CHAPTER 278

Rectoanal Disease

Stefan Unterer

The distal portion of the digestive tract, including the anal canal and rectum, is a very sensitive part of the gastrointestinal (GI) tract and irritation of the rectal mucosa and perianal area frequently causes severe pain, tenesmus and dyschezia. Dysfunction of the anorectum can lead to fecal incontinence, which affects hygienic and social aspects of pet owners' lives and is associated with clinical distress of the patient. Immediate and intense symptomatic treatment and a thorough problem-oriented work-up usually are indicated in patients with rectoanal disease.

Anatomy

Rectoanal structures include the rectum, anal canal, internal and external anal sphincter, muscles of the pelvic diaphragm, as well as the anal sacs (paranal sinus) and circumanal glands (glandulae circumanales) (Figure 278-1). The rectum begins at the pelvic inlet. Before joining the short anal canal, it becomes dilated to form the rectal ampulla, which is absent in cats. The lumen of the anal canal is constricted at the rectoanal junction, where longitudinal folds of the mucosa (more prominent in dogs than in cats) press together to occlude the orifice. The mucosa of the anal canal is divided into three consecutive annular zones, the columnar, intermediate, and cutaneous zones. Endoscopically visible, small, solitary lymph nodules (1-3 mm) are a prominent feature of the rectal mucosa. Fecal continence depends primarily on two sphincters: the internal anal (thickened circular smooth muscle of the gut; continuous maximal contraction under involuntary control) and the external anal (striated muscle; contraction during phases of rectal distention under voluntary control) sphincters.

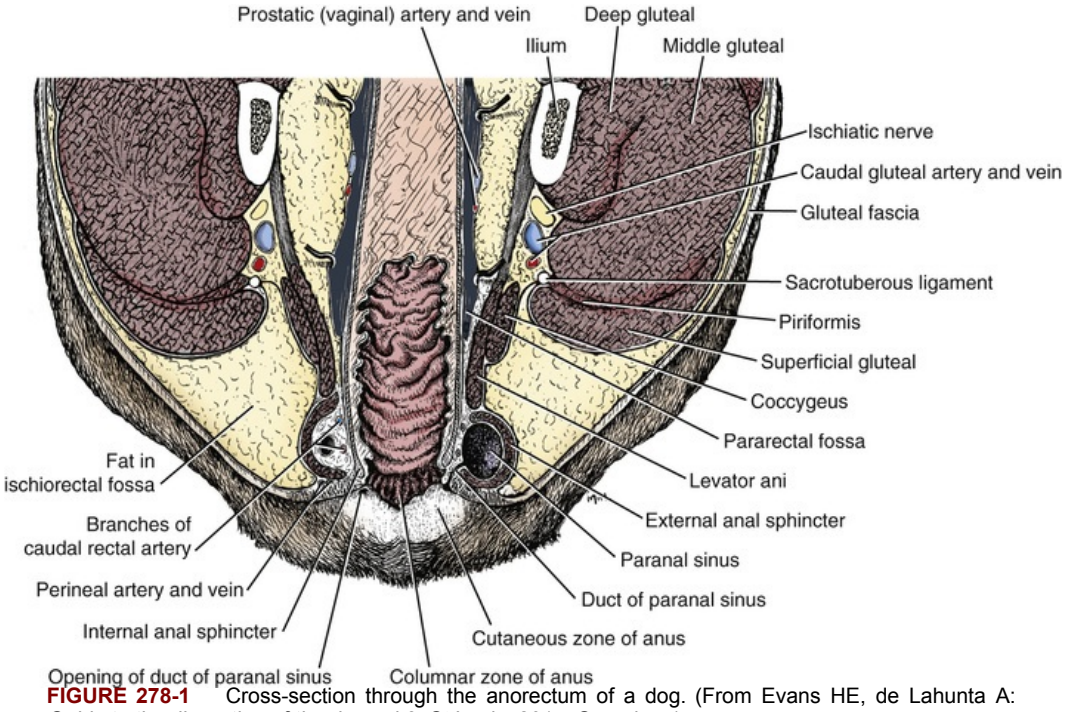

FIGURE 278-1 Cross-section through the anorectum of a dog. (From Evans HE, de Lahunta A: *Guide to the dissection of the dog*, ed 8, St Louis, 2017, Saunders.)

Three glandular areas are present in the rectoanal and perianal regions. The anal glands (glandulae anales) are tubuloalveolar glands that produce a fatty secretion and open to the outside in the columnar and intermediate zones. The paranal sinus glands (glandulae sinus paranalis) lie in the wall of, and open into, the paranal sinuses (anal sacs). Their foul-smelling, serous to pasty secretion is important for territorial marking. The anal sacs are located between the inner smooth and the outer striated muscle of the anus on each side of the anal canal and open ventrolateral to the anus through an aperture 1 to 2 mm wide. The apertures are visible, or can be exposed by pulling the skin on either side of the anus ventrolaterally.

The retroperitoneal part of the rectum and anal tract is supported by connective tissue and by the muscles of the pelvic diaphragm. The pelvic diaphragm is composed of two skeletal muscles (levator ani and coccygeus muscles) and two layers of fascia (external and internal fascia of the pelvic diaphragm). The paired rectococcygeal muscle detaches from the dorsolateral part of the longitudinal layer of the rectal smooth muscle and extends to the fifth and sixth tail vertebrae.[1] The coccygeus muscles cross the rectum laterally and tend to compress the tube, while the rectococcygeus aids the circular muscle layer in moving the fecal column to the outside.[2] Lymphatic drainage of the anal skin via the superficial inguinal lymph nodes and lymphatics from deeper tissues drain into the large medial iliac lymph node.

The descending colon, rectum, and internal smooth muscle sphincter of the anus are innervated by sympathetic fibers originating from L1-L4 or L5 spinal cord segments via the hypogastric nerves. The sympathetic innervation to the descending colon and rectum is inhibitory, whereas it is facilitory to the internal anal sphincter. Parasympathetic fibers originating in the sacral spinal cord innervate the descending colon and rectum via the pelvic nerve and stimulate colonic and rectal motility. Somatic fibers from the sacral cord innervate the striated muscle of the well-defined external anal sphincter via the pudendal nerve, leading to a conscious contraction of the sphincter. Afferent fibers from the rectal wall, sphincters, and perineum ascend in the dorsal and lateral funiculi to the brainstem centers for upper motor neuron regulation and to the cerebral cortex for conscious perception[3] (Figure 278-2).

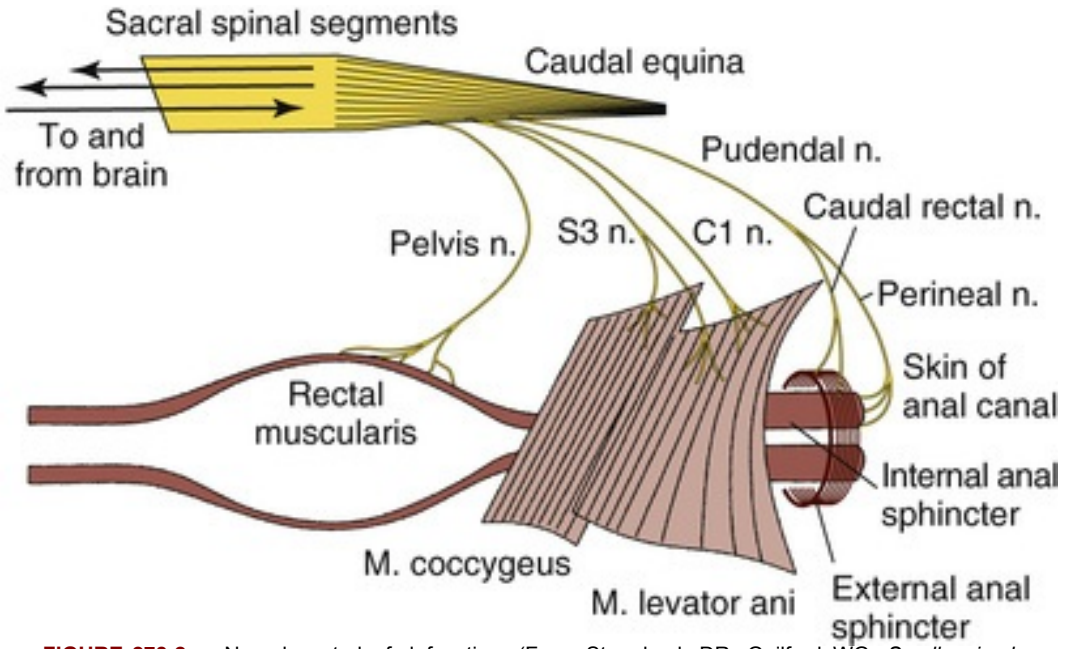

FIGURE 278-2 Neural control of defecation. (From Strombeck DR, Guilford WG: *Small animal gastroenterology*, ed 2, Davis, CA, 1990, Stonegate Publishing.)

Since innervation of the rectum is similar to that of the urinary bladder, dysuria also can be associated with neurologic disorders causing anorectal disease.

Physiology of Defecation

Food intake can stimulate defecation by inducing propagating pressure waves, which move intestinal content into the rectum (gastrocolic reflex).[4] Increased intrarectal pressure causes reflexive relaxation of the internal

anal sphincter (rectosphincteric inhibition reflex).[5,6] However, afferent fibers from the rectal wall ascend in the dorsal and lateral funiculi to the brainstem centers for upper motor neuron regulation and to the cerebral cortex for conscious perception. Prior to defecation, the rectosphincteric inhibition reflex is suppressed and the strength of the striated muscle in the external anal sphincter (mediated by somatic innervation from the sacral spinal cord) is increased until the conscious decision is made to initiate defecation.[7] If defecation is conscious, the suppressed intrarectal pressure declines through relaxation of the rectum (i.e., rectal accommodation). This allows a larger volume of stool to be maintained in the rectum at a lower intraluminal pressure (i.e., storage phase).[8] Progressively increasing fecal volumes stimulate progressively stronger urges to defecate. Defecation usually is preceded by colonic giant migrating contractions which produce the major propulsive power evacuating fecal materials from the rectum.[9,10] Ideally, dogs should be taken for a walk 20-30 minutes after eating to help produce a bowel movement. The actual impulse for defecation originates in the cerebral cortex and descends via motor tracts through the brainstem to the lower motor neurons. The parasympathetic innervation via the pelvic nerve stimulates colonic and rectal motility. Posturing and increasing intrapelvic pressure by contraction of the abdominal muscles and diaphragm facilitate defecation. Coordinated relaxation of the external anal sphincter, mediated by somatic fibers from the sacral plexus and the caudal rectal branch of the pudendal nerve, simulatenously occurring as intrarectal pressure increases, causes expulsion of stool.

History and Physical Examination in Patients With Suspected Rectoanal Disease

Patients with rectoanal disease can present with a variety of clinical manifestations. Common clinical signs include constipation, tenesmus, urgency to defecate, passage of mucus, and hematochezia/rectal bleeding (see ch. 42). Tenesmus ani (i.e., straining to defecate) frequently is observed in obstructive and inflammatory disorders of the anorectum. However, tenesmus also can be seen in patients with urogenital disorders and frequently owners are not able to differentiate between GI or urogenital signs. Asking about urinary habits, observing the patient's posture during straining, and palpation of the pelvic urethra and the prostate in male dogs will help the veterinarian localize the problem.

A good physical examination including a thorough abdominal palpation and digital rectal examination is the first step in differentiating between large bowel obstruction and inflammation once the problem is localized to the lower GI tract (see ch. 2). In obstructive disorders, the bowel typically is fecally impacted before the stenosis. Abdominal palpation often can detect an impacted colon; however, occasionally abdominal radiographs are required. A fecally impacted rectal ampulla can be identified with digital rectal examination. A substantial amount of feces in the rectum of a straining patient is indicative of constipation, and occasionally, rectal examination can identify a cause for obstruction (e.g., rectal stricture or mass, colonic deviation due to perineal hernia, pelvic canal stenosis). If no obstruction or deviation of the rectal wall can be detected, a motility disorder or ingestion of foreign material (e.g., bones, cat litter) is a frequent cause of impaction of the colon and rectal ampulla.

Proctitis—inflammation of the colorectal mucosa—is the most common cause of tenesmus in dogs and cats. It should be suspected with tenesmus, dyschezia, and/or hematochezia in the absence of constipation. The presence of concurrent large bowel diarrhea suggests more widespread inflammation of the colonic mucosa. The duration of clinical signs is of importance, because acute signs frequently are self-limiting and do not require an in-depth evaluation. In chronic disorders, owners should be asked if treatment trials have already been performed and whether a clinical improvement was observed with dietary changes, antimicrobial or anti-inflammatory/immunosuppressive treatment. Chronic tenesmus in a middle-aged to elderly, intact male dog in association with constipation and perianal swelling is typical for perineal hernia. Paradoxical large bowel diarrhea caused by fluid and mucus bypassing the retained fecal mass can be present. A digital rectal examination with unilateral or bilateral outpouching of the rectal wall should be diagnostic of perineal hernia; care must be taken not to perforate the distended rectal wall inadvertently. In dogs with a history of chronic tenesmus due to perineal hernia and an acute episode of severe straining or pain in the rectal area, an incarceration of the urinary bladder or intestine might be present. A retroflexed, filled urinary bladder should be suspected if the hernia is non-reducible by external digital pressure and a firm, fluid-filled structure is felt.

Rectal neoplasia can cause tenesmus/dyschezia due to obstruction (occluding or scirrhous tumors) or irritation of the rectal mucosa. Owners sometimes observe hematochezia and bright red blood coating the surface of formed stools. Rectal tumors are very easy to find when advanced; however, in the early stages, careful, methodical rectal examination and sometimes proctoscopy is necessary. Partial rectal strictures can

easily be missed in large dogs; in giant breeds, one may need to insert two or three fingers in order to see if the anus and rectum can expand to their normal diameters.

Perianal disorders can cause tenesmus/dyschezia due to anal stenosis (e.g., perianal/anal gland neoplasia, stricture formation secondary to chronic inflammation or perianal fistula), inflammation (e.g., perianal fistula associated with colitis, anal gland sacculitis), or constipation in patients avoiding defecation due to pain. Perianal licking and "scooting" are even more specific signs of perianal irritation. Diagnosis usually is straightforward by examination of the perianal area. Because of severe pain, sedation or general anesthesia sometimes is necessary to fully assess the severity of disease. In German Shepherds presenting with fistulous tracts in the perianal region, a diagnosis of perianal fistula usually can be made by physical examination alone. Other differentials for perianal ulceration and fistulation, such as neoplasia and rectal pythiosis, should be considered in any breed (see ch. 277). Anal sacculitis is a relatively common disease, but severe abscessation is infrequent. Careful palpation and expression of the anal sacs while one finger is inserted into the rectum are important to distinguish an impacted or abscessed anal sac from an anal sac tumor.

In animals with reservoir incontinence (i.e., altered rectal sensation due to inflammation), defecation usually is associated with tenesmus and urgency. In animals with sphincter incontinence (no conscious recognition of passage of feces) without obvious abnormalities of the anal sphincter, sacrococcygeal spinal cord dysfunction is very likely. A neurologic evaluation including observation of gait, evaluation of withdrawal reflexes and muscle tone of the pelvic limbs, evaluation of the perineal reflex and anal sphincter tone, and assessment of lumbosacral pain, is indicated in these cases.

Puppies and kittens with anorectal agenesis (imperforate anus) cannot defecate. During the first days postpartum, the abdomen progressively distends and the puppy or kitten becomes inappetent and lethargic. Patients with congenital anal stenosis and rectovaginal fistula can be asymptomatic for several weeks until constipation after weaning from the liquid diet occurs. Affected animals can be restless, start straining, and show an enlarged abdomen and bulging of the perineum.

Diseases of the Rectum

Proctitis

Proctitis—inflammation of the anus and rectum (E-Figure 278-3)—most commonly is associated with colitis (see ch. 277) or inflammatory perianal disorders such as perianal fistulas and sacculitis. Localized proctitis has been described in dogs following pelvic irradiation.[11] Additional causes include traumatic injury (e.g., foreign body) and mucosal reaction after rectal prolapse. Clinical signs of proctitis typically include tenesmus, dyschezia, and hematochezia. Urgency to defecate usually is a prominent sign and discharge of mucus, and less frequently of pus, can be observed. A thorough physical examination should be performed. A rectal examination can reveal evidence of neoplastic infiltration of the rectal wall or anus, a rectal stricture and/or a perineal hernia, all of which can cause clinical signs similar to those of proctitis. A fecal examination (see ch. 81) and rectal cytology are useful to detect parasites and an increased number of fecal leukocytes suggests infectious proctitis. The indication for proctoscopy (see ch. 113) and histologic evaluation of rectal mucosa, which is necessary for a definitive diagnosis, depends on the duration of clinical signs and success of treatment trials. Acute proctitis frequently is self-limiting or responds to empirical treatment with an easily digestible diet, anthelmintics (e.g., fenbendazole; see ch. 163), and short-term focal anti-inflammatory (e.g., budesonide rectal foam) and systemic analgesic (e.g., metamizole [dipyrone], buprenorphine; see ch. 126 and 166) medications. An increased number of leukocytes on fecal/rectal cytologic evaluation could be an indication for empirical antibiotic treatment (e.g., amoxicillin clavulanate, metronidazole; see ch. 220 and 277); routine fecal culture rarely is helpful.

E-FIGURE 278-3 Proctitis in a West Highland White Terrier. (Courtesy Dr. H. Jay Harvey, Cornell University.)

In chronic proctitis not responding to the above, proctoscopy and/or colonoscopy, with histologic evaluation of the colorectal mucosa, would be indicated (see ch. 113). The first biopsy, which should be taken with sterile forceps, should be submitted for culture and sensitivity testing for *E. coli* in order to identify an appropriate antibiotic in case granulomatous colitis/proctitis caused by invasive an *E. coli* strain is identified histologically.[12] Special stains (e.g., Gomori's methenamine silver, periodic acid-Schiff) might be necessary to detect invasive fungal infection.[13] In chronic idiopathic lymphocytic-plasmacytic or eosinophilic proctitis, systemic immunomodulatory drugs such as corticosteroids, aminosalicylates (not in cats), and/or cyclosporine should be used. Rectally administered topical agents could reduce the required dosage of systemic medication. Topical drugs currently used in human ulcerative proctitis include budesonide or hydrocortisone rectal foam, as well as 5-aminosalicylic acid and tacrolimus rectal preparations (see ch. 277).[14]

Perineal Hernia

The pelvic diaphragm of dogs is prone to herniation. Weak pelvic diaphragm muscles (coccygeal and levator ani muscles) fail to provide a strong support for the rectal wall. The muscles become thinner and stretched, resulting in focal, persistent rectal distention and potential fecal impaction. Perianal swelling or excessive laxity ventrolateral to the anus can be present. Due to rectal deviation, fecal material often becomes impacted in the rectum. General prevalence of perineal hernias (PH) in dogs is relatively low (≈0.1%-0.4%).[15] Canine PH occurs predominantly in middle-aged to elderly, intact male dogs and only occasionally in female dogs.[16] PH in cats is rare and generally secondary to underlying problems such as perineal urethrostomy, megacolon, perineal masses, or trauma.[17,18] Breed predispositions have been reported in the Boston Terrier, Boxer, Welsh Corgi, Pekingese, Collie, Poodle, Kelpie, Dachshund and Old English Sheepdog.[19,20]

Diagnosis

Perineal hernia typically can be diagnosed by history and clinical examination. Rectal examination will reveal a lack of support of the rectal wall with a deviation toward the side of the hernia for dogs with a unilateral

hernia and a dilation of the whole rectal ampulla for dogs with bilateral hernia. Most dogs with PH have chronic tenesmus and perianal swelling[21] (Figure 278-4) and typically are presented because of constipation or paradoxical large bowel diarrhea, as described above. Caudal displacement and herniation of the prostate, urinary bladder, and other abominal organs[21,22] can lead to dramatic clinical signs and occurs in 18% to 25% of affected dogs.[20,21,23,24] These structures can become strangulated, leading to an acute abdomen (see ch. 143). A retroflexed, full urinary bladder should be suspected if the hernia is non-reducible by external digital pressure and a firm, fluid-filled structure is felt; cystocentesis through the perineal wall can be confirmatory (see below). Abdominal radiographs can reveal fecal masses, soft tissue opacity due to herniated urinary bladder or prostate and air filled loops of small intestines in the perineal area (E-Figure 278-5 and Figure 278-6).[17] Positive (e.g., barium enema) or negative (e.g., insufflation of air) contrast studies of the rectum can confirm the diagnosis and assess severity and location (uni- versus bilateral) of the PH. Perianal ultrasound can evaluate contents within the hernia and identify urinary bladder retroflexion and herniation of the prostate (E-Figure 278-7). Imaging studies also are valuable for identifying some underlying diseases, such as colorectal obstruction (e.g., intra- and extraluminal masses), and prostatic (e.g., prostatitis, intra- and paraprostatic cysts) and lower urinary tract diseases (e.g., urolithiasis, neoplastic infiltration).

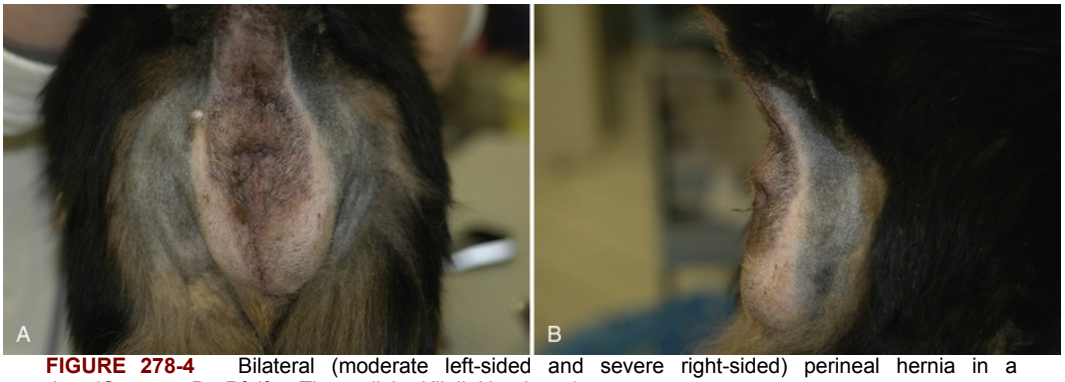

FIGURE 278-4 Bilateral (moderate left-sided and severe right-sided) perineal hernia in a dog. (Courtesy Dr. Pfeifer, Tierärztliche Klinik Nürnberg.)

(Courtesy Dr. Ohlerth, Vetsuisse Faculty, University of Zurich, Switzerland.)

Bloodwork usually is normal but azotemia and hyperkalemia are possible with postrenal obstruction (e.g., retroflexed urinary bladder); an inflammatory leukogram can be noted with necrosis of incarcerated organs, prostatitis, or translocated bacteria through a damaged rectal wall. A minimum database can exclude concurrent disorders prior to anesthesia and surgical repair.

Pathogenesis

In dogs, breed- and sex-specific anatomical differences have been implicated in the development of PH.[25] Predisposition in brachycephalic dogs suggests an inherited weakness of the pelvic diaphragm in these breeds.[15] Finding PH almost exclusively in intact, male dogs suggests a hormonal basis,[15] although serum testosterone and estradiol 17-beta concentrations are not different between affected and non-affected dogs.[26] Increased incidence in male dogs compared to females has been linked to a weaker levator ani muscle, and a decrease in the number of androgen receptors in the levator ani and coccygeus muscle has been proposed.[27] Relaxin affects collagen metabolism, softening the connective tissue components (e.g., birth canal).[28] Relaxin in males mainly is synthesized in the prostate gland and it is secreted in seminal plasma.[29] A higher expression of relaxin receptors has been found in the muscles of the pelvic diaphragm of dogs with PH.[30,31] Growth factors (growth and differentiation) of skeletal muscle also could play a role, because increased expression of epidermal growth factor and active caspase-3, and decreased expression of transforming growth factor-alpha, have been identified in the levator ani from dogs with PH.[32]

Treatment

Patients with small PHs and minimal clinical signs often can be managed with stool softeners (e.g., dietary fiber, lactulose), periodic enemas (see ch. 114), and digital removal of feces. Underlying disorders causing chronically increased intra-abdominal pressure must be treated and/or ruled out. Owners have to be warned that progression of the disease is likely and incarceration of herniated organs is possible and signs could be acute when incarcerated organs are obstructed or ischemic, which represents an emergency situation (see ch. 150).

After assessing the patient's physical condition (signs of systemic illness, bradycardia due to hyperkalemia) and metabolic and hematologic situation (azotemia, hyperkalemia, hypoglycemia, anemia), immediate bladder decompression is indicated if the veterinarian believes the bladder is herniated. Ultrasound-guided cystocentesis from the perianal area using aseptic technique is a useful way to decompress the bladder: it is quick and easy to perform and anesthesia is usually not required. Higher potassium and creatinine

concentrations in aspirated fluid compared to blood also can confirm that the aspirated fluid is urine. The decompressed urinary bladder frequently can be repositioned by external digital compression but if this is not possible, catheterization can keep the urinary bladder empty until surgical repair of the hernia (see ch. 105 and 106).

Advanced PH (e.g., recurrent PH, major dilation of the hernial sac, prostatic disease requiring prostatic omentalization, retroflexed urinary bladder) is an indication for surgery. Defects in the pelvic diaphragm can be closed either with direct suturing or by using autogenous tissues or synthetic mesh. Reported postoperative complication rates of standard herniorrhaphy range from 28.6% to 61%, including a recurrence rate of 10-46%.[15] Currently, transposition of the internal obturator muscle is considered the most reliable technique and has long-term success rates > 90% in uncomplicated cases.[15,33] A 2-step surgical approach (pexy of the colon, urinary bladder, and ductus deferens; then internal obturator muscle flap) is recommended for advanced/complicated PH and has a 90% success rate.[24,34] However, a recent retrospective study reported that laparotomy was not indicated in dogs with PH and urinary bladder retroflexion because the bladder repositioning could be reliably performed during perineal surgery. Urinary bladder retroflexion did not significantly increase the incidence of postoperative complications and had no effect on the long-term outcome.[21]

Prosthetic material such as polypropylene mesh,[35] porcine[36] and canine[37] small intestinal submucosa, autologous fascia lata[38] and tunica vaginalis[16] usually is only needed in those recurrent PH patients with hernia dimensions that do not allow closure by conventional herniorrhaphy. Autologous tunica vaginalis can be harvested during castration.

Routine castration is recommended as a part of PH treatment because the risk of PH recurrence for castrated dogs is 2.7 times less than for non-castrated dogs.[19] Prostatic atrophy makes the pelvic entrance wider (making defecation easier) and relaxin levels are lower.

Pre- and postoperative medical management aims to treat and prevent infection due to bacterial translocation through the damaged rectal wall or to surgical wound infection; to keep the stool soft (e.g., psyllium-enriched diet, lactulose); to prevent tenesmus due to pain; and to address underlying disorders (e.g., chronic colitis, prostatitis, cystitis) predisposing to recurrence of PH (see ch. 277).

Prognosis

The high surgical success rate of >90% must be considered cautiously, because PH recurrence has been documented up to 4 years post-operatively.[2] The prognosis depends on successful treatment of underlying causes, severity and chronicity of disease, and skill of the surgeon in performing the most appropriate repair. In complicated cases with urinary bladder retroflexion, mortality rates of up to 30% have been reported.[20,25,39] Postoperative complications in 25-50% of patients include sciatic nerve injury, fecal incontinence, surgical site infection, prolapsed rectum with excessive straining, misplacement of sutures in the anal sac or rectal lumen, urinary bladder necrosis, urinary incontinence, and PH recurrence.[15]

Rectal Neoplasia

Rectal neoplasia is uncommon in dogs and cats. The most common clinical signs include hematochezia, tenesmus, dyschezia and/or flattened stools. In most cases, a mass can be palpated on digital rectal examination.[40-42] Benign polyps, adenocarcinoma, leiomyoma, leiomyosarcoma, lymphoma, fibrosarcoma, and plasma cell tumors have been reported (E-Figure 278-8).[40-43] Benign polyps can transform into adenocarcinoma *in situ*.[44] Lymphoma, the most common tumor in cats, primarily occurs in the small bowel or the ileocolic junction, but cats occasionally develop intestinal adenocarcinoma.[45,46] Siamese cats are overrepresented.[46,47] Collies and German Shepherds could be predisposed for intestinal tumors, especially adenocarcinomas, rectal carcinoma and polyps,[48,49] and miniature Dachshunds might be predisposed for inflammatory rectal polyps.[50]

E-FIGURE 278-8 Endoscopic image of a benign rectal polyp in a dog. (Courtesy Dr. Melanie Craven, Cornell University.)

Diagnosis

The diagnosis requires cytologic and/or histopathologic analysis of samples obtained endoscopically or surgically (see ch. 113). It is critical to obtain substantial submucosal tissue to distinguish benign from malignant lesions. This can be done endoscopically, with training, using rigid biopsy forceps equipment; alternatively, full-thickness biopsy will be necessary. Full staging, including abdominal ultrasound, thoracic radiographs, a complete blood count, serum chemistry profile, and urinalysis, is recommended prior to therapy. This is because most affected dogs are middle-aged to older and can have co-morbidities. Furthermore, lymphoma by definition is a systemic disease, and metastasis from rectal adenocarcinoma has been reported.

Treatment

Surgical resection is the treatment of choice for malignant or benign localized rectal masses. A variety of surgical approaches has been described, including rectal pull-through (E-Figure 278-9), open abdominal or transpelvic approach for both benign and malignant masses, and transrectal endoscopic removal of benign tumors.[40,42,51-55] In addition to surgery, piroxicam, a nonsteroidal anti-inflammatory drug, may help alleviate and reduce clinical signs associated with rectal polyps in some dogs.[44]

E-FIGURE 278-9 Rectal pull-through technique for surgical resection of a localized rectal mass. (Courtesy Dr. Pfeifer, Tierärztliche Klinik Nürnberg, Germany.)

Prognosis

Survival times vary widely depending on tumor type, stage, and surgical technique used. Prolonged survival of many months to years after successful removal of the primary tumor[40,52] resection and/or chemotherapy of rectal lymphoma[43] has been reported.

Rectal Prolapse

Rectal prolapses are classified as complete external rectal prolapse (full thickness rectal prolapse; rectal wall externally visible, most common form), partial external rectal prolapse (mucosal prolapse; protruded mucosa externally visible, can sometimes be observed in patients during episodes of tenesmus or permanently in mild forms of rectal prolapse) (Figure 278-10), or internal rectal intussusception (invagination of rectal wall; not visible externally, not yet described in small animals).[56]

FIGURE 278-10 Mucosal rectal prolapse in a dog with colitis/proctitis. (Courtesy Dr. Tomsa, Ennetseeklinik für Kleintiere, Switzerland.)

Diagnosis

Rectal prolapse can be detected on physical examination; however, for accurate treatment selection, protruded rectal mucosa must be differentiated from an ileocolic intussuception that has prolapsed through the anus.[57] Careful insertion of a blunt, well-lubricated probe between the rectal wall and the prolapsed tissue will be possible if there is an intussusception but not if there is rectal prolapse.[58] The protruded rectal wall should be examined for neoplastic infiltrates. After repositioning, ultrasound, negative contrast radiographs, or endoscopy should be considered. For investigation of complex congenital abnormalities of the colonic wall (e.g., colonic duplication), negative contrast computed tomography or magnetic resonance imaging might be useful.[59] Abdominal imaging, endoscopic biopsies, and urinalysis could identify further causes of straining.

Pathogenesis

Rectal prolapse usually is due to an underlying urogenital or GI disorder producing severe or persistent straining. The most common causes of rectal prolapse are dyschezia from severe colitis or secondary proctitis due to parasites.[60] Other causes include:

- Intestinal conditions: intestinal neoplasia, foreign body, constipation, and congenital defects.[40,61-64]
- Anorectal abnormalities: perianal fistula, sacculitis, and surgical repair of perineal hernia without colopexy.[65]
- Anal sphincter incompetence, due to neurologic or muscular dysfunction.[66]
- Urogenital causes: lower urinary tract inflammation, urolithiasis, cystic or urethral neoplasia, and prostatic disorders.[62,67]
- A cystocele (protrusion of the urinary bladder into the vagina) has been reported.[68]
- Conformational abnormalities (recessed vulva, vestibulovaginal stenosis) causing stranguria.[69]

Treatment

Treatment should be prompt, to reduce further mucosal trauma and minimize discomfort. Conservative

management includes treating underlying causes of chronic straining and post-surgical tenesmus. Surgery usually is indicated, and three surgical techniques include perianal pursestring suture, colopexy, and rectal resection.[58,65] For mild rectal prolapse with minimal tissue damage, the protruded mucosa should be cleaned and rehydrated with a warm isotonic solution, lubricated with a water-based gel, and repositioned by gentle digital manipulation. A perianal pursestring suture is placed that leaves an opening large enough to allow passage of soft feces but not further prolapse; temporary placement of a tube through the anus during pursestring suturing, and removal of the tube immediately after the ligature is complete, can help prevent overtightening of the suture.[58] Medical management includes lactulose to keep the stool soft, topical corticosteroids (e.g., hydrocortisone foam), systemic corticosteroids (prednisolone 1 mg/kg PO q 24 h), metronidazole, and analgesic medications/opioids (e.g., buprenorphine). Defecation must be adequate to avoid constipation after pursestring suture placement.

Colopexy is useful where tissue is viable, if manual reduction of the prolapse is difficult or with recurrent prolapses.[34,70] It is usually performed by celiotomy and may be combined with other procedures (e.g., appositional herniorrhaphy with perineal hernias).[24,68,70,71] Minimally invasive laparoscopic technique is an alternative.[72] Rectal resection should be performed only when absolutely necessary and with the owner's full understanding of the risks, as serious complications may result.[58] Indications include necrotic mucosa and elimination of redundant rectal tissue. A silicone elastomer sling implantation technique has been described for patients with anal sphincter abnormalities. The resultant fibrous tissue can increase anal tone, preventing rectal prolapse during defecation.[66] Postoperative care is similar to rectal prolapse and, importantly, this includes addressing underlying causes.

Prognosis

The prognosis in mild forms with a treatable underlying cause usually is good. In patients with recurrent and severe forms of rectal prolapse requiring complex surgery procedures, the prognosis is guarded. Postoperative complications include stricture formation, incontinence, and dehiscence, which can be life-threatening.

Rectal and Anal Stricture

Rectal and anal strictures occur when the rectal lumen or anal opening is constricted by scar tissue from chronic inflammation, trauma or cancer.[73-75] Congenital stenosis also can narrow the rectoanal canal.[76] Rectal strictures in dogs are rare. Reported causes include: proctitis/colitis, anastomotic stricture post-neoplastic mass resection, chronic perianal inflammation, foreign bodies, histoplasmosis, and congenital malformation[75] and as a late complication of irradiation.[11] Rectal and anal strictures are uncommon in cats.

Since strictures can be congenital, inflammatory, or neoplastic, all ages can be affected. German Shepherd dogs are predisposed to perianal fistulas and inflammatory bowel disease, which can be associated with anorectal strictures.[77,78] Otherwise, no breed predilection is reported.[75] Strictures can be silent until the luminal caliber is small enough to cause obstruction. Most patients are presented because of tenesmus due to constipation.[75] Other clinical signs can include anorexia, abdominal pain, and vomiting.[79] Decreased intestinal motility and obstruction can lead to secondary intestinal bacterial overgrowth and excessive gas production manifested as abdominal bloating, borborygmus, and flatulence. Animals with partial obstruction can produce narrow ribbons of feces. Additional presenting complaints include hematochezia, diarrhea, and rectal bleeding.

Rectoanal strictures usually can be identified during digital rectal examination, which typically reveals a firm, circumferential fibrotic band that cannot be stretched.[75] In rectoanal stenosis due to infiltrative disorders, stenosis of the rectoanal canal can be present over a longer distance (several millimeters to centimeters), and sometimes an asymmetric mass can be felt. However, some colorectal carcinomas form strictures, which cannot be distinguished from benign fibrosing bowel constriction.[74] Sometimes, strictures with a very small luminal diameter (e.g., 1-2 mm) cannot be crossed by digital examination without causing tissue damage.

Diagnosis

Although strictures usually are detected by rectal examination, additional diagnostics characterize the lesion and identify underlying causes. Radiographic contrast studies (air and barium) (E-Figure 278-11) evaluate the

extent and location of rectal strictures.[73,75,76] Ultrasound can detect mural thickening of the rectal wall, abdominal lymph node enlargement, and metastatic lesions (intrapelvic location and colorectal gas might limit visualization). Proctocolonoscopy (see ch. 113) can allow visualization of the stricture but can be difficult to perform if the stricture is close to the anus.[80] When a distal stricture can be passed with a small diameter endoscope, a retroflexed view should be used for assessing the lesion (see ch. 277). Biopsies differentiate benign from malignant strictures.

E-FIGURE 278-11 Contrast study with rectal barium instillation showing a rectal stricture. (Courtesy Prof. Neumann, Georg-August-University Göttingen, Germany.)

Treatment

Optimal treatment depends on length, quality of tissue (fibrotic versus muscular) and underlying cause. Repeated balloon dilation under endoscopic or fluoroscopic control usually manages benign fibrotic rings,[73,75] exerting a radial force on the tissue and rupturing the fibrous, collagen-rich stricture. Multiple (1-3) procedures 4-6 days apart gradually increase stricture diameter without excessive tearing, thereby reducing likelihood of recurrent stricture formation. Treatment number depends on the degree of recurrent tissue contraction and clinical signs. Balloon size is based on the diameter of the stricture orifice, degree of tissue destruction, and size of the patient (e.g., cats and small breed dogs: 10-18 mm; medium and large breed dogs: balloon size in mm = weight in kg + 5). Concurrent intralesional triamcinolone injections could result in better success rates because corticosteroids inhibit scar tissue reformation.[73,81] Bougienage with a well-lubricated anal dilator might be easier and cheaper in medium- to large-breed dogs and can be continued, daily, by the owner at home to reduce the risk of restricturing. Self-expanding metallic stent placement for alleviation of colonic obstruction is a nonsurgical, palliative treatment for patients with metastatic or systemic disease in which surgical resection might not be possible or warranted (see ch. 123).[74,82] Surgical correction is reserved for strictures caused by rectoanal neoplasia, recurrent rectoanal strictures after unsuccessful dilation, and for long stenosis.[83,84] Transanal rectal pull-through amputation for *en bloc* resection can be associated with a high incidence of complications (e.g., fecal incontinence, rectal bleeding, dehiscence, infection).[55]

Additional treatments include a low-residue diet, stool softeners for several weeks, and pain management during the post-operative phase.

Prognosis

Many patients with benign strictures can be managed satisfactorily by dilation alone.[75] If surgery is necessary, postoperative complications confer a guarded prognosis. Malignant lesions are associated with a poor prognosis but palliative treatment can improve quality of life.[74]

Rectoanal Malformations

The most frequently reported rectoanal malformation in small animals is atresia ani, with a reported prevalence of ≈0.007% in dogs. As surgical correction is challenging and many affected dogs and cats are euthanized at the time of diagnosis, the true prevalence is difficult to determine. Females and some breeds (Finnish Spitz, Boston Terrier, Maltese, Chow Chow, German Shorthaired Pointer, Miniature Poodle, Toy Poodle, and Miniature Schnauzer) are predisposed.[85] Four types of atresia ani (Figure 278-12) include: Type I: congenital anal stenosis (fibrous ring at the anal opening); Type II: imperforate anus alone (just a thin membrane over the anus); Type III: imperforate anus combined with more cranial termination of the rectum as a blind pouch (in dogs ≥1 cm beneath the terminal rectal end and perineal skin); Type IV: discontinuity of the proximal rectum with normal anal and terminal rectal development. The embryonic cloaca represents a communication between GI, urinary, and reproductive tracts and rectoanal abnormalities occasionally are associated with urogenital malformations; rectovaginal fistula combined with type II atresia ani is the most common of these.[86-89] Rectoanal malformations also can be associated with other congenital anomalies (sacrocaudal dysgenesia and hydrocephalus).[86]

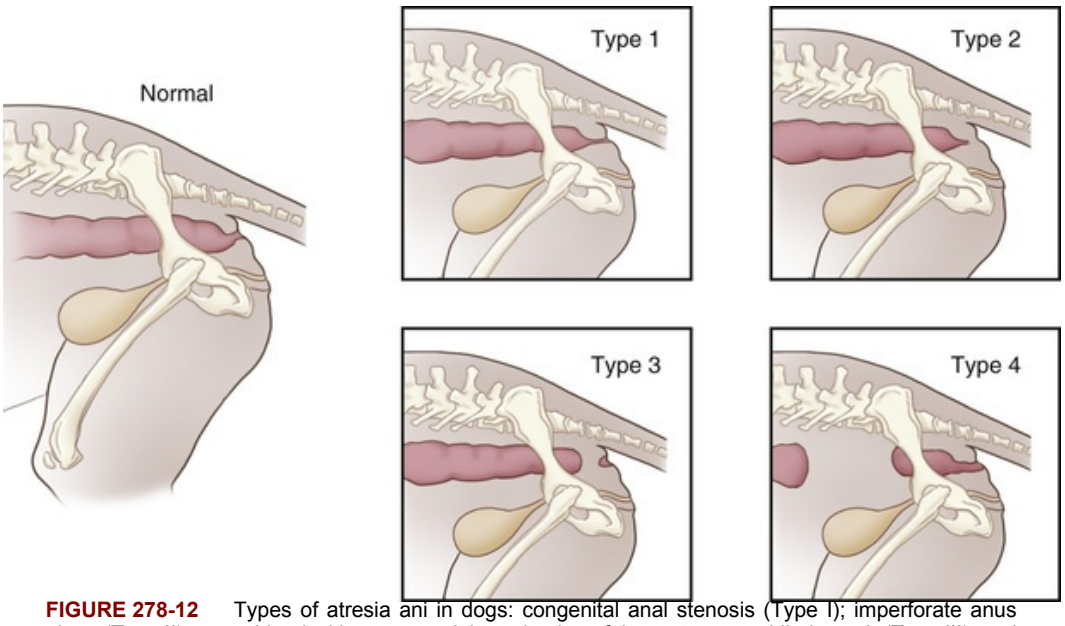

FIGURE 278-12 Types of atresia ani in dogs: congenital anal stenosis (Type I); imperforate anus alone (Type II) or combined with more cranial termination of the rectum as a blind pouch (Type III); and discontinuity of the proximal rectum with normal anal and terminal rectal development (Type IV). The red shaded areas identify the colon and rectum. (Redrawn from Vianna ML, Tobias KM: Atresia ani in the dog: a retrospective study. *J Am Anim Hosp Assoc* 41:317-322, 2005.)

Diagnosis

The diagnosis is based on history, clinical signs, and physical examination findings. Puppies and kittens with anorectal agenesis (imperforate anus) without fistula cannot defecate. Meconium and feces accumulate within the rectum postpartum, the abdomen progressively distends, and the puppy or kitten becomes inappetent and lethargic. Patients with congenital anal stenosis (atresia ani Type I) and with rectovaginal fistulas may be asymptomatic for several weeks until constipation after weaning from liquid diet occurs.[90] In female dogs or cats with passage of feces through the urogenital tract, vulvar irritation and cystitis will develop.[89,91] A ball-tipped probe can be used for gently exploring the anus and determining whether the tract ends blindly (i.e., Type I and IV).[87] Concurrent congenital abnormalities can include cleft palate, open fontanelle, hydrocephalus, skeletal deformation, abdomenal omphalocele, and congenital cardiac defects. Abdominal

radiographs can help determine the extent of rectal atresia, the degree of colonic dilation, and any sacrococcygeal deformities; iodinated contrast medium infused through the vagina or fistula can characterize the type of rectoanal malformation. Urinalysis with urine culture and sensitivity testing is indicated in every case with a communication between the GI and urinary tracts.

Treatment

Surgery is the treatment of choice for atresia ani, although anal stenosis has been corrected with bougienage and balloon dilation[90] (Figure 278-13 and ch. 123). All forms of imperforate anus (atresia ani type II-IV) require immediate surgical correction.[76,85,87] A fistula flap technique, described in the treatment of rectovaginal fistula and atresia ani, reduces the risk of iatrogenic damage to the external sphincter muscle and its innervation.[86] Postoperative analgesia and maintenance on a low-residue diet and stool softeners are recommended.

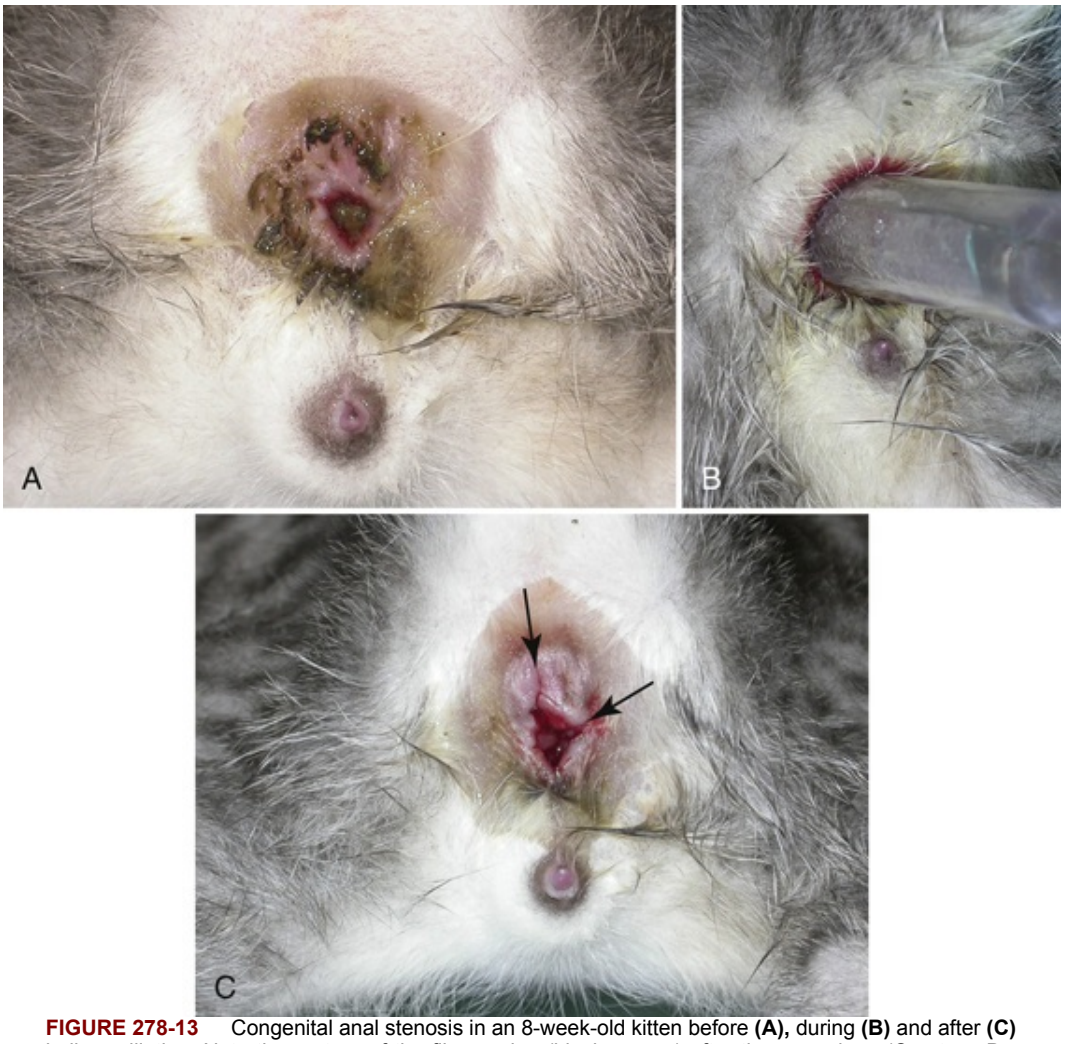

FIGURE 278-13 Congenital anal stenosis in an 8-week-old kitten before **(A),** during **(B)** and after **(C)** balloon dilation. Note the rupture of the fibrous ring (black arrows) after the procedure. (Courtesy Dr. Tomsa, Ennetseeklinik für Kleintiere, Switzerland, © GST | SVS.)

Prognosis

Surgical repair and balloon dilation of atresia ani type I and II result in fecal continence in most cases.[85,87,90] The prognosis for kittens and puppies with more complex anomalies (i.e., atresia ani type II and IV, rectovaginal fistula) is guarded. Postoperative wound dehiscence, stricture formation and incontinence are common complications.[76]

In contrast to older cats with megacolon, which is usually irreversible, colonic function and megacolon frequently improve after correction of atresia ani. Ascending urinary tract infection leading to chronic renal damage can affect the overall prognosis.[86]

Perianal Fistula

Perianal fistula (PAF, anal furunculosis) in dogs is a chronic inflammatory disease causing ulceration and fistulous tracts in the anal and perianal areas. As the disease progresses, perianal fistulization can become extensive (Figure 278-14). Anal stricture can develop. A multifactorial immune-mediated mechanism in genetically susceptible hosts is suspected.

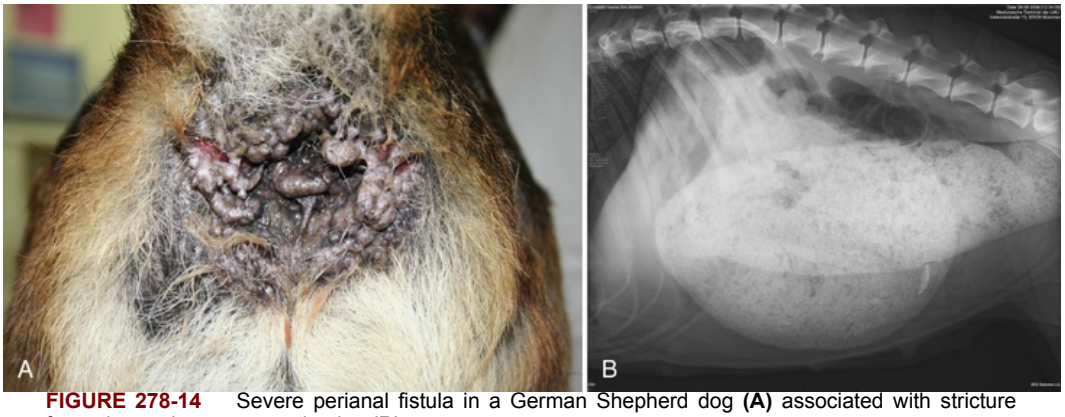

FIGURE 278-14 Severe perianal fistula in a German Shepherd dog **(A)** associated with stricture formation and severe constipation **(B).**

The German Shepherd breed is uniquely predisposed to PAF, representing >80% of cases.[92] Other breeds affected include the Irish Setter, Labrador Retriever, Old English Sheepdog, Collie, Border Collie, English Bulldog and Bouvier des Flandres.[92,93] A broad-based tail and a low tail carriage are hypothesized to predispose to bacterial overgrowth and inflammation. The disease usually affects middle-aged dogs, with a mean age of 4-7 years[94] and it is not reported in cats.

The presentation of PAF varies considerably. Initial clinical signs can include persistent perineal licking, then over time, dyschezia, hematochezia, tenesmus, purulent perianal discharge, self-mutilation, and fecal incontinence.[95,96] Dogs can present with obstruction due to scarring causing anal stenosis or, conversely, fecal incontinence due to damaged sphincter muscles and corresponding nerves. Weight loss and systemic illness can occur in severely affected patients.[77,97-101] Sedation and analgesia often are required for a thorough examination of the perianal area to accurately assess the severity (often after clipping and cleaning) and to perform a digital rectal examination with minimal discomfort. Examination—including evaluation of the anal sacs—aims to detect abscesses, determine the length and interconnection of fistulous tracts, assess any involvement of adjacent structures, and record the number and size of the fistula openings. Fistulous tracts should be flushed with sterile saline and probed with a sterile blunt instrument. The anal sphincter should be assessed for thickening and evidence of rectoanal stenosis. An associated perineal hernia gives a worse prognosis.

Diagnosis

Diagnosis is usually based on signalment (notably breed and age), history, and characteristic physical examination findings. Other causes of fistulization (e.g., chronic anal sac abscessation, perianal tumors, trauma from bites or foreign bodies) should be ruled out. Colonoscopy and colonic biopsies (see ch. 113) could be indicated, as 50% of dogs with PAF have concurrent colitis.[96] Histopathologic assessment of tissue can rule out neoplasia. Fistulograms can be helpful if surgical excision of draining tracts is considered; they also can document rare, true rectocutaneous fistulas. Abdominal radiographs are indicated to look for evidence of constipation, which can occur due to rectoanal stenosis or pain (see Figure 278-14).

Pathogenesis

Human Crohn's disease is associated with PAFs in 15-43% of patients.[102] By extrapolation, a similar, multifactorial, immune-mediated disease with a genetic predisposition is suspected in canine PAF. The responsiveness to immunosuppressive therapy, the histopathologic dense sheets of plasma cells and perivascular lymphoid nodules, and an increased expression of Th 1-cell-mediated cytokines (mRNA for IL-1-beta, IL-6, tumor necrosis factor alpha, IL-8, IL-10 and transforming growth factor beta) detected in biopsies from PAF tissues add support to this hypothesis.[103] The ulcerative nature of canine PAF could be due to an upregulation of macrophage-derived matrix metalloproteinase (MMP) enzymes, particularly MMP-9 and MMP-13, which are zinc-dependent endopeptidases capable of degrading components of the extracellular matrix.[104]

Canine PAF is thought to have a complex pathogenesis involving multiple genetic factors. A selective immunoglobulin A (IgA) deficiency demonstrated in the German Shepherd breed is a possible immunological factor leading to PAF.[105] A significant association with canine major histocompatibility complex (MHC) class II gene allele and PAFs has been described.[106] MHC class II molecules are responsible for antigen presentation and subsequent T-cell activation.

In humans, single nucleotide polymorphisms (SNPs) in the nucleotide oligomerization domain 2 *(NOD2)* play an important role in the etiology of Crohn's disease.[107] A recent mutational analysis study identified an association of four SNPs in exon 3 of *NOD2* with inflammatory bowel disease in the German Shepherd but no other canine breeds (genotype forms analyzed in an overdominant model).[108] Finally, a genome-wide association study to identify regions nominally associated with canine PAF in the German Shepherd revealed *ADAMTS16* and *CTNND2* gene regions on chromosome 34 were most significantly associated with disease.[109] Little is known about the function of *ADAMTS16*, but an inverse relationship between the expression of *ADAMTS16* and *MMP-13* was found in a previous study.[110] *MMP-13* is an endopeptidase that is overexpressed in canine PAF. It plays a potential role in the pathogenesis of human Crohn's disease.[104,111] The *CTNND2* gene encodes for delta-catenin, possibly responsible for dysregulation of angiogenesis.[109] Many other factors have been incriminated in the pathogenesis of PAF, including adverse food reaction,[112] anatomical factors such as higher density of apocrine glands in the perianal skin,[113] microenvironmental and hygienic factors due to tight tail carriage[95] and secondary bacterial infections.[92,114]

Treatment

Neither medical nor surgical therapy usually proves to be curative. The primary goal of therapy is to improve the patient's quality of life by inducing and maintaining remission. Medical management is the current treatment of choice. Surgery only is recommended for incompletely resolved fistulas after at least 6 weeks of medical treatment or for treatment of complications. Medical therapy includes immunosuppression, decreasing perianal area bacterial populations, helping the patient defecate, dietary therapy, and pain management.

The perianal area should be clipped of hair, kept dry, and cleansed daily with a mild disinfectant (e.g., diluted chlorhexidine solution, antimicrobial shampoo). Antibiotics effective against anaerobic bacteria (e.g., metronidazole) are administered for several weeks. Stool softeners (e.g., psyllium, lactulose) help to reduce pain during defecation, and analgesics that do not negatively affect GI motility (e.g., metamizole [dipyrone], gabapentin) are indicated. Attention to diet is recommended. An increased incidence of PAF in dogs with adverse food reactions[112] and a beneficial response to novel protein diets in combination with prednisolone have been reported (see ch. 178).[115] Cyclosporine (CsA), a calcineurin inhibitor, is the treatment of choice for PAF in German Shepherds.[116] It leads to inhibition of proliferation and activation of both T-helper and T-cytotoxic lymphocytes.[117] The microemulsion form of CsA (Atopica, Elanco) approved for atopic dermatitis is recommended. It offers greater bioavailability plus less variability in blood concentrations compared to other formulations.[118] 4 to 8 mg/kg PO is administered q 24 h for 2-4 months. Once clinical signs have improved substantially, the dosage can be reduced by approximately 25% every 4-8 weeks based on clinical response. Measurement of blood cyclosporine concentrations (see ch. 165) is only recommended with inadequate clinical improvement or suspicion of drug toxicosis (significant GI signs, serum liver enzyme concentrations > 3 times normal, acute renal azotemia). A strong correlation between cyclosporine blood concentrations and clinical efficacy has not been recognized.[118] Coadministration of ketoconazole (5-10 mg/kg PO q 24 h) usually halves the dose requirement of CsA via competitive inhibition of hepatic P450 microsomal enzymes, which can reduce costs when ketoconazole is less expensive than CsA. This combined therapy has produced a

remission rate of > 90% in 9-16 weeks in different studies.[99-101] An anti-inflammatory dosage of prednisolone (e.g., 1 mg/kg PO q 24 h, tapered as low as possible on improvement) can be a useful palliative treatment to increase appetite and well-being and reduce inflammation. Immunosuppressive dosages of prednisolone only improve one third of patients and unwanted adverse effects are common.[115] Azathioprine has been used as an adjunct to glucocorticoids but adverse effects can include GI signs, bone marrow suppression, hepatotoxicosis, and pancreatitis.[119]

Tacrolimus, another calcineurin inhibitor, is 10-100 times more potent than CsA. One study reported complete resolution of perianal lesions in 5/10 dogs, a partial response in 4/10 dogs and no improvement in 1 dog.[98] Tacrolimus (0.1%) is applied to the perianal region q 12 h (using gloves) in the induction phase, to reduce the dosage of concurrent systemic drugs. After complete resolution of clinical signs, application may be reduced to the lowest frequency that controls inflammation.

Due to the high complication rate of surgery (i.e., up to 70%)[120,121] and the high success rates with calcineurin inhibitors,[100,101] surgery should be restricted to resection of residual draining tracts and abscessed anal sacs after several weeks of intensive medical treatment.[97] Cryosurgery, laser excision, and chemical cauterization have been reported, with variable success rates.[122,123] Cautious anal dilation may be needed for treatment of anal stricture or stenosis.

Prognosis

With intensive medical treatment, including cyclosporine, metronidazole, local cleaning, and topical tacrolimus, many cases with mild to moderate disease will achieve complete remission. However, long-term immunosuppressive therapy usually will be necessary, and financial constraints can limit optimal treatment. Severe cases may require surgical therapy, which can result in complete resolution of PAF but risks complications.

Diseases of the Anal Sacs

Anal Sac Impaction, Sacculitis and Abscess

Non-neoplastic anal sac disorders are relatively common in dogs, but infrequent in cats. Anal sac impaction was the third most prevalent health disorder recorded in dogs attending primary-care veterinary practices in England in one study.[124] Anal sacculitis and anal sac abscess can be difficult to manage. Sacculectomy is required in some cases with chronic and recurrent anal sac inflammation. Previous studies have reported perianal pruritus in >95% of dogs with anal sac disease,[125] while other causes include adverse food reactions and canine atopic dermatitis.[126]

Chihuahuas and Miniature Poodles have been reported as being predisposed to anal sacculitis and Cavalier King Charles Spaniels and Labrador Retrievers were significantly over-represented for anal sac disease in one study.[127]

Diagnosis

Diagnosis of canine anal sac disease is based on clinical signs, physical examination, and evaluation of anal sac secretions. Anal sac content varies in color and consistency in normal dogs, and is not a reliable basis for diagnosis of anal sac disease.[126,128] Anal sac impaction can be suspected if an anal sac is enlarged and difficult to express. Swollen and painful anal sacs suggest sacculitis (E-Figure 278-15). Microscopic examination of anal sac content is performed frequently. However, a recent prospective, blinded study of cytologic evaluation of anal sac secretions showed no significant difference in inflammatory cells and bacteria between asymptomatic dogs and dogs with a history typical of anal sac disease.[125] Differential diagnoses include anal sac or perianal neoplasia, fungal infection, perianal fistulae, and trauma.

E-FIGURE 278-15 Severe anal sac swelling and abscessation in a dog. (Courtesy Dr. Tomsa, Ennetseeklinik für Kleintiere, Switzerland.)

Pathogenesis

The specific cause of impaction and sacculitis is unknown[128]; foreign bodies are uncommon.[127] Antimicrobial substances, such as lysozyme, IgA, lactoferrin, and the peptide group of beta-defensins are products of the anal glands.[129] Changes in these secretory products could reduce the microbial defensive barrier, change the exudate consistency, or both. Soft feces and/or a small duct might predispose to anal sac obstruction and permit bacterial proliferation. *Escherichia coli, Streptococcus faecalis, Clostridium* spp. and *Proteus* are most commonly encountered in sacculitis.[130] Anal sac impaction, inflammation, and abscessation can develop in association with perianal fistulae.[77]

Treatment

Anal sac impaction is treated by manual expression of the anal sacs and possibly flushing with warm saline as needed. For sacculitis without abscessation, instillation of a topical antibiotic and corticosteroid ointment after flushing might suffice. Systemic antimicrobial treatment for 2-3 weeks (e.g., amoxicillin-clavulanate; cephalexin; or trimethoprim-sulfonamide) in combination with local therapy (e.g., cooling compresses, corticosteroid ointments) might be required in severe, resistant, or recurrent cases. Abscessed anal sacs (Figure 278-16) must be opened surgically and flushed under general anesthesia; warm packs applied prior to surgery can help bring the abscess to a point at which it can be opened.

FIGURE 278-16 Ruptured anal sac abscess in a dog with perianal fistula. (Courtesy Dr. Schmitz, University of Giessen, Germany.)

Surgical anal sac removal should be considered in cases that do not respond satisfactorily to medical management. Closed techniques are reportedly associated with a lower complication rate compared to open techniques.[131] Pain management and preventing the dog from licking the perianal area is indicated in every case with substantial anal sac inflammation.

Prognosis

The prognosis with anal sac impaction and mild inflammation is generally good. Most patients with substantial inflammation respond to intensive medical treatment. Anal sacculectomy has an overall postoperative complication rate of 32%. Dogs weighing <15 kg had an increased risk of postoperative complications including perineal pruritus, incisional dehiscence, temporary fecal incontinence, constipation, and diarrhea in one study. The risk of permanent damage of the anal sphincter appears to be very low with careful surgical technique.[127]

Perianal Neoplasia

Perianal—or circumanal or hepatoid—glands (so named because cytologically and histologically, cells resemble hepatocytes) are considered nonsecretory, modified, sebaceous glands in the dog.[132,133] Cats do not have an analog to canine perianal glands and perianal adenoma and perianal adenocarcinoma are very rare.

Most cases of perianal adenoma have a history of non-painful, slow-growing mass or masses (E-Figure 278-17). Tumors can be single, multiple, or even diffuse. Typically found in the hairless perianal area, they can extend to haired regions, ulcerate, and become infected. They rarely adhere to deeper structures.[132] Perianal adenocarcinomas typically grow more rapidly, are larger and firmer, become ulcerated, and adhere to underlying tissues as compared to their benign counterpart.[134] Malignant disease should be suspected in

castrated males with a newly diagnosed or recurrent perianal tumor, because adenocarcinomas are not hormone-dependent.

E-FIGURE 278-17 Perianal adenoma in a dog. (Courtesy Dr. Pfeifer, Tierärztliche Klinik Nürnberg, Germany.)

Diagnosis

A routine geriatric work-up prior to anesthesia, potentially including thoracic radiographs and abdominal ultrasound, is desirable, even in an intact male dog with a perianal mass highly suspicious for benign perianal adenoma. Fine needle aspiration for cytologic evaluation might not differentiate benign from malignant perianal tumors, but it can rule out other forms of cancer or mass development. Histopathologic assessment of specimens is recommended. Metastasis in perianal adenocarcinoma is reported in 15% of cases.[134]

Pathogenesis

Perianal adenomas are the most common perianal neoplasm (59-96% of cases).[132,135] Tumor development and progression are androgen-driven and estrogen-suppressed. Older intact male dogs are at a high risk, with a mean age of 10 years.[136,137] Adenomas in female dogs are almost exclusively found in spayed females, where low estrogen levels do not suppress tumor formation; reports suggest testosterone secretion from adrenal glands in rare cases of hyperadrenocorticism.[138,139] Perianal gland adenocarcinomas are less common and represent 3-12% of perianal tumors.[134]

Treatment

Over 90% of intact male dogs will be cured with castration and mass removal and this is the treatment of choice for benign lesions.[132,136] Surgery is recommended in males with ulcerated or recurrent tumors and in female dogs. In addition to standard surgical techniques, cryosurgery and carbon dioxide laser for mass removal have been reported.[140,141] However, margin assessment for invasiveness, which is a hallmark feature of perianal adenocarcinomas, is not possible with these techniques.[142] For perianal adenocarcinomas, complete surgical removal with adequate margins is indicated.[136] As local recurrence is common with adenocarcinoma, incisional biopsy to plan for radical surgical resection is encouraged when this diagnosis is suspected. Postoperative radiotherapy might improve local control, but data are lacking.

Prognosis

Perianal adenomas have a good prognosis following surgery and castration, whereas for adenocarcinomas,

the prognosis is worse.[132,134,136] In one series of 41 dogs, tumors <5 cm in diameter (T2 stage) were associated with tumor control rates of >60% at two years. Metastasis at time of diagnosis was negatively related to survival. Median survival time for dogs with lymph node or distant metastasis was only 7 months in one study, but intensive treatment was not attempted in 5/6 dogs.[134]

Anal Sac Neoplasia

Apocrine gland adenocarcinomas arising from the anal sacs are rare, representing approximately 17% of all tumors in the perianal region and 2% of all skin and subcutaneous tumors.[133,142] This tumor is rare in cats, although the Siamese breed could be overrepresented.[143-148] The reported median age is 9-11 years in dogs and 12 years in cats.

There is no gender predilection.[135,149-151] For early identification and treatment, a thorough rectal and perianal examination should be routine for every adult dog presented in the clinic.[152-154]

Apocrine gland anal sac adenocarcinomas (AGASACA) usually affect one anal sac, but bilateral tumors have been reported.[152-155] These tumors can be very aggressive, and high metastatic rates at the time of diagnosis (average of 50%, range 46%-96%) have been reported. Metastasis is found most commonly in sublumbar/pelvic lymph nodes early or lungs and lumbar/pelvic bones later in the disease.[135,149-151,153-156] A study in English Cocker Spaniels, a high-risk breed, showed an association between tumor development and major histocompatibility complex haplotype (DLA-DQB1 allele), suggesting a genetic factor in tumor development.[157]

Clinical signs in dogs with AGASACA can be due to the physical presence of the primary mass, metastasis to regional lymph nodes, or paraneoplastic hypercalcemia (see ch. 352). Animals can show evidence of pain on defecation, hematochezia, and/or inflamed discharge from the anal sacs. In some cases, the problems caused by severely enlarged sublumbar lymph nodes, such as flattened stools or straining to defecate, dominate. Polyuria and polydipsia, anorexia, lethargy, or vomiting can be caused by paraneoplastic hypercalcemia, which is mediated by tumor secretion of parathyroid hormone-related peptide.[149,150] Approximately 27% of dogs with AGASACA have elevated serum calcium levels (see ch. 69). In up to 39% of dogs, the primary tumor has been an incidental finding on physical examination.[150] Like dogs, affected cats can be presented for tenesmus, constipation, scooting, presence of a mass, or hemorrhagic discharge.[143,146,147] Paraneoplastic hypercalcemia is not commonly reported in the cat.[143]

Diagnosis

A firm and discrete mass in the area of the anal sac, sublumbar lymphadenomegaly, and polyuria and polydipsia are highly suggestive. Tumors of the anal sacs can become secondarily inflamed and infected. Definitive diagnosis is made cytologically or histopathologically. Because AGASACAs have a very high rate of metastasis, staging should include thoracic radiographs and abdominal ultrasonography or abdominal radiographs. Ultrasonographic evaluation of lymph nodes is superior to plain radiographs and can identify other potential sites of abdominal metastasis.[158] Patients with lameness or bone pain should be evaluated radiographically or by nuclear scintigraphy for evidence of bony metastasis. A careful rectal examination and a complete blood count, serum chemistry panel, and urinalysis are recommended. Medical management of hypercalcemia or impaired kidney function could be necessary prior to surgery because hypercalcemia can result in kidney injury (see ch. 322 and 352). The same guidelines for staging anal sac tumors in dogs apply to feline patients with a suspected AGASACA.

Treatment and Prognosis

Comprehensive surgical removal of the primary tumor and enlarged metastatic sublumbar lymph nodes either alone or in combination with adjuvant chemotherapy and/or radiation therapy leads to median survival time of 16-18 months.[150,151] Even dogs with metastatic disease can have a good quality of life for months. Aggressive surgical resection of large tumors can risk causing fecal incontinence. Negative prognostic factors include large primary tumor size,[150,151] presence of lymph node metastasis,[151] presence of distant metastasis,[150,151] advanced clinical stage,[151] non-pursuit of surgery or chemotherapy alone,[150] and no therapy at all.[151] There are conflicting results regarding the prognostic significance of hypercalcemia in AGASACA.[149-151,153,154]

Radiation therapy can be palliative or definitive for nonresectable disease or treatment of metastatic lymph

nodes (see ch. 340).[159] Definitive radiation therapy is utilized for treatment of microscopic disease after surgical removal of the primary tumor to prevent local recurrence.[153] Side-effects can include intestinal irritation or rupture, diarrhea, and painful defecation in the short term and possibly rectal stricture long-term.[159]

The most commonly used chemotherapeutic agents are cisplatin, carboplatin, actinomycin D or mitoxantrone.[149,151,153] Toceranib phosphate, a tyrosine kinase inhibitor, has shown modest efficacy, with a median response duration of 19-23 weeks in 33 dogs refractory to prior therapies.[160] A significant relationship between a modified staging system and survival was found in a study of dogs treated prospectively according to a predefined management algorithm.[151] In cats, conflicting survival times and prognosis for this disease are reported. One study of 39 cats demonstrated a median survival time of 3 months (range 0-23 months) with 85% of cats succumbing to local or distant disease.[143]

Fecal Incontinence

Fecal incontinence is the involuntary passage of stool through the anus, in contrast to anal discharge of small amounts of mucus, pus, or blood. Continence depends on functional internal and external anal sphincters. Normal sensation of rectal distention and adequate reservoir capacity of the rectum are necessary to prevent fecal incontinence (reservoir incontinence). Anatomic derangements and neurologic diseases can be responsible for fecal incontinence. A detailed history is essential to differentiate reservoir from sphincter incontinence. Animals with sphincter incontinence are not aware of fecal passage and typically do not posture appropriately to defecate. With sphincter incontinence, unconscious anal dribbling can be worsened by increased intra-abdominal pressure (e.g., coughing, excitement). See also ch. 42.

In animals with reservoir incontinence, defecation is usually associated with tenesmus and urgency. Altered rectal sensation due to inflammation (e.g., proctitis) can produce incontinence. These animals typically have diarrhea, hematochezia, and fecal mucus.

Since neurogenic sphincter incontinence commonly is associated with cauda equina dysfunction,[161-163] evidence of lower motor neuron sacrococcygeal dysfunction should be sought (see ch. 266). The gait is assessed for ataxia; the pelvic limbs for decreased withdrawal reflexes and decreased muscle tone; and the tail for low carriage, reduced tone, and loss of sensation (see ch. 259).[164] The perineal reflex and anal sphincter tone can be reduced due to sacral nerve dysfunction. Loss of the detrusor reflex can produce urine dribbling due to overflow from a full bladder, in which case urine can be expressed easily. Fecal and urinary incontinence can occur with cauda equine syndrome, and the most common sign of this syndrome is pain elicited on palpation of the lumbosacral area or tail manipulation (see ch. 266). Severe lesions (e.g., those causing paraplegia) cranial to the sacral spinal cord (i.e., upper motor neuron dysfunction), can cause loss of voluntary control over defecation.

Diagnosis

A complete neurologic examination usually will reveal deficits that suggest neurogenic and anatomic reasons for incontinence. The rectum and perianal area should be carefully evaluated for non-neurogenic causes of incontinence. With disease localized to the sacrococcygeal spinal cord, survey radiographs often identify discospondylitis, fractures, or neoplasia, although computed tomography and magnetic resonance imaging are more sensitive,[165,166] especially for compressive spinal cord lesions missed by myelography. Inflammatory spinal cord disease can be identified with cerebrospinal fluid examination (see ch. 115), and myoneural abnormalities can be detected by electrodiagnostics (see ch. 117). The diagnostic approach for reservoir incontinence includes fecal examination for parasites (see ch. 81) and proctoscopy/biopsy for diagnosis of proctitis or neoplastic infiltration (see ch. 113).

Pathogenesis

Defecation involves coordinated activity in the autonomic (both parasympathetic and sympathetic) and somatic nervous systems. Dysfunction in the sacral components of this innervation causes neurogenic sphincter incontinence. In young animals, congenital abnormalities of the anorectum can be associated with anal sphincter incompetence (e.g., atresia ani type I, rectovaginal fistula). In adult dogs and cats, severe inflammation (e.g., perianal fistula), neoplastic infiltration, trauma, and perianal surgical procedures can damage the anal sphincter or its innervation.

Treatment and Prognosis

Decompressive laminectomy is effective for degenerative lumbosacral stenosis causing cauda equine syndrome in dogs, and fecal incontinence can improve postoperatively. A retrospective study of 69 dogs showed that fecal incontinence was present prior to surgery in 6% of these cases. In general, dogs with urinary or fecal incontinence have a worse prognosis than do dogs that are continent before surgery.[167] When due to compressive thoracolumbar disc disease, a 6.8% prevalence of permanent fecal incontinence has been reported. Dogs with paraplegia before surgery had a higher frequency of fecal incontinence compared to dogs that were ambulatory.[168] Fecal incontinence caused by postoperative and/or traumatic rectoanal injury can improve with time. Fecal incontinence was the most common (42 of 74 dogs) complication after rectal pull-through surgery in dogs with rectal masses and was transient in 19, and permanent in 23, dogs.[55] Postoperative defecation complications have occurred in 9/62 dogs following anal sacculectomy.[127] Fecal incontinence occurred in 2/51 dogs after surgical management of perianal fistula.[169] Novel surgical techniques and experimental studies for patients with loss of anal sphincter function have been described, including spiral rectal diaphragm technique,[170] implantation of a silicone elastomer sling,[66] transposition of a semitendinosus muscle flap[171] and reinnervation of the anal sphincter with a femoral motor nerve to pudendal nerve transfer.[172] Inflammatory colorectal disease can cause incontinence and should be treated (see above and ch. 277). Treatments include anthelmintics, hypoallergenic diets, antibiotics (e.g., tylosin), and/or anti-inflammatories (e.g., corticosteroids, sulfasalazine). Some patients with inflammatory bowel disease can respond to a high-fiber diet. Others benefit from highly digestible, low-residue diets, which reduce fecal volume and frequency of defecation. Administration of small-volume enemas (see ch. 114) to periodically stimulate defecation can keep the colon and rectum empty and improve continence in some cases. Loperamide (0.1-0.2 mg/kg PO q 8 h), an opioid that slows colonic transit and increases internal anal sphincter tone, might help manage fecal incontinence in diarrheic patients. Loperamide should not be used in dogs with MDR1 defect.

Fecal incontinence can be difficult to manage. Although it does not represent a life-limiting problem, some patients will be euthanized due to inconvenience and hygiene aspects.

CHAPTER 279

Peritonitis

Thandeka Roseann Ngwenyama, Rance K. Sellon

Anatomy and Physiology of the Peritoneum

The peritoneal cavity extends from diaphragm to pelvis and is bordered by the lumbar vertebrae, sublumbar musculature, and oblique, transversus, and rectus abdominis muscles. The diaphragm has three natural openings (esophageal, caval, and aortic hiatuses), as well as paired slit-like openings dorsally that can allow movement of fluid or air between the pleural and peritoneal cavity.[1,2] The peritoneum, a serosal membrane of embryonic mesodermal origin, is composed of a single layer of mesothelial cells anchored on a basal membrane with a deeper connective tissue layer of adipose cells, macrophages, lymphocytes, fibroblasts, and elastic collagen fibers.[1,3-6] The parietal peritoneum lines the abdominal cavity and reflects into the visceral peritoneum to cover the abdominal organs; the peritoneal reflections form the mesenteries, omentum, and abdominal ligaments. The peritoneal cavity is a potential space between the parietal and visceral peritoneum.[1,2] The peritoneum is highly permeable to water and low-molecular weight solutes, allowing bidirectional exchange between the peritoneal cavity and plasma; a fenestrated basement membrane allows some particulate matter to pass easily into lymphatics.[5,7] Healthy animals have peritoneal fluid that consists of <1 mL/kg of clear, straw-colored plasma dialysate characterized as a transudate, with <3000 nucleated cells (monocytes, lymphocytes and mesothelial cells)/mcL and <2.5 g/dL (<25 g/L) of protein (albumin).[5,8] Mesothelial cells make small amounts of surfactant to lubricate organs and prevent friction.[6] The peritoneum is capable of both absorption and exudation and in the normal patient there is a balance between them.[7] Changes in intraabdominal pressure during respiration promote circulation of peritoneal fluid cranially along the ventral abdomen, then dorsally along the diaphragmatic surface of the liver.[9] Peritoneal fluid drains via diaphragmatic lymphatics and the thoracic duct to the sternal and mediastinal lymph nodes.[1] Thus, sternal lymphadenopathy identified on thoracic radiographs likely reflects intraabdominal disease. Innate peritoneal defenses consist of complement, neutrophils, basophils, mast cells, lymphocytes, macrophages, natural killer cells, lymphatic drainage, peritoneal-associated lymphoid tissue, absorption and localization capacity, and omentum, which has immunogenic activity.[10] Peritoneal compartmentalization of disease results in greater concentrations of inflammatory cytokines and biomarkers in peritoneal fluid than in peripheral blood; the peritoneum can act as a barrier to decrease the absorption of substrates to create this gradient.[11]

Definitions, Classification, and Pathophysiology

Peritonitis, inflammation of the peritoneum, can be caused by non-infectious or infectious etiologies (Table 279-1). Peritoneal injury elicits an intense inflammatory reaction, resulting in accumulation of inflammatory cytokines in the peritoneal cavity, complement activation, immunoglobulin production, release of vasoactive substances, and an imbalance of pro-inflammatory and anti-inflammatory mediators. Inflammation results in vasodilation, increased vascular permeability, occlusion of peritoneal stomata by fibrin, and adhesion formation. Peritonitis can lead to systemic inflammatory response syndrome (SIRS) and attendant clinical features (see ch. 132).[1,3]

TABLE 279-1

Etiology of Peritonitis (Primary[12,13] versus Secondary[14-37])

PRIMARY CAUSES	EXAMPLES

Viral	Feline infectious peritonitis (FIP)
Bacterial *most common isolates	*E. coli**, *Enterococcus* spp.*, *Clostridium* spp.*, *Salmonella typhimurium, Chlamydia felis, Propionibacterium, Bacillus, Staphylococcus, Bacteroides, Fusobacterium, Actinomyces, Morganella morganii, Peptostreptococcus* spp.
Parasitic	*Mesocestoides, Sparganum proliferum*
Fungal	*Blastomyces, Histoplasma,* and *Candida* spp.
SECONDARY CAUSES	**EXAMPLES**
Chemical	Gastric acid, bile, pancreatic enzymes, urine, barium
Mechanical, foreign body	Suture, hair, surgical swabs ("gossypiboma") Cotton, silk, linen, migrating grass awn
Starch, granulomatous	Surgical glove powder (talc, corn starch)
Parasitic	Cestodes
Protozoal	*Neospora, Toxoplasma*
Septic causes	
Gastrointestinal origin	Leakage/rupture (secondary to ulceration, foreign body obstruction, neoplasia, trauma, torsion with ischemic damage or dehiscence of a previous surgical incision)
Hepatobiliary origin	Liver abscess, liver lobe torsion/ischemia with bacterial colonization, ruptured biliary tract (caused by necrotizing septic cholecystitis, iatrogenic or blunt trauma), septic necrotizing pancreatitis or pancreatic abscess
Urogenital origin	Septic uroperitoneum, renal abscess, pyometra, uterine rupture, uterine torsion/ischemia with bacterial colonization, traumatic breeding, prostatic abscess
Hemolymphatic origin	Splenic abscess, splenic torsion/ischemia with bacterial colonization, mesenteric lymph node abscess
Penetrating wounds	Bite wounds, gunshot wounds, vehicular trauma
Iatrogenic surgical	Surgical peritoneal contamination
Peritoneal dialysis or abdominal drainage (closed suction, open abdomen)	If ascending bacteria/fungal infection

Peritonitis can be classified by etiology (primary vs. secondary vs. tertiary), distribution (focal or diffuse), and duration (acute or chronic).[1] Primary peritonitis is caused by an extra-abdominal source, such as hematogenous dissemination, and likely some component of immunocompromise. Other proposed routes are via translocation from the gastrointestinal (GI) tract, across the natural openings of the diaphragm from the pleural space, and from the ovarian bursae.[5,12] The best example of primary peritonitis in veterinary medicine is the effusive form of feline infectious peritonitis (FIP) caused by hematogenous spread of mutated feline enteric coronavirus (see ch. 224). Other reported causes of primary peritonitis in veterinary medicine include infection with bacteria, fungi, and parasites (see Table 279-1).[12,13]

Secondary peritonitis is caused by septic or aseptic intra-abdominal disease and is the most common type in dogs and cats (see ch. 143). Secondary septic peritonitis from GI leakage or rupture caused by ulceration (selective cyclooxygenase-2 inhibitor administration),[14,15] infiltrative disease, foreign body obstruction, leakage of feeding tube sites, neoplasia, penetrating trauma, ischemic damage, torsion, volvulus, or dehiscence of a previous surgical incision is common.[16-29] The most frequent origin of GI leakage reported in dogs is surgical wound dehiscence,[18,29] although perforating intestinal foreign body has also been reported as the most common cause.[20,25] In one study, GI leakage in cats primarily was associated with neoplasia,[24] while another study identified trauma as the predominant cause.[26] Septic peritonitis is often polymicrobial, but the most frequently isolated microbe regardless of underlying cause is *E. coli.*[20,21] Bile peritonitis develops as a consequence of biliary tract trauma, necrotizing cholecystitis, and post-operative complications of biliary tract surgery (e.g., dehiscence of a cholecystotomy incision)[30-33]; bile from normal dogs is sterile, and septic biliary peritonitis is associated with a higher mortality rate. Proposed sources of bacteria include open or penetrating wounds, rupture of an infected gallbladder, ascension from the GI tract, translocation of enteric bacteria, or

systemic and portal endotoxemia and bacteremia.[31,33] Blunt abdominal trauma with subsequent rupture of the urinary bladder is the most common cause of uroperitoneum in dogs and cats (see ch. 143). Other causes of uroperitoneum include rupture secondary to urethral obstruction, neoplasia, and iatrogenic (urethral catheterization, manual bladder expression, cystocentesis, inadvertent penetration during abdominal surgery).[34-37]

Tertiary peritonitis is recurrent intra-abdominal infection after initial surgical and antimicrobial therapy of secondary bacterial peritonitis.[3] This category predominantly is recognized in human medicine.

Historical Findings, Clinical Signs, and Physical Examination

Signalment can help prioritize the likely causes of peritonitis. Young animals are more likely to have foreign body obstruction or infectious disease, while neoplasms are more likely in geriatric patients. In sexually intact patients, prostatitis and pyometra are differentials. Large- and giant-breed dogs are predisposed to intestinal and gastric volvulus. Pertinent historical information to gather in all cases includes: toxin exposure, dietary indiscretion, possible foreign body ingestion, other animals in the household affected, preexisting medical conditions (e.g., mast cell tumor), current medications (nonsteroidal anti-inflammatory drugs [NSAIDs], glucocorticoids), history of trauma or recent GI surgery, exposure to other animals, progression and duration of clinical signs (acute versus chronic), and review of systems.

Clinical signs can be variable and non-specific depending on inciting cause. Signs can include anorexia, lethargy, depression, weakness, collapse, vomiting, diarrhea, polyuria/polydipsia, dysuria, anuria, hematuria, and vulvar or preputial discharge. In a recent study, only 48% of cats with peritonitis had a history of vomiting; depression/lethargy and anorexia were the most common findings.[26] Physical examination abnormalities can include evidence of peritoneal effusion (distended abdomen, fluid wave on ballottement [see ch. 17]); signs consistent with systemic inflammatory response syndrome (SIRS), such as tachycardia/bradycardia, tachypnea, pyrexia/hypothermia, and leukocytosis/leukopenia; and clinical signs consistent with progressive states of shock. Other findings could include penetrating wounds, hernias, icterus, and abdominal pain. Dogs are more likely than cats to exhibit signs of abdominal pain.[5] In two recent studies, only about half of cats with peritonitis exhibited signs of abdominal pain.[24,26]

Diagnostics

History and physical examination often guide initial diagnostics, but peritoneal fluid analysis is likely the most beneficial diagnostic test. Abdominocentesis can be done blindly if large volumes of fluid are present, or with ultrasound guidance for smaller volumes. Ultrasound-guidance, four-quadrant sampling, or diagnostic peritoneal lavage (see ch. 90) increase success rate and yield. Peritoneal fluid analysis includes evaluation of the gross appearance (color, character), protein concentration, specific gravity, and cytologic examination (see ch. 74). Biochemical analysis (glucose, bilirubin, creatinine, potassium) of the effusion can help differentiate underlying causes in some patients.

In most patients with peritonitis, fluid will be an exudate (protein >3.5 g/dL [>35 g/L]; nucleated cell count >5000/mcL). Fluid from a septic abdomen is an exudate with predominantly degenerate neutrophils and infectious organisms such as intracellular bacteria. The accuracy of cytologic examination of fluid for the diagnosis of septic peritonitis has ranged from 57-100%[5,21,38,39]; previous antibiotic therapy or location of sample collection could result in false negatives. Peritoneal fluid nucleated cell count is considered one of the most reliable variables for diagnosis of septic effusion in dogs and cats.[38] In one study, a peritoneal fluid nucleated cell (predominantly neutrophils) count > 13,000 cells/mcL was 86% sensitive and 100% specific in dogs, and 100% sensitive and 100% specific in cats, for the diagnosis of septic effusion.[38] A difference of >20 mg/dL (>1.1 mmol/L) between paired blood and peritoneal fluid glucose was 100% sensitive and 100% specific for the diagnosis of septic peritonitis in dogs, and 86% sensitive and 100% specific in cats. A lactate difference <2 mmol/L between blood and peritoneal fluid was predictive of septic peritonitis in dogs (63% sensitivity, 100% specificity); this same association has not been demonstrated in cats.[38] Levin et al found all dogs with septic effusions had a peritoneal fluid lactate >2.5 mmol/L.[39] Blood-to-peritoneal fluid glucose and lactate difference might not be as dependable for the diagnosis of septic peritonitis postoperatively when evaluating abdominal fluid collected from closed suction drains.[40] Dogs with neoplasia have had significantly lower glucose concentrations and higher lactate levels in their abdominal fluid than dogs without neoplasia.[41] Peritoneal fluid protein concentrations do not reliably distinguish septic and non-septic effusion in either

dogs or cats. Bacterial aerobic and anaerobic culture and sensitivity of abdominal effusion obtained at the time of preliminary diagnosis and prior to initiation of antibiotic therapy is recommended in cases of suspected septic peritonitis. Uroperitoneum is diagnosed if peritoneal fluid creatinine concentration exceeds the serum creatinine concentration greater than two-fold, or if peritoneal fluid potassium concentration exceeds the serum potassium concentration by more than a factor of 1.4 (dogs) or 1.9 (cats).[34-37] Bile peritonitis is diagnosed if peritoneal fluid bilirubin concentration exceeds serum bilirubin concentration by greater than a factor of 2; cytological examination can reveal bile pigment or crystals.[31]

A complete blood count (CBC), serum biochemistry profile, arterial blood gas analysis (see ch. 128), and coagulation panels (see ch. 196) are recommended to guide treatment. These tests contribute prognostic information, but results can be non-specific and vary with etiology. CBC abnormalities can include marked neutrophilia with a left shift, toxic changes, and anemia, especially in cats. In a study of cats with septic peritonitis, band neutrophilia was identified in 64%, toxic leukocytes in 36%, and anemia in 35%.[24] Leukopenia and marked neutrophilia have been associated with increased mortality in cats.[42] The severity of a degenerative left shift is significantly associated with outcome (risk of death or euthanasia) in dogs and cats with septic peritonitis.[43,44]

Common abnormalities on serum biochemistry profiles and blood gas analyses include metabolic acidosis with hyperlactatemia; hypocalcemia; hyperkalemia (uroperitoneum); hyperglycemia followed by hypoglycemia (cats>dogs>people); hypoalbuminemia; elevated liver enzyme activities and hyperbilirubinemia; and azotemia of prerenal, renal (acute kidney injury) or post-renal (uroperitoneum) origin. High plasma lactate concentration on admission, poor lactate clearance, and persistent postoperative hyperlactatemia are associated with increased mortality and morbidity in dogs with septic peritonitis (see ch. 70).[45] Hypocalcemia is common in critically ill patients, including those with septic peritonitis, but the pathophysiologic mechanism has not yet been clearly established. Persistent hypocalcemia during hospitalization could be a negative prognostic indicator in both dogs and cats with septic peritonitis.[46,47] Uroperitoneum patients develop hyperkalemia because urine, which is high in potassium, accumulates in the abdominal cavity and potassium is reabsorbed into the systemic circulation through the peritoneum; life-threatening cardiac arrhythmias can result (see ch. 248).[35,37] Peritoneal effusions have been associated with a decreased sodium : potassium (Na : K) ratio.[48,49] Proposed mechanisms include decreased effective circulating volume due to loss of sodium-rich fluid and subsequent activation of the renin-angiotensin-aldosterone system (RAAS), and antidiuretic hormone (ADH) release. Decreased sodium delivery to the distal renal tubules and decreased kaliuresis can decrease Na : K ratio.[50] Abnormalities in blood glucose concentration can be a feature of peritonitis. In a study of cats with septic peritonitis, hypoglycemia was identified in 10, and hyperglycemia in 6, of 46 patients.[24] Hypoalbuminemia is common with septic and non-septic peritonitis and has been reported as a complication of open peritoneal drainage in dogs and cats.[24] Increased activities of alanine aminotransferase (ALT) and gamma-glutamyl transferase (GGT) are associated with increased mortality in dogs with diffuse peritonitis treated with open peritoneal drainage.[20] Hyperbilirubinemia can be seen in dogs and cats with various causes of peritonitis, especially bile peritonitis or pancreatitis.

The presence of bacteriuria and pyuria in a urine sample should prompt urine culture and sensitivity, as bacteria in urine could be similar to those found in peritoneal fluid if septic. With severe sepsis, there can be prolongation of clotting times (PT, PTT), thrombocytopenia, decreased fibrinogen, elevation in fibrin degradation products and D-dimers, and/or decreased antithrombin (AT) levels, consistent with disseminated intravascular coagulation (see ch. 197). Deficiencies of protein C and AT, and hypercoagulability, appear to be consistent features of naturally occurring canine sepsis and could be useful prognostic indicators in canine septic peritonitis.[51] Ancillary tests, such as pancreatic-specific lipase immunoassays (PLI), can be helpful in evaluation of pancreatitis (see ch. 289, 290, and 291) as a possible cause of peritonitis.

Abdominal imaging can help in the diagnosis of peritonitis. Survey radiographs can show local or generalized loss of detail, evidence of volvulus or torsion, a GI foreign body or evidence of mechanical obstruction, mass effect, prostatomegaly, pyometra, or pneumoperitoneum. GI rupture secondary to gastric dilation-volvulus, neoplasia, NSAIDs, or glucocorticoids accounted for the majority of cases of spontaneous pneumoperitoneum in one study.[52] Horizontal beam radiography is more sensitive for detection of small volumes of gas and can help differentiate gas bubbles superimposed over the GI tract.[52] Idiopathic pneumoperitoneum is a diagnosis of exclusion when intraabdominal disease is absent and it is considered a nonsurgical disorder.[53-56] Abdominal ultrasonography can show localized peritoneal effusion, define an underlying etiology of peritonitis, and help guide abdominal fluid sampling (see ch. 88 and 89). Contrast

radiography can evaluate the upper GI tract and assess gastrostomy or jejunostomy tube site integrity; excretory urography or cystourethrography can confirm uroperitoneum. Contrast-enhanced multi-detector computed tomography (CE-MDCT), where available, can be performed safely and successfully in awake or lightly sedated patients with acute abdominal conditions[57] and can accurately differentiate surgical from non-surgical acute abdominal conditions in dogs (also see ch. 143).[58]

Treatment

Medical Stabilization

The goals of medical treatment are to restore effective circulating volume, correct acid-base disturbances, maintain electrolyte balance, and minimize ongoing contamination. Patients can present in varying degrees of hypovolemic shock (see ch. 127) and require fluid resuscitation with crystalloids and/or colloids (see ch. 129), and blood products (see ch. 130). The goals during the first 6 hours of resuscitation using the approach of early goal-directed fluid therapy are: mean arterial pressure (MAP) ≥65 mm Hg (see ch. 99), central venous pressure (CVP) 8-12 mm Hg (see ch. 76), urine output ≥0.5 mL/kg/h (see ch. 106), central venous oxygen saturation ≥70% (see ch. 98), and lactate <2 mmol/dL (see ch. 70).[59-62] Fluid resuscitation is initiated using small boluses (10-20 mL/kg over 5-15 minutes) of isotonic crystalloids, barring clinically significant primary heart disease. Similarly, synthetic colloids can be administered in dosages of 5 mL/kg over 5-10 minutes and/or hypertonic saline (7-7.5% sodium chloride) given at 4-6 mL/kg.[63,64] Vasopressors, such as norepinephrine, epinephrine, vasopressin, and dopamine, are advocated for shock that does not respond to fluid resuscitation; norepinephrine is the first-line vasopressor for septic shock.[65] Electrolytes (potassium, phosphate, magnesium) and dextrose can be supplemented if indicated. Albumin administration may be needed in hypoalbuminemic patients with decreased colloid osmotic pressure (see ch. 130). The need to give large volumes of plasma to increase circulating albumin concentrations makes concentrated albumin sources preferred unless unavailable. Human serum albumin (5% and 25% solutions) has been transfused safely in critically ill patients, including those with peritonitis, to increase albumin concentrations and systemic blood pressure.[66,67] Lyophilized (5%) canine albumin has been given to hypoalbuminemic dogs following surgical treatment for septic peritonitis.[68]

Intensive monitoring may be needed for hemodynamically unstable patients. Arterial catheters (see ch. 75) allow measurement of blood gas values and continuous direct blood pressure monitoring. Jugular central venous catheters, or peripherally inserted central catheters (see ch. 76), allow measurement of central venous pressure and aid in deciphering whether a patient has received an adequate fluid volume or is fluid overloaded. Central venous pressure measurement can help determine when vasopressors are required beyond fluid resuscitation. Urinary catheters (see ch. 106) allow assessment of urine production and monitoring of fluid needs, and may be used for urine diversion in patients with uroperitoneum. Fresh whole blood, packed red blood cells and plasma administration may be indicated in patients with anemia or coagulopathies (see ch. 130).

Early initiation and appropriate selection of broad-spectrum antibiotic therapy are important in septic peritonitis. Antimicrobials likely to be effective against the bacterial organisms causing septic shock (predominantly *E.coli, Clostridium* spp. and *Enterococcus* spp.[21]), and that have good penetration into presumed infected tissues should be given intravenously within the first hour after severe sepsis or septic shock has been recognized (see ch. 161). Source control should be attempted within 6 hours.[65] After initial broad-spectrum antibiotic therapy, the antibiotic regimen should be reviewed based on the patient's condition and results of culture and sensitivity to reduce therapy to the fewest drugs and lowest dosages necessary (antibiotic de-escalation).[65] For community-acquired infection with no evidence of renal insufficiency, a combination of amikacin (15 mg/kg IV q 24 h) and clindamycin (12 mg/kg IV q 12 h) is recommended. If there is evidence of renal insufficiency, then a third-generation cephalosporin, such as cefotaxime (22 mg/kg IV q 8 h), is recommended in place of amikacin. If *Enterococcus* infection is suspected, then either of the previous regimens in conjunction with ampicillin (22 mg/kg IV q 8 h) is advised.[69]

Treatment: Surgical Stabilization

The need for surgical treatment depends on the underlying cause of peritonitis. Immediate surgical intervention might not be necessary for primary bacterial peritonitis, idiopathic pneumoperitoneum, and uroperitoneum.[12,13,37,53-56] Surgical goals for septic peritonitis are abdominal exploration, elimination of the

source of contamination, debridement of necrotic material, repair, lavage, and drainage. Feeding tube placement should be considered during initial surgical exploration (see ch. 82). The omentum should be preserved for its beneficial functions including fluid drainage, adhesion, angiogenesis, and immune activity.[1] There is no reported difference in outcome between open, closed, or closed-suction drain management of septic peritonitis.[20-23,29,70,71] Primary closure without drainage is recommended if the source of contamination can be controlled with repair, debridement and lavage.[22] Open abdominal drainage and closed-suction drains are recommended if debridement and lavage cannot remove the infectious and foreign material load, or if the source of contamination cannot be repaired. Closure of an open abdomen can typically be performed 3-5 days following the initial surgery. Disadvantages of open peritoneal drainage are loss of copious amounts of fluid and plasma proteins from the peritoneal cavity, evisceration of abdominal organs, nosocomial infections, the need for intensive nursing care, adhesion of viscera to bandage material, and continued peritonitis and sepsis.[20,23] Vacuum-assisted closure has been used successfully in veterinary medicine for the management of septic peritonitis (Video 279-1).[70,71]

Postoperative Care

Comprehensive postoperative management and intensive monitoring in critically ill patients with peritonitis may be necessary. Placement of an arterial catheter, central venous catheter, and urinary catheter will allow more sophisticated monitoring. A urinary catheter can be used for measuring intraabdominal pressure, using the intravesicular technique, to prevent the abdominal compartment syndrome.[72] Cardiac telemetry monitoring provides information on heart rate and cardiac dysrhythmias that could necessitate treatment (see ch. 248). Abdominal drain management consists of keeping exit sites clean, monitoring and recording drainage volume and character, and serial cytologic examinations of the fluid. The clinician should monitor fluid "ins" received and "outs" lost in urine, bandages, and drainage, and adjust fluid therapy accordingly. Analgesia predominantly is provided by constant rate infusion of opioids, but multimodal analgesia with ketamine, lidocaine, local anesthetics, dexmedetomidine, and epidural continuous infusion might be necessary to control severe pain (see ch. 126). Early enteral nutrition via nasoesophageal, nasogastric, esophagostomy, or gastrostomy feeding tubes is advocated in critically ill patients (see ch. 82). Possible complications of enteral feeding include vomiting/regurgitation, diarrhea, electrolyte/acid-base disturbances, and feeding tube malfunction (obstruction, dislodgement, exit site infection). Parenteral nutrition (see ch. 189) can be delivered through a central vein (total parenteral nutrition) or a peripheral vein (peripheral or partial parenteral nutrition). Parenteral nutrition is associated with more metabolic complications and intensive nursing care is needed for aseptic admininstration.[73] A study in dogs that survived septic peritonitis found that early nutrition (within 24 hours of hospitalization for both parenteral and enteral routes) was associated with significantly shorter hospitalization length (by 1.6 days).[74] Other specific postoperative care can be directed towards treatment of secondary complications including anemia (see ch. 198), systemic inflammatory response syndrome (see ch. 132), disseminated intravascular coagulopathy (see ch. 197), aspiration pneumonia (see ch. 242), pancreatitis (see ch. 290 and 291), vasculitis, and multiple organ dysfunction (acute kidney injury, hepatic dysfunction and cholestasis, acute respiratory distress syndrome).

Prognosis

The prognosis associated with peritonitis varies with underlying etiology, species, patient population, comorbidities, and medical or surgical management of cases. The overall survival rates for animals with septic peritonitis are reported as being between 47-85% in dogs[12,16,18,20-23,25,29,68-70] and 44-71% in cats.[12,13,16,21,23,24,28] Poor prognostic indicators in septic peritonitis include high serum liver enzyme activities (GGT, ALT),[20] refractory hypotension, cardiovascular collapse, disseminated intravascular coagulopathy, pulmonary dysfunction, and multiple organ dysfunction.[15,75] The overall survival rate for dogs with septic bile peritonitis is 27-45% and 87-100% for non-septic bile peritonitis.[30,31] The reported survival rate of cats with uroperitoneum without concurrent traumatic injuries was approximately 62% in one study; there are no corresponding studies for dogs.[34] A favorable outcome for patients with peritonitis depends on early recognition, intensive medical stabilization, source control using surgical management when needed, and comprehensive post-operative care.

CHAPTER 280

Diagnostic Evaluation of the Liver

Sarah Cocker, Keith Richter

Introduction

The liver plays a critical role in many biologic processes essential to life. Major functions of the liver include: immunoregulation; storage of vitamins, trace minerals, glycogen, blood, and triglycerides; detoxification and excretion of toxins and other substances; digestive functions; and metabolism of carbohydrates, lipid, protein, vitamins, and endocrine hormones.[1] The liver has a remarkable regeneration capacity after significant loss. The liver can restore itself to its original size with removal of up to 70% within only 5-7 days in rats.[2] However, liver diseases associated with fibrosis, inflammation or viral infections impair this regenerative process and liver function deteriorates.[2] Because the liver has such an incredible ability to regenerate, more specific signs of liver disease such as icterus, ascites, bleeding tendencies, hypoglycemia, and hepatic encephalopathy (HE) typically do not develop until the end stages of a disease process. Early clinical signs of liver disease such as vomiting, diarrhea, lethargy, polyuria (PU), polydipsia (PD), and inappetence are extremely nonspecific. Thus, diagnosing primary hepatobiliary disease can be challenging. A logical approach encompassing patient signalment, history, physical exam findings, biochemical and hematologic abnormalities, diagnostic imaging, and liver sampling should be used to obtain a diagnosis.

Signalment and History

Breed Predispositions

For some liver diseases there are strong breed predispositions that can help raise the suspicion of hepatobiliary disease even in light of nonspecific early signs, as well as suspicion for specific hepatopathies. In other instances, the history is often very suggestive of a specific hepatopathy. For example, middle-aged, overconditioned cats with a recent history of weight loss and anorexia should raise suspicion for feline hepatic lipidosis (FHL).[3] Accumulation of copper within hepatocytes can occur secondary to increased intake, primary defects in hepatic copper metabolism, or from altered biliary excretion of copper.[4] Histopathologic findings in patients with inherited copper storage disorders will demonstrate copper accumulation located centrilobularly, whereas in patients with copper accumulation secondary to cholestasis, copper is found in the periportal parenchyma.[4,5] While there are many breeds predisposed to copper storage disease, such as the Labrador Retriever, Doberman Pinscher, Dalmatian, Skye Terrier, and the West Highland White Terrier, the specific gene mutation (COMMD1) has only been found in the Bedlington Terrier.[4] Accumulation of copper in hepatocytes may start in patients when they are less than a year old, but they typically do not present with clinical signs until they are at least a few years of age.[4] Dobermans and Labradors seem to have a female predilection.[4] Copper storage disease has also been diagnosed in cats, with possible predispositions for Siamese and European Shorthair breeds.[4] Idiopathic chronic hepatitis has been described to be breed-related in Labrador Retrievers, Standard Poodles, Doberman Pinschers, American and English Cocker Spaniels, and English Springer Spaniels (in the United Kingdom).[4,6,7] Chronic hepatitis is often seen along with copper storage accumulation in Labradors and Doberman Pinschers. Hepatic amyloidosis has been documented in Abyssinian, Oriental, and Siamese cats, as well as in Chinese Shar-Pei dogs.[8,9]

Portosystemic Shunts

Portosystemic shunts (PSS) can be congenital or acquired (see ch. 284). Congenital PSS are typically a single intra- or extrahepatic shunting vessel. Dogs with congenital extrahepatic PSS are typically pure-breed small-

and toy-breeds. The most common breeds affected include Yorkshire Terriers, Havanese, Maltese, Dandie Dinmont Terriers, Pugs, and Miniature Schnauzers.[10] Most congenital intrahepatic PSS are found in larger breed dogs, with an increased prevalence in Irish Wolfhounds, Labrador and Golden Retrievers, Australian Cattle Dogs, and Australian Shepherds.[10] In cats, PSSs tend to be extrahepatic, and overrepresented breeds include the Domestic Short Hair, Persian, Siamese, Himalayan, and Burmese.[10] The majority of pets with congenital PSS on presentation are less than 1-2 years of age, but may not present until they are much older. The median age of animals with multiple acquired extrahepatic PSS has been reported as 3 years of age at the time of presentation. These pets are typically small in stature, with a history of being dull or lethargic at times. They may have a history of anesthetic intolerance, weight loss, ataxia, and bizarre behavior (intermittent blindness, head-pressing, staring into walls or corners, pacing, random barking, or aggression).[10] Association between meal ingestion and onset of signs has been reported in 30-50% of patients.[11] A history of gastrointestinal signs, PU/PD and lower urinary tract signs is also fairly common. In cats, copper-colored irises inappropriate for the breed has been documented (Figure 280-1).[12]

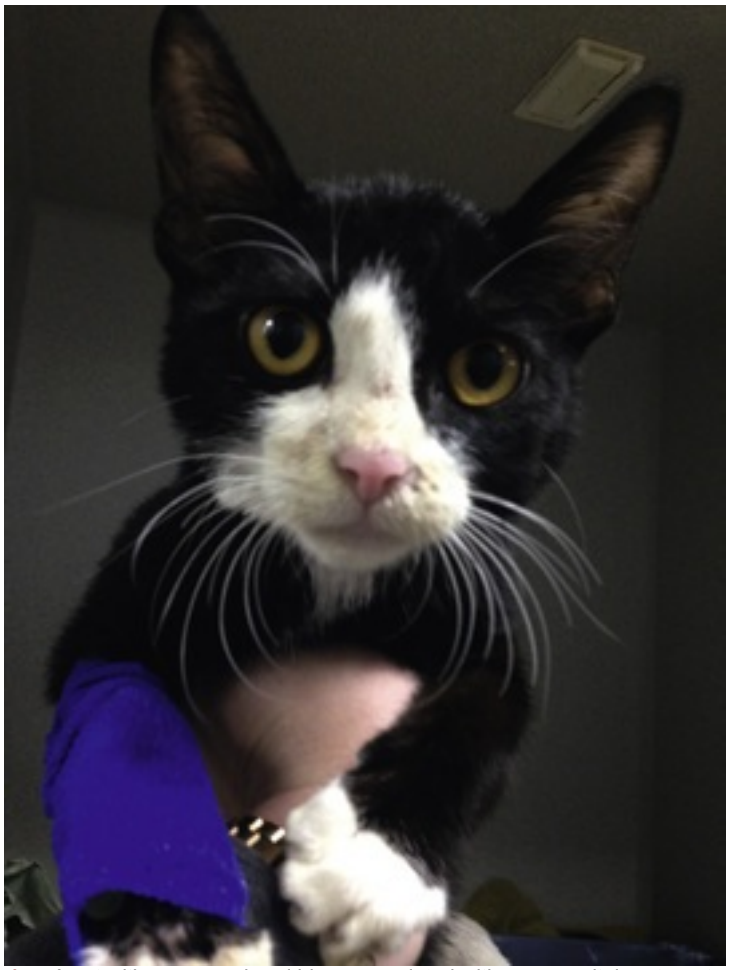

FIGURE 280-1 A cat with copper colored irises associated with a congenital portosystemic shunt.

Other Hepatopathies

Patients with congenital portal vein hypoplasia (PVH) without a macroscopic shunt (also known as microvascular dysplasia or MVD) present later in life, rarely develop clinical signs, and have an excellent long-term prognosis (see ch. 284). Maltese dogs, and Cairn and Yorkshire Terriers are overrepresented in patient populations with MVD.[13-15] The median age of these patients at the time of presentation is 3.25 years, but may range up to 10 years of age.[13] Progressive vacuolar hepatopathy is recognized as a breed-related

disorder in Scottish Terriers.[15,16] A recent study showed that vacuolar hepatopathy in this breed may be linked to adrenal steroidogenesis and a predisposition to hepatocellular carcinoma.[16]

General Information to Obtain

Pertinent historical information includes current medications as well as exposure to drugs, toxins, nutraceuticals, and supplements that may be kept in the home; the environment of the patient including time and supervision outdoors; exposure to environmental toxins and infectious agents; travel history; and vaccination status. See Box 280-1 for a list of common liver toxins. Box 280-2 lists common infectious agents affecting the liver. Middle aged, overconditioned cats with a recent history of weight loss and anorexia should raise suspicion for feline hepatic lipidosis (FHL).[3]

  - *Blastomyces dermatitidis*
  - *Cryptococcus neoformans*
  - *Histoplasma capsulatum*
  - *Coccidioides immitis*
- Parasitic
  - *Platynosomum fastosum*
  - Toxoplasmosis
  - Schistosomiasis
  - Migrating larvae

Physical Examination

Icterus

One of the most common manifestations of hepatobiliary disease is icterus. The most sensitive places to look for icterus on physical examination are the sclera, third eyelid, soft palate, and below the tongue (Figure 280-2). Usually, icterus cannot be detected until the serum bilirubin concentration is greater than 3.0 mg/dL (and often up to 5.0 mg/dL). On the other hand, visibly icteric plasma (seen on microhematocrit tubes) or serum can be seen when the bilirubin concentration is over 0.5-1.0 mg/dL. A discussion of bilirubin is found below later in this chapter.

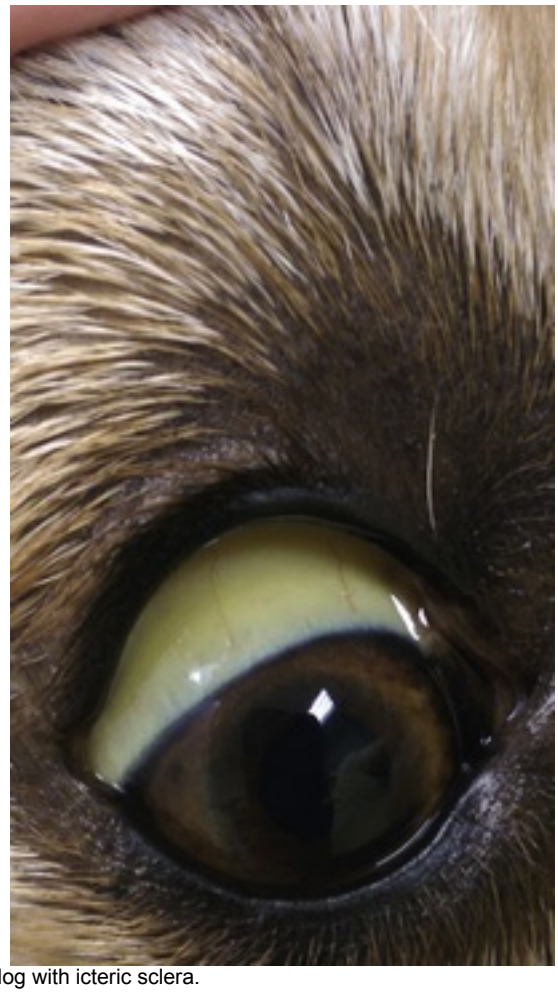

FIGURE 280-2 A dog with icteric sclera.

Dermatologic Signs

Hepatocutaneous syndrome is a form of superficial necrolytic dermatitis and has been reported in some dogs and cats with liver disease (see ch. 285). It typically manifests in dogs as hyperkeratosis with subsequent crusting and fissuring of the paw pads. Erythema, erosions or ulcerations, serous to purulent discharge, crusts, and hyperkeratotic plaques may be seen at other sites including perioral, perianal, perivulvar, preputial, and scrotal skin.[17] Lesions in cats may not appear on the footpads as they do in dogs. Ulceration and crusting of oral mucocutaneous junctions and ulceration of the pinnae, periocular areas, interdigital areas, ventral abdomen, and inguinal areas with or without crust formation is seen in cats.[17]

Ascites

Ascites is the accumulation of free fluid within the abdominal cavity (see ch. 17). Dogs and cats with severe ascites may present with a distended abdomen (Figure 280-3) and have a ballottable fluid wave on abdominal palpation (see ch. 17). Ascites in liver disease is typically due to portal hypertension (PH), though decreased vascular oncotic pressure from hypoalbuminemia may also play a role. Ascites can also be seen secondary to gallbladder rupture or effusion from hepatic neoplasms (including hemoabdomen). Ascites solely secondary to decreased oncotic pressure typically doesn't occur until serum albumin concentrations are <1.5 g/dL.[18] Portal hypertension occurs secondary to increased resistance, increased blood flow or both in the portal circulation.[19] Causes of PH are classified based on anatomical location as prehepatic, intrahepatic, or posthepatic.[19-24] Prehepatic causes occur because of increased resistance in the extrahepatic portal vein and are associated with mural or intraluminal obstruction (e.g., congenital atresia or fibrosis, thrombosis, neoplasia) or extraluminal compression.[5,20,25-31] Hepatic arteriovenous fistulas also cause prehepatic PH (see

ch. 284).[5,32-34] Patients with prehepatic PH are typically young, and have ascites and signs of hepatic encephalopathy.[19] Intrahepatic PH occurs because of increased resistance in the microscopic portal vein tributaries, sinusoids, or small hepatic veins.[19] Intrahepatic PH is further divided into presinusoidal, sinusoidal, and postsinusoidal.[19] Chronic hepatitis with fibrosis or cirrhosis is the most common cause of intrahepatic PH. Posthepatic PH occurs secondary to obstruction of larger hepatic veins such as the posthepatic caudal vena cava or the right atrium.[19] Examples of posthepatic PH include right heart failure, pericardial disease, pulmonary hypertension, and Budd-Chiari syndrome.[35-38] Ascitic fluid secondary to prehepatic and presinusoidal PH and possibly sinusoidal intrahepatic PH has a low protein concentration (<2.5 g/dL), whereas ascitic fluid secondary to posthepatic, postsinusoidal, and sinusoidal intrahepatic PH has a high protein concentration (>2.5 g/dL).[19] Portal hypertension can also lead to the development of multiple acquired portosystemic shunts (MAPSS) and hepatic encephalopathy.[19]

FIGURE 280-3 A dog with a distended abdomen due to ascites.

Hepatic Encephalopathy

Hepatic encephalopathy (HE) is a dysfunction of the brain secondary to liver dysfunction (see ch. 281 and 284).[39] This syndrome occurs less commonly in cats than in dogs.[18] The pathogenesis for HE is multifactorial, and is associated with toxins derived in the gastrointestinal tract that bypass hepatic metabolism.[19] Ammonia is one of the most important of these toxins. Other toxins implicated in the pathogenesis of HE include aromatic amino acids, bile acids, endogenous benzodiazepines, gamma aminobutyric acid, glutamine, phenol, short-chain fatty acids, tryptophan, decreased alpha-ketoglutarate, and false neurotransmitters.[10] There are two forms of HE: an acute type and a chronic type. The acute form is caused by fulminant hepatic failure. These animals typically die within a few days and the encephalopathy is severe.[18] The chronic form is much more common than the acute and carries a better prognosis as long as the underlying liver disease is reversible.[39,40] The chronic form is typically secondary to a lesion in portosystemic collateral circulation (multiple acquired PSS or congenital PSS).[18] Chronic HE can also be seen in cats with hepatic lipidosis because cats cannot synthesize arginine in the liver and depletion of arginine occurs with prolonged fasting.

Arginine is necessary for completion of the urea cycle and without it ammonia detoxification is impaired.[18] Rare causes of chronic HE are congenital disorders of metabolism in which one of the enzymes involved in ammonia metabolism is abnormal.[18] Early clinical signs of HE are subtle and include apathy, listlessness, and decreased mental alertness. In advanced, more severe disease, signs include ataxia, circling, head pressing against stationary objects, salivation, stupor, and coma. Seizures are uncommon, but may be seen in conjunction with other signs of HE.[18] Ammonia tolerance testing can be used to try and help confirm the diagnosis of HE if an ammonia level is not conclusive and HE is still suspected. The performance of this test is discussed in the ammonia section of this chapter. This test is not useful in patients with elevations in basal ammonia values, because HE is already proven.[41]

Laboratory Evaluation of Hepatobiliary Disease

Liver Enzymes (also see ch. 65)

Overview

Elevated serum liver enzyme activities are often the first finding that prompts suspicion of the presence of hepatobiliary disease. Liver enzymes evaluated on typical biochemical panels include alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and gamma-glutamyl transpeptidase (GGT). These enzymes reflect hepatocyte membrane integrity (ALT and AST), hepatocyte or biliary epithelial necrosis (ALT and AST), cholestasis (ALP and GGT), or an induction phenomenon (ALP and GGT).[42] The pattern of liver enzyme elevations can be helpful in prioritizing a differential list. Liver enzymes are classified into hepatocellular leakage enzymes (ALT, AST) indicating hepatocellular injury, and inducible enzymes (ALP, GGT) associated with increased synthesis. The magnitude of liver enzyme elevation is considered mild if <5 times the upper reference range; moderate if 5-10 times the upper reference range; and markedly elevated if >10 times the upper reference range.[42] It is important to remember that abnormal liver enzyme activity is more common than the presence of primary liver disease as there are several other clinical conditions that increase liver enzyme activities (Box 280-3). Elevated liver enzyme activities in the absence of hepatobiliary damage can be a consequence of exogenous administration of corticosteroids or phenobarbital, endogenous increases in corticosteroids, damage in non-liver tissues which also contain these enzymes (e.g., bone isoenzyme of ALP), and secondary injury from damage to organs that have portal venous drainage, especially the gastrointestinal tract and pancreas. The latter process is known as a reactive hepatopathy. There are also significant diseases of the liver that can have normal or only mildly elevated liver enzyme activities. These include vascular disorders (PSS and MVD), metastatic hepatic neoplasia (up to half of these cases can have normal liver enzyme activities), and end-stage cirrhosis (in which there is enzyme depletion).

Osteosarcoma or other bone tumors
Acute severe hemolysis
Postcaval syndrome
Mammary tumors
Young growing animal
Laboratory error

While elevations in serum hepatobiliary enzyme activities are very sensitive for the detection of hepatobiliary disease and the magnitude of elevation can correlate with the degree of damage, they are not indicative of the anabolic or catabolic functional capacity of the liver. Other biochemical parameters and liver function tests need to be assessed to determine the functional capacity of the liver.

ALT and AST

Elevations in activities of ALT and AST occur secondary to leakage from the hepatocyte after damage to the hepatocyte membrane; thus they are termed hepatocellular leakage enzymes. The half-life ($T_{1/2}$) of ALT is 48-60 hours in the dog and presumed to be around 6 hours in the cat.[43,44] The plasma $T_{1/2}$ of AST is approximately 22 hours in the dog and an estimated 77 minutes in the cat.[45,46] Typically, ALT activity is elevated to a greater magnitude than AST activity, partly due to its longer half-life. Hepatocellular leakage enzymes are present in high concentrations in the liver, but are also found in other tissues. AST is found in high concentrations in the liver, muscle, and red blood cells.[42] ALT, however, is primarily located in the liver with concentrations many times higher than in muscle.[42] Because the vast majority of ALT is found in the liver compared to the other hepatocellular enzymes, it is the most specific of the hepatocellular enzymes for liver injury. Evaluation of serum creatinine kinase (CK) activity is often helpful in differentiating ALT and AST elevations due to muscle injury versus liver injury.[47] The activity of CK increases rapidly after muscle injury, with peak levels occurring approximately 6 to 12 hours post-injury, and decreases within 24 to 48 hours due to a short half-life.[48] Elevations in AST activity typically parallel those of ALT but to a smaller magnitude.[44] Increased AST activity with a normal ALT indicates an extrahepatic enzyme source (muscle or red blood cell). Thus, if serum AST activity is greater than serum ALT activity, elevated serum CK activity supports a muscle origin of AST. If serum CK activity is normal with the pattern of serum AST greater than serum ALT, red blood cell origin of AST is another explanation (as would occur with *in vitro* or *in vivo* hemolysis).

Most ALT and AST resides within the soluble fraction of the cytosol and about 20% of AST is found within mitochondria.[42] The presence of a portion of AST in the mitochondria is one reason elevation of its serum activity is less sensitive than ALT for detecting liver injury (along with its shorter half-life). Additionally, because AST is found in high concentration in other organs, it is less specific than ALT for hepatocellular injury. The largest increases in ALT occur secondary to hepatocellular necrosis and inflammation, while moderate to severe elevations can occur with hepatic neoplasia, biliary tract disease (obstructive or nonobstructive), and cirrhosis.[42,49] Following severe hepatocellular injury, ALT activity typically increases markedly within 24-48 hours to values of 10- to 100-fold greater than normal, peaking the first 5 days post-injury.[50-56] In acute liver disease, a decrease of 50% or more over a few days (the half-life of serum ALT) is considered a good prognostic sign.[42] It is important to note, however, that declining liver enzyme activities may represent a decline in viable hepatocytes in chronic liver disease, severe toxicosis, or toxin-suppressed transaminase synthesis (e.g., microcystin, aflatoxin).[42] Chronic hepatitis is associated with fluctuations in liver enzymes. As the injury resolves, ALT declines, but serum ALP may increase due to the regenerative

proliferative process.[42] Following severe acute hepatocellular necrosis, AST drastically increases in the first 3 days to values 10- to 30-fold above the reference range in dogs and up to 50-fold above the reference range in cats.[50,52,57] Administration of glucocorticoids to dogs may cause a mild increase in serum AST that will resolve several weeks after discontinuing glucocorticoid therapy.[58]

ALP

In contrast to the liver leakage enzymes, ALP is attached to cell membranes by glucosyl phosphatidylinositol linkages.[42] The release of ALP from its cell membrane linkage is facilitated by the presence of bile acids, which exert a detergent-like effect on the membrane anchor.[59,60] Increases in serum ALP occur secondary to *de novo* hepatic synthesis or elution of the enzyme from the cellular membrane. Elevated ALP is the most common abnormality on canine biochemical panels, and of the liver enzymes, has the lowest specificity for hepatobiliary disease.[42] In dogs, the sensitivity and specificity of elevated ALP for hepatobiliary disease is 80% and 51%, respectively.[44] Alkaline phosphatase in the dog is present in the highest quantities, in descending order, in the intestinal mucosa, renal cortex, placenta, liver, and bone.[42] In the cat it is debatable which tissues contain the highest concentrations of ALP.[61-63] There are three major ALP isoenzymes in canine serum: bone-induced (B-ALP), liver-induced (L-ALP), and corticosteroid-induced (C-ALP).[64-67] The intestinal, renal, and placental isoenzymes contribute little, if any, to elevations in serum ALP due to their extremely short half-lives.[42] In adult dogs, it is primarily L-ALP and C-ALP that are responsible for elevated serum ALP on the biochemistry panel, whereas in adult cats it is primarily L-ALP.[42] The plasma $T_{½}$ of L-ALP and C-ALP is 70 hours in the dog, whereas the plasma $T_{½}$ of the liver isoenzyme is only 6 hours in the cat.[61,68,69] Total serum ALP activity can be induced in dogs, but not in cats, by exogenous or endogenous steroids and certain drugs.[42] Measuring the specific C-ALP fraction is not clinically useful in differentiating between primary hepatobiliary disease or the effects of endogenous or exogenous glucocorticoids because C-ALP activity is elevated in many primary hepatopathies. In cats, ALP is less sensitive (50%) but more specific (93%) for hepatobiliary disease due to its short half-life, the fact that cats lack C-ALP, and because feline hepatocytes contain less ALP.[44] Elevations in serum B-ALP are seen due to its release secondary to bony growth and remodeling in juvenile dogs and cats, or with pathologic conditions such as osteomyelitis, osteosarcoma or other bone tumors, or renal secondary hyperparathyroidism.[42,61,64,69,70] The B-ALP may also contribute significantly to the elevations in serum ALP noted in some cats with hyperthyroidism.[63,70-72] The largest elevations in serum ALP activity (up to 100 times normal or greater) in dogs are seen with cholestatic disorders, massive hepatocellular carcinoma, bile duct carcinoma, and with administration of glucocorticoids.[42]

GGT

Like ALP, GGT is bound to the cell membrane of hepatocytes. GGT in dogs and cats is found in highest concentrations in the kidney and pancreas, with lesser amounts in the liver, gallbladder, intestine, spleen, heart, lungs, skeletal muscle, and erythrocytes.[73-75] Serum GGT activity is largely derived from the liver, and increased serum GGT reflects enhanced liver synthesis and elution from cellular membrane surfaces.[42] Similar to their influence on ALP, glucocorticoids and other microsomal enzyme inducers may stimulate GGT production in dogs.[42] In dogs, the sensitivity and specificity of GGT for detection of hepatobiliary disease is 50% and 87%, respectively.[44] Concurrent elevations in ALP increase the specificity for hepatobiliary disease to 94%.[44] Serum GGT is more sensitive (86%) but less specific (67%) than ALP in cats with inflammatory liver disease.[44,76] In cats with hepatic lipidosis, where the underlying cause is not associated with necroinflammatory hepatobiliary disease, the magnitude of increased serum ALP activity (relative to the upper limit of normal) will almost always be greater than the magnitude of increased serum GGT activity. In contrast, cats with necroinflammatory hepatobiliary disorders, with or without secondary hepatic lipidosis, will usually have increases in GGT activity of a greater magnitude than elevations in serum ALP activity.[42] Neonatal dogs can have elevations in GGT activity secondary to colostrum ingestion; this is not the case for the cat.[77-79]

Liver Function Parameters and Liver Function Testing

Glucose

Hypoglycemia only occurs after approximately 75% of hepatic function is lost and is the result of reduction in hepatic glycogen stores, gluconeogenesis, and clearance of insulin (see ch. 61).[44,47] Hypoglycemia can also be seen periodically in patients with PSS. It is important to remember that there are many other differentials for hypoglycemia other than synthetic liver failure, such as hypoadrenocorticism, sepsis, decreased intake in young growing animals, toxins (xylitol) with or without hepatic involvement, insulinomas, and other neoplasms causing a paraneoplastic syndrome (see ch. 352).

Blood Urea Nitrogen (BUN)

With a significant decrease in liver function or shunting of blood past the liver, the conversion of ammonia to urea decreases and a low BUN may be noted on biochemical profiles.[44] The abnormal shunting of blood around the liver in patients with PSS results in decreased delivery of ammonia to the liver for entry into the urea cycle, which results in hyperammonemia and decreased BUN.[47] Patients on strict low-protein diets and anorexic patients may also exhibit low BUN (see ch. 62).

Albumin/Globulin

The liver is responsible for the synthesis of albumin. Hypoalbuminemia can occur with chronic liver disease once approximately 70% of liver function has been lost.[44] Generally, when the serum albumin concentration is low due to advanced liver disease, the serum concentration of globulins will be normal to increased. Hyperalbuminemia has rarely been reported in patients with hepatocellular carcinoma.[80] The liver is responsible for the synthesis of alpha and beta globulins and these can be decreased with hepatobiliary disease, but gamma-globulin production is primarily dependent on B lymphocytes and plasma cells.[47] Hypoglobulinemia is mainly seen with gastrointestinal protein loss, not with liver dysfunction. Hyperglobulinemia can be seen in patients with shunts or decreased hepatic mass (fewer Kupffer cells) secondary to decreased filtration and clearance of toxins and microbial agents from the portal circulation (see ch. 60).[47]

Cholesterol

Serum cholesterol concentrations can be variable with hepatobiliary disease (see ch. 63). Cholestatic disease is typically associated with hypercholesterolemia, whereas hypocholesterolemia may be seen in end-stage liver disease.[44]

Bilirubin

Bilirubin is the pigment that gives bile its yellow-brown color.[18] Elevated bilirubin in the systemic circulation can lead to accumulation in tissues and clinical icterus (see Figure 280-2). Causes of hyperbilirubinemia are divided into three main categories: increased production (hemolysis), also termed prehepatic; hepatic disease causing inadequate uptake, conjugation and/or excretion of bilirubin; and posthepatic causes (abnormal biliary excretion of bilirubin) (Figure 280-4).[18,44] Hyperbilirubinemia can also be caused by cholestasis of sepsis, where cytokines inhibit the expression of hepatocyte transporters necessary for bilirubin transport, and can occur without the presence of hepatobiliary disease.[44] Mild elevation of serum bilirubin can also occur with the artifacts of hemolysis or lipemia. The measurement of direct (conjugated) or indirect (unconjugated) bilirubin is of no value in distinguishing causes of increased serum bilirubin. Patterns in liver enzyme elevations are also of little help to the clinician in determining if the bilirubin elevation is secondary to hepatic or posthepatic causes. Rather, imaging (most commonly ultrasound examination) is required to distinguish hepatic or posthepatic causes of elevated serum bilirubin concentration.

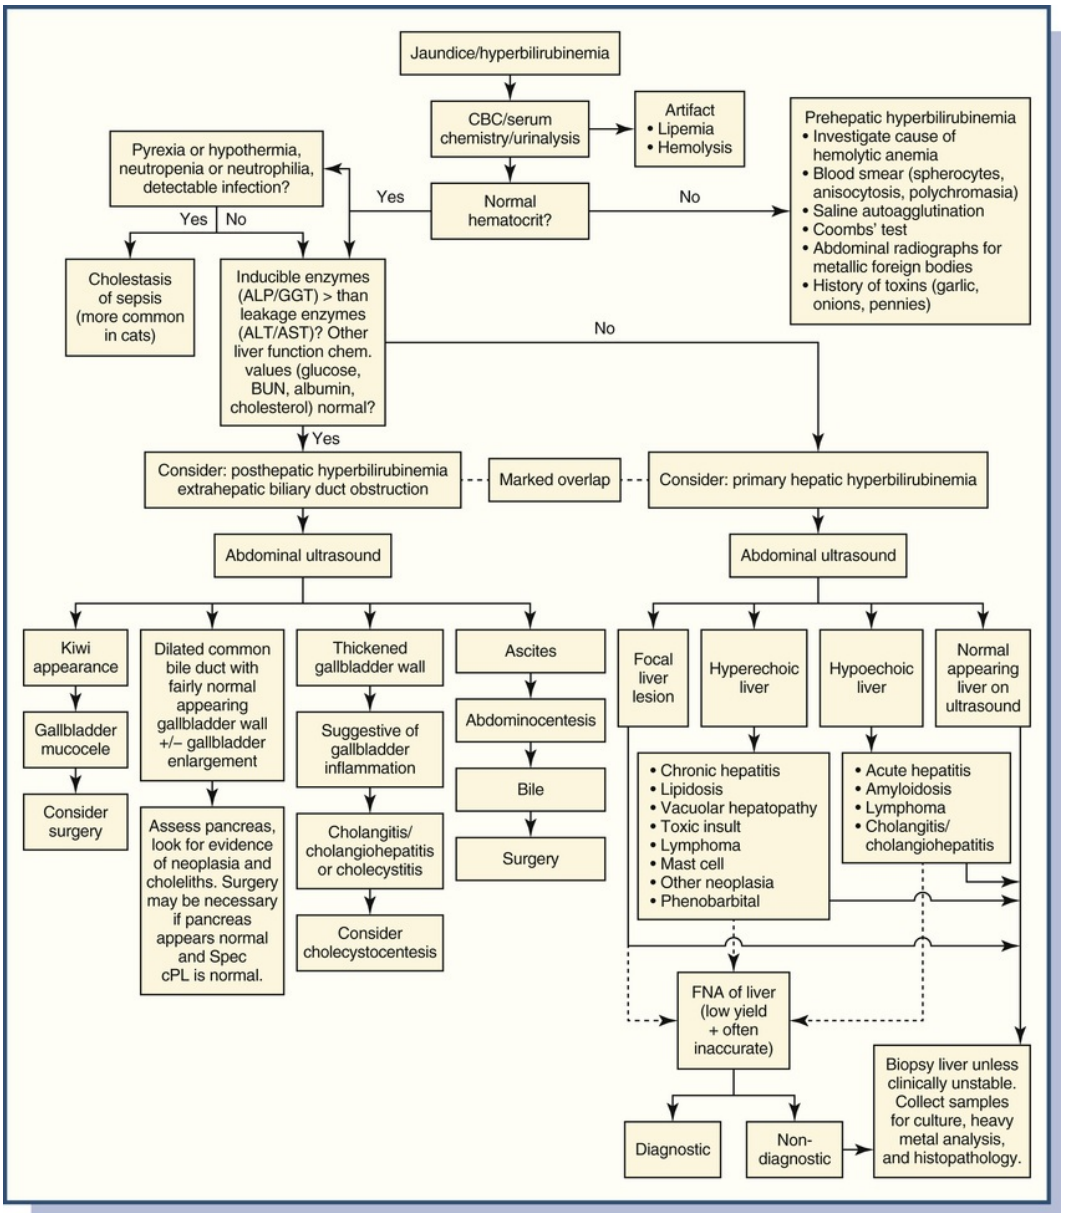

FIGURE 280-4 Diagnostic algorithm for hyperbilirubinemia. *ALP,* Alkaline phosphatase; *ALT,* alanine aminotransferase; *AST,* aspartate aminotransferase; *BUN,* blood urea nitrogen; *CBC,* complete blood count; *GGT,* gamma glutamyltransferase; *Spec cPL,* canine pancreas-specific lipase.

Usually prehepatic causes (hemolysis) are detected when the hematocrit is significantly decreased, and/or other hallmarks of hemolytic anemia are present (such as spherocytosis and/or a positive Coombs' test). Approximately 10% of all patients with liver disease have clinical jaundice.[18] In cats with hepatic lipidosis, greater than 95% present with hyperbilirubinemia.[3] Complete extrahepatic biliary duct obstruction (EHBDO) may cause acholic feces due to absence of stercobilin in stools.[18] With bile duct obstruction, conjugated bilirubin in plasma binds irreversibly covalently with albumin (called delta bilirubin), whose half-life is about 2 weeks. Therefore, a patient may remain visibly icteric for several weeks despite resolution of a bile duct obstruction.[18] Bilirubin concentration is not affected by abnormal liver perfusion; therefore, animals with congenital PSS will not be icteric.[18]

Bile Acids

Bile acids are synthesized by the liver exclusively from cholesterol, which is the major route of cholesterol excretion.[18] Bile acids are then excreted into the biliary tract and stored in the gallbladder. Cholecystokinin is secreted by the duodenal mucosa in response to fat or protein in ingesta and acts as the major stimulus for

contraction of the gallbladder.[81-84] The gallbladder contraction occurs slowly, over 1-2 hours.[18] Once the gallbladder contracts, bile acids are excreted into the duodenum to help solubilize dietary lipids.[85] They are then reabsorbed in the ileum and transported back to the liver via the portal vein, where >95% of the bile acids are removed and the process starts all over again.[85] This pathway is called the enterohepatic circulation, and its disruption due to liver dysfunction or portosystemic shunting leads to elevations in serum bile acids concentration. Increases in serum bile acid concentration can be seen with portosystemic shunts, parenchymal hepatic disease, and cholestasis.[86]

An estimation of the efficacy of enterohepatic circulation can be done by evaluation of serum bile acids. A blood sample is typically taken after a 12-hour fast (preprandial) and then two hours after a small meal (postprandial).[44] Typical cutoff values for pre- and postprandial bile acids are 15 mcmol/L and 25 mcmol/L, respectively. Pre- and postprandial bile acids elevations have been reported to be 99% sensitive and 95-100% specific for the diagnosis of a PSS in dogs and cats.[10,44] A study investigating the sensitivity and specificity of fasting bile acids in diagnosing PSS found them to be 93% and 67% in dogs, and 100% and 71% in cats, respectively. When increasing the cutoff value to 58 mcmol/L in dogs and 34 mcmol/L in cats the sensitivity was unchanged in dogs (91%) and was decreased in cats (83%), but the specificity increased in both species (84% in dogs, 86% in cats).[85]

While bile acids are quite useful for the diagnosis of PSS in dogs and cats and cirrhosis in dogs (sensitivity of essentially 100%), their value is limited for the screening of most other hepatobiliary diseases (sensitivity 54-74%).[44] Higher pre- than postprandial values may occur secondary to interdigestive gallbladder contraction or due to variations in gastric emptying, intestinal transit, or response to cholecystokinin release. This has no clinical significance, and whichever value is highest is used for interpretation. Falsely elevated postprandial values can occur with lipemia. Falsely decreased postprandial values may result from failure of cholecystokinin release to result in gallbladder contraction if the meal is inadequate in fat or protein content or an insufficient amount is consumed.[44] Severe ileal disease or previous resection of the ileum can decrease bile acid reabsorption, thus decreasing postprandial bile acids.[44] When used as a test of hepatobiliary function, the magnitude of elevation in serum bile acids does not allow differentiation of the category of disease, with the exception that patients with vacuolar hepatopathy rarely have marked elevations (greater than 75-100 mcmol/L).

Ammonia

Ammonia is derived primarily from the action of colonic bacteria on the breakdown products of ingested protein.[19] Intestinal ammonia is absorbed and enters the portal vein. In healthy states, ammonia is nearly completely removed from portal circulation during one passage through the liver via conversion to urea in the urea cycle.[18,85] The liver has a huge reserve capacity for detoxifying ammonia; therefore, HE typically only occurs when ammonia-rich blood bypasses the liver due to portosystemic shunting.[18] Hyperammonemia can also occur secondary to errors of metabolism in the urea cycle. This can be seen in anorexic cats with liver disease due to a lack of arginine, which is essential as a substrate for the detoxification of ammonia in the urea cycle.[85] Hepatic failure must cause an approximately 70% reduction in urea cycle function in order for hyperammonemia to develop.[12] Normal plasma ammonia levels in healthy animals are low (<45 mcmol/L).[18] The sensitivity and specificity of utilizing elevations in fasting ammonia for the diagnosis of PSS in dogs is reported to be 98% and 89%, respectively.[87]

Sample handling is extremely important for accurate measurement of ammonia. Ammonia should be measured in a fasted patient from non-hemolyzed fresh blood samples collected in lithium heparin tubes. Samples should be spun down in a refrigerated centrifuge within 30 minutes of collection and transferred on ice.[18,85] If kept at room temperature, ammonia is spontaneously liberated from nitrogenic sources.[18] The unreliability of enzymatically determined ammonia measurements and the lability of ammonia compromise the use of this test for diagnosing HE.[3] If bile acids and baseline ammonia are equivocal, the ammonia tolerance test can be performed to better assess the presence of HE. The ammonia tolerance test is performed by administering 2 mL/kg of a 5% NH_4Cl solution deep (10-20 cm) rectally via a soft catheter. A pre NH_4Cl sample as well as samples at 20 and 40 minutes post administration are collected. Patients without HE will have basal values within the normal range and will show a minimal increase in ammonia with this test. This test is not safe to perform in patients with basal ammonia values >150 mcmol/L.[41]

Coagulation Proteins

The liver can affect hemostasis in many ways. First, the liver produces all of the clotting factors except for the von Willebrand subtype of Factor VIII.[18,88] Second, cholestasis can cause malabsorption of fat-soluble vitamins such as vitamin K.[47] Vitamin K dependent clotting factors are II, VII, IX, X, protein C, and protein S.[89] Malabsorption of vitamin K and decreased activation of vitamin K dependent factors may lead to a prolonged prothrombin time (PT), but does not usually lead to a clinical coagulopathy.[90,91] This is the most common coagulation abnormality in cats with hepatobiliary disease.[92] Third, many clotting inhibitory proteins, including antithrombin III, protein C, and protein S, are synthesized in the liver. Fourth, splanchnic pooling of blood can lead to prolonged capturing of platelets at their degradation site in the spleen, which can induce thrombocytopenia. This is termed hypersplenism and occurs secondary to portal hypertension. Hypersplenism has been documented in humans, but to date has not been reported in veterinary patients with portal hypertension.[18,89] Fifth, some clotting factors, such as fibrinogen, act as acute phase reactants and are produced in excess by hepatocytes in cases of inflammatory or neoplastic disease, which leads to an increased consumption of fibrinogen.[18] This typically occurs in diffuse liver diseases associated with significant hepatocyte necrosis such as active forms of hepatitis and hepatic lymphoma.[88] Finally, some hepatobiliary disease can lead to disseminated intravascular coagulation (DIC). This is represented biochemically as low fibrinogen concentration, thrombocytopenia, prolonged PT and activated partial thromboplastin times (aPTT), and elevated fibrinogen degradation products and D-dimers (see ch. 197). While coagulation test abnormalities are common in dogs and cats with hepatobiliary disease, spontaneous bleeding is very rare. However, the presence of marked coagulation abnormalities in patients with liver disease is prognostic and seems to parallel the extent of functional hepatic failure.[93]

Plasma protein C is a disulfide-linked glycoprotein with a molecular weight similar to that of albumin. As stated earlier, it is synthesized in the liver and circulates as a plasma zymogen with a $T_{½}$ of approximately 6 hours. Once activated, protein C binds protein S and together they exert their anticoagulant effects by degrading factors Va and VIIIa.[94] In a study assessing the utility of plasma protein C for the detection of hepatobiliary disease and PSS in dogs, it was found that a protein C activity of less than 70% was common in patients with PSS (88%), but rare in patients with MVD (5%).[94]

Hematologic Findings

The most consistent abnormalities found on a complete blood cell count (CBC) include microcytosis (associated with impaired iron transport in patients with vascular abnormalities), target cells, poikilocytosis and Heinz body formation (cats).[44] Anemia may occur secondary to hemorrhage from gastrointestinal ulceration seen with advanced liver disease, a bleeding disorder, or anemia of chronic disease.[44] Some patients may also have a mild thrombocytopenia.[44] Poikilocytosis is found in 63% and anemia is noted in 22% of cats on presentation with hepatic lipidosis.[3]

Urinalysis

There are a few abnormalities one may note on analysis of the urine that may be consistent with the presence of liver disease (see ch. 72). The majority of these are nonspecific. The one specific finding for liver disease on a urinalysis is that of bilirubinuria in cats. Bilirubin in feline urine is always abnormal and indicates hepatobiliary or hemolytic disease.[18] In dogs, however, particularly in male dogs, there is a low threshold for bilirubin excretion. Additionally, their kidneys have the enzymes necessary to produce bilirubin from heme and to conjugate it. Thus, the urine of healthy dogs, especially males, may contain bilirubin.[18] Cats with hepatic lipidosis may have refractile fat globules in the urine (lipiduria) on urine sediment examination.[3] About half of dogs with portosystemic shunts will have ammonium biurate crystals found on urine sediment examination.[18] These crystals can also be found in the urine sediment of cats with portosystemic shunts.[95] This occurs because of the reduced hepatic conversion of uric acid to allantoin and of ammonia to urea.[96] Ammonia and uric acid aggregate in acidic urine to form crystals.[18] These crystals are infrequently associated with hepatic insufficiency due to other causes.[97] It is important to remember, however, that there are certain breed predispositions for the development of ammonium biurate crystals in the absence of hepatobiliary

disease, such as the Dalmatian, English Bulldog, and possibly Siamese cats.[98-101] The urine specific gravity in patients with hepatobiliary disease may be low. This is thought to be secondary to a loss of renal medullary hypertonicity (due to low BUN concentrations), impaired hormone metabolism (decreasing cortisol metabolism and creating a "Cushing's-like" syndrome), and psychogenic polydipsia may also play a role.[102] A Fanconi-like syndrome (presence of glucosuria despite euglycemia ± proteinuria; see ch. 326) has recently been recognized in some patients with copper storage hepatopathies secondary to accumulation of copper in the renal tubules.[103]

Imaging of the Liver

Radiography

In comparison with scintigraphic and ultrasonographic imaging, measurements made from right lateral abdominal radiographs have been found to have the highest correlation with actual liver weight in dogs.[104,105] The liver size can be determined on radiographs by measurement of the length of the liver and based on gastric axis position.[106-109] The normal gastric axis is described as perpendicular to the spine to parallel with the last rib.[110] Radiographically, hepatomegaly appears as round or blunted caudoventral liver margins, extension of liver margins beyond the costal arch, and displacement of the gastric axis.[106] Microhepatica appears as cranial displacement of the gastric axis and decreased distance between the diaphragm and gastric lumen on radiographs.[107] The position of the gastric axis can be affected by factors other than the size of the liver; therefore, measurement of the liver length may be more reliable for assessing liver size.[108,109] This can be done by measuring the length of the liver in cm as the length of the axis from the ventral border of the caudal vena cava to the apex of the hepatic caudal border and comparing it to the length of T11 (measured at the level of the midpoint parallel to the long axis of the vertebral body).[110] The normal length of the liver has been stated to be 5.5 ± 0.8 times the length of T11.[109] A recent study evaluating normal liver length in Pekingese dogs found it to be less than the previously stated normal range at 4.64 times the length of T11.[110] Loss of serosal detail is suggestive of the presence of ascites.[19] Free gas in the region of the liver is concerning for a ruptured hepatic abscess or emphysematous cholecystitis (see ch. 288).

Ultrasonography (see ch. 88)

The typical hepatic features evaluated during abdominal ultrasound examination include parenchymal echogenicity, parenchymal uniformity, vascular structures, biliary structures and an estimate of liver size.[111-115] These features are evaluated to determine: (1) the presence of focal lesions; (2) the liver architecture and structure; (3) the diameter of the lumen and the thickness of the wall of the extrahepatic and intrahepatic bile ducts and the gallbladder; (4) vascular changes, especially of the portal vein but also the presence of arteriovenous fistulas; (5) the presence of free abdominal fluid; and (6) echo Doppler evaluation of the portal blood flow velocity and direction.[88] It is important to remember that the liver may appear sonographically unremarkable even in the presence of severe disease.[116] While an unremarkable ultrasound exam was statistically significantly associated with the absence of histopathologic liver disease, 63% of these cases had abnormalities on histopathology in a study comparing hepatic ultrasound findings with histopathology.[117] The majority of dogs in this study with hepatobiliary disease and unremarkable ultrasound exams were diagnosed with inflammatory hepatopathies or degenerative lesions. Hepatic ultrasound changes are also not predictive of the presence, absence, or degree of hepatic fibrosis.[117] Hyperechoic hepatic parenchyma can be seen with chronic hepatitis, lipidosis, steroid hepatopathy, other vacuolar hepatopathies, toxic insult, lymphoma, mast cell disease, histiocytic sarcoma, and phenobarbital administration.[118] To determine if the liver is hyperechoic, its echogenicity should be compared to that of the falciform fat or spleen, both of which should normally be more hyperechoic (brighter) than the liver. Hypoechoic hepatic parenchyma may be noted with acute hepatitis, amyloidosis, lymphoma, or cholangitis/cholangiohepatitis.[118]

Ultrasound examination is quite useful for the assessment of EHBDO (see ch. 288). Neoplasia, pancreatitis, choleliths, sludge balls, inflammation, or gallbladder mucoceles can cause EHBDO.[118] The common bile duct can measure up to 3 mm in diameter in normal dogs and up to 4 mm in diameter in normal cats.[119,120] Color Doppler can be used to differentiate biliary from vascular structures. The gallbladder may be normal in size or enlarged with EHBDO. Therefore, the presence of a normally sized gallbladder should not be used to rule

out an EHBDO.[118] Portal markings may appear prominent, the gallbladder and bile duct walls may be thickened, and there may be increased amounts of sludge in the gallbladder with cholangiohepatitis.[118] Cholecystitis is indistinguishable from cholangiohepatitis on ultrasound exam.[118] A thickened gallbladder wall can also be seen with hepatitis, free peritoneal fluid, and hypoproteinemia.[121] In a previously mentioned study, sonographic identification of a thickened gallbladder wall was significantly associated with inflammation on histopathology.[117] Choleliths are more common in dogs than cats and appear as hyperechoic structures within the gallbladder or bile duct that produce acoustic shadowing.[118] Emphysematous cholecystitis can be seen as gas within the biliary tract and may be due to infections with *Escherichia coli* or *Clostridium perfringens* bacteria and has also been associated with diabetes mellitus.[118]

Ultrasonographic features of gallbladder mucoceles include immobile bile sludge that does not change according to gravity, and/or echogenic bile in a stellate or finely striated pattern, also called the "kiwi fruit-like" pattern (see ch. 288).[122] No association has been found between the ultrasonographic bile pattern and the likelihood of cholecystic rupture in a study of 14 dogs with gallbladder mucoceles.[123] However, another study showed that an incomplete stellate pattern was statistically more common in dogs that ruptured their gallbladder, although this was not pathognomonic for gallbladder rupture and gallbladder rupture was still unable to be predicted based on the ultrasonographic bile patterns.[122] Most of the dogs in this study did not develop thickened gallbladder walls or extrahepatic bile duct dilation. When gallbladder rupture does occur, it is typically diagnosed by observing a discontinuation of the gallbladder wall directly and indirectly based on evidence of pericholecystic changes such as hyperechoic fat and fluid accumulation.[122] The sensitivity for diagnosing gallbladder rupture via ultrasonography is reported as 85%.[124] It is important to remember that biliary dilation is not always associated with active biliary disease, because the canine biliary tract may remain dilated after resolution of disease.[125]

Ultrasonography can be helpful in the diagnosis of PSS (see ch. 284). The reported sensitivity for ultrasonographic identification of MAPSS is 67% compared with that of congenital PSS (90-100%),[126] though the detection of shunts is very operator- and machine-dependent. One study found the liver to be small in 96% of dogs with primary vascular disease, and in 100% of dogs with MVD.[117] Portal vein : aorta and portal vein : caudal vena cava ratios of greater or equal to 0.8 and 0.75, respectively, consistently ruled out an extrahepatic PSS in one study.[126] Portal vein : aorta ratios less than or equal to 0.65 were consistently found in extrahepatic shunts.[126] Uroliths and renomegaly are common findings in dogs and cats with PSS.[127-129] Extrahepatic shunting vessels generally originate from the portal, splenic, right or left gastric, or gastroepiploic vein.[126,130] Portocaval shunts terminate in the caudal vena cava and their entrance is characterized by turbulent flow with color and spectral Doppler.[118] Ascites can be seen with portal hypertension and MAPSS, but is uncommon with CPSS.[30,131-133] Typically, MAPSS are visualized in the left dorsal perirenal area as a plexus of small, tortuous splenic to renal vessels.[5,126,134,135] Other findings suggestive of portal hypertension include reduced portal blood flow velocity (<10 cm/s), hepatofugal flow, enlarged portal vein, and a dilated left gonadal vein.[19] Arteriovenous fistulas create connections between the portal vein and hepatic arteries.[121]

The presence of a hepatic mass on abdominal ultrasound examination should raise concern for neoplasia (see ch. 287). A study by Murakami et al reported that dogs with large liver masses and peritoneal effusion were most likely to have malignant hepatic neoplasia.[136] However, the diagnosis must be confirmed with histopathology as there are several benign conditions that may appear mass-like on ultrasound such as degeneration, inflammation, or nodular hyperplasia.[117] Hepatic abscess can have a variable mass-like appearance on ultrasound and may be associated with the presence of free gas (reverberation artifacts).[118] Cystic lesions appear as anechoic cavitary structures that generally have sharply defined borders; they can be round or irregular in shape, and may contain hyperechoic septae.[118] Other anechoic lesions in the liver include necrosis and some cavitary neoplasms. Granulomas can be secondary to a multitude of infectious organisms or foreign material and appear sonographically as multifocal hyperechoic and well-marginated parenchymal lesions.[118,121] Liver lobe torsion is rare in dogs. The affected lobe appears hypoechoic, and color Doppler shows reduced or absent blood flow within the lobe.[118]

Contrast-enhanced ultrasound allows assessment of the perfusion patterns of organs in a noninvasive manner. It is typically used to try and distinguish malignant from benign lesions and is divided into the early phase and the late phase. The early phase is composed of an arterial phase (wash-in) and a portal venous

phase (wash-out).[118] During portal and late phases all benign lesions, except cysts and thrombosed hemangiomas, exhibit isoenhancement or slight enhancement compared to surrounding liver tissue. Malignant liver lesions show hypoenhancement or do not perfuse at all.[137] The sensitivity and specificity for diagnosing benign versus malignant liver nodules is 100% and 94.1%, respectively.[118]

Other Imaging Modalities

Computed Tomography (CT)

CT can be useful for determining liver size, and for the diagnosis of hepatic mass lesions and PSS. Contrast enhancement of masses may help in differentiation benign versus malignant lesions.[118] CT angiography has a sensitivity of 96% and specificity of 89% for the diagnosis of congenital PSS in dogs and is 5.5 times more likely to correctly determine the presence or absence of a congenital PSS than abdominal ultrasound.[138] CT has many advantages: it is noninvasive, is able to accurately depict the origin of the anomalous vessel, has the potential for three-dimensional reconstructions, and is less operator-dependent than ultrasonography.[118,139,140] The disadvantages are that general anesthesia is required in most cases and the possibility of motion artifact exists, which can require repeat scanning.[118] CT is quickly becoming one of the more commonly used methods of diagnosing extrahepatic PSS.

Magnetic Resonance Imaging (MRI)

Similar to CT, MRI has been shown to be helpful for the diagnosis of hepatic mass lesions and PSS. One study investigating the utility of contrast-enhanced MRI for distinguishing benign versus malignant mass lesions found MRI to be accurate in 33 of 35 lesions for a sensitivity and specificity of 100% and 90%, respectively.[141] The reported sensitivity and specificity of magnetic resonance angiography for the diagnosis of single congenital PSS are reported to be 79% and 100%, respectively.[142] MRI is rarely used for the diagnosis of PSS because CT angiography is able to provide similar detail more rapidly and at a lower cost compared to MRI.[143]

Portal Scintigraphy Using ^{99M}Tc-Sulfur Colloid

^{99M}Tc-sulfur colloid are small colloidal particles that localize within the reticuloendothelial system. In normal dogs, most of the ^{99M}Tc-sulfur colloid will localize in the liver, whereas in patients with PSS a significant portion will localize within the lung.[144] This technique is not specific for PSS in dogs because uptake in the lungs occurs with other causes of hepatic insufficiency and cannot be used in cats for the diagnosis of PSS because lung uptake is seen in normal cats.[144,145]

Per-Rectal Portal Scintigraphy (PRPS)

This technique involves administration of a radionuclide (typically sodium pertechnetate) into the colon. In normal patients, pertechnetate will first be visualized in the liver and then the heart. In patients with PSS, the portal blood containing the pertechnetate bypasses the liver and will be seen in the heart first.[146] Lower magnitude shunts may have simultaneous arrival of the pertechnetate to the liver and heart.[146] Quantitative analysis of the PRPS can be performed with an imaging computer that calculates a shunt fraction (SF), which is an estimation of the percentage of portal blood that bypasses the liver.[145,147] Normal dogs should have a SF of <5%. Most patients with congenital PSS will have SFs >60% and typically between 80-95%.[146] The main disadvantage of PRPS is that there is poor anatomic detail, so the exact location and type (congenital or acquired) of the shunt is usually unable to be identified and the studies can occasionally be nondiagnostic (typically due to poor absorption from the colon).[146] Patients with MVD will appear normal with PRPS.[146]

Trans-Splenic Portal Scintigraphy (TSPS)

Trans-splenic portal scintigraphy is performed using ultrasound guidance for injection of the radiopharmaceutical (sodium pertechnetate) into a central region of splenic parenchyma.[146] The resulting images are of higher quality than those obtained using PRPS.[148,149] Normally, the radiopharmaceutical is rapidly absorbed from the spleen into the splenic vein, flowing into the left gastric vein and then into the main portal vein to be delivered to the liver. The radiopharmaceutical will then pass through hepatic

sinusoids, to the hepatic vein, caudal vena cava, and then to the heart.[146] The normal SF for dogs is approximately 2.64%.[146] Visualization of shunting vessels occurs in 90% of cases.[148,149] Trans-splenic portal scintigraphy can distinguish between portoazygous and portocaval/splenocaval shunts, and sometimes between congenital versus acquired shunts.[146] Portosystemic shunts located caudal to the entrance of the splenic vein into the portal vein may be missed with this technique.[146] Similar to PRPS, lower-magnitude shunts may have simultaneous arrival of the pertechnetate to the liver and heart.[146] ^{99m}TC-mebrofenin can be used as an alternative to sodium pertechnetate and may allow the location of the shunt to be more easily identified.[146] As with PRPS, TSPS is not useful for the diagnosis of MVD.[146]

Sampling of the Liver

Fine-Needle Aspiration of the Liver

Fine-needle aspiration (FNA) of the liver is much less invasive, has fewer risks, yields faster results, and is less expensive than obtaining hepatic biopsy samples (see ch. 89 and 93). This procedure typically can be performed without the use of sedation, analgesia, or anesthesia unless the patient is aggressive or struggling in response to restraint. Local anesthetics are also typically not used. Fine-needle aspiration of the liver is generally considered safe, but owners should be warned of the risk of hemorrhage, though this is rare. Fine-needle aspiration of the liver should be performed with ultrasound guidance and typically using a 22G to 25G needle. Often less blood contamination is obtained with rapid agitation of the needle without a syringe ("sewing machine technique") compared with aspiration using a syringe. Several aspirates from different sites should be collected in patients with diffuse disease. The collected sample should be sprayed onto glass slides and thin smears should be made. The authors advise staining 1-2 slides with a Diff-Quik stain in hospital and evaluating those slides under light microscopy to look for the presence of hepatocytes. This ensures an adequate sample has been collected prior to submission for cytology review. Specific stains can be applied to the slides to look for intrahepatic copper granules (rubeanic acid or rhodanine stain), lipids (Sudan stain) and glycogen (periodic acid-Schiff stain).[88]

The main disadvantages of cytologic diagnosis from FNAs of the liver are the high frequency of inaccurate results due to low cellularity and artifacts, and the absence of tissue architecture for assessing lesions.[150] The overall agreement of cytologic and histologic diagnosis is reported to range between 30-61%.[151,152] A recent retrospective study evaluating the accuracy of ultrasound-guided FNA of focal liver lesions found the highest sensitivity for vacuolar change (57.9%), followed by neoplasia (52%).[153] This study also showed that round cell tumors (positive predictive value [PPV] 75%) and non-hepatocellular origin carcinomas (PPV 85.7%) were the most readily diagnosed neoplasms with cytology. The PPV for hepatocellular carcinoma was 100%. The study also found that only approximately 50% of patients with a histopathologic diagnosis of neoplasia had neoplastic cells detected on cytology. These findings suggest that while a diagnosis of neoplasia on cytology is most likely correct, cytology alone cannot be used to exclude the diagnosis of neoplasia.

Cytology of FNAs of the liver can be helpful in confirming the diagnosis of feline hepatic lipidosis (see ch. 284). Diffuse hepatocellular triglyceride vacuolation is characteristic of this syndrome.[3] However, if the underlying cause of hepatic lipidosis is a primary liver disease, a definitive diagnosis could be missed with cytology alone, as cytologic diagnosis of other hepatobiliary disorders can be remarkably discordant with biopsy specimens.[3]

Hepatic Biopsy

The diagnosis of most hepatobiliary diseases requires histopathologic examination of liver tissue. Diffuse liver disease may be sampled randomly, but focal lesions require more selective sampling (see ch. 89 and 95). For large focal lesions, samples should be collected at the periphery of the lesion as large masses may have a necrotic center. Risks of hepatic biopsy include anesthetic complications especially in patients with advanced liver disease due to an inability to metabolize anesthetic agents, hemorrhage, air embolism (laparoscopy) and vagotonic shock.[3,88,154] Vagotonic shock is typically associated with needle biopsy and the risk is increased in patients with dilated bile ducts and when a rapid-firing automatic biopsy needle is used. There is little objective evidence that coagulation status assessed via PT, aPTT, fibrinogen concentration, platelet count, or buccal mucosal bleeding time (BMBT; see ch. 80) correlates with the risk of bleeding following liver biopsy.[155,156] Vitamin K_1 and/or fresh frozen plasma can be administered prior to pursuing a liver biopsy if

the clinician is concerned about an increased bleeding risk.

The three most common hepatic biopsy techniques are core needle biopsy, laparoscopic biopsy, and surgical biopsy. General anesthesia is required for surgery and laparoscopy, and may be necessary for some patients undergoing core needle biopsies. Needle biopsies have limitations due to their small sample size. One good core needle biopsy represents 1/50,000 of the entire liver.[157] A 14G needle diameter is recommended for medium to large dogs and 16G for small dogs and cats.[88] Needle biopsies can be obtained percutaneously with ultrasound guidance or under visual control during laparoscopy or surgery. The Tru-Cut-type needle technique is the most widely used and typically can be performed with ultrasound guidance.[88] There are 3 types of Tru-Cut-type needles: manual, semi-automatic, and automatic. Manual devices are difficult to handle and are only advised with direct visual control during surgery.[88,155] Semi-automatic and automatic types are more commonly used. The main disadvantages of ultrasound-guided liver biopsy include the need for sedation or anesthesia in some patients, difficulty of imaging small livers, difficulty of obtaining liver tissue in patients with fibrosis, and samples that carry a questionable representation of the underlying hepatic disease process. This questionable accuracy is in most part due to potential for sampling error. This method still results in a relatively small sample size, possible fragmentation of fibrous tissue, and may not enable sampling of abnormalities located in other lobes (the left medial or lateral lobes are generally sampled due to their ease of imaging). In one study, the diagnostic accuracy of the Tru-Cut needle biopsy was compared to the gold standard of surgical wedge biopsy of the liver in 124 patients.[158] The overall discordance between the two methods was 53% in dogs and 50% of cats, with >60% discrepancy occurring with chronic hepatitis or cirrhosis, cholangitis/cholangiohepatitis, portosystemic vascular anomalies, microvascular dysplasia, fibrosis, and miscellaneous disorders. These disorders are the most commonly seen among dogs and cats with hepatobiliary disease. The greatest accuracy was with neoplasia (80% concordance). Use of a 14G needle versus 18G may reduce this discordance as it increases the number of portal triads sampled. A recent study investigating transjugular liver biopsy in canine cadavers found it to be a feasible technique. However, further studies are needed before this technique can be recommended in the clinical setting.[159]

Laparoscopy involves distention of the abdominal cavity with gas followed by placement of a rigid telescope though a portal (cannula) in the abdominal wall to examine the contents of the peritoneal cavity (see ch. 91).[155] Biopsy forceps and other instruments are then passed into the abdomen via adjacent portals to allow more thorough inspection of abdominal organs and collection of biopsy samples.[88,155] This technique enables gross evaluation of the entire liver, extrahepatic biliary system, and surrounding structures while obtaining multiple large specimens of liver (see ch. 283). The ability to obtain multiple samples decreases the risk for sampling artifact in cases of regional diversity within the liver. Additionally, by directly visualizing the hepatic parenchyma, the clinician can correlate the histopathologic findings and clinical data with the gross appearance of the liver to render the most accurate diagnosis. This method also enables the visualization of smaller masses and irregularities that may not be evident with ultrasonographic imaging. There is generally minimal bleeding during this procedure, even in patients with *in vitro* coagulopathies. Using a "spoon" or oval cup forceps typically results in a marked decrease in the amount of hemorrhage when compared to needle biopsies. Any hemorrhage can be directly visualized for adequate clot formation. If hemorrhage persists, direct pressure using a blunt probe for five minutes can be used. If the site continues to bleed, electrocautery can be applied to the biopsy site or a topical hemostatic agent (Gel Foam) can be placed directly on the biopsy site using laparoscopic forceps. The main disadvantages of laparoscopy are the need for general anesthesia, increased cost, and the need for technical expertise and equipment. In an unpublished review, the complication rate of diagnostic laparoscopy was less than 2%.[88] Laparoscopy can also be used to obtain biopsies of other organs besides the liver such as the pancreas, kidney, spleen, lymph node, and intestine, as well as for cholecystocentesis (aspiration of the gallbladder).[88] Biopsy samples obtained via laparoscopy are significantly larger (approximately 5 × 10 mm) than those obtained by needle biopsy, but are still smaller than samples obtained surgically (1-2 cm).[88]

Liver biopsy alone is rarely an indication for surgery if laparoscopy is available. Laparotomy is indicated over laparoscopy when there is concern for a biliary duct obstruction or vascular anomaly that may require surgical correction in addition to obtaining a liver biopsy, or when the patient is undergoing surgery for an issue unrelated to its hepatobiliary disease. The advantage of surgery is the exposure, ability to manipulate the tissues, ability to obtain a larger sample, and ability to monitor the biopsy site for bleeding.[88] The major disadvantages to surgery are the increased pain and postoperative recovery time.

The World Small Animal Veterinary Association (WSAVA) has set standards for unification of diagnostic

criteria and nomenclature of liver diseases.[5] The authors obtain at least 4-5 biopsies from different liver lobes for histopathology, 1 biopsy for aerobic and anaerobic culture, and 1 for quantitation of copper and other heavy metals.[88] It may be necessary to obtain additional samples for histopathology when using needle biopsy techniques to improve the likelihood of obtaining a diagnosis.

CHAPTER 281

General Principles in the Treatment of Liver Disease

Jonathan Andrew Lidbury

Client Information Sheet: Treatment of Liver Disease in Dogs and Cats

Veterinarians are frequently required to devise therapeutic plans for dogs and cats with hepatic disease. This can prove to be challenging for a number of reasons. First, the efficacy of many of the drugs and nutraceuticals that are used to treat hepatic disease in these species has not been rigorously established.[1] Therefore, the decision to use these agents is often made based on there being a supporting pathophysiologic rationale, evidence inferred from studies in humans, a lack of perceived adverse effects, or a combination of these reasons. This lack of evidence is concerning and as a profession we should strive to confirm the efficacy and safety of the drugs that we use by performing randomized placebo controlled clinical trials. Additionally, the underlying etiology of many canine and feline liver diseases has not been well established. For example, in many cases the underlying cause of canine chronic hepatitis cannot be identified.[2] This means that we are often limited to the provision of supportive rather than definitive treatment. Finally, because of the limitations of the current non-invasive tests for hepatic disease, assessing a patient's response to therapy can be challenging.

Drugs Commonly Used to Treat Hepatic Disease

Cytoprotective Agents (Table 281-1)

Because of its functional location between the splanchnic and systemic circulations, its central role in the metabolism of drugs and toxins, as well as its large resident population of macrophages (Kupffer cells), the liver is susceptible to oxidative damage.[3] Glutathione, a tripeptide synthesized from L-glutamate, L-cysteine, and glycine, is an essential antioxidant that is mainly stored in hepatocytes.[4] Reduced hepatic concentrations of glutathione have been found in cats with extrahepatic bile duct obstruction, cats with hepatic lipidosis, and dogs and cats with necroinflammatory liver disease, supporting the importance of oxidative injury in a wide range of canine and feline hepatobiliary diseases.[5]

TABLE 281-1

Hepatic Cytoprotective Agents

AGENT	CLASS/MECHANISM OF ACTION	SUGGESTED INDICATIONS	DOSAGE	POTENTIAL SIDE EFFECTS	COMMENTS
S-adenosyl methionine	Antioxidant, anti-inflammatory, modulates apoptosis, anticarcinogenic	Acute liver injury, canine chronic hepatitis, feline hepatic lipidosis	20 mg/kg PO q 24 h	Occasional vomiting and decreased appetite	Give at least 1 hour before feeding, u proven bioavailal product
N-acetylcysteine	Antioxidant	Acute liver injury, feline hepatic lipidosis	140 mg/kg IV initially followed by dosages of 70 mg/kg q 8-12 h	Often leads to vomiting if administered PO; well	Use instead of S-adenosyl methionine in patients who can

				tolerated when given IV	tolerate oral medications, administer a 10% solution diluted 1 over 20 minutes through a 0.25 micron non-pyrogenic in-line filter
Silymarin	Antioxidant, immunomodulator, antifibrotic, choleretic	Acute liver injury, canine chronic hepatitis, feline hepatic lipidosis	5-10 mg/kg PO q 24 h (combined with phosphatidylcholine) in dogs and 10 mg/kg PO q 24 h in cats (combined with phosphatidylcholine)	Generally well tolerated	Phosphatidylcholine increases the absorption of silymarin; use a proven bioavailal product
Vitamin E	Antioxidant	Acute liver injury, canine chronic hepatitis, feline hepatic lipidosis	Alpha-tocopherol acetate 10-15 IU/kg PO q 24 h	Generally well tolerated	Ideally give with foo efficacy has not been proven
Ursodeoxycholic acid	Choleretic, displaces hydrophobic bile acids, antiapoptotic	Feline cholangitis, chronic hepatitis, non-surgical gall-bladder mucoceles	10-15 mg/kg PO q 24 h	Occasional diarrhea	Does not appear to have an importar effect on serum b acid testing

S-adenosyl Methionine (SAMe)

S-adenosyl methionine (SAMe) plays a central role in the synthesis of glutathione via the transsulfuration pathway.[4] Therefore, the main rationale for treating dogs and cats with SAMe is that it may help to prevent oxidative damage by preventing the depletion of hepatic glutathione. It has also been claimed that SAMe may have anti-inflammatory properties, modulate apoptosis, and be anticarcinogenic.[4] At the recommended dosage of 20 mg/kg PO q 24 h on an empty stomach, SAMe has rarely been reported to have side effects in dogs or cats other than causing occasional vomiting and a decreased appetite.[6] There is limited evidence that SAMe is efficacious in dogs and cats. First, it has been shown that a combination of SAMe and silymarin inhibits the production of proinflammatory cytokines and the development of oxidative stress in canine hepatocyte cell cultures.[7] Second, oral administration of SAMe was shown to improve hepatic and erythrocyte redox status in healthy cats.[8] Additionally, a study of 12 healthy dogs showed that administration of SAMe diminished the oxidative stress associated with the administration of an immunosuppressive dosage of prednisone although it failed to prevent the development of histological changes consistent with vacuolar hepatopathy.[9] Lastly, in a study of dogs being treated with the chemotherapeutic agent lomustine, dogs supplemented with a product containing silymarin, SAMe, and phosphatidylcholine (Denamarin) were shown to have smaller increases in serum alanine aminotransferase and alkaline phosphatase activities and serum bilirubin concentration than those that were not, suggesting a hepatoprotective effect.[10] However, further clinical trials are needed to fully assess the efficacy of SAMe in treating dogs and cats with hepatic disease. From a practical perspective, because of the important role of oxidative injury in experimental models of hepatic disease and humans with hepatic disease, the author uses SAMe as an adjunctive treatment in a wide variety of hepatic diseases in dogs and cats. These include acute liver injury due to drugs or intoxications in dogs and cats, chronic hepatitis in dogs, copper associated chronic hepatitis in dogs, and feline hepatic lipidosis.

N-acetylcysteine (NAC)

N-acetylcysteine (NAC) is a formulation of L-cysteine that helps replenish hepatic intracellular cysteine and

glutathione concentrations, thereby providing protection against oxidative injury.[3] Oral administration of NAC is frequently associated with vomiting in dogs and cats.[6] Therefore, this medication is usually given intravenously when it is used to treat hepatic disease in these species. In a study of dogs undergoing bile duct ligation, NAC improved markers of hepatic circulation and redox status.[11] Additionally, a recent study demonstrated that supplementation with NAC during the first 48 hours of hospitalization stabilized erythrocyte glutathione concentrations in ill dogs.[12] However, investigators were unable to show a beneficial effect of NAC in experimental canine models of ischemic liver injury and reperfusion.[13] Intravenous NAC has been shown to be beneficial in treating acetaminophen intoxication in humans and is an accepted albeit not critically evaluated therapy for acetaminophen intoxication in dogs and cats. NAC is usually given as a 10% solution diluted 1 to 2 with saline as an IV bolus over 20 minutes through a 0.25 micron non-pyrogenic in-line filter at a dosage of 140 mg/kg initially followed by dosages of 70 mg/kg q 8-12 h.[6,14] Concern has been raised that administration over longer periods of time might lead to the impairment of ammonia metabolism via the urea cycle.[14] The author considers using this drug as part of the initial treatment of dogs and cats with acute liver injury due to other drugs or intoxications and of cats with hepatic lipidosis. Once these patients can tolerate oral SAMe, the NAC is discontinued.

Silymarin

Silymarin is a mixture of at least 7 flavanolignans and 1 flavonoid extracted from the milk thistle plant.[15] Silibinin is the most abundant and biologically active component of silymarin.[16] Silymarin is believed to have antioxidant effects by scavenging free radicals and reducing lipid peroxidation.[17] Experimental evidence and studies in human patients suggest several other potential benefits. First, silymarin is believed to have several anti-inflammatory effects, including suppression of tumor necrosis factor-alpha, interleukin-1 beta, and nuclear factor kappa-beta and may also inhibit hepatic fibrosis by reducing hepatic stellate cell DNA synthesis, proliferation and migration, as well as reducing hepatic collagen expression.[18-20] Additionally, silymarin has been shown to act as a choleretic agent in rats.[21] At commonly used doses silymarin does not appear to cause any side effects.[18] Despite decreasing the activity of cytochrome P-450 enzymes, UDP-glucuronosyltransferase enzyme, and reducing P-glycoprotein transport in humans silymarin has a limited effect on the pharmacokinetics of several drugs *in vivo.* However, care is still advised when co-administering silymarin and pharmaceuticals to human patients.[22] The bioavailability of silymarin is improved when it is combined with phosphatidylcholine, which acts as a solubilizing agent.[23] For this form of the drug a dose of 5-10 mg/kg PO q 24 h has been proposed. It has been recommended to give less bioavailable forms of silymarin at a dose of 20-50 mg/kg/day PO divided q 6-8 h.[6] However, currently there is limited evidence supporting the efficacy of this nutraceutical in the veterinary literature. It has been shown that a combination of SAMe and silymarin inhibits canine hepatocyte inflammation and oxidative stress *in vitro.*[7] In one study of Beagles administered *Amanita phalloides* toxin, all 11 dogs treated with intravenous silibinin survived whereas four of twelve control dogs died.[24] Therefore, it is prudent to administer silymarin to dogs and cats with *Amanita* mushroom intoxication. Another study did not find strong evidence that silymarin has a protective effect after carbon tetrachloride ingestion in dogs.[25] When used in combination with SAMe and phosphatidylcholine, silymarin was shown to have a hepatoprotective effect when dogs were administered the chemotherapy agent lomustine.[10] Although more clinical trials are needed to prove its efficacy, the author uses silymarin in dogs and cats with acute liver injury due to drugs/toxins, dogs with chronic hepatitis, dogs with copper associated chronic hepatitis, and cats with hepatic lipidosis (see ch. 282-286).

Vitamin E

Vitamin E is actually a family of eight lipid soluble vitamins, alpha-tocopherol being the most biologically active.[1] The main role of vitamin E is that of an antioxidant, protecting phospholipids from oxidative injury by scavenging free radicals.[26] Generally vitamin E is well tolerated in dogs and cats and side effects are rarely observed.[6] Alpha-tocopherol is usually given at a dosage of 10-15 IU/kg PO q 24 h to dogs and cats. Some clinicians consider using this supplement as part of the treatment regimen for dogs and cats with liver diseases that can lead to oxidative damage, such as acute liver injury due to drugs or intoxications, feline hepatic lipidosis, chronic hepatitis, and copper associated chronic hepatitis.[6] There is currently no clinical evidence supporting the efficacy of vitamin E in dogs or cats with hepatic disease. However, recent studies have shown a beneficial effect (improved clinical signs, markers of oxidative stress, or inflammatory markers)

in dogs with atopic dermatitis[27] or degenerative joint disease[28] suggesting that vitamin E can be an effective antioxidant in this species.

Ursodeoxycholic Acid (UDCA)

Ursodeoxycholic acid (UDCA) is a hydrophilic bile acid that is believed to have several beneficial properties: UDCA may displace more toxic hydrophobic bile acids from the circulating pool,[29] it has a choleretic effect[30] which increases the excretion of endogenous toxins in the bile, it has a cytoprotective effect by inhibiting hepatocyte apoptosis,[31] and immunomodulatory effects, such as the suppression of interleukin-2 expression.[32] It is the only Federal Drug Administration approved treatment for primary biliary cirrhosis in humans.[33] When used at a dosage of 10-15 mg/kg PO q 24 h in dogs and cats, this drug has few side effects other than occasionally causing diarrhea.[6] Because of its choleretic effect and the displacement of more toxic hydrophobic bile acids, there is a rationale behind using this drug in dogs and cats with intrahepatic and extrahepatic cholestasis, such as cholangitis in cats. In a recent retrospective study of cats with lymphocytic cholangitis, those treated with prednisolone survived longer than those treated with UDCA.[34] However, this study does not prove that UDCA lacks efficacy for treating feline lymphocytic cholangitis as for ethical reasons treatment was not compared to a placebo. The use of UDCA in dogs and cats with complete bile duct obstruction is controversial as some clinicians are concerned about the possibility of it increasing the probability of gallbladder rupture.[6] Other clinicians feel comfortable using UDCA in this situation and studies in rats where bile duct ligation was performed actually indicate that it has a beneficial effect on markers of oxidative stress and apoptosis.[35] However, it is important to note that surgical intervention is indicated in most dogs or cats with complete bile duct obstruction. Where the patient has no or mild clinical signs, UDCA is sometimes used as part of the medical management of non-obstructed, canine gallbladder mucoceles.[36] Furthermore, due to its purported immunomodulatory and antiapoptotic effects there is a theoretical reason to use UDCA in dogs with chronic hepatitis although its efficacy in this condition has not been critically evaluated.

Anti-Inflammatory/Immunosuppressive Drugs

Corticosteroids

Corticosteroids are used to treat alcoholic liver disease[37] and autoimmune hepatitis[38] but at higher doses they may increase viral load in human patients with hepatitis C infection.[39] As inactive prednisone is converted to active prednisolone by the liver theoretically it makes more sense to treat dogs with advanced liver disease with the latter.[40] However, it is not known if this choice makes any difference in their clinical outcome. Cats should be given prednisolone in preference to prednisone. While hepatic copper accumulation is an important cause of chronic hepatitis, for a large proportion of dogs with chronic hepatitis an underlying etiology cannot be identitifed.[2] Frequently these dogs have hepatic inflammation and necrosis often in the periportal zones. There is an association between chronic hepatitis and dog leukocyte antigen class II alleles and haplotypes in Doberman Pinschers[41] and English Springer Spaniels[42] supporting the role of autoimmunity in causing chronic hepatitis in these breeds. However, further studies are needed to determine whether or not autoimmunity is a cause of chronic hepatitis in these and other breeds. There is some clinical evidence to suggest that prednisolone is an effective treatment for chronic hepatitis in dogs. A retrospective study of 151 dogs with chronic hepatitis of various causes found that those treated with corticosteroids survived longer than those that were not.[43] However, these results should be interpreted with caution as the retrospective design of this study meant that it was susceptible to bias as the clinicians may have decided to start corticosteroids in dogs that were more likely to have a favorable response. The results of a more recent retrospective uncontrolled study of 36 dogs with idiopathic chronic hepatitis found that hepatic inflammation decreased and coagulation parameters returned to normal after 6 weeks prednisolone treatment and in some dogs the stage of hepatic fibrosis remained the same or improved. However, the majority of these dogs had a recurrence of clinical signs or residual disease at the end of treatment.[44] It should also be noted that glucocorticoids often cause adverse effects including polyuria/polydipsia, polyphagia, panting, dermatological changes, and importantly can have a detrimental effect on the liver causing vacuolar hepatopathy and possibly oxidative stress.[8] Prospective placebo controlled clinical trials assessing the efficacy of prednisolone in treating canine idiopathic chronic hepatitis are needed before definitive recommendations can be made. The author considers performing a therapeutic trial with prednisolone in dogs with chronic

hepatitis that do not have chronic copper associated hepatitis (based on copper staining and quantification) and have a negative hepatic and/or bile bacterial culture, especially if there is moderate to severe hepatic inflammation on histological examination of a liver biopsy specimen. Prednisolone/prednisone are usually given at a dosage of 1-2 mg/kg PO q 24 h with a subsequent gradual taper.[45] As glucocorticoid administration makes it difficult to assess the patient's response to treatment by serial measurement of serum liver enzyme activities, some clinicians advise that liver biopsy is repeated 6 weeks after starting treatment.[46] Prednisolone is often used to treat cats with lymphocytic cholangitis and chronic neutrophilic cholangitis after a negative bile bacterial culture and failure to respond to trial therapy with antimicrobials. Cats with lymphocytic cholangitis that were treated with prednisolone were shown to survive longer than those treated with UDCA.[34]

Azathioprine

Azathioprine is a purine analog that is occasionally used as an immunosuppressive agent in dogs with idiopathic chronic hepatitis, usually with the aim of allowing a lower dosage of prednisolone/prednisone to be used.[46] A dosage of 2 mg/kg PO q 24 h for 2 weeks then reduced to q 48 h has been advised for this purpose. However, the efficacy of azathioprine for treating canine idiopathic chronic hepatitis has not been evaluated and in a recent study 5 out of 34 dogs (15%) treated with this drug were suspected to have developed hepatotoxicosis.[47] Azathioprine should not be used in cats.

Cyclosporine

Cyclosporine is a T-cell inhibitor than has been use to induce remission of autoimmune hepatitis in children.[48] A few dogs with idiopathic chronic hepatitis have been reported to respond well to cyclosporine (5 mg/kg PO q 12-24 h) without concurrent corticosteroid use (David Twedt and Allison Bradley, unpublished communication). However, critical evaluation of the efficacy and safety of using cyclosporine in this setting is needed before it can be recommended.

Medications Used to Treat Hepatic Copper Accumulation

D-penicillamine

D-penicillamine is a chelating agent that combines with copper (and certain other heavy metals), allowing it to be mobilized from the liver and excreted in the urine. Penicillamine may also have an antifibrotic effect as it prevents the formation of crosslinks between collagen molecules[49] and may have immunomodulatory properties.[50] This drug is indicated for the treatment of copper associated chronic hepatitis in dogs.[51] D-penicillamine is effective at reducing hepatic copper concentrations in Bedlington Terriers, but lifelong treatment and a copper restricted diet seem to be required.[52] D-penicillamine treatment has also been shown to be effective at treating chronic copper associated hepatitis in Labrador Retrievers[53] and Doberman Pinschers.[54] This drug is given at a dosage of 10-15 mg/kg PO q 12 h and pharmacokinetic studies indicate that it is better absorbed when given on an empty stomach.[55] Gastrointestinal side effects are common in dogs receiving D-penicillamine. When these occur, dose reduction, administration with a small amount of food, or discontinuation may be necessary.[51] Prolonged chelation can lead to copper deficiency, manifested by microcytic hypochromic anemia, anorexia, vomiting, and weight loss.[52,56] In humans penicillamine has been associated with a variety of side effects including fever, cutaneous eruptions, lupus like syndromes, lymphadenopathy, proteinuria, cytopenias, and it has also been shown to be teratogenic.[57] In humans D-penicillamine can also cause depletion of vitamin B_6[58] and although this has never been reported to occur in dogs, some clinicians supplement this vitamin during treatment. Recently copper chelation using D-penicillamine was reported in 5 cats with presumed primary or secondary hepatic copper accumulation. Notably, one of these cats developed hemolytic anemia that resolved upon discontinuation of D-penillamine.[59]

Trientine (2,2,2-Tetramine)

Trientine (2,2,2-tetramine) is another chelating agent that can be used in dogs with copper associated chronic hepatitis. This drug is usually a second choice treatment in dogs that have not tolerated D-penicillamine due to its gastrointestinal side effects. Trientine has been shown to be effective at causing increased urinary

excretion of copper in dogs[60] and is used in human patients with Wilson's disease.[61] Trientine may remove more copper from the circulating pool and less from the tissue pool compared to D-penicillamine[61] and therefore might be a good choice in a dogs with hemolysis caused by high serum copper. This drug is given at a dosage of 10-15 mg/kg PO q 12 h and should be given on an empty stomach.[51] This drug is thought to be associated with fewer side effects than D-penicillamine, although vomiting and anorexia can still occur and there is currently little clinical data to support its use in dogs.

Zinc

Zinc decreases the absorption of copper from the gastrointestinal tract. Its mechanism of action is that it induces increased synthesis of metallothionein by enterocytes. Metallothionein binds copper with a higher affinity than zinc, thus preventing the copper from entering the circulation. When the intestinal cells die and are sloughed, the copper inside them is passed in the feces.[61,62] Oral zinc acetate supplementation was shown to decrease hepatic copper concentrations in dogs with primary hepatic copper accumulation over several years without apparent side effects.[63] In a recent study of Labradors with copper associated chronic hepatitis, adjunctive treatment with zinc did not appear to increase the copper-lowering effects of dietary management.[62] Once chelation therapy has reduced the hepatic copper concentration to a level that is close to normal, zinc is commonly used in conjunction with dietary copper restriction as a maintenance treatment.[51] It is interesting to note that because of its efficacy and a reduced rate of adverse effects, zinc has been recommended as sole treatment for humans with asymptomatic Wilson's disease in place of chelating agents.[61] Zinc is usually given to dogs at a dosage of 5-10 mg/kg elemental zinc PO q 12 h, ideally between meals. However, it is sometimes necessary to give it with a small amount of food as zinc can cause vomiting and nausea.[51] Zinc acetate is better tolerated than other forms of zinc. Plasma zinc concentrations should be monitored during therapy. Normal plasma zinc concentrations for dogs are 70-200 mcg/dL. Concentrations around 200 mcg/dL seem to effectively reduce copper absorption[63] but concentrations exceeding 800-1,000 mcg/dL may cause hemolysis.[64] Commercial diets formulated for dogs and cats with hepatic disease are often supplemented with zinc.

General Treatment Recommendations

Acute Liver Injury/Acute Liver Failure

Acute liver injury can lead to acute liver failure, which in humans is characterized by increased serum bilirubin concentrations, hepatic encephalopathy, and coagulation disorders.[65] When treating dogs and cats with acute liver injury, it is important to attempt to address the underlying cause. Examples are discontinuing a hepatotoxic drug, inducing emesis in a patient that has recently ingested a hepatotoxic substance, or treating leptospirosis with doxycycline. However, etiology specific treatment is not always possible, and as liver transplantation is not an option in dogs and cats, supportive care is crucial. As oxidative injury is often a primary or secondary component of acute liver injury, treatment with antioxidants including SAMe, vitamin E, and silymarin is justifiable.[6] In patients that cannot tolerate oral medications, NAC can be given intravenously in place of SAMe. As multiple organ dysfunction syndrome, acute kidney injury, and acquired respiratory distress syndrome are complications of acute liver failure, the function of other organ systems should be closely monitored. Fluid therapy is often required and care should be taken to address dehydration, acid-base abnormalities, and electrolyte abnormalities as these can precipitate hepatic encephalopathy (HE). Vomiting patients benefit from treatment with antiemetic drugs such as ondansetron (0.2 mg/kg IV q 8-12 h for dogs and q 12 h for cats) and metoclopramide (1-2 mg/kg/day IV as a constant rate infusion). Maropitant is metabolized by hepatic cytochrome P-450 enzymes so it may be prudent to decrease the dose and/or the frequency of administration when using this drug in patients with hepatic failure. Gastroduodenal ulceration is also a potential complication of acute liver injury and when suspected, treatment with omeprazole (0.5-1 mg/kg PO q 12-24 h) or pantoprazole (0.5-1 mg/kg q 12-24 h) and sucralfate (0.5-1 g/dog or 0.5 g/cat PO q 8 h) is indicated. Cerebral edema is a recognized complication of acute liver failure in humans[65] and HE is also associated with low-grade cerebral edema.[66] If signs suggesting cerebral edema, such as worsening forebrain deficits, and increased systemic blood pressure possibly with reflex bradycardia, are noted, mannitol (0.5-1 g/kg IV) should be administered.[67] Slight elevation of the patient's head may facilitate venous drainage and help reduce intracranial pressure. Human patients with acute liver failure by definition have coagulopathies, but these infrequently lead to spontaneous bleeding. Therefore, in

human patients it has been recommended that plasma and other blood products should be reserved for those with spontaneous bleeding or in preparation for an invasive procedure.[65] Further research is needed to determine whether or not this recommendation is also appropriate for dogs and cats with acute liver failure. Care should be exercised when administering stored red blood cells to dogs and cats with acute liver injury as ammonia concentrations can increase substantially during storage.[68] As patients with acute liver injury are sometimes vitamin K deficient due to cholestasis, treatment with vitamin K (0.5-1.5 mg/kg SC q 12 h for 3 doses) is recommended. Sepsis is a potential complication of human patients with acute liver failure.[69] Prophylactic antimicrobial use decreases the incidence of infection but has not been shown to confer a survival benefit and may promote the development of antimicrobial resistant infections.[70] Therefore, it is recommended that dogs and cats with acute liver failure be actively screened for infection and that broad-spectrum antimicrobials are only started if bacterial infection is suspected.

Chronic Hepatitis

Chronic hepatitis is more common in dogs than cats, the latter more frequently developing cholangitis. Although the hepatoprotectant agents described above are often used and may be beneficial in treating dogs with chronic hepatitis, they are not a substitute for treating the underlying causes of liver disease. Hepatic biopsy is required to diagnose chronic hepatitis and also to attempt to identify an underlying etiology.[46]

Copper accumulation is an important cause of chronic hepatitis in dogs, so sections of liver should routinely be stained for copper and an unfixed liver biopsy specimen should be sent for quantitative copper analysis. Even then, deciding in which cases to initiate copper chelation is not always straightforward (Figure 281-1). For most laboratories the reference interval for the hepatic copper concentration of healthy dogs is <400 mcg/g dry weight. However, 9 healthy research dogs fed a standard commercial diet were shown to have hepatic copper concentrations ranging from 199 to 997 mcg/g while feral dogs presumed to eat a diet of foraged food had concentrations ranging from 69 to 372 mcg/g.[71] This might be because commercial dog food contains more copper than the foraged food. Hepatic copper accumulation can occur due to inherited defects in copper excretion or secondary to cholestasis. In dogs with primary copper hepatopathy, the copper tends to accumulate in the centrilobular zone of the liver and be present in high concentrations, typically >1,000 mcg/g dry weight. When copper accumulation occurs secondary to cholestasis it tends to be located in the periportal zones of the liver, is associated with lower copper concentrations, typically <750 mcg/g dry weight, and usually does not require chelation.[18,72] Based on work in Bedlington Terriers most laboratories report that concentrations >1,500 mcg/g dry weight are toxic to the liver.[73] However, these values may represent too high a threshold for the initiation of chelation in other breeds. Further research is needed to define exactly when it is appropriate to start chelation therapy. From a practical perspective, even if it is not the primary insult, hepatic copper accumulation has the potential to cause oxidative damage and subsequent necroinflammatory activity. Therefore, the author institutes chelation therapy in dogs with hepatic copper concentrations >1,500 mcg/g dry weight regardless of the distribution and considers doing so when hepatic copper concentrations are >750 mcg/g dry weight if there is centrilobular copper accumulation, especially in breeds known to develop primary copper hepatopathy. These dogs should be fed a copper restricted diet. In a recent study, Labrador Retrievers with hepatic copper concentrations >1,500 mcg/g dry weight needed treatment for at least 10 months to reach a hepatic copper concentration of 400 mcg/g dry weight, and those with initial hepatic copper concentrations between 1,500 mcg/g and 1,000 mcg/g dry weight needed treatment for approximately 6 months.[53] Successful treatment is ideally confirmed 6 months after starting chelation by measuring the copper concentration of a liver biopsy specimen. For breeds other than Bedlington Terriers, it is often possible to stop chelation therapy and start maintenance treatment with zinc while continuing to feed a copper restricted diet.

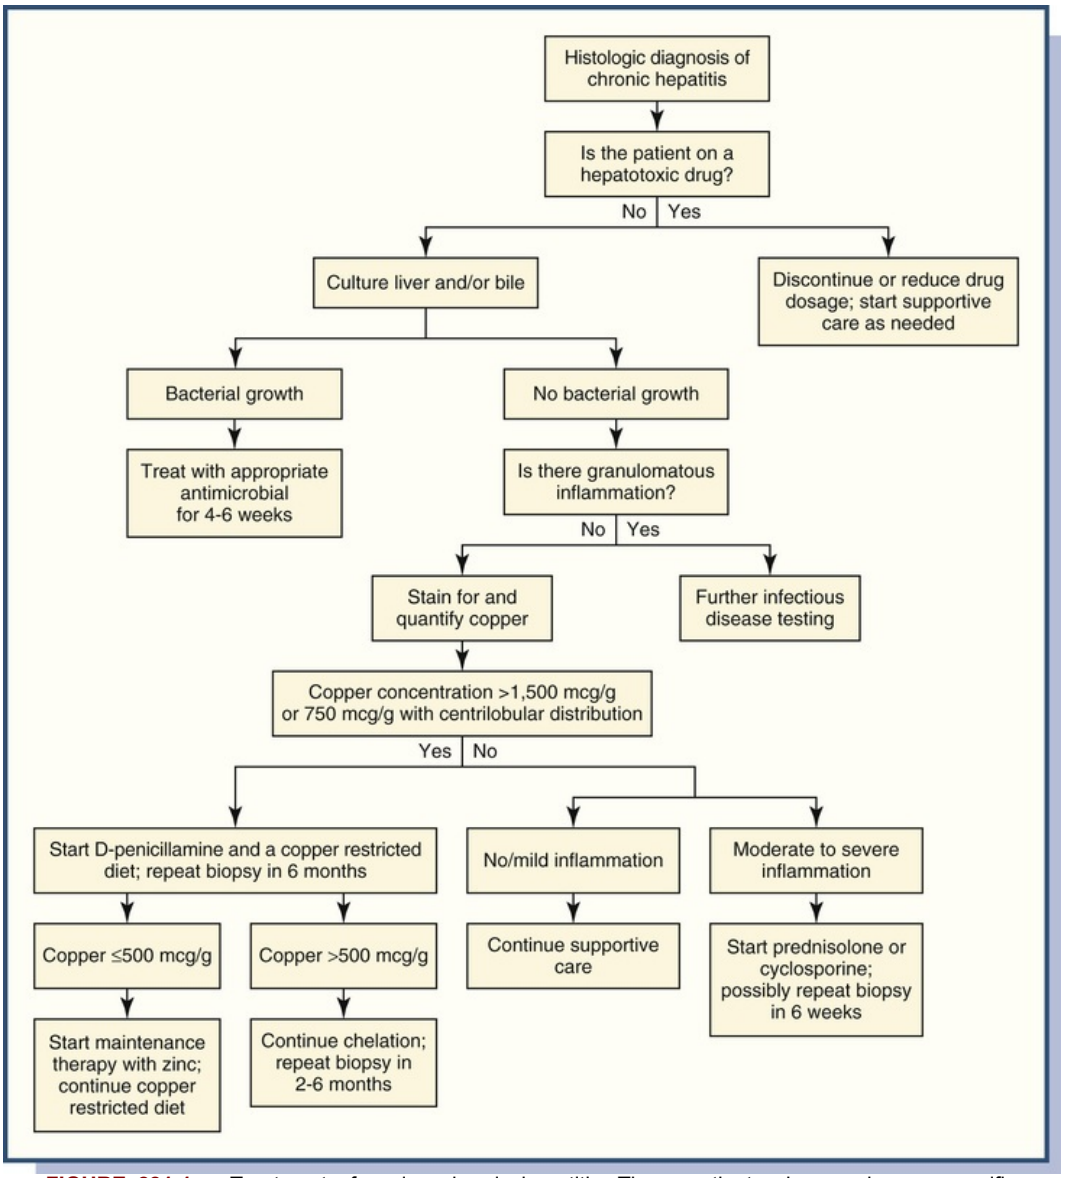

FIGURE 281-1 Treatment of canine chronic hepatitis. These patients also require non-specific supportive treatment including cytoprotective agents (see Table 281-1), and when necessary treatment of the gastrointestinal complications of hepatic disease, hepatic encephalopathy, or ascites. When granulomatous hepatitis is diagnosed, further testing for infectious causes is indicated, including histological staining for bacterial and fungal organisms, PCR testing for *Bartonella* spp., testing for canine schistosomiasis if geographically relevant, and possibly culture for mycobacteria.

Aerobic and anaerobic bacterial infections should also be ruled out by culturing bile and liver tissue. When granulomatous hepatitis is diagnosed further testing for infectious causes is indicated, including histological staining for bacterial and fungal organisms, polymerase chain reaction (PCR) testing for *Bartonella* spp., testing for canine schistosomiasis if geographically relevant, and possibly culture for mycobacteria. Even if these organisms are not identified it may be prudent to perform therapeutic trials with medications that should be effective against them before immunosuppressive medications are started. If the chronic hepatitis is suspected to be caused by chronic exposure to a drug, such as phenobarbital, the drug is discontinued if possible. If there is a convincing component of inflammation, especially if it is lymphoplasmacytic in nature, in the absence of a treatable underlying cause, trial treatment with prednisolone should be considered.[43] Once prednisolone has been started, the serial assessment of serum liver enzyme activities should be performed but has limited value for monitoring the response to treatment. Therefore, repeated hepatic biopsy 6 weeks after the initiation of treatment to determine whether or not there has been a beneficial effect has been recommended.[44,46] As discussed above, there is a pathophysiological basis for treating these dogs with SAMe, silymarin, UDCA, and vitamin E.[6] General supportive care is also important for dogs with chronic hepatitis.

Dogs with hepatic disease, especially those with portal hypertension, are at increased risk of gastroduodenal ulceration.[74] Consequently, if gastroduodenal ulceration is confirmed or suspected, omeprazole and sucralfate should be started. Antiemetic drugs may also be indicated. The provision of adequate high quality nutrition is important and dogs without HE do not need to be fed a protein restricted diet.[75]

Hepatic Fibrosis

There are no proven treatments for hepatic fibrosis of dogs or cats so the following recommendations are made based on pathophysiological principles and data generated from other species. Chronic hepatic inflammation can lead to activation of myofibroblasts including hepatic stellate cells and portal fibroblasts, which can in turn cause hepatic fibrosis.[76] Where possible, addressing the underlying cause of hepatic inflammation is essential. Treatment with anti-inflammatory/immunosuppressive agents is also rational when it is not possible to successfully identify/treat the underlying cause of the chronic inflammation. In a previously mentioned study of dogs with idiopathic chronic hepatitis, after treatment with prednisolone, hepatic fibrosis resolved in 14% of dogs and improved in a further 11%.[44] Oxidative injury may also lead to hepatic stellate cell activation[77] so antioxidants such as SAMe and silymarin may also be indicated. Colchicine binds to tubulin thereby inhibiting microtubule polymerization during mitosis therefore impeding several cellular processes including inflammation and fibrosis. However, there is insufficient evidence in the human literature to determine the efficacy of colchicine for treating hepatic fibrosis in patients with alcoholic liver disease and its use is associated with high rate of adverse effects.[78] Other than a few case reports,[79-81] from which it is difficult to establish a positive effect, the efficacy of colchicine has not been evaluated in dogs. Because of this and the high incidence of gastrointestinal side effects associated with colchicine, the author does not advocate its use. The therapeutic use of this drug has not been reported in cats and this species seems to be particularly susceptible to the toxic effects of colchicine, which can be fatal.[82] In rats the angiotensin II receptor antagonist losartan has been shown to have an antifibrotic effect on the liver. However, these results have not been consistently reproduced in human patients[83,84] and there are no studies evaluating the efficacy of this drug for treating hepatic fibrosis in dogs or cats.

Hepatic Encephalopathy

It is important to identify and manage factors that potentially precipitate HE such as gastrointestinal bleeding, infection, dehydration, electrolyte abnormalities, and alkalosis, as well as to provide supportive care.[85] As in humans[86] severe protein restriction is no longer recommended for dogs with HE as this can lead to protein malnutrition.[75] Non-meat protein-based diets are often recommended for dogs with HE. In a study of dogs with congenital portosystemic shunts fed two types of low-protein diets, one with meat and the other with soy, both diets decreased the severity of HE. However, improvements in ammonia concentrations and coagulation parameters were significantly greater in dogs fed the soy-based diet.[87] Once the signs of HE are controlled with a commercial hepatic support diet, it has been recommended to add non-meat protein to the patient's diet to help prevent protein malnutrition.[88] Cats have higher dietary protein requirements than dogs as they cannot downregulate protein catabolism even when food is withheld.[89] Therefore, severe protein restriction is inappropriate for this species. The osmotic laxative lactulose is commonly used to treat HE in dogs and cats. Lactulose can be given orally to patients with chronic HE at a dosage of 1-3 mL per 10 kg body weight q 6-8 h for dogs and cats. This is then adjusted until the patient passes three to four soft stools per day. Lactulose can be given *per rectum* after a cleansing warm water enema in patients that are stuporous or comatosed.[67] Neomycin is a poorly absorbed aminoglycoside antibiotic that is sometimes used to treat HE in dogs and cats (20 mg/kg PO q 8 h). The gastrointestinal absorption of neomycin is usually very low but substantial systemic absorption can cause ototoxicity and nephrotoxicity. In humans, neomycin is no longer used in the treatment of HE for these reasons.[90] Metronidazole is sometimes used for the treatment of HE in dogs and cats (7.5 mg/kg PO q 8-12 h). Metronidazole is metabolized by the liver and can have neurological side effects that mimic those of HE. However, these are more likely to occur at the higher dosages used for other purposes.

Ascites

Furosemide can lead to dehydration/hypovolemia, hypokalemia, and metabolic hypochloremic alkalosis, all

of which can precipitate HE in humans.[66] For this reason, the aldosterone receptor antagonist spironolactone, initially started at a dose of 2 mg/kg PO q 24 h, is preferred for the treatment of ascites that is caused by hepatic disease in dogs and cats. This dosage can gradually be increased to 4 mg/kg PO q 24 h. It is prudent to check the patient's body weight, hydration/circulatory status, hematocrit, serum creatinine concentration, and serum electrolyte concentrations during diuresis. If treatment with spironolactone is ineffective, furosemide can be started at a low dosage (1-2 mg/kg PO q 12 h).[91] Once the ascites resolves it may be possible to taper the dose of diuretics. Mild dietary sodium restriction is also advisable and commercial diets for dogs and cats with liver disease meet this specification. Therapeutic abdominocentesis can lead to worsening of hypoalbuminemia and therefore should be reserved for animals that are refractory to medical management and/or have respiratory compromise due to a large volume of ascites. In humans, abdominocentesis has been reported to lead to hypovolemia.[92] Therefore, simultaneous volume expansion with a synthetic colloidal solution or plasma should be considered in dogs and cats undergoing this procedure.[91]

CHAPTER 282

Canine Inflammatory/Infectious Hepatic Disease

Craig B. Webb

Hepatic disease in humans most often is caused by a viral infection (hepatitis A-E) or alcoholism.[1] Chronic alcohol consumption is not an issue in veterinary patients, and with the advent of canine adenovirus-2 (CAV-2) vaccines, infectious canine hepatitis is now a rare cause of acute liver disease in dogs.[2] Two less common hepatic diseases in humans, non-alcoholic fatty liver disease and autoimmune hepatitis, may have relevance to the veterinary population because of potential similarities in pathophysiology or treatment strategies (see ch. 280).[3] Even within our small animal patients, the primary location of hepatic lesions appears distinctly different between cats and dogs, with the biliary system being predominantly affected in cats and the parenchyma being the primary target of disease in dogs.

The World Small Animal Veterinary Association Liver Standardization Group standardized the classification and nomenclature for canine and feline liver diseases.[4] Cholangitis (inflammation of the bile duct) is divided into four groups: neutrophilic cholangitis, lymphocytic cholangitis, destructive cholangitis, and chronic cholangitis associated with liver fluke infestation. Neutrophilic and lymphocytic cholangitis are found almost exclusively in cats, fluke infestation is found predominantly in cats, while destructive cholangitis is a rare condition of dogs.[4] Portal inflammation, fibrosis, and bile duct proliferation are consistent histopathologic findings in cases of cholangitis, but ultrasound of the biliary system and cytologic examination and culture of the bile are required for the most clinically useful diagnosis. Feline hepatic disease is covered in ch. 283.

Hepatitis (inflammation of the hepatic parenchyma), seen predominantly in dogs, is most often classified into acute and chronic forms.[5] The chronic form is further characterized histopathologically according to the pattern, location, cellular infiltrate, severity and extent of inflammation, hepatocyte apoptosis and necrosis, fibrosis, cirrhosis, and loss of architecture.[6] Infectious causes of canine hepatic disease exist within each of these categories, although an acute infectious hepatitis can start progressive changes that result in chronic hepatitis after the original infectious agent is gone. Granulomatous, eosinophilic, and lobular dissecting hepatitis are three additional but rare histopathologic classifications. The majority of cases of primary canine hepatitis, as opposed to secondary or reactive hepatitis, are idiopathic. Specific causes of acute hepatitis in dogs are shown in Box 282-1. For chronic hepatitis, most cases also are idiopathic, although differentials to consider include infection, toxins, drugs, metabolic causes, and an immune-mediated process.[7]

Box 282-1

Causes of Acute Canine Hepatitis

Infectious

CAV-1 (adenovirus)
Leptospirosis
Clostridium spp.
Canine monocytic ehrlichiosis *(E. canis)*

Toxins (see ch. 152)

Mycotoxins, aflatoxicosis
Cyanobacteria—microcystin toxicosis ("blue green algae" or algal bloom)
Amanita mushrooms
Xylitol (sugar substitute)

Manganese overdose (joint supplement)
Alpha lipoic acid
Organic solvents (CCl_4)

Drugs

Carprofen, acetaminophen
Trimethoprim-sulfonamide antibiotic
Azathioprine
Amiodarone
Mitotane

Idiopathic

Acute Hepatitis

Similar to acute pancreatitis, acute hepatitis in dogs can be rapidly fatal, completely reversible, or progress to a condition of chronic hepatitis over time. Early recognition and intensive intervention, starting with specific treatment of the inciting cause, if known, are keys to a successful outcome in these cases. The clinical presentation is sudden in onset and can include any number of nonspecific signs, such as lethargy, anorexia, vomiting or diarrhea, fever, abdominal pain, polyuria and polydipsia, and dehydration. Some dogs can be jaundiced, while few if any would be expected to present with ascites. These dogs often have marked elevations of serum alanine aminotransferase (ALT) or alkaline phosphatase (ALP) liver enzyme activity, with variable elevations in serum gamma glutamyltransferase (GGT) and aspartate aminotransferase (AST) activity. Dogs may or may not present with hyperbilirubinemia and decreased serum blood glucose, cholesterol, or blood urea nitrogen (BUN), depending in part on the time frame and severity of the inciting cause. Hypoalbuminemia rarely is present in acute cases, and clotting abnormalities are unlikely, although hemostasis should be monitored. A complete blood count (CBC) could indicate stress or inflammation while urinalysis may be unremarkable. A histopathologic diagnosis is rarely sought in cases of acute hepatitis where the inciting cause is more likely to be identified through history of exposure to drugs and toxins, or with various blood tests and serology looking for infectious agents.

Dogs with infectious canine hepatitis caused by CAV-1 present acutely with fever, lethargy, anorexia, cranial abdominal pain, melena, vomiting, diarrhea, and biochemical abnormalities indicative of liver and kidney involvement. Dogs can develop bronchopneumonia, conjunctivitis, photophobia, and a corneal opacity or "blue eye," the result of anterior uveitis and corneal edema (see ch. 11). With the advent of effective vaccination protocols that include CAV-2 to induce cross-protection without pathogenicity, the prevalence of this disease has been significantly reduced, although not eliminated.[2,8,9]

Leptospirosis currently is the most commonly recognized infectious cause of acute hepatitis in dogs, although historically the infection most frequently has been associated with acute kidney injury and more minor liver involvement (see ch. 217).[10,11] Leptospirosis, caused by serovars of *Leptospira interrogans* or *kirschneri* in dogs, also is an important zoonotic disease, and appropriate isolation and barrier precautions should be used in suspect cases. The most prevalent serovars and risk factors seen with affected dogs shift with the advent of different vaccine protocols and products, as well as exposure and environmental factors.[12-15] Common clinical signs include vomiting, lethargy, icterus, diarrhea, polyuria/polydipsia, and anorexia. Conjunctivitis and uveitis can be seen, as well as signs of pulmonary disease and respiratory compromise, coagulopathies, and vasculitis. Dogs often are febrile, azotemic, with elevated serum liver enzyme activities, hyperbilirubinemia, electrolyte abnormalities, leukocytosis, thrombocytopenia, and possibly prolonged clotting times. The urinalysis can reveal hyposthenuria, glucosuria, and proteinuria, with bilirubin, red blood cells, and white blood cells present.[16] Diagnostic evaluation and treatment recommendations[16] are presented in ch. 217 and Table 282-1.

TABLE 282-1

Treatment Considerations for Canine Acute and Chronic Hepatitis

CONDITION	TREATMENT	DOSE AND DOSAGE CONSIDERATIONS*

Leptospirosis	Doxycycline Ampicillin	5 mg/kg PO or IV q 12 h for 2 weeks 20 mg/kg IV q 6 h in hospital
Enterobacteriaceae: *E. coli* *Enterococcus, Bacteroides, Streptococcus, Clostridium*	Ciprofloxacin Aminoglycosides Others: enrofloxacin, clindamycin, cephalexin, etc.	
Acute hepatitis	Plasmalyte, Normosol: balanced isotonic crystalloid Fresh frozen plasma: colloid, clotting factors 2.5% dextrose + 0.45% NaCl: fluid supplementation, hypoglycemia	Variable, based on multiple parameters Variable, based on multiple parameters Variable %, based on serum blood glucose
	Vitamin K_1: vitamin K-dependent clotting factors	2.5 mg/kg SC q 12 h, 1.6 mg/kg PO q 24 h
	N-acetylcysteine: antioxidant, methyl donor, ↑[Glu]	140 mg/kg IV once, 70 mg/kg IV/PO q 6 h
Hepatic encephalopathy	Lactulose; ↓colonic pH, trap ammonia, osmotic agent	Variable, based on signs and consistency of stool, 5-30 mL PO or enema
	Metronidazole: antibiotic, anaerobes	7.5 mg/kg PO q 12 h
	Neomycin: antibiotic, poorly absorbed	22 mg/kg PO q 8 h
	S-adenosylmethionine: (SAMe) antioxidant, methyl donor, transsulfuration	20 mg/kg PO q 24 h
	Silymarin: *Amanita* mushroom intoxication, antioxidant, anti-inflammatory, anti-fibrotic, hepato-protective	20-50 mg/kg PO q 24 h
	Vitamin E: lipid peroxidation antioxidant, anti-fibrotic	400-600 IU PO q 24 h
	Vitamin B complex	1-4 mL/dog SC, IM, IV q 24 h
Enteric cyanotoxins	Cholestyramine: bile acid sequestrant	172 mg/kg PO q 24 h
Chronic hepatitis	Diet: low Cu content, Zn & antioxidants added	Protein: ↓quantity ↑quality; ↑fermentable CHO; ↓Na
	Prednisolone: contraindicated in acute hepatitis	1-2 mg/kg PO q 24 h, taper per response
	Azathioprine: purine antagonist immunosuppressive	2 mg/kg PO q 24 h, then taper
	Cyclosporine: cellular immunosuppressive	5 mg/kg PO q 12 h
	Mycophenolate mofetil: purine synthesis inhibition	10 mg/kg PO q 12 h
	Ursodeoxycholic acid: hydrophilic bile acid, choleresis, immune modulation, ↑ [Glu] production, cytoprotective	7.5 mg/kg q 24 h or 10-15 mg/kg PO q 24 h
Copper accumulation	D-Penicillamine: chelates Cu in circulation	5-15 mg/kg PO q 12 h, 2 h before food 6 months minimum
	Zinc acetate: (35% elemental Zn), prevents Cu absorption	15 mg/kg q 12 h with food
	2,2,2-tetramine tetrahydrochloride (Trientine): Cu chelator	5-15 mg/kg PO q 12 h, 2 h before food
	Ammonium tetrathiomolybdate	20 mg PO q 8 h
Fibrosis	Colchicine	0.025-0.03 mg/kg PO q 24 h
	Polyunsaturated phosphatidylcholines	50-100 mg/kg PO q 24 h
Portal hypertension	Spironolactone: aldosterone antagonist diuretic Furosemide: loop diuretic	1-2 mg/kg PO q 12-24 h 2-4 mg/kg PO or IV q 8-12 h

*Disclaimer: Clinicians should always check dose/dosage recommendations with the most currently available information.

Glu, Glutathione.

Clostridium spp. cholangiohepatitis was diagnosed by ultrasound-guided cholecystocentesis and culture of bile in a Yorkshire Terrier presenting for acute onset of vomiting and diarrhea. Biochemical abnormalities were consistent with cholestasis and histopathologic evaluation showed hepatic inflammation and necrosis. The dog was treated successfully with clindamycin, amoxicillin-clavulanate, and ursodeoxycholic acid.[17]

Clostridium piliforme was identified in one puppy with multifocal necrotizing hepatitis.[18] *Clostridium* spp. are one of the most common isolates from biliary cultures in dogs and cats with hepatobiliary disease.[19]

There is one report of an adult German Shepherd presenting with clinical signs and biochemical abnormalities consistent with acute hepatitis where the eventual diagnosis was *Ehrlichia canis* infection; following identification of *E. canis* using cytologic, immunohistochemical, and polymerase chain reaction (PCR) testing, the dog was treated successfully with supportive care and doxycycline.[20]

Acute hepatitis secondary to aflatoxicosis has been seen in dogs following ingestion of contaminated commercial dog food. Presenting signs are consistent with an acute toxic hepatopathy and historical identification of a probable source of exposure should prompt discontinuation and testing of the product. Treatment is nonspecific and supportive.[21,22]

Acute hepatitis caused by cyanobacterial microcystin toxicosis following exposure to an algal bloom usually is fatal, but several dogs have been treated successfully with some combination of 0.9% NaCl fluid supplemented with KCl and dextrose, fresh frozen plasma and whole blood, S-adenosylmethionine (SAMe) and silibinin, vitamin B complex, vitamin K, famotidine, procaine penicillin G, and the oral bile acid sequestrant cholestyramine.[23-25]

Amanita spp. mushroom ingestion causes acute hepatic inflammation, necrosis, and failure in dogs. The diagnosis is often presumptive based on exposure and clinical signs, although alpha-amanitin can be detected in liver tissue by liquid chromatography-mass spectrometry.[26] There are rare reports of successful treatment of *Amanita* mushroom intoxication, but the condition most often is fatal despite the use of N-acetylcysteine and silibinin.[27]

Hepatocellular necrosis has been reported secondary to carprofen administration in a number of dogs. Clinical signs include anorexia, vomiting, and icterus. Biochemical abnormalities include hyperbilirubinemia and elevated liver enzyme activity. Urinalysis is consistent with renal tubular disease. Supportive care results in successful resolution in many, but not all, cases, and the toxicosis is thought to be an idiosyncratic drug reaction (see ch. 169).[28,29]

Hepatic necrosis and failure have been reported in 4 dogs within a month of starting trimethoprim-sulfonamide (TMS) antibiotic administration. All of these patients died or were euthanized despite intensive supportive care, and it was determined that TMS hepatotoxicosis most likely is an idiosyncratic drug reaction.[30]

Although copper accumulation is presented as a form of chronic hepatitis, there is a report of acute hepatic failure in a young Dalmatian associated with excess hepatic copper accumulation.[31] This could be an indication that copper toxicosis has a genetic component in this breed.

Chronic Hepatitis

The majority of cases of canine chronic hepatitis are idiopathic.[5,32] The etiology most commonly identified as a cause or contributor to chronic hepatitis is excess hepatic copper accumulation. In at least one breed, copper accumulation is the direct result of a metabolic defect, while in other breeds it may be an epiphenomenon, albeit a treatable one. In cases of acute hepatitis, there could be a morphological and clinical progression to chronic hepatitis despite the elimination of the original inciting cause, and in this sense, many of the differentials for acute hepatitis (see Box 282-1) can be included as potential causes of chronic hepatitis. Some form of immune-mediated process is also postulated as an etiology for chronic hepatitis in dogs, and although this condition remains poorly defined, it is frequently the target of chronic hepatitis treatment.

The clinical presentation of canine chronic hepatitis varies from little more than persistently elevated liver enzyme activity, to a gradual decrease in the dog's activity, appetite, and weight that may be attributed to "old age," to the seemingly acute onset of jaundice, anorexia, ascites, and abnormal mentation indicative of hepatic encephalopathy. Biochemical abnormalities can indicate a significant reduction in hepatic metabolism, including hypoglycemia, hypocholesterolemia, hypoalbuminemia, a low BUN, and hyperbilirubinemia, along with an elevation in liver enzyme activity. Eventually, the liver enzyme activities can appear normal, or even below the reference range, because of a severe loss of hepatic parenchyma (see Box 280-3). A decrease in the clotting factors normally produced by the liver can be clinically apparent as prolonged bleeding from a venipuncture site, or as prolonged clotting times (see ch. 196). If serum total bilirubin is not yet elevated in cases of suspected chronic hepatitis, a pre- and post-prandial serum bile acids test is an excellent measure of hepatic function (see ch. 280). Although non-hepatic differentials for hyperbilirubinemia must be considered, bile acids testing will be abnormal in dogs if total bilirubin is

significantly elevated because of liver disease, and bile acids are therefore a redundant test in this situation. These dogs often are polyuric, polydipsic and can be hyposthenuric. Other urinalysis abnormalities include hyperbilirubinuria (0 to 1+ being considered normal in a dog) and ammonium biurate crystalluria. A CBC likely will show a stress or inflammatory leukogram and could reveal the anemia of chronic disease. Alternatively, the CBC could show a microcytic, hypochromic anemia consistent with a chronic gastrointestinal (GI) bleed secondary to portal hypertension and intestinal edema. Imaging can reveal a small, bright, irregular liver with evidence of portal hypertension or acquired shunts and ascites. The gold standard for the diagnosis and characterization of chronic hepatitis is liver biopsy. Unfortunately, these dogs often are presented when the disease process makes them poor anesthetic or surgical candidates. Even attempting laparoscopic liver biopsy in dogs with end-stage chronic liver disease could result in further decompensation of the clinical condition. However, laparoscopic liver biopsy (see ch. 91) with histopathologic evaluation, metal analysis (copper, iron, and zinc), and culture of tissue or bile, is an excellent diagnostic opportunity in those dogs that are relatively stable, presumably earlier in the disease process, and possibly suffering from a treatable condition or at least treatable component, such as copper accumulation. The presence of bridging fibrosis or cirrhosis distorting the hepatic parenchyma, along with hepatocellular necrosis and mixed inflammation is both diagnostic, and unfortunately, likely prognostic, in cases of chronic hepatitis.

Acute hepatitis caused by toxins (e.g., aflatoxicosis) or drugs (e.g., TMS, nonsteroidal anti-inflammatory drugs) can progress to chronic hepatitis over time if the dog survives the initial insult. The drugs most commonly associated with chronic hepatitis following chronic administration are anticonvulsants.[33,34] Although primidone is rarely used, there are reports of phenytoin hepatotoxicosis, and phenobarbital remains a common choice for treating seizures in dogs.[35-37] Although phenobarbital is thought to induce the production of canine ALP liver enzyme activity much like glucocorticoids, histopathologic examination suggests that the elevation of ALT activity with phenobarbital therapy could be due to hepatic damage.[38-40]

As with toxins, infectious causes of acute hepatitis can set the foundation for morphologic changes that eventually manifest as chronic hepatitis. With early recognition and treatment, many dogs with acute leptospirosis-associated hepatitis recover, do well, and possibly clear the organism. Some percentage of these dogs could go on to develop chronic hepatitis much later in life, whether due to a persistent low-grade infection, an immune-mediated reaction to the original infection, or a continuation of the inflammatory response. Identifying infectious causes of chronic hepatitis has otherwise been challenging.[41,42] In dogs and cats with hepatic inflammation, the most common organisms cultured from bile were *E. coli, Enterococcus* spp., *Bacteroides* spp., *Streptococcus* spp., and *Clostridium* spp.[19] *Helicobacter canis* was isolated from the liver of one dog with multifocal necrotizing hepatitis, while *Yersinia pseudotuberculosis, Salmonella* spp., *Clostridium piliforme, Campylobacter jejuni,* and rickettsial organisms also are potential causes of infectious chronic hepatitis.[43] Granulomatous hepatitis is a form of chronic hepatitis where the etiology often is infectious, including mycobacteria (see ch. 212), fungal organisms, migrating nematode larvae, *Leishmania* (see ch. 221), and possibly *Bartonella* spp. (see ch. 215).[44,45] Chronic hepatitis with a large eosinophilic component also can be caused by parasitic infections and migrating larvae. Histopathologic assessment and microbial culture would be essential components of a correct diagnosis and an effective treatment plan. Young female English Springer Spaniels appear predisposed to a form of chronic hepatitis where the histopathologic findings are similar to those of viral hepatitis in humans, but to date, no causal virus has been identified.[46] Serologic testing, PCR testing, and fluorescence *in situ* hybridization (FISH) are advanced technologies currently being employed as diagnostic tools in the search for infectious causes of hepatic inflammation. As this latter technology becomes more readily available, it is very likely to clarify the role of bacteria in canine hepatitis, and in doing so, help target specific antibiotic therapy to those cases where it is most appropriate.

Anti-inflammatory and immunosuppressive therapy often are used in the treatment of canine chronic hepatitis, frequently to good effect according to anecdotal reports. This would suggest that some number of these cases have an immune-mediated component to either the etiology or the progression of the disease. Ideally, a diagnosis of an immune-mediated condition would include the direct demonstration of that arm of the immune system that is responsible for the disease, whether it be antibody- or cell-mediated. Unfortunately, that level of specificity rarely exists in veterinary medicine (e.g., immunohistochemistry and electron microscopy in cases of glomerulonephritis). Most often the evidence is circumstantial, as with the infiltration of lymphocytes and plasma cells in cases of inflammatory bowel disease, red blood cell agglutination in immune-mediated hemolytic anemia, or the marked response to immunosuppressive drugs in cases of immune-mediated polyarthritis. Circumstantial evidence also exists for an immune-mediated component to canine chronic hepatitis, but response-to-treatment remains the most compelling clinical argument for the continued use of immune-modulatory drugs in cases of canine chronic hepatitis.[47-51]

Hepatic copper accumulation is the most commonly diagnosed treatable component of canine chronic hepatitis. Copper (Cu) exists in a number of forms, of which the cupric oxidation state (Cu^{2+}) likely is responsible for most of copper's hepatotoxicity. Copper is a key component in the redox cycling that generates oxidative radicals that deplete hepatic antioxidant defenses and damage multiple cellular components.[52] A tremendous amount of ongoing research is aimed at identifying a genetic defect or marker in a number of breeds, the specific metabolic defect involved, the role of dietary copper, and the most effective treatment protocol for this aspect of the disease process.

The copper hepatopathy seen in Bedlington Terriers is the result of a primary defect in hepatic copper metabolism resulting in marked lysosomal copper accumulation.[53,54] At least one genetic defect has been identified in affected Bedlington Terriers, a deletion in exon 2 of the *COMMD 1* (copper metabolism gene MURR1-containing domain 1) gene and the pattern of inheritance appears to be autosomal recessive.[55-58] The metabolic consequence of this mutation is a defect in the ability to excrete copper from hepatocytes into bile canaliculi.[7,59,60] The role of dietary copper and oxidative damage is further discussed in ch. 285. The diagnosis of copper toxicosis in the Bedlington is based on histopathologic features and hepatic copper concentration and location.[61,62] Hepatic copper accumulation, clinical signs, decreased hepatic function, and morphological damage are progressive in this breed. The condition can present as an acute hepatopathy or the more common chronic form, both of which are clinically similar to other forms of acute and chronic hepatitis. Young Bedlington Terriers can be pre-clinical and asymptomatic except for an elevation in hepatic enzyme activity. An acute hemolytic crisis is a rare presentation, following massive release of copper from the liver into the circulation, which can happen in any dog with excessive hepatic copper storage. Normal hepatic copper content is <400 ppm dry weight, while levels >2000 ppm result in functional, morphological, and clinical disease. Bedlington Terriers present with the highest levels of copper accumulation, up to 50 times normal, while other breeds most often present with 10-20 times normal levels. In Bedlington Terriers homozygous for the genetic defect, hepatic copper accumulation can begin as early as 8 to 12 weeks of age, or might not be evident until a year of age, and is progressive. In heterozygotes, there can be an increase in accumulation around 6 months of age, but hepatic copper levels normalize by 15 months of age. Clinicians cannot rely on serum liver enzyme elevations as a sole marker of copper storage disease in this breed, because these can be normal in some cases. This pattern makes genetic testing an important diagnostic tool when attempting to determine which individuals are affected at a young age. The "CT deletion test" and "CT Marker Test" are available from Veterinary Genetic Services and can help guide breeders facing husbandry decisions.[63]

So far, the Bedlington Terrier is the only breed where a genetic cause for copper storage hepatopathy has been identified. The possible heritability of the condition in Doberman Pinschers has been studied extensively, although, as with many breeds, it is not yet established whether Cu accumulation is a primary problem or a secondary consequence.[64-66] In West Highland White Terriers, Skye Terriers, Dalmatians, and Labrador Retrievers, it could be a familial condition.[67-71] A growing number of other breeds present with excess hepatic copper storage as either a cause or a consequence of their condition. The increasing prevalence of copper toxicosis in both purebred and mongrel dogs highlights the likely importance of environmental factors, particularly dietary, that undoubtedly contribute to this condition.[72]

The histologic distribution of hepatic copper could assist in differentiating primary from secondary causes. If copper is found both in hepatocytes adjacent to necrotic, inflammatory tissue and in hepatocytes distant from these lesions, it suggests that copper accumulation is the primary cause of the hepatopathy. In these cases, copper accumulates in zone 3 (centrilobular) as well as in regenerative nodules, and the degree of accumulation in Kupffer cells and hepatocytes correlates with the histopathologic severity (see ch. 285). If copper accumulation is secondary to some other disease process, it usually is found in zone 1 (periportal), restricted to those areas of tissue directly adjacent to cellular injury, and not correlated with the severity of the disease. One reason histopathologic evaluation of a tissue specimen is preferred over cytologic evaluation of liver aspirates is because of the importance of these zonal patterns of distribution. Even the histopathologic findings can be variable and range from no cellular changes other than copper accumulation in zone 3, to lipogranulomas and mixed inflammatory infiltrate with cytosolic copper, to fibrosis, cirrhosis, and loss of normal hepatic architecture. Rubeanic acid and rhodamine are copper-specific stains, but a quantitative measure of copper (atomic absorption spectroscopy) is ideal. A copper level >400 ppm dry weight is abnormal, with many cases of hepatitis reaching levels >800 ppm, and severe cases measuring >1,500 ppm. Zinc and iron are the two other metals most often quantified from hepatic biopsies. Both metals have complex roles in liver disease, and both are potentially therapeutic targets, with zinc supplementation and iron

chelation, although neither is as direct a concern as copper accumulation.[73]

Treatment (see Table 282-1)

To date, there is surprisingly little evidence on which to base treatment decisions in cases of acute or chronic hepatic inflammation. The first target—treating the cause—is rarely an option because in the majority of cases the inciting cause is never identified and the label "idiopathic" has to be applied. In the absence of a specific target, the focus of therapy becomes the pathophysiologic processes at work, and the clinical consequences of those processes. These processes include the extent and severity of inflammation and the predominant cell type involved; biliary stasis; copper accumulation; the amount and extent of fibrosis, the loss of normal architecture, the progression to cirrhosis with portal hypertension; and the loss of liver function.

In cases of acute hepatitis secondary to toxin or drug ingestion, the offending agent, if known, is discontinued immediately. Because of the liver's central role in metabolism, hepatotoxicosis is one of the most frequently listed side effects for a wide variety of medications, and a common target of toxins and toxic metabolic byproducts. A careful and complete history, including all prescription and non-prescription drugs, nutraceuticals, supplements, and treats, is a critical part of the assessment. Inadvertent or malicious intoxication also can occur through diet or environmental exposure, so both of these must be queried. Leptospirosis is a particularly important differential for acute hepatitis because of the imminent zoonotic risk, the time and effort required to reach a definitive diagnosis, and the minimal and safe treatment requirements (see ch. 217). Even in an area with a low prevalence and questionable exposure, appropriate barrier precautions and antibiotic treatment frequently are implemented as soon as the patient is hospitalized, until such time as leptospirosis can be confidently removed from the list of possible etiologies. Further information on the handling and treatment of dogs with leptospirosis can be found in the 2010 ACVIM consensus statement.[16]

The foundation of treatment for cases of acute hepatic inflammation is otherwise supportive care, dictated in large part by the condition of the patient. Fluid therapy is a key component in correcting dehydration (see ch. 129); addressing acid-base status and electrolyte balance (see ch. 128); supporting volume, blood pressure, and tissue and organ perfusion (see ch. 99 and 127); and supplementing glucose. Antibiotics and ursodeoxycholic acid were the most frequently employed treatments in one survey of idiopathic acute hepatitis, while prednisone, D-penicillamine, and zinc gluconate were most commonly administered in cases of copper-associated acute hepatitis.[5] N-acetylcysteine acts as a free radical scavenger and a methyl donor, and is used in cases of acute, severe hepatitis to increase hepatic concentrations of the antioxidant glutathione. Several other antioxidants and glutathione precursors can be given in cases of acute hepatitis, such as SAMe, silymarin (silibinin), and vitamin E, although the administration of oral medications is often problematic in acute hepatitis.[74] Colloid support is controversial, although plasma is still used in cases of documented coagulopathy. Antiemetics, gastric acid reducers, gastric ulceration medications, appetite stimulants, and analgesics are all non-specific treatment considerations in these cases. Glucocorticoids are contraindicated in the majority of cases of acute hepatitis.

Treatment of chronic hepatitis also is dictated by the condition of the patient, and ideally, by WSAVA Standardized histopathologic findings, copper quantification, culture results, and sequential monitoring of clinical and biochemical parameters. If a cause is identified, it is targeted specifically, but the majority of cases are, again, idiopathic.[75]

The use of antibiotics clearly can be called for in cases of suspected leptospirosis; following a positive bacterial culture result; in a febrile dog with CBC changes that include a left shift or toxic neutrophils; with a suppurative inflammatory hepatic infiltrate; or in those cases where advanced diagnostics such as FISH identify a target organism in association with the inflamed tissue. In these cases, the choice of antibiotic usually is based on the desire to cover a broad spectrum of possible organisms, or is targeted toward those organisms most frequently identified in culture-positive samples: *Escherichia coli*, *Enterococcus* spp., *Bacteroides* spp., *Streptococcus* spp., and *Clostridium* spp.[19] Antibiotic susceptibility is becoming a key component of effective therapy in veterinary medicine. The majority of Enterobacteriaceae isolated from gallbladder aspiration were susceptible to ciprofloxacin or aminoglycosides in one report, with first-generation aminopenicillins and cephalosporins being much less effective.[19] Doxycycline, enrofloxacin, clindamycin, cephalexin, amoxicillin-clavulanic acid, and marbofloxacin all have been used in cases of suspected bacterial hepatitis.

Antibiotics also are indicated in cases of hepatic encephalopathy. Here, the goal is to impact the GI microbiome in such a way as to decrease the production, and therefore the potential absorption, of ammonia.

Hence, antibiotics are chosen based on their targeting of specific components of that microbiome, such as metronidazole, or based on their predominant site of action being the GI tract, such as neomycin. Lactulose is another standard therapy for patients with signs of hepatic encephalopathy, the goal being a reduction in the absorption of ammonia by changing the pH of the GI contents.[76,77]

The targeted treatment of hepatic copper accumulation is most strongly justified in patients for whom the actual hepatic copper content has been quantified at >1,500-2,000 ppm. Outside of the Bedlington Terrier and perhaps several other breeds, the role of copper accumulation as a primary defect is less clear and the indiscriminate use of copper chelating therapy is more problematic. However, in cases where hepatic copper accumulation is demonstrated, studies show that the long-term use of D-penicillamine is beneficial.[78,79] A low-copper diet and zinc supplementation also are used commonly to reduce copper exposure and remove accumulated copper; therapy is required for months and ideally, follow-up includes a repeated liver biopsy and copper quantification.[80-82] If used concurrently, D-penicillamine actually can chelate zinc from the blood, reducing its effectiveness. D-penicillamine can cause substantial GI side effects. Trientine HCl is one alternative Cu chelator with anecdotal evidence of efficacy in a number of dogs, and ammonium tetrathiomolybdate, historically used for copper poisoning in sheep, is being investigated for use in dogs.[83,84]

Therapy aimed at reducing ongoing oxidative damage and addressing depleted antioxidant defenses most commonly includes the nutraceuticals SAMe, silymarin (silibinin), and vitamin E. Although the depletion of antioxidant defenses has been shown in dogs with hepatic disease, effective antioxidant supplementation strategies are still based predominantly on theoretical considerations.[85]

Ursodiol (ursodeoxycholic acid), a synthetic hydrophilic bile acid, can have a number of properties that would be beneficial in cases of hepatic inflammation. Ursodiol is a choleretic that is used frequently to combat cholestasis and displace toxic, hydrophobic bile acids, and it can help flush out excess iron or copper. Ursodiol could have immunomodulatory and cytoprotective properties, as well as an ability to replenish antioxidant defenses.[74]

Portal hypertension is common in cases of chronic hepatic inflammation where fibrosis has progressed to cirrhosis. Portal hypertension, often occurring in dogs that are also hypoalbuminemic, results in ascites, edema, and ulceration of the GI tract, and signs of hepatic encephalopathy. Treatment of the GI signs is nonspecific and supportive, and includes the use of sucralfate, H2 blockers, and proton pump inhibitors. Plasma, colloids, or human albumin can be used for trying to maintain vascular oncotic pressure, but these treatments carry with them substantial side effects. Spironolactone in combination with furosemide is a medical approach to ascites, if time and clinical signs permit; otherwise, therapeutic abdominocentesis is used in cases where the ascites is causing cardiorespiratory compromise (see ch. 90). Signs of hepatic encephalopathy (HE) call for dietary intervention with a high quality but decreased quantity of protein, preferably plant-based, with fermentable fiber and limited fat content. Lactulose, given orally or as an enema, is a standard HE treatment used to acidify the colonic pH and reduce ammonia production and absorption.

Large amounts of inflammation without evidence of infection, lymphocytic-plasmacytic infiltration consistent with an immune-mediated process, or the need to address significant fibrosis, are all arguments for the use of corticosteroids in cases of chronic hepatitis.[86] Ongoing corticosteroid treatment is contraindicated in cases of infectious hepatitis, but because of the diagnostic uncertainty, corticosteroids often are co-administered with antibiotics early in the course of treatment. This strategy has a number of potential pitfalls and it highlights the importance of a thorough diagnostic work-up and rigorous follow-up to help direct therapy. Colchicine and zinc also are used for trying to slow the progression of fibrosis, while additional immunomodulatory drugs being used with some frequency include azathioprine, cyclosporine, and mycophenolate mofetil.

Summary

Important advances are being made in our understanding of inflammatory and infectious liver disease in dogs. The standardization of histopathologic interpretation and nomenclature has unified the classification scheme for liver disease in dogs. Continued advancements in molecular techniques and diagnostic technologies such as PCR and FISH will continue to help identify and unravel the underlying etiology in canine liver disease. Finally, new frontiers in treatment, particularly of canine chronic hepatitis, include exciting possibilities such as tissue transplantation and stem cell therapy.[87,88]

CHAPTER 283

Feline Inflammatory/Infectious Hepatic Disease

Marnin A. Forman

Client Information Sheet: Feline Inflammatory/Infectious Liver Disease

Introduction

Feline inflammatory and infectious hepatobiliary diseases are common causes of morbidity and less frequent mortality in cats.[1] Inflammatory hepatobiliary diseases are one of the most common feline hepatic conditions in the United States, United Kingdom and Europe.[2] In one study, 45 of 175 feline liver biopsies (26%) revealed inflammatory disease.[3] Two common feline inflammatory hepatopathies include cholangiohepatitis (acute [suppurative] and chronic [non-suppurative or mixed]) and lymphocytic portal hepatitis.[3,4] More recently, the World Small Animal Veterinary Association (WSAVA) standardization committee recommended a distinct classification system for histologic features of lymphocytic portal hepatitis and chronic lymphocytic cholangitis[5] and an internationally accepted group of diagnostic terminologies for hepatopathies.[6] This scheme differentiated inflammation of the bile ducts (cholangitis) into 4 categories: neutrophilic cholangitis, lymphocytic cholangitis, destructive cholangitis, and chronic cholangitis associated with liver fluke infestation.[6]

Infectious hepatobiliary diseases, diagnosed less often, remain an important differential diagnosis when formulating treatment plans. Overlap in defining infectious from inflammatory hepatobiliary diseases exists, especially with neutrophilic cholangitis. Multiple primary hepatic infectious diseases have been documented which result in secondary inflammation. Feline hepatic lipidosis, the most common hepatic disease in cats, is covered in ch. 285. Hepatic neoplastic conditions and copper storage diseases are possible and will be briefly discussed (also see ch. 285). Signalment clinical signs, minimum database, and imaging can help differentiate inflammatory, infectious, and neoplastic conditions, as well as hepatic lipidosis. However, cytology or histology is essential to reach a definitive diagnosis.

Neutrophilic Cholangitis/Cholangiohepatitis

Definitions

Neutrophilic cholangitis (NC) is more common in cats than in dogs[6] and is subclassified into acute neutrophilic cholangitis (ANC) and chronic neutrophilic cholangitis (CNC).[1] The proposed pathogenesis is an ascending intestinal bacterial infection.[1,7] Histologically, neutrophils are noted within the bile duct lumen, closely associated with the bile duct or between the biliary epithelial cells. If the inflammation extends beyond the limiting plate and into the hepatic parenchyma, the diagnosis is cholangiohepatitis (CH). Progressive disease can result in bile duct rupture with bile leakage, necrosis or abscesses.[6]

Clinical and Routine Laboratory Features

Early reports suggested cats with acute neutrophilic disease were younger and more likely to have fever, weight loss, and a neutrophilic left shift.[3,5,8] More recently, overlap in clinical and laboratory findings were noted in cats with acute or chronic disease.[1] Common clinical signs included lethargy, vomiting, weight loss and decreased appetite. Physical examination abnormalities are not common, but include fever (22%), icterus (34%) and hepatomegaly (21%). Abnormalities on complete blood counts (CBCs) are detected in less than half of cats with NC and, when present, include leukocytosis (39%), band neutrophils (33%), and anemia (34%).

Cats with moderate to severe cholangitis can have normal serum liver enzyme activities but increases in aspartate transaminase activity (AST) have been noted in 98% of cats. Variable increases in alanine transaminase (ALT) in 50-57%, alkaline phosphatase activities (ALP) in 14-48% and gamma-glutamyl transferase (GGT) have been noted. Many cats with cholangitis have liver enzyme values (ALT, ALP, GGT) within laboratory reference intervals, but about 2/3 are hyperbilirubinemic.[3] Hepatic function parameters were infrequently abnormal (hypoglycemia 7%, decreased blood urea nitrogen 0%, hypoalbuminemia 13%, and hypocholesterolemia 6%).[1,3] Fasting and post-prandial serum bile acid concentrations, using cutoffs of 15 micromol/L and 20 micromol/L, respectively, had higher specificity than did enzymatic testing and should be considered if hepatic disease is suspected in cats with normal enzyme activities and bilirubin concentration.[9] For coagulation testing, the most common abnormalities cited have varied and are most likely influenced by the studied population and testing methodology.[10] Abnormalities included prolongation of prothrombin time (PT: 4-77% of cases), prolonged partial thromboplastin time (PTT: 25-55%), reduced activities of factors VII (68%) and XIII (31-78%, 75% for cats with inflammatory liver disease) and increased PIVKA (75%), D-dimer concentrations (83%) and alpha-2-plasmin inhibitor activity (67%) (see ch. 196).[10-12]

Ultrasonography (US) and US-Guided Fine-Needle Aspiration (FNA)

Hepatobiliary abnormalities are frequently detected during abdominal US examination in cats with NC, including hyperechoic parenchyma with or without hepatomegaly, bile duct or gallbladder distension and increased gallbladder sediment (see ch. 88 and E-Figure 283-1). Other abnormalities commonly noted in cats with NC are pancreatic enlargement, hypoechoic parenchyma and hyperechoic peri-pancreatic parenchyma. Gastrointestinal (GI) tract abnormalities include thickened walls and fluid distension.[1] One retrospective study of several hepatobiliary US assessments (liver parenchymal echogenicity and echotexture, portal venous clarity, gallbladder wall thickness, bile duct diameter, and character of gallbladder content) failed to differentiate healthy cats from those with diffuse infiltrative hepatic disease (inflammation, cancer, or lipidosis).[13] Another study failed to detect any features to discriminate lymphocytic from neutrophilic forms of cholangitis.[14] Diagnosis of diffuse liver disease based solely on US ± routine clinical biochemical or hematologic data should be made with caution, even by skilled ultrasonographers.[13]

E-FIGURE 283-1 Relatively normal hepatic ultrasound image, except for dilated interlobular ducts in

an l4-year-old female spayed Domestic shorthair cat with *E. coli* growth from a hepatic biopsy sample and marked neutrophilic portal hepatitis with bile duct hyperplasia.

US does permit guided percutaneous collection of samples for cytologic or histologic examination (see ch. 89). FNA with cytologic examination has distinct advantages and limitations in evaluating cats with hepatic disorders. It is cost-effective, expedient, relatively straight-forward to perform, provides quick diagnostic information as compared with liver histopathology, complications are uncommon, needed pre-procedure testing is limited (coagulation is not typically required) and can usually be performed without anesthesia or sedation.[15] With US-guidance, FNA can be helpful diagnostically in cats with diffuse or focal disease. The important limitation with liver cytology is the small sample size (cells), which does not reflect morphology of the parenchymal architecture and limits the ability to correctly identify the primary hepatic disorder.[15] In one study, only 51% of cats had overall agreement in both the cytologic and histopathologic diagnosis. Inflammatory disease was correctly diagnosed in 27% of the cases.[16] Vacuolar hepatopathies had the highest agreement rate, correctly diagnosed in 83% of the cases.[16] However, 4 cats with lymphoma were incorrectly diagnosed as having hepatic lipidosis on FNA cytology.[17] The concern raised in this report was that FNA cytology may not detect infiltrative lesions, particularly if nodular, multifocal, or periportal.[17] While FNA cytology is a useful diagnostic procedure with advantages, a logical step-by-step diagnostic approach is preferred, especially in cats with nonvacuolar disease, equivocal diagnoses, or a cytologic diagnosis of hepatic lipidosis without improvement with treatment.[15,17]

Biopsy and Culture

Overview

Histopathology results from cats with hepatic disorders are classified as focal, multifocal, zonal, locally extensive, or diffuse panlobular.[18] Cholangitis, initially described as a diffuse process, is now either classified as diffuse or limited in distribution (focal, multifocal).[6,8,19] Severity of liver histopathology varies between liver lobes,[1] supporting the recommendation to obtain liver biopsies from multiple liver lobes.[1]

US-Guided Percutaneous Techniques and Complications

Automated spring-triggered biopsy needles are most commonly used for percutaneous sampling, but manual biopsy needles are used and recommended (see ch. 89).[20] Needle biopsies provide a rapid, cost-effective, minimally invasive method to obtain liver tissue; however, compared to wedge biopsies, this technique has been shown to result in a 1/3 reduction in the median surface area of the biopsy specimen (Figure 283-2), which can result in sampling errors, missed pathologic lesions, and severity being misjudged.[18] Fragmentation of needle biopsy specimens, common with needle biopsies, does not cause significant interference in reaching a diagnosis.[18] While 18G needle biopsies are generally too small, 16G needle devices provide good samples in cats.[15] Needle biopsy sampling was believed to have a low incidence of complications.[18] A more recent report included fatal complications that might have occurred secondary to intense vagotonia and shock when using an automatic biopsy instrument (Pro-Mag Ultra). This complication was not observed with use of a semiautomatic device (VET-core biopsy needle).[20] The most common adverse reaction, hemorrhage, has been shown to be independent of prior coagulation testing results, aside from being more likely to occur if a cat has thrombocytopenia (≤80 × 10^3/mcL platelets) or elevated activated PTT (aPTT). Other less frequent complications include sampling unintended tissues (e.g., large blood vessels, biliary structures, body wall, digestive tract, pancreas, diaphragm or lung), and pain.[18,20-22] Major complications are usually noted within 30 minutes to an hour, but can be recognized as long as 10 hours after the procedure.[15,22]

FIGURE 283-2 This photograph shows 3 hepatic biopsies obtained with a 16G ultrasound-guided percutaneous needle biopsy device.

Laparoscopic-Assisted Biopsy or Surgical Wedge Biopsy

The major advantage of laparoscopic-assisted biopsies or wedge biopsies obtained via a laparotomy is the larger sample size, allowing opportunity for more accurate diagnosis (see ch. 91).[18] Laparoscopic biopsy forceps typically provide samples about 5 mm in diameter (45 mg of liver tissue; Figure 283-3). Surgically obtained samples are, ideally, 2 cm deep.[15] Disadvantages of laparoscopy may include cost, facilities required, need for advanced operator training, longer procedural times (compared to percutaneous needle biopsy but usually shorter than laparotomy), and requirement of general anesthesia. Advantages of laparoscopy in cats include the ability to obtain a large biopsy sample size, improved accuracy in obtaining liver, an ability to visualize the liver and target abnormal areas for sampling, a limited degree of invasiveness, an opportunity to obtain non-hepatic biopsies (pancreas, kidney, spleen, lymph node, and intestine) or perform gallbladder aspiration (cholecystocentesis).[15] Magnification available with laparoscopy allows location of small (<0.5 cm) lesions, not easily observed otherwise.[15] Other advantages of laparoscopy include rapid recovery, shorter hospital stays, and low rates of postoperative morbidity, infection, or pain (Figure 283-4).[15] While laparoscopic-assisted cholecystectomy or cholecystostomy tube placement have been performed in cats, they are not common.[23] Most feline hepatopathies (NC/CH) are nonsurgical. Conventional surgical laparotomy with wedge biopsy is indicated if a cat has a primary hepatic or concurrent abdominal, surgical condition, or if laparoscopic-assisted biopsy is not an option.

FIGURE 283-3 This photograph demonstrates 6 hepatic biopsies obtained with a laparoscopic cup biopsy forceps.

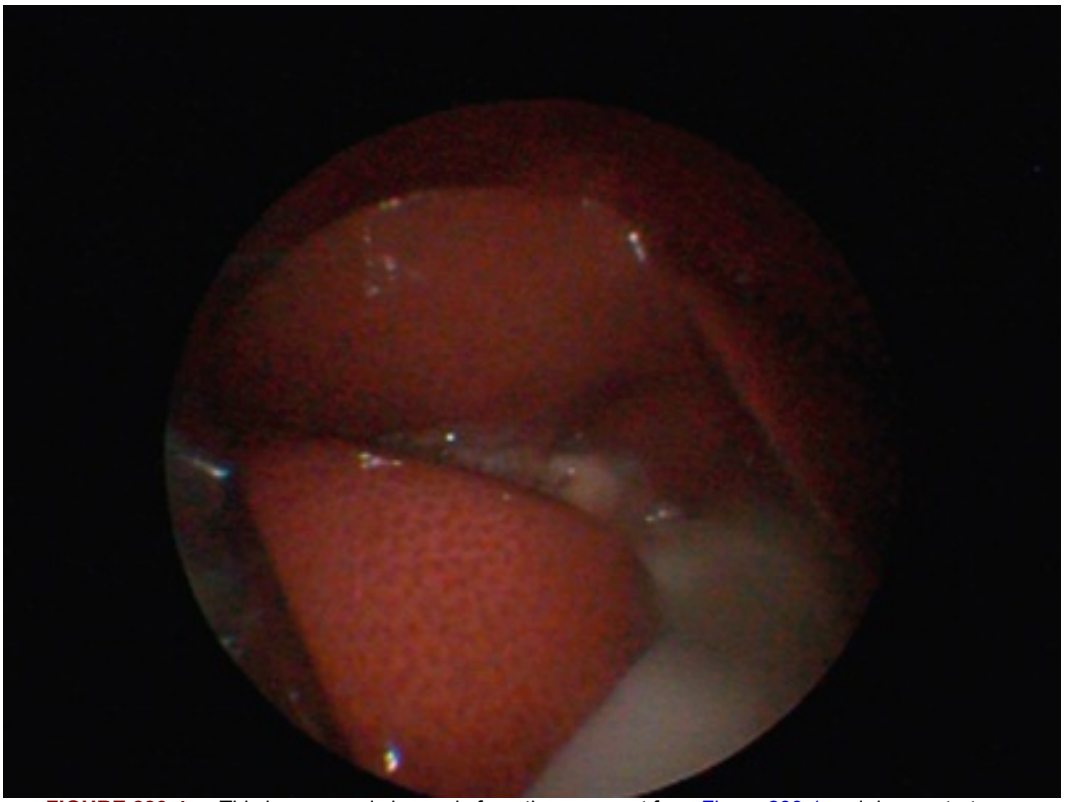

FIGURE 283-4 This laparoscopic image is from the same cat from Figure 283-1 and demonstrates a relatively normal hepatic appearance except for rounding of the liver margins.

Culture

Aerobic and anaerobic bacterial cultures can be quite valuable in evaluating cats with hepatobiliary disease. In one study, 36% of bile samples and 14% of liver tissue samples had positive bacterial growth, with 83% of cats having a single bacterial species.[24] Bile samples can be obtained by percutaneous US-guided cholecystocentesis, laparoscopic-assisted cholecystocentesis, or at surgery (see ch. 88 and 89).[25] Uncommon complications include gallbladder rupture and bile peritonitis.[5,25] Cats with NC may have evidence of neutrophilic inflammation in their bile. *E. coli*, alone or in combination with obligate or facultative anaerobes, is the most common organism in bile cultures, but other organisms include Enterobacteriaceae (*Salmonella enterica, Klebsiella, Enterobacter), Streptococcus, Enterococcus, Actinomyces, Acinetobacter, Pasteurella, Clostridium* and *Bacteroides* species.[5] Bacteria have been isolated via aerobic or anaerobic culture in a minority of cats with NC/CH.[4] Use of newer tests, such as fluorescent *in situ* hybridization (FISH), may be more sensitive for detecting bacterial infection.[7] Ascending infection with enteric bacteria is the most likely source of these infections; however, hematogenous seeding is possible.[5,7] The unique dual entry of the common bile and pancreatic ducts at the major duodenal papilla in the duodenum increases risk of enteric content and/or pancreatic secretion reflux.[5] The association of pancreatitis and cholangitis may be associated with this anatomic condition.[1]

Treatment and Prognosis

Antibiotics

Antibiotics are the primary therapy for NC/CH (Table 283-1).[26] Ideally, antibiotics are chosen based on results of bacterial culture and sensitivity testing. Often, however, antibiotics are started empirically until the culture results are available. Antibiotics should be active against aerobic and anaerobic enteric bacteria and excreted while active into bile. Commonly utilized antibiotics include ampicillin, amoxicillin and clavulanate potassium (Clavamox), ampicillin-sulbactam (Unasyn), ticarcillin disodium and clavulanate potassium (Timentin) and metronidazole. Less frequently used antibiotics include chloramphenicol, tetracycline, and erythromycin. Therapy for 2 months has been suggested, but the optimal duration is not known.[4]

TABLE 283-1

Medical Therapies for Feline Hepatopathies

TREATMENT	DOSE
Fluid Therapy (see ch. 129)	
Isotonic crystalloids: i.e., 0.9% NaCl	Shock 45-55 mL/kg/h IV; correct dehydration; Maintenance 40-45 mL/kg/day IV
Synthetic colloids: Hetastarch, dextran 70	2-5 mL/kg IV once; if needed, 10 mL/kg/day IV CRI
Fresh frozen plasma transfusion	10-40 mL/kg IV over 24 h
Antihypotensive Agents	
Dopamine HCl	5-15 mcg/kg/min IV CRI
Dobutamine HCl	0.2-2 mcg/kg/min IV CRI
Epinephrine	0.5-2 mcg/kg/min IV CRI
Norepinephrine	0.5-2 mcg/kg/min IV CRI
Vasopressin	0.01-0.04 U/min IV (in patients with vasodilatory shock unresponsive to fluid resuscitation and catecholamine)
Antibiotics	
Ampicillin	20-40 mg/kg IV q 6-8 h

Amoxicillin	10-20 mg/kg PO, IV, SC q 12 h
Amoxicillin + clavulanic acid (Clavamox)	10-20 mg/kg PO q 8 h
Ampicillin + sulbactam (Unasyn)	20-40 mg/kg IV q 8-12 h
Ticarcillin disodium and clavulanate potassium (Timentin)	40-60 mg/kg IV q 6-8 h
Metronidazole (Flagyl)	15 mg/kg PO, IV q 12 h
Chloramphenicol	10-20 mg/kg PO, IV, IM, SC q 12 h
Tetracycline	7 mg/kg IV, IM q 12 h
Erythromycin	10-20 mg/kg PO, IV q 8 h
Appetite Stimulants	
Mirtazapine (Remeron)	3.75 mg (1/4 of a 15-mg tablet) PO q 24-72 h
Cyproheptadine (Periactin)	2-4 mg/cat PO q 12-24 h
Diazepam (Valium)	1-4 mg/cat PO q 12-24 h
Nausea/Vomiting Therapy	
Ranitidine	0.5-2 mg/kg PO, IV q 12 h
Famotidine	0.5-1 mg/kg PO, IV, SC, IM q 12-24 h
Metoclopramide	0.2-0.4 mg/kg PO, SC, IM q 8 h* 1-2 mg/kg/day IV CRI
Chlorpromazine	0.5 mg/kg IV, IM, SC q 6-8 h
Dolasetron mesylate	0.6-1 mg/kg PO, IV, SC q 12 h
Ondansetron	0.1-1 mg/kg IV (slowly), SC, IM or PO q 6-12 h
Maropitant citrate	1 mg/kg SC, PO q 24 h
Pain Management	
Buprenorphine	0.005-0.01 mg/kg IV, IM q 4-8 h
Butorphanol	0.2-0.4 mg/kg IM q 2-4 h
Assorted Medications	
Cobalamin (Vitamin B_{12})	250 mcg/cat SC weekly
Prednisolone	2.2-4.4 mg/kg PO q 24 h 1-2 mg/kg PO q 12 h
Ursodeoxycholic acid (Actigall)	10-15 mg/kg PO q 24 h
Vitamin K_1	5 mg/cat IM q 24-48 h
Lactulose	0.5-1 mL/kg PO q 8 h
Neomycin	20 mg/kg PO q 8-12 h
Azathioprine	0.3 mg/kg PO q 48-72 h
Methotrexate	0.4 mg per cat total dose given on one day in three divided doses. Repeat every 7-10 days. Use in conjunction with ursodeoxycholic acid (15 mg/kg PO q 24 h) and folate (0.25 mg/kg PO q 24 h).
Cyclosporine	3-4 mg/kg PO q 12 h
Praziquantel	20 mg/kg SC or IM, q 24 h, 3-5 consecutive days

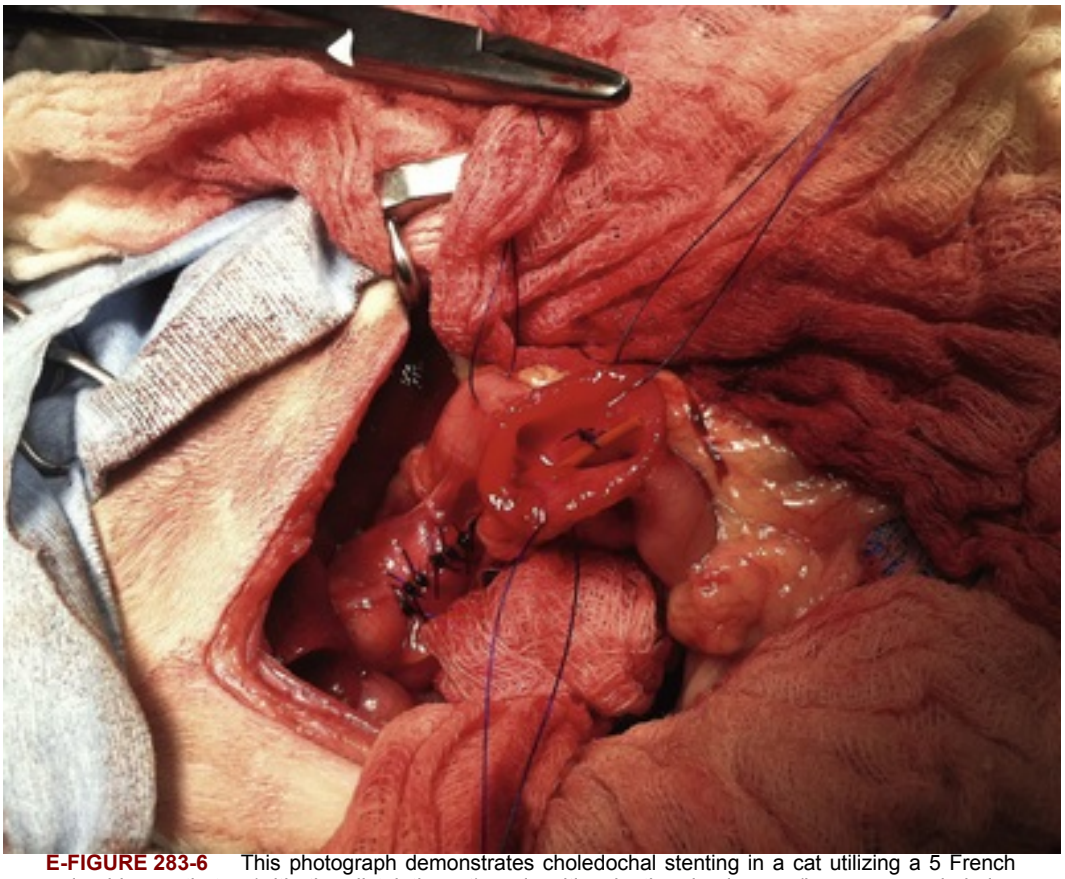
*Consider alternative therapy; less efficacious in cats.

CRI, Constant rate infusion; *IM*, intramuscular; *IV*, intravenous; *PO*, by mouth; *SC*, subcutaneous.

Nonspecific Therapies

Some cats with NC/CH are critically ill and require therapy for dehydration (see ch. 129), serum electrolyte abnormalities (see ch. 67-69), coagulopathies (see ch. 197), and/or hypotension (see ch. 159). Other cats may benefit from use of appetite stimulants (mirtazapine, cyproheptadine; see Table 283-1) if they have low-grade inappetence. Persistent inappetence can be managed with placement of an enteral feeding tube (esophagostomy or gastric tube; see ch. 82). Protein restriction is only required in cats with hepatic encephalopathy; otherwise, a highly digestible, moderate fat level diet is often chosen (see ch. 180).[27] Hepatic encephalopathy is less common in cats with acquired liver disease. If present, it can be managed with lactulose and/or antibiotics (see ch. 281 and 284). Other nonspecific treatments include controlling nausea and/or vomiting, lowering gastric acid production, and reducing pain (more commonly detected with pancreatitis). Surgery is likely necessary for cats with complete biliary obstruction and for some cats with choleoliths (Figure 283-5). While biliary-to-intestinal diversion (i.e., cholecystoduodenostomy or cholecystojejunostomy) have been performed for obstructive disease, post-surgical morbidity has been high.[28] Alternative techniques have been proposed that include choledochal stenting (E-Figure 283-6; see ch. 120 and 123).[29] It appears, however, that cats have greater morbidity with choledochal stenting than do dogs.[29] Therefore, ursodeoxycholic acid (Actigall) often is given for its anti-inflammatory, immunomodulatory, and antifibrotic properties. Ursodeoxycholic acid increases the liquid nature of biliary secretions, but benefits of its use should be weighed against risk for a biliary obstruction or choleliths. The prognosis in cats with acute cholangitis is good, with median survival times >1 year.[3,5] Poor outcomes are most likely related to concurrent conditions, such as pancreatitis, inflammatory bowel disease, and to a lesser degree, nephritis.[3,30,31]

FIGURE 283-5 This photograph demonstrates multiple choledocholiths causing a partial obstruction of the common duct removed from a 14-year-old male castrated Domestic shorthair cat with severe lymphoplastic and neutrophilic cholecystitis.



E-FIGURE 283-6 This photograph demonstrates choledochal stenting in a cat utilizing a 5 French red rubber catheter (with the distal tip cut) and exiting in the duodenum (lumen opened during placement).

Lymphocytic Cholangitis

Overview

The signalment, clinical signs and diagnostic evaluation for lymphocytic cholangitis (LC) is reviewed in the "Neutrophilic Cholangitis/Cholangiohepatitis" section with a few exceptions. In addition to nausea, vomiting, lethargy (listlessness) and inappetence, cats with LC often develop gradual weight loss and jaundice (E-Figure 283-7 and Figure 283-8).[32] In contrast to NC/CH, the most consistent biochemical abnormality in cats with LC is hypergammaglobulinemia; however, increases in hepatic enzyme activities and total bilirubin are detected in some cats.[32]

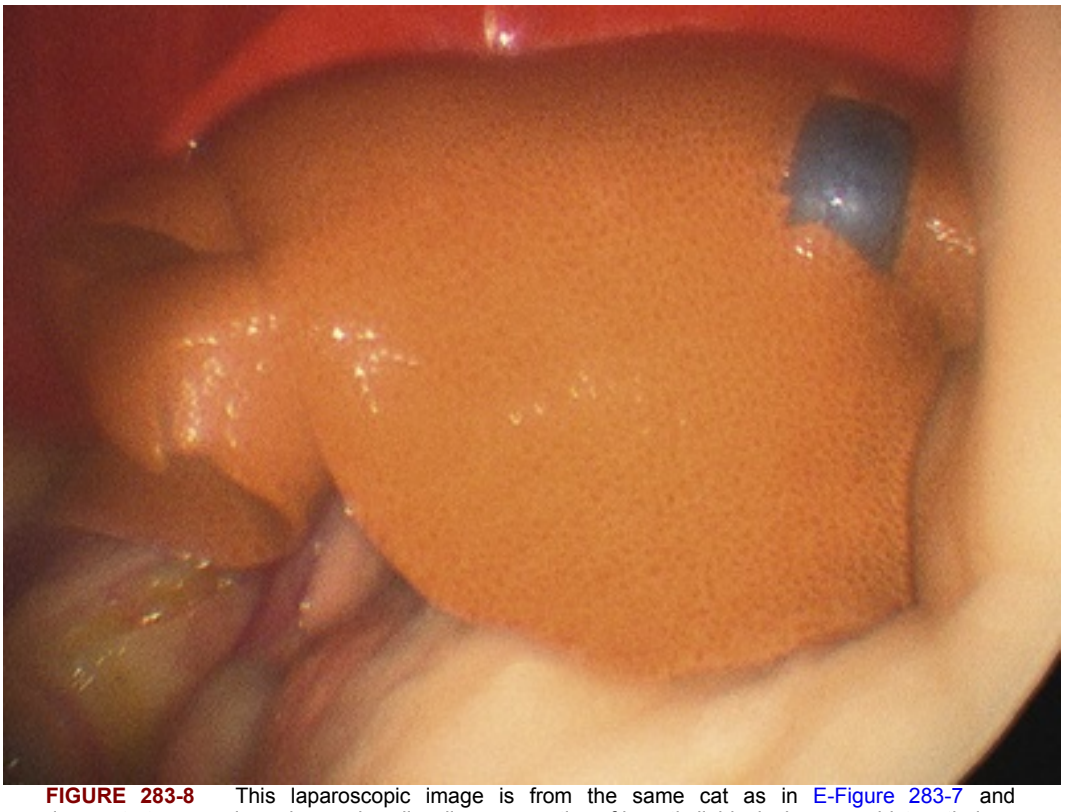


FIGURE 283-8 This laparoscopic image is from the same cat as in E-Figure 283-7 and demonstrates an enlarged, grossly yellow liver suggestive of hepatic lipidosis; however, histopathology revealed moderate chronic lymphocytic and neutrophilic cholangitis and moderate diffuse hepatic lipidosis.

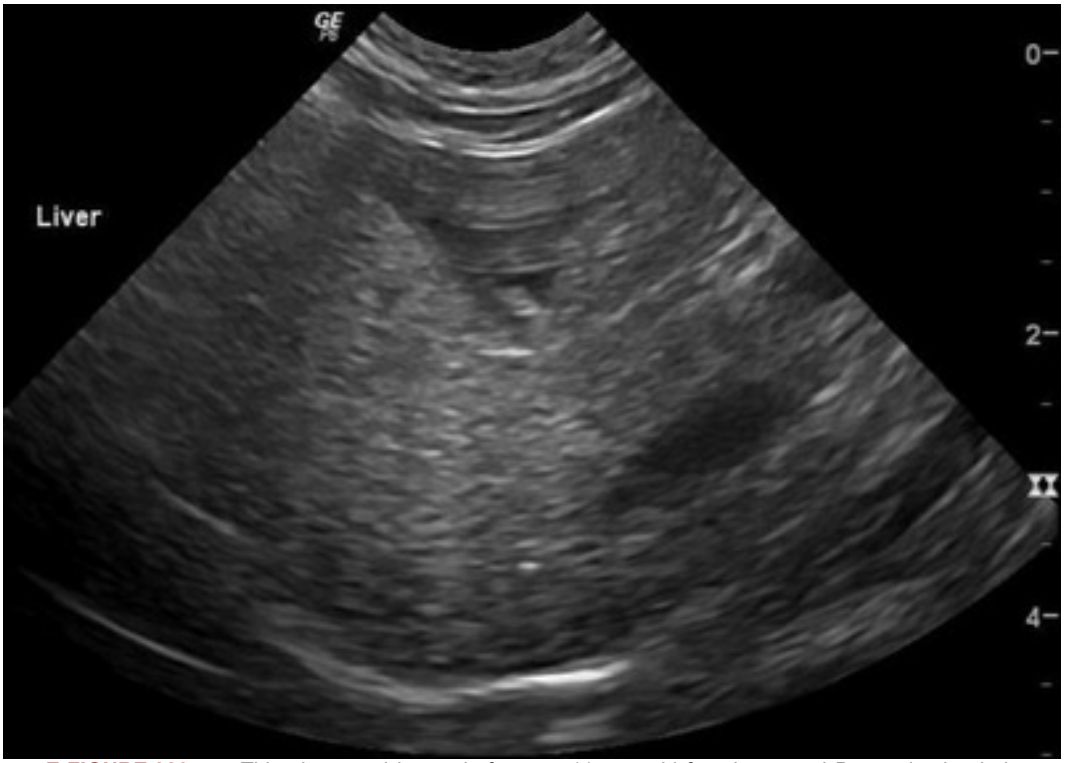

E-FIGURE 283-7 This ultrasound image is from an 11-year-old female spayed Domestic shorthair cat with moderate chronic lymphocytic and neutrophilic cholangitis and moderate diffuse hepatic lipidosis; however, the ultrasound image revealed hyperechoic hepatomegaly suggestive of hepatic

lipidosis.

Pathogenesis

The pathogenesis of LC was thought to be the consequence of chronic bacterial infection in cats with NC.[8] Recent studies using FISH found little evidence to support bacterial colonization as a component of the etiopathogenesis. Rather, immune-mediated mechanisms have been proposed.[7,33] However, a provocative polymerase chain reaction (PCR) study in cats demonstrated *Helicobacter* spp. DNA in 26% of cats with LC (controls 16%) and suggested an etiological role of *H. pylori* in feline LC.[34] In an experimental setting, LC has been induced by inoculating specific pathogen–free cats with *Bartonella henselae*– and/or *Bartonella clarridgeiae*–infected cat blood.[35]

Histologically, LC is characterized by dense aggregates of lymphocytes surrounding bile ducts but not invading the biliary epithelium. Lymphocytes may be detected in the bile lumen (in contrast to NC).[6] The major differential diagnosis is hepatic lymphoma. In addition to histopathologic features, immunophenotyping (B-cell and T-cell) and PCR for T-cell receptor (TCR) gene rearrangement have been shown to assist in discriminating LC from hepatic lymphoma. Bile duct targeting, ductopenia, peribiliary fibrosis, portal B-cell aggregates, portal lipogranulomas and polyclonal TCR are features of LC.[6,33]

Treatment and Prognosis

Specific and nonspecific therapies for LC and NC/CH are similar (see Table 283-1).[4] Many cats are treated with antibiotics while awaiting histopathology and culture results. When infectious causes have been ruled out and/or cats fail to respond to antibiotics, immune suppressive therapy is recommended, assuming that the liver injury is immune-mediated.[4] Prednisolone, the first choice in immunosuppressive therapy, results in longer survival times when compared with cats given ursodeoxycholic acid.[32] In addition to its immunosuppressive properties, prednisolone may limit hepatocellular injury and enhance the appetite. Based on treatment response (resolution of clinical signs) and serial biochemical values, prednisolone can be slowly tapered, but many cats require long-term therapy.[4] The optimal duration of treatment has not been determined. Persistent or progressive increase in ALT and/or ALP activities and serum total bilirubin concentration suggest that treatment has been inadequate.[4] In cats who fail therapy, it is important to ensure the cat does not have occult lymphoma. In cats with confirmed, prednisone-resistant LC/CH, alternative therapies include azathioprine, methotrexate, and cyclosporine.[4] The prognosis in cats with LC is good and likely better than for cats with NC/CH. In one study, median survival time was 795 days with survival rates for 1, 2, and 3 years being 74%, 56%, and 35%, respectively.[32] Purebreds with LC may be more likely to have shorter survival times than Domestic shorthairs.[32]

Infectious Hepatobiliary Diseases

Bacterial Infection

Compared to inflammatory hepatobiliary diseases, primary feline infectious hepatobiliary diseases are reported less frequently. Infection is seen in about 15% of cats with hepatobiliary disease.[1,36] Bacterial infections are more common in NC/CH. Even though cats are the natural reservoir for *Bartonella henselae*, peliosis hepatis secondary to *B. henselae* is not seen in cats.[37] The proposed pathogenesis is a secondary infection due to ascending intestinal bacteria. Both micro- and macrohepatic abscesses have been reported in cats. Other pathogenesis concepts include trauma, alterations in blood flow, liver lobe torsions, extrahepatic infection, sepsis, clinically immunocompromised states and neoplasia.[38] Ultrasound permits detection and diagnosis, via FNA cytology and culture, of hepatic abscesses (see ch. 88 and 89). Aerobic and anaerobic bacterial culture results in cats with hepatic abscesses are similar to those of cats with NC/CH with clinically rare isolates being *Klebsiella, Listeria, Salmonella, Brucella, Yersinia pseudotuberculosis, Actinomyces, Nocardia* and *Pasteurella.*[38] Polymicrobial growth is detected in >50% of cats with solitary abscesses.[38,39] Due to the frequency of polymicrobial growth, broad spectrum antimicrobial treatment that is directed at both aerobes and anaerobes, independent of anaerobic culture results, should be given for at least 6 weeks.[38] Focal abscesses may require surgical drainage or partial hepatectomy. US-guided percutaneous drainage of hepatic

abscesses has been reported in dogs[40] and has been used successfully in cats. In a single study of 14 cats with hepatic abscesses, the overall mortality rate was 79%. Survivors had partial hepatectomies followed by medical management.[39] *Mycobacterium* spp. rarely cause hepatic bacterial infections in cats (see ch. 212). Histopathology may reveal extensive granulomatous disease.[38]

Platynosomum Infections

Chronic cholangitis has been associated with liver fluke infestation from the Platynosomum group (*P. fastosum, P. concinnum* and *P. illiciens;* and may be synonymous to *P. planicipitus, Dicrocelium concinnum, D. lanceolatum* var. *symmetricum* and *Concinnum concinnum*) and *Amphimerus pseudofelineus.*[41,42] *Platynosomum fastosum,* which is prevalent in tropical and sub-tropical regions of North, South and Central America, the Caribbean, and parts of Africa and Asia, is a small hepatic trematode detected in cats' biliary ducts and gallbladder.[42] Lizards, terrestrial snails, and isopods are implicated as intermediate/paratenic hosts.[42] Platynosomiasis or "lizard poisoning" is the name given to this fluke-induced condition. Affected cats likely acquire the parasite by eating infected lizards. Clinical signs can range from none to severe. Signs are secondary to biliary tract obstruction and hepatic failure.[42] Other clinical signs and the diagnostic evaluation for *P. fastosum* are reviewed in the "Neutrophilic Cholangitis/Cholangiohepatitis" section. CBC may reveal eosinophilia in heavily infected cats. Embryonated eggs (golden brown [unstained] oval, 34-50 × 23-35 micron, thick-shelled) are shed in the stool of infected cats; an exception is cats with complete bile duct obstruction.[42] Adult flukes (lanceolate, covered by a thin cuticle, 2.9 to 8 mm long × 0.9 to 2.5 mm wide, sub-terminal oral sucker and a ventral sucker) can be detected in the bile or liver, gallbladder and/or bile ducts. The most effective treatment is praziquantel.[42] In cats with bile duct obstruction, aggressive supportive care and biliary-to-intestinal diversion (i.e., cholecystoduodenostomy or cholecystojejunostomy) or choledochal stenting is indicated (see ch. 123).

Viral Infections

Feline Leukemia Virus (FeLV)

Cats persistently infected with the FeLV often develop leukemia/lymphoma complex or fibrosarcoma. They also develop a wide spectrum of non-neoplastic diseases.[43] In one post-mortem study, 77% of FeLV cats had non-neoplastic FeLV-associated disease and 23% had cancer.[43] In this study, 25% of the icteric cats were FeLV-positive and 8% of FeLV-infected cats were icteric. Histopathology in FeLV-infected cats revealed liver degeneration, described as cell dissociation, fatty liver and focal necrosis. Fatty liver disease and focal liver necrosis were significantly more common in the FeLV-infected cats. The pathogenesis of the liver injury associated with FeLV infection is unknown but may in part be secondary to anemia.[43] See ch. 223.

Feline Calicivirus (FCV)

Virulent mutants of FCV rarely cause hepatic infection in cats, with high morbidity and mortality.[44] FCV is highly infectious and typically causes acute oral and upper respiratory tract disease, but a mutant virus has been identified. Many cats infected with the mutant FCV have died with clinical signs characterized by jaundice, edema, upper respiratory tract disease, ulcerative dermatitis, fevers, lameness, voice loss and inappetence.[44] Hepatic histopathology has revealed disseminated hepatocellular necrosis with mild inflammatory infiltration on light microscopy. FCV antigen in parenchymal and Kupffer cells may be identified by immunohistochemistry. Calicivirus-like particles within hepatocytes can be seen with electron microscopy.[44] Treatment involves aggressive supportive care and strict quarantine to avoid infecting healthy cats, even if vaccinated.[44] See ch. 229.

Feline Infectious Peritonitis (FIP)

FIP, a mutant coronavirus infection, causes clinical disease with high mortality once clinical signs appear. Rarely, infected cats survive for weeks, months or years.[45] FIP is most prevalent among cats <3 years of age (especially those 4-16 months old).[45] Hyperbilirubinemia and hyperbilirubinuria are common in cats with FIP, due to increased red blood cell destruction, slow breakdown and delayed recycling of bilirubin and biliverdin. They usually do not have increased liver enzyme activities. Primary hepatic FIP is not common.[45] The diagnostic evaluation of FIP is reviewed in ch. 224. Ultrasound-guided percutaneous liver biopsy and

FNA liver cytology in 16 of 25 cats were consistent with FIP based on intra-parenchymal pyogranulomatous lesions and/or fibrinous perihepatitis. Feline coronavirus antigen was detected in 6 cats. Of 22 cats, cytologic findings were consistent with FIP in 14 (64%) based on highly cellular pyogranulomatous inflammation. Their livers frequently had histologic FIP lesions, even in the absence of macroscopic changes.[46]

Feline Immunodeficiency Virus (FIV)

FIV, a lentivirus, has been identified in cats throughout the world (see ch. 222). FIV is associated with cytopenias and cancers.[47,48] In the absence of concurrent conditions, FIV rarely causes hepatic disease. In an experimental population of 20 specific pathogen–free cats infected with FIV, only 1 developed primary hepatic disease.[48] This cat had cholangitis, biliary duct hyperplasia, peribiliary fibrosis, and microabscessation. A second cat developed hepatic-renal lymphoma. It was also reported that some FIV cats had generalized hepatic degeneration.[48] Experimental cats infected with FIV and later challenged with *Toxoplasma gondii* developed acute generalized toxoplasmosis, including multifocal to coalescing hepatic necrosis.[48] *T. gondii* tachyzoites were occasionally detected.[48] In a post-mortem study of cats with histologically verified toxoplasmosis, 70% of 90 liver samples examined revealed *Toxoplasma gondii* organisms.[49]

Fungal Infection

The fungal organisms *Histoplasma capsulatum* (see ch. 233), *Coccidioides immitis* (see ch. 232), *Blastomyces dermatitidis* (see ch. 233), *Aspergillosis* sp. (see ch. 235), *Cryptococcus* sp. (see ch. 231), and *Sporothrix schenckii* (see ch. 236) can, rarely, cause primary or disseminated infectious hepatobiliary disease.[38] *Histoplasma capsulatum* is the second most common systemic fungal disease in cats and likely the most common hepatic fungal infection. The liver is involved in cats with disseminated disease along with the spleen, gastrointestinal tract, bone and bone marrow, integument, and eyes.[50] Definitive diagnosis is obtained by demonstration of organisms via cytopathology or culture. The treatment of choice is itraconazole 5-10 mg/kg PO q 12 h for a minimum of 4 to 6 months.[50] In certain regions, epidemics of *Sporothrix schenckii* infections have been noted in cats, dogs and humans. In one small study, all studied cats (n = 10) with sporotrichosis had *S. schenckii* detected by histopathology or culture from the liver. All of these cats were treated with itraconazole; however, 60% had progression of their disease.[40]

CHAPTER 284

Hepatic Vascular Anomalies

Chick Weisse, Allyson C. Berent

Portosystemic shunts (PSSs) are vascular anomalies that connect the portal vein to the systemic circulation, bypassing the hepatic sinusoids and liver parenchyma.[1-6] They are considered the most common hepatobiliary congenital abnormality. Normally, venous blood draining the spleen, pancreas, stomach, and intestine enters the portal vein, perfuses the liver through the sinusoidal network, and drains through the hepatic veins into the caudal vena cava (CVC).[3] Portal blood carries many substances to the liver, including trophic hormones (intestinal and pancreatic), nutrients, bacterial products, and intestinal-derived toxins.[1,2,6] The fetal liver has limited function to process these products, and a large shunting vessel, the ductus venosus, bypasses the hepatic circulation as a protective mechanism.[3,6] This fetal vessel, located on the left side of the liver, normally closes by 3-10 days of age.[3,4,7] Closure is initiated by blood pressure changes after umbilical venous flow ceases; thromboxane or various adrenergic compounds can stimulate contraction of the musculature of the ductus venosus and might aid in the vessel's closure.[3,5,6-8] If the ductus venosus remains patent, or other congenital communications exist, a PSS results. When blood bypasses the liver, trophic factors (particularly insulin and glucagon) are not available to encourage hepatic growth, resulting in poor hepatic development, deficient protein production, reticuloendothelial dysfunction, altered fat and protein metabolism, hepatic atrophy, and eventually liver failure.

Clinical signs are associated with the volume and origin of blood bypassing the liver, resulting in impaired hepatic function, hepatic encephalopathy (HE), chronic gastrointestinal (GI) signs, lower urinary tract signs, coagulopathies, and delayed growth.[2,3,5,6,9] These problems are the result of the body accumulating both exogenous and endogenous toxins that are normally metabolized or eliminated by the liver (E-Table 284-1), as well as the failure of normal hepatic function (e.g., gluconeogenesis, urea cycle, uric acid cycle, glycogenolysis).[2,6,9-12]

E-TABLE 284-1

Toxins Implicated in Hepatic Encephalopathy[10-12,31-33]

TOXINS	MECHANISMS SUGGESTED IN THE LITERATURE
Ammonia	Increased brain tryptophan and glutamine; decreased ATP availability; increased excitability; increased glycolysis; brain edema; decreased microsomal Na-K-ATPase in brain
Decreased alpha-ketoglutaramate	Diversion from Krebs cycle for ammonia detoxification; decreased ATP availability
Glutamine	Alters blood-brain barrier amino acid transport
Aromatic amino acids	Decreased DOPA neurotransmitter synthesis; altered neuroreceptors; increased production of false neurotransmitters
Short-chain fatty acids	Decreased microsomal Na+, K+-ATPase in brain; uncouples oxidative phosphorylation, impairs oxygen utilization, displaces tryptophan from albumin, increasing free tryptophan
False neurotransmitters Tyrosine → octopamine Phenylalanine → phenylethylamine	Impair norepinephrine action Impairs norepinephrine action Synergistic with ammonia and SCFA Decreases ammonia detoxification in brain urea cycle; GIT-derived (fetor hepaticus—breath odor in HE); decreased microsomal Na^+, K^+-ATPase

Methionine → mercaptans	
Tryptophan	Directly neurotoxic; increases serotonin: neuroinhibition
Phenol (from phenylalanine and tyrosine)	Synergistic with other toxins; decreases cellular enzymes; neurotoxic and hepatotoxic
Bile acids	Membranocytolytic effects alter cell/membrane permeability; blood-brain barrier more permeable to other HE toxins; impaired cellular metabolism due to cytotoxicity
Gamma-aminobutyric acid (GABA)	Neural inhibition: hyperpolarize neuronal membrane; increase blood-brain barrier permeability to GABA
Endogenous benzodiazepines	Neural inhibition: hyperpolarize neuronal membrane

ATP, Adenosine triphosphate; *DOPA*, dihydroxyphenylalanine; *GIT*, gastrointestinal tract; *HE*, hepatic encephalopathy; *SCFA*, short-chain fatty acids.

Embryology

The veins in the abdomen are derived embryologically from the umbilical, vitelline, and caudal cardinal veins (Figure 284-1). The paired vitelline veins originate at the yolk sac and form the left hepatic vein, the hepatic sinusoids, the hepatic portion of the CVC, the prehepatic portal vein, and its tributaries.[7] The vitelline and umbilical systems combine to form the ductus venosus and the left branch of the portal vein. The nonportal abdominal, renal, and gonadal veins are derived from the cardinal venous system. The caudal cardinal veins form the CVC caudal to the liver, and the azygos vein.[3,7] In normal animals, the prehepatic and intrahepatic segments of the CVC join at the communication between the cardinal and the vitelline systems. Numerous nonfunctional portocaval and portoazygos communications are present in the fetus but are not patent in the adult unless portal hypertension occurs, forming multiple acquired extrahepatic shunts. When developmental errors create abnormal communications between these two systems, congenital extrahepatic portosystemic shunts (EHPSSs) result.[7] Abnormal vessel patency, or other abnormal development in the vitelline venous system, results in congenital intrahepatic PSS (IHPSS). The majority of IHPSSs are not necessarily subsequent to a patent ductus venosus, and the cause of other left, right, and central divisional IHPSSs or EHPSSs is currently unknown.

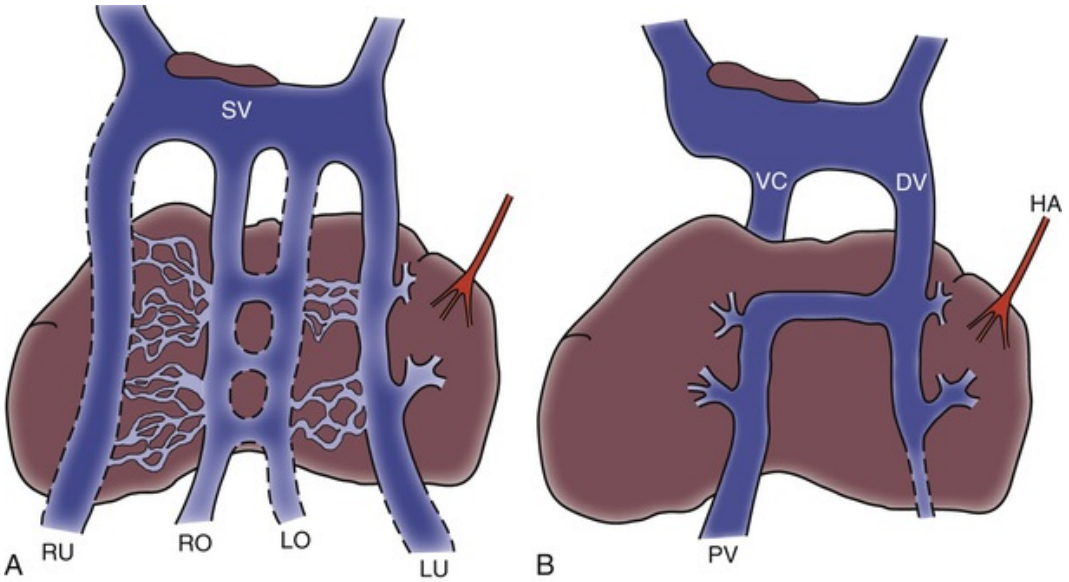

FIGURE 284-1 **A,** Vascular anatomy of the fetal liver. **B,** Developmental changes in the vasculature of the fetal liver. The omphalomesenteric (vitelline) veins form the prehepatic portal vein. Portions of the left umbilical vein and vitelline veins form the ductus venosus (DV). *HA,* Hepatic artery; *LO,* left omphalomesenteric (vitelline) vein; *LU,* left umbilical vein; *PV,* portal vein; *RO,* right omphalomesenteric (vitelline) vein; *RU,* right umbilical vein; *SV,* sinus venosus; *VC,* vena

cava. (Courtesy Dr. Pamela Whiting.)

Anatomy/Classification

The portal vein is formed by the confluence of the cranial and caudal mesenteric veins, providing up to 80% of the blood and 50% of the oxygen content to the liver, with the remainder being supplied by the hepatic arterial blood.[3,5,6,13] Blood from the GI tract, spleen, and pancreas is drained by their respective veins, which join the portal vein. In the dog, the portal vein enters the liver, branching into left and right vessels that supply the various liver lobes. The main right branch supplies the right lateral and caudate process of the caudate lobe, and the main left branch supplies all other lobes, giving off a central branch that supplies the right medial lobe.[3,13] In the cat, the portal vein separates directly into left, central, and right branches.[3,5,13] The portal vein branches into smaller venules where the blood enters the parenchyma via the portal triads. That blood travels through the hepatic sinusoids, is cleansed by the reticuloendothelial system, then drains into central veins that form larger hepatic venules and ultimately hepatic veins that empty into the CVC. When the path is interrupted by an anomalous vessel, blood is diverted away from the liver and along the path of least resistance, reaching the systemic circulation without having traversed the hepatic circulation.

The most recent classification of hepatic vascular anomalies suggests three categories (Box 284-1): (1) congenital IHPSSs and EHPSSs; (2) disorders associated with abnormal hepatic blood flow or portal hypertension, currently termed *primary hypoplasia of the portal vein* (PVH); and (3) disturbances in outflow. The second category, PVH, remains confusing and includes processes that might or might not result in portal hypertension. These are *PVH with portal hypertension* (noncirrhotic portal hypertension [NCPH]/hepatoportal fibrosis[14]/idiopathic hepatic fibrosis[15]/veno-occlusive disease[16]/idiopathic chronic liver disease/nonfibrosing liver disease[17]) and *PVH without portal hypertension* (formerly termed *microvascular dysplasia* [MVD]).[18,19]

Box 284-1

Types of Hepatic Vascular Disease

Congenital (CPSSs)

- Macrovascular portosystemic shunts
  - Intrahepatic (IHPSSs)
  - Extrahepatic (EHPSSs)
- Primary portal vein hypoplasia (PVH)
  - PVH with portal hypertension (e.g., noncirrhotic portal hypertension [NCPH])
  - PVH without portal hypertension (formerly microvascular dysplasia [MVD])
- Disturbances in outflow

Acquired (APSSs)

- Multiple, extrahepatic shunts
  - Secondary to hepatic fibrosis (cirrhosis)
  - Secondary to hepatic arteriovenous malformations (HAVMs)

PSSs can either be congenital or acquired. Congenital shunting is reported in 0.18% of all dogs and 0.05% of mixed-breed dogs.[20] Congenital PSS most commonly occurs as a single vessel that provides direct vascular communication between the portal venous supply and the systemic venous circulation (CVC or azygos veins). This commonly occurs as a single intrahepatic or extrahepatic communication (80%). Rarely, some animals have two or more congenital communications.[21] There are several types of congenital PSS found in both dogs and cats, including intrahepatic portocaval shunts, extrahepatic portocaval shunts, extrahepatic portoazygos shunts, portal vein atresia with resultant multiple portocaval anastomoses, hepatic arteriovenous malformations (HAVMs) causing portal hypertension-induced patency of portosystemic anastomoses, and microintrahepatic PSS (PVH without portal hypertension, formerly MVD).[2,5,22-26] Approximately 25-33% of congenital PSSs are intrahepatic (IHPSSs) in both dogs and cats. Single EHPSSs, with a major solitary portocaval shunt being the most common, constitute 66-75% of congenital single PSSs in both species.[1-4,26]

Most IHPSSs occur in larger-breed dogs, whereas most EHPSSs occur in smaller breeds.[26] Some EHPSSs, like splenocaval shunts, may be associated with less severe clinical signs because splenic blood is not of GI origin and less portal blood is shunted away from the liver. Dogs with IHPSSs generally have the largest volume of diverted portal blood, causing clinical signs earlier, or signs that are more severe.[1,2,27,28]

Acquired shunts (20%) most commonly occur secondary to chronic portal hypertension in which increased portal pressures lead to the opening of fetal, vestigial blood vessels. These have also been seen as congenital abnormalities. These vessels provide an outlet for hypertensive portal blood. Acquired shunts usually are multiple, tortuous, extrahepatic, and located near the kidneys.[22-24] The most common causes of acquired extrahepatic shunts are hepatic fibrosis (cirrhosis), PVH with portal hypertension (congenital NCPH),[23] or HAVMs.[24]

PVH with portal hypertension, or NCPH, has been described in various dog breeds.[23,29] This condition is diagnosed when there is intraabdominal portal hypertension with a patent portal vein and a noncirrhotic liver. The underlying cause is unknown; speculations include severe, diffuse intrahepatic vascular malformations without cirrhosis, resulting in portal hypertension and multiple EHPSSs.

PVH without portal hypertension, formerly MVD, is a microscopic malformation of the hepatic vasculature.[25,28] It is characterized by small intrahepatic portal vessels, portal endothelial hyperplasia, portal vein dilation, random juvenile intralobular blood vessels, and central venous hypertrophy and fibrosis. These lesions can allow for abnormal communications between the portal and systemic circulation at a microvascular level. This can occur as an isolated disease, or in combination with macroscopic PSS. Fifty-eight percent of dogs and 87% of cats with PVH have concurrent congenital macroscopic PSS.[18] Clinical signs in dogs with PVH can be similar to those of PSS; however, when PVH exists without a macroscopic shunt, signs are often less severe, occur later in life, and result in a better long-term prognosis with medical management alone.

HAVM is a rare condition of multiple high-pressure arterial and low-pressure venous communications. This condition, previously termed *hepatic arteriovenous fistula,* is more appropriately named a malformation because most are composed of numerous communications (malformation) rather than a single communication (fistula). They are usually congenital and have been described in both dogs and cats.[24,30] Usually, a branch of the hepatic artery communicates directly with the portal vein via multiple (dozens to hundreds of) aberrant shunting vessels. The high pressure causes hepatofugal blood flow and arterialization of the portal vein; the resulting portal hypertension, which opens multiple extrahepatic shunts to decompress this system, often is associated with ascites. The long-term prognosis for HAVM has been inferior to the more common PSS or PVH.[2,3,24]

Hepatic Encephalopathy

Most of the clinical signs associated with PSSs are due to hepatic encephalopathy, a neuropsychiatric syndrome involving a number of neurologic abnormalities that occurs when more than 70% of liver function is lost.[10-12,31-37] HE is discussed further in ch. 280-283 and 285.

Diagnostic Evaluation

Signalment

Congenital EHPSSs are seen most commonly in small/toy-breed dogs: in a large case series, the Yorkshire Terrier, Havanese, Maltese, Dandie Dinmont Terrier, Pug, and Miniature Schnauzer breeds all had an odds ratio for being affected that was >19.[5,20,26] PSS is suspected to be hereditary in Yorkshire Terriers, where an odds ratio for PSS is 35.9 times greater than that for all other breeds combined.[20,38] In the Maltese, a recessive, partially-penetrant mode of inheritance is suspected for both macroscopic PSS and PVH.[39] In cats, EHPSSs are more commonly identified,[3,38] though IHPSSs are reported.[40-41] Domestic shorthair, Persian, Siamese, Himalayan, and Burmese breeds are overrepresented.[4,41-44] Intrahepatic shunts are overrepresented in larger breed dogs, including the Irish Wolfhound, Retrievers (Labrador, Golden), Australian Cattle Dogs, and Australian Shepherds.[3,4,45-47] Left divisional IHPSSs have been considered heritable in the Irish Wolfhound,[48,49] and right divisional IHPSSs have been overrepresented in the Australian Cattle Dog and male dogs in Australia.[47,50] The Cairn Terrier has been documented to have hereditary PVH that is suspected to be an autosomal inherited trait, and the Yorkshire Terrier was also overrepresented with MVD/PVH in one

report.[25,28] In a recent report[51] of dogs with congenital (CPSS) or acquired portosystemic shunts (APSS), dogs with APSS were older, heavier, in poorer body condition, and were more likely to have ascites, but less likely to have central nervous system (CNS) signs than those with CPSS.

History

Most dogs and cats with PSSs have signs of chronic or acute illness before 1-2 years of age, though some have been older than 10 years of age.[26,52] PSS is far more common in dogs than cats. Multiple acquired EHPSSs in dogs are diagnosed at a median age of 3 years (range: 7 months–7 years),[22] and the median age of dogs diagnosed with PVH is 3.25 years (range: up to 10 years).[2,25] There is no clear gender predisposition in dogs, but males could be overrepresented in cats.[1,26] The history typically suggests the pet has "failed to thrive" since birth, is small in stature (or the runt of the litter), has weight loss (11% of cases) or failure to gain weight, has anesthetic intolerance, is dull or lethargic at times, and displays "bizarre behavior" (41% to 90% stargazing, head pressing, staring into walls or corners, random barking, intermittent blindness, pacing or aggression).[1,2,5,26,53] Some pets have a history of dysuria.[2,54] Polyuria and polydipsia (PU/PD) is common in dogs, possibly due to a poor medullary concentration gradient from a low blood urea nitrogen (BUN), to increased renal blood flow, to increased adrenocorticotropic hormone (ACTH) secretion and associated hypercortisolism, and to psychogenic polydipsia from HE.[3,5,6,55] Ascites occurs in 75% of dogs with HAVMs[24] and can be seen with venous-venous PSSs if hypoalbuminemia is severe. This complication is seen with concurrent protein-losing enteropathy, often associated with GI ulceration/bleeding or inflammatory bowel disease ± lymphangiectasia.

Clinical Signs/Physical Examination

The three most commonly affected body systems are the CNS, GI, and urinary systems.[2,3,5,26] Signs of HE can be obvious or quite subtle and typically are associated with aberrant behavior (see also ch. 9). More obvious CNS signs include ataxia, unresponsiveness, pacing, circling, blindness, seizures, random barking, and coma.[3,7,22,53] Onset of signs correlating with meal ingestion has been reported in only 30%-50% of pets.[5] GI signs (vomiting, diarrhea, anorexia, pica, and/or GI bleeding/melena/hematemesis) occur in ≈30% of dogs but are less frequent in cats.[5,22,26,41] Ptyalism, thought to be a manifestation of HE or GI upset, is very common in cats (75%).[5,6,41,53,56] GI hemorrhage occurs more often in large-breed dogs with IHPSS prior to repair (≈30%) than in dogs with EHPSS.[57] Some animals (20-50%) have signs of lower urinary tract disease: hematuria, stranguria, pollakiuria, or urethral obstruction.[2] Due to decreased urea production, increased ammonia excretion, and decreased uric acid metabolism, formation of ammonium urate calculi is common (30-35.8% of pets with PSSs reported, including in cats[58]) and can be associated with bacterial urinary tract infections.[26,54,58] Cats with PSS and urate urolithiasis tend to be younger (2 versus 7 years) than those with urate urolithiasis without known PSS.[58]

Shunt morphology can be associated with clinical signs. In one case series, preoperative clinical signs occurred in 88% of dogs with portocaval CPSSs, compared to 58% of dogs with portoazygos CPSSs.[59] Clinical signs also were more common if the shunt inserted caudal to the liver (91%) than if it inserted between the liver and diaphragm (67%).[59] CNS signs were most frequent with splenocaval CPSSs, and urinary signs were more common with right gastric vein than gastrosplenic vein origin.[59] With EHPSS, older dogs have been found to have splenophrenic and splenoazygos shunts more commonly than right gastrocaval or splenocaval shunts.[60]

Concurrent congenital defects are common in animals with PSSs. These include cryptorchidism (30% of male cats in one study[61] and 50% of male dogs in another[62]), heart murmurs that could be incidental flow murmurs in young pets or could indicate congenital cardiac defects,[3,5,53,61] and copper-colored irises that are inappropriate for the breed, particularly in cats.[63]

Animals with PVH without macrovascular shunts have a similar signalment and clinical signs to those described earlier. These dogs and cats typically are older and the signs frequently are mild or nonexistent.[5,25] PVH with portal hypertension is diagnosed when there is intraabdominal portal hypertension with a patent but small portal vein and a noncirrhotic liver. Purebred dogs are overrepresented, particularly Doberman Pinschers (27% of cases). Most dogs are <4 years of age and weigh >10 kg.[23] Signs are similar to PSSs or to

hepatic cirrhosis with concurrent portal hypertension, resulting in ascites (60% of cases), PU/PD, GI upset, HE, and weight loss, in association with multiple EHPSSs (Figure 284-2).

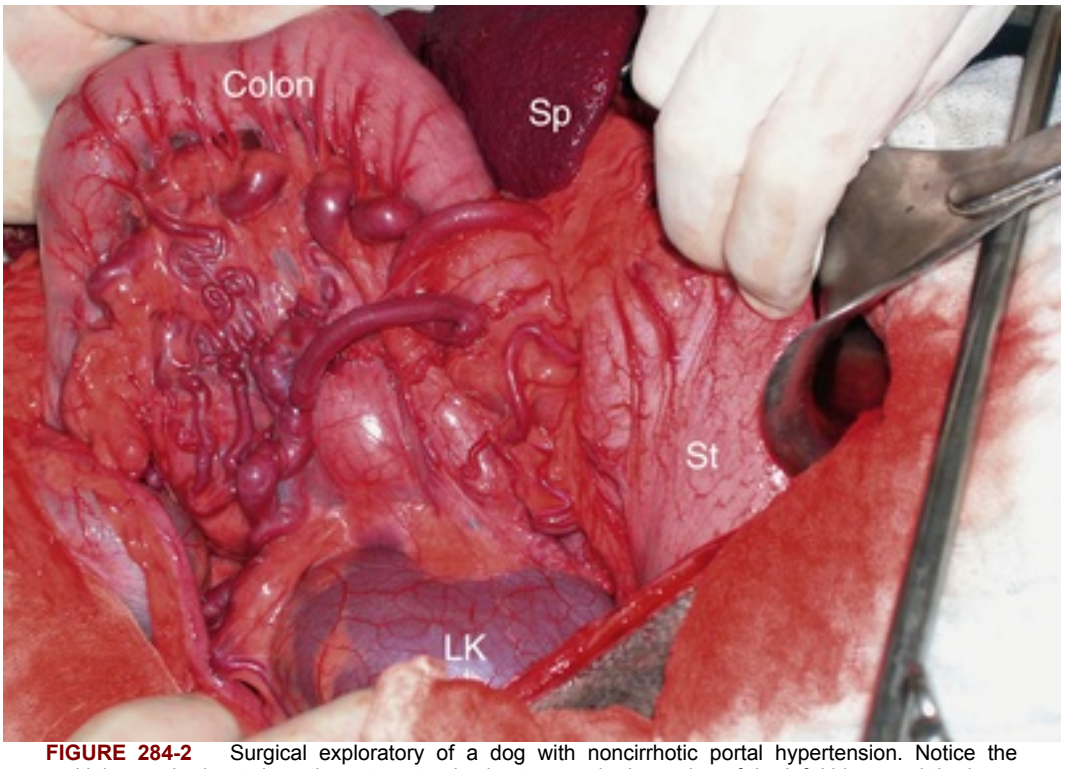

FIGURE 284-2 Surgical exploratory of a dog with noncirrhotic portal hypertension. Notice the multiple acquired extrahepatic portosystemic shunts seen in the region of the left kidney and the large dilated/tortuous veins throughout the abdomen secondary to portal hypertension. *LK,* Left kidney; *Sp,* spleen; *St,* stomach.

Clinical signs associated with HAVMs can be acute or chronic. Most affected pets are diagnosed in the first year of life and signs are associated with multiple EHPSSs from the portal hypertension, or with ascites. All sizes of dogs and a small number of cats have been reported.[5,24] GI signs are common, and many dogs have stunted growth and lethargy.[24] Ascites has been documented in ≈75% of dogs, less than previously suspected, presumably due to decompression of the portal system by the acquired shunts in the remaining 25% (Figure 284-3). Heart murmurs were documented in 20% of dogs with HAVMs in one study.[24] Signs of HE are reported less frequently with HAVMs. In some animals, the sound of turbulent blood flow (bruit) can be ausculted over the liver.

FIGURE 284-3 Young dog with ascites secondary to a hepatic arteriovenous malformation. Note the dorsal muscle wasting associated with malnutrition.

Clinicopathologic Findings

Hematologic changes often include a mild to moderate, microcytic, normochromic, nonregenerative anemia. Erythrocyte target cells in dogs, and poikilocytes in cats, are common on morphologic evaluation.[64] The cause of the microcytic anemia is not fully understood, although studies suggest a defective iron-transport mechanism, decreased serum iron concentrations, decreased total iron-binding capacity, and increased hepatic iron stores in Kupffer cells. This could suggest iron sequestration.[65,66] Microcytosis has been reported with or without anemia in 60-72% of dogs, but only in ≈30% of cats.[3,65,66] Microcytosis usually resolves after shunt correction and is not seen routinely in dogs with PVH/MVD.[5,25] Leukocytosis, due to inadequate hepatic endotoxin and bacteria clearance from the portal circulation, has been associated with a poor prognosis.[1,2,26,45,67] Monocytosis and elevated C-reactive protein concentrations are more commonly associated with HE.[36]

Serum biochemical abnormalities are extremely common in animals with PSSs. Most are due to decreased hepatic synthesis: low albumin (50%), low BUN (70%), hypocholesterolemia, and hypoglycemia. In cats, hypoalbuminemia is uncommon but low BUN and creatinine are common.[42,56] High serum liver enzyme activities are also common. These are usually mild to moderate increases (twofold to threefold) in alkaline phosphatase (ALP) and alanine aminotransferase (ALT).[64] These abnormalities are typical of any hepatic vascular anomaly. Interestingly, the serum ALP concentration typically is higher than the ALT concentration in dogs with PSSs, likely due to the contribution of bone isoenzyme in growing animals, or hepatic organelle injury and increased release or decreased elimination of canalicular ALP.[5,64] In one study, dogs with APSS were more likely to have a lower hematocrit, higher mean corpuscular volume, and higher ALT than dogs with CPSS.[51] In 81% of dogs with CPSS, renal volume and glomerular filtration rate are abnormally high prior to shunt attenuation, and decrease significantly after ligation.[55] This could explain, in part, the low BUN and creatinine concentrations seen biochemically.[55] High hyaluronic acid levels in dogs with CPSS, suspected to be caused by reduced hepatic clearance, improve with shunt attenuation.[68] This suggests that hyaluronic acid levels could be a good test of liver function, including for evaluating the success of shunt attenuation in dogs with CPSS.

Urinalysis abnormalities with CPSS include a low urine specific gravity (>50% are hyposthenuric or isosthenuric) and ammonium biurate crystalluria.[3,5,8,53] The low specific gravity likely results from polydipsia, as well as the poor medullary concentration gradient that occurs with low BUN subsequent to a deficient urea cycle. Hyperammonuria, also resulting from the deficient hepatic urea cycle, combined with hyperuricacidemia due to a deficiency in hepatic purine and pyrimidine metabolism (uric acid cycle), result in excessive renal ammonia and urate excretion. These compounds can precipitate into crystals or stones in the kidney or bladder (stones seen in 30-36% of cases).[8,12,26,54] Ammonium biurate crystalluria is common and can be seen in 26-57% of affected dogs and 16-42% of affected cats.[54,58,62,69,70] Male gender, older age, history of medical management prior to evaluation, but not shunt morphology, appear to be associated with urolithiasis in dogs with congenital EHPSS.[54] Proteinuria is common in dogs with PSSs, suspected to be secondary to glomerulopathy (e.g., glomerular sclerosis, glomerulofibrosis, membranoproliferative glomerulonephritis; see ch. 325).[71] This link between severe liver disease and glomerulonephritis, which has been seen in people, is speculated to follow accumulation of antigens reaching the kidneys that the liver would have otherwise cleared with a normal portal circulation and resulting in immune-mediated glomerulonephritis.[72]

Liver Function Testing

Measurement of fasting (12-hour) and 2-hour postprandial serum bile acid (SBA) is the test of choice for evaluating liver function in animals suspected of having PSSs. Bile acids are synthesized in the liver from cholesterol and, following conjugation, are secreted into the bile canaliculi and stored in the gallbladder until released into the duodenum. They aid lipid absorption via intestinal fat emulsification and metabolism, are reabsorbed from the ileum, transported into the portal system, and extracted by hepatocytes for recirculation.[73-76] Production, excretion, and enterohepatic recirculation are all evaluated when measuring bile acid concentrations. These measurements can be affected by the timing of gallbladder contraction, the rate of intestinal transport, the degree of bile acid deconjugation in the small intestine, the rate and efficiency of bile acid absorption in the ileum, portal blood flow, and the function of the hepatocyte uptake and canalicular transport. Increases in postprandial bile acids have been found to be 100% sensitive for detecting PSSs in dogs and cats in some studies.[73-76] Others suggest paired samples are 100% sensitive, but not individual measurements. A small subset of affected animals have normal postprandial bile acids, with elevated fasting samples, and an even larger number have normal fasting and elevated postprandial bile acids.[26,74] Normal Maltese dogs can have elevated SBAs without evidence of hepatocellular dysfunction.[50] Other "false"-positive results unrelated to PSSs are due to inappropriate sample timing, other hepatobiliary diseases/cholestasis, glucocorticoid or anticonvulsant therapy, tracheal collapse, seizures, and GI disease.[6,64,75,77] Falsely low results can occur with delayed intestinal absorption from prolonged transport time, lack of gallbladder contraction, inadequate food intake/delayed gastric emptying, and malabsorption or maldigestion. Gallbladder contraction can occur between meals, resulting in higher preprandial than postprandial bile acid levels. The persistent bile acid concentration elevations identified in animals with PSSs are due to the shunting of reabsorbed SBA to the systemic circulation.[6,64,75]

When false-negative test results are suspected, an ammonia tolerance test can be performed. Two samples are evaluated: prior to, and 30 minutes following, ammonium chloride administration (100 mg/kg; maximum, 3 g) via nasogastric tube, oral capsule, or a high colonic infusion enema. This test has been documented to have a sensitivity of 95-100% for hepatic insufficiency.[8,78,79] The test should be considered carefully and is contraindicated in animals with HE.[79] The primary source of blood ammonia is from GI tract absorption, with >75% being generated by colonic bacterial metabolism.[6,12,53] Portal blood delivers ammonia to hepatocytes, where it is converted to urea via the urea cycle. In animals with PSSs, or other liver deficiencies, this conversion does not occur efficiently, resulting in increased concentrations of ammonia. Plasma separation and laboratory analysis need to be done within 20 minutes of sample collection, making this test problematic. In cats with hyperammonemia and HE, an inborn error in ammonia metabolism due to an enzyme deficiency (ornithine transcarbamylase) in the urea cycle has been reported.[80] Other causes of hyperammonemia in young animals include methylmalonic acidemia, other urea cycle enzyme deficiencies, and urethral obstruction–induced hyperammonemia.[5,80] These conditions are not associated with PSSs.

Ammonia concentrations are not as sensitive (62-88% of PSS animals are abnormal) as the SBA test, especially after prolonged fasting or with effective medical management of HE.[6,26,50,62] Both false-positive

(Irish Wolfhound puppies), and false-negative, baseline ammonia levels have been documented, making a high ammonia level supportive of, but not diagnostic for, PSSs.[26,79,81] Measurement of 6-hour postprandial blood ammonia concentrations increased detection sensitivity from 62% to 91% in dogs with PSSs.[82] Elevations in any of these function tests are suggestive of hepatic insufficiency, but are not diagnostic for PSSs.

Coagulation Profiles

Prolonged coagulation times (see ch. 196) are recognized in most dogs with PSSs, though spontaneous bleeding is rare and does not usually occur until surgical intervention is attempted.[83,84] In one study, postoperative mortality increased in those dogs that had a dramatic worsening of coagulopathy after surgery.[85] Because liver parenchymal cells synthesize most clotting factors (I, II, V, IX, X, XI, XIII [and VIII via the liver vascular endothelium]), animals in liver failure, as seen in PSSs, would be expected to have some deficiencies and resultant coagulopathies. Prolonged prothrombin time (PT) and/or activated partial thromboplastin time (PTT) occur after ≈65-80% of factor loss occurs.[6,12,83] The liver also regulates coagulation via clearance of activated factors, so that regeneration of inactivated factors and fibrinolytic factors can occur.[84,86,87] Animals with chronic liver disease, as with PSSs, typically have prolongation only of PTT, whereas animals with acute liver disease can have prolongations of both PT and PTT.[86] The prolonged PTT in PSSs is suspected to be due to impaired hepatic synthesis, qualitative abnormalities, and clearance of coagulation factors.[83-85] Interestingly, deficient factors include those involved in the common (II, V, and X) and extrinsic (VII) pathways, leading one to expect the PT to be prolonged as well. One possible explanation is a factor XII deficiency that can cause prolongation in PTT alone without overt bleeding.

Dogs with PSSs have abnormally low platelet counts preoperatively, which is worse postoperatively (mean: 161,000/mcL).[83] No reported decrease in platelet count has been low enough to cause clinical bleeding. This may be supportive of a postoperative consumptive coagulopathy. Overall, coagulation status (PT, PTT, and platelet count) returned to normal in one study by 6 weeks after PSS surgical correction, but not in animals that had persistent shunting.[83]

In some dogs with CPSS, coagulation parameters and thromboelastography have revealed hemostatic abnormalities consistent with markers for coagulopathy and a concurrent hypercoagulable state.[88] In this study, the presence of a hypercoagulable state was found to be 40 times more likely to be associated with clinical HE.[88]

Abdominal Effusion

Ascites is rarely seen in dogs with single congenital PSSs, unless there is severe hypoproteinemia, severe GI bleeding, or portal hypertension associated with HAVM, NCPH, or acquired multiple EHPSS (chronic liver disease/cirrhosis). Typically, the fluid for any of these conditions is a pure transudate that is clear and relatively acellular with total protein <2.5 g/dL, specific gravity <1.017, and <1000 nucleated cells/mcL.[64]

Histopathology

Most dogs with CPSSs have microscopic bile duct proliferation, hypoplasia of intrahepatic portal tributaries, hepatocellular atrophy (lobular), arteriolar proliferation or duplication, lipidosis and cytoplasmic vacuolar changes (lipogranulomas), smooth muscle hypertrophy, increased lymphatics around central veins, and Ito cell and Kupffer cell hypertrophy.[6,89-92] Some animals have evidence of mild fibrosis around the central veins and a few have signs of necrosis or inflammation.[6,89] In an evaluation of histopathologic data versus prognosis in dogs with CPSS, there was no statistically significant association between histologic features and survival times.[89] Historically, histologic features associated with a poor prognosis included fibrosis, biliary hyperplasia, and necrosis.[5,6,90] Some dogs with PSSs have focal lesions consisting of Kupffer cells and/or macrophages with cytoplasmic brown pigments (ceroid and hemosiderin) and lipid vacuoles called *lipogranulomas*.[92] These changes have inconsistently been associated with prognosis.[89,92,93]

Another study assessed hepatic histopathologic lesions in relation to clinical findings and ability to completely attenuate the shunt in dogs with CPSS.[94] The lack of identifiable portal veins (36% of dogs) was associated with increased hepatic arteriolar proliferation, decreased tolerance to complete surgical

attenuation, and decreased opacification of intrahepatic portal vessels on portovenography. Surgical CPSS attenuation resulted in significant clinical, serum biochemical and portovenographic changes indicative of improved liver function, but only subtle changes on hepatic histologic re-examination.[94]

In a study of dogs with congenital EHPSS, larger liver volumes were associated with fewer lipid droplets per tissue point histopathologically.[93] The number of lipogranulomas was positively associated with age, but the presence of hepatic lipidosis and lipogranulomas had no demonstrable effect on development of acquired shunts or the magnitude of increased liver volume after shunt attenuation.[93] In a study of 40 cats with CPSS evaluated before and after surgical attenution histopathologic analysis showed portal vein hypoplasia and arteriolar hyperplasia in all samples.[95] Hepatocyte swelling with microvesicular vacuolar change (50%), fibrosis (42.5%), hepatocyte swelling with macrovesicular vacuolar change (30%), biliary hyperplasia (20%), and hemosiderin within Kupffer cells (5%) were seen in variable amounts. Cats with macrovesicular vacuolar changes were significantly older (median age 18.5 months versus 8.5 months). On follow-up biopsy samples after partial attenuation, there were no significant differences in histopathological features, though intrahepatic vasculature was improved on portovenography.[95]

Dogs with PVH without (MVD) or with (NCPH) portal hypertension share hepatic histopathologic changes seen in dogs with macroscopic CPSS. These syndromes can, therefore, be confused histologically if correct history and signalment are not provided.[23,25,29] Dogs with NCPH often have more significant fibrosis that extends into the parenchyma, particularly along the portal tracts or even bridging to other portal areas or central veins.[23]

Dogs with HAVMs that have had biopsies taken from liver lobes not involved in the arteriovenous communication often have similar histopathologic findings to those with venous-venous shunting. The liver tissue in close proximity to the malformation often has largely dilated portal venules, marked arteriolar hyperplasia, muscular proliferation, and sinusoidal capillarization. Some portal veins have evidence of thrombus formation and recanalization.[5,24]

Dogs with HE can have histopathologic changes in the CNS that include polymicrocavitation of brainstem, cerebellar nuclei, or cerebral cortex, and hypertrophy and hyperplasia of cerebral cortical protoplasmic astrocytes.[3,8]

Diagnostic Imaging

Various imaging modalities can be used for diagnosing PSSs. Survey abdominal radiographs often demonstrate microhepatica (60-100% of dogs, 50% of cats) and bilateral renomegaly.[3,5] In dogs with PVH, liver and kidney size can be normal radiographically.[5,25] Marginally radiopaque calculi can be seen in the bladder, urethra, ureters, and/or kidneys. These are usually ammonium biurate stones with associated calcium salt or struvite shells; these stones also can be radiolucent. To definitively diagnose a macroscopic shunt using contemporary imaging modalities, abdominal ultrasonography, scintigraphy, angiography (portal or arterial), computed tomographic angiography (CTA), or magnetic resonance angiography (MRA) may be necessary.

Abdominal Ultrasonography

Ultrasonography (US) is the most widely used diagnostic tool for PSSs. It is noninvasive, does not require general anesthesia (though sedation makes finding EHPSSs more reliable in many circumstances), and does not require special licensing/handling (versus scintigraphy). Decreased numbers of hepatic and portal veins, a subjectively small liver, and an anomalous vessel are most often seen in congenital PSSs (Figure 284-4). EHPSSs have been documented to be more difficult to diagnose with US due to small patient size, small vessel size, variable location, and the presence of gas in the bowel and lungs. Multiple EHPSSs often are harder to find and typically are located near the left kidney. Sensitivity for detection of shunts has ranged from 74% to 95% and specificity from 67% to 100%.[96-98] Correct distinction of IHPSS from EHPSS was possible in 92% of cases in one study. Sensitivity is higher for IHPSS (95-100%) than EHPSS due to the presence of liver parenchyma surrounding the shunting vessel, and the typically large diameter of the intrahepatic shunting vessel and associated portal vein.[96] Results are operator- and experience-dependent. Color-flow and pulsed-wave Doppler imaging are useful for identifying changes in flow direction because HAVMs classically have hepatofugal flow and venous-venous shunts have hepatopetal flow through the portal vein (Figure 284-5). Portal flow velocity was increased or variable in 53% of dogs with EHPSS and in 92% of dogs with IHPSS.[5] Dogs and cats with EHPSS have been documented to have reduced portal vein-to-

aorta size ratios. US also is useful for detecting uroliths in dogs and cats with hepatic vascular anomalies because these stones often are radiolucent.[96,99,100]

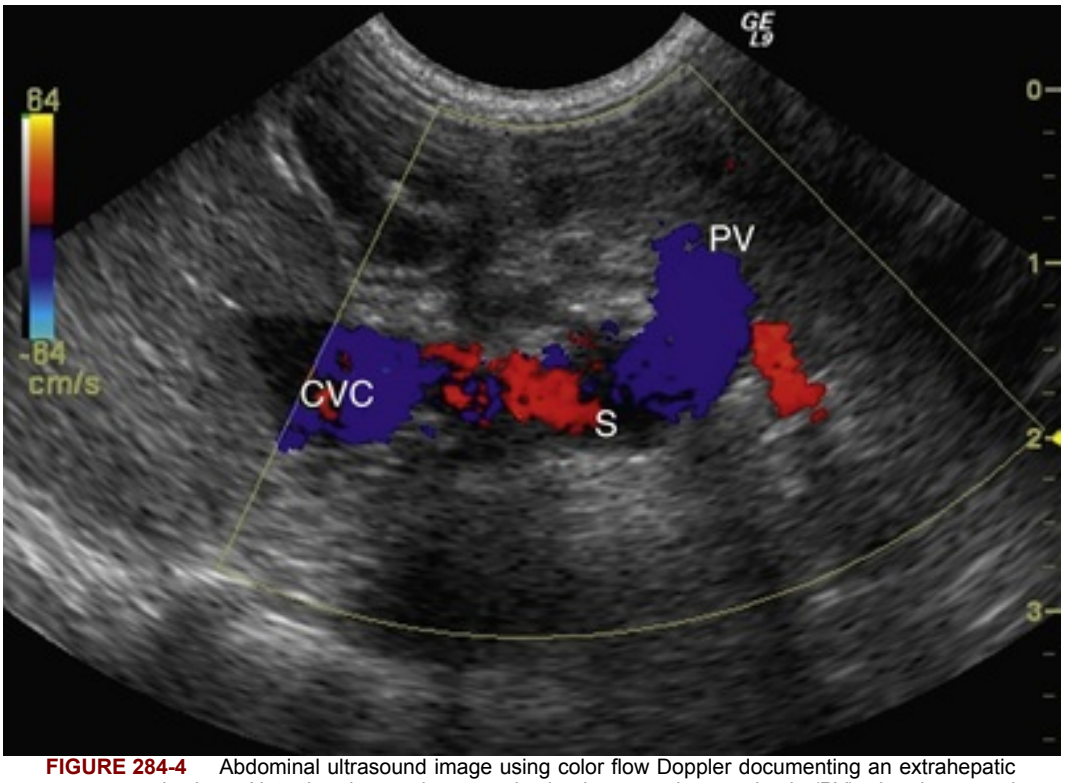

FIGURE 284-4 Abdominal ultrasound image using color flow Doppler documenting an extrahepatic portosystemic shunt. Note the abnormal communication between the portal vein (PV), shunting vessel (S), and caudal vena cava (CVC).

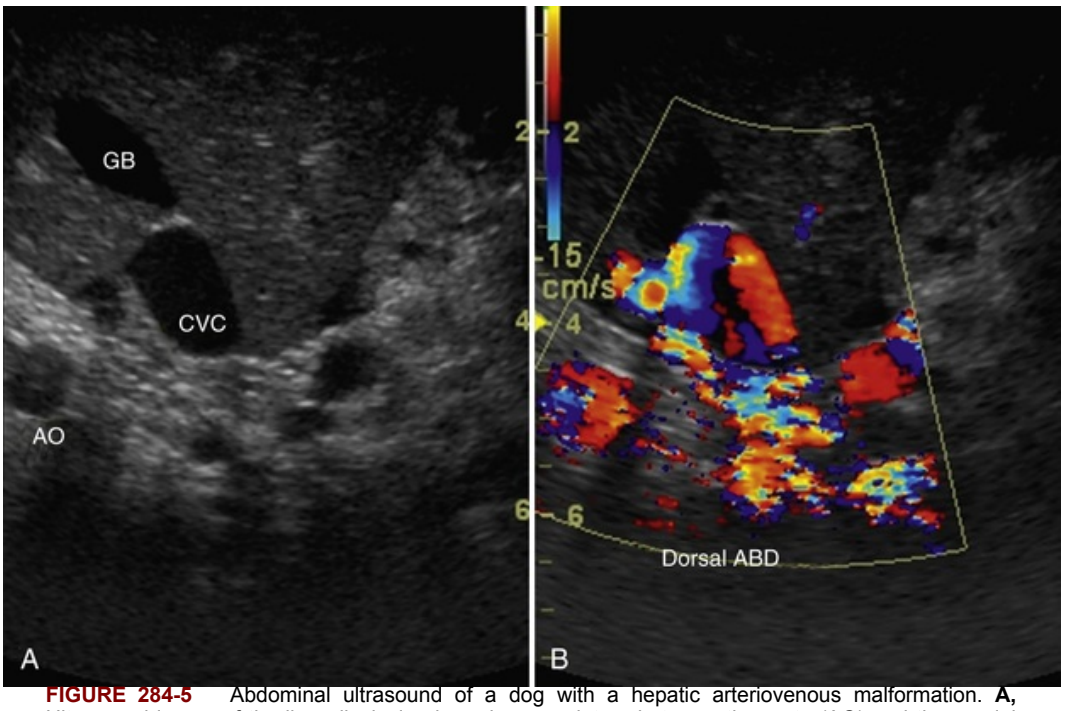

FIGURE 284-5 Abdominal ultrasound of a dog with a hepatic arteriovenous malformation. **A,** Ultrasound image of the liver displaying irregular vasculature between the aorta (AO) and the caudal vena cava (CVC). **B,** Color flow Doppler of the turbulent flow of blood in the portal vein and acquired

shunts. *ABD*, Abdomen; *GB*, gallbladder.

Ultrasound contrast venography has involved US-guided percutaneous injection of a mixture of agitated saline and 1 mL autologous heparinized blood into the spleen.[101] When visualizing the vena cava, portal vein, and right atrium in dogs with CPSS, it is possible to differentiate between intrahepatic and extrahepatic shunts depending on the entry point of microbubbles into the CVC. Portoazygos and portocaval shunts also can be differentiated this way.[101]

Scintigraphy

Transcolonic scintigraphy utilizing the radioisotope technetium (^{99m}Tc) pertechnetate is a useful, noninvasive method for detecting a PSS.[100] A bolus is infused into the colon, per rectum, and the pet is imaged with a gamma camera. The isotope normally, in order, is absorbed and drained through colonic veins and then the caudal mesenteric vein, portal vein, liver, and heart. In a PSS, the isotope reaches the heart, bypassing the liver, and then returns to the liver through the arterial circulation (Figure 284-6).[100] If a shunt is present, a shunt fraction can be calculated, giving an estimate of the percentage of portal blood bypassing the liver. A fraction <15% is considered normal, whereas most dogs with PSS have fractions >60% to 80%. Some cats (52% in one study) have lower fractions than dogs.[102] There is considerable variation (variable colonic absorption, operator variability, fecal matter in the colon), so comparisons at different time points are difficult and should not be used for assessing postoperative success.[103] If the isotope is administered "too high" into the rectum, absorption directly into the CVC can occur, resulting in falsely elevated shunt fractions. The half-life of technetium pertechnetate is 6 hours, so animals must be isolated for at least 24 hours after the procedure. Scintigraphy does not provide morphologic information regarding shunt type or location, cannot distinguish IHPSS from EHPSS, and cannot differentiate single from multiple shunts. Scintigraphy can be normal or abnormal in dogs with MVD/PVH. Shunt fractions can be lower in dogs with MVD than macroscopic PSSs. Shunt fraction estimation is inexact and prone to interoperator and intraoperator variability. Use of transsplenic portal scintigraphy for diagnosis of a PSS, using $^{99M}TCO_4^-$, has helped distinguish single from multiple shunts but not IHPSS from EHPSS, and is not used routinely.[104]

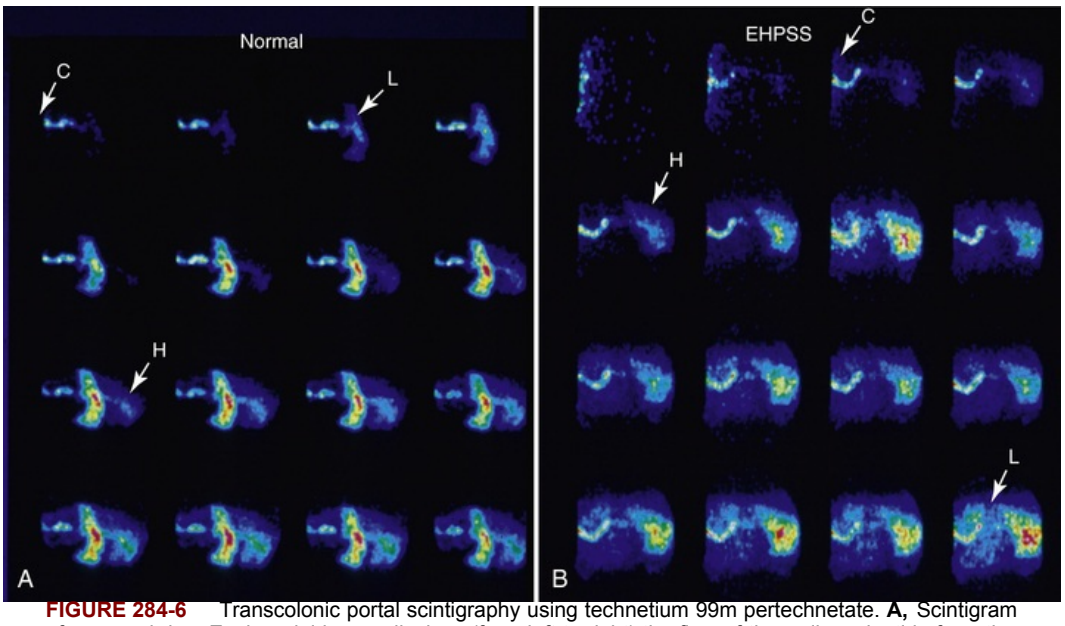

FIGURE 284-6 Transcolonic portal scintigraphy using technetium 99m pertechnetate. **A,** Scintigram of a normal dog. Each serial image displays (from left to right) the flow of the radionucleotide from the colon (C), where it is initially rapidly absorbed, to the portal vein, perfusing the liver (L), later reaching the heart (H). When this is compared with **B,** a dog with an extrahepatic portosystemic shunt (EHPSS), the nucleotide is seen to reach the heart (H) prior to the liver (L), indicating a portosystemic shunt. (Courtesy Dr. Lillian Aronson.)

A recent study correlated liver volume, portal vascular anatomy on CTA, hepatic perfusion, and

scintigraphy in dogs with CPSS before and after attenuation with an ameroid constrictor.[105] Decreased hepatic arterial perfusion and portal shunt fraction, based on scintigraphy, correlated with liver volume, and were both indicators for successful shunt attenuation. Additionally, dogs that did not have visible portal vasculature on CTA preoperatively had visible vasculature postoperatively.[105]

Computed Tomographic Angiography (CTA)

CTA is the gold standard for evaluating the portal venous system in people.[106] It is noninvasive, fast, and it images all portal tributaries and branches from a single peripheral venous contrast injection. It can be used in any species and any size of animal with accuracy, allowing for further image manipulation after completing a study. Dual-phase CTA provides a complete evaluation of portal and hepatic vasculature and is considered superior to single-phase CT.[107] This study is most valuable in animals with suspected IHPSS, HAVM, or for which US is not diagnostic and more invasive imaging such as portography is not desired (Figure 284-7). CTA is helpful in preprocedural planning for both surgical and interventional radiologic (IR) approaches to IHPSS or HAVM by reducing excessive liver dissection or manipulation during surgery and minimizing contrast load during IR procedures.

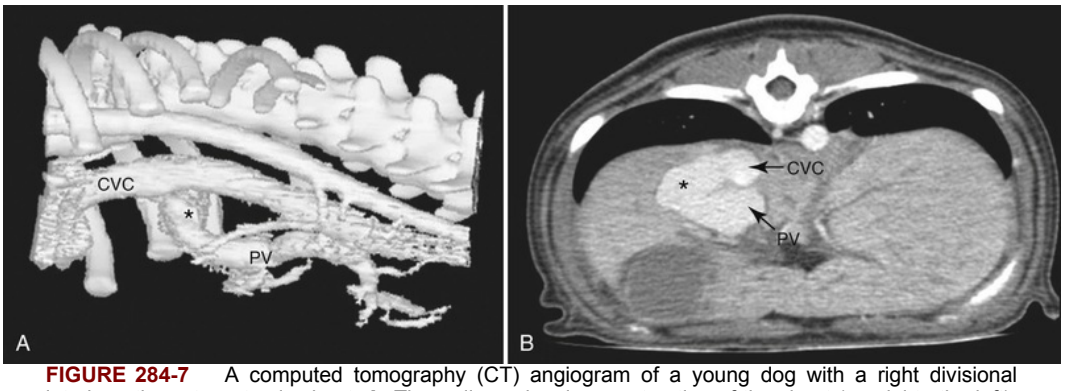

FIGURE 284-7 A computed tomography (CT) angiogram of a young dog with a right divisional intrahepatic portosystemic shunt. **A,** Three-dimensional reconstruction of the shunt (cranial to the left). The portal vein (PV) can be seen terminating in the shunt (*), which enters the caudal vena cava (CVC). **B,** Axial CT dual-phase angiographic image; the right side of the dog is on the left of the image. Note the contrast material enhancing the communication between the PV and CVC through the shunt.

A recent study of canine EHPSS using CTA found that CTA provided an excellent overview of shunt anatomy, and provided information about various tributary vessels that could be overlooked during surgical exploration.[108]

Magnetic Resonance Angiography (MRA)

MRA also can provide three-dimensional, preoperative shunt images, aiding in preprocedural planning (Figure 284-8). Images from dual-phase CTA are relatively easy to interpret, provide superior detail (particularly with newer multisliced CT scanners), and are less costly than MRA. Magnetic resonance imaging without gadolinium-enhanced angiography is less promising, with sensitivities ranging from 63% to 79%, though specificity as high as 97% has been described.[5] Contrast enhanced MRA (CE-MRA) can identify both EHPSS and IHPSS,[109] and was diagnostic of a portal vascular anomaly in 16/17 dogs, including IHPSS (n = 13), EHPSS (n = 2), HAVM (n = 1), and no shunt (n = 1) in one study.[110]

FIGURE 284-8 Magnetic resonance angiogram of a young dog with a left divisional intrahepatic portosystemic shunt. Notice the contrast enhancement of the caudal vena cava (CVC), which is communicating with the portal vein (PV) through the abnormal portosystemic shunting (PSS) vessel. *H,* Heart; *RK,* right kidney.

Portovenography

Portography/portovenography is not commonly performed due to availability of other less invasive imaging modalities (US, scintigraphy, CTA/MRA). Surgical mesenteric portography is the most commonly performed angiographic test for documenting PSSs in dogs and cats. It allows visualization of a shunting vessel but requires a laparotomy, fluoroscopy, and intravenous (IV) contrast material (Figure 284-9). The sensitivity of intraoperative portography is 85-100% and is dependent on patient positioning and the presence of digital subtraction of the fluoroscopic image.[3-5] Classically, differentiation of IHPSS from EHPSS on portography is based on the point where the shunt diverges from the portal vein. If this point is cranial to the thirteenth thoracic vertebra, the shunt is typically intrahepatic, and caudal to the thirteenth thoracic vertebra is usually extrahepatic.

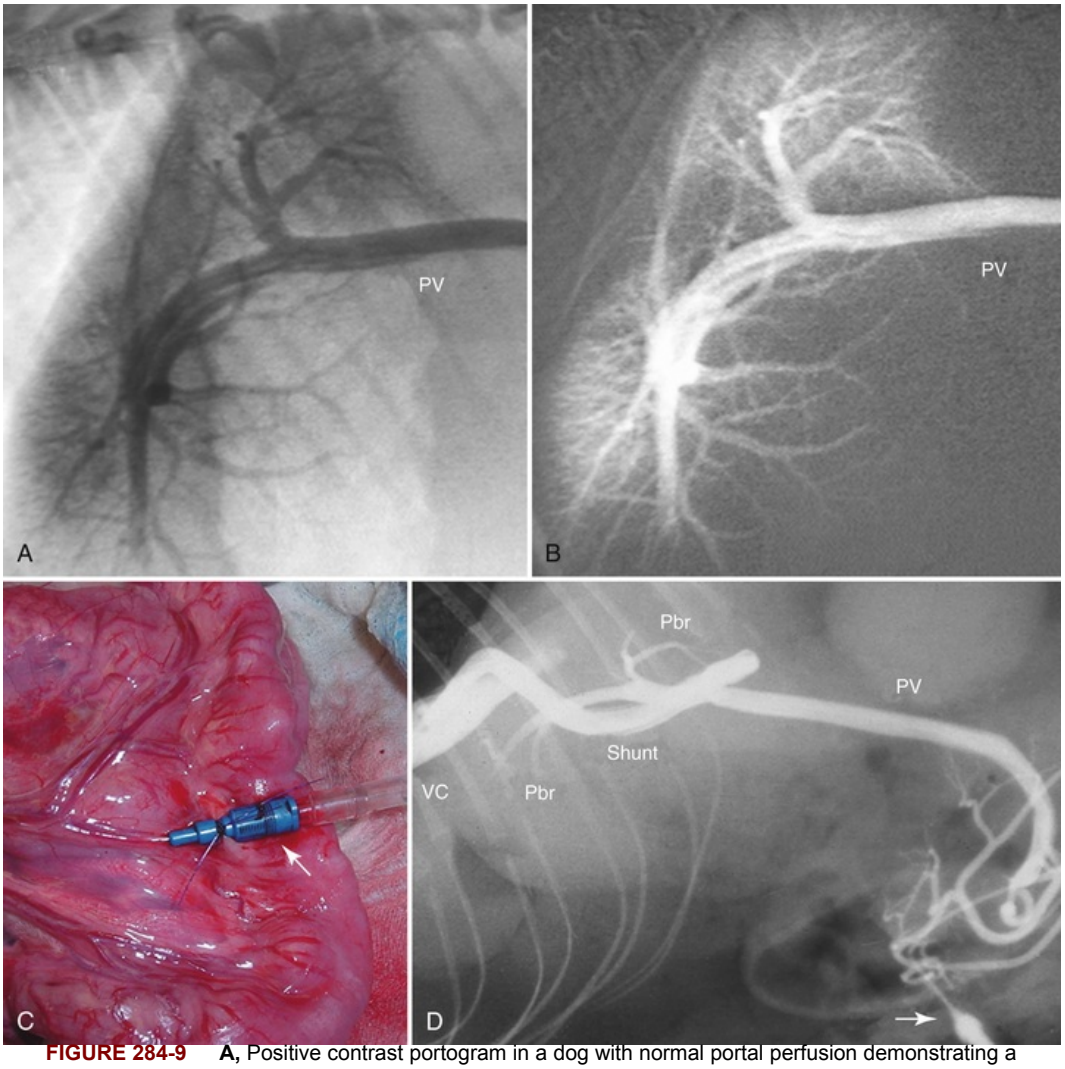

FIGURE 284-9 **A,** Positive contrast portogram in a dog with normal portal perfusion demonstrating a well-developed portal vein (PV) and portal branching. **B,** Digital subtraction portogram of the same dog demonstrating improved visualization of vascular anatomy. **C,** Jejunum with 22-gauge catheter secured in a jejunal vein for performing portography and portal pressure measurements. **D,** Mesenteric portogram performed through jejunal catheter (arrow) demonstrating PV and hypoplastic portal branches (Pbr), as well as portosystemic shunt (Shunt) entering the caudal vena cava (VC).

An alternative to surgical portal venography is percutaneous, ultrasound-guided splenic venography. Under US guidance, a bolus of ≈2-4 mL/kg of iohexol (240-360 mg/mL) is injected into a splenic vein. Fluoroscopy or radiography is used for imaging splenic venous drainage through the portal vein, and hepatic or systemic venous flow is identified (Figure 284-10). Caudally-located EHPSSs can be missed with this technique, however, if the portal branch communicates with the CVC in a more caudal location than the splenic vein.[111]

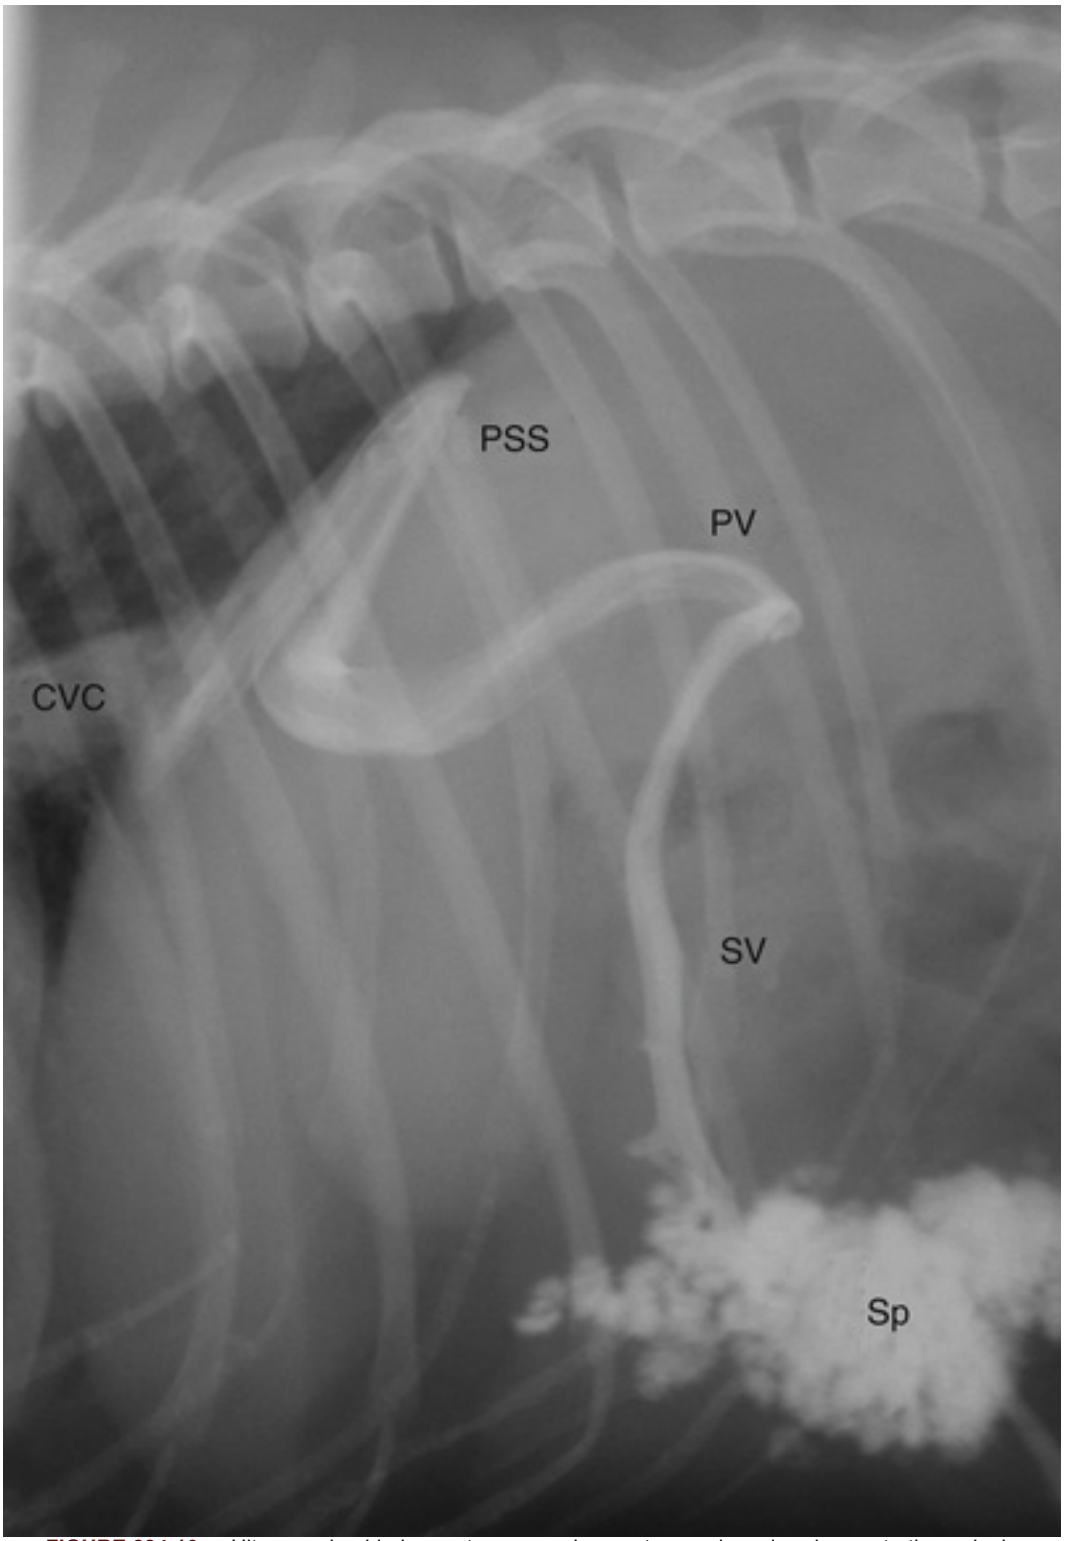

FIGURE 284-10 Ultrasound-guided percutaneous splenoportogram in a dog demonstrating splenic contrast uptake (Sp), splenic vein (SV), portal vein (PV), and portosystemic shunt (PSS) entering the caudal vena cava (CVC). Notice the obvious lack of portal perfusion present in this liver. (Courtesy Dr. Skye Stanley.)

Injection of contrast material into the mesenteric artery, known as a *cranial mesenteric arteriogram* via access through the femoral artery, is not commonly utilized due to many less invasive alternatives.

Differential Diagnosis

In any animal suspected of having a congenital PSS, conditions causing similar clinical signs (e.g., GI parasitism, hypoadrenocorticism, protein-losing enteropathy, other primary hepatopathies, MVD/PVH, NCPH, and HAVM) should be ruled out. If bile acid concentrations are suggestive of PSSs, differentiating MVD, NCPH, HAVM, and PSS is necessary, notably with the diagnostic imaging modalities mentioned above. Plasma protein C activity has been documented to help differentiate MVD from PSS (protein C levels were >70% in 88% of dogs with MVD and low in dogs with PSS).[112] If a macroscopic PSS still is not identified but remains highly suspected, then liver biopsy with or without measurement of portal pressures should be obtained to diagnose various forms of PVH. If an HAVM is not found in a young dog with ascites and clinicopathologic evidence of hepatic dysfunction, then NCPH is possible and histologic examination of liver tissue is necessary to rule out other severe hepatopathies and to guide treatment. Other liver diseases (chronic hepatitis, cirrhosis, or leptospirosis) can produce similar signs but are more common in older dogs and they often have hyperbilirubinemia. If hyperammonemia and HE are detected in an animal without evidence of PSS, a urine metabolic screen should be evaluated for evidence of ornithine transcarbamylase deficiency, methylmalonic acidemia, or other urea cycle metabolic abnormalities.[80]

Treatment

Medical Management

Medical management (Table 284-2) of animals with portovascular anomalies should be required prior to surgical or IR correction of PSS, in cases of MVD or NCPH, or for macrovascular shunts where surgery is not possible or is declined. Medical management is aimed at controlling clinical signs associated with shunting but does not treat the underlying diminished hepatic perfusion. When a dog or cat with signs of HE is examined, rapid stabilization is required and intensive efforts should be implemented to decrease ammonia levels to near normal. Nothing should be given orally until the pet is alert and aware. IV fluid therapy to replace and maintain hydration can be necessary, especially if an animal is unable to drink or is dehydrated. Lactated Ringer's solution often is avoided due to the need for hepatic conversion of lactate to bicarbonate. Potassium supplementation often is necessary due to potassium depletion from chronic diarrhea or decreased intake, and hypokalemia can also contribute to HE.[10,53]

TABLE 284-2

Recommended Medical Management for Portosystemic Shunts

DISORDER	THERAPY
Bacterial translocation/decreasing bacterial byproduct absorption (ammonia)	Cleansing enemas with warm water or 30% lactulose solution at 5-10 mL/kg (see ch. 114) Oral lactulose: 0.5-1 mL/kg PO q 6-8 h to effect of 2-3 soft stools per day Antibiotics Metronidazole 7.5 mg/kg IV or PO q 12 h Ampicillin 22 mg/kg IV q 6 h Neomycin 22 mg/kg PO q 8 h (avoid if any evidence of intestinal bleeding, ulcerations or kidney disease)
Coagulopathy (symptomatic; postoperative)	Fresh frozen plasma 10-15 mL/kg over 2-3 h (see ch. 130) Vitamin K_1 1.5-2 mg/kg SC or IM q 12 h for 3 doses, then q 24 h (see ch. 197)
Gastrointestinal ulceration (very common with IHPSS—begin treatment before intervention) (very common with HAVM due to portal hypertension)	Gastric acid suppressant Famotidine 0.5-1 mg/kg IV or PO q 12 h Omeprazole 0.5-1 mg/kg PO q 12-24 h Esomeprazole 0.5 mg/kg IV q 12-24 h Misoprostol 2-3 mcg/kg PO q 12 h Protectant Sucralfate: 1 g/25 kg PO q 8 h Correct coagulopathy
Seizure control	Avoid benzodiazepines* Phenobarbital (4 mg/kg IV q 3-6 h for 4 doses)

	KBr: should be avoided in cats due to bronchospasm Loading: 400-600 mg/kg/day divided over 1-5 days PO with food; can be given per rectum if needed Maintenance: 20-30 mg/kg PO q 24 h Sodium bromide can be used if an IV form is necessary Propofol 1-3.5 mg/kg IV bolus, followed by CRI of 0.01-0.25 mg/kg/min* Keppra 20 mg/kg (up to 60 mg/kg) PO or IV q 8 h (*there is no evidence-based medicine to support this)
Decrease cerebral edema	Mannitol: 0.5-1 g/kg bolus over 20-30 min
Nutritional support	Moderate protein restriction 18%-22% for dogs and 30%-35% for cats (on dry matter basis); dairy or vegetable proteins preferred Vitamin B complex supplementation (1 mL/L IV fluid therapy) Multivitamin supplementation
Hepatoprotective therapy (for chronic conditions that are unable to be fixated-MVD, NCPH, MEHPSSs, etc.)	S-adenosyl-L-methionine: 17-22 mg/kg/day PO Ursodeoxycholic acid: 10-15 mg/kg/day PO Vitamin E: 15 IU/kg/day PO Milk thistle (silymarin): 8-20 mg/kg PO divided q 8 h L-carnitine: 250-500 mg/day PO (cats)

*Controversial.

CRI, Constant rate infusion; *HAVM*, hepatic arteriovenous malformation; *IHPSS*, intrahepatic portosystemic shunt; *MVD*, microvascular dysplasia; *NCPH*, noncirrhotic portal hypertension; *MEHPSSs*, multiple extrahepatic portosystemic shunts.

Metabolic acidosis (see ch. 128) can contribute to HE and should be corrected slowly with fluid therapy and, rarely, sodium bicarbonate. It is important to verify that concurrent respiratory acidosis does not exist prior to sodium bicarbonate therapy. Glucose should be supplemented in IV fluids, particularly in young puppies with PSS, where glycogen stores and gluconeogenesis are minimal. Therapy for acute, severe HE includes feeding nothing by mouth (PO), administering cleansing enemas with warm water and/or lactulose (see ch. 114), oral lactulose therapy, antibiotic therapy (metronidazole, ampicillin, or neomycin), and anticonvulsant therapy if necessary (see Table 284-2). Gamma-aminobutyric acid (GABA) and its receptors have been implicated in the pathogenesis of HE.[10] Using a benzodiazepine antagonist like flumazenil (0.02 mg/kg IV to effect) has been shown to be of benefit in humans with HE-induced comas. Mannitol should be considered in pets with severe HE or after seizure activity (see ch. 148).[10] In people, there is an association between HE and cerebral edema.[2,10]

Seizure control often is initiated with low-dose midazolam (a benzodiazepine that is preferred to diazepam due to the lack of propylene glycol as a carrying agent, which requires liver metabolism). Once seizures are controlled, loading with either phenobarbital, potassium bromide, sodium bromide, or levetiracetam (Keppra) can be considered (see Table 284-2 and ch. 35 and 260). A study found that significantly fewer (0/42) dogs pretreated with levetiracetam (20 mg/kg PO q 8 h for a minimum of 24 h preoperatively) experienced postoperative seizures after attenuation of CPSS, whereas 4/84 (5%) of dogs not pretreated with levetiracetam experienced seizures.[113] In 3 dogs with status epilepticus after PSS attenuation, a propofol bolus and constant rate infusion, combined with phenobarbital, led to recovery and discharge in all dogs over 7-9 days, without recurrent CNS signs.[114]

Lactulose, a disaccharide that is metabolized by colonic bacteria to organic acids, can be administered either by enema or PO. It promotes the acidification of colonic contents, trapping ammonia in the form of ammonium, while decreasing bacterial numbers and eliminating ammonium and bacteria in the feces. The osmotic effect results in catharsis, reducing fecal transit time and exposure to bacteria for proliferation and ammonia production. Antibiotics, such as metronidazole, neomycin, or ampicillin, decrease GI bacterial numbers, allowing for a further reduction in ammonia production. Metronidazole and ampicillin also decrease the risk of bacterial translocation and systemic infections. In pets with signs of bleeding or anemia, transfusion of packed red blood cells, whole blood, or fresh frozen plasma may be of benefit (see ch. 130). If there is evidence of HE, fresh whole blood is preferred, as stored blood contains a decreased number of clotting factors and elevated ammonia levels, potentially worsening HE.

Nutritional management is important, particularly in young animals with poor body condition. Diets should be readily digestible, contain a protein of high biologic value (enough to meet the animal's needs, but not to encourage HE), supply enough essential fatty acids, maintain palatability, and meet the minimum requirements for vitamins and minerals. Milk and vegetable proteins are lower in aromatic amino acids

(tyrosine and phenylalanine) and higher in branched-chain amino acids, such as valine, leucine, and isoleucine. These sources are less likely to precipitate HE.[2,10] Protein content of 18-22% for dogs and 30-35% for cats (dry matter basis) should be the goal, with dairy or vegetable proteins preferred.

Gastric bleeding/ulceration should be treated with acid receptor blockade (famotidine), proton pump inhibitor (omeprazole) +/- with sucralfate. Animals with IHPSS have a predisposition to develop GI ulcerations (Figure 284-11).[57,115] Use of lifelong gastric acid suppressant therapy in dogs with IHPSS decreases morbidity associated with GI bleeding. Nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided in any dog with liver disease, but particularly those with IHPSS, as this could perpetuate GI ulceration.

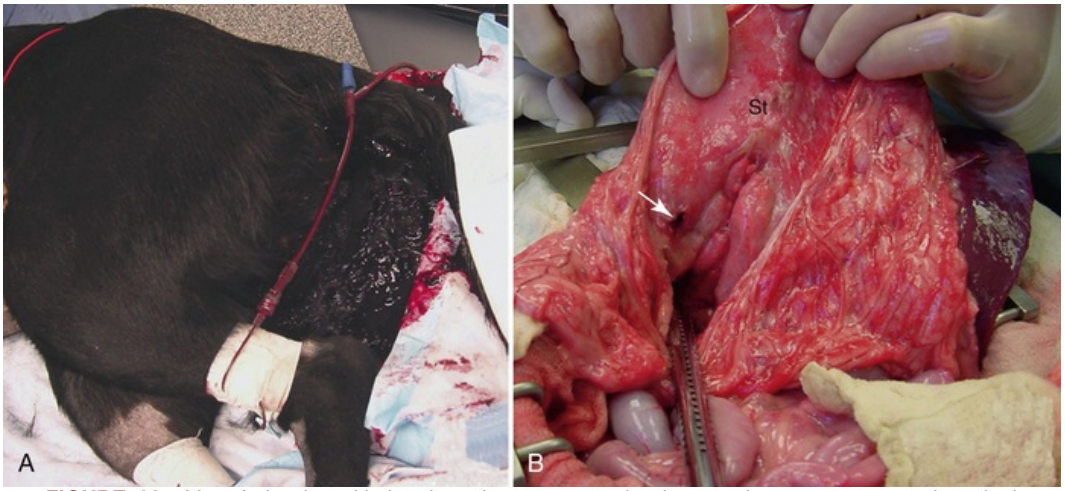

FIGURE 284-11 Labrador with intrahepatic portosystemic shunt and concurrent gastrointestinal ulceration. **A,** Severe hematochezia and melena requiring packed red blood cell transfusion. **B,** Exploratory laparotomy in the same dog demonstrating perforated ulcer (arrow) in the pyloric antral portion of the stomach (St).

Ascites and fibrosis can occur in pets with HAVM and NCPH, but rarely with PSSs unless there is severe hypoalbuminemia. If ascites is due to poor oncotic pressure, colloidal therapy should be considered. If ascites is due to portal hypertension, diuretic therapy and low sodium diets should be considered (see ch. 183). Additional sodium sources (particularly treats) can exacerbate ascites and should be avoided. Spironolactone is the initial diuretic of choice for its potassium-sparing effects. Furosemide also can be necessary but should be used with caution because it potentiates further hypokalemia. In some instances, therapeutic abdominocentesis is necessary to make the pet more comfortable and make ventilation easier (see ch. 90). A number of drugs theoretically could decrease connective tissue formation and hepatic fibrosis: prednisone (1 mg/kg PO q 24 h), D-penicillamine (10-15 mg/kg PO q 12 h), and colchicine (0.03 mg/kg PO q 24 h).

Supportive nutraceutical therapy has been recommended for a variety of liver diseases but is not necessary in portovascular anomalies that can be repaired surgically or interventionally. For those animals that do not have a corrective alternative (MVD, NCPH, multiple EHPSS) or when shunts remain patent (e.g., HAVMs, many IHPSSs), some nutraceuticals may be useful, including S-adenosyl-L-methionine (SAMe), ursodeoxycholic acid, vitamin E, and milk thistle/silymarin (see Table 284-2). SAMe has hepatoprotective, antioxidant, and antiinflammatory properties. It is important in membrane structure, fluidity, and function. It also aids in the metabolism of glutathione (GSH), which participates in many metabolic processes and plays a critical role in detoxification mechanisms of the cell. Depletion of hepatic GSH can indirectly cause toxic effects in these cells by increasing oxidative stress, particularly in cats. Vitamin E is another antioxidant and it should be considered to prevent and minimize lipid peroxidation within hepatocytes. Ursodeoxycholic acid is recommended for most inflammatory, oxidative, and cholestatic liver diseases and often is used in NCPH. It has antiinflammatory, immunomodulatory, and antifibrotic properties, as well as increasing fluidity of biliary secretions, promoting choleresis and decreasing the toxic effects of hydrophobic bile acids on hepatocytes. Silymarin is the active extract in milk thistle. There is an abundance of data in both *in vivo* and *in vitro* experimental animal models showing the antioxidant and free radical scavenging properties of silymarin.[10] Specifically, it has been shown to inhibit lipid peroxidation of hepatocyte and microsomal membranes and protect against gene damage by suppression of hydrogen peroxide, superoxide, and lipoxygenase. Silymarin

also increases hepatic GSH content, appears to retard hepatic collagen formation, and has hepatoprotective effects through inhibition of Kupffer cell function. Milk thistle has low toxicity and few side effects.

Outcomes with Medical Management Alone

In humans with congenital PSSs, the long-term prognosis without surgery is reported to be excellent. In veterinary medicine, one report describes 27 dogs with CPSSs that were evaluated after long-term medical management alone; 14/27 (51.8%) were euthanized, with a median survival time (MST) of 9.9 months (median age at the time of euthanasia: 20 months); 4/27 (14.8%) were lost to follow-up; and 9/27 (33%) survived long term with an MST of 56.9 months (4.7 years; range 5 months to >7 years) with many of those still alive at the time of evaluation.[45] Of 27 dogs, 9 had EHPSS, 17 had IHPSS, and 1 was complex. This distribution likely is due to the fact that more veterinarians are hesitant to treat IHPSS surgically than EHPSS due to reported complications and technical difficulty. Dogs with IHPSS treated only medically had CNS signs as or more often, GI signs less often, and urinary tract signs as often as they had prior to treatment. In contrast, dogs with EHPSS had clinical signs occur with similar or lower frequency once medicated.[45] Dogs treated medically had a significant decline in total protein, ALP, and ALT levels. Bile acids, BUN, albumin, and mean corpuscular volume did not show significant changes long term. Eleven of 17 (64.7%) dogs with IHPSS were euthanized, usually due to uncontrolled signs of HE, and 3/9 (33%) dogs with EHPSS were euthanized.

Prognostic indicators for medical management of dogs with CPSS include age at onset of clinical signs (longer survival in older dogs) and BUN level (higher level associated with longer survival); there were no correlations among bile acid levels, serum protein levels, albumin, ALP, ALT, MCV, and survival time. Overall, >50% of dogs treated medically could be expected to be euthanized within 10 months of diagnosis and ≈33% can survive long term with medical management alone, though clinical signs do not necessarily resolve. Euthanasia is most often due to persistent signs of HE, and in some cases, progressive hepatic fibrosis and subsequent portal hypertension.[63] A second study of dogs with CPSS found that 24/27 dogs (88%) treated only medically died or were euthanized, compared to 21/97 dogs (21.6%) treated surgically.[116] Survival in this study was not affected by age or shunt morphology. Considering these statistics, surgical or interventional attenuation, when possible, is the treatment of choice for congenital PSS.[116,117]

Surgical Management

Presurgical Patient Management

Many pets are debilitated, in poor body condition, and not neurologically stable prior to anesthesia and surgery. Intensive medical management as described earlier is recommended routinely, even in animals without clinical signs. Following diagnosis, the pet may be discharged to return for surgery weeks to months later. No time for performing surgery has been identified as ideal, but most surgeons prefer to have the pet treated medically first, in order to improve clinical signs, control encephalopathy, and gain weight prior to intervention. In addition to the potentially reduced risk of postoperative seizures, smaller debilitated pets are at risk for perioperative hypothermia, hypoglycemia, and complications associated with intraoperative hemorrhage. The use of preoperative anticonvulsant therapy remains a debated topic, and is often employed for patients that present with HE. Preliminary evidence shows that pretreatment with levetiracetam can decrease the risk of postoperative seizures and improve survival (see above).[113,118] It is not clear whether anticonvulsants should routinely be employed preoperatively while the patient is receiving appropriate medical therapy.

General anesthesia for animals with liver disease has been described elsewhere.[119] Briefly, anesthetic agents that are highly protein-bound or dependent on liver metabolism are avoided. In addition, glucose support is often initiated with anesthesia because these animals often are thin, debilitated, and have been fasted prior to surgery. Colloidal support often is used (particularly in IHPSS cases) with anesthesia induction (see ch. 130). Although plasma can be utilized without excessive expense in small pets, the authors prefer synthetic colloids (1-2 mL/kg/h IV) when possible to reduce the risk of blood transfusion reactions and perioperative thrombosis of the manipulated PSS that could theoretically result from excessive plasma administration. Additionally, since these patients are not routinely clinically hypocoagulable, and more data would support a hypercoagulable state, the use of plasma for colloidal support should not be recommended routinely. Perioperative antibiotics are recommended for these patients, who are young and immunologically incompetent, as well as the fact that an implant is being used. Many already receive antibiotics as part of the preoperative medical management regimen. Blood type and coagulation screens are obtained routinely, particularly in IHPSS, regardless of risk of bleeding.

Clipping of fur should be wide and should include the thorax (particularly for IHPSSs being treated surgically or when the anatomy of the shunt is unknown preoperatively) in order to prepare for a caudal sternotomy. Clipping of the ventral neck can be helpful if jugular catheterization is used because intraoperative central venous pressures are occasionally desired. Hypothermia should be anticipated and forced warm air or fluid blankets with or without warm water bottles should be used. Water bottles cool quickly, so they should be changed regularly. For interventional procedures both jugular veins (IHPSS) or the femoral artery (HAVM) should be clipped of fur for venous access.

Surgery

The goal of surgery for PSSs is to attenuate the abnormal vessel in order to reestablish blood flow through the hepatic parenchyma. Complete shunt attenuation remains the goal of surgery because partial shunt occlusion has a worse prognosis.[91,120] Unfortunately, the majority of affected pets have insufficient portal development to permit complete acute shunt ligation at surgery, and ≈32-52% of dogs with EHPSS and <15% of dogs with IHPSS have tolerated complete shunt attenuation (Figure 284-12).[91,120-122] Therefore, a delicate balance remains: shunt attenuation in order to increase portal blood pressure sufficiently to encourage development of portal perfusion without causing excessive portal hypertension. If portal hypertension occurs acutely, the patient could develop ascites, intestinal congestion, diarrhea, hypoxemia, and possibly bowel death. If portal hypertension occurs more chronically, when the portal vasculature fails to develop, multiple acquired PSSs may develop. The introduction of progressive occlusion devices can reduce the risk of acute portal hypertension, but it remains unclear if these devices reduce the development of chronic portal hypertension and subsequent multiple acquired shunts. Reportedly, 40-50% of dogs redevelop clinical signs following partial ligation of EHPSS, months to years after surgery (not including gradual occlusion devices).[26,120,123] It is not clear if these dogs had a worse prognosis because of the partial attenuation or the reduced portal vascular development present at the time of surgery that prevented complete acute attenuation. Further, it is often unclear whether these dogs had persistent shunting or developed acquired PSSs.[91]

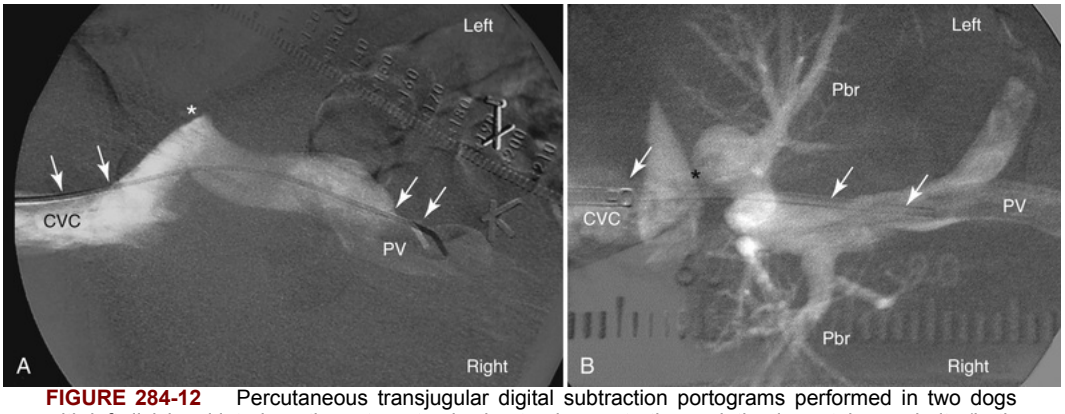

FIGURE 284-12 Percutaneous transjugular digital subtraction portograms performed in two dogs with left divisional intrahepatic portosystemic shunts, demonstrating variation in portal vascularity (both dogs in ventrodorsal position with head to the left). **A,** Portogram with catheter (arrows) through the shunt (*) and in the portal vein (PV) demonstrating the shunt entering the caudal vena cava (CVC) and no portal perfusion evident. **B,** Portogram with catheter (arrows) through the shunt (*) and in the PV demonstrating good portal perfusion via developed portal branches (Pbr) throughout the liver.

Following identification and careful dissection, the shunt is isolated and an encircling suture is placed as close to the systemic circulation (shunt termination) side as possible. Shunt attenuation in this location ensures that all portal vessels joining the shunt will be attenuated as well. Placement of the shunt occlusion on the portal vein side of the shunt (shunt origin) may permit continued shunting around the liver if any contributing branches are missed. The surgical procedure has been described in detail elsewhere.[123-131] It is important to note that following temporary shunt attenuation, intraoperative portal pressures >9-10 cm water above resting (preligation) pressures or absolute pressures >17-24 cm water have been associated with greater postoperative complications.[91,132,133] Clinical signs also have been used for determining if complete acute shunt occlusion can be tolerated. In one study, 11 of 12 nonencephalopathic dogs with clinical signs attributable only to ammonium biurate urolithiasis tolerated complete occlusion safely.[134] Animals with portal aplasia apparently are surviving due to hepatic arterial perfusion, often indicated by liver biopsies

describing hepatic arteriolar proliferation.[89,90] It is more likely that there is a wide spectrum of shunt size and portal vascular development in these pets, which would explain why a portion with PSSs have minimal clinical signs and can live long lives with or without medical therapy.

When performing surgery, complete abdominal exploration is indicated because animals with one congenital abnormality often have others. The urinary bladder should be carefully palpated to identify the presence of calculi that should be removed. Spay or castration is recommended. Liver biopsies have been recommended, though one study reported no ability to predict prognosis based upon preligation biopsy results alone.[89] The authors do not perform liver biopsies routinely; however, liver biopsy may be indicated when a macroscopic shunt cannot be identified with surgery or portography.

Extrahepatic Portosystemic Shunts

Following identification of the EHPSS, the surgeon may decide if complete attenuation is possible using portal pressure measurements, portal venography, and/or visual inspection. If complete acute shunt attenuation is possible, it is recommended; however, complete attenuation may increase the risk of the procedure.[91,120]

Gradual-occlusion devices, such as ameroid constrictors (ACs) and cellophane bands (CBs) have changed the way the majority of EHPSSs are managed. Historically, it was believed that the hygroscopic casein in ACs gradually absorbs peritoneal fluid, resulting in expansion that is concentric, not eccentric, due to a surrounding stainless steel ring (Figure 284-13). This produced complete shunt attenuation in 6/12 dogs at 1 month and an additional 3/12 dogs by 7 months of surgery.[128] However, different results, including partial occlusion and thrombosis, have been noted with ACs placed on dogs' iliac veins.[135] Furthermore, if shunt occlusion is too rapid (or if occlusion is affected by the amount of dissection needed for AC placement, the weight of the AC on the thin-walled PSS vessel, repeated resterilization of an AC,[136] or the size of the AC or extent of tissue reaction surrounding the AC[137]), multiple acquired PSSs could result, as has been reported in 17% of dogs following AC placement.[127,128] Reported complication rates are 7-20% and mortality rates are 0-17% following AC placement for EHPSS, with good to excellent outcomes in 94% of dogs and estimated median survival times of 152 months.[26,127,128,138,139] Dogs with incomplete shunt attenuation can still have a good prognosis: continued flow through the shunt after AC placement was identified in 21% in one study with good to excellent outcomes.[138] Compared with suture ligation, ACs have been demonstrated to reduce surgery times, as well as intraoperative complication rates.[138,140] With AC placement for EHPSS in dogs, CTA and perfusion scans have demonstrated smaller preoperative liver volumes to have the largest subsequent increases in volume, and hepatic arterial perfusion and portal scintigraphy both have correlated with successful shunt attenuation.[105]

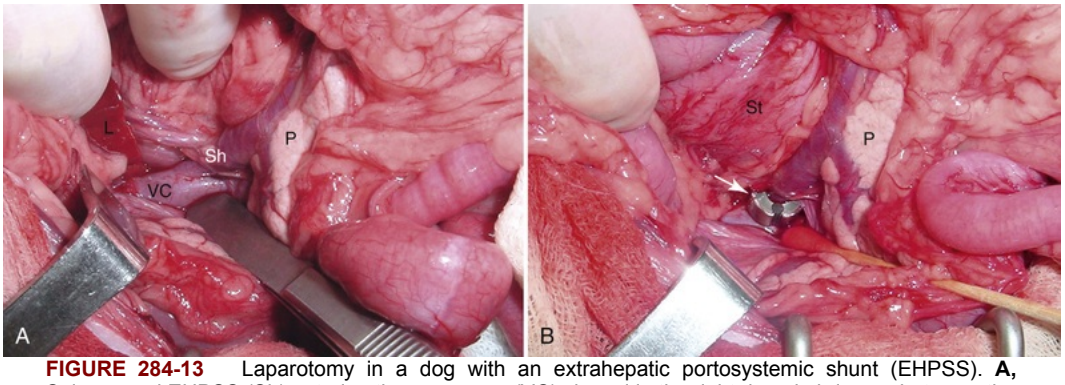

FIGURE 284-13 Laparotomy in a dog with an extrahepatic portosystemic shunt (EHPSS). **A,** Splenocaval EHPSS (Sh) entering the vena cava (VC) viewed in the right dorsal abdomen between the liver (L) and pancreas (P). **B,** The same dog following placement of an ameroid constrictor (arrow) at the shunt termination onto the VC. *St,* Stomach.

The alternative implant evaluated for gradual occlusion of EHPSS has been CBs. This inexpensive material is derived from plant cellulose and often is obtained from cigarette or giftwrap packaging. This material is inflammatory and causes progressive fibrosis around vessels. The material is easily sterilized and stored, lightweight (will not kink the PSS), and requires less dissection around the shunt. Recent evidence suggests

that most commercially available "cellophane materials" are not actually consistent with cellophane, the latter being distinguished from the others by visible striations (and confirmed using infrared spectroscopy).[141] The more progressive attenuation achieved with a CB in experimental studies[126] is hypothesized to reduce the incidence of acquired PSS.

Following shunt dissection and isolation, a three-layer folded piece of cellophane ≈3-4 mm in diameter is placed around the shunt and secured with hemoclips (Figure 284-14). Complete shunt occlusion appears to be possible without initial shunt attenuation during placement, and in fact partial attenuation at the time of CB placement could be associated with development of APSSs.[142]

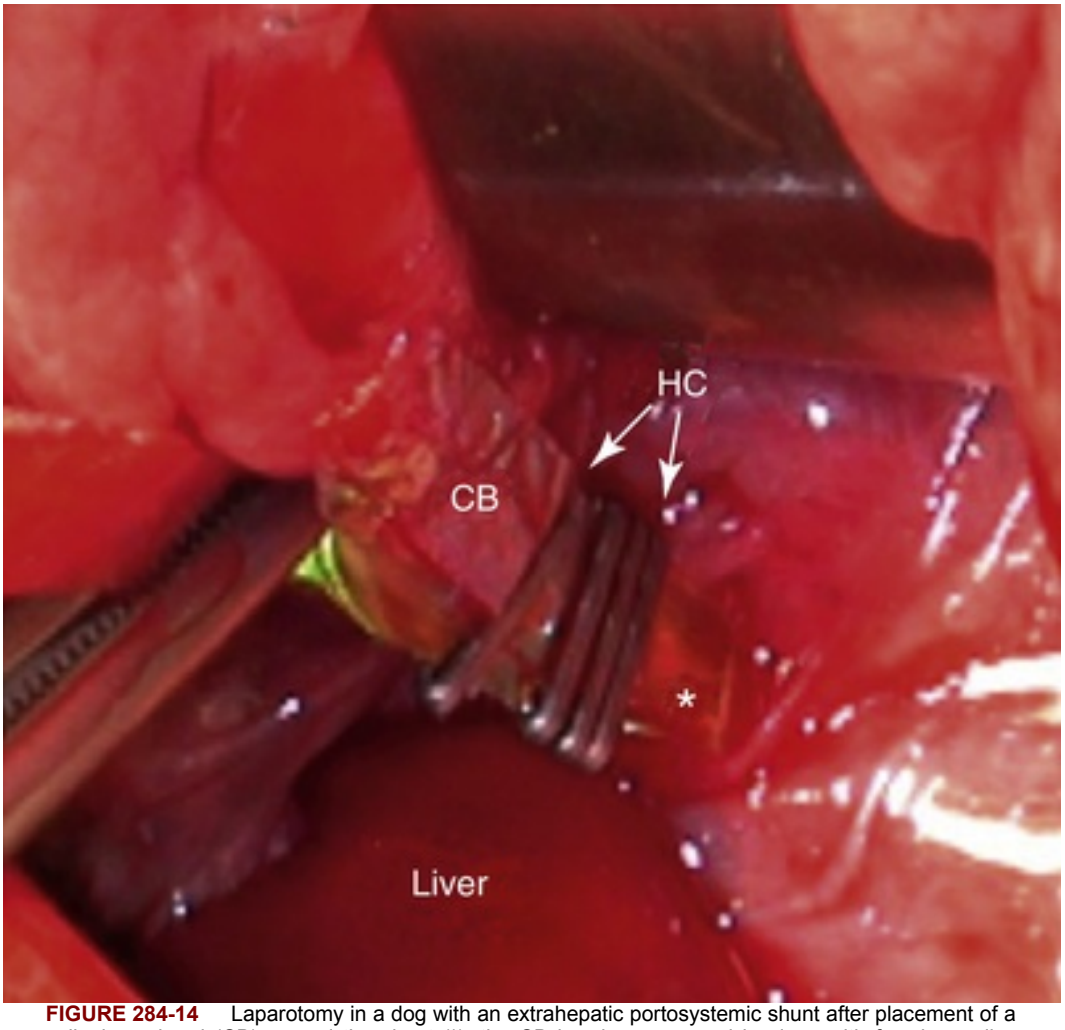

FIGURE 284-14 Laparotomy in a dog with an extrahepatic portosystemic shunt after placement of a cellophane band (CB) around the shunt (*); the CB has been secured in place with four hemoclips (HC). (Courtesy Dr. Eric Monnet.)

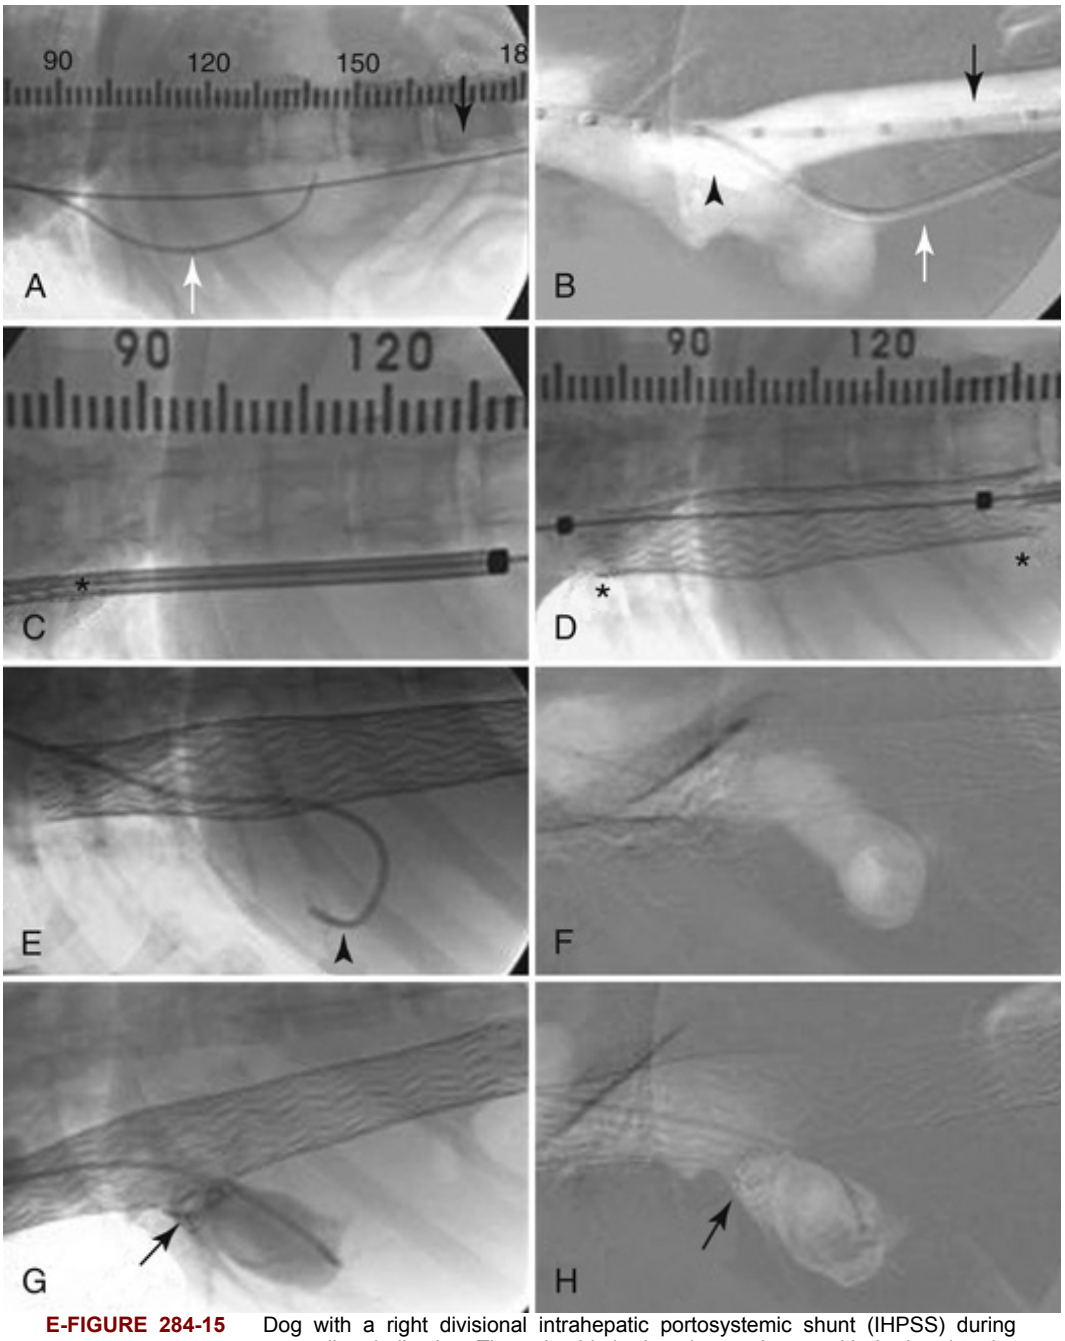
Complication rates are ≈10-13% and mortality rates 3-9% following CB of EHPSS, with good to excellent outcomes in ≈84% of dogs.[142,143] However, multiple APSSs were demonstrated in 3/16 dogs (19%) with elevated shunt fractions 6 weeks following CB placement.[144] In general, on review of the literature, it would seem that many dogs with PSSs can experience resolution of clinical signs with persistent shunting.[121,138,139,144]

Intrahepatic Portosystemic Shunts

Dogs and cats with IHPSSs represent a much more complex situation. These shunts typically are much larger, located within the hepatic parenchyma, and often are not readily apparent. Soft spots can occasionally be felt within the affected lobe where the often large IHPSS resides, but this may not help identify the ideal location for dissection. When treated surgically, left divisional shunts are commonly approached posthepatically

(cranial to the liver) because these often enter the left hepatic vein that enters the CVC at the level of the diaphragm. For right and central divisional shunts that often enter the CVC intrahepatically, the surgical approach is often performed prehepatically (caudal to the liver) in order to dissect the contributing portal vein branch (which typically is much larger than the left portal branch). Various preoperative (CTA, MRA) and intraoperative (portovenography) methods can help identify shunt anatomy. Surgical options include surgical dissection and attenuation with suture, AC, CB, or hydraulic occluder (HO), complete IHPSS occlusion with jugular venograft creation of an EHPSS, temporary hepatic inflow occlusion with intravascular dissection, and percutaneous transvenous coil embolization (PTCE) via the jugular vein (the latter described in detail in ch. 123) (E-Figure 284-15).[2,57,132,143,145-151]



E-FIGURE 284-15 Dog with a right divisional intrahepatic portosystemic shunt (IHPSS) during percutaneous transvenous coil embolization. The animal is in dorsal recumbency with the head to the left in each image. **A,** A guidewire (black arrow) is placed from the jugular vein, through the cranial and caudal vena cava (CVC) and extending down the CVC. A second catheter is extending from the jugular vein, through the cranial and CVC, the right hepatic vein, the portosystemic shunt, and into the portal vein (white arrow). **B,** An angiogram being performed under digital subtraction angiography fluoroscopy. Contrast material is in both the CVC and portosystemic shunting vessel. The mouth of the

shunt is apparent (arrowhead). Using a marker catheter (black arrow), the CVC measurements can be extrapolated for appropriate stent size selection. **C,** The constrained stent and delivery system (asterisk) are advanced over the wire and across the mouth of the shunt. **D,** The stent is then deployed in the selected location with each end confirmed to extend beyond the shunt (asterisks). **E,** The mouth of the shunt is again selected with a catheter (arrowhead). **F,** Repeat digital subtraction angiography confirms that the stent is covering the entire mouth of the shunt. **G,** Thrombogenic coils are placed through the catheter and into the shunting vessel (arrow) until portal pressures have increased sufficiently. **H,** Repeat digital subtraction angiogram is performed, and final portal pressures are recorded.

Surgical complication rates are substantially higher in IHPSS (29-77%) compared with EHPSS.[123,152] Mortality rates are 6-23% following ligation or 0-9% following placement of an AC, with good to excellent outcomes in ≈75-100% of dogs following ligation and ≈70-90% following AC placement.[147,153,154] Good to excellent outcomes were reported in only 50% of dogs that underwent CB with a 55% perioperative complication rate and a 27% perioperative mortality rate.[143]

Persistent shunting and unreliability of progressive occlusion devices led to investigating HOs, an adjustable silicone cuff placed around the IHPSS and attached to actuator tubing, and a vascular access port placed SC at the time of surgery (Figure 284-16). This device can be manually inflated with saline using a Huber needle placed transcutaneously into the port in the awake dog weeks to months after placement, as needed, to slowly inflate the cuff and progressively occlude the shunt.[155] Immediate survival was 100% for 10 dogs undergoing HO attenuation of intrahepatic shunts with a 20% intraoperative complication rate, and surgical revisions were needed in 3 of 10 dogs before device modifications were made. Resolution of clinical signs, and long-term survival, were documented in eight dogs,[155] but persistent shunting, APSSs, and/or hepatic dysfunction was suspected based on persistently elevated bile acids (4/8) and positive scintigraphy scans (5/8) 2 weeks following complete HO closure.[21,147,155,156]

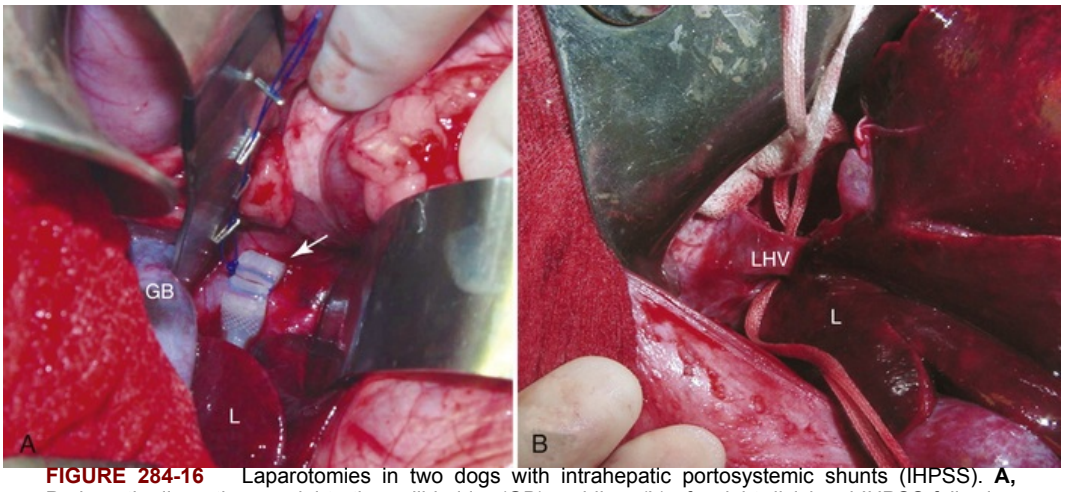


FIGURE 284-16 Laparotomies in two dogs with intrahepatic portosystemic shunts (IHPSS). **A,** Prehepatic dissection caudal to the gallbladder (GB) and liver (L) of a right divisional IHPSS following placement of a hydraulic occluder (arrow) secured in place with polypropylene suture. **B,** Posthepatic dissection of the left hepatic vein (LHV) between the liver (L) and diaphragm for a left divisional IHPSS before placement of a suture. Complications Following PSS Attenuation

Intraoperative complications typically are associated with anesthetic complications or hemorrhage during shunt dissection. Postoperative complications associated with PSS usually include neurologic abnormalities, acute portal hypertension, and persistent shunting (either through the original shunt or via the development of APSSs). Postoperative seizures not associated with HE or hypoglycemia have been reported in up to 12% of dogs.[118] Preoperative phenobarbitone appeared to reduce the severity but not the incidence of neurologic sequelae following shunt surgery in one study.[118] In another study, levetiracetam 20 mg/kg PO q 8 h for ≥24 h preoperatively significantly reduced the incidence of postoperative seizures in dogs with EHPSS.[113] Postoperative seizures occur in dogs and cats, are independent of the type of attenuation performed, can occur days later, and do not appear to be caused by the original HE. Reports are conflicting as to whether

older animals are at increased risk.[118,157,158] Possible explanations include the acute removal of endogenous benzodiazepines or changes in brain amino acid concentrations or ratios.[10,11,159] All patients having undergone surgery for PSS should be monitored closely for neurologic sequelae. There is no agreed-upon algorithm for treating these signs; however, intensive management should be instituted immediately with anticonvulsant therapy and/or propofol boluses (1-3.5 mg/kg IV) followed by propofol IV constant rate infusions (CRIs) (0.1-0.2 mg/kg/min or higher).[160] Phenobarbital loading is preferred because therapeutic plasma levels can be achieved rapidly and levels can be readily monitored. The concern over using a potentially hepatotoxic medication in a patient with a PSS is of less concern when the expectation is for short-term use. Recumbent, sedated, and possibly comatose pets are difficult to load with potassium bromide, and levetiracetam (Keppra) levels are not yet well understood or measurable in dogs.

Ventilation may be necessary in some pets and others can take weeks or longer to recover. Acepromazine has been reported to help decrease seizure activity in dogs without PSS, contrary to the previous concern of acepromazine decreasing the seizure threshold.[161] It has been used at low dosages (0.005-0.01 mg/kg IV) for postprocedural seizures. In general, the prognosis is considered poor; however, many can recover with time and aggressive supportive care. Recovery might not be complete and some could still display some degree of neurologic dysfunction in the long term. Reports have described 6 of 10 dogs and 9/11 dogs recovering completely following postligation neurologic dysfunction, albeit some incompletely.[118,143]

Some degree of portal hypertension can occur following acute partial or complete shunt attenuation as characterized by mild ascites with or without incisional drainage. Life-threatening forms, however, are fairly uncommon, particularly with the introduction of progressive attenuation devices. Worrisome postoperative signs include vomiting, abdominal distension, progressive ascites, abdominal pain, and hypotension. These can lead to shock and disseminated intravascular coagulation. Immediate removal of the attenuating device is recommended in those dogs and cats that do not respond to initial intensive supportive care; however, once clinical signs have been recognized, patient recovery is uncommon. The use of anticoagulants and/or thrombolytics postoperatively to prevent or manage these situations has not been sufficiently evaluated. Portal hypertension has not been a problem with the IHPSS PTCE technique in general.[21] This is likely due to the fact that shunt attenuation occurs post-sinusoidally at the shunt orifice on the CVC. Increased pressures generated at this location seem to be relieved through intrahepatic venous collaterals before (at lower pressures) pre-sinusoidal portal hypertension is experienced. This has the dual effect of reducing the risk of portal hypertension complications and reducing the likelihood of restoring complete hepatic portal flow without some degree of shunting; this may be a reasonable trade-off between risk and benefit and likely occurs with any type of IHPSS attenuation performed at this location. This phenomenon also likely explains the persistence of abnormal clinical, biochemical, and scintigraphic evaluations following what was perceived to have been a complete shunt occlusion at the time of the procedure using a variety of shunt attenuation techniques.[21]

Postoperative hypoglycemia (see ch. 61) and hypothermia (see ch. 49) usually can be prevented with appropriate patient care. Recently, hypoglycemia was reported in 44% of dogs following EHPSS surgery and approximately one third did not respond to dextrose supplementation. Some of these animals can respond to supraphysiologic glucocorticoid administration (dexamethasone 0.1-0.2 mg/kg IV once) as well as hastened anesthesia recovery. A relative glucocorticoid insufficiency (see ch. 133) has not been documented in these animals.[162]

Recurrence or persistence of clinical signs is the most common long-term complication seen after treatment of PSS. Many reports do not have sufficient long-term follow-up to know the true incidence of these problems. Recurrence of clinical signs suggests that the original shunt remains patent, another shunt was present originally, an incorrect vessel was attenuated, multiple acquired shunts have developed, concurrent hepatic parenchymal disease is present, or concurrent neurologic disease is present. Serum biochemistry and liver function tests can confirm this suspicion but additional imaging is needed to identify the cause. If imaging confirms shunt occlusion without APSSs, a presumptive diagnosis of PVH/MVD can be made.

Dogs with IHPSS have a separate but important additional potential complication: severe GI ulceration and bleeding, the most common cause of long-term morbidity and mortality in one case series.[21] Following the introduction of lifelong gastric acid-suppressing therapy in IHPSS dogs, mortality from GI ulceration in our cases decreased from 25% to 3.2%. There are many theories as to why GI ulceration occurs so commonly in dogs with IHPSS (e.g., hypergastrinemia, abnormal GI blood flow, hypoprostoglandinemia, poor mucosal integrity, abnormal mucus production, abnormal cell turnover). Hypergastrinemia does not seem to be the cause.

Surgical Management of Feline Portosystemic Shunts

Perioperative management of cats is similar to dogs; however, a higher frequency of neurologic signs both preoperatively and postoperatively, despite appropriate medical treatment, has resulted in use of anticonvulsant therapy preoperatively in cats. Levetiracetam or phenobarbital can be used, due to potential respiratory complications associated with the use of potassium bromide. Surgical management of PSSs in cats is technically similar to dogs in terms of shunt identification and methods of attenuation. Although some surgeons use suture ligation, most use AC or CB in cats even though there are some concerns regarding the feline inflammatory response to such devices being sufficient to consistently result in progressive fibrosis and occlusion of a shunt.

Like in dogs, the perioperative mortality rate for feline EHPSS is low.[56,163,164] Two critical differences between PSS management in cats (compared with dogs) are the high perioperative complication rates and the worse long-term outcomes, particularly due to continued neurologic sequelae. Complication rates have been approximately 37-60% (neurologic sequelae) following suture ligation, 8-77% following AC placement, and in 1/5 cats and 3/9 cats following use of CB.[56,143,163-166] Neurologic signs include seizures in 8-33% of cats and central blindness (usually transient) in up to 44%.[52,143,163-165] Lower intraoperative mesenteric portography scores (reduced portal perfusion) recently have been shown to be associated with a higher incidence of post-attenuation neurological complications.[166] A more recent, separate classification of splenosystemic shunts in cats has been described, predominantly identified in older spayed female cats often with concurrent hepatopathies that may have been associated with portal hypertension; this is a different population of PSS patients and therefore, treatments will vary accordingly.[167]

Outcomes must be interpreted with caution due to different follow-up durations; however, fair to excellent outcomes have been reported in 75% of cats following suture ligation, 25-75% following AC placement, and 66% and 100% (5/5) following CB placement.[52,143,163-165] Many cats have a good clinical outcome despite persistent biochemical signs of liver dysfunction: about 33-66% of cats have had abnormal liver function testing and 57% have had persistent shunting postoperatively.[143,163,164] The contrary is also true because some cats with persistent CNS dysfunction show normalized liver function test results.[56] In that same report, approximately one third of cats were euthanized within 1 year due to persistent CNS dysfunction following AC placement, despite most having normalized liver function test results.[56] IHPSSs are rare in cats, making predictions on outcome difficult. Feline IHPSS can be treated similarly with suture, AC, CB, or transvenous coil embolization.[56,143,145,163,164]

Surgical and Interventional Treatment of Hepatic Arteriovenous Malformations

HAVMs are rare vascular anomalies involving multiple arterial communications to the portal vein (Figure 284-17). Because they usually involve multiple, rather than single, communications with a central nidus, or "nest," the term *malformation* rather than *fistula* is appropriate. These communications are usually from the hepatic artery but also have involved the gastroduodenal artery, left gastric artery, and phrenic arteries. Angiography, CTA, or MRA helps identify the origin and course of these numerous vessels (Figure 284-18). Due to the high-pressure arterial blood shunting to the portal vein, there is severe, chronic portal hypertension (often with subsequent massive ascites) that results in multiple APSSs to decompress the portal vein, as discussed in detail earlier. Multiple APSSs have been observed in every dog with HAVM.

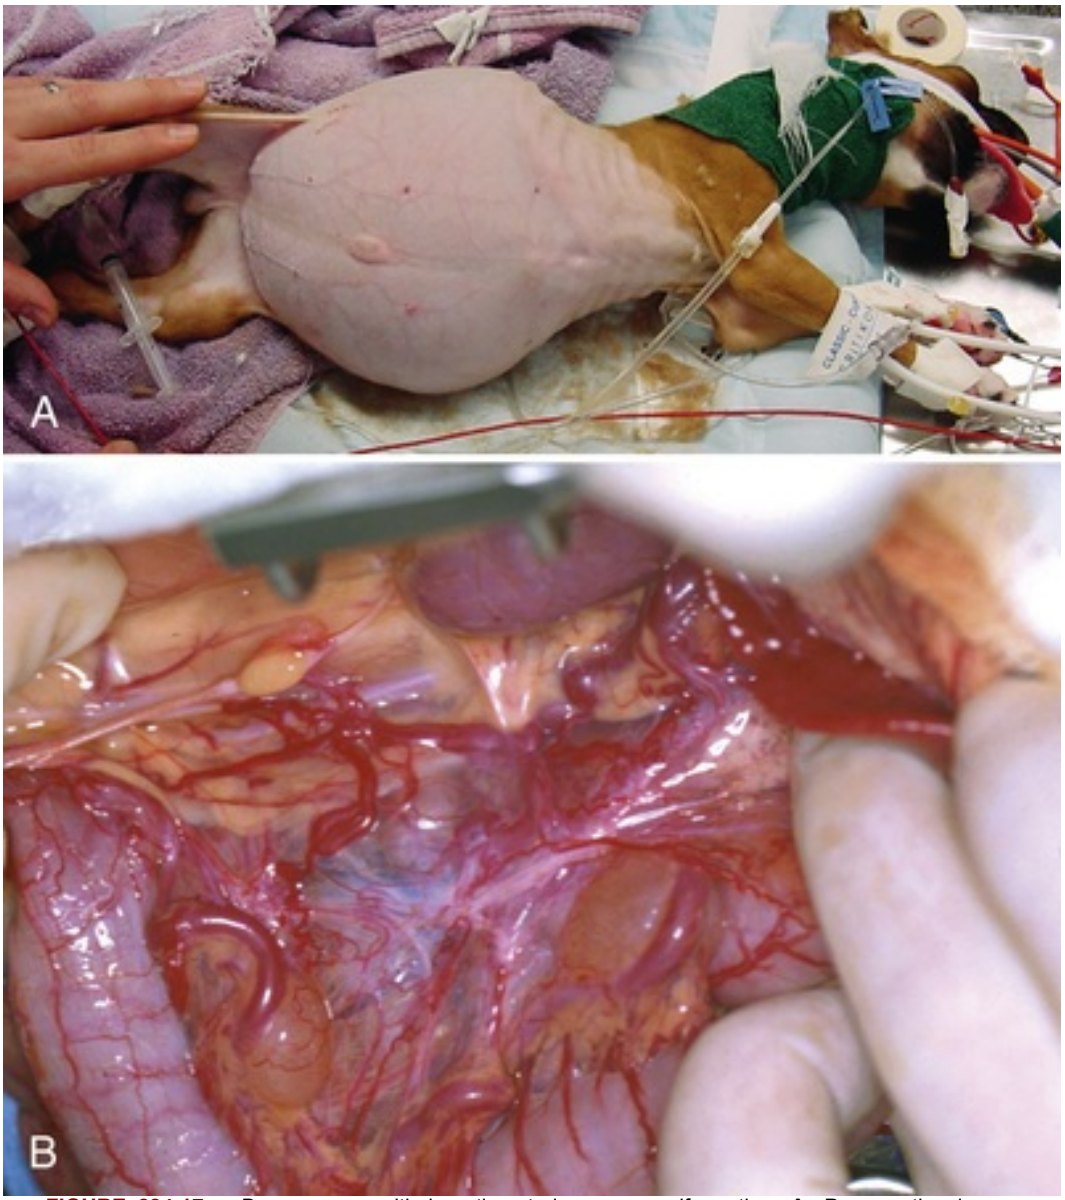

FIGURE 284-17 Boxer puppy with hepatic arteriovenous malformation. **A,** Preoperative image demonstrating severe abdominal distension due to ascites, and marked muscle wasting. **B,** Intraoperative image following abdominal fluid removal, showing multiple acquired extrahepatic portosystemic shunts resulting from severe portal hypertension.

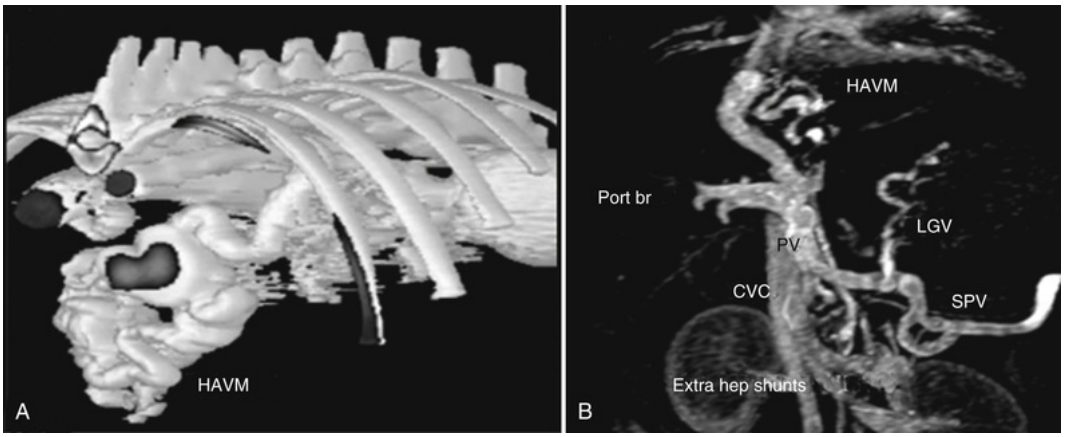

FIGURE 284-18 **A,** Three-dimensional reconstructed computed tomography angiogram of a dog with a hepatic arteriovenous malformation (HAVM). **B,** Magnetic resonance angiogram of a different dog with an HAVM demonstrating the left gastric vein (LGV), splenic vein (SPV), portal vein (PV), portal branches (Port br), caudal vena cava (CVC), and acquired multiple extrahepatic portosystemic shunts (Extra hep shunts).

Treatments for HAVM have included liver lobectomy, ligation of the nutrient artery, or fluoroscopically-guided glue embolization of abnormal arterial vessels.[24,168] Most HAVMs are located in the right or central liver lobes, and 25% have involved two lobes. Lobectomy can be challenging because of vascularity and proximity to the gallbladder and CVC (Figure 284-19). Temporary occlusion of the portal vein and celiac artery (and often the cranial mesenteric artery) is recommended during partial lobectomy to reduce intraoperative hemorrhage.[168] In addition, lobectomy may be contraindicated if the HAVM involves the majority of the liver parenchyma, because the remaining liver mass after arteriovenous malformation (AVM) resection might not provide sufficient hepatic function. For glue embolization of HAVM (E-Figure 284-20), the procedure is described in ch. 123. More recently the authors have been investigating venous occlusion of HAVM, as these vascular anomalies resemble the large pelvic AVMs in humans that can benefit from a venous (rather than arterial) embolization. The concept is that a single, proximal draining vein immediately distal to the AVM nidus will provide occlusion and such occlusion could be safer and more effective than attempting to embolize the innumerable small arterial feeding branches just proximal to the nidus. Although this approach is promising, only a single case has been treated to date.[169]

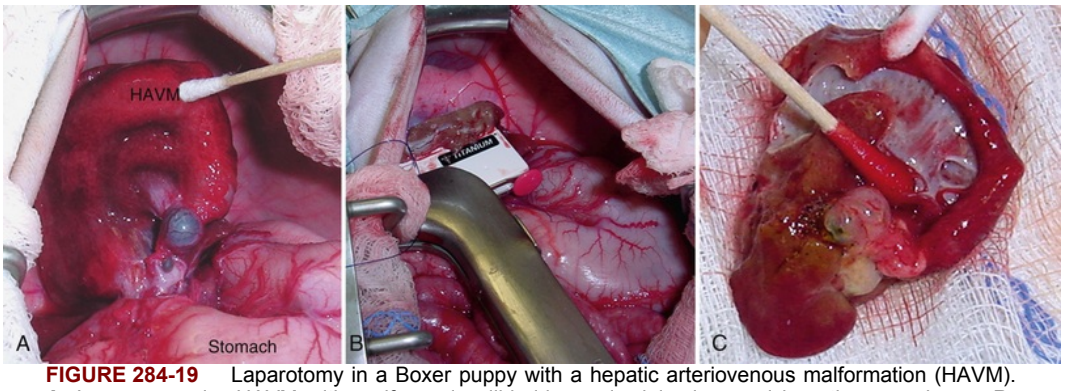

FIGURE 284-19 Laparotomy in a Boxer puppy with a hepatic arteriovenous malformation (HAVM). **A,** Large, vascular HAVM with malformed gallbladder and minimal normal hepatic parenchyma. **B,** Thoracoabdominal stapler across the base of the HAVM after stapling and excision of the involved lobe. **C,** Sectioned HAVM following excision demonstrating vascular dilations within the parenchyma.

E-FIGURE 284-20 Digital subtraction (DS) arteriograms in a dog with a hepatic arteriovenous malformation (HAVM) in ventrodorsal recumbency (with the head to the left) following placement of a 4-Fr catheter in the hepatic artery. **A,** DS hepatic arteriogram demonstrating enlarged hepatic artery (HA) and normal gastroduodenal artery (GDA) with large, vascular HAVM and little perfusion to the hepatic parenchyma. **B,** Repeat DS hepatic arteriogram following glue embolization of the HAVM demonstrating improved perfusion of the splenic (SA) and left gastric arteries (LGA) with reduced HAVM perfusion and appearance of a previously unidentified contributing vessel (arrows). **C,** DS arteriogram of contributing branch (arrows) demonstrating substantial HAVM filling. **D,** Repeat DS hepatic arteriogram following glue embolization of contributing branch confirming complete HAVM embolization.

Complications of surgery include hemorrhage, portal hypertension, systemic hypotension, bradycardia, and portal or mesenteric vein thrombus formation.[24] Perioperative survival was 100% in dogs undergoing glue embolization, with or without partial hepatectomy, and 75% to 91% of dogs undergoing surgery alone.[24] Long-term outcome was fair or good for 38% to 57% of dogs treated with surgery alone and 100% for a small number of dogs treated with glue embolization. Overall, 75% of dogs continue to require dietary or medical management of clinical signs due to patent acquired EHPSS.[24] Recurrence of arteriovenous communications can occur and recurrence of clinical signs has been seen requiring additional embolization procedures. Long-term survival is considered fair to good with this interventional technique, but too few cases have been performed to be certain.

Postoperative Care

After surgery or IR treatment, patients are maintained on IV fluids until they are eating and drinking. Dextrose is added to the fluids when blood glucose is <80 mg/dL. Patients are monitored for hypoglycemia (see ch. 61), hypothermia (see ch. 49), delayed anesthetic recovery, hemorrhage (see ch. 135), seizures (see ch. 35), and signs of portal hypertension. Animals usually require opioid analgesics such as buprenorphine for 1 to 3 days after surgery, although no analgesics have been necessary following PSS coil embolization. Sedation with a low dosage (0.005-0.02 mg/kg IV) of acepromazine might be necessary if dogs are vocalizing or showing abdominal splinting, as these activities will increase portal pressure. Acepromazine does not seem to precipitate seizures in dogs with shunts (and may even prevent them); however, it should not be used in hypotensive animals.[161]

A protein-restricted diet, antibiotics, and lactulose are continued after surgery until liver function improves.

Weaning protocols vary among surgeons and no ideal protocol has been demonstrated. Weaning may be further delayed for gradual occlusion devices, particularly the CB that has the slowest attenuation rate. Biochemical panels are evaluated 1 month after surgery. If liver functional parameters are normal, medical management is then weaned over 2-4 weeks. At 3 months, SBAs are evaluated in EHPSS dogs and cats. This is not routinely done in IHPSS dogs, or dogs with HAVMs, particularly if the patients are doing clinically well and are able to be weaned off of medical management because persistent shunting is common; instead, in these patients, preprocedural and postprocedural protein C levels have been monitored instead along with routine complete blood count and biochemistry values.[112] If bile acid concentrations are moderately increased, animals are rechecked 5 to 7 months after surgery. Some clinicians recommend supplementation with silymarin (milk thistle) or S-adenosyl-L-methionine because of their hepatoprotective and antioxidative effects (see Table 284-2); clinical studies of efficacy in animals with congenital PSSs or PVH are lacking.[171]

Patients are weaned off medical therapy typically 1 month after IR treatment, and this weaning process takes approximately 1-2 months starting with the metronidazole, then the lactulose, then transitioning to an adult maintenance food (see ch. 180). If this is all well tolerated, blood count and serum protein C and biochemical parameters improve (mean corpuscular volume; albumin, BUN, cholesterol, glucose), and no return of clinical signs occur, then the outcome is considered good, regardless of bile acids test results. It has been shown repeatedly that return of bile acids to normal after PSS attenuation is not necessarily correlated with long-term outcome.[26,83,120,152]

Prognosis

Prognostic indicators, outcomes, and survival are described in Table 284-3.[170]

TABLE 284-3

Reported Prognosis for Hepatic Vascular Anomalies

HEPATIC VASCULAR ANOMALY	PROGNOSIS
Medical management[45]	The **prognosis** for medical management alone is *guarded to poor* due to progressive hepatic atrophy and progressive clinical signs. **Prognostic indicators** for animals with medical management alone: age at onset of clinical signs (older → longer survival), BUN (higher level → longer survival). No correlation between survival time and bile acid levels, serum protein levels, albumin, ALP, ALT, or MCV.
EHPSS[26,52,67,83,121,125,138,142,143]	**Mortality rates:** 2-32% (ligation), 7% (ameroid constrictor placement), 6-9% (cellophane banding). **Age** has been shown *not* to be associated with long-term outcome: older dogs (>4 years) have done as well as younger dogs at the time of surgery. The most common **cause of death** after PSS attenuation is severe persistent neurologic signs. Other causes include intraoperative hemorrhage, postoperative coagulopathy, portal hypertension, and hemorrhagic gastroenteritis. In dogs undergoing **ameroid constrictor placement,** preoperative hypoalbuminemia has been associated with persistent postoperative shunting. **Other factors:** Preoperative hypoalbuminemia or leukocytosis, occurrence of seizures after surgery, and persistent shunting at 6-10 weeks after surgery are reported to be predictive of poor long-term outcome.
IHPSS[21,46,67,120,123,132,133,143,152,153,172-174]	Reported **median survival times** range between 1 and 3 years. **Better short-term outcome and lower risk of complications** have been noted in association with body weight (>10 kg), and total protein (>4 g/dL), serum albumin (>2.6 g/dL), and BUN (>7.4 g/dL) levels. **Better long-term survival** has been associated with higher PCV and total protein (>4 g/dL). **Poorer long-term outcome** has been associated with preoperative hypoalbuminemia or leukocytosis, occurrence of seizures after surgery, and persistent shunting at 6-10 weeks after surgery. **Postoperative complications** have been reported to be as high as 77% with

	surgery, with short-term mortality ranging from 11-28%. **Overall mortality rates** range from 23-63.6%. In dogs with IHPSS, postoperative serum bile acid levels returning to normal have *not* been associated with short- or long-term survival (have remained elevated in dogs with improved clinical signs, irrespective of complete or partial ligation). **Perioperative mortality during the PTCE procedure** has declined to <5%, with long-term mortality <30% (<15% since initiating lifelong gastric acid suppressant therapy). **Gastrointestinal (GI) ulceration and bleeding** is the most common cause of long-term morbidity and mortality in these patients. With lifelong gastric acid suppression therapy, mortality from GI ulceration has decreased from 25% to 3.2%.
HAVM24,169	**Survival:** Dogs with HAVM have had a periprocedural survival rate of 100% with glue embolization, with or without hepatectomy, and 75%-91% with surgery alone. **Long-term outcome** has been fair or good for 38-57% of dogs (surgery) alone and closer to 70% (glue embolization). Serial embolization procedures may be necessary as arterial tributaries open up. Overall, 75% of dogs continue to require dietary or medical management of clinical signs regardless of approach. It is possible that these patients could benefit from caval banding if the portal system is well-developed.
MVD/PVH25	**Survival:** 22/24 (92%) have had good long-term survival or have died of reasons unrelated to MVD.
NCPH23	**Survival:** 13/33 have survived long term (40%), but many were euthanized due to findings at surgery without attempting medical management. The overall prognosis should be considered favorable.
Feline PSS5,41,42,56,145,163,164,175,176	**Perioperative mortality rates:** 0-23% after attenuation. **Postoperative complications** are reported in up to 75% of cats. The most common are neurologic dysfunction, including generalized seizures and central blindness, which can resolve a few months after surgery. **Outcome.** Of surviving cats available for follow-up, good or excellent long-term outcome has been reported in 66-80% undergoing various attenuation techniques. Excellent outcome has been reported in 25% of cats with persistent shunting; conversely, continued or recurrent neurologic abnormalities have been reported in 57% of cats with normal scintigraphy or hepatic function tests. Persistent shunting is common in cats after the procedure, likely due to the development of multiple EHPSS. Despite the higher rate of complications in cats, the mortality rate is low, comparing favorably to dogs.
Acquired PSS3,5,22,23,173	**Ligation of the individual shunts** is *not* considered appropriate or effective since they are typically relieving portal hypertension. **Caval banding** (surgical constriction of the caudal vena cava cranial to the EHPSS) to redirect blood flow to the portal vein has been attempted. Complications that can occur include ascites, hindlimb edema, development of other portoazygos shunts, and persistent poor portal perfusion. Survival times in these cases, compared to those treated medically, are similar. **Multiple EHPSSs have been reported to occur after ameroid placement** in both dogs and cats for single congenital EHPSS in nearly 10%-20% of cases. Treatment should be aimed at controlling the clinical signs of HE and slowing the progression of the liver disease (typically hepatic fibrosis).

ALP, Alkaline phosphatase; *ALT*, alanine aminotransferase; *BUN*, blood urea nitrogen; *EHPSS*, extrahepatic portosystemic shunt; *HAVM*, hepatic arteriovenous malformation; *HE*, hepatic encephalopathy; *IHPSS*, intrahepatic portosystemic shunt; *MCV*, mean corpuscular volume; *MVD*, microvascular dysplasia; *NCPH*, noncirrhotic portal hypertension; *PCV*, packed cell volume; *PSS*, portosystemic shunt; *PTCE*, percutaneous transvenous coil embolization; *PVH*, portal vein hypoplasia; *SBA*, serum bile acid.

CHAPTER 285

Metabolic Diseases of the Liver

Penny J. Watson

Introduction

The liver is centrally involved in many metabolic pathways in dogs and cats (see ch. 280 and 281). It is therefore not surprising that the liver is affected by many metabolic diseases. There are notable species differences in many of the liver's metabolic pathways, which are particularly marked between cats and dogs. This could partly explain why the metabolic diseases seen in dogs and cats often are very different.

A metabolic hepatopathy could be defined as any insult to the liver due to accumulation of products of normal or abnormal metabolic pathways. This encompasses primary and secondary conditions and there is an overlap between these two. For example, a secondary, clinically insignificant accumulation of fat (steatosis) due to primary familial hyperlipidemia in a dog may be associated with development of gallbladder mucocele and clinically significant biliary stasis. Copper accumulation also can result in primary liver disease in true copper storage disease, or can be secondary to dietary overload and biliary stasis, but in both cases copper accumulation can lead to hepatocyte necrosis, particularly if accompanied by another insult such as nonsteroidal anti-inflammatory drug toxicosis.

Vacuolar Hepatopathies, Steatosis, Hyperlipidemia and Feline Hepatic Lipidosis

Introduction

The most common predominantly secondary metabolic hepatopathies in small animals are the vacuolar hepatopathies, where hepatocytes become loaded with fat (steatosis) or glycogen or water (hepatocellular swelling, or cloudy swelling).[1] There are histological features that help differentiate the types of vacuolation (Figure 285-1), but this can be challenging and special stains are necessary to be certain (periodic acid–Schiff [PAS] for glycogen and oil red O for fat). Several lysosomal storage diseases in dogs and cats also lead to hepatocyte vacuolation. Cloudy swelling occurs when hepatocytes are injured and less able to maintain fluid homeostasis. If hepatocyte swelling is severe and chronic, it can cause hepatocyte death, fibrosis, and even cirrhosis.

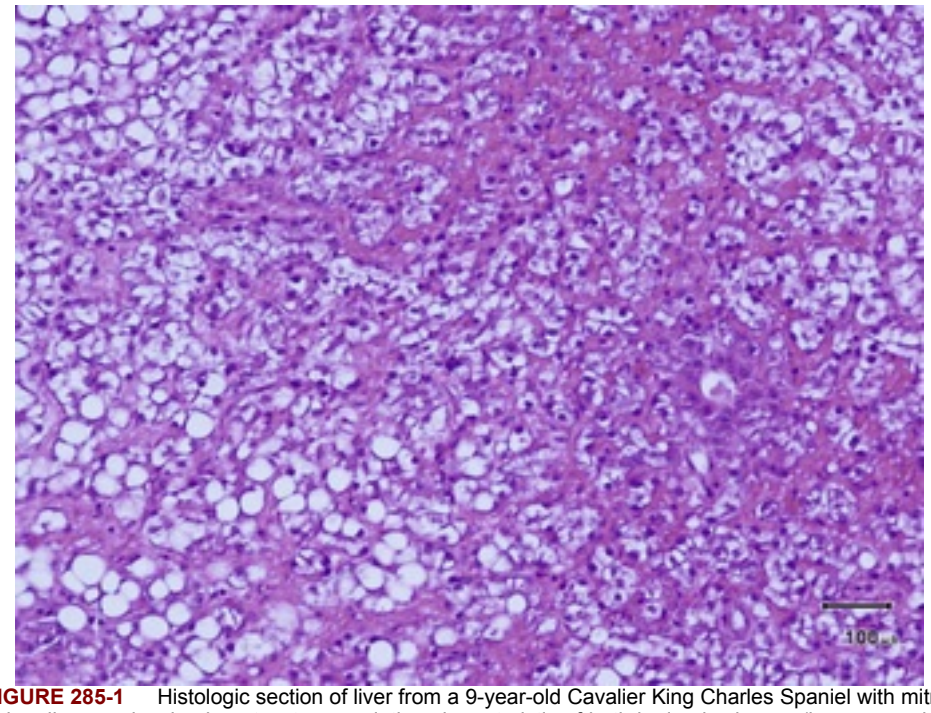

FIGURE 285-1 Histologic section of liver from a 9-year-old Cavalier King Charles Spaniel with mitral valve disease showing hepatocyte vacuolation characteristic of both hydropic change (lacey vacuoles; right-hand side of picture) and steatosis (cells with clear cytoplasm; left-hand side of picture). Special stains would be necessary to confirm this. The dog was on a number of medications for heart disease and a high-fat diet but the cause of the vacuolation was unclear. Hematoxylin and eosin stain ×100. (Image courtesy the Pathology Department; Department of Veterinary Medicine; University of Cambridge, UK.)

Many insults can cause vacuolar hepatopathy, such as hepatic hypoxia associated with right-sided congestive heart failure or intoxication (Box 285-1). Severe congenital cobalamin deficiency also has been reported to cause foamy vacuolation of hepatocytes, lipogranulomas, single cell necrosis, and mild fibrosis in dogs, possibly due to secondary hyperhomocysteinemia.[2] Therefore, "vacuolar hepatopathy" is not a diagnosis and is not always due to glucocorticoid excess; rather, this histologic finding should trigger a search for an underlying disease or intoxication (see ch. 286). The process is not always benign and reversible; in dogs, progression to overt hepatic dysfunction and death has been recorded,[3] and predisposition to hepatocellular carcinoma is possible in humans[4] and Scottish Terriers.[5]

Box 285-1

Causes of Primary and Secondary Vacuolar Hepatopathies in Dogs and Cats

Steroid Hepatopathy and Cloudy Change

- Steroid hepatopathy—secondary to high concentrations of circulating corticosteroids (exogenous or endogenous)
- Vacuolar hepatopathy of Scottish Terriers (overlap with steroid hepatopathy?)
- Deficiency or toxicosis, e.g., severe cobalamin deficiency in dogs
- Secondary to hepatic insult from another disease process, e.g., congestive heart failure, neoplasia, other hepatobiliary disease, gastrointestinal disease, renal disease, infectious disease

Steatosis

- Feline hepatic lipidosis—primary or secondary
- Toxicoses—for example, aflatoxin (dogs); vitamin A intoxication (cats)
- Secondary to canine familial hyperlipidemia
- Secondary to endocrine disease: hypothyroidism and diabetes mellitus (dogs); occasionally

hyperthyroidism (cats)

Steroid Hepatopathy

The distinctive hepatopathy seen in dogs receiving exogenous glucocorticoids or with hyperadrenocorticism was first reported in 1977.[6] Typically, hepatocytes become vacuolated with marked cytoplasmic, or even nuclear, increases in glycogen.[1] Vacuolation starts in the centrilobular region (zone 3) and becomes generalized when chronic.[7] The associated marked increase in serum alkaline phosphatase (ALP) is unique to dogs and it could be a result of delayed clearance of the intestinal isoenzyme due to hyperglycosylation in the liver under the influence of glucocorticoids, although it is unknown why this occurs in dogs and no other species.[8]

Steroid hepatopathy traditionally has been considered benign in dogs. However, the reported association between glycogen-like hepatopathy and hepatic remodeling and carcinoma in Scottish Terrier dogs, and between hyperadrenocorticism and gallbladder mucocele, suggests that all canine vacuolar hepatopathies should be taken more seriously, particularly when they are chronic and severe.

The most effective treatment for steroid hepatopathy is to remove the source of exogenous or endogenous glucocorticoids. Where this is not possible, antioxidants are indicated (see ch. 281). S-adenosylmethionine given to dogs with steroid-induced hepatopathy has increased total hepatic glutathione and had a beneficial effect on the oxidized : total glutathione ratio in hepatocytes, but had no effect on the histological appearance of vacuoles.[9]

Glycogen-Like Vacuolar Hepatopathy of the Scottish Terrier

A particular form of idiopathic vacuolar hepatopathy has been reported in Scottish Terriers in the USA and France. It is characterized by a marked increase in serum ALP and an apparently increased risk of hepatocellular carcinoma.[5,10,11] The syndrome is most common in middle-aged dogs (median age, 8 years [range 1-14 years]; mean age, 8.3 years), although dogs with hepatocellular carcinoma are older. There is no gender predominance. There is usually a moderate to marked elevation in serum ALP and a milder increase in alanine aminotransferase (ALT) and nearly half of affected dogs show clinical signs suggestive of hyperadrenocorticism (hepatomegaly; pot-bellied appearance; polydipsia and polyuria). However, the results of adrenal function testing are variable: there is an inconsistent cortisol response to adrenocorticotropic hormone (ACTH) stimulation testing and low-dose dexamethasone suppression testing, and 5/7 dogs showed normal results of urine cortisol : creatinine ratio testing in one study (also see ch. 306).[5] The most consistent endocrine abnormalities in affected dogs are increases in progesterone and androstenedione post-ACTH stimulation. Adrenal glands were enlarged on ultrasound in 26% of cases. Gallbladder mucocele was reported in 16% of cases.[5] Ultrasonographically, the liver most often has a mottled or coarse appearance. The development of hypoechoic nodules appears to mirror hepatocyte death and collapse histologically.[5] Affected dogs appear to respond poorly to traditional treatments for hyperadrenocorticism, with severe side-effects reported with mitotane or ketoconazole and lack of efficacy of trilostane. Current treatment recommendations are therefore unclear, apart from regular monitoring with ultrasound for development of hepatocellular masses or mucocele and surgery as necessary. It would make sense also to give affected dogs antioxidant supplements, particularly S-adenosylmethionine, given the reduction in oxidized glutathione reported with S-adenosylmethionine supplementation in other vacuolar hepatopathies in dogs.[9,12]

Hepatic Steatosis

Accumulation of fat within hepatocytes is termed *steatosis* (or lipidosis or fatty change by veterinary pathologists). Steatosis is the preferred term as it is used in human medical and toxicology textbooks and avoids confusion with the clinical syndrome of hepatic lipidosis in cats.[1] In routine, formalin-fixed sections, fat appears as clear vacuoles in the cytoplasm because lipid is lost in processing. Demonstrating fat with special stains therefore requires frozen sections. Microvesicular steatosis describes multiple vacuoles that are smaller than the cell nucleus and it is typical of diabetes mellitus in dogs (see Figure 285-1). Macrovesicular steatosis describes larger vacuoles, which often displace the nucleus to the periphery of the cell. Feline hepatic lipidosis usually is associated with a mixture of micro- and macrovesicular steatosis[1] (Figure 285-2).

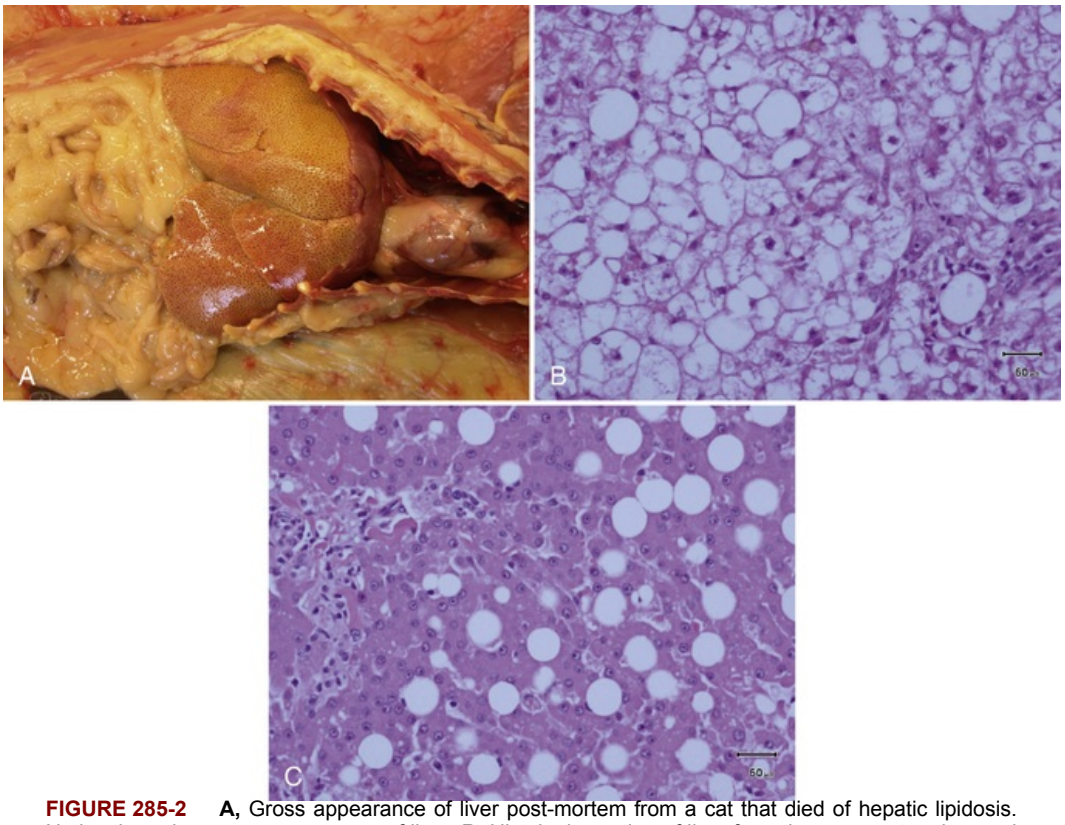

FIGURE 285-2 **A,** Gross appearance of liver post-mortem from a cat that died of hepatic lipidosis. Notice the pale orange appearance of liver. **B,** Histologic section of liver from the same cat as in panel A, showing marked steatosis of hepatocytes. Hematoxylin and eosin stain ×200. **C,** Histologic section from a different cat showing prominent Ito (stellate) cells. Note the large cells with pale cytoplasm and peripherally placed nucleus. Surrounding hepatocytes appear normal. This is a common response to hepatic insult or increased vitamin A in the diet and should not be confused with hepatic lipidosis. (Images courtesy Fernando Constantino-Casas, the Pathology Department; Department of Veterinary Medicine; University of Cambridge, UK.)

Steatosis can occur as a result of hepatocyte injury (fatty degeneration), as with aflatoxicosis in dogs.[13] Chronic vitamin A intoxication in cats results in hypertrophy of lipid-laden hepatic stellate cells with or without hepatocellular steatosis and fibrosis.[1,14] Steatosis also has been reported in dogs with congenital portosystemic shunts, although it is apparently of no prognostic significance post-ligation.[15,16] Hepatocyte steatosis also occurs secondary to a number of primary or secondary disorders of fat metabolism in dogs and cats (see ch. 182). In cats with hepatic lipidosis, this fat accumulation is severe enough to cause inhibition of hepatocyte function and an acute, reversible liver failure (see Feline Hepatic Lipidosis, below). However, in dogs, although hepatic steatosis can become very marked in such diseases as diabetes mellitus, it is not believed to result in inflammatory liver disease and liver failure. This is in contrast to humans where non-alcoholic liver disease and steatohepatitis is an increasingly important cause of progressive liver disease, cirrhosis, and liver failure. Fat metabolism differs in important ways between dogs and humans (see ch. 182) —notably, dogs are very resistant to atherosclerosis and do not develop the triad of hyperlipidemia, hypertension, and type 2 diabetes known in humans as the metabolic syndrome.[17] This might partly explain why dogs are so resistant to progressive hepatic failure with steatosis.

Feline Hepatic Lipidosis

Introduction

Feline hepatic lipidosis (FHL) was first reported in 1977 in two cats in the USA.[18] Many reports followed in the USA but it remained uncommonly reported in Europe. However, more recently, the recognition of FHL has been increasing in Europe, where the secondary disease appears to be more common than the primary idiopathic disease. The reasons for the changing epidemiology are unclear. FHL has been defined as "a diffuse involvement of >50% of hepatocytes with cytoplasmic vacuoles consistent in appearance with lipid."[19] Cats have a propensity to develop mild to moderate hepatic steatosis when anorexic for any reason and also

in response to toxic hepatic insults. It is important to differentiate this mild steatosis from true hepatic lipidosis. It is also important to differentiate lipidosis of hepatocytes from Ito cell proliferation (Figure 285-2).

Pathophysiology

Although the pathophysiology is still poorly understood, obesity, anorexia, and stress are important predisposing factors. FHL is reported in two forms: primary idiopathic and secondary. The primary form occurs in overweight cats that have been fasted for a prolonged period of time but have no identified underlying disease. The period of fasting and degree of obesity required to produce the disease seem to be variable. In one study, cats developed hepatic lipidosis after more than 25% weight loss.[19] In another study, six obese laboratory cats developed FHL after 6-7 weeks of anorexia and a 30-40% loss of body weight.[20] Secondary FHL is recognized in association with another disease, particularly cholangitis, pancreatitis, inflammatory bowel disease, neoplasia, diabetes mellitus, or hyperthyroidism.[19,21,22] In both primary and secondary disease, it is proposed that fasting combined with stress increases peripheral lipolysis and that there is a bottleneck effect in the liver, such that the mobilized lipids become trapped, with reduced export. Cats with FHL have elevated circulating triglycerides and non-esterified fatty acids, consistent with lipolysis of peripheral fat and reduced function of hormone sensitive lipase.[23] The triglyceride content of a normal cat's liver is 1% whereas it increases to 43% in a cat with FHL[24] (see Figure 285-2). They also have higher serum beta-hydroxybutyrate levels than do normal cats, indicating hepatic ketogenesis.[25] The cat is still able to mobilize triglycerides from the liver to some degree, as demonstrated by studies showing significant increases in very low-density lipoproteins in the serum of cats with FHL.[25] It is proposed that they cannot remove triglycerides fast enough to compensate for the marked increase in mobilization. The reason for this imbalance remains unclear, as does the reason why some cats appear to be more susceptible than others. It has been suggested that concurrent protein deficiency and negative nitrogen balance associated with fasting reduce the ability to produce apoproteins to export fat from the liver and that taurine and carnitine deficiencies contribute to the pathogenesis, although the experimental evidence for these effects is limited.

Circulating insulin concentrations of cats with FHL are normal or reduced, suggesting affected cats are not insulin-resistant[23,26] which also contrasts with the situation in human non-alcoholic fatty liver disease (NAFLD). When obesity is induced experimentally in cats, they do develop insulin resistance and high insulin concentrations, but this is then replaced by low insulin levels during anorexia and the development of FHL. It is also notable that it takes many months to induce obesity in cats with dietary manipulation, but only a few weeks of fasting an obese cat to cause FHL.[27] A recent study showed that affected cats have high adiponectin and leptin concentrations.[26] This, too, contrasts with humans with NAFLD, where adiponectin is reduced. High leptin concentrations should result in reduction of the lipid content of non-adipose tissues like liver, so affected cats must be leptin-resistant.

The resultant marked steatosis of hepatocytes interferes with the metabolic activity of the cells and produces a secondary cholestasis due to compression of small intrahepatic cholangioles. Thus, the result is a form of acute (potentially reversible) liver failure, with severe clinical signs and effects on hepatic function. This acute clinical syndrome associated with hepatic lipidosis in cats is in marked contrast to humans and dogs where hepatic steatosis occurs but does not result in liver failure. Clinical signs in humans only occur late in the disease process when the disease becomes inflammatory (steatohepatitis).

Signalment and Clinical Findings

Clinical studies report an increased prevalence of FHL in younger to middle-aged female cats. Most, although not all, affected cats are reported to be obese prior to the onset of a period of anorexia and then the disease. Idiopathic cases tend to be younger than secondary cases.[19,23] Clinical signs are typical of acute-onset hepatic insufficiency with vomiting, anorexia, weakness, and weight loss. Hypersalivation and depression occur, likely as manifestations of hepatic encephalopathy, whereas other manifestations of encephalopathy are uncommon. On physical examination, affected cats usually have palpable hepatomegaly and jaundice. Dehydration is common and evidence of recent weight loss usually is apparent, with loss of body mass over the spine but retention of inguinal and abdominal fat typical of weight loss in cats. The falciform fat pad typically is retained and can be seen on abdominal radiographs.

Diagnosis

The diagnosis relies on results of hepatic biopsy, but the history and typical clinicopathologic and imaging

findings increase the index of suspicion of FHL. Serum biochemistry results typically reveal moderate to marked elevations in bilirubin, ALP, and ALT, while in primary cases, gamma-glutamyl transferase (GGT) typically is normal. Finding a marked elevation in ALP with normal or only mildly elevated GGT in a cat increases the index of suspicion for FHL rather than biliary tract disease.[19] However, a cat with severe secondary FHL also can have a very elevated GGT if it has concurrent disease with biliary stasis (e.g., pancreatitis, cholangitis). Hypokalemia is a common finding, due to prolonged anorexia and vomiting, and has been reported as a poor prognostic indicator.[19] Hyperglycemia is common (40-50% of cats) but usually is transient.[19,23] However, since diabetes mellitus is a reported predisposing factor for secondary FHL, this must be carefully differentiated, such as with measurement of serum fructosamine and serial monitoring of blood glucose during treatment. Moreover, if the cat has ketosis it is likely to have diabetes mellitus. Coagulation times are prolonged in about half of affected cats but clinically significant bleeding is rarely reported.[19]

Abdominal ultrasound examination usually shows a diffusely hyperechoic liver that is more hyperechoic than the adjacent falciform fat. Visualization of hepatic blood vessels may be reduced. Ultrasound also allows assessment of other organs for concurrent disease, particularly the pancreas. In one study assessing diagnostic accuracy of ultrasound for liver diseases in dogs and cats, FHL had the highest accuracy with a correct diagnosis in 50-71% of cases, depending on the ultrasonographer.[28] Obese cats without lipidosis can have a hyperechoic liver[29] so the sonographic appearance should be interpreted along with clinical and clinicopathological findings.

Definitive diagnosis requires histologic assessment of a tissue biopsy. Ideally, an ultrasound-guided core biopsy (see ch. 89) or a wedge biopsy (see ch. 91) should be taken to rule out significant underlying disease. Fine-needle aspiration (FNA) with cytologic evaluation of smears has been unreliable in some cases and can even lead to a false diagnosis of FHL in a cat with hepatic lymphoma or cholangitis.[30,31] In these cases, it is probable that FHL is present but as a secondary change to an underlying severe liver disease. However, taking a biopsy requires normalization of coagulation times and general anesthesia, which carries an increased risk in the acutely sick cat. An FNA of the liver can be taken quickly and safely, either with ultrasound guidance or blindly under digital guidance if there is palpable hepatomegaly. Blind aspiration should be performed on the left side to avoid puncturing the gallbladder. If cytologic features of smears are strongly suggestive of FHL, the cat can be treated appropriately including intensive feeding. If the cat fails to respond as expected to treatment, then a biopsy should be taken when the cat is stable. The clinician and owner should be aware of the increased risk of liver biopsies in cats with FHL: coagulation times should be normalized first, and if an ultrasound-guided biopsy is undertaken, the use of semi-automated biopsy guns should be avoided because fatalities have been reported in cats when these are used.[32] Laparoscopy or laparotomy for wedge biopsies are the preferred techniques, not least because the liver can be monitored for hemorrhage and the pancreas and other organs can also be inspected for abnormalities. The liver is friable with hepatic lipidosis and in one study of 195 dogs and 51 cats undergoing various biopsies of abdominal organs in one institution, only 3 animals had major post-biopsy complications: two were cats and both had FHL.[33]

Treatment

The single most important factor affecting prognosis in cats with FHL is early intensive feeding, which usually requires some form of tube feeding (see ch. 82). Without assisted feeding, the mortality rate in affected cats has been up to 90%, whereas with the institution of intensive dietary management, mortality has fallen to 40% or lower.[19] Appetite stimulants are not indicated in cats with FHL because they are not effective enough and cats with FHL will not reliably resume voluntary feeding. Rapid institution of tube feeding in one study resulted in a survival rate of 6/7 cats (86%).[20] Another study identified that mortality was slightly higher in cats with secondary FHL compared with primary FHL, which could reflect a delay in instituting tube feeding.[19] It is equally important to institute early, intensive nutritional management in cats with secondary disease as with primary disease. However, it is also important to identify and treat any underlying disease in these cats as well.

Tube feeding can be commenced within 12 hours as soon as fluid and electrolyte imbalances have been addressed (see ch. 82 and 180). Nasoesophageal tube feeding is useful in the short term because it has the advantage of not requiring general anesthesia for placement. However, a more permanent tube such as an esophagostomy or gastrostomy tube will need to be placed once the cat has stabilized since spontaneous return to voluntary food intake takes at least 12-16 days and often longer.[20] Feeding should be introduced slowly using as high a protein-content diet as possible. High-protein diets are the most effective at reducing

hepatic lipid in experimentally induced FHL.[34] There is a significant reduction in stomach volume in cats after prolonged fasting.[35]

In the acute stage, cats almost invariably will need intravenous fluid therapy (see ch. 129) to reverse dehydration and correct electrolyte abnormalities, particularly hypokalemia (see ch. 68). Addition of potassium chloride to the tube feed is also wise and potassium or sodium phosphate may need to be added if the serum concentrations fall on re-feeding. The re-feeding syndrome has been reported in a tube-fed cat with FHL, with a precipitous drop in serum potassium and phosphate resulting in hemolysis, so these parameters should be monitored carefully in affected cats.[36] Some authors also recommend adding other nutrients to the tube feed, such as B vitamins, carnitine, and taurine, but there is no evidence that routine addition of extra nutrients to feline critical care diets is necessary. However, it is wise to measure serum cobalamin in affected cats because it may be low, particularly in cats with concurrent gastrointestinal disease. Parenteral supplementation of cobalamin is recommended if it is deficient. There is strong evidence that affected cats have systemic and hepatic oxidant injury; therefore, supplementation with antioxidants such as S-adenosylmethionine (20 mg/kg PO q 24 h on an empty stomach, or 100-400 mg/cat/day) and vitamin E (ideal dosage unclear, but 100 IU PO daily is convenient) is wise.[12] Affected cats often have prolonged coagulation times and these normalize with parenteral vitamin K treatment. Supportive therapy may also be necessary: antiemetics if the cat is vomiting, with maropitant being an ideal choice because it also has an anti-nausea effect. Prokinetics might be necessary if there is delayed gastric emptying after tube feeding. Ranitidine is a good initial choice because of its prokinetic cholinergic action and it can be given intravenously.

A small number of cats can develop clinically significant hepatic encephalopathy (HE), which needs to be managed. This aspect of treatment is discussed in ch. 281, 283, and 284. Current advice for treatment of cats with FHL and HE is not to feed a reduced-protein diet, but to reduce the amount fed; feed in smaller, more frequent meals; and institute therapies for any concurrent inflammatory disease.

Canine Hyperlipidemia

Hyperlipidemia is defined as an increase in either triglycerides or cholesterol in the serum or both.[37-55] Lipid disorders are described in ch. 182.

Gallbladder Mucocele

A gallbladder mucocele describes cystic mucinous hyperplasia of the gallbladder wall with accumulation of thick mucus.[41,56-64] First reported in dogs in 1995,[56] they are uncommon but appear to be increasing in frequency and show an association with vacuolar hepatopathies.[57] This disorder is covered in ch. 288.

Superficial Necrolytic Dermatitis

Introduction and Pathophysiology

Superficial necrolytic dermatitis (hepatocutaneous syndrome, metabolic epidermal necrosis, necrolytic migratory erythema) is an uncommon but very characteristic hepatopathy that is assumed to be secondary to an underlying metabolic disorder. The resulting hepatic and cutaneous changes are characteristic and much more severe and serious than those associated with the common secondary vacuolar hepatopathies reported with many endocrinopathies. In humans, most cases have a glucagon-secreting tumor and concurrent diabetes mellitus (DM). A few dogs have been reported with glucagonomas, which are usually metastatic,[65-67] and one case has been reported in a dog with an insulinoma.[68] However, in most canine cases, there is no identifiable mass, serum glucagon concentration is normal, and the cause remains obscure. Superficial necrolytic dermatitis also has been reported in 11 dogs being treated with phenobarbital,[69] although the contribution of the antiepileptic to the disease was unclear in this retrospective study and the response to stopping treatment was not known.

The characteristic features are typical histologic findings on skin biopsies and the characteristic appearance of the liver on ultrasound. The underlying pathogenesis of the skin lesions appears to involve amino acid deficiencies. Low serum amino acid concentrations have been found in all affected dogs in which they have been measured.[66,67,70] Zinc and fatty acid deficiencies also are implicated and, in humans, multiple deficiencies have been identified, including B vitamins. Deficiencies are proposed to be due to upregulated hepatic metabolic activity under the stimulus of increased glucagon activity, or to an unidentified stimulus in

dogs with normal glucagon concentrations.[71]

Clinical Presentation

Superficial necrolytic dermatitis most commonly affects older, small-breed dogs, although it has been reported in a variety of breeds including Golden Retrievers and Border Collies. In one study, 75% of affected animals were male with both mean and median age of 10 years and a range of 5 to 15 years.[70] Affected dogs usually present because of the skin lesions: typical lesions are hyperkeratotic, erythematous, crusting lesions particularly on the extremities (paw pads, nose, periorbital and perianal regions), around the genitals, and often on pressure points. Lesions often develop fissures and become secondarily infected with bacteria and are painful. Dogs may also show signs of diabetes mellitus (DM) which affects between 25 and 40% of cases, although DM often develops later in the disease. In humans, it is proposed that DM develops due to the marked insulin resistance caused by high circulating glucagon concentration. In dogs with normal glucagon concentrations, the cause of DM is unclear. Presentation because of clinical signs of liver disease is uncommon. In cases with glucagonoma, dogs may also present with clinical signs of metastatic neoplasia.

Dogs with superficial necrolytic dermatitis associated with phenobarbital treatment also have been older, with a median age of 10 years. In one study, dogs had been receiving phenobarbital for a median duration of 6 years before developing lesions.[69]

Diagnosis

The diagnosis is made on the basis of skin biopsy results, ruling out other causes, and the typical appearance of the liver on imaging and histology. Skin biopsies show typical parakeratotic hyperkeratosis with inter- and intracellular edema, which results in a classic "red, white, and blue" appearance on hematoxylin and eosin–stained sections of skin. The only differential diagnosis for this is zinc responsive dermatosis, which can be ruled out on the basis of breed and diet history (see ch. 10 and 186).

On the serum biochemistry profile, elevations of ALP and ALT are common and about half of reported cases have hypoalbuminemia, suggestive of negative nitrogen balance. Hyperglycemia and glucosuria are recognized in those cases with concurrent diabetes mellitus.

Ultrasound of the liver demonstrates a very characteristic Swiss cheese–like appearance, with variably sized, hypoechoic nodules surrounded by hyperechoic borders.[72] This corresponds histologically to nodular areas of normal hepatocytes surrounded by zones of collapsed parenchyma with vacuolated hepatocytes. With glucagonoma or other pancreatic tumor, the primary mass and metastases may be visible on ultrasound, but histologic evaluation with immunohistochemical stains are necessary to identify the tumor type.

Treatment

Superficial necrolytic dermatitis carries a poor prognosis in most dogs, with death or euthanasia often reported within 6 months of diagnosis. Cure is very unusual: there is a report of resolution of skin lesions after complete removal of a pancreatic tumor. Another case with metastatic glucagonoma was controlled for 6 weeks with subcutaneous octreotide injections, although the dog was then euthanized because of signs related to the tumor.[65] It is unknown whether cessation of phenobarbital therapy and replacement with an alternative anticonvulsant would resolve superficial necrolytic dermatitis in those cases associated with phenobarbital therapy.

In most cases, where no underlying cause is identified, treatment is supportive. The most important consideration is an ample supply of amino acids, because the disease is associated with amino acid deficiency. Proprietary hepatic diets therefore are not indicated, as they are protein-restricted. Ideally, a high-quality, digestible, high-protein diet should be fed, such as a food designed for gastrointestinal disease or convalescence. Supplementation with extra zinc and essential fatty acids is also often recommended. Some authors report administering weekly parenteral amino acid treatment although there are too few cases treated to give evidence for the efficacy of this approach. Feeding egg yolks has been reported to be beneficial in humans and in one dog that was fed a daily egg yolk together with hepatic support diet, essential fatty acids, and colchicine. The skin lesions resolved and the dog was well 22 months after presentation.[73]

Supportive treatment of skin lesions should include appropriate antibiotics for secondary infections, topical shampoos, and analgesia. The use of corticosteroids should be avoided if at all possible because of the risk of precipitating diabetes mellitus.

Superficial Necrolytic Dermatitis in Cats

Superficial necrolytic dermatitis is much less commonly reported in cats than in dogs. Of five reported cases, 3 had pancreatic tumors, suggesting a pathophysiologic mechanism similar to that of humans.[74,75] Presentation and diagnosis are similar to dogs.

Hepatopathies Caused by Excessive Normal or Abnormal Storage of A Metal or Metabolite

Copper and the Liver

Excessive accumulation of copper within the liver is an important cause of chronic hepatitis in dogs[76-79] and to a lesser degree in cats.[80,81] This process is described in ch. 281 and 282.

Iron Overload: Hemochromatosis

Iron overload in the liver, or hemochromatosis, also can occur as either a primary or a secondary condition. Iron is not excreted in bile, so secondary disease will occur if there is increased absorption in the intestine, abnormal excretion, or increased hepatic storage secondary to red cell hemolysis.

Primary hemochromatosis is relatively common in humans and is inherited in an autosomal recessive manner. More than 90% of cases in Northern Europe are due to one mutation, which can be traced back to Celtic ancestry. Iron accumulates periportally, leading to fibrosis and hepatic lesions. This contrasts with reports in dogs and cats, where increases in iron are very commonly reported in the liver, but are always secondary and do not appear to result in lesions unless the iron build-up is marked or accompanied by other metals. In one study, increases in iron in the livers of dogs only resulted in lesions when combined with increases in copper.[78] It is possible to give dogs clinically significant hemochromatosis experimentally with marked dietary iron overload[82] and liver lesions also have been reported in dogs with severely increased liver iron concentrations associated with hemolytic anemia due to pyruvate kinase deficiency[83] and repeated therapeutic blood transfusions.[84] In all these cases, the liver lesions have been similar to those of humans with hemochromatosis, with loading of macrophages and Kupffer cells with hemosiderin, hepatocellular degeneration, and periportal fibrosis progressing to bridging fibrosis and cirrhosis. There is no doubt, therefore, that excessive iron is damaging to the liver. However, this is rare in dogs and cats. Anecdotal reports of hemochromatosis in litters of Yorkshire Terriers in the UK and USA have not been confirmed with publications.

Alpha-1 Anti-Trypsin Deficiency

Alpha-1 anti-trypsin deficiency was suggested as a cause of liver disease in dogs in Sweden, particularly Cocker Spaniels, in 1994.[85] However, there have been no further reports in the veterinary literature since 1982 and the original studies described a syndrome that was rather different from alpha-1 anti-trypsin deficiency in humans, so the potential contribution of alpha-1 anti-trypsin deficiency to liver disease in dogs remains unconfirmed.

Alpha-1 anti-trypsin is a neutrophil elastase manufactured in the liver. Alpha-1 anti-trypsin deficiency is a common disease in humans, resulting in hepatopathies in some affected patients. The predominant clinical sign of alpha-1 anti-trypsin deficiency in humans is emphysema as a result of unregulated neutrophil elastase activity in alveolar walls, and only a small proportion of individuals suffer from liver disease. Affected humans typically present in infancy, in a similar way to a lysosomal storage disease, with giant cell hepatitis and PAS-positive diastase-resistant granules in hepatocytes.

In dogs, three forms of alpha-1 anti-trypsin have been identified by isoelectric focusing, termed fast, intermediate, and slow.[85] The intermediate form was most common in Cocker Spaniels with chronic hepatitis, although it was not identified in all the Cocker Spaniels with chronic hepatitis in one study.[85] Some dogs also had globular inclusions in their endoplasmic reticulum. However, the serum concentrations of alpha-1 anti-trypsin in most dogs were normal or increased. It is possible to measure canine alpha-1 anti-trypsin concentrations in both serum and feces,[86] but serum deficiency is extremely rare in dogs. The fecal test is much more frequently used as a test of protein-losing enteropathy.

Measurement of alpha-1 anti-trypsin has been validated in cats and fecal alpha-1 anti-trypsin appears to be

increased in protein-losing enteropathy in this species.[87] There are no reports of serum deficiency or liver disease associated with alpha-1 anti-trypsin deficiency in cats.

Amyloidosis

Amyloid is a complex protein which can exist in two forms: either the "normal" soluble form or an "abnormal" auto-aggregated fibrillar form of beta-pleated sheets. It is the accumulation of the aggregated form that causes disease. Amyloidosis can be systemic or local, and familial or acquired (sporadic). There are many different amyloid proteins associated with different diseases. Some are found in single organs, such as the form reported in human and feline pancreatic islets, whereas others are more generalized. The most common generalized form reported in small animals is serum amyloid A (SAA), which is usually secondary to inflammatory disease. SAA is an acute phase protein that is made by hepatocytes and its transcription is regulated by cytokines. Together with C-reactive protein, it is the acute phase protein that is produced in the largest amount in the face of inflammation. An increase in SAA is necessary to develop consequent amyloidosis, but not all individuals with increased SAA develop disease: the reason why some animals develop amyloidosis and others do not is poorly understood but likely involves an interaction of genetic predisposition and environmental triggers.

Amyloidosis due to amyloid AL, which is monoclonal IgG light chain, is rarely reported in small animals although it has been described in association with tracheal disease in dogs and extramedullary plasmacytoma in both dogs and cats. Liver involvement does not appear to be important with amyloid AL.

Feline Hepatic Amyloidosis

Introduction and Signalment

The tissue tropism of SAA varies between dogs and cats and between individual animals and breeds. Hepatic amyloidosis, where the liver is the primary site of clinical importance, is described most commonly in cats. Amyloidosis in cats is most commonly familial and systemic (associated with SAA), although it can be sporadic. In Abyssinian cats, the disease usually presents as chronic kidney disease, with the renal medulla involved more than the glomeruli (see ch. 324). The liver often is involved in Abyssinians, but usually is not the reason for clinical presentation or death. However, Siamese cats with amyloidosis often present with hepatic involvement and the majority of cases of predominantly hepatic amyloidosis in the veterinary literature are in Siamese cats. Hepatic amyloidosis also has been reported in domestic shorthairs (DSHs), oriental shorthairs and a Devon Rex.[88-91] Cases are usually young adults. Studies of the structure and genes coding for feline SAA have shown that both Siamese and Abyssinian cats produce a very limited range of SAA types compared with DSH cats. Distinctive Abyssinian and Siamese SAA molecules have been identified but it is unknown if these differences account for the different tissue tropisms in different breeds.[90,92]

Clinical Presentation

Cats with hepatic amyloidosis most commonly present because of acute intraabdominal bleeding from the fracture of a very friable liver, causing anemia and hypotension that can be fatal. Non-fatal cases autotransfuse and slowly recover, but can suffer repeated episodes.[91] Cats also can present with jaundice and hepatomegaly as primary findings. On physical examination, hepatomegaly is common. The physical exam also should aim to identify any concurrent inflammatory disease, such as chronic gingivitis or upper respiratory tract disease that could predispose to production of SAA.

Diagnosis

The definitive diagnosis relies on histologic findings from a liver biopsy, to be performed only after careful assessment of coagulation times. Amyloidosis is not reliably diagnosed with FNA and cytology, although this has been reported to be diagnostic in a canine case.[93] Clinicopathological and ultrasonographic findings are supportive but not diagnostic. Cats with predominantly hepatic amyloidosis often have elevations of liver enzyme activities and bilirubin, and anemia. There are mild to marked increases in ALT activity and globulins but biliary enzymes are rarely increased. Azotemia is found in some but not all cats.[91] Cats may have concurrent inflammatory diseases, which complicates the blood picture: one cat with hepatic amyloidosis also had feline infectious peritonitis (FIP) as a co-morbidity.[91] Ultrasonography shows hepatomegaly with a normal biliary tract and a diffuse increase in hepatic echogenicity. FIP, lymphoma and

hepatic lipidosis are important rule-outs.

Treatment

To date, there is no effective treatment for feline hepatic amyloidosis. Supportive care and control of concurrent systemic inflammatory disease is the current standard of care in affected cats. Colchicine is used in Shar Pei dogs and humans with familial Mediterranean fever but there are no reports of its use in cats and its toxicity is likely to be limiting in this species. Treatments blocking interleukin 1-beta are being trialed in humans but have not yet been reported in small animals.

Amyloidosis in Dogs

Dogs, like cats, suffer most from the renal effects of serum amyloid A. They most commonly present with protein-losing nephropathy as a result of predominantly glomerular disease (see ch. 325). There are two main groups of canine amyloidosis: the form seen in a variety of dog breeds, which is relatively common, affects predominantly older animals, and rarely affects organs other than the kidneys; and the multi-organ disease recognized in Chinese Shar Pei dogs, which can affect the liver.[94]

The disease in Chinese Shar Peis causes recurrent episodes of fever and joint swelling, which is similar to Mediterranean fever in humans (see ch. 203). Primary hepatic involvement is not common, but has been reported in four dogs where it was the predominant cause of clinical signs.[93,95,96] Three dogs were spayed females and one was a neutered male; they presented with anorexia and lethargy and serum biochemical abnormalities suggestive of cholestatic disease. One suffered spontaneous hepatic rupture. All cases were diagnosed on liver biopsy, although diagnosis of hepatic amyloidosis with FNA and cytology also has been reported in one Shar Pei.[93] Affected dogs are treated with colchicine (see ch. 281).

Lysosomal Storage Diseases and the Liver

A large number of lysosomal storage diseases reported in dogs[1] (and humans) result in vacuoles in hepatocytes and sometimes hepatomegaly. However, the predominant clinical signs usually are not hepatic but rather neurological and skeletal (see ch. 260). The exception is lipid storage disease (cholesterol ester storage disease), which has been reported in one small family group of Fox Terriers in Germany and in which the predominant clinical sign is hepatosplenomegaly due to accumulation of lipid and cholesterol crystals in the liver and spleen.[97] The prognosis for affected dogs is unclear but this is considered a benign disease in humans.

CHAPTER 286

Toxic Hepatic Diseases

Lauren A. Trepanier

Introduction

The liver is a common target of xenobiotic toxicity. It is the site of first-pass biotransformation of many orally absorbed compounds, some which can generate reactive metabolites. Two major categories of drug-induced hepatotoxicosis are recognized.

The first is cytotoxic, due to hepatocyte toxicosis from the parent compound or a locally generated metabolite; this mechanism typically leads to a hepatocellular pattern of liver injury due to hepatocyte necrosis. The second mechanism is cholestasis, which can occur when compounds inhibit or downregulate transporter pumps in the sinusoidal or canalicular membranes, thus interfering with bile salt efflux and hepatocyte function. A cholestatic pattern can also result from mitochondrial injury leading to steatosis, as seen in alcoholic liver disease in humans.[1] In humans, these patterns are defined using an "R" value based on serum alanine aminotransferase (ALT) and serum alkaline phosphatase (SAP) activities, where R = (ALT/upper limit of normal)/(SAP/ upper limit of normal). An R value > 5 indicates hepatocellular injury, an R < 2 indicates cholestatic injury, and an R of 2 to 5 represents a mixed pattern.[2]

Hepatotoxicosis can also be characterized as dosage-dependent or idiosyncratic, although there can be some overlap between the two. For dosage-dependent, or intrinsic, hepatotoxicosis, there is increasing toxicity with increasing dosage in one or more species, and virtually all members of a population or species will be affected at high enough dosages. Dosage-dependent hepatotoxicosis can be caused by the parent compound, or by a metabolite that is reliably generated in the treated species (Figure 286-1). These reactions are relatively predictable, and therapeutic drug monitoring may be helpful in prevention. They require a dosage reduction, but usually not permanent drug discontinuation (Box 286-1).

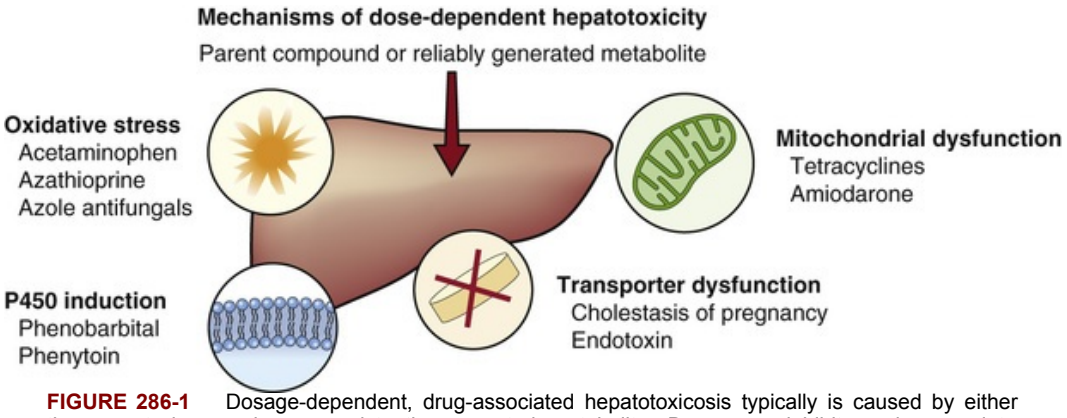

FIGURE 286-1 Dosage-dependent, drug-associated hepatotoxicosis typically is caused by either the parent drug or by a consistently generated metabolite. Drugs can inhibit or downregulate transporter pumps and lead to a functional cholestasis, as can occur with endogenous hormone metabolites during pregnancy. Many drugs yield reactive metabolites that cause oxidative stress; examples include acetaminophen, azathioprine, and azole antifungals. For these compounds, antioxidant supplementation may be effective for treatment or prevention of liver toxicosis. Drugs that interfere with mitochondrial function can lead to steatosis from inhibition of fatty acid beta-oxidation, or can lead to more severe hepatocellular damage due to impaired cellular respiration. Finally, drugs that act as P450 inducers, such as phenobarbital, may mediate hepatotoxicosis by chronic bioactivation of environmental toxins.

Box 286-1

Drugs and Chemicals Commonly Associated with Dosage-Dependent Hepatotoxicosis in Dogs (D) or Cats (C)

Acetaminophen (D, C)
Aflatoxin (D, C)
Amanita mushrooms (D, C)
Amiodarone (D)
Azathioprine (D)
Azole antifungals (D, C)
CCNU (D)
Cycads (Sago palm) (D)[92]
Glipizide (C)[93]
Phenazopyridine (rhabdomyolysis predominates)[94]
Phenobarbital (D)
Phenytoin (D)[95]
Primidone (D)[95]
Xylitol (D)

Idiosyncratic hepatotoxicosis is more difficult to predict, since these reactions develop in only a small proportion of patients that are exposed (Box 286-2). Toxicity does not increase with dosage in the general population (therefore they are not considered "dosage-dependent"), but toxicity can increase with dosage in susceptible individuals. Idiosyncratic toxicity is often caused by reactive metabolites that are variably generated among individuals. These reactive metabolites may cause oxidative stress, mitochondrial damage, or lead to haptens that trigger a humoral or T cell–mediated immunologic response (Figure 286-2). Although idiosyncratic hepatotoxic reactions are sometimes called drug hypersensitivities, they may or may not involve an adaptive immune response. Idiosyncratic hepatotoxicosis usually requires discontinuation of the suspect drug, and structurally related drugs can cause a similar reaction. Also see ch. 169.

Box 286-2

Drugs Most Associated with Idiosyncratic Hepatotoxicosis in Dogs (D) or Cats (C)

Carprofen (D)
Diazepam (C)
Mitotane (D)[96]
Methimazole (C)
Potentiated sulfonamides (D)
Zonisamide (D)[97,98]

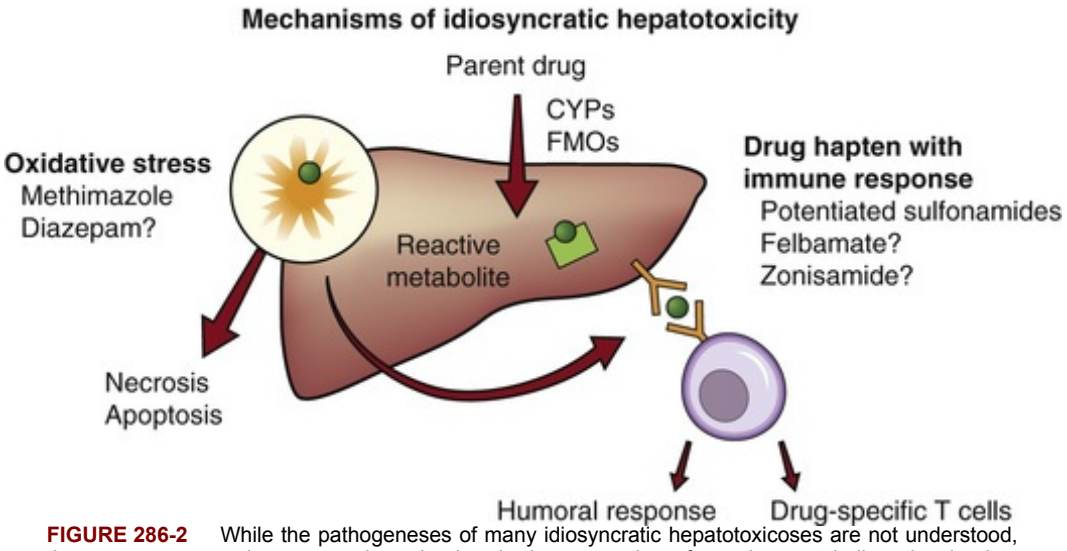

FIGURE 286-2 While the pathogeneses of many idiosyncratic hepatotoxicoses are not understood, the most common, demonstrated mechanism is the generation of reactive metabolites that lead to oxidative stress and/or hapten formation. Reactive metabolites are typically generated locally in the liver by cytochrome P450s (CYPs), flavin mono-oxygenases (FMOs), or other pathways. These metabolites may bind to critical proteins and impair hepatocyte function, or generate reactive oxygen species that damage hepatocyte membranes. Drug-protein adducts also can be processed and presented to the immune system in association with MHC molecules. In the presence of a "danger" signal such as oxidative stress, presentation of drug-bound peptides can lead to clonal expansion of drug-specific T cells, and/or the generation of drug-specific antibodies that target hepatocyte proteins.

Dosage-Dependent, Drug-Induced Hepatotoxicoses

Acetaminophen

Acetaminophen is a classical dosage-dependent hepatotoxin in many species. This drug can be safely used as an antipyretic and analgesic in dogs at dosages of 10-15 mg/kg PO q 8 h, without the gastrointestinal (GI) toxicity of standard nonsteroidal anti-inflammatory drugs (NSAIDs). However, dosages >150-250 mg/kg lead to acute centrilobular hepatic necrosis.[3] In cats, hematologic toxicosis, characterized by methemoglobinemia and cyanosis, appears to predominate over direct liver toxicosis.[4] Cats are much more susceptible to acetaminophen toxicity due to absent expression of UGT1A6, the enzyme that glucuronidates acetaminophen[5] and possibly also due to decreased expression of the ABCG2 transporter, which exports acetaminophen sulfate in humans.[6]

Acetaminophen is bioactivated to the reactive metabolite, NAPQI (N-acetyl-p-benzoquinone imine), which is detoxified by glutathione conjugation. This provides the rationale for treatment of overdoses with the standard regimen of the glutathione precursor N-acetylcysteine (140 mg/kg loading IV, then 70 mg/kg q 6 h for 7 treatments). Although N-acetylcysteine is most effective in humans when given within 8 hours of acetaminophen ingestion, this antidote still has beneficial effects on survival when given much later in the course of intoxication.[3]

S-adenosylmethionine (SAM-e) also can be used for intoxication in dogs that can tolerate oral medications; the protocol that has been used successfully is a 40 mg/kg PO loading dose, followed by 20 mg/kg PO q 24 h for 7 days.[7] Cimetidine has been recommended to inhibit oxidation of acetaminophen to NAPQI; however, this drug has no effect on NAPQI generation *in vitro*,[8] and is not effective in humans with acetaminophen overdose. Cimetidine is therefore not recommended.[3] For dogs and cats with accompanying methemoglobinemia from acetaminophen intoxication, ascorbate (vitamin C; 30 mg/kg SC or IV q 6-8 h) may be effective to restore functional hemoglobin.[9] However, the efficacy of ascorbate for acetaminophen intoxication in dogs and cats has never been evaluated.

Phenobarbital

Hepatotoxicosis from phenobarbital appears to be dependent on cumulative dose, with possible individual modulating factors. Signs typically develop after a year or more of phenobarbital treatment, and the duration

of administration is associated with the degree of histologic injury in epileptic dogs.[10] Presentation can range from subclinical increases in serum bile acids to fulminant liver failure.[11] Typical histologic findings in dogs with clinical signs are bridging portal fibrosis, bile duct hyperplasia, and nodular regeneration. Higher phenobarbital dosages or serum drug concentrations have not been correlated with the development of abnormal serum bile acids across epileptic dogs; however, individual dogs with phenobarbital hepatotoxicosis can improve clinically following phenobarbital dosage reduction.[11]

One hypothesized mechanism of phenobarbital hepatotoxicity is induction of cytochrome P450 enzymes, with secondary bioactivation and hepatotoxicity of other drugs, dietary components, or environmental toxins.[10] For example, phenobarbital increases the hepatotoxicity of carbon tetrachloride in dogs,[12] of chloroform in mice,[13] and of acetaminophen in human hepatocytes.[14] Phenobarbital hepatotoxicity could therefore be modulated by environmental exposures in individual dogs. It is interesting to note that phenobarbital does not lead to either enzyme induction[15] or hepatotoxicosis in cats.

For dogs with hepatotoxicosis during chronic phenobarbital treatment, phenobarbital should be discontinued, or the dosage minimized, by adding another anticonvulsant (see ch. 35 and 260). For example, potassium bromide (KBr) can be substituted at a maintenance dosage of 40-60 mg/kg PO q 24 h, and phenobarbital can then be discontinued with a rapid taper over 1-3 weeks. Clinically significant hepatotoxicosis can be preempted in most dogs by serial monitoring of serum bile acids, phenobarbital concentrations, and a liver panel, ideally every 6 months. Serum phenobarbital concentrations >40 mcg/mL should be avoided, as this can be a risk factor for hepatotoxicosis.[11] In addition, the presence of hyperbilirubinemia, new hypoalbuminemia, or discordant increases in serum ALT > SAP is clinically significant. Newly noted sedation on a stable dosage of phenobarbital might also indicate impaired hepatic clearance of the drug, and is an indication for bile acids testing.

Azole Antifungals

Ketoconazole, itraconazole, and fluconazole all can lead to increases in serum ALT in dogs, although clinical signs such as jaundice are uncommon.[16,17] Mild, clinically insignificant increases in ALT also have been reported in cats treated with itraconazole and fluconazole.[18,19] In dogs with blastomycosis, higher dosages of itraconazole (10 mg/kg/day PO) have been associated with a greater risk of ALT abnormalities than 5 mg/kg/day PO, with no difference in efficacy.[20] Further, increases in both ALT and SAP have been correlated with itraconazole plasma concentrations, which supports a dosage-dependent mechanism.

In animal models, ketoconazole hepatotoxicity has been attributed to an oxidative metabolite, N-deacetyl ketoconazole, which leads to covalent binding to liver proteins and glutathione depletion.[21,22] Fluconazole appears to be less hepatotoxic overall than either ketoconazole or itraconazole in both humans and animal models.[23-25] In dogs with blastomycosis, we observed increases in serum ALT in 26% of dogs treated with itraconazole (median increase: 2.7-fold), and in 17% of dogs on fluconazole (median increase: 1.5-fold).[17] While these were not statistically different, we have anecdotally observed increases in serum ALT during treatment with itraconazole that have resolved following a switch to fluconazole during treatment for blastomycosis in dogs.

Subclinical hepatopathies during azole antifungal treatment are common enough to warrant routine monitoring.[17,20] If new increases in liver enzymes are noted (particularly ALT), an antifungal dosage reduction is indicated, preceded by a rest period depending on severity. When the drug is initiated at a lower dosage, repeat clinical and biochemical monitoring should be performed in one week and at subsequent rechecks. For dogs that develop hepatotoxicosis with itraconazole, a switch to fluconazole may be considered, with careful follow-up monitoring. Given the data in rodent models of hepatotoxicosis, co-treatment with glutathione precursors such as SAM-e can also be considered in dogs that develop increased liver enzyme activities on azole antifungals.

Azathioprine

Azathioprine can lead to increases in ALT and/or SAP activities in about 20% of dogs[26]; these abnormalities usually are subclinical, but have been associated with jaundice and clinical signs in some dogs.[27] Liver enzyme abnormalities are observed a median of 14 days (range, 9-52 days) after starting azathioprine, which is significantly sooner than when cytopenias typically develop (median of 53 days).[26]

In animal models, azathioprine liver injury is associated with the generation of oxidative metabolites and

depletion of hepatic antioxidants,[28,29] and can be prevented by pre-treatment with N-acetylcysteine experimentally.[30] Oxidative metabolites of azathioprine are generated by xanthine oxidase; in fact, the xanthine oxidase inhibitor allopurinol has been used for preventing azathioprine hepatotoxicosis in human patients.[28] However, this intervention requires careful monitoring of azathioprine metabolites to avoid exacerbation of myelosuppression, and is not recommended in dogs.

Dogs treated with azathioprine should be routinely monitored for increases in liver enzyme activities, especially in the first 2-8 weeks of treatment.[26] If glucocorticoids are also being administered, liver enzyme interpretation can become clouded; however, discordant increases in ALT relative to SAP, or even subtle increases in serum bilirubin, are cause for concern. Risk factors for azathioprine hepatotoxicosis in dogs are not clear, but German Shepherds appear to be at higher risk for these enzymopathies.[26] Liver enzyme activities can stabilize or normalize with azathioprine dosage reduction. Supplementation with glutathione precursors might be effective in preventing or reversing azathioprine hepatotoxicosis in dogs, but this has yet to be evaluated.

Amiodarone

Amiodarone leads to clinically significant hepatotoxicosis in about 45% of dogs treated for refractory atrial fibrillation and ventricular arrhythmias, a median of 16 weeks after starting maintenance therapy.[31,32] Predominant increases in ALT are typically observed, with or without hyperbilirubinemia. Hepatopathy can be accompanied by neutropenia in some dogs.[31] These abnormalities slowly resolve over 1-3 months after drug discontinuation.

Toxicity in animal models has been attributed to two oxidative metabolites, mono-N-desethylamiodarone (MDEA) and di-N-desethylamiodarone (DDEA), which generate reactive oxygen species that uncouple oxidative phosphorylation and lead to mitochondrial damage.[33] These metabolites are generated by CYP3A4 in humans, and their generation can be inhibited by ketoconazole *in vitro*.[33]

Because of the prevalence of hepatotoxicosis and neutropenia, a baseline complete blood count (CBC) and serum biochemical panel are recommended in all dogs prior to amiodarone initiation, with a recheck of liver enzymes after a loading period and monthly during treatment.[32] The development of substantial increases in serum ALT is an indication for dosage reduction or drug discontinuation.

Lomustine (CCNU)

CCNU is an alkylating agent used for single agent chemotherapy in dogs with mast cell tumors, lymphoma, histiocytic sarcomas, and other tumors. However, CCNU is associated with substantial increases in serum ALT (>5 fold baseline) in about 29% of dogs.[34,35] Enzyme elevations can occur suddenly, and are most common after 1 to 3 doses of CCNU when given at 3- to 4-week intervals. Dogs also can develop modest hyperbilirubinemia. The risk of ALT elevations is greatest in the Boxer breed and in younger dogs (≤5 years old).[34]

Clinical signs of hepatotoxicosis occur in an estimated 6% of CCNU-treated dogs, are most commonly noted after a median of 4 doses, and are associated with a higher cumulative dosage (median, 350 mg/m^2).[36] Histopathologic evaluation of the liver shows portal aggregates of hemosiderin-laden Kupffer cells, enlargement of hepatocyte nuclei, and hepatocyte vacuolization.[34,36]

The mechanism(s) for CCNU hepatotoxicity is/are not known. Hepatotoxicosis is not a common side effect of CCNU in human patients, and while rats dosed with CCNU show liver toxicosis, the cholestatic pattern and bile canalicular lesions that develop appear to be distinctly different from those seen in dogs.[37]

Dosage reduction or drug discontinuation (for severe enzyme elevations) is associated with improvement in ALT activities in most dogs. However, discontinuation of CCNU chemotherapy is not ideal in tumor-bearing dogs. Some dogs that first presented with advanced liver disease (ascites and acquired shunts) have been euthanized; therefore, liver enzyme monitoring is warranted in all dogs treated with CCNU. In a randomized, placebo-controlled trial, SAM-e in combination with silybin (Denamarin, Nutramax Laboratories, Lancaster, SC) was effective in decreasing the incidence and severity of CCNU hepatopathy in client-owned dogs with various tumors.[38] Therefore, this supplement should be considered for adjunctive therapy in all dogs treated with CCNU.

Tetracyclines

Historically, high dosages of intravenous tetracycline have been associated with microvesicular steatosis in human patients, particularly in pregnant women.[39] The mechanism appears to be inhibition of beta-oxidation of fatty acids in hepatic mitochondria, as well as inhibition of hepatic lipoprotein secretion.[39,40] Although tetracycline inhibits fatty acid beta-oxidation in canine hepatocytes *in vitro*,[41] there is no histologic evidence for steatosis from either tetracycline or doxycycline use in dogs.

In a recent retrospective study of 386 dogs treated with doxycycline (median dosage, 16 mg/kg/day), 36-39% of dogs showed an increase in ALT or SAP into the abnormal range during treatment. Increases were up to 23-fold for ALT and up to 16-fold for SAP.[42] However, no control group was followed, and liver enzymes were checked at clinician discretion, so other causes of enzyme increases could not be ruled out. Given the widespread use of doxycycline and the lack of reports of hepatopathy with clinical signs, these findings are surprising and need further evaluation.

Idiosyncratic, Drug-Induced Hepatotoxicoses

Potentiated Sulfonamides

Potentiated sulfonamides are the most common antimicrobials associated with idiosyncratic hepatotoxicosis in the dog. Trimethoprim-sulfadiazine (Tribrissen, Coopers Animal Health), ormetoprim-sulfadimethoxine (Primor, Zoetis Animal Health), and generic trimethoprim-sulfamethoxazole have all been implicated. Clinical signs are usually seen 5-30 days after starting sulfonamides, with a mean of 12 days.[43] A hepatocellular pattern can progress over several days to cholestatic in some dogs. Hepatic necrosis is the predominant histologic lesion. Signs also can include fever (55% of cases), transient neutropenia, thrombocytopenia, hemolytic anemia, polyarthropathy, proteinuria, keratoconjunctivitis sicca, skin lesions, or uveitis.[43] Dobermans are overrepresented among dogs with idiosyncratic sulfonamide toxicosis, although arthropathy and glomerulonephropathy, not hepatotoxicosis, are typically reported in this breed.[44,45]

Sulfonamide antimicrobials are oxidized to form nitroso metabolites that covalently bind to proteins and act as haptens. Idiosyncratic sulfonamide toxicosis is convincingly immune-mediated in humans, with anti-drug antibodies and drug- and metabolite-specific T cells documented. If potentiated sulfonamides need to be prescribed, the client should be educated to look for any subtle signs of illness. Failure to discontinue sulfonamide antibiotics at the time of initial development of adverse signs can lead to fatal outcomes.

Although specific antidotes for sulfonamide hypersensitivity have not been evaluated, this author recommends supplementation with a glutathione precursor (SAMe or N-acetylcysteine, using the same protocols as for acetaminophen toxicosis, above) and ascorbate (30 mg/kg IV q 8 h [empirical dosage]), based on our finding that both glutathione and ascorbate can reverse haptenization of the nitroso metabolite to canine liver microsomes *in vitro* (Lavergne & Trepanier, unpublished observations). Glucocorticoids are not recommended during the acute hepatic necrosis stage because of the potential risk of exacerbating hepatic encephalopathy or bacterial translocation, but based on our experience, glucocorticoids may be considered in the subacute setting, particularly if a cholestatic pattern persists after drug discontinuation and support.

Carprofen

Potential hepatotoxicosis from carprofen is well-recognized among veterinary clinicians, with an estimated incidence from the manufacturer of 1.4 cases per 10,000 dogs treated (0.05%). Clinical signs of acute hepatic failure are noted 5 to 30 days after drug initiation, with a median of 19 days.[46,47] Clinical signs have even been seen in an untreated dog that ingested feces from another carprofen-treated dog in the household.[48]

A predominant hepatocellular or mixed pattern is found in all reported dogs.[46-48] Importantly, no dogs have been reported with increased SAP activities in the absence of clinically significant concurrent increases in ALT activities. Bridging hepatic necrosis is the predominant histopathologic finding. Although Labrador Retrievers were overrepresented in the initial report,[46] this most likely reflects the high ownership of this breed and its risk for osteoarthritis, since the syndrome could not be reproduced in Labradors under controlled conditions (Personal communication, Pfizer Animal Health).

Given the low incidence and abrupt onset of idiosyncratic hepatotoxicosis from carprofen in dogs, routine monitoring of liver enzymes is not an efficient approach to preventing clinical toxicosis. It is more important to educate dog owners to watch for subtle signs of illness during NSAID administration, to include

inappetence, vomiting, diarrhea, lethargy, or dark urine. Dogs should be promptly evaluated if clinical signs are seen. A normal ALT in the face of clinical illness essentially rules out carprofen hepatotoxicosis. If carprofen hepatotoxicosis is diagnosed, inflammatory pain control should be addressed with a structurally different NSAID, but only after recovery is complete.

Methimazole

About 1-2% of hyperthyroid cats that are given the antithyroid drug methimazole develop clinical evidence of hepatopathy with jaundice,[49] typically in the first month of treatment. These changes are distinct from "innocent" increases in ALT and SAP seen with untreated hyperthyroidism. Hepatopathies can present with a predominantly hepatocellular or cholestatic pattern, with or without hyperbilirubinemia. These reactions usually are reversible with drug discontinuation, but can be fatal if not detected promptly.

Methimazole hepatotoxicosis in animal models presents as increases in serum ALT and dosage-dependent centrilobular hepatic necrosis, which are manifested in the presence of glutathione depletion.[50] Hepatotoxicity has been attributed to an oxidative metabolite, N-methylthiourea, which is directly generated by flavin mono-oxygenases.[51] This pathway has yet to be evaluated in cats.

Cats treated with methimazole should be screened for increases in ALT and SAP if clinical signs of lethargy or anorexia are noted. If cats develop adverse clinical signs, idiosyncratic toxicosis (hepatopathy, blood dyscrasias, or facial excoriation) should be ruled out with a physical exam, CBC, and biochemical panel. The presence of these idiosyncratic adverse events warrants discontinuation of methimazole, given the risk of progression to more severe manifestations.[49] The transdermal route does not appear to be beneficial in preventing idiosyncratic methimazole toxicosis, including hepatotoxicosis.[52] Given the role of glutathione depletion in methimazole hepatotoxicosis in experimental models, the efficacy of glutathione precursors needs to be evaluated in the management of this adverse drug reaction.

Diazepam

Diazepam represents a classic idiosyncratic in cats, first recognized and reported in the mid-1990s.[53-55] Cats developed clinical signs of anorexia and overt sedation 5 or more days after drug initiation, with progression to jaundice and overt hepatic failure. Blood work showed dramatic increases in ALT activities in all cats. Marked centrilobular hepatic necrosis, with mild to marked biliary hyperplasia, was seen on liver biopsies.[53] Relative hypoglycemia was common. Affected cats typically were healthy prior to oral diazepam administration for behavioral problems. The syndrome of diazepam hepatotoxicosis in cats has been reported with both generic and brand-name diazepam,[53] but has not been observed with parenteral diazepam administration as a pre-medicant.

Unfortunately, the mechanism for this potentially fatal adverse drug reaction has not been explored. Comparable chronic daily dosages of diazepam in rats lead to necrotic changes, but without the fulminant presentation seen in cats.[56] A similar clinical syndrome has not been reported in humans.

Subsequent reports of diazepam hepatotoxicosis have since appeared on online veterinary message boards (Veterinary Information Network) in cats given oral diazepam for seizures or urethral spasm. Although toxicosis appears to be relatively rare, there are safer alternative drugs for behavioral problems, seizures, and urethral spasm in cats. This makes chronic oral diazepam administration a poor first choice in this species, particularly without an adequate discussion of risks and alternatives with the client.

Household and Environmental Hepatotoxins

Aflatoxin

Aflatoxins are produced by *Aspergillus* spp. and can be found in moldy corn, peanuts, or soy; contaminated pet food, and wild bird seed.[57] Aflatoxin B1 is a dosage-dependent hepatotoxin in many mammals, including dogs and cats.[58] Aflatoxin B1 is bioactivated by cytochrome P450 enzymes to electrophilic epoxide metabolites that lead to protein and DNA adducts and glutathione depletion.[59] Several large outbreaks of aflatoxin hepatotoxicosis from commercial dog foods have been reported recently, involving more than one hundred fatalities in pet dogs.[57,60]

Clinical signs of aflatoxin hepatotoxicosis are typical for acute liver failure, and can include peracute death.[60,61] Decreases in serum protein C, antithrombin, and cholesterol appear to be more sensitive than

increases in liver enzyme activities or bilirubin early in the course of disease.[60] As expected, hyperbilirubinemia, hypoalbuminemia, and hypocholesterolemia are poor prognostic indicators. The most prominent histopathologic finding is diffuse hepatocyte lipid vacuolation, along with fibrosis and biliary hyperplasia; cirrhosis also can be seen with chronic exposure.[60,62] It is important to note that massive hepatic necrosis is not a feature of aflatoxicosis in dogs.

If a patient is suspected of aflatoxin hepatotoxicosis, a careful dietary history over the previous 8 weeks should be obtained, because some dogs are affected only after subchronic exposure.[61] Owners might report an initial reluctance to eat a new brand or bag of dog food when first introduced.[63,64] Samples of food (several unopened cans or 1 kg of dry food) should be reserved for analysis of aflatoxin B1,[63] and vomitus, serum, and urine should be saved for analysis of the M1 metabolite of aflatoxin B1.[62] In addition, the pet food label and lot number should be documented, and both the manufacturer and the Food and Drug Administration should be contacted. The prognosis is guarded, and only about one third of affected dogs survive with intensive treatment for hepatic failure.[60,61]

Xylitol

The artificial sweetener xylitol is found in sugarless chewing gums, hard candies, baked goods, toothpastes, nasal sprays and even some drug suspensions and total parenteral nutrition formulas. When ingested by dogs at dosages of 0.15 g/kg or higher, xylitol leads to acute intoxication characterized by insulin release and clinical signs of hypoglycemia within 30 to 60 minutes (see also ch. 152).[65] In some dogs, this can be followed by acute hepatic necrosis 6 to 72 hours after exposure, sometimes leading to a consumptive coagulopathy and fulminant liver failure.[65,66] However, not all dogs that develop hepatopathy have evidence of preceding hypoglycemia.

The mechanism of xylitol hepatopathy is not known, but could be due to interference with intermediary metabolism or accompanying redox stress.[65] Oral ingestion does not lead to hepatopathy in other species, but high-dosage intravenous administration leads to hepatic depletion of ATP in humans,[67] and has been associated with hyperbilirubinemia (apparently without increases in transaminases) in human subjects.[68]

Vomiting should be induced in dogs that are observed to ingest xylitol (see ch. 151), but is contraindicated once signs of hypoglycemia are observed. Activated charcoal is not contraindicated but might not effectively adsorb xylitol.[69] Dogs should be further monitored for signs of hepatocellular damage for up to 72 hours after ingestion, and early treatment with a glutathione precursor (SAM-e or N-acetylcysteine) is probably indicated.[65,66]

Amanita Mushroom

The death cap mushroom *(Amanita phalloides)* is found throughout North America, and in the U.S., it is concentrated in forests on the West coast from Los Angeles to Vancouver, and the East coast from Maryland to Maine.[70] These fungi contain amatoxins, notably alpha-amanitin, which are highly toxic to humans and other mammals. Amatoxins inhibit RNA polymerases,[71,72] which leads to decreased mRNA generation, arrested protein synthesis, and necrosis of metabolically active cells, including intestinal crypt cells, hepatocytes, and renal tubular cells.[73,74]

Dogs can be exposed to *Amanita* spp. while foraging in the woods. Clinical signs of vomiting, bloody diarrhea, and abdominal pain occur within 6 to 24 hours of ingestion, followed by severe hypoglycemia at 24 to 48 hours, caused by insulin release stimulated by alpha-amanitin.[75] Finally, massive hepatic necrosis and renal tubular necrosis develop after 36 to 84 hours.[73] As little as one or two mushrooms can be fatal to an adult dog.

Silybin, found in milk thistle, inhibits amatoxin uptake by hepatocytes *in vitro,* which is mediated by the OATP1B3 transporter.[76,77] Notably, silybin (50 mg/kg PO) prevented fatalities when given at 5 and 24 hours after experimental *Amanita* intoxication in dogs.[78] Other inhibitors of OATP1B3 include, in order of decreasing potency, cyclosporine A, rifampicin, montelukast, penicillin G, and prednisolone phosphate[77]; in fact, penicillin G has also been shown to be protective against alpha-amanitin toxicosis in rodent models.[79]

A definitive diagnosis of aflatoxicosis can be made by measuring alpha-amanitin in urine, serum or plasma, kidney, or liver, although mushroom fragments also can be found in vomitus or gastric contents.[73] If a sample

of the suspect mushrooms can be obtained, the website of the North American Mycological Association can provide the names of volunteers nationwide who can assist with mushroom identification (http://www.namyco.org/toxicology/index.html). Any wild mushroom ingestion in a dog should be considered serious, and admitting clinicians should contact a veterinary poison control hotline for advice specific to their region.[80]

Blue-Green Algae

Blue-green algae, which are not actually algae but are photosynthetic cyanobacteria, proliferate in warm, stagnant, nutrient-rich waters. Genera that produce hepatotoxins include *Microcystis aeruginosa* (found in freshwater lakes, ponds, and reservoirs) and *Nodularia spumigena* (found in brackish and ocean waters). The cyanotoxins microcystin and nodularin inhibit serine/threonine protein phosphatases in the liver,[81] with subsequent hyperphosphorylation and disruption of cytoskeletal proteins. This leads to hepatocyte dissociation, hepatic necrosis, and glutathione depletion.[82,83]

Dogs can be exposed while drinking or swimming in warm, stagnant waters with visible blue-green "pond scum" or "algal bloom," or by eating mats of scum washed onshore.[84] Dogs can develop signs of acute illness and hepatic failure within hours of ingestion. Exposure to nodularin can also lead to proximal renal tubular necrosis and anuric kidney injury,[85,86] and can resemble acute leptospirosis at clinical presentation.

A diagnosis can be supported by cytologic exam of vomitus,[84] and toxicologic analysis of water, vomitus, feces, or samples of liver for nodularin or microcystin.[86-88] Although hepatotoxicosis can be rapidly fatal, dogs have been reported to survive with intensive supportive therapy, including glutathione precursors (see above).[89] In addition, cholestyramine can avidly bind cyanotoxins in the gut, and was associated with clinical response and survival in a single case report (cholestyramine 170 mg/kg PO q 24 h) of a dog with confirmed microcystin intoxication.[90]

Cycad Palms

The Sago palms (or fern palms; *Cycas revoluta, Cycas circinalis,* and *Zamia floridana*) are cycad plants found in subtropical regions. Intoxications in the U.S. are seen predominantly in the southern states, where seeds fall to the ground in early spring.[91] Seeds are most toxic, but ingestion of roots and leaves also can lead to clinical signs.[92] The toxic principle, cycasin, is bioactivated to methylazoxymethanol by gut bacteria; this metabolite leads to gastrointestinal and hepatic toxicosis.

Gastrointestinal signs can develop within minutes to hours of ingestion, while biochemical signs of hyperbilirubinemia and increases in hepatocellular and cholestatic enzyme activities may not develop for 24 to 48 hours.[92] Neurologic signs such as ataxia, proprioceptive deficits, or seizures are seen in 20-50% of dogs with cycad toxicosis.[91,92] Histopathologic liver lesions include centrilobular hemorrhage and necrosis, with stromal collapse seen in more severely affected dogs.[91]

Mortality rates can approach 50%,[91,92] and intensive monitoring and support are indicated. Administration of activated charcoal is associated with improved survival.[91]

CHAPTER 287

Neoplasms of the Liver

Nick Bexfield

Client Information Sheet: Tumors of the Liver

Introduction

Prevalence

Tumors of the liver and the biliary tree in dogs and cats may be primary or metastatic. Primary tumors are relatively uncommon, representing 0.6-1.5% of all tumors in dogs.[1-3] Primary liver tumors represent about 1-3% of all tumors in cats, but up to about 7% of all nonhematopoietic tumors.[4,5] Metastatic tumors are approximately three times more frequent than primary liver tumors in dogs and most commonly originate from spleen, gastrointestinal (GI) tract and pancreas.[3,6] Primary tumors are more common than metastatic tumors in cats.[4] Benign tumors are more common in cats, but in dogs they are usually malignant.[1,3,5,7,8] Although peak incidence of primary hepatobiliary cancer occurs at 10-12 years of age in both species, cats develop malignant hepatic tumors at a younger age than benign tumors.[3,6,8-11]

Primary Tumor Tissues of Origin and Morphology

There are four general tissue types from which primary hepatic tumors are derived: hepatocellular, bile duct, neuroendocrine and mesenchymal. The morphologic types of primary hepatic tumor are massive, nodular and diffuse.[1] "Massive" is defined as a large solitary mass confined to one liver lobe; "nodular" tumors are multifocal and may involve multiple lobes; and "diffuse" disease includes multifocal or coalescing nodules affecting all lobes or diffuse effacement of the hepatic parenchyma.[4,12] The liver can also be involved in other neoplastic processes, including lymphoma (see ch. 344), systemic mastocytosis (see ch. 349) and malignant histiocytosis (see ch. 350).[5,12]

Dogs

The most common primary hepatic tumors in dogs are the hepatocellular adenoma and carcinoma. Bile duct adenoma and carcinoma are observed less frequently.[1] Fibromas, fibrosarcomas, hemangiomas and hemangiosarcomas are relatively uncommon primary hepatic neoplasms in dogs. In one study, 106 canine primary hepatic neoplasms were separated into well-defined groups based on histopathology and immunohistochemical stains for markers representative of hepatocytic and cholangiocytic (bile duct) lineages.[13] Results demonstrated 77% hepatocellular, 9% bile duct, and 3% hepatic neuroendocrine tumors.[13]

Cats

Bile duct adenomas are the most common (>50%) primary feline hepatobiliary tumor.[8,10,14-16] In a report of 61 feline primary liver tumors, classified into well-defined groups based on histopathologic and immunohistochemical examination, there were 41% bile duct, 34% hepatocellular, and 13% hepatic neuroendocrine tumors.[17] In this latter study, all the bile duct tumors were carcinomas, and no bile duct adenomas were identified. Further studies using immunohistochemistry may lead to an improved understanding of canine and feline primary hepatic tumors.

Nodular Hyperplasia: An Important Differential Diagnosis for Any Liver Mass

Hepatic nodular hyperplasia is relatively common and is identified in 15-60% of older dogs.[5] Nodular hyperplasia also occurs in older cats and can result in single or multiple nodules, often as an incidental finding during laparotomy or at post-mortem examination.[17,18] Nodular hyperplasia is often diffuse with a "classic appearance" of liver cancer. Thus, histology must be performed before condemning a dog or cat.

Pathology

Hepatocellular Tumors

Hepatocellular Carcinoma (HCC)

HCC is the most common primary hepatic tumor in dogs, accounting for >50% in some studies. It is the second most common tumor in cats.[1,4,5,8,10,12-14] The average age of affected dogs is 12 years; >80% of dogs are >10 years of age.[1,2,19] Although most studies failed to identify a breed or sex predisposition, 16% of affected dogs in one report were Miniature Schnauzers.[1,2,13,19] Morphologically, 53-83% of HCCs are massive, 16-25% are nodular and up to 19% are diffuse.[1,12] The left lateral and medial lobes and the caudate lobe are involved in over two thirds of dogs with massive HCC.[1,2,19,20] Metastasis is more common in dogs with nodular or diffuse HCC; common sites include the regional lymph nodes, peritoneum and lungs.[1,12,14] The metastatic rate varies from 0-37% for dogs with massive HCCs and 93-100% for dogs with nodular or diffuse HCCs.[1,2,8,10,12,14,19,20]

Hepatocellular Adenomas (Hepatomas)

Hepatomas are often an incidental finding at necropsy in dogs and only rarely cause clinical signs unless they rupture and hemorrhage.[12] In cats hepatocellular adenoma occurs more frequently than HCC.[14] In dogs and cats, adenomas can be encountered as palpably obvious abdominal masses that are sometimes pedunculated. Care must be taken to distinguish benign from metastatic disease. Solitary adenomas can become quite large and encroach onto other organs. Hepatoblastoma is rare and only reported in one dog.[21]

Tumor Lineages

On the basis of histopathology and immunohistochemical stains for markers representative of hepatocytic and cholangiocytic lineages, hepatocellular tumors in dogs could be divided into three subgroups, each with specific morphologic and immunohistochemical characteristics.[13] By far the largest subgroup were hepatocellular tumors with 0-5% positivity for keratin 19 (K19), likely derived from mature hepatocytes, which were well differentiated and had no evidence of metastasis.[13] A second group contained tumors with >5% positivity for K19, which were poorly differentiated and had intrahepatic and/or distant metastasis. These exhibited characteristics of hepatic progenitor cells (HPCs) without further differentiation towards cholangiocytic or hepatocellular lineages and may be derived from HPCs or through dedifferentiation of mature hepatocytes. A final small group had an intermediate position with regard to K19 staining and malignancy. In a similar study in cats, histopathology and immunohistochemistry classified 21 of 61 primary hepatic tumors as being of hepatocellular origin, and these were subdivided into adenomas (n = 18) and carcinomas (n = 3).[17] All of the hepatocellular carcinomas had evidence of intrahepatic and/or distant metastases.[17]

Bile Duct Tumors

There are two bile duct tumor types in dogs and cats: bile duct carcinoma and adenoma. Previous studies report that bile duct carcinoma, or cholangiocarcinoma, is the most common malignant non-hematopoietic hepatic tumor in cats, and second most common in dogs (Figure 287-1).[1,8,10,12,14] In a recent study where feline primary hepatic tumors were classified based on histopathology and immunohistochemical stains for markers representative of hepatocytic and cholangiocytic lineages, bile duct tumors (100% of which were malignant) were most common.[17] Previous reports suggested bile duct carcinomas account for 22-41% of all malignant liver tumors in dogs.[1,6] In one study, however, there was a relatively low frequency (9%) of bile

duct tumors in dogs.[13] In this study, all canine bile duct carcinomas were positive for immunohistochemical markers suggestive of derivation from differentiated mucin-producing cholangiocytes normally present in larger bile ducts.[13]

FIGURE 287-1 Gross appearance of a diffuse primary hepatic cholangiocarcinoma from a 7-year-old female Cavalier King Charles Spaniel. The dog presented comatosed with severe hepatic encephalopathy.

A breed predilection for Labrador Retrievers[22] and a sex predisposition for females have been suggested for canine bile duct tumors.[1,23,24] There are no apparent breed or sex predispositions for bile duct carcinomas in cats, in whom 37-46% are massive, up to 54% are nodular and 17-54% diffuse.[1,12,22,24] Bile duct carcinomas can be intrahepatic, extrahepatic or within the gallbladder. Intrahepatic locations are more common in dogs, whereas an equal distribution of intrahepatic to extrahepatic tumors has been reported in cats.[1,14] Bile duct carcinoma of the gallbladder is rare in dogs and cats and is an aggressive cancer with metastatic rates as high as 88% in dogs and 78% in cats. Metastasis occurs most often to the regional lymph nodes and lungs.[1,8,10,14,22,24] In one study, all feline bile duct tumors had infiltrative growth or vascular invasion together with intrahepatic and/or distant metastases. Three tumors were associated with adult-type congenital hepatic cystic disease.[17] In cats, 67-80% had diffuse intraperitoneal metastasis and carcinomatosis.[8,10]

Benign adenomas of the bile duct, due to their cystic appearance, are also called biliary or hepatobiliary cystadenomas. They can be single or multiple and usually do not cause clinical signs until large and compressing adjacent organs.[15,16,25] They have accounted for more than 50% of all feline primary hepatobiliary tumors.[5,8,10,14,15,25] However, in a recent study using histopathology and immunohistochemical stains for markers representative of hepatocytic and cholangiocytic lineages, none of 61 primary feline hepatic tumors was an adenoma.[17] In other reports, male cats appear to be predisposed, although no clear breed predispositions have been reported.[15,16] In a similar study using histopathology and immunohistochemistry, no biliary adenomas were noted among 106 dogs with primary hepatic tumors.[13]

Neuroendocrine Tumors

Neuroendocrine tumors, also known as hepatic carcinoids, arise from neuroectodermal cells and are infrequently reported in dogs and cats.[1,10,12-14,26,27] In one study, the frequency of neuroendocrine carcinomas in dogs (3%) and cats (13%) was relatively low.[13,17] Immunohistochemical stains used in the identification of human neuroendocrine tumors are useful in determining cell origin.[13,17,26,27] They are usually intrahepatic, although neuroendocrine tumors of the gallbladder have also been reported.[26,28-30] They tend to occur at a younger age than other hepatobiliary tumors, with a mean age of 7 years.[1,29] Primary hepatic neuroendocrine tumors are biologically aggressive and not usually surgically resectable due to their diffuse nature.[1,26,29] Frequent sites of metastasis include the regional lymph nodes, peritoneum, and lungs, with other reported sites including the heart, spleen, kidney, adrenal glands and pancreas.[29]

Mesenchymal and Other Tumors

Primary tumors of mesenchymal origin are rare in cats and dogs.[1,8,10,12,14,31] In two recent studies of 106 primary hepatic tumors in dogs and 61 in cats, no mesenchymal tumors were identified.[13,17] Hemangiosarcoma, leiomyosarcoma and fibrosarcoma are more frequently identified. Other reported sarcomas include rhabdomyosarcoma, liposarcoma, osteosarcoma, chondrosarcoma and malignant mesenchymoma.[1,8,10,12,14,31-36] Hemangiosarcoma is the most frequently reported primary hepatic mesenchymal tumor in cats and leiomyosarcoma the most common in dogs. Massive and nodular morphology have been reported in 33% and 67% of cases respectively.[1,31] Males appear predisposed to mesenchymal tumors with no known breed associations.[1] Hepatic mesenchymal tumors are biologically aggressive, with pulmonary and splenic metastasis reported in 86-100% of dogs.[1,31] Dogs with disseminated histiocytic sarcoma often have hepatic involvement.[37-39] Myelolipomas are a benign hepatobiliary tumor of cats and can be single or multifocal.[4,5,40,41] Histologically they are composed of adipose tissue intermixed with normal hematopoietic elements. They are usually benign in behavior.

Clinical Signs and Physical Examination Findings

Clinical signs of hepatic neoplasia are usually vague, nonspecific, and they include lethargy, inappetence, weight loss, vomiting, polyuria/polydipsia, pyrexia and ascites.[5] Uncommonly, neurologic signs may develop due to paraneoplastic hypoglycemia, hepatic encephalopathy or central nervous system metastasis.[1,26,27,42,43] Weakness due to myasthenia gravis associated with a HCC has been described in one dog.[44] Icterus is more common in dogs with bile duct carcinomas and diffuse neuroendocrine tumors.[1,12,24] Clinical signs are of relatively little value in differentiating primary or metastatic liver tumors from nonneoplastic hepatic disease. Approximately 50% of cats and 25% of dogs with hepatobiliary tumors show no clinical signs. Many are diagnosed with a liver tumor only during investigation of increased liver enzyme activities.[5] Physical examination is often unrewarding, aside from palpating a cranial abdominal mass or hepatomegaly in up to 75% of dogs and cats with a liver tumor. Paraneoplastic alopecia has been reported in one cat with an advanced HCC.[45]

Diagnosis

Clinical Pathology

Hematology and Coagulation Testing

Clinicopathologic features are usually nonspecific. Hematology may reveal a mild nonregenerative anemia due to chronic disease, red blood cell (RBC) sequestration, RBC destruction or iron deficiency.[5,46] Neutrophilic leukocytosis may be seen with neoplasia-associated inflammation or necrosis.[1,2,19,20] Thrombocytosis is seen in approximately 50% of dogs with massive HCC.[20] Primary or metastatic hepatic hemangiosarcomas may result in a regenerative anemia and thrombocytopenia.[5] Prolonged coagulation times are a potential consequence of any liver disease, although they are rarely clinically significant unless liver failure has occurred as a consequence of diffuse disease. About 20% of dogs with extensive or advanced HCC have prolonged coagulation times (see ch. 196 and 197).[19,20] Animals with hepatic hemangiosarcoma are at

risk of developing disseminated intravascular coagulation (DIC).[47]

Serum Biochemistries

Liver enzyme activities are commonly increased in dogs and cats with hepatobiliary tumors, indicative of hepatocellular or biliary epithelial damage or biliary stasis.[5,48] However, increased hepatic enzyme activity is not specific for hepatic neoplasia and does not reflect degree of hepatic neoplastic involvement. Compared with metastatic hepatic tumors, primary hepatic tumors are more likely to result in hypoproteinemia, hypoglycemia and increases in serum alkaline phosphatase and alanine transaminase activities. They are less likely to cause hyperbilirubinemia.[3,48] In dogs, an aspartate aminotransferase to alanine aminotransferase (AST : ALT) ratio of <1 was consistent with a HCC or bile duct carcinoma in one study, whereas a higher ratio was more likely with neuroendocrine or mesenchymal tumors.[1]

Hepatic Testing

Elevated serum bile acid concentrations, a nonspecific abnormality, have been reported in 50-75% of dogs and 33% of cats with liver tumors. While biliary neoplasia is more common in cats, only 33% have icterus. Other biochemical changes may include hypercalcemia, hyperglobulinemia, and hypoglycemia.[1] Hypoglycemia may be seen as a paraneoplastic effect due to a large tumor mass consuming glucose or reflect production of an insulin-like substance (see ch. 352).[42,43] Hypoalbuminemia, more common in dogs than cats, may reflect a negative acute phase response, catabolism and poor nutritional intake, or hepatic insufficiency. Increased serum pancreatic lipase (PL) activity was reported in six dogs with either pancreatic or hepatic neoplasia.[49] Alpha-fetoprotein (AFP), a glycoprotein produced by fetal, neoplastic, and regenerating hepatocytes, is increased in about 75% of dogs with HCC and 55% with bile duct carcinomas.[50,51] Serum AFP levels decrease in dogs after surgical removal of HCC.[52] However, AFP has multiple potential sources in dogs, both neoplastic and non-neoplastic, limiting its utility as a diagnostic or therapeutic marker.[50,51] No studies have been performed to assess AFP in cats with liver tumors.

Imaging

Radiology

Imaging is valuable for the diagnosis, staging and surgical planning of animals with hepatobiliary tumors. Abdominal radiography may identify a cranial abdominal mass with caudal and lateral displacement of the stomach. Ascites may interfere with visualizing a mass.[5,19,23] Occasionally, dystrophic mineralization of a mass or the biliary tree is identified.[4] Assessment of thoracic radiographs is considered critically important to exclude metastatic disease.

Abdominal Ultrasound (US)

Abdominal US (see ch. 88) offers several advantages over abdominal radiographs in animals with hepatic disease. It can be used for determining presence of a hepatic mass and for identifying any mass as massive, nodular or diffuse.[5,53-55] In focal disease, US can be used to determine mass size, location, and its relationship to surrounding structures. For the detection of mass lesions, however, sensitivity varies widely and is dependent on operator skill, equipment, and tumor type.[55,56] Diffuse tumors are usually seen as having hypoechoic, heterogeneous, or multifocal parenchymal nodules or masses. Less commonly, mass lesions appear diffusely hyperechoic or, occasionally, normal.[57] A cystic component may be seen in biliary cystadenomas or hepatic hemangiosarcomas. However, one must be cautious with hepatic masses seen on US since a recent study demonstrated marked variability in US appearance for all types of liver disease in dogs. No associations between US appearance and histologic diagnosis could be made.[57] The most prevalent US features were multifocal hepatic lesions in 63% of dogs with hemangiosarcoma and 43% with HCC. Target lesions associated with malignancy were identified in 67%.[57] Doppler (color flow) assessment of mass lesions may demonstrate vascularization patterns helping to distinguish tumors from other benign processes.[5,58] The Doppler perfusion index can be of value in assessing lymph nodes and liver for metastases.[59] Contrast-enhanced US can help differentiate benign from malignant lesions.[60-62]

Computed Tomography (CT) or Magnetic Resonance Imaging (MRI) Scans

Advanced imaging techniques can be useful for diagnosis and staging of liver tumors. MRI of focal hepatic or splenic lesions in dogs was reported to have high sensitivity (100%) and specificity (90%) in differentiating malignant from benign masses. MRI results correctly identified HCC.[63] In humans, CT and MRI are excellent for detecting small hepatic lesions and determining the relationship of liver masses to surrounding structures.[32] MRI provides superior soft-tissue contrast and is likely to provide better lesion detection, quantification and localization when compared to CT.

Fine Needle Aspiration (FNA) and Biopsy

Results of diagnostic imaging and clinical pathology do not typically provide definitive diagnoses in patients with liver masses. Obtaining samples for cytology and/or histology can be vital in providing additional information and, in many cases, a definitive diagnosis. Exceptions may be made for solitary and massive hepatic masses, when surgical resection is performed without a preoperative histologic diagnosis because surgery can provide both diagnosis and treatment. Samples can be collected by FNA or biopsy via US-guided needle core biopsy (see ch. 89), laparoscopy (see ch. 91), or laparotomy. Coagulation profiles are advised prior to any biopsy (see ch. 196). Mild to moderate hemorrhage is a relatively frequent complication (about 5%).[53,55,56,64] General anesthesia or heavy sedation should be used to avoid patient movement during needle biopsy.

The main disadvantage of FNA cytology is its limited diagnostic accuracy. In one study, agreement between cytology and histopathology was about 30% in dogs and 50% in cats.[65] With focal lesions, FNA can prove useful and may negate need for biopsy. In dogs with focal hepatic lesions, sensitivity of US-guided FNA cytology versus histopathology for the identification of neoplasia was 52%. Cytology had the highest positive predictive value when the lesion was neoplastic (87%).[66] FNA for diagnosis of diffuse hepatic neoplasia is generally more reliable.[67] More invasive techniques, such as laparoscopy and laparotomy can also be used to obtain tissue for definitive diagnosis or staging. Follow-up US several hours after biopsy should also be performed to assess the biopsy site for bleeding. Careful postoperative monitoring, ideally for 24 hours, is also advised.

Treatment

Solitary Hepatocellular Carcinoma

Surgical resection, usually lobectomy, is recommended for most solitary primary hepatic tumors that have not metastasized, especially in dogs with a massive HCC.[20] Surgery is rarely an option for most nodular or diffuse hepatobiliary tumors, as complete resection is impossible. However, localized resection of primary or metastatic nodules is sometimes considered if likely to provide palliation of clinical signs, such as reducing potential for life-threatening hemorrhage. Biliary tree diversion (biliary enteric anastomoses) should be considered for obstructive lesions involving the extrahepatic biliary structures because long-term palliation is possible and chronic biliary tree occlusion results in cirrhosis. Advanced imaging prior to surgical resection of liver tumors can accurately assess tumor location and extent. Preoperative preparation of patients for liver lobectomy includes correction of volume deficiency, electrolyte abnormalities, anemia and clotting factor deficiencies. In 42 dogs with massive HCC treated by liver lobectomy, intraoperative mortality rate was about 5% and the complication rate almost 30%.[20] Complications of surgical resection include hemorrhage, vascular compromise, reduced hepatic function and hypoglycemia.[4,20,69]

Nodular or Diffuse Hepatocellular Carcinoma

Radiation therapy has little place in managing hepatic tumors. The liver is exquisitely sensitive to even low amounts of radiation and there is difficulty in limiting tissue exposure.[5] HCC is considered "chemo-resistant" in humans, with response rates <20%.[32] Adjunctive, postoperative chemotherapy generally does not provide significant benefit in dogs or cats with primary liver tumors. However, single-agent gemcitabine therapy has been used in dogs with HCC (4 massive, 10 nodular and 4 diffuse). Their median survival time was 983 days.[70] In one study, 1/4 dogs with massive HCC treated with mitoxantrone had complete resolution.[71] No comparable information is available on the use of gemcitabine or mitoxantrone in cats.

Although liver transplantation, directed delivery of chemotherapeutic agents (intraarterial chemotherapy), transarterial chemoembolization, and immunotherapeutic regimens using tumor-specific antigen have been

used in humans with HCC, these have not been explored extensively in animals.[72,73] Blind embolization and chemoembolization have been reported with moderate success in treating a limited number of dogs with non-resectable HCC (see ch. 125).[74,75] Liver lobectomy is recommended for cats with a single bile duct adenoma or multiple lesions confined to one or two lobes.[8,10,15,16,25] Lobectomy is also recommended for cats and dogs with a massive bile duct carcinoma.

Nodular or Diffuse Bile Duct Carcinomas

There is no known effective management option for animals with these cancers. Surgical resection is not possible and these tumors are not sensitive to radiation or chemotherapy.[5] As most neuroendocrine tumors are nodular or diffuse, and behave aggressively, they are generally not amenable to surgical resection. There are no reports of the use of radiation therapy or chemotherapy for this tumor type in dogs or cats.

Solitary Massive Mesenchymal and Other Tumors

Lobectomy is recommended for solitary and massive mesenchymal tumors, although many have metastasized at the time of diagnosis.[1,31] Radiation therapy is usually of limited efficacy in primary hepatic mesenchymal tumors. There are few reports of chemotherapy for the management of these hepatic cancers. Based on the response to chemotherapy for mesenchymal tumors at other sites, it is likely that primary mesenchymal hepatic tumors will respond poorly. However, adjunctive chemotherapy may be considered for visceral hemangiosarcomas.[76-78] There are few reports on management options for unusual primary hepatic tumors, although liver lobectomy is recommended for cats with a single primary hepatic myelolipoma.[5] Hepatic lymphoma (see ch. 344), systemic mastocytosis (see ch. 349) and malignant histiocytosis (see ch. 350) may all be managed by systemic chemotherapy.[5]

Prognosis

Dogs

Prognostic factors for dogs with massive HCC include tumor location, serum ALT and AST activity, and ratios of alkaline phosphatase (ALP) to AST and ALT to AST.[20] Histopathologic subtype of HCC and anaplastic characteristics may also influence prediction of metastasis and prognosis. Median survival time of 42 dogs with massive HCC managed by liver lobectomy was not reached after more than 1460 days of follow-up.[20] In comparison, the median survival time was only 270 days for dogs managed conservatively, and these were about 15 times more likely to die of tumor-related causes than dogs treated surgically.[20] While location of a massive HCC may increase surgical risk, location has no impact on outcome for dogs that survive surgery. The prognosis for dogs with massive HCC is good, with local tumor recurrence reported in 0-13% following lobectomy.[19,20] However, metastatic disease to other parts of the liver or other organs has been reported to be as high as 37%.[19,20] In contrast, as surgical resection is not usually possible, the prognosis for dogs with nodular and diffuse HCC is poor.

Cats

The prognosis for cats with surgically resectable bile duct adenomas is excellent, with no reports of local recurrence or malignant transformation.[8,15,25] However, survival times for cats and dogs with massive bile duct carcinoma managed by surgical resection are poor, with the majority dying within six months due to local recurrence or metastatic disease.[5,8] The prognosis for primary hepatic neuroendocrine tumors is poor as they are rarely resectable, and metastasis to regional lymph nodes, peritoneum and lungs has usually occurred by the time of diagnosis.[1,29] Despite surgical resection being an option for some primary hepatic mesenchymal tumors, as metastatic disease is often present at the time of diagnosis, the prognosis is again poor.[1,31] However, this strategy may provide palliation of space-occupying effects of the tumor, or prevent life-threatening hemorrhage from occurring. The prognosis for cats with primary hepatic myelolipoma is excellent, with prolonged survival times and no reports of local recurrence.[4,41]

CHAPTER 288

Diseases of the Gallbladder and Extrahepatic Biliary System

Ale Aguirre

Client Information Sheet: Diseases of the Gallbladder

Anatomy and Physiology

The gallbladder is a teardrop-shaped organ situated in the cranioventral abdomen between the right medial and quadrate liver lobes. The gallbladder is a reservoir where bile is stored, modified, and eventually expelled. Bile is formed in the hepatocytes and is actively secreted into the bile canaliculi. From the canaliculi, bile flows to the intralobular ducts and ultimately to the lobar ducts. The lobar ducts give rise to the left and right hepatic ducts. The cystic duct is an offshoot of the hepatic ducts and travels toward the gallbladder. The cystic duct is an important landmark distinguishing the otherwise continuous hepatic ducts from the common bile duct (Figure 288-1). There is substantial variation in the number of hepatic ducts and their anastomoses with the common hepatic and cystic ducts.[1-3] Bilobed and duplex gallbladders have been observed in some cats.[4]

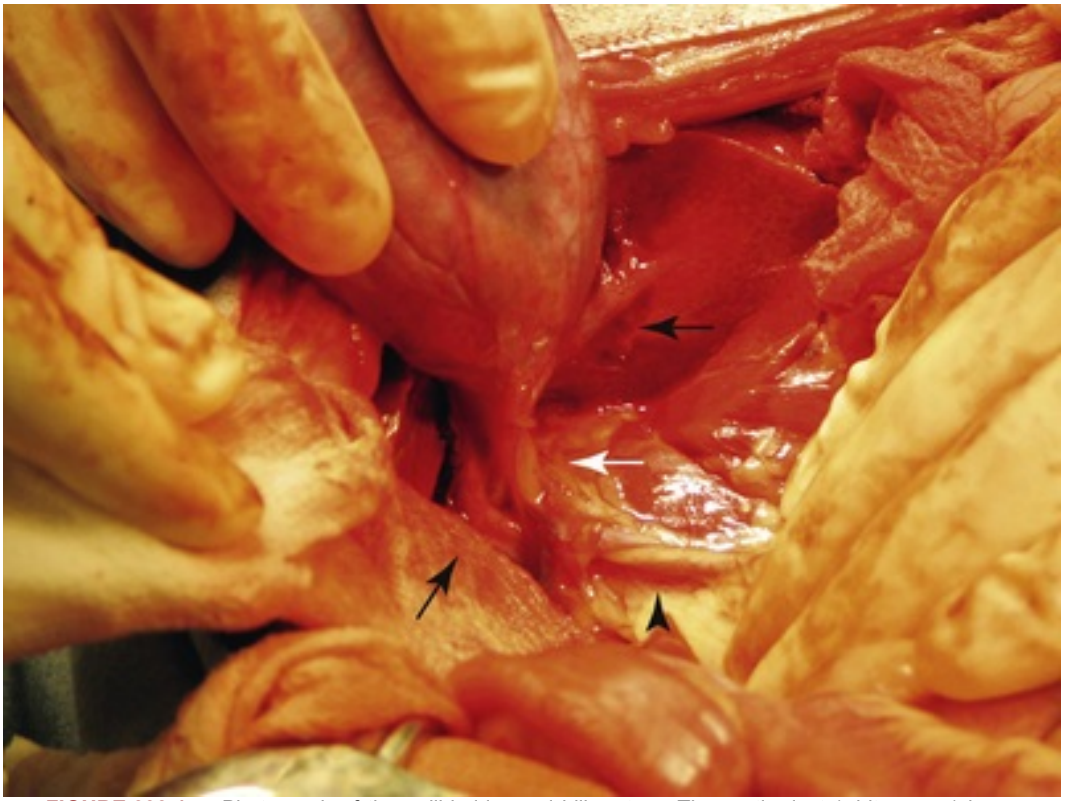

FIGURE 288-1 Photograph of the gallbladder and biliary tree. The cystic duct (white arrow) is an important landmark because it joins the gallbladder to the biliary tree and separates the more proximal hepatic ducts (black arrows) from the more distal common bile duct (black arrowhead).

Bile is composed of cholesterol, lecithin, phospholipids, and bile salts. Bile emulsifies fat and neutralizes acid in partially digested food. Gallbladder contraction releases bile into the common bile duct where it enters the duodenum through the sphincter of Oddi. In the dog, the common bile duct joins the minor pancreatic duct and both exit separately at the major duodenal papilla.[5] In the cat, the common bile duct fuses with the major pancreatic duct before entering the duodenum.[1]

See algorithm for diseases of the gallbladder and extrahepatic biliary system (Figure 288-2).

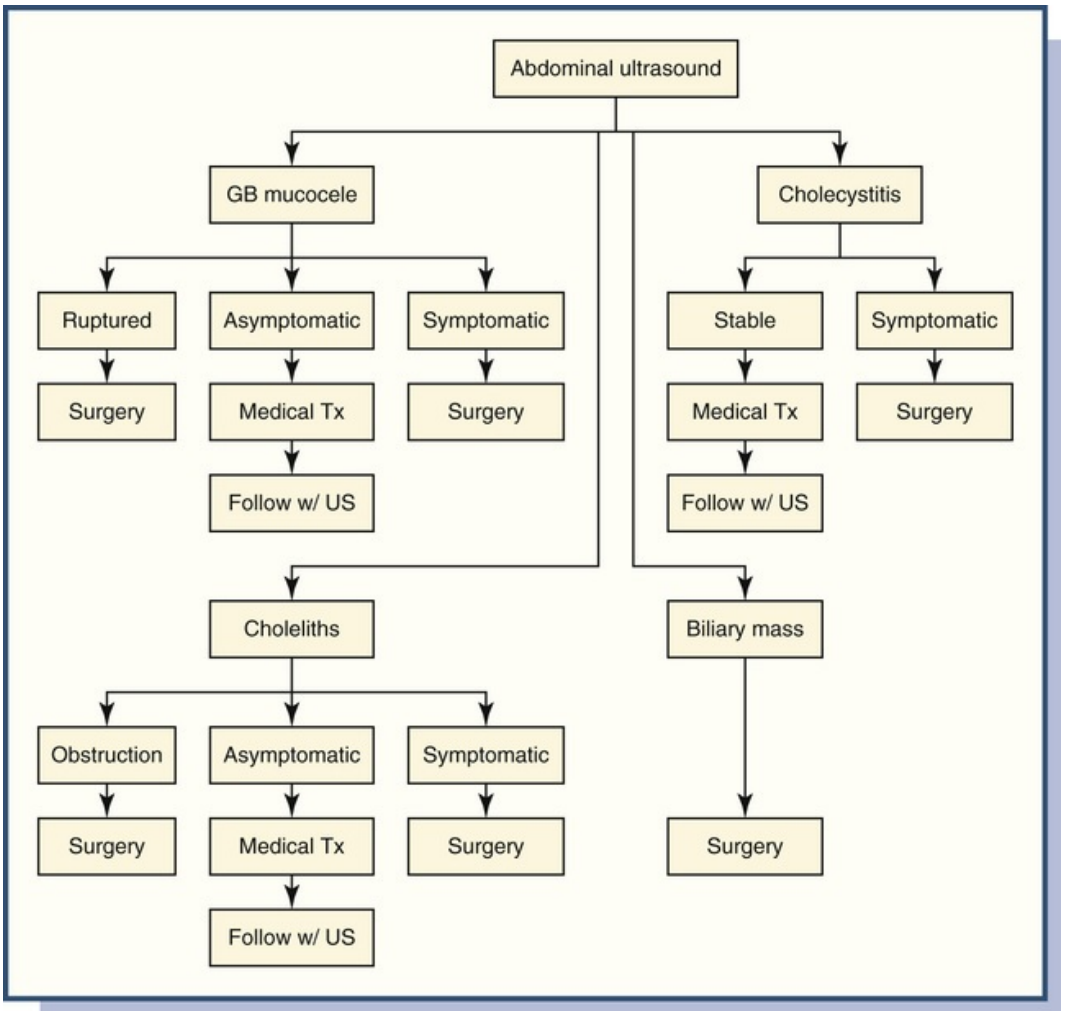

FIGURE 288-2 Algorithm for diseases of the gallbladder and extrahepatic biliary system.

Cholelithiasis and Choledocholithiasis

Etiology

Choleliths, or gallstones, are one of the more commonly recognized abnormalities of the gallbladder.[6,7] Older female dogs are predisposed and breeds most commonly affected include Miniature Schnauzers and Miniature Poodles. In the dog, cholesterol, bilirubin, and mixed choleliths have been reported.[6] Calcium-based stones are rare due to the ability of the canine gallbladder to absorb free calcium in bile.[2,8] Feline choleliths contain cholesterol, bilirubin derivatives, and calcium salts.[9]

The origin of choleliths is only partly understood and species variation is evident. Cholesterol is strongly hydrophobic, necessitating transport in micelles to remain suspended in solution. When an imbalance occurs between bile salts and cholesterol, bile becomes more viscous leading to the formation of gallstones. Various abnormalities may promote cholelithiasis. These include gallbladder dyskinesia, hypercholesterolemia,

hypertriglyceridemia, hyperbilirubinemia, endocrine disease, and cholesterol absorption and transport defects in the gallbladder. Breed and species predisposition also play a role.[10]

Choledocholiths, stones in the common bile duct, may be primary or secondary. Primary stones develop directly in the common bile duct. Secondary stones are more common and form in the gallbladder, later passing into the common bile duct.

Clinical Signs

A variety of clinical presentations are possible with choleliths. Many small animal patients are asymptomatic. In more serious cases, the gallbladder or bile duct may rupture, leading to bile peritonitis.[11] Of those presenting for medical care, abdominal pain, vomiting, anorexia, and icterus are the most consistent clinical signs. Caution must be taken in interpreting clinical signs as many abdominal disorders such as pancreatitis, gastroenteritis, gastrointestinal foreign bodies, and abdominal neoplasia manifest in similar manners.[2,6,7]

Diagnosis

Laboratory findings vary widely with cholelithiasis. A stress leukogram is the most common finding. However, a neutrophilic leukocytosis with a left shift is typical in patients with biliary rupture. Mild to moderate nonregenerative anemias occur in patients with chronic disease. The total bilirubin, alkaline phosphatase (ALP), and gamma-glutamyltransferase (GGT) are frequently elevated. Bilirubinuria is often evident and generally precedes clinical jaundice. Due to the short half-life of ALP in the cat (6 hours compared with 72 hours in dogs), even mild increases are significant.[2,12] Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) elevations, when present, are less dramatic than rises in ALP and GGT. Mild hypercholesterolemia occurs with cholestasis and severe elevations are observed with biliary obstruction. Hypoalbuminemia and hypoglycemia may occur if sepsis or endotoxemia are present.[2,6,7]

Abdominal radiographs are often of limited diagnostic value as most stones contain insufficient calcium to be seen. If visualized, they appear as single or multiple radiopaque structures in the cranioventral abdomen on lateral radiographs and in the right cranial abdomen on ventrodorsal radiographs.[6]

Ultrasonography is the diagnostic modality of choice. An experienced ultrasonographer may identify gallstones, thickened gallbladder wall, biliary tree dilation, or pericholecystic fluid.[6,13-15] Extrahepatic ductular dilation may be evident within 24 to 48 hours of complete obstruction, whereas intrahepatic duct dilation takes 5 to 7 days to develop.[13] In cats, a common bile duct greater than 5 mm is indicative of extrahepatic biliary obstruction.[14] Ultrasonographic gallbladder contraction studies using Lipofundin and erythromycin have been studied and may aid in the determination of a biliary obstruction.[16-20]

Treatment

Medical dissolution therapy for acute obstructing choleliths is rarely successful. Treatment is aimed at supportive care until the stone or stones pass. Intravenous fluids, antibiotics, and analgesics aid patients with mild to moderate biliary obstruction. In patients with severe obstructive disease, reestablishing patency of the biliary tract is paramount and best accomplished with surgery. Multiple surgical procedures have been described. Choleliths lodged in the bile ducts may often be removed after a cholecystectomy, but occasionally require a choledochotomy. Cholecystectomies and choledochotomies have lower morbidity and mortality rates and are therefore the treatments of choice.[21] In contrast, other procedures may be necessary depending on several factors including viability of the bile ducts, presence of strictures, and location of the biliary obstruction, but these generally carry higher mortality rates.[5,22,23] Minimally invasive biliary diversions techniques exist and include ultrasound-guided transhepatic or transabdominal percutaneous drainage or laparoscopic assisted transperitoneal percutaneous catheter placements.[24,25]

Biliary Stenting

Surgically and endoscopically placed choledochal stents are revolutionizing the treatment of extrahepatic biliary disorders in both dogs and cats (see ch. 123).[26-29] Two general types of biliary stents exist. Plastic (polyurethane) stents are used to facilitate drainage and to maintain patency of the biliary tree. Plastic stents often dislodge after weeks to months on their own or they may be removed endoscopically if desired (

Video 288-1). Self-expanding metallic stents are considered more permanent and are generally reserved for recurrent disease or malignancies of the bile duct (Figure 288-3). Both types of stents have been successfully placed for quite some time through open surgical approaches.[26,27,29]

FIGURE 288-3 Photograph following placement of an endoscopic metallic biliary stent for a recurrent distal common bile duct obstruction in a German Shepherd.

Endoscopic retrograde cholangiopancreatography (ERCP) uses a combination of endoscopy and fluoroscopy to evaluate the biliary tree in a less invasive manner (see ch. 123). New reports have demonstrated its use in clinical patients.[28-32] A side-view endoscope is advanced in the proximal duodenum allowing for direct visualization of the major duodenal papilla. A sphicterotome catheter and guidewire are inserted through the endoscope into the major duodenal papilla. Fluoroscopy is used to monitor the advancement of the guidewire. Once access to the common bile duct has been obtained, contrast is injected and monitored fluoroscopically during the ERPC portion of the procedure. Strictures, stones, and malignancies are visualized with experience. A sphincterotomy is performed to open the sphincter of Oddi and to facilitate the advancement of other instrumentation. Stones or sediment, if present, may be removed by sweeping the bile duct with balloons. In addition, dilation of strictures and tumors may be performed to restore the flow of bile. To maintain patency of the biliary tree, a stent can be placed in the common bile duct via the endoscope (see Video 288-1). Complications are infrequent, but may include pancreatitis, duodenal or biliary perforation, bacterial cholangitis/cholangiohepatitis, and stent-induced strictures.[28,29,33]

Cholecystitis

Etiology

Cholecystitis has been used to define both inflammatory conditions of the gallbladder, as well as gallbladder-related symptoms in the absence of gallstones.[34] The term encompasses a wide variety of acute and chronic diseases, with or without bacterial or parasitic infections. The origin of cholecystitis in companion animals is poorly understood. Predisposing factors include bile stasis, gallbladder mucoceles, ascending bacterial or parasitic diseases, and biliary neoplasia.[34] Infarction and hematogenous spread of bacteria may also be involved. In cats, bacterial infections are thought to be secondary to inflammation rather than the inciting

factor.[35] Concurrent choleliths are identified in some patients, but the causal relationship is unknown.[2,6,36]

Some patients with cholecystitis develop necrotizing cholecystitis. Necrotizing cholecystitis is often referred to as a separate disease entity because of its severe manifestation, increased risk of complications, and higher mortality rate.

Clinical Signs

Cholecystitis may be either acute or chronic in nature. Mild cases are often asymptomatic. With moderate to severe acute cholecystitis, anorexia, vomiting, abdominal pain, and fever predominate. The presence of icterus is variable. Chronic cholecystitis is much more difficult to diagnose. Clinical signs may include intermittent anorexia, vomiting, and progressive weight loss. Abdominal pain may be present, but can be difficult to detect on examination. Abdominal effusions occur with cholecystitis due to gallbladder rupture and bile peritonitis.

Diagnosis

Similar to cholelithiasis, laboratory findings vary widely with cholecystitis. Most clinicopathologic changes are consistent with cholestasis or posthepatic biliary disease.[2,36] In cats with cholecystitis, elevations in ALT, ALP, and total bilirubin correlate well with ultrasonographic changes and potentially indicate more clinical significance.[37]

Aspirates of effusion typically yield a yellow green fluid suggestive of bile.[38,39] Analysis of bilious effusion is characterized by suppurative inflammation with or without bile pigment. Intracellular and extracellular bacteria are common. Total protein measurements range from 2.9 to 5.6 g/dL. If the bilirubin in the effusion is greater than twice that of circulating blood, then a biliary rupture is present.[38,39]

Radiographic features vary and may include decreased serosal detail consistent with an abdominal effusion, choleliths, or emphysema of the gallbladder.[39] Diagnosis through ultrasonography is the current gold standard in companion animals.[13] Ultrasound reliably reveals suspended sediment, choleliths, thickened gallbladder wall, extrahepatic biliary obstruction, and emphysema of the gallbladder (Figure 288-4). Hyperechoic sludge in the gallbladder or extrahepatic biliary tree is particularly concerning in cats and is often indicative of cholecystitis.[14,37,40] In contrast, biliary sludge is common in older dogs and is often insignificant.[41] In cats, a gallbladder wall thickness of greater than 1.0 mm accurately predicts gallbladder disease.[42] Pericholecystic fluid and omental adhesions, if detected, are suggestive of perforation.[15] Abdominal effusions are readily observed and may contain particulate material.

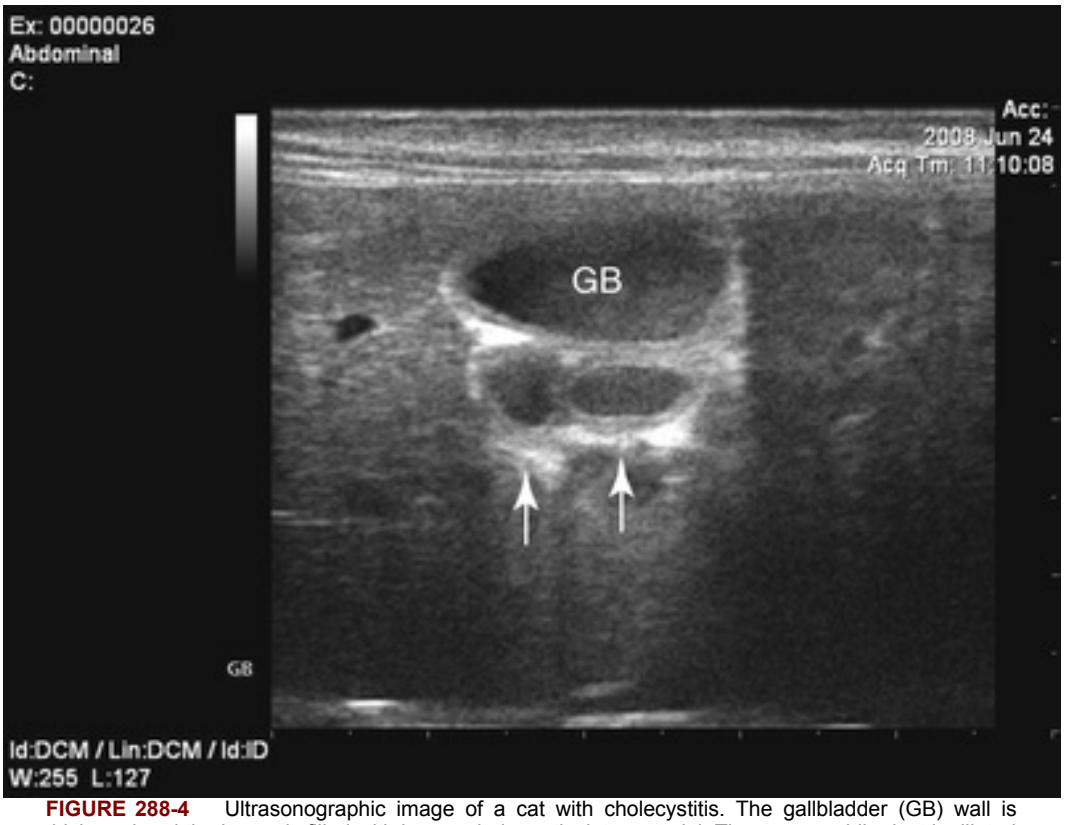

FIGURE 288-4 Ultrasonographic image of a cat with cholecystitis. The gallbladder (GB) wall is thickened and the lumen is filled with hyperechoic particulate material. The common bile duct is dilated and tortuous (arrows).

Treatment

Both medical and surgical management are available for patients with cholecystitis.[2,6,36,43] Medical management routinely includes antimicrobials, IV fluids, and analgesics. Cholecystocentesis is useful both as a diagnostic tool and method of therapy.[44] The transhepatic approach is preferable as the liver provides internal compression at the drainage site. The procedure has minimal risk when the gallbladder is drained completely, limiting the possibility of leakage. Bile peritonitis and vasovagal collapse are known complications. Positive bacterial cultures have been found in 62% of patients with cholecystitis. *Escherichia coli, Enterococcus* spp., *Bacteroides* spp., *Streptococcus* spp., *Clostridium* spp., and *Helicobacter* spp. are the most common isolates.[35,45] Culture results revealed 80% of the organisms were sensitive to ciprofloxacin and aminoglycosides. First-generation penicillin and cephalosporin efficacy is less reliable.[45] Antibiotic selection should be based on specific culture results when possible and treatment continued for a minimum of 1 month and potentially longer to ensure adequate resolution. In severe cases of cholecystitis or patients with bile peritonitis, cholecystectomy is the preferred treatment as it immediately removes the major source of infection.[36,39] Ultrasonographic gallbladder contraction studies may aid in the decision whether to pursue medical versus surgical treatment.[16-20]

Emphysematous Cholecystitis

Emphysematous cholecystitis is a rare manifestation of acute cholecystitis complicated by gas-producing organisms.[11,46-50] Gas may accumulate in the lumen, wall, or pericholecystic tissues. It is a rare disease entity in the dog and extremely rare in cats. An association with diabetes mellitus has been documented in the dog.[48]

Clinical signs and clinicopathologic data are similar to cholecystitis. Radiographically, the disease is characterized by a spherical to ovoid gas opacity superimposed over the hepatic silhouette.[46-48] On ultrasound, a gas interface is seen in the area of the gallbladder with variable distal shadowing. The

gallbladder wall, echogenic sediment, and fluid may be obscured depending on the amount of reverberation.[46-48] Adhesions, localized pericholecystic fluid, or generalized echogenic effusions often correlate with biliary rupture.[15] Computed tomography (CT scan) is ideal for the diagnosis as it allows for direct visualization of gas in the gallbladder lumen, wall, and biliary ducts.[34] Surgical intervention is most appropriate due to the high risk of gallbladder rupture and septic peritonitis.[36,39,46-48] Anaerobes are most commonly isolated and include *E. coli* and *Clostridium perfringens.*[48] Fluoroquinolones, metronidazole, and chloramphenicol are commonly used as they achieve high concentrations in bile and have strong anaerobic activity. Necrotizing cholecystitis and small bacterial abscesses in the gallbladder wall are often seen on histopathology.[36,48] A favorable prognosis is possible if the patient survives the perioperative period. Death is often due to sepsis, shock, or peritonitis.

Biliary Neoplasia

Primary tumors of the gallbladder and biliary tree are exceedingly rare, yet the number of reported cases is increasing in both dogs and cats.[2,51-57] Biliary cystadenomas and biliary adenocarcinomas (cholangiocarcinoma) are well-established tumors of the biliary tree.[58] Recently large cell lymphoma in dogs as well as small cell lymphoma and neuroendocrine carcinomas in cats have been recognized due to improved diagnostic capabilities.[54-57]

Biliary Cystadenomas

Biliary cystadenomas occur with some frequency in elderly cats and are rare in dogs. They arise most commonly from the intrahepatic bile ducts and less frequently from the extrahepatic bile ducts.[53] They comprise greater than 50% of all feline hepatobiliary tumors.[51] A male predisposition has been observed in the cat.[53] They can be single or multifocal and involve one or more hepatic lobes. Malignant transformation has been observed in some cats.[51]

Biliary cystadenomas are often incidental findings in older cats.[51-53] Hematologic changes are generally absent. Mild elevations in hepatic transaminases on routine health screens may be the only indication. Few clinical signs are noted and if present are associated with space-occupying disease. Ultrasound-guided aspirates of cystadenomas typically reveal a yellow to clear fluid with variable cellularity. A definitive diagnosis is best achieved with a tissue core, laparoscopic wedge, or open surgical biopsies.

Small multifocal cystadenomas should be followed with ultrasound and surgical resection is rarely necessary. Large cystadenomas may require surgery and carry a favorable prognosis even when partial resection is achieved.[51,53]

Biliary Carcinomas (Cholangiocarcinoma)

Biliary carcinomas are the most common feline hepatobiliary tumor and the second most common hepatobiliary tumor in dogs.[51] Biliary carcinomas are likely to arise from intrahepatic ducts in dogs; however, cats may have both intrahepatic and extrahepatic tumors. Labrador Retrievers and female dogs are thought to be at increased risk.[51] Biliary carcinomas of the gallbladder itself are exceedingly rare in both species.

Most biliary carcinomas are slow-growing neoplasms that are initially locally aggressive. Tumors are often advanced at the time of diagnosis, as clinical signs are rarely present prior to the onset of biliary obstruction. Patients with advanced biliary adenocarcinomas often present with lethargy, vomiting, weight loss, and icterus.[59] Metastatic disease is common at the time of diagnosis. In cats, chronic parasitic cholangitis may lead to biliary adenocarcinomas.[60]

Surgical resection is the treatment of choice for biliary adenocarcinomas when the tumor or tumors are confined to a single lobe and there is no evidence of metastatic disease.[51,59] Diffuse biliary adenocarcinomas carry a grave prognosis. Biliary diversion techniques using various stents have been investigated for nonmalignant diseases and are currently being evaluated for nonresectable tumors.[26,27] Percutaneous arterial embolization and chemoembolization of hepatic tumors have been performed in a small number of patients and their use is steadily growing.[61]

Parasitic Disease of the Biliary System

Etiology

Some species of flukes readily infect the biliary tree and liver of cats (*Platynosomum fastosum, Platynosomum concinnum,* and *Amphimerus pseudofelineus*).[2,60,62-65] Ova of the flukes are passed in the feces of the cat. A land snail must ingest the ova. An amphibian or reptile such as a toad, gecko, or lizard subsequently eats the snail. Cats ingest the second intermediate hosts to maintain the cycle. Outdoor predatory cats are at increased risk, particularly if they live in the Southeast United States, Caribbean, or Hawaii.[2] There is no known breed or sex predilection. Bacterial cholangitis, cholangiohepatitis, ductal fibrosis, extrahepatic biliary obstruction, hepatic failure, and death are known sequelae of parasitic cholangitis.[2,60,62,63,65] A recent investigation revealed chronic biliary parasitism may lead to the development of cholangiocarcinomas.[60]

Clinical Signs

The clinical signs of parasitic biliary disease depend on the degree of liver injury and biliary obstruction. Many cats are asymptomatic carriers. Weight loss, anorexia, and vomiting are the most common complaints in symptomatic cats. Jaundice and abdominal distention may be identified on physical examination in endemic parts of the country.[2,62,63]

Diagnosis

Complete blood counts are often nonspecific but may include a stress leukogram or mature neutrophilia. An eosinophilia is suggestive of parasitic infection if present. Clinical chemistries are variable but may include elevated liver values and total bilirubin, particularly if the patient is clinically ill. Fecal sedimentation (ch. 81) is the most reliable method of confirming a diagnosis.[2] Abdominal radiographs are usually unremarkable or may reveal hepatomegaly. Ductal dilation, hepatic cysts, and biliary obstruction are well documented and are readily seen on abdominal ultrasound. Aspiration and cytology of bile are useful for identifying fluke eggs if fecal testing is negative.[63,65] Hepatic biopsies may reveal flukes and/or ova.[62,63]

Treatment

Anthelminthics are the treatment of choice. Praziquantel at 20 mg/kg as a single dosage or once daily for 3 consecutive days is effective in eliminating the parasite.[2] Dosages as high as 40 mg/kg once daily for 3 days may be necessary, particularly with *A. pseudofelineus*.[64] Ursodiol may be helpful as a choleretic and an anti-inflammatory, but controlled studies demonstrating a definitive benefit are lacking. The acute death of numerous flukes may incite a severe inflammatory response. Steroids and antihistamines, started prior to treatment, may help limit the inflammatory cascade.[63] Patients presenting with biliary obstruction frequently require surgery. Antibiotics are indicated in patients with neutrophilic cholangitis on histopathology. Patients requiring surgery and those with extensive hepatic involvement have a guarded prognosis.[2,62,63]

Gallbladder Mucoceles

Etiology

A gallbladder mucocele is defined as the presence of bile-laden semisolid to immobile mucoid material within the gallbladder.[66-70] The mucocele has become one of the preeminent biliary diseases of the dog. Expansion of the mucocele within the gallbladder lumen is thought to stretch the gallbladder wall and disrupt blood flow, resulting in pressure necrosis of the wall and subsequent bile peritonitis.[66,68,69] Predisposing factors include dyslipidemias, dysmotility of the gallbladder, endocrine disease, and exogenous steroid administration.[68] Breed predispositions include Shetland Sheepdogs, Cocker Spaniels, and Miniature Schnauzers.[66,68,70] Mucoceles occur most commonly in older canine patients. The median age is 10 years with a range of 3 to 17 years.[66,68-70] Potential complications of mucoceles include extrahepatic bile duct obstruction, cholecystitis, necrotizing cholecystitis, bile peritonitis, and pancreatitis.

Recent advancements have proposed etiologies for mucoceles. Hyperadrenocorticism is known to dramatically increase the risk of a mucocele.[71] New investigations have found that high-dosage exogenous

steroids result in significantly higher levels of unconjugated bile acids within the extrahepatic biliary tree.[72] Unconjugated bile acids are more hydrophobic and when in disproportionate levels, lead to injury of the biliary epithelium. Mucin secretion increases as a result of the injury and ultimately leads to mucinous hyperplasia, one of the defining histologic features of a mucocele.[73-75] Hypothyroidism has also been speculated as a mechanism by which mucoceles form. It has been established that bile flow is reduced in humans with hypothyroidism. With reduced levels of thyroxine, sphincter of Oddi relaxation is impaired, liver cholesterol metabolism is altered and bile secretion diminishes.[76,77] Mucin is thought to organize and solidify under these conditions. Interestingly, xenobiotics have recently been linked with the development of mucoceles. Shetland Sheepdogs treated with flea products containing imidacloprid were more likely to develop a mucocele than members of the breed that were not treated with the drug. Other breeds did not display the same sensitivity making the findings specific to Shetland Sheepdogs.[78]

The identification of gallbladder mucoceles in cats is increasing.[79-81] Biliary stasis is suspected to be the predominant mechanism as endocrinopathies are less common. An estimated 12% of cats have congenital biliary abnormalities, which may suggest an underlying structural or drainage issue predisposing to the development of mucoceles and other biliary diseases in this species.[82]

Clinical Signs

Gallbladder mucoceles are thought to develop slowly, and therefore clinical presentation varies widely. Increased awareness of the disease has facilitated the detection of incidental mucoceles on abdominal ultrasonography. Alternatively, patients may present with signs of an acute abdomen associated with extrahepatic bile duct obstruction, pancreatitis, or bile peritonitis. Symptomatic patients are frequently evaluated for vomiting, anorexia, lethargy, and abdominal pain. Fever is commonly associated with bacterial cholecystitis or bile peritonitis. Icterus is apparent in approximately 40% of patients.[66,69,70]

Diagnosis

Routine clinicopathologic abnormalities are often indistinguishable from other hepatobiliary diseases. ALP is the predominant enzyme elevation.[66-70] ALT, GGT, and total bilirubin are frequently elevated, particularly in symptomatic patients. Cholesterol is markedly elevated in patients with bile duct obstruction. Neutrophilic leukocytoses and left shifts occur most commonly with bile peritonitis, bacterial cholecystitis, or bacterial cholangiohepatitis.

Abdominal radiographs are useful to exclude other hepatobiliary diseases, but are inadequate to definitively diagnose patients with mucoceles. Ultrasound remains the gold standard for gallbladder mucocele detection.[66-70] Ultrasonographic changes are often marked by stark contrasting layers within the gallbladder (Figure 288-5 and Video 288-2). In the immature mucocele, hyperechoic biliary sludge may be suspended or gravity dependent. Anechoic fluid, or liquid bile, is present in varying amounts. A hypoechoic to anechoic rim (mucin layer) separates the biliary sludge from the gallbladder wall. Fracture lines are often visible in the mucin layer and typically form either a stellate or striated appearance.[66] It is the striated or stellate appearance that is often referred to as a kiwi fruit. In the mature gallbladder mucocele, a hypoechoic to anechoic rim is the predominant finding and the biliary sludge is often centrally located and immobile. Mucin fragments and choleliths may be seen suspended in the gallbladder, lodged in the cystic or common bile ducts, and in rare cases, free in the abdominal cavity. The gallbladder wall may be normal or diffusely thickened. Fluid and hyperechoic fat may be visualized near the gallbladder and are suggestive of gallbladder rupture or localized peritonitis.[15] It is important to note that the appearance of mucoceles can vary widely and the ultrasonographic pattern does not always correlate with the severity of disease.[82]

FIGURE 288-5 Ultrasonographic image of a mature gallbladder mucocele in a Cocker Spaniel exhibiting a stellate appearance. The mucin layer is hypoechoic while the echogenic bile is centrally located. There is a small volume effusion (white arrow) and the adjacent fat is hyperechoic (black arrow). Both features are suggestive of gallbladder rupture. Note the resemblance to a cut kiwi fruit.

Histologically, mucoceles are characterized by cystic mucinous hyperplasia of the gallbladder mucosa with thick gelatinous mucin adhered to the luminal surface.[66,68-70] Lymphoplasmacytic or neutrophilic cholecystitis, or a combination of both, may be present.

Treatment

Surgical correction is indicated in many patients and is essential when bile peritonitis is present.[66,68-70] A cholecystectomy is the most common curative procedure and in uncomplicated mucoceles may be performed laparoscopically.[83] Aerobic and anaerobic cultures are essential at surgery as 9% to 66% of patients have concurrent bacterial infections.[66,70] Bacterial organisms may include *Enterococcus* spp., *Enterobacter* spp., *E. coli, Staphylococcus* spp., and *Streptococcus* spp.[66,68,69]

Medical therapy for gallbladder mucoceles has been successful in some patients, particularly those with hypothyroidism.[66-68] A combination therapy of cholerectics and antibiotics is most frequently attempted. Cholerectics, such as ursodiol and S-adenosylmethionine (SAMe), alter the microenvironment of the gallbladder and increase bile flow. Ursodiol is a hydrophilic bile acid that decreases the secretion of mucin from the biliary epithelium and reduces the formation of cholesterol crystals.[84] Care should be taken in patients with biliary obstruction as cholerectics may induce rupture of the gallbladder or biliary tree. Antibiotic selection based on culture results of bile is ideal. However, empiric therapy against anaerobic bacteria is a logical choice. Therapy should be continued for a minimum of 4 to 8 weeks.[42-44] In addition, low-fat diets are likely beneficial.[67,68]

The long-term prognosis for patients with gallbladder mucoceles is highly variable. Patients with septic and bile peritonitis carry the highest mortality rate. Stable patients with nonruptured mucoceles have the most favorable prognosis. Perioperative mortality for patients varies from 22% to 40%.[66,70] The prognosis is excellent for patients surviving the perioperative period.[66,68-70] Evaluation and treatment of concurrent endocrine diseases is always advised.

CHAPTER 289

Pancreatitis

Etiology and Pathophysiology

Thomas Spillmann

Acute pancreatitis (AP) in dogs and cats is defined as a fully reversible inflammation of the pancreas with the histologic presence of edema, neutrophilic infiltrate, and necrosis. The disease can be local or can lead to the systemic inflammatory response syndrome (SIRS; see ch. 132) with possibly fatal multiple organ failure.[1-6] Chronic pancreatitis (CP) is characterized by continuing inflammation (lymphocytic/lymphoplasmacytic) with irreversible changes such as fibrosis. The clinical course of CP can be subclinical or recurrent with episodes of more or less severe illness, as in acute-on-chronic pancreatitis. In some cases, the loss of pancreatic tissue leads to decreased exocrine and/or endocrine function.[1-6] Canine and feline pancreatitis present with a wide variety of clinical signs overlapping not only with non-pancreatic diseases but also between AP and CP (see ch. 290 and 291).[4,5] Also, clinical signs and results of laboratory tests and abdominal ultrasound can be conflicting.[3-8] The morphologic differentiation of pancreatic inflammation is, however, rarely performed, despite the proven safety and validity of ultrasound-guided fine-needle aspiration (see ch. 89) and surgical or laparoscopic pancreatic biopsy (see ch. 91).[9-14] The diagnostic value of the procedures is, however, influenced by an uneven distribution of pancreatic inflammation.[1,2]

The etiology of acute and chronic pancreatitis remains idiopathic. Several risk factors have been proposed for both dogs and cats, most based on experimental studies, analogies from human medicine, or case reports.

Breed predisposition has been documented in retrospective and case-control studies. Miniature Schnauzers, as well as Yorkshire and other Terriers, appear to be predisposed to AP.[15-19] The majority of cats with acute necrotic and suppurative pancreatitis is of the domestic shorthaired breed.[20,21] CP appears to more often affect Cavalier King Charles and English Cocker Spaniels, Boxers, and Collies.[22-24]

Genetic associations with cationic trypsinogen *(PRSS1)*, cystic fibrosis transmembrane conductance regulator *(CFTR)*, and serine protease inhibitor Kazal-type 1 *(SPINK1)* genes are documented in humans. In dogs, no association of pancreatitis with *PRSS1* or *CFTR* gene mutations has been found. The role of *SPINK1* gene variants in Miniature Schnauzers remains controversial.[16,17,25,26] There have so far been no such studies in cats.

Gender association appears possible for dogs with AP. Retrospective, partly case-controlled studies have proposed being neutered (male/female) or male as risk factors.[18,19,27] Post-mortem examinations in dogs with CP revealed that being female did not increase the relative risk for the disease, despite a higher number of affected females.[22]

Hypertriglyceridemia and obesity have been considered important risk factors for canine pancreatitis.[27] Prospective case-control studies in Miniature Schnauzers revealed that dogs with a history of pancreatitis were five times more likely to have hypertriglyceridemia. In dogs with serum triglyceride levels ≥862 mg/dL (≥9.7 mmol/L), a 4.5-fold higher likelihood of having serum canine pancreatic lipase immunoreactivity (PLI) values consistent with pancreatitis was observed.[15,28] A prospective cross-sectional study in overweight and obese dogs demonstrated an association of hypertriglyceridemia with a markedly increased serum cPLI concentration, but no development of clinical pancreatitis.[29]

Dietary indiscretion, including access to trash and table scraps, was regarded a risk factor for AP in dogs in a retrospective case-control study and one case report.[27,30] Although fat-rich diets have been proposed as a risk factor, this association has never been reliably documented.

Infections have been reported in connection with canine and feline AP. In dogs with babesiosis, AP was

documented in several retrospective studies and appears to be of prognostic value for patient survival.[31-34] Canine monocytic ehrlichiosis does not cause AP in experimentally infected Beagles, but spontaneously diseased dogs can have increased serum cPLI concentrations without clinically apparent pancreatitis.[35] AP in connection with granulocytic ehrlichiosis and leishmaniasis was documented in two case reports, suggesting an individual complication rather than a regular sequela of these infections.[36,37] Bacterial or septic pancreatitis has not been reported so far. However, bacterial translocation to the pancreas can be induced experimentally in both dogs and cats.[38-40] Recently, bacterial colonization was documented in the pancreas of cats with spontaneous pancreatitis, with fluorescence *in situ* hybridization indicating more frequent colonization in moderate to severe than in mild pancreatitis.[41,42] Bile duct obstruction might exacerbate pancreatitis and impair the ability to clear bacteria in cats with pancreatic fibrosis and disorders of the major papilla due to the joint termination of the common bile duct and pancreatic duct in this species.[6,42,43] Successful culture of bacteria *(Enterococcus hirae)* has, however, been reported in only one cat with ascending cholangitis and pancreatitis.[44] Concurrent inflammation of the pancreas, liver, and intestine is considered a frequent sequela in cats, but the cause-effect relationship is still open.[42] A highly virulent feline calicivirus infection with severe AP was reported in two independent case series.[45,46] Pancreatic and hepatic flukes rarely have been involved in feline pancreatitis, being documented only in occasional case reports.[47-50] *Toxoplasma gondii* and *Bartonella* spp. do not appear to cause feline pancreatitis. A recent study found no significant association between feline PLI serum concentrations and the presence of antibodies against both pathogens.[51]

Drug reactions appear to be idiosyncratic rather than true risk factors, as proposed for potentiated sulfonamides (see ch. 286).[52,53] Widely used drugs with occasional case reports of AP include azathioprine, L-asparaginase, meglumine antimonate, N-methyl-glucamine, and clomipramine.[54-62] Prospective studies have revealed no evidence for pancreatitis in dogs receiving L-asparaginase for lymphoma or meglumine antimonite for leishmaniasis.[58,59] Phenobarbital/potassium bromide treatment was suspected to cause pancreatitis in up to 10% of treated dogs included in one retrospective study.[63] This has been supported by findings of elevated serum cPLI concentrations and hypertriglyceridemia in dogs treated with these antiepileptic drugs.[64,65] In cats, experimental acute hypercalcemia induced AP after local arterial but not after peripheral venous calcium gluconate infusion.[66-68] There have been no reports of spontaneous hypercalcemia with AP in cats. Cholecystokinin-8 and cerulein injections can induce AP in dogs.[69-71]

Intoxications appear to be rare causes of AP, with zinc intoxication being documented in several case reports.[72-75] Snake bites can be of regional importance, as reported for fatal *Vipera xanthina palestinae* envenomation with acute necrotic pancreatitis (see ch. 156).[76] Organophosphate intoxication was investigated in experimental trials showing that the canine but not the feline pancreas is sensitive (see ch. 152). In contrast to dogs, cats do not appear to have abundant pancreatic tissue-fixed butyrylcholinesterase.[77,78] Easter lily poisoning in cats is rather nephrotoxic, and the pancreotoxic effect is limited to the degeneration of acinar cells without inflammation (see ch. 155).[79]

Endocrine disorders linked to canine AP include hyperadrenocorticism (see ch. 306), hypothyroidism (see ch. 299), and diabetes mellitus (see ch. 304) including diabetic ketoacidosis.[19,80-82] CP is considered a cause rather than a consequence of diabetes mellitus in both species.[4,83,84]

Trauma and surgical or minimally invasive interventions also are possible risk factors. Traumatic pancreatitis can result from high-rise syndrome in cats.[85] Previous surgery other than neutering has been associated with an increased odds ratio (OR = 21.1) for pancreatitis in dogs.[27] Endoscopic retrograde cholangiopancreatography (ERCP) has the potential to induce AP (see ch. 123). Dogs and cats can have transiently elevated serum pancreatic enzyme activities and concentrations after ERCP without clinical signs of pancreatitis.[46,86-90] This phenomenon might be caused by subclinical inflammation.[91]

The pathophysiology of acute pancreatitis has been the focus of recent, thorough, topical reviews.[3,5,6,42,92-94] Experimental animal models are the main basis for current knowledge on subcellular events leading to acinar cell destruction, as well as factors promoting complex local and systemic inflammatory responses.[92-94] Acute pancreatitis (AP) and acute pancreatic necrosis are suggested to be responses to the same stimuli with a different progression and outcome. Mild AP, therefore, is a localized process with uncomplicated full recovery. In contrast, severe AP with necrosis can be localized but also cause SIRS, resulting in multiple organ dysfunction syndrome (MODS) and death.[3,5,92-94]

The key factor initiating pancreatic inflammation appears to be the activation of trypsin within the acinar cells, being caused by three basic scenarios: (1) blockage of the acinar cell apex in the pancreatic duct, leading to the co-localization and fusion of zymogen and lysosomal granules; (2) oxidative stress; or (3) hypotension. The self-defense mechanism against activated trypsin is its neutralization by an intracellular pancreatic secretory trypsin inhibitor, which is overwhelmed when more than 10% of intracellular trypsin is activated.[3,93] Trypsin, in turn, activates other inactive pro-enzymes that normally are stored in zymogen granules. The release of activated digestive enzymes into the pancreatic tissue initially causes local inflammation with migration of neutrophils to the pancreas. This is followed by the subsequent production of reactive oxygen species and nitric oxide, which contributes to the inflammation.[3,93] The shift from apoptosis to necrosis is thought to be caused by neutrophils along with endothelin-1 and phospholipase A3.[3,93] Disturbed pancreatic microcirculation and increased vascular permeability contribute to pancreatic edema and necrosis, with necrotizing pancreatitis resulting in a progressive reduction in capillaries not responsive to fluid resuscitation.[93] Further local inflammation and SIRS is caused by a combination of different inflammatory pathways involving a large variety of mediators such as tumor necrosis factor-alpha, interleukin (IL)-1beta, IL-6, IL 10, platelet activating factor, intercellular adhesion molecule-1, CD40L, complement component C5a, chemokines, substance P, and hydrogen sulfide, as well as the kinin-kallikrein and the renin-angiotensin-aldosterone systems.[93,94] Of possible clinical value are the discoveries that pancreatic substance P and neurokinin (NK)-1 receptors are highly upregulated in mice with induced AP, and that knockout mice deficient in NK1 receptors are protected against AP and the associated lung injury.[95,96] NK1-receptors also appear to play a role in mediating pancreatic pain in rats, and their blockage protects septic mice against lung injury.[97,98] The usefulness of NK1-receptor antagonists for treating dogs and cats with AP remains to be studied.[93]

The development of systemic complications can be summarized as the following chain of events: AP leads to SIRS, which results in MODS. Features of MODS requiring special attention in humans and being partly documented in dogs and cats with AP include acute lung injury (see ch. 242), acute kidney injury and uremia (see ch. 322), disseminated intravascular coagulation (see ch. 197), and cardiac arrhythmias (see ch. 248).[93,98-101] Local complications after AP include pancreatic fluid accumulation, pseudocysts, and necrotic pockets that are prone to infections in humans. Case reports in dogs and cats have, however, only described sterile processes.[93,102-104]

Chronic pancreatitis is thought to be either a late complication of AP or a consequence of chronic immune-mediated inflammation, as proposed for the duct-destructive CP of English Cocker Spaniels.[4,5,24,93] In cats, CP is considered to be more common than AP.[6] Canine and feline CP is characterized by pancreatic tissue loss due to fibrosis, which can, in its end stage, lead to exocrine pancreatic insufficiency (EPI) and/or diabetes mellitus.[4,5,6,23,42,105,106] In dogs, EPI is, however, more often caused by pancreatic acinar atrophy following another pathophysiologic mechanism (see ch. 292).[107] The clinical course of CP extends from subclinical to recurrent episodes of acute-on-chronic pancreatitis. The pathophysiology of this phenomenon still needs to be elucidated. It is thought that increased pancreatic duct pressure might be a contributing factor to acute-on-chronic pancreatitis. Pancreatic duct abnormalities are a feature of CP in humans and also have been documented with magnetic resonance cholangiopancreatography in cats with induced or spontaneous CP.[108-110]

CHAPTER 290

Canine Pancreatitis

Diagnosis and Treatment

Jörg M. Steiner

Client Information Sheet: Pancreatitis in Dogs

Introduction

Canine pancreatitis is now recognized to be a common disease in dogs. In one study of more than 200 dogs that had died or had been euthanized for a wide variety of reasons and that were evaluated at necropsy, more than 8% showed macroscopic evidence of pancreatitis.[1] Furthermore, approximately 50% of these dogs had microscopic lesions suggestive of chronic pancreatitis and approximately 30% had lesions suggestive of acute pancreatitis.[2] This work has raised the awareness of clinicians for pancreatitis dramatically, but many cases, especially those that are subclinical, remain undiagnosed. The consequences of failing to diagnose subclinical pancreatitis are unknown. However, known consequences of mild chronic pancreatitis are acute exacerbations, diabetes mellitus, and exocrine pancreatic insufficiency. Thus, diagnosis of pancreatitis, even in cases of mild chronic disease would therefore be beneficial to the DVM, the pet and the owner.

Diagnosis

Clinical Presentation

The clinical presentation of dogs with pancreatitis can range widely. Many dogs, especially those with chronic disease, are subclinical, while others have mild nonspecific clinical signs, and yet others show clinical signs of severe disease and systemic complications. The classical clinical signs associated with severe acute pancreatitis in dogs include vomiting, abdominal pain, lethargy, and dehydration.[3] Some patients may also have diarrhea and others may have fever.[3] Systemic complications of canine pancreatitis are associated with clinical signs of that specific complication. For example, kidney injury may be associated with oliguria, anuria, or even polyuria; pulmonary failure is associated with an increased respiratory rate and effort; pancreatic encephalopathy can be associated with neurologic signs, and disseminated intravascular coagulation can be associated with bleeding diatheses. In contrast, patients with chronic mild disease may only show nonspecific clinical signs, such as hyporexia or anorexia, lethargy, or behavioral changes.[4]

Diagnostic Imaging

Pancreatitis can be associated with radiographic changes, such as decreased contrast in the cranial abdomen and displacement of abdominal organs.[3] However, these changes are subjective and abdominal radiography is insensitive and nonspecific for canine pancreatitis. Nonetheless, abdominal radiography is important in dogs with suspected pancreatitis to rule out other differential diagnoses, such as a gastrointestinal foreign body in a patient with acute vomiting and abdominal pain.

Abdominal ultrasound can be very useful for the diagnosis of canine pancreatitis, but does have important limitations. The sensitivity of abdominal ultrasonography is dependent on several factors, including equipment resolution, operator skills, level of suspicion of the ultrasonographer, but most importantly the severity of disease. In dogs with severe acute pancreatitis, pancreatic necrosis is evidenced by hypoechoic areas within the pancreas (E-Figure 290-1).[3] Other ultrasonographic findings in dogs with pancreatitis include

pancreatic enlargement, peritoneal effusion, hyperechoic peripancreatic fat or mesentery, an enlarged duodenal papilla, or a dilated pancreatic duct.[3] Some patients with chronic pancreatitis may show a hyperechoic pancreas due to pancreatic fibrosis.[5] The specificity of abdominal ultrasound is limited by other lesions that lead to the same or similar ultrasonographic changes as those seen in patients with pancreatitis (Videos 290-1 and 290-2). For example, any disease process leading to abdominal effusion could potentially be misinterpreted as pancreatitis.[5] Pancreatic enlargement can also occur due to portal hypertension.[6] Finally, pancreatic nodular hyperplasia, a condition that is recognized to be extremely common in older dogs and is not believed to be associated with current or previous pancreatitis, can lead to echogenicity changes that may be misinterpreted as pancreatitis.[7] Thus, diagnostic success is dependent on judicial utilization of this modality by an experienced ultrasonographer.

E-FIGURE 290-1 Abdominal ultrasound image of acute pancreatitis. Sagittal/oblique plane abdominal ultrasound image of the left cranial abdomen of a 7-year-old female spayed Basset Hound with pancreatitis. The left lobe of the pancreas (arrowhead) is enlarged, rounded, and hypoechoic. The surrounding fat is hyperechoic and hyperattenuating. The stomach (*) shows mild diffuse wall thickening, which is consistent with gastritis and/or gastric wall edema. (Image courtesy Dr. Jay Griffin, Texas A&M University.)

Abdominal computed tomography and magnetic resonance imaging are routine procedures in humans suspected of having pancreatitis, but historically both were considered to be insensitive for the diagnosis of pancreatitis in the dog.[8] However, newer studies would suggest that the diagnostic accuracy of these diagnostic modalities can be improved.[9,10]

General Clinical Pathology

A wide variety of hematological and serum biochemical changes has been reported in dogs with acute severe pancreatitis.[3] However, these changes should be viewed as manifestations of the systemic condition of the patient and as an indication of potential systemic complications, rather than as a direct indication of pancreatic inflammation. Also, findings on a complete blood count (CBC) and serum chemistry profile may help to direct the clinician towards alternative differential diagnoses and should thus be considered crucial for the work-up of any dog suspected as having pancreatitis.

Serum Amylase Activity

Amylases are enzymes that catalyze the hydrolysis of complex carbohydrates and are synthesized and secreted by several different cell types in the body, including pancreatic acinar cells. While some dogs with spontaneous pancreatitis do show increases in serum amylase activity, many others do not. Also, because amylases are synthesized and secreted by other tissues, increases in serum amylase activity can also be seen with various other conditions.[11] Thus, measurement of serum amylase activity is of little value in the diagnosis of canine pancreatitis.

Total Serum Lipase Activity

Lipases hydrolyze lipids, such as triglycerides, which are apolar lipids that are very important for long-term energy storage in the body. As a result, triglycerides need to be moved in and out of cells on a routine basis and because triglycerides are completely apolar, they first must be hydrolyzed into more polar lipolysis products, such as glycerol, monoglycerides, diglycerides, and fatty acids. This is why there are many different lipases in the body, including gastric lipase, pancreatic lipase, hepatic lipase, and hormone-sensitive lipase. The exact number of lipases in the body is unknown, but there are many, and while some of them show structural similarities, many of them just share function (i.e., lipolytic activity). Total serum lipase activity can be measured by many different methodologies, all using a different substrate. Many assays utilize 1,2-diacylglycerol as a substrate. These assays have been shown to have a limited specificity (approximately 50%) for the exocrine pancreas and a limited sensitivity (also approximately 50%) for canine pancreatitis.[11] Over the last 20 years a synthetic substrate, resorufin (DGGR), has been used as an alternative substrate in both human and veterinary medicine. While some studies would suggest a higher specificity for the exocrine pancreas than 1,2-diacylglycerol-based assays, other studies did not confirm these findings.[12,13] While the overall clinical utility of DGGR-based assays is probably better than those based on 1,2-diacylglycerol, more studies are needed to confirm these results, and this substrate is by no means specific for the exocrine pancreas in dogs. Also, a point of care assay has been described that uses triolein as a substrate.[14] However, thus far the only study available shows this assay to correlate with the measurement of serum pancreatic lipase immunoreactivity when exclusively evaluated in serum samples that are not lipemic, icteric, or hemolyzed, changes that are rather common in dogs with pancreatitis.[14] Also, this assay is not specific for the exocrine pancreas.

Trypsin-Like Immunoreactivity

Trypsin-like immunoreactivity (TLI) is specific for exocrine pancreatic function. However, the sensitivity of serum TLI concentration for pancreatitis in dogs is much lower than that of serum cPLI concentration or abdominal ultrasound.[15] This is probably due to the fact that trypsinogen, which is the form of trypsin present in tiny quantities in the serum under physiologic conditions, is very small and thus is quickly removed from the vascular space through renal excretion. During pancreatitis, trypsinogen is prematurely activated to trypsin, but trypsin is quickly scavenged from the serum by proteinase inhibitors. However, it must be noted that serum cTLI concentration remains the diagnostic test of choice for the diagnosis of exocrine pancreatic insufficiency (EPI; see ch. 292).

Pancreatic Lipase Immunoreactivity (PLI)

A specific assay for the measurement of pancreatic lipase immunoreactivity in dogs (cPLI, now measured by Spec cPL, IDEXX Laboratories, Westbrook, Maine) is available.[16] This assay is based on the detection of pancreatic lipase by use of a specific antibody. Thus, this is the only assay that can measure pancreatic lipase exclusively. This was confirmed by immunohistochemistry, which showed that of all tissues evaluated, only pancreatic acinar cells stained positive for pancreatic lipase.[17] Also, serum cPLI was measured in a group of dogs with EPI, showing undetectable or severely decreased serum cPLI concentrations in all dogs.[18] In another study serum cPLI was evaluated in healthy dogs that had been euthanized at an animal shelter showing a specificity of serum cPLI concentration (as measured by Spec cPL) of 97.5%.[19] Serum cPLI concentration was significantly increased in dogs with experimentally induced chronic kidney disease, but most dogs had serum cPLI concentrations within the reference interval and none of the dogs had serum cPLI concentrations that were above the recommended cut-off value for pancreatitis.[20] Also, long-term oral

administration of prednisone did not have any effect on serum cPLI concentrations.[21]

Several clinical studies have evaluated the sensitivity of serum cPLI concentration in dogs with pancreatitis. In general, the sensitivity is dependent on the severity of disease, but in most studies, sensitivities above 80% have been described for dogs with acute clinical pancreatitis and sensitivities above 60% for dogs with mild pancreatitis.[15,22-24] These data show that serum cPLI concentration is the most sensitive diagnostic tool for the diagnosis of canine pancreatitis currently available, though, as for most diagnostic tests in veterinary or human medicine, sensitivities are less than 100% and careful integration of history, other clinical data, and measurement of serum cPLI concentration are required to arrive at the correct diagnosis.

Also, a patient-side test for the semi-quantitative assessment of cPLI is available (SNAP cPL, IDEXX Laboratories, Westbrook, Maine).[24] This test is useful to rule out pancreatitis in dogs with suggestive clinical signs when the test is negative. Also, a positive test result suggests pancreatitis. However, a serum sample should also be sent to the laboratory for measurement of cPLI (by Spec cPL) to confirm the diagnosis and to achieve a baseline value that can then be used to monitor progression of the disease.

Special mention should be made of dogs that either have no clinical signs or only have clinical signs that are not commonly associated with pancreatitis, but show a serum cPLI concentration that is diagnostic of pancreatitis (Figure 290-2). The first response should be to have a thorough discussion with the owner to ensure that no subtle clinical signs are present (e.g., behavioral changes, finicky eating behavior, or other). If such signs are absent, the cPLI should be re-evaluated after 10 to 14 days. If cPLI has decreased by this time no further work-up is required. If, however, cPLI continues to be increased, the patient should be evaluated for any risk factors of chronic pancreatitis by assessing serum triglyceride and calcium concentrations and discussing the drug history with the owner. If a risk factor is identified, the patient should be managed accordingly. However, even if no such risk factors can be identified, further diagnostics and management are prudent to prevent long-term complications from chronic mild pancreatitis.

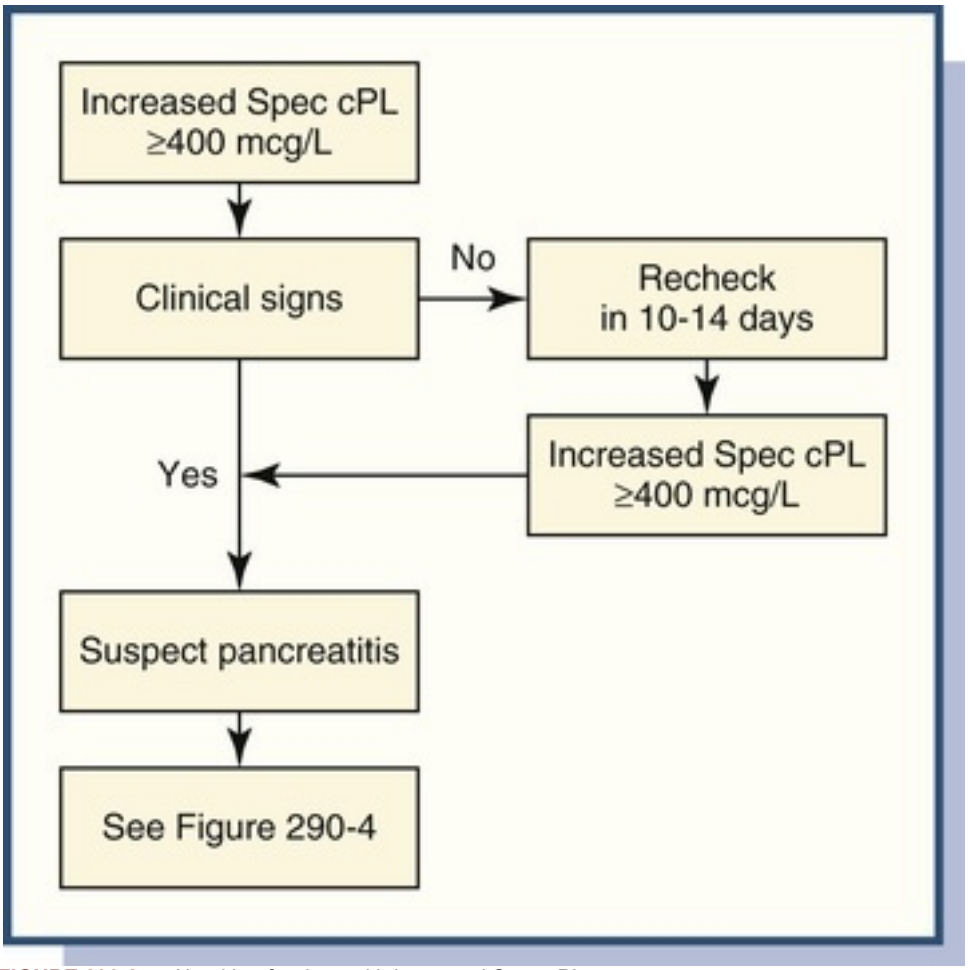

FIGURE 290-2 Algorithm for dogs with increased Spec cPL.

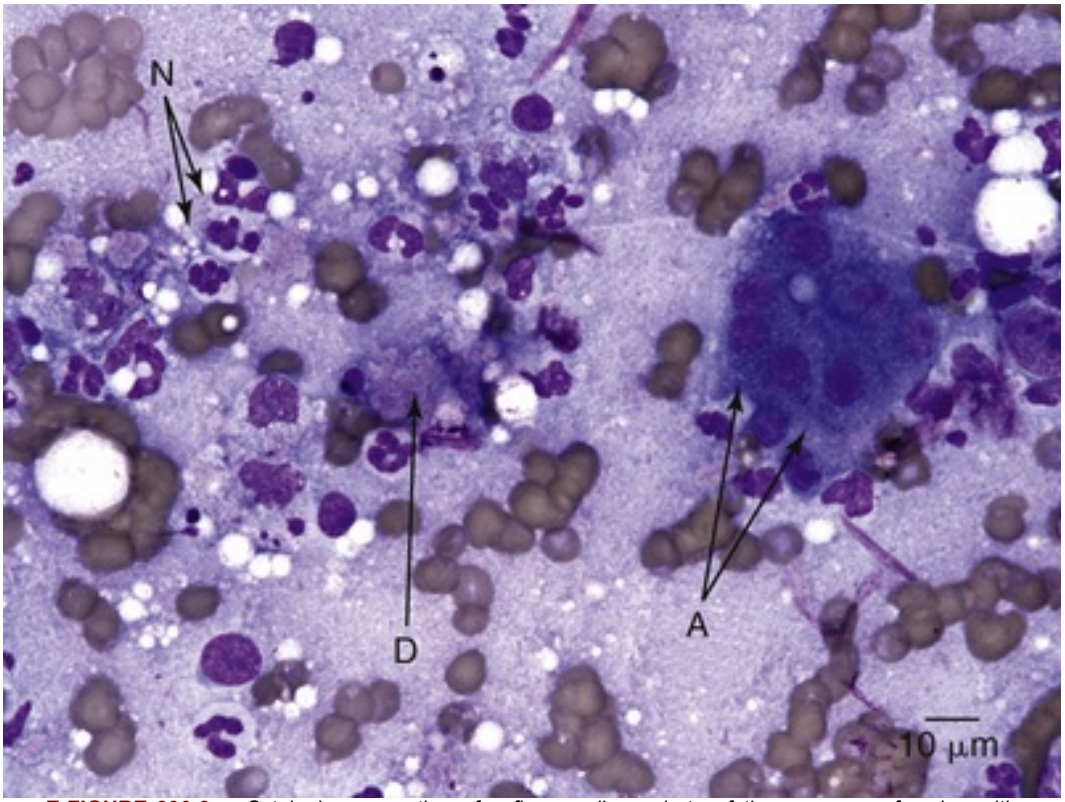
Cytology and Histopathology

Cytologic evaluation of a fine-needle aspirate of the pancreas (see ch. 89) is a great diagnostic modality to confirm a diagnosis of pancreatitis. Various studies have shown that there is little risk of a fine-needle aspirate of the pancreas.[25] The presence of pancreatic acinar cells confirms the successful aspiration of the pancreas and a presence of inflammatory cells in the same aspirate confirms the presence of pancreatic inflammation (E-Figure 290-3).[26] However, in patients with severe pancreatic necrosis, only cellular debris may be aspirated and the cytological evaluation may be inconclusive. Also, lack of inflammatory cells in the infiltrate does not rule out pancreatitis as inflammatory lesions may be highly localized.[1]



E-FIGURE 290-3 Cytologic preparation of a fine-needle aspirate of the pancreas of a dog with suspected pancreatitis. Note the neutrophilic infiltration (N). Some intact acinar cells (A) can also be seen. The image also shows debris (D), suggesting pancreatic necrosis. (Image courtesy Dr. Mark Johnson, Texas A&M University.)

Traditionally, histopathologic evaluation of a pancreatic biopsy has been viewed as the most definitive diagnostic tool for pancreatitis. Pancreatic biopsies can be collected during abdominal exploratory or by laparoscopy (see ch. 91).[27,28] The presence of pancreatitis can easily be suggested by gross appearance of the pancreas in some cases and histopathologic evaluation can definitively confirm pancreatitis.[22,28] However, the absence of pancreatitis cannot be proven by histopathology even if multiple biopsies are taken. With mild chronic pancreatitis, lesions can be highly localized.[1] It should also be noted that while a pancreatic biopsy in itself is not associated with many complications, many patients with severe pancreatitis pose a high anesthetic risk and the potential of hypotension; anesthesia is considered a risk factor for worsening pancreatitis.[28]

Treatment of Acute Severe Pancreatitis

Ultimately, acute and chronic pancreatitis can only be conclusively differentiated based on histopathology (i.e., chronic pancreatitis is characterized by irreversible changes such as pancreatic atrophy and pancreatic fibrosis). However, many if not most cases of mild acute pancreatitis are probably not presented to a veterinarian and most cases of chronic pancreatitis are mild.

Treatment of Cause

Whenever possible the cause of the disease should be removed or treated. However, this may prove difficult to accomplish as most cases of canine pancreatitis are considered idiopathic. Several causes and risk factors for canine pancreatitis have been identified. Dietary indiscretion is considered to be an important risk factor for pancreatitis in dogs.[29] Also, severe hypertriglyceridemia is considered a risk factor for the disease and in one study serum triglyceride concentrations > 850 mg/dL (approximately 9.6 mmol/L) were associated with a significant increase in the risk for pancreatitis in Miniature Schnauzers.[30,31] Pancreatitis is especially common in the Miniature Schnauzer and recently, 3 different mutations in the SPINK-1 gene have been identified in affected dogs.[32] While mutations of this gene have also been associated with hereditary pancreatitis in humans, SPINK-1 mutations are not a common cause of hereditary pancreatitis in humans. Blunt external trauma (e.g., due to road traffic accidents) can also cause pancreatitis in dogs. Surgical trauma can cause pancreatitis, but human patients that undergo surgery of organs distant from the pancreas have also been shown to be at an increased risk for pancreatitis, suggesting that hypoperfusion of the pancreas during anesthesia may be of bigger concern than surgical handling of the organ itself.[33] In rare instances, infectious organisms have been suspected to cause pancreatitis, including *Babesia canis* and *Leishmania infantis*.[34,35] Many pharmaceutical compounds have been implicated in causing pancreatitis in humans, most of them causing pancreatitis as an idiosyncratic reaction that is not predictable or dose-dependent.[36] In dogs there is some evidence that potassium bromide, phenobarbital, calcium, and L-asparaginase can cause pancreatitis, but many drugs may be responsible for isolated cases.[37-39] A careful history will be useful to identify many of the risk factors mentioned, including a history of trauma or dietary indiscretion. Also, a careful drug history may identify drugs that have been described as potential risk factors for pancreatitis. If the patient has been on any medication, it should be carefully evaluated whether the patient needs this specific medication or whether the drug can be discontinued or replaced with a different drug. A complete blood count and a serum chemistry profile, including triglycerides and calcium, may provide further clues as to a possible etiology.

Supportive Care

Aggressive fluid therapy is the mainstay of supportive care for dogs with severe forms of pancreatitis (see ch. 129). Fluid, electrolyte, and acid-base imbalances need to be assessed and corrected as early as possible. This is especially important since systemic complications are associated with a worse outcome and many of the systemic complications, once established, are difficult if not impossible to treat. Recent studies in humans have shown that minimal differences in blood urea nitrogen (BUN) concentrations at time of admission to the hospital and also minimal changes of BUN during the first 24 to 48 hours after admission to the hospital can have a dramatic impact on the outcome in patients with acute pancreatitis.[40]

Traditionally, food was withheld from dogs with pancreatitis, but over the last 10 years this practice has been questioned based on experiences in humans.[41] There is good evidence in humans with severe forms of pancreatitis that alimentation is crucial to counterbalance the catabolic effects of the disease.[42] Also, it has been shown in several studies that enteral nutrition is superior to parenteral nutrition.[43] A recent study has made similar observations in dogs.[44] While there was no difference in mortality between dogs fed by esophagostomy tube or total parenteral nutrition, dogs fed by esophagostomy tube improved significantly faster than did dogs fed parenterally.[44] Also, studies in humans have shown that alimentation entering the digestive tract before the duodenal papilla is not associated with a worse outcome when compared to patients fed by a jejunostomy tube.[45] Thus, in general, dogs with pancreatitis should be fed whenever possible.[45] An ultra-low-fat diet should be chosen. If patients are not interested in eating, feeding by gastrostomy, esophagostomy, or nasogastric tube should be attempted (see ch. 82).[45] If the patient vomits relentlessly (i.e., consistent vomiting even with aggressive antiemetic therapy), a jejunostomy tube should be placed or the patient should be fed by partial or total parenteral nutrition.[45]

Analgesia

Abdominal pain is the key clinical sign in human patients with both acute and chronic pancreatitis and is described in excess of 90% of all human patients (see ch. 143).[46] Abdominal pain is not always appreciated in dogs with pancreatitis. In one report only 58% of dogs with severe pancreatitis were considered to have abdominal pain.[3] However, it would appear unlikely that abdominal pain occurs less frequently in dogs than

in humans and it appears more plausible that pain remains unidentified in many canine patients. Thus, the presence of abdominal pain should be assumed and analgesic drugs utilized in all dogs with pancreatitis (see ch. 126). Meperidine, butorphanol tartrate, buprenorphine, morphine, fentanyl, methadone, or combinations of multiple analgesic drugs all at standard dosages can all be used in hospitalized patients.

Antiemetics

Antiemetic therapy (see ch. 39) is important for the treatment of patients with severe pancreatitis not only because nausea and vomiting are incapacitating, but also because nausea and vomiting may prevent proper nutritional support. Maropitant, an NK_1 antagonist, is the drug of choice as an antiemetic agent for dogs with severe pancreatitis.[47] It acts centrally by inhibiting substance P in the central nervous system and thus blocks both peripheral and central stimuli for vomiting. Maropitant is given subcutaneously at a dosage of 1 mg/kg q 24 h. Once the patient no longer vomits, the drug can also be given orally at 2 mg/kg q 24 h. While vomiting in many patients can be successfully managed with maropitant alone, addition of a 5-HT_3-antagonist such as ondansetron can have additive effects. Similarly to maropitant, 5-HT_3-antagonists act on both peripheral and central receptors, and they also block both peripheral and central stimuli for vomiting. Ondansetron is used at a dosage of 0.1-0.2 mg/kg slowly IV q 6-12 h. Once vomiting has stopped, the drug may also be administered orally. Other 5-HT_3 antagonists are also available. Metoclopramide is not a strong antiemetic and is usually insufficient in dogs with severe pancreatitis.

Proteinase Inhibitors

Based on the understanding of the pathophysiology of acute pancreatitis, proteinase inhibitors have long been at the center of new strategies for the management of pancreatitis. Unfortunately, no studies have been able to show strong evidence that such proteinase inhibitors are efficacious in dogs with spontaneous pancreatitis. This is in contrast to experimental pancreatitis in dogs where the proteinase inhibitor Trasylol had been shown to prevent death when administered at the same time as pancreatitis is being induced.[48] This is likely due to the fact that, while premature activation of trypsinogen to trypsin plays a role in the initial pathogenesis of pancreatitis, it does not appear to play an important role in the progression and development of systemic complications.

Fresh Frozen Plasma

Fresh frozen plasma and fresh whole blood contain alpha$_2$-macroglobulin, albumin, and both anticoagulant and coagulation factors (see ch. 130). In clinical trials in human patients with acute pancreatitis, there was no benefit of plasma administration.[49] There has been a recent study in dogs that would even suggest that the administration of fresh frozen plasma is associated with a worse outcome.[50] However, the study design was retrospective and it is possible that patients with more severe disease and more complications more likely received plasma.[50] Anecdotally, fresh frozen plasma is believed to be useful in dogs with severe forms of pancreatitis. Further studies are needed to answer this question definitively.

Antibiotics

In contrast to humans, dogs with pancreatitis rarely have bacterial infectious complications. Also, even though such complications do frequently occur in human pancreatitis patients and are estimated to be responsible for approximately 25-50% of all deaths associated with acute pancreatitis, a clear advantage of routine antibiotic use has not been demonstrated to date.[51,52] Therefore, the use of antibiotic agents should be limited to those dogs that have a demonstrated bacterial infectious complication (e.g., aspiration pneumonia, infected necrosis) or where such an infectious complication is strongly suspected.

Anti-inflammatory Agents

Glucocorticoids have not been shown to have any benefit in human patients with severe pancreatitis that do not have autoimmune pancreatitis and their use should be limited to canine pancreatitis patients with cardiovascular shock. Nonsteroidal anti-inflammatory agents all have been implicated in potentially causing pancreatitis and also did not show any benefit in human studies.

Other Therapeutic Strategies

Many other therapeutic strategies have been evaluated either in experimental models of pancreatitis or in clinical trials. However, no consistent beneficial effect could be demonstrated for any of these treatment strategies. Many studies have evaluated the benefit of various antioxidants in patients with severe acute pancreatitis, but none of the controlled studies was able to show any benefit.[53] One study evaluated the use of a probiotic in patients with severe acute pancreatitis, but outcome was worse in treated patients than those not treated with the probiotic.[54] Also, antacids and antisecretory agents (i.e., anticholinergics, calcitonin, glucagon, somatostatin) have not shown any promise. Treatment with platelet activating factor inhibitors (PAFANTs) initially showed promising results, but a large international multi-center trial failed to demonstrate any benefits.[55,56] Dopamine has been shown to be useful in preventing progression of pancreatitis in cats with experimentally induced pancreatitis when administered within 12 hours of initiating the disease.[57] While this time-limit would preclude dopamine to be effective in routine therapy of pancreatitis, patients that have to undergo anesthesia may benefit from treatment with dopamine during anesthesia.

Surgical Intervention

In human pancreatitis, management of patients with severe acute pancreatitis has become more and more conservative over the last 30 years.[58] While historically necrosectomy or abdominal lavage were considered useful, these interventions are now believed to be detrimental to the patient. The only scenarios where surgical intervention would appear indicated in canine patients with severe pancreatitis would be those with an infected necrotic or other type of infected fluid accumulation (some of which have previously been termed pancreatic abscess, but this term is no longer used in human pancreatology). Most patients with secondary biliary obstruction do not have a complete obstruction and rupture of the bile duct is rare. Thus, surgical intervention is rarely needed and may prove detrimental to an already debilitated patient.[59]

Treatment of Mild Chronic Pancreatitis (Figure 290-4)

Many dogs with pancreatitis have mild forms of chronic pancreatitis.

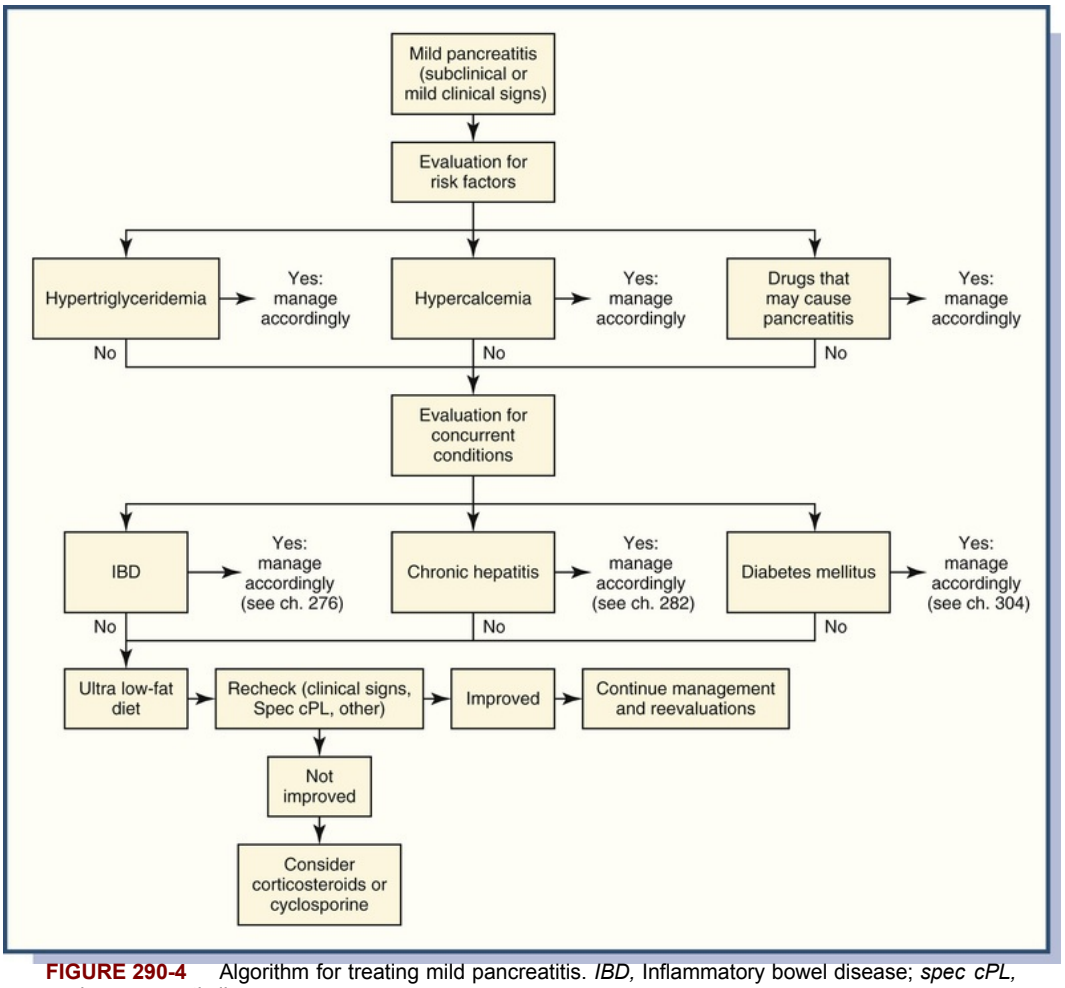


FIGURE 290-4 Algorithm for treating mild pancreatitis. *IBD*, Inflammatory bowel disease; *spec cPL*, canine pancreatic lipase.

Treatment of Cause

As for acute pancreatitis, treatment of the cause of mild chronic pancreatitis is also of prime concern. For this purpose, several risk factors should be evaluated, including evaluation of the patient for hypertriglyceridemia and hypercalcemia, and obtaining a detailed drug history. Also, the patient should be evaluated for any possible concurrent conditions that may have an impact on management, such as idiopathic inflammatory bowel disease, chronic hepatitis, and diabetes mellitus. While definitive diagnosis of such concurrent conditions may be challenging, the clinician should look at reasonable evidence for such complicating conditions, including serum glucose concentration, serum cobalamin and folate concentrations, and serum hepatic enzyme activities. Further diagnostics may be warranted if any abnormalities are identified and the overall management of the patient may need to be adjusted. Also, the patient should be carefully evaluated to determine whether antiemetic and/or analgesic therapy is needed. If the patient has no clinical signs at all, pain medication may not be warranted. If the patient does not have any signs of abdominal discomfort, but is otherwise unwell, mild analgesics such as oral butorphanol or tramadol may be administered (see ch. 356). Overt abdominal discomfort may require the use of fentanyl patches (see ch. 126). Any sign of vomiting or nausea (i.e., hyporexia, anorexia, salivation, gagging) may require the use of an effective antiemetic, such as maropitant and/or a 5-HT_3-antagonist (see ch. 39). Standard dosages are used orally for about 5 days, which hopefully is long enough for pancreatitis to improve and associated clinical signs to ameliorate. Dogs with chronic mild pancreatitis should be switched to an ultra-low-fat diet, which is a diet with less than 20 g of fat/1,000 kcal (see ch. 179). Also, it is crucial to discuss dietary fat intake with the owners and remind them that treats may also contain significant amounts of fat. Thus, it is important to switch the patient to low-fat treats, such as vegetables, fruits, low-fat treats that follow the same guidelines as mentioned above, or home-made treats (for example, made from ultra low-fat diets). Some patients may have concurrent conditions that

may also require special dietary considerations, such as concurrent food hypersensitivity (see ch. 178 and 186) or chronic kidney disease (see ch. 184). In most of these patients, the dietary requirements for pancreatitis trump those of the concurrent condition, as pancreatitis may lead to an acute exacerbation more quickly than does the concurrent condition. Another alternative is to consult with a veterinary nutrition service to have a home-prepared diet formulated that fulfills the dietary requirements for both pancreatitis and the concurrent condition. Initially, the patient should be rechecked every 2-3 weeks to evaluate the clinical signs and measure a serum Spec cPL concentration. As the condition improves or reaches a plateau, the frequency of rechecks can be decreased based on the individual patient.

Over the last two decades, a new form of pancreatitis, autoimmune pancreatitis, has been described in humans; it is characterized by a lymphocytic-plasmacytic infiltration of the pancreas.[60] Humans with autoimmune pancreatitis respond favorably to the administration of corticosteroids. Recently, there have been a few publications describing English Cocker Spaniels with chronic pancreatitis that share some of the features of human autoimmune pancreatitis.[61,62] Also, several clinicians have started to cautiously treat canine patients with chronic pancreatitis using corticosteroids when such patients do not respond to other treatments, and have found this treatment strategy to be beneficial in a portion of cases. The author utilizes a treatment protocol of measuring a baseline Spec cPL concentration, then treating the dog with prednisone for 5 days at 2 mg/kg PO q 12 h, followed by 1 mg/kg PO q 12 h for another 5-7 days, and a recheck of clinical signs and another Spec cPL concentration. If there is any improvement of clinical signs or the Spec cPL is significantly decreased, prednisone therapy is continued at a slowly decreasing dosage. Also, successful treatment of a canine patient with chronic pancreatitis with cyclosporine has been reported in one case and a clinical trial is under way.[63] The author measures a baseline serum Spec cPL concentration and then uses 5 mg/kg of Atopica PO q 24 h for 3 weeks, after which another recheck is performed to evaluate the patient clinically and measure another Spec cPL concentration. Treatment continues long-term based on above mentioned criteria. However, further studies are needed before these treatment strategies can be recommended for more routine use in dogs.

Prognosis

The prognosis for dogs with pancreatitis is directly related to disease severity, extent of pancreatic necrosis, occurrence of systemic and pancreatic complications, duration of the condition, and the presence of concurrent disease. Several prognostic systems have been developed to predict the outcome in human pancreatitis patients early after admission to the hospital.[64-66] All of these systems are aimed at identifying high-risk patients early on and to be able to aggressively treat these patients. Several of these systems have been adapted for and evaluated in dogs.[67,68] Unfortunately, none of these prognostic systems has proven useful in a routine clinical setting.

CHAPTER 291

Feline Pancreatitis

Diagnosis and Treatment

Craig G. Ruaux

Client Information Sheets:
Managing Acute Pancreatitis in the Cat
Managing Chronic Pancreatitis in the Cat

Our understanding and recognition of inflammatory diseases of the feline pancreas has undergone a remarkable change within a relatively short period of time. As recently as the late 1990s, acute pancreatitis in cats was felt to be a relatively uncommon disorder and chronic pancreatitis was thought to have "limited clinical importance."[1] We now know that pancreatitis is the most common disorder of the exocrine pancreas in cats[2] and chronic pancreatitis is common as a primary disease and a comorbidity with many other diseases of the cat.[3-5] In no small part this explosion in our understanding of the disease is due to marked improvements in diagnostic imaging modalities, minimally invasive clinical chemistry testing methods, and the simple recognition that the clinical manifestations of pancreatic disease in the cat are markedly different from those seen in the dog.

Histological Characterization of Pancreatitis in Cats

As pancreatitis is, by definition, an inflammatory disease, objective documentation of the presence of inflammation in the pancreatic parenchyma via histopathological examination is still held to be the gold standard for diagnosis of this disorder.[6-8] Histological scoring systems for assessing the type and degree of severity of pancreatitis in the cat have been described.[6] Most authors make a distinction between acute pancreatitis (typified by interstitial edema, neutrophilic infiltration and possible mesenteric fat necrosis) and chronic pancreatitis (typified by lymphocytic infiltration, fibrosis and cystic acinar degeneration) when describing inflammatory disease in the pancreas of the cat.[1,6] However, it is common for histological sections of the pancreas to show a mixed pattern of infiltration, and the distribution of lesions within the feline pancreas may be patchy, as has been described in dogs.[9]

Some reports suggest that chronic pancreatic inflammation (particularly lymphocytic infiltrates and/or fibrosis) is quite common in the domestic cat. In one study describing 115 cats presented for necropsy, regardless of cause, evidence of pancreatitis was found in 67% of sick cats and 45% of clinically normal cats (i.e., cats with no history of disease, typically dying because of trauma).[6] Chronic pancreatitis was the most common finding, being observed in 60% of all samples; just over 50% of the samples had only chronic pancreatitis. In the same group of cats, acute pancreatitis was documented in 18 cases (15.7%), with 7 cases showing only acute pancreatitis and 11 cases showing a mix of acute and chronic changes. In a recent study assessing indications for and complications from pancreatic biopsy, chronic or "acute on chronic" pancreatitis was identified in 10/19 cats, while "pancreatitis" without specification of acute vs. chronic was identified in another two cases, giving a total of 12/19 (63%) of cases where pancreatic inflammation was identified in cats with a clinical suspicion of pancreatic disease.[10] It is interesting to note that in this study, dogs were less frequently diagnosed with pancreatic lesions than cats were.

Clinical Signs of Pancreatitis in the Cat

One of the great challenges in managing the cat with pancreatitis is the vague nature of clinical signs typically manifested in these cats. Based on the aggregation of data from three studies, involving a variety of underlying histological diagnoses and apparent disease severities, the most common clinical signs of pancreatitis in the cat are reduced appetite, lethargy, dehydration and vomiting (Table 291-1). Abdominal pain, a very common clinical sign of pancreatitis in the dog, is much less frequently recognized in the cat. Accurate assessment of abdominal pain in the cat (see ch. 126) can be quite difficult, and thus the true frequency of this problem in cats with pancreatitis may be underestimated[11]; however the central observation that abdominal pain is rarely appreciated by clinicians assessing cats with pancreatitis remains true. Given the vague nature of clinical signs of pancreatitis in the cat, this disease should be considered in the differential diagnosis of any cat with vomiting, anorexia/hyporexia or lethargy where another, more proximate cause has not been identified.

TABLE 291-1

Common Historical and Clinical Signs of Pancreatitis in Cats Aggregated from Three Separate Studies[1,12,28]

CLINICAL SIGN	STUDY				TOTAL	OVERALL PREVALENCE
	STOCKHAUS ET AL[28]	FERRERI ET AL[12] (ANP)	FERRERI ET AL[12] (CP)	HILL & WINKLE[1]		
Number of cats	33	30	33	40	136	
Inappetence	32 (97%)	19 (63%)	23 (70%)	39 (98%)	113	83%
Lethargy	33 (100%)	15 (50%)	17 (52%)	40 (100%)	105	77%
Dehydration	24 (73%)	10 (33%)	17 (51%)	37 (93%)	88	65%
Vomiting	18 (55%)	13 (43%)	13 (39%)	14 (35%)	58	43%
Icterus	6 (18%)	5 (16%)	8 (24%)	21 (53%)	40	29%
Weight loss	3 (9%)	12 (40%)	7 (21%)	NS	22	16%
Abdominal pain	17 (52%)	NS	NS	10 (25%)		

Cats from one study (Ferreri et al.[12]) are subdivided into acute necrotizing (ANP, n = 30) and chronic nonsuppurative (CP, n = 33) presentations. NS = Not specified. Overall prevalence is rounded to the nearest whole percentage value.

It is not possible to distinguish acute from chronic pancreatitis in cats based on clinical presentation, duration of clinical signs or apparent severity of the disease.[2,12,13] While chronic pancreatic disease is commonly thought to be less severe than acute pancreatitis in the cat,[13] either disease can present with complications or comorbidities that are potentially life-threatening, and attempting to draw a distinction between these two conditions is not particularly clinically helpful.

The Diagnostic Approach to the Cat with Suspected Pancreatitis

Routine Biochemistry and Complete Blood Count

Clinical biochemistry and hematological abnormalities are common in cats with pancreatitis, but there are no individual abnormalities or patterns of findings that are specific for pancreatitis in the cat. Abnormalities that are commonly encountered include leukocytosis, left shift neutrophilia, elevated ALT and ALP activities, elevated bilirubin, azotemia, hypercholesterolemia, hypoalbuminemia, hypokalemia, hypocalcemia and hyperglycemia.[11-14] The presence of hypocalcemia is often associated with more severe, necrotizing presentations and warrants more aggressive therapy (see below).[11,14,15]

While no specific pattern of results in routine biochemistry panels suggests pancreatitis in the cat, routine clinical pathology testing remains a valuable part of the diagnostic and therapeutic plan. Recognition of serum biochemical abnormalities, particularly elevated liver enzyme activities, elevated bilirubin, and electrolyte abnormalities is an important part of treatment planning and is critically important in the early

recognition of common comorbidities such as hepatic lipidosis (see ch. 285) and diabetes mellitus (see ch. 305) that require additional interventions.

Pancreas-Specific Diagnostic Tests

The lack of specific biochemical findings, vague nature of clinical signs, and variable presence of abdominal pain in the cat with pancreatitis all combine to make the search for sensitive, specific and minimally invasive diagnostic tests for pancreatic disease in the cat one of great recent interest and activity. It is still common for many reference laboratories and in-house chemistry systems to provide estimates of serum amylase and lipase catalytic activities on routine chemistry panels in both dogs and cats (see ch. 64). These enzyme activities are widely considered to have poor to no diagnostic utility for the assessment of pancreatic disease in the cat.[2,11-13,16,17] Additionally, very high degrees of inter-instrument and between-instrument variability have been reported for these (and many other) clinical pathology analytes in the cat[18,19]; thus, the use of traditional amylase and lipase activities, regardless of laboratory type, has questionable utility in the assessment of the feline patient.

The pancreas is a source of several proteins and peptides that are solely synthesized in this organ. Several of these proteins (see ch. 271) have received at least some attention as diagnostic tests for pancreatitis in the cat, including feline trypsinogen (fTLI),[20] the trypsin-activation peptide (TAP),[21] and pancreas-specific lipase (fPLI & Spec fPL) (see ch. 289).[22] The underlying assumption with these tests is that only very small amounts of these proteins are normally present in the circulation (often at concentrations at or below the detection limit of the assay), but in the presence of acinar cellular dysfunction, these proteins leak into the interstitium and circulation, where they may be detected. The detection of increased concentrations of these proteins is thus considered to be evidence of acinar cellular abnormalities, and felt to be consistent with a diagnosis of pancreatitis.[8,13]

The actual sensitivity and clinical utility of both fTLI and fPLI/Spec fPL have been assessed in numerous studies. Using a serum fTLI concentration >100 mcg/L as a threshold value for diagnosing pancreatitis, sensitivities ranging from approximately 28 to 64% have been reported by various authors for the detection of either acute or chronic pancreatitis in cats.[20,21,23] These studies are quite variable in terms of patient numbers, study designs, and additional diagnostic methods used, and thus, direct comparison of the reported sensitivities is questionable. Regardless, the highest reported sensitivity, approximately 64%, is suboptimal at best given that it was obtained in a relatively small group (n = 10) of cats with strong evidence of significant pancreatic disease (either characteristic ultrasonographic changes or histologically confirmed on pancreatic biopsy). A normal serum fTLI concentration does not reliably rule out the presence of pancreatic disease in the cat.[24] The specificity of elevated fTLI concentrations has also been thrown into doubt by some authors, who identified elevated fTLI concentrations in cats with no strong evidence of pancreatic disease and in the presence of other, significant diseases such as idiopathic inflammatory bowel disease, gastrointestinal lymphoma, and azotemia.[23,25] An alternative interpretation of these data, supported by the observation that pancreatic disease in the cat often has vague or "silent" clinical signs and is a common comorbidity of many conditions, would be that comorbid pancreatic disease was quite likely in many of these cases.

Detection of elevated serum concentrations of specific pancreatic lipase (fPLI or Spec fPL) has a higher reported sensitivity and specificity than fTLI. In one study, where fTLI achieved overall sensitivity and specificity of 28% and 82%, respectively, fPLI achieved overall sensitivity and specificity of 67% and 67%, respectively.[26] In the same study, sensitivity of fPLI for the diagnosis of "moderate to severe" pancreatitis was 100%. A larger study (n = 182 cats) of the Spec fPL assay reported an overall sensitivity for this test of 79%, with a specificity of 82% for detection of pancreatitis in this group.[27] Overall, the Spec fPL has the highest currently reported sensitivity and specificity of any diagnostic modality for the detection of pancreatitis in the cat.[24] The use of Spec fPL measurement as a prognostic marker and monitoring parameter for recovery has received limited attention at this time.[28] Elevation of Spec fPL to >20 mcg/L was found to be associated with a poorer prognosis in cats hospitalized with pancreatitis. No data in the literature indicate that greater elevations in Spec fPL are associated with poorer response to therapy in cats with chronic pancreatitis, assuming adequate management of comorbidities.

The low sensitivity and specificity of traditional amylase and lipase activities for the diagnosis of pancreatitis, in all species, may be partly explained by low substrate specificity for most of the catalytic assays. The substrates used in these assays vary in terms of selectivity for pancreatic lipase, with some substrates showing much higher selectivity for pancreatic-origin lipases in the circulation. 1-2-o-Dilauryl-*rac*-

glycero-3-glutaric acid-(6'-methylresorufin) ester (DGGR) is a lipase substrate with relatively high substrate specificity for pancreatic lipases.[29] This assay has been validated and assessed in the domestic cat.[30] The overall agreement between DGGR-lipase and Spec fPL was high, with Cohen's kappa coefficients between 0.60 (moderate agreement) and 0.75 (substantial agreement) at varying cutoffs applied for either DGGR-lipase activity and Spec fPL values for diagnosing pancreatitis.[30] In this same study of 251 client-owned cats with a clinical suspicion of pancreatitis, DGGR-lipase activity >26 U/L showed a sensitivity of 48% with a specificity of 63%, while Spec fPL >5.3 mcg/L showed a sensitivity of 57% and specificity of 63%.[30] This study suggests that DGGR-lipase activity may have some clinical utility in the assessment of cats; however, this would be reliant on the use of this specific substrate in whichever analytical system is being used. Information regarding the actual substrates used by the various reference laboratories and in-house chemistry systems commonly found in veterinary practice is not readily available at this time.

Diagnostic Imaging

Plain radiographic changes accompanying acute pancreatitis in the cat are similar to those described in dogs, and include reduced abdominal contrast, dilation of bowel loops and pleural effusion. These signs are subtle, non-specific, and show low sensitivities (28-50% for reduced abdominal contrast, 24-42% for bowel dilation, 20-29% for pleural effusion).[1,12,20,31,32] Plain radiographic signs of chronic pancreatitis in the cat are not well characterized.

The increasing availability of high-resolution abdominal ultrasonography in companion animal practice (see ch. 88) has dramatically improved the use of diagnostic imaging to characterize pancreatic disease in the cat. The ultrasonographic appearance of the normal feline pancreas, and changes consistent with pancreatic disease, have been described (Figure 291-1, *A* and *B*).[12,32-34] Pancreatic enlargement, hyperechoic mesentery and abdominal fat, altered parenchymal echogenicity (most commonly hypoechogenicity or a mixed pattern), abdominal effusions, pancreatic cysts or pseudocysts, corrugation of the duodenum and dilation of the pancreatic duct are all considered consistent with pancreatitis in cats with compatible clinical signs.[12,23,32,35] While these findings are reasonably specific indicators of the presence of pancreatic disease, their sensitivity for accurate diagnosis of histologically confirmed pancreatitis is quite variable, with reported sensitivities ranging from ≈11 to 80%.[12,23,26] Sensitivity of abdominal ultrasound for the detection of feline pancreatic disease appears to be highly operator-dependent.[32] Several recent publications have investigated the degree of agreement between abdominal ultrasonography findings and pancreas-specific, minimally invasive tests (Spec-fPL and DGGR lipase activity).[35,36] Given the variable and often low sensitivity of abdominal ultrasound examination for the diagnosis of pancreatitis in cats, this modality cannot be reliably used as a "rule-out" test for this disease. However, significant additional information useful for management of these cases is often obtained, particularly when screening for comorbid conditions such as cholangitis/cholangiohepatitis or the presence of extra-pancreatic disease that could explain the clinical signs. Thus, abdominal ultrasonography, carried out by a well trained and experienced operator, is recommended in all cats where there is a clinical suspicion of pancreatitis.

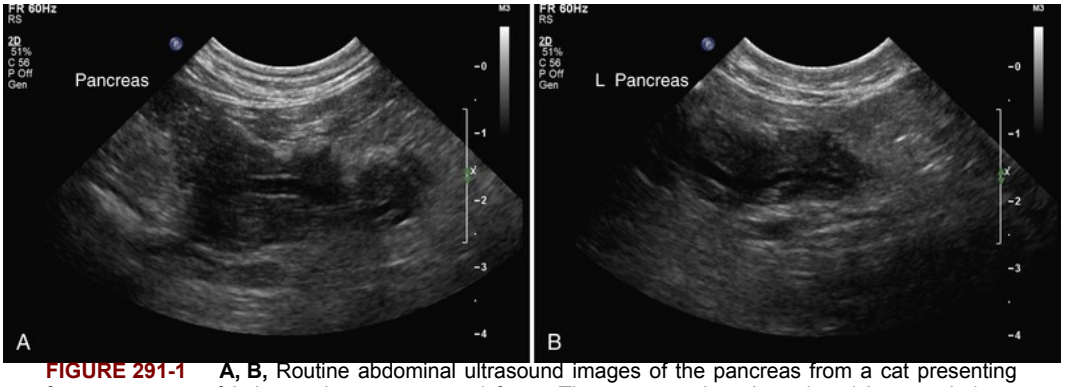

FIGURE 291-1 **A, B,** Routine abdominal ultrasound images of the pancreas from a cat presenting for acute onset of lethargy, inappetence and fever. The pancreas is enlarged and heteroechoic to hypoechoic, while surrounding mesenteric fat is hyperechoic. The pancreatic duct is prominent and increased in diameter (approximately 4 mm). These findings are consistent with the presence of acute pancreatitis in this patient.

A recent report described the use of endoscopic ultrasonography in the cat, including both healthy controls and cats with a diagnosis of pancreatitis.[37] While this study showed that the technique is feasible in the cat, and visualization of the entire pancreas appeared better with the endoscopic technique, endoscopic ultrasonography did not alter the diagnosis in these cats.

Higher-level imaging modalities, such as computed tomography, have received some attention in cats with pancreatitis.[20,26,38] In these studies, sensitivity was low, or changes in pancreatic appearance were not appreciated between normal and symptomatic groups. Combined with the cost of computed tomography examination and need for either heavy sedation or anesthesia for this procedure, these findings argue strongly against the use of computed tomography in the assessment and diagnosis of pancreatitis in the cat.

Pancreatic Biopsy and Histopathology

As stated earlier, most sources consider the histological demonstration of pancreatic inflammation as the gold standard diagnostic test for pancreatitis, regardless of species.[10,24] Pancreatic biopsy in the cat has not been a common procedure in routine veterinary practice, likely due to both the invasiveness of celiotomy/laparotomy approaches and ongoing concern that surgical manipulation of the pancreas may result in post-surgical pancreatitis.[7] A recent retrospective study has shown that pancreatic biopsy often yields diagnostically useful information, with biopsies from 14/19 cats with a clinical suspicion of pancreatitis showing at least some degree of histological abnormality.[10] In this study, chronic pancreatitis was the most commonly detected abnormality in the feline patients.

Laparoscopic techniques for visualization and biopsy of abdominal organs, including the pancreas, have a lower level of invasiveness than exploratory laparotomy, and have been shown to be safe in clinically healthy cats (see ch. 91).[39,40] An earlier retrospective study reported that only 9/13 cats undergoing laparoscopy for assessment of signs consistent with pancreatitis actually had a pancreatic biopsy taken, yet in the same report there were no postoperative complications noted (n = 31 cases).[7] In a more recent report,[10] postoperative complications were seen in 10/43 dogs and cats following surgical biopsy of the pancreas, with 5/10 cases showing signs suggestive of post-surgical pancreatitis. In the feline patients, 3/19 showed some evidence of post-surgical signs that could be considered suggestive of pancreatitis.

While surgical biopsy of the feline pancreas is underutilized, and the relatively low rate of minor complications reported in the literature to date argues that this modality should be considered more frequently, some shortcomings of pancreatic biopsy need to be recognized. In the dog, pancreatic lesions often show a patchy distribution, and assessment of multiple biopsies is necessary to obtain the greatest utility from this technique.[9] While similar studies have not been published in cats, it is reasonable to assume that pancreatic lesion distribution may be similarly patchy in this species, and assessment of a single biopsy (common with laparoscopic biopsies) may result in false negative findings. Even using laparoscopic techniques, surgical biopsy of the pancreas is invasive and expensive, requiring specialized equipment and skills. Surgical biopsy requires anesthesia, which may be high-risk in hemodynamically unstable patients with more severe presentations; therefore, the greatest use of this procedure is likely to be in cats with chronic pancreatitis.[7,24,40]

Therapeutic Approach to the Cat with Suspected Pancreatitis

A rational approach to the initial assessment, therapeutic planning and management of a cat with suspected pancreatitis is given in Figure 291-2. As necrotizing "acute" pancreatitis and non-necrotizing, "chronic" pancreatitis in the cat cannot be distinguished on the basis of clinical findings, abdominal imaging, clinical chemistries or results of specialized pancreatic tests, and pancreatic biopsy is still a relatively uncommon procedure, the initial diagnostic step necessary in these cases is to assess the overall state of health of the patient and apparent severity of the disease. Cats with suspected pancreatitis presenting with marked abdominal pain, tachypnea, tachycardia, significant fever, collapse or other evidence of systemic inflammatory syndrome or circulatory shock are considered to have severe disease, and require immediate and aggressive, hospital-based care. The existence of multiple abnormalities in screening clinical chemistries, particularly hypoalbuminemia and hypocalcemia, is a strong indicator of severe and potentially life threatening disease.[11] Cats presenting with weight loss, poor appetite, occasional vomiting and lethargy but without immediate evidence of significant hemodynamic compromise are considered to have less severe, likely chronic, disease and are treated on an outpatient basis.

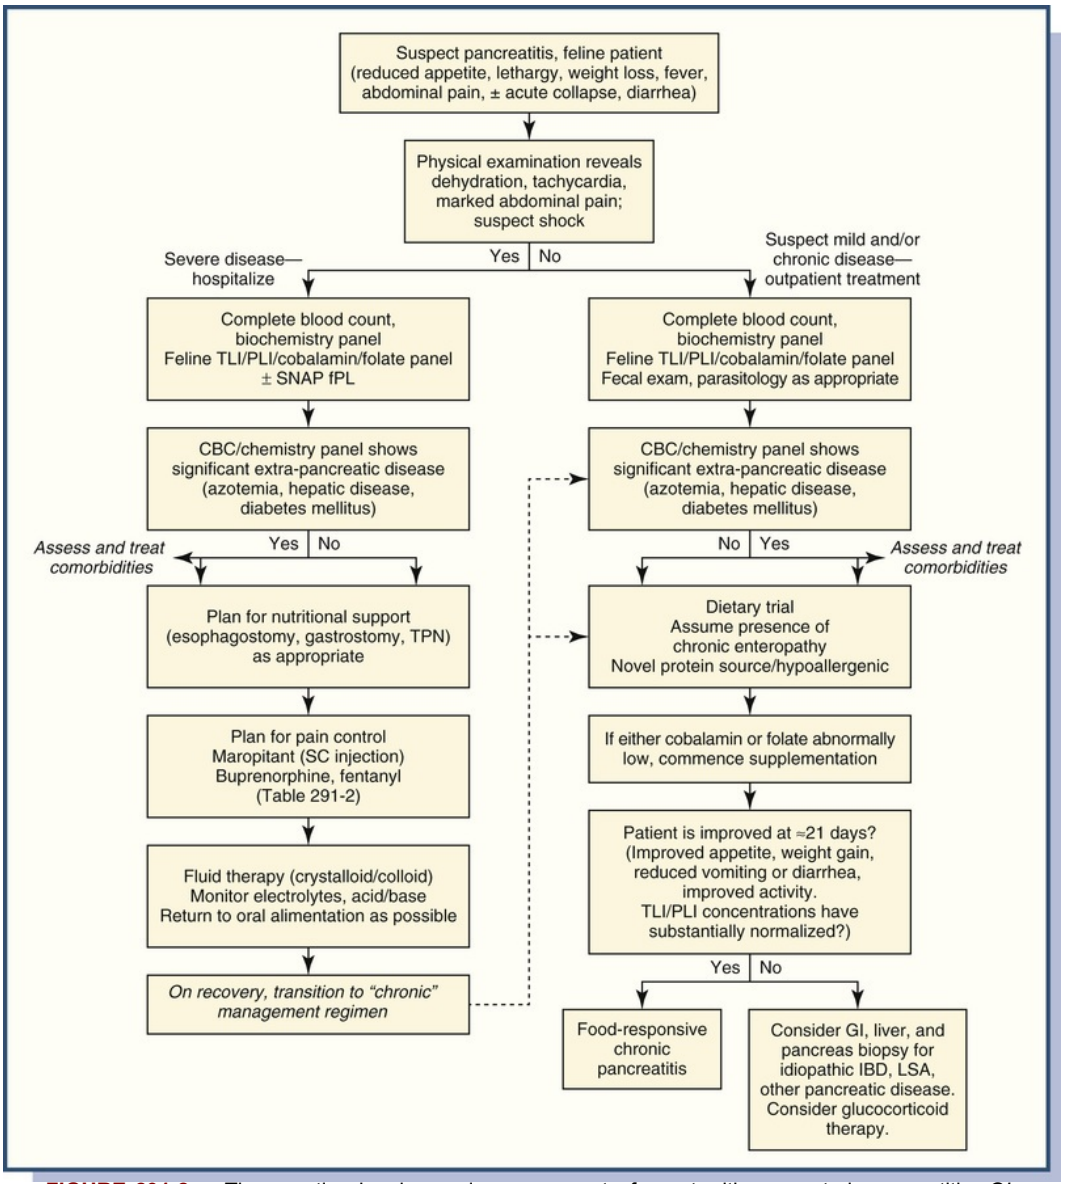

FIGURE 291-2 Therapeutic planning and management of a cat with suspected pancreatitis. *GI,* Gastrointestinal; *IBD,* inflammatory bowel disease; *LSA,* lymphoma; *PLI,* pancreas-specific lipase; *SC,* subcutaneous; *TLI,* trypsin-like immunoreactivity; *TPN,* total parenteral nutrition.

Cats presenting with severe disease require aggressive therapy, including fluid therapy (see ch. 129), effective analgesia (see ch. 126), and early planning for nutritional support (see ch. 82 and 189) given the risk of hepatic lipidosis as a comorbidity. The aims of therapy are to replace circulating fluid volume, restore and maintain end organ perfusion (particularly of the pancreas, as pancreatic ischemia is a significant contributor to the development of necrotizing pancreatitis[13]), and restore and maintain plasma colloid oncotic pressure. Colloid fluids, such as synthetic hydroxyethyl starches, are often highly beneficial in the initial resuscitation of these cases. Fresh-frozen feline plasma can also be considered, and likely provides oncotic support while replenishing coagulation cascade proteins (see ch. 130); however, there is little information in the veterinary literature regarding use of plasma in severe feline pancreatitis cases. We typically use a combination of synthetic colloid and crystalloid fluids for initial resuscitation and volume maintenance in these cats in our clinic. Substantial electrolyte abnormalities, particularly hypokalemia and hypocalcemia, should be anticipated in these cats.[2,11] Supplemental potassium is administered in combination with crystalloid fluids following routine guidelines for concentrations based on serial determination of serum potassium (see ch. 68 and 129).

Effective analgesia and control of vomiting are important aspects of management of severe pancreatitis in all species, including the cat. A selection of medications that are often useful in the management of

pancreatitis in the cat is summarized in Table 291-2. Narcotic pain control is typically indicated in cats with sufficiently severe pancreatitis to warrant hospitalization. Transdermal fentanyl patches (25 mcg/h) can be very effective for longer term (up to 72 h) analgesia without the need for frequent handling and injection in these patients, but initial therapy with an injectable or sublingual agent (commonly buprenorphine) is necessary as it can take up to 12 hours for therapeutic fentanyl concentrations to be reached.[2] Maropitant, a neurokinase-1 receptor antagonist, is both an effective antiemetic and has antinociceptive effects in the viscera.[41] The combination of maropitant with a 5-HT_3-receptor antagonist, such as ondansetron or dolasetron (see Table 291-2), provides an effective control for vomiting and nausea in these patients with minimal need for repeated handling during the day.

TABLE 291-2

Common Medications Used in the Management of Cats with Pancreatitis

CLASS	DRUG	MECHANISM	MAIN INDICATION	DOSAGE AND ROUTE	ADMINISTRATION NOTES
Analgesic	Buprenorphine	Opioid	Acute, severe	0.01-0.02 mg/kg SC, IM, IV, TM	Mixed agonist/antagonist.
	Fentanyl	Opioid	Acute, severe	25 mcg/h transdermal patch 5 mcg/kg IV bolus, CRI 2-4 mcg/kg/h	Titrate CRI to effect; start with low dosage in critical patients.
	Butorphanol	Opioid	Acute, severe	0.1-0.5 mg/kg SC, IM, IV	
Antiemetic Antinausea	Maropitant	Neurokinin-1 receptor antagonist	Acute, severe Chronic	1 mg/kg SC q 24 h 1 mg/kg PO q 24 h	Also provides some pain control. May be useful in outpatient management for acute-on-chronic disease.
	Dolasetron, ondansetron	5-HT_3 receptor antagonist	Acute, severe	0.8-1 mg/kg IV q 24 h	Can use in combination with maropitant, metoclopramide.
	Metoclopramide	Dopamine D_2 receptor antagonist	Acute, severe	0.2-0.5 mg/kg PO, SC, IM q 6-8 h 1-2 mg/kg/24 h CRI	Recommend use as CRI in critical patients.
Gastric acid suppressant	Omeprazole	Proton pump inhibitor	Acute, severe	1-1.3 mg/kg PO q 12 h	q 12 h dosing is necessary for effective gastric pH control in cats.[48,49]
	Pantoprazole	Proton pump inhibitor	Acute, severe	0.7-1 mg/kg IV q 12 h	Useful in patients where vomiting is not yet controlled.
	Ranitidine	Histamine H_2 receptor antagonist	Acute, severe	3.5 mg/kg PO q 12 h	Used mainly for prokinetic effect, NOT an effective acid suppressant in cats.
Anti-inflammatory	Prednisolone, prednisone	Glucocorticoid	Chronic	2-4 mg/kg PO daily, tapering at 0.5 mg/kg increments every 14 days	Taper and titrate doses to minimum effective dosage. Insulin resistance may limit utility in diabetic/prediabetic cats. Many cats show poor response to prednisone (ineffective).
	Cyclosporin A	Calcineurin inhibition	Chronic	5 mg/kg PO q 12-24 h	Consider in poorly regulated patients, or those with history of diabetes mellitus.

	Chlorambucil	Alkylating agent	Chronic	0.1-0.2 mg/kg/day PO or 0.15-0.3 mg/kg PO q 72 h	Consider in poorly regulated patients, or those with history of diabetes mellitus. Monitor for myelosuppression. Taper dosage to minimum effective over several months.
Appetite stimulant	Mirtazapine	Tricyclic antidepressant	Acute, severe Chronic	3.75 mg/cat PO q 72 h	Dose represents ¼ of a 15 mg tablet.
	Cyproheptadine	Histamine H_1 and 5HT receptor antagonist	Chronic	1-4 mg/cat/day PO	Questionable efficacy.

CRI, Constant-rate IV infusion; *TM*, transmucosal.

Extra-pancreatic comorbidities, particularly hepatic disease and diabetes mellitus, should be screened for and treated appropriately, including early reintroduction of feeding as appropriate. While there are limited data available regarding cats and early enteral nutrition with severe pancreatitis, our clinical experience is that this is generally well tolerated and advantageous. In both humans and dogs, there is accumulating evidence that early return to enteral nutrition is associated with improved outcomes, shorter hospital stays and a low frequency of side-effects.[42-44]

Cats with a clinical suspicion of chronic pancreatitis are treated in essentially the same manner as cats with chronic enteropathies or diagnoses of idiopathic inflammatory bowel disease (see ch. 276). There is no meaningful way to distinguish between chronic pancreatitis as a solitary disease entity and the presence of multi-organ inflammatory disease (so-called feline inflammatory disease or "triaditis").[5,45] Initially, dietary modification, typically by use of a novel protein source or hypoallergenic diet, is suggested. In contrast to dogs, where fat restriction is a cornerstone of management for most cases of chronic pancreatitis, fat restriction is not recommended in cats due to their high constitutive requirement for arachidonic acid.[46,47] Many cats will respond to dietary manipulation; in those who fail to respond to dietary manipulation, it is rational to consider anti-inflammatory or immune-modulatory therapies, assuming that there are no other comorbidities present that would contraindicate the use of these medications.

CHAPTER 292

Exocrine Pancreatic Insufficiency

Jörg M. Steiner

Client Information Sheet: Exocrine Pancreatic Insufficiency

Introduction and Definition

Exocrine pancreatic insufficiency (EPI) describes a syndrome that is characterized by the insufficient synthesis and secretion of digestive enzymes from the exocrine pancreas. The most common cause of EPI is an absolute lack of pancreatic acinar cells that is due to destruction of acinar cells due to chronic pancreatitis (both dogs and cats) or depletion of acinar cells due to pancreatic acinar atrophy (dogs). In either, all pancreatic digestive enzymes are lacking. In rare cases a single enzyme may be lacking, but lack of a single enzyme, even if complete, most often does not lead to clinical signs. However, isolated pancreatic lipase deficiency has been reported as a cause of clinical signs of EPI in humans and in one dog.[1,2] Another infrequent cause of EPI is an obstruction of the pancreatic duct by either a tumor or surgical damage, which can lead to lack of digestive enzymes in the small intestinal lumen, despite normal acinar production. Pancreatic aplasia or hypoplasia could also lead to clinical signs of EPI. This may be suspected when patients are being diagnosed with EPI at a very early age (Figures 292-1 and 292-2), but to date no case has been conclusively demonstrated in a puppy or kitten.

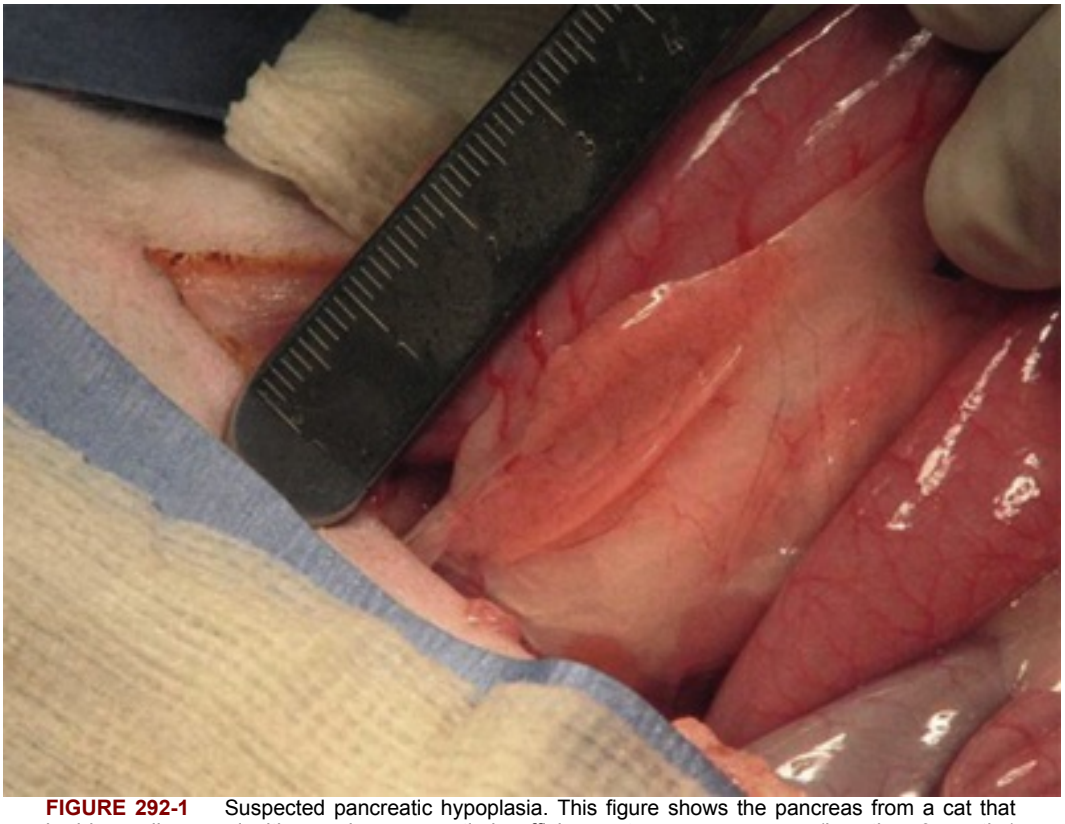

FIGURE 292-1 Suspected pancreatic hypoplasia. This figure shows the pancreas from a cat that had been diagnosed with exocrine pancreatic insufficiency at a very young age (less than 3 months)

during a routine spay. Note that the pancreas appears extremely small in size, suggesting pancreatic atrophy or pancreatic hypoplasia.

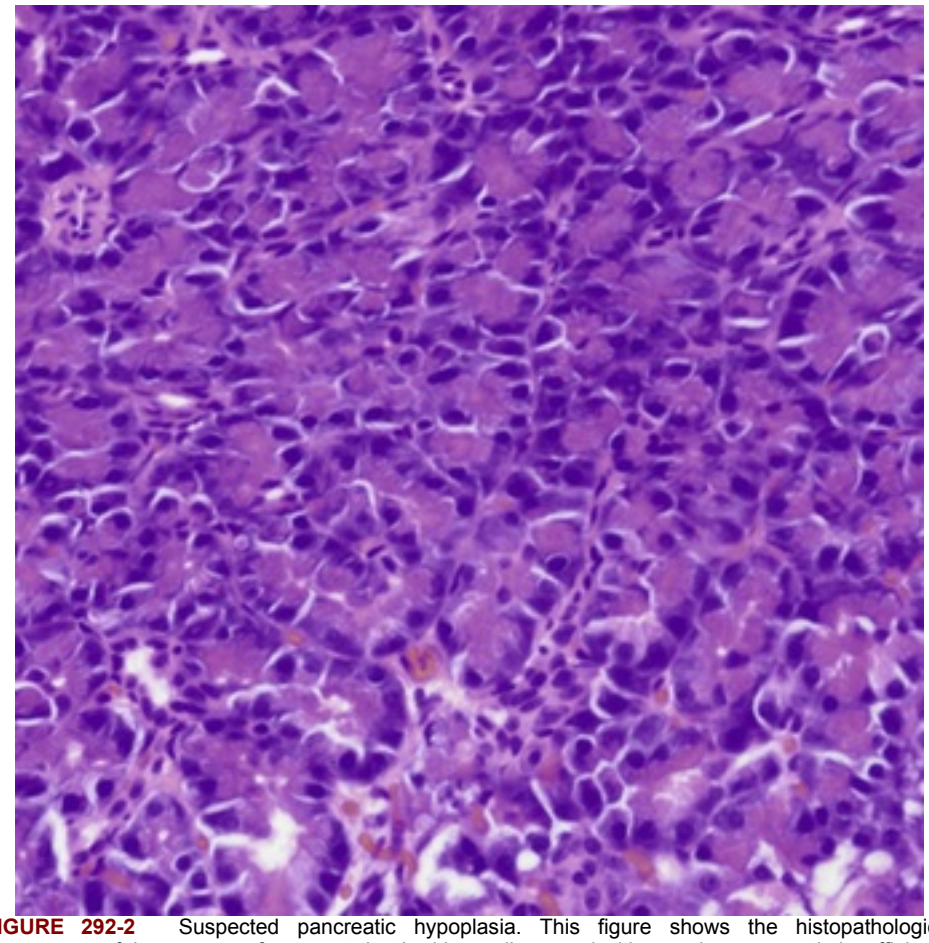

FIGURE 292-2 Suspected pancreatic hypoplasia. This figure shows the histopathological appearance of the pancreas from a cat that had been diagnosed with exocrine pancreatic insufficiency at a very young age. Note that the acinar structure appears to be normal and there is no evidence of either inflammation or fibrosis, suggesting pancreatic hypoplasia.

Etiology

The most common cause of EPI in both dogs and cats is chronic pancreatitis, which is suspected to be the cause of EPI in nearly 100% of cats and in approximately 50% of dogs with EPI. In dogs, the other approximately 50% of EPI cases are caused by pancreatic acinar atrophy (PAA), which is almost exclusively seen in German Shepherd dogs, Rough-coated Collies, and Eurasians.[3,4] Several studies have suggested that PAA is inherited as an autosomal recessive trait in the German shepherd dog and also the Eurasian.[5-7] However, the search for a genetic marker for this disease has been largely unsuccessful, despite the entire canine genome having been scanned using a set of microsatellite markers and SNPs, having revealed several regions that appear to be associated with the condition.[8] Interestingly, a breeding study of an affected male and an affected female German Shepherd only resulted in 2 of 6 affected offspring, strongly suggesting against inheritance as a simple autosomal recessive trait.[9] Thus, this condition is likely polygenic.[10]

Pathogenesis

Digestive enzymes or inactive preforms of digestive enzymes (i.e., zymogens) for the digestion of all major food components are secreted by pancreatic acinar cells. When pancreatic acinar cells are lacking, regardless of the cause, maldigestion ensues. It is, however, important to note that the gastrointestinal (GI) tract is highly

redundant and that there is usually more than one digestive enzyme that fulfills the same digestive function. For example, pancreatic lipase is crucial for fat digestion, but the stomach also synthesizes and secretes gastric lipase, which is responsible for a significant portion of normal fat digestion in the dog.[11] Also, physiologically, the exocrine pancreas has a large reserve capacity, and it has been estimated that clinical signs of EPI only ensue when more than 90% of exocrine pancreatic function has been lost.

Maldigestion leads to undigested food components in the intestinal lumen, which can lead to diarrhea, proliferation of the small intestinal microbiota, and weight loss. However, it has been suspected that clinical signs are not only due to maldigestion, but that EPI also leads to malabsorption. This has been theorized to be due to a lack of trophic factors normally secreted by the exocrine pancreas that help maintain a normal GI mucosa.

The exocrine pancreas also is the major source of intrinsic factor in both dogs and cats.[3] In sharp contrast to humans, where intrinsic factor is mainly secreted by the gastric mucosa, intrinsic factor in dogs and cats is mainly of exocrine pancreatic origin (see ch. 271).[12] In one study, 82% of dogs with EPI were shown to have a decreased serum cobalamin concentration with 36% having marked hypocobalaminemia.[13] All cats with EPI described in the literature where cobalamin has been assessed were found to have hypocobalaminemia.[14-16]

Clinical Presentation

EPI can be subclinical and two large case series of German Shepherd dogs identified several dogs with severely decreased serum trypsin-like immunoreactivity (TLI) concentrations that did not have any clinical signs.[7,17] Some of the dogs underwent exploratory laparotomy and the pancreatic mass was found to be severely decreased.[17] The most common clinical sign reported in both dogs and cats with EPI is weight loss (Figures 292-3 and 292-4).[15,18] Loose stools are also commonly observed (Figure 292-5), but watery diarrhea is rather uncommon.[15,18] Often times, patients have a poor hair coat and dogs with EPI are commonly reported to have borborygmus and increased flatulence.[18] Many dogs and cats with EPI will show an increased appetite, while dogs may even show coprophagia or pica.[18] In cats, a greasy soiling of the hair coat in the perineal region can be observed, but this is not a common finding.[15]

FIGURE 292-3 Cat with EPI. This photograph shows Theo, a 4-year-old male castrated cat with exocrine pancreatic insufficiency (EPI). Note the thin appearance of the cat. (Photograph courtesy Dr.

Kenneth Jones, Jones Animal Hospital, Santa Monica, CA; Reprinted from Steiner JM: Exocrine pancreatic insufficiency. In August JR, editor: *Consultations in feline internal medicine*, St Louis, 2010, Saunders Elsevier, pp 225-231.)

FIGURE 292-4 Cat with exocrine pancreatic insufficiency, treated. This picture shows Theo, the cat shown in Figure 292-3, two months after starting enzyme replacement therapy. Theo had gained almost 3 pounds during this time and was reported to be more active. (Photograph courtesy Dr. Kenneth Jones, Jones Animal Hospital, Santa Monica, CA; Reprinted from Steiner JM: Exocrine pancreatic insufficiency. FIGURE 292-5 EPI stools. This large stool sample is from a cat with exocrine pancreatic insufficiency (EPI) (cat shown in Figure 292-3). Note the typical loose consistency and the light brown color. Also, the stool sample appears to contain a lot of undigested food particles. (Photograph courtesy Dr. Kenneth Jones, Jones Animal Hospital, Santa Monica, CA; Reprinted from Steiner JM: Exocrine pancreatic insufficiency. In August JR, editor: *Consultations in feline internal medicine*, St Louis, 2010, Saunders Elsevier, pp 225-231.)

Diagnosis

Measurement of serum TLI is the diagnostic test of choice for both dogs and cats suspected of having EPI. Serum concentration is measured by a species-specific assay for TLI. The TLI assay measures the concentration of cationic trypsinogen, cationic trypsin, and some cationic trypsin molecules bound to proteinase inhibitor molecules. Under physiologic conditions, only a small amount of the trypsinogen synthesized by pancreatic acinar cells is released into the vascular space. Trypsinogen and trypsin are rather small molecules and thus are quickly excreted by the kidney. Therefore, only if the pancreas is functioning normally can a small amount of trypsinogen be detected in the serum (Video 292-1). In contrast, in patients with EPI, regardless of the cause, the amount of trypsinogen released into the blood stream is severely decreased (current cut-off values for a diagnosis of EPI: 2.5 mcg/L in dogs and 8.0 mcg/L in cats) to undetectable (see Video 292-1). In general, serum TLI is highly sensitive and specific for the diagnosis of EPI in both dogs and cats. There are two special scenarios, however, where serum TLI can be normal despite the patient having EPI. The first scenario is isolated pancreatic lipase deficiency, which has been described in one dog.[2] The second scenario where serum TLI concentration could be normal in a patient with EPI is a patient with an obstructed pancreatic duct. Such cases have not yet been described in the literature but a single dog with this condition has been identified (Hill S, personal communication, 2007).

There are other tests that have been recommended for the assessment of exocrine pancreatic function, including the plasma turbidity test, the para-amino benzoic acid test, and fecal proteolytic activity; however, none of them is considered useful for a diagnosis of EPI in dogs or cats.[19,20] Also, a fecal assay for the measurement of pancreatic elastase is now marketed in Europe. Initial studies showed acceptable sensitivity and specificity of the assay, but the estimated positive predictive value was less than 60%.[21,22] In another study, fecal elastase concentration was shown to be associated with a high number of false positive test results (23%).[23] Thus, a diagnosis of EPI based on a severely decreased fecal elastase concentration must be

verified by measurement of serum TLI concentration to prevent a misdiagnosis of EPI.

Therapy

Digestive enzyme replacement is the mainstay of therapy for EPI.[24,25] Pancreatic enzymes can be replaced by a variety of different options and a wide variety of products and options is listed at epi4dogs.com.[26] Dried pancreatic extract from pork pancreas is by far the most common and effective means of pancreatic enzyme replacement. Therapy is started with 1 teaspoon of dried extract per 10 kg body weight and meal. After the patient completely responds to therapy, the dosage can be slowly decreased until a minimally effective dose has been reached. It is important to note that the content of enzyme activity in the product may vary from container to container and thus the minimally effective dose may vary slightly over time. Pancreatic enzymes are also available as tablets and capsules but studies in humans and dogs have shown that powder is preferable to other formulations.[25,27] Complications of enzyme supplementation are rare, but one study reported 3 of 25 dogs being treated with pancreatic enzyme supplements developing oral bleeding.[28] When this occurs, a coagulation profile should be evaluated to exclude a vitamin K responsive coagulopathy, which has been reported in two cats with EPI.[29] In case of a normal coagulation profile, the dosage of pancreatic enzymes should be lowered. Two dogs in the study cited above continued to do well on the lower dosage, but in one of the dogs clinical signs did return.[28] If a patient does refuse to consume the pancreatic powder mixed into the food or in the rare case of a food allergy to the porcine pancreatic powder, fresh raw pancreas from various species can also be used.[25] Beef, pork, sheep, and game pancreas have all been used. One to 3 ounces (approximately 30 to 90 g) of raw pancreas replace 1 teaspoon of dried pancreatic extract. The pancreas should be finely chopped, divided into portions for one meal each, and immediately frozen. The frozen pancreatic tissue maintains its enzymatic activity for long periods of time. Concerns have been raised about the potential threat of infectious contamination of such raw frozen pancreas. Theoretically, raw bovine and ovine pancreas carries the risk of bovine spongioform encephalopathy transmission and raw porcine pancreas carries the risk of transmission of pseudorabies (Aujeszky's disease). However, this risk is more or less academic, as dried pancreatic powder would carry exactly the same risk. Game and ovine pancreas can be infested with *Echinococcus* spp. and infestation with this parasite could potentially cause significant disease and even death. This risk should thus be discussed with the owner before initiating therapy with raw pancreas from these sources. Preincubation of the food with the pancreatic extract does not appear to be necessary to achieve a therapeutic response.

Some authors have recommended feeding of a low fat diet. However, experimental studies have shown that in dogs treated with pancreatic supplements, fat digestibility does not return to normal, suggesting that fat restriction would only increase the risk of deficiencies of fat-soluble vitamins and essential fatty acids.[30] One study did not show any benefit of feeding fat-restricted diets in dogs with EPI.[13] Also, two other studies did not reveal a significant effect of diet on treatment success in dogs with EPI.[31,32] Therefore, the author believes that a high-quality maintenance diet would best be used. However, diets with high fiber content should be avoided as dietary fiber may interfere with fat absorption.

As mentioned above, many patients with EPI are cobalamin deficient and thus every dog and cat with EPI should be evaluated for possible cobalamin deficiency. While the measurement of serum cobalamin concentration cannot provide an estimate of cobalamin status on a cellular level, measurement of methylmalonic acid (MMA) in serum is more expensive and only available on a limited basis, and thus measurement of serum cobalamin is considered the routine tool for assessment of cobalamin status in both dogs and cats. Based on the measurement of both cobalamin and MMA in large numbers of dogs and cats, it is currently recommended to supplement any patient with EPI if the patient has a serum cobalamin concentration less than 400 ng/L. Traditionally, cobalamin is supplemented by weekly subcutaneous injections of cyanocobalamin (250 mcg in cats and 250-1,500 mcg in dogs, roughly based on body weight). Rarely, hydroxocobalamin is used. Doses are given weekly for 6 weeks, then one more dose after a month, and a recheck of serum cobalamin concentration a month later. There are some preliminary data that would suggest that daily oral supplementation is equally effective, but this needs to be confirmed by a prospective trial before using this treatment modality routinely.[33] Many EPI patients that have been treated appropriately will have a normal or even supranormal serum cobalamin concentration at the time of re-evaluation and cobalamin supplementation can be discontinued, but many others need to be supplemented life-long. Serum concentrations of most fat-soluble vitamins have been shown to be decreased in dogs with EPI and can also be assumed to be decreased in cats.[31] However, systematic vitamin supplementation of fat-soluble vitamins

has not been investigated in these patients and over-supplementation with fat-soluble vitamins may cause side effects. Anecdotal reports of vitamin E supplementation (400-500 IU PO q 24 h for 1 month) are available but the beneficial effect of such therapy has not been evaluated.

Many patients with EPI will respond well to enzyme replacement therapy and cobalamin supplementation, if indicated. However, some patients may not respond adequately to standard therapy. Potential causes of treatment failure should be evaluated. The type, formulation, and dosage of the enzyme supplement should be reviewed and if there is any suspicion that enzyme replacement may be insufficient, the protocol should be adjusted accordingly. Also, patients should be evaluated for concurrent conditions, such as inflammatory bowel disease (see ch. 276), diabetes mellitus (see ch. 304 and 305), or small intestinal dysbiosis (see ch. 276). If there is no evidence of any concurrent disease, a therapeutic trial with an antimicrobial agent can be attempted. The treatment of choice is tylosin (Tylan powder at 25 mg/kg PO q 12 h for 6-8 weeks), but other antibiotic agents, such as metronidazole, may also be used.

If patients still do not respond to treatment, antacid therapy can be attempted. A large portion of pancreatic lipase supplemented orally is irreversibly destroyed by the low pH in the stomach.[34] By increasing the pH in the stomach this portion may be decreased and the therapeutic response may improve. However, it must be noted that while an increase in gastric pH will decrease the amount of pancreatic lipase being destroyed during passage through the stomach, it also will increase the amount of gastric lipase being destroyed and the final result may not lead to a significant change in fat digestibility. However, a trial with omeprazole at 0.7-1 mg/kg PO q 12 h can be attempted and may be associated with significant improvement.

If none of these measures leads to control of the clinical signs, a decrease in the dietary fat content may be effective. However, as mentioned above, feeding a low-fat diet may be associated with complications and should only be viewed as a last resort.

Prognosis

EPI has traditionally been considered a life-long condition as pancreatic acinar cells were generally considered to not be able to regenerate. However, there are experimental data that would suggest some regenerative capacity of pancreatic acinar cells.[35] Also, there are anecdotal reports of isolated patients with EPI who improve and no longer require enzyme supplementation. One study has evaluated prognostic factors for dogs with EPI.[13] The only factor associated with a poor outcome in this study was the presence of marked hypocobalaminemia, which was associated with a median survival time of 1346 days compared to dogs without such marked hypocobalaminemia of 2709 days ($p = 0.012$).[13] In general, most dogs and cats with EPI can be successfully managed and will have a normal quality of life and a normal life expectancy.

CHAPTER 293

Exocrine Pancreatic Neoplasia

Peter Bennett

Client Information Sheet: Cancer of the Pancreas

Incidence and Origin

Exocrine pancreatic tumors, usually identified in older dogs, may have an increased incidence in Airedale Terriers and females.[1-5] The prevalence of pancreatic carcinoma has been variably described, usually as uncommon to rare.[1,3,6-10] Estimated rates of about 18 and 12 per 100,000 patient years at risk have been reported for dogs and cats, respectively.[5] Benign hyperplasia and adenomas are uncommon, of little clinical relevance, and most frequently described as an incidental finding at post mortem in cats.[4,8,11-13]

Pancreatic carcinoma is one of the more common causes of cancer-related death in people and has shown little improvement in outcome in the last 40 years.[14] Malignant exocrine pancreatic tumors arise from either pancreatic ducts or acinar structures. In dogs, malignant exocrine pancreatic tumors are typically of acinar origin, whereas in man (and possibly cats) they are more often ductal.[4,10,12,15,16] Some tumors have characteristics of both acinar and ductal tissue.[17] Studies have demonstrated that pancreatic carcinoma cells display such marked plasticity that origin cannot be readily determined using routine histology.[18,19] Pancreatic neoplasia cells with mixed exocrine and endocrine characteristics have been reported in dogs and cats.[20,21] Carcinosarcoma has been diagnosed in a cat.[22]

Etiology and Pathophysiology

An etiological cause for pancreatic neoplasia has not been identified in dogs or cats, but injecting the carcinogen N-ethyl-N′-nitro-N-nitrosoguinidine into pancreatic ducts of normal dogs led to development of pancreatic exocrine carcinoma.[23] In people, there have been links with high fat diets, cigarette smoking, chronic alcohol abuse, chronic pancreatitis, and exposure to industrial carcinogens or alkylating chemotherapy agents.[24,25] Cases with concurrent neoplastic and inflammatory disease are reported.[25] One young Bengal cat with pancreatic pseudocysts developed exocrine pancreatic carcinoma within 6 months.[26] Early onset exocrine pancreatic carcinoma was reported in two gray Collie dogs with cyclic hematopoiesis but the relationship between the two conditions is unknown.[27] K-ras mutations have been identified in people and dogs with exocrine pancreatic cancer.[28-30]

While biologic behavior of pancreatic carcinomas can vary, they are typically aggressive with local invasion and metastases present at time of diagnosis.[1,2,10,12,31] The duodenum, regional lymph nodes, liver and lungs are the most common metastatic sites.[8] Abdominal carcinomatosis likely arises from direct seeding of cancer cells into the peritoneal cavity.[32] Most case reports describe rapid progression from the time of diagnosis, but there are exceptions.[33] A series of dogs with a hyalinizing variant of pancreatic carcinoma had better outcomes than are usually reported; 1 dog with metastatic disease at diagnosis lived 15 months without treatment.[34] Aggressiveness of exocrine pancreatic carcinoma and its resistance to therapy appears associated with, in part, the limited vascular network that contributes to hypoxia and poor nutrient supply. A complex reprogramming of metabolic pathways enables cancer cell survival. Targeting such dysregulated pathways may provide a means of improving outcome (see ch. 338).[14]

Clinical Signs and Physical Examination

Patients with exocrine pancreatic neoplasia have a wide range of signs.[13,35] Vague and nonspecific signs include reduced appetite, weight loss, diarrhea and abdominal discomfort. Some pets have signs consistent with acute pancreatitis: nausea, vomiting, anorexia and abdominal pain (see ch. 290 and 291).[9,12,36-40] Abdominal effusions can be seen.[40] Pain, common in people, is not prominent in dogs or cats.[16] The duration of signs can range from days to months.[13,35]

Cats can have extensive alopecia, most prominent on the ventral abdomen but sometimes involving the limbs and paws; such paraneoplastic alopecia has been observed with other internal malignancies (see ch. 352).[41-45] Bone metastases are uncommon, but could cause pain or lameness.[38] Multifocal necrotizing steatitis has been reported in a few dogs and one cat leading to multiple SC masses, fever and draining tracts.[46,47] Polyuria and polydipsia have been reported secondary to paraneoplastic hypercalcemia and 1 dog had a metastatic lesion in the pituitary leading to central diabetes insipidus.[48,49] Two dogs, one with an adenoma the other with a carcinoma, had a combination of panniculitis, polyarthritis and osteomyelitis.[50]

Often, pets with a pancreatic adenoma have no clinical signs unless the tumor has caused ascites, if it is causing obstruction or, in cats, where it can be large enough to be palpated.[51] Pancreatic carcinomas may also be palpable.[52] Pain is variable and not observed as often as in people.[53] Palpation of the mass can induce nausea. Compression of the extrahepatic bile duct can lead to icterus (Figure 293-1). About 10% of cases of extrahepatic biliary obstruction are due to pancreatic exocrine carcinoma.[54] Evidence of weight loss will be seen in some patients. In cats with alopecia, the skin can appear glossy and thin.

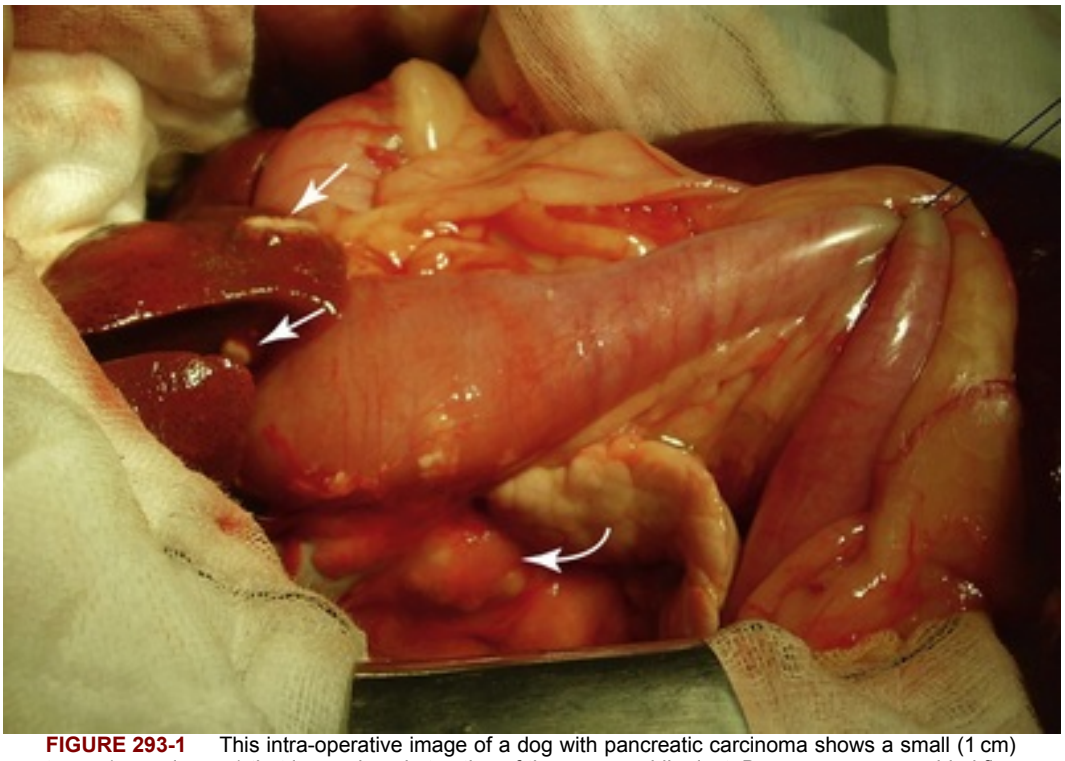

FIGURE 293-1 This intra-operative image of a dog with pancreatic carcinoma shows a small (1 cm) tumor (curved arrow) that is causing obstruction of the common bile duct. Bypass surgery provided five months of good quality life. Metastatic lesions are visible in the liver (straight arrows).

Diagnosis

Routine Hematology, Serum Biochemistry and Urinalysis Results

Routine hematology results are often nonspecific.[8] Mild to moderate nonregenerative anemia can be seen, as with any chronic disease. White cell parameters can be normal or, if there is significant peri-tumoral inflammation, exhibit a neutrophilic left shift.[12,55] Unless there is significant bleeding, platelet counts are

usually normal. Thrombocytopenia has been reported with bone marrow metastases.[55]

Serum biochemical results may include increased amylase and lipase values. Lipase may be markedly elevated.[2,50,56] Marked lipase increases in conjunction with minimal changes to amylase should lead to suspicion of pancreatic or hepatic neoplasia.[56] Bilirubin and liver enzyme activities can be increased secondary to obstruction of the common bile duct or with liver metastases (see ch. 53 and 65).[2] The changes in liver parameters can be more prominent than markers of pancreatic disease.[1] Hypercalcemia has been reported in some affected dogs.[48] Urinalysis is usually unremarkable unless positive for glucose. Neither diabetes mellitus (DM) nor exocrine pancreatic insufficiency is associated with pancreatic tumors in dogs or cats.[1,8,57] However, the conditions may occur concurrently. Two cats were reported to have concurrent DM and exocrine pancreatic carcinoma, but each had hyperadrenocorticism.[58] In a recent review of exocrine carcinoma in cats, 5/34 had DM.[40]

Imaging

Radiographic abdominal changes are often minimal, but mass effect with displacement of the duodenum and/or loss of serosal detail due to ascites can be seen.[1,38,59] A mass effect can be seen in cats with nodular hyperplasia or adenoma.[51] Nodular lung disease can be seen with lung metastases. Ultrasound (US) is useful for diagnosis of pancreatic carcinoma and is more sensitive than radiography (see ch. 88).[60] Even with US, differentiating early carcinoma from chronic pancreatitis or nodular hyperplasia can be difficult.[61] The pancreas usually appears larger than usual and can be hypoechoic or have a mixed appearance. Cystic lesions are uncommon in dogs and cats. Surrounding fat can be normal, or have the hyperechogenicity typical of pancreatitis. Enlargement of the regional lymph nodes is common.[51] The liver should be examined carefully for nodular lesions that can be hypoechoic, hyperechoic or mixed, including target lesions. If ascites is the result of carcinomatosis, the peritoneal lesions are usually not visualized.[32] Mass lesions including pseudocysts and abscesses, sometimes seen following acute pancreatitis, can be large enough to palpate in dogs and must be differentiated from neoplastic lesions.[62,63] Use of US contrast agents may help in differentiating chronic pancreatitis from pancreatic carcinoma. Contrast may also improve identification of hepatic metastases.[64] Contrast US, in dogs, may improve discrimination of pancreatic exocrine from endocrine tumors.[65] Endoscopic US improves the visualization of the pancreas in people.[66] There are no studies on the sensitivity of computerized tomography (CT) versus US in dogs and cats, but CT is considered superior in people.[25] CT is also more sensitive for identifying metastases. There does not appear to be an advantage in using magnetic resonance imaging (MRI) for pancreatic neoplasia in people.[67]

Fine Needle Aspiration (FNA), Cytology and Biopsy

Cytology (see ch. 93) has a fairly good positive predictive value but moderate to poor negative predictive value.[9,35,68,69] Risk of complications following FNA in people is low.[68] Atypical cells can be identified in ascitic fluid.[2,35] Cystic lesions, not often noted in dogs or cats, may be somewhat common in people. FNA of such cystic fluid had fewer false negatives than either surgical or needle biopsy-obtained samples.[70] Cytology can be helpful in diagnosing metastases from distant cancers to the pancreas, such as lymphoma.[17]

Biopsy and histopathology is the gold standard for diagnosis of pancreatic neoplasia.[36] Samples can be obtained using core biopsy needles under US-guidance or during surgical exploration (see ch. 89 and 91).[35] As with cytology, if biopsies are taken from metastatic sites, it is usually not possible to definitively identify the tissue of origin as pancreas. Biopsy results may be described as consistent with pancreatic carcinoma. Use of immunohistochemical stains for amylase and carboxypeptidase may help in determining that metastatic lesions were of pancreatic origin.[71] In cats with alopecia, the lesions are characterized by follicles in late telogen with moderate epidermal hyperplasia, hyperkeratosis and superficial, perivascular dermatitis.[44] These lesions are similar to those seen in hyperadrenocorticism, but skin fragility is not a feature.[44]

Treatment

When resection is possible, surgery has had the best long-term outcome in afflicted people. Results may be similar in dogs and cats, but surgery is not likely curative given the high metastatic rate prior to diagnosis.[1,8,9]

Cure is possible but requires a lesion that is completely removable and in people is more likely if the regional lymph nodes are negative.[72] Total and subtotal pancreatectomy has been described in normal dogs with acceptable morbidity and long-term management with insulin and pancreatic enzyme supplementation (see ch. 293, 304, and 305).[73] There are few reports of surgery of the pancreas in cats.[74] Surgery can be palliative in many pets by relieving obstruction.[36] Various techniques are being evaluated in people due to continued poor surgical outcomes.[66,75] Common bile duct stenting may relieve obstructions (see ch. 123), while duodenal obstructions can be relieved with Billroth type II procedures. Both are considered palliative, having been used in people in combination with other therapies.[66]

Pancreatic carcinoma has shown a poor response to chemotherapy in people as well as dogs and cats. Gemcitabine is the chemotherapy drug of choice for afflicted people. It has been used alone or in combination with carboplatin in cats and dogs with carcinoma of the exocrine pancreas.[40,76,77] Preclinical work with targeted drugs, especially tyrosine kinase inhibitors, had promise which has not translated to clinical utility. Small improvements in survival have been found when the tyrosine kinase inhibitor erlotinib, that has activity against the epidermal growth factor receptor, was given in addition to gemcitabine chemotherapy.[76] Radiation has been used, including intraoperative therapy, in people. Normal dogs treated during surgery in conjunction with a Billroth procedure suffered high rates of morbidity and mortality.[78] Use of nonsteroidal anti-inflammatory drugs in patients with exocrine pancreatic carcinoma might be of limited value. In a study looking at COX-2 expression in carcinomas from cats, positive staining was seen only in 25%.[79]

Prognosis

Overall, the outlook for patients with carcinoma of the exocrine pancreas is very poor. In cats, the overall median survival was 97 days.[40] There was improvement in survival to a median of 165 days in cats managed with either surgery or chemotherapy, compared to cats that had palliative treatment or had abdominal effusions. Median survivals were 26 and 30 days, respectively.[40] In 8 cats reported, most died or were euthanized within a week of diagnosis.[13]

Feline Growth Hormone Disorders

Stijn J.M. Niessen

Client Information Sheet: Feline Hypersomatotropism/Acromegaly

Feline Hyposomatotropism

Prevalence

Growth hormone (GH) is critically important in terms of its direct and indirect anabolic effects. Lack of GH during growth, the most important anabolic phase of an animal's life, causes dramatic pathological consequences. Congenital feline hyposomatotropism (CHS; "pituitary dwarfism") seems rare, since only a few such cats have been described.[1,2] Documented acquired feline hyposomatotropism (AHS) is also rare, with the exception of the assumed asymptomatic documented decreases after hypophysectomy to remove a pituitary tumor.

Causes

CHS is thoroughly described in dogs, in whom the condition may represent primary failure of complete differentiation of the craniopharyngeal ectoderm of Rathke's pouch into a healthy functioning anterior pituitary; mutations in the *LHX3*-gene encoding transcription factors essential to pituitary development have been implicated (see ch. 20 and 295).[3] The cause(s) in cats is unknown, although similar deficiencies may be relevant. An association with congenital hydrocephalus was implied in one cat.[2] AHS could be a consequence of a process impairing normal anterior pituitary lobe production and secretion of GH, including any inflammatory, infectious, immune-mediated, traumatic (including iatrogenic via hypophysectomy) or neoplastic process.[1]

Clinical Presentation

Congenital Feline Hyposomatotropism

Veterinary consultation of a GH-deficient kitten is usually sought when stunted growth is observed at 1 to 2 months of age. This is most obvious when a littermate is available for comparison (Figure 294-1). The initial postnatal growth period of 1 to 2 months is mostly genetically determined and, therefore, appears normal. Concerns develop when the second GH-driven growth phase does not materialize.[1] If isolated GH deficiency is present (all other pituitary hormones normal) the short stature will be proportional (proportionate dwarfism). Should a kitten be deficient in other anterior pituitary hormones, particularly TSH, proportions may well be distorted. Physical features of congenital hypothyroidism in kittens may include a square, chunky contour, as seen with isolated congenital hypothyroidism (see ch. 299 and 300).[1] CHS may also cause prolonged retention of deciduous teeth. The hair coats of affected cats are often dry and dull with potential for retention of secondary hairs and concurrent lack of primary or guard hairs.[1,2] Bilateral corneal edema, due to reduction in corneal endothelial cell density and corneal epithelial cell layers, was reported in one cat who may have had hypothyroidism.[2] Other observations include generalized weakness and lethargy. Hypoglycemia could be associated with enhanced insulin sensitivity caused by the absence of the anti-insulin effects of GH or low glucose may merely be related to the fragile nature of a small unthrifty kitten with limited gluconeogenic capacity.

FIGURE 294-1 Two sibling Domestic Short Hair cats of 5 months of age; the cat on the right was presented for stunted growth, displayed proportionate small stature and was subsequently diagnosed with congenital hyposomatotropism, through documentation of an undetectable serum IGF-1 and exclusion of more common causes for stunted growth. (Photo credit: Dr Ruth Gostelow, Royal Veterinary College.)

Feline Acquired Hyposomatotropism

AHS has not been reported in cats.[1] After completion of the growth phase, the clinical ramifications of GH deficiency would likely be subtle, possibly too subtle for owners or veterinarians to notice. People with adult-onset acquired GH deficiency have increased morbidity and mortality together with decreased quality of life.[4-6] As experience with hypophysectomy to treat feline hypersomatotropism and other pituitary tumors increases, AHS could become a matter of concern. However, clearly deleterious clinical consequences have not been our experience in cats with subnormal serum insulin-like growth factor-1 (IGF-1) concentrations following hypophysectomy.

Diagnosis

CHS should be based on a suggestive clinical picture and exclusion of more common causes of proportionate dwarfism that include hepatic disease (particularly portosystemic shunt), malnutrition, gastrointestinal disease, renal or cardiovascular disease, or inappropriate growth expectations. Diagnosis can be confirmed with randomly obtained, below-reference-range serum GH concentrations. However, reliable feline GH assays are rarely commercially available. When available, results from healthy cats and those with CHS might overlap, in part because GH, like all anterior pituitary hormones, is secreted in a pulsatile manner.[7] Stimulation (provocative) tests that are gold standards for diagnosing a GH deficient state in humans and dogs have not been validated in cats.

An alternative to GH-based testing is to document low or undetectable serum IGF-1 concentrations. Hepatic IGF-1 production is primarily induced by GH, its secretion is non-pulsatile, and results reflect GH concentrations over the preceding 24 hours. Clinicians should bear in mind that certain diseases and medications can influence both GH and IGF-1 testing, falsely implying deficiencies. For example, IGF-1, primarily synthesized by the liver, might be decreased with liver dysfunction. Moderate but not severe

decreases in IGF-1 have been reported in cats with lymphoma, newly diagnosed diabetes mellitus (DM), and renal disease.[7,8] Serum IGF-1 concentrations also correlate with body size, which could be relevant in small-stature kittens. A 7-month-old male kitten with congenital hypothyroidism and retarded disproportionate growth had moderately decreased serum IGF-1 concentrations that normalized after 6 weeks of thyroid replacement therapy.[9]

Treatment and Prognosis

GH replacement therapy has not yet been described for the cat, though it likely is similar to that for dogs (see ch. 295). Since there are no commercial feline GH products, there is concern over antibody formation when using GH from another species (porcine, human). Concurrent pituitary hormone deficiencies, if present, should be treated. If GH replacement is too expensive or undesirable (a major potential adverse effect is development of DM), treatment of concurrent pituitary hormone deficiencies (if present) could be the sole management strategy. Progestins have been employed to induce mammary gland secretion of GH in dogs (see ch. 295) but failed to increase GH or IGF-1 concentrations in cats, despite the expression of feline GH genes in mammary tissue undergoing progestin-induced fibroadenomatous changes.[10,11]

Replacement GH therapy for AHS, post-hypophysectomy, has not been pursued given the perceived lack of significant clinical consequence. An adjustment in the daily caloric intake seems appropriate in cats with documented decreases in IGF-1 or GH, because GH deficient people have increases in their fat mass (especially abdominal).[4] In our experience, there is risk of obesity in cats undergoing successful hypophysectomy.

Few GH-deficient cats have undergone treatment and been reported. This precludes full assessment of treatment alternatives or prognosis of feline CHS. Left untreated, the condition seems to carry a poor prognosis with a shorter lifespan and development of infectious, degenerative or neurological complications.[1,2]

Feline Hypersomatotropism

Overview

While GH deficiency appears to be a clinical concern only in kittens and young cats with growth issues, feline hypersomatotropism (FeHS; acromegaly) should be considered in any middle-aged to older cat with DM. Excess GH causes insulin resistance and subsequent DM by reducing insulin receptors, interfering with a range of post-insulin-receptor processes, and other mechanisms.[12]

Prevalence

FeHS is a relatively common underlying cause for feline DM. Prevalence rates have ranged from 18-32%, with potential for geographic variances and/or differences in recruitment or screening methods.[12-15] In the largest screening study to date, conducted on 1221 cats in the United Kingdom, recruitment was initiated by offering free fructosamine determinations for cats with DM. Spare serum was assayed for IGF-1 and, if extremely increased, confirmative tests (including contrast-enhanced pituitary computed tomography [CT]) were offered. From the 1221 samples assayed for IGF-1 (IGF-1 >1000 ng/mL was the arbitrary cutoff), 319 cats (26%) were suspected and 95% of those cats were confirmed to have FeHS.[15] Based on these prevalence data and the precedent of screening for less common conditions (e.g., urinary tract infections in feline DM; prevalence estimate 12%), it is recommended that cats with recently diagnosed DM be screened for FeHS (Figure 294-2).[16] Screening all newly diagnosed diabetics is wise when the dramatic implications of concurrent FeHS are considered. Treatment, potential for diabetic remission, and prognosis are changed.

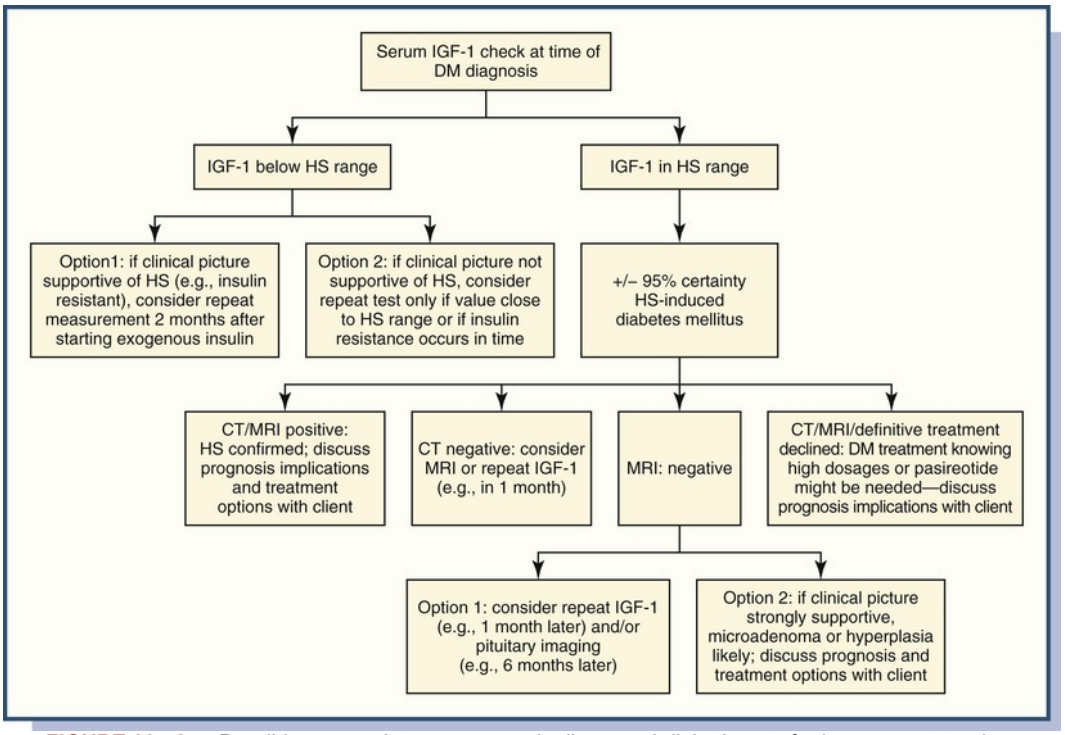

FIGURE 294-2 Possible approach to screen newly diagnosed diabetic cats for hypersomatotropism (HS). *IGF-1,* Insulin-like growth factor-1; *DM,* diabetes mellitus.

Causes

Overview

FeHS is caused by a neoplastic transformation of acidophils (somatotrophs) in the anterior pituitary, leading to increased frequency and amplitude of the pulsatile secretion patterns of GH. Most such tumors are adenomas, but a small number of pituitary carcinomas and some non-neoplastic hyperplasias have been described.[12,17] The cause for tumor development is not understood, with environmental and genetic factors proposed.

Environmental Causes

Organohalogenated contaminants (OHCs) have been implicated in endocrine oncogenesis conditions in various species, including humans and cats.[18-24] OHCs are persistent and bio-accumulative chemicals found in organochlorine pesticides, industrial chemicals (such as polychlorinated biphenyls [PCBs]), and brominated flame retardants (BFRs) added to materials to reduce flammability (such as polybrominated diphenyl ethers [PBDEs]). Cats and humans are continuously exposed to such chemicals, at least in part via food and indoor (dust) contamination. Dust may be especially relevant in cats with their intense grooming behavior. In one report, significantly higher levels of all studied contaminants were identified in cats with FeHS as compared to cats with primary DM and those without an endocrinopathy.[18] Data also suggested that FeHS may reduce a cat's capacity to metabolize persistent chemicals like PCBs. Similar contaminants have been implicated in the emergence of feline hyperthyroidism (see ch. 301).[19-22]

Genetic Causes

Human pituitary adenomas were considered monoclonal in origin, suggesting they form as a consequence of an acquired single cell somatic mutation.[25] It was then demonstrated that an additional mechanism for development of GH-secreting pituitary adenoma involved germline mutations that inactivate tumor suppressor genes.[26-30] Mutations of the aryl-hydrocarbon-receptor interacting protein (AIP) gene, a tumor suppressor protein, have been demonstrated in as many as 40% of people with isolated familial or spontaneous GH secreting adenomas. AIP has a range of effects that include activation of xenobiotic metabolizing enzymes, making the previously discussed link with exposure and accumulation of

environmental OHCs even more interesting.[27-30] In a study of genomic DNA, 2 of 10 cats with FeHS (and no control) had a single non-conservative single nucleotide polymorphism in exon 1 of the AIP gene (AIP:c.9G>T), suggesting some cats may be genetically predisposed to developing FeHS.[31]

Clinical Presentations

Early Signs of FeHS

Initial clinical signs in cats with FeHS are determined, in part, by the timing of owner concern. Most cats ultimately diagnosed as having FeHS are first seen by a veterinarian after an owner becomes concerned about polyuria and polydipsia (PU/PD) secondary to DM and the osmotic effects of glucosuria. Insulin treatment is usually initiated and can lead to successful amelioration of clinical signs in some cats (temporary diabetic remission can even occur). In most, however, it is difficult to attain reasonable glycemic control. Only rarely have cats with FeHS not had concurrent DM. These cats may have phenotypic acromegalic changes, described in this section, and/or extreme polyphagia. In a study of 319 cats suspected as having FeHS, their mean age was 11.3 years (range 4-19) and 70% were neutered males. While many breeds were included, 87% were Domestic Short Hair cats.[15] These observations are similar to those for cats with primary DM and not useful in gaining an index of suspicion of FeHS. Body weight and fructosamine were significantly higher in cats with IGF-1 in the hypersomatotropism range (compared to those with IGF-1 < 1000 ng/mL), despite significantly higher daily insulin dosages (mean 15 IU/day versus 6 IU/day).[15] Nevertheless, cats with FeHS ranged in body weight from large to small and in insulin requirements (from modest to high). Data suggest that FeHS should be suspected when weight gain is noted in a cat with suboptimal diabetic control or whenever unexplained insulin resistance is encountered. Characteristic phenotypical changes eventually develop as a consequence of the anabolic effects of both GH and IGF-1 and are only obvious when a cat has had longer-standing disease. Only 24% of clinicians indicated a strong suspicion of FeHS before their patient was identified as having the condition.[15]

Signs Associated with Chronic FeHS

When the condition becomes chronic, cats with FeHS may have "classic" clinical signs (Box 294-1). The relatively high incidence (53%) of upper respiratory stridor in cats with FeHS is due to tissue swelling. The narrowed nasopharynx often causes an owner to notice their cat "snoring."[17,32] Increased width of the head and broad facial features (Figure 294-3) might be the most obvious feature on physical examination. However, these changes can be subtle and difficult to appreciate because of facial hair, breed-related conformational variation and the tendency for owners not to notice changes that have developed quite gradually. In summary, presence of so-called typical physical changes might help the clinician, though their absence should not decrease the suspicion of FeHS, especially in cats with DM. Further, it seems more appropriate to use the term "hypersomatotropism" and not acromegaly because the latter term incorrectly implies that affected cats should have characteristic phenotypical changes.

Box 294-1

Possible Clinical Signs Encountered in Cats with Hypersomatotropism

1. Diabetes mellitus-related signs (polyuria, polydipsia, polyphagia)
2. Weight gain despite suboptimal diabetic control (although weight loss is also possible)
3. Polyphagia independent of diabetic control (possibly extreme)
4. Inspiratory stridor (snoring)*
5. Broad facial features* (see Figure 294-3)
6. Prognathia inferior (protrusion of lower jaw)* (see Figure 294-3)
7. "Clubbed" paws (enlarged distal limbs/ paws)*
8. Abdominal enlargement with organomegaly*
9. Mobility problems due to arthropathy* and/or diabetic neuropathy
10. Insulin resistance (exogenous insulin requirement exceeding 1.5 IU/kg/injection)
11. Heart murmur and congestive heart failure*
12. Central nervous system signs (e.g., circling, blindness, seizures, depression)*

*Indicates presence is usually only associated with longstanding disease; clinical signs are not consistently present.

FIGURE 294-3 An 11-year-old Domestic Short Hair cat suffering from hypersomatotropism-induced diabetes mellitus. Broad facial features can be seen, though they had not been noted by the cat's owner. These facial changes tend only to be present when hypersomatotropism has been present for a longer period of time.

Diagnosis

Serum or Plasma GH and IGF-1

For most veterinarians, serum total IGF-1 assessment represents the most feasible and accessible means of screening for FeHS.[17] Fortunately, the positive predictive value of an IGF-1 > 1000 ng/mL was shown to be a respectable 95% with one particular radioimmunoassay.[15,17] However, readers are warned to only use independent and specific laboratory-generated reference ranges. An IGF-1 ELISA assay has been validated.[33]

The weakness of randomly obtained blood samples for IGF-1 concentrations as a screening test for FeHS is that hepatic IGF-1 synthesis is dependent on adequate concentrations of portal insulin. Such insulin can be deficient in cats newly diagnosed with DM, resulting in false-negative IGF-1 results in about 9% of untreated cats. Additionally, increased IGF-1 concentrations have been reported in non-FeHS diabetic cats.[17] Further, differences in IGF-1 assays exist.[34] All these factors should be kept in mind when screening cats with DM for FeHS (see Figure 294-2). Serum IGF-1 concentrations are useful as a marker for treatment success post-

hypophysectomy, but not adequately sensitive to document the less pronounced GH decreases that might occur following radiotherapy.[17] Commercially available GH assays remain elusive, despite all tested cats with FeHS having shown an elevation above the reference interval.[7] GH suppression tests (often using oral glucose) considered gold standard for the diagnosis of human hypersomatotropism have thus far not been found useful in the cat.[7,17]

Alternative Blood Tests

Since FeHS is associated with tissue growth, serum type III procollagen propeptide (PIIIP), a peripheral indicator of collagen turnover, has been evaluated.[35] Median serum PIIIP was five times higher in cats with FeHS-induced DM as compared to cats with primary DM. Serum ghrelin, a GH secretagogue, was shown to be lower in FeHS as compared to healthy control cats, but results were similar to those from cats with primary DM.[36] Serum ghrelin monitoring might prove useful in assessing treatment. Significant increases were documented after successful radiotherapy for FeHS while changes in IGF-1 were not significant.[36]

Computed Tomography (CT) and Magnetic Resonance Imaging (MRI) Scans

Advanced imaging confirmation of FeHS is recommended and often helpful by demonstrating pituitary enlargement using either contrast-enhanced CT (Figure 294-4) or MRI. Absence of a mass or of enlargement should not, however, be interpreted as excluding the possibility of FeHS. Microadenomas and acidophil hyperplasia can occur and might be more common than is currently appreciated. As cats are diagnosed earlier in the course of disease, the number of visible masses on advanced imaging is expected to decline. In longer-standing cases, CT may demonstrate FeHS-related prognathia inferior (about 25% of affected cats), temporomandibular-joint malformations, and increased thickness of the skin, subcutaneous tissues and calvarium bone.[32]

FIGURE 294-4 Main picture: A CT scan of the brain of a diabetic cat with hypersomatotropism; the pituitary can be found at the base of the skull and proves enlarged, extending beyond the dorsal rim of the sella turcica and showing heterogeneous contrast uptake. Inset: CT scan of the same cat after successful hypophysectomy. The pituitary is approached through the nasopharynx, after incision of the soft palate. The cat entered diabetic remission 2 weeks after the procedure.

Treatment and Prognosis

Hypophysectomy

As veterinary experience with hypophysectomy continues, it is recognized as the definitive, "gold standard" treatment for FeHS, provided there are no contraindications.[37,38] Contraindications, still being evaluated, include a particularly large tumor size, significant comorbidities that prevent a safe anesthetic and postoperative recovery (particularly significant renal or cardiovascular disease), or an owner who opposes surgery. The financial commitment for surgery can be an obstacle, although it is important for the owner to be educated about the cost of ineffective insulin treatment or radiotherapy.

In our experience, pituitary tumors are approached from the skull base, with the neurosurgeon operating through the cat's mouth and nasopharynx (transsphenoidal approach; soft palate is incised). Approximately 85% of cats enter diabetic remission within 2 months of surgery and the remainder attain good glycemic control with more traditional insulin dosages. These responses demonstrate the enormous resilience of the cats' pancreatic beta-cells, which seem to recover after months or even years of severe insulin resistance. The peri- and postoperative mortality rate, in our experience, is about 10%. This is an acceptable risk for most cat owners, especially given the paucity of effective treatment alternatives. After surgery, cats are treated with low hydrocortisone and levothyroxine dosages (both lifelong) and desmopressin acetate (DDAVP, which can be discontinued in most cats). GH replacement therapy is not deemed necessary (see previous discussion on AHS).

Medical Management

Somatostatin (SST) analogues and dopamine agonists have not been effective.[17] Fortunately, pasireotide (Signifor, Novartis, Basel, Switzerland), a novel multi-receptor ligand SST analogue with high binding affinity for SST receptor subtypes 1, 2, 3 and 5, has recently been shown to effectively suppress the somatotropinoma in cats with concurrent FeHS and DM.[39,40] Treated cats had significant decreases in serum IGF-1, average 12-hour blood glucose, fructosamine and insulin requirements. A short-acting q 12 h injectable form and a once-monthly long-acting injectable form have been tested. About 25% of cats treated with the once monthly form entered diabetic remission. Disadvantages include mild gastrointestinal side-effects (loose stools/diarrhea) and cost.

Radiotherapy

Although radiotherapy was initially suggested to be optimal, even use of stereotactic or gamma-knife technology fails to rival results of hypophysectomy.[17,41-45] The effect of radiotherapy has proven particularly unpredictable in terms of whether response will occur; when a response should be expected; to what extent radiotherapy will change insulin requirements; and how long effects of radiotherapy will persist. Lack of response in terms of IGF-1 normalization puts further doubt over its true efficacy, even in cats who required less insulin.[36] Indeed, FeHS changes have been shown to progress, even if diabetic improvement or resolution is achieved.[45] Radiotherapy can still serve as a valuable method for shrinking a tumor and can be considered for cats with a large pituitary mass that increases risk of surgery, or when hypophysectomy or pasireotide treatments are declined.

Diabetes Mellitus Treatment Only

If definitive treatment options are declined by owners, the only remaining therapeutic option (barring euthanasia) is to solely treat the secondary DM. Treatment approach is that recommended for primary DM (see ch. 305), apart from the fact that high insulin dosages will often be needed to achieve an acceptable quality of life. Some suggest insulin dosages should not exceed a certain level, but our experience indicates that use of extremely high doses is sometimes the only way to achieve an acceptable quality of life. Use of high-dose insulin therapy does mean owners need to be prepared for, and indeed need to accept, the possibility of iatrogenic hypoglycemia, but it seems to be rare. The pituitary tumor does retain its pulsatile GH secretory patterns, which explain the episodes of low GH and increased insulin sensitivity.

Appropriate insulin dosages should be determined by gradually increasing the amount as required, usually increasing by no more than 1 IU/injection/cat/week. Ideally, periodic blood glucose curves are obtained along with careful assessment of the clinical condition. If insulin doses increase too quickly, there is increased risk of encountering Somogyi phenomena. Negative sequelae of the progressive acromegalic changes may require attention: including treatment for arthropathies (see ch. 203 and 353), congestive heart failure (see ch. 247), or

chronic kidney disease (see ch. 324). Central nervous system signs (e.g., seizures, blindness, depression) due to an expanding pituitary mass are rare, given their slow-growing nature. However, signs can occur and could warrant additional palliative treatment strategies (see ch. 260). Regular quality of life assessments should be planned and euthanasia considered if treatment response proves unsatisfactory (see ch. 7).[46] This is especially important in those cats whose DM cannot be controlled or those suffering from GH-induced extreme polyphagia. Fluoxetine has been used to decrease polyphagia with mixed success.

CHAPTER 295

Canine Growth Hormone Disorders

Hans S. Kooistra

Client Information Sheets:
Pituitary Dwarfism in Dogs
Acromegaly (Growth Hormone Excess) in Dogs

Growth Hormone

Sources

Growth hormone (GH) is a rather large single-chain polypeptide containing 190 amino acids. The amino acid sequence of GH varies considerably between species, but GH in dogs and pigs is identical.[1] Anterior pituitary hormones, including GH, are secreted in rhythmic pulses separated by intervening troughs. Pituitary GH secretion is regulated mainly by the opposing actions of the stimulatory hypothalamic peptide GH-releasing hormone (GHRH) and the inhibitory hypothalamic peptide somatostatin (Figure 295-1). The GH pulses predominantly reflect the pulsatile delivery of GHRH, whereas the concentrations between pulses are primarily controlled by somatostatin. GH synthesis and secretion can also be stimulated by non-GHRH secretagogues, which exert their effect via non-GHRH receptors. The endogenous ligand for these receptors is ghrelin, synthesized and secreted from the stomach.[2] In young dogs, ghrelin is more potent than GHRH in stimulating synthesis and secretion of GH.[3] Ghrelin also stimulates food intake as well as gastric and intestinal emptying. Fasting and food intake are associated with higher and lower circulating ghrelin concentrations, respectively.[4]

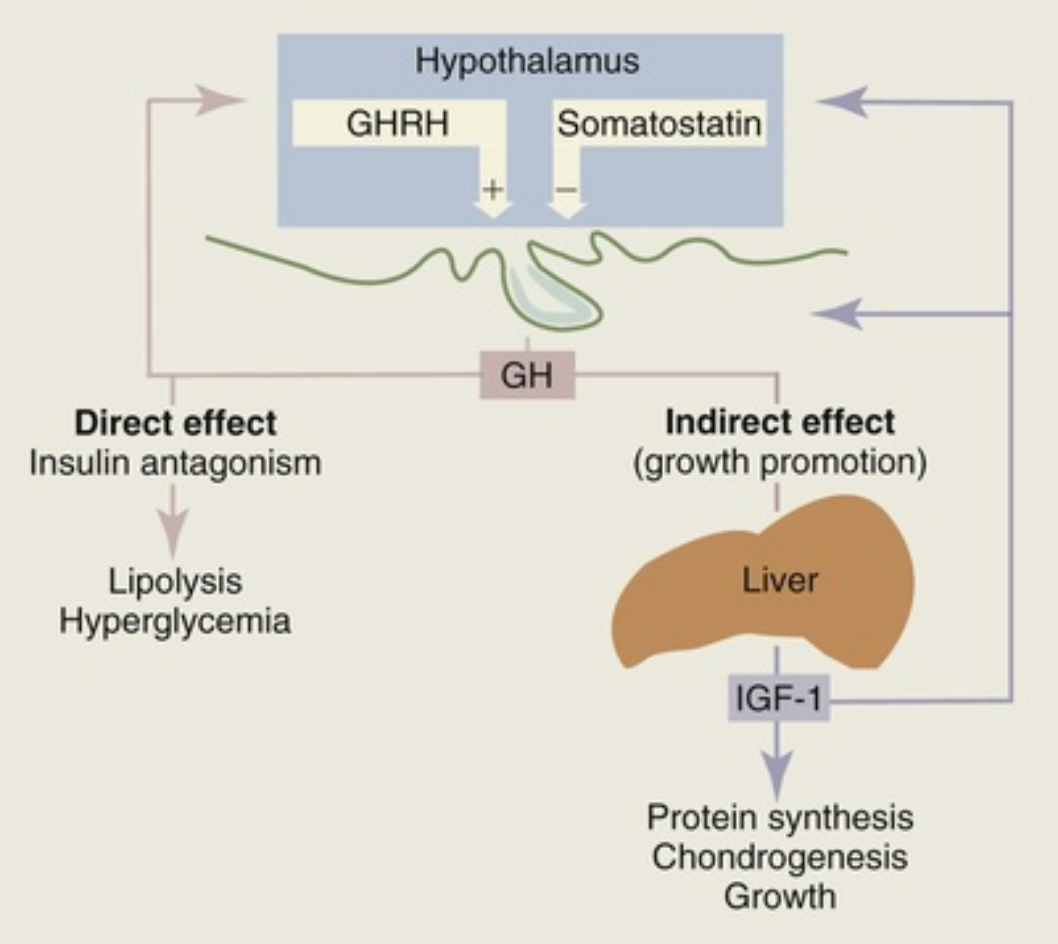

FIGURE 295-1 The pituitary secretion of growth hormone (GH) is under inhibitory (somatostatin) and stimulatory (GH-releasing hormone [GHRH]) hypothalamic control and is also modulated by negative feedback control of insulin-like growth factor-1 (IGF-1) and GH itself. The direct catabolic (diabetogenic) actions of GH are shown on the left side of the figure, and the indirect anabolic actions are shown on the right. (Redrawn from Rijnberk A, Kooistra HS, editors: *Clinical endocrinology of dogs and cats*, ed 2, Hannover, Germany, 2010, Schlütersche.)

In dogs, GH is synthesized in both pituitary and mammary tissues. Administration of progestins can increase plasma GH concentrations in dogs but this secretion is not pulsatile, not sensitive to GHRH, and not inhibited by somatostatin. Moreover, progestin-induced plasma GH concentrations do not decrease after hypophysectomy, indicating that this GH originates from an extra-pituitary site. Rather, this GH is synthesized in foci of hyperplastic mammary ductular epithelium.[5] Mammary GH is biochemically identical to pituitary GH and the gene encoding mammary GH is identical to that in the pituitary gland.[6]

The typical pulsatile secretion pattern of GH changes during the luteal phase (diestrus) of healthy bitches, with higher basal concentrations and fewer pulses. Progesterone-induced mammary GH may partially suppress pituitary GH secretion. Thus, mammary GH synthesis is normal during diestrus in healthy bitches, likely promoting proliferation of mammary tissue in preparation for lactation via local autocrine and paracrine effects.[7] Significant GH concentrations have been identified in canine mammary gland secretions and, particularly, in colostrum.[8] Colostrum GH may promote neonatal gastrointestinal development. The progestin-induced mammary GH production may also play a role in mammary gland tumor development or tumor progression.

Physiologic Effects

The effects of circulating GH can be divided into two main categories: rapid catabolic actions and slow (long-lasting) anabolic actions (see Figure 295-1). The rapid effects are mainly due to insulin antagonism, resulting in enhanced lipolysis, gluconeogenesis, restricted glucose transport across cell membranes and hyperglycemia. Slow anabolic effects are mediated by insulin-like growth factors (IGFs) produced in a variety

of tissues (primarily the liver) that have about 50% sequence similarity with insulin. These IGFs have local paracrine or autocrine growth-promoting effects. In contrast to insulin, IGFs are bound to binding proteins (IGFBPs), which prolongs half-life and is consistent with long-term growth-promoting actions. IGFs are important determinants in the regulation of body size, by stimulating protein synthesis, chondrogenesis, and growth.

Distinction of the opposing biologic effects of GH is neither strict nor absolute. There is evidence that GH exerts its growth-promoting effect not only via IGFs but also directly on target cells. GH may be the major determinant of body size. It appears that young large breed dogs go through longer periods of high GH release (i.e., juvenile hypersomatotropism) than do young small breed dogs.[9] On the other hand, there is strong linear correlation between plasma IGF-1 concentrations and body size. Furthermore, an IGF-1 single-nucleotide polymorphism haplotype has been reported as a major factor in the final body size of dogs.[10] IGF-1 exerts an inhibitory effect on GH release, directly inhibiting secretion and indirectly inhibiting secretion via stimulating release of somatostatin. GH also suppresses GHRH synthesis and secretion at the hypothalamic level (see Figure 295-1).

Acromegaly

Pathogenesis

Acromegaly is a syndrome of bony and soft tissue overgrowth and insulin resistance due to chronic and excessive GH secretion. In middle-aged and elderly dogs, either endogenous progesterone (luteal phase of the estrous cycle) or exogenous progestins may cause excess GH due to mammary GH secretion. Acromegaly has also been reported in a dog with a GH-producing mammary tumor.[11] Hypothyroidism, in dogs, is associated with increased plasma concentrations of GH and IGF-1.[12,13] Rarely, a pituitary somatotroph adenoma may cause acromegaly in dogs, in contrast to the much greater frequency of this condition in cats (see ch. 296).[14]

Clinical Manifestations

Signs of GH hypersecretion tend to develop slowly and often include soft tissue swelling of the head, neck and abdomen. In some acromegalic dogs, severe hypertrophy of oral and pharyngeal soft tissues can cause snoring and even dyspnea (Figure 295-2). Articular cartilage proliferation, periarticular periosteal reaction and spondylosis deformans may result in stiffness, difficulty in rising, and neck rigidity. Affected dogs often have polyuria and sometimes polyphagia. The polyuria is usually without glucosuria, but diabetes mellitus (DM) can develop due to insulin resistance. Physical examination may reveal thick skin folds, especially in the neck; prognathism; and wide interdental spaces (see Figure 295-2). Chronic GH excess may also lead to generalized increase in organ size and subsequent abdominal enlargement. Laboratory investigation often reveals hyperglycemia. Increased serum alkaline phosphatase activity may be the result of the intrinsic glucocorticoid activity of progestins. German Shepherd Dogs appear predisposed to acromegaly.[15] Acromegaly secondary to hypothyroidism tends to be far more subtle than in other types. Large compressive somatotroph adenomas may cause central nervous system signs.

FIGURE 295-2 The mouth of a 4-year-old Beagle dog with progestin-induced growth hormone excess. Note the hyperplasia of the gingiva, the widening of the interdental spaces and the relatively large tongue.

Diagnosis

Basal plasma GH concentrations in acromegalic dogs often exceed the reference range, but may not be abnormal if the condition is mild or early in its course. Increased GH concentrations, alone, may result from sampling soon after a GH pulse secretion from a normal pituitary. Diagnosis of acromegaly is supported if GHRH (1 mcg/kg IV) fails to stimulate GH secretion or if somatostatin (10 mcg/kg IV) fails to suppress GH. Because the amino acid sequence of GH varies among species, GH should be determined by a species-specific, homologous assay. Commercial GH assays are not widely available.

Since plasma IGF-1 is bound to plasma proteins, its concentration does not fluctuate as widely as does GH. In addition, the amino acid sequence of IGF-1 is less species-specific and concentrations can be determined with heterologous (human) assays. Because of the strong linear correlation between the plasma IGF-1 concentration and body size, breed-specific reference ranges are required.[16] If GH excess is noted in a dog not given progesterone or progestins, one should test for hypothyroidism. Advanced diagnostic imaging of the pituitary area may reveal a somatotroph adenoma.

Treatment

Progesterone-induced acromegaly in dogs can be treated effectively by ovariectomy. If GH excess did not lead to complete exhaustion of the pancreatic beta cells, ovariectomy may prevent or reverse DM. Dogs with progestin-induced GH excess should have those drugs discontinued. Administration of progesterone receptor blockers, such as aglépristone, significantly decreases plasma concentrations of GH and IGF-1 in dogs with progestin-induced acromegaly.[17] Treatment of dogs with primary hypothyroidism with levothyroxine results in normalization of plasma concentrations of GH and IGF-1.[12]

In dogs with acromegaly due to a somatotroph adenoma, treatment should be directed at the pituitary mass. Therapeutic options include medical management, radiation treatment, and hypophysectomy. Medical treatment with (expensive) long-acting somatostatin analogues, such as octreotide and lanreotide, decreases symptoms, normalizes plasma IGF-1 concentrations, and reduces tumor size in about 50% of acromegalic people. GH-receptor antagonists developed for human use, such as pegvisomant, also may be effective in dogs. Radiation may shrink a pituitary tumor. Disadvantages of radiation therapy include persistent excess GH secretion despite shrinkage, limited availability, extended hospitalization, frequent anesthesias, expense,

and the possibility of relapse should an initial response be seen. Transsphenoidal hypophysectomy has been performed successfully in dogs with hypercortisolism due to a corticotroph adenoma and in cats with acromegaly due to a somatotroph adenoma.[18] Experience in dogs with acromegaly is limited.

Pituitary Dwarfism

Pathogenesis

Any defect in pituitary gland organogenesis may cause isolated or combined pituitary hormone deficiencies. Congenital GH deficiency or pituitary dwarfism is the most striking example of pituitary hormone deficiency. Congenital GH deficiency has been described in several dog breeds. The condition is encountered most often as a simple, autosomal recessive inherited abnormality in the German Shepherd Dog. Genealogical investigations indicate that the origin of the recessive gene is a mutation that occurred around 1940, with several champion carrier dogs identified.[19,20] German Shepherd Dog dwarfs typically have combined GH, thyroid stimulating hormone (TSH), and prolactin deficiencies, impaired release of gonadotropins, and normal adrenocorticotropic hormone (ACTH) secretion (Figure 295-3).[21] Congenital GH deficiency was thought to result from pressure atrophy of the anterior pituitary due to cyst formation in Rathke's pouch. Indeed, pituitary cysts are present in most German Shepherd Dog dwarfs.[21] However, young German Shepherd Dog dwarfs may have no or only a small cyst and little evidence for pressure atrophy.[21] Further, preservation of ACTH secretion argues against cyst formation in Rathke's pouch as the primary cause of pituitary dwarfism.

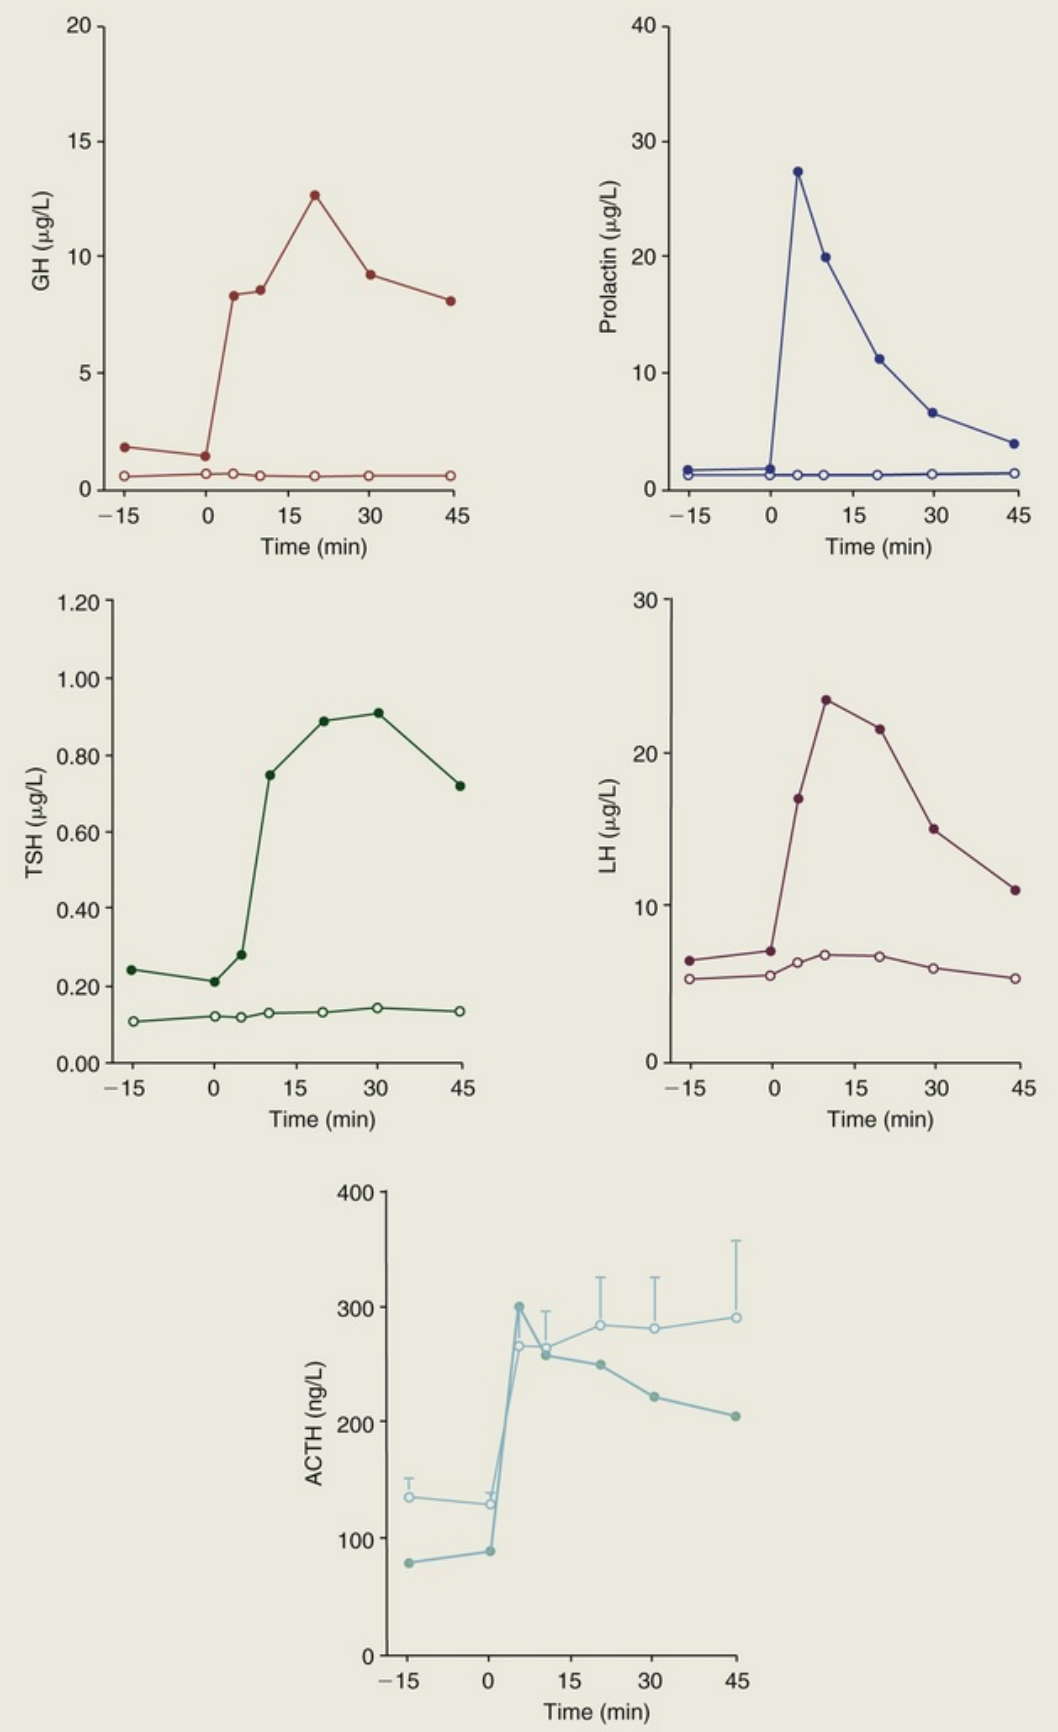

FIGURE 295-3 Results of a combined pituitary anterior lobe function test (mean and SEM) in eight German Shepherd Dogs with dwarfism (○) and in eight healthy Beagle dogs (●). *ACTH,* Adrenocorticotropic hormone; *GH,* growth hormone; *LH,* luteinizing hormone; *TSH,* thyroid-stimulating

hormone. (From Kooistra HS, Voorhout G, Mol JA, et al: Combined pituitary hormone deficiency in German Shepherd Dogs with dwarfism. *Domest Anim Endocrinol* 19:177, 2000. With kind permission of Domestic Animal Endocrinology.)

Genetic studies have demonstrated that pituitary dwarfism is due to a mutation in *LHX3*.[22] LHX3 is a member of the LIM homeodomain protein family of DNA-binding transcription factors. Molecular defects in the *LHX3* gene in humans and mice result in deficits of all anterior pituitary hormones, sparing ACTH. These findings are identical to the endocrine phenotype of German Shepherd Dog dwarfs. Analysis of intron 5 of *LHX3* revealed that dwarfs have a deletion of one of six 7 base pair (bp) repeats, reducing the intron size to only 68 bp, resulting in defective *LHX3* splicing.[22] This genetic defect is also the cause of pituitary dwarfism in Saarloos Wolfdogs and Czechoslovakian Wolfdogs; both are German Shepherd dog-wolf cross-breeds.[23] Screening a number of clinically healthy Saarloos and Czechoslovakian Wolfdogs demonstrated that 31% and 21%, respectively, are carriers. These results indicate that pituitary dwarfism is a relevant disorder and the need for screening is emphasized. Pituitary dwarfism and its associated DNA defects are often incompatible with life, explaining why the condition is uncommon.

Clinical Manifestations

Pituitary dwarfism can lead to a wide range of clinical manifestations.[24] Pituitary dwarfs are usually brought to a veterinarian between 2 and 5 months of age because of proportionate growth retardation, retention of lanugo or secondary hairs, and lack of primary or guard hairs (Figure 295-4). The lanugo hairs are easily epilated and there may be gradual development of truncal alopecia, beginning at the points of wear, sparing the head and the extremities. The skin becomes progressively hyperpigmented and scaly. Secondary bacterial infections are common. The dwarfs usually have a pointed muzzle, resembling a fox. Due to impaired gonadotropin release, male dwarfs often have unilateral or bilateral cryptorchidism and females commonly fail to ovulate due to absence of a luteinizing hormone surge. The *LHX3* mutation is also associated with malformations of the atlanto-axial joint, which can lead to instability and dynamic compression of the cervical spinal cord.[25] Pituitary dwarfs are usually active and alert, but inappetence and decreased activity usually develops by about 2-3 years of age due to secondary hypothyroidism and impaired renal function.

FIGURE 295-4 A 6-month-old male German Shepherd Dog with growth retardation, retention of secondary hairs (puppy coat), and lack of primary hairs due to pituitary dwarfism.

Diagnosis

Although the clinical signs of pituitary dwarfism may be obvious, other endocrine and non-endocrine causes of growth retardation and/or alopecia must be excluded. No abnormalities, aside from increases in serum creatinine, are noted on routine laboratory examination of dogs with naturally occurring pituitary dwarfism.[21] GH deficiency (± thyroid hormone deficiency) causes abnormal glomerular development and impaired renal function. Low plasma IGF-1, TSH, and serum T_4 concentrations are common. However, low IGF-1 concentrations do not provide a definitive diagnosis of pituitary dwarfism.

Because basal plasma GH values may also be low in healthy animals, the definitive diagnosis of GH deficiency should be based on results of stimulation testing. For this purpose GHRH (1 mcg/kg) or alpha-adrenergic drugs, such as clonidine (10 mcg/kg) or xylazine (100 mcg/kg) can be used. The plasma GH concentration should be determined immediately before and 20 to 30 minutes after IV administration of the stimulant. In healthy dogs, plasma GH concentrations should increase at least twofold to fourfold after stimulation. In dogs with pituitary dwarfism there is no significant rise in circulating GH levels (see Figure 295-3). Supra-pituitary stimulation with corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), or gonadotropin-releasing hormone (GnRH) may reveal the presence of other pituitary hormone deficiencies.[21] A plasma GH concentration more than 5 mcg/L, 20 minutes after IV administration of 2 mcg/kg ghrelin, excludes pituitary dwarfism.[26]

Diagnostic imaging of the pituitary area (computed tomography or magnetic resonance imaging) often reveals the presence of pituitary cysts in dogs with congenital GH deficiency.[21] Despite the presence of cysts, the majority of young dogs with pituitary dwarfism have an extremely small pituitary, compatible with pituitary hypoplasia (i.e., a lack of endocrine cells in the pituitary anterior lobe). Cyst size gradually enlarges during life.[27] When cysts are large, pituitary size may also increase. Because healthy dogs may have pituitary cysts, definitive diagnosis of pituitary dwarfism cannot be based solely upon the presence of pituitary cysts.

A DNA test has been developed to aid in identifying the *LHX3* mutation.[22,23] The availability of this test

not only allows a proper diagnosis of dogs with congenital GH deficiency, but also enables breeders to prevent dwarfs from being born by testing the carrier status of potential breeding animals and applying a correct breeding program.

Treatment

Canine GH is not available. Attempts have been made to treat dogs with congenital GH deficiency using heterologous GH. Antibody formation precludes the use of recombinant human GH.[28] Administration of porcine GH does not result in antibody formation, because the amino acid sequence of porcine GH is identical to that of canine GH.[1] The recommended SC dosage for porcine GH, 0.1 to 0.3 IU/kg three times per week, may result in GH excess and side-effects, such as DM. Therefore, monitoring of plasma GH and glucose concentrations is recommended 3 times during each week of treatment. Long-term dosages should be determined based on measurements of the plasma IGF-1 concentration. Whether administration of porcine GH will lead to linear growth is dependent on the status of the growth plates when treatment is initiated. A beneficial response in the skin and lanugo hair growth usually occurs within 6 to 8 weeks of starting therapy, but growth of guard hairs is variable.

Demonstration of progestins' ability to induce expression of the GH gene in the canine mammary gland, with subsequent secretion of GH into the systemic circulation, has raised the possibility of treating congenital GH deficiency with progestins. Treatment of young German Shepherd dwarfs with SC injections of medroxyprogesterone acetate using dosages of 2.5 to 5 mg/kg, initially at 3-week intervals and subsequently at 6-week intervals, resulted in some increase in body size and development of an adult hair coat. Parallel with the physical improvements, plasma IGF-1 concentrations rose sharply while increases in plasma GH concentrations were seen but did not exceed the reference range upper limit.[27] Treatment of pituitary dwarfs with proligestone has been reported to result in the development of an adult hair coat, increased body weight, and elevated plasma IGF-1 concentrations.[29] However, administration of progestins may cause recurrent periods of pruritic pyoderma, skeletal maldevelopment, development of mammary tumors, acromegaly, DM and cystic endometrial hyperplasia. As with the treatment using porcine GH, monitoring plasma concentrations of GH, IGF-1 and glucose is important. Bitches should be ovariohysterectomized before starting progestin treatment. Treatment with levothyroxine should be started as soon as there is evidence of secondary hypothyroidism.

Prognosis

The long-term prognosis of German Shepherd Dog dwarfs is usually poor without treatment. By 3 to 5 years of age, these dogs usually become dull, thin, and bald. These changes may be due to progressive loss of pituitary functions, continuing expansion of pituitary cysts, and progressive renal failure. At this stage, owners usually request euthanasia. Although the prognosis improves considerably when dwarfs are properly treated with levothyroxine and either porcine GH or progestins, their prognosis still remains guarded.

Acquired GH Deficiency (AGHD)

In addition to dogs and cats who develop AGHD following elective hypophysectomy to remove a tumor and those who develop AGHD following traumatic brain injury, there are reports of mature dogs developing naturally occurring GH deficiency.[30] It has been proposed that GH deficiency may explain some forms of alopecia in the Pomeranian, Miniature Poodle, Chow Chow, Keeshond, and others. The alopecia has been described in dogs of either gender, neutered or sexually intact, and of any age. However, the condition is most commonly recognized in dogs 1 to 3 years of age. Their alopecia usually involves the trunk, caudal thighs, perineum, and neck and their skin often becomes darkly pigmented. This alopecia does not appear to be attributable to any of the endocrine diseases known to result in skin atrophy and hair loss (i.e., hypothyroidism, hypercortisolism, or hyperestrogenism due to testicular tumor). Although treatment with heterologous GH[31] or medroxyprogesterone acetate[32] has had poor to moderate results, the condition has been given names such as “adult-onset GH deficiency” and “GH-responsive dermatosis.”

Uncertainty about the role of GH in this condition is further illustrated by other names it has received, such as “castration-responsive alopecia,” “biopsy-responsive alopecia,” and “alopecia X.”[31,32] The entity is not well defined because one-third of dogs have a normal GH response to stimulation. Yet in some with a normal response to stimulation, treatment with GH was reported to be effective. In others, seemingly unrelated

measures such as castration or administration of testosterone were followed by the appearance of a new hair coat.[33] When GH stimulation tests were performed on Pomeranians with alopecia and a control group without alopecia, mean circulating GH concentrations failed to increase significantly in either group.[34] Thus, the association between some forms of this adult-onset alopecia and decreased GH secretion is poorly supported. True GH deficiency is not likely since plasma IGF-1 concentrations have invariably been within reference ranges.[31]

CHAPTER 296

Diabetes Insipidus

Robert E. Shiel

Client Information Sheet: Diabetes Insipidus

Physiology

Source and Structure of Vasopressin

Arginine vasopressin (AVP), the principal hormone responsible for water homeostasis, is a small peptide derived from a larger precursor within magnocellular neurons of the hypothalamic paraventricular and supraoptic nuclei.[1,2] Pre-pro-vasopressin is comprised of the signal peptide and the polypeptides that later form AVP, neurophysin-2 and the glycoprotein copeptin. Following cleavage of the signal peptide, pro-vasopressin is transported into the endoplasmic reticulum. Neurophysin 2 is necessary for correct processing, transport, cleavage and may have a role in protecting AVP from enzymatic degradation. The function of copeptin is unknown. The prohormone is packaged in neurosecretory granules before axonal transport through the hypothalamic-neurohypophyseal tract and storage in the posterior pituitary. Enzymatic cleavage into the constituent molecules occurs during transport and storage.

Secretion Stimuli

In response to a stimulus for AVP release, an action potential is generated in the hypothalamic cell body and is propagated along the axon to the posterior pituitary with resultant calcium-dependent exocytosis of granule contents and release of all three products. As the posterior pituitary gland lacks a blood-brain barrier and contains fenestrated capillary vessels, entry into the systemic circulation is rapid.[3] The main stimulus for AVP release is an increase in plasma osmolality (OSM) (E-Figure 296-1). Various circumventricular organs, including the subfornical organ and the organum vasculosum of the lamina terminalis, act as osmoreceptors with the capacity to alter AVP secretion and thirst.[4] In addition, magnocellular neurons can be directly stimulated via alterations in plasma sodium (Na^+) concentration.[5] A 1% increase in plasma OSM is sufficient to stimulate AVP release. As the half-life of AVP is estimated to be <6 minutes in dogs, a decrease in plasma OSM is quickly followed by decreases in AVP secretion.[6] Blood volume is primarily controlled by the renin-angiotensin-aldosterone system. However, high-pressure arterial baroreceptors in the carotid sinus and aortic arch and low-pressure volume receptors in the atria and pulmonary venous system can inhibit AVP secretion via the glossopharyngeal and vagal nerves.[2] A 10-15% decrease in blood volume or pressure can decrease this inhibitory input, resulting in AVP secretion. Other factors affecting AVP secretion include stress, nausea, pain, structural brain disease, drug therapy, hypoglycemia and exercise. Drinking, associated with decreases in AVP secretion prior to changes in plasma OSM, may be mediated by pharyngeal volume- or osmo-receptors.[7,8]

E-FIGURE 296-1 Effect of change in plasma osmolality (pOsm, in mOsm/kg of H_2O) on plasma arginine vasopressin (PAVP, in pg/mL) and consequent effects on urine osmolality (UOsm, in mOsm/kg of H_2O) and urine volume (L/day). The shaded area represents the normal range. **A,** Small changes in pOsm induce changes in PAVP, typically between less than 0.5 and 5 to 6 pg/mL. **B,** Changes in PVAP induce changes in UOsm through the full range, from maximally dilute to maximally concentrated urine. Although PAVP can rise to higher levels than 6 pg/mL, this does not translate into increased UOsm, which has a maximum determined by the osmolality of an inner medulla of the kidney. **C,** The relationship of urine volume to UOsm is logarithmic, assuming a constant osmolar load and the urine volume that would excrete that osmolar load at the UOsm indicated. As a result, urine volume changes relatively little with small changes in the other parameters until there is almost complete absence of PAVP, after which the urine volume increases dramatically. (Calculated from a formula presented in Robertson G, Shelton R, Athar S: The osmoregulation of vasopressin. *Kidney Int* 10:25-37, 1976. Figure by A.G. Robinson, University of California at Los Angeles, used with permission of Macmillan Publishers, Ltd.)

Interaction of Regulatory Mechanisms and Various AVP Sites of Action

Regulatory mechanisms are highly interactive. For example, increased concentrations of angiotensin II can stimulate both AVP secretion and thirst via the subfornical organ while baroreceptors can stimulate both renin and AVP release.[4] Similarly, natriuretic peptides contribute to regulation of Na^+ and water balance. Brain (B-type) natriuretic peptide has an inhibitory effect on renin, aldosterone and AVP release. AVP and angiotensin II have stimulatory effects on atrial natriuretic peptide (ANP) release.[9,10]

The actions of AVP are mediated through a variety of G-protein associated receptors. In the absence of AVP, principal renal luminal collecting duct cell surfaces have minimal permeability to water. AVP binding to basolateral V2 receptors increases cyclic AMP and activates protein-kinase A, a phosphorylative pathway that causes fusion of aquaporin 2-containing intracytoplasmic vesicles (known as aggregophores) with apical cell membranes. The resultant increased expression of aquaporin 2 enhances permeability and water reabsorption via passive movement of molecules from the hypotonic tubular lumen to the isotonic cortex and/or hypertonic medullary interstitium. Once receptor stimulation has ceased, the aquaporins are re-internalized and stored into aggregophores through a clathrin-mediated process. Stimulation of magnocellular neurons also leads to increased synthesis of AVP; however, there is a lag effect of several hours before newly formed AVP is ready for release. For that reason, relatively large quantities of AVP are stored within the posterior pituitary. Release of AVP is not restricted to the nerve terminals and axonal swellings within the posterior pituitary; release can occur from various sites within the neuron, including the hypothalamic soma and dendrites, and undilated axons.

The actions of AVP extend far beyond the control of water balance. Binding to V2 receptors can lead to the release of von Willebrand factor, tissue plasminogen activator and atrial natriuretic peptide. AVP also stimulates synthesis of nitric oxide and increases circulating concentrations of coagulation factor VIII. Activation of V1a receptors causes vascular smooth muscle contraction, glycogenolysis and platelet activation. Binding to V1b receptors within the anterior pituitary acts synergistically with corticotropin releasing hormone to stimulate ACTH release. Stimulation of V1b receptors in other endocrine tissues can increase catecholamine and insulin secretion. AVP has also been identified as an important neurotransmitter and chemical mediator within the brain, with central roles in various areas including memory retrieval, learning, circadian timekeeping and social behavior.

Pathophysiology of Diabetes Insipidus (DI)

Overview

DI is associated with decreased production or action of AVP. Although rare in dogs and cats, the condition is well described and is an important differential for polyuria and polydipsia (PU/PD), particularly when severe.

Central Diabetes Insipidus (CDI)

CDI is characterized by complete or partial deficiencies in AVP. In people, traumatic pituitary stalk transection or pituitary surgery may lead to a pattern known as triphasic DI.[2,27,28] The first stage is acute CDI due to axon shock and an inability to release AVP. The second, antidiuretic phase, is due to unregulated AVP release from large posterior pituitary reservoirs. Phase 3 begins after these AVP stores are depleted and CDI

recurs. This third phase may be permanent, but partial recovery and subclinical deficiencies can occur due to the capacity for AVP release from the remaining neuron components.

CDI can also be caused by mutations within the AVP gene of people, usually affecting the signal peptide or neurophysin.[2] It is likely that mutant precursors are retained in the endoplasmic reticulum, explaining decreases in AVP and the cellular toxicity observed in some cases. Such genetic causes have not been investigated in dogs or cats, but congenital CDI has been described in Afghan Hound littermates.[15] Individual young dogs and cats have been described with either partial or complete CDI.[11,20,25]

In dogs and cats, CDI has been described most commonly due to structural defects within the hypothalamus, posterior pituitary or both. Pituitary neoplasia is most often implicated in dogs and trauma in cats; however, several other causes are described (Box 296-1).[11-26] The triphasic pattern described in some people has not been observed in dogs or cats, but hypophysectomy in dogs with pituitary-dependent hyperadrenocorticism leads to prolonged CDI (greater than 2 weeks post-surgery) in 53% of dogs. Approximately 42% of those dogs require permanent therapy.[29] Changes during the initial post-operative period are not well characterized due to the frequent supplementation of dogs with synthetic AVP following surgery, but CDI was more likely in dogs with pituitary enlargement. CDI may be less common following hypophysectomy in cats.[30] Idiopathic CDI has been reported in both dogs and cats. Advanced imaging was not performed in many of those pets and the possibility of underlying disease not excluded.

Nephrogenic Diabetes Insipidus (NDI)

NDI is characterized by decreased action of AVP within the kidneys. Secondary NDI is a feature of several conditions (see ch. 45) including hyperadrenocorticism (see ch. 306), pyometra (see ch. 316), hypercalcemia (see ch. 69 and 297), hyponatremia (see ch. 67 and 309), pyelonephritis (see ch. 327), and liver disease (see ch. 284). Primary (familial) NDI is a rare genetic disorder, associated with qualitative or quantitative alterations in aquaporin-2 expression. In people with familial NDI, specific mutations have been identified which affect the V2 receptor and aquaporin-2 genes, with >90% of patients having an X-chromosomal mutation (sex-linked) of the V2 receptor gene.[31] About 10% of these people are believed to develop *de novo* mutations. Autosomal aquaporin-2 mutations are less common.

Primary NDI was suspected in a litter of Siberian Huskies in which 3 of 4 males had normal V2 receptor numbers within the inner medulla but a ten-fold lower binding affinity for AVP.[32] Since clinical signs were confined to males, involvement of the V2-receptor gene, also located on the X-chromosome in dogs, was implicated. Isolated cases of primary NDI have been reported.[33-35] Primary NDI has not been reported in cats.

Clinical Features

Signalment

DI can occur at any age and in any breed. Signalment depends largely upon the underlying cause. Neoplastic causes are more likely in older animals and congenital disease in the young. Clinical signs may develop acutely or gradually progress over weeks to months.

Clinical Signs

DI is classically associated with severe polyuria and polydipsia (PU/PD), with water intake commonly estimated by owners as 5-20 times normal. Animals may display continuous thirst and select water over food, which can lead to weight loss. Ingestion of large volumes can lead to vomiting. The severe PU often causes nocturia and urinary overflow incontinence. Neurological abnormalities are common in dogs with hypothalamic or pituitary neoplasia (see ch. 259). In one series, 7 of 17 dogs with CDI developed neurological signs 2 weeks to 12 months after initial diagnosis.[11] Signs included seizure, obtundation, behavioral changes and tremor. Neurological abnormalities can also develop if water is withheld or if the animal fails to drink. The resultant hypertonic dehydration can lead to cellular dehydration and the development of anorexia, weakness, ataxia, seizures and death. Hypertonic dehydration may also cause development of osmotic demyelination. Likewise, neurological signs may develop in animals given free access to water following a period of water restriction. This can cause rapid decrease in plasma OSM and cerebral edema.

Clinical signs associated with endocrine abnormalities may also be observed. For example, dogs with a functional pituitary chromophobe tumor and secondary cortisol excess may only have signs of hyperadrenocorticism. Likewise, hypothalamic and pituitary structural defects or hypophysectomy can lead to clinical signs associated with central hypothyroidism, or less commonly, secondary hypoadrenocorticism.[36] Deficiencies of growth hormone and gonadotropin may occur, but do not cause signs. Persistent endocrine deficiencies are common in people following head trauma.[37] Such deficiencies may be subclinical and underrecognized in dogs and cats.[12,24,38]

Routine Testing

Routine clinicopathologic testing may reveal no abnormalities in animals with CDI, provided water has not been restricted and other disorders are not present. Decreased urea concentration may be due to renal medullary washout and decreased AVP-dependent reabsorption. If water has been restricted, changes indicative of dehydration may develop, including increases in hematocrit, protein, Na^+, or chloride, as well as pre-renal azotemia. Serum OSM may be normal or increased in affected dogs. Hyposthenuria is the only consistent clinicopathological finding in animals with complete CDI or NDI. In partial CDI, isosthenuria or minimally concentrated urine may be observed. In one series, bacterial cystitis was detected in 4 of 17 dogs.[11] Bacterial culture should be performed in all cases to exclude pyelonephritis as a cause of secondary NDI.

Confirmatory Testing

Central and Nephrogenic DI versus Primary Polydipsia (PP)

There is no single test with excellent sensitivity and specificity for diagnosing DI. Due to the effects of multiple conditions on AVP release and action, it is essential to exclude other causes of PU/PD before pursuing a diagnosis of DI. Several methods are available to distinguish between CDI, primary NDI and PP. Primary NDI can usually be excluded based on signalment. However, distinguishing CDI from PP can be challenging and test interpretation complicated by not fully understanding the pathophysiological processes in these conditions. For example, AVP secretion is not normal in most people with PP, with altered rates and set-points for AVP release.[39,40] It is unclear if these changes represent downregulation of AVP release in response to chronic overhydration or if primary abnormalities in the control of AVP exist, while osmoreceptor disorders may concurrently affect both thirst regulation and AVP secretion. Similarly, the AVP response and urine concentrating ability in dogs with PP have been characterized as exaggerated, subnormal or nonlinear.[41,42] This is further complicated by the pulsatile and variable nature of AVP secretion in dogs and the potential effects of chronic over- or underhydration on AVP secretion and action.[43]

The Modified Water Deprivation Test (MWDT)

Indications and Phase 1

The MWDT is the most commonly recommended aid for discriminating CDI, NDI and PP (Figure 296-2). The test is time-consuming and can be associated with risk, even if appropriately performed. Phase 1 of the test is a 3- to 5-day period of progressive water restriction. In theory, this allows re-establishment of some renal medullary concentration gradient, likely to be decreased in animals with chronic PU/PD. Dry food should be fed and a calculated total volume of water divided and given in as many small portions as possible, to avoid prolonged periods of complete water deprivation. Although often performed at home, it is possible that hypertonic dehydration and associated signs could develop during this water restriction phase. Therefore, owners must be educated regarding potential adverse effects of restricting water and they should monitor their pet's body weight and demeanor. Hypertonic dehydration is more likely to occur in animals with severe PU. Therefore, it may be prudent to hospitalize such pets for observation.

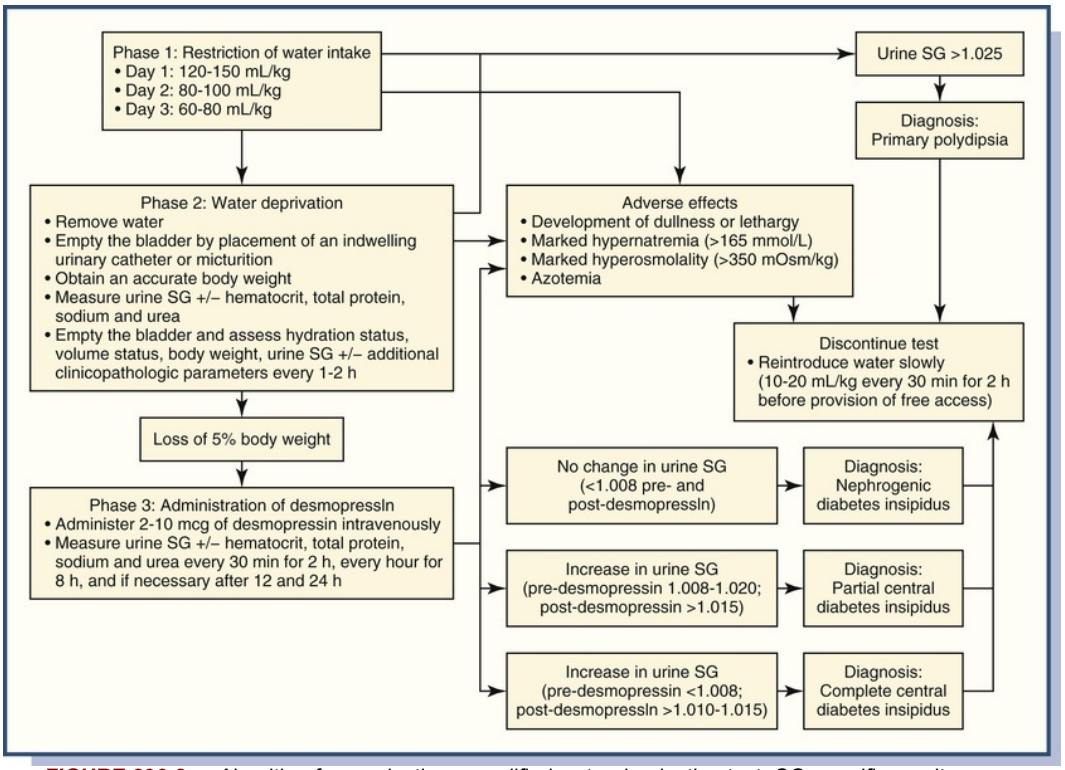

FIGURE 296-2 Algorithm for conducting a modified water deprivation test. *SG*, specific gravity.

Phase 2

Water is completely withdrawn to begin Phase 2. Adequate monitoring is essential because life-threatening hypertonic dehydration can develop quickly. The test is begun early in the morning to enable close observation of the patient throughout the day. An accurate scale is essential as the pet should be weighed at least every 60 minutes with the beginning of Phase 2. Also essential is the ability to monitor serum electrolyte concentrations, blood urea nitrogen, hematocrit and total solids at least every 60 minutes. The MWDT should be discontinued if the pet becomes dull, lethargic, azotemic, or if the serum Na^+ concentration increases excessively. Urine specific gravity and OSM, emptying the bladder each time, should be monitored every 30-60 minutes. Water deprivation is continued until 3-5% of body weight has been lost or until urine specific gravity exceeds 1.025. In most animals with complete CDI or primary NDI, this endpoint is achieved within 3-10 hours. However, in animals with partial CDI or PP, it may take considerably longer. If urine specific gravity increases to >1.025, a diagnosis of PP can be made and the test discontinued.

Phase 3

This phase begins once the pet has lost 3-5% of body weight and has been given desmopressin (1-deamino, 9-D-arginine vasopressin [DDAVP]), a synthetic analogue of AVP (2-10 mcg, IV). Maintenance volumes of fluid can be given IV during this stage to decrease likelihood of progressive dehydration. Urine specific gravity is

monitored every 30 minutes for 2 hours, then every hour for 8 hours, and if necessary after 12 and 24 hours. Maximal urine concentration is typically observed after 4-8 hours; however, the test can be discontinued sooner if the urine specific gravity increases to greater than 1.015. Following completion of the test, water should be reintroduced slowly, about 10-20 mL/kg every 30 minutes for at least 2 hours before providing free access to water. If the pet begins drinking ravenously, free access should be discontinued immediately to avoid vomiting and risk of severe dehydration.

Test Interpretation

Interpretation of results can be challenging. PP is characterized by an increase in urine specific gravity in response to water restriction alone. However, failure to restore the renal medullary concentration gradient may result in an incomplete response. Increased urine specific gravity after administering DDAVP is consistent with CDI, while a lack of response suggests NDI. Partial CDI may be associated with limited concentration in response to water restriction, and a further increase in urine specific gravity after DDAVP is administered (Figure 296-3). However, in some partial CDI cases, the presence of severe dehydration could induce maximal secretion of AVP and a failure to respond to DDAVP.

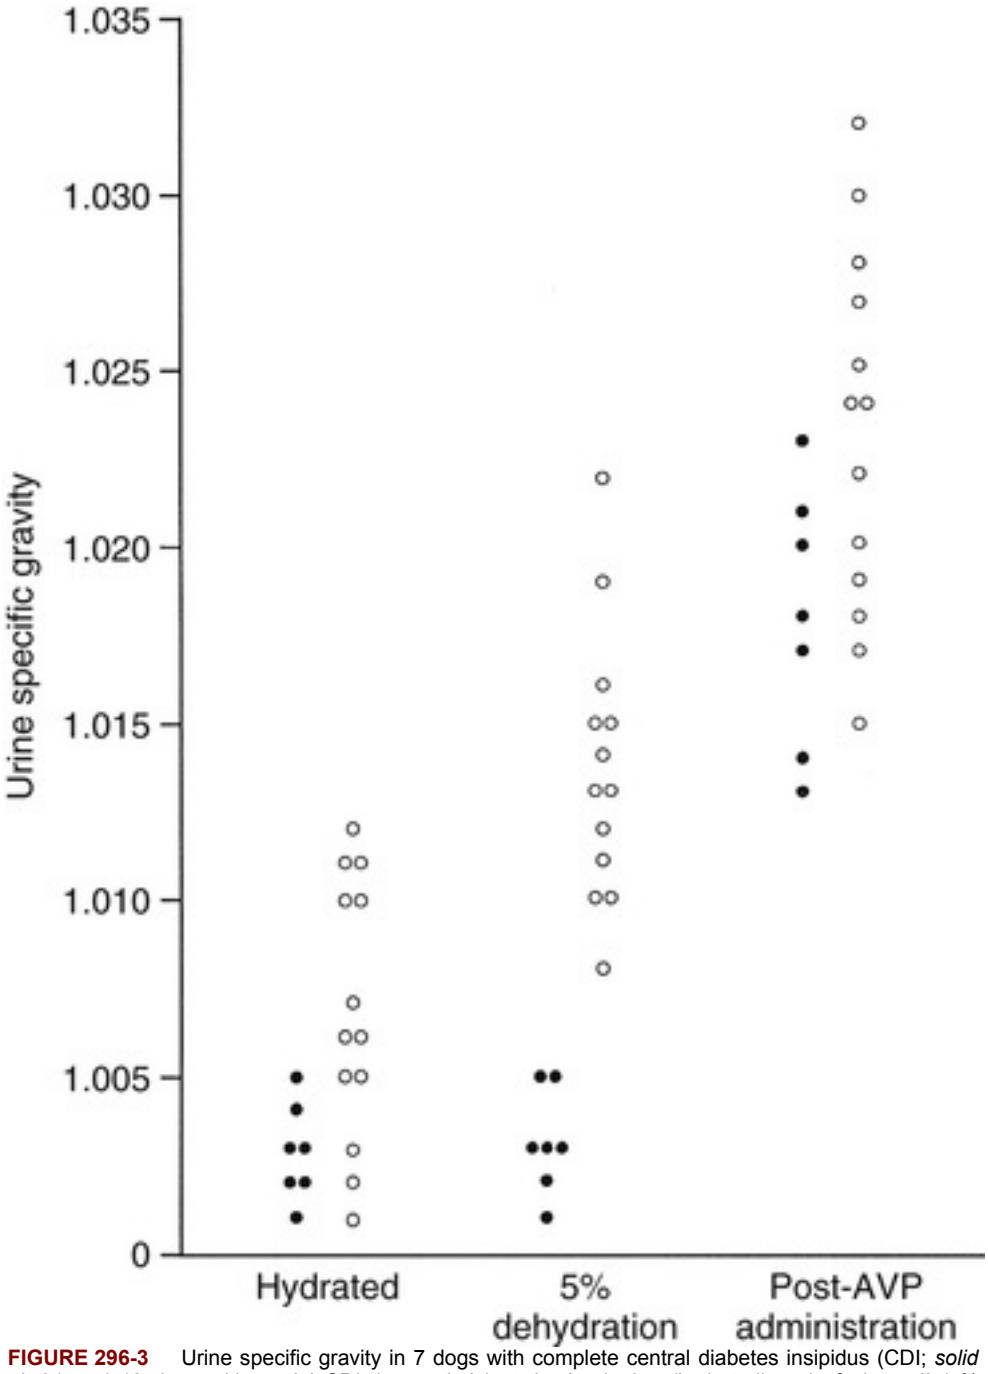

FIGURE 296-3 Urine specific gravity in 7 dogs with complete central diabetes insipidus (CDI; *solid circle*) and 13 dogs with partial CDI *(open circle)* at the beginning (hydrated) end of phase II (5% dehydration) and end of phase III (post-arginine vasopressin [AVP] administration) of the modified water deprivation test. Note the similarity of response between urine specific gravity and urine osmolality. (From Feldman EC, Nelson RW, Reusch CE, et al: *Canine & feline endocrinology,* ed 4, St Louis, 2015, Elsevier, Inc.)

Trial Desmopressin (DDAVP) Therapy

A simple alternative to the MWDT is DDAVP trial therapy. Average daily water intake is determined by the owner prior to commencement. Therapy is administered over 5-7 days and response assessed by noting changes in water intake. Urine specific gravity measurements can be made to confirm subjective opinions. In dogs with CDI, a dramatic decrease in water intake and increase in urine specific gravity is typically observed. Dogs with primary NDI and those with PP fail to respond. Exclusion of other causes of PU/PD is essential before commencing DDAVP. Partial responses may be observed in animals with secondary NDI or

PP. Advantages of trial therapy include a lower risk of life-threatening dehydration, decreased need for intensive monitoring and the ability to conduct the trial without hospitalization. Although adverse effects associated with DDAVP are rare, giving this drug to an animal with persistent increased water intake due to PP could, theoretically, result in water intoxication and hyponatremia.

Other Tests

Measurement of AVP alone provides little diagnostic value due to the pulsatile and variable nature of AVP secretion. Samples require meticulous handling and validated assays are not widely available. The hypertonic saline infusion test was once considered the gold standard method for differentiating between CDI, NDI and PP. The test is based upon the AVP response to a 20% sodium chloride infusion. A decreased AVP response is considered consistent with CDI. A normal or exaggerated AVP response without a corresponding increase in urine specific gravity is supportive of NDI, while a normal AVP response with appropriate rise in urine specific gravity suggests PP. However, the test does not reliably differentiate between CDI and PP.

Urinary aquaporin-2 expression has been shown to closely reflect changes in AVP exposure in healthy dogs, but has not been used clinically. Similarly, the concentration of plasma copeptin, the c-terminal of the AVP precursor, has been shown to correlate with AVP secretion in humans and to be of value in evaluating DI suspects, but this marker has not been evaluated in dogs or cats.[44] Magnetic resonance imaging (MRI) and computed tomography may be useful to document structural pituitary and hypothalamic lesions such as those associated with neoplasia or trauma.[45,46] In people, hyperintense MRI signals within the sella turcica are believed to represent phospholipid or secretory granules within the neurohypophysis and are absent in most CDI patients. In dogs, neurohypophysis intensity on T1 weighted MR images has been shown to be proportional to AVP content. However, changes have not been investigated in a clinical setting.

Treatment

Central Diabetes Insipidus

Treatment of CDI may not be necessary in all cases, provided access to water is continuously available and the PU/PD is not distressing to animal or owner. The synthetic AVP analogue desmopressin (DDAVP) can be used in cases of complete and partial CDI. Although it is a potent V2 receptor agonist, excessive volume expansion and hyponatremia have not been reported with currently recommended treatment protocols in dogs with CDI. DDAVP has minimal effects on V1a receptors and hypertension has not been reported as an adverse effect. The administration of DDAVP is successful in controlling clinical signs in most pets. The optimal dosage and dosing frequency is largely anecdotal, and regimens have been appropriately based on individual response. DDAVP, available as an intranasal solution for people, is commonly administered at empirical doses in dogs. Dosages have ranged from 1-4 drops (about 1.5-5 mcg/drop) into the conjunctival sac or nose, q 24 h to q 8 h. Alternatively, injectable preparations can be administered at a dosage of 2-5 mcg q 24 h or q 12 h. The tablet form can be given at dosages of 100 mcg q 24 h or q 12 h. Although experimental studies have demonstrated a dose-dependent increase in plasma concentrations of desmopressin following oral administration of the drug, the therapeutic response is variable. In cats, oral (25-50 mcg q 12 h or q 8 h), SC (4 mcg q 24 h) and conjunctival (1 drop q 12 h) routes of administration have been described. In both dogs and cats, dosage and dosing interval should be adjusted to achieve adequate control in each individual. Response to treatment is rapid and PU returns rapidly if treatment is discontinued. Some owners may elect to treat only at night to decrease the likelihood of nocturia.

Nephrogenic Diabetes Insipidus

Primary NDI is extremely rare in dogs and cats. Most treatment recommendations have been extrapolated from people, in whom a minority experience partial antidiuretic effects to high dosages of DDAVP.

Thiazide diuretics decrease Na^+ absorption from distal tubules, resulting in decreased blood volume and subsequent decreased glomerular filtration rate with increases in Na^+ and water reabsorption from proximal tubules. As a result, there is decreased water delivery to the distal tubule and decreased water loss. Additional effects may include a tubuloglomerular feedback response-mediated reduction in glomerular filtration rate and up-regulatory effects on aquaporin-2 and distal Na^+ transporter expression.[47-49] To further decrease the urinary solute load, a diet low in Na^+ and protein is recommended. Nonsteroidal anti-inflammatory drugs (NSAIDs) may have a synergistic effect; however, adverse effects are common.[50]

Potassium-sparing diuretics may also be used to help avoid iatrogenic hypokalemia. Chlorpropamide has been used, although usually for treating partial CDI. Its mode of action is not known, although evidence suggests it may exert its effect through upregulation of AVP receptors and unmasking constitutive receptor signalling.[51] Thiazide diuretics have been given to dogs with primary NDI. Effect has been variable, with urine volume reduced by as much as 50% in a minority.[33-35] The recommended dosage of hydrochlorothiazide is 2.5-5 mg/kg PO q 12 h in both dogs and cats.

Prognosis

The prognosis for dogs with CDI is variable depending upon the cause. Idiopathic and traumatic cases can be successfully managed for several years while those with progressive hypothalamic or pituitary neoplasia have a poorer prognosis. In one case series, seven of 17 dogs were alive 18-72 months after diagnosis.[11] The remaining ten dogs died or were euthanized 1 week to 2 years after diagnosis, most commonly because of the development of neurological signs.

CHAPTER 297

Primary Hyperparathyroidism

Barbara J. Skelly

Client Information Sheet: Primary Hyperparathyroidism

Calcium Homeostasis in Dogs and Cats

Calcium—Function

Calcium (Ca), the most abundant element in the body due to its presence in skeletal bone, is necessary for diverse processes, such as transmitting many signals received on cell surfaces to intracellular locations, nerve conduction, neuromuscular transmission, muscle contraction, blood coagulation, hormone secretion and hepatic glycogen metabolism. Adverse effects on organ systems are noted when Ca homeostasis is disrupted. The skeleton acts as a reservoir of Ca for correcting decreases in serum concentrations. Ca can be excreted or absorbed in the kidneys and the small intestine. The Ca sensing receptor (CaSR), responsible for ensuring that circulating Ca concentrations are maintained within a limited range, is a G-protein present in parathyroid glands, kidneys, cartilage and bone.[1] Interactions between the CaSR and parathyroid hormone (PTH), synthesized and secreted by the parathyroid glands, can lead directly or indirectly to effects on skeletal bone, gastrointestinal (GI) tract, and kidneys to maintain circulating Ca concentrations within a narrow reference range.[2]

Calcium Measurement and Its Serum Regulation

Calcium, in common with other important electrolytes, is regulated closely to maintain narrow reference intervals. Total serum Ca concentrations (TCa) are usually about 2.3-2.8 mmol/L (9.2-11.2 mg/dL) in dogs and 2.1-2.5 mmol/L (8.4-10.0 mg/dL) in cats. Reference intervals vary between laboratories. Whenever there are concerns about this electrolyte, it is recommended that both TCa and ionized Ca concentrations (iCa), the biologically active form of the electrolyte, be assessed. About 50% of the TCa concentration is iCa, about 40% is protein-bound (albumin plus a small amount of globulin) and <10% is complexed with anions, such as bicarbonate or citrate. Spectrophotometric methods are used to measure TCa in serum or heparinized plasma. The anticoagulants citrate, ethylenediamenetetraacetic acid (EDTA), and oxalate are not suitable as they chelate calcium. Hemolysis and lipemia can falsely increase measured TCa concentrations. Hypoproteinemia lowers measured TCa concentrations but does not affect measured iCa concentrations. Clinically, the most important serum Ca concentration is the iCa, measured with an ion-specific electrode. However, the proportion of iCa in a sample can be altered by sample handling. When samples are stored, red cell metabolism increases lactic acid concentrations, pH decreases, and the iCa fraction increases. Conversely, when samples are exposed to air, CO_2 is lost, the pH rises, and the iCa fraction decreases.

Control of Serum Calcium Concentration

Circulating Ca concentrations are under control of four main factors: parathyroid hormone (parathormone, PTH), parathyroid hormone–related protein (PTHrP), vitamin D (vitamin D_3, calcitriol, 1,25-$[OH]_2$-cholecalciferol), and calcitonin. The CaSR senses extracellular Ca concentrations. Hypercalcemia activates the CaSR, reducing PTH synthesis and secretion. Hypocalcemia inactivates CaSR, increases PTH secretion, enhances *PTH* gene expression, and promotes parathyroid gland cellular proliferation. Ca homeostasis is disrupted when CaSR activity is abnormal or when pathological processes interfere.

Parathyroid Hormone

Description and Function

PTH is a small polypeptide hormone (84 amino acids) synthesized and secreted by the parathyroid glands. Dogs and cats have four parathyroid glands (two pairs). One pair is either embedded within or closely associated with each thyroid lobe (Figure 297-1). Cranial, "external," glands are usually situated outside the thyroid capsule and caudal, "internal," glands are usually located within thyroid tissue. Parathyroid glands consist of cords or nests of cells around capillaries (Figure 297-2). Parathyroid chief cells synthesize PTH, which increases serum Ca concentrations (both TCa and iCa) and decreases serum phosphate concentrations either directly or indirectly via activity in 3 major target organs: bone, kidney, or GI tract (Figure 297-3). PTH is continuously synthesized by chief cells and metabolized quickly. Secretory granules within chief cells contain intact active hormone, including the 34-amino-acid, biologically active N-terminus and the carboxy-terminus portions required for PTH activity.[2-4] When the serum Ca concentrations are low, the secretory granule rate of degradation is reduced. Conversely, when serum Ca concentrations are increased, the degradation rate is enhanced. Vitamin D influences the dynamics of PTH synthesis and secretion: high concentrations of vitamin D slow PTH gene transcription and reduce the rate of synthesis of the hormone. High phosphate concentrations reduce intact PTH breakdown and increase hormone secretion.

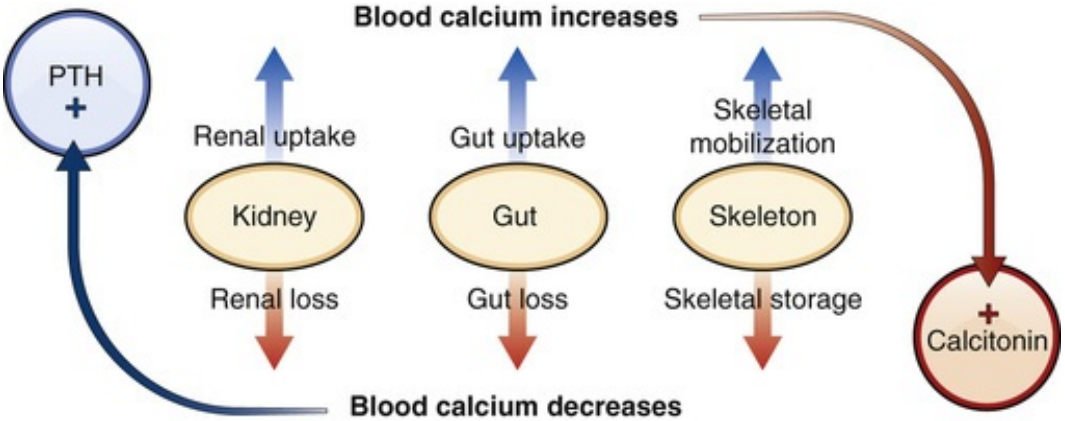

FIGURE 297-3 Calcium homeostasis. The release of PTH causes increased uptake of calcium in the kidney and gut and mobilization from the skeleton.

Parathyroid Hormone Assays

PTH and its fragments cleaved from the intact molecule circulate. Biologically active intact PTH (amino acids 1-84) must be measured for reliable assessment of parathyroid function.[5,6] Assays developed for PTH are sensitive and specific. Older PTH assays used antibodies directed at both the C-terminal (amino acids 39-84) and N-terminal (amino acids 12-24, or 26-32). However, such assay results included concentrations of some fragments cleaved between amino acids 1-12. Current (usually ELISA) assays use antibody combinations that only measure intact hormone.[7] A canine-specific ELISA, which has also been validated for cats, is available. Some laboratories have validated human-specific PTH testing kits for use in the dog and cat.[8,9] Since assay availability changes, new methods should be validated for the species being tested. EDTA plasma samples are

preferred for assaying PTH. Since PTH is labile, samples should be immediately separated and frozen until assayed. The laboratory should provide handling information, and many also provide freezer packs for sample submission. The reference interval for PTH is approximately 20-65 pg/mL in the dog and <25 pg/mL in the cat but may differ depending on the laboratory and assay system used.

Parathyroid Hormone–Related Protein

Description and Function

PTHrP is integral to calcium homeostasis in the fetus. Following birth, PTHrP becomes virtually undetectable in healthy animals. Increased concentrations of PTHrP have been proven to cause humoral hypercalcemia of malignancy (HHM).[10] PTHrP has the same physiological effects as PTH, increasing concentrations of TCa and iCa, while decreasing serum phosphate concentrations. Measuring PTHrP is an important and valuable aid in evaluating hypercalcemic dogs and cats, particularly when neoplasia is possible. Normal or low PTHrP concentrations do not definitively exclude the possibility of a neoplastic process, whereas increases are usually associated with a malignant cancer (see ch. 352).

Assaying PTHrP

PTHrP can be reliably measured using two-site immunoradiometric (IRMA) or N-terminal radioimmunoassays (RIAs). Several circulating forms of PTHrP, in addition to the intact 1-141 amino acid hormone, have biological activity. These include an N-terminal 1-36 amino acid fragment and a 1-86 amino acid N-terminal-and-midregion fragment. Roles of these different forms are not completely understood. Like PTH, PTHrP is not stable, is measured preferentially in EDTA plasma, and samples should be handled as described for PTH. The reference interval for PTHrP is generally <0.5 pmol/L in both dogs and cats.

Vitamin D (Vitamin D_3, Calcitriol, 1,25-$[OH]_2$-Cholecalciferol)

Synthesis of cholecalciferol, hydroxylated once by the liver to produce 25-OH-cholecalciferol (25-OH vitamin D, calcidiol) and not closely regulated, produces a reservoir pool of inactive vitamin D ready for activation to 1,25-$(OH)_2$-vitamin D, calcitriol. This step *is* regulated, takes place in the kidney, and its synthesis is stimulated by PTH via alpha-1-hydroxylase and suppressed by increased concentrations of phosphate. 25-OH-cholecalciferol can also be catabolized by 24-hydroxylation, then excreted. Vitamin D (25 and 1,25-$[OH]_2$ D) can be measured in cats and dogs by veterinary specialist laboratories.

Calcitonin

Calcitonin, a peptide synthesized by thyroid gland C cells, reduces serum Ca concentrations and has a role in limiting postprandial hypercalcemia. Though calcitonin can counteract the effects of PTH, its role is relatively minor. Following total thyroid and parathyroidectomy, the clinical consequence is hypocalcemia due to hypoparathyroidism, not hypercalcemia due to calcitonin deficiency. Similarly, when there is neoplasia of the C cells (medullary thyroid carcinoma) and excessive production of calcitonin, calcium homeostasis is not disrupted. In people, release of calcitonin by Ca-stimulated CaSR activity is unlikely to substantially contribute to Ca homeostasis. Calcitonin is not usually assessed in patients with Ca disorders, and no assays are commercially available.

How Do These Hormones Act Together to Maintain Calcium Homeostasis?

PTH is the primary regulator of Ca homeostasis. PTH increases serum Ca concentrations by enhancing resorption via increasing the number of osteoclasts on bone surfaces, by increasing renal tubular Ca absorption from distal convoluted tubules and thick ascending loops of Henle, and by increasing the hydroxylation of 25,OH vitamin D to 1,25-$(OH)_2$ vitamin D, which increases Ca absorption from the small intestine.[2,3]

The Differential Diagnosis of Hypercalcemia in Dogs

Hypercalcemia can be caused by access to exogenous agents that alter Ca concentrations or it can be the result

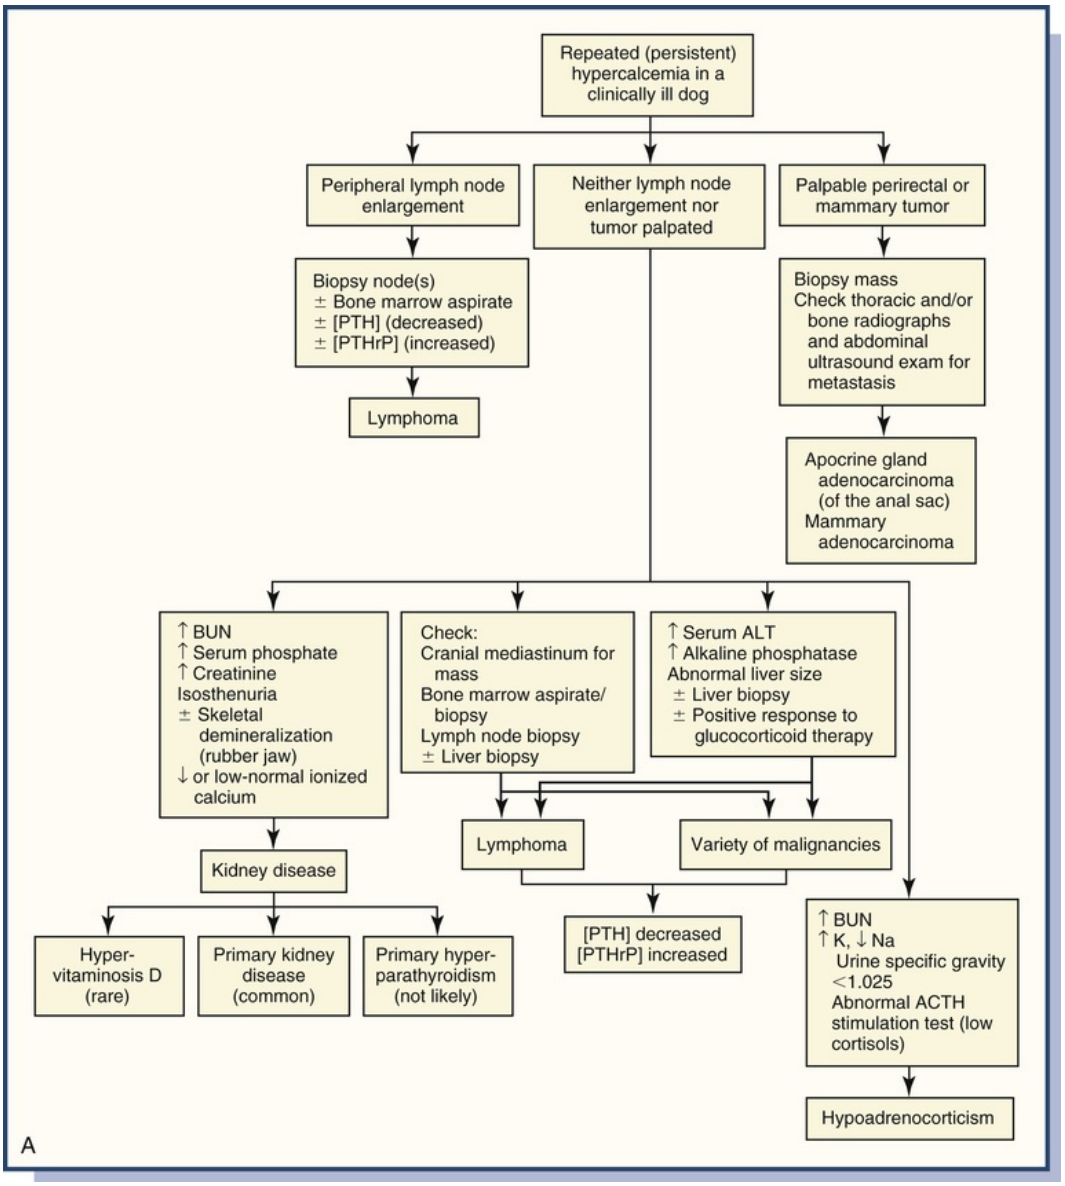
of abnormalities in one of the endogenous homeostatic mechanisms (Table 297-1; see ch. 69). The approaches used in the systematic workup of clinically stable or ill hypercalcemic dogs are reviewed in Figure 297-4, *A* and *B*.

TABLE 297-1

Classification, Cause and Characteristics of Various Hypercalcemic Conditions

CLASSIFICATION	CAUSE	CHARACTERISTICS
Parathyroid dependent	Primary hyperparathyroidism (parathyroid adenoma, hyperplasia, or adenocarcinoma)	PTH within reference range or increased tCa and iCa both elevated PO_4 low or low normal
	Chronic kidney disease	PTH elevated tCa mildly elevated iCa usually normal PO_4 elevated
Parathyroid independent	Malignancy (lymphoma, anal sac adenocarcinoma, other carcinomas, thymoma, multiple myeloma, metastatic or primary bone neoplasia)	PTH normal or low PTHrP may be elevated; not all tumors associated with hypercalcemia produce PTHrP Osteolytic bone lesions
Vitamin D dependent	Iatrogenic (cod liver oil supplementation, etc.) Plants (calcitriol glycosides found in "nightshade" fruits and vegetables, jasmine/jessamine plants and flowers, and other plants) Rodenticide intoxication (cholecalciferol) Antipsoriasis creams (calcipotriol and calcipotriene)	PTH suppressed tCa and iCa elevated PO_4 elevated Vitamin D may be measurably elevated depending on which form has been ingested
Granulomatous disease—dependent on local vitamin D production	Panniculitis Blastomycosis Other granulomatous disease	Can be difficult to characterize due to unknown etiology of hypercalcemia. Sometimes elevated vitamin D is implicated.54-56 Elevated PTHrP also reported.57
Mechanism unknown	Hypoadrenocorticism (Addison's disease) Feline idiopathic hypercalcemia (FIH)	Associated with no measurable changes in key molecules

iCa, Ionized calcium; *PTH*, parathyroid hormone; *PTHrP*, parathyroid hormone-related peptide; *tCa*, total calcium.



Repeated (persistent) hypercalcemia in a clinically ill dog
Peripheral lymph node enlargement
Neither lymph node enlargement nor tumor palpated
Palpable perirectal or mammary tumor
Biopsy node(s)
± Bone marrow aspirate
± [PTH] (decreased)
± [PTHrP] (increased)
Lymphoma
Biopsy mass
Check thoracic and/or bone radiographs and abdominal ultrasound exam for metastasis
Apocrine gland adenocarcinoma (of the anal sac)
Mammary adenocarcinoma
↑ BUN
↑ Serum phosphate
↑ Creatinine
Isosthenuria
± Skeletal demineralization (rubber jaw)
↓ or low-normal ionized calcium
Check:
Cranial mediastinum for mass
Bone marrow aspirate/ biopsy
Lymph node biopsy
± Liver biopsy
↑ Serum ALT
↑ Alkaline phosphatase
Abnormal liver size
± Liver biopsy
± Positive response to glucocorticoid therapy
Kidney disease
Lymphoma
Variety of malignancies
Hyper-vitaminosis D (rare)
Primary kidney disease (common)
Primary hyper-parathyroidism (not likely)
[PTH] decreased
[PTHrP] increased
↑ BUN
↑ K, ↓ Na
Urine specific gravity <1.025
Abnormal ACTH stimulation test (low cortisols)
Hypoadrenocorticism

Primary Hyperparathyroidism (PHPT) in Dogs

Definition

PHPT, an uncommon condition in dogs and rare in cats, should be considered among the possible causes of hypercalcemia, particularly in older relatively asymptomatic dogs.[12-14] PHPT is defined by hypercalcemia and inappropriately high concentrations of PTH (either within or above the reference interval), with no other identifiable underlying cause (Figure 297-5).

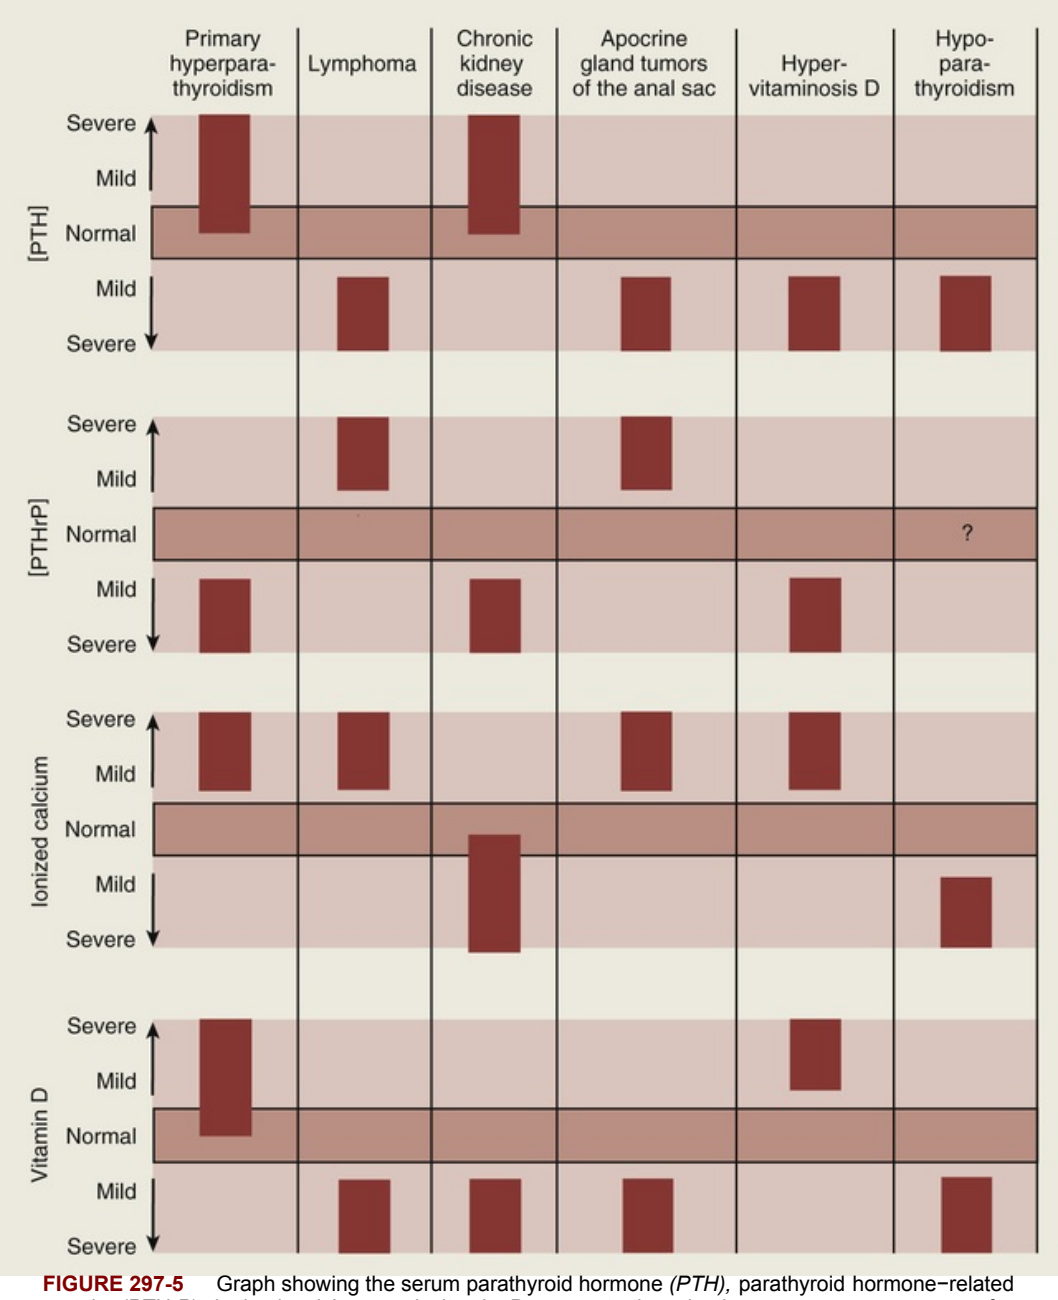

FIGURE 297-5 Graph showing the serum parathyroid hormone *(PTH),* parathyroid hormone−related protein *(PTHrP),* ionized calcium, and vitamin D concentrations in the most common causes for hypercalcemia of dogs. (From Feldman EC, Nelson RW, Reusch CE, et al: *Canine and feline endocrinology,* ed 4, St Louis, 2015, Saunders.)

Cause

PHPT develops after one or more parathyroid glands begins to function autonomously. Secondary hyperparathyroidism develops after nonendocrine disruption of Ca homeostasis associated with chronic kidney disease (CKD) or chronic deficiency in dietary Ca. PHPT is usually caused by a solitary adenoma, carcinoma or adenomatous hyperplasia of one parathyroid gland. More than one gland involved is noted in <10% of dogs with PHPT. In a case series of dogs that went to surgery, 87% had a solitary adenoma, 8% had hyperplasia and 5% had carcinoma.[15] Functional metastatic parathyroid tissue has been reported in only 1 of hundreds of dogs with PHPT in the veterinary literature.[16]

As a consequence of the pathological change in one or more parathyroid glands, persistent excess secretion of PTH, independent of serum Ca concentration, takes place. When hyperparathyroidism is primary, usually one affected gland is the source of autonomous PTH secretion. In the secondary condition,

hyperparathyroidism is usually due to hyperplasia of more than one parathyroid gland in response to more generalized stimuli to produce PTH. In reality, discriminating primary from secondary hyperparathyroidism can be difficult. Histologic evaluation of extirpated parathyroid glands seldom shows clear-cut and definitive evidence of being benign or malignant. Hyperplasia may not affect each gland uniformly and, though most frequently associated with secondary disease, has been described as a cause of PHPT in cats and dogs.[14,17,18]

Comparisons with Human PHPT

In humans, PHPT can occur sporadically or be associated with a syndrome including other endocrine or neoplastic diseases. Sporadic PHPT has been found to be initiated by somatic *MEN1* mutations (the gene mutated in cases of multiple endocrine neoplasia) in approximately 35% of cases. Other mutations occur at low frequencies[19,20] Nonsporadic forms of the disease include familial isolated hyperparathyroidism, the only nonsyndromic manifestation (FIH, OMIM:145000), familial hypocalciuric hypercalcemia (FHH, OMIM:145980), multiple endocrine neoplasia type 1 (MEN1, OMIM:131100) and type 2A (MEN2A, OMIM:171400) and hyperparathyroidism-jaw tumor syndrome (HPT-JT, OMIM:145001). Separate genes have been associated with FHH (calcium-sensing receptor *[CaSR],* adaptor protein-2 *[AP2S1],* G-protein subunit alpha11 [GNA11]), MEN1 (*MEN1,* encoding a tumor suppressor), MEN2 *(RET)* and HPT-JT (*HRPT2,* encoding parafibromin, another tumor suppressor).[21-24] Mutations in these genes do not account for all clinical cases, suggesting that other loci may be involved. FIH has been associated with mutations in three genes, *MEN1, CaSR* and *HRPT2*.[25,26] A diagnosis of FIH is reached if the diagnostic criteria for any of the other phenotypes are not met when using standard, nonmolecular genetic tests. In human FIH patients, the *MEN1* and *CaSR* genes are assessed initially, since *HRPT2* is a less common cause of disease.[26,27] The Keeshond is the only dog breed identified to have a familial predisposition to PHPT. Keeshonden have been studied using a candidate gene approach.[28,29] *MEN1, CaSR* and *HRPT2* mutations were ruled out as causative mutations leading to PHPT in the Keeshond. Despite using genome-wide association analysis in the Keeshond, the causative mutation has yet to be defined.

Signalment

PHPT is a disease of older dogs (mean age 11.2 years; range 6-17 years) with no apparent gender predisposition.[15] In one review, Keeshonden were found to have the highest breed-associated odds ratio, at 50.7.[28,30,31] Cats are infrequently affected, and no information about breed predisposition is available. Neonatal PHPT has been reported in a litter of German Shepherd puppies, but this seems to have been an isolated event.[17]

History and Clinical Signs

Overview

PHPT is not a dramatic disease. Rather, PHPT is slowly progressive, insidious, and subtle (Box 297-1). Since affected dogs tend to be older, many clinical signs are attributed to simple aging by owners who may not seek veterinary advice until later in the course of the disease. Hypercalcemia is usually a serendipitous finding when blood samples are taken for other reasons. Of 210 dogs with PHPT, 42% were identified as having hypercalcemia when presented for other reasons, such as a routine geriatric check, or when preanesthetic blood testing was performed for procedures such as dental treatment.[30] An association between owners concerned about their dog having jaw pain or difficulty eating hard foodstuffs and PHPT may exist, particularly in the Keeshond. The most common reason for seeking veterinary advice were clinical signs related to urolithiasis (pollakiuria, stranguria and hematuria) or urinary tract infection (50% of the 210 cases).[30] Urolithiasis can cause acute urinary outflow obstruction in dogs with PHPT (see ch. 107 and 331).

Other

Dental pain
Difficulty eating
Stiff gait*
Lameness*

*Uncommon to rare.

Polyuria and Polydipsia (PU/PD) and Other Signs *(see Box 297-1)*

PU/PD were noticed by <10% of owners of dogs with PHPT; this is a surprisingly small number, given that Ca antagonizes effects of vasopressin (antidiuretic hormone, ADH) in the collecting ducts of the kidney and hypercalcemia inhibits tubular uptake of sodium and chloride, further inhibiting urine concentrating mechanisms. Affected dogs are PU with secondary compensatory PD. This clinical sign may be overlooked by dog owners because it progresses gradually and, perhaps, nocturia and incontinence in these older animals is simply tolerated. Dogs with PHPT often have reduced activity levels, appear listless and may seem depressed. Again, these signs may be attributed to aging and sometimes are not mentioned until after successful treatment, when dogs are often described as having been "rejuvenated."

In people, the signs of PHPT are remembered using the mnemonic "stones, bones, abdominal groans, thrones and psychiatric moans." Some people with PHPT are depressed and/or debilitated by bone pain. The "thrones" in the mnemonic refers to the constipation commonly noted in people with PHPT. However, recent literature suggests this classic view is changing, as more patients are diagnosed despite having few or no symptoms and the disease usually progresses in a benign manner, even without treatment.[32,33] Whether this is also true in dogs and cats is unclear, as there are no large-scale animal studies. In contrast to the canine experience, people with PHPT are at risk of an uncommon and potentially life-threatening hypercalcemic crisis. This syndrome is associated with rapid multiorgan functional deterioration and is associated with a 100% mortality rate, if untreated.[34] There are no veterinary reports of this syndrome, but there is a spectrum of disease severity and progression among dogs diagnosed as having PHPT. Each dog must be assessed individually and requirement for intervention evaluated. GI signs include inappetence, vomiting and constipation. These signs can be secondary to Ca-induced gut smooth muscle hypoexcitability and dysmotility.

Kidneys and Urinary Tract Stone Formation

In addition to causing PU and compensatory PD, hypercalcemia due to PHPT may increase risk of developing kidney failure. Kidney failure affects some dogs with PHPT, but not others. Phosphate concentrations should be at the low end or below reference intervals in dogs with PHPT. If this were not the case, renal insufficiency might already be developing, albeit before overt azotemia is recognized. In these cases, closer monitoring and a more guarded prognosis should be given. It has been suggested that

calculating the Ca × phosphate product may help predict the likelihood of renal failure; dogs with PHPT with low phosphate concentrations and a relatively low Ca × phosphate product are thought to be at lower risk. In the large case series of 210 dogs, the risk of renal failure was deemed to be low, while in a smaller case series (29 dogs), approximately 25% developed chronic kidney disease (CKD). In that study, the Ca × phosphate product was a poor predictor of renal impairment.[35] The genetically homogeneous Keeshond population allows investigation of CKD in those carrying the mutation linked to PHPT. If untreated, some PHPT dogs continue to have normal renal function despite having prolonged, and in some cases severe, hypercalcemia (>4.0 mmol/L). Other PHPT dogs succumb to renal failure with much more modest Ca elevations. Some dogs develop nephroliths and urolithiasis. One dog with PHPT died with a large nephrolith and renal failure after disease management had seemingly been successful (Figure 297-6). It is therefore clear that predicting long-term outcome with or without treatment is fraught with problems. Erring on the side of caution when managing hypercalcemia is recommended and delays to treatment should be avoided to protect renal function.

FIGURE 297-6 Ventrodorsal **(A)** and lateral **(B)** abdominal radiographs showing a large nephrolith in the left kidney and multiple smaller urocystoliths.

Urolith formation is common in dogs with PHPT due to the increased concentrations of Ca filtered by the kidney and lost in urine (see ch. 331). Although PTH increases Ca uptake from renal tubules, in PHPT there is also overt hypercalciuria, presumably as reuptake is unable to match the amount of Ca filtered. Dogs with PHPT also have increased phosphate excretion, and their urine is, therefore, supersaturated with both Ca and phosphate. This enhances precipitation and stone formation. Dietary oxalate uptake from the gut is reduced when there is abundant intraluminal Ca, because Ca oxalate is not absorbable from the intestine. If intestinal Ca absorption increases, oxalate absorption also increases. In this scenario, the kidney filters more Ca and oxalate, again leading to urine supersaturation. In hypercalcemic people, evaluation of the quantity of Ca lost into urine is commonly assessed by measuring the calcium-to-creatinine ratio in urine. Such studies have not been widely used in animals (see ch. 73).

Physical Examination (PE)

Relevant findings on PE are few and nonspecific (see Box 297-1). They may include stiffness and gait abnormalities, dull mentation, weakness, and muscle wastage. Little information is gathered from palpation of the ventral neck area as parathyroid masses are usually too small to be palpated.

Total Calcium (TCa), Ionized Calcium (iCa), Phosphate, PTH, PTHrP

TCa and iCa

When hypercalcemia is identified, one should also assess iCa, phosphate, PTH and PTHrP. The hallmark of PHPT is an increase in both TCa and iCa while PTH concentrations are within or above reference intervals. In the series of 210 dogs with PHPT, mean TCa concentration was 3.6 mmol/L (14.5 mg/dL).[30] There was a range in severity of hypercalcemia: mild increases in 52% of dogs (>3.0-≤ 3.5 mmol/L, >12-≤14.0 mg/dL), moderate

increases in 30% (>3.5 to < 4.0 mmol/L, >14.0 to <16.0 mg/dL), serious increases in 12% (>4.0-≤4.5 mmol/L, >16.0 to <18.0 mg/dL), and severe hypercalcemia (>4.5 mmol/L, >18 mg/dL) in 6%. iCa concentrations paralleled TCa concentrations in the 210 dogs. The mean plasma iCa concentration was 1.71 mmol/L (range 1.22-2.41 mmol/L, reference range 1.12-1.41 mmol/L).

Severity of hypercalcemia is likely dependent on disease duration. Keeshonden from families with PHPT generally start to show mild hypercalcemia (up to 3.5 mmol/L, 14 mg/dL) when they are 6-8 years of age, and this gradually worsens over subsequent years. Some untreated dogs continue to experience increased Ca concentrations until serious hypercalcemia is reached (>4.0 to <4.5 mmol/l, >16 to < 18.5 mg/dL). After this point some stabilization occurs and concentrations do not continue to rise inexorably, similar to the condition in people. Keeshonden who are untreated have had serious hypercalcemia until their deaths due to other diseases at ages ranging between 13 and 15 years. As the genetic basis for PHPT in other breeds is not known, it is not clear how reproducible this pattern is between breeds, but in all breeds the disease appears slow and insidious. Affected dogs are not considered to be ill by their owners.

Phosphate

PHPT, hypercalcemia and normal renal function causes hypophosphatemia, an unusual finding in dogs (Box 297-2). PTH inhibits renal phosphate resorption, and serum concentrations are low-normal or below reference ranges. In the series of 210 dogs with PHPT, the mean serum phosphate concentration was 2.8 mg/dL (0.9 mmol/L; range 1.3 to 6.1 mg/dL, 0.4 to 1.9 mmol/L; reference range 3.0-6.2 mg/dL, 0.9-2.0 mmol/L).

Box 297-2

Causes for Hypophosphatemia

Decreased Intestinal Absorption

Decreased dietary intake
Malabsorption/steatorrhea
Vomiting/diarrhea
Phosphate-binding antacids
Vitamin D deficiency

Increased Urinary Excretion

Primary hyperparathyroidism
Diabetes mellitus ± ketoacidosis
Hyperadrenocorticism (naturally occurring/iatrogenic)
Fanconi syndrome (renal tubular defects)
Diuretic or bicarbonate administration
Hypothermia recovery
Hyperaldosteronism
Aggressive parenteral fluid administration
Hypercalcemia of malignancy (early stages)

Transcellular Shifts

Insulin administration
Parenteral glucose administration
Hyperalimentation
Respiratory alkalosis

Parathyroid Hormone

Circulating PTH concentrations should be assessed in hypercalcemic dogs, after increases in TCa and iCa have been confirmed and more obvious causes ruled out (lymphoma). If a hypercalcemic dog has a PTH concentration within the upper half or above the reference range (i.e., in the upper half of the reference interval >35 pg/mL for dogs, reference range 20-65 pg/mL), it is abnormal and consistent with PHPT. In most cases of hypercalcemia not caused by PHPT, TCa and iCa concentrations are increased but PTH concentrations are low or undetectable.

Parathyroid Hormone–Related Peptide

PTH is usually measured in conjunction with PTHrP. If PHPT is not the cause of hypercalcemia, PTHrP results may aid in narrowing the differential list to include malignancies that may not have been identified. The reference interval for PTHrP is generally <0.5 pmol/L in both dogs and cats.

Other Biochemistries, Complete Blood Count (CBC), Urinalysis

Serum biochemistries, other than Ca and phosphate, are usually unremarkable in dogs with PHPT. Since hypercalcemic dogs may be at risk for renal damage, blood urea nitrogen, creatinine and phosphate should be assessed and may be increased due to pre-existing renal damage or prerenal factors. This may complicate diagnosis, since changes associated with PHPT with secondary renal failure can mimic those of primary renal disease with secondary PTH elevation and hypercalcemia (Table 297-2). CBC parameters show no consistent changes, although anemia of chronic disease may be identified if the hypercalcemia is chronic. Since hypercalcemia causes secondary nephrogenic diabetes insipidus, urine specific gravity is expected to be <1.020 and some are hyposthenuric. Hematuria, proteinuria, bacteriuria, pyuria and crystalluria are common.

TABLE 297-2

A Comparison of the Clinicopathological Features of PHPT and Renal Secondary Hyperparathyroidism

	PRIMARY HYPERPARATHYROIDISM	SECONDARY RENAL HYPERPARATHYROIDISM
Total calcium	↑	↓ or normal or ↑
Ionized calcium	↑	↓ or normal
Phosphate	↓	↑
PTH	↑ or high normal	↑ or high normal
PTHrP	Normal	Normal

Imaging

Ultrasonography (US) of the ventral neck is the most useful imaging modality when investigating a dog suspected of having PHPT, with 90-95% having a parathyroid nodule identified by experienced radiologists.[30] A high-frequency transducer of 7.5-10 MHz is required for adequate resolution. In healthy dogs and cats, the parathyroid glands are usually <3 mm in greatest diameter, seen only with excellent facilities and expertise. When they are either hyperplastic or enlarged and adenomatous, or when there is a parathyroid carcinoma, the parathyroid glands are identified as 2-20 mm diameter, round to oval, hypoechoic nodules within or near thyroid tissue (Figure 297-7).[36] Incidentally identified thyroid nodules were identified on cervical US in 14 of 91 (15%) dogs being evaluated for hypercalcemia.[37] The finding of a thyroid nodule may complicate diagnosis because it may not represent the origin of hypercalcemia but may indicate multiple concerns. Scintigraphy using technetium-99m sestamibi has been tried in dogs as an aid to parathyroid identification, but unlike in humans, it lacks sensitivity and specificity and is not recommended.[38] Plain abdominal radiographs or US is recommended to search for any abnormalities, including calcium-containing renal or cystic calculi. Rarely, extensive renal calcification is noted (see Figure 297-6).

FIGURE 297-7 Ultrasonographic image showing the typical appearance of a parathyroid adenoma.

Genetic Testing for PHPT in the Keeshond

A genetic test for familial PHPT in the Keeshond is available, which aims to identify Keeshonden that carry the mutated allele responsible for the autosomal dominant disease. The test is available through the Animal Health Diagnostic Center at Cornell University, and details are available at: https://ahdc.vet.cornell.edu/Sects/Molec/PHPTtesting.cfm. Since the molecular basis for this test has not been peer-reviewed, sensitivity and specificity are not known. It is recommended that Keeshond breeders be aware of the genotype of their breeding lines and that they test the progeny of untested dogs. Keeshonden at risk should be monitored periodically to identify hypercalcemia, usually noted by 6-8 years of age. However, PHPT can develop earlier or later, or indeed may never manifest in the dog's lifetime.

Pretreatment Management of Hypercalcemia

Fluid Therapy

Emergency therapy for hypercalcemia is rarely required in dogs with PHPT unless the Ca concentration is in the "serious" to "severe" range. Some believe that virtually no dog with PHPT requires therapy of any kind prior to specific treatment of the PHPT, regardless of the degree of hypercalcemia. Others suggest that serious to severe hypercalcemia be treated in an attempt to lower serum Ca concentrations while awaiting test results. Since PTH and PTHrP assays are usually performed by specialist laboratories, there may be a delay between making a presumptive diagnosis of PHPT and having that diagnosis confirmed. Renal damage caused by persistent hypercalcemia due to PHPT is quite uncommon but impossible to predict (see ch. 324). All affected animals must be considered at risk if significantly hypercalcemic.

Fluid therapy (see ch. 129) focuses on enhancing renal Ca excretion and minimizing bone resorption. It is the cornerstone of managing hypercalcemia. Diuresis using 0.9% sodium chloride at rates of 5-10 mL/kg/h should increase renal Ca excretion and lower serum concentrations. Fluid therapy should aim to correct any dehydration or volume deficit and expand the extracellular fluid volume to increase glomerular filtration rates. Sodium chloride is the fluid of choice because sodium ions compete with Caions and reduce tubular reuptake. When an animal is considered optimally hydrated, furosemide (2 mg/kg PO q 12 h/q 8 h) can further enhance renal Ca excretion. When using sodium chloride at high rates, particularly coupled with furosemide, one must avoid inducing hypokalemia. If fluid therapy fails to lower serum Ca concentrations, glucocorticoids, bisphosphonates, calcitonin, or plicamycin can be considered.

Glucocorticoids

Glucocorticoids do not have much effect on serum Ca concentrations in dogs with PHPT and rarely lower measured values. The use of glucocorticoids (in the dosage range of approximately 1 mg/kg prednisolone or equivalent) to decrease the serum Ca should be restricted to those dogs clearly diagnosed but in whom there will be a delay in treatment and are most effective when given to pets with hypercalcemia of malignancy. Glucocorticoids cause rapid tumor lysis and reduce synthesis and secretion of PTHrP. Glucocorticoids increase renal Ca loss, decrease intestinal calcium uptake and decrease bone resorption. When used in undiagnosed patients, there is risk of masking and complicating the diagnosis of neoplasia.

Bisphosphonates

Bisphosphonates decrease bone resorption by inhibiting osteoclastic activity and inducing osteoclast apoptosis. Several different bisphosphonates have been employed. Those used most include oral drugs (clodronate, etidronate, alendronate) and IV pamidronate. Although oral preparations are convenient for owners, this route is not very effective, with <1% of a dose being absorbed.[39] An IV infusion of pamidronate is more reliable (1.3-2 mg/kg in 150 mL of 0.9% saline, given over 2 hours). Pamidronate, approximately 100 times more potent than etidronate, has effects that can last up to 3 weeks. Dosing can be repeated as required. This drug is generally well tolerated[40] but can cause GI side effects and hypocalcemia, particularly if overdosed. Pamidronate has been used frequently to treat people with hypercalcemia of malignancy, but a more potent bisphosphonate, zoledronate, is now superseding pamidronate as the drug of choice. Zoledronate is more than 100-850 times more active than pamidronate, can be infused more rapidly, but has not been used much in dogs.[41]

Calcitonin

Salmon calcitonin is commercially available and, like bisphosphonates, inhibits osteoclastic activity. It also inhibits renal reabsorption of Ca. It is useful as an emergency treatment to decrease Ca concentrations but carries the disadvantage in that after the initial IV infusion (4 IU/kg), treatment must continue daily (4-8 IU/kg, SC, q 12-24 h).[42] Calcitonin can cause anorexia and vomiting, is expensive, and is rarely used. Animals may become resistant to the effects of calcitonin after a few days of treatment.

Plicamycin (Mithramycin)

There are few reports of this drug being used in dogs. A dosage of 25 mcg/kg, IV, in 5% dextrose over 2-4 hours every 2 to 4 weeks has been suggested.[43]

Cinacalcet

This drug is a calcimimetic that interacts with the Ca sensing receptor directly and can control Ca, phosphate and PTH concentrations in human dialysis patients. It has been suggested that this drug may be useful in dogs and cats with hypercalcemia, particularly cats with idiopathic hypercalcemia but there are no data to support its use.

Definitive Treatment Options

Surgical Parathyroidectomy

Surgery is the treatment of choice at many referral institutions, especially if the parathyroid nodule is large (>10 mm in greatest diameter).[44] Good visualization of each thyroid lobe is essential during surgical exploration of the neck, achieved using a ventral midline approach. Parathyroid adenomas, carcinomas or hyperplastic glands are usually easily discriminated from normal parathyroid glands, often looking darker and larger (Figure 297-8). When the internal parathyroid glands are affected, they can be identified by palpation and may be visible through the ventral or dorsal aspect of the thyroid gland. Identification of the solitary, autonomously functioning, abnormal parathyroid tissue can be aided greatly if its location has been previously identified with US.

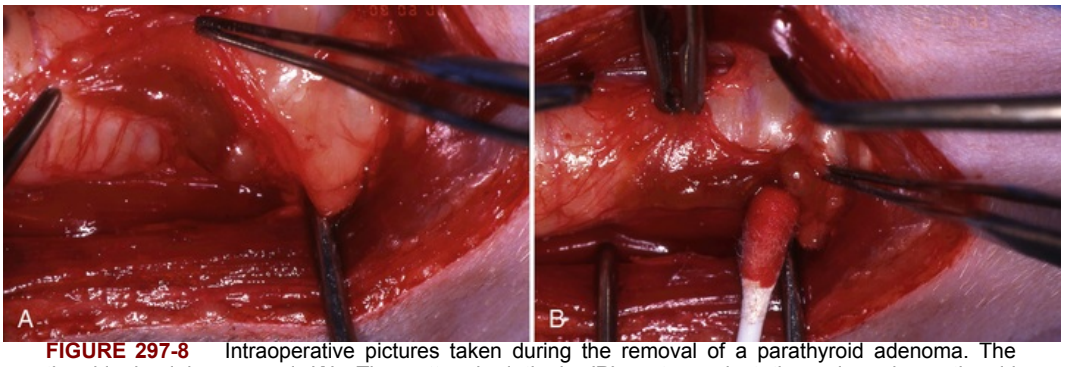

FIGURE 297-8 Intraoperative pictures taken during the removal of a parathyroid adenoma. The thyroid gland is exposed **(A).** The cotton bud tip in **(B)** rests against the enlarged parathyroid gland. (Photos courtesy Ed Friend.)

Parathyroid adenomas can be removed either by dissection of the enlarged gland from the adjacent thyroid tissue or by partial thyroidectomy, where the parathyroid nodule and part of the thyroid gland are removed *en bloc.* In dogs with PHPT, usually only one gland is affected. If more than one gland is enlarged, then up to three glands may be removed at one time. At least one parathyroid gland should be left *in situ* so that Ca homeostasis can be maintained. When multiple glands are enlarged, it is more likely that they are hyperplastic rather than adenomatous, and therefore secondary rather than primary hyperparathyroidism should be suspected.

Techniques to determine if functional abnormal parathyroid tissue has successfully been removed intraoperatively have been described.[45] In one study, samples were taken pre-, intra-, and postoperatively (20 minutes after adenoma removal) to evaluate how PTH concentrations varied and to try to confirm that functional tissue had been removed. All dogs in this study showed a significant decrease in PTH concentration from pre- to postoperative samples with an increase in PTH at times when parathyroid gland manipulation was taking place. This may help with surgical identification of parathyroid tissue but only retrospectively as analysis of samples in most veterinary centers is not done on site and inevitably involves a delay of several days.

Percutaneous, Ultrasound-Guided Ethanol Ablation

In order for parathyroid nodules to be effectively treated using ethanol injection, they must be identified by US examination and be >3 mm in greatest diameter so that a 27-gauge needle can be inserted into the nodule accurately. Animals must be under general anesthesia. Ethanol causes coagulation necrosis and thrombosis in the parathyroid nodule.[46] Success is operator-dependent, in that skill is needed for accurate needle placement and injection so that the closely associated carotid artery and vagosympathetic trunk are not compromised. When three techniques for treating PHPT were compared, ethanol ablation was the least successful, with a positive outcome achieved in 13/18 procedures (72%), compared with 45/48 (94%) for surgery and 44/49 (90%) for heat ablation.[44] However, only a small number of cases were treated by ethanol ablation and in a more recent report, a success rate of >90% in 30 dogs was reported.[47]

Percutaneous, Ultrasound-Guided Heat Ablation

This technique is the least frequently used of the three because few institutions have the necessary equipment. The technique involves inserting an insulated needle attached to a radiofrequency unit into the parathyroid nodule. The radiofrequency unit is turned on and wattage adjusted to achieve visible thermal necrosis at the needle tip.[48] The dog is anesthetized, positioned on an electrocautery ground pad, and a 20-gauge over-the-needle catheter is inserted into the affected parathyroid nodule. Usually, the initial radiofrequency is applied at 10 watts and slowly increased as needed until the entire gland becomes hyperechoic (Video 297-1).

Pre- and Post-Treatment Considerations

Vitamin D

When PHPT is treated successfully, serum PTH and, therefore, Ca concentrations should decrease rapidly and, in some circumstances, a hypocalcemic crisis may be encountered. This usually happens if the

pretreatment Ca has been seriously or severely elevated for some time prior to treatment. Predicting the dogs at greatest risk for a hypocalcemic crisis is difficult.[49-50] Generally, hypocalcemia is more likely to be encountered if the pretreatment TCa is >3.5 mmol/L (14 mg/dL) or the iCa >1.80 mmol/L for more than a few months, although this is variable. Also pivotal to the development of clinical signs may be the rate at which the iCa concentration decreases. Occasionally (rarely), clinical signs of hypocalcemia (muscle fasciculations, vocalization, panting and tetany; see ch. 298) can be seen in animals whose Ca is dropping sharply but is not yet within or below the reference range.

Presence of an autonomously functioning parathyroid adenoma causes the previously normal parathyroid glands to atrophy, making them unable to immediately support normal Ca homeostasis once abnormal tissue is removed. This effect may be more pronounced if more than one parathyroid gland is removed. Such a crisis can be averted by administering vitamin D ± oral Ca in the immediate post-treatment period or, when the Ca concentration is moderately to severely elevated, by starting calcium and vitamin D supplementation 12-24 hours before treatment. Vitamin D is available in several different preparations. It is important to use a preparation that will have a relatively rapid onset of action or the time of initiation of treatment has to be earlier. The two preparations most frequently recommended are calcitriol and alfacalcidol. Calcitriol (1,25-dihydroxycholecalciferol) is active vitamin D and does not require metabolism to become active. It has a rapid onset of action (1-4 days) and a short half-life. Toxic effects would be expected to resolve in 2-7 days. This drug comes in capsules of 0.25 or 0.5 mcg. The dosage used is 20-30 ng/kg PO q 12 h.[51] Alfacalcidol is a formulation also commonly used. The hepatic 25-hydroxylation required before this drug becomes active occurs rapidly in a relatively unregulated fashion. There is no significant difference in the time required to reach maximal effect, as compared with calcitriol. The drug is available as 0.25, 0.5 and 1 mcg capsules and as a liquid (2 mcg/mL) at a dosage of 0.01-0.03 mcg/kg q 24 h. However, these *dosages have flexibility and must be titrated* up or down as needed by the individual animal.

Calcium

Vitamin D may be given with or without oral Ca supplementation. Three Ca options include Ca gluconate, Ca lactate, or Ca carbonate. These doses are calculated on the basis of **elemental** calcium in each preparation (25-50 mg/kg/day divided q 12 h or q 8 h), **not** on the mg tablet content. Thus, the dosages are the same once the elemental Ca content has been taken into account (e.g., 1 mg elemental Ca = 11.2 mg Ca gluconate, 7.7 mg Ca lactate, or 2.5 mg Ca carbonate). Often, (particularly when postoperative hypocalcemia has been severe and symptomatic), Ca supplementation is used for short-term patient stabilization. In the longer term, it is rarely necessary to use Ca supplementation because most pet foods contain more than adequate amounts of Ca. Vitamin D dosage is quite important, as it allows dietary Ca to be absorbed.

Emergency, Short-Term Treatment of Hypocalcemia

IV Ca supplementation may be required for dogs that become seriously hypocalcemic after treatment, either symptomatically or asymptomatically. The clinical signs of hypocalcemia are listed in Box 297-3 and are described in ch. 298. Dogs hospitalized and not being exercised or unduly stressed may be stable with Ca concentrations below the reference interval, but they are best supplemented and carefully monitored in an attempt to avoid a hypocalcemic crisis. When a hypocalcemic crisis is encountered, IV 10% Ca gluconate is the treatment of choice. Symptomatic (tetanic) dogs can be given 0.5-1.5 mL/kg, IV, slowly over 20-30 minutes until clinical signs have subsided and the dog is considered stable. Ideally, an ECG is used to monitor cardiac activity during infusion. Less sensitive pulse monitoring can be used if necessary. The IV Ca infusion should be stopped if ST segment elevation, QT shortening or arrhythmias develop.

Box 297-3

Signs of Hypocalcemia

Signs Associated with Neuromuscular Excitability

Muscle fasciculations or tremors
Face rubbing, biting the paws
Hypersensitivity to external stimuli
Stiff, stilted gait

Tetanic seizures
Respiratory arrest

Behavioral Changes

Agitation
Anxiety
Vocalization
Aggression

Other

Panting
Hyperthermia

Thereafter, a CRI of 10-15 mg/kg/h (10-15 mL/kg over 24 h) should be employed until oral therapy can be safely started. IV Ca can be a caustic vascular irritant leading to thrombophlebitis if the concentration of infused Ca is maintained at a high level for a protracted period (more than 1-2 days). IV catheters should be repeatedly inspected for patency and efficacy in an attempt to avoid extravasation of Ca-containing fluids outside the vein. This also can result in extensive tissue damage (Figure 297-9).

FIGURE 297-9 Photo of the hindlimb of a Bichon Frise dog that had received intravenous calcium gluconate using a saphenous vein over several days and had suffered severe thrombophlebitis and tissue sloughing as a consequence of the irritant effects of calcium. (Photo courtesy Christina Strand Thomsen and James Warland.)

There are varying opinions regarding use of SC Ca supplementation. Sterile abscess formation and skin sloughing have been reported in some dogs after Ca salts were administered SC.[13] However, some authors recommend Ca gluconate be so-administered, as it is much less likely to cause a problem. Although it is true that Ca gluconate may be given SC with no adverse effects, it can cause dramatic skin sloughing. For this reason, only IV and oral routes of administration are recommended (Table 297-3). When the pretreatment TCa concentration is >3.5 mmol/L (14 mg/dL) or the iCa >1.8 mmol/L and particularly when the increase in TCa or iCa is severe (>4.0 mmol/L, 16 mg/dL; >2.0 mmol/L), it is advisable to begin vitamin D supplementation 24-36 hours before treatment in order to slow the decrease in Ca after treatment and avoid severe hypocalcemia. This treatment is always something of a balancing act, as it is not advisable to exacerbate the pre-existing hypercalcemia. However, given the known delay in onset of activity of the vitamin D preparations, pretreatment for one day is not expected to be detrimental.

TABLE 297-3

Calcium and Vitamin D Drugs Available for Treating Hypocalcemia

	DRUG	DOSAGE	PRECAUTIONS
Acute	10% Calcium gluconate	0.5-1.5 mL/kg over 20-30 minutes	Monitor heart by auscultation, pulse palpation or ECG for bradycardia, shortened QT interval and ST segment elevation
	10% Calcium borogluconate	0.5-1 mL/kg over 20-30 minutes	
	10% Calcium chloride	0.16-0.5 mL/kg over 20-30 minutes	
Subacute	10% Calcium gluconate	10-15 mL/kg over 24 hours in 0.9% NaCl	Do not give subcutaneously
	10% Calcium borogluconate	6-9 mL/kg over 24 hours in 0.9% NaCl	
	10% Calcium chloride	3-5 mL/kg over 24 hours in 0.9% NaCl	
Chronic	Calcium carbonate Calcium gluconate Calcium lactate	25-50 mg/kg of *elemental* calcium*	Can be stopped once vitamin D dosage is appropriate
	Calcitriol	20-30 ng/kg/day PO divided twice a day	Time to maximum effect < 4 days
	Alfacalcidol	0.01-0.03 mcg/kg daily	Time to maximum effect < 4 days
	Dihydrotachysterol	0.02-0.03 mg/kg daily reducing to 0.01-0.02 mg/kg every 24-48 hours as required	Time to maximum effect < 7 days

*1 mg calcium = 11.2 mg calcium gluconate = 7.7 mg calcium lactate = 2.5 mg calcium carbonate.

ECG, Electrocardiogram.

Prognosis

The short- to mid-term (<2 years) prognosis for PHPT is excellent in all breeds. In all breeds except the Keeshond, the long-term prognosis also appears to be good. In Keeshonden, as in many human forms of PHPT, recurrence is a distinct possibility. This is not surprising in people, given the mechanisms of pathogenesis of the disease and the role of tumor suppressor genes in the evolution of hyperparathyroidism. When PHPT is managed surgically in humans, a subtotal parathyroidectomy is carried out, where only a small amount of parathyroid tissue remains *in situ* for ongoing calcium homeostasis. Keeshonden have a genetic drive to develop parathyroid adenomas, and after one has been removed more may follow if the dog lives long enough. Keeshonden that have had PHPT should be monitored throughout life for disease recurrence, particularly if first surgery was performed at a relatively young age (<9 years). An alternative approach would be to remove all but one parathyroid gland at the time of the first surgery in Keeshonden with inherited PHPT. In this author's experience, this can result in severe postoperative hypocalcaemia, which in some cases requires lifelong supplementary therapy to control. One Keeshond, first successfully treated at the age of 10 years, became hypercalcemic again at 11 and a half and had a second surgery. Although two parathyroid glands remained, this dog was never able to maintain a normal serum calcium concentration and received vitamin D until he died of other causes several years later. This variability in response to surgery and requirement for supplementary calcium makes successful perioperative disease management complex with the Keeshond, especially presenting many longer-term difficulties.

Primary Hyperparathyroidism in Cats

PHPT has been reported in a few middle-aged to older cats. Clinical signs described have included vomiting, PU/PD, weight loss and palpable cervical mass.[52] Although the abnormal parathyroid gland may not be palpable, similar to dogs, parathyroid disease is often associated with cystic structures that make the mass effect more noticeable. Since hyperthyroidism is a much more common cause for palpating a cervical mass in cats, this condition must be ruled out first. PU/PD may be more subtle in cats and urine specific gravity may

not be significantly altered unless the cat is suffering from concurrent renal insufficiency.[14] Cats, like dogs, may also suffer from calcium-containing urolithiasis.[53] The treatment of choice for PHPT in cats is removal of abnormal parathyroid tissue.[12] As in dogs, treatment success is greatly enhanced when US is used before surgery to identify the parathyroid mass or masses. Long-term prognosis is good postsurgery. Other treatment techniques have not been reported in cats. Treatment with Ca and vitamin D analogues may be necessary in cats due to the development of hypocalcemia after parathyroid gland removal. There is less information available in cats about when to prescribe calcium and vitamin D to pre-empt a postoperative hypocalcemic crisis, but the same principles apply that have been outlined for dogs. Again, it is difficult to predict which patients will need supplementation and for how long.

CHAPTER 298

Hypoparathyroidism

Patty Lathan

Client Information Sheet: Hypoparathyroidism

Background

The parathyroid glands were first discovered in the Indian rhinoceros by Richard Owen in 1850. Ivar Sandstrom was the first to name and describe them in 1880 while Giuilo Vassale and Francesco Generali in 1900 reported that complete parathyroidectomy resulted in tetany.[1] Naturally occurring hypoparathyroidism was first described in dogs in 1966 and cats in 1990.[2,3] Idiopathic primary hypoparathyroidism remains an extremely uncommon disease in both dogs and cats.

Pathophysiology

Normal parathyroid physiology is presented in ch. 297. Loss of parathyroid hormone (PTH) or its activity results in hypocalcemia and hyperphosphatemia through a combination of mechanisms: decreased resorption of calcium (Ca; see ch. 69) from bone causing decreased release of Ca and phosphorus (PO_4) into the circulation, decreased absorption of Ca and PO_4 from the small intestine, and decreased reabsorption of Ca and decreased excretion of PO_4 via the renal tubules. Renal effects of PTH have the greatest impact on serum PO_4 concentration. Lack of PTH leads to hyperPO_4. In health, Ca stabilizes neuronal membranes by limiting sodium (Na) permeability and membrane depolarization. In hypoCa, however, both peripheral and central nervous system neurons become hyperexcitable, leading to the common signs of seizures, muscle tremors/fasciculations, and stiff gait (due to muscle pain and/or muscle tetany).

Etiology

Most severely hypoCa dogs and cats without a history of neck surgery or trauma are classified as having idiopathic primary hypoparathyroidism. However, an immune-mediated etiology is suspected in some since the parathyroid glands can be quite small on necropsy and their histology often reveals markedly decreased numbers of parenchymal cells, infiltration with lymphocytes and, to a lesser degree, plasma cells and neutrophils.[4-6] Resolution of hypoparathyroidism in one dog given immunosuppressive therapy supports an immune-mediated process as cause in some.[7]

Clinical Features in Dogs

Signalment

Dogs with primary hypoparathyroidism, at the time of diagnosis, have ranged in age from 6 weeks to 13 years (mean: about 6 years). Females, Miniature Schnauzers, Poodles, German Shepherd Dogs and Terriers are predisposed.[4,5,8,9] St. Bernards are overrepresented in Australia and New Zealand.[8,10]

Clinical Signs

Most clinical signs associated with hypoparathyroidism are related to neuromuscular "tetany" or "hyperexcitability." Seizures, muscle tremors, muscle fasciculations, and a stiff gait are reported in most dogs, and jaw "champing" is seen in about half of the dogs with fasciculations (Video 298-1).[4,8] Panting, facial

rubbing, biting at paws, and behavior changes (such as restlessness, anxiety, and aggression) are often identified on careful owner questioning. These signs may be explained either by muscle cramping and pain or a tingling sensation in the muscles.[4,8] On occasion, ataxia or circling is noted. Nonspecific signs include inappetence, vomiting, "weakness," lethargy, and diarrhea. The duration of clinical signs preceding diagnosis ranges from a few hours to a year or more (median: about 2 weeks).[4,8] Neuromuscular signs typically become more severe with time, are episodic, and are exacerbated by exercise or excitement. Virtually every clinical sign associated with hypoparathyroidism resolves with therapy.

Physical Examination

On physical examination dogs with primary hypoparathyroidism are often hyperthermic, tense, anxious, nervous, stiff-gaited and may growl or snap at being touched or palpated. For example, a tense abdomen may be due to pain in the abdominal muscles, pain elsewhere, or the dog may be anticipating pain because petting may have caused muscle cramping and pain in the past. Dogs may sometimes be aggressive or resist petting, particularly on the head. Thoracic auscultation reveals tachyarrhythmias in some dogs. Lenticular cataracts, appearing as small punctate to linear opacities in the anterior and posterior cortical subcapsular region, may be noted at initial presentation or following initiation of therapy (see ch. 11). The mechanism of cataract formation is unclear, but they do not appear to impair vision.[4,8,11]

Clinical Features in Cats

In contrast to dogs, male cats are overrepresented in those with primary hypoparathyroidism. The clinical signs in cats are similar to those in dogs, but cats are inappetent and lethargic more often. Lenticular cataracts and/or prolapse of the third eyelids are seen in some cats.[3,11-13] A cat with myocardial failure and echocardiographic findings consistent with dilated cardiomyopathy had resolution of cardiac changes after treatment for hypoparathyroidism.[14]

Diagnostic Evaluation in Dogs and Cats (Figure 298-1)

Serum Biochemistry, Complete Blood Count (CBC), Urinalysis (UA), Electrocardiogram (ECG)

At diagnosis, hypoCa is present in all pets with hypoparathyroidism and almost all are hyperPO_4. Repeating the serum total Ca (tCa) is recommended in pets with severe hypoCa, simply because the condition is uncommon but especially if clinical signs are not consistent. Using blood from an EDTA ("purple top") tube or even contaminating the needle with EDTA prior to injecting blood into another tube can artificially decrease Ca due to its binding by EDTA. Since ionized Ca (iCa) is biologically active, its measurement may provide a more accurate representation of the severity of hypoCa. In hypopara, the decreases in tCa and iCa tend to be similar in severity. In the absence of hypoalbuminemia, if measurement of iCa is not possible, repeatedly demonstrating low tCa concentrations in a patient with compatible clinical signs is generally adequate to confirm hypocalcemia. Clinical signs of hypoCa are not usually observed until the tCa concentration is <7 mg/dL or the iCa concentration <0.8 mmol/L. Signs may occur at higher values in acute hypoCa. Patients with hypoparathyroidism may have profoundly decreased tCa concentrations (as low as 2.7 mg/dL).[4,8] Since some dogs and cats do not exhibit clinical signs, it is assumed that their disease has progressed so chronically that there has been some physiologic adaptation.[11]

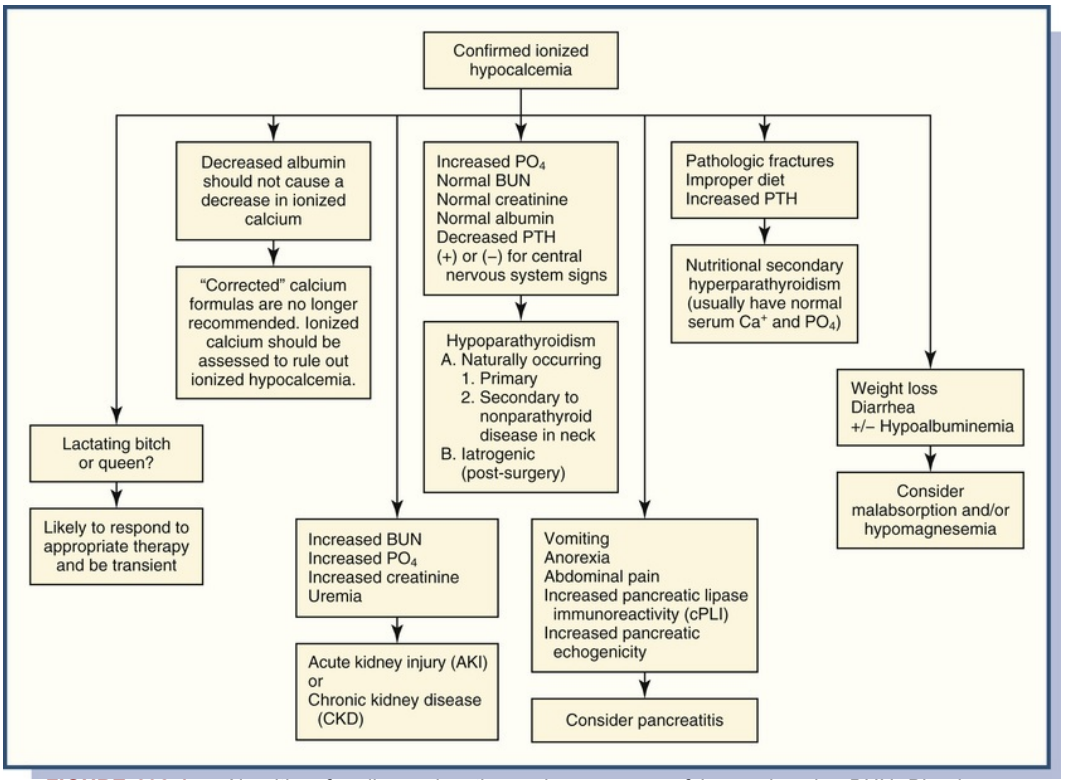

FIGURE 298-1 Algorithm for diagnosing the various causes of hypocalcemia. *BUN,* Blood urea nitrogen; *PTH,* parathyroid hormone. (From Feldman EC, Nelson RW, Reusch CE, et al: *Canine and feline endocrinology,* ed 4, St Louis, 2015, Saunders.)

Hypomagnesemia (Mg; see ch. 68) has been documented in Yorkshire Terriers with concurrent hypoCa and protein-losing enteropathy. The low Mg concentrations may contribute to decreased PTH secretion.[15] However, Mg concentrations are normal in most dogs with primary hypoparathyroidism and only mildly to moderately decreased in a few. Since these dogs recover without Mg supplementation, the significance of this finding is unknown.[4,11] The balance of serum biochemistries, CBC, and UA is unremarkable in pets with primary hypoparathyroidism. Increased creatine kinase activity has been reported in a cat and dog and would be expected in any animal with excess muscle activity.[14,16] HypoCa causes prolonged duration of ECG cardiac action potentials, resulting in S-T segment, and subsequent QT-interval, prolongation (see ch. 248).[8]

Parathyroid Hormone

Diagnosis of primary hypoparathyroidism requires the documentation of low Ca concentrations with inappropriately low PTH concentrations. Due to tight Ca regulation, PTH concentrations should be increased above the reference range in healthy animals with hypoCa. Thus, serum PTH concentrations in dogs and cats with primary hypoparathyroidism may be low or in the low end of the reference range.

Differential Diagnoses

The differential diagnosis of hypoCa includes a few common conditions and a variety of uncommon causes. The parathyroid-related conditions include primary gland concerns, such as immune-mediated destruction, idiopathic destruction, surgical removal, and rare conditions in people not yet reported in dogs or cats (see ch. 69). Conditions uncommonly associated with hypoCa are hypomagnesemia, acute kidney injury (AKI), chronic kidney disease (CKD), pancreatitis, diabetes mellitus, eclampsia, malabsorption syndromes, urinary tract obstruction, and use of phosphate-containing enemas. Hypoalbuminemia causes nonworrisome decreases in tCa but not iCa because of albumin binding. Other miscellaneous causes have been seen (see ch. 69).

Therapy

Acute Treatment

Intense IV

Dogs with severe hypoCa should be treated initially with an IV bolus of Ca gluconate and maintained using a constant rate infusion (CRI) of Ca gluconate (usually in the IV fluids) (see ch. 146). Oral Ca supplementation is also provided until calcitriol (1,25-dihydroxycholecalciferol; 1-25-dihydroxyvitamin D_3; active vitamin D_3) takes effect for long-term management. Initially, a tetanic dog or cat should be given the IV 10% Ca gluconate, 0.5-1.5 mL/kg (5-15 mg/kg) slowly, over 10-15 minutes. Note that 10% Ca gluconate contains 9.3 mg Ca/mL. The ECG should be monitored during infusion and the infusion discontinued if bradycardia, premature ventricular contractions, or shortening of the Q-T intervals are seen. Once the ECG normalizes, infusion can begin again, but at a slower rate. Ca chloride should not be used in dogs and cats since it is extremely caustic and can cause tissue sloughing if extravasated (see next section on SC calcium administration). Following initial Ca gluconate bolus, the serum tCa or iCa concentration should be rechecked. Clinical signs in most pets improve significantly, well before the Ca concentrations normalize.

After stabilization, Ca gluconate should be added to any maintenance IV fluids and given at 2.5-3.5 mg/kg/h (0.3-0.4 mL/kg/h), remembering that there is 9.3 mg/mL of Ca/mL.[17] Repeated boluses are only recommended for acute signs of tetany. Ca concentrations should be checked once to twice daily for the first few days and infusion rates adjusted accordingly. Following oral supplementation of Ca and vitamin D (calcitriol) and stabilization of serum Ca concentrations, the pet can be weaned off calcium.

Subcutaneous (SC) Conservative Therapy

SC Ca gluconate therapy has been used as an alternative to CRI. While uncommon, SC Ca can cause significant morbidity due to tissue damage (resulting in death in one dog) and is no longer recommended. If for any reason a CRI is not possible, the owners should be counseled on the potential complications of SC Ca administration. Calcinosis cutis has been reported in two dogs and a cat after each received SC Ca gluconate.[8,16,18] One protocol for SC therapy involves giving the same dose SC as was given in the initial IV bolus, diluted 1 part Ca gluconate to 1 part crystalloid, q 6-8 h. Frequency and dosage are decreased as oral Ca and calcitriol begin to take effect.[17]

Chronic Treatment

Background

In primary hypoparathyroidism, Ca cannot be obtained from the skeleton or diet without PTH or vitamin D, nor is it reabsorbed by the kidneys. Since PTH is not commercially available, oral vitamin D analogues are cornerstones in the long-term treatment of hypoparathyroidism. Supplementation with oral Ca may be used early in therapy and can usually be discontinued after a few weeks if the dog or cat is eating well, because dietary Ca should be sufficient for daily needs. Currently available options for vitamin D supplementation include calcitriol and ergocalciferol (vitamin D_2). Dihydrotachysterol, a synthetic vitamin D analogue, is no longer commercially available.

Calcitriol

Calcitriol is the active form of vitamin D_3 with a much shorter time to maximal effect (1-4 days) and less time required to resolve toxicosis (1-7 days) than ergocalciferol (5-21 days and 1-18 weeks, respectively). Thus, calcitriol is preferred over ergocalciferol, unless financial limitations preclude its use (see ch. 297 for alternatives to calcitriol).[11] Initial dose of calcitriol (20-40 ng/kg/day; 0.02-0.04 mcg/kg/day) is usually given for 2 to 4 days and then decreased to 10-20 ng/kg/day (0.01-0.02 mcg/kg/day). Dosing calcitriol using commercially available formulations can be challenging since gel capsules only come in limited sizes (0.25 microgram and 0.5 microgram, Rocaltrol), which are not convenient for use in dogs and cats. Based on clinical observation, compounded formulations have not provided consistent products. Thus, for each patient, the product should be purchased from the same experienced compounding pharmacy each time and should not be used past the marked expiration date.

Ergocalciferol

The initial dosage of ergocalciferol is 4000-6000 U/kg/day. Once serum Ca concentrations stabilize between 8 and 9.5 mg/dL, the dose can usually be decreased to every other day. From that point, the patient should

determine frequency need via monitoring. Ca concentrations should then be monitored weekly and the dose adjusted as necessary.[11]

Oral Calcium

Oral Ca supplementation should also be provided initially but can usually be tapered and discontinued within a week of starting calcitriol. The starting dosage in cats is 0.5-1 g/day, divided. In dogs, 1-4 g/day is given, divided. Ca gluconate and lactate can be used, but Ca carbonate is most frequently chosen due to its availability. It is important to dose based on the amount of elemental Ca. Ca carbonate, gluconate, and lactate are 40%, 9%, and 13% elemental Ca, respectively (1 g of Ca carbonate contains 400 mg elemental Ca).[19]

Treatment Goals

The goal is to maintain serum Ca concentrations just below the low end of the reference range (about 8-9.5 mg/dL). This is high enough to prevent clinical signs of hypocalcemia, decreases degree of calciuresis due to the lack of PTH, and is low enough to prevent vitamin D toxicosis: hyperCa, hyperPO_4, and AKI. As soon as serum Ca concentrations increase to 7.5-8 mg/dL on oral vitamin D and Ca and the patient is eating and drinking well, they are returned to the owner. Rechecks initially should be every 2 to 3 days. As serum Ca concentrations stabilize, recheck intervals can be progressively prolonged, up to once every 2 to 3 months. Owners should be instructed to return if any signs of hypoCa or hyperCa occur. HyperCa should be treated by discontinuing vitamin D administration until it normalizes; additional therapy, including IV fluids and furosemide, is infrequently necessary.

Prognosis

Hypoparathyroid dogs and cats with dedicated and capable owners have an excellent prognosis. Owners must be reminded that this disease requires life-long therapy and frequent monitoring to help prevent hypocalcemia or hypercalcemia. Most dogs and cats die of causes unrelated to hypoparathyroidism if appropriate therapy is pursued.[4,8,11]

CHAPTER 299

Canine Hypothyroidism

Carmel T. Mooney

Client Information Sheet: Canine Hypothyroidism

Introduction

Hypothyroidism is the most common thyroid disease and one of the most common endocrine disorders in dogs. Its prevalence has been estimated between 0.2 and 0.8%.[1-3] A survey of insured dogs from Sweden, however, suggested a lower prevalence of 0.07%.[4] This may be a more accurate reflection as it is not biased towards a referral population and includes a large number of pedigree animals more likely to suffer from hypothyroidism.[5]

Physiology

The thyroid gland of dogs consists of two separate lobes, one on either side of the trachea. Each lobe is composed of microscopic follicles lined by a single layer of thyroid epithelium. The lumen of each follicle contains colloid, a storage substance for thyroglobulin secreted by follicular cells. Thyroglobulin is a large glycoprotein containing iodotyrosines, components of thyroid hormones. Most of the steps involved in thyroid hormone synthesis are catalyzed by the enzyme thyroid peroxidase (TPO).

The primary function of the thyroid gland is to produce the active thyroid hormones, 3,5,3′,5′-L-tetraiodothyronine (thyroxine, T_4) and 3,5,3′-L-triiodothyronine (triiodothyronine, T_3; Figure 299-1). Almost all these hormones are protein-bound in the circulation. Approximately 60% of T_4 is bound to thyroxine binding globulin, 17% to transthyretin, 12% to albumin and 11% to various lipoprotein fractions.[6] T_3 binding is similar. Binding affinities for thyroid hormones are lower in dogs than humans and, consequently, canine total concentrations are lower, free fractions higher (estimated at approximately 0.1-0.3% for T_4 and 1% for T_3), and serum half-lives shorter (10-16 h for T_4 and 5-6 h for T_3). Only the free fraction is metabolically active with the protein bound moiety serving as a passive reservoir to buffer hormone delivery to tissues. T_3 is approximately three to five times more potent than T_4. Up to 60% of T_3 is produced not by the thyroid gland but by peripheral outer ring monodeiodination of T_4, a step that may be autoregulated. Inner ring deiodination results in formation of metabolically inactive reverse T_3 (rT_3).

In Melmed S, Polonsky KS, Larsen PR, et al, editors: *Williams textbook of endocrinology,* ed 12, Philadelphia, 2011, Elsevier, pp 327-361.)

Thyroid hormones affect most body tissues largely by interaction with specific nuclear receptors to modify the expression of a diverse array of genes. Thyroid hormones therefore influence multiple metabolic processes from regulation of mitochondrial oxygen demand to control of protein synthesis. Some effects can be demonstrated within minutes to hours but others may require weeks to months. Thyroid hormone production is controlled principally by negative feedback (Figure 299-2). The hypothalamus secretes thyrotropin-releasing hormone (TRH), which stimulates specific anterior pituitary cells to promote synthesis and secretion of thyrotropin (thyroid-stimulating hormone; TSH). TSH promotes iodide trapping by the thyroid, as well as the synthesis and release of thyroid hormones.

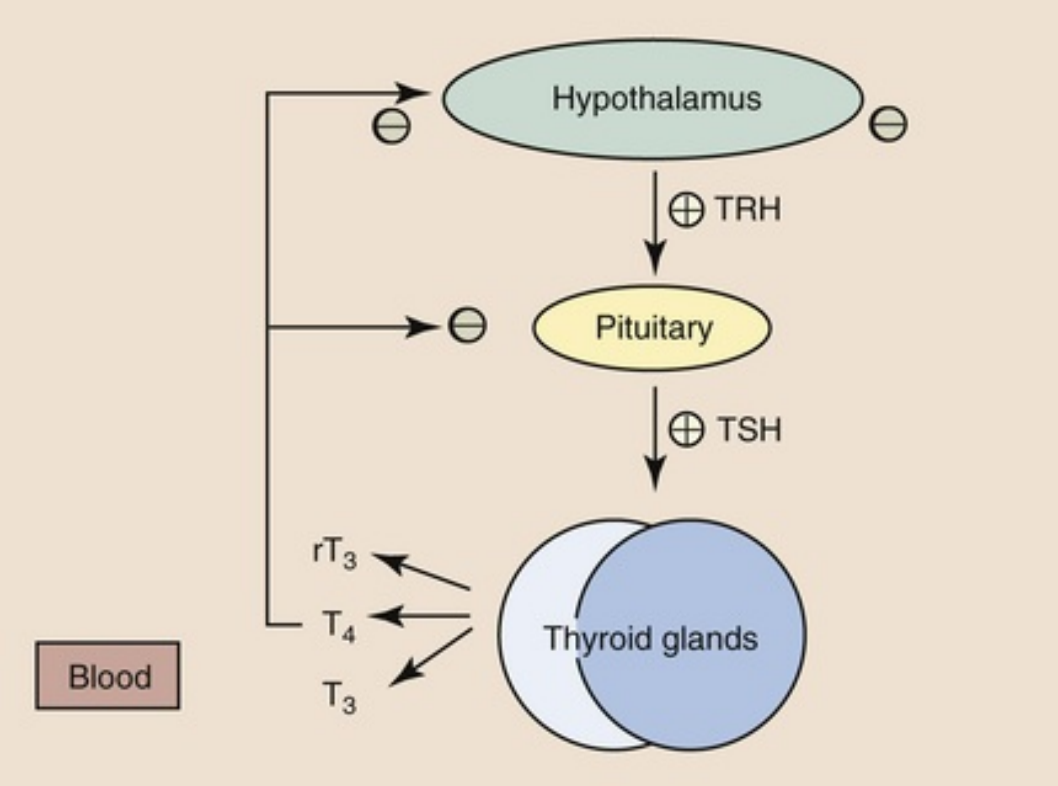

FIGURE 299-2 Regulation of thyroid hormone concentrations. Thyroid hormone concentrations are controlled by the hypothalamic-pituitary-thyroid axis, which operates as a negative feedback loop. Thyrotropin (TSH) causes synthesis and release of T_4 and lesser amounts of T_3 from the thyroid gland. Intracellular T_3, derived from deiodination of T_4 within the pituitary gland, causes decreased TSH synthesis and secretion and is the main determinant of TSH concentration. Thyrotropin-releasing hormone (TRH), secreted by the hypothalamus, modulates TSH release from the pituitary gland. Increased thyroid hormone concentrations are also believed to decrease TRH synthesis and secretion. Hormones that inhibit TSH secretion include dopamine, somatostatin, serotonin, and glucocorticoids. TRH, prostaglandins, and alpha-adrenergic agonists increase TSH secretion. (From Scott-Moncrieff CR: Hypothyroidism. In Ettinger SJ, Feldman EC, editors: *Textbook of veterinary internal medicine,* ed 7, St Louis, 2010, Elsevier, pp 1751-1761.)

The presence of excess circulating free T_4 (FT_4) and T_3 produces negative feedback to the hypothalamus and anterior pituitary, decreasing TRH and TSH synthesis and release and, subsequently, thyroid hormone production. Thyroid hormones have a major influence on metabolic rate, growth, central nervous system (CNS) development, and tissue turnover. Thyroid hormones have positive inotropic and chronotropic effects on the heart, are necessary for cholesterol synthesis and metabolism, and are capable of stimulating erythropoiesis. When deficient, the spectrum of possible abnormalities is extensive.

Pathogenesis of Hypothyroidism

Overview

Hypothyroidism results from decreased production of T_4 and T_3. It can arise because of an abnormality in any step of the hypothalamic-pituitary-thyroid axis. It is referred to as primary or central (including secondary and tertiary) depending on whether the underlying lesion lies within the thyroid gland (primary), pituitary gland (secondary) or hypothalamus (tertiary). It is also described as congenital or acquired depending on the age at which it develops.

Congenital Hypothyroidism

Congenital hypothyroidism is significantly less common than acquired. It results from thyroid hypoplasia or aplasia, dysgenesis or dyshormonogenesis. Congenital hypothyroidism may be more prevalent than currently appreciated because some are undiagnosed and others die at birth or shortly thereafter. Central hypothyroidism (resulting from TSH or TRH deficiency) has been reported sporadically and in one family of

Giant Schnauzers.[7-11] TSH deficiency is common in pituitary dwarfism, and dogs with thyroid dysgenesis have been noted.[12-14] Congenital hypothyroidism with goiter, as a result of dyshormonogenesis and TPO deficiency, has been reported sporadically and as a fully penetrant autosomal recessive disorder in Toy Fox and Rat Terriers for whom genetic tests are available.[15-17] Different mutations with a similar phenotype have been reported in Tenterfield Terriers, Spanish Water Dogs and Papillons.[18-20] Congenital hypothyroidism may develop in pups born to dams fed an iodine-deficient diet, dams given various drugs, or pups exposed to iodine deficiency or excesses when young.[21-23]

Acquired Hypothyroidism

Central

Central disease (TRH or TSH deficiency) is rare, accounting for <5% of hypothyroid dogs. Pituitary neoplasia and surgical hypophysectomy account for the vast majority of reported cases, with posttraumatic deficiencies less common.[24-26] One dog with tertiary hypothyroidism related to neoplasia has been reported, but this is so uncommon that clinical indications for differentiating secondary from tertiary disease appear limited.[27] Secondary hypothyroidism is a potential, uncommon and reversible condition due to glucocorticoid excess.[28,29] Central hypothyroidism results in thyroid atrophic degeneration, characterized by follicles distended with colloid and flattened surrounding epithelium, changes quite different from those associated with primary thyroid disease.[11]

Primary

Acquired primary thyroid disease accounts for the overwhelming majority of dogs with hypothyroidism. Histologically, lymphocytic thyroiditis and thyroid atrophy are equally common. Lymphocytic thyroiditis is a destructive autoimmune process characterized by multifocal or diffuse infiltration of the thyroid gland by lymphocytes, macrophages and plasma cells and progressive replacement by fibrous connective tissue.[30,31] It is associated with systemic inflammation and a dominant cellular immune response.[32] By contrast, idiopathic atrophy is described as a degenerative process with minimal inflammatory change and gradual replacement of thyroid tissue by adipose and connective tissue.[30] Some believe that idiopathic atrophy is the end stage of lymphocytic thyroiditis and associated with similar markers of inflammation.[32] Regardless, the inciting cause for these conditions is unclear.

Thyroid biopsy is required for definitive diagnosis of lymphocytic thyroiditis, but its existence can be inferred by demonstration of circulating autoantibodies to thyroid antigens such as thyroglobulin, T_4, T_3 and thyroid peroxidase. Thyroglobulin autoantibodies (TgAAs) are most common, while the others rarely occur in isolation.[33-35] TgAA assays, widely available, have excellent diagnostic sensitivity and specificity.[36-38] Approximately 50% of hypothyroid dogs have circulating TgAAs, corresponding to the frequency of lymphocytic thyroiditis.[35,39-44] Lymphocytic thyroiditis is slowly progressive, causing signs of hypothyroidism after about 75% of the gland has been destroyed. Its progression can be divided into four stages (Table 299-1). The rate of progression through these stages is variable, and not all dogs develop functional hypothyroidism. Approximately 20% of TgAA-positive euthyroid dogs develop hormonal evidence of thyroid dysfunction within a year of testing, but only 5% become clinically hypothyroid.[45] Most dogs remain TgAA positive and asymptomatic, while a small number later test negative without evidence of thyroid dysfunction. Some TgAA-positive hypothyroid dogs later become TgAA negative, supporting the concept that thyroid atrophy represents an end stage of lymphocytic thyroiditis. Theoretically, the complete destruction of all thyroid tissue leads to a reduction in immune stimulation, absence of histologic thyroiditis, and conversion to autoantibody negativity. Histopathologic progression from lymphocytic thyroiditis to follicular atrophy has been described.[46] Moreover, TgAA-positive euthyroid dogs (silent/subclinical thyroiditis) are younger than both TgAA-positive dogs with hypothyroidism and TgAA-negative hypothyroid dogs.[42] The proportion of hypothyroid dogs that are TgAA-positive or -negative varies from breed to breed, reflecting different rates of disease progression or different susceptibilities.

TABLE 299-1

The Progressive Stages of Lymphocytic Thyroiditis

	THYROID TISSUE HISTOPATHOLOGY	TgAA STATUS	THYROID HORMONE CONCENTRATIONS	
			TSH	T_4/T_3
Silent	Majority normal, mild infiltration	Positive	Normal	Normal
Subclinical	More marked infiltration	Positive	Increased	Normal
Clinical	>75% replaced	Positive	Increased	Decreased
	Minimal thyroid tissue, limited inflammation	Negative	Increased or decreased	Decreased

TgAA, Thyroglobulin autoantibody; *TSH*, thyroid stimulating hormone (thyrotropin); T_4, thyroxine; T_3, triiodothyronine.

This classification system is largely based on studies indirectly assessing lymphocytic thyroiditis by measurement of circulating thyroglobulin autoantibody status.

From Mooney CT: Canine hypothyroidism. A review of the aetiology and diagnosis. *N Z Vet J* 59:105-114, 2011.

Reported breed predispositions, together with the familial nature of hypothyroidism in purebred dogs, are consistent with a strong hereditary component to the condition.[47] Some breeds have a high prevalence of TgAA positivity and a significantly increased risk for developing hypothyroidism. These breeds include but are not confined to the English Setter, Golden Retriever, Rhodesian Ridgeback, Cocker Spaniel and Boxer.[42] Familial hypothyroidism is also recognized in Great Danes, Beagles and Borzoi colonies, and, in Sweden, Hovawarts and Giant Schnauzers.[40,46,48,49] Several genetic and environmental risk factors have been recognized for development of autoimmune thyroid disease in people, but similar observations are less clear in dogs. In dogs, specific major histocompatibility (MHC) dog leukocyte antigen (DLA) haplotypes and alleles confer an increased susceptibility for hypothyroidism in a number of breeds: Doberman Pinscher, Rhodesian Ridgeback, English Setter and Giant Schnauzer.[50-53] Anecdotally, a link between intensive vaccination protocols and development of autoimmune disease in general and thyroiditis in particular has been suggested but not supported in studies of thyroiditis in Beagles.[54] Season of the year (summer versus fall) and geography (different states within the USA) may influence prevalence via unknown mechanisms.[42]

Clinical Observations

Signalment

Hypothyroidism can occur in dogs of any breed but typically affects the purebred animals listed. The mean age at diagnosis is approximately 7 years and ranges from 0.5 to 15 years. It is an uncommon diagnosis in dogs less than 2 years of age. Breeds predisposed to lymphocytic thyroiditis tend to develop hypothyroidism at an earlier age. Intact males and neutered females may be at increased risk for becoming hypothyroid.[1-3]

Clinical Signs

General Features

Hypothyroidism causes a variety of clinical signs (Table 299-2). The onset of hypothyroidism is insidious, and since there are no pathognomonic features, hypothyroidism is included as a differential for both common and uncommon problems. The most common clinical signs relate to metabolic and dermatological abnormalities that occur concurrently in about 70% of affected dogs. Often the dermatological features are most prominent and worrisome for owners. Less commonly, cardiovascular, neuromuscular, reproductive, ophthalmic, and/or gastrointestinal signs are described.

TABLE 299-2

Clinical Abnormalities Associated with Hypothyroidism

Metabolic signs	Lethargy
	Obesity or weight gain
	Exercise intolerance
	Cold intolerance

Dermatological abnormalities	Alopecia
	Dry/poor-quality coat
	Skin hyperpigmentation
	Pyoderma
	Seborrhea
Others	Various neuropathies, central vestibular disease, myxedema coma, subclinical myopathy, lipid corneal dystrophy, bradycardia, disproportionate dwarfism, decreased fertility, parturient problems, decreased tear production

Metabolic Features

A decline in metabolic rate is typical.[55] Associated clinical signs, noted in about 80% of dogs, include lethargy, weight gain, exercise intolerance, mental dullness, cold intolerance, generalized weakness and shivering.[1,2] Although 40 to 50% of affected dogs are overweight or obese, hypothyroidism is the cause in only a minority of obese dogs.

Dermatological Features

Thyroid hormones play an important role in the maintenance of hair growth, and in humoral, and cellular immune responses. Dermatological abnormalities occur in up to 80% of hypothyroid dogs and can be extensive.[1,2,56] Changes include hair thinning, dry coarse hair coat, alopecia that usually involves the flanks and thighs, and failure to regrow hair after clipping. Hypothyroidism is classically associated with an "endocrine alopecia" that is non-pruritic, bilaterally symmetrical, and a tendency to spare the head and extremities. Alopecia is often noted in areas of friction. These include the neck in dogs that wear collars, the lateral extremities in large dogs, and the tail, resulting in the so-called "rat-tail" of hypothyroidism. Focal, multifocal and asymmetric alopecia can occur. While alopecia involving the nasal planum is thought to be highly associated with hypothyroidism, it is nonspecific. In a few dogs, retention of the coat occurs and it becomes dull and often lighter in color because of environmental bleaching. Other signs of hypothyroidism include dry scaly skin, seborrhea, otitis, hyperpigmentation, and secondary bacterial infections (although pyoderma is reported in <10% of affected dogs). *Malassezia* has also been reported. Pruritus may be present if infection or pyoderma occurs. Hypothyroidism may be suspected particularly after standard treatment is ineffective.

In people, hypothyroidism is associated with accumulation of hyaluronic acid in the dermis (myxedema) resulting in a non-pitting puffy appearance to the skin that is pale and cool to the touch. Myxedema also occurs in dogs, is most noticeable over the head, and gives rise to the "tragic facial expression" caused by thickened lips, thickened skin over the forehead, and drooping of the eyelids. Rarely, mucinous vesiculation may develop.[57] Common histologic changes associated with hypothyroidism are also observed in other endocrine disorders, including a predominance of hairs in telogen and hairless telogen follicles (kenogen follicles).[58,59] While hyperpigmentation, atrophic and dystrophic follicles are also described, they are less common as compared with other endocrine disorders. A thickened dermis and vacuolated erector pili muscles are considered more specific for hypothyroidism.[59] Dermatitis with secondary infection may obscure these findings.

Cardiovascular Features

Thyroid hormones have a direct positive inotropic effect, which stimulates myocardial function and increases responsiveness to adrenergic stimulation. Theoretically, hypothyroidism could significantly impair cardiac function but does so rarely. In reports on large numbers of hypothyroid dogs, cardiac abnormalities are rarely recorded apart from dogs (about 15%) with asymptomatic bradycardia.[1,2] On the electrocardiogram, hypothyroidism is associated with low-voltage R waves, inverted T waves, sinus bradycardia and occasionally first- or more rarely second-degree atrioventricular block.[60,61] Hypothyroidism is a possible cause for bradydysrhythmias, particularly if other consistent clinical signs are present.

Echocardiographically, hypothyroidism is associated with a reversible decrease in fractional shortening and a mild increase in left ventricular end systolic diameter, suggestive of reduced myocardial function. There are a few case reports of congestive heart failure and myocardial dysfunction with atrial fibrillation partially or fully responsive to appropriate cardiac and/or thyroid hormone supplementation.[62-64] However, it is unclear

whether hypothyroidism was causative, coincidental or capable of exacerbating an underlying subclinical cardiomyopathy. Larger studies have focused on breed-specific dilated cardiomyopathies. The prevalence of hypothyroidism is no higher in Dobermans with dilated cardiomyopathy (with or without congestive heart failure) compared with those with non-cardiac disease.[65] A causal relationship between hypothyroidism and dilated cardiomyopathy may exist, as not all dogs in the non-cardiac group underwent echocardiography. Some may have had subclinical disease. Another study failed to demonstrate an association between hypothyroidism and dilated cardiomyopathy in Dobermans, but there is increased risk of hypothyroidism in Dobermans with dilated cardiomyopathy.[66] These results may reflect independent predispositions for the conditions or a common pathway in their pathogenesis.

In humans, atherosclerosis is a known complication of the hypercholesterolemia and lipid abnormalities induced by hypothyroidism. Atherosclerosis is rare in dogs, presumably because of differences in their lipoprotein composition and metabolism (see ch. 182). Of the limited number of postmortem cases reported, hypothyroidism, like diabetes mellitus, appears to be common.[67,68] Cholesterol concentrations are consistently highest in dogs that develop atherosclerosis, but specific patterns of hyperlipidemia have not yet been elucidated. The clinical consequences of atherosclerosis are unclear but may affect the cardiovascular and neurological systems. There are a few reports of aortic thromboembolism and severe atherosclerosis associated with hypothyroidism.[62,69] A cholesterol-based pericardial effusion has been described in a hypothyroid dog.[70]

Neuromuscular Features

Various neurological disorders have been associated with hypothyroidism, from dysfunction of single or multiple cranial nerves, to generalized peripheral neuropathies, and CNS disease. Although hypothyroidism can interfere with neurologic function through accumulation of mucopolysaccharides, impaired axonal transport, or atherosclerosis, there is limited evidence of a direct causal effect. Reports of Horner's syndrome, facial nerve paralysis and laryngeal paralysis caused by hypothyroidism are unreliable due to questions concerning diagnosis.[71-73] Facial nerve paralysis, laryngeal paralysis, megaesophagus, peripheral vestibular disease and lower motor neuron dysfunction (generalized weakness, proprioceptive deficits, diminished segmental reflexes with potential progression to paraparesis or tetraparesis) have all been described in hypothyroid dogs.[1,2,74,75] Thyroid hormone-responsive cricopharyngeal achalasia has been described.[76]

Although experimental induction of hypothyroidism does not accurately reflect the insidious course of the naturally occurring disease, neurological dysfunction is rare after radioactive iodine thyroid ablation.[77] In hypothyroid dogs, a concurrent disorder may be responsible for the neurological signs. In others, response to thyroid hormone supplementation is difficult to assess either because other treatments may have been employed or because spontaneous resolution of the neurologic condition may have occurred. While a reasonable response to thyroid hormone supplementation is expected in hypothyroid-induced neurological dysfunction, only a minority of dogs with megaesophagus exhibits discernible clinical or radiographic response.[74,78] Indeed, hypothyroidism is not a significant risk factor for developing megaesophagus.[79] Similarly, myasthenia gravis has been associated with hypothyroidism but may represent a concurrent immune-mediated disease.[2,80,81]

Reports of CNS disease in hypothyroidism are less common but perhaps less tenuous. Central vestibular dysfunction is a rare but reversible complication, even if other signs of hypothyroidism are absent.[82,83] Potential mechanisms include atherosclerotic vascular disease causing brain infarction and/or metabolic derangements directly due to thyroid hormone deficiency. CNS atherosclerosis has been described in one dog and suspected in Labrador Retrievers with neurological disease and severe hyperlipidemia.[84,85] Hypothyroidism has also been associated with myxedema coma, a life-threatening sequela characterized by profound mental dullness, stupor, weakness, hypothermia (often without shivering), hypoventilation, bradycardia and hypotension.[86-88] In many, there is evidence of precipitating factors: surgery, cardiac failure, drug therapies or overwhelming sepsis. Seizures have been described in a hypothyroid dog with atherosclerosis, but hypothyroidism has only been diagnosed in about 3% of dogs with metabolic or toxin-associated seizures.[89,90]

Perhaps the most controversial association between hypothyroidism and the nervous system relates to behavior (see ch. 9). There is little evidence to support the suggestion that hypothyroidism causes aggressive behavior. The few case reports of dominance- and fear-related aggression in hypothyroid dogs were usually longstanding behaviors that did not entirely resolve with thyroid hormone supplementation.[91-93] The

prevalence of hypothyroidism in dogs with behavior problems is low and no greater than in dogs without such problems.[94,95]

It can be difficult to distinguish clinical signs due to neuropathies (see ch. 268) from those due to myopathies (see ch. 354). Myopathies due to hypothyroidism may cause gait abnormalities, weakness and exercise intolerance (see ch. 31). Experimentally, hypothyroidism could cause exercise-induced hyperkalemia that may contribute to decreased performance and endurance.[96] In situations in which experimental hypothyroidism did not cause neuropathy, it did result in subclinical, biochemical, electrophysiologic and morphologic evidence of myopathy.[97] Histologically, myopathies are usually characterized by nemaline rod inclusions, an increase in type I myofibers, a decrease in type II fibers, abnormal mitochondria and myofiber degeneration with substantial depletion of skeletal muscle free carnitine.[97] Nemaline rod myopathy has been associated with clinical signs, including cardiac involvement in two dogs.[98,99]

Ophthalmic Features (see ch. 11)

Hypothyroidism, via hyperlipidemia, can result in arcus lipoides. Although not common, it has been well described, particularly in German Shepherd Dogs.[100] Association between keratoconjunctivitis sicca and hypothyroidism is speculative. In experimental hypothyroidism, the Schirmer tear test, intraocular pressure measurements and ophthalmoscopy remained unchanged for as many as 17 weeks. No histologic abnormalities were noted after necropsy.[101] Reduced tear production has been reported in hypothyroid dogs that could exacerbate other underlying ocular pathology.[102]

Reproductive Features

Various reproductive abnormalities have been ascribed to hypothyroidism. Short-term (median 19 weeks) experimental induction of hypothyroidism in bitches resulted in prolonged parturition and reduced pup survival without affecting the interestrus interval, fertility, litter size or gestation length.[103] More chronic hypothyroidism (at least 40 weeks) resulted in decreased fertility, increased periparturient mortality and lower birth weights, without effect on interestrus interval, gestation duration or breeding behavior.[104] Experimentally induced hypothyroidism is not associated with any effect on male reproductive indices (sperm count, scrotal width, sperm motility/morphology, libido) over a 2-year period.[105] A survey of five breeds (Great Dane, Dogue de Bordeaux, English Mastiff, Leonberger and Golden Retriever) identified no association between infertility and hypothyroidism, but the prevalence of hypothyroidism was too low for firm conclusions.[106] One dog with hypothyroidism, hyperprolactinemia and galactorrhea was described.[107] Pituitary function tests in hypothyroid dogs suggest that hyperprolactinemia is only likely in intact bitches.[108]

Other Features

Anecdotally, constipation, vomiting and diarrhea have been associated with hypothyroidism, but evidence is lacking.[1,2] Hypothyroid people are often constipated due to decreased gastrointestinal (GI) peristaltic activity.[109] Diarrhea associated with small intestinal bacterial overgrowth, possibly due to reduced intestinal motility, has been suspected.[110] An association between gallbladder mucocele and hypothyroidism has been proposed but not confirmed.[111,112] Hypothyroidism is not associated with either acute or chronic kidney disease or polyuria/polydipsia except in rare cases of thyroiditis-associated-glomerulonephritis.[113] Decreases in glomerular filtration rate have been demonstrated in hypothyroidism, but its significance is not known.[114,115] It has been suggested but not demonstrated that hypothyroid dogs require less anesthetic agents for a given effect and are more difficult to manage during anesthesia. Experimentally, the cardiovascular effects and minimum alveolar concentrations of isoflurane were not different in hypothyroid versus healthy dogs.[116,117]

Congenital Hypothyroidism

Dogs affected early in life can develop any of the signs noted in hypothyroid adults. However, dogs with congenital hypothyroidism have striking disproportionate dwarfism. Affected pups appear normal at birth, but signs usually become evident by about 8 weeks of age. Affected animals have disproportionately wide skulls, macroglossia, delayed dental eruption, a square trunk and short limbs.[20] These features help differentiate this condition from the proportionate features of pituitary dwarfism. Constipation may be noted, and mental impairment is usually obvious. Goiter may or may not be evident depending on the underlying

cause. When present, goiter can mechanically cause dysphagia/dyspnea. Radiographically, delayed skeletal maturation and epiphyseal dysgenesis are common and may eventually cause degenerative joint disease or other orthopedic disorders.[13,118]

Immunoendocrinopathy Syndromes

Most autoimmune endocrine disorders in people occur in isolation, but there are instances when two or more such disorders occur concurrently or sequentially. Autoimmune polyendocrine syndrome type 1 (APS-1) is a rare autosomal recessive disorder characterized by the triad of mucocutaneous candidiasis, autoimmune thyroid disease and Addison's disease. These people have increased susceptibility to other autoimmune diseases.[119] Autoimmune polyendocrine disease type II (APS-II) is more common, less well defined, and is associated with familial aggregation and susceptibilities determined by multiple genetic factors.[119] Previously known as polyglandular autoimmune disease or Schmidt's syndrome, it is usually defined by the development of two or more of the following: Addison's disease, Graves' disease, autoimmune thyroiditis, type 1A diabetes mellitus, primary hypogonadism, myasthenia gravis and celiac disease. Addison's disease together with type 1 diabetes mellitus (52% of patients) or with hypothyroidism (69% of patients) is most common.[120,121]

Such disorders are less well defined in dogs. Single case reports and case series have described combinations that mimic the human condition, including hypothyroidism and diabetes mellitus,[1-3,122-124] hypothyroidism and hypoadrenocorticism,[3,125-133] together with adenohypophysitis,[134] hypothyroidism, hypoadrenocorticism, diabetes mellitus and hypoparathyroidism,[128] hypothyroidism and myasthenia gravis,[2,80,81] and occasionally with other autoimmune diseases.[135] The prevalence of diabetes mellitus in hypothyroid dogs has been estimated as between 1.2% and 10% while the prevalence of hypothyroidism in diabetic dogs is estimated at 4%.[1,3,124] The prevalence of hypoadrenocorticism in hypothyroid dogs ranges from 1% to 3% while the prevalence of hypothyroidism in dogs with hypoadrenocorticism is about 4%.[2,3,128] Hypothyroidism should be suspected in dogs with hypoadrenocorticism, particularly if there is a poor response to mineralocorticoid therapy, persistent hyponatremia or bradycardia, inappropriate hypercholesterolemia or other supportive clinical signs.[129] In a study of 35 dogs with two or more concurrent endocrine disorders, the combination of hypothyroidism and diabetes mellitus (29%) was more common than hypothyroidism and hypoadrenocorticism (23%).[136]

Undoubtedly, there are difficulties in reliably confirming hypothyroidism in dogs suffering from other illnesses. The combinations are all potentially immune-mediated and may be genetically related, but other explanations are possible. Clinically, hypothyroidism has been recognized as an uncommon cause of insulin resistance in diabetic dogs.[122] Hypothyroidism is known to induce insulin resistance in experimental dog models. Their glucose tolerance is maintained via compensatory increase in insulin secretion.[137,138] While obesity may play a partial role in resistance, other factors associated with thyroid hormone deficiency may also be important.[137] Naturally occurring and experimental hypothyroidism has been associated with growth hormone (or IGF-1) excess, perhaps due to transdifferentiation of somatotropic pituitary cells to thyrosomatotropes.[108,137,139-141] Growth hormone excess is highly diabetogenic.[142] One dog with hypothyroidism, acromegaly, and diabetes mellitus reversed with thyroid hormone supplementation.[143] Additional genetic and clinical studies are required to fully investigate the existence of autoimmune polyendocrine disorders in dogs.

Routine Clinicopathology

Overview

Various hematological and biochemical changes are described as “common” in hypothyroid dogs, but none is specific. Their presence provides supportive evidence of hypothyroidism but, more importantly, they may aid in including or excluding non-thyroidal illnesses. Non-thyroidal illness may account for a patient's clinical signs or may affect interpretation of thyroid function tests. The most frequent abnormalities in hypothyroidism include anemia, hypercholesterolemia, hypertriglyceridemia, increased creatine kinase (CK) activity and decreased fructosamine concentrations.

Complete Blood Count (CBC)

The anemia in hypothyroidism is typically mild, normochromic and normocytic. It occurs in 32 to 44% of cases.[1,2,144] Hematocrit values are rarely below 25%, an anemia not often detected on physical examination. Often termed a "physiological" anemia, it is likely the result of decreased erythropoietin production and the lack of stimulatory effect of thyroid hormones on bone marrow.[145] Non-anemic hypothyroid dogs usually have red cell counts in the lower quartile of the reference interval. An increased white cell count is extremely unusual in hypothyroid dogs.

Hypothyroidism has been associated with increased platelet counts and small platelet size, a result of an inverse relationship between thrombopoiesis and erythropoiesis.[148] Easy bruisability has anecdotally been associated with hypothyroidism, perhaps the result of decreases in plasma von Willebrand factor antigen (vWf:Ag).[149] However, hypothyroidism is not associated with prolonged buccal mucosal bleeding times or significant changes in vWf:Ag concentrations, which decrease with thyroid hormone supplementation.[150,151] Links between hypothyroidism and von Willebrand's disease likely reflect breed predispositions to both conditions. Thyroid supplementation of euthyroid Dobermans with von Willebrand's disease does not affect the concentration or activity of vWf:Ag in plasma.[152]

Serum Biochemistry Results

Hypercholesterolemia occurs in about 75% of hypothyroid dogs and is often accompanied by hypertriglyceridemia.[1,2,144] The higher the cholesterol concentration, the more likely a dog is to have hypothyroidism. Thyroid hormones stimulate lipid synthesis, mobilization and degradation. Degradation is more severely affected in hypothyroidism, resulting in lipid accumulation. Plasma lipoprotein analyses of hypothyroid dogs demonstrate increased concentrations of low density lipoprotein, very low density lipoprotein, and high density lipoprotein.[146] Increased CK activity occurs in 18 to 35% of hypothyroid dogs but does not usually exceed twice the upper limit of the reference interval.[1,2] Often considered to result from decreased metabolism or excretion, hypothyroid-induced myopathy may also be responsible for changes in CK.[97] Fructosamine concentrations are high in 36-82% of cases, presumably due to reduced protein turnover rather than significant prolonged hyperglycemia.[1,147] Such increases may impact treatment monitoring in diabetic dogs with hypothyroidism. Mild increases in liver enzyme activities, particularly alkaline phosphatase and gamma-glutamyltransferase, occur in as many as 30% of hypothyroid dogs, perhaps due to mild hepatic lipid deposition.[1,2] If enzyme activities are markedly increased, another underlying disorder should be considered.

Thyroid Testing

Overview

The ability to accurately diagnose hypothyroidism, while greatly improved in recent years, can be challenging. Several tests are available and recommendations for their use and interpretation vary. Commonly used assays include total T_4 (TT_4), total T_3 (TT_3), free T_4 (FT_4), canine TSH (cTSH), the presence of TgAA, T_4AA, and T_3AA. Assays for free T_3 and reverse T_3 (rT_3) are available but not used in diagnosis. Dynamic function tests include TRH and TSH stimulation tests. The thyroid gland may be assessed by ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), or by qualitative and quantitative thyroid scintigraphy. Not all tests directly assess thyroid function but may provide indirect evidence of thyroid abnormalities. Of the tests available, no single test has 100% diagnostic sensitivity. Importantly, there is a myriad of non-thyroidal factors that may influence results of thyroid testing, adversely affecting diagnostic specificity.

Non-Thyroidal Factors Affecting Thyroid Hormone Concentrations

Breed, gender, age, neuter status, body condition and physical activity are known to significantly affect thyroid hormone concentrations. Importantly, non-thyroidal illness and previous and ongoing drug therapies can alter results. Assay methodology may influence accuracy and credibility of the results obtained.

Assay Methodologies

Total Thyroid Hormone Assays

Total thyroid hormone assays measure circulating protein-bound and free concentrations. Radioimmunoassay (RIA) remains the standard reference technique for measurement of TT_4 and TT_3. Assays have evolved to include non-isotopic methods and the more research-utilized liquid chromatography-tandem mass spectrometry (HPLCMS). RIAs are less expensive and use smaller sample volumes but are subject to radiation restrictions and cannot be fully automated. Non-isotopic methods can be fully automated (preferred by commercial laboratories) or developed for in-house use. These methods use enzymes, chemiluminescence or fluorescence, rather than radioisotopes as signals. They can be quantitative (preferred) or semi-quantitative.

There is reasonable agreement across the different assay methodologies for TT_4 even when human RIAs are used, if modified to allow measurement of the lower concentrations found in dogs.[153-155] Different concentrations do occur with different assay types, emphasizing the need for method- and laboratory-specific reference intervals. Anecdotally, erroneous values are more likely with enzyme or fluorescence methods. Enzyme methods are considered least accurate.[156] TT_3 concentrations are similar in humans and dogs, such that assays designed for human use do not require modification.

Both TT_4 and TT_3 results can be affected by autoantibodies, which can falsely increase or decrease results, depending on the assay and separation systems used. Autoantibodies increase measured values with assay systems that use the antibody-bound hormone for estimating hormone concentrations, as with most of the commonly used TT_4 assay systems. When T_4AAs are present, the measured value may be within or above the reference interval. If the estimation of hormone concentration is based on the unbound hormone fraction, autoantibodies falsely decrease results. Some TT_3 assays are thus affected, with concentrations becoming undetectable.

There are few studies objectively assessing the effect of autoantibodies on test results. One study identified no difference in TT_4 concentrations estimated by chemiluminescence and HPLC (theoretically free from interference with autoantibodies) in dogs that were T_4AA positive with reference interval TT_4 concentrations.[157] However, only two such samples were evaluated and the thyroid status of each patient was unclear. Others suggest that TT_4 concentrations are below, within or above the reference interval in approximately 54%, 34% and 12% of T_4AA-positive hypothyroid dogs, respectively (PA Graham, personal communication). Increased and reference interval TT_4 results have been reported in several TgAA-positive, confirmed hypothyroid dogs.[158]

Free (Unbound) Hormone

Circulating FT_4 concentrations are similar in humans and dogs. As such, assays used for people can be employed without modification. Equilibrium dialysis and ultrafiltration-based methods are generally considered to be gold standards for measuring FT_4 concentration. Such methods involve separating the FT_4 fraction followed by its estimation using a highly sensitive RIA. These assays, used by large commercial laboratories, are laborious and expensive. However, accurate measurement of FT_4 concentration by other methods is controversial. The most frequently used assays use hormone analogs with molecular structures similar to T_4 and claim to be non-reactive with binding proteins, thus being able to compete with FT_4 within the sample. In humans, they are thought to merely estimate FT_4 concentrations, offering little advantage over TT_4 assays. Use of these assays is considered most problematic in accurately measuring FT_4 concentrations in patients with disorders associated with abnormal thyroid hormone binding proteins, non-thyroidal illness, high free fatty acid concentrations and thyroid hormone autoantibodies.[159]

In comparison to techniques using equilibrium dialysis, FT_4 concentrations in dogs are significantly lower using different direct FT_4 analog RIAs, particularly in patients with non-thyroidal illness.[160] The accuracy and agreement between direct chemiluminescent and equilibrium dialysis FT_4 assays have been reported as adequate or limiting.[161,162] However, combined measurement of TT_4 and FT_4 by analog methods adds little diagnostic information to assaying either alone, suggesting that the assays may not be measuring FT_4 concentrations.[163] These assays, like TT_4, are influenced by the presence of T_4AAs.[158]

Thyroid Stimulating Hormone (TSH) Assays

The assessment of TSH requires a species-specific assay. Canine-specific TSH (cTSH) chemiluminescent and

immunoradiometric assays are available and reasonably correlated.[164] These assays fail to detect low concentrations, which is less important in dogs with primary hypothyroidism as they should have increased cTSH results. However, this limitation can have implications when attempting to diagnose central hypothyroidism or when assessing overdose in thyroid hormone–treated dogs.

Thyroglobulin Autoantibody (TgAA) Assays

Species-specific assay methods for canine TgAA are commercially available. The assay has been modified to decrease nonspecific IgG binding, thereby reducing the rate of false-positive and equivocal results previously reported. The presence of T_3AAs and T_4AAs may be inferred if discordant total hormone results are detected in TgAA-positive dogs. They can also be specifically measured by some specialized laboratories.

Storage and Interferences

Most thyroid hormones and cTSH are relatively stable in storage. However, concentrations of FT_4 significantly increase if stored at room temperature for prolonged periods. Sample separation, refrigerated transport and expedient measurement are indicated. RIAs are generally resistant to the effects of hemolysis, lipemia and hyperbilirubinemia, but the same cannot be guaranteed with non-isotopic methods.[165] Severe lipemia may falsely increase FT_4 concentrations when measured by equilibrium dialysis.[166]

Physiologic Factors

Sample Timing, Age, Gender

Sample timing is not important, as a circadian rhythm for thyroid hormone secretion has not been identified in dogs. Episodic fluctuations occur that may cause spurious subnormal results.[167-169] TT_4 concentrations decline with age and may be below reference intervals in older dogs.[170] Conversely, dogs <3 months of age have values two to five times higher than adults. Gender and stage of estrus have been variably reported to affect thyroid hormone concentrations but are not clinically significant.

Breed and Exercise

Initial investigations suggested that thyroid hormone concentrations were lower in larger dogs, but these observations were likely breed-, not size-, related.[171] Sighthounds, for example, are known to have relatively low circulating thyroid hormone concentrations. Magnitude and hormones affected vary among breeds. TT_4 values below standard reference intervals are noted in about 90% of Greyhounds, 75% of Basenjis, 65% of Sloughis, 55% of Salukis, 25% of Whippets, but only 5% of Scottish Deerhounds.[172-177] In many, concentrations are so low (at or below limit of detection of assay) that a breed-specific reference interval cannot be calculated. Low TT_3 results are found in Salukis and Irish Wolfhounds, but not Greyhounds.[172,175,178] FT_4 concentrations can measure low in Greyhounds, Irish Wolfhounds, and Salukis, but not Whippets.[172,175,176,178] TT_4 concentrations are also low in the Dogue de Bordeaux and Giant Schnauzer.[171,179] TSH concentrations appear to be largely unaffected by breed. Intense training and exercise are associated with decreases in thyroid hormone concentrations, but brief exercise has little effect.[176,180-183]

Non-Thyroidal Illness

Illness can induce profound changes in thyroid hormone concentrations in people (Table 299-3). Previously dubbed "euthyroid sick syndrome," "low T_3 syndrome" and the "low T_4 state of medical illness," the term "non-thyroidal illness syndrome" is now used to describe changes in thyroid hormone concentrations secondary to acute and chronic illnesses. There are numerous potential mechanisms for this condition, including reduced peripheral conversion of T_4 to T_3, reduction in binding affinity of the thyroid hormone binding proteins, altered thyroid hormone metabolism, changes in thyroid hormone receptor expression or function, or altered hypothalamic/pituitary function. The most common abnormality associated with non-thyroidal illness syndrome in people is suppression of circulating TT_3 concentrations with TT_4 values remaining within reference intervals.[184] As diseases progress in severity, suppression of both T_3 and total T_4 occurs, and this is associated with a poorer outcome. FT_4 and TSH concentrations are less affected, but in severe illness suppression of both may be observed. Occasionally, transient increases in FT_4 are observed.

Circulating TSH values may increase during the recovery phase of illness.

TABLE 299-3

The Effect of Non-Thyroidal Illness on Serum Concentrations of Thyroid Hormones and Thyrotropin

SEVERITY OF ILLNESS	HORMONE			
	TOTAL T_3	TOTAL T_4	FREE T_4	TSH
Mild	↓	↔	↔	↔
Moderate	↓↓	↓	↔↓↑	↔↓
Severe	↓↓↓	↓↓	↔↓	↓↓
Recovery	↓↔	↓↔	↔↓	↑↔

T_3, Triiodothyronine; *T_4*, thyroxine; *TSH*, thyroid stimulating hormone (thyrotropin); ↓, concentrations decrease; ↔, concentrations remain the same; ↑, concentrations increase.

These effects are largely known for T_3 and T_4. In the case of TSH, data are extrapolated from humans. Most research concerning dogs has not implicated any effect of illness on TSH, but this is complicated because of the inability of the currently used assay to detect low and suppressed concentrations.

The number of arrows indicates increasing severity.

Decreased thyroid hormone concentrations have been reported in a wide variety of illnesses affecting numerous body systems.[185-197] Mechanisms have not yet been elucidated, but a preliminary study demonstrated decreases in transthyretin concentration, although likely to be of minor importance.[198] Recombinant interleukin-2 infusions have been shown to induce changes similar to those in non-thyroidal illness in experimental dogs.[199] In one comprehensive study of non-thyroidal illness in dogs, concurrent reductions in TT_3 and TT_4 followed sole reductions in TT_3. Isolated suppression of TT_4 was uncommon.[188] Greater decreases in TT_4 and TT_3 were associated with more severe illness and poorer prognosis.[186-188,200-202] FT_4 concentrations (by equilibrium dialysis) are typically maintained within reference intervals in all but the most severe illnesses[187,188] and in hyperadrenocorticism.[28,187,188] Occasionally, increases in FT_4 are noted, although poorly defined.[203,204] Understanding the influence of illness on cTSH concentrations is hampered by the poor sensitivity of current assays, as normal values cannot be distinguished from low values. Increases are known to occur in the recovery phase of illnesses.[203,204] Altered thyroid hormone concentrations should not be expected in minor illness and, if present, another explanation should be sought. Thyroid hormone concentrations are unaffected by osteoarthritis, recurrent seasonal flank alopecia, atopic dermatitis, or pyoderma.[205-208]

Drug Therapy

Several drugs are known to alter thyroid hormone concentrations, ranging from TT_4 alone to a state mimicking primary hypothyroidism (Table 299-4). Offending drugs include but are not confined to glucocorticoids, phenobarbital, aspirin, ketoprofen, carprofen, clomipramine and sulfonamide-containing antibiotics.[209-213] For many, dosage and duration of therapy dictate magnitude of effect. Sulfonamides require special mention, as they may induce hypothyroidism and even myxedema coma because of their ability to reversibly inhibit TPO.[214-218] About an additional 15% decrease in TT_4 concentration is expected in ill dogs being treated with thyroid-suppressive medications.[188] The effect of numerous other drugs has not been specifically evaluated in dogs, but they can be considered as affecting hormone concentrations until proven otherwise. Thyroid hormone concentrations normalize once drug therapy is withdrawn. For many drugs, including thyroxine, at least a 6-week withdrawal period is recommended before thyroid function testing, perhaps longer after sulfonamide treatment.[209,218,219]

TABLE 299-4

The Effect of Drug Therapy on Serum Concentrations of Thyroid Hormones and Thyrotropin

DRUG	HORMONE		
	TOTAL T_4	FREE T_4	TSH
Prednisone/prednisolone	↓↔	↓↔	↔↓
Phenobarbital	↓↔	↓↔	↔↑ (↓)*
Potassium bromide	↔	↔	↔
Sulfonamides	↓	↓	↑
Propranolol	↔	↔	↔
Clomipramine	↓	↓	↔
Aspirin	↓	↓↔	↔
Ketoprofen	↓	↔	↔
Carprofen	↓↔	↓↔	↔↓
Deracoxib	↔	↔	↔

*Phenobarbital has been associated with a significant increase in TSH concentrations. However, values rarely exceed the upper limit of the reference interval. The increase in TSH is unexpectedly low for the decrease in thyroid hormone concentrations and this may indicate a suppressive effect of this drug on TSH.

Diagnosis of Hypothyroidism: Basal Hormone Tests

Overview

The various diagnostic tests used in the investigation of hypothyroidism are summarized in Table 299-5.[36-38,189,194,220,221]

TABLE 299-5

The Diagnostic Performance of Thyroid Hormone Concentrations, Thyrotropin and Thyroglobulin Autoantibodies for Diagnosing Hypothyroidism

	TOTAL T_4	FREE T_4	TSH	TGAA
Sensitivity	89-100%	80-98%	58-87%	91-100%
Specificity	73-82%	78-94%	82-100%	94-100%

T_4, Thyroxine; *TgAA,* thyroglobulin autoantibodies; *TSH,* thyroid-stimulating hormone (thyrotropin).

Data compiled from references 36-38, 189, 192, 194, 220, 221.

TT_3 Concentrations

Measurement of TT_3 is of limited value for diagnosing hypothyroidism due to its low sensitivity. TT_3 values are maintained within or above reference intervals in up to 90% of hypothyroid dogs.[192] These findings may be related to enhanced secretion of T_3 from the thyroid gland or peripheral conversion from T_4 as thyroid function declines. This is of potential short-term benefit to the individual, as T_3 is the more potent of the active thyroid hormones. Depending on the assay system used, the presence of T_3AAs may also play a role by falsely increasing measured concentrations. T_3AAs are present in >5% of samples from dogs suspected of having hypothyroidism.[34] While this seems small, T_3AAs are present in >40% of TgAA-positive hypothyroid

dogs.[42] Specificity of TT_3 for diagnosing hypothyroidism is also poor. Low values are common in certain breeds, in association with non-thyroidal illness, and with administration of various drugs. The only value of measuring TT_3 is in breeds such as the Greyhound, known to have low TT_4 but to maintain TT_3 concentrations within reference intervals.[172]

TT_4 Concentrations

Circulating TT_4 concentrations are decreased in most hypothyroid dogs. Its diagnostic sensitivity is excellent and it is frequently recommended as a screening test. Results within reference intervals are often used for ruling out hypothyroidism, but T_4AAs can falsely increase results. T_4AAs are present in <2% of samples from dogs suspected of having hypothyroidism, but the number of dogs with T_4AAs increases to 14% among TgAA-positive hypothyroid dogs.[34,42] This decreases diagnostic sensitivity and means hypothyroidism cannot be ruled out by either a reference interval or increased TT_4 result. An even greater concern of relying solely on TT_4 is its poor specificity due to the myriad non-thyroidal factors that result in decreased concentrations in euthyroid animals. These include breed, age, non-thyroidal illness and drug therapies. TT_4 should never be used as the sole diagnostic test for hypothyroidism in dogs.[175]

FT_4 Concentrations

FT_4 values are below reference intervals in most hypothyroid dogs. It is unclear why a small proportion of hypothyroid dogs has results in the low end of the reference range, but this decreases diagnostic sensitivity. However, FT_4 concentrations (by equilibrium dialysis) are less affected than TT_4 by extrathyroidal factors. Thus, its diagnostic specificity for hypothyroidism is high. Measurement of FT_4 is, therefore, considered the single most accurate test for diagnosing hypothyroidism.[220]

cTSH Concentrations

cTSH concentrations are expected to be increased in dogs with primary hypothyroidism due to a lack of thyroid hormone negative feedback. However, the cTSH assay has only moderate sensitivity as a diagnostic test because results from a significant proportion of hypothyroid dogs are within reference intervals. Perhaps a proportion of hypothyroid dogs have central rather than thyroid-mediated disease, but this is unlikely given that values are often within reference intervals rather than decreased or at the limit of detection of the assay. Random fluctuation of cTSH within reference intervals has been demonstrated to occur in hypothyroid dogs but is an unlikely explanation for all of the low values encountered.[222,223]

There is evidence from experimental studies that pituitary secretion of TSH decreases with chronic hypothyroidism, presumably as a result of TRH-receptor desensitization. Such a phenomenon could occur in the naturally occurring disease.[108,139-141] While this may be a plausible explanation for reference interval cTSH values in some hypothyroid dogs, it could be argued that few have disease spanning the time period necessary to induce such changes. It is possible that high cTSH values are suppressed in hypothyroidism because of concurrent non-thyroidal illness or drug therapies.[220] It has also been suggested that current assays do not measure all possible isomers of cTSH. Although diagnostic sensitivity of this test is poor, measurement of cTSH concentration offers relatively good diagnostic specificity. High results are less commonly encountered in euthyroid dogs, as cTSH is largely unaffected by non-thyroidal illness or drugs, with the exception of sulfonamides. High values are, however, a feature of silent and subclinical hypothyroidism.[42]

Thyroglobulin Autoantibodies (TgAA)

Positive TgAA results are associated with lymphocytic thyroiditis but may be present in the circulation long before a dog becomes clinically hypothyroid.[42] As such, TgAAs provide no information on thyroid function. TgAA positivity, uncommon in dogs with non-thyroidal illness, is suggestive of underlying pathology.[38,43,224] A positive TgAA does, indirectly, support a diagnosis of hypothyroidism.

Basal Hormone Tests in the Context of Clinical Information

As discussed, less than ideal sensitivity and specificity of the tests available create difficulties in reliably confirming a diagnosis of hypothyroidism, and this diagnosis should never rely solely on test results. Rather,

testing should be carried out on dogs likely to have the disease: those of appropriate signalment with supportive clinical and clinicopathological features having significant non-thyroidal illness excluded and with no history of recent thyroid suppressive medication (Figure 299-3). Then, a combination of tests with high sensitivity/low specificity and high specificity/low sensitivity should be selected, which reduces their weaknesses. Use of TT_4 with cTSH offers the most cost-effective and widely available combination. FT_4 can be reserved for dogs whose TT_4 is likely to be affected by concurrent illnesses or drug therapies. Measurement of TgAA serves as a screen for the potential influence of T_4AA and also provides information on pathogenesis.

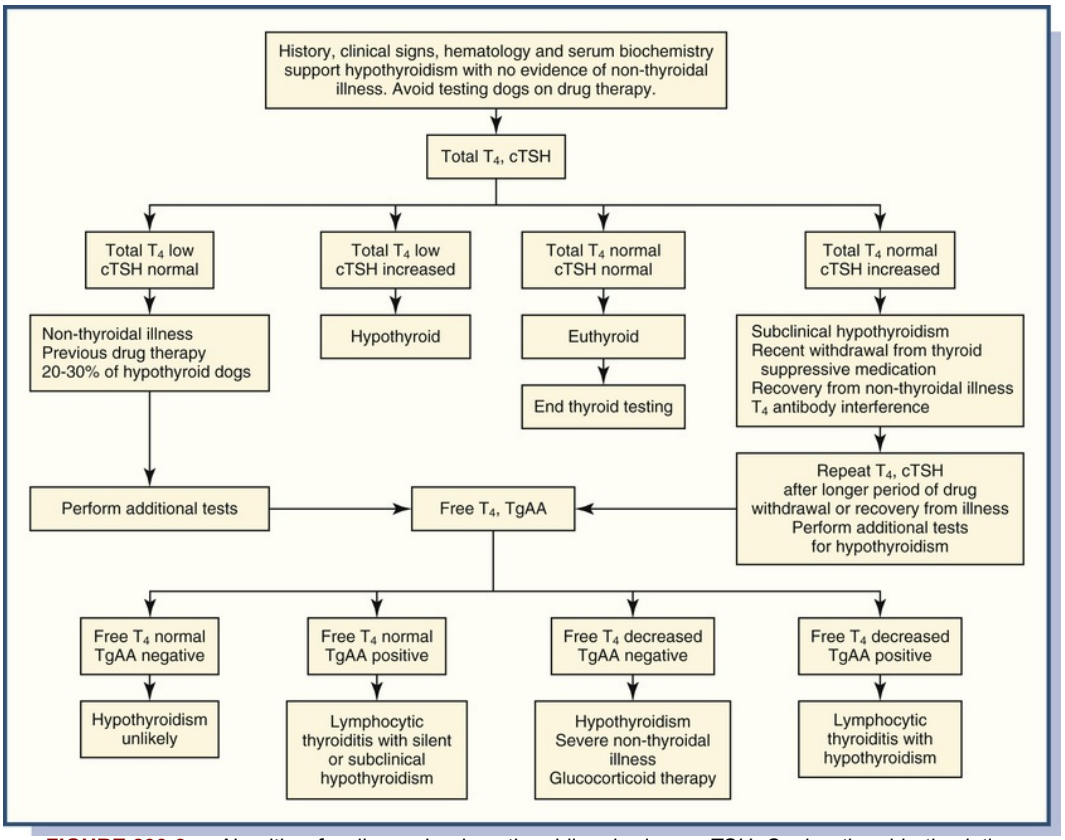

FIGURE 299-3 Algorithm for diagnosing hypothyroidism in dogs. *cTSH,* Canine thyroid stimulating hormone; *T4,* thyroxine; *TgAA,* thyroglobulin autoantibody. (From Mooney CT: Canine hypothyroidism. A review of the aetiology and diagnosis. *N Z Vet J* 59:105-114, 2011.)

Diagnosis of Hypothyroidism: Use of Stimulation (Provocative) Tests

Indications

The TSH and TRH stimulation tests previously were routinely recommended as aids for confirming a diagnosis of hypothyroidism. Provocative testing should now be reserved for dogs whose diagnosis cannot be confirmed using clinical signs and basal tests. Stimulation tests may also be used for evaluating test performance when a reliable and independent method of differentiating hypo- from euthyroidism is required.

TSH Stimulation

The TSH stimulation test was considered the "gold standard" for diagnosing canine hypothyroidism. In early studies, bovine TSH, no longer available, was used. Comparable results are obtained using human recombinant (rh) TSH.[225] Recommended IV dosages include 50 to 75 mcg per dog or 100 mcg for dogs >20 kg, with samples taken before and 6 hours after administration.[226-228] A 150-mcg per-dog dose has been suggested to more accurately distinguish hypothyroidism from non-thyroidal illness.[229] Unlike bovine TSH, adverse reactions have not been reported, even with repeated administrations. Reconstituted rhTSH can be

stored at 4°C for 4 weeks or −20°C for up to 12 weeks without loss of biological value, allowing multiuse from one vial, and reducing cost.[227,230] Criteria for interpretation vary.[231] Generally, euthyroid dogs increase their TT_4 concentration >1.5 times the basal level with an absolute value >30 nmol/L. Hypothyroid dogs show minimal stimulation, with a post-TSH TT_4 <20 mmol/L. Some dogs have results that do not fall into either category and are difficult to interpret.

TRH Stimulation

The TRH response test, whereby TT_4 concentration is measured before and after TRH administration, was once recommended as a useful alternative to TSH stimulation. Unfortunately, the TRH response test is considerably less reliable than most of the other currently available baseline tests. At best, a good response to TRH can confidently exclude hypothyroidism. However, the lack of T_4 response to TRH is not confirmatory of hypothyroidism, being a common finding in a wide variety of non-thyroidal illnesses, in dogs receiving certain medications, and in health.[232]

The cTSH response to TRH can be assessed.[140] Low dosages (10 mcg/kg) of TRH cause peak pituitary stimulation about 20 minutes after IV administration, while minimizing side-effects. Humans with primary hypothyroidism exhibit an exaggerated and prolonged TSH response to TRH. However, while there is limited TSH response to TRH in hypothyroid dogs, the test adds little to information gained from basal thyroid hormone analyses.[233] TRH stimulation is largely confined to research studies.

Diagnostic Imaging

Overview

Thyroid imaging is a well-established tool for investigating cats with hyperthyroidism and dogs with thyroid neoplasia.[234,235] Theoretically less affected by non-thyroidal illness or drugs, interpretation of certain imaging techniques is similar to that of TgAA. Thus, imaging can provide information on gross appearance rather than thyroid function.

Ultrasonography (US)

Each thyroid lobe is usually described as fusiform in longitudinal section, triangular in cross section, having a smooth capsule, and an echogenicity that is homogeneous and isoechoic or hyperechoic compared to the adjacent sternothyroid muscle in healthy dogs and dogs with non-thyroidal illness. Thyroid lobes of hypothyroid dogs display significantly less echogenicity, are not homogeneous but irregular in outline, are small, and more rounded.[185,236,237] Any of these changes may be present in hypothyroid dogs, and appearance of the lobes may differ. However, there may be differences in thyroid US results depending on breed.[238] In addition, results of thyroid US is dependent on operator skill, experience and opinion.

Advanced Imaging

CT and MRI of thyroid lobes in healthy dogs have been described.[239,240] Comparisons with hypothyroid dogs are not yet published. Given their expense and need for anesthesia, advanced imaging has limited usefulness.

Technetium-99M Scans

Use of technetium-99M (as pertechnetate ($^{99M}TcO_4^-$) for quantitative calculation of thyroid gland uptake (TCTU) has been suggested as the most accurate technique for distinguishing dogs with primary hypothyroidism from those with non-thyroidal illness.[241] Uptake values in hypothyroid dogs range from 0.03-0.26% and in euthyroid animals with low total T_4 concentrations from 0.39-1.86%. However, these marked differences are not uniformly accepted, as glucocorticoids in particular appear capable of decreasing TCTU, producing equivocal results.[242] In people, altered radioisotope uptake has been described in association with several non-thyroidal illnesses and medications. The scintigraphic appearance of inflammatory thyroid disease is variable. However, evaluation of TCTU has shown promise in confirming euthyroidism in Greyhounds, in investigating central hypothyroidism and in differentiating dysgenesis from dyshormonogenesis in congenital hypothyroidism.[235,243]

Treatment

Background

Hypothyroid dogs require thyroid hormone replacement therapy (THRT) for life. "Natural" or desiccated thyroid extracts are crude and unreliable compared to synthetic products, which are more predictable and have a longer shelf life. Synthetic T_4 is the treatment of choice as it is the principal secretory product of the thyroid gland and is the physiologic prohormone for the more metabolically active T_3. Administration of T_3 circumvents this normal physiological process, increasing the risk of thyrotoxicosis. Since T_3 has a shorter half-life, it must be given several times a day and may cause T_4 deficiency in the brain and pituitary gland, although the consequences of this are unclear. Products containing a combination of T_4 and T_3 used in humans are not recommended for dogs as the ratio is inappropriate, resulting in excess T_3. T_4 is widely available as generic and licensed proprietary forms and both tablet and liquid formulations for oral administration.

T_4 Supplementation

Dosage

The total daily secretion of T_4 in dogs has been estimated to be about 2.5 mcg/kg.[244] However, when this amount of T_4 is given IV or SC to thyroparathyroidectomized dogs, circulating concentrations remain severely low.[245] An IV dosage four times greater is needed to normalize T_4 concentrations, and even higher oral dosages are required. The oral requirement can be explained because GI absorption of T_4 is estimated to be only 10 to 50% of that given orally. But the reasons for a high IV dosage requirement are unknown.[244] Poor GI absorption is presumably related to intraluminal contents, dietary factors and intestinal bacteria that bind T_4 and reduce its availability. The bioavailability of T_4 is almost halved when administered with food.[246] This does not imply that all dogs should be fasted prior to T_4 administration; instead, the temporal association between feeding and oral dosing must be standardized in each animal, particularly on the day of monitoring. Varying dietary components could have an effect on T_4 absorption. Therefore, providing a consistent diet is recommended.[247] Bioavailability will also vary depending on the T_4 product used. Greater variation in bioavailability occurs with generic products but can also occur with proprietary products.[248] The bioavailability of an oral liquid formulation was approximately twice that of a tablet in one study but was comparable using different products in another, indicating that not all products can be used interchangeably.[246,249]

Frequency

The pharmacokinetics of T_4 are similar in hypothyroid and healthy dogs.[250] When administered orally (either once or twice daily), T_4 is rapidly absorbed, peak concentrations are achieved at about 3 to 5 hours, and the serum half-life is usually 9 to 15 hours.[246,250,251] Higher dosages are associated with shorter half-lives, suggesting a degree of dose-dependent kinetics.[251] In a large number of hypothyroid dogs, peak T_4 concentrations were noted about 4 to 6 hours after administration.[248] Steady-state concentrations are quickly established, allowing early evaluation of efficacy (e.g., within two weeks) after initiating therapy.[246]

The optimum dosage and frequency of administration of T_4 for hypothyroid dogs remain somewhat controversial. Total daily doses ranging from 0.02 to 0.04 mg/kg BW and given once, twice or three times daily have been recommended. Most published studies have evaluated the use of 0.02 mg/kg administered once daily, on the premise that the serum half-life of T_4 does not necessarily reflect its biological effect.[55,252,253] This regimen has been successful, although an increase in dosage is required by about 35% of dogs.[253] This percentage can be lowered depending on the T_4 preparation used and by ensuring consistency with feeding times.[252] The number of dogs requiring a dosage reduction with this protocol is about 6-10%. Twice-daily dosing is associated with lower peak concentrations and less fluctuation in circulating TT_4.[248] Twice-daily dosing of 20 mcg/kg has also been used successfully but may not be superior to once daily. There are no reports evaluating the number of dogs in which dosage adjustments are required using twice-daily dosing. It

is important to note that the effect of a given dose of T_4 varies with each individual. Thus, clinical, clinicopathological and hormonal monitoring is critically important in determining each dog's T_4 dosage and frequency. This may require several adjustments. A practical advantage of once-daily dosing could be related to greater owner compliance, as therapy is lifelong.

Clinical Response

Adequately treated hypothyroid dogs should have no clinical signs of disease, remembering that improvement can take weeks to months to become apparent. Generally, metabolic changes such as dullness and lethargy are first to improve within days of commencing therapy and an expected 10% loss of weight occurs within the first few months. Dermatological improvements are expected within a month of commencing treatment but can take 2-3 months to normalize, often with a phase of increased hair loss preceding hair regrowth. Improvement in neurological signs may take as long as 6 months.[254]

Clinicopathologic Response

Normalization of the clinicopathologic abnormalities associated with hypothyroidism occur broadly in parallel with the clinical response.[253] Serum cholesterol and triglyceride values often decrease dramatically, while red blood cell values increase progressively during the first 3 months of THRT. Fructosamine concentration decreases significantly, as protein turnover increases.[147,253] THRT rapidly reverses hypothyroid-induced changes in adiponectin, leptin and glomerular filtration rate.[115,255]

Monitoring

Therapeutic monitoring is aimed primarily at understanding owner satisfaction with response to treatment, together with identifying the peak circulating TT_4 concentration. Successful response in dogs treated once daily is associated with a median peak TT_4 concentration (6 hours after administration) of approximately 4 mcg/dL (50 nmol/L).[55,253] Values below 2.7 mcg/dL (35 nmol/L) are usually associated with an inadequate clinical response, and an increase in dosage is indicated. Markedly increased peak TT_4 concentrations >7 mcg/dL (>90 nmol/L) occasionally occur. Although dogs are usually resistant to severe clinical thyrotoxicosis, such values should prompt a decreased dosage. Using twice-daily dosing, TT_4 values should be at the high end or just above the reference interval 4-6 hours after administration and remain within the reference interval prior to the next dose. In general terms, doubling the T_4 dose administered increases peak circulating TT_4 concentrations by about 50 to 60% because of bioavailability issues and dose-dependent pharmacokinetics.[248,251] While this can be used to select the exact magnitude of a dosage alteration, it is more usually dictated by the next available tablet size when tablets are used. More accurate dosage adjustment may be possible using the liquid formulation.

Measurement of cTSH provides a longer-term assessment of the adequacy of treatment, unlike TT_4, which only provides information concerning treatment on that particular day.[253] Measurement of cTSH assists in identification of poor owner compliance where a particular effort to administer the medication is made on days corresponding to the monitoring visit. Unfortunately, in the hypothyroid dogs that did not have increased pretreatment cTSH values, measurement during THRT is of no value. Additionally, circulating cTSH can be highly sensitive to the effects of THRT, such that suppression of cTSH may be achieved without achieving optional clinical control. The limitations of the current cTSH assay do not allow identification of oversupplementation.

Overdose

Dogs appear to be particularly resistant to the thyrotoxic effects of excessive T_4 supplementation.[252,253] Some dogs require up to 20 times the standard dosage of T_4 to induce clinical thyrotoxicosis. Clinical signs of thyrotoxicosis include polydipsia, polyuria, polyphagia, panting, weight loss, hyperactivity, tachycardia and hyperthermia. Most signs should resolve within a few days of withdrawing therapy. Corresponding TT_4 concentrations are usually >7 mcg/dL (>90 nmol/L). The development of thyrotoxicosis has been reported in one dog because of the consumption of feces from a supplemented housemate.[256]

Gradual Introduction of T_4 Supplementation

Gradual introduction of supplementation (25-50% of starting dose) has been recommended in dogs with concurrent illnesses such as cardiac disease, hypoadrenocorticism and diabetes mellitus. However, using a once-daily dose of 20 mcg/kg was not associated with adverse effects in dogs with such disorders, conferring another advantage to this regimen.[253]

Failure to Respond

A failure to respond to therapy usually arises because of a failure to achieve appropriate circulating thyroid hormone concentrations and usually responds to dosage adjustment. However, the use of T_3 may be required in dogs with concurrent GI disease and impaired T_4 absorption. Failure to achieve the expected clinical response when thyroid hormone concentrations are adequate should prompt investigation of another underlying disease process. Daily but not every-other-day antiinflammatory doses of prednisolone in treated hypothyroid dogs decrease TT_4 concentrations; however, dosage adjustments are not required as FT_4 concentrations remain unaffected.[257]

Myxedema

Myxedema coma is associated with a significant reduction in metabolic rate and, potentially, hypovolemia/dehydration. Neither oral nor SC/IM routes of administration are adequate, at least initially. In these dogs, T_4 should be administered IV at a dosage of 5 mcg/kg q 12 h. Once stabilized, oral administration can be substituted. Resolution of abnormal mentation, ambulation and systolic hypotension should be expected within 30 hours.[86,88]

Anecdotal Treatments

T_4, potentially, has numerous pharmacological effects unrelated to its physiological effects when supplemented in thyroid-deficient states. As a consequence there are anecdotal but rarely proven accounts of the use of T_4 in various clinical situations including the use of T_4 to improve coat condition.[58] THRT has been used in dogs with owner-directed aggression and borderline low thyroid hormone concentrations without any significant effect.[258] In humans, T_4 treatment of patients with non-thyroidal illness syndrome is controversial and there is limited persuasive evidence that it improves outcome with the possible exception of patients with cardiac disease.[184] In dogs, the addition of T_4 to standard therapy for congestive heart failure due to myocardial failure does not improve survival compared to placebo (see ch. 133).[259] Equally, T_4 supplementation does not alter the development of cardiac complications of chronic doxorubicin treatment in dogs.[260]

Prognosis

Overall the prognosis for hypothyroid dogs is excellent.

CHAPTER 300

Feline Hypothyroidism

Sylvie Daminet

Client Information Sheet: Feline Hypothyroidism

Etiology

Overview

Iatrogenic, congenital and spontaneous naturally occurring adult-onset hypothyroidism have been described in cats. Practitioners are most likely to be confronted with *iatrogenic* hypothyroidism. The potential impact of iatrogenic hypothyroidism on renal function merits particular attention. Although a few well-documented cases of *congenital* feline hypothyroidism have been reported, *spontaneous* adult-onset feline hypothyroidism has been only rarely recognized.

Iatrogenic Hypothyroidism

Iatrogenic hypothyroidism is a well-recognized consequence of treating cats for hyperthyroidism (see ch. 301). It can result from an overdose of anti-thyroid drug administration, bilateral thyroidectomy or radioactive iodine (^{131}I) therapy. Unilateral thyroidectomy may result in transient hypothyroidism. Anti-thyroid drug administration commonly leads to serum total thyroxine (TT_4) concentrations below the reference range, often without clinical signs, perhaps because total tri-iodothyronine (TT_3) concentrations (the active hormone) are usually normal.

Hyperthyroidism, usually caused by autonomously functioning abnormal thyroid tissue, chronically suppresses endogenous thyroid stimulating hormone (TSH) release from the pituitary, ultimately leading to atrophy of normal thyroid tissue. After treating hyperthyroidism with ^{131}I (see ch. 301), the combination of destroying cells that were previously over-active together with the slow recovery of hormone production from atrophied "normal" thyroid tissue can lead to a period of transient hypothyroidism. This simple explanation for the pathogenesis of iatrogenic hypothyroidism is similar to the transient hypothyroidism that follows surgery or even medical treatment. Once the TT_4 decreases in a cat that was hyperthyroid, TSH concentrations should increase. TSH, in turn, stimulates atrophied thyroid cells to function. Following ^{131}I treatment or after thyroidectomy, a transient period of iatrogenic hypothyroidism is common.[2] Hyperthyroid cats with normal renal function and transient hypothyroidism after treatment do not usually have clinical signs of hypothyroidism and do not need hormone supplementation. Administration of thyroid medication will actually delay the recovery of atrophied cells. The incidence of post-radioactive iodine hypothyroidism likely depends, at least in part, on dosage of ^{131}I administered, length of follow-up and the criteria used to define low thyroid function. Thus, the reported incidence varies from as uncommon as 5% to as common as 83%.[2,3] Cats with scintigraphic uptake by both lobes on a pertechnetate scan appear predisposed to development of hypothyroidism after treatment with ^{131}I.[3]

Congenital Hypothyroidism

In general, congenital primary hypothyroidism can be divided into two main categories: *thyroid dyshormonogenesis* (a defect in the biosynthesis of thyroid hormones) and *thyroid dysmorphogenesis* (a defect in anatomic thyroid development, usually described as hypoplasia or aplasia). Both forms in people are likely due to an inherited, autosomal recessive, genetic defect. Dyshormonogenesis is a condition of decreased

synthesis of thyroid hormone, decreased negative feedback to the pituitary (and hypothalamus), increased TSH secretion, thyroid gland hyperplasia, and thyroid gland enlargement (goiter). Dyshormonogenesis associated with defective thyroid peroxidase activity and impaired iodine organification has been described in related domestic shorthair and Abyssinian cats.[4,5] Dysmorphogenesis does not cause thyroid enlargement and has been documented in related cats, whose condition is consistent with an autosomal recessive mode of inheritance.[6] Hypothyroidism secondary to TSH resistance has been suggested in a family of Japanese cats.[7] Hypothalamic or pituitary deficiencies, with secondary congenital hypothyroidism (central hypothyroidism), have not yet been reported in cats.

Adult-Onset Hypothyroidism

Only a few well-documented cats with *spontaneous* (naturally occurring) acquired primary hypothyroidism have been described.[8-10] Histopathologic features of their thyroid glands have been diverse. They include marked lymphocytic infiltration, idiopathic atrophy, and diffuse hyperplastic goiter. Secondary hypothyroidism due to head trauma has been reported.[11]

Clinical Manifestations

Overview

The most common clinical manifestations of iatrogenic, congenital and adult acquired forms of feline hypothyroidism are outlined in Table 300-1 and illustrated in Figure 300-1, *A* and *B* and Video 300-1. Although many signs of hypothyroidism in cats are similar to those considered typical in hypothyroid dogs (see ch. 299), there are differences. For example, few hypothyroid cats, regardless of etiology, develop severe bilaterally symmetrical, non-pruritic alopecia. Inappetence and profound mental dullness are frequently seen. Kittens with congenital hypothyroidism can develop severe constipation.

TABLE 300-1

The Most Important Clinical Features Observed with Iatrogenic, Congenital and Naturally Occurring Adult-Onset Hypothyroidism in Cats

	IATROGENIC HYPOTHYROIDISM	CONGENITAL HYPOTHYROIDISM	NATURALLY OCCURRING ADULT-ONSET
Lethargy	+	+ (May include mental dullness)	+ (May include mental dullness)
Weight gain or obesity	+	+	+
Inappetence	+	+	+*
Constipation	+	+* (May include megacolon)	+
Goiter	− or +	Possible	−
Disproportionate dwarfism	−	+*	−
Delayed closure of growth plates (radiographically)	−	+*	−
Dermatological signs (especially seborrhea and easy to epilate)	+	+	+*

*Indicates this is a key feature.

Clinical features can be mild or severe.

+, Usually present; −, absent.

From Mooney CT, Peterson ME, editors: *Manual of canine and feline endocrinology*, ed 3, Gloucestershire, England, 2011, British Small Animal Veterinary Association, pp 111-115.

FIGURE 300-1 **A,** This 5-year-old male neutered Devon Rex had a history of lethargy, mental dullness and inappetence. The cat also had diabetes mellitus. This cat had low TT_4 serum values, as well as an increased cTSH, confirming primary hypothyroidism. This cat also had a seborrheic hair coat that was easily epilated. Note the bilateral ceruminous otitis. **B,** Same patient as in **A,** one year before onset of clinical signs of hypothyroidism. (Photograph from E. Mercier and S. Daminet.)

Adult-Onset Hypothyroidism (Iatrogenic and Spontaneous)

Lethargy, inappetence and skin changes are common clinical signs and may be severe. Dermatologic signs are characterized by a dull, dry, unkempt haircoat (with possible matting) and seborrhea sicca. Alopecia of the pinnae can develop in some cats. The hair coat is easily epilated and poor regrowth after clipping is possible. Hypothermia and bradycardia are occasionally noted on physical examination. In naturally occurring adult hypothyroidism, signs are often pronounced, perhaps as a result of the profession's low index of suspicion. Thus, the condition is not recognized until it is severe. A puffy face, presumably resulting from myxedema, was reported in one cat.[8]

Congenital Hypothyroidism

Many of the signs observed in adult-onset hypothyroidism can also be seen in affected kittens. Since thyroid hormone is essential for normal post-natal skeletal and nervous system development, kittens with congenital hypothyroidism have striking disproportionate dwarfism and neurologic abnormalities. Affected kittens usually appear normal at birth. Their delayed growth, as compared with littermates, usually becomes evident by 2 month of age and their disproportionate dwarfism develops over the following months. Signs include a large broad head, small ears, a round body, short neck and short limbs. Affected kittens seem mentally dull. They may suffer from severe recurrent episodes of constipation. Sometimes, dullness and retarded growth may go unrecognized by the owners, who present their cat because of recurrent constipation. Seizures were reported as a major problem in two littermates with congenital hypothyroidism.[6] Affected cats have hair coats covering their entire body, but their hair is mainly undercoat with few guard hairs. The teeth are underdeveloped and delays in tooth eruption and replacement of deciduous teeth are common. On physical examination, hypothermia, bradycardia and sometimes palpable goiter (with organification defects) may be detected.

Survival of untreated affected kittens depends largely on the etiology of the congenital hypothyroidism. It is likely that many affected kittens die undiagnosed as part of the "fading kitten syndrome." Affected kittens can die within a few months, while those with partial defects in peroxidase activity can live to adulthood without ever displaying obvious clinical signs of the disease.

Diagnosis

Overview

Diagnosis of feline hypothyroidism can be challenging, regardless of underlying cause. As in dogs, a presumptive diagnosis can be made based on a combination of compatible clinical features and abnormalities noted on routine laboratory test results (anemia and hypercholesterolemia). Confirming a diagnosis of hypothyroidism requires hormone testing or thyroid scintigraphy. Even cats with *iatrogenic hypothyroidism* present a few diagnostic pitfalls despite their recent history of being treated for hyperthyroidism. As geriatric individuals, concomitant conditions are common (e.g., chronic kidney disease), potentially causing the so-

called "euthyroid sick syndrome" (see ch. 299). Also misleading to an owner or veterinarian can be reduced activity and/or weight gain post-therapy. On one hand, these changes are expected as hyperthyroidism resolves. But, on the other hand, they may represent illness or hypothyroidism. Thus, the clinical signs of iatrogenic hypothyroidism and those expected with return to a euthyroid status can somewhat overlap.

Therapy for Hyperadrenocorticism Causing Hypothyroidism or Azotemia

After therapy with ^{131}I, many cats develop a marked but transient decrease in TT_4 to below normal followed by a return to euthyroidism within 3 to 6 months. In most treated hyperthyroid cats with normal renal function, their transient hypothyroidism is not clinically significant and does not need to be treated. It is advisable to wait 3 to 6 months after therapy with ^{131}I before making a diagnosis of *permanent* iatrogenic hypothyroidism, especially if clinical signs of hypothyroidism are not convincing and the cat remains non-azotemic.

There is potential for serious negative impact of hypothyroidism on renal function (see ch. 301), especially in cats with a pre-existing renal condition.[1,12,13] Cats with iatrogenic hypothyroidism (following ^{131}I or thyroidectomy) and azotemia should be treated with L-thyroxine supplementation without delay, because it should enhance glomerular filtration rate, improve renal function, and reduce the severity of azotemia. If a hyperthyroid cat becomes azotemic while receiving anti-thyroid medication, its dosage should be tapered or discontinued. Iatrogenic hypothyroidism has been shown to worsen azotemia and shorten life expectancy in cats with pre-existing chronic kidney disease (CKD).[1] Administration of L-thyroxine immediately following hospitalization after ^{131}I treatment is recommended.[14] Preliminary results in hyperthyroid cats with CKD IRIS stage 2 or 3 suggest the benefit of treating iatrogenic hypothyroidism to avoid worsening azotemia.[14] Also, a protocol using ultra-low dosages of ^{131}I (1-2 mCi) was effective in restoring euthyroidism without inducing iatrogenic hypothyroidism (3%) in mildly hyperthyroid cats with small thyroid nodules.[15]

Spontaneous (Congenital and Adult-Onset) Hypothyroidism

Spontaneous (congenital and adult-onset) hypothyroidism is probably underdiagnosed, but remains rare. Kittens often appear normal at birth and the onset of typical features such as disproportionate dwarfism is often delayed. Some kittens die early or could be misdiagnosed as having idiopathic megacolon or some other congenital condition.

Routine Clinicopathological Features

The incidence of mild normochromic normocytic anemia and/or hypercholesterolemia in hypothyroid cats is not known, but they are observed most frequently in cats with the iatrogenic condition. In congenital hypothyroidism, these changes are inconsistent.[6]

Hormone Concentrations (Figure 300-2)

Total Thyroxine (TT_4)

Low circulating TT_4 concentrations are expected in any hypothyroid cat. A TT_4 result within reference intervals strongly supports euthyroidism and strongly refutes hypothyroidism as a concern. As in dogs, however, TT_4 can be suppressed by non-thyroidal illnesses and the more severe the condition, the lower the TT_4 concentration. Therefore, a decrease in TT_4 concentration is sensitive but nonspecific and should not be considered diagnostic of hypothyroidism. In addition, a variety of drugs has been shown to significantly suppress TT_4 concentrations in dogs.[17] This has not yet been investigated in cats. Because the diagnosis of primary spontaneous hypothyroidism should not be based solely on basal TT_4 results, serum canine TSH (cTSH) measurement, recombinant human TSH (rhTSH) response test or thyroid scintigraphy is indicated to confirm the disease.

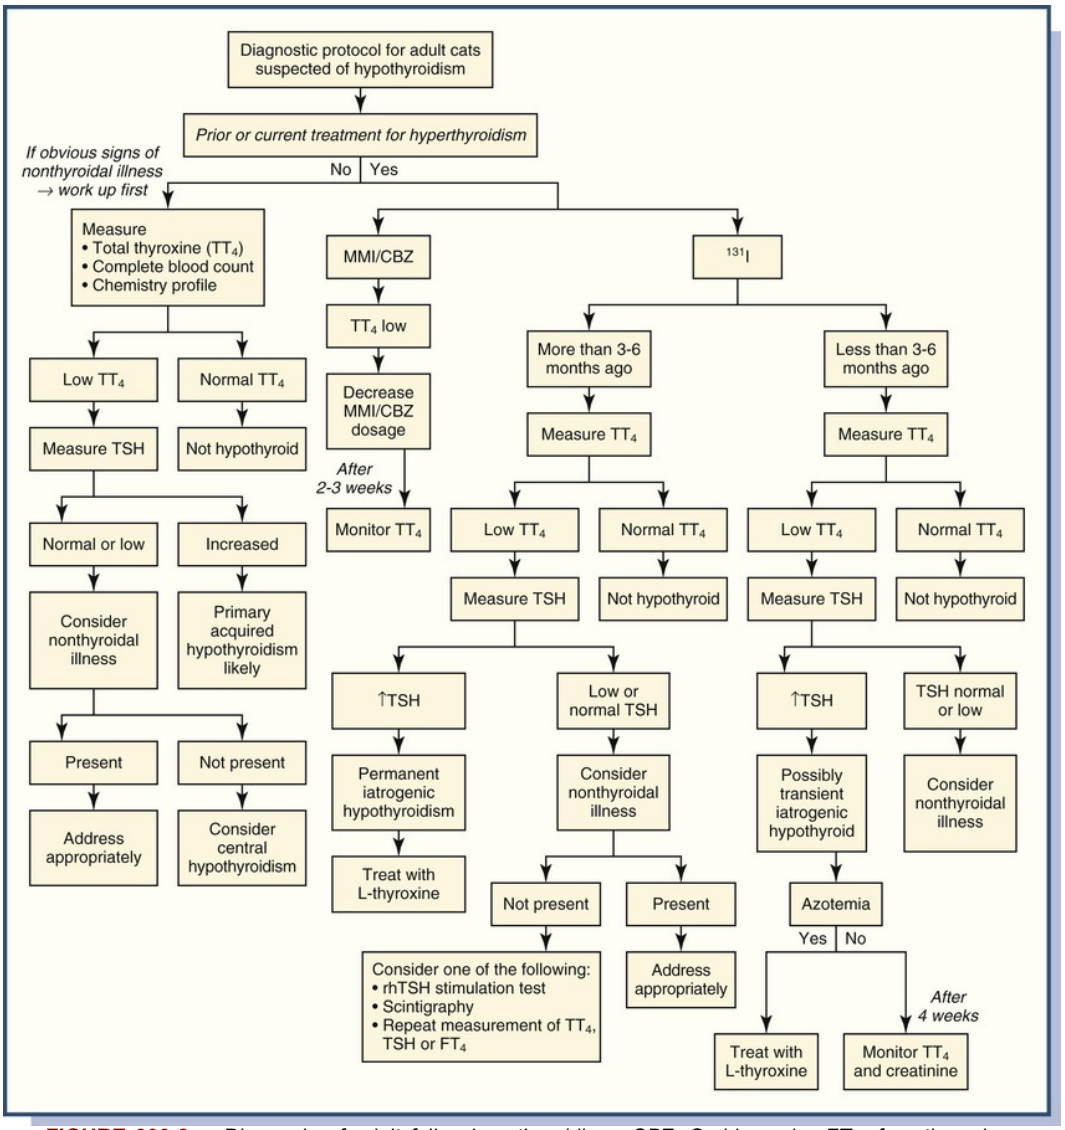

FIGURE 300-2 Diagnosis of adult feline hypothyroidism. *CBZ,* Carbimazole; *FT_4,* free thyroxine; *MMI,* methimazole; *rhTSH,* recombinant human thyroid stimulating hormone; *T_4,* thyroxine; *TSH,* thyroid stimulating hormone.

Free Thyroxine (FT_4)

In contrast to dogs, the benefit of measuring FT_4 as compared with that of TT_4 as diagnostic aids for cats is unclear. Decreased values for FT_4 (after equilibrium dialysis) are expected in hypothyroid cats, but also in the presence of non-thyroidal illness. In one report, however, increased FT_4 concentrations were noted in euthyroid cats with non-thyroidal illness.[16,18]

Endogenous Thyrotropin (TSH)

In dogs with hypothyroidism, an increased serum TSH concentration may confirm primary (located within the thyroid gland) hypothyroidism. A specific assay for feline TSH measurement is not yet available. However, the use of the canine immunoradiometric assay has been described in cats.[19] An increased cTSH concentration was observed in two cats with primary adult-onset hypothyroidism.[9,10] Cats with iatrogenic hypothyroidism should also have increased serum cTSH concentrations.[1,20,21] Use of cTSH (and hopefully feline TSH in the near future) should be helpful in discriminating congenital primary from secondary hypothyroidism (TSH deficiency).

Dynamic Thyroid Function Testing

The rhTSH response test has been described in cats to distinguish non-thyroidal illness from iatrogenic hypothyroidism following ^{131}I therapy.[22] Although evaluated in a limited number of cats, it appears to be a valuable alternative to bovine TSH for stimulation testing. To perform the rhTSH stimulation test in cats, a blood sample is collected for basal TT_4 measurement. Then, 25 mcg rhTSH is administered IV and finally a second blood sample is taken 6 hours later. rhTSH is available as Thyrogen (Genzyme Corporation, The Netherlands) and vials can be aliquoted and stored frozen as previously described to make this test more affordable.[22,23]

Diagnostic Imaging

Radiography

As in dogs (see ch. 299), radiography can be particularly useful in recognizing congenital hypothyroidism. Many of the changes observed are virtually pathognomonic. Radiographs demonstrate retarded skeletal development particularly epiphyseal dysgenesis of vertebral bodies and long bones.

Thyroid Scintigraphy

Uptake of technetium as pertechnetate (99m $TcO4^-$) by thyroid lobes is both sensitive and specific for the diagnosis of canine hypothyroidism or feline hyperthyroidism (see ch. 301) and holds promise for becoming an important tool for diagnosing feline hypothyroidism. It might be especially useful in cats in whom the diagnosis is in doubt, such as in cats with concomitant disease (euthyroid sick syndrome). The expected finding in adult-onset hypothyroidism is a reduction or absence of uptake of 99m $TcO4^-$ by the thyroid glands (Figure 300-3, *A* and *B*). Thyroid scintigraphy was used as a non-invasive technique to confirm the diagnosis of spontaneous hypothyroidism in one cat.[9]

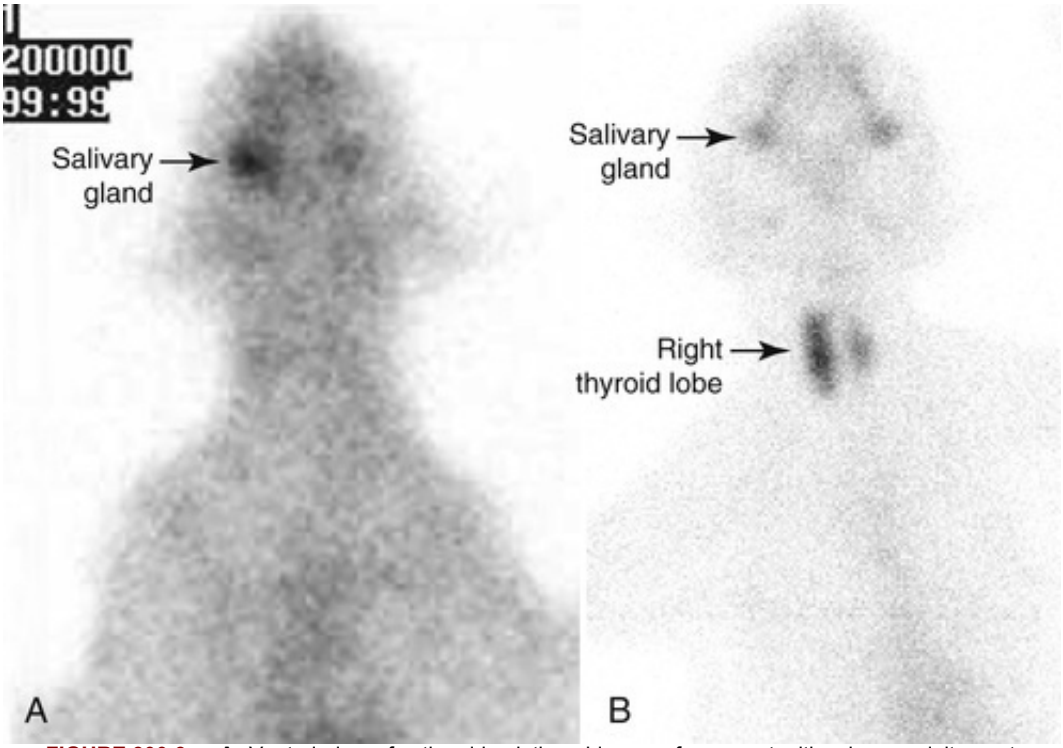

FIGURE 300-3 **A,** Ventral view of a thyroid scintigraphic scan from a cat with primary adult onset hypothyroidism. Note the uptake of pertechnetate in the salivary glands (arrow), and the absence of uptake in the cervical (thyroid) region. **B,** For illustration purposes, this figure shows the increased uptake of pertechnetate visible in the thyroid glands of a hyperthyroid cat. (Images from K. Peremans.)

Further, scintigraphy with ^{123}I can be a helpful diagnostic tool to clarify the underlying mechanism in

congenital hypothyroidism. In cases of dysmorphogenesis, an absence of uptake of ^{123}I is expected. Uptake of ^{123}I may be normal in cases with a thyroid peroxidase deficiency. However, organification (incorporation of iodine) is deficient and abnormal discharge of ^{123}I is observed after administration of perchlorate (perchlorate discharge test).

Practitioners have often used trial therapy with levothyroxine as a diagnostic tool for hypothyroidism. Unfortunately, positive response to treatment does not mean the cat is truly hypothyroid. Combining TT_4 and cTSH measurements is likely to be the most efficient and economic method for diagnosing primary hypothyroidism. When results are equivocal, further diagnostic tests such as rhTSH stimulation test or scintigraphy should be considered before initiating trial therapy with levothyroxine.

Treatment

Although pharmacokinetic data are only available in healthy cats, recommended oral dosages for thyroxine supplementation vary between 100 mcg per cat q 24 h and 10 to 20 mcg/kg q 24 h. Recent preliminary data suggest that twice daily treatment (0.075 mg q 12 h) on an empty stomach might be most efficacious.[24] As in dogs, affected cats should be re-evaluated after 4 to 8 weeks. Further adjustment of therapy should be based on clinical response and post-pill total T_4 therapeutic monitoring. With appropriate therapy, the prognosis is excellent in acquired hypothyroidism. For congenital hypothyroidism, the prognosis is guarded and will largely depend on the underlying etiology of the hypothyroidism and age at diagnosis.

CHAPTER 301

Feline Hyperthyroidism

Thomas K. Graves

Client Information Sheet: Feline Hyperthyroidism

Since its first description in the veterinary literature only 35 years ago, hyperthyroidism has become the most common endocrine disease of domestic cats and one of the most important diseases in feline practice. There are various prevalence estimates of the disease in North America and Europe indicating that the incidence of the condition appears to be increasing.[1-3] The overall prevalence of feline hyperthyroidism (FHT) is 2% to 4% and at least 6% in cats >9 years of age. By some estimates nearly 10% of geriatric cats will develop FHT.

Pathophysiology

Human Hyperthyroid Conditions (Graves' Disease and Toxic Nodular Goiter)

Thyroid hormones control the body's metabolic rate (thyroid physiology is reviewed in ch. 299). Increase in systemic thyroid hormone concentrations leads to a hypermetabolic state responsible for the abnormalities seen in hyperthyroidism. In people with Graves' disease, the most common form of hyperthyroidism, the condition is the result of autoantibodies activating thyrotropin (TSH) receptors which, in turn, leads to excess synthesis and secretion of thyroid hormone. Evidence of an immune-mediated cause has not been identified in cats, whose thyroid condition is often considered analogous to human toxic nodular goiter (Plummer's disease).[4,5] Toxic nodular goiter and FHT share some histopathologic features. Both are caused by adenomatous hyperplasia of thyroid tissue leading to nodules that secrete thyroid hormone autonomously, escaping control by the hypothalamus and pituitary gland. These nodules rarely demonstrate characteristics of malignancy and are considered benign endocrine tumors. Although there is some controversy in the literature, Plummer's disease is thought to be caused by activated mutations in the TSH receptor or its downstream signaling molecules, leading to high constitutive secretion of thyroid hormone.[6]

Feline Hyperthyroidism

There are conflicting results in the literature, but TSH receptor mutations have been identified in some hyperthyroid cats, as have mutations in the cAMP-activating G protein alpha subunit.[7,8] Decreases in expression of inhibitory G proteins have also been demonstrated in feline goiters, which could decrease the ability to inhibit cAMP production resulting in sustained secretion of excess thyroid hormone.[9] This is likely one of many factors that may contribute to development of FHT. There have been several studies implicating goitrogens in food. Certain types of canned cat food have been implicated in a few epidemiologic studies of FHT and this association continues to be studied.[10,11] It has been suggested that widely disparate concentrations of iodine in commercial cat foods could be responsible for varying levels of TSH stimulation and development of thyroid nodules in cats.[11]

The presence of polybrominated diphenyl ethers (PBDEs) in canned food and in the cat's indoor environment have also been suggested to play a role in the etiopathogenesis of FHT.[12,13] PBDEs are used as flame retardants in any number of household products and can be highly concentrated in house dust ingested by cats during self-grooming. Thyroid disruption caused by PBDEs is postulated to lead to chronic and excessive TSH secretion, which could have a hypertrophic effect on the thyroid gland and eventually result in adenomatous hyperplasia or neoplasia. An association between PBDEs and FHT has not been proven, in part

due to lack of a reliable feline TSH assay and difficulties of studying effects of endocrine disruptors over the lifespans of cats.

Unilateral and Bilateral Thyroid Disease and Histology

Hyperfunctioning thyroid nodules in cats most commonly affect both thyroid gland lobes. Unilateral disease is found in less than a third of cases.[14] Bilateral asymmetric disease occurs in >50% of cats with FHT. Ectopic disease is relatively uncommon, occurring in about 4% of cats. A small percentage of cats with FHT has been diagnosed as having a functional thyroid adenocarcinoma.[14-16] Incidence of thyroid carcinoma has been estimated to be 1-2%, but this is questionable because histology is not often available in afflicted cats.

Clinical Features

Signalment

The largest surveys of clinical findings in cats with FHT were published decades ago.[17-19] Veterinarians have progressively become more aware and better at diagnosing the disease. Thus, some previously published clinical descriptions are no longer commonly encountered.[17-19] FHT is a disease of middle-aged and older cats with no clear breed or sex predilection. In our review of 160 cats with FHT seen at the University of Illinois, the mean age at diagnosis (12.5 years) agrees with earlier reports suggesting 12 to 13 years with a range from 4 to 20 years of age.[17-19]

History (Clinical Signs)

Common

The clinical signs of FHT are variable, reflecting the generalized and multi-systemic nature of the disease. Because of its high prevalence, routine screening with basal serum thyroid hormone testing in middle-aged and older cats is common. FHT diagnosis is often made in cats with subtle (or absent) clinical signs. Common clinical signs (Table 301-1) include weight loss, increased appetite, hyperactivity, vomiting, diarrhea, polyuria/polydipsia, poor grooming, and behavioral changes. Any combination of clinical signs and varying degrees of severity are common. Weight loss is the most common sign of FHT. Afflicted cats are often in poor body condition and have a generally unkempt appearance. Despite their age, cats with FHT may appear hyperactive, aggressive, or exhibit signs of anxiety. Impaired stress tolerance and panting are common.

TABLE 301-1

Percentage of Each Clinical Finding Among Hyperthyroid Cats

HISTORICAL FINDINGS		PHYSICAL EXAM FINDINGS	
Weight loss	88%	Goiter	83%
Polyphagia	49%	Thin	65%
Vomiting	44%	Heart murmur	54%
PU/PD	36%	Tachycardia	42%
Hyperactivity	31%	Gallop	15%
Decreased appetite	16%	Aggression	15%
Diarrhea	15%	Unkempt	9%
Lethargy	12%	Increased nails	6%
Weakness	12%	Alopecia	3%
Dyspnea	10%	CHF	2%
Panting	9%	Neck ventroflexion	1%
Large fecal volume	8%		
Anorexia	7%		

CHF, Congestive heart failure; *PU/PD,* polyuria/polydipsia.

From Broussard JD, Peterson ME, Fox PR: Changes in clinical and laboratory findings in cats with hyperthyroidism from 1983 to 1993. *J Am Vet Med Assoc* 206:302, 1995.

Uncommon

While hyperactivity and increased appetites are common, a small percentage of FHT cats are lethargic, obtunded and have poor appetites. This uncommon condition is referred to as "apathetic" hyperthyroidism. In people, apathetic hyperthyroidism, also termed asymptomatic hyperthyroidism, occurs mainly in the elderly in association with concurrent diseases and/or therapies that cause the lethargy and decreased appetite.[20,21] However, this condition has been described in younger patients.[22] The mechanism of apathetic FHT has not been established. An association between underlying disease states and apathetic FHT has not been published.

Thyroid Palpation

One or more thyroid nodules are usually palpable in FHT. Differing techniques for palpating the feline thyroid gland have been described. The most common and successful technique is performed by placing the cat in a sitting position and extending the head to expose the ventral neck (Figure 301-1, Video 301-1). While holding the cat's head and neck in extension with one hand, the thumb and forefinger of the other hand are slid with moderate pressure from the larynx caudally to the thoracic inlet several times in a slow sweeping motion. Enlargement of the thyroid gland will be felt as a slip of nodular tissue passing under the fingertip. Nodules may be felt on one or both sides of the trachea. This method of palpation is well-tolerated by most cats. Ventral cervical nodules are also palpable in many non-hyperthyroid cats.[23,24] In one study, palpable ventral cervical nodules were present in nearly 70% of euthyroid cats suspected of having FHT.[25] The clinical significance, if any, of these nodules is unknown. In some cats, they may represent non-functional benign adenomas of thyroid or parathyroid origin.[23] Such nodules may or may not progress to endocrine disease. While cats with FHT tend to have larger palpable goiters than those without the disease, no clear relationship between thyroid palpation and functional activity of the feline thyroid gland has been established.

FIGURE 301-1 Proper technique for palpation of the feline thyroid gland. Note that the distal thumb

and forefinger should be extended to provide as much contact with the surface of the cat's ventral neck as possible.

General Examination

Many of the signs described by owners are also obvious on physical examination. Some cats with FHT are periodically or persistently resistant to restraint. Use of an open basket may relax some cats with FHT, allowing a more thorough examination (see ch. 2). Strong or firm restraint of any cat is not recommended, but can result in severe signs in cats with FHT. Weight loss, the most common clinical sign, can be associated with decreased skin elasticity. These cats are not usually dehydrated but can be easily over-loaded if mistakenly thought to be in need of fluid therapy.

Cardiovascular System

The Heart

Systolic heart murmurs, tachycardia, and gallop rhythm are common in cats with FHT, occurring in 54%, 42% and 15%, respectively. Overt congestive heart failure is diagnosed in about 2% of cats with FHT. Thyroid hormone, mainly tri-iodothyronine (T3), has a wide range of cardiac effects.[26] Thyroid hormone has a positive chronotropic effect, causes shorter atrioventricular conduction times, and upregulates myocardial beta-adrenergic receptors. The positive inotropic effects of thyroid hormone (both T3 and thyroxine [T4]) are due to alterations in ion channel activities and enhanced activities of cardiac myosin isoenzymes. Myocardial hypertrophy is common in cats with FHT and is due to increased expression of myocardial proteins and, perhaps, to concurrent hypertensive myocardial hypertrophy.

Blood Pressure

The association between FHT and hypertension is somewhat tenuous. Recognizing hypertension in cats with FHT is not straightforward. Blood pressure measurements are fairly reliable in healthy cats using either oscillometry or Doppler ultrasonography (see ch. 99). Both correlate well with intra-arterial measurements.[27,28] The "white coat effect" is not always recognized in cats, but it may be more pronounced in the stress-intolerant cat with FHT. Initially, prevalence of hypertension in cat with FHT was thought to be high. One publication identified a prevalence of 87%, but their definition of "hypertension" may have been unrealistically low.[29] While the study was well-controlled, with FHT cats being compared to normal cats and to cats with chronic kidney disease (CKD), later reports identified prevalence rates of 5% and 20%.[30,31] Significant "white coat effect" in cats with FHT has been demonstrated, with no decrease in blood pressure after treatment.[30] Interestingly, an increased occurrence of hypertension in cats was seen after being treated for FHT.[31]

Hypertension occurs rarely in hyperthyroid people, and when associated with thyrotoxicosis, the hypertension is usually systolic only. Thyroid hormone causes pronounced decrease in peripheral vascular resistance. Hemodynamic effects of thyrotoxicosis include increased heart rate and increased stroke volume. It has been proposed that increased heart rates cause summation of pressures in peripheral arteries resulting in overall systolic hypertension.[32] Whether or not this also occurs in cats with FHT is not known. Cats with FHT have been reported to have diastolic hypertension, possibly related to underlying CKD. Furthermore, beta-adrenergic blockers are effective in treating hyperthyroid people with systolic hypertension, but the effect of atenolol on hypertension in FHT cats is inconsistent.[33] It is difficult to know if FHT causes hypertension. There is an association between the two, but cause and effect has not been established and hypertension may not be common. In one study, only 5 of 30 cats with hypertension had FHT.[34] In a study of cats with hypertensive retinopathy, only 5 of 69 cats were hyperthyroid.[35]

Urinary System

Polyuria and polydipsia (PU/PD) are seen in more than a third of FHT cats and several mechanisms may explain this effect. Hyperthyroid people have exaggerated thirst responses to small changes in plasma osmolarity as compared with euthyroid subjects. This led investigators to propose primary polydipsia as a cause of polyuria in hyperthyroidism.[36] Thyroid hormone–associated down-regulation of aquaporin water channels in the renal tubules and increased tubular solute excretion have also been implicated as possible

causes of primary polyuria in hyperthyroidism.[37] Neither mechanism has been examined in cats with FHT, but either or both could have roles.

Thyroid hormones affect a wide range of physiologic processes taking place in the kidneys.[38-40] Because thyroid hormone affects cardiac output and peripheral vascular tone, thyroid hormone impacts renal blood flow and glomerular function. The concept of increased renal blood flow in FHT is supported by thyroid hormone–induced decrease in systemic vascular resistance causing relaxation of smooth muscle within capillaries. Also, relaxation of smooth muscle follows action of local vasodilators, increased responsiveness to acetylcholine, and decreased response to endothelin.

In the renal cortex, thyroid hormone excess is accompanied by increased nitric oxide synthase activity (causing increased vasodilation), increased numbers of beta-adrenergic receptors, and decreased vascular resistance. These may lead to activation of the renin-angiotensin-aldosterone system. Decreased afferent arteriolar resistance and increased hydrostatic pressure lead to increases in glomerular filtration rate. There are also multiple effects of thyroid hormone on renal tubular function, including upregulation of chloride channels and enhanced reabsorption of chloride ion in proximal tubules and the loop of Henle. This, in turn, decreases the chloride load sensed in the macula densa of the distal tubule, increases tubuloglomerular feedback, and increases glomerular filtration. Excess thyroid hormone increases sodium-potassium ATPase activity and sodium-hydrogen exchange, leading to enhanced Na+/Ca++ exchange and tubular re-absorption of calcium ion. An association between hyperthyroidism and mild hypercalcemia, while not documented in cats, has been recognized for many decades in thyrotoxic people. The opposite, hypocalcemia, has been reported in FHT cats.[41,42] Thyroid hormone decreases serum creatinine concentrations by increasing its tubular secretion, increasing GFR, and decreasing skeletal muscle mass. Serum creatinine, derived from the breakdown of creatinine and phosphocreatine in muscle, is inversely proportional to muscle mass. Despite mechanisms that could lower serum creatinine concentrations in FHT cats, roughly 25% are azotemic at the time of diagnosis. While increased serum urea nitrogen was noted in 26% and creatinine in 23% of cats with FHT, these findings likely reflect the reality of both conditions being common in cats.[18]

Gastrointestinal System

Vomiting and diarrhea are common in cats with FHT (see Table 301-1). Vomiting in non-pregnant thyrotoxic people is uncommon and thought to be caused by thyroid hormone stimulating the chemoreceptor trigger zone or related to gastric stasis.[43,44] The mechanism of hyperemesis in FHT is not clear. Thyrotoxicosis changes small intestinal muscular contractions, increases intestinal motility, and markedly decreases mouth-to-cecum transit times, contributing to the diarrhea common in hyperthyroidism.[45,46]

Routine Diagnostic Evaluation

Urinalysis

There are no urinalysis findings that are specific for FHT. However, FHT cats are often isosthenuric, as previously discussed. Because FHT cats may have concurrent CKD, diabetes mellitus, or a myriad of other conditions, urinalysis is essential (see ch. 72).

Complete Blood Count

Mild erythrocytosis is noted in about half the cats with FHT. Because "anemia of chronic disease" is expected in older sick cats, a high-normal or slightly increased hematocrit should alert the clinician to consider FHT even if serum thyroid hormone concentrations are normal. Increased cellular oxygen demand is an established mechanism of thyroid hormone-erythropoietin-induced erythropoiesis in hyperthyroidism.[47,48] Thyroid hormone may also act directly on the bone marrow. Eosinopenia and lymphopenia are additional complete blood count (CBC) abnormalities in FHT cats, occurring in 34% and 40%, respectively.[18]

Serum Biochemistry

Increased liver enzyme activity is common in hyperthyroid cats.[17-19] More than 80% of cats with FHT have increased alanine aminotransferase activities and more than half have increased alkaline phosphatase activities. The causes for these changes are multifactorial and are likely related to metabolic hepatic stress, passive congestion, direct toxicity of thyroid hormone, and other factors. About one fourth of hyperthyroid

cats are azotemic at the time of diagnosis. Some of this can be pre-renal, but concurrent renal disease is common.

Confirming the Diagnosis

Total and Free Thyroxine (tT4, fT4), T3, and Thyroid Stimulating Hormone (TSH) Assays (Figures 301-2 and 301-3)

Blood Tests Available and Use of Total T4 as a Screening Test

Thyroid hormone assays, including assays for total thyroxine (tT4), total tri-iodothyronine (tT3), and, to a lesser extent, free T4 (fT4), are widely available. Serum thyrotropin (TSH) measurement is not widely used cats, but may be of value. Measurement of basal serum concentrations of tT3 is not of diagnostic value because of the large degree of overlap between normal cats, FHT cats, and cats with non-thyroidal illness.[49,50] The most commonly used screening test is measuring the serum tT4 concentration. A result above reference intervals confirms the diagnosis in more than 91% of FHT cats.[50]

FIGURE 301-2 Daily fluctuation of serum total T4 concentrations in a cat with hyperthyroidism over a period of 15 days. Fluctuation into the normal range (shaded area) may explain the phenomenon of occult hyperthyroidism in some cats. (Data from Peterson ME, Graves TK, Cavanagh I: Serum thyroid hormone concentrations fluctuate in cats with hyperthyroidism. *J Vet Intern Med* 1:142, 1987.)

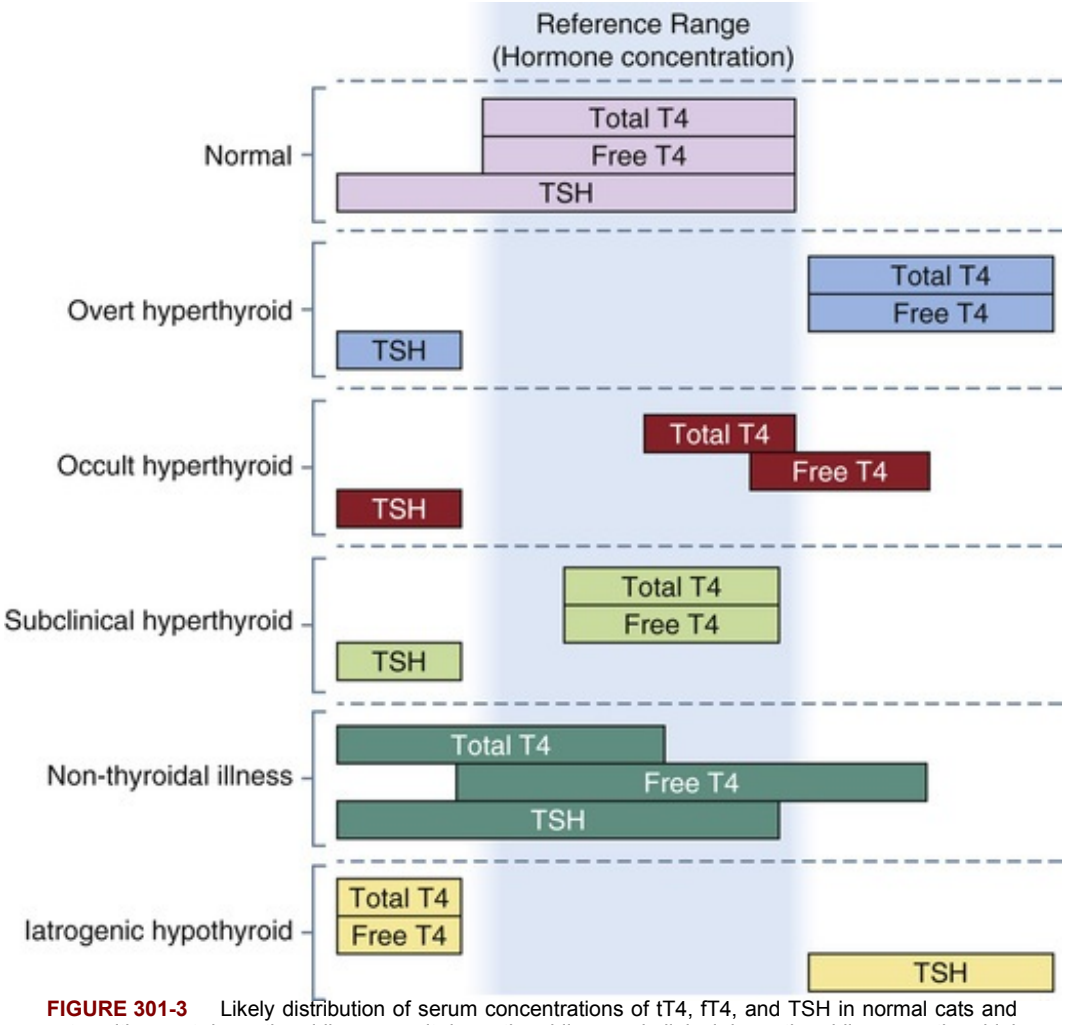

FIGURE 301-3 Likely distribution of serum concentrations of tT4, fT4, and TSH in normal cats and cats with overt hyperthyroidism, occult hyperthyroidism, subclinical hyperthyroidism, nonthyroidal illness, and iatrogenic hypothyroidism. The normal reference ranges for all three hormones are represented by the shaded area. (Based on data published in references 3, 50, 51, 52, 53, 54, 55, and 57.)

tT4 within Reference Limits?

Finding a normal serum tT4 concentration does not exclude the diagnosis of FHT. A relatively high number of hyperthyroid cats have normal or high-normal serum basal tT4 results, a phenomenon referred to as "occult hyperthyroidism" with several possible explanations. First, thyroid hormones fluctuate from day to day in FHT.[51] Even cats with severe FHT have tT4 concentrations that occasionally decrease into reference ranges for a few days at a time (Figure 301-2). Therefore, the simplest approach to a cat strongly suspected to have FHT but in which the tT4 concentration is normal is to simply recheck the tT4 on another day. Another possible explanation for the finding of normal serum tT4 concentration in a cat with FHT is presence of non-thyroidal illness (Table 301-2). Almost any concurrent disease can lower serum tT4 concentrations, causing false negative test results in FHT.

TABLE 301-2

Mean Serum Total Thyroxine (tT4) Concentrations in Normal Cats and Cats with Various Nonthyroidal Illnesses

DISEASE	MEAN TOTAL T4
Diabetes mellitus	4 nmol/L

Hepatic disease	8 nmol/L
Chronic kidney disease (CKD)	10 nmol/L
Systemic neoplasia	12 nmol/L
Congestive heart failure	11 nmol/L
Inflammatory bowel disease	18 nmol/L
Inflammatory airway disease	14 nmol/L
Focal neoplasia	16 nmol/L
Normal cats	**24 nmol/L**

From Peterson ME, Gamble DE: Effect of nonthyroidal illness on serum thyroxine concentrations in cats: 494 cases (1988). *J Am Vet Med Assoc* 197:1203, 1990.

Free T4 (fT4)

fT4 represents the small fraction of tT4 not bound to serum proteins. fT4, therefore, is available for conversion to T3 (the active hormone). Diagnosis of FHT can be confirmed by measuring serum concentrations of fT4, provided that the assay is validated for cats. fT4 has a high sensitivity for FHT, being positive in more than 98% of cats with FHT.[50] Possibly more important is the finding that serum fT4 concentrations are increased in 95% of cats with occult hyperthyroidism.[50] Even though the sensitivity of fT4 appears to be higher than that of tT4, it is not recommended as a first-line diagnostic screening test for FHT because of its poor specificity and its poor positive predictive value. As many as 12% of cats with non-thyroidal disease have increased serum concentrations of fT4, indicating that a given fT4 measurement only be interpreted in context of the clinical signs and results of the urinalysis, CBC, serum chemistry profile and tT4.[49,52]

In addition to its lower specificity, fT4 assays tend to be expensive and assay methodologies can be controversial. There are various types of assays for fT4 and correct assay methods should be used. Basically, there are two general types of fT4 assays. In the one-step assay, fT4 is measured in plasma or serum in the presence of protein-bound T4. In two-step assays, techniques such as dialysis or ultracentrifugation are used to separate the fT4 from the sample in the first step, and then a highly sensitive fT4 assay is used. While the equilibrium dialysis method of assaying fT4 is valid, published studies to support the recommendation that only this type of assay be used are lacking.

Combined Use of Total and Free T4

Although one study indicated that combining serum tT4 and fT4 did not improve diagnostic accuracy of either test used alone,[53] the combination may still be of use in individuals. Cats with non-thyroidal illness and an increased fT4 are expected to have a low serum tT4 concentration and cats with occult FHT are expected to have an increased fT4 and a normal or high-normal tT4. However, tT4 concentrations below the mid-point of reference ranges have been reported in cats with occult FHT.[51]

Serum TSH

In one series of cats with both FHT and CKD, serum TSH concentrations were low in all cats.[54] TSH values have been used to describe "subclinical hyperthyroidism" in cats as well.[3,55] In subclinical FHT, basal serum thyroid hormone concentrations, including fT4, are normal, while serum TSH is low. Cats with this constellation of hormone results have an increased likelihood for histologic evidence of nodular hyperplasia and/or adenoma of the thyroid gland.[55] These cats are more likely to develop FHT within a shorter time-frame than cats with normal serum TSH concentrations.[3] However, reliable assays for feline TSH measurement are not widely available. Canine TSH assays have been used, but when using recombinant feline TSH, the canine assay detects ≤40% of feline TSH, making low concentrations difficult to interpret.[56] Finding an increased serum TSH result may be more useful because it can indicate iatrogenic hypothyroidism following treatment of hyperthyroidism.[57]

T3 Suppression Testing

Indications

In cats with clinical signs of FHT but with equivocal basal thyroid hormone results, T3 suppression testing can be used.[58,59] FHT cats have autonomously functioning thyroid nodules that secrete thyroid hormone independent of pituitary control. As such, pituitary TSH secretion is expected to be chronically suppressed. In normal cats, administration of exogenous T3 suppresses pituitary TSH secretion and subsequently causes a drop in the serum concentration of tT4. In cats with FHT, however, administration of exogenous T3 has little or no effect on serum tT4 concentrations. The T3 suppression test reliably differentiates cats with occult hyperthyroidism from cats with normal thyroid function. The test takes 2 days and 2 hospital visits for blood collection and may be inconvenient.

Protocol and Interpretation

Blood is collected, serum separated, and stored frozen or refrigerated before giving 7 doses of T3 (liothyronine sodium, Cytomel, Pfizer, New York, NY). Beginning the day after initial blood sampling, T3 is administered (25 mcg/cat PO q 8 h for 2 days). On the morning of day 3, the cat is given its seventh dose of T3 and then returned to the clinic for post-T3 blood sampling. Both the pre- and post-T3 samples are assayed for tT4 and tT3 on the same assays to mitigate intra-assay variation. If owners were successful in administering T3, the serum concentration of tT3 is higher in the second sample (the only reason tT3 is measured). In healthy cats, serum concentrations of tT4 are suppressed by exogenous T3, whereas in FHT cats, decreases in serum tT4 are either blunted or absent. There is little or no overlap between post-T3 serum tT4 concentrations comparing euthyroid and hyperthyroid cats. The T3 suppression test can be valuable for diagnosing FHT in cats with normal basal thyroid hormone test results.

Thyrotropin-Releasing Hormone Stimulation Testing

When administered IV to healthy cats, TRH causes consistent increases in serum tT4 concentrations, usually about twofold. In FHT cats, the post-TRH rise is either blunted or absent, potentially making the test a useful tool for diagnosis of occult FHT.[60] This test is performed by measuring serum tT4 concentrations before and 4 hours after IV TRH (0.1 mg/kg); normal cats exhibit >60% increase in tT4. tT4 increases in cats with FHT are <50%.[60] While this test may be of use in diagnosing FHT in cats with normal resting serum tT4 concentrations, it has significant drawbacks. While available in some countries, commercial TRH was removed from the U.S. market in 2002 and laboratory-grade TRH cannot be recommended for clinical patients.[61] One report suggested limited diagnostic accuracy of the TRH stimulation test in cats with concurrent illness, a group that may include cats with the occult form of FHT.[62] Administration of TRH often causes severe cholinergic and central nervous system–mediated reactions.[63-66] Within seconds of being given TRH, cats often exhibit transient but severe salivation, tachypnea, micturition, nausea, vomiting and diarrhea.

Thyroid Scintigraphy

Thyroid gland uptake of pertechnetate or radioactive iodine is extremely sensitive for diagnosing FHT.[67] Either thyroid pertechnetate uptake or thyroid-to-salivary ratio can be calculated. Both correlate strongly with hyperthyroxinemia. The use of these tests is limited by their availability. In a recent large-scale study of thyroid scintigraphy results in FHT, nearly 99% had a thyroid-to-salivary ratio of >1.5 versus healthy cats' ratio of <1 (Figure 301-4). Thyroid-to-background ratio is less sensitive than the thyroid-to-salivary ratio. Because these tests require sophisticated facilities, sedation, and injection of a radioactive agent, thyroid scintigraphy is not commonly used to confirm a diagnosis of FHT. Its greatest value may be in the pre-surgical evaluation of cats undergoing thyroidectomy because it can be used to identify unilateral versus bilateral disease, ectopic disease, intrathoracic disease, and can raise the index of suspicion for thyroid carcinoma.

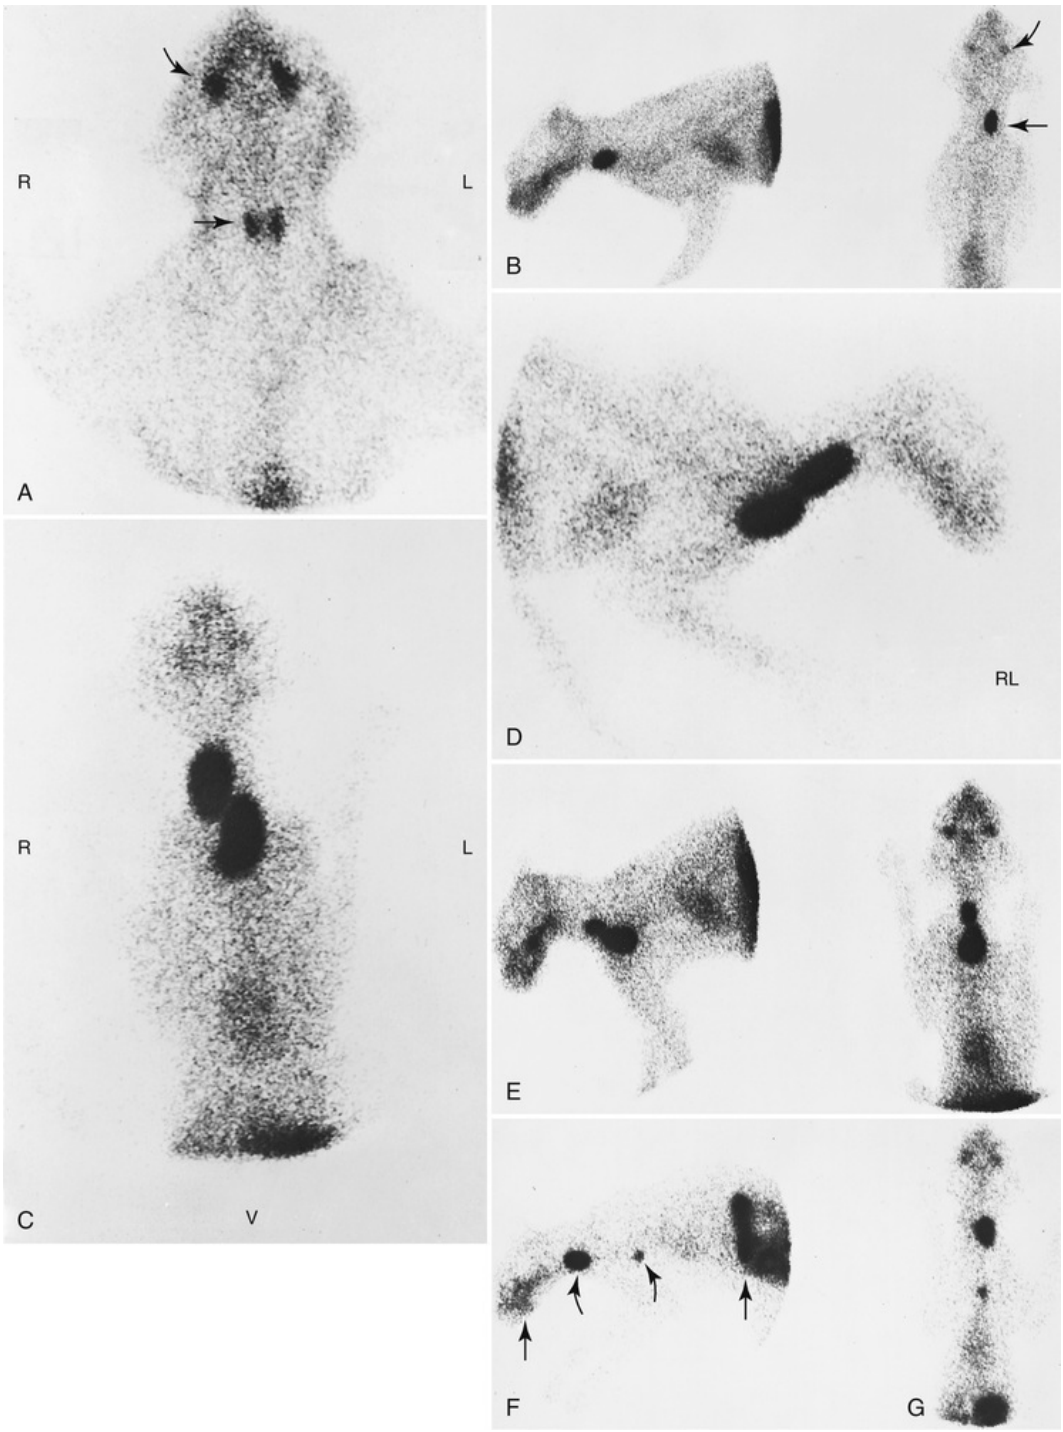

FIGURE 301-4 **A,** Thyroid scan (radioactive technetium-99m [99mTc]) of a normal cat. Note the similar size and density of the thyroid lobes (straight arrow) and the salivary glands (curved arrow). **B,** Thyroid 99mTc scan from a thyrotoxic cat with a unilateral thyroid tumor. Note the density of the thyroid (straight arrow) compared with that of the salivary glands (curved arrow). **C** and **D,** Thyroid 99mTc scan from a thyrotoxic cat with bilaterally symmetric adenomatous hyperfunctional thyroids. **E,** Thyroid 99mTc scan from a thyrotoxic cat with bilaterally asymmetric adenomatous hyperfunctional thyroids. **F** and **G,** Lateral and dorsoventral views of a thyroid 99mTc scan from a thyrotoxic cat with bilaterally asymmetric adenomatous hyperfunctional thyroids. Note that this scan shows the larger thyroid above the smaller rather than the more common larger mass descending further and usually located below the smaller mass **(C-E). F** and **G,** Note the large thyroid in the neck (large curved arrow on lateral view); the small, adenomatous thyroid tissue in the anterior mediastinum (small curved arrow); the salivary glands and the saliva, which concentrates pertechnetate (small straight arrow); and the gastric mucosa, which concentrates pertechnetate (large straight arrow). (From Feldman EC, Nelson RW, Reusch CE, et al: *Canine and feline endocrinology and reproduction,* ed 4, St Louis, 2015, Saunders.)

Treatment

Overview and Prognosis

If hyperthyroidism is untreated, the condition usually progresses to severe metabolic compromise, heart disease, and death. Although survival times in untreated FHT have not been reported, median survival times for cats treated with radioiodine have ranged from 2 to over 5 years (Table 301-3).[68-70] Although female cats apparently survive longer than do males after FHT treatment, both can live long lives. FHT can be treated with anti-thyroid drugs (thioureylenes), radioiodine, surgical thyroidectomy, or via dietary elimination of iodine (Table 301-4). Side-effects are associated with all treatments for FHT. Adverse effects after resolving FHT include renal insufficiency and hypothyroidism.

TABLE 301-3

Effect of Age and Gender at Diagnosis on 5-Year Survival Rates in Cats with Hyperthyroidism

AGE AT DIAGNOSIS	GENDER	5-YEAR SURVIVAL
10 years	F M	42% 28%
13 years	F M	25% 13%
16 years	F M	11% 4%

Comparison of Treatment Considerations for Feline Hyperthyroidism

	THIOUREYLENE DRUGS	RADIOIODINE	THYROIDECTOMY
Initial cost	Low	High	High
Long-term cost	Moderate	Low	Low
Anesthesia	Never	Sometimes	Always
Ease of use	Easy	Moderate	Difficult
Recurrence	Common	Rare	Moderate
Time to euthyroid	2-4 weeks	Immediate	2-4 weeks
Hospitalization	None	3-10 days	1-3 days
Blood dyscrasias	Rare	Never	Never
Hypocalcemia	Never	Never	Common
GI side-effects	Common	Never	Never

Thioureylene Anti-Thyroid Drugs

Action

Methimazole is the most commonly used drug to treat FHT. Methimazole is available and approved for use in cats in the United States, while both methimazole and carbimazole, a "pro-drug" of methimazole, are approved for use in Europe. A third anti-thyroid drug, propylthiouracil, is available but rarely used due to early reports of its causing hemolytic anemia and thrombocytopenia.[71,72] Thioureylenes inhibit thyroid follicular cell thyroperoxidases, inhibiting iodination of tyrosyl residues in thyroglobulin, and inhibiting

coupling of tyrosyl residues into T4 and T3. These drugs decrease production of thyroid hormone, deplete follicular cellular stores of pre-made hormone, decrease circulating concentrations of thyroid hormone and reverse thyrotoxicosis.

Oral Administration

Because the degree of thyrotoxicosis varies from patient to patient, anti-thyroid drugs must be titrated to individual needs.[73] The recommended methimazole starting dose is about 2.5 mg/cat PO q 12 h. Carbimazole, available in a sustained-release formulation, is started at 10 or 15 mg, PO, once daily. Dosage adjustments should be based on response to treatment. Euthyroidism should return within 2 to 3 weeks if the dose of anti-thyroid drug is adequate. Most cats are controlled on the 2.5 mg PO q 12 h dose of methimazole, and reported successful doses have ranged from 2.5 to 20 mg/day for methimazole and 10 to 20 mg/day for sustained-release carbimazole. In general, doses should be adjusted to achieve a basal serum tT4 concentration that is at or below the middle of the reference range for tT4. Methimazole-treated cats with high-normal serum tT4 concentrations do not consistently exhibit resolution of clinical signs.[74] While some have suggested larger once-daily doses of methimazole can be substituted for the recommended q 12 h protocol, once-daily methimazole is not as effective.[75]

Transdermal

Although oral anti-thyroid drugs are typically well-tolerated by cats and the owners who are required to administer the pills, some cats cannot be so-treated.[76] Some cats exhibit adverse gastrointestinal (GI) effects and some owners are unable to administer the medication. In such cases, transdermal methimazole can be used.[77,78] Transdermal formulations are typically produced by compounding pharmacies and care must be taken to ensure their quality and consistency (see ch. 168). Effective dosages of transdermal methimazole do not differ significantly from oral requirements, but some considerations must be kept in mind. First, there is evidence to suggest that it takes longer to achieve euthyroidism (4 weeks) with transdermal methimazole.[78] It is reasonable, therefore, to begin monitoring tT4 later. Also, owners must be warned to use gloves when administering transdermal methimazole to avoid all dermal contact. Methimazole is much more potent in people than cats and transdermal methimazole is highly effective in treating hyperthyroid people, so even small amounts could have an effect on an owner.[79] Response to transdermal methimazole has been less consistent than with the oral drug in achieving reference range serum tT4 concentrations.[80]

Severe Adverse Side-Effects

Unwanted side-effects are common when treating cats with antithyroid drugs. Because some adverse reactions can be life-threatening (Table 301-5), it is important to initially monitor cats closely. Adverse reactions usually occur within the first 3 months of starting treatment and this is the recommended time period to closely monitor cats.[74] Life-threatening adverse reactions include agranulocytosis, thrombocytopenia, severe hepatopathy, and non-thrombocytopenia-associated bleeding. If any of these reactions occurs, the anti-thyroid drug used must be stopped immediately. The mortality rate with these adverse drug reactions is high. These severe adverse reactions seen with methimazole therapy are not reported with carbimazole, but they can still happen. It makes little sense that adverse reaction profiles would be very different between the two drugs because carbimazole is metabolized to methimazole in order to exert its therapeutic effect. It is also important to note that while GI side-effects are less common in cats treated via the transdermal route, the risk of life-threatening adverse reactions is certainly not mitigated by switching from oral to transdermal therapy, and may even be worse. No cohesive study comparing the adverse effects of randomly assigned anti-thyroid drugs used to treat FHT has been completed, so drug comparisons are difficult.

TABLE 301-5

Frequency of Suspected Life-Threatening Adverse Reactions to Methimazole

	ORAL METHIMAZOLE	TRANSDERMAL METHIMAZOLE
Hepatopathy	2.6%	4%

Bleeding diathesis	2.5%	Not reported
Thrombocytopenia	2.8%	8%
Agranulocytosis	2.7%	6.1%

Other reported suspect adverse reactions include case reports of myasthenia gravis and aplastic anemia.

Adapted from Daminet S, Kooistra HS, Fracassi F, et al: Best practice for the pharmacological management of hyperthyroid cats with antithyroid drugs. *J Small Anim Pract* 55:4, 2014.

Common and Mild Adverse Effects

The more common adverse reactions seen with anti-thyroid drugs are not life-threatening but can be reasons for treatment failure (Table 301-6). GI signs, including nausea, vomiting, lethargy, and diarrhea, are common. Carbimazole apparently carries a greater risk of GI side-effects.[73] Leukopenia, eosinophilia, and lymphocytosis have been noted. These changes should be monitored, as they usually resolve despite continuing treatment. The mild leukopenia seen with thioureylene use can be unsettling because of the fear of agranulocytosis, but stopping treatment is not usually necessary. Facial excoriation, a severe but not life-threatening reaction, is seen in some cats treated with anti-thyroid drugs. It is thought that cats probably experience pruritus in their facial skin as a drug reaction, since they scratch themselves excessively, causing bleeding wounds of the face, head, and neck. This adverse drug reaction requires cessation of anti-thyroid drug therapy. When side-effects that are not life-threatening necessitate cessation of an anti-thyroid drug, reactions to later re-challenge with the drug are not predictable.

TABLE 301-6

Frequency of Suspected Non-Life-Threatening Adverse Reactions to Methimazole and Carbimazole

	ORAL METHIMAZOLE	TRANSDERMAL METHIMAZOLE	ORAL CARBIMAZOLE
Gastrointestinal signs (vomiting, anorexia)	22%	3.7%	33%
Mild hematological abnormalities (leukopenia, eosinophilia, lymphocytosis)	16.4%	Not reported	34.9%
Facial excoriations	4%	8%	11.6%

Owner Compliance

One of the major drawbacks of using methimazole or carbimazole for the long-term management of FHT is the need for prolonged owner compliance. Because anti-thyroid drugs do not "cure" the clinical condition, they must be given for the life of the cat and this can be difficult for some owners. In addition, the disease tends to advance despite treatment with anti-thyroid drugs, and this commonly necessitates increases in the drug dosage over time in order to maintain euthyroidism. Although reasons are not clear, one study indicated that cats treated with methimazole alone have less than half the median survival of cats treated with radioiodine or those cats initially treated with methimazole and eventually treated with radioiodine.[69] This may have nothing to do with the treatment, but rather on the condition of the cats and the financial means of the owners when selecting treatment.

Radioiodine Therapy

Overview

Use of ^{131}I may be the treatment of choice for FHT.[70,81] Thyroid hormones and thyroglobulin are the only iodinated organic molecules in the body, so any ingested or injected iodine is taken up by the sodium-iodide symporter of thyroid follicular epithelial cells. Thus, radioactive isotopes of iodine are concentrated in the thyroid gland where their beta-particles exert significant local tissue damage, destroying hyperactive thyroid tissue. Adjacent normal tissue can certainly be affected as well, but radioiodine is administered at dosages

aimed to achieve euthyroidism.

Dosage, Protocol and Adverse Effects

Several methods are used for calculating dose of radioiodine needed to treat FHT. Use of radioiodine tracer kinetic studies is the most cumbersome method for dose determination. Some clinicians use a fixed dose of ^{131}I for all cats, typically 4 to 5 mCi. A third method of radioiodine dose determination uses a scoring rubric that employs thyroid gland size, clinical signs, and the serum tT4.[70] No method has a clear advantage. Different methods of administering radioiodine include IV, SC, and PO.[81] It is common for FHT cats to be treated with anti-thyroid drug therapy prior to choosing radioiodine therapy. Radiation therapists often recommend that methimazole use be discontinued for a specified period of time prior to radioiodine administration, but this practice is questionable. In a report of response predictors for radioiodine therapy, there was no difference in treatment outcomes in comparing cats whose methimazole was withheld more or less than 5 days prior to treatment.[82] Other than post-treatment renal insufficiency and, sometimes, hypothyroidism, adverse reactions to radioiodine therapy are rare. Transient dysphagia, likely due to radiation-induced inflammation in the thyroid gland, has been reported rarely.[70]

Patient selection is important when considering radioiodine therapy. Most cats tolerate radioiodine therapy without problems. Because cats will be housed in an isolated environment for radiation safety purposes, cats with concurrent medical conditions that require frequent observation or treatments are poor candidates, as are cats suffering from extreme anxiety due to separation from their families. Hospitalization times for cats undergoing radioiodine therapy typically range from 3 to 10 days depending on the individual facility's radiation licensing requirements.

Surgical Thyroidectomy

When performed by a skilled and experienced surgeon, results of surgical thyroidectomy are usually satisfactory for permanently resolving FHT with few complications (Figure 301-5).[16] Surgical complications included transient hypocalcemia (due to removal of or damage to the parathyroid glands or their blood supply) in 6% of cats and death within 3 days of surgery in 3%. Development of hypocalcemia is the most important reason to monitor cats for 2 to 3 days post-surgically in-hospital. If hypocalcemia develops, it is treated with calcium and vitamin D supplementation (see ch. 298). Hypocalcemia is nearly always transient. An argument against surgical thyroidectomy as a treatment for FHT is anesthetic risk. Therefore, it is often recommended that cats be treated to achieve euthyroidism with anti-thyroid drugs prior to surgical thyroidectomy. While logical, there are no reports supporting this recommendation.

Dietary Management

Background

An iodine-restricted diet for treating FHT (Hill's y/d) is commercially available. Iodine is necessary for the production of thyroid hormone. Strict restriction of dietary iodine can be expected to reduce thyroid hormone concentrations. Early data on the efficacy of this diet were only available in abstract form, authored by the manufacturer. This raised concern regarding the effectiveness of diet in controlling hyperthyroxinemia and its clinical signs. There were also concerns about possible adverse effects of iodine deficiency in cats. A prospective non-controlled study, funded by the diet manufacturer, provides answers to some of these concerns.[83]

Efficacy

A large number of FHT cats, some previously treated with a different modality and some newly diagnosed, were fed the iodine-restricted diet for 8 weeks in a recent study. Clinical signs of FHT, as reported by owners or primary care clinicians, improved significantly by week 4 of dietary management. No adverse effects observed. Serum tT4 concentrations decreased to the reference range in 68% of cats at week 4 and in 75% of cats at week 8. Serum tT4 concentrations, however, remained in the upper reference range. Ratios of upper limit of normal tT4 concentration to measured value were 0.91 and 0.69 at 4 and 8 weeks, respectively. Some could consider it questionable that clinical hyperthyroidism would resolve when tT4 concentrations remain at the upper end of the normal range. Cats exhibit reversal of signs more consistently, for example, when post-methimazole serum tT4 concentrations are in the lower half of the normal range.[74] A compelling result from the study of van der Kooij et al is that there was no decrease in serum creatinine or urea nitrogen concentrations in the cats fed the iodine-restricted diet. This could have important implications for cats that develop renal failure following treatment of hyperthyroidism; conversely, it could be viewed as further evidence that dietary treatment was not effective.

Recommendation

If an iodine-restricted diet is chosen to treat FHT, the following points should be taken into consideration. First, because little iodine is required for thyroid function, only the iodine-restricted diet can be fed. All other food, treats, or captured prey would likely have enough iodine content to counteract the effects of the diet. Second, FHT cats in multi-cat households must either be fed separately or all cats in the household must be fed the iodine-restricted diet. The possible deleterious effects of long-term iodine restriction on cats, normal or hyperthyroid, have not been reported.

Other Treatments

Various other treatments for feline hyperthyroidism have been described. Non-surgical treatment of thyroid nodules using ultrasound-guided percutaneous radiofrequency heat ablation or intrathyroidal ethanol injection has been studied.[84-86] These techniques are of questionable efficacy and safety, and are not recommended. Iopanoic acid, an orally administered contrast agent used in cholecystography, has been evaluated to a limited extent for use in the treatment of FHT. While it can lower serum thyroid hormone concentrations, long-term use is not recommended because of the transient effect of the drug.[87]

Post-Treatment Renal Insufficiency

Overview

Most cats treated for hyperthyroidism eventually develop chronic kidney disease (CKD; see ch. 324) and die of renal failure.[68,69] Treatment of FHT can have deleterious effects on renal function in cats, likely because FHT may mask pre-existing underlying CKD.[88-93] Treatment of FHT, regardless of modality, causes a consistent, and sometimes disastrous, drop in glomerular filtration rate (GFR) and development of overt CKD. Estimates of CKD prevalence following treatment of FHT vary, 15% over an 8-month period in one study and 60% over a 6-month period in another.[93,94]

Predicting Post-Treatment Renal Failure

Pre-treatment clinical parameters that could help predict development of post-treatment renal failure in FHT have not been convincing.[93,95] There is a commonly held belief that cats with well-concentrated urine (specific

gravity > 1.035) have adequate renal function and less risk of post-treatment renal insufficiency.[96,97] This is not supported by evidence. In one report, 20 cats with FHT that developed overt renal insufficiency within 6 months of radioiodine treatment were compared to 19 post-treatment cats in which overt renal failure did not develop.[95] Ten of the 20 cats that developed azotemia (50%) had urine specific gravity measurements before treatment that were greater than 1.035. Three of those cats had urine specific gravity measurements above 1.050. Therefore, urine specific gravity should not be used as a predictor of post-treatment renal status in hyperthyroid cats.

It may be unwise to treat hyperthyroidism in a cat with questionable renal function. This has led to the recommendation that cats with impaired renal function be treated with methimazole initially, because its effects may be reversible. One study showed consistent decreases in GFR with methimazole treatment of FHT. Reversal of this effect was noted when methimazole therapy was stopped in one cat.[89] While it seems logical to choose a reversible treatment for FHT and to assess the renal response to treatment prior to treatment with radioiodine or surgery, there are no studies to confirm the benefits of this strategy. When renal insufficiency is diagnosed in a cat previously treated for FHT, clinicians must attempt to balance treatments for FHT and renal failure.

Managing Post-Treatment Renal Insufficiency

Clinicians managing cats in overt renal failure after being treated for FHT may consider thyroid hormone supplementation as a means of restoring renal blood flow and increasing GFR. There is evidence to suggest that iatrogenic hypothyroidism contributes to the development of renal failure after treating FHT.[93] In that study, development of azotemia did not affect the survival times of cats that were euthyroid following treatment of FHT. However, cats that were both hypothyroid and azotemic following treatment for FHT survived for a shorter period of time, suggesting that iatrogenic hypothyroidism may contribute to the development of azotemia in cats treated for FHT.

Because iatrogenic hypothyroidism has been associated with decreased survival and azotemia in cats with FHT, the renal effects of reducing dosages of carbimazole or methimazole to achieve euthyroidism were studied.[94] Restoring euthyroidism was accompanied by a decrease in serum concentrations, but this was accompanied by decreases in body weight and increases in heart rate, hematocrit, and serum alkaline phosphatase activities. Thus, decrease in muscle mass may have contributed to the decline in serum creatinine concentrations. The other changes are consistent with uncontrolled FHT. In an unpublished study, we followed cats treated with thyroxine following post-treatment renal failure and found discouraging results. Treatment with thyroxine resulted in an increase in the concentration of tT4 in the serum, as expected, but there was no significant decrease in blood urea nitrogen or creatinine. Body weight and body condition remained unchanged in our small group of cats.

CHAPTER 302

Canine Hyperthyroidism

Cynthia R. Ward

Unlike in cats, hyperthyroidism is an uncommon clinical condition in dogs that almost always arises from a functional, malignant, thyroid tumor that secretes excessive thyroid hormone. Thyroid tumors are usually easily palpable cervical masses. Uncommonly, feeding uncooked diets containing thyroid gland tissue may cause clinical hyperthyroidism.

Pathogenesis

Naturally Occurring Thyroid Cancer

Thyroid cancer has a prevalence of 1% to 4% of all reported neoplasms in dogs and is their most common neuroendocrine tumor. Canine thyroid tumors are usually malignant. Ten to 30% of canine thyroid tumors are benign adenomas.[1,2] Adenomas, typically small and nonfunctional, are usually not diagnosed until noted as an incidental necropsy finding. With increased use of cervical ultrasonography (US), however, incidentally discovered thyroid masses have been noted.[41] Size is not a predictor of malignancy.[1] Most clinically significant thyroid tumors are carcinomas, either follicular cell or medullary cell in origin; the latter also are termed *parafollicular cell* or *C-cell carcinomas.* Follicular cell carcinomas, about 70% of canine thyroid tumors, arise from thyroid follicular cells that stain for thyroglobulin on immunohistochemistry. Medullary thyroid carcinomas, about 30% of tumors, arise from parafollicular cells that produce calcitonin and stain for calcitonin antibodies on immunohistochemistry.[3-5]

Iatrogenic Hyperthyroidism

Clinical signs of hyperthyroidism can be seen in dogs without primary thyroid gland disease. Iatrogenic hyperthyroidism may result when a dog is oversupplemented with L-thyroxine for hypothyroidism or by accidental ingestion. In general, dogs seem resistant to exhibiting signs of hyperthyroidism if there are small excesses of exogenous thyroid hormone. Recent reports have implicated food sources, including raw food or dried uncooked diets that contain thyroid tissue, as a cause of thyrotoxicosis in dogs.[6,7] The dogs described in these studies had clinical signs of hyperthyroidism that resolved when the suspect diets were removed.

The Role of Thyroid Stimulating Hormone (TSH) in Tumor Development

The etiology of canine thyroid carcinoma is unknown. In people, risk factors include exposure to radiation and lack of dietary iodine intake.[8] Individuals who lack dietary iodine or who consume iodine-blocking foods have decreased pituitary negative feedback and excess thyroid stimulating hormone (TSH) secretion (see ch. 299). TSH directly stimulates thyroid cell mitogenesis, hormone synthesis, and has been postulated to be involved in thyroid neoplastic transformation (Figure 302-1). Other evidence of excess of TSH activity causing development of thyroid neoplasia is the mutations in the TSH receptor that have been shown to cause benign toxic nodular goiter in humans.[9] Furthermore, increased TSH concentrations have been shown to induce angiogenesis in thyroid cancer cell lines, which may be relevant to thyroid tumor development in dogs.[10] About 50% of Beagles with induced untreated lymphocytic thyroiditis and increased TSH concentrations developed thyroid tumors. Carcinomas were more common than adenomas.[11] Thus, chronic exposure to excess TSH can cause unregulated cell growth and function in dogs. A familial relationship in the development of thyroid carcinoma was also demonstrated in the colony of Beagles by sibling pair analysis.

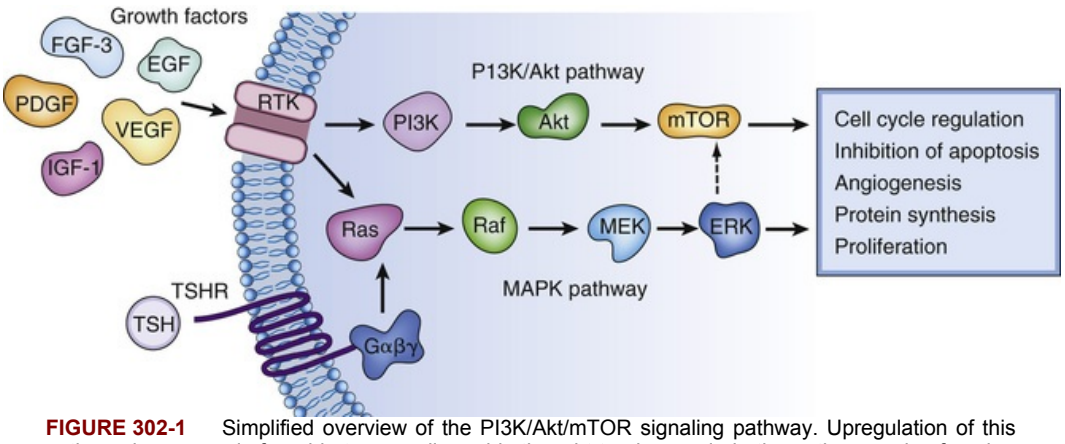

FIGURE 302-1 Simplified overview of the PI3K/Akt/mTOR signaling pathway. Upregulation of this pathway is commonly found in tumor cells and is thought to play a role in the pathogenesis of canine thyroid carcinoma. *EGF,* Epidermal growth factor; *ERK,* extracellular-signal-regulated kinase; *FGF-3,* fibroblast growth factor-3; *IGF-1,* insulin-like growth factor-1; *MAPK,* mitogen-activated protein kinase; *MEK,* MAPK/ERK kinase; *mTOR,* mechanistic (or mammalian) target of rapamycin; *PDGF,* platelet-derived growth factor; *PI3K,* phosphoinositide 3-kinase; *RTK,* receptor tyrosine kinase; *VEGF,* vascular endothelial growth factor; *TSH,* thyroid-stimulating hormone; *TSHR,* TSH receptor. Genetic Etiology of Tumor Development

Several genetic abnormalities in cell signal transduction proteins have been described as causative agents for human thyroid carcinoma. These include point mutations in the ras gene and abnormalities in the PI3K/Akt pathway (see Figure 302-1). These signal transduction pathways are coupled to cell surface receptor tyrosine kinases and G protein–coupled receptors such as the TSH receptor. In human follicular cell carcinoma, abnormalities in the PI3K/Akt pathway have been implicated.[12] Important genes in this pathway are the vascular endothelial growth factors *VEGFR-1* and *VEGFR-2*. VEGF is a target for TSH activation of angiogenesis in thyroid cancer cell lines.[13] In 74 dogs with thyroid neoplasia, immunohistochemical staining revealed VEGF in follicular cell and medullary carcinomas, supporting a role as an angiogenic factor in development of thyroid carcinoma.[14] As canine thyroid carcinoma cells bind TSH in a normal fashion, this may explain the effect of chronic excess TSH exposure contributing to the neoplastic transformation seen in the Beagle colony dogs.[11,15]

Studies of genetic signaling molecule abnormalities in canine cancer cells have been limited. Point mutations of p53, a tumor suppressor gene, were found in only 1 of 23 dogs with canine thyroid carcinoma.[13] In 59 dogs with canine thyroid carcinoma, mRNA expression of several genes in the PI3K/Akt pathway were greater than those in normal canine thyroid tissue.[16] In addition, missense mutations of K-RAS that would cause unregulated activation were documented. Microarray analysis comparing thyroid tumor versus normal thyroid gene expression in dogs identified differential expressions of osteopontin, a protein overexpressed in human follicular cell carcinomas and implicated in activation of the PI3K/Akt pathway. This was found in all five dogs with thyroid tumors, but also in four euthyroid dogs.[17] Molecular abnormalities in mitogenic pathways are a likely component of canine thyroid carcinoma pathogenesis.

Signalment

The mean age of dogs with thyroid carcinoma is 9 to 11 years.[3,18-22] One study suggested that the median age may be somewhat older at 10 to 15 years.[2] There is no sex predilection. Breeds that may be predisposed to thyroid carcinoma include Golden Retrievers, Beagles, Boxers, and Siberian Huskies.[2,3] Medullary thyroid carcinoma in a family of mixed breed dogs with Alaskan Malamute influence on the pedigree has been reported.[23]

History

The initial presenting complaint for most dogs with thyroid carcinoma is the owner's discovery of a cervical

mass. Most animals are diagnosed within 1 to 2 months after discovery of the mass; however, there may be delays of 1 to 2 years.[37] On palpation, thyroid masses are usually firm, nonpainful, freely movable or fixed. Mass "movability" is an important factor in tumor staging and for predicting surgical success (see Table 302-1). Both right and left thyroid lobes may be involved equally in tumor development, and tumors may be bilateral.[19,21] Sedation may improve one's ability to fully palpate the area, but usually is not needed. Regional peripheral lymph nodes should also be palpated carefully for increased size or pain. Ectopic thyroid carcinomas may be suspected if a non-painful swelling is noted in any location from the tongue to the thoracic inlet.[39]

Most thyroid carcinomas are not functional. Clinical signs, therefore, are usually associated with space-occupying issues caused by the mass and these can include difficulty swallowing, dysphonia, coughing, dyspnea or recognizable head or forelimb edema.[3,18,24] Dyspnea may also occur because of metastatic tumor spread to the lungs. Thyroid carcinomas have been reported to invade major blood vessels causing local or thoracic bleeding.[25] Ectopic thyroid carcinomas have been reported in the mediastinum, heart base and sublingually; therefore, clinical signs may relate to tumor size in these areas or invasion into these tissues.[26-33] Thyroid hormone status can vary in dogs with thyroid carcinoma; approximately 10% are hyperthyroid.[22,34-36] Hyperthyroid dogs often show classic signs of vomiting, diarrhea, weight loss, hyperactivity, panting, polyuria/polydipsia, and systemic hypertension (Figure 302-2; see ch. 301).

FIGURE 302-2 A 10-year-old female, spayed mixed breed dog was diagnosed with a functional thyroid carcinoma. Her clinical signs included weight loss, polyuria, polydipsia, panting, and hyperactivity. Her serum T_4 was elevated. A well-encapsulated thyroid carcinoma was removed surgically. Her thyrotoxicosis resolved after surgery.

Diagnosis

Differential Diagnosis

Most dogs with thyroid carcinoma are brought to a veterinarian after an owner notes the presence of a cervical mass. However, signs of hyperthyroidism may be the first concern seen by some owners. In those dogs, a palpable cervical mass is usually noted on physical examination. Differential diagnoses of a cervical mass include an enlarged lymph node, salivary gland, granuloma, abscess, or foreign body. Thus, a complete diagnostic work up should be pursued and further examination of the cervical mass attempted.

Laboratory Testing

If a thyroid tumor is present, blood work may reveal paraneoplastic hypercalcemia (see ch. 352).[38] Urine specific gravity is often <1.020 if a dog is hypercalcemic and/or hyperthyroid. To determine tumor function, serum total T_4 (TT_4), freeT_4 (fT_4) by equilibrium dialysis, and canine TSH (cTSH) concentrations should be evaluated. Anti-T_4 antibodies should also be assessed. If a functional thyroid tumor is present, usually both

TT_4 and fT_4 are increased. The cTSH should be decreased due to negative feedback caused by the excess thyroid hormone (see ch. 299). T_4 autoantibodies that may interfere with certain assay procedures should not be measurable.

Imaging

Plain radiographs often confirm the presence of a soft-tissue mass deviating or compressing the trachea, larynx, and/or esophagus. Ultrasound (US), a rapid, noninvasive, and reliable screening modality for defining thyroid tumors, can provide additional detail regarding vascularity and/or invasion of other structures (Figure 302-3).[40] Clinicians should interpret US findings cautiously, however, as clinically insignificant thyroid masses can be identified. Fourteen of 91 hypercalcemic dogs (15%) without a palpable cervical mass had a total of 15 thyroid masses identified on US examination; 2 were thyroid adenocarcinomas and 13 masses were likely insignificant cysts or benign nodules.[41] Computed tomography (CT) can provide further information regarding the nature of thyroid masses, especially invasion of surrounding tissues (Figure 302-4).[39,42] In a study of 23 dogs with suspected thyroid carcinoma, CT had the highest specificity (100%) and magnetic resonance imaging (MRI) had the highest sensitivity (93%) in diagnosing thyroid carcinoma.[40] CT also allows assessment of the lungs for possible metastases. It is recommended that CT or MRI be performed for tumor staging and prior to potential surgery.

FIGURE 302-3 Ultrasound image of a canine thyroid carcinoma. Transverse view of the right cervical area demonstrating a thyroid mass diagnosed as a carcinoma. (Image courtesy Dr. Scott Secrest.)

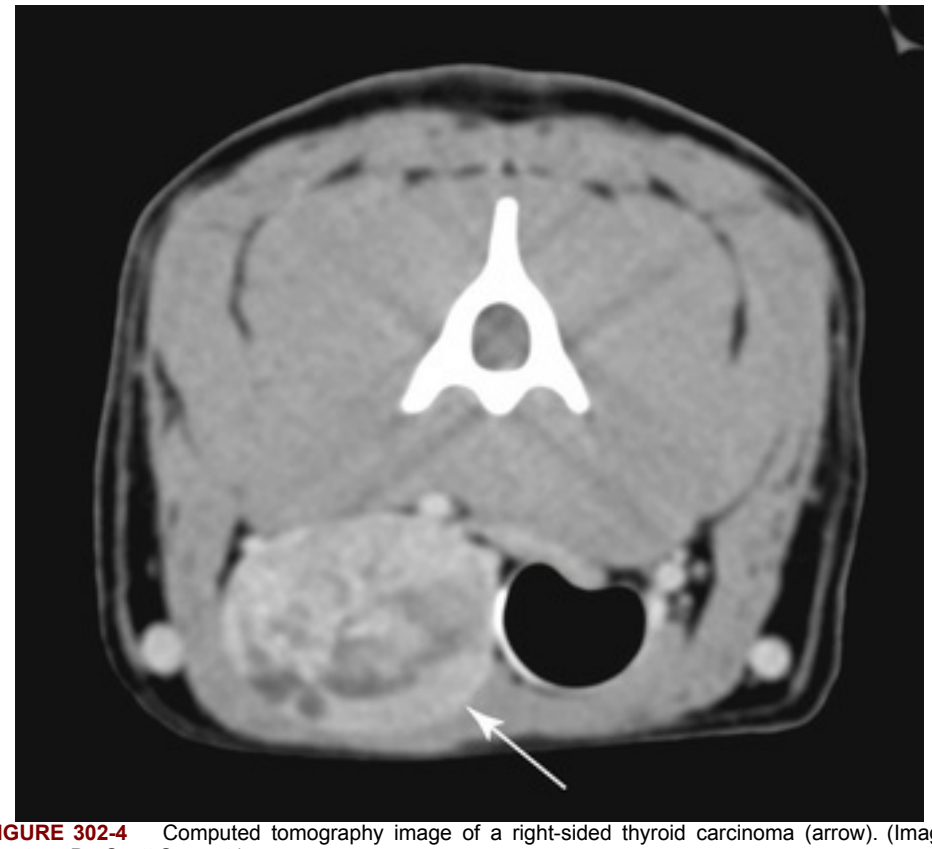

FIGURE 302-4 Computed tomography image of a right-sided thyroid carcinoma (arrow). (Image courtesy Dr. Scott Secrest.)

Scintigraphy is an effective imaging modality to aid in the diagnosis and staging of thyroid carcinoma. ^{99m}Tc-pertechnetate ($^{99m}TcO_4$) uses the relatively specific sodium-iodide transporter present in thyroid and salivary glands. Since the transporter protein is upregulated as thyroid gland activity increases, levels of radionuclide uptake can be correlated with thyroid function. Therefore, scintigraphy is sensitive for identifying some thyroid carcinomas and, potentially, ectopic and/or metastatic tissue (Figures 302-5 and 302-6).[32] The pattern of radionuclide uptake cannot be correlated with tumor histology, but it can predict the degree of capsular disruption and local tissue invasion.[19,43] This information can be helpful in predicting surgical resectability and long-term prognosis, as invasive thyroid carcinomas carry a poorer prognosis.[44] Scintigraphy is not sensitive in identifying pulmonary metastases and is inferior to plain thoracic radiographs and CT for staging.[3,19,43] ^{123}I may be superior to $^{99m}TcO_4$ for scintigraphy since the target-to-background ratio favors specific uptake by thyroid tissue. However, lower radioactivity of the compound requires longer image acquisition times, so it may not be practical.[43]

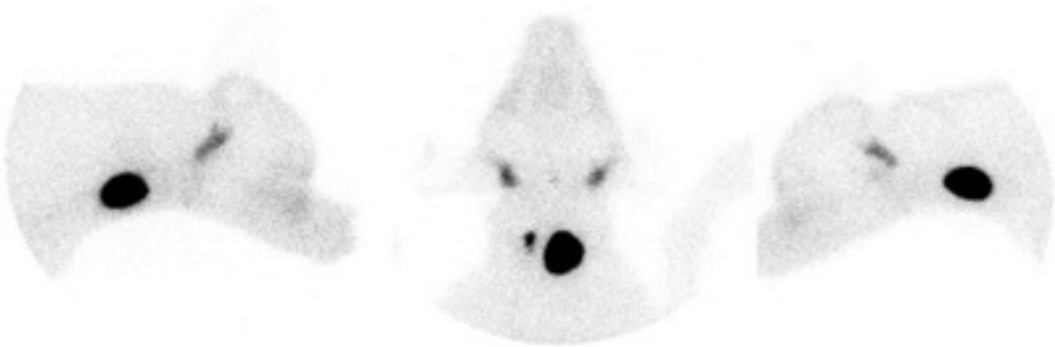

FIGURE 302-5 Scintigraphic images of a dog with a functional thyroid carcinoma. Note the increased uptake in the left lobe of the thyroid gland with minimal uptake in the right. This indicates decreased right thyroid activity in response to thyroid stimulating hormone suppression caused by the

unregulated excess secretion of the tumor. (Image courtesy Dr. Gregory Daniel.)

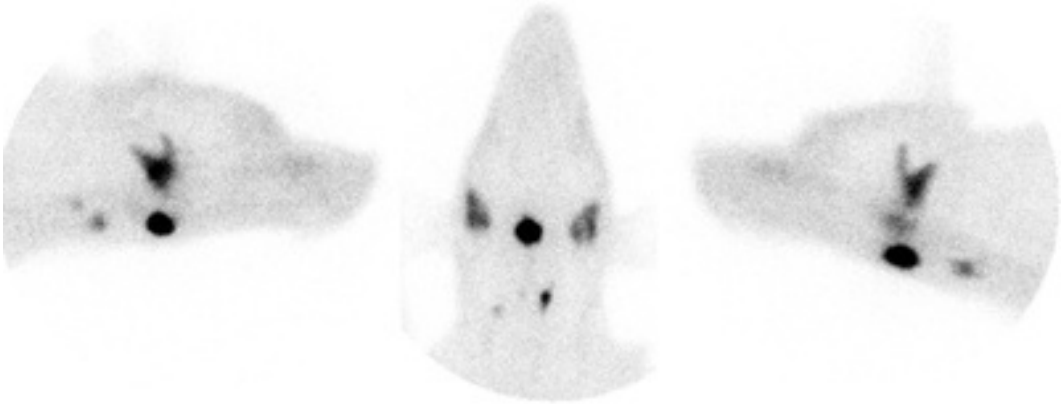

FIGURE 302-6 Scintigraphic images of a dog with ectopic, sublingual thyroid carcinoma. Note the increased uptake in the sublingual area with minimal uptake in the thyroid glands. (Image courtesy Dr. Gregory Daniel.)

Histology

Definitive diagnosis of thyroid carcinoma requires identification of malignant cells in a cytologic or, preferably, a histologic sample. Cytology via fine needle aspirate (FNA) is often used for definitive diagnosis of thyroid carcinoma in humans,[8] but its use for canine thyroid carcinoma is less reliable (see ch. 93). Since thyroid carcinomas are highly vascular, samples obtained by FNA often contain few cells but large amounts of blood.[22] However, depending on owner or patient restrictions, FNA cytology can provide an inexpensive and noninvasive means of diagnosis.[45] US guidance is recommended for FNA to avoid highly vascular areas.

Histology is the gold standard by which thyroid carcinomas are diagnosed. For small and noninvasive tumors, excisional biopsy may provide diagnosis and be curative. Usually, canine thyroid tumors are moderately to well differentiated.[1,3,20] Malignancy is defined by the presence of capsular or vascular invasion. Unlike people, histologic subtype does not appear to carry prognostic significance in dogs with well-differentiated thyroid tumors.[3,20,22] Therefore, it is crucial to determine invasive qualities of the tumor for prognosis. Since thyroid tumors are highly vascular, a hypothesis has been promoted that identifying microvessels is prognostic. However, microvessel density was not shown to help predict metastasis or survival.[21] Immunohistochemistry is essential for determining origin of thyroid carcinomas.

Staging

Canine thyroid tumors are staged based on the size of the primary tumor and whether spread to regional lymph nodes or distant metastases is identified (Table 302-1). Full staging of dogs with thyroid carcinoma is recommended so appropriate treatment options and prognoses may be presented to the owners.

TABLE 302-1

Clinical Staging of Canine Thyroid Tumors

STAGE	PRIMARY TUMOR DIAMETER	REGIONAL LYMPH NODE INVOLVEMENT	DISTANT METASTASIS
I	<2 cm; a or b	No	No
II	No evidence of tumor (microscopic disease)	Ipsilateral	No
	<2 cm; a or b	Ipsilateral	No
	2-5 cm; a or b	None or ipsilateral; a	No
III	>5 cm	Any	No

	Any size	Ipsilateral or bilateral; b	No
IV	Any size	Any	Yes

Substage a = tumor or lymph node freely movable. Substage b = tumor or lymph node fixed to surrounding structures.

Adapted from Owen LN, editor: *TNM classification of tumours in domestic animals,* Geneva, IL, 1980, World Health Organization, pp 51-52.

Treatment

Surgery

For the solitary, well-encapsulated, freely movable thyroid carcinoma, surgical excision is recommended (see Figure 302-2).[20,24] Mass removal not only reduces tumor burden but also may relieve compression of surrounding tissues. Invasive tumors are less amenable to surgical excision. Adjacent structures invaded by thyroid tumors include the recurrent laryngeal nerves, carotid artery, jugular vein, larynx, trachea, or esophagus. These structures could be further damaged if surgical excision is attempted. Additionally, thyroid carcinomas are highly vascular and extensive hemorrhage may result from a poorly planned surgery or by coexisting bleeding disorders.[22] Advanced imaging should be employed prior to surgery to determine extent of invasion. Other potential complications of surgery include hypocalcemia from removal of parathyroid glands or disruption of their blood supply. This would be quite rare if a unilateral thyroidectomy is performed. Bilateral thyroidectomy may be attempted in those unusual cases in which discrete, movable carcinomas are present in both thyroids. In these cases, parathyroid glands must be preserved by the surgeon or removed parathyroid tissue should be minced and re-implanted in a location other than the neck.[46,47] Most dogs undergoing bilateral thyroidectomy require life-long thyroid hormone replacement to manage the iatrogenic hypothyroidism (Table 302-2). If no parathyroid tissue is preserved, dogs can be successfully treated with long-term calcitriol therapy to correct hypoparathyroidism (see Table 302-2; see also chs. 297 and 298). However, long-term treatment of hypoparathyroidism is difficult and should be avoided if possible. Median survival time for dogs after unilateral thyroidectomy is approximately 3 years and for bilateral thyroidectomy, it is a similar 30 to 39 months.[46,47] Removal of ectopic thyroid carcinoma is also recommended if possible. A surgical technique has been described involving partial resection of the hyoid apparatus during surgical excision of ectopic cervical thyroid carcinomas in five dogs, four of whom survived at least 20 months after surgery.[33]

TABLE 302-2

Medications Used for Supportive Treatment for Canine Hyperthyroidism

DRUG	CLASS	INDICATION	DOSAGE	MONITORING
Methimazole	Anti-thyroid	Thyrotoxicosis	2.5-5 mg PO q 12-24 h Titrate dosage according to serum T_4 concentrations	Serum T_4 1-2 weeks following initiation of medication
Atenolol	Beta-adrenergic blocker	Prevention of thyroid storm	0.25-1 mg/kg PO q 12 h	Blood pressure
Propranolol	Beta-adrenergic blocker	Prevention of thyroid storm	0.1-0.2 mg/kg PO q 8 h	Blood pressure
Enalapril or Benazepril	Angiotensin-converting enzyme (ACE) inhibitor	Thyrotoxic hypertension	0.25-0.5 mg/kg PO q 12-24 h	Blood pressure
Amlodipine	Calcium channel blocker	Thyrotoxic hypertension	0.1-0.5 mg/kg PO q 24 h	Blood pressure
Pamidronate	Bisphosphonate	Paraneoplastic hypercalcemia	1-2 mg/kg IV diluted in 250 mL 9% NaCl and given over 2 hours q 3-4 weeks	Renal function parameters and serum calcium
Alendronate	Bisphosphonate	Paraneoplastic	0.5-1 mg/kg PO q 24 h	Esophageal erosions and

		hypercalcemia		serum calcium
Calcitriol	Vitamin D analog	Post-surgical hypocalcemia	0.03-0.06 mcg/kg/day	Maximal effect in 2-4 days. Monitor serum calcium
Levothyroxine	Thyroid supplementation	Post-surgical hypothyroidism	0.022 mg/kg q 12-24 h	Monitor serum T_4

External Beam Radiation

In dogs with a thyroid tumor that is fixed due to extensive local invasion, surgery is not usually a reasonable option. Radiation therapy should be considered as either a primary therapy for local control or as a means for reducing tumor size so that surgery may be a future option. External beam radiation is most commonly used in dogs with thyroid carcinoma.[21,48,49] In 25 dogs with non-resectable thyroid carcinoma and no visible metastases, the mean progression-free interval was 45 months after radiation therapy.[21] The 1- and 3-year progression-free survival rates were 80% and 72%, respectively. The time to maximal tumor reduction was a highly variable 8 to 22 months. In a study of eight dogs, the median survival time was 24.5 months after radiation therapy; none had primary tumor regrowth, but four died from metastatic disease.[48] Acute side-effects of radiation therapy include inflammation of the esophagus, trachea, or larynx resulting in dysphagia; cough or hoarseness; and alopecia and erythema at the radiation site. These occurred in approximately half of the dogs treated; however, they resolved in most dogs within 2 to 3 weeks. Late side-effects including permanent alopecia, chronic dry cough, and skin fibrosis may occur.[21]

In dogs with metastatic disease, external beam radiation therapy may provide palliation of the primary tumor. This takes advantage of the generally slow-growing nature of thyroid carcinomas so that any procedure to reduce tumor burden is beneficial. In 13 dogs with metastatic disease receiving weekly fractionated radiation, tumor growth was halted in all dogs and 10 of the tumors decreased in size by at least 50%.[49] Median survival time was approximately 8 months, including the dogs with previously identified pulmonary metastases.

Radionuclide Therapy

Radioiodine (^{131}I) therapy is commonly used postoperatively in humans with thyroid carcinoma.[8] It is effective at delivering high dosages of beta-emitting radioactivity to the thyroid gland and is used to destroy microscopic carcinomas anywhere in the body. Uptake of ^{131}I is enhanced by treatment with TSH, usually given immediately prior to ^{131}I. ^{131}I has been shown to be taken up by thyroid carcinoma cells, although at lower levels than by normal thyroid cells.[50] ^{131}I has been effective in treating dogs with stage II to IV thyroid carcinoma.[44,51,52] Direct comparison of studies is difficult due to differing ^{131}I dosing protocols, the absence or presence of concurrent treatment with TSH, a variety of adjunctive therapies, and differing pre-treatment hormone evaluations. However, in 100 dogs, median survival times ranged from 12 to 34 months and were longest in dogs given ^{131}I as an adjunct to surgery.[44,52] Effectiveness of ^{131}I treatment was not correlated to thyroid status in these studies. A serious side-effect of ^{131}I therapy includes irreversible bone marrow suppression, seen in dogs given doses ≥0.2 GBq/kg or 5.5 mCi/kg.[51,52]

Although ^{131}I shows some promise in the treatment of thyroid carcinomas, especially as an adjunct to surgery, handling large amounts of radioactivity and providing appropriate isolation areas to house radioactive dogs remains problematic. In humans, TSH is routinely given with ^{131}I in order to decrease the iodine dosage. The use of recombinant human TSH on the uptake of radioactive iodine in nine dogs with thyroid tumors was reported using the isotope ^{123}I, with a shorter half life than ^{131}I. TSH administration had no effect on ^{123}I uptake in the thyroid glands of these nine dogs.[53]

Chemotherapy

There are few studies examining the role of chemotherapeutic agents in treating canine thyroid carcinoma, probably because initial results have been disappointing. Doxorubicin, cisplatin, and mitoxantrone have been used in small numbers of dogs with thyroid malignancy.[54-57] Of these, cisplatin was demonstrated to have the greatest effect, with a median survival of 11 months. The greatest effect of these drugs is likely against

microscopic metastatic disease, and further studies are required to demonstrate possible effectiveness as adjunctive therapy.

Supportive Medical Therapy

Approximately 10% of canine thyroid carcinomas are functional and secrete excess thyroid hormone systemically.[22,34-36] Affected dogs may have classic signs of hyperthyroidism including polyuria, polydipsia, hyperactivity, weight loss, hypertension, polyphagia, and tachycardia. Thyrotoxicosis should be treated before a dog undergoes anesthesia for advanced imaging or surgical techniques. Furthermore, the hyperthyroidism in dogs with nonresectable functional thyroid tumors should be treated to enhance longevity and quality of life. Hyperthyroidism can be managed with methimazole, similar to its use in cats (dosage = 2.5 to 5 mg/dog PO q 24 h or q 12 h). Serum T_4 levels should be monitored 1 to 2 weeks after initiation of therapy and suitable adjustments initiated. Treatment effectively controls clinical signs with negligible side-effects. In hyperthyroid dogs undergoing anesthesia or surgery, a beta-adrenergic blocker, such as atenolol, should be considered the night before and the day of the procedure to prevent tachycardias related to potential thyroid storm (see Table 302-2; see also ch. 301).[58]

Hyperthyroid dogs may also have significant systemic hypertension (see ch. 99).[36] Although removal of the functional thyroid tumor may return blood pressure to normal, systemic hypertension should be managed in dogs with non-resectable tumors or in those with functional metastatic thyroid carcinoma (see ch. 158). Antihypertensives such as an ACE inhibitor and/or amlodipine may be used for such patients. Paraneoplastic hypercalcemia may also occur in rare cases of thyroid carcinoma (see ch. 352).[38] Calcium-lowering drugs such as pamidronate or alendronate may be used to manage such cases if the tumor burden cannot be lowered (see Table 302-2; see ch. 297 and 298).

CHAPTER 303

Insulin-Secreting Tumors

Johan P. Schoeman

Client Information Sheet: Insulin-Secreting Tumors

Insulinoma is an insulin-secreting tumor of pancreatic beta cells. Excess insulin secretion causes clinical signs of hypoglycemia. It is an uncommon condition in dogs and rare in cats. This chapter will focus on canine insulinoma, first described in a dog in 1935.[1]

Pathology

Insulin-secreting pancreatic beta cells comprise approximately 70% of cells in the islets of Langerhans and, consequently, beta cell tumors are the most common canine islet-cell neoplasm. Most canine insulinomas are malignant; in one report utilizing immunocytochemistry, 17 of 18 were carcinoma, and 1 was an adenoma.[2] About 80% of insulinomas are solitary, located in one pancreatic limb rather than in the body of the pancreas (Figure 303-1).[3-5] Occasionally, no discrete nodule is seen during gross pancreatic examination and histology is required to identify the tumor.

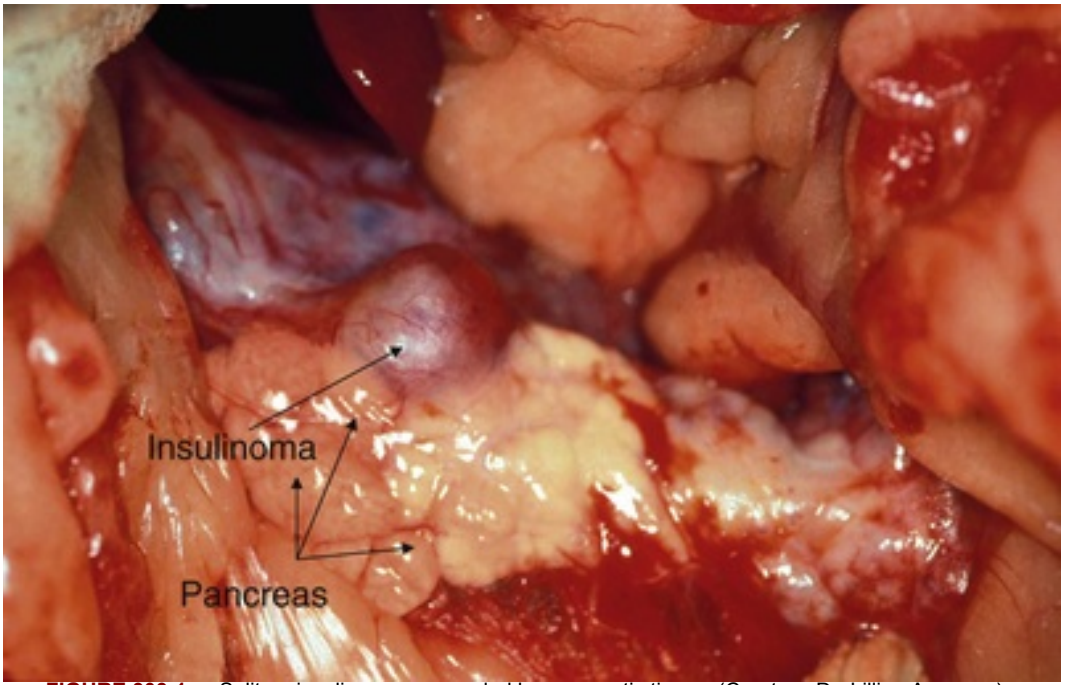

FIGURE 303-1 Solitary insulinoma surrounded by pancreatic tissue. (Courtesy Dr. Lillian Aronson.)

The rate of detected metastatic lesions in 179 dogs from different studies ranges from 45% to 64%. It is higher in studies based on necropsy versus studies using samples obtained surgically.[3,6,7] Clinical staging of pancreatic tumors according to the World Health Organization defines stage I as $T_1N_0M_0$ (presence of a primary Tumor and absence of regional lymph Node or distant Metastases), stage II as $T_1N_1M_0$, and stage III

as $T_1N_1M_1$ or $T_1N_0M_1$. The majority of dogs with insulinoma have stage II or III disease and the most common sites of metastases are regional lymph nodes and liver. Metastatic disease has an unlimited distribution.[8] Although the etiology of insulinoma is not known, local growth hormone (GH) production not associated with increased plasma GH concentrations has been documented in primary and metastatic canine insulinoma, possibly promoting islet cell proliferation via paracrine or autocrine mechanisms.[9]

Pathophysiology

Neoplastic proliferation of pancreatic beta cells causes autonomous excess secretion of insulin and resultant hypoglycemia. The most important compensatory mechanisms for hypoglycemia are inhibition of insulin secretion and stimulation of counter-regulatory hormone secretion. Glucose, the primary regulator of insulin secretion, enters pancreatic beta cells, is metabolized to ATP and closes ATP-sensitive K^+ channels. Closure results in decreased K^+ efflux, depolarization of beta cells, opening of voltage-sensitive Ca^{+2} channels and insulin exocytosis. In healthy animals, insulin secretion is completely inhibited when blood glucose is <80 mg/dL. However, insulin secretion from neoplastic beta cells, independent of blood glucose concentration, persists despite low blood glucose concentrations and represents one of the biochemical hallmarks of insulinoma: high or normal blood insulin concentrations despite low blood glucose concentrations. The four counter-regulatory hormones secreted in response to hypoglycemia are glucagon, catecholamines, GH, and glucocorticoids. Of these, glucagon and catecholamines are most important in short-term responses to low blood glucose concentrations.

Clinical Features

Signalment

The mean age of dogs with insulinoma is 9 years, with a range of 3 to 15 years. Although any breed of dog can develop insulinoma, it has been reported most commonly in medium- to large-breed dogs. Controlled studies of breed risk for insulinoma have not been published and there is no apparent sex predilection for the disease.

Clinical Signs

Clinical signs are usually due to the effect of hypoglycemia on the central nervous system (neuroglycopenia), or to hypoglycemia-induced release of catecholamines. Glucose is the single most important source of energy for the brain. Because both carbohydrate storage and the brain's ability to utilize other fuels are limited, function is dependent on a continuous glucose supply. Clinical signs attributable to neuroglycopenia include seizures, collapse, weakness, ataxia, disorientation, mental dullness, and visual disturbances. Clinical signs related to excess catecholamine release and stimulation of the sympathetic nervous system include tremors, hunger, and nervousness.

Severity of clinical signs is partly correlated to the blood glucose nadir. Severe hypoglycemia can ultimately result in coma and death. However, clinical signs may also be related to the duration and rate at which hypoglycemia develops because gradual decreases in blood glucose concentration are less likely to stimulate catecholamine secretion. Occasionally, clinical signs are episodic, because secretion of counter-regulatory hormones increases blood glucose concentration, transiently resolving neuroglycopenic signs. Feeding can alleviate clinical signs if it restores blood glucose concentration to normal. However, feeding may also counter-intuitively exacerbate clinical signs by stimulating further insulin secretion. Moreover, fasting, exercise, or excitement can worsen clinical signs by decreasing blood glucose concentration or increasing sympathetic stimulation. Clinical signs reported in 198 dogs from several studies are listed in Table 303-1. Although most dogs have more than one of these clinical signs, some dogs have none. Reported duration of clinical signs prior to diagnosis varies from 1 day to 3 years.

TABLE 303-1

Clinical Signs Due to Insulinoma Reported in 198 Dogs from Several Studies[3-5,7,8,10]

CLINICAL SIGN	NUMBER (%) OF 198 DOGS

Seizure	95 (48)
Collapse	79 (40)
Generalized weakness	74 (37)
Shaking/trembling/muscle twitching	40 (20)
Ataxia	40 (20)
Exercise intolerance	30 (15)
Hind limb weakness	28 (14)
Disorientation/bizarre behavior/hysteria	19 (10)
Polyphagia	16 (8)
Polyuria and polydipsia	16 (8)
Stupor/lethargy	12 (6)
Focal facial seizures	6 (3)
Obesity or weight gain	6 (3)
Blindness	5 (2.5)
Anorexia	5 (2.5)
Diarrhea	4 (2)
Head tilt	2 (1)
Nervousness	2 (1)

Physical Examination

Physical examination is unremarkable in most dogs with insulinoma.[4,6,10] Dogs may be overweight due to the anabolic effects of insulin. Postictal changes may be apparent if a seizure occurred quite recently. A peripheral polyneuropathy characterized by posterior paresis or tetraparesis and decreased or absent appendicular reflexes has been described in 13 dogs with insulinoma.[8,11,12] The etiology of this insulinoma-associated peripheral neuropathy is not known, but may develop as a paraneoplastic immune-mediated disorder unrelated to the metabolic changes of insulinoma.[12]

Differential Diagnoses

Differential diagnoses for hypoglycemia may be separated into those associated with excess secretion of insulin or insulin-like factors, those caused by decreased glucose production, others due to excess glucose consumption, the occasional drug-associated scenario, or the hypoglycemia could be spurious. Disorders in which the most important mechanism for hypoglycemia is excess secretion of insulin or insulin-like factors include insulinoma, extrapancreatic tumor (i.e., hepatic tumors), or beta cell hyperplasia. Conditions associated with decreased glucose production include hypoadrenocorticism (see ch. 309), hypopituitarism (see ch. 295), GH deficiency (see ch. 295), liver insufficiency (see ch. 280 and 285), and glycogen storage diseases (see ch. 260). Neonates and toy breeds may have impaired glucose production. Fasting, malnutrition, or pregnancy may also result in hypoglycemia. Excess glucose consumption may develop in sepsis or extreme exercise (especially in hunting dogs). Some of the many drugs reported to induce hypoglycemia in people include insulin, oral hypoglycemics (e.g., sulfonylurea), salicylates (e.g., aspirin), acetaminophen, beta-blockers (e.g., propranolol), beta-2 agonists, ethanol, monoamine oxidase inhibitors, tricyclic antidepressants (e.g., amitriptyline), angiotensin-converting enzyme inhibitors (e.g., captopril), antibiotics (e.g., tetracycline), lidocaine overdose, and lithium. Fictitious hypoglycemia may occur when blood cells are not promptly separated from serum or in animals with severe polycythemia or leukocytosis.

Diagnostic Evaluation

Serum Glucose and Insulin Concentrations

An algorithmic approach to hypoglycemia is depicted in Figure 303-2. Clinical suspicion of insulinoma begins

with documentation of appropriate clinical signs, hypoglycemia (blood glucose concentration less than 60 mg/dL), and concurrent hyperinsulinemia (serum insulin concentrations within or above reference intervals).[13] Identification of a pancreatic mass with imaging studies may strengthen this suspicion. The diagnosis of insulinoma is confirmed with histologic examination and immunohistochemical staining of a pancreatic mass.

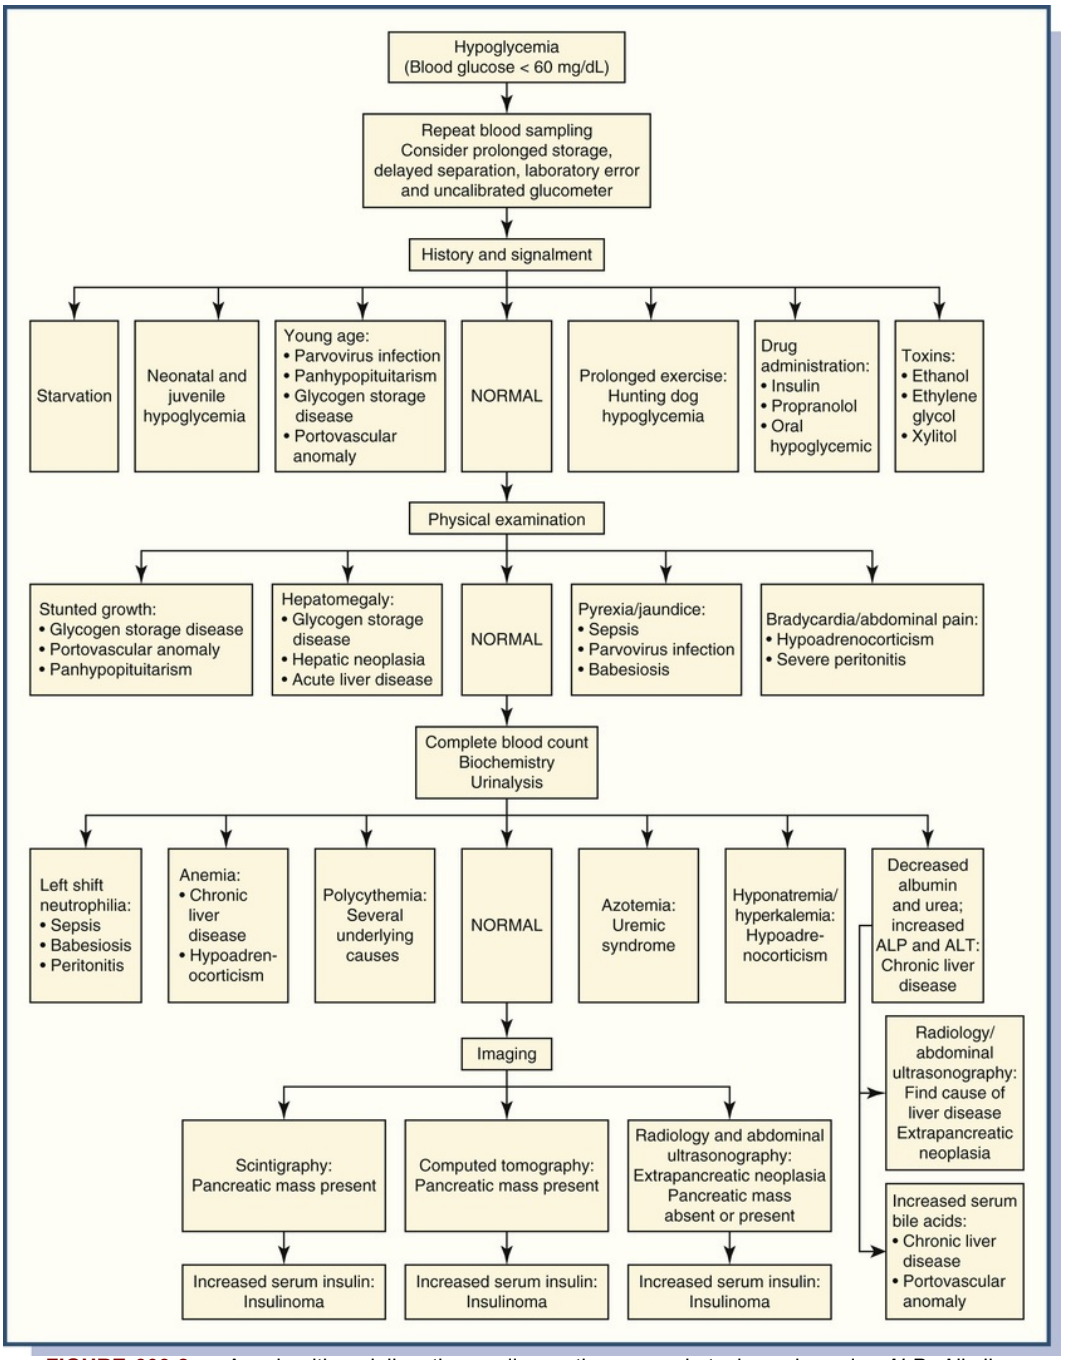

FIGURE 303-2 An algorithm delineating a diagnostic approach to hypoglycemia. *ALP,* Alkaline phosphatase; *ALT,* alanine aminotransferase.

Aside from the often serendipitous hypoglycemia, complete blood count, chemistry screen, and urinalysis are usually unremarkable.[4,7] Although hypoglycemia is observed on randomly obtained blood from most dogs with insulinoma, especially if repeated, it is important to note that some are euglycemic.[7,14] Mild hypokalemia and increased alkaline phosphatase and/or alanine aminotransferase (ALT) activities have been

documented.[5,7] When a dog suspected of insulinoma is euglycemic, it should be closely monitored for hypoglycemia when fasted. Blood glucose concentration should be measured every 30 to 60 minutes. In most dogs with insulinoma, hypoglycemia (blood glucose <60 mg/dL) develops within 12 hours of the previous meal.

Serum for measurement of insulin concentration should be submitted from the same sample in which hypoglycemia is documented. An extremely limited number of dogs with insulinoma do not exhibit hypoglycemia, even with repeated measurements or after a prolonged fast of 48 to 72 hours.[7] Low fructosamine has been used to strengthen the clinical suspicion of insulinoma in several dogs with euglycemia.[14] Glycosylated hemoglobin A1c concentration has been low in some, but not all, dogs with insulinoma.[15] Repetition of serum insulin measurements may also aid in the diagnosis. One study of canine insulinoma found that 76% of dogs had increased serum insulin concentration when measured once and 91% when measured twice.[7]

Ratios and Other Tests

Other tests have been described for the diagnosis of insulinoma in euglycemic dogs with normal serum insulin concentrations. Insulin-to-glucose and glucose-to-insulin ratios are not recommended because of their low sensitivity, and the amended insulin-to-glucose ratio is not recommended because of its low specificity. Additional tolerance and stimulation tests have been described, but are not advocated because of questionable usefulness and/or potentially fatal side effects due to hypoglycemia.

Imaging

Radiographs and Ultrasonography

Most dogs with insulinoma have unremarkable abdominal and thoracic radiographs.[4,6,8,16] When combining results of studies in which abdominal ultrasonography (US) was performed, 49 of 87 (56%) dogs had a pancreatic mass identified. Abdominal metastases were noted in 17 (19%).[3,5,8,16] Although abdominal US may be helpful in supporting a clinical suspicion of a pancreatic mass and metastases, both false-positive and false-negative results have been described (Figure 303-3). Recently, contrast-enhanced US was successfully employed in discriminating insulinoma from pancreatic carcinoma.[17,18]

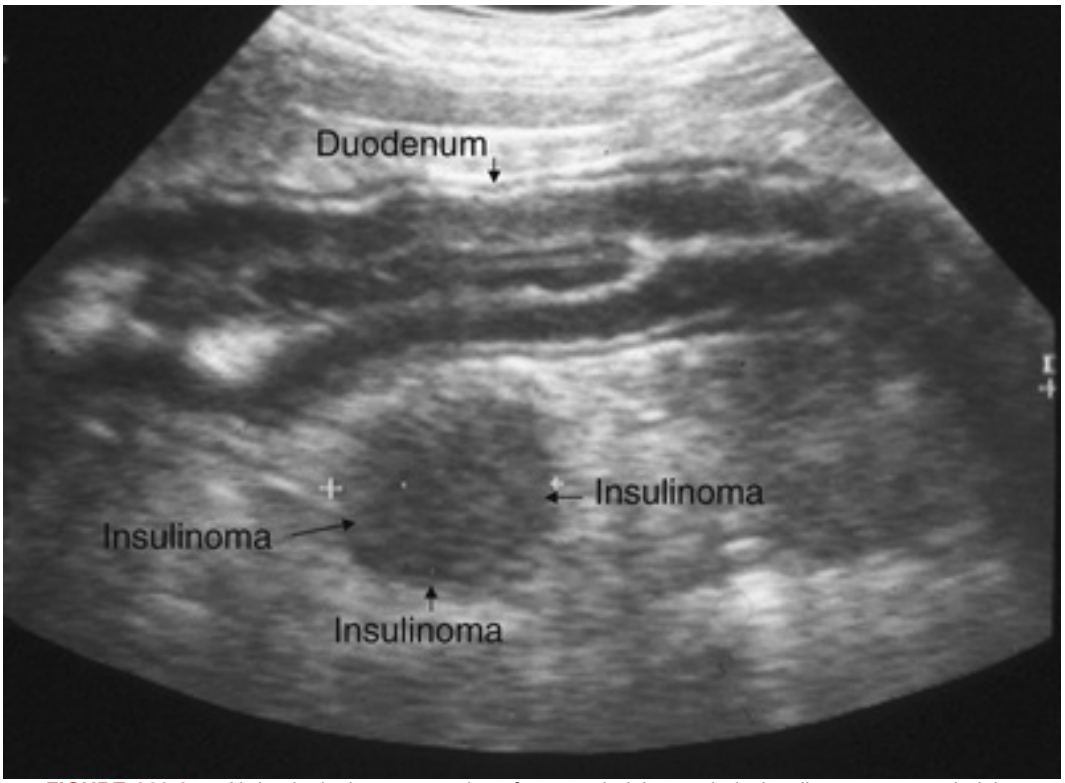

FIGURE 303-3 Abdominal ultrasonography of a rounded hypoechoic insulinoma surrounded by pancreatic tissue. Above the pancreas, the duodenum is visualized. (Courtesy Dr. Wilfried Mai.)

Advanced Imaging

An optimal imaging technique for identifying insulinoma in people has yet to be identified.[19] However, high-quality, dual-phase, thin-section multidetector computed tomography (CT) of the pancreas is effective in identifying a pancreatic mass in most.[19] In people, intraoperative, intra-duct US (not widely available) is more sensitive than CT in detecting small (1- to 3-mm diameter) insulinomas.[19] Use of CT has been reported in a small number of dogs with insulinoma, but its sensitivity has yet to be determined.[20-22] In one study, 14 insulinomas were imaged by US, CT, and single-photon emission CT. CT scans correctly identified the highest number of tumors (10/14, 71%).[22]

In another study, each of three dogs with insulinoma had a mass detected with dual-phase CT angiography (CTA), two of which did not have a pancreatic mass detected on US.[20] Two of these dogs had strong enhancement of their insulinoma only noted during the arterial phase of the study, underscoring the value of dual-phase (Figures 303-4, 303-5, and 303-6).[20] Intravenous (IV) administration of radioactively labeled synthetic somatostatin followed by whole body scintigraphy is of limited value in visualizing insulinomas in people, likely because the number of somatostatin receptors expressed in human insulinomas is low.[19] Somatostatin-receptor-scintigraphy has been reported in a small number of dogs with insulinoma.[23,24] Abnormal foci of activity were observed 1 to 24 hours after administration of the radioligand, but accurate localization of the tumor was achieved in only 1 of 5 dogs.[24]

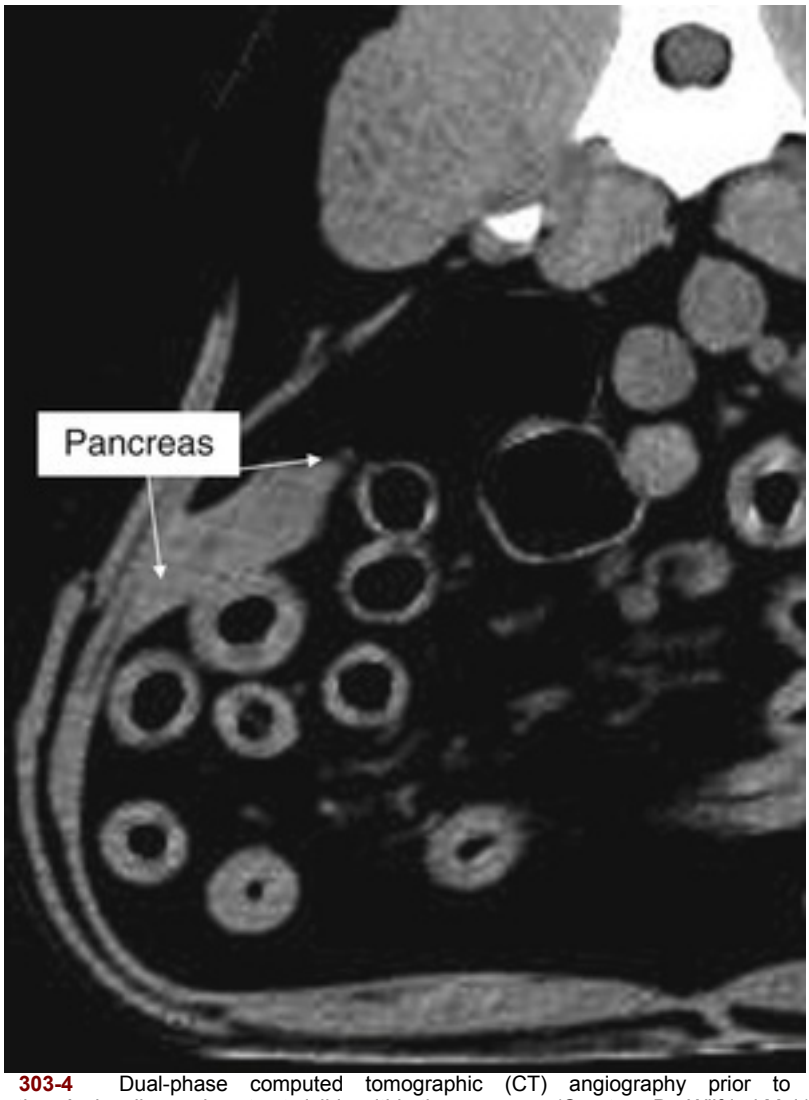

FIGURE 303-4 Dual-phase computed tomographic (CT) angiography prior to contrast administration. An insulinoma is not yet visible within the pancreas. (Courtesy Dr. Wilfried Mai.)

FIGURE 303-5 Dual-phase CT angiography during the venous phase of the study. Some enhancement of the insulinoma is apparent. (Courtesy Dr. Wilfried Mai.)

FIGURE 303-6 Dual-phase CT angiography during the arterial phase of the study. Strong enhancement of the insulinoma is apparent. (Courtesy Dr. Wilfried Mai.)

Treatment

Acute Hypoglycemia

During an acute hypoglycemic crisis, 50% dextrose should be given as a slow bolus (0.5 g/kg IV, diluted at a ratio of 1 : 3 in 0.9% sodium chloride). The bolus should be followed with an IV continuous rate infusion (CRI) of 2.5% to 5% dextrose. The lowest amount of glucose deemed necessary must be administered with caution because glucose stimulates insulin secretion. This can cause rebound hypoglycemia and a vicious circle that may be difficult to break. Dextrose administration should be discontinued when clinical signs resolve, even if mild hypoglycemia persists. In most dogs, neuroglycopenia will resolve with administration of dextrose. However, if the animal fails to respond to dextrose administration alone, dexamethasone (0.1 mg/kg IV q 12 h) and/or a somatostatin analogue (10 to 50 mcg SC q 8-12 h) may be administered. In severe cases, the animal may benefit from sedation with diazepam or pentobarbital for several hours to resolve seizure activity. Cerebral hypoxia may lead to cerebral edema and, if suspected, can be treated with mannitol (1 g/kg IV given as a 20% solution at 2 mL/kg/h) and furosemide (1 to 2 mg/kg IV q 4 h) (see ch. 148).[25]

An IV CRI of glucagon (5 to 13 ng/kg/min with or without concurrent 10% dextrose) has been reported in one dog with insulinoma-associated hypoglycemia. Clinical signs attributed to hypoglycemia resolved within 20 minutes and hypoglycemia resolved within an hour. Glucagon increases blood glucose concentration by promoting glycogenolysis and gluconeogenesis. However, glucagon also increases insulin secretion and animals so-treated also require close monitoring for worsening or rebound hypoglycemia.[26]

Long-Term Care

Surgery

The long-term treatment of choice for insulinoma is surgical resection of both the tumor and any obvious metastases.[5] Two dogs have reportedly undergone successful resection of tumor thrombi that had extended into their pancreaticoduodenal veins.[27] One dog had a prolonged disease-free interval after primary tumor resection, despite presence of metastatic lesions.[28] Surgical exploration and biopsy of a pancreatic mass can confirm a diagnosis and may help in estimating survival time.[10] When postoperative hyperglycemia develops, it is usually transient and resolves once normal beta cells, suppressed by autonomous insulin secretion from neoplastic cells, regain function. About 10% of dogs with an insulinoma develop diabetes mellitus after tumor removal and require exogenous insulin for a completely unpredictable length of time (1 to 37 months).[6,7,10] Other postoperative complications include pancreatitis, diabetic ketoacidosis, delayed wound healing, cardiac arrhythmias or arrest, hemorrhage, sepsis, and leukopenia.[3,5,7]

Medical Therapies

Overview

This review of medical therapy is limited to agents whose use has been reported in dogs with naturally occurring insulinoma. The use of additional medications is discussed elsewhere.[25] Medical treatment may be indicated prior to surgery, postoperatively if needed, and in dogs in which surgery is not performed. Medical therapy can be divided into cytotoxic treatment directed at destroying insulin-secreting beta cells versus treatment aimed at relieving hypoglycemia.

Streptozocin

Streptozocin, a nitrosourea antibiotic, selectively destroys beta cells in pancreatic or metastatic locations. The drug is nephrotoxic in dogs. Diuresis with saline decreases drug contact time with renal tubular epithelial cells and may reduce risk of nephrotoxicosis. In one study, 17 dogs, most of which had surgery with incomplete resection of gross lesions, were treated with 0.9% sodium chloride (18 mL/kg/h IV) for 3 hours prior to, 2 hours during, and 2 hours following streptozocin infusion. Streptozocin (500 mg/m^2) was given every 3 weeks for 5 treatments. Butorphanol (0.4 mg/kg IM) was administered immediately following streptozocin therapy as an antiemetic, but vomiting was still observed in about one-third of treatments. Other side effects included diabetes mellitus; transient hypoglycemia and seizures; transient hyperglycemia; transient increase in ALT activity; azotemia; mild thrombocytopenia; or mild neutropenia. Median duration of normoglycemia in streptozocin-treated dogs was 163 days, not significantly different than that of dogs treated surgically or medically.[8] In a study of 19 dogs, the same dosage and saline protocol was used, but at an intensified 2-week interval. Unfortunately, 8/19 developed diabetes mellitus and 2/19 had nephrotoxicity, while the median progression free interval was similar (196 days).[29] Further studies are necessary before recommending streptozocin therapy.

Common Therapies

The main modes of relieving hypoglycemia include dietary modification and treatment with prednisone, diazoxide, or synthetic somatostatin. Small, frequent meals (every 4 to 6 hours) of a diet high in proteins, fats, and complex carbohydrates are recommended (see ch. 181). Simple sugars (present in soft moist dog foods and IV solutions) should be avoided. Prednisone, the least expensive and most commonly used drug, increases blood glucose concentration by increasing gluconeogenesis and glucose 6-phosphatase activity while decreasing blood glucose uptake into tissues and stimulating glucagon secretion. Glucocorticoids can be administered IV during an acute hypoglycemic crisis as dexamethasone. Prednisone is usually used when a dog is stable, given at an initial oral dosage of about 0.5 mg/kg/day. Doses can be gradually increased as needed usually until the drug no longer is perceived as decreasing seizure episodes or intolerable signs of iatrogenic hyperadrenocorticism (polyuria/polydipsia) develop.[10,25]

Diazoxide

Diazoxide is a benzothiadiazine derivative whose main action is to inhibit closure of pancreatic beta cell ATP-dependent K^+ channels, preventing depolarization and inhibiting opening of voltage-dependent Ca^{2+} channels. Decreased Ca^{2+} influx results in decreased exocytosis of insulin-containing secretory vesicles.

Diazoxide also increases blood glucose concentration by increasing glycogenolysis and gluconeogenesis and inhibiting tissue uptake of glucose.[30] About 70% of dogs exhibit a response to diazoxide doses of 10 to 40 mg/kg/day PO divided q 12 h or q 8 h. Again, it is important to begin with the lowest dosage and gradually increase as needed.[7] Side effects in dogs are uncommon and include ptyalism, vomiting, and anorexia. Additional limitations of diazoxide therapy are its limited availability and considerable expense.

Octreotide

Octreotide is a long-acting synthetic somatostatin analogue whose primary mode of action is inhibition of insulin secretion through its binding affinity to any of five somatostatin receptor subtypes present in insulin-secreting tumors. Dogs show a variable response to octreotide, likely because octreotide variably inhibits glucagon and GH secretion.[31] If suppression of glucagon and GH secretion is of greater magnitude and duration compared with suppression of insulin secretion, octreotide may actually worsen hypoglycemia. While some canine insulinomas may lack somatostatin receptors, 12 dogs with insulinoma treated with a single octreotide dose of 50 mcg/dog SC (median weight 23 kg) had decreases in plasma insulin concentration but concentrations of glucagon, GH, and ACTH were not changed.[32] These findings warrant studies using long-acting octreotide in dogs with insulinoma. No adverse side effects were reported. Side effects in people include mild pain at the injection site (lessened if warmed before administration), nausea, vomiting, abdominal pain, constipation, or steatorrhea.

Prognosis

Median survival time of 142 dogs that underwent partial pancreatectomy, reported in different studies, was 12 to 14 months with a range of zero days to 5 years.[3-5,7,10] Dogs with clinical stage I disease have a significantly longer disease free interval; about 50% are expected to be normoglycemic 14 months postoperatively, compared to only 20% of dogs in clinical stage II or III.[6] Additionally, young dogs and those with persistent post-operative hypoglycemia have a poorer prognosis.[6] In contrast, dogs with postoperative hyperglycemia or normoglycemia have a significantly better prognosis.[3]

One study reported a median survival time of 785 days in 19 dogs with insulinoma that underwent partial pancreatectomy, which improved to 1316 days in the subgroup of dogs that also received prednisone.[33] These survival times are most likely attributable to earlier detection, more radical tumor resection protocols and continued medical therapy following relapse. It was also demonstrated that tumor size and mitotic rate, as depicted by the Ki67 index (a proliferation marker), act as significant prognostic markers in canine insulinoma.[34] This was followed up with a tissue microarray immunohistochemistry study, which corroborated the above findings in 32 insulinoma samples. Multivariate analysis showed that tumor size and Ki67 index retained predictive power for survival time, as did tumor size for disease free interval.[35] Conversely, age, sex, body weight, clinical signs and their duration, US detection of pancreatic mass, tumor location, gross presence of metastatic disease, and blood glucose or insulin concentration have not been significantly associated with prognosis.

Insulin-Secreting Islet Cell Neoplasia in the Cat

Feline insulinoma is rare and has been reported in seven cats ranging in age from 12 to 17 years. Three of these cats were Siamese and five were neutered males.[25,36-38] History and clinical signs are similar to those reported in dogs with insulinoma. Diagnosis is based on documentation of increased serum insulin concentration at the time of hypoglycemia and is aided by abdominal US and histology.[38] Immunohistochemistry of feline insulinoma revealed insulin, chromogranin A and somatostatin expression, with no glucagon or pancreatic polypeptide expression.[39] Care must be taken to use an insulin assay validated for cats. Therapy consists of surgical resection of the pancreatic mass and metastases followed by prednisone treatment and frequent small meals. Use of neither diazoxide nor octreotide has been reported in cats.

CHAPTER 304

Canine Diabetes Mellitus

Federico Fracassi

Client Information Sheet: Canine Diabetes Mellitus

Introduction

Diabetes mellitus (DM) is a common endocrine disorder characterized by chronic hyperglycemia resulting from a deficit in insulin production, action, or both. The prevalence of DM in dogs has been estimated from about 1% of dogs in referral institutions to about 0.3% in first opinion practices.[1-4] The reported incidence of DM in a population of 182,087 insured dogs in Sweden was about 13 cases per 10,000 (0.13%) dog-years at risk.[5]

Classification and Etiology

"Types" of Diabetes Mellitus

There are two predominant forms of DM in people, once referred to as "juvenile-onset" and "adult-onset" DM. These terms were updated to "insulin-dependent" (IDDM) and "non-insulin-dependent" (NIDDM). Currently, the terms type 1 and type 2 DM are employed, with type 1 explaining the condition for about 10% of diabetic people and type 2 DM, almost identical to the previous "NIDDM," used to define the condition in about 90% of people with DM worldwide.[6] The most common form of DM in dogs resembles the human type 1 condition, characterized by permanent hypoinsulinemia, no increase in endogenous serum insulin or C-peptide concentrations following administration of an insulin secretagogue (e.g., glucose, glucagon, amino acids), and an absolute need for exogenous insulin to control glycemia, avoid ketoacidosis, and survive.[7] With rare exceptions, all diabetic dogs require exogenous insulin therapy to manage their hyperglycemia.[8]

Histology and Possible Primary Causes

Common histologic observations in pancreatic tissue from dogs with DM include a reduction in the number and size of pancreatic islets, a decreased number of beta cells within islets, and beta cell vacuolization, enlargement and degeneration.[9,10] The underlying cause of pancreatic beta cell dysfunction/destruction in dogs is not established. In humans and dogs, DM is undoubtedly a multifactorial disease involving both genetic and environmental factors (Box 304-1).[8,11-15] The concept of genetic predisposition has been based on familial associations, pedigree analyses of Keeshonden and several other breeds, and genomic studies to identify susceptibility and protective major histocompatibility complex haplotypes.[1,5,16] A number of genes linked with susceptibility to DM in people are also associated with increased risk in dogs.[17] Canine DM has been associated with major histocompatibility complex (MHC) class II genes (dog leukocyte antigen; DLA). Similar haplotypes and genotypes have been identified in the most susceptible breeds. A region containing a variable number of tandem repeats (VNTR) as well as several polymorphisms has been identified in the canine insulin gene, with some alleles associated with susceptibility or resistance to DM in a breed-specific manner.[17]

Box 304-1

Potential Factors Involved in the Etiopathogenesis of Canine Diabetes Mellitus

Insulin Deficiency

Insulin deficiency in dogs is characterized by a loss of beta cells. The etiology of beta cell deficiency/destruction in diabetic dogs is currently unknown but a number of disease processes are thought to be involved:

- Congenital beta cell hypoplasia/abiotrophy
- Immune-mediated beta cell destruction
- Beta cell loss associated with pancreatitis
- Beta cell exhaustion/glucose toxicity as a consequence of prolonged insulin resistance

Insulin Resistance

Insulin resistance usually results from antagonism of insulin function by other hormones and can also be exacerbated by the presence of infection or inflammation:

- Diestrus/pregnancy
- Concurrent hormonal disease
  - Cushing's syndrome
  - Hypothyroidism
  - Acromegaly
- Iatrogenic
  - Glucocorticoids
  - Progestagens
- Carbohydrate intolerance associated with obesity
- Infection
- Concurrent illness
- Renal insufficiency
- Cardiac disease
- Hyperlipidemia
- Insulin receptor deficits such as those seen in humans might exist in canine diabetic patients, although these have not so far been reported

Modified from Davison LJ: Canine diabetes mellitus. In Mooney CT, Peterson ME: *BSAVA manual of canine and feline endocrinology*, ed 4, Gloucester, England, 2012, British Small Animal Veterinary Association, p 117.

The American Diabetes Association has recommended sub-categorizing human type 1 DM (T1DM) into types 1A (immune-mediated) and 1B (idiopathic severe insulin deficiency).[18] Type 1A DM is characterized by lymphocytic infiltration of the islets, known as "insulitis," and by the presence of serum autoantibodies to pancreatic components (insulin, intracellular glutamic acid decarboxylase 65 [GAD65] or insulinoma antigen 2 [IA-2]) prior to development of hyperglycemia (Figure 304-1).[19] An immune-mediated component has been implicated in development of canine DM. Lymphocytic infiltration of pancreatic islets has been reported and antibodies directed against islet cells, insulin, proinsulin, GAD65 and IA-2 have been identified in dogs with DM.[20-24] Despite these studies, the role of autoimmunity in the pathogenesis of canine DM remains unsettled. A recent study did not find evidence for an islet autoimmune etiology.[9] Unlike human T1DM, which occurs primarily in adolescence and early adulthood, dogs are usually diagnosed when middle-aged or older.[25] It has been proposed that canine DM most closely resembles people with "latent autoimmune diabetes of adults" (LADA).[11,26]

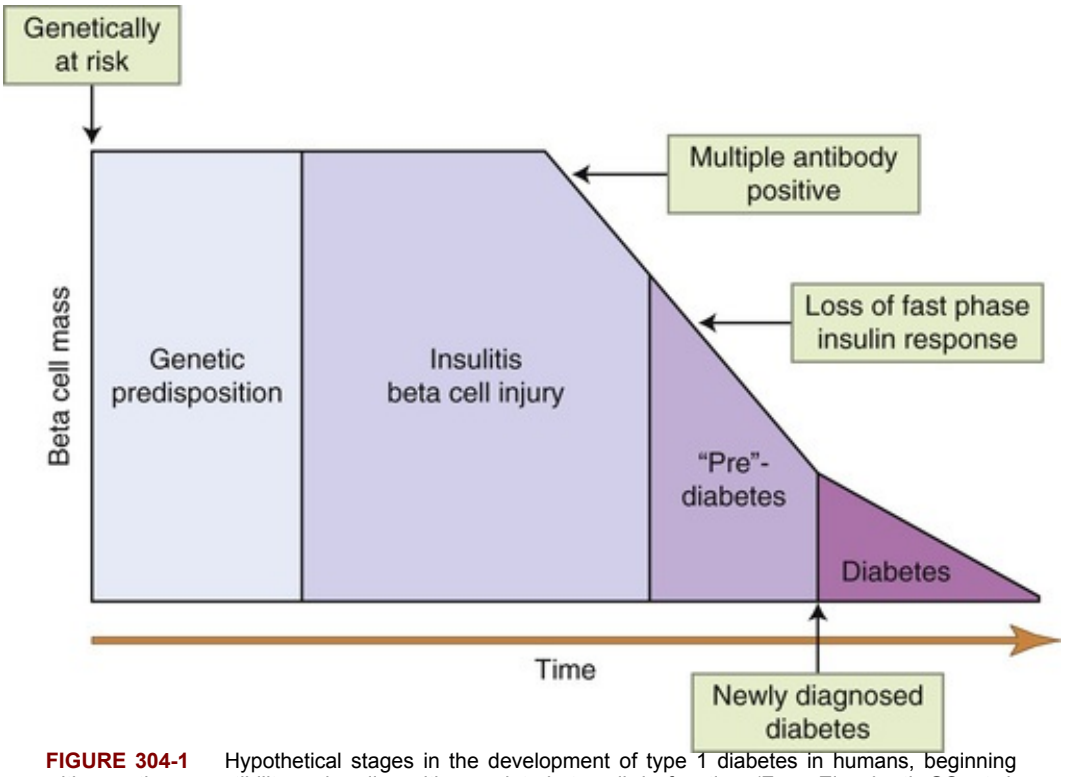

FIGURE 304-1 Hypothetical stages in the development of type 1 diabetes in humans, beginning with genetic susceptibility and ending with complete beta cell dysfunction. (From Eisenbarth GS, et al: Type 1 diabetes mellitus. In Kronenberg HM, Melmed S, Polonsky KS, et al, editors: *Williams textbook of endocrinology*, ed 11, Philadelphia, 2008, Saunders Elsevier, p 1398.)

Secondary Causes

DM may occur secondary to disorders of the exocrine pancreas or any process that diffusely injures the pancreas, most notably pancreatitis.[27] The incidence of histologically identifiable, often severe, pancreatitis in diabetic dogs ranges from 30% to 40% and is believed to be a contributor to development of DM and diabetic ketoacidosis (DKA).[28-30] Loss of beta cell function is irreversible in dogs with DM and lifelong insulin therapy is necessary for survival. Transient or reversible DM is extremely uncommon in dogs, usually recognized in subclinical diabetics with a concurrent insulin-antagonistic condition (i.e., diestrus, pregnancy) or who were given an insulin antagonistic drug (i.e., glucocorticoids). Following estrus, all normal bitches (pregnant or not) enter the luteal, progesterone-dominated phase (diestrus) of their ovarian cycle. Diestrus lasts 60 to 90 days, every 6 to 12 months. Progesterone (Pg) stimulates growth hormone (GH) secretion from mammary tissue. Both Pg and GH antagonize the effects of insulin.[31] Older females are frequently diagnosed with DM while in diestrus (whether or not pregnant), when serum Pg and GH concentrations are increased.[32-34] Treatment with ovariohysterectomy removes the source of Pg and, in turn, the stimulus for GH secretion. If an adequate population of functional beta cells is still present in the pancreas, hyperglycemia may resolve without insulin treatment. Failure to quickly correct insulin resistance often results in progressive loss of beta cells and a greater likelihood of permanent insulin dependency.[33]

"Honeymoon Period"

A "honeymoon period" occurs in some dogs with newly diagnosed DM, characterized by excellent glycemic control in response to small doses of insulin (<0.2 U/kg/injection), presumably due to residual beta cell function. Typically, glycemic control in these dogs becomes more difficult and insulin doses need to be increased within months of beginning treatment, as those residual functioning beta cells die and fail to be replaced. Endogenous insulin secretion declines.[35] Type 2 or NIDDM is rare in dogs and usually associated with a concurrent insulin antagonistic condition or treatment. Obesity-induced insulin resistance has been documented in dogs although progression to type 2 DM has not yet been demonstrated.[36]

Pathophysiology

Diabetes mellitus is the result of a relative or absolute deficiency of insulin secretion by pancreatic beta cells. Insulin deficiency, in turn, causes decreased tissue utilization of glucose, amino acids, and fatty acids, accelerated hepatic glycogenolysis and gluconeogenesis, and accumulation of glucose in the circulation, causing hyperglycemia.[37] Neither intestinal glucose absorption nor glucose entry into erythrocytes, kidney or brain is affected. As renal tubular capacity for glucose reabsorption is exceeded, usually when blood glucose concentrations are >180 to 220 mg/dL, glycosuria occurs. The resulting glucose-induced osmotic diuresis causes polyuria (PU), water loss, and activation of the thirst mechanism (polydipsia; PD). The negative calorie balance resulting from an inability to utilize glucose, some loss of calories via glycosuria, and tissue catabolism leads to polyphagia (PP).

The physiology of the consequences of DM is virtually identical to that of starvation. Protein metabolism shifts toward decreases in synthesis and increases in proteolysis. These available amino acids increase hepatic gluconeogenesis, a good response to starvation, but in DM it further contributes to hyperglycemia at a price of negative nitrogen balance, loss of muscle mass and possible cachexia.[38] The continuing lack of insulin and intracellular glucose then accelerate lipid catabolism with mobilization of triglycerides that leads to increased levels of plasma free fatty acids (FFAs). FFAs are transported to the liver where they undergo beta-oxidation to acetyl CoA, the amount of which may exceed the need for ATP production via oxidation in the Krebs cycle. Acetyl CoA is, therefore, metabolized into its alternative product: ketone bodies. Again, in response to starvation, ketones are an acceptable short term source for energy. In prolonged starvation or in DM, production of excess ketone bodies can lead to ketosis and, in diabetics, ketoacidosis. Increased hepatic concentration of fatty acids also increases hepatic synthesis of both triglycerides and very low density lipoproteins (VLDL), causing hyperlipidemia and hepatic lipidosis (see ch. 285).

Signalment

DM is most commonly diagnosed in middle-aged and older dogs, 5 to 12 years of age.[1,3,5] Rarely, DM in juvenile dogs has been reported.[3,39] Peak prevalence is 7 to 10 years and most, but not all, studies suggest females are at a greater risk.[1,3-5,40] Regional differences in breed popularity or variation in neutering practices may influence sex predispositions within a population, although associations identified between neutering and diagnosis of DM also vary. Genetic predisposition for or against the development of DM in dogs has been suggested (Table 304-1). For example, Boxer dogs are seldom reported in epidemiologic studies on DM and may have one of the lowest incidences. Genetic differences within the same breed due to different blood-lines also impact predispositions. For example, Swedish and Norwegian Elkhounds, Australian Terriers and Samoyeds have the highest incidence of DM in Sweden while Irish Setter and English Setter dogs are overrepresented in Italy.[2,5]

TABLE 304-1

Breed Risks for Developing Diabetes Mellitus

BREEDS AT HIGH RISK	ODDS RATIO	BREEDS AT LOW RISK	ODDS RATIO
Australian Terrier	9.39	German Shepherd Dog	0.18
Standard Schnauzer	5.85	Collie	0.21
Miniature Schnauzer	5.10	Shetland Sheepdog	0.21
Bichon Frise	3.03	Golden Retriever	0.28
Spitz	2.90	Cocker Spaniel	0.35
Fox Terrier	2.68	Australian Shepherd	0.44
Miniature Poodle	2.49	Labrador Retriever	0.45
Samoyed	2.42	Doberman Pinscher	0.49
Cairn Terrier	2.26	Boston Terrier	0.51
Keeshond	2.23	Rottweiler	0.51

Maltese	1.79	Basset Hound	0.56
Toy Poodle	1.76	English Setter	0.60
Lhasa Apso	1.54	Beagle	0.64
Yorkshire Terrier	1.44	Irish Setter	0.67

Derived from analysis of the Veterinary Medical Database (VMDB) from 1970 to 1993. The VMDB comprises medical records of 24 veterinary schools in the United States and Canada. VMDB case records analyzed included those from first hospital visits of 6078 dogs with a diagnosis of diabetes mellitus and 5922 randomly selected dogs with first hospital visits for any diagnosis other than diabetes mellitus seen at the same veterinary schools in the same year. Only breeds with more than 25 cases of diabetes mellitus are included.

From Guptill L, et al: Is canine diabetes on the increase? In *Recent advances in clinical management of diabetes mellitus,* Dayton, Ohio, 1999, Iams Company, p 24.

Anamnesis

The typical history of a dog with DM includes the classical clinical signs of PU/PD/PP and weight loss. PU/PD are constant in diabetic dogs. PP may be diminished by a concurrent condition that decreases appetite (e.g., pancreatitis, ketosis, DKA). Weight loss may not be noticed in dogs that have only recently become diabetic. The most common reasons for dogs with undiagnosed DM to be brought to their veterinarian are their need to urinate at night or that they urinate in the home. In the event that a dog has free access to urinate out-of-doors, the owner may consult the veterinarian due to concerns over weight loss, ravenous appetite, sudden blindness caused by cataract formation (Figure 304-2), or signs associated with DKA (e.g., lethargy, anorexia, vomiting, weakness). Time from onset of clinical signs to development of DKA is unpredictable, ranging from days to months, and may be dependent on type and severity of concurrent disorders causing insulin resistance and/or stimulating ketone production.

FIGURE 304-2 Bilateral complete cataracts secondary to diabetes mellitus causing blindness in a dog.

Physical Examination

In dogs with newly diagnosed DM, abnormalities detected on physical examination (PE) depend on the duration of DM, presence of concomitant disorders, and whether DKA has developed. A thorough PE is critically important, especially to detect issues due to a concomitant disease. Dogs with uncomplicated DM are usually in good condition and their PE may be unremarkable. Diabetic dogs can be of normal weight, underweight or obese. Lethargy may be evident. The haircoat in newly diagnosed or poorly controlled DM may be dull. Hepatomegaly due to diabetes-induced hepatic lipidosis is commonly palpable. Cataracts are also common. Anterior uveitis and keratoconjunctivitis sicca may be present. The neurologic signs commonly observed in diabetic cats (e.g., weakness in the hind limbs, ataxia, plantigrade stance) are uncommon in dogs.

Diagnosis

The diagnosis of diabetes mellitus is made on the basis of appropriate clinical signs, persistent fasting hyperglycemia (>200 mg/dL), and concomitant glycosuria. Persistent hyperglycemia and glycosuria are both of paramount importance in the diagnosis of DM. Hyperglycemia distinguishes DM from primary renal glycosuria and glycosuria separates DM from other causes of hyperglycemia (Box 304-2). Mild hyperglycemia, concentrations below renal threshold (>100 and <180 mg/dL), is asymptomatic and often viewed as an incidental finding. DM is quite unlikely if a dog has mild hyperglycemia without glycosuria. Stress-induced hyperglycemia is common in cats, but rare in dogs. A diagnostic evaluation for disorders causing insulin resistance is indicated if mild hyperglycemia persists in a fasted, unstressed dog, but insulin therapy is not indicated because clinical DM is not present. Concurrent evidence of ketonuria establishes a diagnosis of diabetic ketosis (DK), whereas ketonuria and metabolic acidosis with increased anion gap establishes a diagnosis of DKA. Blood ketone concentrations can be assessed with one drop of blood, using a hand-held electrochemical sensor for 3-beta-hydroxybutyrate (3-HB). Low to moderate 3-BH blood concentrations are usually indicative of DK, whereas higher values (>3.8 mmol/L) are suggestive of DKA (see ch. 142).[41]

Box 304-2

Causes of Hyperglycemia and Glycosuria in Dogs

Hyperglycemia Causes

Diabetes mellitus
Stress, aggression, excitement, nervousness, fright (quite uncommon)
Pancreatitis
Postprandial (diets containing monosaccharides, disaccharides, and propylene glycol)
Hormonal antagonism:
- Cushing's syndrome
- Diestrus
- Pheochromocytoma
- Acromegaly

Iatrogenic:
- Glucocorticoids
- Progestagens
- Thiazide diuretics
- Alpha 2-agonist sedatives
- Dextrose-containing fluids
- Parenteral nutrition solution

Head trauma

Glycosuria Causes

Diabetes mellitus
Renal tubular dysfunction:
- Fanconi syndrome
- Primary renal glycosuria
- Acute kidney injury (e.g., leptospirosis)

- Nephrotoxins

Iatrogenic:

- Dextrose-containing fluids

Causes of false positive glycosuria:

- Glucose in the owner's collecting jar for urine (e.g., jam jar)
- Vitamin C or pigment in urine can affect dipstick results

Once DM is diagnosed, it is extremely important to thoroughly evaluate the overall health of a dog. One should identify any clue to a condition that may have contributed to DM development (e.g., Cushing's syndrome [see ch. 306], hypothyroidism [see ch. 299], pancreatitis [see ch. 290]) or which could represent a consequence of DM (e.g., weight loss, weakness, urinary tract infection). The minimum laboratory evaluation in a dog newly diagnosed with DM should include a complete blood count (CBC), a serum biochemical profile that includes a serum fructosamine concentration, and urinalysis with bacterial culture. Serum Pg concentrations should be assayed in any intact diabetic female. Abdominal ultrasound (US; see ch. 88) is indicated to evaluate patients for evidence of pancreatitis, adrenal enlargement, masses, pyometra, ovarian cysts, and other concerns. Because of the relatively high prevalence of pancreatitis, pancreatic lipase immunoreactivity (cPLI) should be considered, especially if US is unavailable. Other tests, including thoracic radiographs, may be indicated (Box 304-3).

Box 304-3

Clinicopathologic Abnormalities Commonly Found in Dogs with Uncomplicated Diabetes Mellitus

Complete Blood Count

1. Typically normal
2. Neutrophilic leukocytosis or toxic neutrophils may be observed if pancreatitis or infection is present

Biochemistry Panel

1. Hyperglycemia
2. Hypercholesterolemia
3. Hypertriglyceridemia (lipemia)
4. Increased alanine aminotransferase activity (typically <500 IU/L)
5. Increased alkaline phosphatase activity (typically <500 IU/L)

Urinalysis

1. Urine specific gravity typically >1.025
2. Glycosuria
3. Variable ketonuria
4. Proteinuria
5. Bacteriuria

Ancillary Tests

1. Hyperlipasemia if pancreatitis is present
2. Serum trypsin-like immunoreactivity usually normal
   a. Low with pancreatic exocrine insufficiency
3. Pancreatic lipase immunoreactivity usually normal
   a. High with acute pancreatitis
   b. Normal to high with chronic pancreatitis
4. Variable serum baseline insulin concentration
   a. Insulin-dependent diabetes mellitus: low, normal
   b. Insulin-resistance-induced: low, normal, increased

Management Issues

Plan and Therapeutic Goals

Successful treatment of DM in a dog requires excellent owner compliance and excellent owner/veterinary team interaction. The "owner" may be one person or several while the veterinary team involved in the long-term care of these dogs should include veterinarians, technicians, and non-technical personnel. The owner should be thoroughly educated regarding DM, how it is managed differently in dogs when compared with people, and the goals of therapy. Establishing and agreeing on the definition of "successful management" is extremely important. For most veterinarians, their primary goal in the long-term management of DM should be to have the owner pleased with the status of their dog. This is usually achieved if PU can be eliminated or significantly reduced, body weight is stable and acceptable, PP is tolerable, and the dog interacts normally with others in the home. Owners who are informed and involved in the management of their dog seem to have more success and satisfaction in providing care. A highly motivated owner who works with their veterinarian is key. Dogs with DM typically require two daily injections of insulin and a relatively fixed routine. Owners must be willing to administer insulin, and have sufficient finances for insulin, consumables, testing necessary to manage the DM over time, as well as possible intermittent periods of hospitalization.[42] It is important to give the owners detailed information on all the technical aspects of DM and to provide ready access to care, if needed. Furthermore, treatment should follow a precise and understandable protocol (Box 304-4).

Box 304-4

Protocol for the Management of Diabetic Dogs

- Diagnosis of diabetes mellitus (history, physical examination, hyperglycemia, glycosuria, increased fructosamine)
- Routine laboratory evaluation (complete blood count, serum biochemistry, urine analysis, urine culture)
- Abdominal ultrasonography, canine pancreatic lipase immunoreactivity if indicated
- Cessation of diabetogenic drugs
- Administration of intermediate-/long-acting insulin (Caninsulin/Vetsulin, NPH, Lantus): 0.25 U/kg SC q 12 h
- Institution of treatment for concurrent problems (e.g., urinary tract infection)
- Prescribe a commercial "diabetic" diet. Feed the dog with 2 meals of equal size just before each insulin injection. If overweight, aim to achieve 1% to 2% weight loss per week. High-fiber, low-calorie diets should not be fed to thin or emaciated diabetic dogs until glucose control is established and a normal body weight is attained using a calorie-dense, lower-fiber diet designed for maintenance. Dietary recommendations for concurrent disorders (e.g., chronic kidney disease, food allergy, pancreatitis) have priority over a specific diabetic diet.
- Owner instructions (requires at least 1 hour)
  - With intact bitches, make an appointment with the owner for spaying. This procedure should be done soon as possible.
  - Provide written instructions

Reevaluation 1 Week after Diagnosis

- History, physical examination, body weight
  - Administration of food and insulin at the clinic. For dogs that are unwilling to eat at the clinic, food and insulin are given at home and the blood glucose curve (BGC) started upon arrival at the clinic (as soon as possible).
- Glucose measurement every 1-2 hours for the remainder of the day
- Fructosamine
- Adjustment of insulin dosage if required: 10% to 25%

Reevaluation 2 to 3 Weeks after Diagnosis

- Repeat all the procedures performed at the first reevaluation (history, physical examination, body weight, BGC, fructosamine, dosage adjustment)
- Introduction to home monitoring (HM) and instruction on all relevant technical aspects (requires at

least ½ hour)
- Owner should measure fasting blood glucose twice weekly and generate a BGC twice a month

Reevaluation 6 to 8 Weeks after Diagnosis
- Repeat all procedures performed in first reevaluation (history, physical examination, body weight, BGC, fructosamine, dosage adjustment). BGC may not be required if the dog appears clinically well, if blood glucose measured close to the time of insulin administration is 180 to 250 mg/dL, and fructosamine is 350 to 450 micromol/L.
- Owner administration technique should be evaluated for those doing HM

Reevaluation 10 to 12 Weeks after Diagnosis
- Repeat all procedures done 6 to 8 weeks after diagnosis

Further Reevaluations Every 4 Months
- Repeat all procedures done 6 to 8 weeks after diagnosis

Goals of Therapy
- Clinical signs: resolution of polyuria/polydipsia and polyphagia, normal body weight
- Blood glucose concentration: ideally between 250 mg/dL (before insulin administration) and 90 mg/dL (nadir)
- Fructosamine concentration: ideally between 350 and 450 micromol/L. (please note: fructosamine concentration is the least important variable for evaluation of metabolic control)

Initiating Insulin Therapy

Once diagnosed, treatment for DM should begin. Dogs in good condition and with an excellent appetite can be managed as "uncomplicated diabetics," even in the presence of ketonuria. The goals of therapy are to reduce or resolve clinical signs, prevent short-term complications (e.g., hypoglycemia, DKA), achieve the previously discussed areas of clinical improvement, and have a good quality of life. In DM dogs, this can be accomplished with exogenous insulin therapy, an appropriate diet, exercise, prevention or control of concurrent inflammatory, infectious, neoplastic or hormonal disorders, and avoidance of insulin-antagonistic drugs (see ch. 358). Aiming for normal or near-normal blood glucose concentrations is not recommended, as it increases risk of hypoglycemia, a common, serious and potentially life-threatening complication. Hypoglycemia is usually the result of overzealous insulin therapy. Most diabetic dogs are described as being well if their blood glucoses are maintained between 90 to 250 mg/dL.

Owner Education (see ch. 79)

Educating owners is of paramount importance to achieve success in managing a dog with DM. Owners should be familiar with the clinical signs of DM. They should be aware of changes in water intake, urine output, appetite and body weight. Poor appetite, vomiting, diarrhea or unusual lethargy is always worrisome and worth veterinary consultation. Insulin should, initially, be given after the dog eats to avoid the conundrum of having given insulin to a dog who refuses to eat. It should be emphasized that consistency in timing of injections, meals, type and amount of food, and exercise will make control of DM easier. Owners must learn the signs of hypoglycemia and DKA. Unfortunately, many dogs with DM become blind from cataract formation (see Figure 304-2). This may occur despite an owner's best efforts for excellent control.

While owners are the key to good DM control, decisions regarding insulin, dose and frequency of administration must always be made by the owner/veterinary team. Insulin should be stored in a refrigerator in an upright position. Insulin must be mixed correctly. Vetsulin/Caninsulin should be shaken, some insulins do not require mixing, and some insulin products should be gently rolled. Owners must use appropriate syringes (40 U/mL for veterinary insulin products and 100 U/mL for human insulin products), learn to eliminate air bubbles, and administer the insulin SC over the lateral wall of the chest. The use of nonmatching syringes based on conversion tables for U40 and U100/mL, or the owner's own calculation, should be avoided as it can be confusing. Often U40 insulin syringes have scales in both mL and Units; the owner must be instructed to use the Units scale. The injection technique should be demonstrated until the owner is comfortable (practice at home with an over-ripe banana can be beneficial). If an insulin pen device is to be

used for insulin administration, owners must be specifically trained with this tool. Written instructions are useful. Owners of DM dogs should be encouraged to keep detailed records of their dogs' blood glucose, urine glucose, urine ketones, and any change in other parameters.

Dietary Recommendations (see ch. 181)

Food given to DM dogs must be palatable to ensure regular consumption. Diets must be nutritionally complete and have day-to-day consistency with regard to composition, ingredients and calories. These factors improve the chance for consistent insulin requirements and consistent response. Ideally, near optimal body condition is achieved and maintained. A dog with DM may be overweight or underweight. In either, near ideal weight is a reasonable goal. Insulin is an anabolic hormone and insulin-treated diabetics gain weight easily. Since insulin is anabolic, having an obese dog with DM lose weight is far more difficult. However, obesity-induced insulin resistance has been documented in dogs and weight loss improves glucose tolerance.[43] Weight loss diets should be considered for obese DM dogs as they are typically rich in insoluble fiber, low in fat, and have decreased caloric density. Such diets should not be fed to underweight DM dogs. Once glucose control is established and a near-normal body weight attained, giving a consistent calorie-dense and lower-fiber diet designed for maintenance should be considered.[37]

Several commercial prescription diets are available for DM dogs. To minimize postprandial hyperglycemia, no diet should contain significant amounts of simple sugar. Calories should be provided mainly by complex carbohydrates and proteins. The amount of fat in the diet should be minimized to avoid increasing circulating cholesterol, triglycerides, free glycerol, and free fatty acids.[44] Dietary fat may directly contribute to insulin resistance, promote hepatic glucose production and, in healthy dogs, suppress beta cell function.[45,46] Dietary fat should be particularly restricted in any dog with a history of pancreatitis or persistent hyperlipidemia.

Several, but not all, studies evaluating the role of high-fiber diets in the management of DM dogs demonstrated higher dietary fiber content improves glycemic control.[47-49] One study failed to demonstrate benefit from feeding normal weight DM dogs a high-fiber diet.[44] Most diets for DM contain a blend of soluble and insoluble fibers. Common complications of feeding high-fiber diets include increased frequency of defecation (insoluble fiber); constipation and obstipation (insoluble fiber); soft to watery stools (soluble fiber); and excessive flatulence (soluble fiber).[37] Problems with palatability, which are usually the result of switching diets too quickly, can be avoided in many by gradually transitioning from one diet to another. With time, dogs may become less interested in fiber-rich diets and palatability can be improved by adding minced boiled meat. Diet should also take concurrent conditions into consideration (i.e., inflammatory bowel disease, chronic kidney disease, food allergy/intolerance), which may have priority over a specific DM diet.

To simplify management, most DM dogs should be fed two equal-sized meals daily, about every 12 hours, immediately prior to giving insulin, thus avoiding the situation of a dog refusing to eat after receiving insulin. In dogs with a consistently good appetite, food can be given immediately after the insulin injection, helping the dog associate the unpleasant injection with the more pleasurable meal. Ad libitum feeding can be of benefit in some diabetic cats but is not recommended in dogs. Dogs who are finicky eaters should be fed at the time of insulin administration and have any uneaten food available throughout the day.

Exercise

Consistent exercise can make management of canine DM easier and should be encouraged (see ch. 355 and 359). Physical activity decreases glucose concentrations by increasing the absorption of insulin from its injection site, increasing blood flow and insulin delivery to exercising muscles, stimulating translocation (i.e., upregulation) of glucose transporters (primarily GLUT-4) in muscle cells, and increasing glucose disposal despite basal insulin concentrations.[50,51] Timing and amount of exercise each day should be as consistent as timing of meals and insulin. For example, it is not appropriate for a diabetic dog to have little or no exercise during the week and then work hard on weekends. Strenuous and sporadic exercise can induce hypoglycemia and should be avoided. On the day that a DM dog is expected to be involved in intense or unusual exercise (i.e., hunting), it is important to reduce that morning dose of insulin. The percent reduction necessary to prevent hypoglycemia is not predictable; thus, an initial reduction of 50% is reasonable. Further adjustments should be based on experience with issues like symptomatic hypoglycemia or PU during or after exercise. Owners of DM dogs should always have a glucose source readily available, in case signs of hypoglycemia are observed while doing physical activity.

Insulin

Overview

Various types of insulin are used to treat DM long-term. Based on duration of action and potency, they include intermediate-acting (lente, Neutral Protamine Hagedorn [NPH]) and long-acting insulins (protamine zinc insulin [PZI], insulin glargine, insulin detemir) (Table 304-2). Lente (Vetsulin, Caninsulin) is a porcine–origin zinc 40 U/mL insulin consisting of 30% short-acting amorphous insulin and 70% long-acting, microcrystalline insulin. NPH (100 U/mL; Humulin N, Novolin N) is recombinant human insulin, usually administered q 12 h. Postprandial hyperglycemia can occur in some well-regulated dogs.[58] A long-acting PZI 40 U/mL insulin made with recombinant human insulin is approved for use in cats (ProZinc). This insulin may be useful for some dogs in whom duration of intermediate-acting insulins is too short.[54] The insulins glargine and detemir are synthetic long-acting insulin analogues designed to maintain basal insulin concentrations in diabetic people. Their use in dogs is increasing.

TABLE 304-2

Commonly Used Insulin Preparations for Treating Uncomplicated Diabetes Mellitus in Dogs

INSULIN	PRODUCT	ORIGIN	CONCENTRATION (U/mL)	DURATION OF EFFECT (hours)	FREQUENCY OF ADMINISTRATION	STARTING DOSAGE (U/kg/injectio
Lente	Vetsulin/Caninsulin	Porcine	40	8-14	q 12 h	0.25
NPH	Humulin N, Novolin N	Recombinant human	100	4-10	q 12 h	0.25
PZI	ProZinc	Recombinant human	40	10-16	q 12 h	0.25-0.5
Glargine	Lantus	Recombinant human	100	8-16	q 12 h (q 24 h)	0.3
Detemir	Levemir	Recombinant human	100	8-16	q 12 h (q 24 h)	0.1

*Dogs weighing <15 kg.

†Dogs weighing >15 kg.

NPH, Neutral protamine Hagedorn; *PZI*, protamine zinc insulin.

Insulin Analogues

Insulin analogues are modified from human insulin peptides, have similar physiologic effects, and are commonly used in treating diabetic cats and dogs.[59] The amino acid asparagine in human insulin is replaced with glycine at position A21 and two positively charged arginine molecules are added to the C-terminus of the B chain to create insulin glargine (Lantus).[60] This structure results in low aqueous solubility at neutral pH but complete solubility at a pH of 4. The acidic glargine solution injected into the pH-neutral milieu of the SC forms insulin-analogue-microprecipitates that slow absorption and delays onset of action. The result is a

relatively constant, peakless, basal supply of insulin.[60] Due to the importance of pH, glargine should never be diluted or mixed with any solution that could alter pH. In dogs, insulin glargine has been shown to be safe and efficacious for good to moderate glycemic control.[55,56]

The amino acid threonine, at position 30 of the B chain, has been removed and a 14 carbon fatty acid (myristic acid) has been bound to the amino acid lysine at B chain position 29 to create insulin detemir (Levemir). These modifications permit this insulin to reversibly bind to albumin, slowing absorption and prolonging its consistent metabolic effect for as long as 24 hours in people.[61] In dogs, insulin detemir is about four times more potent as compared with other insulin preparations. Insulin detemir, given SC, q 12 h, is a potential treatment for dogs with DM. Due to the higher potency of this insulin in dogs, lower dosages are required to control glycemia. A starting dose of 0.1 U/kg, q 12 h is recommended. Detemir should be used with caution, especially in small dogs.[57] Use of diluent specifically designed for this insulin allows safer delivery of small doses.

Storing, Mixing and Diluting Insulin

Freezing or heating inactivates insulin. While storing insulin at room temperature is acceptable, owners should be instructed to store insulin inside the refrigerator door to maintain a stable and consistent environment, bottle to bottle, patient to patient. Some veterinarians recommend replacing insulin every month to avoid inactivation or contamination. However, the "shelf-life" of commercially produced insulin, stored and handled appropriately, is much longer than the manufacturer's recommendations. Problems with loss of insulin potency or sterility are extremely rare. Routine monthly replacement is not recommended. While shaking rather than gentle mixing was thought to inactivate insulin, recent studies again demonstrate that insulin is resistant to being destroyed in this manner. For consistency, however, gentle rolling is suggested for most insulin products. Vetsulin/Caninsulin, should be "shaken thoroughly" until a homogeneous, uniformly milky, suspension is seen. Diluting insulin can be quite useful in small dogs, particularly when using detemir that is four times more potent than other insulins. Only diluent solutions provided by the manufacturer should be used. It is important to emphasize that insulin glargine is pH-dependent and should not be diluted.

Insulin Pen Devices

Dosing pens, designed for use by diabetic people, should make measurement and administration of insulin easier, less painful, and more accurate. Insulin dosing pens have been shown to decrease anxiety, discomfort, and social embarrassment associated with insulin administration.[62] Limited information is available on using these devices in dogs. Lente porcine insulin is the only veterinary insulin product marketed with a pen. They are available in two sizes, a maximum 8 U/dose VetPen (0.5 to 8 U) with 0.5 U dose increments and a maximum 16 U/dose VetPen (1 to 16 U) with 1 U increments. Owners choosing to use this apparatus must be trained in its assemblage (Video 304-1) and use (Video 304-2).

Initial Insulin Recommendations

Treatment of canine DM requires exogenous insulin to maintain glycemic control. In newly diagnosed DM dogs, the first insulins usually recommended are from the intermediate-acting group, such as lente (Vetsulin, Caninsulin) or recombinant human NPH. With either, one should begin with about 0.25 U/kg SC q 12 h. This conservative approach should be sufficient to prevent symptomatic hypoglycemia or the Somogyi response. Dogs may be hospitalized for 1 or 2 days to complete the diagnostic evaluation and begin therapy. Blood glucose concentrations should be checked two to three times daily to identify hypoglycemia, if present. If the blood glucose decreases <80 mg/dL, the insulin dosage should be reduced. It is not recommended to increase the dosage if glucoses remain high, however, because insulin action may improve after a few days (so-called equilibrium).[38] Insulin therapy can be started on an outpatient basis, which is less expensive and considered more efficacious by some.

Females in Diestrus

Intact bitches diagnosed with DM should undergo ovariohysterectomy as soon as feasible, ideally 1 to 3 days after starting insulin.[38] Ovariohysterectomy is most important if the bitch is in diestrus and under the

influence of Pg, because surgery will reduce insulin resistance by eliminating Pg and, in a few dogs, remission of DM may occur after a few days or weeks.[63] All intact bitches with DM should be spayed, even if no obvious relationship is established between diestrus and onset of DM. After spaying, glycemic control should be closely monitored with appropriate adjustments in insulin dosage. Although spaying does not lead to remission of DM in most dogs, it does prevent Pg-induced secretion of mammary-derived GH in subsequent cycles, insulin resistance, and worrisome decompensation. If spaying is not possible, administration of the Pg receptor antagonist aglepristone may reduce insulin resistance.[64]

Concurrent Conditions

Concurrent inflammatory, infectious, neoplastic and metabolic conditions are common in dogs newly diagnosed with DM, can interfere with tissue responsiveness to insulin, and can produce a negative impact on DM management. Similarly, glucocorticoids and Pgs reduce sensitivity to insulin (ch. 358). Concurrent disorders and diabetogenic drugs may cause insulin resistance by altering insulin metabolism (pre-receptor issues), decreasing concentration or binding affinity of cell membrane insulin receptors (receptor issues), interfering with the insulin receptor signaling cascade (post-receptor issues), or any of these in combination.[37] Insulin resistance can be mild (e.g., obesity) to severe (e.g., Cushing's syndrome) or may fluctuate (e.g., chronic pancreatitis) (Table 304-3).

TABLE 304-3

Recognized Causes of Apparent Insulin Ineffectiveness or Insulin Resistance in Diabetic Dogs

CAUSED BY INSULIN THERAPY	DISORDERS TYPICALLY CAUSING SEVERE INSULIN RESISTANCE	DISORDERS TYPICALLY CAUSING MILD OR FLUCTUATING INSULIN RESISTANCE
Inactive insulin	Cushing's syndrome	Obesity
Diluted insulin	Diestrus in intact female	Infection
Improper administration technique	Progesterone secreting adrenocortical tumor	Hypothyroidism
Inadequate dose	Diabetogenic drugs	Chronic inflammation
Somogyi response	GlucocorticoidsProgestagens	Chronic pancreatitis
Inadequate frequency of insulin administration		Inflammatory bowel disease
Impaired insulin absorption		Disease of the oral cavity
Insulin-binding antibodies		Chronic kidney disease
		Hepatobiliary disease
		Cardiac disease
		Hyperthyroidism
		Pancreatic exocrine insufficiency
		Hyperlipidemia
		Neoplasia
		Glucagonoma
		Pheochromocytoma

Thorough evaluation (history, PE and in-hospital testing) of dogs newly diagnosed with DM is extremely important. Identification and treatment of concurrent diseases are integral to successful management of DM. Some conditions (e.g., chronic pancreatitis) are, like DM, never permanently resolved and require long-term management. Owners should be informed that treating DM alone can be challenging. Concurrent conditions can make successful therapy even more difficult. Frequent monitoring and dosage adjustments are almost always required. Administration of glucocorticoids or Pgs should be discontinued and alternative medications used if possible (see ch. 358). If glucocorticoids are absolutely required, dosage and frequency should be kept as low as possible. Consistency in dosage and frequency will make control easier to achieve.

Monitoring Diabetes Mellitus

Overview

Long-term care of diabetics and adjustments in their medications should be based, primarily, on owner observations supplemented by periodic in-hospital examinations. The in-hospital assessments should include

body weight, PE, and serum glucose and fructosamine concentrations. Glucose levels and glucose curves should initially be carried out in-clinic. Subsequently, if appropriately trained, most owners are able to perform home monitoring by measuring capillary blood glucose with a portable blood glucose meter (PBGM).

Frequency of In-Hospital Evaluations (see Box 304-4)

Veterinary team members and owners should appreciate that 1 to 3 months are typically required before reasonable and stable glycemic control is achieved. In some, the process is straightforward and takes little time. In others, adjustments in insulin and other factors never cease. Periodic monitoring is used to help ensure safe and effective treatment. Initially, reevaluations are recommended at 1, 2 to 3, 6 to 8, and 10 to 12 weeks after diagnosis. Dogs are then usually examined about every 4 months, or as needed.

History and Physical Examination

The most relevant parameters for assessment of glycemic control are owner opinions regarding their pet, specifically, status of PU/PD/PP, body weight, and general health. Body weight is emphasized since insulin-underdosed diabetics tend to lose weight and insulin-overdosed diabetics tend to gain weight. Well-controlled diabetics have stable, near ideal, body weight. Objective findings on PE are used in concert with owner thoughts. If the owner is satisfied, body weight stable, and PE consistent with good glycemic control, further testing is only directed at avoiding overdose. Owners should specifically report any possible hypoglycemic episodes (e.g., weakness, ataxia, "acting intoxicated"). Persistence or recurrence of clinical signs or unwanted change in weight are suggestive of poor glycemic control or presence of a concurrent disease. Serum fructosamine concentration and blood glucose curves (BGCs) may help characterize the issue, guide changes in treatment, and may indicate need for additional testing.

Serum Fructosamine

Fructosamines are glycated proteins produced via irreversible non-enzymatic reactions between glucose and plasma proteins present in the circulation.[65] It is estimated that fructosamine concentrations in dogs are determined by the average blood glucose concentration over the previous 2-3 weeks. Serum fructosamine is not affected by acute changes in blood glucose. Higher average glucose levels result in greater amounts of blood fructosamines. Excellent glycemic control, defined as blood glucose concentrations near normal most of the time, results in fructosamine concentrations within or only slightly above reference ranges. Lower fructosamine, independent of blood glucose, has been observed with hypoproteinemia, azotemia, hypoalbuminemia, hyperlipidemia, and hemolysis.[66,67] Increased serum fructosamines have been observed in hypothyroidism and in 2 dogs with hyperglobulinemia caused by multiple myeloma.[68,69] Each laboratory should generate a reference range, but most are from about 200 to 360 micromol/L.

In most newly diagnosed diabetic dogs, fructosamine levels are >400 micromol/L. Some may reach 1500 micromol/L. It is important to remember that neither normoglycemia nor normal fructosamine concentrations should be the therapeutic target when treating dogs with DM. Blood glucose concentrations, in well-controlled DM dogs, fluctuate between normal and slightly above renal threshold. Well-controlled dogs usually have some glycosuria and are moderately hyperglycemic throughout the day. Thus, serum fructosamines within reference intervals (especially in the lower half) are more suggestive of prolonged episodes of hypoglycemia due to insulin overdose. Serum fructosamine concentrations of 360 to 450 micromol/L suggest good glycemic control, 450 to 550 micromol/L suggest moderate control, and concentrations >550 micromol/L suggest poor DM control.

Increased fructosamine concentrations, even if >550 micromol/L, do not help identify a cause for poor control. All possible causes must be considered. These include insulin underdose, short duration of insulin effect, errors in preparation or administration of insulin, improper diet, any disease known to cause insulin resistance, and the Somogyi response (see Table 304-3). Serum fructosamine concentration should never be used as the sole indicator of glycemic control and should always be interpreted in conjunction with owner opinion, clinical signs, body weight and blood glucose concentrations. Discrepancy between a fructosamine concentration and the clinical picture/blood glucose concentration profile are sometimes observed. For example, a high fructosamine concentration suggests poor control. But, if the dog is clinically well with glucoses within a desired range, one should maintain current therapy and reassess. The discrepancy between fructosamine concentrations and the clinical picture may remain ambiguous and there may be individual

differences with regard to protein glycation.[70] In some, fructosamine is not helpful.

Urine Glucose Monitoring

Daily owner monitoring of urine for sugar and ketones can be useful. Most diabetics have varying amounts of glucose present in virtually every urine sample, with an occasional negative. Persistent absence of sugar may be indicative of insulin overdosage or excellent control. Ketonuria suggests inadequate control and decompensation. Upon seeing ketones in the urine of a pet who rarely has them, the owner should contact the veterinarian. Decisions are usually based on the dog's condition. Owners should not adjust insulin dosage on the basis of morning urine glucose because this commonly leads to overdose and increases likelihood of insulin-induced hypo- followed by hyperglycemia (Somogyi response). Excess glucose in the urine can be caused by numerous issues.

Single Blood Glucose

A single blood glucose measurement is rarely useful in monitoring DM with the exception of finding a low result, always indicative of an overdose. Single glucose measurements may be sufficient when an owner believes the dog is virtually asymptomatic, the PE is unremarkable and serum fructosamine levels are between 360 to 450 mcmol/L. In such cases, glucose concentrations between 180 and 250 mg/dL around the time of the insulin injection are consistent with good glycemic control and additional blood glucose measurements are not usually necessary.

Portable Blood Glucose Meters

During the initial adjustment phase and in subsequent long-term management phases of therapy, if signs of DM persist, signs recur, or fructosamine levels are high, single glucose measurements should be avoided and a BGC obtained instead. Serial BGCs can provide guidelines for making rational adjustments in insulin therapy. Blood glucose concentrations are typically determined by a hand-held portable blood glucose meter (PBGM). To avoid multiple venipunctures, one may collect capillary blood from the ear (Videos 304-3 and 304-4; see also ch. 79).[71] Several portable glucose meters are available. The accuracy of PBGM devices designed for people varies considerably when used in dogs.[71-75] Some PBGM devices designed for humans are sufficiently accurate and precise to monitor canine blood glucose concentrations. However, most give lower results than laboratory reference methods. This bias may result in an incorrect diagnosis of hypoglycemia or the misconception that the animal's glycemic control is better than it actually is. The AlphaTRAK blood glucose meter (Abbott Animal Health) is specifically designed for use in dogs and cats and is more accurate and precise than the PBGMs designed for humans.[73] Additional advantages of the AlphaTRAK are the small volumes of blood needed (0.3 mcL) and the extended measurement range (20 to 750 mg/dL). Conversely, AlphaTRAK tends to overestimate blood glucose values, potentially missing hypoglycemia. The meter is less accurate in dogs with a hematocrit <30%.[76] If there is any doubt regarding accuracy, measurements can be compared with laboratory results.

Blood Glucose Curves and Insulin Dose Adjustments

When conducting a BGC, the dog should be seen early in the morning and blood glucoses sampled every 1 to 2 hours throughout the day. One should begin just prior to the first insulin dose and continue until the next dose is due. A recent study failed to find relevant differences in glucose concentrations during the day versus night. Most dogs respond well to the same dose of insulin morning and evening.[77] If different blood glucose concentrations are suspected during day versus night (e.g., good BGC and control of clinical signs during the day but presence of PU/PD during the night), a 24-hour BGC or use of a continuous blood glucose monitoring device should be considered.[37]

When performing a BGC, the insulin and feeding schedules followed by the owner should be maintained. Poor appetite can strongly affect the results of a BGC. Food and insulin can be administered at the clinic after the first blood glucose measurement. If a dog refuses to eat in the clinic, the BGC should be abandoned. Subsequently, the owner should feed the dog at home, administer insulin, and then bring the dog to the clinic as soon as possible to begin the BGC. The evaluation of the BGC allows the clinician to determine if the insulin administered is effective and identify the glucose nadir, time of peak insulin effect, duration of insulin

effect, and degree of fluctuation in blood glucose concentrations. In well-controlled DM, glucose concentrations should stay between 90 and 250-300 mg/dL (Figure 304-3). Insulin efficacy is evaluated, in part, by determining the difference between highest and lowest glucose concentrations. A small difference (e.g., 50 mg/dL) is acceptable if the highest blood glucose level recorded is <220 mg/dL but not acceptable if it is >300 mg/dL.[38] The most important parameters are the glucose nadir and the duration of the insulin effect.

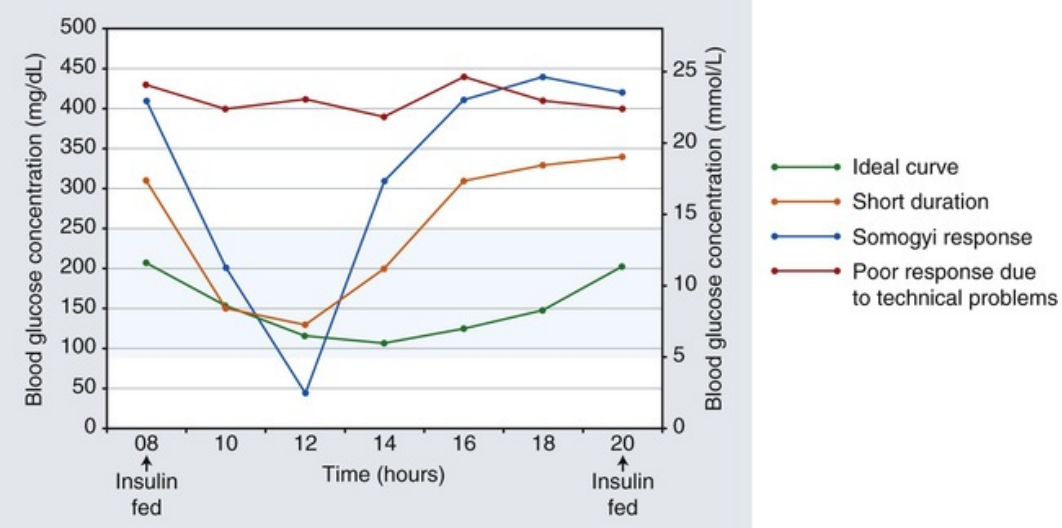

FIGURE 304-3 Representative blood glucose curves in dogs treated with an intermediate-acting insulin q 12 h. The blue area is the preferred range of blood glucose concentration in treated diabetic dogs (90 to 250 mg/dL). Green line: ideal curve. Orange line: short duration of insulin effect. Blue line: Somogyi response with counterregulation after rapid decrease in blood glucose concentration. Red line: poor response due to technical problems, the counterregulatory phase of the Somogyi response, insulin resistance, poor insulin absorption, or insulin antibodies. (Modified from Reusch CE, Robben JH, Kooistra HS: Endocrine pancreas. In Rijnberk A, Kooistra HS, editors: *Clinical endocrinology of dogs and cats*, ed 2, Hannover, Germany, 2010, Schlütersche, p 165.)

The glucose nadir should, ideally, be between 90 and 150 mg/dL. A lower nadir can be caused by insulin overdose, excessive overlap of the insulin action (common if long-acting insulin analogues are used), prolonged periods without food (the dog refused to eat in-hospital), or strenuous exercise. A glucose nadir >160 mg/dL can be caused by an insufficient insulin dose, insulin resistance, counterregulatory phase of the Somogyi response, stress, and technical problems attributable to the owners. In a dog already treated with high dosages (e.g., >1.5 U/kg per injection), owner error, insulin resistance and the Somogyi response are the main differential diagnoses.

Duration of insulin action can be determined if the glucose nadir falls within the desired range. Duration is defined as the time from injection through the glucose nadir until the glucose concentration exceeds 250 mg/dL. When duration is too brief (e.g., <8 hours), signs of DM are usually exhibited. When duration is too long (e.g., >14 hours), risk of hypoglycemia or Somogyi response is higher. Duration of action may be altered with changes in diet. One may change to an insulin product with a different action profile. Performing BGCs on consecutive days is not recommended because it promotes stress-induced hyperglycemia.

BGCs should never be assumed to be reproducible. Day-to-day variables and the diabetic condition itself are rarely static. Variables include the amount of insulin drawn into the syringe each time, the amount of insulin absorbed after each injection, and the interactions between insulin, diet, exercise, stress, excitement, presence of concurrent disorders, and secretion of the counterregulatory hormones (e.g., glucagon, epinephrine, cortisol, growth hormone). All these factors change with time and alter chances of reproducible BGCs. Lack of consistency in BGC results can create frustration unless expected. Lack of consistency is common and reflects any variable that could alter glucose concentrations. When dose change appears appropriate, it should not exceed 10% to 25%. However, in documented or suspected hypoglycemia, the dose should be decreased by at least 50%. Insulin doses should not be modified more frequently than every 5 to 7 days, except in hypoglycemia.

Home Monitoring

Owners should be encouraged to assess their dog's DM on a daily basis (see earlier section). Initially, body weight should be measured and recorded every week. Glucose measurement with PBGM using capillary blood is feasible at home and should be recommended. Capillary blood can be obtained using lancing devices on various sites: the inner aspect of the pinna is a good site for capillary sampling (see Video 304-4; see also ch. 79); good alternatives are the buccal mucosa (Video 304-5) or the paw pad (Video 304-6).[78] Owners must be thoroughly familiar with their PBGM, but access to veterinary support should be available. A good time for introducing the concept of home monitoring is after 3 to 4 weeks of treatment. By that time, the client will be somewhat familiar with DM and will understand the time needed for its care. Once familiar with the procedure, the owner can perform a BGC by measuring the morning blood glucose concentration before giving insulin and food, and then every 2 hours until the next injection is due. Interpretation of home BGCs should be the same as those performed in-hospital. One problem that can be anticipated are the overzealous owners who monitor blood glucose concentrations too frequently and begin to interpret the results and adjust the insulin dosage without consulting the veterinarian, a practice that frequently leads to confusion, poorer control of DM and increased risk of overdose.

Continuous Glucose Monitoring

Continuous glucose monitoring systems (CGMSs) are routinely used for people with DM and are beginning to be used in DM dogs.[79] These systems allow glucose concentrations to be monitored without need for repeated blood sampling. The CGMS measures interstitial glucose rather than blood glucose concentrations. Interstitial fluid is easily accessible and results are virtually the same as with blood glucose.[79-81] The CGMS most frequently used (Guardian REAL-time) measures interstitial glucose with a small, flexible sensor inserted through the skin into the SC space and secured to the skin with tape. The sensor, connected to a transmitter and also fixed with tape, sends wireless data over a maximal distance of 3 meters to a pager-sized monitor. Data are collected every 10 seconds and a mean glucose value computed every 5 minutes. Data can be downloaded to a computer for analysis.

CGMS devices have some limitations. They need to be calibrated two to three times daily, which requires blood sampling. Sensors are quite expensive and can be used only for days. The monitor displays glucose concentrations from 40 to 400 mg/dL; concentrations outside this range are correctly recorded but need to be downloaded to be seen. A new CGMS (FreeStyleLibre by Abbott) produced for humans has extremely small sensors, does not require calibration, is rather inexpensive and the sensor can be used for as long as 14 days (Figure 304-4). One recent study has shown that this CBGM is accurate in hyperglycemia and euglycemia, but less accurate if blood glucose concentrations are <100 mg/dL.[81a] CGMS can provide insight into glucose levels throughout the day and help identify fluctuations, episodes of hypoglycemia and trends that may otherwise go unnoticed.[70]

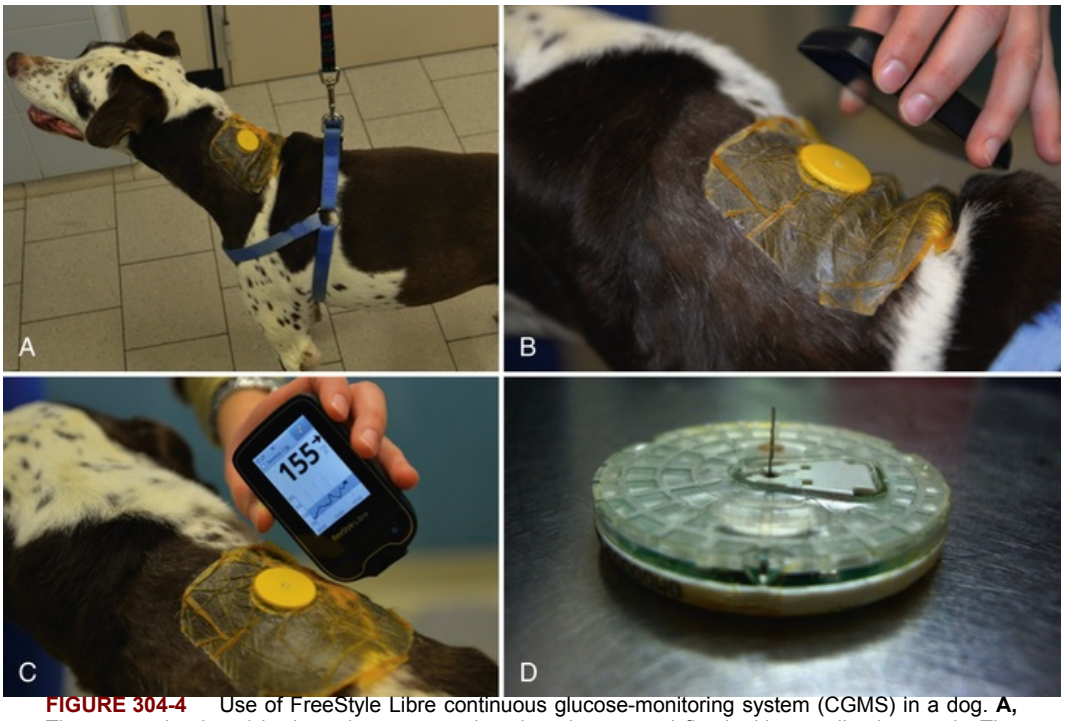

FIGURE 304-4 Use of FreeStyle Libre continuous glucose-monitoring system (CGMS) in a dog. **A,** The sensor is placed in the subcutaneous dorsal neck area and fixed with an adhesive patch. The sensor in this picture has been in place for 12 days (the regrowth of the hair below the patch is evident). **B,** The sensor patch must be "scanned" with the reader to obtain real time glucose values. This can be done holding the reader within 4 cm of the sensor. The sensor patch stores up to 8 hours of glucose data at that time (values are taken every minute). **C,** Glucose levels are displayed in real time. Here the glucose is 155 mg/dL. **D,** Sensor removed 14 days after placement.

Conditions Causing Persistence or Recurrence of Clinical Signs

Overview

Persistence or recurrence of clinical signs is a frequent problem in any dog with DM. Recurrence of signs can be noted at any time. Common causes include technical issues in administering insulin, use of the incorrect (for this patient) insulin type, and less than ideal dosage or frequency of administration. Other common problems are insulin responsiveness caused by concomitant inflammatory, infectious, neoplastic or hormonal disorders (Figure 304-5).

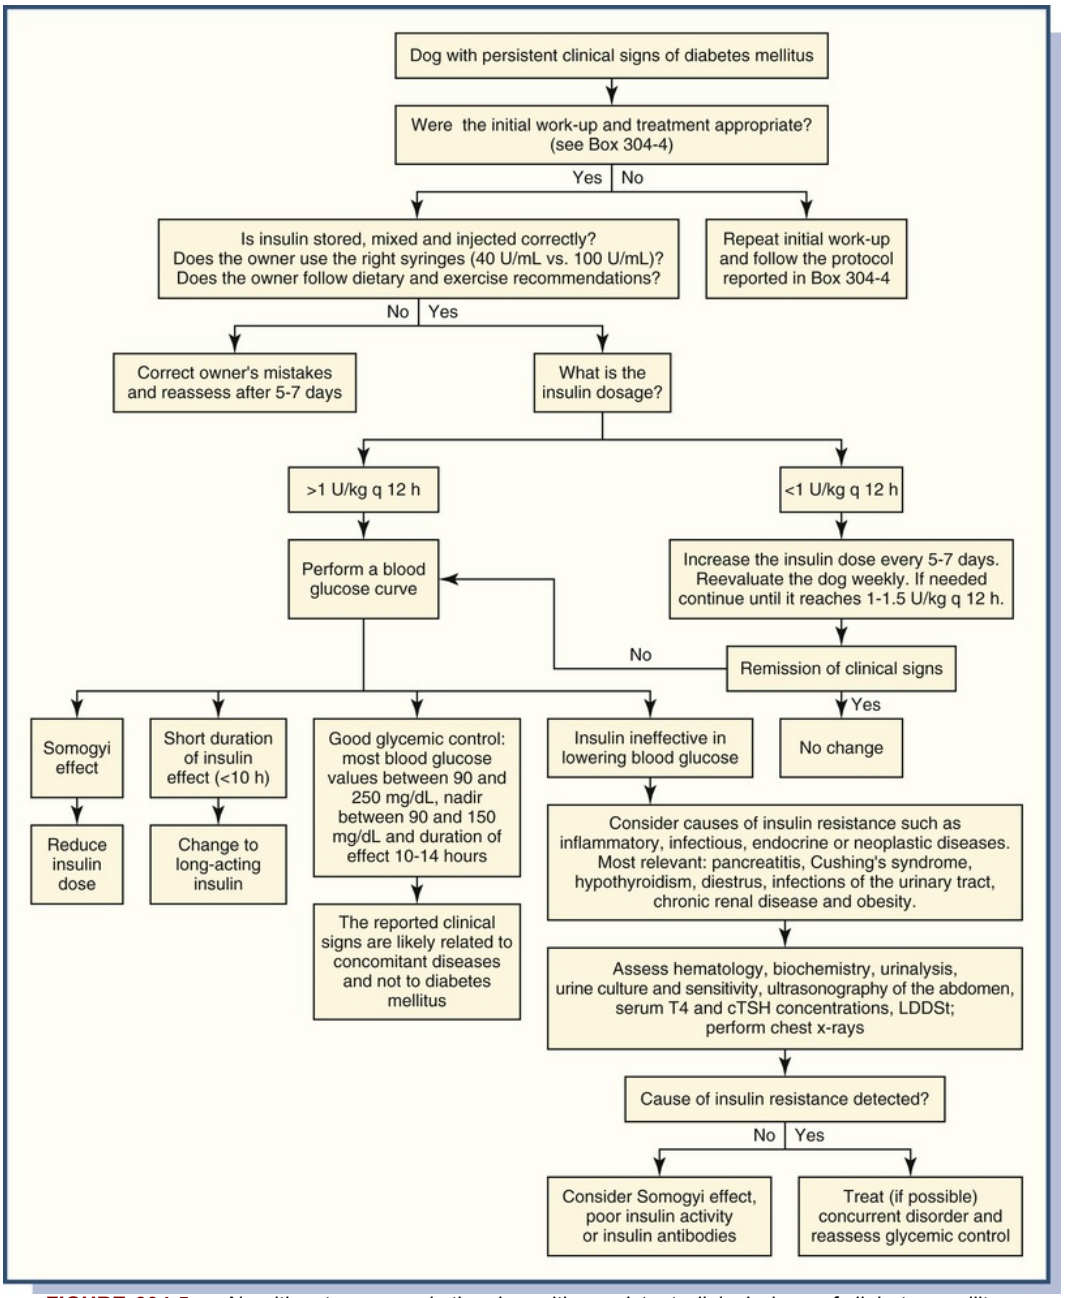

FIGURE 304-5 Algorithm to approach the dog with persistent clinical signs of diabetes mellitus. *cTSH,* Canine thyroid-stimulating hormone; *LDDSt,* low-dose dexamethasone suppression test; *T4,* thyroxine.

Technical Issues

Common reasons for poor glycemic control are errors in handling or injecting insulin. Specifically, failure to mix the preparation correctly; use of an improper diluent; use of insulin that has been frozen, heated, or is out of date; incorrect injection technique using a syringe or insulin dosing pen, or inappropriate insulin dose or syringe size (U-40/mL vs. U-100/mL is a frequent error). These problems can be identified by carefully evaluating the history and asking the owner to bring their insulin and syringes or pen device to appointments. If concerns arise, the veterinarian or technician can observe the entire procedure, providing assistance until the owner is able to master the technique.

Insulin Underdose

Most dogs are well controlled with insulin doses ≤1 U injection/kg SC q 12 h. If the insulin dosage is considerably less than 1 U injection/kg and the dog is receiving insulin q 12 h, underdosing can explain poor glycemic control. In this scenario, the dose should be gradually increased by 10% to 25% per week.

Insulin Overdose and Glucose Counterregulation (Somogyi Response)

The Somogyi response is defined as rebound hyperglycemia caused by the physiologic response to hypoglycemia, which induces secretion of counterregulatory hormones. In the acute response, glucagon and epinephrine are secreted. They, in turn, stimulate the longer acting response via secretion of cortisol and GH. This "counterregulation" occurs when the blood glucose is <65 mg/dL, although it may also occur when blood glucose concentrations drop rapidly (in 2 to 3 hours) regardless of the nadir.[82] Clinical signs due to hypoglycemia are not seen in every case, whereas signs of the hyperglycemic response (PU/PD) are obvious. Thus, a cyclic history of days of good control followed by several days of poor control should raise the suspicion of a Somogyi response.

Diagnosis requires evidence of hypoglycemia or rapid drop of glucose followed within hours by hyperglycemia (>300 mg/dL). Serum fructosamine concentrations are unpredictable but are usually increased (>500 micromol/L). Rebound hyperglycemia and insulin resistance can persist for 24 to 72 hours. Diagnosis may be difficult and may require several BGCs, best conducted in the home using a PBGM or a CBGMS. Sometimes it is not easy to differentiate Somogyi response from a short duration of insulin effect. If Somogyi is documented or assumed to have occurred, the insulin dose should be arbitrarily reduced gradually (1 to 5 U depending on the size of the dog and dosage of insulin) and the owner should monitor the dog's clinical signs over the following 2 to 5 days. If no change is seen, further dose reductions may be attempted. If clinical signs worsen, a different cause for insulin ineffectiveness should be considered (i.e., short duration of insulin effect; see Table 304-3).

Short Duration of Insulin Action

In some diabetic dogs, the effect of NPH and lente insulins may last less than 8 hours (see Figure 304-3). As a result, significant hyperglycemia (above the renal threshold of about 200 mg/dL) may continue for hours each day. Owners of dogs whose insulin is not lasting long enough usually report PU/PD. The issue may be demonstrated on a BGC. Treatment involves switching to a long-acting insulin q 12 h (i.e., PZI, glargine or detemir; see Table 304-2).

Prolonged Duration of Insulin Effect

Problems with prolonged duration of action may occur if insulin lasts longer than 12 hours; in these cases q 12 h-administered insulin overlaps and increases risk of hypoglycemia. Hypoglycemia, in turn, could lead to the Somogyi response and to clinical signs caused by hypoglycemia, hyperglycemia, or both. Prolonged duration of insulin action is usually observed when the glucose nadir occurs 10 or more hours after injection. Treatment options include decreasing the frequency of administration from q 12 h to q 24 h when using detemir or glargine. One may also consider changing insulin to one with a shorter duration of action.

Anti-Insulin Antibodies

Canine, porcine and human insulin are similar. Development of significant insulin antibodies is uncommon in DM dogs treated with porcine or recombinant human insulin.[22] Canine and beef insulins, however, differ significantly. Antibodies to insulin have been identified in 40% to 65% of dogs treated with beef/pork or 100% beef source insulin.[83,84] The presence of anti-insulin antibodies may alter exogenous insulin pharmacokinetics and/or pharmacodynamics. The result is usually an erratic response to insulin, poor control of glycemia, inability to control DM for extended periods of time, need for frequent adjustments of the insulin dose and, occasionally, development of insulin resistance.[37] Bovine insulin, widely used in the past to treat canine DM, is no longer used, decreasing the incidence of anti-insulin antibodies. Although uncommon, insulin antibodies may develop in dogs treated with recombinant human insulin and should be considered as a possible cause of poor glycemic control if no other explanation is identified.[37] Documentation of serum anti-insulin antibodies should utilize assays validated for dogs. Switching to a 100% porcine-source insulin should be considered if anti-insulin antibodies are identified in a poorly controlled DM dog.

Concurrent Disorders Causing Insulin Resistance

Most DM dogs can be regulated with insulin doses ≤1 U/kg q 12 h. In dogs with higher insulin requirements, concurrent disorders should be suspected after "technical problems," Somogyi response or short duration of insulin action have been ruled out. No insulin dosage clearly defines insulin resistance. It has been proposed that insulin resistance should be suspected when glycemic control is poor despite insulin doses >1.5 U/kg q 12 h, when high doses (>1.5 U/kg) are required to maintain blood glucose <300 mg/dL, or when glycemic control is erratic and the insulin dose must be continuously adjusted.[37] Any inflammatory, infectious, neoplastic or endocrine disorder can cause insulin resistance, as do obesity and many drugs, especially glucocorticoids and progestagens.

Insulin resistance is most commonly caused by glucocorticoid administration, diestrus, hypothyroidism, chronic pancreatitis, chronic kidney disease, infection, neoplasia, hyperlipidemia, severe obesity, and Cushing's syndrome. The most common sites of infection are oral (dental) and urinary tract. Other less common causes of insulin resistance are pancreatic exocrine insufficiency, cardiac disease, liver insufficiency, glucagonoma and pheochromocytoma (see Table 304-3).

Anamnesis and physical examination are the most important first "tests" in trying to identify concurrent disorders. In most instances, a complete diagnostic work-up, including CBC, serum biochemical profile, urinalysis with bacterial culture, abdominal US and thoracic radiographs should be considered as initial "screens" for concurrent illness. When indicated, one may consider a low-dose dexamethasone suppression test, serum progesterone concentration (in intact females), thyroid function tests, serum pancreatic lipase immunoreactivity (cPLI), serum trypsinlike immunoreactivity (TLI) and computed tomography or magnetic resonance imaging (pituitary mass).

Long-Term Complications of Diabetes Mellitus

Hypoglycemia

Hypoglycemia is an extremely common complication of insulin treatment. It is, rarely, fatal.[85] Hypoglycemia may be due to large increases in insulin dosage, sudden increase in insulin sensitivity due to treatment or improvement of concurrent disorders (e.g., treatment of hypothyroidism), inadvertent insulin overdose, overly stringent glycemic control, excessive overlap of the insulin action in dogs receiving insulin q 12 h, excessive exercise, and inappetence resulting in relative insulin overdose. Signs of hypoglycemia include lethargy, weakness, ataxia and increased appetite. Most owners describe hypoglycemia as their dog appearing intoxicated. If the dog is not fed and the hypoglycemia allowed to progress, seizures, coma and death can occur.

Symptomatic hypoglycemia should be treated with glucose administered as sugar-rich food. If the dog is unable to eat, glucose can be applied to the dog's oral mucous membranes in the form of glucose gel or glucose solution (Karo syrup), where it can be directly absorbed. Once recovered, the dog should be fed.[42] Collapsed dogs should be given IV dextrose immediately as an initial IV bolus of 1 mL/kg of 33% dextrose followed by a 5% dextrose infusion. Rates can be changed if necessary. After symptomatic hypoglycemia, owners should be instructed to stop insulin until glycosuria recurs and then give 25% to 50% less. Subsequently, the insulin dose should be adjusted as needed to improve clinical response and blood glucose measurements.[37] Treatment of asymptomatic hypoglycemia also requires insulin dosage reductions of about 10% to 20%, or that insulin should be replaced with one that has a shorter duration of effect.

Ocular Complications

Cataract formation is the most common long-term complication in diabetic dogs (see Figure 304-2). A retrospective-cohort study on 132 DM dogs referred to a university referral hospital found cataract formation in 14% of DM dogs at the time of diagnosis. In that study, the time interval for 25%, 50%, 75%, and 80% of the study population to develop cataracts was only 60, 170, 370, and 470 days, respectively.[86] Cataracts are thought to occur as a result of altered osmotic relationship in the lens induced by intra-cellular accumulation of sorbitol and galactitol, produced following the metabolism of glucose and galactose by enzymes within the lens. The accumulation of sorbitol and galactitol in lens cells increases intracellular osmolality, causes an influx of fluid with subsequent swelling and rupture of lens fibers, and causes the development of cataracts.[87] Once cataract formation begins, it is irreversible and can evolve quite rapidly. Blindness may be avoided by removing the abnormal lens. Vision is restored in 80% to 90% of DM dogs that undergo cataract removal.[88,89]

Other ocular complications of diabetes can include uveitis, keratoconjunctivitis sicca, bacterial conjunctivitis and diabetic retinopathy.

Diabetic Neuropathy

Diabetic neuropathy has been described in dogs, although its prevalence is unknown.[90-93] Subclinical neuropathy seems to be most common. Clinical signs of diabetic neuropathy (weakness, muscle atrophy, hyporeflexia, hypotonia) are most commonly recognized in dogs that have been diabetic for 5 years or longer.[37,93] Diabetic neuropathy in dogs is primarily a distal polyneuropathy, characterized by segmental demyelination and axonal degeneration.

Diabetic Nephropathy

Diabetic nephropathy has occasionally been reported in diabetic dogs but its clinical relevance remains unknown. Microscopic changes can include membranous glomerulonephropathy with fusion of the foot processes, glomerular and tubular basement membrane thickening, increase in the mesangial matrix material, presence of subendothelial deposits, glomerular fibrosis, and glomerulosclerosis.[94,95] Microalbuminuria is used as an early marker for the development of diabetic nephropathy in humans. In one study, increased urine albumin was found in 11 (55%) of 20 DM dogs, with over half having concurrent increases in urinary protein-to-creatinine ratio.[96] Similar results were observed in a study where proteinuria, blood pressure and diabetic retinopathy were monitored over a 2-year follow-up period. No significant effect of time since diagnosis or glycemic control was detected for any of the measures examined.[97] The predictive value and the clinical relevance of microalbuminuria in diabetic dogs remains to be clarified. In most DM dogs, chronic kidney disease is thought to develop as an independent condition.[37]

Prognosis

The prognosis for dogs diagnosed with DM depends, in part, on the owner's commitment to treating the disorder, ease of glycemic regulation, presence and reversibility of concurrent disorders, and avoidance of chronic complications associated with the diabetic state. In a large study involving insured dogs in Sweden, 347 dogs survived at least 30 days after the first DM claim. The proportion of those surviving 1, 2, and 3 years was 40%, 36% and 33%, respectively.[5] A relatively high mortality rate exists during the first 6 months of treatment due to concurrent diseases such as ketoacidosis, pancreatitis or infections. It is a common opinion that well-controlled diabetic dogs that survive the first 6 months of treatment have a life expectancy similar to that of non-diabetic dogs of the same age, gender and breed.

CHAPTER 305

Feline Diabetes Mellitus

Jacquie Rand, Susan A. Gottlieb

Client Information Sheet: Feline Diabetes Mellitus

Pathogenesis

Types of Diabetes Mellitus

Diabetes mellitus (DM) is characterized by persistent hyperglycemia caused by insufficient insulin secretion from pancreatic beta-cells. The mechanisms involved in the failure of pancreatic beta-cells form the basis for classification of types of DM. Current classifications used in human DM, and generally accepted in veterinary medicine, involve four types: 1, 2, gestational and other specific types.[1] Type 1 DM in people follows immune-mediated destruction of beta-cells with genetic predispositions and environmental triggers, leading to an absolute insulin deficiency.[1] Type 1 DM is rare in cats based on histological studies and absence of circulating beta-cell autoantibodies.[2,3] However, clinical signs, histologic findings, and islet cell antibodies consistent with type 1 DM were reported in a 5-month-old kitten.[4] Type 2 DM is characterized by insulin resistance with concomitant failure of beta-cells to mount an adequate compensatory response to maintain euglycemia.[1] Type 2 is the most common form of DM in cats, based on risk factors (old age and obesity), clinical and endocrine characteristics (insulin resistance, variable insulin secretion and remission) and islet histology (islet vacuolation and amyloid deposition).[5-7] Type 2 DM appears to account for about 80% to 90% of cats examined at primary care veterinary practices in Western countries based on remission rates and other clinical and phenotypic characteristics.[8,9] Gestational DM is first diagnosed during pregnancy, but has not been reported in cats, but is reported in dogs.[1,10,11]

Other specific types of DM, in cats, include loss of pancreatic islets due to pancreatitis or neoplasia. Insulin resistance and DM can occur secondary to hypersomatotropism (acromegaly; see ch. 294) or hyperadrenocorticism (Cushing syndrome; see ch. 307) in cats.[2,12-15] These "other" types of feline DM probably represent less than 20% of cases seen at primary care practices, but may be overrepresented in referral practices. Acromegaly typically begins clinically as poorly controlled DM, despite use of insulin doses considered adequate.[15,16] Pancreatic adenocarcinoma is reported in 8-19% of feline DM euthanized in tertiary referral institutions.[2,12] Pancreatitis (see ch. 291) is present at the time of DM diagnosis in as many as 60% of cats based on biochemical and imaging findings, although clinical signs are infrequent.[17-19] Histologically, most lesions are consistent with chronic pancreatitis, while acute or subacute necrotizing pancreatitis is a cause of mortality.[2,20] In most cats, pancreatitis does not appear to be sufficiently severe to cause DM, but may contribute to beta-cell loss and reduce probability of DM remission.[19,20]

Prevalence and Risk Factors

Estimates regarding the prevalence of feline DM vary from about 0.25-1%.[21-25] Several studies from Australia and the UK place the prevalence at about 1 in 200 cats (0.5%).[23,24,26] In the U.S., the reported prevalence in veterinary teaching hospitals increased from 1 in 1250 (0.08%) in 1970 to 1 in 81 (1.2%) in 1999.[25] It is not known whether this apparent increased prevalence is due to factors such as obesity.[25] Breeds with increased susceptibility to DM include the Burmese in Australia, New Zealand, and the UK; Maine Coon, Russian Blue and Siamese in the United States.[23,24,27-29] The Burmese has a DM frequency about 4 times the rate in other cats, and about 10% ≥8 years of age have DM. The gene or genes involved in this process appear to be

autosomal rather than sex-linked, with few signs of fully penetrant dominant gene action.[22-24,27,30]

Type 2 Diabetes

Human versus Cats

Human type 2 DM has a complex etiology, is caused by genetic factors and environmental interactions, and risk increases with age.[1] Similarly, risk factors for feline DM include old age, male gender (male : female ratio 1.5 : 1), obesity, physical inactivity, indoor confinement, breed, and repeated or long-acting steroid or megestrol acetate administration.[21,24,25,31] Most of these factors decrease insulin sensitivity and increase demand on beta-cells to produce insulin.[32-34] Type 2 DM in humans is a polygenic disease with complex inheritance, although genetic variants account for <10% of overall risk, highlighting the importance of environmental factors.[35] Over 60 genetic loci are associated with type 2 DM and most are involved with beta-cell biology, reflecting the significance of beta-cell failure in pathogenesis.[36,37] In domestic cats, polymorphism in the melanocortin 4 receptor gene *(Mc4R)* is associated with DM in overweight cats, similar to humans.[38] Mutations of this gene in people increase appetite and obesity. In cats, the mutation also appears associated with progression to DM.[38] This polymorphism was 3.7 times more likely in overweight DM cats vs. overweight non-DM, but no difference was noted between obese and lean non-DM cats.

In humans, some genetic loci associated with increased risk for the metabolic syndrome are located within genes known to be associated with lipid metabolism.[39] Burmese cats appear to have a propensity for dysregulation in lipid metabolism, and lean Burmese cats demonstrate similar gene expression patterns to obese domestic cats.[40] Clinical features of DM in cats are similar to an atypical DM seen in African-Americans and Asians: classical signs of polyuria, polydipsia (PU/PD) and weight loss, and relatively high blood glucose concentrations. They are susceptible to ketosis but many go into remission within a few weeks of starting insulin therapy. Patients have a type 2 phenotype and a family history of DM.[41,42,42a] Atypical DM is associated with a number of genetic loci.[43-45]

Insulin Resistance

Type 2 DM is a multifaceted disease characterized by beta-cell failure and insulin resistance.[35] Insulin sensitivity, defined as the ability of a given concentration of insulin to decrease blood glucose, is genetically determined in people. Insulin sensitivity decreases with obesity, physical inactivity and is a side effect to glucocorticoids and progestins.[32,46-50] Reduced insulin sensitivity (resistance) is the key feature of type 2 DM. Cats with DM are about six times less sensitive to insulin than normal, causing increased hepatic glucose production and reduced glucose utilization in peripheral tissues.[7,51] Each kg increase in body weight above ideal in cats causes about a 30% decrease in insulin sensitivity and a gain of 44% reduces insulin sensitivity and glucose effectiveness (capacity of glucose to enhance its own cellular uptake and to suppress endogenous production) by 50%.[32,47,52] Although it is unclear if insulin sensitivity is genetically determined, lean cats with underlying low insulin sensitivity are at increased risk for developing glucose intolerance with obesity.[32]

Reduced Insulin Secretion

Reduced insulin secretion secondary to beta-cell failure is the second key feature of type 2 DM. In health, beta-cells respond to changing requirements and undergo hypertrophy and hyperplasia to meet increased needs, such as with obesity.[53] However, in a minority of obese patients, beta-cells fail. Processes associated with obesity (disturbed glucose, fatty acid, and amino acid metabolism) damage beta-cells, reducing their secretory capacity.[35] Obesity and type 2 DM are associated with chronic inflammation that increases cytokine and immune-cell infiltration into tissues involved in energy homeostasis (fat, liver, muscle, pancreatic islets).[35] Such infiltrates have been reported in DM and obese cats.[19,54-57] The inflammatory cytokine interleukin-1beta and its expression was increased in a hyperglycemic/obese cat model.[58]

Beta-cell failure is not fully understood, especially in early stages. Several mechanisms adversely affect beta-cells and impair insulin secretion via decreased insulin gene expression and reduced beta-cell capacity to proliferate in response to increased demand. These factors contribute to beta-cell death (E-Box 305-1).[35,59] Toxicity of misfolded and polymerized intracellular fibrils (oligomers) of islet amyloid polypeptide (IAPP) and glucolipotoxicity are involved in triggering some of these mechanisms. Both islet amyloid deposition of misfolded IAPP oligomers (Figures 305-1 and 305-2) and glucotoxicity are documented to decrease beta-cell

numbers and their function in cats.[6,60-63] Although not an initial cause of beta-cell failure, chronic hyperglycemia has a central role in beta-cell dysfunction and the progressive inability to secrete insulin.[62-64] In cats, glucose toxicity is dose dependant. At persistent glucose concentrations of 540 mg/dL (30 mmol/L), insulin concentrations are reduced to basal values within 3-7 days. Ketonemia occurs within 10 to 30 days of marked insulin deficiency (E-Figure 305-3).[62,63] Increased free fatty acids also reduce beta-cell function, predominantly observed in the presence of high glucose (glucolipotoxicity).[62,64]

E-Box 305-1

Mechanisms Contributing to Beta-Cell Failure by Impairing Insulin Secretion, Reducing Beta-Cell Capacity to Proliferate and Increasing Beta-Cell Dedifferentiation and Beta-Cell Death[35,59,67,71,72,244-251]

Mechanisms

Accumulation of misfolded IAPP oligomers as aggregates and fibrils in beta-cells, and as amyloid within islets, leads to beta-cell death. Intracellular aggregation is particularly toxic and triggers apoptosis. It also contributes to islet inflammation by recruiting and activating macrophages and beta-cell production of chemokines and cytokines.

Generation of reactive oxygen species (ROS) secondary to nutrient overload. Chronic hyperglycemia increases glucose metabolism through oxidative phosphorylation, which induces mitochondrial dysfunction and production of ROS. ROS are also increased in chronic hyperlipidemia. Oxidative stress results in down-regulation of insulin and amylin production, and up-regulation of pro-inflammatory and apoptotic pathways.

Beta-cell endoplasmic reticulum (ER) stress occurs secondary to conditions that require prolonged high insulin production such as insulin resistance and high glucose concentrations, and with lipotoxicity and inflammatory conditions. ER stress results in reduced protein folding capacity of the ER, and accumulation and aggregation of unfolded proteins, including insulin. If the accumulation of unfolded protein is in excess of what can be managed by the unfolded protein response (UPR), it reduces insulin secretion and triggers apoptosis.

Increased glucose flux through the hexosamine biosynthetic pathway results in alteration in protein function, changes in gene expression, and decreased insulin secretion.

Exposure of beta-cells to overabundant supply of nutrients—glucose, free fatty acids and branched chain amino acids—associated with insulin resistance and obesity leads to beta-cell dysfunction and

death.

Chronically increased glucose leads to **glucotoxicity,** which has a central role in beta-cell failure by decreasing both beta-cell function and mass.

Increased long chain free fatty acids (FFAs) and lipid intermediates associated with obesity lead to **lipotoxicity.**

Enhanced toxicity occurs when both glucose and free fatty acids are increased (glucolipotoxicity).

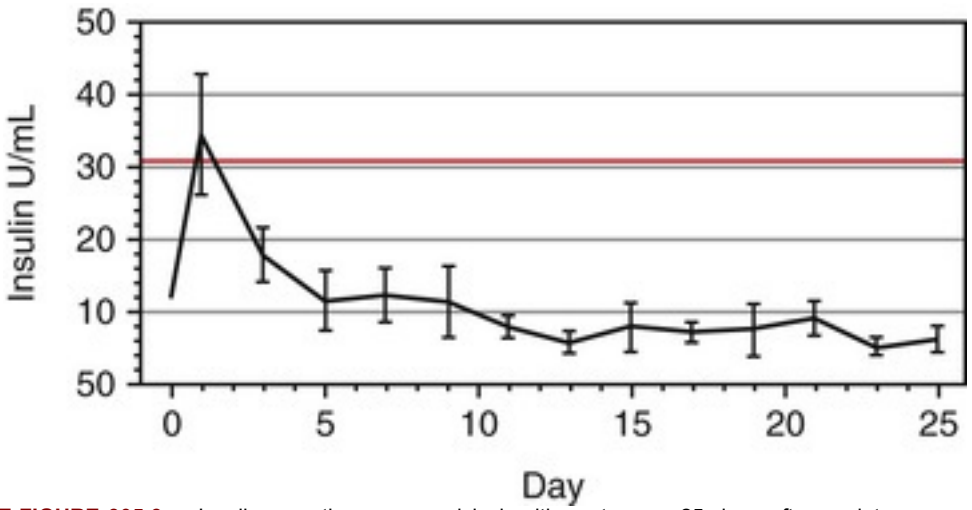
Increased branched-chain amino acids may have a role in beta-cell failure—for example, increased leucine results in decreased beta-cell function and insulin resistance.

Advanced glycation end products (AGEs) form secondary to increased glucose concentrations and result in damage to tissues including beta-cells.

Inflammation is initiated when there is over-nutrition and obesity resulting in high concentrations of glucose, free fatty acid and branched chain amino acids, but the mechanism is not fully characterized. Beta-cell induction of proinflammatory cytokines and chemokines results in immune cell infiltration into islets, including macrophages. Islets respond to glucolipotoxicity by generating inflammatory factors such as IL-1 and IL-6. IL-1 release is stimulated by hyperglycemia and IL-1 blockade improves beta-cell function.

Beta-cell dedifferentiation: Beta-cells progressively lose beta-cell characteristics, which to a certain degree is reversible. Dedifferentiation is triggered by glucolipotoxic conditions, ER and oxidative stress, and inflammation, but the relative contribution to beta-cell dysfunction and loss in type 2 diabetes is unknown.

Beta-cell death through apoptosis, necrosis and autophagy (programmed cell death) is triggered by many of the mechanisms above.



E-FIGURE 305-3 Insulin secretion measured in healthy cats over 25 days after an intravenous glucose infusion was begun at day 0. Persistently high blood glucose concentrations in the range typically seen in newly diagnosed diabetic cats (e.g., 540 mg/dL; 30 mmol/L) cause rapid suppression of insulin secretion from beta-cells even in healthy cats, to levels seen in newly diagnosed diabetic cats. Ketonemia occurs 10-30 days after insulin suppression. Eventually glucotoxicity leads to loss of beta-cells.

Amylin and Islet Amyloid Polypeptide (IAPP)

Deposition of misfolded amylin or IAPP is typical of type 2 DM in humans and cats.[6,58,60,61,65] Amylin or IAPP is a hormone which modulates insulin action, is co-secreted with insulin, and larger quantities are secreted by individuals with insulin resistance.[61] Amylin, in humans and cats, may fold into beta-pleated sheets and form polymerized and misfolded amylin oligomers which act as toxic intracellular aggregates and fibrils. They contribute to islet inflammation and beta-cell death.[60,61,65] Islet amyloid deposition is enhanced in feline models of hyperinsulinemia due to insulin resistance and is associated with overt DM.[66] Islet amyloid deposition and toxic intracellular IAPP oligomers or fibrils, as contributors to beta-cell failure, may explain why humans and cats are uniquely susceptible to type 2 DM, whereas obese dogs and other species

do not develop type 2 DM.

Oxidative Damage

Oxidative stress and modifications likely play a central role in beta-cell dysfunction. Beta-cells have limited antioxidant capacity and are susceptible to oxidative stresses.[67] Glucotoxicity and lipotoxicity are associated with oxidative modifications to beta-cells via excessive production of reactive oxygen species secondary to increased cellular respiration.[68,69] Induction of uncoupling protein-2 (UCP-2) is initially used by beta-cells as a mechanism to protect against excessive mitochondrial respiration. However, activation of UCP-2 causes increased oxygen free-radical generation and oxidative stress.[70] Oxidative stress down-regulates insulin and amylin production while up-regulating pro-inflammatory or apoptotic pathways such as NF-κB and c-JUN N-terminal kinase (JNK).[67,71,72]

Diagnosis

Blood Glucose, Glucose Tolerance and the Diagnosis of Overt Diabetes Mellitus

Once blood glucose concentration exceeds proximal tubular capacity for reabsorption from the glomerular filtrate (approximately 250-290 mg/dL or 14-16 mmol/L), glycosuria occurs.[73,74] Glucose loss in urine contributes to weight loss and stimulates appetite, but not nearly as significantly as cellular inability to gain access to glucose for normal function. Water losses caused by the glucose-osmotic diuresis stimulate polydipsia to maintain fluid balance. Thus, the classic clinical signs of DM result: polyuria, polydipsia, polyphagia, and weight loss. The upper limit for blood glucose concentration in cats is about 113-117 mg/dL (6.3-6.5 mmol/L) using a portable glucose meter and after overnight hospitalization and an 18-24 hour fast.[75,76] Concentrations persistently above this should be considered pre-DM unless overt DM is confirmed. Values ≥180-288 mg/dL (≥10-16 mmol/L) have been reported to be diagnostic for overt DM.[77,78]

The statistically established glucose value in senior cats (≥8 years) is <176 mg/dL (<9.8 mmol/L) 2 hours after 0.5 g/kg glucose, or <117 mg/dL (<6.5 mmol/L) 3 hours after 1 g/kg glucose, as measured in a simplified glucose tolerance test.[75,76] Using these criteria, 20% of obese cats ≥8 years of age are glucose intolerant.[75] It is recommended that the measured 2 hour glucose concentration be adjusted downward by 1.8 mg/dL (0.1 mmol/L) for each body condition score unit above 5 out of 9, to account for relative glucose overdosing in obese cats.[79] Abnormal glucose tolerance is best confirmed by a repeat test.

Impaired Glucose Tolerance and Pre-Diabetes Mellitus (Pre-DM)

Humans with blood glucose concentrations above normal but below DM when fasted or at the 2-hour point in a glucose tolerance test are classified as having impaired fasting glucose or impaired glucose tolerance, respectively.[1,80] They are considered pre-DM and at high risk of developing type 2 DM (5-10% progress to overt DM/year).[1,80-83] Over 50% of DM people are undiagnosed and 3 to 4 times more have undiagnosed pre-DM.[1,80,84] The undiagnosed number of cats with DM may be as large. If identified before progression to overt DM, people often have reasonable glycemic control with weight loss, dietary management, and exercise.[80] Twelve percent to 26% of people in the USA, Europe and Australia have impaired fasting glucose, a percent that increases to 39% by age 65.

Impaired fasting glucose is rarely diagnosed in cats. Mild hyperglycemia is often attributed to stress caused by travel to the clinic, the "white coat effect," restraint, or illness.[81,84-86] As in people, identification and treatment of pre-DM or subclinical DM in cats may delay or prevent progression to overt DM. Most cats in DM remission continue to have disturbed glucose metabolism consistent with pre-DM and have high risk of relapse.[76] Cats in DM remission with normal fasting glucose concentrations and normal glucose tolerance did not develop DM within 12 months. However, DM reoccurred within 9 months of testing in 67% of cats with moderately impaired glucose tolerance (>252 mg/dL; >14 mmol/L at 3 hours during a 1 g/kg IV glucose tolerance test) and in 100% of cats with moderately impaired fasting glucose (≥135-162 mg/dL; ≥7.5-9 mmol/L).[76] Blood glucose concentrations below the renal threshold (250-290 mg/dL; 14-16 mmol/L) but above the point for DM (180 mg/dL; 10 mmol/L) are unlikely to cause clinical signs and should be classified as subclinical DM.[73] Asymptomatic cats with persistent blood glucose concentrations above 117 mg/dL

(6.5 mmol/L) may avoid overt DM or would likely benefit from a low carbohydrate diet, weight loss, and, perhaps, insulin sensitizers such as darglitazone.[87]

Screening Blood Glucose Results (see ch. 61)

When blood is obtained soon after arrival to a clinic, a normal screening blood glucose should be <166 mg/dL (9.2 mmol/L). This high upper value for normal is due to the confounding effect of stress on blood glucose concentrations in cats, capable of markedly increased glucose concentrations within minutes of a stressor.[88] Peak glucose concentrations occur 10 minutes after acute stress and do not return to baseline, in some cats, for >3 hours.[85] Struggling alone increases glucose concentration a mean of 74 mg/dL (4.1 mmol/L) and as much as 195 mg/dL (10.8 mmol/L) within 10 minutes in some cats. This increase parallels lactate and norepinephrine concentrations.[85] Due to the effects of stress, screening blood glucose may not be a useful predictor of DM relapse in cats that had been in remission because of the confounding effects of the stress of travel and handling, and in some cats, the effects of eating (Figure 305-4).[76] Senior cats with glucose concentrations >117 mg/dL (>6.5 mmol/L) should be hospitalized, retested 4 and 24 hours later and managed appropriately based on test results (Figure 305-5).

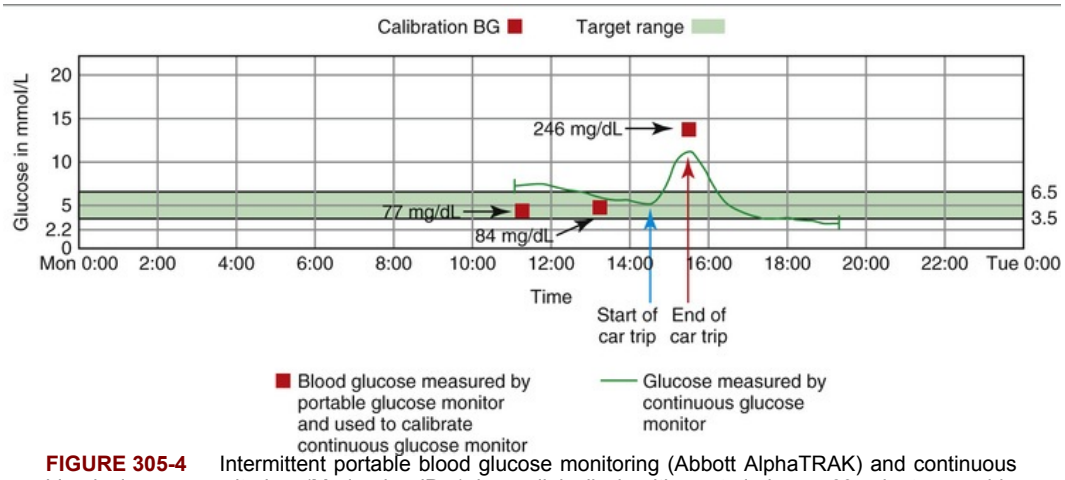


FIGURE 305-4 Intermittent portable blood glucose monitoring (Abbott AlphaTRAK) and continuous blood glucose monitoring (Medronics iPro) in a clinically healthy cat during a 60 minute car ride between the clinic and home. Blood glucose concentrations steadily increased from 84 mg/dL (4.7 mmol/L) to 245 mg/dL (13.6 mmol/L), and decreased to normal over a similar time.

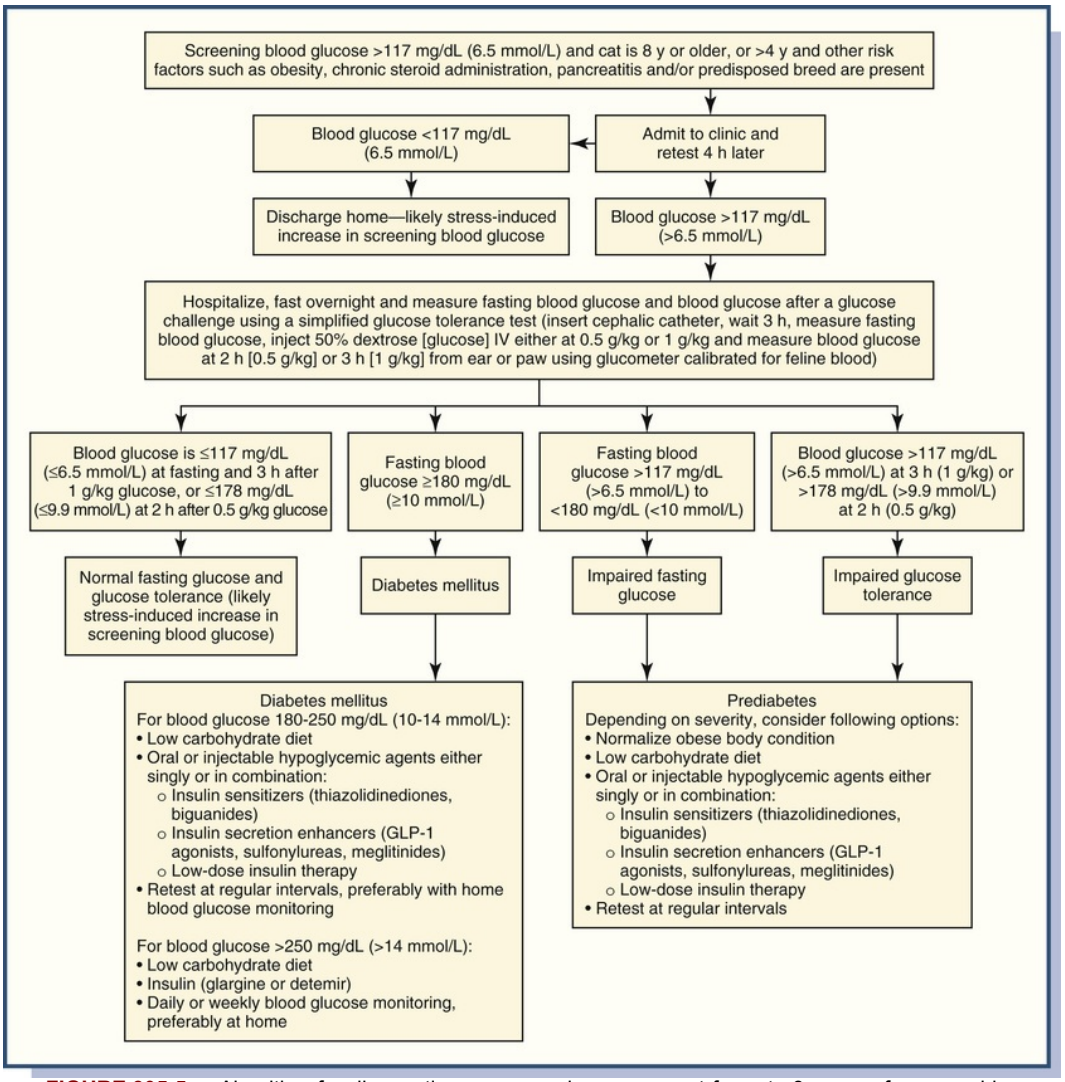

FIGURE 305-5 Algorithm for diagnostic process and management for cats 8 years of age or older with screening blood glucose (not fasted and on entry to the clinic) >117 mg/dL (6.5 mmol/L). *GLP-1*, Glucagon-like peptide 1.

Diabetic Ketosis (DK) and Diabetic Ketoacidosis (DKA) (see ch. 142)

At the time of DM diagnosis, 12-37% of cats have DKA and some are ketotic but not acidotic (DK).[2,77] DKA can be triggered by concomitant disease (especially infection) and signs include depression, vomiting and anorexia.[89] Ketosis can occur over a period of 10 to 30 days once a cat becomes markedly insulinopenic, and does not necessarily require concomitant disease.[63] Once ketotic and without insulin treatment, DKA progresses rapidly. Small doses of insulin can prevent acidosis, even if hyperglycemia persists.[63] Sixteen days after healthy cats had experimentally induced hyperglycemia (540 mg/dL; 30 mmol/L), beta-hydroxybutyrate ketonemia (>0.5 mmol/L) was evident. Ketonemia did not occur at glucose concentrations of 306 mg/dL (17 mmol/L), reflecting the protective effect of insulin.[63] Beta-hydroxybutyrate ketonuria occurred after marked hyperglycemia persisted for a mean of 23 days, although individual times varied widely, as did the renal threshold (19.6 mg/dL, range 3.1-40.6 mg/dL; 1.88 mmol/L, range 0.3-3.9 mmol/L). Ketonuria was detected after 5 days with urine test strips that measured acetoacetate and acetone. By day 27, most cats had acetone-smelling breath and gross lipemia. Based on this study, when blood glucose concentrations are <360 mg/dL (<20 mmol/L), plasma betahydroxybutyrate is unlikely to be increased (>10 mg/dL; >1 mmol/L) and should not be relied on to differentiate stress hyperglycemia from diabetes.

Fructosamine

Fructosamine is produced by a non-enzymatic reaction between glucose and amino groups of plasma proteins, and is a useful measure of glycemic control for cats where home or in-hospital blood glucose monitoring is not possible. It may also aid in diagnosing DM.[90] When hyperglycemia (306 or 540 mg/dL; 17 or 30 mmol/L) was experimentally induced in cats, fructosamine concentrations increased above the reference range (331 mcmol/L) within 3 to 5 days. However, mean fructosamine level did not increase above 350 mcmol/L when blood glucose was maintained at 306 mg/dL (17 mmol/L) for 6 weeks.[91] In cats, fructosamine concentration probably reflects the mean blood glucose concentration for the preceding week. Only changes >33 mcmol/L in an individual are likely to have significance.[91] Fructosamine should not be used to differentiate stress-hyperglycemia from DM when the blood glucose concentration is ≤360 mg/dL (20 mmol/L). Differentiation should be based on serial blood glucose concentrations, and if present, glycosuria and clinical signs. For a given blood glucose concentration, plasma fructosamines vary widely between individual cats. False-positive results (normal cats with high fructosamine levels) and false-negative results (DM cats with normal fructosamine levels) occur, including in DM cats with hyperthyroidism.[90,92,92a]

Goals of Therapy and Diabetic Remission

Newly Diagnosed Diabetics

Tight Glycemic Control

In newly diagnosed DM, the aim of therapy is normal or near-normal blood glucose concentrations (72 to <180 mg/dL; 4 to < 10 mmol/L) while avoiding clinical hypoglycemia. Excellent glycemic control to resolve glucotoxicity, achieved early in newly diagnosed DM cats, increases the probability of DM "remission," defined as persistent euglycemia for at least 2 to 4 weeks without need for exogenous insulin or oral hypoglycemic therapy.[8,76,93] For example, 84% of newly diagnosed DM cats started on a protocol aimed at rigorous glycemic control achieved remission within 6 months, as compared with only 35% ($p < 0.001$) when tight glycemic control was not instituted for at least 6 months.[94]

Remission

Factors reported associated with DM remission include a low carbohydrate diet (12% versus 26% of energy), long-acting insulin (glargine versus PZI or lente), higher age, lower maximum dose of insulin (mean maximum dose of glargine of 0.4 U/kg versus 0.7 U/kg or <3 U/cat versus >3 U/cat), early institution of tight glycemic control (<6 months versus ≥6 months), recent corticosteroid administration, absence of neuropathy, lower mean blood glucose concentrations after treatment with insulin, and lower cholesterol concentrations.[8,93-96] Older cats developing DM have higher remission rates, possibly suggesting a slower disease progression.[93] Mean blood glucose <288 mg/dL (<16 mmol/L) after 17 days of glargine treatment was significantly associated with remission.[8]

Although remission is reported with a variety of oral hypoglycemic drugs, insulin therapies, insulin dosing protocols and diets, the highest remission rates (>80%) are reported in newly diagnosed diabetic cats managed with a protocol aimed at achieving normal or near-normal blood glucose concentrations using a long-acting insulin (glargine or detemir), a low carbohydrate diet (≤6% of energy from carbohydrate), frequent in-hospital or home blood glucose monitoring and appropriate insulin dosage adjustments using a dosing protocol aimed at tight glycemic control.[8,94,97] However, the contributions of small case numbers, lack of blinding, or reliance on owner interpretation are not known.[98]

Corticosteroid Administration

Corticosteroid administration in the 6 months before diagnosis of DM is associated with the highest remission rates.[94] In humans, drug-induced DM is considered an "other specific type" distinct from type 2. It may be easier to reverse this underlying pathophysiologic process or steroid administration may unmask beta-cell defects associated with another disease such as type 2 DM or pancreatitis, resulting in the owner seeking treatment more promptly (see ch. 358).[1]

Peripheral Neuropathy (PN)

PN at the time of DM diagnosis is associated with decreased probability of remission (Figure 305-6 and Videos 12-2, 305-1, and 305-2) and was present in 79% of cats that did not achieve remission despite

implementation of a protocol aimed at intensive glycemic control.[94] Because neuropathy appears later in the course of the disease, it is likely that these cats had DM chronically, with greater beta-cell damage.[94]

FIGURE 305-6 A plantigrade stance and/or muscle weakness is observed in a significant proportion of newly diagnosed diabetic cats and is negatively associated with the probability of diabetic remission. (Photo with permission from R. Marshall.)

Long-Term Diabetes Mellitus without Remission

Cats managed for more than 6 months without achieving DM remission have slightly different treatment goals: to control clinical signs while avoiding clinical hypoglycemia. Remission may be noted in a small number of cats, even after 2 years or more of insulin treatment, if rigorous glycemic control is implemented.

Relapse

Most cats in DM remission do not have normal beta-cell function or sufficient insulin to maintain normal tolerance when challenged with glucose and they should continue to be considered pre-DM. Approximately 76% have impaired glucose tolerance evident after a glucose challenge and 19% have impaired fasting glucose concentrations (mild persistent hyperglycemia >117 mg/dL to <180 mg/dL; >6.5 to <10 mmol).[76] A reduced number of pancreatic islet cells is evident histologically, despite DM remission, including decreased beta-cell density when compared to control cats (1.4% compared to 2.6%).[96] Approximately 25-30% of cats in DM remission relapse, once again requiring exogenous insulin, and <25% of those cats achieve a second remission.[76,93,94] Home blood glucose monitoring and glucose tolerance tests can be used to identify cats at risk of relapsing. Fasting blood glucose of ≥135 mg/dL (≥7.5 mmol/L) and moderate impaired glucose tolerance with either ≥5 hour return to ≤117 mg/dL (≤6.5 mmol/L) or blood glucose concentration >252 mg/dL (>14 mmol/L) at 3 hours during a glucose tolerance test (1 g/kg dextrose IV) were each associated with relapse within 9 months of achieving remission.[76]

Remission was longer in cats with higher body weight at the time of diagnosis, possibly indicating that cats with lower body weight had longer duration of DM and fewer functional beta-cells.[93] As in pre-DM people, drugs which improve insulin sensitivity (thiazolidinediones, biguanides), improve insulin secretion

(glucagon-like peptide 1 [GLP-1] agonists, sulfonylureas, meglitinides) or low-dose insulin therapy may have a role in managing cats with impaired glucose tolerance or increased fasting blood glucose to reduce probability of DM relapse.[80]

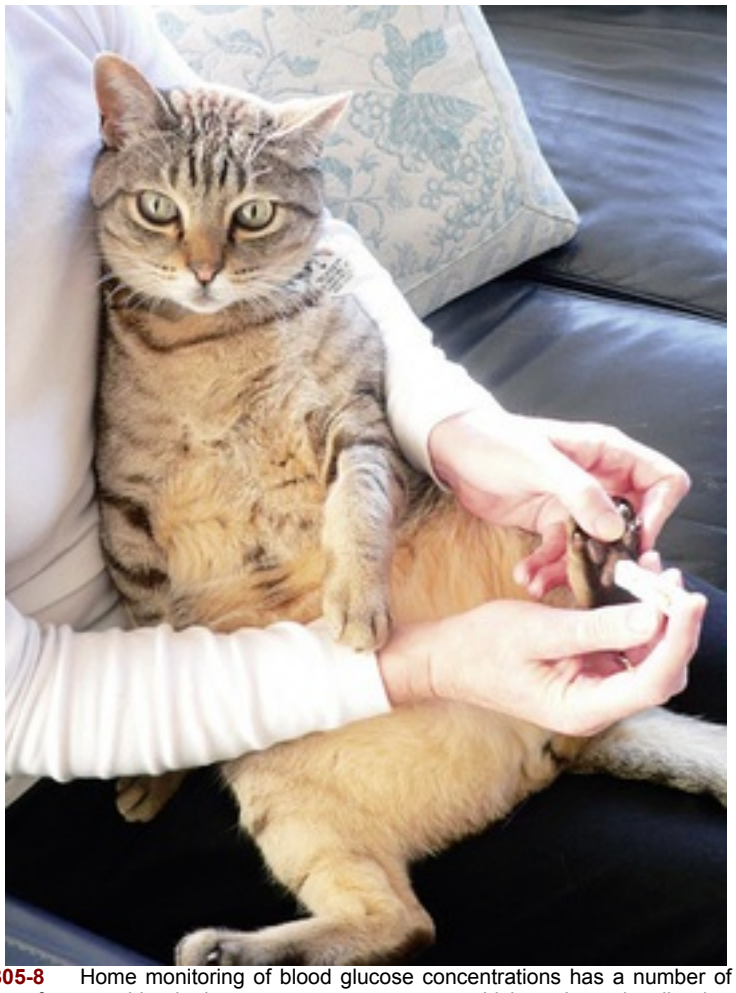
Monitoring Response to Treatment

Blood Glucose, Fructosamine

The aim of therapy is to achieve consistently normal or near-normal blood glucose concentrations (3-10 mmol/L) to maximize chances of remission, minimize clinical signs of hyperglycemia, and avoid hypoglycemia. Monitoring clinical signs (water intake, body weight, appetite) is useful but a relatively insensitive indicator of glycemic control, particularly when glucose concentrations are below renal threshold (252-288 mg/dL; 14-16 mmol/L). Fructosamine is a useful indicator of glycemic control over the previous week, but different assays vary in methodology and reference ranges (321-400 mcmol/L), so within-cat comparisons over time are most useful.[76,91,99,100] Measuring home water consumption correlates more closely with mean blood glucose concentration in a 24 hour period than does fructosamine concentration.[101]

To maximize the probability of DM remission, blood glucose concentration is the most useful variable for adjusting insulin dosage, especially when near normal. Blood glucose concentration is best measured with a portable glucose meter calibrated for cats and measured from the ear or pad (Figure 305-7 and E-Figure 305-8; see ch. 79). Because stress hyperglycemia can be unpredictable and confusing, home blood glucose monitoring is recommended. It is most valuable prior to insulin injection, to prevent inadvertent over-dosing when blood glucose concentration is around the normal range.

FIGURE 305-7 Ear sampling of blood for home blood glucose monitoring. (Photo from Mia Reeve-Johnson.)



E-FIGURE 305-8 Home monitoring of blood glucose concentrations has a number of advantages including more frequent blood glucose measurements on which to base insulin dose increases. Glucose concentration is less likely to be affected by stress or inappetence. Reduced cost and greater convenience for the owner are also factors. Foot pad is warmed for 20 seconds using a warmed, moist cotton wool ball, or massaged to facilitate blood flow. (Photo from W. Milledge with permission.)

Continuous Blood Glucose Monitoring Systems (CBGMS)

CBGMS facilitate identification of hyperglycemia and hypoglycemia and are primarily used for monitoring blood glucose in hospitalized cats. With more compact units becoming available which provide 6 to 7 days of data, they will increasingly be used for home monitoring.[102-104] CBGMS reduce the number of blood samples required during intensive monitoring, guide insulin dosing for tight regulation, are useful for difficult-to-stabilize DM cats fluctuating between hyperglycemia and hypoglycemia, and assist with identification of short-duration of insulin action and rebound hyperglycemia (Somogyi).[102] Units provide real-time or retrospective data. Compact units are suited to home monitoring. Real-time units are most used in-hospital, where they provide immediate information for adjusting each insulin dose.

Disadvantages of current CBGMS are considerable: they are expensive, they require calibration 2 to 3 times a day with blood glucose measurements obtained by other methods, the glucose concentration range measured is less than most portable glucose meters, transmitting range of wireless units is restricted, and life of the sensor is finite (needing replacement within 3 to 7 days) (E-Table 305-1). Sensors can be placed in the flank, lateral thorax, inter-scapular space, lateral stifle fold or dorsal neck. The neck site provides the best continuity of data (Figure 305-9, Video 305-3).[102,104,105] Depending on the expected activity of the cat, the monitor may need to be secured in place with tissue glue, taping or bandaging.[102]

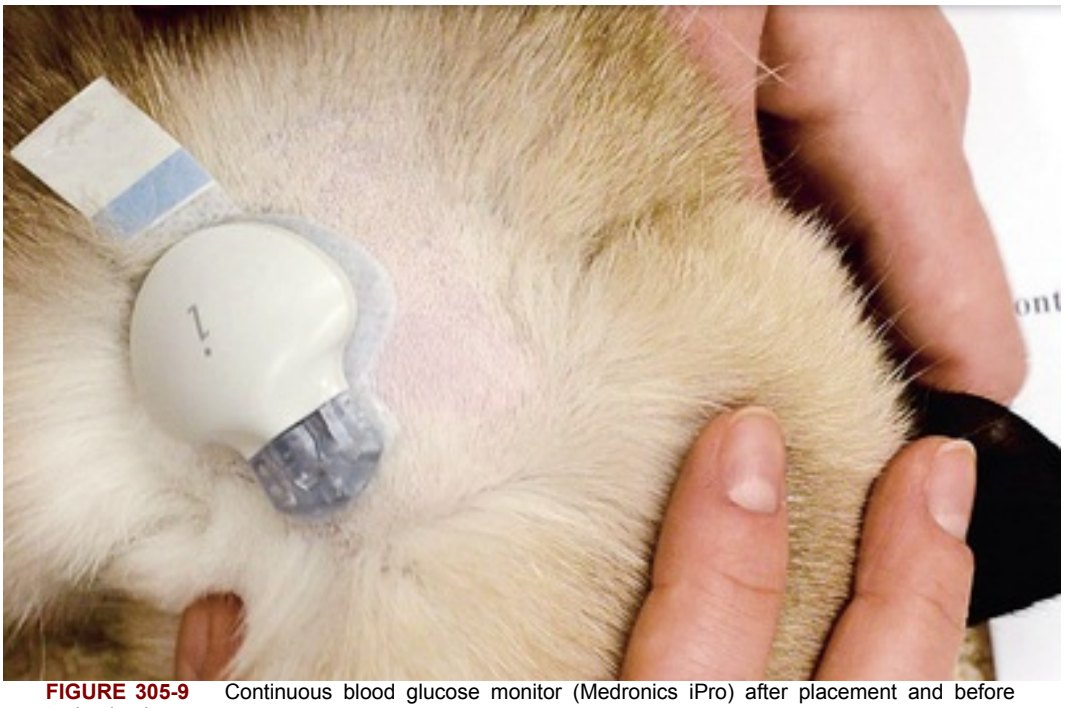


FIGURE 305-9 Continuous blood glucose monitor (Medronics iPro) after placement and before taping in place.

Insulin Therapy

Exogenous insulin is the most effective and reliable treatment for attaining excellent glycemic control.[8,106] There are several types of insulin available for therapy.

Lente Insulin (Caninsulin/Vetsulin, Merck Animal Health)

Lente (Vetsulin Caninsulin) is an intermediate-acting, porcine derived, 40 U/mL insulin that consists of 30% amorphous semilente (short-acting) and 70% crystalline ultralente (long-acting).[107] The 40 U/mL concentration differs from the 100 U/mL insulins registered for human-use and some veterinary-registered insulins. To avoid dosing errors, it is important that the appropriate 40 U/mL syringes are not inadvertently changed for 100 U/mL syringes. Starting dosages for lente insulin are 0.25 to 0.5 U/kg body weight SC q 12 h and should not exceed 3 U/cat (E-Table 305-2).[108] In a 12-month study of 25 cats (15 newly diagnosed), 84% were considered to have a good or excellent response to treatment, based on owner satisfaction and resolution of clinical signs and 28% achieved DM remission within 16 weeks of starting treatment.[109] Median starting dosage was 0.5 U/kg SC q 12 h and did not change significantly over the course of the study. In another study of 46 DM cats (39 newly diagnosed), good to excellent control was achieved in 72%, based on resolution of clinical signs, and 15% achieved remission within 20 weeks.[110] Clinical signs of hypoglycemia were evident in 20% of the cats, and mostly occurred at dosages greater than 0.5 U/kg or 3 U/cat.[110]

E-TABLE 305-2

Parameters for Insulin Dosage and Frequency Based on Blood Glucose Measurements Using Lente (Caninsulin/Vetsulin; Merck Sharp and Dohme) or NPH in Diabetic Cats*

BLOOD GLUCOSE VARIABLE	RECOMMENDATION
Use an initial dosage 0.5 U/kg of lean body weight SC q 12 h if blood glucose is >360 mg/dL (>20 mmol/L) and 0.25 U/kg q 12 h if glucose <360 mg/dL (<20 mmol/L); do not increase in first week, but decrease if necessary	
If pre-insulin blood glucose concentration is ≤180 mg/dL (≤10 mmol/L)	Provided cat has been treated for a minimum of 2 weeks with insulin, withhold insulin and monitor blood glucose carefully over next 24-48 hours to determine if cat is in diabetic remission; if treated for less than 2 weeks, reduce dose by 1 U/cat and recheck in 1 week
If pre-insulin blood glucose concentration is 198-270 mg/dL (11-15 mmol/L)	Total dose should be no more than 1 U/cat q 12 h
If nadir blood glucose concentration is <72 mg/dL (<4 mmol/L)	Dosage should be reduced by 50%
If nadir blood glucose concentration is 72-90 mg/dL (4-5 mmol/L)	Dosage should be reduced by 1 U if poor control of clinical signs of diabetes, to determine if dose was excessive and leading to reduced duration of insulin action or a Somogyi effect. If clinical signs do not substantially improve within 7 days, switch to long-acting (glargine or detemir). Dosage should remain the same if exemplary control of clinical signs.
If nadir blood glucose concentration is 91-180 mg/dL (6-9 mmol/L)	Dosage should remain the same
If nadir blood glucose concentration is	Dosage should be increased by 1 U

>180 mg/dL (>10 mmol/L)	
If nadir blood glucose concentration occurs within 3 hours of insulin administration, or blood glucose returns to baseline within 8 hours	Change to longer acting insulin (i.e., glargine, detemir or PZI) or increase frequency of administration
If the nadir blood glucose concentration occurs at 8 hours or later	Once daily administration may be used, although twice daily administration at a reduced dose is preferred

*Based on monitoring blood glucose concentration in hospital or at home every 1 to 2 weeks with serial measurements every 2 hours over 12 hours using a portable glucose meter calibrated for feline blood measuring whole blood glucose concentration

Normal reference range for cats (54-117 mg/dL; 3-6.5 mmol/L) as target glucose concentrations.[113]

After giving lente to DM cats, the blood glucose nadir typically occurs in about 3 to 6 hours (mean 4 hours), and blood glucose concentration returns to pre-injection values between 8 to 10 hours (termed return to baseline or duration of action).[110,111] Because of this relatively short duration of action, even with q 12 h dosing, hyperglycemia typically occurs for several hours twice daily (prior to each injection).[111,112] As a result, even though appropriate nadirs may be achieved, blood glucose concentration is often high (≥360 mg/dL; ≥20 mmol/L) prior to each insulin injection, making this our fourth choice insulin in cats. Twice daily marked hyperglycemia likely contributes to lower remission rates in cats treated with lente insulin compared to long-acting insulin. Insulin dosage should be adjusted based on nadir glucose concentrations to achieve concentrations in the normal range. Do not base the dosage on blood glucose concentration at the time of insulin injection, unless the concentration is <360 mg/dL (<20 mmol/L). This indicates that insulin action is longer than 12 hours, or more often, return of endogenous insulin secretion and pending remission (see E-Table 305-2).[113]

Protamine Zinc Insulin (PZI)

PZI has protamine and zinc added to prolong its duration of action.[114] While not available for human use since the 1990s, it is still available for use in cats in the USA and the United Kingdom. Originally animal-origin, it is now human-recombinant PZI (ProZinc, Boehringer Ingelheim).[115,116] ProZinc has a concentration of 40 U/mL, and therefore, use of appropriate insulin syringes must be discussed with the owner to avoid inadvertently using 100 U/mL syringes and incorrect dosing. Some compounding pharmacies in the USA provide bovine origin PZI for veterinary use, but in one study only 1 of 12 pharmacies consistently made PZI that met required specifications of the United States Pharmacopeia.[117] Recommended initial dosage is either 1-3 U/cat or 0.25-0.5 units/kg ideal body weight, with the actual dosage chosen based on severity of clinical signs and hyperglycemia (Table 305-3).[8,118]

TABLE 305-3

Glargine, Detemir or PZI Dosing Protocol, Monitoring Glucose Every 1-2 Weeks Using a Glucometer Calibrated for Cats (e.g., AlphaTRAK, Abbott Animal Health)

PARAMETER USED FOR DOSAGE ADJUSTMENT	CHANGE IN DOSAGE
Begin with 0.5 U/kg SC q 12 h if blood glucose >360 mg/dL (>20 mmol/L) or 0.25/kg SC q 12 h of ideal weight if blood glucose is lower Do not increase in first week unless minimal response to insulin occurs, but decrease if necessary. Monitor response to therapy for first 3 days. If no monitoring is occurring in first week, begin with 1 U/cat SC q 12 h	
If pre-insulin blood glucose concentration >216 mg/dL (>12 mmol/L) provided nadir is not in hypoglycemic range **OR** If nadir blood glucose concentration >180 mg/dL (>10 mmol/L)	Increase by 0.25-1 U depending on total insulin dose (greater or less than 3 U/cat) and degree of hyperglycemia (how close blood glucose is to 180 mg/dL [10 mmol/L])

If pre-insulin blood glucose concentration ≥180-≤216 mg/dL (≥10-≤12 mmol/L) **OR** Nadir blood glucose concentration is 90-160 mg/dL (5-9 mmol/L)	Same dosage
If nadir glucose concentration is 63-<72 mg/dL (3.5-<5 mmol/L)	Use nadir glucose, water drunk, urine glucose and next preinsulin glucose concentration to determine if insulin dosage is decreased or maintained
If pre-insulin blood glucose concentration <180 mg/dL (<10 mmol/L) **OR** If nadir blood glucose concentration <63 mg/dL (<3.5 mmol/L)	Reduce by 0.25-1 U depending on total insulin dose (greater or less than 3 U/cat) and degree of hyperglycemia (how close blood glucose is to 180 mg/dL [10 mmol/L]) If total dose is 0.5-1 U q 12 h, change to q 24 h If total dose is 0.5-1 U q 24 h, stop insulin and check for diabetic remission
If clinical signs of hypoglycemia are observed	Reduce by 50%

If using a plasma-equivalent meter calibrated for human blood, decrease target blood glucose concentration by 9 mg/dL; 0.5 mmol/L.[8,94,97]

Of 133 DM cats treated with PZI (120 newly diagnosed and 13 previously treated with other insulin), 85% obtained good control within 45 days based on improved clinical signs, stabilization of body weight and reduction in the mean blood glucose concentration 9 hours after PZI administration and/or reduced serum fructosamine concentration.[116] Biochemical hypoglycemia was identified in 64% of the cats, although only 2 had clinical signs. In a study of newly diagnosed DM cats, 3/8 achieved remission within 112 days, not significantly different from the remission rate of 2/8 achieved in cats treated with lente insulin.[8] In healthy cats, PZI results in a biphasic blood glucose concentration curve. The first nadir occurs at about 4 hours (range 1.5 to 8 hours), and a second nadir at 14 hours (range 6 to 24 hours). Mean duration of action is 21 hours (range 9 to >24 hours).[119] In DM cats, the first nadir blood glucose concentration occurred at 5 to 7 hours.[116] This is our third choice for DM in cats.

Glargine (Lantus, Sanofi-Aventis, Patent Protection Expired Feb 2015)

Glargine (100 U/mL) is a long-acting human insulin analogue. Asparagine at position A21 is replaced by glycine, and two arginines added to the B chain at positions 31 and 32, hence the name.[120] These alterations result in insulin that is soluble in acidic solutions but which microprecipitates in the neutral pH of SC tissues, prolonging its release.[120,121] In humans, glargine provides basal insulin concentrations for 24 hours, and is typically used together with short-acting insulin administered at the time of eating to mimic normal patterns of endogenous insulin secretion.[120] Using the euglycemic clamp method in healthy cats, glargine had a duration of action of 10 hours (6.6-13 hours).[122] However, using an insulin response test in healthy cats, their glucose nadir was reached at 14 hours (10-24 hours), after glargine administration, and duration of action was 22 hours (12->24 hours).[119] In healthy cats, duration of action is significantly longer than lente insulin (10 hours, range 5-24+), although similar to PZI (21 hours, range 9-24+).[119] In healthy cats, no significant difference in duration of action was noted in comparing doses of 0.5 U/kg SC q 24 h and 0.25 U/kg SC q 12 h.[123]

It is recommended that glargine (q 12 h) be used as a sole insulin for cats with DM, together with a low carbohydrate diet to minimize postprandial increases in blood glucose.[119] Dosing q 12 h facilitates overlap of insulin action from one injection to the next, resulting in consistent glucose lowering effects over 24 hours, increasing chances of DM remission.[119,122,123] Importantly, glycemic control was not significantly different between glargine administered once daily and lente administered twice daily.[124] Recommended starting dosages for glargine are 0.25 U/kg of ideal body weight SC, if blood glucose concentration is <360 mg/dL (<20 mmol/L), or 0.5 U/kg (maximum 3U/cat) SC if blood glucose is higher (see Tables 305-3 and 305-4).[8,94,118] If no blood glucose monitoring is intended in the first week of therapy, a starting dose of 1 U/cat is recommended, although this approach may delay resolution of clinical signs. When transitioning from another insulin to glargine, if the dose is <3 U, one should use the same dose. For doses ≥3 U, conservative dosing is recommended: for example, starting with 50-66% of the dose, but increasing within 48-72 hours if control is not adequate.[125]

TABLE 305-4

Glargine or Detemir Dosing Protocol and Intensive Home Blood Glucose Monitoring (Minimum 3 Measurements Per Day with Average of 5) during Stabilization Period (6-12 Weeks) Using a Plasma-Equivalent Meter Calibrated for Cats (e.g., AlphaTRAK from Abbott Animal Health)[94]

PARAMETER USED FOR DOSAGE ADJUSTMENT	CHANGE IN DOSAGE
Phase 1: Initial dosage and first 3 days on glargine.	
Begin with 0.25 U/kg of ideal weight SC q 12 h **OR** If the cat received another insulin previously, increase or reduce the starting dose, taking this information into account. Glargine has a lower potency than lente insulin or PZI in most cats.	
Cats with a history of developing ketones and blood glucose remains >300 mg/dL (>17 mmol/L) after 24-48 hours of beginning insulin	Increase by 0.5 U
If nadir blood glucose is <72 mg/dL (<4 mmol/L) and no clinical signs of hypoglycemia.	Reduce dose by 0.25-0.5 U depending on whether cat is on low or high dose of insulin (greater or less than 3 U/cat) and severity of hypoglycemia
Phase 2: Increasing the dosage.	
If nadir blood glucose concentration >300 mg/dL (>16.6 mmol/L)	Increase every 3 days by 0.5 U
If nadir blood glucose concentration 200-300 mg/dL (11.1-16.6 mmol/L)	Increase every 3 days by 0.25-0.5 U depending on whether cat is on low or high dose of insulin and severity of hyperglycemia
If nadir blood glucose concentration 117-<200 mg/dL (6.5-<11 mmol/L) and peak is >200 mg/dL (>11 mmol/L)	Increase every 5-7 days by 0.25-0.5 U depending on whether cat is on low or high dose of insulin, and severity of hyperglycemia
If nadir blood glucose is <63 or <72 mg/dL (<3.5 or <4 mmol/L)	Actual concentration used to decrease dose depends on frequency of monitoring and previous response to insulin dose changes when blood glucose is around the lower limit of the normal range. Reduce dose by 0.25-0.5 U depending on whether cat is on low or high dose of insulin. If clinical signs of hypoglycemia occur, reduce dose by 0.5 to >1 U depending on severity
If blood glucose at the time of the next insulin injection 72-117 mg/dL (4-6.5 mmol/L)	Initially test which of the alternate methods is best suited to the individual cat: a. Feed cat and reduce the dose by 0.25-0.5 U depending on whether cat is on low or high dose of insulin b. Feed the cat, wait 1-2 hours and when the glucose concentration increases to >117 mg/dL (>6.5 mmol/L) give the normal dose. If the glucose concentration does not increase within 1-2 hours, reduce the dose by 0.25 U or 0.5 U (as above). c. Split the dose: feed cat, and give most of dose immediately and then give the remainder 1 to 2 hours later, when the glucose concentration has increased to >117 mg/dL (>6.5 mmol/L) If all these methods lead to increased blood glucose concentrations, give the full dose if pre-insulin blood glucose concentration is 72-117 mg/dL (4-6.5 mmol/L) and observe closely for signs of hypoglycemia. In general for most cats, the best results in phase 2 occur when insulin is dosed as consistently as possible, giving the full normal dose at the regular injection time.
Phase 3: Holding the dosage. Aim to keep blood glucose concentration within 72-200 mg/dL (4-11 mmol/L) throughout the day.	
If nadir blood glucose is <63 or 70 mg/dL (<3.5 or 4 mmol/L)	Reduce dose by 0.25-0.5 U depending on whether the cat is on low or high dose of insulin
If nadir or peak blood glucose	Increase dose by 0.25-0.5 U depending on whether the cat is on low or high dose of

concentration >200 mg/dL (>11.0 mmol/L)	insulin and the degree of hyperglycemia
Phase 4: Reducing the dosage. Phase out insulin slowly by 0.25-0.5 U depending on dosage.	
When the cat regularly (every day for at least one week) has its lowest blood glucose concentration 63-117 mg/dL (4-6.5 mmol/L), and stays under 117 mg/dL (6.5 mmol/L) overall	Reduce dose by 0.25-0.5 U depending on whether the cat is on low or high dose of insulin
If the nadir glucose concentration is 55-<63 mg/dL) (3-<4 mmol/L) at least three times on separate days	Reduce dose by 0.25-0.5 U depending on whether the cat is on low or high dose of insulin
If nadir is <55 mg/dL (<3 mmol/L) once	Reduce dose immediately by 0.25-0.5 U depending on whether the cat is on low or high dose of insulin
If peak blood glucose concentration >200 mg/dL (>11 mmol/L)	Immediately increase insulin dose to last effective dosage
Phase 5: Remission. Euglycemia for a minimum of 14 days without insulin. Monitor blood glucose at least 2 to 3 times daily for 14 days to ensure it remains ≤117 mg/dL (≤6.5 mmol/L), then 1 to 2 times weekly thereafter. If blood glucose increases to 117-<180 mg/dL (6.5-<10 mmol/L), institute other therapy such as insulin sensitizers or GLP-1 agonists to maintain blood glucose ≤117 mg/dL (≤6.5 mmol/L); if ≥180 mg/dL (≥10 mmol/L), reinstitute insulin once or twice a day depending on severity of hyperglycemia.	

Significantly lower mean blood glucose concentrations at day 17, and significantly higher remission rates were achieved by 16 weeks of treatment with glargine (8/8 cats), compared to lente insulin (2/8) and PZI (3/8) in newly diagnosed DM, fed a low carbohydrate diet (6% of energy from carbohydrate) and given insulin q 12 h.[8] Eighty-four percent of 55 DM cats achieved remission within 6 months of diagnosis after being treated with glargine and using a protocol aimed at achieving euglycemia.[94]

In humans with type 1 and type 2 DM, fewer hypoglycemic episodes are reported with glargine compared to shorter-acting insulins.[126,127] While biochemical hypoglycemia (<54 mg/dL or <3 mmol/L) occurred in newly diagnosed DM cats treated with glargine, none of 8 cats developed clinical signs, compared to 2 cats treated with lente and 1 cat treated with PZI.[8] In a larger study of 55 cats treated with glargine and a protocol aimed at achieving euglycemia, biochemical hypoglycemia (<50 mg/dL or <2.8 mmol/L) was frequent when measured with a glucose meter calibrated for whole human blood, although only one cat developed mild signs of clinical hypoglycemia (restlessness).[94] Glargine is our first choice of insulin in cats and can also be used for treatment of DKA (see ch. 142).[128]

Detemir (Levemir, NovoNordisk)

Detemir (see ch. 304) is a long-acting human insulin analogue (100 U/mL). The B30 amino acid threonine is removed and a 14-carbon, myristoyl fatty acid is covalently bound to lysine at position B29.[121] The protracted action of detemir is a result of slow absorption into blood after injection because it self-associates into hexamers and dihexamers that also reversibly bind to albumin, prolonging residence time at the injection site. Some further retention occurs in the circulation associated with albumin binding.[121,129,130] In type 2 DM humans, detemir and glargine are similar in action, but detemir has less variability in effect.[130] While q 24 h dosing is adequate in humans to provide basal insulin concentrations, duration of action in healthy cats using the euglycemic clamp method is shorter and q 12 h is recommended.[122] Detemir has a slightly later onset of action compared to glargine (1.8 hours, range 1.1–2.5 vs. 1.3 hours, range 0.9-1.6) in healthy cats using the euglycemic clamp method. Duration of action (11.7 hours, range 9.1-14 compared to 10 hours, range 6.6-13) and end of action (13.5 hours, range 11-16 compared to 11.3 hours, range 8-14.5) were not significantly different from glargine, but there was less variability between cats than with glargine.[122]

Initial dosages and protocol for dosage increases are the same as for glargine (see Tables 305-3, 305-4, and E-Table 305-5).[97,118] Most cats initially require about 25-30% less detemir than glargine (1.75 U compared to 2.5 U), although final dosages may be similar.[94,97] Cats can exhibit an initial increased sensitivity to detemir, which is transient and typically lasts for 24-48 hours. Therefore, if changing from glargine or other insulin, start with about half the current insulin dosage and increase within 48 hours if insufficient glucose lowering is

occurring. Increase the dosage every 3-7 days until blood glucose is controlled. Similar to findings in glargine-treated cats, remission occurred in 81% of cats treated with detemir within 6 months of diagnosis and a protocol aimed at euglycemia, whereas this was only 42% if tight glycemic control was delayed for 6 months or longer.[97] Detemir is our second choice insulin due to less experience, but cats on glargine with poor control, especially with short duration of action, should be tried on detemir while looking for concomitant disease.

E-TABLE 305-5

Simplified Home Blood Glucose Monitoring Protocol for Clients Dosing Glargine and Using Only Pre-Insulin Blood Glucose Concentration to Adjust Dosage (Glucose Cutpoints Are for a Human Plasma-Equivalent Glucometer)

Pre-Insulin Blood Glucose	
Newly Diagnosed Diabetics (<2 Months Insulin Therapy)	
Blood glucose concentration >215 mg/dL (>12 mmol/L)	Increase the dose by 0.5 U
Blood glucose concentration 108-215 mg/dL (6-12 mmol/L)	Keep the dose the same
Blood glucose concentration 54-<108 mg/dL (3-<6 mmol/L)	Decrease the dose by 0.5 U
Blood glucose concentration <54 mg/dL (<3 mmol/L)	Do not give insulin and call the clinic to discuss. If signs of hypoglycemia, measure blood glucose and call clinic immediately.
Longer-Term Diabetics (>2 Months Insulin Therapy)	
Blood glucose concentration >450 mg/dL (>25 mmol/L)	Increase the dose by 1 U
Blood glucose concentration 252-450 mg/dL (14-25 mmol/L)	Increase the dose by 0.5 U
Blood glucose concentration 108-<252 mg/dL (6-<14 mmol/L)	Keep the dose the same
Blood glucose concentration 72-<108 mg/dL (4-<6 mmol/L)	Decrease the dose by 0.5 U
Blood glucose concentration <72 mg/dL (<4 mmol/L)	Do not give insulin and call clinic to discuss. Check for diabetic remission depending on insulin dose.

If using a meter calibrated for feline blood, increase glucose cutpoints by 9 mg/dL or 0.5 mmol/L). Protocol used in a feline-only practice for 8 years in >80 diabetic cats (unpublished data Marshall and Gottlieb).

Insulin Storage

The manufacturer's recommended shelf-life at room temperature after opening glargine is 28 days and 6 weeks for detemir. However, they are relatively stable in solution, and many owners of DM cats effectively use refrigerated glargine or detemir for 6 months or longer. The short expiration periods on multiple-use injectable medication vials, even if a preservative is present, is due to the FDA's assessment of bacterial contamination risk, which is extremely low. Glargine and detemir preparations contain the antimicrobial preservative meta-cresol, which is bacteriostatic and most effective at room temperature. Owners should be instructed to immediately dispose of insulin appearing cloudy or discolored.

Administering Small Doses of Glargine and Detemir

Administering small doses using 100 U/mL insulin (detemir or glargine) can be problematic and limits their use when doses of less than 1 U are required. Dosing pens are recommended for doses less than 2 U, providing better accuracy, stability, and minimizing risk of bacterial contamination compared to diluting insulin.[131-133] Insulin dosing pens such as the HumaPen Luxura HD (Eli Lilly) and the NovoPen Junior

(USA)/Demi (other countries) (NovoNordisk) deliver accurate and precise insulin doses in 0.5 U increments (see ch. 304). However, in some cats, particularly those going into remission and regaining some beta-cell function, dosage adjustments may be required in increments less than 0.5 U.

Detemir can be diluted using a special diluting medium available from NovoNordisk, but in some countries the company will not supply this to veterinarians. Detemir can also be diluted with sterile water or saline, but this also dilutes the antimicrobial additive (meta-cresol).[134] Minimize bacterial contamination risk by diluting just prior to each administration. If diluted in a bottle and kept refrigerated, discard insulin after 30 days. Potency may be adversely affected using this method. Neither dilution nor mixing with other insulins is recommended for glargine. However, humans with DM have successfully mixed glargine with other insulins, despite a cloudy precipitate forming in the syringe.[135] Dilution of both detemir (1 : 10) and glargine (1 : 100) with saline is reported for management of transient human neonatal DM to facilitate administration of very small doses, although the effect of dilution on efficacy or stability has not been reported for humans or cats.[134]

Choosing an Insulin

Prior to the availability of long-acting insulin, the aims of treating DM cats were to resolve clinical signs and improve quality and length of life. Given the high rates of DM remission when using long-acting insulin, low carbohydrate diets, and protocols aimed at achieving normal or near-normal blood glucose concentrations, insulin should be chosen to maximize this opportunity. DM remission has welfare advantages for the cat, cost advantages for owners, and quality of life advantages for both. Glargine and detemir are associated with the highest rates of remission in cats with newly diagnosed DM. These should be the first choice insulins for a newly diagnosed DM cat. However, neither glargine nor detemir is registered for use in cats. In some countries, laws require use of veterinary-approved products first, and only allow off-label use of glargine or detemir if there is failure of treatment. If use of veterinary-registered insulin is legally mandated, PZI is recommended, but it is only available in a limited number of countries.

Diet

Background

The role of diet in the management and prevention of DM is unquestioned (see ch. 181). Commercial feline dry food diets derive up to 60% of energy from carbohydrates (mean 41%).[25,136,137] Cats are obligate carnivores and, based on meta-analysis of data from 27 studies of natural prey of feral cats, their mean daily energy intake is about 2% carbohydrate (nitrogen free extract), 52% crude protein, and 46% crude fat.[138] Cats are relatively glucose intolerant as compared with dogs and humans.[1,139-141] There is evidence that cats limit intake when carbohydrate content is >40% ME (E-Table 305-6).[139,142-145]

E-TABLE 305-6

Characteristics of Glucose Metabolism in Cats, Some of Which Contribute to the Higher and Longer Postprandial Increase in Blood Glucose Concentrations and Relative Glucose Intolerance Following a High Carbohydrate Load in Cats Compared to Dogs

Markedly reduced or absent hepatic glucokinase concentrations[252,253]	• Cats rely on low-capacity hexokinase to clear a glucose load
Delayed gastric empyting[143]	• When fed mean energy requirement (MER) once a day and food is consumed shortly after feeding, food is slowly released from the stomach over 24-26 hours. When fed 50% MER, food is released over 12-14 hours.
Reduced and delayed insulin secretion[139]	After high protein, low carbohydrate meal with added glucose (2 g/kg) in dogs and cats • Peak insulin secretion was half that of dogs and occurred three times later (210 min versus 90 min) • Peak glucose concentration was higher in cats (10.0 mmol/L; 180 mg/dL versus 6.3 mmol/L; 114 mg/dL) • Peak glucose concentration occurred later in cats (120 min versus 60 min)

	• Return to baseline for glucose concentration was longer in cats (270 min versus 90 min), indicating relative glucose intolerance compared to dogs
Reduced small intestinal disaccharidase activity139,254	• Prolongs glucose absorption from the gastrointestinal tract, and reduces peak postprandial concentrations
Reduced downregulation of gluconeogenic pathways255	• Hepatic glucose production continues after eating even after a high carbohydrate meal

Role of Diet in Preventing Diabetes

Overweight cats have 4.6 times greater risk of DM than cats in ideal body condition and obesity is the most important acquired risk factor (see ch. 176).[24,77] Approximately 25 to 63% of cats are overweight or obese and 20% of obese cats >8 years of age are pre-DM with impaired glucose tolerance or impaired fasting glucose.[75,146-150] In cats, humans and dogs, carbohydrate is the principal macronutrient determining the magnitude of the postprandial increase in plasma glucose and insulin.[151-153] In either meal or *ad libitum* fed lean cats, carbohydrate results in significantly higher postprandial blood glucose concentrations than equivalent amounts (% ME) of protein or fat. Peak glucose concentration was 151 mg/dL (8 mmol/L) or 31% higher for a high carbohydrate diet (carbohydrate 47% ME, 12.9 g/100 kcal) than for a high protein diet (protein 46% ME, carbohydrate 27% ME, 7.1 g/100 kcal) with a peak of 115 mg/dL (6 mmol/L) ($P < 0.001$). Postprandial insulin concentrations had a similar trend.[153] There also was a consistent trend for glucose and insulin concentrations to be lowest for the high protein diet compared to the high fat diet (both with 27% ME from carbohydrate).

Importantly, the magnitude and duration of postprandial hyperglycemia is exacerbated by weight gain.[32,154] In overweight cats fed a high carbohydrate commercial diet (51% ME; 14.5 g/100 g/kcal), mean postprandial glucose concentrations over 24 hours were 119 ± s.d. 18 mg/dL (6.6 ± 1 mmol/L) and peak glucose concentrations were as high as 241 mg/dL (13.4 mmol/L) and in the DM range for cats.[77,154] Feeding high fat diets in excess of maintenance energy requirements is associated with obesity, and therefore increases the risk of DM.[150,155,156] One study comparing wet and dry foods found that cats fed only wet diets (higher in fat, lower in carbohydrate) had 3 times higher risk of DM, while feeding only dry diets (higher carbohydrate, lower fat) was associated with 2 times higher risk, suggesting that the adverse effect of obesity from a higher fat diet is a greater risk for DM, although a higher carbohydrate intake also increases risk, presumably from increased postprandial glycemia.[24] While high carbohydrate diets (≥50% ME) may have insufficient protein for cats, moderate carbohydrate diets (20-30% ME) are unlikely to be detrimental to young adult, lean cats with normal beta-cell function. However, diets with ≤12% of energy from carbohydrate are indicated for cats at increased risk of DM. Since age is a risk factor for DM, older cats with other risk factors (breed, corticosteroid use, obesity) would likely benefit from a low carbohydrate diet to minimize the insulin secretion required to maintain euglycemia.[157]

Role of Diet in Managing Diabetes (see ch. 181)

The primary goal in managing feline DM is to achieve remission. Minimizing dietary carbohydrate (CHO) reduces demand on pancreatic beta-cells to produce insulin. Data from a number of studies in DM cats indicate that low-carbohydrate diets (≤13% ME; <4 g/100 kcal ME) may improve glycemic control, reduce fructosamine concentration and increase the probability of diabetic remission.[8,94,95,97,158,159] When fed over 16 weeks to 63 diabetic cats (11 newly diagnosed and 52 previously diagnosed), a low carbohydrate–low fiber diet (12% ME; 3.5 g CHO/100 kcal) resulted in significantly higher remission rates (68% versus 41%) and better glycemic control based on resolution of clinical signs and serum fructosamine concentrations <400 mcmol/L (81% versus 56%) compared with a moderate carbohydrate–high fiber diet (7.6 g CHO/100 kcal, 26% ME).[95] There are no reported studies comparing diets of ≤6% ME with 12% ME.[98] However, the highest reported remission rates (>80%) are associated with using a carbohydrate restricted diet (<6% ME) combined with insulin protocols aimed at achieving normal or near-normal blood glucose concentrations.[8,94,97] In long-term obese DM cats who have not lost weight or achieved remission with appropriate management, DM remission is unlikely. Priority should then be given to achieving an ideal body condition to reduce the risk of other comorbidities associated with obesity in cats.

Normalizing body condition and muscle mass are dietary goals and controlled weight loss via energy restriction is important.[157] Although remission may occur prior to significant weight loss, achieving ideal body condition is likely important for maintaining remission and improving insulin sensitivity.[47,93,94] A suitable weight loss diet for a DM cat is fat <4 g/100 kcal, carbohydrates <3 g/100 kcal and protein >10 g/kcal, however, energy intake must also be controlled.[157] Canned food helps decrease energy intake and body weight because moisture increases food volume and hydration.[160]

Chronic kidney disease (CKD) is reported in 26-62% of DM cats (see ch. 324).[94,97] Controlled amounts of protein and restricted phosphorus improve survival time in cats with CKD and, therefore, high-protein and low-carbohydrate diabetes diets are likely contraindicated, especially in cats with IRIS 2 or 3 CKD (see ch. 184).[161] If a cat has a good appetite, administering acarbose with a moderate-carbohydrate prescription renal diet may assist in reducing postprandial glucose concentrations.[162] Grocery-line ultra-low carbohydrate diets (≤2% ME), mostly fish or meat-based, are often considerably higher in phosphorus than available veterinary prescription diets designed for feline DM and should be avoided in CKD.

Oral Hypoglycemics

Background

Oral hypoglycemic medications may be used as the sole therapy in diabetics with sufficient endogenous insulin to maintain euglycemia or combined with insulin therapy. The oral drugs act by stimulating insulin secretion from pancreatic beta-cells, increasing insulin sensitivity in tissues, or slowing intestinal absorption of glucose.[163] In general, unless the client would otherwise elect euthanasia, oral hypoglycemic drugs are not recommended as sole agents in newly diagnosed DM cats with overt signs because their glycemic control is far better with insulin.[8,106,173] However, oral hypoglycemics could be effective in managing subclinical or pre-DM in cats, and in some cats, when combined with insulin therapy.

Sulfonylureas

Sulfonylureas stimulate insulin secretion from pancreatic beta-cells by binding to ATPases, which sequentially close potassium (K) and open calcium (Ca) channels in cell membranes. The resulting influx increases intracellular Ca concentrations, triggering release of stored insulin.[164,165] Glipizide is the most often used sulfonylurea in cats. It improved signs in 30% of DM cats, with 15% having good to excellent control based on near-normal blood glucose concentrations, resolution of clinical signs and no glycosuria.[106,166] However, 56% had worsening of glucose concentrations and required insulin.[106] DM remission has been reported in only 12% of newly diagnosed cats treated with glipizide.[106] Cats most likely to respond are non-ketotic, have mild signs of DM, acceptable body condition and good health.[167] Recommended starting dose is 2.5 mg PO q 12 h with food, which can be increased to 5 mg PO q 12 h if no improvement in glycemic control is noted.[166,167] In 5-10% of cats, glycemic control becomes inadequate within weeks to years, necessitating insulin therapy.[166,168]

Meglitinides

These drugs also stimulate insulin secretion by binding to ATPases on pancreatic beta-cells at different sites than the sulfonylureas, and trigger the same cascade of reactions. Synergistic effects occur when the 2 are combined.[164,169] The effect of the meglitinide nateglinide on blood glucose and insulin secretion were compared with the sulfonylurea glimepiride in healthy cats using a 0.5 g/kg IV glucose tolerance test. Nateglinide had a faster onset of action (20 minutes vs. 60) but shorter duration of action (60 minutes vs. 180).[170]

Biguanides

Biguanides have an insulin sensitizing effect that requires functional beta-cells since they increase hepatic and peripheral tissue response to insulin thereby decreasing glucose production and increasing glucose uptake.[169-171] Although the exact mechanism of action is unknown, they interrupt mitochondrial oxidative processes in the liver and correct imbalances in intracellular Ca metabolism in peripheral tissues.[172]

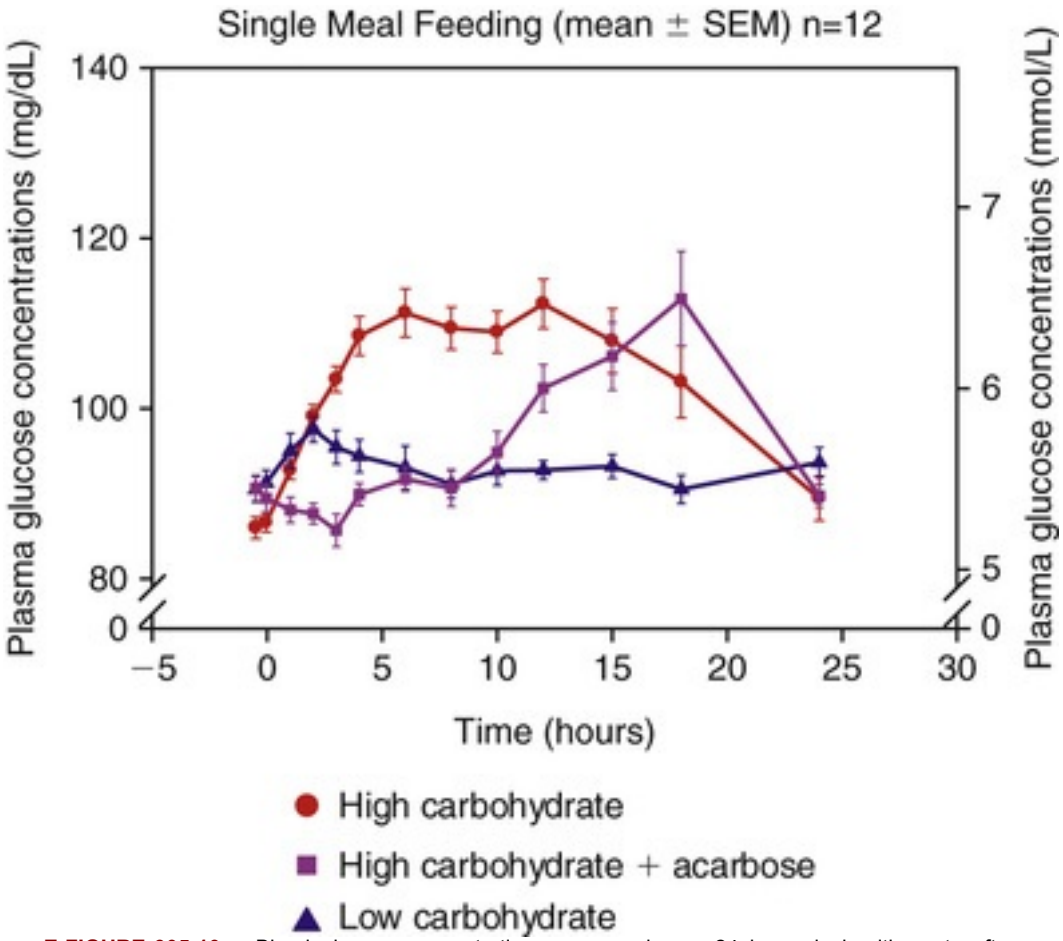
Metformin, the only commercially available biguanide, was given to 5 newly diagnosed DM cats (mean blood glucose concentrations 487 mg/dL or 27 mmol/L); 1 of the 5 had measurable serum insulin concentrations pre-treatment and this was the only cat that achieved good glycemic control (mean blood glucose concentration 167 mg/dL or 9.3 mmol/L). That cat required a dose of 50 mg PO q 12 h for >8 weeks.[173]

Thiazolidinedione

Thiazolidinediones (TZDs) bind to the peroxisome proliferator-activated receptor-gamma in the nucleus and alter gene expression, leading to improved insulin sensitivity in adipose tissue, muscle and liver.[174,175] This decreases hepatic gluconeogenesis and increases glucose metabolism in muscle, resulting in decreased fasting blood glucose concentrations.[174] Darglitazone increased insulin concentrations in obese cats during an IV glucose tolerance test, but did not normalize their insulin secretion pattern.[87]

Alpha-Glucosidase Inhibitors

Drugs such as acarbose reduce postprandial blood glucose concentrations by inhibiting action of membrane-bound brush-border disaccharidases (glucoamylase, sucrose, isomaltase, maltase) in the small intestine. By delaying breakdown of complex carbohydrates, they slow intestinal glucose absorption and reduce peak postprandial glucose concentrations.[166,169] In healthy cats, acarbose administered at 25 mg/cat PO q 24 h with a high carbohydrate meal (50% energy from carbohydrate) significantly reduced mean glucose concentrations in the first 12 hours compared to cats fed the meal alone (91 mg/dL or 5.1 mmol/L vs. 106 mg/dL or 5.9 mmol/L) (E-Figure 305-10).[162] However, blood glucose concentrations were not significantly lower (93 mg/dL or 5.2 mmol/L) than cats fed a low carbohydrate meal (6% energy from carbohydrate) and there was no difference in mean blood glucose concentrations when the low carbohydrate diet was fed with or without acarbose.[162] The glucose lowering effect was only evident in the first 12 hours after acarbose administration and was minimally effective in cats eating multiple small meals. In cats with CKD, where a restricted-protein, moderate-carbohydrate diet is indicated, acarbose can be used to reduce glucose absorption from the gastrointestinal tract. However, because acarbose is most effective when cats consume all their food within a short time after administration, it is likely to be minimally effective in cats with IRIS stage 3 or 4 CKD that have reduced appetite and consume small amounts of food multiple times daily. Acarbose administered at 12.5 mg/cat PO q 12 h, with a low carbohydrate diet were not associated with greater reductions in median insulin requirements or glycemic control than cats fed the low carbohydrate diet alone (insulin dosage reduction from 5 U/cat SC q 12 h to 1 U/cat SC q 12 h).[159]



E-FIGURE 305-10 Blood glucose concentrations measured over 24 hours in healthy cats after eating a meal of a high carbohydrate (50% ME) or low carbohydrate (6% ME) diet. Note that blood glucose concentrations after eating a high carbohydrate diet remain elevated for 20 hours after eating, and are significantly higher than after eating a low carbohydrate diet. Some cats fed the high carbohydrate diet were given acarbose 25 mg/kg orally at the time of feeding. Acarbose decreases blood glucose concentrations for 8 hours after eating. Feeding a low carbohydrate diet is as effective as acarbose. (From Singh R, Rand J, Coradini M, et al: Effect of acarbose on postprandial blood glucose concentrations in healthy cats fed low and high carbohydrate diets. *J Feline Med Surg* 17[10]:848-857, 2015.)

Trace Elements

Chromium, vanadium and tungsten may improve insulin sensitivity. Chromium is a cofactor for insulin function that increases glucose transport to the liver, adipose tissue and muscle.[169] Oral supplementation at doses of greater than 300 ppb resulted in improved glucose tolerance, with doses of 600 ppb leading to a significant decrease in blood glucose concentration (139 mg/dL or 7.7 mmol/L compared to 150 mg/dL or 8.3 mmol/L) in healthy normal weight cats.[176] Lower doses of 100 mcg in obese cats had no effect on glucose tolerance.[177] Vandium at 0.2 mg/kg/day reduced blood glucose and serum fructosamine concentrations and improved clinical signs (polyuria and polydipsia) in cats with early DM.[178] In DM cats treated with PZI, vanadium supplementation at 45 mg/cat/day improved glycemic control, with a mean insulin requirement of 3 U in vanadium-supplemented cats compared to 5 U in cats treated with PZI alone.[179]

New and Emerging Therapies

Incretin-Based Therapies

Incretins are gastrointestinal hormones (see ch. 310) rapidly released in response to food intake that stimulate synthesis and release of insulin while suppressing glucagon secretion.[180] They include glucagon-like peptide

1 (GLP-1), secreted by L cells in the distal portion of the intestinal tract that bind to G-protein-coupled receptors in pancreatic alpha and beta-cells.[180-182] GLP-1 also enhances beta-cell survival, delays gastric emptying, and suppresses appetite.[181,182] GLP-1 has a short half-life and is degraded by dipeptidylpeptidase-4 (DPP-4), found in various tissues and the plasma. Within the intestine it degrades GLP-1 by cleaving the molecule and decreasing receptor affinity.[181,183] GLP-1 concentrations are reduced in obese cats and humans after glucose challenge. The insulinotropic effect of GLP-1 is reduced in human type 2 DM.[184-187]

Additional drugs include GLP-1 agonists that are resistant to DPP-4 degradation, and DDP-4 inhibitors.[185,188] As GLP-1's actions are glucose dependent, hypoglycemia is rare.[186] Exenatide (twice-daily) and extenatide extended-release (once weekly) are injectable GLP-1 agonist preparations used as adjunctive or sole therapy in human type 2 DM.[186] In healthy cats, exenatide (1 mcg/kg) increased insulin by 2.4 fold within 15 minutes during a hyperglycemic isoglycemic clamp.[189] During a meal response test in healthy cats, 2 mcg/kg (exenatide) and 200 mcg/kg (extended release) were the optimum dosages, increasing insulin concentrations by 330% and 178%, respectively.[190] In healthy cats, insulin response after a meal was similar comparing exenatide, exenatide extended-release, and the DPP-4 inhibitor sitagliptin.[191] Transient mild gastrointestinal effects (vomiting and diarrhea) were seen with all 3 drugs. In newly diagnosed DM cats treated with glargine and a low-carbohydrate diet, cats also treated with exenatide extended-release tended to improved glycemic control, lower insulin dose, and higher remission rates (44% vs. 25%) compared with placebo-treated cats.[192] Mild and transient adverse-effects included reduced appetite, nausea, and vomiting.

Amylin

Amylin, co-secreted with insulin from pancreatic beta-cells, suppresses glucagon secretion, delays gastric emptying and promotes satiety.[193,194] In DM, decreases in amylin production are associated with pancreatic beta-cell dysfunction and loss.[193,195] In human type 1 and type 2 DM patients using insulin, the synthetic amylin analogue pramlintide injected at meal times decreased postprandial glucose concentrations and insulin dose, decreased energy intake, improved postprandial satiety and induced weight loss.[194,196,197] In healthy cats, amylin given 5 minutes before beginning an IV arginine stimulation test (0.2 g/kg), IV glucose tolerance test (0.5 g/kg) or meal response test caused a decrease in plasma glucagon and insulin concentrations in the IV arginine and glucose tolerance tests.[198]

Smart Insulin

One synthetic insulin product designed to be long-lasting and responsive to glucose concentrations displayed activities similar to that of healthy mouse pancreas. Addition of an aliphatic domain to the insulin facilitates hydrophobic interactions and provides longer residence time in blood. An attached phenylboronic acid (PBA) molecule reversibly binds glucose, resulting in activation of insulin only when glucose concentrations are high.[199] Clinical trials are pending.

Poorly Controlled Diabetic Cats

Differential Diagnosis

While good glycemic control or remission is achieved in most DM cats once appropriate insulin therapy and monitoring are instituted, some cats are difficult to control, often requiring high doses of insulin. Failure to achieve clinical and glycemic control of DM may be due to poor owner compliance or administration technique, inappropriate insulin or dosing (dosage and/or frequency), or underlying diseases contributing to insulin resistance.

Storage, Mixing, Syringes

Inappropriate storage of insulin leading to loss of potency, incorrect administration (e.g., poor injection technique, drawing up some air bubbles) or irregular dosing can each contribute to poor glycemic control.[74] Inadequate mixing of lente insulin suspension can result in erratic dosing because insulin concentrations vary with each dose. These should be ruled out by discussion with clients before further investigation. These factors may be easily rectified with proper education. Insulin dosing errors can occur when one type of syringe is changed for another and the owner continues to dose insulin based on number of gradations on the

syringe barrel. For example, if a cat receiving porcine lente insulin (40 U/mL, Vetsulin/Caninsulin, Intervet) and normally dosed with 40 U/mL syringes (1 gradation = 0.025 mL) has the type of syringe inadvertently changed to 0.3 mL, 100 U/mL syringes (1 gradation = 0.01 mL), it will result in only 40% of the dose being administered. Similar errors occur when 0.3 mL syringes are accidently dispensed to a client using 1 mL insulin syringes (1 gradation = 0.02 mL). However, if the substitution is in reverse, it may appear there is increased sensitivity to insulin leading to hypoglycemia.

Short Duration of Insulin Action

In cats treated with intermediate-acting insulin such as lente, duration of action may be too short to maintain prolonged decreases in blood glucose concentration even when given q 12 h.[111,119] Nadir blood glucose concentration is reached 3 to 5 hours after porcine lente injection in DM cats, and blood glucose concentrations typically return to baseline within 9-10 hours.[110,111] Therefore, most cats treated q 12 h with porcine lente insulin have no appreciable glucose lowering effect from exogenous insulin for 2 to 3 hours prior to each insulin injection. Continued presence of basal insulin concentrations is important in suppressing hepatic gluconeogenesis.[200] The short duration of action likely accounts for the marked hyperglycemia (≥360 mg/dL; 20 mmol/L) prior to each insulin injection in many lente-treated cats, even when there is good glucose lowering following insulin administration, and appropriate nadir concentrations are achieved. Serial blood glucose measurements, especially if measured at home, can help identify this problem. In these cats, a change to longer-acting insulin such as glargine or detemir typically resolves the poor control.

Underlying Disease

Background

Underlying diseases can contribute to insulin resistance and poor control despite good client compliance and appropriate insulin selection and dosing. Further testing should be offered if insulin doses exceed 1.0-1.5 U/kg q 12 h, and blood glucose control remains poor (mean blood glucose >270 mg/dL or >15 mmol/L).

Acromegaly

Acromegaly, or hypersomatrotropism, results from increased production of growth hormone (GH), typically due to a pituitary adenoma (see ch. 294). Increased GH causes post-receptor defects in insulin action at target tissues. This insulin resistance may be extreme.[14] Despite substantial beta-cell hyperplasia, insulin resistance may exceed the insulin secretory capacity to maintain euglycemia resulting in concurrent DM.[14] Secretion of insulin-like growth factor 1 (IGF-1) also increases, mediating the associated anabolic changes.[201] Common clinical signs of acromegaly in cats include polyuria and polydypsia, polyphagia and weight gain. Enlarged abdominal organs, a systolic heart murmur, broadening of the facial features, prognathia inferior, clubbed paws and respiratory stridor may also occur as the disease progresses. Initially, many cats with acromegaly appear normal.[16] Acromegaly, with its anabolic effects, should be considered in the differential diagnosis of any poorly controlled DM cat with stable or increasing body weight.[14,202] Acromegaly is the most common underlying disease in poorly controlled DM cats, perhaps accounting for 25-30%.[15,201,203] A small minority of DM acromegalic cats initially respond to insulin and occasionally even achieve remission. However, acromegalic cats typically require more than twice the insulin of non-acromegalic DM, with median doses of 7 U q 12 h (range 1-35 U), and some doses are so extreme (20 to >70 U) they would induce fatal hypoglycemia in most cats with DM.[16,201]

IGF-1 testing is the most commonly used diagnostic test for acromegaly, with concentrations typically increased >1000 mg/mL in afflicted cats.[201] Because production of IGF-1 is dependent on stimulation of hepatic GH receptors by insulin, the insulinopenia present at the time of DM diagnosis may falsely lower results. It is recommended that IGF-1 testing be delayed until 6 to 8 weeks after insulin therapy is started.[16] In practical terms, it is rare to identify insulin resistance before 6 weeks after initiation of therapy because insulin dose is slowly increased and some weeks are often required before resistance would be recognized. Intracranial imaging with magnetic resonance imaging or computed tomography is also useful to confirm diagnosis, particularly if curative treatment is being considered. Treatment options include palliation with insulin, surgery, radiation and medical management. Surgical hypophysectomy has high success rates and the majority of cats achieve diabetic remission.[204,205] Radiation therapy may reduce tumor size and hormone secretion, but does not normalize GH and IGF-1 concentrations.[16,202,206] Both surgical and radiation treatment

are limited in their geographical availability. Although medical options have previously been unsuccessful, in a recent report, a novel somatostatin analogue (Pasireotide, Novartis) reduced insulin requirements of acromegalic cats, but is prohibitively expensive.[16] Palliation with high insulin doses is a conservative approach and is likely the most common method used. In some cats, it can be moderately successful in controlling clinical signs of DM for a period of time. Home blood glucose monitoring is recommended if increasing insulin doses are being used to control blood glucose concentrations, because of fluctuation in GH secretion, and therefore, of blood glucose concentrations.

Hyperadrenocorticism (HAC), Glucagonoma

HAC is characterized by excess endogenous glucocorticoids caused by either a functional pituitary tumor increasing secretion of adrenocorticotropic hormone (ACTH) and subsequently adrenal cortisol, or a functional tumor of the adrenal cortex increasing secretion glucocorticoids (see ch. 307).[16] Glucocorticoids induce DM by impairing insulin sensitivity, decreasing glucose uptake in peripheral tissues, increasing hepatic gluconeogenesis, and may inhibit insulin secretion from pancreatic beta-cells.[16] Excess cortisol concentrations commonly lead to abdominal fat accumulation, which also is a predisposing factor for insulin resistance and DM.[207-209] About 80% of cats with HAC have DM at the time of diagnosis.[202] HAC is a less common cause of insulin resistance than acromegaly, and rarely results in insulin doses as high.[16] There is concern that poorly controlled DM may increase activity of cats' hypothalamus-pituitary-adrenal gland axis that may cause abnormal test results. However, a low-dose dexamethasone suppression test performed in 22 diabetic cats 6 weeks after insulin therapy showed complete suppression at 4 and 8 hours in 20 cats regardless of glycemic control, concluding that this is a suitable test for diabetic cats. The remaining two cats had HAC.[210]

Glucagon is an insulin antagonist. Tumors producing glucagon would be expected to induce or worsen DM.

Pancreatitis

Pancreatitis can destroy pancreatic beta-cells, cause loss of function, and decrease tissue sensitivity to insulin (see ch. 289 and 291).[18,202] It may worsen glycemic control, decrease probability of DM remission, or be associated with DM relapse.[19,76] Pancreatitis can be difficult to diagnose, relying on interpretation of clinical signs, ultrasonography (US) and feline serum pancreatic lipase immunoreactivity (fPLI) assay results. While few DM cats have clinical signs of pancreatitis, about 60% have biochemical and imaging findings consistent with pancreatitis at diagnosis.[2,19] However, histologic evidence of pancreatitis is also common in non-DM cats (14-67%). The number of neutrophils, macrophages, T and B lymphocytes and pancreatitis scores were not different in DM and non-DM cats, making the clinical relevance of the findings debatable.[17,19,55,211]

Pancreatitis was only diagnosed in 14% of DM cats investigated for poor glycemic control.[2] DM cats with post-mortem histologic evidence of chronic pancreatitis had higher mean blood glucose concentrations than cats without histologic lesions, but this was not significant, nor was there a difference in mean survival time between the two groups.[2] The percentage of DM cats (83%) with increased fPLI >11 mmol/L was greater than for non-diabetic cats (66%), but there was no significant association between fPLI concentrations in DM cats and their glycemic control.[212] In 17% of DM cats, fPLI was markedly (>50 mcg/L) increased, whereas only moderate (20-50 mcg/L) or mild (12-20 mcg/L) increases were present in non-DM cats.[212] DM cats with chronic pancreatitis may benefit from budesonide, cyclosporine (5 mg/kg PO q 12 to 24 h), or chlorambucil (2 mg/cat PO q 48 to 72 h) if pancreatitis recurs frequently and is associated with poor glycemic and insulin resistance.[18,213] Cats diagnosed with acute pancreatitis around the time of DM onset can achieve remission and some may return to normal glucose tolerance with resolution of their disease.[18,76] However, acute necrotizing pancreatitis can be a cause of mortality in DM cats.[2]

Hyperthyroidism, Urinary Tract Infections (UTI), Other Conditions

Impaired glucose tolerance has been reported in hyperthyroid cats, but in DM cats, insulin resistance is not usually clinically appreciable (see ch. 301).[214] Infections of the urinary tract, oral cavity, skin or other organs may contribute to insulin resistance.[202] Decreased glucose tolerance, insulin resistance and hyperinsulinemia occur as side-effects of bacterial infections in humans.[215,216] About 12-13% of DM cats have a UTI (most often *E. coli*), perhaps due to decreased urine concentration and glucosuria (see ch. 330).[217,218] People with DM

have increased risk of fungal UTI *(Candida albicans* or *C. glabrata)* which have been reported in cats.[219,220]

Chronic Kidney Disease

Diabetic nephropathy, characterized primarily by glomerular disease, is diagnosed in 20-40% of DM people.[196] Hyperglycemia alters microvascular anatomy and causes glomerular damage by changing blood flow, vascular permeability, cell loss and decreased production of trophic factors.[221] Although CKD is common in older cats, DM nephropathy is an uncommon histological finding (see ch. 324). However, 50% of DM cats had glomerular changes compatible with those seen in DM people and 33% had tubule-interstitial changes.[222] In non-DM cats with CKD, glomerular lesions were identified in 15% and tubulointerstitial disease in 70%.[223] In people, DM nephropathy begins with microalbuminemia and progresses to overt proteinuria.[196] Microalbuminemia and urine protein/creatinine ratio were demonstrated to be significantly higher in DM cats (70% and 70%, respectively) compared with healthy controls (18% and 9%, respectively).[224,225] Research is needed to study the importance of proteinuria in cats with DM. Urea and glucose were significantly higher in cats in DM remission compared to control cats, even after exclusion of cats with IRIS stage ≥2 CKD. The increase in urea may be because it is a by-product of the glucose-alanine cycle. Pyruvate in muscle is converted to alanine and transported to the liver where it is converted to pyruvate, releasing urea. Pyruvate is a substrate for gluconeogenesis, a likely contributor to the mild hyperglycemia in these cats.[226]

Hypoglycemia

Diagnosis and Management

Physiology and Signs

Hypoglycemia is a potential complication of insulin treatment in any diabetic (see ch. 61 and 303). In cats, low glucose can be a mainly biochemical, asymptomatic issue or it can be symptomatic. Signs of hypoglycemia variably appear at blood glucose concentrations <60 mg/dL (<3.5 mmol/L) and severe hypoglycemia (≤18 mg/dL or 1 mmol/L) is life-threatening.[227,228] The brain is unable to synthesize or store glucose. It requires a continual supply from the blood and the cells do not require insulin for use.[227-230] Clinical signs of hypoglycemia in cats include lethargy, trembling, depression, ataxia, or in severe cases, seizures and coma. In people, repeated episodes of hypoglycemia can impair compensatory responses and result in hypoglycemic unawareness. Early clinical warning signs such as trembling, normally triggered in response to epinephrine release, are absent. In these individuals, sudden onset of seizures or coma are associated with neuronal glycopenia.[231] A similar condition has been reported in dogs and may occur in cats.[89,232] In humans, cut-offs for biochemical hypoglycemia have been determined based on the threshold for glucagon and epinephrine activation (<70 mg/dL or <3.9 mmol/L).[231] In cats, blood glucose concentrations <50 or 54 mg/dL (<2.8 or 3 mmol/L) have been used as indicators of biochemical hypoglycemia when measured with a meter calibrated for whole human blood.[8,94] When measured with a meter calibrated for feline blood, the lower limit was 50 mg/dL (2.8 mmol/L) in cats fasted and hospitalized overnight.[76]

Iatrogenic hypoglycemia in DM occurs due to insulin overdose. This may occur in cats recovering the ability to synthesize and secrete endogenous insulin, i.e., pending remission.[8] In this scenario, there is risk of administering too much insulin when blood glucose concentrations are no longer high. Other common causes of overdose leading to hypoglycemia include errors in drawing insulin into a syringe or when an incorrect syringe is used. Such errors can be life-threatening and not detected until serious hypoglycemia occurs. The hypothalamus contains glucose sensing neurons that detect and respond to hypo- or hyperglycemia.[227] Rapid compensation for hypoglycemia occurs by inhibiting insulin production while stimulating pancreatic glucagon and adrenal epinephrine.[228] Decreasing pancreatic insulin cannot occur in DM, since the insulin was administered exogenously.[231] Glucagon increases hepatic glycolysis and gluconeogenesis. Epinephrine acts on both the liver and kidney to increase glucose production.[200,228] However, glucagon's production by pancreatic alpha-cells in response to hypoglycemia can be absent or diminished in DM, secondary to lack of signaling from pancreatic beta-cells.[229]

Management

If possible, hypoglycemic cats are fed a high carbohydrate meal (>35% of energy from carbohydrate) and insulin therapy discontinued until hyperglycemia recurs (recommendations vary from >117 to >216 mg/dL; >6.5 mmol/L to >12 mmol/L). Subsequent insulin doses should be reduced by 25-50%.[89,233] If more severe signs occur, such as ataxia, a glucose containing syrup designed for human or veterinary DM patients can be administered orally or mixed in food (give 0.5-1 g and repeat 15-20 min later if required). Honey or maple syrup can be used in home emergencies, but Karo syrup (corn syrup with 15-20% glucose) is preferred. In an emergency, prior to or during transport to the hospital, one can rub glucose solutions onto the gums or give them via enema.[227,234] In-hospital treatment typically consists of an initial IV dextrose bolus (0.5 g/kg) followed by continuous infusion (CRI) of 2.5% dextrose until normal or increased blood glucose concentrations are maintained.[227,234]

In people with DM and severe hypoglycemia, glucagon injection can be used to stimulate hepatic gluconeogenesis and glycolysis.[228] Glucagon has successfully been used in dogs with refractory hypoglycemia or seizures associated with insulin overdose, insulinoma, and paraneoplastic hypoglycemia (see ch. 303).[235,236] In a cat, glucagon markedly improved neurologic signs which had persisted after euglycemia had been restored by dextrose infusion.[235] No adverse effects of the infusion were noted. Glucagon for injection (1 mg vial) is readily available, is reconstituted with the manufacturer's diluent, and their instructions for use should be followed. It can be added to 1000 mL of 0.9% NaCl (not to any dextrose infusion), and administered IV as an initial bolus of 50 ng/kg, then as a CRI at 10 to 15 ng/kg/min. The dosage may need to be adjusted as high as to 40 ng/kg/min.[235]

Somogyi (Insulin-Induced Hypoglycemia with Rebound Hyperglycemia)

Hypoglycemia due to insulin overdose may trigger a counter-regulatory response leading to a rebound hyperglycemia, known as the Somogyi effect.[89,237] A recent study of 10,767 blood glucose curves from 55 cats treated with an intensive glargine protocol found that while biochemical hypoglycemia occurred frequently (93%), only 0.42% of blood glucose curves were consistent with rebound hyperglycemia (<50 mg/dL or <2.8 mmol/L followed by >300 mg/dL or >16.7 mmol/L within 4-10 hours).[238] Numerous studies in people with DM have concluded that rebound hyperglycemia is rare and is not associated with higher levels of GH, cortisol, or glucagon, but is inversely correlated with insulin concentrations.[239-243] Therefore, most cases of apparent rebound hyperglycemia result from relative insulin deficiency rather than a response to antagonist hormones.

While the dose of any insulin should be reduced if a cat develops asymptomatic hypoglycemia, it should not be reduced on the assumption of a Somogyi event when blood glucose concentrations are high and poorly responsive to insulin. In the initial weeks of insulin treatment, blood glucose concentrations commonly fluctuate. This usually resolves with time and consistent dosing but could be incorrectly attributed to rebound hyperglycemia.

Summary

In summary, in general veterinary practice, DM affects approximately 1 in 200 cats, most of whom have type 2 disease. Other types of DM occur and acromegaly appears common in poorly controlled cats. Goals of therapy involve early implementation of rigorous glycemic control to maximize the probability of remission while avoiding clinical hypoglycemia. The highest remission rates reported involve use of long-acting insulin (glargine or detemir), a low carbohydrate diet (≤6% of energy from carbohydrate), frequent glucose monitoring, preferably at home, and appropriate adjustment of insulin dosage aimed at achieving normal or near-normal glucose concentrations. Most cats in DM remission have abnormal glucose homeostasis and should be considered pre-DM. Diabetic relapse occurs in 25-30% of cats within 1-2 years and is more likely in cats with moderately impaired fasting glucose concentrations (≥135-162 mg/dL; 7.5-9 mmol/L). Continued home blood glucose monitoring is recommended for cats in remission to detect early deterioration in blood glucose homeostasis and facilitate early implementation of appropriate therapy.

CHAPTER 306

Hyperadrenocorticism in Dogs

Dolores Pérez-Alenza, Carlos Melián

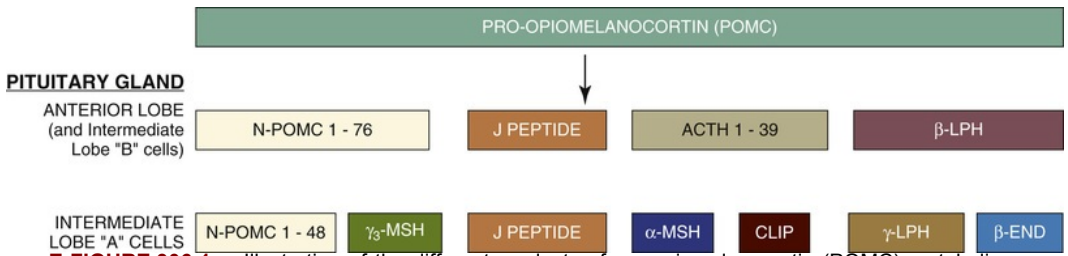
Client Information Sheet: Hyperadrenocorticism in Dogs: Initial and Long-Term Management

In 1932, Dr. Harvey Cushing described clinical signs in people with pituitary basophil adenomas. The tumors likely produced excessive adrenocorticotropic hormone (corticotrophin, ACTH) causing chronic excessive stimulation of the adrenal cortices, secondary bilateral adrenocortical hyperplasia and chronic excesses in serum cortisol concentration, a "hallmark" of hyperadrenocorticism (HAC). The most common cause of naturally occurring canine HAC is pituitary dependent hyperadrenocorticism (PDH), in which a functioning pituitary adenoma (rarely, a carcinoma) autonomously and excessively secretes ACTH and causes the same changes as outlined. A hypothalamic disorder causing pituitary hyperplasia has not been documented in dogs. Ectopic (non-pituitary) excess ACTH production has been described in dogs, but is extremely rare. The second most common cause of canine HAC is a functional adrenocortical tumor (FAT; adenoma or carcinoma) that autonomously produces excessive cortisol. Readers are reminded that the most common cause of "Cushing's syndrome" in dogs is iatrogenic, as use of glucocorticoids is common in managing a variety of neoplastic, inflammatory or immune-mediated conditions (see ch. 164 and 165).

Physiology of the Hypothalamus–Pituitary–Adrenal Axis

Hypothalamus

The hypothalamus has primary control of pituitary gland function. The pituitary regulates adrenocortical function and cortisol secretion. Corticotropin-releasing hormone (CRH), a 41 amino acid polypeptide, has a plasma half-life of about an hour. The hypothalamus-hypophyseal portal system delivers CRH to the anterior pituitary, where it stimulates corticotropes to secrete ACTH. Stimulation of hypothalamic CRH secretion is mediated by cytokines (interleukins [IL] 1 and 6, TNF-alpha), leptin, dopamine, arginine-vasopressin (AVP) and angiotensin II.[1] Inhibition of CRH is mediated by glucocorticoids and somatostatin. Glucocorticoids are the dominant negative-feedback regulators of CRH. ACTH (molecular weight: 4500 daltons), a single-chain 39-amino acid peptide hormone, is cleaved from the precursor molecule pro-opiomelanocortin (POMC). Canine and human ACTH differ by the amino acid residue at position 37. The 1 to 18 amino terminal end of the ACTH molecule is responsible for its biologic activity. Other POMC fragments are biologically active (E-Figure 306-1): beta-lipoprotein (beta-LPH), beta-endorphin, alpha and gamma-melanocyte–stimulating hormone (MSH), joining peptide (J peptide) and N-terminal fragment.[2,3]



E-FIGURE 306-1 Illustration of the different products of pro-opiomelanocortin (POMC) metabolism in the anterior lobe of the pituitary as compared with the products formed in the intermediate lobe of the pituitary. *ACTH,* Adrenocorticotropic hormone; *CLIP,* corticotropin-like intermediate lobe peptide; *END,* endorphin; *J peptide,* joining peptide; *LPH,* lipoprotein; *MSH,* melanocyte-stimulating hormone.

Pituitary

There are three functional units in the canine pituitary gland: the anterior pituitary (formed by the pars infundibularis and pars distalis); the intermediate lobe (pars intermedia) and the posterior pituitary (neurohypophysis; E-Figure 306-2). One pars distalis product, ACTH (less importantly, beta-LPH), is stimulated primarily by CRH and suppressed primarily by glucocorticoids (cortisol). The pars intermedia contains "A" cells that produce alpha-MSH and corticotropin-like intermediate lobe peptide (CLIP) and "B" cells that synthesize POMC cleaved to ACTH and beta-LPH. "B" cells are regulated, in part, by tonic dopaminergic inhibition.[4-6] Secretion of beta-LPH and beta-endorphin is similar to that of ACTH; stress and hypoglycemia increase their secretion while glucocorticoids suppress it. Beta-endorphins may act as "endogenous opiates," suggesting a role in pain alleviation; the physiology of beta-LPH is unknown. MSH is involved in secretion of melanin (melanogenesis) by melanocytes in skin and hair. Hypoglycemia increases plasma levels of N-terminal fragments, but their role is unknown. In humans, both CRH and ACTH are secreted in a pulsatile manner with a diurnal rhythm that results in a peak before waking in the morning. In dogs, ACTH is also secreted in a pulsatile manner, with 6 to 12 daily peaks. A diurnal rhythm has not been identified. Secretion of ACTH is regulated by CRH, response to stress, feedback inhibition by cortisol, and immunologic factors. Physical, emotional, and chemical stressors such as pain, trauma, hypoxemia, acute hypoglycemia, cold exposure, surgery, and pyrogens stimulate ACTH and cortisol secretion.

(From Meij B: Hypophysectomy as a treatment for canine and feline Cushing's disease. *Vet Clin North Am Small Anim Pract* 31:1015-1041, 2001.)

The Adrenal Cortices

The adrenal cortices have three distinct layers (zones): the outer zona glomerulosa, the middle zona fasciculata, and the inner zona reticularis. Synthesis of most adrenal steroids is mediated by cytochrome P450 oxygenase enzymes. Due to differences in these enzymes, the adrenal cortex functions as distinct units. The outer zona glomerulosa, the only source of mineralocorticoids (primarily aldosterone), is deficient in 17-alpha-hydroxylase activity and unable to synthetize cortisol or androgens. Aldosterone synthesis is regulated primarily by the renin–angiotensin system and serum potassium concentrations. ACTH has a minor role.

The fasciculata and reticularis zones of the cortices function similarly with regard to cortisol and androgen production. Only cells in these zones have 17-alpha-hydroxylase activity and can synthesize 17-alpha-

hydroxypregnenolone and 17-alpha-hydroxyprogesterone, precursors of cortisol and adrenal androgens. These two zones are regulated primarily by ACTH, which stimulates rapid synthesis and secretion of cortisol (and androgens). Chronic ACTH stimulation leads to adrenocortical hyperplasia. Chronic ACTH deficiency results in decreased steroidogenesis and adrenocortical atrophy (see ch. 309).

Pathogenesis

Pituitary-Dependent Hyperadrenocorticism

About 80 to 85% of dogs with naturally occurring HAC have PDH: excessive secretion of pituitary ACTH (>90% have a detectable pituitary tumor), bilateral adrenocortical hyperplasia, and chronic excessive secretion of glucocorticoids (Figure 306-3).[7] Pituitary tumors may arise from the pars distalis (about 70%) or from the pars intermedia (about 30%).[7] While ACTH secretion in the relatively avascular pars intermedia is regulated in part by CRH, pars intermedia activity is mainly controlled by dopaminergic and serotoninergic fibers from higher centers. The predominant cells of the pars intermedia (A cells) immunostain intensely for alpha-MSH and weakly for ACTH whereas pars intermedia B cells stain strongly for ACTH and weakly for alpha-MSH. The intense ACTH staining of pars intermedia B cells is similar to the staining characteristics of ACTH-producing pars distalis cells.[7,8]

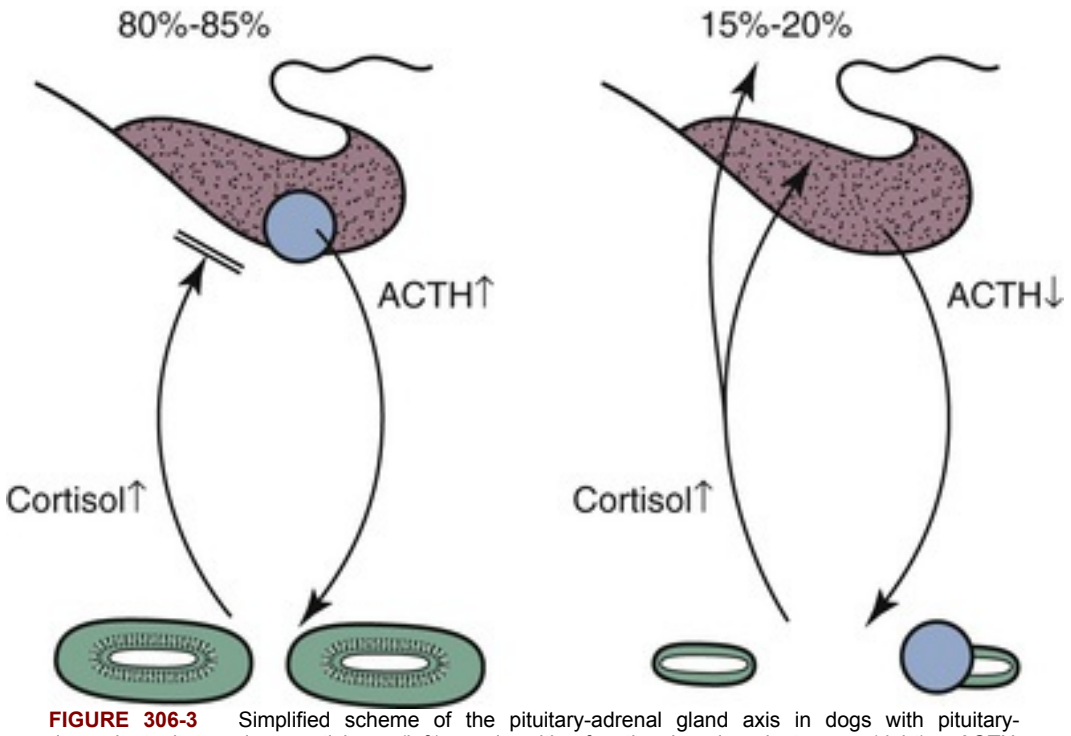


FIGURE 306-3 Simplified scheme of the pituitary-adrenal gland axis in dogs with pituitary-dependent hyperadrenocorticism (left) and with functional adrenal tumor (right). *ACTH*, Adrenocorticotropic hormone.

Pituitary tumors are usually classified histologically as adenoma (well delineated from adjacent parenchyma), invasive adenoma (exhibiting local invasion of brain parenchyma or adjacent structures) or carcinoma (with distant intra- or extracranial mestastasis).[9] Twenty of 33 dogs with pituitary tumors had an adenoma in one study, and 80% had HAC; 11/33 had an invasive adenoma, and 45% had HAC; and 2/33 had HAC and a carcinoma.[9] Since large pituitary tumors tend to be resistant to dexamethasone negative feedback, pituitary tumor size may be related to that tumor's degree of insensitivity to glucocorticoid feedback. Tumors originating in the pars intermedia may grow larger than those in the pars distalis, but pituitary tumors do not always maintain their characteristics of origin. Tumors from dogs with PDH cannot easily be distinguished as originating from the pars distalis or pars intermedia, even with plasma alpha-MSH levels or dexamethasone resistance.[10-12] Pituitary hyperplasia has also been mentioned as a cause of PDH in dogs; however, proof of such a condition is lacking.

The two mechanisms proposed regarding the pathogenesis of pituitary tumors include (1) a hypothalamic theory and (2) a monoclonal (pituitary) theory.[13] The hypothalamic theory, not widely accepted, is that chronic stimulation of pituitary corticotrophs by hypothalamic CRH and vasopressin, together with acquired glucocorticoid receptor defects, lead to a lower inhibitory action of cortisol. Also, dopaminergic neurodegeneration in aged animals or lower expression of dopamine receptors contribute to decreased feedback actions of cortisol. This reduced inhibition could lead to excessive secretion of ACTH, pituitary hyperplasia, and eventually neoplastic transformation of some corticotrophs, due to a somatic mutation.

The pituitary theory is that a tumor is the primary cause of HAC and it developed after somatic mutation of a corticotroph, creating a tumor clone.[13] This theory is widely accepted and is supported, in part, by low CRH concentrations reported in dogs with PDH together with studies demonstrating that nearly all corticotroph adenomas are monoclonal.[14,15] The occurrence of PDH in a family of seven Dandie Dinmont Terriers is also supportive.[16] Canine corticotroph adenomas likely contain stem cells that drive tumor growth and are the result of a multistage process of tumorgenesis, the first being the somatic mutation preceding clonal expansion of the tumor.[17]

Functional Adrenocortical Tumors

About 15 to 20% of dogs with naturally occurring HAC have an adrenocortical tumor that autonomously secretes excessive amounts of cortisol. Hypothalamic CRH and circulating plasma ACTH concentrations are suppressed by cortisol from the tumor, causing atrophy of the opposite uninvolved adrenal and of non-neoplastic cells in the tumor-containing adrenal. No clinical or biochemical feature allows dogs with FAT due to adenoma to be discriminated from those with carcinoma.[18] Adrenal masses >2 cm in diameter and those invading regional vasculature are more likely to be carcinomas. Malignancy is confirmed if distant metastases appear similar histologically. Cytology is not reliable in discriminating benign from malignant tumors and even histologic differentiation can be difficult. Malignancy is more likely with masses that have broken through the capsule or invaded the vasculature.[19] FATs are usually unilateral with no obvious tendency regarding side. Bilateral adrenocortical tumors have been described. A few dogs have had a cortisol-secreting adrenal tumor in one gland and a pheochromocytoma (see ch. 311) in the other.

Cortisol secretion by FATs is episodic, random, independent of ACTH control and suppresses ACTH synthesis and secretion. The role of ACTH receptors (ACTHR) in cortisol secretion by FAT may be limited. Some dogs with a FAT exhibit no cortisol response to exogenously administered ACTH, some dogs have a normal response and still others have exaggerated responses. Up-regulation of steroidogenic enzymes does not appear to be involved in FAT pathogenesis but down-regulation of ACTHR may be related to malignancy.[20] Ectopic expression of gastric inhibitory polypeptide (GIP) and vasopressin 2 (V2) receptor proteins obeserved in the zona fasciculata of FATs may have a role in tumor pathogenesis.[21] Steroidogenic factor 1 (SF1), associated with the pathogenesis of adrenal tumors in humans, is expressed in canine FAT and may have use as a prognostic marker or a therapeutic target.[22]

Concurrent PDH and FAT, Nodular Hyperplasia, Ectopic ACTH Secretion

The coexistence of pituitary and adrenal tumors has been described in 17 dogs. Each had an adrenocortical tumor and contralateral adrenal hyperplasia; 10 dogs had a unilateral adrenocortical adenoma; 4 had bilateral adrenal cortical adenomas; and 3 had an adrenal carcinoma.[23] Pituitary lesions included a chromophobe microadenoma in 12, pituitary macroadenoma in 4, and pituitary carcinoma in 1 dog. It is possible that such adrenal tumors have transitioned from initial hyperplasia. Dogs with PDH usually develop symmetrical bilateral adrenocortical hyperplasia. However, some may develop adrenocortical *nodular* hyperplasia, in which one or both glands can have one or many varying sized nodules. With time, such nodules may be difficult to distinguish from adrenocortical tumors.

Ectopic ACTH secretion, derived from any of a variety of tumor types, is responsible for about 15% of people with HAC.[24] The ectopic HAC condition can be clinically more severe than PDH. Small cell lung carcinoma is the most common cause of ectopic ACTH secretion in humans, but it has been associated with carcinoid tumors (i.e., of the lung, bronchus, gut, liver, pancreas, and ovary), thymoma, pancreatic islet cell tumors, olfactory neuroblastoma, medullary carcinoma of the thyroid, and pheochromocytoma.

The ectopic ACTH syndrome is exceedingly rare cause of HAC in dogs. An 8-year-old German Shepherd Dog with ectopic ACTH secretion, thought initially to have PDH, was treated with transsphenoidal

hypophysectomy but had recurrence of clinical signs, plasma ACTH concentrations and abnormal urine corticoid to creatinine ratios. A pancreatic mass with liver involvement was then detected. Histologic examination revealed a neuroendocrine tumor, considered the source of ectopic ACTH secretion. The dog was treated and responded well to trilostane.[25]

Epidemiology

Hyperadrenocorticism is relatively common in older dogs. In one study during a 15-year period at a veterinary teaching hospital, HAC was diagnosed in more than 1 per 100 dogs, exceeding previous estimates of 1-2/1000.[26,27] This apparent rising disease prevalence can be due to an increase in the life expectancy of dogs, increased awareness of the disease, and the reality that the study was completed at a referral center.

Signalment

Naturally occurring HAC is most commonly diagnosed in middle-aged to older dogs. The age at diagnosis ranges from 6 months to 20 years with a mean age of 11 years. Almost all dogs with HAC are older than 6 years at diagnosis.[28,29] More than 75% of dogs with PDH and 90% of dogs with FAT are >9 years of age at the time of diagnosis. HAC is a disorder without significant breed predisposition.[27] PDH tends to occur in smaller dogs: Poodles, Dachshunds, Terrier breeds. About 75% of dogs with PDH weigh less than 20 kg whereas almost 50% with FAT weigh more than 20 kg. Sex predilection in dogs with HAC is possible, with 60 to 65% being female.[29]

Clinical Manifestations

Overview

Most clinical and laboratory abnormalities in dogs with HAC are caused by chronic cortisol excess. In a few dogs, signs may be caused by pituitary or adrenal tumor growth and/or invasion, metastases, diabetes mellitus (DM), systemic hypertension, or thromboembolism. Clinical signs are a consequence of the combined gluconeogenic, immune-suppressive, anti-inflammatory, protein catabolic, and lipolytic effects of glucocorticoids. PDH cannot be distinguished from FAT on signs nor their duration.[30] Signs vary from being subtle to quite severe. Some dogs have HAC confirmed after following their progress with time. Because of the heightened awareness of HAC by veterinarians, dogs are being evaluated at earlier stages of the disease, when clinical manifestations may be mild.[30]

History

Duration

HAC is typically a chronic and progressive disease. Clinical signs might be present for months since these dogs are usually in good condition with an excellent appetite. Owners might attribute early signs to normal aging and seek veterinary help only when signs become intolerable: polyuria (urinating in the house) or polyphagia (stealing food, eating garbage, begging continuously, and occasionally aggressively attacking or protecting food).

Questions to Consider

The first step in gaining a suspicion that a dog may have HAC is always based on the history. Owner-noted clinical signs must be carefully obtained. One must avoid “leading the owner.” Rather than asking whether their pet is drinking and urinating excessively, it is preferred to ask vaguely about water intake and urine output. Also, it is important to be aware of signs not consistent with HAC (e.g., vomiting, diarrhea, anorexia, or pain), to avoid performing tests for HAC on dogs with non-adrenal illnesses.[30] Medication history can be extremly important, including topical drugs, since the clinical signs of iatrogenic and naturally occurring Cushing's syndrome are identical. Several medications (e.g., anticonvulsants, diuretics, etc.) have side effects that mimic HAC. Some of the most important questions when HAC is suspected include: (1) Has your dog currently or recently been given any medication?; (2) What is your dog's drinking, urinating and appetite like now as compared with 12 months ago?; (3) Can your dog jump off furniture or out of a car and, if “yes,” can the dog jump into the car or onto furniture? If “no,” how long?; (4) What is the dog's breathing like (dog

panting while at rest)?; and (5) Is the dog sleeping more? Dogs with HAC may have just one or several clinical signs, each of which may vary in intensity. Either polydipsia-polyuria (PU/PD; the most common clinical sign) or alopecia suggestive of an endocrine disease can be the only clinical sign in some dogs with HAC.

Common Signs

Classic owner observations include PU/PD, polyphagia (PP), apparent weight gain (pot belly), muscle weakness, panting, and hair loss (Table 306-1). PU/PD is observed in about 90% of dogs with HAC. PU is likely due to increased glomerular filtration rates and inhibition of antidiuretic hormone (ADH) action at the renal tubular level, leading to a decrease in renal tubular water reabsorption. Exogenous ADH causes dramatic reduction in PU/PD, suggesting that cortisol interference with ADH release is responsible.[29] Urinary tract infections (UTI) are common in dogs with HAC and are likely due to: immunosuppressive effects of cortisol excess, decreased bactericidal properties of dilute urine, and urine retention that occurs, especially in indoor dogs. Many PU dogs develop a degree of decreased bladder tone, which can lead to overflow incontinence. However, signs of pollakiuria, hematuria, and stranguria are not common, perhaps due to the anti-inflammatory actions of cortisol.

TABLE 306-1

Clinical Manifestations of Canine HAC at the Time of Initial Presentation

COMMON	LESS COMMON	UNCOMMON
Polydipsia	Lethargy	Thromboembolism
Polyuria	Hyperpigmentation	Ligament rupture
Polyphagia	Comedones	Facial nerve palsy
Panting	Thin skin	Pseudomyotonia
Abdominal distention	Poor hair regrowth	Insulin-resistant diabetes mellitus
Endocrine alopecia	Urine leakage	
Hepatomegaly	Testicular atrophy	
Muscle weakness	Persistent anestrus	
Systemic hypertension		

HAC, Hyperadrenocorticism.

Modified from Behrend EN, Kooistra HS, Nelson R, et al: Diagnosis of spontaneous canine hyperadrenocorticism: 2012 ACVIM consensus statement (small animal). *J Vet Intern Med* 27:1292, 2013.

Appetite, Appearance, Muscle Strength, Respiration

Most dogs with HAC are described as having an excellent appetite or PP, a direct and unique canine response to glucocorticoids. Even though some dogs with HAC gain weight, most have a pot-bellied appearance (Figure 306-4) that mimics weight gain. Five to 10% of dogs with HAC develop diabetes mellitus (DM, see in this chapter "Serum Biochemistry Profile: Blood Glucose" and ch. 304) and these dogs may exhibit weight loss (Figure 306-5). The pendulous abdomen is secondary to weakness of the abdominal musculature coupled with increased weight of abdominal content due to hepatomegaly, a chronically distended bladder, and re-distribution of peripheral fat to the mesentery. Leptin concentrations are significantly higher in obese HAC dogs than in healthy obese dogs and may be a factor.[31] Muscle weakness is quite common, resulting from muscle wasting secondary to the catabolic effects of glucocorticoids. Infrequently, muscle weakness is so profound that dogs may not be capable of rising and may have difficulty standing. Excessive panting is common and attributed to decreased pulmonary compliance, respiratory muscle weakness, pulmonary hypertension, or the direct effects of cortisol on the respiratory center. Signs may be exaggerated by excitement or exercise. Pulmonary thromboembolic disease, a rare complication of HAC, can also cause moderate to severe respiratory distress (see ch. 243). Radiographic evidence of pulmonary mineralization is common in dogs with HAC and might contribute to hypoxemia in some.[32]

FIGURE 306-4 Distended abdomen and dermatological signs in a French Bulldog with pituitary hyperadrenocorticism.

FIGURE 306-5 Muscle wasting and distended abdomen in a mixed-breed dog with hyperadrenocorticism and diabetes mellitus.

Central Nervous System (CNS)

CNS signs develop in 10-25% of dogs with PDH due to the "pituitary macrotumor syndrome," a tumor invading and compressing tissues dorsal to the sella turcica. Moderate to severe lethargy is the most common disturbance, but other signs include inappetence or even anorexia, stupor, circling, aimless wandering (Video 306-1), ataxia, behavioral changes and seizures.

Uncommon Signs/Myotonia

Less common clinical signs in dogs with HAC are ligament laxity that may lead to tearing and lameness (Figure 306-6), unilateral or bilateral facial nerve paralysis, anestrus, testicular atrophy, or thromboembolism due to hypercoagulability.[30] Adrenal tumors can invade the phrenicoabdominal vein, caudal vena cava, or both, causing thrombus formation. Quite uncommonly, tumors can cause abdominal or retroperitoneal hemorrhage or pelvic limb edema. Rarely, dogs with HAC develop a myopathy characterized by persistent, active muscle contraction after cessation of voluntary effort, known as Cushing's pseudomyotonia. It usually affects the pelvic limbs causing a stiff gait (Video 306-2) or, in more advanced cases, an inability to ambulate (Figure 306-7). Diagnosis may be confirmed by electromyography (see ch. 117), on which myotonic, bizarre and high frequency discharges are noted. Muscle histology reveals a noninflammatory degenerative myopathy.

FIGURE 306-6 Plantigrade stance due to severe ligament laxity in a mixed-breed dog with pituitary hyperadrenocorticism.

FIGURE 306-7 Mixed-breed dog with hyperadrenocorticism causing advanced clinical signs including pseudomyotonia.

Physical Examination

Common Features

Abdominal distension is the most common feature on physical examination of dogs with HAC. Truncal, bilaterally symmetrical, endocrine alopecia is common. Initially, the hair coat becomes dull and dry. With time, the skin becomes hypotonic and signs such as failure to regrow shaved hair, comedones, increased susceptibility to bruising, hyperpigmentation, and seborrheic changes may occur. Some dogs have severe alopecia, with only the head and distal extremities retaining a coat. The thin skin and the suppressed immune system predispose dogs with HAC to pyoderma, present in about 50% of dogs with HAC.

Calcinosis Cutis

This is an uncommon but characteristic dermatologic condition in dogs with either naturally occurring or iatrogenic Cushing's syndrome (see ch. 10 and Figure 306-8). It is characterized by irregular plaques in or under the skin caused by dystrophic calcium deposition and located on the temporal areas of the head, dorsal midline, neck, ventral abdomen, or inguinal areas. The gluconeogenic and protein catabolic activities of cortisol are involved in the pathogenesis of calcinosis cutis, in which rearrangement of molecular protein structures leads to formation of an organic matrix that attracts and binds calcium, forming apatite crystals.[33]

FIGURE 306-8 Severe calcinosis cutis in a mixed-breed dog with hyperadrenocorticism.

Sexually Intact Dogs

Testicular atrophy and anestrus in females are less common sequelae to HAC. Cortisol's negative feedback to the pituitary gland decreases synthesis and secretion of FSH and LH. Males usually have bilaterally small, soft, spongy testicles and females are in anestrus, the duration of which may be indicative of the duration of HAC.

Acute Illness

Occasionally, dogs with HAC may develop acute signs of severe lethargy, weakness, pale mucous membranes and pain. This rare complication may occur as a consequence of an adrenal tumor rupture leading to acute intra-abdominal or retroperitoneal hemorrhage and is one of the few scenarios (along with pulmonary thromboembolism, which is also rare) in which a dog with HAC may have an acute, life-threatening condition.[34]

Sudden Acquired Retinal Degeneration Syndrome

An association between sudden acquired retinal degeneration syndrome (SARDS), an idiopathic retinal disorder that produces sudden and permanent blindness in adult dogs (see ch. 11), and HAC has been suggested, but evidence is lacking.[35] Loss of vision in dogs with PDH, while quite uncommon, has been related to increased serum triglyceride concentrations or changes in retinal vascular flow.[36] Blindness, associated with increased IL-6 and decreased nitric oxide concentrations adversely affects blood flow and increases risk of vision loss.[37]

Clinicopathologic Findings (Table 306-2)

Overview

Diagnosis of HAC should always be initially suspected from owner observations, with or without physical alterations. Endocrine tests should only be performed when clinical signs are consistent with HAC.[30] With a clinical suspicion of HAC, results of complete blood count (CBC), serum chemistry profile, urinalysis with culture, and abdominal ultrasound (US) should be reviewed before considering hormone testing. Various alterations are common, but none is pathognomonic for HAC. Absence of abnormalities does not rule out HAC.

TABLE 306-2

Common Laboratory Abnormalities in Dogs with HAC

CBC	SERUM BIOCHEMISTRY PANEL	URINALYSIS
Neutrophilic leukocytosis	Increased alkaline phosphatase	Specific gravity ≤1.018-1.020
Lymphopenia	Increased alanine aminotransferase	Proteinuria
Eosinopenia	Hypercholesterolemia	Urinary tract infection (often without evidence of inflammation)
Thrombocytosis	Hypertriglyceridemia	
Mild erythrocytosis	Hyperglycemia (mild and not associated with diabetes mellitus)	

CBC, Complete blood count; *HAC*, hyperadrenocorticism.

Modified from Behrend EN, Kooistra HS, Nelson R, et al: Diagnosis of spontaneous canine hyperadrenocorticism: 2012 ACVIM consensus statement (small animal). *J Vet Intern Med* 27:1292, 2013.

Complete Blood Count (CBC)

Lymphopenia due to steroid lympholysis, eosinopenia caused by bone marrow sequestration, neutrophilia, and monocytosis due to steroid-enhanced capillary demargination are common in dogs with HAC. Together, these white blood cell changes are referred to as "stress leukogram" but are not specific. Other CBC changes associated with HAC include increased platelet counts and a mild erythrocytosis (direct bone marrow stimulation or ventilatory issues).

Serum Biochemistry Profile

Serum Alkaline Phosphatase (ALP), Alanine Aminotransferase (ALT), Cholesterol, Triglyceride

Increases in ALP activity are the most consistent laboratory abnormality, observed in 85-95% of dogs with HAC. In many, the increases are marked (>10 times the reference interval) but results are not specific (observed in numerous conditions). ALP should never be considered a sceening test for HAC. There is no correlation between ALP activity and HAC severity, response to therapy, or prognosis.[38] Almost all ALP in dogs with HAC is a steroid-induced hepatic isoenzyme (SALP), an isoenzyme response unique to dogs. Normal SALP can help rule out HAC.[39,40] Alanine aminotransferase (ALT) activities are often increased in dogs with HAC, but are usually mild to moderate. These increases may be due to damage caused by swollen hepatocytes, glycogen accumulation, interference with hepatic blood flow, or hepatocellular necrosis. Mild to moderate increases in cholesterol and triglyceride concentrations are observed in >50% of dogs with HAC.

Blood Glucose

Mild fasting hyperglycemia (below the threshold necessary for glucose to appear in the urine) is common in dogs with HAC. Overt DM (glucose >250 mg/dL and glucosuria) is not common, occurring in about 5% of dogs with HAC. Glucocorticoids increase hepatic gluconeogenesis and decrease peripheral utilization of

glucose by interfering with insulin action at the cellular level (receptor and post-receptor defects). Gene expression of insulin signal molecules (post-receptor) is suppressed in dogs with HAC.[41] Hypercortisolism-induced hyperinsulinemia to maintain carbohydrate tolerance is usually not adequate to completely normalize glycemia in all dogs.[42] Hyperinsulinemia and insulin resistance are probably related to abdominal fat and adipokines, as obese dogs with HAC have higher leptin and insulin concentrations when compared with healthy obese dogs. Concentrations of leptin and insulin decline with trilostane therapy.[31] Other adipokines and related factors (adiponectin, TNF-alpha, IL-6) are not different.[31] Dogs with HAC and DM usually are insulin-resistant. Adrenocortical testing may be considered in dogs with DM and persistently poor response to high dosages of insulin. However, the reader is encouraged to appreciate the numerous potential explanations for a diabetic dog appearing to be insulin-resistant (see ch. 304). In this context, HAC is an uncommon explanation.[30]

Blood Urea Nitrogen (BUN), Phosphate (PO_4), Calcium (Ca), Bile Acids, Pancreas

Approximately 30 to 50% of dogs with HAC have a BUN below reference intervals due to diuresis. Azotemia is uncommon in dogs with HAC and, if present, is an indication not to treat HAC, for some authors. Hypophosphatemia might occur in dogs with HAC due to increased urinary excretion. Urinary Ca is also increased and may result in secondary hyperparathyroidism and hyperphosphatemia in >40%.[38,43,44] Bile acid test results may be mildly increased in as many as 30% of dogs with HAC.[45] HAC dogs without clinical pancreatitis have higher levels of canine pancreatic lipase immunoreactivity (cPLI) than do healthy dogs, but specificity is low (45-65% depending on technique). Increased cPLI in dogs with HAC must be interpreted with caution (see ch. 290).[46]

Coagulation Parameters

Pulmonary thromboembolism (see ch. 243) is a recognized complication in dogs with HAC, perhaps due to an underlying hypercoagulable state (see ch. 196). While not completely understood, increases in procoagulant factors (factors II, V, VII, IX, X, XII, and fibrinogen) and decreases in antithrombin were described in one study. In another study, no difference in coagulation parameters, using whole blood viscoelastic assays, were identified.[47,48] Decreased antithrombin levels and increased platelet aggregation were observed in dogs treated with prednisone.[49] Furthermore, a hypercoagulable tendency, defined as finding at least one abnormality in a coagulation panel utilizing thromboelastography and coagulation profiles, has been observed in >80% of dogs with HAC.[50,51] The most common abnormalities include shorter prothrombin times (PT), higher fibrinogen concentrations, and increased thrombin-antithrombin complexes. Among the thromboelastography parameters, higher maximum angle (MA) thrombin, increased alpha-angles and shorter k values were documented.[50-52] Most of these abnormalities persist despite trilostane treatment.[52] Co-morbidities (hypertension, hypercholesterolemia, DM) might be associated with hypercoagulability. Correlation between blood pressure, cholesterol concentration, or triglyceride concentration was not observed with any coagulation testing result.[50]

Urinalysis (see ch. 72)

Most dogs with HAC have PU and urine specific gravities <1.020 (commonly <1.012). Glucose is usually negative. Proteinuria is common, with urine protein to creatinine ratios (UP : C) not usually higher than 1 to 6. The UP : C was >1.0 in about 45% and >0.5 in about 70% of dogs with untreated HAC.[53-56] Proteinuria persists in about 20-40% of dogs with controlled HAC.[53-55] Pretreatment glomerular filtration rates are increased in about 60% of dogs with HAC, which decreases with treatment.[55] Thus, UP : C should be initially measured in dogs with HAC and monitored during treatment in proteinuric dogs. Dogs with HAC are predisposed to UTI due to immunosuppression and urine retention. Approximately 40% to 50% of dogs with Cushing's syndrome have a UTI at the time of initial examination.[57] However, due to the anti-inflammatory effects of chronic hypercortisolism, many of these dogs do not have clinical signs nor alterations in urinalysis suggestive of UTI and, therefore, urine culture using a sample obtained by cystocentesis is recommended.

Thyroid Function Tests

Dogs with HAC and those with hypothyroidism have some overlap in clinical and laboratory results, including alopecia, weight gain, lethargy and hypercholesterolemia. Dogs with HAC have polyphagia whereas hypothyroid dogs have poor appetites. Serum total thyroxine (TT_4) and free T_4 (fT_4) concentrations are commonly decreased in dogs with HAC.[58-60] fT_4 concentrations are increased in some.[58-60] Alterations in serum thyroid hormone binding or in peripheral hormone metabolism may contribute. Dogs with HAC who have decreased thyroid hormone concentrations tend to have normal to decreased circulating thyroid-stimulating hormone (cTSH) concentrations whereas hypothyroid dogs have normal to increased results. The hypothalamic-pituitary-thyroid axis is suppressed by cortisol excess and, after successful treatment, cTSH concentrations increase.[59]

Diagnostic Imaging

Thoracic Radiographs

Dogs suspected or known to have HAC should be evaluated with thoracic radiographs to search for metastatic lesions and to evaluate the patient for any unsuspected concern. Common nonspecific findings in dogs with HAC are an interstitial lung pattern in many and mineralized bronchi or tracheal rings in a smaller number.[20]

Dogs with HAC and pulmonary thromboembolism (PTE), rare despite their "hypercoagulable state," may have hypovascular lung fields (areas of increased radiolucency due to decreased perfusion distal to a thrombus) or alveolar pulmonary infiltrates. Alveolar infiltrates correspond to areas of atelectasis, hemorrhage, or infarction. Enlargement of the main pulmonary artery, right-sided cardiomegaly, and pleural effusion have been reported in dogs with PTE.

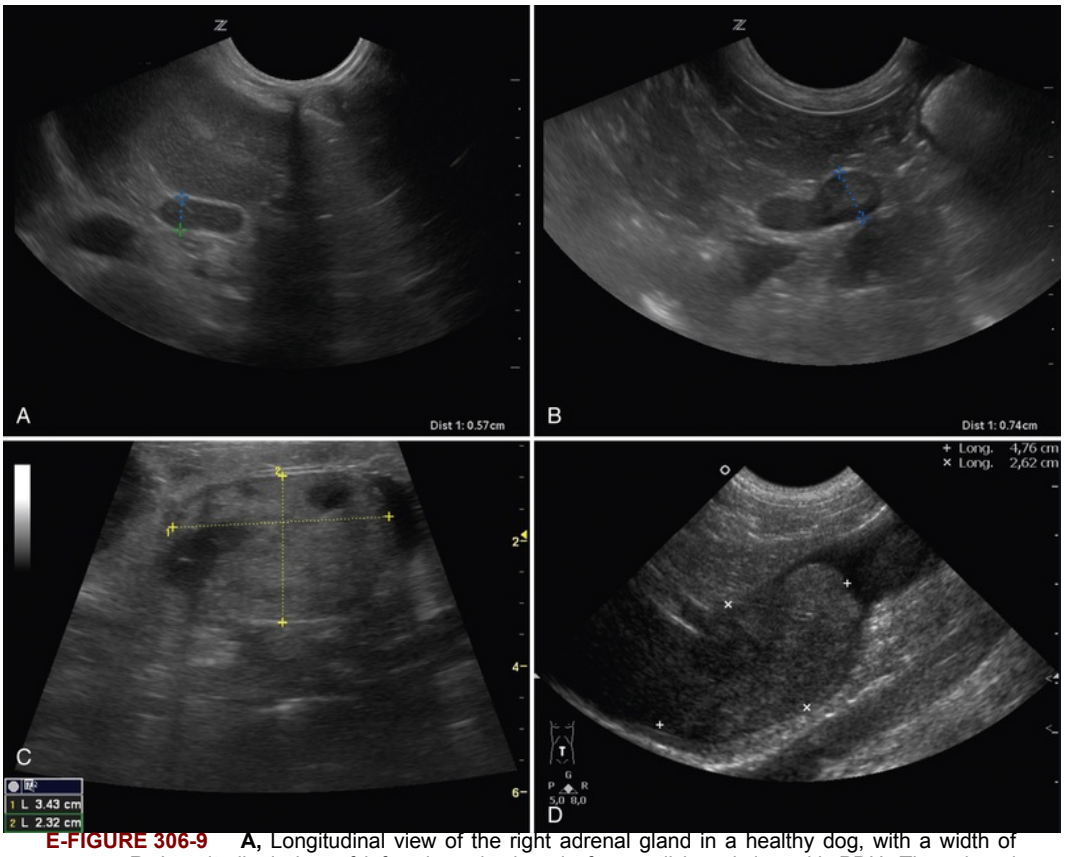
Abdominal Radiographs

Abdominal distension, excellent radiographic contrast due to abdominal fat deposition, hepatomegaly and bladder distension are commonly observed in dogs with HAC. Calcium-containing uroliths are occasionally identified.[61] About half of adrenal adenomas and carcinomas calcify, allowing their visualization, but not indicating their malignant potential.[62] Dystrophic calcification in skin, renal pelvis, liver, gastric mucosa, or branches of the abdominal aorta has been reported in dogs with HAC. Osteopenia is mild and not of clinical importance. Radiographic assessment of bone density is not sensitive.[63]

Ultrasonography (US)

Pituitary-Dependent Hyperadrenocorticism (PDH)

Complete abdominal US, including visualizing both adrenal glands, is a valuable diagnostic aid in evaluating dogs with suspected HAC (see ch. 88). US may be useful for differentiating PDH from FAT. If an adrenal mass is visualized, US should be used to evaluate size, invasive nature, and possible metastasis. US can help assess squelae to HAC (urinary calculi, gallbladder mucocele, etc.) and to rule out nonadrenal conditions (Video 306-3). The adrenal glands are normally hypoechoic, flattened, bilobed organs located craniomedial to the kidneys (E-Figure 306-9, *A*). Adrenal gland width is considered the most reliable indicator of enlargement and a limit of 7.4 mm, regardless of the dog's size or breed, was used as the upper limit of normal.[64,65] However, recent studies have shown the reference range threshold does vary by breed and body size. The upper limit of height at the caudal adrenal pole in a longitudinal plane is 5.4 mm (left) and 6.7 mm (right) in Yorkshire Terriers and 7.9 mm (left) and 9.5 mm (right) for Labrador Retrievers.[66] Adrenal glands of older dogs tend to be larger than those of younger dogs.[67] A majority of PDH dogs have bilaterally symmetrical adrenomegaly (see E-Figure 306-9, *B*), although at least 25% have normal-sized glands.[68] In some PDH dogs, adrenal enlargement can be asymmetrical due to nodular hyperplasia and is more difficult to interpret (Video 306-4). Adrenal gland size should not be used to diagnose HAC, due to the overlap between normal dogs, ill dogs, and those with HAC.[64,65]



E-FIGURE 306-9 **A,** Longitudinal view of the right adrenal gland in a healthy dog, with a width of 5.7 mm. **B,** Longitudinal view of left enlarged adrenal of a small breed dog with PDH. The adrenal gland has an increased thickness (7.4 mm) while maintaining its characteristic peanut shape. **C,** Longitudinal view of a rounded, left adrenocortical tumor (23.2 mm) in a dog with adrenal hyperadrenocorticism. **D,** Caudal vena cava thrombus in a dog with a right adrenal tumor and hyperadrenocorticism.

Functional Adrenocortical Tumor (FAT)

US can be valuable in visualizing a FAT and vascular or local tissue invasion (see E-Figure 306-9, *C* and *D*). An adrenal tumor should be suspected if the gland is enlarged, irregular (losing its normal peanut shape), or invading or compressing adjacent structures. Echogenicity of a FAT ranges from solid to mixed-cystic appearances. The finding of moderate asymmetry, contralateral adrenocortical atrophy (adrenal width <4-5 mm), destruction of normal tissue architecture, or some combination of these is consistent with a FAT. US does have limitations: it is difficult to differentiate bilateral nodular hyperplasia from bilateral adrenal tumors, benign masses cannot be distinguished from malignant, and a FAT cannot be distingished from pheochromocytoma, aldosteronoma, a metastatic mass, or a non-functional adrenal tumor.

Contrast-Enhanced Ultrasonography (CEUS)

CEUS is a noninvasive method for quantifying adrenal gland vascular patterns in dogs.[69,70] Adrenal blood flow and volume increases in PDH dogs. Their perfusion patterns were not similar to those in control dogs, but more studies are needed.

Computed Tomography (CT), Magnetic Resonance Imaging (MRI) Scans and the "Macrotumor Syndrome"

Pituitary tumors >1 cm in diameter (macroadenomas or macroadenocarcinomas) are relatively easy to visualize with either CT or MRI. Smaller masses approaching 1 cm in greatest diameter may be identified via CT scan but MRI is more sensitive for visualizing pituitary microadenomas. Fifty-six percent of dogs with PDH have a normal-appearing pituitary gland using CT.[71] CT or MRI should be performed in dogs with PDH with central nervous system (CNS) signs. Signs associated with a large pituitary mass can be vague or severe.

Vague subtle signs include lethargy, inappetence and mental dullness. Among many more worrisome signs are severe obtundation, aimless wandering (see Video 306-1), complete anorexia, circling, and changes in behavior. Sixty-six percent of PDH dogs with neurological signs had a detectable pituitary tumor. However, >70% of dogs without neurological abnormalities had a detectable pituitary mass and 20% had a macrotumor (i.e., a tumor ≥10 mm in height).[72]

Abdominal CT or MRI Scanning and the Incidentally Identified Adrenal Mass

CT and MRI are considered accurate and reliable modalities for visualizing adrenal glands. With CT or MRI, adrenal tumor location, presence of vascular or tissue invasion and distant metastasis can be identified. CT may help differentiate PDH from FAT.[71] An unexpectedly visualized adrenal mass (*adrenal incidentaloma,* see ch. 308) is detected in a small percentage of people or dogs undergoing abdominal imaging.[73-75] Most incidentally discovered masses are benign and non-functional.

Endocrine Tests

Overview of Screening and Discrimination Testing

Endocrine testing is essential in diagnosing HAC, but test results should only be used to confirm a strong clinical suspicion. Indications for pursuing a diagnosis of HAC include a history suggestive of HAC, visualizing a pituitary macrotumor or an adrenal mass, a diabetic dog with insulin resistance not attributed to another cause, or persistent hypertension.[30] Many diseases affect the results of HAC tests. Thus, testing for HAC should be avoided in dogs with moderate to severe non-adrenal illness. Further, it is extremely rare to recommend therapy for HAC in any dog ill from a non-HAC condition. Once HAC is confirmed, clinicians then can attempt to discriminate PDH from FAT.

Screening tests most commonly used for distinguishing dogs with from dogs without HAC include the urine corticoid to creatinine ratio (UCCR), the ACTH stimulation test (ACTHST), and the low-dose dexamethasone suppression test (LDDST). No test is 100% accurate and each has advantages and disadvantages. Since these tests were introduced to veterinary medicine years ago, reference ranges and cut-off values should be periodically re-established by each laboratory.[30] Tests used to discriminate PDH from FAT include the LDDST, high-dose dexamethasone suppression test (HDDST), HDDST using the UCCR, measurement of ACTH concentrations, and adrenal US, CT and MRI scans.

Distinguishing Dogs with HAC from Dogs without HAC (Screening Tests)

Urine Corticoid to Creatinine Ratio

Urinary corticoid excretion, determined from a morning sample, is a reflection of adrenal glucocorticoid secretion over a period of several hours, negating concerns regarding fluctuating blood concentrations. Several studies have demonstrated UCCR as a sensitive screening test (nearly 100%) but with low specificity (20-77%).[76-79] Due to its sensitivity, UCCR is a good test for ruling out HAC, since a normal result makes the diagnosis extremely unlikely. Since the UCCR is non-specific and increased in dogs with various conditions, further testing is warranted if the UCCR is increased in a dog suspected of HAC. Urine is best obtained at home, at least 2 days after visiting a veterinarian, to avoid the effect of stress.[80] Dogs with PDH tend to have higher UCCR values than those with FAT and if >100 (reference range, <10), the probability of PDH is 90%.[81] UCCR requires little time, and is not invasive. Determination of basal UCCR can be performed in tandem with a HDDST, allowing evaluation of cortisol production and sensitivity of the pituitary gland to exogenous glucocorticoid administration.[30]

Hair Cortisol

It has been reported that hair cortisol concentrations are higher in dogs with HAC compared to control dogs.[82,83] This noninvasive technique might be considered as a screening test for HAC in dogs, but further studies are needed.

ACTH Stimulation Test

The ACTHST evaluates adrenocortical response to maximal ACTH stimulation, is a test of adrenal gland reserve and is the test of choice for identifying iatrogenic HAC (Figure 306-10). Dogs with naturally occurring HAC may have a normal or exaggerated response to exogenous ACTH and those with iatrogenic Cushing's syndrome have a sub-normal response. The sensitivity of ACTH stimulation test is 85% for the diagnosis of PDH and 60% for the diagnosis of FAT, and specificity is 85% to 90%.[84]

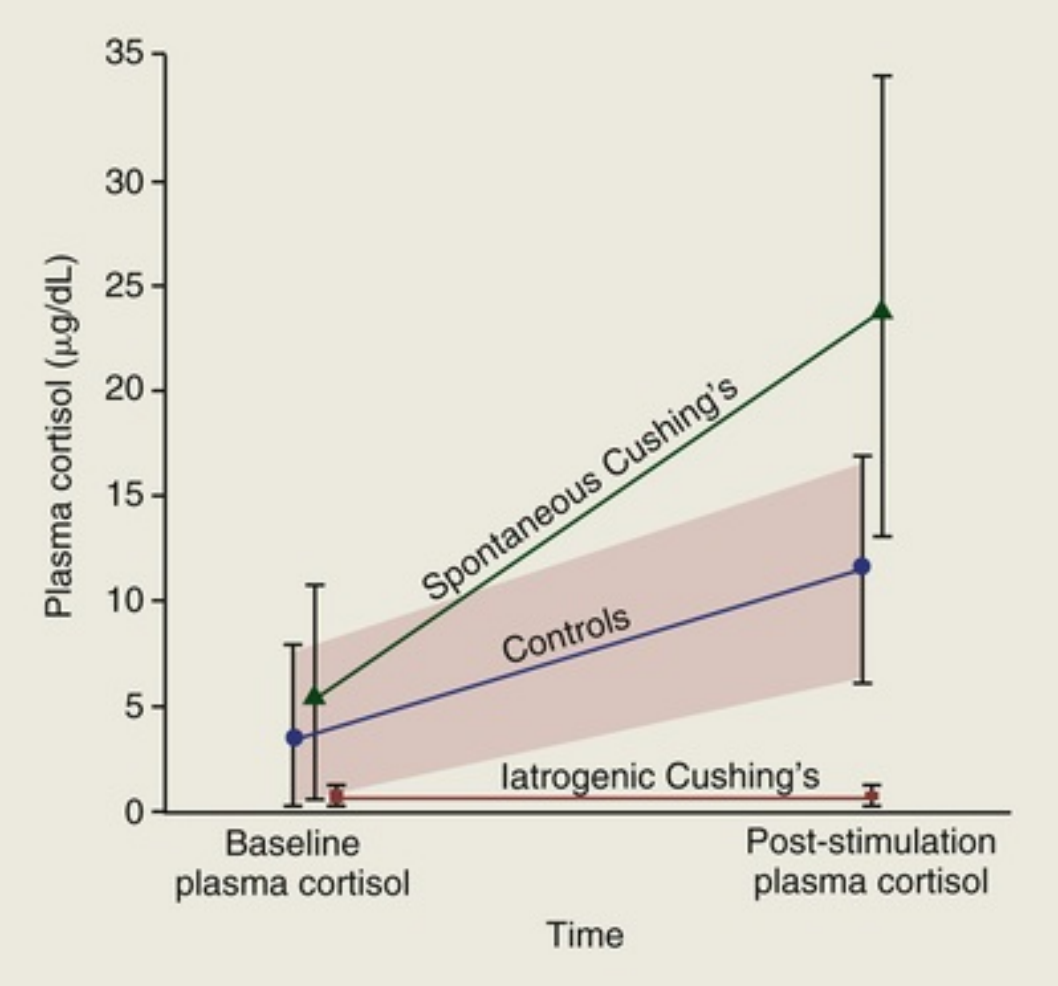


FIGURE 306-10 ACTH stimulation test. Mean radioimmunoassay plasma cortisol concentrations (±2 SD) determined before and 1 hour after administration of synthetic adrenocorticotropic hormone in control dogs, dogs with spontaneous hyperadrenocorticism, and dogs with iatrogenic hyperadrenocorticism.

Several test protocols have been described using either a synthetic peptide containing the first 24 amino acids of ACTH (Cortrosyn, Synacthen, Nuvacthen) or aqueous porcine ACTH gel (Acthar Gel, Questcor Pharmaceuticals, Inc., Union City, CA, USA; not available in certain countries). Most recommend obtaining blood before and 1 hour after giving 250 mcg/dog or 5 mcg/kg of ACTH IM or IV.[85,86] Reconstituted ACTH can be stored in plastic syringes at −20° C for 6 months.[87] Depot tetracosactide (250 mcg/kg IM) and cosyntropin (5 mcg/kg IV) produced similar responses after 60 minutes in healthy dogs.[88] When using ACTH gel, plasma or serum samples for cortisol are obtained before and 1 to 2 hours after IM injection of 2.2 IU/kg. The relatively low sensitivity of ACTHST results together with the limited availability and rising cost of synthethic ACTH have reduced its use. ACTHST results cannot differentiate PDH from FAT. Despite its relatively low sensitivity, it is less affected by non-adrenal illness, is not time-consuming and is the only test for differentiating iatrogenic from naturally occurring HAC.

"Atypical" HAC and ACTHST

Another potential use for the ACTHST is for dogs suspected of having *"atypical"* HAC. *"Atypical" or "occult"*

HAC refers to a dog with clinical signs, physical examination and clinicopathologic findings compatible with HAC but with results of LDDST, UCCR, and ACTHST within reference ranges. It has been hypothesized that these dogs have a derangement of the steroid synthesis pathway which leads to abnormally increased precursor concentrations but normal concentrations of cortisol. Measurement of 17-hydroxyprogesterone (17-OH-P), a cortisol precursor, before and after ACTHST might help diagnose this rare form of HAC by documenting an exaggerated 17-OH-P response to ACTH.[89,90] However, results of ACTHST should be interpreted carefully since false positive results have been documented in dogs with nonadrenal illness and no evidence of HAC.[91] The diagnosis of "atypical" HAC has been questioned. Dogs with mild or early HAC "normal" on tests using current cutoff values may be diagnosed using revised reference ranges. Also, variable cortisol sensitivity might exist and some dogs with high sensitivity may show clinical signs of HAC at lower cortisol concentrations than others.[30,92]

The Low-Dose Dexamethasone Screening Test

The LDDST is considered the "test of choice" for confirming a diagnosis of naturally occurring HAC in dogs.[30,93] The normal pituitary-adrenocortical axis response to the negative feedback associated with exogenous dexamethasone (a glucocorticoid) is ACTH suppression causing decreases in cortisol secretion. Dogs with HAC are abnormally resistant to dexamethasone suppression. LDDST sensitivity is excellent. Results are consistent with HAC in about 90-95% of PDH dogs and virtually 100% of dogs with a FAT. While LDDST sensitivity is excellent, specificity can be as low as 40 to 50%, especially when assessed in a population of dogs with non-adrenal illness.[79] Thus, diagnosis of HAC should never be based solely on LDDST results. Testing should be delayed in any ill dog. The test is not helpful in the detection of iatrogenic HAC, is affected by more variables than the ACTHST, requires 8 hours (or 3 days if using the UCCR protocol; see below), and does not provide information useful in monitoring treatment.

Serum or plasma samples are collected for cortisol concentration before, 4, and 8 hours after dexamethasone administration. Dexamethasone in polyethylene glycol (0.015 mg/kg, IV or IM) or dexamethasone sodium phosphate (0.01 mg/kg, IV) can be administered with equivalent results (Figure 306-11).[29] Reliable results may not be obtained from dogs under stress or being treated with phenobarbital. In a dog with clinical signs of HAC, lack of adequate cortisol suppression is consistent with the diagnosis. Basal and 8-hour post-dexamethasone cortisol results are used for the "screening" portion of interpretation. Results from the sample taken after 4 hours may be helpful for discriminating PDH from FAT. Approximately 30% of dogs with PDH exhibit serum cortisol suppression at 4 hours (< 1.4 mcg/dL or <40 nmol/L), with a higher cortisol concentration at 8 hours. This escape or "V" pattern is consistent with PDH and further discriminatory tests are not necessary.[84] Dogs with a serum cortisol concentration at 4 or 8 hours that has decreased to less than 50% of the baseline serum cortisol concentration (pre-dexamethasone) are also most likely to have PDH. Approximately 65% of dogs with PDH demonstrate suppression using one of these 3 criteria.[93] Failure to suppress (cortisol at both 4 and 8 hours >1.4 mcg/dL and >50% of basal cortisol concentration) is consistent with a diagnosis of HAC, but is not helpful in discriminating PDH from FAT. LDDST interpretation should be based on updated reference ranges and cut-off values established by each laboratory.

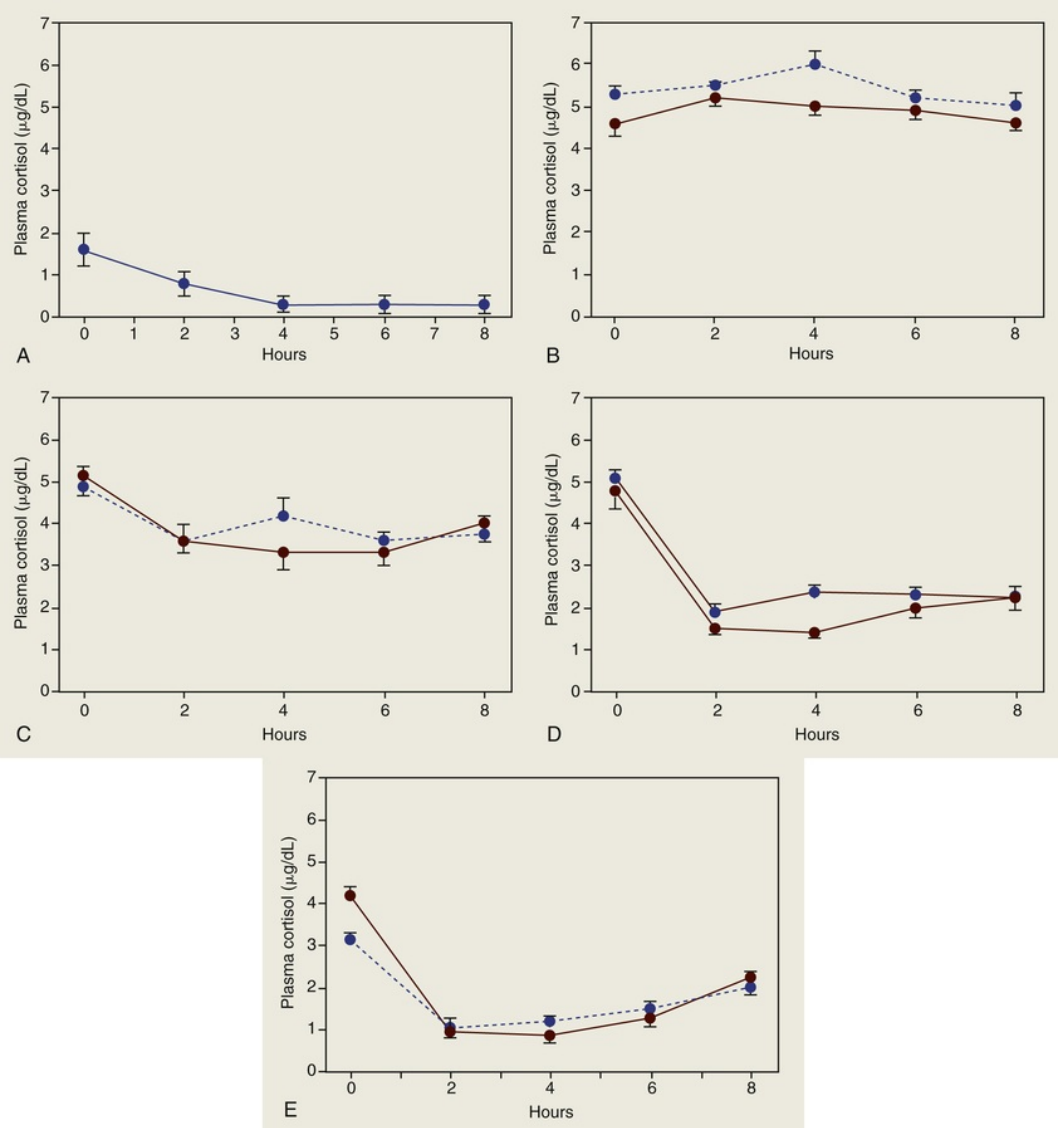

FIGURE 306-11 Mean plasma cortisol concentrations before and after administration of a low dose of dexamethasone in 27 normal dogs **(A);** 48 dogs with adrenocortical tumors **(B);** 130 dogs with pituitary-dependent hyperadrenocorticism (PDH) **(C);** the dogs among the 178 with Cushing's syndrome that had at least one plasma cortisol concentration less than 1.4 mcg/dL after dexamethasone administration (total, 54; each had PDH) **(D);** and the dogs among the 178 with Cushing's syndrome that, after dexamethasone administration, had at least one plasma cortisol concentration decreased to less than 50% of the baseline concentration (total, 95; each had PDH) **(E).** Note the two curves for graphs **B, C, D,** and **E.** These represent the use of dexamethasone sodium phosphate (dashed line) and dexamethasone in polyethylene glycol (solid line). No significant difference in results is seen with these dexamethasone products. (From Feldman EC, Nelson RW: *Canine and feline endocrinology and reproduction,* ed 2, Philadelphia, 1996, Saunders, p 227.)

UCCR/LDDST Combined

The LDDST can be carried out by obtaining urine for UCCR rather than using serum or plasma cortisol.[94] With this protocol, the owner collects urine samples on 2 consecutive mornings at about 8 a.m. for baseline UCCRs. After collecting the second sample, the owner gives 0.01 mg/kg dexamethasone PO. The dog's bladder should be emptied voluntarily or via catheterization at 2 p.m. A third and final urine sample is collected at 4 p.m., 8 hours after giving dexamethasone. Results suggest that >50% suppression in mean UCCR and a decrease in ratio to <10 would be expected in healthy dogs.[94] Dogs with HAC would not be expected to demonstrate suppression.

Discrimination Tests in Dogs with HAC (PDH versus FAT)

LDDST

The LDDST can aid in discriminating PDH from FAT. Results are consistent with PDH if 1 of 3 criteria is met: (1) a 4-hour cortisol concentration <1.4 mcg/dL; (2) a 4-hour cortisol concentration <50% of basal; (3) an 8-hour cortisol concentration <50% of basal but ≥1 mcg/dL). About 65% of dogs with naturally occurring PDH meet at least one of these criteria.[93] However, updated cut-off values are also needed. Dexamethasone resistance, in which none of these criteria is met, is seen in about 35% of dogs with PDH and virtually all dogs with a FAT. In these dogs, another discrimination test is indicated.

High-Dose Dexamethasone Suppression Test

Most dogs with PDH exhibit some resistance to suppression during the LDDST, but higher doses of dexamethasone can overcome this resistance. In contrast, due to chronic suppression of pituitary ACTH in dogs with a cortisol-secreting FAT, administration of dexamethasone, regardless of dose, fails to suppress cortisol concentrations.[93] The recommended protocol for HDDST is to collect blood before and 4 or 8 hours after giving 0.1-1 mg/kg dexamethasone (IV or IM). Dexamethasone in polyethylene glycol or dexamethasone sodium phosphate can be used with equivalent results.

Demonstrating a decrease in cortisol concentration <1.4 mcg/dL (40 nmol/L) is generally considered diagnostic for PDH and excludes a FAT. Interpretation of results should also be based on the laboratory's reference ranges for both dose and dexamethasone used. Lack of suppression is not diagnostic for a FAT, as about 35% of dogs with PDH fail to demonstrate cortisol suppression. Evidence suggests that dogs with large pituitary tumors are less likely to demonstrate response, regardless of dosage.[95] In dogs with confirmed HAC that do not demonstrate suppression via HDDST, there remains a greater chance of PDH than FAT.

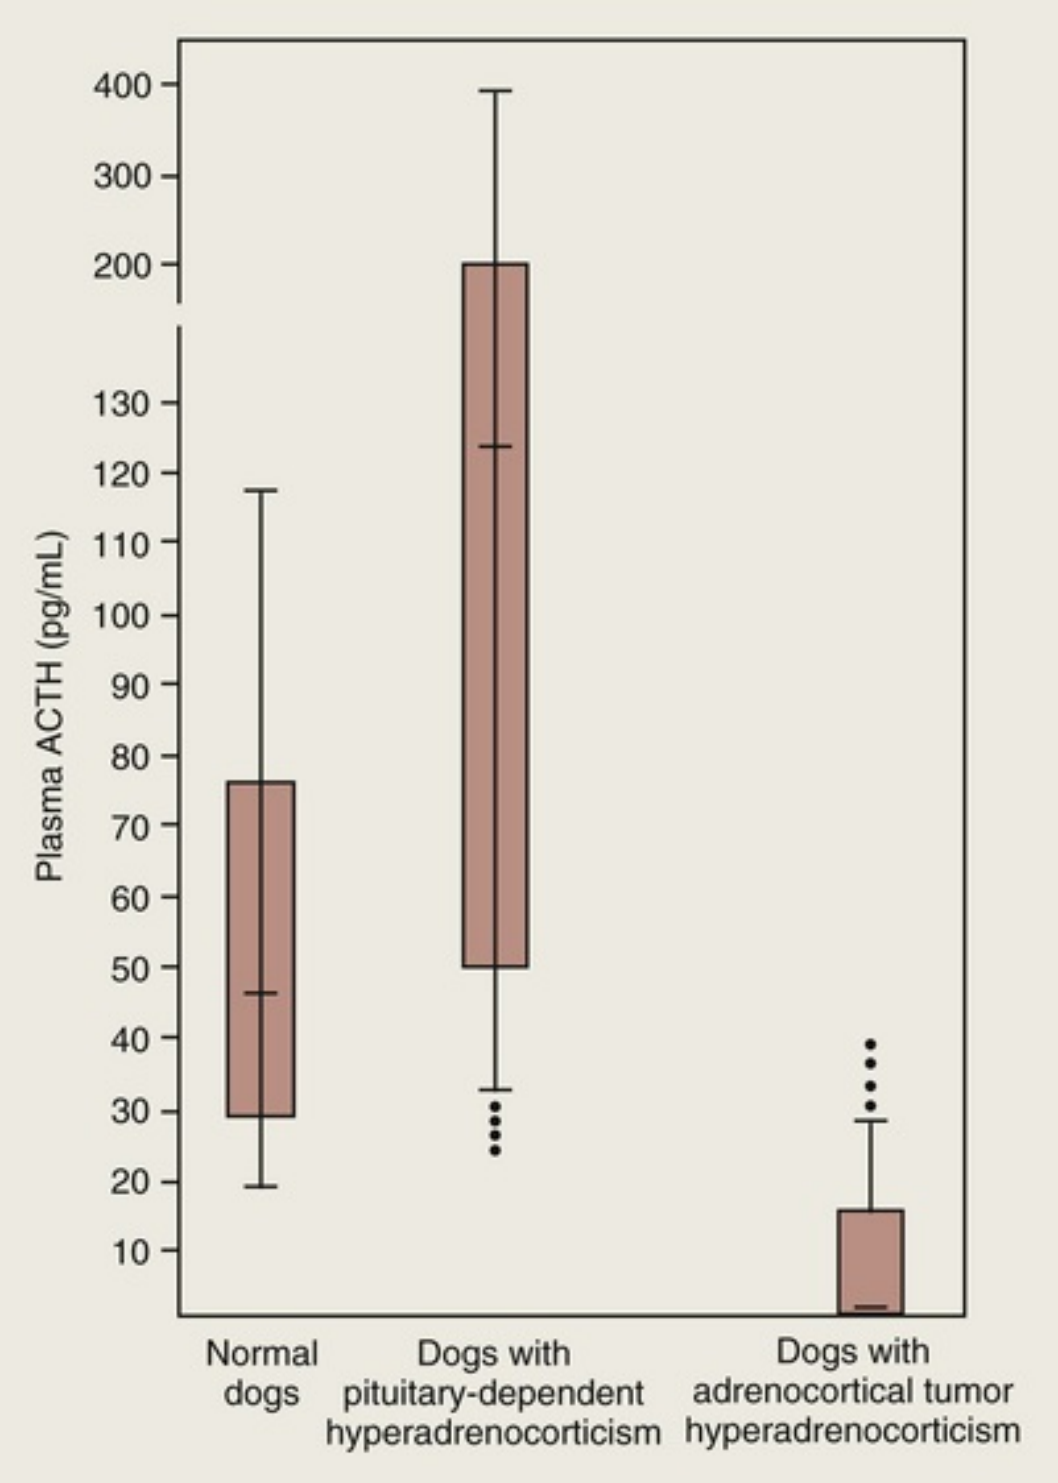
Most of the dogs with PDH that show suppression of cortisol on HDDST also show cortisol suppression on the LDDST. The HDDST results provided additional information in only about 10% that failed to suppress on LDDST.[93] Therefore, it is useful to perform a LDDST routinely in dogs suspected of having HAC. However, when dexamethasone resistance is demonstrated on the LDDST, it would be more efficient to perform another differentiating test, such as adrenal imaging or measurement of endogenous ACTH.

UCCR/HDDST Combined

This combination can be used as the initial endocrine test in evaluating a dog for HAC. A urine sample is collected on 3 consecutive mornings, at home, for UCCR. After the second sample is collected, the owner gives 0.1 mg/kg dexamethasone, orally, to the dog 3 times at 8-hour intervals. The mean baseline UCCR is calculated from the first two results. If the baseline UCCR is increased, consistent with HAC, PDH is likely if the third UCCR result is <50% of baseline.[81]

Endogenous ACTH (eACTH)

Measurement of basal eACTH concentration is of little value as a screening test for HAC, but it can be valuable to discriminate PDH from FAT after HAC has been confirmed. There is little overlap in eACTH concentrations in results from dogs with PDH versus those with FAT.[96] eACTH concentrations are normal to increased in dogs with PDH (e.g., >40 pg/mL or >8.8 pmol/L) and usually low or undetectable (e.g., <20 pg/mL or <4.4 pmol/L) in dogs with FAT or iatrogenic HAC (E-Figure 306-12). Approximately 20% of dogs with HAC have randomly obtained eACTH results in a nondiagnostic range (20-40 pg/mL) and, in such dogs, the test can be repeated or an imaging study may be indicated.



E-FIGURE 306-12 Endogenous plasma adrenocorticotropic hormone (ACTH) concentrations from clinically normal dogs, dogs with pituitary-dependent hyperadrenocorticism, and dogs with functioning adrenocortical carcinomas or adenomas. Each box represents the interquartile range from the 25th to the 75th percentile (the middle half of the data). The horizontal bar through the box is the median. The "whiskers" represent the main body of data, which in most cases is equal to the range. Outlying data points are represented by the circles. (From Feldman EC, Nelson RW, Reusch CE, et al: *Canine and feline endocrinology and reproduction,* ed 4, St Louis, 2015, Saunders.)

Sampling, handling, and assaying samples for reliable eACTH results can be difficult and costly. Samples must be collected in heparin or EDTA tubes and centrifuged immediately. Plasma is then placed into plastic or polypropylene tubes (ACTH will adhere to glass) and immediately frozen until assayed. Plasma samples should be sent on dry ice by overnight delivery service. If such conditions are not feasible, aprotinin, a

protease inhibitor, can be added to the EDTA tube as a preservative for ACTH; in such cases, the sample can be shipped cold via refrigeration packs and freezing is not necessary.[97]

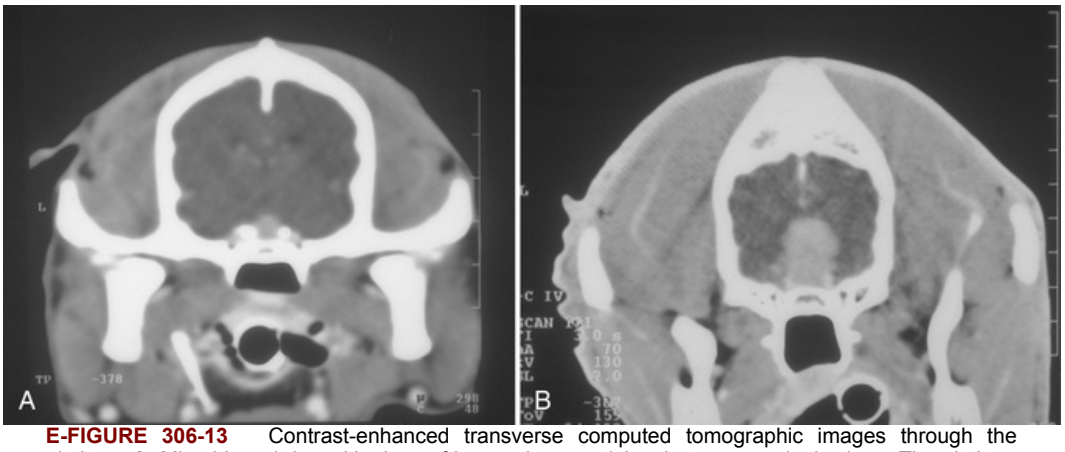
Ultrasonographic Examination of the Abdomen and Adrenal Glands

Bilateral symmetrical enlargement is expected in dogs with PDH. A solitary adrenal mass and atrophy of the contralateral gland is expected in dogs with FAT. However, some dogs with PDH have normal-appearing adrenal glands while others have asymmetrical nodular hyperplasia that can be mistaken for an adrenal mass. Some dogs with adrenal masses have a normal-appearing contralateral gland. Maximal thickness of the smaller gland is helpful to differentiate adrenal tumors (<5 mm) versus asymmetrical hyperplasia (>5 mm).

Computed Tomography and Magnetic Resonance Imaging Scans

US is usually acceptable for assessing adrenals for a mass while CT and MRI are the only modalities available for visualizing a pituitary mass. CT and MRI scan results cannot be used to replace endocrine function testing. About 50% of pituitary tumors are not visible with either modality and neither can determine function.[45] Invasive adenomas, seen with CT or MRI have a mean height (1.8 ± 0.7 cm) significantly greater than non-invasive adenomas.[9] Pituitary tumors in dogs usually expand dorsally due to the minimal resistance encountered at the incomplete diaphragma sella. Growth may result in invagination into the third ventricle and may compress and/or invade the hypothalamus. The optic chiasm, rostral to the pituitary, is rarely impacted by an expanding pituitary mass, sparing vision.

Pituitary gland size depends on breed and individual variation. Pituitary gland CT measurements in healthy dogs revealed sizes of 3.2-5.1 mm (height), 4.2-6.9 mm (width), and 3.6-7.2 mm (length).[98] The first sign of pituitary enlargement is an increase in height (dorsal extension into the suprasellar region). When the dorsal contour of the gland protrudes above the suprasellar extension of the intercrural cisterns, easily recognized on CT scans, enlargement is likely (E-Figure 306-13).[95] Alternatively, ratio of pituitary height to brain area as measured on an image through the center of the pituitary (P : B ratio) can be used to discriminate between an enlarged (P : B >0.31) or normal (P : B ≤0.31) pituitary gland size.[98]

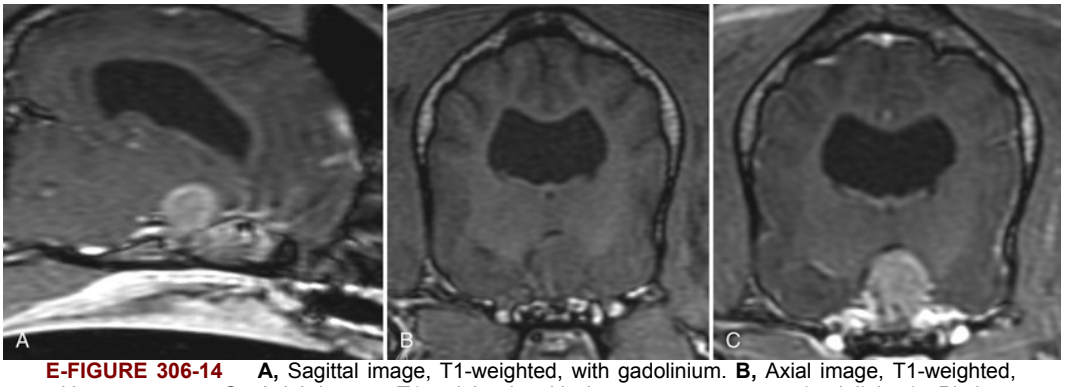


E-FIGURE 306-13 Contrast-enhanced transverse computed tomographic images through the pituitary. **A,** Mixed-breed dog with signs of hyperadrenocorticism but no neurologic signs. The pituitary is enlarged (0.6 cm in height). **B,** Bergamasker with hyperadrenocorticism that had been treated with mitotane for 2 years, after which neurologic signs developed (i.e., disorientation, ataxia, aggressive behavior). The pituitary is grossly enlarged (2.1 cm in height).

Large tumors are usually easily detected on contrast-enhanced CT images because of their size and altered shape. In 50% to 60% of dogs with PDH, a pituitary mass can be detected by CT. Forty percent to 50% of PDH dogs have a smaller tumor (<3-4 mm), not visible despite contrast enhancement. CT modalities using a series of transverse scans through the center of the pituitary during and after rapid IV injection of contrast medium ("dynamic" CT) can often help distinguish the posterior from anterior pituitary, due to differences in vascularity. In normal dogs, an early, strong enhancement of the central posterior pituitary ("pituitary flush") is seen, as well as a slightly delayed, weaker enhancement of the peripheral anterior gland. Displacement or distortion of the posterior flush may reveal the existence of small tumors.[99]

Although CT and MRI are both effective at identifying large pituitary tumors, MRI is superior at defining

the full tumor extent and its effect on surrounding structures. It appears more accurate in identifying small masses (E-Figure 306-14). Size, signal, and contrast enhancement MRI characteristics of the normal canine pituitary gland have been described. One study found that about 50% of PDH dogs with no neurologic signs have a pituitary tumor that can be visualized on MRI scans, ranging from 4 to 12 mm in size.[100,101]



E-FIGURE 306-14 **A,** Sagittal image, T1-weighted, with gadolinium. **B,** Axial image, T1-weighted, without contrast. **C,** Axial image, T1-weighted, with intravenous contrast (gadolinium). Pituitary enlargement (13.3 mm antero-posterior, 11.1 mm latero-lateral, and 12.9 mm dorso-ventral diameters, respectively) with suprasellar extension and hydrocephalus in a female Boxer dog with PDH causing neurologic signs (stupor, head-pressing, and anorexia). The dog was treated with trilostane. (Images obtained in a General Electric 3 Tesla in the Ruber Internacional Hospital. Courtesy Dr. Ana Vicente, Montaña.)

Treatment

Treatment Considerations

The choice of treatment for a dog with HAC depends on several factors: PDH vs FAT, severity of the condition, presence of HAC complications or concurrent diseases, the available treatments, treatment efficacy, side effects, and clinician and client preferences. Cost and need for frequent follow-up evaluations may be essential considerations. It is important to remember, however, that not all dogs with HAC, especially dogs with PDH, need immediate treatment. Since none of the screening or differentiating tests for HAC is perfect, a dog that has no signs or only minimal clinical signs despite abnormal biochemical and/or endocrine tests consistent with HAC should not be treated.[30] Treatment of HAC is never benign and should not be initiated unless the dog shows unambiguous clinical signs of the condition. These factors are further emphasized with the goals of therapy being, primarily, owner-perceived clinical improvement.

Overview of Treating Pituitary-Dependent Hyperadrenocorticism

PDH can be treated medically or surgically. Hypophysectomy is the treatment of choice in humans with PDH and has been well described in dogs. Hypophysectomy is not widely used due to the limited number of surgeons with expertise, its related side effects, and the success achieved with medical therapies. Most dogs with PDH are treated medically with drugs that inhibit synthesis of adrenocortical hormones (i.e., trilostane or ketoconazole) or that cause partial or complete necrosis of the adrenal cortices (i.e., mitotane). A drug claimed to decrease ACTH secretion (selegiline) is not efficacious.

While trilostane has become the treatment of choice for dogs with HAC, mitotane also has successfully been used to resolve the clinical and biochemical abnormalities of HAC. Both trilostane and mitotane have caused serious adverse side effects. Both drugs decrease plasma cortisol and increase ACTH secretion, which may enhance pituitary tumor growth.[102-104] Dogs with pituitary macroadenomas can benefit from radiation therapy, which can decrease tumor size and reduce neurological signs. On one hand, treating PDH is costly and requires periodic monitoring; on the other, most dogs have a good or excellent response to treatment.

Trilostane Therapy

History and Pharmacology

Use of trilostane for treatment of canine PDH was first reported in 1998 and several studies have confirmed its clinical efficacy for treating dogs with HAC.[102,103,105-117] Trilostane is a synthetic steroid analogue that acts as a competitive inhibitor of the enzyme 3-beta-hydroxysteroid dehydrogenase (3-beta-HSD), which catalyzes adrenocortical conversion of pregnenolone to progesterone. Inhibiting this enzyme's action blocks synthesis of cortisol and, to a lesser extent, aldosterone (Figure 306-15).[106] Trilostane reaches peak concentrations <2 hours after administration and is completely metabolized within 10-18 hours. Trilostane's inhibition of 3-beta-HSD is confirmed by decreases in plasma cortisol concentrations with concurrent increases in 17-alpha-OH-pregnenolone. 17-alpha-OH-progesterone concentrations do not change, suggesting that trilostane may also inhibit 11-beta-hydroxylase, influencing the interconversion of active cortisol to inactive cortisone by 11-beta-hydroxysteroid dehydrogenase (11-beta-HSD).[102] Adrenal gland mRNA and protein expression of 11-beta-HSD type 1 are increased while mRNA and protein expression of 11-beta-HSD type 2 are decreased.[118]

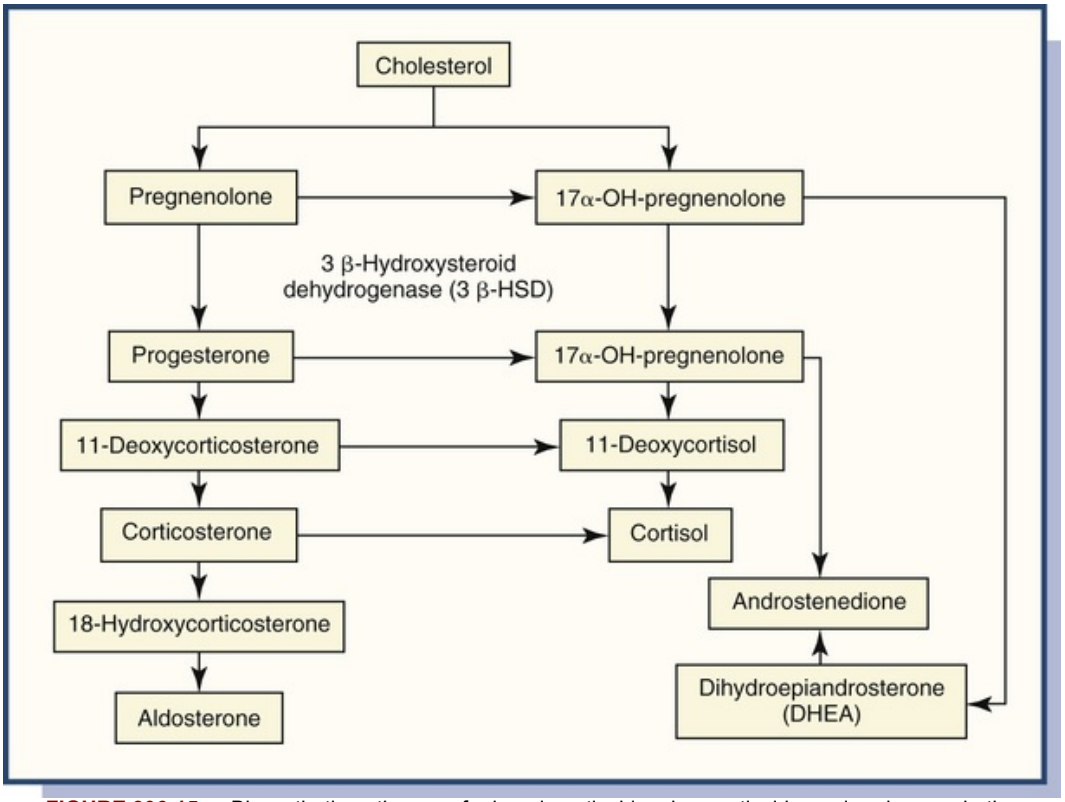


FIGURE 306-15 Biosynthetic pathways of mineralocorticoids, glucocorticoids, and androgens in the adrenal cortex. **3-Beta-hydroxysteroid dehydrogenase,** which converts pregnenolone to progesterone and dehydroepiandrosterone to androstenedione, is blocked by trilostane.

Initial Dosage and Frequency of Administration

Dosage, frequency of administration and monitoring protocols for trilostane continue to be evaluated. Dosages used in early studies (as much as 50 mg/kg/day) were higher than current recommendations. Manufacturer-recommended starting dosages range from 3-6.7 mg/kg PO q 24 h, depending on body weight. However, several studies have shown that doses as low as 0.2-1 mg/kg PO q 12 h are effective and may cause fewer adverse side effects.[113,114,116,117] As body weight increases, required trilostane dosage decreases.[113,114] The initial dosage of trilostane should be based on body weight and planned frequency of administration. In dogs with HAC, the duration of cortisol suppression caused by trilostane varies. In most, cortisol concentrations were suppressed for <12 hours, explaining why q 24 h protocols are not effective in all dogs.[105,108] The proportion of dogs demonstrating good control of their HAC improves with q 12 h administration.[108,109,113,115-117] Also with q 12 h protocols, the total daily dose needed for good control is generally lower.[108,109,113-117] One study evaluating survival time of q 12 h-trilostane-treated PDH dogs, found higher median survival times (900 days) than reported in a study evaluating PDH dogs treated q 24 h (662

days).[110,111] Even though most dogs with HAC are well controlled with q 24 h or q 12 h administration, some respond best to trilostane given q 8 h.[108,113]

An initial dose of 0.5-1 mg/kg PO twice a day is recommended. Once-daily protocols (1-2 mg/kg) should be reserved for owners who refuse the q 12 h alternative. Although low initial dosages may prolong the time needed to control clinical signs, more often these dosages have been adequate while reducing risk of overdose.[108] Some dogs fail to exhibit a good clinical response on q 24 h treatment despite test results indicating adequate cortisol suppression at trilostane peak effect. In these dogs, consideration should be given to q 12 h (see use of urine specific gravity). Regardless of the selected initial dosage and frequency of administration, treatment must be individualized to the needs of the patient and the owner.

Judging Trilostane Response and Dosage Adjustments

It is expected that trilostane-treated dogs will require dosage adjustments, based on clinical response and/or test results. Within 7-10 days of starting trilostane, owners should notice increased activity and decreased PU/PD/PP. PP, of the 3, may decline more slowly, over several weeks. Dermatological problems may take months to completely resolve. The hair coat in some dogs initially appears to worsen, as dead hair and dead dry skin is shed, creating worsening alopecia and severe flaking.

Treatment adjustments should be based on clinical signs (PU), CBC, serum biochemical profile, and ACTHST results (Figure 306-16). ACTHST results reflect adrenocortical reserve and this is the most objective, specific, and sensitive test for assessing therapeutic response.[102,119-121] ACTHS testing in relation to time of trilostane administration is extremely important. Recommendations include starting the test to coincide with either the peak (2-3 hours post-pill) or trough (just before giving the next dose) in trilostane action. In a study comparing results of ACTHST performed 2 versus 4 hours after trilostane administration, maximal effect in most dogs (lowest cortisol concentration) was detected when starting the test 2 hours post-pill.[121] Results of this study also emphasize the importance of consistency in timing ACTHST. The ACTHST can be started 8-12 hours post-pill in dogs treated q 12 h to evaluate trough effects and duration of action.[108,109] Starting the ACTHST 24 hours post-pill can similarly document trilostane's duration of action, if it is being given once daily.

Monitoring Trilostane Treatment of Canine Hyperadrenocorticism without Access to ACTH Stimulation Testing

Ian Ramsey, Laura Macfarlane

Glasgow, United Kingdom

ACTH is not consistently available or it may be prohibitively expensive. There is need, therefore, to identify alternative methods for monitoring trilostane treatment in order to obtain safe and reasonable control of clinical signs without risk of iatrogenic hypoadrenocorticism. Owner opinion regarding response to trilostane administration is the most important information for any veterinarian to consider when treating a dog for hyperadrenocorticism. Daily owner records, similar to those kept by owners of diabetic pets, may help the veterinarian appreciate any trend or concern. However, if owner opinion and records are used as the sole criteria for assessing control and for dose adjustments, there is a risk of trilostane overdosing if subtle early warning signs are missed by an owner. Secondly, clinicians less familiar with trilostane and/or hyperadrenocorticism may not feel as confident in assessing information provided by owners. Some owners may themselves be unreliable in their assessments and recording. Finally, a clinical history provided by even the best of owners does not provide parameters for safely determining how much change in trilostane dose might be indicated to improve response.

A proposed method for monitoring dogs being treated with trilostane without the use of ACTH stimulation test results includes the use of the serum cortisol concentration measured just before giving the morning dose of trilostane.[1,2] The "pre-pill cortisol" has been found to be in better agreement with an owner-based scoring scheme than the post-ACTH cortisol in one study based on 70 measurements made on 53 dogs, most treated once daily but some being treated twice daily, when monitored after 1 month on a consistent dose of trilostane.[3,4]

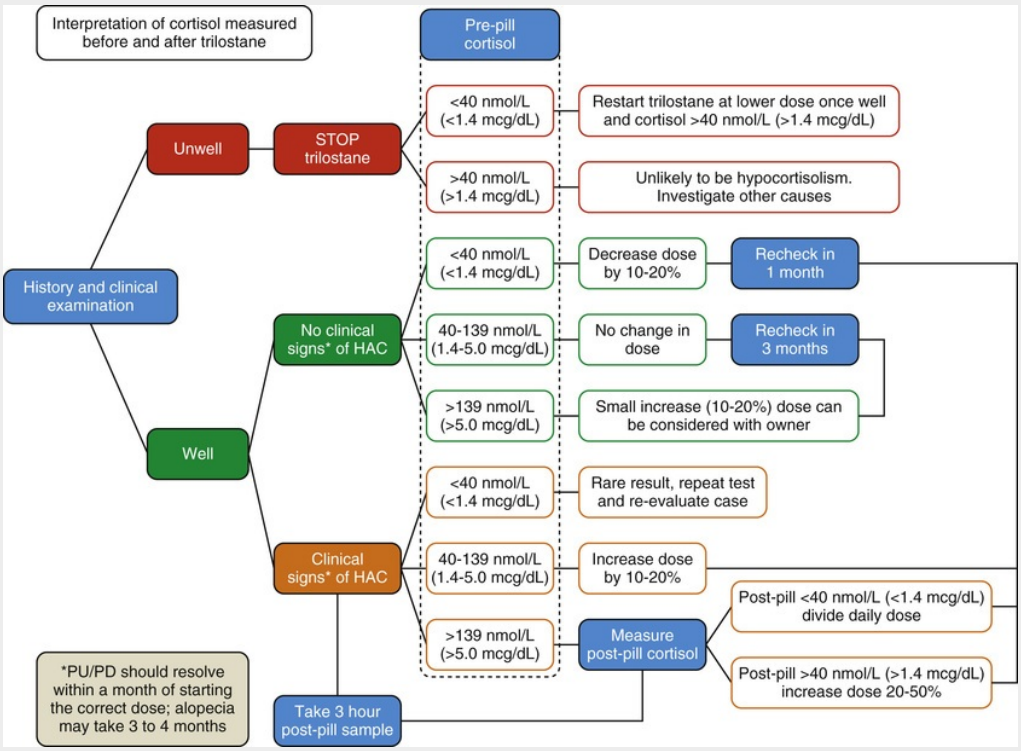
Good clinical control tends to be associated with pre-pill cortisol concentrations in the range of 40-139 nmol/L (1.4-5.0 mcg/dL) and can be regarded as the approximate target range. As with ACTHST results, it is imperative that the results of pre-pill cortisol measurements be interpreted in the context of owner observations and physical examination. If, for example, the clinical signs of polyuria, polydipsia and polyphagia have resolved but the pre-pill cortisol concentration is higher than ideal, it may be sensible to continue the same dose and monitor closely or employ a small (10-20%) dose increase. Decisions regarding changing dose and/or frequency of administration are best made by the veterinarian-owner team, rather than by either alone.

If the clinical signs have resolved but the pre-pill cortisol concentration is less than 40 nmol/L (1.4 mcg/dL) then a dose reduction of 10 to 20% is warranted, even if the dog is clinically well.

If the dog is not well controlled and the pre-pill cortisol concentration is in the target range, the implication is that trilostane's duration of action is long enough but that degree of suppression is insufficient for that particular dog and a small (10-20%) increase in dose should be discussed with the owner.

Some dogs that are not well controlled may have a pre-pill cortisol above the target range. Another serum sample obtained at the nadir for post-pill cortisol concentrations may assist in dose change decisions. This nadir is about 3 hours after giving trilostane.[5] If the post-pill concentration is >40 nmol/L then about a 20-50% increase in dose may be required. If the post-pill concentration is <40 nmol/L then an increase in frequency, while keeping the total daily dose the same, may be useful.[6]

A summary flowchart of these interpretations is provided below. Regardless of monitoring method selected, it is important that the cortisol assay employed be properly validated and the appropriate reference ranges used. The figures provided (cortisol values) are valid for one type of chemiluminescent assay (Immulite series; Siemens).



5 Case Scenarios Are Provided Below

CLINICAL HISTORY	PRE-PILL	POST-PILL	ACTIONS
Vomiting, diarrhea and off food	168 nmol/L (2.1 mcg/dL)	ND	Stopped trilostane. Diagnosed with gastric mural mass, pancreatitis. Euthanized at owner's request.
Generally well but slightly lethargic	34 nmol/L (0.7 mcg/dL)	23 nmol/L (0.8 mcg/dL)	Stopped trilostane. Dog reported to be much livelier within 24 hours. Diagnosed hypocortisolism. Treatment restarted at 50% of original dose once dog well.
Polyuria, polydipsia after 2 months of treatment	169 nmol/L (6.1 mc	154 nmol/L (5.6 mc	Increased dose by 50%. One month later pre-pill cortisol reduced to 148 nmol/L and post-pill cortisol to 75 nmol/L and dog was clinically better.

	g/dL)	g/dL)	
Not PU/PD but still alopecic after 2 months of treatment	89 nmol/L (3.2 mcg/dL)	17 nmol/L (0.6 mcg/dL)	No change in treatment. Re-examined 2 months later, coat regrown and dog still doing very well.
Very well, would not know dog had HAC	53 nmol/L (1.9 mcg/dL)	20 nmol/L (0.7 mcg/dL)	No change in dose. Rechecked every 3 months for a year. Consistently similar results.

Adverse Side Effects to Trilostane

Trilostane is well-tolerated in most dogs. Side effects, if present, are usually mild and caused by low cortisol and/or low aldosterone concentrations. Some dogs may develop lethargy and decreased appetite within a few days of initiating therapy. Severe adverse effects may occur. These include depression, anorexia, vomiting, diarrhea, shaking, weight loss, obtundation and death. If a trilostane-treated dog has worrisome signs, trilostane should be immediately discontinued while serum electrolytes, renal parameters, blood glucose, and blood pressure are assessed.[107,109,110] An ACTHST can be completed, although results may not be as helpful in managing an acute severe illness or crisis.

Trilostane-Induced Adrenocortical Necrosis

Once overdosed with trilostane, adrenal function in dogs may remain suppressed for days, months or longer.[109] Prolonged hypoadrenocorticism is not anticipated after giving a drug known to inhibit the adrenocortical enzymes for <12 hours, but variable degrees of adrenocortical necrosis and hemorrhage caused

by trilostane, especially within the zona fasciculata, have been documented.[122] Prolonged hypocortisolism can occur with or without mineralocorticoid deficiency. Worrisome adverse effects have been documented to begin days, months or years after beginning treatment in as many as 25% of trilostane-treated dogs.[109,123] A study in rats given increasing trilostane dosages demonstrated that secondary increasing eACTH concentrations may be responsible for the adrenal necrosis.[124] Therefore, avoiding hypocortisolism may prevent signs and decrease chances of adrenal necrosis. Considering these potentially serious complications, it is extremely important to carefully monitor dogs receiving trilostane and perform the recommended evaluations, even if a dog is doing well clinically.

Long-Term Trilostane Dosage and Frequency Adjustments

Dogs given trilostane should be evaluated after 10 to 15 days of treatment and again after 1 month, 3 months and every 3-6 months thereafter. At each recheck, a complete history and physical examination should be obtained. CBC and serum biochemical panel with electrolytes may be indicated. In addition, one should perform an ACTHST at each visit. The test should be started 2 to 4 hours after trilostane administration and that time interval should be maintained on all subsequent rechecks. Dosage adjustments should be based on clinical response and results of routine and endocrine testing (see Figure 306-16). A post-ACTH cortisol concentration of 1.5-5.5 mg/dL (41-152 nmol/L) is considered adequate when the ACTHST has been performed at 2-4 hours post-pill.[125,126] The primary goal of the first re-evaluation is to avoid an overdose. Trilostane dosage should not be increased on the first assessment, even if clinical signs have not improved and post-ACTH cortisol concentration is above 5.5 mcg/dL. After the first recheck, if clinical signs of HAC persist and the post-ACTHST cortisol is >5.5 mcg/dL, the dosage of trilostane should be increased. If a dog on q 24 h or q 12 h trilostane is doing clinically well but the post-ACTHST cortisol concentration is <1.5 mcg/dL, trilostane must be discontinued for 5-7 days and then restarted at a 25-50% lower dosage. If, after another 2 to 4 weeks, the serum cortisol values remain low, trilostane should be discontinued indefinitely and ACTHST scheduled every few months or whenever an owner observes recurrence of signs. Trilostane should only be re-started if clinical signs of HAC recur and post-ACTHST cortisols are once again increased.

Long-Term Trilostane Dosage and Frequency Adjustments Using Urine

One can use urine obtained prior to trilostane administration to aid in long-term adjustments. In this scenario, ACTHST results are used to determine trilostane **dosage** and urine specific gravity used to determine **frequency.** For example, if a dog continues to exhibit PU/PD, has a pre-pill urine specific gravity <1.020 (glucose negative), and post-ACTHST serum cortisol concentration >1.5 and <5.5 mcg/dL, frequency of administration should be increased.[104,108,113]

Hypocortisolism

If clinical signs consistent with hypocortisolism are seen, trilostane should be stopped while an ACTHST and serum biochemistry profile are obtained and assessed. If hypocortisolism is confirmed but serum electrolytes are normal, one should stop trilostane, administer glucocorticoids as needed, and repeat the ACTHST 2-4 weeks later. Based upon these results, trilostane may need to be reinstituted if the dog begins showing clinical signs of HAC and the post-ACTHST cortisol concentration is >10 mcg/dL. If hypoadrenocorticism persists, adrenal necrosis is likely. If hypoadrenocorticism is confirmed together with hyperkalemia and/or hyponatremia, one should discontinue trilostane for at least a month and treat as an Addisonian crisis (see ch. 309). ACTHSTs should be repeated after a month and then every 3 to 6 months to determine when treatment for Addison's can be stopped and whether trilostane therapy should be restarted.

Use of Trough Cortisols and/or US

Assessing the basal cortisol at peak trilostane action (usually 2 to 4 hours post-pill) has been evaluated as a monitoring tool in dogs with HAC and to detect hypocortisolism (cortisol <1.5 mcg/dL). A 2- to 4-hour post-trilostane basal cortisol concentration 1.5-4.4 mcg/dL has been considered indicative of adequate control. This approach is not widely accepted, in part because of considerable overlap between excessive, adequate and inadequate control. ACTHSTs are considered far more informative than basal cortisol assessment.[119,120]

The US appearance of adrenal glands changes with trilostane treatment, usually enlarging due to increases in ACTH secretion secondary to reduced cortisol negative feedback.[118,127,128] A marked increase in echogenicity of the outer zone has also been described. Small and heteroechoic adrenal cortices may be indicative of necrosis.[123]

Alternative Therapies

Discussion of mitotane, retinoic acid, cabergoline, ketoconazole and other drugs for treatment of HAC is reviewed in E-Boxes 306-2 and 3. A recombinant ACTH vaccine resulted in production of antibodies against ACTH in healthy dogs; however, effect on the pituitary adrenal axis is subtle and transient.[145] Epidermal growth factor receptor (EGFR) has been proposed as a therapeutic target for canine ACTH secreting tumors.[146].

E-Box 306-2

Mitotane and Other Therapies

Mitotane

Mitotane is an adrenocorticolytic agent with a direct cytotoxic effect on the adrenal cortex, resulting in selective, progressive adrenocortical necrosis and atrophy.[29,32,34,35,39,40,42,45,47,53,54,57-65,74-81,84-87,89-91,93-112,122,123,125-134] Mitotane causes selective necrosis of the zona fasciculata and zona reticularis of the adrenal cortex (sites of glucocorticoid production). The zona glomerulosa (site of mineralocorticoid production) is less sensitive to this drug; however, at high dosages, mitotane can cause complete necrosis of the adrenal cortex. Mitotane is fat-soluble and should always be administered with a meal. This drug can be used in an attempt to cause partial destruction of the adrenal cortex, preserving the zona glomerulosa (standard protocol) or complete necrosis of the entire adrenal cortex (nonselective protocol).

Standard Protocol: Initial Induction or Loading Dosage

The induction dosage of mitotane is 30 to 50 mg/kg/day, administered orally for 10 days or until adverse effects suggestive of hypoadrenocorticism develop.[135] An induction dosage of greater than 50 mg/kg/day is rarely required and will cause a higher incidence of hypoadrenocorticism. In moderate- to large-sized dogs, dividing the daily dosage into two equal doses may be better; however, because mitotane is available only as a scored, 500-mg tablet, it may be impossible to divide the daily dosage in small and toy breeds of dog.

Concurrent oral glucocorticoid supplementation with prednisone or prednisolone (0.15 to 0.25 mg/kg/day, up to a maximal daily dose of 5 mg/day/dog) can be used to mitigate the adverse effects associated with serum cortisol concentrations falling rapidly into the normal or subnormal range during this initial treatment period. The major disadvantage of providing a low-maintenance dosage of glucocorticoid during the induction period is that it may not be possible to know if and when an adequate total induction dose of mitotane has been administered, or even if overdosage has occurred, because clinical signs of glucocorticoid deficiency may not develop. If the veterinarian elects not to provide glucocorticoid supplementation during the induction period, it is imperative that owners be supplied with prednisone or prednisolone in case signs of life-threatening hypoadrenocorticism develop and immediate veterinary care is not available.

Clinical signs that the owners should monitor both before and during the administration of mitotane to their dog include the dog's attitude, appetite, and water intake. Awareness of these signs will help determine if the drug should be stopped before completion of the 10-day induction period and when monitoring by the ACTH stimulation test is necessary. Inasmuch as the ACTH stimulation test is the best means to determine the ability of the adrenal cortex to secrete cortisol (and therefore judge the thinning of the cortex), this is the test of choice for monitoring the effects of mitotane.

At home, the most reliable means that the owner has of monitoring the effects of mitotane induction is careful monitoring of the dog's appetite. A common, early adverse sign is decrease in appetite, which almost always occurs before development of any of the other adverse clinical signs (such as vomiting, weakness, and complete anorexia). Therefore, the dog's appetite should be observed by the owner before administration of the daily dosage. If the dog rapidly consumes the meal, the owner should administer the dose of mitotane immediately after the dog finishes the food. If the dog's appetite diminishes (the food is consumed either slowly or not at all), the owners should not administer any more mitotane, at least until they consult with their veterinarian. In addition to providing an important monitoring tool, administrating mitotane at the time of feeding enhances its gastrointestinal absorption because it is a fat-soluble drug.

After completion of mitotane induction, the veterinarian should again see the dog and complete a

thorough history and physical examination. Whether the dog has responded clinically or not, the efficacy of induction should always be determined by performing an ACTH stimulation test. If glucocorticoid was administered during mitotane induction, it should not be given on the morning of ACTH stimulation testing, because most glucocorticoids (e.g., prednisone and prednisolone) can cross-react in the cortisol assay to falsely elevate the serum cortisol concentration. Once the ACTH stimulation test has been completed, that day's glucocorticoid dose can be given, if needed.

The goal of treatment with mitotane is to achieve an ACTH stimulation test result that suggests relative, but not complete, hypoadrenocorticism. In other words, the basal (resting) cortisol should be lowered into the reference range (1 to 4 mcg/dL; or 25 to 125 nmol/L), with little to no rise in cortisol concentration after ACTH stimulation (i.e., post-ACTH cortisol concentration should also be lowered into the reference range for basal cortisol, i.e., <4 mcg/dL or <125 nmol/L). In most dogs with PDH, initial daily mitotane treatment succeeds in decreasing both basal and post-ACTH serum cortisol concentrations into the desired range. In some dogs, however, the ACTH-stimulated serum cortisol concentration will be subnormal (<1 mcg/dL or <25 nmol/L) after the initial treatment period, indicating near-total adrenocortical destruction. In this situation, mitotane should be stopped and glucocorticoid provided until the serum cortisol concentration rises to within the reference range for basal cortisol (1 to 4 mcg/dL; or 25 to 125 nmol/L). After overtreatment with mitotane, the low serum cortisol concentration typically increases naturally into the normal resting range within 2 to 6 weeks; however, in a few dogs, cortisol remains low for up to 18 months without further mitotane. Conversely, about 10% to 15% of dogs still respond to exogenous ACTH with the serum cortisol concentration rising to above the desired range (>4 mcg/dL; or >125 nmol/L) after initial daily mitotane treatment. In these dogs, daily mitotane administration should be continued and the ACTH stimulation test repeated at weekly intervals until adverse clinical signs develop or the circulating cortisol concentration falls into the desired range. Dogs have individual sensitivity to mitotane during the induction period and the length of daily treatment needed to adequately reduce adrenal reserve can range from 5 days to 2 months. No reliable method has been determined for predicting either the duration of treatment necessary or the amount of mitotane necessary to destroy enough adrenal tissue for a detectable response.

Standard Protocol: Maintenance Dosage

Once adrenal reserve has been appropriately reduced, as determined by ACTH stimulation test results, orally-administered mitotane should be continued at a maintenance dosage of approximately 50 mg/kg/week, divided into two to four equal doses. In small or toy breeds of dogs, it may not be practical to attempt to divide the weekly dosage. Daily glucocorticoid supplementation is rarely necessary during maintenance mitotane treatment. During periods of stress or illness, however, glucocorticoid support may be necessary. Despite initial control of HAC with mitotane, relapse commonly occurs during long-term treatment.

About half of dogs treated with initial loading and maintenance dosages of mitotane relapse within 12 months of treatment, as evidenced by recurrence of clinical signs and higher than desired basal and ACTH-stimulated cortisol concentrations. To ensure continued control and prevent serious relapse during mitotane treatment, ACTH stimulation testing should be repeated after 3 and 6 months of maintenance treatment and every 6 months thereafter. If basal and post-ACTH cortisol concentrations rise above desired ranges (>4 mcg/dL; or >125 nmol/L), the dog should be reloaded (i.e., the mitotane dosage should be increased to 30 to 50 mg/kg PO daily for 5 to 7 days, or longer if needed). Once circulating cortisol concentrations have been again lowered into the desired range, the weekly maintenance dosage should be increased by approximately 50% to help prevent further relapse. Because of multiple relapses, some dogs eventually require extremely high mitotane dosages to control HAC.

Side effects are relatively common and should be anticipated during mitotane administration, especially during induction with mitotane. The adverse effects most commonly observed include lethargy, weakness, anorexia, vomiting, diarrhea, and ataxia. Up to a quarter of dogs can develop one or more of these problems during the initial daily mitotane administration, but they are relatively mild in most dogs. These effects develop as the serum cortisol concentration falls rapidly to normal or subnormal (glucocorticoid withdrawal) and typically resolve rapidly when mitotane is discontinued and glucocorticoid supplementation increased.

When side effects develop during the induction period, mitotane should be discontinued and a glucocorticoid administered (e.g., prednisone, 0.2 to 0.5 mg/kg PO q 24 h) until the dog can be examined, and ACTH stimulation testing performed to evaluate adrenal reserve. Most dogs show a clinical response to the glucocorticoid dosage within 2 to 3 hours; persistence of problems for longer than a few

hours after administering or increasing the glucocorticoid dosage usually signifies another medical problem.

Likewise, adverse reactions may occur in dogs during maintenance mitotane therapy, most commonly shortly after beginning maintenance therapy or during relapses when daily therapy is reinstituted. Again, the development of side effects is associated with a subnormal circulating cortisol concentration in most dogs. If side effects occur during the maintenance period, mitotane should be discontinued and glucocorticoid supplementation provided. Should adverse signs persist for longer than a few hours after administration of a glucocorticoid, the dog should be evaluated as soon as possible to exclude other disorders including mineralocorticoid insufficiency. In most dogs, it will be necessary to resume maintenance mitotane in 2 to 8 weeks as determined by ACTH stimulation test results and clinical signs.

In a few dogs treated with mitotane, adverse reactions may result from direct drug intolerance rather than absolute or relative hypoadrenocorticism. In such dogs, the serum cortisol concentration is not low and no improvement in adverse clinical signs occurs with glucocorticoid supplementation. First, one must be certain that the drug is given immediately after the dog has eaten. Giving this drug on a full stomach enhances absorption and reduces adverse effects. In addition, dividing the daily or weekly dose of mitotane into smaller doses may lessen or eliminate the adverse reactions in these dogs.

The most serious adverse effect associated with mitotane administration is the development of total or near-total adrenocortical destruction, with concomitant glucocorticoid and mineralocorticoid deficiency and hyperkalemia and hyponatremia (Addison's disease). Iatrogenic Addison's disease secondary to mitotane is relatively rare with this protocol, developing in fewer than 5% of dogs. The complication may develop any time during maintenance treatment but is most likely to develop during the first year. Unfortunately, predicting which dogs will develop Addison's disease does not seem possible. In one study, no difference was found in the maintenance dosages of mitotane between those dogs that developed complete adrenocortical insufficiency and those that did not.

In general, Addison's disease should be suspected if a dog develops side effects during mitotane administration and does not promptly respond to glucocorticoid supplementation. Iatrogenic Addison's disease is confirmed in these dogs by ACTH stimulation testing (i.e., undetectable serum cortisol concentration) and serum electrolyte determination (i.e., hyperkalemia and hyponatremia). If Addison's disease does develop, mitotane should be discontinued and appropriate glucocorticoid and mineralocorticoid replacement therapy instituted immediately. Of the dogs that develop complete, iatrogenic adrenal insufficiency, all can be expected to require mineralocorticoid and glucocorticoid replacement therapy for the remainder of their lives. Therefore, further mitotane administration is usually not necessary.

Nonselective Protocol

This protocol consists of a longer period of daily treatment with mitotane to produce a complete destruction of the three layers of the adrenal cortex with resultant iatrogenic hypoadrenocorticism.[136,137] In this protocol, mitotane is administered orally at a dosage of 50 to 75 mg/kg/day (divided into two or three smaller doses given with food) for 25 days. Life-long administration of mineralocorticoids (fludrocortisone, 0.01 mg/kg PO q 12 h) and glucocorticoids (prednisone, 0.2 mg/kg; or hydrocortisone, 1 to 2 mg/kg/day) is started on the third day of mitotane administration. The dose of fludrocortisone is adjusted based on the clinical response and results of biochemical evaluation including BUN and serum electrolytes. The dose of glucocorticoids will be adjusted to the lowest dose needed to achieve a good clinical control of hypoadrenocorticism (usually hydrocortisone 0.5 to 1 mg/kg/day). Dogs treated with the nonselective protocol are less likely to have a relapse of HAC (30% to 40%) compared with dogs treated with the standard protocol (50% to 60%). In a large number of dogs, however, daily mitotane administration must be stopped for a short period because of adverse side effects, such as anorexia, vomiting, diarrhea, weakness, and neurologic symptoms.

Ketoconazole

Ketoconazole is an imidazole antifungal drug that also inhibits the synthesis of glucocorticoids and androgens.[138,139] It effectively lowers circulating cortisol concentrations but has minimal effect on mineralocorticoid production. Ketoconazole controls HAC in some dogs, but unfortunately, the drug is not efficacious in many dogs with the disease. In our experience, one third to one half of dogs fail to adequately respond.

Ketoconazole is started at a dosage of 5 mg/kg PO q 12 h for 1 week. If the drug is well tolerated (i.e., no decrease in appetite or icterus is seen), the dosage is increased to 10 mg/kg PO q 12 h for 2 weeks. The

efficacy of the initial 14-day course of treatment is determined by an ACTH stimulation test. To ensure adequate control of HAC, both the basal and post-ACTH serum cortisol concentrations must be lowered into the basal reference range. If the serum cortisol concentrations remain above this range, the dosage is increased to 15 mg/kg PO q 12 h, and an ACTH response test repeated in 14 days. Most dogs require an oral daily dose of 30 mg/kg for a long period to achieve good clinical control. The disadvantages of ketoconazole are the expense, the requirement for twice-daily administration for life, side effects, and the drug's lack of efficacy in some cases. Less than 2% of veterinary specialists (internal medicine and dermatology) use ketoconazole as the treatment of choice for HAC.[133]

Selegiline Hydrochloride

Cushing's disease in dogs can be caused by adenoma or hyperplasia of cells in either the pars distalis or pars intermedia.[10] Approximately 70% of dogs with Cushing's disease have a pituitary adenoma that arises from the pars distalis, whereas 30% have a tumor that arises from the pars intermedia. In dogs, the neurotransmitter dopamine appears to primarily inhibit the secretion of ACTH peptides from the pars intermedia and a central disturbance of dopamine may play a role in the pathogenesis of canine Cushing's disease. L-deprenyl (selegiline hydrochloride) is a selective and irreversible inhibitor of monoamine oxidase type B, which helps restore the central dopamine concentration and facilitates dopaminergic transmission by several mechanisms. L-deprenyl may down-regulate ACTH secretion by enhancing the dopamine concentration, thereby controlling PDH. The use of L-deprenyl for the treatment of HAC in dogs is controversial. Selegiline has been described as a safe and effective treatment after a partial to complete clinical improvement was observed in more than 80% of treated dogs with PDH.[140] However, later studies that included an adrenal function test to evaluate the efficacy of the drug have shown that this drug is ineffective.[141,142] Several of the owners reported an increase in the level of activity of the dog during treatment. L-deprenyl is metabolized into substances with amphetamine-like structures, which may explain the increased activity.

Other Drugs

A variety of other drugs (bromocriptine, cyproheptadine, metyrapone, aminoglutethimide) have been investigated for the treatment of HAC without favorable results. Two medical therapies (cabergoline and retinoic acid) for canine Cushing's syndrome have also been described.[143,144] These treatments might be helpful in decreasing ACTH secretion, urine cortisol to creatinine ratio, and the size of the pituitary tumor. However, additional studies are warranted before recommending this treatment to general practitioners (see E-Box 306-3).

E-Box 306-3

Treatment of Pituitary-Dependent Hyperadrenocorticism (PDH) without Access to Trilostane or Mitotane

Maria Fernanda Cabrera Blatter

Buenos Aires, Argentina

Overview of Need for Alternative Therapies

PDH is diagnosed in dogs by veterinarians worldwide. While success has been achieved in treating afflicted dogs with trilostane or mitotane (o,p'-DDD), there are countries in which these medications are not available and alternatives are used.

Ketoconazole (also see E-Box 306-2)

Background

When given at dosages higher than those used for combatting fungal disease, ketoconazole reversibly suppresses steroid synthesis, including cortisol, mineralocorticoids, estrogen, testosterone and progesterone. Ketoconazole may also directly suppress adrenocorticotropic hormone (ACTH)-secreting pituitary tumors, perhaps explaining the lack of increased ACTH concentrations despite suppression of cortisol synthesis.

Protocol

Ketoconazole is recognized to cause adverse side effects in dogs, especially at dosages required to control PDH. Side effects include anorexia, vomiting, diarrhea and an idiosyncratic hepatopathy. Side effects can be minimized or completely avoided by initiating ketoconazole at sub-therapeutic doses and slowly increasing to effective amounts. While the initial low dosages have little effect on PDH, dogs usually develop a tolerance to the drug over a period of 1 to 4 weeks. Initially, 5 mg/kg PO q 24 h should be administered following a meal. Every 2 or 3 days, the oral dose should be increased by 2.5 mg/kg until reaching 20 mg/kg/day. Serum biochemical profiles should be evaluated every 2 to 3 weeks to identify hepatotoxicosis reflected as increases in alanine aminotransferase (ALT).

Cabergoline

Overview

Corticotropic cells express D2 dopaminergic receptors. Function of both the pituitary pars intermedia and pars distalis can be suppressed by dopamine, inhibiting the synthesis of ACTH and melanocyte stimulating hormone (alpha-MSH). In dogs, ACTH-secreting tumors can originate in either or both areas of the pituitary. Cabergoline is a D2 dopaminegic receptor agonist. It has high affinity for the pituitary, with anti-proliferative and pro-apoptotic effects in dogs. Together with its action on the dopaminergic system, cabergoline may normalize enzymatic pro-convertases (cleavage of ACTH to yield alpha-MSH). Inhibitory effects on the thyroid axis and hypotension have also been described.

Protocol, Side Effects, Response

Initially, cabergoline should be administered at a dosage of 0.022 mg/kg PO q 48 h. The first few doses often cause vomiting, but subsequent doses are usually better tolerated. Less worrisome side effects (8-12 % of dogs) include dry hair coat, lack of hair growth, and change in coat color. Approximately 40% to 60% of cabergoline-treated dogs begin to demonstrate resolution of clinical signs after about a month of treatment. Along with clinical improvement, there is decrease in urinary cortisol, ACTH, and alpha-MSH concentrations. Pituitary tumor size may also decrease. In animals responding favorably, survival is longer than in dogs treated only with ketoconazole. Therapy with cabergoline is most effective in dogs with pars intermedia pituitary tumors <5 mm in greatest diameter. Following early response for several months, some dogs appear to become resistant to cabergoline.

Retinoic Acid

Background

Retinoic acid can inhibit cell proliferation and induce apoptosis. It affects receptors at the genomic level that regulate gene expression of transcription factors required for synthesis of pro-opiomelanocortin (POMC), the precursor of ACTH. Retinoic acid not only suppresses tumor synthesis of POMC and ACTH, but it also suppresses tumor growth by inhibiting mitosis and inducing apoptosis.

Protocol

Retinoic acid is administered as the isoform isotretinoin 9-Cis (enteric capsule; 2 mg/kg PO q 24 h given in the evening). About 80% of dogs treated with retinoic acid have demonstrated clinical improvement after approximately a month, in association with decreases in urinary cortisol, ACTH, and alpha-MSH concentrations. Pituitary tumor size has also decreased in some dogs. Side effects include mild diarrhea, skin dryness and hyperkeratosis. While hepatotoxicosis has been described, this author has administered retinoic acid to dogs for as long as 6 months, safely. Frequent liver function test assessments are recommended and the drug should be discontinued if increases occur. No other side effects have been observed. (Editor's note: The proven risk of severe human teratogenicity and fetotoxicity must be discussed with the owner, who must accept full responsibility for appropriate and safe handling, use, and storage of the drug, prior to prescription and/or refill.)

Combination Protocols

Cabergoline and Retinoic Acid

These drugs have different mechanisms of action and together they have a particularly strong synergistic effect, especially in dogs with mixed tumors (pars distalis and intermedia). Dosages for each drug are the same as described for single drug therapy: cabergoline 0.022 mg/kg PO q 48 h plus isotretinoin (2 mg/kg/day PO). This mixed protocol can be used safely for 6 months. After this period, the dog should be examined to determine if medication can be completely stopped since treatment often has a residual effect. Alternatively, some dogs either continue with this or another protocol according to the response. (Editor's note: Owner informed consent is mandatory, as indicated above.)

Cabergoline and Ketoconazole

This combination provides rapid resolution of clinical signs due to ketoconazole effect and at the same

time, it allows an upregulation of the D2 receptors (dopaminergic) as the ACTH-secreting pituitary adenoma becomes more sensitive to the effect of cabergoline.

Pasireotide (SOM 230)

SOM 230 (pasireotide) is an analogue of somatostatin with the ability to affect the receptors (SSTR) of the subtypes 1, 2, 3 and especially 5 in pituitary ACTH-secreting adenomas. SOM 230 has antiproliferative and anti-secretory actions. Dogs treated with pasireotide have demonstrated clinical improvement, usually without side effects. The side effect to consider is that it can generate hyperglycemia, as the analogues of the somatostatin inhibit insulin secretion at the pancreatic level, and diminish glucagon-like peptide 1 release, even though insulin sensitivity is not affected. Treated dogs have also shown significant decreases in urinary cortisol concentrations, serum ACTH concentrations, and in pituitary tumor size. Pasireotide can be considered a therapeutic alternative for dogs that do not respond to conventional treatments.

Surgical Treatment of PDH (Hypophysectomy)

Transsphenoidal surgical removal of the pituitary tumor causing PDH is the treatment of choice for humans, while complete surgical hypophysectomy has been used for dogs with PDH.[7,147,148] After hypophysectomy in PDH dogs, the 1-year estimated relapse-free fraction was 90%. The 1, 2, 3, and 4-year estimated survival rates (86, 83, 80, 79%, respectively) compare favorably to results seen in dogs treated with either mitotane or trilostane.[148]

Complications associated with hypophysectomy include permanent or prolonged diabetes insipidus, secondary hypothyroidism, transient reduction or cessation of tear production, transient mild postoperative hypernatremia, and recurrence of PDH months later. Treatment failures included procedure-related mortalities and incomplete hypophysectomies. Central diabetes insipidus occurred more frequently in dogs with enlarged pituitaries than in dogs with nonenlarged pituitaries. Factors related with an increased risk of death are old age, large pituitary size, and increased preoperative plasma eACTH concentrations. Factors associated with disease recurrence were large pituitary size, thick sphenoid bone, high urinary cortisol/creatinine ratio, and increased plasma alpha-MSH concentrations before surgery.[148] A modification of the transsphenoidal approach using CT localization of the sella turcica with a high definition video telescope system has recently been used in dogs with HAC. Their reported 1-year survival rate was >80%.[149]

Radiation Therapy for PDH

Reducing Mass Size

Cobalt 60 radiotherapy has potential for dramatically reducing size of a visible pituitary tumor in dogs with PDH without neurologic signs.[150] In one study, 6 dogs received radiation doses of 44 Gy divided into 11 equal fractions using a telecobalt 60 unit. Plasma eACTH concentrations transiently decreased in all dogs; however, clinical signs of HAC resolved in only 3/6 dogs and recurred in 2 of those 3. One year after radiotherapy, no tumor could be visualized in 4 dogs and tumor size decreased by 25% in 2. No dog developed neurologic abnormalities. Experience with radiation therapy for dogs with large pituitary masses has varied.[45,151,152] In 24 dogs with pituitary macrotumors and neurologic signs treated with megavoltage irradiation (48 Gy during 4 weeks on an alternate-day schedule of 4 Gy/fraction), a significant correlation was found between relative

tumor size (i.e., size of tumor relative to calvarium size), severity of neurologic signs, and remission of those signs after radiation.[151] As severity of neurologic signs worsened, prognosis worsened. This was the most reliable prognostic factor. Since radiation therapy is more effective in dogs with relatively small tumors, early treatment should improve prognosis and longevity. It has been recommended that dogs with pituitary masses equal to or greater than 8 mm at greatest vertical height undergo radiation as the initial mode of therapy.[45] Since radiation effectively shrinks tumors but is far less successful at resolving clinical HAC, use of medical management should be anticipated. There are few complications. Disadvantages of radiation include cost and availability.

Clinical Response

Pituitary tumors are relatively sensitive to radiation. Dramatic and relatively rapid improvement may be seen in some dogs despite initial severe neurologic signs. Generally, prognosis and severity of clinical signs are inversely related: dogs with severe neurologic signs and a tumor >20 mm at greatest diameter have a much poorer prognosis than dogs with more mild signs and a mass <20 mm. While some dogs improve during radiation therapy, others require weeks or months. Therefore, owners should be encouraged to allow their dogs several months to respond.

Endocrine Response

In most dogs with PDH, radiation has little effect, no effect, or only a transient influence on the tumor's secretory nature. Therefore, medical treatment is usually required to control HAC, despite mass shrinkage. Recurrence of neurologic signs weeks to years later is possible but rare. In such dogs, deterioration may be rapid. CT or MRI could be recommended for each dog diagnosed as having PDH, but especially dogs exhibiting dexamethasone resistance on LDDST or HDDST. Radiaton therapy is advisable for dogs with tumors >7 mm, regardless of presence or absence of neurologic signs.[150]

Stereotactic Radiosurgery (SRS)

SRS delivers a single large radiation dose to a well-defined target and has been used for dogs with pituitary tumors.[153] SRS treatment requires only a single anesthetic procedure, has fewer acute adverse effects, and survival times in early studies appear comparable to conventional radiation therapy.

Treatment: Functional Adrenocortical Tumors

Overview

Ideal treatment for dogs with FAT causing HAC is surgical removal of the tumor. Surgery can be curative, permanent, and requires no long-term therapy. However, some dogs with FAT are treated medically. Reasons for medical therapy include: to improve a patient's clinical condition prior to surgery, an inoperable tumor, metastases at the time of diagnosis, poor surgical candidate, or owner decision. The adrenocorticolytic drug mitotane (o,p'-DDD) can be used in an attempt to destroy the tumor, but this is rarely achieved.[154] Trilostane is efficacious for controlling signs of HAC, improving quality of life, and survival times are similar to those achieved with surgery or mitotane.[155,156] In dogs diagnosed with FAT, pre-surgical trilostane (0.2-1 mg/kg PO q 12 h) is recommended to resolve clinical signs and laboratory abnormalities (which might take 1 to 2 months). Surgery is then done on a healthier individual.

Adrenalectomy

Surgical adrenalectomy is considered the treatment of choice for adrenal tumors. Adrenalectomy, via celiotomy or laparoscopy, is technically challenging and should be performed by a skilled surgeon. Postoperative complications, including pancreatitis, pneumonia, pulmonary thromboembolism, acute kidney injury/oliguria/anuria, sepsis, disseminated intravascular coagulation and hypoadrenocorticism, are worrisome but less common after appropriate pre-treatment.[45] Intraoperative and postoperative complications have been reported in a highly variable percentage of dogs with FAT.[157-162] As surgical skill and patient management improves, morbidity and mortality rates are decreasing. Perioperative mortality (13.5-30%) is decreasing and use of minimally invasive technology (laparoscopy) are anticipated to decrease mortality and morbidity further.[157-162]

Prognostic Factors

In one review of dogs with FAT treated with adrenalectomy, tumor size (≥5 cm), distant metastases and vein thrombosis (vena cava) were associated with poorer prognosis.[161] In another study, invasion of the caudal vena cava was associated with a higher surgical mortality rate but did not affect long term prognosis.[162] The median survival time of dogs with FAT undergoing adrenalectomy is about 2 to 4 years.[160-162] It is important to remember that the average age at diagnosis is about 11 years.

Pre-Surgery

Prior to adrenalectomy, HAC should be treated and controlled with trilostane. Immediately prior to surgery, results of a CBC, serum chemistry profile, and thoracic radiographs should be assessed. Repeat US is helpful not only for visualizing the mass, but to search for evidence of metastasis or venous tumor thrombosis (Video 306-5). US has a reported sensitivity of 100% and specificity of 96% in correctly identifying abdominal metastases.[163] Autonomous cortisol secretion from the tumor results in atrophy of the contralateral gland and thus, intraoperatively and postoperatively glucocorticoid supplementation is necessary. IV fluids should be administered at a maintenance rate at the start of anesthesia, during surgery and in the postoperative period (see ch. 129). When the surgeon recognizes the adrenal tumor, dexamethasone should be placed in the IV infusion bottle at a dosage of 0.05 to 0.1 mg/kg and given over a 6 hour period. Dexamethasone should be given 2 or 3 times daily until oral medication can be tolerated.[29] Hydrocortisone, with both glucocorticoid and mineralocorticoid activity, can replace dexamethasone. During surgery, hydrocortisone can be given IV (4 to 5 mg/kg) and thereafter 1 mg/kg, IV, every 6 hours until oral medication is tolerated. An ACTHST, completed the morning after surgery and about 8 hours after the last dose of dexamethasone, helps to determine whether the tumor was completely excised (low serum cortisol concentrations before and after ACTH) and to determine need for continuing glucocorticoid supplementation.

Post-Surgery

Intensive postoperative monitoring is essential for preventing or responding to complications. Hyperkalemia and/or hyponatremia should be treated with mineralocorticoid (see ch. 309): oral fludrocortisone (0.01 to 0.02 mg/kg q 12 h) or IM desoxycorticosterone pivalate (DOCP; 2.2 mg/kg SC every 21-25 days). Electrolyte abnormalities may reflect mineralocorticoid deficiencies and are usually, but not always, transient, only lasting a few days. Antibiotics, analgesia, and heparin (75 units/kg SC q 8 h) are recommended.[162] Pre-surgical trilostane treatment for a month or 2 may negate the need for heparin. Oral prednisone should be considered for all dogs whose post-surgical ACTHST results were below normal. An initial dosage of 0.5 mg/kg PO q 12 h for 3 days is then tapered to 0.2 mg/kg/day over 2-4 weeks. Results of an ACTHST performed then, and months later, should be used to determine need for continuing glucocorticoid supplementation.

Medical Management of Adrenocortical Tumors: Mitotane

When the patient is not a good candidate for adrenal surgery, mitotane is an alternative option to attempt complete or partial destruction of the adrenal tumor. Dogs with FAT can be treated with the standard mitotane protocol previously described for dogs with PDH (see mitotane treatment for PDH), but at a daily dosage of 50-75 mg/kg PO. An ACTH stimulation test is performed every 10 to 14 days to evaluate adrenal reserve. An oral glucocorticoid (e.g., prednisone or prednisolone, 0.2 mg/kg/day) is administered throughout the period of mitotane administration to try to avoid clinical signs of hypoadrenocorticism. Daily mitotane (loading dose) is continued at this dosage or increased until desired cortisol levels are reached or drug intolerance develops. In dogs with FAT, this loading period is usually longer compared to dogs with PDH, with a cumulative mitotane induction dose up to 10 times higher than dogs with PDH. Once adequate post-ACTH cortisol concentrations are achieved, maintenance mitotane is started at 75 to 100 mg/kg PO, weekly, in divided doses together with daily glucocorticoid supplementation. In dogs with adrenal tumors, a maintenance dose of mitotane is also commonly greater than 100 mg/kg, and relapses during treatment are common (more than 60% of dogs).[164] Trilostane is preferred to mitotane because it is more efficacious in the control of clinical signs. Mitotane-related side effects, seen in as many as 60% of treated dogs, include anorexia, weakness, vomiting, diarrhea, and lethargy. Adverse effects may be due to development of hypoadrenocorticism, but in approximately 50% of dogs, they are due to direct drug toxicity.[164] If adverse reactions do occur, the drug should be stopped and the dog evaluated as soon as possible since complete glucocorticoid and mineralocorticoid deficiency (Addison's disease) may occur. If toxicosis is suspected,

mitotane must be discontinued. It can be re-started again 5-7 days later at a 25% to 50% lower dosage. Reinstitution of the higher maintenance dosage can be attempted later but usually results in recurrence of adverse effects. In this situation, a different treatment (trilostane) might be chosen.

Medical Treatment of FAT: Trilostane

The efficacy of trilostane in controlling clinical signs of hypercortisolism in dogs with FAT has been demonstrated.[155,156,165,166] Furthermore, the survival time of dogs with FAT treated with trilostane (median 11.5 to 14 months) is similar to that observed in dogs treated with mitotane (median 3 to 15.6 months).[155,156] Thus, trilostane is the best medical treatment for dogs with FAT.

Complications and Concurrent Conditions Associated With HAC

Large Pituitary Tumors

Definitions

Approximately 50% of dogs with PDH have a tumor visible on CT or MRI scan at the time of diagnosis. Neurologic signs caused by expansion of a pituitary tumor are seen in about 15% to 20% of dogs with PDH, including a small number of dogs with signs when first diagnosed as having HAC. Most are diagnosed sometime after treatment is started.[100] Improved long-term medical management of dogs with PDH may simply provide enough time for smaller masses, which represent the majority at the time of PDH diagnosis, to expand sufficiently to cause clinical signs. Most PDH dogs with signs caused by a large tumor have been medically treated for more than 6 months, some more than several years. Pituitary tumors are often categorized according to size as macrotumors (≥10 mm in greatest diameter) or microtumors (<10 mm). These arbitrary designations, however, have little use clinically.[72] Clinical manifestations of an enlarging pituitary tumor do not correspond only to size, but may be related to growth rate, size of the skull cavity, or the presence of peri-tumoral inflammation, edema or hemorrhage. It seems more appropriate to use the term "macrotumor" to describe tumors visible by means of CT or MRI and the term "microtumor" for masses that only be visualized microscopically.[45]

Signs, Diagnosis, Treatment

The onset of neurologic signs may precede, coincide with, or follow (most commonly) diagnosis and long-term medical management of HAC. The initial clinical signs associated with an expanding pituitary mass are usually subtle decreases in appetite and changes in behavior noted only by someone extremely familiar with the dog. Other signs that begin slowly and progress are dullness, listlessness, restlessness, loss of interest in normal activities, episodes of apparent disorientation, severe loss of appetite, and weight loss. Later in the course of the disease, signs may include ataxia, aimless pacing, circling, stupor, and seizures. Antemortem confirmation of a pituitary tumor requires advanced imaging, such as CT or MRI. Radiation or hypophysectomy are available therapeutic options, discussed previously (see Surgical Treatment of PDH).

Hypertension

Systemic hypertension, defined as systolic blood pressure greater than 160 mm Hg (see ch. 99), is present in 38% to 86% of dogs with untreated HAC (see ch. 157).[55,167] Systemic hypertension may lead to proteinuria, also frequently noted in dogs with HAC (44 to 68%). Both may improve or resolve with treatment, but neither resolves in all treated dogs.[55] Glomerular filtration rates are increased before treatment and decrease with treatment for PDH. Persistence of proteinuria or hypertension after successful HAC treatment should warrant attention.[55] Plasma aldosterone concentrations may contribute to hypertension in dogs with untreated HAC. However, several studies have found that aldosterone levels are often below normal in dogs with PDH but high in dogs with FAT.[167,168] Further studies are needed to elucidate the mechanism of hypertension in dogs with HAC. Proteinuria and systemic hypertension (present in up to 80% of dogs with untreated HAC) are major factors in the development and progression of chronic kidney disease, and should be monitored in dogs with HAC with persistent hypertension despite a good control of HAC.

Diabetes Mellitus (see ch. 304)

The diagnosis of HAC in dogs already diagnosed as having diabetes mellitus (DM) should not be

complicated, assuming that classic signs of HAC are observed. For example PU (with a urine specific gravity <1.008), bilaterally symmetrical alopecia, pot belly, thin skin, panting, calcinosis cutis and low BUN are typical of HAC but not DM. Since the most common signs of DM are the same as those in HAC (PU/PD/PP), diagnosis in poorly controlled diabetics with only these signs must be questioned. Appropriate use of screening tests enhances their sensitivity and specificity, but they should never be used as the sole indicator of HAC. US diagnosis of adrenalmegaly is non-specific. No diagnostic aid is as sensitive and specific as history and physical examination.

CHAPTER 307

Feline Hyperadrenocorticism

Ian K. Ramsey, Michael E. Herrtage

Client Information Sheet: Feline Hyperadrenocorticism (Cushing's Disease)

Introduction

Feline hyperadrenocorticism (HAC; Cushing's syndrome; hypercortisolism) is less common but more serious and more challenging to diagnose or treat than canine hyperadrenocorticism. Feline HAC has a worse prognosis than the condition in dogs. Unlike dogs, feline HAC is strongly associated with diabetes mellitus (DM) and/or a skin hyperfragility syndrome, either of which may complicate management. Basic pathophysiology and other aspects of feline HAC are similar to the canine (see ch. 306). This chapter focuses on the clinical condition resulting from the chronic excessive production of cortisol or other hormones with a cortisol-like action. Cats with progesterone-secreting adrenocortical tumors may have clinical signs consistent with feline HAC (see ch. 308).[1,2] Some adrenocortical tumors can cause primary hyperaldosteronism (see ch. 308).

Pathophysiology

Feline HAC is a multisystemic disorder resulting from excessive production of cortisol by the adrenal cortices. There are single case reports describing cats with HAC and several case series that, together, total more than 100.[3-24] Both pituitary-dependent HAC (PDH), caused by excessive pituitary secretion of adrenocorticotropic hormone (ACTH), and adrenal-dependent HAC (ADH), caused by a functional adrenocortical tumor, have been reported in cats.[4] About 85% of cats with naturally occurring HAC have PDH and the remaining 15% have ADH (E-Table 307-1). ADH may be caused by either a benign or a malignant adrenocortical tumor. A small number of cats with multihormonal pituitary tumors, including ACTH-secreting tumors causing PDH, has been reported.[18,25-28] Iatrogenic HAC has been described in cats associated with glucocorticoid or progestogen administration.[29-31] The progestogen megestrol acetate, a particularly potent steroid in cats, may cause prolonged adrenocortical suppression after being discontinued.[32]

Clinical Signs

Overview

Many of the earliest reported cats with HAC had dramatic and obvious clinical signs. Clinical signs had often been present for many months before diagnosis. Now, feline HAC is becoming better recognized, with variations in clinical presentation and associated biochemical disorders better appreciated (see E-Table 307-1).[6] Earlier diagnosis may avoid severe clinical signs particularly in the diabetic cat population (Table 307-2 and Figure 307-1).

TABLE 307-2

Approximate Frequency of Clinical Findings in Feline Hyperadrenocorticism

FINDING	FREQUENCY
Concurrent diabetes mellitus	79%
Polyuria/polydipsia	79%
Polyphagia	60%
Abdominal distension	54%
Alopecia/failure to regrow hair	43%
Skin hyperfragility/spontaneous tearing	40%
Weight loss/muscle atrophy	31%
Weakness/lethargy	29%
Weight gain/obesity	23%
Poor coat (dry, seborrhea, etc.)	15%

From data provided in seven published series of cases with a combined total of 77 cases.[3-6,8-10] Note that three of these series (a total of 30 cases) were selected by treatment modality; however, there was no apparent difference in the presenting signs. See E-Table 307-1 for further information.

Age, Breed and Sex

Feline HAC is most common in middle-aged to older cats (median age in the various studies was 9.5 to 13 years; range from 3 to 15 years). There appears to be no sex or breed predilection.

Skin Changes

Cutaneous manifestations of feline HAC include truncal and abdominal alopecia, but far less frequently than in dogs. An unkempt hair coat and seborrhea are common. Their thin skin is prone to traumatically induced tears, bruising and secondary bacterial or fungal infection (Figures 307-2 and 307-3). The hyperfragile skin is particularly distressing to owners and unwary clinicians. Cats with HAC should always be treated gently (Figures 307-4 and 307-5). Calcinosis cutis has not been reported in naturally occurring nor iatrogenic HAC.

FIGURE 307-5 A 9-year-old neutered female domestic shorthair cat with pituitary-dependent hyperadrenocorticism. **A,** Spontaneous skin tearing. **B,** Close-up view.

Metabolic Alterations

Polyuria, polydipsia (PU/PD) and polyphagia (PP) are the most commonly reported metabolic signs of HAC in cats. PU/PD and PP are usually associated with glucocorticoid-induced DM with its consequent glycosuria and osmotic diuresis. PU/PD in feline HAC can also be associated with chronic kidney disease (CKD), a rare concomitant condition in dogs with HAC. Weight loss may be observed in feline HAC, but some cats exhibit weight gain despite their poorly controlled DM (Figures 307-6 and 307-7). PU/PD does not appear to be a feature of the disease in the absence of DM or CKD. Thus, PU/PD cannot be used to recognize the early stages of disease.

FIGURE 307-6 A 10-year-old domestic longhair cat with hyperadrenocorticism and diabetes which had lost a significant amount of weight. The coat is in poor condition.

FIGURE 307-7 A 9-year-old neutered female domestic shorthair cat with pituitary-dependent hyperadrenocorticism. The cat is obese with a pendulous abdomen (body weight 10 kg) despite diabetic ketoacidosis and pancreatitis.

Physical Changes

A pendulous abdomen, generalized muscle wasting, hepatomegaly and weight gain are common. A minority of afflicted cats lose weight and some have softer tongue barbs. Occasionally, ulcers along the periphery of the tongue are noted (Figure 307-8), although not reported in any case series.

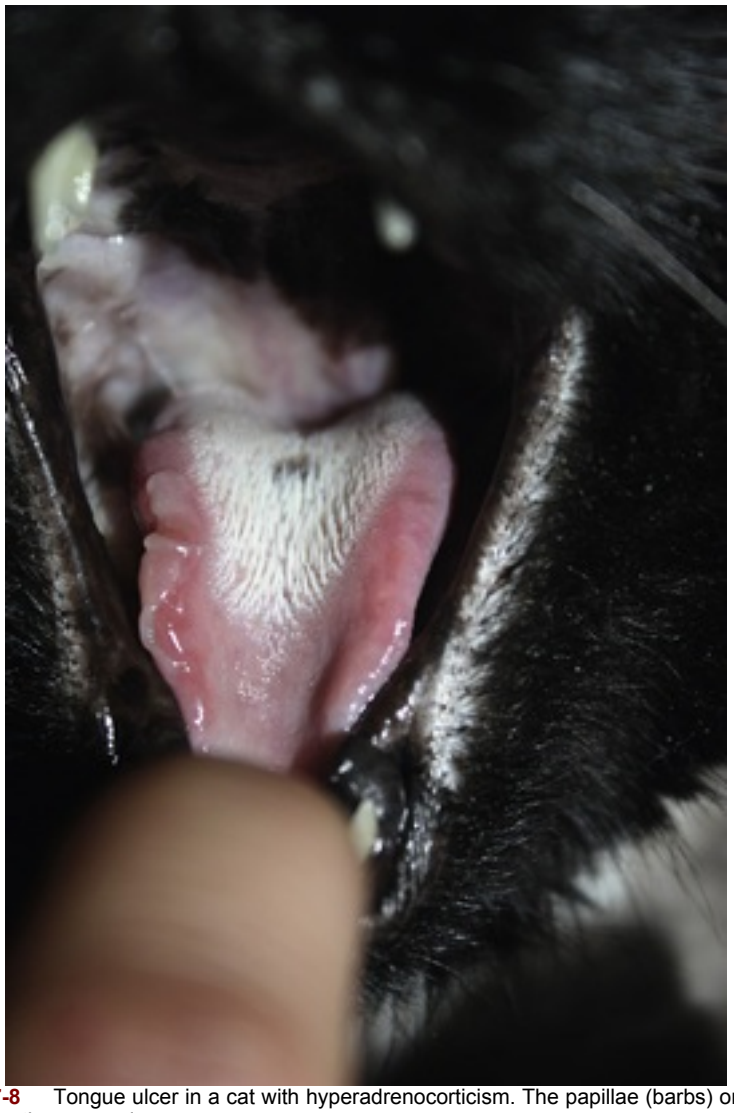

FIGURE 307-8 Tongue ulcer in a cat with hyperadrenocorticism. The papillae (barbs) on the tongue were far softer than normal.

Concurrent Diseases

Most cats diagnosed with HAC also have DM; in one case series, 27 of 30.[10] Several other series have indicated that a majority, but not all, cats with HAC have concurrent DM.[6,9] Cats with concurrent DM and HAC are often insulin resistant, requiring large daily doses of insulin (≈2 units/kg) to control their hyperglycemia and glycosuria.[3,6]

Many cats with HAC develop infections, sometimes unusual, but almost always difficult to resolve.[3,8,10,16] This apparent predisposition to infection suggests that cats with HAC are more immunosuppressed than dogs with HAC or that their fragile skin, DM, and other concurrent conditions increase infection severity.

Cats with HAC may have concurrent CKD (also see ch. 324). There is no evidence of a direct correlation between the two nor that presence of one makes the other more difficult to manage.[10] The incidence of cats with both conditions is far greater than with HAC dogs. Most HAC cats with urine specific gravity <1.020 have also had CKD. Cats with HAC may also develop pancreatitis (also see ch. 291), but the effect of increased cortisol concentrations on feline pancreatic lipase immunoreactivity (fPLI) has not been investigated. By extrapolation from the dog, fPLI may not be a reliable indicator of pancreatitis in cats with HAC.[10,33] About 20% of cats with HAC are hypertensive (see ch. 99), less common than in canine HAC.[10,34] Acute blindness due to bilateral retinal detachment was reported in a hypertensive cat with HAC (see ch. 157).[22]

General Laboratory Testing and Diagnostic Imaging

Serum Biochemistry, Complete Blood Count, Urinalysis

Hyperglycemia, seen in about 80% of cats with HAC, is the most common laboratory abnormality. A majority of these cats also have overt DM, but hyperglycemia is often present even in those who do not have overt DM (Table 307-3). Hypercholesterolemia has been reported in about 50% of cats with HAC, probably related to poorly controlled DM and increased lipolysis. In one review, >50% of cats with HAC also had increases in blood urea nitrogen (BUN) and >25% had increases in both BUN and creatinine concentrations.[35] In contrast to dogs, cats lack a steroid-induced isoenzyme of alkaline phosphatase (ALP) and the half-life of feline ALP is shorter. Mild increases in ALP activity are present in about 30% of cats with HAC. Increases in ALP and the hepatocellular enzyme alanine aminotransferase (ALT) are probably related to DM. The distribution of white blood cells expected with hypercortisolemia, lymphopenia, eosinopenia and neutrophilia occurs inconsistently in cats with HAC. Despite a glucose-induced diuresis in cats with both HAC and DM, non-diabetic cats with HAC seem able to maintain urine specific gravities >1.020. In comparison to dogs with HAC, cats tend to have more dramatic physical changes and less dramatic clinicopathological changes.

TABLE 307-3

Approximate Frequency of Clinicopathologic Findings in Feline HAC

FINDING	FREQUENCY

From data provided in four published series of unselected cases with a combined total of 47 cases.[3,4,6,10]

Diagnostic Imaging

Overview

Advances in diagnostic imaging have improved the ability of veterinarians to identify a pituitary mass or bilateral adrenal enlargement in cats with PDH and adrenal masses in cats with ADH, as well as vessel or organ invasion usually by a malignant adrenal tumor. This information can be used to tailor treatment for each individual. However, identifying a pituitary or adrenal mass does not necessarily indicate function. Therefore, diagnostic imaging should always be interpreted within the context of clinical signs and endocrine test results.

Radiography

Radiographic examination of the thorax and abdomen is advisable in all cats suspected or proven to have

HAC. Although "diagnostic" information is only obtained in the small number of cats in which adrenal enlargement can be detected (Figure 307-9), survey radiographs of the thorax and abdomen may allow identification of concurrent abnormalities, which may alter treatment plan and/or prognosis. Abdominal contrast is usually enhanced by the marked increase in intra-abdominal fat. Neither steroid-induced osteopenia nor calcium containing uroliths have been reported in cats with HAC. Parathyroid hormone activity in cats with HAC has not been reported.[36] In dogs, adrenal mineralization is usually associated with benign or malignant adrenal neoplasia. However, adrenal calcification may be a benign and incidental finding in older cats (Figure 307-10).

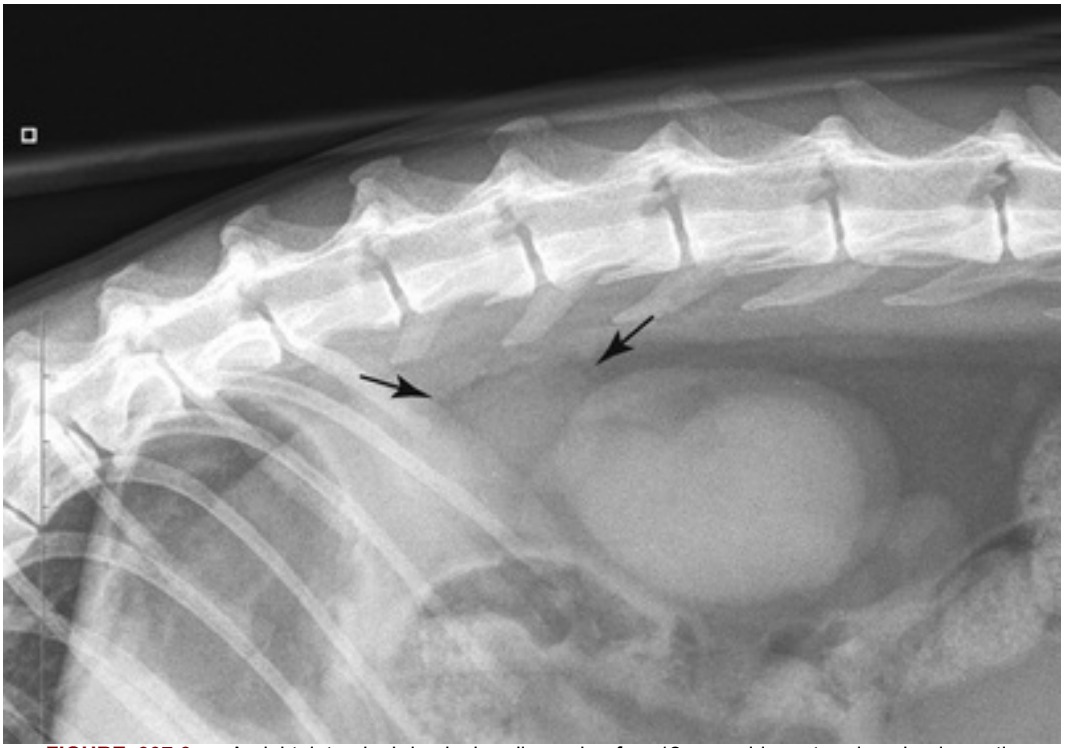

FIGURE 307-9 A right lateral abdominal radiograph of a 12-year-old neutered male domestic shorthair with hyperadrenocorticism due to an adrenal mass (arrows).

FIGURE 307-10 A lateral radiograph of a 10-year-old domestic shorthair with calcified adrenal glands. This can be an incidental finding in older cats and is not necessarily associated with abnormal adrenal function.

Abdominal Ultrasonography (US)

Using high-resolution US equipment, an experienced ultrasonographer can usually identify both adrenal glands in most healthy cats (see ch. 88). The best adrenal images are obtained by scanning from the right and left lateral intercostal and abdominal approaches. The right adrenal gland is more difficult to identify because of its deeper cranial location under the ribs. Normal feline adrenal glands are oval to bi-lobed and hypoechoic compared with the surrounding tissues. The healthy adrenal medulla can be slightly hyperechoic compared to the cortex, but is not always clearly visible. Healthy feline adrenal glands are about 4.5-13.7 mm in length and 2.9-5.3 mm in width.[37]

The challenge for the ultrasonographer is to distinguish normal from hyperplastic or neoplastic glands. Although the adrenal glands of cats with PDH have been characterized as being symmetrically enlarged and of normal conformation, diagnosis of adrenal hyperplasia can be subjective. Hyperplastic adrenals tend to be larger and easier to identify than healthy glands, but should still have a normal homogeneous hypoechoic pattern (Figure 307-11). US can increase suspicion for presence of an adrenal tumor (Figure 307-12). Bilateral adrenal tumors have been reported, but are rare.[2,3] Malignant adrenal tumors have a propensity to invade nearby blood vessels and surrounding tissues. Thus, thorough US examination of adjacent vessels and tissues should be performed. If an adrenal mass is identified, the liver, spleen and kidneys should also be carefully examined for evidence of metastases.

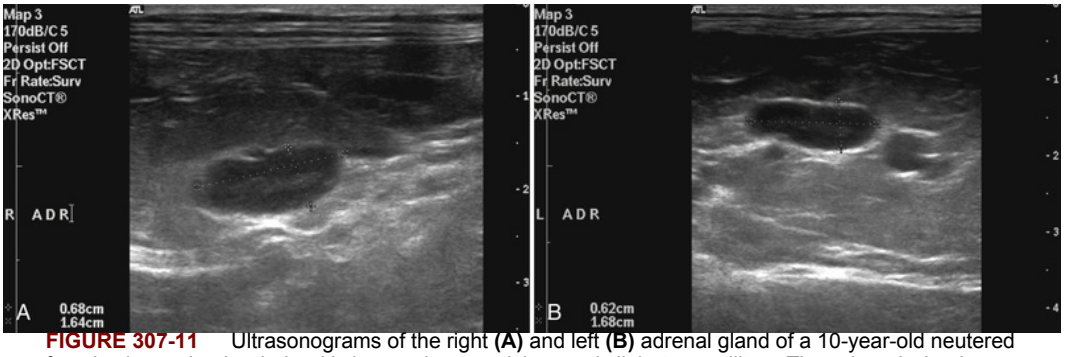

FIGURE 307-11 Ultrasonograms of the right **(A)** and left **(B)** adrenal gland of a 10-year-old neutered female domestic shorthair with hyperadrenocorticism and diabetes mellitus. The adrenal glands are both enlarged, with the width greater than 0.53 cm (>5.3 mm). The adrenals are of normal shape and

similar size, indicating that the cause is pituitary dependent.

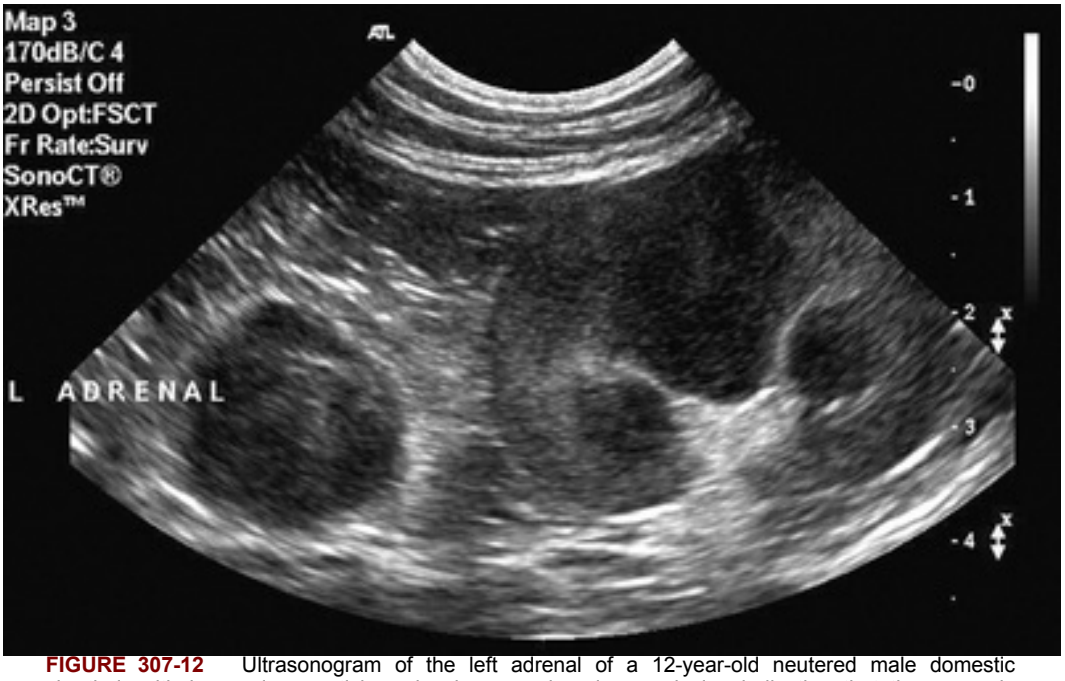

FIGURE 307-12 Ultrasonogram of the left adrenal of a 12-year-old neutered male domestic shorthair with hyperadrenocorticism showing an adrenal mass lesion indicating that the cause is adrenal dependent.

Computed Tomography (CT) and Magnetic Resonance Imaging (MRI) Scans

CT and MRI scanning have proved useful in the diagnosis of adrenal tumors, adrenal hyperplasia and pituitary tumors. Contrast abdominal CT may also help identify tumor invasion of the caudal vena cava, invasion of other blood vessels, or adhesions in the area of the mass. These considerations comprise some of the presurgical planning in cats for whom adrenalectomy is an option.

Correlation between pituitary tumor size and presence or development of neurological signs is not clear. In those cats with neurological signs, MRI or CT examination of the brain is essential if pituitary surgery or irradiation is being considered.

Endocrine Testing

Overview (see E-Table 307-1 and Figure 307-1)

The "best test" for confirming a diagnosis of feline HAC has not been established. Basal cortisol concentrations are of little use in the assessment of adrenal function in cats and therefore dynamic testing is essential (Table 307-4). Measurement of cortisol in feline plasma has not been subjected to as much scrutiny as for dogs. Even assuming similar methodologies, reference ranges generated in different laboratories using different machines cannot be used interchangeably.[38,39] Clinicians should, wherever possible, use the specific reference range from their laboratory and should consult with their laboratory personnel before using values from other laboratories or the literature in test interpretation.

TABLE 307-4

Approximate Frequency of Endocrine Findings in Feline HAC

TEST	CRITERIA FOR DIAGNOSIS OF HAC	FREQUENCY
ACTH stimulation test	60 or 90 minute post ACTH cortisol greater than	28 of 39

	400 nmol/L (14.5 mcg/dL)	(71%)
Low-dose (0.01 mg/kg IV) dexamethasone screening test positive (greater than 27 nmol/L [1 mcg/dL])	8 hour post dexamethasone greater than 27 nmol/L (1 mcg/dL)	25 of 26 (96%)
Dexamethasone suppression test (0.1 mg/kg IV)	8 hour post dexamethasone greater than 27 nmol/L (1 mcg/dL)	38 of 45 (84%)
Endogenous ACTH	Greater than 20 pg/mL (=4.4 pmol/L) to diagnose PDH	14 of 19 (73%)
Adrenal ultrasound	Bilateral adrenomegaly or symmetrical adrenal glands (PDH) Adrenal mass (ADH)	49 of 53 (92%)

From data provided in eight published series of cases with a combined total of 84 cases.[3-10] Note that four of these series (a total of 37 cases) were selected by treatment modality.

ACTH Stimulation Test (ACTHST)

The ACTHST can be useful for the diagnosis of feline HAC. However, the peak response in cats is variable in both timing and magnitude. Samples should be obtained at 60 and 90 minutes after administering tetracosactrin, 5 mcg/kg or 0.125 mg/cat IV.[40,41] Reported test sensitivity varies from 56 to 80%.[3,6,8,10] Normal cats and cats with chronic disease rarely have a post-ACTH cortisol >400 nmol/L (>14.5 mcg/dL).[42] However, some conditions (e.g., hyperthyroidism) can result in post-ACTH cortisol concentrations as high as 600 nmol/L (21.7 mcg/dL). As in the dog, cortisol values >600 nmol/L (>21.7 mcg/dL) are quite suggestive, and values between 400 and 600 nmol/L (14.5 and 21.7 mcg/dL) are supportive of HAC in the context of appropriate clinical signs. However, cats with HAC tend to have lower cortisol concentrations than dogs with HAC and they rarely have post-ACTH cortisol concentrations >800 nmol/L (>29 mcg/dL). An ACTHST result within that laboratory's reference interval does not rule out a diagnosis of feline HAC.

Dexamethasone Suppression Tests (DST)

Both the degree and duration of adrenocortical suppression produced by dexamethasone varies among healthy cats. Generally, the "low-dose" DST uses a higher dosage (0.1 mg/kg IV) in cats than for dogs. Serum cortisol concentrations in healthy cats are reliably suppressed with this dose and the test is excellent if used as a screening test to distinguish cats with HAC from those who do not have the condition. However, the test has also been used as an aid in discriminating ADH from PDH without evidence that this is an appropriate use.[3,5,42] Importantly, cortisol concentrations after giving 0.1 mg/kg dexamethasone are suppressed in cats with DM but not those with HAC and DM, independent of glycemic control.[43] The 0.1 mg/kg DST has good specificity. However, while cortisol fails to suppress at either 3-4 or 8 hours in cats with ADH, some cats with PDH suppress at 8 hours, reducing sensitivity. It has been recommended that the low-dose DST, using the standard "canine dose" (0.01 mg/kg IV; with blood samples obtained before and 8 hours after injection), be used to "screen" cats for HAC.[3] However 20% of healthy cats do not suppress after being given 0.01 mg/kg.[44] Thus, increased sensitivity is offset by a lack of specificity. This "low-dose DST" may be useful in certain circumstances since "normal suppression" would make the diagnosis of HAC quite unlikely. Equally, if a cat showing clinical signs of HAC has a "normal response" on the 0.1 mg/kg DST, then the 0.01 mg/kg test may be indicated. Four cats in one study had both dexamethasone tests performed, but their results did not alter diagnosis in any cat.[10]

Urine Corticoid : Creatinine Ratio (UCCR)

Urine should always be collected at home (not in the hospital environment) as any stressful situation may increase the ratio. Almost all cats with HAC will be positive (good sensitivity), but false-positive test results may be seen in cats with non-adrenal illness (poor specificity).[45] Importantly, hyperthyroid cats often have increased UCCR results.[42,46] Thus, the UCCR must be regarded as lacking specificity in a group of cats that might be suspected of having HAC. It is known that there are considerable differences between tests for urinary corticoids in the dog. Since the same may be true regarding assay validity for cats, results may vary according to the assay; thus, an individual reference range should be generated for a specific test rather than

using published reference ranges.[47,48]

Other Tests

A combined DST/ACTHST protocol was suggested for cats; however, it has not been sufficiently validated to be recommended. Thyroid hormone concentrations are usually normal in cats with HAC, which is important since hyperthyroidism may be considered in any cat with PU/PD and weight loss. In one study, 4 of 25 cats with HAC had a low thyroxine level.[10] It has been suggested that endogenous ACTH precursors (pro-opiomelanocortin [POMC] and pro-ACTH) may be useful in identifying cats with PDH.[49] However, such assays are not yet widely available.

Tests to Distinguish Between PDH and ADH (see E-Table 307-1)

The reliability of any test for distinguishing cats with PDH from those with ADH has not been assessed. Endogenous plasma ACTH concentrations should be normal or increased in cats with PDH and low or non-detectable in cats with an adrenal tumor. This test appears to be useful for distinguishing PDH from ADH, once the diagnosis of feline HAC has been confirmed. However, it is essential that any assay be validated for cats.[9,10] Radiography, US, CT, and MRI can be extremely helpful in distinguishing PDH from ADH.[3,6,7,49]

Treatment

Cats with HAC, whenever possible, should be treated. Diabetic control will likely improve if treatment is successful and the risk of serious adverse consequences of chronic HAC likely reduced, e.g., skin hyperfragility and unusual or difficult-to-treat infections.

Surgery

ADH

Whenever possible, adrenal tumors should be surgically removed. Accurate diagnostic imaging with abdominal US or contrast-enhanced CT should be employed, if available, to assess for invasion of major vessels or kidneys. Post-operative hypoadrenocorticism is common and requires management with fludrocortisone or desoxycortone pivalate (though this has not been reported). Prednisolone, needed initially, can usually be tapered over time. Diabetic cats may go into remission in the months following surgery. Those that remain diabetic often require much lower insulin doses.[5] Successful laparoscopic adrenalectomy has been reported and should be considered for the treatment of unilateral functional adrenal neoplasia in cats when diagnostic imaging has ruled out intravascular invasion and metastatic disease.[50]

PDH

Surgical options for PDH include trans-sphenoidal hypophysectomy and bilateral adrenalectomy.[5,7] Cats successfully treated with either modality require medical therapy afterwards. Trans-sphenoidal hypophysectomy is the only definitive treatment for PDH. The first report of 7 cats with PDH undergoing trans-sphenoidal hypophysectomy included 2 cats dying within weeks. However, in the surviving 5 cats the treatment was successful. With greater experience in managing concurrent illnesses and careful closure of the soft palate, success rates will improve.[7,51] Post-operative treatment for central diabetes insipidus (see ch. 296) is needed. Mineralocorticoid and glucocorticoid replacement are usually required for several weeks. Despite high initial remission rates in dogs with PDH following hypophysectomy, recurrence in about 25% is a concern.[52] Similar rates of recurrence may be seen in cats, though there are no published studies. Morbidity and mortality appear less for cats undergoing bilateral adrenalectomy than dogs; however, complications are frequent.[5,6] Resolution or improvement of the diabetic state may be seen in the months following surgery, but long-term prednisolone and fludrocortisone are required. As such, surgery is not a reasonable option for cats difficult to medicate orally. It should be noted that skin wounds caused by spontaneous tearing should be closed. One of the authors has found tissue glue to be effective, thereby avoiding the need for anesthesia and further risk of tearing. Suturing is also possible.

Medical Treatment

Trilostane

Trilostane, a competitive inhibitor of 3beta-hydroxysteroid dehydrogenase, has been successfully used to treat cats with HAC.[8,9] Of 20 cats in two series, 17 survived for more than 3 months and many survived more than 1 year. This is much better than with any other medical treatment. There have been no pharmacokinetic studies of trilostane or its metabolites in cats; however, on the basis of one case in which cortisol was measured sequentially, it would appear that the effect on cortisol production is rapid and its duration of action is <12 hours.[8] Manufacturers do not recommend trilostane be used if concurrent hepatic or renal disease is present.

Trilostane should be given at a starting dosage of 1-2 mg/kg PO q 24 h. However, it would seem logical to give trilostane at the same frequency as insulin. If insulin and trilostane are being used twice daily, the trilostane dose should also be divided, given at a dosage of 0.5-1 mg/kg PO q 12 h. Reformulation is often necessary. Trilostane seems to be well-tolerated and improvement is often noted within weeks.[9] In a series of 9 cats with HAC and DM treated with trilostane, insulin dosage requirements decreased by 36% on average in 6 cats. One cat had an insulin dosage requirement increase. DM remission did not occur.[9] Important possible complications of trilostane include anorexia, lethargy, hyponatremia and/or hyperkalemia.

There are no published criteria critically evaluating any method to monitor treatment response. Although the ACTHST is often used, target cortisol concentrations and test timing have been extrapolated from dogs. However, cats have been successfully treated with trilostane using these extrapolated values.[8,9] In general, the target is a post-ACTHST cortisol concentration, 4 hours after trilostane dosing, >40 nmol/L (>1.4 mcg/dL) and below about 140 nmol/L (5 mcg/dL). However, ACTHST results have now been shown to be unreliable predictors of clinical status in dogs with HAC being treated with trilostane. Therefore, it is recommended to closely monitor history and physical examination as critical parameters during treatment.

Other Medical Options

Mitotane (o,p'-DDD, Lysodren) appears to be well tolerated by cats despite their sensitivity to chlorinated hydrocarbons.[11] However, mitotane is frequently ineffective in controlling clinical signs of feline HAC in cats.[3] One reported case given 50 mg/kg/day PO for 1 week then 50 mg/kg/wk PO was well controlled for 40 weeks before developing signs compatible with hypoadrenocorticism.[12]

If trilostane and mitotane are unavailable or ineffective, other steroid synthesis inhibitors may be used. Metyrapone, an inhibitor of the 11beta-hydroxylase enzyme that converts 11-deoxycortisol to cortisol, proved effective at least transiently in controlling clinical signs and suppressing cortisol production in one cat (65 mg/kg PO q 12 h).[14] Whether long-term therapy with metyrapone can control feline HAC or whether rising ACTH concentrations eventually break the blockade has not been determined. It would, however, appear to be potentially useful for presurgical stabilization.[13]

Ketoconazole, an antifungal imidazole, is an inhibitor of steroidogenesis in humans and dogs, but is ineffective in cats. Its safety has been questioned because anorexia, weight loss, vomiting, and diarrhea have been commonly reported. Hepatotoxicosis and thrombocytopenia have also been noted.[53,54] Ketoconazole is no longer available in some parts of the world, having been replaced by itraconazole. There are no reports of the use of itraconazole for feline HAC.

Pituitary Irradiation

For cats with neurologic signs associated with a large pituitary tumor, pituitary radiation therapy can prove beneficial. In one report, neurologic signs and endocrine signs improved following radiation therapy in 7 cats with either HAC or acromegaly caused by large pituitary tumors.[55] Median survival was 17.4 months, but detailed evaluation of changes in endocrine status was not reported. Pituitary irradiation has been associated with improved diabetic control in acromegalic cats, but similar improvement in diabetic control in cats with HAC has not been reported.[56]

Prognosis

Untreated or unresponsive feline HAC is a progressive disorder with a poor prognosis. These cats usually die from severe infection, uncontrolled DM or are euthanized. With appropriate therapy, cats with adrenal adenomas or PDH appear to have a good to excellent prognosis. Many of the diabetic cats with feline HAC require less insulin to manage their diabetes. Complete remission of DM may occur in those cats undergoing

successful definitive treatment for HAC.

CHAPTER 308

Non-Cortisol-Secreting Adrenocortical Tumors and Incidentalomas

Ellen N. Behrend

Client Information Sheet: Non-Cortisol-Secreting Adrenocortical Tumors and Incidentalomas

Introduction

Non-cortisol-secreting adrenal tumors are being recognized more often due to the common use of abdominal ultrasonography (US). An adrenal mass is not necessarily a primary adrenal tumor (AT) and not all ATs are cortisol-secreting. Non-tumor possibilities include nodular hyperplasia, cyst, abscess, hematoma, and granuloma. In one study, 27% of canine and 60% of feline ATs were metastatic lesions.[1] Pulmonary, mammary, prostatic, gastric, and pancreatic carcinomas and melanoma had the highest rates of adrenal gland metastasis in dogs. A primary AT can be benign or malignant and may or may not be functional (i.e., secreting a hormone); myelolipomas or lipomas can occur in the adrenal cortex. Functional masses secrete steroids from the cortex or adrenergic hormones from the medulla, i.e., a pheochromocytoma (see ch. 311). Of primary ATs, approximately 75% are adrenocortical and 25% are of neuroendocrine origin.[2]

Incidentaloma

Clinical Presentation

Ultrasonography is employed routinely for evaluation of abdominal soft tissue structures (see ch. 88). Occasionally, a seemingly incidental adrenal gland mass (IAGM), i.e., an "incidentaloma," is seen. These are defined as "a focal enlargement of the adrenal gland in patients without prior evidence of adrenal gland disease." An AT should be suspected when there is loss of the typical shape of an adrenal gland regardless of size, when asymmetry in shape and size between the adrenal glands is present, or the mass appears to have infiltrated the phrenicoabdominal vein, vena cava, or surrounding soft tissues (see Figures 306-9 and 307-9 to 307-12). The incidence of IAGM is estimated at 4% overall in dogs, but in one study dogs with an IAGM were significantly older and heavier than a control group.[3] Only 17% of dogs with IAGM were <9 years of age, and the median weight of dogs with an IAGM was 21 kg as compared to 14 kg in the control group. Incidence of adrenal incidentalomas in cats is unknown. As the first step, abdominal US should be repeated to ensure that a mass is consistently seen (Figure 308-1). Once an IAGM is confirmed, a number of differentials, as discussed, need to be considered. Many factors influence the aggressiveness of the diagnostic and therapeutic approach. These include the severity of concurrent problems, the original reason for performing abdominal US, age, the likelihood the mass is hormonally active and/or malignant, the size and invasiveness of the mass, and the client's desires.

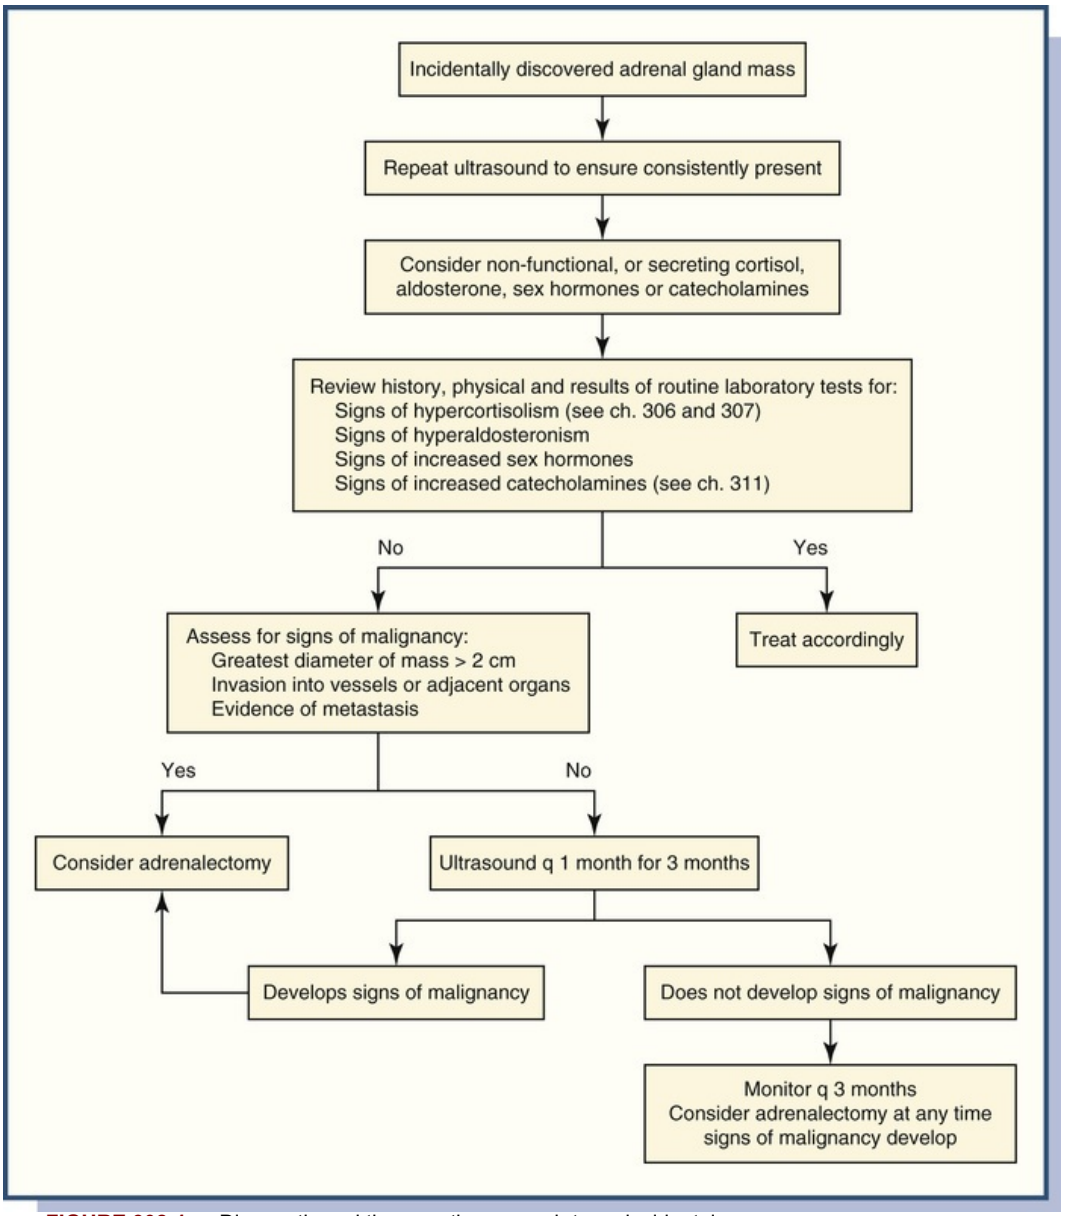

FIGURE 308-1 Diagnostic and therapeutic approach to an incidentaloma.

Diagnostic Approach

Initial Database

Results of the history, physical examination, and routine blood and urine tests should be assessed for evidence of hypercortisolism (see ch. 306 and 307), hyperaldosteronism, pheochromocytoma (see ch. 311), or sex hormone excess. Appropriate testing should be performed as indicated. Aldosterone- and sex hormone–secreting tumors are discussed in this chapter.

Malignancy Assessment with US

While 14 to 30% of IAGMs are malignant, it is difficult to determine whether one particular IAGM is neoplastic and/or malignant.[3] These diagnoses require histologic evaluation. Although cytology has 90-100% accuracy for differentiating cortical from medullary origin, it is not reliable for distinguishing benign from malignant.[4] Imaging may be helpful but must be interpreted carefully. Characteristics that do not help differentiate adrenal adenoma and carcinoma are mineralization or US echogenicity. Both adenomas and carcinomas can contain mineral densities or appear as a mass cranial to the kidney (see Figures 307-9 and 307-

10). While diffuse, ill-defined mineralization usually is associated with adrenal neoplasia, discrete, well-marginated mineralization develops in clinically normal animals and may be a dystrophic change.[5] On US, both benign and malignant ATs may be hypo-, iso- or hyper-echoic compared to the renal cortex or have mixed echogenicity.

Thoracic Radiographs and US-Guided Sampling

Evidence of metastases may be identified on thoracic radiographs. Suspected metastases to abdominal organs, especially the liver, can be visualized and confirmed by US-guided biopsy (see ch. 89). If the greatest diameter of the AT is >2 cm, chances of malignancy and growth are increased.[3,6] Evidence of invasion into surrounding tissues and/or the vena cava is suggestive of a carcinoma. Invasive nature of masses, however, may not be observed.[7] Of 34 dogs with 36 ATs, US was 100% sensitive and 96% specific for identifying the presence of a tumor thrombus within the caudal vena cava. However, when all forms of vascular invasion were evaluated, including vascular wall invasion without a concurrent thrombus, sensitivity and specificity were 76% and 96%, respectively.[8] The presence of tortuous vessels and heterogeneity of contrast enhancement as judged by contrast-enhanced US may also be markers of malignancy.[9]

Computed Tomography (CT)

On abdominal CT, poor glandular demarcation, irregular contrast enhancement and a non-homogenous texture are evidence of malignancy.[10] Vascular invasion can be detected using CT with high, but not perfect, accuracy.[11-13] In one study, vascular invasion was identified correctly using contrast-enhanced CT in 11 of 12 dogs. The sensitivity and specificity of contrast-enhanced CT for vascular invasion, compared with surgery or necropsy, were 92% and 100%, respectively. In one dog, invasion of the phrenicoabdominal vein was not identified on CT.[11] Conversely, enlarged adrenal glands may adhere to or compress the vena cava suggesting invasion when not present.[10]

Management and Follow-Up

If the IAGM is suspected to be malignant, adrenalectomy is recommended. If clinical signs, physical examination, or results of routine blood and urine tests are not consistent with a functional AT, there is no evidence of tissue or vascular invasion or of malignancy, and the tumor is <2 cm in greatest diameter, a conservative non-surgical approach is suggested. Initially, monthly US monitoring is recommended to determine if the mass is growing or changing in appearance. Growth of IAGM is unpredictable. In a study on 7 dogs with an IAGM, 3 of the suspected masses were not identified >4 months later on repeat US and no growth was detected after >6 months in 2 dogs. In 1 dog, the IAGM grew from 1.6 to 2.5-cm in greatest diameter and had invaded the vena cava within 10 months. In 1 dog, the IAGM grew from 2.5 to 3.1 cm in greatest diameter within 8 months.[3] In 9 dogs with non-cortisol-secreting AT followed for 12 months, no change was seen in 7. The two tumors that did grow were originally 2.0 and 2.5 cm in length.[6]

If an IAGM has not increased in size after 3 months, the time interval between US evaluations can be increased. However, if the IAGM is enlarging, changing in appearance, compressing or infiltrating surrounding blood vessels or soft tissues, or if clinical signs affiliated with excess hormone secretion develop, adrenalectomy may be warranted. For non-cortisol-secreting ATs, median survival without surgery in 14 dogs was 29.8 ± 8.9 months (range 1-96 months). Larger tumor size was associated with shorter survival.[6]

Aldosterone-Secreting Adrenal Tumors

Aldosterone is the principal mineralocorticoid synthesized and secreted by the zona glomerulosa, the outermost zone of the adrenal cortices. Its primary functions are regulation of serum sodium (Na) and potassium (K) concentrations and intravascular fluid volume homeostasis. Increases in serum K directly stimulate aldosterone secretion. Decreases in blood pressure, primarily sensed within the kidneys, stimulate synthesis and release of renin which, through angiotensin II, stimulates aldosterone secretion, i.e., the renin-angiotensin-aldosterone system (RAAS; see ch. 246). Aldosterone acts on distal nephrons to promote Na reabsorption and K and hydrogen excretion. In conserving Na, aldosterone indirectly conserves water, raising blood volume and, in turn, blood pressure; it also directly increases blood pressure via enhancement of total peripheral resistance (see ch. 157). Aldosterone is synthesized in heart, brain and vasculature tissues as well, where it may have paracrine or autocrine actions.[14]

Hyperaldosteronism can be primary or secondary. Primary hyperaldosteronism (PHA) is defined as autonomous aldosterone secretion by adrenocortical cells. It is characterized by circulating aldosterone excess and, through negative feedback, renin suppression. Secondary hyperaldosteronism is the result of a condition, e.g., heart failure or chronic kidney disease (CKD), which stimulates the RAAS. Thus, it is associated with enhanced renin concentrations.

Feline Aldosterone-Secreting Tumors

Definitions of Primary Tumor-Related PHA and Non-Tumor-Related PHA

Feline PHA was first reported in 1983,[15] and has been diagnosed increasingly in the last 20 years. Cats with an AT causing PHA, i.e., aldosteronoma, usually have a unilateral cortical adenoma or carcinoma, but bilateral adrenal adenomas have been reported.[16] The incidence of malignant tumors exceeds that of benign.[17] Non-tumor-related PHA (see ch. 324) has been described.[18-20] Affected cats have bilateral adrenocortical hyperplasia and most have evidence of CKD. Some cats have nodular hyperplasia of the zona glomerulosa, renal arteriolar sclerosis, glomerular sclerosis, tubular atrophy and interstitial fibrosis.

Signalment and History in Tumor-Related PHA

No breed predisposition for feline aldosteronoma is apparent. Median age at diagnosis is approximately 13 years and the majority are >10 years of age. Both genders have been represented and most affected cats have been neutered.[21] Clinical signs relate mainly to hypokalemia or systemic hypertension. The most common clinical signs are persistent and progressive weakness, i.e., "hypokalemic polymyopathy,"[17] typically observed when serum K concentration is <3 mmol/L. Cervical ventroflexion, hindlimb weakness (sometimes plantigrade stance), difficulty jumping, listlessness, and ataxia are common owner concerns. A few cats have had limb rigidity, dysphagia, or collapse. Episodic signs and acute onset have been reported.[18] Respiratory failure secondary to respiratory muscle weakness is rare.[22,23] Owners may note acute blindness and/or see a sudden change in eye color, typically due to intraocular hemorrhage or retinal detachment (see ch. 11) secondary to hypertension (see ch. 157). On occasion, hypertension may cause seizures, ataxia or behavior changes as a result of central nervous system edema, hemorrhage or ischemia.[21] Polyuria and polydipsia (PU/PD) occurs in <20% of cats with PHA.[21] Some cats with PHA have had concurrent progestogen excess, which may cause PU/PD.[24,25] Hypokalemia can cause reversible nephrogenic diabetes insipidus and PU/PD. Appetite is variable and can be increased, normal or decreased. Polyphagia may be a sign of concurrent excess of another hormone, e.g., progesterone.

Physical Examination

Physical examination findings are usually related to hypokalemia (see ch. 68) or hypertension (see ch. 157). Weakness is usually apparent. Evidence of hypertension includes tortuous retinal vessels and retinal detachment, hemorrhage, and/or edema (see ch. 11). Clinical signs consistent with glucocorticoid or progestogen excess include fragile skin, alopecia and a pot belly (see ch. 307). Heart murmurs, gallop rhythms or arrhythmias may be auscultated secondary to left ventricular hypertrophy, a sequela of hypertension (see ch. 55).

Diagnosis

Routine Laboratory Testing

The single abnormality typical for PHA on routine laboratory testing is hypokalemia (see ch. 68). Most cats with an aldosteronoma have had moderate to severe hypokalemia, possibly because PHA is not considered until persistent hypokalemia, especially despite K supplementation, is documented.[17] An increased urinary fractional K excretion can confirm the etiology of hypokalemia to be renal (see ch. 73). Due to an "aldosterone escape" phenomenon, hypernatremia is uncommon in PHA. Hypertension and volume expansion can overcome the Na-sparing effects of aldosterone and cause natriuresis (see ch. 73). Creatine kinase (CK; see ch. 66) is usually increased due to hypokalemic myopathy, but its severity is variable. Metabolic alkalosis is common, likely due to aldosterone-mediated hydrogen ion excretion.[17] Aldosteronoma should be considered

in any cat with unexplained hypertension, especially if refractive to therapy. About 85% of affected cats are persistently hypertensive.[14]

Imaging

Radiology is not often helpful, but a large tumor may be visible on abdominal imaging (see Figure 307-9). Adrenal calcification is present in approximately 33% of older, healthy cats, and should not be over-interpreted (see Figure 307-10). Pulmonary metastases are uncommon. Conversely, US is highly useful. All reported cats with aldosteronoma have had an AT detected with US (see Figures 307-11 and 307-12). A few cats have had bilateral AT and only one of two tumors visualized.[16,26] The contralateral adrenal gland should be evaluated since a decrease in size suggests the AT is functional and secreting glucocorticoids or progestogens.[25] Bilateral masses are uncommon, but do occur.[16] Evidence of malignancy should be sought. Lack of apparent invasion into surrounding tissues or vasculature should be viewed with caution, as US has failed to identify existing vascular invasion in some cats with aldosteronoma.[26,27] Abdominal CT and magnetic resonance imaging (MRI) can be used, but reports are limited.[16,27] Adrenal mass cytology can be helpful in determining origin, but not function or its malignant versus benign nature.[28]

Serum Aldosterone

While presence of an AT in a cat with persistent hypokalemia and/or hypertension is highly indicative of aldosteronoma, confirmation relies on demonstration of increased basal aldosterone concentrations. Assays are usually available and no special sample handling is required. To date, aldosterone concentrations have been increased in all cats reported to have an aldosteronoma. The highest aldosterone concentrations occur with AT. However, aldosterone concentrations reported for primary and secondary hyperaldosteronism overlap. Concentrations >1000 pmol/L have been reported with secondary PHA, especially in cats with CKD. In addition, as suspicion for PHA is becoming more common, testing will likely occur earlier in the course of disease. In early disease it is anticipated that aldosterone concentrations in some cats with PHA will be within the upper end of reference ranges.

Plasma Renin Activity (PRA)

Since increased aldosterone concentrations are not 100% specific for a diagnosis of aldosteronoma, diseases that cause secondary hyperaldosteronism must be ruled out. Hypertensive cats can have elevated aldosterone concentrations.[29] It is difficult to distinguish PHA from CKD, and they often coexist. CKD can cause hyperaldosteronism and vice versa. Ideally, PRA and aldosterone concentrations would be assessed on one sample. In cats with PHA, PRA has been below or within the reference range because the hyperaldosteronism and hypertension exert negative feedback to decrease PRA. In secondary hyperaldosteronism, such as CKD, PRA is increased. Unfortunately, a feline PRA assay is not currently commercially available in the United States; in addition, they require a large volume of plasma, and separated plasma must be instantly frozen.

Other Endocrine Tests

Other confirmatory tests for PHA, besides PRA, have been investigated. Measurement of a urinary aldosterone to creatinine ratio (UACR) theoretically provides a reflection of aldosterone concentrations over time, whereas blood provides the concentration at a single moment in time. However, in 9 cats with PHA, only 3 had increased UACR.[19] A test requiring administration of fludrocortisone, a synthetic corticosteroid with mineralocorticoid activity, has also been investigated, as oral mineralocorticoid administration (0.05 mg/kg PO q 12 h × 96 h) significantly suppresses aldosterone secretion (median 78% from baseline) in healthy cats.[19,30] One cat with confirmed metastatic aldosteronoma had an increased UACR following fludrocortisone administration.[30] The diagnosis of PHA in hypertensive cats, with or without hypokalemia, can be excluded if the UACR on day 4 suppresses >50%, from baseline.[19]

Thus, fludrocortisone suppression has merit as a diagnostic test for feline PHA. However, urine is not the route of excretion of major aldosterone metabolites in cats and urinary aldosterone concentration may not accurately reflect blood concentrations.[31] Indeed, in one study, basal plasma aldosterone concentrations more clearly separated cats with and without PHA than did the UACR.[19] Additionally, urine collection from cats in a hospital setting typically requires cystocentesis, which can be difficult with insufficient bladder size or a fractious cat. Urine collection at home can be cumbersome or impossible and twice-daily oral administration of fludrocortisone for 4 days can be challenging. Further, the fludrocortisone can suppress serum K

concentrations below reference ranges and cause muscle weakness.[19] In healthy cats, administration of only 3 doses of fludrocortisone (0.05 mg/kg PO q 12 h) significantly suppressed serum aldosterone concentration, but further study in cats with PHA is needed to determine test utility.[32] Due to the glucocorticoid activity of fludrocortisone, as few as 3 doses significantly suppress cortisol concentrations; thus, signs of glucocorticoid deficiency could occur after a suppression test is complete.[32]

In conclusion, suspicion of aldosteronoma arises with identification of hypokalemia and hypertension (Figure 308-2). Elevated plasma aldosterone concentration and identification of a discrete tumor within an adrenal gland are required for diagnosis. Histopathologic confirmation of tumor origin, resolution of clinical signs, and normalization of aldosterone concentrations postoperatively further confirm the diagnosis.

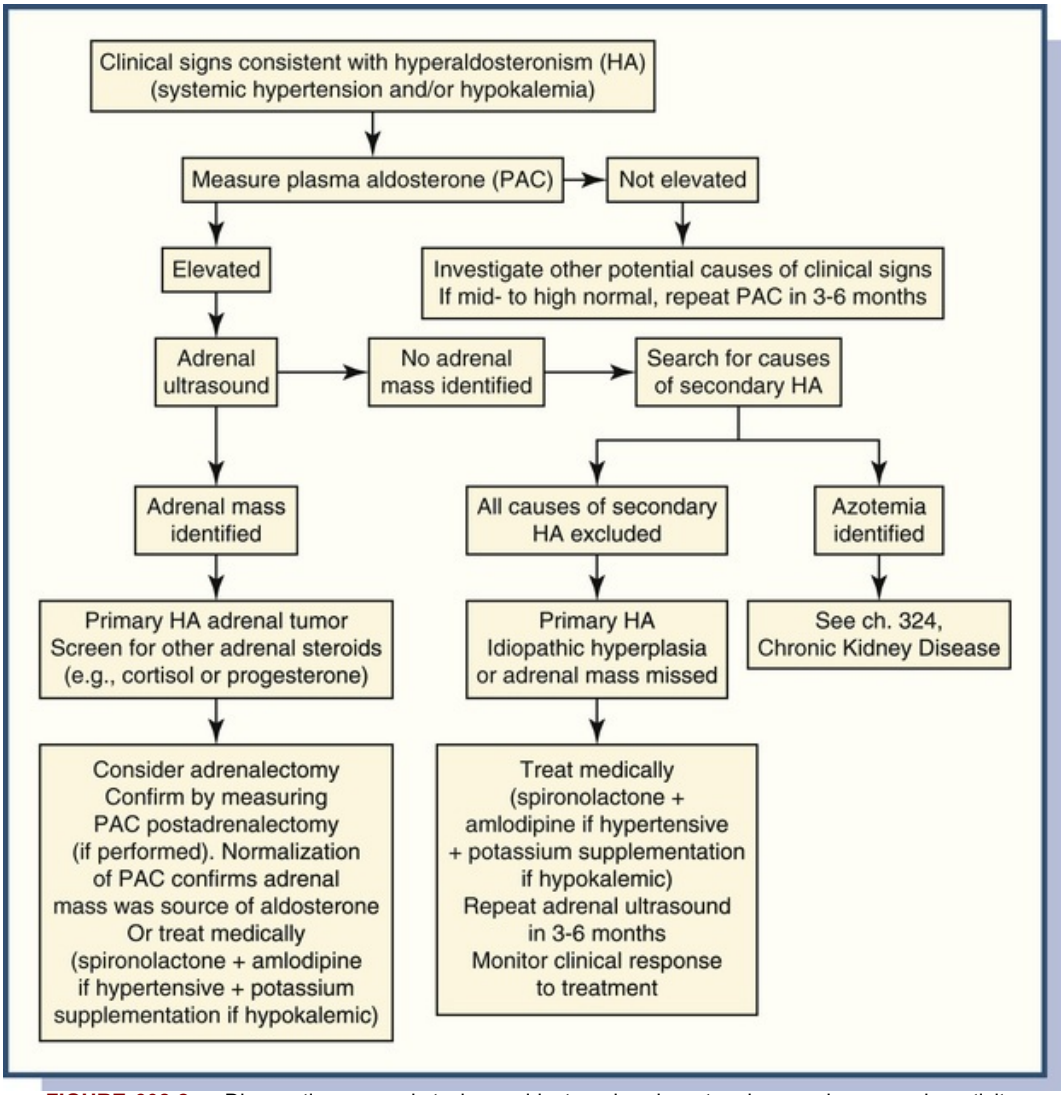

FIGURE 308-2 Diagnostic approach to hyperaldosteronism in cats when a plasma renin activity (PRA) assay is not available. (Reprinted with adaptation from Refsal KR, Harvey AM: Primary hyperaldosteronism. Treatment and Prognosis

Adrenalectomy via celiotomy or laparoscopy is the treatment of choice for feline aldosteronoma.[27,33] Unilateral adrenalectomy is potentially curative; however, it is a high risk, challenging procedure and should be undertaken only by experienced surgeons in a hospital with a well-equipped intensive care unit (ICU) and 24-hour observation and care. Preoperatively, hypokalemia should be corrected with oral and/or parenteral

K. Assessment for tumor thrombi and metastases is imperative. The presence of tumor thrombi may increase the possibility of complications. Metastases may decrease chances of survival, and surgery will not be curative. In addition, the possibility of the tumor secreting a hormone other than aldosterone should be considered and tested for as indicated. If a glucocorticoid or progestogen is secreted, adrenalectomy can cause transient cortisol deficiency (see ch. 307).

In theory, autonomous aldosterone secretion from an AT should suppress normal zona glomerulosa cells within the contralateral adrenal gland and hypoaldosteronism could occur postoperatively. Serum electrolyte concentrations must be monitored frequently and IV fluid therapy adjusted accordingly to maintain serum K and Na concentrations within or near reference intervals. Administration of a synthetic mineralocorticoid post-surgically to manage hypoaldosteronism is not usually necessary.

In earlier reports, perioperative complications occurred in 8 of 17 cases, including lethargy, anorexia, vomiting, dysphagia, hyperthermia, upper respiratory infection, intra- or post- operative intra-abdominal hemorrhage, acute kidney injury, sepsis and suspected thromboembolism. In 6 of these 8 cats, the outcome was fatal.[14,27] In a more recent report, only 2 of 10 cats with aldosteronoma had a fatal outcome.[27] The mean perioperative hospital stay for all cats was 5 days. Two cats were euthanized 2 and 10 days postoperatively due to surgical complications (1 also had a pancreatic mass). Hemorrhage was not predicted by tumor type, location, size, or vascular invasion. Of the 8 cats discharged from the hospital, blood pressure and serum K concentrations normalized and long-term therapy was unnecessary. Long anesthesia time was significantly associated with decreased survival. Median survival was 1,297 days (range 2-1,582 days) and there was no significant difference in length of survival comparing cats with adenoma (median, 1,329 days) and those with adenocarcinoma (248 days; P = 0.2), but the number of cats was small. Blindness due to retinal detachment may resolve with time (see ch. 11). No deaths after discharge were known to be due to the AT. However, 2 cats were euthanized due to CKD, which would have been exacerbated by the PHA.[27]

Cats that do not undergo surgery can be treated medically to control the hypokalemia and/or systemic hypertension. Potassium supplementation (2-6 mEq PO q 12 h) has been effective. Amlodipine besylate (0.625-1.25 mg/cat PO q 24 h) is the treatment of choice to lower blood pressure (see ch. 158). Up to 2.5 mg can be used if the blood pressure is not controlled; however, hypertension may become refractory to the medication. Spironolactone, a competitive aldosterone receptor antagonist, can be used (2-4 mg/kg PO q 24 h) to both decrease blood pressure and increase K. Doses in excess of 4 mg/kg may cause anorexia, vomiting and diarrhea. Medical management has yielded survival times of 7 months to 984 days in 4 cats, but another survived only 50 days due to owner non-compliance.[17]

Canine Aldosterone-Secreting Tumors

Background and Clinical Signs

In dogs, PHA is typically caused by a unilateral solitary adenoma or carcinoma. Rarely, bilateral idiopathic adrenocortical hyperplasia is diagnosed.[34-37] Primary hyperaldosteronism is a disease of middle-aged to older dogs and common owner concerns include lethargy, anorexia, weakness and PU/PD. Also, like cats with an aldosteronoma, tumors secreting both mineralocorticoids and glucocorticoids occur uncommonly,[35-37] so clinical signs and laboratory changes consistent with glucocorticoid excess may be present.

Diagnosis

The presence of hypokalemia and a serum Na concentration at the upper end of or mildly above the reference range together with finding an AT on US should raise suspicion for PHA. Some aldosterone-secreting tumors are quite small and not seen on US. Alternatively, idiopathic adrenocortical hyperplasia may be present. Other findings consistent with a diagnosis of PHA include systemic hypertension and the presence of a metabolic alkalosis. Confirmation of an aldosteronoma requires documentation of an increased baseline plasma aldosterone concentration and suppressed PRA in conjunction with exclusion of other causes of hypokalemia. In dogs with aldosteronoma, aldosterone concentrations have been >3000 pmol/L. Unfortunately, a canine PRA assay is not currently available. Urine tests, such as the UACR, may have limited to no diagnostic value in dogs. The major aldosterone forms that are present in human urine are free aldosterone, aldosterone-18-glucuronide and tetrahydroaldosterone.[38] Kits available for aldosterone measurement detect free aldosterone and aldosterone-18-glucuronide (after acid hydrolysis of the glucuronide). Canine urine contains less aldosterone-18-glucuronide than does human urine and, unlike cats or people, contains no detectable free aldosterone.[31]

Treatment

Unilateral adrenalectomy is the treatment of choice for a solitary adrenal mass, especially if no evidence of distant metastasis, vascular invasion, or infiltration into the kidney or body wall is found. Oral K, mineralocorticoid receptor blockers (spironolactone), and anti-hypertensive drugs (amlodipine) should be administered until surgery can be performed. Medical therapy is indicated for the long-term management of PHA when adrenalectomy is not performed and for dogs with suspected idiopathic adrenocortical hyperplasia.

Serum electrolyte concentrations must be monitored frequently postoperatively and IV fluid therapy adjusted to maintain serum K and Na concentrations within or near reference intervals. If hypokalemia persists, oral K supplementation can be initiated. Serum ionized magnesium concentrations should be monitored and hypomagnesemia treated, especially if hypokalemia is refractory to IV fluid therapy (see ch. 68). Mineralocorticoids (oral fludrocortisone acetate or injectable desoxycorticosterone pivalate [DOCP]) should be administered if hyperkalemia and hyponatremia persist for longer than 72 hours, but this is rarely needed. Only one injection of DOCP is usually needed and if daily fludrocortisone acetate is employed, it can usually be tapered and discontinued within a week. Systemic hypertension usually improves or resolves within 48 to 72 hours of adrenalectomy. Anti-hypertensive medication should be initiated if hypertension persists. Attempts to wean off anti-hypertensive medications should be initiated during the ensuing month. Glucocorticoid replacement therapy is usually not indicated postoperatively, unless the tumor was secreting a glucocorticoid. An ACTH stimulation test can be performed 6 to 8 hours after adrenalectomy to assess the function of the remaining adrenal gland (see ch. 306).

Prognosis

Surgical removal of an adenoma carries an excellent prognosis. The prognosis is guarded for dogs with a carcinoma. If metastatic sites exist, hyperaldosteronism, hypokalemia and the associated clinical signs usually persist or recur. However, these tumors can be slow-growing and recurrence may not occur for more than a year. Management of recurrence with metastasectomy can be successful.[37] The prognosis for idiopathic adrenocortical hyperplasia is unknown and depends on the effectiveness of medical therapy. Bilateral adrenalectomy in theory, may offer a cure, but glucocorticoids and mineralocorticoids would be needed for life.

Non-Aldosterone, Mineralocorticoid-Secreting Tumors

Tumors secreting mineralocorticoids other than aldosterone, e.g., desoxycorticosterone, are rare.[39-41] Clinical findings are the same as with PHA but aldosterone concentrations are low. As no desoxycorticosterone assay is commercially available, diagnosis would be presumptive based on the constellation of diagnostic test results.

Sex Hormone–Secreting Adrenal Tumors

Overview

Adrenocortical tumors have the potential for synthesizing and secreting a variety of steroids other than cortisol and aldosterone. Excess secretion of sex hormones by tumors may be associated with aberrant biosynthetic pathways and/or enzyme deficiencies. Progestins may bind glucocorticoid receptors or displace cortisol from its binding protein, increasing serum free cortisol concentrations.[42,43] In dogs, progestins suppress endogenous ACTH secretion and cause adrenal atrophy, actions consistent with glucocorticoid activity.[44]

Feline Sex Hormone–Secreting Adrenocortical Tumors

Clinical Information

A small number of cats with sex hormone–secreting AT has been described.[24,25,45-48] Six cats ranged in age from 7-15 years; 2 were spayed females and 4 were neutered males. Breeds included domestic longhair and shorthair and Himalayan. A 14-year-old, female spayed domestic shorthair cat with bilateral adrenal enlargement and excessive estradiol and testosterone production has been reported.[49] Excess production of a

progestin (e.g., progesterone or 17-hydroxyprogesterone) may cause signs of cortisol excess, such as a poor haircoat, dermal atrophy and skin fragility. Three of 4 cats with a progesterone-secreting tumor had diabetes mellitus, described as poorly regulated in 2.[24,25,45,46] Excess androgen production can cause a change in the urine odor, urine spraying behavior, aggression and development of penile spines.[47,49] Hyperestrogenemia may cause cyclic estrous behavior and vulvar enlargement.[48,49] Tumor type was known in 5 cats: 1 adenoma, 4 carcinoma.[24,25,45-48]

Diagnosis

Suspicion of a sex hormone–secreting tumor begins with clinical signs. No result of a routine test, e.g., CBC or serum biochemistry profile, will aid in diagnosis. Finding an AT on US should increase suspicion. As with aldosteronomas, sex hormone–secreting tumors are typically seen with US. In one cat, however, the tumor had replaced the normal tissue and only mild enlargement and a round shape were noted on US.[48] Signs of malignancy should be sought and thoracic radiographs obtained.

Definitive diagnosis of tumor functionality and type of hormone secreted has been made, for the most part, using ACTH stimulation testing (125 mcg cosyntropin IV per cat) with blood drawn before and 1 hour after injection.[24,25,45-48] Cortisol and sex hormones are measured pre- and post-ACTH. If a progestin is secreted, cortisol concentrations will be at the lower end or below the reference range. Thus, if a cat appears to have hypercortisolism but does not have the expected abnormalities on tests for hyperadrenocorticism, consideration of a sex hormone disorder is reasonable. Estradiol does not increase with ACTH injection. In a cat with an estrogen-secreting tumor, the basal estradiol concentration was increased but the post-ACTH value was not.[48]

Treatment and Prognosis

Surgical or laparoscopic removal of an AT is the treatment of choice. Prognosis may depend on presence of metastasis, successful tumor removal, and patient stability preoperatively. If cortisol secretion has been suppressed by the tumor, glucocorticoid replacement must be given postoperatively. Hyperprogesteronism can cause issues such as thin skin that make a cat a poor surgical candidate.[46] Four cats with sex hormone–secreting AT have undergone adrenalectomy. One cat died due to unknown causes 3 days postoperatively.[24] One cat was euthanized 10 months postoperatively with CKD, and 2 cats were lost to follow-up at 8 weeks and 12 months post-surgery.[45,47,48] Aminoglutethimide is the only medical treatment that has been tried to control sex hormone secretion from an AT, and response was transient.[46] Trilostane was used to control secretion of sex hormones in a cat with bilateral adrenal hyperplasia. After approximately 6 months, clinical signs returned, and no further assessment or treatment were sought.[49]

Canine Sex Hormone–Secreting Adrenocortical Tumors

Clinical Information

A small number of dogs with sex hormone–secreting AT has been reported but none with clinical signs of hyperestrogenemia or hyperandrogenemia.[50-53] Two dogs with AT, an 11-year-old spayed female Labrador Retriever and a 9-year-old castrated male miniature Poodle, had clinical signs of hyperadrenocorticism despite markedly suppressed ACTH-stimulated serum cortisol concentrations.[52] Thus, the clinical signs were likely due to hyperprogesteronemia. Both dogs had PU/PD and polyphagia. One also had changes in coat color, weight gain, increased panting and abdominal enlargement. Signalment and clinical signs in other dogs with sex hormone–secreting tumors were not delineated but presenting complaints were stated to be consistent with hypercortisolism.[50,51,53]

Diagnosis

Suspicion for a sex hormone–secreting AT will arise with clinical signs. The primary indication for sex hormone measurement is the finding of cortisol concentrations below reference intervals in a dog tested for hyperadrenocorticism using ACTH stimulation or low-dose dexamethasone suppression testing (see ch. 306).[52,53] If exogenous glucocorticoids in any form or medications that alter cortisol synthesis (e.g., ketoconazole) are ruled out, a sex hormone–secreting AT may be present. Ultrasound finding of an AT further supports the diagnosis, but lack of a detected adrenal mass does not rule out the diagnosis.

To document sex hormone elevations, an ACTH stimulation test should be performed (see ch. 306). Sex

hormones are measured in samples drawn before and 1 hour after administration of ACTH. However, sex hormone concentrations should be interpreted cautiously. For estradiol, a wide range of variability exists within and between dogs; random, basal estradiol concentrations in individual dogs often exceed the reference range.[54] Many dogs without hyperadrenocorticism can have sex hormone concentrations as much as 40-50% above reference intervals.[55-57] In 6 dogs with pheochromocytoma or non-functional AT, androstenedione, progesterone, 17-hydroxyprogesterone, testosterone and/or estradiol concentrations were increased.[58]

Treatment and Prognosis

Adrenalectomy, in theory, is the treatment of choice. However, detailed information is available for only two dogs with sex hormone–secreting AT. One dog underwent adrenalectomy and did well for at least 13 months after surgery. A second was treated medically with mitotane for approximately 20 days at a dosage of 47 mg/kg daily with no response, and the owners declined further therapy. Given the resistance of AT in general to mitotane, lack of response is not surprising given the dose and short duration of treatment.

CHAPTER 309

Hypoadrenocorticism

Rebecka S. Hess

Client Information Sheet: Hypoadrenocorticism (Addison's Disease)

Introduction

Dr. Thomas Addison first described disease of the "supra-renal capsule" (adrenal cortex) in an 1855 case series describing 11 people with what is now known as hypoadrenocorticism (HA) or Addison's disease.[1] The adrenal cortex is divided into three layers: the outermost zona glomerulosa, the widest middle zona fasciculata, and the innermost zona reticularis. The adrenal cortex secretes glucocorticoids and mineralocorticoids, essential for survival. Therefore, hypofunction or dysfunction of the adrenal cortex, such as that seen in HA, can be life-threatening. Glucocorticoids are secreted from all three cortical layers whereas aldosterone, the most important mineralocorticoid, is secreted from the zona glomerulosa, the only zone containing aldosterone synthase. Basic adrenal physiology is discussed in ch. 306. Hypoadrenocorticism is common in dogs and rare in cats. Therefore, the discussion that follows pertains to dogs and is followed by a brief discussion of HA in cats.

Pathophysiology

In humans, HA is a rare autoimmune disorder. Most patients have antibodies against the steroidogenic enzyme 21-hydroxylase, present in all three adrenal cortical layers.[2] These antibodies are believed to lead to destruction of the adrenal cortices.[3] Presence of 21-hydroxylase antibodies or other adrenal autoantibodies in dogs with naturally-occurring HA has not been documented in sufficient numbers to support antibodies being the cause.[4] However, lymphoplasmacytic adrenalitis and adrenocortical atrophy have been documented in some dogs with HA, in support of this being an immune-mediated disease.[5] Dogs that develop both HA and hypothyroidism support the concept of a systemic immune-mediated process.[6] Adrenal lymphocytic inflammation and formation of autoantibodies precedes atrophy of other endocrine glands (such as the thyroid gland). Finally, some of the genetic characteristics of the disease involve immune function.

The concept of a genetic component being involved in the etiology of canine HA is supported by the fact that certain breeds are known to be at increased risk. Familial HA has been reported in some breeds (Leonbergers and Pomeranians) and Great Danes have greater risk as compared with other dogs.[7-9] A study of the heritability of the disease in Bearded Collies revealed that the mode of inheritance was not autosomal dominant and that more than one major gene was involved in the pathophysiology of the disease.[10] However, in Standard Poodles and Portuguese Water Dogs, the inheritance does appear to be influenced by a single locus with a major effect, and the mode of inheritance in these breeds may be autosomal recessive.[11-13] In Portuguese Water Dogs and Springer Spaniels two immune function genes, the major histocompatibility complex coding for dog leukocyte antigens and the cytotoxic T-lymphocyte-associated protein 4, are reportedly associated with HA.[10,14] A third immune function gene, *PTPN22*, is over-expressed in Cocker Spaniels with HA.[15]

The major histocompatibility complex has been reported to have a role in the etiology of HA in the Nova Scotia Duck Tolling Retriever, Cocker Spaniel, Labrador Retriever, West Highland White Terrier, Bearded Collie, and standard Poodle.[14,16,17] However, methodologies employed in some of these studies have come under question and further studies are needed.[18] It is possible that the genetic etiology of the disease is different among breeds. Importantly, it is not yet clear whether any of these genetic differences are

responsible for formation of anti-adrenal autoantibodies and atrophy of the adrenal cortices.

Classification

Primary Hypoadrenocorticism

Primary HA is the most common form of the disease. It involves direct failure of the adrenal cortices. Classic HA involves a decrease in both glucocorticoid and mineralocorticoid secretion from the adrenal glands. *Atypical primary HA* is a term used to describe direct failure of the adrenal cortex in which cortisol secretion is absent but sodium (Na) and potassium (K) concentrations are still normal.[19] Some dogs are initially diagnosed with only a glucocorticoid deficiency based on normal Na and K concentrations but develop hyponatremia and hyperkalemia with time.[7,19,20] In these dogs, the "atypical" HA is transient. However, other dogs diagnosed as having atypical HA maintain normal Na and K concentrations for years.[19,20] Interestingly, some dogs with documented HA with normal Na and K concentrations have low aldosterone concentrations suggesting that maintenance of electrolyte concentration in these dogs is not completely dependent on aldosterone.[20] If HA in dogs is indeed an immune-mediated condition developing due to anti 21-hydroxylase antibodies, it is possible that the destruction of the zona glomerulosa, the aldosterone producing zone, lags behind destruction of the other two zones because its concentrations of 21-hydroxylase are lowest of the three zones.

Primary HA, whether typical or atypical, develops as a result of adrenal cortex atrophy (Figure 309-1). Rarely, HA develops secondary to an infiltrative process which destroys the adrenal cortex. Neoplasia is the most common cause of this rare condition, while tuberculosis, fungal disease, other granulomatous or infectious diseases, and infarcts are possible.[21-23] A rare case of HA in which aldosterone depletion preceded glucocorticoid depletion has been reported.[24] Primary transient or permanent iatrogenic HA can be caused by the drugs used to treat hyperadrenocorticism (Lysodren or trilostane; see ch. 306). Isolated hypoaldosteronism (without glucocorticoid deficiency) has been reported but is extremely rare.

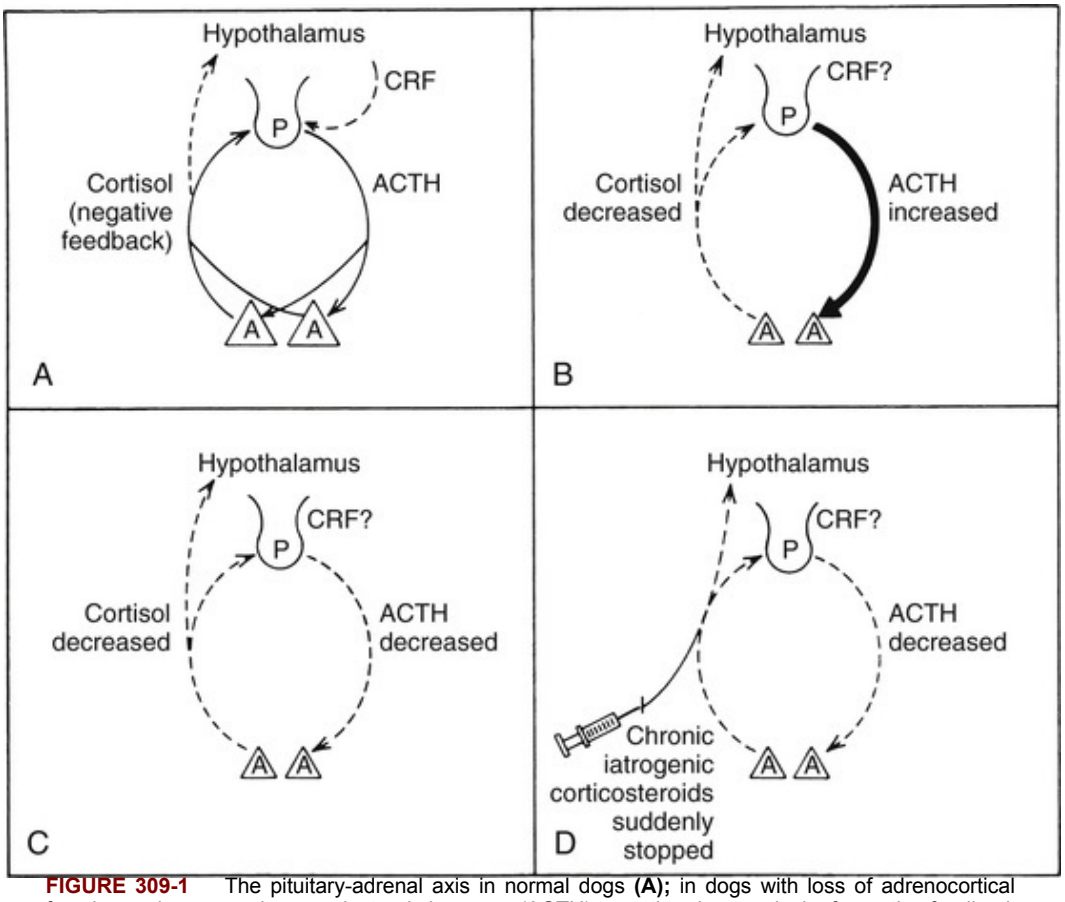

FIGURE 309-1 The pituitary-adrenal axis in normal dogs **(A);** in dogs with loss of adrenocortical function and excess adrenocorticotropic hormone (ACTH) secretion due to a lack of negative feedback

(the most common form of hypoadrenocorticism) **(B);** in dogs with failure to secrete ACTH and secondary atrophy of the adrenal cortex, specifically the zona fasciculata and zona reticularis **(C);** and in dogs that are chronically overtreated with exogenous glucocorticoids, causing insufficiency in pituitary ACTH secretion and secondary atrophy of the adrenal cortex **(D).** *A,* Adrenal; *CRF,* corticotropin-releasing factor (hormone); *P,* pituitary. (From Feldman EC, Nelson RW, Reusch CE, Scott-Moncrieff JCR: *Canine and feline endocrinology and reproduction,* ed 4, St Louis, 2015, Saunders.)

Secondary Hypoadrenocorticism

Secondary HA is rare. It is due to failure within the hypothalamus or pituitary due to neoplasia, inflammation, infection, infarct, or trauma, causing impaired adrenocorticotropic hormone (ACTH) secretion from the pituitary or decreased corticotropin-releasing hormone (CRH) secretion from the hypothalamus.[25-28] As with most diseases of the central nervous system (CNS), neurologic signs and other hormonal deficits would be expected, but enigmatic idiopathic secondary HA has been reported in dogs with no neurologic signs and long-term survival with glucocorticoid therapy alone. Since aldosterone secretion is regulated largely by the renin-angiotensin-aldosterone system (RAAS), and not by ACTH or CRH, this condition involves only glucocorticoid deficiency, with Na and K concentrations normal. Unlike atypical primary HA in which Na and K are also normal, in secondary HA, ACTH concentrations are low (see Figure 309-1). Iatrogenic secondary HA can develop with long-term hypophysectomy or steroid administration (see Figure 309-1).[29] Exogenous steroids suppress ACTH secretion, and time is required for those cells to regain function after steroid administration is stopped. This is the reason that glucocorticoid administration should always be decreased gradually, allowing ACTH secreting cells and then adrenocortical cells to return to normal function.

Signalment, History, Signs, Physical Examination

Age

HA is a disease of young to middle aged dogs, with an approximate median age at diagnosis of 3-4 years. However, the age range at diagnosis is wide: 2 months to 12 years (Table 309-1). Females may be at increased risk for the disease.[7,30] Hypoadrenocorticism can develop in any breed but a specific genetic disposition in certain breeds was discussed. Golden Retrievers, Yorkshire Terriers, Pit Bulls, Chihuahuas, and Lhasa Apsos have decreased risk.[31]

TABLE 309-1

Comparison of Clinical Characteristics and Complete Blood Count Findings in Sick Dogs with and without Hypoadrenocorticism

VARIABLE	53 DOGS WITH HYPOADRENOCORTICISM	110 DOGS IN WHICH HYPOADRENOCORTICISM WAS SUSPECTED AND EXCLUDED	P
Age (years)	4.8 (0.6-11.8)	6.8 (0.4-16.0)	0.07
Vomiting with or without diarrhea	43 (81%)	88 (80%)	0.87
Hematemesis or melena with or without hematochezia	6 (11%)	28 (26%)	0.04
Depression, weakness, or lethargy	51 (96%)	85 (77%)	0.002
Abdominal pain	14 (26%)	45 (41%)	0.07
Systolic blood pressure (mm Hg)	90 (40-150)	140 (50-210)	<0.001
Length of hospitalization (hours)	49 (16-240)	66 (3-312)	0.02
Survived to hospital discharge	52 (98%)	100 (91%)	0.11
Hematocrit (RR: 40.3-60.3%)	46.1 (20.1-68.8)	42.2 (14.1-61.5)	0.006

WBC count (RR: 5.3-19.8 cells × 103/mcL)	11.7 (5.6-31.2)	12.6 (0.9-64.2)	0.87
Neutrophils (RR: 3.1-14.6 cells × 103/mcL)	7.75 (2.77-25.90)	9.87 (0.68-53.93)	0.007
Lymphocytes (RR: 0.9-5.5 cells × 103/mcL)	2.38 (0.80-8.20)	1.07 (0-6.00)	<0.001
Eosinophils (RR: 0-1.6 cells × 103/mcL)	0.57 (0-4.00)	0.12 (0-7.00)	<0.001
Neutrophil : lymphocyte ratio	3.00 (0.76-14.59)	9.51 (1.23-95.15)	<0.001

Data are expressed as median (range) or number (frequency). Hypoadrenocorticism was diagnosed if serum cortisol concentration was ≤1.0 mcg/dL 1 hour after adrenocorticotropic hormone (ACTH) administration. The diagnosis of hypoadrenocorticism was excluded if basal serum cortisol concentration was >2.0 mcg/dL, or if serum cortisol concentration after exogenous ACTH administration was >5.0 mcg/dL.[30]

History and Clinical Signs

History in General

Dogs with HA may exhibit one or more of the following clinical signs with various degrees of severity: anorexia, weight loss, vomiting, diarrhea, lethargy, weakness, polyuria (PU), polydipsia (PD), shaking, and in extreme cases, collapse (see Table 309-1). Most clinical signs are attributed to lack of cortisol. Clinical signs can be mild, vague and wax and wane over a period of time until an astute owner seeks veterinary care or the dog undergoes rapid deterioration requiring emergency intervention. Sometimes stressful circumstances, such as surgery or boarding at a kennel, can push a borderline compensated "occult HA" dog with little adrenocortical reserve and limited capacity to devolve into a crisis.

Role of Glucocorticoids and Mineralocorticoids

Glucocorticoids are important for maintaining the mucosal gastric barrier, which protects the gastrointestinal (GI) mucosa from its acidic contents. Glucocorticoids also help maintain blood pressure, body temperature, and glucose concentrations.[32] If the GI mucosal barrier is ineffective due to HA, anorexia, vomiting, diarrhea, and ensuing weight loss are common, but bloody vomiting and diarrhea are not (see Table 309-1). In a study of dogs admitted for intensive care in need of IV fluid resuscitation, hematemesis, melena, and hematochezia were significantly less common in dogs with HA when compared with non-HA dogs. In that same study, weakness and lethargy were significantly more common in HA dogs.[30] Lethargy, weakness, shaking, and collapse can develop due to hypoglycemia if glucose is inadequately synthesized due to lack of glucocorticoids. Glucocorticoids mediate catabolism of glycogen and synthesis of glucose by gluconeogenesis in fasting or stressful conditions. PU is attributed to lack of mineralocorticoids. Aldosterone deficiency causes Na loss via the urine. That urine Na acts as an osmotic agent, leading to osmotic diuresis. PD is compensatory for the PU in an attempt to maintain hydration.

Physical Examination

Physical examination abnormalities vary from mild to severe and can include: weak pulses, dehydration, hypotension, bradycardia, muscle weakness, thin body condition, abdominal pain, and in extreme cases, hypovolemic or hypotensive shock or seizures (see ch. 2). Dehydration in dogs with HA is due to urine Na losses, the ensuing osmotic diuresis, and then illness, which interferes with water intake. Among dogs requiring IV fluid resuscitation, dogs with HA have lower systolic blood pressure compared to dogs in which a diagnosis of HA was excluded. Median systolic blood pressure (see ch. 99) in 53 dogs with HA was 90 mm Hg (range 40-150 mm Hg; see Table 309-1). Hypotension is attributed to the lack of glucocorticoids and their important role in maintaining normal blood pressure (see ch. 159).[33] Bradycardia is attributed to hyperK. When K concentration in cardiac extracellular fluid is abnormally high, the concentration gradient between the intracellular and extracellular compartments decreases and K is retained in the cells. The outward K current needed for phase 3 final rapid repolarization of the cardiac action potential diminishes, leading to bradycardia (see ch. 248). Abdominal pain is thought to develop due to lack of the gastroprotective effects of glucocorticoids.

Diagnosis

Overview

Suspicion of HA begins with the history, clinical signs, and physical examination findings. Careful interpretation of complete blood count (CBC) and chemistry screen should be helpful in deciding when to pursue adrenal axis testing. The diagnosis of HA can be confirmed with results of an ACTH stimulation test (ACTHst). Adrenal axis testing requires only 1 to 2 hours for completion. A urinalysis and urine culture should be considered when evaluating any dog with PU/PD. Fecal analysis for parasites, fecal bacterial culture for *Salmonella* and *Campylobacter,* and abdominal radiographs may be warranted for evaluation of anorexia, vomiting, or diarrhea. If acute pancreatitis is suspected, abdominal ultrasound (US) and measurement of pancreatic lipase concentration might be warranted. When arrhythmias are noted, an electrocardiogram and chest radiographs can be of value.

Complete Blood Count

A study of 53 dogs with HA who were compared with 110 sick control dogs highlighted some useful differences between CBC findings in dogs with and without HA.[30] While median blood cell counts in dogs with HA were within reference limits, dogs with HA had lower neutrophil counts and higher lymphocyte and eosinophil counts than did ill dogs without HA (see Table 309-1). An absolute lymphocyte count >2000 cells/mcL was about 58% sensitive and 85% specific as a screening tool for HA.[30]

Routine Serum Biochemistry Profile

Overview

The chemistry screen can reveal no or many abnormalities, which can be mild or severe. Most of the abnormalities noted on initial laboratory tests in dogs with HA resolve within hours to days of starting treatment. Severe biochemical abnormalities are rarely irreversible. This is important when discussing possible outcomes with an owner before intensive care or a definitive diagnosis has been established. Unlike other diseases, severe azotemia, increased liver enzyme activities, and other altered parameters are almost always completely reversible with treatment.

Electrolyte, Kidney and Acid-Base Values

Numerous electrolyte abnormalities including hyponatremia, hyperkalemia, hypochloremia, hypercalcemia (hyperCa), and mild acidosis are common in dogs with HA. Hyponatremia and hyperkalemia have been documented in >80% of dogs with HA due to aldosterone deficiency.[7,31] Using the Na : K ratio allows the clinician to use both measurements when deciding whether to pursue testing for HA. When cutoffs of >27 or 28 are used as the reference value for Na : K, about 95% of dogs are identified correctly as either having or not having HA.[7] When the Na : K ratio is <24, it is quite likely that an ACTHst result will confirm HA.[7] Use of both the lymphocyte count and the Na : K ratio as screening tools maximizes the likelihood of making the correct decision in regard to performing an ACTHst. Lymphocyte counts are affected by glucocorticoids and the Na : K ratio is influenced by mineralocorticoids.

Pre-renal azotemia is common in dogs with HA secondary to hypovolemia and dehydration. Severe dehydration can lead to acute kidney injury (AKI), but in most HA dogs, renal parameters quickly and completely return to reference values with therapy. There is no evidence suggesting that any permanent kidney damage follows a life-threatening hypovolemic crisis due to HA. Since aldosterone facilitates urine hydrogen ion excretion, mineralocorticoid deficiency leads to acidemia in about 60% of HA dogs.[7,34] Hypochloremia is observed in 40-60% of dogs with HA, probably because Na and chloride (Cl) are co-transported from blood to urine.[7,31,35] Hypercalcemia has been reported as an increase in total Ca (tCa) and less commonly an increase in ionized Ca (iCa). The pathophysiology of hypercalcemia in dogs with HA is incompletely understood, but does not appear related to altered parathyroid hormone, parathyroid hormone–related protein, or serum 1,25 dihydroxyvitamin D concentrations.[36,37] Glucocorticoids facilitate calciuresis and their deficiency can lead to Ca retention and hypercalcemia. It is also possible that acidemia contributes to an increase in iCa concentration as an excess of positively charged hydrogen ions compete for albumin binding and displace positively charged Ca ions.

Glucose, Cholesterol, Albumin, Liver Enzymes, and Urinalysis

Hypoglycemia develops in <20% of dogs with HA and tends to be mild when present. Quite uncommonly, hypoglycemia can be life-threatening and cause seizures.[38] Hypoglycemia is likely the result of cortisol deficiency decreasing both glycogen breakdown and gluconeogenesis. Increased insulin secretion does not appear to be a cause of hypoglycemia.[39] Leakage of cytosolic enzymes is attributed to poor perfusion and ischemic damage to hepatocytes. Hypoalbuminemia and hypocholesterolemia are not common, but are likely due to acute GI tract ischemia rather than liver dysfunction.[7,31] Urinalysis commonly reveals isosthenuria due to Na loss and resultant PU.

Other Tests

The extent and focus of other testing depends on individual clinical signs. Dogs with mild waxing and waning lethargy, inappetence, and weight loss will be assessed differently than dogs critically ill with acute severe vomiting and dehydration. Additional testing is performed to identify a variety of possible conditions in either scenario. In dogs with HA, urine culture, fecal parasite exam, and fecal cultures are typically negative. Abdominal radiographs are usually normal, although some dogs with HA have been described as having a small liver. In dogs with bradycardia, an electrocardiogram might reveal complete lack of P waves, wide QRS and tall T waves, and possibly some degree of heart block, consistent with hyperK (Figure 309-2). Thoracic radiographs may reveal microcardia due to severe hypovolemia (Figure 309-3). Megaesophagus, reported anecdotally in humans with HA, has not been established as occurring secondary to HA in dogs. If acute pancreatitis is suspected, abdominal US and pancreatic lipase quantification might be warranted. US should not be used to assess adrenal function, but thickness of adrenal glands in dogs with HA is usually <3 mm.[40]

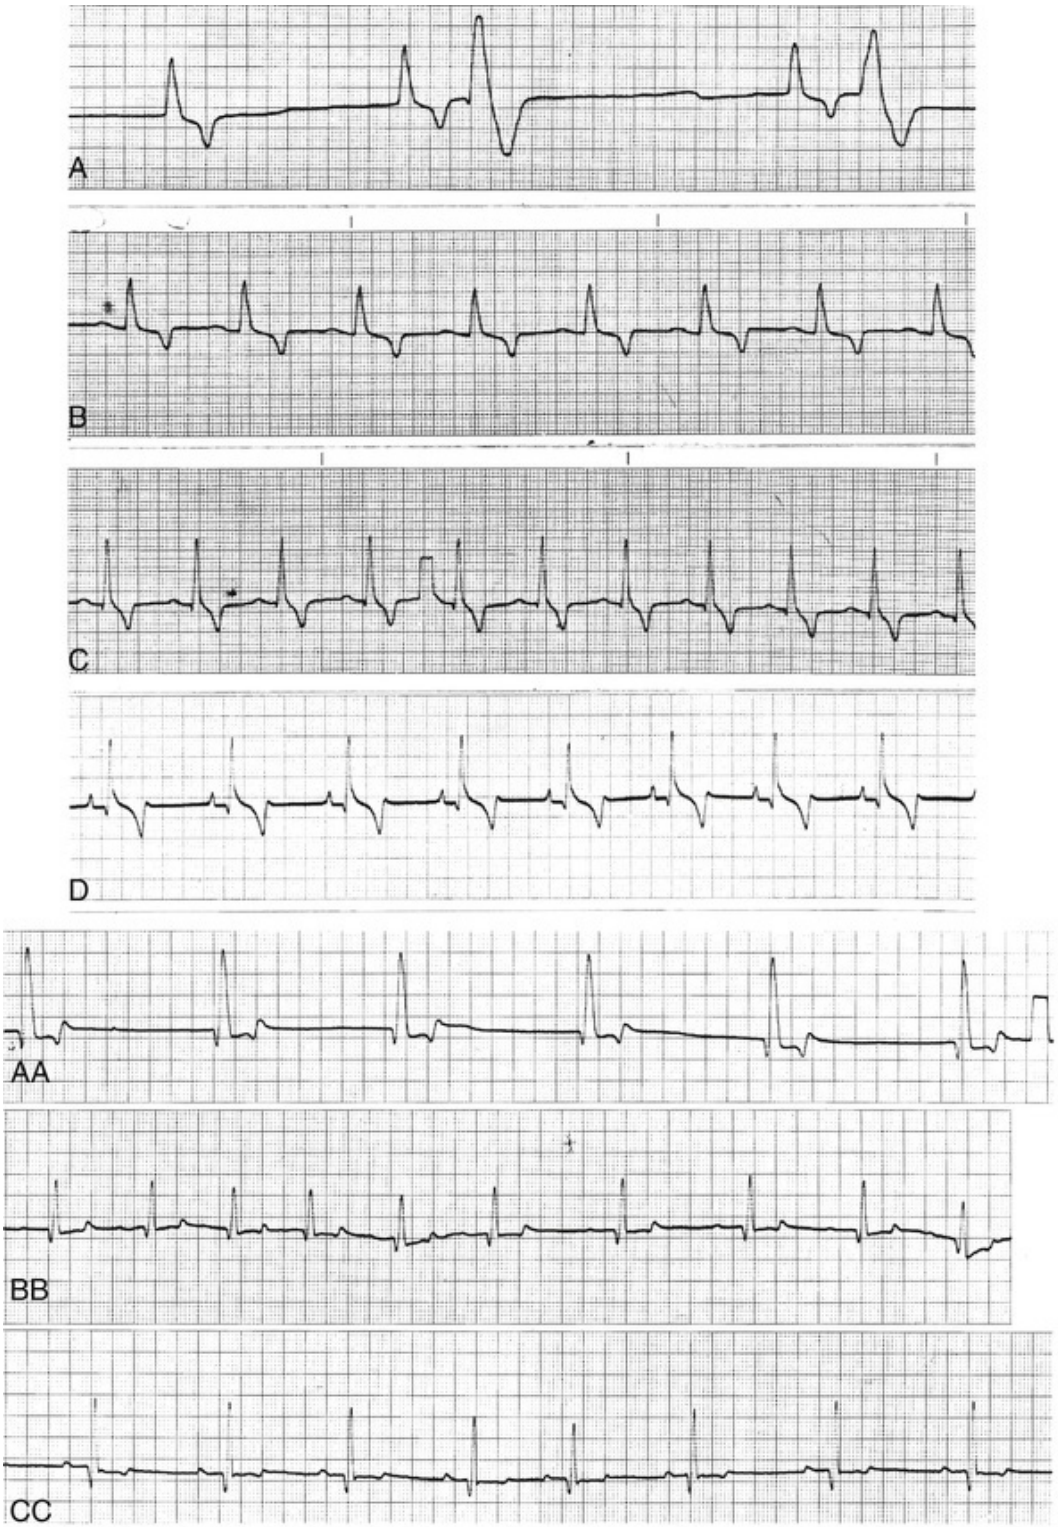

FIGURE 309-2 Serial electrocardiogram (ECG) segments obtained from two dogs with hypoadrenocorticism and hyperkalemia. **A** and **AA** both illustrate the effect of severe hyperkalemia, with the dog in **A** having a serum potassium concentration of 8.6 mEq/L and the dog in **AA** a measurement of 9.4 mEq/L. Note the lack of visible P waves, the short and wide QRS complexes, and the T waves, which are not of excessive amplitude. The ECG in **A** also reveals two instances of a bizarre-looking QRS complex following a more normal-appearing QRS complex at a shorter R-R interval (i.e., 2 wider, more bizarre-looking premature beats). These represent premature ventricular complexes that could be the result of acidemia, myocardial hypoxia, or other metabolic imbalances. **B** and **BB** are ECGs from the same dogs as in **A** and **AA,** respectively. They were each obtained approximately 1 hour after institution of intravenous normal saline as the only treatment. The serum potassium concentrations had decreased to 7.6 mEq/L and 7.9 mEq/L, respectively. Two important factors to note: (1) improvement is seen in each case with the return of P waves, a more rapid heart

rate, and disappearance of ventricular escape beats; and (2) abnormalities are still present, most obviously the prolonged P-R intervals (first-degree heart block), which alone suggest hyperkalemia, especially when associated with a widened QRS complex and a short Q-T interval. There are numerous other causes of P-R interval prolongation. In **C** and **CC,** the serum potassium concentrations are considerably lower, 6.2 mEq/L and 5.9 mEq/L, respectively. The P-R interval and P, QRS, and T waves are of shorter duration, and the R waves are taller. **D,** ECG from the dog in **A;** the serum potassium concentration is 5.6 mEq/L and a more spiked T wave is seen. (From Feldman EC, Nelson RW, Reusch CE, et al: *Canine and feline endocrinology and reproduction,* ed 4, St Louis, 2015, Saunders.)

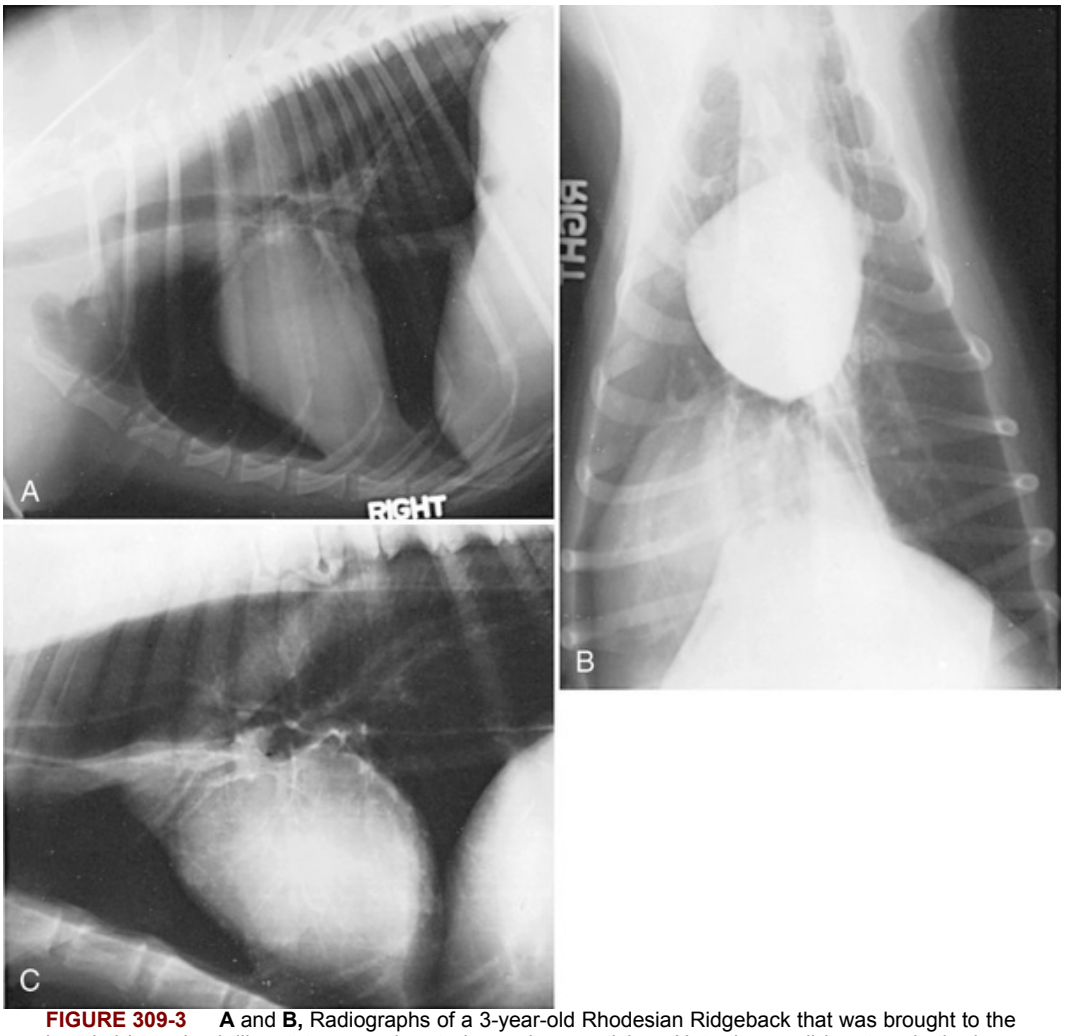

FIGURE 309-3 **A** and **B,** Radiographs of a 3-year-old Rhodesian Ridgeback that was brought to the hospital in a shock-like state secondary to hypoadrenocorticism. Note the small heart on both views and the small pulmonary vasculature due to poor cardiac output. **C,** Lateral thoracic view radiograph of a 5-year-old hypoadrenal dog with microcardia, a flattened caudal vena cava, and a dilated, air-filled esophagus. The esophageal dilation, which may be associated with hypoadrenocorticism resolved with appropriate hormonal therapy for the primary disease. (From Feldman EC, Nelson RW, Reusch CE, et al: *Canine and feline endocrinology and reproduction,* ed 4, St Louis, 2015, Saunders.)

Adrenal Axis Testing

ACTH Stimulation Testing (ACTHst)

Confirming a diagnosis of HA requires testing adrenal gland function. Glucocorticoid and mineralocorticoid functions are investigated independently and the ACTHst is the test of choice for the diagnosis of HA. The ACTHst is performed by measuring serum cortisol concentrations before and 1 hour after giving 5 mcg/kg synthetic ACTH, IV.[41] Since the volume of ACTH is small, care must be taken to ensure IV administration. If accidentally given SC, ACTH will not stimulate the adrenal glands and could lead to erroneous test results.

Because synthetic ACTH is expensive, some clinics save any excess to reduce client cost. After reconstitution with 0.9% saline, the ACTH can be refrigerated or frozen. Refrigeration (4-8° C) for up to 60 days has been reported for use in humans. Our experience suggests using refrigerated synthetic ACTH within 14 days or using previously frozen ACTH (at −20° C in plastic syringes) within 6 months.[42,43]

In a dog with normal adrenal function, injection of ACTH should result in a surge of cortisol secretion from the adrenal glands. Therefore, serum cortisol concentration before ACTH administration is expected to be between 0.5-6 mcg/dL and after ACTHst it is expected to be >2 mcg/dL. In a dog with HA, the adrenals have been destroyed and are unable to mount an appropriate response to ACTH. In most dogs with HA, serum cortisol concentrations before and after ACTHst are <1 mcg/dL (undetectable; Figure 309-4). A small number of dogs with HA can have serum cortisol concentrations between 1-2 mcg/dL after ACTHst; however, diagnosis of HA with serum cortisol concentration >1 mcg/dL post-ACTH should be made with caution and only when all other differential diagnoses have been excluded.

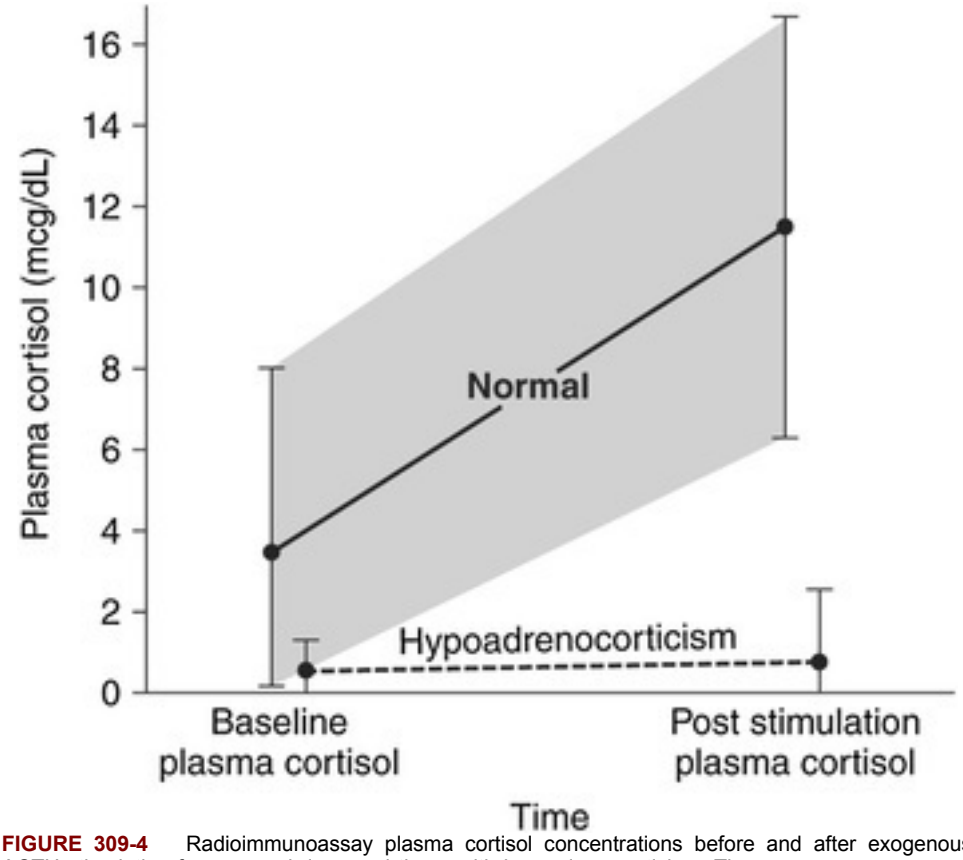

FIGURE 309-4 Radioimmunoassay plasma cortisol concentrations before and after exogenous ACTH stimulation from normal dogs and those with hypoadrenocorticism. The ranges are means ± 2 SD. (From Feldman EC, Nelson RW: *Canine and feline endocrinology and reproduction*, ed 3, St Louis, 2004, Saunders.)

Cortisol: Endogenous ACTH ratio (C : eACTH)

The cost of synthetic ACTH and its lack of availability in some countries have led to studies investigating other options for HA diagnosis. While most dogs with HA have resting (basal) serum cortisol concentrations <1 mcg/dL, this may also be true of a few dogs who do not have HA. Thus, resting cortisol alone cannot be used to diagnose HA.[44,45] C : eACTH holds promise as a diagnostic aid for diagnosis of HA, requiring only one blood sample. The C : eACTH has been shown to be significantly lower in HA dogs when compared to healthy dogs, with no overlap in ratio results.[46] In a study of C : eACTH in 15 dogs with HA compared to 5 dogs with non-adrenal disease in which HA was suspected and excluded, there was again no overlap between the ratio results from the two groups.[47] Five of the 15 dogs with HA, however, had their eACTH measured after exogenous ACTH had been administered.[47] A larger number of dogs must be studied before

this test can be recommended for the definitive diagnosis of HA.

Mineralocorticoid Testing

Assessing serum Na and K concentrations is an indirect but good reflection of aldosterone function. The ratio of plasma aldosterone concentration to plasma renin activity in dogs with HA has been investigated and shown to be significantly lower than in healthy dogs, with no overlap.[46] However, overlap was noted between individual plasma aldosterone concentrations and plasma renin activities, indicating that the individual test results are less specific than their ratio.[46] It remains to be seen whether the ratio can be used to confirm a diagnosis of HA.

Basal Cortisol Concentrations

While not useful for diagnosing HA, basal cortisol concentrations are quite useful as a simple screening test to exclude HA from any list of differential diagnoses. Dogs with basal cortisol concentrations >2 mcg/dL are unlikely to have HA.[44] This test is particularly useful in dogs with normal Na : K ratios suspected of having glucocorticoid deficiency only.

Secondary Hypoadrenocorticism and Isolated Hypoaldosteronism

Rarely, dogs have "secondary" HA caused by a deficiency of pituitary ACTH. The eACTH concentrations from these dogs are low while serum Na and K concentrations should be within reference intervals. Regulation of Na and K is controlled primarily by renin and angiotensin, not by the pituitary or hypothalamus. In the singular instance of isolated hypoaldosteronism, cortisol concentrations before and after ACTHst are normal. These dogs can be identified by the combination of hyperkalemia, hyponatremia, low plasma renin activity, and low aldosterone concentrations before and after ACTHst.[48]

Critical Illness

A review of the hypothalamic-pituitary-adrenal axis response to critical illness and the condition's effect on testing is provided in ch. 133.

Differential Diagnoses

The term *"pseudo-Addison's disease"* is used to describe conditions that resemble Addison's disease in their clinical and/or clinicopathologic results. This is especially true of concurrent hyperkalemia and hyponatremia. Some severe GI diseases (especially trichuriasis and salmonellosis), periparturient illnesses, and chylothorax are among the conditions that may mimic HA.[49-52] ACTHst results should discriminate HA from other conditions. The differential diagnoses for PU/PD (see ch. 45), azotemia (see ch. 62), isosthenuria (see ch. 72), eosinophilia (see ch. 58), hyperkalemia (see ch. 68), hyponatremia (see ch. 67), hypercalcemia (see ch. 69), hypoglycemia (see ch. 61), increased liver enzymes (see ch. 65), hypocholesterolemia (see ch. 63), hypoalbuminemia (see ch. 60), and acidemia (see ch. 128) are covered in their respective chapters.

Treatment

Acute Hypoadrenal Crisis

Overview and Fluid Therapy

Fluid therapy is the single most important and vital component of therapy (see ch. 129). Although no studies yet guide specific fluid choices, 0.9% NaCl (saline) is recommended because it contains more Na and Cl and less K than other crystalloid fluids. Concerns can be raised regarding the relatively low pH of saline, but the clinical significance of hyponatremia and hyperkalemia far outweighs risk of iatrogenic acidosis. Any acidosis associated with HA is usually mild and corrects within 12-24 hours of IV saline administration. Glucose and insulin are occasionally employed. Dexamethasone is rarely administered in the peracute stages of therapy, in order to begin and complete ACTHst. Bicarbonate treatment is not indicated.

Sodium (Na) and Potassium (K)

Acute and profound hyponatremia can cause brain edema. Rapid correction of hyponatremia can also result

in potentially fatal osmotic shifts. It is recommended that hyponatremic people have their serum Na concentration increase about 1-2 mEq/L in the first 2-3 hours of treatment and about 8-12 mEq/L during the first 24 hours.[53] During the first few hours of treatment, Na and K concentrations should be measured every 2-6 hours, depending on severity of the electrolyte abnormalities and the dogs' clinical status. Hyperkalemia usually dramatically improves and sometimes resolves with intensive IV saline alone.

Glucose, Insulin, DOCP, Bicarbonate

If severe hyperkalemia persists following 6-8 hours of fluid therapy or if bradycardia is profound, IV dextrose can be administered. Glucose stimulates insulin secretion, which moves K from the extracellular fluid into cells, quickly decreasing circulating K concentrations. If dextrose administration alone fails to decrease the K, IV insulin can be safely administered if the blood glucose concentration is above 200 mg/dL. When insulin is administered, glucose must be monitored closely to ensure that hypoglycemia can be quickly identified and treated, if needed. Severe hypoglycemia (blood glucose <60 mg/dL) at admission or after insulin administration should be addressed with adequate glucose added to the IV saline to create a 5% dextrose solution. Alternatively, a dextrose bolus (0.25-0.5 g/kg, diluted 1 : 3) can be given IV. It is important to remember that glucose administration may cause transient hyperglycemia. Hyperglycemia, in turn, causes serum Na concentrations to measure low because the increasing glucose concentration results in fluid shifting to the extracellular space, diluting Na. In humans it has been suggested that there is usually about a 1 mEq/L decrease in measured serum sodium concentration for every 62 mg/dL increase in glucose concentration above normal. Finally, once the dog is rehydrated, if hyperkalemia and hyponatremia persist, the ACTHst is completed, and other major differential diagnoses excluded, dogs should be treated with IM or SC DOCP (2.2 mg/kg) to provide long-term, effective, mineralocorticoid replacement. In the very unlikely event that acidosis is severe (pH < 7.1) and does not correct with fluid therapy, bicarbonate can be administered at increments of 1/4 (0.3 × base deficit × body weight in kg) every 20 minutes while monitoring venous pH.

Glucocorticoid Therapy

Usually it is not necessary to administer glucocorticoids in the acute stage of treatment and it is possible to wait at least the 1 hour needed to complete the ACTHst. Since ACTHst results may dictate lifelong treatment, it is best to avoid concerns of glucocorticoid treatment initiated before or during ACTHst. Once beginning glucocorticoid treatment, it must be withdrawn gradually. Dogs must not receive oral prednisone for at least 48 hours before an ACTHst. If glucocorticoids are deemed vital before an ACTHst is performed, dexamethasone is preferred and given IV. It has a rapid onset of action and does not interfere with cortisol assays if an ACTHst is subsequently performed. While dexamethasone does not cross-react with cortisol assays, it does suppress pituitary secretion of ACTH and CRH from the hypothalamus. This could impact ACTHst results.

Long-Term Therapy

Overview

Long-term treatment begins after an HA dog is hydrated, fluid therapy has been discontinued, serum electrolyte concentrations have normalized, and the dog no longer has vomiting, diarrhea, or anorexia. This stage of treatment generally begins 24-48 hours after admission for a crisis, or on an outpatient basis, if the diagnosis is established. Long-term treatment consists of mineralocorticoid and glucocorticoid supplementation. In dogs with normal serum Na and K concentrations, only glucocorticoids are needed.

Glucocorticoids

Glucocorticoids can be supplemented with prednisone, the most commonly used glucocorticoid, or fludrocortisone acetate. Immediately following an acute crisis, prednisone can be administered at a relatively high dosage of 0.5 mg/kg PO q 12 h for 2-3 days. Following these first few days, the prednisone dosage can be quickly decreased to physiologic needs (0.1-0.2 mg/kg PO q 12-24 h). Many dogs require much lower dosages for health. Low dosages should avoid the polyphagia, weight gain, PU/PD, and other adverse side effects typically caused by glucocorticoids in dogs. Finding the “best” dosage is based on trial and error. If lethargy, anorexia, vomiting, and diarrhea recur, the dosage of prednisone can be increased. Owners should have extra prednisone available for a crisis or in anticipation of stressful situations (travel, kennel, house guests). In these situations, owners are instructed to give higher dosages of prednisone (0.5 mg/kg). Fludrocortisone acetate contains both glucocorticoids and mineralocorticoids. However, it is difficult to supplement both hormones

properly with this drug. Some dogs develop typical glucocorticoid-induced side-effects when given enough fludrocortisone to correct electrolyte abnormalities. Others require prednisone in addition to the fludrocortisone to prevent GI clinical signs consistent with HA.

Mineralocorticoids

Mineralocorticoids can be supplemented with DOCP or fludrocortisone acetate. DOCP is administered SC approximately every 25 days.* The recommended dosage is 2.2 mg/kg q 25 days, but clinical experience and reports suggest that DOCP can successfully maintain normal serum Na and K concentrations at lower dosages and/or when given less often.[54] One should begin treatment at the labeled dosage of 2.2 mg/kg SC, measuring serum Na and K 14 and 25 days later. If the Na : K ratio is above 32 at day 14, the next dose of DOCP can be decreased by about 10% (2 mg/kg). If the Na : K ratio is above 32 on day 25, the DOCP injection can be postponed for at least 5 days, at which time the process is repeated. Once the serum Na begins to decrease or the serum K increases, the DOCP should be given. The new time between injections can be maintained. If the interval between injections is increased, the Na : K ratio should be measured in the middle and end of this new interval, with a goal of 29-32. The dose is increased or interval decreased if <28 and the opposite if >32. This process should be repeated several times during the first few months (Figure 309-5).

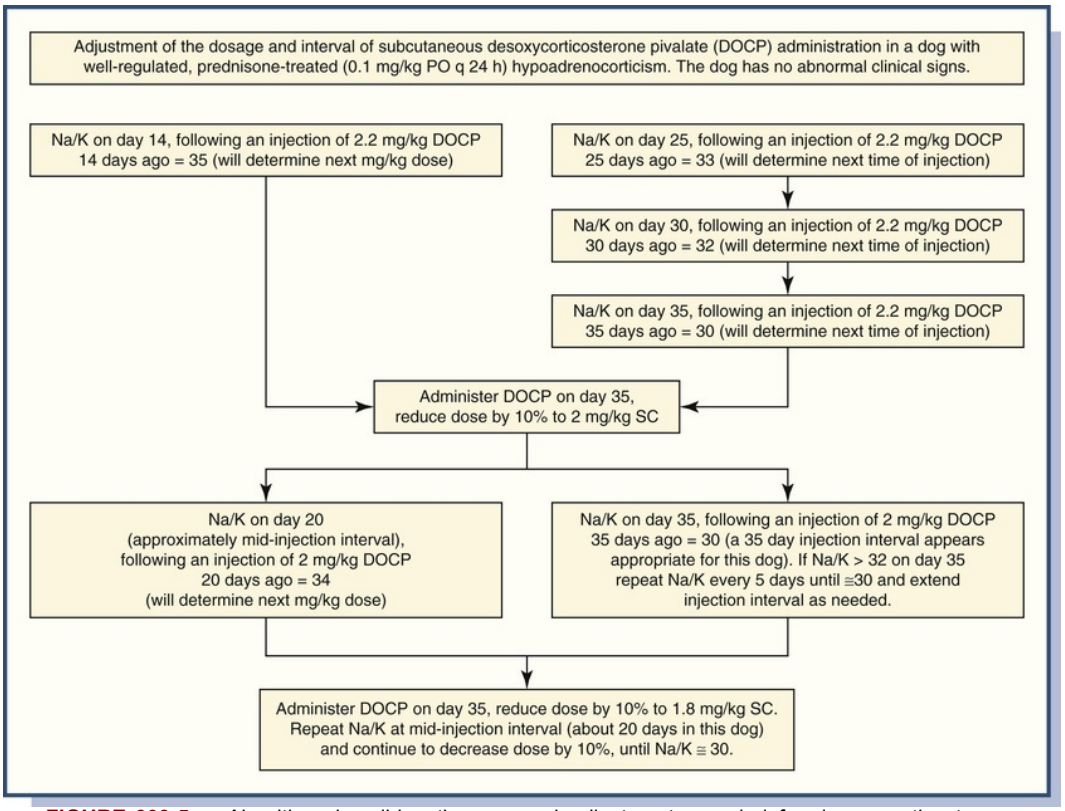

FIGURE 309-5 Algorithm describing the use and adjustments needed for desoxycorticosterone pivalate (DOCP) treatment of dogs with hypoadrenocorticism.

Fludrocortisone is given orally, in tablet form twice daily (0.01 mg/kg PO q 12 h).[55] The dosage should be adjusted by assessing serum Na and K concentration every 5 days and it should be increased until the Na : K ratio is above 28. Treatment of dogs with DOCP and prednisone allows for successful supplementation of glucocorticoids and mineralocorticoids, separately. A recent study also reported that DOCP was more effective than fludrocortisone in decreasing plasma renin activity, increasing Na, and decreasing K in dogs with HA.[56]

Monitoring

The recommended treatment protocol of monitoring and adjusting the dosage of DOCP requires frequent

veterinary visits. Although there is expense, the costs of treating a second HA crisis or of the drugs used in treatment are also significant. Ultimately it is less expensive to determine needed doses. If one can give a smaller dose, less frequently, it will be best for the dog and less expensive for the owner. Owners must keep in mind that a "perfect dose" can change for any of a myriad of reasons. Rechecking Na and K concentrations is warranted every few months, even in well-regulated dogs.

Glucocorticoid doses should be tapered as needed for the dog to appear stable and healthy. One wants to avoid signs and biochemical alterations of hypo- or hyperadrenocorticism. Monitoring mineralocorticoid treatment is performed by measuring the Na : K ratio, as described. Plasma renin activity can also be used to monitor mineralocorticoid treatment; however, the assay is not widely available.[56] Owners should monitor their dog carefully and report any worrisome clinical signs, especially those suggestive of too much or too little glucocorticoid. PU/PD can develop in dogs treated for HA for several reasons and identifying the specific cause can be challenging. DOCP can cause PU/PD without causing any increase in serum Na. Specific glucocorticoids or fludrocortisone can cause PU/PD. Thus, PU/PD are signs of HA and of hyperadrenocorticism. Further, any dog can develop another of the many conditions that cause PU/PD. Therefore, this relatively common issue must be evaluated carefully.

It is important to remember that dogs diagnosed with atypical HA may well progress to a state in which they are mineralocorticoid-deficient. Therefore, periodic assessment of their Na and K concentrations should be considered critically important.

Prognosis

The prognosis for HA is excellent, provided that the acute crisis is treated successfully and a diagnosis is established. Most dogs with HA that require IV fluid therapy are discharged from the hospital about 48 hours after admission (see Table 309-1).

Feline Hypoadrenocorticism

Hypoadrenocorticism is extremely rare in cats, but from the few cases published, cats appear to have similar clinical signs, physical examination findings, and clinicopathologic abnormalities as seen in dogs with HA.[57] Spontaneous typical and atypical HA, iatrogenic HA associated with withdrawal of steroids, and neoplastic invasion of adrenals have been reported.[57-60] Pseudohypoadrenocorticism with hypoNa and hyperK has also been documented in 4 cats with peritoneal effusion.[61] Feline HA should be suspected after more common disorders have been excluded, and clinicopathologic findings are supportive of the diagnosis. The protocol for an ACTHst in cats is different than the protocol in dogs (see ch. 306). Treatment is based on glucocorticoid and mineralocorticoid supplementation, after treating the acute crisis. The prognosis for cats with HA does not appear to be as good as it is for dogs.[57]

*Editor's comment: Recently, the DOCP commercially available in Europe (and perhaps elsewhere) seems far more potent and much longer lasting than any previous report would indicate. Veterinarians are encouraged to consult with specialists in their area to understand if the dose and/or frequency of administering DOCP has changed since publishing this textbook.

CHAPTER 310

Gastrointestinal Endocrinology

Thomas Schermerhorn

Client Information Sheet: Gastrointestinal Neuroendocrine Tumor (NET)

Introduction

By some measures, the gastrointestinal (GI) tract is the largest endocrine organ in the body. Endocrine functions of the pancreas and GI tract are diverse and involve more than 30 hormones responsible for integrating and coordinating physiologic processes that regulate appetite, digestion, and energy metabolism.[1] These are true hormones, entering the bloodstream to act at target tissues distant from their site of origin. Some products have paracrine or neurotransmitter functions. Some hormones have multiple isoforms and others produce different actions depending on the tissue target. The biochemical diversity of the hormones produced by the GI tract and pancreas is as broad as the functions they regulate, resulting in a complex clinical endocrinology. Within some hormone families, such as gastrin and glucagon, further diversity is conveyed by the production of alternatively spliced mRNAs and the production of preprohormones by specific genes that then undergo various post-translational modifications to produce a variety of structurally-related but functionally-distinct protein products. Thorough exploration of the genetic, biochemical, and physiologic mechanisms that regulate these complex hormones is beyond the scope of this chapter, but a brief review allows discussion of clinical syndromes associated with abnormalities of gut hormone production. Many GI and pancreatic hormones share biochemical and structural similarities that permit classification into various hormone families (Table 310-1). From a clinical perspective, the secretin, insulin, and gastrin families are among the most relevant. Other hormones, such as serotonin that cause defined syndromes in humans, have less defined roles in animals. Some, such as ghrelin and glucagon-like peptide-1 (GLP-1), may have emerging roles in the treatment of endocrine disorders (see ch. 304 and 305).

TABLE 310-1

Overview of Important Gastrointestinal Hormones

SUBSTANCE	PHYSIOLOGIC STIMULUS	TARGET TISSUE	PHYSIOLOGIC EFFECTS
Gastrin	Gastric distention Intraluminal peptides	Gastric parietal and chief cells Pancreatic acinar cells Gastric, intestinal, pancreatic tissue	Acid and pepsinogen secretion Pancreatic enzyme secretion Trophic effect: growth
Cholecystokinin	Nutrients in duodenum (fatty acids, amino acids) Hydrogen ion (H^+)	Gallbladder Sphincter of Oddi Pancreatic acinar cells Stomach	Contraction Relaxation Enzyme secretion Trophic effect: pancreatic growth Inhibits gastric emptying
Secretin	Intraduodenal fatty acids Hydrogen ion (H^+)	Ductal cells (pancreas) Biliary tree Duodenum	Stimulates secretion of bicarbonate and water
Glucagon-like peptide-1 (GLP-1)	Intraluminal fatty acids (duodenum and ileum)	Pancreatic islets of Langerhans (beta cells) Stomach	Incretin effect: stimulates insulin secretion in presence of glucose Inhibits gastric emptying

Gastric inhibitory peptide (GIP)	Nutrients in duodenum (fatty acids, glucose, amino acids)	Gastrointestinal tract (stomach, duodenum, jejunum, ileum)	
Somatostatin	Nutrients (lipid and protein) Bile	Stomach Gallbladder Pancreas Intestine	Inhibits acid and pepsinogen secretion Inhibition of gallbladder contraction Inhibition of insulin and exocrine secretion Inhibition of intestinal motility; decrease nutrient absorption
Motilin	Nutrients (lipid) Hydrogen ion (H^+)	Intestine	Coordinates migrating motility complex (MMC) Coordinates gastric, pancreatic, and biliary secretions
Ghrelin	Nutrients (protein)	Pituitary	Modulates growth hormone

Pancreatic and Gut Hormones

This family of hormones includes various products of GI or pancreatic islet origin. Clinically important members of the secretin family include secretin, glucagon, glucagon-like peptide (GLP), and gastric inhibitory peptide (GIP). Other important hormones in this group include gastrin, cholecystokinin (CCK), somatostatin, motilin, ghrelin, and serotonin.

Secretin

Secretin, a peptide hormone produced by S cells located principally in the duodenum, is released in response to hydrogen ions (H^+) contained in gastric secretions.[2] Like some other gut hormones (e.g., CCK), secretin circulates in one of several sized molecular forms (27-, 28-, 30-, and 71- amino acid polypeptides have been described). Each polypeptide may serve a slightly different function. The major endocrine actions of secretin are stimulation of bicarbonate-containing fluid and bile, respectively, from pancreatic ductal cells and biliary epithelium. Other effects include inhibition of gastrin secretion, gastric acid production, and GI motility. Expression of secretin or its receptor has been reported in central nervous system (CNS) neurons, heart and lung, but further study is needed to define its role(s) in these non-enteric sites.

Glucagon, Glucagon-Like Peptide, and Gastric Inhibitory Peptide

Glucagon from pancreatic islet alpha cells and enteroglucagons from GI L cells are products of the same gene. Diversity within this peptide family arises from tissue specific processing of primary gene transcripts. In islet alpha cells, primary mRNAs encode glucagon while in L cells, mRNAs derived from the same gene encode GLP, GIP, enteroglucagon and glicentin.[3] Glucagon, a vital hormone in energy homeostasis and nutrient metabolism, has actions that generally counter the anabolic actions of insulin. Glucagon is the principal hormone stimulus for hepatic glycogenolysis and gluconeogenesis, actions opposite those of insulin. GLP (GLP-1 and GLP-2) and GIP are enteroglucagons known as incretins because their actions enhance nutrient-induced insulin secretion. Of the incretins, GLP-1 is the most potent insulin secretagogue. It has been studied extensively as a potential therapeutic aide for diabetes mellitus (DM). GLP-1 and GLP-2 are released from L cells in response to intraluminal nutrients and they also modulate intestinal glucose absorption via inhibition of gastric motility and GLP-2 mediated upregulation of glucose transporters.[4,5]

Gastrin

Gastrin, synthesized and secreted by neuroendocrine G cells located in the stomach antrum and duodenum, is stimulated by ingested protein and gastric distention and inhibited by low intraluminal pH (<3). Gastrin circulates in several different molecular forms that vary in molecular weight (e.g., gastrin-34, -17, and -14), which bind on target tissue surfaces.[6] Gastrin-34 is the major circulating gastrin, but the less abundant gastin-17 has more potent biological effects on gastric acid secretion, the primary biologic action of this hormone. Gastrin acts in concert with acetylcholine from autonomic parasympathetic nerve endings and histamine to regulate H^+ secretion from gastric parietal cells. Gastrin has trophic effects on gastric epithelium and stimulates mucosal blood flow, pepsinogen release, and antral motility. Gastrin also influences pancreatic

enzyme production and has trophic effects on pancreatic and duodenal tissue.

Cholecystokinin (CCK)

CCK, synthesized by I cells located in the duodenum and jejunum, is released in response to a variety of substances entering the duodenum, especially H^+, fatty acids, and amino acids.[7] During synthesis, the CCK transcript undergoes processing that results in a multitude of circulating isoforms. Of the seven CCK isoforms identified, CCK-33, CCK-39, and CCK-58 are responsible for the principal GI effects. CCK-8, expressed in neurons, serves as a peptide neurotransmitter in the enteric nervous system. Other isoforms, such as CCK-5, CCK-12, and CCK-63, have functions of lesser GI importance. Major CCK actions include stimulating gallbladder contraction and pancreatic enzyme secretion, both mediated via presynaptic cholinergic neurons. CCK also serves to coordinate overall digestive function including stimulation of pancreatic fluid secretion (in the presence of stimulatory levels of secretin), inhibition of gastric emptying, sphincter of Oddi relaxation, and stimulation of pancreatic growth.

Somatostatin

The peptide somatostatin is synthesized in the hypothalamus, pancreatic islet delta cells, GI D cells, and subsets of neurons in the CNS and enteric nervous system. Intestinal D cells release somatostatin in response to nutrients (fats and protein) and bile in the gut lumen. The endocrine, paracrine, and neurotransmitter effects of somatostatin principally inhibit: gastric acid, pepsinogen, gallbladder contraction, insulin secretion, pancreatic exocrine function, GI motility, and nutrient (amino acids and glucose) absorption.[8]

Motilin

Motilin, a peptide hormone synthesized in GI cells, is structurally related to ghrelin. Secretion is cyclic, dependent on being in a fasted or fed state, but its main endocrine actions occur during fasting. Between meals, motilin initiates and coordinates migrating motility complexes (MMCs), which serve to clear the intestines in interdigestive states. After eating, motilin is released in response to stomach acid (H^+) or lipid entering the small intestines. In the fed state, motilin serves to coordinate gastric, pancreatic, and biliary secretions.[9]

Ghrelin

The hormone ghrelin, structurally related to motilin, was recently identified as an important mediator of appetite and energy metabolism.[10] Ghrelin, synthesized and secreted in the stomach, stimulates appetite, adipocyte growth, and pituitary growth hormone (GH) synthesis and secretion. Ghrelin provides a link between dietary nutrients, caloric energy, and the pituitary-GH axis vital for growth regulation.

Serotonin

Serotonin (5-hydroxytryptamine [5-HT]) is a neuropeptide and hormone located within enteric neurons and enterochromaffin cells distributed throughout the GI tract. 5-HT of enterochromaffin origin acts as an endocrine and paracrine agent to stimulate GI smooth muscle contraction and intestinal secretion.[11]

Insulinoma

Neuroendocrine tumors, uncommonly diagnosed in dogs and cats, are most often located in the pancreas, where they arise from islet cells (islet cell tumors; see ch. 303). Metastatic lesions are common in the mesentery, intestine, and liver. Insulinoma is uncommon, but is the most common neuroendocrine tumor reported in dogs, and is rare in cats (see ch. 303).[12-15] The pancreas is the most frequent location for insulinoma formation but these tumors may also be found in mesenteric, splenic, and hepatic locations. It is not clear whether non-pancreatic insulinomas represent primary or metastatic tumors. Insulinomas cause fluctuating increases in circulating insulin concentrations that are not under physiologic control. As a result, pets with an insulinoma have episodic hypoglycemia. The balance of this chapter is focused on gastrinoma, glucagonoma, and other less common conditions.

Gastrinoma

Overview

Gastrinoma is an uncommon tumor of dogs and cats[16-20] and no large-scale studies of canine or feline gastrinoma have been published. Gastrin overproduction by gastrinomas may lead to the Zollinger-Ellison syndrome, clinically associated with gastric antral hypertrophy, hyperacidity and ulceration.[21] Treatment is surgical removal. Supportive treatment is directed at suppressing gastric acid production.

Signalment and Clinical Signs

The veterinary literature cites fewer than 50 cases of gastrinoma in dogs and cats, most in dogs. Mean age at diagnosis in dogs is about 8 years and cats have been slightly older. Frequent owner observations include vomiting, diarrhea, and weight loss. Less frequent concerns include apparent abdominal pain, GI bleeding, polydipsia, and constipation. Gastrin-induced hyperacidity can lead to reflux esophagitis with resultant regurgitation, and esophageal colic (see ch. 273). Gastropathy, characterized by mucosal hypertrophy, mucosal ulceration, and, in severe cases, outflow obstruction, leads to vomiting and weight loss. Diarrhea may develop due to the inhibitory effects of gastrin on intestinal water absorption. Gastrinomas, usually quite small, are not typically detected during abdominal palpation. Physical examination findings depend on the stage of disease. Signs, if any, are not specific. Early in the disease, the physical examination is often unremarkable. Animals with esophagitis, gastric ulceration or gastric perforation exhibit pain on esophageal or abdominal palpation, evidence of dehydration, fever, and signs of shock.

Laboratory Findings

Gastrinoma is not associated with specific changes on complete blood count (CBC) or serum biochemistry panels. Non-specific findings of leukocytosis, neutrophilia with left shift, anemia, and pan-hypoproteinemia caused by inflammation and blood loss may be seen secondary to gastric ulcerations. Other reported biochemical abnormalities include hypoalbuminuria, hypokalemia, hypochloremia, hyponatremia, metabolic alkalosis, hyperbilirubinemia, and increased liver enzyme activities. Biochemical changes may not be caused by gastrinoma per se, but may develop secondary to consequences of hypergastrinemia, such as chronic vomiting, diarrhea, or hepatic metastasis. Some dogs with gastrinoma had concurrent disorders (myelofibrosis, bile duct obstruction) that contributed to clinicopathologic disturbances. Some gastrinomas may produce and secrete hormones in addition to gastrin; concurrent secretion of insulin and adrenocorticotropic hormone (ACTH) have been reported.

Routine Diagnostic Imaging

Ultrasonography (US; see ch. 88) is generally more useful than radiography in the diagnostic work-up for gastrinoma. Abdominal US, more efficient in detecting a pancreatic mass than radiographs, may reveal gastric changes consistent with ulceration, mucosal and rugal fold hypertrophy, and thickened gastric walls. US may allow detection of metastases to extra-pancreatic sites, such as liver or lymph nodes. Plain radiography is generally not helpful or reveals only nonspecific changes. The use of contrast radiography, described in several case reports, identified gastric rugal fold hypertrophy, narrowing of the antrum due to hypertrophy, and mucosal defects caused by ulceration. Endoscopy, of limited value in obtaining a definitive diagnosis, may provide useful information regarding esophageal inflammation and ulceration, prominent gastric folds, antral hypertrophy, gastric and duodenal ulceration, and hypersecretion of gastric fluid (see ch. 113). Endoscopic biopsy may permit histologic characterization of GI changes but is not likely to provide definitive diagnosis of gastrinoma.

Diagnosis

Overview

An array of testing options is available, including measuring serum gastrin concentrations, basal acid production, secretin- and calcium-stimulation of gastrin secretion and tumor imaging using a labeled somatostatin for scintigraphic localization. In dogs and cats, these studies are not common.

Basal Measurements: Serum Gastrin Concentrations and Gastric pH

Serum gastrin concentrations are usually increased in people and dogs with gastrinoma. In people, serum gastrin levels > 1000 ng/L together with gastric pH < 2.5 is considered diagnostic for gastrinoma. This pairing of gastrin and gastric acid measurements has not been used extensively in veterinary medicine. Serum gastrin concentrations in dogs with histologically confirmed gastrinoma have ranged several fold above the upper limit of reference ranges, but no specific cutoff for normal has been established. Blood gastrin concentrations in dogs and cats may be increased in kidney disease, gastropathies, hepatopathies, and with use of drugs that inhibit gastric acid production. Measurements of pH and/or gastric acid secretion, reported in a few dogs with gastrinoma, have noted low gastric pH. Measurement of serum gastrin concentrations cannot be used as a sole test to confirm gastrinoma, even if high. Such results are most helpful when clinical suspicion for gastrinoma is high and other disorders that might cause hypergastrinemia have been ruled out.

Provocative Testing

Provocative tests measure gastrin release in response to secretin or calcium (Ca). Neither secretin nor Ca injection leads to an increase in gastrin in normal individuals but both cause gastrin release from gastrinomas. The secretin stimulation test is the most frequently employed provocative test in people, but experience with this test in animals is quite limited. The test principle relies on the enhanced responsiveness of gastrinoma tissue to secretin. One protocol used in dogs was to obtain serum samples before and 2, 5, 10 and 20 minutes after IV injection of secretin (2 to 4 U/kg).[22] An alternative protocol is to obtain samples before and 2, 5, 10, 30 and 60 minutes after IV injection of 2 U/kg secretin.[23] Samples from the 2- and 5-minute periods are most useful for gastrinoma diagnosis, since tumor response to injected secretin is typically rapid and short-lived. Humans with gastrinoma have about a two-fold increase in gastrin following secretin injection. While reports of secretin stimulation tests in dogs are scarce, results have been similar to those reported in humans. However, not all dogs with gastrinoma showed an increase in gastrin more than two-fold above baseline.[22]

The Ca stimulation test, an alternative to secretin stimulation, may be preferred because it is inexpensive and widely available. Adverse cardiac effects during infusion are a potential disadvantage, requiring appropriate precautions (see ch. 298). The protocol described includes serum samples collected before and 15, 30, 60 and 90 minutes after IV infusion of Ca (2 mg/kg IV, given over 1 minute).[24] Maximum gastrin secretion was detected at 60 minutes. Humans with gastrinoma typically have a two-fold increase in serum gastrin concentrations after stimulation, as did the few dogs with confirmed gastrinoma.

Pathology

Gastrinomas are usually solitary neoplastic nodules located in the pancreas, but multiple masses have been reported. In the dog, the tumor is more often located in the right limb or body of the pancreas and metastases are common at the time of diagnosis. Metastatic lesions may be identified in non-pancreatic sites (lymph nodes, mesentery, peritoneal surfaces, spleen and liver) in as many as 85% of cases. Microscopically, gastrinomas are carcinomas of endocrine cell origin and stain using immunohistochemistry. On ultrastructural studies, identification of specific intracellular granules may permit definitive diagnosis of gastrinoma. Although rarely performed, hormone measurements on extracts of tumor tissue may also be used to confirm gastrin production. GI ulceration secondary to hypergastrinemia is common, may affect esophagus, stomach, and intestine, and may result in perforation and peritonitis. Hypertrophy of the gastric wall has been reported. Additional endocrine disorders noted in some dogs include thyroid carcinoma and adrenal hyperplasia.

Glucagonoma

Overview

Glucagonoma is a rare endocrine tumor that has been reported in a several dogs[25-27] and a single cat.[28] It arises from neuroendocrine alpha cells in pancreatic islets. Excess circulating glucagon concentrations are due to autonomous secretion that induces hepatic gluconeogenesis and glycogenolysis, which in turn produce insulin resistance, glucose intolerance and, in some cases, overt DM. Definitive treatment is accomplished by surgical removal of the glucagonoma. Necrolytic migratory erythema (NME), a dermatologic condition characterized by crusting and a rash, is considered pathognomonic for glucagonoma in people.[29] In dogs, this condition has been seen in glucagonoma, but is most commonly associated with liver disease (see ch. 10 and 285).[30]

Signalment and Clinical Signs

At diagnosis, the few dogs described to have glucagonoma were middle-aged or older and the cat was 6 years old. Along with nonspecific signs, such as lethargy and decreased appetite, a few dog owners were concerned about non-healing skin erosions and ulcers. The distribution of lesions and involvement of mucocutaneous sites are also consistent with auto-immune skin diseases. Lesions have been reported to involve lips, nose, ears, muzzle, paws, the ventrum, inguinal region, and extremities (Figure 310-1). Dogs with uncontrolled DM at the time of diagnosis exhibit polydipsia, polyuria, and weight loss. Insulin therapy may be relatively ineffective in controlling the hyperglycemia, requiring high doses.

FIGURE 310-1 Necrolytic migratory erythema lesions on the foot and footpad of a dog with glucagonoma.

Laboratory Findings

Numerous nonspecific laboratory abnormalities have been reported in dogs with glucagonoma, but none is specific. Increased serum activities of alanine aminotransferase (ALT) and alkaline phosphatase (ALP) together with decreases in albumin, blood urea nitrogen (BUN) and cholesterol have been identified in some dogs with NME and glucagonoma. When considering a diagnosis of glucagonoma, it is worth remembering that abnormal liver parameters in dogs with glucagonoma mimic primary liver disease, a more common cause of NME in dogs. Liver function tests, such as bile acids and blood ammonia levels, have been normal in dogs with glucagonoma but may be important when investigating the possibility of liver disease.

Diagnostic Imaging

Abdominal US (see ch. 88) is more sensitive than radiography for detecting a pancreatic mass but masses have not been detected in most dogs with glucagonoma reported. Computed tomography (CT) examination identified a pancreatic mass in one dog. Abnormalities in the US appearance of the liver were frequently observed in dogs with glucagonoma but no consistent pattern was noted. In dogs with NME, it is important to remember that liver disease is a more common cause than glucagonoma. Hepatic abnormalities on US should be assessed in the context of whether or not a pet has primary liver disease or glucagonoma.

Diagnosis

Definitive diagnosis of glucagonoma relies on demonstration of hyperglucagonemia, noted in most dogs with glucagonoma previously reported. The hyperglucagonemia in affected dogs showed variability, with elevations ranging from approximately 1.5 to 15 times the upper limit of reference range. No serum concentration is diagnostic of glucagonoma but serum concentrations of >1000 ng/L are considered diagnostic for glucagonoma in humans. Since serum glucagon may increase in disorders other than glucagonoma, diagnosis is appropriately made only when hyperglucagonemia occurs in association with clinical signs of hormone excess. Diagnostic efforts may be complicated by lack of commercially available serum assays for canine and feline glucagon. Measurement of plasma amino acids may provide support for a diagnosis of glucagonoma. Hyperglucagonemia stimulates hepatic gluconeogenesis, accelerates amino acid turnover and lowers plasma amino acid concentrations. Concentrations of arginine, histidine, and lysine were reduced in all of the dogs with glucagonoma in which measurements were performed.

Pathology

Pancreatic glucagonoma is usually a solitary neoplasm that can arise from any region of the pancreas (limbs, body) and reports suggest that metastasis is common in dogs. The liver was the primary site of metastasis in most, although lymphatic metastasis has been seen. Metastatic nodules may be functional (liver metastasis was the only site where glucagon production was documented in one dog with glucagonoma), suggesting incomplete surgical removal of metastases could result in persistent signs. By convention, these tumors have positive staining for glucagon when examined using immunohistochemistry. Expression of other islet hormones and neuroendocrine markers may be detected. Most dogs with glucagonoma have exhibited positive cellular staining against multiple hormones although it is not clear whether these tumors secrete hormones other than glucagon.

Other Neuroendocrine Tumors

Carcinoid

Neuroendocrine tumors that secrete vasoactive substances such as 5-HT (also known as serotonin) or kinins are referred to as carcinoid tumors. These tumors may arise from neuroendocrine cells located in the epithelium of the bronchial tree, lung, biliary system, GI tract, and other sites. In people, the "carcinoid syndrome" is characterized by watery diarrhea, abdominal discomfort, abdominal cramps, bronchoconstriction and hyperemia of the cheeks and forehead ("facial flushing"). Carcinoid tumors are rare in dogs and cats. Most information about these tumors has come from single case descriptions.[31] In dogs, carcinoids have been found in the stomach, duodenum, jejunum, ileocolic region, colon, and rectum.[32-36] Based on just a few reports featuring cats, locations included the liver, pancreas and GI tract.[37,38] Metastasis to lymph nodes and other sites, including lung, was common.

The majority of carcinoids reported in dogs and cats cause signs related to the physical presence of the tumor and do not appear to be functional. The carcinoid syndrome has not been reported in cats. The one dog reported to have carcinoid syndrome did not have elevated concentrations of vasoactive substances 5-HT or kinins.[39] Diagnosis of carcinoid is often made postmortem but when identified antemortem, surgical removal of the carcinoid is recommended. Tumor removal may improve signs that result from its physical presence (intestinal obstruction, for example) although the high frequency of metastasis makes complete tumor removal unlikely. In the sole case report of suspected carcinoid syndrome in a dog, tumor removal resulted in improvement or resolution of the dog's clinical signs.[39] Serum concentrations of 5-HT and other vasoactive substances may be measured to confirm suspected carcinoid in people but these tests have not been performed in animals. Histologic examination of tumor tissue is required to confirm the diagnosis.

Pancreatic Polypeptidoma

Pancreatic polypeptidoma is a poorly understood neuroendocrine tumor that occurs as part of the multiple endocrine neoplasia (MEN) syndrome in people but also develops sporadically in humans and has been reported in the dog.[24] Many functional neuroendocrine tumors of pancreatic islet origin stain positively for several peptide hormones, including pancreatic polypeptide (PP). When the principal protein hormone expressed is PP, the tumor is designated a pancreatic polypeptidoma. The clinical signs associated with excess PP secretion are minimal and most pancreatic polypeptidomas are considered non-functional.[40] A minority of human pancreatic polypeptidomas has been suspected of producing clinical signs related to tumor release of

PP. Signs reported with PP excess include abdominal pain and diarrhea. Some have had pancreatitis. In a dog, increased plasma PP concentrations were associated with chronic vomiting, duodenal ulcers, and evidence of hypertrophic gastritis. The dog also had a pancreatic adenocarcinoma, which stained positively for PP and insulin but not other peptides typically produced by canine pancreatic neuroendocrine tumors (gastrin, glucagon, or somatostatin).[24]

CHAPTER 311

Pheochromocytoma

Sara Galac

Client Information Sheet: Pheochromocytoma

Background and Definition

Pheochromocytoma is a catecholamine-producing neuroendocrine tumor arising from chromaffin cells of the adrenal medulla.[1] It is considered to be malignant. The manifestations are diverse and can mimic those of various conditions, which often results in erroneous and delayed diagnosis. Not surprisingly, pheochromocytoma has therefore earned the title "great mimic." The clinician's awareness of pheochromocytoma represents a crucial initial step in making a diagnosis, but for confirmation, biochemical evidence of excessive catecholamine production and diagnostic imaging are needed.[2,3] Most pheochromocytomas are unilateral, but occasionally both adrenals are affected. Pheochromocytoma may coexist with other endocrine neoplasms, such as cortisol-secreting adrenocortical tumor, adrenocorticotropic hormone (ACTH)-secreting pituitary tumor, thyroid tumor, insulinoma, or parathyroid tumor or hyperplasia.[4-8] The etiology of pheochromocytoma in dogs is largely unknown. Recently, mutation analysis demonstrated a missense mutation of succinate dehydrogenase subunit D (*SDHD*).[9] In humans, germline mutation of *SDHD* is commonly present in familial forms of pheochromocytoma, in addition to *SDHD, NF1, RET1,* and *VHL* mutations.[10,11] There is a high sequence homology between canine and human *SDHD* and theoretically this mutation could be responsible for the development of pheochromocytoma in dogs.[9]

Physiology

The adrenal medulla originates from the sympathetic nervous system, but without the axons and dendrites of neurons. The medullary cells, called pheochromocytes or chromaffin cells, release epinephrine and norepinephrine into the bloodstream. The medulla is highly vascularized and directly connected to the abdominal aortic system. There is a close vascular relationship between the medulla and the cortex. Blood flowing from the zona reticularis leaves the gland via vessels in the medulla. The unique innervation and vascularization of the adrenal medulla underlies the "fight or flight" response.[12]

Catecholamines (epinephrine and norepinephrine) are synthesized from the amino acid tyrosine via a series of modifications (Figure 311-1). When tyrosine enters chromaffin cells, it is converted to L-dihydroxyphenylalanine by the enzyme tyrosine hydroxylase. This first step in the pathway is the committed rate-limiting step and is feedback-inhibited by norepinephrine. Intracellular catecholamine depletion rapidly increases enzyme activity, whereas increased catecholamine levels lead to its downregulation.[13] In most sympathetic postganglionic neurons, norepinephrine is the final product. However, the adrenal medulla expresses an additional enzyme not present in adrenergic neurons, phenylethanolamine-N-methyltransferase (PNMT).[12] Because only the adrenal medulla is exposed to high levels of cortisol (due to the centripetal blood flow from the cortex), induction of *PNMT* gene expression is allowed. This physiological mechanism needs to be taken into account in diagnostic procedures for pheochromocytoma.[14] Within the adrenal medulla, norepinephrine is released from the chromaffin vesicles to the cytoplasm and is converted to epinephrine. The amount of stored epinephrine and norepinephrine varies from species to species. In dogs, catecholamines usually include more epinephrine (70%) and less norepinephrine (30%). The percentages are 60 and 40% in cats, 80 and 20% in humans.[15]

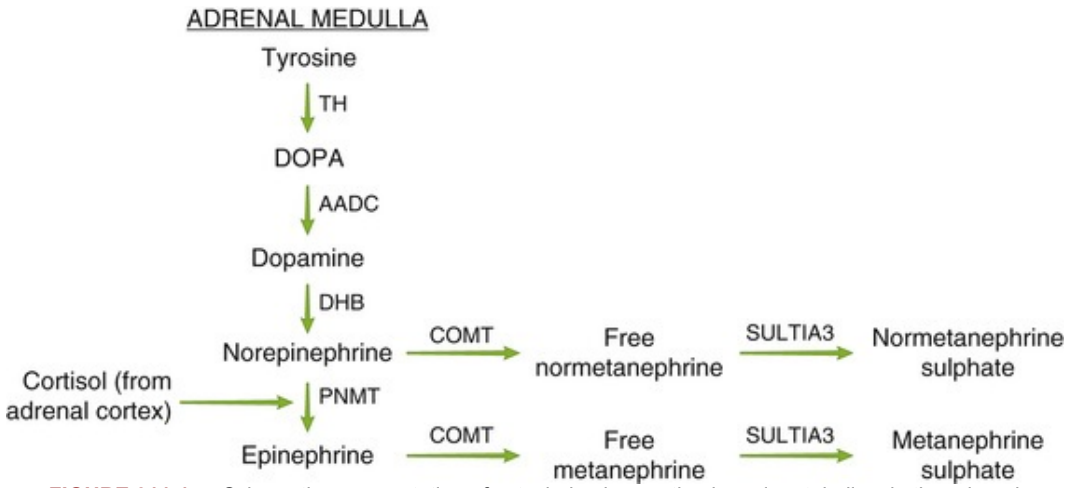

FIGURE 311-1 Schematic representation of catecholamine synthesis and metabolism in the adrenal gland. Tyrosine is converted to L-dihydroxyphenylalanine (DOPA) by the enzyme tyrosine hydroxylase (TH), and subsequent metabolism to dopamine is orchestrated by the enzyme aromatic L-amino acid decarboxylase (AADC). Dopamine is converted by the enzyme dopamine beta-hydroxylase (DHB) to norepinephrine, which is finally converted to epinephrine by the enzyme PNMT, stimulated by cortisol from the adrenal cortex. The catecholamines are metabolized by the enzyme catechol-O-methyltransferase (COMT) and can be measured as free normetanephrine and normetanephrines in plasma. The conjugation of normetanephrine and metanephrine by the enzyme sulfotransferase (SULTIA3) occurs in the gastrointestinal tract, kidneys, and liver, and sulfate-conjugated metanephrines can be measured in urine.

Catecholamines are released by exocytosis upon stimulation of the chromaffin cell by acetylcholine from the sympathetic nervous system. The release signal is triggered by stressors, such as anxiety, fear, pain, trauma, hemorrhage or other fluid loss, changes in blood pH, hypoglycemia, or exposure to excessive heat or cold. The plasma half-life of circulating catecholamines is short and their inactivation begins within a few minutes.[16,17] They are metabolized in the liver and kidney but can also be inactivated by deconjugation in the gastrointestinal (GI) tract. In addition to this extra-adrenal metabolism of circulating catecholamines, there is continual metabolism of norepinephrine and epinephrine within the adrenal medulla due to leakage of norepinephrine and epinephrine from their storage granules. This leads to the substantial intracellular production of O-methylated metabolites, metanephrine (MN) and normetanephrine (NMN) (see Figure 311-1). These metabolic processes within the medulla are independent of exocytotic release of catecholamines, and represent the primary source of circulating MN and NMN. In humans, about 93% of circulating MN and 25 to 40% of circulating NMN are derived from catecholamine metabolism within adrenal chromaffin cells. There is a misconception that vesicular stores of catecholamines exist in a static state until a stimulus evokes release into the extracellular space.[13] Rather, vesicular stores are in a highly dynamic equilibrium with catecholamines in the surrounding cytoplasm. Rapid active transport from the cytoplasm to vesicles counterbalances passive outward leakage from vesicles. Although only a small fraction of the catecholamines in the cytoplasm escapes vesicular sequestration, it remains a major source of catecholamine metabolites.[18] Catecholamines activate adrenergic G-protein-coupled receptors, which are divided into alpha and beta types and their subtypes. An overview of the location of the receptors and their physiological relevance is given in Table 311-1.

TABLE 311-1

Catecholamine Types and Subtypes, Tissue Location, and Effects

ORGAN/TISSUE	RECEPTOR TYPE	EFFECT
Cardiovascular system	Beta-1	Increase in heart rate and contractility
	Alpha-2	Vasoconstriction
	Beta-2	Vasodilatation of skeletal muscle arterioles, coronary arteries, and all veins
Bronchial muscles	Beta-2	Relaxation

Gastrointestinal tract	Beta-2	Decrease in motility
Pancreatic islets	Alpha-2	Decrease in insulin and glucagon secretion
	Beta-2	Increase in insulin and glucagon secretion
Liver	Beta-2	Increase in glycogenolysis and gluconeogenesis
Adipose tissue	Beta-2	Increase in lipolysis
Urinary bladder	Alpha-2	Increase in sphincter tone
	Beta-2	Relaxation of detrusor muscle
Eye	Alpha-1	Mydriasis

Modified from Galac S, Reusch C, Kooistra H, et al: Adrenals. In Rijnberk A, Kooistra HS, editors: *Clinical endocrinology of dogs and cats*, ed 2, Hannover, 2010, Schlütersche, p 140.

Clinical Manifestations

Signalment

Pheochromocytoma is diagnosed most often in older dogs (average: 11 years).[5,7,19] There is no apparent gender or breed predilection. The frequent description of pheochromocytoma in some breeds (Rhodesian Ridgeback, Labrador Retriever, Boxer, Golden Retriever, Terrier breeds) reflects their popularity more than their relative risk of disease.[15,20] In cats, pheochromocytoma is considered extremely rare; only three cases have been reported in the veterinary literature.[21-23]

Clinical Signs

Clinical signs associated with pheochromocytoma are related to the direct actions of secreted catecholamines and/or the space-occupying or invasive nature of the adrenal mass. Hormone secretion from the tumor is sporadic and unpredictable. Clinical manifestations due to excess circulating catecholamines vary considerably. Dogs with pheochromocytoma most often have intermittent episodes of collapse, weakness, and/or panting.[5,7,19] The episodes are paroxysmal and may occur several times per day or per week, or only at intervals of weeks to months. They can be mild or life-threatening and may progress with time. Clinical manifestations related to catecholamine excess can be categorized as follows[15]:

- Cardiorespiratory system and/or systemic hypertension: tachypnea, panting, tachycardia, arrhythmias, collapse, pale mucous membranes, nasal-, gingival-, or ocular hemorrhage, acute blindness
- Neuromuscular system: weakness, anxiety, pacing, muscle tremors, seizures
- Nonspecific: anorexia, weight loss, lethargy
- Miscellaneous: polyuria/polydipsia, vomiting, diarrhea, abdominal pain

Large pheochromocytomas may become invasive. Their heterogeneous structure makes them predisposed to episodes of bleeding and necrosis. Clinical manifestations of a space-occupying adrenal pheochromocytoma may be related to:

- Invasion by the tumor of the vena cava: ascites, hind limb edema, distension of the caudal epigastric veins
- Invasion by the tumor of the aorta (aortic thromboembolism): painful and weak hind limbs, paraparesis, absence of the femoral pulse, cold distal extremities[5,24]
- Spontaneous tumor rupture: retroperitoneal hemorrhage (lethargy, tachypnea, tachycardia, weakness, pale mucous membranes, abdominal pain)[25]

In dogs, pheochromocytomas may metastasize to the liver, kidneys, spleen, regional lymph nodes, lungs, heart, bone, and the central nervous system (CNS). Metastatic disease can cause organ-specific clinical signs. In dogs, paresis due to metastasis within the vertebral canal and lameness, swelling, and pain due to metastasis to bones have been reported several times.[26-28]

Physical examination is most often unremarkable. When signs are present, panting and tachypnea are most common, followed by weakness, tachycardia, and cardiac arrhythmias.[7,29,30] However, physical findings greatly depend on the presence or absence of secretory activity by the tumor. This kaleidoscope of clinical manifestations and the infrequent diagnosis of pheochromocytoma require a high level of clinical awareness

for diagnosis; otherwise, this condition can be easily overlooked.

Diagnostic Evaluation

Overview

Pheochromocytoma is a diagnostic challenge (Figure 311-2). Initial suspicion could follow the fortuitous finding of an adrenal mass during diagnostic imaging, commonly referred to as an "incidentaloma" (see ch. 308). Confirmation of this diagnosis, however, requires biochemical evidence of excessive catecholamine production.[31] Veterinary diagnosis of pheochromocytoma improved dramatically with introduction of assays for plasma and urinary catecholamine metabolites, NMN and MN.[15] There are not, as yet, generally accepted guidelines for a "test of choice" or for algorithms used in confirming, locating or excluding the diagnosis of pheochromocytoma.

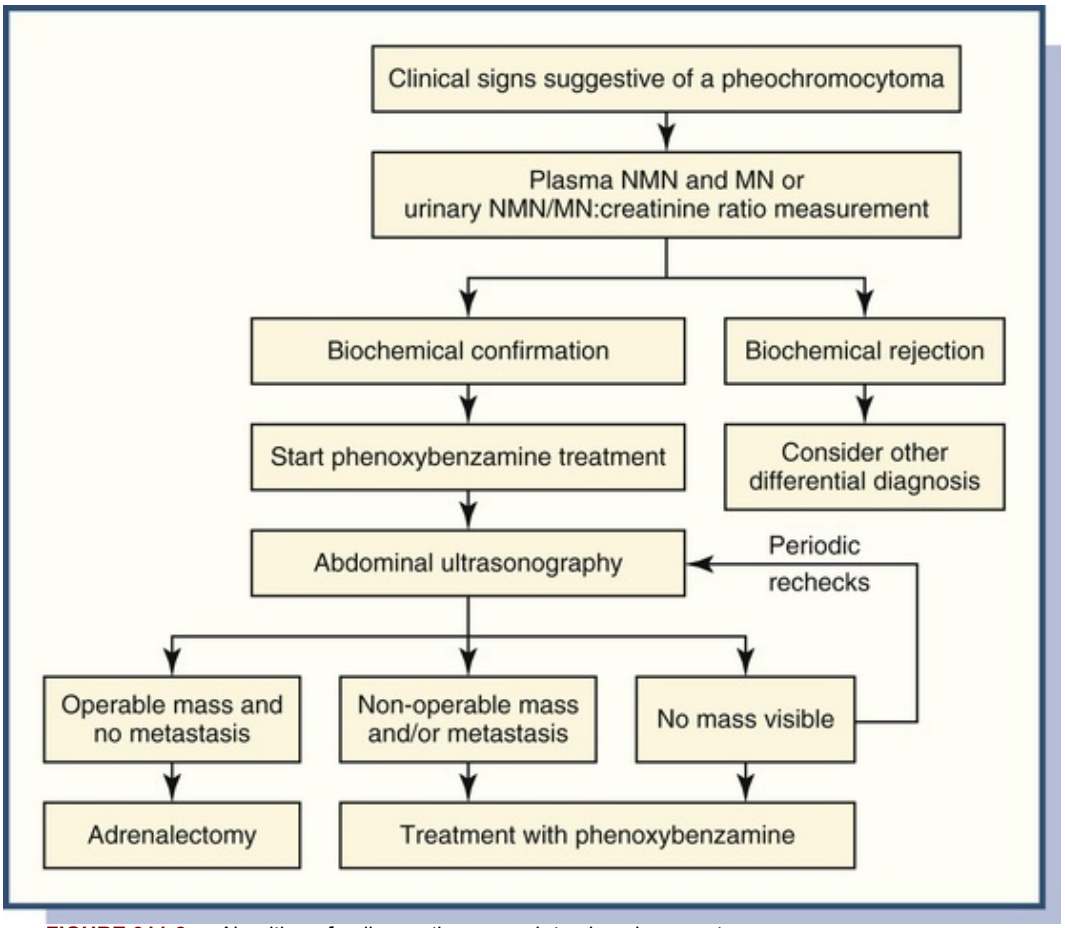

FIGURE 311-2 Algorithm of a diagnostic approach to pheochromocytoma.

Clinical Pathology

No specific abnormality in complete blood count (CBC), serum biochemical panel, or urinalysis would raise suspicion of pheochromocytoma.[15] Many abnormalities identified in results of routine blood and urine tests are caused by concurrent disorders that are commonly present in dogs with pheochromocytoma. Increases in serum liver enzyme activities have been reported in 10 to 25% of dogs with pheochromocytoma,[7] but abnormal values may be secondary to systemic hypertension and changes in hepatic perfusion, or may be caused by any number of potential concurrent diseases. The CBC is usually unremarkable. Hyperglycemia has been reported in approximately 20% of dogs with pheochromocytoma. Proteinuria, a result of hypertensive glomerulopathy or concurrent illness, is also observed in approximately 20%.[5,7]

Hyposthenuria/isosthenuria may be due to the inhibitory effect of circulating catecholamines, especially norepinephrine, on antidiuretic hormone (ADH) secretion and activity.[15]

Systemic Blood Pressure

Although arterial hypertension is one of the hallmarks of the disease, it is detected in only about 50% of dogs with a pheochromocytoma at the time of examination.[15] Various patterns of hypertension have been described in humans with pheochromocytoma.[2,16] They can have persistent and stable hypertension or hypertension/normotension with paroxysmal peaks of extreme hypertension; about 10% are normotensive. It has been suggested that such variable blood pressure patterns exist in dogs as well, but this awaits confirmation in a large group of patients.[32] Measurement, preferably repeated, of systemic arterial blood pressure (see ch. 99) is indicated in any dog with suspected pheochromocytoma, because hypertension requires prompt treatment (see ch. 158). On the other hand, a failure to document systemic hypertension does not rule out pheochromocytoma.

Diagnostic Imaging

Overview

Diagnostic imaging provides important information about adrenal size and structure, unilateral or bilateral involvement, and contact with or invasion of neighboring organs and blood vessels.[1,30] Based on selective criteria, imaging can provide an estimate of potential malignancy and can be extremely helpful in selecting the best therapeutic approach, but it cannot predict the histological type of the adrenal mass.

Radiology

Abdominal radiographs are of little value in visualizing pheochromocytoma, because in contrast to cortical tumors, they are usually not mineralized.[30] Thoracic radiography, prior to adrenalectomy, was recommended to screen for metastasis, but has been largely replaced by computed tomography (CT) scanning.[30,33,34] Abnormalities on thoracic radiographs may include generalized cardiomegaly, right or left ventricular enlargement, pulmonary congestion, and pulmonary edema, presumably resulting from systemic hypertension.

Abdominal Ultrasonography (US)

Pheochromocytomas may be visualized as nodules a few millimeters in diameter or as heterogeneous masses with a diameter >10 cm. Their echogenicity may be hypoechoic or heterogeneous, and large masses may have a multilobular and/or multicystic architecture with anechoic foci of necrosis and hemorrhage. There is no US observation considered pathognomonic for pheochromocytoma.[30,35] Most pheochromocytomas are unilateral, enlarged, adrenal gland masses with a contralateral adrenal gland that is normal in size and shape. However, bilateral pheochromocytomas do occur and are challenging to differentiate from adrenocortical hyperplasia. An attempt to differentiate between adrenal tumor types has been made using contrast-enhanced US.[36] In pheochromocytomas, there is no contrast enhancement in necrotic or hemorrhagic areas or cysts, but the same is true of adrenocortical carcinomas. The most important differential diagnosis is between cortical and medullary neoplasia and these cannot be discriminated via US. Pheochromocytomas are reported to invade the surrounding structures and blood vessels more often than do other types of adrenal tumor. Invasion of the caudal vena cava occurs in 15 to 55% of pheochromocytomas. Right-sided adrenal tumors are more likely to invade the caudal vena cava.[29,37,38] Invasive behavior does not necessarily indicate malignancy; rather, it can represent mass expansion into areas presenting the least resistance.[2]

Computed Tomography (CT) and Magnetic Resonance Imaging (MRI) Scans

CT imaging scans are considered more accurate than abdominal US for detecting vascular luminal invasion by adrenal masses.[30,33,39] Presence and extent of vascular invasion influences choice of therapy and are, therefore, important. Pheochromocytomas have variable appearances in CT images, having multiple foci of low attenuation interspersed with hyperattenuating, highly vascularized areas, especially in large tumors.[30,39] These features, typical of hemorrhage and necrosis, are not specific for pheochromocytoma and are more likely when adrenal tumors attain a certain size. One additional benefit of CT scanning is that abdominal

imaging can be combined with thoracic screening for metastases. The use of an IV contrast medium is controversial in patients suspected of having a pheochromocytoma. In people, an ionic contrast medium may stimulate release of catecholamines and induce a hypertensive crisis.[40,41] Although no such complications with ionic contrast media have been reported in dogs with pheochromocytoma, non-ionic contrast media are preferred because they do not exert such an effect on catecholamines. Alternatively, MRI scanning can be performed without any IV contrast agents. The sensitivity and specificity of CT and MRI scanning of pheochromocytomas are comparable in humans,[42] but there have as yet been no reports of MRI scanning results of pheochromocytomas in dogs.

Nuclear Imaging

The primary indication for nuclear imaging in people is to detect any extension of pheochromocytoma not identified by anatomic imaging (CT or MRI scan), such as bilateral or multiple tumors or metastatases.[31] The procedure of choice is scintigraphy using ^{123}I-MIBG (metaiodobenzylguanidine), a radiopharmaceutical which competes with norepinephrine for uptake and storage in neurosecretory granules of catecholamine cells, thereby revealing functional medullary tissue. Its use in dogs has been reported.[43] Positron emission tomography (PET) with ^{18}F-MIBG (fluorobenzylguanidine) is reserved for rapidly growing, dedifferentiated tumors in which ^{123}I-MIBG uptake is negative. There is little experience with functional imaging of pheochromocytoma in dogs.[44]

Percutaneous Fine-Needle Aspiration Biopsy

Use of cytology is straightforward in discriminating primary cortical adrenal masses from those of medullary origin.[45] While large case studies would be needed to confirm the reliability of this approach, the question remains whether the benefits of this procedure outweigh its risks. Adrenal biopsy can, potentially, have fatal complications associated with catecholamine release; hence, fine-needle aspiration biopsy is suggested in people only after pheochromocytoma has been ruled out.[46,47] Although published reports in the veterinary literature have described no complications, their numbers are small. Concerns about the risks associated with this procedure remain. Given that the cytological findings usually do not change management strategies and cannot discriminate between benign and malignant primary adrenal tumors, this approach remains controversial.

The Incidentally Discovered Adrenal Mass

The prevalence of a pheochromocytoma in dogs who have had an adrenal mass identified serendipitously on an imaging study is unknown (see ch. 306, 308, and 310). Since dogs with a pheochromocytoma can have any of a plethora of clinical signs and can be easily missed, testing for a pheochromocytoma is recommended for a dog with an incidentally discovered adrenal mass. This is emphasized when the imaging phenotype of heterogeneity, calcification, irregular borders, local invasion, and/or areas of necrosis are suspected. If a diagnosis of pheochromocytoma cannot be made, but there is strong suspicion of malignancy on imaging, endocrine testing for cortisol and aldosterone excess should be performed before adrenalectomy. Here, the purpose of testing is to anticipate proper postoperative hormonal supplementation. Confirming malignancy is difficult even on histopathology. Therefore, imaging can only provide a suspicion. In clinical situations, when there is lack of structural changes in the adrenal mass, monitoring mass size, at 3- to 6-month intervals, is recommended. Although no size cut-off has been identified that can confirm or exclude malignancy, an increase in size of adrenal masses, if corroborated by other imaging and/or clinical features, is an indication for adrenalectomy.

Biochemical Testing

Overview

Biochemical demonstration of excessive production of catecholamines is essential for the diagnosis of pheochromocytoma.[31,48] Biochemical evaluations typically include measurement of plasma and urinary catecholamines and their metabolites, MN and NMN, the so-called metanephrines.[3] The principle of measuring metanephrines is based on the intramedullary metabolism of catecholamines. The production of metanephrines in tumor cells is autonomous and continuous. Metanephrine concentrations more accurately reflect tumor mass than catecholamine concentrations, which are secreted episodically.[13] In humans,

measurement of urinary-fractionated metanephrines or plasma-free metanephrines provides better diagnostic sensitivity than do urinary or plasma measurements of catecholamines (epinephrine and norepinephrine) and other catecholamine metabolites.[3,48]

Urinary Catecholamines

Measurement of urinary catecholamines in dogs should be performed on a single voided sample, with concentrations expressed as a ratio to the creatinine concentration in that same sample.[32,49] The urinary NMN-to-creatinine ratio has a higher sensitivity than the MN-, epinephrine-, or norepinephrine-to-creatinine ratios.[49] While urinary epinephrine- and norepinephrine-to-creatinine ratios overlapped to some degree between healthy dogs and those with pheochromocytoma, urinary NMN was consistently higher in those with pheochromocytoma. This might indicate that most pheochromocytomas produce norepinephrine, which is metabolized to NMN and continuously released into the circulation, while norepinephrine is secreted only paroxysmally.[31,50] Corresponding to urinary measurements of NMN, measurement of plasma free NMN was superior to measurement of free MN in the diagnosis of pheochromocytoma.[51,52] There is no consensus on plasma versus urine testing; however, according to the latest studies, the urinary NMN-to-creatinine ratio has been most reliable.[52] In addition to assay accessibility and personal experience, the availability of reference ranges may influence whether one uses plasma or urine for these tests. For example, plasma-free NMN and MN are much higher in healthy dogs than in humans, and the importance of species-specific reference ranges should not be underestimated.

Interfering Drugs and Conditions

An important aspect of the biochemical diagnosis of pheochromocytoma is the interference by some drugs with measurements of catecholamine and their metabolites.[17] Phenoxybenzamines increase norepinephrine and NMN concentrations in people. Testing in dogs with suspected pheochromocytoma should be completed before any treatment. Endogenous and exogenous glucocorticoids have physiological interactions with catecholamines and increase their production.[13] In addition, there are similarities in the clinical features of pheochromocytoma and hyperadrenocorticism, making their differentiation even more challenging. The discrimination between the two groups was again superior for NMN, but there was some overlapping of NMN values in both plasma and urine between the groups. In people, a cut-off value 4 times the upper limit of normal is recommended to distinguish true-positive from false-positive results in patients with hypercortisolism, and a similar rule has been proposed for dogs.[49] This merits further study.

Serum Inhibin

Measuring serum inhibin concentrations can be helpful. Inhibin should be undetectable in dogs with pheochromocytoma, but not in those with hyperadrenocorticism.[53] This assay is not applicable in sexually intact dogs because serum gonadal and adrenocortical inhibin cannot be distinguished.

Treatment

Background

Adrenalectomy is the optimal treatment for a dog with pheochromocytoma.[15,54] Removal of the adrenal tumor will reverse the clinical signs and symptoms associated with catecholamine release and avoid the complications of uncontrolled growth of the tumor. Complications occurring during and after surgery are catecholamine-induced effects, which are serious and potentially life-threatening. Prerequisites for success are preoperative medical treatment, an experienced anesthetist, and intensive postoperative care.[1] If the tumor is inoperable or surgery is prevented by concurrent disorders or for other reasons, medical treatment is indicated to block alpha-adrenergic response to circulating catecholamines.[29] Medical treatment does not appear to alter secretion or growth of pheochromocytomas.

Preoperative Management

The aim of medical treatment is to prevent catecholamine-induced complications: hypertensive crisis, cardiac arrhythmias, pulmonary edema, and cardiac ischemia. Phenoxybenzamine is an alpha-adrenergic receptor antagonist that irreversibly binds to $alpha_1$- and $alpha_2$-adrenergic receptors and blocks the alpha-adrenergic

response to circulating epinephrine and norepinephrine.[55] Since phenoxybenzamine has a long duration of action, surges of circulating catecholamines cannot override inhibition. In dogs pretreated with phenoxybenzamine, the mortality rate after adrenalectomy was significantly lower than in untreated dogs.[29] The current recommendation is to start with a dosage of 0.25 mg/kg PO q 12 h and to increase it stepwise every few days until the final dosage of 1 mg/kg is reached. During this period, the dog should be monitored for clinical signs of hypotension (lethargy, weakness, or syncope) or other adverse effects (vomiting, tachycardia) and the dosage adjusted, if needed.[15] Pretreatment with phenoxybenzamine should be initiated at least 2 weeks prior to adrenalectomy. However, the optimal dosage and duration of treatment have not yet been established.

In patients with tachyarrhythmia, blocking of beta-adrenoreceptors should be added to alpha-blockade (e.g., atenolol, 0.2 to 1 mg/kg PO q 12-24 h). This addition, however, should never be initiated before the blockade of alpha-adrenoreceptors, since loss of beta-adrenoreceptors-mediated vasodilatation leaves alpha-adrenoreceptor stimulation unopposed, which could result in hypertensive crises.

Surgery

Adrenalectomy should only be undertaken by an experienced surgeon in adequate facilities. Close communication between the surgeon and the anesthetist is essential, because manipulation of the tumor can cause a surge in catecholamine release, leading to hypertension, tachycardia, and arrhythmias. The anesthetist should be able to anticipate these critical stages by deepening the anesthesia in advance. If this is not sufficient, a short-acting alpha-adrenergic antagonist can be administered to combat hypertension. An ultra-short-acting $beta_1$ antagonist may be added if tachycardia persists.[15] Laparoscopic adrenalectomy has gained popularity. Observational studies have shown more rapid recovery, shorter hospitalization, fewer wound complications, and shorter surgical time compared to laparotomy.[56,57] The size of the adrenal tumor and the extent of vascular invasion are the most important criteria in choosing between laparoscopy and open laparotomy. Masses up to 5 cm in diameter and without invasion of the caudal vena cava are amenable to laparoscopy, while open adrenalectomy is indicated if there is invasion of the vena cava. Removal of tumor thrombi and thrombectomy are possible and not associated with higher morbidity and mortality with an appropriate team approach.[34,58-60] However, an extensive tumor thrombus is associated with higher postoperative mortality.[29]

Postoperatively, patients should be kept under close surveillance for at least 48 hours. Complications include cardiac arrhythmias (see ch. 141 and 248), respiratory distress (see ch. 139), hemorrhage (see ch. 135 and 197), and hypertension (see ch. 157 and 158). Hypotension (see ch. 159) is also possible, due to the abrupt fall in circulating catecholamines after tumor removal in the continuing presence of alpha-adrenoreceptor blockade (by phenoxybenzamine).

Medical Therapy

In dogs with an unresectable pheochromocytoma, metastasis, serious concurrent disease, and/or owner constraints, medical treatment with phenoxybenzamine is used.[15] The preoperative management protocol is applied and if there are tachyarrhythmias, a selective $beta_1$ antagonist can be added after an alpha-adrenergic blocker has been administered for at least a few days. There are as yet insufficient data for an appraisal of the survival of dogs receiving medical treatment alone.

Histopathology

The definitive diagnosis of pheochromocytoma rests upon histological examination. Pheochromocytomas consist of neoplastic cells arranged in lobules supported by a fine fibrovascular stroma. The neoplastic cells are round to polyhedral with eosinophilic to basophilic cytoplasm and hyperchromatic nuclei with variable mitotic activity.[7,30] There may be compression of the adrenal cortical zonal architecture, as well as necrosis and hemorrhage, especially in large tumors. Differentiation between cortical and medullary adrenal tumor is made by immunohistochemistry. Neuroendocrine markers are stained, chromogranin A being the most commonly used.[61] It is normally present in chromatin granules in cells of the medulla but not in adrenal cortical cells, which renders it an ideal marker. Differentiation between benign and malignant pheochromocytoma based on histopathology is unreliable. The presence of metastasis is the only reliable

indicator of malignancy,[62] while the significance of capsular and vascular invasion with tumor thrombi remains controversial.[62,63]

Prognosis

The size of the tumor, its endocrine activity, vascular invasion, and the presence of metastasis may affect the prognosis. With regard to surgical removal, both pretreatment with the alpha$_2$-adrenergic blocker phenoxybenzamine and the extent of vascular invasion play a role. Additional prognostic factors are age, general well-being, and the presence of concurrent disease.

Manipulation of the Estrous Cycle
Estrous Cycle and Estrous Cycle Abnormalities
How to Manage an Accidental Breeding

The Reproductive Cycle

The canine reproductive cycle has historically been divided into 4 stages: proestrus (attractive to males but unwilling to breed), estrus (receptive to mating), diestrus (luteal/progestational phase that follows breeding) and anestrus (reproductive quiescence). Such classification was proposed by Heape in 1900 and is based on reproductive behavior and related clinical changes of external genitalia of the bitch without taking into account the fine interplay of reproductive hormones.[1] Despite the abundance of diagnostic tools now available, Heape's classification remains valid and continues to be used in scientific as well as clinical settings. The term *estrus* may be understood by some, but breeders and dog owners commonly employ the term *heat* in reference to the entire follicular phase (proestrus + estrus). The term *standing heat* is used to denote the period of breeding (estrus). The term *diestrus* does not fully encompass the canine luteal phase, which begins early in estrus due to pre-ovulatory luteinization. However, diestrus is regarded as an appropriate term to indicate the period during which the canine corpora lutea (CLs) are actively secreting progesterone (P4) and the bitch is no longer willing to breed. The term *metestrus* in food animals refers to the entire time a female is under the influence of CLs and includes the early period of developing (but immature) CLs with little if any serum P4 production.

Seasonality of Estrous Cycles and Interestrous Intervals

The canine is generally regarded as a mono-estrus species (only one estrus is completed during each reproductive cycle) and non-seasonal (the occurrence of estrus is not influenced by season of the year). Family pets housed indoors tend to come in season in any month of the year[2] although cycling activity estimates based on litter registration data of the American Kennel Club show peaks in late winter and spring.[3] Such spring peaks of cycling activity have been observed in Beagle bitches housed outdoors in Northern Europe[2] and are anecdotally reported elsewhere in dogs living in temperate climates. Seasonality of canine reproduction has been an object of debate based on the seasonality (one cycle yearly) of wolves, dingoes and Basenjis.[4,5] Although most domestic dog breeds appear to have lost their photo-responsiveness, an influence of photoperiod on the hypothalamic-pituitary function of the bitch is demonstrated by an annual rhythm to prolactin (PRL) secretion in mixed-breed dogs housed constantly outdoors.[6] Genetic selection for performance and external appearance may have diluted effect of season which may remain in individual females or in some bloodlines within specific breeds. From a practical standpoint, spring should always be considered as a time of the year in which the probability of any bitch coming in season may be highest.

The interval between the beginning of consecutive canine estrous cycles (interestrous period) varies a great deal within and among breeds. The vast majority of pure- and mixed-bred dogs cycle every 5½ to 6½ months. There are a few notable exceptions: the Basenji and Tibetan Mastiff cycle once yearly and some Collie bitches cycle every 9 to 11 months. Some lines of German Shepherd, Doberman, Rottweiler, Labrador

Retriever, Basset Hound and Cocker Spaniel cycle 3 times yearly.[7-14] Variations in interestrous intervals are likely due to genetic differences in anestrus duration.[7] In general, there seems to be a negative correlation between body size and cycle frequency. Large-size bitches have fewer estrous cycles yearly when compared to the smaller breeds. Dogs >6 years of age tend to have progressively lengthening interestrous intervals. Whether or not gestation, followed by whelping and lactation, increases duration of interestrus is debatable and onset of proestrus in individuals is unpredictable.[2,9-11]

Proestrus

Definition, Estrogen-Induced Changes and Signs *(Table 312-1)*

The term *proestrus* describes the transition phase between reproductive quiescence and the onset of breeding behavior. The onset of proestrus is usually signaled by the appearance of a bloody vaginal discharge, lasting an average of 9 days, but duration can vary from a few days to almost 4 weeks.[11,12] Proestrus begins with development of ovarian follicles and secretion of their primary product: 17-beta-estradiol (E2), which increases progressively throughout proestrus to peak at concentrations of 50-120 pg/mL.[13,14] The increasing serum E2 concentrations increase blood flow to the reproductive system, affecting the endometrium (by causing growth and branching of endometrial glands with consequent increased thickness of the entire endometrium), the cervix (by causing cervical relaxation and secretion of mucus), the vagina (by causing growth of mucosal folds, increased elasticity and mucus secretion) and the vulva (by causing increased thickness of the mucosa, swelling and turgidity), but does not appear to involve mammary tissue.[14,15] Proestrual changes in blood flow and hormonal status cause vaginal and anal sac secretions to release potent pheromones to attract males.[16,17] Breeding is not allowed by the bitch in proestrus. She may join activities normally preceding mating but often powerfully refuses any further approach by turning on or growling at male dogs if she is during early or mid-proestrus. By late proestrus, the bitch may reject breeding by simply sitting or lying down.

TABLE 312-1

Relationship between Cytologic (1st Day of Cytologic Diestrus), Behavioral (End of Male Acceptance) and Endocrine Parameters vs. the Surge in Luteinizing Hormone (LH), Ovulation, Cervical Closure and Onset of Diestrus in the Bitch

	1ST DAY OF CYTOLOGIC DIESTRUS (DAYS)	END OF MALE ACCEPTANCE (DAYS)	SERUM PROGESTERONE CONCENTRATION (ng/mL)
LH surge	−7 to −10	+6 to +19	2.0
Ovulation	−5 to −8	+3 to +10	4.0-10.0
Cervical closure	−2 to 0	−1 to +3	≈25.0 or higher
1st day of cytologic diestrus		−2 to + 2	≧19.0-25.0

Serum progesterone (P4) is the more reliable way of staging the cycle, but the information from a single sample may not allow precise staging in specific cases unless vaginal cytology and/or behavior are assessed jointly. Vaginal cytology alone is more reliable than behavior alone, but behavioral assessment may become important when evaluating serum P4 data if a vaginal smear could not be collected.

Vaginal Discharge and Endoscopy

The bloody vaginal discharge observed in proestrus is the result of mostly red but also white blood cell diapedesis through intact endometrial capillaries into the uterine lumen, then flowing through the cervix due to myometrial contractions, and finally mixing with cervico-vaginal fluids. Pulsatility of canine E2 secretion makes serum assays less useful than vaginal cytology. Vaginal cytology is an excellent reflection of 24-hour E2 secretion by maturing follicles (see ch. 44 and 119). Vaginal smears from bitches in early proestrus contain predominantly red blood cells, a few white blood cells, and mostly non-keratinized (parabasal, small and large intermediate) vaginal epithelial cells. In most bitches, the number of red blood cells decreases during the progression from proestrus to estrus (making the vulvar discharge progressively less bloody in appearance)

while the ratio between keratinized and non-keratinized cells progressively increases, reaching values of 30-50% in late proestrus. E2 causes the vaginal mucosa to become deep pink and edematous which, on vaginoscopy, during proestrus and early estrus, appears as round and swollen vaginal folds with some blood-tinged fluid between (see ch. 119).[18] The canine cervix also is swollen and palpable abdominally from late proestrus onward. As the cervix is not normally palpable during anestrus, its palpation can be an indirect sign that the bitch is in heat. Also the uterus becomes enlarged and more easily identifiable on abdominal palpation.

Hormone Profile *(see Table 312-1)*

Following the initial estrogen increase responsible for clinical signs of proestrus, serum E2 concentrations continue to rise, peaking in late proestrus. This peak and the following decrease marks the end of proestrus and likely contributes to stimulating the LH surge, onset of estrus and ovulation. Although E2 is the most important hormone of canine proestrus for all its clinically relevant effects on behavior and the reproductive system, increasing concentrations of other reproductive hormones also play roles. Serum progesterone (P4) increases >0.5 ng/mL, to about 1.0 ng/mL, during the final 24-48 hours of proestrus. This indicates that development of luteal tissue within the wall of maturing canine follicles has begun. This early rise of serum P4, called *pre-ovulatory luteinization,* is a peculiarity of the canine and is also of value in staging ovulation.[19,20]

In late anestrus, serum luteinizing hormone (LH) and follicle stimulating hormone (FSH) concentrations increase above basal values to values of about 1-6 and 150-300 ng/mL, respectively (Figures 312-1 and 312-2). E2 production from cohorts of growing tertiary follicles stimulates the pituitary without causing enough LH-FSH release to cause pre-ovulatory luteinization. LH and FSH values then decrease as proestrus progresses, due to E2 and inhibin negative feedback, and remain low until the end of proestrus. The continuing follicular growth despite decreases in LH-FSH values in early proestrus likely indicates that follicular development in dogs is autonomous.[21] Androgen concentrations (testosterone and androstenedione) increase in late proestrus, reaching levels at the time of the LH peak comparable (10-25 ng/mL) to those of adult intact males.[22] No correlation has been made between such androgen values (which may reflect intermediate conversion steps between progesterone and estrogen) and expression of estrous behavior in the bitch, despite the occasional observation of male-like or mounting behavior in some bitches.

Estrus

Definition and Signs

Estrus is the stage in which both breeding and ovulation occur (Figure 312-3). Clinical signs of proestrus remain evident during estrus although they tend to change slightly: the vulva is still larger than normal but becomes softer while the vulvar discharge becomes progressively less bloody and more straw-colored. Both the cervix and uterus are palpable abdominally. Behavioral signs of receptivity increase in intensity during estrus, as bitches in estrus accept the male's interest, are amenable to play and to be mounted. The most obvious and consistent signs of the follicular phase (proestrus + estrus) are "winking" (upward tipping of the vulva when the dorsal aspect of the vulvar skin is touched), stiffening of the hind limbs (when the skin on either side of the vulva is touched), and "flagging" (vertical or contralateral deviation of the tail when the vulvar skin is touched on either side). These signs are almost always fully displayed during estrus and may be observed near the end of proestrus in some. The onset of "flagging" signals the beginning of estrus, willingness to breed, and is coincidental with the LH peak on the first day of estrus. Occasionally, bitches may remain unreceptive to mating throughout the entire estrus despite no other abnormal finding. In Beagle bitches, cervical closure occurred 5 +/− 1 days after ovulation or as early as 1 day prior to the end of estrus, with serum P4 concentrations averaging 25 +/− 4 ng/mL.[23]

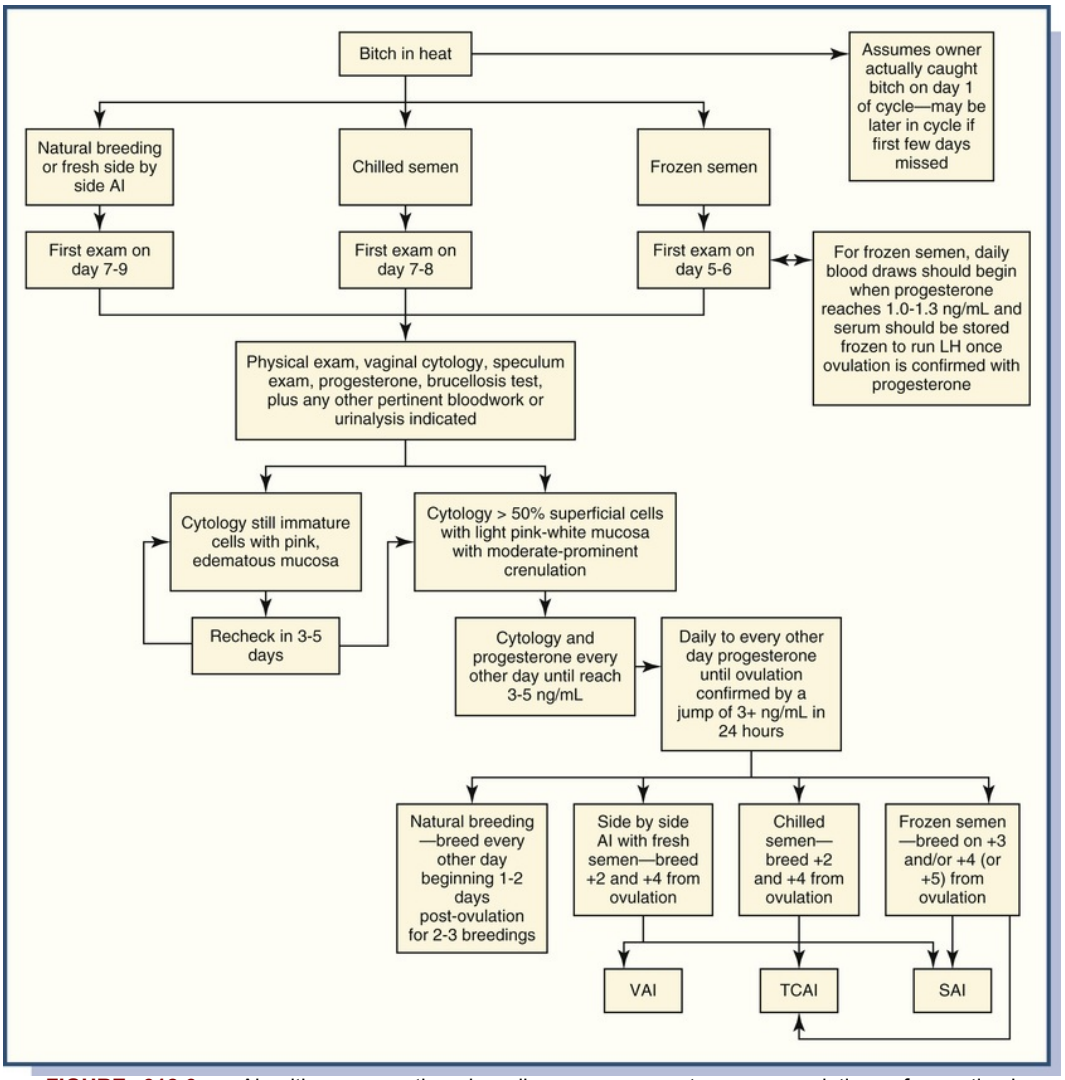

FIGURE 312-3 Algorithm presenting breeding management recommendations for optimal conception rates in healthy bitches. *AI,* Artificial insemination; *SAI,* surgical artificial insemination; *TCAI,* trans-cervical artificial insemination; *VAI,* vaginal artificial insemination.

The average duration (9 days) and range (4-24 days) of canine estrus are based on the number of days that bitches are willing to breed per cycle.[9,24] There is remarkable variation in breeding behavioral patterns in dogs. Although rare, an estrous bitch may refuse to be bred by a specific male because she is dominant or because of apparent dislike which may lead the owner to think that a bitch is not yet or no longer in estrus. Thus, the duration of estrus as judged by clinical observation may not be entirely correct and can explain discrepancies between vaginal cytology and behavior. Individual bitches may begin breeding from 2-3 days before to as long as 4-5 days after reaching >50% keratinization of their vaginal smear.[25,26]

Vaginal Cytology and Endoscopy *(see Table 312-1)*

A pattern of >50% vaginal epithelial cell keratinization (nucleated and anuclear superficial cells) reflects onset of sexual receptivity in most bitches. This percent of superficial cells present on vaginal cytology is not sensitive nor specific, as it may appear for the first time as early as 6 days before to as late as 4 days after a bitch is willing to breed.[27] "Full estrus" is diagnosed when >70% of vaginal epithelial cells appear keratinized (see ch. 44 and 119).[28] The effect of decreasing E2 concentrations can be observed in the quick resorption of edema from the vaginal mucosa. On endoscopy, vaginal mucosal folds appear dry, white, and wrinkled. Such a pattern is described as "crenulation" and is indirect proof of decreasing E2.[18]

Hormonal Profile *(see Table 312-1)*

The three key hormonal patterns of estrus are the LH peak, decreasing concentrations of E2 (from the peak reached at the end of proestrus) and rising concentrations of P4. Coincidental with or within a few hours following E2 reaching its peak proestrus concentrations, pituitary LH secretion increases rapidly from basal concentrations to values of 10-22 ng/mL and maintained at that serum level for about 24 hours. Duration of the LH surge can be as brief as 18 to as long as 96 hours.[20,26,29-32] Ovulation occurs about 2 days after the onset of the LH surge and continues within a narrow standard deviation of this date.[12] The fine balance and synergism of E2, P4 and LH play major roles in breeding behavior. E2 secreted during proestrus "primes the system" and P4 secreted at ovulation "activates the system." Full receptivity appears to be triggered by the coincidental decrease of E2 and increase in P4.[33,34] The decrease in E2 probably plays the major role as this is what actually causes the LH surge, while the P4 increase seems to enhance and synchronize the bitch's estrous behavior.[35]

Serum P4 concentrations rise from values <1.0 ng/mL at the end of proestrus to around 2.0 ng/mL on the day of the LH peak, subsequently reaching values of 4-10 ng/mL 2 days later when ovulation is taking place and primary oocytes are being released into the oviducts where they undergo their final maturation. The initial rise of serum P4 >2.0 ng/mL is generally coincident with the LH surge, although the surge may occur up to 20 hours after in a few bitches.[32] During the ovulatory process, serum P4 concentrations rise quickly with daily increases of 3-10 ng/mL or more. The magnitude of increase is due to the number of follicles ovulated, follicular size, the amount of developing luteal tissue, and how much P4 each CL produces. Increases <3 ng/mL/day should be a reason for concern as they may suggest ovulation failure and additional samples should be obtained over the next 1-2 days. Following completion of the ovulatory process and final CL maturation, serum P4 concentrations continue to increase during the first 2 weeks following estrus to values in the range of 15-60 or more ng/mL.

Use of Serum P4 Assay Results for Ovulation Timing *(Table 312-2; see Figure 312-3)*

Serum P4 assay results can help discriminate bitches in early estrus (who might not achieve the best conception rate, or might even not conceive if bred by a male of low fertility) from those who are ovulating and most fertile. Assay results can confirm ovulation and stage the estrous cycle reliably from 2 days before to 2 days after ovulation, a time when P4 concentrations rise from 1-2 ng/mL to >10-12 ng/mL. However, assaying a single serum P4 sample collected at or after onset of the LH surge is less informative regarding the number of days that have elapsed since the beginning of ovulation due to individual, breed, or age-related variabilities. Serum P4 results are comparable, regardless of radioimmunoassay (RIA), chemiluminescent immunoassay (CLIA) or enzyme-linked fluorescent assay (ELFA).[26,36,37] If a human assay is used, care should be taken to calibrate it for canine serum. Species-specific differences in degree of hormonal binding to carrier proteins in serum may alter results as much as 20%. Assays should be validated on an annual/biannual basis or every 1000-3000 samples run by commercial veterinary laboratories using hormonal kits marketed for human use. A conversion factor is generally necessary when using a human ELFA system.[37]

TABLE 312-2

Progesterone Concentrations and Associated Follicular Events

ENDOCRINE/FOLLICULAR ACTIVITY	PROGESTERONE CONCENTRATION (RANGE ng/mL)
Baseline	<0.5
Early follicular development	0.5-1.3
LH surge	1.3-1.9
Ovulation begins	4-8 average (range 4-10)
Post-ovulation	>10 ng/mL

Combining Behavior Observation, Vaginal Cytology and Serum Hormone Analysis

Assay of serum E2 is not used because of its pulsatility. However, vaginal cytology remains an excellent biologic assay for E2. Vaginal cytology data coupled with serum P4 concentrations and behavioral assessment are instrumental in staging the estrous cycle and identifying ovulation. However, each of these tools, alone, is

far less reliable. Estrous behavior, vaginal cytology and serum P4 assay remain the 3 fundamental pillars for breeding management (see Management of Breeding section) as well as for determining length of estrus and ruling in/out ovarian conditions (ovarian cysts/neoplasia). Additional diagnostic tests (such as LH assay, ovarian ultrasonography, vaginoscopy) can be helpful in improving the accuracy of estrus and ovulation staging if one uses them consistently, developing specific expertise. Impedometry and arborization of cervical mucus are not accurate in ovulation timing (see Table 312-1).

Diestrus

Definition and Signs

Diestrus is defined as the luteal or progestational phase of the cycle. Diestrus normally follows ovulation and lasts precisely 8 weeks in pregnant vs. 6-10 weeks in non-pregnant bitches. The vulva, which becomes less edematous and swollen during the last few days of estrus, continues to shrink through the first week or so of diestrus. Little to no bloody vulvar discharge is present and male dogs are not attracted. The vaginal mucosa appears flat, thin, dry and blotchy pink to red, with capillaries easily visible on vaginoscopy (see ch. 119). The cervix is palpable for the first few days of diestrus, while the uterus remains palpable and may increase in size under the influence of P4.

Vaginal Cytology, Behavior

Clinically, the first day of diestrus (D1) is defined as the first day a bitch refuses to breed or as the day on which a sudden change in vaginal cytology is seen: keratinized vaginal epithelial cells decrease from 70-100% to <30% on cytology, replaced by large and small intermediate and parabasal epithelial cells. White blood cells, absent from cytology smears after the first few days of proestrus and throughout estrus, reappear (see ch. 119). These changes usually occur within 24 hours of the onset of diestrus although either can first be observed within a range of 4 days; willingness to breed may stop 1-2 days prior to or persist 1-2 days after onset of "cytologic diestrus." Changes in vaginal cytology may occur 5-8 days following ovulation and 7-10 days after the LH surge (see Table 312-1).

Observing D1 on a vaginal smear indicates that estrus has ended and that it probably is too late to achieve optimal conception rates (normal litter size) using natural breeding. However, fertility rates of 5 to 40% have been reported in Beagles when natural breeding occurred between D1 and D3. Although litter size is likely to be small with natural breeding in early diestrus, normal litter size can still be achieved using intrauterine semen deposition during this same time frame.[23] Clinically, D1 can be considered the end of the first week of pregnancy: therefore, in pregnant bitches the interval between D1 and parturition is approximately 57+2 days.[38]

Reproductive behavior is not as reliable as vaginal cytology in determining D1. P4 concentration should not be of use, as P4 progressively increases throughout estrus and this trend continues for the first few weeks of diestrus. Nevertheless, behavioral assessment should never be disregarded and particularly so when discussing progression from estrus into diestrus. Breeders should always be encouraged to identify the first day a bitch refused to breed, as this information is used in determining duration of estrus and may help in timing ovulation. However, it is wise to ask if someone observed the refusal to breed or was this assumed based on other criteria. Breeders should be instructed and encouraged to establish dates of onset and cessation of male acceptance by watching the behavior of their bitches when brought to an intact male on a daily basis.

Hormonal Profile

Serum P4 concentrations continue to increase, reaching peak values of 15-90 ng/mL about 2 to 4 weeks into the luteal phase. Subsequently, serum P4 starts a gradual decline in both pregnant and non-pregnant bitches. The decrease in P4 usually does not drop to <5.0 ng/mL until the last week in pregnant bitches and it never drops below 2.0 ng/mL until 24-36 hours pre-partum. Luteotrophic support for canine CLs appears to originate from the pituitary, with PRL being regarded as the most important factor supporting canine ovarian P4 production. LH has a stimulatory rather than permissive role.[39-41] Canine PRL starts to be secreted during the 4th week of the luteal phase as soon as serum P4 concentration begins to decline.[42] The actions of canine PRL include supports of ovarian P4 synthesis and mammary tissue development regardless of pregnancy, but of greater magnitude in pregnant bitches. Serum PRL concentrations are significantly higher in pregnant vs. non-pregnant bitches after about day 35 post-LH peak. Administration of PRL to bitches during the luteal phase causes an increase in P4 secretion.[43-45] The CLs of pregnant bitches produce more P4 than those of the

non-pregnant. Since P4 metabolism is higher in pregnant bitches, differences between the pregnant and non-pregnant are not always obvious.[14,20,29,46] The increase in ovarian P4 production observed in pregnant females following implantation may be mediated by pregnancy-specific relaxin secreted from the ovaries during diestrus. Canine placental syncytiotrophoblasts, during pregnancy, contribute to the onset of PRL secretion.[47,48] Relaxin acts by inhibiting myometrial contractility and promotes modification of the cervix at the end of pregnancy in preparation for parturition.[49] The roles of estradiol, testosterone and androstenedione produced during the luteal phase by CLs[22,50-52] are not clear. Their concentrations are likely the result of intermediate steps in the synthesis of P4, and their measurement is currently considered of little, if any clinical use.

Progesterone and Pregnancy Monitoring *(see Tables 312-1 and 312-2)*

The magnitude of P4 concentration reached during the first 3 weeks following D1 may depend on breed, age, health, degree of environmental and social stress, and perhaps level of inbreeding. There is a lack of homogenous data on canine serum P4 concentration for different breeds and age classes throughout pregnancy, preventing provision of reliable guidelines on "normal" values of serum P4 during the canine luteal phase or "minimum thresholds" of serum P4 concentrations below which intervention (e.g., supporting a pregnancy with exogenous P4) may be justified. Anecdotally, the minimum P4 concentration for maintaining pregnancy during weeks 3 through 7 is likely >15 ng/mL. P4 concentrations <15 ng/mL in a high-risk pregnancy or in a bitch with a history of recurrent pregnancy failure may indicate need for exogenous P4.[53]

At the end of the luteal phase, cessation of ovarian P4 production occurs abruptly (within 24-36 hours) in pregnant and gradually (over 1-2 weeks) in non-pregnant bitches.[11,39,42] The luteolytic effect of endogenous prostaglandin F2-alpha (PGF2-alpha) plays a major role in terminating luteal activity in pregnant bitches. There is no increase in PGF2-alpha secretion in non-pregnant bitches so CLs function longer and are terminated by an immune-mediated process driven by leukocyte-derived cytokines (interleukin [IL]-8, IL-10, IL-12, tumor necrosis factor alpha and transforming growth factor-beta-1) which are increasingly present within the canine luteal tissue throughout diestrus.[50,54] In pregnant bitches, the abrupt decline in serum P4 occurring at the end of the luteal phase triggers a decrease in body temperature and an increase in serum PRL. A decrease of about 1.0-2.0 °C in rectal temperature, after the decline in serum P4, is often observed in whelping bitches or following a PGF2-alpha or aglepristone treatment, while it is not reported in non-pregnant bitches at the end of the luteal phase due to their gradual fall of serum P4.[55]

Prolactin, Progesterone and Whelping

The increase in serum PRL concentration is immediate and strong prior to whelping as a consequence of the sudden pre-partum luteolysis while the increase is more subtle in non-pregnant females, again due to the slower demise of their CLs.[56] Regardless of pregnancy, PRL secretion at the end of the luteal phase has little effect on CLs but does stimulate onset of lactation and maternal behavior. The strict interdependence between P4 and PRL in dogs has several practical implications: the use of antiprolactinic drugs (dopamine agonists or serotonin antagonists) at any time from mid-pregnancy onwards (when P4 concentrations are still high) will cause luteolysis and abortion,[57] while any time P4 concentration drops (i.e., following a luteolytic or a progesterone receptor blocker treatment, ovariectomy in diestrus, withdrawal of a progestin treatment, etc.) there will be a rise in serum PRL followed by milk secretion and display of maternal behavior. Monitoring serum PRL concentrations is not commonly used, despite potential clinical applications in monitoring pregnancy or pseudopregnancy. Monitoring serum P4 concentrations, however, is a fundamental tool in canine reproduction to stage ovulation and for managing bitches with luteal insufficiency, prolonged gestation, dystocia or elective C-section.

Effects of Progesterone and Growth Hormone (GH)

A further clinically relevant implication of ovarian P4 production during diestrus is secretion of GH from the mammary glands,[58] a normal physiologic process. Under the influence of P4, mammary duct epithelial cells secrete GH increasing basal serum GH levels, and then negatively feeding back to suppress normal and pulsatile pituitary GH secretion.[59] Mammary GH promotes the normal proliferation of mammary glands through local autocrine/paracrine effects, prepares the endometrium for implantation by promoting (together with ovarian P4) hyperplasia of the uterine epithelium, and causes insulin resistance. This latter effect may

have evolved to avoid hypoglycemia when pregnant, since predators often have extended intervals between meals. Clearly, these GH effects in the bitch carry a potential risk for causing or exacerbating clinical conditions such as mammary and uterine disease as well as diabetes. Therefore, as appropriate, some bitches might benefit from careful monitoring during diestrus: clinical, hormonal, uterine ultrasonography, and particularly serum biochemistry in case of suspected diabetes mellitus.[60,61] There is also evidence that mammary GH concentrates in colostrum, thus stimulating gastric and intestinal development of suckling newborns.[62]

Pseudopregnancy

The most common effect of the concerted actions of P4 and GH is mammary development during the second half of the luteal phase followed by the onset of lactation (as soon as P4 drops and PRL peaks) occurring in both pregnant and non-pregnant bitches, albeit with much less intensity in the latter group. The occurrence of mammary development, lactation and display of maternal behavior in non-pregnant bitches is referred to as pseudopregnancy or pseudocyesis, a paraphysiologic condition. In wolves, pseudopregnancy in some is of benefit if a female dies or is otherwise unable to nurse her litter after parturition to allow another pack member to assume that role. Since PRL secretion normally occurs in non-pregnant as well as pregnant bitches, pseudopregnancy is considered a normal phenomenon. The condition undergoes spontaneous remission, but becomes obvious when hormone secretion is high causing persistent lactation and strong maternal behavior, two conditions which prompt the bitch to become nervous, adopt inanimate objects and be anorectic. When necessary, this condition can be treated with antiprolactinic drugs such as cabergoline (5 mcg/kg PO q 24 h), metergoline (0.5 mg/kg PO q 12 h) or bromocriptine (20-50 mcg/kg PO q 12 h).

Anestrus

Definitions, Signs

In bitches, diestrous and anestrous behaviors do not differ, with the exception of the first few days of cytologic diestrus, during which some bitches may still attract males and occasionally breed. Past those few days, the clinical, metabolic and behavioral transition from diestrus to anestrus is smooth and devoid of any relevant clinical signs. As in diestrus, the vulva is small, no vulvar discharge is present and male dogs are not attracted. On vaginoscopy, the vaginal mucosa is dry and thin, appears flat and pinkish-red to dark red and blotchy, with capillaries readily visible. As a consequence, anestrus cannot be differentiated from diestrus based on reproductive behavior. Anestrus varies from as short as 2 to as long as >9 months. Variations in the duration of anestrus account for the difference in interestrous intervals between individuals. While the P4 of diestrus is a potential source of clinical problems in bitches at risk for pyometra, mammary neoplasia or diabetes, anestrus is not characterized by such issues, as the ovaries do not secrete significant quantities of E2 or P4. Educating caregivers regarding these differences is important, since they should be aware of diestrus-associated diseases.

Hormone Profile

Anestrus is defined as the period beginning with serum P4 concentrations <1.0 ng/mL. A precise serum P4 concentration defined as basal is still a matter of study. Functioning luteal tissue is considered absent when P4 is <1.0 ng/mL. Bitches in anestrus have serum P4 concentrations <0.7 ng/mL, usually <0.3 to 0.5 ng/mL. Concentrations <0.3 ng/mL could be a requirement for stimulating onset of proestrus.[11] This low (and perhaps progressively decreasing) serum P4 concentration persists for 1 to 6 months in most healthy bitches, only to increase after pre-ovulatory luteinization occurs in late proestrus of the following cycle. During early to mid-anestrus, E2 concentrations are also low at 5-10 ng/mL.[30] Because of this low ovarian steroid secretion pattern, the first 1-2 months after the end of diestrus may be referred to as early or "deep" anestrus due to the poor sensitivity of canine ovaries to GnRH.

As anestrus progresses, there is an increase in the number and amplitude of hypothalamic GnRH pulses, paralleled by increased pituitary responsiveness and an increase in ovarian sensitivity to gonadotropins through development of FSH and LH receptors.[63] This is followed by episodes of E2 secretion which enhances hypothalamic estrogen receptors and establishes a positive feedback loop.[64,65] This interplay of hypothalamic-pituitary-ovarian events in late anestrus confirms earlier observations of occasional elevations of E2 levels to 25-50 ng/mL during the 2 months preceding the onset of proestrus.[25,30,66] Late anestrus increases in E2 concentrations are associated with a slight vaginal keratinization but not vulvar swelling or

serosanguineous vulvar discharge.[30] GnRH secretion followed by higher serum concentrations of FSH and LH are two key factors in the onset of proestrus, as supported with GnRH being given in pulses or via subcutaneous (SC) implant, or LH- or FSH-based products that can induce proestrus.[67]

Dopamine and Estrus Induction

Studies on the role of dopaminergic pathways on resumption of cyclicity in the bitch have involved 3 major brain circuits: the mesolimbic, mesocortical and nigrostriatal pathways which innervate the limbic system (memory, behavior), frontal cortex (cognitive control, emotional response) and striate nucleus (motor control), respectively. A 4th dopaminergic pathway is the tuberoinfundibular pathway, connecting hypothalamus with the pituitary, where it influences the secretion of hormones such as PRL. The observations that dopamine agonists lower serum PRL concentrations and shorten anestrus led to the conclusion that the two events were related: that lowering PRL was important for estrus induction in the bitch.[68] However, non-dopamine-agonist PRL-lowering drugs do not shorten anestrus when used at pharmacologic dosages and anestrus can be shortened using dopamine agonists at dosages too low to suppress PRL concentrations.[69,70] Activating the tuberoinfundibular neural pathway in the bitch by giving a dopamine agonist is followed by a resumption of basal serum FSH and LH concentrations which mimic the physiologic milieu occurring in late anestrus, followed by the onset of proestrus. Dopamine agonists such as bromocriptine (20 mcg/kg PO q 12 h) and cabergoline (5 mcg/kg/day PO or as low as 0.6 mcg/kg/day) shorten the duration of anestrus (thereby inducing estrus) in the bitch, with their effectiveness increasing as the bitch advances further into her mid or late anestrus.[70-72]

Uterus in Anestrus

Uterine involution requires desquamation of the endometrial lining followed by its complete regeneration. This is a fundamental prerequisite for maximizing chances of fertility on the following cycle. When parturition and fetal membrane detachment occur normally after parturition, endometrial repair starts immediately, but requires an estimated 143 to 155 days after the onset of estrus to be completed. In the non-parous bitch, this process is complete approximately 2 weeks earlier.[73]

Irregular Patterns of Ovarian Cyclicity

Importance of a Thorough History

Bitches may show irregular patterns in any cycle stage. Some owner concerns may be due to a lack of understanding what is considered "normal." Therefore, clinicians should always carefully review as much historical data as possible with the caregiver. One should verify date/s of onset of proestrus and male acceptance/refusal as well as timing and pattern of vulvar discharge. Any previous serum P4 profile can be quite valuable. Occurrence of behavioral or mammary signs of false pregnancy (indicating the ovulation took place 1-2 months previously) should be noted.

Prolonged Proestrus or Estrus

Failure to Ovulate

The duration of the canine follicular phase exhibits great variation. Both proestrus and estrus can last from a few to as many as 24 days.[9,11,12,24] Rarely, follicular phases lasting as long as 40 days have been reported and care should be taken to differentiate normal but unusual cycles from true abnormalities such as split heat or slow P4 rise. Normal ovulation is the result of a complex process that requires sufficient follicular estrogen to stimulate hypothalamic release of GnRH which causes the pituitary to release adequate LH to cause normal luteinization of pre-ovulatory follicles. Disruption at any step due to environmental, management, social or health stress may cause ovulation to fail. Diagnosis of anovulation is based on serum LH and P4 concentrations failing to exceed 2.0 and 10 ng/mL respectively, using a quantitative assay (CLIA, RIA or ELFA) on serum samples collected daily, or less ideally, every other day during proestrus and estrus. Quantitative LH assays are not widely available. Use of qualitative testing is less ideal since the LH surge may be <24 hours in length and even daily testing may not be frequent enough. Since serum LH concentrations in anovulatory bitches has never been reported, the extent and amount of LH secretion in these bitches is unknown. Therefore, the value of quantitative assaying LH to diagnose failure to ovulate is questionable, although serum LH may not reach the typical ovulatory concentration of 4-10 ng/mL. Thus,

failure to ovulate is typically documented by progesterone never exceeding 10 ng/mL.

Bitches experiencing an anovulatory cycle typically have normal patterns of vaginal keratinization, attract males and often stand to be mounted. However, serum P4 fails to increase >10 ng/mL.[74,75] Failure to ovulate is rare, estimated to occur in about 1% of bitches seen for breeding management.[74] The authors have anecdotally observed failure to ovulate more frequently in medium-large size bitches (e.g., German Shepherds, Bernese Mountain Dogs, Labrador Retrievers, Bullmastiffs). Anovulation, in theory, could be treated using GnRH, hCG or deslorelin, but there is a lack of scientific studies using these drugs for this purpose. The potential for disrupting normal ovarian function should not be underestimated. Because of its rare incidence, anovulation could be regarded as a physiologic derangement. Once potential stressors are identified and removed, it would probably be wiser to wait for (or perhaps induce) the next heat, rather than treat an anovulatory bitch with hormones.

Slow P4 Rise

Pre-ovulatory luteinization of mature ovarian follicles causes serum P4 concentrations to increase marginally (1-2 ng/mL) prior to and during the LH peak. The LH surge then causes a steady progression of follicular wall luteinization after ovulation with serum P4 concentrations reaching 4-10 ng/mL within 48 hours. Lack of increasing concentrations, with serum P4 concentrations remaining at values compatible with the LH peak stage, indicates an abnormality in the ovulatory process defined as slow P4 rise.[75] When serum P4 rises slowly, its concentration will remain at values corresponding to the LH peak (2.0 ng/mL) from a few to 7 days but eventually this plateau is followed by a rise to values compatible with ovulation.

There is little information on incidence and etiology of this condition. Causes for slow P4 rise include too little estrogen to stimulate the hypothalamic release of GnRH, too little LH from the pituitary or delayed response of follicles to LH, or simply more pre-luteinization of pre-ovulatory follicles prior to the LH surge. The duration of the LH peak in normal bitches has been reported to be as long as 96 hours.[20,26,29-32] Therefore, it is possible that bitches experiencing a 3-4 day plateau in serum P4 may have had a longer, slower rise in LH with the peak occurring around a P4 concentration of 3-4 ng/mL instead of the usual 1.3-2 ng/mL. Ovulation has been shown to begin soon after the LH is >1 ng/mL and is considered the first day of ovulation. Retrospectively, counting back from parturition, the estimated day of the LH peak may be found to be either at the beginning or at the end of the P4 plateau.[75]

Although bitches with a slow P4 rise will eventually ovulate and therefore can be bred, breeding management of these animals is more complicated, as it may require repeatedly monitoring serum P4 concentrations and, possibly, LH as well. Therefore, when a slow P4 rise is suspected or confirmed, the use of frozen or chilled semen or traveling long distances to reach an important stud should be avoided, and the bitch bred to a local male. Also, establishing the due date based on serum P4 concentration can be more challenging and should be confirmed with ultrasonography between 25 and 35 days from the first breeding.[76]

Split Heat

Split heat is defined as a short follicular phase, often with signs typical of proestrus or even by short-lived male acceptance, but serum P4 concentrations fail to increase above basal. Such brief anovulatory cycles are followed by an ovulatory cycle, in about 50% of bitches, within 3 months. Normal cycles may follow a normal interestrous interval (for that breed) in the others.[74] Split heat may recur as suggested by the bitches presented with split heat who may have a history of short interestrous intervals (<3 months). Although short interestrous intervals may be caused by an insufficient luteal phase, whenever a bitch has a history of short interestrous intervals, breeding management should be carefully reviewed, taking into account the possibility of a split heat. Causes of split heat are thought to be the same as those of failure to ovulate and slow P4 rise: low estrogen secretion, low hypothalamic GnRH release, low pituitary LH release, failure of follicles to respond to LH. Deciding whether or not to treat a bitch with split heat to induce ovulation should be carefully considered as there is no information on effectiveness of any suggested treatments. In bitches with a history of short interestrous intervals who present with a split heat, the use of mibolerone at the dosage suggested for estrus suppression has been advocated to prolong the interestrous interval to 6 months.[75,77] Pregnancy can be achieved in these dogs if the post-mibolerone progesterone profile is normal.[75]

Hypoluteoidism

Also termed luteal insufficiency, premature luteolysis, or insufficient luteal phase, *hypoluteoidism* is defined as
