is the oxidation product of its colorless precursor urobilinogen, a bacterial degradation product of intestinal bilirubin reabsorbed into the bloodstream. An increased bilirubin concentration in the urine may give it an intense yellow color, similar to that of concentrated urine (see Figure 47-1, *B*). When exposed to light, it may oxidize and turn brown to almost black.

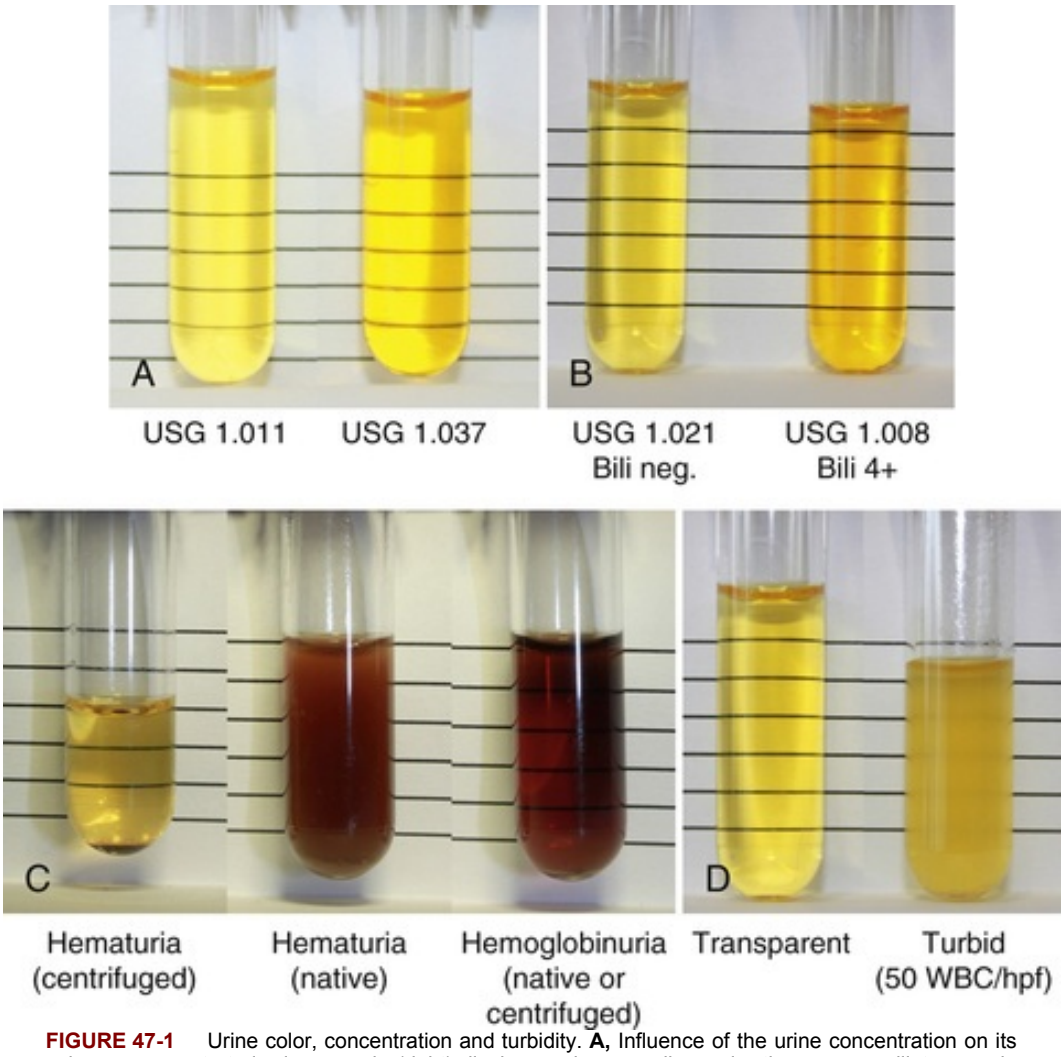

FIGURE 47-1 Urine color, concentration and turbidity. **A,** Influence of the urine concentration on its color—a concentrated urine sample (right) displays a deeper yellow color than a more dilute sample (left), due to different concentrations of the endogenous pigment urochrome. **B,** The presence of bilirubinuria (right) gives the urine sample a deep yellow to amber color and thus the wrong impression of concentrated urine. **C,** The visual inspection of a native red-brown urine sample often allows the distinction between hematuria (center, turbid) and hemoglobinuria (right, transparent). Centrifugation further indicates a clear supernatant on a red blood cell pellet in hematuria (left) and an unchanged sample in hemoglobinuria. **D,** Milky turbid appearance of a urine sample from a dog with urinary tract infection and pyuria (right) compared to a normal transparent urine sample with the same specific gravity (1.020). *Bili,* Bilirubin; *USG,* urine specific gravity; *WBC,* white blood cells.

Discolored Urine

Any urine color other than yellow or amber is abnormal. There are many potential causes of discolored urine (Table 47-1). The most common abnormal urine colors in dogs and cats are red, brown, or black. These colors may be caused by hematuria, hemoglobinuria, myoglobinuria, and possibly bilirubinuria (Figures 47-1, *C* and 47-2).[1-3]

TABLE 47-1

Potential Causes of Discolored Urine[1]

URINE COLOR	MOST RELEVANT CAUSES (DESCRIBED IN ANIMALS)	FURTHER CAUSES (DESCRIBED ONLY IN HUMANS)
Colorless	Very dilute urine (diuretics, diabetes	

	mellitus, diabetes insipidus, glucocorticoid excess, fluid therapy, overhydration)	
Yellow or amber	Urochrome, urobilin	
Deep yellow	Highly concentrated urine Phenolsulfonphthalein (in acidic urine)	Quinacrine, nitrofurantoin, phenacetin, riboflavin (large quantities)
Orange-yellow	Highly concentrated urine, bilirubinuria Excess urobilin, phenazopyridine	Orange food dye; 2, 4-D; acetazolamide; fluorescein sodium; flutamide; phenacetin; quinacrine; sulfasalazine
Yellow-brown or green-brown	Bile pigments	
Red, pink, red-brown, red-orange, or orange	Hematuria, hemoglobinuria, myoglobinuria, porphyrinuria Congo red, rifampicin, doxorubicin, phenolsulfonphthalein (in alkaline urine), neoprontosil	Chronic heavy metal poisoning (lead, mercury) Red food dye, food pigments (rhubarb, beets, blackberries), acetazolamide, bromsulphalein, carbon tetrachloride, phenytoin, emodin, eosin, phenazopyridine, phenindione, phenothiazine, rifabutin, warfarin
Brown	Methemoglobinuria, copper toxicosis, fecal contamination (rectal-urinary fistula) Melanin	Anthracin, bismuth, clofazimine, chloroquine, fava beans, furazolidone, mercury, methocarbamol, metronidazole, naphthalene, nitrofurantoin, phenacetin, primaquine, rhubarb, sorbitol, sulfasalazine, sulfonamides
Brown to black (brown or red-brown when viewed in bright light in thin layer)	Methemoglobinuria, hemoglobinuria, myoglobinuria, bile pigments Melanin	Aniline dyes, chlorinated hydrocarbons, homogentisic acid, naphthalene, nitrites, nitrofurantoin, phenolic compounds, thymol
Blue	Methylene blue, mitoxantrone	*Pseudomonas* infection Blue food dye, indigo carmine and indigo blue dyes Amitriptyline, anthraquinone, chlorophyll, indicans, rhubarb, toluidine blue, triamterene
Green	Bilirubinuria, biliverdin, urate crystalluria Methylene blue, dithiazanine	Green food dye, indigo blue, Evans blue Amitriptyline, anthraquinone, phenol, riboflavin, thymol, triamterene
Milky white	Lipiduria, pyuria, crystalluria	

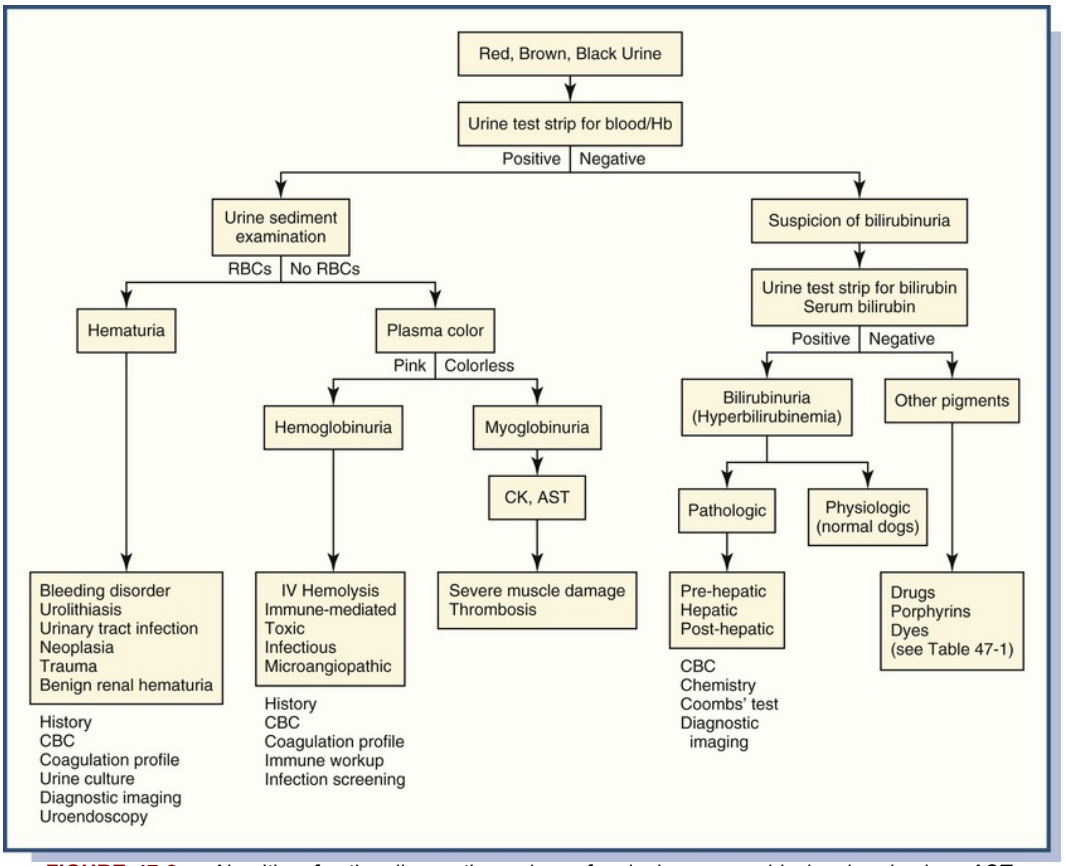

FIGURE 47-2 Algorithm for the diagnostic workup of red-, brown-, or black-colored urine. *AST,* Aspartate aminotransferase; *CBC,* complete blood count; *CK,* creatine kinase; *Hb,* hemoglobin; *RBCs,* red blood cells.

Pale Yellow Urine

Pale yellow or clear urine may be normal or indicative of polyuria (see Figure 47-1, *A*; ch. 45 and 72). Pale urine usually indicates a urine specific gravity of less than 1.015. Urine may be appropriately dilute if it is associated with recent consumption of water, administration of fluids, consumption of a low-protein or high-salt diet, or administration of diuretics, barbiturates, or glucocorticoids.[4] Urine would be considered inappropriately dilute in the presence of dehydration, indicating failure of physiological water-sparing mechanisms. Renal diseases, hyperthyroidism, diabetes insipidus, hyperadrenocorticism, hypoadrenocorticism, pyometra or other infections with lipopolysaccharide-producing bacteria, hypokalemia, and hypercalcemia may be associated with persistently dilute urine. However, dogs and cats with severe polyuria from uncomplicated diabetes mellitus usually have urine specific gravities of 1.025 to 1.035 due to the presence of glucose in the urine. Their urine often appears deeper yellow in color.

A simple test to determine whether polyuria is persistent is to determine the specific gravity of several owner-collected morning urine samples or to compare the specific gravity from different urine samples collected throughout the day. Based on dilute urine, the clinician may recommend a serum biochemical analysis and complete urinalysis. A complete blood count, abdominal imaging, measurement of serum thyroxine concentration, adrenal function testing, or monitoring urine specific gravity after several days of desmopressin administration may be warranted (see ch. 45 and 296).

Red, Brown, or Black Urine

Freshly collected urine that is red, brown, or black suggests the presence of blood, hemoglobin, myoglobin, or some of their degradation products (see Figure 47-1, *C*). Urine concentration, pH, and time in contact with blood can affect color. Red blood cells progressively disintegrate and release hemoglobin in urine. This may be oxidized to methemoglobin and result in a brown or black urine color. A thin layer of black urine viewed under a bright light usually appears brown or deep reddish-brown. Hematuria, hemoglobinuria, and

myoglobinuria cause the test for blood on reagent strips to read positive. "Blood" indicates presence of a globin with a heme group. Additional investigations are required to differentiate these possibilities (see Figure 47-2).[2,4]

A negative reagent strip test for blood in red, black or brown urine suggests presence of a chromogen other than hemoglobin or myoglobin.[1,5] Oxidized **bilirubin** should be ruled out first. An intense yellow coloration of plasma suggests hyperbilirubinemia, which can be quantified by measuring serum bilirubin concentration. Hyperbilirubinemia may result from pre-hepatic hemolysis, liver failure, or post-hepatic obstruction or rupture of the biliary tract (see ch. 53, 143, and 145).

A positive reagent strip test for blood should be followed by analysis of the urine sediment. If the discoloration is due to **hematuria,** there will be numerous red blood cells and increased turbidity. In contrast, urine remains transparent when color change is due to hemoglobinuria (see Figure 47-1, *C*). If no red blood cells are present on microscopic examination of the urine sediment, hemoglobin or myoglobin should be suspected. Examination of the plasma color may aid in differentiating these explanations. If the discolored urine is due to **myoglobin,** the plasma will usually be clear because myoglobin is not bound significantly to proteins and it is rapidly excreted. Myoglobinuria is indicative of severe muscle damage and serum creatine kinase (CK; see ch. 66) activity is usually markedly increased. Concentration of this muscle enzyme is typically used to confirm myoglobinuria rather than the more complex characterization of the urinary heme proteins using immunoassays. The serum CK activity offers the additional advantage of being cleared slowly from the blood which may allow a delayed diagnosis.

If plasma from a non-traumatic venipuncture sample is pink, it is suggestive of **hemoglobin.** When present in small quantities in the circulation, hemoglobin is bound to haptoglobin, hindering its glomerular filtration. When the binding capacity of haptoglobin is exceeded, however, free hemoglobin is filtered and appears in the urine. Hemoglobinemia and hemoglobinuria are therefore indicative of significant intravascular hemolysis, resulting from immune-, parasite-, or drug-mediated destruction of red blood cells or from fragmentation due to microangiopathic conditions. A marked red-brown discoloration of the urine may also cause false-positive reactions on other urine dipstick test pads and this should be taken in consideration in their interpretation (see ch. 72).

Milky White Urine

Milky white–colored urine may be due to presence of white blood cells (pyuria), lipid, or crystals. The more concentrated the urine, the more opaque it may appear. The presence of pyuria secondary to bacterial urinary tract infection is the most common cause of milky white urine (see Figure 47-1, *D*). However, pyuria may also occur due to non-infectious inflammations. The presence of lipid droplets in the urine of healthy animals is usually a microscopic observation. However, lipid droplets could contribute to urine turbidity. Lipiduria may be increased in cats with hepatic lipidosis. Crystalluria, if heavy and present in a concentrated urine sample, may also result in milky white urine color. Microscopic examination of urine sediment will aid in the differentiation of these causes.

Fever

Ian K. Ramsey, Séverine Tasker

"Fever is a mighty engine which Nature brings into the world for the conquest of her enemies."
Thomas Sydenham (1624-1689)

Client Information Sheet: Fever

Defining Fever, Hyperthermia, and Fever of Unknown Origin

Body temperature can be increased as a result of fever (pyrexia) or hyperthermia (Figure 48-1). For the purposes of this chapter, fever is defined as an increased body temperature associated with a raised (and often more variable) thermoregulatory set point in the anterior hypothalamus that is secondary to the release of pyrogens (fever-inducing substances). Hyperthermia, in contrast, is not associated with an alteration in the thermoregulatory set point. The hyperthermic animal will therefore make more efforts (physiologically and behaviorally) to cool itself at a given temperature when compared to a pyrexic animal at the same temperature. Hyperthermia most frequently arises from exposure to an increased environmental temperature, which is addressed in ch. 134. Hyperthermia also can arise due to exercise (especially in hot, humid environments by overweight dogs or those with respiratory impairment), seizures, hypermetabolic disorders (e.g., hyperthyroidism, hypocalcemia), certain medications (e.g., opioids and ketamine in cats, selective serotonin reuptake inhibitors in dogs and cats), intoxications (e.g., cocaine in dogs), malignant hyperthermia, and stress.[1-6]

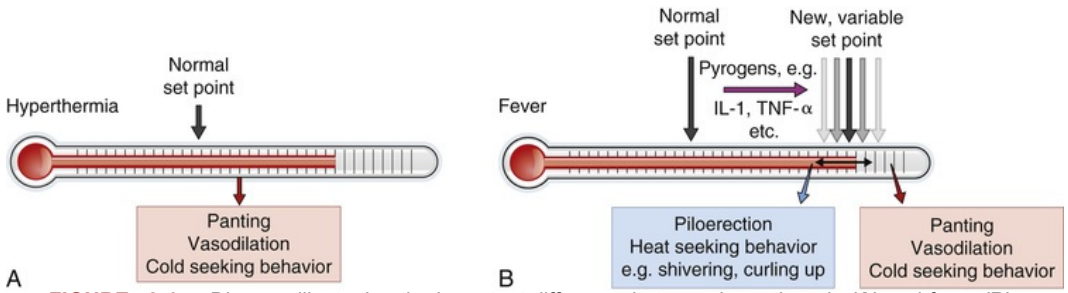

FIGURE 48-1 Diagram illustrating the important difference between hyperthermia **(A)** and fever **(B)**. Set point refers to thermoregulatory set point in the hypothalamus. *IL-1*, Interleukin-1; *TNF-α*, tumor necrosis factor-alpha.

Fever of unknown origin (FUO) is a term used relatively frequently in veterinary medicine[7,8] and definitions vary, as they have done in human medicine.[9,10] Extrapolating from the definition of classic FUO in humans,[9] FUO in dogs and cats could be defined as a temperature of >39.2° C (102.5° F) of at least 3 weeks' duration in which no obvious cause is apparent following at least 3 visits to the veterinarian and/or 3 days of hospitalization including a basic evaluation of history, clinical signs, clinical examination and minimal diagnostic testing (complete blood count, serum biochemistry profile, urine analysis). Additionally, FUO in dogs and cats often is only considered after a short (e.g., 7-10 days) course of an antibacterial agent to address possible bacterial infections has not resolved the fever.[5,11-13] In human medicine, over 200 diseases have been associated with FUO.[10] However, as a cause is found in many so called "FUO" cases, and as the causes of fever and FUO are not sufficiently different, it is suggested that cases of FUO should be considered within a

continuum of "fever." Perhaps, in the future, the term FUO should be reserved for those cases that truly remain unknown, despite the extensive investigations for fever outlined below. This chapter will focus on the pathophysiology, differential diagnoses, and approach to fever, including FUO, in dogs and cats.

Pathogenesis of Fever

Fever is an important part of the nonspecific adaptive response of the body to a disease process. The response has benefits and risks, the balance of which changes with time and the particular process and patient.[14] Similar to other adaptive processes, the animal usually gains short-term benefits from the process but in the long term, starts to develop unwanted complications.

Pyrogens may be classified into internal (endogenous) and external (exogenous) groups; however, exogenous pyrogens often exert most of their pyrogenic activity via endogenous routes.[15] Endogenous pyrogens, particularly the cytokines interleukin (IL)-1, IL-6 and tumor necrosis factor alpha (TNF-alpha), are released from neutrophils, monocytes, and many other cells, and they activate the arachidonic acid cascade.[16] This arachidonic acid cascade increases prostaglandin E2 concentrations, which acts on thermoregulatory neurons and raises the hypothalamic set point. More recent research has also suggested an important role for neural rather than humoral pathways for the initiation of the febrile response.[17]

Equally, the body produces endogenous antipyretics, including glucocorticoids, neuropeptides and certain cytokines (such as IL-10), to protect the body against the effects of fever.[18] It is even possible that at high temperatures, pyrogens (such as TNF-alpha) act as cryogens, limiting the severity of fever.[14] For these reasons, true fevers rarely exceed 41.1° C (106° F).

Benefits of Fever

In evolutionary terms, fever is a very old (at least 360 million years) response by the body to infection.[16] The conservation of this response suggests that possessing the ability to develop a fever confers significant evolutionary advantage. The proposed benefits of fever include the following:

- *Improved survival:* Several studies, both in human medicine and experimental, have shown that those patients that develop a fever are less likely to die and the higher the fever, up to a limit, the better the chances of survival.[19] A good veterinary example is the association between survival and the development of fever in rabbits with *Pasteurella* infections.[20] However, not all studies in human medicine have shown similar results, resulting in controversy.
- *Shorter length of illness:* Several studies have shown that fever reduces the symptomatic phase of illness and may reduce the time taken for viral and parasitic excretion.[21,22]
- *Improved immune system function:* Neutrophil mobility and phagocytic abilities initially are enhanced by fever, as are macrophage function and lymphocyte proliferation.[16] However, not all immune cell functions are improved by fever, and natural killer cells are less active at fever temperatures.[16] At temperatures higher than 41.1° C (106° F), neutrophil and monocyte functions are impaired.[16]
- *Production of heat shock and acute phase proteins:* These are important free-radical scavengers as well as preservers of cellular components.[23]

One widespread fallacy is that fever kills bacteria. In fact, the bacteria most commonly associated with infections continue to multiply and survive well above temperatures that would prove fatal to an animal.[20] Fever has evolved as a *response to* infection rather than occurring as a result of infection: the host is trying to improve its response to infection rather than the higher temperature itself directly killing the bacteria.

Costs of Fever

The proposed costs of fever include:

- *Increased number and severity of clinical signs,* leading to a reduction in animal welfare and increased owner concerns. However there is very little evidence that mild fever is actually harmful.[24]
- *Increased metabolic rate:* Typically the resting energy requirement is increased up to 1.3 times.[25,26] If this exceeds the energy intake of the host, energy deficits will occur in critical tissues, with increased oxygen demand and increased carbon dioxide production.

- *Reduction in some constitutive processes:* For example, hemoglobin's oxygen-binding affinity is reduced by fever, so at the very time that the peripheral tissues have an increased oxygen demand, the hemoglobin is less able to deliver oxygen.[27]

The published evidence to date suggests the benefits of fever often are limited to those with less severe disease, and in more severe diseases or more severe (or prolonged) fevers, the adverse effects start to outweigh these benefits.[19]

Measurement of Temperature

Invasive contact devices such as esophageal and pulmonary artery thermistors are considered the gold standard for assessing core body temperature,[28] but these are not suitable for conscious veterinary patients and are reserved for anesthetized or critical care cases.[29] Good agreement has been shown between rectal and core body temperatures in dogs.[29,30] Similar studies have not been performed in cats. However, it can be difficult to obtain rectal temperatures, particularly in fractious patients or in those with rectal or perianal disease. Rectal thermometers also are a potential source of cross-contamination and rectal injury. In addition, the accuracy and repeatability of rectal temperature measurements can be negatively affected by depth of measurement, the presence of feces, and conditions affecting local blood flow.[30,31]

There have been several studies examining the validity of measuring auricular or axillary temperatures as an alternative to rectal temperatures.[29-38] Auricular temperatures may be measured using dedicated thermometers, which use pyroelectric sensors to measure infrared radiation emanating from the tympanic membrane (TM). Auricular TM thermometers are quicker and better tolerated than rectal thermometers. However, they show greater variability between measurements than rectal temperatures.[31,35,36] Axillary temperatures may be measured with a standard rectal thermometer and are well tolerated but may be less reliable than rectal temperatures in overweight animals and dogs with thick coats.[32,33,35] Although the various studies have produced conflicting results, most authors agree that TM and axillary temperatures should not be used interchangeably with rectal temperatures. When rectal temperature measurement is not possible in dogs, then TM temperature is recommended over axillary temperature as it is better tolerated and significantly fewer dogs have clinically unacceptable differences of more than 0.5° C (0.9° F).[35] When rectal temperature measurement is not possible in cats, then axillary temperature is recommended over TM temperature as it is better tolerated and significantly fewer cats have clinically unacceptable differences of more than 0.5° C (0.9° F).[37,38]

Normal Temperature

Normal cats and dogs have a rectal temperature in the range of 38.0° C (100.5° F) to 39.2° C (102.5° F) but normal dogs and cats can reach as high as 39.7° C (103.5° F) in the consulting room.[39,40] Studies on the repeatability of these measurements have shown that rectal temperatures measured in the morning in hospitalized dogs can fluctuate about 0.7° C (1.26° F) day to day, due to spontaneous variation alone.[41] Exercise can increase the rectal temperature of a normal Labrador as high as 42.2° C (108.0° F), and most dogs can reach 41.1° C (106.0° F) immediately after exercise.[42,43]

Body temperatures that exceed 41.1° C (106° F) at rest are life-threatening, as they can result in neurological damage, disseminated intravascular coagulation (DIC), and metabolic abnormalities. Such levels are more likely to occur in hyperthermic patients (see ch. 134), and active cooling is required as immediate treatment.

Differential Diagnoses for Fever

Causes of fever, and especially FUO, can be divided broadly into infectious, immune-mediated, neoplastic, inflammatory, and miscellaneous categories.[13,44] In dogs, infectious, immune-mediated and neoplastic causes are important.[7,8,12,13] One study of 66 dogs with fever in a UK referral center described 33% of cases to be immune-mediated (including inflammatory conditions), 27% infectious, 8% neoplastic, 9% miscellaneous and 23% were undiagnosed,[7] whereas an earlier study, also from the UK, of 101 referred cases of canine FUO described 22% of cases to be immune-mediated, 16% infectious, 9.5% neoplastic 11.5% miscellaneous and 19% undiagnosed. In the latter study, 22% of cases were classified as having primary bone marrow diseases but these largely were of a neoplastic etiology; the higher overall prevalence of neoplasia in this study was

attributed to an oncology bias within that center at that time.[8] Another study of 50 dogs with fever that presented to a university veterinary hospital found that 48% of cases were due to so-called non-infectious inflammatory diseases (which included immune-mediated diseases), with only 18% of cases being infectious in origin and 6% neoplastic.[45] There have been no case series describing causes of fever and FUO in the cat, but it is believed that infectious causes are more common than primary immune-mediated diseases or neoplasia in this species.[5,11,13] The differences between the above 3 studies and the lack of studies from primary care clinics or cats illustrates the difficulties in quantifying the causes of fever.[46] Box 48-1 lists causes of fever in dogs and cats that have been identified in the peer-reviewed literature.

Box 48-1

Causes of Fever in Dogs and Cats

Infectious Diseases

Systemic Bacterial Infections

Bacteremia (from any source in the body)

Localized Bacterial Infections

Abscesses in any part of the body, e.g., subcutaneous tissues, liver, prostate, lung, tooth root ("periapical"). Septic (and infective) arthritis (D>C),[51] bacterial endocarditis (D>C),[52,53] cholangitis (C>D),[54] discospondylitis (D>C),[55,56] osteomyelitis (D>C),[57] prostatitis (D),[58] pyothorax,[59] pyometra (including stump) (D>C)[60,61]

Other Bacterial Infections

Anaplasmosis (D>C),[62,63] bartonellosis (C>D),[64,65] borreliosis (Lyme disease) (D),[66] ehrlichiosis (D>C),[67,68] tularemia—*Francisella tularensis* (C>D),[69,70] hemoplasmosis (C),[71] leptospirosis (D),[72] mycobacterial infections (C[73]>D), cutaneous nocardiosis (C),[74] plague (C>D)[75,76]

Viral Infections

Canine distemper virus (D),[77] adenovirus (D),[78] parvovirus (D>C),[79,80] influenza virus (D),[81] feline calicivirus (C),[82] feline herpesvirus (C),[83] feline infectious peritonitis (as a result of feline coronavirus infection) (C),[84] feline immunodeficiency virus (C),[85] feline leukemia virus (C),[86] poxvirus (C)[87]

Fungal Infections

Aspergillosis (disseminated, invasive or atypical) (D>C),[88,89] blastomycosis (D>C),[90] coccidioidomycosis (D>C),[91,92] histoplasmosis (D>C),[93,94] sporotrichosis (C>D)[95,96]

Protozoal Infections

Babesiosis (D>C),[97,98] hepatozoonosis (D>C),[99,100] toxoplasmosis (C>D)[101,102]

Inflammatory Diseases

Fat necrosis, steatitis and pansteatitis (C>D),[103-105] hypereosinophilic syndrome (C>D),[106-109] juvenile cellulitis (D),[110] myositis,[111] pancreatitis/sterile pancreatic abscesses (D>C)[112,113]

Immune-Mediated Diseases

Immune-mediated hemolytic anemia (D>C),[114,115] polyarthritis (including rheumatoid arthritis) (D>C),[7,116] polymyositis (D>C),[111] thrombocytopenia (D>C),[117,118] polysystemic immune-mediated diseases (e.g., systemic lupus erythematosus) (D>C)[119,120]; steroid-responsive meningitis arteritis (D[121]), vasculitis,[122] nodular panniculitis (D),[123] trapped neutrophil syndrome (D)[124]

Neoplastic Diseases

Lymphoproliferative diseases (D>C), e.g., leukemias,[125] lymphoma,[8,126] multiple myeloma (D)[8]; myeloproliferative diseases, e.g., histiocytic disease[127]; solid tumors, e.g., renal tumors,[128] Sertoli cell tumors,[129] lung tumors,[130] metastatic disease,[131] any necrotic or infected tumor

Miscellaneous Diseases

Idiosyncratic reactions to drugs (especially sulfonamides) or vaccines (D>C),[132,133] myelodysplasia (C>D),[134,135] metaphyseal (hypertrophic) osteopathy (D>C),[136,137] panosteitis (D)[138]

Examples of conditions in which fever, including FUO, is an important presenting sign (original references cited were possible and then list augmented from several sources[7,8,13]). Worldwide geographical variation in the prevalence of some of the diseases listed exists; those reported in the area in which the animal lives, or has travelled to, should be considered. *D* indicates dog, *C* indicates cat, with indications given as to any prevalence differences that may exist. If no species is stipulated, the disorder should be considered equally prevalent in both dogs and cats.

Note: Hypermetabolic diseases such as hyperthyroidism and pain can cause hyperthermia (not fever).

There is minimal evidence for portosystemic shunts or inflammatory bowel disease directly causing fever, but they can predispose animals to bacteremias. It is also worth noting that certain infections, e.g., leishmaniasis (dog or cat),[139,140] cryptococcosis (dog or cat)[141,142] and neosporosis (dog),[143] are not *usually* associated with fever.

Approach to a Fever

First, it is important to distinguish between fever and hyperthermia (Figure 48-2), as hyperthermia may require urgent therapy to reduce body temperature (see ch. 134). Fever is a common clinical finding in small animal practice but owners usually report non-specific signs such as lethargy, anorexia, depression, hyperpnea, and stiffness.

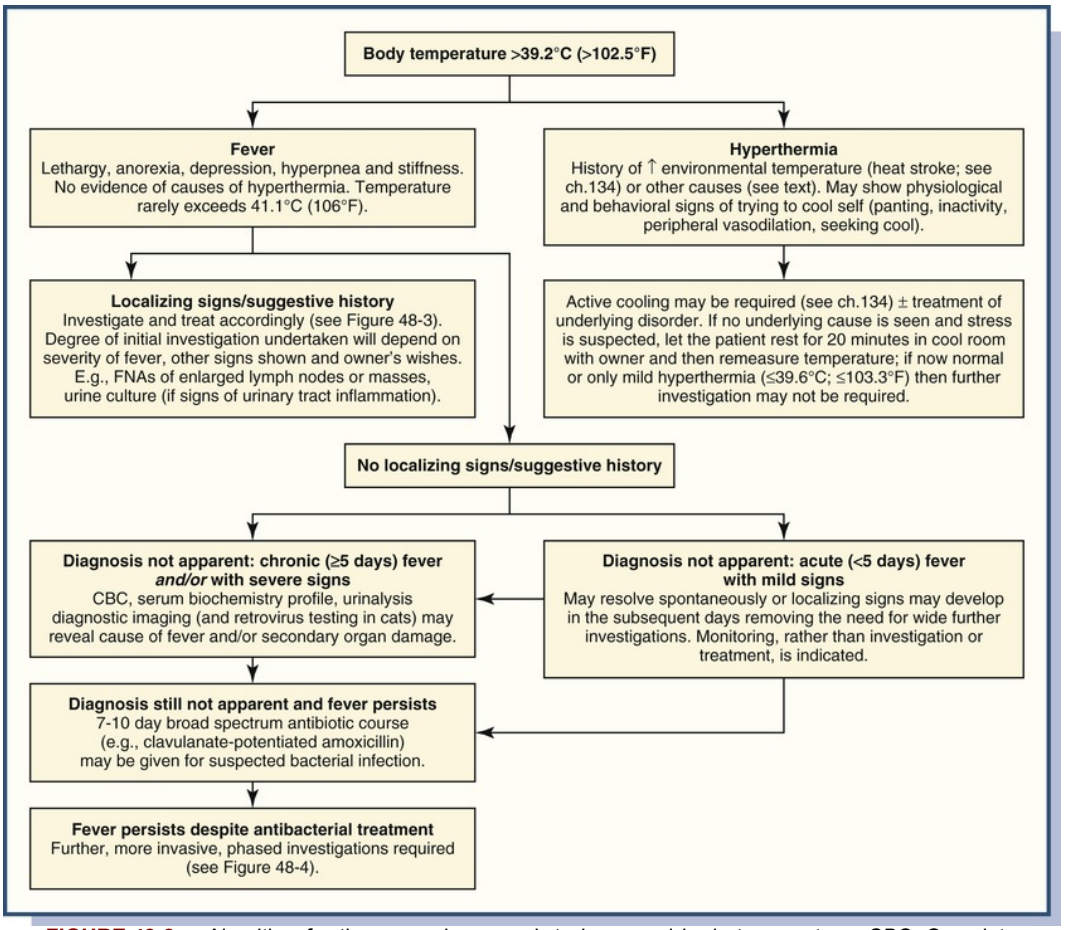

FIGURE 48-2 Algorithm for the general approach to increased body temperature. *CBC*, Complete blood count; *FNA*, fine needle aspirate.

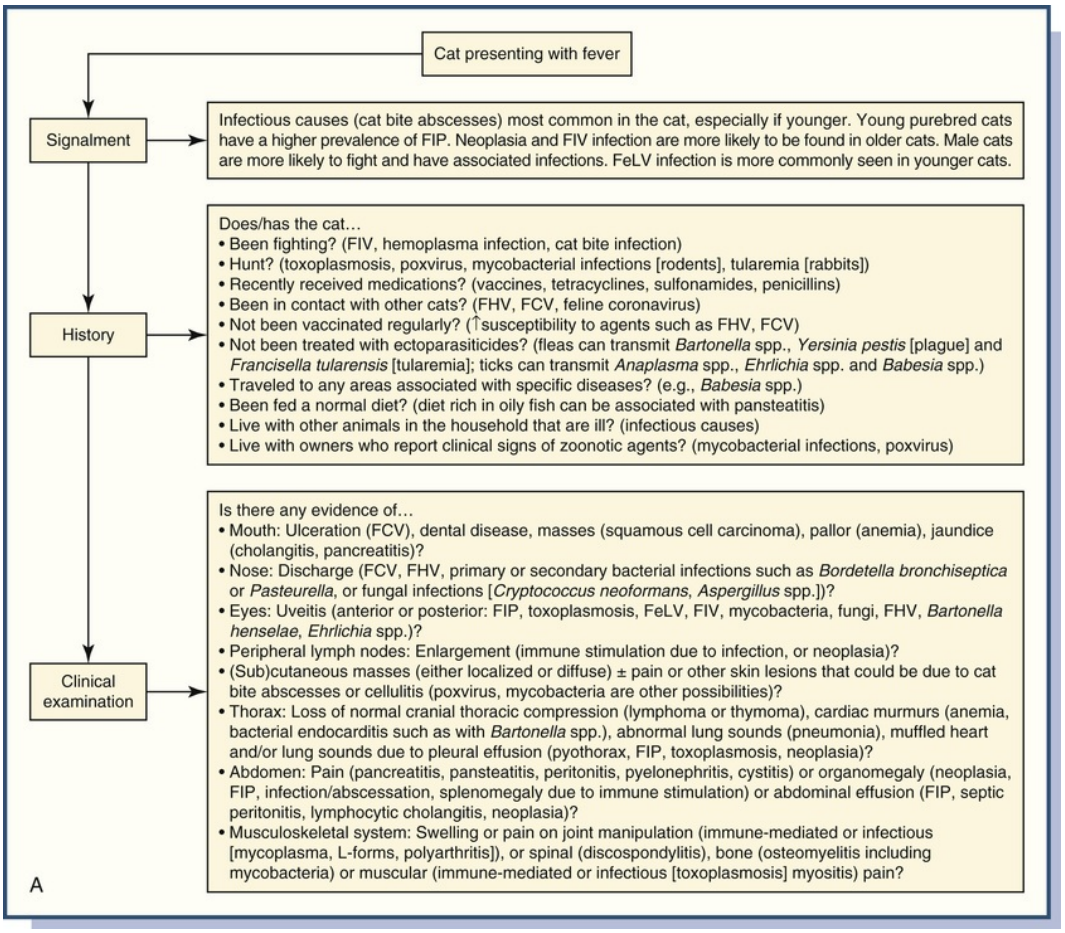
The initial consultation can provide important clues as to the etiology of the fever, and these may either lead to a diagnosis themselves or point to diagnostic investigations that should help confirm a diagnosis.

Figure 48-3 shows algorithms depicting information based on signalment, history and clinical examination (including ophthalmic and neurological examinations) that can be important to consider when first presented with fever in a cat (see Figure 48-3, *A*) or a dog (see Figure 48-3, *B*). The first presentation of an animal with fever can usually be dealt with relatively easily. Many causes of fever can be identified during a thorough clinical examination, e.g., bite wound, upper respiratory tract infection, periapical dental abscess (see Box 48-1). These should be treated appropriately and further diagnostic investigations may not be required.



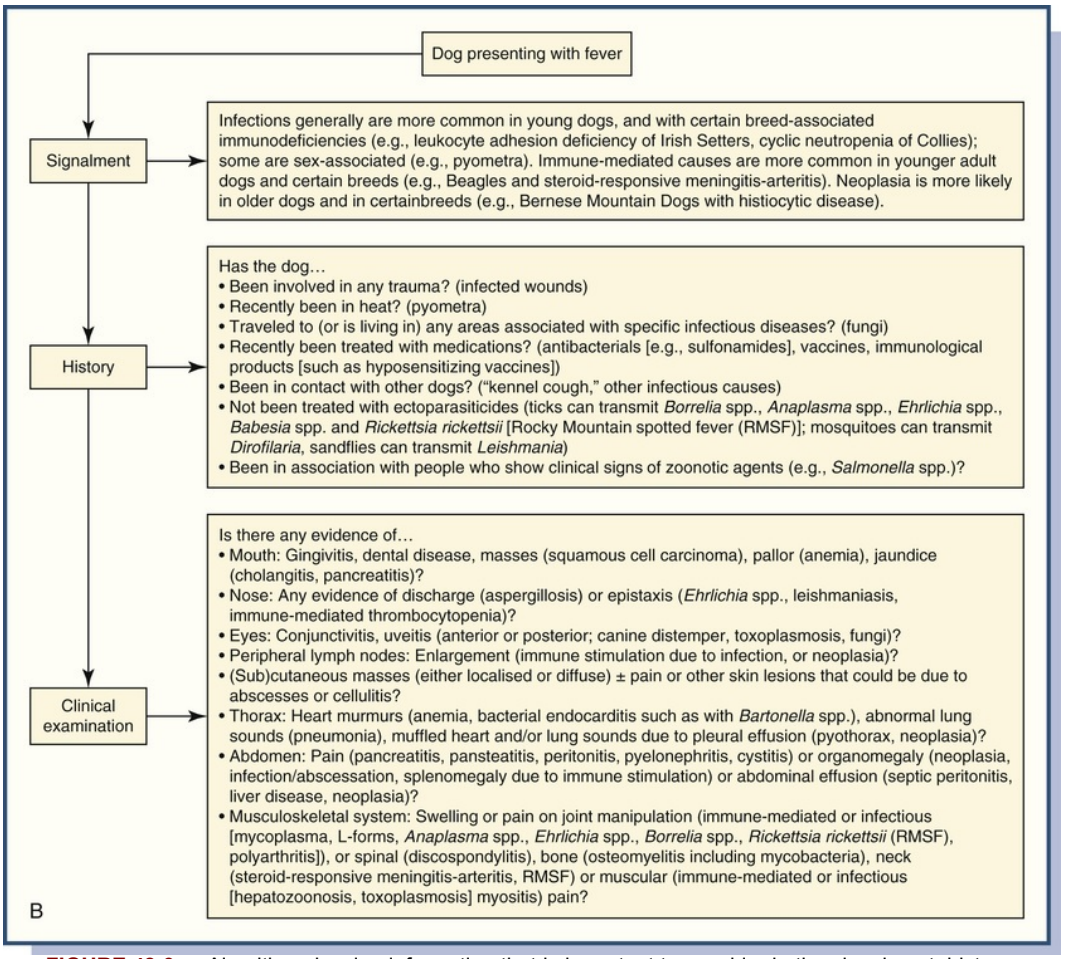


FIGURE 48-3 Algorithm showing information that is important to consider in the signalment, history, and clinical examination when investigating **(A)** cats and **(B)** dogs with fever. *FCV*, Feline calicivirus; *FeLV*, feline leukemia virus; *FHV*, feline herpesvirus; *FIP*, feline infectious peritonitis; *FIV*, feline immunodeficiency virus.

If localizing signs are not evident and the effects of the fever are relatively mild, and the temperature is below 41.1° C (106° F), then detailed diagnostic investigations may not be necessary as the underlying cause may become readily apparent. The fever should be monitored and the patient supported appropriately. A question that may arise at this stage is whether to give antipyretic and/or antibacterial therapy without a definitive diagnosis. Discussion of this is given in the Treatment section, below. However, if the fever causes severe side-effects, then early investigation may be warranted.

If the cause of the fever is not apparent on clinical examination within 5 days of initial presentation, and the fever persists, then a diagnostic plan is formulated. This will usually include a complete blood cell count, serum biochemistry panel, and urinalysis, with feline leukemia virus (FeLV) antigen and feline immunodeficiency virus (FIV) antibody testing in cats (Figure 48-4 and Table 48-1). While these tests are ongoing, 7 days of empirical antibacterial therapy can be a reasonable approach. Antipyretic therapy may also be *considered*, but depending on the severity of the clinical signs rather than the severity of the fever. If the fever persists despite this (and therefore has persisted for more than 12 days) then other diagnostic investigations can be planned according to the clinical findings or the results of initial diagnostic investigations, especially if the fever can be localized to a body system or region. Table 48-1 lists the diagnostic tests that can be used in the investigation of fever. It is important to repeat diagnostic investigations, particularly thorough clinical examinations, over time if the fever persists, as new abnormalities can develop that may provide important clues to the etiology or localization of the fever (see Figure 48-4). Subsequent examinations may reveal pain (e.g., in the neck or joints) or changes in ophthalmic or neurologic examinations (see ch. 11 and 259). In cases where the etiology of the fever remains elusive despite the above tests, then a sequential series of investigations which could include urine culture, blood culture, bacterial and fungal cultures of any discharges or lesions, arthrocentesis (see ch. 94), cerebrospinal fluid collection (see ch. 115), fine needle aspirates of any masses and some lymph nodes (even if normal on

palpation; see ch. 89), ultrasonography (see ch. 88), radiography (thoracic, abdominal, limbs and vertebrae), echocardiography (see ch. 104), serology and/or bone marrow samples (see ch. 92) should be started.[7,8] Cytology can be helpful in diagnosis, even in cases showing no clinical abnormalities of the body systems sampled.[7,8] Indeed, a recent study[45] found that cytology, or histopathology, were the most useful tests in determining the etiology of fever in a group of dogs, and other studies have similarly found cytology to be useful in enabling a diagnosis.[7,8] There may also be a role for magnetic resonance imaging in some cases. The exact order of diagnostic tests will depend on individual patient factors and consideration of regional variations in disease prevalence. As in human medicine, it is probable that there is no uniformly useful diagnostic algorithm for the further investigation of fever beyond the initial clinical examination.[10]

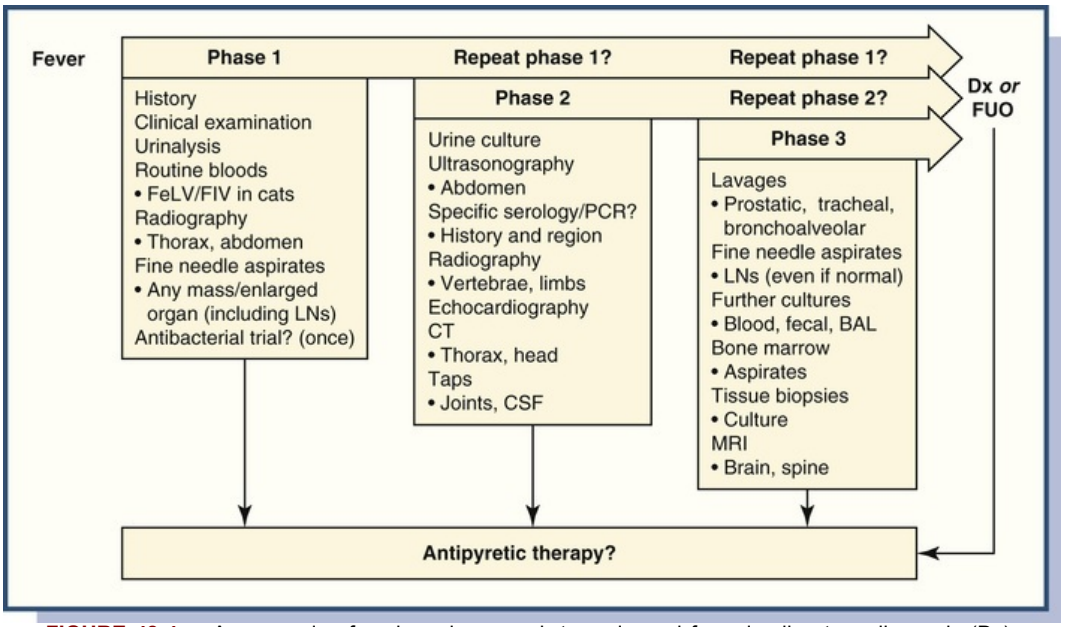

FIGURE 48-4 An example of a phased approach to prolonged fever leading to a diagnosis (Dx). *BAL,* Bronchoalveolar lavage; *CSF,* cerebrospinal fluid; *CT,* computed tomography; *Dx,* diagnosis; *FeLV,* feline leukemia virus; *FIV,* feline immunodeficiency virus; *FUO,* fever of unknown origin; *LNs,* lymph nodes; *MRI,* magnetic resonance imaging; *PCR,* polymerase chain reaction. The contents of each phase will vary with patient signalment, presenting signs, and local disease prevalence. Each phase may be spread over several consultations. Inherent in this diagram is the concept that the investigation of fever is a continuing and repetitive process and a patient cannot be said to have a "fever of unknown origin" until all of these tests have been performed and most of the ones in the earlier phases have been performed multiple times. Fever of unknown origin has to be truly unknown to be so described.

TABLE 48-1

Information That Can Be Obtained from Diagnostic Tests Used for Investigating Persistent Fever

TEST	DIAGNOSTIC INFORMATION
Urinalysis (including sediment examination) (1)	Urinary tract inflammation
Urine protein to creatinine ratio (2) (if urine sediment is inactive)	Assists assessment of renal function (urine specific gravity) Glomerular disease
Complete blood count (CBC) including blood smear examination (1)	Infection/inflammation* Hemoparasites, hematologic malignancy, and bone marrow disorders
Serum biochemistry profile (1)	Many metabolic organ diseases
Serum protein electrophoresis (2) if abnormal serum globulins are found	Systemic consequences of fever Monoclonal/polyclonal gammopathies
Acute phase proteins assay (2) (if neutrophil count	Acute phase proteins useful for monitoring response to therapy (not very

normal)	useful for diagnosis)
Culture & sensitivity—urine (2), fecal (2 or 3), and/or blood (3)	Urinary, enteric or blood-borne infections (bacteremia)
Fine-needle aspirates of any enlarged or abnormal lymph nodes or masses (1) or normal lymph nodes (3)	Lymphoma, lymphadenitis, metastatic disease, reactive lymphadenopathy
Thoracic radiography (2)	Pneumonia, mycobacterial infections, pleural effusion (pyothorax), intrathoracic masses
Abdominal radiography (2)	Organomegaly, abdominal effusions (peritonitis), lack of abdominal contrast (pancreatitis, pansteatitis), mass lesions
Abdominal ultrasonography with sampling of any abnormalities if appropriate (2). Examine, as far as possible, at least the liver, biliary tract, spleen, gastrointestinal tract, pancreas, urogenital tract, prostate, uterus, and lymph nodes.	General or localized changes in echotexture of organs or their size/shape. Opportunity to sample tissues or fluids (e.g., bile, abdominal effusions) by fine needle aspiration (2), core biopsy (3), or prostatic wash (2), for cytologic or histopathologic evaluation and/or Gram/acid-fast bacillary staining and/or culture and sensitivity.
Serology (2)	Evaluate for infectious causes (e.g., feline immunodeficiency virus, *Ehrlichia* spp., leptospirosis, toxoplasmosis) and/or immune-mediated diseases (e.g., Coombs' test, rheumatoid factor analysis, antinuclear antibody)
Polymerase chain reaction (PCR) test (2)	Alternative to culture to detect certain infectious agents in which culture is not possible or unreliable or slow (e.g., hemoplasmas)
Biopsies of abnormal tissues (3) (histopathology and culture) (e.g., lymph node, renal or liver)†	Lymphoma, lymphadenitis, metastatic disease, certain infectious agents (e.g., feline infectious peritonitis)
Skeletal radiography (including dental radiography) (3)	Discospondylitis, panosteitis, metaphyseal osteopathy, osteomyelitis, polyarthritis, bone metastases, multiple myeloma, mycobacterial infections, dental disease
Echocardiography—if murmur (2), if no murmur (3)	Valvular mass lesions (bacterial endocarditis) Myocarditis
Arthrocentesis—if stiff/lame/swelling (2), or if not (3). Samples submitted for cytology and/or Gram staining and/or culture.	Immune-mediated arthropathies or septic arthritis
Computed tomography (3), particularly of thorax and head	Pneumonia, intrathoracic masses, nasal disease, tooth root abscesses, skull osteomyelitis, temporomandibular joint abnormalities
Magnetic resonance imaging (3), particularly of brain and spinal cord before doing cerebrospinal fluid tap	Meningitis, encephalitis, discospondylitis
Cerebrospinal fluid tap—if head/neck pain (2), or if not (3). Submit samples for cytology and/or culture and sensitivity and/or PCR for infectious agents and/or antibody titers.	Steroid-responsive or septic meningitis Encephalitis Toxoplasmosis, neosporosis, feline coronavirus
Bone marrow aspirate and biopsy—if CBC abnormality (2), or if not (3)	Bone marrow disease (e.g., leukemia, multiple myeloma)
Bronchoscopy and bronchoalveolar lavage (or tracheal wash) (2 or 3). Samples can be submitted for cytology and/or culture and sensitivity and/or PCR.	Respiratory infections/inflammation (e.g., eosinophilic pulmonary disease, *Bordetella bronchiseptica* pneumonia)
Trial antibacterial treatment (1, 2, or 3)	Non-localizing or occult infections

*In fever, neutrophilia is more commonly seen with inflammatory and immune-mediated conditions (versus infectious causes).[45]

†The diagnostic value of exploratory laparotomy, laparoscopy, thoracoscopy without appropriate localizing signs is normally very limited.

(1) Tests often used early on in investigations, (2) tests that are usually employed based on the results of earlier tests, and (3) more advanced or invasive tests usually employed based on the results of tests in phases 1 and 2. Many of the tests can be sequentially repeated to enable detection of changes in the animal and provision of more clues to the etiology of the fever.

If all of these tests have been performed and the cause of the fever is still unknown, then it is reasonable to term this FUO but until then the distinction of fever and FUO in terms of differential diagnoses and

investigations is unclear and the two conditions should be regarded as a continuum. Assuming that only a small fraction of cases of fever are referred, then cases of true FUO are rare; out of 217 dogs referred to specialist centers, no diagnosis was achieved in 48 (22%) and some of these belonged to owners who did not wish to pursue all diagnostic options.[7,8,45] The majority of humans who develop true FUO will eventually recover spontaneously, and this may occur in dogs as well.[7,8,46]

Treatment

The treatment of fever assumes that fever is, at least in part, noxious, and that its suppression will reduce the noxious effects. Yet, despite many attempts, there is no evidence to suggest that specific treatment of fever actually improves survival or worsens the prognosis.[47] Furthermore, it has been shown that treatment of fever delays diagnosis of the inciting cause in dogs.[7] Patients treated with antipyretics undoubtedly look (and probably feel) better and are at less risk of fever-related complications ranging from the mild (e.g., inappetance) to the potentially life-threatening (e.g., DIC). However, such treatment prevents any of the benefits of fever described earlier. Many of the clinical improvements seen from antipyretic therapies could be due to the concomitant analgesic and/or anti-inflammatory actions of these drugs.

Therefore, antipyretic therapy ideally should be reserved for severe or prolonged fever. Mild acute fevers for which no cause has been identified are probably better left untreated. It may be more appropriate to educate clients that fever is often *good* for the animal and the use of medications might delay the development of important clinical signs that could help to identify the cause of the fever.

Physical Cooling

Active cooling of patients (as described in ch. 134) with fans, cool water, and other methods is not required unless the patient's temperature is greater than 41.1° C (106° F), when a degree of hyperthermia can be assumed. Obese patients or those with upper respiratory tract compromise are more prone to this situation and therefore should be monitored more closely.

Fluid Therapy

Fever increases insensible water losses and can reduce water consumption. Dehydration is therefore more common in febrile animals. Intravenous fluid therapy may be required, and at the very least, careful attention needs to be paid to monitoring the hydration status of an animal with fever.

Antibacterial Therapy

Antibiotics should be administered to all dogs and cats with fever and signs of bacterial infection, as well as all those with an unexplained fever of more than 5 days duration. The prevalence of systemic or unidentified bacterial infections in cases of fever is sufficiently high to warrant such treatment. Such therapy should use a single broad spectrum antibacterial with adequate penetration into most of the common sites of infection. As such, clavulanate-potentiated amoxicillin is a logical choice, though by no means exclusively so. In areas where vector-borne pathogens are common, then doxycycline may be a preferred alternative. Most authorities would regard fluoroquinolones, aminoglycosides, and later generations of the cephalosporins as being inappropriate first-line choices. The administration of multiple antibacterials in rapid succession over several days is unlikely to be successful and can increase antibacterial resistance (see ch. 209).

Nonsteroidal Therapy

Nonsteroidal anti-inflammatory drugs (NSAIDs) have been at the forefront of antipyretic therapy for many years.[24] They act by reducing the synthesis of thromboxane and prostaglandins from arachidonic acid in the hypothalamus by directly inhibiting cyclooxygenase (COX) enzymes and downregulating their expression.[47] This returns the thermoregulatory set point to its normal level. There is also evidence that NSAIDs might exert a variety of non-COX-dependent actions on the pyrogenic cascade, such as by suppressing tissue inflammation, reducing pyrogenic cytokine production, or through enhanced expression of endogenous antipyretics.[47] They also have analgesic characteristics, such that they are capable of mollifying many clinical signs of illness and thereby improve patient welfare. However, NSAIDs are associated with a small number of undesirable side effects, including renal and hepatic impairment (which can in rare cases lead to kidney

and liver failure), gastrointestinal ulceration, vomiting, and blood dyscrasias. Repeated use of NSAIDs increases the risks of many of these undesirable side effects.[48]

Glucocorticoids

Glucocorticoids are potent antipyretic drugs that act in many different ways, including some of the same ways as NSAIDs. However, their use is associated with more side-effects than NSAIDs and, in addition, they reduce the chances of successful diagnosis and, for some conditions, successful treatment.[7] They are therefore indicated only once a diagnosis (such as an immune-mediated disease) has been established. However, on those occasions when it is difficult to differentiate primary immune-mediated from infectious causes of fever in cats (e.g., some arthropod-borne blood infections) that may also have a secondary immune-mediated disease, then glucocorticoid administration alongside an effective antibacterial (such as doxycycline) is unlikely to exacerbate such diseases, and will help control fever and other clinical manifestations of disease.[5] The concept of "relative adrenal insufficiency" has been largely and substantially discredited in human medicine and while equivalent evidence is not yet available in veterinary medicine, this concept should not be used as a generalized justification for the administration of steroids to a patient with fever, even if associated with sepsis (see ch. 133).[49,50]

CHAPTER 49

Hypothermia

Justine A. Lee

Hypothermia, a subnormal body temperature in a homeothermic organism,[1] is defined as a core body temperature (CBT) <37° C (98.6° F).[2] Hypothermia is a result of the body's inability to maintain thermoregulatory homeostasis, and typically is due to excessive heat loss, decreased heat production, or a disruption of normal thermoregulatory functions.[2] Untreated, hypothermia can result in profound physiologic effects on the cardiovascular, respiratory, neurologic, and metabolic (including electrolyte, acid-base, and coagulation) systems, potentially increasing morbidity and mortality in the critically ill patient.[2,3]

Hypothermia can be primary or secondary. *Primary* hypothermia is defined as "accidental" hypothermia, and is a result of exposure to low environmental temperatures in the presence of normal heat production; an example is a dog living outside with poor shelter in a cold environment. *Secondary* hypothermia is more commonly observed in veterinary medicine, and is a sequela of disease (e.g., hypothyroidism, neoplasia, etc.), injury (e.g., with secondary hypoperfusion), surgery, or drug-induced alterations in thermoregulation and heat production (e.g., anesthetics, analgesics).[2-4]

Hypothermia is traditionally classified as the following[3,5]:

- Mild: 32° C to 37° C (90° F to 99° F)
- Moderate: 28° C to 32° C (82° F to 90° F)
- Severe: 20° C to 28° C (68° F to 82° F)
- Profound: <20° C (<68° F)

However, this grading scale is more accurate for primary hypothermia.[3] Some have proposed a newer classification of hypothermia based on the body temperature and clinical signs[2,3] (Table 49-1).

TABLE 49-1

Classification and Clinical Signs of Hypothermia[3]

CATEGORY	TEMPERATURE	CLINICAL SIGNS
Mild	36.7° C to 37.7° C (98° F to 99.9° F)	↑ HR, normal MAP, normal RR, normal LOC
Moderate	35.5° C to 36.7° C (96° F to 98° F)	↓ MAP, ↓ HR (cats), ↑ HR (dogs), mental dullness
Severe	33° C to 35.5° C (92° F to 96° F)	↓ HR, ↓ MAP, respiratory depression, severe CNS depression
Critical	33° C (<92° F)	Moribund, may appear dead, high mortality rate

CNS, Central nervous system; *HR*, heart rate; *LOC*, level of consciousness; *MAP*, mean arterial pressure; *RR*, respiratory rate.

Normally, complex mechanisms within the body help closely maintain CBT. The hypothalamus acts as the "thermostat" of the body, with temperature changes sensed by the preoptic and anterior hypothalamic nuclei, along with sensors throughout the body (within the skin, spinal cord, great veins, and abdominal viscera).[2] Both behavioral and physiologic changes occur when hypothermia develops, including curling up, heat-seeking behavior, piloerection, shivering, and peripheral vasoconstriction.

Causes for hypothermia occur due to heat loss, and are due to four main mechanisms:

- *Conduction:* transfer of heat occurs from the body surface to the air surrounding the body.[2] An example of this is the "wind chill factor," where circulated air results in heat transfer.[2]

- *Convection:* transfer of heat from the body surface to objects contacting the body. An example of this is an anesthetized patient on a stainless steel examination table.
- *Radiation:* loss of heat to surrounding structures that do not directly contact the body. Photons are emitted from any object that has a temperature above absolute zero, resulting in energy transfer.[2] An example of this is a marathon runner who wraps a reflective blanket around his or her body to minimize heat loss.
- *Evaporation:* transfer of heat from the respiratory tract or through moisture on the body surface to the environment. An example of this is an animal that has a large area of the body surface wet secondary to excessive surgery scrub.

In animals, heat loss generally occurs by convection and conduction.[6] Patients at risk for hypothermia include neonates (due to their ratio of body surface area to volume), geriatric patients, anesthetized patients, and those with underlying disease as their heat generation or temperature-regulating mechanisms may be impaired.

Cardiovascular Effects

Cardiovascular changes associated with hypothermia include an initial tachycardia followed by progressive bradycardia, arrhythmias,[7-9] conduction disturbances (e.g., lengthening of the PR, QRS, and QT intervals and the presence of pathognomonic Osborn waves, also known as J waves, in humans),[2,6] and changes in vasomotor tone (see ch. 103 and 248).[10] Potent constriction of the peripheral arteries can cause an increase in central venous pressure,[2,11] resulting in increased systemic vascular resistance.[2,12] As hypothermia and acidosis progress, there is a lack of responsiveness to catecholamines,[3] leading to progressive vasodilation and secondary hypotension.[2,3] With severe hypothermia (e.g., 28° C or 82.4° F), the heart rate can decrease by 50% as a result of decreased spontaneous depolarization of the cardiac pacemaker cells.[6] This profound bradycardia, which is often unresponsive to atropine,[6] can result in a progressive decrease in mean arterial pressure (MAP), peripheral vasoconstriction, and secondary fluid shifts. Increased blood viscosity, increased afterload, and capillary sludging can further develop, which reduce cardiac output.[6] As CBT approaches 23.5° C (74.3° F), death typically occurs due to the development of ventricular fibrillation and asystole.[2,6]

Respiratory Effects

Hypothermia can depress ventilation, resulting in reduced respiratory rate, minute ventilation, and tidal volume.[3] This can lead to secondary alveolar hypoventilation, hypercapnea, and respiratory acidosis. With increased blood viscosity, capillary blood flow is impaired and secondary hypoxemia can develop. Likewise, fluid shifts into the alveolar space can affect gas exchange, contributing to hypoxemia.[10] Finally, hypothermia causes an increased hemoglobin affinity (i.e., a left shift in the oxygen-hemoglobin dissociation curve) for oxygen, resulting in reduced oxyhemoglobin unloading at the tissue level,[10] further contributing to blood sludging.[3]

Neuromuscular Effects

Hypothermia results in disturbed cerebral autoregulation, decreased cerebral blood flow, and central nervous system depression as a result of decreased cerebral metabolism. For each Celsius degree decrease in CBT, there is a 6% to 10% drop in cerebral metabolism.[2,3,13] A flat electroencephalogram can occur with severe hypothermia (with CBT of 19° to 20° C or 66.2° to 68° F), and can potentially result in the misdiagnosis of death in a live patient.[6,14] At temperatures approaching 30° C (86° F), clinical signs of confusion, impaired judgment, decreased level of consciousness (LOC), and coma are reported in humans.[2] In veterinary patients, ataxia, hyporeflexia, and decreased LOC can be seen.[2]

Clinicopathologic Effects (Acid-Base, Coagulation, Electrolytes)

Hypothermia can result in increased catecholamine and cortisol production, resulting in hyperglycemia[3]; with severe hypothermia, this can progress to hypoglycemia due to impaired gluconeogenesis and glycogen depletion.[3] Acidosis also can be observed due to both a metabolic acidosis and respiratory acidosis (see ch.

128).[2,3] The presence of a metabolic acidosis can be due to poor perfusion with increased lactic acid production along with increased muscle activity (secondary to shivering).[2,3] Impairment of immune function also can occur with hypothermia due to impaired chemotaxis of, and phagocytosis by, granulocytes; impaired oxidative killing by neutrophils; and decreased mobility of macrophages.[2,3] Hemostasis also can be impaired by hypothermia with thrombocytopenia (due to sequestration of platelets in the liver and spleen),[2,3] coagulation factor dysfunction, reversible platelet dysfunction,[15] and a disruption of the fibrinolytic equilibrium.[2] Secondary hemostatic abnormalities also can be seen with hypothermia. Either a physiologic hypercoagulable state or disseminated intravascular coagulation (DIC) can occur (see ch. 197).[2] Evaluation of thromboelastography on hypothermic blood from dogs has demonstrated platelet dysfunction due to poor aggregation.[16]

Renal and Metabolic Effects

With hypothermia, a *cold diuresis* can be seen regardless of hydration state; this is due to the initial increase in blood volume caused by peripheral vasoconstriction.[2,3] Hypothermia can also cause a decreased production and responsiveness of the distal tubule to antidiuretic hormone, resulting in decreased resorption of water and electrolytes.[2] With moderate hypothermia, decreased glomerular filtration rate occurs due to decreased cardiac output and renal blood flow.[2,3] In humans, 40% of patients admitted into an intensive care unit due to accidental hypothermia had evidence of acute kidney injury.[2] Due to the reduction in tubular function, acidosis and hyperglycemia can develop as a result of decreased H^+ ion excretion and renal clearance of glucose.[2] The severity of hyperglycemia also can be worsened by decreased insulin sensitivity and reduced insulin secretion from the pancreas.[2] Electrolyte changes such as hypophosphatemia, hypomagnesemia, and hypokalemia may be seen secondary to hypothermia-induced intracellular shifts and renal tubular dysfunction.[2,3] Finally, decreased hepatic enzyme activity is associated with hypothermia, and is likely due to reduced perfusion of the liver.[2] This can potentially result in prolonged drug clearance and metabolism of substances commonly used for treating critically ill patients (e.g., opioids, benzodiazepines, anticonvulsants, propofol, etc.).[2]

Treatment

To minimize the physiologic dangers of hypothermia, the goals of therapy should include:

- Early detection and immediate correction of hypothermia (while providing safe rewarming rates)
- Prevention of further heat loss
- Support of vital cardiopulmonary and organ function (e.g., intravenous fluid therapy)
- Achievement of normothermia, and
- Reducing the risks of rewarming complications.

These goals can be addressed through passive and active warming techniques, and both should be implemented, as described below.

Passive Warming

Passive warming refers to minimizing loss of heat to the environment and augmenting the patient's own ability to generate heat.[2] This includes prevention of conduction losses by providing insulation from cold surfaces (e.g., stainless steel tables during anesthesia), wrapping the patient in insulated blankets, keeping the animal as dry as possible (e.g., using scrub only on the surgical site and removing excess scrub solution), and preventing evaporation of body fluids or liquids used for surgical preparation. Passive warming is effective for patients that are only minimally hypothermic.

Active Warming

Active warming is the use of exogenous sources of heat, and is generally used for moderate to severe hypothermia; typically, the patient is unable to generate enough heat to be able to rewarm itself appropriately.[2] Examples of commonly used active external rewarming (AER) techniques used in veterinary

medicine include the following (Video 49-1):

- External warming devices (e.g., hot water blankets, heated pads, electric heating blankets, radiant heat, hot water bottles, warm rice packs, etc.); however, with some of these modalities, there is the risk for thermal injury from direct or indirect contact.
- Forced-air rewarming (e.g., 3M Bair Hugger), which provides forced air through disposable blankets to allow convective transfer of heat to patients (E-Figure 49-1).
- Resistive heating (e.g., Hot Dog warming blanket), which transfers heat to the patient using a non-disposable, semi-conductive polymeric fabric that warms by electrical resistance (e.g., low voltage electricity) (Figure 49-2 and E-Figure 49-3).

FIGURE 49-2 Use of a resistive heating blanket (e.g., Hot Dog) to prevent hypothermia in a patient undergoing a dental procedure. (Photo courtesy John Bayard.)

E-FIGURE 49-1 Forced air blanket used to treat hypothermia in a feline post-operative patient. (Photo courtesy Dr. Garret Pachtinger.)

E-FIGURE 49-3 Wrapping a patient in a resistive heating blanket (e.g., Hot Dog) during surgery and anesthesia to prevent hypothermia during ovariohysterectomy. (Photo courtesy John Bayard.)

Other methods of active warming include the use of warm saline to lavage the abdomen during surgery, warm fluids (typically by the intravenous route, although gastric, colonic, or peritoneal lavage can be considered), or warm inhaled air (if the patient is intubated). However, a recent study found that prewarming IV fluids might be minimally effective: even prewarming crystalloids to 60° C and administering them through a typical IV line at 300 mL/h produced a temperature at the point of delivery of only 24.2 +/− 1° C.[17] Goals of rewarming should be limited to an increase of 0.5° C to 2° C/hour.[2,3] General safe recommendations for rates of rewarming are found in Table 49-2.

TABLE 49-2

Rewarming Rates (Degrees Celsius Per Hour)[2]

	PASSIVE EXTERNAL REWARMING	ACTIVE EXTERNAL REWARMING	INHALATION OF WARM AIR	PERITONEAL LAVAGE (LESS COMMONLY DONE)
1st hour	1.4	1.5	1.0-2.5	1.5
2nd hour	1.4	2.4	2.0	2.5

Complications of Rewarming

Rarely, complications of rewarming can occur including rewarming shock, thermal injury, and overheating. Heat should be aimed at warming the trunk rather than the extremities; this helps minimize peripheral vasodilation and secondary pooling of blood, which can lead to *rewarming shock*. When superficial surfaces are rewarming, peripheral vasodilation can occur resulting in potential hypovolemia. Another complication includes the risk of thermal injury, which can be avoided by providing safer alternatives of heat support. Overheating should also be prevented. Active rewarming devices should always leave an area of the incubator or cage floor that is free of external heat, so the animal can move away from the heat source once normothermic if the heat is excessive. Clinicians should be aware of normal physiologic parameters when it comes to rewarming; this is especially important when providing heat support for neonates (e.g., normal rectal temperature of 36-37° C [96.8-98.6° F] at birth).

The Use of Hypothermia for Treatment

The use of therapeutic hypothermia (with a target temperature of 32° to 34° C or 89.6° to 93.2° F) has been investigated for its neuroprotective effect in patients with underlying cerebral injury, post-cardiac arrest, or secondary to hemorrhagic shock. Therapeutic hypothermia is thought to prevent cell death after cell injury, suppress free radical reactions, reduce cerebral oxygen demands, and retard destructive enzyme reactions.[2] Recently, the Reassessment Campaign on Veterinary Resuscitation (RECOVER) initiative suggested that the use of mild hypothermia might be beneficial when implemented as soon as possible and when maintained for longer than 12 hours after return to spontaneous circulation.[18] While limited studies have been investigated in veterinary medicine, preliminary evidence is promising; additional prospective studies are warranted.

CHAPTER 50

Pallor

Dan G. Ohad

Client Information Sheet: Pallor

Pallor is defined as the paleness of a tissue.[1] Assessing tissue color in animal patients is practical mostly by evaluating the color of mucous membranes, but can also involve areas of hairless skin. This simple but essential test is a component of the routine physical examination performed as a part of the overall assessment of each and every patient.

In normal animals the mucous membranes should be moist and pink, and they are considered pale when their color is subjectively judged to be too light. This is determined by the amount of oxygenated hemoglobin in the blood, and by the degree of tissue blood perfusion. It can be altered or even masked by the presence of other serum pigments, such as bilirubin or myoglobin. By the same token, pallor, if severe enough, can sometimes mask other conditions such as cyanosis, which should be considered when suspecting left-sided congestive heart failure, right-to-left shunting cardiovascular disease, or some intoxications (see ch. 52).

One should note that since hematocrit differs between species and between age groups within a given species, normal mucous membranes appear lighter in cats than they are in dogs, as they do in puppies or kittens relative to adult pets.

Pallor is most commonly sought by assessing non-pigmented areas of the inner side of the lips, the gums, and the conjunctiva. The tongue, nares and urogenital (penis and prepuce or vulva and vagina) mucous membranes can also be assessed, as can the rectoanal mucous membranes. Such membranes are rich with capillary vessels and are easily visible. Changes in perfusion or in their level of oxygenation, therefore, can be readily identified when examined appropriately. Such changes can occur due to either systemic or local pathological processes.

Pallor can result from anemia or from decreased tissue perfusion, or from a combination thereof. Any condition resulting in compromised capillary perfusion such as a decreased cardiac output, or a reduced red blood cell concentration can lead to the development of pallor.[2] Decreased cardiac output may result from extreme tachycardia or bradycardia, a highly irregularly irregular tachyarrhythmia, extreme systolic myocardial failure, cardiac tamponade, severe pulmonary arterial hypertension, shock of all kinds (hypovolemic, anaphylactic, distributive, cardiogenic or neurogenic), or systemic hypotension.

Systemic or localized arteriolar vasoconstriction, too, can trigger generalized or localized pallor, respectively.[3] This might depend on an elevation in sympathetic tone accompanying stressful conditions such as severe pain, fear, or heart failure.

While pallor is not necessarily present in every anemic patient, mucous membrane pallor is the most common clinical sign of all types of anemia, whether chronic or acute, regenerative or non-regenerative, regardless of tissue capillary perfusion. Acute hemorrhage can trigger pallor first via hypovolemia, and later via loss of hemoglobin, while chronic anemia triggers pallor mostly by the ongoing hemoglobin loss, typically when hematocrit is <25-30%. When blood loss is acute, pallor can already be identified at higher hematocrit levels.

Evaluation

An integrative, rapid, yet thorough assessment of a patient with pallor can sometimes be crucial and promote a life-saving decision, especially because some of the common etiologies can involve an emergency situation. Careful attention to the patient's signalment, history, and co-existing physical examination findings can provide important clues as to the underlying reason for pallor, and guide the clinician into prompt action such as fluid therapy for patients in shock, blood transfusion for patients with severe anemia, or intravenous

diuretic therapy for patients in congestive heart failure. Inadvertently choosing one modality when another is actually needed can sometimes be detrimental (if not catastrophic) for the patient, as some of the above mentioned conditions warrant an opposite approach from others. Nevertheless, whether pallor results from anemia or from decreased tissue perfusion (or both, when coexisting), other physical findings can sometimes guide the clinician towards the more likely reason for pallor. One should bear in mind however, that certain accompanying findings can sometimes result from several potential etiologies, which can be confusing. Possible examples include compensatory sinus tachycardia (when cardiac output and perfusion are too low, or when anemia-related hypoxemia has developed), compensatory tachypnea (when anemia-related hypoxemia is present), weakness, cool mucous membranes or extremities, or an abnormal demeanor. These are not always helpful in determining which of the two disorder categories is the one contributing the most to pallor. This is the reason why utmost efforts towards careful integration of all findings should be made prior to taking corrective action.

History and physical examination may both be consistent with external (e.g., melena or epistaxis) or internal blood loss: the combination of pallor and icterus (or the presence of pigmenturia) highly suggests anemia due to hemolysis.

One of the most informative parameters that can aid in differentiating decreased perfusion versus anemia is the capillary refill time (CRT). It is determined by lightly compressing a non-pigmented mucous membrane surface to blanch the mucosa by transiently arresting capillary flow and observing the time (in seconds) it takes for prior mucous membrane color to return. It will be longer than normal when capillary perfusion pressure is diminished. However, if the applied manual pressure is hard enough to actually compress arterial flow as well, CRT may become overly prolonged and lead to an overestimated severity of the true compromise. In contrast, CRT may remain unchanged even in the presence of severe anemia, especially when chronic. Normal CRT is 1.0 to 2.0 seconds; prolonged CRT is >2.0 seconds and is considered diagnostic for poor tissue perfusion.[2,4] However, this is a highly subjective and insensitive test, which can often appear normal in highly compromised patients, and vice versa, especially when not integrated into a panel of other tests and assessments.

While pets with decreased perfusion frequently present with rapid and weak peripheral pulsation and a prolonged CRT, those with chronic anemia (i.e., without concurrent hypovolemia resulting from acute blood loss along with its accompanying compensatory mechanisms) often present with rapid but bounding pulses, with a normal CRT. As both their intra- and extravascular volumes remain normal, their strong arterial pulsation results from a decreased blood viscosity combined with a compensatory increase in cardiac output. A simple blood test such as hematocrit or packed cell volume (PCV) measurement can supplement the physical examination findings in providing guidance as to which of these conditions is responsible for pallor.

Pulse quality may provide additional information regarding the underlying disease (see ch. 56). For example, when decreased during inspiration and increased during expiration (a "paradoxical pulse"), especially when accompanied by tachycardia, muffled heart sounds, and jugular venous congestion, cardiac tamponade should be suspected as the reason for pallor, and should be promptly treated, if confirmed (see ch. 254). When pulse pressure (the difference between arterial systolic and diastolic pressures), which dictates the palpable arterial pulse intensity, is abnormally high or low, this does not necessarily mean that tissue perfusion will follow the same pattern. A good example is severe bradycardia, which translates into an elevated systolic arterial pressure (due to longer diastolic filling of the left heart ventricle, and therefore an increased force of left ventricular contraction), in parallel to a decreased arterial diastolic pressure (resulting from the longer opportunity for diastolic pressure to drop to a lower value than usual). The combination of an elevated systolic and a decreased diastolic arterial blood pressure means the pulse pressure is increased for two different reasons, leading to a bounding palpable pulse (see ch. 56). This, however, should not give the wrong impression regarding capillary perfusion, which can still be highly compromised due to the overall decreased cardiac output, if bradycardia is severe enough. Pallor in this context can provide the astute clinician enough of a clue to keep this risk in mind, especially if combined with other physical examination findings such as core or regional hypothermia, or stupor.

Mucous membrane moisture might decrease with compromised hydration, which should not be expected in well-hydrated, anemic pets. Hydration status can also be evaluated non-invasively by testing skin turgor: if the inter-scapular skin promptly returns to its normal position after having been pulled dorsad and released, dehydration is less likely. When in doubt, however, selective blood tests (e.g., PCV, total solids) can supplement these subjective impressions.

Tachyarrhythmia with frequent premature cardiac cycles can explain a pulse deficit as a factor contributing to pallor, if severe and frequent enough (see ch. 248). A simple electrocardiographic rhythm strip can test this possibility (see ch. 103).

Figure 50-1 provides a suggested diagnostic test algorithm to be considered by clinicians and potentially follow integrated information gathered from the patient's signalment and history, when identifying pallor upon physical examination. It prioritizes physical examination tests and illustrates how the evaluation of a patient with pallor might help determine the cause, and how pallor may have more than one cause, all occurring at the same time.

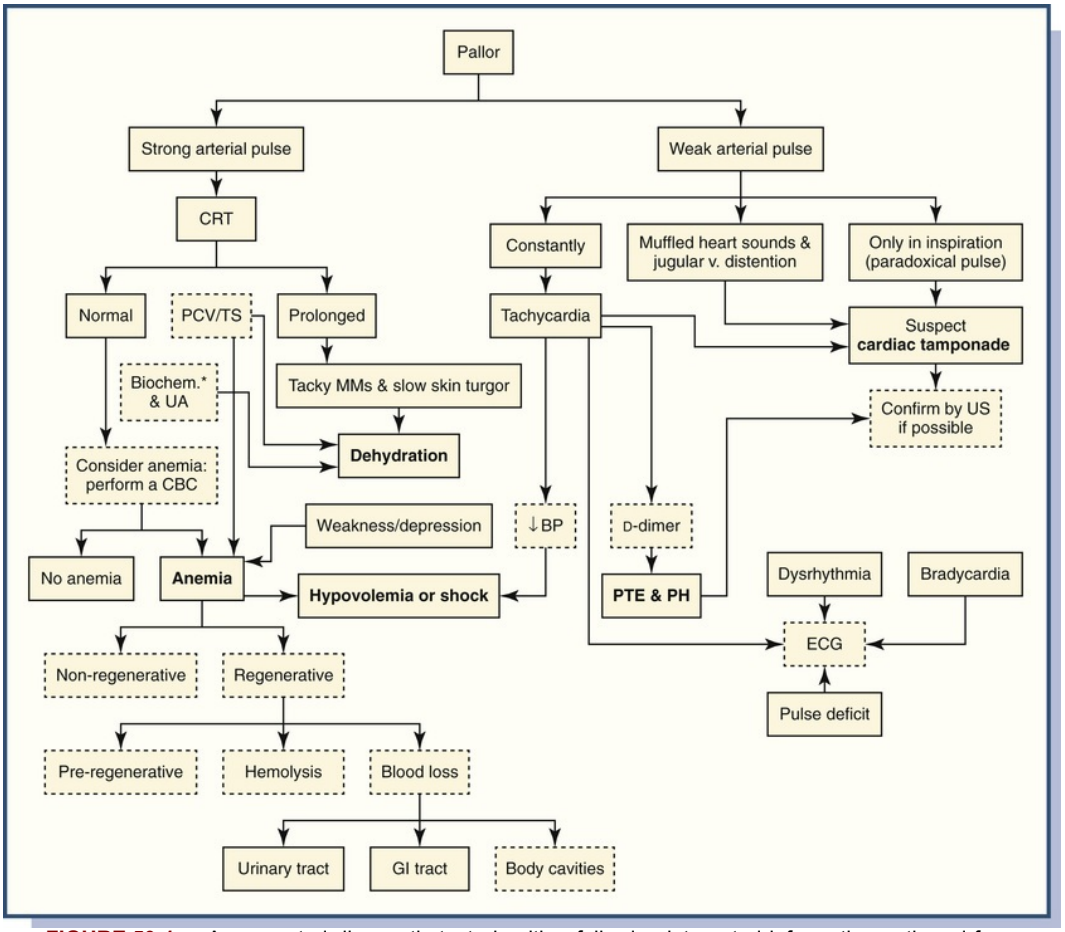

FIGURE 50-1 A suggested diagnostic test algorithm following integrated information gathered from the patient signalment and history, when identifying pallor upon physical examination. The flow chart illustrates how the evaluation of a patient with pallor might help determine the cause, and how pallor may have more than one cause at the same time. Physical examination findings are in solid boxes. Other, ancillary tests to be considered are in boxes defined by a broken line. CHAPTER 51

Hyperemia

Anthony C.G. Abrams-Ogg

Client Information Sheet: Hyperemia

Hyperemia refers to increased arterial (pre-capillary) blood flow to a tissue. Active hyperemia is a normal physiologic response when there is increased metabolic activity in a tissue, as in exercising muscle, where the hyperemia delivers more oxygen and nutrients to the tissue.[1] Hyperemia is also a key pathophysiologic response as part of inflammation[2] (Figure 51-1). The main clinical sign associated with hyperemia is erythema, which will be less obvious in an anemic animal. Hyperemia is distinguished from congestion, which results from decreased removal of post-capillary blood, which does not cause erythema. This chapter addresses generalized hyperemia of peripheral mucous membranes, which are sentinel tissues for circulatory status because of rich vascular supply and ease of examination. Hyperemia is most likely to be initially recognized as gingival and conjunctival erythema during general physical examination. It is important to ensure that these are not caused by gingivitis or conjunctivitis. If gingivitis is present, the buccal mucosa should be examined. If pigmentation or patient behaviors preclude recognition of gingival, buccal mucosal or conjunctival hyperemia, and also to confirm generalized hyperemia, the vulva or penis and prepuce should be examined. In some cases, generalized cutaneous erythema may also be detected. The term "injected mucous membranes" is variably used by clinicians as a synonym for hyperemia or to refer to a subset of hyperemia characterized by brick-red mucous membranes, most often associated with sepsis, heat stroke, and hypoadrenocorticism.

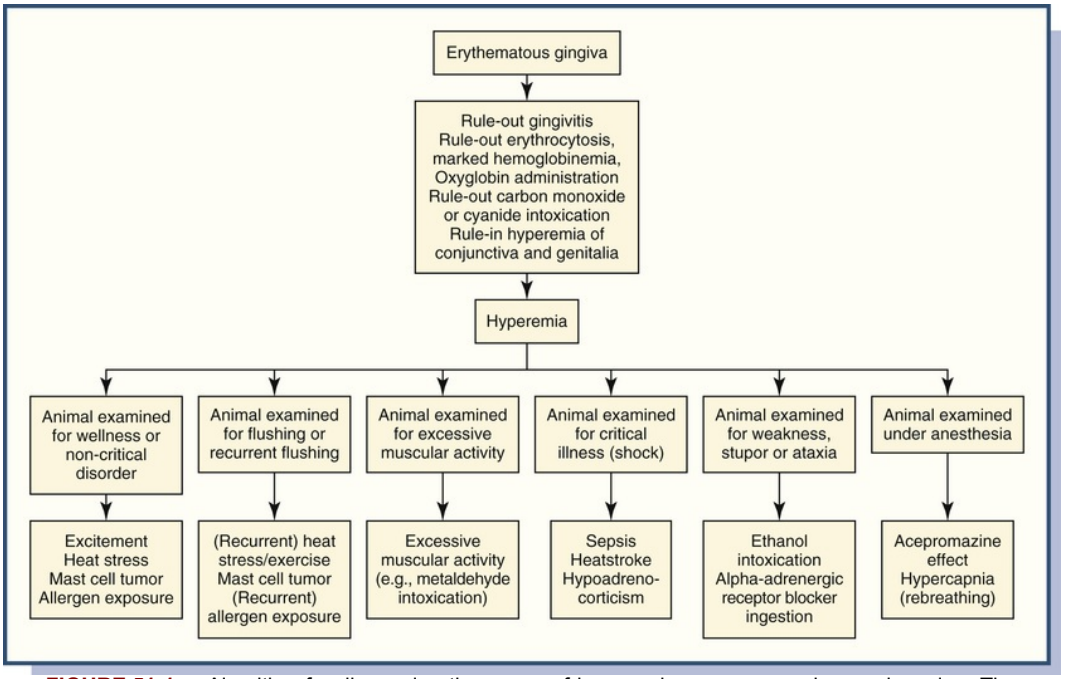

FIGURE 51-1 Algorithm for diagnosing the cause of hyperemic mucous membranes in a dog. The algorithm may also be used for cats but hyperemia is infrequently recognized.

Erythematous mucous membranes and skin may also be caused by erythrocytosis, hemoglobinemia, and treatment with Oxyglobin, which may be ruled out by history and a hemogram. The mucous membranes of neonatal pups and kittens are also relatively dark compared to their color at around 6 weeks of age due to high fetal mean corpuscular volume.[3] Experimentally, carbon monoxide and cyanide poisoning may cause bright red mucous membranes. In the former this is due to carboxyhemoglobin formation, in the latter it is because oxygen is not extracted from hemoglobin, and in both cases there is likely a hyperdynamic response.[4] Carbon monoxide and cyanide poisoning are most often encountered with smoke inhalation, where red mucous membranes are not commonly reported and other signs predominate.[5,6] These poisons may also be used for malicious poisoning and extended suicide.[7]

As with other tissues, blood flow through mucous membranes is predominantly determined by cardiac output and arteriolar vascular tone. Hyperemia cannot occur without vasodilation, and as such the causes of hyperemia will be causes of vasodilation, although not all causes of vasodilation will cause hyperemia. Vasomotor tone is under local (intrinsic) and extrinsic control. Local control signals include metabolic products, endothelin-1, nitric oxide (NO), thromboxane A2, prostacyclin, histamine, and bradykinin.[1] The main extrinsic control mechanisms are neurohormonal reflexes of the autonomic nervous system (e.g., secretion of acetylcholine).[1]

Capillary refill time (CRT) is typically determined while examining peripheral mucosa. It is a measure of gingival perfusion. The subjectivity and inconsistency of CRT has brought its utility into question in human medicine.[8] These factors likely affect judgment of CRT in animals as well, but it remains an important element of the physical examination. For hyperemic mucous membranes, the CRT will be normal (0.5-2 sec) to fast (<0.5 sec) if there is normal-to-increased cardiac output. Although seemingly paradoxical, prolonged CRT (>2-3 sec) may occur in hyperemic mucous membranes, and indicates severe vasodilation and risk for associated hypotension. When testing CRT, light pressure for 1-2 sec to blanch the tissue should be used. Excessive or prolonged pressure, and repeated testing in one area, may result in an exaggerated response from reactive hyperemia, the increase in above normal blood flow following transient vascular occlusion.

Hyperemia is infrequently recognized in cats compared to dogs, probably because of lower hematocrit, lower relative blood volume, and lower prevalence of disorders that cause hyperemia, and possibly because of high sympathetic tone in stressful conditions promoting vasoconstriction. Recognition of hyperemia in cats may also be complicated by the common occurrence of gingivitis and the lack of routine examination of genitalia except in cats with lower urinary tract signs.

The most common cause of hyperemia in the dog is the normal physiologic response to increased heat (Video 51-1). Increased heat may be internal or external. One function of the circulatory system is the transport of normal products of metabolism for elimination, and internal heat above what is needed to maintain normal body temperature is one of these products.[1] In the classical model of vasodilation, increased metabolism causes decreased oxygen concentration from consumption, and causes increased carbon dioxide, potassium, adenosine and lactic acid concentrations, all of which promote vasodilation. The classical model has been challenged by the "bang bang" model, where membrane NADPH oxidase is turned off and on based on the supply of oxygen and glucose relative to the demand. When NADP oxidase is turned on, there is release of superoxide anion into the interstitial space and subsequent neutralization of interstitial NO.[9] The increased blood flow to the skin will increase convective cooling in the dog to some extent, but panting is the main mechanism to increase evaporative cooling, which is facilitated by oral mucosal hyperemia. Increased physical activity and/or excitement will increase heat production from skeletal muscle. Increased activity is most often due to situation-related normal or abnormal behavior for an individual dog. One scenario of overheating unrelated to behavior is the work of breathing associated with Coonhound paralysis (see ch. 269). Pathologic muscular activity may also occur with metaldehyde poisoning.

Increased external heat comes from high ambient temperature or external warming sources, and external heat stress will exacerbate internal heat load. Increased ambient humidity will also exacerbate heat stress as it reduces the effectiveness of evaporative cooling. Cats that are overexcited and/or subjected to a high ambient temperature may also pant and have relatively hyperemic mucous membranes.

Initially, overheating will be associated with normal CRT, which will progress to rapid CRT with increasing heat stress, and then to heat stroke and eventual shock with pallor and prolonged CRT (see ch. 134).[10]

Fever is an adaptive response and does not in itself cause hyperemia (see ch. 48). However, fever is often due to sepsis, which is often associated with hyperemia. Unlike hyperthermia, where there is appropriate vasodilation, in sepsis the inflammatory mediators bradykinin, histamine, serotonin, and many others, cause inappropriate vasodilation[11] (Video 51-2). The hyperdynamic phase of septic shock is characterized by

fever, hyperemia, normal-to-increased CRT, and tachycardia. It may progress to hypodynamic septic shock characterized initially by prolonged CRT, followed by pallor and hypothermia. Hyperdynamic shock is infrequently recognized in cats.

Certain drugs and toxins may cause hyperemia. These include acepromazine, phenoxybenzamine, prazosin and other drugs that block alpha-adrenergic receptors; animals with hyperemia caused by these drugs will typically be sedated. Ethanol may cause peripheral vasodilation; the mechanism may be modulation of extrinsic vasomotor control mechanisms.[12] Animals with hyperemia will probably be ataxic. Ethanol ingestion may result from malicious/accidental poisoning, bread dough ingestion, or treatment of ethylene glycol poisoning (see ch. 152).[13] Hypercapnia caused by rebreathing during anesthesia may directly cause peripheral vasodilation. If blood pressure and oxygenation are adequate, the mucous membranes may be hyperemic. The animal may also be hyperventilating. It is emphasized that hypercapnia may occur without these signs.[14]

Some dogs with atypical and classical hypoadrenocorticism have presented with profound hyperemia with prolonged CRT, and in some cases have initially been misdiagnosed as septic (see ch. 309).[15] Cortisol is necessary for a normal response to adrenaline and inhibits NO synthesis; therefore, cortisol deficiency results in vasodilation. Dogs with hypoadrenocorticism may also present with pallor from volume contraction and peripheral vasoconstriction, and the variable circulatory findings are one more reason this disorder is "the great pretender." Low serum sodium : potassium ratio and/or absence of a stress leukogram will often be present, but protracted vomiting may lower the serum potassium concentration, and unrelated inflammation may mimic a stress leukogram. Hypoadrenocorticism may occasionally cause a fever.[16] An ACTH stimulation test should be considered in cases with unexplained hyperemia, but in interpreting an ACTH response test in this scenario, the possibility of critical illness-related corticosteroid insufficiency must also be considered (see ch. 133).[17]

Histamine is a potent vasodilator, and dogs with mast cell tumors will occasionally present with periodic self-limiting hyperemia not associated with increased activity or ambient temperatures (see ch. 349). Intermittent exposure to an allergen could also cause this sign. If history does not reveal repetitive allergen exposure and thorough examination of the skin does not reveal a mass, then imaging and/or aspiration of the spleen, liver and bone marrow should be considered (see ch. 89, 92, and 93).

Altered NO mechanisms are involved in menopausal vasomotor symptoms in humans. An animal model of vasodilation in the tail of forced exercise ovariectomized rats exists, but post-ovariohysterectomy vasomotor signs have not been recognized in dogs and cats.[18]

CHAPTER 52

Cyanosis

Anna Tidholm

Client Information Sheet: Cyanosis

Cyanosis (*cyan* = blue, Greek) is defined as bluish discoloration of the mucous membranes and/or skin due to excessive amounts of deoxygenated (reduced) hemoglobin (Hb) in capillary blood. The presence of cyanosis is a subjective assessment, observed in different disease processes, and is typically categorized as *central* or *peripheral*.

Central cyanosis is caused by a systemic deoxygenation of arterial blood, most commonly due to cardiovascular or pulmonary disease, or the presence of increased amounts of non-oxygen carrying hemoglobin (e.g., methemoglobinemia). *Peripheral cyanosis* is caused by a localized reduction in oxygenated hemoglobin, secondary to obstructive causes (e.g., thromboembolism, tourniquet application, foreign body), vasoconstriction (e.g., shock, hypothermia, low output cardiac failure), decreased arterial supply, or any of the causes of central cyanosis. Central cyanosis is generally most evident in the oral mucous membranes, whereas peripheral cyanosis is most evident at the footpads and nail beds of the affected limb(s) (Figures 52-1 and 52-2).

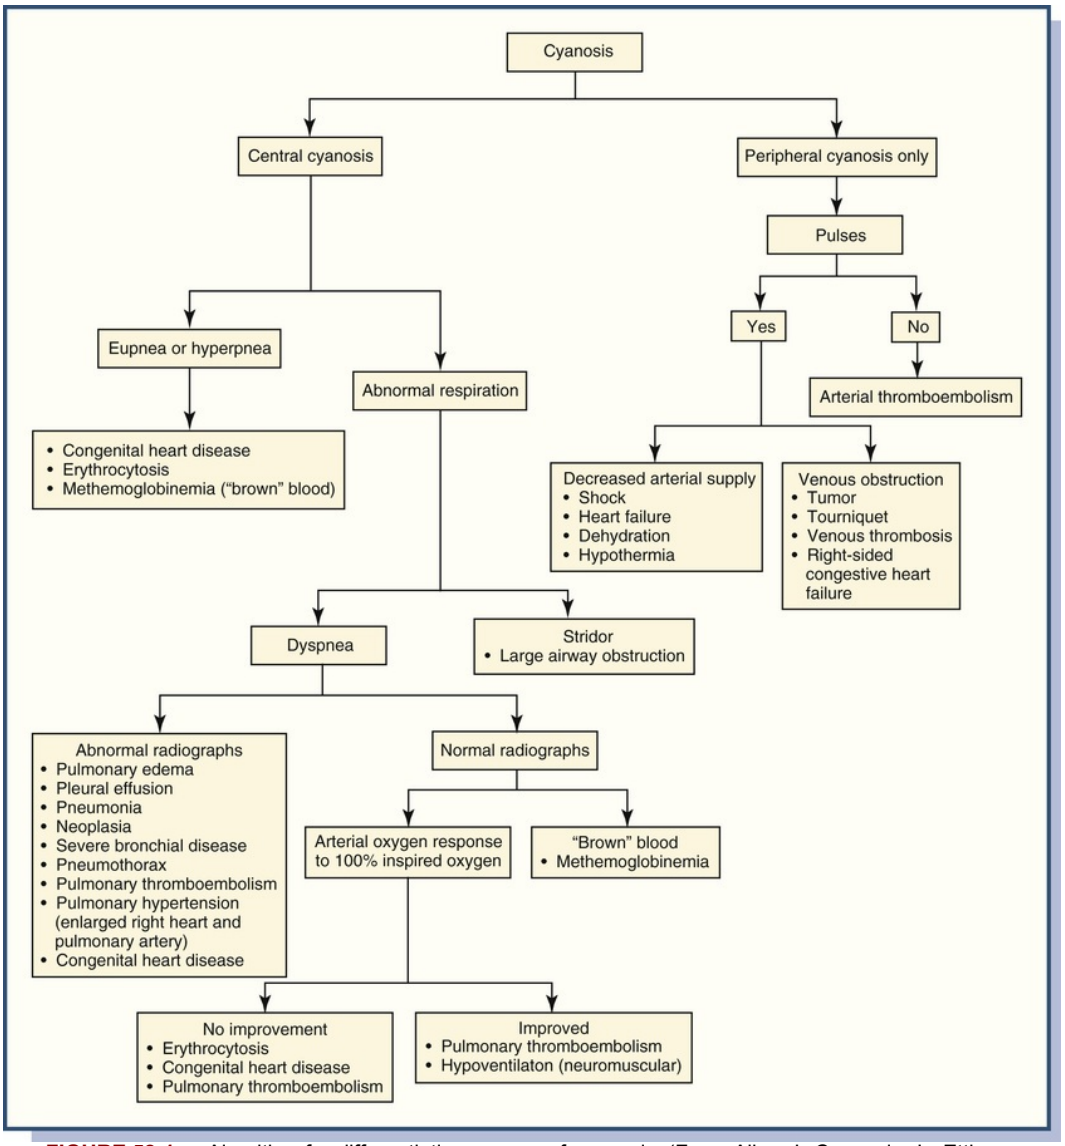

FIGURE 52-1 Algorithm for differentiating causes of cyanosis. (From Allen J: Cyanosis. In Ettinger SJ, Feldman EC, editors: *Textbook of veterinary internal medicine,* ed 7, St Louis, 2010, Elsevier, pp 283-286.)

FIGURE 52-2 Central cyanosis (cat on right; cyanosis especially visible on the nasal planum) due to right-to-left shunting in a cat with a ventricular septal defect. The cat on the left is normal, for comparison. (Courtesy Dr. Etienne Côté.)

Physiology and Pathophysiology

Cyanosis is generally detected when deoxygenated Hb exceeds 5 g/100 mL blood within *capillary* beds. However, *arterial* deoxygenated Hb need only reach 3-3.5 g/100 mL blood to cause detectable cyanosis. The amount of deoxygenated Hb depends on the Hb concentration and percent saturation of Hb in arterial blood (SaO_2), which is related to arterial oxygen tension (PaO_2). The alveolar oxygen tension (PAO_2) is approximately 100 mm Hg when breathing room air and SaO_2 is approximately 97%, resulting in a PaO_2 of approximately 95 mm Hg. When decreased inspired oxygen concentration results in decreased SaO_2, arterial deoxygenated Hb increases and cyanosis becomes clinically detectable when the 3-3.5 g/100 mL threshold is reached. In animals with normal hemoglobin concentrations (approximately 10 to 20 g/100 mL blood), SaO_2 must decrease to concentrations below 73-78% (PaO_2 <39-44 mm Hg) to produce consistently visible cyanosis. As a result, cyanosis is an insensitive indicator of blood oxygen content, and detection of cyanosis in animals without cyanotic heart disease indicates severe arterial hypoxemia. *Erythrocytosis* is a condition characterized by an elevated red blood cell (RBC) concentration, which in dogs and cats most commonly is secondary to conditions resulting in chronic hypoxemia, but may also be primary (see ch. 57). Animals with erythrocytosis have higher total Hb concentrations, making it easier for reduced hemoglobin to accumulate. For example, in an animal with a hematocrit of 65%, 5 g of deoxygenated Hb/100 mL blood may be present if SaO_2 drops below 89%. Conversely, in anemic animals, cyanosis is rarely present as an absolute reduction in hemoglobin means that SaO_2 must decrease to concentrations incompatible with life to produce cyanosis.

Causes of Central and Peripheral Cyanosis (Box 52-1; see also Figure 52-1)

Central cyanosis is most commonly caused by cardiovascular or pulmonary diseases resulting in arterial deoxygenation (hypoxemia). Causes of hypoxemia can be categorized by the type of pathophysiology present (see ch. 128).

Box 52-1

Causes of Central and Peripheral Cyanosis

Central Cyanosis

Pulmonary

- Ventilation-perfusion mismatch
  - Pulmonary infiltration
    - Edema
    - Inflammation/infection
    - Neoplasia
    - Acute respiratory distress syndrome (ARDS)
    - Chronic obstructive pulmonary disease or pulmonary fibrosis
    - Pulmonary contusions/hemorrhage
  - Pulmonary thromboembolism
- Hypoventilation
  - Pleural effusion, pneumothorax
  - Respiratory muscle failure (e.g., fatigue, myopathy, or neurologic abnormalities)
  - Intoxication (e.g., sedative or anesthetic overdose)
  - Primary neurologic disease (e.g., neoplasia, inflammatory)
- Obstruction
  - Laryngeal paralysis
  - Foreign body (e.g., laryngeal, tracheal)
  - Mass lesion of large airways (e.g., neoplasia, parasitic, inflammatory)
  - Inadequate oxygen concentration of inspired gas (e.g., high-altitude, anesthetic complication)

Cardiac (Right-to-Left Shunting)

- Extracardiac
  - Reversed-shunting patent ductus arteriosus (PDA) (differential cyanosis)
  - Pulmonary arteriovenous fistulas
- Intracardiac
  - Tetralogy of Fallot
  - Atrial or ventricular septal defect with pulmonic stenosis or pulmonary hypertension
  - Endocardial cushion defect
  - Pulmonary artery atresia
  - Right ventricular hypoplasia
  - Double outlet right ventricle
  - Transposition of great vessels
  - Non–Oxygen Carrying Hemoglobin (Hg) (e.g., Methemoglobinemia)

Peripheral Cyanosis

- Central cyanosis (e.g., congestive heart failure)
- Arterial thromboembolism
- Peripheral vasoconstriction (e.g., hypothermia, shock)
- Decreased arterial supply
- Low cardiac output
- Obstruction of venous drainage
  - Tourniquet or foreign object (i.e., rubber band)
  - Venous thrombosis
  - Right-sided congestive heart failure

Ventilation-perfusion mismatch is probably the most common cause of hypoxemia encountered in clinical practice. In pulmonary thromboembolic disease and in diseases causing pulmonary infiltration (e.g., edema, pneumonia, neoplasia, hemorrhage, fibrosis) alveolar ventilation and oxygen exchange are impaired, so that blood flowing to those areas is inadequately oxygenated. This creates a "physiologic shunt," as the deoxygenated blood mixes with the oxygenated blood returning from better-ventilated areas of lung.

Hypoventilation is another potential cause of decreased PaO_2, where alveoli are not ventilated due to elevated pleural pressure (pleural effusion or pneumothorax), depressed respiratory drive (neurologic disease, drug overdose), or respiratory muscle failure. *Obstructive causes* of hypoxemia, such as laryngeal paralysis or tracheal foreign body, result in decreased oxygen availability. *Venous-to-arterial shunts* (right-to-left congenital cardiac or extracardiac shunts) cause deoxygenated venous blood to mix with oxygenated arterial blood, which can result in hypoxemia and cyanosis (see Figure 52-2). If cyanosis is present in a young animal, congenital heart disease must be suspected. A right-to-left shunting patent ductus arteriosus (PDA) results in *differential cyanosis* due to the location of the shunt. Deoxygenated blood from the pulmonary artery is shunted through the PDA to the aorta distal to the brachiocephalic trunk and subclavian artery, producing cyanosis of the caudal portion of the body whereas the cranial part of the body is supplied by adequately oxygenated blood. Other congenital heart defects should be considered in central cyanosis, such as tetralogy of Fallot, atrial or ventricular septal defects or endocardial cushion defects with concomitant pulmonary hypertension or pulmonary stenosis, pulmonary artery atresia, hypoplastic right ventricle, double outlet right ventricle and transposition of great vessels (see ch. 250).

Methemoglobin is a normal product of hemoglobin oxidation, which is maintained at low concentrations (≈1% of total Hb) by the enzyme methemoglobin reductase within the erythrocytes. The percentage of methemoglobin may increase due to exposure to oxidants or if erythrocyte methemoglobin reductase is deficient. Oxidants resulting in methemoglobinemia include acetaminophen (Tylenol), benzocaine, methylene blue, phenazopyridine, nitrates, and nitrites. As methemoglobin is incapable of carrying oxygen, hypoxemia may occur. When the concentration of methemoglobin exceeds 10% of total Hb, a brown discoloration of arterial blood may be grossly visible. Methemoglobinemia may be detected as brown or chocolate colored mucous membranes.

Peripheral cyanosis occurs when there is inadequate oxygenation of peripheral capillary blood. This may be caused by desaturation of Hb in the arterial blood supply, i.e., any of the conditions causing central cyanosis, or result from excessive desaturation of Hb in peripheral tissues due to an imbalance between oxygen supply and the metabolic need of the tissue, due to a variety of causes. Peripheral cyanosis is most commonly due to arterial thromboembolism (saddle thrombus) and/or shock, or other causes including occlusion to venous drainage (such as a tourniquet) and hypothermia.

Evaluation of the Cyanotic Animal

Clinical differentiation of cyanosis is based on history, physical examination findings, and diagnostic testing. History may include exposure to toxicants (such as acetaminophen) or sedatives that may have caused hypoventilation. Physical examination includes assessment of the patient's respiratory pattern (tachypnea, dyspnea, paradoxical breathing pattern), as well as assessment of airway patency (see ch. 28). Stridor, if noted, is indicative of upper airway obstruction, which may necessitate emergency tracheostomy or endotracheal intubation. It is essential to establish whether or not the cyanosis is central or peripheral. Both cranial (oral mucous membranes and tongue) and caudal (vagina or preputium) aspects of the body should be examined for evidence of differential cyanosis suggesting the presence of right-to-left shunting PDA. Differential cyanosis may be associated with hind limb weakness often worsening with exercise. The causes of central cyanosis are often associated with abnormal findings on physical examination reflecting the etiology. Peripheral cyanosis may present with signs of acute lameness or paresis of the affected limb(s). Physical examination of these patients may reveal signs of thromboembolism (pain, pulselessness, pallor, palpable coolness, and paresis) of the affected limb(s), a mass or foreign body (i.e., rubber band) causing venous occlusion, or generalized peripheral cyanosis due to vasoconstriction that may respond to warming or massage of the extremities.

Diagnostic Tests

Arterial blood gas (ABG) analysis is the gold standard for evaluating central cyanosis (see ch. 128). Although venous samples can contribute information, arterial samples provide definitive evidence of abnormalities in SaO_2, PaO_2 and $PaCO_2$, and response to oxygen. ABG can be evaluated when the animal is breathing room air, but for maximal diagnostic information, oxygenated ABG values must be obtained while the animal is receiving 100 percent oxygen. Unfortunately, the latter generally requires anesthesia, which may not be tolerated in many patients with cyanosis.

Pulse oximetry, which approximates SaO_2, is readily available in most clinics for evaluation of central cyanosis (see ch. 128). If a satisfactory signal can be recorded, there is reasonably good correlation between

pulse oximetry estimates and invasive measurements of SaO_2 in dogs. PaO_2 values are extrapolated from SaO_2 using the dissociation curve for oxygen. It should be noted that the use of pulse oximetry does not allow differentiation between oxygenated Hb, carboxy Hb, methemoglobin and cyanide toxicosis. Results of pulse oximetry registration may be influenced by hypovolemia, vasoconstriction and severe anemia. Although pulse oximetry has important limitations, it can be useful to evaluate baseline oxygenation and response to oxygen supplementation when ABG analysis is not available or practical.

Differentiating between deoxygenated Hb and methemoglobin in dogs with central cyanosis can be readily accomplished by exposing venous blood to air. Deoxygenated Hb quickly turns bright red on exposure to air, whereas methemoglobin remains dark brown.

Erythrocytosis may indicate congenital heart disease or chronic hypoxemia (see ch. 57). Evaluation of *lactate concentrations* in different limbs may help diagnose differential cyanosis or peripheral cyanosis caused by thromboembolism or other causes of decreased arterial supply or impaired venous drainage (see ch. 70). In cats and dogs with acute arterial thromboembolism, peripheral venous blood glucose concentrations in the affected limb(s) have been reported to be decreased compared to central venous blood glucose concentrations (see ch. 256). *Thoracocentesis* can be both diagnostic and therapeutic for pleural effusion and pneumothorax, and should be performed prior to other diagnostic tests if paradoxical breathing pattern suggests the presence of free fluid or air within the pleural space (see ch. 102). *Thoracic radiography* is essential to differentiate the many causes of cyanosis, such as pulmonary edema, pneumonia, pleural effusion, pneumothorax, or bronchial disease. The necessity of radiography must however be weighed against patient stability. *Echocardiography* may be extremely helpful in identifying cardiac disease, pulmonary hypertension, and pleural or pericardial effusion. Bubble studies can help determine if right-to-left shunting lesions are present (see ch. 104). *Computed tomography* may be needed to diagnose pulmonary thromboembolism and may help to diagnose right-to-left shunting intracardiac and extracardiac lesions.

Treatment

Central cyanosis is a potentially life-threatening condition that requires immediate attention. Presence of a patent airway is confirmed or established and oxygen is administered immediately while basic stabilization and evaluation are performed (see ch. 131). Most animals with central cyanosis will improve with oxygen therapy. Hypoxemia and cyanosis due to hypoventilation, diffusion impairment, and ventilation-perfusion mismatch (unless severe) will show the greatest improvement. Subsequent treatment greatly depends on the underlying etiology of cyanosis. Supplementing oxygen is not helpful when cyanosis is caused by right-to-left shunting congenital heart disease, because the amount of venous blood reaching the arterial blood is not diminished. Most animals with cyanotic congenital heart disease are relatively comfortable at rest and emergency intervention is not necessary. Therapy of methemoglobinemia involves elimination of the cause and attempt to limit tissue injury. Methylene blue and N-acetylcysteine are recommended for acute therapy of methemoglobinemia (see ch. 151-153). Oxygen supplementation is not useful as methemoglobin cannot bind oxygen. In all cases in which oxygen is administered, repeated evaluation of mucous membranes and measurements of oxygen saturation and ABG values are used to assess efficacy of therapy.

Peripheral cyanosis, although often indicative of serious disease conditions, is usually not life-threatening and therapy is directed toward resolution of the underlying disease process.

CHAPTER 53

Jaundice

Christina Alanna Bradbury

Client Information Sheet: Jaundice: What It Means, Why It Happens and What to Do About It

Jaundice is defined as yellow discoloration of the sclera, skin and mucous membranes due to deposition of the pigment bilirubin. Icterus is another term used interchangeably with jaundice. Hyperbilirubinemia, however, is applicable whenever the serum bilirubin exceeds normal. When bilirubin serum levels rise above 2.0 mg/dL in a dog or cat, one is typically able to discern the yellow hue. "Jaundice" is not a disease; rather, it is a clinical manifestation of an underlying disease process. There is a multitude of disease processes that can ultimately result in jaundice. A basic understanding of bilirubin metabolism and excretion is essential for a methodical and logical clinical assessment and diagnostic approach.

Pathophysiology

Bilirubin is the terminal product of heme metabolism. Heme is liberated from hemoglobin when senescent or damaged erythrocytes are removed from the blood via the mononuclear phagocytic system of the spleen, liver and bone marrow. Within the mononuclear cell (typically a macrophage), the red oxygen-carrying pigment, heme, is cleaved by heme oxygenase, forming the green pigment biliverdin. Biliverdin is reduced by biliverdin reductase to bilirubin, which is then excreted into the blood in its unconjugated lipophilic form and transported to the liver bound to albumin. Additionally, some aging red blood cells are destroyed intravascularly and hemoglobin is released directly into the blood. Free hemoglobin is bound to haptoglobin and delivered as a complex to the hepatic reticuloendothelial system for degradation to unconjugated bilirubin.

Bilirubin passes through the sinusoidal surface membranes of hepatocytes by both passive and facilitated diffusion. Once within hepatocytes, lipophilic bilirubin is processed and "conjugated" into a water soluble form via glucuronidation. The water soluble, conjugated bilirubin is excreted into bile canaliculi by an ATP-dependent active transporter. Conjugated bilirubin is incorporated into bile, stored in the gallbladder, and excreted into the duodenum via the common bile duct. Within the intestinal tract, bilirubin is converted by bacterial flora into urobilinogen (colorless), urobilin (orange-red), stercobilinogen, and, finally, stercobilin, the pigment that imparts the brown color to feces. In complete biliary obstruction, feces lack these pigments and are grey- or clay-colored, termed "acholic." In normal homeostasis, the liver and biliary system process and excrete all bilirubin produced via heme metabolism. If any aspect of this system becomes overwhelmed or deranged, jaundice may result.

Causes of Jaundice

Separating causes of jaundice into three primary conditions is logical when assessing a patient: moderate to severe hemolysis (pre-hepatic), inability of hepatocytes to properly process and transport bilirubin out of the hepatocyte (hepatic), and the inability to excrete bile into the duodenum due to an obstruction (post-hepatic) (Box 53-1). Pre-hepatic jaundice is usually due to extravascular hemolysis as intravascular hemolysis produces only small amounts of bilirubin. Excessive production of bilirubin overwhelms hepatic absorption, processing, and excretion. Bilirubin then accumulates in the blood. The most common cause of pre-hepatic jaundice in dogs is immune mediated hemolytic anemia (IMHA). Some infectious diseases and immune-mediated destruction of erythrocytes also cause hemolysis in cats. Feline red blood cells are particularly sensitive to oxidative damage and hemolysis may follow another disease, such as hepatic lipidosis. Therefore, careful evaluation of the entire patient and clinical picture is always indicated. In both dogs and cats, intoxications (zinc, onions, acetaminophen), genetic disorders (pyruvate kinase deficiency, osmotic fragility

syndrome, etc.) and hypophosphatemia are less common causes of hemolytic anemia.

Box 53-1

Causes of Jaundice

Pre-hepatic (Hemolysis)

Immune-mediated hemolytic anemia
Infectious
- *Mycoplasma* spp., *Babesia* spp., *Cytauxzoon felis*

Heinz body anemia
- Toxins/drugs (acetaminophen, onions, zinc)
- Hepatic lipidosis

Hypophosphatemia
Genetic disorders
- Osmotic fragility syndrome, phosphofructokinase deficiency, pyruvate kinase deficiency

Hepatic

Infectious
- Viral (feline infectious peritonitis, canine adenovirus-1)
- Bacterial (*Leptospira* spp., *Salmonella* spp., rickettsial disease)
- Protozoal (*Toxoplasma gondii, Neospora caninum*)
- Fungal (histoplasmosis, coccidioidomycosis)
- Parasitic (*Heterobilharzia americana*, visceral larval migrans)

Inflammatory/immune-mediated disease
Toxins
- *Amanita* spp., aflatoxin, Sago palm, cyanobacteria

Drugs
- Carprofen, acetaminophen, azathioprine, methimazole

Neoplasia
Copper-associated hepatopathy
Lysosomal storage disease

Post-hepatic

Intraluminal bile duct obstruction
- Mucocele, cholelith, inflammation, stricture, neoplasia

Extraluminal bile duct obstruction
- Pancreatitis, neoplasia, lymphadenopathy, duodenal foreign body

Hepatic hyperbilirubinemia in both dogs and cats is associated with hepatocellular dysfunction, due to toxins (drugs [carprofen], *Amanita* spp., blue green algae, aflatoxin, xylitol; see ch. 152), immune-mediated or inflammatory conditions (see ch. 282 and 283), infectious disease (bacterial, fungal, protozoal, viral), neoplasia, or genetic abnormalities in copper metabolism (copper-associated hepatitis; see ch. 285). Hepatic lipidosis is a common cause of jaundice in cats. Lipidosis follows rapid mobilization of peripheral fat to the liver where the hepatocytes become overwhelmed and cell function is compromised. Cats have also been shown to develop mild hyperbilirubinemia in response to significant systemic inflammatory disease, especially sepsis. However, these cats do not usually become clinically jaundiced as the serum bilirubin concentration is usually <2.0 mg/dL.

Post-hepatic jaundice, obstruction of the biliary system, can occur from abnormalities within the biliary system or secondary to diseases affecting organs surrounding the biliary tree (see ch. 288). Obstruction may be partial or complete. Common intraluminal causes of extrahepatic biliary duct obstruction (EHBDO) in dogs include biliary mucocele, cholelithiasis, infection or neoplasia. Infectious cholangitis causing partial obstruction is more common in cats than dogs, and biliary mucoceles are exceedingly rare in cats. Extraluminal causes of EHBDO include pancreatitis, neoplasia, enlarged regional lymph nodes, or an intestinal foreign body at the level of the papilla. Regardless of cause, complete obstruction of the biliary system is a medical and surgical emergency.

Clinical Approach (Figure 53-1)

Signalment and a thorough history are extremely valuable. Signalment may offer clues to explain the cause of jaundice since certain breeds are predisposed to genetic disorders such as pyruvate kinase deficiency or copper storage disease. Age is important because, for example, an adult dog is far less likely to have canine adenoviral hepatitis than is an unvaccinated puppy. A complete history should include travel, ectoparasite exposure, current medications, possible environmental toxins, and vaccination history. A variety of drugs may cause hemolytic anemia or liver toxicosis. Appetite, water intake, urination and defecation may further elucidate the nature of the underlying problem. Establishing duration and progression of clinical signs may prove to be important. For example, a dog who was clinically healthy and now has acute vomiting and sudden onset of jaundice is more likely to have a biliary obstruction or IMHA than copper-associated hepatitis.

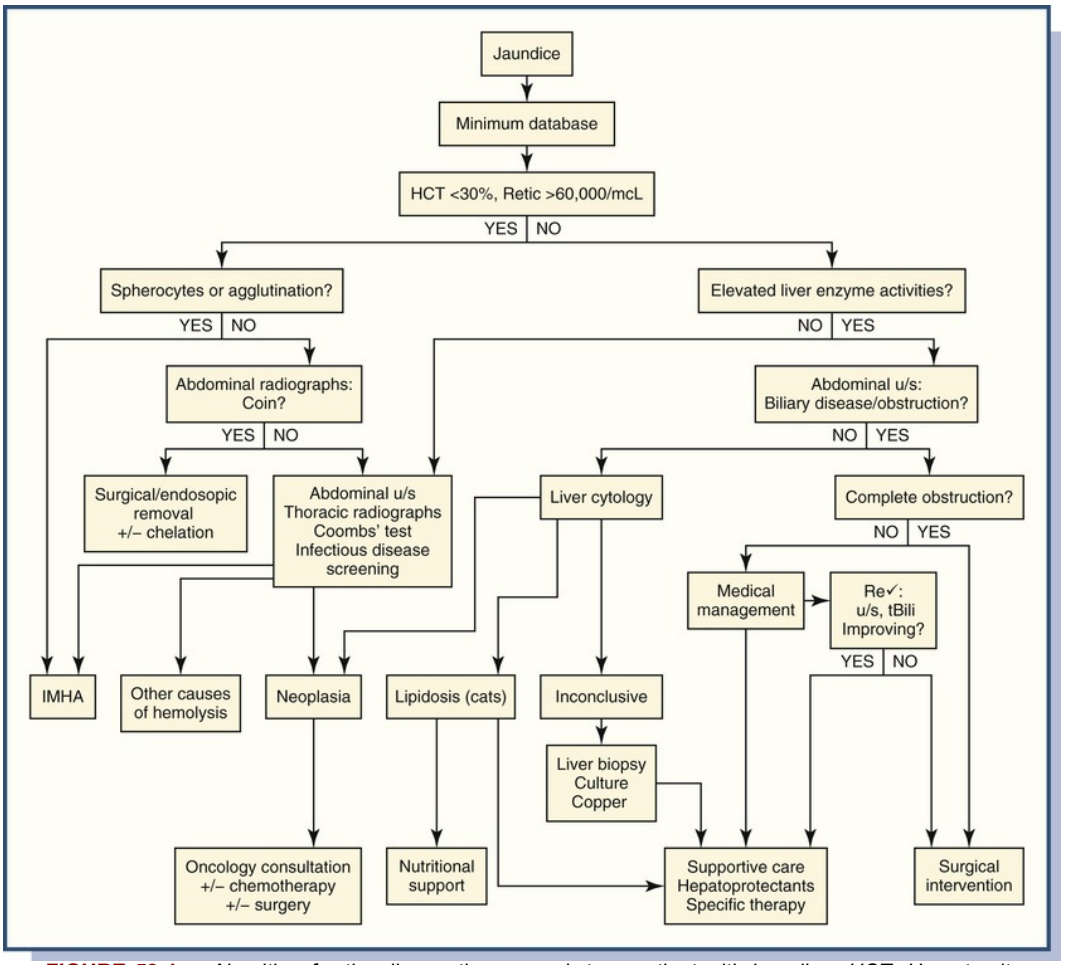

FIGURE 53-1 Algorithm for the diagnostic approach to a patient with jaundice. *HCT,* Hematocrit; *IMHA,* immune-mediated hemolytic anemia; *Retic,* reticulocyte; *tBili,* total bilirubin; *u/s,* ultrasound.

Results of a complete physical examination may further narrow the focus of the investigation. Careful attention to mucous membrane color, heart rate and pulse quality are essential in diagnosing anemia. Abdominal palpation may reveal hepatomegaly, cranial abdominal pain, masses or effusion. Fever is suggestive of an infectious or inflammatory process such as IMHA, pancreatitis, bacterial cholangitis or a ruptured gallbladder. Bleeding abnormalities can be associated with IMHA (Evans' syndrome, disseminated intravascular coagulation [DIC]), hepatic failure, and severe cholestasis; therefore, close inspection of the skin and mucous membranes may reveal petechiae or ecchymoses (see ch. 54). Rectal palpation may reveal melena or evidence of gastrointestinal (GI) bleeding secondary to drug exposure (for example, carprofen) and/or liver failure. A neurologic exam should be performed (see ch. 259), as hepatic encephalopathy may occur with hepatic lipidosis, acute liver failure and cirrhosis. In patients with hepatic encephalopathy, frequent neurologic exams should be performed, assessing response to therapy and progression of disease.

Information gathered from signalment, history and physical examination should aid in developing a prioritized list of differential diagnoses and the diagnostic approach. For example, pale mucous membranes, tachycardia, weakness, tachypnea and bounding pulses should lead the clinician to immediately assess the hematocrit in-hospital. Acute cranial abdominal pain, vomiting, fever, and dehydration are typical of biliary obstruction or pancreatitis and warrant aggressive diagnostic evaluation.

Diagnostic Plan

The classic "minimum data base" should be collected in any patient with jaundice. The complete blood count (CBC) should help identify and characterize the anemia, if present. Hemolysis typically causes a macrocytic, hypochromic, regenerative anemia while chronic liver disease may cause a microcytic, normochromic non-regenerative anemia. Microcytic hypochromic anemia is typically due to chronic blood loss, such as occurs with severe flea infestation or GI bleeding. Cats with hepatic lipidosis may develop a regenerative Heinz body anemia. Spherocytosis and autoagglutination confirm immune-mediated destruction of erythrocytes, and an inflammatory leukogram is often present. Thrombocytopenia may be noted with IMHA or DIC, which can develop secondary to liver failure or severe inflammatory states like pancreatitis or bile peritonitis.

The chemistry panel should include alkaline phosphatase (ALP), alanine aminotransferase (ALT), aspartate aminotransferase (AST), gamma-glutamyl transferase (GGT), cholesterol, blood urea nitrogen (BUN), albumin, glucose and bilirubin. Post-hepatic jaundice will generally reveal hyperbilirubinemia, marked cholestatic enzyme elevation (ALP, GGT), moderate to marked hypercholesterolemia, and moderate increases in "hepatocellular leakage enzymes" (ALT, AST). Liver function, as assessed with BUN, albumin and glucose are typically unremarkable unless other co-morbidities exist. In patients with hepatic jaundice, increases in serum ALT are similar to those in ALP, while BUN, albumin and glucose may be abnormal. IMHA may also cause increases in liver enzyme activity. An ALP > ALT coupled with a normal GGT in an obese, jaundiced cat is virtually pathognomonic for hepatic lipidosis. Bilirubinuria, proteinuria, glycosuria, or renal tubular casts may suggest multi-organ dysfunction requiring further investigation.

Abdominal imaging, with either radiographs or ultrasound, is valuable. Abdominal radiographs may show a penny or other foreign body causing zinc toxicosis, mass lesions or choleliths. Thoracic radiographs should be assessed for metastatic disease, pneumonia or other causes of secondary IMHA. Ultrasound is valuable for non-invasive evaluation of the biliary system and hepatic parenchyma. Splenomegaly is common in hemolytic anemia. Gallbladder content and wall thickness, liver morphology, the biliary tree, the pancreas, the surrounding mesentery and the surrounding lymph nodes should be carefully evaluated. Abdominal ultrasound may also identify incidental findings that alter recommendations and prognosis. Exploratory laparotomy is recommended when there is a persistently dilated common bile duct with increasing hyperbilirubinemia, biliary mucocele, gallbladder rupture, or cholelithiasis with evidence of obstruction. Without evidence of complete biliary obstruction, patients with suspected cholangitis or pancreatitis are treated medically. If cholangitis is suspected, ultrasound-guided fine-needle aspiration (FNA) of the gallbladder with culture of the bile is recommended to guide antimicrobial therapy. If cholangitis is suspected but culture is not possible, empirical antimicrobial therapy may be considered. If a partial obstruction is suspected, monitoring bilirubin and serial ultrasound exams may be useful indicators of response to therapy. If a hepatic cause of jaundice is suspected, cytology of an ultrasound-guided liver FNA is recommended (see ch. 89 and 93). Cytology is most useful in diagnosing diffuse infiltrative neoplasia and hepatic lipidosis. Liver biopsy may be recommended if cytology results are inconclusive.

Jaundice in any patient indicates a significant underlying pathologic process. Clearly, the etiologies are disparate. The veterinary clinician is encouraged to consider all aspects of the condition before recommending any tests. Often, with a logical approach and basic understanding of the underlying processes, it is possible to identify the cause and therefore make appropriate recommendations regarding treatment and prognosis.

CHAPTER 54

Petechiae and Ecchymoses

Shauna Blois

Client Information Sheet: Petechiae and Ecchymoses (Bruising)

Petechiae and *ecchymoses* are red to purple discolorations of the skin or mucosal surfaces, resulting from small blood vessel bleeding. Petechiae are typically <3 mm in diameter, resulting from capillary bleeding; ecchymoses are larger lesions caused by bleeding from small arterioles and venules. In human medicine, the term *purpura* is used for describing similar lesions (typically 3-10 mm in size). Signs of surface bleeding usually result from a platelet or blood vessel abnormality, but can be due to a more global bleeding disorder.

Pathophysiology

Blood vessel walls are lined by a single layer of endothelial cells, connected by tight junctions and anchored to a basal membrane. This selective barrier prevents the leakage of red blood cells from the circulation. The blood vessel has an active role in hemostasis. Under normal conditions, the endothelium expresses anticoagulant properties. Adequate numbers of circulating platelets help maintain endothelial structure and function. With vascular injury, the subendothelial matrix is exposed, allowing platelets to interact with collagen and other matrix molecules. Circulating platelets adhere to the site of the vascular defect, and recruit even more platelets to aggregate. Some of the major mediators of these processes include von Willebrand factor (vWF) and platelet integrin alpha-IIb–beta$_3$.[1] Coagulation proteins bind to and interact with phospholipids on activated platelet membranes of the platelet plug, accelerating and amplifying the coagulation reaction, eventually producing a fibrin clot.[2] The essential role of platelet-vascular interactions in maintaining hemostasis is illustrated when there is a quantitative or qualitative primary hemostatic disorder. Thrombocytopenia is the most common cause of petechiae and ecchymoses; thrombopathias and vascular diseases can also cause signs of surface bleeding.

Thrombocytopenia

Thrombocytopenia can be caused by increased platelet destruction, consumption, or sequestration, or can be secondary to decreased bone marrow production (see ch. 201). Immune-mediated thrombocytopenia (IMT) is the most common cause of severe thrombocytopenia in dogs. IMT is caused by antibodies directed against platelets (less commonly megakaryocytes), leading to platelet phagocytosis by the reticuloendothelial system. Primary IMT is idiopathic; secondary IMT can result from infectious, inflammatory, or neoplastic diseases, or drug therapy.[3] Primary IMT is rare in cats.[4] In addition to thrombocytopenia, IMT can cause platelet dysfunction.[5]

Disseminated intravascular coagulation (DIC) is a serious complication that can arise from various systemic diseases. Patients with DIC initially are hypercoagulable but the disorder can progress to a consumptive coagulopathy, resulting in thrombocytopenia and decreased circulating coagulation proteins. Clinical signs include petechiae, ecchymoses, and overt bleeding.[6] Other causes of platelet consumption include vasculitides.

Other causes of thrombocytopenia typically do not cause hemorrhage. Platelet sequestration can occur secondary to hepatomegaly, splenomegaly, hypotension, endotoxemia, and hypothermia. Moderate thrombocytopenia can result from hemorrhage.[7] Additional causes of thrombocytopenia include neoplasia and adverse drug reactions.[8]

Bone marrow diseases such as myelodysplasia can cause thrombocytopenia, as well other cytopenias.[9]

Bone marrow platelet production can be suppressed secondary to drugs, infections, and neoplasia.

In some conditions, thrombocytopenia can result from a combination of the factors stated above. For example, thrombocytopenia associated with rickettsial infections can be due to immune-mediated and non-immune-mediated platelet destruction, platelet consumption from vasculitis and DIC, splenic platelet sequestration, and decreased bone marrow platelet production.[10,11]

Thrombopathia

Platelet function defects can be inherited or acquired (see ch. 201). Inherited platelet dysfunctions have been reported in some dog breeds, including Glanzmann's thrombasthenia in Great Pyrenees Dogs and Otterhounds, thrombopathias of Basset Hounds and Spitz dogs, and delta-storage pool deficiency in American Cocker Spaniels.[12-16] Dogs with inherited platelet disorders can have a history of petechiae, ecchymoses, and other spontaneous bleeding, as well as increased hemorrhage after surgery or trauma. Inherited platelet dysfunction is rare in cats.

Platelet dysfunction can result secondary to infectious diseases such as rickettsial infections, hepatic disease, uremia, and neoplasia. Drugs such as aspirin and clopidogrel are used therapeutically to inhibit platelet function but petechiation, ecchymoses, and other signs of hemorrhage are rarely associated with therapy.[17,18] *In vitro* platelet dysfunction has been described secondary to various drugs and other agents including carprofen, hydroxyethyl starch solutions, and omega fatty acids, but clinical relevance is not known.[19-21]

Von Willebrand Disease

Von Willebrand disease (vWD; see ch. 201) is the most common inherited bleeding disorder in dogs, and is characterized by quantitative or qualitative defects in vWF. vWF molecules are essential for platelet adhesion to sites of vascular damage. Dogs with vWD form ineffective platelet plugs, leading to petechiae, ecchymoses, and other signs of mucosal and cutaneous bleeding.[22] vWD is rare in cats.[23]

Vascular Disorders

Signs of surface bleeding in patients with a normal platelet count and normal platelet function are suggestive of a vascular disorder. Immune-mediated vasculitis causes inflammatory changes to the blood vessel wall, and can result in edema, ecchymoses, and hemorrhage either spontaneously or after mild trauma. Progressive clinical signs include ulcerative and necrotic skin lesions, as well as pain. Vasculitis can be a primary immune-mediated event, or it can occur secondary to a variety of medications, infections, neoplastic conditions, and other diseases.[24]

Diagnostic Approach

A thorough patient history is essential in diagnosing primary hemostatic disorders. A patient or familial history of bleeding tendencies is suggestive of an inherited platelet disorder. A complete medication history is essential to rule out drug-associated thrombocytopenia, thrombopathia, and vascular disorders. Recent vaccination, tick exposure, travel history, and other current or previous medical history are relevant.

Platelet and vascular disorders can occur secondary to a wide spectrum of conditions. A detailed physical examination will help identify not only the extent of hemorrhage, but also signs of underlying disease. Petechiae are most commonly found on the inner pinnae, ventral abdominal and inguinal skin, and mucous membranes of the oral cavity and genitalia (E-Figure 54-1). Ecchymoses are most commonly found on ventral abdominal and inguinal skin, as well as over sites of recent venipuncture (E-Figure 54-2). Other clinical signs of primary hemostatic defects include gingival bleeding, gastrointestinal hemorrhage (hematemesis, melena, hematochezia), hematuria, epistaxis, ocular hemorrhage, and hematoma formation.[3,4] Excessive bleeding during or immediately after surgical procedures or minor trauma is observed in dogs with significant platelet disorders. Clinical signs unrelated to thrombocytopenia depend on the presence of an underlying disease, such as polyarthritis, hemolytic anemia, and proteinuria, suggestive of a systemic immune-mediated disorder.

E-FIGURE 54-1 Petechiation of the pinna of a dog with immune-mediated thrombocytopenia.

E-FIGURE 54-2 Marked ecchymoses on the ventral abdomen/inguinal area of a dog with immune-mediated thrombocytopenia.

The diagnostic approach to patients with petechiae and ecchymoses should begin with a platelet count (Figure 54-3). When thrombocytopenia is detected on a complete blood count, a blood smear should be reviewed to rule out analytical error (e.g., platelet clumping from suboptimal venipuncture), especially in cats.[25,26] In an emergency, a platelet count is estimated from the blood smear by multiplying the number of platelets per high powered field (1000× magnification) by 15-20,000/mcL.[27] The risk of spontaneous bleeding progressively increases as the platelet count declines below 30,000/mcL. Most IMT cases have platelet counts <10,000/mcL.[3,28]

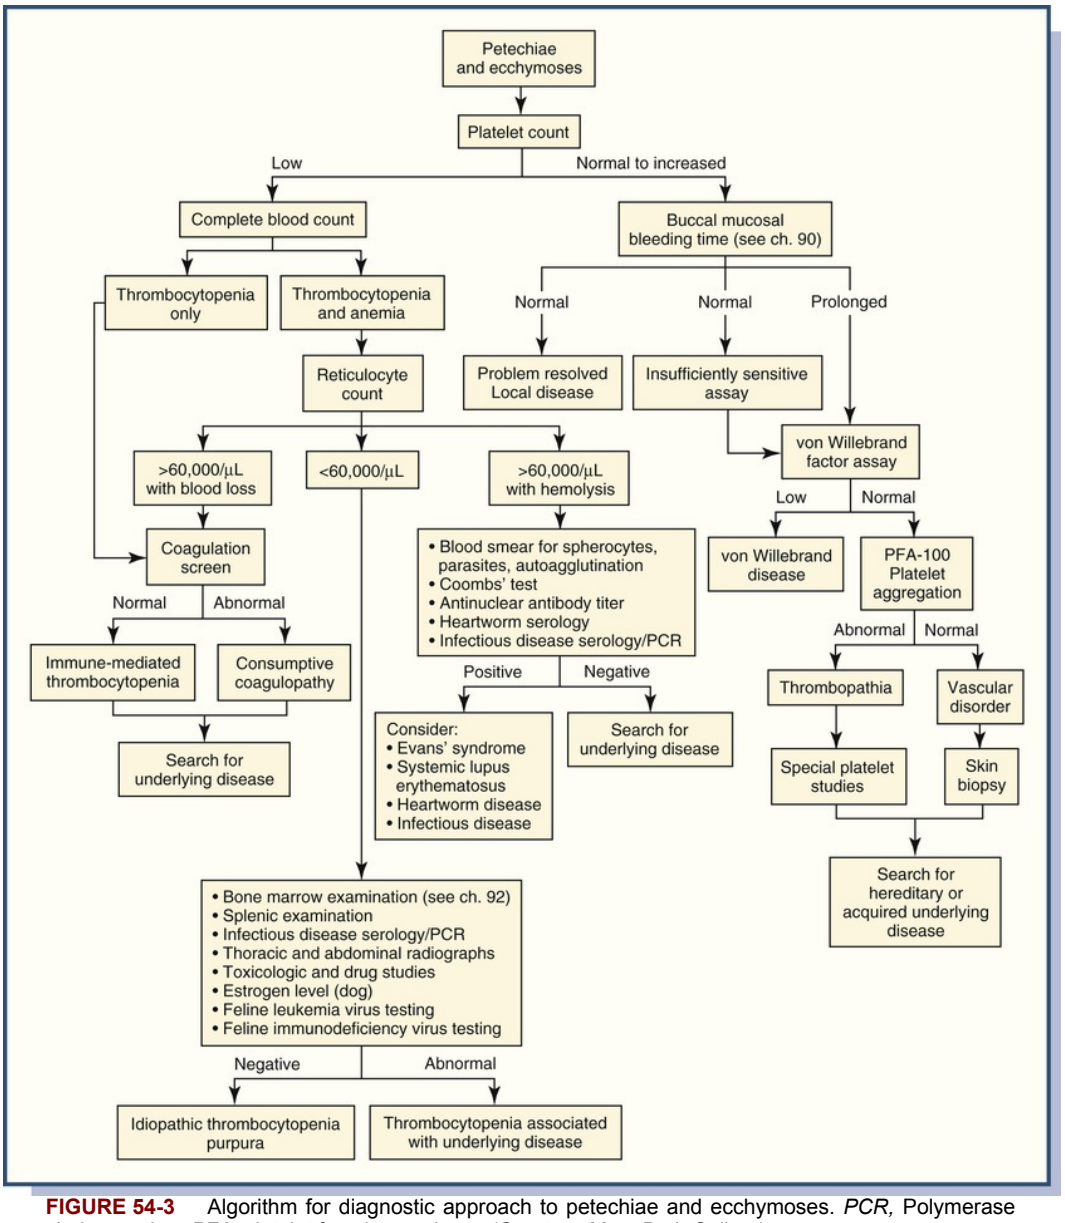

FIGURE 54-3 Algorithm for diagnostic approach to petechiae and ecchymoses. *PCR*, Polymerase chain reaction; *PFA*, platelet function analyzer. (Courtesy Mary Beth Callan.)

Other information from the blood smear and complete blood count may be suggestive of the cause of thrombocytopenia. Immune-mediated thrombocytopenia is diagnosed after ruling out other possible causes of thrombocytopenia. Increased mean platelet volume (MPV), platelet distribution width (PDW), or numbers of reticulated platelets could reflect increased megakaryopoiesis and release of large platelets into circulation of patients with IMT.[29,30] Concurrent anemia and thrombocytopenia can be due to blood loss, combined immune-mediated hemolytic anemia (IMHA) and IMT, or bone marrow disease. Presence of anemia plus red blood cell agglutination and/or spherocytosis is suggestive of concurrent IMHA. Presence of schistocytes on

the blood smear is suggestive of DIC. Pancytopenia is indicative of bone marrow disease, such as myelodysplasia or myelophthisis. When possible, jugular venipuncture should be avoided in patients with a suspected platelet defect or coagulopathy, due to the potential of large hematoma formation in an area that is not amendable to effective manual compression.

A coagulation profile (prothrombin and activated partial thromboplastin times; PT and aPTT, respectively) should be performed to rule out a combined coagulopathy (e.g., DIC) as the cause of bleeding. Prolongation of PT and/or aPTT in conjunction with thrombocytopenia and elevated fibrinogen degradation products or D-dimers is suggestive of DIC.[31] Activated clotting time (ACT) can be assessed to evaluate coagulation protein activity. Marked thrombocytopenia can prolong ACT due to decreased levels of phospholipid available to support clotting.

Bone marrow aspirate and biopsy (see ch. 92) can help rule out primary bone marrow disorders as the cause of thrombocytopenia, especially in patients with other cytopenias or atypical cells in circulation. Bone marrow aspirate and biopsy generally is unrewarding in patients with primary IMT, but should be considered in patients not responsive to therapy.[32] Marked thrombocytopenia is not a contraindication to bone marrow sampling, as excessive hemorrhage at the entry site is rare.

Platelet Function Tests

Platelet function should be evaluated when platelet count is normal in patients with petechiae and ecchymoses. Buccal mucosal bleeding time (BMBT) evaluates *in vivo* platelet-vascular interactions (see ch. 80). Normal BMBT is <4 minutes in dogs and <2 minutes in cats. Thrombopathias, vWD, and vascular disorders can prolong BMBT. BMBT will be prolonged in thrombocytopenic patients, and is contraindicated if platelet count is known to be low. Anemia alone can increase bleeding potential, and may influence BMBT results in the absence of primary hemostatic disorders.[33]

Because vWD is the most common inherited bleeding disorder in dogs, this disorder should be ruled out before additional platelet function testing is performed. The platelet function analyzer (PFA-100, PFA-200) is a point-of-care test that can be used for identifying platelet disorders and vWD.[34,35] Testing for vWD is necessary to differentiate an abnormal result from a primary platelet disorder. However, replacement of the patient's plasma with that from a normal dog will correct PFA results in cases of vWD but not in cases of a primary platelet disorder.[36] Anemia and thrombocytopenia prolong PFA results.[37]

Genetic testing is available for vWD and some other platelet defects. Other specialized tests (platelet aggregometry, flow cytometry) may be required to diagnose other platelet defects, but are not widely available.

Treatment

Treatment of platelet disorders is variable depending on the underlying cause. Dogs suspected to have IMT might initially be treated with doxycycline in addition to immunosuppressive therapy if they live in, or have traveled through, a region that has a high prevalence of rickettsial diseases causing thrombocytopenia. Medications that could cause thrombocytopenia (e.g., sulfa antibiotics, methimazole) should be discontinued.

Thrombocytopenic or thrombocytopathic patients uncommonly require blood transfusion support. Patients with critical hemorrhage may benefit from red blood cell transfusion (see ch. 130). Platelet transfusion usually is not indicated, due to the limited lifespan of transfused platelets, especially in IMT patients. However, if animals are showing signs of life-threatening hemorrhage (especially central nervous system hemorrhage or uncontrolled blood loss), platelet transfusion using fresh whole blood, platelet concentrate, or platelet-rich plasma can provide short term benefit while therapy directed at the underlying disorder is initiated (see ch. 130).[28]

CHAPTER 55

Abnormal Heart Sounds and Heart Murmurs

Robert Prošek

Cardiac auscultation is an important tool in the clinician's armamentarium. Interpretation of heart and lung sounds is predicated on the clinician's understanding of their genesis in health and a variety of clinical disorders. Cardiovascular sounds of short duration are referred to as *transient heart sounds* and include the normally heard first heart sound (S_1) and second heart sound (S_2) (Audio 55-1). Heart murmurs are auditory vibrations of longer duration created when laminar flow is disrupted.

Implementing good technique with a quality stethoscope is fundamental. During auscultation the animal should be standing or sitting in a quiet environment. Both sides of the thorax should be carefully auscultated using the stethoscope's diaphragm and bell with special attention to the areas overlying the cardiac valves. The clinician should correlate the various heart sounds to the events of the cardiac cycle. A good orientation is palpation of the precordial impulse (left apex beat) that occurs just after S_1, and the arterial pulse that is felt between S_1 and S_2.

Transient Heart Sounds

The First (S_1) and Second (S_2) Heart Sounds

The first heart sound (Figure 55-1) is associated with closure and tensing of the atrioventricular valves (mitral and tricuspid) at the onset of systole coinciding with the QRS complex on the electrocardiogram. S_1 is longer, louder, and lower pitched than the second heart sound. Causes of increased intensity of S_1 include thin chest wall, tachycardia, high sympathetic tone, systemic arterial hypertension, and anemia. Diminished intensity of S_1 may be auscultated in animals with obesity, pleural or pericardial effusion, diaphragmatic hernia, dilated cardiomyopathy, hypovolemia, emphysema, or a prolonged P-R interval. Splitting of S_1 is occasionally auscultated at the cardiac apex in healthy, large-breed dogs or may result from electrical disturbances (ectopic beats, bundle branch blocks, cardiac pacing) or mechanical factors (tricuspid or mitral stenosis).

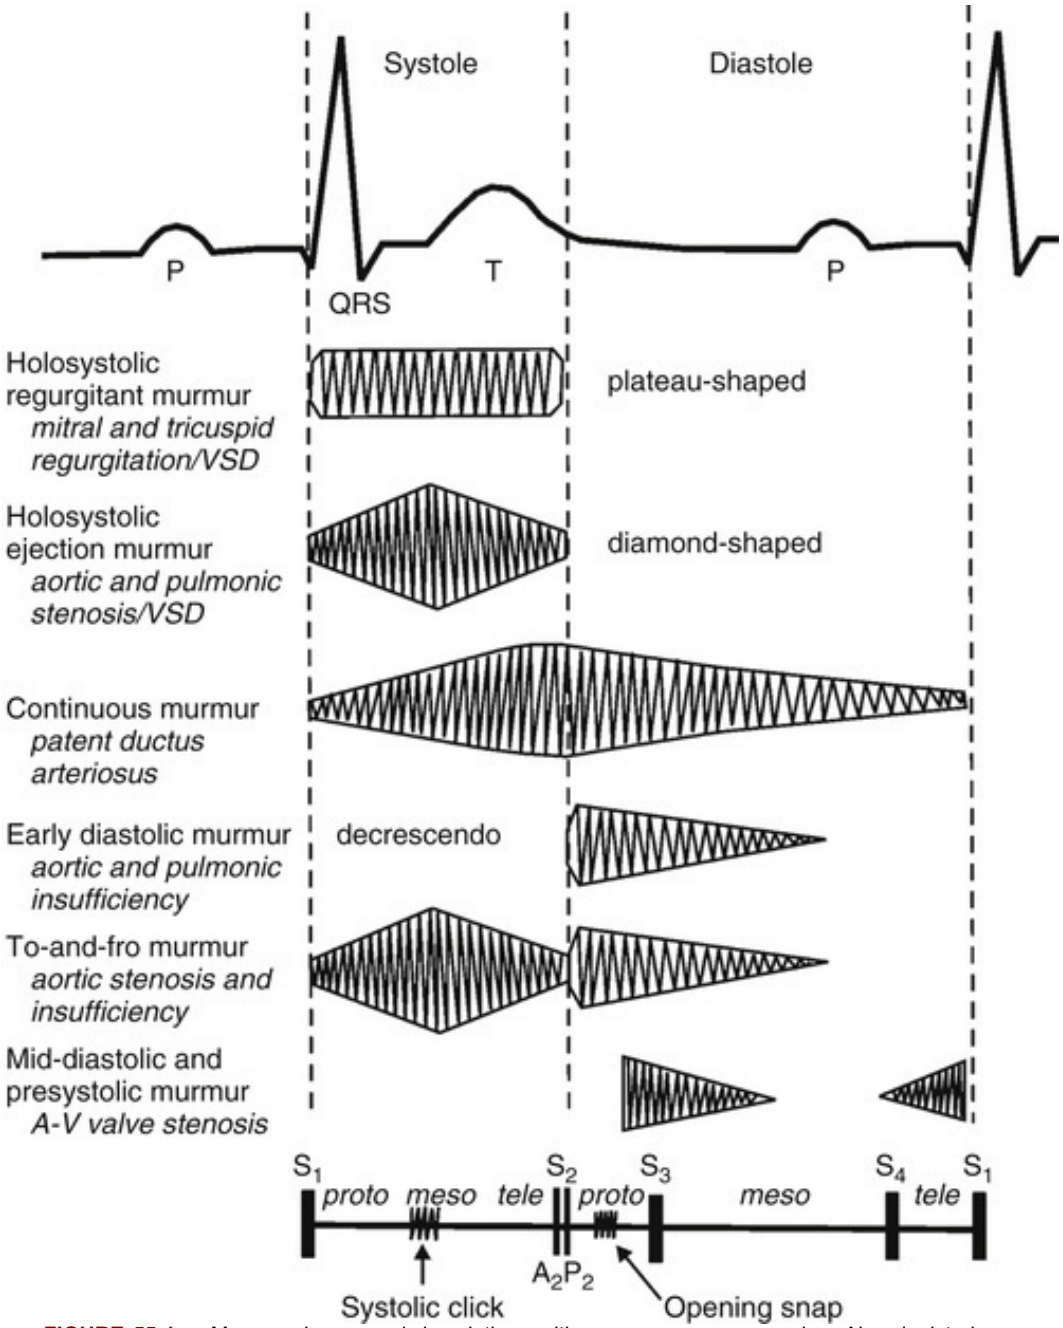

FIGURE 55-1 Murmur shapes and descriptions with some common examples. Also depicted are normal and abnormal transient heart sounds and their location within the cardiac cycle. *A_2,* Aortic valve closure; *A-V,* atrioventricular; *meso,* mid; *P_2,* pulmonic valve closure; *proto,* early; *S_1,* first heart sound; *S_2,* second heart sound; *S_3,* third heart sound; *S_4,* fourth heart sound; *tele,* late; *VSD,* ventricular septal defect.

The second heart sound (see Figure 55-1) is associated with closure of the semilunar valves (aortic and pulmonic) at the end of systole following the T wave on the electrocardiogram. In dogs and cats, pulmonic valve (P_2) closure follows aortic valve (A_2) closure by a very short interval, which causes S_2 to be heard as a single sound. On occasion an audible, split second heart sound may be seen in healthy, large-breed dogs during inspiration due to a longer right ventricular ejection period. Pathologic splitting of S_2 occurs with heartworm disease (Audio 55-2), primary pulmonary hypertension and right-to-left patent ductus arteriosus.

Delayed closure of P_2 also occurs with left-to-right intracardiac shunts (atrial septal defects), pulmonic stenosis, right bundle branch block, ectopic beats, and ventricular pacing. Premature A_2 closure can on

occasion be noted with mitral insufficiency and mitral stenosis. Paradoxical splitting of S_2 results from delayed closure of the aortic valve and is sometimes audible in dogs with aortic stenosis, left bundle branch block, ectopic beats, and systemic hypertension.

The Third (S_3) and Fourth (S_4) Heart Sounds

The third and fourth heart sounds occur during diastole and are not audible in normal dogs and cats. S_3 and S_4 heart sounds are of lower frequency than S_1 and S_2 and are usually best heard with the bell of the stethoscope. When heard, S_3 and S_4 may sound like the triple cadence of a galloping horse (Audio 55-3).

The term *gallop rhythm* should probably be avoided because the presence of an audible S_3 or S_4 has nothing to do with the heart's underlying electrical rhythm. Rapid ventricular filling generates the S_3 sound, also known as *S_3 gallop, protodiastolic gallop,* or *ventricular gallop*. An audible S_3 (Audio 55-4) is most commonly heard with diastolic volume overloading as in dilated cardiomyopathy, patent ductus arteriosus, and mitral insufficiency. In dogs with mitral insufficiency, the S_3 gallop may be mistaken for the second heart sound if a loud pansystolic (holosystolic) murmur extends through the second heart sound. Protodiastolic gallop sounds in cats are most commonly associated with dilated cardiomyopathy, anemia, and hyperthyroidism.

The presystolic gallop, also called *S_4 gallop* or *atrial gallop,* is heard just before S_1 and occurs just after the P wave on the electrocardiogram. This low-frequency sound is generated by blood flow into the ventricles during atrial contraction; hence the absence of S_4 gallops with atrial fibrillation. An audible S_4 (Audio 55-5) in the cat and dog is usually associated with increased ventricular hypertrophy and stiffness and is sometimes audible in animals with third-degree atrioventricular block.

At fast heart rates, rapid ventricular filling and atrial systole transpire very close together, which makes differentiation between S_3 and S_4 impossible. The resulting single accentuated sound is referred to as a summation gallop.

Ejection Sounds, Systolic Clicks, Opening Snaps, and Pericardial Knocks

Ejection sounds are left basilar high-frequency sounds generated by opening of the semilunar valves or dilatation of the great vessels during early systole. These sounds are occasionally noted in pulmonic stenosis, aortic stenosis, tetralogy of Fallot, and heartworm disease. Systolic clicks are mid to late high frequency sounds usually heard best over the mitral valve area (Audio 55-6). Systolic clicks are occasionally associated with degenerative valvular disease, mitral valve prolapse, and mitral dysplasia. The genesis of the sound in dogs is uncertain but is likely caused by the sudden tensing of redundant valve leaflets or elongated chordae tendineae as they buckle into the left atrium. A systolic click should be differentiated from a split (hear Audio 55-2) or gallop heart sound (hear Audio 55-3). Pericardial knocks are uncommon early diastolic sounds caused by restrictive pericardial disease. Timing of the sound is similar to S_3 and appears to be generated by abrupt restriction to ventricular filling by a diseased pericardium. See Figure 55-1 for timing of transient heart sounds and description of murmurs.

Cardiac Murmurs

Cardiac murmurs represent sounds of longer duration than the transient heart sounds. Cardiac murmurs are caused by turbulent blood flow in the heart or adjacent blood vessels created upon disruption of normal laminar flow. The development of turbulent blood flow can be created by high-velocity flow, flow from narrow restricted area into a larger area, or low blood viscosity. The relationship of cardiac murmurs and flow velocity, vessel size, and blood viscosity is defined by the Reynolds number. When the number reaches a critical high level, blood flow becomes turbulent.

$$\text{Reynolds number} = (\text{Radius})(\text{Velocity})(\text{Density}) \div \text{Viscosity}$$

Murmurs can be characterized and described by their timing within the cardiac cycle (systolic, diastolic, portions thereof), location (point of maximal intensity), radiation, intensity (loudness), shape, and frequency

(pitch).

Timing

Systolic murmurs may start immediately at the first (S_1) heart sound and last through the second (S_2) heart sound (pansystolic murmur), may start immediately after S_1 and last until S_2 (holosystolic), or may occur in early (protosystolic), mid (mesosystolic), or late (telesystolic) systole. Diastolic murmurs most commonly occur in early diastole (protodiastolic), throughout diastole (holodiastolic), or can occasionally be audible only at the end of diastole (presystolic).

Location and Radiation

The location of a murmur refers to the valve area at which the murmur is heard best (point of maximal intensity). Alternatively, location can be described simply by the terms *apex* or *base* (e.g., left apex or mitral valve area). Some murmurs may also radiate to other areas, yielding important clues as to the source of the murmur. For example, the murmur of subvalvular aortic stenosis (point of maximal intensity [PMI] at left heart base) may radiate to the ventral neck area due to turbulence in the carotid arteries and may also be heard on the right cranial thorax.

Intensity (Loudness)

The intensity of the murmur is commonly graded on a 1 to 6 scale, with grade 1 murmur the softest and grade 6 the loudest (Box 55-1).

Box 55-1

Grading of Cardiac Murmurs

Grade 1: Very soft, localized murmur detected in a quiet room after intently listening for a few minutes
Grade 2: Soft murmur but easily heard after a few seconds
Grade 3: Moderate-intensity murmur
Grade 4: Loud murmur but not accompanied by a palpable thrill (vibration)
Grade 5: Loud murmur accompanied by a palpable thrill
Grade 6: Very loud murmur that produces a palpable thrill still audible after stethoscope is removed from the chest

A grade 1 murmur is the faintest murmur and is heard in a quiet environment with particular effort, whereas grade 5 and 6 murmurs are associated with palpable vibrations on the chest wall (palpable thrill). The intensity of the murmur at its origin is determined by blood flow velocity and the rate of flow (velocity × flow = force). The intensity of the murmur at the body surface is affected by direction of the turbulent jet, character of tissue between auscultation area and the turbulent jet, and the frequency of the murmur. Often the intensity of a heart murmur is not directly correlated with the severity of a lesion. However, describing the loudness of a murmur is important for serial examinations, and in certain heart diseases at least a rough correlation exists.

Pitch (Frequency)

A murmur's quality and pitch relate to its frequency components, which may be high, medium, low, or of mixed frequency. Most murmurs consist of midrange mixed-frequency sounds. On occasion high-frequency musical tones or low-frequency “honks” are auscultated. Musical murmurs (whoops) are most commonly identified in dogs with modest mitral valve disease.

Shape

Heart murmurs are often described by their frequency profile within the cardiac cycle in relation to their shape on a phonocardiogram. Terms that are commonly used include *plateau-* or *band-shaped murmurs* for those murmurs of equal intensity throughout their duration; *decrescendo* for murmurs that gradually taper off

from an initial peak; and *crescendo decrescendo* (diamond-shaped, ejection murmur) for murmurs that build up to a peak intensity and then taper in intensity.

Systolic Heart Murmurs

Mitral Insufficiency

The murmur of mitral insufficiency is best heard at the left apex (mitral valve area) and commonly radiates dorsally and to the right thorax, making reliable diagnosis of tricuspid regurgitation difficult.

The characteristic murmur is plateau (band-shaped) and holosystolic; however, in its early stages the murmur may be protosystolic and with mitral valve prolapse the murmur may develop in mid- to late-systole. A mitral insufficiency murmur is typically of mixed frequency and harsh sounding (Audio 55-7), but it may be high-pitched or musical (whooping) in quality (Audio 55-8).

Mitral insufficiency can be caused by chronic degenerative valvular disease (endocardiosis), endocarditis, hypertrophic obstructive cardiomyopathy, congenital malformations, and diseases that cause left heart enlargement and dilation of the mitral annulus (e.g., patent ductus arteriosus, dilated cardiomyopathy).

Tricuspid Insufficiency

The murmur of tricuspid insufficiency sounds similar to that of mitral insufficiency but is loudest over the right apex (tricuspid valve area). It is often difficult to distinguish tricuspid insufficiency from a radiating murmur of mitral insufficiency. Tricuspid murmurs might be a different pitch compared with a radiating mitral murmur and can be accompanied by jugular pulsations. Tricuspid insufficiency can result from congenital malformations of the valve, chronic degenerative valve disease, or any disorders that cause marked right heart enlargement and valve annulus distention, such as pulmonary hypertension and arrhythmogenic right ventricular cardiomyopathy. Tricuspid valve endocarditis is extremely rare in dogs and cats.

Aortic Stenosis

Valvular and subvalvular aortic stenosis (SAS) produce a systolic ejection (crescendo-decrescendo) murmur that is usually best heard at the left heart base (Audio 55-11).

The murmur is usually of mixed frequency and harsh, and it sometimes radiates towards the right cranial thorax and up the neck along the carotid arteries. Mild obstructions cause soft murmurs that are difficult to distinguish from innocent or functional murmurs. Murmurs that vary dramatically in intensity with exercise or excitement should prompt consideration of a dynamic left ventricular outflow tract obstruction. Dynamic outflow tract obstruction is the most common type of ejection murmurs in cats with hypertrophic cardiomyopathy and its onset and duration coincide with systolic anterior motion of the mitral valve (Audio 55-9). Dynamic left ventricular outflow tract obstruction occurs uncommonly in dogs as an isolated abnormality or in association with mitral valve dysplasia or hypertrophy of the interventricular septum.

Pulmonic Stenosis

The pulmonic stenosis murmur is typically a high-frequency crescendo-decrescendo (ejection) holosystolic murmur, best heard at the left heart base over the pulmonic valve (Audio 55-10). The murmur can be very similar to the aortic stenosis murmur (hear Audio 55-8) described above but should not radiate along the carotid arteries. As the pressure gradient between the right ventricle and pulmonary artery increases, the murmur intensity becomes louder and peaks later in systole.

Ventricular Septal Defect

Ventricular septal defects (VSDs) produce murmurs that vary tremendously in shape and quality. Most often the murmur is a harsh, mid- to high-frequency holosystolic murmur best heard on the right cranial thorax (Audio 55-18).

Murmur intensity may be reduced when the VSD is large and as pulmonary hypertension develops. With severe pulmonary hypertension, the murmur may be entirely absent and splitting of the second heart sound is noted (hear Audio 55-2).

Atrial Septal Defect

Heart murmurs in dogs and cats with an atrial septal defect (ASD) result from increased flow across the pulmonic valve as a result of the left to right shunting. This murmur resembles that of mild pulmonic stenosis but is often accompanied by a fixed splitting of the second heart sound. Flow across the atrial septal defect is usually not audible.

Physiologic and Innocent Murmurs

Functional (physiologic) murmurs are usually caused by decreased blood viscosity or increased cardiac output. Physiologic murmurs are most often noted in animals with anemia, fever, pregnancy, hyperthyroidism, thin thoracic walls, and increased sympathetic tone. These murmurs usually are proto- to mesosystolic, soft to moderate intensity (grade 1/6 to 3/6), and loudest at the left heart base (Audio 55-12). They tend not to radiate extensively.

Innocent murmurs should disappear as the dog matures and appear to be the result of larger stroke volumes in puppies for the size of their great vessels in comparison with adult dogs.

In some cats, turbulent blood flow can be noted in the region of the right ventricular outflow tract, often causing a soft systolic apical sternal murmur ranging in grades from 1 to 3/6, with no evidence of structural heart disease and little clinical consequence (Audio 55-13).

Diastolic Heart Murmurs

Aortic Insufficiency

The murmur of isolated aortic insufficiency is typically a decrescendo murmur starting at the time of S_2 and extending variably into diastole (Audio 55-14).

In young dogs, aortic insufficiency can occur as an isolated defect or in combination with subaortic stenosis or a ventricular septal defect. Detection of aortic insufficiency in an adult dog or cat should prompt consideration of bacterial endocarditis.

When the regurgitant volume is large, the diastolic murmur is often accompanied by a soft mesosystolic ejection murmur, creating a distinct "to-and-fro" murmur (Audio 55-15).

The systolic ejection component tapers off in late systole and allows recognition of S_2 and differentiation from a continuous murmur. Other causes of "to-and-fro" murmurs include ventricular septal defects that cause loss of aortic root support and pulmonic valve stenosis and significant pulmonic insufficiency (rare). Occasionally massive aortic regurgitation causes premature closure of the mitral valve producing functional mitral stenosis and a diastolic murmur referred to as an *Austin Flint murmur*.

Pulmonic Insufficiency

The murmur of pulmonic insufficiency is similar to that of aortic insufficiency; however, clinically significant pulmonic insufficiency is uncommon. It is sometimes detected in animals with pulmonary hypertension, pulmonic valve dysplasia, or idiopathic dilation of the pulmonary artery.

Mitral Stenosis

The diastolic murmur of mitral stenosis is difficult to recognize in dogs and cats. This low-frequency murmur begins in mesodiastole and has presystolic accentuation due to atrial contraction (Audio 55-16). Mitral stenosis might be accompanied by other cardiac malformations, which cause murmurs such as valvular or subvalvular aortic stenosis. In dogs, mitral stenosis may be more common in breeds that are prone to congenital mitral valve malformations such as the Bull Terrier breed, in which it is often associated with aortic stenosis (see ch. 250).

Continuous Murmurs

The most common cause of a continuous murmur at the left heart base is patent ductus arteriosus (PDA). This classic "machinery-like" murmur of a PDA is usually audible throughout the cardiac cycle with peak intensity near S_2 (Audio 55-17).

The intensity of the murmur is diminished in late diastole in dogs with very slow heart rates and the diastolic component can also disappear with the development of pulmonary hypertension. Less common causes of continuous murmurs include aorticopulmonary windows, ruptured aneurysms of sinus of Valsalva, and coronary arteriovenous fistulas.

Auscultation and Beyond

Historical findings may suggest underlying heart disease; however, a thorough auscultation with identification and understanding of abnormal heart sounds and their genesis will permit recognition of the most likely cause (Figure 55-2).

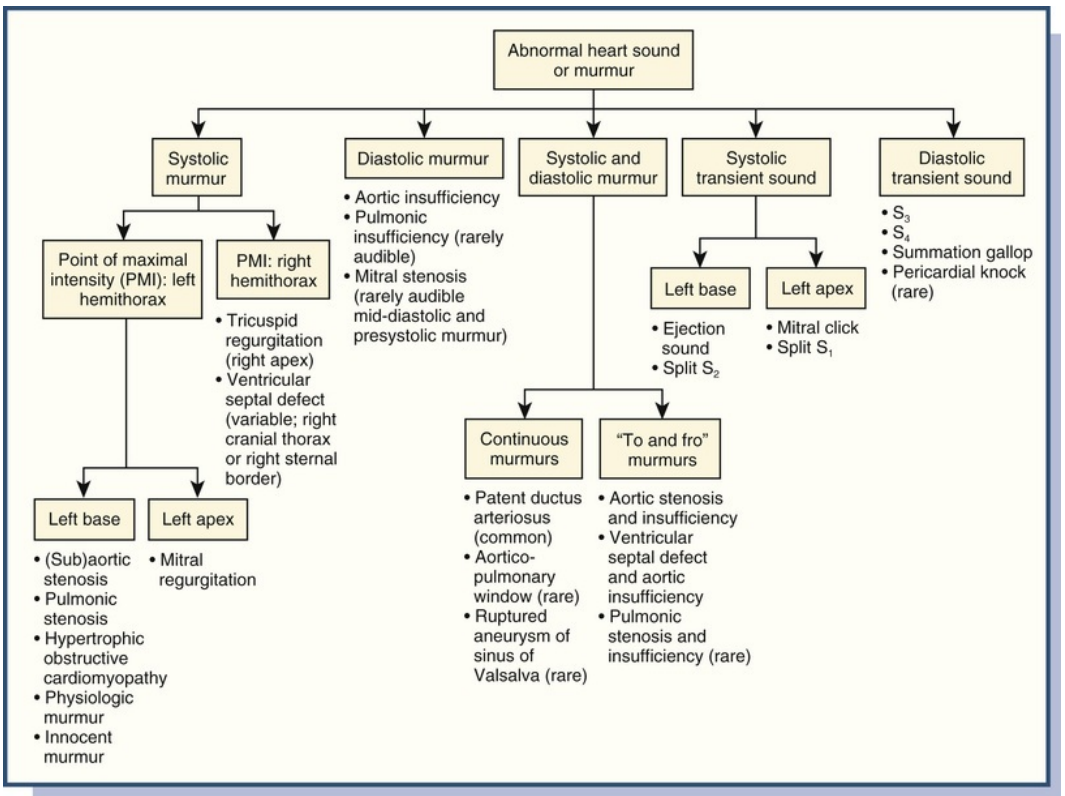

FIGURE 55-2 Algorithm for differentiating causes of abnormal heart sounds and murmurs.

As important a tool as cardiac auscultation is, it should be one part of a complete physical exam that integrates evaluation of lung fields, jugular veins, arterial pulses, and peripheral circulation. Increasingly the affordability and availability of next-generation electronic stethoscopes will allow the clinician to pick up difficult-to-hear heart sounds and other body sounds.

Additionally, other diagnostic tests might be needed to further classify and define the animal's abnormality, and in some cases differentiate a pathologic from a physiologic murmur (especially cats).

CHAPTER 56

Pulse Alterations

Christopher Little

Client Information Sheet: Pulse Alterations

Clinical examination of veterinary patients is grounded in tangible physical findings that we can appreciate with our senses. Evaluation of the rate, strength, and regularity of the pulse is the oldest, cheapest, quickest and easiest way to assess cardiac output.[1] The astute clinician will assess the pulse alongside the audible heart rate and rhythm while also assessing the color and refill of the capillaries. This chapter explores how and why pulse alterations occur.

The pulse usually is assessed by applying the tips of the fingers over one or both femoral arteries. Other sites, such as the dorsal pedal and median caudal arteries, can also be used. If the patient is restless, shivering, very hirsute, dirty, matted, or obese, these factors will hamper assessment of the pulse.

The pulse rate, under normal circumstances, will be identical to the heart rate. In the clinical setting, most dogs exhibit pulse rates between about 80 and 140 pulses per minute. There is a very weak relationship between body weight and heart rate in the dog, contrary to what was once believed.[2-5] Cats have faster heart/pulse rates than those of the dog, varying from about 130-240 per minute.[6-8]

The heart is the servant of the brain. Heart rate changes from instant to instant because of altering neural traffic from the brainstem.[9-14] During sinus rhythms, heart rate is determined by the sino-atrial node (SAN) where intrinsic heart rate is modified by the autonomic nervous system. The intrinsic rate of the canine SAN is about 150-180 beats per minute (bpm).[15-17] Sympathetic tone is sometimes described as the cardiac accelerator and parasympathetic tone the decelerator but this is an unhelpful and misleading description. A more accurate concept is that there are two autonomic oscillators which influence the SAN. Parasympathetic tone predominates in the healthy dog, especially at rest, so that the heart rate is usually much lower than the intrinsic rate of the SAN.[18-20] Varying parasympathetic tone adjusts heart rate by increasing the pulse interval (i.e., slowing the rate) to a variable degree. Changes in parasympathetic tone can, and do, occur extremely rapidly, within a period of less than one cardiac cycle.[11,21-23] Sympathetic tone, on the other hand, slowly changes heart rate over a time frame of many seconds; as sympathetic tone increases, the heart speeds up.[11,21,24,25] Thus, an increase in heart and pulse rate can occur by reduction in cardiac parasympathetic tone, or an increase in sympathetic tone, or both, whereas a reduction in heart/pulse rate may be brought about by an increase in parasympathetic tone, a reduction in sympathetic tone, or both. In healthy dogs at rest, sinus arrhythmia often is discernible, in which heart/pulse rate varies from beat to beat due to rapid oscillations of cardiac parasympathetic tone carried in the efferent fibers of the vagus nerve. Sinus arrhythmia is found in other species too, including horses and humans; it is fairly uncommon in cats during clinical examination, and is usually quite subtle in that species.

If the rhythm of the heart is regular, then usually the pulse strength will be regular too. Normally, each heartbeat causes ejection of blood into the systemic circulation. If the intervals between heartbeats vary substantially, preloading of the ventricles from beat to beat will change, and this will lead to variability in stroke volume from beat to beat. As each stroke volume is ejected into the aorta, the elastic tissue of the arteries is stretched and a pulse wave travels towards the periphery, which can be detected by a clinician feeling the pulse. The pulse pressure represents the difference in blood pressure from the end-diastolic arterial pressure to the maximum systolic arterial pressure. The pulse pressure is not related to absolute pressure (Figure 56-1). The rapidity of the increase in pulse pressure depends on the flexibility, or compliance, of the arteries as well as the inotropic behavior of the heart. If the heart beats very strongly, or the arteries are very stiff, or both, the pulse pressure will rise sharply. As blood runs off from the central arteries towards the periphery, the pressure within the arteries falls. The slope of this falling pressure curve is essentially an index

of total peripheral resistance; when peripheral resistance is high, the fall-off in arterial pressure will be shallow. On the other hand, if there is low peripheral resistance, run-off will be rapid and the slope of the falling pressure curve will be steep.[26] Unfortunately, the changing shape of the pulse pressure curve varies in too subtle a manner to be easily detected by the practicing clinician, but it is an arena where invasive monitoring, and more recently non-invasive electronic technologies, such as photoplethysmography, have provided useful insights.[27]

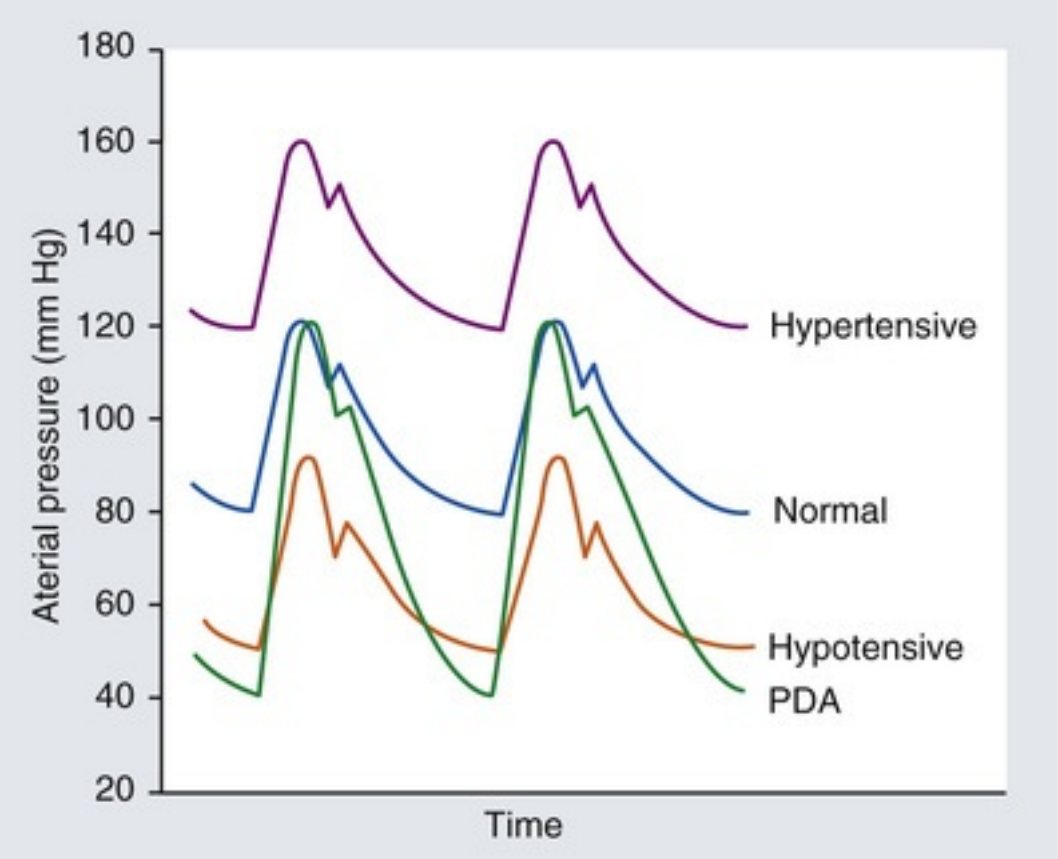

FIGURE 56-1 Normal and abnormal arterial pressure tracings. The strength of the palpable pulse depends on the *pulse pressure:* the difference between systolic and diastolic arterial pressures. *Blue:* in a normal individual, the peak systolic pressure may be 120 mm Hg and the lowest diastolic pressure 80 mm Hg. The normal pulse therefore reflects a pulse pressure of 120 − 80 = 40 mm Hg. *Purple:* in a hypertensive patient, the peak systolic pressure may be 160 mm Hg and the lowest diastolic pressure 120 mm Hg. The pulse pressure is still 40 mm Hg (160 − 120 mm Hg) so the pulse quality is normal. This example shows why systemic hypertension does not produce an unusually strong pulse. *Green:* in patent ductus arteriosus (PDA), diastolic runoff through the ductus greatly reduces diastolic pressures. The peak systolic pressure is 120 mm Hg, but the lowest diastolic pressure is 40 mm Hg. The pulse pressure is very high (120 − 40 = 80 mm Hg), which explains the bounding or "waterhammer" pulse that is characteristic of PDA. *Orange:* in moderate hypotension, both systolic and diastolic pressures can be low but again the pulse pressure may still be normal. If the pressures are very low a very weak or "thready" pulse will be felt, if any pulse is palpable at all. (Courtesy Dr. Etienne Côté.)

For any given peripheral resistance, end-diastolic pressure within the arteries will be lower when the inter-beat interval is prolonged and higher if the interval between beats is short. Thus, the perceived strength of the pulse can vary as a result of several factors. When the heart rate is slow, end-diastolic pressures will be lower because there is a long time for peripheral run-off of blood, and preloading of the left ventricle will tend to be enhanced, leading to a higher stroke volume, a stronger systolic impulse, and a higher maximum systolic pressure. On the other hand, fast heart rates tend to give a weaker pulse since stroke volume tends to be lower and end-diastolic pressure has less time to fall. When the heart rate varies widely from beat to beat, pulse pressure, too, will vary from beat to beat. This phenomenon is most frequently found in association with sinus arrhythmia in dogs, but any intermittent cardiac rhythm can lead to a variable pulse interval and strength or, if severe, the palpable pulse rate may be lower than the ausculted heart rate; this is known as a pulse deficit.

If the pulse pressure is high, the pulses are said to be hyperkinetic, whereas a low pulse pressure is designated hypokinetic (Figures 56-1 and 56-2). Aortic insufficiency and patent ductus arteriosus are forms of structural heart disease where the femoral pulses are hyperkinetic due to rapid diastolic run-off of blood from the aorta. Conversely, dogs with severe aortic stenosis may have a weak hypokinetic pulse, and/or may have a pulse pressure that has a later-than-normal peak in systole due to prolonged ejection time; this is sometimes termed *pulsus parvus et tardus*.

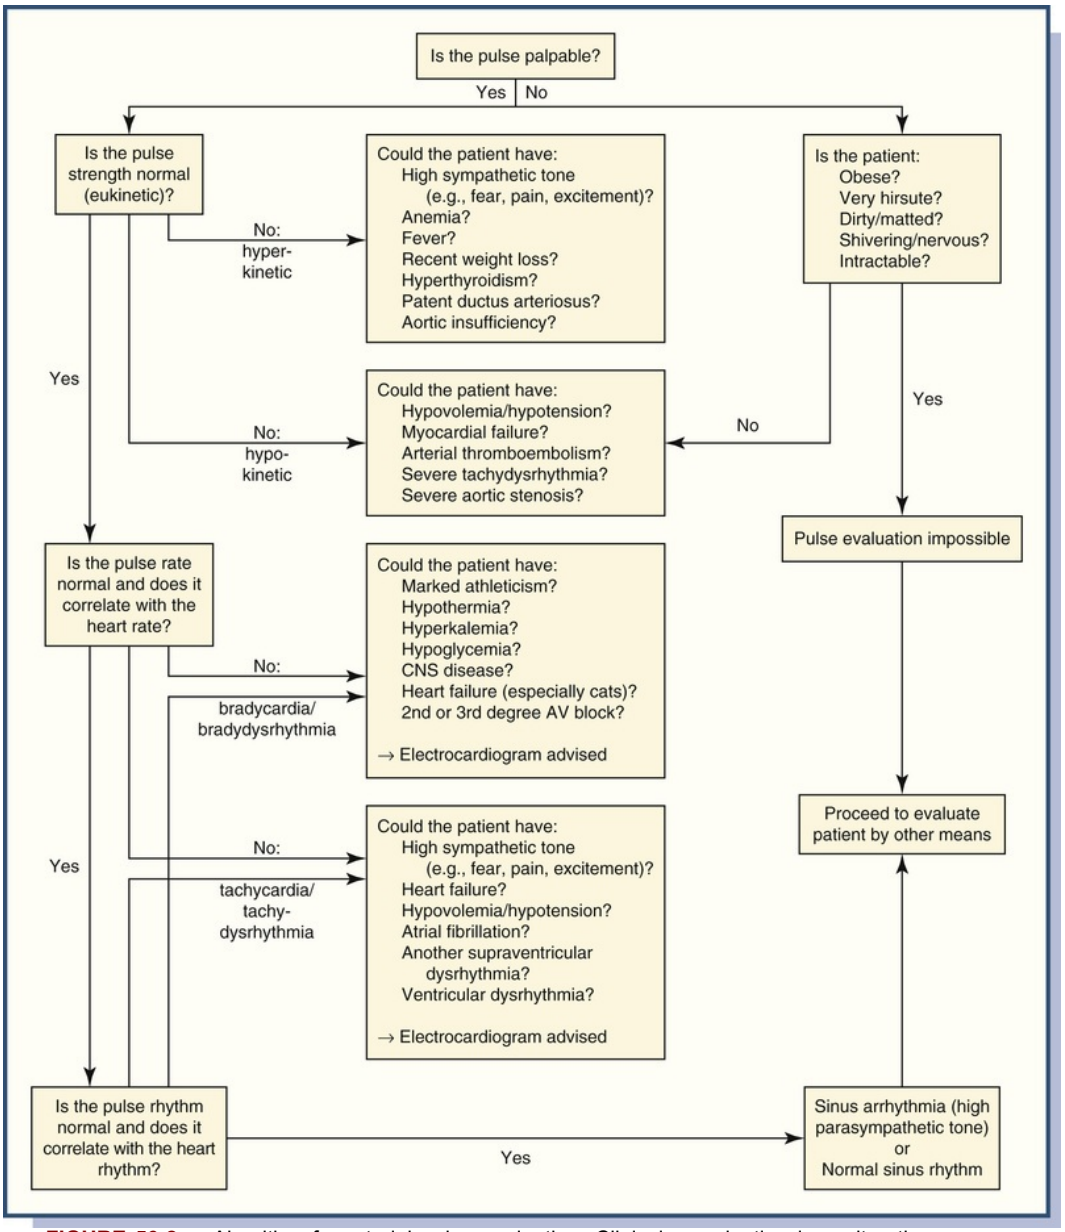

FIGURE 56-2 Algorithm for arterial pulse evaluation. Clinical examination is an iterative process which is informed and directed by the patient history. Pulse rate and rhythm should always be assessed in conjunction with other signs, especially the patient's level of arousal, body temperature, and auscultation findings. Pulse rate and rhythm should always resemble heart rate and rhythm; if they do not, then consider performing an electrocardiogram. *AV*, Atrioventricular; *CNS*, central nervous system.

Most changes in pulse rate and rhythm are due to altered cardiac autonomic tone. A fast, regular pulse can occur when an animal is exercising or excited, or is suffering from fear, anxiety, pain, fever, or anemia. These are situations in which parasympathetic tone is depressed and sympathetic tone tends to be elevated. Holter studies of dogs show peaks of tachycardia prior to and during exercise, or feeding, and whenever these animals are stimulated, such as when owners return from work.

Important disease states associated with tachycardia include hyperthyroidism and those conditions that are associated with hypovolemia, e.g., dehydration or recent blood loss. Animals that are febrile will often exhibit tachycardia together with a hyperdynamic pulse due to low peripheral resistance. Myocardial failure can produce a tachycardia with a weak (also called "thready") pulse. In this case, the low stroke volume occurs because of intrinsic cardiac disease. Atrial fibrillation, which is frequently found in dogs and cats with serious cardiac disease, may be recognized as a chaotic tachydysrhythmia that produces frequent pulse deficits (see ch. 248). When a patient has atrial or ventricular ectopic beats, the pulse pressure will often be variable too; again, pulse deficits can be recognized when the premature beat forces the ventricles to contract while inadequately filled, such that the heart sounds are ausculted but no pulse is felt.

In health, sinus bradycardia is seen mainly during rest and sleep when sympathetic tone is virtually absent and parasympathetic tone is dominant but varying. Bradycardias can be of major clinical significance, however; for instance, bradycardia may be found in patients with hypothyroidism, hypoglycemia, hypothermia, hyperkalemia (e.g., in acute hypoadrenocorticism), or central nervous system (CNS) disorders in which intracranial pressure is elevated ("Cushing's reflex").[28,29] In the author's experience, if a cat is presented in acute respiratory distress and with a heart rate of 140 beats/minute or less, it will frequently be found to be hypothermic and in heart failure.

There are a few pulse abnormalities which present very typical patterns that are said to be almost pathognomonic of certain diseases. Careful clinicians will be skeptical about such pattern recognition but *pulsus paradoxus* denotes an exaggerated decrease in systolic, mean, and pulse pressure on inspiration, and an exaggerated increase on expiration. This phenomenon in veterinary patients is particularly suggestive of cardiac tamponade due to a pericardial effusion (see ch. 254), although in human and experimental medicine it is found in other circumstances such as acute asthma, chronic obstructive pulmonary disease, bronchospasm and hypovolemic shock.[30-35] It can be difficult to recognize in many dogs because their panting creates very rapid fluctuations in intrathoracic pressure and venous return to the heart. *Pulsus alternans* refers to alternating strong and weak pulses that may occur sometimes when the left ventricle is severely dysfunctional, such as in dilated cardiomyopathy. Systemic thromboembolism, secondary to feline cardiomyopathy or hypercoagulable states, may result in a complete loss of arterial pulses (see ch. 256).

Venous Pulses

Venous pressures are always much lower than arterial pressures; this means that venous pulses, if they are perceived at all, are seen but not felt. This is impossible in hirsute patients. Jugular venous distension occurs when right atrial pressure is increased, as jugular venous pressures correlate with right atrial and ventricular pressures. Visible jugular venous pulsations sometimes occur when significant tricuspid regurgitation is present (large v waves). In normal animals, the jugular pulsations should not extend more than one third the distance up the neck from the thoracic inlet. Pulsations in the underlying carotid arteries may mimic jugular venous pulsations; occlusion of the jugular vein by manual compression will help differentiate venous pulsations from arterial pulsations. Performing the *hepatojugular* or *abdominojugular reflux test*, by applying abdominal pressure for about 30 seconds, may enhance jugular venous distension, as increased venous return in the presence of right-sided heart disease may elevate right atrial pressure.

CHAPTER 57

Anemia, Erythrocytosis

Tracy Stokol

Anemia is defined as reduced red blood cell (RBC) mass and is recognized by a packed cell volume (PCV), hematocrit (HCT), hemoglobin concentration, or RBC count below established reference intervals for that species. Conversely, an increased RBC mass is called erythrocytosis and is recognized by values that are higher than the upper reference limit for these tests. Note that although "polycythemia" and "erythrocytosis" have been used interchangeably, they are not synonymous. Polycythemia is a more general term, referring to increases in any of the cells in blood (RBC, leukocyte, platelet) with polycythemia vera referring to a chronic myeloproliferative disorder specifically involving only the erythroid lineage. Erythrocytosis specifically refers to an *absolute* increase in RBCs (or a true increase in RBC mass) and will be used herein. The tradition in veterinary medicine is to use PCV or HCT (the default used herein) as the main indicator of RBC mass.

The first step in interpretation of HCT results is to decide whether the result is truly abnormal for that individual animal, i.e., interpret results in context of signalment (breed, age, sex, reproductive status). In this sense, the use of reference intervals can potentially be misleading because they are usually established from presumably healthy adult animals of various breeds and will be insensitive to breed- and age-specific changes. For instance, a HCT of 0.45 L/L (45%) is within established reference intervals for most laboratories, but this HCT would be compatible with anemia in a Greyhound, a breed which typically has higher HCTs than other breeds.[1] In addition, reference intervals can be broad and may be insensitive to changes in an individual animal. For this reason, the author considers it worthwhile to obtain baseline complete blood count and clinical chemistry results when a dog or cat has reached adulthood (generally 12 months of age in small or medium dog breeds and cats, and 2 years of age in large dog breeds), so that subsequent individual-specific abnormalities can be identified using a critical difference approach.[2] Unfortunately, critical differences are analyzer- and method-specific and have not been established for HCT (or other hematologic tests) in dogs and cats, so a subjective assessment of the degree of change in an individual animal must be made by the individual clinician. Once anemia or erythrocytosis has been conclusively identified, a systematic approach can be used to identify the pathophysiologic mechanisms and, hopefully, the underlying cause.

Anemia

Anemia is the most common hematologic abnormality encountered in veterinary clinical practice and can be the cause of disease (e.g., immune-mediated hemolytic anemia [IMHA]) or a marker of underlying disease (e.g., cancer, chronic kidney disease). There are three main pathophysiologic mechanisms for anemia: hemorrhage (loss), hemolysis (decreased lifespan), and decreased production. Distinguishing between these mechanisms is important for identifying the underlying disease or cause of anemia (Box 57-1) and is best accomplished by using a combination of signalment, historical information, clinical signs, imaging findings, and clinical pathologic results. Anemia can be multifactorial in origin, which can complicate discovery of the underlying cause and there are always going to be those challenging and potentially frustrating cases, where the mechanism and cause of the anemia remain ambiguous.

Box 57-1

Pathophysiologic Mechanisms for Anemia with Helpful Blood Smear Features (also see Box 57-3)

Hemorrhage: Acute or chronic
- Internal into body cavities, e.g., hemoperitoneum from splenic or hepatic trauma
- External via the skin or respiratory, genitourinary or gastrointestinal tracts, e.g., melena from an

ulcerated gastrointestinal tumor. Chronic external blood loss can result in a concurrent iron deficiency anemia, which may be regenerative or non-regenerative.

Hemolysis: Intravascular or extravascular

Immune-mediated*: Primary or secondary to infectious agents, blood group incompatibility (transfusions, neonates) or drugs. Uncommon in cats. Helpful smear features: Spherocytes, agglutination, ghost cells*.

Infectious agents: ***Babesia*** sp., ***Theileria*** sp., *Mycoplasma haemocanis* and *haemofelis, Leptospira* sp.[17-19] Only *Mycoplasma haemofelis* is a common cause of hemolytic anemia in cats. The other feline hemotropic mycoplasmas are not typically associated with an anemia.[20]

Oxidant-induced, e.g., zinc poisoning, onion ingestion, exposure to skunk musk in dogs,[21-23] acetaminophen toxicosis or accidental onion ingestion in cats. Helpful smear features: Heinz bodies, eccentrocytes, pyknocytes.

Fragmentation injury (microangiopathic hemolytic anemia), e.g., vasculitis, DIC. Helpful smear features: Acanthocytes, keratocytes, schistocytes. This type of anemia is frequently non-regenerative due to concurrent anemia of inflammatory disease.

Aberrant macrophage activity: Reactive or neoplastic histiocytic disorders, e.g., hemophagocytic histiocytic sarcoma[24]

Inherited defects of the RBC membrane (e.g., stomatocytosis in Alaskan Malamutes, spherocytosis in Golden Retrievers) or metabolic pathway enzymes (e.g., **phosphofructokinase deficiency** in dogs, pyruvate kinase deficiency in dogs and cats) (rare).[25-27] Helpful smear features: Stomatocytes, sphero-echinocytes (pyruvate kinase deficiency in dogs).

Miscellaneous: **Severe hypophosphatemia, snake** or **bee venoms.**[28,29] Helpful smear features: Echinocytes (certain snake venoms), ghost cells*.

Decreased production

Suppression from extramedullary disease (common)

Inflammatory disease ("chronic" disease): Inflammatory cytokines suppress erythropoiesis, erythropoietin release, and response to erythropoietin, and sequester iron via hepcidin. Can have an extravascular hemolytic component (particularly in cats).

Chronic kidney disease: Decreased erythropoietin (other factors may contribute, including hemorrhage from gastrointestinal ulcers, hemolysis from uremic toxins)

Endocrine disease: Hypothyroidism, hypoadrenocorticism

Bone marrow disease

Increased intramedullary cell death (ineffective erythropoiesis): Immune-mediated, i.e., non-regenerative immune-mediated anemia or precursor-directed immune-mediated anemia[30-33]; drugs or hormones (e.g., estrogen); toxins; infectious agents (e.g., *Ehrlichia canis*); histiocytic disorders (reactive or neoplastic)

Abnormal production with intramedullary cell death: Neoplasia (myelodysplastic syndrome or primary myelodysplasia; in cats, this is often secondary to feline leukemia virus infection)

Destruction or damage to erythroid progenitors: Immune-mediated (pure red cell aplasia), infectious agents including viruses (e.g., parvovirus) and bacteria (e.g., *Ehrlichia*), drugs (e.g., recombinant human erythropoietin[34,35]), toxins

Decreased hemoglobin production: Iron deficiency (chronic blood loss, functional deficiency secondary to portosystemic shunts), chronic lead toxicosis

Decreased or abnormal DNA production: vitamin B_{12} or folate deficiency (rare), feline leukemia virus infection

Primary (e.g., acute myeloid leukemia) or infiltrative (e.g., histiocytic sarcoma, multiple myeloma in cats, lymphoma in dogs) marrow neoplasia: Multiple mechanisms including myelophthisis, immune-mediated, inflammatory cytokines

DIC, Disseminated intravascular coagulation; *RBC,* red blood cell.

*Causes of intravascular hemolysis are highlighted in **boldface**. Ghost cells will only be seen when intravascular hemolysis is occurring. Be careful not to mistake "artifactual" ghost RBCs from ghost RBCs created by intravascular hemolysis (RBCs can lyse *in vitro* with stored blood samples or when the blood smear is prepared).

Mechanisms of Anemia

If an anemia is "adequately" regenerative, the underlying mechanism is hemorrhage or hemolysis. Distinguishing between these two mechanisms relies primarily on clinical signs, physical examination, imaging, and other laboratory tests, i.e., specifically identifying a source of hemorrhage or a cause for hemolysis on a blood smear examination (Figure 57-1). Note that in some diseases, the anemia may be due to a combination of hemorrhage and hemolysis.

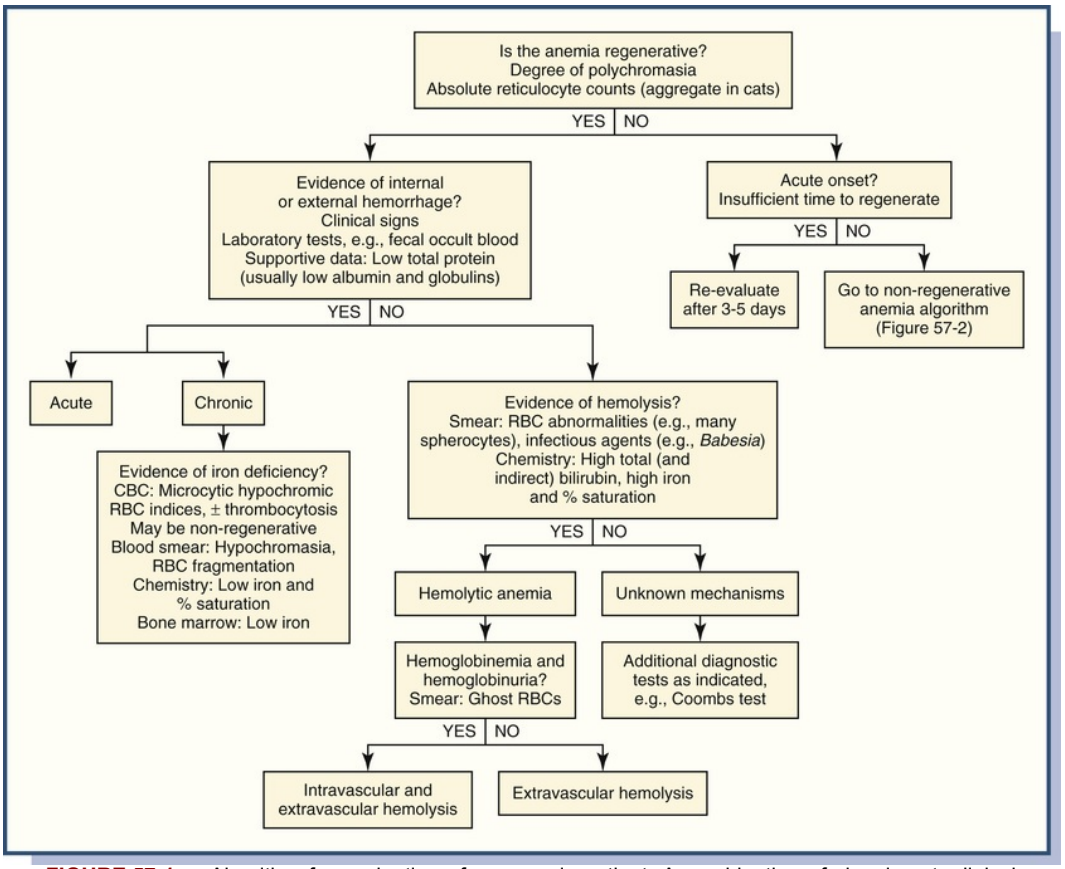

FIGURE 57-1 Algorithm for evaluation of an anemic patient. A combination of signalment, clinical signs, physical examination, imaging results and clinical pathologic testing results are used to determine whether the anemia is regenerative (due to hemorrhage or hemolysis) or non-regenerative (due to extramedullary or primary bone marrow disease). Hemolytic anemia can be extravascular or intravascular and extravascular, with specific disease entities causing intravascular hemolysis (see Box 57-1). *CBC*, Complete blood count; *RBC*, red blood cell. (Modified from eClinPath.com [section on anemia].)

Hemorrhage

This can be internal (into a body cavity) or external ("lost" from the body, e.g., from gastrointestinal hemorrhage) (see ch. 135). Low total protein (especially the combination of low albumin and globulins) would support the conclusion that an anemia is due to hemorrhage, but it is not specific for hemorrhage. A normal serum total protein concentration also does not rule out hemorrhage, since peracute hemorrhage, internal bleeding, or chronic intermittent external blood loss may not result in low protein concentrations. If external hemorrhage is chronic and occult, iron deficiency can ensue, which can be recognized by hypochromic RBCs and microcytic hypochromic RBC indices. Serum iron and percentage saturation of transferrin are usually quite low with iron deficiency anemia, but decreases in these test results are also seen with inflammatory disease. Newer diagnostic tests for iron content in reticulocytes can be helpful for confirming an iron deficiency anemia in dogs but these results are not generally available and are not specific for iron deficiency, being abnormal in dogs with inflammatory disease, portosystemic shunts or breed-associated microcytosis.[3]

Hemolysis

Decreased RBC lifespan can be due to extravascular (i.e., phagocytosis of RBCs by macrophages) or intravascular (i.e., rupture of RBCs in vessels) destruction of RBCs. Intravascular hemolysis is usually accompanied by extravascular hemolysis, but the latter can occur alone and is the most common mechanism of increased RBC destruction in a hemolytic anemia (see ch. 195 and 198). It is important to distinguish intravascular from extravascular hemolysis, because this helps narrow the differential diagnostic list (see Box 57-1). Intravascular hemolysis is characterized by hemoglobinemia and hemoglobinuria. Ghost RBCs and relevant RBC changes (e.g., oxidant injury) or pertinent infectious agents (e.g., *Babesia canis*) may also be seen on blood smears, but should not be relied upon for distinguishing intravascular from extravascular hemolysis. Ghost RBCs are RBCs on blood smears that have "lost" the bulk of their hemoglobin and look like faded RBCs; ghost RBC from intravascular hemolysis must be distinguished from *in vitro* hemolysis with ghost cell formation as an artifact of storage or blood smear preparation. Hemolytic anemia of any type is usually associated with a normal or high serum total protein concentration and can result in bilirubinemia, especially due to unconjugated (indirect) bilirubin. Note that conjugated (direct) bilirubin may increase and even dominate in dogs with IMHA and sick anorectic cats (due to bile sludging). Liver enzyme activities may be increased from hypoxic injury but can be normal. Serum iron and percentage saturation of transferrin are consistently increased in dogs and cats with hemolytic anemia, and siderocytes (RBCs with faint iron inclusions) may be seen on a blood smear in dogs. None of these results is specific for hemolytic anemia and they should be considered as supportive not confirmatory results. The lack of these findings does not rule out hemolysis either.

Decreased Production

If the anemia is non-regenerative or "inadequately" regenerative, this indicates a problem with RBC production in the bone marrow, of which there are many causes (see Box 57-1 and ch. 199). Clues as to the mechanism of a non-regenerative anemia can be gleaned from the severity of the anemia, RBC indices, and other hematologic findings, particularly concurrent cytopenias (specifically, neutropenia and thrombocytopenia) and abnormal (neoplastic) cells (Figure 57-2). A mild normocytic normochromic anemia is the most common form of non-regenerative anemia and is usually due to extramedullary disease, particularly anemia of inflammatory disease (also called anemia of chronic disease). The most common causes of a severe non-regenerative anemia, without other cytopenias, are immune-mediated conditions and feline leukemia virus infection in dogs and cats, respectively. Feline leukemia virus-associated hematologic disorders are far less frequent since vaccination was introduced.

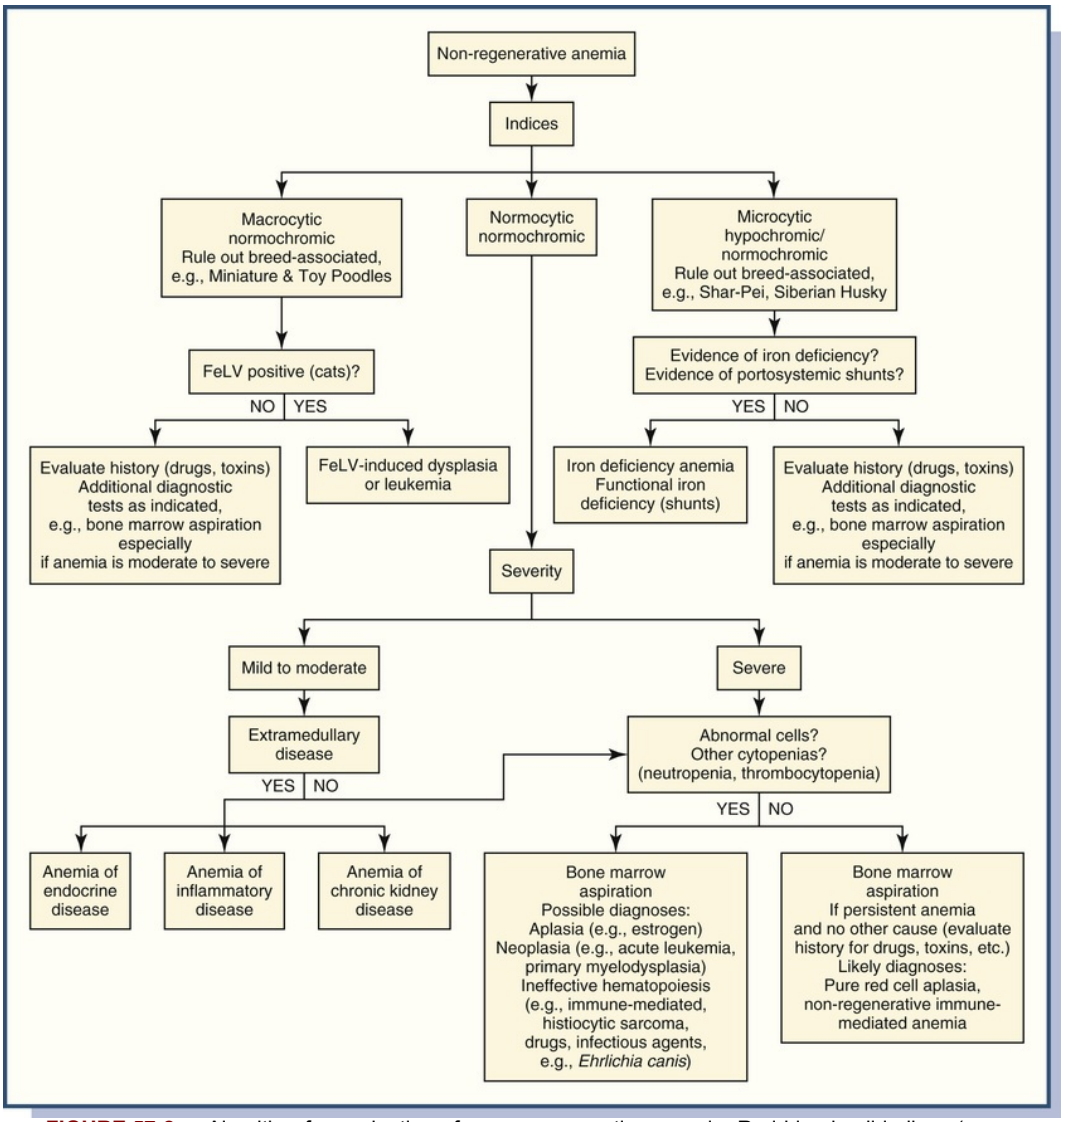

FIGURE 57-2 Algorithm for evaluation of a non-regenerative anemia. Red blood cell indices (mean corpuscular volume and mean corpuscular hemoglobin concentration) can be guides as to the potential underlying mechanism, as can the presence of other cytopenias or abnormal cells (e.g., leukemia). *FeLV,* Feline leukemia virus. (Modified from eClinPath.com [section on anemia].)

A Mechanistic Approach to Anemia

A stepwise approach can be used for distinguishing between mechanisms of anemia (see Figures 57-1 and 57-2) and is based on the following four questions (Box 57-2):

1. How acute is the anemia? This is important for assessing whether an anemia is regenerative (question 2 below). The bone marrow takes approximately 3-5 days to mount a regenerative response. An anemia of acute onset may appear "non-regenerative" if the bone marrow has had insufficient time to respond. Clinical signs and history can help with determining the duration of anemia, but this can be difficult because anemia frequently manifests with vague clinical signs that may be missed by the owner. Unless there has been a known traumatic event, a regenerative response should be manifest by the time of presentation in most affected patients. The expected marrow response will also depend on the degree of anemia. A robust regenerative response is expected in a moderate to severe anemia; however, a weaker response would be expected in a mild anemia.
2. Is the anemia regenerative? The bone marrow responds to an anemia by releasing immature anucleated RBCs, which are characterized by increased RNA content. These immature RBCs can be identified using intravital dyes that precipitate RNA and can be visualized on smears (e.g., new methylene blue) or fluorescent dyes that bind to RNA/DNA and can be detected with lasers in automated hematology

analyzers. When identified with these dyes, the immature anucleated RBCs are called reticulocytes and are quantified as a percentage of the RBC count (note that only aggregate reticulocytes or immature anucleated RBCs that contain aggregates or large amounts of RNA are quantified in cats). Due to their higher RNA content, immature anucleated RBCs can also be recognized as polychromatophilic (purple) RBCs on Romanowsky-stained blood smears (Diff-Quik, Wright's stain) and regeneration can be subjectively estimated from the degree of polychromasia in blood smears from both dogs and cats. As an example, in the monolayer of a blood smear there are approximately 100 RBCs per 100× oil immersion field. Counting 3 polychromatophilic RBCs per field (average the number in ten 100× oil immersion fields) would be roughly equivalent to 3% reticulocytes. However, there will be far fewer than 100 RBCs in the microscopic field in a severely anemic animal and this should be considered when estimating regeneration from a blood smear. A high reticulocyte percentage alone or the presence of small numbers of polychromatophilic RBCs in a smear does not necessarily mean that the bone marrow is responding appropriately to the anemia; therefore, various formulae are available to assess "adequacy" of regeneration by taking into account the severity of anemia, including the absolute reticulocyte count, corrected reticulocyte percentage (which is handy for practitioners because it is based on PCV and does not require an RBC count) and the reticulocyte maturation index. Which formula is used is a matter of personal preference; however, the author uses the absolute reticulocyte count (e.g., with our current reference intervals, an absolute reticulocyte count >95,000/mcL [dog] or >60,000/mcL [cat] generally indicates a regenerative response).[4] Note that nucleated RBCs (nRBCs) and Howell-Jolly bodies (nuclear fragments) may be seen in blood smears of animals with a regenerative anemia but are not used for evaluating the regenerative response because they can be seen in other conditions (e.g., heatstroke and bone marrow injury for nRBCs). Also, with newer hematology analyzers, the RBC indices (mean corpuscular volume and mean corpuscular hemoglobin concentration) are usually normal in a regenerative anemia (i.e., the anemia is not macrocytic and hypochromic) and should not be relied upon as an indicator of regeneration.[5] If an anemia is regenerative (i.e., absolute reticulocyte count above the reference interval), then the anemia is due to hemorrhage or hemolysis and decreased erythropoiesis can be ruled out. If the anemia is non-regenerative (i.e., absolute reticulocyte count is within reference intervals, even if the percentage of reticulocytes is high) and the bone marrow has had time to respond, mechanisms of decreased RBC production are operative and diagnostic testing should focus on identifying the underlying cause (see Box 57-1).

3. Is a cause for the anemia evident on a blood smear? Blood smear examination is an essential part of the assessment of an anemic patient and it provides a wealth of information. Changes in morphologic features of RBCs (and other cell lineages) and detection of infectious agents or neoplastic cells can provide clues to, or specifically identify, the cause of an anemia (Boxes 57-1 and 57-3). Finding abnormal RBC morphologic features in a blood smear does not necessarily mean they are of pathologic relevance. Relevance is subjective and depends on both the type and number of abnormalities and should always be determined in context of the patient. For example, a few schistocytes, keratocytes and acanthocytes may be seen as a consequence of mechanical fragility in iron deficiency anemia, whereas in a critically ill patient with thrombocytopenia, the same number of these RBC changes could reflect underlying disseminated intravascular coagulation (DIC) and should trigger additional testing for this hemostatic disorder. Naturally, the identification of these RBC abnormalities is highly dependent on the skill of the observer.
4. Which additional tests are indicated? Results of complete clinical pathologic testing (complete blood count, clinical chemistry, urinalysis) and imaging, combined with cytologic or histologic assessment of tissues, is essential in all anemic patients for identifying extramedullary disease that could be causing the anemia or suppressing the bone marrow's response. Testing for infectious diseases is worthwhile in animals with an unexplained regenerative or non-regenerative anemia, because blood smear examination can be insensitive for organism detection. Even if a cause of the anemia is identified on a blood smear, additional testing is frequently performed for confirmatory purposes, e.g., Coombs test for IMHA, antinuclear antibody testing for systemic lupus erythematosus, and genetic or serologic-based infectious disease tests. In general, bone marrow aspiration is not indicated in a regenerative anemia or a mild non-regenerative anemia, unless looking specifically for occult infectious agents or underlying neoplasms (e.g., *Leishmania* sp., multiple myeloma, lymphoma). Pancytopenia (defined as a non-regenerative anemia, thrombocytopenia, and neutropenia, regardless of severity of the anemia) and a severe non-regenerative anemia (alone or with other cytopenias) indicate a bone marrow problem, and bone marrow aspiration is warranted in affected patients. Similarly, bone marrow aspiration is worthwhile in animals with identifiable neoplastic cells in circulation (for staging lymphoma or

confirmatory diagnosis of leukemia). Bone marrow aspiration with Prussian blue staining for iron is also the gold standard test for confirmation of iron deficiency in dogs, but not in cats (stainable iron is absent in the bone marrow of healthy cats). However, marrow aspiration rarely is performed for the latter purpose.

Box 57-2

The Question-Based Approach to Anemia

1. How acute is the anemia?
2. Is the anemia regenerative?
3. Is a cause identifiable from a blood smear?
4. Which additional tests are indicated?

Box 57-3

Useful RBC Abnormalities in a Blood Smear

Acanthocytes: Fragmentation injury, iron deficiency anemia (mechanical fragility), vascular neoplasms (e.g., hemangiosarcoma), DIC. Usually seen with keratocytes and schistocytes. Can be a non-relevant finding (rarely seen in healthy young animals, potentially as a congenital or inherited disorder) or a finding of uncertain relevance in various diseases.[36]

Agglutination: IMHA, EDTA-dependent pseudo-agglutination.[37] Must be differentiated from rouleaux (usually by microscopic examination of a 1 : 4 to 1 : 10 dilution with saline). Macroscopic slide tests are less reliable.

Eccentrocytes: Oxidant injury. Low numbers may be seen in various diseases without indicating an oxidant-induced hemolytic anemia.[38]

Elliptocytes: Usually secondary to non-regenerative immune-mediated anemia or pure red cell aplasia in dogs (indicates myelofibrosis in these disorders[30]) and liver disease in cats (particularly lipidosis). Inherited in dogs[39] (rare).

Heinz bodies: Indicate oxidant injury. Small Heinz bodies can be normal in cats and do not result in anemia. Large or multiple Heinz bodies in cats or any size Heinz bodies in dogs are supportive of an oxidant-induced hemolytic anemia. Can be seen concurrently with eccentrocytes, ghost cells, pyknocytes (cells which resemble spherocytes)[40] and methemoglobinemia, depending on the oxidant.

Keratocytes: Fragmentation injury (vasculitis, DIC, iron deficiency; seen with acanthocytes and schistocytes) or oxidant injury (seen with eccentrocytes ± Heinz bodies). Low numbers may be normal in cats.

Poikilocytes: RBCs with various shapes can be seen in cats with liver disease, but may not result in anemia.

Rouleaux formation: Increased globulins secondary to antigenic stimulation (e.g., chronic liver disease), inflammation (e.g., feline infectious peritonitis) or B cell or plasma cell neoplasia (e.g., chronic lymphocytic leukemia, multiple myeloma). Serum protein electrophoresis is helpful.

Schistocytes: Fragmentation injury. Often concurrent with acanthocytes and keratocytes.

Siderocytes (particularly dogs): Hemolytic anemia, lead toxicosis, drugs (hydralazine), portosystemic shunts.

Spherocytes: Moderate to many spherocytes are usually diagnostic of IMHA. Can be seen concurrently with siderocytes (increased RBC turnover) and ghost cells (if intravascular hemolysis). Partial spherocytes (smaller RBCs with a small amount of central pallor) can be seen in dogs with non-regenerative variants of IMHA.[30] A few spherocytes can be seen in fragmentation injury and transfused RBCs can be sphered. Spherocytes are difficult to detect in cats (RBCs normally lack central pallor).

Erythrocytosis

An increased RBC count or HCT is occasionally seen in dogs and is quite rare in cats. A high HCT may be normal for specific breeds of dogs[1,6] and has been observed in individual animals of certain breeds (Jack

Russell Terriers and German Shepherd Dogs) by the author. Hence, breed-specific associations should be excluded before evaluating an animal for pathologic causes of a high RBC count or HCT. Similar to anemia, a sequential mechanistic approach can be used for diagnostic evaluation of an animal with a high HCT (Figure 57-3).

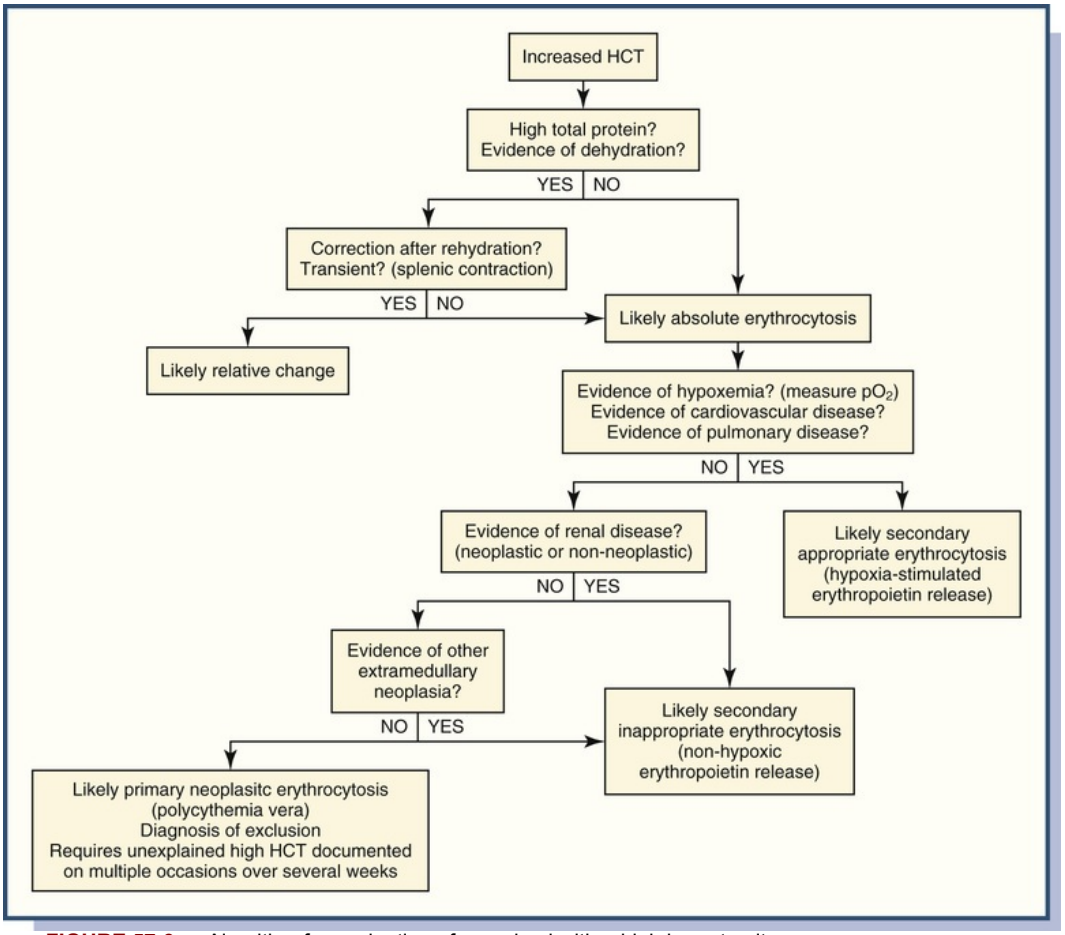

FIGURE 57-3 Algorithm for evaluation of an animal with a high hematocrit.

Mechanisms of Erythrocytosis

Erythrocytosis refers to an absolute or true increase in RBC mass and not just increased RBC numbers. High RBC numbers (or HCT) may be seen as a relative change, i.e., change in RBC numbers in relation to water content. A relative increase in HCT is due to a decrease in body water (e.g., dehydration) or release of RBCs from the spleen. Up to one third of RBCs are stored in the splenic red pulp and can be released with splenic contraction under the influence of epinephrine, although this is uncommon in dogs and cats. Measurement of total protein concentrations (high results expected) and rehydration of a dehydrated animal with sequential testing to confirm persistence of a high HCT are tools that can be used to rule out a relative from an absolute increase in HCT.

Erythrocytosis is a true increase in RBC mass due to increased RBC production (also called absolute increase in HCT). This can be separated into a primary or secondary erythrocytosis. Primary erythrocytosis can be inherited in some species (not dogs or cats) or can be an acquired neoplastic disorder, called polycythemia vera. The latter is a chronic myeloproliferative disorder that is quite rare in dogs and cats. Up to 90% of human patients with polycythemia vera have a mutation in the JAK2 non-receptor tyrosine kinase which is downstream of the erythropoietin receptor.[7] The mutation drives constitutive, usually erythropoietin-independent, stimulation of erythropoiesis. A mutation in JAK2 has been identified in a dog with polycythemia vera and may facilitate diagnosis of this rare disease (which is usually a diagnosis of exclusion; see Figure 57-3).[8] Secondary erythrocytosis due to increased erythropoietin is a far more common

cause of an increased HCT in both dogs and cats than polycythemia vera. Secondary erythrocytosis can be subclassified as appropriate or inappropriate, which refers to the stimulus for erythropoietin release. Appropriate release of erythropoietin occurs in hypoxemic conditions and can result in secondary erythrocytosis in dogs and cats with respiratory or cardiac conditions.[9] An inappropriate release of erythropoietin is most frequently seen in certain renal diseases but it also is seen as a paraneoplastic response with renal and non-renal neoplasia.[10-14] High erythropoietin concentrations support a diagnosis of secondary erythrocytosis but studies have shown an overlap in erythropoietin concentrations with different causes of erythrocytosis, limiting the usefulness of the test.[15,16] Bone marrow aspirates will not be informative because they will reveal an erythroid hyperplasia with any cause of erythrocytosis (whether primary or secondary). Thus, differentiating between causes of erythrocytosis requires other diagnostic tests (see Figure 57-3 and ch. 200).

CHAPTER 58

Leukopenia, Leukocytosis

Amy E. DeClue, Dennis R. Spann

Introduction

Peripheral blood leukocytes are primary components of the innate and adaptive immune systems. As such, their numbers are dynamic and affected by a large variety of stimuli. These stimuli include but are not limited to: infection, inflammation, autoimmune disease, tissue damage, parasitic infestation, and hormones. Leukocytes are produced continuously, in a series of steps, from hematopoietic stem cells in the bone marrow (see ch. 202). These initially pluripotent stem cells are self-renewing, but reproduce infrequently. They give rise to a variety of common lymphoid and myeloid cell lines after progression from hematopoietic stem cells to their respective progenitor cells, differentiating further to result in more determined and restricted cell lines. The bone marrow microenvironment of the precursor cells, essential for hematopoiesis, is composed of endothelial cells, stromal cells, adipocytes, osteoblasts, macrophages, lymphocytes, extracellular matrix and growth factors. The correct microenvironment, cell interactions, and extracellular matrix attachments are requisite to optimal proliferation, differentiation, and survival of hematopoietic stem cells. Alterations to the microenvironment can dramatically impact hematopoiesis.

Neutrophils in the bone marrow are included in two pools: a mitotic pool and a maturation and storage pool. Myeloblast maturation and release from the bone marrow generally take about 6-9 days, but maturation is expedited by certain inflammatory signals.[1-4] Interleukins (ILs)-1, 2, 3, 6 and 11, granulocyte-macrophage colony stimulating factor (GM-CSF), granulocyte colony stimulating factor (G-CSF) and stem cell factor (SCF) are inflammatory mediators that stimulate neutrophil production while GM-CSF, G-CSF, tumor necrosis factor (TNF) and C5a mediate release from the bone marrow. Monocytes originate from the granulocyte-monocyte progenitor cell under the influence of IL-3, IL-34, GM-CSF, and macrophage colony stimulating factor (M-CSF). Monocytes are produced more quickly than are granulocytes, and there is minimal reserve in the marrow; replication, rather than rapid release, is responsible for increases in monocyte numbers in the blood.[4-6] Eosinophils are derived from the eosinophil progenitor line under the influence of GM-CSF, IL-3 and IL-5 produced by activated Th2 lymphocytes.[7] Basophils are produced from the bipotential basophil-mast cell progenitor under the influence of IL-3, IL-5, GM-CSF, transforming growth factor beta (TGF-beta) and nerve growth factor.[8] In addition to microenvironment and cytokines, the role of microRNAs is under active study in regulation of inflammation and hematopoiesis.[9]

B lymphocytes, T lymphocytes and natural killer (NK) cells are derived from combined lymphocyte progenitor cells under the influence of SCF, Flt3L, insulin-like growth factor (IGF) and IL-7.[4] The Notch gene plays an important role in the B cell T cell lineage switch.[10] Lymphoblasts leave the marrow and migrate to the thymus where they develop into T lymphocytes because of stimulation from compounds in the thymic microenvironment, Notch gene product, and growth factors including Flt3L and IL-7.[10] NK cell production is thought to be stimulated by IL-2, IL-7, IL-15 and SCF. NK cells are produced in the bone marrow in approximately 7 days; NK cells also could arise from the lymph nodes, liver, and spleen.[4,11]

The peripheral white blood cell count is a function of the rate of production in the bone marrow, release from the bone marrow, the proportion of cells in the marginated versus circulating pools, and the rate of egress of white cells from the blood into the tissues. Peripheral blood leukocytes are divided into approximately equal circulating and marginated pools, although there is some species variation in the ratio. The marginated cells are found rolling along the endothelium, preparing to exit the circulation and migrate to target tissues. Marginated cells interact with the vascular endothelium through interactions between L-selectins on leukocytes and P- and E-selectins on endothelial cells as well as other cellular receptors. Marginated cells can return to the circulation during times of increased blood velocity or due to the effects of cortisol or epinephrine. Changes in the relative ratio of marginated to circulating pools of cells will alter the

white blood cell count, as only the central or circulating pool is evaluated in the complete blood count (CBC).

Leukocytosis

Because they are the most numerous and dynamic populations of white blood cells, neutrophils and to a lesser extent lymphocytes are the cell lines most commonly responsible for leukocytosis (see also ch. 202). Rarely, other cell lines expand sufficiently to result in a leukocytosis. Exercise, epinephrine, and cortisol are associated with a mild to moderate increase in neutrophils, largely due to shifts of cells from the marginal to the circulating pools with a rapid return to baseline cell counts. The neutrophil count should not be greater than twice the upper limit of the reference interval, nor should a left shift be present if the neutrophilia is the result of these physiologic effects alone.[4] Infection, inflammation, and neoplasia are associated with neutrophilia of varying magnitude with no clear cut-off that is discriminatory between each category of disease.

As an inflammatory process continues, increased demand for neutrophils triggers early release of neutrophils from the maturation pool, resulting in a *left shift* towards more immature forms of neutrophils. If the number of mature forms exceeds immature forms, the pattern is known as a *regenerative response*. When the demand for neutrophils exceeds the marrow's capacity to provide mature neutrophils, increasing ratios of immature forms are released resulting in a *degenerative left shift*. In both dogs and cats, a degenerative left shift most commonly is caused by infection and it is associated with a more guarded prognosis,[12-14] with a hazard ratio for the risk of death or euthanasia of 1.9 in affected dogs[12] and 1.75 in affected cats.[14]

Toxic changes are morphologic changes of neutrophils caused by accelerated maturation. They may include: cytoplasmic basophilia, Döhle bodies, increased vacuolization, decrease nuclear condensation and increased granules (Figure 58-1). Neutrophilic leukocytosis with a left shift and/or toxic changes should raise suspicion of infection such as peritonitis, pleuritis and pneumonia; however, the absence of a left shift or toxic changes does not exclude infection, and noninfectious inflammatory disease such as severe pancreatitis or hemolytic anemia and others can be associated with neutrophilia, left shift and toxic change.

(Photos courtesy Dr. Angela B. Royal, Veterinary Medical Diagnostic Laboratory, University of Missouri.)

Severe leukocytosis (>35,000 cells/mcL) is often termed a *leukemoid response,* although this term generally has fallen out of favor.[15] Typically, neutrophils are the predominant cell type involved with severe leukocytosis, although other cells could be involved. The most common causes of severe neutrophilic leukocytosis include infection, tissue necrosis, neoplasia, and immune-mediated disease (Table 58-1).[13,15,16]

Other important differential diagnoses include leukocyte adhesion deficiency,[17] paraneoplastic leukocytosis,[18-20] *Babesia* infection,[21] *Hepatozoon canis* infection,[22,23] immune-mediated hemolytic anemia,[24] and bacterial prostatitis.[25]

Causes of Severe Neutrophilic Leukocytosis (WBC > 50,000/mcL) in the Dog and Cat

CATEGORY	CANINE		FELINE
Study	Lucroy et al[13]	Weltan et al[15]	Lucroy et al[16]
Infection	40/115 (34%)	106/182 (58%)*	38/104 (37%)
Immune-mediated	38/115 (32%)	20/182 (11%)	23/104 (22%)
Neoplasia	24/115 (20%)	26/182 (14%)	24/104 (23%)
Tissue necrosis	12/115 (10%)	23/182 (13%)	19/104 (18%)

*Here we combined the infection group (56/182) and babesiosis group (50/182), which were listed as separate groups in the original paper.

Lymphocytosis sometimes can be profound enough to result in leukocytosis. Physiologic lymphocytosis usually is mild. Increased circulating concentration of epinephrine, but not cortisol, results in a lymphocytosis. Cats are more likely than are dogs to have reactive lymphocytosis in response to inflammation.[6,26,27] Lymphocytosis secondary to inflammation is usually mild, but it can be 2-3 times the upper limit of the reference interval.[26] Lymphocytosis occasionally can be associated with chronic infectious etiologies such as feline leukemia virus, feline immunodeficiency virus, toxoplasmosis, and *Ehrlichia canis*.[28] Hypoadrenocorticism is associated with lymphocytosis, but it rarely results in leukocytosis.[26] Lymphoma, chronic lymphocytic leukemia (CLL), and acute lymphocytic leukemia (ALL) can be associated with marked leukocytosis. Because the cells in CLL are mature, distinction between reactive lymphocytosis and CLL may require advanced techniques like immunophenotyping or clonality testing via polymerase chain reaction (PCR) for antigen receptor rearrangements (PARR). Leukemic lymphoma can be difficult to distinguish from ALL, though nodal infiltration is less common with ALL and the lymphocyte count associated with ALL tends to be greater.

Eosinophilia and monocytosis are uncommon causes of leukocytosis. The main categories of disease resulting in eosinophilia are parasitism, hypersensitivity reactions, mastocytic disease, hypoadrenocorticism, hypereosinophilic syndrome, and occasionally lymphoid neoplasia. Chronic granulomatous disease can cause moderate to severe monocytosis. Other causes of monocytosis include chronic infections and cellular and tissue damage. Myelomonocytic leukemia is a rare cause of leukocytosis and frequently is associated with concurrent neutropenia and thrombocytopenia.[29,30]

Leukopenia

Because neutrophils make up the largest fraction of the white blood cell count, leukopenias most commonly are secondary to neutropenia. Though reference ranges vary from one laboratory to another, neutropenia generally consists of a neutrophil count <3,000 cells/mcL (<3 × 10^9 cells/L, <3 × 10^6 cells/mL).[27] Neutropenia is classified as mild when the neutrophil count is 1,500-3,000 cells/mcL, moderate if it is 500-1,500 cells/mcL, and severe if it is <500 cells/mcL. Severe neutropenia often is associated with fever and opportunistic infection, since neutrophils are first-line defenders against a variety of pathogens and therefore, any animal with moderate to severe neutropenia and a fever should be treated emergently. Conversely, severe infections can cause neutropenia, making cause-and-effect sometimes challenging to discern. Increased demand of neutrophils secondary to pneumonia, peritonitis, ulcerative dermatitis, and viral and fungal infections all have been identified as causes of neutropenia in dogs and cats (Table 58-2).[31]

TABLE 58-2

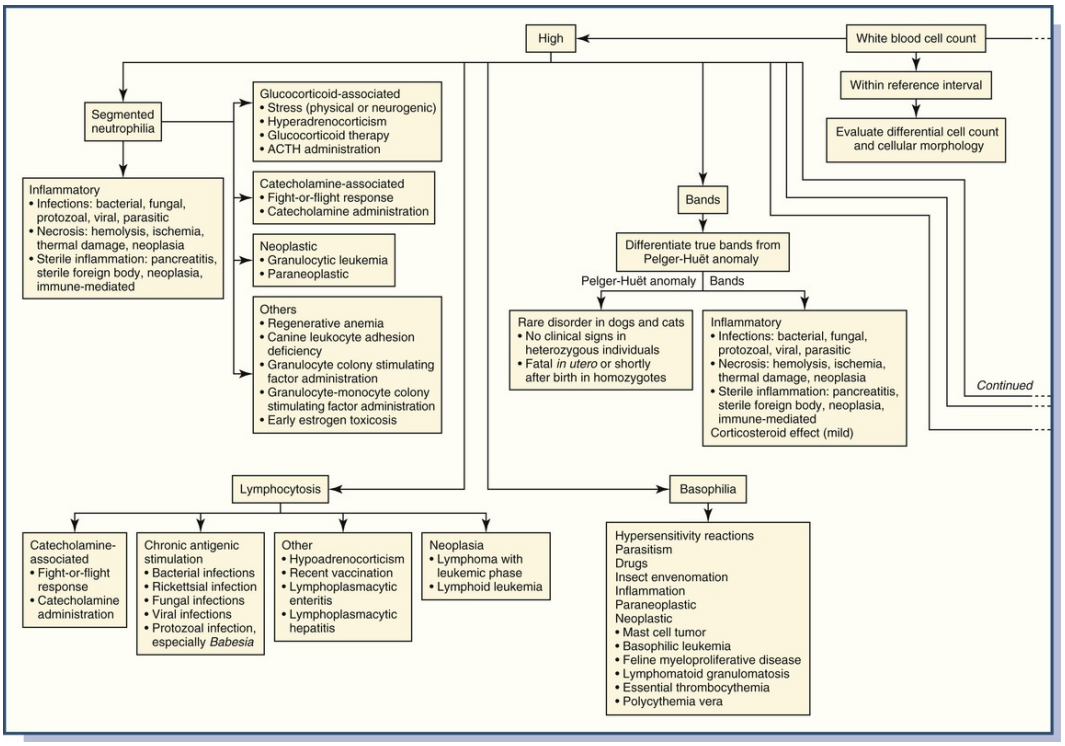
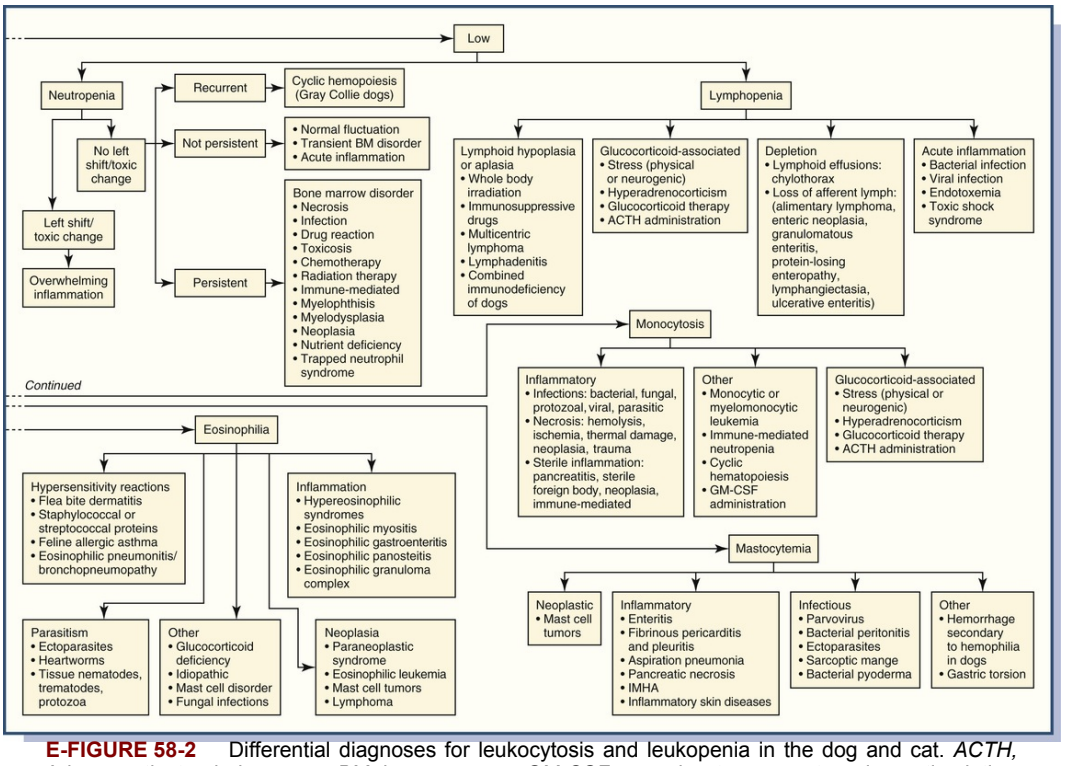
‡Bacterial or viral.

The number of affected cats, total number of cats in the study and then percentage of affected cats in study are noted.

General mechanistic causes of neutropenia include decreased marrow production, increased peripheral usage, vascular sequestration (anaphylaxis and sepsis), and immune-mediated destruction of either mature neutrophils (in the periphery or in marrow reserves), or immature precursors (E-Figure 58-2).[32] Causes of peripheral neutrophil usage include severe infections (bacterial, viral or fungal), and specifically, septic peritonitis, pyometra, pyothorax and enteric salmonellosis among others.[33,34] Inflammatory diseases like pancreatitis, bile peritonitis, organ torsion or tissue infarction also can cause neutrophil migration. Most of these conditions can result in neutrophilia; however, if demand exceeds production of neutrophils, neutropenia could result.[31] Neutrophils follow a cytokine and haptenic pathway composed of C5a, CXCL-8, leukotriene B4 and platelet activating factor among other signals to the site of inflammation.[35-37] Decreased bone marrow production of neutrophils or other cell lines occurs secondary to failure of the elements of the hematopoietic niche.[38] Pharmacologic agents like chloramphenicol, azathioprine, phenobarbital, phenylbutazone, methimazole, sulfa derivatives, and others have been linked to neutropenia and other cytopenias.[36,39-42] Additionally, chemotherapy or neoplastic infiltration of the bone marrow can result in marrow hematopoietic suppression or collapse.[43-46]





E-FIGURE 58-2 Differential diagnoses for leukocytosis and leukopenia in the dog and cat. *ACTH*, Adrenocorticotropic hormone; *BM*, bone marrow; *GM-CSF*, granulocyte-monocyte colony stimulating factor; *IMHA*, immune-mediated hemolytic anemia. (Adapted from Jackson ML: Leukocytes in health and disease. In Ettinger SJ, Feldman EC, editors: *Textbook of veterinary internal medicine*, ed 7, St Louis, 2010, Saunders, p 809; Stockham SL, Scott MA: Leukocytes. In *Fundamentals of veterinary clinical pathology*, Ames, IA, 2002, Iowa State Press, pp 49-83; and Stockham SL, Keeton KS, Szladovits B: Clinical assessment of leukocytosis: distinguishing leukocytosis caused by inflammatory, glucocorticoid, physiologic and leukemic disorders or conditions. *Vet Clin North Am Small Anim Pract* 33(6):1335-1357, 2003.)

Lymphopenia rarely is a cause of leukopenia but it could contribute to a reduction in leukocyte count. Lymphopenia is most commonly due to viral infection, or the effect of glucocorticoids in ill animals. A decrease in circulating monocytes, eosinophils, or basophils rarely results in leukopenia because they account for a minor percentage of leukocytes.

Approach to Evaluation of Leukocytosis and Leukopenia

Leukocytosis and leukopenia are common findings on the CBC. Therefore, a systematic approach to assessing leukocytosis or leukopenia is essential. Changes in white blood cell counts generally are nonspecific findings and rarely are pathognomonic for a particular disease process. Rather, these changes help alert the clinician of possible disease. Additionally, a normal white blood cell count does not rule out infection, inflammation, autoimmune disease or neoplasia.

The first step in assessment of the peripheral blood white cell count should always include an overall absolute cell count, a differential cell count, and morphologic description of the cells. Machine-generated differential cell counts can be inaccurate; therefore, evaluation of the blood smear to determine a differential cell count and evaluate cellular morphology is an indispensable step in the diagnostic evaluation for any animal with leukocytosis or leukopenia. Often during the initiation of inflammation, a transient leukopenia develops, either due to a shift in the leukocyte pool or when, in cases of overwhelming inflammation, the demand for leukocytes transiently exceeds the supply. Care should be taken to identify if leukopenia is transient or persistent by serially evaluating the white blood cell count, the differential count, and morphology of the leukocytes. In general, transient leukopenia due to acute inflammation resolves within 4-24 hours.

Discriminating among the possible causes of leukocytosis and leukopenia (see E-Figure 58-2) requires identification of the specific pattern of cells affected, coupled with the clinical history and physical examination findings. A complete history (clinical signs, past or recent illnesses, exposure to toxins, medications, trauma, travel, vaccination, exposure to infectious agents) and performance of a thorough

physical examination allow the clinician to prioritize differential diagnoses. Exam findings of fever or hypothermia, scleral injection, lymphadenomegaly, organomegaly, effusions, abscesses, or heart murmurs are particularly important. A serum biochemical profile and urinalysis should be reviewed to look for clues not identified on physical examination. Based on the information gained, a list of likely differential diagnoses can be assembled and a logical approach can be planned for additional diagnostics. Testing may include imaging with modalities such as radiographs, ultrasound, computed tomography, or magnetic resonance imaging. Additional testing may include serologic titers, aspiration or biopsy of enlarged or morphologically altered organs or of effusions, cardiac ultrasound, and microbial cultures of blood, urine, effusions, or purulent material. Bone marrow aspiration or biopsy frequently is indicated in instances of suspected leukemia or when persistent leukopenia, bicytopenia, or pancytopenia is identified. Specialized tests like flow cytometry, PARR, and anti-neutrophil antibody testing can be employed to identify neoplasia or immune-mediated neutropenia if indicated.[47-49]

CHAPTER 59

Thrombocytopenia, Thrombocytosis

Marjory B. Brooks

Platelets are small anucleate cell fragments that play a critical role in hemostatic and pathologic thrombus formation. Quantitative defects of platelet number are readily detected as increased or decreased platelet number in the complete blood count (CBC, hemogram). A consistent diagnostic strategy helps streamline the management of patients with thrombocytopenia or thrombocytosis.

Platelet Life Cycle

Platelets are produced from bone marrow megakaryocytes and they circulate for approximately 5-9 days in dogs and cats.[1] The cytokine thrombopoietin (TPO) is the major regulator of megakaryocyte maturation; however, additional non-TPO growth factors act synergistically with TPO. The liver is the primary site of TPO synthesis and, upon release, TPO binds to a ligand (c-Mpl) expressed on megakaryocytes and platelets. Free TPO levels maintain a constant platelet mass. As the platelet count falls, free TPO levels increase to stimulate thrombopoiesis. Conversely, as the platelet count rises, free TPO levels fall and thrombopoiesis slows. In addition to constitutive expression, senescent platelets, lacking sialic acid residues, bind to specific receptors on hepatocytes to induce upregulation of TPO production.[2]

Platelets in circulation undergo transient splenic sequestration, with approximately one third of total platelet mass compartmentalized within the spleen in healthy individuals.[3] Prothrombotic and inflammatory stimuli induce platelet activation and incorporation into a hemostatic plug, or egress into tissues from microvascular leakage. Non-activated platelets undergo gradual apoptotic death and subsequent clearance by hepatic and splenic macrophages.

Disease processes that upset the balance of platelet production, activation, and clearance result in an increase or decrease in platelet count. Thrombocytopenia is among the most common acquired bleeding disorders in small animal practice, whereas thrombocytosis more often is identified as an abnormal laboratory finding with no specific clinical signs. The reference intervals for platelet counts in dogs and cats are indicated in Table 59-1.

TABLE 59-1

Reference Intervals for Canine and Feline Platelet Count and Mean Platelet Volume*

	PLATELET COUNT ($\times 10^3$/mcL)	MEAN PLATELET VOLUME (fL)
Canine	186-545	8.4-14.1
Feline	195-624	9.1-24.3

*Advia 2120 Hematology System (Siemens Healthcare).

Values current 2014, Clinical Pathology Laboratory, Cornell University, Ithaca, NY.

Diagnosis of Thrombocytopenia (Figure 59-1)

Clinical Signs

The characteristic physical signs of thrombocytopenia include petechiae, ecchymoses, mucosal hemorrhage (e.g., epistaxis, hematemesis, hematuria, melena) and prolonged bleeding after injury (see ch. 201). The signs

can overlap with signs of acquired or hereditary platelet dysfunction, coagulopathies, von Willebrand disease, vasculopathies, or vascular injury. A platelet count is indicated as a quick assessment to confirm thrombocytopenia and guide subsequent testing. While the risk of bleeding is not strictly correlated with the platelet count, thrombocytopenia rarely is the sole cause of severe or spontaneous hemorrhage at counts >30,000/mcL. Hemorrhage can be exacerbated, however, in thrombocytopenic patients with concurrent coagulation disorders or vascular defects.

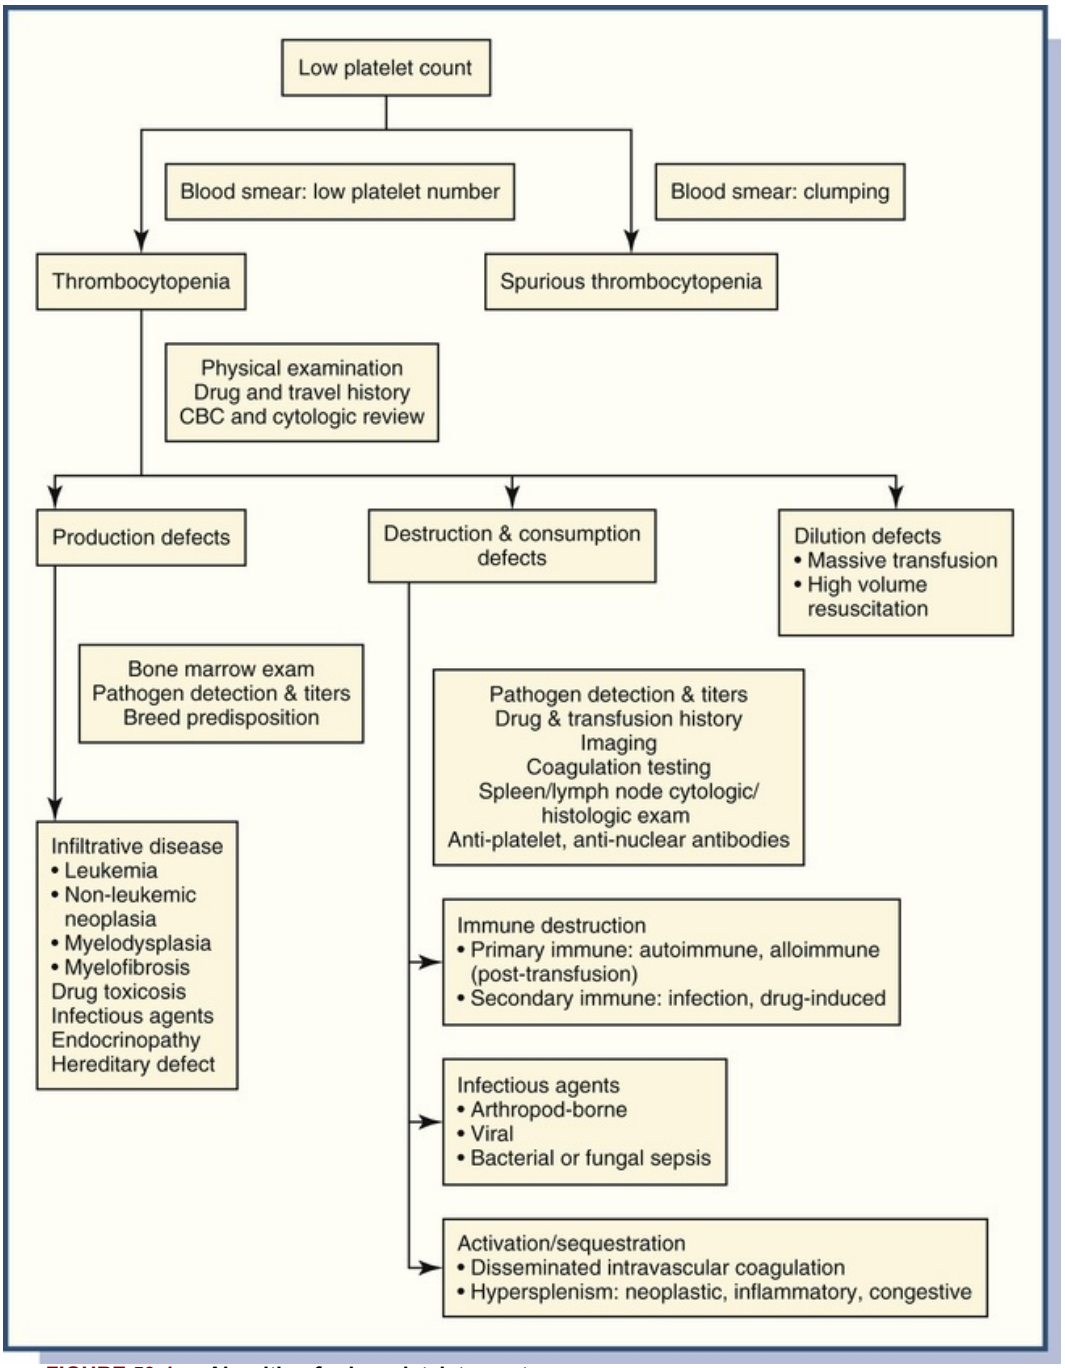

FIGURE 59-1 **Algorithm for low platelet count.**

Diagnostic Testing

Platelet Count and Blood Smear Examination

The platelet number for healthy dogs and cats ranges from approximately 200,000 to 500,000/mcL.[1,3,4] Hematology analyzers also measure mean platelet volume (MPV), an indicator of platelet size that could be useful in characterizing and monitoring thrombocytopenia. Species-specific reference intervals should be developed for in-house methods, or provided by each testing laboratory (see Table 59-1). Thrombocytopenia detected by manual or automated count should next prompt a careful blood smear examination.

Blood smear examination confirms a low platelet number and rules out spurious thrombocytopenia. Platelets are highly reactive and subject to activation and clumping in the process of blood collection or storage.[5] These artifacts are minimized by atraumatic venipuncture, blood collection directly into citrate anticoagulant, limited storage time, and avoidance of cold temperature. After review of the smear edges to detect platelet margination, platelet count is estimated from counting 10 oil immersion fields (100×) on the blood film monolayer as follows: Platelet count (per mcL) = average platelets/field × 15,000.

Additional Diagnostic Evaluation

A diagnosis of thrombocytopenia should prompt a CBC; detailed cytologic review of the blood smear; evaluation of drug and travel history; physical examination to include funduscopic examination; and careful evaluation of spleen, liver, and lymph nodes. Subsequent work-up can include bone marrow examination (see ch. 92), serologic or direct detection of pathogens, imaging with collection of cytologic or biopsy specimens, and coagulation testing (Table 59-2) (see ch. 196).

TABLE 59-2

Diagnostic Tests for Thrombocytopenia and Thrombocytosis

TESTS	SPECIFIC ASSESSMENTS
CBC (hemogram)	Platelet count, MPV, morphology, % reticulated platelets Abnormal cell morphology, cellular inclusion, infectious agents, neoplastic cells
Bone marrow cytology/biopsy	Megakaryocyte maturation, iron stores, infectious agents, lymphoid and myeloid neoplasia, myelodysplasia, myelofibrosis
Spleen/lymph node cytology/biopsy	Infectious agents, neoplastic cells, extramedullary hematopoiesis
Immunophenotyping	Expression of cell surface and cell-type specific markers on peripheral blood, bone marrow, lymph node or splenic cells
Imaging	Hepatosplenomegaly, lymphadenopathy, gastrointestinal and urinary tract integrity
Serologic assays	Detection of pathogen-associated antigens, antibodies directed against pathogens, or autoantibodies to nuclear antigens (ANA) or platelet antigens
Molecular assays	PCR, microarray, sequencing for specific pathogens
Isolation and culture	Pathogen detection
Coagulation assays	Coagulation screening tests (aPTT, PT), fibrinogen, antithrombin, D-dimer
Platelet associated antibody	Detection of immunoglobulin (IgG, IgM) bound to platelets
Mutation detection	*Beta1 tubulin* mutations in CKC Spaniels, Norfolk, Cairn Terriers

Classification of Thrombocytopenia (Figures 59-1 and 59-2; also see ch. 201)

Patients with a variety of systemic diseases can develop transient, mild to moderate thrombocytopenia (platelet count 100,000-150,000/mcL) that resolves as the patient recovers.[6,7] In contrast, persistent or progressive thrombocytopenia indicates an ongoing imbalance in platelet production or consumption, or more complex combined defects.

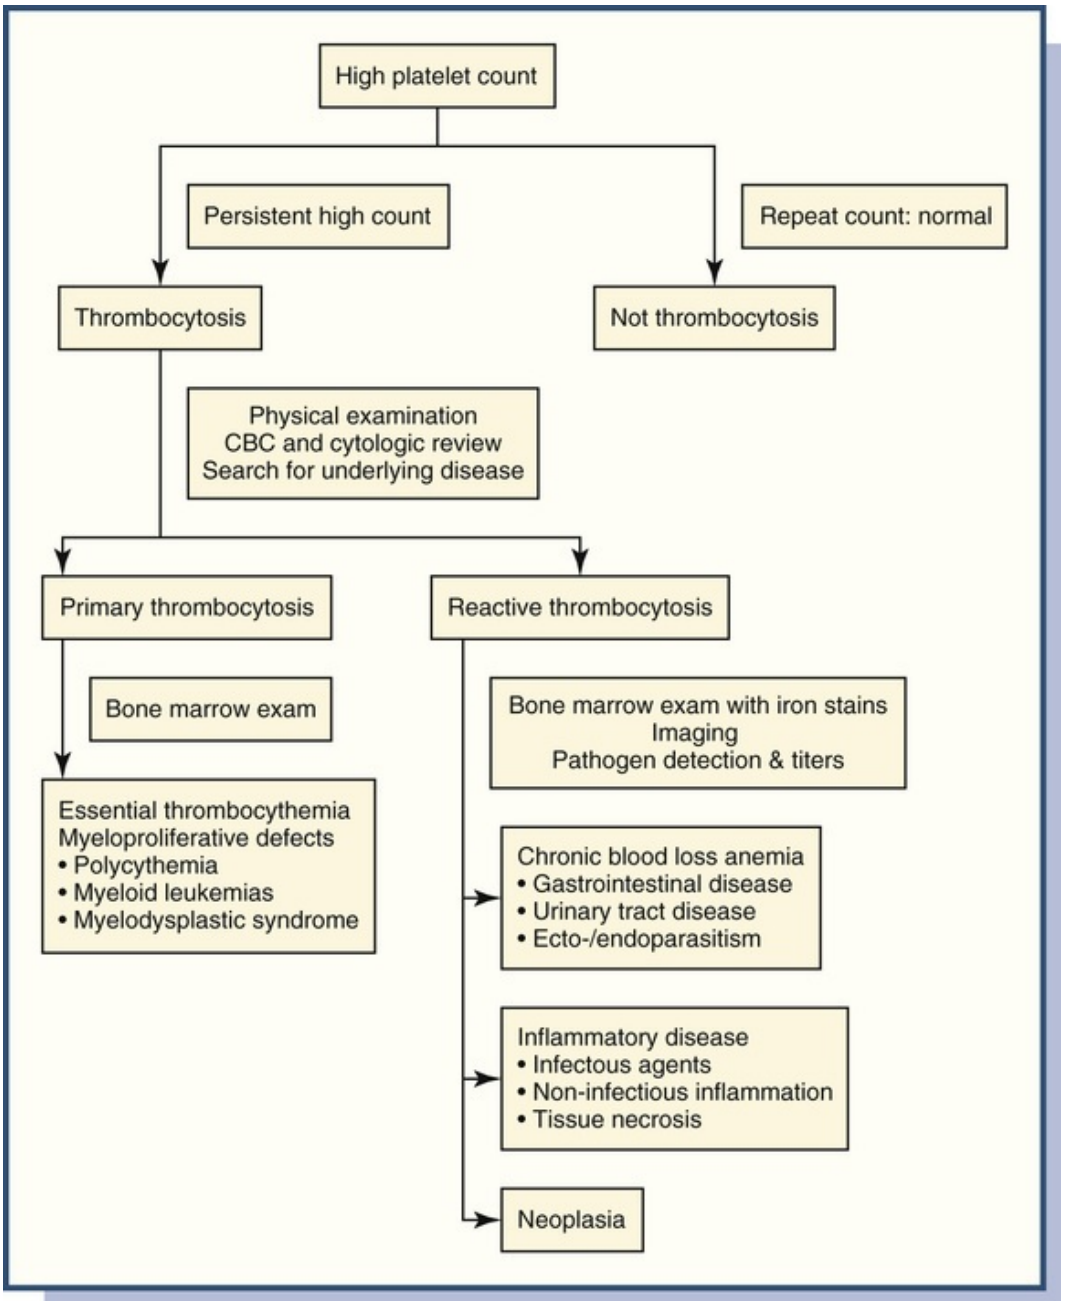

FIGURE 59-2 **Algorithm for high platelet count.**

Production Defects

Thrombocytopenia combined with leukopenia and/or anemia often is an indicator of defective hematopoiesis caused by an underlying bone marrow disorder.[4,6,8] High MPV and thiazole-orange-stained or "reticulated" platelets are characteristic of newly released platelets; however, direct examination of the bone marrow is the best means to evaluate thrombopoiesis (see ch. 92).

- Infiltrative disorders: Bone marrow infiltration by neoplastic cells typically results in hematopoietic failure, and systemic signs that include hemorrhage directly referable to thrombocytopenia. The clinical course, CBC, and bone marrow examination are used for classification of acute versus chronic leukemia and lymphoid versus myeloid leukemia (see ch. 344).[3,4,8] Beyond cell morphology, the most accurate classification includes immunophenotyping to characterize cell surface markers.[9] Bone marrow exam may reveal non-leukemic neoplastic infiltrates, e.g., lymphoma, multiple myeloma, mast cells, histiocytes, and metastatic carcinoma.[8,10] Clonal expansion of hematopoietic precursors (myelodysplasia) also causes

dysregulated cell maturation and cytopenias.[11] Myelofibrosis describes a non-cellular, fibrous matrix that replaces bone marrow stroma. Myelofibrosis results from excessive proliferation of bone marrow fibroblasts in response to injury. Inciting causes of myelofibrosis include chronic drug therapy, hemolytic anemia, bone marrow neoplasia, and prolonged inflammation.

- Drug toxicosis: Drug-induced thrombocytopenia can result from bone marrow suppression, in addition to immune-mediated destruction.[12] Drugs with stem cell toxicity cause pancytopenias, although signs of thrombocytopenia can develop first. Thrombocytopenia is a known side-effect of many chemotherapeutic agents, and a possible complication of the administration of drugs such as estrogen, chloramphenicol, methimazole, penicillin, procainamide, and sulfa antibiotics[13] (Box 59-1).

Box 59-1

Drugs Associated with Thrombocytopenia

Antibacterial and antifungal agents
  Cephalosporins, chloramphenicol, griseofulvin, penicillins, sulfonamides
Anti-inflammatory/analgesic drugs
  Acetaminophen, carprofen, ibuprofen, phenylbutazone
Cardiac and respiratory drugs
  Procainamide, quinidine, thiazide diuretics
Cytotoxic drugs
  Azathioprine, chlorambucil, cisplatin, cyclophosphamide, doxorubicin
Miscellaneous drugs
  Estrogen, phenobarbital, propylthiouracil, methimazole

- Infectious thrombocytopenias: Infectious agents can cause bone marrow suppression, peripheral platelet activation or sequestration, and immune-mediated platelet destruction. The apparent prevalence of infectious thrombocytopenias is increasing due to more advanced diagnostics and opportunities for exposure to infectious agents arising from pet-friendly travel, suburbanization, and climate change–induced vector range expansion[14-16] (Box 59-2). Point of care tests (ex. SNAP 4Dx, IDEXX Laboratories) are now available to rapidly screen for exposure to certain tick-borne agents. In addition to thrombocytopenia, infectious agents often cause systemic illness. Disease diagnosis is based on these physical exam and laboratory abnormalities and pathogen detection (e.g., immunologic assays, polymerase chain reaction [PCR] amplification, isolation and culture, direct visualization) and/or antibody assays that measure the host immune response to the infectious agent.

Box 59-2

Pathogens That Cause Infectious Thrombocytopenia

Viral agents
  Feline: Feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), panleukopenia virus, feline infectious peritonitis (FIP) coronavirus
  Canine: Distemper virus, herpesvirus, parvovirus, adenovirus
Arthropod-borne agents
  Anaplasma *(A. platys, A. phagocytophilum), Babesia, Bartonella, Cytauxzoon felis, Dirofilaria, Ehrlichia (E. canis, E. platys, E. ewingii), Leishmania, Mycoplasma haemofelis, Rickettsia rickettsii*
Fungal and bacterial agents
  Septicemia: Gram-negative and Gram-positive bacteria
  Histoplasma, Candida, Leptospira sp.

- Endocrine disorders: Estrogen causes bone marrow suppression in dogs and can cause severe thrombocytopenia or pancytopenia.[13] Functional ovarian granulosa cell tumors and Sertoli cell tumors are sources of endogenous estrogen excess that typically are diagnosed and treated through examination and surgical excision. Although such treatment is now uncommon, drug history could reveal exogenous

estrogen prescribed for pseudopregnancy, mismating, incontinence, or prostatic hypertrophy. Hypothyroidism is associated with general bone marrow depression; however, clinically severe thrombocytopenia due to thyroid insufficiency is unlikely.

- Hereditary thrombocytopenias: A large survey of Greyhounds revealed a mild, clinically silent reduction in platelet count.[17] Hereditary macrothrombocytopenia of Cavalier King Charles Spaniels is attributed to aberrant platelet microtubule assembly caused by a point mutation in the *beta1 tubulin* gene.[18] Homozygotes have high MPV and platelet counts from 25,000 to 75,000/mcL. A second, distinct *beta1 tubulin* mutation has been found in Norfolk and Cairn Terriers.[19] A *beta1 tubulin* structural variant unique to felids is also speculated to cause the relatively wide variation in platelet size and count in domestic cats.[20] Despite low counts, platelet mass is preserved in macrothrombocytopenic defects and the traits do not cause a bleeding tendency.

Destruction and Consumption Defects

Excessive platelet activation, sequestration, or targeted destruction can exceed the bone marrow's capacity to maintain platelet numbers. Among these mechanisms, immune-mediated destruction often is associated with the most severe thrombocytopenia (<20,000/mcL) (see ch. 201).[6,21,22]

- Immune-mediated destruction: Primary immune-mediated thrombocytopenia (ITP) is an autoimmune disorder characterized by production of antibodies directed against normal "self" platelet antigens.[21-23] Secondary immune thrombocytopenias are associated with an underlying disorder (e.g., infection, neoplasia, drug exposure, transfusion) that introduces neoantigens or upsets the host's immune balance. Anti-platelet antibody assays screen for antibodies bound to the patient's platelets (platelet surface immunoglobulin [PsAIg]) or circulating antibodies capable of binding platelets.[22] However, PsAIg or indirect antibody assays do not differentiate primary from secondary ITP, and non-specific platelet antibody binding further limits their clinical utility.
  Primary ITP is more common in dogs than in cats. Case series of canine ITP indicate a disease of middle-aged dogs, over-representation of females, and breed predispositions (Cocker Spaniels, Poodles, Old English Sheepdogs).[21,24] The diagnosis typically is based on combined clinical and laboratory criteria: exclusion of underlying disease, severe thrombocytopenia (<50,000/mcL), normal to increased megakaryopoiesis, and response to immunosuppressive therapy.
- Platelet activation and consumption defects: Platelet activation and depletion accompany infectious and non-infectious vasculitides through thrombus formation and egress from the vascular space. Thrombocytopenia is a common feature of endotheliotropic pathogens and is often present in cats with feline infectious peritonitis (FIP)–associated immune-complex vasculitis.[25,26] Certain snake venoms can directly activate platelets and indirectly result in activation and clearance due to tissue injury and vascular leakage.[27] Progressive platelet consumption is a feature of disseminated intravascular coagulation (DIC).[28,29] Diagnosis of activation and consumptive defects usually involves characterization of a DIC process through coagulation testing and screening for an underlying infectious agent, neoplastic disorder, or inflammatory syndrome. Cardiopulmonary bypass is uncommon in companion animals, but when it is performed, *ex vivo* platelet activation and thrombocytopenia can complicate pump circulation and associated drug therapy.[30,31]
- Sequestration defects: Diseases that cause splenic enlargement can result in platelet sequestration and clearance, or hypersplenism. Diagnostic efforts are based on the differentials for splenomegaly, such as infectious agents, neoplasia (often mast cell neoplasia, lymphoma, hemangiosarcoma), and congestion secondary to portal hypertension or heart failure (see ch. 206 and 344).

Dilutional Defects

Rapid administration of high volumes of crystalloid fluids or plasma expanders, and massive transfusion (replacement of >1 blood volume in 1 day, >50% blood volume in 4 hours) can result in a decreased platelet count.[32] Although uncommon, dilutional thrombocytopenia can be sufficiently severe to impair *in vivo* hemostasis.

Diagnosis of Thrombocytosis (see Figure 59-2)

Mild to moderate increases in the platelet count develop as a "reactive" bone marrow response to chronic

blood loss or inflammation. Reactive thrombocytosis requires no treatment beyond correction of an underlying disorder. Autonomous (primary) thrombocythemia is characterized by marked elevation in platelet count (>900,000/mcL) and is a feature of rare, potentially fatal myeloproliferative disease.[33]

Clinical Signs

Reported signs of primary thrombocythemia include fever, splenomegaly, anemia, evidence of thrombosis, and hemorrhage. Reactive thrombocytosis does not typically cause specific signs.

Diagnostic Testing

The presence of thrombocytosis should first be confirmed by repeating the CBC and reviewing the blood smear, followed by appropriate work-up to identify an underlying disorder.[33-36] Persistently high platelet counts also can occur after splenectomy. Primary thrombocythemia is diagnosed by bone marrow examination, often with assessment of iron stores to rule out iron deficiency.

Classification of Thrombocytosis

Primary (Essential) Thrombocythemia

Essential thrombocythemia refers to an isolated increase in platelet count. However, thrombocytosis can be a prominent feature of other myeloproliferative disorders, including myeloid leukemias, polycythemia, and myelodysplastic syndrome.[35]

Secondary (Reactive) Thrombocytosis

A general upregulation of cytokine growth factors, including TPO, is the presumed cause of reactive thrombocytosis. Chronic blood loss, infection, inflammation, malignancy, and tissue necrosis are among the disease processes associated with this response. Occult neoplasia and gastrointestinal or urinary blood loss can require concerted diagnostic efforts including careful imaging to identify the inciting cause of persistent thrombocytosis.

CHAPTER 60

Hypoproteinemia, Hyperproteinemia

Shelley Burton

Measurement of Serum and Plasma Protein

On serum biochemical panels, protein concentrations determined by automated analyzers are reported as total protein, albumin, and globulin(s). The globulin concentration is obtained by subtracting the albumin concentration from the total protein concentration, so is comprised of all proteins which are not albumin. These are mainly antibodies, with acute phase proteins and numerous other proteins making up the rest. Compared to serum, plasma includes coagulation factors such as fibrinogen, which are absent from serum due to clot formation. Therefore, a plasma sample typically has a slightly higher protein concentration than a concurrently collected serum sample. Plasma protein concentrations obtained as part of a complete blood count are determined via refractometry, with total solids causing a proportional change in refractive index. The presumption that the refractive index is proportional only to protein assumes typical concentrations of other substances like glucose or lipids. However, high concentrations of these substances will increase the refractive index to result in falsely elevated protein readings. Because plasma contains coagulation proteins absent from serum, and refractometry and automated analysis are different methods, perfect numerical agreement in total protein concentrations is unreasonable. However, a good rule of thumb is that the two readings should generally agree within ≈0.5 g/dL (= 5 g/L). If the difference is beyond ≈1.0 g/dL, interfering substances or problems with the refractometer or analyzer should be investigated, but the reason is not always readily found.

Serum protein electrophoresis separates proteins via charge and weight within a gel or other substance to allow rough quantitation of protein groups and characterization of the migration pattern. Peaks on the resulting electrophoretogram correspond to gel areas to which proteins have migrated. Electrophoretograms are divided subjectively into sections, most typically alpha 1, alpha 2, beta and gamma. The alpha 1 and alpha 2 areas are where the majority of positive acute phase proteins migrate. IgM migrates to the beta region and IgA and IgG to the gamma region. Protein concentrations in each electrophoretic category are determined by multiplying area percentages by the total protein concentration. Minor changes in these are not significant and the overall electrophoretic pattern is much more useful. An increase in the gamma or sometimes beta region is termed a gammopathy; these are divided based on pattern shape into two types. Monoclonal gammopathies are characterized by a single narrow based peak and polyclonal gammopathies by a broad based smooth peak or series of peaks (Figure 60-1).

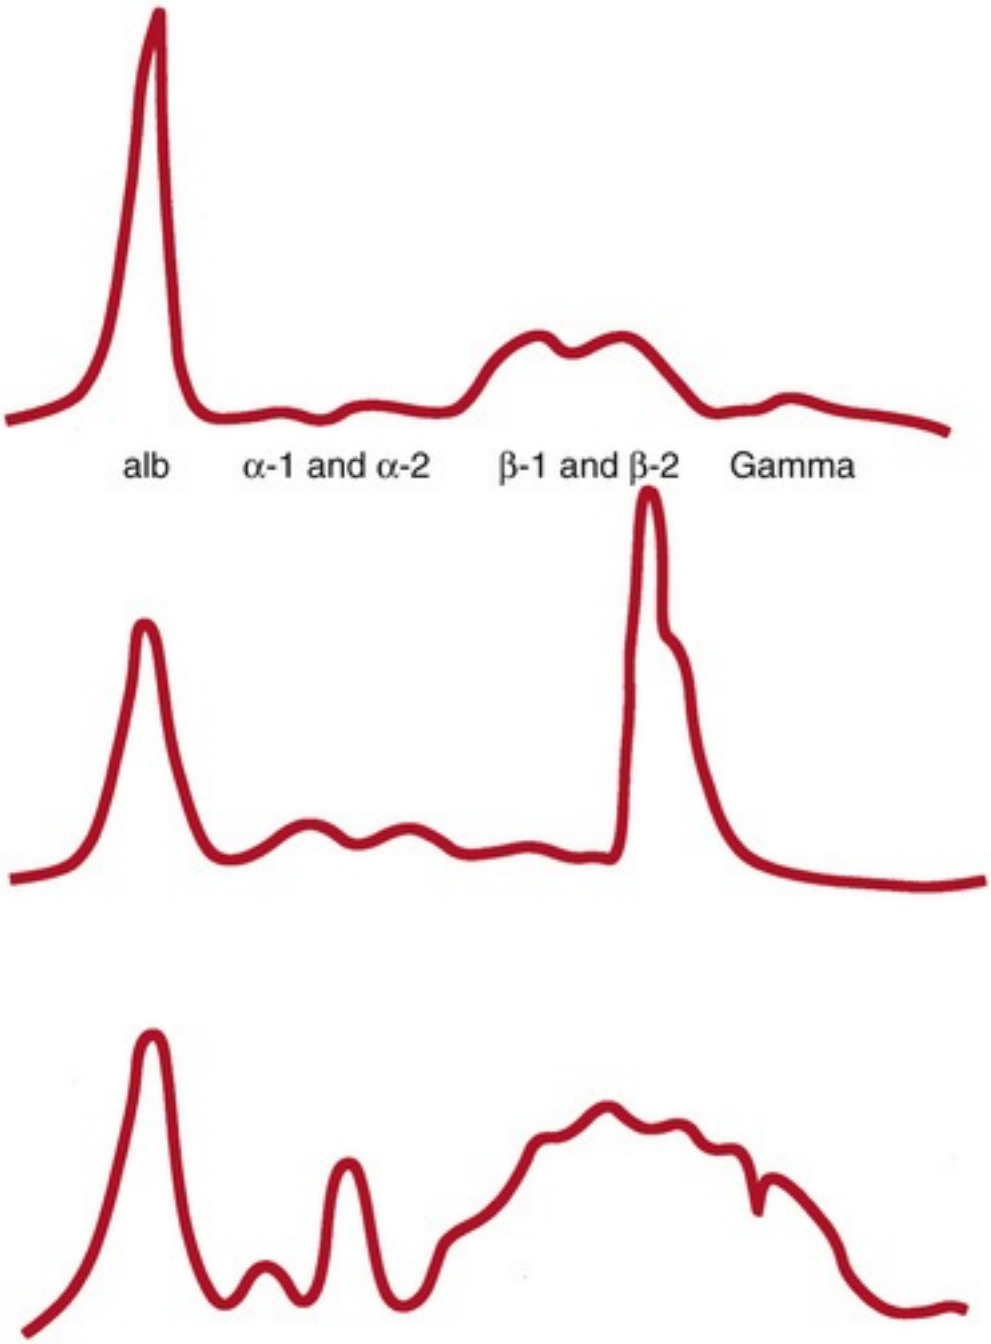

FIGURE 60-1 Serum protein electrophoretograms showing a normal pattern, a monoclonal gammopathy and a polyclonal gammopathy. *alb,* Albumin. (Courtesy Couto CG: Hyperproteinemia. In Nelson RW, Couto CG, editors: *Small animal internal medicine,* ed 5, St Louis, 2014, Elsevier, pp 1276-1278.)

Positive and Negative Acute Phase Proteins

Increased positive acute phase protein concentrations in serum or plasma support inflammation, but testing is not widely available. These are produced by the liver and include C-reactive protein, serum amyloid A, haptoglobin, and many others.[1] The degree of increase and the type of proteins produced vary between species. The acute term is a partial misnomer; although protein production does increase rapidly, it can also continue for many months if inflammation is ongoing. Aside from fibrinogen and haptoglobin, even marked increases in positive acute phase protein production do not increase total serum or plasma protein concentrations. Negative acute phase proteins are those with decreased serum or plasma concentrations in

inflammatory states. Cytokines such as interleukin (IL)-6 and IL-1 cause hepatocytes to decrease production of these proteins while increasing production of positive acute phase proteins.[2] Albumin is the main negative acute phase protein[2] and mild hypoalbuminemia is commonly found in patients experiencing inflammation.

Causes of Hypoproteinemia

Marked hypoproteinemia has serious consequences, especially if albumin concentrations are too low to maintain colloid osmotic pressure. Edema and effusions can result.[3] Hypoproteinemia can be due to a decrease in concentrations of albumin, globulin or both; this latter situation is termed panhypoproteinemia. A normal albumin : globulin (A : G) ratio is expected in panhypoproteinemia, a low ratio if only albumin is decreased and/or globulins are increased, and a high ratio if only globulins are decreased. A diagnostic pathway for hypoproteinemia is found in Figure 60-2.

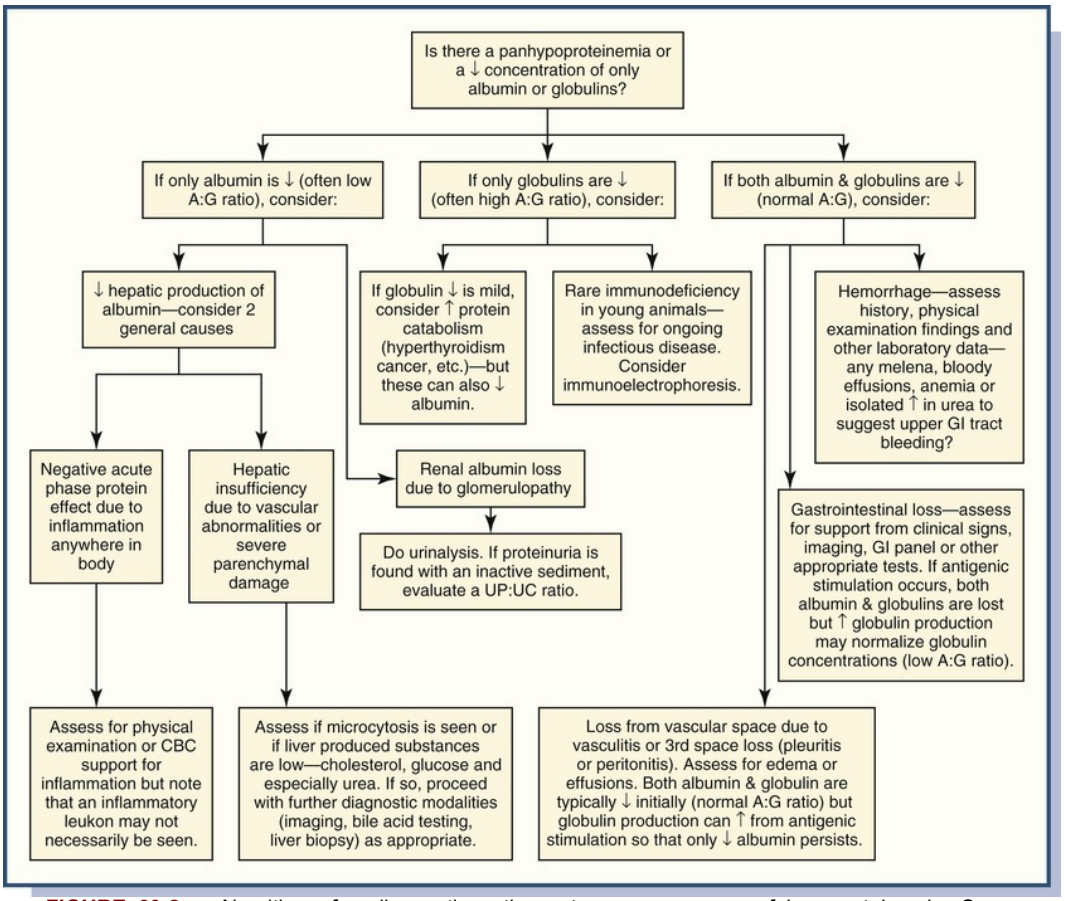

FIGURE 60-2 Algorithm of a diagnostic pathway to assess causes of hypoproteinemia. Some conditions overlap depending on severity and stage. *A : G,* Albumin : globulin; *CBC,* complete blood count; *GI,* gastrointestinal; *UP : UC,* urine protein : urine creatinine.

Panhypoproteinemia is seen in hemorrhage and is a typical feature of protein-losing dermatopathies and loss from the vascular space due to vasculitis, pleuritis, or peritonitis.[4] It also is common in protein-losing enteropathies,[5] but if sufficient antigenic stimulation occurs due to inflammatory bowel disease or other conditions, increased antibody production can offset globulin loss. This can instead result in normal or even high serum globulin concentrations (see ch. 276).[6] The same is true for chronic vasculitis, pleuritis, or peritonitis in which antigenic stimulation is occurring. Hypoalbuminemia with normal globulin concentrations should also prompt concern for decreased liver production and/or renal loss. Decreased hepatic production of albumin as a negative acute phase protein effect takes several days to occur, and clinical or hematologic support for inflammation can be found. The degree of albumin concentration decrease is typically mild (<30% from the patient's normal value)[4] so a more marked decrease should prompt

investigation into other causes. Decreased albumin production also occurs in hepatic insufficiency due to vascular anomalies such as portosystemic shunts[7] or from advanced hepatic parenchymal disease (see ch. 282, 284, and 285). The degree of hypoalbuminemia is typically more severe than that caused by inflammation. Serum concentrations of other liver-produced substances may be low, such as urea, cholesterol, and sometimes glucose. A diagnostic clue in some cases is microcytosis due to abnormal iron status.[8] Hepatic insufficiency is confirmed and characterized with bile acid testing, diagnostic imaging, and biopsy (see ch. 280). Another consideration for hypoalbuminemia is renal loss due to various glomerulopathies (see ch. 325).[9] Since albumin has a relatively low molecular weight,[3] it is lost more readily than the immunoglobulins making up the majority of the globulin component of serum or plasma. Finally, when marked hyperglobulinemia is seen, albumin concentrations tend to decrease. This could reflect decreased albumin requirement for oncotic pressure maintenance if the globulins are performing some of this role, but other disease-related causes might be contributory.[4]

Specific decreases in serum or plasma globulin concentration are not common, but considerations include rare inherited immunodeficiency syndromes or a decrease seen in racing sled dogs.[10] Mild hypoglobulinemia with or without mild hypoalbuminemia is a common finding in hyperthyroid cats in the author's diagnostic laboratory, presumably due to increased protein catabolism.

Breed differences must be considered when evaluating serum or plasma protein concentrations. Healthy Greyhounds have low total serum protein concentrations compared to canine reference intervals derived from other breeds[11]; this also occurs in other sighthounds but is less well documented. In Greyhounds, it is due to low concentrations of alpha and beta globulins, a consideration when interpreting electrophoretic patterns in this breed.[12]

Causes of Hyperproteinemia

Increased serum or plasma protein concentrations can be due to proportional or disproportional increases in the albumin and globulin components. In a proportional increase, the A : G ratio is normal; this is termed panhyperproteinemia or occasionally non-selective hyperproteinemia.[4] This is a relative hyperproteinemia resulting from hemoconcentration due to dehydration. Related findings can include erythrocytosis and pre-renal azotemia. In contrast, an absolute hyperproteinemia characterizes a high total protein concentration due to enhanced production of either albumin or globulin. This disproportional increase shifts the A : G ratio and is sometimes termed selective hyperproteinemia.[4]

It is rare for an appreciable increase in albumin concentration to occur without an increase in globulin concentration; this should prompt consideration of a laboratory error or rarely albumin production from a hepatic tumor.[13] In most cases, a disproportional increase in total protein concentration is due to increased globulin concentrations rather than a change in albumin. Increased globulin production is due to antigenic stimulation or, less commonly, due to production by a B-lymphoid or plasma cell neoplasm.

When marked hyperglobulinemia is detected, serum protein electrophoresis to classify the pattern as a polyclonal or monoclonal gammopathy is the next logical step. In antigenic stimulation due to infectious or immune-mediated disease, a polyclonal gammopathy pattern is expected. Increased production of antibodies that vary mainly in charge and weight by many clones of B-lymphocytes migrate widely to produce a smooth or jagged broad-based peak on the electrophoretogram. In contrast, the narrow peak of a monoclonal gammopathy pattern occurs due to restricted migration of many identical immunoglobulins or immunoglobulin fragments, both of which are termed paraproteins, or M proteins. A true monoclonal gammopathy reflects clonal proliferation of a single neoplastically transformed B-lymphocyte or plasma cell. This is seen in various cancers, including multiple myeloma, B-cell lymphoma or leukemia, or rarely Waldenstrom's macroglobulinemia (see ch. 344). Hyperviscosity due to high concentration of paraproteins in these conditions can cause signs such as bleeding,[14,15] ophthalmic disease,[16] or seizures (see ch. 352).[17]

Infectious or immune-mediated diseases occasionally can stimulate multiple clones of B-lymphocytes or plasma cells to produce antibodies which are so similar in charge and weight that they migrate similarly during electrophoresis. This results in a narrow peak which mimics a monoclonal gammopathy, and indeed is characterized as such on pattern evaluation. This has been more properly termed a restricted pattern oligoclonal gammopathy and is likely the explanation for monoclonal gammopathies reported in infectious or immune-mediated diseases such as pyoderma[18] or plasmacytic enteritis.[19] Awareness of this dictates that B-lymphoid or plasma cell neoplasia is never diagnosed solely on the presence of a monoclonal gammopathy. For example, other criteria needed to diagnose multiple myeloma in dogs include hypercalcemia, lytic bone

lesions, and marked marrow plasmacytosis.[20] The presence of immunoglobulin light chains in urine, termed Bence-Jones proteins, is also a supportive finding.[21] Detection of these is challenging but is supported by a thermal precipitation test or urine electrophoresis (see ch. 344).

Not all pathologic changes in protein components result in hyperproteinemia. While antigenic stimulation is a common cause of hyperglobulinemia, it does not necessarily increase total protein concentrations, especially if mild or early. In any situation of concurrent hypoalbuminemia and hyperglobulinemia, the A : G ratio will decrease but the total protein concentration may stay within the reference interval. There are also rare cases of increased production of paraproteins which cause a monoclonal pattern but do not result in hyperproteinemia[22] or those that cause Bence-Jones proteinuria without a detectable monoclonal gammopathy.[23]

CHAPTER 61

Hypoglycemia, Hyperglycemia

Yaiza Forcada

Hypoglycemia

Definitions and Clinical Signs

Hypoglycemia in cats and dogs is defined as an inappropriately low blood glucose (BG), falling below the lower limit of the reference interval of the chosen measurement method. The exact number can vary, although <60 mg/dL is often quoted. Hypoglycemia should be repeatable (preferably by a standardized method). Clinicians should be aware of possible factors that could cause spurious hypoglycemia prior to embarking on further investigations. Such factors include a delay in separation of the plasma or serum which could lead to *in vitro* glycolysis in the cellular components of blood (most severe in pets with erythro- or leukocytosis), hemolysis, or the use of human-specific hand-held blood glucose devices.[1,2]

In most patients, clinical signs of hypoglycemia do not occur until the blood glucose is 10 to 20 mg/dL below laboratory reference intervals, although this can vary depending on chronicity and cause of hypoglycemia. Some of the most common clinical signs associated with hypoglycemia are associated with adrenaline-driven activation of the sympathetic nervous system: tremors, nervousness, anxiety, hunger and aggression. Clinical signs are also caused by neuroglycopenia, since the brain is dependent on blood glucose for cellular metabolism. Neuroglycopenia-related signs include weakness, ataxia, behavioral changes, seizures and coma. Clinical signs can be acute or progress over time, e.g., with insulin-producing tumors.

Causes of Hypoglycemia

The causes of hypoglycemia can broadly be divided into the following groups:

- **Decreased glucose production:** this is the most common cause of hypoglycemia seen in young cats or dogs (especially toy breeds). Hypoglycemia in puppies and kittens is most often related to inadequate food intake. Their glycogen stores are reduced when compared with healthy adults. Thus, hypoglycemia in fasting healthy adult animals is extremely rare. Additionally, pets with acute liver failure, end-stage chronic liver disease (see Section XIX) or cortisol deficiency (see ch. 309) can have a reduction in hepatic glycogen stores, as well as impaired gluconeogenesis and glycogenolysis. Hypoglycemia is relatively uncommon in pets with porto-systemic shunts (PSS; see ch. 284).
- **Increased glucose removal from the blood:** conditions in this category include over dosage of insulin or an oral hypoglycemic agent. Naturally occurring hypoglycemia can be caused by an insulin- or insulin-like-substance-producing tumor, usually in older pets (see ch. 303).[3-11] Toxins that induce inappropriate insulin release, such as xylitol, can cause hypoglycemia in dogs.[12,13] Primary renal glycosuria rarely leads to hypoglycemia.

Box 61-1 contains a more comprehensive list of the differential diagnoses to consider in both these groups. The list includes conditions that cause hypoglycemia due to a combination of factors or through unknown mechanisms.

Box 61-1

Causes of Hypoglycemia in the Dog and Cat, According to Pathophysiological Classification

Hypoglycemia Due to Reduced Glucose Production

Portosystemic hepatic vascular shunt
Acute liver failure
Chronic end-stage hepatopathy (mild hypoglycemia)
Hypoadrenocorticism (mild hypoglycemia)
Toxins: ethylene-glycol/ethanol
Medications/toxins: propranolol*
Growth hormone deficiency*
Glycogen storage disease*
Type I: von Gierke's disease
Type III: Cori's disease

Hypoglycemia Due to Increased Removal of Glucose

Insulin overdose
Oral hypoglycemic agents
Insulinoma
Insulin-like-substance-producing tumors: hepatoma, leiomyoma, leiomyosarcomas, carcinomas, melanomas, plasma cell tumors, etc.
Polycythemias: primary erythrocytosis, leukemias*
Toxins: xylitol, oleander[16,17]*
Renal glycosuria*
Infection: *Bartonella*[18]*

Other Causes: Combination of Factors/Unknown

Sepsis/systemic inflammation[19,20]
Babesia infection*
Cardio-pulmonary arrest/resuscitation[21]
Toxins: alpha-lipoic acid[22]*
Acute/chronic renal failure*
Hunting dog*

*Indicates a rare cause of hypoglycemia.

Diagnostic Approach (Figure 61-1)

When determining the cause of hypoglycemia in a pet, it is recommended to start by thoroughly reviewing history and a full physical examination. These may provide essential clues and help identify whether hypoglycemia is responsible for the patient's clinical signs. If a clinical suspicion of hypoglycemia is not supported on initial testing, it is recommended to repeat BG measurements following a closely monitored period of fasting or exercise. In general, puppies and kittens are at a higher risk of hypoglycemia after periods of anorexia, as are those pets with PSS, sepsis, growth hormone (GH) deficiency, glycogen storage diseases, or toxin ingestion. Adult younger dogs with hypoglycemia are candidates for having hypoadrenocorticism, PSS, liver failure, sepsis, systemic inflammatory disease or toxin ingestion. Older dogs are more likely to suffer from neoplastic disease producing insulin or insulin-like factors, hypoadrenocorticism, chronic end-stage liver failure, sepsis/systemic inflammatory disease or toxin ingestion.

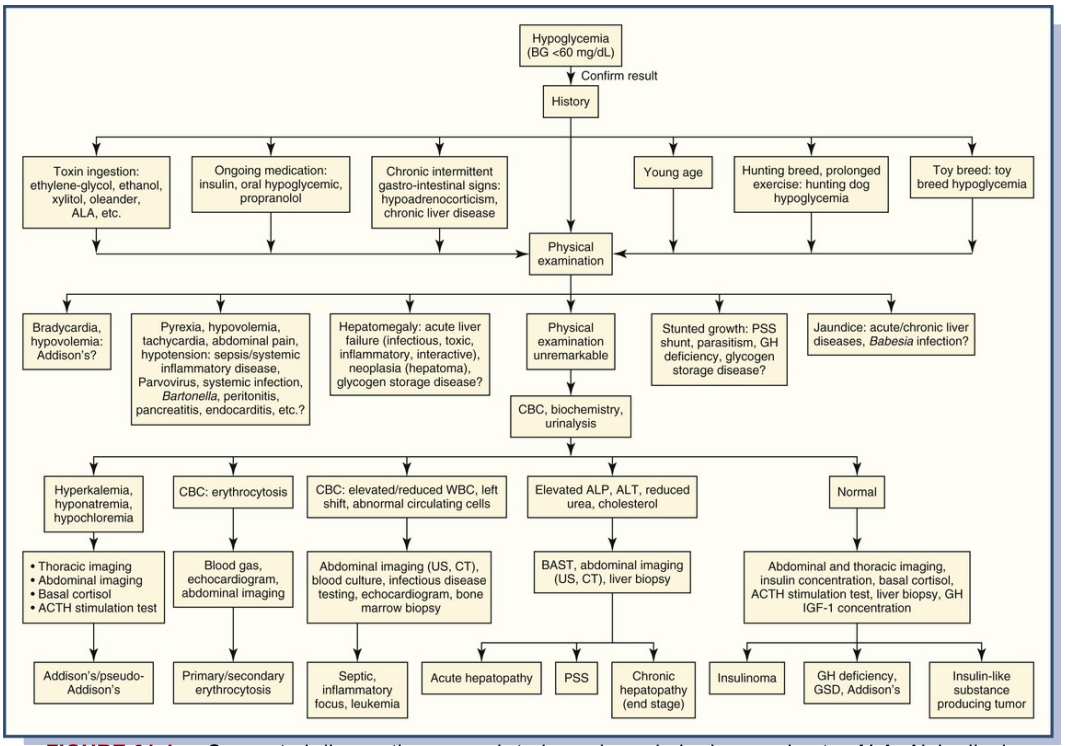

FIGURE 61-1 Suggested diagnostic approach to hypoglycemia in dogs and cats. *ALA,* Alpha-lipoic acid; *BAST,* bile acid stimulation test; *CBC,* complete blood count; *CT,* computed tomography; *GH,* growth hormone; *GSD,* glycogen storage disease; *IGF-1,* insulin-like growth factor-1; *PSS,* porto-systemic shunt; US, ultrasound.

A complete blood count (CBC), serum biochemistry panel and urinalysis can further assist in identifying the cause of hypoglycemia. CBC may reveal polycythemia, evidence of sepsis (leukocytosis/leukopenia, left shift) or the lack of a stress leukogram (hypoadrenocorticism). Patients with PSS or liver failure may have decreases in albumin, urea and/or cholesterol concentrations. Increased liver enzyme activities or serum bilirubin concentration may be observed in liver failure (not usually PSS). A bile acid stimulation test in these pets is likely to be abnormal. Animals with hypoadrenocorticism may have the typical electrolyte abnormalities of hyponatremia, hypochloremia and hyperkalemia. Absence of "classic" electrolyte changes does not, however, rule out hypoadrenocorticism. When hypoadrenocorticism is suspected, a basal cortisol or results of an adrenocorticotropic hormone (ACTH) stimulation test should be considered to confirm or exclude this diagnosis. The presence of glycosuria together with hypoglycemia may suggest possible primary renal loss as a cause for the hypoglycemia. Alternatively, the most common cause of hypoglycemia in an animal with glycosuria would be previous hyperglycemia exceeding renal threshold that decreased precipitously, as sometimes occurs in insulin-treated individuals. Pets with insulinoma or insulin-like factor–producing tumors do not usually have significant abnormalities in the minimum database.[14,15]

Survey diagnostic imaging of the thorax and abdomen (radiography, ultrasound or computed tomography) may prove helpful in identifying septic/inflammatory foci or neoplasia. For confirmation of an insulin-producing tumor, a blood sample should be taken strictly *at the time of hypoglycemia* (preferably when BG is below 50 mg/dL); a normal or high insulin concentration confirms pathological hyperinsulinemia.

Hyperglycemia

Definitions and Clinical Signs

Hyperglycemia in cats and dogs is defined as an inappropriately high BG concentration, exceeding the upper limit of the reference interval of the chosen measurement method. As with hypoglycemia, the exact number can vary, though is often quoted to be >130 mg/dL. Clinical signs of hyperglycemia appear when the blood glucose exceeds the renal threshold (this can be variable, though usually around 180-200 mg/dL in the dog and 200-280 mg/dL in the cat). Excess glucose in the renal tubules causes an osmotic diuresis which leads to polyuria (PU), secondary polydipsia (PD) and, if the water loss is not compensated by increased water intake, dehydration. Additional clinical signs of the primary disease can occur, e.g., weight loss in diabetes mellitus;

coat changes, excessive panting or abdominal enlargement with hyperadrenocorticism (see ch. 306 and 307).

"Stress-Induced" Hyperglycemia

Clinicians should remember that cats, far more commonly than dogs, can develop a physiological hyperglycemia thought to be "stress induced." Stress is associated with catecholamine, cortisol, glucagon and GH secretion, leading to an increase in blood glucose and interference with the actions of insulin. In addition, transformation of lactate generated through muscle activity in stressed animals has been implicated.[23] In suspected "stress hyperglycemia," a repeat BG measurement can be performed at a less stressful time (or at home) or urine can be screened for glycosuria since most of these pets do not have hyperglycemia that exceeds renal threshold (Figure 61-2). A small number, however, do have glycosuria. Alternatively, measurement of fructosamine concentration should help differentiate long-standing versus the brief stress hyperglycemia.[24]

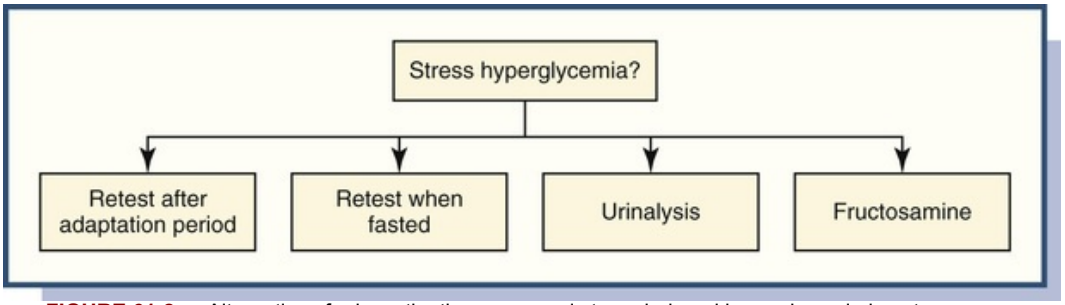

FIGURE 61-2 Alternatives for investigating presumed stress-induced hyperglycemia in cats.

Pathological Causes (Box 61-2)

Pathological causes of hyperglycemia include diabetes mellitus, diestrus diabetes, acromegaly, hyperadrenocorticism, pheochromocytoma, head trauma, pancreatitis, pancreatic neoplasia or iatrogenic (e.g., progestagens, glucocorticoids, megestrol acetate, glucose-containing fluids).

Box 61-2

Differential Diagnoses of Hyperglycemia in Cats and Dogs

Physiological Causes

Stress/excitement (cats)
Post-prandial
Diestrus

Endocrine Causes

Diabetes mellitus
Impaired glucose tolerance (pre-diabetes)
Acromegaly
  Cats: GH-producing pituitary tumor
  Dogs: GH produced in mammary glands during diestrus
Hyperadrenocorticism
Pheochromocytoma
Hyperthyroidism (common in cats, uncommon in dogs)

Problems Originating Initially from Exocrine Pancreas

Acute pancreatitis
Chronic pancreatitis (can be associated with EPI and/or diabetes mellitus)
Pancreatic neoplasia

Iatrogenic

Glucocorticoids
Progestagens
Alpha-2 agonists (medetomidine)
Beta-blockers
Glucose-containing fluids
Parenteral nutrition solutions

Miscellaneous

Toxins: Ethylene-glycol
Head trauma

EPI, Exocrine pancreatic insufficiency; *GH,* growth hormone.

Diagnostic Approach (Figure 61-3)

A thorough history and physical examination is extremely valuable. The clinician should determine if the patient has been receiving any medications that can account for the high BG. One should evaluate the displayed clinical signs and determine if they are related to hyperglycemia or if they give clues about a specific condition. A minimum database including CBC, biochemistry and urinalysis (including culture) is recommended in all cases to provide information about causes and possible consequences of the hyperglycemia. Abdominal imaging will be useful in patients with abdominal pain or to evaluate the adrenal glands. Further investigations such as thyroxine (T_4) concentration or endocrine testing can be considered as necessary.

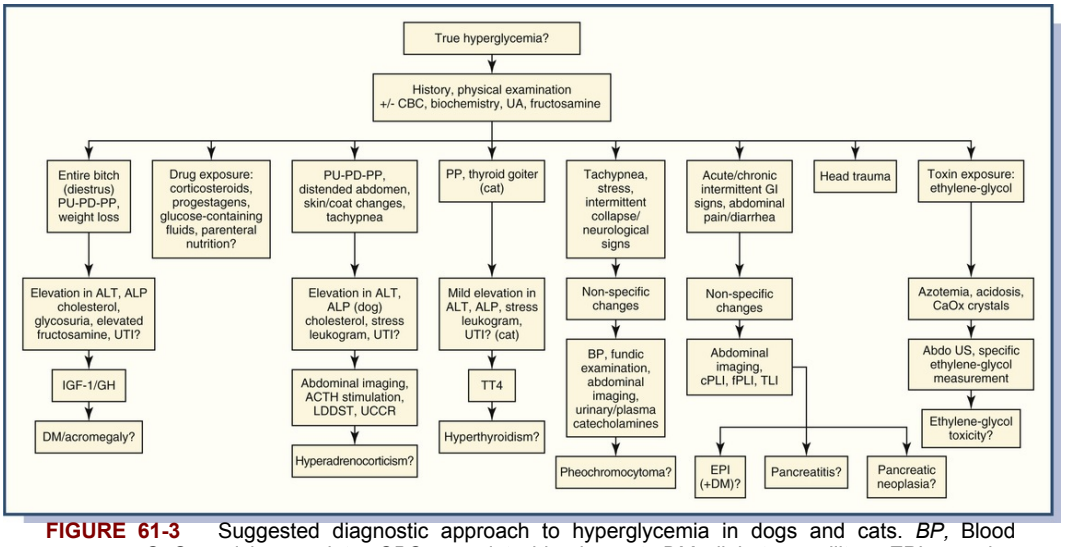

FIGURE 61-3 Suggested diagnostic approach to hyperglycemia in dogs and cats. *BP,* Blood pressure; *CaOx,* calcium oxalate; *CBC,* complete blood count; *DM,* diabetes mellitus; *EPI,* exocrine pancreatic insufficiency; *GH,* growth hormone; *GI,* gastrointestinal; *IGF-1,* insulin-like growth factor-1; *LDDST,* low-dose dexamethasone-suppression test; *PD,* polydipsia; *PP,* polyphagia; *PU,* polyuria; *UA,* urinalysis; *UCCR,* urine cortisol-to-creatinine ratio; *US,* ultrasound; *UTI,* urinary tract infection.

CHAPTER 62

Blood Urea Nitrogen and Creatinine

Carrie A. Palm

Introduction and Definitions

Blood urea nitrogen (BUN) and serum creatinine concentrations are biomarkers commonly used in the health assessment of companion animals. While often evaluated together, each has unique value. Clinicians should appreciate how to utilize each in diagnosis and treatment monitoring. This chapter is dedicated to BUN and creatinine, with a focus on such factors as compound generation and excretion that should be considered in any interpretation.

Terms relating to BUN and creatinine must be defined in order to ensure understanding. Azotemia refers to an increase in concentration of nitrogen-containing substances in the blood, primarily BUN and creatinine. Since BUN and creatinine are both nitrogen-containing compounds, an increase in either compound is, by definition, "azotemia." Uremia or "uremic syndrome" refers to the significant accumulation of substances (uremic toxins) usually excreted in the urine under normal physiologic conditions in a healthy animal. The term uremia is used to describe more severe azotemia, when adverse clinical manifestations are present, while azotemia is defined by any increase in BUN and/or creatinine. BUN and creatinine are the most commonly measured uremic toxins. BUN and creatinine, themselves, are relatively benign and non-toxic, each acting as a marker for many unmeasured uremic toxins that are associated with development of "uremic syndrome."

Blood Urea Nitrogen

Urea is a nitrogen-containing compound excreted in urine, usually expressed in mmol/L. BUN is a measure of the amount of urea nitrogen in the blood and is expressed in mg/dL. These two values give similar information and BUN will be used for the majority of the following discussion. Urea represents a nitrogenous waste product excreted in urine. During protein catabolism, liberated amino acids are converted to ammonia, which is subsequently metabolized to urea through the urea cycle in the liver. Blood urea nitrogen is freely filtered at the glomerulus. BUN is an unreliable estimate of glomerular filtration rate (GFR), however, as urea can be passively reabsorbed in renal tubules. Therefore, the BUN concentration in urine is not necessarily equivalent to the amount filtered at the glomerulus. Understanding BUN production, filtration and reabsorption should help clinicians effectively apply this test result in any patient. For example, remembering that BUN is synthesized in the liver allows the clinician to conclude that a decrease in BUN concentration below the laboratory reference interval may indicate hepatic dysfunction.

Creatinine

Creatinine is generated from breakdown of phosphocreatinine in muscle and, therefore, muscle mass plays an important role in assessment of a patient's serum creatinine concentration. Like BUN, creatinine is freely filtered at the glomerulus. In contrast to BUN, creatinine can be used to provide an estimation of GFR, as there is no significant reabsorption or secretion of creatinine during transit through the nephron. There is, however, significant variation in "normal" serum creatinine concentrations associated with muscle mass and with breed size. Healthy small-breed dogs have creatinine values much lower than those of healthy giant-breed dogs. Serum creatinine concentrations increase from puppyhood through adulthood. Ideally, each patient would have at least one baseline serum creatinine concentration determined in conjunction with a urine specific gravity when they are a healthy young adult. It is critical to evaluate test results in the context of the individual patient.

Symmetric Dimethylarginine (Idexx SDMA)

Please see discussion under chronic kidney disease (CKD).

Causes of Azotemia (Increases in BUN and/or Serum Creatinine)

Background

Azotemia can be subcategorized into being caused by pre-renal (or volume-responsive), renal, or post-renal conditions. These subcategories all represent causes for a decrease in glomerular filtration rate with subsequent decreased excretion of the renal biomarkers, BUN and creatinine. While BUN and creatinine are the most commonly measured biomarkers, they represent only a fraction of the molecules that undergo decreased excretion in azotemia and then contribute to the "uremic syndrome." Azotemia, defined as BUN and creatinine concentrations above their defined reference intervals, requires that the function of approximately 75% of nephrons be impaired. Obviously, "abnormal" values are seen relatively late in a progressively worsening condition. Therefore, it underscores the importance of not simply looking for results above established reference intervals but understanding that small increases in BUN and/or creatinine concentration may indicate significant pathology. While discussed separately, it is important to note that these subcategories of azotemia may co-exist (Figure 62-1).

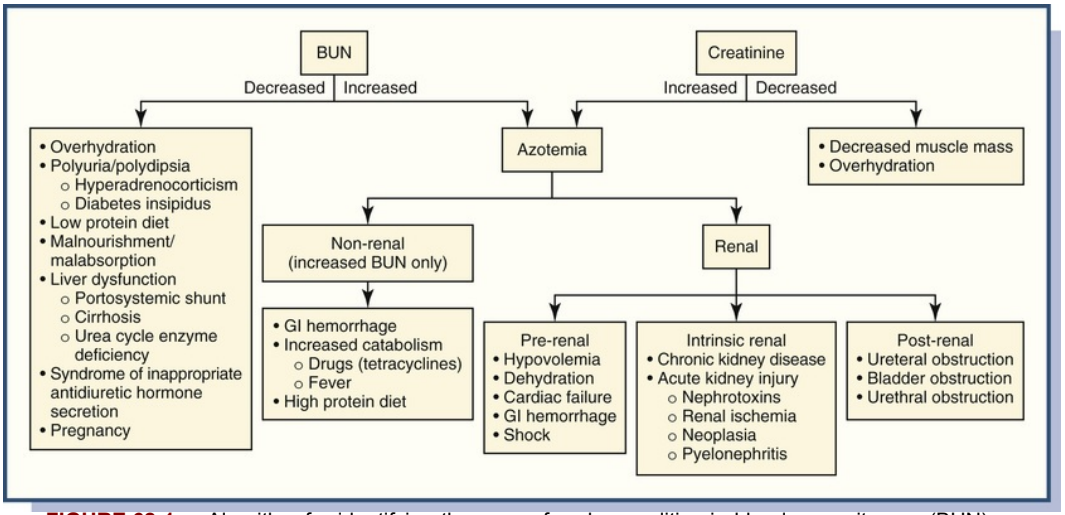

FIGURE 62-1 Algorithm for identifying the cause for abnormalities in blood urea nitrogen (BUN) or serum creatinine concentrations in dogs and cats. *GI*, Gastrointestinal.

Pre-Renal Azotemia

Pre-renal or volume-responsive azotemia is defined as a decrease in GFR secondary to hypoperfusion of structurally normal kidneys. In this condition, correction of hypoperfusion leads to rapid resolution of the azotemia, provided that secondary intrinsic renal injury has not developed. Hypovolemia due to dehydration, poor cardiac output secondary to cardiovascular dysfunction, and pathologic vasodilatory conditions (such as shock) are common causes for pre-renal azotemia. With pre-renal azotemia, the BUN to creatinine ratio often increases (greater than approximately 20:1) due to reabsorption of BUN in nephrons as physiologic mechanisms take place to re-establish a euvolemic state. Hypoadrenocorticism is an example of a condition commonly associated with pre-renal azotemia, sometimes mistaken for intrinsic renal disease (see ch. 309). Assessment of azotemia should include analysis of urine specific gravity. Suspicion for pre-renal azotemia increases when a corresponding urine sample is concentrated. However, in conditions where altered urinary concentrating ability is also present (i.e., hypoadrenocorticism), pre-renal azotemia can occur without the presence of concentrated urine.

Intrinsic Renal Azotemia

Definitions

Renal azotemia refers to abnormal decreases in the excretion of nitrogenous wastes due to intrinsic kidney dysfunction. This includes both acute kidney injury (AKI) and chronic kidney disease (CKD). With renal azotemia, careful evaluation of creatinine is crucial, as renal disease may be missed if only established reference ranges are used in decision making. Significant renal dysfunction can occur before serum creatinine concentrations increase above reference ranges. Familiarity with these concepts, and each patient, may allow identification of early kidney injury.

Acute Kidney Injury

The term AKI (see ch. 322) has replaced the various and ever-changing definitions for "acute renal failure" (ARF). AKI represents a spectrum of renal injury and disease severity, ranging from injury that is clinically non-detectable to severe damage resulting in fulminant ARF. When using traditional evaluation of BUN and creatinine based on laboratory reference ranges, many dogs and cats with intrinsic renal injury are not diagnosed until they have progressed to ARF, given that approximately 75% of renal function must be lost before BUN and creatinine values exceed their respective reference ranges. An entire kidney could theoretically cease functioning without a patient becoming azotemic. Application of the International Renal Interest Society (IRIS) AKI grading system allows a diagnosis of AKI to be made based on small changes in creatinine in non-azotemic patients (see ch. 322). Identification of more sensitive biomarkers for early diagnosis of AKI is being pursued.

Chronic Kidney Disease

CKD occurs when renal tissue is compromised secondary to a prolonged and irreversible disease process. The IRIS CKD staging system, based on creatinine concentration, defines early stages of non-azotemic kidney disease. Stage 1 CKD includes patients with creatinine concentrations <1.4 mg/dL (dogs) and <1.6 mg/dL (cats). Stage 2 includes creatinine concentrations of 1.4-2.0 mg/dL (dogs) and 1.6-2.8 mg/dL (cats). With these classifications, a dog or cat with a creatinine concentration within the laboratory reference range that has evidence of CKD on ultrasound should be classified as having CKD. Other factors that can affect creatinine, such as breed, hydration (i.e., ruling out pre-renal causes) and muscle mass must be considered to fully understand the clinical applications of BUN and creatinine results. Symmetric dimethylarginine (IDEXX SDMA) is a novel marker of GFR that is not affected by muscle mass and that detects CKD earlier than traditional evaluation of creatinine. Studies have shown SDMA to detect CKD an average of 9 months earlier in dogs and 17 months earlier in cats.[1,2]

Post-Renal Azotemia

Post-renal azotemia occurs secondary to obstruction of the urine drainage system (renal pelvis, ureter, bladder or urethra). When relief of obstruction is achieved, complete correction of azotemia should occur rapidly if there is no coexisting pre-renal or intrinsic renal disease. As discussed, unilateral ureteral obstruction may lead to non-azotemic kidney disease. Astute clinicians may observe and appreciate the importance of small but significant increases (i.e., >0.3 mg/dL) in serum creatinine concentrations that could aid early detection.

Non-Renal Effects on BUN and Creatinine

Increased BUN Concentration

Gastrointestinal hemorrhage and high protein intake can lead to azotemia through increased BUN generation; in this scenario a concurrent increase in serum creatinine may not occur. Catabolic states caused by prolonged fever, and less commonly tetracycline administration, can cause increased BUN concentrations.

Decreased BUN Concentration

The disease state most commonly associated with a decrease in BUN concentration is liver dysfunction, particularly cirrhosis and portosystemic shunting (see ch. 284). In both scenarios, the volume of functional liver is decreased, and subsequently, too few hepatocytes are available to convert ammonia into urea, resulting in decreased BUN concentrations. When portosystemic shunts are successfully treated, the BUN often increases. Urea cycle enzyme deficiencies, as seen in Irish Wolfhounds, can also lead to decreased synthesis of BUN. Iatrogenic overhydration and disease states preventing water removal or causing polyuria

and polydipsia, such as diabetes insipidus, the syndrome of inappropriate antidiuretic hormone secretion and hyperadrenocorticism can cause decreased BUN concentrations. Chronic feeding of a low protein diet or malabsorption can also lead to decreased BUN concentrations.

Decreased Creatinine Concentration

Decreases in muscle mass can cause associated decreases in serum creatinine concentration through decreased creatinine generation. This could lead to serum creatinine concentrations below established reference ranges in a puppy, whose "normal" reference range should be lower than those based on adult dogs. It could also cause a muscle-wasted patient to falsely have a serum creatinine concentration within the established reference range. In the latter case, because BUN generation is not affected by muscle mass, the BUN may be above the reference range and more representative of renal function than creatinine. Like BUN, creatinine values may decrease in fluid-overloaded patients and the measured results may under-represent the degree of renal compromise.

Understanding the intricacies of BUN and creatinine will allow a clinician to interpret these values beyond only using established reference ranges. With such critical evaluations and an understanding of how to evaluate these biomarkers in context of each individual patient, appropriate use of these tests is employed and accurate diagnoses can be made.

CHAPTER 63

Cholesterol, Triglycerides

Panagiotis G. Xenoulis

Introduction and Terminology

Disorders of lipid metabolism are common in dogs but less so in cats. The term *hyperlipidemia* refers to an increased concentration of lipids (i.e., triglycerides, cholesterol, or both) in the blood (serum or plasma). Specifically, an increased blood concentration of triglycerides is referred to as *hypertriglyceridemia,* while an increased blood concentration of cholesterol is referred to as *hypercholesterolemia*. Because both triglycerides and cholesterol are transported in the blood combined with specific proteins called *apoproteins* or *apolipoproteins* (the lipid-protein complex is referred to as *lipoprotein*), the term *hyperlipoproteinemia* is often used interchangeably with the term hyperlipidemia. The term *lipemia* is used to describe a grossly visible turbid or lactescent appearance of serum or plasma. Lipemia is a result of moderate and severe hypertriglyceridemia (typically >200-300 mg/dL), but not hypercholesterolemia nor very mild hypertriglyceridemia. The terms *hypotriglyceridemia* and *hypocholesterolemia* refer to decreased concentrations of triglycerides or cholesterol in the blood, respectively. Finally, the term *dyslipidemia* is a more general term for describing any kind of disturbance in the quality and/or quantity of blood lipids and/or lipoproteins.

Canine and feline lipoproteins can be divided into four major classes based on their hydrated density after ultracentrifugation: chylomicrons, very low-density lipoproteins (VLDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL). An intermediate-density lipoprotein (IDL) also likely exists in cats. Several subclasses of the above mentioned major classes of lipoproteins exist in dogs and cats, but their nature and clinical significance have not been fully elucidated.

Canine Hyperlipidemia

Major Causes of Canine Hyperlipidemia

Fasting Samples

A list of the most important causes of canine hyperlipidemia is shown in Table 63-1.[1] Postprandial hyperlipidemia is physiologic and typically resolves within 7-12 hours after a meal.[2,3] Therefore, determination of serum lipid concentrations should always follow a fast of at least 12 hours. However, recent evidence suggests that food might need to be withheld >12 hours when assessing fasting concentrations of serum triglycerides.[4]

TABLE 63-1

Main Causes of Hyperlipidemia in Dogs and Cats and Expected Lipid Abnormalities

	TYPE OF LIPID ABNORMALITY	COMMENTS
Postprandial Hyperlipidemia*†	HTG (rarely HCH)	Increases are typically mild and last <15 hours Most common cause of hyperlipidemia
High Fat Diets	HTG and/or HCH	Fat content must be very high (typically >50%) to cause fasting hyperlipidemia
Secondary Hyperlipidemia		
Disease		

Diabetes mellitus*†	HTG (mainly) and/or HCH	HTG and HCH can range from mild to marked; present in >50% of cases
Hypothyroidism*	HTG and/or HCH	HTG and HCH can range from mild to marked; present in >75% of cases
Hyperadrenocorticism*	HTG and/or HCH	HTG and HCH can range from mild to marked
Pancreatitis*	HTG and/or HCH	HTG and HCH are typically mild if other causes of hyperlipidemia are excluded; present in ~30% of cases
Obesity*†	HTG and/or HCH	HTG and HCH can range from mild to marked; present in ~25% of cases
Protein-losing nephropathy*	HCH	HCH is part of the nephrotic syndrome; HCH is usually mild
Cholestasis*	HTG and/or HCH	Increases are usually mild
Hepatic insufficiency*	HTG and/or HCH	Increases are usually mild
Lymphoma	HTG with or without HCH	Hyperlipidemia might persist despite treatment
Leishmania infantum infection	HTG and HCH	Increases are typically mild if present
Parvoviral enteritis	HTG	HTG is typically mild if present
Hypernatremia?	HTG and HCH	Based on a case report and evidence from human medicine
Hepatic lipidosis?		
Drugs*		
Glucocorticoids	HTG and/or HCH	Increases can range from mild to marked
Phenobarbital	HTG	HTG can range from mild to marked; present in ~30% of cases
Megestrol acetate	HTG and/or HCH	Mainly in cats
Primary Hyperlipidemia		
Miniature Schnauzer*	HTG with or without HCH	HTG can range from mild to marked; HCH may be mild to moderate; present in >30% of all Miniature Schnauzer dogs in the U.S.; prevalence increases with age
Beagle*	HTG and/or HCH	Increases are usually mild to moderate
Shetland Sheepdog*	HCH with or without HTG	HCH might be marked; HTG is typically mild; present in >40% of Shetland Sheepdogs in Japan
Doberman Pinscher	HCH	HCH is usually mild
Rottweiler	HCH	HCH is usually mild
Briard	HCH	HCH in Briards has only been reported in the UK
Rough-Coated Collie	HCH	Reported in a single family in the UK
Pyrénées Mountain Dogs	HCH	HCH is usually mild
Cats	HTG and/or HCH	Idiopathic hyperchylomicronemia
Cats	HCH	Idiopathic hypercholesterolemia

*Indicates common causes in dogs

†Indicates common causes in cats

HCH, Hypercholesterolemia; *HTG*, hypertriglyceridemia.

Secondary Hyperlipidemias

Persistent fasting hyperlipidemia is abnormal and can be either primary or secondary to other diseases or drug administration. Secondary hyperlipidemia is the most common form of hyperlipidemia in dogs. Most commonly, secondary canine hyperlipidemia is the result of an endocrine disorder, such as hypothyroidism, diabetes mellitus, or hyperadrenocorticism (see ch. 299, 304, and 306).[5-12] Hyperlipidemia has also been considered to be the result of naturally occurring pancreatitis in dogs (see ch. 289 and 290).[5,6,13,14] However,

results of a recent unpublished study in dogs with naturally occurring pancreatitis indicate that when concurrent diseases (e.g., diabetes mellitus, hypothyroidism) and use of certain drugs are excluded, hypertriglyceridemia and hypercholesterolemia occur infrequently (18% and 24%, respectively) as a result of pancreatitis and are typically mild.[15] Therefore, fasting hyperlipidemia (especially when severe) in dogs with pancreatitis likely reflects concurrent hyperlipidemia (primary or secondary to other causes, such as an endocrine disease), and warrants further diagnostic investigation. Several other causes of secondary hyperlipidemia have been reported in dogs and are discussed elsewhere.[1,3,16-30]

Primary Hyperlipidemias

Primary lipid abnormalities are usually, but not always, associated with certain breeds (see Table 63-1). Depending on the breed, the prevalence of a primary lipid abnormality can vary widely. Also, the geographic region of the canine population tested seems to play an important role due to genetic differences. Primary hyperlipidemia is very common in Miniature Schnauzers in the United States (>30% of Miniature Schnauzers are affected based on one study)[31-33] and has also been reported in Japan[34] and likely commonly exists in other countries as well. Based on anecdotal evidence, hyperlipidemia in this breed might be considerably less common in Europe. Primary hyperlipidemia in the Miniature Schnauzer is typically characterized by hypertriglyceridemia with or without hypercholesterolemia.[32,33,35] Primary hyperlipidemias have also been reported in Shetland Sheepdogs (in Japan and possibly other countries),[34,36,37] Beagles,[38] Briards,[39] a family of rough-coated Collies from the United Kingdom,[18] and anecdotally in Doberman Pinschers and Rottweilers.

Clinical Importance of Hyperlipidemia in Dogs

Canine hyperlipidemia has emerged as an important clinical condition that requires a systematic diagnostic approach and appropriate treatment (see ch. 182). Although hyperlipidemia itself does not seem to lead directly to the development of major clinical signs, it has been shown to be associated with the development of other diseases that are clinically important and potentially life-threatening (Table 63-2). Hyperlipidemia, and more specifically hypertriglyceridemia, has long been suspected as a risk factor for canine pancreatitis (see ch. 289 and 290), although this remained largely unproven.[1,13,14] The results of two recent clinical studies provided stronger evidence that hypertriglyceridemia, especially when severe (>900 mg/dL), is a risk factor for pancreatitis in Miniature Schnauzers.[40,41] In one of those studies, Miniature Schnauzers that developed pancreatitis were 5 times more likely to have hypertriglyceridemia before the development of pancreatitis than dogs of the same breed that did not develop pancreatitis.[41] Therefore, severe hypertriglyceridemia in Miniature Schnauzers should be treated even when clinical signs are not present, due to the risk of developing pancreatitis.

TABLE 63-2

Possible Consequences and Complications of Hyperlipidemia in Dogs and Cats

DISORDER	TYPE OF LIPID ABNORMALITY RESPONSIBLE

Atherosclerosis	HCH
Cats	
Xanthomata	HTG
Ocular disease	HTG/HCH
Other?	

HCH, Hypercholesterolemia; *HTG,* hypertriglyceridemia.

Clinical studies and anecdotal observations suggest that two hepatic disorders are associated with hypertriglyceridemia in dogs: diffuse vacuolar hepatopathy and gallbladder mucocele (see ch. 285 and 288).[1] Hyperlipidemia-associated vacuolar hepatopathy has been anecdotally reported and associated with primary hyperlipidemia in dogs. It is characterized by hepatocellular accumulation of triglycerides and glycogen, and it is often referred to as hepatic lipidosis or steatosis.[1] Gallbladder mucoceles have been commonly reported in dog breeds that are predisposed to primary hyperlipidemia (e.g., Miniature Schnauzers and Shetland Sheepdogs).[37] In a recent study, primary hypertriglyceridemia was found to be associated with increased serum hepatic enzyme activities in clinically healthy Miniature Schnauzers.[42] In that study, 60% and 45% of the Miniature Schnauzers with serum triglyceride concentrations ≥4.52 mmol/L (400 mg/dL) had increased serum alkaline phosphatase and alanine aminotransferase activities, respectively.

Another potential complication of hypertriglyceridemia in dogs is insulin resistance. In a recent study, almost 30% of Miniature Schnauzers with primary hypertriglyceridemia had evidence of insulin resistance as determined by serum insulin concentration.[43] However, the clinical importance of hypertriglyceridemia-associated insulin resistance remains to be determined. Other potential complications of hyperlipidemia in dogs include atherosclerosis (mainly as a result of secondary hypercholesterolemia due to endocrinopathies),[44-47] ocular disease (e.g., lipemia retinalis, lipemic aqueous, lipid keratopathy, solid intraocular xanthogranuloma in hyperlipidemic Miniature Schnauzers),[48,49] seizures and other neurologic signs,[50,51] and possibly cutaneous xanthomata and lipomas.

Diagnostic Approach to Dogs with Hyperlipidemia

Hyperlipidemia is typically diagnosed by measurement of fasting serum triglyceride and/or cholesterol concentrations. Because hyperlipidemia is most commonly the result of other diseases, it can serve as an important diagnostic clue. Hyperlipidemia is usually the only abnormality in dogs with primary hyperlipidemia. In order not to miss existing hyperlipidemia, the clinician should consider measurement of serum cholesterol and triglyceride concentrations as part of every "routine" chemistry profile. Measurement of the serum triglyceride concentration is often not included in a typical chemistry profile and has to be specifically requested by the clinician. Moderate and severe hypertriglyceridemia (but not hypercholesterolemia or mild hypertriglyceridemia) can be suspected based on inspection of serum or plasma that has a turbid or lactescent appearance. However, even in those cases, measurement of serum triglyceride and cholesterol concentrations is mandatory in order to reach an accurate assessment of the severity and spectrum of hyperlipidemia. In some cases, use of a meal challenge to diagnose postprandial hyperlipidemia might be necessary, although experience with such a test is limited.[4]

The general diagnostic approach when evaluating dogs with hyperlipidemia is presented in Figure 63-1. After hyperlipidemia has been diagnosed, the next step is to determine whether the patient has a primary or a secondary lipid disorder. If hyperlipidemia is secondary, the condition responsible for causing hyperlipidemia should be diagnosed and treated. Thus, specific diagnostic investigations should be performed in order to diagnose or rule out specific diseases that can cause secondary hyperlipidemia. If secondary hyperlipidemia is excluded, a tentative diagnosis of a primary lipid disorder can be made.

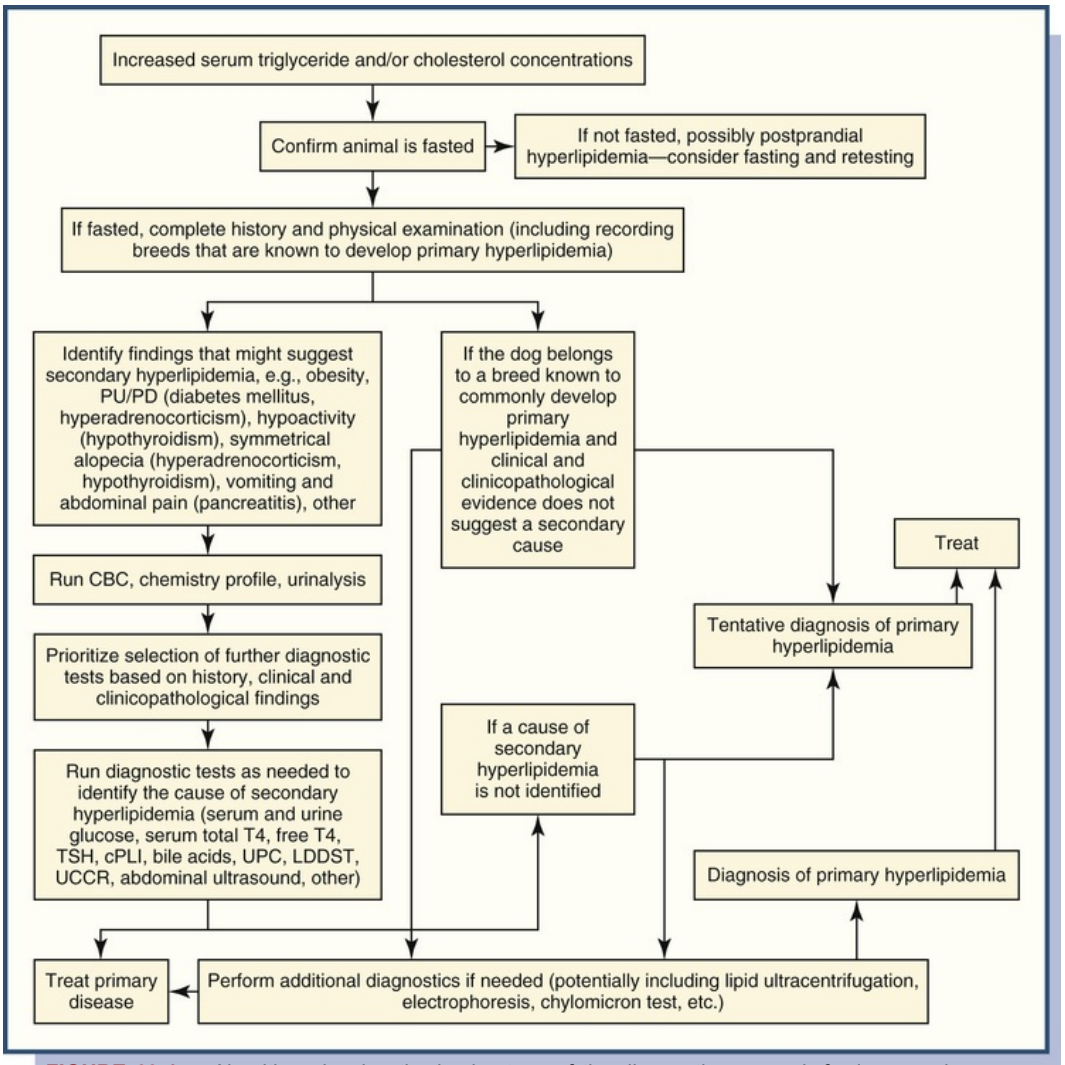

FIGURE 63-1 Algorithm showing the basic steps of the diagnostic approach for increased serum triglyceride and/or cholesterol concentrations in dogs and cats. *cPLI,* Canine pancreatic lipase immunoreactivity; *T4,* thyroxine; *TSH,* thyroid stimulating hormone; *UPC,* urine protein : creatinine ratio; *UCCR,* urine cortisol : creatinine ratio; *LDDST,* low dose dexamethasone screening test.

A detailed history should be obtained and physical examination performed. These are crucial because dogs with secondary hyperlipidemia typically show clinical signs of their primary disease (e.g., obesity, polyuria and polydipsia in dogs with diabetes mellitus or hyperadrenocorticism, hypoactivity and hair loss in dogs with hypothyroidism), which can help prioritize diagnostic tests and construct an appropriate diagnostic plan. Dogs with primary hyperlipidemia may or may not have clinical signs. Dogs with hyperlipidemia should have at least a complete blood count (CBC), chemistry panel, and urinalysis performed. Additional tests that may be useful for the diagnostic investigation of dogs with hyperlipidemia include measurement of serum total and free thyroxine concentrations, serum thyroid-stimulating hormone (TSH) concentration, serum glucose concentration and urine glucose (if not previously performed), serum pancreatic-lipase immunoreactivity concentration, serum bile acid concentrations, urine protein : creatinine ratio, and a "screening test" for hyperadrenocorticism.

Tests recommended after review of the history, physical examination, and routine laboratory test results should be tailored for each patient. A more general and wide selection of tests might be necessary for patients that have vague or no clinical signs. It should be noted that dogs with hyperlipidemia are often clinically healthy. It is likely that at least some of these dogs have some form of primary hyperlipidemia. If it is mild or moderate, there may be no need for detailed diagnostic investigations. Primary hyperlipidemia is common in Miniature Schnauzers from certain geographic regions. A detailed diagnostic investigation of hyperlipidemia may not be necessary in this breed in the absence of clinical signs suggesting an underlying cause. However, if hypercholesterolemia is the main abnormality (without or with only mild hypertriglyceridemia), then it is

more likely that the dog has some form of secondary hyperlipidemia, warranting recommendations for further diagnostic investigation.

To further characterize or investigate the cause of primary hyperlipidemia in dogs, one may employ the chylomicron test (i.e., lipemic serum is left for 12 hours undisturbed at 4° C; if chylomicrons are present, a cream layer will form; the remaining serum can be clear or turbid indicating an excess of VLDL), lipoprotein electrophoresis, ultracentrifugation, measurement of specific apoproteins, and indirect measurement of lipoprotein lipase activity with a heparin response test (i.e., measurement of serum triglyceride concentrations before and after IV administration of 90 IU/kg heparin; heparin activates lipoprotein lipase). None of these tests is used routinely in clinical cases and their availability is limited. Genetic testing for specific lipid disorders related to mutations of genes involved in lipid metabolism is currently not available.

Feline Hyperlipidemia—Species Differences[52-63]

Hyperlipidemia is encountered less frequently in cats than in dogs. In general, the same principles described above for dogs also apply for feline hyperlipidemia, which can be postprandial, primary or secondary. The conditions causing secondary hyperlipidemia in dogs likely also cause hyperlipidemia in cats, the most common and important being diabetes mellitus, obesity, nephrotic syndrome and possibly severe hepatic lipidosis (see Table 63-1; see ch. 176, 305, and 325). In addition, drug-induced hyperlipidemia may be encountered with administration of corticosteroids or megestrol acetate. The diagnostic approach for cats with hyperlipidemia does not differ from the one described for dogs (see above and Figure 63-1). Secondary causes should be excluded first using appropriate testing; if secondary hyperlipidemia is excluded, then a tentative diagnosis of primary hyperlipidemia is made. Use of more specific diagnostic tests (e.g., chylomicron test, ultracentrifugation) may be required at that stage to further characterize the type of hyperlipidemia. Primary hyperlipidemias in cats include an inherited hypertriglyceridemia (often called inherited hyperchylomicronemia) characterized by decreased lipoprotein lipase activity and idiopathic hypercholesterolemia (see Table 63-1). Cats with severe primary hyperlipidemia may develop cutaneous xanthomata, xanthomata in other tissues (e.g., liver, kidneys, heart), and ocular manifestations (e.g., lipemia retinalis). Complications of canine hyperlipidemia such as pancreatitis and atherosclerosis have not been proven to occur in cats.

Hypocholesterolemia and Hypotriglyceridemia

The main causes of hypocholesterolemia in dogs and cats include protein-losing enteropathy (e.g., severe inflammatory bowel disease, intestinal lymphoma, lymphangiectasia), hepatic insufficiency (e.g., cirrhosis, portosystemic shunts), and selected malignancies. History, physical and clinicopathological findings usually provide adequate information to identify the cause of hypocholesterolemia. In cases where it is unclear, additional diagnostics might be needed, including ultrasound, serum bile acids, fecal $alpha_1$-proteinase inhibitor, endoscopy or laparoscopy with biopsies, etc. Severe malnutrition may also lead to hypocholesterolemia. With the possible exception of severe malnutrition, hypotriglyceridemia is not known to be clearly associated with any disease.

CHAPTER 64

Amylase, Lipase

Peter Hendrik Kook

Inflammatory diseases of the exocrine pancreas in dogs and cats occur relatively frequently, vary in severity and can be divided into acute and chronic forms based on histologic findings. Results of studies on the sensitivity and specificity of tests for the diagnosis of pancreatitis are controversial. Part of this confusion arises from the fact that there is no easily applied gold standard against which diagnostic methods can be evaluated. Clinically, nonspecific findings such as anorexia, vomiting, lethargy, diarrhea, abdominal pain, and weight loss may be seen, but this combination of clinical signs can also occur in other conditions. Because chronic pancreatitis is usually associated with decreased enzyme leakage due to fibrous pancreatic remodeling, the ability to clinically classify pancreatitis as acute or chronic would help in the interpretation of serum enzyme results. However, clinicopathologic assessment of the severity of pancreatitis can be very difficult in individual patients. The same holds true for the evaluation of disease chronicity when previous bouts of pancreatitis may have been clinically silent or simply misdiagnosed. The situation becomes even more complicated when one considers the results of 2 recent studies on the agreement of specific ultrasonographic pancreatic variables, generally regarded as useful diagnostic tools for pancreatitis, and concurrent serum lipase values (catalytic assay and immunoassay).[1,2,25] It was concluded that the results of pancreatic ultrasonography performed by radiologists using state-of-the-art equipment agreed only poorly with the results of serum lipase determinations in cats and dogs suspected of having pancreatitis.[1,2,25] However, these conclusions appear somewhat problematic because in previous clinical studies that evaluated the diagnostic accuracy of laboratory tests in the absence of histologic evaluation as the gold standard, the diagnosis relied on a combination of clinicopathologic and ultrasonographic findings.[3-5] Although a definitive diagnosis of pancreatitis requires histologic confirmation, histology *per se* does not represent the ideal gold standard because histologic evidence of mild forms of acute and chronic pancreatitis may not be associated with clinical disease, rendering the clinical significance of histologically mild pancreatitis questionable. Moreover, pancreatic biopsy is performed infrequently because of its inherent invasiveness, the possibility of highly localized disease that can be missed with a single biopsy,[6] and relatively few direct therapeutic consequences. Therefore, based on a review of the literature to date concerning the clinical utility of laboratory tests (e.g., serum amylase and lipase activities, results of immunoassays), it can be concluded that it is virtually impossible to reliably diagnose pancreatitis without a standardized pancreatic histologic examination, which is not practical in a clinical setting.

Dogs

Although pancreatitis is a relatively common disorder in dogs, its diagnosis can be clinically challenging. This is especially true with mild forms of the disease, which seem to prevail in dogs.

Serum Amylase Activity

An older study reported that a threefold increase in serum amylase activity supported a diagnosis of pancreatitis,[7] but this finding has never been clinically proven. Measurement of serum amylase activity was the least sensitive test for the diagnosis of mild or moderate to severe pancreatitis in 2 recent studies and should not be used as an initial screening test because of low sensitivity and specificity.[5,8] Exceptions are cases of pancreatitis secondary to organophosphate ingestion, which is usually accompanied by marked increases in serum amylase activity.

Serum Lipase Activity

Until recently, it was believed that catalytic assays for measuring serum lipase activity were less reliable for the diagnosis of pancreatitis because of unsatisfactory sensitivity and specificity. The conclusion that catalytic lipase assays were suboptimal tests for diagnosis of pancreatitis in dogs was based on studies that used assays that are no longer available[7-9] or the 1,2 diglyceride (1,2 DiG) assay,[5,8,10,11] which is still used by major commercial laboratories. However, a more recent prospective study that evaluated markers for pancreatitis in dogs with histologic evidence of pancreatitis found that the catalytic 1,2 DiG lipase assay had the overall highest sensitivity (54% for mild pancreatitis, 71% for moderate to severe pancreatitis), followed by pancreas-specific lipase measured by an immunoassay (Spec cPL cutoff >400 mcg/L; 21% for mild pancreatitis, 71% for moderate to severe pancreatitis); the reported specificity (for all forms of pancreatitis) of the 1,2 DiG lipase assay was poor at only 43% compared with 100% for the Spec cPL (cutoff >400 mcg/L).[8] In 2005, a novel catalytic assay, the 1,2-o-dilauryl-rac-glycero-3-glutaric acid-(6′-methylresorufin) ester (DGGR) assay, for colorimetric determination of serum lipase activity was validated for use in dogs.[3] We have used this more cost-effective DGGR lipase assay for about 10 years at our institution and believe it is useful in the investigation of pancreatitis. There was good agreement and a very strong correlation between the results of the DGGR lipase and Spec cPL assay in a recent investigation that evaluated 144 dogs suspected of having pancreatitis.[2] Similar conclusions were drawn by other veterinary teaching hospitals in North America and Europe.[12,13] Our current reference range for the DGGR lipase is 24-108 U/L. There may be intraindividual variability in serum lipase activity in healthy dogs with values outside the reference interval. In addition, it is virtually impossible to prove that transient mild pancreatitis does not occur in clinically healthy dogs. Therefore, we chose to integrate a twofold DGGR lipase "gray zone" (108-216 U/L) similar to what is currently used for interpretation of Spec cPL results. Presently it is not known which assay yields better diagnostic accuracy and further work is needed, especially considering the marked difference in cost and turnaround time between the two methods.

Cats

Chronic pancreatitis is much more common than acute pancreatitis in cats.[14-17] Unfortunately the available laboratory tests have poor sensitivity and specificity in chronic pancreatitis, presumably because there is little or no enzyme leakage from remodeled fibrous acinar cells, and this poses a diagnostic challenge for the clinician.

Serum Amylase Activity

Although extensive studies have not been done, serum amylase activity appears to be of no clinical value in the diagnosis of acute pancreatitis in cats.[18,19] Our own unpublished data show very poor agreement between elevated serum amylase activity and the results of DGGR lipase, Spec fPL, and pancreatic histology in cats suspected of having pancreatitis. Interestingly, experimentally induced acute pancreatic injury in cats resulted in rather low amylase activity,[20,21] but this finding has not been investigated in spontaneous acute feline pancreatitis. More recent work has shown that amylase activity may also be influenced by serum glucose concentration in cats,[22] and at this point in time, low amylase activity alone should not be considered a marker for pancreatitis. Even though studies on the usefulness of serum amylase activity in cats with chronic pancreatitis are lacking, it seems wise to assume that it offers no diagnostic benefit.

Serum Lipase Activity

Evidence for the poor performance of traditional catalytic lipase assays in cats is weak and based on only a few cases.[18,23,24] However, the type of lipase assay must be carefully considered because methodologies used for the determination of serum lipase vary and the 1,2 DiG lipase assay, which is the most commonly used commercial catalytic assay to date, has no doubt contributed to the general poor perception of traditional catalytic lipase assays for pancreatitis in cats. A newer catalytic serum lipase assay (DGGR lipase) was recently validated for use in cats and compared with the feline pancreas–specific lipase assay (Spec fPL) in larger scale studies of cats suspected of having pancreatitis.[1,12,16] There was substantial agreement and strong correlation between the results of the 2 lipase assays, and the DGGR assay seems to be a useful method compared with the feline pancreas–specific lipase test, particularly when cost is taken into consideration.[1] In the largest retrospective study on feline pancreatitis to date, pancreatic histopathology was available in 31 cases. Compared with the results of histologic evaluation, which was considered the gold standard, the

sensitivity of both lipase assays (DGGR lipase and Spec fPL) was 100% for acute pancreatitis and 47% (Spec fPL) and 37% (DGGR lipase) for chronic pancreatitis.[16] Intuitively, sensitivities in this range appear to be of little clinical value. It is important to critically assess these data because false-negative lipase results in cats with chronic pancreatitis may indicate a lack of active inflammation or be due to mild histologic changes, as recently demonstrated in dogs.[8] Unfortunately, the relevance of severity and type (acute versus chronic) of inflammation as well as its parenchymal distribution cannot be clarified without a standardized histologic examination of the entire pancreas. The same problem holds true for the assessment of the specificity of lipase results because the histologic diagnosis of pancreatitis may be missed during necropsy or surgery when focal disease is present. For this reason, we prospectively compared lipase measurements (DGGR lipase and Spec fPL) with a standardized histologic assessment of freshly procured pancreata (n = 60) where the entire pancreas was examined with serial sections every 0.5 cm.[17] Distribution of acute (15%) and chronic pancreatitis (64%) was similar to the findings of an earlier study.[15] The sensitivity of both lipase assays (DGGR lipase and Spec fPL) for detecting pancreatitis was calculated based on a pancreatitis activity index described earlier[6] and was 66.7% for DGGR lipase and 61.1% for Spec fPL. The specificity was 78.6% (DGGR lipase) and 69% (Spec fPL).[17] When the aforementioned pitfalls involved in the antemortem diagnosis of pancreatitis and the shortcomings of histologic evaluation as the gold standard are taken into consideration, the DGGR lipase assay appears to be as useful a method as the Spec fPL assay and more attractive in terms of cost.

CHAPTER 65

Liver Enzymes

Andrea N. Johnston

Clinical Enzymology

Enzymes catalyze biochemical reactions in every cell in the body. Substrate specificity is manipulated to detect and quantify enzyme activity.[1] To be clinically relevant markers of disease, there must be correlation between changes in circulating enzyme concentrations and changes in the tissue of interest. Since many factors affect enzymatic activity *in vivo* and *in vitro* (pH, temperature, salt or protein concentration, ionic strength, cofactor concentration, inhibitors), interpretation also requires accurate assays. Serum or heparinized plasma samples are used in enzyme assays.[2] Citrate complexes divalent cations and EDTA inhibits activity of almost all enzymes; neither should be used for enzyme analysis.[1]

Liver Enzymology

Although numerous hepatic enzymes exist, only 4 are routinely used as biomarkers for hepatobiliary disease in dogs and cats: alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP) and gamma-glutamyl transferase or transpeptidase (GGT, GGTP).[1,3,4] These enzymes have relatively stable circulating concentrations due to normal and continuing cellular turnover. Concentrations may increase with membrane injury, whether reversible or irreversible (cell death). Concentrations may also rise with increased rates of synthesis (transcription and translation), decreased clearance, or, although not yet described in veterinary medicine, the presence of enzyme-autoantibody complexes (macroenzymes) which extend enzyme half-life.[1,5,6] Lactate dehydrogenase (LDH), commonly used with other species, is an oxidoreductase that catalyzes conversion of lactate to pyruvate. LDH resides in the cytoplasm of all cells and is of little value as a marker of canine or feline hepatic disease.

Serum liver enzyme activities aid in the identification, differentiation, and monitoring of liver disease but do not measure hepatic function. They are broadly classified as either "hepatocellular leakage enzymes" (ALT, AST) or "cholestatic enzymes" (ALP, GGT) based on their subcellular location and response to hepatocellular injury (Figure 65-1).[2,4,7] ALT and AST reside predominantly in cytosol, although a mitochondrial AST isoenzyme exists in humans and dogs. These enzymes are the first to leak into the peri-sinusoidal space and enter the systemic circulation secondary to hepatic necroinflammation that damages plasma membranes. ALP and GGT are associated with the hepatocyte canalicular membranes and, in the case of GGT, cholangiocytes. These enzymes are released as a result of bile acid membrane solubilization or cleavage of the membrane binding domain (GGT) during cholestatic injury.[2,4,7]

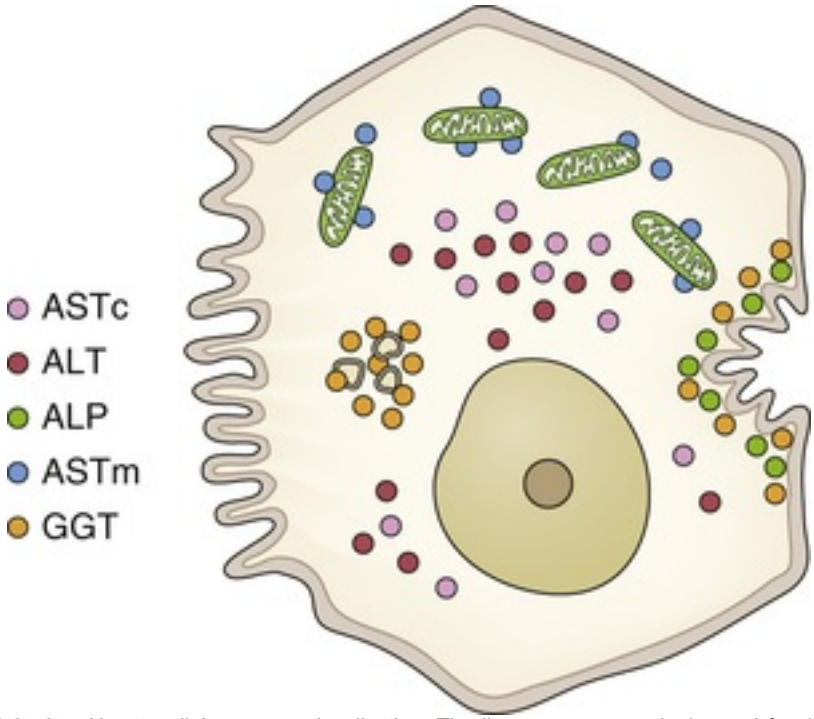

FIGURE 65-1 Hepatocellular enzyme localization. The liver enzymes routinely used for diagnosis are located in the cytosol, canalicular membrane (right), microsomes (SER; 3 beige rounded triangles at center-left), and the mitochondria (4 green ovals; top). Alanine aminotransferase (ALT) and cytoplasmic isoenzyme of aspartate aminotransferase (ASTc) are located in the cytosol. These leakage enzymes are released with plasma membrane damage. The canine mitochondrial AST (ASTm) is associated with the mitochondria. Both isoenzymes of alkaline phosphatase (ALP) are located at the canalicular membrane. Gamma-glutamyl transferase (GGT) is found at the canalicular membrane and in the microsome (SER), where it can respond to enzymatic induction. The latter 2 enzymes are released in cholestasis by bile acid membrane dissolution or cleavage of the plasma membrane binding domain. (Copyright Elsevier: Pincus MR, Tierno PM, Fenelus M, et al: Evaluation of liver function. In McPherson RA, Pincus MR, editors: *Henry's clinical diagnosis and management by laboratory methods*, ed 22, Philadelphia, 2011, Saunders, pp 296-311.)

Liver enzyme increases are commonly identified on biochemical screening tests, but do not definitively identify significant underlying liver disease (Table 65-1).[8] None of the aforementioned enzymes is entirely liver specific and isoenzymes exist. Further, the hepatic enzyme induction phenomenon may cause marked increases without histologic evidence of liver lesions.[3,8-13] Isoenzymes, or isozymes, have different amino acid sequences, varying subunit combinations (LDH), unique post-translational modifications (ALP), or protein structure (AST) but catalyze the same reactions. Enzymes modified by serum proteases to slightly different forms are called isoforms.[1] For example: the intestinal ALP isoenzyme has a different protein structure as compared with the tissue-nonspecific renal, liver, and bone isoenzymes, which have identical amino acid sequences but different carbohydrate composition.[1,10]

TABLE 65-1

Liver Enzyme Activities Not Associated with Primary Hepatic Disease

CONDITION	CAUSES OF INCREASED ENZYME ACTIVITY
Cardiovascular	Congestion, hypotension, ischemia
Endocrinopathies	Adrenal disease (cortisol and sex steroid abnormalities), diabetes mellitus, hyperthyroidism (cats), hypothyroidism (dogs)
Gastrointestinal disease	Diarrhea, constipation/obstipation, gastric dilatation volvulus, pancreatitis
Infectious disease	Abscessation, rickettsial disease, pyelonephritis, pyometra/prostatitis, septicemia, viral disease (parvovirus, coronavirus, feline respiratory disease)

Miscellaneous	Strenuous exercise, trauma, myopathies, severe anemia, malignant hyperthermia
Neoplasia	Bone, mammary, metastatic
Osseous	Growth, metabolic bone disease, osteomyelitis

Abnormal hepatic enzyme activities must be interpreted in the context of patient signalment, physical examination findings, and an owner history that includes previous and current medications, environmental exposure to hepatotoxins or infectious organisms, and comorbidities. Sequential monitoring of enzymes is needed to map the course of disease with particular attention to duration of elevation (acute, chronic), stability (increasing, decreasing, waxing and waning) and pattern (cholestatic, necroinflammatory, induced). For example, increased activities after an acute hepatic injury due to hepatotoxin exposure may rapidly return to reference limits (see ch. 285 and 286). However, activities that progressively increase or wax and wane may reflect chronic and/or progressive disease (necroinflammatory disease) (see ch. 280, 282, 283, 284, 287, and 288).[4,7,14-23]

The Leakage Enzymes: The Aminotransferases, ALT and AST

Overview

ALT and AST catalyze the transfer of the alpha-amino group of alanine or aspartic acid to alpha-ketoglutarate, resulting in the formation of glutamic acid and pyruvate or oxaloacetic acid, respectively.[3] These enzymes are integral components of the glucose alanine cycle. ALT and AST require pyridoxal 5′ phosphate (P_5P), the active metabolite of vitamin B_6, as a cofactor. Alanine reacts with P_5P to yield pyruvate plus pyridoxine. Pyridoxine reacts with alpha-ketoglutarate resulting in glutamate and regenerated P_5P. Decreased transaminase activities are associated with low systemic vitamin B_6 concentrations due to disease or drug administration (cephalosporin, cyclosporine, and isoniazid).[2,3] ALT and AST are cleared by adsorptive endocytosis in sinusoidal hepatocytes; therefore, clearance rates may be altered in severe liver disease and in cases of sinusoidal hypoperfusion (ischemia, portosystemic vascular anomalies).[4,24]

ALT and AST rise within 24 to 48 hours of acute hepatocellular injury, most markedly with necrosis. While there is a direct correlation between the degree of aminotransferase increase and the number of hepatocytes injured (mild, <5-fold high normal reference range value; moderate, 5- to 10-fold; severe, >10-fold), such values are not prognostic. Serial monitoring of enzyme activities and of serum albumin, cholesterol, coagulation factors, and bilirubin concentrations are needed.[3,4,9,15] Generally, following acute hepatic insult, transaminase activities decrease within 2 to 3 days and normalize in 2 to 3 weeks. Waxing and waning transaminase values are seen with chronic inflammatory conditions (see ch. 282 and 283).[4,18,19] Reducing values in chronic liver disease may be due to improvement in the disease process or diminished hepatocyte numbers.

Alanine Aminotransferase

ALT, while regarded as "liver-specific" in the cat and dog, is also present in lesser intracellular quantities in heart, kidney, and skeletal muscle. The half-life of ALT in dogs is 59 hours and is less than 24 hours in cats.[2,7] Mild to moderate increases may be seen with enzyme induction (anticonvulsants, glucocorticoids [dogs]), vacuolar hepatopathy, portosystemic vascular anomalies, and passive hepatic congestion (see ch. 284). Increases in canine serum ALT activity have the highest sensitivity (80% to 100%) for hepatic necrosis and hepatic failure but are less sensitive (50% to 80%) in cirrhosis, vacuolar hepatopathy, passive hepatic congestion, or portosystemic vascular anomalies.[4] In cats, ALT is sensitive for extrahepatic bile duct occlusion and cholangitis/cholangiohepatitis (80% to 100%).[4] ALT is non-specific for liver disease in both species (<25%). The largest ALT increases are seen in necroinflammatory diseases.[4,6,9,14,15] Acute necroinflammatory hepatic injury may be caused by drug-induced liver injury (Box 65-1; see also ch. 286), hepatic toxin ingestion (heavy metals, amanita toxin, cycads, xylitol), and infectious/inflammatory disease (leptospirosis, toxoplasmosis, copper associated hepatopathy, autoimmune disease; see also ch. 282, 283, and 285).[4,6,14,15,25,26] Not all cases of hepatic necrosis will result in transaminase elevation. Microcystin and aflatoxin B1 inhibit hepatic biosynthesis of ALT and AST, and therefore cannot be used as biomarkers of liver disease following intoxication.[15,27]

Box 65-1

Commonly Implicated Hepatotoxic Drugs in Cats and Dogs (see also ch. 286)

Acetaminophen
Amiodarone
Anabolic steroids
Carprofen
Cyclosporine
Diazepam
Diethylcarbamazine/oxibendazole
Fluoroquinolones
Griseofulvin
Halothane
Itraconazole
Ketoconazole
Mebendazole
Methimazole
Methoxyflurane
Mibolerone
Pennyroyal oil
Phenobarbital
Phenytoin
Primidone
Sulfonamides
Tetracyclines

Aspartate Aminotransferase

The greatest concentrations of AST are found in skeletal muscle, cardiac myocytes, and the kidneys. AST is also present in brain, small intestine, spleen, liver, and erythrocytes. A muscular isoenzyme may be considered as the source of increases in AST activity if there are concurrent increases in creatine kinase (CK) concentrations; however, in chronic myopathy the shorter half-life of CK may not allow differentiation.[2] AST is located in 2 canine hepatocyte subcellular sites: the cytosol (80%) and mitochondria (20%). Cytosolic AST is most important in veterinary medicine.[28,29] The half-life of AST in the dog is thought to be approximately 22 hours, but significantly longer periods have been reported.[2,4] In the cat, AST's half-life is 77 minutes. As a soluble cytosolic liver enzyme, serum AST activities mirror ALT activities. However, AST is the smaller moiety that diffuses into the sinusoidal circulation more rapidly following plasma membrane disruption. It may also become quiescent earlier than ALT due to its shorter half-life.[29] In the cat, AST is a more sensitive indicator of hepatocellular damage, particularly in hepatic necrosis, cholangiohepatitis, myeloproliferative diseases, infiltrative lymphomas, and chronic bile duct obstruction.[4,7,9]

The Cholestatic Enzymes: Alkaline Phosphatase and Gamma-Glutamyl Transferase or Transpeptidase

Alkaline Phosphatase

ALP is a membrane-bound glycoprotein that hydrolyzes phosphate esters.[1] In dogs and cats, ALP resides within cells of the renal cortices, placenta, intestine, bone, and liver.[2] Several ALP isoenzymes have been identified, usually from distinct organs or tissues.[10,13,30] In the dog, glucocorticoid-induced ALP (G-ALP) is believed to be a product of the intestinal ALP gene expressed in hepatocytes. Transcription of G-ALP is delayed approximately 10 days after beginning exogenous steroid administration. It may continue to rise with ongoing treatment.[10] The dog is unique in the expression of 2 hepatic canalicular membrane ALP isoenzymes.[4] The liver isoenzyme (L-ALP) is also inducible by glucocorticoids and is the first isoenzyme to be serologically detected.[10] Although transcription of L-ALP plateaus after approximately 10 days of prednisone

treatment, the enzyme continues to be translated, making differentiation of the 2 isoenzymes irrelevant.[10,28] The ALP induction phenomenon is not limited to glucocorticoids. G-ALP activity is also associated with inflammation and chronic disease (possibly secondary to increases in endogenous glucocorticoid secretion) and drugs: anticonvulsants (phenobarbital, phenytoin, primidone).[11,31,32] Therefore, ALP activities should not be used for confirming or suspecting a diagnosis of canine hyperadrenocorticism.

L-ALP and G-ALP isoenzymes have half-lives of approximately 70 hours.[2,4] Canine placental, renal, and intestinal ALP half-lives are less than 6 minutes. Feline intestinal ALP half-life is less than 2 minutes. In the cat, the placental isoenzyme can be detected in late term pregnancy.[4] The half-life of feline L-ALP is brief (6 hours). L-ALP, G-ALP and bone isoenzyme (B-ALP) are the 3 primary isozymes in the dog. Cats do not express G-ALP. B-ALP is present in growing dogs and cats up to 7 months of age. It is also seen in renal secondary hyperparathyroidism, bone tumors (negative prognostic indicator for osteosarcoma), osteomyelitis, and feline hyperthyroidism, partly due to increased parathyroid-hormone–induced bone mobilization.[7,12,33,34]

Increased serum ALP activity is one of the most commonly reported biochemical abnormalities in dogs.[8] ALP has a high sensitivity but low specificity for hepatobiliary disease. If a concurrent GGT elevation is identified, specificity for liver disease is significantly improved in both dogs and cats.[35,36] Canine serum ALP activity may increase with necroinflammatory, neoplastic, or cholestatic injury. The degree of ALP activity has not proven to be helpful in distinguishing between intra- and extrahepatic causes of cholestasis. Enzyme synthesis may be induced (secondary to inflammatory mediators or endogenous/exogenous glucocorticoids) or released from the hepatic canaliculi via bile acid solubilization. Vacuolar hepatopathy associated with mild to severely increased ALP activity and cytosolic glycogen accumulation was long considered a benign manifestation of steroidogenic hormones (cortisol and sex steroids) and a multitude of non-adrenal diseases. However, there is evidence that excess glycogen accumulation can become pathologic.[4,37] Many recent publications have highlighted a vacuolar hepatopathy breed-related disorder in Scottish Terriers. Increases may also be associated with development of hepatocellular carcinoma in some affected dogs.[9,38-41]

ALP elevation is less specific in cats but still clinically relevant, particularly in feline hepatic lipidosis wherein ALP elevations tend to predominate except in cases of underlying cholangitis/cholangiohepatitis.[4,7] Hepatocellular swelling, altered osmotic influx, and cholestasis due to cellular swelling likely cause the marked ALP increases associated with in feline hepatic lipidosis.[4,7,42]

Gamma-Glutamyltransferase or Transpeptidase

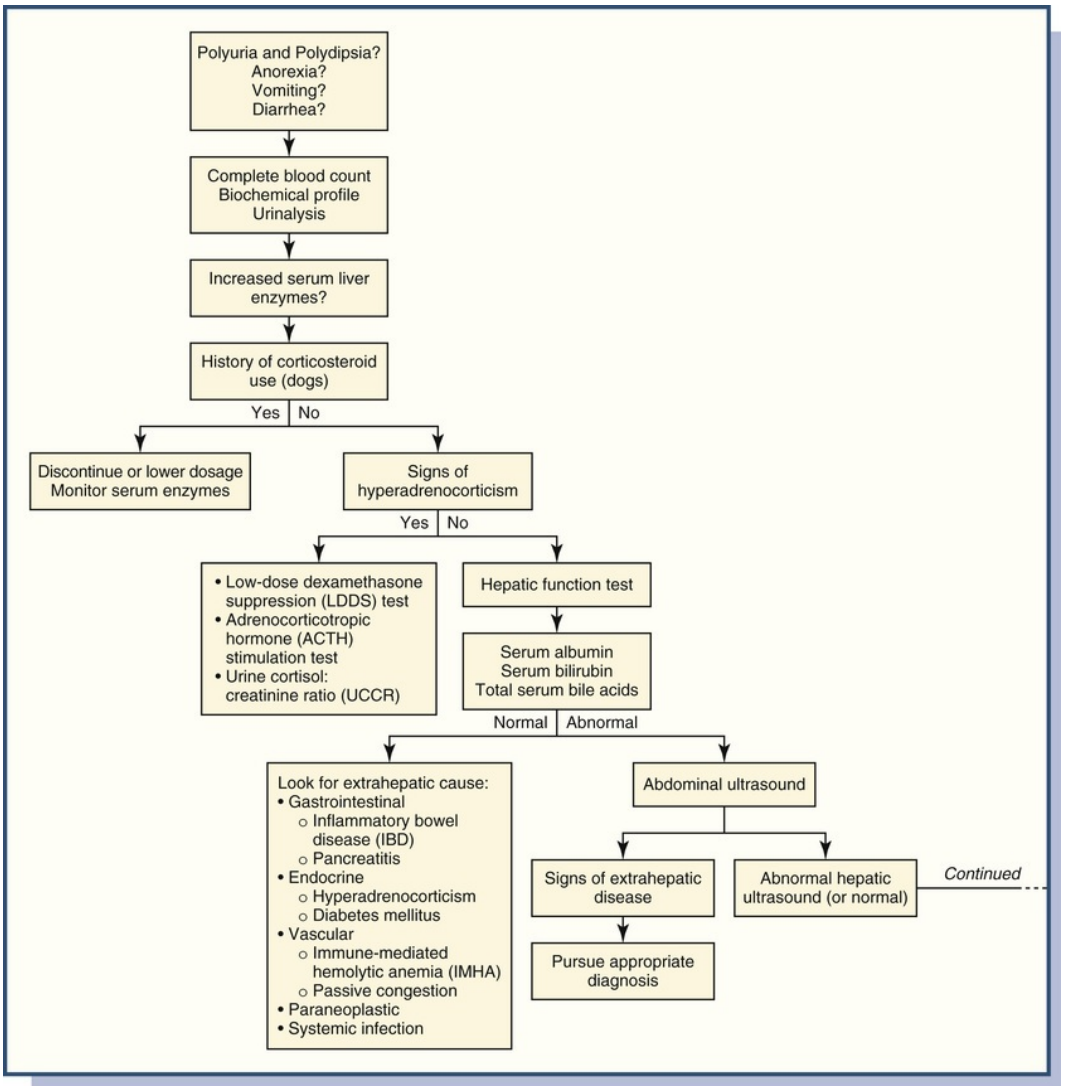
GGT catalyzes transfer of the gamma-glutamyl group from glutathione (GSH) to an acceptor, forming glutamate. This enzyme regulates amino acid transport across cell membranes and is critical for the cellular redox pathway. GGT is found in cell membranes of kidney, pancreas, biliary epithelium, hepatocytes (zone 1, periportal), intestine, spleen, heart, lungs, skeletal muscle and erythrocytes.[2,3] The half-life of GGT in dogs and cats remains undetermined.

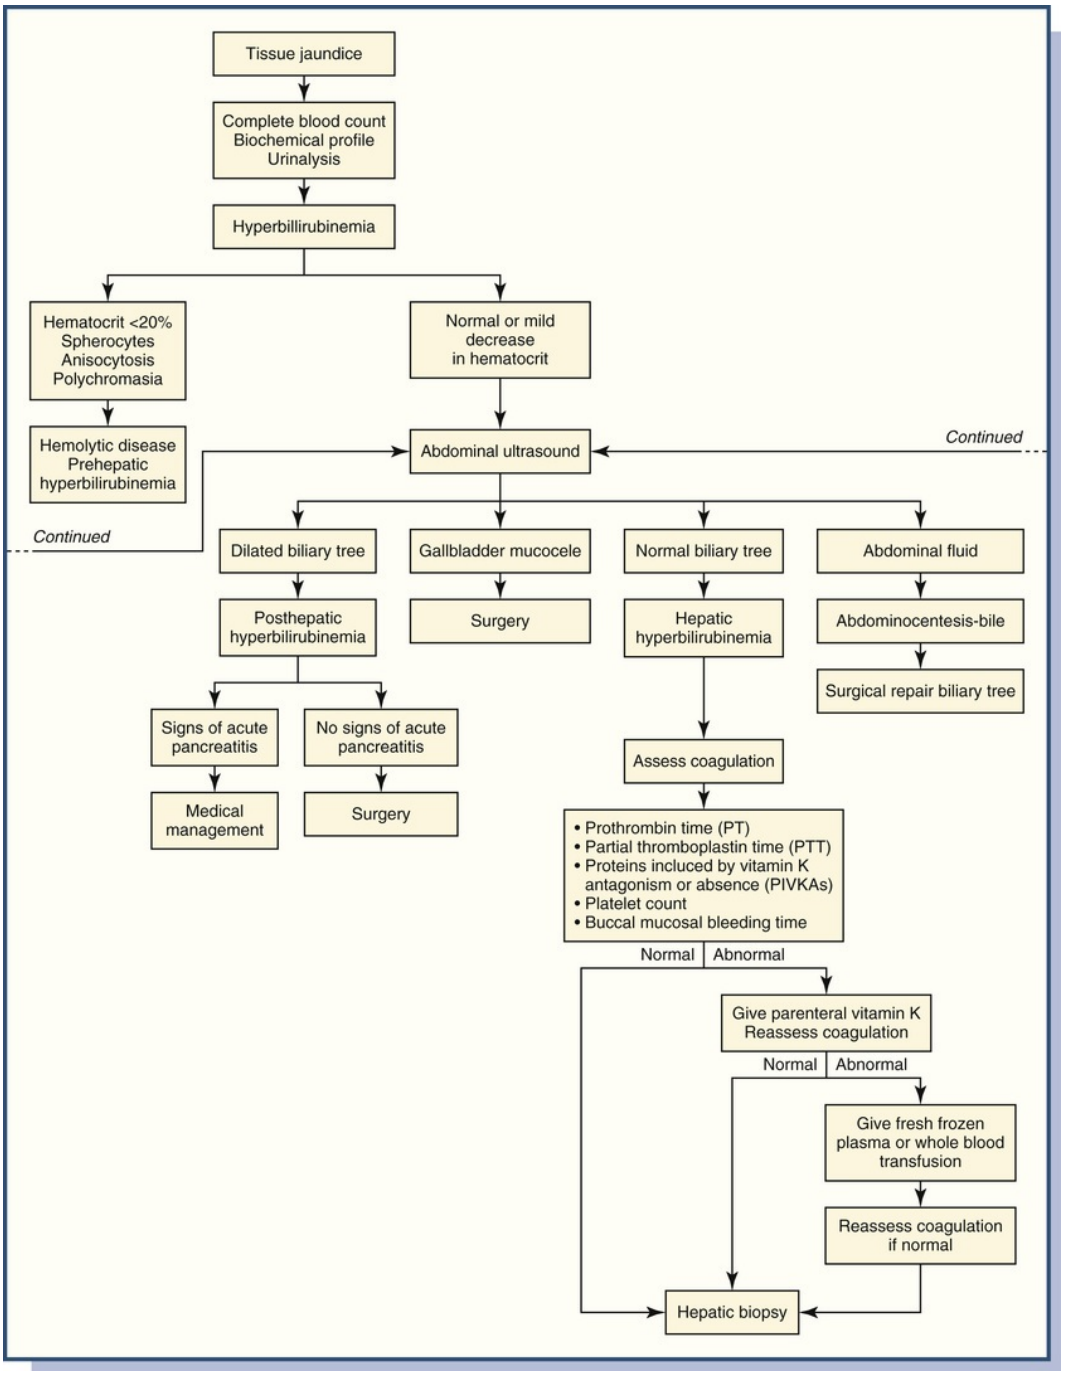
In dogs, GGT has its largest tissue concentration in the proximal renal tubules and pancreas. However, its epithelial location in these tissues results in loss into urine or pancreatic lumen, rather than into the circulation.[2,4] Microsomal enzyme induction occurs in dogs treated with glucocorticoids (up to 10-fold); this has not been proven in the cat. Mild increases may be seen with anticonvulsants (phenytoin, primidone) which increase further if hepatotoxicosis develops. Hepatobiliary and pancreatic carcinogenesis moderately increases GGT activity. Canine neonates exhibit markedly increased GGT activities during the first 1-3 days of life secondary to colostrum intake. This is not observed in kittens.[2,4]

GGT also increases expression in conditions of oxidative stress. GGT is a cholestatic liver enzyme and its activity increases when cleaved from its plasma membrane anchor by bile acid solubilization. GGT is not a sensitive marker of liver disease in the dog (40%) but it has a higher specificity than ALP.[4,35] In cats, sensitivity (55%) exceeds specificity of ALP for detecting inflammatory diseases and GGT activity is most markedly increased in necroinflammatory diseases of the portal triad, biliary tree, and pancreas.[4,36,43,44] GGT is minimally elevated in canine and feline hepatic necrosis affecting zones 2 and 3. Extrahepatic bile duct obstruction causes moderate to severe increases, typically greater in dogs than cats. Reportedly, cats with underlying necroinflammatory disease and bile duct obstruction or cholestasis may develop a higher-fold increase in GGT than ALP.[36,45-48]

Summary

Liver enzyme abnormalities are commonly encountered in practice. Interpretation of liver enzyme abnormalities requires a complementary approach including bilirubin, paired serum bile acids, arterial ammonia, and coagulation factors to determine the next step (Figure 65-2).[9,49-51] Imaging modalities may eliminate nonhepatic causes of liver enzyme activity (thoracic and abdominal radiographs) or increase suspicion for a specific diagnosis (abdominal ultrasound) prior to liver biopsy.[52,53]





Tissue jaundice
Complete blood count
Biochemical profile
Urinalysis
Hyperbillirubinemia
Hematocrit <20%
Spherocytes
Anisocytosis
Polychromasia
Normal or mild decrease in hematocrit
Hemolytic disease
Prehepatic hyperbilirubinemia
Continued
Abdominal ultrasound
Continued
Continued
Dilated biliary tree
Gallbladder mucocele
Normal biliary tree
Abdominal fluid
Posthepatic hyperbilirubinemia
Surgery
Hepatic hyperbilirubinemia
Abdominocentesis-bile
Surgical repair biliary tree
Signs of acute pancreatitis
No signs of acute pancreatitis
Assess coagulation
Medical management
Surgery
• Prothrombin time (PT)
• Partial thromboplastin time (PTT)
• Proteins incluced by vitamin K antagonism or absence (PIVKAs)
• Platelet count
• Buccal mucosal bleeding time
Normal
Abnormal
Give parenteral vitamin K
Reassess coagulation
Normal
Abnormal
Give fresh frozen plasma or whole blood transfusion
Reassess coagulation if normal
Hepatic biopsy

CHAPTER 66

Creatine Kinase

Susan M. Taylor

Normal Activity and Tissue Distribution

Creatine kinase (CK) is an intracellular enzyme that catalyzes the reversible exchange of high energy phosphate bonds between phosphocreatine and ADP, generating ATP needed for muscle contraction. CK exists as three main dimeric isoenzymes (CK-MM, CK-MB, and CK-BB), a mitochondrial isoform (CK-MT) and two macroenzymes of uncertain significance. CK-MM accounts for 100% of CK activity in muscle, is the most common isoform found in serum, and is considered an important marker for muscle disease. Almost all CK activity in nervous system tissues is CK-BB and this isoenzyme may be increased in the serum of dogs and cats with neurologic disease. Cerebrospinal fluid CK-BB activity, for example, negatively correlates with prognosis for walking in dogs paralyzed due to intervertebral disk disease. Increased cerebrospinal fluid CK-BB concentrations may be associated with higher mortality in dogs with intracranial disease. CK-BB is also found in the small intestine and serum concentrations may be increased with intestinal necrosis or infarction. In people, the isoenzyme CK-MB predominates in cardiac muscle and is a reliable marker for myocardial infarction. However, in canine and feline myocardial tissue, most (97%) of the CK activity is CK-MM, rather than CK-MB. Total serum CK is often increased in dogs with ischemic, inflammatory and traumatic myocardial diseases and in dogs and cats with poor perfusion of skeletal muscles due to cardiac failure. The utility of measuring the activity of tissue specific isoforms of CK continues to be investigated, but total CK appears to be the most useful diagnostic test for dogs and cats.

Serum CK concentrations are usually slightly higher than plasma concentrations due to CK release from platelets during blood clotting. Serum CK activity is stable for 7 days at +4º C and for 1 month at −20º C, after which CK activity decreases. Hemolysis and hyperbilirubinemia increase measured CK but lipemia has no effect. The activity of CK in blood peaks 2 to 4 hours after muscle injury, and returns to reference concentrations within 24 to 48 hours if CK release has stopped. Puppies and kittens, less than 8 weeks of age, usually have higher CK concentrations than adult animals (1.5 to 2×). Greyhounds and other muscular breeds have been reported to have slightly higher (1.5 to 2×) CK activity than other dog breeds. Serum CK concentrations are not affected by site of sampling, but incorrect venipuncture technique can result in higher activity (2-3× normal) if underlying muscle has been penetrated.

Effect of Exercise on Serum CK Concentrations

An important factor in interpreting CK concentration results from normal individuals is their level of recent physical activity. Measured CK increases after physical activity, especially in untrained or poorly conditioned dogs. The increases seen with moderate activity for 60 minutes or strenuous activity for 10 minutes are generally not clinically significant (less than 5× increase), with CK activity peaking 2 to 4 hours after exercise and returning to baseline within 8 hours. More dramatic increases (5-15×) occur and persist for 24 to 48 hours in some dogs strenuously exercising for prolonged periods, such as sled dogs running in endurance races longer than 1000 km. These increases in CK activity suggest that mild muscle injury occurs whenever energy consumption within the muscle exceeds energy supply. Exercise past exhaustion can occasionally be a trigger for life-threatening exertional rhabdomyolysis, where intracellular calcium rises uncontrollably within myofibers, and release of calcium-dependent proteases results in myonecrosis. Individuals with rhabdomyolysis experience painful muscles (myalgia), weakness, marked elevations of CK (often >1000×) and myoglobinuria.

Disorders Causing Increased Serum CK Concentrations (Figure 66-1)

Increases in CK are considered to be diagnostically useful as a marker for myofiber damage (see ch. 354).

However, increases in CK also occur in association with many disorders that are not specifically muscle-related. Mild increases in CK (<5× reference range) occur commonly after physical restraint or moderate exercise. Prolonged recumbency, surgery, metabolic diseases causing acidosis and/or dehydration, pancreatitis, spinal cord or brain injury, dirofilariasis, endocarditis and myocarditis may each contribute to mild or moderate increases (usually <10×). Anorexia in cats has been associated with 10× to 100× increases in CK, presumably due to the breakdown of skeletal muscle for amino acids and energy. Muscle trauma (following injections, bite wounds or blunt trauma), severe dehydration, shock, disseminated intravascular coagulation, aortic thromboembolism, tissue hypoperfusion or infarction due to sepsis have been associated with moderate to severe increases in CK.

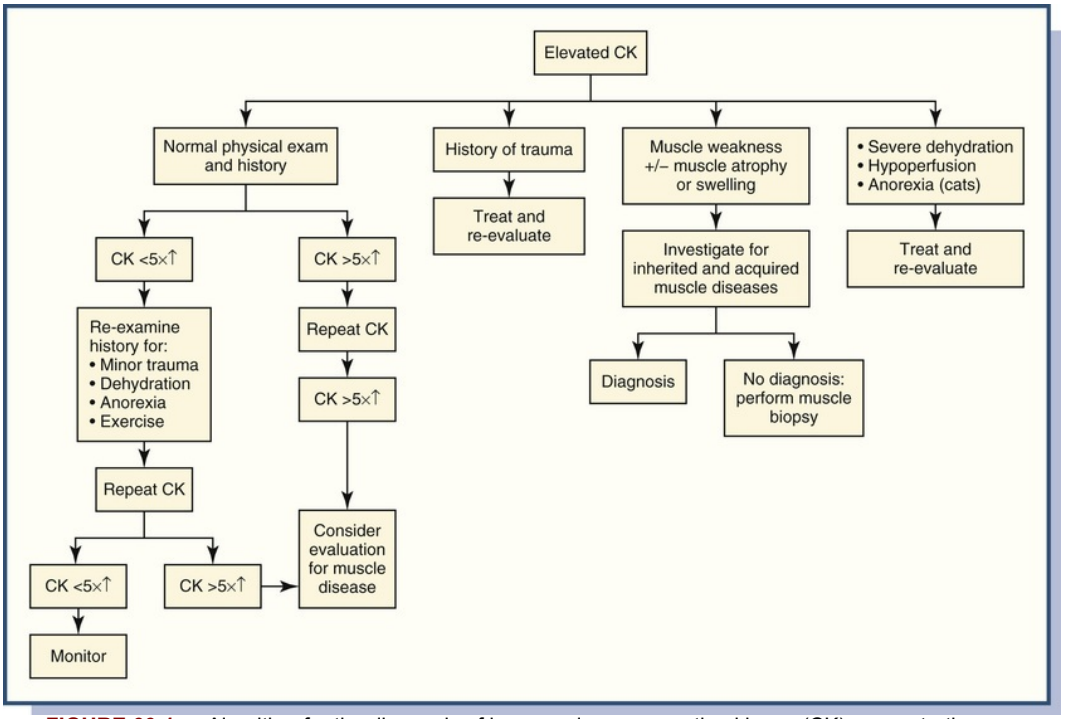

FIGURE 66-1 Algorithm for the diagnosis of increased serum creatine kinase (CK) concentrations.

In a well-hydrated, hemodynamically stable patient with no history of trauma, persistently increased serum CK concentrations should lead to a suspicion of muscle disease. The most marked increases in CK generally occur in dogs and cats with necrotizing, inflammatory and dystrophic myopathies (see ch. 354). Muscle necrosis (rhabdomyolysis) can be seen as a consequence of excessive exercise, hyperthermia, sepsis, drug reaction, crush injury, ischemia, or snake envenomation. Immune-mediated polymyositis and infectious myositides (neosporosis, toxoplasmosis, sarcocystosis, hepatozoonosis, babesiosis, etc.) typically cause moderate increases in CK, but occasionally muscle inflammation progresses to myonecrosis, resulting in marked increases. Dystrophin-deficient muscular dystrophies consistently have dramatic increases in CK (usually >100×) due to a loss of myofiber stability, leading to myonecrosis. Most other clinically severe congenital myopathies, including centronuclear/myotubular myopathies, central core myopathies, congenital nemaline rod myopathies, mitochondrial myopathies, and lipid storage myopathies have little (less than 5×) or no increase in CK. This distinction should allow clinicians to use serum CK activity in determining the likelihood of muscular dystrophy in symptomatic young dogs or cats. Metabolic testing and muscle biopsy are recommended in animals with muscle weakness even if CK results are normal or only mildly increased (see ch. 116). These tests should be considered in all animals with persistent moderate-to-severe increases in CK concentrations when a precipitating cause is not obvious.

CHAPTER 67

Sodium, Chloride

Dan Rosenberg

Overview

Sodium (Na) and chloride (Cl) are the primary cation and anion, respectively, in extracellular fluid (ECF). Both are crucial for maintaining osmolality and tonicity. Since their concentrations usually "parallel," clinicians focus more on Na concentration ([Na]) than on Cl concentration ([Cl]) when assessing water balance (see ch. 73). However, Cl and Na content are independently regulated, plus Cl is involved in acid-base regulation (see ch. 128). Thus, distinct differential diagnoses are needed, at times, for changes in [Na] versus changes in [Cl].

Hypernatremia (Figure 67-1)

Definitions

Body Sodium versus Water Content

The serum [Na] refers to the amount of Na relative to the amount of water in the ECF. Changes in serum [Na] often reflect changes in total body water stores rather than changes in total body Na content.[1,2] True hypernatremia always results in a hyperosmolar/hypertonic condition, indicating a deficit of water.[1,3] Not only mild measured hypernatremia but even subtle increases in serum [Na] within a reference interval initiate correction through thirst to increase body water and vasopressin (antidiuretic hormone [ADH]) secretion to decrease water loss.[3,4]

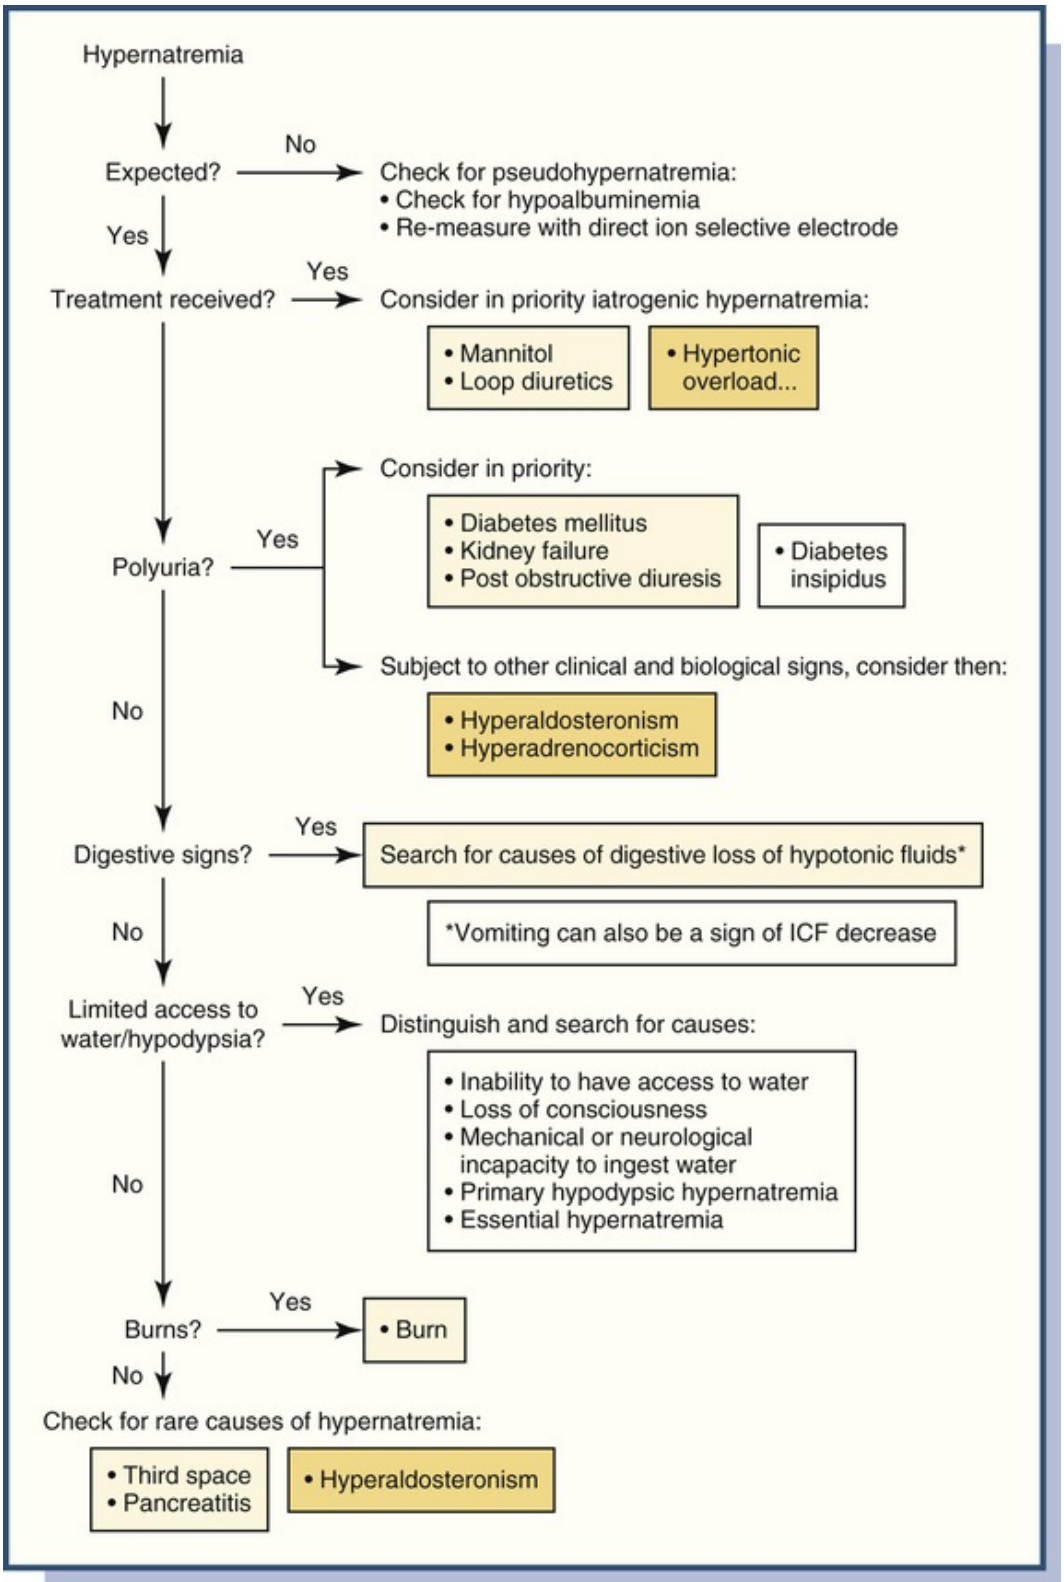

FIGURE 67-1 Diagnosis approach to hypernatremia in dogs and cats. For each diagnosis orientation, check for its clinical consistency by extracellular fluid assessment: unchanged or mildly decreased for causes of pure water deficit (non-shaded boxes), mildly to markedly decreased for causes of hypotonic losses (lightly-shaded boxes), increased for sodium overload causes (darkly-shaded boxes).

Osmolality and Osmolarity *(see ch. 296)*

Osmolality is a measure of solute concentration (osmotically active particles) in a liquid. Osmolality in healthy dogs ranges from about 290 to 310 and in cats from 300 to 330 mOsm/kg.[5-10] Although not absolutely equivalent, osmolarity (in mOsm/L) is used clinically because of availability and cost. Since all cell membranes display some degree of permeability to water (with the quasi-exception of some cells comprising the thick-ascending loop of Henle), the osmolality of the intracellular fluid (ICF) space and that of the ECF are similar.[11] Some solutes (e.g., urea) move freely across cell membranes. These so-called permeant solutes do not induce water movement or affect tonicity of either compartment. Compartmental tonicity is dependent on non-permeant solutes. ECF or plasma osmolality in dogs and cats can be estimated using the formula: plasma osmolarity (mOsm/L) = 2 [Na] + [BUN] + [Glu] when all concentrations are expressed in mmol/L or 2 × [Na] + [BUN in mg/dL]/2.8 + [Glu in mg/dL]/18.[8,9] Plasma tonicity is usually estimated using the equation: 2[Na] + [Glu] (in mmol/L). When insulin is absent or inactive, glucose is non-permeant while it is negligeable (averaging 5.6 mmol/L) and permeant in nondiabetic states. Thus it can be omitted except in pets with diabetes mellitus.[12]

Assays

Serum [Na] is reliably assayed in most veterinary situations.[13] Hyperlipidemia and hyperproteinemia can decrease measured [Na] *in vitro* when indirect methods requiring a dilution step are used and the opposite can cause [Na] to be incorrectly measured as increased.[14] Syndromes of pseudohypernatremia and pseudonormonatremia (sodium underestimation in a hypernatremic patient) should be given consideration when incidental hypernatremia is identified or when hypernatremia is suspected, though not confirmed, in a hyperproteinemic or hyperlipidemic dog or cat.[15-17] Na measurement using a direct selective electrode method is required if such concerns are present (see Figure 67-1). True hypernatremia can result from a deficit of pure water, a loss of hypotonic fluids, or an excessive Na gain (E-Box 67-1).

E-Box 67-1

Causes of Hypernatremia

Pseudohypernatremia

In theory, hypoproteinemia

Pure Water Deficit

Total body water ↓—Unchanged total body Na (ICF volume depletion—minimal change of ECF volume)

Isolated disturbance of water intake
- Inability to have access to water
- Loss of consciousness
- Inability to ingest water
- Primary hypodypsic hypernatremia and essential hypernatremia

Uncompensated loss of free water
- Diabetes insipidus with water restriction
- Heatstroke
- Fever with water consumption decrease

Uncompensated Hypotonic Loss

Total body water ↓—Total body sodium ↓ (signs of ECF volume depletion expected)

Renal loss
- Solute diuresis
  - Diabetes mellitus
  - Mannitol administration
  - Postobstructive diuresis
- Kidney dysfunction (except diabetes insipidus)
  - Chronic kidney disease
  - Polyuric intrinsic acute renal failure
  - Loop diuretics

Digestive loss
Vomiting
Diarrhea
Other loss
Peritonitis
Pancreatitis
Burns

Sodium Overload

Unchanged total body water—Total body sodium ↑ (signs of ICF volume depletion expected)

Excessive sodium intake
Salt poisoning
Iatrogenic
IV sodium-containing fluids (hypertonic saline, sodium bicarbonate)
Sodium-phosphate–containing enemas
Endocrine
Hyperaldosteronism and aldosterone precursor-secreting tumors
Hyperadrenocorticism

Causes

Isovolemic Hypernatremia

Simple water deficiency is an uncommon explanation for hypernatremia, usually caused by primary hypodipsia or an increased set point for secretion of ADH in association with diencephalic malformation, trauma, or neoplasia.[3,18-29] Decreases in intake can also be caused by lack of water for any reason. Pathologic conditions associated with free water loss (fever, diabetes insipidus) do not cause increased ECF tonicity if compensated by water intake. Failure to compensate with appropriate water intake would cause hypernatremia.[30,31] Compensation for pure water deficits is seen in both the ECF and ICF. Since the ICF volume is twice that of the ECF, most compensatory mechanisms initially involve the ICF.[3] Oncotic pressure also limits water movement from the ECF. Thus, pure water deficits are designated as causes of "isovolemic hypernatremia" with minimal, if any, signs of extracellular dehydration. Clinical signs associated with ICF volume depletion begin with the nervous system and are influenced by how quickly the ICF dehydration developed. Acute hypernatremia results in shrinkage of nervous system cells causing disorientation, ataxia, seizures, vomiting, anorexia or coma. Most animals with chronic hypernatremia are asymptomatic unless the [Na] is markedly increased and associated with increases in tonicity.[3]

Hypernatremia Secondary to Hypotonic Fluid Loss

Uncompensated losses of hypotonic fluids are the main causes of hypernatremia.[3] Unlike pure water loss, hypotonic fluid loss causes deficits in whole body Na content.[1] Renal hypotonic fluid losses (kidney disease, diabetes mellitus and diuretics) and digestive fluid losses (diarrhea and vomiting) account for most scenarios but hypotonic losses associated with third-space fluid accumulation (pancreatitis, burns) may be considered (see E-Box 67-1).[3,32-38] The impact of hypotonic losses on ECF volume depends on their tonicity. Loss of fluids with tonicity similar to that of the ECF compartment only affects the ECF volume as they do not induce osmotic changes. Hypernatremia develops if there is lack of compensation for the fluid loss.[3] Evidence of a depleted ECF volume can include loss of skin elasticity, delayed capillary refill time, weak pulse, and tachycardia.

Uncommon Causes of Hypernatremia

Na overload is a rare cause of hypernatremia in dogs and cats, salt poisoning having been described occasionally.[39-41] Over-administration of Na-containing fluids can generate hypernatremia, especially in cases of oliguria or marginal renal function (see ch. 129).[42-44] In rare cases, hyperaldosteronism, aldosterone precursor-secreting adrenocortical tumors and hyperadrenocorticism can be associated with mild hypernatremia (see ch. 306-308).[45-49] As these endocrinopathies often have obvious clinical manifestations plus expected clinicopathological abnormalities (e.g., hypokalemia for hyperaldosteronism and aldosterone

precursor-secreting tumors), the finding of this mild biochemical abnormality is rarely decisive in diagnosis.

Hyponatremia (Figure 67-2)

Physiologic Associations

Hyponatremia often, but not always, results in a hypotonic state.[3] Hypotonic hyponatremia, also termed dilutional hyponatremia, is a reflection of water retention (see E-Box 67-2).[50] Normotonic hyponatremia (pseudohyponatremia) refers to low Na concentrations measured in hyperproteinemic or hyperlipidemic patients who do not have hyponatremia (see previous discussion). Hypertonic hyponatremia refers to water translocation when osmoles other than sodium (glucose in diabetics) accumulate in one compartment because they do not cross cellular membranes, drawing water from the other space.[51-56] Incoming water dilutes concentration of all solutes in the ECF, including Na.[2] This hyponatremia is enhanced in ketoacidosis due to additional renal and gastrointestinal losses.

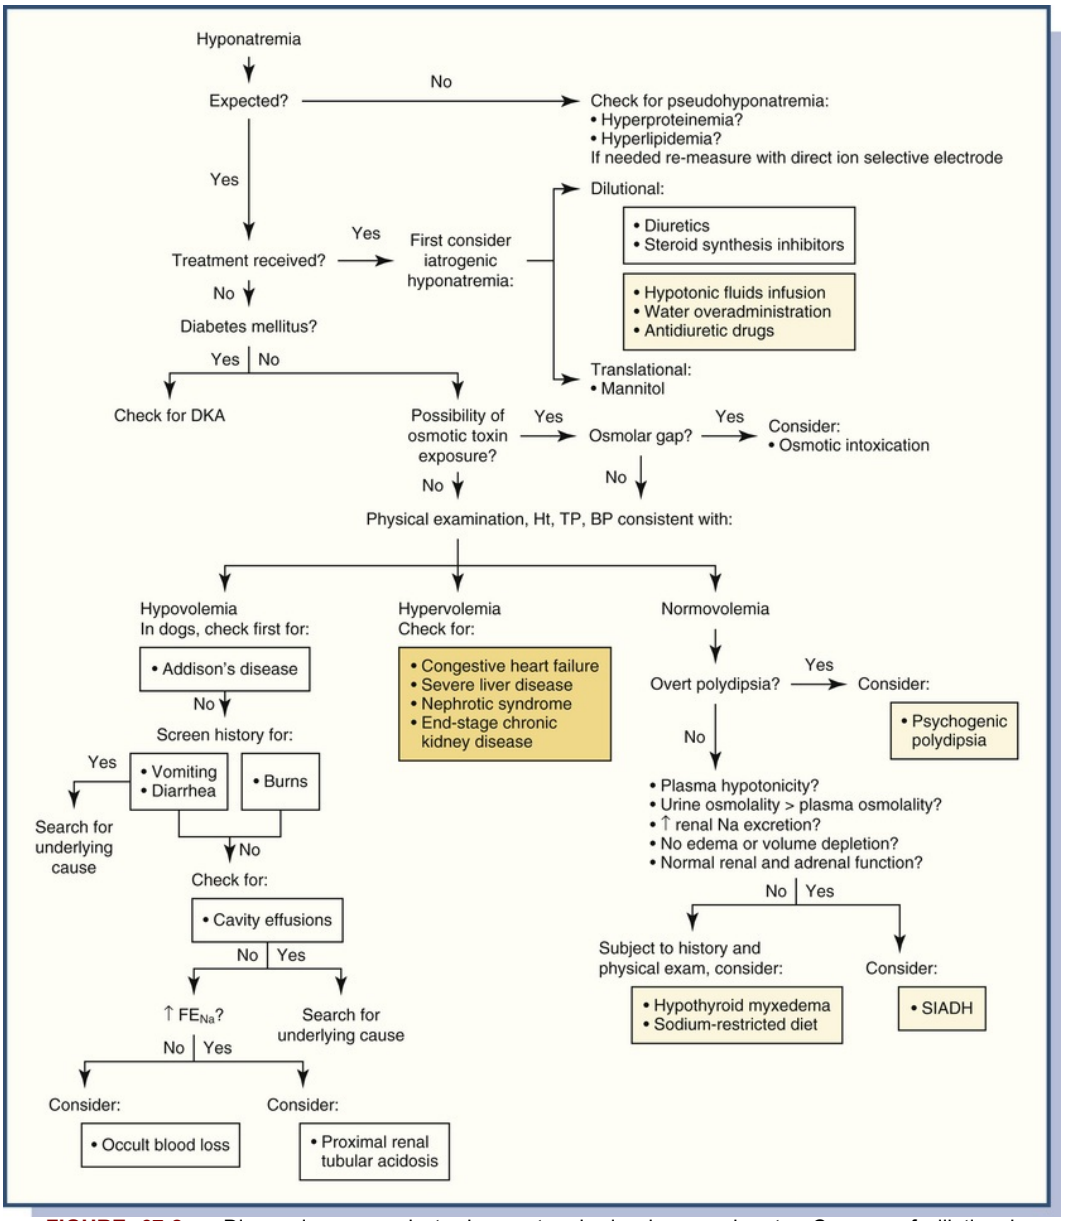

FIGURE 67-2 Diagnosis approach to hyponatremia in dogs and cats. Causes of dilutional hyponatremia are discriminated according to their corresponding extracellular volume: decreased (non-shaded boxes), unchanged (lightly-shaded boxes), increased (darkly-shaded boxes). *BP,* Systemic blood pressure; *DKA,* diabetic ketoacidosis; *FE_{Na},* fractional sodium excretion; *Ht,* hematocrit; *TP,*

serum total protein concentration.

E-Box 67-2

Causes of Hyponatremia

Non-Dilutional Hyponatremia

Pseudohyponatremia

Hyperlipidemia
Hyperproteinemia

Translocational (Hypertonic) Hyponatremia

Diabetes mellitus
Mannitol administration
Intoxication by other permeant molecules

Dilutional (Hypotonic) Hyponatremia

Loss of Sodium > Loss of Water

Total body water ↓—Total body Na ↓↓↓ (signs of ECF volume depletion expected)

Renal loss of sodium and water
- Hypoadrenocorticism
- Diuretic administration
- Proximal renal tubular acidosis

Non-renal loss of sodium and water
- Gastrointestinal loss
  - Vomiting
  - Diarrhea
- Third-space loss
  - Pancreatitis
  - Peritonitis
  - Uroabdomen
  - Other peritoneal effusion
  - Pleural effusion
  - Pericardial effusion
  - Uterine effusion
- Cutaneous loss
  - Burns
- Chronic blood loss

Pure Water Retention

Total body water ↑—Unchanged total body sodium (normal ECF volume)

Psychogenic polydipsia
Iatrogenic water retention
- Antidiuretic drugs
- Hypotonic fluids administration
- Uncontrolled enteral water administration

Sodium-restricted diet
Syndrome of inappropriate antidiuretic hormone secretion (SIADH)
Hypothyroid myxedema coma
Exercise-associated hyponatremia

Low Effective Circulating Volume

Total body water ↑↑↑—Total body sodium ↑ (ECF volume expansion)

Congestive heart failure
Severe liver disease
Nephrotic syndrome
End-stage chronic kidney disease

Miscellaneous
Sepsis and systemic inflammatory response syndrome
Babesiosis
ECF, Extracellular fluid.

Causes

Hypertonic Hyponatremia

Hypertonic hyponatremia can follow mannitol administration or ingestion of other permeant molecules (e.g., ethylene glycol).[10,57-63] Identifying the cause of hypertonic hyponatremia is usually straightforward (see Figure 67-2). If the possibility of an alcohol intoxication is raised, measuring osmolality can help by identifying a "gap" between that which is measured and the lower calculated value. These solutes are not included in the formula used for osmolality calculation (discussed earlier).[64]

Hypotonic Hyponatremia

Dilutional (hypotonic) hyponatremia can be associated with decreased, normal, or increased Na stores and, thus, with decreased, normal or increased ECF volumes (see E-Box 67-2 and Figure 67-2).[2] Chronic hyponatremia tends to cause few signs.[2] When hypotonic hyponatremia takes place gradually, the brain adapts to ECF hypotonicity.[65] Treatment of chronic hyponatremia is beyond the scope of this chapter but rapid correction of electrolyte concentrations can have worrisome consequences (see ch. 129).[2,3,50,66] In acute hyponatremia, water moves from the dilute ECF space to the more concentrated ICF, including into brain cells (cerebral edema), which increases intracranial pressure and leads to signs that can appear vague but are serious: lethargy, nausea, vomiting, and depression, before incoordination, seizures and death.[3] Rapid correction of acute hyponatremia is not as worrisome.[66]

Dilutional Hyponatremia

Dilutional hyponatremia is associated with an appropriate non-osmotic stimulation of ADH secretion, or in rare cases, with a deregulated (inappropriate) secretion of ADH. In combination with other mechanisms, secretion of ADH explains why even hypotonic losses (e.g., gastrointestinal losses) result in hyponatremia through volume preservation at the price of decreased osmolality via thirst and enhanced renal preservation of water.[3] Exceptions include primary polydipsia, exercise-induced hyponatremia (see ch. 173) and advanced CKD in which ADH secretion is adequately suppressed (see ch. 324).

Hypovolemic Hyponatremia

Most hyponatremic patients are hypovolemic. Their sodium losses exceed water losses due to compensation via water intake. Thus, identifying clinical signs of ECF dehydration and perfusion deficits (e.g., loss of skin elasticity, dry mucous membranes, sunken eyes, delayed capillary refill time, rapid heart rate), or of third-space fluid (abdominal fluid wave, abdominal distension, dyspnea, muffled heart sounds, distended jugular veins) is critical. Measuring serum albumin, hematocrit and arterial or central venous blood pressure are cornerstones to understanding hyponatremia (see Figure 67-2).[67] Knowing the ECF volume constitutes only one piece of a larger puzzle that includes other historical and clinical data.[68] For example, only half of dogs with Addison's disease exhibit clinically perceptible dehydration.[69] Addison's disease (see ch. 309) is an obvious cause of renal NaCl loss and this condition should be considered, especially if the patient is hyperkalemic (see Figure 67-2). Although suggestive, concurrent hyperkalemia and hyponatremia are not pathognomonic for Addison's disease. This electrolyte pattern has been uncommonly observed with gastrointestinal diseases, whipworm parasitism, chylothorax, pregnancy, urethral obstruction, and other conditions.[70-74] Use of diuretics and proximal renal tubular acidosis are additional renal causes of hypovolemic hyponatremia.[3,32,75]

Extrarenal causes of hypovolemic hyponatremia include Na losses due to vomiting, diarrhea, third-space fluid accumulation, and chronic blood loss (combined with an inappropriate Na dietary intake in some cases; see E-Box 67-2).[34,70,71,76-83] Fractional renal Na excretion should be appropriately low (see ch. 73).[84] The pathophysiology of hyponatremia in third-space effusions is multifactorial and, in some cases, overlaps with hypervolemic hyponatremia. Conditions such as congestive heart failure, severe liver disease and the

nephrotic syndrome can lead to low effective arterial blood pressure. This, in turn, stimulates renin-angiotensin-aldosterone to retain Na and water while ADH secretion is stimulated to expand ECF volume through water reabsorption.[3] [Na] is diluted by the increase in ECF volume despite an increase in total body Na: hypervolemic hyponatremia (see E-Box 67-2). Na moving into fluid in a body cavity, into an edematous space, and the use of diuretics as treatment enhance the likelihood of hyponatremia.[81] Hypervolemic hyponatremia may also be seen in advanced CKD (see ch. 324) because of defective renal salt and water excretion capacities.[3] The recognition of clinical signs of hypervolemia (e.g., effusions, jugular distension, peripheral or pulmonary edema) is crucial for treatment.

Psychogenic polydipsia can overwhelm renal water excretion capacities leading to dilution.[2] The syndrome of inappropriate ADH secretion (SIADH) can cause normovolemic hyponatremia. Criteria for diagnosing SIADH include: hyponatremia with hypotonic plasma; urine osmolality above that of plasma; increased renal Na excretion; absence of edema or volume depletion; normal renal and adrenal function.[85-87] SIADH has been reported in dogs and cats secondary to dirofilariasis, hypothalamic neoplasia, Rathke's cleft cyst, *Acanthamoeba* meningitis, congenital hydrocephalus, liver disease, and vinblastine overdosage.[88-98] Increased ADH secretion may cause dilutional hyponatremia secondary to hypothyroid myxedema.[99-107] Parenteral hypotonic fluid administration, enteral water overload, and use of certain antidiuretic drugs (nitrous oxide, barbiturates and narcotics) can cause normovolemic hyponatremia.[3,108-110] Hyponatremia has been described in a puppy fed a Na deficient diet, in dogs with babesiosis or sepsis, a cat with toxoplasmosis, and as a syndrome of inadequate compensation for renal Na losses in Alaskan sled dogs (see E-Box 67-2).[111-118]

Hypochloremia (Figure 67-3)

Serum chloride (Cl) concentration assays are typically reliable, although hyperproteinemia, lipemia, and administration of bromides may alter results.[119-122] Cl ions constitute about two thirds of ECF anions; most of the balance is bicarbonate (bicarb).[123] Apart from maintaining ECF tonicity, Cl has an inverse relationship with bicarb with a key role in renal acid-base regulation.[124-127] Proportionality in these electrolytes can be demonstrated with the formula: [corrected Cl^-] = [measured Cl^-] × [mid-reference range Na^+]/[measured Na^+]. Measured hypochloremia with normal serum corrected Cl concentration is suggestive of increases in ECF water.[123] In this scenario, the differential diagnoses for hyponatremia and hypochloremia are similar (E-Box 67-3; see also Figure 67-3).[123] Corrected hypochloremia and a reference range measured serum Cl concentration is usually associated with hypernatremia.

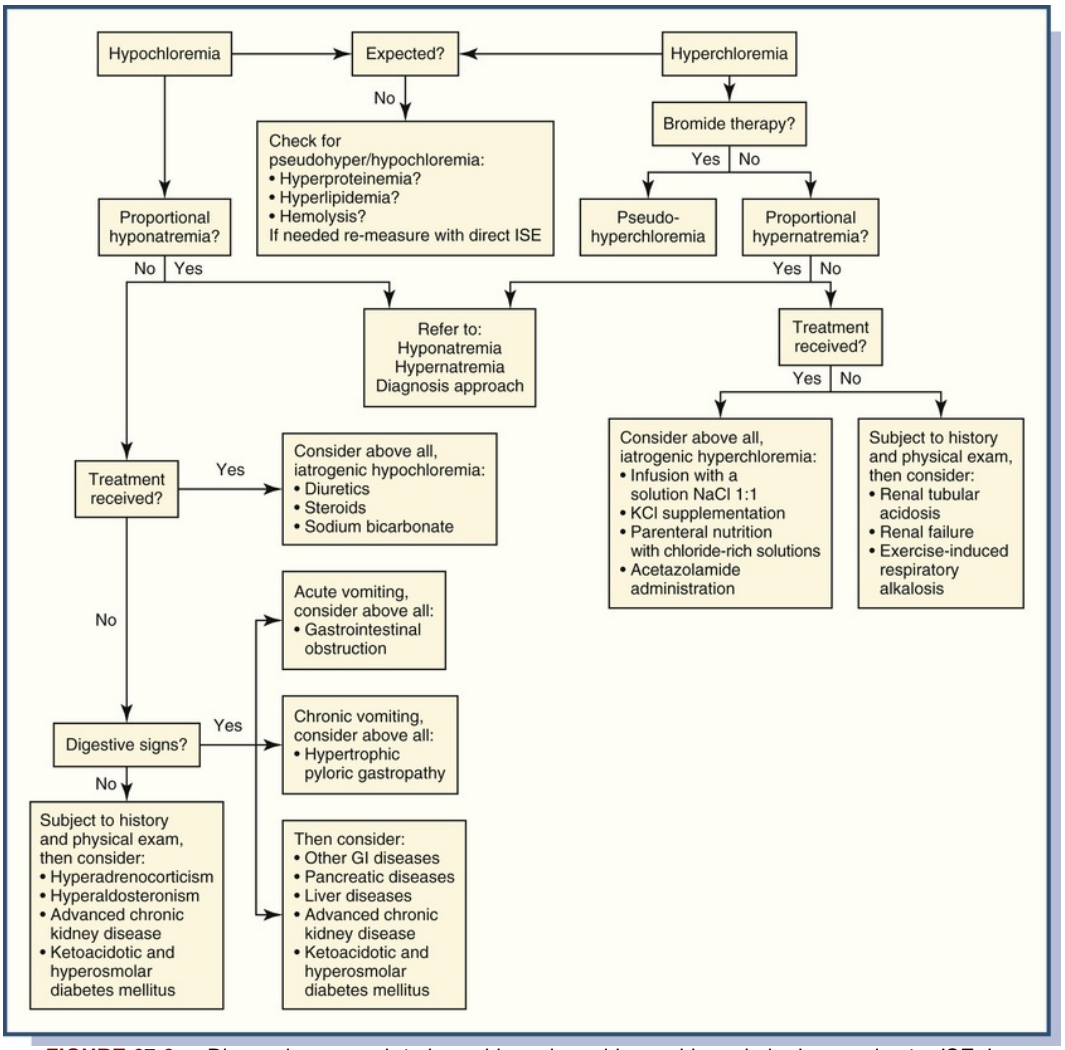

FIGURE 67-3 Diagnosis approach to hypochloremia and hyperchloremia in dogs and cats. *ISE,* Ion selective electrode.

Hyperchloremia with Proportional Hypernatremia (Measured Hyperchloremia—Corrected Normochloremia)
Pure water deficit (refer to E-Box 67-1)
Uncompensated hypotonic loss (refer to E-Box 67-1)
Salt overload (refer to E-Box 67-1)

Hyperchloremia without Proportional Hypernatremia (Corrected Hyperchloremia)

Excessive Chloride Intake (Compared to Sodium)
Isotonic NaCl, hypertonic NaCl, or Ringer's solution infusion
KCl supplementation
Parenteral nutrition with chloride-rich solutions

Chloride Renal Retention
Renal tubular acidosis
Renal failure
Babesiosis
Acetazolamide administration
Exercise-induced respiratory alkalosis

*With colorimetric methods of chloride measurement.
†Described in humans.

Decreases (or increases) in serum Cl are not associated with clinical signs, but their identification may be of value in pursuing a diagnosis. Measured and corrected hypochloremia without parallel hyponatremia can be observed with gastrointestinal (GI) or renal losses and in mixed acid-base disturbances. When serum Cl concentrations decrease with GI or renal loss, bicarb reabsorption increases proportionally, resulting in metabolic alkalosis. Conversely, in chronic respiratory acidosis, the increase of bicarb reabsorption is assumed to be associated with increased urinary losses of Cl and hypochloremia.[128,129] Hypochloremia is common in pets with chronic hypertrophic pyloric gastropathy, those with GI obstruction, and some with other GI, liver and pancreatic conditions, usually secondary to vomiting and metabolic alkalosis.[77,130-138] In one study, dogs suspected but proven not to have hypoadrenocorticism had lower serum [Cl] than did dogs with hypoadrenocorticism.[69,139]

Renal Cl losses can be caused by administration of loop or thiazide diuretics and hypochloremia is enhanced if a pet is fed a salt-restricted diet.[123,140-143] Mild hypochloremia has been documented in naturally-occurring hyperadrenocorticism, hyperaldosteronism, and after receiving steroids.[45,144-148] About 33% of untreated diabetic cats and a larger percentage of dogs and cats with end stage CKD are hypochloremic, the severity of which is worse if hyperosmolar and/or ketoacidotic.[37,53,149-153] Hypochloremia has been

documented in dogs with early stages of babesiosis.[37,118] A decrease in serum Cl concentration may be observed after Na bicarb administration, due to simple dilution by a non-Cl Na salt solution and because an increase in serum bicarb will cause a reciprocal decrease in Cl.[10]

Hyperchloremia

Bromide therapy, hemolysis, and hyperlipidemia can cause pseudohyperchloremia (see E-Box 67-3; see also Figure 67-3).[121,122,154] Water deficits and loss of hypotonic fluids result in parallel increases in serum [Na] and [Cl]. When the serum corrected Cl concentration is within the reference range but serum [Cl] is measured high, the differential diagnosis for hypernatremia should receive priority (see E-Box 67-3 and Figure 67-3).[3] A similar approach is suggested with salt overload and in rare dogs with hyperadrenocorticism and hyperchloremia.[39-41,45] One may calculate hyperchloremia when the measured concentration is within the reference range with hyponatremia. Causes of calculated hyperchloremia without measured hyperchloremia are reviewed in the section on hyponatremia.

An excessive gain of Cl compared with Na can result in calculated hyperchloremia.[126] For example, an isotonic saline IV infusion or use of a parenteral nutrition formula rich in Cl can cause mild increases in serum Cl concentration without hypernatremia.[3,10,123,155] Hyperchloremia has been described in both proximal and distal tubular acidosis in dogs and in distal tubular acidosis in cats.[75,153,156-158] Compromised reabsorption of bicarb and altered secretion of hydrogen ions may have a role in development of proximal and distal tubular acidosis respectively. Similar inhibition of bicarb reabsorption within the proximal tubule by the carbonic anhydrase inhibitor acetazolamide results in a hyperchloremic metabolic acidosis.[159,160] Tubular dysfunction may have contributed to the hyperchloremia described in a few cases of cats and dogs with kidney disease and in dogs with babesiosis.[32,35,115,132,161] Hyperchloremia has been observed in dogs during exercise.[162-167] Increases in serum Cl concentration are likely multifactorial but respiratory alkalosis and subsequent Cl compensation of the renal bicarbonate loss may be involved.[162,165]

CHAPTER 68

Potassium, Magnesium

Ann-Marie Della Maggiore

Potassium

Overview

Potassium (K^+), the body's primary intracellular cation, is essential for numerous physiologic processes including enzymatic action, neuromuscular and cardiac conduction, and routine cell function. Membrane permeability and the ratio of K^+ concentrations in the intracellular fluid (ICF) as compared with that in the extracellular fluid (ECF) are major determinants of resting cell membrane potentials. ICF K^+ (95% of total body K^+) has important roles in maintaining cell volume and growth. ECF K^+ concentrations (5% of total) are tightly regulated; serious increases or decreases in circulating K^+ concentrations are invariably worrisome and may be life-threatening. Reference intervals for serum or plasma K^+ concentrations should be determined by each laboratory, independently. Most reference intervals have a mean of approximately 4 to 4.5 mEq/L. Assays using serum or plasma are sensitive and specific for K^+ concentrations that usually, but not always, reflect total body K^+ status. An exception is inorganic acidosis (diabetic ketoacidosis, for example) in which extra- and intracellular K^+ concentrations become dissociated.

Dietary intake of K^+ is critical for normal homeostasis. K^+ is absorbed from the gastrointestinal tract (stomach and small intestine), distributed throughout the body, and excreted primarily by the kidneys (90-95%) and colon (5-10%).[1] Aldosterone has a critical role in determining the amount of K^+ excreted from the distal renal tubule and, thus, is a primary regulator of K^+ balance (see ch. 308, 309, and 326). Insulin and epinephrine are known to increase K^+ uptake by muscle and liver cells. Acute changes in pH will shift K^+ between fluid compartments.

Hypokalemia

Clinical Signs

Clinical signs due to hypokalemia in dogs and cats vary with severity and duration of the condition. Significant hypokalemia (< ≈3.0 mEq/L for most laboratories) usually results in vague-and-mild to profound muscle weakness. Hypokalemia may impair urinary concentrating ability, resulting in polyuria and secondary polydipsia. Severe deficiencies (< ≈2.0 mEq/L) have been associated with rhabdomyolysis and respiratory muscle paralysis.[2,3]

Differential Diagnosis and Approach (Figure 68-1)

Causes of hypokalemia include decreased intake, excessive or abnormal translocation between the ECF and ICF spaces, and/or excessive loss through the kidneys or gastrointestinal systems. Prolonged starvation as a cause of clinically significant hypokalemia is unlikely in otherwise healthy animals (i.e., no excessive K^+ losses) because aldosterone and the kidneys, within hours to days, adjust K^+ excretion to maintain serum concentrations. Administration of IV replacement fluids insufficiently supplemented with K^+, however, can lead to hypokalemia in anorectic patients, depending on duration and cause of their illness. Remember that the K^+ content of fluids such as Ringer's solution (4 mEq/L) is trivial and not adequate for long-term maintenance (saline contains no potassium). Ingestion of bentonite-containing clay cat litter can bind K^+ within the gastrointestinal tract.[4,5]

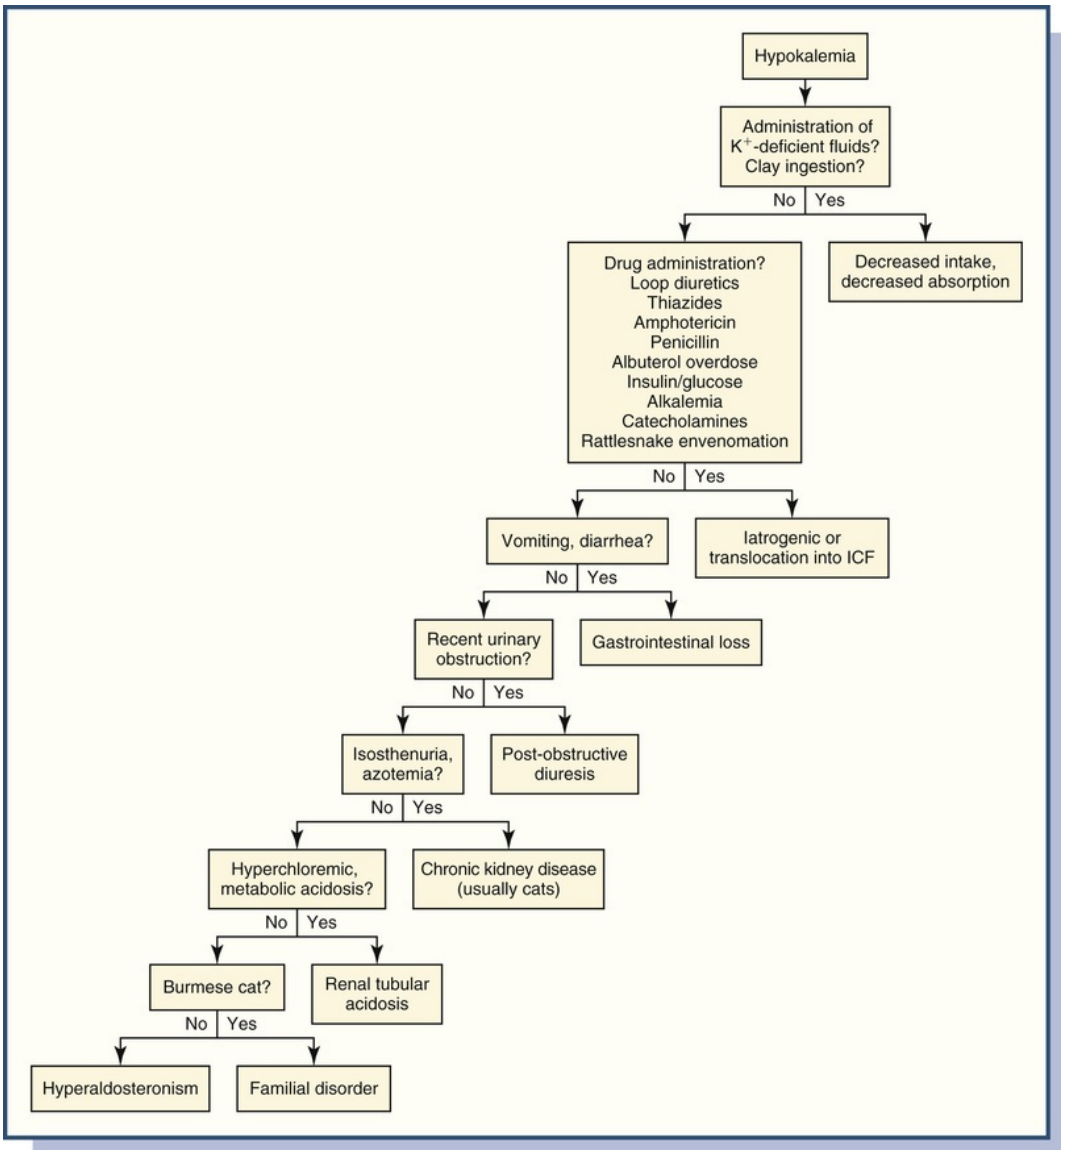

FIGURE 68-1 Algorithm for the evaluation of hypokalemia. *ICF,* Intracellular fluid compartment.

Dogs and cats severely ill with diabetic ketoacidosis are typically depleted in total body potassium stores following anorexia, vomiting, diarrhea, polyuria with and then without compensatory polydipsia (individuals decrease or stop drinking due to illness and become dehydrated). In these patients, excessive translocation of K^+ from the ECF to the ICF in response to administration of insulin, IV fluids, sodium bicarbonate, and glucose can be profound and life-threatening. Close monitoring to recognize and manage alterations in K^+ is critically important (see ch. 142). Catecholamine release, alkalemia, beta$_2$-adrenergic drug overdose, rattlesnake envenomation, and hypothermia may result in hypokalemia. There is a familial disorder of K^+ translocation in Burmese cats.[6-10]

Gastrointestinal losses of potassium, associated with vomiting and/or diarrhea, are one of the most common causes of hypokalemia. Although vomitus may not contain large quantities of K^+, loss of gastric secretions promotes increased renal losses. Urinary losses of potassium are also common, with as many as 20-30% of cats with chronic kidney disease (CKD) having hypokalemia.[11-13] It has been suggested that many cats thought to have primary kidney disease and secondary hypokalemia may indeed have primary hyperaldosteronism, which results primarily in hypokalemia and chronically leads to secondary CKD. Hypokalemia is less common in dogs with CKD. The incidence of primary hyperaldosteronism in dogs and cats is not known but likely underestimated in both species. Urinary potassium losses can be significant during post-obstructive diuresis, in some forms of renal tubular acidosis, and rarely following peritoneal dialysis.[14-16] Hypokalemia is uncommon in pets with polyuric disorders. Medications that lead to diuresis

and potential for hypokalemia include loop and thiazide diuretics, amphotericin B, and glucocorticoid excess (rare in hyperadrenocorticism).[17-19]

Hyperkalemia

Overview

Hyperkalemia is most frequently associated with acute kidney injury (AKI) or CKD because these conditions are common and failing kidneys may fail to excrete adequate quantities of potassium. Hyperkalemic dogs and cats may not show clinical signs until the condition becomes severe (>7.5-8 mEq/L) and even then the only typical observation is weakness (the same clinical sign associated with hypokalemia). Many severely hyperkalemic pets have bradycardia and the classic loss of P waves on electrocardiogram (ECG). The ECG from these patients may also reveal the less obvious and less specific "tented" T waves, shortened Q-T intervals, and prolonged P wave and P-R interval durations (prior to P wave disappearance).[20] ECG alterations do not consistently correlate with specific serum K^+ concentrations.

Differential Diagnoses and Approach (Figure 68-2)

Pseudohyperkalemia may occur with severe thrombocytosis (platelet numbers >1,000,000/mcL), severe leukocytosis (WBC >100,000/mcL), hemolysis in neonates and animals with high intracellular K^+ (e.g., Akitas, Shiba Inu, others?). If one of these issues is suspected, serum K^+ should be reevaluated. In breeds known to have high intracellular K^+ concentrations, attention must be paid to avoiding hemolysis and quickly separating red blood cells from serum or plasma.

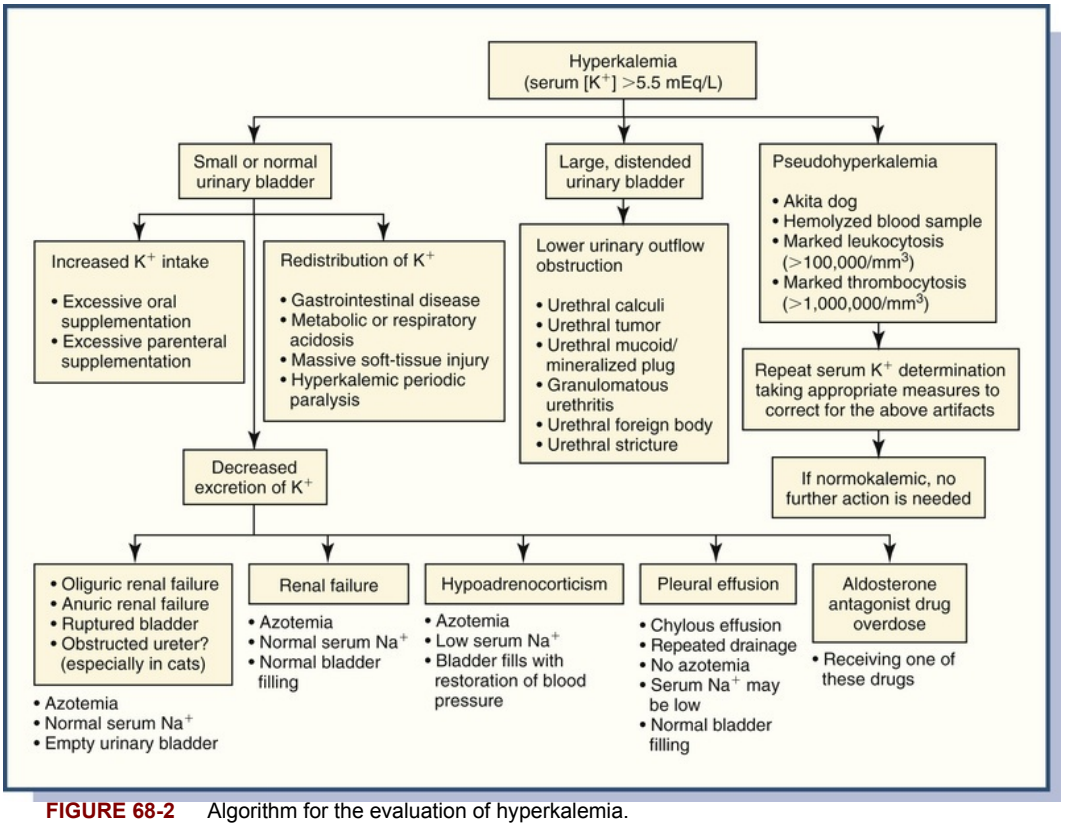

FIGURE 68-2 Algorithm for the evaluation of hyperkalemia.

As discussed, hyperkalemia is commonly associated with renal failure. Increased oral K^+ intake may contribute to hyperkalemia but is unlikely to be the sole cause. Hyperkalemia occurs when excessive amounts are administered IV. Several medications may contribute to hyperkalemia: ACE inhibitors, angiotensin receptor blockers, K^+-sparing diuretics (e.g., spironolactone), prostaglandin inhibitors (e.g., nonsteroidal anti-inflammatories), trimethoprim, cyclosporine, nonspecific beta-blockers (e.g., propranolol), and heparin.[21]

Serum potassium concentrations may transiently increase following oral potassium bromide administration, but sustained hyperkalemia is likely only in animals with compromised renal function. Tissue breakdown following severe exercise or due to rhabdomyolysis can cause hyperkalemia.

Hypoadrenocorticism, the classic cause of hyperkalemia and hyponatremia, is typically a condition resulting from mineralocorticoid and glucocorticoid deficiencies (some dogs with Addison's disease do not have serum electrolyte abnormalities; see ch. 309). Hyperkalemia and hyponatremia have been uncommonly reported in pets with chronic pleural or peritoneal effusion (see ch. 244) and with certain gastrointestinal diseases: parasitism (e.g., trichuriasis), infection (e.g., salmonellosis), or a perforating duodenal ulcer (see ch. 276).[22,23] Hyperkalemia and impaired renal K^+ excretion may occur despite increased aldosterone concentrations if rates of distal renal tubular flow markedly decrease (e.g., hypovolemia).

Urethral obstruction or bilateral ureteral obstructions prevent urine excretion. Urethral obstruction is a common cause of hyperkalemia. The hyperkalemic animal with a small or non-palpable bladder should be evaluated for oliguric or anuric renal failure (consistent with either AKI or end-stage CKD) or rupture. A history of trauma or urinary tract calculi and straining should make urinary rupture a consideration. Animals with hyperkalemia and urinary tract obstruction or rupture are usually severely ill, requiring rapid and thorough evaluation and treatment (see ch. 150).

Metabolic acidosis can result in K^+ translocation from the ICF to the ECF (e.g., lactic acidosis and ketoacidosis). Ill diabetics who have deficiency in total body K^+ may have normal or even increased circulating K^+ concentrations. It is important for the clinician to recognize that these animals are predisposed to life-threatening hypokalemia when treatment with insulin, IV fluids, sodium bicarbonate and glucose commences, each of which enhances K^+ movement from the ECF space to the ICF. The concern of over- or under-dosing potassium requires extremely close monitoring and appropriate responses (see ch. 142).

Magnesium

Overview

Magnesium (Mg), an abundant water-soluble intracellular divalent cation, plays critical roles in multiple cellular processes: stabilization of phosphorylation reactions, enabling glucose utilization and synthesis, supporting ion transport, and enhancing macromolecule synthesis (proteins, fats, and nucleic acids).[24] The study of magnesium-related disorders has been challenging simply because 99% of Mg is in the ICF space. We can only measure a portion of the ≈1% of total body Mg that is in the ECF. Approximately 67% of total body Mg is stored with calcium and phosphorus in bone. About 20% of total body Mg is found within muscle and about 10% in other soft tissues.[25,26] Extracellular Mg has been identified in three major forms: the biologically active free or unbound ionized Mg (≈55%); protein-bound (20-30%), and complexed (15-25%). The ICF distribution of Mg has made assessment of serum Mg concentrations of uncertain value. No gold standard test exists for determining total body Mg deficits or excesses. Serum total and ionized Mg concentrations are currently used to assess for hypomagnesemia but may not reflect total body stores. Studies, such as 24-hour urinary Mg excretion, Mg retention, ionized-to-total Mg ratios, and determining parenteral Mg tolerance are being evaluated.

Magnesium homeostasis is dependent on the interaction of three key organ functions: intestinal uptake, bone stores, and kidney filtration/excretion. The kidneys control Mg balance through glomerular filtration and reabsorption in the thick ascending loop of Henle and distal convoluted tubule. Gastrointestinal Mg absorption occurs primarily in the colon of dogs.[27]

Hypomagnesemia

Humans

Numerous causes of hypomagnesemia have been documented in human critical care patients. Hypomagnesemia is most common in hospitalized ill patients who have decreased Mg intake and increased loss through the gastrointestinal tract or altered kidney function. Causes of hypomagnesemia in veterinary patients are not as well documented, but general mechanisms of loss are believed to be similar between species.

Differential Diagnosis and Approach *(Figure 68-3)*

Causes of hypomagnesemia include decreased intake, alterations in cellular distribution, increased renal or

gastrointestinal loss, or any combination of these mechanisms. Gastrointestinal disorders that may cause hypomagnesemia include chronic diarrhea, malabsorption, short bowel syndrome, and colonic neoplasia. Drugs associated with hypomagnesemia in people include diuretics, gentamicin, cisplatin, cyclosporine, ticarcillin, carbenicillin, and proton pump inhibitors.[22] Renal losses of Mg may be seen secondary to diabetes mellitus, diabetic ketoacidosis, AKI, postobstructive diuresis, and renal tubular acidosis.[22]

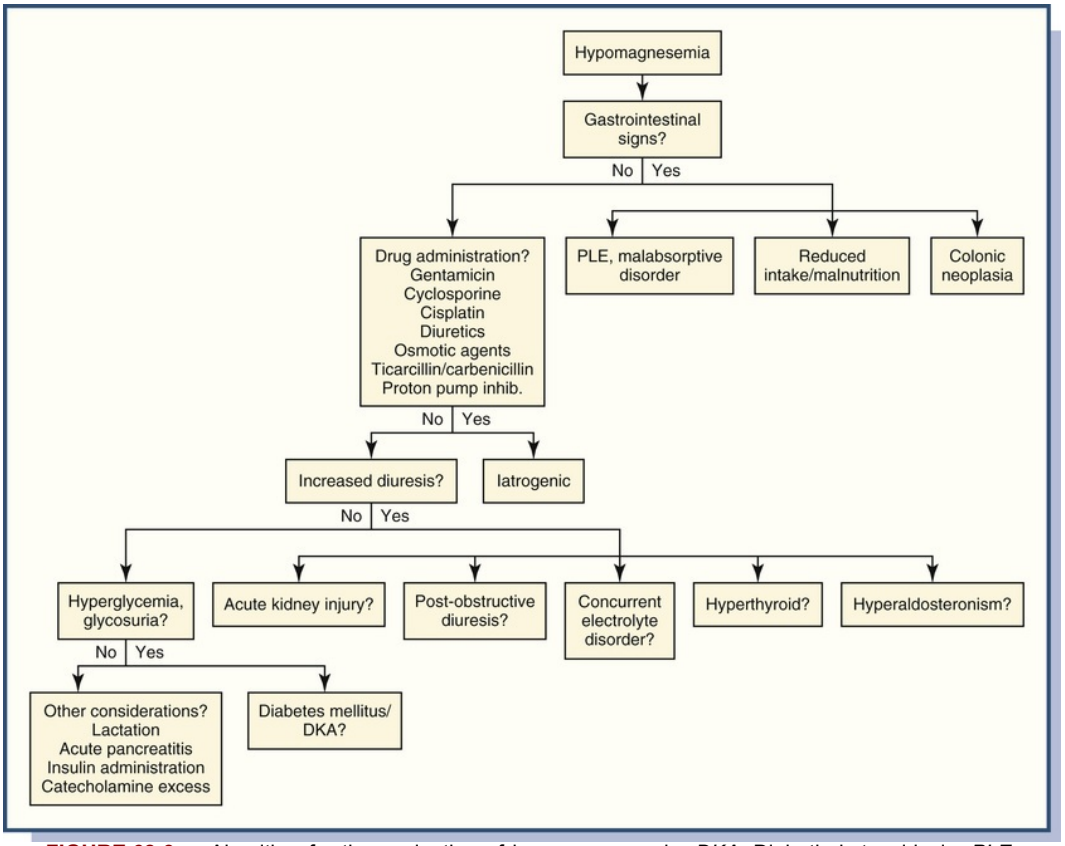

FIGURE 68-3 Algorithm for the evaluation of hypomagnesemia. *DKA*, Diabetic ketoacidosis; *PLE*, protein-losing enteropathy.

Hyperaldosteronism, hyperthyroidism, and primary hypoparathyroidism are endocrine conditions associated with hypomagnesemia. Hypomagnesemia is commonly seen with hypoparathyroidism (32% of dogs, 85% cats).[28] Magnesium depletion may impair parathyroid hormone (PTH) secretion and decrease sensitivity of receptors to ionized calcium. Thus, animals with hypoparathyroidism may appear refractory to calcium and calcitriol supplementation until their hypomagnesemia is treated.[22] Other causes of hypomagnesemia include excessive loss from lactation, myocardial infarction, acute pancreatitis, insulin administration or catecholamine excess.[26] Hypomagnesemia has been documented to occur with increased frequency in Bulldogs.[29]

Hypermagnesemia

Overview

Hypermagnesemia may be less clinically relevant in veterinary medicine than its counterpart. Hypermagnesemia has been observed in 18% of hospitalized cats and 13% of hospitalized dogs.[30,31] There is limited information in the veterinary literature documenting clinical signs of hypermagnesemia. Symptoms reported in humans include paresis, paralysis, impaired respiration, hypotension, nausea, vomiting, and electrophysiological derangements of cardiac conduction.[22] Significant cardiovascular effects, including arrhythmias, hypotension, and death have been noted in patients whose plasma concentrations were greater than 12 mEq/L.[32] Monitoring both blood pressure and ECG for irregularities is recommended during

parenteral Mg administration.

Differential Diagnosis and Approach (Figure 68-4)

Magnesium is predominantly excreted via the kidneys. Thus, renal insufficiency and post-renal azotemia are the most common causes of excess circulating concentrations of magnesium. Iatrogenic overdose through parenteral or oral administration has been documented in people but not dogs or cats. Hypermagnesemia has been associated with administration of methylpredacetate in cats and ACE inhibitors and spironolactone in dogs with degenerative valve disease.[28,33] While 35% of dogs with newly diagnosed hypoadrenocorticism had hypermagnesemia at the time of diagnosis in one study, it was not considered clinically significant.[34] Magnesium concentrations did not correlate with serum creatinine or pH.

CHAPTER 69

Calcium, Phosphorus

Richard John Mellanby

Calcium Overview

As well as causing clinical signs which may require urgent treatment, finding an altered serum calcium concentration is often of considerable assistance during the diagnostic evaluation of an animal showing vague clinical signs. Calcium is found in three forms in the circulation: the physiologically active ionized form which accounts for about 50%; the chelated form complexed with lactate, citrate and bicarbonate accounting for about 10%; and the protein-bound form accounting for about 40% of the total measured serum calcium concentration. The percentage of calcium in each form can vary depending on albumin and other protein concentrations, acid-base balance, and on the presence of potential chelators. An animal's serum total calcium concentration should always be interpreted together with the albumin concentration since hypoalbuminemia can result in spurious hypocalcemia or mask hypercalcemia. Changes in blood pH can lead to alterations in negative charges on protein molecules which in turn can alter the amount of calcium which is protein-bound. The primary hormones involved in regulating calcium metabolism in healthy animals are parathyroid hormone (PTH), 1,25 dihydroxyvitamin D (1,25$(OH)_2$D) and calcitonin (see ch. 297 and 298).[1-7]

Hypercalcemia in Dogs

Clinical Signs

Clinical signs associated with hypercalcemia vary depending on underlying cause. The neuromuscular, gastrointestinal, renal and cardiac systems are most commonly affected (Table 69-1). Hypercalcemia inhibits the action of antidiuretic hormone (ADH), leading to an inability to concentrate urine and polyuria and polydipsia. Urine specific gravities are commonly <1.012 and almost always <1.020 on home-caught samples of hypercalcemic dogs. Long-standing hypercalcemia, especially if accompanied by hyperphosphatemia, may result in renal tubular damage and intrinsic renal azotemia. Other common clinical signs include lethargy, muscle weakness, poor appetite, and weight loss. Vomiting, constipation, and diarrhea are uncommon and seizures are quite rare.

TABLE 69-1

Clinical Signs Noted in Hypercalcemic Dogs and Cats[17,27]

CLINICAL SIGN	FREQUENCY (%) IN HYPERCALCEMIC DOGS	FREQUENCY (%) IN HYPERCALCEMIC CATS
Anorexia	88	70
Polydipsia/ polyuria	68	24
Vomiting	53	18
Muscular weakness or twitching	23	0

Differential Diagnosis

Overview

The most common causes of hypercalcemia in dogs are malignancy, hypoadrenocorticism, primary hyperparathyroidism and chronic kidney disease (Box 69-1). Lymphoma and apocrine gland adenocarcinoma of the anal sac are the two most common causes of malignancy-related hypercalcemia. Less common causes of hypercalcemia include hypervitaminosis D (vitamin D toxicosis), granulomatous diseases, dehydration, healthy juvenile animals and laboratory error.

Box 69-1

Conditions Associated with Hypercalcemia

Common Causes

Malignancy
- Lymphoma
- Adenocarcinoma of the apocrine glands of the anal sac (rarely diagnosed in cats)
- Multiple myeloma

Primary hyperparathyroidism
Chronic kidney disease (CKD)
Hypoadrenocorticism (an infrequent cause of hypercalcemia in cats)
Some granulomatous diseases
Hypervitaminosis D
- Cholecalciferol rodenticide toxicosis
- Excessive dietary supplementation
- Ingestion of human medication containing calcitriol
- Oversupplementation for hypoparathyroidism

Less Common Causes

Idiopathic (cats)
Miscellaneous tumors (squamous cell carcinoma, lung carcinoma, malignant melanoma)
Hyperlipidemia
Juvenile dogs
Lab error
Hyperproteinemia

Rare Causes

Osteosarcoma
Metastatic bone tumors
Mammary carcinoma

Malignancy

Lymphoma is the most common cause of malignancy-related hypercalcemia. Hypercalcemic dogs with lymphoma frequently, but not invariably, have increased circulating concentrations of parathyroid hormone related peptide (PTHrP) synthesized by the cancer and suppressing PTH concentrations (see ch. 297). Normocalcemic dogs with lymphoma have low or undetectable concentrations of PTHrP.[1] Apocrine gland adenocarcinomas of the anal sac may also synthesize PTHrP, causing malignancy-related hypercalcemia.[8,9] A variety of other neoplasms have been associated with hypercalcemia, including thymoma, pulmonary carcinoma, nasal carcinoma, malignant melanoma, multiple myeloma and leukemia.[10-15] Since hypercalcemia of malignancy is typically driven by tumor PTHrP production, both total and ionized calcium concentrations are increased while serum phosphate is usually low or in the lower portion of the reference range (Table 69-2).

TABLE 69-2

Pertinent Circulating Serum Biochemistry and Hormone Results in Dogs with Conditions Associated with Hypercalcemia

	PRIMARY HYPERPARATHYROIDISM	MALIGNANCY	HYPERVITAMINOSIS D	CKD	HYPOADRENOCORTICISM
Total calcium	↑	↑	↑	↑ or N or ↓	↑
Ionized calcium	↑	↑	↑	N or ↓	↑
Phosphate	N or ↓	N or ↓	N or ↑	↑	N or ↑
Urea/creatinine	↓ N or ↑	N or ↑	N or ↑	↑	N or ↑
PTH	N or ↑	↓	↓	↑	N
PTHrP	-	↑	-	-	-
1,25(OH)2D	N or ↑	↑ or N or ↓	↑	N or ↓	N
25(OH)D	N or ↓	N or ↓	N or ↑	N or ↓	N

↑, Increased; ↓, decreased; -, negative; *CKD,* chronic kidney disease; *N,* normal.

Primary Hyperparathyroidism

Primary hyperparathyroidism is well recognized as a cause of moderate to marked hypercalcemia in dogs, most of whom have low or low normal serum phosphate concentrations (see Table 69-2).[16]

Chronic Kidney Disease (CKD)

Dogs and cats in later stages of CKD have phosphate retention and hyperphosphatemia. Mass law effects lead to decreases in circulating calcium concentrations, a condition enhanced by the kidney's reduced ability to synthesize vitamin D. Decreases in vitamin D lead to reduced calcium absorption from the intestine and increased PTH concentrations from the parathyroid gland. This sequence of physiologic events initially returns serum calcium concentrations toward "normal" (CKD patients are usually normocalcemic or less commonly hypocalcemic). If renal dysfunction progresses, these processes may become insufficient to support serum calcium concentrations and hypocalcemia develops. Thus, the hallmarks of CKD are azotemia, hyperphosphatemia, normocalcemia or mild hypocalcemia and isosthenuria. However, a small proportion of dogs and cats with CKD become hypercalcemic. The etiology of hypercalcemia in patients with CKD is poorly understood but may be due to autonomous secretion of PTH, a raised set point for calcium autoregulation or increased binding of calcium to retained anions (see Table 69-2).

Hypoadrenocorticism

Approximately 30% of dogs with hypoadrenocorticism are hypercalcemic when first examined.[17,18] Total and ionized hypercalcemia, when it occurs, tends to be mild. PTH, PTHrP and vitamin D metabolites are typically within reference ranges.[19,20] Hypercalcemia does tend to occur in patients with the highest potassium concentrations and usually quickly resolves with therapy. Unpublished data suggest that resolution of hypercalcemia in these patients follows fluid resuscitation together with glucocorticoid and mineralocorticoid replacement therapy.

Other Causes

Young healthy animals often have mild hypercalcemia and hyperphosphatemia when utilizing adult reference intervals. Hypercalcemia can follow ingestion of vitamin D–containing rodenticides, consumption of certain topical psoriasis preparations for people, overzealous dietary supplementation, or during vitamin D treatment of hypoparathyroidism.[6,21,22] Vitamin D increases gastrointestinal absorption of calcium and phosphate. Excessive vitamin D can lead to hypercalcemia, hyperphosphatemia, increased ionized calcium concentrations and suppressed PTH concentrations. Hypercalcemia is occasionally associated with granulomatous diseases such as blastomycosis, aspergillosis and schistosomiasis.[23-25] The cause of hypercalcemia associated with granulomatous diseases is likely an excessive production of $1,25(OH)_2D$ by

macrophages or via synthesis of PTHrP.[7,26]

Hypercalcemia in Cats

Review

Many causes of hypercalcemia in cats are the same as those discussed for dogs. There are also some important differences. The most common clinical signs in hypercalcemic cats are anorexia and lethargy, with polydipsia and polyuria less common (see Table 69-1). Malignancy and kidney disease are common causes of hypercalcemia in cats.[27] Squamous cell carcinoma was associated with hypercalcemia as frequently as was lymphoma.[17,27] Adenocarcinoma of the anal sac apocrine glands is rare and hypoadrenocorticism is uncommon in cats.[28,29]

Idiopathic hypercalcemia is an important differential in cats.[30] This diagnosis is reserved for cats where the underlying cause of the hypercalcemia cannot be identified despite extensive diagnostic evaluation and long-term follow-up. Both total and ionized calcium concentrations are moderately increased, PTH concentrations are normal-to-low, and PTHrP concentrations normal. It is important to rule out known causes of hypercalcemia in these cats prior to symptomatic treatment (see ch. 297).[30,31]

Diagnostic Approach to Hypercalcemia

A thorough history should be obtained and assessed followed by a careful physical examination in all hypercalcemic animals (Figure 69-1). Duration of any signs and the potential for access to toxins or medications containing vitamin D should be determined. Severity of illness may contribute to prioritizing potential causes. The peripheral lymph nodes should be assessed for size and the anal sac areas carefully palpated. Any enlarged lymph nodes should be fine-needle aspirated or biopsied. Consideration should be given to aspiration or biopsy of any other palpable mass, since malignancies and granulomatous lesions can cause hypercalcemia.

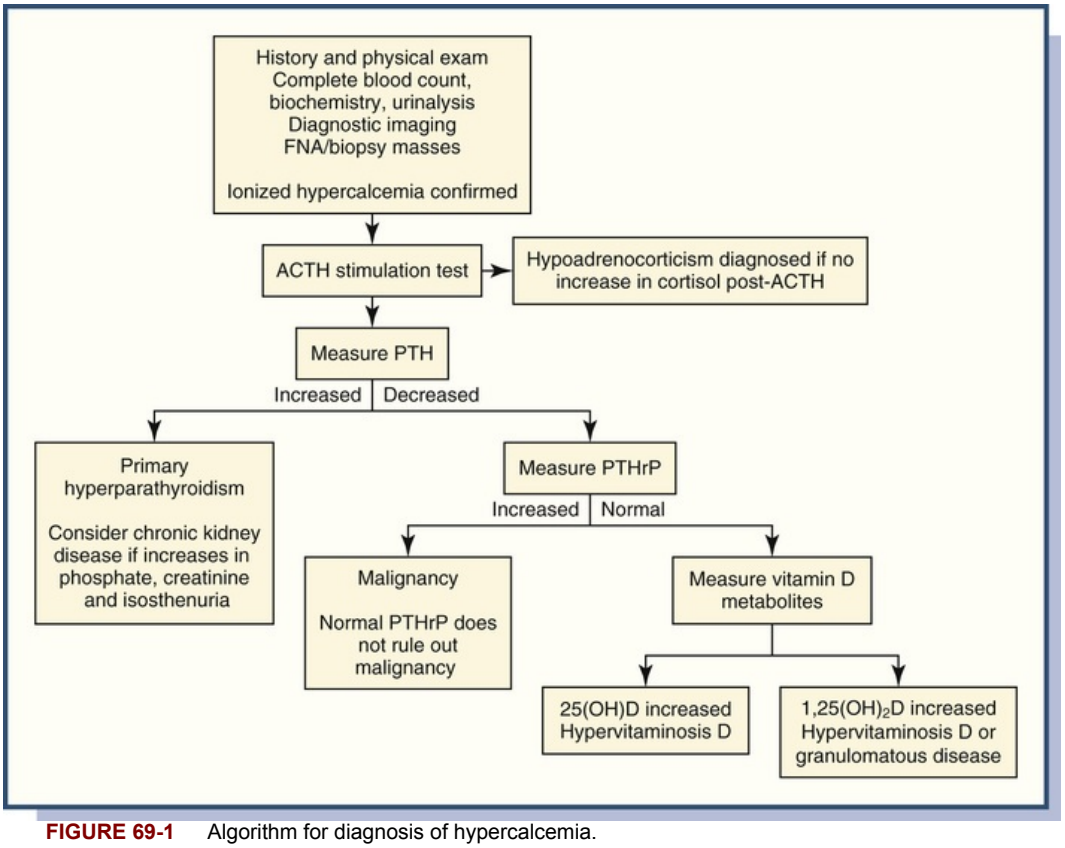

FIGURE 69-1 Algorithm for diagnosis of hypercalcemia.

Serum biochemistry results are invariably informative. Particular attention should be paid to electrolytes, albumin, urea (BUN), phosphate and creatinine concentrations. Evaluation of urine specific gravity is also valuable. However, urine specific gravity results from patients with CKD (usually isosthenuric) may not be different from those with hypoadrenocorticism or hypercalcemia due to PTH or PTHrP-driven conditions, who also may be isosthenuric (see ch. 324). Hypoadrenocorticism should be considered whenever hypercalcemia is documented in a dog or cat with hyperkalemia. An adrenocorticotropic hormone (ACTH) stimulation test should be considered when appropriate (see ch. 309).[18]

Thoracic imaging is of value since mediastinal cancers, such as lymphoma and thymoma, can be visualized and are the most common causes of hypercalcemia (see ch. 344 and 352). Abdominal ultrasonography may help to identify neoplastic or granulomatous lesions. Aspirates or biopsies of any abdominal masses may be helpful (see ch. 89). Ultrasonography of the ventral neck region may be helpful since a parathyroid nodule is frequently observed in cases of primary hyperparathyroidism (see ch. 297). Results of PTH and PTHrP assays may allow the clinician to understand the pathogenesis of hypercalcemia and may be necessary for confirming a diagnosis (see Figure 69-1). If available, reliable, and cost-effective, vitamin D metabolite assay results will also be of value.

Hypocalcemia

Overview and Clinical Signs

Hypocalcemia is caused by a relatively small number of conditions. Clinical signs may vary slightly depending on underlying cause. Some animals are asymptomatic despite low circulating calcium concentrations, but most exhibit signs directly attributable to hypocalcemia-induced increases in neuronal excitability. These signs include nervousness, behavioral changes, focal muscle twitching (especially ear and facial muscles), facial rubbing, chewing at the paws, muscle cramps, stiff gait, tetany and seizures (see ch. 298). Exercise, excitement and stress may induce or worsen clinical signs. Additional abnormalities include fever, cataracts and cardiac arrhythmias.

Causes of Hypocalcemia

Hypocalcemia has been reported in a variety of clinical conditions and occurs when there is either impaired PTH secretion or action, impaired vitamin D synthesis or action or in cases of calcium precipitation or chelation (Box 69-2).

Box 69-2

Conditions Associated with Hypocalcemia

Common Causes

Hypoalbuminemia
Acute and chronic renal failure
Hypoparathyroidism
Eclampsia
Protein-losing enteropathies
Pancreatitis
Exocrine pancreatic insufficiency
Trauma
Systemic inflammatory response syndrome

Uncommon Causes

Phosphate-containing enemas
Tumor lysis syndrome
Hypomagnesemia
Nutritional secondary hyperparathyroidism

Hypoalbuminemia

Hypoalbuminemia is a common cause of hypocalcemia which can occur secondary to protein-losing enteropathies, protein-losing nephropathies or liver disease. This hypocalcemia is not typically of clinical significance unless circulating ionized calcium concentrations are decreased, which can occur in dogs with a protein-losing enteropathy (see ch. 276).[32]

Impaired PTH Secretion

Naturally-occurring idiopathic primary hypoparathyroidism, rare in dogs and cats, can result in severe hypocalcemia.[33,34] Iatrogenic hypoparathyroidism may follow accidental damage or removal of parathyroid glands during cervical surgery, most commonly thyroid surgery in cats (see ch. 298).

Increased Calcium Loss

Eclampsia (lactation-induced hypocalcemia) occurs most commonly in young small dogs and is relatively rare in large dogs or in cats. Clinical signs are usually seen 2-5 weeks post-whelping, although it has been reported in a few dogs during late gestation and others >5 weeks post-whelp. Other potential causes include parathyroid gland atrophy and poor dietary supply of calcium.[35]

Vitamin D Deficiency

CKD in both dogs and cats may lead to mild decreases in ionized calcium concentrations but total calcium concentrations are typically within reference intervals (see ch. 324).[36] Reduced intestinal absorption of vitamin D in dogs and cats with protein-losing enteropathy or exocrine pancreatic insufficiency may lead to hypocalcemia.[32,37] Inadequate dietary vitamin D is a rare cause of hypocalcemia.

Precipitation or Chelation of Calcium

Ethylene glycol toxicosis results in calcium binding with oxalic acid in the renal tubules. This causes calcium oxalate crystalluria and increased renal loss of calcium. In acute kidney injury (AKI), rapidly rising phosphate complexes with calcium leading to hypocalcemia. Increased renal tubular loss of calcium exacerbates hypocalcemia. Urinary tract obstruction may cause mild-to-moderate hypocalcemia, likely due to increased binding of calcium with phosphate. Phosphate enemas have been reported to cause hypocalcemia in cats, again due to rapidly rising serum phosphate levels. In the acute tumor lysis syndrome, hypocalcemia may occur. In pancreatitis, hypocalcemia may result from sequestration of calcium in peripancreatic fat or soft tissues as a result of saponification (see ch. 289-291).[38] Hypocalcemia may follow citrated blood transfusion due to chelation of calcium.

Diagnostic Approach to Hypocalcemia

There are relatively few common causes for hypocalcemia. Findings on history, physical examination, hematology, biochemistry and urinalysis are often quite helpful or sufficient in establishing a diagnosis. Serum bile acids may be helpful in evaluating liver function and trypsin-like immunoreactivity and/or canine pancreatic lipase may be useful if pancreatic disease is suspected. Abdominal imaging may be helpful in evaluating anatomy of the gastrointestinal tract, liver, pancreas, and kidneys. A measurement of circulating parathyroid hormone concentration is required to definitively confirm primary hypoparathyroidism (see ch. 298).

Phosphorus

Overview

Phosphorus is essential for normal cellular function and is the body's major intracellular anion. The majority of total body phosphorus is found in bone. Although phosphorus is present in both organic and inorganic forms in the plasma, most clinical laboratories measure inorganic phosphate. Phosphorus absorption and excretion is regulated with calcium. PTH decreases phosphorus reabsorption in the kidney and $1,25(OH)_2D$ increases gastrointestinal absorption of phosphate.

Hyperphosphatemia

Hyperphosphatemia indicates the presence of an underlying disease and only rarely causes clinical signs by

itself unless associated with significant hypocalcemia. Hyperphosphatemia can occur due to increased intestinal phosphorus absorption, decreased phosphorus excretion via the kidneys into urine, or after a shift in phosphorus from the intracellular to extracellular compartment. CKD is the most common cause of hyperphosphatemia in dogs and cats (Box 69-3). Other causes of hyperphosphatemia include hypervitaminosis D, urinary tract obstruction, AKI, hypoparathyroidism and hyperthyroidism.

Box 69-3

Conditions Associated with Hyperphosphatemia

Common Causes

Young growing healthy animals
Hypervitaminosis D
AKI or CKD
Hypoparathyroidism

Uncommon Causes

Excessive dietary intake
Osteolytic bone lesions
Uroabdomen
Hyperthyroidism
Hyperadrenocorticism
Metabolic acidosis
Tumor cell lysis syndrome
Iatrogenic: e.g., phosphate-containing enemas, IV phosphorus administration
Lab error

Hypophosphatemia

Hypophosphatemia can occur due to decreased intestinal absorption, increased renal excretion or from transcellular shifts. Hypophosphatemia is commonly associated with excesses in circulating PTH or PTHrP, e.g., primary hyperparathyroidism and malignancy, respectively. Hypophosphatemia also occurs secondary to treatment of diabetic ketoacidosis (Box 69-4). Mild hypophosphatemia is not typically associated with clinical signs, although marked hypophosphatemia can be associated with hemolysis, respiratory distress and neurological abnormalities.

Box 69-4

Conditions Associated with Hypophosphatemia

Common Causes

Primary hyperparathyroidism
Malignancy-associated hypercalcemia
Diabetic ketoacidosis

Uncommon Causes

Vitamin D deficiency
Decreased dietary intake
Renal tubular disorders
Respiratory and metabolic acidosis
Iatrogenic: e.g., phosphate binders, parenteral glucose or sodium bicarbonate administration

CHAPTER 70

Lactate

Kari Santoro Beer

Introduction

Lactate is the end-product of anaerobic metabolism, although small amounts are also produced during normal aerobic glycolysis. An elevated plasma lactate level in the absence of a metabolic acidosis is termed hyperlactatemia; lactic acidosis is characterized by an elevated plasma lactate concentration in conjunction with a decrease in systemic blood pH.[1-3] Hyperlactatemia and lactic acidosis are common in states of hypoperfusion and hypoxia, and have also been reported in association with other conditions (sepsis, neoplasia, drugs/toxins, mitochondrial dysfunction, inborn errors of metabolism).[4-6] Clinically, measurement of serum lactate has demonstrated utility in assessing tissue perfusion and oxygenation, as a risk stratification tool, and for predicting outcome or response to therapy in critically ill human patients.[7] Recent studies suggest that lactate measurement may have similar applications in veterinary medicine.[8-11]

Lactate Physiology and Metabolism

A small amount of lactate is produced under normal aerobic conditions, in which glucose is converted to pyruvate in the cell cytoplasm. Most of this pyruvate diffuses into the mitochondria, where it is eventually converted to CO_2 and H_2O via the Krebs cycle. The following net reaction summarizes aerobic oxidation of glucose: Glucose + 6 O_2 + 36 ADP → 6 CO_2 + 36 ATP + 42 H_2O.[5] However, in cells that do not contain mitochondria, such as red blood cells, pyruvate is converted to lactate by the enzyme lactate dehydrogenase (LDH). This reaction allows NADH to be oxidized back to NAD^+ so that glycolysis can continue: CH_3COCOO^- (pyruvate) + NADH + H^+ ↔ $CH_3CHOHCOO^-$ (lactate) + NAD^+.[8] Normal daily lactate production in humans is around 1300-1800 mmol/day, with the arterial lactate concentration reflective of net production and clearance, generally 0.5-1 mmol/L.[3,12,13] In dogs, the current reference range is 0.3-2.5 mmol/L; in cats, 0.5-2.0 mmol/L.[14,15]

During anaerobic conditions, glycolysis is much less efficient and total energy production is significantly reduced compared to aerobic metabolism. Anaerobic glycolysis of 1 mole of glucose occurs as follows: Glucose + 2 ADP → 2 $lactate^-$ ions + 2 ATP + 2 H_2O.[5] As lactate is produced from pyruvate in hypoxic cells, it crosses the cell membrane and diffuses into the blood. The formation of lactate with free hydrogen is favored at physiologic pH, and while hydrogen ions are initially titrated by body buffers, acidemia eventually occurs as lactate accumulates.[3,4,8]

The liver and kidneys are responsible for the majority of lactate metabolism and clearance. Other tissues such as skeletal muscle remove the remainder.[5] While lactate is freely filtered at the glomerulus, it is almost completely resorbed in the proximal tubule. Elevated blood lactate levels will increase urinary excretion of lactate, but this accounts for only 10-12% of lactate clearance in the kidneys and the remainder is metabolized to glucose during gluconeogenesis.[8] Renal and liver dysfunction have been associated with varying levels of reduced clearance.[12]

While all tissues in the body produce some lactate, the greatest producers are skeletal muscle, brain, heart, skin, intestine and red blood cells.[4,6,16] In critically ill patients, lactate production also occurs in the splanchnic organs, in the lungs during acute lung injury, and from leukocyte activation during sepsis.[7]

Two forms of lactate exist: L-lactate and D-lactate. The most commonly measured, L-lactate, is the levorotatory isomer and is produced by cellular metabolism in healthy monogastric animals. D-lactate, the dextrorotatory isomer, is produced during bacterial glucose metabolism or from alternate metabolic

pathways in some cases of intoxications or certain diseases.[7] While D-lactic acidosis is uncommon in monogastric animals, it has been reported in a cat with exocrine pancreatic insufficiency,[15] and in cases of diabetes mellitus, propylene glycol intoxication, and intestinal bacterial overgrowth.[8,17,18] While commercial lactate analyzers only measure L-lactate, total plasma lactate (including D- and L-lactate) can be measured using gas chromatography and mass spectrometry. In patients with an acidosis and gastrointestinal disturbance but normal L-lactate, increased D-lactate should be investigated.[8,18]

Lactic Acidosis: Types and Causes

Lactic acidosis occurs when production of lactate exceeds utilization and clearance, and results in an elevated plasma lactate concentration with a decrease in arterial pH to less than 7.35.[2,8,16] There are two major types of lactic acidosis: type A and type B. Common causes of each type are described in Table 70-1.

TABLE 70-1

Causes of Lactic Acidosis in Veterinary Medicine[1,8]

TYPE OF LACTIC ACIDOSIS	MECHANISM	CAUSES
Type A	Tissue hypoxia or hypoperfusion	Decreased O_2 delivery Anemia (PCV <10%) or severe hypoxemia (PO_2 <30 mm Hg) Shock: cardiogenic, hypovolemic, septic Regional hypoperfusion Global hypoperfusion Carbon monoxide toxicosis Increased O_2 demand Exercise Seizures Uncontrolled shivering
Type B1	Decreased lactate clearance	Liver disease Diabetes mellitus Sepsis, SIRS Renal failure Hyperthyroidism Neoplasia Alkalosis
Type B2	Drugs or toxins that interfere with oxidative phosphorylation	Ethylene glycol Propylene glycol Catecholamines Carbon monoxide Bicarbonate Salicylates Acetaminophen Others: cyanide, strychnine, nitroprusside, halothane, terbutaline, activated charcoal
Type B3	Mitochondrial defects	Mitochondrial myopathies Inborn Acquired
D-lactic acidosis	Production of D-lactate from bacterial glucose metabolism or alternate metabolic pathways	Diabetes mellitus Small intestinal bacterial overgrowth Exocrine pancreatic insufficiency Propylene glycol toxicosis

PCV, Packed cell volume; *SIRS*, systemic inflammatory response syndrome.

Type A lactic acidosis is the most common and is caused by tissue hypoxia and increased lactate

production due to anaerobic glycolysis. Common causes of tissue hypoxia include hypoperfusion from hypovolemia or decreased cardiac output, severe anemia and decreased blood oxygen content, or decreased ability of the tissues to move oxygen from the capillaries as with severe edema.[19]

Type B lactic acidosis is less common and occurs when oxygen delivery is adequate but there is altered mitochondrial function or carbohydrate metabolism. There are three subtypes of B lactic acidosis: B1 includes diseases that cause decreased lactate clearance; B2 includes drugs or toxins that interfere with oxidative phosphorylation; and B3 includes mitochondrial defects.[8]

While type A lactic acidosis is often the most common cause of hyperlactatemia in critically ill patients, both types likely exist together in many patients. A number of factors may contribute to both type A and type B lactic acidosis, including tissue hypoperfusion, increased metabolism due to inflammation, decreased lactate clearance and decreased entry of pyruvate into the Krebs cycle, and impaired mitochondrial function.[1,7,8]

Lactate Measurement

As lactate's use as a monitoring tool has increased, new point-of-care analyzers with improved speed, accuracy and ease of use have been developed. These tools may be useful clinically as a recent human study demonstrated improved clinical outcomes for critically ill patients when a more rapid turnaround time for lactate results was possible.[20]

There are two methods used to measure lactate: enzymatic colorimetry and enzymatic amperometry. In blood chemistry analyzers, enzymatic colorimetry is used, which measures NADH production when L-lactate is oxidized by NAD+ when catalyzed by LDH. The NADH is detected by spectrometric absorption at 340 nm and is proportional to the amount of lactate in the sample. Enzymatic amperometry is commonly used in most blood gas analyzers and it measures lactate based on the amount of hydrogen peroxide produced by the reaction of L-lactate with a lactate oxidase-containing membrane; an electrical potential is applied and the hydrogen peroxide is oxidized, creating an electron current that is proportional to the lactate level in the sample.[21,22]

A number of factors can affect blood lactate measurements. While sampling site (venous versus arterial) does not seem to result in clinical differences,[8,14,23-25] other factors including recent exercise, stress, seizures, excitement, food intake and prolonged venous stasis during collection can all increase lactate concentrations by 2.5-10 mmol/L.[1,26] In neonatal puppies (less than 28 days old), venous lactate concentrations may be significantly higher than in adult dogs, with values normalizing to adult reference ranges by 70 days of age. Increased lactate in puppies is hypothesized to be secondary to ischemia-reperfusion injury during birth, higher baseline levels to prevent hypoglycemia, and decreased hepatic clearance.[27] In cats, stress at the time of sampling may increase lactate levels, with one study demonstrating a 10-fold increase in healthy cats that were stressed before sample collection.[28] However, a more recent study showed that struggling during sampling did not cause statistically significant differences in lactate concentrations in cats.[29]

Ethylene glycol and propylene glycol can both increase lactate measurements. Ethylene glycol causes a false increase in lactate when measured using enzymatic amperometry because a major metabolite of ethylene glycol, glycolate, is chemically similar to lactate.[30] Propylene glycol is metabolized to L-lactate and D-lactate, and elevated lactate concentrations have been reported in dogs given activated charcoal containing propylene glycol.[17,31] Lactated Ringer's solution (LRS) is a balanced electrolyte solution commonly used in veterinary patients, and it contains a racemic mixture of D- and L-lactate.[32] The L-lactate in LRS is metabolized to glucose or oxidized to water and CO_2, both of which result in the consumption of hydrogen ions and an overall alkalinizing effect. Administration of LRS does not typically cause an increase in lactate,[1,33-35] although small amounts of LRS in catheters at the time of sample collection can result in increases in measured lactate.[8,24]

Clinical Utility and Applications in Veterinary Medicine

Lactate monitoring is commonly used in human patients to guide treatment and for prognostication purposes, based on the idea that severity of lactic acidosis is correlated with severity of disease, extent of tissue hypoperfusion and overall decrease in oxygen delivery.[16,36] In human patients, as blood lactate concentrations increase, the probability of survival decreases,[37-42] and patients with a lactic acidosis have a

higher mortality rate and are at a greater risk of developing multiple organ failure.[43,44] Because even mild lactate elevations have been correlated with worse outcomes in human patients, especially those with sepsis or septic shock, any elevation should be a cause for concern; the accepted threshold in human guidelines for early goal-directed therapy and care bundles is traditionally 4 mmol/L.[12,45-47]

More recently in human medicine, the emphasis has been placed on monitoring serial lactate concentrations. Studies in human patients have consistently demonstrated that patients who clear elevated lactate levels have improved outcomes compared to those who do not clear their lactate, and slower lactate clearance is associated with worse outcomes.[41,43,48-52] In one multicenter trial of septic human patients, those with a lactate clearance of ≥10% decrease from their initial measurement had a 41% decrease in mortality compared to those with lesser clearance.[49]

In veterinary medicine, the majority of lactate studies have been limited to dogs. Overall, measurement of lactate concentrations using venous samples has demonstrated that lactate in veterinary patients, similar to human patients, can be used to identify hypoperfusion and assess response to therapy.[9-11,14,53-55]

Elevated lactate levels have been documented and correlated with disease severity and survival in critically ill and injured dogs, including those with gastric dilatation-volvulus, babesiosis, and immune-mediated hemolytic anemia.[9-11,53,56,57] A number of these studies and several others have also supported monitoring of lactate over the course of treatment, with lactate clearance being associated with improved outcomes.[53,57-59]

Analysis of lactate in body fluids other than blood also has demonstrated diagnostic utility in veterinary medicine.[54,55] In dogs and cats with septic peritonitis, comparing peritoneal fluid and peripheral blood lactate and glucose measurements can aid in diagnosis. A blood-to-fluid glucose difference of >20 mg/dL was found to be 100% sensitive and specific for the diagnosis of septic effusion in dogs and 86% sensitive and 100% specific in cats. Septic peritoneal fluid also had higher lactate concentrations than peripheral blood, with a fluid-to-blood lactate difference of >2 mmol/L suggestive of septic peritonitis.[54] Comparisons of lactate levels have also been made in dogs with pericardial effusion, and while dogs with confirmed neoplasia had significantly higher pericardial effusion lactate levels, the difference was not helpful clinically due to overlap between the groups.[55]

CHAPTER 71

Ammonia

Allison Bradley

Ammonia is produced in the gastrointestinal tract through bacterial degradation of nitrogenous compounds. It is carried up the portal circulation to hepatocytes, where the urea cycle detoxifies the ammonia, allowing for urea excretion by the kidneys. When this process cannot occur, either due to fulminant hepatic failure or, more commonly, due to portosystemic shunting (PSS), hyperammonemia results. Although many toxins have been implicated in the pathogenesis of hepatic encephalopathy (HE), ammonia is the only readily measured factor and is often regarded as one of the most important. However, not all patients with HE have hyperammonemia[1,2] and not all hyperammonemic patients exhibit overt HE.[1]

The most common indications for measuring ammonia are corroboration of suspicion of HE and to screen for PSS (Figure 71-1). Findings of different studies vary, but in general, resting ammonia is thought to be less sensitive than paired bile acids for identification of PSS.[3] Reported sensitivity of resting ammonia for detection of PSS is 62-100% compared to 79-100% for paired bile acids in dogs (80-100% for ammonia compared to 94-100% for bile acids in cats).[1,4-9] Ammonia measurement is, however, more specific for PSS than bile acids, because ammonia levels are not affected by cholestasis, which occurs to some extent in almost all hepatobiliary diseases.[10] Reported specificity of resting ammonia when screening for PSS is 86-89% (76% in the cat), whereas the specificity of bile acids in diagnosing PSS is 18-68% (71% in the cat).[4,8] Ammonia is less sensitive than bile acids for hepatobiliary disease not associated with PSS. Because the liver has a large reserve capacity for detoxifying ammonia, a majority of functional tissue must be lost before hyperammonemia results; therefore, ammonia measurement is an insensitive test for hepatic dysfunction.[10] Ammonia measurement may be useful in testing icteric animals (in which bile acids will be useless) for evidence of hepatic dysfunction or PSS and for confirming the benign bile acid elevations seen in some Maltese dogs and with portal vein hypoplasia.[11] Other causes of hyperammonemia are listed in Box 71-1.

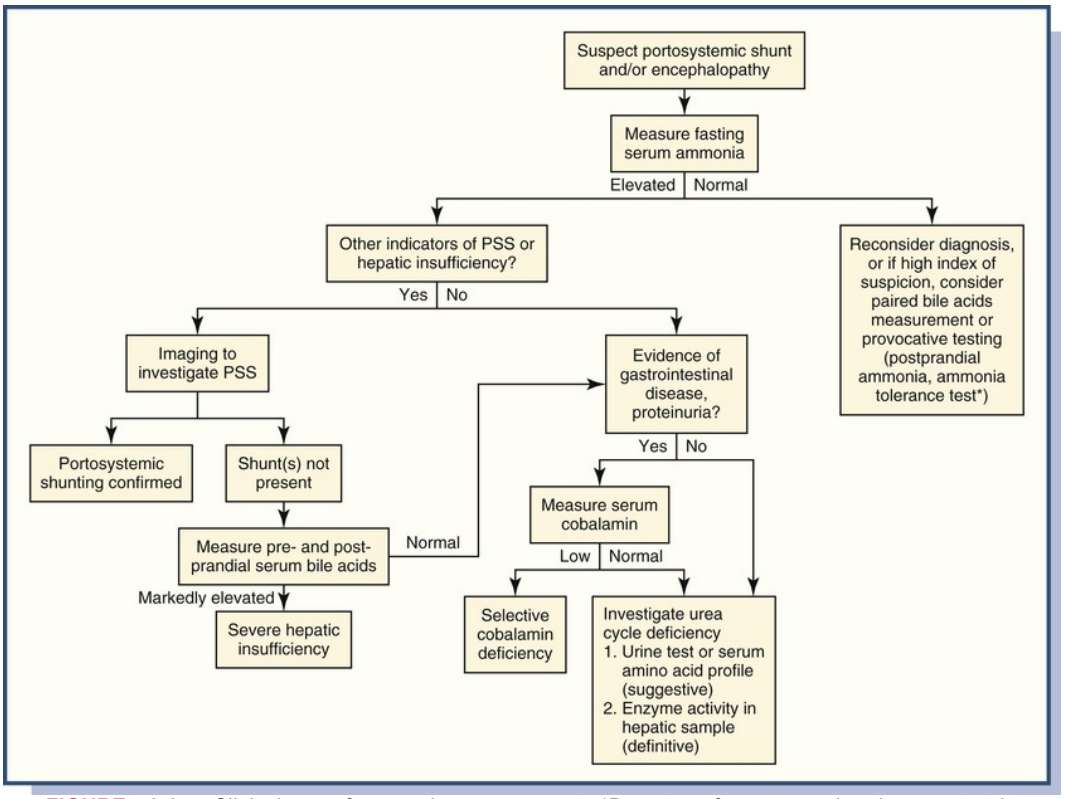

FIGURE 71-1 Clinical use of ammonia measurement. *Do not perform ammonia tolerance test in encephalopathic patients.

Box 71-1

Causes of Hyperammonemia

Portosystemic shunt—congenital or acquired
Fulminant hepatic failure
Urea cycle defect
- Transient and asymptomatic (e.g., Irish Wolfhound puppies)[12,13]
- Persistent enzyme deficiency[14,15]
- Selective cobalamin deficiency[16]
- Arginine deficiency (cats)[17]

Urinary tract obstruction especially in conjunction with urease-producing bacteria[18]
L-asparaginase therapy[19]

There is a variety of technical considerations for completing an ammonia measurement that limit its use in many settings. Although arterial blood contains higher concentrations of ammonia,[20] venous samples are more widely used. A 12-hour fast is typical prior to sample acquisition. The blood must be drawn into a tube containing anticoagulant (EDTA or heparin) and cooled immediately on ice (some authors advocate pre-chilling the tube as well). The blood must then be separated in a cooled centrifuge within 20-30 minutes. The assay should also be performed within 20-30 minutes. Sample storage and shipping is not advised.[21] Point-of-care analyzers available in some markets eliminate the need for complicated sample handling, but their quality is variable and only some yield accurate results.[22,23]

Pre-analytical and analytical errors reported to cause false positive results include: hemolysis, failure to adhere to rapid sample cooling and processing, ammonia or cigarette smoke in the air, and sweat or saliva contacting the sample tube stopper or reagent strips.[10] Patient factors reported to cause false positive results include: use of valproic acid, asparaginase, narcotics, and ammonium salts; hyperalimentation; a high protein

meal or gastrointestinal bleeding; strenuous exercise; hypokalemia; and alkalosis. Factors associated with false negative results include administration of antibiotics, probiotics, lactulose, enemas, and diphenhydramine.[3] Prolonged fasting has also been reported to result in false negative results.[24]

The sensitivity of the resting ammonia test can be improved by performing an ammonia tolerance test (ATT). Although this test is typically safe,[10] caution is advised, as it may result in vomiting (rectal administration of the ammonium chloride reduces this side effect[10]) as well as HE. An ATT should not be performed in a patient with HE or resting hyperammonemia. The details of performing an ATT have been described elsewhere.[1,3,10,25] Six-hour postprandial ammonia measurement has also been reported to increase the sensitivity of resting ammonia and may be safer[9] but less definitive than the ATT.[10]

CHAPTER 72

Urinalysis

Peter A. Graham

Overview and Indications

The urinalysis (UA), inexpensive and easily performed, is a minimum database component that often provides crucial information to assist with diagnosis and/or patient management. Urine is the combined result of glomerular filtration plus renal tubular resorption and secretion and its analysis can provide insight to both urinary and systemic conditions. Since UA results cannot be predicted, it is reasonable to suggest that it should be included in routine screening and in any disease investigation. The most obvious need for UA is dogs and cats with polyuria and polydipsia (PU/PD); urinary tract signs (dysuria, hematuria, stranguria, pollakiuria); a history of urinary tract disease, infection, acute kidney injury (AKI), chronic kidney disease (CKD), current or previous urolithiasis; or systemic illness. Fanconi syndrome, urinary tract cancer and specific non-urinary conditions such as diabetes mellitus, diabetes insipidus, hemolytic disease and hepatic dysfunction may be better understood after reviewing UA results. When used for screening asymptomatic dogs or cats, dilute urine, proteinuria or crystalluria can indicate the need for a change in management or further investigation. UA results may be helpful in monitoring and in early detection of side-effects to medications that may impair renal function or damage renal tissue. Interpreting UA results in the context of serum biochemistry (SB) and complete blood count (CBC) results enhances value of each.

Collection and Care of Urine Samples

Reliable UA results require that the sample be collected and handled appropriately. Collection method may alter UA results or interpretation. For example, urine collected from a table-top may contain micro-organisms or chemical cleaning agents while cystocentesis samples are free from environmental and lower urinary tract contaminants, but small numbers of red blood cells (RBCs) from the needle causing bleeding may be seen (see ch. 105).

Urine should be analyzed within 30-120 minutes of collection. Delay in analysis of room temperature urine may cause changes in pH, allow growth of contaminating bacteria, cause loss of cellular detail, or result in disintegration or deterioration of casts. Refrigeration may promote precipitation of crystals. For chemical analyses only, urine may be frozen. Both refrigerated and frozen urine samples must be rewarmed to room temperature before analysis. Samples shipped to an external laboratory should contain suitable preservative, particularly if culture is to be requested. Tubes containing boric acid assist in preserving most aspects of UA, but not pH or specific gravity (USG).

Urine samples must be gently mixed before a standardized volume (allowing semi-quantitative comparisons) is centrifuged in a conical tube for sediment examination. Urine test dipsticks can be employed before centrifugation. A relative centrifugation force (RCF) of 400-450 for 5 minutes is recommended. Sometimes, dipstick results should be repeated on the supernatant, as with visibly turbid or bloody samples. The elements of a standard UA (physical, chemical, and microscopic properties), dipstick results and reference values are important aspects of urinalyses (E-Box 72-1; E-Tables 72-1 and 72-2).

Other cells	Few transitional epithelial	Few transitional epithelial
Bacteria	None	None
Casts (/lpf)	<2 hyaline	<2 hyaline
Crystals	Variable but can include struvite and calcium oxalate (urate in Dalmatians)	Variable but can include struvite and calcium oxalate
Lipid	Uncommonly encountered	Commonly encountered

Physical Analysis

Visual Examination (Color, Turbidity, Odor)

Urine color is often related to hydration or renal status since it crudely correlates to concentration. In general, absence of color or pale urine is consistent with a dilute USG. Most concentrated samples are deep yellow or yellow-brown. Because bilirubinuria can appear as dark yellow urine, color should be interpreted in the context of USG and blood test results. The oxidation product of bilirubin, biliverdin, imparts a green color while hematuria, hemoglobinuria, myoglobinuria, and Oxyglobin cause urine to be red, pink, orange, dark brown or black. Urine pigments may interfere with dipstick test results (see ch. 47).

Urine transparency or turbidity should be reported semi-quantitatively. Turbidity can result from excessive white blood cells (WBCs), RBCs, epithelial cells, sperm, casts, mucus, crystals, bacteria, or lipid in urine. Lipiduria and pyuria occasionally appear milky, with lipid sometimes causing the surface of an unmixed sample to look cloudy. Turbidity may increase if analysis is delayed. Cooling and pH change can lead to crystal precipitation. Warming cooled samples may provide more accurate sediment examination. Fresh normal urine has a slight odor of ammonia, which increases with time or with some infections. An acetone smell is consistent with ketonuria.

Urine Specific Gravity (USG) and Osmolality

USG is the first and arguably most important test performed after initial visual inspection and is the only result that can provide information on renal function. Technically, USG is the ratio of urine weight to that of distilled water as estimated by its refractive index. The refractive index may be influenced by temperature and the number, type and size of solute molecules. Temperature effect is moderated in refractometers by mechanisms in the apparatus. Veterinary refractometers should have a separate scale for cat and dog urine, because their refractive indexes are distinct.[1]

Osmolality (see ch. 45 and 67) is the measurement of solute concentration independent of molecule type. USG and osmolality are closely related but osmolality, a more reliable indicator of renal concentrating ability, is recommended for estimating urine concentration in provocative tests.[2] One molecule of glucose and one molecule of albumin exert the same osmotic effects, but the higher weight of a protein results in greater effect on USG than does glucose. In the ratio of urine to plasma osmolality, >1 is consistent with renal concentrating and <1 renal diluting capability. If USG is above the refractometer's range, the sample may be diluted 50 : 50 with distilled water. This result can then be doubled, i.e., diluted 1.035 equals an undiluted result of 1.070. Dipstick USGs are not recommended.

No "reference range" exists for USG since healthy kidneys can produce extremely dilute or extremely concentrated urine ranging from 1.001 to >1.075. USG is influenced by hydration, electrolyte status, diet, and individual variation (E-Table 72-3).[3,4] Administration of fluids, glucocorticoids or diuretics lowers USG. Knowing hydration status, recent therapies, presence of protein or glucose in the urine, blood urea nitrogen and serum creatinine concentrations enhances the quality of any USG interpretation.

E-TABLE 72-3

Urine Specific Gravity Values

Typical values	1.015-1.050 Dog 1.035-1.060 Cat	Equivalent to 450 to 2000 mOsm (dogs), 1500 to 2000 mOsm (cats). These are estimated ranges only. Results can be affected by canned vs. dry diet, etc. Normal animals may have results outside these ranges.
Lowest to highest	1.001-1.070 Dog 1.001-1.080 Cat	Occasionally, higher USGs can be observed.
Isosthenuria	1.008-1.012	Approximately 300 mOsm. Urine and plasma osmolality are similar (urine is neither concentrated nor diluted). Normal animals may have a USG in this range but persistent findings in this range or if in combination with azotemia or dehydration indicate that failure of renal function is likely.
Hyposthenuria	<1.008	Urine is more dilute than plasma and therefore there must be renal tubular function. Central and nephrogenic diabetes insipidus are differentials as are conditions that interfere with the concentration of urine such as hypercalcemia, sepsis (e.g., pyometra, pyelonephritis), hepatic disorders, hypoadrenocorticism, hyperadrenocorticism and psychogenic polydipsia.
Evidence of adequate renal concentrating ability in azotemic or dehydrated animal	>1.040 Dog >1.045 Cat	Some authors suggest USG 1.030 for dog and 1.035 for cats; it would be prudent to consider USGs between these limits as questionable in terms of renal concentrating ability. When USG > 1.035 (dogs) or > 1.040 (cats) is present in combination with azotemia, the azotemia is classified as pre-renal.
Possible renal or extra-renal impairment of concentrating ability in azotemic or dehydrated animal	1.007-1.029 Dog 1.007-1.039 Cat	Primary renal failure is likely in azotemic patients but further investigation is warranted. When dehydration (or polyuria) is present in the absence of azotemia, extra-renal causes of polydipsia in addition to primary renal failure are possible differential diagnoses.

Chemical Analysis

pH

Urine pH usually reflects total body acid-base balance. It may be influenced by diet, time of day and disease (E-Table 72-4). High protein (e.g., meat) diets acidify while vegetable or cereal based diets alkalinize urine (see ch. 185). Urine obtained after a meal is often alkaline due to gastric acid secretion. Urine dipstick pH pads estimate to the nearest 0.5 or 1 unit, which is adequate for clinical use. A pH meter might provide more accurate results.[5,6] Results, regardless of instrument used, will be most accurate if performed on fresh urine. Struvite crystals form in alkaline urine while cystine and uric acid crystals tend to form in acid urine. The relatively uncommon urinary tract infections (UTI) due to urease producing bacteria (e.g., *Staphylococcus aureus*, *Proteus*) cause alkaline urine. The urine pH may indicate that other UA results may be unreliable (e.g., positive interference on protein test pad from alkaline urine). Interpretation of urine pH in the context of current blood gas, electrolyte and bicarbonate results assists in identifying renal tubular acidoses (see ch. 326).

E-TABLE 72-4

Causes of Acidic and Alkaline Urine pH

ACIDIC URINE	ALKALINE URINE
Meat based diet Protein catabolism Urinary acidifiers Acidosis (respiratory or metabolic)	Vegetable/Cereal diet Aged sample Alkalosis (respiratory or metabolic) Post-prandial

Paradoxical aciduria Metabolic alkalosis, hypochloremia, hypokalemia Loss of stomach acid (obstruction/severe vomiting)	Urease-positive urinary tract infection *(Staphylococcus, Proteus)* Urinary alkalinizers Renal tubular acidosis (relative alkalinuria in an acidotic animal)

Proteinuria (Figure 72-1)

Urine dipstick test pads assess protein content from their lowest detectable concentrations of 10-30 mg/dL ("trace") to their highest: 500 mg/dL − 2 g/dL ("+++"). There is higher sensitivity for albumin than globulin. Normal animals excrete negligible quantities of protein into urine and results must be placed in context of USG and pH. A "+" reading is unlikely to be significant if USG is high, but could be relevant if the USG is dilute. High pH or disinfectant contaminated urine may give false positive results whereas false negative results are seen with low pH or dilute urine. Quantitative protein analysis may be indicated to confirm dipstick proteinuria, if globulinuria is suspected, or with high pH. A ratio of urine protein to creatinine (UPC) is used to more accurately determine protein content. It is recommended to confirm all canine dipstick "++" and above results and all "+" results in samples <1.012 USG with UPC.[7] The sulphosalicylic acid (SSA) test is a semiquantitative alternative to UPC.

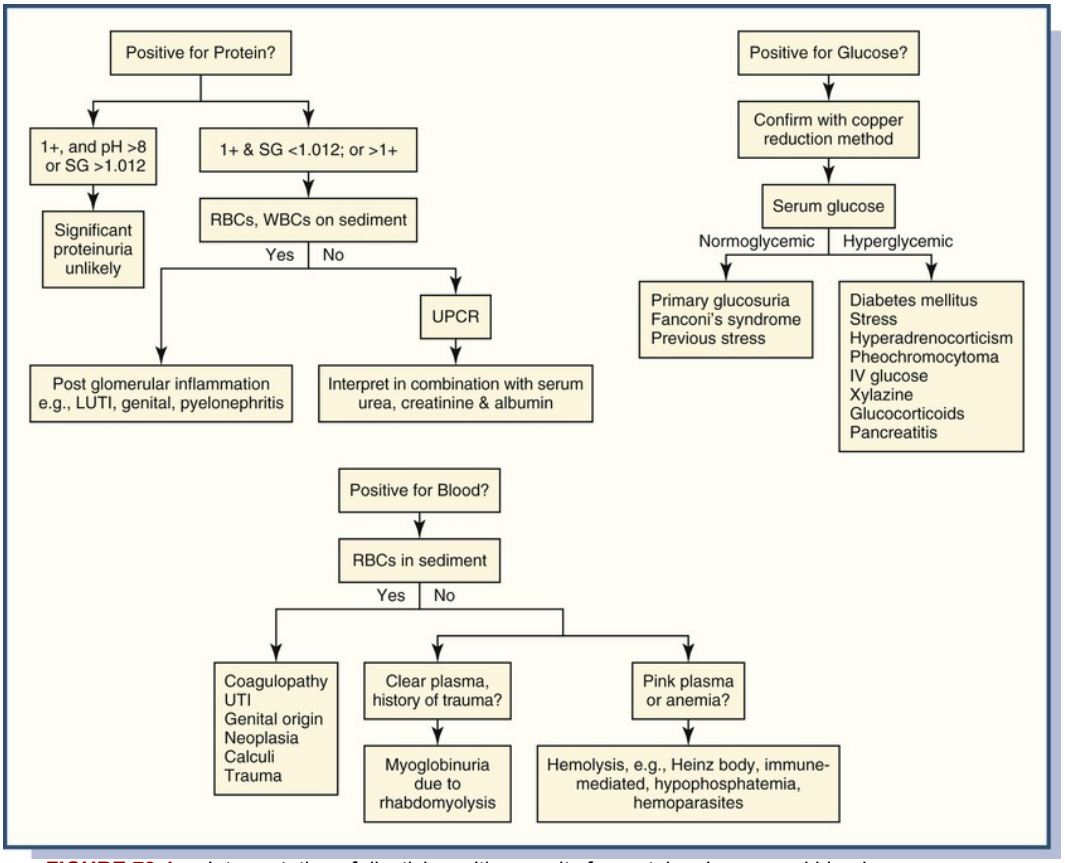

FIGURE 72-1 Interpretation of dipstick positive results for protein, glucose and blood.

Proteinuria is usually categorized as pre-renal/overflow, renal (glomerular or tubular), or post-renal. Interpretation of proteinuria should be made in the context of the sediment examination. Presence of RBCs and WBCs is indicative of renal or post-renal issues. Absence of RBCs or WBCs indicates a renal origin for proteinuria (glomerulonephritis, amyloidosis). Pathological pre-renal causes of proteinuria include hemolysis (hemoglobin), rhabdomyolysis (myoglobin) or plasma cell cancers (immunoglobulins). Functional pre-renal origins include strenuous exercise, fever and seizures.

Renal proteinuria may be functional and transient (e.g., inflammation) or persistent and pathological. Glomerular proteinuria is associated with loss of albumin, whose severity may cause hypoalbuminemia. Damaged or diseased renal tubules, whether due to congenital defects or an acquired AKI (e.g., Fanconi's

syndrome, gentamicin toxicosis), can interfere with resorption of filtered low molecular weight proteins and albumin (see ch. 60, 322, and 324-328).

Post-renal proteinuria can be associated with pathologic processes affecting the urinary tract from renal pelvis to urethra and the extra-urinary genital tract. Conditions include infection, inflammation, neoplasia or urolithiasis. Obtaining urine by cystocentesis avoids contamination by more distal areas. Quantitative analysis from post-centrifugation supernatant limits protein contribution from sediment. Presence of hematuria or pyuria does not necessarily interfere with usefulness of UPC, and proteinuria may not be detected in some pets with significant pyuria and bacteriuria.[8-10]

Glucose and Ketones (see Figure 72-1)

Glucose

Glucose passes through the glomerulus and is actively reabsorbed in proximal tubules. When capacity for reabsorption is exceeded (blood glucose concentrations >170-180 mg/dL in dogs and >260-310 mg/dL in cats) glucose appears in urine (see ch. 304 and 305). While glucosuria is usually due to hyperglycemia (diabetes mellitus, stress hyperglycemia, medication), normoglycemic glucosuria can occur (e.g., primary renal glucosuria, Fanconi syndrome; E-Table 72-5).

E-TABLE 72-5

Glucosuria

HYPERGLYCEMIC GLUCOSURIA	NORMOGLYCEMIC GLUCOSURIA
Diabetes mellitus Secondary diabetes mellitus Hyperadrenocorticism Pheochromocytoma Stress Excitement Exercise Certain conditions Intravenous fluids containing glucose Therapeutics Glucocorticoids Alpha$_2$ agonists	Renal tubular injury Nephrotoxic medications Severe renal hypoxia/hypovolemia Congenital Primary renal glucosuria Fanconi syndrome
FALSE POSITIVE GLUCOSURIA	**FALSE NEGATIVE GLUCOSURIA**
Oxidizing agents (dipstick) Peroxide/hypochlorite/bleach (e.g., floor/table samples) Non-glucose reducing sugars (Clinitest) Ascorbic acid (Clinitest) Minor/uncommon Formaldehyde (Clinitest) Medications (Clinitest) Salicylates, cephalosporins, nalidixic acid, penicillin, sulfonamides	Cold sample (dipstick) Marked bilirubinuria (dipstick) Marked ketonuria (dipstick) Formaldehyde (dipstick) Ascorbic acid (dipstick)

Urine dipsticks reliably measure glucose, provided the manufacturer's instructions are followed. Allow cooled urine to reach room temperature before testing and read the glucose result at the appropriate time after urine exposure. Dipstick technology is based on glucose oxidase; an alternative copper reduction test (Clinitest tablets) is useful if dipstick results need confirmation. Factors which can cause false results are listed in E-Table 72-5. Depending on manufacturer, urine glucose dipstick and tablet tests report in %, mg/dL or mmol/L: 1000 mg/dL (55 mmol/L; 1%), 500 mg/dL (28 mmol/L; 0.5 or 1/2%), 100 mg/dL (5.5 mmol/L; 0.1 or 1/10%). USG increases by 0.001 for each 270 mg/dL (15 mmol/L) of glucose.

Ketones

Ketones (acetone, acetoacetate and beta-hydroxybutyrate) accumulate when there is a shift from carbohydrate to fat metabolism, as occurs with untreated insulin-dependent diabetes mellitus (see ch. 142); they appear in urine when the renal threshold is exceeded. Dipstick test pads utilize nitroprusside, detecting acetone and acetoacetate but not beta-hydroxybutyrate. As diabetes is treated beta-hydroxybutyrate synthesis is reduced,

but its conversion to acetoacetate can result in the continuing presence or increasing concentration of measured urine ketones, which can create a false impression of continuing or worsening illness. False positives are not common but could occur with darkly pigmented urine, use of captopril or cysteine. Delay in analysis or in appropriate refrigerated storage may cause false negatives as acetone is volatile. UTI bacteria could degrade acetoacetate. Ketonuria is extremely rare in starvation, anorexia, vomiting, or low carbohydrate intake. It is also rare in lactating females and after extreme exercise.

Bilirubin

Bilirubin is a normal product of RBC turnover as heme is broken down within macrophages of the spleen and liver. Only conjugated ("direct") bilirubin is water soluble and therefore able to enter glomerular filtrate. Unconjugated ("indirect") bilirubin is protein bound and is not filtered. Urine dipstick pads for bilirubin are based on diazonium; a more sensitive confirmatory tablet test is available (Ictotest). Conjugated bilirubin is light- and (room) temperature-sensitive. Concentrations decrease when less soluble free bilirubin is liberated or bilirubin is converted to biliverdin. Dipstick tests for bilirubin should be performed on uncentrifuged urine, because bilirubin can adsorb to calcium precipitates. Test sensitivity is reduced if ascorbic acid is present. Chlorpromazine can cause false positives.

Bilirubinuria with hyperbilirubinemia is expected with RBC destruction (hemolysis), intrahepatic disease, cholestasis and biliary obstruction (see ch. 53). In dogs, since the renal threshold for bilirubin is low it may be detected in urine before hyperbilirubinemia is obvious. Canine kidneys synthesize bilirubin; thus, not all is derived from the blood. Low but detectable bilirubin concentrations may be found in concentrated samples from healthy male dogs. Bilirubinuria in cats is significant.

Blood (Hematuria, Hemoglobinuria, Myoglobinuria) (see Figure 72-1)

Dipstick methodology is based on the pseudoperoxide activity of heme reacting with organic peroxide. Detection of hematuria, hemoglobinuria or myoglobinuria occurs at levels not visually apparent; test pad sensitivity is 5-20 RBCs/mcL compared with 2,500 RBCs/mcL for visual recognition. Test strips detect intact RBCs (hematuria), hemoglobinuria and myoglobinuria. When RBCs exist without free hemoglobin, color changes on the pad are blotchy. Intact RBCs must be suspended for detection and unmixed urine can be falsely negative. False positives may occur in urine contaminated with cleaning agents (hypochlorite, bleach, peroxide). Dipstick assessment of blood must be made in the context of USG, sediment, the appearance of serum, and muscle enzyme concentrations. Hematuria is common, while hemoglobinuria is less common and myoglobinuria rare.

Hematuria may be present due to bleeding within the urinary tract due to trauma (cystocentesis), uroliths, inflammation, infection, neoplasia, or a coagulopathy (see ch. 47). Confirmation by sediment examination is recommended. Extraurinary (genital) sources of bleeding are possible. Hemoglobin may be present in urine either as a result of hemoglobinemia (intravascular hemolysis) or RBCs that have lysed in dilute or alkaline urine. Hemoglobin appears in urine when haptoglobin binding capacity in plasma is exceeded and renal tubular resorption mechanisms are overwhelmed. Myoglobinuria can occur if there is muscle trauma, ischemia or necrosis (see ch. 354).

Centrifugation of urine and comparison of uncentrifuged and supernatant can assist in confirming presence of intact RBCs to explain a positive result. Hemoglobinuria due to intravascular hemolysis is expected to result in pink-tinged plasma, whereas plasma would be clear with myoglobinuria. Peripheral blood smear evidence of parasites, spherocytes, ghost cells or Heinz bodies would support intravascular hemolysis as the origin of hemoglobinuria. When urine is discolored due to myoglobin, it may be described as red/brown rather than pink/red. Elevations in serum creatine kinase and/or aspartate aminotransferase activity would be expected with myoglobinuria (see ch. 65 and 66). Hemoglobinuria without icterus suggests acute hemolytic disease but when combined with hyperbilirubinemia is suggestive of chronic hemolysis. Discordant results in comparing dipstick results and sediment examination occur for several reasons (E-Table 72-6).

E-TABLE 72-6

Discordant Dipstick and Sediment Examination Results for Hematuria

POSITIVE TEST PAD & NEGATIVE SEDIMENT EXAMINATION	NEGATIVE TEST PAD & POSITIVE SEDIMENT EXAMINATION

Hemoglobinuria Myoglobinuria Lysis of hematuria cells by hyposthenuric or dilute urine Incorrect identification of red cells on sediment exam (e.g., bubbles) False positive test pad reaction (e.g., bleach)	Sample not mixed for dipstick test Low number of red cells that fail to lyse on surface of test pad Incorrect identification of, e.g., bubbles as red cells on sediment exam Inappropriately stored reagents False negative test pad reaction (e.g., formalin contamination)

Leukocytes (WBCs)

The leukocyte test pad is neither sensitive nor specific for WBCs in feline urine. Dipstick results on canine urine are specific but insensitive. Positive results have correlated well with canine bacteriuria (positive urine culture).[11]

Microscopic Sediment Examination

Overview

Urine sediment should be examined for RBCs, WBCs, epithelial cells, casts, crystals and organisms, each of which can settle to the bottom of a tube and be missed unless the sample is mixed before analysis. Sediment examination has added importance if macroscopic abnormalities are observed, but elements tend to deteriorate if UA is delayed.[12,13] Prompt evaluation is ideal (E-Table 72-7). Sediment assessment requires technical competence, appropriate instruments and standardized protocols (specific volume to be centrifuged, etc.) to provide consistent, reliable information.[11,14] Protocols vary between laboratories, and each should establish independent reference intervals. Consistently submitting 5 mL of urine is a compromise between providing sufficient volumes to identify elements in urine versus the practicalities of collecting urine from small animals. If 5 mL cannot be obtained, accurately recording the volume centrifuged and the re-suspended volume along with the microscope field number (low power [lpf] or high power [hpf]) and the volume under the coverslip will allow calculation of estimated sediment element concentration per mL (E-Box 72-2). Increasing centrifuged volumes with smaller resuspension volumes improves technique sensitivity. Casts are generally reported per lpf (although also viewed at high power for accurate identification) and cellular elements per hpf. Sediment stains can help identify some items but can dilute and alter semi-quantitative counts. One can place a drop of unstained and one of stained sediment on one slide for comparison.

E-TABLE 72-7

Factors Affecting Quality of Urine Sediment Examination

FACTOR	CONSEQUENCE
Inadequate sample mixing prior to transfer to centrifuge tube	Missed sediment elements
Volume of urine centrifuged not standardized	Variable quantitative results and difficulty in interpretation
Inadequate volume of urine examined	Missed sediment elements
Delay in analysis	Deterioration and loss of sediment elements. Refrigeration will assist in preservation but samples should be warmed prior to analysis—refrigeration will promote amorphous crystal formation
Volume of sediment examined	High volumes allow heavier elements (casts) to escape the edges of the coverslip
Centrifugation	Inconsistent speed/duration leads to inconsistent results Centrifuge braking disturbs the sediment
Voided sample	Higher numbers of red and white cells in normal samples
Urine concentration	Hyposthenuric urine will lyse cells Moderate numbers of cells/hpf in relatively dilute urine may be more significant than the same number in concentrated urine High concentration may result in crenated appearance to cells

pH	Highly alkaline urine will lyse cells and casts

E-Box 72-2

Example Standard Protocol for Urinalysis

1. Allow refrigerated sample to warm to room temperature.
2. Mix the sample well.
3. Transfer 5 mL well-mixed urine to a clean conical centrifuge tube. Record volume transferred.
4. Centrifuge for 5 minutes at 400 × g.
5. Decant supernatant leaving approx 0.5 mL urine and sediment.
6. Resuspend the sediment gently (flick the base of the tube with a finger).
7. Transfer a drop of the suspension by pipette onto a glass slide and place a coverslip gently over.
8. Adjust microscope for unstained examination.
9. Review at low magnification (×10 objective) for large elements (casts, crystals, parasites), count elements and report per low-power field (lpf).
10. Examine using ×40 objective to count red, white and epithelial cells, smaller crystals, count elements and report per high-power field (hpf) as average over at least 10 fields of view.
11. If desired, estimate concentrations as elements per mL by multiplying by "field conversion factor" specific to the microscope and the standardized slide/coverslip or commercial slide system being used.

Field Conversion Factor

1. Determine field of view (FOV = diameter of field in mm) for each of lpf and hpf
   a. Divide eyepiece field number by objective magnification (check microscope specifications), e.g., 20/40 = 0.5 mm
2. Determine $\text{"area of view"} = \pi\left[\frac{\text{FOV}}{2}\right]^2$,

e.g., $3.14 \times 0.25^2 = 0.196\ \text{mm}^2$

3. Calculate number of views per area possible by dividing area of coverslip or commercial urinalysis slide system by "area of view."
   a. E.g., 22 × 22 mm coverslip area possible = 484 mm^2; Kova System 32 mm^2
   b. E.g., 32 mm^2/0.196 mm^2 = 163 possible fields of view; 484 mm^2/0.196 mm^2 = 2470
4. Calculate "concentration factor" = volume urine centrifuged/volume of resuspended sediment examined;

e.g., 5 mL/0.5 mL = 10

5. Determine volume of urine sediment examined
   a. E.g., 22 mm × 22 mm coverslip holds approximately 0.02 mL sediment, Kova System holds 0.006 mL sediment
6. Calculate field conversion factor
   a. $$\frac{\text{Number of possible fields of view}}{\text{Volume of sediment examined} \times \text{concentration factor}}$$
   b. E.g., $$\frac{2470\ \text{possible fields of view}}{0.02\ \text{mL} \times 10} = \text{approx } 12{,}350\ \text{hpf/mL}$$
7. Using field conversion factor convert "per field" result into "per mL" by multiplication
   a. E.g., 4 RBCs/hpf × 12,350 hpf/mL = approx 49,400 RBCs/mL
   b. Field conversion factor need only be calculated once for each microscope/slide-system combination.

Hematuria (see Figure 72-1)

Small numbers of RBCs are commonly seen in the urine of normal dogs and cats. The fewest RBCs are seen in free catch samples. Cystocentesis samples from healthy dogs and cats often have fewer RBCs than samples obtained via catheterization. Manual expression of the bladder can be traumatic and a source of RBCs. One should assess dipstick results in the context of sediment analysis and USG. On sediment examination, unstained RBCs appear as pale yellow anucleate biconcave discs. RBCs may be shrunken and crenated in concentrated urine or swollen and lysed (therefore absent) in dilute or alkaline urine. RBCs can be distinguished from other round elements, yeast or lipid droplets, by their uniform size. Lipid droplets tend to float to the sample surface and remain at a different focal plane. Hematuria may be grossly visible or only seen microscopically. There are numerous causes for RBCs (see ch. 47).

Pyuria

Small numbers of WBCs are common in urine from healthy dogs and cats, with a ratio to RBCs of about 1 : 1. Neutrophils are the most common WBC, recognized by their size (1.5 − 2 × RBC), granular cytoplasm and distinctive lobed nuclei. Their morphology may vary depending on pH and USG, making it difficult at times to distinguish neutrophils from lymphocytes, monocytes or tubular epithelial cells. WBCs shrink in concentrated and swell or lyse in dilute or alkaline urine. Nuclear characteristics may be enhanced with sediment stains or by clearing with 2-10% glacial acetic acid. Numbers of WBCs/hpf may be slightly higher in normal samples obtained via catheterization or voiding as compared with cystocentesis.

Large numbers of WBCs are consistent with inflammation (infectious or non-infectious) and often accompanied by some degree of hematuria and/or proteinuria. Finding numerous bacteria with WBCs is consistent with active infection. Failure to see bacteria does not exclude infection, hence the recommendation to culture pyuric urine. Non-infectious causes of pyuria include neoplasias and uroliths. Recent antibiotic therapy can be expected to eliminate bacteria from sediment and result in a negative urine culture. Bacteria may be observed without WBCs in immunocompromised pets or as contaminants in inappropriately stored or transported samples.

Epithelial Cells

Renal Tubular Cells

Round with a round central nucleus and granular cytoplasm. Their size is from the same as to 4 times larger than WBCs. Unless embedded in casts, these cells can be difficult to identify. Columnar cells with a brush border originate in proximal tubules.

Transitional Epithelial Cells

Line the urinary tract from the renal pelvis to the urethra, have granular cytoplasm, and are present singly or in clumps. They are usually equal to or larger than WBCs, larger than renal tubular cells and smaller than squamous epithelial cells. They may be round, oval, caudate, spindle, or polyhedral. Large numbers are indicative of inflammation, although mechanical abrasions, neoplasia and other causes may be suspected.

Squamous Epithelial Cells

Common in low numbers in voided urine or that collected by catheterization. They are urethral or vaginal in origin, large, flat, thin polygonal cells with either no nucleus or a small dense eccentric nucleus. They may be present as individual cells or as sheets. Rolled up squamous epithelial cells should be carefully differentiated from casts.

Neoplastic Cells

It may be difficult to differentiate clumps of hyperplastic transitional epithelial cells from carcinoma. Cytological examination of stained fixed smears may help identify criteria of malignancy (see ch. 351). Catheterization, bladder lavage and urine cytospin may aid in harvesting neoplastic cells for cytological examination. However, histological examination of tissue biopsy is required to confirm neoplasia.

Bacteria

Both cocci and bacilli are observed in urine sediment; cocci in chains are relatively easy to identify. While normal urine is sterile, samples may contain bacteria from the distal urethra or genital tract in voided or

catheter samples. Small numbers of bacteria from the urethra or genital areas, in fresh catheterized or voided samples, are common. Delay in analysis or lack of preservative may result in a significant proliferation. Therefore, when large numbers of bacteria are seen without WBCs, contamination should be suspected. False positive results may occur if debris, lipid droplets or small amorphous crystals are misidentified as bacteria or if stain is contaminated.[15,16] Identification of bacteria in urine sediment may or may not be significant and failure to identify bacteria does not rule out their presence. Large bacterial numbers in cystocentesis, fresh or preserved catheterized samples are suggestive of UTI, particularly when accompanied by pyuria. Urine culture is indicated to confirm UTI. Bacteria seen on sediment but without growth on culture occurs with contaminated unpreserved stored urine, bacteria rendered non-viable by preservation method or recent antibiotic therapy.

Cylindruria (Casts)

Overview

Material concentrated in a tubule can be excreted in that shape, i.e., appearing as little tubes, called "casts" (cylinders). Casts are usually composed of cells and mucoprotein (Tamm-Horsfall) derived from the loop of Henle, distal tubules and collecting ducts. Casts from any of these areas are cylindrical, have parallel sides with rounded, square, irregular or tapered ends. Their width depends on the diameter of the tube in which they were formed; wider casts are usually formed in collecting ducts or dilated tubules. Any material trapped in mucoprotein, such as cells, and excreted within a cast and identified is the basis of cast classification. Time within a tubule may allow degeneration of trapped material, changing its structure and classification. Low numbers of hyaline or granular casts may be observed in healthy urine but not cellular casts (epithelial, WBCs).

Hyaline Casts

Hyaline casts are almost entirely composed of Tamm-Horsfall mucoprotein, colorless, homogenous, nearly transparent when unstained, and with rounded ends. Staining may help their identification. They are associated with renal or physiologic proteinuria. Small numbers of hyaline casts (e.g., up to 2/lpf) can be observed in normal moderately concentrated urine.

Epithelial Cell, Granular, Fatty, and Waxy Casts

Epithelial cell, fatty, granular and waxy casts may represent different stages of one process, the degradation of renal tubular epithelial cells within the cast. Epithelial cell casts contain tubular epithelial cells detached from their basement membrane. Their appearance is similar to that of free tubular epithelial cells. Since it is difficult to classify degenerated cells, reports may vaguely state "cellular casts." Casts containing granular material may contain cell degradation products rather than cells. This appearance may indicate duration rather than severity of tubular lesions. Epithelial cell casts indicate significant renal tubular injury/necrosis due to ischemia, inflammation or toxins.

Some casts are reported as "granular," because of their opaque granular content, and further categorized by granule size: coarse to fine. Granule size likely represents stages in cell degeneration and is not of significance. Necrotic debris of renal tubular epithelium origin may also be present. Low numbers of granular casts (e.g., 1 or 2/lpf) are occasionally seen in urine from healthy animals. Fatty casts, whose origin and importance are the same as other granular casts, contain refractive lipid droplets derived from degenerating cell cytoplasm. Waxy casts are colorless, homogenous, extremely refractive, look "waxy" with brittle jagged or sharply broken ends, may appear quite twisted, and are relatively stable in dilute or alkaline urine. Waxy casts are granular casts at an end stage of degeneration. Their presence suggests an extended period within tubules and prior tubular injury and/or urinary stasis. They are often seen in pets with CKD.

White Blood Cell Casts

WBC casts, composed of Tamm-Horsfall mucoprotein and WBCs, are indicative of tubular and interstitial inflammation. Since it is sometimes difficult to discriminate WBC from epithelial cell casts, they may simply be reported as "cellular casts." Staining may help identify neutrophil nuclei and one should distinguish WBC casts, most likely of renal origin, from mucus strands containing strings of free urinary WBCs, most likely from the lower urinary tract. After degeneration, WBC casts become granular. Tubular inflammation can exist without WBC casts. A mixture of WBC and epithelial cell casts may be observed following acute tubular necrosis.

Red Blood Cell Casts

RBC casts are rare, red-orange-yellow in color, and fragile. Their presence localizes bleeding to nephrons. When urine samples are bloody, RBC casts must be distinguished from clumped RBCs by visualization of the mucoprotein structure.

Broad Casts

Broad casts are much wider than other casts, but represent any of the described casts. Their wide diameter suggests formation during urinary stasis within collecting ducts or dilated tubules. They are often waxy. While broad casts imply a severe disorder, they may also imply recovery as urine begins to flow again following oliguria.

Pigmented Casts

Casts may be pigmented with golden-brown hemoglobin as RBC casts degenerate. The pigment may be yellow or golden brown bilirubin in pets with bilirubinuria.

Bacterial Casts

Bacterial casts are uncommon and challenging to distinguish from the more common granular casts. Cytological or Gram stain may help demonstrate bacteria-filled casts. Their presence would be consistent with severe tubular bacterial infection.

Crystalluria

Overview

Struvite, amorphous phosphate and oxalate crystals are commonly seen in urine of healthy animals. Urate, cysteine, or large quantities of calcium oxalate crystals are usually abnormal (see ch. 331 and 332). Some crystals are indicative of significant disease or a metabolic disorder and others may provide preliminary information concerning the structure of uroliths, if present. Crystals form in supersaturated urine. Factors that influence the detection of crystals in urine include USG, temperature, time to analysis, pH and diet.[17] Refrigeration promotes crystal formation and is not indicative of *in vivo* crystalluria. Urine samples for sediment examination should be rewarmed before analysis. The pH of urine is important because some crystals require a certain pH to form. Indeed, *in vitro* alteration of pH can make detection of certain crystals easier and may assist in identification of unusual crystals as will the medication history since some result from precipitation of drugs or their metabolites. Most common companion animal urinary crystals are easily recognized by shape, size, color and sample pH (E-Table 72-8).

E-TABLE 72-8

Characteristics of Urinary Crystals

TYPICAL PH RANGE	CRYSTAL	SHAPE	COLOR	INVESTIGATIONAL CHARACTERISTICS
<5-7	Uric acid	Variable including diamond or rhombic plates ± concentric rings, oval with pointed ends, occasional cystine-like hexagons	Yellow, yellow-brown	Dissolves in alkali
≤7	Amorphous urates (Na, K, Ca, Mg)	Amorphous, granular. Monosodium urate: slim pencil-like prism in small clusters	Yellow, yellow-brown	Dissolves in alkali and at 60° C. Convert to urate with acid.
	Bilirubin	Granules or needles, clustered or branching like twigs, granules	Amber to red-brown	
	Cholesterol	Large flat rectangular ± stacked plates with a notched corner	Colorless	Dissolves in organic solvent
	Leucine	Spheres with concentric circles/striations	Dark yellow/brown	Dissolves in alkali

	Tyrosine	Needle-like in sheaves or clusters. Similar to bilirubin crystals.	Colorless or yellow	Dissolves in alkali
	Radiographic contrast	Depending on agent used, flat cholesterol-like or needle sulfa-like	Colorless	Associated with high USG
	Ampicillin	Long thin needles or prisms. May form wheat-sheaf pattern like "sulfa" crystals.	Colorless	Lignin test negative
	Sulfonamide	Waisted "wheat-sheaves" or fans of fine needle-like crystal. Striated spheres.	Yellow-brown	Lignin test positive (equal drops of urine and dilute hydrochloric acid on newspaper—bright yellow-orange color is positive)
5-8	Calcium oxalate	Dihydrate (weddellite): 3-dimensional octahedral, dipyrimidal, "envelope" forms, squares with diagonal lines from corners. Monohydrate (whewellite): ovoid, dumbbell, "picket fence"/"stake" and "hemp seed" shapes (dumbbells are not likely to be calcium carbonate in canine and feline urine).	Colorless	Dissolves in dilute HCl
	Cystine	Thin hexagonal plates, layered, clumped or individual	Colorless	Enhance detection by acidifying and refrigeration of alkaline samples. Dissolves in alkali.
6-8	Calcium phosphate	Long, thin prisms often one tapered end, clumped into rosettes or as needles	Colorless	Dissolves in dilute acid
≥7	Amorphous calcium phosphate	Amorphous granular form similar to amorphous urates and xanthine	Colorless	Dissolves in acid (e.g., acetic). Insoluble at 60° C.
	Struvite	Orthorhombic, "coffin-like" prisms, plates with 3 to 6 sides and oblique ends	Colorless	Dissolves in acetic acid
	Ammonium biurate	May also be observed in neutral and slightly acidic urine. Spheres with irregular protrusions "thorny-apple."	Brown, yellow-brown	Dissolves in acetic acid and at 60° C. Convert to urate with concentrated acetic or acetic acid.

Bilirubin Crystals

Bilirubin crystals can be normal in concentrated urine and found in large numbers with significant bilirubinuria.

Calcium Oxalate Crystals

Calcium oxalate crystals are seen as either dihydrate or monohydrate. Dihydrate crystals may be seen in urine from healthy dogs, healthy cats, and pets with calcium oxalate uroliths. Monohydrate crystals form with hypercalciuria or hyperoxaluria (ethylene glycol intoxication, oxalate rich foods).[18]

Calcium Phosphate Crystals

Calcium phosphate crystals can be amorphous or needle-like. Amorphous calcium phosphate can be distinguished from similar-appearing amorphous urates or xanthine by pH, solubility in acid or alkali and susceptibility to heat. Calcium phosphate crystals are commonly seen, sometimes in large numbers, in urine from healthy pets. They may also be present in conjunction with calcium oxalate/calcium phosphate or struvite uroliths.

Cholesterol Crystals

Cholesterol crystals are non-specific, occasionally observed in healthy dogs, and likely originate from degenerating cell membranes. An association has been made with proteinuria and hypercholesterolemia (e.g., nephrotic syndrome).

Cystinuria

Cystinuria is an inherited defect reported in Scottish Deerhound, Newfoundland, English Bulldog, Chihuahua, Dachshund, Mastiff, Bullmastiff, American Staffordshire Terrier and mixed breeds. Dogs with cystine urolithiasis are far less common than dogs with crystals. Crystals resembling cystine may occasionally be formed by struvite or uric acid (see ch. 331).

Drugs

Drugs that are associated with crystal formation include sulfonamides, ampicillin and radiocontrast agents. Other drugs might initiate crystal formation.

Magnesium Ammonium Phosphate (Struvite) Crystals

Magnesium ammonium phosphate (struvite) crystals are common in healthy dogs and cats. They are also seen in pets with struvite urolithiasis, other uroliths and non-urolith urinary tract disease. UTI with urease-producing bacteria may provide a source of ammonia (see ch. 331 and 332).

Tyrosine Crystals

Tyrosine crystals are rarely seen in people with liver disease or aminoaciduria. They are rarely observed in canine and feline urine.

Urate Crystals

Urate crystals may be observed as amorphous urates or as biurate. Amorphous forms may be present in normal canine and feline urine. Biurate crystals may be seen in normal Dalmatians and English Bulldogs. They are also seen in hepatic failure, portosystemic shunting (hyperammonemia), and with ammonium urate uroliths.

Uric Acid Crystals

Uric acid crystals are seen under the same circumstances as amorphous urates and ammonium biurate.

Xanthine

Xanthine crystals are similar in appearance to amorphous urates and ammonium biurate. They are present in urine as a consequence of allopurinol therapy. They have also been rarely recognized along with xanthine urolithiasis in cats and as a consequence of an inherited disorder in Cavalier King Charles Spaniels.[19]

Lipids

Variably sized refractile lipid droplets may be present in urine. If left to sit before examination, lipid should float to underneath the coverslip, whereas other elements will sink to surface of the slide, meaning that they should be on a different focal plane from the other formed elements. Lipid droplets are more common in feline urine; it is believed that lipid may originate from degeneration or turnover of lipid-laden tubular epithelial cells. It is important that they are recognized so that they are not mistaken for other elements.

Other Elements

Spermatozoa may be present in the urine of intact males. Parasites including *Dirofilaria, Pearsonema (Capillaria), Dioctophyma* and contaminating fecal parasitic ova may be observed. Yeast and fungi are usually contaminants although occasionally urinary yeast infections (e.g., *Candida* spp.) or rarely polysystemic fungal infection (e.g., blastomycosis) may be identified.

Mucus strands are irregular in shape and longer allowing them to be differentiated from casts.

Other Routine Tests

Cytology

Examination of urine sediment on stained air-dried smears provides more detailed information on cell types, inflammatory cells, infectious agents and malignant characteristics.

Smears are prepared from urine sediment, spread on a slide by "blood smear" or preferably "line smear" technique to concentrate elements along a line at the end of the smear where the spreader slide has been abruptly lifted towards the end of the smear. Alternatively, cytospin preparations can be made. Bear in mind that urine is not an ideal medium for the preservation of cells; consequently, some cellular distortion and swelling is to be expected which should not be misinterpreted for a neoplastic appearance. Preferred stains include Papanicolaou's or Romanowsky-type (e.g., Wright's, Diff-Quik). This technique is also more sensitive for the detection of urine bacteria than unstained preparations.[15,20,21]

Indications for urine cytology include the presence of atypical cells on routine sediment examination in addition to the clinical presentations of hematuria, stranguria, suspicion or imaging evidence of a bladder mass or prostatomegaly. Transitional cell carcinoma is the most commonly recognized neoplasm and cytological criteria of malignancy should distinguish neoplastic from hyperplastic/reactive cells. However, the distinction is not always straightforward and fine-needle aspirate cytology or biopsy may be required.

Bacterial Culture

The observation of bacteria on urine sediment examination is not equivalent to a diagnosis of UTI (see ch. 327 and 330). However, if found on an aseptically obtained sample in combination with pyuria, UTI is more likely. That said, urine sediment examination is a relatively insensitive method to detect bacteria in urine and conversely, contaminating bacteria may be present in sediment. Bacterial culture is a much more sensitive method capable of detecting <10 bacteria/mL vs. 10,000 (rods) to 100,000 (cocci)/mL needed for visualization on sediment and has the advantages of being able to provide a quantitative result and to correctly identify the (predominant) species present and if required, the relevant antibiotic sensitivity. The number of bacteria (colony forming units; cfu)/mL that is considered significant and indicative of urinary tract infection varies according to collection methods[22] and differs between dogs and cats. Bacterial counts of $\geq 10^2$ cfu/mL are significant in canine and feline urine obtained by cystocentesis; counts of $\geq 10^3$ cfu/mL are significant in feline and male canine urine obtained by catheterization. Counts of $\geq 10^5$ cfu/mL are significant in female canine catheterized samples. Voided samples are generally unreliable for quantitative bacterial counts but $\geq 10^5$ cfu/mL in dogs and $\geq 10^4$ cfu/mL in cats has been considered significant. In cases of urolithiasis, culture of urolith or bladder mucosal biopsy may be necessary.[23] Reflex urine culture is not cost-effective in dogs with USG ≤1.013 in the absence of active urine sediment or high clinical suspicion for UTI.[24]

Creatinine

The measurement of urine creatinine allows for the calculation of creatinine clearance (CC) when urine production rate is known during timed collections and fractional excretion (FE) of electrolytes (see ch. 73), urine protein creatinine ratio (UPCR) and urine corticoid creatinine ratio (UCCR) in spot samples.

$$CC = \frac{\text{Creatinine}_{\text{Urine}} \times (\text{urine volume (mL)} / \text{collection interval (min)} / \text{bodyweight (kg)})}{\text{Creatinine}_{\text{Plasma}}}$$

$$FE_{\text{Analyte}}(\%) = \frac{100 \times \text{Analyte}_{\text{urine}} \times \text{Creatinine}_{\text{plasma}}}{\text{Analyte}_{\text{plasma}} \times \text{Creatinine}_{\text{urine}}}$$

UPCR

Urine-protein to creatinine ratio provides a good indication of quantitative proteinuria without the difficulties of obtaining a 24-hour urine collection (see ch. 325). UPCR quantification of proteinuria is recommend in samples with "2+" dipstick proteinuria and USG >1.012 and in samples with "1+" dipstick proteinuria and USG < 1.012. UPCR has been utilized to assist in the standardized classification of renal dysfunction.[25] Multiple samples collected at least 24 hours apart are recommended to mitigate the risk of overinterpretation of a single sample positive result.

UCCR

Urine corticoid creatinine ratio is used to screen for hyperadrenocorticism (see ch. 306 and 307). It is considered to be a highly sensitive but non-specific test for hyperadrenocorticism. Depending on the analytical process, this ratio may be reported as either urinary "corticoid" or "cortisol" creatinine ratio. The term corticoid implies no pre-analytical preparation and the analytical antibodies detecting all cross-reacting steroid and metabolites. Because there are several antibody types for the detection of cortisol, the results and consequently diagnostic cut-off values vary by laboratory. Much of the literature on UCCR is based on a particular detection antibody not commonly used in most international commercial laboratories. Consequently literature cut-off values are in the range of 10×10^6, whereas many commercial laboratories' cut-offs are in the range $24\text{-}30 \times 10^6$.

Non-Routine Tests

Bence-Jones and Urine Protein Electrophoresis

Bence-Jones proteins are light-chain immunoglobulins found in the urine of patients with plasma cell neoplasia (myeloma) (see ch. 344). They may not be detected by routine protein detection methods and should be requested when monoclonal gammopathy is suspected. Their identification is based on their precipitation at lower temperatures than other proteins (40° to 60° C). Urine protein electrophoresis may be helpful in further classifying proteinuria.

GGT, NAG

N-acetyl-beta-D-glucosaminidase (NAG) is a lysosomal enzyme and gamma-glutamyl-transferase (GGT) a membrane enzyme of the proximal tubular epithelium. Their presence in urine indicates renal tubular injury.[26] They are reported as a ratio with urine creatinine to provide a surrogate of 24-hour excretion[27] (see ch. 326 for further detail on urinary enzymes).

CHAPTER 73

Urinary Electrolyte Concentrations

Steven Epstein

Introduction

Urine sodium (Na^+), potassium (K^+), and chloride (Cl^-) concentrations are infrequently utilized in veterinary medicine. Interpretation of *urine* electrolyte concentrations is based on what is "appropriate" given that patient's physiologic condition, as there is no normal range that applies to all patients. Knowing the urine electrolyte concentrations can aid in determining etiology of *serum* electrolyte abnormalities as well as some disorders of acid-base metabolism. Randomly obtained urine samples may be adequate. In certain disorders the utility of urine electrolyte concentrations is enhanced when interpreting results in the context of urine osmolality or creatinine.

Disorders of Sodium (Na^+)

Overview of Urinary Free Water Clearance and Urine Na^+

Abnormal serum Na^+ concentrations (dysnatremias) are associated with increased in-hospital mortality.[1,13] Severity of dysnatremia correlates with higher mortality rates, but whether it is the Na^+ concentration itself or the condition causing the disturbance is unknown.[1,13] Identifying the cause of dysnatremia can be extremely useful in patient care. Combining urinary free water clearance with urine Na^+ concentrations or fractional excretion of sodium (Fe_{Na}) can aid in determining the cause of hyponatremia or hypernatremia.

Urinary free water clearance, determined using urinary cations rather than osmolality, may provide a more accurate representation of water balance for dysnatremias.[2] When the urinary free water clearance is negative, the kidneys are conserving water and when positive, they are excreting free water.[3] Assessment of randomly obtained urine can provide a snapshot of how a patient's kidneys are regulating free water clearance during the time that urine was produced. If a urinary catheter has been placed, a sample drawn from the catheter can represent current renal free water regulation. A sample obtained from a closed collection system over a specified time period can provide an averaged assessment from the time the system was last emptied. Closed collection system urine volume can be multiplied by urinary free water clearance to provide a calculated volume of free water cleared or conserved by the kidneys. This volume can be integrated into the fluid plan for returning serum Na^+ concentrations toward normal.

Urinary free water clearance is determined primarily by the amount of water ingested and amount of antidiuretic hormone (ADH) released (Box 73-1).[4] The primary regulation for ADH release is an increased plasma tonicity with its major component being Na^+ concentration. As plasma tonicity increases, ADH is secreted and urinary free water clearance is negative. If plasma is hypotonic due to disease or ingestion of water, ADH secretion is inhibited and urinary water clearance is positive. ADH can also be secreted in response to low circulating blood volume or pressure. Large drops in blood pressure (10-15 mm Hg) stimulate ADH secretion, conserving free water to restore volume and pressure (non-osmotic ADH release). The result of this water conservation effort is to increase blood volume, and as a result the Na^+ concentration will decrease. These scenarios involving ADH release are physiologic and considered appropriate. However, ADH is sometimes secreted inappropriately. Examples of conditions associated with inappropriate ADH secretion include hypoadrenocorticism, hypothyroidism, and the "syndrome" of inappropriate ADH secretion (SIADH; Box 73-2). These conditions are associated with low serum Na^+ concentration and a negative free water clearance.

Box 73-1

Urinary Free Water Clearance Calculation

$$\text{Urinary free water clearance (\%)} = 1 - \frac{(\text{Urine [sodium]} + \text{Urine [potassium]})}{\text{Serum [sodium]}}$$

All three values should be in the same units.

Box 73-2

Potential Etiologies of SIADH

- Vascular event to the brain
  - Traumatic brain injury
  - Subarachnoid hemorrhage
  - Ischemic stroke
- Neoplastic production of ADH
- Pulmonary diseases
- Emotional state
  - Neuropsychiatric disorders
  - Pain
  - Nausea
- Medications
  - Amitriptyline
  - Carbamazepine
  - Cyclophosphamide
  - Oxytocin
  - Vasopressin

Apart from urinary free water clearance calculations, urine Na^+ concentrations can be of value in assessing blood volume status. The kidneys respond to decreased perfusion by conserving both Na^+ and water to expand the extracellular fluid (ECF) volume, in part by activation of the renin-angiotensin-aldosterone system. When aldosterone is secreted, the kidneys can conserve sodium such that in hypovolemic states, the urine Na^+ should be <20 mEq/L and may be as low as 1 mEq/L.[5] Values of 20-40 mEq/L are equivocal, while >40 mEq/L of Na^+ implies the kidneys are interpreting a normal blood volume. An exception would be conditions in which renal Na^+ handling is impaired, as with CKD or selective renal or glomerular hypoperfusion.[5] Determining the Fe_{Na} (Box 73-3) has been thought to help discriminate prerenal azotemia from acute kidney injury (AKI). A Fe_{Na} <1% is consistent with hypovolemia and >1% consistent with AKI.[6] Recent evidence suggests that this is not foolproof and a Fe_{Na} <1% has been associated with AKI, fluid therapy, and the use of vasoactive drugs or diuretics.[7]

Box 73-3

Fractional Excretion of Sodium Calculation

$$\text{Fractional excretion of sodium } (Fe_{Na})\ (\%) = 100 \times \frac{\text{Urine [sodium]} \times \text{Plasma [creatinine]}}{\text{Plasma [sodium]} \times \text{Urine [creatinine]}}$$

Hyponatremia

Overview and Definitions

Hyponatremia is common and, when documented, should be categorized as either true hyponatremia or pseudohyponatremia caused by hyperlipidemia, hyperproteinemia, hyperglycemia, or mannitol administration.[1,8] It is assumed in this discussion that pseudohyponatremia has been ruled out. Hyponatremia in association with a reduced free water clearance involves an abnormality in either the generation of free water in the loop of Henle/distal tubule or enhanced water conservation due to ADH secretion in the collecting ducts.[9]

Positive versus Negative Water Clearance

When constructing differential diagnoses for hyponatremia, free water clearance should be assessed. Positive free water clearance is considered appropriate handling. This excess water accumulation likely occurred via ingestion (voluntary, or via feeding tube) or IV hypotonic fluid therapy. Negative free water clearance may indicate inappropriate renal handling of water. To help determine if renal water handling is appropriate or inappropriate, the ECF volume should be assessed. Hyponatremia can be associated with hypovolemia, euvolemia, or hypervolemia and assessment of volume status is important in this context relative to urine Na^+ concentration and free water clearance (Figure 73-1).

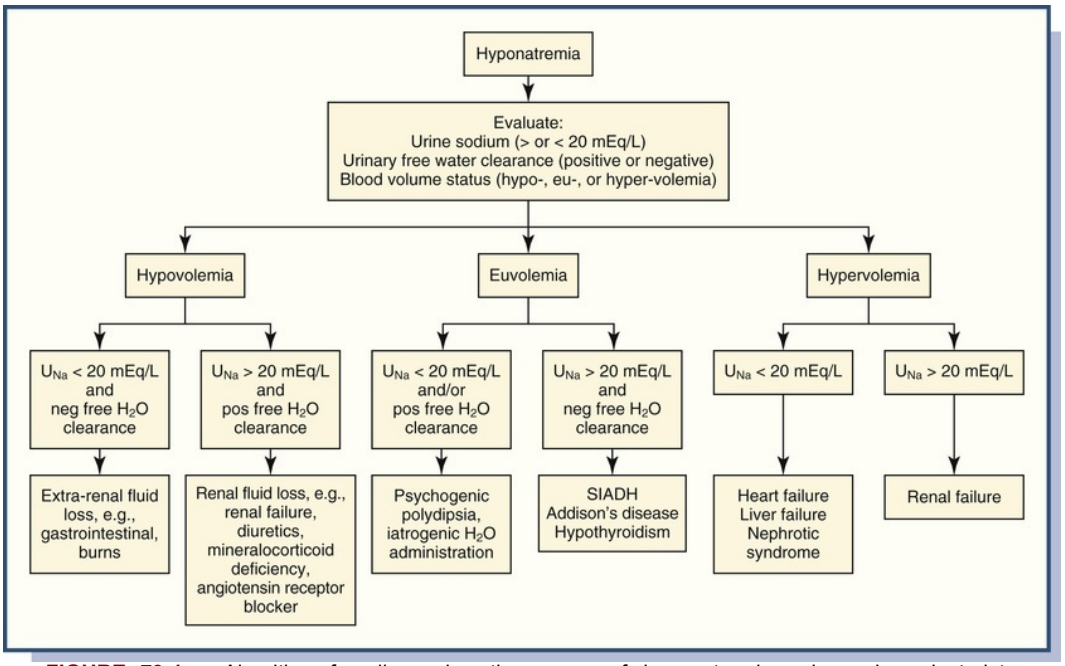

FIGURE 73-1 Algorithm for diagnosing the cause of hyponatremia using urine electrolyte concentrations. *Neg,* Negative; *Pos,* positive; *U,* urine.

Hypovolemia

A patient judged to be hypovolemic with appropriate kidney function should have increased aldosterone

concentration, negative free water clearance, and a urine Na^+ concentration <20 mEq/L. If present, this would indicate extrarenal fluid loss as the cause of hypovolemia. This is most likely associated with gastrointestinal loss or loss from the skin due to burns, and the associated nonosmotic release of ADH. If the urine Na^+ is >20 mEq/L, hypovolemia is likely to be secondary to renal losses from renal disease, diuretic administration, angiotensin receptor blocker administration, or mineralocorticoid deficiency (Addison's disease).

Euvolemia

When the patient is considered euvolemic with a urine sodium <20 mEq/L and a positive free water clearance, the history of the patient should be evaluated for polyuria/polydipsia which would indicate psychogenic polydipsia as the cause in the absence of any other iatrogenic water administration. Euvolemia, a urine sodium >20 mEq/L, and a negative free water clearance are compatible with SIADH, hypothyroidism, or glucocorticoid deficiency. Diagnosis of SIADH is based on the above findings and exclusion of hypothyroidism and Addison's disease.

Hypervolemia

Patients judged to be hypervolemic with an expanded ECF volume and urine Na^+ concentrations <20 mEq/L are most likely to have heart failure, liver failure, or nephrotic syndrome. If the urine sodium is >20 mEq/L, intrinsic renal disease is most likely.

Hypernatremia

Overview

Hypernatremia develops after increased consumption of Na^+ or most commonly after water loss. If hypernatremia is persistent, it is due to an inability to consume adequate amounts of water, whether due to failure to sense thirst or a failure to ingest water. Failure to drink may be due to metabolic illness, change in mental status, congenital adipsia, or lack of water (e.g., NPO status while hospitalized). As with hyponatremia, volume status, urine Na^+ concentration, and urinary free water clearance can help rule in or out conditions under consideration as causes for hypernatremia.

Hypervolemia

For patients that are deemed to be hypervolemic, it is usually a gain of sodium that is the factor that generates the hypernatremia. Urinary sodium concentrations are often >100 mEq/L and free water clearance is negative.[10] Causes include hyperaldosteronism, hyperadrenocorticism, administration of hypertonic solutions (sodium bicarbonate, total parenteral nutrition, 7.2% sodium chloride), dialysis, or excess ingestion of a hypertonic solution such as milk replacer. Patients with kidney failure receiving IV replacement fluids are at risk for developing hypernatremia due to their limited capacity for renal conservation of free water and the excess sodium being administered from fluid therapy.

Euvolemia or Hypovolemia

In these patients hypernatremia is most likely from water loss. Potential causes are listed in Box 73-4. To aid in distinguishing these disorders, free water clearance is evaluated together with urine volume. If free water clearance is negative and urine volume is low, extra-renal hypotonic fluid loss is likely (gastrointestinal or insensible losses). If free water clearance is negative, but urine volume is high, there is likely to be a renal source of hypotonic fluid loss (glucosuria, post-obstruction diuresis, mannitol administration). Positive free water clearance suggests a deficiency in ADH action on the kidneys, either from lack of secretion (central diabetes insipidus) or lack of renal sensitivity (nephrogenic diabetes insipidus).

Box 73-4

Etiologies of Water Loss

Insensible water loss
- Burns
- Respiratory tract

Renal loss

Diabetes insipidus (central or nephrogenic)
Osmotic diuretics (hyperglycemia, mannitol)
Gastrointestinal loss
Lactulose
Activated charcoal with sorbitol
Infectious diarrhea

Potassium (K^+) Disorders

Trans-Tubular Potassium Gradient (TTKG)

Urinary K^+ concentration can be helpful in determining cause of hypo- or hyperkalemia. Spot check urinary K^+ concentrations are not often useful, but TTKG determination can be helpful (Box 73-5). This formula is only useful when urinary Na^+ concentrations are >25 mEq/L, to ensure that renal Na^+ delivery is not rate limiting.[11] Healthy people usually have a TTKG ranging from 8 and 9; no values are established for dogs and cats.

Box 73-5

Transtubular Potassium Gradient Calculation

$$\text{Transtubular potassium gradient} = \frac{\text{Urine [potassium]} \times \text{Plasma osmolality}}{\text{Urine osmolality} \times \text{Plasma [potassium]}}$$

Hypokalemia

Hypokalemia is usually a result of inadequate intake, increased entry into cells, gastrointestinal loss or renal loss. The TTKG can help differentiate renal loss (TTKG >3) from other causes (TTKG <3).[12] Increased urinary losses are often associated with diuretic use, nasogastric tube suctioning, amphotericin B administration, mineralocorticoid excess, or hypomagnesemia.

Hyperkalemia

Hyperkalemic patients are often broken down into having one of three major causes: increased intake (oral or IV), transcellular movement, or decreased urinary excretion. Pets with non-renal causes of hyperkalemia have a TTKG <7, indicating defective renal secretion of K^+. Values >7 indicate excess intake or transcellular movement.[11] Decreased renal excretion of K^+ may be associated with renal failure, decreased distal renal tubular flow from decreased effective circulating blood volume, or hypoaldosteronism.

CHAPTER 74

Fluid Analysis

Thoracic, Abdominal, Joint

Tracy Stokol

Thoracic and Abdominal Cavity Fluid

The thoracic and abdominal cavities are bathed in small amounts of fluid that cannot normally be aspirated. Therefore, any fluid accumulation is abnormal. Aspiration of fluid with subsequent cytologic analysis is a routine part of the diagnostic evaluation of patients with pleural or abdominal effusions. Aspiration is a relatively innocuous, minimally invasive, and inexpensive procedure that can yield clues as to the cause of the effusion and, in some cases, provide a definitive diagnosis of the underlying disease.

Fluid Analysis

Analysis starts at the moment of collection, with assessment of fluid color and ease of collection. If the fluid is clear initially and becomes bloody during collection, or vice versa, blood contamination is likely. If the fluid remains bloody throughout collection, then hemorrhage or red blood cell (RBC) diapedesis is likely occurring. If the fluid resembles peripheral blood, this could be due to severe hemorrhage or aspiration of a highly vascularized organ, such as the spleen. Differentiation between these possibilities can be accomplished by placing the bloody fluid into a non-anticoagulant (red top) tube. Because blood clots and lyses rapidly *in vivo*, the absence of a clot supports *in vivo* hemorrhage versus blood contamination. In contrast, clots in the fluid would support blood contamination, although peracute hemorrhage is possible. Visual inspection of fluid color and clarity after collection also yields other helpful information and can guide smear preparation and additional diagnostic testing (Box 74-1).

Box 74-1

Visual Characteristics of a Fluid Yield Clues as to the Mechanism and Potential Cause of an Effusion

Colorless, transparent: Likely low-protein transudate, low cellularity (sediment and direct smears recommended); assess patient for low albumin and protein-losing conditions and liver disease (portal hypertension).

Light to moderate yellow, transparent to slightly turbid: Likely transudative effusion (low- or high-protein); low to moderate cellularity (sediment and direct smears recommended). Various causes (see Table 74-1).

Light to moderate red to red-yellow, slightly to moderately turbid: Likely transudative effusion (high or low protein, but frequently high) with concurrent hemorrhage, RBC diapedesis, or blood contamination; low to moderate cellularity (sediment and direct smears recommended). Various causes (see Table 74-1).

Light to moderate yellow, transparent to lightly turbid, viscous, ± fibrin clot (cats only): Likely exudative effusion; moderate to high cellularity (direct smears likely sufficient); high total protein by refractometer (>2.5 g/dL); suspect feline infectious peritonitis.

Yellow to yellow-white, opaque to flocculent, may be lightly or moderately red, supernatant clears after centrifugation: Suspect exudative effusion; high cellularity (direct smears sufficient); culture or additional testing may be warranted, e.g., total bilirubin or creatinine concentrations if suspected biliary or urinary tract rupture or leakage.

White to pink to light red, opaque to opalescent with a cream layer on refrigeration, supernatant opaque after centrifugation: Suspect chylous effusion with concurrent hemorrhage, RBC diapedesis, or blood contamination (if red or pink); moderate to high cellularity (direct smears usually sufficient); additional testing may be warranted, e.g., triglyceride measurement.

Green to green-brown, moderately turbid to opaque: Likely high cellularity (direct smears sufficient); suspect bile peritonitis, enterocentesis, or ruptured GI tract (particularly if flocculent with food or particulate material); evaluate smear before accepting cell counts (bacteria, food debris counted as "cells").

Dark red (mimics blood), opaque, does not clot in a non-anticoagulant tube, measurable packed cell volume: Suspect hemorrhagic effusion (direct smears usually sufficient, although in laboratories buffy coats are prepared as well as direct smears).

Dark red (mimics blood), opaque, clots in a non-anticoagulant tube, measurable packed cell volume (EDTA): Aspiration of the spleen, peracute hemorrhage from large vessel, splenic or liver rupture.

Sample Handling, Storage and Submission

Fluid should be placed into an EDTA-anticoagulated (purple top) tube for cytologic examination. EDTA inhibits bacterial growth and preserves cellular features. Collection into a non-anticoagulant tube is helpful with bloody fluids and is always recommended (volume permitting) in the event biochemical tests or bacterial culture is desired, although submission of a culturette is preferred for the latter. Also, several smears should be made from fluids immediately after collection and rapidly air-dried (with a hair dryer on high aimed at the back of the slides) (see ch. 93). At the very least, a direct smear from unconcentrated fluid should be made; however, this can be paucicellular if the total nucleated cell count (TNCC) is low. Thus, sediment smears from centrifuged samples are recommended for fluids suspected to be of low cellularity (transparent to lightly turbid; see Box 74-1). Only a portion of the fluid should be centrifuged with the remainder left for cell counts and total protein estimation. Most laboratories also prefer to make their own cytologic smears. Smears and tubes should be labeled with the patient identification, date of collection, fluid (and smear) type, and a complete history provided. Submission of smears with fluid samples is critical to avoid storage-associated changes that impact cytologic interpretation and diagnostic accuracy of fluid analysis. These changes include:

- Deterioration of cells with storage: This affects cell counts and cell identification.
- Swelling of neutrophils: Mimics degenerative change.
- *In vitro* phagocytic activity: Phagocytosis of RBC and bacteria can occur within 30-120 minutes of sample collection, due to *in vitro* cellular activity.
- Bacterial proliferation: This can cause cellular lysis.

To minimize these storage-associated changes, fluid samples should be shipped promptly and kept refrigerated (on ice packs, avoiding direct contact with the pack to prevent freezing). Smears should be kept at 22° to 24° C and shipped in a break-proof container.

Cytologic Results

Most laboratories provide gross fluid characteristics, TNCC and RBC counts, a total protein estimate, and cytologic analysis on optimally concentrated smears (the smear type is dictated by the cell counts). Cytologic assessment can be done in-house using quick stains (e.g., Diff-Quik) and is worthwhile for rapid diagnosis and improving cytologic skills (e.g., comparing results to those of a clinical pathologist) (see ch. 86, 89, and 93).

- Cell counts: These can be done manually with a hemocytometer or with electronic counters. Point-of-care hematology analyzers should not be used for fluid analysis due to their poor sensitivity. Body cavity fluids also can plug or clog the analyzer. Not all nucleated cells are leukocytes (they could be mesothelial or cancer cells) and bacteria and particulate debris can be counted as "cells," falsely increasing the TNCC.
- Total protein: Estimates are obtained with a refractometer and are done on fluid supernatants after centrifugation if the fluid is turbid. A more accurate total protein measurement can be obtained from automated chemistry analyzers, but is more expensive and not usually required. Some laboratories provide specific gravity in lieu of total protein.
- Cytologic assessment: Smears are examined for the relative proportions of leukocytes, degenerate neutrophils (supporting bacterial sepsis), cytophagia (RBCs or other cells) and a potential cause; e.g.,

neoplastic cells, infectious agents. If RBCs are numerous, platelets would indicate blood contamination or peracute hemorrhage, whereas erythrophagia, hemosiderophages or hematoidin crystals support prior hemorrhage. If sample volume is insufficient for all tests, preference should be given to cytologic assessment, because cell counts can be estimated from direct smears. Cell counts and total protein measurement done in isolation may result in erroneous diagnoses.

- Other tests: Additional diagnostic tests may be desired, e.g., bilirubin, creatinine, pancreatic-specific lipase immunoreactivity or lipase,[1] lactate, pH, and glucose.[2,3] The latter 3 tests are best done in-house, because storage will yield erroneous values. Advanced cancer diagnostic tests, e.g., flow cytometric–based immunophenotyping[4,5] and clonality tests,[5] are best done on fresh samples (<3 days old).

Classification of Effusions

The author uses a mechanistic approach for fluid classification, which differs from the traditional classification scheme ("pure" transudate, "modified" transudate, exudate). Fluids accumulate in body cavities due to the following mechanisms: transudation, exudation, or viscus/vessel rupture (Table 74-1; Figure 74-1).

TABLE 74-1

Mechanistic Classification of Body Cavity Effusions*

TYPE OF EFFUSION	TOTAL PROTEIN (g/dL)	TOTAL NUCLEATED CELL COUNT ($\times 10^3$/mcL)	CYTOLOGIC FINDINGS	SOME CAUSES (NON-EXHAUSTIVE LIST, ITALICIZED ARE COMMON)
Transudative Effusions Venous or lymphatic hypertension, blockage, obstruction or dilatation (lymphangiectasia)				
Transudate (low-protein)†	<2.5	<5.0, usually <1.5	Mixture of macrophages and neutrophils, few lymphocytes and mesothelial cells (rare in cats), few RBCs	**Peritoneal:** *Chronic liver disease* (portal hypertension), hypoalbuminemia (<1.5 g/dL), non-exfoliating neoplasia, lymphangiectasia **Pleural** (uncommon): Neoplasia, cardiac disease, lung lobe torsion
Transudate (high-protein)†	>2.5	<5.0	Mixture of macrophages and neutrophils, few lymphocytes and mesothelial cells (rare in cats), variable RBC (diapedesis or hemorrhage, former more common)	**Peritoneal:** *Congestive heart failure* (dog), *chronic liver disease* (sinusoidal hypertension), *non-exfoliating neoplasia* **Pleural:** *Neoplasia, cardiac disease,* lung lobe torsion, etc.
Chylous effusion	>2.5 (can be falsely increased by lipid)	Variable, >3.0	High proportion of small lymphocytes, lipid vacuoles in macrophages; neutrophils may dominate if longstanding	**Peritoneal fluid** (rare): Neoplasia, lymphangiectasia, abdominal abscess, granuloma or adhesions **Pleural fluid:** *Cardiomyopathy* (cats), *idiopathic* (dogs, cats),

				neoplasia (e.g., thymoma), parasitic granuloma
Exudative Effusion Increased vascular permeability with or without leukocyte chemotaxis				
Classic exudate	>2.5	>5.0	Neutrophils dominate and may be degenerate or mixture of neutrophils and macrophages, cause may be identified	*Bacteria,* fungi, parasites (e.g., Mesocestoides), *neoplasia,* foreign body, *ruptured or leaking viscus, tissue/organ inflammation* (pancreatitis, pneumonia)
Feline infectious peritonitis	>2.5, often >5.0	<5.0, sometimes higher	Mixture of neutrophils (60-80%) and macrophages (20-40%), fibrin clots, proteinaceous background, few mesothelial cells and lymphocytes	
Vessel or Viscus Rupture May initially start out with transudative counts and low protein (biliary, urinary rupture) and become exudative with time				
Hemorrhage (usually >1 × 106/mcL RBC or a packed cell volume > 1%)	Usually >2.5	Depends on peripheral blood count	Many RBCs, no or very few platelets, erythrophagia and/or hemosiderin in macrophages and/or hematoidin crystals, leukocytes are blood-associated unless concurrent inflammation	**Both cavities:** *Trauma,* hemostatic disorder (e.g., anticoagulant rodenticide intoxication), neoplasia **Pleural cavity:** Angiostrongylus vasorum,[9] Streptococcus zooepidemicus[10] **Peritoneal cavity:** *Neoplasia* (e.g., hemangiosarcoma), ruptured liver (e.g., amyloidosis in cats)
Biliary rupture/leakage	Variable, often >3.0	Variable, often >5.0	If exudative, mixture of neutrophils (dominant) and macrophages, yellow-brown bile in background or in phagocytes, may see "white" bile (mucus), concurrent hemorrhage (erythrophages, hemosiderophages); patient may be icteric, confirm with bilirubin measurement of fluid (often >2× serum)	*Trauma, mucocele* (dogs), cholelithiasis, neoplasia, or severe necrotizing inflammation (cholecystitis)
Uroperitoneum	Variable	Variable	Initially low protein and cell count (dilution with urine if large rupture), becoming exudative with time; concurrent hemorrhage (see above); confirm with creatinine measurement of fluid (usually >2× serum)	*Trauma,* urolithiasis, neoplasia or severe necrotizing inflammation
Gastrointestinal rupture/leakage	Variable	Variable (often unreliable if interference from bacteria or intestinal contents)	Food material and/or phagocytized bacteria with peritoneal fluid cells (must be differentiated from a partial enterocentesis), may see concurrent hemorrhage	Trauma, severe inflammation, obstruction, torsion
Neoplasia Causes effusions through various mechanisms, including transudation, exudation and viscus rupture/leakage				
Neoplastic effusion	Variable,	Variable	Neoplastic cells in fluid (more common with round	*Lymphoma, carcinoma,*

	often >2.5		or epithelial cell tumors), usually fluid is transudative, but can be exudative (tumor necrosis, inflammatory cytokines, sepsis) with concurrent hemorrhage	mast cell tumor, mesothelioma, others

*This classification is based on a combination of total protein concentration, nucleated and red blood cell (RBC) count and cytologic findings, and is helpful for narrowing down the differential diagnostic list for the cause of the effusion.

†Differentiation of transudates into low- and high-protein effusions is only meaningful for peritoneal effusions.

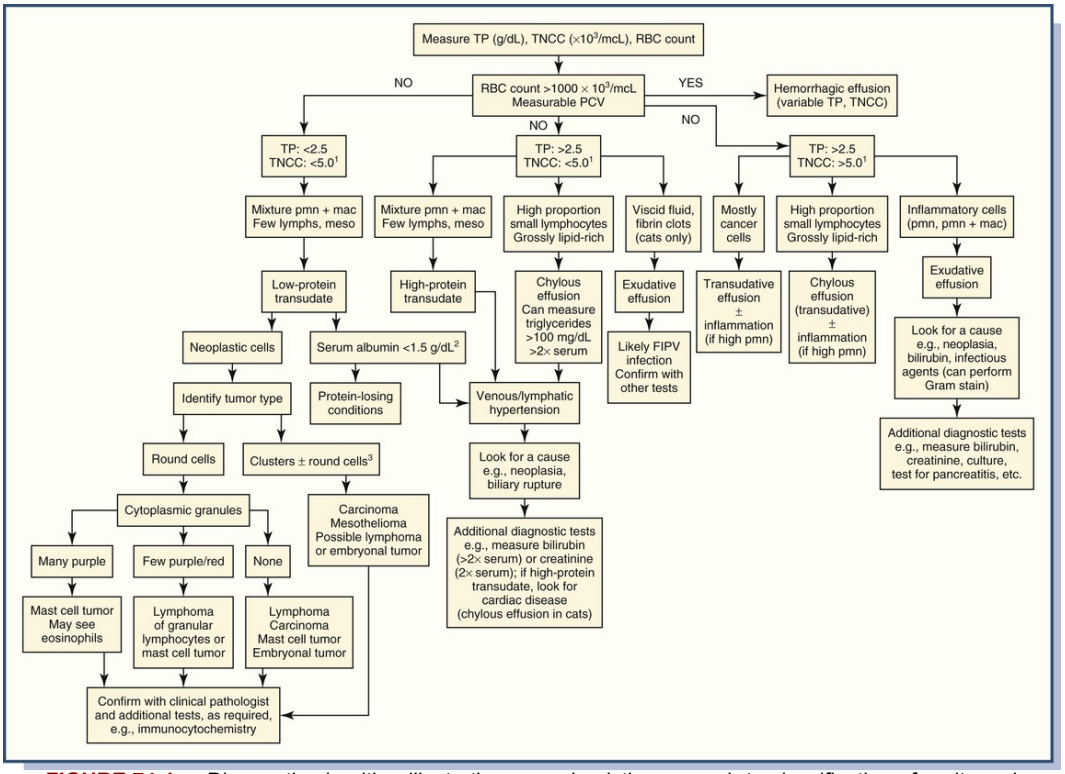

FIGURE 74-1 Diagnostic algorithm illustrating a mechanistic approach to classification of peritoneal and pleural cavity effusions in small animal patients. *FIPV,* Feline infectious peritonitis-associated coronavirus; *Lymphs,* lymphocytes; *Mac,* macrophages; *Meso,* mesothelial cells; *PCV,* Packed cell volume; *PMN,* neutrophils; *RBC,* red blood cell; *TNCC,* total nucleated count; *TP,* total protein by refractometer. [1]If RBC count is > 50 × 10^3/mcL and no overt contamination is noted during collection, there is likely concurrent diapedesis (transudates) or hemorrhage (exudates or less frequently, transudates). [2]Hypoalbuminemia is an uncommon solitary cause of transudative effusions, and usually other transudative mechanisms are concurrently at play, e.g., venous hypertension. [3]Tumor cells must be distinguished from reactive mesothelial cells, particularly in dogs. This distinction is based on cytologic criteria of malignancy but can be difficult in individual patients, necessitating additional diagnostic tests. (Adapted with permission from eClinPath.com.)

Transudation

This is the most common type of effusion and is due to alterations in hydrodynamic forces, typically venous or lymphatic hypertension or obstruction. A marked decrease in oncotic pressure from severe hypoalbuminemia (<1.5 g/dL, e.g., due to nephrotic syndrome) can also result in a transudative effusion, but is rarely the sole cause (usually accompanied by venous or lymphatic hypertension). Transudative effusions often are light to medium yellow, transparent to lightly cloudy, with TNCC <5,000/mcL and total protein usually <5.0 g/dL. RBC counts are variable. A mixture of non-degenerate neutrophils and macrophages, with fewer lymphocytes and mesothelial cells (rare in cats), is seen on cytologic smears. RBCs can be due to blood contamination, diapedesis (from the increased pressure) or less frequently, hemorrhage. Erythrophagia (and rarely hemosiderophages) will be seen with diapedesis and prior hemorrhage (unless peracute). Unfortunately, a cause frequently is not evident cytologically with transudative effusions. In peritoneal but

not pleural fluid, transudative effusions can be separated into "low-protein" and "high-protein" transudates. This distinction is useful because it identifies the location of the hypertension, which helps narrow down the list of causes (see Table 74-1).

- Low-protein (protein-poor or pure) transudates: Colorless to light yellow fluid with minimal blood. Prehepatic (mesenteric lymphatics) or hepatic presinusoidal (portal) or early sinusoidal hypertension causes leakage of low-protein intestinal lymph. The most common cause is liver disease, followed by protein-losing conditions.
- High-protein (protein-rich or modified) transudates: Light to moderately yellow fluid that is frequently blood-tinged from concurrent diapedesis. Hepatic sinusoidal or post-sinusoidal hypertension causes leakage of high protein hepatic lymph. Common causes are liver disease, cancer and congestive heart failure (dogs can develop pleural and peritoneal effusions, with the latter being more common, particularly with right-sided heart failure; in cats, pleural effusion can be seen with biventricular or right-sided heart failure).
- Chylous effusion: This transudative variant is more common in pleural fluid. The fluid is usually opaque and white and frequently blood-tinged (pink to light red). A fat layer can form on standing or refrigeration due to buoyant chylomicrons. The TNCC is variable (can be >5,000/mcL) and consists of high proportions of small lymphocytes, along with non-degenerate neutrophils and macrophages, which can contain cytoplasmic lipid droplets. In longer-standing chylous effusions, concurrent inflammation can be present from the irritating effects of chyle. In the latter fluids, neutrophils can dominate, but lymphocyte proportions are still high. A chylous effusion can be confirmed by high fluid triglyceride concentrations (usually >2× serum or >100 mg/dL). Chylous effusions from some anorectic animals may not be grossly chylous and may have low triglyceride concentrations. Chylous pleural effusions can be seen in cats with cardiomyopathy, presumably due to high hydrostatic pressure in the cranial vena cava. However, the absence of heart disease in many cases, and successful treatment using such techniques as thoracic duct ligation and pericardiectomy, suggest that other as yet unknown mechanisms (potentially associated with pericardial disease) may lead to the development of chylous effusions in cats with or without cardiac disease.[6] Chylous ascites is rare and is caused by lymphangiectasia or lymphatic blockage (neoplasia, adhesions, abscesses, etc.).

Exudation

Exudative effusions are caused by increased vascular permeability due to inflammation, with leakage of serum protein and inflammatory cell chemotaxis. Exudative effusions are usually yellow to white, lightly to moderately cloudy to opaque or flocculent, with TNCC >5,000/mcL and total protein >2.5 g/dL. The supernatant can clear after centrifugation (cells pellet). Variable proportions of neutrophils and macrophages with fewer lymphocytes are seen on cytologic smears, with clusters of reactive mesothelial cells (rare in cats). The dominant inflammatory cell will depend on the cause and duration of the effusion. Neutrophils usually comprise >80% of cells with acute bacterial infections and sterile peritonitis, whereas a more mixed inflammatory infiltrate (<80% neutrophils and >20% macrophages) occurs with longer duration effusions or specific causes, e.g., some fungal infections and cancer. Although degenerate neutrophils are considered evidence of bacterial sepsis, they can also be seen with sterile inflammation, e.g., bile peritonitis.

Culture of the fluid is indicated in animals with an exudative effusion, whether or not degenerate neutrophils or infectious causes are seen on smears. There are various causes of an exudative effusion, including infectious agents (bacteria, fungi, tapeworm, coronavirus causing feline infectious peritonitis [FIP]), foreign bodies (e.g., retained surgical sponge,[7] penetrating grass awn), viscus leakage or rupture, and tissue inflammation (e.g., pleuropneumonia, pancreatitis, steatitis). FIP deserves special mention due to the unique characteristics of the effusion. Although the effusion is exudative (from a vasculitis), leukocyte chemotaxis is not prominent, yielding a high-protein, light- to moderate-yellow viscid fluid, with fibrin clots, and a TNCC usually <5,000/mcL. Smears contain a mixture of slightly degenerate neutrophils with moderate macrophages and few lymphocytes or mesothelial cells, with protein crescents or precipitated protein in the background. In the author's experience, immunocytochemical staining for FIP coronaviral antigen[8] is unrewarding, and therefore, a confirmatory diagnosis still relies on the histopathologic finding of pyogranulomatous inflammation with positive histochemical staining for FIP-associated coronaviral antigen in macrophages (see ch. 224).

Vessel or Viscus Rupture or Leakage

These can be separated into hemorrhagic effusions, bile and uroperitoneum and gastrointestinal (GI) leakage or rupture (see Table 74-1) (see ch. 90 and 102).

- Hemorrhagic effusion: These effusions are bloody throughout collection, resemble peripheral blood, do not clot in a non-anticoagulant tube (see Box 74-1), and have a measurable packed cell volume (>1%). Direct and buffy coat smears (to concentrate nucleated cells) usually are prepared for examination. On smears, the fluid resembles blood with blood-associated leukocytes and variable numbers of mesothelial cells. There is evidence of chronic or prior hemorrhage (erythrophagia, hemosiderophages, hematoidin crystals) with no or few platelets. In peracute hemorrhage, platelets can be seen and the fluid can clot. Common causes of abdominal hemorrhage are trauma, neoplasia (hemangiosarcoma), and anticoagulant rodenticide intoxication. Hemorrhagic pleural effusions are uncommon and can be due to trauma, neoplasia, or parasitic or bacterial infection.[9,10] Any animal with an unexplained hemorrhagic effusion should be tested for an underlying hemostatic disorder, e.g., anticoagulant rodenticide intoxication.
- Bile peritonitis: Depending on the degree of leakage, the fluid can be transudative or exudative, although an exudative effusion with mixed non-degenerate neutrophils and macrophages is typical. Free or phagocytized green-brown to yellow bile pigment can be seen, but small amounts might be missed and can resemble other pigments, e.g., hemosiderin. In some patients, there are only aggregates of light blue mucus, so-called "white bile."[11] High bilirubin concentrations (usually >2× serum) in the effusion can confirm a bile peritonitis; however, low bilirubin concentrations can be seen in dogs with ruptured mucoceles, in which only "white bile" is present in the fluid. Note that mucus also can be seen with mucinous adenocarcinomas and myxosarcoma[12] and small amounts might be mistaken for fibrin (or vice versa).
- Uroabdomen: In an acute rupture, urine may flood the abdomen, yielding a low-protein transudate. However, with time, a sterile peritonitis will develop. There are no cytologic findings typical of uroabdomen, so confirmation requires finding high creatinine concentrations in the fluid compared to blood (usually >2×).[13]
- Gastrointestinal leakage or rupture: This results in a septic peritonitis with free and phagocytized mixed bacteria typical of gut flora, including Gram-positive cocci in pairs and various Gram-negative rods. If there is a yeast or bacterial overgrowth, offending organisms can also be seen. Bacterial phagocytosis is a key finding for differentiating a partial enterocentesis (with aspiration of abdominal fluid and GI contents) from an acute GI rupture. Intracellular bacteria are not expected with the former (in smears made from freshly collected fluid). If an aspirate only consists of intestinal contents (food debris and mixed bacteria), an enterocentesis is likely.

Neoplastic Effusions

Although neoplastic effusions are not part of the mechanistic classification scheme, identification of neoplastic cells can provide an immediate diagnosis. Neoplasia can yield effusions via all of the above mechanisms and more than one mechanism may be operative, e.g., hemorrhagic effusion with inflammation. Tumors of round (particularly lymphoma and mast cell tumor) and epithelial cell origin exfoliate readily, whereas neoplastic cells from sarcomas are rarely seen (unless the primary tumor is directly aspirated).

- Lymphoma: Lymphoma is diagnosed readily when there are many individual intermediate to large discrete cells with high nuclear to cytoplasmic ratios (see ch. 344). Low numbers of tumor cells or cells from a small-cell lymphoma are more difficult to distinguish from reactive and normal counterparts, respectively. Advanced diagnostic testing, such as flow cytometric or immunocytochemical-based immunophenotyping and clonality tests, can be performed on body cavity fluids but should only be done if there is a sufficient number of questionable tumor cells (to avoid misdiagnosis, e.g., pseudoclonality). Other tumors also can resemble lymphoma, including poorly granulated mast cell tumors, embryonal tumors (e.g., nephroblastoma), and carcinomas.
- Mast cell tumors: These also exfoliate as individual cells and can be distinguished from lymphoma by lower nuclear-to-cytoplasmic ratios and variable numbers of purple granules dispersed in the cytoplasm (see ch. 349). Accompanying eosinophilic inflammation can also be seen. Poorly granulated tumors can be difficult to distinguish from a lymphoma of granular lymphocytes[14,15] without other testing, e.g., tryptase or CD3 immunostaining.
- Carcinomas: These exfoliate as variably sized clusters of round to polygonal cells, with some individual cells. The tumor cells must be distinguished from reactive mesothelial cells (particularly in dogs; it is rare to find many reactive mesothelial cells in effusions in cats), and macrophages (which can be seen in small aggregates in some fluids). Distinction can be difficult unless the tumor cells are showing prominent cytologic criteria of malignancy, e.g., marked anisokaryosis and/or macronucleoli. Mesothelial cells can become quite reactive and demonstrate abnormal features (e.g., trinucleation) in effusions. Ultimately, the

diagnosis of carcinoma can rely on documentation of the tumor in internal organs, particularly if the cells are bland and mimic mesothelium.

- Mesothelioma: This tumor should not be diagnosed with certainty from an effusion. Neoplastic mesothelial cells can resemble reactive counterparts (can lack cytologic criteria of malignancy) and exfoliated carcinoma cells. Even if the cells resemble mesothelial cells (central nuclei, moderate cytoplasm with a fringe or "corona") and are displaying features of malignancy, a diagnosis of mesothelioma requires documentation of tissue invasion on histopathologic examination. Because mesothelioma is an uncommon neoplasm, if clusters of cells with prominent cytologic criteria of malignancy are seen in a fluid, an underlying carcinoma is far more likely. The presence of multiple body cavity effusions is not specific for mesothelioma.

Joint Fluid

Unlike thoracic and abdominal fluid, synovial fluid can be aspirated from normal joints (see ch. 94). Normal synovial fluid is light yellow and transparent, with no blood, and is quite viscous due to its hyaluronic acid content. The fluid should be collected into EDTA and handled as described above for other body cavity fluids, with emphasis placed on rapid drying of smears. This is because cells "ball up" in the viscous fluid and are difficult to identify, let alone find intracellular structures that may be informative, e.g., infectious agents. Cytologic analysis of joint fluid usually includes cell counts, measurement of total protein by refractometer, a viscosity estimate, and smear examination. Viscosity usually is measured subjectively as the length of a "strand" of fluid that forms between a needle tip and a slide or the edge of the collection tube and tip of a plastic pipette (a gloved fingertip can be used in place of the tip of a needle or plastic pipette; Figure 74-2). Joint fluid of normal viscosity should form a strand that is at least 2 cm long. As with other body cavity fluids, when a low-volume sample is obtained, preference should be given to cytologic assessment of well-made smears over cell counts or measurement of protein content.

FIGURE 74-2 Normal synovial fluid forms a strand between a gloved fingertip and the microscope slide on which it has been placed.

Normal TNCC in synovial fluid from dogs ranges from 500 to 3,000/mcL between different joints, with <3,000/mcL being used as a general "normal" upper limit, although most fluids have counts <1,000/mcL. Counts generally are <1,000/mcL in cats.[16] The normal total protein concentration by refractometer is

<2.5 g/dL. On smears, the fluid consists of mononuclear cells (mostly large, with <20% lymphocytes) with <10% neutrophils, and a stippled or stringy pink to purple background from the viscosity. It can be difficult to distinguish lymphocytes from non-reactive macrophages and macrophages from synoviocytes; therefore, many clinical pathologists use the term "small and large mononuclear" cells. The term "reactive" means that the macrophage has increased cytoplasm that appears foamy, and could contain vacuoles or phagocytic debris, versus a non-reactive macrophage, which has non-vacuolated cytoplasm and does not demonstrate phagocytic activity. Other biochemical analyses are not usually performed on joint fluid.

Cytologic Interpretation

Results of joint fluid analysis rarely are specific for a particular disorder and rather fall into two general categories: non-inflammatory and inflammatory disease. These can be distinguished by TNCC, total protein concentration, and proportion of cell types in smears (Figure 74-3).

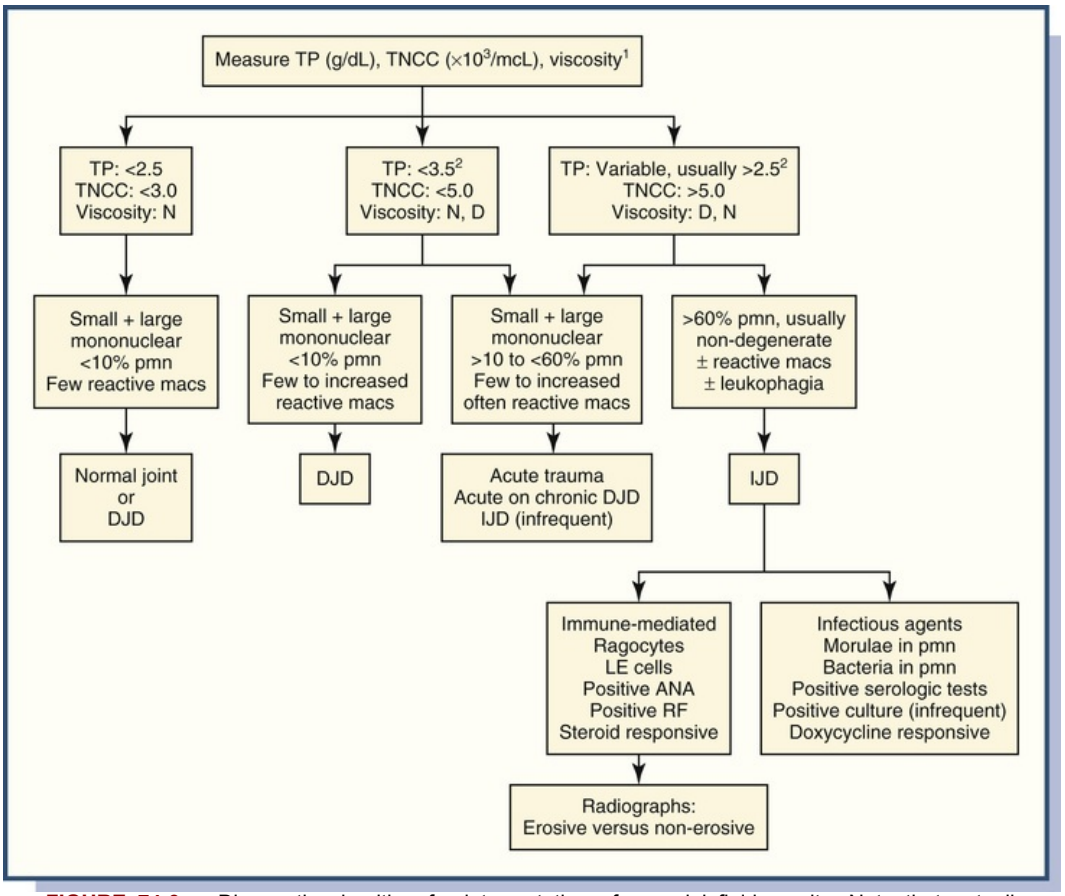

FIGURE 74-3 Diagnostic algorithm for interpretation of synovial fluid results. Note that not all scenarios are covered (e.g., neoplasia or hemarthrosis, but these are uncommon). *ANA,* Antinuclear antibody testing; *D,* decreased; *DJD,* degenerative joint disease; *IJD,* inflammatory joint disease; *macs,* macrophages; *N,* normal; *pmn,* neutrophils; *RF,* rheumatoid factor testing; *TNCC,* total nucleated cell count; *TP,* total protein. [1]A red blood cell (RBC) count should also be performed. Moderate to severe RBC contamination will increase the TNCC, total protein concentration, and proportion of neutrophils, which could hinder identification of an inflammatory arthropathy. Standard cytologic principles apply for differentiation of blood contamination and *in vivo* hemarthrosis (see text for abdominal and thoracic cavity effusions). [2]EDTA can falsely increase the refractive index in samples of small volume (<0.2 mL).[19] (Reproduced with permission from eClinPath.com.)

Non-Inflammatory Joint Disease

This term is used for joints with degenerative disease, due to musculoskeletal abnormalities (e.g., osteochondrosis) or trauma. The fluid lacks evidence of active inflammation (<10% neutrophils) and can be normal or show mild cytologic abnormalities, such as mildly increased total protein concentration, increased

proportions of reactive macrophages, mildly increased TNCC (usually <5,000/mcL) and decreased viscosity, alone or in various combinations. Some cases have evidence of synovial hyperplasia (multinucleated or aggregates of synoviocytes) or cartilage erosion (osteoclasts).

Inflammatory Joint Disease

This term applies to joints with active inflammation, specifically high TNCC (usually >5,000/mcL) with increased proportions of neutrophils (usually >20%).[17,18] There are two general causes: infectious agents and immune-mediated disease (primary, or secondary to vasculitis or infectious agents, e.g., borreliosis/Lyme disease). These causes are difficult to distinguish based on cytologic assessment alone, because neutrophils rarely are degenerate in septic joints and unique diagnostic features often are absent (see below). A single affected joint should raise suspicion for a bacterial infection (e.g., from a penetrating foreign body), whereas a polyarthropathy localized to carpi and tarsi is highly suspicious for immune-mediated disease. All animals presenting with signs of a monoarthropathy should be carefully examined for involvement of other joints so that a polyarthropathy is not missed. Note that acute joint trauma (e.g., cranial cruciate rupture) can result in mild inflammation (TNCC up to 12,000/mcL with up to 65% neutrophils); however, this abnormality should be localized to the affected stifle joint. Inflammatory joint disease of various causes usually affects dogs and is rare in cats.[19,20] The most common cause of an inflammatory polyarthropathy in dogs is immune-mediated disease,[17,18] although tick-borne infections (borreliosis, *Anaplasma phagocytophilum* or *Ehrlichia ewingii* infections) are becoming increasingly frequent. Neutrophils should be carefully examined for bacteria (e.g., *Anaplasma* morulae), protozoa (e.g., *Leishmania*[21]), and particulate (ragocytes) or homogenous nuclear material (lupus erythematosus cells), but these diagnostic findings are rarely observed. Cytologic analysis alone usually is not conclusive as to the cause of joint inflammation and other tests are required for a specific diagnosis, e.g., serologic tests. In some cases, diagnosis relies upon an appropriate response to therapy, e.g., doxycycline treatment for borreliosis.

Venous and Arterial Puncture

Linda Merrill

Venipuncture is utilized for phlebotomy or intravenous injections. Patient and sample identification help avoid unnecessary venipuncture. A sampling catheter (see ch. 76) should be considered in patients requiring frequent assessment. The most commonly utilized veins include the cephalic, external jugular, femoral (cats), and lateral saphenous (dogs) (E-Table 75-1 and Video 75-1), but sublingual, pedal, auricular, and abdominal veins have been used. Hospital-acquired anemia is a concern in small animal medicine; it can be minimized by combining laboratory tests, utilizing microtainer vials, and using existing samples for additional tests. In humans it is of greatest importance when there is preexisting anemia and in cases that require frequent monitoring.[1] Ideally, blood samples should be collected at least 2 hours postprandially, but preferably after a >4-hour fast.[2]

E-TABLE 75-1

Venipuncture

Pull List—Materials and Equipment	
	Best practice—non-sterile gloves; accepted practice—washed or sanitized hands
	Clippers
	Isopropyl alcohol
	Skin preparation for blood culture—best practice >0.5% chlorhexidine with alcohol
	Tourniquet or manual occlusion
	Cotton ball, gauze square or Telfa pad
	Tape or wrap to use as an adhesive bandage if needed
	Tube holder and needle or syringe and needle or winged collection set
	Sample collection tubes as indicated by the prescribed tests
	Sharps container

Commonly Used Veins			
VEIN	**COMMONLY USED**	**LOCATION**	**COMMENTS**
Jugular	Dog/cat	Both sides of the neck, in furrow, beside trachea	Usually the largest, accessible vein, good for large samples
Cephalic	Dog/cat	Front leg veins	Don't use if scheduled for surgery or chemotherapy
Lateral saphenous (tarsal)	Dog	Lateral aspect of tarsal joint	Easy to visualize but very mobile vein
Medial saphenous/femoral	Cat	Medial aspect of thigh	Good choice for fractious cats

Checklist for Performing Venipuncture

	1. Hand hygiene—accepted practice; also put on non-sterile gloves—best practice
	2. Assemble needed equipment and materials, ensure they are within easy reach
	3. Confirm patient identity and samples needed
	4. Place tourniquet or manually occlude selected vein
	5. Clip hair if needed/required
	6. Use a small amount of alcohol if needed to visualize the vein
	7. Palpate vein—determine size, depth, direction and if suitable for venipuncture
	8. Release tourniquet or manually occlusion
	9. Cleanse the skin—surgical prep required for blood cultures
	10. Reapply tourniquet or manual occlusion
	11. Anchor vein with non-dominant hand—pull skin taut, flex joint, and/or stabilize
	12. Perform venipuncture—bevel up, angle of entry of 15-30°, under skin first if needed
	13. Using a tube holder, fill tubes in appropriate order OR Draw required amount blood
	14. Release tourniquet or manual occlusion
	15. Remove the needle and simultaneously cover venipuncture site
	16. Apply moderate pressure for 1-2 minutes
	17. Clean venipuncture site if needed
	18. Apply tape or wrap to use as an adhesive bandage if needed
	19. Place sharps into sharps container
	20. Label collection tubes
	21. Hand hygiene

Hand hygiene is essential; the use of non-sterile examination gloves is recommended. Palpation using gentle pressure allows for determination of the direction, size, and depth of the vein. Isopropyl alcohol can facilitate visualization of the vein but alcohol contamination of the sample may result in hemolysis. Clipping a small amount of hair is usually acceptable and can decrease the use of alcohol. The skin should be free of gross contaminants, cleansed, and dry. Surgical preparation is required prior to blood culture collection.

The vein should be stabilized with the non-dominant hand placed next to the vein, or pulling the skin taut, or flexing the limb. Venous occlusion should not last >1 minute, which can cause hemoconcentration and discomfort.[3] In dehydrated, thick- or loose-skinned patients, the needle may need to be placed through the skin first, before entering the vein. To enter the vein, the needle should be centered over the vein with the bevel facing up, then advanced using a swift, continuous motion until the entire bevel is within the lumen of the vein. The needle entry angle should be 15° (superficial veins) to 30° (deeper veins). A slight release in resistance may be detected when entering the vein. If no blood enters the syringe, it is appropriate to withdraw, slightly redirect, and advance the needle, minimizing the number of such changes to avoid tissue trauma. The negative pressure applied to the plunger should be slight and continuous. After collecting the sample, venous occlusion is released; then the needle is quickly withdrawn. Moderate pressure should be applied to the phlebotomy site with a cotton ball for 1-2 minutes to prevent bleeding. The phlebotomist must check the site before dismissing the patient. Hand hygiene should be performed post-procedure. Materials and a stepwise approach are listed in E-Table 75-1.

Complications are uncommon when phlebotomy is performed correctly. A hematoma may form if the needle is only partially inserted into the vein, if both the top and bottom walls are pierced, or if the patient moves during the procedure; if noted, stop immediately, withdraw the needle, and apply pressure to the site. Phlebitis can be minimized with aseptic technique and minimal movement of the needle tip. Referencing anatomic relationships of veins to nerves can minimize the chance of injury and nerve pain.[4] Vasovagal syncope during phlebotomy may be more likely to occur in patients with cardiac disease. A good maximum number of blood draw attempts is two, with reasonable certainty of accessing the vein on each attempt. Some test results may be altered by stress, anxiety or fear (E-Table 75-2) and multiple venipuncture attempts increase complications. A change in personnel, restraint, or technique, or the use of sedation, may resolve the problem.

E-TABLE 75-2

Effects of Hemolysis, Lipemia, and Stress on Laboratory Values

TEST	HEMOLYSIS EFFECT	LIPEMIA EFFECT	STRESS EFFECT
ALT	↑ Values	↑ Values	
Albumin	↑ Values	↑ Values	
Amylase	↑ Values	↓ Values	
Ammonia	↑ or ↓ Values		↑ or ↓ Values
AST	↑ Values	↑ or ↓ Values	
Bilirubin	↑ or ↓ Values	↑ Values

Commonly Used Blood Tubes, Their Draw Order, and Handling Instructions

COLOR	SIZES	ADDITIVE	ANTICOAGULANT?	SPECIAL DIRECTIONS	COMMON USES
NA	20 mL	Culture media		Sterile skin prep	Blood culture
Clear	3 mL	No	No	Sterile tube	Discard tube
Light blue (BTT)	1.8 mL	Sodium citrate	Yes	Invert 3-4 times, requires a full draw	Coagulation studies, minimum of 90% fill
Red (RTT)	3 mL	No (glass) coating (plastic)	No	Do not invert—glass Invert 5 times—plastic	Serum chemistry, therapeutic drug monitoring
Red/gray (SST)	3.5 mL	Gel separator and clot activator	No	Invert 5 times	Known as a serum separator or tiger top tube, used for serum chemistry
Yellow (gold)	Microtainer	Same as SST	No	Invert 5 times	Serum chemistry
Green	4 mL, microtainer	Heparin	Yes	Invert 8 times	Plasma chemistry

Lavender (LTT)	2 mL, microtainer	EDTA	Yes	Invert 8 times	Hematology
Gray	3 mL	Potassium oxalate, sodium fluoride	Yes	Invert 8-10 times	Glucose

ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase; *BTT,* blue top tube; *GGT,* gamma-glutamyltransferase; *LTT,* lavender top tube; *NA,* does not apply; *RTT,* red top tube; *SST,* serum separator tube.

This table lists the most common blood collection tubes utilized. Tubes are listed in the recommended order of draw, first to last. Other options exist for specialized, rarely used tests. (Estridge & Reynolds, 2012) (WHO, 2010).

Placement of Peripheral Venous Catheters

A peripheral venous catheter is indicated when ongoing venous access is required. Selection of a vein for a catheter is dependent on the indication, expected duration of use (short/long term), and quantity and type of infusate. The first attempt at catheterization should be as distal on the limb as is practical if difficulties are expected, so repeat attempts can occur more proximally. In all but emergent situations, the smallest gauge catheter adequate for the prescribed therapy should be selected, for adequate blood flow around the catheter and lower risk of phlebitis. Central and jugular catheters are described in ch. 76.

Materials and a stepwise approach are listed in E-Table 75-3 and demonstrated in Videos 75-2 and 75-3. Prior to placement, the catheter should be pre-flushed with saline and spun on the stylet (to ease its advancement off the stylet). Topical anesthesia or local block may be indicated for patient comfort. To prevent intravascular catheter-related bloodstream infections (CRBSI), a complete, aseptic, surgical preparation of the skin using >0.5% chlorhexidine with isopropyl alcohol should be performed.[5] Aseptic technique must be maintained throughout. After successful venipuncture with the catheter and stylet, a blood flash occurs in the hub. Hypotensive patients may not show this indicator, requiring aspiration to confirm placement. The entire bevel of the stylet *and* 1-2 mm more must be entirely in the lumen of the vein. Then, the entry angle is reduced to make the catheter almost parallel to the skin, and the catheter is advanced off the stylet and into the vein. If resistance is felt, the catheter is repositioned until free blood flow is obtained, and then catheter advancement off the stylet is attempted again. The catheter is never pulled back over the stylet, which can cut the catheter tip causing embolization.[6] Digital pressure can be applied proximal to the catheter hub to prevent blood loss during port placement. If the catheter is in the vein lumen but will not advance farther, a "fluid stylet" can be used: the stylet is removed and replaced with a 3-5 mL saline syringe, aspiration confirms that the catheter tip is still in the vein, and then gentle saline infusion allows the catheter to be advanced and "floated" into place. This is demonstrated in Video 75-4. Tape and bandaging material are used for stabilizing, protecting connection points, and securing the catheter.

E-TABLE 75-3

Intravenous Catheter

Pull List—Equipment	
	Best practice—non-sterile gloves; accepted practice—washed or sanitized hands
	Clippers, skin preparation—best practice >0.5% chlorhexidine with alcohol
	Over-the-needle IV catheter—size appropriate to patient and vein
	Local anesthetic
	Injection port and optional T port—useful in small or short-legged patients
	Saline flush
	Tourniquet or manual occlusion
	Tape
	Band-aid or sterile nonadherent (Telfa) pad
	Bandaging material such as cast padding, stretch gauze, non-adhesive wrap

	Sharps container
Some IV Catheter Options for Consideration	
Shaving	Small rectangular shave provided the sterile field is adequate Complete circumferential shave may be indicated in long-haired animals
Asepsis	Cover hair just distal to field to protect catheter sterility during placement Place a Band-aid or sterile nonadherent (Telfa) pad over the venipuncture site
Tape	1-2 pieces with tabs for easy removal is adequate for short-term catheters Cross tape alters the direction of the pull Over/under taping isolates the port for easier injection
Wrap	Simple wrap helps to secure the catheter and ports to the limb Complete wrap of the limb may prevent distal edema
Checklist for IV Catheterization	
	1. Hand hygiene—accepted practice; also put on non-sterile gloves—best practice
	2. Assemble needed equipment and materials; ensure they are within easy reach
	3. Pre-flush catheter and ports with saline
	4. Place tourniquet or manually occlude selected vein
	5. Palpate vein—determine size, depth, direction, and if suitable for catheter
	6. Release tourniquet or manual occlusion
	7. Clip hair—area sufficient for sterile placement up to entire circumference of limb
	8. Surgical preparation of the skin—best practice >0.5% of chlorhexidine with alcohol
	9. Reapply tourniquet or manual occlusion
	10. Anchor vein with non-dominant hand—pull skin taut, flex joint, and/or stabilize
	11. Perform venipuncture—bevel up, angle entry of 15-30°, under skin first if needed
	12. Decrease angle, advance the catheter off the stylet, into the lumen of the vein
	13. Release tourniquet or manual occlusion
	14. Remove the stylet, ± manually occlude vein to minimize blood loss
	15. Place injection port, T-port or venoset into catheter
	16. Secure catheter to limb with tape
	17. Saline flush
	18. Cover venipuncture site with Band-aid or Telfa pad
	19. Apply additional tape and/or bandage material to further secure catheter
	20. Place sharps into sharps container
	21. Hand hygiene

Catheter maintenance should include the following[7]:

- Hand hygiene procedures before and after every catheter maintenance.
- Flushing of the catheter every 4 hours if continuous fluid therapy is not in use.
  - Use plain saline for flushes.[8,9] Aspirate and flush to check for patency.
- Evaluation of the site daily, including removal of the dressing if needed. Assessment for: (1) dampness of bandaging material; (2) tightness of the tape; (3) evidence of phlebitis (pain), thrombosis (palpable venous cord), or infection (warmth); (4) extravasation; and (5) limb swelling distal to the catheter.
- In humans, daily cleansing of the site with 2% chlorhexidine decreases CRBSI.[5]
- Swabbing needleless access ports with chlorhexidine before use (reduce contamination).

To minimize the risk of nosocomial infection, catheters should be replaced every 4 days,[5] if soiled, or if any problems are noted during catheter maintenance. The four recognized routes for contamination of catheters in human medicine are: migration of skin organisms at the insertion site to colonize the catheter tip (most

common), direct contamination of the catheter or catheter hub by contact (hands, fluids, devices), seeding of catheters from another focus of infection (less common), and infusate contamination (rare).[5]

When removing a catheter, material should be cut away or removed until the venipuncture site can be visualized. A cotton ball is placed on the venipuncture site and then the catheter is removed. Moderate pressure is applied for 1-2 minutes and then a wrap is placed for ≈30 minutes. The catheter should be inspected for signs of damage or infection.

Arteries: Arterial Puncture

Arterial puncture is used primarily for assessment of arterial blood gas (ABG) or acid base status (see ch. 128). The dorsal pedal and femoral arteries are used most commonly in dogs and cats (E-Table 75-4) but under certain circumstances, the sublingual, radial, brachial, or aural arteries can be utilized. The choice of artery also depends on adequate collateral circulation, which, in the rare event of arterial occlusion, ensures adequate perfusion to the limb. Arterial puncture is contraindicated in animals with severe bleeding disorders.

E-TABLE 75-4

Arterial Puncture

Pull List—Equipment	
	Best practice—non-sterile gloves; accepted practice—washed or sanitized hands
	Clippers
	Isopropyl alcohol
	Cotton ball or gauze square
	Tape or wrap to use as an adhesive bandage if needed
	Heparin-coated 1-3 mL syringe with a small gauge needle, or blood gas syringe
	Ice bath if collecting blood for blood gas analysis
	Cork or syringe cap
	Sharps container

Commonly Used Arteries		
ARTERY	**LOCATION**	**COMMENTS**
Dorsal metatarsal artery (pedal)	Dorsal aspect of the metatarsus	Smaller but easier access than other arteries
Femoral artery	Medial aspect of the thigh	Increased chance of hematoma formation

Checklist for Arterial Puncture	
	1. Hand hygiene—accepted practice; also put on non-sterile gloves—best practice
	2. Assemble needed equipment and materials, ensure they are within easy reach
	3. Confirm patient identity and sample needed
	4. Clip hair
	5. Palpate artery—determine size, depth, direction and if suitable for puncture
	6. Cleanse the skin
	7. Palpate artery with two fingers of the non-dominant hand
	8. Perform artery puncture—bevel up, angle entry of 45-60°, under skin first if needed
	9. Blood should spontaneously flow, aspirate if needed
	10. Remove the syringe/needle and immediately cap to prevent exposure to air
	11. Place sample in ice bath

	12. Simultaneously cover puncture site and apply moderate pressure for 5 minutes
	13. Clean patient if needed
	14. Apply tape or wrap to use as an adhesive bandage if needed
	15. Place sharps into sharps container
	16. Label syringe
	17. Hand hygiene

If utilizing a syringe, 1000 units (1 mL) of heparin should be drawn into the syringe to thoroughly coat the inside surface, then expelled. No air (falsely lowers $PaCO_2$, falsely elevates PaO_2) or heparin (falsely lowers $PaCO_2$) should be left in the syringe.[10] Use of an arterial blood gas syringe precludes the need for this preparation. Materials and a stepwise approach are listed in E-Table 75-4 and demonstrated in Video 75-5. Skin preparation is as for venipuncture. The preferred technique for arterial palpation is to place two fingers from the non-dominant hand proximal to the puncture site, to determine the location, direction, size, and depth of the artery. Use of Doppler ultrasound may aid localization. Some prefer to hold the syringe and needle like a dart and place the needle in one movement. Others prefer to first place the needle under the skin, then as with venipuncture, advance it into the arterial lumen. A sharper entry angle (45°-60°) minimizes vessel trauma and allows smooth muscle fibers to occlude the puncture site afterward.[10] Bevel-up and bevel-down positions are recognized; the current human recommendation is bevel up. Blood should spontaneously flow into the syringe, but hypotensive or small animals may require aspiration of the plunger. Afterward, manual pressure should be applied to the site for >1 minute, or longer if bleeding or a hematoma is seen. Frequent removal of the pressure should be avoided, but close monitoring of the site is indicated for at least 5 minutes.

Quality assurance techniques for arterial puncture are similar to venipuncture. In addition to residual air or heparin artifacts, the inadvertent submission of venous blood will produce erroneous results. If assessment of the patient breathing room air is needed, oxygen therapy should be discontinued 5-10 minutes before collecting an arterial sample when feasible.[2]

Placement of Arterial Catheters

Arterial catheters are placed for serial ABG assessment or monitoring of arterial blood pressure (see ch. 99). Indications and contraindications include those of arterial puncture and venous catheterization. Additionally, thrombotic risk factors identified in humans are: larger catheter size, hypotension, smaller arterial dimension, multiple arterial sticks, duration of cannulation, administration of vasopressor and inotropic agents, and the cannulation site.[11]

Catheters used for venous catheterization are used for arterial catheterization, although longer catheters are often selected. Material and a stepwise approach are listed in E-Table 75-5 and demonstrated in Videos 75-6 and 75-7. The approach is as described, above, for arterial puncture and venous catheter placement. Placement should be rapid to avoid arterial spasm. The bubble test for confirming arterial catheterization is demonstrated in Video 75-6.

E-TABLE 75-5

Arterial Catheter

Pull List—Equipment	
	Best practice—non-sterile gloves; accepted practice—washed or sanitized hands
	Clippers
	Skin preparation—best practice >0.5% chlorhexidine with alcohol
	Over-the-needle IV catheter—size appropriate to patient and artery
	Injection port
	Heparinized saline flush
	Tape

	Band-aid or sterile Telfa pad
	Bandaging material such as cast padding, stretch gauze, non-adhesive wrap
	Sharps container
Checklist for Arterial Catheterization	
	1. Hand hygiene—accepted practice; also put on non-sterile gloves—best practice
	2. Assemble needed equipment and materials, ensure they are within easy reach
	3. Pre-flush catheter and ports with heparinized saline
	4. Palpate artery—determine size, depth, direction and if suitable for catheter
	5. Clip hair—area sufficient for sterile placement up to entire circumference of limb
	6. Surgical preparation of the skin—best practice >0.5% chlorhexidine with alcohol
	7. Palpate artery with two fingers of the non-dominant hand
	8. Perform artery puncture—bevel up, angle entry of 45-60°, under skin first if needed
	9. Decrease angle, advance the catheter off the stylet, into the lumen of the artery
	10. Blood should spontaneously flow into the hub
	11. Remove the stylet, ± manually occlude artery to minimize blood loss
	12. Place injection port into catheter
	13. Secure catheter to limb with tape
	14. Heparinized saline flush
	15. Cover puncture site with Band-aid or nonadherent (Telfa) pad
	16. Apply additional tape and/or bandage material to further secure catheter
	17. Clearly label as "Arterial Catheter" as indicated by hospital's standard operating procedure
	18. Place sharps into sharps container
	19. Hand hygiene

The importance of catheter stabilization, secure connection points, and protective taping/wrapping is essential for arterial catheters, as substantial blood loss is possible if the catheter is dislodged, the connection leaks, or the catheter is removed prematurely. Arterial catheters must be clearly identified as such to prevent inadvertent administration of infusates. In addition to the venous catheter maintenance list, arterial catheters should be flushed hourly with heparinized saline.[12] Arterial catheters should be removed as soon as possible. When removing an arterial catheter, direct digital pressure should be applied for a minimum of 5 minutes and the limb should then be bandaged for at least 30 minutes.

CHAPTER 76

Jugular Catheterization and Central Venous Pressure Measurement

Meri F. Hall

Jugular catheterization is useful for administration of intravenous fluids, drugs, hyperosmolar solutions, and parenteral nutrition, for blood sample collection, and for measurement of central venous pressure. Jugular catheters usually are well-tolerated, and are less likely to be contaminated in patients with vomiting or diarrhea than are peripheral catheters. Jugular catheters also are unlikely to be chewed out by a patient. Jugular catheters should be used with caution in patients with increased cranial pressure, which catheter placement can exacerbate, with coagulation abnormalities (risk of hemorrhage), or with an increased risk of thrombus formation, notably in patients with hyperadrenocorticism or immune-mediated hemolytic anemia (blood clots can form on the catheter surface).

When placing jugular catheters, it is important to use aseptic technique. This includes aseptic preparation of the skin, sterile draping, and use of sterile gloves. Prior to placing a jugular catheter, it is important to measure the distance from the point of insertion to the thoracic cavity just cranial to the right atrium (e.g., fourth rib), as this will indicate the length of the indwelling portion of the catheter. It is not required to sedate the patient, but sedation could be needed to aid in maintaining sterility due to patient movement. Placement of the jugular catheter can be achieved with the patient in dorsal recumbency, but it is best done with the patient in lateral recumbency. The patient's neck is extended and the forelimbs positioned caudally. A rolled towel can be placed under the neck to help with accessibility to the vessel. A wide area is clipped and prepared with aseptic scrub. The vein is located and visualized. Local anesthetic can be infiltrated, but is not required. The type of jugular catheter used will determine the steps to placement.

There are several types of catheters that can be placed in the external jugular vein: over-the-needle (structure is similar to a standard peripheral IV catheter) or through-the-needle, and single- or multilumen. Over-the-needle catheters are less expensive, but many are not long enough to reach the cranial vena cava except in very small patients, and cannot be used for central venous access in most dogs. For all catheter types, the insertion point into the skin and external jugular vein should be just cranial to the midpoint between the angle of the mandible and the point of the shoulder.

Through-the-needle catheters traditionally have been used in veterinary medicine; the catheter itself is passed inside the needle and into the jugular vein. These catheters are longer than most over-the-needle catheters, but can be problematic if the needle isn't placed in the guard and secured appropriately.

Multilumen catheters are available in double-, triple- or quadruple-lumen versions. They permit the administration of otherwise incompatible fluids, and concurrent fluid administration and central venous pressure measurement.

Placement: Seldinger Technique

Over-the-needle catheters are placed using the Seldinger guidewire technique or using a peel-off sheathed needle (Figure 76-1). The Seldinger technique uses a small introducer catheter and a guidewire to obtain venous access and position the jugular catheter in the vessel (Video 76-1). With the patient recumbent, the assistant holds the animal's forelimbs caudally and briefly occludes the external jugular vein with manual pressure at the thoracic inlet, to identify the vessel's location. The area around the venipuncture site is prepared first. The operator who will place the catheter locates and visualizes the vessel, then opens the catheter pack, keeping the contents sterile. The operator then puts on sterile gloves, flushes each port with sterile saline, and, using aseptic technique, drapes the site with sterile towels. The operator measures the appropriate distance for catheter insertion, as described above, and infiltrates the insertion site with local anesthetic if indicated. Pushing the skin dorsally, away from the jugular vein temporarily to avoid lacerating

it, the operator uses the scalpel blade to make a small (few mm) full-thickness skin incision, then allows the skin to return to its natural position so the incision lies directly over the vessel. The assistant occludes the vein and the operator advances the introducer catheter through the incision and under the skin. The operator directs the introducer catheter into the vein, confirming correct placement by observing blood flow. The operator removes the stylet and advances the guidewire into the vein (Figure 76-2). Many guidewires have a flexible J-tip at the distal end to prevent vessel puncture. The operator passes approximately two thirds the length of the guidewire, distal tip first, into the vein. Keeping hold of the guidewire, the operator removes the needle over the wire. The operator then passes the vascular dilator over the wire and, using a back-and-forth twisting motion, guides it into the vessel, keeping hold of the proximal end of the guidewire. The operator now withdraws the dilator, keeping the wire in place; bleeding is expected from the dilated venostomy site, and it can be controlled with direct pressure if needed. The operator now places the distal tip of the catheter onto the proximal tip of the wire and advances the catheter over the wire up to the venotomy site. The proximal tip of the guidewire will begin to emerge from the proximal port of the catheter. Holding this proximal tip of the guidewire securely, the operator now feeds the catheter farther over the wire and into the vein the desired distance. With the catheter in place, the operator withdraws the guidewire, withdraws any air from the port just vacated by the wire using a syringe, caps and flushes all ports of the catheter with sterile saline, and clamps them.

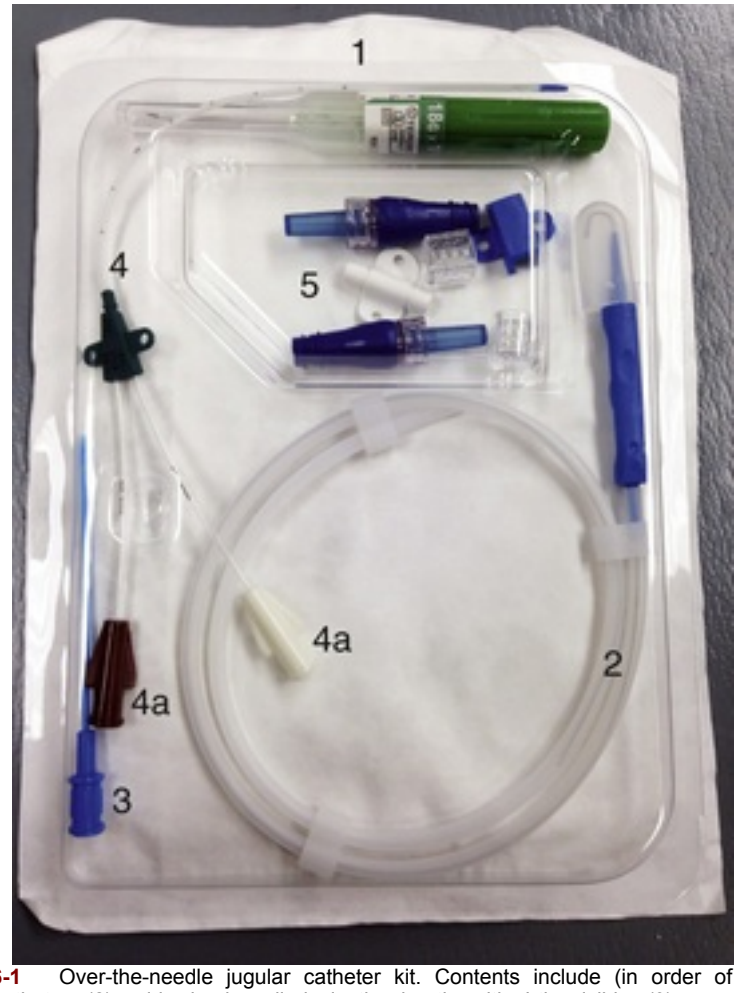

FIGURE 76-1 Over-the-needle jugular catheter kit. Contents include (in order of usage): (1) introducer catheter; (2) guidewire in coiled plastic sheath, with J-tip visible; (3) vessel dilator; (4) double-lumen jugular catheter, with 2 proximal ports (4a); (5) catheter caps and positioning adapters.

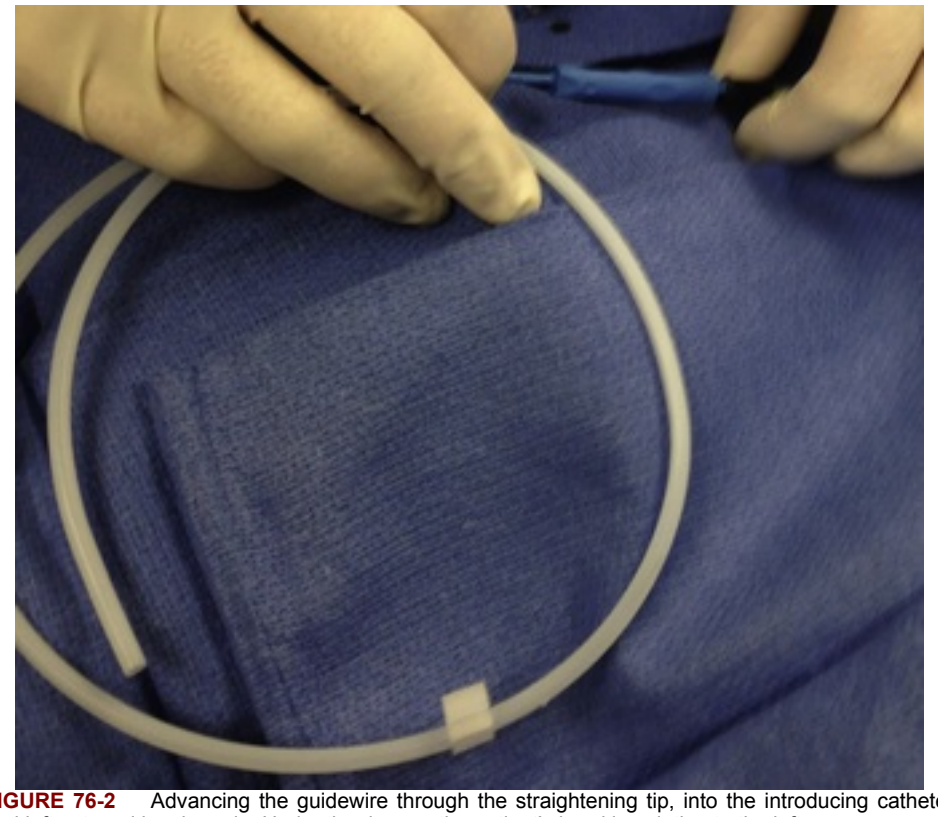

FIGURE 76-2 Advancing the guidewire through the straightening tip, into the introducing catheter and left external jugular vein. Under the drapes, the patient's head is pointing to the left.

The peel-away method uses a special introducer needle that is placed into the vessel like a peripheral catheter. The catheter is introduced through this needle. Once the catheter is in place, the introducer is peeled away and the lumen catheter is left in the vessel.

Once the catheter is in place with either method, it is sutured to the skin across the groove on the catheter base, and via the butterfly wings on the catheter or its positioning adapter (E-Figure 76-3). Special care is essential to not suture through the catheter itself. The area should be cleaned and the catheter bandaged in place. The operator should be sure to incorporate ports into the bandage to avoid contamination and tension when connected to IV tubing (Figure 76-4).

FIGURE 76-4 A soft, complete neck bandage covers the catheter insertion site and protects the catheter, leaving the 2 capped ports accessible. The patient's head is pointing to the right.

E-FIGURE 76-3 Fixation of the catheter by suturing it to the skin, both across the groove in the catheter base (center right) and through the butterfly wings of the catheter (center left). The patient's head is pointing to the left.

Peripherally Inserted Central Catheters

Peripherally inserted central catheters (PICCs) do not involve the jugular vein; therefore, they are useful in animals with head trauma or where there is a concern with increased intracranial pressure during placement. PICC lines are very long and are placed in either the medial or lateral saphenous vein (Video 76-2). Before placement, the distance from the insertion site to the vena cava is measured. They are placed using peel-away introducers and are sutured in place and bandaged to prevent the patient from chewing out the catheter and to keep them as clean as possible.

In small dogs and in cats, the use of a "long-through-short approach" works well. For this approach, an over-the-needle catheter is placed in the saphenous vein; then, the needle is removed from the through-the-needle catheter and the through-the-needle catheter is passed through the indwelling peripheral catheter. The hubs will seat together and a 20-gauge peripheral (over-the-needle) catheter will accommodate a 22-gauge long (through-the-needle) catheter. In small dogs and cats, the lateral or medial saphenous vein is used and the long catheter will be in the vena cava. If the long catheter needs to be replaced, it can be removed leaving the peripheral catheter in place and a new long catheter fed through the peripheral catheter.

After placing any central catheter, a confirmatory lateral radiograph should be taken to ensure proper placement prior to use (Figure 76-5). The bandages should be removed and the catheter site inspected as needed or at a minimum every 24 hours. There should be no clinical signs of thrombosis, infection or phlebitis. In very rare circumstances, a central venous catheter may need to be replaced. As long as the vessel is healthy this can be done by feeding a guidewire into the catheter, removing the current catheter and placing a new one over the guidewire.

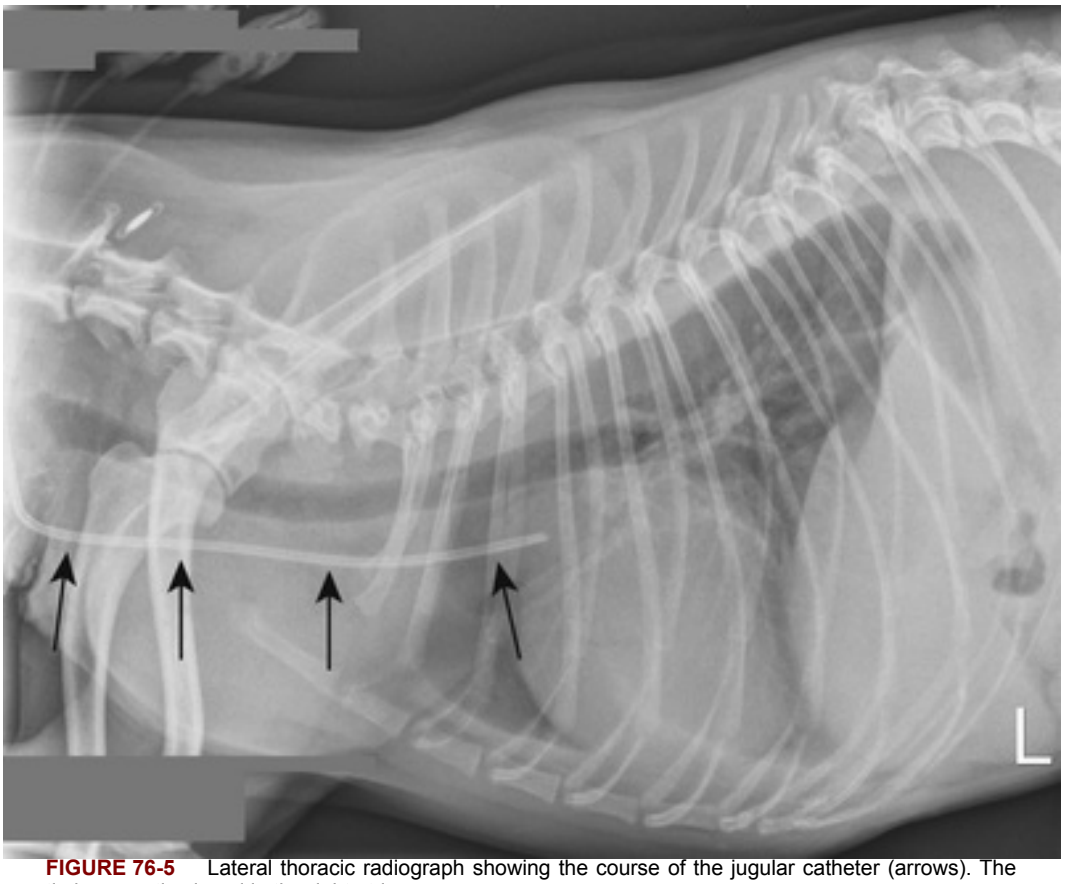

FIGURE 76-5 Lateral thoracic radiograph showing the course of the jugular catheter (arrows). The tip is correctly placed in the right atrium.

Central Venous Pressure Measurement

Central venous pressure (CVP) measurement is determined using either a jugular catheter ending at the point of the right atrium or a PICC line ending in the caudal vena cava. Measurement of CVP is useful in patients with pre-existing heart disease or in cases of high-volume intravenous fluid administration. CVP gives an estimate of the blood pressure entering the right atrium (Figure 76-6). The normal value of CVP is 0-10 cm H_2O. In optimally-perfused canine patients, CVP = 5-10 cm H_2O and in feline patients it is 2-5 cm H_2O. Repeated CVP measurements are very useful for identifying trends in individual patients. An increase in the value can indicate overperfusion, where a decrease in the value can indicate hypovolemia.

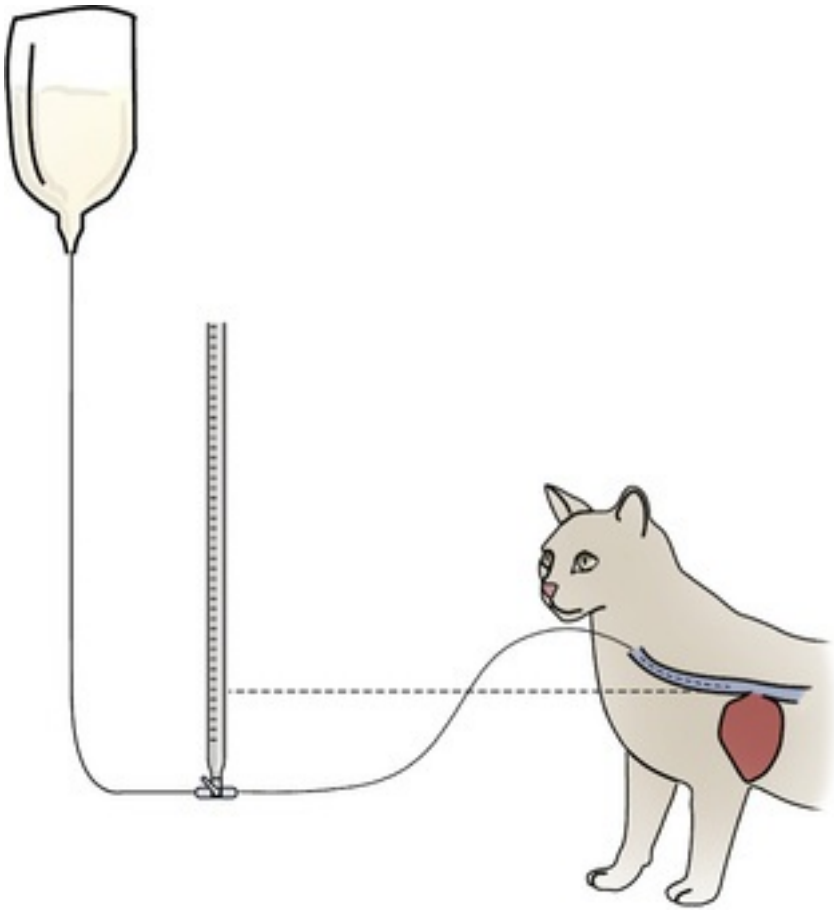

FIGURE 76-6 Correct positioning of the zero mark for manual measurement of CVP. Relative to the floor or bottom of the cage, the zero mark should be at the same height as the right atrium.

In critically ill patients, monitoring of the CVP is used as a guide for maintaining adequate organ perfusion. To obtain a CVP, a centimeter ruler, a manometer, or an electronic monitor will give equivalent results. The CVP can be measured hourly or continually depending on the method used. Confirmation of catheter placement in the cranial or caudal vena cava is required. The patient should be placed in right lateral recumbency, but sternal recumbency is also acceptable.

For manual measurement (ruler or manometer) the system is assembled using a bag of sterile 0.9% NaCl, a three-way stopcock, a measuring system, and extension lines. The "zero" of the ruler or manometer is placed at the level of the right atrium. The stopcock is turned off to the patient, and the manometer or the extension line is taped to the ruler and filled with 0.9% NaCl. The stopcock is then turned off to the fluid bag and in continuity with the patient. The level of the fluid in the manometer is permitted to settle, and this value is recorded as the CVP. Due to natural fluctuations in intrathoracic pressure, the level of the fluid in the manometer can change slightly with respiration.

For electronic monitors, the extension set is connected to a transducer that is attached to the monitor. The system is zeroed in the same manner as with the manometer. The stopcock is turned off to the fluid bag and the number on the monitor is the CVP (Figure 76-7).

FIGURE 76-7 Continuous measurement of CVP produces a numerical value that is displayed in real time on the monitor (arrow).

CHAPTER 77

Intraosseous Catheters

Andre C. Shih

Introduction

Rapid vascular access can be a lifesaving event in many emergent situations encountered by the veterinary practitioner. Intravenous (IV) catheterization remains the gold standard for rapid vascular access and fluid and drug administration (see ch. 75 and 76). However, catheterization of central and peripheral veins can be technically challenging (if not impossible) in emergent situations including vascular collapse, catastrophic shock, and cardiopulmonary arrest.[1] In addition, small patient size, obesity, and venous thrombosis can further delay successful venous catheterization. Among the techniques available to the practicing veterinarian, the intraosseous (IO) route provides safe, rapid, and reliable vascular access for the administration of medications and fluids when IV catheterization is not possible.[1,2] In small animals, an IO catheter can be placed in <2 minutes.[3]

The IO route provides access to the systemic venous circulation via the bone marrow. The marrow is composed of several venous sinusoids that are drained by a venous canal that empties into the venous circulation. These vessels do not collapse even during severe hypovolemia or cardiac arrest.[1,2] Because the intramedullary vessel empties directly into the large central venous system, the time of onset of medications administered via the IO route is comparable to that of medications administered IV. In one study, Congo red administered IO was detected in the central circulation and heart within 10 seconds.[4] There was no difference in the hemodynamic variables between the IO and IV administration of hydroxyethyl starch (HES) in a hypovolemic animal model.[4] Administration of emergency drugs like epinephrine and atropine had faster onset of action by IO route when compared to endotracheal (ET) administration.[4]

Contraindications and Possible Complications

Overall, IO catheter placement appears to be a clinically safe and effective route of vascular access.[1] One large-scale human study examined 4,270 cases of pediatric IO cannulation and found an overall rate of morbidity of <1%.[4] There are, however, some risks to the use of IOs when compared to IV catheters (Table 77-1). Possible complications include fluid extravasation, skin infection, skin necrosis, bone fracture, osteomyelitis, fat embolization, compartment syndrome, and pain at the injection site.[3] In the author's opinion, the most common complication noticed in veterinary medicine is needle dislodgement with inadvertent subcutaneous drug/fluid administration. The IO catheter might be difficult to secure and maintain in place, leading to potential malfunction at a critical time.

TABLE 77-1

Comparison of Possible Complications with Intravenous (IV) Cut-Down Technique versus Intraosseous (IO) Catheterization

IV CUT-DOWN	IO CATHETER
Infection Need to stop chest compressions (CPR) during placement Proper training and surgical supplies required	Infection Dislodgement and fluid extravasation Risk of fracture, embolization, and infection Proper training required

The administration of hypertonic or strongly alkaline agents should be avoided. They have been associated with an increased incidence of local infection, transient medullary histologic changes, and myonecrosis in animal models.[4] Other potential complications include iatrogenic fracture or growth plate injury.[2,4] There is a theoretical risk of bone marrow or fat embolization to the lungs. Animal studies have revealed that high pressure and high volume of fluid administered IO increase the risk of embolism.[4] Despite these animal studies, there have been no documented cases of either fat or cortical bone emboli after IO infusions in veterinary medicine.

There are few absolute contraindications to IO placement. These include severe bone diseases, or the presence of a fracture. Sites that were used previously for IO access should not be used for >1–2 days and repeated attempts at the same site are discouraged.[4]

Techniques

Chemical Restraint and Anesthesia

Adequate sedation or general anesthesia is humane to the patient and will greatly facilitate the insertion of an IO catheter. If the animal is presented comatose, no sedation is usually necessary. Conversely, a conscious, wide-awake patient usually requires some sedation, such as an opioid (e.g., butorphanol 0.3-0.5 mg/kg IM). Patients also will benefit from a local anesthetic block (bupivacaine or lidocaine, 2 mg/kg) administered proximal to the IO site. Care is essential with neonates to avoid the toxic dosage of local anesthetic (the small volume to be injected can impede accurate dosing; do not exceed 4 mg/kg for either bupivacaine or lidocaine).

Equipment

Various needles and devices have been used for obtaining IO access.[3] A simple 20-22 gauge spinal needle can suffice for young kittens and puppies. At that age, bone is soft enough to permit easy placement. This has proven particularly useful in neonatal emergency cases with severe anemia/hypovolemia when presented for initial fluid resuscitation.[3] Hypodermic needles are not as successful: the lack of a handle makes it difficult to properly engage the needle tip in the dense cortical bone. The use of needles without stylets also cause higher incidence of obstruction by bony spicules. Spinal needles or bone marrow aspiration needles such as the Jamshidi needle (Baxter Healthcare, Deerfield, IL) have a stylet and handle for ease of insertion (Figure 77-1 and ch. 92).[5]

FIGURE 77-1 Cat with 15-gauge Jamshidi (Baxter Healthcare, Deerfield, IL) IO needle. Device has a handle to facilitate placement and a stylet to prevent obstruction by bone plug.

Beyond manual devices, there are several products available that have simplified the insertion of an IO needle, as they are not dependent on the manual process.[3,6-8]

The EZ-IO (Vidacare, San Antonio, TX) is a reusable, lithium—battery-powered device that is shaped and operates very much like a small drill (Figure 77-2). It uses a beveled, drill-tip 15 gauge needle that rotates into the IO space at a preset depth. Once the needle enters the IO space by the drilling motion, which is noted by a loss of resistance, the stylet is withdrawn and a metal catheter remains with a Luer-lock attachment left in place. A connection system (EZ-Connect) comes with each needle set and a 90° low-profile extension for delivery of medications and/or fluids (see Figure 77-2).[6-8]

FIGURE 77-2 EZ-IO (Vidacare, San Antonio, TX) battery-powered device used for drilling an IO catheter into position.

The Bone Injection Gun (B.I.G., WaisMed, Kansas City, MO) is a single-use disposable IO device. The "gun" is positioned 90° to the skin and pressed firmly against the skin to trigger a spring-loaded mechanism that actively drives the IO needle into the cortex (Figure 77-3). Once the IO space is penetrated, the device is removed, and the IO needle is left in place. A safety latch slides over the needle to keep it securely placed before taping.[6-8]

FIGURE 77-3 The pediatric version of the Bone Injection Gun (B.I.G., WaisMed, Kansas City, MO) is a single-use disposable IO device.

Both devices are being used in veterinary medicine. A study in dogs found the B.I.G. to provide more rapid

access than the manual insertion of the Jamshidi needle (JN) for fluid administration.[5] A follow-up study in cats demonstrated that all three IO access methods (EZ-IO, B.I.G., and manual JN IO needle) appear clinically acceptable.[3] The EZ-IO device, however, was significantly faster and easier to secure in cat cadavers[3] (Table 77-2).

TABLE 77-2

Success Rate, Insertion Time and Subjective Ease of Insertion for 3 IO Access Techniques in Cat Cadavers[3]

	EZ-IO	B.I.G.	JN
Success rate (%)	96	75	88
Insertion time (sec)	74.4 ± 15	113.0 ± 71	125.2 ± 39
Ease of insertion (quantitative score)	17.1 ± 20	45.5 ± 28	41.7 ± 23

B.I.G., Bone injection gun; *JN*, Jamshidi needle.

Inserting the Intraosseous Catheter

The use of adequate sedation or general anesthesia will greatly facilitate the insertion of IO catheter. Sites used for IO catheterization are the proximal humerus, the craniomedial aspect of the proximal tibia, the trochanteric fossa of the femur, and the iliac crest.

The proximal humerus is an easily accessible site in dogs and cats. The greater tubercle is easily palpated and the needle is placed in the flat area of the craniolateral aspect of the humerus, slightly distal to the greater tubercle. The dominant hand should remain sterile when securing the IO needle, while the other hand firmly holds the distal humerus and externally rotates the humerus to better expose the greater tubercle. The needle is inserted perpendicular to the long axis of the humerus (Videos 77-1 and 77-2).

Another site that is used frequently is the craniomedial surface of the proximal tibia. The flat surface of this portion of the tibia is covered by skin and subcutis but little or no muscle, making access to the bone easier. The dominant hand should remain sterile when securing the IO needle and the other hand firmly holds the distal tibia/fibula region and externally rotates the tibia to better reveal the medial surface of the proximal tibia. The needle is directed perpendicular to the bone and away from the physis (growth plate)[2] (Videos 77-3 and 77-4).

Other less-popular sites for IO catheterization include the trochanteric fossa of the proximal femur, and the iliac crest. The trochanteric fossa is medial to the greater trochanter femur and is best exposed with adduction and medial rotation of the limb. The needle is inserted parallel to the long axis of the femur. The iliac crest is the widest and most dorsal aspect of the wing of the ilium.[2] The crest can be used for bone marrow aspiration but is not commonly used for IO catheter placement because of the high chance of needle displacement during movement. It also can be difficult to palpate in large obese animals.

The selected site should be palpated and the area prepared using aseptic technique, including hair clipping and antiseptic scrub. The operator should put on sterile gloves, and then should make a small stab skin incision over the area using a scalpel blade (#11 or #12). The needle is placed through the stab incision down to the periosteum. The operator drives the needle through the cortex with a firm, back-and-forth rotating action along the long axis of the needle. Usually a decrease in resistance will occur when the needle tip enters the marrow cavity. Once the needle is properly positioned, it should feel firmly seated in the bone. Placement is confirmed by moving the limb: the needle should be firmly embedded in the bone and should move freely with the limb. The stylet can now be removed, a syringe with sterile heparinized saline attached, and the IO catheter flushed and capped (see Videos 77-1, 77-2, 77-3, and 77-4). The IO catheter should be secured using light bandage material and tape. It is important to avoid excessive movement of the limb. If not in use, the catheter should be flushed every 8 hours. Most of the time, IO catheters are removed once long-term IV catheterization is successful.

CHAPTER 78

Constant Rate Infusions

Steven L. Marks

Client Information Sheet: Constant Rate Infusions

The intravenous administration of drugs is commonly utilized in veterinary medicine and allows for immediate and somewhat predictable effects. A constant rate infusion (CRI) is a technique for providing consistent serum, plasma or tissue concentrations of an intravenously administered compound. This method of administration can be utilized in lieu of intermittent bolus techniques.

CRIs can be delivered in parenteral fluids as a component of the patient's fluid therapy or can be delivered independent of the patient's fluid requirements.

After a constant rate infusion is started it takes approximately 5 drug half-lives to achieve steady state.[1] Drugs that are most suited for CRI are drugs with rapid onset and short half-life, which allows them to be titrated to effect. In cases where an immediate therapeutic effect is required, a loading dose of the agent may be administered and followed by the CRI.

In veterinary medicine there are specific indications for the use of CRI. These include but are not limited to time-dependent antibiotics, analgesic agents, antiarrhythmic agents, vasopressors, insulin and antiemetic agents.

See Table 78-1 for commonly used agents and dose protocols.[2,3]

TABLE 78-1

Commonly Used Agents and Dose Protocols

AGENT	CONCENTRATION	DOSAGE
Butorphanol	10 mg/mL	0.2-0.4 mg/kg IV then 0.1-0.2 mg/kg/h
Diazepam	5 mg/mL	0.2 mg/kg/h
Dobutamine	12.5 mg/mL	5-20 mcg/kg/min
Dopamine	40 mg/mL	1-3 mcg/kg/min
Epinephrine	1 mg/mL	0.025-0.3 mcg/kg/min
Fentanyl	0.05 mg/mL	0.003 mg/kg IV then 2-5 mcg/kg/h
Furosemide	50 mg/mL	3-8 mcg/kg/min
Insulin (regular)	100 U/mL	0.1 U/kg/h
Ketamine	100 mg/mL	0.3 mg/kg/h
Lidocaine	20 mg/mL	1-2 mg/kg bolus then 20-80 mcg/kg/min
Medetomidine	1 mg/mL	0.0015 mg/kg/h
Metoclopramide	5 mg/mL	1-2 mg/kg/24 h
Nitroprusside	10 mg/mL	1-10 mcg/kg/min
Norepinephrine	1 mg/mL	0.5-2 mcg/kg/min
Propofol	10 mg/mL	4-6 mg/kg slow bolus then 100-400 mcg/kg/min
Vasopressin	20 U/mL	0.001-0.004 U/kg/min

There are three devices which can be used to administer a CRI to a patient. These devices are volumetric fluid infusion pumps (Figure 78-1), syringe pumps (Figure 78-2) or buretrols (Figure 78-3).

FIGURE 78-1 Fluid infusion pump. (Courtesy Heska, Loveland, CO.)

FIGURE 78-2 Syringe pump. (Courtesy Medfusion, Smiths Medical, Dublin, OH.)

FIGURE 78-3 Buretrol (Pfizer, Inc., New York, NY).

Volumetric infusion pumps are used when adding drug to parenteral fluids. There are numerous manufacturers of these pumps and most are very accurate. When using this technique the clinician must know the dose of drug to be delivered, the fluid rate being administered and the total volume of fluid the drug is being added to. It will also be important to make sure the drug is compatible with the solution it is being added to.[4] As a general guide, the volume of drug being added to fluid bag should be removed from the bag prior to instillation. Overfill volume of fluid bags should also be considered. Multiple pumps can be used to infuse different agents.

Syringe pumps allow the clinician to provide very accurate infusions with minimal difficulty. There are numerous manufacturers. Most syringe pumps are able to be programmed with drug concentration and dose and the pump will deliver at a set rate. Syringe pumps can accommodate a varying size of syringes. The advantage of a syringe pump is that the compound can be delivered either undiluted or in a small volume of fluid.

Both types of infusion pumps have advanced safety features which can detect air in the line, occlusion and when an infusion is complete.

A buretrol is an infusion device which holds a limited amount of fluid to be infused. It is placed in line between a fluid bag and a volumetric infusion pump. This technique is very similar to using the volumetric pump alone but limits the amount of fluid to be administered.

In many cases, multiple IV access points must be used. This will require multiple lines and all lines and pumps should be labeled accurately. There are some multichannel pumps commercially available (Alaris, Carefusion, San Diego, CA) that can deliver multiple CRI agents simultaneously.

In order to calculate how much agent to add to fluids to administer a CRI there are several formulas which can be used.

Formula #1:

$$\text{Drug (mL/h)/Fluid rate (mL/h)} = \text{X mL of drug/total volume of fluid}$$

Example:

Metoclopramide (5 mg/mL) administered at 1 mg/kg/24 h
Patient body weight is 20 kg
Fluid rate is 50 mL/h
20 mg of metoclopramide must be delivered in 24 h, which is 0.83 mg/h
0.83 mg/5 mg/mL = 0.17 mL of metoclopramide/h
0.17 mL/h/50 mL/h = X mL of drug/1000 mL
3.4 mL of metoclopramide 5 mg/mL is added to the liter bag

Formula #2:

$$M = (D)\,(W)\,(V)/(R)\,(16.67)$$

or

$$R = (D)\,(W)\,(V)/(M)\,(16.67)$$

M = mg of drug to add to solution
D = dosage of drug in mcg/kg/min
W = patient body weight in kg
V = volume (mL) of solution
R = rate of delivery (mL/h)
16.67 = conversion constant

Example:

Metoclopramide (5 mg/mL) administered at 1 mg/kg/24 h
Patient body weight is 20 kg
Fluid rate is 50 mL/h
To calculate D: 1 mg/kg/24 h, or 1000 mcg/kg/24 h, or 41.7 mcg/kg/h, or 0.69 mcg/kg/min
D = 0.69 mcg/kg/min
W = 20 kg
V = 1000 mL
R = 50 mL/h
M = (0.69) (20) (1000)/(50) (16.67)
M = 16.6 mg
Metoclopramide is 5 mg/mL, so 16.6/5 = 3.3 mL added to 1 L bag

Formula #3

This is a quick technique for adding drug to a constant volume using a constant flow rate.

$$D \times W = \text{mg of drug to add to 250 mL bag of fluid infused at a rate of 15 mL/h}$$

D = drug dosage (mcg/kg/min)
W = body weight of patient (kg)

Example:

Lidocaine (2% or 20 mg/mL) to be infused at a dose of 50 mcg/kg/min
Patient body weight is 20 kg

50 × 20 = 1000 mg (50 mL) of lidocaine added to 250 mL of fluid run at a rate of 15 mL/h

In addition to these formulas there are web-based CRI calculators which can be used to minimize error (http://www.aucsoc.com/html/dosage_calculator.html).

When using CRI infusions it is important to double and triple check the calculations. Areas of confusion often involve dose (mg or mcg) or time of delivery (minutes, hours or days).

Whenever possible, make sure a second person reviews the calculations and make sure IV lines, fluid bags and syringes are clearly labeled, dated and initialed (Figure 78-4).

CHAPTER 79

Ear Vein Blood Glucose Monitoring

Melanie D. Thompson

Client Information Sheet: Home Blood Glucose Monitoring

In dogs and cats with diabetes mellitus, owner observation of clinical signs and in-hospital evaluation of serial blood glucose curves are common methods for assessing glycemic control. These parameters are also used as aids in determining insulin dose, the type of insulin to be used, and the frequency of injections needed (see ch. 304 and 305). Diabetic dogs and cats are typically hospitalized for glucose monitoring and blood samples are collected at 1- to 2-hour intervals by means of direct venipuncture of a peripheral vein.[1,2] Hospitalization, restraint for blood sample collection, and venipuncture have all been associated with stress hyperglycemia (especially in cats), and some hospitalized pets may not eat.[2] This can complicate interpretation of any blood glucose curve.

Most human diabetics perform self-monitoring of blood glucose concentrations using a portable blood glucose meter (PBGM) and capillary blood. Blood is obtained usually by pricking a fingertip with a lancet device. Such PBGMs are being used to generate serial blood glucose curves in diabetic dogs and cats. These meters are inexpensive, require only a single drop of blood for analysis, and provide results rapidly. In addition, the results obtained with these meters have been shown to be sufficiently accurate for use in clinical practice.[3-6] When only a small amount of blood is required for analysis; use of an ear vein for blood sampling can minimize patient discomfort, preserve the integrity of peripheral veins, and decrease need for physical restraint during sample collection. Studies have shown that the marginal ear vein (MEV) nick technique is a reasonable alternative to venous blood collection for serial measurement of blood glucose concentrations.[7] Two methods of blood sampling from the ear of dogs and cats are described here. Both methods are quick and easy to perform (Video 79-1).

Capillary Blood Sampling with Conventional Lancet Device

The first technique utilizes conventional lancet devices designed for pricking the fingertips of human diabetics. A device with a variable needle depth should be chosen. This allows the appropriate depth to be selected in order to provide an adequate amount of blood for the test (dogs usually require greater depth compared to cats). Although any portion of the inner pinna can be sampled for capillary blood, use of the MEV usually results in little discomfort, the site can be used repeatedly, and size of the drop of blood is usually excellent.

First the MEV is identified (Figure 79-1, *A*). A warm, damp gauze pad (or warm washcloth) can be applied to the MEV to increase perfusion as needed. A thin small film of petroleum jelly should be spread over the sampling site in longhaired pets. This allows the drop of blood to form without dissipating into the fur. The automatic lancing device is then placed over the vein (Figure 79-1, *B*); the ejected needle will nick the ear, causing a drop of blood to form (Figure 79-1, *C*). The person performing the test should place a folded gauze pad between the pinna and the individual's finger to avoid an inadvertent finger nick (the lancet rarely penetrates through the ear). The PBGM (AlphaTRAK2, Abbott Laboratories) with the test strip already inserted is then applied to the drop of blood to measure the blood glucose concentration (Figure 79-1, *D*).

FIGURE 79-1 **A,** The marginal ear vein is visualized. **B,** The automatic lancing device is placed over the ear vein. A folded gauze pad is placed so that the individual performing the test does not inadvertently get nicked. **C,** After the ejected needle nicks the ear, a drop of blood will form. **D,** The portable blood glucose meter with the test strip already inserted is applied to the drop of blood.

Capillary Blood Sampling with Vacuum Lancing Device

A second technique utilizes a vacuum lancing device (Microlet Vaculance, Bayer Diagnostics), to facilitate collection of an adequate drop of blood by creating negative pressure (Figure 79-2, *A*). The device was designed to allow blood collection from body sites other than the fingertips in people and is easily used for obtaining blood from the inner pinna in dogs and cats. It also has variable needle depth. The tip of the pinna is held between thumb and index finger. The surface of the pinna is laid flat by the remaining 3 fingers (Figure 79-2, *B*). The lancet device is then set on a non-haired area of the pinna. An airtight seal between the device and the ear is obtained by pushing the outer (haired surface) of the pinna against the device with the tip of one finger. The entire edge of the endcap must be in contact with the skin (Figure 79-2, *C*). The site is lanced by pressing the plunger cap down until it comes to a complete stop. While pressure is maintained between the endcap and the skin, the plunger is slowly released. This creates negative pressure which is maintained until an adequate drop of blood is obtained. The skin slightly bulges up into the endcap (Figure 79-2, *D*). The person performing the test should place a folded gauze pad or bandage roll between the ear and the individual's finger to avoid an inadvertent finger nick. When an adequate drop of blood has formed, the plunger is pressed three fourths of the way down to release the vacuum and remove the device. The PBGM with the test strip already inserted is then applied to the drop of blood to measure the blood glucose concentration.

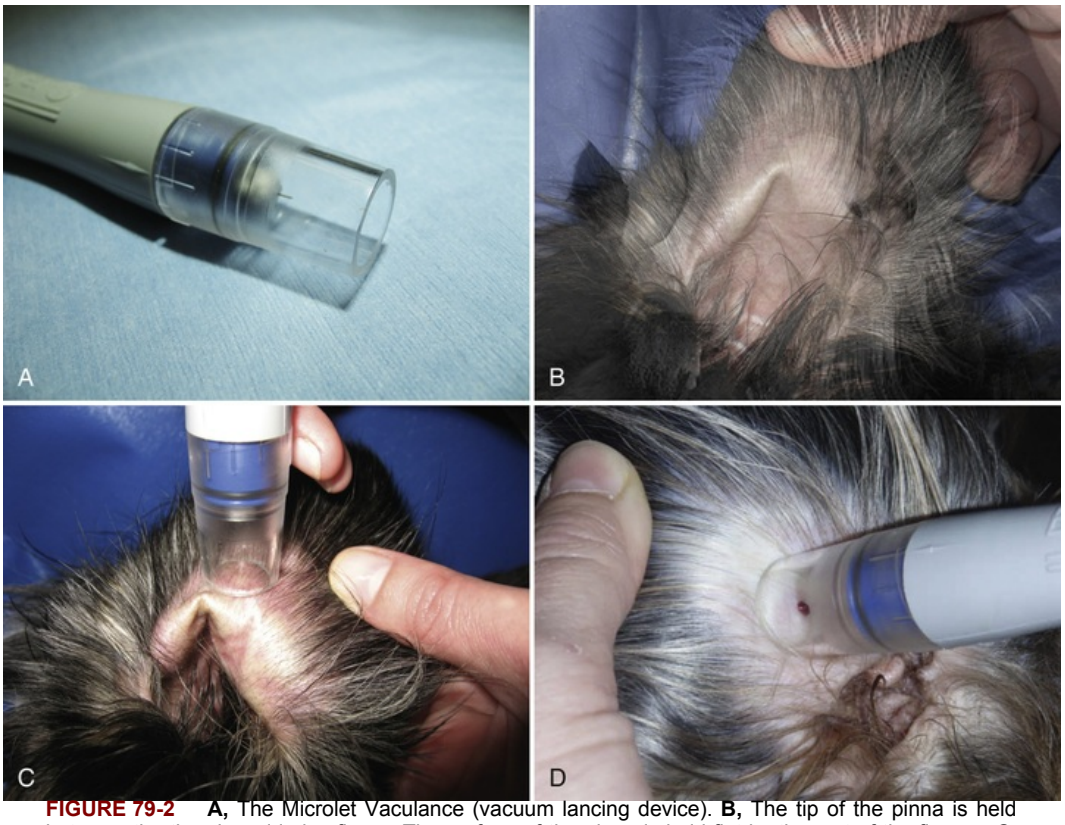

FIGURE 79-2 **A,** The Microlet Vaculance (vacuum lancing device). **B,** The tip of the pinna is held between the thumb and index finger. The surface of the pinna is held flat by the rest of the fingers. **C,** The lancet device is set on a non-haired area of the pinna. The outer surface of the pinna is pushed against the device to form an airtight seal. **D,** After lancing the pinna, pressure is maintained and the plunger is slowly released. Negative pressure causes the skin to bulge up into the endcap.

Other sites can be used for capillary blood sampling (see ch. 304 and 305). In dogs and cats, the carpal and metacarpal pads, respectively, have been validated as an alternative sampling site (Figure 79-3, *A*).[8,9] In dogs, the buccal mucosa has also been validated as an alternative sampling site (Figure 79-3, *B*).[10] Dry the buccal mucosa first with a dry gauze pad prior to sampling. Using the same site can help ensure consistent results. Many veterinarians and technicians who choose not to use the lancet device just hold the lancet or a small gauge needle for direct stick.

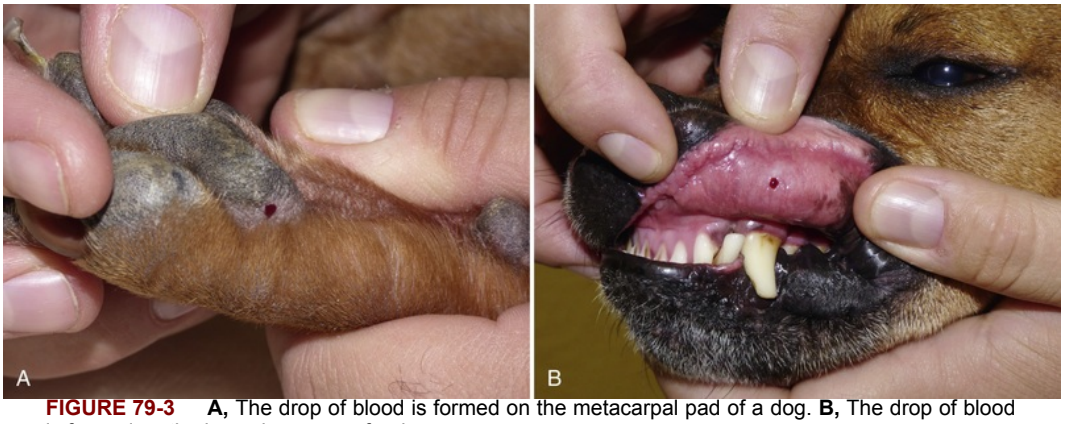

FIGURE 79-3 **A,** The drop of blood is formed on the metacarpal pad of a dog. **B,** The drop of blood is formed on the buccal mucosa of a dog.

Clinicians should be aware that there are limitations to the use of a PBGM. In particular, several factors can affect the accuracy of the blood glucose concentrations obtained with PBGM. These include the level of user training, whether the meter is properly maintained, whether appropriate quality control checks are

performed, whether the animal has any concurrent diseases, and the patient's hematocrit. Other factors that may affect results include altitude, environmental temperature and humidity, the triglyceride concentration, or presence of hypotension or hypoxia.

A PBGM that is simple to operate should be chosen. Portable blood glucose meters are constantly being improved; newer units offer greater precision, faster measurement, decreased blood volume, and decreased operator dependence. Blood glucose results from most PBGMs are lower than the results obtained by reference laboratories and the difference in test results typically increases as the severity of hyperglycemia worsens.[11] A veterinary glucometer (AlphaTRAK, Abbott Laboratories) has been introduced that has been shown to be superior to meters marketed for human use.[11,12] The meter is species-specific (calibrated and validated for use in dogs and cats), accurate, and easy to use. Glucose results obtained from the AlphaTRAK meter were significantly closer to corresponding reference results compared with other PBGMs. Importantly, glucose results should be taken "at face value" because results with this meter may be slightly higher or lower than laboratory results.[11] It is important to become familiar with the PBGM and perform routine maintenance. With practice, veterinarians, veterinary technicians, and veterinary students can become proficient in these techniques, minimizing errors. Capillary blood sampling can become the routine method of generating serial blood glucose curves in the hospital. These techniques can also be taught to clients for home monitoring of blood glucose concentrations. Owners also can be directed to Web sites dedicated to diabetic pets, which contain information on home monitoring of blood glucose. In the search field, type "home blood glucose monitoring of diabetic pets."

CHAPTER 80

Buccal Mucosal Bleeding Time

Christine Savidge

Buccal mucosal bleeding time (BMBT) is an easy, readily available, diagnostic test used to screen for primary hemostatic abnormalities in cats and dogs. Primary hemostasis involves the interactions of functioning platelets, the vascular endothelium, and von Willebrand factor (vWf).[1] Diseases in cats and dogs known to affect primary hemostasis and platelet function include thrombocytopenia (see ch. 59); von Willebrand disease (vWD), thrombasthenia, congenital and acquired thrombocytopathies (see ch. 201); and vascular disorders.

Clinical signs consistent with an abnormality in primary hemostasis include superficial cutaneous bleeding (petechiae, ecchymoses, excessive bleeding at surgical or traumatic sites), mucosal bleeding (gingival bleeding, epistaxis, hematuria and gastrointestinal bleeding) and scleral hemorrhage. Petechiae and ecchymoses develop most commonly on the pinnae, gingiva, ventral abdomen, axillae and inguinal area.[2] See ch. 54 for differential diagnoses of petechiae and ecchymoses. By contrast, secondary hemostatic defects (i.e., disorders of the coagulation cascade) would typically cause hemorrhage into body cavities (e.g., hemothorax, hemoabdomen) or potential spaces (e.g., hemarthrosis).

Initial diagnostic steps to evaluate primary hemostasis in a bleeding or at-risk patient include a thorough history, physical exam, complete blood count, serum biochemistry profile and urinalysis. The history should include drug administration to screen for medications that can trigger thrombocytopenia or coagulation disorders. The complete blood count should focus on platelet parameters such as a platelet estimate on a blood smear, automated platelet count, and mean platelet volume. If quantitative platelet parameters are normal, a bleeding time can be used as a screening test for abnormal platelet function.[3]

The bleeding time is a measure of how long it takes for a small, standardized incision to stop bleeding, an indication of the effectiveness of initial platelet plug formation.[4] The BMBT is a point-of-care test that provides a reliable indicator of primary hemostatic abnormalities in cats and dogs.[1,5] A prolonged bleeding time can identify deficiencies in platelet number, deficient von Willebrand factor, abnormalities in vascular integrity, or abnormalities in platelet function. See ch. 197 and 201 for more information on diseases resulting in abnormal platelet adhesion and aggregation or vascular endothelial dysfunction. The BMBT is most useful in the presence of a normal platelet count. In a moderately to severely thrombocytopenic patient (<70,000 platelets/mcL), a BMBT provides no additional clinical information, as the bleeding time will be predictably prolonged. The magnitude of a prolongation of the bleeding time does not correlate with the clinical severity of abnormal primary hemostasis. Additionally, not all conditions that cause platelet dysfunction will result in an abnormal BMBT. Additional qualitative measures, such as vWf concentration, and *in vitro* platelet function tests, such as optical aggregometry, aperture closure time, and flow cytometry, can be used for complete evaluation of primary hemostasis.[1]

Performing a BMBT[2]

Materials (Figure 80-1):

- Adequate assistance for lateral or sternal recumbency or chemical restraint of the patient
- Fully automated spring-loaded device to make a standardized incision (5 mm long × 1 mm deep)
  - Surgicutt Adult template bleeding device (International Technidyne Corp., Edison, NJ)
  - Simplate II (Organon Teknika Corp., Durham, NC)
- 5 cm wide roll gauze
- Blotting paper/filter paper Whatman #1 filter disc (Fisher Scientific Co., Clifton NJ)
- Stopwatch

FIGURE 80-1 Material and equipment for performing a buccal mucosal bleeding time.

The BMBT test (Video 80-1) can be performed in conscious, sedated,[6] or anesthetized dogs and in sedated or anesthetized cats. With the patient in lateral or sternal recumbency, the maxillary lip is everted and held in place with a gauze strip tied around the muzzle. In a conscious dog, the gauze is not well tolerated around the maxilla alone, and as a result, tying the gauze around the entire muzzle (maxilla + mandible) will be necessary. The gauze is tied tightly enough to create venous congestion. In cats or brachycephalic dogs, the gauze is tied caudal to the ears.

It is important to use a standardized device that creates a 5 mm long and 1 mm deep incision, as devices that create smaller incisions, such as Surgicutt Junior or Newborn for people (Kitvia, Labarthe-Inard, France), or a scalpel blade, can result in different bleeding times,[7] thereby increasing the likelihood of an inaccurate result.

After removing the safety clip, the automated, spring-loaded blade device is gently and evenly placed against the labial mucosa at the level of the maxillary canine tooth, rostral to the gauze. It is important to avoid visible blood vessels and highly vascularized areas.[5] The incision is made either perpendicular or parallel to the lip margin.[2,5] The device is activated, and as an incision is made, the time is started on the stopwatch. The device is removed and discarded immediately after making the incision. With blotting paper, blood droplets are caught 2-4 mm below the incision. It is important that the incision remains clearly visible, because it is essential to not disrupt the forming clot by touching the incision. In an awake dog, any blood that reaches the patient's mouth or tongue can bother the patient, resulting in movement or attempted licking and disrupting the procedure. Blood droplets continue to be caught and absorbed on the filter paper, until the incision is not actively bleeding. At this time, the stopwatch is stopped. The bleeding time is defined as the length of time from the creation of the incision to the time when bleeding has stopped, indicating initial platelet plug formation.[4]

Published reference intervals for normal BMBT are 1.8-4.7 minutes in dogs[4,5,8] and 0.5-2.5 minutes in

cats.[9,10] For clinical purposes, BMBT <4 minutes is considered normal in dogs and BMBT <3 minutes is considered normal in cats.[9] Dogs with thrombopathia,[5] thrombasthenia,[11] type II or III vWD[5] and cats with Chédiak–Higashi syndrome[10] can have bleeding times >13 minutes.

For any given test there is operator variability, and with the BMBT even intra-operator repeatability can differ by more than a minute.[12]

There are many advantages of the BMBT in assessing primary hemostasis in cats and dogs. The BMBT is a simple test to perform. It is specific and fairly sensitive for both quantitative and qualitative primary hemostatic dysfunctions, though not specific for the type of abnormality.[8] The BMBT is considered to be essentially painless, non-invasive, and well tolerated in an easily restrained patient.[8] The required equipment is minimal (see Video 80-1), inexpensive, and readily available to practitioners. Limitations to the BMBT include that it is operator-dependent[12] and not sufficiently sensitive to detect mild bleeding disorders.[13] In humans, poor sensitivity is seen with mild type I vWD.[14] The BMBT is not helpful in identifying clotting factor disorders/coagulopathies and offers no additional information in a thrombocytopenic patient. The location and plane, as well as the vascularity and capillary density, of the chosen site of the incision and the extent of venocongestion can affect the BMBT.

In screening people for primary hemostatic disorders, bleeding times have been replaced by platelet function analyzers (e.g., PFA-100 assay) with increased reproducibility and improved sensitivity. While the PFA-100 assay may be superior to BMBT and is ideal when available, the PFA-100 assay is ideally run within 5 hours of sample collection[13] and equipment is not always accessible to many practitioners. The BMBT stands as a good screening test for abnormal primary hemostasis in small animal patients.

Causes of a Prolonged BMBT

See ch. 201 for a complete list of platelet disorders.

Inherited thrombocytopathies: intrinsic platelet function defects are rare.

- Impaired platelet adhesion and aggregation in vWD, a hereditary deficiency of vWF reported in various dog breeds and rarely in cats. vWD can result in a bleeding time more than three times normal.[5]
- Disorders of platelet membranes include Glanzmann's thrombasthenia in Otterhounds and Great Pyrénées dogs.[11]
- Disorders of platelet secretion are seen in Spitz[15] and Basset Hound thrombopathy[15] and platelet granule storage pool deficiency in American Cocker Spaniels[16] and feline Chédiak-Higashi syndrome.[10]

Acquired thrombocytopathies: platelet function is not consistently altered.

- Uremia, due to defective platelet adhesion[17]
- Hepatic disease, due to decreased platelet aggregation[18]
- Anemia[5,19]
- Dysproteinemias and disseminated intravascular coagulation are thought to result from platelet coating by paraproteins and fibrin degradation products.[5]
- Infectious causes that may prolong BMBT include: canine leishmaniasis,[20] ehrlichiosis, and anaplasmosis.[21]
- Myeloproliferative diseases and vasculopathies, e.g., vasculitis and inherited vascular defects[1]
- Intravenous infusion of dextran 70 in dogs[5]
- Nonsteroidal anti-inflammatory agents that inhibit cyclooxygenase 1 (COX-1) result in decreased thromboxane A_2, which will interfere with platelet function. Aspirin inconsistently prolongs the canine BMBT[22,23] while COX-1–sparing drugs, like carprofen and meloxicam,[24] do not.

Cutaneous bleeding times are described as an alternative to BMBT in dogs.[23,25] Results are not standardized, as there is great variation in skin thickness in different breeds. Cuticle bleeding times, performed by clipping a toe nail and determining the bleeding time, have been used for assessing coagulation. These are difficult to standardize, do not differentiate between primary and secondary hemostasis, and are painful unless performed under general anesthesia.[4,8] The cutaneous and cuticle bleeding times are not recommended by the author.

BMBT is a valuable diagnostic test when screening a patient for moderately to severely delayed primary hemostasis. The BMBT can be used prior to surgery when there is a concern for acquired or congenital

platelet dysfunction. The BMBT is an important part of the diagnostic workup for any bleeding patient with normal quantitative platelet parameters and normal prothrombin and activated partial thromboplastin times when specific platelet function tests are not immediately available.

CHAPTER 81

Fecal Examination

Byron L. Blagburn, Jane D. Mount

Internal parasites are prevalent and important disease agents in companion animals, and a potential cause of zoonotic disease in pet owners (see ch. 40, 42, 210, 276, and 277).[1,2] Fecal detection of internal parasites is an important component of veterinary practice. Techniques include direct smear (wet mount), sedimentation, flotation (both centrifugal and standing), Baermann procedure, and fecal immunologic and molecular biologic techniques. Although the latter are not yet used commonly in the veterinary hospital, they are available at some diagnostic and reference laboratories, or can be requested from academic laboratories. Failure to employ "best practices" techniques when conducting fecal examination procedures can result in failure to detect parasite stages in fecal specimens.[3-7]

Collecting and Storing Fecal Specimens

For most procedures, we recommend the use of at least 2 grams of feces. Two grams of firm, normal feces will form a cube approximately ½ to ¾ of an inch on a side. Occasionally it is necessary to use a sample obtained with a fecal loop or a rectal thermometer. In these cases, a negative result can be meaningless; a positive result can imply a high level of parasitism. The specimen size should be increased as the amount of water in the sample increases. Ironically, diarrheic fecal specimens from animals with a large burden of parasites may contain fewer fecal parasite stages because of this dilution effect.

Collect fresh fecal specimens immediately after defecation, if possible. Specimens collected from the ground may contain eggs, larvae or other stages of free-living organisms. Feces should be stored in a container that will exclude air. A plastic bag or container with a tightly secured lid will suffice. Specimens should be held in a cool dry location, out of direct sunlight. Storage in a standard refrigerator would be ideal, although most clients are reluctant to do so. Samples can be refrigerated for several days to a week without affecting most parasites. Trophozoites of *Giardia* and *Tritrichomonas,* and certain nematode larvae, will not survive storage. When these parasites are suspected, the specimen must be examined immediately. It is best to examine specimens as soon as possible after submission. If fecal specimens are maintained at room temperature for more than a day or two prior to examination, many eggs and oocysts will begin to embryonate or sporulate. Recognition of partially embryonated or sporulated eggs or oocysts can be a challenge. Fecal specimens can be fixed in 5-10% buffered formalin if a sample is to be submitted to another laboratory. If molecular or immunologic techniques are to be used by the reference laboratory, it is always a good idea to inquire as to how best to fix and submit the specimen.

Gross Examination of the Fecal Specimen

Fecal specimens should be examined grossly for consistency (formed, semi-fluid or pulpy, fluid), and for the presence of fresh blood (hematochezia), mucus, or intact parasites. Parasite-induced damage to the small intestine often results in dark, tarry feces (melena), indicating the presence of partially digested blood (see ch. 41). Color, consistency and the presence of mucus or froth (air bubbles) are often indicators of gastrointestinal disease that may be caused by parasites (see ch. 40, 42, 276, and 277).

Fecal Smear

We have included a video and photographs depicting the following procedures (Figures 81-1 through 81-15; Video 81-1). The direct fecal smear or "wet mount" is used to detect motile protozoa such as *Giardia, Tritrichomonas, Pentatrichomonas,* amoeba, or larvae that may be damaged by flotation solution. Some presume

that if only a small amount of feces is available, the direct smear should be the procedure of choice. This is not true. Selection of techniques should not be dictated by the amount of feces. If an overall assessment for parasites were intended, the best technique would be centrifugal flotation. If the sample is fluid, it is probably best to examine the specimen using both a direct smear and centrifugal flotation even though the size of specimen may be small for each.

FIGURE 81-13 Add flotation solution to form a meniscus.

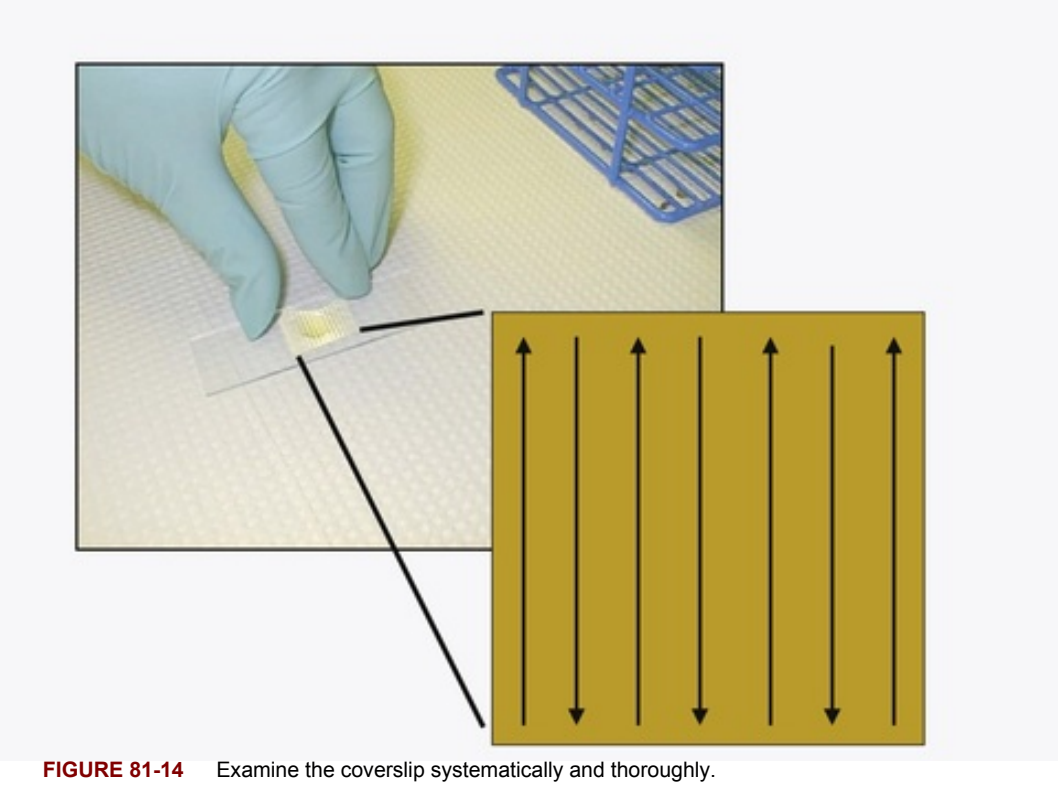

FIGURE 81-14 Examine the coverslip systematically and thoroughly.

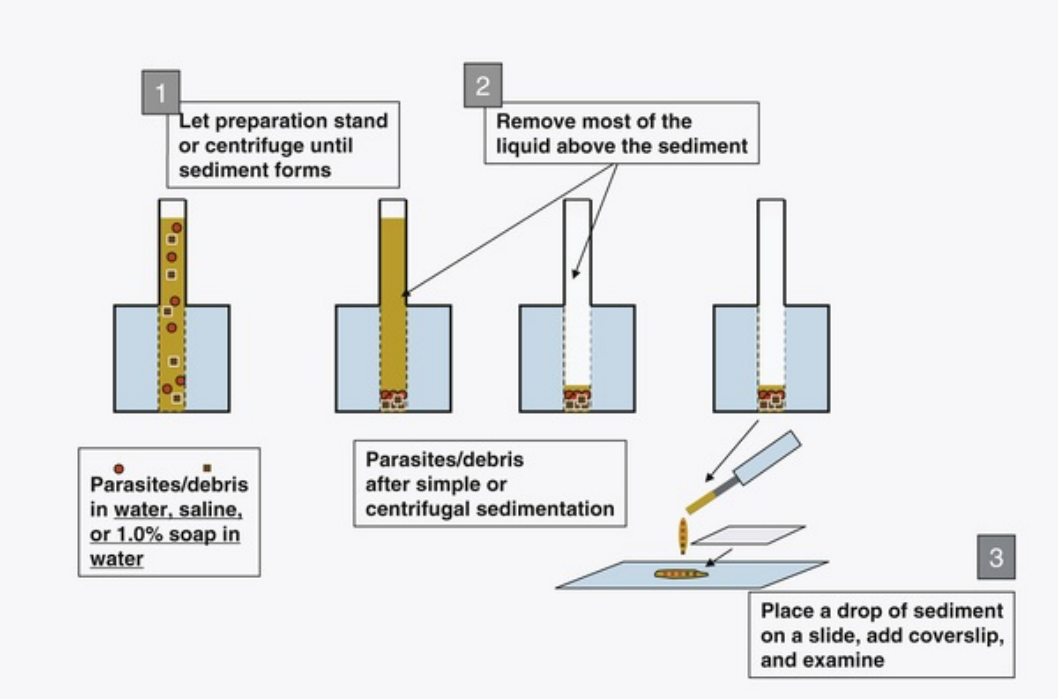

FIGURE 81-15 Performing a fecal sedimentation procedure.

The direct smear is performed by placing a small amount of feces (some say peppercorn size), using an applicator stick into a small amount of warm or room temperature 0.85-0.9% saline or lactated Ringer's solution (Figure 81-1). Do not use tap water because it will usually rupture fragile protozoa. We use 22 × 22 mm coverslips, but some parasitologists use 22 × 40 mm coverslips and claim that they make the specimen layer thinner and easier to read. The most common mistake in preparing a direct smear is using too much

fecal sample. Prepare specimens so that newsprint can be read when placed under the slide containing the preparation (see Figure 81-1). Always adjust the contrast on the microscope by rotating the sub-stage condenser to better see small parasites. Do not lower the sub-stage condenser because this will decrease the resolution of the microscope. We often add a drop of Lugol's or D'Antoni's iodine to the slide prior to adding the coverslip or we "wick" it under the edge of the applied cover slip (Figure 81-2). This will increase the detail of internal structures. Keep in mind that iodine will kill the organisms so that they are no longer motile. Other parasite stages, such as hookworm eggs and coccidial oocysts will also stain brown and may not be recognized. Smears may also be stained with methylene blue or other stains.

Fecal Flotation Techniques

Fecal flotation is the most common fecal procedure performed in veterinary clinics and laboratories. Fecal flotation is intended to separate parasites from other objects and debris based on their different densities.[3] Fecal flotation is based on the principle that when a fecal specimen is placed in a sugar or salt solution, parasites (and other objects) that are less dense than the flotation solution will move to the top; those that are more dense will eventually settle to the bottom. The densities of some common parasites and flotation solutions are given in E-Box 81-1 and E-Table 81-1.

E-Box 81-1

Common Fecal Flotation Solutions

Magnesium Sulfate

($MgSO_4$: SG = 1.20)
Add 450 g of $MgSO_4$ to 1,000 mL of warm tap water

Zinc Sulfate

($ZnSO_4$: SG = 1.18-1.20)
Add 331 g of $ZnSO_4$ to 1,000 mL of warm tap water

Sodium Nitrate

($NaNO_3$: SG = 1.18-1.20)
Add 338 g of $NaNO_3$ to 1,000 of warm tap water

Sodium Chloride

(NaCl: SG = 1.18-1.20)
Add 350 g of NaCl to 1,000 mL of warm tap water

Sheather's Sucrose Solution

(SG = 1.27)
454 g granulated sugar
355 mL tap water
6 mL formaldehyde

1. Heat the water to near boiling.
2. Add the granulated sugar and stir until it is dissolved.
3. Allow the mixture to cool to room temperature before adding the formaldehyde.
4. Check the specific gravity. Adjust to 1.27 using either tap water or sugar.

E-TABLE 81-1

Densities of Common Parasites and Flotation Solutions*

FLOTATION SOLUTION	DENSITY (SPECIFIC GRAVITY)	PARASITE EGG	DENSITY (SPECIFIC GRAVITY)

Sodium nitrate (338 g/L of water)	1.18-1.20	*Toxocara canis*	1.09
Zinc sulfate (331 g/L of water)	1.18-1.20	*Toxocara cati*	1.10
Sheather's sucrose[†] (454 g/355 mL of water, 6 mL of formaldehyde)	1.25-1.27	*Ancylostoma* spp.	1.06
Sodium chloride (350 g/L of water)	1.18-1.20	*Trichuris vulpis*	1.15
Magnesium sulfate (450 g/L of water)	1.20	*Taenia* spp.	1.23
		Physaloptera spp.	1.24

[*]Modified from references 4 and 6.

[†]Heat the water to near boiling. Add the granulated sugar and stir until it is dissolved. Allow the mixture to cool before adding the formaldehyde. Check the specific gravity and adjust to 1.27 by adding either water or sugar.

In preparing fecal specimens for flotation, it is desirable to eliminate large debris (Figures 81-3 through 81-6; see Video 81-1). First, the fecal specimen is added to flotation solution and the tube is filled to about 80% of its capacity. The mixture is stirred to distribute the fecal material. If sucrose is used, you can minimize air bubbles by stirring slowly. The mixture is poured through a strainer or 1 to 2 layers of gauze sponges into another clean container, and then into a centrifuge tube. In our laboratory, we use disposable paper cups, disposable tongue blades and washable tea strainers (Figure 81-7).

Flotation Solutions

Common densities of fecal flotation solutions and parasites are listed in E-Box 81-1 and E-Table 81-1. Notice that the densities of most of the solutions are between 1.18 and 1.20. Also notice that the densities of most of the common parasites in E-Table 81-1 are less than 1.18. We are often asked why flotation solutions are not prepared at the highest density possible. Couldn't we then recover the heavier parasite stages (i.e., *Taenia* and *Physaloptera;* see E-Table 81-1)? We could prepare the solutions at densities of 1.35. The problem with very dense flotation solutions is that they not only float the heavier parasites, they also float the heavier debris. Too much debris on the slide can make the preparation more difficult to read, or it can interfere with the flotation of parasites. High flotation densities also can damage or distort certain parasites. We recommend specific gravities between 1.18 and 1.27 for optimal recovery of parasites.[4] Sucrose solution prepared at a specific gravity of 1.27 and combined with centrifugal flotation results in the highest parasite recovery.[7] Check the density of the solution with a hydrometer when they are prepared and at weekly intervals (see E-Table 81-1; Figure 81-8). Instruments used to measure specific gravity of urine or salt-water fish should not be used to measure flotation solutions.

Centrifugal Flotation vs. Standing Flotation

Centrifugal flotation is more sensitive than standing flotation. The reason is simple; forces that we can apply to the parasites when we spin the tubes in a centrifuge are greater than the forces that we apply during standing flotation. Recovery is greatly improved for heavier eggs such as *Trichuris vulpis* (whipworms) and *Taenia* spp. (tapeworms), and substantially for *Eucoleus (Capillaria)* spp. and *Cystoisospora* (coccidia) spp. when centrifugal flotation was used.[4-7] Given that well-cared-for pets harbor fewer parasites than feral or stray animals, it is important to use centrifugation to increase parasite recovery rates.[4,5]

Contrary to presumption, swinging bucket and fixed angle centrifuges require little hospital bench space. Many are less than 16 inches in length. Most centrifuges are reasonably priced and can be used for decades with minimal service and little or no repair. Also, a variety of rotors is available to suit the needs of the busiest of practices. Examples of commercially available centrifuges are given in E-Tables 81-2 and 81-3, and Figure 81-9 (see Video 81-1).

Standing Flotation

Standing flotation (sometimes called "passive," "simple" or "table-top" flotation), depends on the force of gravity to move heavier objects (debris) to the bottom of the tube, and the buoyant force to move lighter objects (parasites) to the top. The procedure is detailed in Figure 81-10. Specimens are prepared as described above and in Figures 81-3 through 81-6. The fecal specimen is mixed with flotation solution and passed through a tea strainer or gauze sponge. The filtrate is added to a tube, a reverse meniscus is formed, and a coverslip is placed. The preparation is allowed to stand for a minimum of 15 minutes. The coverslip is then removed and examined for parasites.

Centrifugal Flotation

Centrifugal flotation is the procedure of choice for concentration of parasites from feces.[7,8] It is considered to be the gold standard for fecal examination.[8] The term used for characterizing the force applied to parasites in a centrifuge is relative centrifugal force (RCF). If the RCF is known, a centrifugal procedure can be reproduced using any centrifuge for which the rotor radius can be measured. A nomogram is used to determine the revolutions per minute that will achieve a comparable RCF on centrifuges with different rotor sizes (see Figure 81-10).[9] Centrifugal flotation can be performed using either a swinging bucket or fixed angle centrifuge. We prefer the swinging bucket centrifuge because it decreases the number of times that the specimen is handled (Figure 81-11). When using a swinging bucket centrifuge, place the specimen into a tube holder (bucket) in the centrifuge. Add flotation solution to form a reverse meniscus at the top of the tube. Gently place a coverslip on the tube. It is important to avoid trapping air bubbles under the slide. This can be prevented by placing one side of the coverslip in contact with the tube and then slowly "layering" the remainder of the coverslip over the meniscus of the specimen. The speed of the rotor should be increased gradually. This is only possible if the centrifuge is equipped with a dial, knob or digital entry button that will allow you to increase the speed incrementally. If the rotor speed is increased gradually to the target speed, the centrifuge bucket will move slowly to a horizontal position and the coverslip will remain in place. If the speed of the rotor is increased too rapidly, the coverslip may be dislodged from the specimen tube. If the centrifuge does not have variable speeds, follow the instructions below for the fixed angle centrifuge. After the required centrifuge time of 10 minutes, turn off the centrifuge and allow the rotor to come to a complete stop. Remove the coverslip in one upward motion and place it on a microscope slide. Place one side of the coverslip on the slide first and "layer" it onto the glass slide as described previously to prevent entrapped air bubbles.

Centrifugal flotation using a fixed angle centrifuge requires a change in procedures after spinning the sample (Figure 81-12). Because the specimen is placed in the centrifuge at an angle, it is not possible to form a meniscus at the top of the centrifuge tube or to place a coverslip on the tube. Also, since the tube is not topped with a coverslip, the final speed at which the specimen is centrifuged is not as important, nor is it necessary to start the centrifuge at a slower speed. However, faster centrifuge rates can be used without adversely affecting the result. We do not suggest reducing the centrifuge time to less than 5 minutes. Allow the centrifuge to stop as described above. Remove the centrifuge tube, place it in a holder and add flotation solution to form a reverse meniscus (Figure 81-13). Follow the same procedure for placing the coverslip as described previously. Allow the specimen to stand for a minimum of 10 minutes before removing the coverslip to a slide and examining it for parasite stages. If sucrose is used as a flotation solution, we have found that it may be necessary to allow the tube and coverslip to stand for 15-20 minutes to recover all of the parasites stages. It is not necessary to wait longer than 10 minutes when all other flotation solutions are used.

Proper Examination of the Coverslip

The coverslip should be examined thoroughly and systematically. A prepared fecal slide is three-dimensional, meaning that it has length, width and depth. The latter is the most important. Focus on dust on the top of the coverslip and then move downward. The smaller parasites (i.e., *Giardia, Cryptosporidium,* small coccidia) will be found in the top-most layer. The next layer down will contain the large eggs (roundworms, hookworms, whipworms), larger oocysts and larvae. Begin at one corner of the coverslip and move systematically through the specimen as shown in Figure 81-14. Focus up and down as you move through the specimen, unless a parasite of particular size is suspected. If this is the case, you may concentrate your efforts at the layer in which that parasite is found. The entire coverslip should be examined using the 10× objective (total magnification 100×). Small parasites or other objects should then be examined using the 40× objective (total magnification of 400×). The 100× (oil immersion) objective should not be used to examine fecal flotation slides. Some laboratories will "spot-check" 5-10 fields in the center of the slide using 400× magnification to ensure that very small parasites are not overlooked.

Fecal Sedimentation

Sedimentation is used to concentrate eggs or larvae that are too dense to float in flotation solutions or that might be distorted by the solutions. Sedimentation can be performed using either the standing or centrifugal procedure, but without flotation solution. We prefer to use a centrifuge because it results in faster movement of parasites to the bottom of the tube. To perform the procedure, mix the fecal specimen with either saline, water, or 0.1 to 1.0% soap in water solution and add the mixture to a centrifuge tube (Figure 81-15). Centrifuge the specimen or allow the tube to stand undisturbed for 30 minutes. Most of the supernatant is then removed and the entire sediment is examined microscopically. Some parasitologists recommend re-suspending the sediment a second time and then repeating the above steps.

Baermann Procedure
