CHAPTER 346

Soft-Tissue Sarcomas*

Margaret C. McEntee

Client Information Sheet: Injection-Site Sarcomas in Cats

Introduction

Definitions

Collectively, soft-tissue sarcomas (STSs) include several histologic subcategories derived from neoplasms of mesenchymal origin (Box 346-1). Distinct biologic behaviors have been described for tumors in each of these subcategories but the collective experience of pathologists and specialists managing sarcomas in dogs has permitted development of a histologic grading scheme that describes predicted tumor behavior by the degree of differentiation rather than by specific histologic type (Table 346-1). Histologic grade of a tumor can suggest radical versus functional surgery or be used in the decision process regarding the addition of radiation therapy (RT) or chemotherapy. Tumor size and location also impact surgical options for local control.

Box 346-1

Histologic Categories of Soft-Tissue Sarcomas in Dogs and Cats

Fibrosarcoma
Peripheral nerve-sheath tumor (malignant schwannoma, neurofibrosarcoma, hemangiopericytoma)
Myxosarcoma
Malignant fibrous histiocytoma
Synovial cell sarcoma
Neurofibrosarcoma
Rhabdomyosarcoma
Leiomyosarcoma
Liposarcoma
Schwannoma
Undifferentiated sarcoma

TABLE 346-1

Proposed Grading Criteria for Canine Soft-Tissue Sarcomas

SCORE	DEGREE OF DIFFERENTIATION	MITOTIC INDEX*	NECROSIS
1	Normal appearance	0-9	None
2	Specific histologic type	10-19	<50%
3	Undifferentiated	≥20	>50%
Grade (Cumulative Score)			
1	3 or 4		
2	5 or 6		

3	7, 8, or 9		

*Number of mitotic figures/10 high-powered fields (40×).

Adapted from Kuntz CA, Dernell WS, Powers BE, et al: Prognostic factors for surgical treatment of soft-tissue sarcomas in dogs: 75 cases (1986-1996). *J Am Vet Med Assoc* 211:1147-1151, 1997.

Despite the general consensus that grade may influence success in complete tumor removal, debate continues regarding the universal applicability of histologic STS grade as a clinically meaningful predictor of response to therapy in dogs. To date, no consistent convincing evidence exists for comparison of grade with outcome for feline STSs. Cellular proliferation as measured by argyrophilic nucleolar organizing regions score, as well as intratumoral microvessel density using factor VIII–related antigen as the endothelial marker, have been investigated in canine STSs and may supplement the prognostic information provided by tumor grade.[1,2] Specific histopathologic types of tumors that have been reported in cats with injection-associated sarcomas (IAS; previously referred to as *vaccine-associated sarcomas [VAS])* include fibrosarcoma, undifferentiated sarcoma, osteosarcoma, rhabdomyosarcoma, liposarcoma, malignant fibrous histiocytoma (or myofibrosarcoma), and leiomyosarcoma. Hemangiosarcomas (see ch. 347), synovial cell sarcomas (see ch. 348), and mast cell tumors (see ch. 349) are discussed separately. Other, less common sarcomas are not included due to insufficient information to consider them in the collective terminology (e.g., rhabdomyosarcoma).

Descriptions

STSs are typically focal, solitary, palpable, soft to firm lumps found in the dermis, subcutaneous (SC) tissue, or deeper muscular and musculofascial compartments. Masses that have grown rapidly or those that are large because they have been present for a prolonged time can have ulcerated surfaces and may be painful. Most STSs are 2 to 4 cm in diameter at the time of initial examination. Tumor size can vary depending on a number of factors, including location; specifically, is the mass located superficially in the dermis or deep in a muscle? Other factors include how quickly an owner identifies a new lump and overall body condition, because masses are more easily observed on a trim pet or those with shorter hair.

STSs can develop in any location on the body but are most common on the limbs or head. Depending on tumor location, other clinical signs may include vomiting, diarrhea, and/or weight loss with gastrointestinal tumors; pain and/or lameness with peripheral nerve root tumors; and halitosis, difficulty prehending food, and other signs with oral tumors. In cats, STSs are frequently associated with sites of vaccination/injection and therefore are more commonly located on the trunk, either in the interscapular region, dorsal lumbar, or flank region, with location changing as recommendations are made regarding the best sites to vaccinate cats (see ch. 208).

Factors in Diagnosis and Management

STSs are usually painless SC masses similar to other benign or malignant nodules. Therefore, accurate diagnosis is critical for appropriate treatment planning. An incisional biopsy is recommended for all but the smallest of nodules to prevent disruption of the surrounding normal tissue prior to definitive surgical planning. Excisional biopsies should be avoided unless the mass is small (<1 to 2 cm proportional to the size of the dog or cat) and surrounded by abundant normal tissue. In addition, all biopsy procedures should be carefully planned for SC nodules to avoid inadvertent contamination of surrounding tissues. Definitive surgery requires excision of the biopsy tract and although local control is expected with complete surgical removal, local recurrence is often observed following suboptimal surgical procedures. Aggressive treatment at the first opportunity is required for successful management of STSs. The challenge of surgical planning, the improved prognosis with multimodal therapy in many instances, and the potential for metastases despite local control in high-grade sarcomas (44% rate of metastases in one report[3]) add complexity to the decision-making process. It is particularly important to meet these challenges for successful management of IAS in cats.

Etiology

Genetic, Biochemical, Radiation Exposure

The genetic or specific biochemical mechanisms responsible for development of STSs in dogs and cats remain

largely unknown.[4,5] Most STSs in dogs occur sporadically, although there is evidence that Golden Retrievers have an increased risk of tumors in general, including STSs.[6] Germline mutations or familial forms of sarcomas have been confirmed in people. Provocative anecdotal epidemiologic evidence suggests similar processes may be present in dogs. However, detailed genetic or pedigree characterization of dogs that develop STSs at a young age (<2 years), or where a breed prevalence seems likely, have not been conducted.

It is well established that exposure to radiation, viral infection (feline sarcoma virus), trauma, or chronic inflammatory conditions can be associated with development of sarcomas in dogs and cats. Conventional irradiation schedules for management of a primary cancer carries risk of a second cancer developing in <5% of cases. Radiation-induced tumors occur 3 years or more after radiation therapy (RT).[7] The benefits of primary tumor control outweigh the risk of radiation-induced second tumors. High intraoperative doses of RT given once are more likely to produce sarcomas (20% to 25%) in dogs after a median latency of 4 years.[8]

Injection-Associated Sarcomas (IAS)

Risk Factors

In a large study of risk factors associated with development of IAS in cats, no specific brand, no type of vaccine within antigen class, and no vaccine practice altered risk of developing IAS.[9] Furthermore, some long-acting injectable medications (penicillin, methylprednisolone acetate) may also be associated with sarcoma formation, thus the term injection-associated sarcoma (IAS).[9,10] There are also case reports of STSs in cats at sites of cisplatin injection, a deep nonabsorbable suture, retained surgical sponge, microchip, or SC fluid port.[11-15] Likely, a combination of local inflammatory reactions and genetic factors is involved.[16] Similarly, the development of ocular sarcomas in cats is often associated with a history of ocular trauma.[17]

Molecular and Cellular Abnormalities

The molecular development of IASs in cats is not yet fully defined. There have been several reports eliminating the most common feline viral infections (oncorna, papilloma, polyoma viruses) as causative etiologies.[18-20] Unique molecular features of IASs have been identified. Epidermal growth factor/receptor (EGFR), platelet-derived growth factor/receptor (PDGF), and transforming growth factor-beta–expressions are abundant on tumor cells and infiltrating lymphocytes in IASs. Such changes are not expressed in cells from non–injection-site feline sarcomas.[21] An overexpression of C-Jun, a protooncogene, has also been identified in feline IASs and may be the result of persistent growth-factor stimulation.[21] Fibrosarcomas at presumed sites of injection have been reported in dogs, as well as at the site of microchip implant in two dogs, but are not well documented as a distinct entity.[22-24]

P53 abnormalities have been reported in feline IASs. In one report, approximately 43% of samples from sarcomas strongly overexpressed the p53 protein and, in another, 5 of 8 tumor samples with overexpressed p53 protein contained mutated genes.[25,26] No cats from a control group of 13 IASs, without p53 protein overexpression, had gene mutations.[26] In this latter study, no surrounding tissue had p53 mutations, suggesting that abnormalities in p53 function did not exist prior to tumor development. One study demonstrated an association of germ-line polymorphisms in the p53 gene with genetic predisposition to feline IAS.[27] These data indicate that molecular and cellular abnormalities exist and suggest several hypotheses, but no specific cause has been associated with the development of feline IAS.

Abnormalities in p53 and MDM2, a gene whose product suppresses p53 expression, have been reported in canine STS.[28] Twenty percent of sarcomas had base substitutions resulting in single amino acid misreads in the p53 gene. Three of 6 tumors with mutations were malignant nerve-sheath tumors. Canine MDM2 gene amplification (threefold or greater) was identified in 5 of the 30 sarcomas. In all but one of these combined samples, there was coordination of these abnormalities, resulting in p53 disruption (mutations) or secondary p53 suppression due to MDM2 overexpression. Thus, directly or indirectly, almost one third of canine sarcomas appear to have altered p53 function and 5 of 7 malignant peripheral nerve-sheath tumors had p53 functional abnormalities.

Initial Clinical Evaluation

History, Physical Examination and Initial Assessments

Evaluation of dogs and cats should begin with a thorough history (see ch. 1) and physical examination (see

ch. 2). Tumor staging includes assessing the extent of local disease and detecting any evidence of regional and/or distant metastasis. Further, comorbidities and concurrent primary tumors should be identified via laboratory testing, thoracic radiography and abdominal ultrasound (US).[29] Thorough description and measurement of masses in three dimensions can be valuable for documenting subsequent growth if there is a delay in initiating therapy and/or documenting response to therapy. STSs, in general, have a relatively low metastatic rate, but rates increase with increasing tumor grade. The greatest concern of metastasis is with high-grade sarcomas via hematogenous routes. The most common sites for spread are lung and liver. Regional lymph nodes should be evaluated by aspiration and/or biopsy, particularly if enlarged or if the STS is a high-grade tumor, even though this is not the most likely site of spread. The incidence of metastasis for sarcomas at initial diagnosis is considered to be low, but without specific examination of regional lymph nodes or careful follow-up, the actual incidence is unknown. In cats with vaccine-associated fibrosarcomas, sites of metastasis include lung, skin, SC, regional lymph nodes, mediastinum, liver, and pelvis.

Imaging

Appropriate imaging for evaluation of the primary tumor, as well as thoracic radiographs and abdominal US (see ch. 88 and 89), should be conducted during the staging process if malignancy is confirmed. Imaging techniques may also aid in planning biopsy and treatment options. US evaluation of the primary tumor may aid in determining the best site for biopsy. US-guidance may be necessary for accurate sampling of deep-seated tumors. Imaging of STSs increasingly involves cross-sectional studies, such as computed tomography (CT) or magnetic resonance imaging (MRI).[30] CT scans, with IV contrast, can assist in delineating the extent of local disease as well as invasion into the surrounding tissues. It is highly recommended that imaging precede therapeutic intervention. Particularly for IASs in cats, the extent of invasion into surrounding tissues can be substantial and an initial excisional biopsy can impair the ability to achieve local tumor control. Tumor volume, measured from contrast-enhanced CT studies of feline sarcomas, can exceed physical measurements by 2 to 5 times. Also, attachment of the tumor to surrounding muscle and tissue can be more extensive than expected (Figure 346-1).[31]

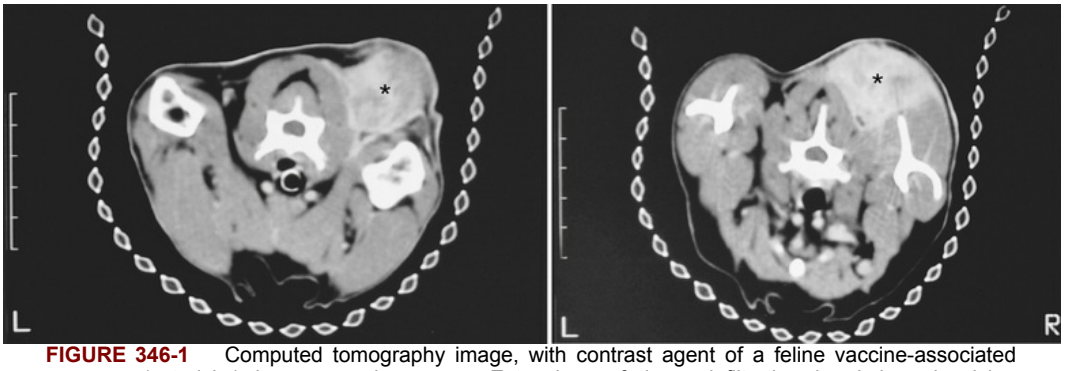

FIGURE 346-1 Computed tomography image, with contrast agent of a feline vaccine-associated sarcoma (asterisks) in prescapular space. Extensive soft-tissue infiltration is obvious involving numerous muscles adjacent to tumor tissue.

Surgery without accurate prior knowledge of tumor extent for feline injection-site sarcomas is not recommended. Furthermore, in dogs, STSs frequently occur on the extremities, where they are difficult to resect with adequate margins. An initial biopsy and imaging can provide both a diagnosis and an understanding of disease extent, with preplanning possible such that an owner can be apprised of whether combination therapy is indicated, considering its potential for increased duration of medical management and cost. Of interest is a report on surgical outcomes in 350 dogs with STSs managed in first-opinion practices. This study revealed differences in extent of staging prior to surgery and the apparent tendency for lower grade tumors to be managed at primary care, rather than at referral, practices.[32]

Diagnosis

Fine Needle Aspiration and Cytology

A definitive diagnosis is needed to determine the best treatment strategy. Aspiration cytology can provide

initial information on a dermal or SC lump that may support the diagnosis of a nonneoplastic process (see ch. 87, 89, 93, and 95). Aspiration cytology can be diagnostic for neoplasia and may suggest that a mass is most likely of round cell, epithelial, or mesenchymal origin. Cytology is not usually definitive regarding specific histologic classification. Mesenchymal tumors are less likely to exfoliate during aspiration. For STSs, aspiration cytology is performed primarily to rule out other disease processes, although some may be diagnostic for sarcoma.

Biopsy

An incisional biopsy is recommended to obtain a definitive diagnosis and to determine the specific histopathologic type and tumor grade (see ch. 86). The biopsy procedure for sarcomas should be carefully planned to obtain a representative sample of the tumor and prevent any unnecessary complications or contamination of surrounding tissue with tumor. If a cutting needle is to be used, care should be taken not to penetrate beyond the known tumor perimeter to avoid tumor seeding. Sarcomas often adhere to adjacent tissues, and extension along fascial planes can be difficult to appreciate on physical examination. Therefore, biopsy samples such as those obtained from limited incisions, punch biopsy tools, or cutting needles are preferred to excisional biopsy to minimize tissue disruption. The acquisition of a biopsy sample allows grading of the tumor based on assessment of a number of histopathologic features, although there can be discordance between the pre-treatment biopsy and the excisional biopsy results with either under- or overestimation of the tumor grade.[33]

Histology

Histologic features assessed in STSs to assign a tumor grade include degree of differentiation, percentage of necrosis, and mitotic rate (see Table 346-1, see ch. 87 and 93). Tumor grade for STSs in dogs can have prognostic significance, with a more progressive course and higher likelihood of metastasis with a high-grade tumor. Obtaining complete margins on histopathology is predictive for non-recurrence. Histologic grade has been shown to be a strong predictor for recurrence of marginally excised SC STSs in dogs, with increased likelihood of local recurrence with increasing grade.[34,35] One report on prognosis in cats after surgical excision of fibrosarcomas showed a correlation between mitotic index (sum of mitotic figures in 10 high-power fields [400× magnification]) and median survival.[36] For cats with a mitotic index <6, the median survival was 32 months, as compared to 4 months if the mitotic index was ≥6. Most studies have not shown a correlation between tumor grade and survival in cats with injection-site sarcomas, which may represent a more aggressive tumor overall.

General Treatment Considerations

Surgery versus Multi-modal Therapy

Surgical excision of any tumor without preplanning can result in incomplete removal and need for a second, more extensive surgical procedure, radiation therapy (RT), and potentially a higher complication and/or failure rate. STSs in particular are likely to be incompletely removed with close marginal excision due to tumor extension beyond visible tumor tissue or because they can appear well encapsulated. However, these are usually pseudo-capsules: compressed tumor tissue and reactive fibrovascular tissue. Higher morbidity and higher cost associated with incomplete resection justify the referral of STS pets with large or high-grade tumors for consideration of multidisciplinary evaluation and possibly multimodal therapy. Figure 346-2 represents a decision-making algorithm for soft-tissue sarcomas, or any superficial nodule, based on the initial estimation of surgical success. Pivotal decision points in this algorithm include the determination of whether curative surgery is possible; the success of surgery based on thorough evaluation of the margins; and the need for any adjuvant chemotherapy based on grade and stage.

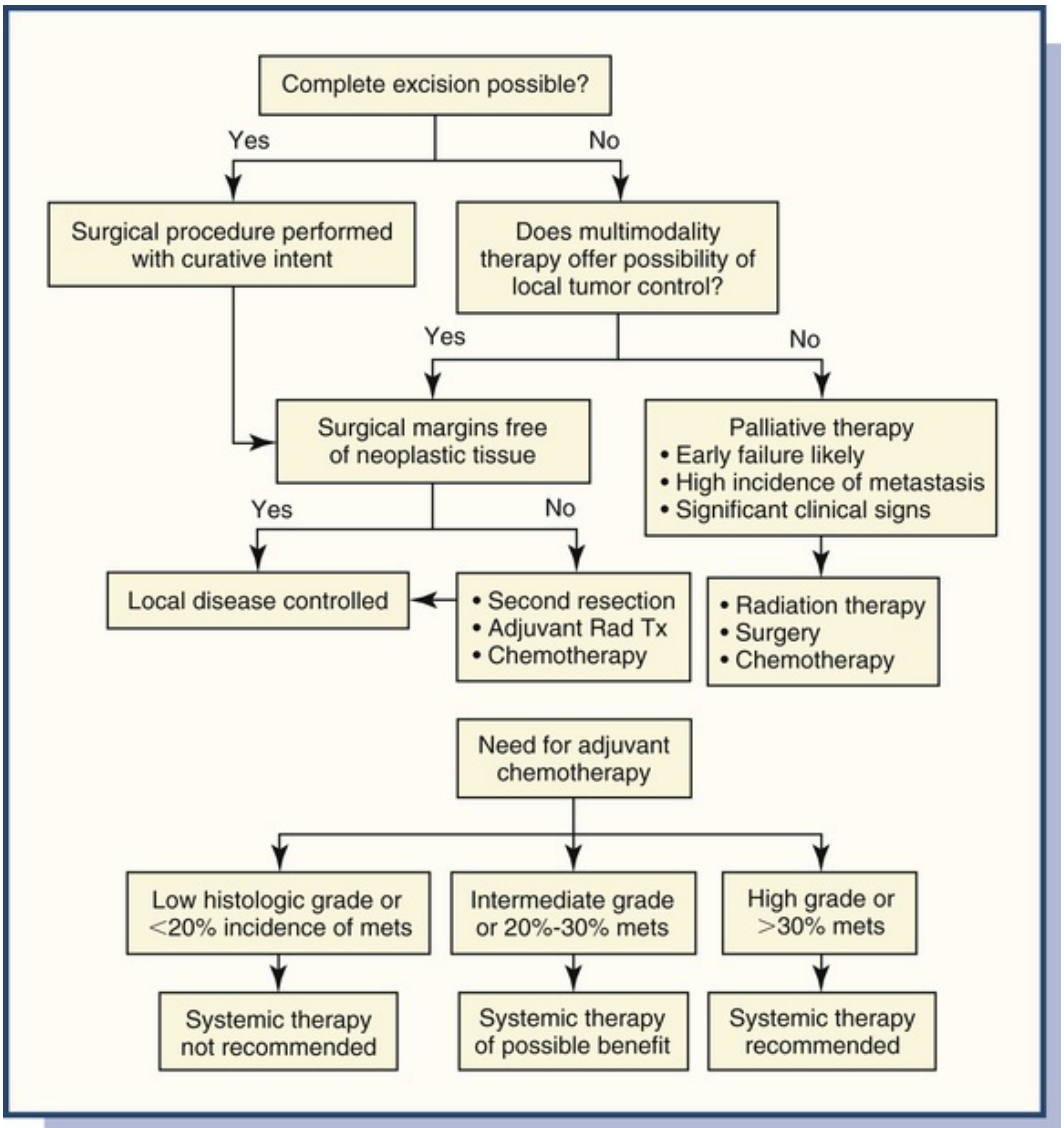

FIGURE 346-2 Treatment algorithm for peripheral solid tumor (clinical and histologic staging completed). *Mets*, Metastases; *Rad Tx*, radiation therapy.

The decision regarding surgical resection of a STS is perhaps the most critical point in the algorithm. The decision to attempt resection should be made from accurate measurement of the mass, assessment of deep tissue attachments, location, surrounding normal tissue limitations for deep resection, and the surgeon's skill. A retrospective study of 100 dogs with mast cell tumors or STS demonstrated that level of surgical training impacted success of complete excision.[37] The surgical procedure should be well planned to accomplish complete resection and reduce or prevent likelihood of inadvertent tumor seeding of the site or surrounding tissues. New and aggressive oncologic surgical techniques are being evaluated and implemented.[38-41] In a pilot study of a novel imaging system, dogs with sarcomas received an IV fluorescent probe to aid detection of residual tumor after wide surgical resection; in 9 of 10 cases histopathologic assessment of surgical margins correlated with intraoperative imaging.[42] Planned resection with a vascularized flap to close the defect facilitates timely initiation of postoperative RT, with a high success rate associated with flaps that are irradiated.[43]

Assuming the Surgical Field Is Contaminated with Tumor Cells

Following a surgical procedure, it must be assumed that the entire operating field, including the scar, is potentially contaminated. The use of appropriate technique is essential, including incision planning, avoidance of unnecessary manipulation of the tumor itself, or placement of drains with distant tissue

dissection. During the procedure, hemoclips may be used to define the deep and lateral extent of the tumor and surgical plane. This will be of benefit to determine the area of re-resection or RT, if needed.[44,45]

Examination of the lateral and deep margins for completeness of resection is of critical importance for determining local tumor control. This explains the paramount importance of submitting the entire resected specimen rather than only a portion. The histopathologic analysis of tumor margins is aided by marking the surgical margins with permanent dye and thoroughly describing the specimen orientation.[46-48] In one study, the investigators used a three-dimensional histological technique for evaluating lateral and deep surgical margins in 48 excised feline IASs; this approach has the potential to increase the accuracy of margin assessment.[49] Adequate margins around the tumor tissue can be difficult to estimate once the tissue has been processed for fixation and microscopic evaluation. Surgical margin definitions vary in the literature and include but are not limited to: incomplete (excision with tumor cells at or within 1 mm of surgical margins), narrow or close (excision with no tumor cells at surgical margin but histologically normal tissue extending <1 cm beyond histologic margins, or less than 3 mm), and wide or complete (excision with histologically normal tissue >1 cm at the surgical margin, or a minimum of 3-5 mm).[35] A minimum of 10 cell diameters between tumor and deep surface is recommended for classifying a mass as completely resected. This arbitrary designation should be carefully examined with more defined measurements of distance that could be correlated to the required margin necessary to prevent recurrence for different grades of sarcoma.

Palliative Therapy

Palliative therapy may be necessary for tumors that are not amenable to definitive approaches, such as aggressive surgery or multimodal therapy. Palliative therapy should be actively pursued, and numerous treatment options have been devised specifically for management of patients with incurable tumors or patients with significant morbidity associated with the presence of the tumor.

Management of Canine Soft-Tissue Sarcomas

Detection

There are no known risk factors that allow early detection or prediction of canine STS of clinical use. Therefore, general recommendations for cancer screening and detection (frequent physical examination, radiographs, other imaging studies) represent the only means of early STS recognition. Any mass should be characterized with measurements, appropriate imaging, and biopsy as soon as is possible. If a STS is identified, the procedures outlined above for treatment planning should be implemented.

Treatment Planning and Surgical Aggressiveness (see Figure 346-2)

Decisions regarding primary tumor management and whether chemotherapy for adjuvant treatment should be instituted following local control must be made, ideally decided by the entire veterinary and owner team. Surgical resection should be the first consideration for any STS. Concluding a mass is potentially curable with surgery should be closely scrutinized, because local recurrence represents a serious complication of inadequate surgery and will impact future treatment options.[50] The importance of the type of surgery performed is demonstrated in a report of 56 dogs with liposarcoma in which the median survival was 1188, 649, and 183 days, respectively, if they had a wide excision, marginal excision, or incisional biopsy.[51]

A report on the results of marginal excision of low-grade spindle cell sarcomas of the canine extremities documented a low local recurrence rate (10.8%) with a mean survival time of 703.5 days (median was not reached yet).[52] Wide local excision (2 cm lateral margin, and 1 fascial plane deep) of STSs in 31 dogs (primary excision in 21; scar revision after incomplete resection in 10) with tumors involving the distal limb demonstrated excellent long-term local control; the majority of wounds healed completely by second intention (median time of 53 days, range 25-179 days).[53] The majority of STSs of the digit, the third most common digital tumor, are controlled by amputation of the digit.[54] Referral for more extensive tumor evaluation and aggressive management is warranted for STS in areas of complex musculofascial anatomy, because adequate normal tissue removal around the sarcoma improves local control.[55] Multimodal therapy is an appropriate consideration for tumors not easily resectable, with preplanning of paramount importance.

Radiation Therapy (RT)

RT has been shown to be of significant benefit for local control of STS not completely resectable (see ch. 340). The use of preoperative or postoperative definitive RT can be considered, although ideally the schedule for application of RT should be made before initiating treatment.[56] Furthermore, there are specific considerations to bear in mind when combining surgery and RT, such as the impact of preoperative irradiation on wound healing.[57] Several studies have demonstrated that RT results in long-term control of STSs in dogs.[58,59] Local relapse-free survival has been estimated at 75% to 85% for 3 or more years, and this combination should be recommended for all incompletely excised canine STS. Hypofractionated radiation protocols have been applied in the microscopic disease setting and are associated with long-term control in the majority of dogs.[60,61] Intentional marginal excision of canine STS on an extremity followed by hypofractionated RT (8-9 Gy/fraction, weekly, 32-36 Gy total dose) potentially reduces surgical complications but may be associated with increased late radiation side effects when using a large dose per fraction.[60] Current treatment schedules and technology make RT of tumor sites less likely to result in limiting side effects.[62] However, STSs can arise in any tissue, and adjacent normal structures can be difficult to avoid without compromising tumor control.

Chemotherapy

There are several indications for chemotherapy in STS (see ch. 339): when patients have an inoperable STS but a measurable reduction might allow function-preserving resection; for patients with recurrent STS not amenable to second surgical procedures; in dogs with high-grade STS, to reduce or delay metastatic nodules; and in dogs with STS that have an inherently greater likelihood of metastasis.[63,64] Doxorubicin has been considered the most active single agent for canine STS, but based on one study, it has not been shown to improve outcome in dogs with high-grade sarcomas.[3] Other options include platinum-containing agents and ifosfamide. Intraoperative cisplatin has been used in the treatment of canine STS to increase local drug concentrations while reducing systemic toxicosis, but an unacceptable 16 of 19 dogs had local complications.[65] There may be a role for the use of metronomic chemotherapy for high-grade STS or incompletely excised STS with the goal of inhibiting angiogenesis as opposed to direct cytotoxicity associated with full dose chemotherapy, as well as modulation of the immune system.[64,66-68] Metronomic chemotherapy with cyclophosphamide and piroxicam significantly delayed tumor recurrence in 30 dogs with incompletely excised STSs as compared to 55 control dogs; but 40% developed usually mild treatment-related adverse effects.[67] Although no definitive evidence exists to make adjuvant chemotherapy a general recommendation for dogs with high-grade STS, many specialists feel that the chance (≈40%) for distant metastasis, even with local control, warrants a recommendation of treatment with chemotherapy.[3,55]

Palliative Therapy

Palliative therapy is available for dogs with significant functional abnormalities directly related to the tumor mass. Irradiation schedules for palliative management are designed to deliver a significant dose to the tumor without debilitating side-effects and with minimal hospitalization; these can be effective in the short term.[69] Tumors causing pain, dysphagia, dyspnea, dyschezia, or dysuria, and those that are assumed to be incurable with surgery, should be considered for palliative RT. Palliative chemotherapy may also be offered in hopes of reducing the mass causing debilitating clinical signs. Palliative surgical procedures designed specifically for improved quality of life in patients with extensive disease include resolution of ulceration and management of secondary infection.

Canine Soft-Tissue Sarcomas With Unique Clinical Features

Overview

Most STSs (see Box 346-1) can be managed with the principles described above after considering the histologic grade and the likelihood of local control. Special consideration should be given to select sarcomas due to unique presentations or tumor biology, e.g., the retroperitoneal location for soft-tissue sarcomas, although rare, is associated with a high rate of local recurrence and metastasis with a short survival time (median 37.5 days).[70] Synovial cell sarcoma (see ch. 348), and hemangiosarcoma (see ch. 347) are discussed in their respective chapters.

Leiomyosarcoma/Gastrointestinal (GI) Stromal Tumors

Sarcomas of smooth muscle occur most often in the GI tract and require special management considerations related to their site of origin. After reclassifying canine GI smooth-muscle tumors, gastrointestinal stromal tumors (GISTs) are considered distinct from leiomyomas and leiomyosarcomas.[71-74] GISTs express c-kit as detected by immunohistochemistry (IHC), and many have activating mutations that are thought to drive oncogenesis.[75] GISTs may be responsive to receptor tyrosine kinase inhibitors that target KIT.[76-78] More recently, DOG1 (discovered on GI stromal tumors protein 1) has been shown to be a sensitive and specific marker for the diagnosis of canine gastrointestinal stromal tumors.[79] It has been recommended that both DOG1 and KIT IHC be included in diagnostic panels to improve the diagnostic accuracy of canine GISTs.

Since second surgeries are unlikely, it is recommended that GI tumors be resected widely, and any lymph nodes or other sites of concern in the abdomen also be resected to aid in staging. Several reviews reported clinical outcomes of approximately 100 dogs with intestinal leiomyosarcoma.[80-82] In addition, data describing the site or origin and metastases of 158 dogs and 22 cats with leiomyosarcomas have been summarized.[83] Leiomyosarcomas are most often located in the stomach, small intestine, spleen, or urogenital tract. GISTs appeared to develop more frequently in the cecum and large intestine, although in one study they occurred mainly in the small intestine.[71,84] Feline leiomyosarcomas are uncommon but occur in the GI tract more often than other sites. If complete surgical resection can be accomplished, median survival times are about 18 to 37 months. Many dogs die from causes other than recurrence or metastasis. Reports vary on whether there is a difference in survival depending on whether it is a GIST or a leiomyosarcoma, with one report indicating a shorter median survival for leiomyosarcomas.[71] Metastatic lesions are reported in 15-30% of dogs with leiomyosarcomas and are most likely to be found in the mesentery, spleen, or liver. Metastases may be slow to develop (1 to 2 years) and relatively slow to progress. Information on response to chemotherapy is limited.[71]

Management of Feline Sarcomas

Investigations are being carried out to determine the optimal treatment approach for IAS. Best success lies in early detection and aggressive management. Ideally, development of IAS can be prevented.[110] Analysis of alterations in p53 may be of utility in both directing therapy for individual cats that are at increased risk of recurrence, and in the future, for use in molecular targeting of mutant p53.[96,111]

Surgery

Need for Wide Margins

Surgical excision of soft-tissue sarcomas in cats represents the best chance of effecting local tumor control.[31,85-88] An initial biopsy of a suspected STS in a cat together with cross-sectional imaging (CT or MRI) will provide the most accurate assessment of tumor extent and assists in treatment planning.[89,90] An excisional biopsy of an IAS is rarely complete, is likely to result in local recurrence, and a second, more difficult surgery will be necessary. Tumor recurrence has been documented to occur as early as 2 weeks after surgery, but will typically occur within 6 months of incomplete resection.[91] An aggressive surgical resection is necessary to effect local control, and this can entail resection of the tumor with 3- to 5-cm margins, removal of associated bone (e.g., dorsal spinous processes, partial scapulectomy), and at least one fascial plane deep to involved tissues.

There has not been consistency between studies in terms of prognostic factors identified for cats with soft-tissue sarcomas. In a group of 42 cats with a variety of different STSs treated with surgery alone, median survival time was longer in cats with tumors <2 cm in diameter and in cats with fibrosarcomas or nerve-sheath tumors, compared to cats with a malignant fibrous histiocytoma; median survival time for all cats was 608 days.[92] In a report of 91 cats treated by radical excision with 5-cm margins around the palpable tumor and deep margins, including 2 muscle planes or bone deep to the tumor without adjunctive treatment, the overall median survival time was 901 days despite not performing preoperative cross-sectional imaging.[93] Radical surgery was complete in 88 of 91 cats and the local recurrence rate of 14% is lower than previously reported with surgery alone or in combination with adjuvant therapy. Major complications occurred in 10 cats (7 with incisional dehiscence).[93]

Recurrence and Metastasis

Tumor recurrence and metastasis were significantly associated with survival time. Median survival of cats with (n = 13; 14%) and without recurrence was 499 and 1461 days, respectively. Median survival of cats with (n = 18; 20%) and without metastasis was 388 and 1528 days, respectively. In a retrospective study of 49 cats that underwent wide excision (3 cm margin based on contrast-enhanced CT imaging) of IAS on the trunk, duration of surgery was related to the complexity of the procedure. Length of surgery was identified as the best predictor of wound healing complications; 19 cats (major in 8 cats; minor in 11 cats).[94] Although some pathologists consider all IAS to be high-grade based on their biologic behavior, in one study cats with high-grade IAS were more likely to develop metastasis (IASs were graded low, medium and high), which was associated with significantly shorter (165 versus 929 days) median survival times.[95] There appears to be a strong association of somatic deletion in the conserved region of the p53 gene with postsurgical recurrence and decreased survival.[96]

Tumor Location and Use of Multimodal Therapies

IASs have commonly occurred in the interscapular space, a difficult location for surgery that requires removal of dorsal spinous processes and the surrounding musculature. For this reason, the Vaccine-Associated Feline Sarcoma Task Force (VAFSTF) recommends vaccinating with rabies and feline leukemia virus (FeLV) in the distal hindlimb (right and left hindlimb, respectively), such that amputation is possible, should IAS develop (see ch. 208). Even with amputation or hemipelvectomy, it may not be possible to completely excise an IAS.

It is often necessary to use a multimodal approach, combining radiation therapy (RT) and surgery. For instance, preoperative irradiation of a proximal limb sarcoma may be necessary prior to amputation. The use of RT preoperatively often reduces tumor size and, theoretically, sterilizes peripheral tumor components that could otherwise result in incomplete resection and the potential for rapid tumor regrowth (see ch. 240).[56,97] RT with stereotactic body radiation therapy (24-32.5 Gy delivered in 3-5 fractions) employed to treat 11 cats with IAS documented a partial response in 5 and complete response in 3 cats. The median progression-free interval was 242 days and overall survival was 301 days.[98] This approach is an option for palliation of tumors, but requires additional study to determine its role in combination therapy. In a retrospective study of 79 cats with STSs treated with preoperative (n = 24) or postoperative (n = 55) RT, the overall median survival was 520 days.[99] The median survival of cats treated with preoperative RT (310 days) was significantly shorter than cats irradiated postoperatively (705 days), but this may have been due to selection bias because the cats with larger tumors were irradiated preoperatively. Of note, anemia was determined to be a negative prognostic factor with a median survival of 308 days for cats with a PCV <25%, and 760 days for cats with a PCV ≥25%.[99]

Chemotherapy

Chemotherapy may be used in the management of IAS as adjuvant therapy to address potential metastatic disease, as neoadjuvant therapy to reduce the tumor in size prior to surgical resection, or as palliative therapy for nonresectable tumors. Combining doxorubicin and cyclophosphamide for 12 cats with nonresectable tumors had a 50% overall response rate.[100] The median survival time was significantly longer in those cats that responded (242 days) than in those that did not respond (83 days). In a study of 69 cats, no significant difference in survival or disease-free interval was reported among cats that had surgery alone versus those who had surgery and received doxorubicin.[101] Twenty-one cats with IAS received 3 cycles of neoadjuvant chemotherapy with epirubicin prior to surgical resection, followed by 3 additional cycles in the adjuvant setting.[102] Chemotherapy was well tolerated, and their mean survival time was 2014 days. Cats treated for gross disease with ifosfamide had a 70 day median duration of response.[103] Cats with IAS dosed with carboplatin based on glomerular filtration rate may improve responses.[104,105] In a Phase I/II prospective trial of 28 cats with IAS treated with lomustine, their overall response rate was 25% with a median response duration of 82.5 days.[106]

Combining Surgery, Radiation Therapy, and Chemotherapy

A combination of surgery, radiation therapy, and chemotherapy may result in the greatest potential for long-term tumor control. In 92 cats given preoperative RT for IAS, their median time from the start of treatment to local recurrence, metastasis, or date of death or euthanasia was significantly longer (986 days, n = 59 cats) if complete resection was accomplished when compared with those who had incomplete resection (292 days, n

= 28 cats).[97] There was a trend toward improved survival with the addition of chemotherapy (carboplatin, other) with a median time to first event of 1059 days (n = 33 cats) in cats that received chemotherapy, versus 584 days (n = 59 cats) in cats treated only with RT and surgery. The overall rate of metastasis was about 20%, although complete follow-up was not available for all cats. In 71 cats, concurrent doxorubicin extended the disease-free interval in cats undergoing postoperative RT (median disease-free interval of 15.4 versus 5.7 months) but did not significantly impact survival.[107] Ten cats with advanced STSs were treated with concomitant liposomal doxorubicin and palliative 5-7 daily fractions of RT with a median total dose of 20 Gy (range 20-31.5 Gy).[108] One dose of liposomal doxorubicin was administered at the beginning of RT and 7 cats received further free or liposomal doxorubicin after completion of the liposomal doxorubicin/RT protocol. Five of the 10 cats achieved a partial response and 2 had a complete response; median response duration was 237 days. The median progression-free interval (PFI) was 117 days and median overall survival time was 324 days. Concomitant liposomal radiochemotherapy was overall well tolerated.

A retrospective study of 73 cats treated with definitive RT (n = 46, majority with clean margins; 1 cat also received chemotherapy), or coarse fractionated RT (n = 27, majority with macroscopic disease or incomplete margins) showed that both approaches are options for the treatment of IAS.[109] Cats treated with postoperative definitive RT had a median survival of 43 months and a median PFI of 37 months. In the group treated with coarsely fractionated RT, median survival was 24 months and median PFI 10 months. In this latter group predictors of a better outcome included lack of a visible mass (n = 10) as opposed to macroscopic disease (n = 17, survival 30 versus 7 months); adjuvant chemotherapy for gross disease (n = 5/17, survival 29 versus 5 months), and a small number of surgeries prior to RT.

Prevention

The etiology of most canine STS is unknown; therefore, it is not feasible to develop strategies for prevention. However, for cats it may be possible to decrease risk of developing STS. Considerations include limiting the number of vaccinations administered to cats to only those necessary to maintain health (see ch. 208). Also, one should follow recommendations provided by the VAFSTF: limit to one vaccine per site and document the location of each vaccine (right hindlimb for rabies, left hindlimb for FeLV, and right-lateral scapular region for feline viral rhinotracheitis, calicivirus, panleukopenia vaccine). These recommendations have been further refined by the American Association of Feline Practitioners to vaccinate cats distal to the elbow joint or below the stifle joint specifying each vaccine and its appropriate location.[112] In this way, even if a tumor is to develop, owners can be informed where and what to look at when checking for a possible tumor.

A pilot study has shown that tail vaccination is well tolerated, with similar serological responses when compared to vaccination in the distal limbs.[113] Vaccines have been developed that do not appear to result in a local inflammatory response and may therefore translate into a decreased risk of tumor development at that site. However, a study of the prevalence of feline IASs submissions from 1992 to 2010 showed no decrease in prevalence or increase in age of affected cats despite changes instituted in vaccine formulation or recommended changes in vaccination protocols.[114] Furthermore, although a study of 392 cats with IAS demonstrated that veterinarians are partially complying with recommendations, more attention needs to be paid to vaccinating as distally as possible on a limb.[115] There have been isolated reports of tumors developing in cats at sites not associated with vaccination, but rather due to some other inciting event that has resulted in a local inflammatory response. Increased awareness of the variable inciting causes of feline sarcomas will likely aid early detection as well as potential avoidance of these products when feasible.

CHAPTER 347

Hemangiosarcoma

Craig A. Clifford, Louis-Philippe de Lorimier

Client Information Sheet: Canine Hemangiosarcoma

General Features, Pathology, and Biologic Behavior

Hemangiosarcoma (HSA; angiosarcoma, malignant hemangioendothelioma) is a highly malignant tumor with an aggressive biologic behavior.[1-5] It was long thought this disease had an endothelial ontogeny; however, recent data suggest that these tumors arise from bone marrow progenitor cells with differentiation arrest at the angioblast or hemangioblast stage and subsequent transit to peripheral vascular sites.[6,7] HSA is diagnosed more frequently in dogs than in any other domestic species and it accounts for ≈2 % of all canine tumors.[1-5,8,9] HSA tends to affect older dogs of either sex (although several reports have suggested a male predominance) with a median age of 10 years at diagnosis.[1-5,9,10] While dogs of any breed can develop HSA, German Shepherds, Golden Retrievers, and other large or giant breeds appear to be predisposed.[1-5,9,10]

Primary HSA has been reported in many sites in dogs. However, the spleen, heart (right atrium or auricle), skin or subcutaneous tissues, and liver are the four most common primary sites (Figure 347-1). Other reported primary sites include kidney, retroperitoneal space, muscle, bone, oral/nasal cavity, urinary bladder, and lungs.[2-5,9,11-15] The biologic behavior varies depending on primary tumor location, with certain sites, such as the skin, being associated with a more favorable prognosis in comparison to others. Generally, local infiltration and metastatic dissemination occur early in the course of disease, either hematogenously or via local seeding following tumor rupture and subsequent intra-abdominal implantation (Figure 347-2). Metastasis can occur at any site; the liver, omentum, and lungs are the most frequent sites of dissemination.[1-5] Sometimes, it is difficult to discern the true site of origin because of the multifocal nature of the disease. Interestingly, HSA is the most common sarcoma to metastasize to the central nervous system (CNS).[16,17]

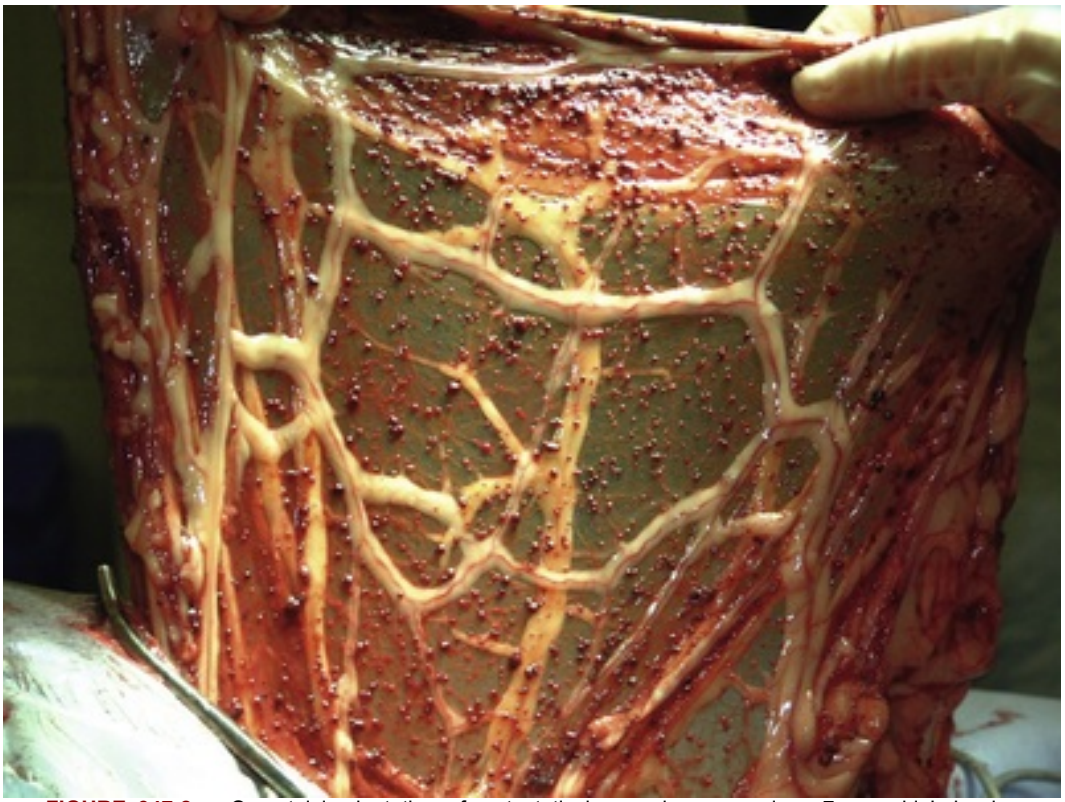

FIGURE 347-2 Omental implantation of metastatic hemangiosarcoma in a 7-year-old Labrador Retriever. (Photo courtesy Julius Liptak, BVSc, MVetLinStud, FACVSc, DACVS, DECVS.)

The spleen is the most commonly affected primary organ in dogs, and based on a number of pathology

studies, the "rule of two thirds" was informally established. The summary of these findings suggested that approximately two thirds of dogs with a splenic mass have a malignancy, and, as such, one third are not malignant. Of the two thirds with malignant splenic tumors, approximately two thirds are HSA.[8,10] Two other large pathology studies evaluating canine spleens noted that closer to 50% had malignant disease, with 50-74% of those malignancies being HSA.[18,19] More recent retrospective studies evaluating patients presenting with a non-traumatic hemoabdomen noted that 68-80% were secondary to visceral neoplasia, with 63-70% of all dogs confirmed to have HSA.[20-22] Although there is some discrepancy in the exact prevalence of splenic HSA, it is undoubtedly the most common primary splenic neoplasm in dogs. However, the differential diagnosis for a splenic mass also should include other neoplasms, such as malignant fibrous histiocytoma, leiomyosarcoma, fibrosarcoma, anaplastic/undifferentiated sarcomas, and lymphoma. Common non-neoplastic diagnoses include nodular hyperplasia, extramedullary hematopoiesis, and splenic hematoma.[8,18,19] Grossly, intra-abdominal HSA can present as a solitary mass or it can be characterized by multifocal lesions that appear soft with a dark red appearance and could be oozing blood constituents.

The heart is another common primary site for HSA in dogs, and HSA represents the most common primary tumor of the canine heart. Specifically, the tumor most commonly originates on the right atrium/auricle; however, other cardiac sites have been reported (see ch. 254).[5,23-27] It was previously reported that ≈25% of dogs with splenic HSA also have a second primary HSA in the heart, consistent with synchronous or metachronous disease.[28] More recent data suggest this phenomenon is less common (8.7%).[29] The kidneys, although an uncommon site for primary HSA, can be associated with a more prolonged clinical history, generally smaller lesions, less-advanced disease at diagnosis, and a more favorable prognosis compared to other internal presentations of HSA.[12] HSA represents the most common tumor type affecting the retroperitoneal space, and it is associated with a high metastatic and recurrence rate, with very short survival times (<40 days) when originating in this location.[13]

Data are lacking regarding the true incidence of HSA in cats. However, it appears to occur much less commonly than it does in dogs, and likely represents <0.5% of all feline tumors. Generally, HSA occurs in older cats with no sex predisposition noted. The spleen, liver, gastrointestinal tract, cutaneous/subcutaneous tissue, and mesentery are the most common primary sites. Hemangiosarcoma uncommonly has been reported as a variant of feline injection site sarcoma (see ch. 346). Although HSA occurs less commonly than it does in dogs, its biologic behavior appears to be similar, with common metastatic sites including lungs, liver, and omentum.[30-37] A study evaluating spontaneous hemoperitoneum in 65 cats noted that 30/65 (46%) had abdominal neoplasia, and 54% had non-neoplastic conditions. Sixty percent (18/30) of the cats with a neoplastic etiology had HSA, and the spleen was the most common site of origin for neoplasia (11/30; 37%).[38] Another study evaluating 26 cats with visceral hemangiosarcoma reported pulmonary metastasis and multifocal disease in 33% and 77% of cats, respectively.[34]

Etiology and Pathobiology

The definitive etiology of canine HSA remains unclear; however, several associated risk factors have been reported, including UV light exposure and radiation therapy.[39-41] Chronic UV light exposure with superficial (dermal) HSA along the ventral abdomen and conjunctival locations are noted in lightly pigmented, short haired breeds such as Salukis, Whippets, Italian Greyhounds, and Greyhounds.[40] Development of HSA lesions at previous radiation therapy sites has been reported, but the actual risk is considered quite low. Exposure to toxins such as vinyl chloride, dioxides, radiation, and arsenicals has been reported to be associated with angiosarcoma and HSA in humans,[42-44] but no such data exist in companion animals.

A few studies have suggested a hormonal link with HSA related to neutering (see ch. 313). Specifically, in a study assessing tumors of cardiac origin, cardiac HSA in spayed females was four times more common than in intact females.[23] A study evaluating splenic HSA similarly noted that spayed females had greater than two times the prevalence compared to intact females.[1] More recently, a study evaluating the effects of early neutering in Golden Retrievers noted that the percentage of HSA in "late-neutered" females was four times that of intact or early-neutered dogs.[45] It is important to note that the number of affected dogs in these studies was low; however, this is an active area of interest from both veterinary and public health perspectives.

With the advent of platforms enabling evaluation of genome-wide gene expression, we are beginning to elucidate specific genes associated with HSA. A recent study using such techniques identified three distinct tumor subtypes in dogs with primary hemangiosarcoma. Specifically, these were associated with

angiogenesis, inflammation, and adipogenesis.[46] These findings suggest that tumors either can arise from single multipotent progenitor cells that differentiate down multiple lineages as part of an adaptive process, or that multiple progenitor lineages might contribute to tumor formation, with one progenitor giving rise to endothelial-like and adipogenic-like cells and another progenitor giving rise to myeloid-like cells. Further research using multi-parameter flow cytometry has demonstrated that canine HSA originates from hematopoietic precursor with commitment to the endothelial lineage.[7,47] These data similarly refute the long held belief that HSA represents malignant transformation of mature endothelial cells in the peripheral vasculature. Furthermore, it is conceivable that this modality, which can assess the expression patterns of cell surface markers observed in those multipotential bone marrow–derived stem cells, can aid in confirming the early diagnosis of HSA and possibly be useful in the monitoring of minimal residual disease.[7,47,48]

Differences between malignant and non-malignant endothelial cells have been documented in regards to increased expression of genes involved in inflammation, angiogenesis, adhesion, invasion, metabolism, cell cycle, signaling, and patterning in neoplastic cells. Interestingly, this "signature" has reflected not only a cancer-associated angiogenic phenotype, but has distinguished HSA from other cancers.[49] Furthermore, specific abnormalities in oncogenes and tumor suppressor genes have been identified in HSA, both of which can play a role in tumor formation.[50,51] This explosion of research has identified several cancer "driver" genes associated with aberrant cellular signaling pathways. It is interesting to note that several of these pathways are associated with angiogenesis,[46,49] a process that often is dysregulated in neoplasia. Multiple angiogenic factors and their associated receptors are overexpressed in HSA and increased levels of angiogenic factors are present in the blood of dogs with HSA (also see ch. 338).[52-57]

History and Clinical Signs

Clinical presentation, history, and associated clinical signs are based on tumor location; however, the majority of patients with HSA arising in the spleen, liver, and heart present for urgent veterinary attention secondary to tumor rupture and internal hemorrhage (see ch. 135 and 143). In some cases, this can lead to collapse (see ch. 127) and sudden death. Patients with intra-abdominal or intrathoracic HSA commonly have a history of acute weakness, collapse, and pale mucous membranes secondary to blood loss anemia. Oftentimes, the emergent presentation might not be the first time that similar, albeit less severe, signs have occurred and a thorough history can reveal previous episodes. For splenic or hepatic HSA, it is likely that upon cessation of acute bleeding and resorption of blood from the affected cavity, patients recover and seemingly appear to be clinically normal until subsequent bleeding occurs. Other historical findings include anorexia, weight loss, lethargy, abdominal distension, vomiting, dyspnea, and vocalization.[4,5,20-22,26,27] Similar clinical signs are noted with renal HSA, sometimes with hematuria.[12] Patients with cardiac HSA might require even more rapid attention due to the development of life-threatening cardiac tamponade (see ch. 254). On physical examination, clinical signs in such patients similar to that of right heart failure are present secondary to the pericardial effusion. Specifically, muffled heart sounds and secondary arrhythmias are commonly noted in patients with pericardial effusions.[25-27] Although clinical stage affects prognosis, a delay in complete clinical staging might be necessary to allow for emergency intervention, with subsequent staging performed only once the patient is clinically stable. Clinical presentation with central nervous system (CNS) HSA can vary widely depending on tumor location, with seizures and mentation changes being the most common (see ch. 260).[16,17]

Cutaneous HSA presentations vary depending on whether the lesion is primarily dermal or subcutaneous (also see ch. 10 and 345). Dermal HSAs are typically small, discrete, blood blister–like lesions, while subcutaneous HSAs are deeper, often larger, and more mass-like, with associated bruising. Intramuscular HSAs typically are large masses or "mass effects" with associated distal swelling and lameness when occurring on or near a limb.[39,40,58-62] Metastasis to external and/or internal sites is much more common with subcutaneous and intramuscular HSA compared to the dermal presentation.[59-62]

Diagnosis and Staging

Although histopathologic evaluation of tissue is the gold standard for diagnosis of this tumor, a presumptive diagnosis of HSA often is made based on the history, signalment, and physical examination. Therefore, many times, complete clinical staging is performed even before a histologic diagnosis is achieved if the clinical presentation is suggestive of HSA. Complete staging includes standard laboratory work (complete blood

count, serum biochemistry profile, urinalysis, and coagulation profiles), three-view thoracic radiographs, abdominal ultrasound (see ch. 88), and if applicable and available, multiple image-plane echocardiography (see ch. 104). There also could be a role for the use of advanced imaging and novel biomarkers in the diagnosis and staging of this disease. The results of clinical staging allow accurate assessment of the patient's stage of disease (Box 347-1), information that helps inform prognosis and guide therapy.

Box 347-1

Canine Hemangiosarcoma TNM Clinical Staging System

T = Tumor (Primary Tumor)

T0 = No evidence of tumor
T1 = Tumor confined to primary site and/or dermis and <5 cm in diameter
T2 = Tumor invading SC tissues and/or ≥5 cm in diameter
T3 = Any T1 or T2 with tumor invading adjacent structures and/or muscle

N = Node (Regional Lymph Nodes)

N0 = No evidence of regional lymph node involvement
N1 = Regional lymph node involvement
N2 = Distant lymph node involvement

M = Metastasis (Distant)

M0 = No evidence of distant metastasis
M1 = Distant metastasis

TNM Stages

I = T0 or T1, N0, M0
II = T1 or T2, N0 or N1
III = T2 or T3, N0 or N1 or N2, M1

Pathologic Evaluation

Depending on the specific lesion and clinical presentation, tissue can be evaluated histologically via submission of an entire affected organ after surgical removal, excision of a localized external (i.e., dermal/subcutaneous/intramuscular) mass, or a simple diagnostic (i.e., incisional, wedge, core needle/"Tru-Cut") biopsy of either internal or external lesions, if deemed clinically safe. Histologically, HSA is composed of irregular, anastomosing vascular channels lined by pleomorphic spindle cells with large multifocal cavities filled with blood. Areas of necrosis commonly are noted within the tumor. Marked anisokaryosis and anisocytosis are common, and often a high mitotic index is noted[1,2,9,18,19,26,39,40,58] (Figure 347-3). A classic cause of clinician and owner frustration is related to discordant clinical and histopathologic results. Often, this situation can be associated with the submission of small or wedge sections from a large splenic mass to conserve finances due to high costs of shipping large amounts of formalin or where a large formalin container is not available. In such cases, the sample can be sectioned serially ("bread-loafed") to allow for full fixation by formalin overnight, with removal from formalin and submission in formalin-wetted towels the following day. Additionally, although cytologic analysis is a non-invasive and clinically valuable technique for the diagnosis of cancer in general, the diagnostic yield for HSA is reportedly low.[5,63,64] However, in some cases of subcutaneous or intramuscular tumors, cytologic evaluation of smears may provide a diagnosis in lieu of histopathologic analysis (Figure 347-4).

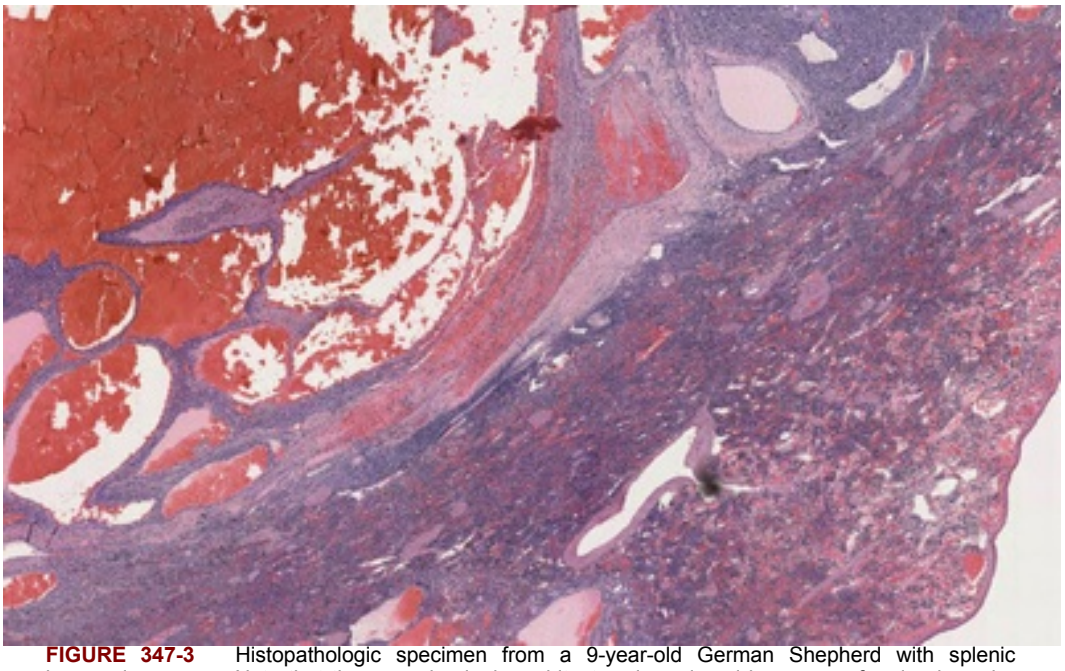

FIGURE 347-3 Histopathologic specimen from a 9-year-old German Shepherd with splenic hemangiosarcoma. Note that the normal splenic architecture is replaced by a mass forming irregular anastomosing vascular channels lined by pleomorphic spindle cells with large multifocal cavities filled with blood. Spindle cells have indistinct cell borders, little eosinophilic cytoplasm and large, irregular, oval, hyperchromatic or stippled nuclei with inconspicuous nucleoli. Anisokaryosis and anisocytosis are moderate to marked, and atypical mitotic figures are common. (Image and description courtesy Danielle Reel, DVM, DACVP, Eastern VetPath.)

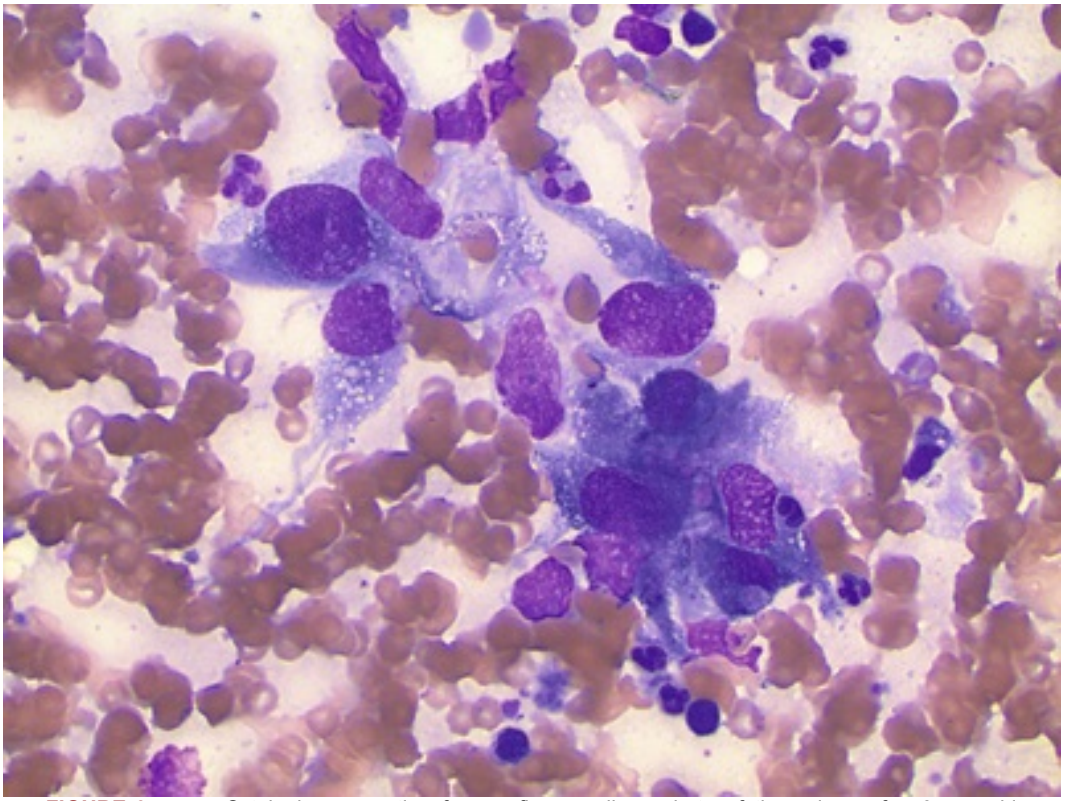

FIGURE 347-4 Cytologic preparation from a fine needle aspirate of the spleen of a 6-year-old neutered male Golden Retriever with splenic hemangiosarcoma and pulmonary metastasis. An aggregate of spindle- to irregularly-shaped cells with wispy basophilic cytoplasm with few punctate vacuoles is seen. The nuclei are oval to irregularly-shaped and exhibit moderate anisokaryosis. 50×

objective/500× magnification. (Image and description courtesy Casey J. LeBlanc, DVM, PhD, DACVP, Eastern VetPath.)

In addition to histopathologic findings, there are several surgical points that are worthy of comment. Given the highly metastatic nature of visceral HSA and the effect of stage on prognosis, any suspicious lesions noted at the time of surgery should be sampled and examined histologically. A recent retrospective study in 79 dogs evaluated the association between macroscopic appearance of hepatic lesions and the corresponding histologic findings in dogs undergoing laparotomy for splenic HSA. All HSA-positive samples were obtained from grossly abnormal livers; however, 59% of histologically benign lesions also were obtained from grossly abnormal livers. Furthermore, only 50% of grossly abnormal livers had HSA metastasis; diagnoses reported in the other 50% of cases included nodular hyperplasia, hepatic vacuolar degeneration, lipogranulomas, extramedullary hematopoiesis, and hemosiderosis.[65] Livers that had multiple nodules and/or dark red or black lesions were more likely to be consistent with HSA (Figure 347-5). Therefore, the presence of gross hepatic abnormalities was associated with a high sensitivity (100%) but low specificity and PPV (41% and 48%, respectively) for HSA, reaffirming the importance of histologic confirmation prior to clinical decision-making. Furthermore, although it cannot be overemphasized that the definitive diagnosis of HSA can only be made via histologic examination, a recent study evaluating 65 dogs that underwent splenectomy, including 30 dogs (46%) with HSA, noted that larger splenic masses, determined by a higher ratio of mass to splenic volume, and heavier spleens (as a percentage of body weight), were more likely to be benign and less likely to be HSA.[66] Although these results do suggest that mass-to-splenic volume ratio and splenic weight as a percentage of body weight could be useful in differentiating between hemangiosarcoma and benign lesions in dogs with splenic masses, no attempts were made to determine sensitivity or specificity of these variables or to identify optimal cut-offs in the referenced study.

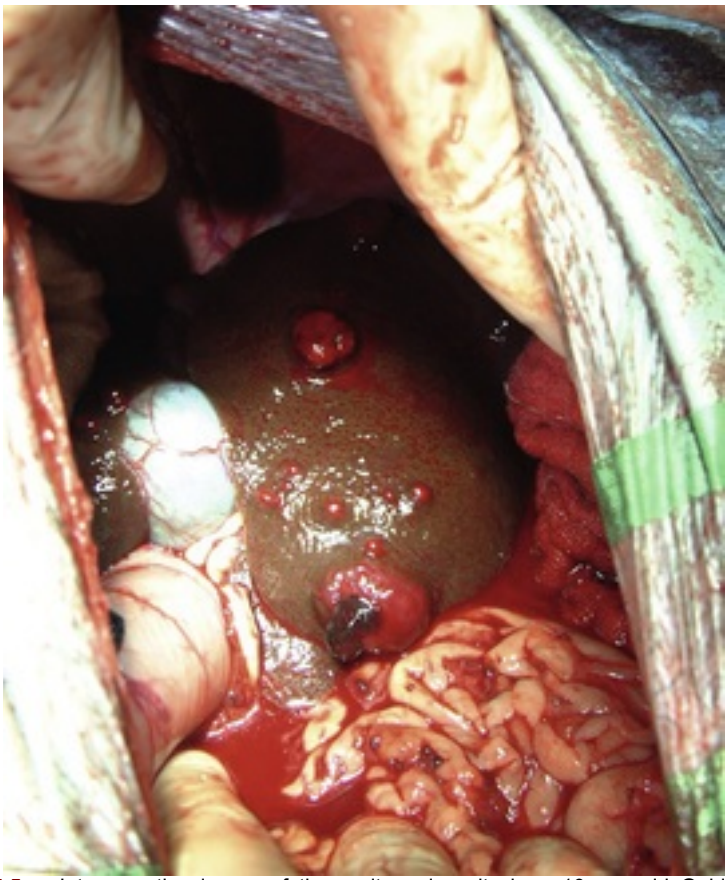

FIGURE 347-5 Intraoperative image of the peritoneal cavity in a 10-year-old Golden Retriever presenting with hemoabdomen secondary to hemangiosarcoma. Note the multiple, raised, red-purple lesions along the liver, some of which were actively bleeding. (Image courtesy Julius Liptak, BVSc, MVetLinStud, FACVSc, DACVS, DECVS.)

Laboratory Evaluation

Several abnormalities on the complete blood cell count can be present in patients with HSA, the most common being anemia. The anemia is generally regenerative and schistocytes, acanthocytes, and nucleated red blood cells often are noted, consistent with microangiopathic-related damage secondary to vasculitis, hepatic insufficiency, deficient reticuloendothelial system, and acute hemorrhage.[67-71] Neutrophilic leukocytosis is another common hematologic abnormality and has been postulated to be a result of a paraneoplastic syndrome and/or necrosis that occurs in large tumors and rapidly growing tumors.[27,72] More recent research suggests that this tumor-associated neutrophilia (and often a monocytosis) could be partially composed of myeloid derived suppressor cells (MDSCs), a subset of granulocytes responsible for suppressing innate anti-tumor immunity and associated with a poor prognosis in some cancers.[73-76] Thrombocytopenia is noted in up to 75% of dogs with HSA and it can be a result of tumor hemorrhage, destruction via fibrin crosslinks within the tumor vasculature, or secondary consumptive coagulopathies such as disseminated intravascular coagulation (DIC; see ch. 197), which has been reported in up to 50% of dogs with hemangiosarcoma.[27,70,71] As a result of DIC, abnormalities can be present on coagulation profiles (prothrombin time, partial thromboplastin time, fibrin[ogen] degradation products, fibrinogen, d-dimers; see ch. 196). The serum biochemistry profile and urinalysis rarely aid in the diagnosis of HSA given their lack of specificity, although in one study, 53% of cats with visceral HSA had increased aspartate aminotransferase (AST) levels.[38]

Other more novel ancillary diagnostic tests could aid in early detection of HSA, since most patients likely have microscopic metastatic dissemination at the time of histologic diagnosis. Early work with flow cytometry has shown the ability to identify cells of specific lineage that co-express certain cell surface markers that are detected in higher numbers in the peripheral blood of dogs with HSA compared to that of healthy control dogs or dogs that are free of measurable HSA following surgical excision.[6]

Diagnostic Imaging

Three-view thoracic radiographs consisting of right and left lateral and ventrodorsal views typically are performed for detection of metastatic disease. The typical radiographic appearance of measurable pulmonary metastatic disease is that of a coalescing miliary pattern; however, either nodular or generalized miliary interstitial patterns also can be observed (Figure 347-6). In one study in which thoracic radiographic and postmortem findings were compared in dogs with histologically confirmed HSA, the radiographic sensitivity was 78% and the negative predictive value was 74% for metastatic pulmonary HSA.[77]

FIGURE 347-6 Three-view thoracic radiographs from a 12-year-old spayed female Labrador Retriever. Numerous poorly- to well-defined, small, soft tissue nodules are present throughout the lungs, consistent with metastatic hemangiosarcoma. (Images and description courtesy Chris Ryan, VMD, DABVP, DACVR.)

Abdominal ultrasonography is one of the most commonly utilized imaging modalities in veterinary medicine and it is readily able to identify effusions, hepatic and splenic lesions, as well as metastatic omental lesions, depending upon the skill level of the operator. Hemangiosarcoma can take on many different echogenic characteristics (anechoic to hypoechoic to mixed) and it often has areas of cavitation (Figure 347-7).[78] More advanced techniques such as contrast harmonic ultrasonography, which can evaluate tissue perfusion dynamics, could hold promise.[79,80] One study demonstrated improved diagnostic yield for hepatic HSA via detection of nodules not seen during traditional gray-scale ultrasound examination.[80] Multiple studies evaluating splenic lesions demonstrated that hypoechogenicity of the splenic lesion during the early and late vascular phases was highly associated with malignancy.[81-83]

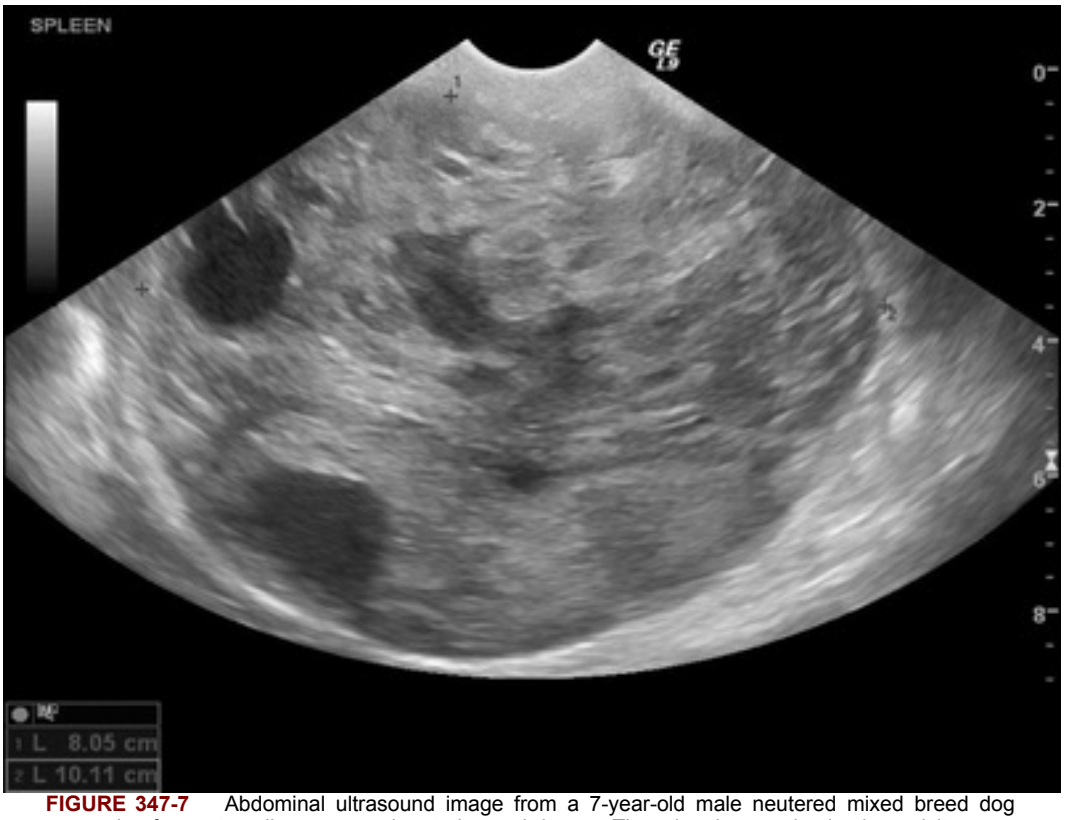

FIGURE 347-7 Abdominal ultrasound image from a 7-year-old male neutered mixed breed dog presenting for acute collapse secondary to hemoabdomen. There is a large, mixed-echogenicity mass with multiple central cavitations effacing the normal splenic architecture and occupying most of the image. (Images and description courtesy Chris Ryan, VMD, DABVP, DACVR.)

Undoubtedly, the presence of acute hemoabdomen (see ch. 143) along with ultrasound findings of a splenic mass are highly suggestive of HSA. In one study evaluating 39 dogs with acute non-traumatic hemoabdomen, 80% were secondary to visceral neoplasia, of which 70% were confirmed as HSA.[20] In a second study evaluating a similar population of 60 dogs, HSA was confirmed in 63% of dogs.[22] Although these data can be considered compelling, it is these authors' belief that no patient with hemoabdomen should be euthanized based on splenic or hepatic lesions that are "consistent with HSA" because many nonmalignant splenic lesions, such as hematomas, appear similar on ultrasound and carry a very good to excellent prognosis with splenectomy alone.[8,18,19] As noted above, a recent study evaluating hepatic abnormalities found at the time of splenectomy for splenic HSA showed that only 50% of dogs with grossly abnormal livers had histologic evidence of hepatic metastasis.[65]

Some groups are investigating combinations of clinical and laboratory parameters in conjunction with ultrasound findings in an effort to increase the confidence of a diagnosis of HSA prior to surgery. One such study evaluated the prevalence of splenic HSA in 71 anemic dogs with a splenic mass and hemoperitoneum in order to identify factors that could differentiate between dogs with HSA versus other splenic masses at the time of hospital admission. Malignant splenic neoplasia was identified in 76% of dogs, of which 92.6% had HSA, and a diagnosis of HSA was significantly associated with a low serum total solids concentration and thrombocytopenia.[21]

Echocardiography remains the modality of choice to identify cardiac (right atrial/auricular) tumors and the presence of pericardial effusion improves the detection of such masses (see ch. 254 and Video 347-1).[84,85] Its use in routine staging for HSA that is first identified in other locations is considered controversial since the overall detection of concurrent lesions is low.[29] However, echocardiography also can be utilized as a screening tool prior to the initiation of doxorubicin chemotherapy to assess heart function in breeds at risk for dilated cardiomyopathy; therefore, its value for such HSA patients can be two-fold.[86] Also, from a cardiac standpoint, perioperative ventricular arrhythmias have been documented in up to 44% of dogs undergoing splenectomy for HSA.[25,87-89] Ventricular arrhythmias in dogs with splenic masses are thought to develop as a result of compromised venous return to the heart, micrometastasis to the heart, and/or DIC, and have been

associated significantly with tumor rupture and anemia. Many dogs experiencing pre- and post-operative cardiac arrhythmias might not be directly clinically affected by these abnormalities and often, their treatment can consist of controlling triggers for the arrhythmias (e.g., treating anemia with blood transfusions, or correcting serum electrolyte imbalances) rather than antiarrhythmic therapy (see ch. 248). In one study, dogs that developed intra-operative arrhythmias had an odds ratio of death that was greater than twice that of dogs that did not experience intra-operative arrhythmias.[89] Resolution of perioperative arrhythmias should be confirmed prior to patient discharge and subsequent adjuvant treatments, as in a small number of cases they could represent underlying organic cardiac dysfunction, a strong contraindication to doxorubicin chemotherapy.[90]

With increased access to more advanced imaging techniques, both computed tomography (CT) and magnetic resonance imaging (MRI) can be utilized for evaluation of subcutaneous, intramuscular, cardiac, splenic, and hepatic HSA. CT and MRI can aid in determining the exact anatomic origin and extent and invasiveness of disease, thereby assisting in the planning of surgical resection and/or radiation therapy.[91] Furthermore, both MRI and CT carry a high sensitivity and specificity in discriminating benign from malignant splenic and hepatic lesions (Figure 347-8).[92,93] An increased sensitivity of thoracic CT for early pulmonary metastasis detection also has been documented.[94,95] As costs for such modalities decrease, they soon could become commonplace in the routine staging of dogs with HSA.

FIGURE 347-8 Computed tomography images of a subcutaneous hemangiosarcoma in a 9-year-old male Boxer dog. Transverse image through the level of the pelvis demonstrates a large subcutaneous mass in the left inguinal region (white arrowheads). The mass is heterogeneously contrast-enhancing at the periphery, non-enhancing centrally, and has multiple thick, irregular, contrast-enhancing septae. (Images and description courtesy Chris Ryan VMD, DABVP, DACVR.)

Biomarkers

The use of HSA-specific biomarkers could be clinically useful not only to enable early detection and intervention but also to monitor the patient's disease status during and after treatment. Several recent studies have evaluated such markers in both the blood and effusions of dogs with HSA. Cardiac troponin I (cTnI) has proven to be a highly specific and sensitive marker for cardiomyocyte damage (see ch. 246).[96,97] A recent study showed that the median plasma cTnI concentration in dogs with cardiac HSA was significantly higher

than the median concentration in dogs with hemangiosarcoma at other sites, dogs with other neoplasms, and dogs with pericardial effusion not caused by hemangiosarcoma (see ch. 254). Specifically, increased cTnI concentrations could identify cardiac involvement in dogs with HSA at any site (sensitivity, 78%; specificity, 71%) as well as identify cardiac HSA in dogs with pericardial effusion (sensitivity, 81%; specificity, 100%).[96] Similarly, serum collagen XXVII peptide concentration was measured in the serum of dogs with hemangiosarcoma and levels in dogs with large metastatic burdens were found to be 9.5-fold higher than those in healthy dogs.[97] It has been proposed that elevations could be related to protein cleavage or degradation in surrounding tissue, or be associated with invasive behavior or angiogenic processes. Interestingly, collagen XXVII peptide concentrations for dogs with other forms of neoplasia (osteosarcoma, lymphoma, carcinomas) and inflammatory disease also were increased, but the values consistently were lower than those for HSA. Reductions in collagen XXVII peptide levels after surgical resection of HSA and subsequent increases with tumor recurrence demonstrate that this peptide could serve as a useful HSA biomarker.[97] Another marker evaluated in dogs with HSA is the cytosolic enzyme thymidine kinase (TK1), the activity of which is closely correlated with DNA synthesis and expression restricted to proliferating cells.[99] A recent study demonstrated that serum TK1 activity was significantly higher in archived serum of dogs with HSA compared to that of healthy dogs. Serum TK1 then was prospectively evaluated in 62 dogs with hemoabdomen secondary to either a benign splenic mass or HSA. Statistically, there was no difference in mean TK1 activity level, but differentiation of the two groups became possible when a specific two-tiered cut-off system was implemented.[99]

Treatment and Prognosis

Localized Therapies

Surgery

Surgery still is the mainstay of therapy for HSA, and splenectomy, liver lobectomy, nephrectomy, excision of dermal, subcutaneous, intramuscular or retroperitoneal masses, and right auriculectomy all have been reported. Such surgeries are performed to remove all macroscopic tumors and prevent further risk of acute hemorrhage, establishment of DIC, and death. The postoperative prognosis associated with HSA is highly dependent on tumor location, stage, completeness of excision, and use of adjuvant therapies.

Specifically, cutaneous HSA that is limited to the dermis without hypodermal invasion (as opposed to subcutaneous/intramuscular lesions) has a lower metastatic rate and often can be controlled with surgery alone. Median survival times (MSTs) of 780-987 days have been reported for dogs after excision of dermal HSA.[58,59] In one study of 94 dogs, predisposed breeds with ventral tumor location and histologic solar changes had even longer survivals. Tumors with subcutaneous invasion were more likely to develop metastasis. Interestingly, even though long-term survival was reported in that study, locoregional recurrence occurred in 77% of dogs.[59] These survival data are in stark contrast to those reported for tumors with subcutaneous or intramuscular involvement, where MSTs of 172 and 307 days have been reported, respectively.[58] For subcutaneous or intramuscular HSA, surgical excision should be as thorough as possible in order to achieve wide margins. Sometimes, this necessitates limb amputation or the use of adjuvant radiation therapy in the event of incomplete or narrow excision, as the local recurrence rate for inadequately excised HSA is substantial.[59,60,62] Furthermore, because of the higher risk of associated and poor long-term survival associated with subcutaneous/intramuscular HSA, adjuvant systemic therapy also is warranted for this particular tumor presentation. Cats with cutaneous HSA treated via surgical excision have been reported to have MSTs of ≈9 months to 4 years.[35,36] Similar to the situation in dogs, feline HSA with subcutaneous involvement was associated with incomplete excision, higher metastatic rate, and tumor-associated euthanasia.[35,36]

Because of the high risk for metastasis, surgery for visceral (most commonly primary splenic) HSA is considered palliative and is associated with a median survival time (MST) of only 19 to 86 days for dogs undergoing splenectomy alone, and 77 days for cats undergoing laparotomy.[1-5,34,100] Therefore, adjuvant chemotherapy, discussed below, is recommended following surgery for essentially all forms of visceral HSA.

For dogs with cardiac HSA, surgical tumor excision typically either is impossible due to the difficult location or is declined due to risks and/or the expected poor to grave prognosis. However, a few case reports and case series exist that describe long-term survival after tumor excision.[101-106] Pericardiectomy via thoracotomy or thoracoscopy is performed more commonly and it can alleviate life-threatening cardiac

tamponade, but alone it is unlikely to significantly prolong survival (see ch. 254).[107]

Although an uncommon variant, primary renal HSA without evidence of hemoperitoneum or metastasis could carry a more favorable prognosis with surgery alone. In a study of 14 dogs with renal HSA, most patients had localized disease on presentation and ten were treated with surgery alone. An MST of 286 days was noted in dogs treated with surgery alone (n = 10), but 10/14 dogs still died of effects secondary to HSA.[12] HSA is the most common histologic diagnosis for retroperitoneal sarcomas in dogs and is extremely aggressive locally, carries a high rate of local invasion and metastasis, and as such, is associated with a poor survival time even when treated with multimodality therapy.[13]

Radiation Therapy

Due to HSA's predilection for inaccessible anatomic sites, its frequently acute presentation, and its high metastatic rate, the use of radiation therapy for HSA has been limited. A study of 20 dogs with measurable, histologically confirmed non-splenic HSA treated with palliative RT showed subjective reduction in tumor size in 14 dogs (70%), with four complete responses and an MST of 95 days.[108] These results are encouraging, and further validation with combination protocols consisting of RT and systemic chemotherapy is needed. Furthermore, although not yet formally evaluated or reported, there also could be a role for the application of strontium-90 plesiotherapy for small and superficial dermal HSA, because it has been shown to provide a high rate of complete response and long-term tumor control in other superficial tumor types.[109]

Systemic Therapies

Conventional Chemotherapy

Doxorubicin (DOX) appears to be the most active agent and has provided the best extension of post-splenectomy survival times to date. Common protocols include single agent DOX; combination DOX and cyclophosphamide (AC protocol); combination vincristine, DOX, and cyclophosphamide (VAC protocol); and combination DOX and ifosfamide.[110-114] Median survival times are related to stage of disease and typically are in the 5-7 month range with the aforementioned DOX-based protocols. In a recent prospective study comparing an AC and DOX/DTIC protocol in 27 dogs with HSA of various locations (20/27 splenic), an overall MST of 142 days was reported for 18 dogs treated with an AC protocol, while the MST for 9 dogs treated with DOX/DTIC was >550 days.[115] However, the small number of dogs in the DOX/DTIC group raises the question about the true significance of these results. An older study evaluating liposome-encapsulated muramyl tripeptide phosphatidylethanolamine (L-MTP-PE), an immunomodulator derived from mycobacterial cell walls that increases monocyte tumoricidal activity, together with DOX, reported the longest survivals to date, where all dogs receiving DOX/L-MTP-PE survived a median of 277 days, with clinical Stage I dogs receiving the combination living a median of 425 days.[116] Unfortunately, L-MTP-PE is no longer clinically available. Therefore, in the absence of L-MTP-PE, it is unclear whether any of the remaining DOX-based protocols is truly superior to the others (Table 347-1).

TABLE 347-1

Selected Median Survival Times with Various Therapies for Canine HSA

TUMOR LOCATION	TREATMENT	MST* (DAYS)	REFERENCES
Spleen	Splenectomy	19-86	1, 2, 10, 100

A, Adriamycin; *C,* cyclophosphamide; *DER,* deracoxib; *doxil,* pegylated liposomal encapsulated doxorubicin; *DTIC,* dacarbazine; *epi,* epirubicin; *HSA,* hemangiosarcoma; *IFOS,* ifosfamide; *L-MTP-PE,* liposomal muramyl tripeptide phosphatidylethanolamine; *LDC,* low dose chemotherapy (cyclophosphamide, etoposide, piroxicam); *MST,* median survival time; *PSP,* polysaccharopeptide *(Coriolus versicolor); ref,* references; *RT,* radiation therapy; *TOC,* toceranib phosphate; *V,* vincristine; *VAX,* tumor lysate vaccine.

Attempts to improve on reported MSTs have been made through the use of dosage-intensified single agent DOX protocols along with both intravenous (IV) and intraperitoneal (IP) administration of the liposome-encapsulated form of DOX (Doxil), but have not resulted in significant survival benefit.[117-119] However, interestingly, the IP-treated dogs had fewer serosal, mesenteric, and omental metastases than historical controls treated with systemic doxorubicin.[119]

Epirubicin, a stereoisomer of doxorubicin, was developed in an effort to decrease cardiotoxicosis in people and has been evaluated in dogs. In a study of 18 dogs receiving epirubicin following splenectomy, an MST of 144 days was noted.[120] Epirubicin was associated with a higher rate of gastrointestinal side effects, often necessitating hospitalization, than the rate of such side effects commonly seen with monotherapy DOX. Regardless, this agent could be an attractive alternative for patients with pre-existing cardiomyopathy. Additionally, in a small study, ifosfamide was administered to six dogs following splenectomy for HSA, resulting in a comparable MST of 147 days.[121]

For dogs with subcutaneous or intramuscular HSA, chemotherapy generally is used in the postoperative setting in order to address the considerable metastatic rate. According to multiple studies, dogs with lower stage disease and with tumors that are less locally invasive appear to have a better prognosis.[58,60,62] Interestingly, the results of two recent retrospective studies evaluating dogs undergoing local therapy followed by adjuvant doxorubicin were quite disparate. In the first study, a median survival time of 1189 days was reported for dogs undergoing surgery and adjuvant doxorubicin ± radiation therapy for non-metastatic subcutaneous HSA (n = 17) and 272.5 days for dogs receiving similar therapy for non-metastatic intramuscular HSA (n = 4).[60] The second study evaluating 71 dogs (subcutaneous HSA n = 55, intramuscular HSA n = 16) reported an overall survival time of 246 days for those dogs having adequate local tumor control of smaller (<4 cm) tumors without metastasis.[62] Possibilities to explain this discrepancy might involve the terminology used for cutaneous and subcutaneous HSA (in the first study, dogs with primary cutaneous HSA with subcutaneous extension might have been included, whereas the second study included only those dogs with tumors arising from the subcutaneous space and excluded those with primary cutaneous HSA) and the small number of dogs in each group.

The MST for dogs with cardiac HSA (see ch. 254) remains notably lower than those achieved for the splenic presentation, likely due to the difficulty in obtaining local control for a cardiac tumor as compared with HSA arising from other anatomic sites. However, when surgical excision is feasible and is combined with adjuvant chemotherapy, survival times comparable to those achieved with splenectomy and chemotherapy might be possible. Specifically, a recent study evaluating 23 dogs with cardiac HSA reported an MST of 42 days for dogs treated with surgery alone versus 175 days for dogs receiving adjuvant chemotherapy.[122] When surgical biopsy is not possible, the diagnosis of cardiac HSA becomes only presumptive. Only recently have some data become available regarding the outcomes of patients undergoing chemotherapy for macroscopic presumed cardiac HSA. A small study of 16 dogs with right atrial masses that received DOX either alone or in combination with cyclophosphamide, ifosfamide, or dacarbazine, documented an MST of 140 days.[123] A second, larger retrospective study evaluated 64 dogs treated with a standardized protocol of single-agent DOX. The objective response rate was 41% and the biologic response rate (measureable responses plus stable disease), or "clinical benefit," was 68%. The MST for treated dogs was 116 days and was significantly improved compared to the MST of 12 days for the 76 untreated contemporary control dogs.[124]

Patients presenting with non-resectable and/or higher stage HSA represent a therapeutic challenge and little information exists regarding treatment of these patients in large number. Due to a perceived poor prognosis, patients often are not treated; however, data exist to suggest that a subset can respond to therapy. A study of 18 dogs receiving DOX-based chemotherapy for non-resectable subcutaneous HSA reported a response rate of 38% for a median duration of only 53 days.[66] Thus, this approach could represent a more palliative therapy or a possible neoadjuvant therapy to downsize tumors to improve resectability. A more drug-intensive protocol combining dacarbazine, DOX, and vincristine (DAV protocol) was evaluated in 24 dogs with advanced stage inoperable HSA and a response rate of 47.4% was reported, including five complete and four partial responses.[125] The median time to tumor progression was 101 days in this study. Another retrospective study evaluated 67 dogs with stage III (n = 25) or stage I/II (n = 42) treated with a VAC chemotherapy protocol.[126] Of the 25 stage III dogs, primary tumor location varied, but a predilection was noted for the spleen (n = 11), subcutaneous tissue (n = 5), and right atrium (n = 4). The overall MST for the 67 dogs was 189 days and interestingly, there was no significant difference between MST for the stage III (195 days) and stage I/II dogs (189 days). Response data were available for 28 dogs and the overall objective response rate for these patients was 86%.[126]

Metronomic Chemotherapy

A shift in the paradigm of chemotherapy administration currently is underway. Specifically, the use of metronomic (low dosage, continuous) chemotherapy is becoming more commonplace and has been evaluated in canine HSA.[127] Conventional chemotherapy typically involves the use of cycles ("pulses" or "bursts") of

chemotherapy given at the maximally tolerated dose (MTD) with long breaks to allow normal cells to recover from damage. Conversely, metronomic chemotherapy utilizes continuous (typically once daily) administration of chemotherapeutics at a dosage well below the MTD, without prolonged drug-free breaks.[127-131] A key feature of metronomic chemotherapy is compression of the drug administration schedule with the cumulative dose being significantly less than with MTD-based chemotherapy, the result of which should be a favorable toxicity profile and the potential for long-term administration without interruption. Unlike MTD chemotherapy, where the tumor cells are the primary targets of therapy, metronomic therapy appears to target cells of the tumor microenvironment including the endothelial cells that support and nourish the tumor. In this context, the chemotherapeutics may act as anti-angiogenic agents.[127-131] The mechanisms of action include direct apoptosis for dividing endothelial cells, suppression of the mobilization of circulating endothelial progenitor cells (CEPs) from the bone marrow, and increasing production of the body's own natural angiogenesis inhibitors.[127-131] Furthermore, metronomic chemotherapy has been shown to selectively inhibit and deplete T-regulatory (Tregs) lymphocytes, thereby decreasing immune tolerance.[127-131] A pilot study evaluated a metronomic protocol consisting of cyclophosphamide, etoposide, and piroxicam in nine splenectomized dogs with stage II HSA. The MST of 178 days compared favorably to an MST of 133 days in 24 dogs with stage II HSA treated with splenectomy and five doses of adjuvant DOX.[127] No severe adverse effects were noted in the dogs treated with the metronomic chemotherapy protocol. Furthermore, dogs with macroscopic primary and metastatic hemangiosarcoma treated with metronomic lomustine (CCNU) had a median survival of 120 days, with no actual measureable responses documented.[132] In another study, low-dosage administration of chlorambucil resulted in stable disease in 3 of 5 dogs with macroscopic HSA.[133] Finally, minocycline is an antibiotic with mild antiangiogenic activity that has been found to be safe in combination with adjuvant AC chemotherapy in dogs with HSA. However no improvement in survival was noted in comparison to controls.[134]

Cyclooxygenase Inhibitors

Cyclooxygenases (COXs) catalyze the initial rate-limiting steps in the conversion of arachidonic acid to prostaglandins and thromboxanes. Two isoforms of this enzyme have been identified: COX-1 and COX-2. Research has shown that COX-2 plays a significant role in the development and progression of cancer, and as such, it represents a novel antineoplastic therapeutic target.[135-139] COX-2 inhibitors are commonplace as part of metronomic protocols and they have documented activity as single agents for certain cancers, specifically carcinomas.[138-142] Unlike most canine carcinomas surveyed so far, canine HSA typically does not appear to overexpress COX-2.[143] However, because COX-2-inhibiting nonsteroidal anti-inflammatory drugs have shown clinical efficacy against other tumors that do not overexpress COX-2, it is reasonable to use them both as part of metronomic chemotherapy[127] and in combination with conventional chemotherapy for HSA. In fact, the addition of a selective COX-2 inhibitor, deracoxib, has been evaluated as part of a protocol for dogs with HSA treated with standard DOX therapy.[111] An overall median survival of 150 days was noted and the dogs with stage III disease had a median survival of 149 days, which is longer than previously reported for dogs with this more advanced presentation of disease.[111]

Novel Therapies

Immunotherapy

Immunotherapy has long been a field of active research in human cancer medicine and more recently it has become of increasing interest in veterinary oncology (see ch. 341). Immunotherapy strategies include biologic response modifiers, recombinant cytokines, and tumor vaccines.[144] A small number of studies investigating immunotherapies in canine HSA have been published. For example, the use of a novel tumor vaccine was evaluated in conjunction with DOX in 28 dogs with various presentations of HSA. The vaccine consisted of lysates from an allogeneic canine HSA cell line mixed with an adjuvant composed of liposome DNA complex. Vaccinated dogs were found to mount strong antibody responses against canine HSA cells, but this response did not translate into improved survival, as the median survival time of 13 dogs with stage II splenic HSA that received the tumor vaccine plus DOX chemotherapy was 182 days.[145] The combination of the AC protocol and the immunomodulator L-MTP-PE resulted in a significant increase in disease free survival and overall survival time (277 days) compared to dogs receiving chemotherapy with placebo liposomes.[116] This improvement was most evident in dogs that presented with Stage I HSA, while dogs with Stage II HSA did

not appear to derive significant additional survival benefit beyond that achieved with DOX-based chemotherapy alone.[116] As noted above, L-MTP-PE currently is not commercially available, thus limiting its clinical use.

Molecular Targeted Therapy

Understandably, given the failure of chemotherapeutic and immunotherapeutic approaches to significantly improve outcomes of dogs with visceral HSA, the potential for the use of more targeted therapies provides a new area of investigation for this disease (see ch. 342). Exploiting the angiogenic nature of this cancer is one such avenue, and analysis of canine HSA cell lines, tumor samples, and blood/effusion samples from dogs with the disease demonstrate active angiogenic pathways.[6,7,46,48] Furthermore, expression of receptor tyrosine kinases including stem cell factor receptor (KIT), platelet derived growth factor receptor (PDGFR), and vascular endothelial growth factor receptor (VEGFR) family members has been documented.[52-57] Targeted small molecule inhibitors such as masitinib, which blocks the function of KIT and PDGFR, demonstrated growth inhibition and the ability to induce apoptosis in canine HSA cell lines *in vitro*.[146,147] The challenge, as with many agents initially evaluated in the *in vitro* setting, is that the drug concentrations required for this effect are unlikely to be achieved *in vivo* without significant toxicosis. Two other small molecule inhibitors—imatinib, which blocks KIT and PDGFR, and dasatinib which blocks KIT, PDGFR, and SRC—also have demonstrated activity against HSA cell lines *in vitro*.[54] Furthermore, imatinib demonstrated significant growth inhibition of canine HSA xenografts in mice. Toceranib phosphate (Palladia) is another small molecule inhibitor that blocks signaling of KIT, PDGFR, and VEGFR family members. Toceranib has demonstrated activity against multiple tumor types, including mast cell tumor, anal sac adenocarcinoma, metastatic osteosarcoma, nasal carcinoma, thyroid carcinoma, and oral squamous cell carcinoma.[148-150] A recent prospective study evaluated the impact of toceranib administration on progression-free survival in 31 dogs with stage I or II HSA following splenectomy and single agent DOX treatment. Disappointingly, there was no significant improvement in median disease free interval (DFI = 161 days) or overall survival (MST = 172 days) for dogs receiving maintenance toceranib.[151]

Natural Products

Alternative therapies using natural products have become a novel source of investigation in HSA. Yunnan Baiyao is a Chinese herbal medicine that, anecdotally, was utilized to control bleeding in dogs with HSA. An *in vitro* study evaluated the effects of Yunnan Baiyao in three canine HSA cell lines and documented a dose- and time-dependent cell death via caspase-mediated apoptosis.[152] Polysaccharopeptide (PSP), the bioactive agent from the mushroom *Coriolus versicolor*, has putative *in vitro* and *in vivo* antitumor effects.[153] In a recent double-blind, randomized, multi-dosage pilot study, high-dose PSP significantly delayed the progression of metastases and improved survival times for canine HSA patients when compared with historical control data of dogs undergoing surgery alone.[154] Although this study's results were promising, it is important to point out that each group contained only five dogs.

Summary

As discussed above, there is variation in the presentation and associated prognoses with the different anatomic forms of HSA. Regardless, HSA remains one of the most aggressive and lethal cancers in companion animals. Certainly, surgical tumor removal followed by adjuvant DOX chemotherapy, as is the current treatment of choice for splenic HSA, remains the approach that is most likely to provide the longest survival benefit for any anatomic presentation of this neoplasm. However, the emergence of more novel therapies could hold promise for potential improvements in historically stagnant survival times associated with this cancer.

CHAPTER 348

Bone and Joint Tumors

Julius M. Liptak

Canine Appendicular Osteosarcoma

The four primary bone tumors are osteosarcoma (OSA), chondrosarcoma (CSA), fibrosarcoma (FSA), and hemangiosarcoma (HSA).[1] Liposarcoma, rhabdomyosarcoma, plasma cell tumors (solitary plasmacytoma and multiple myeloma), and lymphoma also can involve bone, but more typically as a secondary process.[1] OSA is the most common primary bone tumor, accounting for more than 85% to 98% of all appendicular bone tumors.[1,2] OSA can also occur primarily in the axial skeleton and extraskeletal tissues, including visceral organs, skin, and mammary glands.

OSA is a tumor of unknown cause. Repetitive injury to the physis has been proposed, due to the high incidence of OSA in the metaphyseal region of large-breed dogs with late-closing physes. However, published evidence fails to support this theory.[1,3] Other potential causes include viral transmission and a genetic predisposition.[1,4] OSA has been reported in association with previous fractures and/or implants, particularly in the femoral diaphysis, and in other bone diseases such as infarcts and bone cysts.[4] An association between tibial plateau leveling osteotomy (TPLO) and proximal tibial OSA has been proposed, but this is more likely due to the mechanisms associated with fracture-associated sarcomas than to the TPLO procedure specifically.[5,6] Radiation-induced OSA also has been documented and could be associated with protocols involving radiation doses >3.5 Gy per fraction (see ch. 340).[1]

Signalment

Appendicular OSA usually is a disease of large to giant breeds of dogs.[1] OSA also affects smaller breeds, but they are 20 times less likely to develop OSA.[7] Breed predispositions have been reported; however, size, and particularly height, are more important risk factors than breed.[1,8] Neutered dogs, regardless of sex, have a twofold greater risk of developing OSA compared with sexually intact dogs.[8] The age distribution at diagnosis is bimodal, with most dogs between 7 and 9 years of age and a smaller population between 1 and 2 years of age.[1,8]

Diagnosis

Lameness and localized limb swelling are the most common signs.[1] Pain and lameness are caused by microfractures, disruption of the periosteum with tumor extension, and pathologic fracture.[1] Appendicular OSA occurs in the metaphyseal region of long bones. The thoracic limb is involved 1.7 times more frequently than the pelvic limb.[1,9] The distal radius (23.1% of OSA cases) and proximal humerus (18.5%) are the two most common sites for OSA.[1,9] In the hindlimb, OSA occurs in the tibia and femur with equal frequency. The femur is the most common site in dogs weighing <15 kg.[7]

An orthopedic examination (see ch. 353) is necessary to localize the source of lameness and differentiate metaphyseal pain from other common diseases (e.g., osteoarthritis, cranial cruciate ligament rupture, hip dysplasia). Physical examination and a minimum database consisting of a complete blood count, serum biochemistry profile, and urinalysis are important to evaluate general health status and ability to tolerate surgery and chemotherapy.

Regional radiographs are recommended to establish a tentative diagnosis and differentiate primary bone tumors from other orthopedic diseases. Three basic types of OSA exist: endosteal, periosteal, and

parosteal.[1,10] Periosteal and parosteal OSA are rare and arise from the surface of long bones.[1,10] Endosteal OSA is far more common.[1] The radiographic appearance of endosteal OSA can range from lytic to blastic, and it is usually a mixture of both patterns.[1,10] Other characteristic radiographic signs of primary bone tumors include cortical lysis; periosteal proliferation; palisading new bone formation perpendicular to the axis of cortical bone (sunburst effect); periosteal lifting due to subperiosteal hemorrhage (Codman's triangle); loss of the fine, trabecular pattern in metaphyseal bone; and pathologic fracture with metaphyseal collapse.[1,10] Appendicular FSA and CSA have a similar radiographic appearance to OSA and cannot be differentiated radiographically. However, classic signalment and radiographic findings are often sufficient for the diagnosis of a primary bone tumor.[1,10]

Differential diagnoses for primary bone tumors include fungal osteomyelitis, especially *Coccidioides immitis* (see ch. 232) and *Blastomyces dermatitidis* (see ch. 233).[1,10] A thorough history is necessary to determine whether the dog lives in or has traveled through an area where fungal disease is endemic. Dogs with fungal osteomyelitis often have systemic illness and polyostotic bone disease.[1,10] Conversely, dogs with primary bone tumors rarely show signs of systemic illness, and bone involvement usually is confined to one site.[1,10] Bacterial osteomyelitis, atypical bone cysts, and metastatic neoplasia are other potential differential diagnoses.

Bone biopsy can be performed to confirm the diagnosis using closed (see ch. 92) or open techniques.[11-16] Fine needle aspiration (FNA; see ch. 93), with or without ultrasound guidance, is a useful, minimally invasive technique to diagnose sarcoma and differentiate primary bone tumors from metastatic disease and fungal osteomyelitis.[11-14] Core aspirate cytology using a bone marrow biopsy needle has a 95% success rate for the diagnosis of OSA in dogs compared to 85% for FNA cytology.[13] The use of alkaline phosphatase (ALP) staining following either FNA or core aspirate cytology has had a 100% sensitivity for the diagnosis of OSA.[12,13] Closed-needle core biopsy, using either a Jamshidi needle or a Michele trephine, is invasive and requires general anesthesia.[1] Biopsies should be planned and performed meticulously, preferably by the primary surgeon, so the biopsy does not compromise surgical options.[1] The biopsy should be performed to ensure that the biopsy tract can be excised en bloc with the tumor and that unaffected tissues are not contaminated during the biopsy procedure or by postbiopsy hematoma formation.[1] Large core samples can be obtained with a Michele trephine, resulting in a diagnostic accuracy rate of 94%, but the larger bone defect also increases the risk of pathologic fracture.[1,15] Bone biopsies procured with a Jamshidi needle have an accuracy rate of 82%, and the smaller-gauge needle decreases the risk of complications and creates a much smaller biopsy tract.[16] Two to four biopsy samples should be collected from the center and periphery of the lesion through a single stab incision in the skin. The risk of pathologic fracture increases if the biopsy needle penetrates both the near and far cortices.[1] Multiple specimens increase diagnostic accuracy, because small samples can be misdiagnosed due to the heterogeneity of OSA.[1] Central bone biopsies are recommended, because the peripheral aspects of bone tumors often contain reactive bone.[1] After definitive surgery, the entire tumor should be submitted for histologic analysis to confirm the diagnosis.

Appendicular OSA is a highly aggressive tumor. More than 60% of dogs will eventually die because of metastatic disease; however, <15% of dogs have clinically detectable metastasis at the time of initial diagnosis.[1] Metastasis occurs primarily hematogenously, particularly to the lungs and other bone, although metastasis to regional lymph nodes is reported in 4.4% of dogs with OSA.[17,18] Palpation of regional lymph nodes, thoracic radiographs, and nuclear scintigraphy are essential tools for thorough staging of dogs with a suspected primary bone tumor (Figure 348-1). The presence of detectable metastatic disease markedly influences the management options for dogs with OSA.[1,19-21] High-detail, three-view inspiratory thoracic radiographs, including right and left lateral and ventrodorsal or dorsoventral projections, are required for the diagnosis of pulmonary metastases.[1,10] Lesions ≥7 mm in diameter can be detected with good-quality radiographs.[1,22] Computed tomography (CT) provides greater sensitivity to detect metastatic lesions, but has been associated with false-positive diagnoses of metastases.[1,19,22-24] Pulmonary metastatic lesions are detected significantly more frequently with thoracic CT scans (28%-64%) compared to three-view thoracic radiographs (5%-52%).[23,24] However, while the number of metastatic nodules has a significant influence on survival time, the presence of pulmonary metastatic lesions on CT scan has not been significantly associated with survival time.[23] Whole-body bone scintigraphy, using radiolabeled technetium pertechnetate, is highly sensitive for the detection of concurrent skeletal abnormalities, including both primary and metastatic

tumors, but it is not specific for the diagnosis of neoplasia.[1,20,21] In one study, a second asymptomatic bone lesion, consistent with metastatic disease, was identified in 7.8% of 399 dogs with OSA.[21] If a suspicious lesion is identified, fine-detail radiographs of the region should be obtained. Bone biopsy may be performed for confirmation if radiographic results are equivocal. Alternatively, survey radiographs of the skeleton, consisting of lateral radiographs of long bones and ventrodorsal radiographs of the pelvis, can screen for bone metastases if scintigraphy is unavailable.[25] When present, metastatic skeletal disease is a negative prognostic indicator. This becomes extremely important when limb amputation is planned, because occult skeletal metastases may become clinically symptomatic after surgery, rendering the dog nonambulatory.

Treatment

Palliative Management: General

Management options for dogs with appendicular OSA can be classified into two pathways: palliative-intent or curative-intent (E-Figure 348-2). Palliation is indicated for dogs with metastatic disease, or when owners do not want to pursue more intensive treatment options. Palliative therapy is geared toward management of pain and lameness associated with the primary bone tumor but does not improve survival time. Analgesia is the cornerstone for such treatment (Table 348-1).[26] Nonsteroidal antiinflammatory drugs (NSAIDs) may initially be sufficient to manage pain and improve quality of life (see ch. 164). Cyclooxygenase-1-sparing NSAIDs are preferred, as adverse effects are reduced.[26] More potent analgesic drugs, or combinations of drugs, often are required for effective pain relief (see Table 348-1 and ch. 356).[26] Bisphosphonate drugs such as pamidronate have been shown to be safe in dogs and effective in achieving analgesia for >4 months in 28% of dogs, with a 231-day median duration of analgesia when combined with an NSAID.[27,28] Multiple-drug combinations are most efficacious for refractory pain, creating an additive or synergistic analgesic effect. The median survival time (MST) for dogs with appendicular OSA treated with analgesic drugs alone has not been reported, although anecdotal evidence suggests that 1 to 3 months is a reasonable expectation.

TABLE 348-1

Oral and Transdermal Analgesic Drugs Used for the Palliation of Dogs with Appendicular Osteosarcoma[26-28]

ANALGESIC DRUG	DOSAGE	INTERVAL	COMMENTS
NSAIDs			
Carprofen	2.2 mg/kg	12 h	Idiosyncratic hepatic failure, gastric ulceration, kidney injury, and lethargy
Deracoxib	1-2 mg/kg	24 h	Gastric ulceration, kidney injury
Etodolac	10-15 mg/kg	24 h	Gastric ulceration, kidney injury
Meloxicam	0.05-0.1 mg/kg	24 h	Gastric ulceration, kidney injury
Ketoprofen	0.5-1 mg/kg	24 h	Gastric ulceration, kidney injury, and platelet aggregation inhibition
Piroxicam	0.3 mg/kg	48 h	Gastric ulceration, kidney injury
Partial Agonists			
Butorphanol	0.55 mg/kg	1-2 h	Controlled substance; short duration of activity, ceiling effect of analgesia, sedation, and respiratory depression
Opioids			
Morphine	0.5-1 mg/kg	8-12 h	Controlled substance; sedation, euphoria, bradycardia, vomiting, urine retention, and constipation
Fentanyl patch	50 mcg/h (10-20 kg)	72 h	Controlled substance; variable serum concentration due to application site, skin blood flow and temperature, and hydration; correct disposal required, as residual dose can be lethal to humans
	75 mcg/h (20-30 kg)	72 h	
	100 mcg/h (>30 kg)	72 h	
Miscellaneous			
Pamidronate	1-2 mg/kg	28 days	Bisphosphonate drug with antiosteoclastic and possible antineoplastic activity; analgesic effect best when combined with an NSAID; contraindicated with kidney disease

Tramadol	2-5 mg/kg	8-12 h	Constipation with chronic use, lethargy at high doses
Codeine-acetaminophen	0.5-2 mg/kg	6-8 h	Controlled substance, anemia
Amantadine	3 mg/kg	24 h	NMDA antagonist
Prednisone	0.5-1 mg/kg	12-24 h	Anti-inflammatory, synergistic activity with opiates, contraindicated with NSAIDs
Amitriptyline	1-2 mg/kg	12-24 h	Tricyclic antidepressant, alters serotonin and norepinephrine activity

NMDA, N-methyl-D-aspartate; *NSAIDs*, nonsteroidal anti-inflammatory drugs.

E-FIGURE 348-2 A photograph of a dog 6 months after forequarter amputation for a proximal humeral osteosarcoma. Quality of life is often excellent following limb amputation in large-breed dogs, despite their size and body weight and frequent preexisting osteoarthritis.

Palliative Radiation Therapy

Radiation therapy (see ch. 240) is effective for palliation of dogs with primary bone tumors. Many different protocols have been described, most commonly 4 to 10 Gy administered on a 0-7-21–day or monthly protocol.[29-36] These protocols are relatively inexpensive and do not require prolonged hospitalization. Radiation reduces local inflammation, minimizes pain, slows progression of metastatic lesions, and improves quality of life in dogs with primary and metastatic lesions.[29-36] A 50% to 92% response rate has been reported, with the median onset of response 11 to 14 days after initiation of radiation therapy and median duration of response lasting 53 to 130 days.[29-36] The duration of response is significantly improved when <50% of bone length is affected by tumor. Primary bone tumors located in the proximal humerus[32,33] and distal radius[35] have been reported to have better responses. Higher cumulative doses, higher intensity of treatment, and the addition of chemotherapy to palliative radiation protocols have been reported to improve rate and duration of response.[31-33,36] Palliative radiation therapy is not associated with acute effects and does not negatively influence quality of life.[29-36] The MST for dogs with appendicular OSA treated with palliative radiation is 122 to 313 days.[29-36] Radiopharmaceuticals, such as samarium, have been used for the palliation of primary and metastatic bone lesions, but they are expensive and are not widely available in veterinary medicine.[37-39] The

combination of palliative radiation and pamidronate has been recommended, but one study showed a significantly decreased MST in dogs receiving this treatment (122 days) compared to palliative radiation therapy alone or combined with chemotherapy (307 days).[36]

Limb Amputation

Limb amputation can be used as palliative therapy and as part of the curative-intent treatment in dogs with primary bone tumors.[1,17,40,41] Amputation is an effective means of pain control, particularly in dogs with pathologic fracture and lameness unresponsive to analgesic drugs or radiation therapy. Osteoarthritis, neurologic disease, obesity, and large body size have been cited as relative contraindications.[1,40,41] Experience has shown that osteoarthritis, weight, and body size are rarely problematic. Most dogs with OSA are middle-aged to older, large-breed dogs with moderate preexisting osteoarthritis. They rarely have difficulties following amputation (see E-Figure 348-2 and ch. 355).[41] Dogs with neurologic disease or severe signs of osteoarthritis are exceptions, and palliative management or limb-sparing techniques should be considered in these dogs.

When the thoracic limb is amputated, the scapula should be removed, because tumor control is better, particularly for dogs with proximal humeral OSA, and cosmetic appearance is improved.[1] In the pelvic limb, coxofemoral disarticulation should be performed for dogs with OSA distal to the proximal femur, whereas dogs with proximal femoral OSA should be treated with either en bloc acetabulectomy or subtotal hemipelvectomy to achieve adequate tumor control and minimize the risk of local recurrence.

Most dogs are able to ambulate unassisted within 12 to 24 hours after limb amputation. Amputees should be encouraged by the owners to ambulate at home after discharge to speed recovery. Studies have shown that most dogs fully adapt to amputation by 4 weeks after surgery. If the dog was significantly lame from the tumor prior to surgery, full recovery often occurs more quickly than 4 weeks. In addition, a positive attitude by the owners shortens the time to adaptation after amputation.[41] Body weight and thoracic or pelvic limb amputation do not have a significant influence on the time to adaptation after amputation; however, early in the postoperative period, dogs with thoracic limb amputation have greater difficulty in balancing.[41] Behavioral changes, such as increased anxiety and loss of dominance, have also been observed but are relatively uncommon.[41] Complications associated with limb amputation are rare. Intraoperative complications can include hemorrhage, air embolism, and inadvertent thoracotomy (during forequarter amputations). Possible postoperative complications include infection, seroma formation, and stump recurrence. The survival time of dogs treated with amputation alone is significantly better than with the use of analgesic drugs or palliative radiation therapy.[14] The MST for dogs with OSA treated with limb amputation alone is 103 to 175 days with a 6-month survival rate of 47% to 52%, a 12-month survival rate of 11% to 21%, and a 24-month survival rate of 0% to 4%.[17,42-45] The MST of 257 days is longer for small breed dogs with appendicular OSA treated with amputation alone.[46]

Limb-Sparing Surgery

Limb-sparing techniques are more common despite the success of limb amputation in dogs with primary bone tumors.[1,40,47-61] The most common reason for limb sparing in dogs with OSA is owner reluctance to proceed with amputation. Medical indications for limb sparing include previous amputation of another limb, severe concurrent osteoarthritis, or neurologic disease.[1,40]

Limb-sparing surgery is most successful for dogs with primary bone tumors in the distal radius and ulna.[40,47-58] Limb-sparing surgery for other anatomic locations is often associated with a high complication rate and poor postoperative limb function.[55-58] Candidates for limb-sparing surgery include dogs with tumors confined to the bone, minimal extension into adjacent soft tissue, and involvement of <50% of the bone length.[1,40] The extent of bone involvement is most accurately determined using CT scans;[62] bone involvement is overestimated by radiographs, nuclear scintigraphy, and magnetic resonance imaging (MRI).[62-64] Pathologic fractures are a relative contraindication due to local contamination via hemorrhage and hematoma, although the risk of local tumor recurrence can be reduced by preoperative chemotherapy or radiation therapy.[40]

Many surgical techniques have been reported to preserve limb function.[1,40,47-58] After marginal resection of the soft-tissue component of the bone tumor, the osseous defect is filled with a massive cortical allograft (E-Figure 348-3), endoprosthesis (E-Figure 348-4), vascularized ulnar graft, pasteurized or irradiated autograft,

or segmental bone transport osteogenesis.[1,40,47-58] Arthrodesis of the adjacent joint often is required;[1,40] pancarpal arthrodesis is well tolerated in dogs, but arthrodesis of the shoulder, stifle, or tarsal joint results in poor limb function. Joint preservation is possible with OSA of the ulna or diaphysis of any other long bone,[65] and joint-preserving limb-salvage options may become more popular as total joint arthroplasties are adapted for oncologic applications.[66] Weight-bearing and range-of-motion exercises can be started immediately postoperatively, but activity should be restricted to leashed walks for the first 4 weeks.[1,40] Exercise is important to prevent flexure contracture of the digits and to minimize swelling of the paw and digits (see ch. 355). Good to excellent limb use is achieved in >75% of dogs.[1,40,47-49]

E-FIGURE 348-3 Lateral radiographic projection of limb-sparing surgery of the distal radius using a cortical allograft.

E-FIGURE 348-4 An intraoperative image of an endoprosthesis that has been used to reconstruct the bone defect following bone tumor resection in limb-sparing surgery. There is a variety of different limb-sparing techniques, and this procedure is becoming more common in the treatment of dogs with distal radial bone tumors.

The most commonly reported complications with limb-sparing surgery are implant failure, local tumor recurrence, and infection.[1,40,47-59] Implant failure occurs in up to 40% of cases, and techniques exist for reducing the risk of this complication.[49] Local tumor recurrence is caused by incomplete resection or, more commonly, by residual neoplastic cells remaining in the soft tissue adjacent to the tumor capsule.[1,40] Local recurrence has either no effect[49] or a negative influence on survival time,[57] depending on the study cited. Infection is the most significant postoperative complication encountered with limb-sparing surgery, occurring in up to 70% of limb-spare cases where reconstruction is performed with nonautogenous techniques.[1,40,47-61,68] Several different bacteria have been cultured.[61] Initially, infections are treated with appropriate antibiotics based on sensitivity results, isotonic saline lavages, and wet-to-dry bandages.[1,61] Further options include implantation of antibiotic-impregnated methylmethacrylate beads for persistent infection, or limb amputation for uncontrollable infection.[1,59,61]

A variation on limb-sparing surgery is internal or external fixation of pathologic fractures. In a study of 16 dogs, limb use immediately after surgery was good to very good in all but 2 dogs.[69]

Radiation Therapy

Radiation therapy (see ch. 340) most commonly is used for palliation, but it can be used for control of the primary bone tumor in dogs where surgical options are either not indicated or refused.[70-72] Stereotactic radiation has been used successfully for appendicular OSA in a variety of locations.[70] A steep-dose gradient of radiation is administered locally, with the center of the lesion receiving 45 to 60 Gy and the periphery 30 to 35 Gy.[70] Full-course external-beam radiation therapy has been investigated,[71,72] with total doses ranging between 24 to 54 Gy.[71,72] Complications following both stereotactic and full-course radiation include moist desquamation, alopecia, depigmentation, bone marrow suppression, and pathologic fracture.[70-72] The MST for dogs with OSA treated with stereotactic and curative-intent radiation therapy and adjuvant chemotherapy is 363 days and 7 months, respectively.[70-72] Fracture following stereotactic radiation is a relatively common complication and can be treated with internal fixation.[73]

Chemotherapy

Definitive management of dogs with appendicular OSA requires treatment of both the local bone tumor and micrometastatic disease. The efficacy of chemotherapy in other types of primary bone tumors is less clear. Surgery, unless combined with chemotherapy, is considered palliative.[42-45] Conversely, chemotherapy without surgery does not provide a survival benefit over other palliative techniques, although improved MSTs have been reported with the combination of palliative radiation therapy and chemotherapy.[74,75] In most oncology practices, chemotherapy is initiated at the time of suture removal, but this can vary from prior to surgery, perioperatively, to up to 21 days after surgery.[76] Current chemotherapy protocols include the use

of cisplatin, carboplatin, doxorubicin, and gemcitabine, either as a single agent or in combination (Table 348-2).[1,42-45,76-88] Studies have not shown differences in survival times among the different protocols using single or multiple agents[86,87]; however, carboplatin alone had a significantly longer disease-free interval (DFI) than alternating carboplatin-doxorubicin protocols in one study[86] and was associated with significantly fewer adverse effects in another study.[87] Practically speaking, protocol selection often depends on drug cost, adverse effects, and intensity of treatment. While these chemotherapy agents are administered IV, a single SC infusion of carboplatin has been reported in 17 dogs with appendicular OSA following limb amputation with a MST of 365 days.[89] If cisplatin is used, saline diuresis is necessary to minimize the risk of nephrotoxicosis (Table 348-3).[1] Nephrotoxicosis can also be reduced by using carboplatin instead of cisplatin or concurrently administering amifostine.[1,81-83,90] Doxorubicin has been associated with myocardial toxicosis, particularly with cumulative doses greater than 180 mg/m^2. Therefore, a cardiac evaluation (echocardiogram, serum cardiac troponin-I level, or both) is recommended prior to starting chemotherapy, especially in high-risk breeds.[1,90a,90b]

TABLE 348-2

Chemotherapy Protocols Used in the Management of Dogs with Appendicular Osteosarcoma[42-45,76-88]

AGENT(S)	DOSAGE	INTERVAL	NUMBER	COMMENTS
Cisplatin	70 mg/m2	3 weeks	5	Vomiting during administration, nephrotoxicosis, gastrointestinal toxicosis, mild myelosuppression; nadir at 10 days; MST 262-413 days
Carboplatin	300 mg/m2	3 weeks	4	Myelosuppression, gastrointestinal toxicosis; nadir at 11-14 days; MST 321-366 days
Doxorubicin	30 mg/m2	2-3 weeks	5	Anaphylaxis during administration, gastrointestinal toxicosis, myocardial toxicosis, myelosuppression, nadir at 10 days; MST 366 days
Cisplatin Doxorubicin	50 mg/m^2 15 mg/m^2	3 weeks	4	Cisplatin administered on day 1, doxorubicin on day 2; MST 300-540 days
Carboplatin Doxorubicin	300 mg/m^2 30 mg/m^2	3 weeks	6	Carboplatin and doxorubicin administered alternately every 3 weeks for 3 doses each, for a total of 6 doses; MST 388 days

MST, Median survival time.

TABLE 348-3

Saline Diuresis Protocols Used to Minimize Cisplatin-Associated Nephrotoxicosis[1]

PROTOCOL	PHASE I	PHASE II	PHASE III
6-h	Saline, 18.3 mL/kg/h, 4 h	Cisplatin for 20 min	Saline, 18.3 mL/kg/h, 2 h
24-h	Saline, 3.75 mL/kg/h, 16 h	Cisplatin for 16 h	Saline, 3.75 mL/kg/h, 6 h

After administration of chemotherapy, especially after the first dose, dogs should be discharged with antibiotics and antiemetics for palliation of gastrointestinal disease and nausea if needed at home (see ch. 343). A complete blood count should be performed at the time of leukocyte nadir, generally 7 to 10 days after chemotherapy, and immediately before subsequent chemotherapy doses, to assess for myelosuppression. Chemotherapy administration should be delayed, or the dose decreased, if the neutrophil count is <2000/mcL, or platelet count is <100,000/mcL.[1] The MST for dogs treated with surgery and chemotherapy is 235-366 days (12-month survival, 33-65%; 24-month survival, 16-28%).[42-45,76-88] The MST for small breed dogs with appendicular OSA treated with curative intent is 415 days.[46]

The combination of full course chemotherapy and metronomic chemotherapy has been investigated because continuous metronomic chemotherapy might improve outcomes in dogs with OSA. In 30 dogs with

appendicular OSA, metronomic chemotherapy (piroxicam and low-dosage cyclophosphamide) was well-tolerated when combined with either carboplatin alone or alternating carboplatin and doxorubicin, but there were significantly more grade 3 and 4 toxicoses when combined with carboplatin alone.[91]

The role of immunotherapy (see ch. 341) is undefined. A significantly longer DFI and survival time have been reported in dogs treated with a nonspecific immunostimulant, muramyl tripeptide phosphatidylethanolamine.[92,93] The antimicrobial drug suramin plus doxorubicin after amputation for appendicular OSA in 47 dogs was well tolerated, with a MST of 369 days.[88] Increased immune stimulation also is suspected in the prolonged survival times of dogs with infected limb-sparing surgery and four dogs with spontaneous regression of OSA lesions.[49,68,94,95]

Metastasis

Metastatic disease is the most common cause of death or euthanasia in dogs with appendicular OSA after definitive treatment.[1] Pulmonary (Figure 348-5) and skeletal sites are most frequently involved; other metastatic sites include SC tissue, mediastinum, myocardium, diaphragm, kidneys, spleen, small intestine, spinal cord and brain, and lymph nodes.[1,14,17] Interestingly, metastatic disease rarely occurs in dogs undergoing palliative, nonsurgical treatment, but it is the major cause of death in dogs treated with surgery alone, despite the minimal difference in survival time. A recent study, using a mouse OSA model, showed that primary tumor resection enhanced systemic angiogenesis, resulting in progression of distant metastatic lesions.[96] The distribution of metastatic lesions depends on the type of treatment. Pulmonary metastases are more common when only the local tumor is ablated, whereas skeletal metastases are more prevalent when chemotherapy is added to the treatment regimen. Pulmonary metastasis accounts for 61% of all metastatic lesions in dogs treated with amputation alone and 26% when treated with amputation and cisplatin.[17,78] In comparison, skeletal metastases develop in up to 47% of dogs after surgery and postoperative cisplatin.[97]

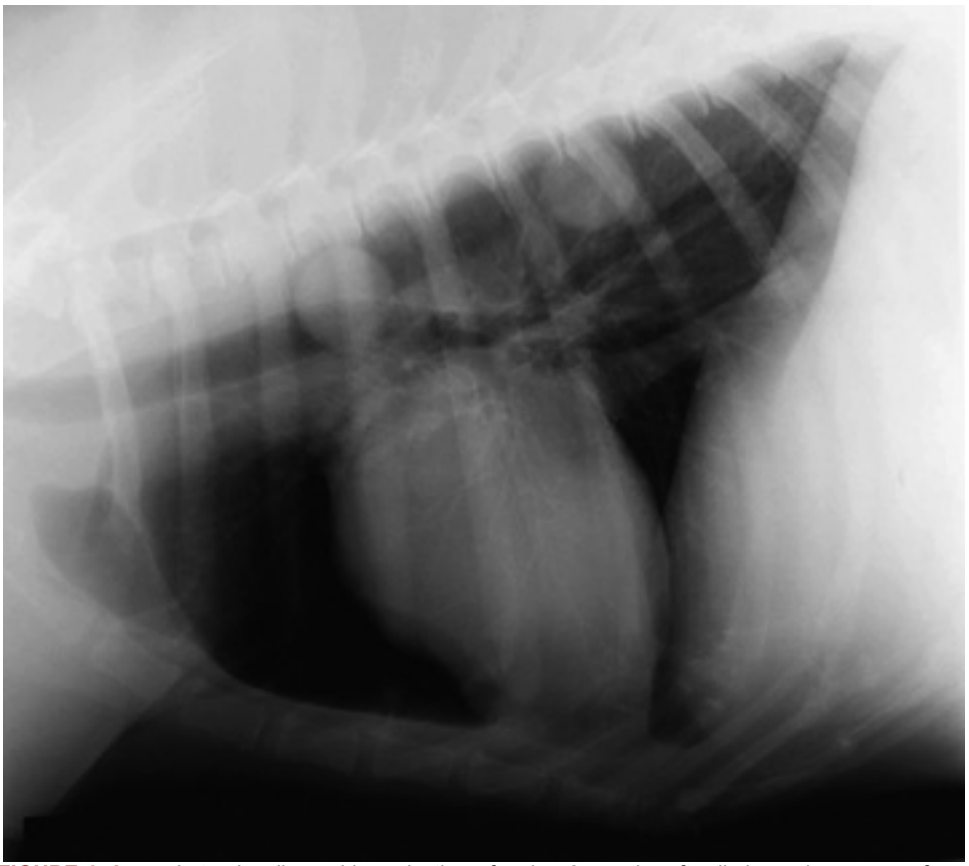

FIGURE 348-5 Lateral radiographic projection of a dog 8 months after limb-sparing surgery for a distal radial osteosarcoma. Two metastatic lesions are seen in the dorsal lung fields.

Generalized malaise is the most common sign in dogs with pulmonary metastasis. Respiratory signs are usually a late development. Occasionally, hypertrophic osteopathy can be the first indication of pulmonary metastasis. Chemotherapy using platinum and antibiotic agents is ineffective in prolonging survival time in dogs with measurable pulmonary metastasis.[97,98] Surgical resection of metastatic lesions, by either subpleural resection or partial lung lobectomy, can significantly improve survival time in select cases (Figure 348-6).[99,100] Candidates for pulmonary metastatectomy include dogs that develop pulmonary metastasis >300 days after initial diagnosis of appendicular OSA, have ≤3 radiographically evident metastatic lesions, have lesions that do not double in size, and have no new lesions develop in a 4-week period.[99] The MST for dogs with metastasis to the lungs is 61 to 95 days when treated with chemotherapy[97,98] and 176 days after metastatectomy.[99] Pulmonary metastatectomy is also recommended for dogs with hypertrophic osteopathy, regardless of the time after diagnosis, as surgical excision of a metastatic lesion can result in immediate resolution of clinical signs.[100]

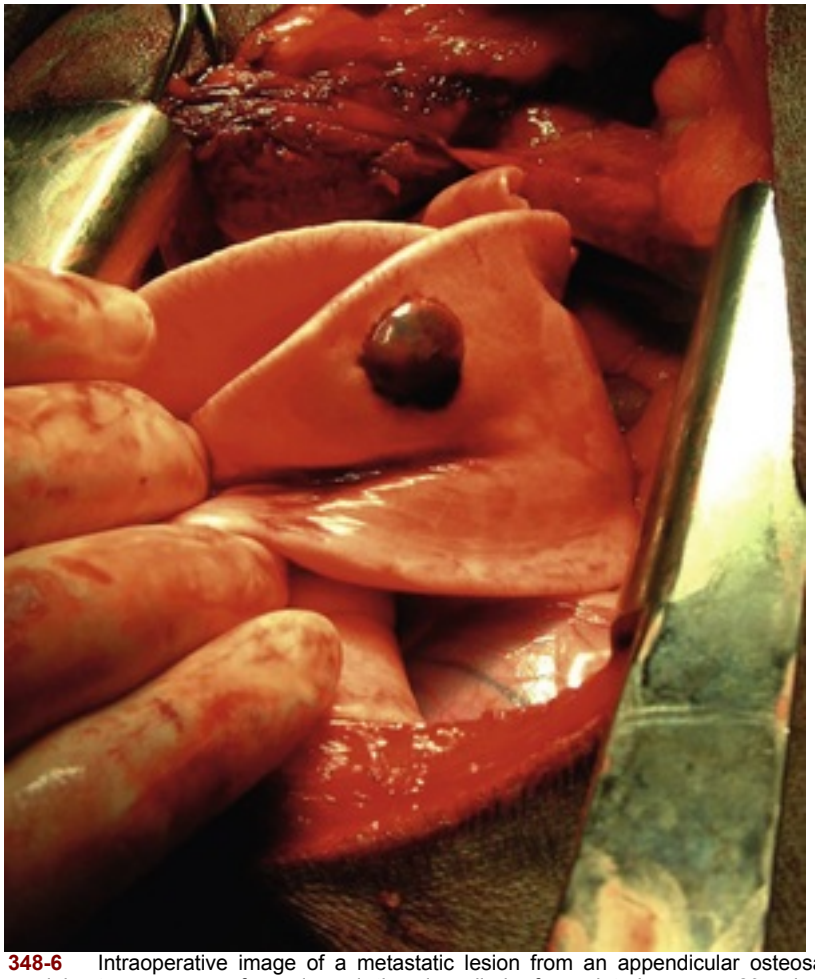

FIGURE 348-6 Intraoperative image of a metastatic lesion from an appendicular osteosarcoma. Partial lung lobectomy was performed, and the dog died of unrelated causes 294 days after metastatectomy.

Management options for dogs with skeletal metastasis include pain control with analgesic drugs, bisphosphonates, and palliative radiation therapy. Bisphosphonates block osteoclast activity, minimizing the risk of pathologic fracture.[27,28,101,102] Dogs with skeletal metastases treated with palliative radiation and chemotherapy have a significantly longer MST (130 days) compared to other palliative treatment modalities and combinations.[103] The combination of pamidronate and an NSAID also can palliate dogs with tumor-related bone pain, with up to 28% of dogs experiencing an analgesic effect for >4 months (median: 231 days).[28] Limb-sparing surgery and curative-intent radiation therapy have been used for treating metastatic skeletal lesions for select cases but are not routinely recommended.[103]

Prognostic Factors

Poor prognostic factors in dogs with OSA include age <7 years or >10 years, body weight >40 kg, large tumor volume, proximal humeral location, increased preoperative total and bone-specific serum alkaline phosphatase (ALP) activity that fails to normalize within 40 days of surgical removal of the tumor, high tumor grade, and presence of metastases.[1,77,84,86,104-107] Dogs with proximal humeral OSA have a significantly shorter DFI and MST than other appendicular OSA sites; however, this could be a function of tumor volume rather than site.[77,86,106,107] The MST for dogs with normal and elevated total serum ALP is 12.5 and 5.5 months, respectively.[105] The MST for dogs with normal and elevated bone-specific serum ALP is 16.6 and 9.5 months.[105] For both bone-specific and total serum ALP, each increase of 100 IU/L increases the risk of death due to OSA by 25%.[104,105] Dogs with limb-sparing-related infection have significantly longer MSTs (685 days) compared to dogs without surgical infections (289 days).[49,68,94] OSA can be histologically subclassified as osteoblastic, chondroblastic, fibroblastic, telangiectatic, and undifferentiated, but histologic subtype has not been shown to be prognostic in dogs or humans.[1]

Canine Appendicular Chondrosarcoma

CSA is the second most common primary bone tumor in dogs.[1] Appendicular CSA accounts for 9-17% of all canine CSA cases.[108-111] The cause is unknown, although CSA has been reported to arise from osteochondroma or sites of previous trauma. Golden Retrievers, German Shepherds, and Boxers are overrepresented. The median age at presentation is 6.0-8.7 years.[108-115] Clinical findings are similar to dogs with appendicular OSA, and biopsy is required to differentiate tumor types. The femur is most commonly involved, and CSA may have a more lytic radiographic appearance than OSA.[110,111] Limb amputation and limb-salvage procedures can be used for managing the local tumor. Metastatic disease is reported in up to 31% of dogs with CSA and is dependent on histologic grade, with distant metastasis reported in 0%, 31% and 50% of dogs with grade I, II and III CSA, respectively.[108-112,115] Chemotherapy does not provide a survival benefit in humans with CSA, and a similar situation probably exists in dogs.[112,113]

The MST for dogs with untreated CSA is 46 days, compared with 540 days to >2618 days for dogs treated with limb amputation alone.[111,112,115] Prognostic criteria in dogs include tumor location and histologic grade.[110,112,114,115] The MSTs for dogs with grade I, II and III appendicular CSA treated with amputation alone are 6.0, 2.7, and 0.9 years, respectively.[115]

Canine Appendicular Fibrosarcoma

FSA is the third most common skeletal neoplasm in dogs and it occurs more commonly in axial than appendicular sites.[109] Two distinct appendicular FSAs exist: central and parosteal.[116] A palpable mass often is present in dogs with parosteal but not central FSA. Parosteal FSA may represent a tumor of soft-tissue origin with secondary invasion into bone.[109,116] The radiographic features of appendicular FSA are similar to OSA, although lytic lesions and pathologic fracture are reported in up to 50% of dogs with FSA.[116] Amputation and limb salvage are the main surgical treatment options. The role of chemotherapy is unknown. Appendicular FSA metastasizes late in the course of disease, often to sites other than the lungs, such as myocardium, pericardium, skin, and other bones.[116] Survival times are difficult to interpret, because >50% of fibroblastic OSAs are misdiagnosed as FSAs.[1,116] The 12-month survival rate for dogs with appendicular FSA treated with limb amputation alone is 66%.[116]

Canine Appendicular Hemangiosarcoma

Skeletal HSA is rare, accounting for 3.6% of all primary bone tumors (see also ch. 347). German Shepherd, Great Dane, and Boxer dogs are overrepresented, with a mean age at presentation of 6.2 to 8.2 years. This is a younger age at presentation than what is reported with most other primary bone tumors.[109] Distribution between appendicular and axial sites is similar, with 43% of cases occurring in the appendicular skeleton.[109,117] The proximal humerus is the most common appendicular site.[117] Skeletal HSA has a different biologic behavior than other primary bone tumors: Most appendicular HSAs have a lytic radiographic appearance, and cortical and periosteal changes may be minimal.[109,117] Polyostotic disease, soft-tissue

extension, and pathologic fractures are common.[109,117] In dogs with appendicular HSA, abdominal ultrasonography and echocardiography are recommended in addition to the other standard staging tests, because 82% of dogs are reported to have extraosseous disease or metastasis.[117] The value of local and systemic treatment is uncertain, because most dogs develop metastases before 6 months, and the 12-month survival rate is <10%.[109,117] However, limb amputation and doxorubicin protocols may be indicated for dogs with nonmetastatic monostotic appendicular HSA.[118] Palliative radiation therapy may be used in dogs with polyostotic disease.

Canine Axial Skeletal Tumors

OSA of the axial skeleton accounts for 25% of all OSA and 59% of OSA in dogs weighing <15 kg.[7,119] However, medium- to large-breed dogs are commonly affected.[118,120] Boxers may be overrepresented, and a female predisposition is reported for all axial sites except the ribs and vertebrae.[119,120] The most common sites of axial OSA are mandible (27% of axial OSA), maxilla (16-22%), vertebrae (7-15%), scapula (13%), skull (11-12%), ribs (10-11%), nasal and paranasal sinuses (9%), and pelvis (4-5%).[119,120] OSA of the hard palate and patella also have been reported.[121,122]

Advanced imaging techniques, particularly CT, are useful for staging and surgical planning. Surgical resection is recommended, although radiation therapy also can be used for local tumor control.[119,120,123] Local recurrence is reported in up to 80% of dogs, and is the most common cause of death. The metastatic rate is 11-46%.[119,120,123-125] The role of chemotherapy is unclear.[119,120,123-130]

The MST for dogs with axial OSA is 120-154 days, with 12- and 24-month survival rates of 26.3% and 18.4%, respectively.[119,120,123] Prognostic factors include anatomic site, body size, breed, increased total serum ALP, and surgical margins.[120,123-130] Smaller-breed dogs have a significantly better survival rate than large-breed dogs.[120] The MST of Golden Retrievers with axial OSA is 100 days, compared with 182 days in purebred dogs and 264 days in mixed-breed dogs.[123] Mandibular OSA has a better prognosis than OSA of the ribs, scapulae, and skull,[120] and in another study, scapular OSA was associated with a 2.8-times increased risk of tumor-related death compared to other non-calvarial axial OSA sites.[131] For dogs with OSA of the mandible, maxilla, or skull, the MST with surgical excision (329 days) is significantly better than with radiation therapy (132 days).[125] Incomplete surgical resection significantly increases the risk of both local recurrence and metastasis.[125-130] The MST after palliative and curative-intent radiation therapy of axial OSA in large-breed dogs is 79 and 265 days respectively,[123] while samarium-153 has been shown to confer a subjective improvement in 4 of 25 dogs with skull tumors.[39]

Skull Tumors

OSA of the skull can involve the calvarium, nasal and paranasal sinuses, maxilla, and mandible. Calvarial OSA accounts for 11-12% of axial OSA.[119,120] Signs include a visible external mass and neurologic signs due to extradural compression of the brain; direct invasion of the brain is rare.[1] Surgical resection is recommended after CT imaging. Perioperative complications can include cerebral edema, brain herniation, pneumomeningocele, aspiration pneumonia, and death.

Axial OSA may also involve the maxilla and mandible; however, it is less common than the other tumors affecting these bones. The most common canine oral tumors are malignant melanoma, squamous cell carcinoma, FSA, OSA, and benign epulides, and these are discussed in ch. 272.[126-130]

The most common cause of death in dogs with axial OSA is local tumor recurrence rather than metastasis. Metastasis is reported in up to 30% of skull OSA. The MST for mandibular OSA treated with mandibulectomy is 7-18 months, with a 12-month survival rate of up to 71%.[124,126-128] Postoperative chemotherapy significantly improves survival time in dogs with mandibular OSA.[124] Histologic grade and score are predictive of survival in dogs with mandibular OSA.[124,128] In contrast, the MST for maxillary OSA treated with maxillectomy is 4.5-10 months, with a 12-month survival rate of 17% to 27%.[129,130] Comprehensive surgical excision with complete histologic margins significantly improves local recurrence and survival rates.[125] Postoperative radiation therapy and chemotherapy have not been shown to improve survival, even in dogs with incomplete tumor resection.[123,125] Similarly, samarium-153 has minimal benefit as sole treatment

for canine calvarial OSA or multilobular osteochondrosarcoma (E-Figure 348-7).[39]

E-FIGURE 348-7 Sagittal CT image of a grade III multilobular osteochondrosarcoma of the vertical ramus of the mandible. Complete resection was performed with a caudal mandibulectomy, and the dog was alive and disease-free at the last follow-up 308 days later.

Scapular Tumors

Scapular OSA accounts for up to 13% of all axial OSA.[109,120,121,123] CSA, FSA, HSA, histiocytic sarcoma, and soft tissue sarcoma also have involved the scapula.[110,132-136] Lameness is the most common clinical sign.[136] Radiographic changes are consistent with appendicular OSA, typically with a mixed pattern of lytic and productive changes.[132] However, due to positioning difficulties and superimposition of the body wall, the extent of disease may be difficult to determine with plain radiographs. CT imaging is helpful to determine the location and extent of involvement (Figure 348-8). Partial or total scapulectomy is recommended, with good to excellent limb function after resection of up to 90% of the scapula.[132-136] A high metastatic rate has been reported in dogs with scapular OSA, and postoperative chemotherapy is recommended.[120,121,136]

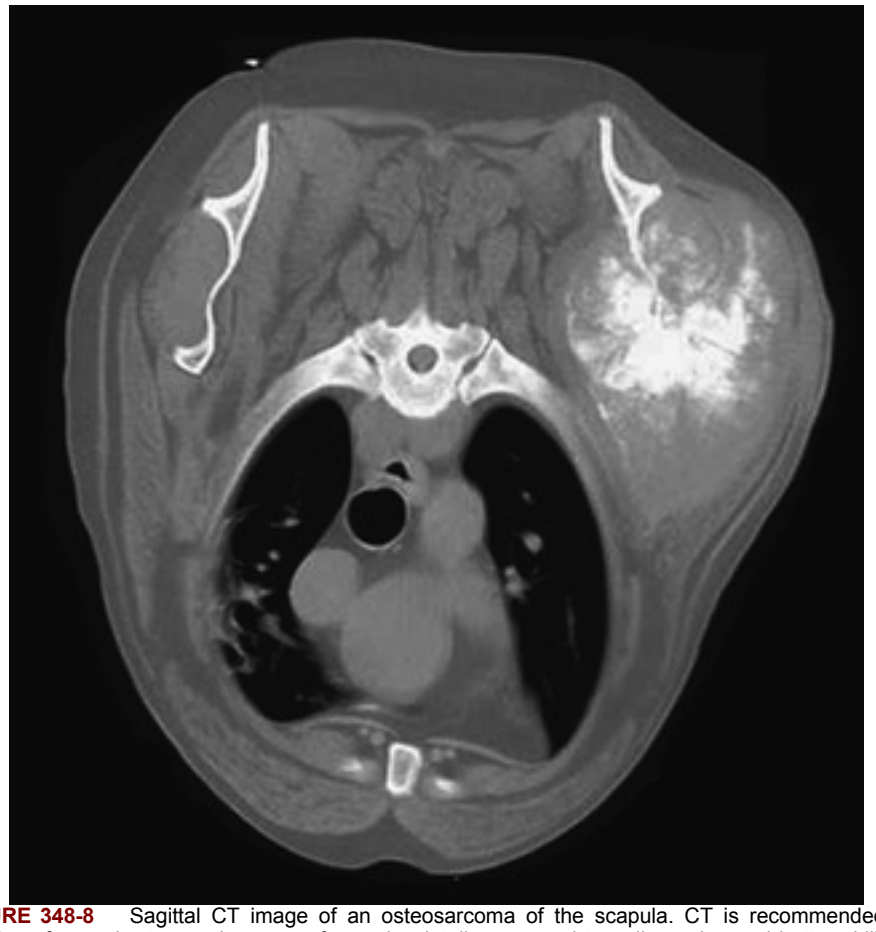

FIGURE 348-8 Sagittal CT image of an osteosarcoma of the scapula. CT is recommended for imaging of scapular tumors because of superior detail, compared to radiographs, and better ability to determine the location and extent of the tumor for surgical planning and the presence of pulmonary metastasis.

Tumors of the Pelvis

OSA of the pelvic bones accounts for 4-6% of axial OSA.[109,119,120] Pelvic FSA, CSA, and OSA occur at similar frequencies.[109,110,111,137,138] Boxer dogs may be predisposed to pelvic CSA.[108] Lameness is common, although tenesmus, due to compression of the rectum, and neurologic deficits, as a result of peripheral nerve compression, have also been observed.[138] Radiographic abnormalities are similar to those of appendicular OSA (Figure 348-9). CT imaging is helpful for local staging and surgical planning.[138] Either subtotal or total hemipelvectomy is the recommended treatment for dogs with pelvic tumors.[137-139] If necessary, the lateral third of the sacrum, lateral to the dorsal sacral foramina, can be resected en bloc with the affected pelvis.[138,139] Limb salvage is possible if the weight-bearing axis can be preserved by internal hemipelvectomy.[139] Chemotherapy should be considered for dogs with pelvic OSA, because the biologic behavior may be similar to that of appendicular OSA.[137,138] In one study, 11/28 dogs treated with hemipelvectomy for pelvic OSA developed metastases and 15 dogs died of tumor-related reasons.[138] The MST for these dogs with pelvic OSA was 533 days with 1- and 2-year survival rates of 51% and 35%, respectively.[138] The MST for dogs with pelvic CSA was 1232 days with a 1-year survival rate of 87%, while the MST for dogs with pelvic and parapelvic soft tissue sarcoma was 373 days, with 1- and 2-year survival rates of 47% and 38%, respectively.[138]

FIGURE 348-9 Ventrodorsal radiograph of a grade I chondrosarcoma of the right ilium. Note the large tumor volume and compression, rather than invasion, of the transverse processes of the sixth and seventh lumbar vertebra. Hemipelvectomy was performed, and the dog was alive and disease-free at the last follow-up 640 days later.

Rib Tumors

Rib tumors are uncommon, and reported tumor types include OSA, CSA, FSA, HSA, multilobular osteochondrosarcoma (MLO; see below), and mast cell tumor (see ch. 349).[1,119,120,123,140-143] OSA is the most common rib tumor, accounting for 73% of rib tumors and 11% of axial OSA.[119,120,140-143] No breed or sex predispositions have been reported, but rib tumors may occur in younger, large-breed dogs with a mean age of 4.5 to 6 years.[119,120,123,140-143]

Rib tumors usually occur in the distal third of the rib, near the costochondral junction.[140-142] A palpable, firm, and fixed mass is the most common clinical sign, although pain and dyspnea are also reported.[143] Radiographic changes include lysis, sclerosis, or a mixture of lytic and blastic patterns, with displacement of adjacent ribs and intrathoracic structures such as the heart and lungs, and medial displacement of the parietal pleura resulting in an extrapleural sign (Figure 348-10).[140-143] Intrathoracic extension and invasion of

pericardium and lung lobes are fairly common.[143] CT is recommended for determining the location and extent of the tumor, potential invasion into adjacent structures, and presence of metastases (E-Figures 348-11 and 348-12). Pulmonary metastasis is common (especially telangiectatic OSA), and up to 45% of dogs with rib OSA have metastases at diagnosis.[140,141] Metastasis was detected in 100% of dogs with rib OSA, 53% to 57% with CSA, 67% with HSA, and 100% of dogs with rib FSA at the time of death.[140,141] Due to the similar biologic behavior of rib and appendicular OSA, rib OSA should be treated with rib resection and postoperative chemotherapy.[141,143] The role of chemotherapy in other tumor types is undefined but warrants consideration due to the high metastatic rate.

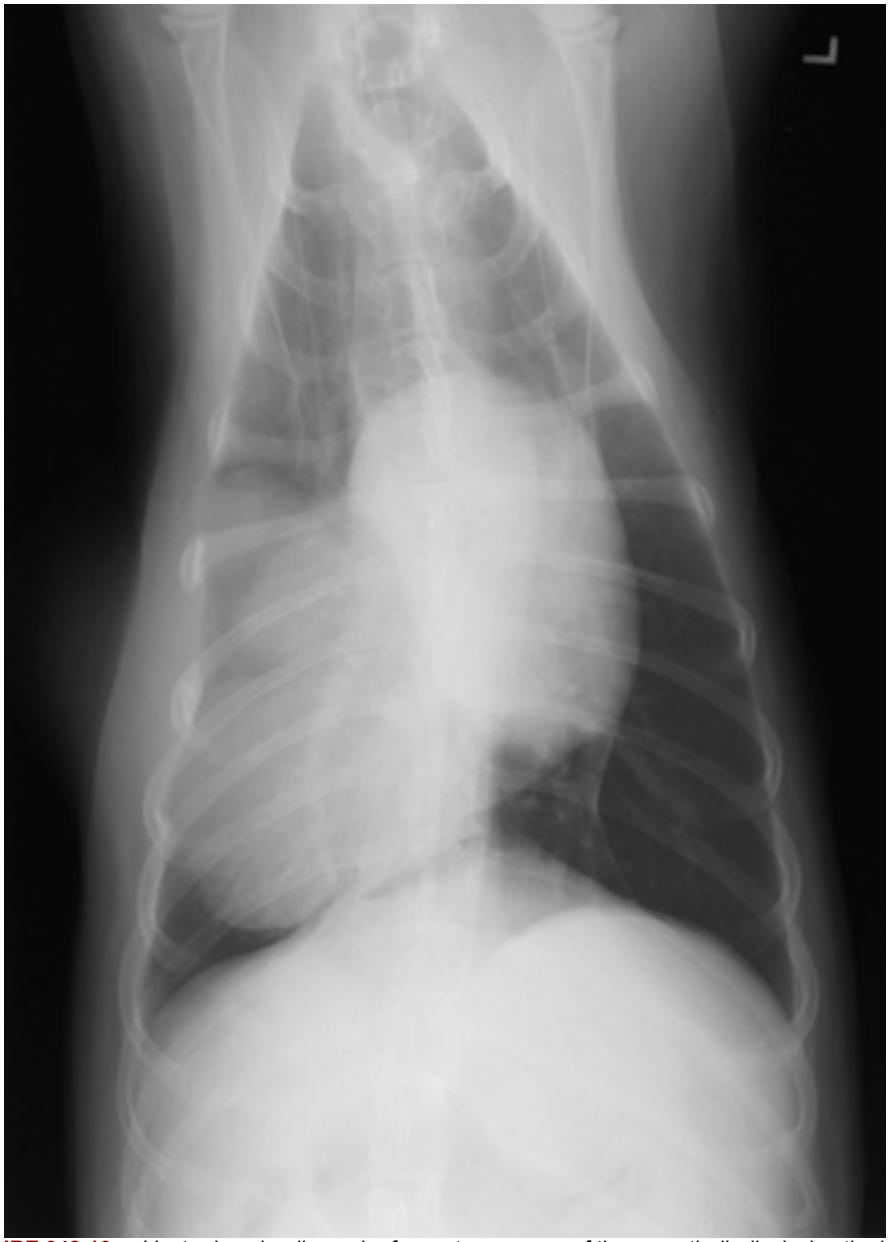

FIGURE 348-10 Ventrodorsal radiograph of an osteosarcoma of the seventh rib displacing the heart and caudal lung lobes to the left side, causing medial displacement of the parietal pleura and resulting in an extrapleural sign.

E-FIGURE 348-11 Sagittal CT image of an osteosarcoma arising from the costochondral junction of the fourth rib. CT scans are preferred for staging of dogs with primary rib tumors, because they provide superior information on the location and extent of the tumor, possible invasion into adjacent pericardium and lungs, and pulmonary metastasis.

E-FIGURE 348-12 Sagittal CT image of an osteosarcoma arising from the dorsal aspect of the rib. A metastatic lesion is visible (arrow). Breath-hold helical CT scans are significantly more sensitive for the detection of metastatic pulmonary nodules, compared to high detail radiographs. This dog also had evidence of tumor invasion into the lung lobe on other CT images.

The MST after rib resection alone for OSA is 90 days; it varies from 1080 days to >1750-3820 days for dogs with CSA.[112,140-143] Most dogs with primary rib CSA can be cured with surgery alone.[112,143] For dogs with primary rib OSA, prognostic factors include preoperative serum total ALP activity and the administration of postoperative chemotherapy. High total serum ALP activity significantly decreases MST, from 675 to 210 days.[143] Postoperative chemotherapy significantly extends MST in dogs with primary rib OSA, to 240-290 days.[141,143] Dogs with incomplete surgical excision are up to 6.7 times more likely to develop local recurrence and possibly metastatic disease.[141,143]

Vertebral Tumors

OSA is the most common extradural tumor of the nervous system and it accounts for up to 16% of axial OSA.[119,120,144,145] Other vertebral tumors include CSA, FSA, HSA, multiple cartilaginous exostoses, lymphoma, liposarcoma, giant cell tumor, plasma cell tumors—either as solitary plasmacytoma or multiple myeloma—and metastatic carcinomas and sarcomas.[144,145] A breed predisposition has not been reported, although German Shepherds, Labrador Retrievers, and Standard Poodles were overrepresented in one study.[144] Large breeds are commonly affected; only 5% of dogs with vertebral tumors weigh <20 kg.[144,145]

Primary vertebral tumors tend to occur in a younger subset of dogs than do metastatic tumors of the vertebrae. The median age for dogs with primary vertebral tumors is 6-8 years, and 8-9 years for secondary tumors.[145] A thorough physical examination (see ch. 2) should be performed to identify possible occult primary tumors. Carcinomas of the mammary and thyroid glands, bladder, and prostate, and visceral HSAs, are known to metastasize to the vertebrae. Thoracic and lumbar vertebrae are most commonly involved.[144] Soft-tissue tumors, particularly histiocytic sarcomas (see ch. 350), can secondarily involve the vertebrae.

Pain and neurologic deficits (see ch. 259) are the two most common signs in dogs with vertebral tumors.[144,145] Neurologic deficits are caused by compression of the nerve roots or spinal cord (see ch. 267).[144,145] Neurologic signs are typically slowly progressive, but pathologic fracture can cause an acute deterioration. A neurologic scoring system has been devised and is prognostic for outcome and survival.[145]

A spectrum of radiographic changes is observed in dogs with vertebral tumors. These changes can be difficult to detect due to inconsistent vertebral shape and superimposition of overlying ribs and soft tissue.[144] Cortical lysis with vertebral body collapse is a characteristic finding in primary vertebral tumors but a late event in metastatic tumors.[144,145] Skip and multiple tumors are reported in up to 25% of dogs with vertebral OSA and can be difficult to differentiate from metastatic tumors.[144] Osteochondromas are well-circumscribed, benign lesions that frequently involve the dorsal lamina and spinous process rather than the vertebral body.[146]

Imaging techniques include myelography, CT, MRI, and nuclear scintigraphy.[147] Nuclear scintigraphy can identify the location of single and multiple lesions but cannot differentiate multifocal OSA from multiple metastatic lesions. Furthermore, most plasma cell tumors are photopenic due to marked osteolysis and minimal new bone production. Myelographic changes include collapse of the subarachnoid space and unilateral or asymmetric cord displacement (Figure 348-13).[144] Advanced imaging is best for evaluating vertebral involvement (Figure 348-14), but differentiating intradural and extradural involvement can be difficult.[147] Surgical resection with vertebrectomy is rarely feasible, although dorsal decompression can provide meaningful palliation in dogs with localized dorsal tumors.[145,148] Radiation therapy, either with palliative or curative intent, can be beneficial in dogs with vertebral tumors.[145] The role of chemotherapy is unknown, even in dogs with vertebral OSA, because most dogs are euthanized due to the local tumor rather than metastatic disease.[145]

FIGURE 348-13 Ventrodorsal myelogram of a dog with an osteosarcoma (OSA) of the sixth cervical vertebra. The OSA is displacing and compressing the spinal cord toward the right side of the spinal canal.

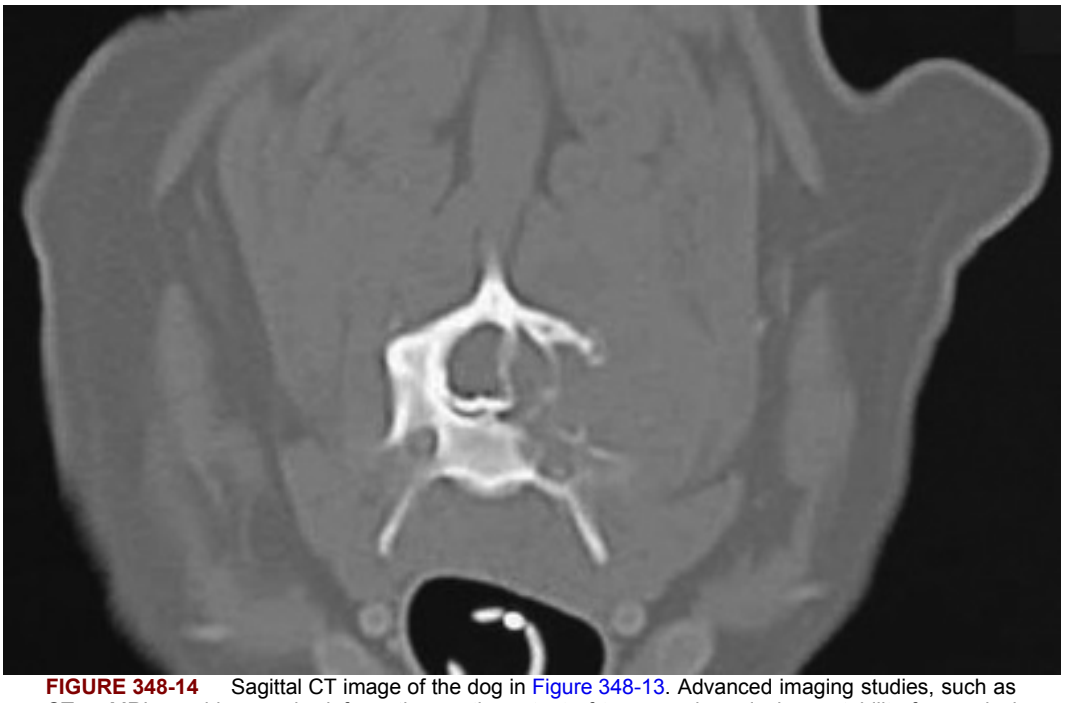

FIGURE 348-14 Sagittal CT image of the dog in Figure 348-13. Advanced imaging studies, such as CT or MRI, provide superior information on the extent of tumor and surgical resectability for surgical and/or radiation planning.

The MST for dogs with malignant vertebral tumors is 135 days.[145] Survival time is not significantly influenced by preoperative neurologic score, tumor type (OSA or FSA), primary or metastatic disease, anatomic location (cervical, thoracic, or lumbar), chemotherapy, or radiation therapy.[145] Although not significant, neurologic score can provide useful information, as dogs with a preoperative score of 1 had a survival time of 330 days, compared with 120 days if the neurologic score was greater than 1.[145] Furthermore, dogs with a posttreatment neurologic score of 1 or 2 were 12 times more likely to survive than dogs with a posttreatment score of 3 or 4.[145] Curative-intent radiation therapy provides a significant improvement in survival time compared to palliative radiation, with survival times of 150 and 15 days, respectively.[145]

Multilobular Osteochondrosarcoma (MLO)

MLO is an uncommon tumor arising from the periosteum of bones formed by intramembranous ossification.[149,150] The skull is most commonly involved, including the calvarium, orbit, zygomatic arch, mandible, and maxilla.[149,150] Other sites include the pelvis, ribs, and hard palate. Cats have also been reported with MLO.

MLO usually is a disease of middle-aged, large-breed dogs.[149,150] No known sex or breed predisposition exists. Clinical signs are dependent on tumor location and include a palpable firm and fixed mass, neurologic signs with calvarial MLO, pain on opening of the jaw with mandibular and zygomatic arch MLO, exophthalmos with orbital MLO, and dyspnea with MLO of the tympanic bulla.[149,150] The imaging changes associated with MLO are characteristic, with the tumor described as having a "popcorn" appearance with well-defined borders and a lobulated pattern on both radiographs and CT scans.[149-152] Advanced imaging is indicated for surgical planning of calvarial MLO, because the extent of intracranial involvement can be extensive (Figure 348-15).[149,150]

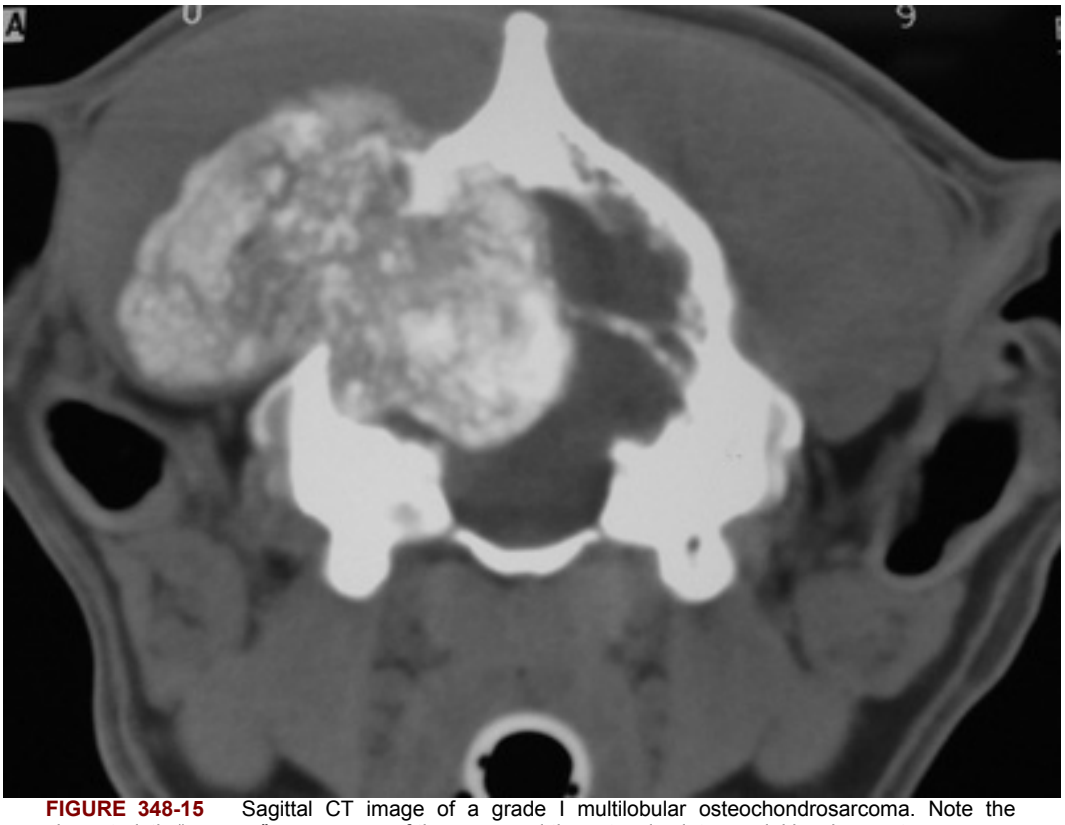

FIGURE 348-15 Sagittal CT image of a grade I multilobular osteochondrosarcoma. Note the characteristic "popcorn" appearance of the mass and the extensive intracranial involvement.

Treatment options include surgical resection and radiation therapy.[149,150] Cranioplasty has been described after calvarial resection but may not be necessary. Neurologic recovery, particularly with marked intracranial involvement, can be prolonged, although most dogs return to normal function within 2 weeks. MLOs grow slowly, usually resulting in a relative resistance and poor response to radiation therapy. Variable preliminary responses have been reported using external-beam radiation therapy and radiopharmaceuticals.[39,150]

A histologic grading scheme for MLO is prognostic for local recurrence and metastasis.[120] Other prognostic factors include site and completeness of surgical resection.[149,150] The rate of local recurrence is 47-58%, with a median DFI of 426-797 days, depending on histologic grade.[149,150] The local recurrence rate for grade I MLO is 30%, with grade II it is 47%, and with grade III, 78%.[149,150] A comprehensive surgical approach is recommended, because incomplete resection significantly increases the risk of local recurrence. The median DFI after incomplete resection is 330 days, but median DFI was not reached and was greater than 1332 days with completely resected MLO.[149,150]

The MST for untreated MLO is 24 days, compared with 669 to 797 days for surgically resected MLO.[149,150] Tumor site is prognostic, with mandibular MLO having a significantly better MST than other sites: 1487 days for mandibular MLO and 528 days for nonmandibular MLO.[150] The MST for grade I MLO is greater than 897 days, whereas the MST for grades II and III MLO is 520 and 405 days, respectively.[150]

Feline Appendicular Osteosarcoma

Primary bone tumors are uncommon in cats.[153-158] Unlike dogs, 10-33% of primary bone tumors in cats are benign.[154] OSA accounts for 70-80% of all feline bone tumors, whereas FSA, CSA, HSA, and rhabdomyosarcoma have also been reported.[153-155,159] The mean age at diagnosis of appendicular OSA is 10-11 years, and males are overrepresented, with a male-to-female ratio of 1.5-1.7 : 1.[154,157] Several differences exist in the presentation and biologic behavior of OSA in cats versus dogs.[157] In feline OSA, bones of the pelvic limb are involved 1.6 times more frequently than those of the thoracic limb.[154] The digits and proximal humerus are the most common sites, closely followed by the distal femur and proximal tibia.[153-158] Radiographic features are similar in cats and dogs, although lytic and juxtacortical lesions are more

common.[153-157] Metastasis is uncommon (<10% of cats with OSA).[153-158] Metastatic sites include lungs, brain, liver, kidneys, and spleen. Due to the infrequency of metastatic disease, limb amputation without chemotherapy is recommended for the treatment of cats with appendicular OSA. The MST after limb amputation alone is reported to be 11.8-49.2 months.[153-158]

Other Feline Appendicular Tumors

FSA and CSA have a similar biologic behavior to OSA (E-Figure 348-16). Limb amputation may be curative, although metastatic disease has been reported for both tumor types.[153,154]

E-FIGURE 348-16 Gross pathologic specimen showing a juxtacortical chondrosarcoma of the proximal humerus of a cat.

Feline Axial Tumors

OSA is the most common tumor of the feline axial skeleton.[153,157] FSA and CSA also are reported to involve the axial skeleton.[153,154] The mean age at presentation for cats with axial OSA is 10.4 years, which is significantly older than cats with appendicular OSA.[157] The skull and pelvis frequently are affected; other sites include ribs, vertebrae, and scapulae.[153-157] Presenting signs, radiographic features, and treatment recommendations are similar to malignant canine axial tumors. Periosteal new bone formation and juxtacortical tumors are more common in cats with axial OSA.[153,157] Complete surgical resection is complicated by tumor location, resulting in incomplete resection and poor tumor control. The MST for cats with axial OSA is 5.5 to 6.1 months, with most euthanized due to local recurrence rather than metastatic disease.[156,157]

Metastatic Bone Tumors

Metastatic bone tumors are infrequently diagnosed in cats and dogs. Metastasis usually occurs

hematogenously. In dogs, urogenital carcinomas, particularly of the bladder and prostate, are the most common primary tumors to metastasize to bone.[7,160] Skeletal metastasis also is reported in dogs with OSA, mammary carcinoma, thyroid carcinoma, pulmonary carcinoma, nasal carcinoma, apocrine gland anal sac adenocarcinoma, and renal tumors.[1,7,160-163] Metastatic lesions represent 24% of all bone tumors in dogs weighing <15 kg and only 5% in large-breed dogs.[1,7,162] The most common metastatic sites are the axial and proximal appendicular skeleton, with <11% of dogs having metastatic lesions distal to the elbow or stifle.[160] In contrast, acrometastasis involving one or more digits is the most common presentation for cats with metastatic pulmonary carcinoma ("lung-digit syndrome").[161-164]

Nuclear scintigraphy is recommended for the identification of multiple bone lesions (E-Figure 348-17). Treatment options for skeletal metastasis include surgery, radiation therapy, and pharmaceuticals.[28,61] Surgical curettage and stabilization of metastatic lesions is uncommonly performed in veterinary medicine but may provide a meaningful response in select cases. Radiation therapy is indicated for management of pain and inflammation.[33]

E-FIGURE 348-17 Nuclear scintigraphy of a dog with prostatic transitional cell carcinoma (lateral view, cranial to the left). Note the numerous metastatic lesions in the proximal radius, proximal humerus, cervical and thoracic vertebrae, ribs, and sternum.

Canine Joint Tumors

Joint tumors usually are primary and malignant.[165-169] Previously, synovial cell sarcoma was considered the most common tumor of the canine joint.[165,166] However, recent evidence suggests that other soft-tissue sarcomas of periarticular tissue are more prevalent. Immunohistochemistry (IHC) is required to differentiate these tumor types.[167,168] Other reported joint tumors include histiocytic sarcoma and malignant fibrous histiocytoma, synovial myxoma and myxosarcoma, OSA, FSA, CSA, HSA, liposarcoma, rhabdomyosarcoma, and undifferentiated sarcoma.[1,167-171] An association between histiocytic sarcoma and pre-existing joint disease has been identified in Bernese Mountain Dogs (see ch. 350).[170]

Synovial cell sarcomas are malignant tumors arising from mesenchymal cells in tenosynovial tissue of joints, bursae, and tendon sheaths.[165] The stifle, elbow, shoulder, carpal, tarsal, and hip joints are most commonly involved, in decreasing order of frequency.[1,165] The mean age at presentation is 6 to 8 years.[165-169] Males are overrepresented, and Flat Coated Retrievers are predisposed.[165-169] Metastasis to the regional lymph nodes and lungs is reported in up to 32% of dogs at diagnosis and in 41% to 54% of dogs during the course of disease.[165-169]

Typically, affected dogs have lameness, signs of joint pain, and synovial effusion. Dogs with suspected joint tumors should be staged with palpation of regional lymph nodes and regional and three-view thoracic radiographs. Regional radiographs often reveal a soft-tissue opacity adjacent to the affected joint. Mineralization of the soft-tissue mass occasionally is seen in humans but rarely in dogs. Bone involvement is observed in 11-100% of cases and can either be smooth and well delineated, due to pressure necrosis from the expansile mass, or permeative to punctate lytic as a result of bony invasion.[165-169]

Biopsy is required for a definitive diagnosis. Synovial fluid analysis usually is consistent with chronic, low-grade inflammation, and neoplastic cells rarely are identified. Large core biopsies, using either a Jamshidi needle or open wedge, can establish the diagnosis and histologic grade.

Synovial cell sarcomas have two distinct populations of cells: epithelioid and spindle.[1,165] Based on histologic features, synovial cell sarcomas are subclassified as either monophasic, with one cell type, or biphasic, with both cell types.[165] However, this histologic appearance is not adequate to differentiate synovial cell sarcoma from other soft-tissue sarcomas. IHC stains have been used for differentiating joint tumors: synovial cell sarcomas stain positively with cytokeratin antibody AE1/AE3, histiocytic sarcomas stain positively with CD18 antibody, and malignant fibrous histiocytomas stain positively with smooth muscle actin.[168]

Limb amputation is the recommended treatment for dogs with a histologically confirmed joint tumor.[165-169] Local recurrence is common after conservative excision and has also been reported with relative frequency in the stump of the amputation site.[165] The role of radiation therapy and chemotherapy is unknown, but chemotherapy does not improve survival time in humans with synovial cell sarcoma.[172] However, a doxorubicin-based chemotherapy protocol is recommended for high-grade synovial cell sarcoma due to their high metastatic potential.

Several prognostic factors have been identified in dogs with synovial cell sarcoma, including clinical stage, treatment, histologic grade, and IHC staining.[165-169] Synovial cell sarcoma is locally staged as well-defined, with no evidence of invasion into regional structures (T_1), or with invasion into the soft tissue (T_2) or bone and joints (T_3).[165] Local staging is not prognostic; however, dogs with metastases to regional lymph nodes or lungs have MSTs of <6 months. Comprehensive surgical resection is important in prolonging both DFI and survival time. Local tumor control is poor after conservative local excision, with a median DFI of 4.5 months compared with 30 months after limb amputation.[165,169] Furthermore, survival time is significantly improved with more extensive local treatment regimens: 93 days with no treatment, 455 days with conservative resection, and 840 days with limb amputation.[169] Histologic grade is also prognostic, because the MST for dogs with grade I synovial cell sarcoma is >48 months; with grade II, 36 months; and with grade III, 7 months.[165]

Clinical staging and surgical recommendations (limb amputation) are the same for dogs with histiocytic sarcoma (see ch. 350). Dogs with periarticular histiocytic sarcoma have a better prognosis than dogs with non-periarticular locations with MSTs of 391 days and 128 days, respectively.[169] However, despite the better prognosis, 68% of dogs with periarticular histiocytic sarcoma present with metastases. Dogs without metastases at diagnosis had a significantly better MST (980 days) than dogs with metastases (253 days).[169] Postoperative CCNU is recommended in dogs with periarticular histiocytic sarcoma because of this high metastatic risk.[173]

Feline Joint Tumors

Synovial cell sarcoma is rarely diagnosed in cats. Based on individual case reports, biologic behavior may be more benign than in dogs.[174,175] However, two cats have been reported with metastatic synovial cell sarcoma (regional lymph nodes in both, and pulmonary 12 months postoperatively in one).[176] Limb amputation is recommended for local management because, similar to dogs, local recurrence has been reported after

conservative excision.[174,175]

CHAPTER 349

Mast Cell Disease

Douglas H. Thamm

Client Information Sheet: Mast Cell Tumors

Canine Mast Cell Tumors

Introduction

Prevalence

Mast cell tumors (MCTs) represent the most common cutaneous malignancy in the dog, accounting for between 16 and 21% of all cutaneous tumors (see ch. 10 and 345).[1] Several breeds are at increased risk for MCTs, including brachycephalic breeds (Boxer, Boston Terrier, English Bulldog, Pug), retrievers, Cocker Spaniels, Schnauzers, Staffordshire Terriers, Beagles, Rhodesian Ridgebacks, Weimaraners, and Shar-Pei.[1-3] While brachycephalic breeds are at higher risk for MCT development, MCTs in these dogs are more likely to be low grade.[1,4] In contrast, anecdotal evidence suggests that Shar-Pei may develop more biologically aggressive MCTs.

Pathophysiology

Perhaps the best-described molecular abnormality in canine MCT involves the receptor tyrosine kinase (RTK) KIT. KIT is expressed normally on a variety of cells including hematopoietic stem cells, melanocytes, and mast cells.[5,6] The ligand for KIT, stem cell factor (SCF), induces KIT dimerization, phosphorylation, and generation of intracellular signaling promoting proliferation, differentiation, and maturation of normal mast cells.[5,6] KIT expression has been demonstrated on canine MCTs and aberrant cytoplasmic localization of KIT in MCTs may be associated with dysregulated KIT function.[7-9] Furthermore, 25-30% of intermediate- and high-grade canine MCTs possess mutations in the *c-kit* gene, which result in constitutive, SCF-independent activation of KIT.[10-13] The presence of an activating *c-kit* mutation is linked to increased risk of local recurrence, metastasis, and a worse prognosis.[10,12,14-16]

History and Clinical Signs

Most MCTs in dogs occur in the dermis and subcutaneous (SC) tissues. Most are solitary, although 11-14% of dogs have multiple lesions.[17-21] A visceral form of MCT has also been described.[22,23] Cutaneous MCTs have an extremely varied range of clinical appearances and are sometimes inadvertently mistaken for non-neoplastic lesions. The history and clinical signs of dogs with MCT may occasionally be complicated by signs attributable to release of histamine, heparin and other vasoactive amines from mast cell granules, such as erythema and edema in surrounding tissues, pruritus, or changes in tumor size. Dogs with substantial tumor burdens (i.e., large tumors, metastatic disease) are more likely to have systemic signs related to the release of mast cell mediators. These may include vomiting, diarrhea, fever, melena, and peripheral edema. Collapse is a rare event. Histamine released from MCT granules is thought to act on gastric parietal cells via H2 receptors, resulting in increased hydrochloric acid secretion.

Diagnosis, Staging, Prognosis

Fine-Needle Aspiration

Most MCTs are readily diagnosed on the basis of fine-needle aspiration (FNA) cytology (see ch. 86 and 87).

Mast cells appear as small to medium-sized round cells with abundant, small, uniform cytoplasmic granules that usually stain purplish red (metachromatic), while a small number do not stain readily.[1,24] In these cases, a Wright-Giemsa or toluidine blue stain will often reveal granules; however, histologic assessment of a biopsy sample may be necessary. Highly anaplastic, agranular MCTs can be challenging to diagnose by routine light microscopy. CD117 (KIT) immunohistochemistry is often used to differentiate anaplastic MCTs from other round cell tumors.[7]

Patient Assessment

Complete staging includes a minimum database (complete blood count [CBC], serum biochemistry profile), cytologic assessment of regional lymph node(s) (see ch. 95), abdominal ultrasound (US; see ch. 88) with cytologic assessment of spleen or liver if warranted (see ch. 89 and 93), and thoracic radiographs. It is likely that extensive staging is not necessary for dogs with node-negative MCTs and no negative prognostic factors (see below; Figure 349-1). If the MCT is in a location amenable to wide surgical excision and no negative prognostic indicators are present, then no further tests other than minimum database and cytology of the regional lymph nodes (even if normal in size) are necessary. If the tumor presents at a site that is not amenable to wide surgical excision or if negative prognostic factors exist, additional diagnostics are recommended prior to definitive therapy. These include abdominal US, FNA cytology of abnormal organs, and thoracic radiographs.[25,26] Incisional biopsy may be performed to determine histologic grade if needed for the owner's decision to pursue therapy.

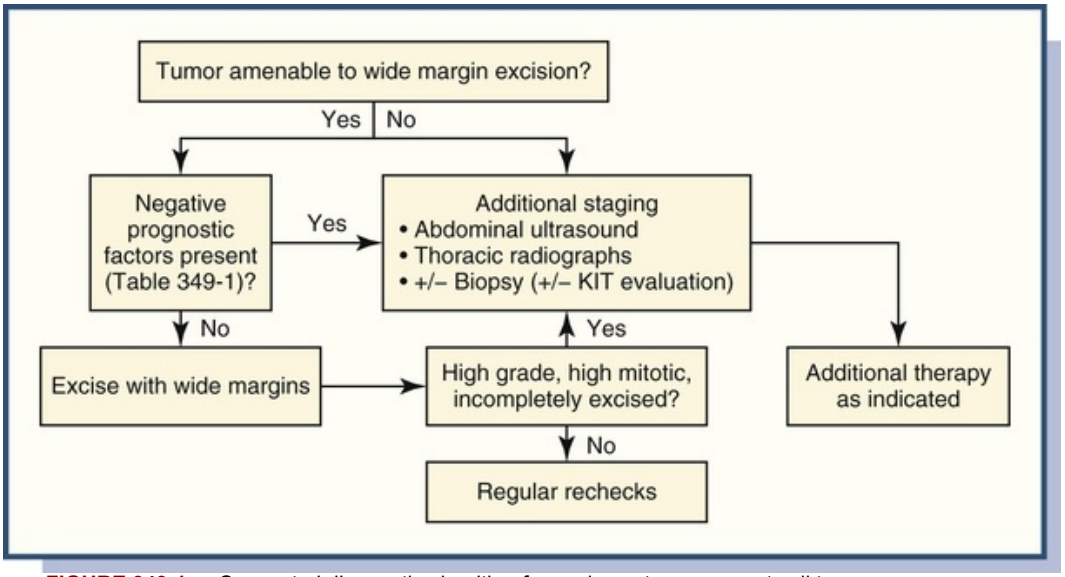

FIGURE 349-1 Suggested diagnostic algorithm for canine cutaneous mast cell tumors.

With respect to cytologic evaluation of lymph nodes, an occasional solitary mast cell is not necessarily indicative of metastasis; rather, clustering and aggregates are more worrisome.[27] Disease in the regional node, but not beyond, should not be considered a reason to avoid surgery; rather, the node should be excised and submitted for histopathology at the time of primary tumor resection. Histologic assessment may be necessary to accurately determine whether mast cells in a lymph node represent metastatic disease. A grading scheme has been proposed to better quantify the degree of lymph node infiltration in canine MCT.[28] With the exception of the extremely rare primary mastocytic leukemia, involvement of marrow or peripheral blood in the absence of disease in regional lymph node or abdominal viscera is unlikely.[29] Therefore, buffy coat smears and bone marrow aspiration cytology are rarely necessary.

Prognostic Factors

The major prognostic factors for dogs with MCTs should be reviewed (Table 349-1). It is important to note that no one factor is entirely predictive of biologic behavior and as such, all prognostic indicators should be taken into consideration when evaluating a patient.

TABLE 349-1

Prognostic Factors for Canine Mast Cell Tumors

FACTOR	COMMENT	REFERENCES
Histologic grade	High grade tumors have an increased risk of both local recurrence and metastasis.	2, 35, 91-93
Clinical stage	Some studies suggest that regional node involvement is a negative prognostic factor. The effect of multiple tumors on outcome is questionable.	17, 18, 20, 21, 27, 36, 41, 48, 50, 53, 55, 92, 94, 95
Location	Subungual, oral, and other mucous membrane sites are associated with more high grade tumors and worse prognosis. Visceral tumors have a very poor prognosis. Subcutaneous tumors are generally associated with a good prognosis.	22, 23, 47, 96-98
Cell proliferation rate	Mitotic index, relative frequency of argyrophilic nucleolar organizer regions (AgNORs), and percent proliferating cell nuclear antigen (PCNA) or Ki-67 immunopositivity, are predictive of post-surgical outcome.	15, 37, 91, 93, 94, 98-107
Recurrence	Local recurrence following surgical excision may carry a more guarded prognosis.	36
Systemic signs	The presence of systemic illness (e.g., anorexia, vomiting, melena, gastrointestinal ulceration) may be associated with a higher stage of disease.	18, 23
Breed	Mast cell tumors (MCTs) in Boxers (and potentially other brachycephalic breeds) tend to be of low or intermediate grade and are thus associated with a better prognosis. MCTs in the Shar-Pei may be higher grade.	1, 4
c-kit mutation	The presence of an activating mutation in the *c-kit* gene is associated with a worse prognosis.	10, 14, 15
KIT protein localization	Predominantly aberrant (cytoplasmic) KIT localization is associated with a worse prognosis.	108

Treatment

"Low Risk" Mast Cell Disease

Surgery

Treatment decisions are predicated on the presence or absence of negative prognostic factors and on the clinical stage of disease. In tumors localized to the skin in areas amenable to wide excision, surgery is the treatment of choice. Surgical excision should include a 3 cm margin of surrounding normal tissue. However, some evidence suggests that 1-2 cm lateral margins and one uninvolved deep fascial plane may be sufficient for complete excision of many MCTs, particularly those that are small and lower grade.[30-33] Surgical margins should be evaluated histologically for completeness of excision. Routine use of neoadjuvant corticosteroids to facilitate surgical resection is not recommended, except in cases where marginal excision is not possible due to location or extent of disease.

Incomplete Surgical Removal

For cases where margins are incomplete, additional local therapy is warranted to prevent recurrence[34-36]; however, not all MCTs with surgically incomplete margins will recur.[37,38] Re-excision of the surgical scar with additional wide margins should be performed if possible. If additional surgery is not possible, adjuvant radiation therapy (RT) can be quite effective (see ch. 240). Two-year control rates of 85-95% can be expected following RT for incompletely resected tumors of low or intermediate grade.[39-41] A less optimal alternative is a combination of surgery and chemotherapy (discussed below).[42,43] For tumors where marginal excision is not possible, RT alone,[41,44,45] RT plus toceranib,[46] or medical therapy alone (see below) may be considered.

Monitoring

Regardless of the local therapy chosen, dogs with low and intermediate grade tumors should be reevaluated

regularly for local recurrence ± metastasis. Local site and regional lymph node evaluation, complete physical examination and aspiration of any new cutaneous masses or enlarged lymph nodes should be considered. More complete staging, including abdominal US, should be included if a dog has had a MCT with high risk for metastasis.

"High-Risk" Mast Cell Disease

Overview

The treatment of "high-risk" MCT remains challenging. This category includes dogs with high grade tumors, intermediate grade tumors with regional or distant metastasis, or high proliferative activity as assessed by mitotic index or special stains. Also included are MCTs arising from a mucous membrane or mucocutaneous junction. Some studies suggest that low/intermediate grade tumors have a better prognosis if there is only regional node involvement than that for high grade tumors. The author recommends, however, that such tumors be treated as if they have a high capacity for metastasis.[47-50] In addition to appropriate local therapy as above, adjuvant medical therapy should be offered for dogs with high-risk MCT in an attempt to delay or prevent further metastasis. Corticosteroids have been reported to be of some benefit[45,51,52]; however, most responses are incomplete and transient. Corticosteroid-induced reduction of peritumoral edema/inflammation may interfere with response assessment.

Use of Chemotherapy

Several studies have evaluated response rates of measurable canine MCT to various cytotoxic chemotherapy protocols.[36,53-59] Response rates as high as 64% have been reported, and multi-agent protocols may confer a higher response rate than single-agent therapy.[36,53,55,57,58] The most commonly employed first-line agents, vinblastine (VBL) and lomustine, are often given with corticosteroids.[36,54,57,59] Importantly, in most instances, the response of a bulky MCT to any chemotherapy protocol tends to be short-lived, stressing the need for local control of disease if at all possible prior to the institution of medical therapy. A few single-arm retrospective studies have evaluated efficacy of post-surgical chemotherapy with vinblastine or lomustine for "high-risk" MCT. Dogs receiving chemotherapy tended to have longer disease-free and overall survival times than surgery alone, with median survival times exceeding 2 years in most studies.[15,48,55,57,60]

Toceranib

Oral tyrosine kinase inhibitors (TKIs) have been developed that inhibit signaling through KIT. The two veterinary-approved TKIs in this class are toceranib (Palladia, Zoetis) and masitinib (Masivet/Kinavet, AB Science). Some studies have also been conducted with the human KIT inhibitor imatinib (Gleevec, Novartis).[61] Following encouraging early-phase clinical trials, a multi-center, placebo-controlled, double-blind, randomized study of toceranib was performed in dogs with recurrent or metastatic intermediate or high grade MCT.[13,62] The objective response rate in toceranib-treated dogs was 37.2% (7 complete, 25 partial) versus 7.9% (all partial) in placebo-treated dogs. The median duration of response and time to tumor progression were 12.0 and 18.1 weeks, respectively. Dogs whose MCT harbored *c-kit* gene activating mutations had objective response rates higher than those with wild-type *c-kit* (69% vs. 37%). Gastrointestinal toxicity (inappetence, weight loss, diarrhea, and occasionally vomiting or melena) were the most common adverse effects, and were generally manageable with symptomatic therapy, drug "holidays" and dose reductions. Other adverse effects include mild to moderate leukopenia and occasional muscle pain.[62] Clinical experience with toceranib suggests that equivalent antitumor activity and reduced adverse effects may be observed if dosages lower than the label dosage are employed. A dosage of 2.4-2.75 mg/kg every other day or 3 days per week (Monday, Wednesday, Friday) is currently utilized by many.[46,63]

Masitinib

A clinical trial of similar design was conducted with masitinib in dogs with recurrent or unresectable MCT, demonstrating improved time to progression in masitinib-treated versus placebo-treated dogs, and again, outcome was improved in dogs with MCT harboring activating *c-kit* mutations and those treated in the first-line setting.[64] Subsequent follow-up of dogs treated with long-term masitinib identified an increased number with long-term disease control compared to those treated with placebo (40% vs. 15% alive at 2 years).[65] Gastrointestinal adverse effects (vomiting or diarrhea) were most common but were usually mild and self-limiting. Mild myelosuppression was also observed. A small percentage of dogs developed protein-losing

nephropathy and edema. Increases in blood urea nitrogen (BUN) and creatinine were observed in some dogs. Hemolytic anemia was also observed rarely.[64]

Combining TKIs and Other Therapies

There are a few studies evaluating combination KIT inhibitors and standard forms of therapy such as RT or cytotoxic chemotherapy, but evidence of benefit when used postoperatively has yet to be demonstrated. One recent clinical trial evaluated a combination of toceranib and vinblastine in dogs with measurable MCT. Significant reductions in vinblastine dosage and frequency were necessary owing to additive myelosuppression.[66] Nevertheless, encouraging clinical activity (71% objective response rate) was observed despite the necessary dosage reductions. Another study investigated the combination of toceranib, prednisone and hypofractionated RT in dogs with non-resectable and/or metastatic MCT.[46] The overall response rate was about 76%, with almost 60% of dogs achieving complete remission (CR) and another 17% having partial remission. The overall median progression free interval was 10.5 months.

Palliative Therapy

Ancillary palliative therapy to address the systemic effects of mast cell mediators is sometimes warranted using both H1 and H2 blockers (e.g., diphenhydramine, famotidine). The proton pump inhibitor omeprazole may be more effective for diminishing gastric acid secretion, particularly in the setting of bulky mast cell disease. These agents are particularly useful in cases where (1) systemic signs are present; (2) the tumor is likely to be extensively manipulated at surgery (i.e., cytoreductive surgery, incisional biopsy); or (3) treatment is undertaken in the context of gross disease (e.g., RT or medical therapy for tumors that are not cytoreduced). There is no clinical evidence that H1/H2 blockers or omeprazole have any antineoplastic effects.

Feline Mast Cell Tumors

Unlike MCTs in the dog, which are primarily cutaneous or SC, MCTs in cats typically occur in three distinct syndromes: cutaneous, splenic/visceral and intestinal. In one study, 67% of cutaneous and splenic/visceral MCT had *c-kit* activating mutations.[67]

Feline Cutaneous Mast Cell Tumors

Definitions

MCTs are the second most common cutaneous tumor in cats, accounting for about 20%.[68,69] The typical feline cutaneous MCT is a solitary, raised, firm, well-circumscribed, hairless, dermal nodule between 0.5 and 3 cm in diameter. Approximately 20% are multiple, although one series reported multiple lesions in most cases.[1] Two distinct types of cutaneous MCT in the cat have been reported: the more typical mastocytic MCT, which is histologically similar to MCT in dogs, and the less common histiocytic MCT. The histiocytic MCT has morphologic features characteristic of histiocytic mast cells, and may regress spontaneously over 4 to 24 months.[70,71] Siamese cats appear to be predisposed to both types.[68-72] The mastocytic form can be subdivided on histologic appearance into two categories: compact (50-90% of all cases) and diffuse (anaplastic).[68,70,73] Well-differentiated compact tumors tend to behave in a benign manner and metastasis is uncommon, while anaplastic tumors may have a high mitotic index, marked cellular and nuclear pleomorphism, and SC infiltration. Clinical behavior of these anaplastic tumors is variable according to the literature.[71,72,74-76]

Diagnosis

Most feline MCTs are easily diagnosed by cytologic examination of FNAs (see ch. 86 and 87). Cats with cutaneous MCTs should be evaluated for evidence of additional tumors, as well as potential splenic involvement by abdominal US (see ch. 88). One study suggested some cats with multiple cutaneous MCTs also had splenic disease.[74] A minimum database is recommended, along with careful examination of local lymph nodes. The histologic grading system described for canine MCTs has provided no prognostic information for the cat and is not used. Tumors with a high mitotic index appear to be at greatest risk for local recurrence and metastasis.[71,72,76,77]

Treatment

The recommended treatment for most cutaneous feline MCTs is surgical excision. Reports have demonstrated

local recurrence rates following excision between 0 and 24%,[68,71,72,74-76] and metastatic rates from 0 to 22%.[71,72,74-76] Histologically anaplastic tumors or those with a high mitotic index may be best managed with systemic therapy as for canine MCT, although statistics regarding efficacy are lacking.[76,78] After biopsy confirmation, conservative resection or active surveillance may be taken with the histiocytic form. Some may spontaneously regress.[68-70] RT may be considered for tumors that are incompletely excised (see ch. 240).[79] Limited information exists concerning the utility of chemotherapy in cats with MCT. Objective responses to lomustine (CCNU) have been reported in cats.[80,81] Anecdotally, prednisone/vinblastine, as used in dogs, appears to be associated with antitumor activity in some cats. Administration of imatinib has been associated with partial responses in cats with MCT expressing activating mutations in *c-kit*.[67,82,83] Neither masitinib nor toceranib has been formally evaluated in cats with MCT.

Feline Splenic/Visceral Mast Cell Tumors

Prevalence and Signs

MCT represents the most common differential for splenic disease in cats, accounting for 15% of submissions in one series.[84] Most cats with splenic MCT do not have a history of cutaneous MCT, although recent evidence suggests that some cats with multiple cutaneous MCTs may also have splenic involvement.[74] While the spleen is the primary site affected by this disease, other organs may also be involved.[68,85] Peripheral blood mastocytosis has been reported in the majority of cases, with peripheral mast cell counts as high as 32,000 cells/mcL reported.[68,86] Cats with splenic MCT may have signs of systemic illness including vomiting, inappetence, and weight loss.[68,85] Clinical signs associated with degranulation, such as GI ulceration, hemorrhage, hypotensive shock and labored breathing may also be noted. Abdominal palpation usually reveals marked cranial organomegaly. Cats with suspected splenic MCT should undergo a standard work-up including minimum database, abdominal US (see ch. 88) and thoracic radiographs. US-guided FNA cytology (see ch. 89 and 93) or cytologic evaluation of effusions is usually diagnostic for splenic MCT.

Treatment

Splenectomy is the treatment of choice for cats with splenic MCT, even if other organ involvement is noted. Long-term survival with good quality of life is common following splenectomy. Even in cats with significant bone marrow and peripheral blood involvement, median survival times are 12 to 19 months.[68,85,87] As with high-risk feline cutaneous MCT, the utility of adjuvant medical therapy is unknown.

Feline Intestinal Mast Cell Tumors

Intestinal MCT is the third most common primary intestinal tumor in cats after lymphoma and adenocarcinoma.[68] Most cats have a history of vomiting, diarrhea and inappetence. A palpable abdominal mass is often evident.[68,88] Enlarged mesenteric lymph nodes and/or hepatomegaly may be noted on physical examination. Peritoneal effusion containing mast cells and eosinophils may be present. Diagnosis is usually made by FNA of the mass or involved organs. Cats with intestinal MCT should be staged with a minimum database, thoracic radiographs and abdominal US. Intestinal MCT in cats carries a poor prognosis, as metastasis is common at the time of diagnosis.[68,88-90] Surgery is the treatment of choice and wide surgical margins are necessary (5-10 cm) as the tumor typically extends histologically well beyond the obvious gross disease.[68,88] Limited information exists regarding the use of medical therapy for feline intestinal MCT.

CHAPTER 350

Canine and Feline Histiocytic Diseases

Laurel E. Williams

Histiocytic diseases represent a diverse and potentially confusing spectrum of syndromes ranging from solitary lesions that spontaneously regress (histiocytoma) to highly malignant tumors involving multiple sites in the body (disseminated histiocytic sarcoma). Also included in this category are reactive conditions associated with underlying immune dysregulation (cutaneous histiocytosis, systemic histiocytosis). The aim of this chapter is to characterize the origin, behavior, clinical presentation and treatment of these various conditions.

Cell Origin and Development

Histiocytes develop from CD34+ bone marrow stem cells, migrate from the bone marrow to the blood as monocytes, and enter various tissues, where they undergo differentiation into macrophages and dendritic cells (DCs). Under the influence of monocyte/macrophage-colony stimulating factor, blood monocytes differentiate into macrophages, while granulocyte-macrophage colony stimulating factor, interleukin-4 and tumor necrosis factor-alpha lead to various DC lineages, including interstitial DC and Langerhans cells (LCs), the latter of which are critically dependent on transforming growth factor-beta1 stimulation.[1-3] Interstitial DCs occur in perivascular locations in many organs, while LCs are predominantly in the epidermis with more recently identified populations identified in lymph nodes and other locations.[4,5]

Histiocytes play a key role in the immune system through phagocytosis (macrophages) and antigen processing and presentation (DCs, LCs). DCs represent the most potent antigen-presenting cells (APCs) for inducing immune responses in naïve T cells. Cells are defined by their expression of molecules essential to their function as APCs (Table 350-1). Canine- and feline-specific monoclonal antibodies for these functionally important molecules aid identification of macrophages, DCs, and LCs in tissues, and can be useful in distinguishing among histiocytic diseases. For this reason, collection of fresh, snap-frozen tissue often is recommended in addition to more routine sample collection for cytologic and histopathologic evaluation.

TABLE 350-1

Characterization of Histiocytic Diseases of Dogs and Cats[8]

DISEASE	SPECIES	CELL OF ORIGIN	IMMUNOPHENOTYPE
Histiocytoma	Dog	LC	CD1a, CD11c/CD18, E-cadherin
Cutaneous Langerhans cell histiocytosis	Dog	LC	CD1a, CD11c/CD18, E-cadherin
Pulmonary Langerhans cell histiocytosis	Cat	LC	CD1a,* CD18, E-cadherin
Cutaneous histiocytosis	Dog	DC	CD1a, CD4, CD11c/CD18, CD90
Systemic histiocytosis	Dog	DC	CD1a, CD4, CD11c/CD18, CD90
Histiocytic sarcoma	Dog, cat	DC	CD1a, CD11c/CD18
Hemophagocytic histiocytic sarcoma	Dog, cat	Macrophage	CD1a (low), CD11d/CD18 (dog)
Feline progressive histiocytosis	Cat	DC	CD1a, CD11†/CD18, CD5 (50%)

*CD1a expected, not assessed to date.

†CD11c expected but not currently assessable in cats.

DC, Dendritic cell; *LC*, Langerhans cell.

Histiocytic Diseases

Canine Histiocytoma

Canine histiocytoma is a common, benign skin tumor originating from LCs. Usually occurring in young dogs, the incidence drops after 3 years of age. In a retrospective study of histologic tumor diagnoses in dogs < 1 year of age in the United Kingdom, cutaneous histiocytoma was the most common diagnosis, representing 89% of the total.[6]

Lesions typically are solitary and they present as hairless dome- or button-shaped masses on the skin surface. The head is a frequent site, although lesions can develop anywhere on the body. Diagnosis requires cytologic evaluation. Cytologic features vary, but typically consist of a population of round cells with benign nuclear features, abundant cytoplasm, and often a high mitotic index.

Histiocytomas usually undergo spontaneous regression, typically within 3 months, and recurrence is uncommon. Regression is mediated by CD8+ T-cells and progressive lymphocyte infiltration is evident within tumors over time.[7] Surgical or medical treatment generally is not needed, but may be considered for lesions that are persistent, recurrent, or problematic for the animal.

Canine Cutaneous Langerhans Cell Histiocytosis

The presence of multiple histiocytomas in dogs is uncommon and may be best considered in the spectrum of cutaneous Langerhans cell histiocytosis (LCH), since the skin is consistently involved and is considered the site of origin.[8] Lesions may be limited to the skin or extend to involve regional lymph nodes and rarely, internal organs. Diagnosis requires cytologic examination with consideration of histopathologic evaluation and immunophenotyping for definitive diagnosis. Lymph node evaluation, thoracic radiographs, and an abdominal sonogram are helpful in determining extent of disease.

Spontaneous regression of lesions can occur and may be delayed, with lesions persisting several months prior to regression. Unfortunately, lack of regression and the challenging management of extensive ulcerated lesions often ultimately lead to euthanasia. Limited information exists on effective treatments, although one case report described transient improvement following administration of CCNU chemotherapy.[9]

Feline Pulmonary Langerhans Cell Histiocytosis

Proliferative disorders of LCs are rare in cats. One report describes 3 cats with primarily pulmonary proliferative disease of LC origin.[10] The cats in this series were older (10-15 years) and presented with signs of respiratory disease and distress ranging from 5 days to 7 months' duration. Thoracic radiographs identified a severe, diffuse, bronchointerstitial pattern in all 3 cats with diffuse miliary to nodular opacities noted in 2 cats. Glucocorticoid therapy in 2 cats did not improve clinical signs. Euthanasia was elected in each case due to progressive respiratory signs. The diagnosis of LCH was made postmortem through histopathologic, immunohistochemical and electron microscopic evaluations. Postmortem evaluation identified metastasis to sites including pancreas, liver, kidneys and visceral lymph nodes.

Canine Reactive Histiocytosis (Cutaneous Histiocytosis, Systemic Histiocytosis)

Reactive histiocytosis consists of a group of non-neoplastic diseases of DC origin. Lesions in affected dogs either can be confined to skin, subcutaneous tissue and draining lymph nodes (cutaneous histiocytosis), or can involve skin and varied other sites including lymph node, liver, spleen, lung, bone marrow, eye, and mucous membranes (systemic histiocytosis). Cutaneous lesions are similar in both forms, and progression from cutaneous to systemic histiocytosis is possible. The exact etiology and pathogenesis are unknown, but dysregulation of immune response mechanisms has been proposed.

Cutaneous Histiocytosis

Cutaneous histiocytosis tends to occur in younger dogs. In a retrospective study of 32 dogs, median age was 4 years (range, 1-8 years).[11] Duration of signs prior to diagnosis is variable, with a median of 1.75 months and

range of 0-30 months reported in this same study.[11] Lesions present as multifocal nodules, plaques, and crusts within the skin and subcutaneous tissues. Ulceration of overlying skin is common.

Diagnosis requires histopathologic assessment and consideration of immunophenotyping. Lesions are characterized by histiocytic infiltrate, with variable angiocentricity, within the dermis and subcutaneous tissues. Lymphoid infiltration is common, comprising up to 50% of dermal infiltrates.[11,12] Histiocyte antigen expression patterns are consistent with DC origin.[12] Lymph node evaluation (see ch. 95), thoracic radiographs, and an abdominal sonogram (see ch. 88) are helpful in distinguishing cutaneous versus systemic forms of disease.

The disease course can be punctuated by remissions and relapses, especially early in the course of the disease. Given its diffuse nature, surgery generally is of limited use. Instead, treatment typically involves administration of systemic immunomodulatory drugs (see ch. 165). Variable responses were seen with systemic administration of corticosteroids in 7 dogs in one study.[12] In another series, complete resolution of dermatologic lesions was reported in dogs receiving a variety of immunomodulatory drugs within a median of 45 days (range, 14-162 days).[11] Immunomodulatory drugs included prednisone alone or in combination with tetracycline/niacinamide or azathioprine, tetracycline/niacinamide alone, and cyclosporine.

Long-term maintenance therapy or repeated treatment courses may be needed. In the report describing complete resolution of lesions, 30% of dogs developed recurrence and each of these dogs responded to further treatment.[11] At the conclusion of the study, with a median follow-up of 25 months, 26 of 32 (81%) dogs were alive with no lesions. The other 6 dogs were deceased with no signs of cutaneous histiocytosis.

Systemic Histiocytosis

Systemic histiocytosis was initially reported in a group of closely related Bernese Mountain Dogs, suggesting a genetic predisposition in this breed.[13] A predilection in Rottweilers, Golden Retrievers and Labrador Retrievers also has been suggested.[12] Systemic histiocytosis predominantly affects middle-aged dogs (median 5 years; range, 1-9 years).[12,13]

Presenting signs often are nonspecific and include depression, anorexia, and weight loss, and vary according to the distribution and extent of lesions. Cutaneous and subcutaneous lesions are similar, though possibly more widespread, to those seen with cutaneous histiocytosis. Involvement of lymph nodes, liver, spleen, lung, bone marrow, eye (conjunctiva, sclera, orbit, third eyelid), and mucous membranes (gingiva, nasal cavity) are variably present.[12,14]

Diagnosis requires histopathologic evaluation and consideration of immunophenotyping. Lesions are identical to those described for cutaneous histiocytosis with the notation that angiocentric infiltration with vascular invasion may be more consistently seen with the systemic form of disease.[12] Lymph node evaluation (see ch. 95), thoracic radiographs, and abdominal sonography (see ch. 88) are helpful in determining extent of disease. These collective features also are helpful in distinguishing systemic histiocytosis from malignant histiocytic and non-histiocytic diseases.

As with cutaneous histiocytosis, the disease course can be punctuated by remissions and relapses. Systemic medications that have shown some efficacy include prednisone, cyclosporine, leflunomide, experimental bovine thymosin fraction 5, and the chemotherapy drug doxorubicin.[12,13] The clinical course can be prolonged, although subsequent relapses often are associated with increased severity of signs and diminishing response to treatment.

A waxing and waning disease course and occasional spontaneous remission complicate the assessment of treatment efficacy. Nonetheless, repeatable responses to immunomodulatory agents capable of inhibiting T-cell activation support the theory that reactive histiocytosis is the result of disordered immune regulation arising from abnormal DC/T-cell interactions and not a neoplastic process.

Feline Progressive Histiocytosis

Histiocytic proliferative diseases are uncommon in cats. One characterized syndrome is feline progressive histiocytosis, a disease of DC origin. Affected cats typically are older, with a median age of 10 years (range, 2-17 years).[15] Cats present with intradermal papules and nodules in the skin that are occasionally solitary, but more often multiple. Similar to reactive histiocytosis in dogs, lesions wax and wane in size, although unlike canine histiocytosis, complete spontaneous regression was not seen in one series of 30 cats.[15]

Diagnosis requires histopathologic examination and consideration of immunophenotyping. Microscopic lesions consist of diffuse dermal histiocytic infiltrates, which may extend into the subcutis. Some lesions

manifest epitheliotropism. Cellular atypia and extension deep into the subcutis are more notable in late-stage lesions.[8,15] Histiocyte antigen expression patterns are consistent with DC origin.[8,15]

Nodules progress in size over time, with some coalescing to form larger plaques that can become ulcerated and painful. In the majority of cats, lesions remain confined to the skin for extended periods. Occasionally, internal involvement is present at the time of diagnosis, as was the case in 4 of 22 (18%) cats in the series noted above.[15] Lymph node evaluation, thoracic radiographs, and abdominal sonography are helpful in determining whether internal sites of disease are present. The disease usually is progressive over months to years (median 13.4 months) and in the advanced disease setting, spread to internal sites becomes more common, as reported in 4 of 18 (22%) cats.[15]

Given its diffuse nature, surgery is of limited benefit and should be reserved for lesions that are particularly bothersome or causing morbidity. In the study cited above, surgery was performed in 8 cats.[15] Local tumor recurrence was seen in 4 cats and all 8 cats developed additional lesions distant from the surgery site. Medical therapy including corticosteroids, chemotherapy agents (L-asparaginase, vincristine, vinblastine, cyclophosphamide, nitrogen mustard) and immune modulating agents (corticosteroids, cyclosporine, leflunomide, interferon-gamma, retinoids) have met with disappointing results.

Feline progressive histiocytosis is characterized by multiple cutaneous nodules and a slowly progressive disease course. Lesions may wax and wane and disease may stay confined to the skin for long periods of time. The etiology is unknown. While certain features are similar to canine reactive histiocytosis, the lack of spontaneous remissions and non-responsiveness to immunomodulatory drugs makes an etiology linked to immune dysregulation unlikely. Instead it appears that feline progressive histiocytosis represents a neoplastic process, initially indolent and ultimately more aggressive.

Histiocytic Sarcoma Complex

Malignant disease of histiocytic origin was first reported in dogs in the late 1970s.[16] One early report described histiocytic sarcoma (HS) in 11 Bernese Mountain Dogs, 9 of whom were closely related, suggesting a genetic predisposition in this breed.[17] Flat-Coated Retrievers, Rottweilers, Golden Retrievers, and Labrador Retrievers also appear to be overrepresented.[18,19] While not considered an at-risk breed for HS in other body regions, Pembroke Welsh Corgis are overrepresented in cases originating within the central nervous system (CNS), comprising 47% of the study population in one report.[20,21] Affected dogs are typically middle-aged.

While classification continues to evolve, *histiocytic sarcoma* has become the preferred term for this group of malignancies, with two forms described: localized HS and disseminated HS (formerly referred to as malignant histiocytosis). Both arise from DCs, with characteristic positive staining for CD11c and CD18 antibodies. While microarray analyses have identified variation in gene expression between localized and disseminated HS,[22] they are morphologically and immunophenotypically identical and are distinguished on the basis of clinical presentation. Localized HS arises from a single organ while disseminated HS is a multisystem disease. Hemophagocytic HS represents another subtype, unique in its macrophage origin, and characterized by positive CD11d and CD18 antibody staining.

Localized Histiocytic Sarcoma

Localized HS most commonly affects the skin and subcutis, most often of the limbs and periarticular tissues, although other reported sites include spleen, lung, brain, spinal cord, nasal cavity, bone, and bone marrow.[18-21,23-26] Periarticular and CNS forms of disease have been described as unique subsets of localized HS.[20,21,23,26] Periarticular HS might be more common in Rottweilers.[23] Lameness and/or periarticular soft tissue swelling are the most common presenting clinical signs, reported in 79% and 68% of dogs, respectively, in one study.[26] The stifle appears to be the most common location, reported in 37-61% of dogs.[23,26] Interestingly, 55% of dogs in one study had a history of cranial cruciate ligament (CCL) rupture in the same joint later developing HS.[23] Inflamed synovium from dogs with CCL rupture contains numerous DCs, although a relationship between inflammation and subsequent tumor development has not been well defined.[27] Radiographs are indicated for dogs with suspected periarticular HS. Sixty percent of dogs in one study had radiographic evidence of osteolysis or proliferation at the tumor site.[26] HS of the CNS can be localized, confined to a single site within the brain or spinal cord, or multifocal (see ch. 260 and 267). Presenting signs reflect neuroanatomic location (see ch. 259) and include seizures, altered mentation or behavioral changes, postural reaction deficits, and paresis.[20,21] Metastasis is present in 15-70% of dogs with localized HS at the time of diagnosis and 50-90% of

dogs eventually develop metastatic disease to lymph nodes, lung, and abdominal viscera.[18,21,23,24,26]

Disseminated Histiocytic Sarcoma

Disseminated HS involves multiple organ systems, suggesting either progression and metastasis from the localized form of disease or a primary multicentric disease with tumors arising simultaneously in multiple locations. Lungs, spleen, liver, lymph nodes, and/or bone marrow are most commonly affected.[18] Diagnosis of HS requires cytologic (see ch. 93) or histopathologic evaluation and consideration of immunophenotyping. With any diagnosis of HS, staging evaluation including lymph node aspiration for cytologic assessment (see ch. 95; or biopsy for histopathologic evaluation), thoracic radiographs, an abdominal sonogram (see ch. 88) ± cytologic assessment of bone marrow (or bone marrow biopsy; see ch. 92) is indicated to characterize extent of disease.

Treatment of Histiocytic Sarcoma

Limited reports document outcome after surgical excision of localized HS. One study reported a median survival time of 6 months in 5 dogs with synovial HS treated with amputation alone.[23] Chemotherapy should always be considered, either as adjuvant therapy for localized HS or for treatment of metastatic or disseminated HS. CCNU appears to be the most effective chemotherapeutic agent for treating HS in dogs. Overall response rates of 29-46% have been reported when CCNU is used for treating gross measurable disease, with a median response duration of 90 days (range, 29-805 days).[28,29] An improved outcome can be achieved for localized HS when local therapy is combined with adjuvant CCNU chemotherapy. In one series, 16 dogs with localized HS and no evidence of distant metastatic disease were treated with intensive local therapy (surgery and/or radiation therapy) and CCNU chemotherapy.[30] Metastatic regional lymph nodes, identified in 4 of 16 (25%) dogs at the time of diagnosis, were resected at the time of primary tumor removal. Median disease-free interval was 8 months and overall median survival time was 18.6 months in this study.[30]

A more favorable outcome has been suggested for dogs with periarticular HS. One study reported a median survival of 391 days (range, 48-980 days) for dogs treated in a variety of ways, including local therapy combined with chemotherapy (47%), chemotherapy alone (42%) or local therapy alone (11%). This outcome was achieved despite an overall metastatic rate of 68% at the time of diagnosis.[26]

Combination chemotherapy may be superior to single-agent therapy, although ideal agents and combinations have yet to be determined. There is limited information regarding other effective chemotherapy drugs, although doxorubicin, paclitaxel, and vinorelbine have shown some promise.[26,31-33] A study reporting the use of alternating doxorubicin and CCNU described an overall response rate of 58% and median time to progression of 185 days (range, 59-268) in dogs with measurable gross disease.[34]

Another area of study has focused on the potential role of the bisphosphonate clodronate, which kills osteoclasts and other macrophages via induction of apoptosis. When clodronate is incorporated within liposomes, uptake by phagocytic cells is greatly enhanced, resulting in selective targeting of macrophages. Susceptibility of HS cells to this approach has been demonstrated *in vitro*.[35] A pilot study of liposomal clodronate demonstrated regression of lesions in 2 of 5 dogs (40%) with HS.[35] Combining bisphosphonates with chemotherapy may prove beneficial. In vitro data suggest an increase in HS cytotoxicity when selected bisphosphonates are combined with either vincristine or doxorubicin.[36]

Hemophagocytic Histiocytic Sarcoma

While DC origin is a common element among other histiocytic diseases, the neoplastic histiocytes in hemophagocytic HS are of macrophage origin. Cells express a distinctive surface antigen profile consistent with their origin within the splenic red pulp and bone marrow. Hemophagocytic HS appears to be more common in certain breeds, including Bernese Mountain Dogs, Golden Retrievers, and Rottweilers.[37]

Its clinicopathologic features also are unique, perhaps the most striking of which is marked erythrophagocytosis by neoplastic histiocytes, resulting in a moderate to marked regenerative hemolytic anemia. Ninety-four percent of dogs in one study presented with regenerative anemia (median Hct 22.6%, range 10.1-37).[37] Other common findings include thrombocytopenia (88%), hypoalbuminemia (94%), and hypocholesterolemia (69%).[37] Splenomegaly with diffuse, ill-defined nodular change is consistently present. Liver, bone marrow, and lungs frequently are diffusely infiltrated and spread occurs via insidious intravascular invasion with minimal mass formation.

Diagnosis is made cytologically or histopathologically, with consideration of immunophenotyping. There

appears to be marked variation in the cytologic characteristics of neoplastic histiocytes, although marked erythrophagocytosis accompanied by foci of extramedullary hematopoiesis is a consistent feature.[37] Not to be confused with immune-mediated hemolytic anemia and thrombocytopenia (Evans syndrome; see ch. 198 and 201), dogs with hemophagocytic HS are Coombs-negative. Staging evaluation including lymph node evaluation (see ch. 95), thoracic radiographs, abdominal sonography (see ch. 88) and bone marrow aspiration (see ch. 92) for cytologic assessment (or biopsy) is indicated to characterize the extent of disease.

Hemophagocytic HS carries a poor prognosis, and reports on durable effective treatments are lacking. In one study of 17 dogs, all dogs died or were euthanized, with a median time from initial onset of clinical signs to death or euthanasia reported as 4 weeks (range 2-32 weeks)[37]; information on attempted treatments was not provided. Given reported activity against other forms of HS, CCNU may be a reasonable consideration. Unfortunately, in one study reporting the use of CCNU, while not specifically characterized as hemophagocytic HS, dogs with anemia, thrombocytopenia, hypoalbuminemia and splenic involvement were significantly less likely to respond to treatment. Further, thrombocytopenia and hypoalbuminemia were associated with a significantly decreased median survival of 28 days or less, compared with 163 days or longer in the absence of these signs.[28]

HS rarely has been reported in cats. In one series of 3 cats, the disease closely resembled hemophagocytic HS in dogs.[38] Age at presentation was variable (1, 4, and 9 years). Anemia (packed cell volume, 9-15%) and thrombocytopenia (31,000-94,000 cells/mcL) were identified in all 3 cats. All cats were euthanized shortly after the diagnosis. Postmortem evaluation identified malignant histiocytic cells exhibiting erythrophagocytosis in the liver, spleen, and bone marrow in each cat. Other sites of disease included lymph node, lung, kidney, brain and urinary bladder.

CHAPTER 351

Urogenital and Mammary Gland Tumors

Juan F. Borrego

Client Information Sheet: Canine Mammary Gland Tumors

Urinary Bladder and Urethra

Prevalence and Risk Factors

Tumors of the urinary bladder are uncommon in dogs and rare in cats but their prevalence appears to be increasing over the last 30 years.[14] Most bladder and urethral tumors are epithelial and malignant. Intermediate to high-grade invasive transitional cell carcinoma (TCC) is by far the most common diagnosis in both species.[1] Other differentials include squamous cell carcinoma, adenocarcinoma, rhabdomyosarcoma, lymphoma, and other mesenchymal tumors.[15] A trigonal location with urethral and prostatic involvement is frequent with this type of tumor, often leading to urinary tract obstruction (Figure 351-1; see ch. 335).[15] Metastatic disease is detected in 10-20% of dogs at time of diagnosis and in up to 58% at necropsy.[16] Common metastatic sites of canine TCC include lymph nodes, lung, bone, and skin.[1,17,18] Feline TCC is uncommon, affects geriatric cats, metastasis is rare, and the majority do not involve the bladder trigone.[19,20]

FIGURE 351-1 Transitional cell carcinoma in the urinary bladder. Sagittal image of the bladder with a lobulated mass in the trigone.

Several risk factors have been described for TCC in dogs. Older (9-11 years) female dogs seem to be predisposed and small breeds, such as Scottish Terriers, are up to 21 times more likely to have TCC. West Highland White Terriers, Shetland Sheepdogs, and Beagles are three to five times more likely to have TCC than are mixed-breed dogs.[14,17,21] Other potential factors include obesity, neutering status, and cyclophosphamide therapy. Exposure to older-generation flea control products and lawn chemicals have been associated with TCC, while newer spot-on flea control products, such as fipronil, appear safer.[21-23] Vegetable consumption has been reported to reduce the risk of TCC in Scottish Terriers.[24]

Signs and Diagnosis

Common clinical signs caused by neoplasia within the bladder or urethra mimic bacterial cystitis or urolithiasis and are typical of lower urinary tract infection (UTI) or inflammation: stranguria, pollakiuria (see ch. 46), hematuria (see ch. 47), dysuria, urinary incontinence (see ch. 46), or any combination thereof. Antibiotic treatment may temporarily resolve signs, since concurrent infections are documented in about 25% of cases at diagnosis.[25] If clinical signs do not completely resolve with antibiotic treatment or if they reoccur, the presence of stones or cancer should be investigated, especially in predisposed breeds (Figure 351-2). In advanced cases, a mass is palpable in the caudal abdomen; abnormalities such as a thickened urethra or enlarged sublumbar or intrapelvic lymph nodes may be identified on rectal examination. Less commonly, dogs can have lameness caused by pain due to bone metastasis. Skin metastases can appear as erythematous, ulcerated, or proliferative lesions.[18]

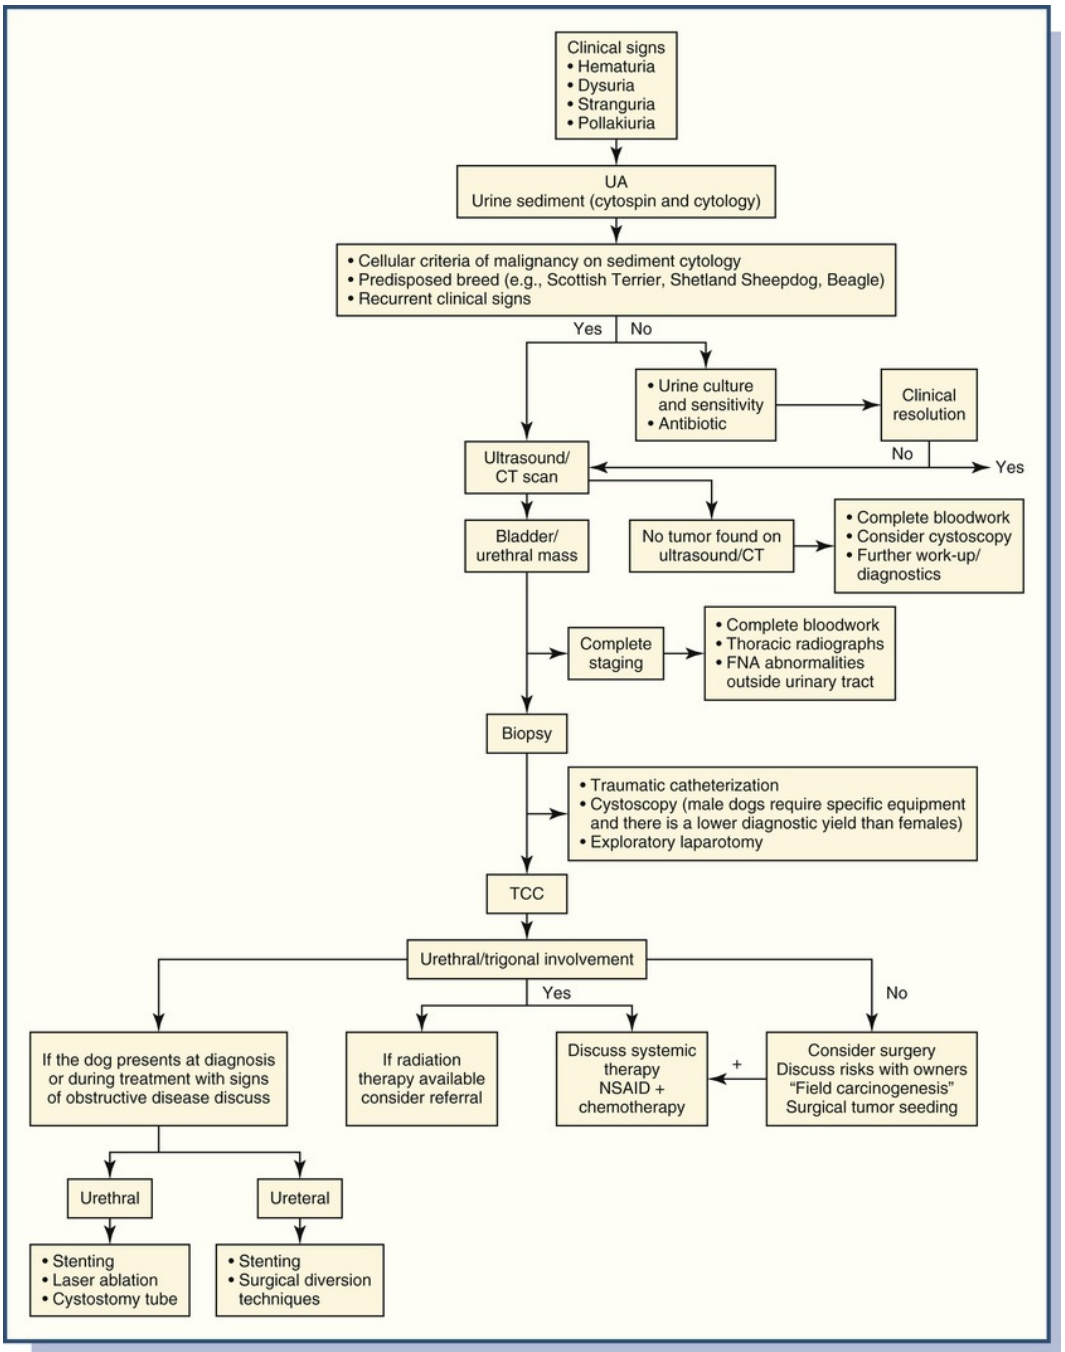

FIGURE 351-2 Algorithm for the evaluation of bladder and urethral tumors. *CT,* Computed tomography; *TCC,* transitional cell carcinoma; *NSAID,* nonsteroidal anti-inflammatory drug; *UA,* urinalysis.

Following a thorough physical examination (see ch. 2), a complete blood count (CBC), serum chemistry profile and urinalysis (UA) should be performed. Due to the high rate of UTI, urine culture and sensitivity tests should be included in the initial evaluation and periodically during treatment.[25] Urine from these patients should be obtained by free catch or catheterization. If cystocentesis is needed, ultrasound guidance should be employed to avoid penetrating the tumor mass. The presence of abnormal epithelial cells in the urine sediment of pets with a bladder mass or thickened wall is suggestive of TCC; however, other inflammatory conditions have "reactive" epithelial cells (Figure 351-3). Thoracic radiography should be performed to assess for lung metastasis. Abdominal ultrasound is preferred for assessing location and extent of disease (E-Figure 351-4). Ultrasonography should not be the only method of assessment due to inter- and intraoperator variability.[26,27] Histological examination of cytology or tissue samples obtained via traumatic catheter (Videos 351-1 and 351-2), surgical, or cystoscopic biopsy often provides a definitive diagnosis (see

ch. 93). Ultrasound-guided aspiration or biopsy is not recommended, as seeding of the biopsy tract with viable tumor cells is a possible complication.[28,29] Cystoscopic biopsy is an effective method to obtain biopsy samples in dogs with TCC of the bladder and urethra. Cystoscopy (see ch. 108) is more likely to produce a diagnostic-quality biopsy sample in female dogs with TCC (96%) than in male dogs with TCC (65%).[30]

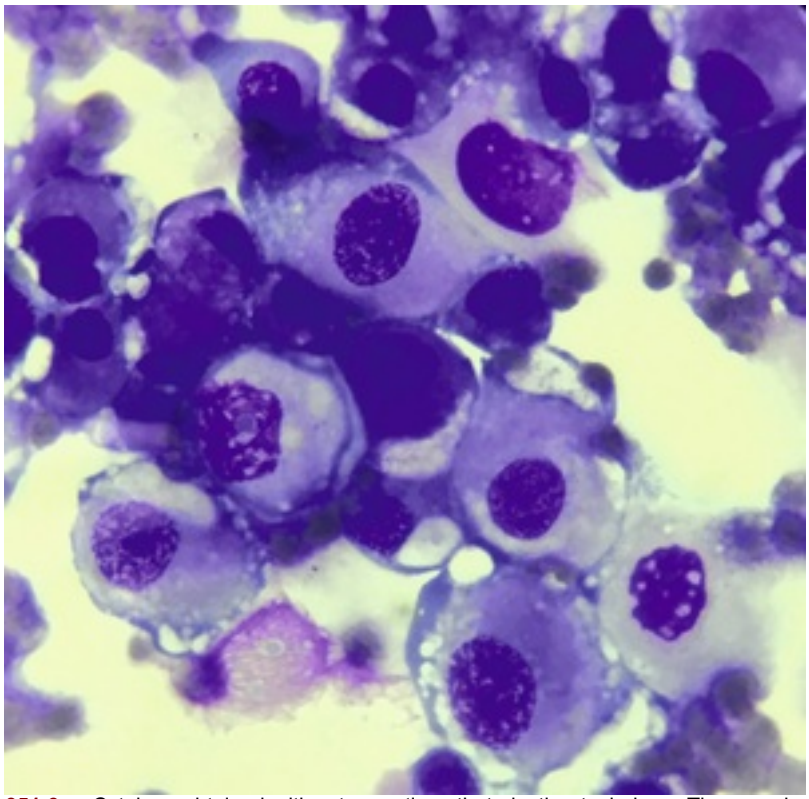

FIGURE 351-3 Cytology obtained with a traumatic catheterization technique. The sample contains dense clusters of round to polygonal cells. There are several criteria of malignancy including moderate anisocytosis and anisokaryosis, variable nuclear-cytoplasmic ratio and prominent nucleoli.

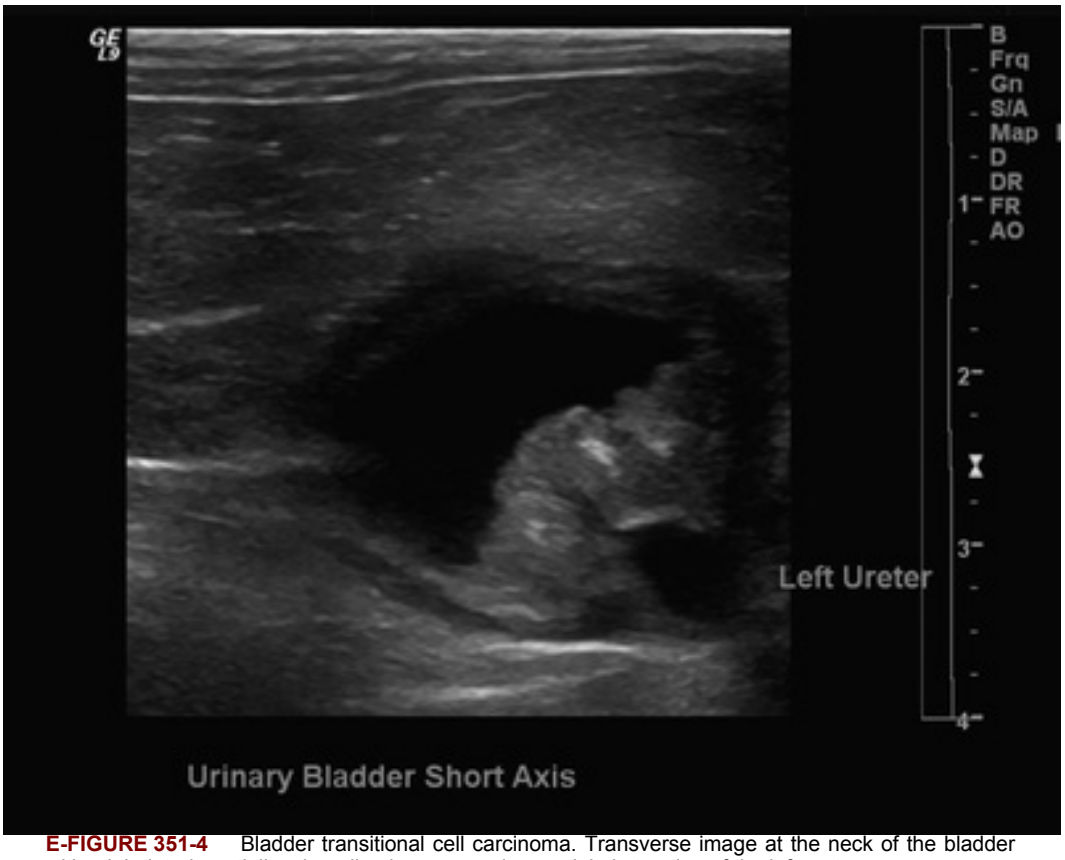


E-FIGURE 351-4 Bladder transitional cell carcinoma. Transverse image at the neck of the bladder with a lobulated, partially mineralized mass causing partial obstruction of the left ureter.

Treatment

Most dogs with TCC are managed with drug therapy and, less commonly, radiation or surgery. Surgery should be considered for tumors located cranially in the bladder; however, because the trigone region is usually involved, complete resection with acceptable postoperative function is rarely feasible. TCC has also been reported in the abdominal wall, most likely due to its highly exfoliative nature. Abdominal wall TCC is likely to have been implanted during procedures such as surgery to obtain biopsy specimens, tumor removal, tumor debulking, cystotomy tube placement or fine-needle aspiration (FNA) of TCC in the urinary bladder, urethra, and prostate.[31] TCC located in the abdominal wall carries a worse prognosis, so caution is warranted to avoid seeding the tumor into the abdomen or along the surgery site during those procedures, especially surgery (Figure 351-5).[31] After handling the mass, new gloves and clean sterilized instruments should be used to close the abdomen.

FIGURE 351-5 Abdominal wall transitional cell carcinoma tumor seeding after a subtotal cystectomy to remove the primary bladder tumor. Transitional cell carcinomas located in the abdominal wall carry a worse prognosis than those in the urinary tract.

Chemotherapy, cyclooxygenase (COX) inhibitors, and combinations thereof are the mainstay of treatment for TCC in dogs. Remission rates are typically less than 20% with single-agent therapy (nonsteroidal anti-inflammatory drug [NSAID] or chemotherapy), and 35-50% with combined chemotherapy including a COX inhibitor.[15,16] Platinum agents appear to be the most active in canine TCC, especially when combined with a COX inhibitor,[32] although combinations of cisplatin and piroxicam should be avoided, due to high rates of nephrotoxicosis and kidney failure.[33,34] Some of the other chemotherapy drugs most often used as single agents include mitoxantrone, doxorubicin, vinblastine, and gemcitabine.[14] Median survival times in dogs with TCC are typically between 130 and 195 days after single-agent drug treatment and >250 days after combination drug treatment.[16] The current treatment recommendations for single-agent therapy are a non-selective COX inhibitor such as piroxicam (0.3 mg/kg PO q 24 h)[16] or a more selective COX inhibitor such as deracoxib or firocoxib.[33,35] In case of combination therapy, a COX inhibitor and a chemotherapy drug with known antitumor activity in this disease should be used, using response to therapy every 4-8 weeks as a guideline for continued treatment.[16] One emerging treatment strategy is metronomic chemotherapy using orally administered chlorambucil, which has had good results, including 67% of patients with stable disease and 3% with partial remissions.[36]

Because TCC in cats is often located in the cranial bladder, surgery is an option to be considered. COX inhibitors (piroxicam and meloxicam) used alone or in combination protocols may have a role in the palliative management of TCC in the urinary bladder of the cat with reported survival times of 261 to 311 days.[19,20]

Newer state-of-the-art radiation therapy equipment enabling the administration of a highly conformal dose of radiation to a select target has made it possible to treat TCC as part of a combination protocol with medical therapy with a much lower risk of damage to surrounding tissues.[37,38] The advantages of this technique are that it is non-invasive, urinary continence is retained, and local control can be achieved. The disadvantages are related to the cost and availability of such radiation facilities.

Palliative Procedures and Prognosis

Most dogs with TCC die from complications secondary to urinary tract obstruction prior to the development of substantial metastatic disease. Several surgical techniques have been described to palliate TCC obstructing the urethra (see ch. 124); however, they are not commonly performed due to morbidity and cost. Uretero-

colonic anastomosis is not recommended because it is associated with neurologic and gastrointestinal complications secondary to hyperammonemia, metabolic acidosis, uremia, and chronic pyelonephritis. Other techniques with better outcomes include total cystectomy and removal of the bladder neck and trigone.[39,40] For neoplasia confined to the urethra, vaginourethroplasty and transurethral resection have been described.[16,41,42]

Cystostomy tubes have been used as a much simpler and better-tolerated procedure to bypass urinary obstructions that allows pets to survive an additional average of 3 months.[43,44] Techniques for placing a cystostomy tube include open approaches to the caudal abdomen, minimally invasive approaches to the abdomen, laparoscopic approaches, or use of fluoroscopy and a self-retaining, pig-tail catheter. Complications are frequent but easily managed, the most common being inadvertent tube removal and UTIs.

Another palliative option is urethral stent placement via interventional radiography (see ch. 124).[45,46] With the caveat of urinary incontinence in 26-39% of dogs, urethral stents are well tolerated and solve urinary tract obstructions in 97% of cases.[45,46] Despite the good short-term urinary tract obstruction resolution rate, this technique remains palliative with short median survival times.[45-47] Another palliative option is ultrasound-guided endoscopic laser and carbon dioxide laser ablations to debulk and remove obstructive or potentially obstructive TCC lesions. The main risk of this procedure is bladder perforation.[48]

Kidney Tumors

See E-Box 351-1.

E-Box 351-1

Kidney Tumors

Primary renal neoplasia is uncommon, estimated to account for 0.3-1.5% of all canine neoplasms.[1] Epithelial tumors and, in particular, renal cell carcinomas are the most common primary tumor of the canine kidney and must be differentiated from other primary epithelial neoplasms, including renal adenomas, renal oncocytomas, nephroblastomas, transitional cell carcinomas, lymphoma and sarcomas.[1-3] The average age of dogs with renal tumors is around 9 years, and males are overrepresented with a reported male/female ratio of 1.2-1.6 : 1.[2,4] An unusual syndrome in female German Shepherds includes the presence of cystadenocarcinoma with concurrent nodular dermatofibrosis and uterine tumors.[5]

The most common renal tumor in cats is lymphoma. In contrast with older reports, most affected cats in the post–feline leukemia virus (FeLV) era are not concurrently infected with the virus; the median age is 9 years, with no breed or sex predilection.[6] Other primary tumors affecting the kidneys in cats include adenoma, adenocarcinoma, transitional cell carcinoma, hemangiosarcoma, nephroblastoma, and squamous cell carcinoma.[1,7]

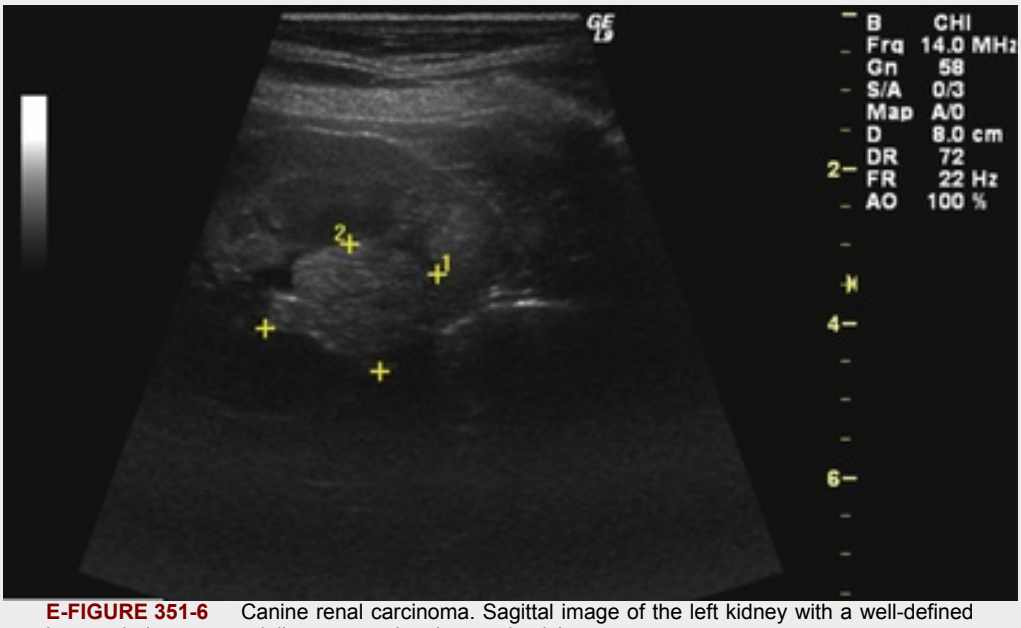
Animals can present with any combination of nonspecific signs, such as inappetence, weight loss, lethargy, vomiting, or hematuria. Physical examination may reveal unilaterally or bilaterally enlarged kidneys, which may be painful on palpation. Renal cystadenocarcinoma may be associated with firm, nodular dermal lesions and benign uterine growths in German Shepherds.

Histopathological examination is required for diagnosis, although ultrasound-guided cytology (see ch. 89) could be diagnostic in the majority of lymphoma cases.[3,6] Tumor tissue can be obtained by ultrasound-guided percutaneous biopsy or at surgery (see ch. 89). Ancillary tests such as a complete blood count (CBC), serum chemistry profile, and urinalysis (UA; see ch. 72) could detect anemia or erythrocytosis secondary to decreased or increased erythropoietin production, nonspecific serum biochemical changes such as azotemia or hypoalbuminemia, and, potentially, certain rarer paraneoplastic syndromes associated with renal tumors, such as neutrophilic leukocytosis.[8]

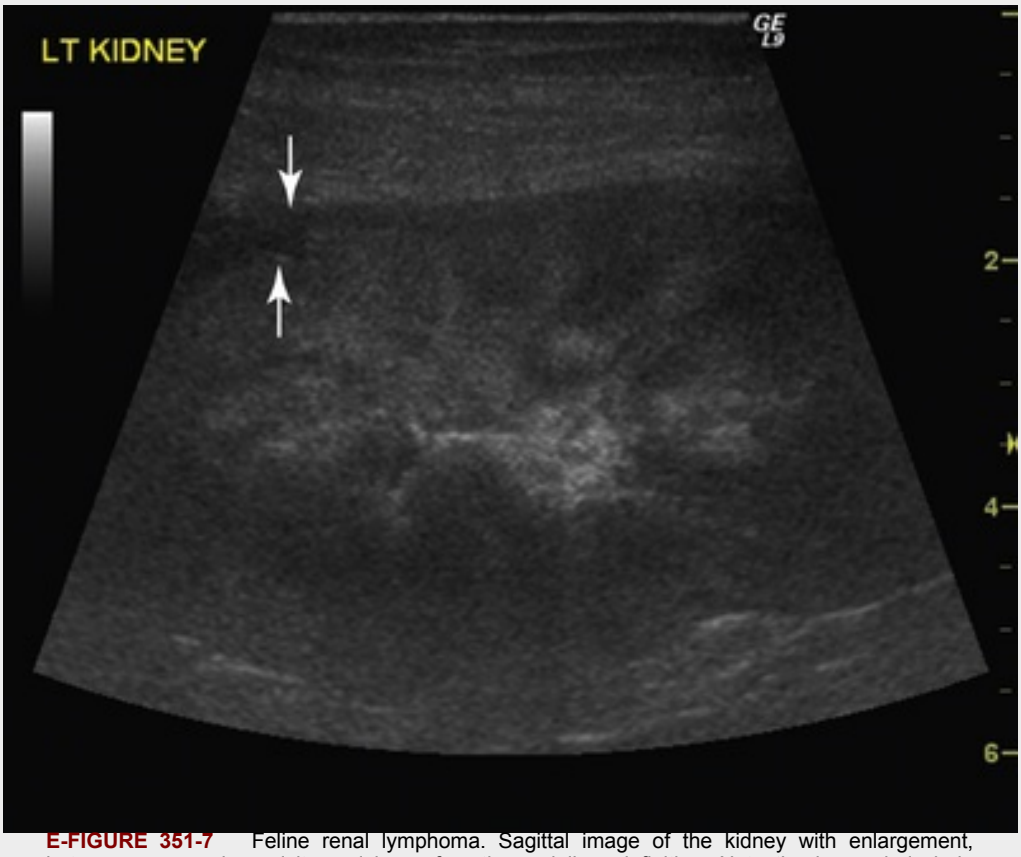
Thoracic radiographs are part of clinical staging since dogs and cats with epithelial renal tumors can develop pulmonary metastases; indeed, this has been reported in as many as half of dogs with primary tumors.[9] Newer studies[3,4] show lower pulmonary metastatic rates at diagnosis in renal cell carcinoma (RCC; 11-18%), probably because dogs today live in an era of increased clinical detection of disease.

In terms of imaging techniques, abdominal ultrasonography (E-Figure 351-6; see ch. 88) is preferred to abdominal radiographs, as it helps with the staging of the patient by enabling examination of regional

lymph nodes and other intra-abdominal structures and guides the fine-needle aspiration (FNA) of these organs.[10] The combination of renomegaly, hypoechoic focal lesions, and bilateral involvement seems to be a common ultrasonographic characteristic in canine lymphoma. Bilateral involvement is common for lymphoma but is rare in patients with carcinoma.[3,10,11] Renal lymphoma imaging in cats usually reveals bilateral (>80%), irregular renomegaly with hypoechoic subcapsular thickening[12] (E-Figure 351-7), as well as the involvement of other organs.



E-FIGURE 351-6 Canine renal carcinoma. Sagittal image of the left kidney with a well-defined hyperechoic mass partially compressing the renal pelvis.



E-FIGURE 351-7 Feline renal lymphoma. Sagittal image of the kidney with enlargement, heterogeneous echogenicity and loss of corticomedullary definition. Note the hypoechoic halo around the kidney (arrows). (Courtesy Ricardo Guillem Gallach, Penn Vet Radiology, University of Pennsylvania, Philadelphia, USA.)

Surgical planning should evaluate renal function. Some of the available tests for doing so include excretory urography, computed tomography (CT), and evaluation of the glomerular filtration rate (GFR) via scintigraphy. Caval invasion by RCC is an uncommon finding; however, it should be assessed by ultrasonography or CT prior to surgery.[4]

With regard to surgery, nephrectomy is the most effective treatment for dogs with unilateral tumors, with median survival times of 16-24 months for carcinomas, 9 months for hemangiosarcomas, and 6 months for nephroblastomas.[3,4,13] A mitotic index >30 seems to be associated with a worse outcome in RCC following surgery.[4] The role of adjunctive therapy in canine renal tumors remains unclear, with some studies suggesting no benefit.[4] Treatment with chemotherapy is indicated for cats or dogs with renal lymphoma (see ch. 344). In addition to being bilateral, the disease is typically systemic, and on rare occasions primary.[10] Extension to the central nervous system (CNS) is frequent in cats (40-50%). Multidrug protocols are more commonly used with the addition of drugs that reach the CNS (e.g., cytosine arabinoside). With treatment, the average survival time is 3-6 months.[6,13] Surgery is the treatment of choice for cats with other renal tumors. Renal cystadenocarcinomas in German Shepherds, although malignant and metastatic, progress more slowly than other renal malignancies, and survival times may be longer.

Prostatic Tumors

Prevalence, Risk Factors, and Signs

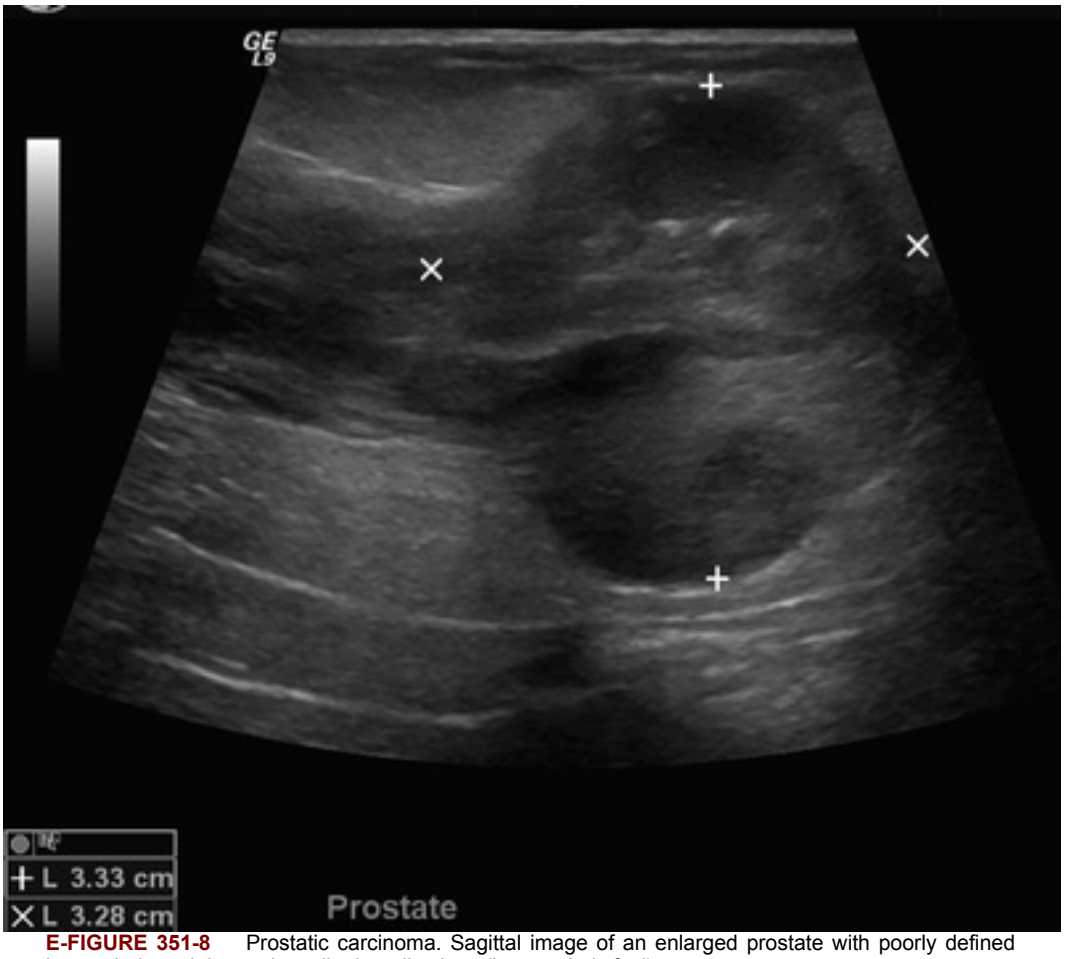
Prostatic tumors are rare in dogs, with a prevalence of less than 1% (see ch. 337). Median age at diagnosis is 10 years. Neutered dogs, Shetland Sheepdogs and Scottish Terriers have an increased risk.[49-51] The majority are carcinomas and may arise from the glandular epithelium, prostatic ducts, or prostatic urethra. Other conditions to be included in the differential diagnosis for prostatomegaly, especially in intact male dogs, are

chronic prostatitis, prostatic abscessation, benign prostatic hyperplasia (BPH), and prostatic cysts.[52] Due to rapid growth and high risk for metastasis (up to 80% in necropsy studies),[53] dogs may be seen late in the course of the disease, when clinical signs are representative of metastatic disease (weight loss, rear limb lameness, pain or neurological signs) rather than a primary urogenital disease (stranguria, hematuria, pollakiuria). Skeletal metastases are documented in as many as 40% of dogs at the time of diagnosis, causing pain, gait abnormalities or lameness. Other clinical signs caused by the enlarged prostate or metastases to local lymph nodes include dyschezia, tenesmus, constipation, or ribbon-like stools.

Diagnosis

Rectal examination usually reveals an asymmetric, fixed, and firm prostate. Continuing careful rectal palpation, one may also be able to detect enlarged intrapelvic lymph nodes. A CBC and serum chemistry profile may show non-regenerative anemia, leukocytosis, azotemia due to obstructive disease, and/or paraneoplastic hypercalcemia (see ch. 352). Bacteriuria is often detected on UA because UTI is common in these dogs. Neoplastic cells may be seen in urine sediment, although differentiation between reactive and neoplastic epithelial cells may not be possible.[53] Due to the high percentage of distant metastatic disease at diagnosis, three-view thoracic radiographs are recommended. Abdominal ultrasound (see ch. 88) is preferred over abdominal radiography to determine locoregional lymph node metastasis, bladder/ureter involvement, and other potentially affected intra-abdominal organs (E-Figure 351-8). Mineralization of the prostate on abdominal radiographs or ultrasound is not pathognomonic for prostatic carcinoma, because other benign processes cause mineralization; however. this finding is highly suggestive of neoplasia.[54] While bone metastasis that appears as lytic, proliferative, or mixed lesions on radiography can occur anywhere, lumbar vertebrae are the most common location, followed by the pelvis and femur (Figure 351-9).

FIGURE 351-9 Prostatic carcinoma. Lateral view of the abdomen with a sublumbar mass extending from L6 to the sacrum. Note the irregular periosteal reaction and poorly defined lysis at L6.



E-FIGURE 351-8 Prostatic carcinoma. Sagittal image of an enlarged prostate with poorly defined hypoechoic nodules and small mineralizations (hyperechoic foci).

Histologic examination remains the gold standard for diagnosis of prostatic cancer. Despite common secondary infections and inflammation, agreement between cytological and histological findings is high for prostatic carcinoma.[52,55] Samples for cytologic examination (see ch. 93) can be collected via traumatic catheterization (see ch. 111), prostatic wash (see ch. 111), or ultrasound-guided needle aspiration (see ch. 89). Cytology or histology of any other suspected metastatic lesions (e.g., lymph node, bone) may aid with diagnosis and staging. Ultrasound-guided aspiration and biopsies should be performed carefully due to the possibility of seeding the tumor. However, only one case of tumor seeding has been published with prostatic tumors.[28] Prostatic adenocarcinoma is the most common tumor, followed by TCC.[53] Immunohistochemistry can be performed to further delineate cell of origin; however, canine prostatic carcinomas express markers of both urothelial and ductal origin, making the differentiation between adenocarcinoma and TCC problematic.

Treatment and Prognosis

Several histological subtypes have been reported, without changing prognosis.[53,56,57] Because the majority of dogs with prostate cancer are diagnosed with advanced disease, the overall prognosis is poor. Therapy is considered largely palliative, focusing on controlling local and distant metastatic disease. Several surgical techniques have been described to achieve local control; however, they are typically associated with high morbidity and poor outcomes (<3-4 months). Subtotal intracapsular prostatectomy could be considered in dogs with early stage disease, since it can immediately palliate local clinical signs and is associated with a lower rate of postoperative complications than total prostatectomy.[58]

Urethral obstructions can be managed with tube cystostomy or urethral stenting (see ch. 124). Palliative stenting can immediately alleviate obstructions in most dogs with a low complication rate. Incontinence and stent dislodgement are the common complications.[47] There is no consensus on standard-of-care systemic therapy to treat prostatic carcinoma, and the role of chemotherapy is still under investigation. However, most

of the treatment options include a COX-2 inhibitor. The use of piroxicam or carprofen was associated with an increased survival rate in treated patients compared to an untreated group. Image-guided intensity-modulated radiation therapy (IMRT) has shown promising results in treating local disease with few side effects and should be considered if there is evidence of distant metastatic disease.[37]

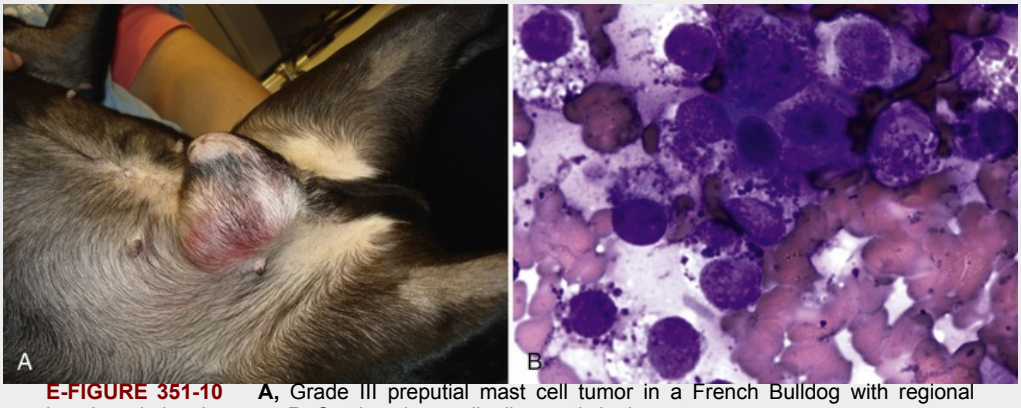
Penile, Preputial and Scrotal Tumors

See E-Box 351-2.

E-Box 351-2

Penile, Preputial, and Scrotal Tumors

Most tumors of the penile area have a soft-tissue origin and do not originate from the penile bone, with the most common type being the transmissible venereal tumor (TVT). Nevertheless, some tumors do occasionally arise from the penile bone, such as ossifying fibroma, chondrosarcoma, osteosarcoma or multilobular osteochondrosarcoma. The prepuce and scrotum could be affected by any cutaneous tumor occurring elsewhere on the skin (E-Figure 351-10). In one recent study, mast cell tumors (see ch. 349) accounted for more than 50% of scrotal tumors, followed by mesenchymal and melanocytic tumors.[59]



E-FIGURE 351-10 **A,** Grade III preputial mast cell tumor in a French Bulldog with regional lymph node involvement. **B,** Cytology is usually diagnostic in these tumors.

Complete staging including a minimum database (CBC, serum chemistry profile, urinalysis) and regional lymph node evaluation (palpation, aspiration or biopsy, and ultrasonography) is recommended prior to surgery. General recommendations for the treatment of penile tumors depend on the tumor site and involve either a partial penile amputation or ablation of the external genitalia with the creation of a urethrostomy in the scrotal area if necessary.[60] Scrotal and preputial mast cell tumors are associated with worse outcomes compared to other locations requiring a multimodal approach that should include local (surgery/radiation therapy) and systemic (chemotherapy/tyrosine kinase inhibitors) treatment.[61,62]

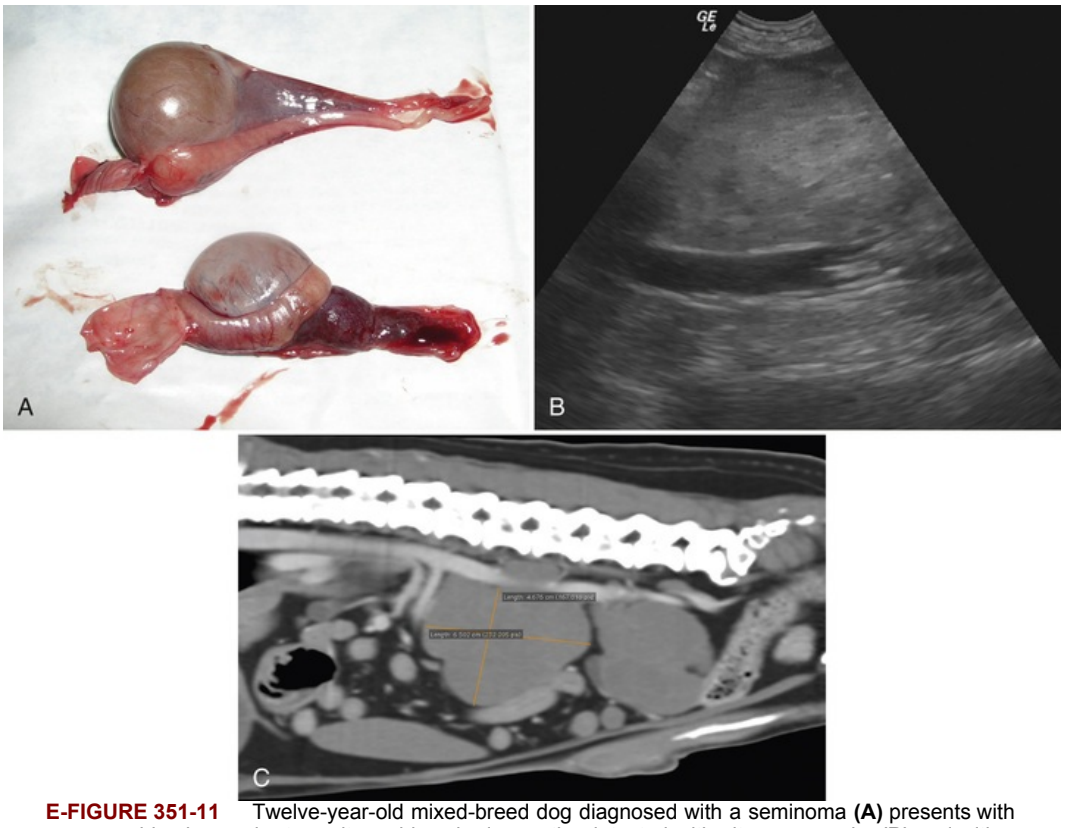
TVT rarely metastasizes, is readily diagnosed via cytology, and is usually curable with vincristine (0.5-0.7 mg/m^2 IV weekly).[63] The involution of the lesions is gradual, with complete remission in 90% of treated cases taking 2 to 8 injections. Therapy should be continued for 1 to 2 doses beyond complete visible resolution. Lesions that are resistant to vincristine may be successfully treated with doxorubicin or radiation therapy.

TESTICULAR Tumors

Prevalence, Diagnosis, Staging

The second most common tumor in intact male dogs (middle-aged to geriatric) is testicular, with three common histologic types: interstitial (Leydig) cell tumor, seminoma, and Sertoli cell tumor. Recent studies suggest a lower prevalence of Sertoli cell tumors (8-16%) and higher incidence of interstitial cell tumors and

seminomas.[64,65] Cryptorchid dogs have a higher risk of developing right-sided Sertoli cell tumors or seminomas, more commonly in testicles in the inguinal area than abdominal, and at a younger age than intact males.[65] Most testicular tumors do not metastasize. If Sertoli cell tumors or seminomas spread (<15%), it is usually to regional lymph nodes (E-Figure 351-11). Although most testicular tumors are incidentally noted on physical examination, clinical signs may include decreased libido, signs of prostatomegaly (stranguria, tenesmus), and inappetence and/or weakness secondary to anemia. Asymmetric testicles, scrotal or inguinal swellings and prostatomegaly secondary to estrogen-induced squamous metaplasia may be noted on physical and rectal examinations. Signs of hyperestrogenism including alopecia, gynecomastia, a pendulous prepuce, and a poor haircoat may be seen in as many as 50% of dogs with Sertoli cell tumors. Feminization signs are rare in seminomas and Leydig tumors. About 20% of dogs diagnosed with one testicular tumor, actually have two. Therefore, it is essential to always palpate both to compare size, shape, and firmness.[66]



E-FIGURE 351-11 Twelve-year-old mixed-breed dog diagnosed with a seminoma **(A)** presents with severe sublumbar and retroperitoneal lymphadenopathy detected with ultrasonography **(B)** and with a CT scan **(C)**.

Complete staging of these patients should include a CBC, abdominal ultrasound to evaluate regional lymph node size and to aid in identifying cryptorchid testicles, and three-view thoracic radiographs. Testicular ultrasound may aid in ruling out non-neoplastic processes such as orchitis or testicular torsion. Histology provides the final diagnosis; however, a diagnosis could also be obtained via FNA and cytology (see ch. 93).[67] Bone-marrow suppression is a rare but well-documented complication of hyperestrogenism, characterized initially by neutrophilic leukocytosis, which ultimately progresses into pancytopenia (see ch. 57, 92, and 199).

Treatment and Prognosis

Bilateral orchiectomy with scrotal ablation is preferred surgery and is curative in most (Figure 351-12). If lymph node metastasis is present, an excisional biopsy should be performed. The role of adjunctive chemotherapy, radiation therapy or novel targeted therapies in dogs with metastatic disease is unknown, with only a few reports showing some degree of efficacy.[68,69] If estrogen-induced myelosuppression has occurred, the prognosis is guarded-to-grave, requiring months of hematologic support and antibiotics.

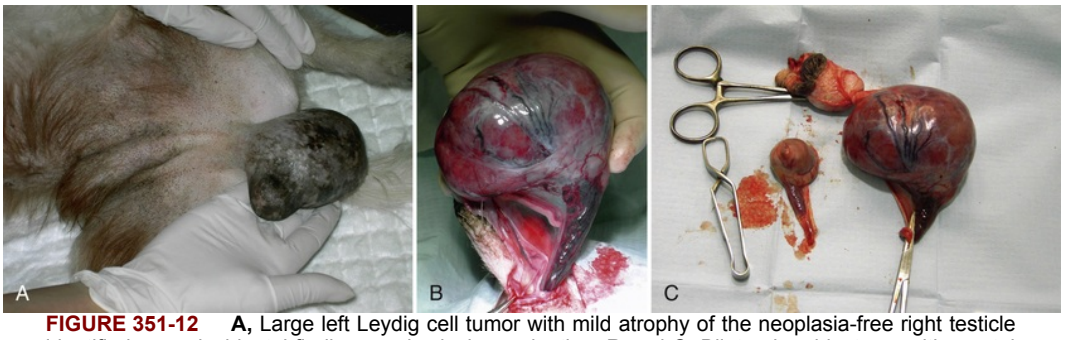


FIGURE 351-12 **A,** Large left Leydig cell tumor with mild atrophy of the neoplasia-free right testicle identified as an incidental finding on physical examination. **B** and **C,** Bilateral orchiectomy with scrotal ablation was performed.

Vaginal and Vulvar Tumors

See E-Box 351-3.

E-Box 351-3

Vaginal and Vulvar Tumors

Tumors of the vagina and vulva most commonly affect older intact nulliparous bitches and are rare in cats. Most are benign smooth muscle tumors. Leiomyoma is the predominant histologic type; polyps and fibromas are also frequently described in histopathology reports.[70] Other benign tumors have been reported in this area, including lipomas and hemangiomas, some of which can be associated with vaginal hemorrhage.[71] The most common malignant tumor is leiomyosarcoma, but other malignant tumors arising on the labia of the vulva have been described (melanoma, TVT, mast cell tumors). Other less frequent tumors in the area include adenocarcinoma affecting the clitoris and the extension of urethral tumors into the urethral papilla.[72]

Tumors may be intraluminal or extraluminal. Intraluminal tumors are often associated with stranguria; owners may see the mass protrude during urination or defecation. These are usually solitary, measure up to several centimeters in diameter, and are attached to the vaginal wall by a thin stalk (E-Figure 351-13). Other possible clinical signs include bleeding, discharge, dysuria, and vulvar licking. Extraluminal tumors appear as slow-growing perineal masses (E-Figure 351-14). Diagnostic evaluation should include vaginal and rectal palpation and a vaginoscopic examination. Fine-needle aspiration of the mass can help in the diagnosis, although histopathology is required. Complete staging with thoracic radiographs and abdominal ultrasound to evaluate for lymph node involvement should be considered in those cases of non-pedunculated masses. Diagnosis of pedunculated intraluminal tumors usually requires excisional biopsy transecting the pedicle, and local recurrence is rare in most cases. For benign, hormonally-responsive tumors, ovariohysterectomy (OHE) performed at the time of tumor removal reduces the risk of recurrence even further and is usually curative.

E-FIGURE 351-13 Vaginal leiomyoma attached to the vaginal wall by a thin stalk. The portion of the mass protruding to the outside was devitalized and friable. These masses can be detected by owners when the mass protrudes during micturition or defecation.

E-FIGURE 351-14 **A–C,** Extraluminal leiomyosarcoma in a 10-year-old intact female Great Dane. Malignant vaginal masses tend to be broad-based and infiltrative, often requiring more extensive surgical resection.

Unlike benign tumors, malignant vaginal masses tend to be broad-based and infiltrative, often requiring more extensive surgical resection. Episiotomy alone, ventral median celiotomy, a combination of ventral median celiotomy with episiotomy and pubic osteotomy, and ostectomy have been reported. More recently, a subtotal vaginectomy technique has been described for invasive benign and malignant vaginal neoplasia or extensive vaginal disease with few complications and good outcomes.[73] Radiation and/or chemotherapy may be discussed for the rare, malignant masses. Based on a small study, the prognosis for cats with vulvar adenocarcinoma appears to be poor; the cats were euthanized for progressive local disease or reoccurrence.[74]

Uterine Neoplasia

Tumors of the uterus, including horn, body and cervix, are relatively rare in dogs and cats, with leiomyomas (85-90%) and leiomyosarcomas (10%) accounting for the vast majority. Other mesenchymal tumors

(fibroadenomas, adenocarcinomas, lipomas, lymphomas and mast cell tumors) are less frequent. Spayed females could develop tumors arising from their uterine stump.[75] Adenocarcinoma is the most common uterine tumor in cats, affecting middle-aged to older animals with occasional reports of cats <1 year of age.[76-78] Some German Shepherd Dogs have a syndrome, with a hereditary component, characterized by renal cystadenocarcinomas, nodular dermatofibrosis, and uterine leiomyomas.[79] Most uterine tumors in dogs are slow-growing, non-invasive, and non-metastatic. In cats, uterine tumors usually are aggressive and widespread metastases are present at time of diagnosis.[76]

Uterine tumors in dogs are rarely associated with clinical signs, although uterine enlargement, abdominal distension, vaginal discharge, and urinary symptoms have been described. Cats may also have signs related to metastatic disease. Laboratory testing and thoracic radiographs should be included in the evaluation, even though abnormalities are not often identified. Abdominal radiographs may confirm the presence of a soft-tissue mass in the caudal aspect of the abdomen. Ultrasound may be more effective in mass identification and in determining the likely tissue involved (uterine body or cervical tumors). Ultrasound appearance of uterine tumors in dogs is variable. Definitive diagnosis is made by histologic examination of surgically excised specimens (Figure 351-15).[80] Ovariohysterectomy (OHE) is often curative for dogs. In cats, however, the aggressive biological behavior of uterine tumors prevents OHE from being curative and this form of neoplasia carries a guarded prognosis. The efficacy of chemotherapy in both dogs and cats is largely unknown.

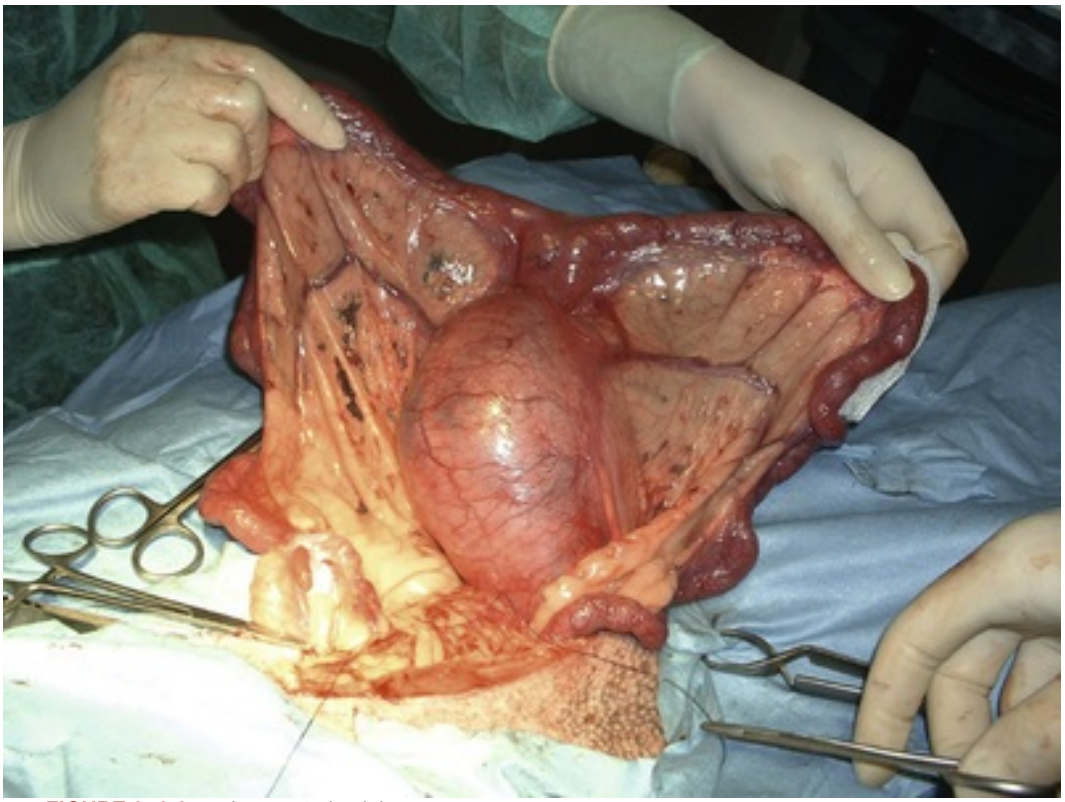

FIGURE 351-15 Large uterine leiomyosarcoma.

Ovarian Tumors

See E-Box 351-4.

E-Box 351-4

Ovarian Tumors

Ovarian neoplasms are rare, probably because a large portion of the canine population is neutered at an early age. The prevalence in intact females is 6.25%, and they affect older dogs, with a median age of 10 to 12 years.[70] Asymptomatic ovarian tumors are most commonly found during routine ovariohysterectomy (OHE) in older animals (E-Figure 351-16); however, other differentials in this situation should be considered, including ovarian cysts, which require histopathologic analysis. Other tumors may attain a larger size prior to detection, presenting clinical signs associated with a space-occupying abdominal mass including a palpable mass or signs of ascites. Rarely, they present with systemic effects of hormone production. Tumors of the ovary are classified based on the human World Health Organization (WHO) classification into epithelial tumors of Mullerian origin, sex cord-stromal tumors, germ cell tumors, and mesenchymal tumors.[81] Most are either epithelial or sex cord-stromal tumors, which account for 80-90% of ovarian tumors.[82] The malignant forms may metastasize to the peritoneum and can cause a malignant effusion; metastases are also seen in the lymph nodes, liver, and lungs.

Feline ovarian tumor types are similar to those of dogs with the exception of mesenchymal tumors, which have not been reported to date. Epithelial ovarian tumors include the histologic diagnoses of papillary adenoma, cystadenoma, papillary adenocarcinoma, and undifferentiated adenocarcinoma. These tumors are typically unilateral, rarely bilateral, usually non-functional, and have a metastatic rate of approximately 50%.[82] Epithelial tumors are rare in cats.

E-FIGURE 351-16 Ovarian granulosa cell tumor in a 7-year-old female Boxer. (Courtesy Lucia Fayos, CV Assisvet, Valencia, Spain.)

Germ cell tumors arise from primordial cells in the ovary and include dysgerminomas, teratomas, and malignant teratomas (teratocarcinomas), making up roughly 10% of ovarian neoplasms in dogs. Dysgerminomas (ovarian seminomas) arise from undifferentiated germ cells, are usually unilateral, and have a low reported metastatic rate (10-30%).[82] Teratomas are made up of more than one germ cell layer (ectoderm, mesoderm, and/or endoderm), and most are well differentiated. Teratocarcinomas have differentiated and undifferentiated components, and metastasis is noted in up to 50% of cases.[82] In cats, approximately 15% of ovarian tumors are dysgerminomas with a similar metastatic rate to that found in dogs.[70]

The granulosa cell tumor is the most common sex cord-stromal tumor and the only tumor in this category that can metastasize, followed by less common histologies, including Sertoli-Leydig tumors, thecomas, and luteomas. They are rarely bilateral, are functional in approximately 50% of cases, and have a metastatic rate of less than 20%.[82] These tumors can produce estrogen and progesterone with clinical signs related to estrogenic effects such as vulvar enlargement, vaginal discharge, and cystic

endometrial hyperplasia. In cats, sex cord-stromal tumors make up roughly 50% of ovarian tumors, and more than 50% are malignant. The most common histologic type in cats is granulosa cell tumors, and hyperestrogenism is commonly seen.

Residual ovarian tissue can become neoplastic in dogs; in one recent study, the incidence proved to be higher (26.3%) than in intact ovaries. All but one of the neoplasms of the ovarian fragment were granulosa cell tumors; a single case was a cystadenoma.[83] Diagnostic evaluation of dogs or cats with ovarian tumors should include a minimum database, thoracic radiographs, and abdominal ultrasound. If ascites is present, cytologic examination of the fluid may be diagnostic for malignancy. Ultrasound-guided FNA has also been described with a high correlation (94%) between cytologic and histopathologic diagnosis.[84,85] The risk of tumor seeding and tumor spillage, especially in malignant cystic tumors has not been evaluated. The ultrasonographic characteristics of ovarian tumors in dogs have been reported, with the tumors ranging from solid to cystic in appearance. Uterine changes, findings consistent with cystic endometrial hyperplasia, and pyometra are commonly found with sex cord-stromal tumors.[86]

Treatment of ovarian tumors relies primarily on OHE and carries an overall good prognosis for benign or localized malignant tumors. Metastatic disease carries a poor prognosis, and the role of conventional therapies such as chemotherapy or radiation therapy has not been widely investigated. In the rare cases of peritoneal metastases or malignant ascites, intracavitary chemotherapy with platinum agents may be of benefit.[87]

Mammary Gland Tumors

Prevalence and Risk Factors

Mammary gland tumors (MGTs) are the most common tumor in intact female dogs and the third most common tumor overall in cats.[88] The incidence of mammary tumors varies greatly between countries, likely due to different attitudes regarding neutering. Older females of either species are more likely to develop a mammary tumor and those with benign tumors are slightly younger than dogs with malignant tumors. Malignant mammary tumors in dogs <5 years of age are rare.[89] Dog breeds at risk include Poodles, English Cocker Spaniels, Brittany Spaniels, English Setters, and German Shepherd Dogs. Siamese cats also have an increased risk. Exposure to ovarian hormones during the first 2 years of life is a well-recognized risk factor for the development of tumors, and OHE greatly decreases the risk of MGT in both species.[90,91] Dogs spayed before their first estrus have a risk of 0.5%; after their first estrus it is about 8% and after their second it rises to 26%. After the third estrous cycle or about 4 years of age, OHE provides only modest protection. There is decreased risk of developing additional mammary tumors if OHE is performed when the first tumor is removed, suggesting a continuous effect of hormones.[92]

Neutering before the first estrus in cats reduces risk by 91%; before the second, it is 86% and before the third, it provides only an 11% risk reduction.[93] After the age of 2 years in cats, there is no benefit associated with OHE. Exogenous hormone exposure also increases risk of benign tumor development. Estrogen and progesterone receptors have been identified in dog and cat MGTs, although there is less expression in poorly differentiated tumors. Although the hormonal association is accepted, male dogs and cats can develop MGTs. In dogs they are usually benign but in cats they are highly malignant.[94-96] Obesity when young and high-fat diets have been linked to increased risk of MGT in dogs, and their tumors are usually a higher grade and are diagnosed at a younger age.[97-99]

Physical Examination and Diagnosis

On physical examination, animals may have single or multiple nodules (>50% of cases) within the mammary gland (E-Figure 351-17). Benign tumors tend to be small, well circumscribed, and firm on palpation. The caudal mammary glands are the most often involved in dogs (Figure 351-18), whereas feline tumors occur with equal frequency in all glands.[89] MGTs may be freely movable, adherent to skin, or abdominal wall. They may be ulcerated, inflamed and edematous, or associated with discharge from the nipple (E-Figure 351-19). Inflammatory mammary carcinomas (IMCs) are rapidly growing tumors with signs of pain, inflammation, and, occasionally, edema of the extremities (Figure 351-20). Differentials for MGT include dermatologic neoplasms, mastitis, lobular hyperplasia, and fibroepithelial hyperplasia in cats.

FIGURE 351-18 Large inguinal mammary gland tumor. Clinical presentation characteristics are prognostic, including the growth pattern, fixation and ulceration.

FIGURE 351-20 Twelve-year-old female shepherd mix with an inflammatory mammary carcinoma. These are generally rapidly growing and painful tumors.

E-FIGURE 351-17 Female dog with several mammary tumors along both mammary chains. Inguinal mammary glands are more commonly affected and more than 50% of patients present with multiple masses at diagnosis. These masses are not usually of a single histological tumor type.

E-FIGURE 351-19 Ulcerated mammary tumor in a feline patient.

Diagnostic evaluation of animals with mammary neoplasia should include a CBC, chemistry profile, and UA. Histological examination of the excised mass is considered the gold standard for the diagnosis of canine mammary tumors. Cytological evaluation of the mass is usually performed (see ch. 87) and may help to distinguish benign from malignant lesions; however, histopathology is still required due to possible underestimation of the tumor's malignant potential. Cytology is most helpful in ruling out other differentials, detecting locoregional lymph node metastasis, and in those cases where dermal extension is suspected (aggressive MGT or IMC; Figure 351-21). Metastatic spread in malignant MGTs occurs via lymphatic vessels to the regional lymph nodes or hematogenously to the lungs.[97] Lymph node histology is required to definitively diagnose metastasis/micrometastasis.[100] Thoracic radiographs are important to evaluate for pulmonary metastatic disease or pleural effusion (common in cats). Abdominal ultrasound should be a component of thorough staging in order to assess locoregional (superficial inguinal, axillary lymph node) or intra-abdominal metastatic lymphadenopathy, especially in those cases where mammary tumors are localized in the caudal mammary glands. Ultrasound-based suspicion of metastasis should be confirmed by cytological analysis of FNAs. Ultrasonography of mammary masses has been reported; however, correlation with histology and recognition of malignancy varies among studies.[101,102]

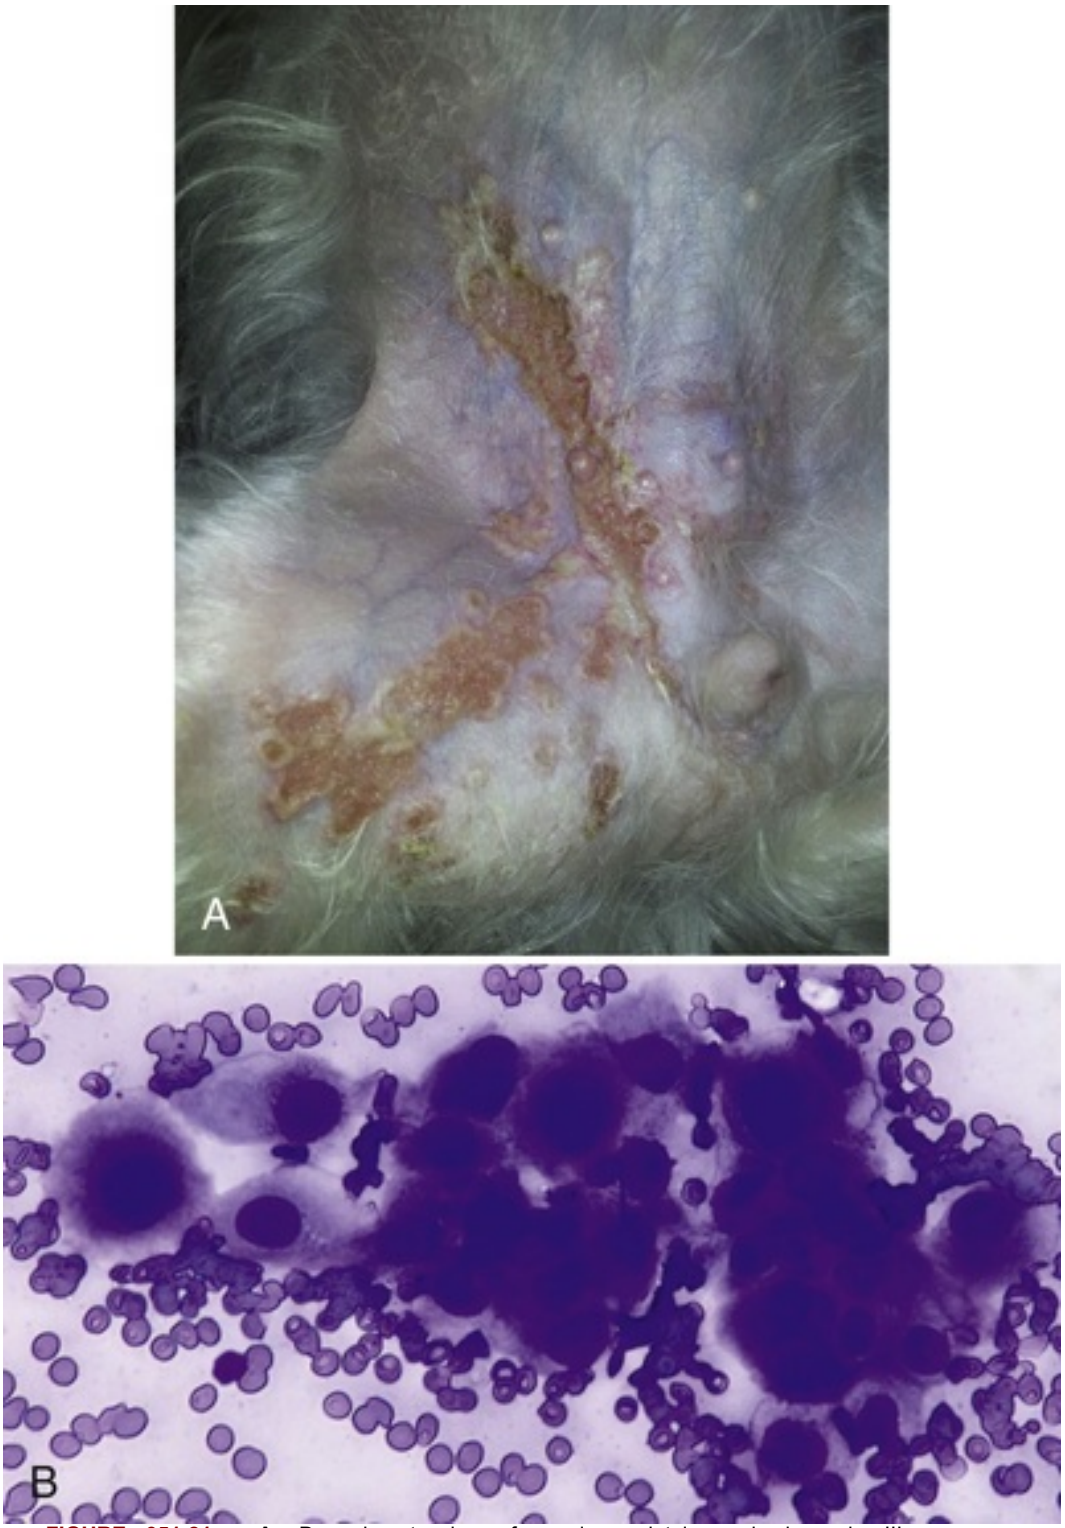

FIGURE 351-21 **A,** Dermal extension of an incompletely excised grade III mammary adenocarcinoma. **B,** Cytologic analysis of cutaneous lesions revealed pleomorphic glandular epithelial cell clusters with several criteria of malignancy (anisokaryosis, anisocytosis, macrokaryosis, and macronucleoli).

Canine Mammary Tumors

In dogs, almost 60% of MGTs are benign, most often fibroadenomas (benign mixed tumors).[103] The most common types of malignancies in dogs are solid carcinomas or tubular adenocarcinomas. Only about 3-5%

are sarcomas and 1% are IMCs. Of the malignant tumors, 50% will recur or metastasize following the first surgical resection.[104] Factors associated with shorter survival in dogs with MGTs include histologic type (poorly differentiated tumors, sarcoma, and inflammatory carcinomas have a worse prognosis), histological grade, stage, tumor size greater than 3 cm, lymph node involvement, histologic evidence of lymphatic or vascular invasion, OHE status, lymphocytic infiltrate intensity, expression of hormone receptors (ER and PR), COX-2 expression, microvessel density, proliferation markers, clinical behavior (growth pattern, fixation, ulceration) and distant metastases.[105-108]

Feline Mammary Tumors

The majority (80-90%) of feline MGTs are malignant adenocarcinomas.[109] IMCs have also been reported in cats, in whom they are biologically aggressive with a high metastatic rate. Survival times vary significantly. Tumor size, disease stage, histological grading, and the extent of surgical intervention have been shown to influence prognosis.[110-112] Tumors >3 cm are associated with survival times of only 4-12 months (E-Figure 351-22).[113,114] Type of surgery and completeness of resection have been shown to be prognostic for the disease-free interval but not for survival time.[109] Histologic grading using the Elston and Ellis system and a revised novel grading system have shown significant correlation with survival.[115]

E-FIGURE 351-22 Large mammary mass in a 12-year-old female spayed cat. Feline mammary tumors larger than 3 cm carry a worse prognosis.

Treatment

Surgery

Surgery remains the gold-standard treatment for mammary tumors in dogs and cats. A major contraindication to surgery are the IMCs associated with high rates of early regional and distant metastases and a high incidence of locoregional recurrence (E-Figure 351-23). IMC should be considered a systemic disease, even if metastases are not identified.[116] In dogs with other MGTs, the goal of surgery is to remove the entire tumor by the simplest procedure possible. For example, a lumpectomy is acceptable for small (≈1 cm) superficial mammary nodules since they are most likely benign. Masses 1 to 2 cm in diameter may require a mammectomy. If masses are present in multiple glands, they may be resected individually or in a chain. Again, the surgery chosen should be the easiest for removing all abnormal tissue. Lymphatic drainage of the

affected glands is a consideration.

E-FIGURE 351-23 Inflammatory mammary carcinoma in a 10-year-old Labrador diagnosed after surgically excising the fourth and fifth left mammary glands. **A,** One month after surgery, the contralateral mammary glands were affected. **B** and **C,** An aggressive bone metastatic lesion on the diaphysis of the right tibia was also detected.

OHE should be recommended at the time of mastectomy to prevent future ovarian or uterine disease and to reduce future mammary tumor development risk.[90,92,105] Prophylactic mastectomies of normal mammary tissues, especially when a tumor is located in a caudal gland, could be considered to prevent new mammary tumors. Dogs that undergo removal of a single mammary tumor are likely to develop new tumors ipsilaterally in up to 60% of cases.[104] The majority of canine MGTs are cured with surgery alone. In cats, because of the possible lymphatic connections between individual glands and between sides, complete unilateral or bilateral mastectomies, including the underlying fascia "en bloc," are recommended (Figure 351-24). For staged bilateral mastectomies, a minimum 2-week interval is recommended. The inguinal lymph node should always be removed with the caudal mammary gland, while the axillary lymph node should only be removed if enlarged.

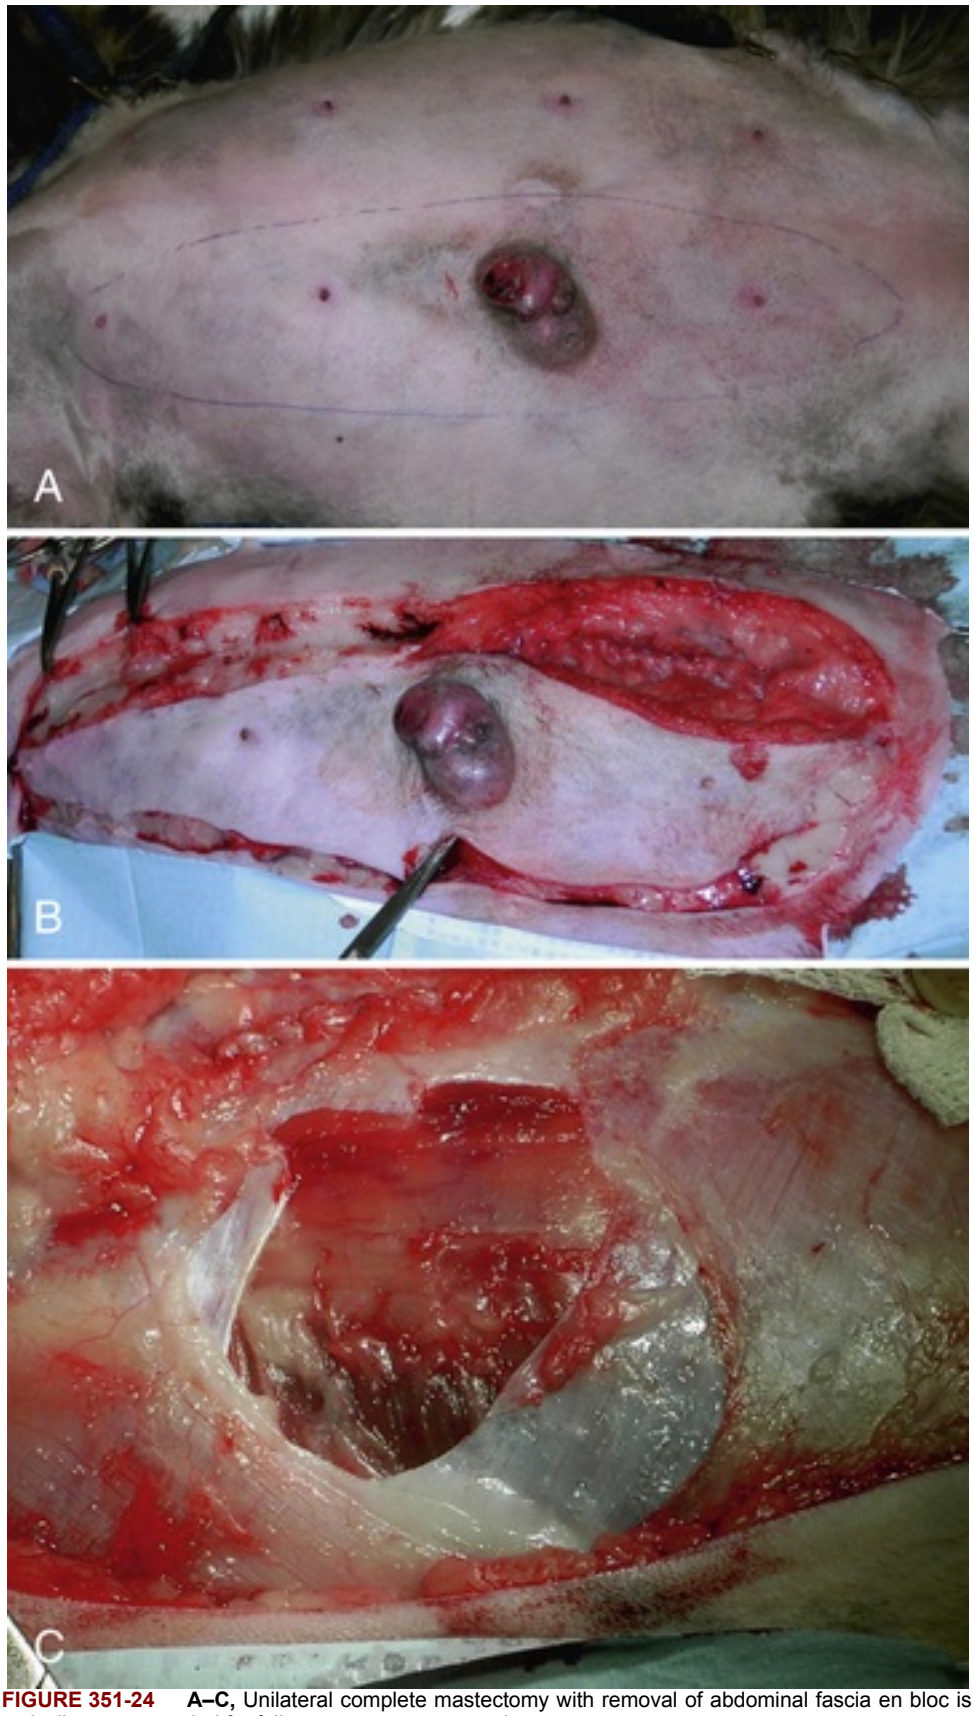

FIGURE 351-24 **A–C,** Unilateral complete mastectomy with removal of abdominal fascia en bloc is typically recommended for feline mammary tumor patients.

Radiation and Medical Treatments

Radiation therapy is not routinely used for this disease in dogs or cats. Despite mammary tumors being common, little information is available regarding the efficacy of chemotherapy for canine or feline MGTs. Most medical treatments are considered experimental, especially those in the adjuvant setting after surgery. In dogs with malignant mammary tumors and additional poor prognostic factors, locally advanced or metastatic disease, or a biologically aggressive histological type, adjuvant treatment such as chemotherapy or antiangiogenic therapy may be beneficial. Several drugs have been used as single agents or in combination protocols in the macroscopic setting with modest results and response rates around 20%, the most common being doxorubicin, carboplatin, mitoxantrone, 5-fluorouracil, and cyclophosphamide.[108] New formulations of paclitaxel, a drug active against mammary neoplasia, are associated with fewer allergic reactions and moderate response rates.[117]

Little information is available regarding the role of chemotherapy in the adjuvant setting after surgery. COX-2 expression is increased in malignant MGTs compared with benign MGTs or normal mammary tissue and is associated with a worse prognosis.[118,119] COX-2 inhibitors have only been described in cases of IMC as part of a multi-therapy treatment to improve quality of life and increase survival rate over chemotherapy alone.[120] Further studies in other canine mammary tumors are needed before the use of COX-2 inhibitors can be routinely recommended as an adjuvant therapy.

Despite the guarded prognosis in pets with IMC (1 to 2 months), medical treatment may improve outcome.[116,120] Administration of 1 mcg/kg desmopressin IV 30 min presurgically and 24 h postsurgically increased disease-free survival and overall survival in a group of dogs with MGTs.[121] Antiangiogenic therapies with toceranib phosphate have shown efficacy against canine and feline MGTs in the macroscopic setting, encouraging further research on its adjuvant role in MGTs.[122,123] Postoperative chemotherapy is usually recommended in feline patients. Doxorubicin is commonly used in feline patients although conflicting reports exist regarding its role in prolonging survival.[113,114,124] Recently, adjunctive carboplatin and mitoxantrone chemotherapy have been reported; however, these studies included few cases, and the role of adjunctive chemotherapy remains largely unknown in this type of tumor in cats.[125,126]

CHAPTER 352

Paraneoplastic Syndromes

Timothy J. Stein

Client Information Sheet: Paraneoplastic Syndromes

Paraneoplastic syndromes (PNSs) are signs arising from the indirect effects of tumors' production and release of biologically active substances. While some oncologists ascribe the term *paraneoplastic syndrome* only to those instances when the compound released by the tumor is not normally produced by the tumor cell of origin, this stringent definition would exclude many commonly cited PNSs including hypoglycemia secondary to pancreatic insulinoma. The signs of PNSs typically arise at sites distant to the tumor location and may be the first evidence of neoplastic disease. These signs often resolve with the successful treatment of the underlying neoplastic process. A recrudescence of these signs may occur prior to grossly detectable recurrence or relapse of the inciting neoplastic process; therefore, the continued monitoring for these signs is important.

Endocrine-Related Paraneoplastic Syndromes

Hypercalcemia of Malignancy

Cancer is the most common cause of hypercalcemia in dogs, whereas non-neoplastic conditions predominate in cats.[1-3] Perturbations in calcium regulation may be caused by a wide variety of non-neoplastic diseases and the diagnostic approach to hypercalcemia is discussed in detail in ch. 69. Hypercalcemia of malignancy (HM) accounts for up to two-thirds and one-third of hypercalcemia in dogs and cats, respectively.[2,3] The primary mechanism of HM is promotion of bone resorption by osteoclasts and the subsequent release of calcium into the bloodstream. Factors released from neoplastic cells may also affect the kidney and intestinal tract's ability to modulate calcium concentrations. The most common of these substances is parathyroid hormone–related peptide (PTHrP).[4,5] Other factors produced and released by neoplastic cells that have been shown to contribute to HM include receptor activator of nuclear factor kappa-B ligand (RAN-kappa-L), transforming growth factor-beta, interleukin-6 (IL-6), and tumor necrosis factor.[6]

Lymphoma, anal sac gland adenocarcinoma, and multiple myeloma are the malignancies most commonly associated with HM in dogs.[7] While this list is not exhaustive, other tumor types associated with HM include mammary gland tumors, melanoma, chronic lymphocytic leukemia, and thymoma.[8-11] In anal sac gland adenocarcinoma, a linear correlation exists between serum calcium and PTHrP concentration, whereas no such correlation exists in canine lymphoma.[12] This suggests other factors contribute to HM in canine lymphoma.

HM in cats is most frequently reported with squamous cell carcinoma and lymphoma, though it is reported in cats with multiple myeloma, osteosarcoma, and bronchogenic adenocarcinoma.[3,13,14] Similar to dogs, PTHrP is considered to be a main culprit of HM in cats.

The serum ionized calcium concentration should normalize rapidly with successful treatment of the inciting tumor. Assessment of serum ionized calcium should be included with follow-up monitoring of any patient with HM. For patients in which the inciting tumor is not amenable to complete removal or refractory to treatment, other supportive measures for managing hypercalcemia (see ch. 69 and 297) should be attempted, though the success of these measures are often short-lived.

Hypoglycemia

Paraneoplastic hypoglycemia should be on the list of differential diagnoses for hypoglycemic animals (see ch.

61). This PNS is most commonly associated with tumors of the pancreatic beta-islet cells (insulinomas).[15] Other non-insulinoma tumors that have been associated with hypoglycemia include hepatocellular carcinoma, hemangiosarcoma, mammary tumors, oral melanoma, multiple myeloma, plasma cell tumors, renal tumors, salivary gland tumors, and smooth muscle tumors (leiomyoma and leiomyosarcoma).[16-20]

Hypoglycemia associated with an insulinoma is due to the overproduction of insulin by the primary tumor. In contrast, hypoglycemia of the extra-pancreatic tumors has been associated with low insulin concentrations and is caused by insulin-like growth factors I and II, and somatomedins.[16] Other potential causes of paraneoplastic hypoglycemia include the increased expression of insulin receptors or glucose utilization by neoplastic cells, or decreased hepatic glycogenolysis or gluconeogenesis, and binding of insulin by M proteins in multiple myeloma.

Paraneoplastic hypoglycemia is optimally treated by the surgical removal of the neoplasm. However, it may be necessary to symptomatically treat the hypoglycemia before surgery, or medically manage the hypoglycemia (see ch. 61 and 303) if surgery is not feasible.

Ectopic Adrenocorticotropic Hormone Syndrome

The ectopic production of adrenocorticotropic hormone (ACTH) or ACTH-like substances by malignancies in animals is extremely rare. Case reports exist describing such a syndrome in dogs with primary lung tumors, an abdominal neuroendocrine tumor, and a hepatic carcinoid.[21-23]

Hyperestrogenism

The most common neoplastic cause of hyperestrogenism is the Sertoli cell tumor.[24] Sertoli cell tumors that arise in the cryptorchid testicle are more likely to produce excess estrogen relative to Sertoli cell tumors in descended testicles.[25,26] Overall, 30-50% of dogs with a Sertoli cell tumor will display signs of hyperestrogenemia.[25,26] Not all dogs with clinical signs of hyperestrogenemia will have detectably high estrogen concentration. The increased production of inhibin-alpha reduces testosterone production, ultimately reducing the testosterone : estrogen ratio, which likely contributes to clinical signs.[27] Clinical signs of hyperestrogenism include bilateral symmetrical alopecia, cutaneous hyperpigmentation, epidermal thinning, gynecomastia, galactorrhea, attraction of other males, preputial atrophy, and atrophy of the non-neoplastic testicle.[27] A pancytopenia may be present on the complete blood count (CBC) of affected animals and bone marrow evaluation (see ch. 92) will reveal a hypocellular marrow.[24] Severely pancytopenic animals may demonstrate lethargy, bleeding secondary to thrombocytopenia, petechiae, and pale mucous membranes.[24]

The successful treatment of paraneoplastic hyperestrogenism is dependent upon the surgical excision of the Sertoli cell tumor. Recurrence of feminization has been documented in a dog with delayed-onset metastatic disease.[28] Pancytopenic animals may require pre-operative care including the administration of broad-spectrum antibiotics and blood or red cell transfusions. Bone marrow recovery may take weeks to months following tumor removal.

Hematologic Paraneoplastic Syndromes

Anemia

Anemia is one of the most common PNSs in dogs and cats. Cancer-related anemia is one of the most frequent causes of anemia in dogs.[29] The majority of paraneoplastic anemias are likely secondary to anemia of chronic disease (ACD), immune-mediated hemolytic anemia, microangiopathic hemolytic anemia, or blood loss anemia. For blood loss anemia to be considered a PNS, the blood loss must occur at a site distant to the primary tumor. Examples of this would include blood loss due to gastrointestinal ulceration secondary to excessive histamine secretion from mast cell tumors (MCTs) or excessive gastrin production by gastrinomas.

ACD is the most common form of anemia seen in cancer patients. ACD arises secondary to impaired iron storage and metabolism resulting in a suppression of erythroid progenitor cell differentiation, decreased erythropoietin production, and decreased survival of erythrocytes. ACD is generally characterized by a mild/moderate, normocytic, normochromic and non-regenerative anemia. This type of anemia is slowly progressive and rarely requires supportive measures.

Paraneoplastic immune-mediated hemolytic anemia (IMHA) is most commonly associated with

hematopoietic tumors, but it has been reported in association with solid tumors. The PNS is considered a secondary IMHA, as the antibodies against tumor cell-membrane antigens cross-react with erythrocytes resulting in their destruction. Clinical signs commonly associated with IMHA are lethargy, weakness, tachycardia, pallor, icterus, hepatosplenomegaly, hemoglobinuria, and anorexia. Diagnostic tests for secondary IMHA are further discussed in ch. 198.

As with most PNSs, the treatment of choice for the paraneoplastic IMHA is removal of the underlying tumor; however, this may not be immediately feasible. Therefore, immunosuppressive dosages of prednisone are frequently used in the treatment of secondary IMHA. Additional immunosuppressive medications including azathioprine, cyclosporine, and cyclophosphamide may be necessary for IMHA cases refractory to prednisone, though the efficacy in treating secondary IMHA with these drugs is poorly defined.[30,31]

Microangiopathic hemolytic anemia is most often associated with the microvascular solid tumors, such as hemangiosarcoma (HSA; see ch. 347), though it may occur with any tumor, including hematopoietic tumors, associated with disseminated intravascular coagulation (DIC; see ch. 197).[32] The fragmentation of erythrocytes may occur as red blood cells pass through intravascular fibrin formed in DIC, or secondary to abnormal vascularity within the tumor, pulmonary intraluminal tumor emboli, or the narrowing of pulmonary arterioles.[32] Successful treatment of the underlying malignancy is considered the only effective therapy for paraneoplastic microangiopathic hemolytic anemia.

Erythrocytosis

Erythrocytosis, or polycythemia, is an uncommon PNS in animals that is most often associated with primary or secondary tumors of the kidney.[33-38] Other neoplasms that have been reported to cause erythrocytosis include lymphoma, schwannoma, nasal fibrosarcoma, transmissible venereal tumor, bronchioalveolar carcinoma, and cecal leiomyosarcoma.[38-43]

Paraneoplastic erythrocytosis is a form of secondary erythrocytosis (see ch. 200), as the underlying mechanism is an increased level of erythropoietin. Clinical findings with polycythemia may include erythema of mucous membranes, polydipsia, and neurologic signs such as disorientation, ataxia, and seizures secondary to hyperviscosity or hypervolemia.

Neutrophilic and Eosinophilic Leukocytosis

The presence of an increased number of mature neutrophils in the absence of infection or leukemia defines a paraneoplastic neutrophilic leukocytosis. Renal carcinomas (transitional cell and tubular), lymphoma, metastatic fibrosarcoma, pulmonary carcinoma, and rectal adenomatous polyps have been associated with this syndrome.[44-50] Neutrophilic leukocytosis is also common in dogs with paraneoplastic hypertrophic osteopathy.[51] This PNS is driven by tumor production of granulocyte colony-stimulating factors (G-CSFs) in cats and both G-CSF and granulocyte-monocyte (GM)-CSF in dogs.[47,49,52] This PNS is most commonly an incidental finding and resolves with successful treatment of the underlying tumor.

Paraneoplastic eosinophilia is rare in dogs and cats. There are case reports of this condition in dogs with pericardial leiomyosarcoma, intestinal T-cell lymphoma, rectal polyps, mammary carcinoma, and oral fibrosarcoma.[48,53-56] Paraneoplastic eosinophilia has been reported in cats with MCTs, intestinal T-cell lymphoma, acute leukemia and transitional cell carcinoma of the bladder.[57-61] Eosinophilia as a PNS is generally an incidental finding.

Thrombocytopenia

Paraneoplastic thrombocytopenia (see ch. 201) has been associated with lymphoma, melanoma, HSA, osteosarcoma (OSA), MCT, histiocytic malignancies, and various carcinomas.[62-64] In one study, up to 36% of dogs with untreated malignancies had thrombocytopenia on CBC.[30] The mechanisms underlying this PNS are common to any causes of thrombocytopenia. Decreased platelet production may occur secondary to myelophthisis induced by marrow-infiltrating malignancies or arise due to estrogen-secreting testicular or ovarian tumors.[65-67] Thrombocytopenia secondary to sequestration may occur with splenic malignancies.[67] Increased platelet destruction may occur through immune-mediated processes and has been associated with lymphoma or multiple myeloma. Thrombocytopenia secondary to consumption may occur with tumors that induce hemorrhage (HSA or MCTs) or coagulopathies such as DIC (multiple metastatic tumors and

HSA).[62,68]

Clinical signs of thrombocytopenia, including petechiation, are not typically evident until the platelet count decreases below 30 × 10^9/L. The treatment of PNS thrombocytopenia depends on the mechanism inciting the thrombocytopenia, although resolution of the primary tumor is the optimal treatment. Fresh whole blood may be indicated prior to tumor resection (see ch. 201).

Thrombocytosis

Thrombocytosis as a PNS is recognized less frequently than thrombocytopenia. In retrospective studies assessing cats and dogs with thrombocytosis, neoplasia was the most commonly diagnosed concurrent illness.[70,71] Thrombocytosis has been described in animals with OSA, gingival carcinoma, chronic myeloid leukemia, bronchoalveolar carcinoma, metastatic squamous cell carcinoma, and in those undergoing chemotherapy.[70-74]

Paraneoplastic thrombocytosis is a diagnosis of exclusion. Causes of thrombocytosis include vinca alkaloid administration, splenectomy, iron deficiency, and myeloproliferative disorders. Resolution occurs with successful treatment of the underlying malignancy.

Platelet Hyperaggregability, Hypercoagulability, and Disseminated Intravascular Coagulation

Changes in platelet function have been demonstrated in dogs with cancer.[75-78] Both platelet hyperaggregation and hypercoagulability were found to be common hemostatic abnormalities in canine cancer patients.[75,78] The assessment and management of bleeding disorders is covered in ch. 197.

DIC is a complex syndrome characterized by the excessive activation of the coagulation cascade, resulting in widespread microthrombosis and multiorgan failure. As a PNS, DIC has been associated with tumors of the vasculature and solid tumors, with a reported incidence of 9.6%.[79] DIC may be present in up to 50% of HSA cases on initial evaluation.[79,80] Along with the mechanisms of DIC common to other diseases, tissue factor (TF) is expressed on cancer cells and complexes with factor VIIa to stimulate thrombin formation and activation of factors IX and X. Patients with paraneoplastic DIC generally have a poor prognosis.

Hyperglobulinemia

Hyperglobulinemia is a PNS most commonly associated with multiple myeloma, although it has also been noted with lymphoma, chronic lymphocytic leukemia, and plasmacytoma.[81-83] Hyperglobulinemia arises due to excess production of immunoglobulins by plasma cells or lymphocytes.[83,84] Most animals with multiple myeloma have an IgG or IgA monoclonal gammopathy. Clinical signs relate to the hyperviscosity secondary to excess globulins in circulation. In addition to hypertension and tissue hypoxia, the decreased production of normal immunoglobulins may result in infections. The hyperviscosity may result in cardiomegaly, renal failure, ocular disorders including retinopathies, and neurologic abnormalities.[85-88] Bleeding tendencies are common with hyperglobulinemia and relate to decreased adhesion of platelets to damaged endothelial surfaces, coating of platelets with immunoglobulins, and release of platelet factor III. Confirmation of hyperglobulinemia is via serum electrophoresis.[104] Treatment of animals with paraneoplastic hyperglobulinemia is dependent upon successful treatment of the inciting tumor, usually with chemotherapy. Cases in which the inciting neoplasia is not amenable to a quick resolution may require plasmapheresis.[88]

Cutaneous ParaneopLastic Syndromes

Feline Paraneoplastic Alopecia

A unique PNS of alopecia occurs in some cats with pancreatic and biliary carcinoma (see ch. 10 and 280).[89-93] Acute, progressive, non-pruritic symmetrical alopecia occurs, with lesions characterized by easily epilated hair and smooth, shiny skin underneath.[89-93] Palliation may be possible with resection of the primary tumor.

Superficial Necrolytic Dermatitis

Superficial necrolytic dermatitis (see ch. 285) is a rare PNS most commonly associated with glucagon-

secreting tumors in dogs. Superficial necrolytic dermatitis as a PNS has also been reported in a cat with a glucagon-producing neuroendocrine carcinoma (hepatic carcinoid).[94] Hypoaminoacidemia is a characteristic feature and may be central to the etiology of this syndrome. The erythema, crusting, exudation, ulceration, and non-pruritic alopecia is characterized histologically by epidermal parakeratosis with laminar hydropic degeneration of the stratum spinosum, hyperbasophilia of the deep epidermis, and hyperplasia of the stratum basale.[95] Resolution of superficial necrolytic dermatitis has been noted with surgical removal of pancreatic tumors and somatostatin therapy.[96,97]

Nodular Dermatofibrosis

Nodular dermatofibrosis is associated with renal cystadenoma or cystadenocarcinoma and rarely with uterine leiomyoma and ovarian adenoma.[97-101] This PNS is commonly associated with German Shepherd Dogs and linked to mutations in the chromosomal region overlapping the Birt-Hogg-Dubé locus.[97-100]

Gastrointestinal Paraneoplastic Syndromes

Cancer Cachexia

Weight loss and metabolic alterations observed in cancer patients despite adequate nutritional intake are termed *cancer cachexia.* In people this has been associated with negative effects on strength, immune function, wound healing, and survival.[102] Similarly, poor body condition has been associated with shortened survival times in feline cancer patients.[103] Cachexia is further reviewed in ch. 177.

Gastrointestinal Ulceration

Paraneoplastic gastrointestinal (GI) ulceration most commonly is secondary to excessive histamine release from mast cell disease. The excessive histamine stimulates gastric H2 receptors, leading to increased secretion of gastric acid. Studies have demonstrated that up 75% of dogs with macroscopic MCT have increased plasma histamine concentration, with approximately 30% demonstrating clinical signs of GI hyperacidity.[104,105] Nonspecific supportive therapies such as proton pump inhibitors, H2 blockers, misoprostol, and sucralfate may benefit patients affected by GI ulceration; however, resolution of the paraneoplastic GI ulceration is expected only for cases in which the primary tumor is adequately controlled. In addition to MCTs, gastrinomas have also been associated with GI ulceration as a PNS.[106,107]

Neurologic Paraneoplastic Syndromes

Myasthenia Gravis

Myasthenia gravis (MG) as a PNS most often occurs with thymoma, but it has been described in association with cholangiocarcinoma, lymphoma, OSA, and an oral sarcoma.[11,108-110] Antibodies against the nicotinic acetylcholine receptors are produced by the tumor, resulting in the failure of synaptic transmission. Clinical signs of MG include weakness, dysphagia, regurgitation, and aspiration pneumonia secondary to megaesophagus. Additional information on diagnostic testing and management of MG is provided in ch. 117 and 269. Removal of the primary tumor is recommended; however, MG may not resolve despite removal of the inciting cause.

Peripheral Neuropathy

Paraneoplastic peripheral neuropathy (see ch. 268) has been reported in dogs and cats with HSA, primary lung tumors, leiomyosarcoma, mammary tumors, multiple myeloma, lymphoma, insulinoma and undifferentiated sarcoma.[111-114] Paraneoplastic peripheral neuropathy is likely secondary to the production of antibodies targeting antigens shared between the primary tumor and peripheral nerves. Removal of the tumor is the only effective treatment for this PNS.

Renal PARANEOPLASTIC SYNDROMES

Glomerulonephritis and Nephropathies

The deposition of tumor-related immune complexes in the renal glomeruli may result in glomerular disorders of cancer-bearing patients. Although the prevalence of paraneoplastic glomerulonephritis is unknown in veterinary medicine, there is a report of immune complex glomerulonephritis in a dog with lymphocytic leukemia.[115] Nephropathy in dogs and cats with neoplasia may occur secondary to paraneoplastic hypercalcemia, resulting in mineralization of the basement membrane. Therapy for paraneoplastic glomerulonephritis and nephropathy should be aimed at removal of the inciting tumor (see ch. 325).

Miscellaneous Paraneoplastic Syndromes

Hypertrophic Osteopathy

Hypertrophic osteopathy (HO) is a well-characterized PNS most often associated with primary intrathoracic masses. Renal, adrenal, metastatic Sertoli cell tumors and urinary bladder tumors have also been associated with this PNS.[51,116-121] Hypertrophic osteopathy is characterized by periosteal proliferation along the shafts of long bones, typically in the distal extremities, and associated soft tissue swelling of the limbs. The syndrome oftentimes affects all four limbs, starting distally and moves proximally. While HO is most commonly associated with neoplastic conditions, it has been associated with infectious/inflammatory pulmonary diseases, *Spirocerca lupi* esophageal granuloma, and bacterial endocarditis.[51,122-124] Dogs and cats affected by HO often present with shifting-leg lameness and/or a reluctance to move. Typically, the distal extremities are warm and swollen on palpation. A diagnosis of HO is aided by radiography of the affected bones and subsequent radiographic evaluation of the thorax. If thorax radiographs are negative for intrathoracic disease, additional diagnostics to evaluate for infectious/inflammatory causes should be pursued.

The stimulation of afferent nerves is thought to be involved with HO, resulting in increased blood flow to the extremities and periosteal proliferation. The resolution of signs in some patients following vagotomy supports this belief. Successful treatment of the primary mass will result in resolution of HO.[51] Efforts to manage the pain associated with HO should be attempted using anti-inflammatory doses of steroids or nonsteroidal anti-inflammatory drugs (NSAIDs).

Fever

Paraneoplastic fever occurs secondary to elaboration of pyrogenic cytokines by either the tumor or by the host immune response to the tumor. These pyrogens include IL-1, IL-6, interferons, and tumor necrosis factor-alpha, which act on the thermoregulatory center of the anterior hypothalamus. In addition to pyrogen-induced fever, neoplastic infiltration into the hypothalamus may result in fever. Therapy is dependent upon the underlying cause of the fever, although symptomatic therapy with NSAIDs may provide some palliation if the underlying cancer cannot be eliminated.

CHAPTER 353

Skeletal Disorders in Companion Animals

Denis J. Marcellin-Little

Client Information Sheet: Osteoarthritis in Dogs

Skeletal disorders in dogs and cats interfere with pain-free movement and mobility; they negatively impact quality of life; and they may require surgery or may lead to euthanasia. Orthopedic problems result from orthopedic injuries or from skeletal disorders. Orthopedic injuries affect all musculoskeletal tissues: bone, ligaments, muscles, and tendons. Because dogs and cats sustain a wide range of trauma, the onset and severity of orthopedic injuries is unpredictable. The diagnosis and management of orthopedic trauma is described elsewhere.[1,2] Skeletal disorders, by comparison, have a much more predictable onset and progression. Skeletal disorders are most often triggered by the presence of faulty genes, of improper nutrition, of infection, by metabolic disorders, or by the presence of developmental disorders affecting bones or joints. Despite these widely ranging causes and pathophysiology, skeletal disorders have common consequences on skeletal health and mobility. The purpose of this chapter is to review the causes and pathophysiology of skeletal disorders in dogs and cats, their clinical impact, their diagnosis, and their treatment options with a focus on medical management.

Causes of Skeletal Disorders

Skeletal disorders in companion animals often have a genetic basis.[3] Orthopedic disorders can result from a single faulty gene or from multiple faulty genes (multigenic diseases). Often, a genetic cause is suspected based on population data but specific genetic links are not identified.[4-6] For example, chondrodystrophy in dogs can result from one of several genetic disorders but little is known about the specific genetic mutations causing these disorders.[7] In humans, dwarfism (achondroplasia) is an autosomal dominant disease resulting from a mutation of the fibroblast growth factor receptor 3 (FGFR3) gene. In dogs, various forms of dwarfism (see ch. 295) lead to having short or deformed long bones and affect limbs (Basset Hound or Dachshund) or the skull (brachycephaly in Boxer dogs).[8-10] Dwarfism is also present in cats (see ch. 294).[10] Dwarfism in cats is generally linked to metabolic diseases, including congenital hypothyroidism (see ch. 300), mucopolysaccharidosis (see ch. 260), and congenital hyposomatotropism (see ch. 294).[11-13] Cats can have a classic chondrodystrophic morphology (Munchkin cats) in the absence of metabolic disorders. Genetic and genomic tests to detect markers of orthopedic disease are in their early stages.[14] The identification of specific genes responsible for developmental orthopedic diseases is challenging and only few genetic markers are in use in orthopedics. For example, the SERPINH1/HSP47 mutation is responsible for osteogenesis imperfecta in the Dachshund.[15] Genomic selection rather than marker-based selection has been suggested as strategy for reduction of canine hip dysplasia[16] and other orthopedic disorders.[17]

Nutrition can impact skeletal disorders directly by causing these disorders, or indirectly by promoting the expression of faulty genes or by accelerating the progression of orthopedic diseases. Nutritional imbalance can cause skeletal disorders (see ch. 192).[18] The most common nutritional imbalance is nutritional secondary hyperparathyroidism (see ch. 171, 172, 174, 187, and 297). Dogs and cats that eat an all-meat diet ingest a low-calcium high-phosphorus diet (see ch. 192) that triggers an increase in parathyroid hormone. That increase promotes a loss of calcium from bones. Affected patients have a loss of bone stiffness that leads to increased bone elasticity (*rubber jaw* syndrome; see ch. 324) or fractures. Bone healing is not negatively impacted. Other nutritional disorders affecting bones and joints include hypervitaminosis A and osteopetrosis (excessive bone density).[19-21] Nutrition has a direct impact on bone growth.[22] Growth rates for bone mineral content, fat, and

lean tissue are influenced by nutrition.[23] The calcium and phosphorus concentrations in the diet of young puppies are reflected in their bones until 5 to 6 months of age.[23] Excess energy (see ch. 171 and 187) in the diet and excess calcium intake negatively impact bone growth (by accelerating it) and appear to promote the expression of genes linked to developmental orthopedic diseases.[22,24]

Infections can affect joints and bones.[25] Tick-borne diseases, particularly Lyme disease (*Borrelia burgdorferi*; see ch. 211), can lead to fibrinopurulent arthritis after several months of incubation.[26] Ehrlichiosis (see ch. 218) can also lead to polyarthritis[27] (see ch. 203). In neonates, omphalophlebitis can lead to bacterial embolization of growth plates (septic physitis), joints (septic arthritis), or bones (osteomyelitis). Septic physitis leads to impaired physeal growth and often results in a severe bone deformity because the physeal problem occurs very early in life. Septic arthritis, if left undiagnosed or untreated, will lead to cartilage damage and osteoarthritis. *Escherichia coli* bacteremia has been found in association with hypertrophic osteodystrophy.[28] In humans, arthritis can result from inflammation associated with bacterial infection, a syndrome described as spondyloarthritis that includes reactive arthritis, psoriatic arthritis, and ankylosing spondylitis (see ch. 15 and 203).[29]

Skeletal fungal infections are uncommon and are generally secondary: Histoplasmosis (see ch. 233) generally involves a primary intestinal lesion, aspergillosis (see ch. 234 and 235) generally involves a sinonasal lesion, and blastomycosis (see ch. 233) and coccidioidomycosis (see ch. 232) generally involve a primary pulmonary lesion.[30-32] Bone or joint lesions associated with fungal disease are not uncommon. Focal inoculations of blastomycosis and coccidioidomycosis have been reported.[33] Paecilomycosis (see ch. 336) of the distal radial epiphysis was reported in one dog.[34] Viral osteomyelitis in dogs has been described.[35] Distemper virus (see ch. 228) has been implicated in the pathogenesis of several proliferative bone diseases: hypertrophic osteodystrophy and panosteitis in dogs and Paget's disease, a proliferative bone disease of the skull, in humans.[36-38] Several parasites can lead to orthopedic problems. Leishmaniasis (see ch. 221) has been associated with polyarthritis.[39-41] Arthritis in dogs with leishmaniasis may be linked to the presence of a *Bartonella* infection (see ch. 215).[42] *Dirofilaria immitis* larvae have been found in joint fluid (see ch. 255).[43,44] In regions with an increased prevalence of *Toxocara canis*, seroprevalence has been associated with rheumatoid arthritis in dogs.[45]

Even if the relevant scientific literature is scant,[46] several orthopedic problems are seemingly linked to metabolic disorders: hyperadrenocorticism (see ch. 306), hypothyroidism (see ch. 299), diabetes (see ch. 304 and 305), and high estrogen and progesterone concentration (in female dogs during the whelping period; see ch. 315). Orthopedic problems in dogs with metabolic diseases include rupture of the cranial cruciate ligament, rupture of the common calcanean tendon, rupture of the palmar fibrocartilage and secondary carpal hyperextension, rupture of the plantar fascia, rupture of the tendon of insertion of the triceps brachii muscle. They appear to result from the loss of collagen strength associated with *negative nitrogen balance.* Growth hormone excess (acromegaly; see ch. 294 and 295) or deficit (proportional dwarfism; see ch. 294 and 295) has consequences on bone development.

Developmental orthopedic diseases are multifactorial diseases that are reportedly influenced by genetics, nutrition, growth, and the mechanical environment of joints. The genetic basis of developmental orthopedic diseases is often suspected, based on breed predisposition. The risk for 10 common developmental orthopedic diseases was evaluated in one study.[47] The most common developmental orthopedic diseases are hip dysplasia, elbow dysplasia, patellar luxation, and osteochondritis dissecans. Less common developmental orthopedic diseases include panosteitis, hypertrophic osteodystrophy, craniomandibular osteopathy, Legg-Perthes disease, and incomplete ossification of the humeral condyle.

Canine hip dysplasia is a ubiquitous disease affecting most if not all dog breeds. It is reportedly the most common canine developmental orthopedic disease and patients with hip dysplasia represented 10% of orthopedic patients in one large survey of dogs treated in veterinary teaching hospitals.[48] In two scientific reports, hip dysplasia was present in more than 40% of Golden Retrievers, Labrador Retrievers, and Rottweilers.[49,50] Hip dysplasia is an inherited developmental condition involving joint laxity and a lack of fit between the femoral head and acetabulum leading to osteoarthritis.[51] When present, hip dysplasia is most often bilateral. Accelerated growth resulting from high caloric intake increases the severity of hip dysplasia (see ch. 187).[52] Cats have hip dysplasia but little is known about the disease in this species. In one study involving 78 cats, there was a weak association between hip dysplasia and patellar luxation: Cats were three times more likely to have hip dysplasia and patellar luxation than to have either disease alone.[53]

Elbow dysplasia is common in dogs. According to statistics provided by the Orthopedic Foundation for Animals for the 50 most affected breeds, elbow dysplasia has been present in 16% of the 180,000 dogs that have been tested. There is a clear lack of awareness among veterinarians, breeders, and owners with regard to elbow dysplasia. It is by far the most common source of pain in growing dogs with a forelimb lameness and the most common source of osteoarthritis affecting the elbow joint. Several pathophysiologic processes have been proposed to explain elbow dysplasia. Most agree that the disease is mechanical in origin and is a consequence of abnormal growth of the radius relative to the ulna or the humeral condyle whilst some think there is humero-ulnar curvature mismatch between the humeral condyle and the ulnar trochlear notch. Impaired longitudinal growth of the radius relative to the ulna can create a transient or permanent humero-radial subluxation that leads to cartilage damage in the elbow within weeks.[54] Similarly, chondrodystrophic dogs often have early elbow osteoarthritis as a result of their impaired antebrachial growth. One key reason for the lack of the early diagnosis of elbow dysplasia in the young dog and of elbow subluxation secondary to dwarfism is that they are difficult to visualize on radiographs. Many patients with elbow dysplasia do not have a problem that can be predictably seen on radiographs of the elbow joint. While ununited anconeal process and osteochondritis dissecans of the humeral condyle can predictably be seen on radiographs, they only affect a minority of patients with elbow dysplasia.[55] However, mild joint incongruity (distal humero-ulnar subluxation or distal humero-radial subluxation) or the presence of an abnormal medial coronoid process are present in a large majority of cases with elbow dysplasia. These cannot be readily seen on radiographs.[56] Advanced imaging (computed tomography, magnetic resonance imaging) and arthroscopy (see ch. 94) greatly increase the detection of these problems but these methods have limited availability and are costly, compared to radiographs.

Patellar luxation is one of the most common orthopedic problems in dogs, reportedly being the cause of 6% of orthopedic referrals.[48] Patellar luxation may be the most common orthopedic problem in small dogs.[48] Patellar luxations are defined as complete dislodgement of the patella medial or lateral to the trochlear groove. Luxations are categorized as grade 1 luxations when they can be manually elicited through digital pressure and are reduced as soon as pressure is released, grade 2 luxations when they are elicited through digital pressure but are not reduced when the pressure is released, grade 3 luxations when they are luxated most of the time but can be reduced through digital pressure, and grade 4 luxations when they are always luxated (and therefore cannot be reduced through digital pressure). Medial luxation is more common than lateral luxation. Some dogs may have medial and lateral luxations, most likely as a result of soft tissue laxity (e.g., Basset Hounds). Traumatic patellar luxations can occur but are rare. In most instances, patellar luxations are a secondary sign of a primary orthopedic problem. In general terms, the *mechanical* axis of the pelvic limb (a virtual line joining the center of the femoral head to the metatarsal pad) is abnormal. The center of the stifle joint may be axially (medially) or abaxially (laterally) displaced compared to the mechanical axis of the limb. In more specific terms, patellar luxations are generally the consequence of an array of geometric problems affecting the femur and tibia, including having abnormal angulation or torsion of the proximal or distal portion of the femur, abnormal tibial angulation or torsion, an abnormally high (generally described as *patella alta*) or low patella *(patella baja),* and abnormal torsional laxity of the stifle joint (Figure 353-1). These abnormalities often coexist. They may be present in dogs with conformation disorders that include bow-legged and knock-kneed stances.

FIGURE 353-1 This three-dimensional reconstruction is based on a computed tomography scan of the pelvic limbs of a dog with medial patellar luxation of the left stifle joint. Angulation and torsion of the femur and tibia, the shape of the trochlea and femoral condyle, and the position of the patella are assessed for both pelvic limbs by manipulating the rendering.

If a patellar luxation occurs early in life while bones and joints are developing, additional abnormalities are likely to develop, including a shallow or absent trochlear groove, and a medially displaced tibial crest. Often, a pattern that includes varus and internal rotation of the distal portion of the femur is the root cause of medial patellar luxation. Sometimes, an underdeveloped lateral femoral condyle and resulting valgus orientation of the tibia is the root cause of lateral patellar luxation.[57,58] In patients with patellae that are severely displaced medially and caudally, a lack of stifle joint extension may result from the fact that the quadriceps femoris ceases to function as extensor muscle of the stifle when the tension generated by muscle contractions is directed along a line that is no longer cranial to the femur (Figure 353-2). Over time, as the femur grows, the caudomedially-displaced quadriceps lacks length and acts as tether, limiting stifle extension. Stifle extension is painful in these dogs, complicating the implementation of manual or exercise-based stretching programs (see ch. 355). Femoral shape, tibial shape, torsional laxity, and stifle extension must be evaluated when assessing dogs with a patellar luxation. The initial evaluation is done when the dog is standing and walking slowly. The clinician should assess limb conformation by asking: Are the pelvic limbs straight, bow-legged, or knock-kneed? Are the paws pointing forward or are they internally or externally rotated? Are stifle joints appropriately held or are they excessively flexed or extended? Limbs are also evaluated with the dog lying in lateral recumbency. The luxation is graded from 1 to 4 and the proximodistal position of the patella is

recorded (high [alta], normal, or low [baja] patella). The presence of angulation (varus or valgus) and limb torsion (internal or external) is assessed with the hip relaxed (not extended nor flexed) and the stifle held in extension. Bone shape is confirmed by making orthogonal radiographs of the femur and tibia. If the dog is sufficiently small, a single craniocaudal radiograph that includes the femur, tibia, and pes is made and used to assess the mechanical axis of the limb. In large dogs, this can be accomplished by making two craniocaudal horizontal beam radiographs of the proximal and distal portions of the limb, respectively, that are made by translating the x-ray source without changing the limb position. Three-dimensional reconstructions based on a computed tomographic scan of the limb allow for more rapid and accurate assessment of bone shape than radiographs (see Figure 353-1). Rotational laxity of the stifle joint is assessed with the joint held at a neutral (≈90-degree) angle. Normal tibio-femoral rotation is approximately 20 degrees. Some patients have 60 to 90 degrees of tibio-femoral rotation, potentially as a result of the torque placed on the tibia by the quadriceps femoris. Palpation of the stifle joint should also observe for joint effusion, crepitus, cranial drawer, and pain response to palpation. Joint effusion, palpable immediately caudal to the patellar ligament on the medial aspect of the stifle, is unusual in dogs with patellar luxation. The presence of effusion should make clinicians suspect the presence of a problem beyond patellar luxation, most commonly a rupture of the cranial cruciate ligament. With a traumatic patellar luxation, stifle joint effusion could result from a tear of the medial or lateral parapatellar fibrocartilage. Crepitus is unusual in dogs with a patellar luxation. Most often, crepitus may result from full-thickness cartilage damage to the patella and the ridge of the trochlea where the patella is luxating. Cranial drawer may be present if a dog has concurrent patellar luxation and cranial cruciate ligament injury. The presence of a patellar luxation seemingly predisposes dogs to cranial cruciate ligament injuries, potentially because of the change in forces sustained by the ligament due to the displacement of quadriceps femoris muscle or due to the displacement of the tibia in relation to the femur. Overall, pain response to palpation of the stifle or to reduction of a luxated patella in dogs with patellar luxation is unusual. However, when pain is present, it can be very pronounced. Pain response to palpation is most often present in dogs with a lack of stifle joint extension (because of tightness in the quadriceps, as described above), in dogs with cruciate ligament rupture (because of the severe joint inflammation resulting from the cruciate ligament rupture), in dogs with *tight* patellae that require significant effort to reduce their patellae, in dogs with patella alta that have bone resorption at the proximal aspect of the trochlea, and in dogs with osteoarthritis.

FIGURE 353-2 This 11-month-old miniature Poodle stands with flexed stifle joints. The dog has grade 4 medial patellar luxation in both hindlimbs. Approximately 60 degrees of extension in both stifle joints is lost because internal rotation of the tibia is so severe that the quadriceps femoris no longer functions as an extensor muscle of the stifle joint.

Osteochondrosis is an abnormal development of the articular surface with delayed focal ossification of the subchondral bone, potentially leading to the formation of a flap of articular cartilage, a problem named **osteochondritis dissecans** (OCD). In dogs, OCD affects the caudal aspect of the humeral head, the medial aspect of the humeral condyle, the distal aspect of the medial and lateral femoral condyles, and the proximal aspect of the medial and lateral ridges of the trochlea of the talus. The pathogenesis of osteochondrosis has two competing theories (mechanical and vascular), both plausible. The mechanical OCD theory is based on the fact that subchondral bone of rapidly growing dogs is coarse and mechanically weak, predisposing to fracture in areas resisting high loads.[22] The vascular OCD theory is based on the loss of blood supply to the epiphysis as a result of cartilage canal vessel degeneration.[59] From a population genetic perspective, OCD of the humeral condyle and fragmentation of the medial process appear to be distinct genetic disases.[4] OCD of the humeral condyle, femoral condyles, and talar trochlea is highly inflammatory to affected joints (with severe, palpable joint effusion) and often triggers the rapid development of osteoarthritic changes. Conversely, OCD of the humeral head appears unlikely to trigger rapid osteoarthritic changes in the shoulder joint.

Several inflammatory bone diseases affect growing dogs. They may affect the shaft of long bones (panosteitis), the metaphyseal regions of long bones (hypertrophic osteodystrophy) or the skull (craniomandibular osteopathy). Panosteitis affects long bones (radius, ulna, humerus, femur) most often in large-breed dogs. It generally affects a single site but can affect several sites in succession, leading to the name of *shifting leg lameness.* The radiographic appearance of panosteitis varies with each phase. Acutely, there is a loss of trabecular pattern in the affected area (the bone looks blurry). After a few weeks, the affected area becomes radiopaque, potentially because new bone is apposed during remodeling of dead trabecular bone. In severe situations, a focal, smooth periosteal reaction centered on the lesion may be visible. The cause of **panosteitis** is not known; some have suggested an infectious cause. Viral genome from canine distemper virus has been linked with bone lesions resembling panosteitis, similar to hypertrophic osteodystrophy (described below).[38,60] Panosteitis is self-limiting; lesions subside after a few weeks.

Hypertrophic osteodystrophy is an inflammatory bone disease that affects the metaphyseal regions of long bones. It is also named metaphyseal osteopathy. The cause of hypertrophic osteodystrophy is not known; (distemper) viral RNA has been identified in osteoblasts of the metaphyseal region of long bones in affected dogs and metaphyseal lesions have been identified in distemper-infected dogs.[37,38] Modified live vaccination has been reported to be a trigger for hypertrophic osteodystrophy.[61] *E. coli* bacteremia has been reported in a pup with hypertrophic osteodystrophy.[28] It is unclear whether bacteremia preceded or followed hypertrophic osteodystrophy. Rapid growth caused by increased food intake has been suggested to increase the likelihood of hypertrophic osteodystrophy.[62,63] In mild cases of hypertrophic osteodystrophy, lesions are generally limited to the distal portion of the radius, ulna, and tibia. In severe cases, lesions often can affect the proximal and distal metaphyses of all long bones. Severe hypertrophic osteodystrophy triggers a thick periosteal reaction around the metaphyseal region of the distal portion of the radius and ulna. That periosteal reaction is often associated with a severe caudal angulation (cranial bowing) of the radius.[64] Hypertrophic osteodystrophy is a self-limiting disease that subsides in the majority of patients (85%, in one study)[65] by the time of physeal closure. However, angulation resulting from severe forms of hypertrophic osteodystrophy persists. Hypertrophic osteodystrophy has been reported in cats.[66]

Retained cartilaginous cores are radiographically visible lesions affecting the metaphyseal regions of long bones, particularly the distal ulna.[67] These cores have been reported in combination with hypertrophic osteodystrophy.[68] While retained cartilaginous cores (in the ulna, and to a lesser extent, in the radius) are often associated with impaired longitudinal growth and the formation of bilateral multiapical valgus and caudal angular deformity of the radius, causation is unclear. In other words, the retained cartilaginous cores and the angular deformities could both be consequences of the same growth disturbance rather than growth disturbance being the consequence of retained cartilaginous cores. Large-breed pups sometimes present with bilateral valgus deformities of the radius and yet they may have a retained cartilaginous core visible in a single limb, suggesting that the retained cartilaginous core is a consequence of the impaired longitudinal growth rather than its cause.

Craniomandibular osteopathy is a proliferative bone disease affecting the mandible and maxilla in skeletally immature dogs.[69,70] The disease is most often associated with West Highland White Terriers but it has been reported in other breeds, including Boxers, Great Danes, and Doberman Pinschers. Craniomandibular osteopathy is also self-limiting.

Legg-Perthes disease is a degenerative disease of the femoral head and neck that occurs in growing small-breed dogs. The disease is often unilateral but may affect both hips. Little is known about the pathophysiology of Legg-Perthes disease. Femoral head remodeling and collapse is thought to be the result of collapse of the vessels supplying the femoral head.[71] Fractures across the proximal femoral physis (also named capital physis fractures, slipped capital physes, femoral head fractures, or epiphysiolysis) occurring in the absence of known trauma have been reported in dogs and cats.[72,73] In two cats, these proximal femoral physeal fractures were the result of multicentric epiphyseal dysplasia.[74] Osteonecrosis of the radial carpal bone similar to Legg-Perthes was reported in one dog.[75]

Incomplete ossification occurs in dog bones, often in subchondral regions of small bones (near to articular surfaces). Incomplete ossification may be due to abnormal forces placed on growing bones as a result of chondrodystrophy or other growth impairment (Figure 353-3).[76-78] Breed predisposition has been reported with some forms of incomplete ossification, suggesting the presence of genetic triggers. For example, ununited anconeal process occurs in German Shepherd Dogs, incomplete ossification of the humeral condyle occurs in spaniel breeds, and incomplete ossification of the radial carpal bone occurs in Boxer dogs.[76,79-81] The articular surface overlying the incompletely ossified bone may be discontinuous, allowing fluid exchange between joint and subchondral bone. Incomplete ossification leads to osteoarthritis potentially because of a step in the articular surface, joint instability, or fluid exchange between joint and subchondral bone.[76] Also, incomplete ossification can act a stress riser, triggering the catastrophic mechanical failure of a long bone, as has been reported in the humeral condyle.[76] In addition to incomplete ossification of the anconeal process, humeral condyle, and radial carpal bone, incomplete ossification of the caudal aspect of the glenoid and the atlas have been reported.[82,83] Delayed ossification of the proximal aspect of the tibia has been reported in Greyhounds and other large-breed dogs.[84,85]

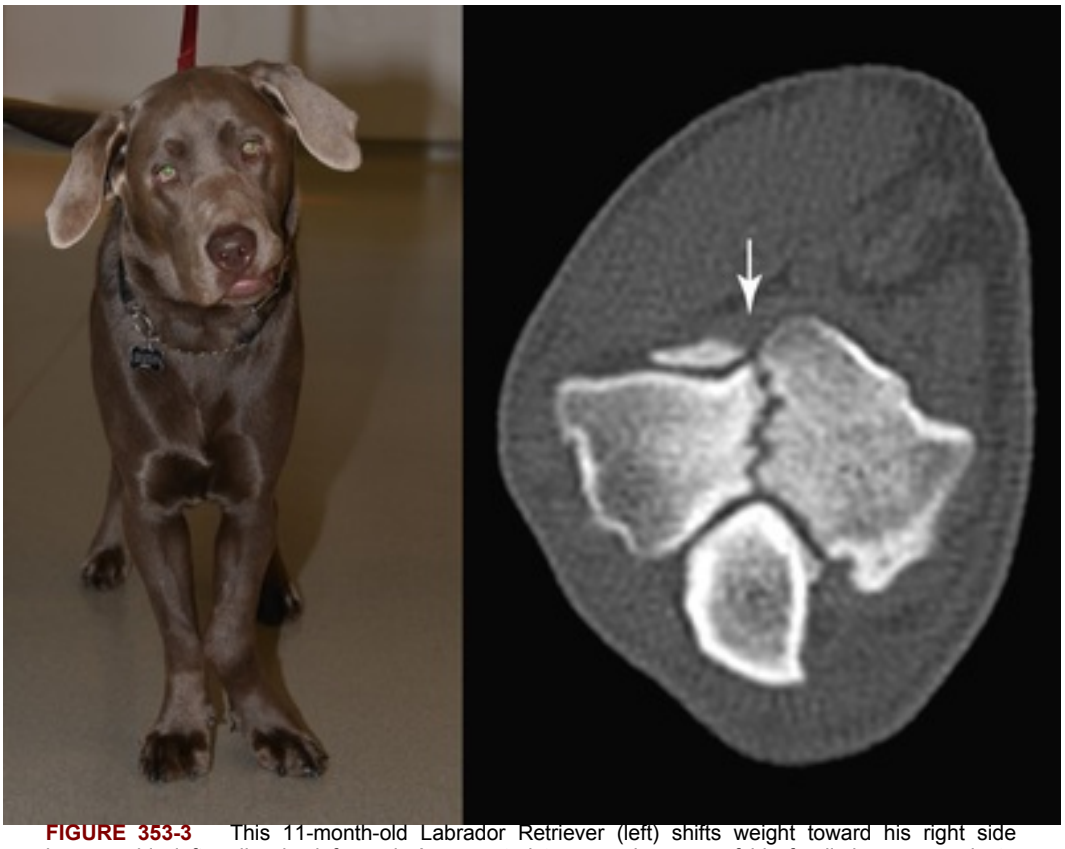

FIGURE 353-3 This 11-month-old Labrador Retriever (left) shifts weight toward his right side because his left radius is deformed. A computed tomography scan of his forelimbs was made to assess the geometry of his deformity. The dog had incomplete ossification of the left and right humeral condyles. The non-ossified region within the right condyle was complete (arrow) and the non-ossified region within the left condyle was partial. The condyles were stabilized with the placement of transcondylar bone screws.

Bone disorders also include **bone cysts.** Large cysts in bones are rare. Cysts can predispose to fracture.[86,87] Cysts can form as a result of arterio-venous fistulae (see ch. 250 and 257).[88] Small subchondral bone cysts are common as a consequence of chronic osteoarthritis.[89] A subchondral cyst of the ulnar notch has been reported in one dog.[90]

Hypertrophic osteoarthropathy, named Marie's disease in humans, is a proliferative bone disease where a slightly irregular diffuse periosteal proliferation occurs in the distal portions of limbs. The disease is caused by the presence of a mass or mass-effect in the chest or abdomen, most commonly lung tumors.[91] Hypertrophic osteoarthropathy also has been reported in dogs and cats as a consequence of pneumonia, bronchitis, megaesophagus, endocarditis, intra-abdominal (renal, liver, bladder) tumors, and spirocercosis.[92-95] Hypertrophic osteoarthropathy has been associated with pregnancy in the horse[96] and in humans. The periosteal proliferation is considered to be most likely the consequence of increased blood flow resulting from a paraphysiologic afferent vagal reflex, but other theories have been proposed.[94,97]

Cranial cruciate ligament (CCL) injuries are among the most common orthopedic problems in dogs. In one large survey, CCL injuries represented 8% of patients.[48] While a minority of CCL injuries results from direct trauma, most CCL injuries result from skeletal disorders. Often, CCL injuries are diagnosed when a veterinarian evaluates a chronic weight-bearing lameness of a pelvic limb in a middle-aged large-breed dog without history of trauma. In one study involving more than 1.2 million dogs treated during a 40-year period, nine breeds were at increased risk of CCL injuries; the breeds at highest risk were the Newfoundland and the Rottweiler.[98] Scientific consensus regarding the chain of events leading to CCL injuries is lacking. CCL injuries are clearly multifactorial. Patellar luxation is a predisposing factor for CCL injury.[99] Some favor a mechanical chain of events as trigger for CCL disease that may include the tibial plateau slope, femoral anteversion angle, width of the trochlear notch, and extensor moment at the hock joint.[100,101] Others favor a biologic chain of events that includes immune-mediated disease, fibrocartilaginous metaplasia, and matrix

degradation as triggers of CCL injury.[102,103] Bacterial DNA has been identified in stifle joints with osteoarthritis.[104] Obesity (see ch. 176) predisposes dogs to CCL injury.[105] Castration and ovariohysterectomy are associated with an increased risk of CCL injury,[106,107] but a causal relationship has not been demonstrated. Rupture of the opposite CCL is common after CCL injury. Median survival of the opposite ligament has been reported to be 947 days.[108] Meniscal injuries are common consequences of CCL injuries, particularly when the CCL is completely ruptured, when dogs are large, and when treatment is delayed.[109,110]

Neoplasia affects bones and joints. The most common tumor affecting bone is osteosarcoma (see ch. 348). Other tumors affect bones and joints, including chondrosarcoma, fibrosarcoma, and malignant melanoma. Multiple cartilaginous exostoses have been reported in dogs[111] and have been found in littermates and across generations.[112,113] In addition to osteosarcoma, melanoma, and hemangiopericytoma, several tumor types specifically affect the digits in dogs, including squamous cell carcinoma in dark-haired dogs, metastatic lung carcinoma, and papilloma.[114-118] Long bone tumors have been reported in association with multifocal bone medullary infarction, such as in Schnauzers with hyperlipidemia, and in association with focal medullary infarction secondary to total hip replacement.[119-121]

Orthopedic disorders include pathologic fractures, fractures that occur in bones weakened by preexisting disease. The most common pathologic fractures are fatigue fractures, also known as stress fractures, defined as fractures induced by normal forces applied to abnormal bone, by comparison with conventional fractures, that are induced by abnormal forces placed on normal bone.[122] Fatigue fractures have only been reported in racing Greyhounds, who can fracture their central tarsal bone, metacarpal and metatarsal bones, and acetabulum.[122-125] Pathologic fractures also occur as a result of bone loss secondary to periodontal disease,[126] osteosarcoma,[127,128] or bone cysts.[86,87] Pathologic fractures also occur in dogs and cats with osteogenesis imperfecta (see ch. 187).[129,130]

General Consequences of Skeletal Disorders

Pain

The clinical signs of orthopedic disorders most often result from **pain** arising from joints, bones, or other musculoskeletal tissues (see ch. 126). Subjectively, joint pain and bone pain have a more severe clinical impact than pain arising from ligaments, muscles, or tendons. Limb use does not appear to be particularly compromised in dogs that have muscle tears. For example, a racing Greyhound that tears its gracilis muscle would be expected to slow down by a few lengths during a race, a slowdown of approximately 3% (1 second over a 35-second race). Similarly, tendonitis is rarely diagnosed as a source of lameness in dogs (presumably because tendonitis does not induce lameness) but when a tendon courses through a joint, gets inflamed, and causes synovitis in the joint that it crosses, clinical signs can be very severe. For example, when the tendon of origin of the biceps brachii muscle becomes inflamed, a tendon that travels through the shoulder joint, clinical signs are often very severe.[131]

The dominant cause of joint pain in dogs is osteoarthritis. Joint pain can also result from immune-mediated joint disease, septic arthritis, joint tumors (synovial cell sarcoma), incomplete ossification, the presence of osteochondral flaps or fragments, or from other causes. Subjectively, one could estimate joint pain secondary to osteoarthritis to be the cause of 99% of joint-related pain because osteoarthritis is common in dogs and other causes of joint pain are rare. Joint disease can be acute or chronic. It can be inflammatory or degenerative. Acute joint pain is generally caused by synovitis. Lameness from synovitis is so predictable that urate crystal-induced synovitis is used as experimental model of transient lameness.[132-134] Synovitis can result from the presence of an osteochondral fragment in the joint (e.g., OCD flap, fragmented medial coronoid process), from full-thickness cartilage damage (hip dysplasia, elbow dysplasia), from fluid exchange between joint and subchondral bone (OCD flap, incomplete ossification), or from the presence of torn collagen fibers in the joint (CCL injury, biceps brachii tendon injury). Intra-articular bleeding induces synovitis[135] and damages cartilage, particularly immature cartilage.[136] Also, subchondral bone exposed to joint fluid becomes inflamed.[137] Acute, inflammatory disease results in pain but it is not associated with structural changes to the joint. In that situation, lameness is present but the range of motion is within normal limits. The pain response to acute inflammatory joint problems is managed like acute pain induced by injury or surgery (see ch. 126 and 166). If joint inflammation persists, over time joint disease becomes chronic: The joint capsule thickens and joint motion is decreased. Local pain amplification (peripheral primary

sensitization) and spinal (central) sensitization are likely. Loss of joint motion is unpredictable. It varies between joints and it varies with different joint motions. For example, with chronic hip dysplasia, Labrador Retrievers lose extension but they do not lose flexion.[138] Chronic joint disease is managed like chronic pain (see below).

Clinical signs can also be caused by bone pain. Overall, bone pain is much less common than joint pain in dogs. In the United States, one can estimate that millions of dogs are suffering from joint pain whereas thousands of dogs are suffering from bone pain.[48,98,139] The two most common causes of bone pain are iatrogenic: failure of fixation after an orthopedic procedure and osteomyelitis. Other causes of bone pain, in decreasing order of frequency, include juvenile inflammatory bone diseases (panosteitis, hypertrophic osteodystrophy, and craniomandibular osteopathy), neoplasia (osteosarcoma chondrosarcoma, metastatic carcinoma, and others), hypertrophic osteoarthropathy, and pathologic fractures. Failure of fixation is a source of bone pain because the first stage of fracture healing is inflammatory. That inflammatory stage persists and increases in intensity in fractures managed without surgery and after failure of fixation. Severe, chronic inflammation is the likely mechanism leading to pain associated with osteomyelitis.[140] Intramedullary edema has been implicated as a factor leading to pain in dogs with inflammatory bone diseases.[141] Excessive osteoclastic activity is a critical factor in the pain resulting from osteosarcoma.[142]

Abnormal Gait

Having an abnormal gait is a common consequence of orthopedic disorders because bones may be abnormally angled or short or because of joint instability resulting from focal or systemic connective tissue problems. Focal connective tissue problems include hyperextension of the carpus or tarsus. Carpal hyperextension is most often reported in large-breed growing dogs, particularly in German Shepherd Dogs (Figure 353-4), in dogs with metabolic disorders, particularly hyperadrenocorticism, and in dogs with immune-mediated joint disease (Figure 353-5; see ch. 203). Abnormal gait also results from the presence of lameness. Lameness can be defined as a voluntary alteration of gait to minimize the pain perceived during locomotion. Lameness varies in dogs based on the nature, severity, and chronicity of orthopedic problems, patient size and behavior (patient "personality"), and other factors.

FIGURE 353-4 This 4-month-old German Shepherd Dog has hypertension of his carpal joints. The

dog is palmigrade. Laxity between the calcaneus and fourth tarsal bone is also present.

FIGURE 353-5 This mixed-breed dog has carpal hyperextension because of a low-grade nonerosive polyarthritis. While carpi and tarsi are often affected in dogs with immune-mediated polyarthritis, carpal hyperextension is generally visible earlier and is more severe than tarsal hyperextension.

Clinical Signs

The consequences of skeletal disorders range widely, from no detectable lameness to non–weight-bearing lameness, where a limb is not used and is held in a flexed position. Owners, clinicians, and researchers use different parameters to judge the severity of orthopedic problems and the response to therapy. Owners generally look at whether their pets are "happy" (a fairly subjective outcome measure), whether they are able to perform their activities of daily living (walking in and out of the house, climbing steps and stairs in and around the house, getting in and out of a vehicle), whether they vocalize in response to pain, and whether they are playful. Owners routinely assess lameness, for example to evaluate disease progression or response to therapy. Little is known about the accuracy of owner assessment of lameness. Owners tend to underestimate the severity of lameness increases over time.[143] Clinicians judge the severity of orthopedic disorders based on the severity of lameness, usually through the use of simple qualitative scales such as mild, moderate, severe weight-bearing or non–weight-bearing lameness.[144-146] Clinicians sometimes attempt to document orthopedic problems more specifically than simple qualitative lameness scores, such as when they perform physical rehabilitation (see ch. 355).[147] Specific orthopedic assessments may include joint effusion, crepitus, the pain response to palpation, and joint motion assessed subjectively or measured objectively using a plastic goniometer (Figure 353-6).[148,149]

FIGURE 353-6 Extension of the hip joint is being measured with a plastic goniometer whose arms are aligned along a line joining the tuber sacrale to the tuber ischiaticum and a line joining the greater trochanter to the craniocaudal midpoint between the patella and lateral fabella, respectively. Normal hip extension in dogs is approximately 160 degrees. In this dog that had undergone a femoral head ostectomy, hip extension was 123 degrees.

Limb Disuse

Limb disuse is a common consequence of severe orthopedic disorders that are responsible for sustained chronic pain (Figure 353-7). With limb disuse, dogs are toe touching or non–weight-bearing (Figure 353-8) when standing and walking. Dogs with limb disuse shift weight away from their affected leg or legs. Dogs with disuse in a single limb shift weight side-to-side onto the opposite side (Figure 353-9 and Video 353-1). Dogs with disuse in two limbs shift weight away from these limbs: forward, if hind limbs are affected (Figure 353-10) or backward, if forelimbs are affected. By doing so, dogs modify the angles of their spine and limb joints (Figure 353-11). These changes in posture become deeply rooted over time and are hard to eliminate, even when the original orthopedic disorder is successfully managed. Physiologically, limb disuse leads to a loss of bone mass, a loss of muscle mass, a loss of cartilage thickness and stiffness, and a loss of ligament strength. Most of these changes are slowly reversible once the cause of limb disuse is treated.

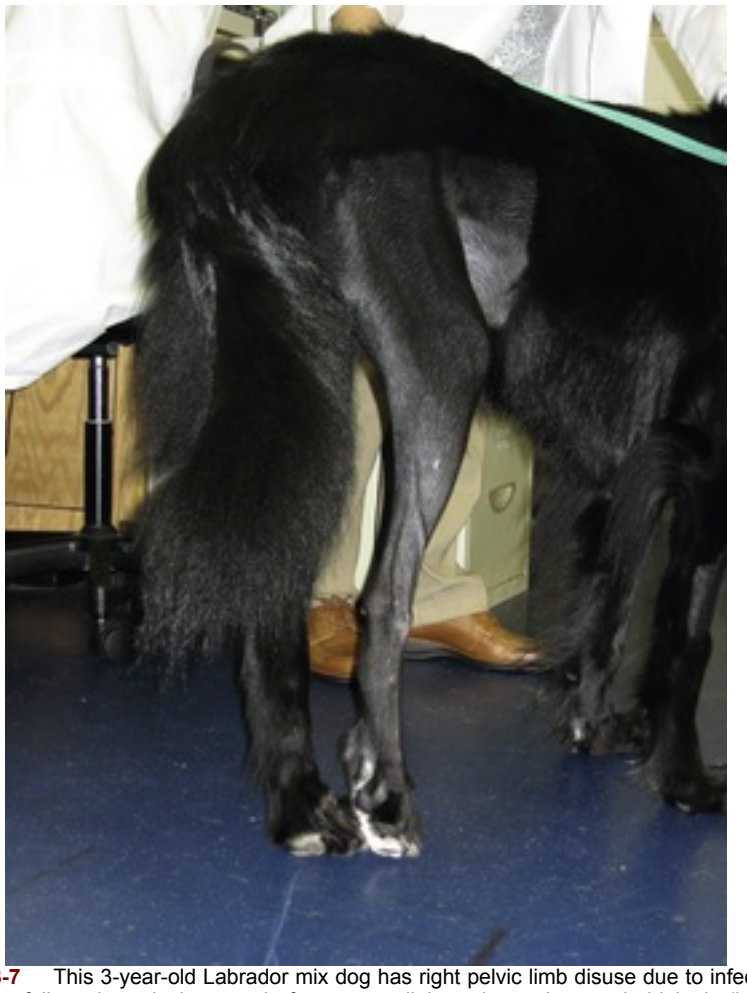

FIGURE 353-7 This 3-year-old Labrador mix dog has right pelvic limb disuse due to infection of the stifle joint that followed surgical removal of a torn medial meniscus. Iatrogenic biologic (infection) or mechanical problems (failure of fixation of a surgical repair) are common causes of limb disuse.

FIGURE 353-8 This 4-month-old Yorkshire Terrier is non–weight-bearing in his left pelvic limb because of a grade 4 medial patellar luxation. The tibia is internally rotated in relation to the femur. Patellar luxation is the most common cause of limb disuse in growing dogs.

FIGURE 353-9 An 11-month-old Siberian Husky is showing signs of disuse of his left pelvic limb. Disuse results from two surgeries—the first to manage a patellar luxation, the second to perform a femoral head ostectomy to manage hip dysplasia. A severe pain response to hip extension was identified during palpation. Hip extension was 123 degrees, a loss of approximately 40 degrees (see Figure 353-6).

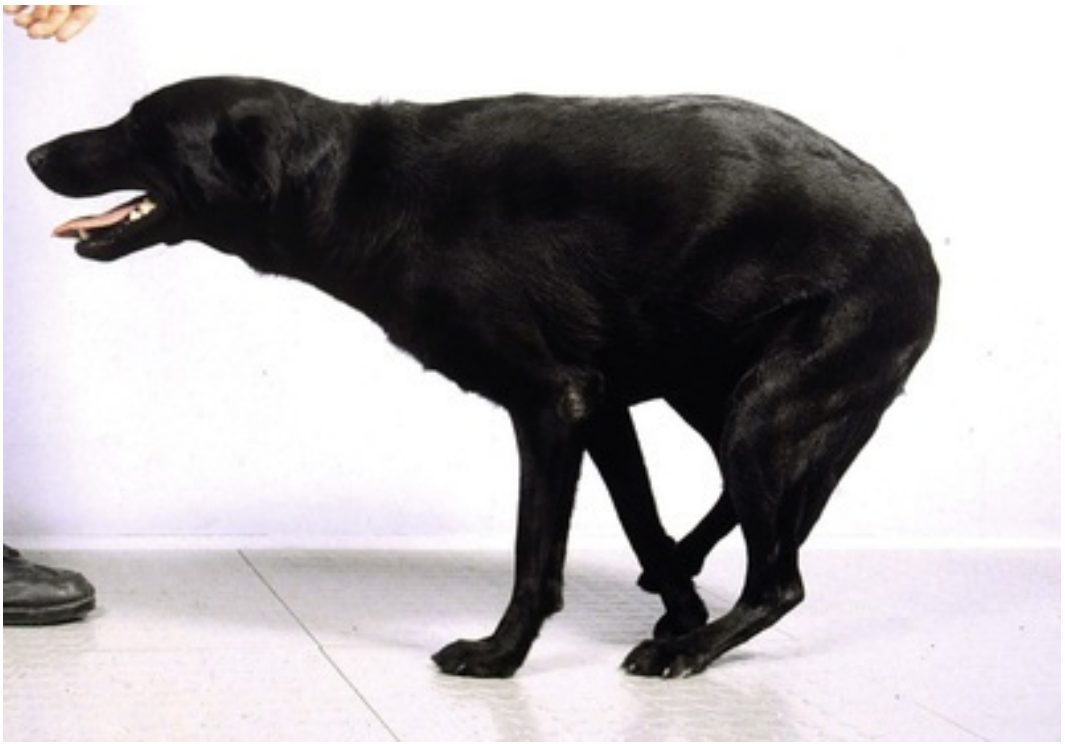

FIGURE 353-10 This Labrador Retriever has a partial tear of his cranial cruciate ligament in both stifle joints. While this dog shifts most of his weight toward his forelimbs, weight shifts are often more subtle.

FIGURE 353-11 This 11-month-old male St. Bernard shifts weight forward and has hyperextended talocrural joints. Tarsal hyperextension resulting from a weight shift is most often seen in young dogs of large and giant breeds that shift weight forward because of hip pain caused by hip subluxation. These

dogs are reluctant to extend their hip joint when they stand and walk and, instead, stretch their talocrural joints toward hyperextension.

The radiographic appearance or progression of osteoarthritis is often used as outcome measure of the progression of orthopedic problems. However, information on the relationship between functional impairment, pain, and radiographic changes is lacking. That relationship was assessed in cats with osteoarthritis, and the findings from joint palpation and radiographic changes correlated poorly.[150,151] In the dog stifle, the progression of osteoarthritis after surgery to manage CCL injury[152-155] and surgical stabilization of patellar luxation[156] have been reported. In the dog elbow joint, the progression of osteoarthritis after surgery to remove fragmented medial coronoid processes[157,158] and as result of being overweight[159] have been reported. In the dog hip joint, the progression of osteoarthritis as a result of being overweight (see ch. 176) has been reported.[50,159] In an unrelated study, the severity of osteoarthritis in Labrador Retrievers with hip dysplasia did not appear to be associated with the severity of lameness.[138] Advanced imaging, including computed tomography, magnetic resonance imaging, or bone scintigraphy, is sometimes used as assessment tool. Computed tomography is widely used to assess the elbow joint, and its findings correlate with findings of arthroscopy.[160] Researchers also judge the severity of orthopedic disorders based on objective kinetic measures (force plate or pressure-sensitive walkway measurements), on objective kinematic measures (2-D or 3-D kinematic analysis), on serum biomarkers, or on histology.

The clinical signs in dogs and cats with specific orthopedic disorders are rarely described with precision and are rarely investigated. Logically, most of the information available in the literature relates to the most common orthopedic disorders: hip dysplasia, elbow dysplasia, and CCL injuries. The clinical signs of hip dysplasia are most often described as acute in skeletally immature or young adult dogs and chronic in older dogs. Acute clinical signs reflect acute pain: a generally severe and often unilateral lameness. Acute signs generally appear during rapid skeletal growth, between 4 and 8 months of age. Affected dogs may show a reluctance to perform propulsive activities, including jumping, climbing steps or stairs, galloping, walking for extended periods of time, or may exhibit behavioral changes including reluctance to play, introversion, or exhibiting aggressive behavior. The chronic clinical signs of hip dysplasia reflect chronic pain and, as a consequence, loss of strength. These signs include exercise intolerance, a reluctance to jump up and climb steps or stairs, and a bunny-hopping gait anomaly at a gallop. Surprisingly, little has been written about the physiologic changes present in dogs with chronic hip dysplasia.[138,161-164] Dogs with hip dysplasia have pain arising from their femoral and acetabular joint surfaces and hip joint capsule, particularly when moving at higher speed and during extension of the hip joints. Over time, dysplastic dogs may lose hip extension but do not appear to lose hip flexion. In a study evaluating a cohort of 60 Labrador Retrievers with hip dysplasia, a statistical model indicated a loss of 1 degree of hip extension per year.[138] Dysplastic hip joints may lose extension because of joint capsule fibrosis or the development of large osteophytes or enthesiophytes on the caudal and ventral aspects of the acetabulum and on the femoral neck and caudal aspect of the greater trochanter, or because of changes in periarticular tissues or regional muscles. Pain response during hip joint flexion, subjectively, is very unusual and may be the consequence of other problems such as a septic arthritis, a bone tumor, or another problem. Most dysplastic dogs lose muscle mass in their pelvic limbs. Some may displace their center of gravity forward by flexing their spine, shoulder, and elbow joints. The clinical signs of hip dysplasia vary widely among affected dogs. Many dogs have very discrete signs that may appear after long periods of exercise or after strenuous exercise[138]; others are severely disabled and may be unable to trot, gallop, or jump. Little is known about the relationship of specific aspects of hip joint disease (dorsal subluxation, dorsal luxation, cartilage wear, dorsal rim wear, joint capsule thickening, osteophytes production, the presence of joint mice) and the type and severity of clinical signs. For the Labrador Retriever cohort mentioned above, 94% of the dogs had no lameness or had a lameness that was deemed mild or moderate and 6% had a severe lameness.[138] Two factors increased the severity of lameness: the presence of hip luxation (compared to hip subluxation and to no luxation nor subluxation) and exercising <20 minutes per day (compared to exercising >60 minutes per day). In that study, the size and location of osteophytes did not correlate well with the clinical signs of hip dysplasia.

Clinical signs appear to be linked to dog size but scientific data confirming the association of size and lameness or assessing factors influencing clinical signs (demeanor, training, human animal bond, etc.) are lacking.

Subjectively, clinicians often state that large dogs may be less likely to be non–weight-bearing or to present with severe limb disuse compared to smaller dogs. This trend seemingly applies to all skeletal problems.

Larger dogs may be less likely to have a toe-touching or a non–weight-bearing lameness than smaller dogs, possibly because it is harder for large dogs than small dogs to stand or ambulate on three limbs.

Hip dysplasia is also common in cats.[150,165] However, little is known about the clinical signs of hip dysplasia in cats. The low correlation between radiographic signs of osteoarthritis, cartilage damage, and abnormal findings during an orthopedic examination complicates the detection of joint disease in cats.[151]

The clinical signs of elbow dysplasia have been described[79] but the relationship of features of elbow dysplasia and clinical signs has only been reported in one study that involved 55 Rottweiler pups.[166] These clinical signs may include a forelimb lameness that can be intermittent or constant, joint effusion, loss of range of motion in flexion and (to a lesser extent) extension, and abnormal posture when resting in a sternal position (flexion of the carpus and supination of the antebrachium; Figure 353-12).[77]

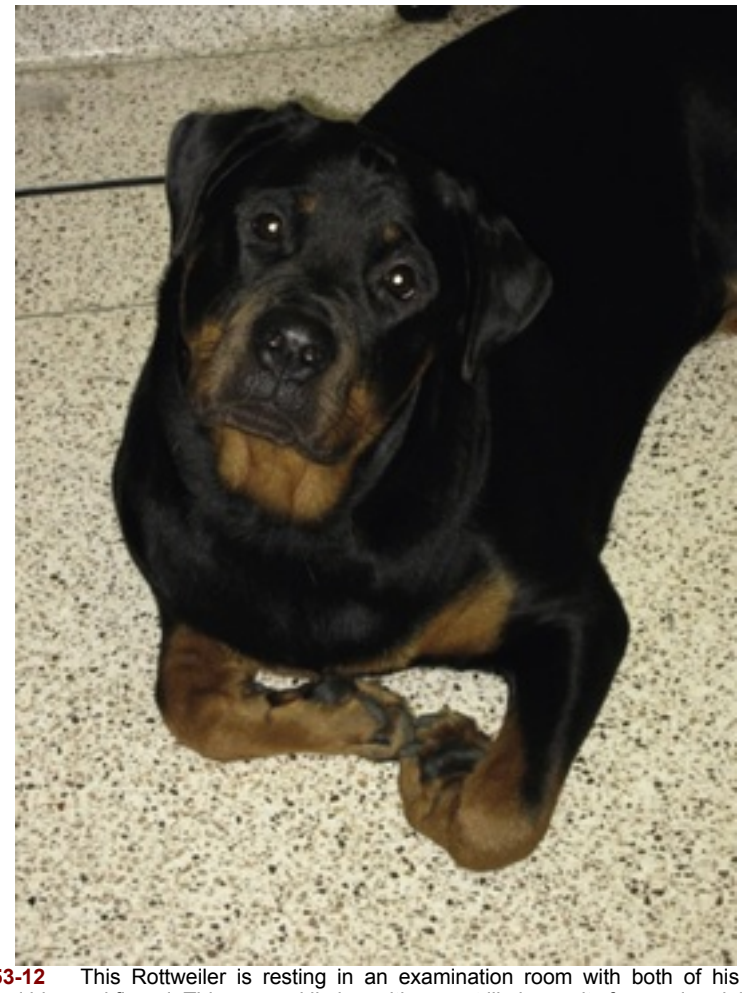

FIGURE 353-12 This Rottweiler is resting in an examination room with both of his antebrachia supinated and his carpi flexed. This unusual limb position most likely results from pain originating in the elbow joints. Pain response to manipulation of his elbow joints was detected during palpation. The dog has bilateral elbow dysplasia.

The clinical signs of CCL injuries have been reported,[167] but the relationship of features of CCL injuries and lameness has not been evaluated. Palpation of the patellar ligament appears to be the most sensitive sign for the detection of CCL injury.[167] The presence of a meniscal click is a strongly suggestive of the presence of a meniscal tear in dogs with CCL injury.[109,168] The clinical consequences of patellar luxation vary widely from no clinical sign to the lack of ability to ambulate. Little is known about factors influencing these clinical signs. Subjectively, dogs with *loose* patellae tolerate patellar luxation well. Dogs with *tight* patellae show signs of lameness. Lameness is also present in dogs with patella alta (these may show signs of bone resorption proximal to the femoral trochlea) and in dogs with loss of stifle joint extension as a result of severe displacement of the patella.

Patient Assessment

The assessment of orthopedic disorders includes the collection of a medical history, the observation of the patient, limb palpation, and imaging.

Medical History

Most owners are knowledgeable regarding the onset and impact of orthopedic disorders on their pet's activities of daily living but these thoughts are rarely organized. The goal of history is to accurately discuss and record information that will identify orthopedic disorders and gauge their severity and progression (see ch. 1). The medical history also aims to detect the presence of clinical signs affecting other organ systems, particularly neurologic signs because manifestations of orthopedic and neurologic problems resemble each other. The medical history is also used to discriminate between orthopedic injuries from non-traumatic orthopedic disorders and to assess the chronicity and the progression of the problem. Questions regarding activities of daily living *(Is the dog able to void independently, to climb steps, and to go on a walk?)* and questions regarding playfulness provide information on the impact of an orthopedic disorder on quality of life. Exercise intolerance reported by owners may be the consequence of a lack of ability or a lack of willingness. Lack of ability may result from loss of strength, loss of joint motion, lack of fitness (rarely) or the presence of a neurologic compromise. Lack of willingness generally results from pain. The duration of an orthopedic disorder is most often underestimated because owners tend to think that the lameness started when they discovered it. That is rarely true. Also, orthopedic disorders are often chronic and it is hard to recall the date of onset of an event that took place months or years in the past. It may be helpful to ask owners whether the patient was already lame at the time of a specific holiday or event (e.g., *Was your dog already limping on the 4th of July?*).

Patient Observation

Patient observation provides valuable information for clinicians (see ch. 2). Dogs react to orthopedic pain in a predictable fashion and the information that follows refers to examining dogs. Observation of the patient starts in a resting position. Dogs are more relaxed before their limbs are palpated and, therefore, assessment of their posture at rest and when getting up, standing, walking, and trotting should occur before palpation. The dog can be observed when resting in a waiting room and when getting up to walk into an examination room. If lameness is difficult to ascertain, it is helpful to have the owner take the dog outside as if they were leaving a clinic and accompany dog and owner. The dog may be more relaxed and lameness may become obvious. It is important to make sure that any lameness that is observed corresponds to the owners' perceived lameness. While most owners are objective, some overestimate the severity of lameness and others underestimate it. Dogs intended for conformation *(show dogs)* sometimes are presented because they pace rather than trot. Pacing is unacceptable during conformation events. Some dogs pace because of chronic orthopedic problems; other dogs pace in the absence of any orthopedic problem. A solid knowledge of gait patterns is helpful to differentiate normal from abnormal gaits. A digital camera, particularly one that can record or show gait in slow motion, is helpful to observe and record lameness.

Dogs adopt the stance that provides the best compromise between pain perceived and energy expanded. When standing, lame dogs often shift weight away from painful limbs. If a single limb hurts, dogs shift weight to the opposite side. Side-to-side weight shifts do not require a large effort.

If both pelvic limbs hurt, dogs shift weight forward by flexing their thoracic spine, shoulders, and elbows, and widening the stance of their forelimbs. Conversely, if both thoracic limbs hurt, dogs shift weight backward by flexing their lumbar spine, hips and stifles and widening the stance of their pelvic limbs. The most classic weight shift is forward, in response to severe bilateral hip dysplasia or bilateral CCL injuries. Dogs with chronic forward weight shift have wide rib cages, abducted elbows, and internally rotated antebrachia (like a Bulldog). Forward or backward weight shifts require a large effort. While the dog is still standing, weight shifts can be appreciated when paws are lifted off the ground. Dogs that shift weight may pant or their limbs may have tremors because of that effort and because of the pain perceived. Tarsal hyperextension may result from a forward weight shift (see Figure 353-11). Forward weight shift in dogs with conformational abnormalities of the pelvic limbs (genu valgum or other) may lead to torsional laxity of the intertarsal joints.[169]

Dogs lift a painful limb from the ground only if the pain perceived decreases when that limb is elevated and when the effort of lifting that limb is offset by the decrease in pain perceived. Because the effort of lifting the limbs is lesser in small dogs than large dogs, small dogs are more often non–weight-bearing than large- and giant-breed dogs. When multiple limbs are involved (for example, after vehicular trauma, immune-

mediated polyarthritis, or a multifocal inflammatory bone disease), dogs become recumbent.

When dogs are sitting, they must hyperflex the stifle and tarsal joints. Dogs with painful stifle joints, most often after CCL injury, are reluctant to sit straight and prefer extending their painful leg or legs to the side. When they stand up, they shift their weight to the front of their body to avoid having to push on their pelvic limbs (see Figure 353-10).

Lameness

Lameness is generally assessed at a walk and trot. It is important to differentiate lameness from a gait abnormality that could be secondary to a problem that interferes with locomotion but is not an active orthopedic disorder—for example, chondrodystrophic dwarfism, a growth deformity secondary to physeal injury, a fracture malunion, or neurologic disease. Dogs with gait abnormalities may or may not have painful limbs. With forelimb lameness, a head bob is present. The head moves up when the sore limb strikes the ground and moves down when the sound leg strikes the ground. Similarly, with pelvic limb lameness the tail base moves up and down. With hip pain, a dog may avoid flexing the hip joint when moving a leg forward, and, instead, will shift the pelvis from side to side. This leads to an oscillating movement of the base of the tail, when the dog is seen from the back. Some orthopedic problems may be more easily detected at a stance; other problems may be more easily detected at a walk, trot, or gallop. Stance should be assessed for lack of joint motion or excessive joint motion. Some orthopedic disorders are more visible at faster gaits. For example, problems associated with joint subluxation, like hip dysplasia, lead to bunny hopping at a gallop. If the lameness is unclear when the dog is walking, it is often useful to observe the dog while trotting or galloping. Head tilts are often more pronounced when trotting than when walking. Most pups with hip dysplasia will have a characteristic bunny-hop when galloping. It may be useful to watch a dog jump up or down, or climb stairs. For example, dogs with contracture of their semimembranosus muscle will have an abnormal gait at a trot and (hunting) dogs with fibrotic contracture of the infraspinatus muscle will have a characteristic circumduction of the forelimb when climbing steps. As a whole, cats are more difficult to observe than dogs. While some cats are easy to examine as they walk around an examination room, many cats are reluctant to walk during an examination (see Video 2-24). They may prefer staying in a cat carrier, crouching in place, or fleeing to hide.

Palpation

Palpation should include the neck, shoulders, trunk, and all limbs. Optimally, palpation should start with the dog standing, facilitating a comparison between the left and right sides of the body. Muscle atrophy of a forelimb often leads to a more prominent spine of the scapula, because of supraspinatus and infraspinatus muscle atrophy. In the hindlimb, muscle atrophy is most readily identified through atrophy of the biceps femoris muscle. That difference can be determined by comparing the circumference of both thighs, using a (calibrated) tape measure. Conscious proprioception of all four limbs should be evaluated. If it is decreased, a full neurologic examination of the dog should be performed. In trauma patients, especially non-ambulatory patients, the neurological examination should include anal tone, panniculus reflex, withdrawal reflex, and deep pain sensation.

Limb palpation is best conducted while the dog is lying down with the feet toward the examiner. If the dog is fractious or nervous, starting with the limb where the lameness originates may be preferable. Otherwise, collecting information on (presumably) non-painful limbs before a painful limb is palpated may be preferable. Information collected during palpation should be compared between left and right sides of the body. It is best to conduct palpation using a consistent method to avoid omissions and maximize efficacy (see ch. 2). Palpation of the forelimb includes digits, metacarpal bones, carpus, radius and ulna, elbow, humeral condyles and greater tubercle, and shoulder joint. Palpation of the hindlimb includes digits, metatarsal bones, tarsus, tibia, stifle, femoral condyles and greater trochanter, and hip joint. When palpating joints, crepitus, range of motion, effusion (or swelling), pain response to palpation and instability should be evaluated. The first letters of these parameters form the acronym CREPI, the first letters of crepitus. These parameters are evaluated simultaneously: While one hand moves the joint throughout its range of motion, the other hand feels crepitus, effusion or instability, and the examiner looks for a pain response. The evaluation of the range of motion is the most critical part of the palpation because in many instances periarticular inflammation or fibrosis will limit the movement of the joint, especially in smaller, more intricate joints. *When palpating bones, crepitus (when a fracture is present), abnormal shape, and pain response are evaluated.* Some joints require specific tests. For example, the Ortolani sign of the hip joint can be evaluated in immature dogs and is a reflection of the degree of subluxation of the joint. Other hip-specific signs include the Barlow sign and Bardens sign (described below) and the palpation of the triangle formed by the tuber sacrale, tuber ischiaticum, and greater

trochanter. The shape of that triangle changes when dogs have a hip luxation. In the stifle, the cranial drawer sign is the craniocaudal translational instability present after rupture of the cranial cruciate ligament. By the end of the orthopedic palpation, the clinician should know which limb or limbs is/are affected and which changes are present in affected joints.

Decision Making for Management of Orthopedic Disorders

Orthopedic disorders may be managed conservatively (i.e., non-surgically) or may be managed by use of surgery. Surgery is the unequivocal choice when stabilizing fractures, particularly fractures involving articular surfaces and growth plates. Few fractures are managed conservatively: some pelvic fractures with minor displacement or pelvic canal collapse, some long bone fractures with minor displacement, and other fractures.[84,170,171] Because so few publications concentrate on conservative fracture management, the outcome of fractures managed conservatively is generally not known scientifically speaking, and appears to be poor based on clinical experience and a few publications. When managing orthopedic disorders, the benefits of surgery are often less obvious.[138,172] Many orthopedic disorders are managed conservatively, including hip dysplasia, elbow dysplasia, limb deformities, patellar luxation, and cranial cruciate injuries.[173-175]

Surgical Management of Orthopedic Disorders

While the technical description of the surgical management of orthopedic disorders is beyond the scope of this chapter, the principles of surgical management are relevant and are described here. Several surgical procedures are performed with the intent to **alter bone growth.** The juvenile pubic symphysiodesis is a surgical procedure where the parasagittal pubic growth plates are heated (or mechanically removed) at a young age to decrease the longitudinal growth of the pubis. The decrease in pubic length leads to a more horizontal position of the acetabulum and an increase in tolerance of hip subluxation.[176,177] The juvenile pubic symphysiodesis is generally performed at 16 weeks of age, after hip laxity has been measured. Hip laxity can be measured objectively using the PennHIP method.[178] In dogs with premature closure of the distal ulnar physis, segmental ulnar ostectomies can be used to avoid the interference of the ulna with radial growth.[179] Bone growth of the proximal aspect of the tibia can be altered with the intent to decrease the slope of the tibial plateau. This surgery has been proposed in young dogs with cranial cruciate ligament injuries.[180] Surgical procedures are also performed to **change the shape of bones**—for example, to manage limb deformities. Deformity correction can be done with an acute, intraoperative correction or with a progressive correction that relies on bone formation within a distraction gap, a process named distraction osteogenesis.[181]

Surgical procedures are performed to **change the relative positions of bones within joints** to improve joint health. Segmental ulnar ostectomies are also performed with the intent to improve load distributions within the elbow joint.[182] Surgical procedures are performed to **increase the stability of joints** and positively impact joint mechanics. Increasing joint stability may be done by arthrodesis, the fusion of joints across an articulation. Arthrodeses of distal joints (particularly intercarpal, carpometacarpal, intertarsal, and tarsometatarsal) are performed more routinely and yield a better functional outcome than arthrodeses of proximal joints.

Non-Surgical Management of Orthopedic Disorders

Many orthopedic disorders are managed without surgery. Also, many orthopedic disorders managed surgically require non-surgical management beyond surgery. The non-surgical management of orthopedic disorders includes orthopedic screening, optimization of musculoskeletal development, pain relief, weight management, and optimization of activity and exercise. Non-surgical management may include more specific goals including strengthening (in weak patients), stretching (in patients lacking joint motion), or ambulation assistance (in patients with impaired mobility). These specific goals are often part of a physical rehabilitation (i.e., physical therapy, physiotherapy) program. While a physical rehabilitation environment is not necessary to manage orthopedic problems (and is generally not available), the fact that there is so much overlap between physical rehabilitation and the long-term management of orthopedic problems makes rehabilitation a very logical environment to develop, implement, and oversee the management of orthopedic disorders (see ch. 355). Braces, also known as orthoses, can also be used to manage specific skeletal disorders (Figure 353-13). Bracing is a growing field that potentially can be part of the management of several orthopedic disorders. The successful use of braces relies on a specific orthopedic assessment, brace design, fabrication, fitting, and

adjustments, and patient and owner training. Bracing is described elsewhere.[183]

FIGURE 353-13 Orthoses (carpal braces) can be used to limit or promote joint motion. These orthoses have been designed to limit carpal extension in a palmigrade young German Shepherd Dog. The orthoses are hinged to allow carpal flexion. The thickness of the soft rubber on the cranial aspect of the carpus can be modified to control the endpoint of carpal extension.

Early Screening

Because many dogs with orthopedic disorders show mild signs that are often undetected by owners or are accounted for as clumsiness or having an "odd" or "funny" gait or posture, orthopedic screening must be initiated by the clinicians rather than by the owner. Orthopedic screening can be done at any point in life but is particularly relevant in the first few months of life, when developmental orthopedic diseases develop and before damage to joints or changes in posture occur. The hip joint, for example, can be evaluated by use of the PennHIP or Orthopedic Foundation for Animals methods after 4 months of age. Screening starts by asking owners specific questions related to the animal's posture, gait, and ability to perform activities of daily living. Screening should include an observation of the pup's resting position, transitioning between body positions (e.g., getting up, squatting down), walking, and trotting. Screening should also include an orthopedic examination. This examination is performed without sedation in most instances. Palpation of skeletally immature patients requires patience and a gentle demeanor. Even though puppies have limited training and a short attention span, a clinician should be able to detect a repeatable pain response to the palpation of major joints, particularly flexion and extension of the elbow joints, stifle joint extension, and hip extension.

Because of the high prevalence of hip dysplasia in many breeds, particularly in large breeds with thick subcutaneous tissue and relatively modest muscle development (St. Bernards, Bernese Mountain Dogs, Mastiffs, Welsh Corgis), hip screening is commonly performed. Hip subluxation is the early manifestation of

hip dysplasia and hip joints should be screened for the presence of hip subluxation at a young age. Hip subluxation may be detected at approximately 4 months of age—16 weeks of age using palpation. Palpation may be performed awake or under sedation. On palpation, generally performed with the patient in lateral recumbency with the hip joint held in a position similar to a standing position, a flat hand may be placed on the proximal and medial aspect of the thigh and with abaxial pressure (elevation of the thigh in relation to the pelvis), abaxial translation of the femur in relation to the pelvis is palpated by feeling the relative position of the greater trochanter and the ischial tuberosity (Figure 353-14 and Video 353-2). This translation is named the *Bardens* sign. Palpation of the reduction of a previously subluxated femoral head into the acetabulum as a result of abduction of the femur can be performed (Figure 353-15 and Video 353-3). This palpation is most conveniently done with the dog held in dorsal recumbency by holding the hip joints in a position matching a standing position with the stifle joint flexed and slowly abducting the stifle joint. Each vertically held femur corresponds to an angle of 0 degrees. Positive angles correspond to abduction and negative angles correspond to adduction past midline. The Ortolani maneuver can also be performed with the dog in lateral recumbency, but, subjectively, the pelvis is more mobile and it is harder to control the orientation of the pelvis when measuring reduction and subluxation angles. If the hip joint is initially subluxated, a clunking sound, named *Ortolani* sign, can be felt or heard as the femoral head relocates into the acetabulum. The angle at which the Ortolani sign occurs is a reflection of potential wear of the dorsal acetabular rim: Larger angles correspond to more severe wear. The *feel* of the Ortolani also matters; a smooth and crisp Ortolani sign suggests that the dorsal acetabular rim is normal or near normal but a subtle Ortolani sign or an Ortolani sign with crepitus indicates significant loss of articular cartilage and damage to the dorsal acetabular rim and femoral head. When the femur is slowly adducted toward a standing position, a discreet translation is felt as the femoral head subluxates again. This subluxation is named *Barlow* sign. As for reduction angles, higher subluxation angles indicate more severe dorsal rim damage. The difference between the angles of reduction and subluxation often ranges between 20 and 40 degrees. Dogs with hip laxity without dorsal rim damage often have angles of reduction of 10 to 20 degrees and angles of subluxation approximately −10 to −20 degrees. Dogs with severe dorsal rim damage often have angles of reduction around 45 degrees and angles of subluxation around 20 degrees. Subjectively, it appears that higher reduction and subluxation angles result from dorsal rim wear rather than pure joint laxity. Dogs with small reduction angles and negative subluxation angles may be able to maintain their hip joint reduced or intermittently reduce their hip joint during locomotion by slightly abducting their femur, just like dogs with patellar luxation may relocate their patella by extending their stifle joint. This may be observed at a walk or trot. With time, most dogs with hip subluxation will develop dorsal rim wear and the positive Ortolani sign will disappear because of permanent dorsal hip subluxation. The frequency and age at which the Ortolani signs disappear in dysplastic dogs has not been scientifically assessed, to our knowledge. Clinically, most Ortolani signs disappear by 18 months of age. Most dogs with positive Ortolani signs will develop hip dysplasia during the first few years of their adult life.

FIGURE 353-14 Hip laxity is palpated by placing a hand medial to the thigh with fingers running along the shaft of the femur, stabilizing the femur with the thumb, and lateralizing the femur in relation to the pelvis while the other thumb detects the translation of the greater trochanter relative to the tuber ischiadicum. This maneuver is named the *Bardens* sign. The Bardens maneuver induces discomfort so it is performed under sedation.

FIGURE 353-15 Hip subluxation can be detected during palpation. With the dog held in dorsal recumbency, a pelvic limb is abducted. Abduction increases dorsal coverage of the femoral head and can lead to the reduction of a subluxated joint. Hip reduction resulting from abduction is referred to as the *Ortolani* sign. The angle of reduction can be measured.

The radiographic assessment of joints in young dogs is often unrewarding, particularly if one solely bases the diagnosis of a developmental joint disease on the presence of osteophytes, because it may take weeks, months, or years to have detectable osteophytes in a joint with a developmental orthopedic disease. Specialized radiographic views are used for the early detection of joint disease. They include the well-established PennHIP method for the screening of hip subluxation. PennHIP evaluations are performed under sedation. While multiple radiographic assessment methods exist, the PennHIP method is the most accurate method used to assess the presence of hip laxity. A PennHIP evaluation includes a distraction view that quantifies the degree of abaxial displacement of the femoral head in relation to the acetabulum during a maneuver resembling the Barden's sign. Reliable hip distraction is achieved using foam-covered adjustable acrylic tubes. The distraction index (DI) is the distance separating the centers of the acetabulum and femoral head during distraction divided by the radius of the femoral head. Dogs with low DI (<0.30) are very unlikely to develop hip dysplasia. Dogs with higher DI (>0.70) are very likely to develop hip dysplasia. Some dog breeds are more laxity tolerant than other breeds. For example, in a study involving 3,729 German Shepherd Dogs and 6,278 Labrador Retrievers older than 24 months, the likelihood of having hip osteoarthritis (OA) in dogs with a distraction index of 0.6 was approximately 58% for German Shepherds compared to approximately 16% for Labrador Retrievers. This shows that joint laxity is not the sole factor leading to the development of hip arthritis, and suggests that differences in anatomy and joint mechanics play an important role in the development of hip dysplasia.[184] In a report assessing 459 clinically normal dogs, palpation was at best moderately correlated with radiographic measures of joint laxity, indicating the need to combine palpation with stress radiography when screening dogs for hip laxity.[185] An oblique view named the distomedial-proximolateral oblique view has been shown to enhance the detection of fragmented medial coronoid process in the elbow joint of dogs.[56]

Optimization of Musculoskeletal Development

The optimization of musculoskeletal development is a critical aspect of the management of orthopedic disorders because many disorders impact patients during growth and because the expression of faulty genes is increased when growth is accelerated. In dogs, growth acceleration results from excessive energy intake (eating too much carbohydrates) or calcium supplementation (see ch. 189).

Dogs that eat as much as they want grow very rapidly. A modest food intake restriction of 25% compared to unlimited *(ad libitum)* feeding dramatically slows growth. For example in growing male Great Danes, a 25% restriction leads to a mean weight of 26 kg at 6 months of age compared to a mean weight of 52 kg for dogs fed *ad libitum*.[22] Dogs with restricted food intake reach the same adult size as dogs fed *ad libitum* but have fewer orthopedic problems. Owners should be instructed to restrict the food intake of growing dogs, particularly large-breed dogs and dogs from breeds predisposed to developmental orthopedic diseases. The protein content of the diet does not influence growth rate and therefore growing dogs should eat a diet with appropriately high protein content. Growing dogs should not receive calcium supplementation, beyond the calcium included in their balanced diet.

Pain Management

Pain is often the key consequence of orthopedic disorders and therefore minimizing pain is the major aspect of the conservative management of orthopedic disorders. Minimizing pain is achieved by optimizing the living conditions of patients, tailoring their activities, encouraging weight loss (see ch. 176), giving pain medications (see ch. 126, 164, and 166), and food supplementation.

While little is known about the impact of living conditions on the clinical signs of orthopedic disorders in dogs, it seems logical to adapt living conditions of dogs to minimize the challenges associated with living in a home and exercising regularly. Changes in temperature (cold wave), humidity, and barometric pressure (decrease in pressure) have been reported to influence the pain perceived from arthritic joints in humans. To minimize the potential impact of weather conditions on arthritic dogs, it may be beneficial to make sure that they are housed in a weather-controlled environment. Minimizing slipping and falling may benefit them as well, and may be achieved by improving the traction of walking surfaces and by avoiding activities requiring sudden changes in direction or speed.

In humans, the signs of joint disease (e.g., osteoarthritis) fluctuate over time. There are periods of relative comfort and periods of sudden exacerbation of signs named flare-ups or flares. With time, flares become more frequent, more severe, last longer, and are more difficult to control. Similarly, in dogs with joint disease, flares

can result from excessive activity in unfit dogs (weekend warrior syndrome) or from events that place excessive stress on abnormal joints, like jumping or stepping in a hole. Flares may last a few hours or may last several weeks. Determining whether or not an abnormal joint has flared is an important part of the initial assessment because treatment methods and management goals differ. Flares are likely in dogs whose clinical signs are significantly more severe than they were in preceding weeks. Patients with joint disease are often in the middle of a flare at the time of first evaluation because owners seek veterinary care due to the sudden increase in clinical signs. A sudden loss of performance (inability to climb steps or climb into a motor vehicle, exercise intolerance) generally results from a flare, can result from a chronic, progressive loss of strength and fitness secondary to OA combined with aging, or can result from a change in the status of an arthritic joint (a subluxated hip joint becomes luxated). Irreversible decisions such as surgery or euthanasia should not be made during flares because patients may appear overly affected and can have a dramatic loss of mobility or independence that will subside when the flare subsides. Instead, focus should be on comprehensive pain management and on rest. Between flares, owners should avoid strenuous activities that trigger flares and lead to an increase in clinical signs. Strenuous activities that can trigger flares include jumping up, chasing, retrieving, and playing with other dogs. Unfortunately, owners often select these activities because dogs love them, because they are easy to perform, and because they require minimal owner participation.

In dogs with severe orthopedic disorders, ambulation assistance may be provided by a step-in sling or harness. Neoprene harnesses with hook-and-loop fasteners are popular because they are ergonomic, relatively soft, durable, and washable. For large, heavy, or independent dogs with locomotion difficulties, an ambulation cart may provide effective ambulation assistance. In most instances, when pain and weakness are limited to the pelvic region, a 2-wheel cart is used. When dogs have problems involving all four limbs, a 4-wheel (quad) cart may be considered. The cart supports the pelvic region during outdoor activity. Carts are much more convenient for small dogs than large dogs. Some dogs learn to negotiate doorframes and may use their cart indoors, while others cannot. Subjectively, neoprene slings may work better than a rigid platform (foam-covered metal rings) for carts in patients with orthopedic disorders, because they have normal motor function during activity, compared to paralyzed dogs, that may function better when using carts with rigid platforms.

Without appropriate pain relief, maintaining joint mobility or regaining lost strength is rarely achievable. Pain relief is achieved by interfering with the peripheral (tissue inflammation and damage) and central (neuropathic; involving the central nervous system) aspects of pain. Nonsteroidal anti-inflammatory drugs (NSAIDs) are the cornerstone of pharmacologic management of peripheral musculoskeletal pain (see ch. 126, 164, and 166).[186] NSAID administration in dogs with joint disease may lead to dramatic improvement in limb use and overall function. Several scientific reports, often used as supporting studies for drug approval, have shown that NSAID administration has led to an increase in the peak vertical force and vertical impulse placed on the pelvic limbs of arthritic dogs.[186] There are no peer-reviewed studies that compared commercially available NSAIDs using blinded, prospective, randomized, crossover designs. Also, the relative occurrence and seriousness of side effects after administration of various NSAIDs in dogs has not been scientifically evaluated. All NSAIDs have infrequent but potentially serious side effects (see ch. 169) and should be used cautiously in dogs, particularly in patients with compromised liver or renal function, hypovolemic patients, and in patients with gastrointestinal disease. This is particularly relevant since many arthritic dogs show an increase in clinical signs later in life when liver, renal, and gastrointestinal problems are more likely to be present. Periodic enzymatic and liver function screening is recommended in dogs receiving NSAIDs. While there is no consensus on the frequency of these screenings, it seems reasonable to perform them before the administration of NSAIDs, after a few weeks of NSAID administration, and if clinical signs arise. The risk of side effects of NSAIDs does not appear to increase when NSAIDs are administered over longer periods of time.[187]

As in all forms of chronic pain, peripheral sensitization and spinal cord wind-up occur with chronic hip dysplasia (see ch. 356). Multimodal drug and non-drug therapy has been recommended to manage this chronic pain. This includes the off-label use of pain medications that are adjunctive or alternative to NSAIDs. Adjunctive drugs may be considered for NSAID-intolerant dogs or for dogs whose clinical signs are only partially improved during NSAID therapy. The scientific information supporting these alternative medications is scant but clinical research in that area is active. Tramadol, a synthetic morphine analogue is seemingly the most commonly used adjunctive drug for chronic hip pain. Other emerging drugs used in the multimodal drug management of OA include the gamma-aminobutyric acid analogue drug gabapentin and the antiviral drug amantadine.[188] Subjectively, dogs with severe arthritic flares may benefit from continuous rate intravenous infusion of a combination of an alpha-2 adrenergic agonist (medetomidine), a sodium

channel blocker (lidocaine), and an N-methyl D-aspartate receptor antagonist (ketamine). Twice-weekly injection of polysulfated glycosaminoglycans between 6 weeks and 8 months of age led to less subluxation and indicated a trend toward less cartilage damage for pups predisposed to the development of hip dysplasia in one prospective study.[189]

Nutritional supplementation has long been used to potentially decrease arthritic pain in humans, most often through the use of compounded herbs and vegetables, such as in traditional Chinese medicine and Indian Ayurvedic medicine. More than 30 herbs or compounds have shown some level of pain relief in prospective randomized trials involving humans with OA. In Western medicine, the attention has mainly focused on the use of glucosamine, chondroitin sulphate, and polyunsaturated (omega-3) fatty acids for the management of arthritic joint pain with several well-structured studies documenting their benefits. By comparison, little is known about the benefits of nutritional supplements in arthritic dogs. However, several clinical trials documented the benefits of a diet containing glucosamine, chondroitin, and eicosapentaenoic acid (EPA), an omega-3 fatty acid, on the clinical signs of hip dysplasia in dogs. Several reports have documented the anti-inflammatory or anti-catabolic effects of omega-3 fatty acids, glucosamine, or chondroitin on human and canine chondrocytes *in vitro*. Increasing the nutritional intake of EPA has been shown to decrease osteoarthritic pain, probably by decreasing arachidonic acid concentrations and increasing EPA concentrations in the cell membranes of canine chondrocytes. Green-lipped mussel supplements also appear to alleviate the clinical signs of osteoarthritis in dogs.[190] Our current body of knowledge suggests that the most reasonable drug administration and nutritional plans for arthritic dogs would be to keep them free of clinical signs by using NSAIDs, omega-3 fatty acids, glucosamine, and chondroitin sulphate, and by potentially adding adjunctive drugs, if deemed necessary based on the clinical signs or as an alternative to NSAIDs if clinical signs of intolerance are present.

There are numerous nonpharmacologic anti-inflammatory options for peripheral pain management, including cold therapy, also known as cryotherapy or icing, and massage. Icing provides direct pain relief by decreasing nerve conduction velocity. It also provides secondary pain relief by decreasing edema (itself a source of pain) and decreasing the overactivity of catabolic enzymes in osteoarthritic cartilage for a few hours after application. Icing is a consideration for osteoarthritic pets with flares. Icing may also help after a period of exercise or before bedtime. Ice cubes or frozen vegetables are not recommended because they have air pockets that decrease cold conduction. Ice bags filled with ice chips or crushed ice or cold packs provide more effective cold delivery. Most cold packs reach therapeutic temperatures after 2 hours in a freezer. For longhaired patients, one approach is to place and hold an ice bag or cold pack directly on the pet's arthritic joint or joints and secure it with a self-adhesive band. A pillowcase may be used between the cold pack or bag and the skin in patients with short or no hair. Some cold packs have a built-in self-adhesive band. A neoprene sleeve may also be used to secure a cold pack or bag. Icing may last for 10 to 15 minutes. Most patients tolerate the treatment. The person applying the ice should make sure the patient is not uncomfortable and that the skin surface feels cold to the touch after icing is complete. The short- and long-term effects of massage in companion animals are not known. Massage may decrease myofascial pain and muscle tension. Nonpharmacologic options for central pain management include low-level heating, massage, and possibly acupuncture, acupressure, and electro-acupuncture. These methods primarily stimulate A-beta sensory fibers with conduction velocities that are more rapid (30 to 70 m/sec) than A-delta (12 to 30 m/sec) and C fibers (0.5 to 3 m/sec). Heat is widely considered to positively impact painful osteoarthritis patients. The use of heat is two-fold. Low-level heat (elevation of tissue temperature by 1° to 2°C) relieves pain through the stimulation of non-nociceptive A-beta sensory fibers, as well as the vasodilation and normalization of blood flow. Tissue relaxation may be achieved by keeping osteoarthritic patients in relatively dry and warm temperatures throughout the day (sleeping in heated indoor environments or providing heated beds). More intense heat (elevation of tissue temperature by 3° to 4°C) is used to increase the effectiveness of stretching while minimizing tissue damage. Intense heating is most often applied by a healthcare professional using a hot pack that is heated by a hydrocollator or microwave oven. Four layers of dry towels are generally placed between a hot pack and the skin, and heat is generally applied for 15 to 20 minutes. Caution must be used when placing a hot pack on a dog because burns can occur. Initially, the packs may not appear excessively hot to the touch, but they can induce thermal damage after several minutes of contact. It is therefore important to check for excessive redness, skin swelling, or blistering every few minutes during intense-heat therapy.

Maintaining Fitness and Limb Strength

The lifelong benefits of having a lighter body weight on osteoarthritis and longevity have been clearly documented in a Labrador Retriever lifelong study.[50] In that study, compared to their overweight

counterparts, the lighter dogs lived 1.8 years longer. For both groups, however, lack of mobility late in life due to OA was the dominant cause of euthanasia.[191] This study proved that OA progressed more slowly and was more easily controlled in lighter dogs. Adult patients with musculoskeletal disorders routinely carry excessive body weight. Excess weight has a clear negative impact and loss of excess weight has a clear positive impact on patients with skeletal disorders.[192,193] In one study, a subjective decrease in lameness detected using a numerical rating scale was observed once weight loss was larger than 6.1% and an objective decrease in lameness detected by use of a force plate was observed once weight loss was larger than 8.5%.[194] Weekly weight loss rates of 1 to 2% body weight are recommended for overweight dogs. This loss may be achieved by feeding an amount approximately equivalent to 60% of the calories needed to maintain body weight. Weight loss in dogs with osteoarthritis does not appear to be associated with an increase in spontaneous activity.[195]

Muscle strength has been shown to decrease in humans with OA and that loss of strength is both quantitative (due to a loss of muscle mass) and qualitative (due to a loss of muscle performance) potentially as a result of limb disuse and the reflex inhibition of the contraction of muscles adjacent to arthritic joints. Loss of muscle mass is commonly observed in dogs with chronic skeletal disorders. However, the extent of loss of strength has not been assessed in dogs with various chronic skeletal disorders and little research has focused on specific strategies to protect against loss of strength or to regain strength. With few exceptions, the maintenance of muscle strength is achieved through active exercises. These exceptions include neuromuscular electrical stimulation and active range of motion therapy. Neuromuscular electrical stimulation may be considered in arthritic dogs with severe loss of muscle strength where successful exercise is not possible because of severe pain or limb disuse. As a general rule, it is simplest and most effective to use therapeutic exercises than other strategies to strengthen patients (Table 353-1).

TABLE 353-1

Therapeutic Exercises Potentially Included in the Management of Canine Hip Dysplasia

PURPOSE	THERAPEUTIC EXERCISES
Increasing limb strength	Daily walk or trot longer than 10 minutes; tunnel-walk repetitions; sit-to-stand and stand-to-sit repetitions
Increasing core strength	Daily walk or trot longer than 10 minutes; swimming
Increasing cardiovascular fitness	Daily walk or trot longer than 10 minutes
Stretching pelvic limbs	Climbing up slopes, hills, and stairs; low jumps
Increasing proprioception	Daily walk or trot longer than 10 minutes; walk on soft surfaces: sand, mulch, gravel, leaves, grass; teeter-totter; pole weaving

Cardiovascular fitness and muscle endurance have been poorly described in dogs. Because chronic skeletal disorders are likely to negatively impact mobility, muscle endurance, and cardiovascular fitness, it is logical to promote regular aerobic physical activities in dogs with skeletal disorders (see ch. 359).

Increasing muscle endurance requires repeated movements over a period of several minutes. Such endurance building is unlikely to be achieved through self-driven activities in areas with limited space, such as a dog being left unattended in an average fenced-in backyard. Instead, dogs should be exercised with purpose on a regular basis. In humans, skeletal disorders and aging contribute to a loss of proprioception. Little is known about the negative impact of naturally occurring osteoarthritis on proprioception in dogs. However, there is clear evidence that osteoarthritis progresses rapidly in patients with joint injuries that have sensory deficits. In older humans with decreased proprioception, balance exercises readily improve proprioception. In dogs with osteoarthritis, a portion of exercise programs should focus on exercises that train proprioception, such as exercises requiring rapid and unpredictable side-to-side weight shifts and, to a lesser extent, front-to-back and back-to-front weight shifts. These exercises include walking on soft or irregular surfaces and gentle agility exercises, including pole weaving and walking on a teeter-totter, dog walk, or over low rails (see ch. 355).

Little is known about the impact of hip arthritis on joint motion. As mentioned above, dysplastic hip joints seemingly lose extension but not flexion. A loss of hip extension of 30 degrees or more likely leads to the dog's inability to gallop, trot, jump up, or climb steps or stairs. It appears beneficial, therefore, to assess joint

motion in dogs with chronic hip dysplasia. Since it is much easier to maintain joint motion than to regain it once lost, it seems reasonable to recommend intermittent physical activities that increase hip joint extension without creating significant clinical signs. These activities may include walking uphill or dancing backward. If regaining joint motion is deemed important, a stretching program may be implemented. Stretching is more effective when tissues are heated immediately prior to and during the stretching session. Empirically and based on techniques used in humans, performing ten to fifteen 20- to 40-second-long sustained stretches during each session can be considered. Sessions may be performed two or three times per day. With chronic loss of motion, a gain of 3 to 5 degrees of joint motion per week is anticipated as a result of a sustained stretching regimen.

Dogs with skeletal disorders with minor locomotion problems have a management program focused on decreasing pain, maintaining limb and core strength, stretching affected joints, and stimulating proprioception. Pain management is generally achieved with simple pharmacologic steps, rest, and exercise. Pharmacologic and other forms of pain relief may be intermittent as long as dogs adhere to a long-term exercise program. For dogs with skeletal disorders with major locomotion problems, it is critically important to implement several support strategies to decrease the impact of the disease on the dogs' well-being and mobility. These strategies can include rest, multimodal pharmacologic management, ice, heat, massage, acupuncture, acupressure, electroacupuncture, or transcutaneous electrical nerve stimulation. Once pain is managed, it is important to initiate a progressive exercise program. Patients with severe osteoarthritis may need temporary or permanent ambulation assistance. Slings are the most common and cost-effective ambulation assistance devices. Severely impaired dogs may benefit from an ambulation cart. Overall, a management program for companion animals with osteoarthritis should be simple and logical: Managing pain is the first priority. The program must then address the most critical aspects of each patient's unique situation and, over time, improve the patient's mobility, strength, proprioception and, above all, quality of life.

CHAPTER 354

Muscular Disorders

G. Diane Shelton

Clinical Overview

Muscle diseases (myopathies) can be diagnostic challenges, as there are many different diseases (Figure 354-1) that share relatively few clinical signs. Recognition of the myopathic phenotype is the important first step (see ch. 2, 31-35 and 259). Clinical signs of muscle disease include variable degrees of muscle weakness, stiffness, myalgia, and muscle atrophy or hypertrophy. Clinical signs can involve just the limb muscles or affect special muscle groups, such as the laryngeal muscles, pharyngeal muscles, masticatory muscles, tongue, and heart. The breed, age of onset, and clinical progression should aid in the differential diagnosis.

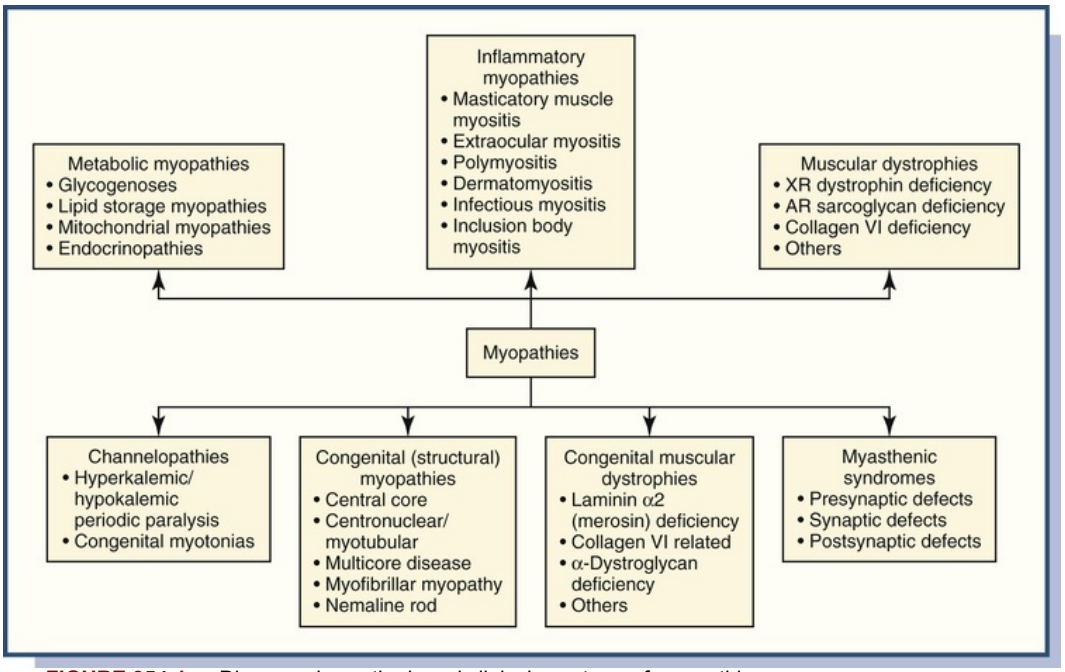

FIGURE 354-1 Diagram shows the broad clinical spectrum of myopathies.

Routine laboratory screening including a complete blood count, serum biochemical profile, and urinalysis can identify some of the most common systemic abnormalities that cause muscle weakness and myalgia (see ch. 12 and 21).[1] Serum creatine kinase (CK) activity (see ch. 66) and thyroid evaluation (see ch. 299) should be included in every neuromuscular minimum database. Even if only mildly elevated, a persistently elevated CK activity would be an indication for further investigation of a muscle disease. At the time of initial diagnosis of hypothyroidism in people, up to 80% report problems attributable to skeletal muscle dysfunction, and nearly 40% have clinical evidence of muscle weakness.[2] Similarly, muscle stiffness and myalgia may be an early indicator of hypothyroidism in dogs without obvious classical clinical signs. Identification of hypothyroid myopathy can prevent unnecessary diagnostic expenses if confirmed by routine diagnostic testing.

Since autoimmune myasthenia gravis (see ch. 269) can mimic any neuromuscular disease, testing for acetylcholine receptor (AChR) antibodies should be included in the minimum database for dogs or cats with acquired clinical signs of weakness, and in particular, in dogs with acquired megaesophagus. The AChR

antibody test remains the gold standard for the diagnosis of acquired myasthenia gravis and confirms an autoimmune response against nicotinic AChRs.[1,3]

The single most important test for the diagnosis of a muscle disease is the muscle biopsy (see ch. 116). This procedure is minimally invasive and does not require extensive surgical training. Muscle biopsies should be evaluated in frozen sections by a laboratory with expertise in the examination of muscle. Unless the myopathy is inflammatory or neoplastic in nature, a formalin-fixed biopsy evaluated in paraffin sections will be of limited diagnostic value and many myopathies will be missed. Fixed muscle specimens are of value for ultrastructural examination of congenital myopathies following a presumptive diagnosis in frozen biopsy sections. An accurate diagnosis is critical given the emergence of genetic testing for inherited muscle diseases and development of new DNA-based tests.

The field of muscle disease is a rapidly expanding one in both human and veterinary medicine.[4] This topic cannot be covered entirely in the limited space devoted to this chapter. Thus, the most common clinical disorders will be covered with references cited to those myopathies less frequently encountered.

Inflammatory Myopathies

Masticatory Muscle Myositis

Masticatory muscle myositis (MMM) is a relatively common, focal, autoimmune muscle disease, primarily affecting dogs[5] and rarely cats. All breeds can be affected and at any age. A particularly severe form of MMM occurs in puppies at 2-3 months of age, notably in Cavalier King Charles Spaniels.[6] Clinical signs are restricted to the muscles of mastication and can vary from an acute onset of swelling of the masticatory muscles with restricted jaw mobility and jaw pain, to slowly progressive atrophy of the masticatory muscles with or without jaw pain or restricted jaw mobility. A retrobulbar abscess and disorders of the temporomandibular joint should be ruled out (see ch. 272). The serum assay for detection of autoantibodies against masticatory muscle type 2M fibers is useful for the diagnosis of MMM.[5,7-9] For most accurate results, serum should be collected prior to administration of corticosteroids. A temporalis muscle biopsy also is useful for the diagnosis of MMM and for prognosis (see ch. 116). It is important to not biopsy the frontalis muscle that overlies the temporalis muscle, as this biopsy will produce a false-negative result.[5]

Response to therapy should be good if MMM is treated early and appropriately.[5] Immunosuppressive dosages of corticosteroids should be used until jaw mobility returns to normal and jaw pain is no longer evident. The dosage should be gradually decreased until the lowest alternate day dosage is reached that will keep the dog free of clinical signs. Low-dosage therapy should be continued for 6-8 months with monitoring of jaw mobility. Relapses are common if treatment is stopped too soon. For end-stage or severe MMM, response to therapy may only be partial. A muscle biopsy is particularly useful in these cases.

Extraocular Muscle Myositis

Extraocular muscle myositis (EOM) is a focal inflammatory myopathy that selectively affects the extraocular muscles while sparing the masticatory and limb muscles. The clinical presentation is exophthalmos in the acute stage while enopthalmos and restrictive strabismus may occur in the chronic stage.[10,11] The serum CK activity usually is normal. The serum 2M antibody titer is negative. The diagnosis of EOM is best made by orbital ultrasound or imaging studies such as computed tomography (CT) or magnetic resonance imaging (MRI). Response to corticosteroid therapy is usually good in the acute stage and treatment is similar to that of MMM (see above).

Immune-Mediated Polymyositis

Immune-mediated polymyositis (PM) is a generalized inflammatory myopathy in which multiple skeletal muscle groups are invaded by nonsuppurative mixed mononuclear cell infiltrations.[12,13] The clinical presentation can vary depending on which muscle groups are affected, and can include generalized weakness (see ch. 21) with a stiff and stilted gait, megaesophagus (see ch. 273), dysphagia (see ch. 38), myocarditis (see ch. 252 and 253), and glossitis.[14-18] While PM can occur in all breeds, genetic predispositions have been identified in Newfoundland[14] and Vizsla[19,20] dogs. PM also can occur as part of a polyarthritis/PM syndrome[21] or as a paraneoplastic disorder (see ch. 352).[22] PM is uncommon in cats and can be associated with thymoma, myasthenia gravis, lymphoma, or concurrent neuritis.[23]

The serum CK activity in PM can be variable, with mild to moderate increases (2000-20,000 U/L) depending on the severity of myofiber damage.[1] A normal or minimally elevated CK activity should not rule out a diagnosis of PM, nor should a markedly elevated CK activity confirm the diagnosis of PM. Markedly elevated CK activities (>20,000 U/L) usually are found in the necrotizing myopathies[24,25] and muscular dystrophies.[26-28] Evaluation of muscle biopsy specimens is the most direct way to distinguish among the inflammatory, necrotizing or dystrophic myopathies (Figure 354-2). Demonstration of antibodies against unidentified sarcolemmal proteins has been useful in the diagnosis of PM in Boxers and Newfoundland dogs.[29] Infectious causes of myositis (see below) should be ruled out before corticosteroid or other immunosuppressant therapy is initiated. Corticosteroid therapy as for MMM and EOM is commonly used. Expression of major histocompatibility complex (MHC) I and MHC II antigens has proven to be diagnostically useful in biopsies taken from areas remote from inflammation[30-32] (E-Figure 354-3). Treatment should be initiated early and appropriately to prevent irreversible muscle fiber loss, fibrosis, and contractures.

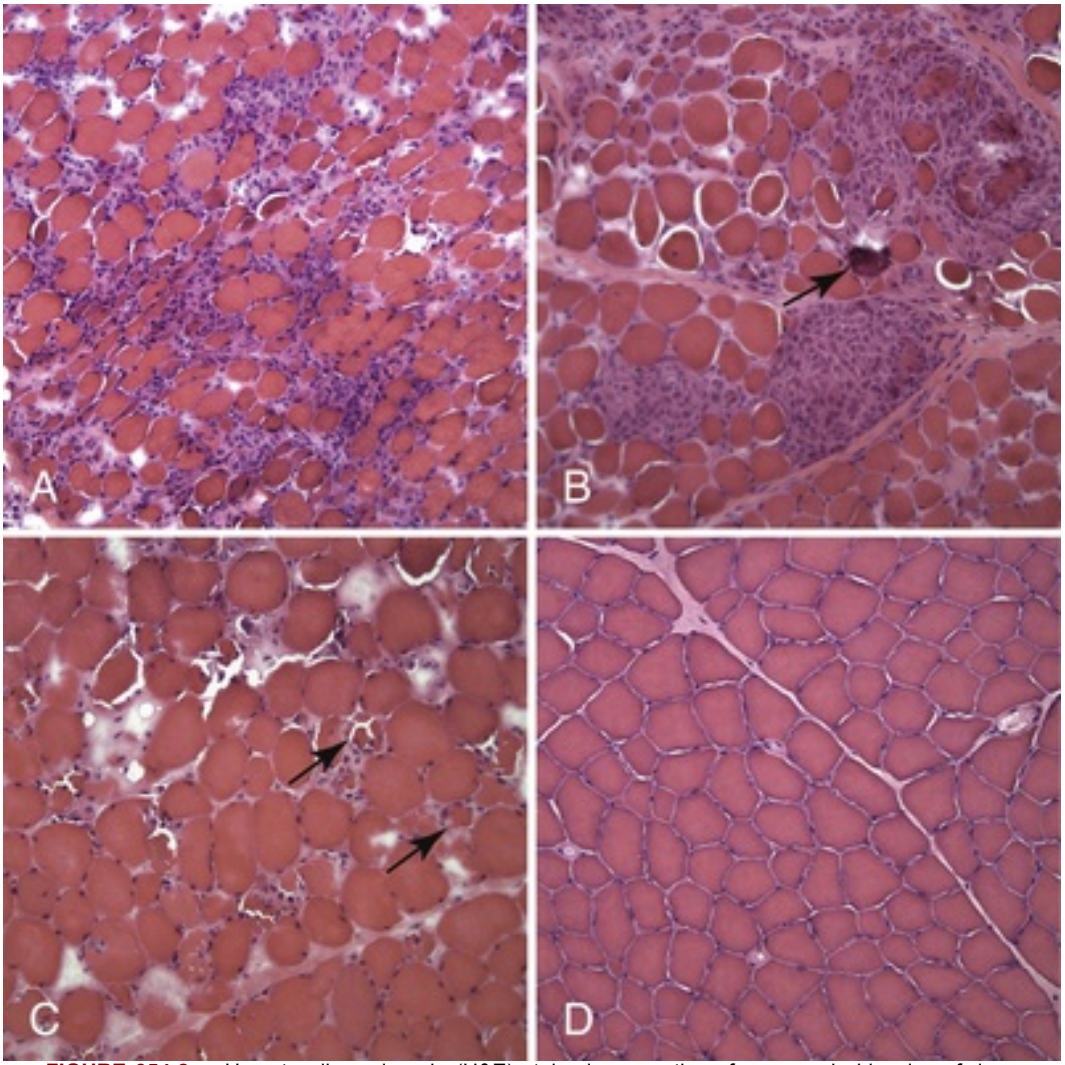

FIGURE 354-2 Hematoxylin and eosin (H&E) stained cryosections from muscle biopsies of dogs with inflammatory myopathy **(A),** muscular dystrophy (**B,** arrow points to calcific muscle fiber), necrotizing myopathy (**C,** arrows point to necrotic muscle fibers) and for comparison from normal dog muscle **(D).** Magnification ×20 for all images.

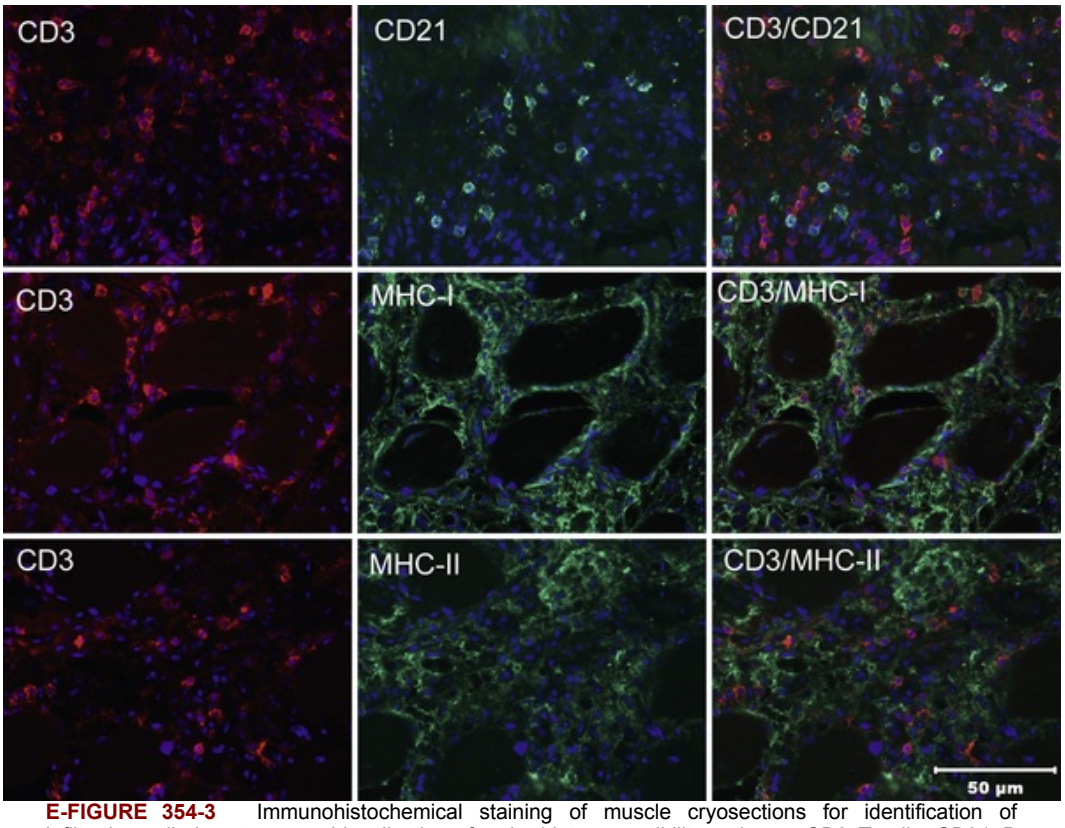

E-FIGURE 354-3 Immunohistochemical staining of muscle cryosections for identification of infiltrating cell phenotypes and localization of major histocompatibility antigens. *CD3,* T cells; *CD21,* B cells; *MHC-1,* major histocompatibility antigen type 1; *MHC-II,* major histocompatibility antigen type 2.

Dermatomyositis

Dermatomyositis (also see ch. 10) is an immune-mediated inflammatory disease of striated muscles, skin, and vasculature. In dogs, the skin lesions predominate, with less obvious myopathic features. A familial form of dermatomyositis has been described in Collies,[33] Shetland Sheepdogs[34] and occasionally in other breeds.[35] Treatment includes prednisone, pentoxifylline, and vitamin E.

Inclusion Body Myositis

Sporadic inclusion body myositis is the most common myopathy in people over the age of 50 years and it also occurs in older dogs.[36] The clinical presentation is of chronic and progressive muscle weakness and atrophy. The diagnosis is made by muscle biopsy, with demonstration of degenerative changes such as vacuoles and Congo–red-positive amyloid deposits, and inflammation. While no specific treatments are available, supplements including L-carnitine and antioxidants may be of some benefit.

Infectious Myositis

Protozoal myositis is caused by *Toxoplasma gondii, Neospora caninum, Hepatozoon canis, Babesia canis, Leishmania,* or *Trypanosoma* organisms (see ch. 221).[37] While thought to be an incidental finding in muscle biopsies, severe cases of myositis associated with *Sarcocystis* spp. infection recently were identified in 2 dogs.[38] Although myositis in general is rare in cats, feline immunodeficiency virus has been reported to cause a subclinical myopathy.[39]

Necrotizing Myopathy

Necrotizing myopathies are characterized histologically by necrosis and phagocytosis without lymphocytic infiltration.[24,25] A necrotizing myopathy should be considered in every case with an acute onset of markedly

elevated CK activity, rhabdomyolysis, and myoglobinuria, or in cases with episodic CK elevations and sporadic myoglobinuria. Etiologies include drug reactions and toxic exposure, bites from venomous insects, electrolyte disorders and infectious diseases. Unfortunately the cause of these disorders is rarely found.[25] Ventilatory support and intensive fluid therapy should result in recovery. Corticosteroid therapy might worsen clinical signs.[40,41] In recurrent cases, metabolic disorders of glycogen and lipid metabolism should be considered. A muscle biopsy is helpful to identify storage products and direct further diagnostics.

Congenital (Structural) Myopathies

Congenital myopathies are a group of genetic muscle disorders characterized clinically by weakness, hyporeflexia, and hypotonia, usually from birth.[42] The congenital myopathies are classified histopathologically on the basis of characteristic morphological features seen on muscle biopsy (Figure 354-4) and include rods (nemaline myopathy),[43,44] cores (central core disease and multiminicore disease),[45] central nuclei (centronuclear[46-49] and myotubular myopathy),[50-52] selective hypotrophy of type 1 fibers (congenital myofiber disproportion)[53] and myofibrillar myopathy.[54] The muscle biopsy (see ch. 116) and analysis of muscle histology, histochemistry, immunohistochemistry and ultrastructure by light and electron microscopy are necessary for reaching the diagnosis of a congenital myopathy.[42]

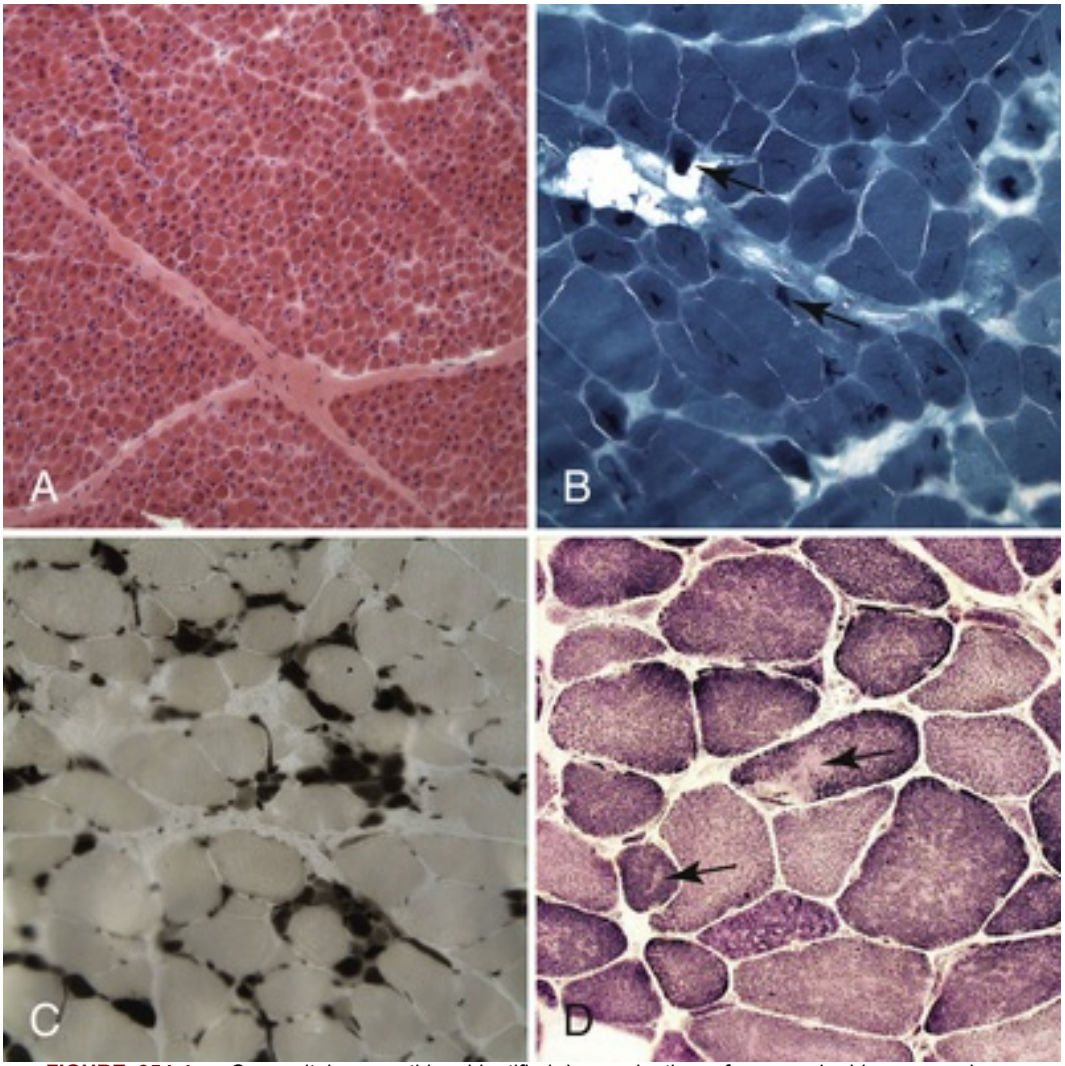

FIGURE 354-4 Congenital myopathies identified by evaluation of a muscle biopsy specimen including the following: **A,** X-linked myotubular myopathy (H&E stain). **B,** Nemaline rod myopathy (modified Gomori trichrome stain; arrows = clumps of rod bodies). **C,** Congenital fiber type disproportion (myofibrillar ATPase reaction at pH 4.3, type 1 fibers are dark). **D,** Multi-minicore disease (NADH-TR reaction; arrows point to areas devoid of oxidative enzyme activity consistent with cores or

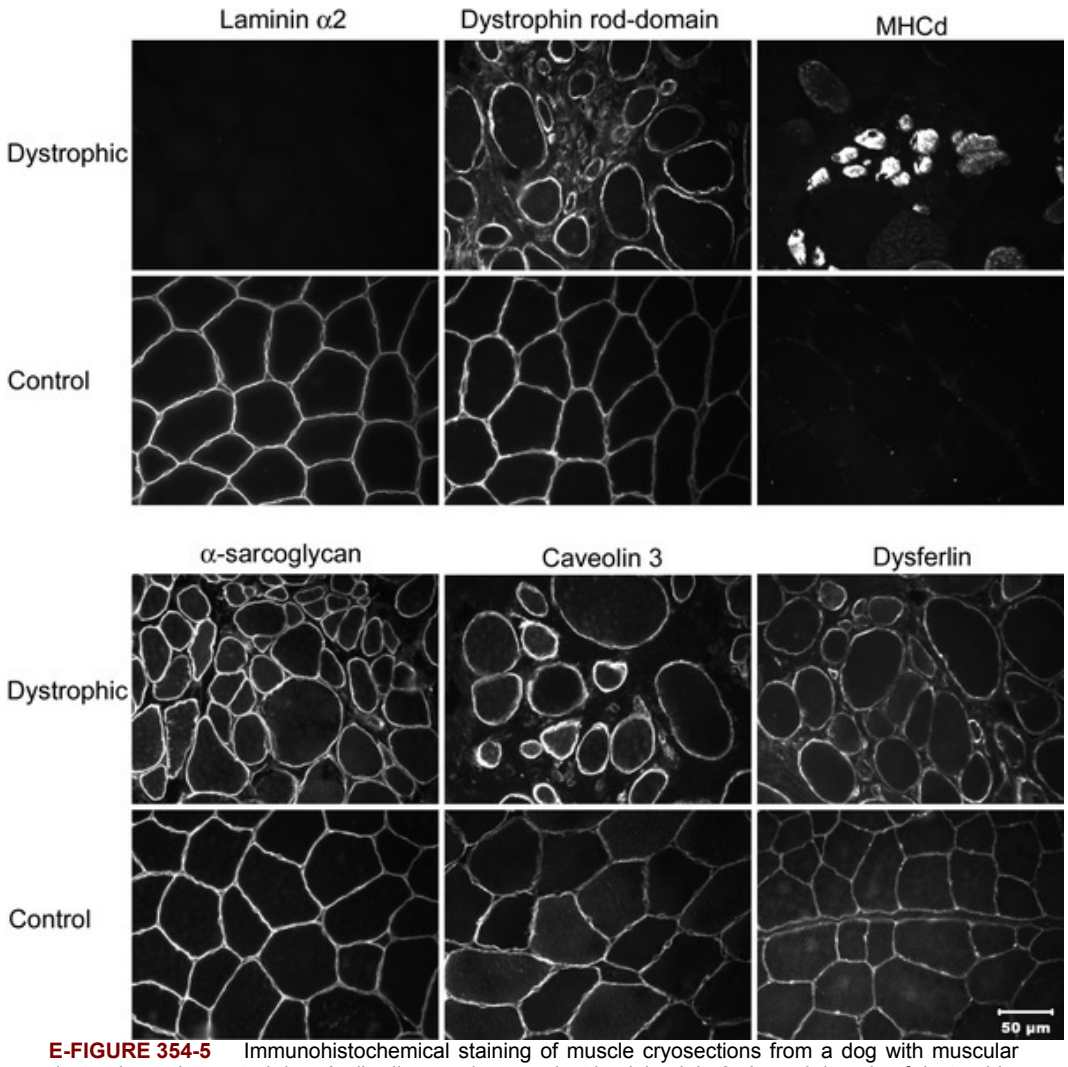
minicores). Magnification ×20 for all images.

Following identification of a structural abnormality, a targeted search for a gene mutation can be initiated. DNA testing is now available for a growing number of neurologic diseases[55] and the list of tests available for inherited myopathies is also increasing. Genetic heterogeneity can occur in the congenital myopathies, with mutations in more than one gene causing a specific myopathy. For example, there are at least eight different genetic loci that can result in nemaline rod myopathy.[42] Different breeds of dogs affected with X-linked myotubular myopathy can have mutations in different loci of the *MTM1* gene, as has been shown for the Labrador Retriever,[50] Rottweiler[52] and Siberian Husky (Shelton, unpublished). No specific therapies for these disorders are clinically available but prevention of the disease with altered breeding strategies should be effective because these myopathies, for the most part, occur early in life.

The centronuclear myopathies (CNMs) have been in the Labrador Retriever and Great Dane population for many years but have been known under various names. Centronuclear myopathy in Labrador Retrievers has been called type 2 fiber deficiency,[56] autosomal recessive muscular dystrophy[57] and inherited myopathy of Labrador Retrievers.[58] In the Great Dane, CNM previously has been referred to as central core myopathy.[59] With the identification of specific mutations in genes associated with the CNMs, these myopathies can now be correctly defined in line with classifications used in human medicine.

Muscular Dystrophies

Muscular dystrophies (MDs) are a heterogeneous group of over 40 different genetic diseases that result in progressive muscle degeneration, repeated cycles of regeneration, and progressive weakness. The most common MDs involve mutations in the gene that encodes the cytoskeletal protein dystrophin[60] and in the dystrophin-associated complex (DAC),[61] which links the extracellular matrix with the actin cytoskeleton, stabilizing the muscle membrane during contraction. Mutations in the dystrophin gene results in X-linked Duchenne- and Becker-type muscular dystrophies in humans.[62] Mutations in other genes of the DAC such as the sarcoglycans result in the group of dystrophies referred to as limb-girdle MDs, which have autosomal dominant or autosomal recessive modes of inheritance.[63] Muscle biopsies (see ch. 116)are an important component of the diagnosis of MD (see Figure 354-1) and immunohistochemistry is an essential component in identification of a specific form of MD (E-Figure 354-5).[64]



E-FIGURE 354-5 Immunohistochemical staining of muscle cryosections from a dog with muscular dystrophy and a control dog. Antibodies used are against laminin alpha2, the rod domain of dystrophin, developmental myosin heavy chain for regenerating fibers, sarcoglycan-alpha, caveolin 3 and dysferlin. The absence of staining with the antibody against laminin alpha2 confirmed a laminin alpha2-deficient congenital muscular dystrophy.

X-Linked (Dystrophin-Deficient) Muscular Dystrophy

Dystrophin-deficient MD is the most common form of MD in dogs[65] and mutations in the dystrophin gene have been identified in several breeds, including the Golden Retriever,[66] Rottweiler,[67] German Shorthaired Pointer,[68] Cavalier King Charles Spaniel,[69] Pembroke Welsh Corgi,[70] Cocker Spaniel, Tibetan Terrier, and Labrador Retriever.[71] Affected dogs have a severe and progressive myopathic phenotype, including gradual loss of muscle mass and development of contractures. Tongue hypertrophy and pharyngeal and esophageal dysfunction result in drooling, dysphagia, and regurgitation. The serum CK activity is persistently and dramatically elevated, which can be detected at a few weeks of age. No specific therapies are currently available. Early death can occur from cardiomyopathy, complications of dysphagia and esophageal dysfunction, or respiratory impairment from a greatly thickened diaphragm. A family of dystrophin-deficient Labrador Retrievers has been identified, with no or very minimal clinical signs of muscular dystrophy but markedly and persistently elevated CK activities.[72] Clinical signs of feline dystrophin deficiency can vary from muscle hypertrophy to atrophy, diaphragmatic thickening, megaesophagus, and an enlarged tongue with white plaques.[73,74] The serum CK activity is markedly and persistently elevated. The prognosis for recovery is poor. Mutations in the feline dystrophin gene have been identified.[74]

Autosomal Sarcoglycan-Deficient Muscular Dystrophy

Sarcoglycans are components of the DAC and, in striated muscle, are composed of alpha, beta, gamma, and delta subunits. Mutations in genes encoding the sarcoglycans result in the diverse group classified in humans as limb-girdle MDs.[63] Sarcoglycan-deficient MDs have been described in Boston Terriers,[75] a Cocker Spaniel,[76] a female Doberman dog,[77] and a domestic shorthair cat.[78] Sarcoglycan deficiency with a mutation in the gene encoding delta-sarcoglycan has been identified in Boston Terriers (Shelton, unpublished). The clinical presentation of a sarcoglycanopathy is similar to that of a dystrophinopathy, and muscle biopsies show the degenerative and regenerative dystrophic phenotype. Immunostaining for sarcoglycan proteins is necessary to distinguish this form of MD from dystrophin deficiency.

Laminin alpha2–Deficient Congenital Muscular Dystrophy

Laminins are large glycoproteins that contribute to the basement membrane in muscle and are connected to the sarcolemma via the DAC.[79] Laminin alpha2–deficient MD has been reported in cats[80,81] and in a Springer Spaniel cross-breed dog.[82] Clinical signs varied from generalized muscle weakness and atrophy to progressive stiffness with limited range of motion of the limb joints and limited opening of the jaw. Laminin alpha2 also is found in the Schwann cell basement membrane.[83,84] A demyelinating neuropathy was evident in one of the dystrophic cats where peripheral nerve was studied.[80] One or more mutation(s) in the laminin alpha2 gene has/have not yet been identified.

Collagen VI–Deficient Muscular Dystrophy

Progressive gait abnormality and multiple joint deformities were described in a young Labrador Retriever with collagen VI deficiency.[85] A mutation in the collagen VI gene has been identified (Shelton, unpublished). This case demonstrates the importance of considering a form of congenital MD in young animals presenting primarily for limb contractures.

Congenital Myasthenic Syndromes

Congenital myasthenic syndromes (CMSs) are heterogeneous disorders in which the safety margin for neuromuscular transmission is compromised by defects in proteins residing at the presynaptic, synaptic, or post-synaptic regions of the neuromuscular junction (NMJ) (see ch. 269).[86] CMSs usually occur in animals between 6-12 weeks of age, are familial, and are characterized by severe, generalized muscle weakness. Affected animals were never clinically normal. To date, CMSs have been reported in the Jack Russell Terrier,[87,88] Smooth Fox Terrier,[89] Springer Spaniel,[90] Smooth-haired Dachshund,[91] and Old Danish Pointing Dog.[92] A mutation in the choline acetyltransferase gene *(CHAT)* has been identified in CMS affecting the Old Danish Pointing Dogs.[93] Recently, an endplate acetylcholinesterase (AChE) deficiency resulting from a mutation in *COLQ*, the gene encoding the collagenous tail of AChE, was identified in a family of young Labrador Retrievers.[94] A mutation in *CHRNE*, the gene encoding the epsilon subunit of the muscle nicotinic AChR, recently has been identified in Jack Russell Terriers (Shelton, unpublished). A CMS also occurs in young Golden Retriever puppies, although the molecular defect has not yet been identified.

In general, the prognosis for CMSs in dogs is poor, since clinical signs usually are severe and desensitization to medications such as pyridostigmine can occur. Drugs that benefit one type of CMS can be ineffective or harmful in another type.[95] In Labrador Retriever dogs with a *COLQ* mutation, an AChE inhibitor resulted in worsening of muscle weakness. Conversely, AChE inhibitors in the Jack Russell Terriers with a mutation in *CHRNE* resulted in an increase in muscle strength. The adrenergic agonists salbutamol and ephedrine were empirically effective in CMS in people caused by a mutation in *COLQ*.[95]

Metabolic and Endocrine Disorders

Compared to the frequency of inflammatory and congenital myopathies in the companion dog and cat population, metabolic disorders involving glycogen, lipid, or mitochondrial metabolism are relatively uncommon.

Glycogen Storage Disorders

Glycogen storage diseases (GSDs) are a group of autosomal recessive disorders of glycogen metabolism that result in glycogen accumulation in tissue and that disrupt glucose homeostasis (also see ch. 260). The clinical phenotype begins early in life and can vary depending on severity of the enzyme defect and specific tissues in which the enzyme is normally expressed. A myopathic phenotype can be found with GSD type II (deficiency of lysosomal acid alpha-glucosidase, Pompe disease) in Finnish and Swedish Lapphund dogs,[96] GSD III (deficiency of glycogen debranching enzyme) in German Shepherd Dogs[97,98] and Curly-Coated Retrievers,[99] and type VII (phosphofructokinase, PFK deficiency) in English Springer Spaniels,[100] American Cocker Spaniels,[101] Whippets,[102] and Wachtelhund[103] dogs. Unlike in humans, where exertional myopathy is the more common presentation of PFK deficiency, hemolytic crisis is the predominant clinical manifestation in dogs. Glycogen storage disease type IV has been identified in Norwegian Forest cats.[104]

Mitochondrial Myopathies and Lipid Storage Disorders

The clinical recognition of mitochondrial disease is often challenging. In addition to a predominantly myopathic or encephalomyopathic presentation, multi-organ system manifestations can occur, in which muscle involvement is only a part. Mitochondrial disorders can present at any age. Organs with a high energy demand typically are affected, including skeletal and cardiac muscle, endocrine organs, kidney, non-mucosal components of the intestinal tract, retina, and the central nervous system.[105]

A mutation in the pyruvate dehydrogenase phosphatase 1 gene *(PDP1)* has been identified in Clumber and Sussex Spaniels having very limited exercise capacity beginning within the first year of life.[106] Markedly elevated resting and post-exercise plasma lactate and pyruvate concentrations with a lactate-to-pyruvate ratio <10 supported a mitochondrial disorder. A high-fat, low-carbohydrate diet and supplementation with L-carnitine, coenzyme Q_{10}, and a B-complex vitamin results in improved exercise tolerance, although the lifespan is shortened. A mitochondrial myopathy associated with altered cytochrome C oxidase activity has been reported in Old English Sheepdog littermates.[107]

Lipid storage myopathies are associated with primary or secondary disorders of carnitine metabolism or disorders of fatty acid beta-oxidation.[108,109] Clinical signs include progressive generalized weakness and prominent myalgia. The diagnosis can only be made by demonstration of excessive and large intramyofiber lipid droplets in type 1 muscle fibers using a stain for neutral triglycerides. Lactic acidemia can be a concurrent finding. Therapy usually is successful, using a combination of L-carnitine, antioxidants, and a B-complex vitamin.

Myopathies Associated with Endocrine Disorders

Myalgia, stiffness, and muscle atrophy or hypertrophy are common findings in senior dogs with endocrine disorders, most notably hypothyroidism (see ch. 299) and Cushing's syndrome (see ch. 306). Neuromuscular signs can occur without the classical clinical signs of an endocrinopathy.[110] Pathologic changes in muscle, such as type 2 fiber atrophy and type 1 fiber predominance, can be the first indication of an endocrine-associated myopathy.[111] With hypothyroidism, the response to thyroid supplementation should be excellent. Muscle weakness in cats with hyperthyroidism has a good response to therapy (see ch. 301). In chronic and untreated Cushing's syndrome, a pseudomyotonia may develop (see Video 306-2) that is poorly responsive to specific therapy for hyperadrenocorticism. Muscle cramping has been reported in hypoadrenocorticism in dogs (see ch. 309).[112]

Channelopathies

Congenital Myotonia and Periodic Paralysis

Congenital myotonias are caused by dysfunction of sarcolemmal ion channels, resulting in abnormal myofiber excitability. Clinical signs occur before 6 months of age and include marked muscle hypertonicity, hypertrophy, and visible percussion dimpling when affected muscles are struck with a reflex hammer. Hypertrophy of the tongue is prominent in cats. Electromyographic examination (see ch. 117) with demonstration of dive bomber potentials is diagnostic. Specific mutations have been identified in Miniature Schnauzers,[113] Australian Cattle Dogs[114] and domestic cats,[115] and DNA screening tests are available.

Membrane-stabilizing agents such as procainamide and mexiletine are considered the most effective treatments.

The periodic paralyses are rarely described in veterinary medicine. Episodic weakness resulting from hypokalemia has been described in Burmese kittens.[116] Oral potassium supplementation prevents episodes. A mutation has been identified and a genetic test is available.[117] Hyperkalemic periodic paralysis responsive to acetazolamide has been reported in a single American Pit Bull Terrier.[118]

CHAPTER 355

Physical Therapy and Rehabilitation

David Levine, Darryl L. Millis

Client Information Sheet: Physical Therapy and Rehabilitation

Physical therapy is a profession with an established scientific basis in humans and companion animals. It has numerous clinical applications in the restoration, maintenance, and promotion of optimal physical function.

In providing physical therapy and rehabilitation, the goal is to restore, maintain, and promote optimal function, fitness, wellness, and quality of life as they relate to movement disorders and overall health.[1-7] In dogs, this may include treating patients during their recovery from orthopedic surgical procedures, such as fracture repair and cruciate surgery, monitoring weight loss programs (see ch. 176), providing overall rehabilitation after neurological injuries such as intervertebral disc disease (see ch. 266), and helping to manage chronic conditions, such as osteoarthritis (see ch. 353), or progressive conditions, such as degenerative myelopathy (see ch. 266).[8-14] A major emphasis is to prevent or minimize the onset, clinical signs, and progression of impairments, functional limitations, and disabilities that may result from diseases, disorders, conditions, and injuries.

Physical therapy and rehabilitation in small animal practice is becoming increasingly common and will likely continue to emerge as an essential aspect of veterinary medicine as the scientific literature continues to expand. In many orthopedic and neurologic conditions, physical rehabilitation is becoming routine as a means to enhance recovery, as in human medicine. Wellness and preventive medicine (e.g., weight reduction, maintenance of muscle strength and function, improving cardiorespiratory fitness, and sport specific conditioning) is also a growing trend in rehabilitation and sports medicine. In the human and canine literature, rehabilitation therapy has been shown to be effective in numerous areas related to internal medicine including pain management, cardiorespiratory function, musculoskeletal and neurological recovery and function, and oncology, to name a few.[15-24]

In 2012, the American College of Veterinary Sports Medicine and Rehabilitation (ACVSMR) was approved as a board-certified specialty under the American Veterinary Medical Association's American Board of Veterinary Specialties (ABVS). This newly formed college is aimed at veterinary practitioners who specialize and excel in sports medicine and rehabilitation. Certificate programs in canine rehabilitation are also available and require on-line and live coursework, externships, and examination processes.

Rehabilitation is a time-intensive specialty and has traditionally employed a collaborative approach that engages multiple professions to maximize outcomes including veterinarians, veterinary technicians, physical therapists, orthotists and prosthetists, behaviorists, trainers, and of course owners.

Physical Therapy/Rehabilitation Evaluation

The physical therapy/rehabilitation process begins with a diagnosis from the veterinarian and a careful physical therapy evaluation. The physical therapy evaluation differs from a medical evaluation in that function is paramount. Range of motion, strength, gait, pain, balance, endurance, and other functional factors are all documented, and a plan for rehabilitation is developed, in conjunction with the owner (Appendix 355-1). The plan of care must be unique to the patient and must take into account all abnormal findings and other factors, including the severity of the condition, the age and disposition of the dog, the expectations for future function and performance, the urgency of the recovery, the available equipment and technical skills of the therapist, and the financial constraints of the owner. The plan of care is then continually modified as needed, based on frequent assessments. A qualified rehabilitation practitioner may or may not be found locally, so home programs are sometimes a necessity. A list of practitioners is available at http://ccrp.utvetce.com/practitioners.asp.

It is important to determine the expectations of the owner during the evaluation to help determine the type and length of program necessary to meet the goals. In most cases, owners are realistic about expectations, especially for pets with chronic, severe conditions in which improved mobility and pain control are desired. Occasionally, an owner will have unrealistic goals, and it is important to discuss the realities of the underlying condition(s) and whether or not the desired objectives are likely to be achieved.

Assessment Techniques

Assessing the outcome of treatments in physical therapy and rehabilitation is essential to determine how an animal is progressing and to assess the effectiveness of the treatment. These techniques should consist of objective data whenever possible because subjectively owners and veterinarians often believe a patient is doing better than the data suggest. In addition, documentation of progress is important to provide incentives for owners to continue rehabilitation and justify continued treatment. Numerous measurements are useful for assessing outcomes, including the ability to perform functional activities of daily living, gait analysis, joint motion and function (Figure 355-1), muscle mass and strength, body composition and weight changes, pain assessment, activity levels, and functional scales.[25-37]

FIGURE 355-1 A 6-month-old Labrador Retriever is recovering from extracapsular stabilization of his left stifle joint after avulsion of his cranial cruciate ligament. The dog is undergoing static weight shifting exercises **(A),** walking in an underwater treadmill **(B),** trotting on a treadmill **(C),** and walking with an elastic band eliminating the external rotation present in his right pelvic limb during the recovery period **(D).** (From Millis DL, Levine D: *Canine rehabilitation and physical therapy*, ed 2, St Louis, 2014, Saunders.)

Common Interventions in Physical Therapy/Rehabilitation

Thermotherapy and Cryotherapy

Superficial heat (thermotherapy) and cold (cryotherapy) have been used therapeutically for centuries on soft tissues and joints. Cryotherapy is commonly used after tissue trauma whether accidental (sprains, strains, etc.) or intentional (surgery, intense exercise), with the goals of decreasing inflammation, swelling, and pain and improving function.[38] Heating connective tissues using superficial heat such as hot packs and

compresses typically is used for chronic conditions, such as arthritis and other disease processes causing stiffness, and helps to increase connective tissue extensibility. Thermotherapy may also be used to decrease pain and facilitate healing.[39] Both of these treatments are easily taught to owners and can be administered at home.

Therapeutic Ultrasound

Therapeutic ultrasound (TUS) is primarily used as a deep heating agent (up to 5 cm) and is used in small animal practice for heating joints, muscles, and tendons, commonly before stretching. It is also used for tissue healing and repair and to enhance the transdermal administration of drugs (phonophoresis). Only two frequencies are used in TUS (in comparison with diagnostic ultrasound), 1 MHz for treating tissues between 3 and 5 cm in depth and 3 MHz for treating tissues 1 to 2 cm in depth.[40-42]

Electrical Stimulation

Electrical stimulation (ES) is a commonly used modality in physical therapy and can be effective for many purposes, including increasing muscle strength and decreasing pain.[14,43-47] These devices work by stimulating motor nerves to cause a muscle contraction and by stimulating sensory nerves to help decrease pain. Many dogs tolerate ES well, but some dogs may dislike the sensation and care must be used when attempting this modality.

Therapeutic LASER

LASER is an acronym for light amplification by stimulated emission of radiation. The concept of the use of light for therapeutic purposes, called phototherapy, originated from the belief that the sun and other sources of light have therapeutic benefits. Therapeutic lasers have become increasingly popular in veterinary rehabilitation for a variety of conditions. The lasers used in rehabilitation are thought to help modulate cellular functions, a process known as photobiomodulation (PBM). PBM has been reported to modulate various biologic processes, such as mitochondrial respiration and adenosine triphosphate (ATP) synthesis, to accelerate wound and joint healing and promote muscle regeneration.[48-58] It is also commonly used for pain control, and some studies have found it to be an effective adjunct in the treatment of musculoskeletal pain. Therapeutic lasers are typically Class IIIb (5 to 500 mW) or Class IV (>500 mW) and possess appropriate infrared wavelengths to penetrate to various tissue depths (Figure 355-2).

FIGURE 355-2 Treatment of an arthritic joint with a therapeutic laser.

Range of Motion and Stretching

Range of motion (ROM) and stretching exercises are extremely important to achieve improved motion of joints after acute injury or surgery (articular fractures) or in patients afflicted with chronic conditions (osteoarthritis). They are also important to help increase flexibility, prevent adhesions between soft tissues and bones, remodel periarticular fibrosis, and improve muscle and other soft tissue extensibility to help prevent further injury.[59] Joint motion may be measured using goniometry, which has been validated in dogs and cats (Figure 355-3).[60,61] These exercises can also be performed at home if the owner has been carefully instructed.

FIGURE 355-3 Joint angles of flexion and extension are measured using a goniometer.

Massage

Massage has many forms and is employed by many practitioners of various backgrounds. One common definition is that massage is the scientific and systematic manipulation of the soft tissues of the body. The use of massage in humans is common for relaxation, pain control, recovery from injury, and improving flexibility[62-66] and is becoming more accepted and commonplace in veterinary practice. In some states (but not all) massage therapists are licensed and regulated, but for small animal practice this is not common. Continuing education courses and schools that teach massage are available.

Therapeutic Exercise

See Videos 355-1, 355-2, 355-3, 355-4, 355-5, 355-6, 355-7, 355-8, 355-9, 355-10, 355-11, 355-12, 355-13, 355-14, 355-15, 355-16, 355-17, 355-18, and 355-19.

Therapeutic exercise is very likely the most common and most valuable modality used in physical therapy and rehabilitation. Therapeutic exercise is an important method to return the animal to the optimal level of independence and function.[13,14,67,68] Some of the common goals of exercises are to improve active range of motion, flexibility, muscle mass and muscle strength, balance, endurance, and performance of activities of daily living.[11,59,68-74] Therapeutic exercise programs designed for the home environment also provide an opportunity for owners to become actively involved in their pet's rehabilitation (Figures 355-4 to 355-8).

FIGURE 355-4 Standing on a balance dome (half ball, half flat surface) or a BOSU ball may be used for core strengthening exercises.

FIGURE 355-5 Dancing activities may also be accomplished with assistance of a physioroll or egg ball. The patient places the front limbs on the roll or ball, and the therapist slowly rolls the ball toward or away from the patient forcing the patient to move the hindlimbs backward or forward.

FIGURE 355-6 Tetraparesis or other conditions causing weakness in multiple limbs. **A,** Use of a sling to help provide support for standing. **B,** As the patient begins to fatigue and attempts to sit, the therapist lifts the dog back into a standing position.

FIGURE 355-7 Walking over cavaletti rails helps dogs learn how to negotiate obstacles and walk over them by lifting their limbs to the appropriate height.

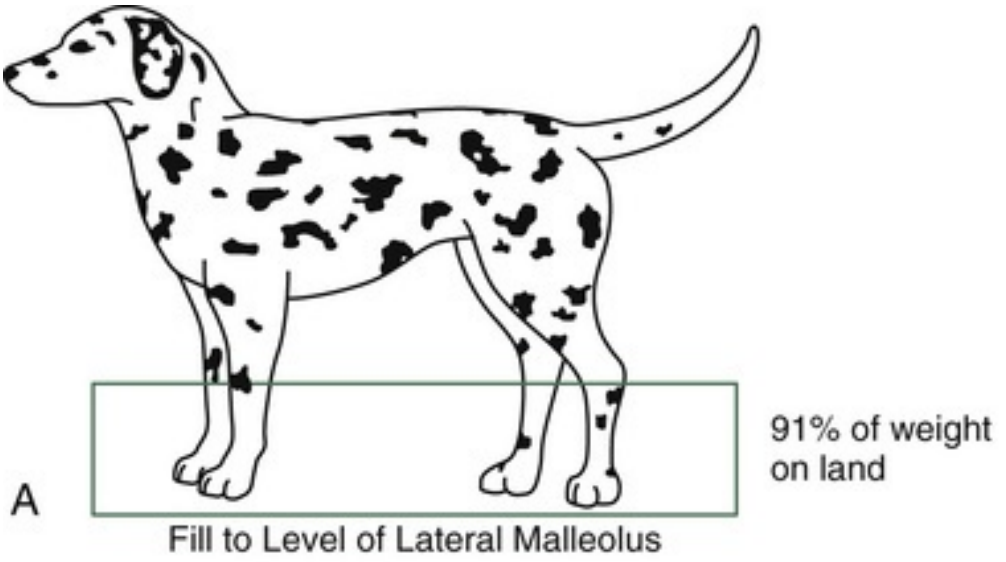
FIGURE 355-8 Standing or walking on foam rubber, mattresses, air mattresses, or trampolines alters the texture of the ground and challenges the animal's functional balance and proprioceptive ability.

Aquatic Therapy

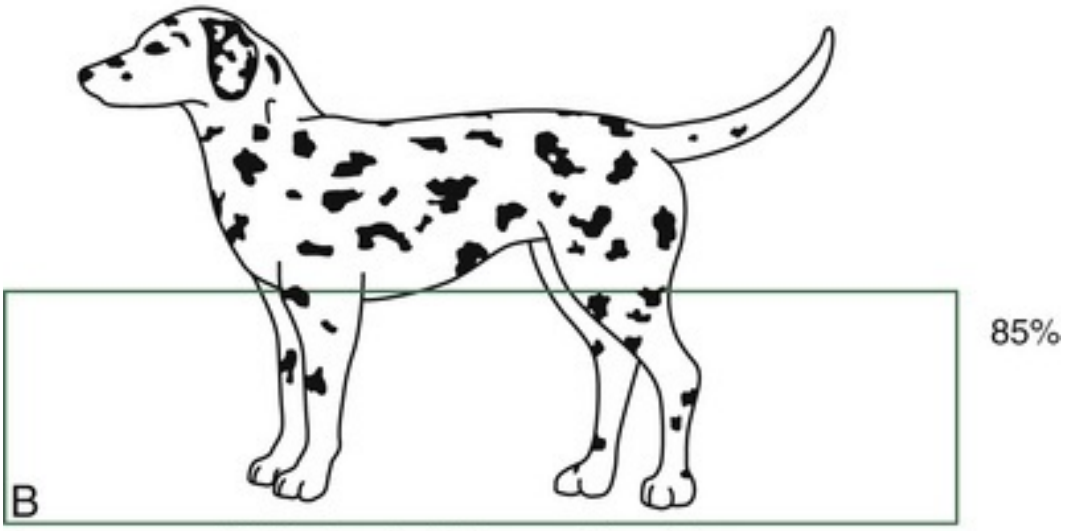
Aquatic therapy has become a very valuable component of veterinary physical therapy and rehabilitation. Underwater treadmills (UWTMs) and pools have become commonplace in veterinary rehabilitation facilities (Figures 355-1, *B* and 355-9). A major benefit of using a UWTM is buoyancy, which decreases the load on the joints during exercise.[12,14,75,76]

FIGURE 355-9 Plastic bumpers in an underwater treadmill to prevent standing on its nonmoving sides. (From Levine D, Millis DL, Flocker J, et al: Aquatic therapy. In Millis DL, Levine D, Taylor RA, editors: *Canine rehabilitation and physical therapy,* St Louis, 2014, Saunders, p 532; with permission.)

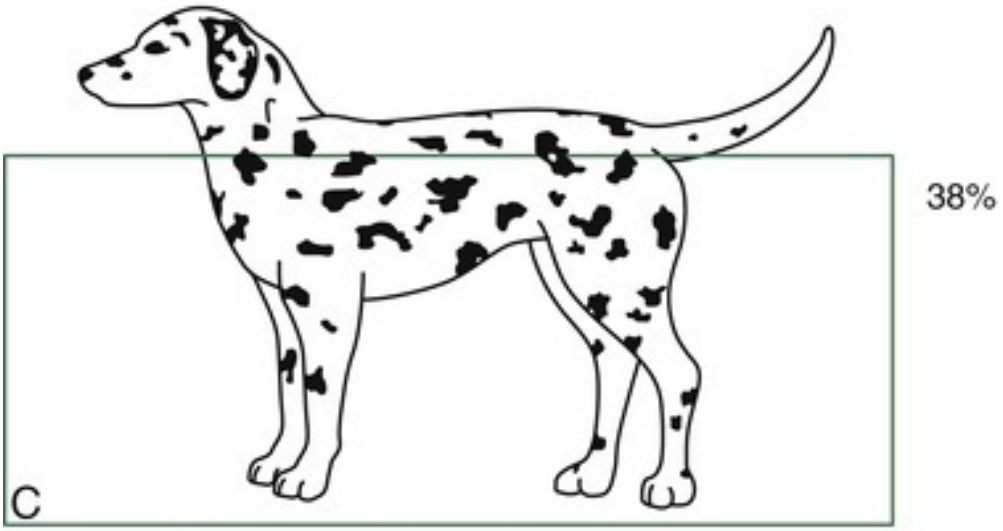
In a study performed on dogs, the amount of body weight borne when the dog was immersed in water (as a percentage of body weight on dry ground) was approximately 91% when the water was at the level of the lateral malleolus of the tibia, 85% at the level of the lateral condyle of the femur, and 38% at the level of the greater trochanter of the femur.[75] This information may be particularly useful when treating patients with conditions such as arthritis because joints may be unloaded as a result of the buoyant properties of water (Figure 355-10, *A-C*). The use of UWTMs is favored for enhancing function such as gait. It also encourages joint motion in a more normal gait pattern compared with swimming. Swimming tends to increase flexion and overall range of motion of the limbs, but joint extension is less compared with UWTW walking. Swimming is a much more difficult activity from an endurance and cardiovascular perspective, though, and just a minute or two can be exhausting, especially for dogs that are in poor condition. Flotation devices are also helpful to allow for greater buoyancy and ease of exercise.



Fill to Level of Lateral Malleolus



Fill to Level of Femoral Condyles



Fill to Level of Greater Trochanter

FIGURE 355-10 **A,** Dog in water to the level of the lateral malleolus. **B,** Dog in water to the level of the lateral epicondyle. **C,** Dog in water to the level of the greater trochanter. (Data from Levine D, Marcellin DJ, Millis DL, et al: Effects of partial immersion in water on vertical ground reaction forces and weight distribution in dogs. *Am J Vet Res* 71:1413-1416, 2010.)

Aquatic therapy such as UWTMs and swimming comes naturally to many patients, which is especially beneficial because exercises in animal patients must be in a form that they naturally perform or can be easily trained to do. It is also an exercise owners can perform with their dogs at home if they have the facilities.

Assistive Devices in Rehabilitation (Carts, Slings, Harnesses, Supports, Orthotics, and Prosthetics)

Numerous assistive devices are used in rehabilitation to assist animals with gait and function (Figures 355-11 and 355-12). These range from adaptive equipment and inexpensive harnesses and supports, to carts and wheelchairs that may be customized to the patient (Figure 355-13). Many of these supports help provide an ergonomic benefit for the owner and provide comfort and safety for the dog.[77,78] Orthotics is the evaluation, fabrication, and custom fitting of braces, known as orthoses. Prosthetics is the evaluation, fabrication, and custom fitting of artificial limbs, known as prostheses (Figure 355-14). Practices offering rehabilitation services have knowledgeable staff regarding obtaining this equipment and training owners in its use.

FIGURE 355-11 An assistive device, such as an abdominal sling, can be used to help a thoracolumbar patient stand and ambulate. (From Millis DL, Levine D: *Canine Rehabilitation and Physical therapy,* ed 2, St Louis, 2014, Saunders.)

FIGURE 355-12 Assisted standing exercise over a therapy roll, performed while eating to encourage standing behavior and provide positive reinforcement. (From Millis DL, Levine D: *Canine rehabilitation and physical therapy,* ed 2, St Louis, 2014, Saunders.)

CHAPTER 356

Chronic Pain

Pathophysiology, Identification and General Management

Lisa Moses

Chronic pain is an enigmatic and intricate problem in veterinary medicine. The maladaptive nature of chronic pain and animals' inability to self-report add to the complexity of management. Pet owners' concerns about chronic pain are not surprising given the prevalence of this problem in people. Chronic pain in adults is considered a global public health crisis, affecting one in five adults for a median duration of 7 years.[1] Chronic pain syndromes that are sufficiently significant to impact quality of life are often a consequence of sustained management of chronic diseases and longer-lived companion animals. The clinical challenge of chronic pain will grow in importance as dogs' and cats' longevity increases. The existence of this new chapter recognizes that management of chronic pain is an integral part of veterinary internal medicine.

Diagnosing and effectively treating chronic pain in patients who cannot self-report is done by proxy. This can feel uncomfortable compared with the general practice of medicine in which a diagnosis is made on the basis of objective data and progress is gauged on seemingly concrete outcome measures. Consequently, chronic pain remains markedly underdiagnosed and undertreated in companion animals, despite evidence of its frequent occurrence.[2,3]

All types of pain are subjective experiences, defined in both sensory and emotional terms. Although veterinarians and clients assume that pain would be fairly easy to assess in verbal patients compared to animals, an "objective" measure of pain in people currently is the subject of intense research. Even physicians are doubtful about the reliability of the gold-standard of self-reporting.[4] For now, the diagnosis of chronic pain depends on functional behavioral changes and response to treatment. Chronic pain states can be inferred from historical and physical examination data and managed in the same way, without posing substantial risk to the patient. Although the problem of underrecognition can be reduced by changing the approach to patients with likely chronic pain, data on effective treatment strategies for animals are still sparse and practice is dependent on extrapolation from adult and pediatric chronic pain medicine.

Chronic Pain: Pathophysiology

A clear distinction exists between the physiology of pain and the pathophysiology of chronic pain. Pain can be a physiologic process meant to protect tissues from potential damage or further injury (nociceptive and acute pain, respectively; see ch. 126) or it can be a maladaptive disease syndrome with no known function (chronic pain).[5,6] Many "definitions" of chronic pain exist in the literature, but none conveys the complexity or totality of this disease. Even Greene's concise and precise definition, "… aberrant somatosensory processing in the periphery or central nervous system (CNS) that is sustained beyond the normal expected time course relative to the stimulus" is acknowleged to be partial.[6] From a pathophysiologic and clinical standpoint, chronic pain is a disease state of the CNS, rather than a clinical sign of long-lasting tissue damage.[7] The clinical marks of chronic pain are altered responses to nociceptive stimulation via allodynia (pain provoked by normally non-noxious stimuli), hyperalgesia (increased sensitivity to noxious stimuli), and sensitization (increase responsiveness by neurons to noxious stimuli).[8] Chronic pain can also be generated spontaneously from CNS activity without tissue damage, or it can persist after tissue healing.[8] These characteristics are clinically very confusing since a structural lesion that explains the pain might seem minor, could have resolved, or might be nonexistent. In chronic pain states, the perception and experience of pain is disconnected from the peripheral lesion.[9]

Chronic pain is caused by both structural and functional changes in pain pathways. Neuronal mechanisms include disinhibition, descending pathway facilitation, and long-term potentiation in the spinal cord and cortex.[10] A main contributor to the generation of chronic pain is the sensitization of the pain signaling system. Central sensitization is a type of CNS plasticity that has been best characterized as a process in the dorsal horn of the spinal cord, importantly involving N-methyl-D-aspartate (NMDA) receptor recruitment.[7] Contemporary research suggests that a similar process of sensitization likely occurs at other CNS sites.[11] Neuronal, immune, and glial-related triggers of central sensitization all appear to be important, besides the frequently mentioned NMDA receptor mechanisms.[8] Both sensitization and tonic activation (another key element) are stimulated by mediators released at all levels of the pain nervous system.[11]

Non-neuronal elements such as glia and immune cells are integral to the transition from acute pain to chronic pain.[8] In fact, recent research has posited that chronic pain is a "gliopathy," or dysregulation of glial function in the nervous system.[10] Activation of glia and neuro-glial interaction involving three types of glial cells (astrocytes, microglia, and satellite glia) are emerging as key processes in the transition to, and maintenance of, chronic pain states.[10-12]

Gene expression in nociceptors is significantly altered in persistent pain (epigenetic change), as is cortical activity as measured by functional magnetic resonance imaging studies.[11] Other contributors to chronic pain mechanisms are genetic or gender differences and bacteria in chronic infections (which can directly stimulate nociceptors).[8]

Chronic pain is not inevitable after acute or even persistent pain. Susceptibility to chronic pain is a complex equation of genetic predisposition and environmental factors. Current research is attempting to link brain imaging techniques with genetic phenotypes or biomarkers in order to better characterize the biological basis for chronic pain.[13,14]

An important functional aspect of pain physiology is the existence of an endogenous pain inhibitory (analgesic) system.[15] The ability of the nervous system to reduce pain appears to be achieved via net inhibition from multiple, interacting, opioid-sensitive circuits at all levels of the nervous system that produce descending modulation of pain signals.[7,15] This system is responsible for the actions of most analgesic drugs and many nonpharmacological methods of producing analgesia including the placebo effect, acupuncture, and exercise.[7,14-16] Many analgesic drugs utilize this circuitry by mimicking the effect of endogenous opiates.[15]

Identification of Chronic Pain and Assessment of Response to Treatment

In contrast to the human species, there is little information about the incidence of chronic pain in veterinary species.[17,18] Recognition of chronic pain in the clinical setting arguably is more difficult than identification of acute pain. Surveys of veterinarians in several cultures have reported the challenge of identification as an obstacle to treatment of chronic pain.[19-21] Although there is widespread acknowledgment of the significance of chronic pain in these surveys, there is also large variation in frequency, duration, and type of treatment provided.

Knowledge of the signs of chronic pain is integral to identification. It is important to bear in mind that some patients show *no* observable signs of chronic pain and some actively hide clues. Important signs of chronic pain in dogs include abnormal postures and movements, changes in willingness to engage in social behaviors, deviations from usual demeanor, trembling, panting, different vocalizations, changes in overall activity level, biting or licking painful areas or forelimbs, and decreased appetite.[22-24] Important signs of chronic pain in cats include changes in jumping up or down, changes in elimination behaviors, lower activity levels, decreased grooming, and social self-isolation.[25,26]

Efforts have been made to identify objective measures of changes due to (primarily) musculoskeletal pain. Physical examination and imaging techniques could yield supportive information in the diagnosis of chronic pain, but their significance is uncertain without a context of functional and/or behavioral changes. Observation methods of lameness scoring and physical exam findings (e.g., joint range of motion) have poor interobserver variability and have not been validated.[22,27] As with assessment of acute pain, measures of homeostasis and physiologic responses to pain are not specific to chronic pain. Radiographic indices of osteoarthritis do not always correlate well with pain levels, particularly in cats.[28-30] Methods that evaluate ground reaction forces like force plate analysis are considered to be the gold standard for assessing lameness even though there are substantial limitations on the clinical utility of this technique.[27,31] Using force plate

analysis as a pain measurement is based on the assumption that lameness equates with pain, but the relationship between pain and lameness is inconsistent and individually variable. Monitors of physical activity have shown promise in some studies, but not others, as indicators of pain relief and have been used clinically in dogs and cats.[26,32-34]

Chronic pain in humans is recognized as a complex and individual experience that cannot be described fully using simple scales that only assess severity (unidimensional).[35] Chronic pain in animals is assumed to be similar given than the "machinery" of pain experience is the same between species.[22] Most authors agree that chronic pain can be identified via changes in behavior, demeanor, and function as observed by veterinarians and caregivers.[26,36,37] The situation could be more complicated in cats, however. Lameness is not the most consistent or reported sign of musculoskeletal pain in cats, and owners might be less able to recognize pain behaviors in cats than in dogs.[28,38] Evidence suggests that veterinarians might not see many of these changes during a routine office visit or even during a thorough physical examination. The most obvious limitation is a lack of self-reporting, but other factors contribute. These include masking of pain signs by release of stress hormones during examination, the inconstant nature of chronic pain, and that chronic neuropathic or visceral pain often is not elicited during palpation of a lesion. Fortunately, caregivers can be accurate reporters of changes in locomotion, behavior, and demeanor even if they do not realize that pain is the cause of the changes.[39-41] Therefore, education of caregivers about pain behaviors is crucial to their understanding of their pet's pain. For example, many owners will attribute signs of pain to normal aging processes.

Validated, multidimensional scoring tools have been developed to assess chronic pain due to osteoarthritis in both dogs and cats and bone tumors in dogs, as well as to measure the effects of chronic pain and cancer on health-related quality of life in dogs.[26,42-44] Health-related quality of life measurement instruments are used in human health care to assess the adverse impact of pain (or other health problems) on health and well-being in a more global way than unidimensional scales.[35] This approach might better describe how patients experience chronic pain and can be used for treatment decision making.

Veterinary tools have also been used to assess response to surgery and medical management of chronic pain and to compare outcome with and without surgery.[25,26,37,40,43,45] Examples of some of these tools can be downloaded from www.vetmed.helsinki.fi/english/animalpain/hcpi and www.CanineBPI.com.

Response to analgesic therapy and withdrawal of analgesia is a valid method of assessing chronic pain, particularly in patients who mask signs or whose owners have difficulty gauging chronic pain levels in pets.[39] Trials with and without analgesics must be coupled with patient-specific outcome measures to be useful.

In assessment of chronic pain or response to treatment, caregiver "placebo" effect is a frequent source of bias and must be considered when evaluating results of assessments.[33,46] The bias can originate from anyone making an assessment (veterinarian or owner). Although this is not a true placebo effect (i.e., the patient does not have a therapeutic effect from the sham treatment), it does impact therapeutic decision making and must be considered when evaluating a patient.

General Approach to the Chronic Pain Patient

Treatment of chronic pain is frequently frustrating to the veterinarian and client (and, probably, the patient). Some of the frustration stems from the limits of approaching this complex clinical problem as a succession of acute events rather than a true chronic illness. Much of the frustration can be generated from unrealistic expectation of clients. Pet owners, like chronic pain patients, frequently seek a simple medical intervention that will fix the problem and its attendant negative impacts on their quality of life. While veterinarians and physicians know this is rarely likely, they can be perceived as ineffective or uncaring when they cannot deliver immediate relief. Since chronic pain is often incurable and progressive, client education and the setting of shared goals and expectations are imperative to outcome success. Changing the paradigm of patients seeking simple symptom relief to that of shared goal setting and responsibility toward longer-term solutions is described as "goal-directed health care."[47] This approach is being used to better treat chronic pain in people and can be helpful for veterinary patients as well. The goals are identified by evaluating the impact of chronic pain on the patient and the caregiver's daily life, their relationship, and the loss of functions that are integral to the patient's well-being. Contextualizing chronic pain as part of daily life can help pinpoint what is most important to try and restore. Client questionnaires simplify the process of assessing the toll taken on daily life and the recognition of realistic goals. An example of the author's client survey can be accessed for use and adaptation at www.angell.org/painsurvey and www.angell.org/catpainsurvey (adapted

from Taylor et al.[48]). For animals with suspected chronic pain, those with chronic illnesses that may cause chronic pain, or geriatric patients, prefilled questionnaires describing functional and social behavior can improve visit efficiency and identify more chronic pain patients.

General Approach to Management of Chronic Pain

Due to the differences between distinct types of chronic pain and the importance of individual genetic phenotype and epigenetics in pain processing, there cannot be a standard formula for treatment. Effective management depends on thorough investigation of all sources of pain, since many comorbidities impact pain states.

Identification of client- and patient-specific outcome measures, derived from initial surveys and visits, are key to gauging progress or lack thereof. Having owners keep a "pain diary" or "comfort journal" consisting of four to five simple, personalized questions can be useful, particularly for those clients who have difficulty identifying changes. It can be especially useful to incorporate the personalized outcome measures in the diary (e.g., "did your pet get on their favorite chair without assistance today?"), to instruct clients to answer the questions once daily at about the same time, and to tell clients not to review the diary for several weeks at a time for best utility.

Recheck examinations, rather than phone or email updates, can identify subtle changes and allow for more accurate management plan adjustments. Accurate pain assessment is improved by having frequent reevaluations by the same observer. Recheck visits also help solidify the partnership between the caregiver and the veterinarian in the goal-directed health care approach.

Multimodal treatment plans and the use of nontraditional analgesics and nonpharmacologic therapies are generally required for successful treatment of significant chronic pain.[5,41,49] Identifying the type(s) and/or source of pain can allow for more precise matching of appropriate treatment strategies.[50] The clinician should recognize that chronic pain states often consist of several types of pain and as disease progresses, the source of pain can change.

The pathophysiology and management of degenerative joint disease has rightly received a great deal of attention, as it is probably the most common cause of chronic pain in veterinary patients.[30,41,51] The reader is referred to ch. 353 and 355 for additional information on this important subject.

Chronic pain can be categorized as inflammatory somatic pain, visceral pain, and neuropathic pain.[52] While inflammatory somatic pain, like pain associated with degenerative joint disease and chronic otitis externa, are familiar and often easily appreciated, visceral and neuropathic pain can be more nebulous. Visceral or neuropathic pain is often episodic and spontaneous, and its signs might not be elicited on palpation.[52] Visceral pain feels diffuse and is difficult to localize even when self-reported.[53] Referred pain is visceral pain that is felt at a somatic location near or distant from the source. Visceral pain, referred or not, can correlate poorly with visceral injury.[53] Chronic visceral and neuropathic pain can be challenging to diagnose and treat, but attention to them can improve outcome in chronic illness that fails to response to therapies only aimed at curing the inciting cause.

Cancer pain etiology is different and often more complex than other types of pain. The specific sources and mechanisms of pain generation morph during the course of cancer proliferation, invasion and metastasis; accordingly, pain management must be adjusted while the disease course is changing.[54] Within the cancer microenvironment, mediators are released that directly stimulate primary nociceptors and indirectly cause increased release of nociceptive mediators. Some of these algogenic (pain-inducing) substances affect both cancer cells and nociceptors. This leads to profound changes in the peripheral nervous system and the CNS due to peripheral and central sensitization. In addition to the changes in the cancer microenvironment, tissue-level and systemic changes occur during invasion and metastasis.[54,55] Therefore, cancer pain can be inflammatory pain, neuropathic pain, and can occur centrally. Pain management plans must address all sources to be effective.

CHAPTER 357

Heart Disease and Kidney Disease

Mark A. Oyama, Shelly L. Vaden, Clarke Atkins

Overview

Cardiovascular disease and kidney disease are highly prevalent in geriatric dogs and cats. Both organ systems are closely involved in the regulation of vasomotor tone and fluid balance. In both health and disease, interaction between systems is critical in determining blood pressure and blood volume. Due to this interdependence, the diagnosis, therapy, and monitoring of animals suffering from concomitant cardiovascular and kidney disease can be challenging. In humans, the term *cardiorenal syndrome* is used to describe conditions in which dysfunction of one system leads to injury and dysfunction of the other.[1] An important facet of the cardiorenal syndrome is the "if and how": whether the close interrelationship between the two organ systems, through common pathophysiological mechanisms, impacts outcome. In people, there is increasing evidence that the "cardiorenal axis" contributes to morbidity and mortality in many types of primary cardiovascular and kidney diseases.[2-4] In 2014, The Cardiorenal Consensus Study Group brought together a group of veterinary heart and kidney specialists to develop a summary statement regarding the definition, epidemiology, pathophysiology, diagnosis, and management of cardiovascular-renal disorders (CvRDs) in veterinary patients. The content of this chapter is based largely on the deliberations and conclusions of that group.[5]

Epidemiology

CvRDs are defined as disease-, toxin-, or drug-induced structural and/or functional damage to the cardiovascular system and/or kidneys leading to disruption of normal interactions between the systems, to the ongoing detriment of one or both. CvRD includes instances wherein primary disease of one organ system is believed to injure the other (e.g., systemic hypertension injuring the glomerulus), as well as instances wherein primary disease coexists in both organ systems (e.g., a cat with hypertrophic cardiomyopathy and tubulointerstitial fibrosis), complicating treatment of either condition. One should not only consider the presence of disease in either system, but the directionality of injury from the primary organ to the "bystander" organ (Box 357-1). Pathophysiological mechanisms likely important in CvRD include hemodynamic alterations, neurohormonal activation, and reactive oxygen species (Figure 357-1); however, the exact nature and existence of CvRD in veterinary patients is largely theoretical and understudied. Accordingly, a key goal of the cardiologists and nephrologists in The Cardiorenal Study Group was to foster collaborative research, based on hemodynamic homeostasis being dependent on the cooperative actions of the cardiovascular and renal systems.

Box 357-1

Potential Etiologies of Cardiovascular Renal Disorders in Dogs and Cats

Primary Cardiovascular Disease Causing Kidney Injury

- Systemic hypertension causing glomerular disease
- Systemic arterial thromboembolism causing infarction of the renal arteries
- Heartworm infection or caval disease causing glomerulonephritis
- Passive congestion of the renal vein during congestive heart failure causing worsening renal function

Primary Kidney Disease Causing Cardiac Injury

- Kidney-mediated systemic hypertension leading to increased afterload, left ventricular hypertrophy, worsening mitral or aortic insufficiency, arrhythmias, vasculopathy, or retinopathy
- Volume overload leading to congestion or systemic hypertension
- Hypokalemia or hyperkalemia leading to cardiac arrhythmias
- Reduced renal clearance of drugs (e.g., digoxin) leading to toxicosis
- Uremic hypodipsia, anorexia, or emesis leading to volume depletion and reduced cardiac output and perfusion
- Uremic pericarditis
- Activation of the renin-angiotensin-aldosterone axis leading to sodium and water retention, cardiac and vascular remodeling, or congestion
- Anemia secondary to chronic kidney disease leading to volume overload, reduced cardiac tissue oxygenation

Systemic Conditions Causing Both Cardiovascular and Kidney Injury

- Septic or neoplastic emboli leading to renal and cardiac infarction
- Gastric dilation and volvulus leading to cardiac arrhythmias and azotemia
- Infectious disease (e.g., *Trypanosoma cruzi*)
- Glycogen storage disease leading to glycogen deposition in the kidneys and heart
- Amyloidosis leading to amyloid deposition in the kidney and cardiac tissues

Adapted from Pouchelon JL, Atkins CE, Bussadori C, et al: Cardiovascular-renal axis disorders in the domestic dog and cat: a veterinary consensus statement. *J Small Anim Pract* 56(9):537-552, 2015.

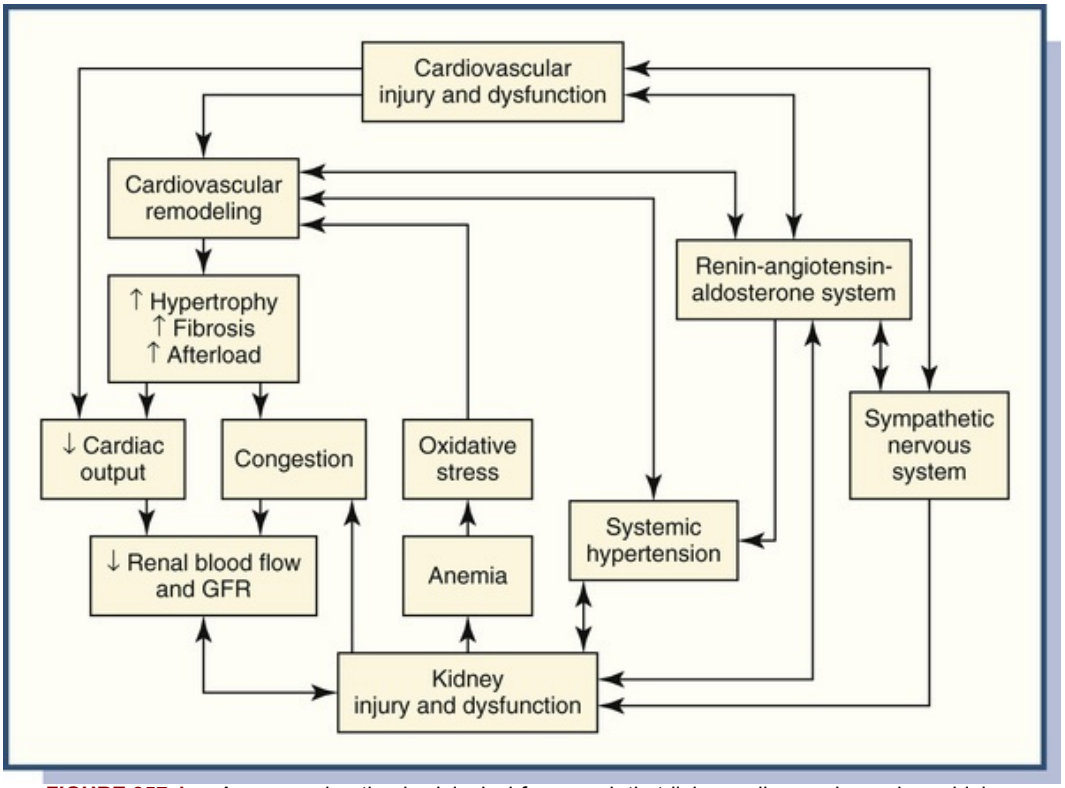

FIGURE 357-1 A proposed pathophysiological framework that links cardiovascular and renal injury and dysfunction in dogs and cats. Injury to the cardiovascular system, kidney, or both potentially causes activation of neurohormonal systems, pathological cardiac remodeling, decreased cardiac function and output, congestion, poor renal blood flow, oxidative stress, and dysregulation of vascular tone. Ultimately, progressive deterioration of either or both systems results. These interconnected and complex series of events require careful consideration when treating disease of each organ system. *GFR,* Glomerular filtration rate. (Adapted from Pouchelon JL, Atkins CE, Bussadori C, et al:

Pathophysiology

There exist both known and suspected adverse effects of kidney disease on the cardiovascular system. These involve electrolyte abnormalities (e.g., hyperkalemia [hyperK]), toxicoses involving drugs primarily cleared by the kidneys (e.g., digoxin, enalapril), volume depletion, volume overload, and systemic hypertension. Likewise, known and suspected adverse effects of cardiovascular disease on kidney function include decreased renal perfusion, activation of neurohormonal systems such as the renin-angiotensin-aldosterone (RAAS) and sympathetic nervous systems, generation of reactive oxygen species by injured endothelial tissue, and passive venous congestion of the kidneys. Some of these effects can be further heightened by administration of diuretics used to treat congestive heart failure (CHF; see ch. 247). For instance, mild acute kidney injury (AKI; see ch. 322), defined as a creatinine concentration >1.6 g/dL (>1.7 to 2.5 [>141 mcmol/L; 142 to 220]) is commonly documented in dogs or cats treated for CHF.[6] Many clinicians, when managing CHF, disregard these elevations as clinically insignificant, yet, regardless of whether transient or permanent, mild AKI may lead to permanent structural damage to the kidneys and worsen outcome. In addition to primary disease of the heart or kidney, CvRD also encompasses conditions outside these systems. Examples of conditions that can cause arrhythmias and/or compromised renal perfusion include sepsis, infectious disease, and gastric dilatation/volvulus.

Management of Heart and Kidney Disease

Heart

Clinical diagnosis, staging, and management of CHF, AKI, and chronic kidney disease (CKD), as separate entities, have been extensively described.[7-9] In brief, heart failure is the condition wherein the diseased heart fails to provide adequate cardiac output or can only do so in the presence of elevated venous filling pressures and risk of congestion (see ch. 246). Treatment involves the use of diuretics, such as furosemide; vasodilators, including angiotensin-converting enzyme inhibitors (ACEIs) such as enalapril or benazepril, and agents such as amlodipine, nitroglycerin, and nitroprusside; neurohormonal blocking agents, including ACEIs, spironolactone, and beta-adrenergic blockers; and positive inotropes such as digoxin, dobutamine, and pimobendan.

Kidneys

AKI (see ch. 322) and CKD (see ch. 324) are conditions wherein diseased kidneys fail to adequately excrete waste products or maintain fluid volume and electrolyte balance. The resulting azotemia, volume alterations, electrolyte abnormalities, and clinical signs of uremia ensue as failure progresses. Treatment may involve the use of parenteral fluids, arterial vasodilators, ACEIs, gastrointestinal protectants, alkalizing and erythropoiesis-stimulating agents, phosphate binders, and dietary modification. Diuretics may be indicated when there is oliguria, volume overload, or hyperK. Relative to this discussion, once disease is present and therapy started, assessment of organ function can be complicated by azotemia that can develop in animals given diuretics or ACEI, as well as those with heart disease and CHF when given fluids.

Treatment of Concomitant Conditions

Overview

A critical aspect of treating either cardiovascular or kidney disease is the requirement to restore and maintain normal fluid homeostasis. AKI and CKD require adequate intravascular volume and pressure for sufficient renal perfusion while avoiding fluid overload and electrolyte imbalances. CHF requires reduction of intravascular volume and hydrostatic pressure through use of diuretics and other preload-reducing therapies. Treatment of CvRD is quite challenging because dogs or cats with advanced kidney disease commonly require fluid replacement therapy to restore perfusion while animals with CHF commonly need diuretic therapy to alleviate congestion (i.e., pulmonary edema or third space effusions). Reduction in vascular volume in cases of CHF or an increase in vascular volume in cases of oliguric kidney disease can lead to adverse effects in the other organ system. Evidence-based guidelines for the recognition and treatment of

CvRD are lacking. The study group's management recommendations are based, primarily, on theory and expert opinion.

Management of Cardiovascular Disease in Consideration of the Kidney

In patients with CHF, relief of congestion should be performed using the lowest necessary dosage of diuretics, particularly after the acute rescue phase. Overzealous diuresis can lead to volume depletion and adverse effects on renal perfusion and function. Strategies to lower incidence of kidney injury include reducing the daily dose of diuretics while augmenting forward cardiac output with inotropic drugs such as pimobendan or dobutamine. A minority of clinicians elect to delay administration of ACEI in acute CHF, due to perceived risk of ACEI-mediated renal injury in the presence of aggressive parenteral diuretic use. One potential strategy, considered by the study group, is to introduce ACEI at the lower end of the recommended dosage range and titrate upwards as kidney function and hydration status permits. Most clinicians recommend *ad libitum* availability of water during diuresis for CHF, as restriction can lead to overly severe volume contraction. In instances of severe volume depletion following diuretic therapy, careful rehydration with attention to sodium (Na) and potassium (K) concentrations using IV, SC, or orogastric fluids is considered. The use of feeding tubes (see ch. 82) should be considered in anorexic animals to provide both nutrition and Na-reduced hydration (see ch. 177 and 189).

Management of Kidney Disease in Consideration of the Heart

AKI, CKD, or a combination typically requires correction of abnormal fluid and electrolyte balance to improve renal function but increases risk of heart failure in animals with preexisting cardiac disease. Fluid therapy, diuretics, and antihypertensive agents should be administered based on hydration status and systemic blood pressure. The goals are to restore and maintain normal fluid balance and blood pressure while avoiding Na or fluid overload. In animals with significant volume depletion and no evidence of CHF, parenteral fluid replacement is commonly given to restore fluid and electrolyte homeostasis and to increase urine production. Patients with AKI and oligoanuria are often prescribed diuretics, despite no evidence of any reduction in morbidity or mortality. A cautious and stepwise approach to fluid replacement and maintenance fluid therapy is recommended for dogs and cats with or at risk for congestion. Low-Na fluids, such as Normosol M or 0.18% NaCl in 1.5% or 4% dextrose, are administered while monitoring body weight, respiratory rate and effort, and arterial blood pressure, as well as being observant for jugular venous distension and/or ascites.

Fluid and drug needs must be continually assessed in order to avoid congestion. Even in the absence of clinical signs of CHF, fluid supplementation should be closely monitored and discontinued if weight gain becomes excessive. In instances where signs of overhydration and congestion occur, fluid administration should be discontinued and diuretic therapy considered. Resting or sleeping (i.e., nonpanting) respiratory rates >40 breaths per minute are a sensitive indicator of early pulmonary edema. In patients with preexisting cardiac disease or in those receiving large doses of fluids, volume expansion puts additional stress on the cardiovascular system and heightens risk of congestion. Except in cases of systemic hypotension, dopamine is not indicated for management of patients with kidney disease because of the lack of proven efficacy and potential for adverse cardiac side effects, such as arrhythmias and sinus tachycardia. Renal replacement therapies, such as hemodialysis (see ch. 110), allow for better control of blood volume. Their role in the management of patients with CvRD warrants study.

General Considerations for Management of CvRD

Systemic Hypertension

Systemic hypertension, by virtue of its ability to cause both cardiac and kidney injury, is a leading cause of cardiorenal disorders in humans and is an important and likely underdiagnosed problem in dogs and cats. The detection and management of systemic hypertension is the subject of several comprehensive reviews,[10-12] as well as chapters in this textbook (see ch. 99, 157, and 158). In brief, accurate measurement of systolic blood pressure requires close attention to equipment and technique. Chronic treatment typically involves calcium-channel blockers (i.e., amlodipine) and ACEI (i.e., benazepril, enalapril) as first-line agents in cats and dogs, respectively. Other antihypertensive drugs, such as diuretics and beta-adrenergic blockers, are used as needed. The authors commonly recommend that cats with systemic hypertension receive combination therapy with both amlodipine and ACEI. In dogs and cats with CvRD, the goal is to maintain normal systolic

blood pressure between 120 and 160 mm Hg, preventing or minimizing hypertensive target organ damage. Typical target organs include the eyes, brain, vasculature, heart, and kidneys. As blood pressure increases above 160 mm Hg, potential for target organ damage increases and antihypertensive treatment is recommended, regardless of evidence for target organ damage. In both dogs and cats, moderate dietary Na restriction is recommended along with concurrent pharmacological therapy (see ch. 183 and 184).

Fluids, Diuretics, Cardiac, and Other Drugs

Animals with CvRD are less likely to be tolerant of extreme changes to volume status (see ch. 129). As such, dosages of diuretics, ACEI, inotropes and/or fluids should be carefully tailored to the needs of the patient, particularly considering body weight, each drug's elimination method, and relative severity of renal and cardiac function. Change in diuretics or fluids (type or dosage) are performed in a stepwise manner, with concurrent monitoring of hydration status, body weight, renal function, blood pressure, and resting heart and respiratory rates. When pets with AKI or CKD require volume expansion, fluid administration should be performed with caution. Low-Na parenteral fluids or Na-reduced enteral hydration via feeding tube should be used. However, any fluid type can precipitate CHF or a hypertensive crisis if saline content is high, if the fluids are administered too rapidly or if excessive volumes are given.

During treatment, the veterinary team members and/or owners should monitor the animals' renal function, respiratory rate and effort, food and water intake, body weight, and urine output. Ideally, within the first 3 to 5 days following any dosage adjustment, renal function, body weight, hydration, electrolyte status, and systemic blood pressure should be reassessed. Change in any parameter may signal changing disease status but could also indicate a change in hydration status and need for medication adjustment. In instances of severe CvRD, in which treatment balance is difficult to achieve, referral to a secondary or tertiary hospital should be considered. Ideally, a cardiologist and internist/nephrologist would jointly formulate diagnostic and treatment plans in patients with CvRD.

Drug Pharmacokinetics and Pharmacodynamics

Drug pharmacokinetic and pharmacodynamic properties can be altered in patients with impaired heart or kidney function. For example, decreased renal perfusion and/or tubular injury decrease active secretion of furosemide across proximal renal tubule cells, thereby decreasing furosemide concentration in the tubular lumen, binding to Na/Cl co-transporters, and expected diuretic response. Many commonly prescribed cardiovascular drugs, such as digoxin, enalapril and atenolol, are primarily excreted by the kidneys and may require dosage reduction in animals with AKI or CKD. Patients with CvRD may have metabolic acidosis or hypoalbuminemia. Dosages of drugs that are highly protein bound (e.g., pimobendan or digoxin) or altered by decreased pH may need to be adjusted. In animals with persistent third-space effusions, presence of ascites or pleural effusion will alter the volume of drug distribution, and drug dosing must then be performed on estimates of lean body weight to avoid overdosing.

Nutritional Support

Ensuring proper nutrition is an important component of managing CvRD (see ch. 183, and 184). The appetite and nutritional needs of the patient should be monitored, with consideration given to feeding a reduced Na and phosphate (PO_4) diet, while providing appropriate protein and caloric intake. Severe protein restriction, occasionally prescribed in animals with severe kidney disease, can contribute to cardiac cachexia in patients with coexisting heart disease (see ch. 177). The development of cardiac cachexia often necessitates a reduction in dosage, as the drug's volume of distribution or protein binding may be altered. Diets that are moderately Na-restricted are appropriate for animals with either kidney or cardiovascular disease. Severe Na restriction can lead to poor caloric intake due to decreased diet palatability or can contribute to dilutional hyponatremia in animals with severe heart failure. Animals with kidney disease may benefit from additional changes in nutrient content including, but not limited to, altering PO_4 and fatty acid content. As previously mentioned, dogs with end-stage heart disease typically lose muscle mass and body condition. Therefore, maintaining adequate protein and caloric intake is an important nutritional goal, and in animals with CvRD, these needs must be weighted against protein and PO_4 intake contributing to azotemia, progressive kidney injury, and clinical signs of uremia. Careful dietary planning, potentially in consultation with a veterinary nutritionist, is recommended.

CHAPTER 358

Diabetes Mellitus and Corticosteroid-Responsive Disease

Lucy J. Davison

Client Information Sheet: Diabetes Mellitus and Corticosteroid-Responsive Disease

The Dilemma

Corticosteroids have a wide range of indications for use in veterinary medicine (Table 358-1). Dogs (see ch. 304) and cats (see ch. 305) affected with diabetes mellitus (DM) commonly suffer from concurrent diseases, which might benefit from corticosteroid treatment; however, this situation leaves the clinician with a dilemma: Anticipated benefits of corticosteroid treatment must be carefully weighed against their potential detrimental effects on glycemic control such as profound insulin resistance. Further, an asymptomatic pre-diabetic pet may develop overt DM once treated with corticosteroids. This chapter reviews the topic of corticosteroid treatment in pre-diabetic and diabetic patients, including discussion of the associated risks and side effects, clinical decision making and potential alternative options for specific indications.

TABLE 358-1

Common Indications for Steroid Therapy and Possible Steroid Alternative or Steroid-Sparing Treatments That May Be Considered

SPECIALTY	CONDITION	USUAL INITIAL DOSAGE	CHRONICITY	POTENTIAL ALTERNATIVE TO ORAL STEROIDS OR POSSIBLE ADDITIONAL STEROID-SPARING MEDICATION
Dermatology	Urticaria (C, D)	Anti-inflammatory	Days	Antihistamines, topical steroid if localized
	Atopic dermatitis (C, D)	Anti-inflammatory	Weeks to months, possibly permanent	Cyclosporine,70 essential fatty acids,71 oclacitinib,70,72 immunotherapy
	Autoimmune diseases (e.g., pemphigus) (C, D)	Immunosuppressive	Weeks to months, possibly permanent	Cyclosporine73 ± azathioprine74 (D only), topical tacrolimus (D)75
Endocrinology	Primary hypoadrenocorticism (C, D)	Physiologic	Permanent	None but use lowest possible daily dose. Consider desoxycorticosterone plus a glucocorticoid76 if fludrocortisone impacting glycemic control via its glucocorticoid action.
	Atypical hypoadrenocorticism (cortisol deficiency) (C, D)	Physiologic	Permanent	None but use lowest possible daily dose
	Hypoadrenocorticism	Physiologic	Permanent	None but use lowest possible daily dose

	secondary to pituitary surgery (C, D)			
Gastroenterology	Inflammatory bowel disease (C, D)	Anti-inflammatory	Weeks to months, possibly permanent	Cyclosporine,77 dietary management, azathioprine (D only), chlorambucil78,79), budesonide,7 metronidazole
	Immune-mediated cholangitis, cholangiohepatitis or hepatitis (C, D)	Immunosuppressive	Weeks to months, possibly permanent	Cyclosporine, chlorambucil, budesonide, metronidazole
	Chronic pancreatitis (C)	Anti-inflammatory	Days	Dietary management, supportive care, antiemetics, antibiotics and analgesia64
Hematology	Immune-mediated hemolytic anemia (C, D)	Immunosuppressive	Weeks to months, possibly permanent	Intravenous gamma globulin and leflunomide80 (D only), cyclosporine, mycophenolate mofetil,81 splenectomy82
	Immune-mediated thrombocytopenia (mostly D)	Immunosuppressive	Weeks to months, possibly permanent	Intravenous gamma globulin and leflunomide80 (D only), cyclosporine
Orthopedic disease	Immune-mediated polyarthritis (mostly D)	Immunosuppressive	Weeks to months, possibly permanent	Cyclosporine (± nonsteroidal anti-inflammatories) or use of a second immunosuppressive to minimize steroid dose or leflunomide83
Cardiovascular system	Vasculitis (C, D)	Immunosuppressive	Weeks to months, possibly permanent	Alternative or steroid-sparing immunosuppressive drugs84 (e.g., cyclosporine85)
Neurologic system	Steroid-responsive meningitis and arteritis (mostly D)	Immunosuppressive	Weeks to months, possibly permanent	Low-dose nonsteroidal anti-inflammatory drug may be appropriate in mild cases86
	Brain neoplasia (C, D)	Anti-inflammatory	Potentially permanent if tolerated	Low-dose steroid may be preferable to surgery or euthanasia
Respiratory system	Asthma (C)	Anti-inflammatory	Weeks to months, possibly permanent	Inhaled steroids (e.g., budesonide,9 fluticasone), bronchodilators, cyclosporine87
	Eosinophilic bronchopneumopathy (D)	Anti-inflammatory	Weeks to months, possibly permanent	Inhaled steroid therapy8 (e.g., fluticasone)
	Secondary complications of parasitic disease (mostly D)	Anti-inflammatory	Days to weeks	Low-dose steroid may be preferable to the inflammation associated with severe parasitic disease
	Allergic rhinitis (mostly D)	Anti-inflammatory	Weeks to months, possibly permanent	Inhaled, nebulized or nasal drop steroids, or nonsteroidal anti-inflammatory with doxycycline88 (D)
	Chronic bronchitis (mostly D)	Anti-inflammatory	Weeks to months, possibly permanent	Inhaled steroid,8 bronchodilators

Ophthalmology	Uveitis (C, D)	Anti-inflammatory	Days to weeks	Topical steroid drops or consider systemic immunosuppression if appropriate
Renal	Glomerulonephritis (C, D)	Immunosuppressive	Weeks to months, possibly permanent	Mycophenolate mofetil,89 cyclosporine
Immunology	Anaphylaxis (C, D)	Anti-inflammatory	Days	Steroid treatment may be required as a lifesaving measure ± epinephrine
	Drug allergy (C, D)	Anti-inflammatory	Days	Dependent on the drug that has triggered the reaction, nonsteroidal anti-inflammatory or antihistamine may be appropriate in milder cases
	Chronic gingivostomatitis syndrome (C)	Anti-inflammatory or immunosuppressive	Months	Recombinant interferon omega90
Oncology	Chemotherapy protocols (C, D)	Anti-inflammatory	Permanent if tolerated in some cases	Steroid-sparing or steroid-free protocols (e.g., single agent doxorubicin for lymphoma91 [D]), Lomustine,92 or exclusion of prednisolone from the protocol

C, Cat; *D*, dog.

Corticosteroid Medications

Actions

Corticosteroids are synthetic analogues of the natural adrenocortical hormones (e.g., cortisol) and can have both glucocorticoid and mineralocorticoid activities.[1] *Glucocorticoid actions* include effects on carbohydrate, protein, and fat metabolism; insulin antagonism; and dose-dependent anti-inflammatory, immunosuppressive, vasoconstrictive and antineoplastic properties (see ch. 164 and 165). *Mineralocorticoid activity* mimics naturally occurring aldosterone and impacts electrolyte and water balance in the renal tubules, primarily leading to sodium and water retention with potassium loss (see ch. 67 and 68).

When treating DM, it is often the glucocorticoid-associated insulin antagonism that is most challenging to overcome because of its impact on glycemic control and appetite. Glucocorticoid receptors are widely expressed in the cytosol, and steroid therapy affects many body systems.[2] Glucocorticoids alter the expression of many anti-inflammatory and pro-inflammatory genes. Their overall effect is to reduce inflammatory and immune responses, making them the treatment of choice in many immune-mediated and inflammatory conditions (see ch. 198 and 201-204).[3] In addition to their effects on the immune system, corticosteroids also affect metabolism with a net effect of raising blood glucose concentration.[4,5] Glucocorticoids stimulate gluconeogenesis in the liver by increasing the expression of the enzymes involved in generating glucose from amino acids and glycerol.[4,6] They promote lipolysis, stimulate amino acid mobilization from tissues, and antagonize effects of insulin, inhibiting uptake of glucose into cells. In a healthy animal corticosteroid-induced, reduced peripheral insulin sensitivity is balanced by increased beta cell function. Hyperglycemia occurs if this compensation is not fully effective but this may be particularly problematic in diabetic or pre-diabetic patients.[2]

Compounds

Corticosteroid compounds have variable glucocorticoid to mineralocorticoid activity ratios, side effects, potencies and durations of action (Table 358-2). Some are predominantly glucocorticoid and others predominantly mineralocorticoid.[6]

TABLE 358-2

Comparison of Glucocorticoid and Mineralocorticoid Activities of Different Corticosteroid Drugs

DRUG	GLUCOCORTICOID PROPERTIES	MINERALOCORTICOID PROPERTIES	GENERAL THERAPEUTIC INDICATION
Glucocorticoids			
Hydrocortisone (S)	1	1	Relatively high mineralocorticoid activity makes it unsuitable for long-term use.
Cortisone (S)	0.8	0.8	Similar to hydrocortisone.
Prednisolone (I)	4	0.8	High glucocorticoid activity makes it useful for long-term treatment and as an anti-inflammatory and immunosuppressant.
Methylprednisolone (I)	5	Minimal	Anti-inflammatory and immunosuppressive.
Dexamethasone (L)	30	Minimal	Anti-inflammatory and immunosuppressive, used especially when water retention is undesirable as it has insignificant mineralocorticoid activity. Long duration of action makes it useful in some conditions.
Betamethasone (L)	30	Negligible	Anti-inflammatory and immunosuppressive, used especially when water retention is undesirable as it has insignificant mineralocorticoid activity. Long duration of action makes it useful in some conditions.
Mineralocorticoids			
Aldosterone	None	500	Useful in mineralocorticoid deficiency. No glucocorticoid activity, so not useful as anti-inflammatory or immunosuppressant.
Fludrocortisone	15	150	Useful in mineralocorticoid deficiency. Very low glucocorticoid activity, so not useful as anti-inflammatory or immunosuppressant.

I, Intermediate acting, biological half-life 18-36 hours; *L*, long acting, biological half-life 36-54 hours; *S*, short acting, biological half-life 8-12 hours.

Adapted from http://cks.nice.org.uk/corticosteroids-oral#!scenario.

Topical and Inhaled

In addition to parenteral formulations, some topical (eye, ear, skin) and inhalant medications contain anti-inflammatory doses of glucocorticoid. Since corticosteroids are generally metabolized by the hepatic p450 system, topical application bypasses the liver and its first pass effect, minimizing doses required and associated side effects.[6] Other steroid preparations include budesonide, a glucocorticoid designed for humans with Crohn's disease, which undergoes extensive first-pass hepatic metabolism resulting in local intestinal effects and, theoretically, avoiding systemic effects.[7] Fluticasone and budesonide may be used as inhaled forms for some respiratory diseases, but systemic effects have been demonstrated in cats and people, potentially having negative impact on glycemic control (see ch. 241).[8-11]

Oral and Injectable

Prednisolone is commonly used because of its high glucocorticoid to mineralocorticoid activity ratio. Prednisone is similar to prednisolone but less well absorbed orally in cats.[12] Dexamethasone has a similar glucocorticoid/mineralocorticoid ratio to prednisolone but is more potent, can be given orally or parenterally, and has a longer duration of activity. Cortisone and hydrocortisone are less potent glucocorticoids, although their relatively high mineralocorticoid activity can be of benefit in treating hypoadrenocorticism. The most commonly used oral mineralocorticoid drug is fludrocortisone, which is prescribed for hypoadrenocorticism. Although high dosages may result in signs of glucocorticoid excess, hyperglycemia is rare. The other major side effect of mineralocorticoid drugs (including desoxycorticosterone pivalate, which does not have any glucocorticoid activity) is potassium wasting. Therefore, it is important that electrolytes be monitored, especially in DM, where insulin may also reduce serum potassium.

Side Effects and Risks of Steroid Therapy in Diabetes Mellitus

Prior to making any recommendations regarding corticosteroid treatment in diabetic dogs and cats, it is necessary to review the pathogenesis of diabetes in these species and the side effects of steroid therapy (see ch. 304 and 305).

Canine Diabetes and Its Management

In dogs, DM (see ch. 304) is almost always a disease of total insulin deficiency and hence an insulin-dependent condition, with some similarities in its management to human type 1 DM.[13] DM is most commonly diagnosed in dogs older than 7 years of age, and most patients respond best to twice-daily insulin injections combined with a careful feeding and exercise routine to achieve glycemic control.[14] Unlike cats, diabetic dogs do not tend to have periods of diabetic remission, nor is there convincing evidence that obesity contributes to DM risk, although it can contribute to insulin resistance.[15-17] The underlying causes of insulin deficiency are heterogeneous in dogs, including exocrine pancreatic inflammation (acute or chronic pancreatitis), islet exhaustion as a result of chronic insulin resistance (e.g., hyperadrenocorticism, diestrus DM in females), and possible autoimmunity.[18,19] Reversible canine DM may occur in specific situations in which a syndrome of insulin resistance (such as pyometra) can be treated by ovariohysterectomy in a timely manner.[20] In general, however, DM in dogs is irreversible. Risk factors for DM in dogs include genetic factors, demonstrated by an increased prevalence in certain breeds (e.g., Samoyed, Tibetan Terrier, Miniature Poodle), as well as a greater risk in dogs with a history of pancreatitis, entire females, pregnant females and dogs with hyperadrenocorticism.[14,21-24] It may be prudent to avoid corticosteroid therapy in dogs with known DM risk factors, as they may already be pre-diabetic.

Feline Diabetes and Its Management

Feline DM (see ch. 305) shares many features with human type 2 DM, which is usually characterized by insulin resistance rather than deficiency.[13] In addition to breed-related risk factors (e.g., Burmese cats), obesity and inactivity increase risk of feline DM.[25] Most cats with acromegaly[26] (excess growth hormone secretion from a pituitary macroadenoma) and most with hyperadrenocorticism[27] have DM. Cats with acute or chronic pancreatitis are at increased risk of developing DM. Unlike dogs, there is no evidence for autoimmune DM in cats. Diabetic cats also often have some pancreatic beta cell function at the time of diagnosis.[25] The choice of therapy depends on blood glucose, clinical signs and underlying cause of insulin resistance. In some cases, mild disease can be managed with weight loss, a reduced carbohydrate diet and/or oral hypoglycemic medication. Increasingly, insulin therapy is employed early in the course of disease to try to achieve a period of DM remission.[28,29] Remission is possible in many cats with DM, even those with a history of diabetic ketoacidosis or pancreatitis at the time of diagnosis, but is less likely in cats with acromegaly or hyperadrenocorticism, particularly without specific treatment of the underlying condition.[30] Clinicians should avoid steroid use in normoglycemic cats with a history of DM, since they are likely to have reduced insulin sensitivity. Similarly, it is wise to avoid corticosteroid therapy where possible in non-diabetic cats with known risk factors, especially obesity and/or inactivity, since they may already be pre-diabetic.[31]

General Side Effects of Steroid Therapy

Corticosteroid therapy is associated with a range of potential side effects, even in healthy pets. The risk of side effects increases with dose and duration of treatment, and side effects are highly variable among individual patients receiving similar dosages, possibly due to variability in numbers of glucocorticoid receptors.[3] Dogs appear to suffer more steroid side effects than do cats. Cats may be more tolerant of higher dosages, although risk of DM being induced by corticosteroids may be higher in cats. It is also likely that very young and very old patients may be more susceptible to steroid side effects. Certain medications may also interact with glucocorticoids (e.g., ketoconazole [may decrease glucocorticoid metabolism], digoxin [may result in hypokalemia if given with prednisolone]), and thus concurrent treatments may increase risk of detrimental effects from corticosteroid therapy.

With long-term glucocorticoid use, especially at high dosages, dogs and cats may develop classic clinical signs of hyperadrenocorticism: abdominal enlargement, muscle wasting, polyphagia, bilaterally symmetric alopecia, polyuria, and polydipsia. Other potential side effects in addition to insulin resistance–induced

hyperglycemia include osteoporosis, destabilization of cardiovascular disease, hypertension, hyperlipidemia, muscle wasting, proteinuria, a hypercoagulable state and increased susceptibility to opportunistic infections (especially bacterial, fungal and yeast infections).[32]

Side Effects of Steroid Therapy in Patients with Diabetes Mellitus

Virtually all the steroid side effects discussed earlier are undesirable in DM, especially insulin resistance. Indeed, there is potential for certain steroid side effects to be more common or severe in DM, for several reasons. Firstly, the majority of DM dogs[22] and cats[33] are middle-aged or older, so they are more likely to have preexisting conditions (e.g., renal or cardiac disease that may be exacerbated by steroid therapy). Secondly, there is also considerable overlap in the clinical signs of DM and the side effects of steroid therapy (e.g., polyuria, polydipsia, polyphagia, liver enlargement, panting, weakness), some of which may be exacerbated by steroid treatment (e.g., polydipsia). In addition, since diabetic pets are at increased risk of infection[22,34] due to persistent hyperglycemia, employing steroids will exacerbate this risk via immune suppression. Furthermore, the insulin resistance as a consequence of infection may complicate things further. Although some effects of initiating corticosteroid treatment may be predictable and dose-dependent, the response of the DM patient depends on a range of individual factors, including presence of preexisting insulin resistance syndromes (e.g., acromegaly in cats; diestrus in dogs), the presence of infection or inflammatory disease and the current degree of glycemic control.[3] Corticosteroid-induced insulin resistance without adequate adjustments in insulin therapy may have catastrophic consequences, including the development of diabetic ketoacidosis or nonketotic hyperosmolar syndrome (see ch. 142). Conversely, overzealous increases in insulin dosage anticipating insulin resistance due to corticosteroid treatment may lead to dangerous hypoglycemic episodes and must also be avoided.

Decision Making in Treating Corticosteroid-Responsive Disease in Diabetic Patients

Overview

The decision to use corticosteroid-based medications in DM patients is challenging. Risks must be weighed against benefits (Figure 358-1). Corticosteroids are preferred to other drugs in many allergic, inflammatory and autoimmune conditions because of their effectiveness; their rapid action; and clinician familiarity with these drugs.[3] However, DM is a complex disease to manage and if any alternative is available, it should be considered. There are some situations where no alternative to steroid therapy exists, e.g., cortisol deficiency associated with hypoadrenocorticism (see ch. 309), where a daily physiological dose of corticosteroid is vital. Topical or local (e.g., inhaled) therapy may be preferable if appropriate, since this may limit systemic side effects (see Table 358-1).

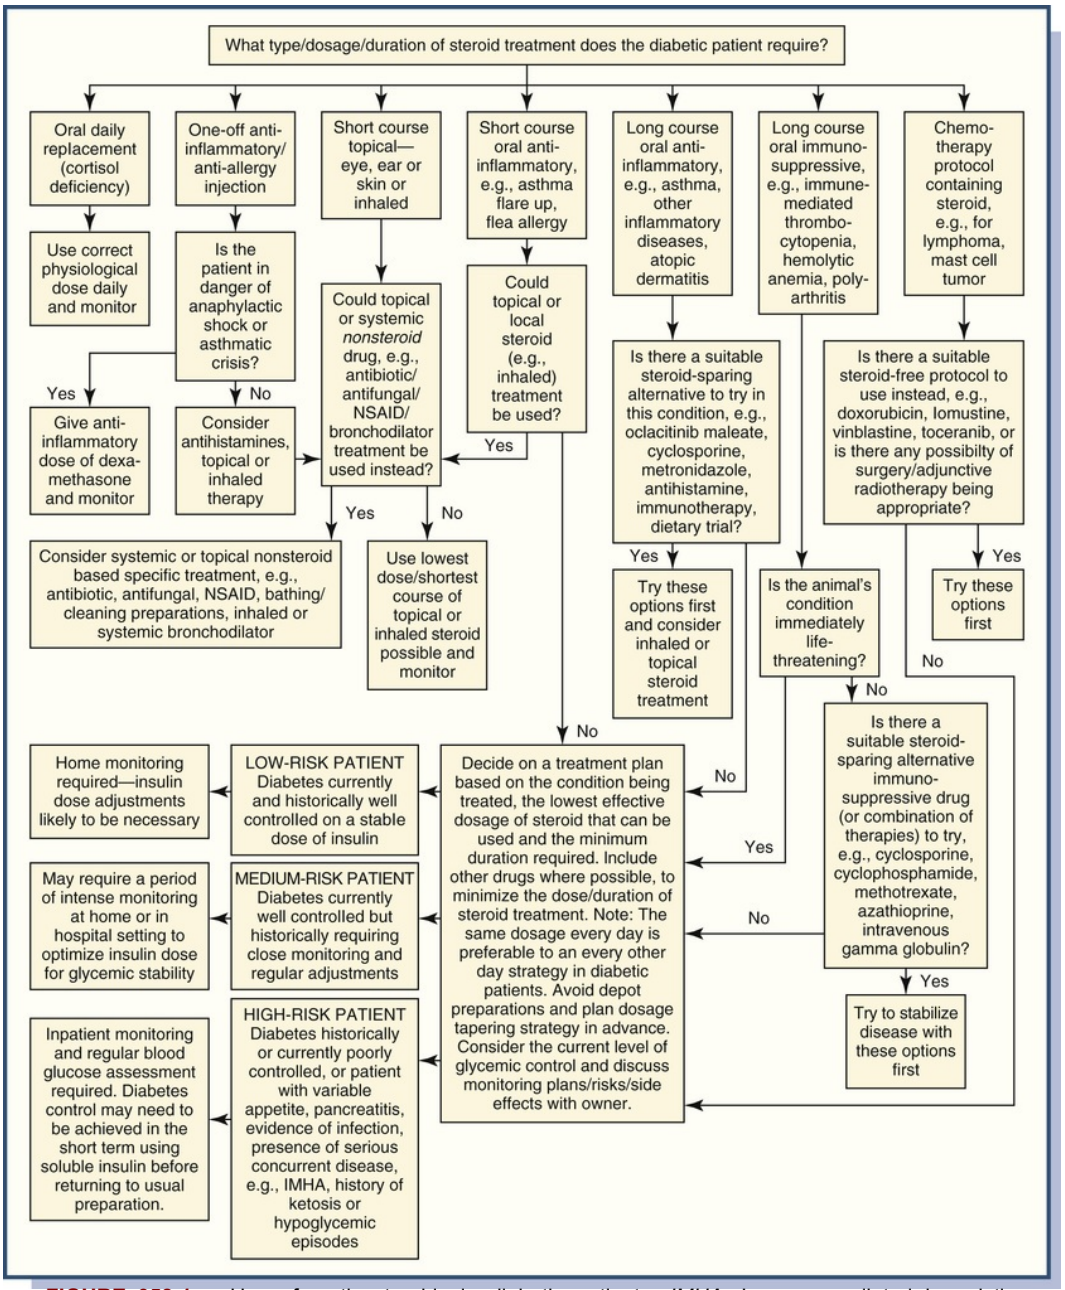

FIGURE 358-1 Use of corticosteroids in diabetic patients. *IMHA*, Immune-mediated hemolytic anemia; *NSAID*, nonsteroidal anti-inflammatory drug.

Steroid Treatment of Diabetic Humans

For type 1 and type 2 human DM patients, guidelines have been developed regarding treatment for common concurrent steroid-responsive diseases (e.g., asthma, inflammatory bowel disease or autoimmune diseases).[35] The most recent statements by the American Diabetes Association and the European Association for the Study of Diabetes emphasize the need for close monitoring and treatment targets individualized to each patient.[36] Various pre-emptive treatments may be used to stabilize blood glucose, tailored to the pharmacodynamics of the glucocorticoid employed.[37,38] No consensus on "best practice" has been developed, highlighting the difficulty in managing DM and a concurrent "steroid-responsive" condition.[39] Although there are likely to be species-specific differences between dogs, cats and humans, it is still beneficial to review the broad principles behind the human guidelines.

The effects of dexamethasone administration on blood glucose in humans occur within a few hours of administration and are dose dependent, with high-dose therapy increasing insulin resistance, characterized

by depressed peripheral utilization of glucose and impaired glucose transport in both preexisting and new-onset DM.[40,41] People with DM receiving steroid therapy more than once daily tend to be hyperglycemic throughout the day. Those receiving prednisolone only once daily, each morning, usually experience hyperglycemia in the afternoon and evening. Plasma prednisolone levels peak at 2-3 hours and return to baseline within 12 hours.[35,42] Adaptation in beta cell function to dexamethasone-induced insulin resistance is lacking in humans with low inherent insulin sensitivity.[43,44] Although dexamethasone-induced hyperinsulinemia is usually accompanied by normoglycemia at rest, the dynamic dysregulation of glucose homeostasis by steroids is emphasized by the presence of postprandial hyperglycemia in some individuals.[45] This effect of poor compensation can also be seen in obese rodent models and may be relevant to the use of corticosteroids in obese cats.[46] Such cats are already likely to have decreased insulin sensitivity and may therefore be at high risk of steroid-induced hyperglycemia and diabetes.[13]

Ulcerative colitis serves as an example of the individualized approach recommended with regard to steroid treatment of diabetic people. This first involves assessment of the DM and then assessment of risks and benefits of steroid therapy for the concurrent disease. In ulcerative colitis, decisions regarding treatment are based on activity and location of the disease.[47,48] In severe illness, the patient with *well-controlled* DM should be treated with corticosteroids. However, initiating corticosteroid treatment requires intense monitoring of blood glucose, evaluation for potential sepsis and ketoacidosis, as well as careful electrolyte control. If the ulcerative colitis patient has *unstable* DM, risk of steroid treatment is considered too high and alternative drugs are used (cyclosporine, monoclonal antibody therapy).[49] In more moderate ulcerative colitis with concurrent DM, to avoid systemic steroids, topical or oral mesalazine and topical steroid such as beclamethasone are recommended.

Evidence of Corticosteroid Impact on Glycemic Control in Cats

Immunosuppressive steroid treatment given to healthy cats resulted in significant increases in serum albumin, glucose, triglycerides and cholesterol after 56 days.[50] In a similar study, investigating the diabetogenic potential of prednisolone and dexamethasone, 14 healthy cats received daily prednisolone (4.4 mg/kg) or dexamethasone (0.55 mg/kg) for 56 days, followed by evaluation of urine glucose and serum fructosamine and glucose tolerance. At study completion, several cats were glycosuric and fructosamine concentrations were elevated. There was also a trend toward dexamethasone having more impact on blood glucose than prednisolone at "equipotent" doses.[5] In a separate study, healthy cats were treated with methylprednisolone by injection, resulting in a substantial increase in serum glucose concentration 3 to 6 days later. Variables only returned to baseline 16 to 24 days after treatment, with response kinetics varying between individuals.[51,52]

Evidence of Corticosteroid Impact on Glycemic Control in Dogs

The potential for corticosteroid therapy to impact blood glucose is illustrated clinically by two case reports of dogs with transient DM by prednisolone therapy.[53,54] Experimentally, in healthy dogs, methylprednisolone significantly enhanced gluconeogenesis and hyperglycemia induced by norepinephrine. This effect was most marked if the glucocorticoid had been given for at least 2 consecutive days prior to the epinephrine challenge, suggesting *de novo* synthesis of gluconeogenic enzymes, as well as more immediate effects.[4] Topical treatment with glucocorticoid has also been shown to impact blood glucose in dogs. Two topical dexamethasone applications (dermal and ototopical) were each associated with an exaggerated rise in insulin in beagles, despite maintenance of normal serum glucose levels.[55] Upon drug withdrawal, it took a week for insulin secretion to return to baseline. Similarly, in atopic dogs treated with prednisolone, serum fructosamine and glucose concentrations were not affected but serum insulin concentrations increased, emphasizing need for functioning and responsive beta cells to maintain euglycemia.[56] Effects of endogenous cortisol on glucose metabolism were examined in a canine DM model using an IV glucose challenge, demonstrating a tendency for glucose tolerance and insulin sensitivity to decrease after 60 minutes.[57] This emphasizes the relatively immediate impact of steroid treatment on glycemic control.

Use of Corticosteroids in Diabetic Dogs and Cats

In managing comorbidities, the optimal approach to treating combined disorders is not always the same as the sum of optimal treatments for the two disorders managed separately.[38] There is also a key difference

between canine and feline DM to consider: the question of insulin sensitivity and secretion. Diabetic dogs usually have no functional beta cells. Diabetic cats may have retained a significant number of functioning beta cells and it is important to preserve or even enhance their survival and function.[13] In some situations—life-threatening anaphylaxis as an example—immediate and short-term use of steroids takes priority over the potential impact on DM management.[3] However, in chronic immune-mediated or neoplastic diseases, consideration can be given to use of alternative immunosuppressive or chemotherapeutic drugs (see Table 358-1).[3] Alternative drugs may be used alone or in combination with lower steroid dosages to minimize impact on glycemic control. Local-acting steroid preparations may control some inflammatory conditions with fewer side effects, e.g., respiratory and inflammatory bowel diseases.[7,8]

Use of Alternatives to Corticosteroids

Importantly, some of the alternative immunosuppressive drugs also have the potential to negatively impact glycemic control or pancreatic function. For example, cyclosporine, an immunosuppressive drug used commonly in atopic disease, can increase glucose and fructosamine concentrations in dogs because of its negative effect on insulin secretion.[58] Arguably, cyclosporine has the potential to precipitate DM in dogs with impaired glucose tolerance.[59-61] It is unlikely, however, for the drug to significantly impact glycemic control of dogs already suffering from DM, as they have no functional islets. Similarly, the immunosuppressive drug azathioprine[62] (which is not recommended for cats) has been linked to the development of pancreatitis in dogs, a disease which is likely to complicate glycemic control.

Indeed, the relationship between corticosteroid treatment and pancreatitis is complex and not well characterized in either dogs or cats, although the disease is commonly associated with DM in both species (see ch. 290).[63] Some clinicians have successfully used anti-inflammatory doses of prednisolone to treat chronic pancreatitis in cats (see ch. 291), while *ex vivo* experimental evidence suggests that corticosteroids may actually have a detrimental effect on pancreas function in dogs.[65] Another option when using corticosteroids in DM, particularly cats, may be to consider the use of oral hypoglycemic drugs or insulin sensitizers such as pioglitazone, which appear to hold some promise in obese cats.[66,67] There is also potential benefit in chromium supplementation in cats with impaired glucose tolerance.[68]

Summary: Important Points When Considering Corticosteroids for Diabetic Dogs or Cats

Once the decision has been made to treat a diabetic dog or cat with corticosteroids, it is recommended that the following guidelines be considered:

1. Oral or parenteral corticosteroids should only be used where a firm diagnosis has been reached and only under careful supervision. The lowest effective dosage should be used, for the minimum period possible, avoiding the use of long-acting depot preparations.
2. The individual patient should be assessed for risk of disease exacerbation by steroid treatment. Clinicians should consider age, other comorbidities (especially infection and insulin resistance syndromes), other drug treatments (e.g., nonsteroidal anti-inflammatories) and the condition being treated.
3. The type and dose of glucocorticoid should be selected carefully and used to inform initial adjustments to the insulin regimen. Short-acting preparations are preferable.[37]
4. Although the diurnal variation in cortisol varies in dogs and little is published on the subject in cats, many veterinarians recommend dosing cats with steroids in the evening and dogs in the morning to minimize adrenal suppression.[69] Regardless of time and frequency chosen, it is important that these dosing times be adhered to in diabetic patients. This will minimize wide fluctuation in steroid concentrations and wide fluctuation in glycemic control. Once-daily dosing may be preferable to every other day protocols to make maintaining glycemic control easier (although this may lead to more adrenal suppression). In patients receiving twice-daily insulin, some clinicians elect to administer the steroid with the evening dose of insulin to minimize issues of postprandial hyperglycemia, since less food is generally consumed overnight than during the day. Alternatively, some clinicians may choose to split the daily steroid dose in two so that in each 12-hour period the patient receives the same food, the same dose of steroid and the same dose of insulin.
5. The clinician should recognize that for long-term steroid use, the insulin dosage is likely to require titration to suit the needs of the individual. Conversely, once steroid therapy is tapered, careful adjustment in insulin dosage must be made to avoid hypoglycemia.

6. Close monitoring of the patient is necessary. For low-dose steroid therapy in a stable diabetic animal, home glucose or urine monitoring to avoid profound hyperglycemia or ketosis may be appropriate, but for more severe disease or in previously unstable diabetic patients, monitoring in a hospital environment may be necessary. Close attention to blood glucose, electrolytes, pancreatitis, infection or destabilization of other diseases is required.
7. Where very high dosages of steroid are required, the patient has a poor appetite, pancreatitis or infection, consideration should be given to switching to a short-acting soluble insulin preparation during the initial phase of steroid therapy. This can be titrated more accurately according to blood glucose and appetite.
8. It is useful to provide the owner of the pet receiving treatment with a steroid information sheet (an example accompanies this chapter) to advise him or her about adverse effects and to ensure that treatment is tapered rather than stopped abruptly.

CHAPTER 359

Comorbidities Associated with Obesity

Angela L. Witzel

Obesity rates among human beings have risen dramatically in the past 30 years and are currently at epidemic proportions.[1] While adipose tissue was once considered a metabolically inactive energy storage depot, we now know a myriad of hormones, cytokines, and inflammatory mediators are produced and disseminated from fat tissue.[2] The combinations of excess mass exerting pressure and force on the body, low-grade inflammation causing oxidative damage, and hormonal alterations leading to metabolic disruption result in obesity being associated with and progressing to a variety of diseases. This chapter reviews the veterinary and applicable human literature to discuss the conditions in which obesity plays a prominent role in disease development or progression.

Being overweight can indirectly contribute to the development of some diseases because overall health assessments are more difficult in the obese patient. For example, abdominal palpation, thoracic auscultation, blood collection, cystocentesis, palpation of peripheral lymph nodes, and diagnostic imaging are all more challenging when thick layers of fat are present.[3] As a result, diagnosis of serious diseases like cancer, chronic kidney disease, and heart valve disorders may be delayed or missed. Obesity (see ch. 176) can also increase the risks and complications associated with anesthetic procedures. Excess adipose tissue can potentially lead to reduced cardiovascular reserves, increase the risk for respiratory compromise, and slow the recovery following inhalation anesthesia due to greater drug deposition in fat tissue.[4] Consequently, the odds of anesthetic death in cats weighing more than 6 kg are nearly three times higher than the odds in cats who weigh between 2 and 6 kg.[5]

Obesity's Impact on Respiratory Disease

It has been well documented in humans that obesity negatively impacts respiratory function. The average respiratory rate of obese patients (body mass index ≥ 40 kg/m^2) is 15 to 21 compared with 10 to 12 breaths per minute in normal-weight individuals.[6] Obese patients also tend to have reduced tidal and lung volumes. Possible mechanisms for the reduction in lung volume are that abdominal fat displaces the diaphragm into the abdomen or excess fat within the chest wall compresses the thoracic cage.[7] Compliance of the respiratory system is also reduced in obese humans due to a combination of limited chest wall and lung compliance. Mild hypoxemia is a common occurrence as well and may result from microatelectasis in the lungs. Weight reduction typically reverses these respiratory changes.[6]

There is only a handful of studies evaluating obesity's contribution to respiratory disease in veterinary patients. One study documented that obese cats have reductions in tidal and minute volume and decreased peak inspiratory and expiratory flows when compared with normal-weight cats.[8] Respiratory tidal volume is also reduced in obese dogs.[9] One notable difference between dogs and cats is the effect of obesity on resting respiratory rate. Obese dogs had their mean respiratory rates increase threefold (11.41 ± 0.94 vs. 33.80 ± 7.89).[9] In contrast, the resting respiratory rates of obese cats did not differ from those in lean cats.[8] Another characteristic respiratory change in obese dogs is increased bronchoreactivity.[9] This may contribute to bronchospasm and is closely associated with asthma and chronic obstructive pulmonary disease in humans.[10]

Anecdotal reports suggest obesity contributes to the severity of certain upper airway diseases such as laryngeal paralysis and tracheal collapse in dogs and asthma in cats (see ch. 241).[11] In humans, obesity is a risk factor for obstructive sleep apnea (OSA), which is the result of pharyngeal dilator muscle relaxation and collapse of the upper airway during inspiration (see ch. 238).[12] The English Bulldog is considered a potential model for OSA.[13] While OSA can lead to hypoventilation and hypercapnia in either asleep or conscious

humans,[14] changes in $PaCO_2$ were not detected in obese dogs under heavy sedation before or after weight loss.[15] While only a few studies have evaluated the connection between obesity and respiratory disease in veterinary medicine, a strong relationship has been established in humans and obese dogs and cats are likely to have similar respiratory consequences. More research is needed to further explore the impact of obesity on respiratory diseases like asthma, OSA, laryngeal paralysis, and tracheal collapse in veterinary patients (see ch. 176, 238, 239, and 241).

Obesity's Impact on Cardiovascular Disease

The link between obesity and cardiovascular disease in humans is well established and focuses primarily on the development of ischemic heart disease and hypertension.[16,17] Obesity appears to have some influence on the development of hypertension in dogs, but the changes attributed to weight gain are mild (5 to 20 mm Hg) and unlikely to have pathologic consequences.[18-20] A consensus statement by the American College of Veterinary Internal Medicine concluded that obesity has minimal impact on the pathogenesis of canine and feline hypertension.[21]

Atherosclerosis is rare in dogs and cats and does not appear connected to obesity.[20] While obese dogs will have elevations in serum total cholesterol and triglycerides, the concentrations remain below levels expected to be atherogenic.[20,22,23] In a study comparing chronically obese cats with lean cats, total cholesterol levels were not different but triglyceride concentrations doubled (21 vs. 48 mg/dL).[24] Dogs and cats have key differences from humans that may protect them from developing atherosclerosis and myocardial infarctions. First, they have high concentrations of high-density lipoprotein (HDL) cholesterol. HDL cholesterol is important for reverse cholesterol transport, which moves cholesterol from arteries and peripheral tissues to the HDL molecules for disposal by the liver.[25] Dogs and cats also appear to lack the enzyme cholesterol ester transfer protein (CETP), which aids in reverse cholesterol transport.[26] CETP has the potential to be atherogenic by increasing the number of very-low and low-density lipoprotein (VLDL and LDL) cholesterol molecules.[25]

Although obese dogs may not have clinically significant risks of ischemic heart disease or hypertension, there are documented structural changes to the heart. Left ventricular (LV) hypertrophy occurs in obese dogs and can be corrected with weight loss.[27-29] In humans, obesity-associated LV hypertrophy is thought to be the result of mild elevations in blood pressure or secondary to chronic hypoxemia from OSA.[30]

In humans, being overweight or moderately obese is associated with increased survival rates in patients with heart failure (the "obesity paradox"; see ch. 177).[31] However, this relationship is less evident in dogs and cats. In a study of 101 cats with heart failure secondary to cardiomyopathy, there was a U-shaped association between body weight and survival time where the lightest and heaviest cats had shorter survivals compared with cats in the center of the curve.[32] While there was no significant relationship between body condition score (BCS; see ch. 2, 170, and 177) and survival, the body weight findings could suggest that cats who are mildly to moderately overweight may benefit from a protective factor.[32] In a similar study evaluating dogs with heart failure, survival time was also not correlated to BCS.[33] While there are several theories explaining why overweight humans are more likely to live longer with heart failure than lean individuals, the fact that myocardial infarctions and ischemic heart disease are the most common causes of heart failure in human means extrapolations to dogs and cats are unreliable.[31] In summary, the cardiovascular consequences of obesity in dogs and cats are not as apparent as in humans.

Obesity's Impact on Musculoskeletal and Intervertebral Disk Disease

In humans, obesity is a well-recognized risk factor for the development of knee osteoarthritis (OA).[34] The combination of increased joint load and changes in the direction of joint forces secondary to instability account for increased risk of OA development with obesity.[35] While changes in biomechanical forces contribute to OA in the knee, there are also associations between obesity and OA in non-weight-bearing joints such as the hand.[36] It is well established that obesity leads to a state of chronic low-grade inflammation. Increases in reactive oxygen species, inflammatory mediators, advanced glycosylated end products, and hormones like leptin may also contribute to the development and/or progression of OA.[37]

Results from a series of projects utilizing data from a now classic lifetime study on canine obesity have shown a direct impact of being overweight on the development and severity of osteoarthritis (see ch. 187 and

353).[38-40] Forty-eight Labrador puppies were evaluated for radiographic evidence of osteoarthritis at various time points throughout their lives. Half the puppies in the study were fed *ad libitum* for the first 3 years of life (control group), and the other half were fed 75% of the food consumed by controls (restricted group). The control group dogs had higher BCS throughout life (6.7/9 vs. 4.6/9 at age 12).[41] The dogs who were restricted in their calorie intake had a reduced prevalence and later onset of hip osteoarthritis when compared with controls (12 vs. 6 years of age).[40] Overweight dogs in the study also had increased radiographic severity of elbow and shoulder arthritis.[38,39] While the results of these studies provide clear evidence that being overweight impacts the development and progression of OA, the dogs in these studies were only mildly overweight with average body condition scores of 6.7/9 at age 12. The results would likely be more dramatic in a population of obese or morbidly obese dogs. In addition to studies showing that being overweight contributes to OA in dogs, there is also evidence that weight reduction can improve clinical signs of arthritis. Weight reduction of just over 6% resulted in decreased lameness in a study of 14 obese client-owned dogs with OA.[42]

Obesity not only affects the development of OA but is also a major contributor to other orthopedic diseases in dogs. Obese dogs are four times more likely to have a single cranial cruciate ligament rupture, and overweight dogs are almost twice as likely to have bilateral tears.[43,44] Hip dysplasia is also less likely in lean compared with overweight Labrador Retrievers.[45] The risk of developing intervertebral disk extrusion (IVDE; see ch. 266) is also increased in obese dogs of various breeds and sizes.[46] For example, Miniature Dachshunds with body conditions scores of 9/9 are about 4 times as likely to have IVDE compared with lean Dachshunds.[46]

Compared with dogs, the research connecting obesity to musculoskeletal disease in cats is sparse. In an epidemiologic study of almost 1500 cats, overweight cats were almost 5 times more likely to require veterinary care for lameness compared with ideal weight cats.[47] In a separate study of approximately 8000 cats, overweight cats had slightly higher rates of arthritis (0.4% vs. 0.3%) and obese cats had higher rates of musculoskeletal disease (0.8% vs. 0.7%) compared with ideal weight cats.[48] A prospective study of evaluating the rate of osteoarthritis in 100 cats greater than 6 years of age found no correlations between OA and BCS. However, only 14 cats in the study had a BCS greater than 6 on a 9-point scale, and none of those cats were scored a 9.[49] It is clear that more research is needed to understand the impact of being overweight or obese on musculoskeletal disease in cats.

Urinary Disease

Obesity is a systemic disease with inflammatory mediators, cytokines, and hormones that affect almost every organ, including the kidneys. In humans, obesity has been linked with higher rates of proteinuria, renal insufficiency, chronic renal failure, and mortality among dialysis patients.[50] Obese patients have higher renal plasma flow, filtration fractions, and glomerular filtration rates when compared with nonobese individuals.[51,52] In addition, renal mass and the diameter of the glomeruli also increase with weight gain.[53] Increased glomerular size without concurrent expansion of podocytes supporting the glomerular basement membrane could lead to gaps and loss in protein filtration selectivity.[50] If podocytes detach or are unable to cover the basement membrane, these areas can become denuded with subsequent glomerulosclerosis.[54] Obesity also stimulates the renin-angiotensin-aldosterone system (RAAS), leading to glomerular hypertension.[50]

In a study evaluating the incidence of proteinuria in overweight and obese dogs, there was no significant difference between dogs with body condition scores greater than or less than 6 on a 9-point scale.[55] In humans, being obese is more likely to result in renal changes than being overweight and while the data were suggestive, this study did not have enough obese dogs (n = 6 out of total n = 44) to detect significant differences in an obese subgroup.[55,56] When obese dogs were enrolled in a weight loss program, multiple markers of early renal disease improved including urine protein-creatinine ratio, urine albumin corrected by creatinine, urine specific gravity, homocysteine, cystatin C, and clusterin.[57] With the high rates of obesity and kidney disease in dogs and cats, characterizing the relationship between these diseases may lead to better treatment and prevention of chronic kidney disease.

In humans, it is well established that obesity increases the risk of kidney stone development.[58] Calcium stones make up the majority of kidney stones in humans, and obesity appears to increase oxalate and reduce calcium oxalate stone inhibitors like magnesium and citrate in the urine.[59] Associations between urinary

bladder stones and obesity in humans have not been determined, and little data are also available for dogs or cats. A recent study evaluating risk factors for calcium oxalate bladder stone development did not find dogs with higher BCS to be at increased risk.[60] An older epidemiologic study found that about 29% of dogs with urolithiasis were also overweight.[61] However, the rate of obesity in the general study population was not provided. While there is some evidence that obesity could contribute to the development of urinary tract stones in dogs, more data are needed to determine if obesity is a significant factor in disease development.

While urinary disease is abundant in felids, there are almost no data evaluating the role of obesity in renal or lower urinary tract disease in cats. Obesity appears to increase the risk of feline idiopathic cystitis (FIC) (see ch. 334).[62] However, some risk factors for FIC also predispose to obesity. For example, indoor cats are more likely to be inactive and gain weight and the lack of environmental enrichment is also thought to contribute to stress-induced cystitis.[62] A study looking for risk factors associated with the diagnosis of chronic kidney disease (CKD) in cats found an inverse relationship between BCS and disease development.[63] This study evaluated cats that were already diagnosed with CKD, and weight loss is often a manifestation of the disease. Therefore, it is difficult to determine if being overweight or obese lowers the risk of disease development, or if being thinner is just a disease sequela. In a separate study, the prevalence of urinary disease was approximately 1.5 times higher in obese and overweight cats compared with normal and underweight cats.[64] Given the clear associations between obesity and urinary disease in humans, more work needs to be done in dogs and cats to determine if epidemiologic associations translate to causative factors.

Cancer

Increased adiposity is estimated to cause approximately 20% to 35% of all human cancers.[65] In 2007, the World Cancer Research Fund found that obesity was associated with increased rates of renal carcinomas, colorectal cancer, and postmenopausal breast cancer.[66] Other meta-analyses also showed relationships between obesity and prostate, endometrial, and esophageal cancers; hematologic malignancies; malignant melanoma; and large B-cell lymphomas.[67-74] As adipose tissue expands, the adipocytes move further from the vasculature and local hypoxia of the tissue occurs.[74] This hypoxia results in low-grade, chronic inflammation as proinflammatory cytokines, such as TNF-alpha, interleukin 6, monocyte chemotactic protein, leptin, and plasminogen activator inhibitor type 1, are released.[75,76] In addition to inflammatory cytokines, the adipose stromal/stem cells (ASCs) can increase proliferation and metastasis of cancer cells. ASCs can differentiate into mesenchymal tissue and are immune privileged since they do not express MHC class II molecules. ASCs can also be recruited to tumor sites and, as in the case of breast cancer, increase the release of tumor-promoting factors.[74] The mechanisms behind obesity and cancer development are also tumor specific. For example, alterations in reproductive hormones are important factors for breast and endometrial cancers while increased insulin production is more likely to affect colon and prostate cancers.[65,77] Many other cancer types may develop secondary to inflammatory conditions.[65]

Another area of concern regarding obesity and cancer is the effect of excess body weight on chemotherapy dosage. Fears of overdosing obese patients using their current weight instead of a more ideal weight are generally considered to be unfounded in human medicine. A consensus article by the American Society of Clinical Oncology recommends dosing chemotherapeutics on current body weight or using a fixed dosage, regardless of body mass index.[78]

While there is clear evidence that obesity contributes to the development and progression of multiple cancer types in humans, there is far less evidence in dogs and cats. Overweight and obese dogs appear to have a greater risk of bladder and mammary cancers.[79-81] There are likely connections between adiposity and other tumor types in dogs and cats, but more research is needed to determine if such relationships exist.

Endocrine Disease

Since the discovery of the adipose hormone leptin in 1996, thousands of investigators have confirmed that fat tissue is an active endocrine organ. However, the goal of this section is to discuss obesity's role in the development or management of clinical endocrine disease. The quintessential obesity-related endocrine disease is type 2 diabetes mellitus (see ch. 304 and 305). It is well established that obese individuals are less sensitive to the effects of insulin in peripheral tissues like muscle, liver, and adipose. As excess free fatty acids are deposited into tissues, they disrupt insulin signaling, insulin-mediated glucose uptake, and glycogen synthesis.[82,83] As a result, glucose accumulates in the bloodstream. Prolonged hyperglycemia damages

pancreatic beta cells that secrete insulin. This damage likely results from a combination of ever-increasing insulin production and the accumulation of reactive oxygen species. Eventually beta cells become "exhausted" and hypoinsulinemia occurs.[84] Once insulin production is unable to keep up with circulating glucose levels, diabetes mellitus occurs.

Numerous studies have confirmed a direct association between obesity and type 2 diabetes mellitus in cats (see ch. 305).[85-89] Appleton et al. demonstrated that weight gain of just under 2 kg reduced insulin sensitivity by approximately 50%.[85] Obese cats are also almost four times more likely to develop diabetes mellitus compared with ideal weight cats.[47]

The association between obesity and diabetes is less clear in dogs (see ch. 304). While obesity has been shown to induce insulin resistance in dogs,[23] this does not appear to progress to type 2 diabetes, and type I diabetes is far more common.[90] There are notable differences between species that develop type 2 diabetes (humans and cats) and dogs. First, dogs do not spontaneously form aggregates of islet amyloid in their pancreas. Islet-amyloid polypeptide (IAPP) (a.k.a. amylin) is cosecreted with insulin. As insulin and IAPP production increase to combat hyperglycemia, toxic intracellular oligomers of IAPP and extracellular amyloid are deposited in the pancreas of humans and cats, but not dogs.[90] Another potentially key difference between humans, cats, and dogs is the first-phase insulin response. Despite years of obesity and documented insulin resistance, dogs still manage to secrete adequate amounts of insulin immediately following a glucose challenge.[91] Blunting of the initial insulin response to glucose in humans is considered an important marker of beta cell damage in humans.[92]

While the impairment of insulin sensitivity that accompanies obese dogs can potentially make regulation of type 1 diabetes more difficult, obesity is probably not a critical factor in disease development. With that being said, obese dogs are at a slightly higher risk of developing pancreatitis and have a higher prevalence of diabetes mellitus compared with lean dogs (0.7% vs. 0.3%).[48,93]

The relationship between obesity and other common endocrine disorders besides diabetes mellitus in dogs is also unclear. While obesity can be a side effect of hypothyroidism (see ch. 299) and hyperadrenocorticism (see ch. 306), it does not appear to be a causative factor. In humans, thyroid-stimulating hormone negatively correlates with resting energy requirements, even when serum thyroid-stimulating hormone (TSH) concentrations are within normal limits.[94] In a study evaluating hormonal function of obese dogs with no clinical signs of endocrine disease, TSH levels were elevated (>0.5 ng/mL) in 15 out of 31 dogs. Eleven out of the 15 dogs with elevated TSH also had low free T4 values. Of the 20 obese dogs that did not have a classic pattern of hypothyroidism on test results, only 13 had both normal free T4 and TSH.[95] The implications of this study are that obesity may interfere with thyroid function, but it could also be that subclinically low thyroid levels contributed to the development of obesity (see ch. 299 and 300).

Central adiposity is a hallmark of hypoadrenocorticism or Cushing's disease in both humans and dogs.[96] Treatment of the disease typically results in a loss of abdominal fat. There is little information regarding the role of obesity in the development of Cushing's disease in dogs, and excess adiposity is seen more as a side effect than a comorbidity.

Exercise-Limiting Disorders

The benefits of exercise in maintaining both physical and mental health in humans are well-established.[97] Anxiety, depression, muscle strength and flexibility, cancer, cardiovascular health, and chronic health conditions are all improved with regular physical activity.[97-100] In addition, moderate exercise and physical fitness reduce mortality rates. For example, one study showed runners with low to moderate intensity running habits had a 30% lower risk of all-cause and a 45% lower risk of cardiovascular mortality with an increased life expectancy of 3 years.[101] The Centers for Disease Control and Prevention currently recommend adults receive about 2½ hours of moderate aerobic activity combined with 2 days of weight training per week.[102]

Little work has been done in veterinary medicine to establish the health benefits and optimum levels of exercise in dogs and cats. However, studies in dogs suggest exercise can reduce noise sensitivity and separation anxiety behaviors, improve the quality of life for patients with chronic mitral valve disease, and lower body weight and BCSs.[103-106] Most of the work related to cats and exercise has focused on the negative relationship between physical activity (indoor vs. outdoor lifestyle) and BCS.[107,108]

One's ability to exercise consistently can be affected by many diseases including obesity, heart disease, respiratory disease, orthopedic pain, neurologic abnormalities, and systemic illnesses, which result in lethargy and malaise. The benefits of exercise go beyond weight management, and physical activity should be encouraged in all our veterinary patients. In addition, veterinarians should be cognizant of the barriers to exercise in our patients and help facilitate more activity. Examples include pain control for patients with orthopedic disease and weight reduction for obese animals. Given the results in humans, even low-intensity exercise is likely to provide health improvements in dogs and cats.[109,110]

Summary

Obesity is the most common form of malnutrition in dogs and cats and with prevalence rates of greater than 35%. It is one of the most common diseases found in companion animals.[48,64,111-113] The physiologic consequences of obesity are numerous and stem from combinations of inflammatory, hormonal, and mechanical changes in the body. The impact of obesity on overall health can be demonstrated by its effect on mortality. In a lifetime study of overweight dogs versus lean dogs, the leaner dogs lived almost 2 years longer on average.[114] Obesity management is critical for preventing or treating conditions related to respiratory, cardiac, urinary, musculoskeletal, and endocrine systems. Obesity also appears to influence the outcomes of several types of cancer. In addition, physical activity is likely to improve the mental and physical health of dogs and cats. The inability to exercise should be considered a comorbidity to conditions which preclude regular physical activity such as obesity, arthritis, cardiac, and respiratory disease.

CHAPTER 360

Concurrent Infection and Immune Suppression

Nathaniel T. Whitley

Client Information Sheet: Infections in Pets with a Suppressed Immune System

A functional immune system protects against pathogens and emergence of neoplasia while preventing adverse responses to self-antigens and harmless commensal, environmental, and food antigens. Whenever the immune system is compromised, there is a risk of infection. Immune compromise occurs due to use of immunosuppressive drugs (ID), congenital immunodeficiency, or acquired immunodeficiency states (which include pathogen damage to host tissues and pathogen subversion of the immune response). Hence, clinicians are frequently required to prevent, diagnose, and treat infection in the face of immunosuppression. This comorbidity presents numerous challenges. Some infections are only seen in immunocompromised patients (e.g., *Pneumocystis jirovecii* pneumonia), and awareness of such unusual pathogens might be low. Some clinical signs attributed to common infections in immunocompetent individuals are the result of immune activation and associated inflammatory responses, which can be impaired or absent in immunosuppressed individuals. Heightened vigilance is required in such patients and sometimes active surveillance and monitoring by laboratory testing for infection. Commercial assays to interrogate many components of the immune response are not available. Therefore, some immunodeficiency states may be suspected or inferred from patterns or infection but are difficult to diagnose definitively without access to a research laboratory.

Infection and Immunosuppressive Drug Use

Infection and Treatment of Immune-Mediated Disease

Autoimmunity in the absence of an identifiable trigger is referred to as primary (idiopathic) autoimmunity. When an infection provokes an immune response against host tissues, this is secondary autoimmunity. However, some infections mimic autoimmunity and it is likely that some conditions currently regarded as primary autoimmunity may be recognized as infectious disorders in the future. A notable recent example of this shift is histiocytic ulcerative colitis in Boxers, which was long considered to be an idiopathic, immune-mediated disease, but recent studies have shown that it is caused by adherent and invasive *E. coli* and responds to appropriate antibiotics (see ch. 277).[1] Infections triggering secondary autoimmunity or mimicking primary autoimmunity sometimes may only be unmasked following weeks or months of ID therapy (e.g., bacterial endocarditis), so constant vigilance and monitoring are appropriate. Immunosuppressive therapy frequently needs to be commenced at short notice, but before prescribing it, the veterinarian should perform an appraisal of previous and ongoing disease states that may confer an increased risk of infection, in order to fully inform the owners, address treatable comorbidities, and plan any supplementary therapy and monitoring. Examples of such considerations are listed in Table 360-1.

TABLE 360-1

Guidelines on Prescribing Immunosuppressant Drugs—Pretreatment Considerations That Influence Risk of Infectious Complications

PREEXISTING FACTOR OR COMORBID CONDITION AND EXAMPLES	INFECTIOUS COMPLICATION THAT COULD BE PRECIPITATED OR WORSENED BY IMMUNOSUPPRESSANT DRUG USE	COMMENT

Latent infection		
Feline calicivirus (see ch. 229) Feline herpesvirus (see ch. 229) Canine herpesvirus (see ch. 228) *Toxoplasma gondii* (see ch. 221)	Reactivation of latent infection and virus shedding	Most cases of *Toxoplasma* reactivation have been associated with cyclosporine therapy
Surgical implants		
Orthopedic—prosthetic hip Cardiac—pacemaker generator and lead (see ch. 249)	Infected implant/osteomyelitis	
	Infected unit/lead/endocarditis	
Urinary tract—urethral and ureteral stents, ureteral bypass devices (see ch. 124)	Urinary tract infection	Urinary tract implants are still relatively new to veterinary medicine; consequently, best practice recommendations for infection surveillance and management are still evolving
Intravenous catheters		
Jugular catheter (see ch. 76)	Local phlebitis, infected thrombus	Potential for embolization of infected material from catheter
Feeding tubes		
Esophagostomy (see ch. 82) Percutaneous endoscopic gastrotomy (see ch. 82)	Bacterial or fungal infections of the skin or stoma, local abscessation	Many immunosuppressants impede wound healing, compromising formation of stable adhesions between the skin and the esophageal or gastric lumen
Body surface inflammation/infection		
Gingivitis/periodontal disease (see ch. 272) Pyoderma Otitis externa (see ch. 237)	Bacteremia	
Severe osteoarthritis		
Legacy of elbow osteochondritis in aged Labrador Retriever (see ch. 353)	Septic arthritis	Blood flow and lymphatic drainage are compromised around severely arthritic joints
Prolonged recumbency		
Pressure sores Reduced clearance of airway secretions	Local pyoderma, abcessation, bacteremia, pneumonia, rhinitis	
Airway compromise		
Laryngeal paralysis (LP) (see ch. 239)	Aspiration pneumonia	Risk still applies following surgical correction. LP often is the first manifestation of a more generalized neuropathy
Dysphagia		
Megaesophagus (see ch. 273)	Aspiration pneumonia	Particular care is required when glucocorticoids are prescribed, as they can exacerbate muscular weakness
Congenital cardiac defect		
Severe subaortic stenosis (see ch. 250)	Bacterial endocarditis	Disease association has been described mainly with subaortic stenosis but may also apply to other

		congenital defects

Many autoimmune diseases are ultimately life-threatening and have a tendency to relapse; therefore, high-dosage, long-duration, generalized (nontargeted) immunosuppressive therapy has been the norm. There is considerable scope for refinement and reduction of current ID use by careful choice of ID, dosage, duration, and monitoring, which should reduce all complications, including infection. See ch. 165 and Box 360-1 for further information.

Box 360-1

Guidelines on Refinement and Reduction of Immunosuppressive Drug Use to Reduce Risk of Infection

1. **Does the disease require ID use?** Not all autoimmune diseases do. For example, canine acquired myasthenia gravis has the potential for spontaneous remission with appropriate supportive care and anticholinesterase therapy.[2]
2. **Consult the latest literature on the disease in question.** Some good-quality, prospective, and often placebo-controlled studies are emerging, improving the level of evidence available to guide prescribing practices. For example, sequential studies on canine immune-mediated thrombocytopenia showed that vincristine in combination with glucocorticoid therapy reduced time for platelet count to increase, resulting in shorter hospitalization times, and that vincristine was as effective as IV human immunoglobulin in this role.[3-5]
3. **Make the best use of available monitoring options**—In dogs with idiopathic immune-mediated polyarthropathy, serial measurements of C-reactive protein (CRP) and interleukin-6 correlate well with levels of disease activity and synovial inflammation, providing objective information to guide weaning of immunosuppressive drugs while reducing the need for serial arthrocentesis[6] (reducing risk of morbidity). Commercial CRP assays are widely available.
4. **Use short-acting, oral, injectable, or topical glucocorticoids,** rather than long-acting or depot preparations, such that immunosuppression is likely to rapidly subside on discontinuing the agent. Consider dosing prednisolone on a body surface area (BSA) basis for larger dogs, rather than dosing based on body weight. Suggested maximum immunosuppressive dose: 50 mg/m^2/24 h (Trepanier L, personal communication, April 8, 2015).
5. **Pharmacogenomics**—Be aware of the potential for individual or breed-related variations in the ability to metabolize or transport drugs in and out of cells. Examples include variation in levels of thiopurine methyltransferase (the enzyme that metabolises azathioprine) and mutations influencing the expression of the drug efflux transporter molecule p-glycoprotein. Some chemotherapeutic agents (doxorubicin, vincristine, vinblastine) are substrates of p-glycoprotein.[8]
6. **Drug interactions**—For example, cyclosporine has numerous potential drug interactions due to its metabolism by cytochrome P450.[9]
7. **Consider monitoring blood levels of the drug** (e.g., there are commercial assays for cyclosporine and leflunomide) to ensure adequate blood levels are achieved as quickly as possible while avoiding overdosage with the associated increase in risk of infection. For cyclosporine, pharmacodynamic monitoring is also available (measurement of activated T-cell mRNA for interleukin 2 and interferon gamma) for further refinement of drug dosing in individual dogs.[10] It is likely that further assays of drug levels and effect will become available in the future.
8. **Scan the horizon**—New drug agents will allow better targeting of specific immune response pathways implicated in specific disease conditions, for which a more potent drug causing more generalized immunosuppression would have been used in the past. Examples include the Janus Kinase inhibitor oclacitinib, approved for use in canine atopic dermatitis[11] and emergent "caninized" monoclonal antibody therapy.[12]

Managing Infection in Patients Being Treated with Immunosuppressive Drugs for IMD

The countless permutations of this comorbidity make it impossible to design a universal algorithm to guide the clinician through every scenario. In some cases, decision making is straightforward. The following case scenarios are typical examples:

- Asymptomatic urinary tract infection with a bacterium that is sensitive to a wide range of antibiotics is documented on routine monitoring in a dog that is being weaned off glucocorticoid therapy. In the first instance, a 7- to 10-day course of bactericidal antibiotics is prescribed, followed by repeat urine culture 7 days after completion of the antibiotic course.
- Mild upper respiratory tract signs consistent with reactivation of latent herpesvirus develop in a cat that is being treated with glucocorticoids and cyclosporine for idiopathic immune-mediated hemolytic anemia, which has just gone into remission. Provided the upper respiratory signs remain mild and nondebilitating, no treatment adjustments are required. If the signs become debilitating, the clinician will need to provide an augmented level of supportive care and consider reducing the dosage of one of the IDs sooner than originally planned. Antiviral therapy could also be instituted.

In other cases, typically those in which life-threatening infection develops in a patient with autoimmunity that is itself either debilitating or life-threatening, decision making will be considerably more challenging. Here, answers are often based on professional opinion born from experience, anecdote, or weak levels of published evidence. This should not detract from the importance of asking these questions, making prompt decisions and frequent observations to determine the effect of the decision on patient status. Table 360-2 lists decisions that need to be made and questions that should be asked to make the best decisions in such cases. The following detailed example demonstrates the application of several of these broad principles to difficult decision points during treatment of concurrent immune-mediated disease and an infectious complication.

TABLE 360-2

Aid to Decision-Making When Life Threatening Infection Develops in a Patient Receiving Immunosuppressive Drugs for Autoimmunity

TYPE OF DECISION AND OPTIONS	RELEVANT QUESTIONS BEFORE MAKING THE DECISION	COMMENTS
Decisions on the Infection		
Whether to treat the infection Yes/No	• Can the infection be treated? • Are there reports of successful treatment of this type of infection in patients receiving IDs? • Is there only one infection? • Any zoonotic implications?	Patient welfare, owner wishes, finances, and prognosis are paramount. Some infections (e.g., aortic valve endocarditis) carry a poor prognosis even in the absence of immunosuppressive drug therapy.
When to treat the infection Immediately or later	**What will kill the patient first—infection or autoimmunity?**	Typically, antimicrobial therapy is commenced immediately, but surgical management of infection might require ID dosage adjustment.
How to treat the infection Medical or surgical management, or both?	• Is the infection localized or generalized? • If surgery may offer a better prognosis, can the patient be made stable for surgery?	Poorly controlled autoimmunity may preclude anesthesia (neuromuscular disease, severe anemia) or surgery (severe thrombocytopenia).
Decisions on the Immunosuppressant Drugs		
Whether to change ID dosage/regime Yes/No	• Is the autoimmune disease under control? • Is this infection exacerbating the autoimmunity? • Has the infection arisen because of drug-induced	Severe infection often exacerbates autoimmunity (numerous mechanisms, predominantly associated with the increase in inflammatory cytokines), but also can suppress immune responses. Therefore, ID dose may need to be increased or decreased. This should be assessed on an individual patient basis.

	immunosuppression? • Is myelosuppression or any other drug toxicosis present? • Are drug interactions likely when antimicrobials are started?	
When to change ID dosage/regime Immediately or later	**What will kill the patient first—infection or autoimmunity?**	
How to change ID dosage/regime • Increase dosage • Start additional drug • No change • Short-term reduction • Accelerated weaning • Complete cessation	See questions relating to whether to change ID dosage. Also consider: Is this the first episode or autoimmunity or a relapse?	Relapsing autoimmunity requires more gradual weaning of immunosuppressants or lifelong therapy, compared with the first bout of autoimmunity.

Example: Management of Concurrent Myasthenia Gravis and Aspiration Pneumonitis/Pneumonia

Acquired myasthenia gravis (AMG) is an immune-mediated disease with varying clinical presentations (see ch. 269). Approximately 85% of cases have megaesophagus, and aspiration pneumonia (see ch. 242) is the leading cause of death in AMG patients. Use of IDs in AMG is destined to remain controversial for the foreseeable future because it is difficult to perform meaningful, controlled studies of a low-prevalence disease with the potential for spontaneous remission. When aspiration pneumonia is present, an additional layer of complexity is added to the decision-making process. Successful management of these two comorbidities and similar pairs of comorbidities requires (1) a good understanding of mechanisms of the comorbid diseases and of the complications associated with their interactions; (2) appropriate selection of IDs; (3) appropriate selection of antibiotics and other essential supportive measures; and (4) monitoring and treatment modification.

1. Reasons that AMG patients develop and succumb to aspiration pneumonia
   - AMG-associated, autoimmune-mediated attack of nicotinic acetylcholine receptors (AChRs) can cause esophageal dysfunction and megaesophagus.
   - Risk of aspiration increases further with weakness of the pharyngeal and laryngeal muscles.
   - AMG patients are frequently recumbent, and some have respiratory muscle weakness, impairing normal airway clearance mechanisms.
   - Other immune-mediated diseases that can affect neuromuscular function sometimes accompany AMG, which, if not recognized and managed promptly, can exacerbate dysphagia. These include hypoadrenocorticism, hypothyroidism, and polymyositis. AMG also occurs as a paraneoplastic phenomenon, mainly secondary to thymoma.
   - The anticholinesterase drugs (pyridostigmine and sometimes neostigmine) that constitute standard therapy for AMG have a narrow therapeutic index and can cause salivation and vomiting, increasing risk of further aspiration. Cholinergic side effects can be reduced by concurrent administration of atropine or giving the drug with food.
2. Indications for, and choice of, immunosuppressive drugs in AMG

   Indications:
   - Dogs with repeatably increased AChR antibody titers that persist despite the passage of time and provision of supportive care.

- Dogs not responding well to anticholinesterase therapy, or where such drugs are causing unacceptable side effects. Dogs with positive AChR antibody titers but negative edrophonium challenge tests might be predicted to respond poorly to other anticholinesterase drugs and thus be candidates for early ID treatment.
- Surgical removal of neoplastic tissue, if possible, is indicated in paraneoplastic AMG, in preference to ID therapy (i.e., elimination of underlying cause).
- Dogma regarding AMG states that IDs should not be commenced until infection is controlled. However, if a patient is experiencing life-threatening pneumonia resulting from frequent and ongoing aspiration events and anticholinesterase therapy is not improving neuromuscular transmission sufficiently to stop these events, rapid-onset immunosuppressive therapy to control the immune-mediated neuromuscular dysfunction could be the only hope of preventing further aspiration events. The pragmatic clinician will realize that in such dire situations, there is little to lose by commencing ID therapy in the face of infection.

Choice of drug:

- Glucocorticoids, if used, can be started at a low dosage (e.g., prednisolone 0.5 mg/kg q 24 to 48 h PO or via feeding tube, or use equipotent dose of an injectable glucocorticoid) and increased every 2 to 4 days. While this can be beneficial, and injectable glucocorticoids are easy to administer, reasons often cited for avoiding glucocorticoids include:
  - Exacerbation in muscle weakness (effects on excitation-coupling and altered ion channel of AChR)
  - Increased thirst and appetite, making regurgitation more likely
  - Increased panting
  - Global immunosuppression, including the innate immune response (neutrophil and macrophage function), worsening pneumonia
  - High-dosage IV methylprednisolone sodium succinate has been suggested for fulminant AMG since it does not exacerbate muscle weakness
- Nonglucocorticoid or "steroid-sparing" options include azathioprine, mycophenolate mofetil, and cyclosporine, which are more lymphocyte selective with fewer effects on innate immune responses (see ch. 165).
  - Azathioprine acts slowly, but in very ill patients, a rapid response is desirable. Myelosuppressive and sometimes hepatotoxic.
  - Cyclosporine—veterinary-approved formulations exist. Injectable formulations exist. Acts within days. Pharmacokinetic and pharmacodynamic monitoring available. A significant proportion (approx. 25%) of cases have transient gastrointestinal upset in the first few days of therapy.
  - Mycophenolate mofetil—rapid acting. Tablet, oral suspension, and intravenous preparations exist. Less myelosuppressive than azathioprine, but high cumulative doses can cause hemorrhagic gastroenteritis. Long-term benefit unproven but may be useful as rescue treatment in severe generalized AMG.

3. Antibiotic choice and other supportive measures
   - The material aspirated into the lungs in AMG may be a combination of oropharyngeal, esophageal and gastric contents and is likely to have substantial bacterial contamination.
   - Ideally, antibiotic therapy is guided by results of lower respiratory tract sampling (see ch. 101), especially if previous therapy has failed or risk factors are present for multiple drug resistance. However, morbidity associated with sedation or anesthesia for such sampling procedures and studies showing that most patients with aspiration pneumonia yield multiple bacterial isolates mandate the use of very broad-spectrum antibiotic therapy for initial empiric treatment.
   - Several antibiotics have the potential to worsen neuromuscular blockade (aminoglycosides, ampicillin, ciprofloxacin, erythromycin, imipenem) and should be avoided.
   - As for other megaesophagus patients, offering food and water from an elevated position is essential (see ch. 273). If unsuccessful, use of oral medications is also likely to be ineffective, and parenterally administered drugs should be given or placement of a percutaneous endoscopic gastrostomy (PEG) tube should be performed (see ch. 82). Since PEG tube placement requires general anaesthesia, the opportunity for concurrent lower airway sampling should be exploited if patient status permits. NOTE: Glucocorticoid therapy will impede formation of a stable adhesion between a newly placed PEG tube and the body wall, probably more so than other immunosuppressive drugs.
   - Oxygen therapy and saline nebulization may also be beneficial if tolerated (see ch. 97 and 131).
   - Coupage should be used with caution in patients with megaesophagus.

4. Monitoring
   - Improvement in respiratory status and pulmonary infiltrates on radiographs indicates improvement in aspiration pneumonia. Antibiotic therapy should be continued for at least a week beyond clinical resolution.
   - Serial AChR antibody titers often correlate well with disease activity in AMG. While a decreasing titer in response to immunosuppressive drugs is encouraging, it should not be interpreted as full remission of the disease until the IDs have been completely weaned with AChR antibody titer remaining below the normal level of 0.6 nmol/L.
   - If AChR titer remains increased, therapy should be continued even if clinical signs have resolved.

See E-Case Study 360-1 (online) for a "real-world" example of managing life-threatening autoimmunity and infection in a dog with immune-mediated hemolytic anemia and infective endocarditis.

Infection and Cancer Chemotherapy (See Ch. 343)

Cytotoxic (myelosuppressive) IDs form the mainstay of many cancer chemotherapy regimens. Once the tumor burden has been reduced from a macroscopic to a microscopic level, a reduction in blood neutrophil count to <3000 cells/mcL has been used as a surrogate marker of likely drug efficacy. It has been suggested that optimal dosage intensity is defined by giving doses of myelosuppressive drugs that deliver a neutrophil nadir between 1000 and 1500 cells/mcL and to consider increasing drug dosage for the next cycle if this is not achieved.[13] If this goal is adopted, it is essential that the logic behind this practice is understood by the patient's owner and all clinicians involved and that hematological monitoring establishes the neutrophil nadir for each myelosuppressive drug. However, with severe neutropenia being the most common dose-limiting toxicosis of these drugs, it is the author's observation that few veterinary oncologists are prepared to sail so close to the wind, with most settling for a nadir approaching, or just below, 3000 cells/mcL. Neutrophil and platelet counts should always be checked before any further myelosuppressive agent is given, with administration postponed until neutrophil count exceeds 3000 cells/mcL. A neutrophil count of <1000 cells/mcL, or long duration of neutropenia regardless of severity, should prompt reduction of all subsequent doses of that myelosuppressive drug, typically by 20% to 30%. Most veterinary oncologists believe that a neutrophil count >1000 cells/mcL is adequate to fight infection and that neutrophil counts at this level still confer a low risk of infection.[14] The risk of sepsis increases markedly at neutrophil counts <500 cells/mcL. Risk factors for chemotherapy-induced severe neutropenia include low body weight, hematological tumors, drug used, and being in the induction phase.[15] Therefore, vigilance is required from the owner and veterinarian regarding any clinical signs that could suggest neutropenia-related infection and an understanding that infections still occur in nonneutropenic chemotherapy patients. The requirement for prophylactic or therapeutic antibiotic use in chemotherapy patients depends on presence or absence of clinical signs, especially fever, and the absolute blood neutrophil count. It should be noted that neutropenia itself does not cause clinical signs.

Management of Asymptomatic Neutropenic Patients

If the neutrophil count is between 1000 and 3000 cells/mcL, antibiotics are not required unless other independent risk factors for infection are present (see Table 360-1). When the neutrophil count is <1000 cells/mcL, prophylactic oral antibiotics are indicated and the neutrophil count should be reassessed in 3 to 7 days. The choice of antibiotic might be restricted by institutional prescribing guidelines. Since sepsis in neutropenic patients is thought most likely to result from gastrointestinal translocation of Gram-negative aerobic bacteria and anaerobic bacteria prevent overgrowth of aerobes in the gut, consideration should be given to prescribing agents with minimal anaerobic spectrum.[15] Although hospitalization is not typically required, close observation is essential and any change in vital signs or demeanor, a reduced appetite, or gastrointestinal signs at home should trigger urgent reassessment by the veterinarian for evidence of infection/sepsis.

Management of Symptomatic Neutropenic Patients

Deterioration in physical status of a neutropenic patient should prompt immediate intervention to prevent or address septicemia. While onset of fever is of particular concern, its presence should not be relied on as an obligatory marker of sepsis (especially in cats), since some septic patients have such severe immune dysfunction they cannot release sufficient quantities of cytokines to generate a fever.[16] Following standard measures appropriate for any patient with serious illness (meticulous physical examination, complete blood

count, serum, biochemistry profile, and urinalysis), the clinician should not allow exhaustive attempts to identify the source of infection to take priority over establishing IV access (using meticulous aseptic technique) and instituting parenteral antibiotic therapy along with appropriate IV fluid therapy and hemodynamic monitoring. Any additional supportive measures that are necessary (e.g., antiemetics, analgesia, blood products) can then be started. Generally, very broad-spectrum (four-quadrant) antibiotic coverage is appropriate initially, unless there is strong initial evidence to implicate a specific organ system and class of bacteria in the illness. Antibiotics may need to be used at the high end of recommended dosages to offset reduced organ perfusion in sepsis.[17] Antibiotic therapy may be refined when culture results become available and in light of case progression, being mindful of the increasing problem of antibiotic resistance in human and veterinary medicine. Most symptomatic neutropenic chemotherapy patients respond to appropriate supportive care within the first 24 hours. Recombinant granulocyte colony stimulating factor (G-CSF) could be considered for use in patients that have received an inadvertent overdose with a myelosuppressive drug or when profound neutropenia persists for over 1 week. However, routine use of G-CSF should be discouraged because neutropenic dogs should have high endogenous G-CSF concentrations and therapy with the human recombinant product carries the risk of cross-reacting antibody formation.[18]

By comparison, management of human patients with fever and neutropenia is governed by stratified risk assessments, based on a larger evidence base and body of expert opinion than is available in veterinary medicine. Algorithms are being developed that encompass empirical or preemptive use of antifungal and antiviral therapy in addition to antibiotics in some subsets of patients. High-risk patients are those with anticipated prolonged (>7 days) and profound (<100 cells/mcL) neutropenia and/or significant comorbid conditions, including hypotension, pneumonia, new-onset abdominal pain, or neurologic changes. Low-risk patients are those with a neutropenia that is anticipated to be brief (<7 days), with no or few comorbid conditions, and these patients are managed with oral antibiotic prophylaxis.[19]

Infection in Organ Transplantation (See Ch. 323)

Renal transplantation is available for cats suffering from irreversible kidney disease at a few centers in North America and one in Australia. Recipients receive lifelong immunosuppressive therapy, typically including glucocorticoids and cyclosporine. Posttransplant infection is a common cause of graft deterioration, morbidity, and mortality. It also can be responsible for delayed discharge and multiple and often prolonged admissions. In the largest published study on infections in cats after renal transplantation, infection accounted for death in 14% of recipients and was second only to graft rejection as a cause of death.[20] Half of the infections developed within 2.5 months of transplantation, when immunosuppression was greatest. Cats with diabetes mellitus were at significantly increased risk of infection. Bacterial infections were most common including those associated with the urinary tract, feeding tubes, *Mycobacterium* spp. and *Nocardia* spp. Viral infections (predominantly affecting the upper respiratory tract) were next most common, followed by fungal and protozoal infections.[20]

Preoperative donor and recipient screening is thorough (see ch. 323). Urinary tract infections must have been successfully treated, with two negative post-treatment cultures. A cyclosporine challenge may be performed if pyelonephritis is suspected, with urine resubmitted for culture after 7 days of cyclosporine administration. One institution has accepted cats with chronic viral upper respiratory tract disease for transplantation if the disease was well managed at the time of assessment and clinical signs did not worsen on a cyclosporine trial.[21] Disseminated toxoplasmosis has been diagnosed in feline and canine renal transplant recipients.[22] As a result, some institutions place cats that are seropositive for *T. gondii* on life-long clindamycin treatment to prevent recrudescence. It is worthy of note that in a small, short-term study performed as part of a cyclosporine licensing application, healthy experimental cats that were seronegative for *T. gondii* and receiving cyclosporine, then challenged with *T. gondii,* suffered more severe disease than cats that were already seropositive when cyclosporine therapy commenced.[23]

When infection occurs in a renal transplant recipient, alongside appropriate antimicrobial therapy, it is imperative that the clinician check that immunosuppression is optimized. Blood cyclosporine levels should not be abnormally high, which would suggest excessive immunosuppression, yet not abnormally low, which could jeopardize the graft. As with other immunocompromised patients, antimicrobial therapy may need to be given for significantly longer and at higher dosages than would routinely be used.

Renal transplantation in dogs is currently beset with challenges that often prove insurmountable, notably high morbidity and mortality rates from infection associated with the substantially more aggressive immunosuppressive drug regimens that are required to prevent graft rejection.[24-26]

Use of Glucocorticoids in the Management of Infectious Disease

Contrary to dogma, there is no absolute contraindication to the use of immunosuppressive drugs in the presence of infection. There are select clinical scenarios where short-term use of anti-inflammatory or immunosuppressive agents (predominantly glucocorticoids) is of great benefit to the patient. However, since there are few veterinary studies evaluating the safety and efficacy of combined immunosuppressive and antimicrobial therapy, clinicians should continuously evaluate the risks versus the benefits of this practice on an individual patient basis. Empirical use of glucocorticoids in all patients with a given infection is not appropriate, but neither is blanket avoidance of their use in the presence of infection.

Infections That Cause Secondary Autoimmunity

Many infections can trigger secondary immune-mediated processes that have an adverse effect on the host, including formation of antibodies against erythrocytes, platelets, megakaryocytes and neutrophils and formation of immune complexes.[27] While numerous viral, bacterial, protozoal and helminth infections can be involved, vector-borne infections are most frequently and increasingly incriminated. The burgeoning literature on vector-borne disease (VBD), changes in taxonomy, identification of new agents and coinfections,[28] and sometimes protracted and expensive testing required for diagnosing VBD all contribute to the significant challenge that the clinician faces in identifying and managing this particular comorbidity, in which the boundaries between primary and secondary autoimmunity can be hard to define. If results of tests for infection are pending but patient status dictates that treatment is commenced, empirical antimicrobial therapy appropriate for the agent suspected should be started before or at the same time as glucocorticoid therapy. Glucocorticoid therapy will not be required for all cases, and prompt antimicrobial therapy increases the chances of spontaneous resolution of secondary autoimmunity without glucocorticoid use. If suspicion of infection lingers, despite negative test results, the clinician should remain skeptical about the longevity of any clinical improvement that follows initial glucocorticoid therapy and be vigilant for subtle signs that could reflect worsening of the infection. Repeat testing should be considered, especially for conditions where culture is appropriate, since glucocorticoid therapy can increase the likelihood of identifying the infection. Examples of pathogens incriminated in immune reactions against self-tissue are shown in E-Box 360-2. One of the few published studies relating to secondary autoimmunity describes experimentally induced Rocky Mountain spotted fever. Dogs treated with doxycycline and immunosuppressive dosages of glucocorticoids did not have more severe disease than dogs treated with doxycycline alone[29]. However, others report relapse of parasitemia when dogs that had recovered from rickettsial infections following doxycycline treatment were subsequently treated with immunosuppressive doses of glucocorticoids.[30] It has also been suggested that glucocorticoid therapy might be beneficial in feline leukemia (FeLV)-associated cyclic cytopenias, FeLV-associated anemias where an autodestructive component is involved or coinfection with hemotropic mycoplasmas exists, and for short-term use in babesiosis. Pure red cell aplasia in cats with FeLV infection has been suggested to benefit from glucocorticoid and cyclosporine therapy.[30]

Infections That Cause Debilitating or Life-Threatening Inflammation

In some infections, inflammation secondary to cellular damage, adverse immune response to pathogen antigens, and further release of inflammatory mediators on death/lysis of the pathogen during treatment become more dangerous than the tissue destruction caused by the pathogen itself. This is especially pertinent in infections involving the lung, eye, or central nervous system. A recent meta-analysis offers fascinating insight into the potential benefits and harms of giving systemic glucocorticoids in combination with disease-appropriate antimicrobials in treating infections in humans.[31] Infections were categorized into groups according to whether glucocorticoids were considered to improve survival (e.g., bacterial or tuberculous meningitis, severe tetanus, *Pneumocystis* pneumonia), reduce long-term disability (bacterial arthritis), significantly relieve symptoms (chronic middle ear effusion, acute laryngotracheobronchitis, cellulitis), or be of uncertain benefit or harmful (viral hepatitis).[31] Duration of therapy was generally short term (<14 days), and glucocorticoid dosage varied widely between studies.

In veterinary medicine, anti-inflammatory glucocorticoid use has been suggested to be of benefit if managing life-threatening pneumonitis induced by treatment of systemic mycoses, heartworm disease, or severe leptospirosis; for protracted cough in dogs with infectious tracheobronchitis; for reducing inflammation in feline infectious peritonitis; and for feline calicivirus-associated ulceroproliferative stomatitis (sometimes with cyclosporine).[30,32] Immunosuppressive dosages of glucocorticoids are considered appropriate for juvenile cellulitis ("puppy strangles").[32]

A retrospective study on concurrent systemic antifungal and glucocorticoid use (prednisolone 0.7 mg/kg/day PO for a mean duration of 3 months) for treatment of ocular blastomycosis in 12 dogs concluded that steroids did not adversely affect survival rate.[33] A brief report comparing glucocorticoid therapy with nonsteroidal anti-inflammatory therapy when combined with antifungal therapy for severe pulmonary blastomycosis in dogs found no difference in outcome.[34] Another study on use of prednisolone or prednisone (2 to 4 mg/kg/day PO) with or without systemic antifungals led to more rapid resolution of hilar lymphadenopathy caused by chronic histoplasmosis than antifungal therapy alone, again without dissemination of the disease; cases were carefully screened to rule out acute histoplasmosis.[35]

Glucocorticoids in Septic Shock

Some practitioners favor use of low-dosage glucocorticoid (hydrocortisone) replacement therapy in volume-loaded vasopressor-refractory hypotension associated with septic shock and related conditions (see ch. 132). Controversies surrounding optimal diagnostic and therapeutic strategies for this phenomenon, termed critical illness–related corticosteroid insufficiency, have recently been reviewed[36] and are discussed in ch. 133.

Immunodeficiency States Not Induced by Immunosuppressive Drugs

Naturally occurring immunodeficiency states may be divided into primary (congenital, usually hereditary) and secondary (acquired) immunodeficiencies. Key features consistent with immunodeficiency include:

- Recurrent or chronic infections (especially respiratory, skin, gastrointestinal, or urinary), often with incomplete response to antimicrobials
- Opportunistic infection with normally harmless or commensal organisms or unusual pathogens, often with severe disease manifestations
- Adverse response to modified live vaccines
- Ill thrift/fading neonates

Primary immunodeficiencies are uncommon in dogs and rare in cats. Knowledge of the more prevalent disorders and affected breeds, or the foresight to consult a list of such disorders when presented with a patient with suggestive clinical features, is central to reaching a diagnosis. Specific disorders have been reviewed elsewhere.[37] Prognosis varies according to the nature of the deficit, with many of the severe immunodeficiencies proving fatal.[38]

Secondary immunodeficiency states are common in dogs and cats and comprise a large, heterogeneous group of disorders that affect animals that are born with all components of the immune system intact but that develop transient or permanent immune impairment due to life stage, a disease state, or exposure to specific drugs, infections, or toxins. Broad categories of secondary immunodeficiency include age-related (e.g., colostrum deprivation), organ dysfunction (especially endocrinopathies), barrier damage (e.g., burns, catheters), nutritional disorders, and immunosuppressive coinfections. In many secondary immunodeficiencies, the underlying disorder either is transient or can be corrected or controlled, maximizing the potential for control of any resultant infection. For example, bacterial urinary tract infections are common in patients suffering from diabetes mellitus or hyperadrenocorticism. Tight control of the endocrinopathy should reduce frequency and severity of urinary infections but does not remove the need for routine surveillance (urine cultures) in diabetics.

Immunosuppression Caused by Infection

Successful pathogens, by definition, must breach physical barriers and suppress or subvert host immune responses to facilitate their own survival and propagation. Thus, infection begets immunosuppression, which begets further infection. Mechanisms of pathogen-induced immunosuppression are as numerous and varied as the pathogens themselves, with the arm of the immune system that is compromised directly influencing the type of secondary infections that occur. Damage to physical barriers and impairment of granulocyte function facilitate bacterial and sometimes fungal invasion. Impaired cell-mediated immunity can allow opportunistic pathogens (e.g., *Nocardia* spp., *Toxoplasma gondii*) to become established,[39] and compromised humoral immunity favors pyogenic bacteria. The archetypal immunosuppressive infection is feline immunodeficiency virus, which has complex effects on the immune system,[40] with depletion of $CD4^+$ T cells (T-helper cells) and activation of regulatory T-cells being key events.[40,41] Several other major pathogens infect cells of the immune system (FeLV, canine distemper, *Ehrlichia canis, Anaplasma phagocytophilum,* and *Leishmania*). Canine and feline parvoviruses have a tropism for rapidly dividing cells, causing the devastating combination of massive barrier damage (loss of intestinal epithelial crypt cells) with associated neutrophil sequestration, and myelosuppression. Other pathogens have downstream effects on immune cells (the glucuronylxylomannan capsule on *Cryptococcus* sp. inhibits phagocytosis, leukocyte migration, complement and Th1 responses) or direct effects on barrier function (*Bordetella bronchiseptica* paralyzes respiratory cilia).[39]

Such is the diversity of pathogen effects on the immune system and other target tissues that coinfections and secondary infections are inevitable. Recognition, management, and avoidance of these secondary infections require not only the ability to diagnose the primary infection but a detailed understanding of the pathogen's effects and survival strategy. Additional information relevant to infection and immune suppression is found online in E-Box 360-3.

E-Case Study 360-1

Immune-Mediated Hemolytic Anemia and Bacterial Endocarditis in a Dog

A "real-world" example of managing life-threatening autoimmunity and infection, with commentary.

Reference ranges used throughout this case:

PCV 37-55
Neutrophils 3000 to 11,500/mcL
Bands 0 to 300/mcL
ALT 0 to 40 U/L
ALKP 0 to 50 U/L
Bilirubin 0 to 0.53 mg/dL
Urea 5.6 to 25.2 mg/dL

Signalment: 4.5 year-old female intact Lhasa Apso, 10 kg

Vaccination and worming were current and appropriate for the geographic area. The dog had not been in an area with a high prevalence of vector-borne disease, and there was no history of flea or tick exposure.

Clinical Scenario: The dog presented with a 12-hour history of dark urine, reduced appetite, and lethargy. Physical examination revealed pallor and fever (39.4°C) and a grade 2/6 systolic murmur. A diagnosis of **idiopathic immune-mediated hemolytic anemia** (IMHA) was made based on a severe,

highly regenerative anemia (PCV = 14%) accompanied by spherocytosis, autoagglutination, moderate icterus, and marked bilirubinuria. Platelet count was normal. Neutrophilia was present (24,400/mcL with bands 300/mcL). Elevations were noted in baseline serum alkaline phosphatase (ALKP) = 170 U/L, alanine aminotransferase (ALT) = 98 U/L, and bilirubin = 2.76 mg/dL. Prothrombin and activated partial thromboplastin times were normal. Abdominal ultrasound and thoracic and abdominal radiographs were normal. Urine culture was negative. Heart valves were echocardiographically normal, suggesting that the murmur was hemic.

Management and progress days 1-9:

The dog remained hospitalized in first-opinion practice following initial diagnostic testing, and the following oral therapy was instituted:

- Prednisolone 1 mg/kg q 12 h
- Aspirin 1 mg/kg q 24 h
- Clopidogrel 25 mg/dog q 24 h
- Omeprazole 1 mg/kg q 24 h

After 24 hours, the dog developed hemorrhagic diarrhea and occasional vomiting, the PCV declined, and tachycardia developed. An indwelling right jugular vein catheter was placed (Seldinger technique), and additional therapy commenced consisting of:

- Intravenous infusion of polymerized bovine hemoglobin (Oxyglobin) over 36 hours with concurrent crystalloids. Ongoing balanced crystalloid therapy when Oxyglobin finished.
- Metoclopramide (IV), maropitant (SC), metronidazole (PO)—these therapies were all withdrawn by Day 6 when gastrointestinal signs had resolved.

Day 5: PCV = 16%, ALT was normal, ALKP = 1565 U/L, bilirubin = 3.51 mg/dL.

Day 6: PCV = 19%. The jugular catheter had become permanently occluded and was removed. The dog was progressively brighter.

Day 7: PCV = 19%, occasional spherocytes present. Azathioprine (25 mg PO q 24 h) commenced.

Day 8: The dog was discharged receiving unchanged dosages of prednisolone, aspirin, clopidogrel, omeprazole and azathioprine.

Commentary: *Gastrointestinal signs are common in IMHA and can also be precipitated by glucocorticoids. Oxyglobin therapy is a convenient, valid alternative to canine packed red cells but causes short-term interference with colorimetric tests on blood and urine. IMHA cases are hypercoagulable, but the optimal anticoagulant regimen is yet to be determined. The rising ALKP is likely to be glucocorticoid associated. Up to this point, this is an unremarkable case of IMHA.*

Management and progress days 9-14:

Day 9: PCV = 18%, spherocytosis, anisocytosis, polychromasia, nucleated erythrocytes, neutrophilia (29,800/mcL) bands (1800/mcL), toxic change. ALKP = 3780 U/L, ALT = 1163 U/L, bilirubin = 9.65 mg/dL, in-saline agglutination negative. The dog showed lethargy, fever, tachycardia, icterus, and cranial abdominal pain. It had vomited bile once. A canine pancreatic lipase immunoreactivity value was normal. Thoracic radiographs were normal. Abdominal ultrasound showed hyperechoic fat/mesentery in the region of the pancreas. Liver parenchyma was normal. A mild abdominal effusion was present, provisionally classified as an exudate containing a predominance of nondegenerate neutrophils, with some macrophages and mesothelial cells. Ascitic fluid and urine samples were submitted for culture. Heart valves were normal on ultrasound. Changes to therapy on Day 9:

- Azathioprine discontinued (prednisolone, aspirin and omeprazole ongoing)
- Parenteral antibiotic therapy started (amoxicillin-clavulanate and enrofloxacin)
- Intravenous crystalloids and oral sucralfate started
- Methadone analgesia, changed on Day 10 to a morphine-ketamine combination

Day 12: PCV 21%, neutrophil count = 56,000/mcL with bands = 7000 mcL. ALKP = 9030 U/L, ALT = 363 U/L, bilirubin = 0.64 mg/dL. Culture results: urine and ascitic fluid yielded coagulase-positive *Staphylococcus.* In addition, the ascitic fluid yielded a lactose-fermenting coliform. Both organisms were sensitive to the antibiotics instituted on Day 9. The dog was more comfortable and the amount of effusion reduced, but ultrasound now showed a 2 × 3 cm area of hypoechoic nodular change in the left medial liver lobe. Fine-needle aspirates of this area showed marked suppurative hepatitis with rare intralesional bacilli.

Day 14: PCV = 22%, spherocytes present, neutrophils = 44,000/mcL, bands = 1900/mcL. Abdominal ultrasound showed the liver lesion unchanged, but thickening and hyperechogenicity of the gallbladder wall. The primary care provider was concerned that the dog might require cholecystectomy and elected

referral to a multidisciplinary specialist practice.

Commentary: *On Day 9, IMHA was incompletely controlled and new cranial abdominal disease was apparent. While the rise in bilirubin and ALT could in part have been related to worsening/exacerbation of IMHA, the fever, toxic left shift in the neutrophil line, and presence of a neutrophilic abdominal exudate could have been explained by pancreatitis, sterile or septic thrombosis affecting the liver or pancreas, septicemia, or emergence of abdominal neoplasia. Septicemia itself can cause icterus due to effects of inflammatory cytokines on bilirubin uptake and intrahepatic processing and by causing intrahepatic cholestasis. The suspicion of infection was confirmed by the results of cultures of the urine and ascitic fluid, and the suspicion of liver involvement was confirmed by the emergence of new ultrasound changes and cytologic evidence of suppurative hepatitis. While azathioprine can cause hepatopathy and pancreatitis, since only 2 days of therapy with this drug had been given it was considered unlikely to have been implicated in the clinical deterioration. The mild increase in PCV seen during this time despite the presence of spherocytes validated the decision not to reduce or discontinue prednisolone treatment. In addition to immunosuppressive drug therapy, there were at least three possible explanations for development of infection in the liver:*

- *Ascending cholangiohepatitis/cholangitis*
- *Increase in bacterial content of portal blood during the hemorrhagic gastroenteritis that occurred in the first week of illness*
- *Liver localization following bacteremia/septicemia (supported by concurrent positive urine culture), which could have developed from infection of the indwelling jugular vein catheter (the catheter was problematic and isolation of Staphylococcus could suggest skin origin)*

Management and progress days 14-20:

At the referral center on Day 14, a grade 3/6 systolic murmur localized to the mitral area was present. There was bruising around the left jugular vein. The right jugular vein could not be located. Echocardiography revealed a vegetative mass lesion on the posterior mitral valve leaflet causing mitral insufficiency. The left atrium was moderately enlarged, with left atrial : aortic ratio of 2 : 1 (normal <1.3 : 1). E-wave velocity indicated significantly increased left atrial pressures. Systolic indices were normal. Blood cultures were submitted. Abdominal ultrasound findings were similar to those reported at the first-opinion practice. Prothrombin time and activated partial thromboplastin times were normal. ALKP = 11,676 U/L, ALT = 420 U/L. Bilirubin = 0.58 mg/dL, PCV = 22%, spherocytes ++, anisocytosis +++, polychromasia +.

The owner was advised that the findings were consistent with recent development of **bacterial endocarditis,** carrying a very poor long-term prognosis, especially in view of the incompletely controlled immune-mediated disease and the need for ongoing immunosuppressive therapy. Despite this, the dog was relatively bright and the owner elected to continue treatment. Medication regimen:

- Prednisolone, aspirin, clopidogrel, omeprazole and sucralfate as before
- Intravenous marbofloxacin and amoxicillin-clavulanate
- Oral clindamycin

Day 15: PCV = 26, ascites almost fully resolved on ultrasound, but liver and gallbladder changes static. New lesion on anterior mitral valve leaflet.

Day 16: PCV = 28, spherocytes absent, neutrophils = 23,600/mcL, bands = 1400/mcL, liver enzymes and bilirubin static.

Day 19: Signs of local peritonitis resolved on ultrasound despite liver and gallbladder changes remaining. Mitral valve lesions enlarging.

Day 20: PC 36%. Dog discharged receiving all above medications orally.

Commentary: *Since initial bacterial colonization of the heart valve endothelium may not be detected on echocardiography, it is difficult to be certain whether bacterial endocarditis caused septic embolization to the liver, or whether hepatobiliary infection was the initiating event that led to bacterial endocarditis. Suppurative hepatitis in isolation is a treatable lesion, which should not imply a poor prognosis in the face of an immune-mediated disease that is responding to treatment. However, superimposed bacterial endocarditis, with valvular lesions that progressed during the days following diagnosis, and with significant volume overload at the time of recognition, was a development that immediately downgraded the prognosis to extremely poor. The risks of congestive heart failure, thromboembolic disease, and ongoing infection were significant. In such circumstances, the very mild mineralocorticoid (sodium loading) effect of prednisolone has to be considered. Despite persistent ultrasound changes in the gallbladder wall and profound elevations in ALKP, hard evidence for imminent or actual biliary tract rupture was lacking, and therefore, cholecystectomy was not indicated. The resolution of the ascitic fluid, subjectively bright demeanor of the patient, and progressive improvements in PCV and neutrophil count with*

disappearance of spherocytes from the blood all added support to the conservative management path. Blood cultures were reported as being negative for growth after 2 weeks' incubation.

Management and progress days 21-60 (first-opinion practice):

Day 23: PCV = 36%. Prednisolone dose reduced from 1 mg/kg q 12 h to 1 mg/kg in a.m., 0.5 mg/kg in p.m. (i.e., a 25% dose reduction).

Day 30: PCV = 30%. Prednisolone dose returned to 1 mg/kg q 12 h. Mitral valve appearance and left atrial size unchanged. Dog bright.

Days 37 and 43: PCV = 30%. Spherocytes absent. Normal reticulocyte count indicating nonregenerative anemia.

Day 57: PCV = 32%. Left atrium unchanged. Owner concerned regarding muscle wasting and other signs of glucocorticoid excess. Prednisolone reduced again to 1 mg/kg in a.m., 0.5 mg/kg in p.m.

Day 59: Dog presented with signs consistent with left-sided congestive heart failure (tachypnea, tachycardia, pale membranes, normothermic), 10.25 kg. PCV 28%, neutrophils = 30,000/mcL, urea = 36.7 mg/dL. Responded well to intravenous furosemide, with resolution of tachycardia and tachypnea after 24 hours. 9.9 kg.

Day 60: Dog discharged receiving the following oral medications:

- Prednisolone 1 mg/kg in a.m. 0.5 mg/kg in p.m., aspirin, clopidogrel, omeprazole, and sucralfate as before
- Marbofloxacin 2 mg/kg q 24 h, amoxicillin-clavulanate 20 mg/kg q 24 h and clindamycin 7 mg/kg q 12 h
- Furosemide 2 mg/kg PO q 12 h, benazepril 0.25 mg/kg q 24 h, pimobendan 0.25 mg/kg q 12 h

Commentary: *The glucocorticoid dosage reduction on Day 23 would normally have been considered premature (PCV was not in the normal range), but the risk of congestive heart failure/thromboembolic disease was considered such that this compromise was acceptable under the circumstances. The reduction was reversed following the decline in PCV 1 week later. The subsequent static PCV and then slowly rising PCV in the absence of spherocytes allowed a further attempt at dosage reduction on Day 57. The dog's nonimmunologic problems gave ample justification for a component of "anemia of chronic disease." Unfortunately, congestive heart failure manifested on Day 59.*

Management and progress days 61-112:

Day 61: Hypokalemia present (furosemide associated)—oral potassium supplementation commenced.

Day 76: PCV = 34%. ALKP = 7000 U/L, ALT = 1403 U/L. Prednisolone dosage reduced to 0.5 mg/kg q 12 h. All other medications unchanged.

Day 84: Prednisolone reduced to 0.25 mg/kg q 12 h. ALKP and ALT unchanged. Ultrasound showed generalized hepatomegaly with hyperechogenicity. The nodular hepatic lesions had resolved. Gallbladder wall changes persisted. Oral S-adenosylmethionine supplementation commenced.

Day 106: PCV 39%. ALKP and ALT elevations unchanged. Prednisolone dose reduced to 0.25 mg/kg q 12 h.

Day 112: Acute onset vomiting, diarrhea, abdominal pain, tachycardia. Abdominal ultrasound revealed mild ascites, small uroliths, evidence of a previous infarct in the right kidney, a mineralized mass at the iliac bifurcation of the aorta causing turbulent blood flow but not impeding femoral pulses. Opioid analgesia was administered before dog suffered cardiopulmonary arrest. Resuscitation was not attempted.

Commentary: *It seems very likely that this dog had ongoing hepatic and biliary tract disease based on the liver enzyme elevations that persisted in the face of reducing doses of prednisolone. Control of IMHA appeared good during this time period, and endocarditis-related congestive heart failure also responded well to treatment. The cause of the signs immediately preceding the dog's demise was not defined, but it seems likely that the dog eventually succumbed to either recurrent infection, thromboembolic disease, or both.*

NOTE: While the case notes shown earlier might not exemplify perfect case management, they represent what could practically be achieved over a significant period of time in order to illustrate some of the challenges and compromises discussed in the main chapter text. The author is very grateful to Jon Camilleri and Theresa McCann for their assistance in case management.

Hyperkalemia
in acute kidney injury, 1906
acute treatment of severe, 1831
albuterol for, 1932
cardiac effects of, 1197–1198
in chronic kidney disease, 1906, 1955
diagnostic approach to, 271*f*, 272–274
differential diagnosis of, 271*f*, 272–274, 291
drugs associated with, 273
heart disease and, 768
in hypoadrenocorticism, 1831
hypoadrenocorticism as cause of, 273
obstructive uropathy as cause of, 2023.*e*1*b*
overview of, 272
renal failure associated with, 273

transtubular potassium gradient in, 291
urethral obstruction as cause of, 273, 416*t*, 2023.*e1b*
in uroperitoneum, 628
weakness caused by, 92
Hyperkalemic periodic paralysis, 2150
Hyperkeratosis, 1408
Hyperlactatemia, 279–280
Hyperlipidemia
blood fat concentrations and, 758–759
canine
atherosclerosis risks, 254
breeds commonly affected, 253*t*
causes of, 253–254, 253*t*
clinical importance of, 254, 254*t*
complications of, 254*t*
diagnostic approach to, 254–256, 255*f*
fasting, 253–254
history-taking for, 255
postprandial, 253, 253*t*
primary, 253*t*, 254
secondary, 253–254, 253*t*
cholesterol absorption inhibitors for, 763–764
definition of, 252
diagnosis of, 759–761, 760*f*
dietary management of, 761–763, 762*t*
in dogs, 758–759
fat absorption inhibitors for, 763
feline
characteristics of, 256
complications of, 254*t*
diagnostic approach to, 255*f*
fibrates for, 763
in glomerular diseases, 1971–1972
insulin resistance and, 758
laboratory testing for, 760*f*–761*f*
low-fat diet for, 761
management of, 761–764, 762*t*
medical management of, 763–764
monitoring of, 759–761
niacin for, 763

ophthalmic changes associated with, 56*t*, 760*f*
pancreatitis and, 749
primary, 761
secondary, 760–761
sodium levels affected by, 265–266
statins for, 763
Hyperlipoproteinemia, 252
Hypermagnesemia, 273*f*, 275
in chronic kidney disease, 1946
weakness caused by, 92
Hypernatremia
activated charcoal as cause of, 631
algorithm for, 266*f*
causes of, 265.*e*1*b*
correction of, maximum rate, 1932
definitions associated with, 265–267
diagnostic approach to, 266*f*
euvolemia and, 291
hyperlipidemia associated with, 253*t*
hyperosmolar/hypertonic condition caused by, 265
hypervolemia and, 291
hypotonic fluid loss as cause of, 267, 265.*e*1*b*
hypovolemia and, 291
isovolemic, 266–267
neurologic manifestations of, 61–62
nontoxicologic causes of, 64*t*–68*t*
pseudohypernatremia, 265–266
pure water deficit as cause of, 265.*e*1*b*
sodium overload as cause of, 267, 265.*e*1*b*
toxicologic causes of, 64*t*–68*t*
Hypernatremic dehydration, 592–593
Hyperosmolality, 595
Hyperosmotic laxatives, 1591
Hyperoxygenation, 336
Hyperparathyroidism
nutritional secondary, 779–781, 780.*e*1*f*
primary
in dogs, 1717–1724
hypercalcemia caused by, 276
renal secondary, 772, 1944, 1945*f*

Hyperphosphatemia
in chronic kidney disease, 1945–1946, 1952–1953
description of, 278–279, 279*b*, 1932–1933
Hyperpigmented viral plaques, 52–53, 52.*e*1*f*
Hyperproteinemia, 244–245, 245*f*, 265–266
Hypersalivation, 146
Hypersensitivity reactions, 571–572, 717, 2064–2065
Hypersomatotropism, feline, 1702–1705, 1703*f*–1704*f*, 1704*b*
Hypersplenism, 1617
Hypertension, 659–671
acute kidney injury as cause of, 660
in adrenal tumors, 661
algorithm for, 659*f*
amlodipine for, 667*t*, 668–670, 1940
angiotensin II in, 660, 660*f*
angiotensin-converting enzyme inhibitors for, 667*t*, 668–669
antihypertensives for, 666*f*, 667*t*
aortic dissection caused by, 662, 663*f*
beta-blockers for, 667*t*, 669
blood pressure measurement for, 378
canine, 668–669
cardiac manifestations of, 662–663
cardiovascular changes caused by, 661
cardiovascular-renal disorders caused by, 2163
in cats, 669–670
chronic kidney disease as cause of, 660, 667–668, 1943
classification of, 666*t*
clinical manifestations of, 661–665, 662*f*–665*f*
cognitive dysfunction secondary to, 665*f*
conditions associated with, 660–661
definition of, 659, 1810–1811
in diabetes mellitus, 661
diastolic dysfunction caused by, 662–663, 664*f*
diuretics for, 669
in dogs, 668–669
feline, 669–670
in feline hyperthyroidism, 1749
in glomerular disease, 1971
in hyperadrenocorticism, 660–661, 1810–1811
in hyperthyroidism

in cats, 1749
description of, 661
in dogs, 1761
idiopathic, 660–661
ischemic myelopathy secondary to, 665, 665*f*
kidney disease as cause of, 660, 668
left ventricular hypertrophy caused by, 662
lifestyle modifications for, 668
mechanism of, 659*f*
in nephrotic syndrome, 1971
nervous system manifestations of, 663–665, 664*f*
neurologic manifestations of, 60
obesity and, 660
ocular manifestations of, 58, 58*f*–59*f*, 661–662, 662*f*
organ systems affected by, 377
pathophysiology of, 659–660, 659*f*
in pheochromocytoma, 1841
proteinuria in, 660, 663
pulmonary. *See* Pulmonary hypertension
renal manifestations of, 663
after renal transplantation, 1936
renin-angiotensin-aldosterone system activation in, 660, 663, 1943
secondary, 660, 666–668, 1943
signalment and, 660
sustained, 667–668
target-organ damage caused by, 659, 661, 666, 666*t*, 670
treatment of, 666–671, 1956*t*
vascular manifestations of, 662, 662*f*–663*f*
weakness associated with, 93
white-coat, 661
Hypertensive crisis, 670–671, 670*f*
Hypertensive encephalopathy, 663–665, 664*f*
Hypertensive retinopathy
illustration of, 58*f*
treatment of, 58
Hyperthermia
antipyretics for, 564
causes of, 195
clinical signs of, 564
cooling measures for, 564

definition of, 562
differential diagnosis of, 563
endothelial damage caused by, 563
fever versus, 195, 196*f*, 198
fluid therapy for, 564
laboratory findings in, 564
metabolic acidosis secondary to, 563
mortality risks in, 566
multiorgan failure associated with, 563, 566
neurologic manifestations of, 62
nonpyrogenic, 562
physical cooling for, 200–202
prevention of, 1470
prognosis for, 566
pyrogenic, 562–563
treatment of, 564–566, 565*f*
Hyperthyroidism
apathetic, 1748
canine
chemotherapy for, 1761
diagnosis of, 1758–1760
external beam radiation therapy for, 1760
histology of, 1760
history-taking for, 1758
iatrogenic, 1757
imaging of, 1759, 1759*f*
laboratory testing for, 1758–1759
pathogenesis of, 1757–1758
radionucleotide therapy for, 1760–1761
signalment and, 1758
staging of, 1760, 1760*t*
surgery for, 1760
treatment of, 1760–1761, 1761*t*
tumor development in, 1757–1758
central nervous system manifestations of, 61
feline
anti-thyroid drugs for, 1752–1755, 1754*t*–1755*t*
cardiovascular system findings in, 1749
clinical signs of, 1748–1750, 1748*t*
description of, 1743

in diabetes mellitus, 1794
diagnosis of, 1750–1752
dietary management of, 1756
gastrointestinal system findings in, 1750
hypertension associated with, 1749
methimazole for, 1752–1755, 1754*t*–1755*t*
muscle weakness associated with, 2150
nutritional management of, 757
pathophysiology of, 1747–1748
polybrominated diphenyl ethers and, 1748
polyuria/polydipsia in, 1749
prevalence of, 1747
radioiodine therapy for, 1745, 1754*t*, 1755
renal insufficiency after treatment for, 1756–1757
signalment and, 1748
surgical thyroidectomy for, 1755–1756, 1755*t*
T3 suppression testing for, 1752
thyroid gland palpation in, 1748–1749, 1749*f*
thyroid hormone assays for, 1750–1752, 1751*f*, 1751*t*
thyroid nodules as cause of, 1748–1749
thyroid scintigraphy evaluations, 1752, 1753*f*
thyroid-stimulating hormone assays for, 1751–1752
thyroid-stimulating hormone receptor mutations in, 1748
thyrotropin-releasing hormone stimulation testing for, 1752
thyroxine tests in, 1750–1752
treatment of, 1745, 1752–1756
urinary system findings in, 1749–1750
vomiting associated with, 1750
hypertension in, 661, 1749
iatrogenic, 1757
neurologic manifestations of, 61–62
peripheral nervous system manifestations of, 62
physical examination for, 102–103, 1748–1750
Hypertonia, 1371
Hypertonic hyponatremia, 267, 267.*e1b*
Hypertonic saline, 537*t*, 538
Hypertonic sodium phosphate enema, 442–443
Hypertonic urethral sphincter, 2015
Hypertriglyceridemia
canine

breeds susceptible to, 761
diffuse vacuolar hepatopathy associated with, 254
gallbladder mucocele secondary to, 254
insulin resistance associated with, 254
pancreatitis risks secondary to, 254, 1681
definition of, 252
Hypertrophic cardiomyopathy
aortic thromboembolism caused by, 824, 1344–1349

Preface 263
About the Cover 265
Client Information Sheets 266
Volume 1 281
Section I The Real Basics of Veterinary Medicine 282
Chapter 1 The Medical History 283
Overview 283
The Approach to the Pet Owner 283
Requirements for a Thorough History 284
The Elements of the History 285
Questions for the Vague Clinical Complaint 286
References 287
Chapter 2 The Physical Examination 288
Observing the Pet and Meeting the Caretaker 288
The Physical Examination Process 296
Completing the Physical Examination 337
Chapter 3 Basic Genetics 339
Important Genetic Terminology 339
Dna to Protein 339
Modes of Inheritance 340
Dna Evaluation 343
References 343
Chapter 4 Clinical Genomics 345
Important Genetic Terminology 345
Clinical Genetics 346
Factors That Impact Clinical Presentation of Familial Disease 350
Genetic Counseling 350
Types of Genetic Tests 352
Pharmacogenetics 352
References 353
Chapter 5 Evidence-Based Medicine 355
References 358

Chapter 6 Biomedical Statistics 360
Hypothesis Testing 360
Statistical Methods 363
Chapter 7 Euthanasia 366
References 370
Section II Differential Diagnosis for Chief Concerns 371
General 372
Chapter 8 “Ain't Doing Right”: The Nonspecific Chief Concern of Ill Thrift 373
Signalment 373
Medical History 373
Physical Examination 374
Diagnostic Tests 374
Treatment 375
Ill Thrift That is Not a Sign of Disease 376
Resolution 376
Suggested Readings 376
Chapter 9 Distinguishing Behavioral Disorders from Medical Disorders 377
Introduction 377
Behavioral Disorders 379
Potential Medical Disorders in Dogs 380
Summary 381
References 382
Chapter 10 Dermatologic Manifestations of Systemic Disease 383
Systemic Diseases Associated with Alopecia 386
Systemic Diseases With Diffuse Hypotrichosis, Scales and Crusts 387
Systemic Diseases With Facial and Dorsal Erythema, Alopecia, Scaling and Crusting 387
Systemic Diseases With Alopecia, Erythema, Scales and Crusts Affecting Face, Legs and Tail; Dermatomyositis (DM) 389
Systemic Diseases With Alopecia and Shiny Skin of Periocular Region, Ventral Neck, Ventral Abdomen and Legs; Feline Paraneoplastic Alopecia (see ch. 352) 390
Systemic Diseases With Cutaneous Erythema, Alopecia, Scales and Crusts of Mucocutaneous Junctions and Footpads 391
Systemic Diseases With Cutaneous Plaques 394
Systemic Diseases With Cutaneous Nodules 397
Systemic Diseases With Skin Fragility 398
Systemic Diseases With Thick Skin 399
References 399
Chapter 11 Ophthalmic Manifestations of Systemic Disease 402
Introduction 402
Ophthalmic Examination 402
Orbital Disease 411
Systemic Hypertension 411
Metastatic Neoplasia 413
References 413
Chapter 12 Neurologic Manifestations of Systemic Disease 415
Diseases Causing CNS Signs 415
Diseases Causing PNS Signs 420

References 421
Chapter 13 Intoxication versus Acute, Nontoxicologic Illness: Differentiating the Two 426
Case History 426
Stabilizing the Patient 426
Toxicologic Versus Nontoxicologic 427
Suggested Readings 432
Chapter 14 Orthopedic Manifestations of Systemic Disease 433
Diagnostic Approach to Orthopedic Manifestations of Systemic Disease (Figure 14-1) 433
Other Causes of “Orthopedic Signs” 437
Diagnostic Testing 437
References 437
Chapter 15 Swollen Joints and Joint Pain 440
Overview and Definitions 440
Physical Examination 440
Pathophysiology 440
Septic Arthritis 441
Immune-Mediated Polyarthritis 441
Erosive Polyarthritis 442
Nonerosive Polyarthritis 442
Other Causes of Mono- or Polyarthropathies 443
Arthrocentesis 443
Joint Fluid Analysis 443
Additional Testing 445
References 446
Chapter 16 Weight Gain 447
Overview 447
History 447
Physical Examination 448
Diagnostic Approach 448
References 449
Chapter 17 Abdominal Enlargement 450
Differential Diagnoses 450
Diagnostic Approach 453
Treatment 454
References 455
Chapter 18 Peripheral Edema 456
Mechanisms of Edema Formation 456
Diagnosis and Treatment of Edematous Diseases 459
References 461
Chapter 19 Weight Loss as a Chief Complaint 462
Background 462
History 462
Physical and Laboratory Findings 464
Diagnostic Plan 464
Therapy 465
References 466

Chapter 20 Failure to Grow 467
Introduction 467
Pathophysiology 467
Endocrine Causes of Failure to Grow 467
Non-Endocrine Causes of Failure to Grow 468
Diagnostic Approach (Figure 20-1) 469
Treatment 471
References 471
Chapter 21 Weakness 472
Specific Mechanisms and Diseases 474
Chapter 22 Restlessness 478
History 478
Intoxications and Drugs 479
Pain or Discomfort 481
Metabolic Encephalopathies 482
Primary Intracranial Conditions 482
Need for Behaviorist? 482
References 482
Suggested Readings 483
Chapter 23 Anorexia 484
Definitions and Consequences 484
Causes 485
Treatment 487
References 488
Chapter 24 Polyphagia 490
Physiology and Pathophysiology 490
History 491
Physical Examination 493
Diagnostic Plan 494
Management 495
Suggested Readings 495
Chapter 25 Body Odors 496
Addressing the Body Odor Issue 496
Normal Pet Odors 498
Normal Pet with an Obvious Non-Medical Cause 498
Primary Medical Condition Resulting in Pet Malodor 499
References 501
Cardiorespiratory 502
Chapter 26 Coughing 503
Coughing Mechanisms 503
History 503
Differential Diagnosis for Coughing 504
Clinical Assessment 506
Clinical Investigations 506
Clinical Management 507
References 508

Chapter 27 Sneezing and Nasal Discharge 510
Clinical Presentations 512
Diagnostic Approach 513
Diagnostic Plan 514
Treatment/Outcome 516
References 516
Chapter 28 Tachypnea, Dyspnea, and Respiratory Distress 518
Pathophysiology 518
Immediate Assessment and Management of the Dyspneic Patient (see also ch. 131 and 139) 518
Important Historical Information 520
Complete Physical Examination 520
Localization 521
Further Diagnosis and Therapy 522
References 522
Chapter 29 Epistaxis and Hemoptysis 523
Epistaxis 523
Hemoptysis 528
References 530
Chapter 30 Syncope 531
Mechanisms and Causes of Syncope 531
History-Taking 533
Diagnostic Approach 534
Summary 535
References 535
Neurologic 537
Chapter 31 Movement Disorders 538
Clinical Evaluation 538
Spasticity 538
Myotonia 538
Tetany 539
Tetanus 539
Paroxysmal Dyskinesia 540
Drug-Induced Dyskinesia 541
Myokymia and Spinocerebellar Ataxia 542
Myoclonus 542
Encephalomyelitis 542
Dancing Doberman 542
Other Abnormal Movements 543
References 543
Chapter 32 Tremors 545
Definition 545
Pathophysiology of Tremor 545
Classification 545
Acute Onset Generalized Tremor Syndromes 547
Other CNS Inflammatory Disease That May Present with Tremor 548
Chronic Onset Generalized Tremor Syndromes 549

References 550
Chapter 33 Ataxia, Paresis, Paralysis 554
Ataxia 554
Paresis and Paralysis 557
Suggested Readings 558
Chapter 34 Stupor and Coma 560
Definitions 560
Pathophysiology 560
Approach to the Patient with Stupor or Coma 561
Diagnostic Plan 564
Treatment Goals 565
Prognosis 566
Suggested Readings 566
Chapter 35 Seizures 567
Seizure Classification 567
Diagnostic Approach 567
Principles of Therapy 570
Outcome 572
References 572
Gastrointestinal 574
Chapter 36 Ptyalism and Halitosis 575
Ptyalism 575
Halitosis 588
References 595
Chapter 37 Gagging 600
Anatomy and Physiology 600
History 601
Clinical Evaluation 601
References 603
Chapter 38 Dysphagia 604
Dysphagia 605
Regurgitation (also see ch. 39) 607
References 609
Chapter 39 Vomiting and Regurgitation 610
Differentiating Regurgitation From Vomiting 610
Regurgitation 611
Vomiting 612
References 618
Chapter 40 Diarrhea 619
Routine Diagnostics 619
Advanced Diagnostics 621
Suggested Readings 622
Chapter 41 Melena and Hematochezia 625
Melena 625
Hematochezia 630
References 632

Chapter 42 Constipation, Tenesmus, Dyschezia, and Fecal Incontinence 633
Definitions 633
Physiology of the Large Intestine 633
Constipation 634
Tenesmus and Dyschezia 636
Fecal Incontinence 637
Chapter 43 Flatulence 639
Physiology and Pathophysiology of Flatulence 639
Pathophysiology 639
Clinical Presentation and Differential Diagnosis 640
Investigation 640
Management 642
References 643
Urogenital 645
Chapter 44 Vulvar and Preputial Discharge 646
Introduction 646
Vaginal Discharge 646
Preputial Discharge 655
References 659
Chapter 45 Polyuria and Polydipsia 660
Introduction 660
Differential Diagnosis 660
Primary Polydipsia 661
Primary Polyuria 661
Diagnostic Approach 662
References 664
Chapter 46 Pollakiuria, Stranguria, and Urinary Incontinence 666
Definitions 666
Pathophysiology 666
Causes of Clinical Signs 667
Diagnostic Workup (Figure 46-1) 668
Treatment 672
References 672
Chapter 47 Hematuria and Other Conditions Causing Discolored Urine 673
Overview 673
Normal Urine 673
Discolored Urine 674
References 677
Section III Differential Diagnosis for Physical Examination Abnormalities 678
Chapter 48 Fever 679
Defining Fever, Hyperthermia, and Fever of Unknown Origin 679
Pathogenesis of Fever 680
Benefits of Fever 680
Costs of Fever 680
Measurement of Temperature 681
Differential Diagnoses for Fever 681

Approach to a Fever 683
Treatment 688
References 689
Chapter 49 Hypothermia 695
Cardiovascular Effects 696
Respiratory Effects 696
Neuromuscular Effects 696
Clinicopathologic Effects (Acid-Base, Coagulation, Electrolytes) 696
Renal and Metabolic Effects 697
Treatment 697
The Use of Hypothermia for Treatment 700
References 700
Chapter 50 Pallor 702
Evaluation 702
References 704
Chapter 51 Hyperemia 705
References 707
Chapter 52 Cyanosis 709
Physiology and Pathophysiology 711
Causes of Central and Peripheral Cyanosis (Box 52-1; see also Figure 52-1) 711
Evaluation of the Cyanotic Animal 713
Diagnostic Tests 713
Treatment 714
Chapter 53 Jaundice 715
Pathophysiology 715
Causes of Jaundice 715
Clinical Approach (Figure 53-1) 717
Diagnostic Plan 718
Chapter 54 Petechiae and Ecchymoses 719
Pathophysiology 719
Diagnostic Approach 720
Treatment 723
References 723
Chapter 55 Abnormal Heart Sounds and Heart Murmurs 726
Transient Heart Sounds 726
Cardiac Murmurs 728
Systolic Heart Murmurs 730
Diastolic Heart Murmurs 731
Continuous Murmurs 731
Auscultation and Beyond 732
Chapter 56 Pulse Alterations 733
Venous Pulses 736
References 736
Section IV Differential Diagnosis for Clinicopathologic Abnormalities 739
Chapter 57 Anemia, Erythrocytosis 740
Anemia 740

Erythrocytosis 746
References 748
Chapter 58 Leukopenia, Leukocytosis 750
Introduction 750
Leukocytosis 751
Leukopenia 752
Approach to Evaluation of Leukocytosis and Leukopenia 754
References 755
Chapter 59 Thrombocytopenia, Thrombocytosis 757
Platelet Life Cycle 757
Diagnosis of Thrombocytopenia (Figure 59-1) 757
Classification of Thrombocytopenia (Figures 59-1 and 59-2; also see ch. 201) 759
Diagnosis of Thrombocytosis (see Figure 59-2) 762
References 763
Chapter 60 Hypoproteinemia, Hyperproteinemia 765
Measurement of Serum and Plasma Protein 765
Positive and Negative Acute Phase Proteins 766
Causes of Hypoproteinemia 767
Causes of Hyperproteinemia 768
References 769
Chapter 61 Hypoglycemia, Hyperglycemia 771
Hypoglycemia 771
Hyperglycemia 773
References 775
Chapter 62 Blood Urea Nitrogen and Creatinine 777
Introduction and Definitions 777
Blood Urea Nitrogen 777
Creatinine 777
Symmetric Dimethylarginine (Idexx SDMA) 778
Causes of Azotemia (Increases in BUN and/or Serum Creatinine) 778
Non-Renal Effects on BUN and Creatinine 779
References 780
Chapter 63 Cholesterol, Triglycerides 781
Introduction and Terminology 781
Canine Hyperlipidemia 781
Feline Hyperlipidemia—Species Differences- 786
Hypocholesterolemia and Hypotriglyceridemia 786
References 786
Chapter 64 Amylase, Lipase 789
Dogs 789
Cats 790
References 791
Chapter 65 Liver Enzymes 793
Clinical Enzymology 793
Summary 798
References 800

Chapter 66 Creatine Kinase 803
Normal Activity and Tissue Distribution 803
Effect of Exercise on Serum CK Concentrations 803
Disorders Causing Increased Serum CK Concentrations (Figure 66-1) 803
Chapter 67 Sodium, Chloride 805
Overview 805
Hypernatremia (Figure 67-1) 805
Hyponatremia (Figure 67-2) 809
Hypochloremia (Figure 67-3) 812
Hyperchloremia 815
References 815
Chapter 68 Potassium, Magnesium 822
Potassium 822
Magnesium 825
References 827
Chapter 69 Calcium, Phosphorus 830
Calcium Overview 830
Hypercalcemia in Dogs 830
Hypercalcemia in Cats 833
Diagnostic Approach to Hypercalcemia 833
Hypocalcemia 834
Phosphorus 835
References 836
Chapter 70 Lactate 839
Introduction 839
References 842
Chapter 71 Ammonia 845
References 847
Chapter 72 Urinalysis 849
Overview and Indications 849
Collection and Care of Urine Samples 849
Physical Analysis 851
Chemical Analysis 852
Microscopic Sediment Examination 856
Lipids 862
Other Elements 862
Other Routine Tests 862
Non-Routine Tests 864
References 864
Chapter 73 Urinary Electrolyte Concentrations 866
Introduction 866
Disorders of Sodium (Na+) 866
Potassium (K+) Disorders 870
References 870
Chapter 74 Fluid Analysis 872
Thoracic and Abdominal Cavity Fluid 872

Joint Fluid 879
References 881
Section V Techniques 883
General 884
Chapter 75 Venous and Arterial Puncture 885
Placement of Peripheral Venous Catheters 888
Arteries: Arterial Puncture 890
Placement of Arterial Catheters 891
References 892
Chapter 76 Jugular Catheterization and Central Venous Pressure Measurement 894
Placement: Seldinger Technique 894
Peripherally Inserted Central Catheters 898
Central Venous Pressure Measurement 899
Chapter 77 Intraosseous Catheters 902
Introduction 902
Contraindications and Possible Complications 902
Techniques 903
Equipment 903
Inserting the Intraosseous Catheter 906
References 906
Chapter 78 Constant Rate Infusions 908
References 912
Chapter 79 Ear Vein Blood Glucose Monitoring 913
Capillary Blood Sampling with Conventional Lancet Device 913
Capillary Blood Sampling with Vacuum Lancing Device 914
References 916
Chapter 80 Buccal Mucosal Bleeding Time 917
Performing a BMBT 917
Causes of a Prolonged BMBT 919
References 920
Chapter 81 Fecal Examination 922
Collecting and Storing Fecal Specimens 922
Gross Examination of the Fecal Specimen 922
Fecal Smear 922
Fecal Flotation Techniques 931
Flotation Solutions 932
Centrifugal Flotation vs. Standing Flotation 932
Standing Flotation 934
Centrifugal Flotation 934
Proper Examination of the Coverslip 935
Fecal Sedimentation 935
Baermann Procedure 935
Fecal Culture for Parasites 935
Immunologic and Molecular Techniques 935
Diagnostic Resources 936
References 936

Chapter 82 Nasoesophageal, Esophagostomy, Gastrostomy, and Jejunal Tube Placement Techniques 938
Overview 938
Enteral Feeding Tube Material and Access Devices 938
Removal of Esophagostomy, Gastrostomy and PEG-J Tubes 946
Replacement of Gastrostomy and Esophagostomy Tubes 947
Complications of Enteral Feeding 948
References 950
Chapter 83 Care of Endoscopic Equipment 952
Overview 952
Nomenclature 953
Handling 956
Instrumentation 956
“Bedside” Testing and Cleaning (Video 83-1) 957
Leak Testing (Video 83-2) 957
Manual Cleaning (Video 83-3) 957
High-Level Disinfection (Video 83-4) 958
Endoscope Storage 959
Documentation 959
References 959
Chapter 84 Hyperbaric Medicine 961
History 961
Physiology 961
Indications 962
Contraindications 964
Complications 965
Equipment and Safety 965
Treatment Protocol (Dive) 965
Summary 965
References 965

Chapter 85 Otoscopy, Ear Flushing, and Myringotomy 969
Indications 969
Equipment 969
Clinical Anatomy 972
Otoendoscopic Exam 974
Deep Ear Cleaning/Aural Flushing 975
Myringotomy 977
Complications of Otoendoscopy 978
References 978
Chapter 86 Scraping, Fine-Needle Aspiration, and Biopsy of Skin and Subcutaneous Tissues 980
Skin Scrapings 980
Getting the Most From a Skin Biopsy (E-Box 86-1) 982
References 989
Chapter 87 Cytology of the Skin and Subcutaneous Tissues 990
Keys to Consider When Submitting or Evaluating Cytologic Samples 1003
Septic Versus Non-Septic Inflammation 1004

Neoplastic Versus Non-Neoplastic Lesions 1004
Benign Versus Malignant Tumors 1004
Types of Neoplastic Lesions 1005
When to Biopsy 1006
References 1006
Abdomen 1008
Chapter 88 Abdominal Ultrasonography 1009
Ultrasound Physics 1009
Tissue Characteristics 1009
Performing the Complete Abdominal Ultrasound Examination (Video 88-1) 1010
Summary 1012
Chapter 89 Abdominal Ultrasound 1013
Background 1013
Indications 1013
Materials 1013
Techniques 1014
Ultrasound-Guided Procedures 1015
Complications 1016
Chapter 90 Abdominocentesis and Diagnostic Peritoneal Lavage 1017
Abdominocentesis 1017
Diagnostic Peritoneal Lavage 1019
References 1020
Chapter 91 Laparoscopy 1021
Equipment 1021
Indications for Laparoscopy 1022
Technique 1022
Laparoscopy-Guided Liver Biopsy (Video 91-1) 1022
Laparoscopic Surgery 1023
References 1024
General Centesis and Biopsy 1026
Chapter 92 Bone Marrow Aspiration and Biopsy 1027
Overview 1027
Materials and Equipment 1027
Preparation and Site Selection 1028
Procedure: Bone Marrow Aspiration 1029
Procedure: Bone Marrow Core Biopsy 1032
References 1032
Chapter 93 Cytology of Internal Organs 1033
Background 1033
Indications/Advantages 1033
Disadvantages or Limitations 1034
Complications and Contraindications 1034
Specimen Preparation (see Video 93-1) 1034
Sending Samples to a Laboratory 1034
Cytology of Different Internal Organs 1035
Chapter 94 Arthrocentesis and Arthroscopy 1063

Anatomy and Physiology 1063
Background and Indications 1063
Techniques 1063
Suggested Readings 1069
Chapter 95 Lymph Node Aspiration and Biopsy 1070
Background 1070
Lymph Node Cytology Techniques (Video 95-1) 1070
Lymph Node Cytology Interpretation 1072
References 1074
Chapter 96 Rhinoscopy, Nasal Biopsy, and Nasal Flushing 1076
Rhinoscopy 1076
Nasal Biopsy 1077
Nasal Flushing 1079
