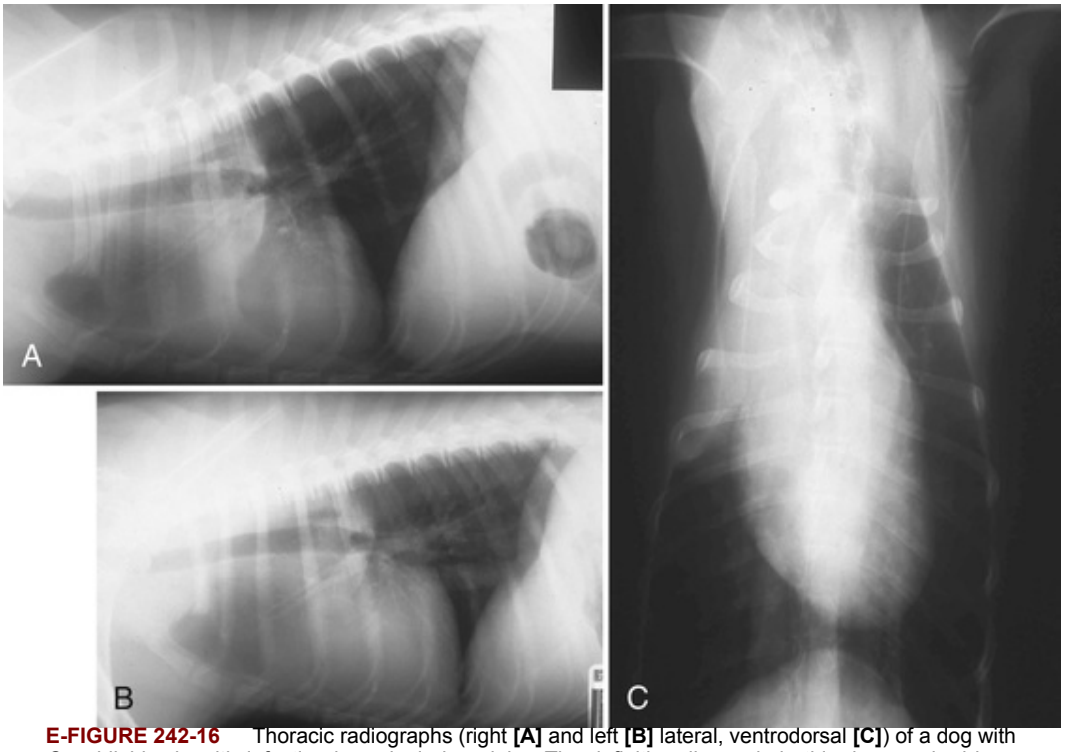
E-FIGURE 242-15 Thoracic radiographs (lateral **[A],** ventrodorsal **[B]**) of a dog with pulmonary blastomycosis. Note the larger, more ill-defined interstitial opacities.



E-FIGURE 242-16 Thoracic radiographs (right **[A]** and left **[B]** lateral, ventrodorsal **[C]**) of a dog with *Coccidioides immitis* infection in a single lung lobe. The definitive diagnosis in this dog required lung lobectomy and histologic assessment of the excised tissue.

Pneumocystis carinii (also known as *Pneumocystis jerovici*) was originally classified as a protozoon but now is considered a fungus. Although this widely distributed saprophyte is not highly virulent, in immunocompromised hosts of many species it can result in severe morbidity with high mortality due to pneumonia. Infection has been described in several small-breed dogs with presumed immunocompromise, but it is overwhelmingly most common in Miniature Dachshunds and Cavalier King Charles Spaniels.[214-220]

A unique immunodeficiency in each breed (common variable immunodeficiency in Dachshunds and in Pomeranians; IgG deficiency in Cavaliers) has been suggested.[216,220,221] Most infected dogs are young, and most are presented for veterinary attention due to progressive lower respiratory disease signs. Although there are no unique physical, radiographic, or laboratory signs, absence of fever despite severe pneumonia is a clue to this type of infection.[221] The diagnosis is complicated because the pathogens are not recovered easily by airway lavage, and special stains such as Grocott-Gomori methenamine silver stain may be required to visualize the organism when it is present.[222] Potentiated sulfonamides appear to be the most effective therapy when administered early in the disease course. Although *Pneumocystis* pneumonia is important in immunocompromised people (e.g., during HIV infection), dogs are not thought to harbor the same strain and thus should pose little zoonotic risk.[223]

Aspiration Pneumonia

Aspiration pneumonitis and pneumonia result from inhalation of materials into the lower respiratory tract. Often, the aspirated material consists of stomach contents with or without solid particulate matter. Iatrogenic aspiration can occur as a result of forced feedings, oral administration of substances such as barium or mineral oil, or inappropriate induction of emesis after oral intoxications (e.g., with petroleum distillates) (see ch. 151; E-Figure 242-17). Depending on the volume of material aspirated, as well as the physical properties of the material (e.g., pH, tonicity, bacterial contamination, particulate volume and size), the result can range from minimal change to fulminant pulmonary edema, necrosis, and hemorrhage. Irritating chemicals (including stomach acid) result in pneumonitis, while aspiration of larger volumes of a more benign fluid can result in a "drowning" event. Aspiration of polyethylene glycol bowel-cleansing solutions can be especially harmful as these substances draw interstitial fluid into the lungs.[224,225] Aspiration of large particulates can result in acute airway obstruction. Because of the low bacterial burden of stomach content, infection seldom is an important initial component of aspiration. However, the damage done to the respiratory tract by acid or other irritants predisposes to secondary bacterial infection. Aspiration injury occurs in phases beginning with an acute airway response, followed by lung inflammation, and often culminating in opportunistic bacterial infection.

E-FIGURE 242-17 Lateral thoracic radiograph of a cat with severe barium aspiration.

A variety of conditions can predispose animals to aspiration (Box 242-11), and many of these are found in

animals hospitalized for diverse reasons. Unwitnessed aspiration should be suspected in any hospitalized animal with a new onset of lower respiratory signs. Although general anesthesia is a risk for aspiration, in a recent multicenter study, the incidence of postanesthetic aspiration pneumonia was only 0.17%; several factors were identified that increased this risk.[226] In retrospective studies of 88 or 120 dogs with aspiration pneumonia, fewer than half were febrile (31% and 43%, respectively).[227,228] Panting or tachypnea were common but inconsistent findings. Most had cough and either harsh/loud, adventitial, or diminished lung sounds on auscultation.[227,228] Leukocytosis, with or without a left shift, was a common but inconsistent finding.[227,228] The classic radiographic appearance of aspiration pneumonia is that of a patchy or focal alveolar infiltrate (Figure 242-18), but one quarter of affected dogs in a retrospective study demonstrated a predominantly interstitial pattern.[227] Radiographic changes can lag behind aspiration because fluid accumulation lags behind chemical lung injury. Radiographs should include both lateral views to improve recognition of pneumonia. The left lateral view is especially important to improve recognition of an alveolar pattern in the right middle lung lobe, a lobe that is largely silhouetted against the cardiac shadow. Because aspiration of liquids is gravity-dependent, the most commonly affected lung lobes are the right middle, right cranial, and caudal portion of the left cranial; however, the lobe affected depends on the position of the animal at the time of aspiration.[227-229] In one study, the prognosis was worse for animals with more than a single involved lung lobe, and more than one third of all dogs had radiographic evidence that 2 or more lung lobes were affected.[228] Airway lavage can be used diagnostically when there is no clear history of aspiration nor any known predisposition to aspiration. Neutrophilic inflammation is expected, and lipid-laden macrophages or debris (e.g., foodstuffs) can be identified. Measurement of pepsin concentration has been used in humans to confirm aspiration.[230] Polymicrobial and anaerobic infections are common but delayed complications of aspiration.

Box 242-11

Conditions That Predispose to Aspiration

Impaired conscious protection of the airways (e.g., general anesthesia, heavy sedation, seizures, coma)
Impaired unconscious protection of the airways (e.g., laryngeal paralysis, surgical alteration of laryngeal anatomy [tie-back], myasthenia gravis)
Impaired swallowing (e.g., achalasia, cranial nerve V deficits, rabies)
Regurgitation (e.g., megaesophagus, motility disorder, esophageal diverticulum)
Gastric overdistention (e.g., overfeeding, ileus, gastrointestinal obstruction)
Vomiting (e.g., primary gastrointestinal disease, pancreatic disease, uremia, hepatic disease)
Forced feeding or administration of oral medications

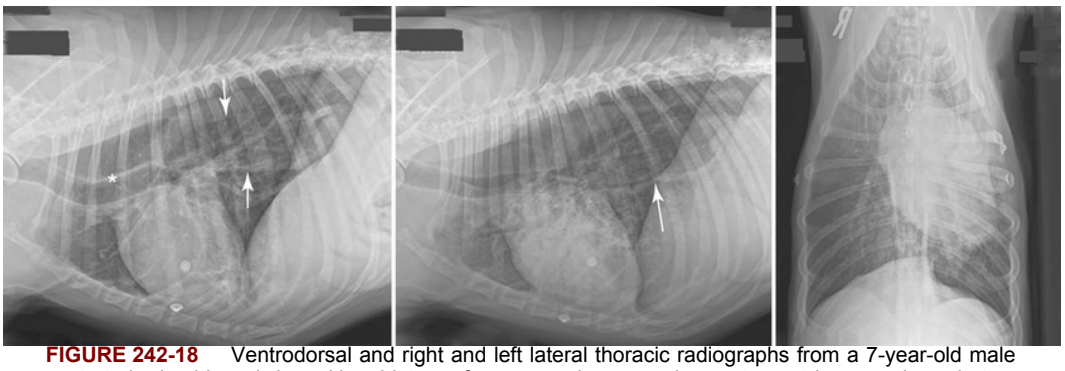


FIGURE 242-18 Ventrodorsal and right and left lateral thoracic radiographs from a 7-year-old male castrated mixed-breed dog with a history of megaesophagus and recent-onset increased respiratory effort. Megaesophagus is evident (arrows; the visible dorsal margin of the trachea [asterisk] suggests highlighting against an air-filled esophagus), and an alveolar pattern consistent with aspiration pneumonia is most seen in both the right middle and the caudal portion of the left cranial lung lobes. The cardiac shadow has shifted into the left hemithorax.

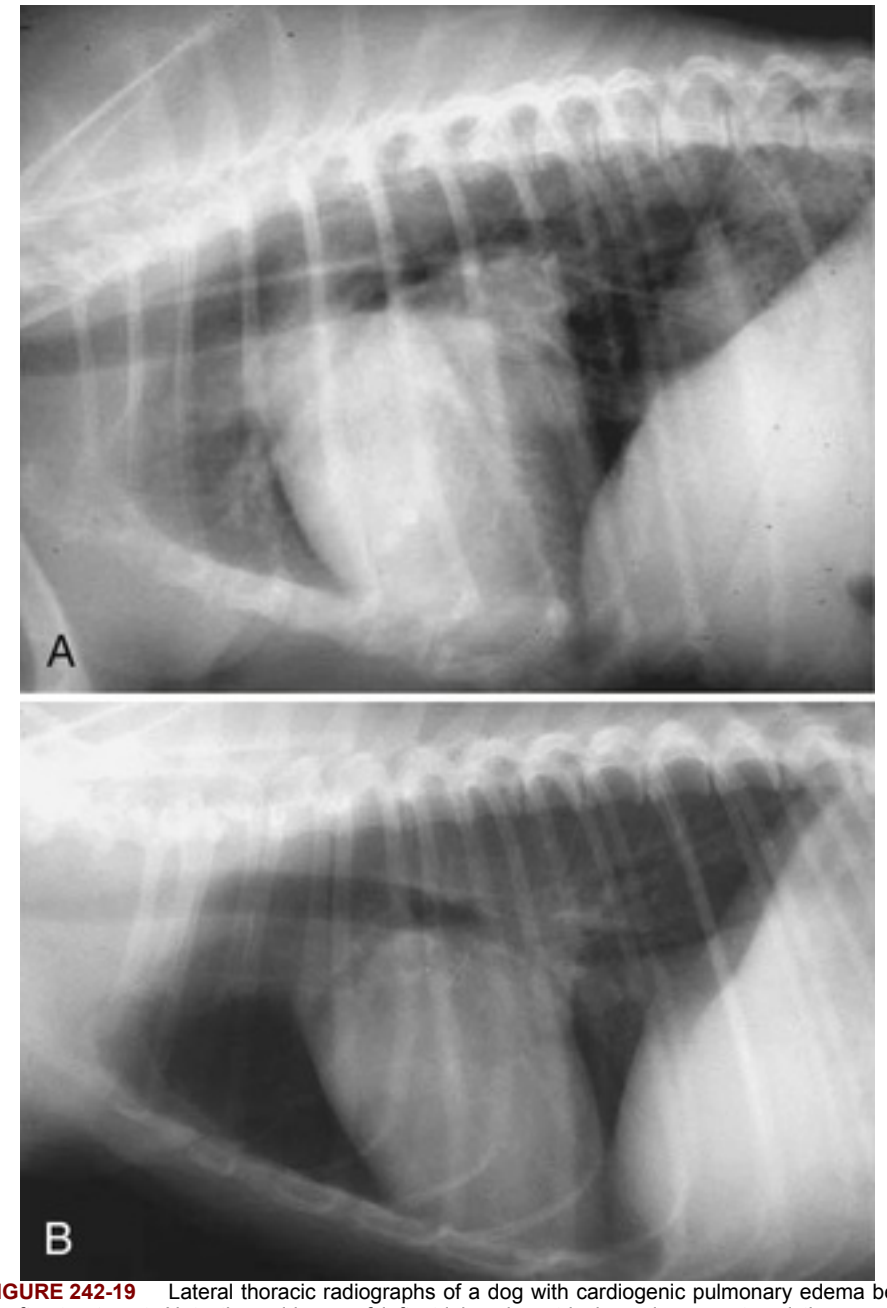
Treatment of aspiration largely is supportive. Efforts should be made to prevent aspiration when possible,

ideally via correction of predisposing factors (see Box 242-11). Animals should be fasted prior to anesthesia and insufflated endotracheal cuffs used when appropriate. For conscious animals with frequent regurgitation or vomiting, or when airway protection is impaired, oral intake should be minimized. Feeding pets with megaesophagus from elevated bowls and keeping the pet upright after feeding are common practices, but efficacy of these techniques to prevent aspiration is unknown. For animals with frequent regurgitation due to megaesophagus, the placement of a gastrostomy tube can facilitate feeding while minimizing risk of aspiration (see ch. 82). Administration of H2 receptor antagonists or proton pump inhibitors increases the pH of stomach content and could lessen chemical lung injury due to aspiration but might also increase gastric bacterial content.[231] Prokinetic drugs such as metoclopramide promote gastric emptying and tighten the lower esophageal sphincter, which might diminish the risk of aspiration of gastric content.[232-234] Unfortunately, neither morbidity nor mortality is decreased in humans given prokinetic or antacid drugs. When aspiration is witnessed (for instance, during anesthesia), physical clearing of the airways may be attempted. Airway lavage also has been used therapeutically to "rinse" irritating substances from the airways following a known aspiration event.[235] Following known aspiration, baseline thoracic radiographs should be obtained and oxygenation monitored. If dyspnea occurs after aspiration, bronchodilators could ameliorate acute bronchospasm. Oxygen supplementation should be employed and adjusted as needed (see ch. 131); overly aggressive oxygen supplementation could worsen oxidative lung injury associated with chemical pneumonitis, however. Secondary bacterial infection could require treatment with appropriate antimicrobial therapy. The prognosis for recovery generally is good, but it cannot be predicted by severity of radiographic changes alone.[236]

Pulmonary Edema

Pulmonary edema is not a disease but is a consequence of disease. As a result of increased hydrostatic pressure, decreased oncotic pressure, impaired lymphatic drainage, or increased vascular permeability (see ch. 18), fluid accumulates in the interstitium and then the alveoli at a rate faster than it can be reabsorbed. Fluid accumulation in the alveolar space leads to ventilation-perfusion mismatching and hypoxemia. Fortunately, the lungs are relatively resistant to edema formation compared with other tissues.

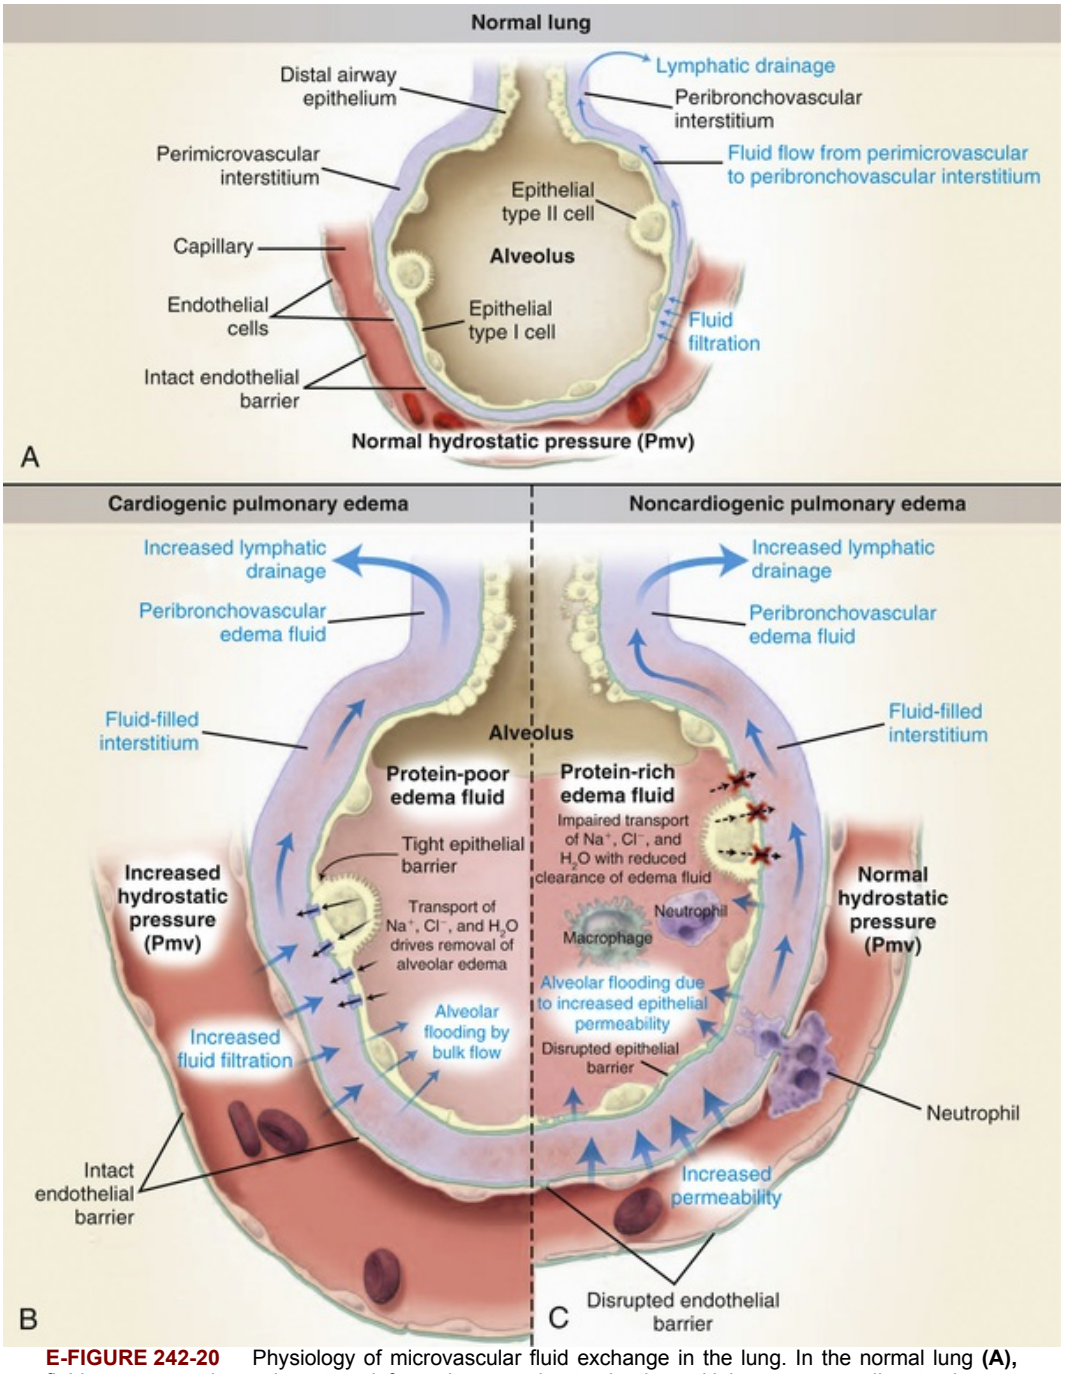
Pulmonary edema is described as either "cardiogenic" or "noncardiogenic." Differentiation is crucial because the conditions are treated differently. Cardiogenic edema, which follows increased venous pulmonary hydrostatic pressure associated with left-sided heart failure, is treated via diuretic administration, afterload reduction, and any specific therapy aimed at the cause of congestive heart failure (E-Figure 242-19). Cardiogenic pulmonary edema and its treatment are discussed in detail in ch. 246 and 247. This section focuses on the noncardiogenic causes of pulmonary edema.



E-FIGURE 242-19 Lateral thoracic radiographs of a dog with cardiogenic pulmonary edema before and after treatment. Note the evidence of left atrial and ventricular enlargement and the engorged pulmonary veins, especially left cranial lobar vein. **A,** There is an interstitial and alveolar pattern present in the pretreatment radiograph not evident in the posttreatment film, **B.**

It is useful to have a basic understanding of microvascular fluid movement in the lung (E-Figure 242-20).[237] In health, minute quantities of fluid and solutes leak from gaps between the capillary endothelial cells and enter the interstitial space. Tight junctions between alveolar epithelial cells prevent the fluid from entering the alveoli. Instead, interstitial fluid moves into the peribronchovascular space, where it is removed by lymphatics and returned to the circulation. Starling's equation for filtration across a semipermeable membrane describes the factors that determine the amount of vascular leakage (see ch. 18) (E-Box 242-12). In congestive heart failure or intravascular volume overload, increased microvascular hydrostatic pressure leads to increased transvascular fluid filtration and pulmonary edema. Because capillary endothelial permeability is unchanged, this edema fluid contains little protein. On the other hand, most noncardiogenic pulmonary edema occurs when vascular permeability increases as a result of direct or indirect lung injury. In contrast to cardiogenic edema, noncardiogenic edema fluid is relatively rich in protein. The protein-rich fluid modifies oncotic pressure gradients, which further alters fluid flux. In both cardiogenic and noncardiogenic edema,

accumulation of alveolar fluid, combined with decreased lung compliance and airway compression resulting from edema, all act to increase pulmonary vascular resistance. Hypoxemia is the consequence of ventilation-perfusion mismatching resulting from each of these factors. Spontaneous removal of alveolar fluid depends on active transport of sodium and chloride from the luminal surface through the epithelial cell and across the basolateral membrane. Water movement passively follows salt movement. Because fluid removal requires active salt transport across the epithelium, injury to the epithelial cells not only leads to edema formation but impedes the lung's ability to resolve edema. As a result of these mechanisms of causation and resolution, noncardiogenic pulmonary edema is more refractory to treatment than is cardiogenic edema.



E-FIGURE 242-20 Physiology of microvascular fluid exchange in the lung. In the normal lung **(A),** fluid moves continuously outward from the vascular to the interstitial space according to the net difference between hydrostatic and protein osmotic pressures, as well as to the permeability of the capillary membrane. The Starling equation for filtration of fluid across a semipermeable membrane describes the factors that determine the amount of fluid leaving the vascular space: Q = K[(Pmv − Ppmv) − (mv − pmv)], where *Q* is the net transvascular flow of fluid, *K* is the membrane permeability, *Pmv* is the hydrostatic pressure in the microvessels, *Ppmv* is the hydrostatic pressure in the

perimicrovascular interstitium, *mv* is the plasma protein osmotic pressure in the circulation, and *pmv* is the protein osmotic pressure in the perimicrovascular interstitium. When hydrostatic pressure increases in the microcirculation, the rate of transvascular fluid filtration rises **(B).** When lung interstitial pressure exceeds pleural pressure, fluid moves across the visceral pleura, creating pleural effusion. Because the permeability of the capillary endothelium remains normal, the filtered edema fluid leaving the circulation has a low protein content. The spontaneous removal of edema fluid from the airspaces of the lung depends on active transport of sodium and chloride across the alveolar epithelial barrier. The primary sites of sodium and chloride reabsorption are the epithelial ion channels located on the apical membrane of alveolar epithelial type I and II cells and distal airway epithelia. Sodium is extruded actively into the interstitial space by means of the Na^+/K^+-ATPase located on the basolateral membrane of type II cells. Water follows passively, probably through aquaporins, which are water channels that are found predominantly on alveolar epithelial type I cells. Noncardiogenic pulmonary edema **(C)** occurs when the permeability of the microvascular membrane increases because of direct or indirect lung injury (including the acute respiratory distress syndrome), resulting in a marked increase in the amount of fluid and protein leaving the vascular space. Noncardiogenic pulmonary edema has a high protein content because the more permeable microvascular membrane has a reduced capacity to restrict the outward movement of larger molecules such as plasma proteins. The degree of alveolar flooding depends on the extent of interstitial edema, the presence or absence of injury to the alveolar epithelium, and the capacity of the alveolar epithelium to actively remove alveolar edema fluid. In edema due to acute lung injury, alveolar epithelial injury commonly causes a decrease in the capacity for the removal of alveolar fluid, delaying the resolution of pulmonary edema. (Reprinted with permission from Ware LB, Matthay MA: Acute pulmonary edema. *N Engl J Med* 353:2788, 2005.)

E-Box 242-12

Starling's Equation for Filtration Across a Semipermeable Membrane

$$Q = K[(Pmv - Ppmv) - (pmv - ppmv)]$$

where Q = net transvascular flow of fluid, K = membrane permeability, Pmv = hydrostatic pressure in the microvessels, $Ppmv$ = hydrostatic pressure in the perimicrovascular interstitium, pmv = plasma protein osmotic pressure in the circulation, and $ppmv$ = protein osmotic pressure in the perimicrovascular interstitium.

There are myriad potential causes of noncardiogenic pulmonary edema (Box 242-13). Severe hypoalbuminemia (<1.5 g/dL) is correlated with diminished vascular colloid oncotic pressure. Although hypoalbuminemia can contribute to pulmonary edema, pulmonary lymphatics are very efficient at fluid removal from the interstitial space. Therefore, animals with low oncotic pressure are far more likely to be presented for ascites, peripheral edema, or even pleural effusion than for pulmonary edema.[238] Nevertheless, hypoalbuminemia will potentiate pulmonary edema in the face of vascular permeability changes or the overzealous administration of crystalloid fluids.[239] Similarly, although lymphatic drainage is an important key to normal interstitial fluid balance, impairment of thoracic lymphatic drainage (e.g., granuloma or neoplasia, lymphangitis) is more likely to result in chylous effusion than in pulmonary edema. Electrical shock or acute insult to the central nervous system can lead to a unique neurogenic form of noncardiogenic pulmonary edema. Although the mechanisms causing neurogenic edema are incompletely understood, both intense pulmonary vasoconstriction (and resultant increased pulmonary hydrostatic pressure) and an inflammatory mechanism are hypothesized to increase pulmonary capillary permeability.[240] Noncardiogenic edema most commonly is related to (direct or indirect) pulmonary epithelial injury. Acute pulmonary inflammation and edema from a variety of initial insults resulting in respiratory compromise may be termed acute respiratory distress syndrome (ARDS).[241,242] These can be direct insults to the lung (e.g., pneumonia, aspiration, smoke inhalation) or indirect injuries (e.g., pancreatitis, uremia, sepsis, major trauma).[243,244] The most recent working veterinary definitions related to this syndrome were developed in 2007 and are no longer in line with the more recent definitions developed for use in humans.[241] For humans, a consensus panel developed a set of definitions related to ARDS known as the "Berlin Definition."[245] In this new system of nomenclature, the term "acute lung injury" has been discarded; ARDS itself is now characterized as mild, moderate, or severe; and specific diagnostic criteria for ARDS have been developed. By these criteria, ARDS is

defined as having a characteristic time of onset (within 1 week of the inciting event or onset/worsening of respiratory signs), thoracic radiographic and/or CT findings (bilateral opacities beyond those expected with effusions, atelectasis, or mass lesions), and noncardiogenic origin (exclusion of heart disease of sufficient severity to cause cardiogenic pulmonary edema).[245] ARDS is characterized as mild (PaO_2/FiO_2 = 200 to 300 mm Hg with positive end-expiratory pressure [PEEP] or continuous positive airway pressure [CPAP] ≥ 5 cm H_2O), moderate (PaO_2/FiO_2 = 100 to 200 mm Hg with PEEP ≥ 5 cm H_2O), or severe (PaO_2/FiO_2 = <100 mm Hg with PEEP ≥ 5 cm H_2O), and these categories of severity have predictive value in regards to outcome of lung injury in humans.[244,245] It is very likely that veterinary medicine will follow the lead of human medicine and revise definitions related to ARDS.

Box 242-13

Predisposing Factors for the Development of Noncardiogenic Pulmonary Edema

Neurogenic pulmonary edema (e.g., seizures, electrocution, head trauma)
Postobstructive pulmonary edema (e.g., strangulation, laryngeal paralysis, pulmonary reexpansion)
Systemic disease predisposing to acute respiratory distress syndrome (e.g., sepsis, shock, severe pancreatitis, virulent babesiosis, paraquat poisoning, envenomation, gastric/splenic/mesenteric torsion, parvoviral enteritis, uremia)
Direct pulmonary injury (e.g., aspiration pneumonia, bacterial pneumonia, lung lobe torsion, smoke inhalation, parasitic pneumonitis, pulmonary contusion, hyperoxia)
Profound hypoalbuminemia (e.g., protein-losing nephropathy, lymphangiectasia, liver failure)
Impaired lymphatic drainage (e.g., lymphangitis, lymphatic neoplasia)
Miscellaneous causes (e.g., vasculitis, drowning, high altitude, air embolus, pheochromocytoma)

Presentation

Regardless of cause, the clinical presentation of animals with noncardiogenic pulmonary edema is similar. Clinical signs can follow rapidly or can be delayed for as much as 72 hours after the inciting insult. The severity of signs depends on the degree of pulmonary injury and amount of fluid accumulation; early signs include exercise intolerance and tachypnea. A moist cough can produce frothy foam. Respiratory distress and orthopnea can be observed, and animals can demonstrate cyanosis and/or hemoptysis. Harsh, loud bronchovesicular sounds are expected, and inspiratory and/or end-expiratory crackles auscultated. Occasionally, lung sounds are quiet when edema is severe. Animals with cardiogenic edema usually have an audible heart murmur or dysrhythmia, but these findings are also possible in animals with noncardiogenic edema; therefore, their *absence* is strongly suggestive of a noncardiogenic mechanism, but the presence of a murmur and/or arrhythmia is nonspecific. Sinus tachycardia is common in animals with cardiogenic edema, whereas vagal stimulation associated with lung disease often causes respiratory sinus arrhythmia. Other abnormalities on physical examination can be associated with the underlying disease process (e.g., fever, pain).

Diagnostic Evaluation

Because animals with pulmonary edema are fragile, thorough diagnostic investigation must follow medical stabilization (see treatment, later). Abnormalities on CBC, serum biochemical profile, and urinalysis depend almost entirely on the underlying disease process. Likewise, radiographic changes vary, depending on both the underlying condition and the degree of edema. An unstructured interstitial and/or peribronchial radiographic pattern that progresses with severity of edema produces an alveolar pattern; patchy infiltrates are common in ARDS. The caudodorsal lung fields often are the most severely affected, but depending on the source of lung injury, the predominant location may be elsewhere (e.g., edema associated with aspiration would be most severe in the affected lobes). Cardiomegaly (especially left atrial enlargement) or pulmonary venous engorgement suggests cardiogenic rather than noncardiogenic edema. Hypoxemia is expected, and typically the alveolar to arterial oxygen gradient (see E-Box 242-1) is increased as a result of ventilation-perfusion mismatching (see ch. 128).

Treatment

Treatment of noncardiogenic pulmonary edema should include measures to address the underlying disorder. In certain cases, it might be impossible to correct the instigating cause (e.g., electrocution) or doing so might require time (e.g., pancreatitis). Treatment must address hypoxemia. When respiratory distress is apparent, or if PaO_2 is <80 mm Hg or the SpO_2 is <94% (see ch. 98), supplemental oxygen should be provided in the least stressful manner possible (see ch. 131). Because animals with hypoxemia often are distressed, judicious use of sedatives (e.g., morphine sulfate or acepromazine IV) could be warranted. Caution must be used because sedatives can depress respiration. Animals in respiratory distress should be allowed to position themselves for comfort, but if recumbent, they should be either supported in a sternal position or placed with the more severely affected lung in the dependent position. Animals with ARDS often have critical respiratory compromise; if stabilization is not possible with less invasive measures, intubation and ventilatory support might be required. Positive pressure ventilation (PPV) should be considered if initial therapy is unable to maintain $SpO_2 \geq 90\%$, $PaO_2 \geq 60$ mm Hg, and $PaCO_2 < 60$ mm Hg; PPV also can be indicated to relieve sustained respiratory effort, which might result in respiratory muscle fatigue.

Diuretic administration is more effective in the resolution of cardiogenic or intravascular volume overload-associated edema than noncardiogenic edema. Neurogenic pulmonary edema results from both increased hydrostatic pressure and vascular permeability changes. Therefore, diuretics such as furosemide could be of some benefit in this condition. Neurogenic pulmonary edema usually resolves without specific treatment, assuming that neurologic and respiratory function can be preserved for 48 to 72 hours after the initiating insult.[240] Alpha-adrenergic blockade and dobutamine have been suggested to be of benefit in the treatment of neurogenic pulmonary edema. Drugs that result in cerebral vasodilation should be avoided. Noncardiogenic edema that results from or is exacerbated by hypoalbuminemia can be addressed with colloidal support. Plasma transfusion is impractical to replenish colloid oncotic pressure due to both the large associated fluid volume required and the high costs of massive plasma transfusion.[246] Instead, synthetic colloids or albumin transfusion should be considered in animals with pulmonary edema resulting from decreased colloid oncotic pressure (see ch. 130). Unfortunately, adverse effects can be associated with either synthetic colloids administration or xenoalbumin transfusion.[247-249] As an additional complication of colloid administration, any increase in pulmonary vascular permeability can lead to colloid leakage into the alveolar space. This may in turn actually worsen edema. The balance between these limitations and the benefits of treatment must be considered on a case-by-case basis.

Medical treatment of ARDS, like the medical treatment of the systemic inflammatory response syndrome (SIRS; see ch. 132) that often accompanies ARDS, is complex. A variety of drugs that inhibit inflammation, alter production of cytokines or enzymes, or act in any of a dozen other ways has been used in the treatment of ARDS, with variable (usually minor) success.[242,250] Intravenous fluid administration could be required for the appropriate treatment of the underlying disease processes (e.g., uremia), but it must be used judiciously to avoid worsening edema via increased pulmonary hydrostatic pressure.[251] Conversely, reduction of hydrostatic pressure via furosemide, which may also cause bronchodilation and improve lymphatic flow, can be considered in well-hydrated animals but will not have the profound effects often observed by resolution of cardiogenic pulmonary edema. Despite the fact that mechanical ventilation can actually exacerbate functional and structural lung alterations, it often is necessary in the treatment of humans with ARDS.[244] The same could be true in animals.[252-254] The treatment of ARDS largely is dependent on supporting oxygenation and treating the underlying disease while allowing the lungs to heal themselves.[244]

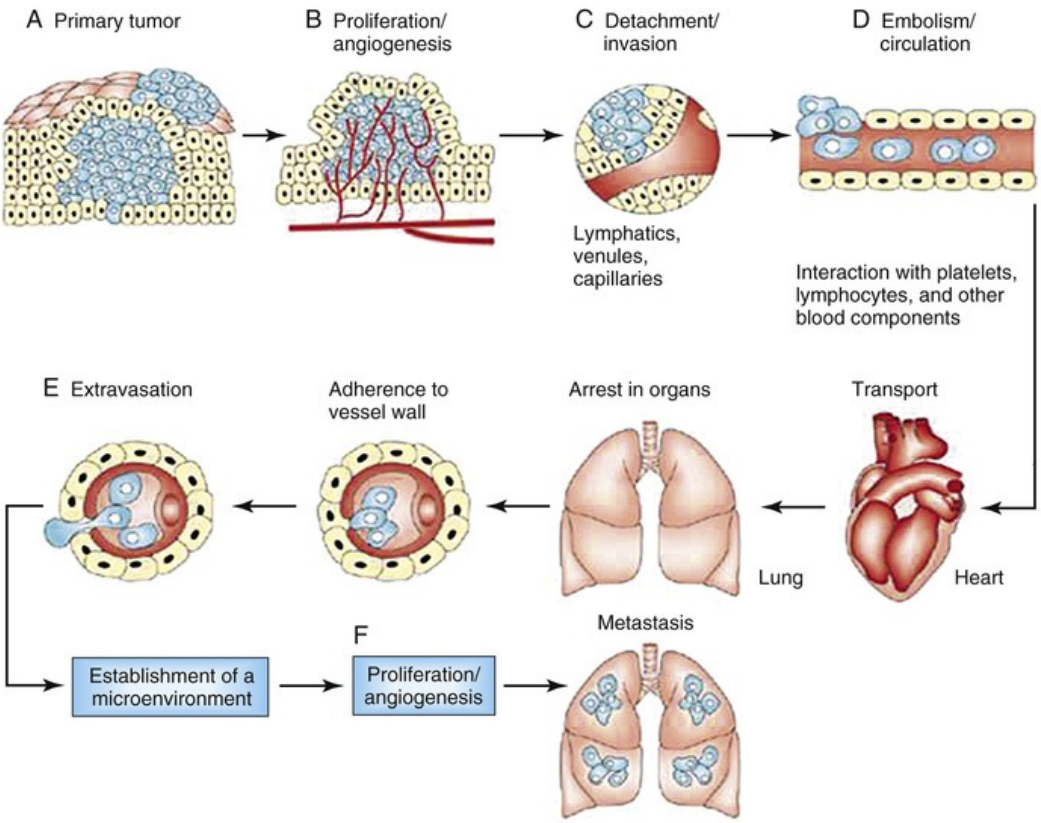
Lung Cancer

Both primary respiratory neoplasia and metastasis of nonrespiratory cancers occur in the lung. Differentiating less-common primary lung tumors from the more common metastatic variety is important because the diagnosis, treatment, and prognosis of primary lung tumors differ from those of metastatic cancer. Animals with lung cancer can be presented for cough, hemoptysis, panting, or other signs of respiratory dysfunction. Often, lung cancers are identified radiographically in animals without respiratory signs during evaluation for nonspecific signs such as weight loss or extrathoracic neoplasia. Occasionally, animals with lung tumors are presented for investigation of paraneoplastic conditions such as hypertrophic osteopathy or polyneuropathy.

Metastatic and Special Lung Cancers

Normally, the pulmonary vascular bed receives the entire output of the right ventricle during each cardiac cycle. The blood passes through numerous small-diameter, well-oxygenated capillary beds, making the lung

an ideal location for metastasis. The "seed and soil" hypothesis describes detached tumor cells as seeds that can only flourish in suitable soil (tissue).[255] Besides simple mechanics, the lung might be targeted specifically by certain tumors as a preferential site of metastasis. Cancer metastasis is complex; cancer cells must detach from the primary tumor, gain access into blood or lymph vessels to be carried to distant sites, migrate from the vessels into the tissues, adhere and then grow in the new site (see ch. 338; E-Figure 242-21).[255] Virtually any neoplasm may metastasize to the lungs, but several that are particularly likely to do so include oral and nail bed melanoma, thyroid carcinoma, osteosarcoma, hemangiosarcoma, and mammary carcinoma.



E-FIGURE 242-21 Pulmonary metastasis. The main steps in the formation of a metastasis (also see ch. 338). **A,** Cellular transformation and tumor growth. Growth of neoplastic cells must be progressive, with nutrients for the expanding tumor mass initially supplied by simple diffusion. **B,** Extensive vascularization must occur if a tumor mass is to exceed 1-2 mm in diameter. The synthesis and secretion of angiogenic factors establish a capillary network from the surrounding host tissue. **C,** Local invasion of the host stroma by some tumor cells occurs by several parallel mechanisms. Thin-walled vessels, such as lymphatic channels, offer very little resistance to penetration by tumor cells and provide the most common route for tumor-cell entry into the circulation. **D,** Detachment and embolization of single tumor cells or aggregates occur next, with most circulating tumor cells being rapidly destroyed. After the tumor cells have survived the circulation, they become trapped in the capillary beds of distant organs by adhering either to capillary endothelial cells or to subendothelial basement membrane that might be exposed. **E,** Extravasation occurs next, probably by mechanisms similar to those that operate during invasion. **F,** Proliferation within the organ parenchyma completes the metastatic process. To continue growing, the micrometastasis must develop a vascular network and evade destruction by host defenses. The cells then can invade blood vessels, enter the circulation, and produce additional metastases. (Reprinted with permission from Fidler IJ: The pathogenesis of cancer metastasis: the "seed and soil" hypothesis revisited. *Nat Rev Can* 3(6):453-458, 2003.)

Presentation and Diagnostic Evaluation

Often, animals with metastatic lung cancer have few respiratory signs despite a large tumor burden. Pulmonary metastasis usually is identified via screening thoracic radiographs. Radiographic screening for metastasis should include a combination of images obtained in dorsal, ventral, right lateral and left lateral recumbencies, because the mild atelectasis that occurs in the dependent lung can obscure identification of tumors (E-Figure 242-22). The radiographic appearance of metastatic cancer varies widely, typically with few

to many interstitial nodules of varying size distributed throughout the lungs (Figure 242-23). However, metastasis can appear as a single nodule, an interstitial or alveolar lung pattern, a miliary interstitial pattern, or even as multiple cysts (Figure 242-24).[257-260] Even with appropriate positioning, summation artifact can make identification of tumors that are <8 to 9 mm in diameter difficult.[17] Although inverse display of digital thoracic radiographs has been postulated to improve ability to detect pulomonary nodules, this was not corroborated in a recent small study.[261] Thoracic CT is a more sensitive means of imaging small tumors (E-Figure 242-25), but the need for anesthesia or sedation, equipment, and financial resources prevent CT scan from serving as a routine screening test.[17,256,260,262] Because there is no pathognomonic radiographic appearance of pulmonary metastasis, animals should not be condemned based on thoracic radiographs alone when a primary tumor has not been definitively identified. Instead, the neoplastic nature of lung disease should be confirmed or refuted via aspirate, lavage, or biopsy techniques (see ch. 240).

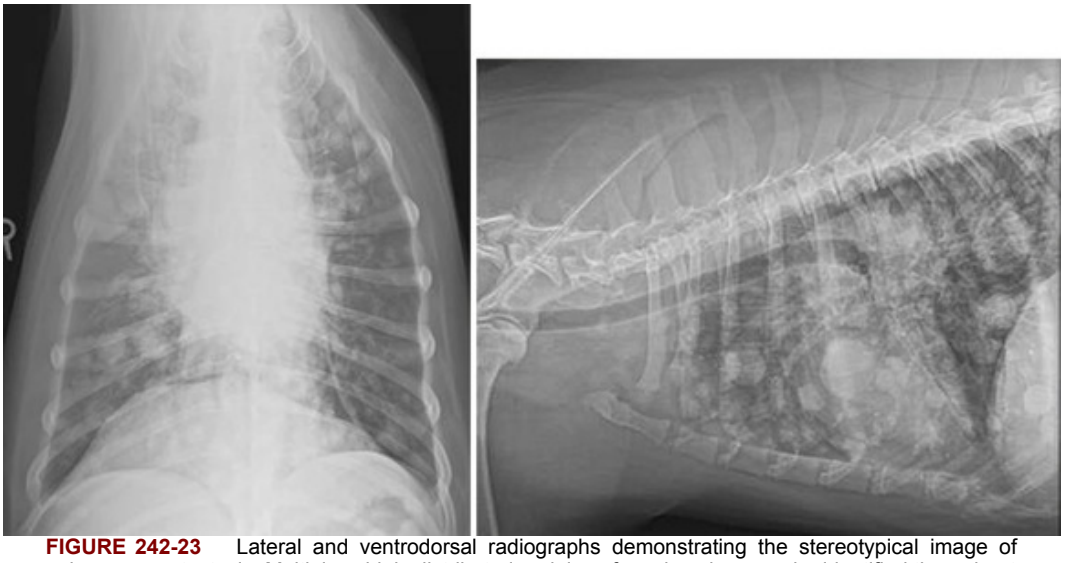


FIGURE 242-23 Lateral and ventrodorsal radiographs demonstrating the stereotypical image of pulmonary metastasis. Multiple, widely distributed nodules of varying sizes can be identified throughout the lung fields.

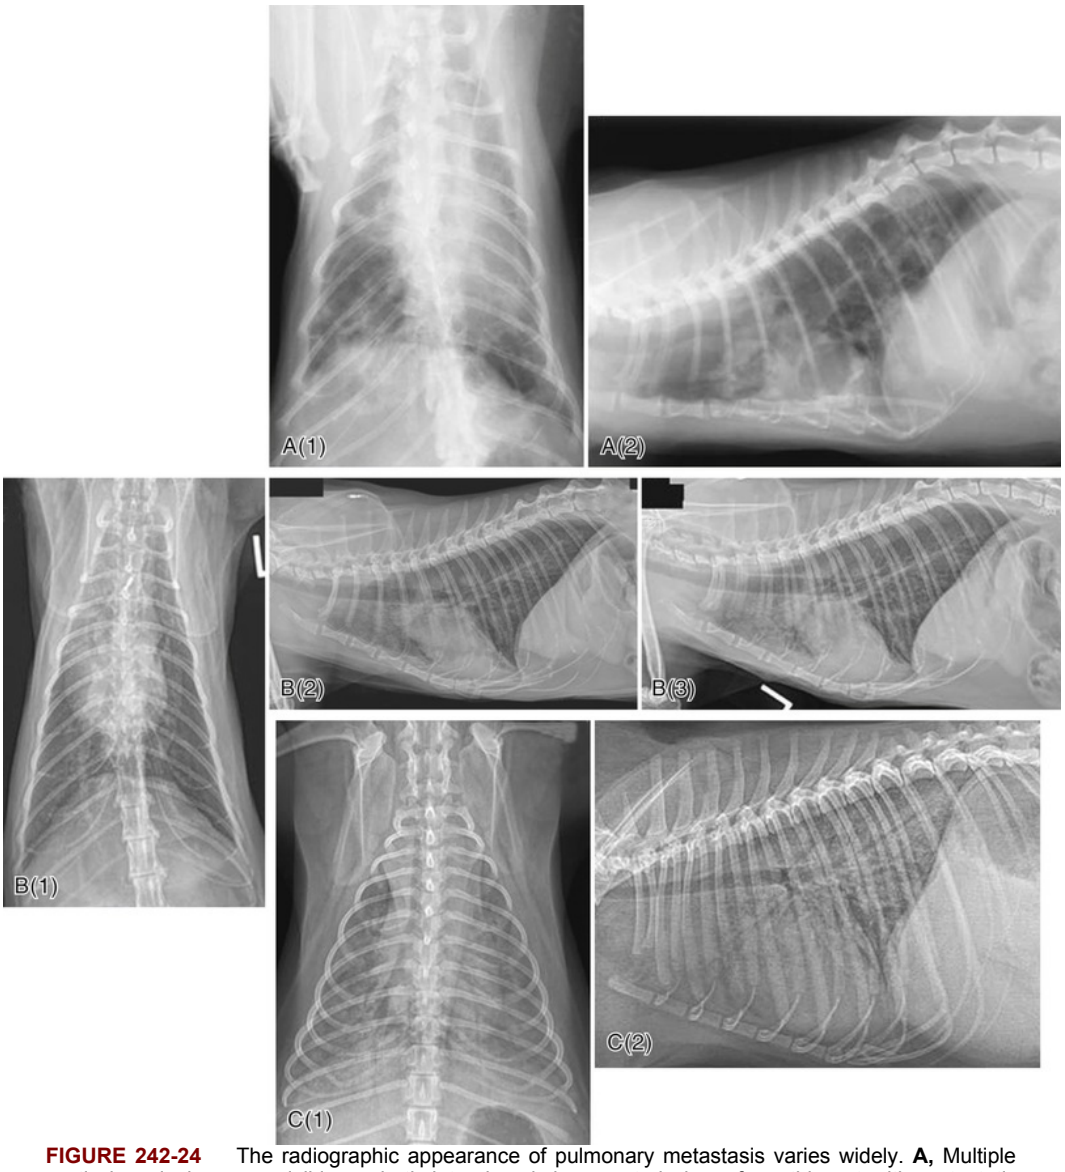

FIGURE 242-24 The radiographic appearance of pulmonary metastasis varies widely. **A,** Multiple cystic lung lesions are visible on both lateral and dorsoventral views from this cat with metastatic squamous cell carcinoma. **B,** A single nodule dorsal to the tracheal bifurcation is visible on the right lateral view, and both alveolar and interstitial patterns are identified in this cat with metastatic mammary carcinoma. **C,** A widespread interstitial to alveolar pattern is present in this dog with disseminated lymphoma.

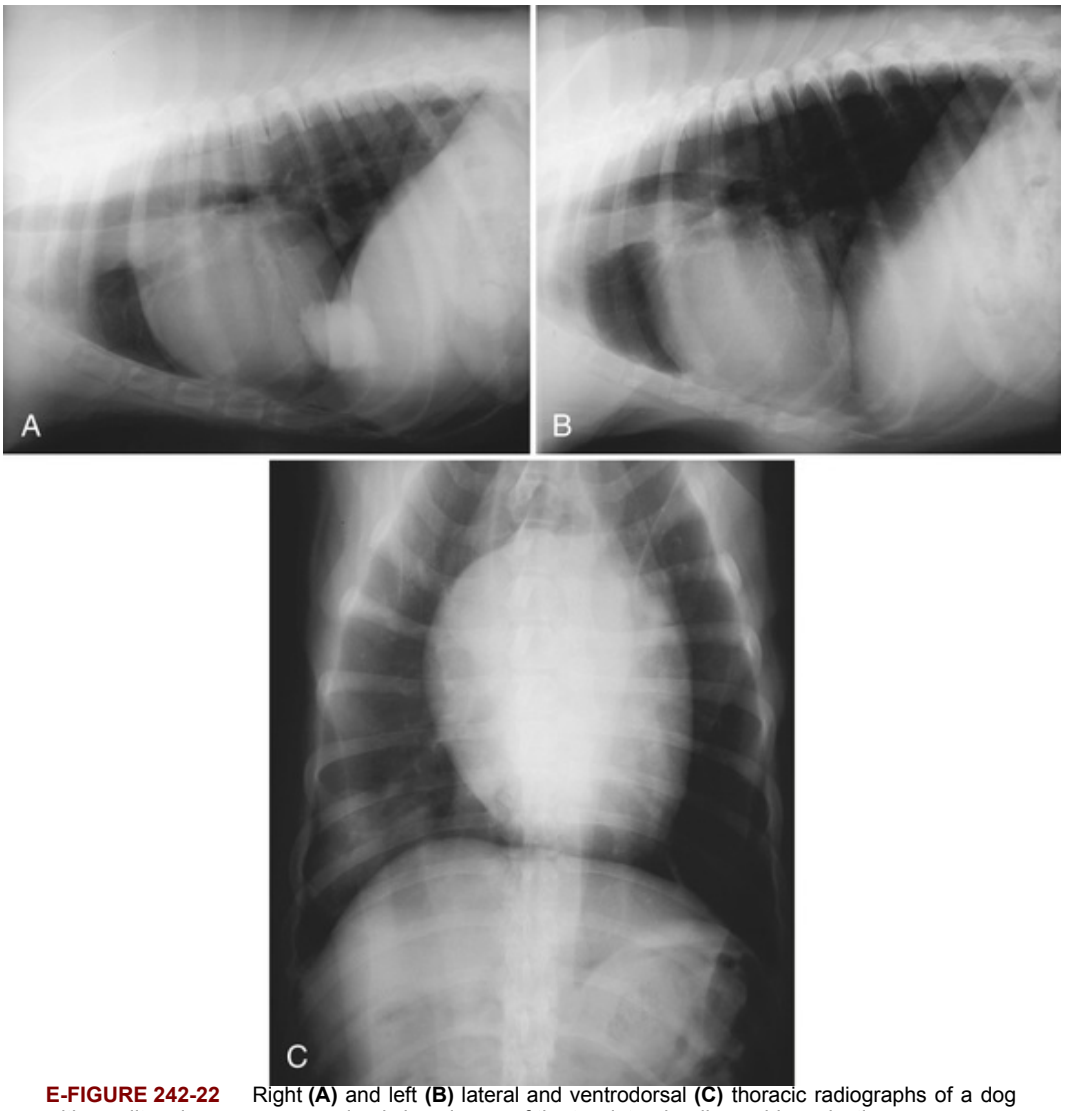
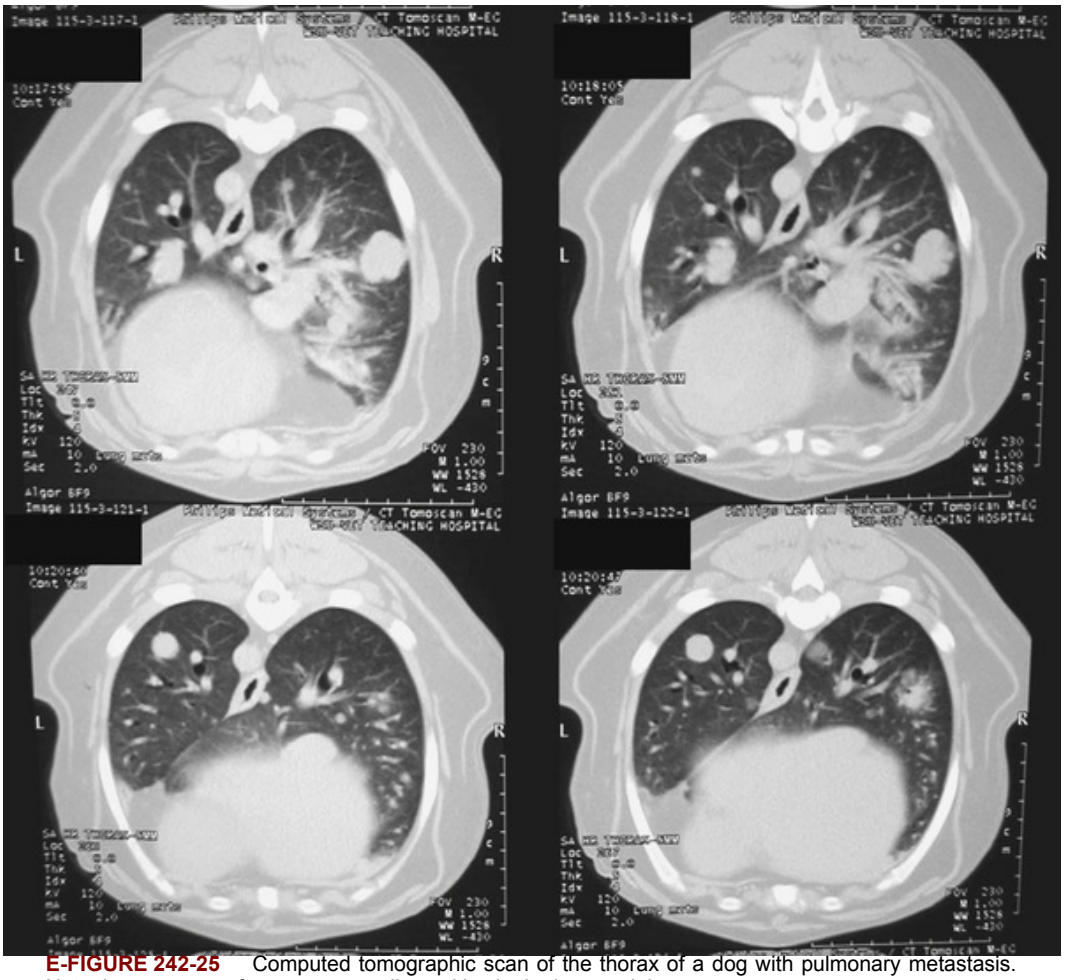


E-FIGURE 242-22 Right **(A)** and left **(B)** lateral and ventrodorsal **(C)** thoracic radiographs of a dog with a solitary lung mass seen clearly in only one of the two lateral radiographic projections.



E-FIGURE 242-25 Computed tomographic scan of the thorax of a dog with pulmonary metastasis. Note the presence of numerous small opacities in the lung periphery.

Treatment

Unfortunately, treatment of metastatic lung cancer is seldom of long-term benefit. Treatment with tyrosine kinase inhibitors could have limited efficacy.[263] In those cases where only a single or few pulmonary nodules is/are present, surgical resection via thoracoscopy or thoracotomy (± adjunctive chemotherapy) may be an option.[264-266] Metastasectomy particularly can be useful in cases where metastasis occurs long after treatment of the primary tumor.[267] Inhalant therapies with chemotherapy drugs, immunologic molecules (i.e., liposomal interleukin-2), and gene therapy resulting in production of immunogenic molecules have been described for the treatment of both primary and metastatic pulmonary neoplasia.[268-273] As of yet, such therapy is not well established or readily available for pet animals.

Pulmonary Lymphoma

Lymphoma can affect the lungs of both dogs and cats, either in conjunction with lymphoid and solid organs or, rarely, without additional tumor burden. Interstitial, alveolar, and mixed pulmonary infiltrative patterns are observed on thoracic radiographs with or without concurrent hilar and mediastinal lymphadenopathy. When lymphoma is confirmed in other tissues and other inciting causes (e.g., advanced heart disease) are absent, radiographic pulmonary infiltrates can be attributed presumptively to lymphoma. FNA, BAL, or lung biopsy may be used for confirming isolated pulmonary lymphoma. A more complete discussion of lymphoma and its treatment can be found in ch. 344.

Pulmonary Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis (LG) is a rare lymphoproliferative cancer in which atypical lymphoid cells infiltrate around and destroy blood vessels. In humans, LG is regarded as a low-grade precursor to T-cell

lymphoma. Immunophenotyping of several canine tumors has demonstrated the presence of T-cell markers and sometimes B-cell markers.[274,275] Although pulmonary involvement is reported most often, other sites including lymph nodes, abdominal organs, and the dermis can be involved. Dogs of any age or gender can be affected, but there are few case reports in cats.[274-281] Leukocytosis with eosinophilia and/or basophilia has been documented in several affected dogs, but concurrent parasite infection was present in some of these animals. Thoracic radiographs typically demonstrate either pulmonary masses and/or lobar consolidation. Interstitial and alveolar infiltrates also are common, as is tracheobronchial lymphadenopathy. Although FNA or airway lavage can be suggestive of lymphoma, pulmonary biopsy is required to achieve a diagnosis because the unique relationship between the granulomatous lymphoid infiltrates and the vasculature defines the disease. Utility of the less-invasive tests is largely to rule out more common causes for pulmonary consolidation. Supportive care might be necessary for hypoxemic animals, but definitive treatment relies on chemotherapy. Protocols used for treatment are identical to those used to treat lymphoma (see ch. 344). Treatment often results in durable remission, but recurrence of pulmonary involvement or development of lymphoma in other organ systems can occur months to years after apparently successful treatment.

Malignant Histiocytosis

Malignant histiocytosis (disseminated histocytic sarcoma) is one of several histiocytic diseases that occur more commonly in dogs than cats (see ch. 350). The condition was first recognized in Bernese Mountain Dogs, a breed for which a genetic basis with a polygenic mode of inheritance is suspected.[282,283] Other breeds overrepresented among those diagnosed with this condition include Flat-Coated Retrievers, Golden Retrievers and Rottweilers. As with lymphoma, malignant histiocytosis can affect any combination of organs, including the bone marrow, central nervous system, abdominal viscera, and lungs.[283,284] Atypical histiocytic cells (a mononuclear cell lineage) accumulate within the affected organs, resulting in dysfunction. Clinical presentation often involves nonspecific signs such as lethargy and anorexia; cough and/or dyspnea are common.[284-287] When pulmonary involvement exists, radiographs can demonstrate thoracic lymphadenopathy (tracheobronchial and sternal nodes, especially); pulmonary nodules (often quite large, and most often found in the right middle lung lobe) or an interstitial infiltrate; and sometimes pleural effusion.[288] On CT scan, most masses are mildly to moderately enhancing and heterogeneous, poorly marginated, and bronchocentric.[288] Diagnosis usually is based on histopathologic assessment of involved tissue or suggestive clinical findings and supportive bone marrow cytologic features. To date, most chemotherapeutic regimens have been largely ineffective and the prognosis remains guarded to grave.

Recently, another histiocytic lung disease, feline pulmonary Langerhans cell histiocytosis, was described in seven cats.[283,289] All were older adults with progressive respiratory failure. Radiographs demonstrated a diffuse bronchointerstitial pattern with miliary to nodular opacities, and all were diagnosed at necropsy.

Primary Lung Cancer

Primary lung cancer is uncommon in dogs and even less common in cats. A relationship between accumulation of inhaled dust (i.e., anthracosis) and primary lung cancers has been proposed, but no definitive link to living with smokers or an urban environment has been confirmed in pets.[290,291] When primary lung tumors do occur in pets, they usually are malignant. Adenocarcinomas predominate, with most other tumors morphologically classified as carcinoma, squamous cell carcinoma, or anaplastic carcinoma.[292-297] Primary mesenchymal lung tumors are exceedingly rare.

Presentation

Most primary lung tumors in small animal medicine are identified in older animals. Just over half of dogs with primary pulmonary neoplasia are presented for evaluation of a chronic, nonproductive cough.[291,294,295,298] Although other respiratory signs can occur as well, as many as one third of dogs with primary lung tumors display no respiratory clinical signs.[294,295,298] Similarly, respiratory signs often are absent in cats with primary lung tumors: Only 20% to 40% of cats with primary lung tumors present with dyspnea.[292,299] Cough, tachypnea, cyanosis, and hemoptysis occur occasionally in dogs or cats. Affected animals of either species can be brought to veterinary attention due to weight loss, lethargy, and diminished appetite with or without concurrent respiratory signs. Animals with primary pulmonary neoplasia also are presented for evaluation of lameness due to either paraneoplastic osteopathy or, in cats, metastasis of the pulmonary neoplasm to the phalanges (lung-digit syndrome).[291,300] Other presenting problems might include

edema of the head and neck, ascites resulting from tumor obstruction of flow through veins or lymphatics, vomiting, and diarrhea. Sometimes, pleural effusion or spontaneous pneumothorax leads to an acute onset of respiratory distress.

Diagnostic Evaluation

Although essentially any radiographic pattern is possible in animals with primary lung cancer, rare or solitary parenchymal masses often are observed.[293,299,301,302] Solitary nodular tumors, other than histiocytic tumors, are identified most frequently in the caudal lung lobes (Figure 242-26).[293,299] On CT scan, primary lung tumors often are well-circumscribed, bronchocentric masses with internal air bronchograms; up to one quarter of these tumors demonstrate metastasis at the time of diagnosis.[301] As with pulmonary metastasis, the radiographic pattern cannot be considered pathognomonic and the differential diagnosis for solitary or multifocal pulmonary nodules must be considered (Box 242-14).

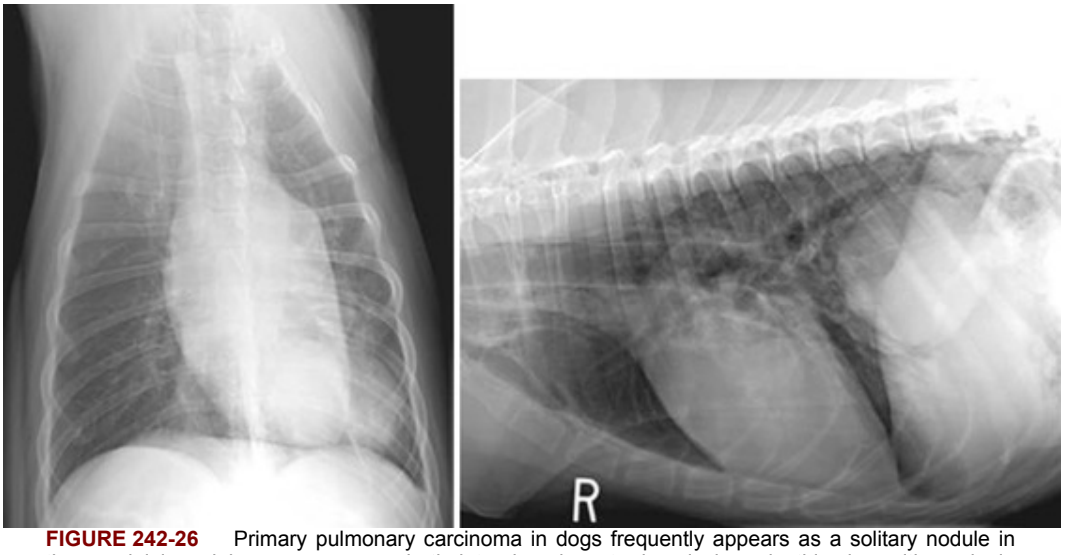


FIGURE 242-26 Primary pulmonary carcinoma in dogs frequently appears as a solitary nodule in the caudal lung lobes, as seen on both lateral and ventrodorsal views in this dog with a single radiographically visible mass in the left caudal lung lobe.

Box 242-14

Differential Diagnoses for Solitary or Multifocal Pulmonary Nodules

Arteriovenous malformation
Atelectasis
Eosinophilic pneumonia (also called pulmonary infiltrates with eosinophilia, eosinophilic bronchopneumopathy, eosinophilic granuloma)
Fluid-filled bullae
Focal pneumonia
Focal bronchiectasis with mucus filling
Fungal granuloma
Foreign body granuloma
Hematoma
Metastatic pulmonary neoplasia
Mucoid impaction
Parasite granuloma
Primary pulmonary neoplasia (usually carcinoma)
Pulmonary abscess
Pulmonary cysts

Pulmonary parasites
Pulmonary thromboembolism
Tuberculosis

Diagnosis must be confirmed by microscopic examination of cells for criteria of malignancy. Samples obtained by BAL or tracheal lavage (see ch. 101) help rule out nonneoplastic disease and rarely demonstrate cells with neoplastic morphology. Radiographic localization of nodules can be used for estimating needle placement for FNA, or aspirates may be obtained with fluoroscopic or CT guidance.[16,26] Nonaerated solid masses located near the edge of the lung could be amenable to ultrasound-guided needle aspiration, but there is a minimal risk of needle-tract seeding.[303,304] Percutaneous lung biopsy should be obtained only with imaging guidance due to the risk of complications (i.e., pneumothorax, hemothorax).[26] Although good correlation has been found between the diagnosis obtained by FNA and percutaneous biopsy, results of FNA are less likely to provide a conclusive diagnosis.[25,26] Other lung biopsy techniques include thoracoscopy, keyhole biopsy, and limited or full thoracotomy.[305-307] Depending on tumor size and location, these techniques also offer the opportunity to completely excise the lung tumor.

Because metastasis greatly affects prognosis, tumor staging should be attempted before lung lobectomy. Reasonable efforts must be made to identify distant tumors because single lung nodules can be either metastatic or primary tumors. Thorough physical examination (including prostate, mammary glands, and long bones), as well as abdominal radiographs and ultrasonographic imaging, are indicated. Ideally, thoracic CT should be performed prior to any planned surgical intervention to identify small masses in other lung lobes that might otherwise be missed; canine primary lung tumors typically appear radiographically as a well-circumscribed solitary mass in the periphery of a caudal lung lobe, but up to one third of primary lung tumors affect multiple lobes.[292,293,295,301] Additionally, CT improves the ability to detect involvement of tracheobronchial lymph nodes, impacting the prognosis.[297,301]

Treatment

Excision is the treatment of choice for primary lung tumors confined to one lobe. Because lymph node involvement negatively impacts prognosis, even normal-sized nodes should be examined histologically.[296-298] Favorable prognostic findings include complete tumor removal, the presence of a single tumor without metastasis, a lack of clinical signs referable to the lung tumor, lower histologic grade or more well-differentiated tumor, peripherally located tumor, and absence of pleural effusion.[292,294,296,298,299,308] Postoperative survival times vary widely but can be up to 2 years. Large reports of traditional radiation or chemotherapy for the treatment of primary lung tumors in dogs and cats are not available. Damage to intrathoracic structures and constant movement of the target associated with respiration have limited the use of traditional radiation therapy in the treatment of lung tumors, but intensity-modulated radiation therapy could offer effective treatment with few adverse effects.[309] Vinorelbine, a mitotic inhibitor that achieves far higher pulmonary concentrations than other vinca alkaloids, has been used with some success to treat two dogs with bronchoalveolar carcinoma.[310,311] Piroxicam, a nonsteroidal antiinflammatory drug that has antitumor effects, also has been speculated to be useful in the treatment of pulmonary carcinoma.[312] Intracavitary chemotherapy occasionally has been utilized to good effect in dogs with malignant pleural effusion, carcinomatosis, sarcomatosis, or mesothelioma.[313,314] Several reports document the potential utility of inhalational chemotherapy or inhalational delivery of biologic response modifiers in the treatment of either metastatic or primary lung cancer.[268-273]

Interstitial Lung Disease

Interstitial lung diseases (ILDs) are a heterogeneous group of noninfectious, nonmalignant respiratory tract disorders that can be definitively diagnosed only with histopathologic examination of lung tissue.[315] Tissue changes center on the space between the basement membrane of the alveolar epithelial cells and the capillary endothelial cells (i.e., the pulmonary interstitium) plus adjacent vasculature and lymphatics. These relatively rare disorders are characterized by inflammation, fibrosis, and/or abnormal accumulations of protein or lipid that restrict effective lung volume and diminish pulmonary compliance. Although recognition of ILDs is increasing, they remain poorly characterized and likely are underdiagnosed in dogs and cats.

As expected for a heterogeneous group of diseases, the causes of ILD are many. Inhalation of toxicants, allergens, and irritants (e.g., mineral fibers) could cause alveolar epithelial inflammation and subsequent reaction, leading to ILD. Tissue damage also can result from systemic exposure to drugs or toxins, or via hypersensitivity reactions. Unfortunately, many ILDs remain idiopathic. Many ILDs have been recognized in dogs and cats, including eosinophilic pneumonia, idiopathic pulmonary fibrosis (IPF), lymphocytic interstitial pneumonitis (LIP), bronchiolitis obliterans with organizing pneumonia (BOOP), endogenous lipid pneumonia, pulmonary alveolar proteinosis, silicosis, and asbestosis (E-Box 242-15).[1,2,316-329] Most ILDs are described as single case reports or small case series.

E-Box 242-15

Uncommon Interstitial Lung Diseases of Dogs or Cats

Numerous interstitial lung diseases (ILDs) have been reported in humans, but far fewer are described in dogs and cats. These disorders often are divided into (1) idiopathic interstitial pneumonia (e.g., idiopathic pulmonary fibrosis [IPF], desquamative interstitial pneumonia, cryptogenic organizing pneumonia); (2) environmental and occupational diseases (e.g., asbestosis, silicosis, extrinsic allergic alveolitis); and (3) multisystem disorders (e.g., sarcoidosis, systemic sclerosis, granulomatosis with polyangiitis [formerly Wegener's granulomatosis]).[461] In addition to IPF, eosinophilic pneumonia, and lipid pneumonia, the following ILDs have been rarely reported in dogs or cats:

Bronchiolitis Obliterans with Organizing Pneumonia (BOOP)

Well-known in humans, both naturally occurring (3 dogs, 1 cat) and experimentally induced BOOPs have been described in pet animals.[155,321,328,462,463] The condition can be idiopathic or secondary. Bronchioles become plugged with connective tissue, leading to a downstream organizing pneumonia.

Familial Acute Respiratory Distress Syndrome

A form of "familial ARDS" has been described in 12 related Dalmatian dogs (3 adult dogs and 9 pups between 5 and 10 months).[464] Unlike the more typical ARDS associated with direct or indirect lung injury, these related dogs developed acute, progressive respiratory distress independently of any recognizable insult. Marked histopathologic changes suggestive of acute interstitial pneumonia characterize this poorly understood interstitial lung disorder.

Lymphocytic Interstitial Pneumonitis (LIP)

Described in feline immunodeficiency virus–infected cats and HIV-infected humans, LIP likely occurs when lentivirus-infected alveolar macrophage and T-cells become activated.[319]

Pulmonary Alveolar Proteinosis (PAP)

Dysfunctional alveolar macrophages and impaired surfactant clearance and alveolar macrophage dysfunction are believed to cause PAP in humans.[343] A similar disorder has been reported in two dogs.[324,326]

Sjögren's Syndrome

An immune-mediated connective tissue disorder characterized primarily by xerophthalmia and xerostomia, Sjögren's syndrome also has a component of ILD.[465] Although not histologically confirmed, a cat presenting with a Sjögren's-like disorder additionally had tachypnea and radiographic pulmonary infiltrates.[466]

Silicosis and Asbestosis

Silicosis and asbestosis develop after exposure to inhaled particulates. Granulomatous interstitial pneumonia with fibrosis follows chronic exposure. Both disorders rarely have been reported as causes of disease in dogs.[322,467] Special studies such as electron microscopy and x-ray diffraction analysis are required to characterize the type of crystalline particles observed on histopathologic examination.

Eosinophilic Pneumonia

Many names have been used for describing eosinophilic diseases of the terminal bronchioles, alveoli, and blood vessels in dogs and cats (see also ch. 241). Variably called eosinophilic pneumonia, pulmonary infiltrates with eosinophilia/eosinophils (PIEs), eosinophilic bronchopneumopathy, pulmonary hypersensitivity, eosinophilic granulomatous pneumonia, pulmonary eosinophilic granulomatosis, hypereosinophilic syndrome, and eosinophilic pneumonitis, there is little agreement on classification of eosinophilic lung disorders.[327,330-336] In humans, eosinophilic pneumonia can be broadly categorized as being of either determined or undetermined origin and either acute or chronic. Eosinophilic pneumonia of determined origin can be caused by parasitic, fungal, or other infectious agents, or by drug administration or toxin exposure.[337] Eosinophilic pneumonia (EP) of undetermined origin in humans is subdivided into systemic disease with pulmonary involvement (i.e., hypereosinophilic syndrome; HES) or isolated eosinophilic pneumonia.

Although reactive eosinophilic airway disease (i.e., asthma) is more common in cats, EP of undetermined origin is more common in dogs. Eosinophilic pneumonia most often is identified in young adult dogs, and more often in females than in males.[338] A predisposition has been reported in Siberian Husky, Alaskan Malamute, and Rottweiler breeds, but dogs of any breed can be affected.[336,338,339] The clinical course of disease can be acute or chronic. Cough is the most consistent clinical finding, but gagging, retching, respiratory effort, and nonrespiratory signs such as weight loss sometimes are identified (particularly in association with systemic infection, neoplasia, or HES). A diffuse bronchointerstitial pulmonary radiographic pattern most commonly is identified in dogs with EP, but alveolar patterns also are recognized (Figure 242-27). Dense infiltrates easily can be mistaken for pulmonary neoplasia (Figure 242-28). EP is one of the most common diseases associated with bronchiectasis in dogs.[339] Although peripheral eosinophilia is identified in ≈50% to 60% of affected dogs, absence of eosinophilia does not rule out EP. BAL fluid from dogs with EP demonstrates increased cellularity (>200 to 400 cells/mcL) with a marked increase in eosinophil percentage (Figure 242-29). Lavage fluid from dogs with suspected EP should be examined carefully for the presence of neoplastic cells (e.g., mast cells, lymphoma), fungal elements, or pulmonary parasites and should be cultured. In dogs with eosinophilic airway lavage, parasitic infections should be ruled out through repeated fecal testing (i.e., zinc sulfate centrifugation-flotation and Baermann sedimentation) and/or deworming, as well as heartworm antigen testing.

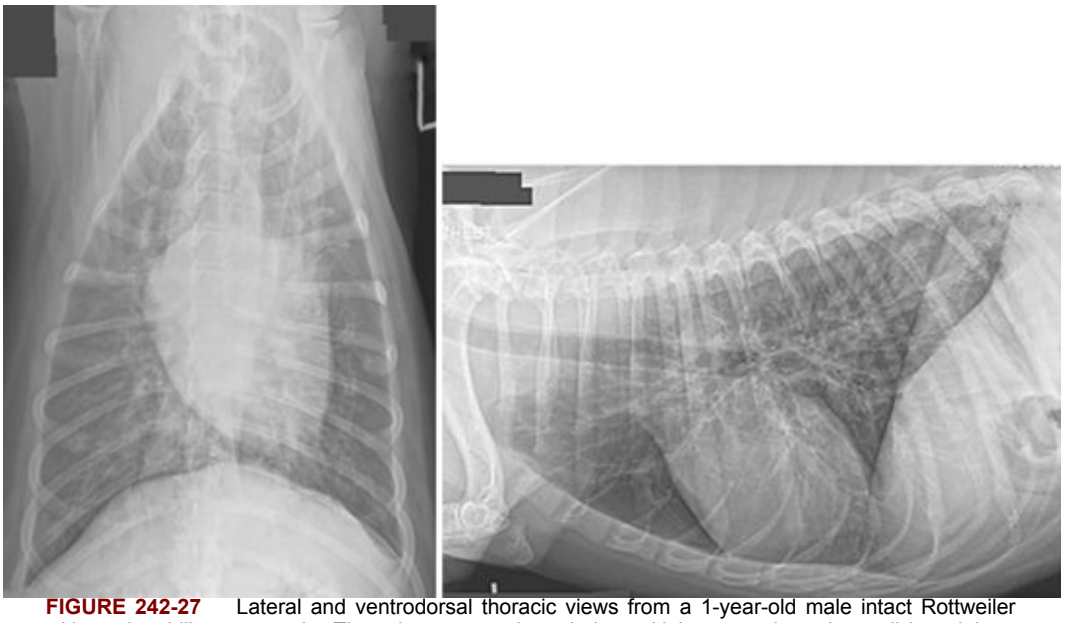

FIGURE 242-27 Lateral and ventrodorsal thoracic views from a 1-year-old male intact Rottweiler with eosinophilic pneumonia. There is a severe bronchointerstitial pattern throughout all lung lobes, and multiple pleural fissure lines are best identified on the ventrodorsal view. Focal patchy alveolar infiltrates are seen over the cardiac apex.

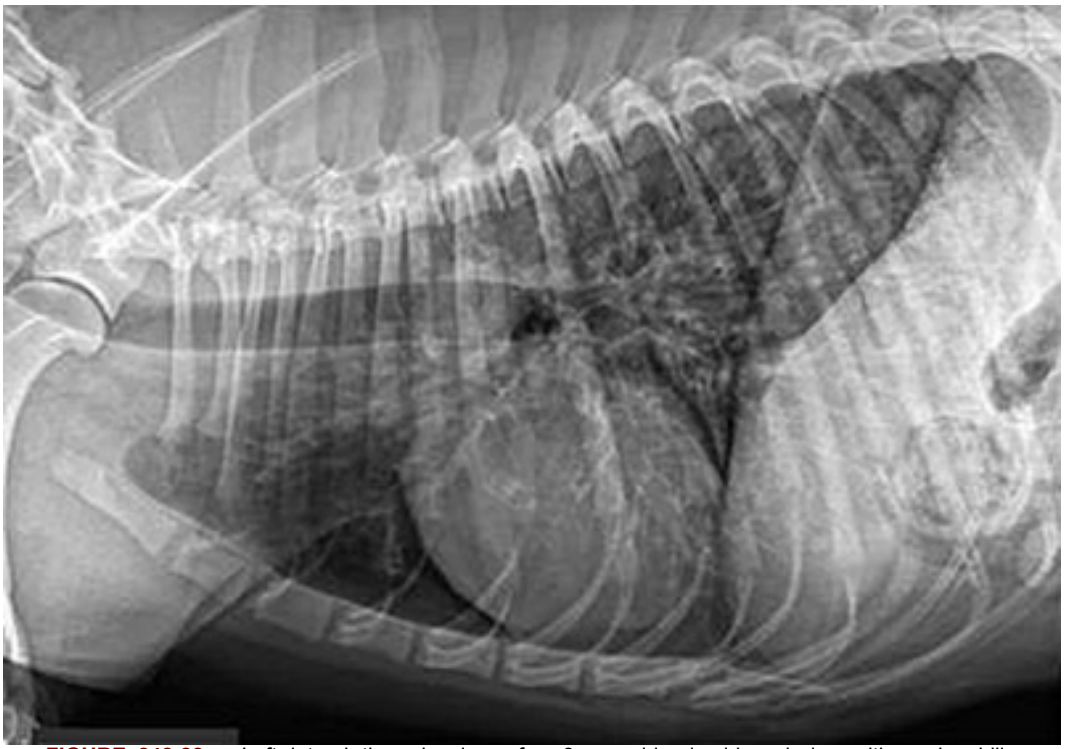

FIGURE 242-28 Left lateral thoracic view of a 3-year-old mixed-breed dog with eosinophilic pneumonia. A marked bronchointerstitial pattern is seen. Dense pulmonary infiltrates easily could be mistaken for pulmonary neoplasia.

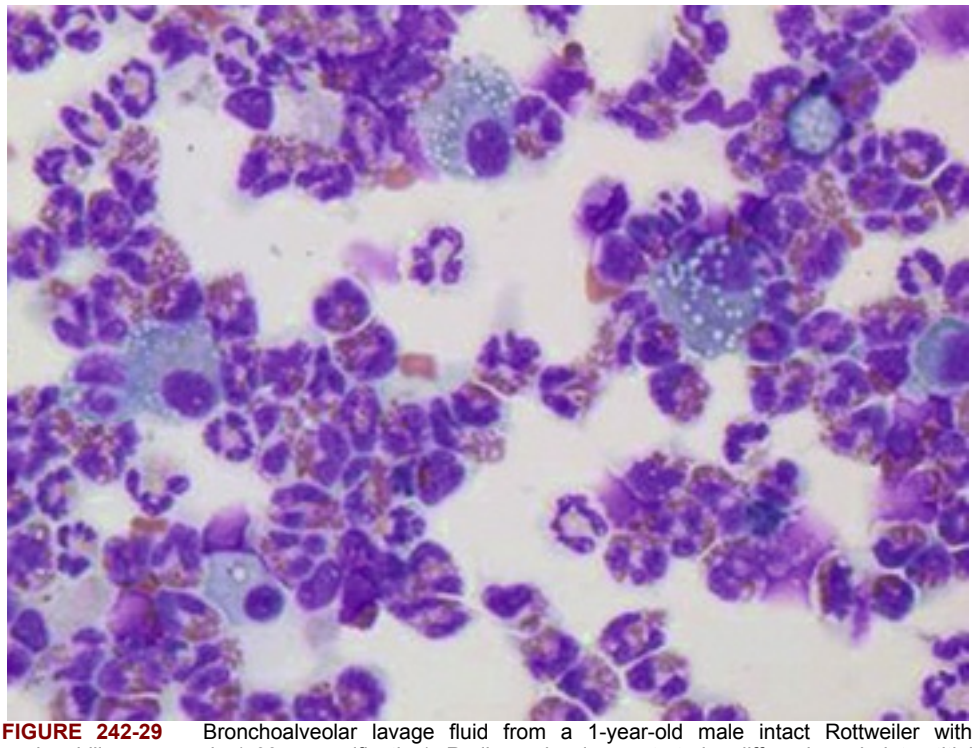

FIGURE 242-29 Bronchoalveolar lavage fluid from a 1-year-old male intact Rottweiler with eosinophilic pneumonia (500× magnification). Radiographs demonstrated a diffuse bronchointerstitial pattern with diffuse alveolar infiltrates (see Figure 242-27). The highly cellular fluid recovered by bronchoalveolar lavage demonstrates 90% to 95% eosinophils with lesser numbers of alveolar macrophages. No organisms or neoplastic cells were identified. (Courtesy Dr. Linda Berent, University of Missouri.)

After underlying infectious, neoplastic, or drug-related causes have been ruled out, treatment of idiopathic EP primarily relies on a tapering course of corticosteroids (e.g., prednis(ol)one 1 to 2 mg/kg PO q 24 h starting dosage). Prognosis for recovery from idiopathic EP is fair to excellent, unless severe bronchiectasis is demonstrated.[327,331,336,338,339] Dogs with isolated pulmonary involvement have a better prognosis than those with other organ infiltrates (i.e., HES).

Lipid Pneumonia

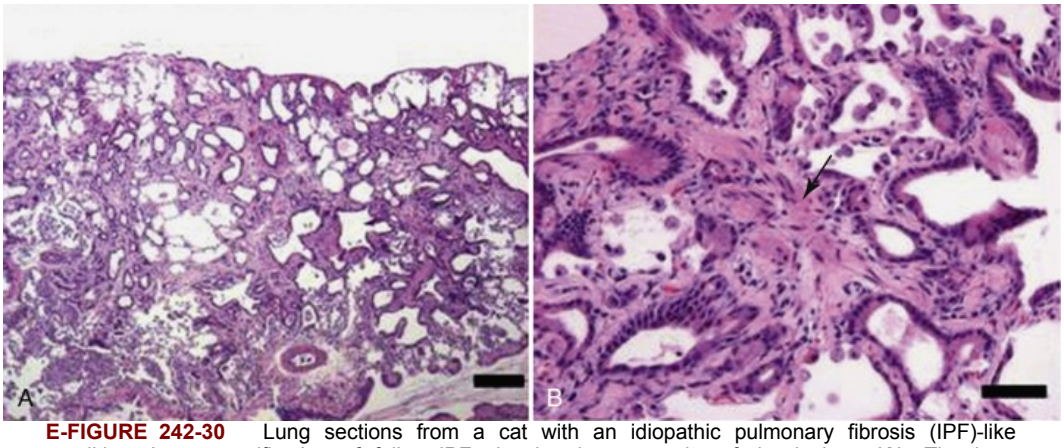
Lipid pneumonia results from an inflammatory response to accumulated globules of lipid in the alveolar airspaces.[2,325] Exogenous lipid pneumonia follows aspiration of lipid—for instance, after the aspiration of mineral oil– or petroleum-based products used for treating constipation or hairballs.[340-342] Endogenous lipid pneumonia (EnLP) is unassociated with aspiration. Although uncommon, EnLP has been reported in a variety of animal species including cats and dogs.[2,3,323,325,329,343] Pneumocyte injury associated with obstructive pulmonary disease, including diseases related to pulmonary neoplasia, has been associated with EnLP.[343,344] Pneumocyte injury leads to cellular degeneration with release of cholesterol and overproduction of cholesterol-rich surfactant.[2] Lipids then are phagocytosed by pulmonary macrophages; these foamy macrophages accumulate in the alveoli. Endogenous lipid also is involved in the pathogenesis of certain infectious pneumonias, such as atypical mycobacterial pneumonia in cats.[167] In other instances, no underlying pulmonary disorder can be identified in association with EnLP.[345]

Endogenous lipid pneumonia is rare enough that no meaningful statements can be made regarding the typical signalment. In a series of 24 cats found to have EnLP on necropsy, ages ranged from 1 to 15 years with a median age of 8.4 years.[2] Cats were presented for veterinary attention due to a variety of nonspecific signs including lethargy, anorexia, and weight loss. Only 16 of 24 had respiratory signs such as dyspnea (11/24; 46%) or cough (8/24; 33%). Serum lipemia was not detected in any of these cats. Radiographic abnormalities were variable and nonspecific. Because animals with EnLP often have additional lung disease (e.g., heartworms, neoplasia, bacterial infection), it is impossible to determine which lesions are most related to EnLP and which to concurrent disease.[2,325,346] BAL in animals with EnLP can be normal, can be suggestive of concurrent respiratory disease, or can demonstrate foamy, lipid-filled macrophages.[345] Necropsy most often

has been used for achieving the diagnosis of EnLP in veterinary patients, meaning there is little information on potential treatment options or prognosis.[2,247,251,325,329] When a specific concurrent lung disease is identified in animals with EnLP, that disease should be addressed directly. In humans, idiopathic EnLP has been reported to respond to corticosteroids.[346a]

Idiopathic Pulmonary Fibrosis

Pulmonary fibrosis can occur as a reaction to lung injury or as a primary disease process of unknown etiology (i.e., IPF).[347] IPF has been recognized in both dogs and cats. The condition in cats shares the histologic features of usual interstitial pneumonia (UIP), which characterizes IPF in humans.[348] These features include interstitial fibrosis, fibroblast and myofibroblast proliferation, enlarged airspaces lined by prominent epithelium (so-called honeycombing), and relatively mild inflammatory changes (E-Figure 242-30). The lungs are heterogeneously affected with areas of normal lung admixed with diseased tissue. Lesions from dogs with IPF contain some histopathologic features of UIP, but even more so those of another common type of human interstitial pneumonia known as "nonspecific interstitial pneumonia."[316,320,349,350]



E-FIGURE 242-30 Lung sections from a cat with an idiopathic pulmonary fibrosis (IPF)-like condition. Low magnification of feline IPF showing heterogeneity of the lesions **(A).** The lung remodeling is patchy, with adjacent affected and unaffected areas present. Honeycomb epithelial metaplasia in feline IPF **(B).** Note the enlarged airspaces lined by cuboidal to columnar epithelial cells with intervening interstitial fibrosis and distinct bundles of smooth muscle present (arrow). Presentation

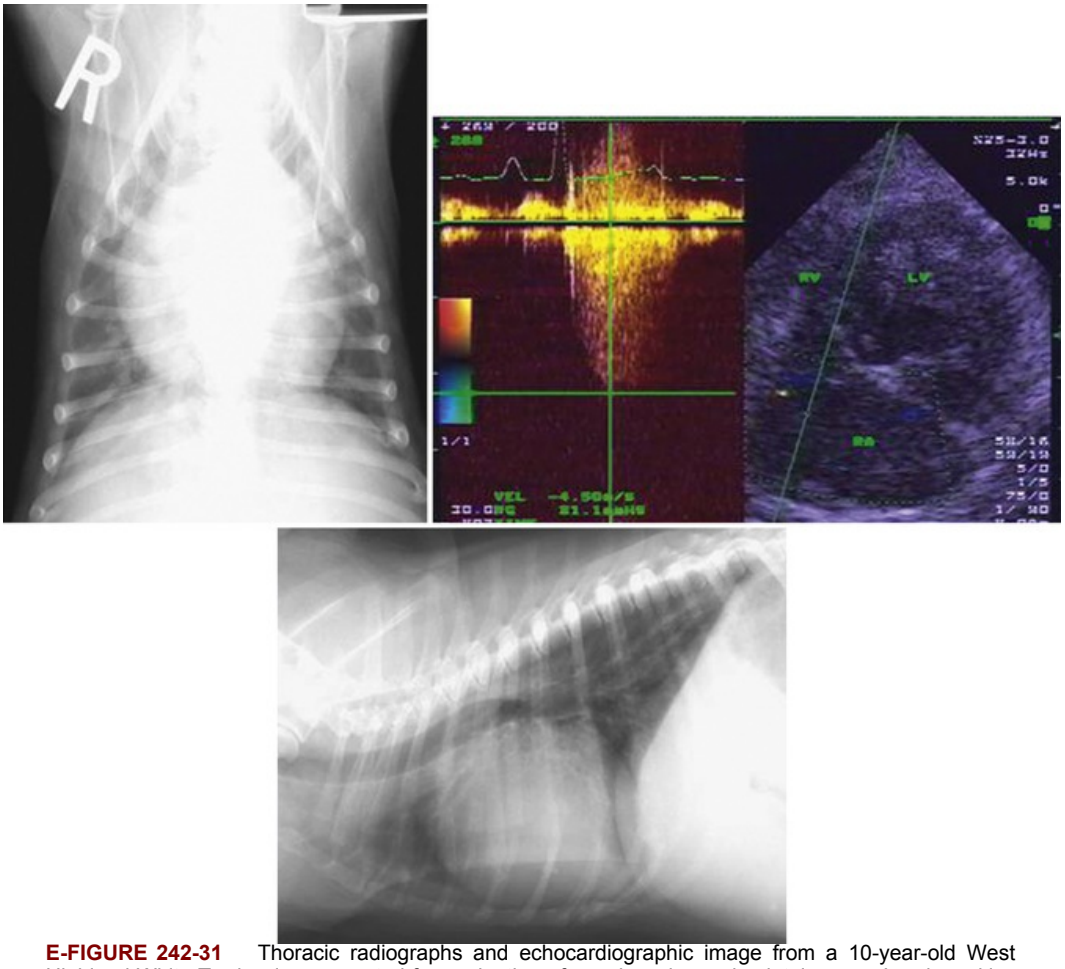
Breed predispositions are well described for canine but not feline IPF, with West Highland White and Staffordshire Bull Terriers overrepresented. In terrier dogs, IPF occurs predominantly in older dogs (mean age 8 years) and manifests initially as cough with exercise intolerance. Respiratory distress occurs later in the disease process.[317,318,320,351-354] As opposed to dogs, cats of any age and either gender can be affected with IPF. Because cats are adept at hiding clinical signs of lung disease, they can present with what appears to be a very acute onset of respiratory distress or even sudden death rather than with cough or insidious increase in respiratory effort.[1,354] Adventitial lung sounds commonly are identified in animals with IPF. In dogs especially, prominent inspiratory crackles are ausculted in all lung fields. A systolic heart murmur of tricuspid regurgitation can be noted, especially in dogs that have pulmonary hypertension/cor pulmonale. Cyanosis is a common finding in dogs (but not cats) with IPF late in the disease process. There are no specific changes on routine blood or urine testing suggestive of IPF, but in the later stages of disease, hypoxemia might result in polycythemia and/or increased serum alkaline phosphatase concentration.[350] Radiographic findings in cats with IPF vary widely and include bronchiolar, interstitial, and alveolar patterns; because this disease commonly is accompanied by pulmonary neoplasia, even lung nodules can be identified in affected cats.[1,354,355] In dogs, bronchointerstitial infiltrates are the most commonly recognized pulmonary radiographic pattern but these changes are neither sensitive nor specific (E-Figure 242-31).



E-FIGURE 242-31 Thoracic radiographs and echocardiographic image from a 10-year-old West Highland White Terrier dog presented for evaluation of cough and exercise intolerance. Loud crackles were heard throughout the thorax, and a grade 2/6 systolic heart murmur was loudest in the tricuspid region. These radiographs reveal a diffuse interstitial lung pattern and predominantly right-sided cardiomegaly. Doppler echocardiographic estimation of the pulmonary artery systolic pressure is increased at 83 mm Hg, compatible with pulmonary hypertension. The presumptive diagnosis was idiopathic pulmonary fibrosis, although confirmatory lung biopsy was not performed.

The identification of loud inspiratory crackles in the absence of an alveolar lung pattern can be an excellent clue to the presence of IPF in dogs.[315,350,351] High-resolution CT is used for supporting a diagnosis of IPF in the absence of histologic tissue examination in humans and has been used similarly in dogs.[350,356,357] The few reports of thoracic CT in cats with IPF describe focally increased soft tissue attenuation, masses, and areas of consolidation.[354] Echocardiography can be used for ruling out congestive heart failure as a cause of clinical signs if no cardiac lesion of sufficient severity is identified to explain the patient's signs; primary heart disease can coexist independently in the same patient population as those affected with IPF, and in such cases, determining whether the pulmonary disease or the heart disease is responsible for clinical signs can be challenging (and worthy of referral to an internist and a cardiologist). Measurement of tricuspid regurgitant velocity can be used for estimating pulmonary artery pressure, a useful measure because pulmonary hypertension frequently is associated with IPF in dogs and can respond to medical treatment (see ch. 243).[350,358] Serologic titers, bronchoscopy, BAL, and similar diagnostic studies help rule out respiratory diseases other than IPF. Several potential biomarkers have been investigated for IPF in dogs, but so far no one such finding can confirm the diagnosis.[351,359-365] No technique other than histologic examination of lung tissue can confirm a diagnosis of IPF, and even when pulmonary fibrosis is documented by biopsy, a diagnosis of IPF depends on ruling out known causes of lung injury that might result in secondary fibrosis.

Treatment and Prognosis

Generally, the long-term prognosis for IPF is poor; however, dogs with pulmonary hypertension who respond well to treatment and/or dogs whose owners are content with calmer pets can live a length and

quality life that approach normal for the dog's age. Most reported cats have survived only days to weeks.[1] In dogs, the disease progresses more slowly with median survival, from onset of signs, of 32 months or less.[351,353] While there are no controlled trials for treatment of IPF in dogs or cats, in humans glucocorticoids, cytotoxic agents, and N-acetylcyseine have not been demonstrated to improve survival or quality of life. Very recently, some efficacy has been demonstrated in treatment of humans with IPF using the tyrosine kinase inhibitor nintedanib or the oral antifibrotic pirfenidone, but these have not been investigated in pets and are financially impractical.[366,367] Because cough can be a prominent component of the disease in dogs, pharmacologic suppression of severe cough can improve the quality of life for the dog and pet owner. Pulmonary hypertension can be a severe complication of IPF, which might benefit from directed therapy. Adequate pharmacologic control of pulmonary hypertension without causing systemic hypotension can be difficult. Treatment with phosphodiesterase-5 inhibitors (e.g., sildenafil 1 mg/kg PO q 8 h; tadalafil) has been shown to significantly improve clinical signs in dogs with naturally occurring pulmonary hypertension.[368-371]

Physical Lung Injury

Physical injury to the lungs may be minor or profound, nonsymptomatic or fatal, depending on severity of injury. The most common means of injury include blunt thoracic trauma, drowning, and smoke inhalation. These conditions seldom pose a diagnostic dilemma because historical circumstances and concurrent wounds typically make the cause of injury apparent.

Thoracic Trauma

Automotive injury and fight wounds are the most common causes of thoracic trauma in small animals (see ch. 149). Regardless of the specific cause, trauma can result in serious concurrent injury including hemorrhage and shock. Thorough examination of the entire patient is warranted not only because additional injuries directly affect therapy, but because the discovery of serious coincident injury (e.g., spinal injury, bladder rupture) can have a substantial impact on extent of treatment, prognosis, and the owner's decision as to whether to embark on treatment (see ch. 147). Trauma can result in airway rupture (see ch. 139 and 241), rib fracture, flail chest, diaphragmatic hernia (see ch. 245), pneumothorax (see ch. 102 and 244), and/or pulmonary contusion, any of which can result in tachypnea and respiratory distress.

Pulmonary contusion results from bleeding into the lung interstitium and alveoli. Occasionally, contusion occurs as the result of coagulopathy rather than thoracic trauma. Respiratory distress occurs as a result of ventilation-perfusion mismatching due to flooding of a large number of alveoli with blood. Crushing lung injury, airway and chest wall injury, and pain often worsen respiratory distress. Although crackles and/or diminished bronchovesicular sounds can be heard, their presence does not confirm contusion and their absence does not rule it out. Hemoptysis (see ch. 29) is uncommon following thoracic trauma but does suggest the presence of pulmonary hemorrhage.[372] Thoracic radiographs are vital to evaluate the extrapulmonary structures (e.g., ribs, diaphragm, pleural space) and the pulmonary parenchyma. Intrapulmonary hemorrhage can be evident as either interstitial or alveolar radiographic lung patterns, or as a combination of the two. Radiographic changes in the pulmonary parenchyma often are delayed by up to 24 hours. Therefore, radiographs taken soon after the injury can underestimate the severity of lung injury. Electrocardiographic monitoring can demonstrate premature ventricular complexes as a result of traumatic myocarditis after substantial thoracic trauma (see ch. 141 and 248).

Animals presenting with tachypnea or respiratory distress after thoracic trauma should receive immediate supplemental oxygen during all diagnostic procedures (see ch. 131 and 149). Many animals with pulmonary contusion have mild to moderate injury and respond well to supplemental oxygen and supportive care. However, when hypoxemia and/or dyspnea persists despite oxygen supplementation, intubation and mechanical ventilation (ideally using positive pressure ventilation) is required.[373]

Specific treatment of traumatic pulmonary contusion is not possible, but therapy for concurrent traumatic injury and its complications (e.g., shock, hypovolemia) is vital. In animals with contusion due to bite wounds, surgical exploration of the wound and thoracic cavity can improve outcome.[374] When pulmonary contusions are due to coagulopathy rather than trauma, specific treatment of coagulopathy is indicated. Because rodenticide intoxication is the most likely nontraumatic cause of pulmonary hemorrhage, administration of fresh or fresh frozen plasma, or fresh whole blood and vitamin K, is indicated if prothrombin time is prolonged in animals with pulmonary contusion (see ch. 152). Antimicrobial drugs are not indicated for pulmonary contusion in the absence of other indications for such therapy (e.g., penetrating trauma). Although fluid therapy can be a vital aspect of treatment for animals with trauma, it should be carefully

monitored to avoid pulmonary edema and worsened lung function.[251] Complications such as cavitary lung lesions or abscessation occur rarely, and most animals that survive the first several hours to a day after pulmonary contusion recover completely from lung injury. The prognosis worsens when pulmonary compromise is sufficient to require mechanical ventilation and is worse in smaller animals than in larger animals.[373]

Drowning

Drowning occurs when submersion or immersion in liquid causes a primary respiratory impairment.[375,376] All drowning (fatal or not) involves aspiration of liquid. Although older literature referred to laryngospasm during or after submersion as "dry drowning," this phenomenon is now believed to be very rare and inappropriately described as drowning.[375,377] The pathophysiology of drowning differs somewhat when hypotonic freshwater is aspirated as compared with hypertonic saltwater. Regardless of minor differences in systemic and pulmonary vascular volumes and electrolyte alterations, the most important immediate consequences of either type of drowning relate to hypoxemia.[376,378,379] Alveoli filling with fluid, diluted and dysfunctional surfactant allowing alveolar collapse, and intrapulmonary vascular shunting all result in ventilation-perfusion mismatching and subsequent hypoxemia. Diminished pulmonary compliance and pulmonary inflammation resulting in noncardiogenic pulmonary edema due to ARDS further contribute to hypoxemia. Hypoxemia leads to lactic acidosis, and hypercapnia due to pulmonary compromise can result in respiratory and metabolic acidosis. Pulmonary injury can be worsened by aspiration of chemicals or bacteria in the water.[379] Rarely, invasive systemic fungal or bacterial infection follows nonlethal drowning.[379-382]

Drowning is far more common in dogs than cats, probably because cats are less likely to enter water than dogs.[383] Because dogs often are strong swimmers, drowning and near-drowning occur most often when circumstances prevent their egress from water (e.g., a swimming pool with steep sides and no steps, falling into an ice-covered pond, strong currents), when medical circumstances prevent their normal airway protective reflexes from working appropriately (e.g., laryngeal paralysis or laryngeal tie-back), or when they lose consciousness while swimming (e.g., seizure).[383] A larger-than-expected proportion of dogs presented for near drowning is young (age <4 months). Typically, drowning victims are presented for care following rescue from the water. Common presentations include respiratory arrest, respiratory distress, cough, altered mental status, or loss of consciousness. Circulatory shock (see ch. 127) and hypothermia (see ch. 49) often are identified concurrently. Thoracic auscultation can reveal either diminished bronchovesicular sounds or a combination of crackles and wheezes. Assessment of oxygenation and acid-base status should be conducted, ideally via arterial blood gas analysis (see ch. 75 and 128). Radiographs typically demonstrate a diffuse interstitial to alveolar pattern, but as with pulmonary contusion, radiographic changes can underestimate the severity of lung injury because radiographic changes often progress following rescue due to development of ARDS. The radiographic appearance of "sand bronchograms" (radiopaque material in the airways) is a poor prognostic indicator. Other poor prognostic indicators include the need for cardiopulmonary resuscitation or mechanical ventilation, and acidosis with a blood pH of <7.0. Level of consciousness at admission was not associated with outcome in a retrospective review of freshwater drowning with full recovery, even of animals presenting in a coma.[383] Supplemental oxygen should be administered immediately (see ch. 131). Often, hypoxemia persists despite delivery of supplemental oxygen. Mechanical ventilation, ideally with continuous positive airway pressure or positive end-expiratory pressure, should be administered if the animal is unable to maintain PaO_2 of >60 mm Hg with an F_IO_2 of >50%.[129,379] Even animals who remain normoxemic following rescue can develop ARDS and should therefore be observed for at least 24 hours. Hypothermic animals should be warmed, and shock directly addressed. There can be a difficult balance between fluid administration to address shock and overhydration in the face of lung injury. Continuous hemodynamic monitoring is indicated, and inotropic support could be necessary. Severe acidosis (pH < 7.1) or electrolyte imbalances can require treatment. Despite the potential occurrence of bacterial pneumonia after drowning, prophylactic antibiotics have not been shown to reduce the risk in humans or animals.[129,379,382-384] If evidence of bacterial pneumonia develops later, airway lavage cytology and culture should guide the choice of antimicrobials. Corticosteroids are not indicated because they neither improve oxygenation nor increase survival.[379,385] Although as yet untested clinically, a recent study demonstrated that pentoxifylline (a nonspecific phosphodiesterase inhibitor) administered by constant infusion after freshwater drowning reduced subsequent lung injury due to ARDS.[386]

Smoke Inhalation

Despite the frequency with which house fires occur, there is limited information on smoke inhalation injury in pet animals.[387-392] Smoke inhalation does not always follow every exposure to fire, but when inhalation occurs, often it results in serious respiratory injury. Upper airway obstruction related to bronchospasm and laryngeal swelling can result from thermal and chemical injury; such obstruction typically peaks within the first 24 hours.[390] Inhalation of soot and noxious gases released through combustion of household components (e.g., hydrogen cyanide, ammonia, aldehydes, acrolein), inflammation of airways and airspaces, systemic inflammatory mediators, inactivation of surfactant, reflex bronchoconstriction, atelectasis, airway edema, and ARDS all can contribute to lung injury in this context.[388,390-393] Carbon monoxide and cyanide exposure further compromise oxygen delivery and utilization by tissues. Exfoliation of dying epithelial cells and soot can result in delayed lower airway obstruction even days after the event, meaning that respiratory compromise from smoke inhalation remains dynamic for up to a week after the inciting event. As a further concern, impaired local and systemic defense mechanisms markedly predispose to secondary bacterial pneumonia.

Animals rescued from fire can be presented for care in apparent good health or with severe injury. Common clinical findings include cough and gag, hyperemic mucous membranes, tachypnea, increased respiratory effort, harsh bronchovesicular or adventitial lung sounds, upper airway noise, nasal discharge, and burns or lacerations.[388,391,392] Additionally, neurologic abnormalities can be identified (e.g., ataxia, stupor) as a result of CNS hypoxia, or such abnormalities can occur days later due to leukoencephalomalacia.[254,394,395] Oxygenation ideally is measured via arterial blood gas analysis (see ch. 75 and 128). Because these patients usually are being provided supplemental oxygen, assessment of PaO_2:F_IO_2 ratio is more useful than simple assessment of PaO_2; a ratio <300 signifies marked respiratory compromise. Only dissolved oxygen is measured via blood gas analysis, so it must be remembered that tissue hypoxia may be profound in animals with carbon monoxide intoxication despite a normal PaO_2. Although carbon monoxide interferes with hemoglobin-oxygen saturation, pulse oximetry cannot distinguish oxyhemoglobin from carboxyhemoglobin. Thus, oximetry can provide an overestimation of the blood's oxygen-carrying capacity in carbon monoxide intoxication cases.[396] If available, a cooximeter can be used for measuring carboxyhemoglobin concentration. On thoracic radiographs, dogs frequently demonstrate an alveolar pulmonary pattern, whereas interstitial and alveolar patterns were identified nearly equally in smoke-exposed cats.[388,392]

Supplemental oxygen should be administered at least until initial assessment is complete; administration of supplemental oxygen (ideally beginning at rescue) can result in rapid clinical improvement (see ch. 131).[388] Supplemental oxygen is useful for treatment of hypoxemia and also facilitates the pulmonary elimination of carbon monoxide. The role of hyperbaric oxygen therapy remains controversial and has limited availability for most veterinarians (see ch. 84).[391,397] Persistent hypoxemia in the face of supplemental oxygen delivery could necessitate mechanical ventilation. Occasionally, upper airway swelling requires either intubation or tracheostomy. Crystalloid fluid therapy certainly is required for animals presenting with burns or in shock. Aggressive fluid therapy could contribute to respiratory edema, however, requiring careful monitoring of both fluid dosage and patient response.[389,391] The use of both colloids and hypertonic saline in humans with burns (which can accompany smoke inhalation) is controversial and should be undertaken with caution.[391] Prophylactic antimicrobial therapy has no proven benefit in humans but has not been evaluated in pets with smoke inhalation injury.[388,392,396] Although some corticosteroid preparations have been beneficial in certain rodent models of smoke inhalation, they were not effective in a clinical study using a dog model and are neither proven effective nor routinely used in humans with inhalation injury.[396,397a] Other therapies sometimes employed to treat animals with smoke inhalation include bronchodilators, saline nebulization and coupage, ocular lubricants, and treatment of concurrent burns (including analgesia). Because ARDS can develop and worsen after initial smoke exposure, monitoring through the first 24 hours is suggested even when animals appear well. Improvement in respiratory status during the first day after rescue is a strong positive prognostic indicator.[388,392] Respiratory deterioration past the first day of hospitalization, the presence of concurrent burns, and the need for mechanical ventilation all are negative prognostic indications.

Miscellaneous Lung Diseases

Atelectasis

Pulmonary atelectasis is simply noninflated or underinflated lung. The term can be used for describing newborn lungs that have not yet inflated, lungs that have collapsed as a result of mechanical compression (including compression associated with recumbency), areas of alveolar collapse resulting from alveolar filling, or areas of alveolar collapse resulting from airway obstruction with resorption of trapped air. Atelectasis is not a primary disease state but a consequence of disease.

Cavitary Lung Lesions

Cavitary lung lesions can vary in size, shape, wall thickness, number, location, and content. There is a multitude of potential causes for cystic or cavitary lung lesions (Box 242-16).[398] A few specific causes are addressed next.

Box 242-16

Potential Causes of Cavitary or Cystic Lung Lesions*

Abscess (partially air filled)
Bronchiectasis
Bullae
Congenital cysts
Hydatid disease (rare)
Idiopathic fibrosis with honeycombing
Metastatic neoplasia
Mycotic granuloma (e.g., *Aspergillus*)
Parasites (especially *Paragonimus*)
Pneumatoceles
Pneumocystis carinii pneumonia
Postaspiration injury
Primary pulmonary neoplasia (e.g., bronchogenic carcinoma)
Pulmonary infarct
Traumatic cysts

*References 41, 121, 258, 259, 341, 342, 403, 413, 441, 442.

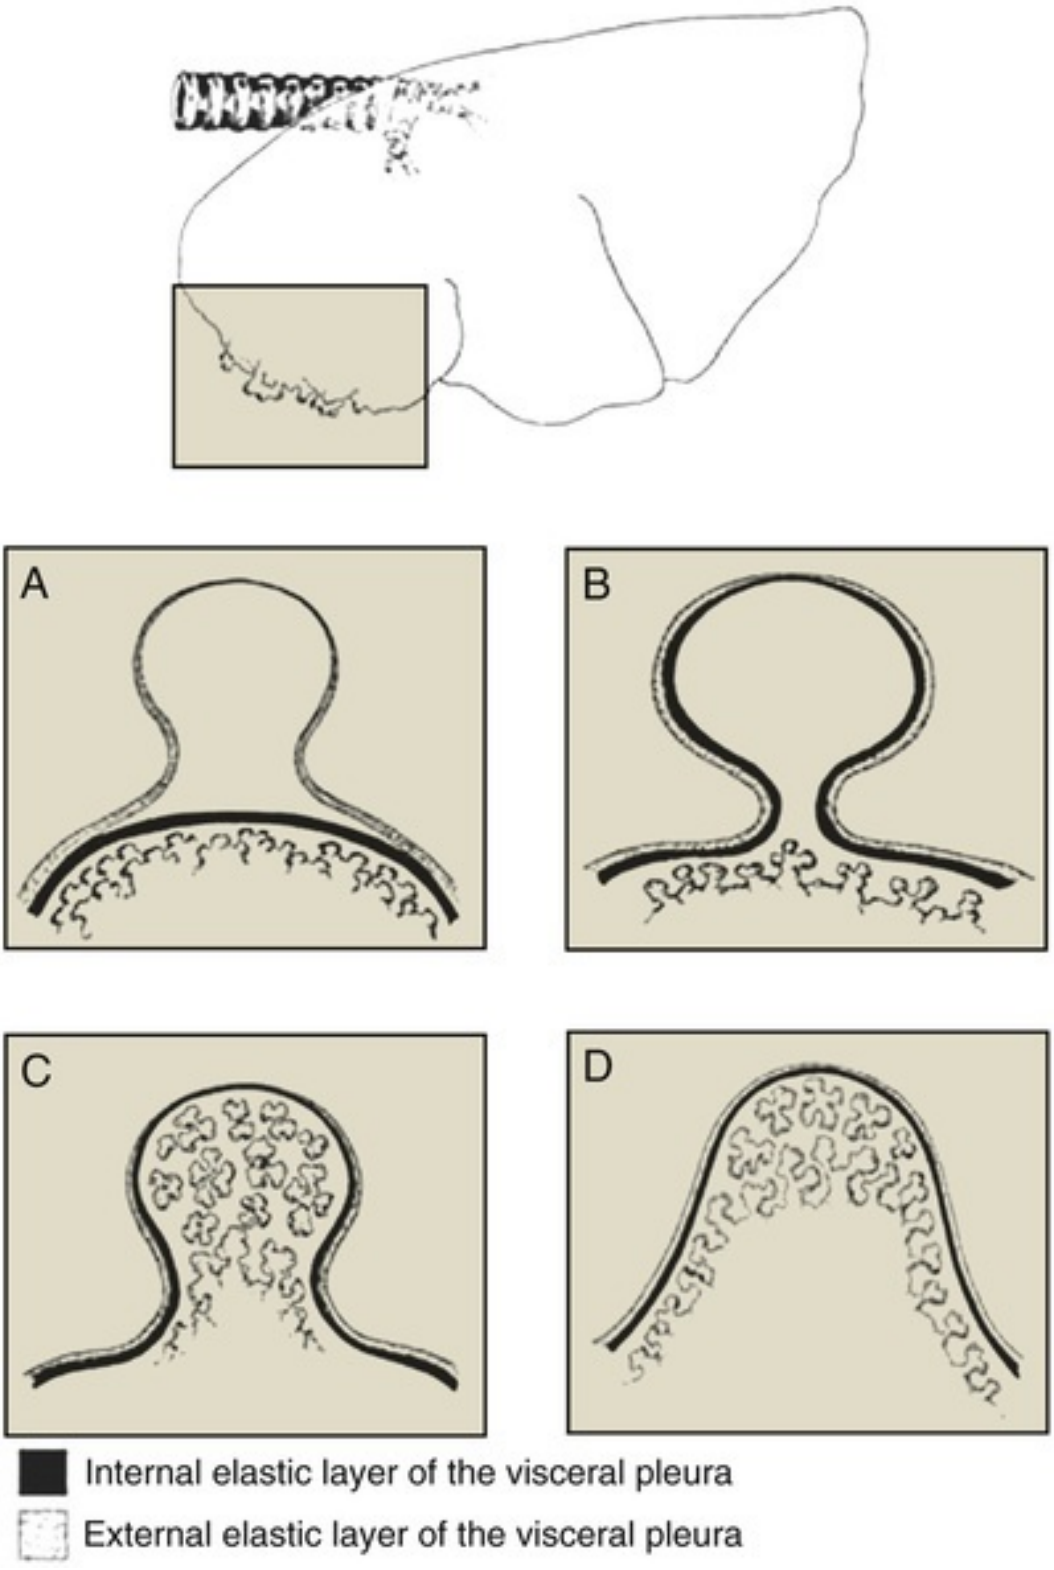
Abscesses

Pulmonary abscessation is an uncommon diagnosis in dogs and cats. An abscess can predominantly be air filled or can have a nodular soft-tissue radiographic appearance due to fluid accumulation; a fluid line can be visible when both air and fluid are present, specifically on horizontal-beam projections. Typically, abscesses occur in areas of otherwise diseased lung (e.g., pneumonic regions, bronchiectasis) and have a thick wall or capsule with an irregular inner margin.[399,400] In humans, lung abscess formation especially is likely as a sequela of aspiration pneumonia with secondary bacterial infection, or when there is obstruction of distal airways as a result of malignancy, inflammation, foreign material (see E-Figure 242-13), or inspissated mucus plugging.[401] Respiratory signs or signs of systemic infection can be identified in dogs with pulmonary abscesses, as might evidence of hypertrophic osteopathy (see E-Figure 242-1).[399,400,402-405] When only a single lung lobe is involved, surgical excision is preferred to antimicrobial therapy alone. The excised lung can be cultured and examined histologically. Sometimes, an underlying cause of abscessation such as foreign material or neoplasia is identified.[137,406] Surgical lobectomy also minimizes the risk of pneumothorax and pyothorax due to abscess rupture.[405] When surgery is not possible, antimicrobial therapy ideally is guided by culture and sensitivity results, but acquiring a specimen carries possible risks: rupture of an abscess during needle aspiration could lead to empyema or pneumothorax, while airway lavage might result in rupture of an air-filled abscess pocket.

Pulmonary Blebs, Bullae, and Emphysema

Bullae are air pockets within the pulmonary parenchyma; they result from destruction of alveolar walls with confluence of adjacent alveoli and are not lined by epithelium as are pulmonary cysts. Bullae have been

classified into several subtypes depending on size and connectivity with surrounding lung tissue. Bullae can be large or small and can occur near the lung surface or deep within the parenchyma.[407] Pulmonary blebs are accumulations of air formed when air escaped from the lung becomes trapped inside the visceral pleura; blebs always are found on the lung surface (E-Figure 242-32).[407] The term *bullous emphysema* sometimes is used for describing bullae.[408] Bullae formation very often is idiopathic, but it can result from lung damage due to parasitic, neoplastic, infectious, or other disease conditions in either dogs or cats. Bullae can be related to congenital disease including bronchopulmonary dysplasia.[409-411] Idiopathic bullae occur predominantly in otherwise healthy deep-chested or large-breed, middle-aged dogs. Idiopathic bullae usually are discovered as a consequence of rupture with resultant spontaneous pneumothorax.[407,408,412] Bullae can be identified radiographically as an incidental finding in dogs or cats with underlying lung disease.[41,259,413,414] Unfortunately, thoracic radiography is insensitive (<5 to 50% detection) for bullae and blebs.[407,408,412,415,416] CT scanning improves detection (up to 75%) but still is imperfect.[408,412] Once significant pneumothorax has occurred, partial lung lobectomy to remove affected lung tissue is recommended whenever possible.[407,408,415,416] Additional information on spontaneous pneumothorax can be found in ch. 244.



E-FIGURE 242-32 Pulmonary bullae and blebs. Line drawings illustrating the apex of the lung (shaded box in top drawing) and a pulmonary bleb **(A),** type 1 bulla **(B),** type 2 bulla **(C),** and type 3 bulla **(D).** Note the accumulation of air between the layers of the visceral pleura in the pulmonary bleb and the different connections to the underlying pulmonary parenchyma in **B, C,** and **D.** (Reprinted with permission from Lipscomb VJ, Hardie RJ, Dubielzig RR: Spontaneous pneumothorax caused by pulmonary blebs and bullae in 12 dogs. *J Am Anim Hosp Assoc* 39:435, 2003.)

Emphysema is any lung condition marked by distention and eventual rupture of alveoli with resultant loss of pulmonary elasticity and lung function. In humans, emphysema most commonly is found in conjunction

with chronic obstructive pulmonary disease (COPD) and often is a consequence of long-term exposure to cigarette smoke or pollution.[417] This form of emphysema is exceedingly rare in pet animals. However, lobar emphysema has been reported in a number of young dogs.[410,418-424] Unlike emphysema of adult humans, congenital lobar emphysema is a condition of infants and young dogs in which a lung lobe becomes overexpanded. The condition can be idiopathic or may result from bronchial obstruction, defect, or compression.[418,424] The enlarged, emphysematous lobe causes compression of the more normal lobes, and increased alveolar pressure in the affected lobe results in progressive emphysema with development of blebs and/or bullae.[420] Radiographic findings usually include lobar hyperinflation with pulmonary blood vessels extending to the lobe margin, contralateral mediastinal shift, caudal displacement of the diaphragm (unilateral or bilateral), thoracic cavity enlargement, atelectasis of unaffected lobes, and possibly pneumothorax.[410,418,419,421,422,424,425] Comparison of inspiratory and expiratory films can be useful because the emphysematous lung will not deflate on expiration. Successful surgical removal of the affected lung has been reported.[411,418,419,422,424]

Lung Lobe Torsion

Lung lobe torsion is uncommon in dogs and rare in cats.[426-430] The lobe usually rotates on the long axis, resulting in occlusion of both the bronchus and pulmonary vasculature at the hilus.[429,431] Because the muscular pulmonary artery continues to allow the passage of small amounts of blood while the thin-walled pulmonary vein collapses completely, the affected lobe becomes congested and consolidated. Eventually, fluid leaves the lobe surface and enters the pleural space resulting in effusion. Although torsion results in pleural effusion, effusion might also predispose to torsion. Torsion can occur spontaneously or can be associated with thoracic neoplasia or trauma.

Presentation

Although torsion can occur in any breed, Afghan Hounds and Pugs are overrepresented.[427,428,432-436] Most affected dogs are young to middle-aged.[427,428] The most common historic complaints are lethargy, anorexia, and increased respiratory effort and rate, although some animals present with little in the way of respiratory signs.[436] Cough, hemoptysis, and collapse also can be presenting complaints. Common physical abnormalities include fever, diminished bronchovesicular lung sounds, and muffled heart sounds. Cyanosis, tachycardia, prolonged capillary refill time, and poor or bounding pulses sometimes are identified.

Diagnostic Evaluation

Peripheral neutrophilia (with or without left shift) is common. Thoracic radiographs often reveal pleural effusion; if so, they should be repeated after thoracocentesis (see ch. 102) to facilitate recognition of lung lobe consolidation (Figure 242-33). Abnormal positioning of the bronchus is inconsistently identified, and a narrowed proximal bronchus can be seen.[427,429,437] When identified, a vesicular gas pattern (small, scattered bubbles) in the affected lobe is strongly suggestive of torsion.[429,437] Thoracic CT (with or without reconstructed "virtual bronchoscopy") is more sensitive and specific than are radiographs for detection of lung lobe torsion.[429] Ultrasonography can be used for further imaging suspected lung lobe torsion.[20,427,428,437] Though seldom necessary, bronchoscopy (see ch. 101) can confirm lung lobe torsion.[438] Evaluation of pleural effusion often reveals a blood-tinged modified transudate with high numbers of neutrophils and lymphocytes, but chylous effusion occurs in some affected dogs and cats.[427,430] Chylous effusions often are identified in Afghan Hounds both with and without lung lobe torsion, making it especially unclear in this breed if effusion leads to torsion, torsion leads to effusion, or some of each occurs.[427,432,433,439,440] Reactive mesothelial cells frequently are identified but seldom indicate mesothelioma. Bacterial culture of effusion or lung tissue from 26 dogs with lung lobe torsion was positive in 8 dogs (*Pseudomonas* spp., *E. coli, Enterococcus* spp., *Proteus* spp., *Staphylococcus* spp., *Enterobacter* spp., and *Serratia* spp.).[42]

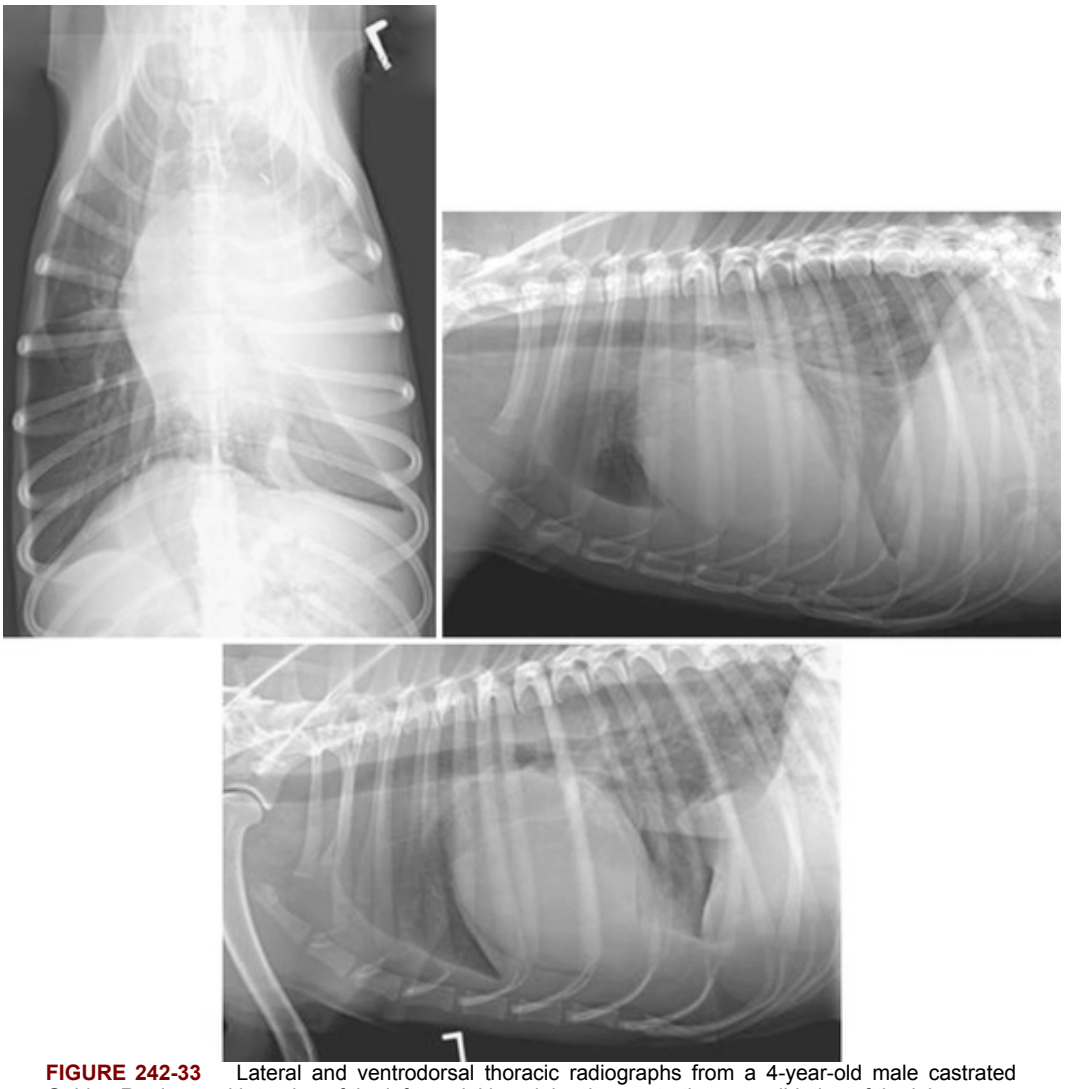


FIGURE 242-33 Lateral and ventrodorsal thoracic radiographs from a 4-year-old male castrated Golden Retriever with torsion of the left cranial lung lobe demonstrating consolidation of the lobe.

Treatment

Once recognized, removal of the affected lobe is the only appropriate treatment for lung lobe torsion. Torsion can occur in any lobe(s). Of 58 dogs described in 3 case series, torsion occurred in the left cranial lobe (n = 37), right middle lobe (34), right cranial lobe (11), right caudal lobe (2), and left caudal lobe (1).[427,428,437] Approximately 60% of dogs recover fully after surgery, with perhaps a better prognosis for complete recovery in pugs.[427,428] Substantial delayed morbidity including pneumothorax, chylous effusion, and torsion of additional lung lobes has been reported in a small proportion of dogs surviving surgery.[427,435]

Pulmonary Thromboembolism

Pulmonary thromboembolism, an occlusion of pulmonary vasculature to aerated sections of lung, results in ventilation-perfusion mismatching and subsequent hypoxemia. For details see ch. 243.

CHAPTER 243

Pulmonary Hypertension and Pulmonary Thromboembolism

Justin G. Williams

Client Information Sheet: Pulmonary Hypertension

Pulmonary Hypertension

Pulmonary hypertension (PH) can be defined as a pulmonary arterial systolic pressure > 30 mm Hg and/or diastolic pressure > 19 mm Hg as estimated by echocardiographic measurements of the tricuspid or pulmonic regurgitation gradients.[1-5] The normal mean pulmonary arterial (PA) pressure is 14 mm Hg.[6] An increased appreciation for the etiologies, symptoms, and treatments of PH has led to improved quality of life and survival.

Pulmonary Physiology & Pathophysiology

The pulmonary vascular bed is a low-pressure, low-resistance, high-capacitance system. Blood flows from the right ventricle (RV) through the PA into a network of thin-walled arteries, capillaries and veins, before returning to the left atrium via the pulmonary veins. Pulmonary arterial pressure (PAP) is determined by RV cardiac output (or pulmonary blood flow), pulmonary vascular resistance (PVR) and pulmonary venous pressure. Pulmonary hypertension develops when there is an imbalance between the factors that control pulmonary artery vasoconstriction, vasodilation, platelet activation and smooth muscle cell proliferation.

Inducers of pulmonary vasoconstriction include alveolar hypoxia, endothelin-1 and serotonin. Hypoxia-induced vasoconstriction is likely a physiologic response that results in deoxygenated blood shunting to better-ventilated areas of the lung. While this might be beneficial acutely, in chronic conditions this may lead to PH. Endothelin-1 (ET-1) is a peptide released from the vascular endothelium in response to changes in blood flow, vascular stretch and thrombin concentrations. ET-1 causes vasoconstriction, stimulates smooth muscle growth, increases collagen synthesis, promotes vascular remodeling, and is increased in people with PH.[7-9] Canines have elevations in ET-1 in diseases linked to PH, such as heartworm[10] and acquired left heart disease.[11]

Prostacyclin and thromboxane A_2 are arachidonic acid metabolites of PA vascular cells with opposing effects on PA vascular tone. Prostacyclin is a potent vasodilator, inhibits platelet activation and has antiproliferative properties.[7] Conversely, thromboxane A_2 is a vasoconstrictor and platelet agonist. In people with PH, thromboxane A_2 predominates, resulting in PA vasoconstriction, thrombosis, and cellular proliferation.[12] Platelet-derived growth factor (PDGF) induces proliferation and migration of PA smooth muscle cells. Expression of PDGF and its receptor are increased in people with idiopathic PH.[13,14]

Nitric oxide (NO) is a vasodilator, inhibitor of platelet activation, and inhibitor of vascular smooth muscle proliferation. It is synthesized from L-arginine and oxygen by NO synthase enzymes in the PA endothelium. Once formed, NO activates cyclic guanosine monophosphate (cGMP), which causes pulmonary vasodilation. This vasodilation is limited by inactivation of cGMP by the phosphodiesterase 5 (PDE5) isoenzyme.[7]

Classification of Pulmonary Hypertension

Pulmonary hypertension can be simply classified based on anatomical location as *pre-* or *postcapillary*, or classified as a five-group system based on the underlying pathological process. Developed for people, this

group system has been amended for veterinary etiologies (Box 243-1). The five groups of PH are: pulmonary arterial hypertension due to arteriolar vascular disease (Group I); pulmonary venous hypertension due to left heart disease (Group II); pulmonary hypertension with chronic lung disease and/or hypoxia (Group III); chronic thromboembolic pulmonary hypertension (Group IV); and pulmonary hypertension from unclear or multifactorial mechanisms (Group V).[15]

Box 243-1

Classification of Pulmonary Hypertension[1-5,15,17-19,21,30-33,35-37,39-50,53,60,62,71,89-96]

I. Pulmonary arterial hypertension (PAH) due to pulmonary arteriolar vascular disease
- Pulmonary vascular parasitic disease
  - *Angiostrongylus vasorum* (French heartworm)
  - *Dirofilaria immitis* (heartworm disease)
- Congenital systemic-to-pulmonary shunts
  - Atrial septal defect (ASD)
  - Patent ductus arteriosus (PDA)
  - Ventricular septal defect (VSD)
- Necrotizing vasculitis/arteritis
- Idiopathic

II. Pulmonary hypertension with left heart disease (pulmonary venous hypertension)
- Mitral valve disease
- Myocardial disease
- Miscellaneous left-sided heart disease

III. Pulmonary hypertension with pulmonary disease/hypoxemia
- Chronic obstructive pulmonary disease
- High-altitude disease
- Interstitial pulmonary fibrosis
- Neoplasia
- Reactive pulmonary artery vasoconstriction (from pulmonary edema and hypoxemia)
- Tracheobronchial disease

IV. Pulmonary hypertension due to thrombotic and/or embolic disease
- Thromboembolism
  - Cardiac disease
  - Corticosteroid administration
  - Disseminated intravascular coagulation
  - Endocarditis (pulmonic/tricuspid valve)
  - Hyperadrenocorticism
  - Immune-mediated hemolytic anemia
  - Indwelling venous catheters
  - Neoplasia
  - Pancreatitis
  - Protein-losing disease (nephropathy or enteropathy)
  - Sepsis
  - Surgery
  - Trauma
- *Dirofilaria immitis* (heartworm disease)

V. Miscellaneous
- Compressive mass lesions (neoplasia, granuloma)

Group I PH includes pulmonary arterial hypertension (PAH) due to pulmonary arteriolar vascular disease. This group includes congenital systemic-to-pulmonary shunts and heartworm disease *(Dirofilaria immitis).* Heartworm disease causes PH via vascular damage, resulting in lesions of medial hypertrophy and intimal proliferation and fibrosis (see ch. 255).[16] *Angiostrongylus vasorum,* also known as French heartworm, is

associated with PAH in dogs (see ch. 241).[17-21] Systemic-to-pulmonary cardiac shunts have low pulmonary resistance and high pulmonary flow causing stress to the pulmonary arterial endothelial lining and leading to PH.[22] Eisenmenger syndrome involves large intra- or extra-cardiac defects that begin as left-to-right shunts but ultimately lead to significantly increased PVR and reversal of shunt flow or bidirectional shunting.[15,23]

Group I also includes genetic or familial PH in people.[15] Polymorphisms of PDE5 have been associated with variable responses to sildenafil and NO, as well as progression of PH in people.[24-26] In dogs, a polymorphism in PDE5 is associated with a reduced expression of cGMP.[27] While this suggests a possible predisposition to PH, a study of dogs infected with *A. vasorum* did not reveal differences in the frequency of the polymorphism between PH and non-PH dogs.[17]

Group II PH involves pulmonary venous hypertension (PVH) due to left heart disease, such as degenerative mitral valve disease (MVD), dilated cardiomyopathy, or any left atrial or left ventricular heart disease. Left-sided heart disease may result in PH via a combination of elevated left atrial pressure and PVH, as well as reactive pulmonary arterial vasoconstriction. These cardiovascular effects are due to acute or chronic hypoxemia, decreased NO availability, elevated endothelin-1 expression, and desensitization to natriuretic peptides.[28,29] Group II has been suggested to be the most common cause of PH in dogs, as MVD may be the cause of PH in 30-74% of naturally occurring PH cases.[1-4,30-32]

Group III PH occurs secondary to pulmonary disease or chronic hypoxemia. In dogs, Group III PH is associated with pulmonary fibrosis, pneumonia, tracheobronchial disease and neoplasia.[4,5] Up to 40% of West Highland White Terriers with chronic interstitial pulmonary disease have some degree of PH.[5]

Group IV PH includes pulmonary hypertension caused by thrombotic or embolic disease. Heartworm disease is again included as it can cause PH by worm embolization and direct obstruction of the pulmonary artery lumen.

Group V PH is a grouping of diseases with multifactorial or unclear mechanisms. This grouping includes myeloproliferative diseases (such a primary polycythemia vera), granulomatous diseases, chronic immune mediated hemolytic anemia, and tumor obstruction.[15,33]

Evidence of feline pulmonary hypertension is limited to case reports. Feline PH has been associated with pulmonary thromboembolism,[34-36] right-to-left shunting patent ductus arteriosus,[37] heartworm disease,[38,39] chronic upper airway obstruction,[40] and *Aelurostrongylus abstrusus* (feline lungworm) infection.[41] A cat with Eisenmenger's syndrome and an atrial septal defect was treated with sildenafil for 10 months.[41a]

Signalment

Most canine patients with PH are small breed and middle- to older-aged, which coincides with the signalment of predisposing etiologies such as degenerative mitral valve disease and chronic pulmonary disease.[2,4,42-46] Terrier breeds may be overrepresented given their predisposition to chronic pulmonary diseases such as interstitial pulmonary fibrosis.[5,42,47]

Clinical Signs and Physical Examination

Since PH causes impaired oxygen transport and reduced cardiac output, clients most often note exercise intolerance, cough (see ch. 26), dyspnea (see ch. 28) and syncope (see ch. 30) in dogs with PH.[3,4,32] Patients may also present with specific clinical signs associated with the underlying cause. A physical exam may reveal abnormal lung sounds, cyanosis (see ch. 52) and/or ascites (see ch. 17).[2-4,42] Respiratory auscultation often reveals pulmonary crackles, wheezes, and harsh or increased respiratory sounds.[4,32,42,48,49] Left- or right-sided murmurs are auscultated in the majority of dogs with PH.[2,32,43,50] A split or abnormally loud second heart sound (S2) may be noted (see ch. 55). Clinical and physical exam signs of feline PH include dyspnea, jugular venous distension and a right-sided systolic heart murmur.[34-37,40,41]

Diagnostics

Echocardiography (ECHO) is the primary means of diagnosing PH in veterinary medicine. While right heart catheterization and direct measurement of the PA pressure is the gold standard in human medicine,[51,52] its use in veterinary patients is often precluded by cost, availability, and requirement of anesthesia in an often unstable patient.

Doppler ECHO provides a noninvasive method of estimating PA pressures in conscious animals. Peak regurgitant flow velocity of tricuspid regurgitation (TR) or pulmonic insufficiency (PI) can diagnose PH (Figure 243-1, *A*). In the absence of pulmonic stenosis, the regurgitant velocity allows estimation of PA pressures by using the modified Bernoulli equation (pressure gradient = 4 × (peak velocity)^2). However, the accuracy of the predicted pressures depends upon operator skill, degree of TR, and patient tolerability of examination, as well as physiological factors such as RV systolic function. A peak TR velocity > 2.8 m/s (peak TR pressure gradient > 31 mm Hg) or a peak PI velocity > 2.2 m/s (peak PI pressure gradient > 19 mm Hg) strongly suggests PH.[2,4,5] PH can be categorized as mild PH (31 mm Hg to 50 mm Hg), moderate PH (51 to 75 mm Hg), and severe PH (>75 mm Hg).[2,5,49,53,54] If known, the right atrial pressure added to the TR pressure gradient theoretically offers the most accurate prediction of pulmonary systolic pressure. Right atrial (RA) pressure has been estimated off ECHO as 5 mm Hg in dogs with a non-dilated RA, 10 mm Hg if the RA is enlarged but without right-sided heart failure, and 15 mm Hg during clinical signs of right-sided heart failure.[30,32,55] Echocardiographic and direct invasive measurements of PH have a moderate correlation but wide variability.[55] In a study of experimental, acute embolic PH in anesthetized dogs, ECHO had a tendency to underestimate direct PH measurements; however, both under- and overestimation was observed.[55]

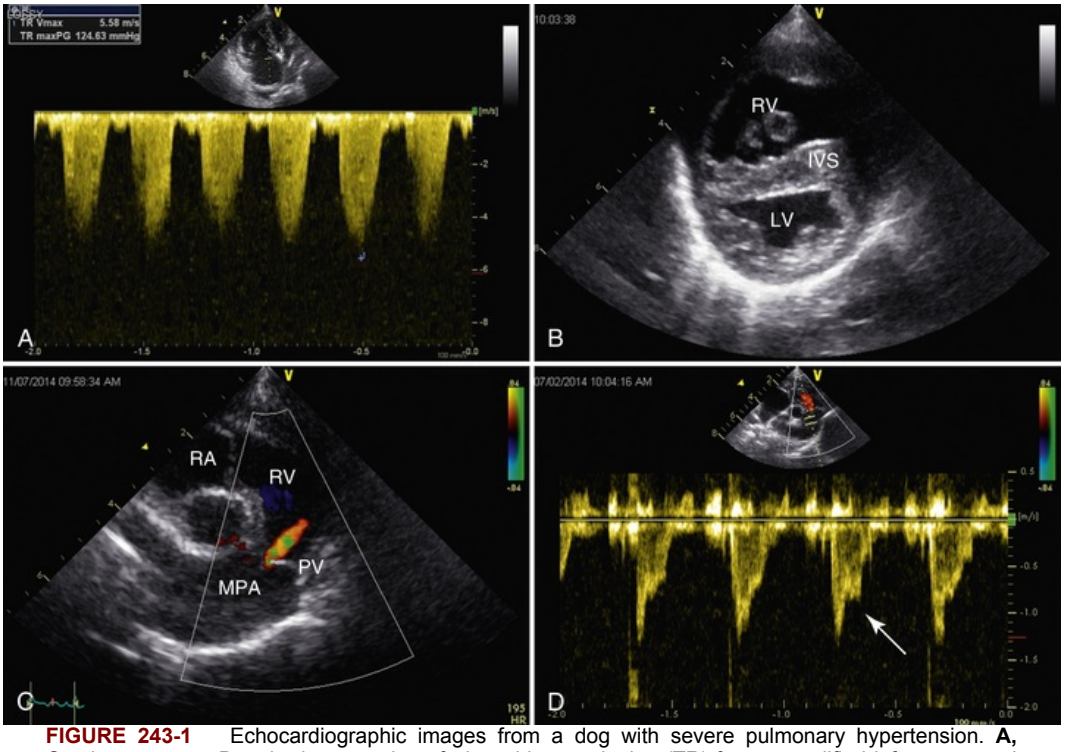

FIGURE 243-1 Echocardiographic images from a dog with severe pulmonary hypertension. **A,** Continuous wave Doppler interrogation of tricuspid regurgitation (TR) from a modified left parasternal four-chamber view. The TR velocity is 5.58 m/sec and the gradient is 124.63 mm Hg, as calculated from the modified Bernoulli equation (pressure gradient = 4 × velocity^2). In the absence of pulmonic stenosis and high right atrial pressures, the TR gradient represents systolic pulmonary artery pressure. **B,** Interventricular septal flattening and right ventricular free wall hypertrophy and chamber dilation. **C,** Obtained from the right parasternal short axis view at the heart base. The image depicts severe dilation of the main pulmonary artery and mild pulmonic insufficiency. **D,** Spectral Doppler across the pulmonic valve from the right parasternal short-axis view. There is an early peak and decrease in velocity with a slight reversal of flow in late systole (indicated by arrow). This pulmonary artery velocity profile is type III, and supports the diagnosis of severe pulmonary hypertension. *IVS,* Interventricular septum; *LV,* left ventricle; *MPA,* main pulmonary artery; *PV,* pulmonic valve; *RA,* right atrium; *RV,* right ventricle.

In the absence of TR or PI, other ECHO findings can be helpful in diagnosing PH. Two-dimensional ECHO can reveal RV concentric hypertrophy or RV eccentric hypertrophy, RA enlargement, septal flattening, and potentially RV systolic dysfunction caused by moderate to severe PH (Figure 243-1, *B* and *C* and Video 243-1).[2,4,5,53,56,57]

Spectral Doppler profiles of the pulmonic valve flow potentially aid in the diagnosis and categorization of

the severity of the PH (Figure 243-1, *D*).[2,4,5,31,32,45,49] Other ECHO measurements supporting a diagnosis of PH in dogs include tricuspid annular plane systolic excursion (TAPSE),[56] right ventricular systolic time intervals,[5,49] right-sided tissue Doppler imaging (TDI),[31,58] main pulmonary artery-to-aorta ratios,[31] the Tei index of myocardial performance (Tei),[31,32,58] and right pulmonary artery distensibility index (RPAD).[59]

While not specific for PH, thoracic radiographs may demonstrate findings supportive of PH. Based on the underlying cause of PH, right-sided heart enlargement, pulmonary artery dilation and/or pulmonary infiltrates may be evident (Figure 243-2). A retrospective study of MVD patients (<15 kg) demonstrated a vertebral heart scale short axis of >5.2 vertebrae (v) and a length of sternal contact > 3.3 v had a predictive accuracy of 85.9% for the detection of PH.[54]

FIGURE 243-2 Ventrodorsal view of a thoracic radiograph from a dog with severe pulmonary hypertension and a one-year history of exercise intolerance, increased expiratory effort, progressive panting and episodes of syncope. Note the severe dilation of the main pulmonary artery and right caudal lobar pulmonary artery with pulmonary infiltrates in the left caudal lung field.

Biomarkers such as NT-pro-B-type natriuretic peptide (NT-proBNP) or cardiac troponins may be useful in the diagnosis of PH. NT-proBNP is a peptide that is released from the ventricular myocardium in response to stress or strain. Traditionally, NT-proBNP has been used to screen for the presence of heart disease, as well as differentiate between cardiac and respiratory diseases.[60,61] However, NT-proBNP can be elevated in dogs with pre- and post-capillary PH.[45,60,62] Dogs with respiratory disease and PH (i.e., Group III PH) have higher median serum NT-proBNP concentrations compared to dogs with respiratory disease but no PH.[60,62] Furthermore, NT-proBNP may correlate with peak TR gradient.[62] However, NT-proBNP is not specific

enough to discriminate between dogs with MVD and those with MVD plus PH.[54] Overall, NT-proBNP elevations increase the suspicion for PH but cannot discriminate between PH and primary cardiac disease.

Cardiac troponin I (cTnI) concentration is a measure of myocardial injury. Pre- and post-capillary PH dogs have been associated with a significant increase in cTnI compared to normal dogs.[30] However, cTnI was not different between dogs with respiratory disease and PH versus those with respiratory disease without PH.[62]

Treatment

Pulmonary hypertension develops from a heterogeneous group of diseases with numerous subgroups. Consequently, treatment should be aimed at the underlying etiologies (see Treatment sections of ch. 241, 242, 247, and 255) as well as direct reduction of PH to improve quality of life. Once labeled the "kingdom of the near dead,"[63] pulmonary hypertension can be treated with a number of therapeutic agents in human medicine. Endothelin antagonists (i.e., bosentan, ambrisentan, macitentan) and prostacyclin analogs (i.e., beraprost, epoprostenol, iloprost) are cost-prohibitive, and often require continuous subcutaneous or inhaled administration, which greatly limits their application in veterinary patients. The value of endothelin antagonists or prostacyclin analogs has yet to be confirmed in canine PH patients. However, phosphodiesterase type V inhibitors (PDE5-I) are commonly prescribed for PH in dogs.

PDE5-I medications, such as sildenafil (Viagra), tadalafil (Cialis) and vardenafil (Levitra), cause vasodilation by increasing pulmonary vascular concentrations of cGMP. This increase subsequently results in increased endogenous NO concentrations.[2,3,64] In addition to directly improving PH via PA vasodilation, PDE5-I medications reduce cardiac remodeling, apoptosis, fibrosis, ventricular hypertrophy, and improve left-heart function in people.[64] Sildenafil is a short acting PDE5-I. In veterinary medicine, sildenafil has been shown to decrease clinical signs of PH and improve quality of life.[2,3,46] A measureable reduction in TR pressure gradients has been found in some studies[3,46] but not in others.[2] Nevertheless, studies demonstrate clinical improvement in dogs receiving sildenafil independent of any change in estimated PH. Sildenafil is well tolerated in dogs at 1-2 mg/kg PO q 8-12 h.[2,3,46] While no consensus exists regarding the use of sildenafil in dogs, one potential clinical decision-making process for Group II and III PH is provided in Figure 243-3. Sildenafil has anecdotally been used in cats, including a case report of a cat with PH from a left-to-right PDA.[65] No clinical trials have been published in cats.

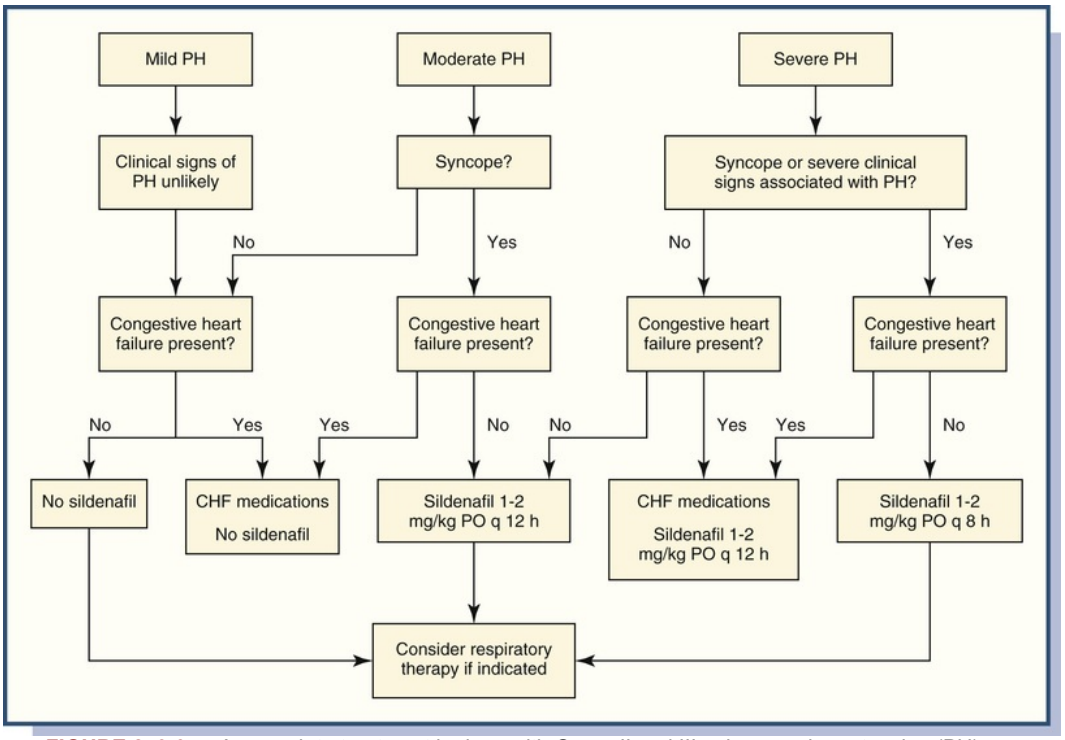

FIGURE 243-3 Approach to treatment in dogs with Group II and III pulmonary hypertension (PH).

Tadalafil is a long-acting PDE5 inhibitor. A single published case study exists of a dog with idiopathic PH treated with tadalafil (1 mg/kg PO q 48 h).[66] This dog demonstrated a decrease in PAP and improved clinical signs. Oral and injectable tadalafil has been shown to reduce experimentally-induced PH in dogs.[67] Vardenafil, another long acting PDE5-I, has yet to be studied in canine PH.

Pimobendan (Vetmedin) is a phosphodiesterase 3 (PDE3) inhibitor and calcium sensitizer. Treatment of PVH (Group II PH) with pimobendan in dogs with MVD reduced NT-proBNP levels. Furthermore, this therapy improved quality of life in the short term, while maintaining a reduction in measureable PVH in the long term.[45]

Considering that *in situ* thrombosis and increased thromboxane A_2 synthesis occurs in people with idiopathic PH, aspirin or clopidogrel have been used.[68] Some veterinary clinicians use antiplatelet therapy in dogs with idiopathic PH; however, its indication and effectiveness are unknown.

Newer therapies are emerging in human medicine, some of which have already been evaluated in dogs. Imatinib (Gleevec) inhibits the activation of platelet-derived growth factor (PDGF) and also inhibits the PDGF receptor. Six dogs with congestive heart failure and PH from MVD or heartworm were treated with imatinib at a 3 mg/kg dosage PO q 24 h for 30 days. These dogs demonstrated improvement in maximum TR velocity, left atrial size and plasma atrial natriuretic peptide concentration.[69]

Outcome

The prognosis for canine PH is quite variable, and often depends upon the underlying cause. Severe PH carries a poor long-term prognosis. Prior to the availability of sildenafil, canine PH was associated with survival only days past diagnosis.[4] With the introduction of sildenafil, published survival has increased to 91 days[3], with some patients surviving almost two years.[2,3] Well-defined prognostic indicators are lacking in veterinary medicine. In people, the degree of PH-induced clinical symptoms as well as achievement of treatment goals (improvement in RV function, NT-proBNP levels and in 6 minute walk distances) are the most predictive long-term prognostic indicators.[70]

Pulmonary Thromboembolism

Etiology/Pathophysiology

Pulmonary thromboembolism (PTE) is the partial or complete obstruction of the PA or its branches by thrombi secondary to other disease processes. Diseases associated with thromboembolic disease are listed in Box 243-1 under Group IV. The pathogenesis of PTE is based on endothelial damage, blood flow stasis and hypercoagulable states (see ch. 197).[71] PTE results in hypoxemia, bronchoconstriction, ventilation-perfusion mismatch, and hyperventilation. Hemodynamic complications associated with PTE depend on the extent of pulmonary vasculature occlusion and pre-existing cardiac and pulmonary dysfunction. Over time, further complications arise such as atelectasis, pulmonary edema, and pleural effusion.

Clinical Signs and Diagnostics

Clinical signs of PTE are highly variable and nonspecific. The most common signs of PTE are dyspnea, tachypnea and lethargy.[71-74]

Antemortem diagnosis of PTE in veterinary medicine is difficult to achieve due to a lack of a feasible and available gold standard diagnostic test. Thoracic radiographs are indicated but findings are often nonspecific, ranging from focal pulmonary infiltrates to normal findings.[73,75] Arterial blood gas abnormalities may increase the index of suspicion, but is not sufficiently specific enough to confirm PTE. The most common blood gas changes associated with PTE include hypoxemia, hypocapnia and increased alveolar-arterial oxygen tension gradient (see ch. 75 and 128).[71,73] Since PTE is a sequela of other disease, broad diagnostics such as a complete blood count, serum chemistry, urinalysis, and heartworm test may identify predisposing factors. PTE is generally suspected in patients in whom no cardiopulmonary disease can be confirmed and the patient is known to have a predisposition to thrombosis. Thromboelastography (TEG) provides a global evaluation of coagulation and fibrinolysis with the potential to identify hypercoagulable states and increase the suspicion of PTE (see ch. 196).[71,75] Unfortunately, antemortem confirmation of PTE is rarely obtained in veterinary medicine.

In people, computed tomography (CT), selective pulmonary angiography and radionuclide

ventilation/perfusion scans are used for screening and confirmation of thromboembolic disease.[51,71] Selective angiography is difficult in unstable veterinary patients considering the need for general anesthesia. However, a small prospective study in dogs demonstrated thoracic CT with simultaneous bolus injection of contrast (i.e., CT pulmonary angiography) was possible under sedation in patients with respiratory clinical signs, and useful toward confirming/refuting PTE.[75]

Since CT angiography availability and associated expertise are limited, the use of widely available blood tests such as D-dimers is appealing. D-dimer is the byproduct of cross-linked fibrin degradation by plasmin and is reflective of fibrinolysis (see ch. 196). While D-dimer is not specific to PTE, a normal or low D-dimer concentration is highly sensitive in ruling out acute PTE in dogs.[76-80] D-dimers should be measured within 1 to 2 hours of a suspected PTE, as levels peak rapidly and can return to baseline within 24-48 hours.[81]

Treatment

The goal of therapy is typically to limit thrombus growth and prevent recurrence.[71] Anticoagulants, antiplatelet therapy and thrombolytics have been used; however, an evidence-based approach or consensus regarding treatment is lacking. Thrombolytic therapy using streptokinase, urokinase or tissue plasminogen activator is particularly controversial therapy and without clinical trials evaluating its use in veterinary PTE. Catheter-directed, local infusion of thrombolytics to a thrombus has been described and may result in a decreased risk for systemic bleeding complications.[82,83] Unfractionated heparin (100 to 300 IU/kg per dose SC q 6-8 h, adjusting the dosage to keep activated partial thromboplastin time [aPTT] at 1.5 to 2 times baseline)[84,85] or low molecular weight heparin (dalteparin 100-150 IU/kg q 8 h in dogs[84] and 100-180 IU/kg SC q 8-24 h in cats[84,86]) has been suggested for initial in-hospital therapy. Supportive care with oxygen (see ch. 131), judicious IV fluids (see ch. 129), sildenafil and bronchodilators can be beneficial (see ch. 139).[71] Successful treatment of acute PTE should be bridged to long-term antiplatelet or anticoagulation therapy. Aspirin is beneficial for thromboprophylaxis in immune mediated hemolytic anemia and protein-losing nephropathy.[71,85] Commonly used aspirin dosages are 0.5 mg/kg PO q 24 h in dogs and 5-81 mg/dose PO q 3 days in cats.[71,84,85,87] Clopidogrel is also often used with suggested dosages of 2-3 mg/kg PO q 24 h in dogs and 18.75 mg/dose PO q 24 h in cats.[85,88]

CHAPTER 244

Diseases of the Pleural Space

Elizabeth Rozanski

Client Information Sheets:
Pleural Effusion
Pneumothorax

Anatomy

The pleural space is defined as the area or potential space between the lungs and the chest wall. Normally, there are no soft tissue structures or free air present in this space. A very small amount (1-5 mL) of fluid, which is undetectable on radiographs or ultrasound, can be present within the thoracic cavity. The pleural cavity is lined by the visceral and parietal pleura, which covers the lungs and the thoracic wall, respectively. In small animals, the two hemithoraces are incompletely separated, which results in pleural effusions being generally divided between the right and left side. In longstanding effusions, fibrous adhesions can result in the presence of unilateral disease, but as a general rule in dogs and cats, the mediastinum is incomplete. As throughout the body, fluid movement reflects Starling's forces, as well as the tissue permeability and lymphatic drainage.[1] In animals with longstanding effusion, the rate of lymphatic drainage can be increased.

Physiology

Adequate lung function is dependent on adequate oxygenation and ventilation, which, in turn, is dependent on lung mechanics and ease of lung expansion. The normal intrathoracic pressure is subatmospheric, with an average pressure of −5 cm H_2O (−3.7 mm Hg). Negative intrathoracic pressure in conjunction with surfactant acts to keep the lungs inflated, which reduces the work of breathing.

Pleural effusion affects lung function by creating a restrictive defect with decreased total lung capacity (TLC) and functional residual capacity (FRC). In advanced cases, there will be increasing ventilation-perfusion mismatch and, left untreated, severe pleural effusion will result in decreased cardiac output and ultimately cardiac arrest.[2] This phenomenon is more common with pneumothorax, where tension pneumothorax can arise quickly, in contrast to pleural effusions, which tend to develop more slowly.

As pleural effusion forms, there is gradual collapse of the lung parenchyma, and also an *increase* in intrathoracic pressure. In the presence of marked effusion, the intrapleural pressure will be positive. While typically it is assumed that removal of isolated pleural effusion will result in immediate improvement in lung function, this is not always the case. In people, two separate categories of non-recruitable lung associated with pleural effusion are recognized. The first is termed *lung entrapment*, which is a disorder that develops in association with active pleural inflammation or neoplasia.[3] Immature fibrin and overlying inflammation prevent re-expansion, and contribute to the failure to recruit lung after thoracocentesis. During longer-standing effusions, there is thickening and constriction of the visceral pleura and thickening of the parietal pleura. This may lead to the development of *trapped lung*, or lung that is tightly constricted by overlying visceral pleura, and cannot adequately re-expand, even in the presence of negative intrathoracic pressure.[3] Trapped lung likely is more common in veterinary patients, as most effusions are associated with more active inflammation. However, the non-recruitable lung has been much less evaluated in dogs and cats than people, but could particularly be associated with the development of thoracocentesis-associated pneumothorax (see below).

Physical Examination

Clinical signs of pleural space disease can include tachypnea, orthopnea, or overt difficulty breathing, with classically rapid/shallow breathing considered the most common manifestation (Video 244-1). Some animals have marked abdominal effort. Physical examination findings can include respiratory distress, use of accessory muscles in respiration, and diffusely (pneumothorax or pleural effusion) or dependently (pleural effusion) muffled heart/lung sounds; occasionally, lung sounds can appear normal. It can be possible to percuss a ventral dullness on the thorax in patients with pleural effusion. Other clinical findings can reflect the underlying disease process (e.g., cardiac gallop sound, intrathoracic mass lesion, fever, trauma). Identification of a pleural space abnormality should be considered a strong clinical sign, but not a final diagnosis. Overall, the prognosis for a patient with pleural effusion is guarded, although many cases respond well to therapy, at least in the short term.

Initial Diagnostic Evaluation

Diagnosis of pleural effusion or pneumothorax can be made either through thoracocentesis, or diagnostic imaging. Radiography has classically been the most common imaging technique to identify either disorder, but ultrasonography is widely used in emergency and general practices (Figure 244-1), especially for detecting pleural effusion but increasingly for detecting pneumothorax (see below). Computed tomography and magnetic resonance imaging also can demonstrate pleural effusions and pneumothorax, but are used less commonly as the initial diagnostic imaging modality (Figure 244-2).

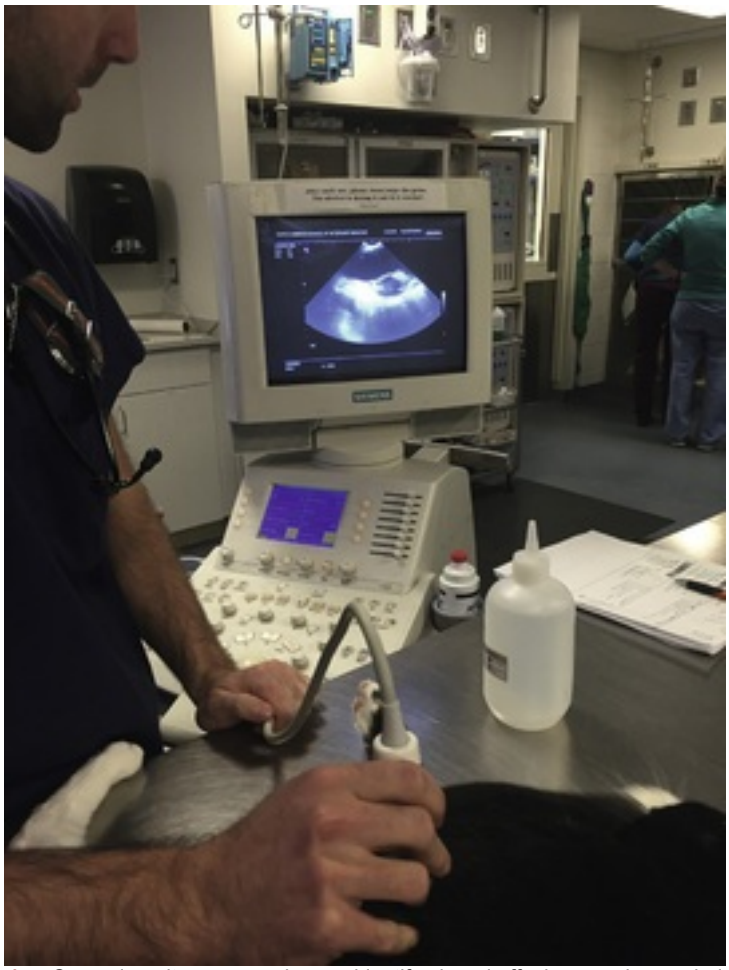

FIGURE 244-1 Screening ultrasonography can identify pleural effusion as a hypoechoic or anechoic space. While advanced ultrasonography skills are needed for specific identification of many diseases, most clinicians can relatively quickly gain the skills required to identify fluid.

FIGURE 244-2 A reconstructed CT image from a dog with mesothelioma causing pleural effusion and subsequent lung torsion. The lung lobe torsion is recognized by the vesicular pattern in the lobe (asterisk), while fluid is gray (arrow).

Radiographic signs of pleural effusion include decreased detail ("whiteout"), scalloping of the ventral lung borders, fissure lines between lung lobes and an obscured cardiac silhouette. A dorsoventral (DV) radiograph is helpful to confirm the presence of pleural effusion with minimal stress on the patient. If available, horizontal beam radiographs also are very useful.[4] Chronic pleural effusions can result in the radiographic appearance of "rounded" lung margins representing pleural fibrosis. On ultrasonography, pleural effusion is recognized as an echo-free area, appearing black.[5,6]

Thoracocentesis (see ch. 102)

Therapy of pleural space disease is directed at both improving respiratory status by removing fluid/air, and at identifying the underlying cause. Thoracocentesis is performed by clipping and aseptically preparing an area between the seventh and ninth rib near the costochondral junction (Videos 244-2A and 244-2B). Occasionally, the site can be more ventral or more dorsal based on suspicion of fluid or air, respectively. The animal should be gently restrained in a sternal or standing position. Typically, in cats and small dogs, a butterfly catheter, stopcock and 5-30 mL syringe are used. In bigger cats and most dogs, a longer needle is required. In dogs, with an expected large volume (> 1 liter) of effusion, an IV catheter and suction may be used for more rapid removal of effusion, often with less stress for the patient as well as potentially less risk of iatrogenic pneumothorax.

Aseptic technique is recommended, and supplemental oxygen may be provided (see ch. 131). A local block (9 : 1 2% lidocaine: 8.4% bicarbonate) or mild sedation may be considered. Fractious patients, whether resisting due to temperament or respiratory distress, may require heavy sedation or anesthesia (see ch. 138); however, the clinical team should be prepared to intubate and ventilate if necessary, as sedation will reduce respiratory drive. A distinct "pop" is felt upon entering the pleural cavity with the needle tip, although junior clinicians may less commonly appreciate this. Volumes of fluid and air retrieved should be recorded; in general 5-30 mL/kg are required to improve ventilatory mechanics; however, a smaller amount can be useful

for diagnostic purposes. As the mediastinum is typically incomplete, the hemithorax chosen as the site of entry (i.e., right or left side) is less important. As much effusion should be removed as possible. The presence of fibrin or loculated effusion can make thoracocentesis more challenging. If thoracocentesis is unsuccessful, the presence of effusion should be re-confirmed, ideally with ultrasound. If the fluid is present, a longer needle could be required to reach the pleural space or a different location can be attempted.

Complications of thoracocentesis are uncommon but can occur. The most significant complication is iatrogenic pneumothorax, which can occur either from damage to thickened/fibrotic visceral pleural and lung parenchyma or from marked drops in intrathoracic pressure which result in the formation of spontaneous tears in the lung/pleura and subsequent creation of a pulmonary-pleural fistula. Small volume iatrogenic pneumothorax can resolve without treatment, but large or ongoing leaks could require placement of a thoracostomy tube or even surgery. Other potential complications include hemorrhage if a great vessel or the heart inadvertently is punctured, or subcutaneous leakage of infected pleural effusion.

Thoracostomy Tubes (see ch. 100)

Thoracostomy tubes (chest tubes) can be required for the management of pleural effusion or pneumothorax in cases with large volume effusion or air that is recurring quickly, in cases of infectious effusion, or post-operatively. Red rubber catheters may be used as chest tubes, but more commonly, either trocar-style catheters or small-bore catheters (e.g., Mila International) are placed. Continuous suction units may be applied to help with fluid and air removal, and are more commonly used in cases of persistent pneumothorax than in pleural effusion. In pneumothorax, as the rate of air accumulation may be quite rapid, chest tubes may be required in order to facilitate the timely removal of air. In animals with trauma, either an unending pneumothorax or recurrence after thoracocentesis should prompt placement of a thoracostomy tube. As with pleural effusion, a variety of options for tube choice exists. Continuous suction units can be particularly useful for preventing reaccumulation of air, and promoting healing of damaged parenchyma.

Fluid Analysis

Fluid analysis should be performed to help characterize pleural effusions (see ch. 74). The gross appearance of the fluid can be purulent, chylous (milky), hemorrhagic, serous or serosanguineous, or icteric. Most effusions are serous or serosanguineous. Pleural effusion associated with pyothorax can be associated with a foul odor (anaerobic bacteria) as well as appearing grossly purulent (Figure 244-3). Fluid should be characterized as a transudate, modified transudate, or exudate based on the protein level and cell count (Table 244-1). After assessing the gross appearance, protein level and cell counts, the cytologic assessment of the effusion often is very helpful in reaching a final diagnosis. Other cytologic findings include the presence of neoplastic cells (carcinoma, lymphoma), small lymphocytes, neutrophils, bacteria, red blood cells, macrophages and mesothelial cells. In rare cases, other cell types can be appreciated, such as melanoma cells (Figure 244-4). In longstanding effusions, mesothelial cells can assume bizarre cytological appearances, which may make distinction from neoplastic cells more difficult.

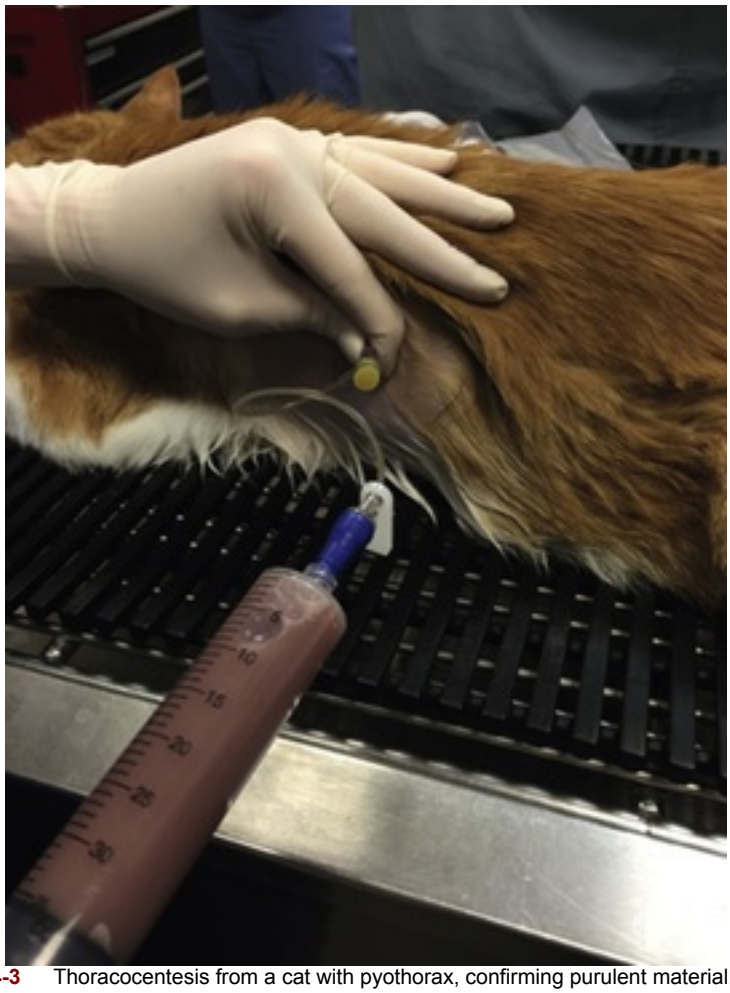

FIGURE 244-3 Thoracocentesis from a cat with pyothorax, confirming purulent material.

TABLE 244-1

Characteristics of Pleural Effusion

	TOTAL PROTEIN	CELLULARITY	CELL TYPES	DISEASE EXAMPLE
Transudate	<2.5 g/dL	<2500 cells/mcL	Nondegenerative neutrophils, macrophages, mesothelial cells	Low albumin (e.g., protein-losing enteropathy)
Modified transudate	2.5-7.0 g/dL	1000-7000 cells/mcL	Nondegenerative neutrophils, macrophages, mesothelial cells, neoplastic cells, lymphocytes	Congestive heart failure (CHF), neoplasia, chyle
Exudate	>7.0 g/dL	>7000 cells/mcL	Varies	Pyothorax

Modified transudates are the most common cause of effusion. The underlying cause of the effusion is the most important predictor of long-term outcome of the pleural effusion patient.

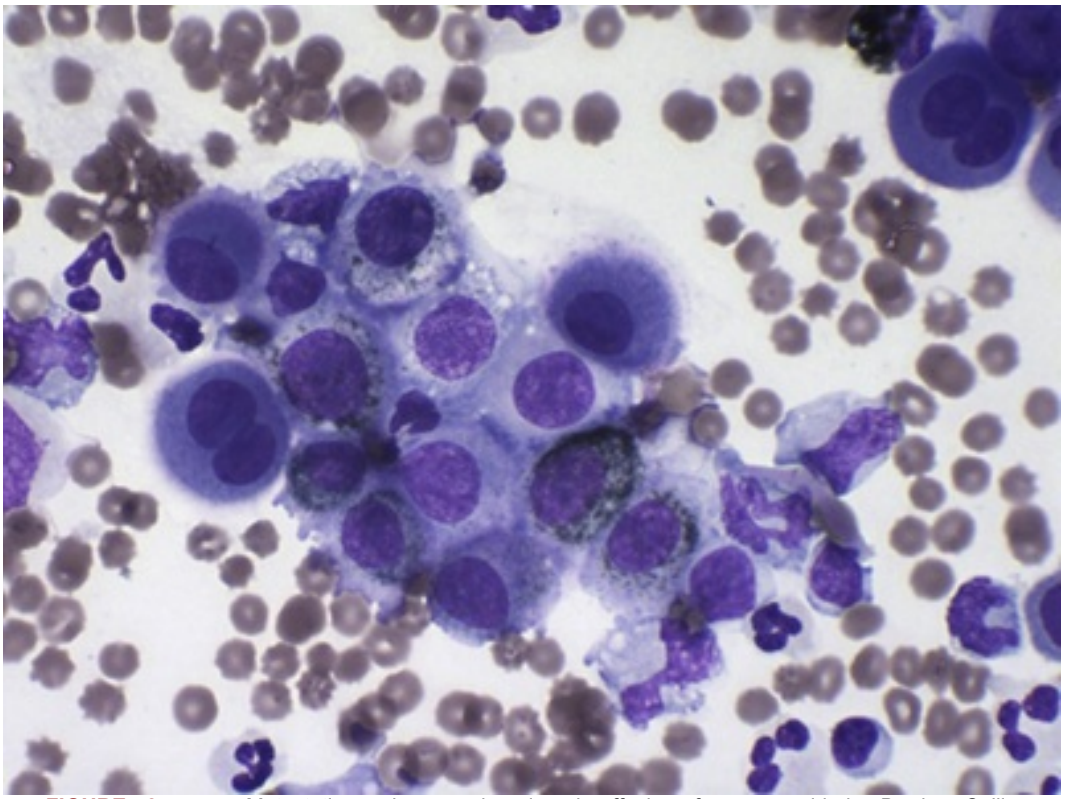

FIGURE 244-4 Metastatic melanoma in pleural effusion from an elderly Border Collie cross. (Photomicrograph courtesy Joyce Knoll, VMD, PhD, DAVCP.)

Biochemical assessment of pleural effusion is useful in some cases. In human medicine, Light's criteria are widely applied to pleural effusion, and recently have been described in cats.[7] Briefly, Light's criteria evaluate the ratio of effusion protein to serum protein, as well as lactate dehydrogenase (LDH) levels; exudates have higher ratios (>0.5) and higher levels of LDH.[8] In people, biochemical analysis of pleural effusion is pursued more commonly than it is in dogs and cats. Biochemical properties of pleural effusion include pH and concentrations of glucose, amylase, creatinine or BUN, cholesterol, triglycerides, and a variety of other substances. In people, pleural fluid amylase concentration has been used for confirming esophageal perforation, for example, but dogs and cats do not produce amylase in their saliva.[9] Biochemical analysis of pleural effusion in dogs and cats has been limited. Lower glucose levels are not as consistently associated with a septic pleural effusion as they are with a septic abdominal effusion.

The NT pro-BNP concentration in pleural effusion is high in cats with congestive heart failure.[10] A pleural fluid NT-proBNP concentration >322.3 pmol/mL was associated with a sensitivity of 100% and a specificity of 94% for differentiating cardiogenic from noncardiogenic pleural effusion in one feline case series.[10] Further studies of biochemical properties of pleural effusion could eventually add useful information to individual case evaluation.

Bacterial culture and sensitivity testing is warranted in cases with suspected infection or with neutrophilic effusions. Recurrent thoracocentesis can predispose a patient to iatrogenic infections. Bacterial culture is most frequently employed for evaluating for aerobic organisms, although pyothorax often is due to anaerobic infections. Anaerobic bacterial cultures can be hard to perform, and limited sensitivity data could be gained. More fastidious organisms might require special culture media and a dedicated microbiological laboratory. Viral infection can result in pleural effusion.[11] PCR testing also is very useful for identification of infectious organisms, and may be pursued, especially for atypical infections.[12]

Further Diagnostic Testing

Other diagnostic testing in patients with pleural effusion should be guided by signalment, physical examination findings, and results of fluid analysis. Routine laboratory testing, including a complete blood count, serum biochemistry profile, and urinalysis are advised to look for systemic disease. Thyroid testing in

cats (see ch. 301), and heartworm testing in endemic areas (see ch. 255) also are recommended.

Thoracic radiographs after removal of pleural effusion often are useful to evaluate for mass lesions, diaphragmatic hernia, or an enlarged cardiac silhouette. Echocardiography is essential to look for evidence of right-sided heart disease or pericardial effusion. Thoracic ultrasound can be useful to identify and biopsy mass lesions and to evaluate the integrity of the diaphragm. Computed tomography also is helpful to evaluate for the underlying cause of effusion.

Exploratory thoracotomy or thoracoscopy may be used to more completely evaluate the thoracic cavity, especially with recurrent or intractable pneumothorax, and to obtain biopsies if indicated.

Types of Effusions (see ch. 74)

Pure Transudate

This type of effusion usually develops in hospitalized pets or in animals with chronic protein-losing conditions. Grossly, the fluid appears similar to water and cellularity is low. Yorkshire Terriers with lymphangiectasia appear particularly likely to develop pleural effusions. Treatment includes thoracocentesis (see ch. 102), possibly colloid support (e.g., plasma, or synthetic colloids; see ch. 129), diuretics, and specific therapy for the underlying condition.

Modified Transudate

These effusions are the most common type observed in dogs and cats. The most common causes include the following diseases.

Congestive Heart Failure (CHF)

Right-sided heart failure can result in substantial accumulations of pleural fluid (see ch. 246 and 247). CHF is a particularly common cause of pleural effusion in cats. Right-sided heart failure can develop in association with chronic valvular diseases, or certain congenital malformations (e.g., tricuspid valve dysplasia). Physical examination typically shows other signs consistent with heart failure, such as abnormal heart sounds, tachycardia, and/or jugular venous distension. Gookin and Atkins described that moderate- to large-volume pleural effusion (≥17-22 mL/kg) will increase central venous pressure (CVP) by a mean of 4.5 cm H_2O (range 0-7 cm H_2O), causing misdiagnosis of pleural effusion as being cardiogenic in a small proportion of cats in one study.[13] Diagnosis of heart failure is based upon echocardiographic demonstration of a cardiac lesion of sufficient severity to be consistent with CHF. Elevations in NT pro-BNP also are supportive of CHF, both in plasma[6,14] and serum.[14] The recent addition of a feline point-of-care SNAP NT pro-BNP test improves the real-time availability of this test (IDEXX Laboratories, Westbrook, ME). Cytologic findings in pleural effusion associated with CHF include mild inflammation, while some animals, particularly cats, have chylous effusion. Treatment of pleural effusion associated with CHF is individualized and ideally is based on an evaluation by a veterinary cardiologist, typically including diuretics, pimobendan, and angiotensin-converting enzyme inhibitors. Medical management is more useful to delay the return of pleural effusion than clearing the effusion; therefore, initial thoracocentesis to remove as much fluid as safely possible is advised (see ch. 102).

Pericardial Disease

Pericardial effusion can result in the development of pleural effusion and ascites due to cardiac tamponade (see ch. 254). Pleural effusion associated with cardiac tamponade commonly will resolve following pericardiocentesis (see ch. 102). The presence of ascites with pericardial effusion suggests a more chronic course, and has been associated with a better prognosis than acute cardiac tamponade without secondary ascites.[14] Constrictive pericarditis also can be associated with the development of pleural effusion.

Malignant

Neoplasia is a common cause of pleural effusion. Some neoplasms exfoliate well (lymphoma, some carcinomas) while in others, cytologic criteria of malignancy are lacking. As stated earlier, longstanding effusions can be associated with reactive mesothelial cells that can be difficult to distinguish from mesothelioma. The lack of cytologic criteria for malignancy does *not* exclude neoplasia from the differential list. Therapy for neoplastic effusions can include periodic thoracocentesis, intracavitary therapy (e.g., cisplatin, bleomycin, carboplatin) or shunting of neoplastic fluid. In animals with pulmonary masses thought

to be associated with a malignant effusion, thoracotomy and resection of the mass rarely will be beneficial, and may be associated with significant morbidity or even mortality.

Exudate

Infectious

Pleural effusions can be infectious in origin. Affected animals often have systemic signs of sepsis (lethargy, fever, leukocytosis or leukopenia; see ch. 132). Cytologic evaluation of infectious effusions demonstrates degenerative neutrophils, and possibly intra- and extracellular bacteria. Infections can be aerobic or anaerobic; anaerobic infections can produce particularly foul-smelling exudates, but precautions must be taken not to expose personnel to infectious agents through inhalation. In cats, bite wounds are considered the most common source of infection, while in dogs, bite wounds and penetrating foreign bodies (sticks/plant awns) frequently are responsible. Occasionally, pleural effusions are identified secondary to bacterial pneumonia (i.e., parapneumonic effusions), but these are quite rare in dogs and cats compared to in people and horses. Other less common infectious causes of pleural effusion include *Bartonella* spp., *Mycobacterium* spp., and viral infections.

Therapy for pyothorax involves drainage (usually via thoracostomy tube; see ch. 100) and antibiotics based on culture and sensitivity. Some animals can require surgical intervention for resection and drainage of affected tissues. The prognosis for pyothorax frequently is good if the pet does not present in a moribund condition. Pyothorax is one of the few pleural effusions that can be cured.

Feline infectious peritonitis (FIP) can cause pleural effusion (see ch. 224). Affected cats usually are young, and usually will have elevated total globulin levels in their plasma and also a high protein level in the pleural effusion (usually >6.0 g/dL). Cytologically, reactive macrophages and neutrophils are present, but in small number. There is no effective therapy for FIP to date.

Hemorrhage

Hemothorax can result from anticoagulant rodenticide intoxication (e.g., brodifacoum; see ch. 152), trauma, lung lobe torsion, or neoplasia.[15] In hemothorax, by definition the hematocrit of pleural effusion is >20%, or is >50% of the patient's peripheral hematocrit. Clinical signs of hemothorax more commonly reflect hypovolemia than the presence of pleural effusion. In dogs with anemia and pleural effusion, it is prudent to check coagulation status prior to thoracocentesis in order to exclude coagulopathy. Therapy of hemothorax is dependent on the underlying cause and can include plasma transfusion, vitamin K therapy, surgery, or rest. Rib tumors can result in hemothorax, with resection required to control hemorrhage. Small-volume traumatic or toxic hemothoraces that are not affecting ventilation and where the underlying cause is controlled may be left alone to resorb.

Chylothorax

Chylous effusion appears milky white or pinkish and, cytologically, it contains high concentrations of small lymphocytes. There are many potential causes of chylous effusion, with idiopathic disease accounting for about 50% of cases. Evaluation of a patient with chylous effusion includes a careful search for an underlying cause, such as cardiac disease, cranial vena caval thrombus or mass, heartworm disease, or neoplasia. Post-surgical chylothorax has been described.[16] Idiopathic chylous effusion is associated with dilation of the lymphatics (lymphangiectasia), but the mechanism remains elusive. Diagnosis is made by identifying a high triglyceride value in the pleural fluid relative to the serum. If a specific cause is found, therapy may be directed against that. In idiopathic effusion, treatment may include periodic thoracentesis (see ch. 102) or surgical intervention. A multitude of different surgical techniques has been proposed to palliate chylous effusion, but no therapy is routinely successful, with cure rate hovering around 50-70%. The best surgical outcome appears to be associated with a meticulous and experienced surgeon.

Idiopathic

In some dogs and cats, despite a concerted effort, no specific cause is identified for pleural effusion. Treatment in this case is directed at ameliorating clinical signs. A search for atypical infections is warranted before initiating any immunosuppressive therapy if immune-mediated disease is suspected.

Miscellaneous

A variety of causes intermittently can be associated with the development of pleural effusion, including lung lobe torsion (see Figure 244-2), pancreatitis, immune-mediated diseases, chronic diaphragmatic hernia, pulmonary thromboembolism, gunshot injuries[17] or recent abdominal or thoracic surgeries. Cats seem particularly predisposed to the postoperative development of pleural effusion.

Chronic Effusions

Chronic pleural effusions may occur secondary to a wide variety of diseases, but are seen most commonly with idiopathic effusions, chylothorax, some congenital heart diseases, and mesothelioma. Survival times with chronic effusions depend on the underlying disease, as well as patient and pet owner characteristics. Some dogs with chronic effusions may be managed for months to years with intermittent thoracocentesis, particularly if their quality of life is otherwise good, there is limited formation of adhesions, and the owner has emotional and financial resources for chronic disease management. Importantly, animals with chronic effusions are much more likely to develop pneumothorax following thoracocentesis, and could develop infected fluid (pyothorax).

Pneumothorax also is a common iatrogenic complication of thoracocentesis in animals with chronic pleural effusion when the effusion results in thickening of the pleura and possibly trapped lung. In this context, pneumothorax can be a devastating complication, as the pleura is unlikely to heal spontaneously. Pleural ports (Figure 244-5) may be placed to permit thoracocentesis without the risk of inadvertent laceration of the pleura.[18] In larger dogs, the size (20 g) of the Huber needle could result in long times required to drain the effusion. Additionally, iatrogenic infections can occur with such a system, particularly if drainage is performed by lay individuals that have not been properly trained. Omentalization also has been described for treatment of chronic effusion.[19]

FIGURE 244-5 A pleural port is observed on this thoracic radiograph from a dog with chronic pleural effusion of unclear cause.

Pleural Pressure Measurement

Pleural pressure determinations potentially are useful in the intensive care unit and emergency department, and may be considered as point-of-care evaluations of physiologic responses to critical illness or injury. Pleural manometry often is recommended in people with pleural effusion, and may be performed easily in animals.[20] Pleural pressure may be monitored during thoracocentesis for pleural effusion or pneumothorax, or continuously if a thoracostomy tube is in place.

Pleural manometry was designed to monitor the pleural cavity for signs of non-recruitable lung, as evidenced by large decreases in intrapleural pressures that subsequently could lead to pain or spontaneous pneumothorax. Iatrogenic pneumothorax is of particular interest, as in veterinary medicine, iatrogenic pneumothorax associated with thoracocentesis is most commonly thought to be associated with inadvertent laceration of the lung. The concept of non-recruitable lung is compelling, as larger increases (e.g., more negative) in pleural pressures might be associated with spontaneous pneumothorax as well, via tearing of the visceral pleura in response to markedly negative pressures. A pilot evaluation of pleural manometry in our hospital, performed by Kendra LaFaunci, DVM, showed findings as illustrated below (Figure 244-6). Interestingly, in Cat 2B, iatrogenic pneumothorax developed after thoracocentesis, potentially associated with trapped lung, and substantially negative intrathoracic pressure. Additionally, the use of pleural manometry is also able to identify whether the needle or catheter is still in the pleural space following re-positioning, patient movement, or apparent completion of the procedure, which in animals is perhaps the most useful insight that can be gained.

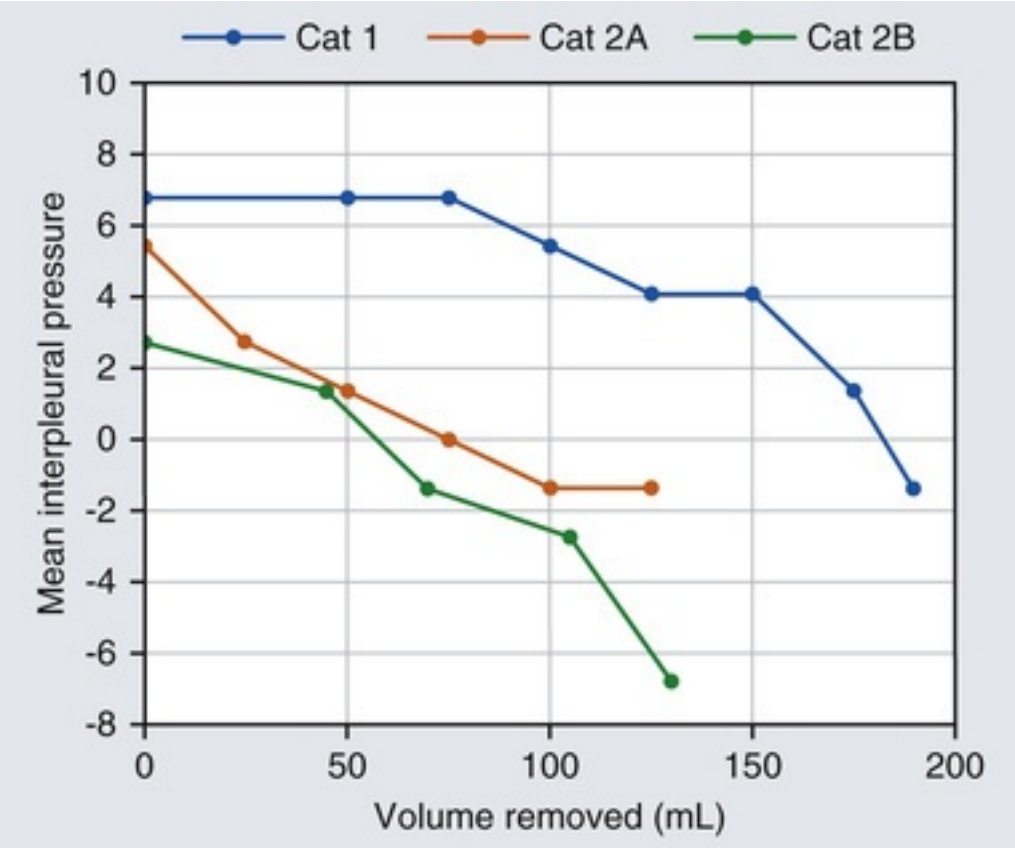

FIGURE 244-6 The graph represents the fall in pleural pressure associated with removal of pleural effusion. The curve for Cat 2B shows pleural pressure readings when thoracocentesis was performed for the second time. A more negative pressure developed in association with the same volume of effusion being removed; this cat subsequently developed pneumothorax, potentially associated with a non-recruitable lung.

Pleural Effusion Summary (Box 244-1)

Pleural effusion is a clinical disorder but not a final diagnosis. Many different conditions can result in the formation of pleural effusion; therapy is more likely to result in their resolution if it is specific to the inciting

cause. Comprehensive diagnostics could be required to reach an answer, and in some cases, the etiology remains elusive.

Box 244-1

Summary of Pleural Effusion

1. Detection of pleural effusion should prompt a thorough search for the underlying cause.
2. Many cases of pleural effusion can be palliated successfully, but true cure is unlikely except with infection, trauma, or intoxication.
3. Iatrogenic air leak can accompany thoracocentesis, particularly in chronic effusions.
4. Cytologic evaluation is warranted with every thoracocentesis, even "repeat offenders."

Pneumothorax

Pneumothorax is defined as free air in the pleural space. It can be characterized as traumatic, spontaneous, or iatrogenic, and as open or closed[21] (Box 244-2). *Tension pneumothorax* is a pneumothorax severe enough to affect cardiac output and, if not promptly evacuated, will result in the death of the patient. A tension pneumothorax can result from any type of pneumothorax, although it almost always is a closed pneumothorax (Figure 244-7).

Box 244-2

Summary of Pneumothorax

1. Pneumothorax can be traumatic, spontaneous, or iatrogenic.
2. Thoracostomy tubes can be required if large volumes of air are accumulating (see ch. 100).
3. Pneumothorax caused by blunt trauma should resolve with supportive care.
4. Pneumothorax caused by penetrating trauma could require surgery to prevent infection and to repair devitalized tissues.
5. Spontaneous pneumothorax in dogs should prompt surgical exploration.
6. Spontaneous pneumothorax in cats should be treated individually.
7. Iatrogenic pneumothorax should be treated on a case-by-case basis.

FIGURE 244-7 Thoracic radiograph from a dog with tension pneumothorax.

Traumatic Pneumothorax

Traumatic pneumothorax results from injury to the thorax. It is divided into *open*, where there is an open wound connecting the pleural space and the outside air, and *closed*, where the air leak is occurring from damaged lung tissue. It is suspected that trauma is the most common etiology of pneumothorax in dogs. Traumatic wounds can be blunt (e.g., hit by car) or penetrating (e.g., bite wounds). Treatment of traumatic pneumothorax reflects the severity of clinical signs, with a principal recommendation being to treat the patient, not any radiographic abnormalities.

As animals with traumatic pneumothorax often have pulmonary contusions or rib fractures concurrently, it can be challenging to determine the contribution of pneumothorax to respiratory distress. If in doubt clinically, diagnostic thoracocentesis (see ch. 102) is advised to avoid missing an opportunity to treat a "treatable" condition.

Identification of traumatic pneumothorax may be made through diagnostic thoracocentesis, thoracic radiographs, or ultrasonography. A negative diagnostic thoracocentesis can be truly negative, or might reflect an inadequate length of needle/catheter or pocketing of the air. A thoracic focused assessment with ultrasound (T-FAST) may be used as a point of care diagnostic test for pneumothorax (see ch. 149), but the clinician is advised that it may be more difficult for the less experienced clinician to identify pneumothorax than pleural effusion with ultrasonography.

Treatment of traumatic pneumothorax reflects the severity of the pneumothorax, and the mechanism of the development of pneumothorax (blunt versus penetrating trauma). Most blunt traumatic pneumothoraces will heal rapidly (1-4 days) with supportive care, and rarely require surgery to control air leak. The prognosis for blunt traumatic pneumothorax is good, with the majority of cases requiring only a short hospital stay. It is important to evaluate the patient fully for other wounds, because injuries such as spinal fractures can be present and can impact the patient's healing and the prognosis.

Penetrating thoracic wounds generally are considered worthy of surgical exploration, as bite wounds can bring fur and other debris into the thoracic cavity. Specifically, in bite wounds, the clinician should recall that

the site of the skin puncture wound can be far removed (several centimeters) from the site of penetration into the thorax. In small breed dogs (e.g., Yorkshire Terriers) that are grabbed and shaken by large dogs, it is very uncommon for a bite wound over the thorax to not actually penetrate the thoracic cavity. Small disruptions in the chest wall (rib fractures or intercostal tears) can be visualized as a paradoxical motion of the chest wall or palpated as a divot (see ch. 149). A flail chest, which is defined as the presence of two or more fractures in 2 or more adjacent ribs, also can occur in conjunction with blunt or penetrating trauma. While surgical stabilization may be considered in association with penetrating wounds, in blunt trauma, rest and pain relief should be adequate to permit healing and normalization of lung mechanics.

Spontaneous Pneumothorax

Spontaneous pneumothorax (SP) is a pneumothorax that occurs atraumatically. Spontaneous pneumothorax is termed primary if there is no underlying lung disease, and secondary if it is due to an underlying pulmonary disorder. Spontaneous pneumothorax is more common in dogs than in cats; the rupture of pulmonary blebs or bullae results in primary spontaneous pneumothorax. Large-breed dogs appear to be affected more commonly. Clinical signs reflect a restrictive breathing pattern, and include restlessness, respiratory distress, and tachypnea. Owners of dogs with suspected SP should be queried as if trauma is a possible cause, because SP in dogs is considered a surgical disease, with prompt surgical intervention and resection of affected lung tissue associated with a better outcome, while blunt traumatic pneumothorax typically is treated conservatively.[22] Preoperative diagnostics should include three-view thoracic radiographs, and baseline laboratory testing. Other testing may be performed at the discretion of the managing clinician. When surgical exploration is undertaken, it typically is done via median sternotomy, which permits for exploration of both hemithoraces. In some cases, despite an open surgical approach, it has been difficult to identify the source of the air leak. In such cases, it can be helpful, while exploring the thorax, to intermittently provide positive pressure ventilation (e.g., inflating the lungs to a pressure of 15-20 cm H_2O) while the thorax is filled with sterile saline; this submerges the lungs and allows the surgeon to watch for bubbles that signify air leak. In cats, primary spontaneous pneumothorax is very rare.

Secondary spontaneous pneumothorax develops without trauma but due to pre-existing lung disease. It has been reported in dogs secondary to neoplasia, pulmonary thromboembolism, and rarely to pneumonia. In cats, the most likely cause is thought to be asthma/lower airway disease or heartworm disease. Patients with small volumes of air can be treated conservatively (medically), although large volumes or those associated with a mass lesion should be treated surgically. The prognosis for spontaneous pneumothorax generally is good with treatment, with the exception of neoplastic lesions.

Iatrogenic Pneumothorax

Iatrogenic pneumothorax is pneumothorax created during the treatment of a patient. The most common causes are thoracocentesis of a pet with chronic effusion, or in association with intermittent positive pressure ventilation associated with high inspiratory pressures.

Treatment of iatrogenic pneumothorax can be difficult, as the pre-existing chronic effusion might preclude thoracotomy or increase the risks associated with surgical intervention. Small volumes (5-20 mL) of air removed during thoracocentesis should trigger careful monitoring of the patient, while larger volumes should prompt more urgent interventions. Blood "patching" has been advised for treating an ongoing air leak.[23] The major benefits of blood patching are that it is easy to perform, and that the patient's blood is readily available. Blood patching recently has been described in a population of eight dogs, with overall results that were encouraging.[24] The most common complication of blood patching seen in people is infection, although tension pneumothorax due to blood clotting in the thoracostomy tube also is possible. Typically, 50 mL of whole blood without anticoagulant is collected and placed into the thorax via a thoracostomy tube. Further investigation of blood patching in dogs and cats is ongoing.

Other Pleural Space Diseases

Other diseases also can affect the pleural space and result in respiratory distress. These conditions are covered more completely in other chapters (see ch. 139, 149, 240, 245, and 273). It is wise to consider whether these could be part of the patient's distress. These conditions include thoracic wall masses, diaphragmatic hernia, mediastinal masses, and esophageal masses or foreign bodies. Thoracic wall masses can arise from the ribs, and the most common causes are osteosarcoma, chrondosarcoma, or fibrosarcoma (see ch. 245). These masses

can be associated with severe hemothorax and can be hard to visualize with radiography if large amounts of effusion are present.[15] Surgical resection can be palliative and even curative in low-grade tumors. Computed tomography (Figure 244-8) can be very useful to help elucidate the extent of such masses.

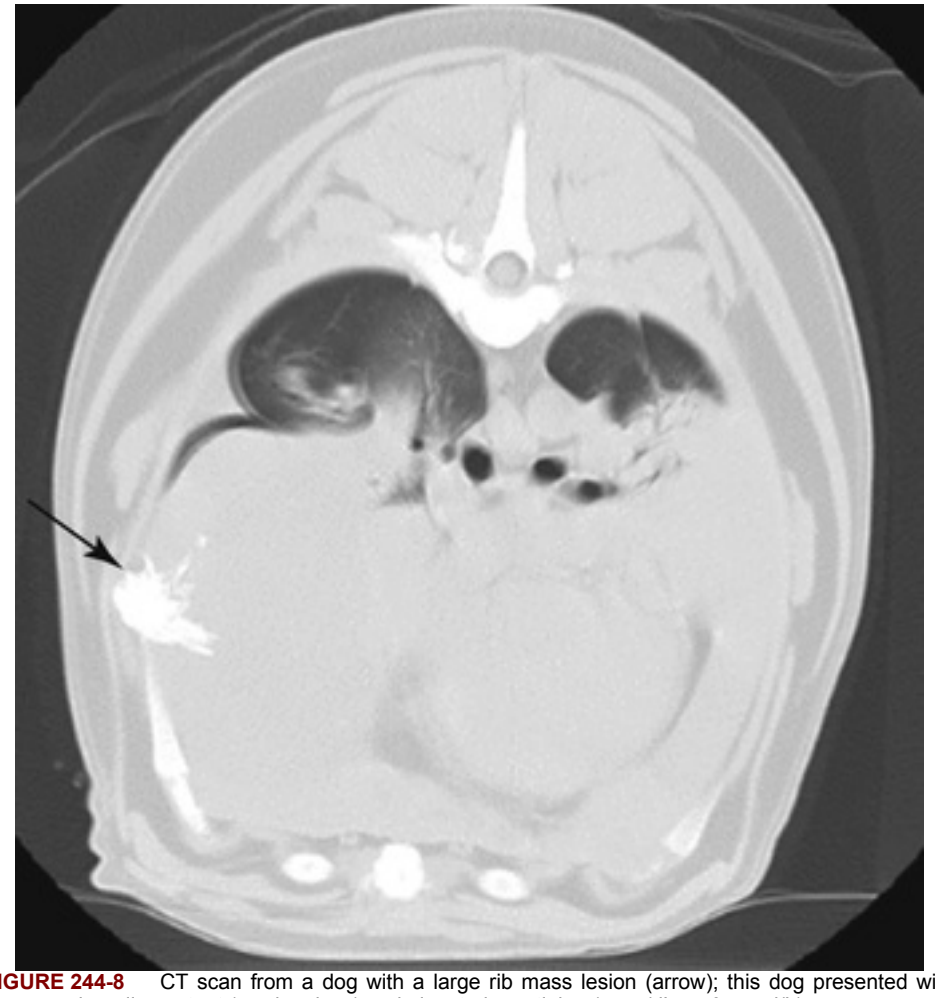

FIGURE 244-8 CT scan from a dog with a large rib mass lesion (arrow); this dog presented with decreased cardiac output (weak pulses) and elevated creatinine (5 mg/dL; 440 mmol/L).

Diaphragmatic hernias (DH; see ch. 245) are most commonly associated with blunt trauma, and may be identified by the loss of the continuity of the diaphragm or by the presence of abdominal contents within the chest cavity. While some DH are easily identified on routine thoracic imaging, in other cases documentation of the lesion can be more challenging. Ultrasound, computed tomography or rarely exploratory surgery may be used to help confirm a diagnosis. Surgical correction should be performed promptly, and on an emergency basis if the patient is unstable or the stomach has herniated into the chest.

Mediastinal masses (see ch. 245 and 344) typically result in respiratory distress through the development of pleural effusion. However, very large masses (e.g., certain thymomas) can result in compression of intrathoracic structures or concurrent myasthenia gravis can result in neuromuscular weakness and subsequent respiratory distress.

Esophageal disease (see ch. 273) usually will result in regurgitation and difficulty swallowing, but in some cases (Figure 244-9), apparent respiratory distress is present. Esophageal perforation may also result in the development of pleural effusion.

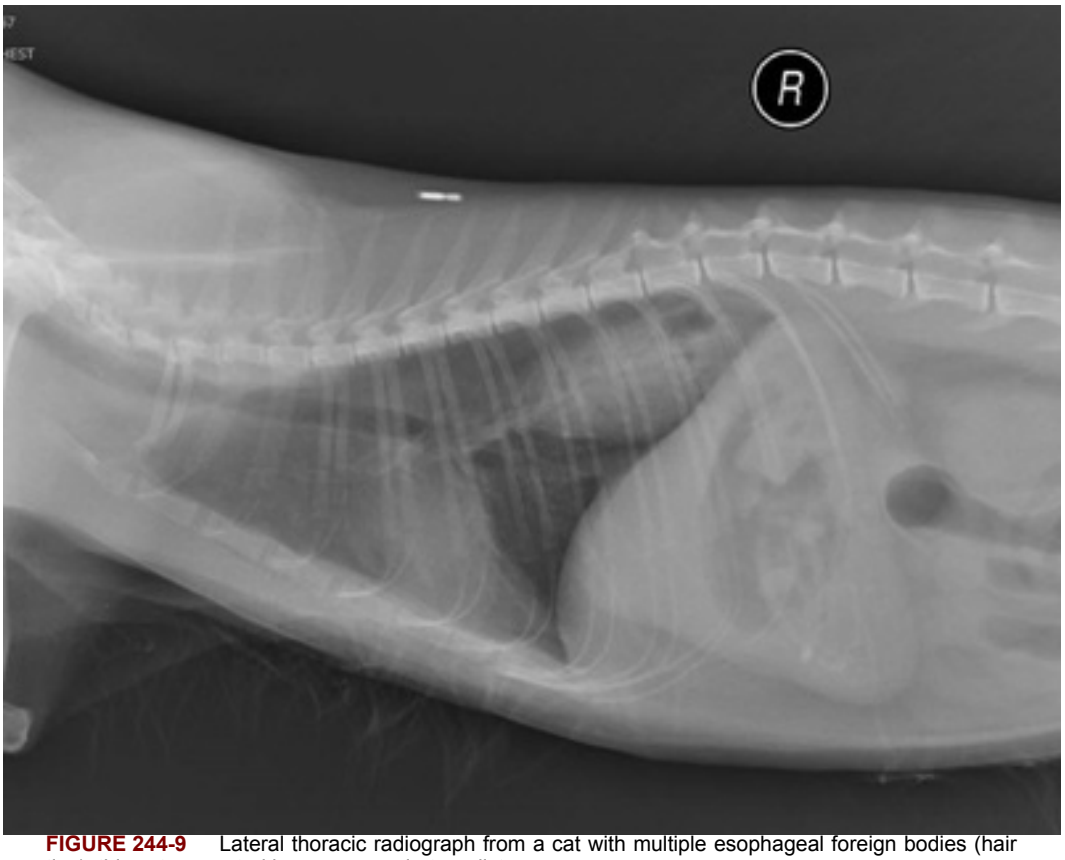

FIGURE 244-9 Lateral thoracic radiograph from a cat with multiple esophageal foreign bodies (hair ties); this cat presented in severe respiratory distress.

Summary

Pleural space disease may be characterized as effusion, pneumothorax, or as a space-occupying lesion. Prompt identification of pleural space disease is vital from a diagnostic standpoint, because an important component of therapy is addressing the underlying cause. Many causes of pleural effusion are associated with chronic disease, and could require long-term management, while pneumothorax can be treated more successfully. Mass lesions can be curable (DH) or could be palliated with appropriate therapy.

CHAPTER 245

Diseases of the Mediastinum, Chest Wall, and Diaphragm

Martha Moon Larson, David S. Biller

The Mediastinum

Anatomy

The mediastinum is a true space created by pleural reflections, and lies between the right and left pleural cavities.[1,2] It is located primarily on the midline of the thorax, although it deviates slightly to the left to accommodate extension of the right cranial and accessory lung lobes. The mediastinum contains and encloses the heart, trachea, esophagus, thymus, thoracic lymph nodes, thoracic duct, vagus nerves, aorta, cranial and caudal vena cava, and all other vessels that enter or leave the heart. The mediastinal space extends dorsally to the longus coli ventral to the thoracic spine, and ventrally to the sternum, and from thoracic inlet to diaphragm. It is not a closed space, but communicates with the cervical soft tissues via the thoracic inlet, and with the retroperitoneal space via the aortic hiatus. Therefore, disease in any of these compartments can spread and communicate. For example, subcutaneous emphysema in the cervical soft tissues can extend into the mediastinum creating a pneumomediastinum, and from there into the retroperitoneal space. The mediastinum is separate from the pleural space, but mediastinal fenestrations allow pleural air and fluid to communicate between thoracic cavities. The mediastinum is divided into 5 compartments: cranioventral, craniodorsal, middle, caudoventral, and caudodorsal.

Three sets of lymph nodes are located within the mediastinum, but are not typically visualized unless enlarged.[3-5] The cranial mediastinal lymph nodes are located along the cranial vena cava, just ventral to the trachea, and cranial to the heart. They vary in number, and receive afferent lymphatics from the trachea, esophagus, heart, pericardium, and pleura, as well as muscles of the neck, thorax, and abdomen, scapula, last six cervical vertebrae, thoracic vertebrae, ribs, thyroid, thymus, and mediastinum. The tracheobronchial (hilar) lymph nodes are paired, with one pair located inside the bifurcation of the mainstem bronchi (carina), just dorsal to the left atrium. They are located slightly more cranially in the cat compared to the dog. Additional tracheobronchial nodes are located lateral to the carina. These nodes receive afferent lymphatics from the lungs and bronchi. The sternal lymph nodes lie along the ventral aspect of the cranial mediastinum, just dorsal to the second and third sternebrae. The feline sternal lymph nodes are located slightly more caudally on the sternum compared to those of the dog. Sternal lymph nodes receive afferents from the diaphragm, pericardium, ventral thoracic and abdominal walls and peritoneal cavity.

Diagnostic Evaluation

The mediastinum is not easily accessible for clinical evaluation due to its location within the thorax, and there are no blood tests that are specific for mediastinal disease. On physical exam, a large cranial mediastinal mass can be suspected, particularly in cats, if the cranial thorax is noncompliant during gentle compression. Loss of normal breath sounds on auscultation also can suggest a mass lesion; pneumothorax is an important differential diagnosis. Imaging of the mediastinum (radiology, ultrasound [US], computed tomography [CT], magnetic resonance imaging [MRI], or nuclear medicine) is essential for noninvasive evaluation.

Survey Radiography

The mediastinum is seen as a soft tissue opacity only in the cranial thorax, ventral to the trachea. This opacity is created by border effacement of several mediastinal structures, including esophagus, cranial vena cava, left subclavian artery, brachiocephalic trunk, and cranial mediastinal lymph nodes. These structures are seen

individually only when air is present in the mediastinum to act as a negative contrast. On the ventrodorsal (VD) or dorsoventral (DV) view, the mediastinum is superimposed over the spine, and should be no more than twice the spinal thickness, although fat deposits in the mediastinum can cause nonpathologic thickening. Thickening due to fat should result in smooth straight margins. In young animals, the thymus may be visualized as a triangular, sail-shaped soft tissue opaque structure in the cranioventral aspect of the mediastinum, just to the left of midline, and cranial to the heart.

Survey radiography is ideal as the first step for localizing mediastinal disease, and can assess size, shape, opacity, and position of abnormalities. In general, mediastinal lesions include mediastinal shift, pneumomediastinum, and increased size and/or opacity of the mediastinum (mediastinal mass).

A mediastinal shift occurs when there is a decrease in volume of one or more lung lobes on one side. The mediastinum will shift towards the affected side to compensate for the loss of volume. The heart is the largest organ in the mediastinum, and a deviation to one side (on a properly positioned VD or DV view) is indicative of a mediastinal shift. The diaphragm on the affected side also can shift cranially to compensate. Alternatively, the mediastinum shifts towards the normal hemithorax when the opposite side has increased in volume, secondary to a large volume of unilateral pleural effusion, or a very large pulmonary mass.

Increased mediastinal size may be due to a mediastinal mass, esophageal enlargement, or fluid in the mediastinum. These diseases will be manifested radiographically as diffuse or focal enlargement of the mediastinum. Diffuse soft-tissue widening can be caused by the accumulation of fluid secondary to inflammation or hemorrhage. Focal mediastinal widening is usually the result of a mass lesion. Masses in the cranial mediastinum are most common, and if large enough, can result in border effacement of the cranial margin of the heart, elevation of the trachea and caudal displacement of the carina (normally located at the sixth intercostal space) and heart. Cranial widening of the mediastinum on VD/DV views is present. Middle mediastinal masses are most commonly due to enlarged hilar lymph nodes. These create a mass effect at the base of the heart, with ventral deviation of the carina and stem bronchi (lateral view), and lateral deviation of the stem bronchi (DV/VD view). Caudal mediastinal masses may be due to esophageal disease, abscess, granuloma, or tumor.

Ultrasonography

Ultrasound of the thoracic cavity is limited in its efficacy for imaging the normal mediastinum, as air in adjacent lung lobes prevents transmission of the sound waves. However, sonographic evaluation may provide useful information in animals with pleural effusion (which creates a window to the mediastinum) or with cranial mediastinal disease.[6-9] Ultrasonography allows visualization of most cranial mediastinal masses. Placing the transducer in a cranial parasternal position or using the heart as an acoustic window may be necessary for adequate evaluation of smaller masses. Ultrasonography is especially helpful in defining the internal architecture of masses as solid or cystic, and providing localization of vascular structures relative to the mass. Although the ultrasound appearance of a mass is not specific for the exact tissue of origin, it can be used for directing needle placement for fine needle aspirate (FNA) or tissue core biopsy.[10] Transesophageal ultrasonography provides excellent visualization of the heart base, major cranial mediastinal vessels, descending aorta, and part of the azygos vein (see ch. 104).[11-13] This modality eliminates imaging difficulties due to obesity, poor intercostal windows, and lung air interference.

Computed Tomography

Computed tomography of the thorax provides more detailed information regarding presence, location, and extent of disease. It provides better contrast discrimination than survey radiographs do, allowing distinction between solid, fatty, or cystic structures.[14] The cross-sectional imaging format eliminates the issue of superimposed anatomy. The ability to do multiplanar reconstruction is an additional advantage. Contrast enhancement after intravenous administration of an iodinated contrast agent provides added information regarding perfusion of soft tissues and vascular anomalies.[14-19] Especially in the presence of pleural effusion, CT is superior to thoracic radiographs in locating mass lesions to the mediastinum, determining their character (cystic versus solid), and determining extent of disease, including regional vascular invasion. This is critical information for determination of surgical resectability of a mass. Computed tomographic angiography is necessary to more reliably evaluate vascular invasion. To control respiratory motion, general anesthesia is usually necessary for thoracic CT examination.

Further Diagnostic Evaluation

Thyroid scintigraphy using technetium 99m or iodine 131 can be used for identifying ectopic or metastatic functional thyroid tissue within the mediastinum.[20,21]

Diseases of the Mediastinum

Pneumomediastinum

Pneumomediastinum is the abnormal accumulation of air within the mediastinum and it can be caused by a variety of mechanisms.[22-25] Tracheal disruption can leak air into the mediastinum, and has been reported with cervical trauma, mechanical ventilation, transtracheal aspiration, tracheostomy, tracheal intubation and overinflation, or central venous catheter placement (see ch. 241).[23,26] General anesthesia with endotracheal intubation and positive pressure ventilation (possible barotrauma and tracheal rupture), followed by trauma and tracheal foreign bodies, were reported as the most common causes of pneumomediastinum in cats.[25,27] Similar to tracheal trauma, esophageal or pharyngeal rupture can result in pneumomediastinum.[28,29] Subcutaneous emphysema from any location can eventually enter the mediastinum via the cervical soft tissues and thoracic inlet. Lung trauma or overdistension and rupture of alveoli can result in free alveolar air dissecting along the pulmonary interstitium and bronchovascular sheath, into the mediastinal space (Macklin effect).[30] This can occur completely separately from lung trauma that results in pneumothorax. Severe pulmonary lesions or preexisting respiratory disease can lead to bronchial or alveolar rupture with subsequent pneumomediastinum.[31,32] Less commonly, air can enter the mediastinum from gas accumulation in the retroperitoneal space. In some cases, the cause of pneumomediastinum is not determined (spontaneous pneumomediastinum).[24,25]

The presence of air in the mediastinum creates enhanced contrast and detail, allowing radiographic visualization of individual mediastinal structures (best seen on lateral images), including cranial vena cava, brachiocephalic trunk and left subclavian artery, esophagus, and azygos vein (Figure 245-1). Visualization of the tracheal wall is enhanced due to the presence of both intraluminal and extraluminal air. Mediastinal air can communicate with the retroperitoneal space via the aortic hiatus, resulting in secondary pneumoretroperitoneum. Pneumomediastinum does not occur secondary to pneumothorax. However, a severe pneumomediastinum has the potential to cause a secondary pneumothorax.

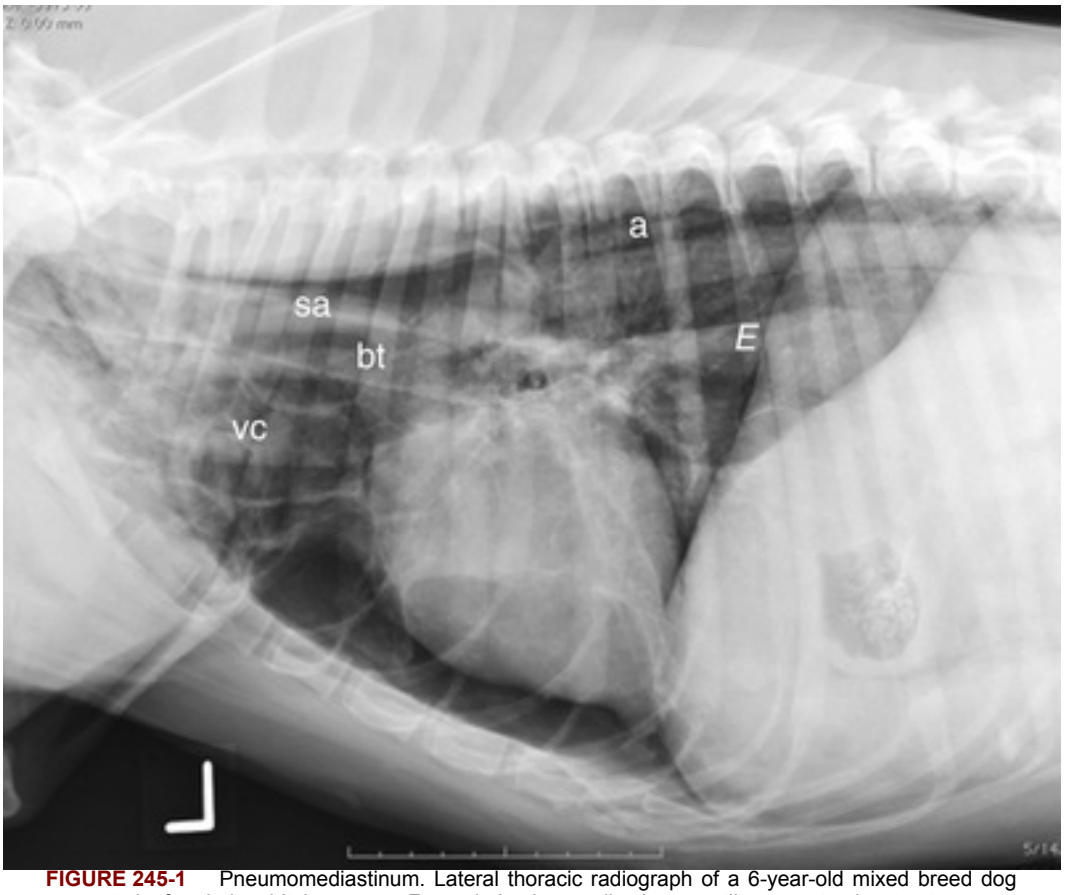

FIGURE 245-1 Pneumomediastinum. Lateral thoracic radiograph of a 6-year-old mixed breed dog presented after being hit by a car. Free air in the mediastinum outlines anatomic structures not normally seen, including cranial vena cava (vc), esophagus (E), inner and outer tracheal walls, brachiocephalic trunk (bt), left subclavian artery (sa), and azygos vein (a).

While pneumomediastinum can create dramatic radiographic changes, respiratory distress typically is absent unless concurrent pleural or pulmonary disease is present. If pneumomediastinum progresses to pneumothorax, tachypnea and dyspnea often are seen (see ch. 244). Animals with pneumomediastinum associated with esophageal rupture present with signs associated with esophageal disease, such as regurgitation, pain, and dysphagia (see ch. 273). The air trapped within the mediastinum does not require treatment and will spontaneously resolve within 2 weeks if there is no ongoing source of air leakage.

Mediastinitis

Clinical signs associated with mediastinitis include tachypnea (likely related to thoracic pain), dyspnea, cough, head and/or neck edema, and regurgitation. Voice changes may occur secondary to recurrent laryngeal nerve involvement. Physical examination may also reveal head and/or neck edema, fever, and decreased lung sounds if pneumothorax or pleural effusion is also present.

Mediastinal inflammation is manifested radiographically as either focal or diffuse widening of the mediastinum. Mediastinal pleural thickening, mediastinal air and fluid, mediastinal lymph node enlargement, and mediastinal mass lesions have been reported with CT.[33,34] These changes may result from esophageal or tracheal perforation, deep cervical soft tissue infections extending along fascial planes into the mediastinum, or extension of infection from the pericardium, pulmonary parenchyma, or pleural space.[35] Migrating intrathoracic grass awns have been reported as a cause of mediastinitis.[33] Chronic granulomatous mediastinitis may be caused by fungal organisms, such as *Histoplasma* or *Cryptococcus* spp., or bacterial organisms, such as *Actinomyces* or *Nocardia* spp.[36,37] Mediastinitis has been documented secondary to spirocercosis in dogs.[38,39] Abscessation of the mediastinum may result from progression of chronic infectious or neoplastic mediastinal disorders.[35] Both mediastinal abscesses and granulomas typically appear on radiographs as mediastinal masses and thus may be mistaken for neoplasia.

Therapy involves resolving the underlying disorder. Esophageal perforation may require surgical repair

and mediastinal masses may require surgical resection and/or drainage, along with appropriate antimicrobial therapy and supportive care.[35,37,39] Mediastinitis without a mass lesion may respond to antimicrobial therapy and supportive care alone.

Mediastinal Hemorrhage

Hemorrhage into the mediastinum usually results from either trauma or coagulopathy.[40-42] The clinical signs associated with mediastinal hemorrhage are related to the effects of acute blood loss. Dyspnea may occur if mediastinal hemorrhage progresses to hemothorax, or if the trachea is compressed by surrounding mediastinal hemorrhage. Radiographic signs include widening of the mediastinum with soft tissue opacity on both lateral and VD/DV views. Tracheal diameter may be narrowed due to compression, or wall thickening may occur due to submucosal hemorrhage (Figure 245-2).[41] Treatment is aimed at resolution of the underlying cause, such as plasma and vitamin K_1 therapy for anticoagulant rodenticide intoxication, along with supportive care (see ch. 152). Mild mediastinal hemorrhage usually does not need specific treatment.

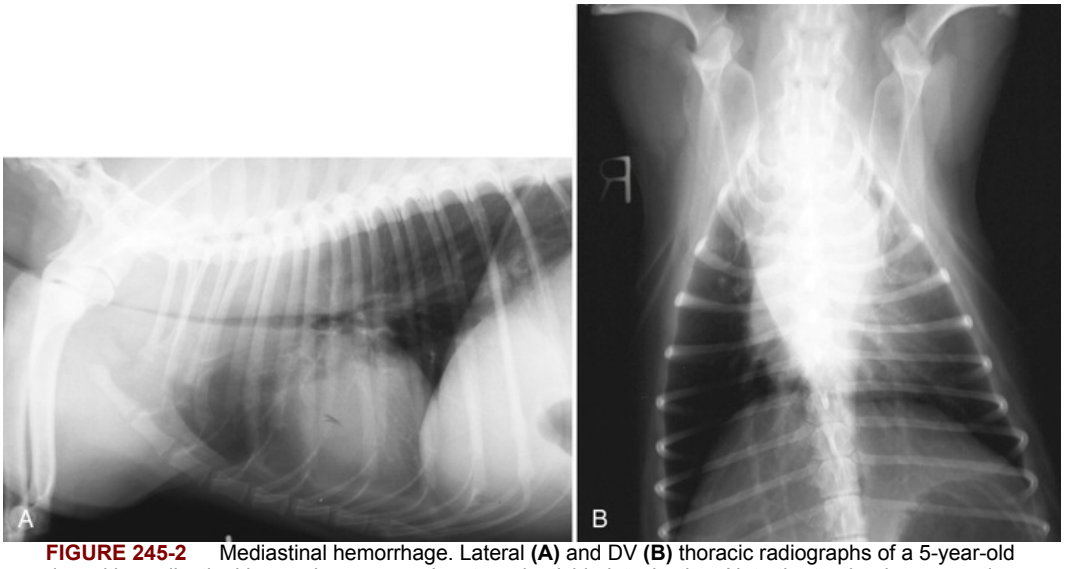

FIGURE 245-2 Mediastinal hemorrhage. Lateral **(A)** and DV **(B)** thoracic radiographs of a 5-year-old dog with mediastinal hemorrhage secondary to rodenticide intoxication. Note the tracheal compression due to surrounding mediastinal hemorrhage (lateral) and widened mediastinum (DV view).

Mediastinal Masses

Mediastinal masses frequently are classified by location (Table 245-1).

TABLE 245-1

Differential Diagnoses for Lesions Associated with Focal Mediastinal Enlargement

REGION	DISEASES
Cranioventral	Lymphadenopathy; abscess; thymic mass; ectopic thyroid; hematoma; granuloma; obesity; vascular mass (aorta, cranial vena cava); esophageal mass, foreign body, or dilatation; tracheal mass
Craniodorsal	Esophageal mass, foreign body, or dilatation; heart base mass; neurogenic tumor; paraspinal or spinal mass; hematoma; lymphadenopathy; aortic stenosis; patent ductus arteriosus; abscess; tracheal mass
Perihilar	Lymphadenopathy; left atrial enlargement; esophageal mass, foreign body, or dilatation; main pulmonary artery mass (poststenotic dilatation); heart base or right atrial mass; spinal or paraspinal mass
Caudodorsal	Esophageal mass, foreign body, or dilatation; hiatal hernia; diaphragmatic hernia or mass; spirocercosis; spinal or paraspinal mass; aortic aneurysm; gastroesophageal intussusception

Caudoventral	Diaphragmatic hernia; peritoneopericardial diaphragmatic hernia; abscess; granuloma; hematoma

Mediastinal Cysts

Benign cranial mediastinal cysts can originate from different anatomic structures (parathyroid cyst, thyroglossal cyst, thymic branchial cyst, and pleural cyst), and are identified most commonly in older cats.[43,44] Radiographically, they appear as focal soft-tissue masses located in the cranioventral mediastinum, often more caudal than other mediastinal masses (Figure 245-3). Ultrasound or CT can be used to demonstrate the fluid contents, and differentiate from solid mass lesions. On ultrasound exam, mediastinal cysts are ovoid/bilobed, thin-walled, contain anechoic fluid, and usually are accompanied by distal enhancement. Solid neoplasms, abscesses, or granulomas may have cystic components and must be differentiated from a simple cyst. Fine needle aspiration with ultrasound guidance is the diagnostic test of choice. Aspirated fluid is typically clear, colorless, and minimally cellular. Mediastinal cysts often are incidental findings that produce no clinical signs unless they are large enough to compress adjacent structures such as the trachea.

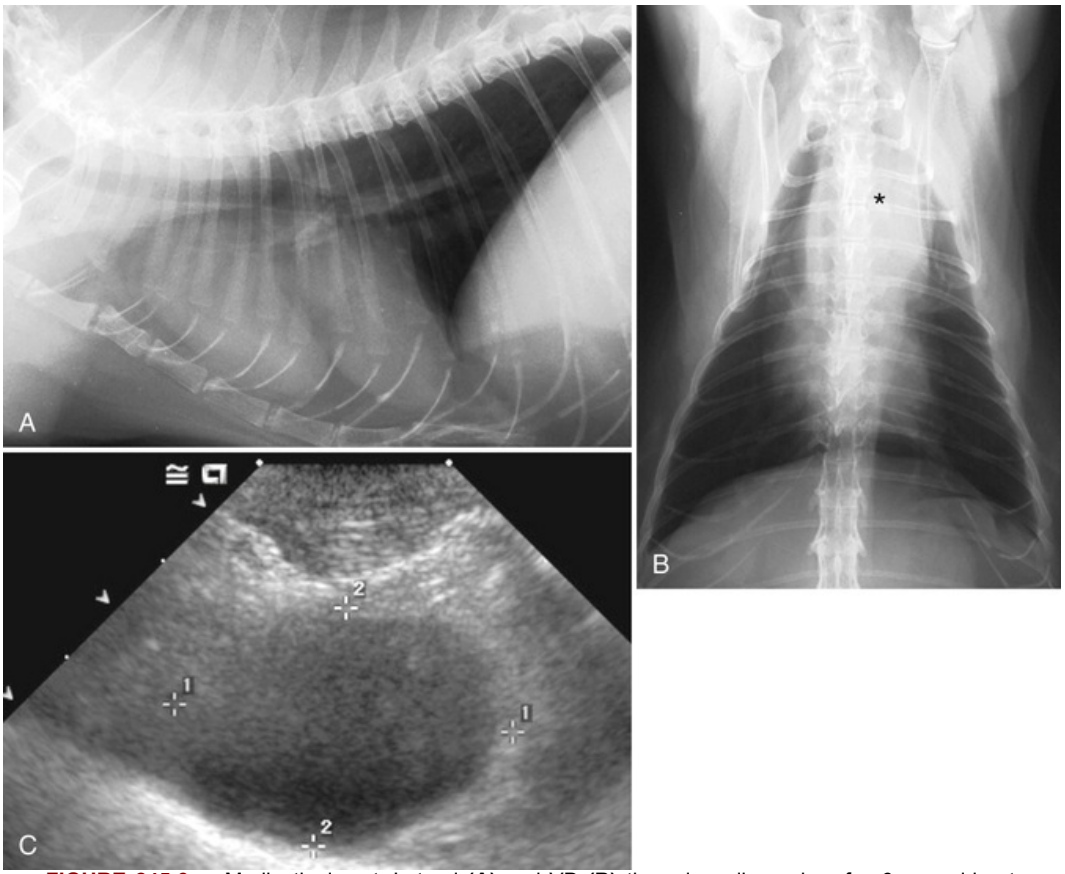

FIGURE 245-3 Mediastinal cyst. Lateral **(A)** and VD **(B)** thoracic radiographs of a 6-year-old cat presented for evaluation of vomiting. A well-marginated, soft-tissue mass is present in the cranial mediastinum just cranial to the heart. The mediastinum is widened on the VD view (*). **C,** Ultrasound image of the cranial mediastinal mass of the same cat. The mass is anechoic and fluid-filled, consistent with a benign mediastinal cyst.

Mediastinal Lymphadenopathy

Mediastinal lymph node enlargement is caused by a variety of diseases. Hilar (tracheobronchial) lymph nodes enlarge most commonly secondary to lymphoma or fungal pneumonia (histoplasmosis, blastomycosis, coccidioidomycosis)[45] (Figure 245-4). Additional causes include histiocytic sarcoma complex, metastatic adenocarcinoma (hepatocellular, anal sac, pancreatic), mycobacterial infections, eosinophilic bronchopneumopathy, eosinophilic pulmonary granulomatosis, and lymphomatoid granulomatosis.[45-55]

There does not appear to be a correlation between the size of the tracheobronchial lymph nodes and the type of disease. Cranial mediastinal lymph nodes receive afferents from the head/neck (see Anatomy section, above), and may enlarge with diseases of these areas. Lymphoma likely is the most common cause of visible enlargement. Sternal lymphadenopathy can be identified early on radiographs, as these nodes are relatively isolated from other soft tissue structures, making enlargement more readily visible. Since these nodes receive afferent drainage from the peritoneal cavity, enlargement should prompt investigation of abdominal disease.

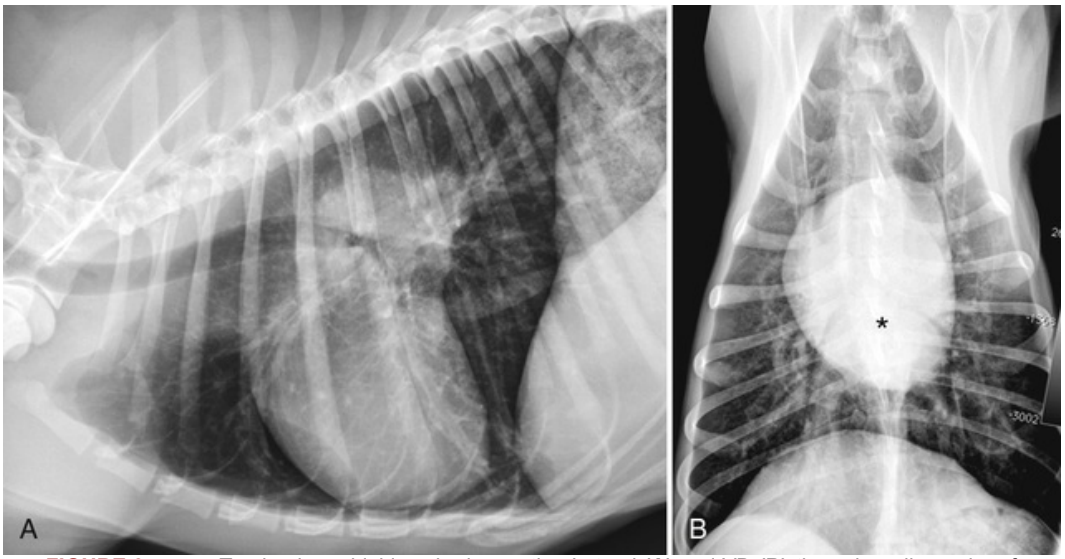

FIGURE 245-4 Tracheobronchial lymphadenopathy. Lateral **(A)** and VD **(B)** thoracic radiographs of a 3-year-old dog presented for coughing. The tracheobronchial lymph nodes are enlarged, and create a mass effect just dorsal to the carina resulting in ventral deviation of the caudal stem bronchi (lateral view). On the VD view, the enlarged tracheobronchial nodes (*) create an increased opacity over the base of the heart, and cause lateral deviation of the caudal stem bronchi.

Mediastinal Neoplasia

Mediastinal tumors can originate from any structure in the mediastinum (lymph nodes, thymus, great vessels, trachea, esophagus, or ectopic thyroid or parathyroid tissue) or from extension of neoplastic lesions in adjacent tissues.[56-59] Mediastinal neoplasms may also be metastatic lesions or components of a multicentric neoplastic process.[59-61] Benign tumors have been documented.[62]

Clinical signs associated with mediastinal tumors are usually caused by compression or invasion of structures such as the great vessels, thoracic duct, esophagus, and trachea, or due to associated pleural effusion. Signs include coughing, dyspnea, dysphagia, regurgitation, and edema of the head, neck, and/or forelimbs. Signs caused by peripheral nerve entrapment are less common and include laryngeal paralysis, vocalization changes, or Horner's syndrome. Signs associated with multicentric disease may reflect other sites of neoplastic involvement or may be related to paraneoplastic syndromes. These signs include anorexia, weight loss, regurgitation, vomiting, diarrhea, and polyuria/polydipsia.

Mediastinal lymphoma originates from either lymph node or thymic tissue in the cranial mediastinum (Figure 245-5 and Video 245-1), and is more common in the cat than the dog.[56,58] It typically occurs in younger cats (2-4 years of age), and they are often feline leukemia virus-positive.[56,58,61] Mediastinal lymphoma is often associated with pleural effusion, which may obscure radiographic visualization of the mediastinal mass. The diagnosis of mediastinal lymphoma can usually be confirmed by cytologic identification of neoplastic lymphocytes in either a sample of pleural fluid or a sample obtained directly from the mediastinal mass via fine needle aspiration (see ch. 74). In dogs, mediastinal lymphoma may be associated with hypercalcemia.[62,63]

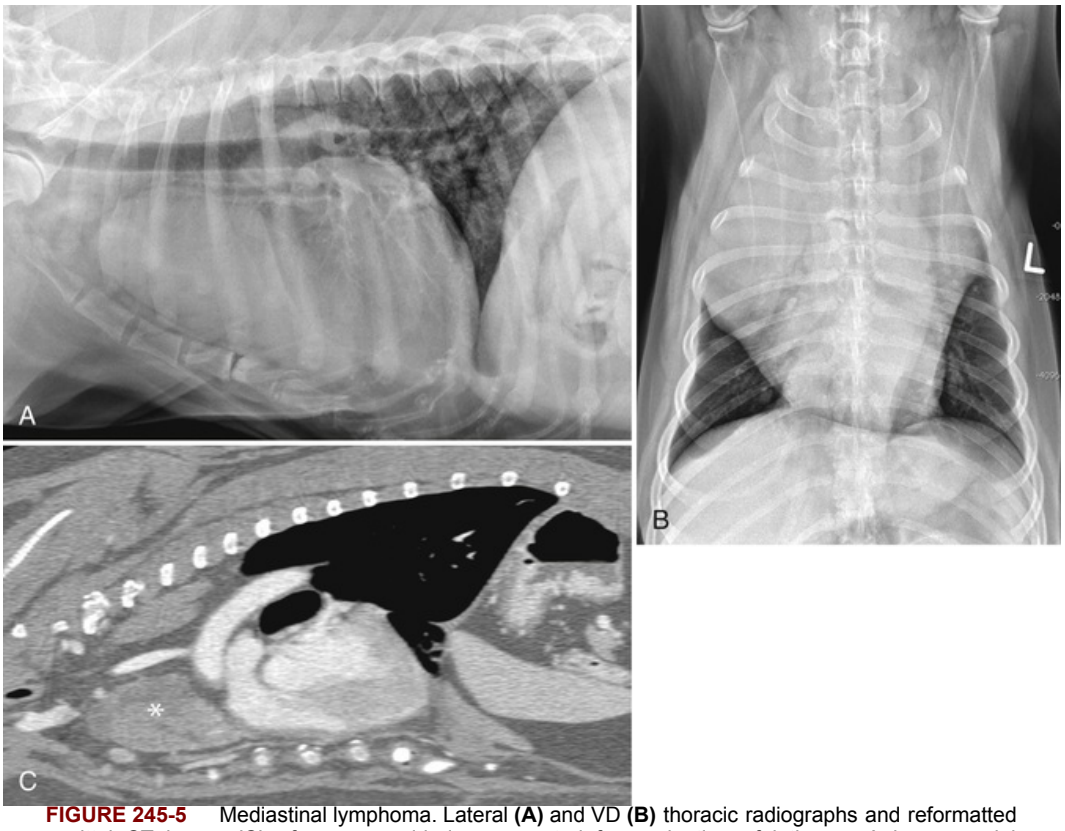

FIGURE 245-5 Mediastinal lymphoma. Lateral **(A)** and VD **(B)** thoracic radiographs and reformatted sagittal CT image **(C)** of a 7-year-old dog presented for evaluation of lethargy. A large cranial mediastinal mass is present. On the lateral view, the trachea is dorsally displaced, and there is border effacement with the cranial margin of the heart. On the VD view, the mass is centralized and cranial to the heart, but extends bilaterally. The CT image shows the cranial mediastinal mass (*). Lymphoma was diagnosed using ultrasound-guided fine needle aspiration, and it was subsequently removed surgically.

Chemodectomas, which are usually aortic or carotid body tumors, are most often identified as heart base masses (see ch. 254) (Figure 245-6).

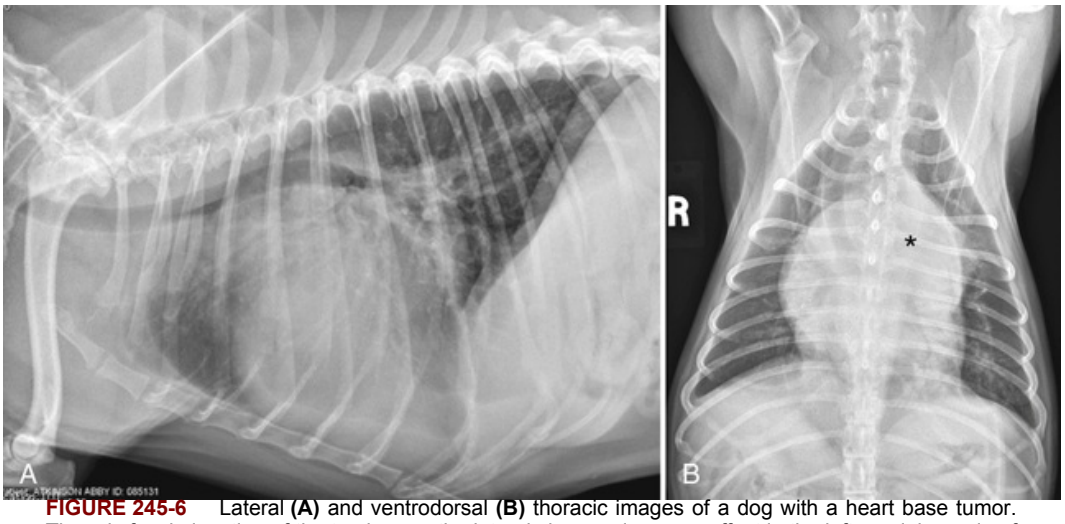

FIGURE 245-6 Lateral **(A)** and ventrodorsal **(B)** thoracic images of a dog with a heart base tumor. There is focal elevation of the trachea on the lateral view, and a mass effect in the left cranial margin of the heart on the VD view (*).

Other less common neoplastic mediastinal masses include ectopic thyroid carcinoma, neuroendocrine carcinoma, and anaplastic carcinoma.[59] The tumor type of a mediastinal mass cannot be determined on

radiographic signs alone. However, it is critical to identify this information, as the recommended treatment for cranial mediastinal tumors other than lymphoma is surgical resection. Computed tomography is invaluable in aiding in a more detailed evaluation of mass location, morphology, involvement with adjacent vessels, and identification of pulmonary metastasis.[64]

Diseases of the Thymus

The thymus extends from the thoracic inlet caudally to the fifth rib in the dog and the sixth rib in the cat. Dorsally, it lies next to the phrenic nerves and cranial lung lobes. Thymic involution in small animals occurs concurrently with the onset of sexual maturity and the loss of deciduous teeth.[65] The thymus atrophies and is gradually replaced by connective tissue and fat, but remnants persist into old age.[65]

Thymic Hemorrhage

An uncommon disease consisting of spontaneous thymic hemorrhage has been described in dogs and one cat.[56,66,67] Although not uniformly fatal, most animals documented with this syndrome have died. Most affected animals are <2 years of age; thus, it appears to be associated with thymic involution. Clinical signs include lethargy, signs of thoracic pain, increased respiratory effort, and dyspnea. Physical examination findings are attributable to acute blood loss/hypovolemia and pleural effusion. Signs include pale mucous membranes, prolonged capillary refill time, tachycardia, tachypnea, and muffled lung sounds. Thoracic radiographs demonstrate a mediastinal mass (hemorrhage, hematoma) usually associated with pleural effusion. Treatment is supportive and involves intravascular volume support (see ch. 129), blood replacement (see ch. 130), and thoracocentesis as needed (see ch. 102).

Thymoma

Thymomas are well-recognized but uncommon tumors in the dog and cat. Thymomas arise from the epithelial cells of the thymus, and can be benign or malignant.[56,57,61,68-71] This assessment appears to be based on invasiveness and resectability rather than histopathologic characteristics.[57] Malignancy is associated with invasiveness, vascular infiltration, and local or distant metastasis. Radiographically, a thymoma appears as a soft-tissue opacity in the cranioventral, or occasionally craniolateral aspect of the thorax (within the mediastinum). Tracheal deviation or compression, pleural effusion, or in some cases, megaesophagus and evidence of aspiration pneumonia, can be seen. Sonographically, thymomas can appear as solid, cystic, or both. Cytologic examination of FNA samples reveals a variable number of mature lymphocytes, which makes cytologic differentiation of thymoma from mediastinal lymphoma difficult. Mast cells also are frequently identified in cytologic samples from thymomas. Surgical or ultrasound-guided percutaneous biopsy is required for a definitive diagnosis. Paraneoplastic syndromes are common with thymoma in both dogs and cats,[68,72] notably myasthenia gravis (see ch. 269), which is often associated with megaesophagus (see ch. 273) in dogs with thymoma (Figure 245-7).[68] Also see ch. 352. Surgical resection is the treatment of choice for thymoma, but recurrence and metastasis have been reported.

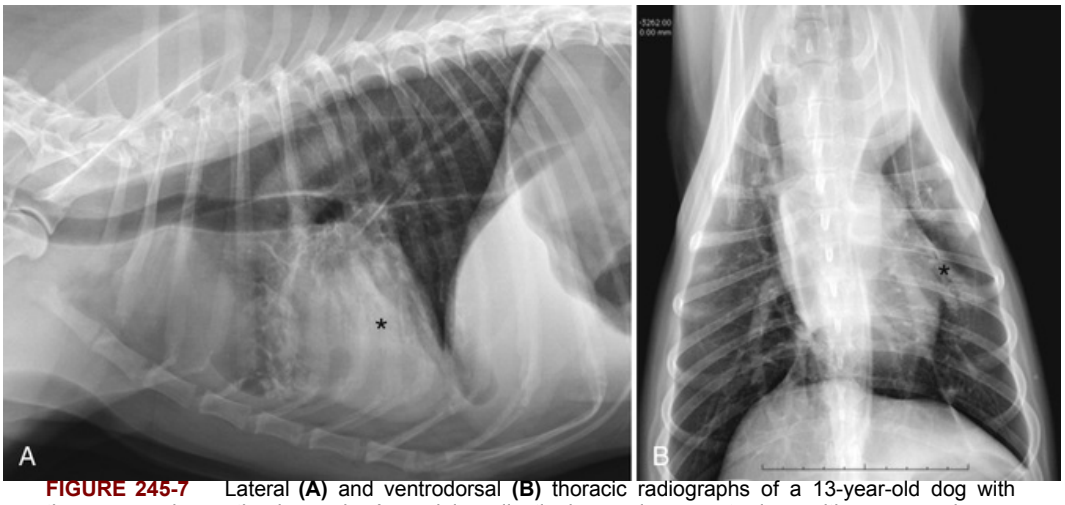

FIGURE 245-7 Lateral **(A)** and ventrodorsal **(B)** thoracic radiographs of a 13-year-old dog with thymoma and myasthenia gravis. A cranial mediastinal mass is present, along with megaesophagus. An alveolar lung pattern consistent with aspiration pneumonia is noted in the cranial subsegment of the left cranial lung lobe (*).

The Chest Wall and Diaphragm

Anatomy of the Chest Wall

The sternum and ribs surround and protect the thorax laterally and ventrally. Thirteen pairs of ribs and 8 sternebrae are normal. However, congenital abnormalities in numbers are common, and typically of no clinical significance. The last set of ribs (13th) may be smaller than normal, or even absent. Sternebrae may be fused or decreased in number. Lesions involving these structures are best evaluated on radiographs or CT scans of the thorax.

Diseases of the Ribs

Rib fractures commonly are associated with trauma, and should be carefully assessed on thoracic images taken after a traumatic incident. Flail chest occurs when at least 2 consecutive ribs are fractured both dorsally and ventrally, resulting in an independent wall segment. This segment demonstrates paradoxical movement with respiration, moving inward with inspiration, and outward with expiration. Mechanical failure secondary to chronic respiratory distress/coughing can result in nontraumatic rib fractures in cats with chronic airway disease.[73,74] These are usually the more caudal ribs (9-13), and involve the midportion.

Tumors involving the ribs, most commonly osteosarcoma and chondrosarcoma, can create an extrapleural mass lesion (a broad-based mass arising peripheral to the parietal pleura, creating a convex margin facing the lungs) and may result in a secondary pleural effusion (Figure 245-8). The ribs should be evaluated with care in patients with pleural effusion of unknown etiology. Computed tomography is an excellent imaging modality for a more detailed evaluation of the ribs and pleural space in these cases.

FIGURE 245-8 Chondrosarcoma of a rib. Dorsoventral thoracic radiograph of a 10-year-old dog presented for respiratory distress. Pleural effusion is present. A lytic lesion of the right 12th rib is present (arrow). Chondrosarcoma was diagnosed.

Diseases of the Sternum

Pectus excavatum is a deformity of the sternum and associated costal cartilages characterized by dorsal deviation of the sternebrae (usually the caudal sternebrae) and a dorsal to ventral compression of the thorax (Figure 245-9).[75-78] This is most often a congenital defect, but acquired pectus excavatum has been described secondary to chronic upper airway resistance, with increased inspiratory effort.[75] Clinical signs are dependent on the severity of the deformity, and are secondary to compression of the heart and lungs. While some patients have no clinical signs, others exhibit exercise intolerance, tachypnea, cyanosis, respiratory distress, and cardiac murmur. The murmur may be functional, secondary to cardiac malposition, or may be due to congenital heart defect concurrent with the pectus excavatum. Clinical signs can be progressive, and in some cases, life-threatening. A mild to severe dorsal deviation of the caudal sternebrae with deviation of the cardiac silhouette are the most common radiographic changes. Treatment is dependent on the severity of the deformity and associated signs, and ranges from conservative management to surgical repair.

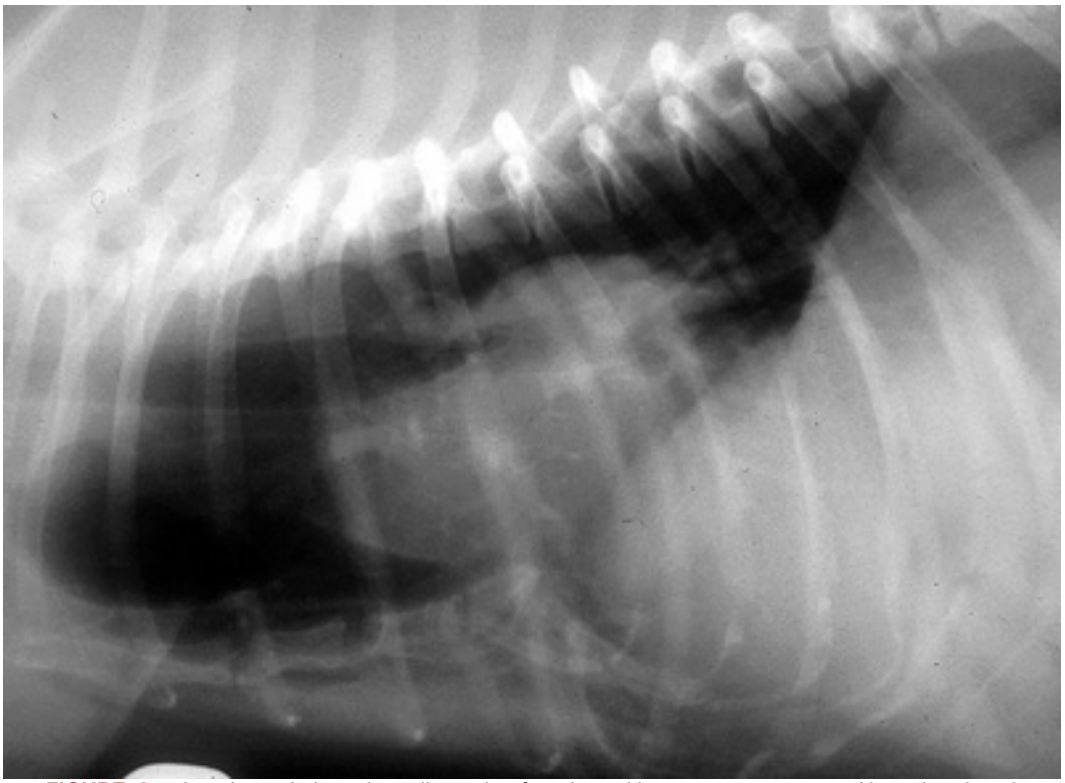

FIGURE 245-9 Lateral thoracic radiograph of a dog with pectus excavatum. Note the dorsal deviation of the caudal aspect of the sternum.

Diaphragm

Anatomy

The diaphragm is the musculotendinous partition between the thoracic and abdominal cavities.[79] The muscular portion is composed of the pars lumbalis, attaching to the ventral aspect of the third and fourth lumbar vertebrae (forming the left and right crura), the pars costalis, which attaches to ribs 8-13, and the pars sternalis, attaching to the xiphoid cartilage of the sternum.

Diaphragmatic Hernia (Traumatic)

The most common disease of the diaphragm is traumatic rupture, often secondary to vehicular trauma or falls. With rupture, varying amounts of abdominal viscera become displaced cranial to the diaphragm; the most frequently herniated organ in the cat is the liver, followed by small intestine, stomach, omentum, spleen, pancreas, and large intestine.[80] A similar order of organ herniation is present in reports in the dog (liver, small bowel, stomach, spleen, omentum).[81,82] Clinical signs of acute diaphragmatic hernia most often are related to respiratory compromise, and include dyspnea, coughing, exercise intolerance, or lethargy. On thoracic radiographs, herniated organs may be visualized cranial to the diaphragm, especially if gas-filled, such as the stomach or intestines (Figure 245-10). The displaced liver or spleen (solid organs) may be difficult to differentiate from pleural effusion or pulmonary consolidation. Cranial displacement of abdominal organs, or absence of visualization in their normal location, may be noted. Occasionally, the herniated viscera have a focal appearance, mimicking a pulmonary mass.[83] Pleural effusion often is present, especially with chronic diaphragmatic hernias.[82] Not all diaphragmatic hernias are recognized immediately, likely due to minimal clinical signs, poorly defined radiographic changes, or lack of awareness of a traumatic incident. Clinical signs of chronic hernias may be nonspecific, and include anorexia, lethargy, vomiting, or weight loss. Not all patients have respiratory signs. Ultrasound and CT are beneficial as adjunct imaging modalities for the detection of abdominal viscera cranial to the diaphragm, especially when pleural effusion obscures visualization on thoracic radiographs.

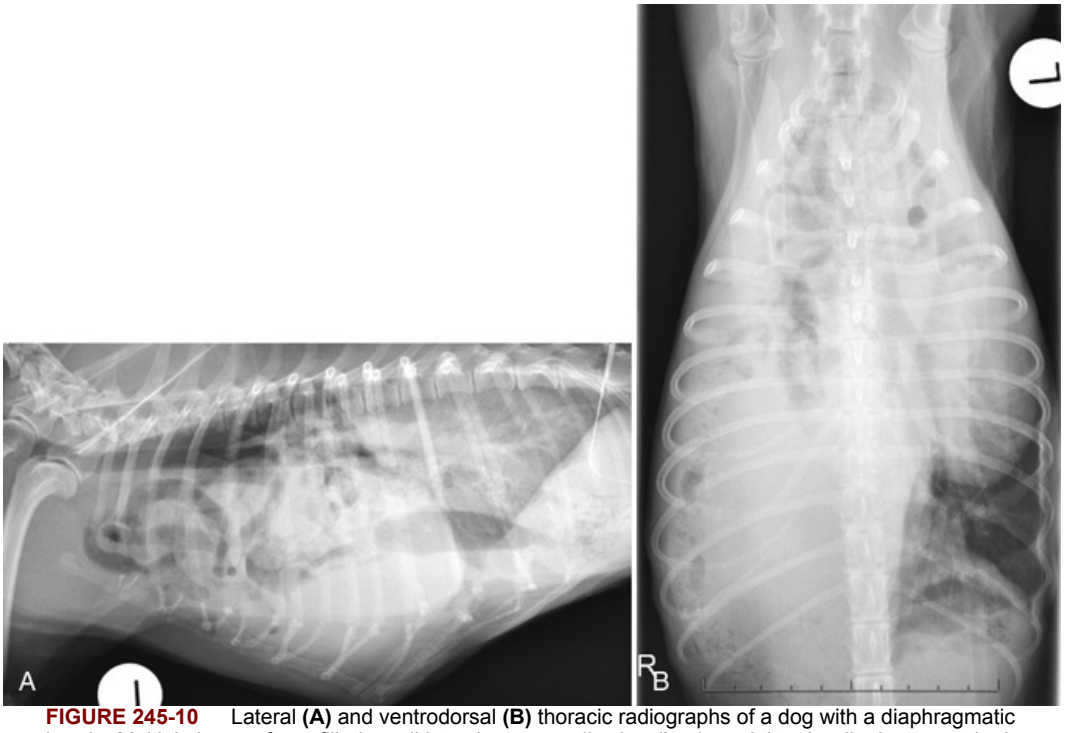

FIGURE 245-10 Lateral **(A)** and ventrodorsal **(B)** thoracic radiographs of a dog with a diaphragmatic hernia. Multiple loops of gas-filled small intestine are easily visualized cranial to the diaphragm on both views. The liver was also herniated.

Peritoneopericardial Diaphragmatic Hernia

Peritoneopericardial diaphragmatic hernia (PPDH) is discussed with pericardial diseases, ch. 254.

Hiatal Hernia

Hiatal hernias (Figure 245-11) are discussed with disorders of the esophagus, ch. 273.

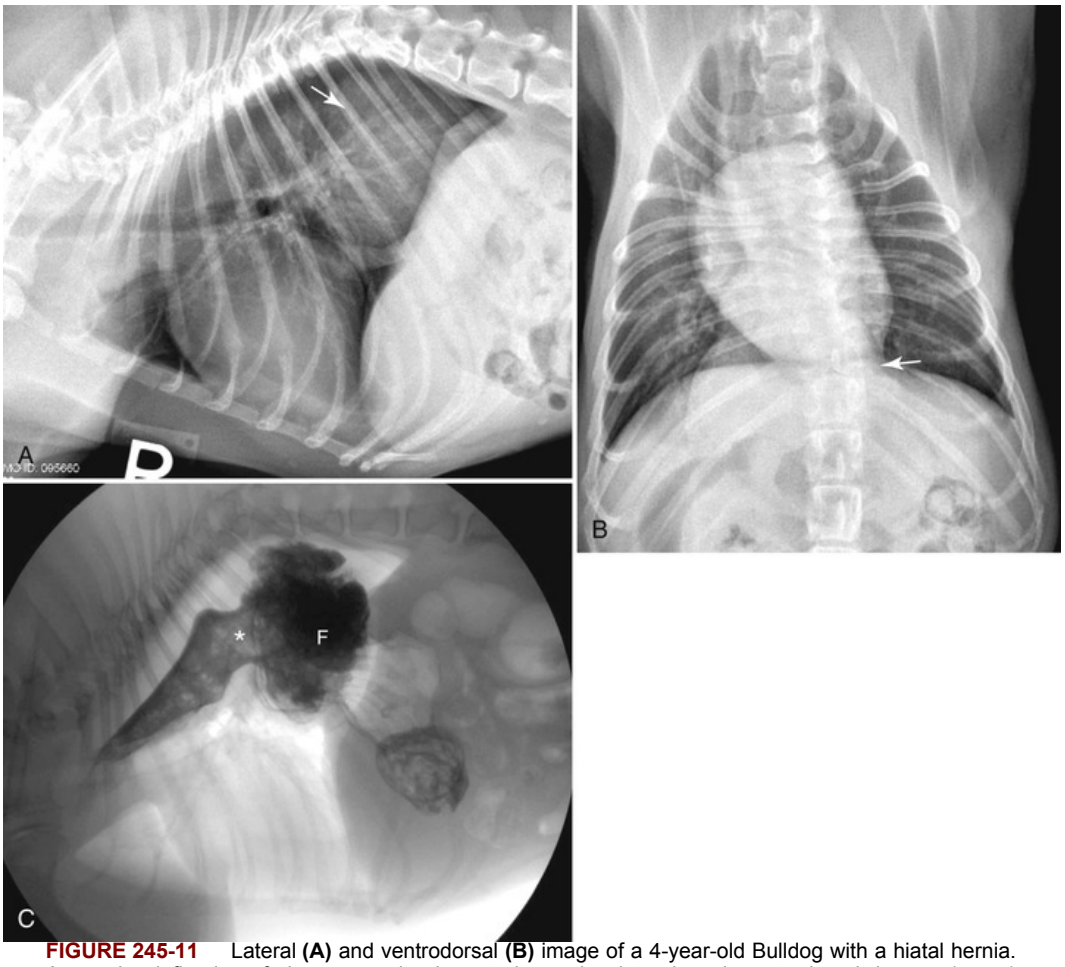

FIGURE 245-11 Lateral **(A)** and ventrodorsal **(B)** image of a 4-year-old Bulldog with a hiatal hernia. A poorly defined, soft-tissue opacity is noted on the lateral and ventrodorsal image (arrow) representing the hernia. A lateral fluoroscopic image **(C)** taken after barium contrast administration shows the cranial displacement of the gastroesophageal junction (*) and fundic portion of the stomach (F).

CHAPTER 246

Pathophysiology of Heart Failure

Katherine F. Scollan, D. David Sisson

The heart has two fundamental mechanical functions that are essential for operation of the circulatory system. One is to eject enough blood into the aorta and pulmonary arteries with sufficient force to meet the perfusion requirements of the metabolizing tissues. The other essential function of the heart is to receive blood from the pulmonary and systemic veins in a manner that provides adequate drainage of the pulmonary and systemic capillary beds and maintains an appropriate distribution of the circulating blood pool. Mean arterial pressure in the systemic arterial tree approximates 90 to 100 mm Hg in healthy dogs and cats, ensuring adequate distribution of blood through the multitude of vascular beds in this high-resistance circuit. Mean arterial pressure in the low-resistance pulmonary circuit averages around 20 mm Hg.

Cardiac failure can be defined as the pathophysiologic state wherein the heart is impaired in its ability to eject or receive blood, and this impairment becomes severe enough to overwhelm the compensatory mechanisms of the cardiovascular system.[1] Heart disease is defined as the presence of any cardiac finding outside the accepted limits of normality, including a cardiac murmur, abnormal cardiac rhythm on electrocardiogram (ECG), or reduced contractility noted on echocardiogram. The presence of identifiable heart disease does not inherently imply that heart failure is currently present or will ever manifest as a clinical problem. Heart failure is present when abnormal cardiac function results in either the retention of sodium and water and elevated venous and capillary pressures *(congestive heart failure or backward failure)* or inadequate cardiac output *(low-output heart failure* or *forward failure)*.

Heart failure can result from functional impairment of the myocardium, heart valves, or pericardium, or as a consequence of increased resistance to ejection. Myocardial failure is defined as a decrease in myocardial contractility and is not synonymous with heart failure. Although myocardial failure is common in patients with heart failure, some patients suffer heart failure even though myocardial function is preserved. Relevant examples include patients that experience massive pulmonary thromboembolism, acute valvular insufficiency, or cardiac tamponade. It is helpful for the practicing clinician to be mindful that normal circulatory function is dependent on the overall functional integrity of the heart, the vascular bed, and the blood, together with its regular mass of circulating red blood cells.[2] Signs of circulatory failure develop with serious compromise of any one of these components of this integrated system. Thus, although all patients with heart failure evidence signs of circulatory failure, the converse is not necessarily true.

Pathogenesis

Heart failure is a progressive disorder that begins with an initial insult or event that perturbs myocyte or myocardial function. It is clinically helpful to characterize patients with heart failure based on the main or the most obvious functional consequences of their underlying disease (Box 246-1). Accordingly, some patients develop signs of heart failure primarily as a consequence of impaired cardiac filling due to restrictive pericardial diseases, mitral and tricuspid valvular stenoses, cor triatriatum, or primary myocardial disorders that reduce ventricular compliance including hypertrophic and restrictive cardiomyopathy. Patients that develop heart failure from these diseases are often appropriately described as suffering from *diastolic heart failure* due to the primary effect of reduced diastolic filling. The concept of ventricular compliance is best explained by a graphic display of the ventricle's end-diastolic pressure-volume relationship, the slope of which defines compliance at any given level of preload (Figure 246-1).[3] Distensibility is closely related to compliance and refers to the pressure that is required to fill the ventricle to a specified volume. Given the same end-diastolic volume, end-diastolic pressure will be higher if the ventricle is stiffer (less distensible and less compliant) than normal.

Box 246-1

Functional Classification of Heart Failure

Heart Failure Resulting from Impeded Cardiac Filling

Pericardial Disease with Restricted Filling
Pericardial effusion with tamponade
Constrictive pericarditis

Valvular Inflow Obstruction
Atrioventricular valve stenosis
Other anatomic obstructions
  Cor triatriatum
  Neoplasms, granulomas

Intrinsic Myocardial Disease with Impaired Diastolic Function
Hypertrophic cardiomyopathy
Restrictive cardiomyopathy

Heart Failure Resulting from Increased Resistance to Ejection

Increased Resistance to the Ejection of Blood (Afterload)
Discrete outflow tract obstruction
  Pulmonic and (subvalvular) aortic stenosis
  Hypertrophy *obstructive* cardiomyopathy
Thromboembolism of the great vessels
Pulmonary hypertension

Heart Failure Resulting from Impaired Ejection or Volume Overload

Primary and Secondary Myocardial Disease with Impaired Systolic Function
Dilated cardiomyopathy
Ischemic, infectious, nutritional, and toxic myocardial disorders

Misdirected Blood Flow Resulting in Volume Overload
Valvular insufficiency
Left-to-right shunts, arteriovenous fistulas

Chronic High-Output States
Thyrotoxicosis, chronic anemia

Heart Failure Resulting from Arrhythmias and Conduction Disorders

Sustained Tachyarrhythmias
Supraventricular tachycardia
Atrial fibrillation

Chronic Bradyarrhythmias
Complete heart block

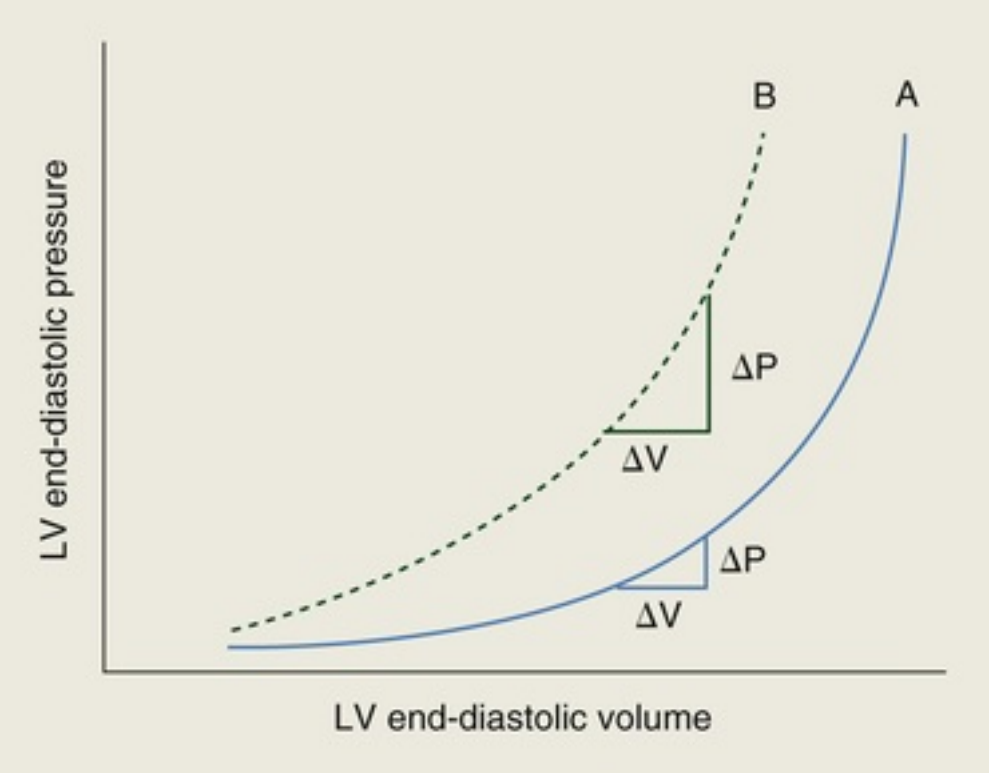

FIGURE 246-1 Ventricular compliance is the reciprocal of stiffness and is determined by the volume and geometry of the chamber, as well as the thickness and tissue characteristics of its walls. This graphic displays the relationship of ventricular end-diastolic pressure to the volume of the ventricle for a healthy subject **(A)** and a patient with reduced ventricular compliance **(B),** defined as the slope of the diastolic pressure-volume relationship. At any given volume, patients with reduced ventricular compliance will have a higher end-diastolic pressure compared with a healthy subject. *LV,* Left ventricle.

In other patients, heart failure results from dramatically increased afterload that impedes ventricular ejection including aortic or pulmonic stenosis, acute pulmonary thromboembolism, and chronic systemic or pulmonary hypertension. Afterload represents the sum of all those forces that oppose the ejection of blood from the ventricle into the circulation and is often expressed as the systolic tension or wall stress experienced by the ventricles during the period of ejection.[4] Afterload is determined mainly by the peripheral (systemic) vascular resistance (SVR), the physical properties (compliance) of the arterial tree, and the volume of blood in the ventricle at the onset of systole.

Volume overload, whether the result of a left to right shunt or valvular insufficiency, is a commonly encountered cause of heart failure wherein ventricular systolic performance is impaired due to the combined influence of misdirected blood flow and a progressive decline in myocardial contractility. Conversely, patients with primary myocardial failure, including dilated and ischemic cardiomyopathy, secondarily develop volume overload due to decreased contractility and altered chamber geometry. Inasmuch as the diastolic and systolic functions of the heart are interrelated, both tend to be concurrently compromised in animals with many heart diseases. It is nonetheless clinically useful to distinguish those patients with reduced systolic pump function from those with compromised diastolic function and normal or nearly normal systolic function.

Cardiac arrhythmias and conduction disturbances may exert adverse effects on systolic or diastolic function depending on the type and duration of the rhythm disturbance (see ch. 248). In some clinical situations, it can be quite difficult to determine if a specific arrhythmia is the cause of the observed functional deficit or an unfortunate complication of pre-existing heart disease. Patients with severe chronic anemia, arteriovenous fistulas, or hyperthyroidism may experience signs of heart failure even though their cardiac output equals or exceeds that of normal animals, termed *high-output heart failure.*[5] In these circumstances, cardiac output after the onset of heart failure is always less than it was prior to the onset of heart failure, indicating that the heart can no longer meet the increased blood flow requirements imposed by the underlying disorder.

Regardless of the inciting abnormality, many patients with heart disease remain asymptomatic for a period of time, likely due to the activation of a number of compensatory mechanisms. Ultimately, sustained

activation of these neurohormonal and cytokine compensatory mechanisms leads to end organ changes and cardiac remodeling, and thus precipitate the progression of heart failure.[2]

Progression of Heart Disease to Heart Failure

Neurohormonal Alterations

There is evidence that suggests that heart failure develops as a result of the overexpression of biologically active agents that are capable of exerting deleterious effects on the heart and circulation.[6] Neuroendocrine responses to developing heart failure have been well documented in human patients wherein there is a demonstrable increase in the activity of the adrenergic nervous system, activation of the renin-angiotensin-aldosterone system, overexpression of atrial and brain natriuretic peptides, augmented synthesis and release of adrenomedullin, endothelin and arginine vasopressin, and amplified expression of a number of proinflammatory cytokines such as tumor necrosis factor-alpha, interleukin-1, and interleukin-6.[7] More recently conducted studies in dogs and cats with heart disease indicate the operation of qualitatively similar neuroendocrine responses.[8] Understanding these complex systems is vital to understanding the pathogenesis of heart failure and the rationale of modern treatment strategies. Based on the neuroendocrine hypothesis that the progression of heart failure is a consequence of the excessive operation of certain maladaptive neuroendocrine responses, such as the adrenergic and renin-angiotensin-aldosterone systems, much investigation has been directed at treatment strategies that blunt or otherwise modify these responses. Familiarity with the mediators of these adaptive responses aids the astute observer in that plasma concentrations of certain neurohormones, such as NT-proBNP, are able to serve as valuable biomarkers that can be used to more accurately establish a diagnosis of heart failure.

Sympathetic Nervous System Activation

Early in the progression of heart failure, increased heart rate and contractility, through the activation of the sympathetic nervous system (SNS), are the dominant compensatory mechanisms employed to combat declining cardiac performance.[2] The primary determinants of stroke volume and cardiac output include preload, afterload, heart rate, myocardial contractility, and ventricular synchrony. Resting cardiac output is often restored to nearly normal levels in patients with heart failure by a moderate increase in heart rate. Sympathetic activation increases heart rate by affecting the rate of SA nodal depolarization. Stimulation of beta-adrenergic receptors increases the firing rate of SA nodal cells by increasing the slow inward calcium current, I_{CaL}. Additionally, SNS activation shifts the activation curve of the inward pacemaker current, I_f, to more positive voltages via G_s-dependent stimulation of adenylyl cyclase. The precise effect of heart rate on cardiac output has immense clinical relevance. Cardiac output increases linearly with heart rate up to a certain threshold value; thereafter, the shortened diastolic interval causes a reduction in stroke volume blunting the slope of this curve (Figure 246-2).[9] At very fast heart rates, stroke volume is diminished to the extent that cardiac output begins to decline. It is noteworthy that stroke volume begins to decline at a lower heart rate and to a greater extent in heart failure patients than in normal individuals. This imposes a very real limitation on this adaptive response and contributes to the dismal performance of heart failure patients attempting to exercise.

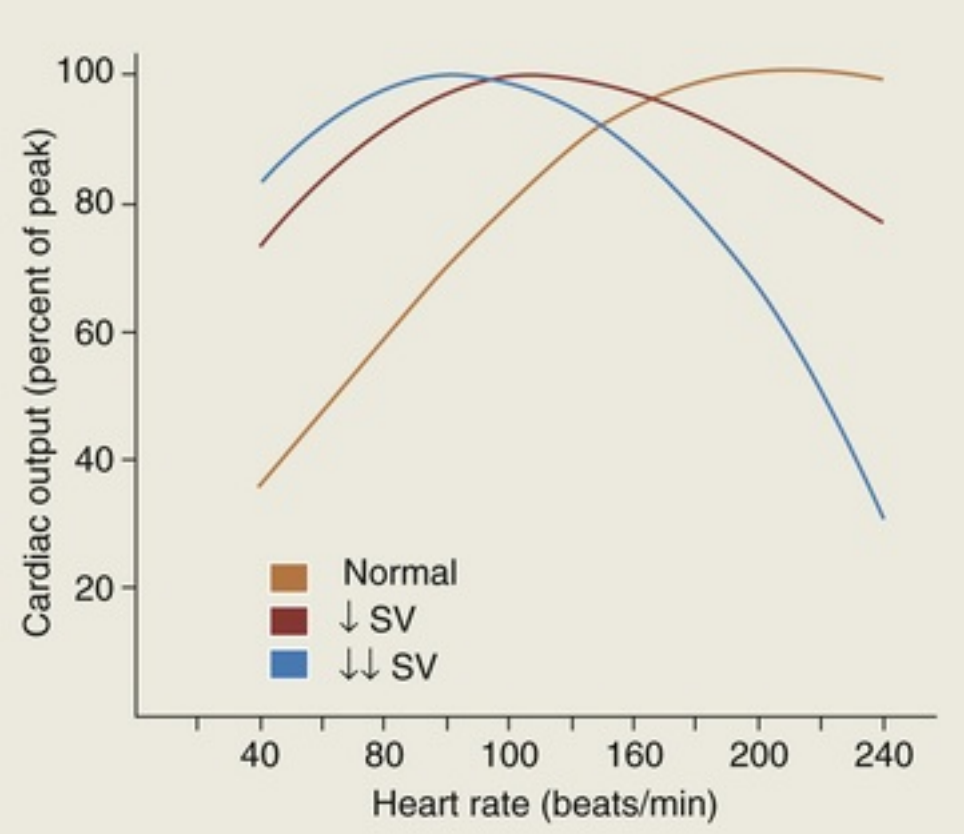

FIGURE 246-2 In dogs with heart disease, maximal cardiac output is achieved at a lower heart rate than in healthy dogs. When ventricular function is compromised, excessive heart rates lead to a substantial decline in stroke volume (SV) and a reduction in cardiac output. It should be noted that it is very difficult to determine optimal heart rate in an individual patient.

Myocardial contractility, the intrinsic force of contraction of the myocardium independent of loading conditions, is increased by adrenergic nervous stimulation, circulating catecholamines, heart rate, and to some extent, afterload. In the early stages of myocardial failure, declining contractility is concealed by adrenergic activation. Through the action of the stimulatory G_s protein, beta-adrenergic stimulation leads to the activation of adenylyl cyclase, and the formation of cyclic AMP (cAMP), which then activates protein kinase A (PKA).[10,11] Activated PKA phosphorylates a number of key proteins (such as the L-type calcium channels, ryanodine, phospholamban, and SERCA2) that facilitate calcium transport across the sarcolemma, augment calcium-induced calcium release by the sarcoplasmic reticulum (SR), and increase calcium reuptake by the SR.[10,11] Protein kinase A also increases the activity of a variety of other proteins that augment the rate and force of contraction of the myofilaments (troponin I and myosin-binding protein C).

Adrenergic venous constriction in patients with heart failure results in an immediate increase in venous return (preload). Increased preload induces a more forceful cardiac contraction and a corresponding increase in stroke volume as described by the Frank-Starling law of the heart (Figure 246-3). Increased diastolic stretch of myocardial fibers increases the sensitivity of the contractile elements to cytosolic calcium, a process that is sometimes referred to as *length-dependent activation*.[12]

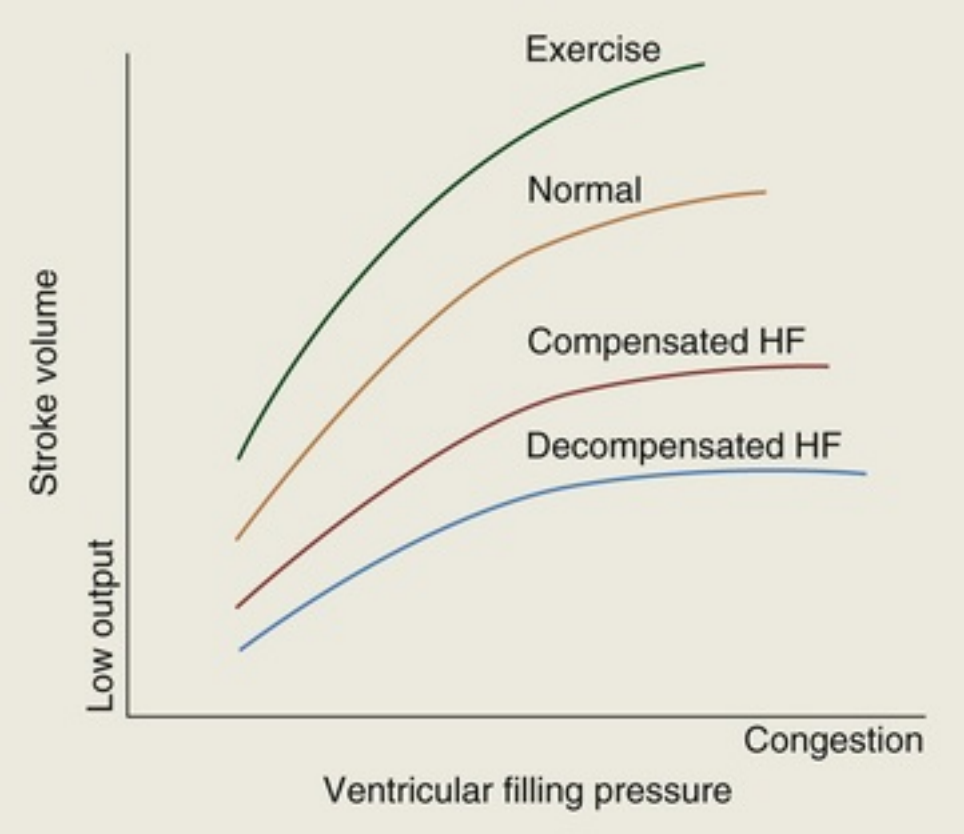

FIGURE 246-3 In normal subjects, ventricular stroke volume increases as venous return and ventricular filling pressures increase. This becomes most dramatic with exercise when increased contractility and reduced afterload augment the Frank-Starling mechanism. In patients with heart failure (HF), the Frank-Starling mechanism is compromised by the combination of reduced contractility, increased afterload, and, in some patients, reduced ventricular diastolic function.

The activation of the SNS provides a short-term mechanism to support cardiac performance, although chronic exposure to high norepinephrine (NE) levels becomes maladaptive. Myocardial performance in patients with diminished contractile reserves may be negatively impacted by the resulting mismatch of afterload to contractility. This consequence is also exaggerated in patients with chronic heart failure wherein downregulation and uncoupling of cardiac beta$_1$-receptors further diminishes the contractile response. Depletion of myocardial norepinephrine stores also augments mismatching as it renders the heart overly reliant on circulating levels of catecholamines. The process of downregulation is accomplished by reduced transcription of mRNA and this mechanism is well established for the beta$_1$-receptor.[6,13] By a distinctly different process, increased myocardial expression of beta-receptor kinase (βARK) facilitates uncoupling of cardiac beta$_1$- and beta$_2$-receptors from G proteins, via the action of beta arrestin, thereby reducing the subsequent production of cyclic AMP.[14] The result of all these perturbations is a diminished increase in heart rate and myocardial contractility in response to adrenergic stimulation.

The adrenal medulla synthesizes and stores both NE and epinephrine (EPI) and releases them into the circulation in response to acute stress. Unlike the adrenal gland, peripheral nerves lack the enzyme phenylethanolamine N-methyltransferase and do not synthesize or release epinephrine. Thus, NE, not epinephrine, plays a central role as a neurotransmitter and is constantly released from terminal sympathetic nerve endings. Despite reuptake and inactivation of most of the NE released in this fashion, a small portion leaks into the circulating blood so that plasma levels of NE, measured at rest, can serve as a useful index of sympathetic nervous system activity. Plasma NE concentrations in human congestive heart failure (CHF) patients correlate with the severity of heart failure and are inversely related to survival.[15] Furthermore, rising concentrations of NE in human patients treated for CHF correlate with a decline in clinical status.[16] Importantly, catecholamine plasma concentrations are known to rise in many circumstances other than heart failure, including emotional stress and physical exertion, emphasizing the rather poor specificity of such measures. For these reasons, interpretation of plasma catecholamine levels in individual patients will always

be problematic.

The estimation of adrenergic activity in dogs and cats in a clinical setting is challenging and there are large variations of such plasma catecholamines even in patients appropriately categorized according to the severity of underlying heart disease. Ware and colleagues[17] first reported significantly elevated plasma NE levels in small numbers of dogs with naturally-occurring heart failure due to dilated cardiomyopathy (DCM) and chronic degenerative valve disease (CDVD) compared with normal dogs. Plasma concentrations of NE correlated directly with the severity of heart failure and they tended to be higher in dogs with DCM compared with dogs with CDVD. Plasma EPI levels in dogs with heart failure were also slightly higher than those measured in control dogs, but the difference was not statistically significant. In a larger study,[18] Sisson et al found that plasma EPI and NE concentrations averaged 133 pg/mL and 254 pg/mL, respectively, when healthy client-owned dogs were sampled by jugular venipuncture. In dogs with heart failure due to CDVD, both EPI and NE were significantly elevated to 314 pg/mL and 314 pg/mL, respectively; and in dogs with DCM, EPI and NE increased to 211 pg/mL and 631 pg/mL, significantly different from controls but not significantly different from the dogs with heart failure due to CDVD. Less dramatic, but still significant, elevations of EPI (290 pg/mL) and NE (445 pg/mL) were identified in dogs with CDVD that had not yet evidenced signs of congestive heart failure. In cats with congestive heart failure or systemic thromboembolism due to hypertrophic and restrictive cardiomyopathy, we found plasma EPI and NE concentrations above 2000 pg/mL and 2500 pg/mL, compared with 250 pg/mL and 1000 pg/mL, respectively, in healthy cats sampled by jugular venipuncture.[19] In healthy, relaxed cats with preplaced jugular catheters we measured EPI and NE concentrations at 221 pg/mL and 424 pg/mL, respectively. In cats with hypertrophic or restrictive cardiomyopathy that were not in heart failure, we found plasma EPI and NE concentrations above 1500 pg/mL and 1700 pg/mL, respectively. These results convincingly establish that sympathetic nervous system activity is increased in dogs and cats with naturally-occurring heart disease, not unlike that observed in human patients.[16,20]

RAAS Activation

Reduced cardiac output and activation of the SNS in heart failure leads to activation of the renin-angiotensin-aldosterone system (RAAS). The components of the RAAS are activated later in HF compared to the SNS. The major stimuli for the release of renin from the juxtaglomerular cells of the kidney include decreased effective renal perfusion, reduced sodium reabsorption by the renal tubules, and beta$_1$-adrenergic stimulation.[21,22] Not surprisingly, low-sodium diets, dehydration, blood loss, and vigorous exercise all stimulate renin release from the juxtaglomerular apparatus. The main action of renin is to accelerate the conversion of the large prohormone angiotensinogen to the decapeptide angiotensin I, which is subsequently converted to the octapeptide, angiotensin II (AT II), by angiotensin-converting enzyme (ACE). Angiotensinogen is a globular glycoprotein produced in the liver and released into the circulating plasma, which serves as the primary storage reservoir.[21] Angiotensin II inhibits renin formation, exemplifying the phenomenon of classic feedback inhibition.

When first discovered, the RAAS was thought to act almost exclusively within the confines of the vascular bed. Now, the vast majority of ACE in the body is known to reside in the tissues, with less than 10% in the circulation.[23] Moreover, all of the various components of RAAS can be found in a variety of tissues including the brain, myocardium, vasculature, adrenal gland, and kidney, and many investigators believe that tissue RAAS is activated at an earlier stage of heart failure than the circulating components.[24] It is likely that the role of the tissue RAAS varies in different circumstances and in accordance with the nature of the underlying disease. Angiotensin II, derived from cardiomyocytes and fibroblasts, plays a particularly substantive role in the development of certain types of pathologic remodeling, acting via G_q and the operation of multiple mitogen activated protein kinases (MAPKs). ACE is a dipeptidyl carboxypeptidase and it acts by cleaving terminal dipeptides from the C-terminus of substrate peptides. The selectivity of ACE is such that it cleaves any substrate peptide, R1-R2-R3-OH, where R1 is a protected L–amino acid, R2 is any L–amino acid except proline, and R3 is any L–amino acid with a free carboxy-terminal. Thus, ACE converts angiotensin I to active angiotensin II and also inactivates the potent vasodilator, bradykinin. The conversion of angiotensin I to angiotensin II can be accomplished by enzymes other than ACE including cathepsin G, elastase, tissue plasminogen activator, chymase, and chymostatin-sensitive AII-generating enzyme (CAGE).[25,26] The importance of these alternate pathways is species-dependent, and several reports suggest that tissue chymase is more active than ACE in the myocardium and extracellular matrix of dog and cats.[26,27] Sequential actions of aminopeptidase and ACE acting on angiotensin I produces angiotensin III, a 7–amino acid peptide

(heptapeptide) that has actions similar to but less potent than angiotensin II.[25,28]

The physiologic actions of AT II have been thoroughly explored and all of its important physiologic effects appear to be mediated by AT_1 receptors, which are abundantly located in blood vessels, the kidney, liver, heart, pituitary, and adrenal glands.[21,28] The half-life of circulating AT II is on the order of 1 or 2 minutes as it is rapidly hydrolyzed to inactive peptide fragments by circulating and tissue angiotensinases. In addition to its role as a potent vasoconstrictor, AT II promotes sodium and water retention via direct effects on the renal tubules and indirectly by stimulating aldosterone production and release from the adrenal glands. Angiotensin II and aldosterone play essential roles regulating sodium and water balance and maintaining vascular pressure when the circulating blood volume is reduced by hemorrhage or salt and water deprivation. Reactive oxygen species (ROS), generated as a consequence of increased AT II and aldosterone expression, are central to the development of myocardial hypertrophy and the detrimental vascular and ventricular remodeling processes observed in patients with chronic heart failure.[25,29,30]

Major stimuli for aldosterone production and release include AT II, elevated potassium levels, and corticotropin (ACTH) (see ch. 308). Other messengers, including plasma catecholamines, endothelin-1, and arginine vasopressin, are also known to promote the production and release of aldosterone into the tissues and blood.[25,30] The main physiologic effects of aldosterone have traditionally been attributed to its effects on the kidney, where it exerts sodium-conserving effects. In this regard, aldosterone acts on epithelial cells of the distal collecting ducts, where it diffuses into the cytoplasm and binds to cytoplasmic mineralocorticoid receptors (MRs).[21,25,30] Following their entry into the nucleus, activated MRs induce a cascade of events that ultimately increase absorption of sodium ions and excretion of potassium. Aldosterone production is not confined to the adrenal gland and mineralocorticoid receptors are more widely distributed than previously realized. In patients with heart failure, aldosterone contributes to baroreceptor dysfunction, enhancing the activity of the sympathetic and diminishing the actions of the parasympathetic nervous systems. Aldosterone also contributes to generalized vasoconstriction via mineralocorticoid receptor-mediated stimulation of sympathetic nervous system activity, via inhibition of NE uptake and degradation in the periphery, and via other complex actions contributing to endothelial cell dysfunction.[21,29,31] Of particular interest is the emerging role of aldosterone as a mediator of inflammation, fibrosis, and other biologic processes, such as oxidative stress, involved in pathologic remodeling in the vasculature, kidney, and heart.[29-31] Aldosterone-induced cytokine synthesis is an important component of these pathologic remodeling processes. Many of the advances in the treatment of heart failure and systemic hypertension realized in the recent past have resulted from the use of compounds that prevent the formation of AT II via inhibition of ACE, that block the interaction of angiotensin II with AT_1 receptors (ARBs), or that antagonize the actions of aldosterone.

Substantial elevations of plasma renin activity and serum aldosterone levels have been identified in dogs with overt congestive heart failure due to mitral regurgitation (MR) and dilated cardiomyopathy (DCM), as well as in cats with hypertrophic or restrictive cardiomyopathy (HCM, RCM). Activation of RAAS is particularly marked in dogs and cats with acquired heart disease when furosemide is used to alleviate congestive signs. There is some disagreement about the role of RAAS in patients with less severe heart disease. Several investigators have noted that plasma renin activity and aldosterone concentrations are within the normal range or only slightly elevated in dogs and cats with heart disease prior to the onset of overt heart failure.[32,33] It is also noteworthy that plasma renin activity and aldosterone concentrations are not always elevated in patients with overt congestive heart failure.[34,35] Given that the physiologic effects of RAAS activation include volume expansion and vasoconstriction, both of which serve to diminish renin production, the activity of this system tends to be phasic and to conceal its activation. Thus, while there is unanimity of opinion regarding the activation of RAAS in dogs and cats with overt congestive heart failure, there is uncertainty regarding the precise point of its upregulation in patients with less severe heart disease.

Neurohormonal Alterations of Renal Function

In heart failure, several mechanisms result in the renal retention of sodium and water.[36] Despite overall volume expansion in the setting of heart failure, inadequate cardiac output results in a decreased effective arterial blood volume. This is sensed by arterial baroreceptors and leads to the sustained activation of the SNS and RAAS. Decreased renal perfusion and increased renal sympathetic nerve-mediated vasoconstriction cause decreased renal blood flow and increased sodium and water retention. Angiotensin II causes increased thirst and stimulates the release of aldosterone and arginine vasopressin (antidiuretic hormone, ADH), both of which cause further water retention. Moreover, norepinephrine augments the activity of the RAAS and

stimulates the synthesis and release of ADH. Blunting of the renal response to natriuretic peptides further tips the imbalance of competing mechanisms from vasodilatory/natriuretic to vasoconstrictive/sodium retention.[37] The eventual results of these alterations include diminished and redistributed renal blood flow, a concomitant reduction in sodium excretion, and elevated plasma levels of arginine vasopressin with retention of solute-free water. The continued sodium and water retention in the setting of heart failure ultimately leads to excessively elevated venous pressures and the development of edema and effusion.

Natriuretic Peptides

Atrial and brain (B-type) natriuretic peptides, ANP and BNP, released from the heart, and C-type natriuretic peptide, located mainly in the vasculature, play important regulatory roles in the circulation and provide balance to the vasoconstrictive and sodium retaining agents. In healthy humans, cats, and dogs, circulating forms of BNP and ANP are probably derived mainly from the atria, where they are stored as precursor molecules, proANP and proBNP, in membrane-bound granules for later release.[38-41] The third natriuretic peptide, C-type or CNP, is located primarily in the vascular endothelium. Circulating levels of CNP are much lower than those of ANP and BNP in healthy animals and humans, suggesting that it acts in a paracrine fashion inducing local relaxation of vascular smooth muscle and inhibiting vascular remodeling. Sudden rises in plasma ANP and BNP levels are accomplished by their release from atrial storage granules mainly by the stimulus of atrial stretch. Sustained increases in circulating ANP and BNP, as seen in patients with heart disease, are accomplished by increased m-RNA expression in different regions of the heart.[42] In patients with myocardial disease, plasma BNP concentrations rise dramatically and often surpass ANP levels as the major site of BNP production switches from the atria to the ventricles.[43,44] In cats with hypertrophic cardiomyopathy, there are marked increases in the expression of BNP in both the atria and ventricles.[45] Others, studying dogs with experimental, pacing-induced heart failure, reported that ventricular BNP expression remains rather modest and that the atria remain the predominant source of most circulating BNP.[46]

The physiologic actions of ANP and BNP generally oppose those exerted by the RAAS.[47,48] Atrial and B-type natriuretic peptides act via the A-type natriuretic peptide receptor, NPR-A, to induce natriuresis and diuresis by inhibiting tubular sodium transport in the inner medullary collecting duct of the kidney. This same receptor type mediates vasorelaxation of systemic and pulmonary arterioles, thereby decreasing systemic and pulmonary vascular resistance. Additional actions of ANP and BNP mediated by NPR-A include direct inhibition of the release of renin by the kidney and aldosterone from the adrenal cortex. A second receptor, NPR-B, responds to ANP and BNP but preferentially mediates vasodilation from locally-produced CNP. The NPR-C receptor acts to clear mature ANP and BNP from the circulation. ANP and BNP are also cleared by the action of membrane-bound neutral endopeptidase, which cleaves them into inactive peptide fragments. Neutral endopeptidase and NPR-C show greater affinity for ANP than BNP, offering an explanation for the longer plasma half-life of BNP.[47-49] N-terminal fragments of proANP and proBNP are thought to be removed more slowly from the circulation than their C-terminal counterparts because clearance of these peptides is more dependent on renal excretion. As a result, NT-proANP and NT-proBNP plasma levels are higher than and not as labile as their C-terminal counterparts. Both N-terminal peptides are sensitive markers of heart disease in humans and their levels tend to correlate closely with the severity of any underlying heart disease.[50,51]

Measurements of plasma natriuretic peptide concentrations, especially BNP, are helpful for discriminating human patients with dyspnea due to heart failure from those with pulmonary disease or other disorders.[51-55] The mean BNP concentrations of human patients with NYHA class III and IV heart failure was eightfold to tenfold higher than the cutoff value for subjects without heart failure.[56] In recently reported studies in cats with myocardial disease, measures of plasma BNP levels appear to have similar diagnostic potential.[57,58] Plasma BNP levels, elevated more than tenfold, distinguished cats with heart failure from control cats better than plasma ANP levels, which were increased fourfold to fivefold. The diagnostic potential of plasma BNP levels does not appear quite as promising in dogs where the magnitude of the change is less dramatic than that observed in cats and humans,[59,60] although a few studies have shown that BNP levels can differentiate between cardiac and noncardiac causes of respiratory distress.[61-63] The recent development of a point-of-care NT-proBNP assay for feline plasma should offer several advantages to the use of BNP as a cardiac biomarker in cats including results being available in-house within ten minutes.[64]

Arginine Vasopressin (AVP)/Antidiuretic Hormone (ADH)

Arginine vasopressin (AVP), often referred to as antidiuretic hormone (ADH) in the veterinary literature, is a nonapeptide with the amino acid, arginine, at the 8 position (see ch. 296).[65,66] The amino acid sequence of the mature peptide is highly conserved in most mammals and is identical in humans, dogs, and cats.[67] Provasopressin, derived from preprovasopressin, is produced by neurons whose cell bodies are located in the hypothalamus. Subsequently, provasopressin is processed into the mature peptide, vasopressin, in vesicles that are transported along the length of the axon to the posterior pituitary, where they become secretory granules containing the active peptide within the nerve endings.[65] Stimuli for release of vasopressin from the neurohypophysis into the circulation include increased plasma osmolality or hypovolemia. When plasma volume is reduced, stretch receptors in the atria and large veins decrease their firing rate, stimulating release of AVP.[65] Sympathetic stimulation and AT II also stimulate AVP release. Following its release, vasopressin reacts with V1A receptors in the vasculature and heart, mediating vasoconstrictive and inotropic actions, and with V2 receptors in the kidney, stimulating water reabsorption.[66,68] This latter effect is accomplished via regulation of the number of aquaporin-2 water channels inserted into the luminal membrane of cells in the renal collecting ducts.[66,68] Baroreceptor V2 receptors respond to elevated plasma AVP levels by augmenting baroreceptor reflexes, which lower the heart rate in order to maintain arterial blood pressure in the normal range.

In dogs with heart failure induced by rapid pacing, plasma levels of arginine vasopressin rise prior to the development of congestive signs in association with activation of the RAA system. Marked increases are observed with the onset of congestive signs. Elevated plasma AVP levels are detectable in some human patients with CHF, particularly those with severe heart failure and dilutional hyponatremia.[65,69] The paradox of increased AVP release in the face of reduced plasma osmolality and high filling pressures may be due to baroreceptor signaling caused by low arterial blood pressure.[70] Whatever the mechanism, selective V2 or combined V1A/V2 receptor antagonists have been shown to normalize plasma sodium concentrations and to alleviate congestive signs in affected patients.[66,71,72] These agents are sometimes referred to as aquaretics because they cause the elimination of free-water without changing urinary excretion of sodium or potassium. Conivaptan, a combined V1A/V2 blocker, has shown efficacy in dogs with experimentally-induced heart failure and in human patients with severe symptomatic CHF.[73,74] Tolvaptan is a more selective orally-active vasopressin V2 receptor antagonist also being evaluated in clinical trials.[75] Increased levels of circulating AVP have been documented in dogs with dilated cardiomyopathy[76,77] and chronic degenerative valve disease,[77] but no observations have yet been reported in cats.

Neurohormonal Alterations of Peripheral Vasculature

Operation of the systemic circulation requires relatively high pressures, and maintenance of systemic blood pressure is a mandated physiologic priority in all patients with heart failure. This involves input from both the autonomic nervous system and local autoregulatory mediators. When cardiac output falls, systemic blood flow is preferentially directed to certain vital centers by a variety of adaptive responses increasing the tone of the resistance vessels supplying less vital regions. The adrenergic nervous system plays a predominant role in redirecting blood flow in patients with heart failure to vital centers (brain and heart), causing much of the observed increase in peripheral vascular resistance.[6] Other influential changes altering the functional and structural properties of the vascular wall include downregulation of parasympathetic tone, upregulation of the RAAS, increased expression and release of endothelin and AVP, and alterations in the processes that autoregulate blood flow to specific vascular beds.

Norepinephrine, angiotensin II, endothelin, and AVP effect vasoconstriction via specific smooth muscle membrane receptors linked to the G protein, Gq, leading to activation of phospholipase C and the inositol triphosphate (IP3) signaling system.[78] The IP3 system regulates calcium ion release via the IP3 receptor (a calcium release channel) in the sarcoplasmic reticulum of smooth muscle cells, thereby stimulating calcium-mediated vasoconstriction. With chronic IP3 signaling, diacylglycerol activates protein kinase C (PKC), initiating a cascade of intracellular signals that initiate smooth muscle hypertrophy and replication, as well as a plethora of associated changes in the extracellular matrix (vascular remodeling).[79] Reduced activity of the parasympathetic limb of the autonomic nervous system contributes to generalized vasoconstriction by withdrawal of its vasodilatory influence. The parasympathetic muscarinic receptors, stimulated by acetylcholine, activate guanylyl cyclase, causing the formation of cyclic GMP, which inhibits calcium entry

into the cell and decreases intracellular calcium concentrations. The increased sympathetic activity and increased circulating vasoconstrictors in heart failure maintain arterial pressure and also increase venous return and cardiac filling via peripheral venoconstriction. Unfortunately, the affiliated increase in afterload stimulates cardiac remodeling and further contributes to cardiac dysfunction.

Endothelin

Vascular tone is modulated by the endothelium-derived vasodilators, nitric oxide and prostacyclin, and by the complex actions of the potent endothelium-derived vasoconstricting peptide, endothelin.[80] Three related peptides, endothelin-1, endothelin-2, and endothelin-3, comprise the endothelin family.[81] Circulating endothelins are derived from larger peptides produced by vascular endothelial cells (myocytes and a variety of other cells) in a sequence of steps analogous to that described for natriuretic peptides.[81-83] Thus, preproendothelin gives rise to biologically inactive proendothelin, also termed big endothelin, which is subsequently cleaved at the N-terminus by endothelial-converting enzyme (ECE) to yield the active mature peptide, endothelin-1 (ET-1). Endothelin-1 mRNA expression and ET-1 production are stimulated by hypoxia and mechanical factors, including stretch and low shear stress; by vasoactive substances such as ATII, AVP, NE, and bradykinin; and by growth factors and cytokines including transforming growth factor beta, tumor necrosis factor alpha, and interleukin-1.[82,83]

Endothelin-1 acts via two receptors, ETA and ETB, to exert complex biologic effects serving to maintain normal vascular tone.[82-85] Vasoconstriction of smooth muscle, increases in myocardial contractility, and aldosterone secretion are among the more prominent effects mediated by ETA receptor stimulation. Chronic stimulation of ETA receptors and persistently elevated ET-1 levels cause proliferation and hypertrophy of vascular smooth muscle and myocardial hypertrophy. In addition to its direct vasoconstricting effects in heart failure, ET-1 inhibits the endogenous nitric oxide (NO) synthase inhibitor, asymmetric dimethylarginine (ADMA), and this effect can be blocked by ETA receptor antagonists.[83] Vasodilation, mediated by increased NO production, and aldosterone secretion results from stimulation of endothelial cell ETB receptors, providing an elegant and complex means of balancing vascular tone. Increased NO levels, in turn, inhibit ET-1 synthesis, exemplifying a negative feedback mechanism. Following intravenous injection of ET-1, blood pressure first declines transiently and then increases, reflecting the action of these two receptor subtypes. The interactions of endothelin and RAAS are complex, but the net effect is suppression of renin production and stimulation of aldosterone secretion.[86] Therapeutic strategies based on blocking ET receptors and inhibition of endothelin-converting enzyme have not produced convincing clinical benefits.

In healthy people and animals, most circulating ET-1 is derived from the vasculature and ET-1 levels are very low, reflecting its paracrine role in the maintenance of normal vascular tone. Myocardial production of ET-1 is thought to contribute to the increased plasma concentrations of ET-1 observed in humans, dogs, and cats with heart failure. It is noteworthy that the magnitude of elevation of ET-1 in heart failure is not as dramatic as that seen with the natriuretic peptides. Plasma ET-1 levels more than double in dogs with CHF due to CDVD or DCM and increase more than threefold in cats with cardiomyopathy and CHF or systemic thromboembolism.[84,85] Significant but more modest elevations are observed in dogs and cats with less severe disease. In a study of dogs presented for dyspnea, plasma ET-1 levels were less accurate than plasma NT-proANP for distinguishing dogs with CHF from those with dyspnea from other causes.[87] Endothelin-1 concentrations are also consistently elevated in patients with pulmonary hypertension and some forms of renal disease, but, interestingly, not in patients with systemic hypertension.[88,89]

NO and Adrenomedullin

Nitric oxide, produced in endothelial cells from L-arginine via the action of endothelial nitric oxide synthase (eNOS), diffuses into smooth muscle cells and contributes to vasodilation by several different mechanisms.[90] Nitric oxide increases intracellular cGMP levels in vascular smooth muscle cells by activating soluble guanylate cyclase and directly activates potassium channels, leading to hyperpolarization of the cell and vasodilation. In patients with heart failure, impaired endothelial cell function causes decreased NO synthesis, contributing further to excessive vasoconstriction.[91]

Adrenomedullin (ADM) is a potent natriuretic and vasodilating 52–amino acid peptide with positive inotropic properties. Adrenomedullin has been detected in a variety of tissues, including the adrenal medulla, heart, lung, and kidney.[92,93] Plasma levels of ADM are increased in human heart failure patients and in dogs

with pacing-induced experimental heart failure. Recent studies indicate that AT II stimulates ADM production and secretion from cardiac myocytes and fibroblasts and that ACE inhibition can block this response. Thus, ADM appears to have endocrine, autocrine, and paracrine effects.[93] Interestingly, ADM serves as a marker of ventricular hypertrophy but acts to attenuate myocardial hypertrophy and collagen production. Adrenomedullin has received little attention in dogs or cats with naturally-occurring heart disease. This is likely to change because there is increasing interest in ADM as a possible therapeutic agent.

Cytokine and Integrin Signaling

Cytokines, more appropriately referred to as protein regulatory factors, are small water-soluble signaling proteins or glycoproteins produced by a wide variety of cell types that are used extensively in cellular communication.[94] Cytokines exhibit a combination of endocrine, paracrine, and autocrine actions via membrane-bound receptors that up- and down-regulate the expression of groups of genes and their transcription factors, thereby acting as potent modifiers of protein synthesis. Increased production and elevated plasma concentrations of proinflammatory cytokines, including interleukin-1, interleukin-6, and tumor necrosis factor alpha (TNF-alpha), have been identified in human patients with chronic heart failure and are regarded as important negative prognostic indicators.[95] Increased TNF-alpha levels act to depress myocardial function, and chronic elevations of TNF-alpha promote apoptosis.[96] Unfortunately, clinical trials of agents blocking the actions of TNF-alpha in human subjects were disappointing.[97]

Cardiac Remodeling

Chronic perturbations in the circulation and pathologic insults to the heart elicit anatomic and morphologic changes in the heart that are broadly referred to as cardiac remodeling. While the maladaptive neurohormonal responses to heart failure explain part of its progressive nature, cardiac remodeling further affects and often exacerbates cardiac dysfunction. The concept of cardiac remodeling does not only affect the size of the cardiac myocytes; cardiac remodeling involves the volume of myocyte and nonmyocyte components, the anatomy and biology of cardiac myocytes, and the geometry of the cardiac chambers.

Myocyte and Nonmyocyte Alterations

Cardiac hypertrophy, the increase in myocyte size, is the foundation of the remodeling response given the extremely limited ability of the heart to add new cardiomyocytes. When the heart is healthy, cardiomyocytes occupy about three fourths of the volume of the heart and comprise about one third of the total number of cells.[98] These muscle cells are embedded in a collagen-rich extracellular matrix produced by large numbers of fibroblasts, and both components are nourished by an extensive network of coronary vessels lined by endothelial cells and richly endowed with smooth muscle cells. Noncellular constituents of the extracellular matrix include mainly type I and type III collagens, a rich soup of proteoglycans and a large variety of signaling peptides and extracellular proteases.[99] Interstitial collagen is organized in a complex fashion that serves to connect and bundle the myofibers in a sophisticated weave that facilitates the primary function of collagen, which is the transmission of force. Endomysial collagen surrounds individual myocytes, giving rise to collagen struts that connect to neighboring myocytes and to capillaries. Perimysial collagen fibers form a complex weave of collagen surrounding groups of myocytes and joining adjacent groups of myocytes to one another. Epimysial collagen forms a sheath that encompasses muscle bundles and is connected to the perimysium by strong, tendonlike cables.[100] From this perspective, the heart can be viewed as a collagen fiber–reinforced composite material that is designed to support the working cardiomyocytes during diastolic filling and systolic ejection. Since the interstitium and myocardium are inextricably linked, changes in either one alter the biologic responses and remodeling processes of the other.

In humans, heart weight can decline by as much as 25% to 30% during prolonged bed rest or weightlessness and can increase to an extreme of 50% to 60% with extreme exercise.[101] Mechanical stress, growth factors, and neurohormonal stimuli act in concert to elicit paracrine and autocrine signaling mechanisms integral to these physiologic remodeling processes. Reorganization of the interstitium is appropriately coordinated with the symmetric growth of myocardial cells, and these changes are reversible once the physiologic challenge is resolved, as in exercise- or pregnancy-induced cardiac hypertrophy. Reverse remodeling is accomplished by deactivation of pro–growth signaling pathways and activation of other signaling pathways that disassemble the adaptive constructs of the hypertrophied heart. The number of

myocytes in the mature heart declines with age and the remaining myocytes must, by necessity, remodel as they assume a greater percentage of the hemodynamic burden.

Pathologic cardiac remodeling shares many of the adaptive processes and signaling pathways of physiologic remodeling, but the end result is often irreversible remodeling, reduced systolic or diastolic performance, and eventual cardiac decompensation. Forty years ago, Meerson and colleagues[102] identified three phases of the hypertrophic response: (1) an initial stage wherein hypertrophy develops in response to increased wall stress, (2) a compensated stage wherein wall stress has been normalized by the hypertrophic response, and (3) an exhaustion phase characterized by the death of cardiomyocytes, development of myocardial fibrosis, ventricular dilation, and reduced cardiac output. Compensatory and adaptive remodeling processes are transformed when the hemodynamic stresses are prolonged in duration or excessive in magnitude, when physiologic patterns of neurohormonal activation are excessively modified (RAAS, NE, ET-1), and when vascular remodeling exerts its toll on myocardial perfusion.

The law of Laplace emphasizes that any increase in chamber size should be accompanied by a proportional increase in wall thickness if normal wall stress is to be maintained. The law states:

$$\text{Wall stress} = \text{pressure} \times \text{radius}/2 \times \text{wall thickness}$$

This relationship provides a rationale for observed changes in cardiac architecture when an abnormal hemodynamic burden is chronically imposed on the heart (Figure 246-4). Hence, pressure overloads are compensated for (wall stress is normalized) by increases in wall thickness with little or no changes in chamber size. Despite this compensation, the total work of the pressure-overloaded heart is increased relative to normal, imposing a persistent requirement for increased energy production and oxygen delivery. Volume overload, in turn, is characterized by an enlarged chamber and only a modest increase in wall thickness, sufficient to normalize wall stress. In this fashion, the workload is redistributed appropriately to the cardiomyocytes, forward stroke volume is normalized, and the patient's functional capacity is, at least theoretically, normalized. The total work of the volume-overloaded heart is increased relative to the normal heart but substantially less than is observed in a pressure-overloaded heart.[10]

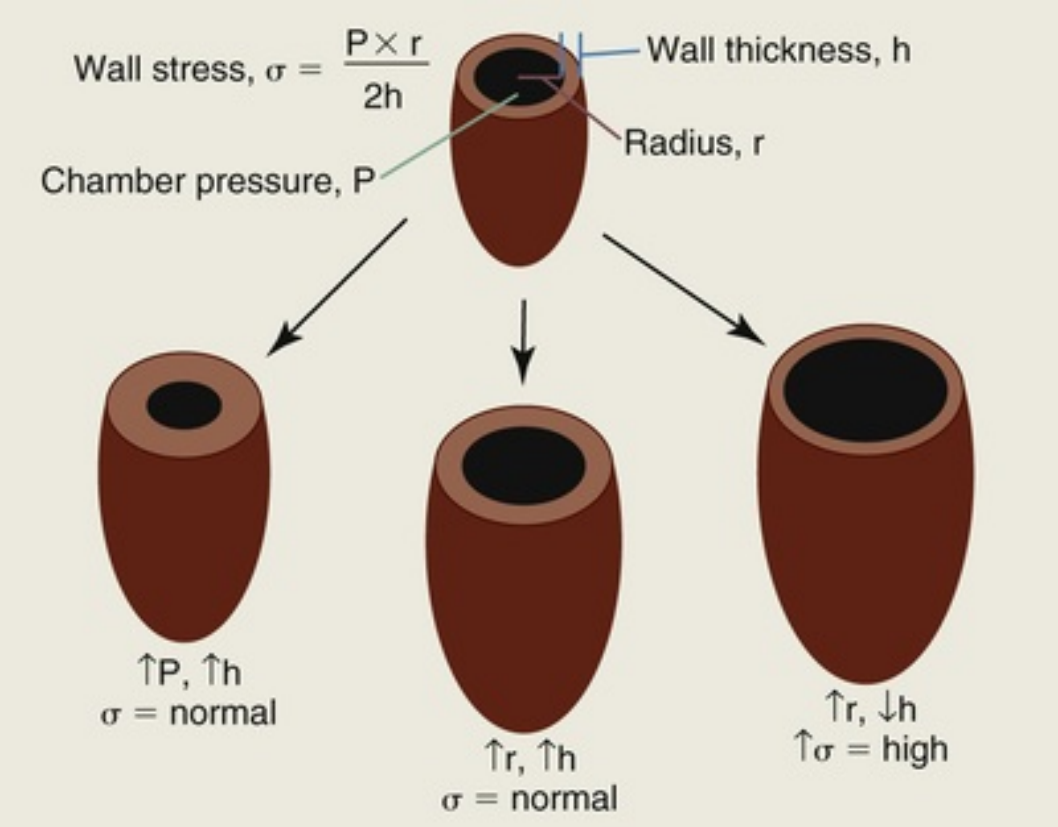

FIGURE 246-4 The heart responds to hemodynamic challenges in a predictable fashion as described by Laplace's equation (top). In response to chronic pressure overload, ventricular wall thickness increases to normalize wall stress (left). Chamber diameter and wall thickness increase proportionally during athletic training and pregnancy to maintain normal wall stress (center). Wall stress is increased in patients with heart failure due to dilated cardiomyopathy as the chamber dimensions increase disproportionately to wall thickness (right).

Abrupt increases in systolic wall stress, such as that caused by experimentally created aortic stenosis, induce an abrupt increase in LV end-systolic volume and a concomitant decrease in stroke volume. During this phase, the size and number of mitochondria increase to meet the increased demands for energy.[103,104] Over time, the myocardium responds to pressure overload through the process of *concentric hypertrophy*, wherein the sarcomeres replicate in parallel (side to side), causing the muscle fibers to thicken, increasing left ventricular and septal wall thickness. The radius of the ventricle is unchanged or may even decrease slightly due to encroachment by the thickened ventricular walls. In this fashion, systolic wall stress is normalized and the patient experiences little or no functional compromise. Fibroblasts in the interstitium also experience the increased pressure load and elevated levels of locally generated transforming growth factor beta-1, AT II, and aldosterone. They respond to these stimuli by proliferating and by increasing the synthesis and deposition of collagen, mediated at least in part by reduced expression of adaptor molecule DOC-2 in activated fibroblasts. In the interstitium, the breakdown of collagen is reduced due to increased expression of tissue inhibitor of metalloproteinase-1 (TIMP-1) and the corresponding reduced activity of the matrix metalloproteinases, MMP-1 and MMP-9.[105]

When the initiating insult is mild, long-term cardiac compensation is achieved with minimal functional compromise, as evidenced by the long survival time of dogs with mild to moderate outflow tract obstructions. However, when pressure overload is sufficiently severe, myocardial function is compromised. Capillary density and myocardial perfusion do not keep pace in proportion to large increases in wall thickness, and chronic myocardial hypoxia results in premature death of myocardial cells and more extensive myocardial fibrosis. Not surprisingly, the most common consequence of severe subvalvular aortic stenosis in dogs is sudden death from ventricular arrhythmia, presumably as a result of myocardial ischemia and its sequelae. In some patients, severe concentric hypertrophy and ischemia-induced myocardial fibrosis act to compromise left ventricular compliance, precipitating diastolic heart failure. On occasion, global systolic pump failure develops as a consequence of terminal remodeling processes culminating in myocardial fiber elongation, myofibrillar lysis, and death of cardiomyocytes. During the exhaustion phase, the rate of collagen breakdown exceeds the rate of synthesis and the hypertrophied ventricle begins to dilate and fail.

The response of the heart to volume overload differs substantially from that observed in pressure overload. Common causes of volume overload include valvular insufficiency and congenital left-to-right shunting lesions, such as patent ductus arteriosus and ventricular septal defect. Pure volume overload is characterized by increased diastolic wall stress to which cardiomyocytes respond by replicating new sarcomeres in series (end to end). The ventricle becomes more spherical and the diameter of the chamber becomes larger in a process referred to as *eccentric hypertrophy*. Wall thickness increases only modestly so as to maintain a normal ratio of wall thickness to radius, thereby normalizing wall stress. The closest clinically relevant model of volume overload is mitral regurgitation wherein the additional volume load is ejected into a low-pressure reservoir, the left atrium. Other forms of volume overload, such as aortic valve insufficiency and patent ductus arteriosus, represent examples of combined volume and pressure overload wherein an additional volume of blood is ejected into a high-pressure reservoir, the aorta. When examining the mechanisms of volume overload, it is useful to focus attention on mitral regurgitation rather than on disorders where cardiac adaptation represents a combination of volume and pressure overload.

Compared with pressure overload, volume overload induces a relatively modest increase in heart weight and protein synthesis.[106] Interestingly, the increase in heart weight occurring secondary to mitral regurgitation results mainly from a reduced rate of protein degradation. This observation reinforces the concept that signals mediating volume overload differ from those elicited by pressure overload and that there must be a corresponding difference in the pattern of gene activation. Myocytes from volume-overloaded hearts are elongated relative to normal or pressure-overloaded hearts.[107] It is presumed that differences in mechanoreceptor signaling are largely responsible for the remodeling differences between pressure and volume overload inasmuch as increased levels of norepinephrine, cardiotrophin-1, and AT II are common to the pathogenesis of both forms of hypertrophy. Nonetheless, the integrated operation of these signaling pathways is still poorly understood and other factors, not apparent at this time, may be responsible for some of the observed differences. The extracellular matrix is drastically altered in the hearts of dogs with experimentally induced mitral regurgitation.[108,109] This change is characterized by a loss of collagen and

disappearance of the elaborate collagen scaffold tethering the cardiomyocytes. Collagen synthesis in cardiac fibroblasts is substantially reduced in dogs with mitral regurgitation, paralleling the observed reduction in sarcomeric protein synthesis. The rate of collagen degradation is augmented by the increased activities of MMP-1 and MMP-9, in absolute terms and relative to MMP tissue inhibitor levels. The population of mast cells in the interstitium increases in dogs with mitral regurgitation.[108] In addition, tissue expression of transforming growth factor-beta-1 is reduced together with downregulation of cell-matrix scaffolding genes controlled by the transformng growth factor-beta-1 pathway. These alterations are most obvious early in the course of volume overload; they tend to normalize during the compensated phase only to reactivate again in the late stages of the disorder.

The remodeling processes of ischemic myocardial disease and dilated cardiomyopathy differ qualitatively and quantitatively from those described for pressure or volume overload. In the compensated phase of ischemic cardiomyopathy, the adaptive responses are more similar to those observed in pressure overload due to the chronic operation of potent neuroendocrine adaptive responses. However, in the decompensated phase, cardiomyocytes begin to elongate, the collagen matrix begins to disintegrate, and the chamber dilates, indicating a shift in intracellular signaling. The hearts of dogs with dilated cardiomyopathy (DCM) show a mixed remodeling pattern as well, but the eccentric hypertrophy phenotype predominates.

Myocyte Biology Alterations

In addition to myocardial hypertrophy, heart failure also results in structural and functional alterations in excitation-contraction coupling components, contractile and regulatory proteins, cytoskeletal proteins, apoptotic signaling mediators, and energy metabolism.[110,111] Calcium cycling is abnormal in most patients with heart failure and these alterations contribute substantially to systolic and diastolic dysfunction.[112,113] Importantly, the total amount of calcium stored in the sarcoplasmic reticulum is reduced in heart failure patients. This reduction has been linked to (1) lowered SERCA levels or reduced SERCA ATPase activity, (2) increased removal of intracellular calcium by the sodium-calcium exchanger, and (3) alterations in calcium release via the ryanodine receptor.[112,114] As a direct consequence, the onset of the peak calcium transient in working cardiomyocytes is delayed and the time to return to baseline is prolonged.[115] Enhanced activity of the sodium-calcium exchanger compensates for diminished reuptake via SERCA to some extent, but eventually the rate of Ca^{++} removal during diastole is reduced.[116] These perturbations in calcium handling predispose the cardiomyocyte to early and delayed afterdepolarizations, increasing the likelihood of serious ventricular arrhythmias and increasing the risk of sudden death.

Myocardial contractility is further impaired by reduced myofibrillar ATPase activity observed in association with altered patterns of troponin I phosphorylation resulting from increased PKC and reduced PKA mediated processes.[117] Different isoforms of the contractile proteins and associated regulatory proteins also may contribute to declining contractility depending on the species and underlying cause of heart failure.[118] Such changes relate to reduced expression of adult isoforms and increased expression of isoforms that were expressed during embryonic development and is sometimes referred to as the fetal gene program.[119,120] The pathways and processes regulating gene expression, protein transcription, myocardial hypertrophy, as well as necrosis and apoptosis are complex with considerable cross-talk between them. They are mediated, in part, through alpha-adrenergic receptor-linked Gq activation of phospholipase C, subsequent translocation and activation of PKC, and activation of extracellular signal-related kinase, ERK1/2.[121] Extracellular signal-related kinase 1/2 is one of four known mitogen-activated protein kinase (MAPK) pathways operating in the heart to regulate protein transcription and gene expression.[13] Additional MAPK pathways, including c-Jun N-terminal protein kinases (JNKs) and the p38 pathway involved in cell differentiation and apoptosis, and other cellular processes modifying gene expression such as the calcineurin–nuclear factor of activated T cells (NFAT) pathway and the Phosphoinositide 3-Kinase/Akt/Glycogen Synthase Kinase-3 (PI3/Akt/GSK-3-beta) signaling system are also involved.[122] This is an understandable if unpardonable oversimplification of processes that orchestrate different responses to differing stimuli and the interested reader is directed to several excellent reviews of these complex systems for further detail.[120,123]

Prior to the onset of heart failure, cardiomyocytes performing additional external work generate more energy and recycle more calcium than do cells that are not similarly burdened. As more energy is produced, more heat is produced and the cell experiences greater oxidative stress. As a result, more energy must also be dedicated to cell maintenance and repair. Thus, it is not surprising that one of the first responses of overworked cells is to increase the number of mitochondria to address the need for energy.[104] Additional

energy must be devoted to the construction and maintenance of the pathways used to store and distribute energy as well. These adaptive processes eventually fall short, resulting in abnormalities of calcium cycling, systolic and diastolic dysfunction, and cell death. In patients with heart failure, there is a switch in substrate utilization from fatty acids to carbohydrates and a decrease in aerobic ATP production.[124] The amount of ATP in failing cardiomyocytes is not altered, but the rate of use and rate of replenishment of ATP are reduced as the capacity of the mitochondria to produce ATP becomes limited.[125] Heart failure is characterized by declining levels of creatine phosphokinase in the cytosol and mitochondria and a correspondingly reduced creatine phosphate/ATP ratio. This alteration has been described in explanted hearts from human patients with end-stage heart failure, in dogs with experimentally created mitral regurgitation, and in dogs with spontaneously occurring DCM.[126,127] O'Brien and colleagues[128] found reduced mRNA content and enzyme activity for markers of calcium cycling, glycolysis, and oxidative phosphorylation in dogs with DCM. More recently, Oyama and Chittur[129] reported reduced expression of genes involved in glycolysis and oxidative phosphorylation. Lopes and colleagues[130,131] reported similar patterns of altered energy production reflected in the protein expression profiles of mitochondria from dogs with pacing-induced and naturally occurring cardiomyopathy.

These functional changes are reflected in structural alterations of the mitochondria, which become smaller and more numerous.[104] These changes are accompanied by alterations and disruption of the internal cristae. In context, there is also a breakdown in the architecture of other cellular constituents with dissolution of the myofilaments and disorganization of cytoskeletal elements. Ischemia is a rather obvious cause of diminished energy production and is of paramount importance in human patients with atherosclerosis. Regional ischemia, associated with vascular remodeling, is a likely cause of altered energy production and cell death in some of our animal patients, most notably in cats with hypertrophic cardiomyopathy and dogs with subaortic stenosis wherein the remodeling of intramyocardial coronary arterioles is often quite marked. These vascular lesions are commonly associated with focal myocardial scars completely devoid of functioning myocytes.

Clinical Signs of Heart Failure

Ultimately, the mechanisms activated to compensate for heart disease including the neurohormonal alterations and cardiac remodeling initiate a vicious circle of inappropriate sodium and water retention and decreasing cardiac function. Most, but not all, patients with cardiac failure develop systemic or pulmonary congestion and are classified as having either right- or left-sided CHF, respectively. This categorization is not comprehensive because some patients experience both systemic and pulmonary congestion, and congestive signs are sometimes absent when heart failure develops suddenly and plasma volume is normal or reduced.

Patients with heart failure are most clearly distinguished from healthy individuals by their limited ability to increase cardiac output in response to exercise. Indeed, most of the clinical schemes devised to categorize the severity of heart failure are based on exercise capacity. Cardiac output at rest is only modestly reduced in most patients with heart failure due to the actions of the adaptive responses acting to augment preload, heart rate, and contractility. Only when heart failure is severe is cardiac output markedly reduced at rest.

Pulmonary or systemic congestion develops in most animals with heart failure as a consequence of excessive elevation of venous pressure caused by the combined effects of increased plasma volume (sodium and water retention) and decreased venous capacitance (venoconstriction). With functional impairment of the left side of the heart, pulmonary venous pressure increases, resulting in pulmonary edema and signs of respiratory distress (Figure 246-5, *A*). Congestive signs, such as cough or labored breathing, are likely to be observed when mean pulmonary capillary wedge pressure (PCWP) exceeds 25 mm Hg (normal < 10 mm Hg). With impairment of the right side of the heart, systemic venous pressures rise, resulting in hepatomegaly and ascites, which usually become apparent when central venous pressure exceeds 15 mm Hg (normal < 5 mm Hg) (Figure 246-5, *B*). Patients with gradually developing heart failure are more tolerant of elevated filling pressures because of adaptive changes in the capacity of lymphatic flow.[132] Filling pressures are often monitored in patients with heart failure to determine if they are responding appropriately to various treatment interventions. This prudent exercise is useful only if attention is focused on the appropriate variable. A common mistake made in clinical practice is to measure central venous pressure (CVP) as a guide to fluid administration in patients with compromised left heart function. The capacitance of the splanchnic veins, where 70% of the circulating blood resides, is much larger than that of the pulmonary circulation and is complemented by an extensive network of systemic lymphatic channels. As a result, pressure rises slowly in the systemic capillary beds when blood volume increases and the manifestations of right-sided congestion tend to develop slowly. Because the capacitance of the pulmonary veins is small, relatively small changes in

blood volume or its distribution can cause a rapid rise in pulmonary venous pressure and pulmonary edema. Sudden increases in sympathetic tone (fear, anxiety, exercise) cause constriction of the splanchnic veins, causing a shift of the circulating blood volume from the systemic to the pulmonary venous reservoir. This can precipitate the rapid onset of pulmonary edema in patients prone to left heart failure.

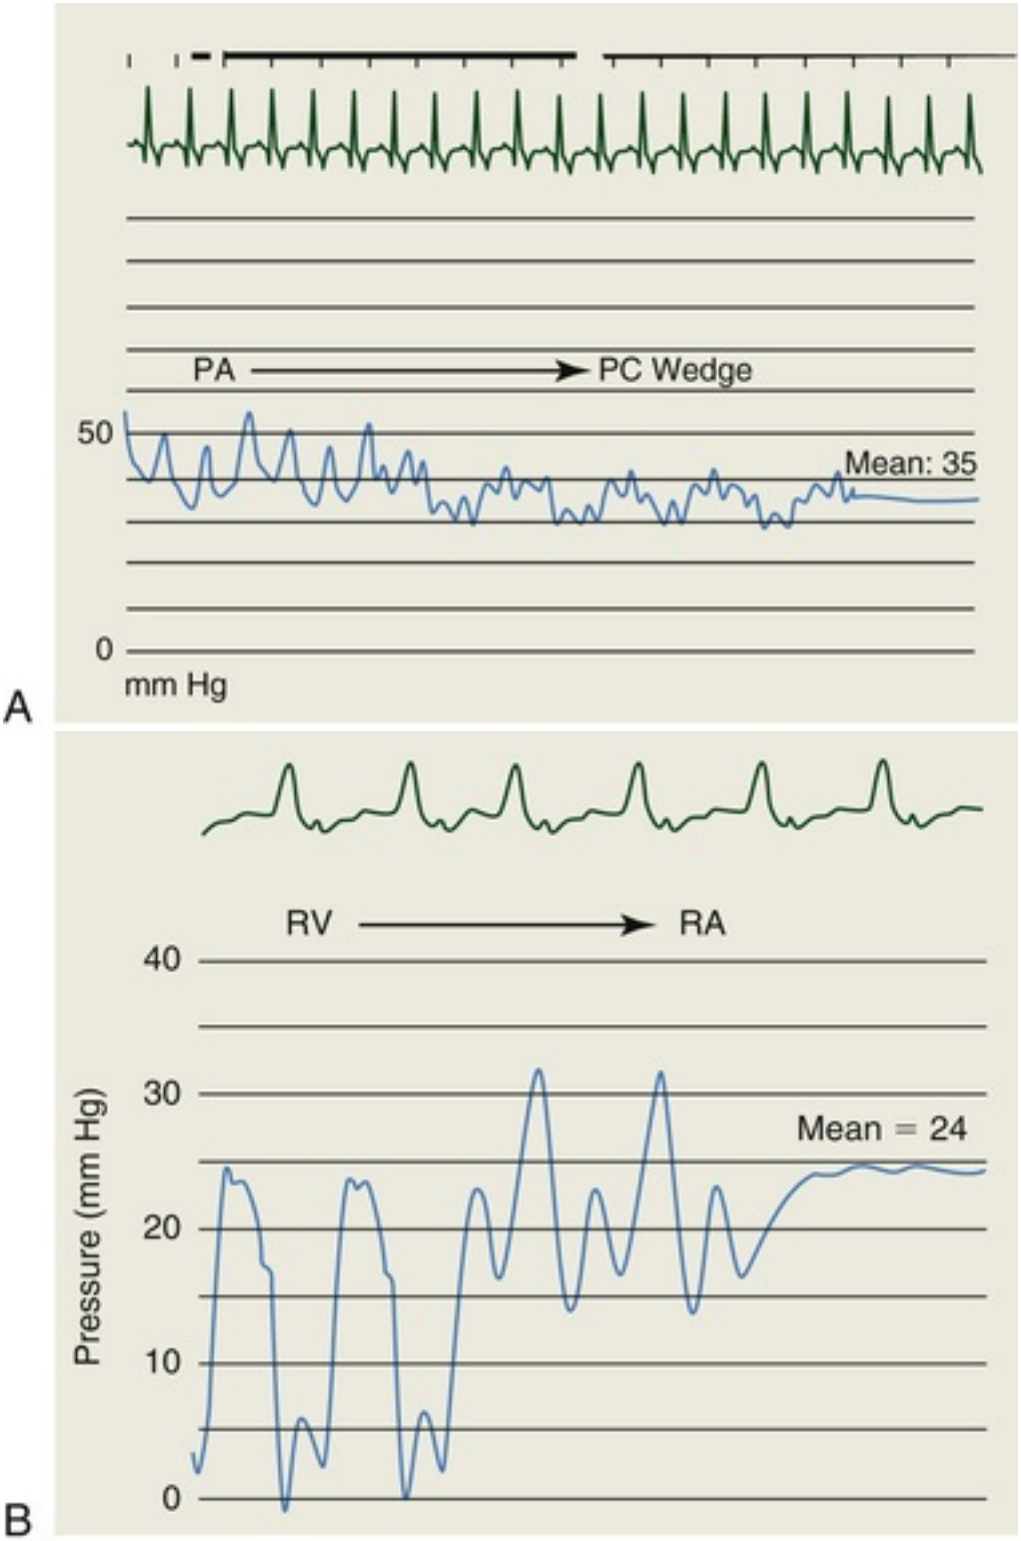

FIGURE 246-5 Pulmonary congestion is likely to develop whenever mean pulmonary capillary (PC) wedge pressure exceeds 25 mm Hg, as shown in this dog with dilated cardiomyopathy **(A).** Systemic congestion is likely to develop when mean right atrial pressure exceeds 15 mm Hg, as shown in this dog with tricuspid valve stenosis **(B).** *PA,* Pulmonary artery; *RA,* right atrium; *RV,* right ventricle.

The pulmonary and systemic circulations operate in series and are, as a direct consequence, interdependent. Dysfunction of either circuit will necessarily impact the operation of the other. Hence, a rise in left atrial pressure, as occurs with mitral regurgitation, results in a corresponding increase in pulmonary artery pressure and the work performed by the right heart. In most instances, this pressure increase is quite modest; however, profound pulmonary vasoconstriction can be induced when the oxygen saturation of the blood is reduced as a consequence of pulmonary congestion, resulting in the development of debilitating pulmonary hypertension and right heart failure. The feline pulmonary vascular bed is more reactive to hypoxemia than that of dogs and, as a result, cats may be more prone to the development of serious pulmonary hypertension as a consequence of left heart failure.[133] The complex relationship between the systemic and pulmonary circulations is also evidenced by the pattern of congestion that develops when both ventricles fail simultaneously. Pleural effusion, which is uncommon with isolated right- or left-sided heart failure, develops frequently when systemic and pulmonary venous pressures are concurrently elevated.[134] In this circumstance, fluid accumulates in the pleural space because lymphatic drainage, derived from both circulations, cannot keep pace with the rate of pleural fluid formation.

Summary

The evolution of treatment of heart failure (see ch. 247) parallels the evolution of our understanding of the pathophysiology of this complex clinical syndrome. Emphasis on the mechanisms of congestion and fluid retention led to the development of effective diuretics. Focus on the hemodynamic alterations in heart failure and the mechanisms of reduced contractility led to the development of positive inotropic drugs and vasodilators. Recognition of the reactive neurohormonal alterations in heart failure provided the rationale for treatment with ACE inhibitors, aldosterone antagonists, and beta-blockers. Understanding of the fundamental processes involved in excitation and contraction, energy production and utilization, and remodeling will undoubtedly lead to a variety of new therapeutic approaches and preventive strategies.

CHAPTER 247

Heart Failure

Clinical Management

Adrian Boswood

Client Information Sheet: Diuretic Therapy for Heart Failure

Introduction

Veterinarians frequently encounter patients with heart failure that require appropriate management to alleviate their clinical signs and improve their quality of life. The most effective treatment of these patients will be provided if the attending clinician approaches management in a systematic manner, cognizant of the type of clinical signs the patient is showing and pathophysiologic mechanisms that are likely to underlie those signs. Not all patients with clinically detectable heart disease will be showing signs of heart failure; many common diseases have lengthy preclinical ("asymptomatic") phases during which the patient is completely free of any clinical signs. It is common for older patients with heart disease to suffer from comorbidities; therefore, not all signs shown by patients with heart disease will be due to their having heart failure.

What Is Heart Failure?

Heart failure can be said to be present when, as a consequence of an abnormality of the heart, patients demonstrate clinical signs because of an inability to sustain a cardiac output sufficient to provide for their metabolic requirements at normal cardiac filling pressures (see ch. 246). Patients therefore can show signs of inadequate cardiac output with normal filling pressures (forward failure); can have clinical signs as a consequence of excessive cardiac filling pressures but a normal cardiac output (backward or congestive failure); or, as is often the case in patients with an emergency presentation, they both can have signs brought about by excessive cardiac filling pressures and concurrently demonstrate signs associated with an inadequate cardiac output. Typical clinical signs of inadequacy of cardiac output include exercise intolerance, syncope (see ch. 30), pallor, cold extremities, and manifestations of hypotension (see ch. 159) such as lethargy and depression. Signs indicating that a patient has excessive cardiac filling pressures typically occur as a consequence of congestion of the venous circulation and include tachypnea and dyspnea due to pulmonary congestion and edema (see ch. 28); abdominal distension due to ascites (see ch. 17); and tachypnea and dyspnea due to pleural effusion (see ch. 244). Occasionally, excessive cardiac filling pressures can be indicated by the development of subcutaneous edema (see ch. 18) but this is a rare presentation in canine and feline patients.

How Do We Decide When Heart Failure Is Definitely Present?

In order to confirm that a patient has heart failure, two things need to be established: first, that *the patient has evidence of heart disease* and second, that the patient *is showing clinical signs as a consequence of that heart disease.*

If a patient only has clinical findings suggestive of heart disease, such as a murmur or an arrhythmia, but is not showing any clinical signs as a consequence of that disease, then that patient is not (yet) in heart failure. The treatment of patients with acquired heart disease that do not yet have signs of heart failure is controversial, and evidence for and against the treatment during the preclinical phase of different heart diseases is covered in specific chapters (see ch. 251-253).

A confounding factor that often complicates diagnosing the presence of heart failure is that patients may

have clinical evidence of heart disease and be showing clinical signs; however, those signs are caused by another condition with which the patient is suffering concurrently. For example, dogs with heart disease can be exercise intolerant due to concurrent osteoarthritis or dyspneic due to laryngeal paralysis. To conclude that a patient has heart failure, one must therefore establish that the patient has heart disease *of sufficient severity to be likely to be the cause of the signs* and *evidence that those signs directly relate to the patient's heart disease.*

A diagnosis of heart failure therefore is usually made on the basis of a combination of a history of clinical signs indicative of heart failure, physical examination findings indicative of the presence of heart disease, and the results of ancillary diagnostic tests that help to establish that the observed signs are a consequence of the patient's heart disease.

In a patient presenting with increased respiratory rate and effort (see Video 252-6), the most useful diagnostic test to establish whether or not those signs are cardiac in origin is usually thoracic radiography. The demonstration of abnormalities of the shape and size of the cardiac silhouette in conjunction with findings consistent with heart failure, such as pulmonary venous congestion and an alveolar pattern is usually considered the gold-standard for establishing a diagnosis of heart failure. Figure 247-1 is a lateral thoracic radiograph that demonstrates characteristic findings taken from a dog with left-sided congestive heart failure secondary to degenerative valvular disease. Thoracic radiographs can be more difficult to interpret if the cardiac silhouette is obscured by the presence of pleural effusion. In such cases, establishing the presence of substantial atrial enlargement with echocardiography can help to rule in (or, when absent, to rule out) heart disease as the cause of the effusion (see ch. 104). In patients presenting with ascites as a possible manifestation of right-sided congestive heart failure, evidence supporting a cardiovascular cause for the ascites would include demonstration of hepatic venous congestion on abdominal ultrasound and/or evidence of substantial right-sided cardiac disease or pericardial effusion on echocardiography. Examples of characteristic findings from the history, physical examination, and supportive results from diagnostic imaging are shown in Table 247-1.

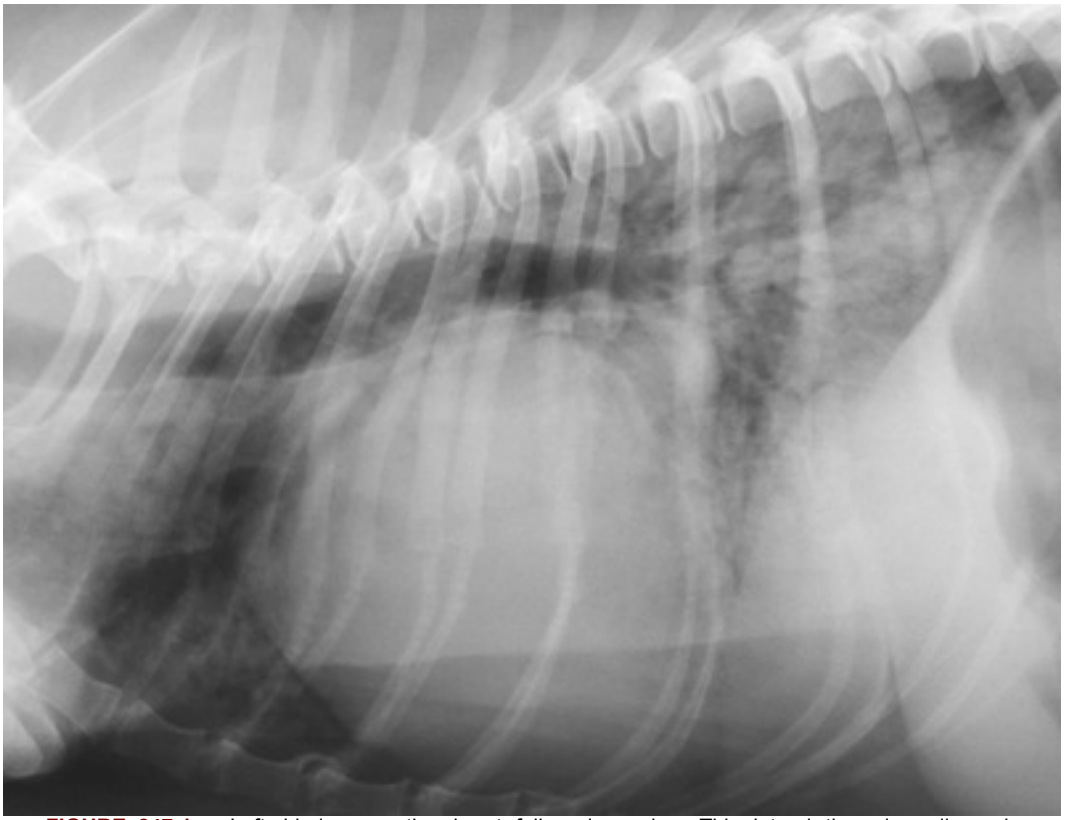

FIGURE 247-1 Left-sided congestive heart failure in a dog. This lateral thoracic radiograph illustrates some of the classic radiographic findings associated with left-sided congestive heart failure. There is marked enlargement of the cardiac silhouette with a widespread opacification of the pulmonary parenchyma consistent with pulmonary edema.

TABLE 247-1

Historical, Physical Examination and Ancillary Diagnostic Testing Findings Consistent with the Presence of Heart Failure

HISTORICAL SIGNS CONSISTENT WITH THE PRESENCE OF HEART FAILURE	PHYSICAL EXAMINATION FINDINGS INDICATIVE OF THE PRESENCE OF *HEART DISEASE*	PHYSICAL EXAMINATION FINDINGS THAT MAY INDICATE THE PRESENCE OF *HEART FAILURE*	ANCILLARY DIAGNOSTIC FINDINGS SUPPORTIVE OF A CARDIAC CAUSE FOR THE PHYSICAL EXAM FINDINGS
Tachypnea, dyspnea, and/or respiratory distress Exercise intolerance Cyanosis Dullness and depression Weakness and lethargy Inappetence	A heart murmur A cardiac arrhythmia An audible gallop sound	Increased respiratory rate and effort with or without audible pulmonary crackles	Thoracic radiographic evidence of cardiomegaly with pulmonary venous congestion and evidence of an alveolar/interstitial pattern in the lung parenchyma
		Increased respiratory rate and effort with ventral dullness on auscultation or percussion	Thoracic radiographic evidence of a pleural effusion with evidence of an abnormal cardiac silhouette (if visible) Ultrasonographic confirmation of pleural effusion with evidence of atrial enlargement
		Abdominal distension with a palpable fluid wave, particularly if accompanied by jugular venous distension and/or hepatojugular reflux	Evidence of hepatic venous congestion on abdominal ultrasound or evidence of significant right-sided heart disease or pericardial effusion on echocardiography
		Pallor and cold periphery	Hypotension that is not attributable to another cause

In order to establish with reasonable confidence that a patient's signs are due to heart failure, the patient should have historical signs consistent with heart failure, physical examination abnormalities suggestive of heart disease and heart failure, in addition to supportive results from ancillary diagnostic tests. For differential diagnosis of some of the signs described here, readers are referred to ch. 26-30.

Measurement of concentrations of circulating cardiac biomarkers such as N-terminal B-type natriuretic peptide (NT-proBNP) can assist in establishing a cardiac cause for observed clinical signs (see ch. 246). Numerous studies in dogs and cats have shown that patients demonstrating signs that could be a consequence of congestive heart failure (e.g., dyspnea) and that have high circulating concentrations of NT-proBNP are more likely to have a cardiac cause for their signs; that is, the likelihood of the patient's signs being due to heart failure is increased considerably when that patient has increased circulating concentrations of NT-proBNP.[1] A recent study has also demonstrated that high NT-proBNP concentrations in the pleural fluid of cats with pleural effusion helps to differentiate those with a cardiac cause of the effusion from those with other causes.[2]

Once a clinician is satisfied that a patient's signs are likely to be a consequence of heart failure, then the clinician should consider how best to manage those signs. In some patients presenting as emergencies with severe and potentially life-threatening clinical signs, it might be impossible to carry out ancillary diagnostic tests without risk to the patient. In these circumstances, the clinician may need to treat the patient on the basis of the most likely underlying condition and then perform appropriate diagnostic tests later, when the patient is more stable and more likely to tolerate them.

Management of Heart Failure

There are four important steps in the management of patients with heart disease causing heart failure:

1. Correct identification of the underlying disease process
2. Staging of the severity of disease
3. Applying "evidence-based medicine" (see ch. 5).
4. In the absence of "best-evidence," making an informed and rational decision, on the basis of the clinical findings, regarding the type of therapy that will be most effective.

These steps ideally should be followed in all cases showing clinical signs of heart failure; however, in some cases, particularly those with acute presentations and severe clinical signs, it may be necessary to initially stabilize the patient prior to performing steps 1-3. The characteristic diagnostic findings of each condition that can result in heart failure are presented in detail in ch. 250-255, as are the most appropriate evidence-based therapy supporting treatment of specific conditions at specific stages. The remainder of this chapter will therefore consider the following points: How can we choose the most effective therapy for a heart failure patient and which clinical findings should guide us in our treatment choices?

Almost all veterinary patients with signs of heart failure will require medical management to resolve their clinical signs. However, there are some exceptions to this generalization—most notably patients with pericardial effusions (see ch. 102 and 254). For some patients, medical management will be the sole intervention required, whereas for others, medical management can be part of a treatment regimen that includes other interventions such as thoracocentesis (see ch. 102) and supplementation of inspired oxygen (see ch. 131).

Some patients may have developed heart failure secondary to a condition that can be surgically managed such as a patent ductus arteriosus. In patients such as these, medical management may be used for stabilizing the patient prior to a more definitive treatment being provided.

Pathophysiological Rationale for Administration of Medications

Patients presenting with signs of heart failure will have abnormalities consisting of one or more of the following:

- Abnormalities of preload
  - Preload can be thought of as cardiac wall stress at end-diastole. This is predominantly determined by the pressure with which blood returns to the heart from the venous circulation (although it is also influenced by the size of the ventricle). Many of the adaptive mechanisms stimulated in patients with heart disease lead to retention of fluid. This causes an increase in filling of the venous circulation and therefore preload. Preload is excessive in patients showing signs of congestion and is primarily modified by drugs that reduce circulating fluid volume **(diuretics)** and dilate veins **(venodilators).**
- Abnormalities of afterload
  - Afterload can be thought of as the force resisting contraction of the myocardium. The main determinant of afterload (in the absence of a ventricular outflow tract obstruction) is the resistance in the vascular bed into which the ventricle is ejecting, i.e., systemic vascular resistance for the left ventricle and pulmonary vascular resistance for the right ventricle. The pathophysiologic response to heart disease is characterized by stimulation of several mechanisms that increase afterload, including the sympathetic nervous system and the renin-angiotensin-aldosterone system (RAAS). Increased afterload will inhibit ventricular ejection, tend to reduce cardiac output, increase myocardial work and may result in signs of poor perfusion. **Vasodilators** are drugs that reduce systemic or pulmonary vascular resistance and they can be used to modify afterload.
- Abnormalities of myocardial contractility
  - Myocardial contractility is one of the main determinants of cardiac output. Primary or secondary impairment of contractility is present, although difficult to quantify, in many patients with signs of heart failure and may underlie signs of inadequate cardiac output. **Positive inotropic drugs** lead to an increase in contractility.
- Abnormalities of cardiac filling
  - In order to fill adequately, the heart must have enough time to fill and the myocardium must be sufficiently flexible to allow adequate venous return to enter the ventricles during diastole. Diseases that cause the myocardium to be excessively stiff, that impair relaxation (impair lusitropy), or that give the heart insufficient time or space to fill, can compromise filling. This necessitates an increase in preload to maintain an adequate output or leads to a reduction in output. Various types of drugs can directly or indirectly influence the ability of the heart to fill. Drugs that directly influence the ability of the myocardium to relax are referred to as lusitropic drugs; these include sympathomimetic agents and calcium channel blockers. Filling can be improved indirectly by modifying heart rate and rhythm such that there is more time for effective ventricular relaxation and filling.
- Abnormalities of heart rate and rhythm
  - Patients with signs of heart failure frequently have changes in heart rate and rhythm. It is quite

appropriate for many patients with heart failure to be tachycardic—to the extent that a mild to moderate sinus tachycardia is to be expected in many patients with heart failure; however some abnormalities of cardiac rhythm cause sufficient impairment of cardiac function to result in the development of heart failure (e.g., third-degree atrioventricular block or tachycardia-mediated cardiomyopathy), or contribute to the worsening of signs of heart failure in patients with pre-existing heart disease. Patients with bradycardia have a drop in cardiac output due to a drop in heart rate. Patients with marked tachycardia have a drop in cardiac output due to insufficient time for the ventricles to fill and, in some cases, a loss of the normal coordinated pattern of ventricular contraction (ventricular dyssynchrony).

Since some or all of the pathophysiological abnormalities outlined above are likely to be present in patients with signs of heart failure, it is easy to understand that drugs which influence these factors are likely to be those which will be effective in the treatment of patients with heart failure. Thus we can categorize drugs used for the treatment of heart failure into those that decrease preload, decrease afterload, enhance systolic function, improve cardiac filling, or optimize cardiac rate and rhythm.

Drugs Used in the Treatment of Heart Failure

Drugs That Decrease Preload

Indications for Preload Reduction

The clinical signs most likely to be present in a patient with excessive preload are those associated with signs of congestion. Excessive preload will be associated with elevated ventricular filling pressure, elevated atrial pressure, elevated venous pressure, and congestion of the vascular beds that drain into the affected side of the heart. A patient requiring preload reduction is therefore likely to have one or more of the following: pulmonary edema, pleural effusion, or ascites.

The two most effective types of drug for the reduction of preload are diuretics and venodilators. Diuretics will reduce a patient's circulating fluid volume, thereby reducing venous filling pressures (Figure 247-2, *A-C*). Venodilators will reduce pressure within the veins by increasing their diameter (Figure 247-2, *D*).

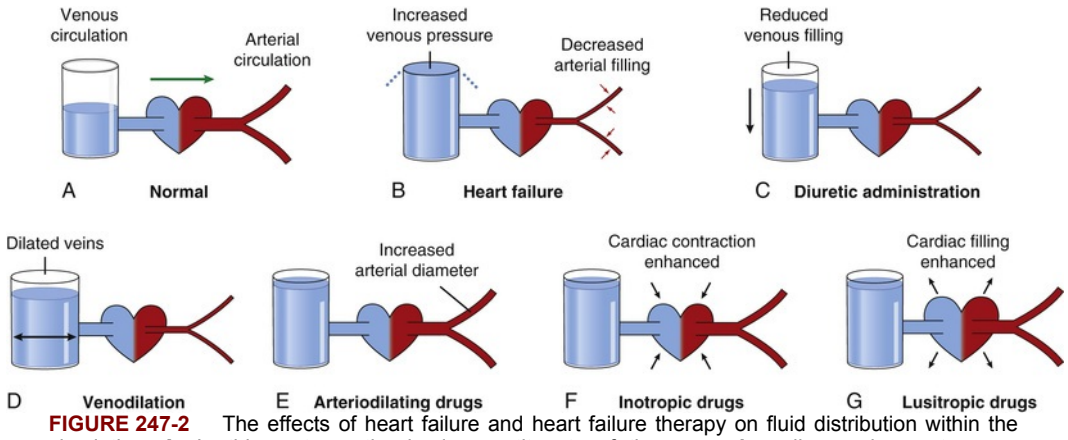

FIGURE 247-2 The effects of heart failure and heart failure therapy on fluid distribution within the circulation. **A,** In this cartoon, the basic constituents of the ***normal*** cardiovascular system are illustrated. The vertically orientated cylinder on the left of the image indicates the venous circulation. The level of blood in this cylinder reflects the pressure within the venous circulation. The heart is in the middle of the cartoon and to the right of the heart is the arterial circulation, indicated by the branching cylinders. The diameter and size of these "arteries" indicates the adequacy of filling of the arterial circulation. The green arrow at the top of the image indicates the direction of flow within the circulation, from the venous circulation through the heart into the arterial circulation. **B,** Illustrates the consequence of ***heart failure.*** Fluid retention has led to increased filling of the venous reservoir, leading to higher venous pressure. Eventually pressure increases to such an extent that fluid begins to leak out of the venous circulation into either tissues or body cavities, leading to "congestive" or "backward" failure. The arterial circulation is underfilled due to reduced cardiac output leading to "output" or "forward" failure. **C,** Illustrates the effect of ***diuretic administration:*** a reduction in circulating fluid volume. This results in reduced venous filling, lowering pressure in the venous circulation below the level at which fluid leaks out, and thus relieving signs of congestion. Diuretic administration alone will have, at best, no effect on cardiac output; therefore, arterial filling is unchanged. **D,** Illustrates the effect of ***venodilation.*** Dilating veins will reduce the pressure within the venous circulation without a change in circulating fluid volume. This is due to the greater capacity of the veins to hold the volume of fluid present. This will have the effect of reducing pressure within the venous circulation below the level at which fluid leaks out. Therefore, the primary effect will be the reduction of signs of congestion and the effect on arterial filling will be, at best, neutral. **E,** Illustrates the effect of administration of ***arteriodilating drugs.*** Decreasing

the resistance to ejection of blood from the ventricle will have the effect of improving delivery of blood into the arterial circulation; therefore, arterial filling will be improved, although this might come with the drawback of a reduction in blood pressure. This may also help to reduce the pressure within the venous circulation by allowing the heart to maintain the same output at a lower preload. **F,** Illustrates the effect of ***inotropic drugs.*** If the force of contraction is increased, the heart will be able to sustain a greater cardiac output, improving arterial filling. The heart may also be able to achieve this output with lower filling pressures, leading to a reduction in venous pressures and improving signs of congestion. **G,** Illustrates the effect of ***lusitropic drugs.*** Improving the capacity of the heart to fill during diastole allows cardiac output to be maintained at lower venous filling pressures. Thus, venous pressures can be reduced and/or cardiac output and arterial filling improved.

Diuretics

Diuretics are, for good reason, the most frequently used medication in patients with congestive heart failure. All diuretics used for the treatment of heart failure patients have a mechanism of action that results in an increase in the excretion of sodium by the patient. If sodium excretion is increased (provided there is not a corresponding increase in intake) there will be a reduction in a patient's extracellular fluid volume. This will result in lower circulating fluid volume and a reduction in preload. A reduction of preload is likely to lead to a rapid improvement in a patient's clinical signs if those signs are a consequence of excessive cardiac filling pressures.

There are several classes of diuretic that increase excretion of sodium by different mechanisms within the nephron (Table 247-2 and Figure 247-3). The relative potency of a diuretic can be expressed by the extent to which it increases the fractional excretion of sodium—the proportion of sodium filtered at the glomerulus that is excreted in the urine (see ch. 73). By this measure, the most potent class of diuretic is the loop diuretics.

TABLE 247-2

Classes of Diuretic, Their Site and Mechanism of Action, and Their Relative Potencies

CLASS OF DIURETIC	EXAMPLES	PRINCIPAL MECHANISM OF ACTION	SITE OF ACTION IN NEPHRON	RELATIVE POTENCY EXPRESSED AS THE MAXIMUM FRACTIONAL EXCRETION OF SODIUM THAT CAN BE ACHIEVED[15]
"Loop diuretic"	Furosemide Torsemide	Blockade of Na+/K+/2Cl− cotransporter	Loop of Henle	Up to 25%
Thiazide	Hydrochlorothiazide	Blockade of Na+/Cl− carrier	Distal tubule and connecting segment	Up to 5%
Potassium-sparing	Spironolactone	Blockade of aldosterone receptors	Cortical collecting tubule	Up to 2%

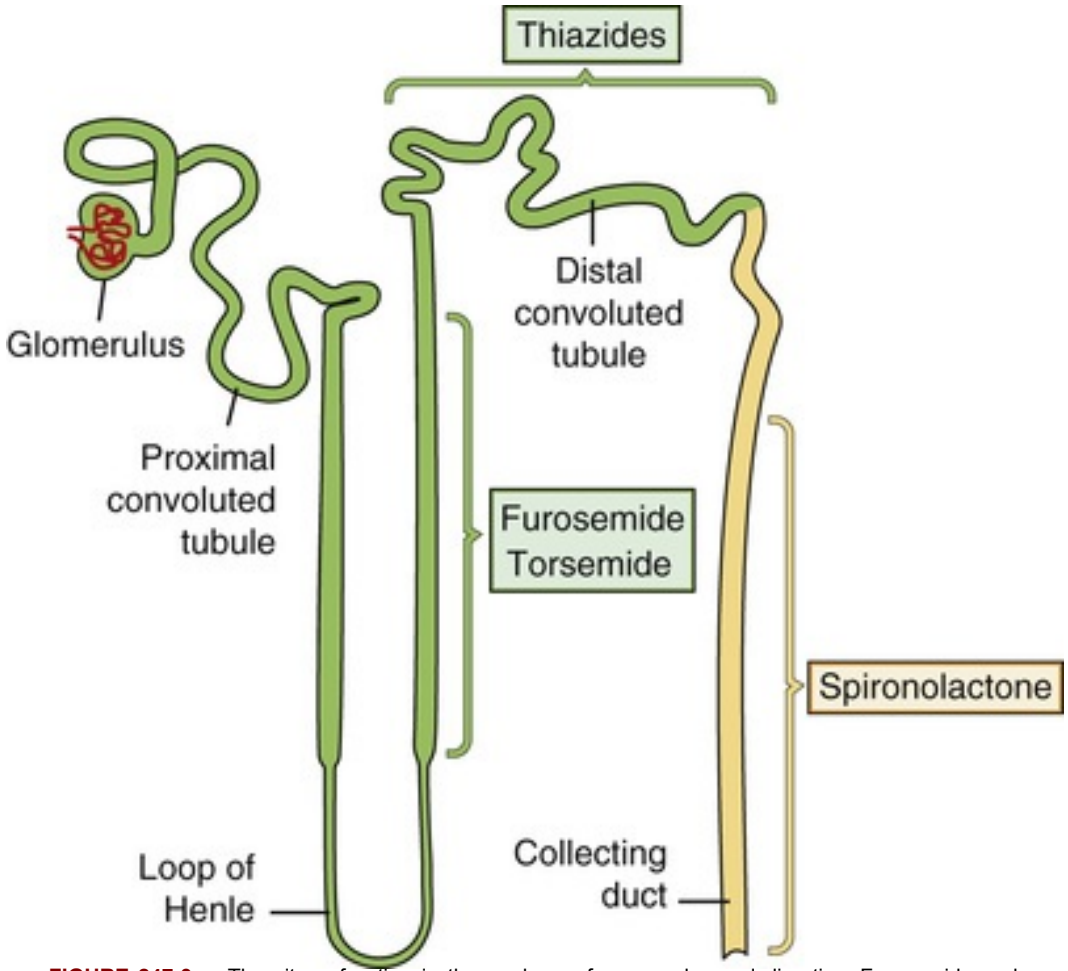

FIGURE 247-3 The sites of action in the nephron of commonly used diuretics. Furosemide and torsemide are loop diuretics and have their principal site of action in the ascending limb of the loop of Henle. Thiazide diuretics act predominantly in the distal convoluted tubule. Spironolactone acts on the collecting duct. Administration of combinations of diuretics with actions at more than one site in the nephron is known as "sequential nephron blockade," which can lead to more potent diuresis.

Three of the most frequently used diuretic agents are furosemide, spironolactone, and torsemide. Thiazide diuretics are also used but usually in combination with loop diuretics to control signs of congestion in patients with more advanced signs of heart failure.

Furosemide should be regarded as first line therapy for any patient requiring medical treatment to relieve clinical signs brought about by congestion. This includes patients that present with dyspnea due to pulmonary edema and pleural effusion, although in the latter case it is likely that the patient will also benefit from thoracocentesis (see ch. 102). Patients with ascites or (rarely) subcutaneous edema due to heart disease will also require diuresis to relieve their clinical signs. If a patient has a large volume of ascites that is causing respiratory compromise, abdominocentesis (see ch. 90) can be indicated to obtain rapid relief of clinical signs but diuretic treatment will still be required to inhibit the redevelopment of the abdominal effusion. Furosemide can be administered by multiple routes including orally, by bolus injection, and by constant rate infusion.[3] Patients that have not previously encountered the diuretic are likely to experience a profound diuresis when the drug is first administered. Patients that have already chronically received furosemide can become refractory to the drug and are likely to have a less profound response to diuresis and in order to achieve control of their clinical signs may require either higher dosages of furosemide or the additional administration of different types of diuretic that act at different sites in the nephron. In dogs refractory to the administration of furosemide, it appears that the administration of torsemide can result in improved diuresis and it has been associated with a sustained resolution of otherwise refractory clinical signs in some cases.[4,5] Initial oral doses of furosemide administered to a canine or feline patient should be in the region of 1-2 mg/kg q 12 h. Doses can be escalated to as high as 4 mg/kg three times a day (up to 12 mg/kg/day). If patients are receiving near to the maximal dosage of furosemide and their signs of congestion are proving

refractory to therapy, rather than further escalation of the dose of furosemide, it is likely that they will benefit more from the co-administration of a second diuretic such as spironolactone, a thiazide, or the administration of torsemide. In cases where patients are apparently refractory to diuretic therapy given at home, it is important to establish that the medication is being administered appropriately. This may require tactfully exploring with the owners their understanding of, and adherence to, the treatment regime prescribed. It is also worth taking a detailed dietary history to determine whether a high-sodium intake is partly responsible for the observed resistance to diuretic therapy (see ch. 183).

Spironolactone is a potassium-sparing diuretic that acts through the inhibition of aldosterone receptors. Benefits demonstrated in human patients with heart failure[6] imply an action independent of the diuretic effect of the agent. This agent should therefore be regarded more broadly as an aldosterone receptor antagonist. Evidence of its effectiveness in the management of canine patients with acquired valvular disease[7] has led to its frequent administration to canine patients with heart failure. Although it has been administered for its diuretic effect, and other putative benefits, in cats with heart disease and heart failure one study in a small number of cats suggested that there may be concern over the development of cutaneous adverse drug reactions.[8] This may have limited the frequency with which it is administered to this species.

In dogs, the effective dosage of spironolactone has been shown to be 2 mg/kg PO q 24 h.[9] In contrast to furosemide, there is little evidence that improved control of clinical signs will be obtained by higher dosages or more frequent administration.

Spironolactone does not have sufficient natriuretic potency to be used as the sole diuretic in patients requiring medical management of signs of congestion. It is better, therefore, to regard it as an agent to be administered alongside other diuretics, particularly loop diuretics, to potentiate their effect. The other argument for its administration is that the benefits associated with its administration are thought to extend beyond diuretic effects. Aldosterone receptor blockade is thought to be of benefit through blocking detrimental effects of aldosterone on the vasculature and cardiac remodeling.

Torsemide (torasemide) is a loop diuretic similar to furosemide that has been used as a salvage agent in patients that have become refractory to high dosages of furosemide during chronic treatment for heart failure. There are several theoretical advantages to the administration of torsemide, including a decreased likelihood of patients becoming refractory to its administration[10] and also possible anti-aldosterone effects,[11] in addition to the effects in the loop of Henle. In patients with refractory signs of congestive failure, torsemide is substituted for the furosemide in the treatment regime and furosemide therapy is ceased. This substitution can take place abruptly with the first torsemide dose administered when the next furosemide dose would have been given. The recommended method of administration is to initiate treatment with a total daily torsemide dose (split into two doses administered at ≈12 hour intervals) that is approximately one-tenth of the total daily furosemide dose the patient was receiving[5] (Box 247-1).

Box 247-1

An Example of a Dosage Conversion from Furosemide to Torsemide

An 11 kg dog currently receives 40 mg of furosemide three times a day and has evidence of ascites that is refractory to current treatment. What dosage of torsemide should be substituted for the current furosemide treatment?

- The current total daily dose of furosemide is 120 mg per day (=10.9 mg/kg/day).
- The total daily torsemide dose therefore should be 120 mg/10 (i.e., 12 mg per day).
- This should be administered as two equal doses approximately 12 hours apart.
- Therefore the dose of torsemide should be 6 mg PO q 12 h.

Thiazide diuretics represent another class of diuretic that is widely used in human patients, particularly those with systemic hypertension. They are also used in canine heart failure patients, especially those with signs of congestion that are refractory to furosemide and spironolactone. Thiazides predominantly act by inhibition of sodium reuptake in the distal convoluted tubule; therefore, when used with a loop diuretic and a potassium-sparing diuretic, this combination produces "sequential nephron blockade," where greater diuresis can be achieved through inhibiting sodium reabsorption at numerous sites in the nephron (see Figure 247-3). Hydrochlorothiazide is a thiazide diuretic agent that can be used in this situation.

Complications of Diuretic Treatment

Although widely used and generally well-tolerated, there are numerous possible complications and side-effects of diuretic administration that warrant the careful monitoring of patients receiving them chronically. The most obvious "side-effect" of diuretics, from the perspective of the animal's owner, is the polyuria and polydipsia that will result from their administration. Owners should always be warned that this is an expected effect of the treatment the pet will be receiving.

All of the most commonly observed complications are direct consequences of the drugs' mechanisms of action and the patient's adaptation to their administration. These include volume depletion and reduction in cardiac output, and electrolyte abnormalities.

Volume Depletion and Reduction in Cardiac Output

The intended effect of diuretic administration is to reduce the patient's circulating fluid volume appropriately. The goal is for the volume to be reduced sufficiently to relieve signs of congestion while allowing the patient to maintain adequate perfusion. If, as a consequence of treatment, the circulating fluid volume is reduced excessively, or if the patient is especially dependent on having a high ventricular filling pressure to maintain an adequate cardiac output (which is particularly likely in patients with predominantly diastolic heart failure, e.g., cats with hypertrophic cardiomyopathy) then there could be a fall in cardiac output and perfusion may be compromised following diuresis. This can manifest in a number of ways, including the patient's becoming hypotensive or azotemic. If a patient does demonstrate these signs after diuresis, it may be necessary to consider one or both of the following:

- Reducing of the intensity of diuretic treatment
- Introducing a more balanced heart failure treatment regime that counteracts the drop in cardiac output by other means, e.g., vasodilation or the administration of inotropic drugs.

One common misapprehension is that a patient showing these signs is "dehydrated" and will therefore benefit from the administration of intravenous fluids. Heart failure—as explained above—is a problem of inappropriate distribution of fluid. In a patient with a normal heart, the administration of fluid into the venous circulation is likely to improve cardiac output and will therefore improve signs of low cardiac output and poor perfusion. In a patient with heart failure, particularly one with signs of congestion, there is already more than enough fluid in the venous circulation; the problem is that the heart is unable to adequately transfer that fluid into the arterial circulation. Adding more fluid into the venous circulation is likely to worsen signs of congestion and is unlikely to improve the signs of poor perfusion. Recently, it has been shown in human patients that intravenous fluid therapy during an episode of acute decompensated heart failure worsens rather than improves outcome.[12] Intravenous fluid therapy is usually contraindicated in patients with signs of congestive heart failure.

Electrolyte abnormalities also commonly occur as a complication of diuretic treatment. The normal physiologic response to increased sodium and water loss is the stimulation of homeostatic mechanisms that attempt to more vigorously retain sodium and water. Predominant among these mechanisms is the RAAS. Less commonly—although significantly—vasopressin release is sometimes also stimulated by a marked fall in blood pressure secondary to heart disease or diuretic treatment. One of the effects of the stimulation of these homeostatic mechanisms is altered handling of electrolytes. Increased activity of aldosterone will tend to favor sodium retention and potassium loss in the distal nephron. This leads to one of the more commonly observed consequences of loop diuretic administration: hypokalemia. Hypokalemia is less likely to be observed in patients if they are concurrently receiving treatments that tend to counteract the RAAS.[13] More widespread use of angiotensin-converting enzyme inhibitors (ACEIs; see below) and spironolactone, in addition to loop diuretics, mean that hypokalemia now is seen less frequently. The situation in which it is now probably most likely to be encountered is during the emergency stabilization of patients where they are likely to receive large doses of furosemide and might not yet have been started on other agents.

Where substantial hypotension arises as a consequence of either severe cardiac disease or vigorous diuretic treatment, vasopressin release can be stimulated. Vasopressin mediates the renal retention of free water. Free water retention will lead to expansion of circulating fluid volume but with the drawback of a reduction in sodium concentration. Thus, severe, advanced heart disease and vigorous diuretic treatment can be associated with the development of hyponatremia.[13] In human studies, the presence of hyponatremia in heart failure patients is associated with a worse prognosis.[14]

After a few days of diuretic administration, a patient will have physiologically adapted to the increased sodium and water loss and reached a new steady state whereby increased sodium loss has been balanced by

more vigorous sodium retention.[15] In this new steady state, sodium intake will equal sodium loss, but crucially this new steady state will have been achieved following a reduction in the patient's circulating fluid volume. After 10-14 days of diuretic treatment, a patient will be in a new equilibrium but with a lower circulating fluid volume. This lower circulating volume will be maintained, and signs of congestion will remain controlled, as long as the patient continues to receive (and respond to) the same diuretic dosage, the sodium intake is consistent, and the heart disease does not significantly worsen. The period during which this new equilibrium develops is the period in which the patient is most likely to develop complications of diuretic treatment; therefore, signs of excessive volume depletion and electrolyte abnormalities are more likely to occur in the 10-14 days following the introduction or modification of a diuretic regime.

Given the frequency with which abnormalities of volume homeostasis, perfusion, and blood electrolyte concentrations occur in patients receiving diuretics, it is good practice to evaluate indicators of renal function and blood electrolyte concentrations before and after the initiation or substantial modification of diuretic treatment. Re-checking serum urea, creatinine, sodium, potassium and chloride concentrations 10-14 days after initiation or alteration of a diuretic regime will allow early detection of abnormalities and necessary adjustments of treatment can be made.

For hospitalized patients with acute heart failure receiving intensive heart failure therapy and frequent dosage adjustments, it is prudent to check serum electrolyte concentrations and indicators of renal function regularly: ideally at least once in every 24 hour period and more frequently in patients experiencing complications.

Venodilators

Venodilators are agents that dilate the systemic veins. Many vasodilators act on both veins and arteries and are described as "balanced" vasodilators (these will be considered further below under afterload reduction). Some vasodilators act predominantly on veins and therefore primarily reduce preload. By dilating veins, these agents increase the volume of the capacitance vessels within the circulation, decreasing the pressure within veins and therefore reducing the pressure at which blood returns to the heart. This will reduce the hydrostatic pressure in the veins and in the capillaries which drain into them—thus tending to reduce signs of congestion that a patient is showing (see Figure 247-2, *D*). Since the two main determinants of the venous hydrostatic pressure are the volume of fluid in the veins and the extent to which those veins are dilated, one can understand how venodilators will tend to act in a complementary way with diuretics in the reduction of preload: Diuretics reduce the volume of blood in the veins and venodilators increase the venous capacity to hold that volume of blood at relatively lower pressures. The class of vasodilators that act predominantly on the veins is nitrate vasodilators and the agent of this class most often administered to veterinary patients is nitroglycerin (glyceryl trinitrate). Some nitrate vasodilators, particularly nitroprusside, have effects on afterload and preload and will be considered with balanced vasodilators, below.

Venodilators tend to be administered in situations where preload reduction is required acutely, i.e., in the management of patients with severe signs of congestion that require emergency management. Nitroglycerin is typically administered as a cutaneous ointment that requires percutaneous absorption in order to be effective. The method of administration and rapid development of tachyphylaxis (tolerance and rapid loss of efficacy) limit the use of nitroglycerin to short periods of administration in hospitalized patients.

There is some evidence of favorable effects of nitrate vasodilators in human patients in the acute setting, but the evidence that exists is relatively weak and does not demonstrate superiority of nitrates over other methods of controlling clinical signs.[16] Long-term, controlled studies of these agents have not been conducted in veterinary patients. Studies in anesthetized normal dogs have demonstrated that splenic volume—and therefore, by inference, capacitance vessel volume—increases in response to transdermal administration of nitroglycerin.[17] In contrast, in a separate study the oral administration of the nitrate vasodilator isosorbide dinitrate was found not to be associated with a redistribution of blood volume between body cavities,[18] implying that this nitrate compound may not be an effective venodilator in dogs.

Drugs That Decrease Afterload

Heart failure is brought about by the chronic stimulation of a number of homeostatic mechanisms responding to a perceived drop in pressure within the arterial circulation (see ch. 246). Many of the systems stimulated in heart failure—including the sympathetic nervous system, the RAAS and the vasopressin system—result in an increase in systemic vascular resistance. This is in an effort to restore blood pressure to a more normal level. Although beneficial as an acute response to a fall in blood pressure, chronic vasoconstriction has a

detrimental effect on cardiac function. Increased vascular resistance will either impair cardiac output or necessitate an increase in cardiac work to maintain an adequate cardiac output. Increased cardiac work will increase myocardial oxygen consumption and, if cardiac work is chronically increased, lead to further deterioration in cardiac function, hastening the further decline of the already failing heart. In the patient with mitral regurgitation, systemic arterial vasoconstriction will resist the ejection of blood from the left ventricle into the aorta and can favor the backward flow of blood through the incompetent valve into the left atrium. The path by which blood leaves the left ventricle in the presence of mitral regurgitation is determined by the relative resistance to ejection into the aorta or back into the left atrium. Reduction of resistance to ejection into the aorta (through reduced systemic vascular resistance) will tend to favor blood leaving the ventricle this way and reduce the magnitude of the regurgitant jet. If the resistance to ejection is reduced, it is also possible that a similar cardiac output will be able to be maintained with a lower ventricular preload—thus, agents that reduce systemic vascular resistance may indirectly bring about preload reduction.

The hypothetical advantages of vasodilators are easy to understand: They should lead to an improvement in cardiac output or alternatively the maintenance of the same cardiac output but with reduced myocardial work (Figure 247-2, *E*).

Clear clinical evidence of the advantages of vasodilation was established in a number of groundbreaking studies in human heart failure patients including the V-HeFT study[19] and the CONSENSUS study.[20] These studies demonstrated improvement in survival of heart failure patients when vasodilators were administered.

There are various classes of drugs that are administered to heart failure patients that act either entirely or partly through a vasodilator effect; these include the nitrates, ACEIs, pimobendan, and calcium channel blockers. Other classes of vasodilator have historically been used in dogs, such as hydralazine[21] and prazosin, but their use has fallen out of favor as evidence to support the use of other agents has strengthened.

A potential disadvantage of vasodilator administration is that reduction in vascular resistance in a patient with already impaired cardiac function could lead to a fall in blood pressure, resulting in signs of hypotension such as syncope, weakness, and hypoperfusion. Patients with certain underlying cardiac diseases might be less able to increase their cardiac output following afterload reduction as a consequence of the type of cardiac disease by which they are affected, and therefore at greater risk of the development of these complications. Patients particularly at risk of this complication are those with outflow tract obstructions and with diseases causing predominantly diastolic dysfunction, such as hypertrophic cardiomyopathy in cats. Despite these valid concerns, the wide variety of benefits, beyond simple reduction in vascular resistance, that are associated with administration of agents such as ACEIs, means that in practice they are frequently given to patients with such underlying diseases. In such cases, more cautious introduction and careful monitoring is warranted.

Nitroprusside

Nitroprusside is a rapidly acting, intravenously administered nitrate vasodilator. It has a balanced effect, meaning that it can achieve preload reduction through venodilation and afterload reduction through arteriodilation. It is rapid acting with profound effects and requires careful administration by constant rate infusion. In an intensive care unit, where blood pressure can be carefully monitored (see ch. 99), it can be a very useful adjunct to other treatments in the acute management of a patient requiring intensive preload and afterload reduction. Administration of nitroprusside in the primary care setting is probably not practicable. Nitroprusside is awkward to administer as it must be protected from light during infusion. As with nitroglycerin, above, patients rapidly become refractory to nitroprusside, which limits its value for chronic administration. It is also metabolized to cyanide, which limits its cumulative use.

Angiotensin Converting Enzyme Inhibitors (ACEIs)

As a class, the ACEIs are one of the most widely used types of agent in the management of veterinary patients with heart failure. There are numerous agents with similar pharmacodynamic effects; these include *enalapril, benazepril, ramipril* and *imidapril,* among others. The effectiveness of ACEIs for the treatment of canine patients with heart failure was established in a number of studies in the 1990s.[22,23] Since then, ACEIs have become, with good reason, a standard part of the chronic therapy for most patients with heart failure. The evidence for their effectiveness in feline patients with heart failure is less well established. One study's preliminary results did suggest that ACEIs were superior to beta-blockers in the treatment of heart failure secondary to myocardial disease in cats.[24] Due to their theoretical (rather than proven) benefits, they are also frequently used as a mainstay of therapy in cats with heart failure.

Through the inhibition of angiotensin converting enzyme, ACEIs tend to both bring about vasodilation and

inhibit fluid retention (see ch. 246). Their interference in this pathway is particularly beneficial in patients that are also receiving diuretics. As described above, diuretic administration leads to sodium loss and RAAS stimulation. It is advantageous to inhibit the pathway by which the patient attempts to circumvent the sodium-wasting effects of diuresis. This complementary effect of the two types of agent is frequently used as an argument for their routine co-administration. Generally ACEIs are administered to most patients with heart failure that require chronic diuresis unless there is a contraindication to their administration. In practice this means that most dogs and cats receiving therapy for heart failure will receive an ACEI. The dosages of some of these agents are outlined in Box 247-2.

Box 247-2

Drugs Commonly Administered for the Treatment of Heart Failure in Dogs and Cats, Including Their Rationale for Administration and Mechanism of Action

Preload Reduction

Diuretics

- Furosemide
  - Oral: 1-4 mg/kg q 8-12 h
  - IV: In the emergency setting, 1-4 mg/kg as a bolus injection; repeat at intervals of 4 hours (or less if signs severe) until clinical signs improve
  - IV CRI: 0.5-1 mg/kg/h until signs improve
  - Total daily doses >12 mg/kg/day should be avoided if possible. Failure of a patient to show improvement after multiple intravenous doses or a CRI for >4 hours should lead to re-evaluation of the diagnosis and modification of the treatment regime.
- Spironolactone
  - Oral: 2 mg/kg q 24 h
- Torsemide
  - Calculate dosage on the basis of the furosemide dose to be replaced (see Box 247-1)
- Hydrochlorothiazide
  - Oral: 0.5-4 mg/kg q 12-24 h. Use lower end of the dosage range when in combination with other diuretics.

Venodilators

- Nitroglycerin
  - Administered as percutaneous ointment
  - 2.5 cm of 2% transdermal ointment per 10 kg body weight

Afterload Reduction

Vasodilators

- Enalapril
  - Oral: 0.5 mg/kg q 12-24 h
- Benazepril
  - Oral: 0.25-0.5 mg/kg q 24 h
- Ramipril
  - Oral: 0.125 mg/kg q 24 h
- Imidapril
  - Oral: 0.25 mg/kg q 24 h
- Amlodipine
  - For heart failure treatment in dogs
  - Oral: 0.05-0.1 mg/kg q 24 h
- Nitroprusside
  - IV CRI: 1-5 mcg/kg/min
  - Start at low dose, titrate up, and monitor blood pressure

Right Ventricular Afterload Reduction

Pulmonary Vasodilator

- Sildenafil
  - Oral: Wide dosage ranges reported from 0.25 mg/kg q 12 h up to 2 mg/kg q 8 h
  - Start low and increase gradually

Improved Cardiac Filling

Lusitropic Agents

- Diltiazem
  - Oral: 10 mg/cat q 8 h
  - Various slow-release preparations are also used, but pharmacokinetics are less well established

Enhanced Cardiac Contractility

Inotropic Agents

- Dobutamine
  - IV CRI: Start at low end of dosage range. Titrate to effect while monitoring for signs of toxicosis, especially arrhythmias.
  - Dog: 2-15 mcg/kg/min
  - Cat: 1-5 mcg/kg/min
- Pimobendan
  - Dog
  - Oral: 0.1-0.3 mg/kg q 12 h (similar dosages have been used empirically in cats)
  - IV: Bolus injection (available in Europe): 0.15 mg/kg

CRI, Constant rate infusion; *IV,* intravenous.

ACEIs are not particularly profound vasodilators and their benefits are more likely to be associated with chronic rather than acute administration. For this reason they are more likely to constitute a part of a chronic treatment regime than be an agent to be administered in the acute heart failure setting.

Much controversy has surrounded whether or not ACEIs have a beneficial effect in preclinical heart disease. Two prospective placebo-controlled studies in dogs with preclinical mitral valve disease[25,26] failed to conclusively demonstrate a prolongation of the time to the onset of congestive heart failure. A retrospective study in dogs with dilated cardiomyopathy[27] suggested that benazepril could be associated with improved outcome, but a prospective placebo-controlled study of these agents has yet to be undertaken in the preclinical stage of this disease. No conclusive evidence currently supports their use at the preclinical stage of feline myocardial disease.

The best evidence, and the majority of expert opinion, support the use of ACEI in most patients with signs of heart failure requiring chronic diuretic administration.

Pimobendan

Pimobendan is described as an "inodilator": an agent with both inotropic and vasodilatory effects. It is impossible to separate these two effects and therefore somewhat artificial to consider the drug as either an "inotrope" or a "vasodilator" here; however, further description of the mechanism of action of, and indications for, this drug will be found below under inotropes.

Calcium Channel Blockers

As a class, the calcium channel blockers have numerous and varied cardiac electrophysiological and vascular effects. The calcium channel blocker most widely administered to veterinary patients for its vasodilator effect is *amlodipine.* It is most frequently used as an antihypertensive agent in cats with systemic hypertension (see ch. 158); however, its marked effects as an arteriodilator have led some to advocate its use as a vasodilator in dogs with heart failure. It may be of particular benefit when that heart failure is secondary to mitral valve disease, for reasons outlined above. Experimental studies have shown a reduction in left atrial pressure in dogs with mitral regurgitation associated with the administration of amlodipine, which suggests a pathophysiological rationale for its administration in dogs with heart failure secondary to this condition;[28] however, a prospective study of the effect of this drug on clinically meaningful outcomes in dogs (or cats) with heart failure has yet to be published.

Therefore, amlodipine could be considered for administration to dogs with heart failure, particularly when secondary to mitral regurgitation, but should probably be given as a second or third line vasodilator to patients that are already receiving pimobendan and ACEI and have refractory signs of heart failure despite receiving such treatment.

Diltiazem is also a calcium channel blocking agent that has been advocated for use in both canine and feline patients with heart failure. In dogs it is widely used as an antiarrhythmic agent and in cats as a possible positive lusitrope so it is considered further for those effects below, and in ch. 248.

Pulmonary Vasodilators

The vasodilators described above act either predominantly or exclusively on the systemic arterial vasculature. Some agents act principally or partially on the pulmonary circulation. In patients with right-sided congestive heart failure, clinical signs can be improved by reduction of the pulmonary vascular resistance. This can improve output from the right side of the heart (and therefore result in an overall improvement in cardiac output) and can also result in a reduction in systemic venous pressures due to more effective transfer of blood from the systemic veins through the pulmonary arteries. Pulmonary vasodilation is most likely to improve a patient's clinical signs when these are, at least in part, a consequence of increased pulmonary vascular resistance, i.e., where the patient has pulmonary hypertension as either the primary cause or a secondary complication of cardiac disease.

Sildenafil is a phosphodiesterase V inhibitor that is widely used with the aim of reducing pulmonary vascular resistance and improving clinical signs in patients with signs of heart failure secondary to increased pulmonary vascular resistance (see ch. 243). Case series have been published describing improvements in clinical signs associated with the administration of this agent in dogs.[29,30] One prospective blinded crossover study suggested that sildenafil, when administered to dogs with heart failure and pulmonary arterial hypertension secondary to degenerative mitral valve disease, is associated with a reduction in pulmonary artery pressures, improved exercise tolerance and quality of life.[31] This agent is most likely to be indicated in patients with heart failure due to causes such as pulmonary vascular parasitic disease or chronic pulmonary diseases. It is also advocated for administration to dogs in the later stages of myxomatous mitral valve disease where right-sided heart failure may develop secondary to the development of pulmonary hypertension (see ch. 251).

Pimobendan may also have pulmonary vasodilatory properties in addition to its systemic vasodilating effects and could therefore also be effective in controlling clinical signs of right-sided heart failure in dogs with more advanced mitral valve disease.

There are occasional reports of the administration of endothelin receptor antagonists (e.g., *bosentan*) to dogs with pulmonary hypertension but there is insufficient evidence currently available to make recommendations regarding their effectiveness. They are also prohibitively expensive.

Drugs That Enhance Inotropic Function

One of the primary determinants of a patient's cardiac output is myocardial contractility. If myocardial contractility is physiologically or pharmacologically enhanced, then a greater cardiac output will be achieved with the same cardiac filling (preload), or the same cardiac output can be achieved with lower cardiac filling pressures. Drugs that enhance contractility therefore have the capacity to increase cardiac output or indirectly decrease preload, by allowing patients to sustain a similar cardiac output at lower filling pressures (Figure 247-2, *F*).

Myocardial contractility is frequently impaired in patients with heart failure. Impairment of contractility can be the primary abnormality causing a patient to have heart failure, e.g., in patients with dilated cardiomyopathy, or may be secondarily impaired due to chronic changes in load imposed upon the heart by other conditions such as valvular heart disease or hypertension. Enhancement of cardiac contractility has the capacity to improve the clinical signs of many patients with heart failure. Patients with signs of forward failure are particularly likely to benefit from improved cardiac output. Indirect reduction of preload can also improve signs of congestion.

Inotropes can be administered in the hospitalized patient with an acute onset of heart failure (or a patient with an acute deterioration of chronic heart failure) or may be chronically administered to patients being managed at home. The inotropic agent most commonly administered to heart failure patients in the acute setting is *dobutamine.* The agent with inotropic properties most commonly administered chronically is *pimobendan.* Other agents with inotropic effects used in the treatment of canine patients include digoxin and milrinone. The former is still frequently administered to dogs but principally because of its

parasympathomimetic effects in dogs with supraventricular arrhythmias (see ch. 248). The latter, a phosphodiesterase inhibitor, is not used commonly.

Dobutamine

Dobutamine is a sympathomimetic agent that acts primarily through stimulation of beta-1 receptors. It therefore enhances both the force of myocardial contraction and the rate at which the myocardium relaxes; i.e., both inotropic and lusitropic effects, respectively. It can only be administered by constant rate intravenous infusion. This means it can only be administered to hospitalized patients. There is a very marked dose-response relationship and higher dosages are more likely to be associated with side-effects such as the induction of arrhythmias. For these reasons, it is an agent that is most safely administered in an intensive care setting where accurate dosing and careful monitoring can be ensured.

Dobutamine is most likely to be indicated in those patients with acute signs of heart failure complicated by either hypotension or primary failure of myocardial contractility (i.e., dilated cardiomyopathy). It is also of value as a "rescue" agent in the treatment of patients with an acute crisis that are already receiving chronic treatment for congestive heart failure of any cause, e.g., dogs with mitral valve disease presenting with signs of heart failure refractory to oral medication.

Due to the restrictions on dobutamine's use imposed by the method of administration, it is inevitable that it will be given for short periods of time—at most a few days—and it should therefore be regarded as a bridge to the development of an effective chronic treatment regime.

Pimobendan

Pimobendan is a widely used agent with both inotropic and vasodilatory properties. These are brought about by phosphodiesterase inhibition and calcium sensitization. Since these effects are inseparable, it is impossible to determine which of pimobendan's effects are brought about through which mechanism and broadly regarding the drug as an "Inodilator" is probably most helpful. Due to effects outlined above, these inodilatory effects will lead to enhancement of cardiac output through reduction of systemic vascular resistance and improved myocardial contractility. It is argued that these combined effects overcome some of the disadvantages of purely inotropic agents, enabling cardiac output to be improved without a substantial increase in myocardial work, due to the simultaneous reduction in afterload.

These hypothetical benefits of pimobendan are supported by a wealth of data from prospective randomized clinical trials demonstrating improved outcomes in dogs with heart failure secondary to both myocardial and valvular heart diseases.[32-34] Although strictly outside the scope of a chapter on the treatment of heart failure, there is also more recent evidence to suggest a potential benefit of pimobendan in delaying the onset of clinical signs of heart failure in dogs with dilated cardiomyopathy[35] and preclinical degenerative mitral valve disease.[35a]

Pimobendan is indicated for chronic administration to all dogs with heart failure secondary to degenerative mitral valve disease or dilated cardiomyopathy, the two most common causes of acquired heart failure in the dog. Although evidence for a benefit of its administration in canine patients with heart failure secondary to other causes is less strong, it can be regarded as indicated in most canine patients unless medical treatment is not appropriate (e.g., in dogs with pericardial effusion causing cardiac tamponade) or where its administration might be contraindicated (e.g., in dogs with a left ventricular outflow tract obstruction).

Pimobendan is usually administered orally; however, an intravenous preparation is available in Europe for administration in the emergency setting.

The benefits of pimobendan in cats suffering from heart failure seem intuitively less obvious in light of the types of diseases that most commonly lead to heart failure in this species. It is more difficult to formulate a pathophysiological rationale for the benefits of an inodilator in patients with hypertrophic cardiomyopathy, since the primary underlying disease process is not one that is conventionally believed to be associated with impaired contractility. Nevertheless, several case series[36,37] and one case-control study[38] have now demonstrated that pimobendan is tolerated, probably safe, and may be associated with improved outcomes in cats with heart failure, even those where the primary underlying disease process is hypertrophic cardiomyopathy. Pimobendan can therefore be considered to be indicated in some cats with heart failure. It is usually administered to cats in addition to an ACEI and diuretic. It is particularly indicated in those presenting with signs of poor cardiac output, in conjunction with signs of congestion and in those already refractory to the more conventional combination of a diuretic and an ACEI.

Drugs That Inhibit Inotropic Function

Beta-Blockade

Some patients with heart disease can have clinical signs precipitated by increased sympathetic stimulation, which increases cardiac contractility and heart rate. This is particularly thought to be the case in cats with hypertrophic obstructive cardiomyopathy, where increased contractility can be associated with worsening of outflow tract obstruction and increased heart rate may further impair already compromised diastolic ventricular filling. Therefore, it has been argued that there could be a benefit of administering drugs that reduce contractility and heart rate to these patients—particularly drugs that inhibit the increase in contractility associated with sympathetic stimulation. For many years, cardiologists advocated the use of beta-blockers such as *atenolol* in the treatment of cats with hypertrophic cardiomyopathy, particularly those with evidence of dynamic left ventricular outflow tract obstruction. More recently, studies have suggested a possible detrimental effect of beta-blockers on outcome in cats with heart failure secondary to myocardial disease[24] and a neutral effect of atenolol on the outcome of cats with preclinical myocardial disease.[39] As a result, the use of beta-blockers in cats with myocardial disease is now falling out of favor.

Studies have been conducted to evaluate the effect of beta-blockade in dogs with dilated cardiomyopathy[40] and mitral valve disease.[41,42] The rationale for these studies has been based on the extrapolation of favorable outcomes associated with beta-blocker administration in human patients with heart failure. None of these studies has demonstrated a clear improvement in clinical status of patients receiving these drugs, nor an improvement in a clinically meaningful outcome, such as survival. Currently, there is insufficient evidence to advocate their administration to dogs with preclinical cardiac disease, and some evidence to suggest that their administration to dogs with overt clinical evidence of heart failure is contraindicated.

The only remaining uncontroversial indication for beta-blocker administration to canine and feline patients with heart failure is due to their effects on cardiac rate and rhythm in patients where arrhythmias are contributing to their clinical signs (see ch. 248).

Improving Cardiac Filling

In order to maintain a normal cardiac output at normal intracardiac filling pressures, the heart must be able to fill normally between contractions. In order to do this, myocardial relaxation must be normal and the myocardium must be compliant. Cardiac filling can be impaired in many ways; there could be inadequate time for the heart to fill if heart rate is excessive, the myocardium might be excessively stiff due to fibrosis or hypertrophy, and normal physiological mechanisms that reduce wall tension at the onset of diastole (principally mechanisms that lead to a reduction in intracellular calcium concentrations) might be impaired.

Heart failure therapy can either directly or indirectly influence cardiac filling. Indirectly, interventions that reduce sympathetic tone and improve oxygenation are likely to result in reduced heart rate and improved myocardial diastolic function. Drugs that directly improve myocardial relaxation are called "lusitropic" agents (Figure 247-2, *G*). Part of the rationale underlying the administration of diltiazem to cats with hypertrophic cardiomyopathy was based on a positive lusitropic effect of the drug. Only weak evidence of a benefit of administering diltiazem to cats with hypertrophic cardiomyopathy has been shown[43] and no peer-reviewed published evidence of superiority of diltiazem over other methods of treatment, such as using ACEI, is available. As such, diltiazem treatment of feline hypertrophic cardiomyopathy is now no longer widely advocated.

Optimizing Cardiac Rate and Rhythm

Patients with heart failure often have abnormalities of cardiac rate and rhythm. Cardiac output is the product of heart rate and stroke volume. Bradyarrhythmias compromise cardiac output due to the reduction in heart rate. Tachyarrhythmias compromise output due to a reduction in stroke volume. Stroke volume is reduced at high heart rates because of reduced time available during diastole for the heart to fill. Some tachyarrhythmias also cause loss of atrioventricular synchrony and/or abnormalities of the sequence of activation of the ventricular myocardium, both of which can further impair stroke volume.

Those patients with signs of heart failure directly attributable to a cardiac arrhythmia, such as those with rapid persistent supraventricular tachycardia or those with bradyarrhythmias like third-degree atrioventricular block, will be substantially improved through control of the arrhythmia. In patients where signs of heart failure are exacerbated by a concurrent arrhythmia, although the arrhythmia may not be the primary cause of the signs, appropriate management of that arrhythmia should also be a specific aim of the

treatment, alongside other attempts to control signs of congestion and poor output (see ch. 248 and 249).

Restoration of a more normal heart rate, by either a reduction or an increase in the heart rate where appropriate, is likely to improve cardiac output. However, it should be borne in mind that many patients with heart failure will have a moderately elevated heart rate and sinus tachycardia. In these patients it can be appropriate, during an acute episode of heart failure, to have a heart rate higher than would be expected in a normal dog. Reduction of heart rate in these patients should be achieved by better control of signs of heart failure rather than by direct administration of negatively chronotropic (heart-rate–reducing) agents such as beta-blockers. Restoration of synchronous atrial and ventricular activation, secondary to abolition of ventricular arrhythmias, is also likely to improve output when such arrhythmias are present.

Monitoring and Adjustment of Heart Failure Therapy

The two main purposes of monitoring patients receiving heart failure therapy are to establish whether the initial aims of treatment have been achieved, and whether any adverse reactions have developed in response to the administration of treatment (Figure 247-4).

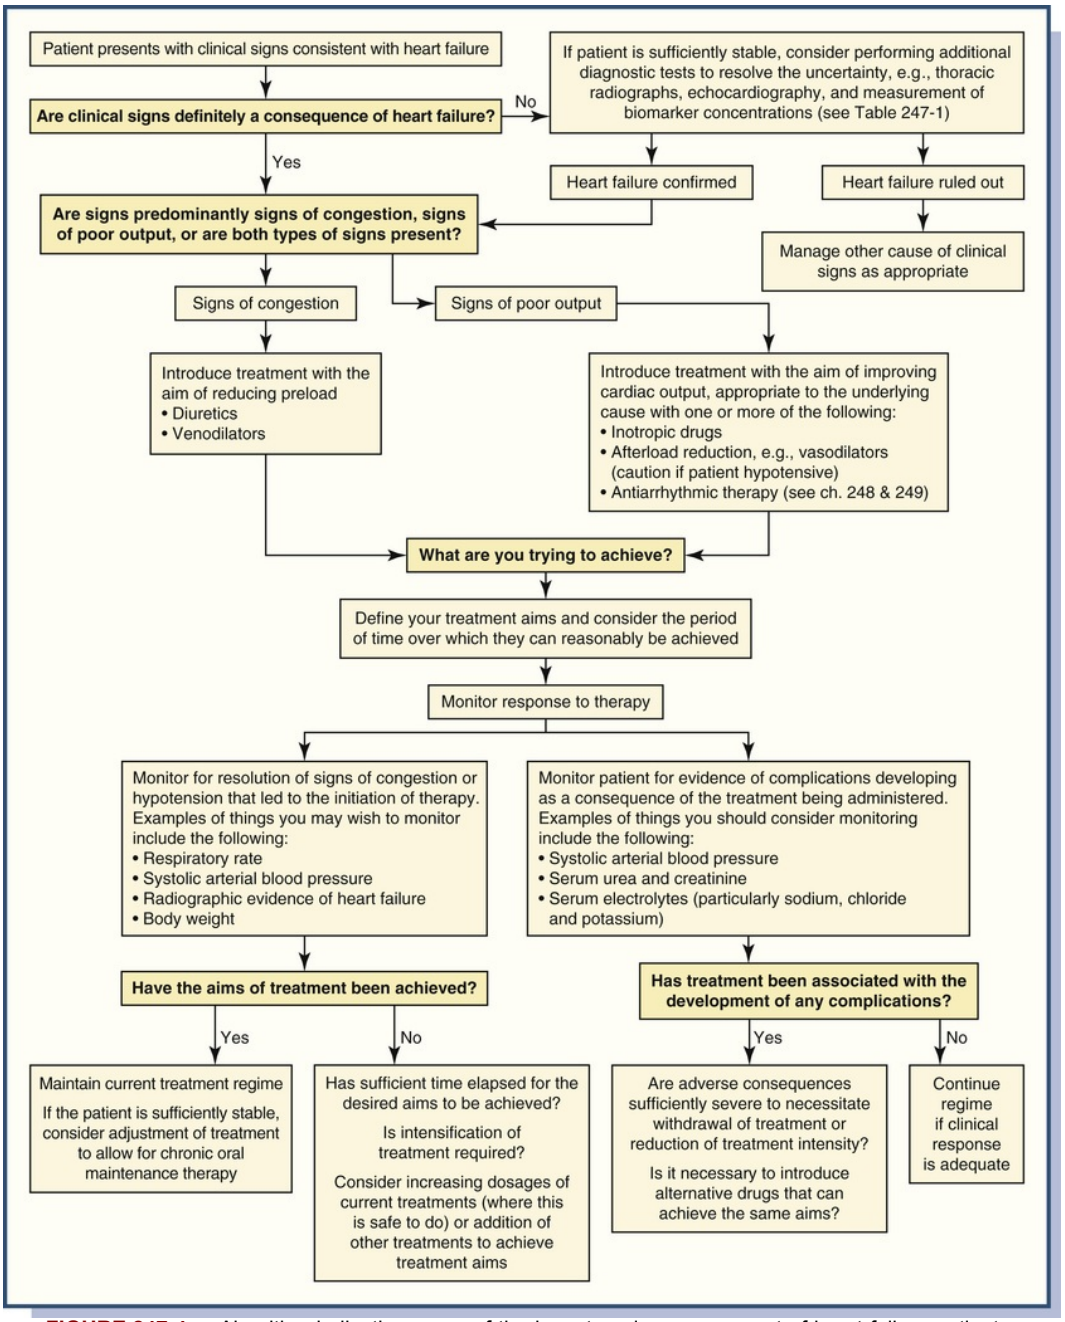

FIGURE 247-4 Algorithm indicating some of the key steps in management of heart failure patients. Boxes highlighted and with boldface font indicate the important questions that a clinician must ask in order to make appropriate therapeutic and monitoring choices.

Complications of diuretic treatment—specifically, their detection and management—are outlined above in the section on diuretics.

The success of therapy will be demonstrated by a resolution of the clinical signs and/or diagnostic findings that necessitated the introduction of treatment. If a patient required treatment because of the presence of pleural effusion leading to dyspnea, then successful treatment would be visible as the resolution of the pleural effusion and restoration of a more normal respiratory rate and effort. Similarly, if the main indication for treatment was dyspnea confirmed radiographically to be secondary to pulmonary edema, successful treatment would be apparent as restoration of normal respiratory rate and effort in conjunction with radiographic resolution of the pulmonary edema.

In a patient hospitalized for the initial management of congestive heart failure, successful treatment ideally would result in an improvement in respiratory rate and effort within the first few hours of treatment. Radiographically detectable improvement of pulmonary edema usually lags behind any improvement in

clinical signs and may take longer to achieve, perhaps 24-48 hours. If clinical indications of congestive heart failure, such as respiratory rate, are not improving, there is probably little point in re-radiographing a patient unless there is doubt over the initial diagnosis of cardiogenic pulmonary edema and alternative explanations for the patient's signs are being sought. The purpose of repeating radiographs therefore is often to confirm and document improvement in the signs of heart failure in a patient already showing clinical evidence of improvement.

In patients that present with clinical signs of poor perfusion, resolution of those signs is likely to indicate successful treatment. If a patient was hypotensive on presentation, then an improvement in blood pressure would be an indication of a favorable response to treatment. Evidence of improved perfusion can be indicated by a patient having warmer extremities. In patients with cardiac disease that present with prerenal azotemia, improved perfusion can result in improvement of the azotemia.

Monitoring of Resting Respiratory Rate

One of the most effective means of chronically monitoring the successful resolution of clinical signs of congestive heart failure appears to be owner measurement of home resting respiratory rate. One study showed that, in dogs receiving heart failure treatment, a resting respiratory rate of <40 breaths per minute was highly predictive of that patient having adequate heart failure control.[44] Similar values are also valid to guide the adequacy of heart failure control in cats. One study showed that normal cats and cats with subclinical heart disease rarely have respiratory rates higher than 30 breaths per minute.[45]

Most owners are able to measure their pet's resting respiratory rate and there is a range of smartphone apps available to facilitate this. Owners can be given, or can themselves establish, ranges of respiratory rates that represent good control of heart failure, and values which would be a cause for concern. In an individual patient, after a period of monitoring, owners can develop a good idea of their own pet's normal range for resting respiratory rate. Owners can then alert their veterinarian if their pet's respiratory rate increases. Some owners can even be given instructions as to how to titrate their pet's diuretic dosage according the respiratory rate; this approach is particularly useful in unstable patients that require frequent adjustment of heart failure therapy, or feline patients that get very stressed when visiting the veterinary hospital.

Adjustment of Chronic Home Therapy

The intensity of a patient's heart failure therapy may be increased or decreased. An intensification of treatment is usually indicated because of poor control of signs of heart failure. Although the majority of patients respond well to the introduction of heart failure therapy, in almost all cases clinical signs of heart failure redevelop after a variable period of time. In the QUEST study, which followed a population of dogs with ACVIM stage C degenerative mitral valve disease, it was common for heart failure therapy to require adjustment and most dogs that had adjustment of their therapy required treatment modification within the first three months of treatment.[46]

The nature of the necessary treatment change is usually indicated by the type of clinical signs the patient is showing. The adjustment most frequently made to treatment is an intensification of diuretic treatment due to the redevelopment of signs of congestion (e.g., tachypnea or dyspnea). In cases where this happens, increasing dosages of furosemide can be administered until the patient's clinical signs are refractory to treatment despite doses of up to 4 mg/kg PO q 8 h. As has been explained above, this often necessitates the administration of multiple diuretics or the substitution of torsemide instead of furosemide.

Occasionally, after a prolonged period of clinical stability, it may be possible to consider reduction of a patient's diuretic dose. This can be done with a sequential reduction in the dosage administered. Every time the diuretic dosage or frequency is changed, the patient should be monitored for a change in respiratory rate. If the respiratory rate remains stable despite the reduction in the diuretic dose, then further dose reduction can be attempted until the lowest dose that continues to adequately control the clinical signs is found.

If a patient redevelops clinical signs of poor cardiac output, then the intensification of therapy aimed at improvement of cardiac output could be required. Depending on the nature of the patient's underlying disease, this may require modification of the dosage of drugs already being administered (such as optimization of the pimobendan dose) or improved control of a patient's arrhythmia.

Outcome of Heart Failure Therapy

Most canine and feline patients can enjoy many months, and in some cases more than a year, of good quality

life as a consequence of successful pharmacological management of their signs. Unfortunately, it remains the case that the most common outcome following the development of signs of heart failure is for the patient, despite treatment, to eventually succumb to their heart disease. Studies in dogs[32,47] and cats[48] with heart disease and heart failure show that the majority of patients with heart failure die of their heart disease within one year of diagnosis. For dogs with dilated cardiomyopathy the median survival time is less than six months.[47]

It is a realistic and laudable aim of therapy to relieve patients' clinical signs, and prolong their life where that life remains of a good quality. It should also be the responsibility of the veterinarian to counsel the owner of the patient about the likelihood of the pet's death and a realistic time frame in which this will probably occur. Although initially hearing about this guarded prognosis can be difficult and distressing for owners, many then feel better prepared for the death of their pet when it eventually occurs.

Eventually, despite the best therapy, patients will succumb to their heart disease. Prioritizing a patient's welfare during end of life care is also of great importance during this phase of their disease.

CHAPTER 248

Cardiac Arrhythmias

Etienne Côté, Stephen J. Ettinger

Well over 100 years after its invention, the electrocardiogram (ECG, EKG) remains the diagnostic test of choice for the clinical evaluation of patients with cardiac arrhythmias.[1-5] The ECG also has valuable applications in monitoring patients with systemic abnormalities, including electrolyte disturbances and hypoxemia. Additionally, abnormalities in the dimensions of various components of the ECG can serve as an approximate guide for evaluating structural heart disease. These ECG morphologic criteria are rarely based on controlled studies identifying specificity and sensitivity, however, and ECG parameters for dogs or cats by breed, body type, age, and sex are not comprehensively established. An abnormal heart may have a normal ECG and vice versa. Therefore the ECG, like a blood count, is not always an absolute indicator of normalcy or disease, and patterns emerging from serial tracings, or additional clinical information, are essential for understanding the true meaning of most patients' ECGs. The technical aspects of electrocardiography, and reference intervals, are presented in ch. 103.

Cardiac Conduction System and Electrocardiography

Each component of an ECG tracing reflects an electrical event occurring in a specific part of the heart.[1,2,5] The sequence of electrical events follows specific anatomic pathways within the heart, and in health, does so precisely and consistently. This has been the subject of a recent and insightful review.[6]

Initiation of the normal heartbeat occurs in the sinoatrial (SA) node. The SA node is located in the subepicardial tissues of the terminal crest in the dorsolateral right atrium (RA), at the junction of the cranial vena cava and right atrium and directly adjacent to the crista terminalis.[7,8] It is perfused by the SA node artery, a branch of the right coronary artery,[9] and has extensive collateral circulation. In the dog, the heartbeat originates from the middle or cranial regions of the node[10] except under high parasympathetic tone when the more ventral portions of the node, and adjacent extranodal tissues, are the site of origin of the heartbeat.[11] This change in site of impulse formation explains the variation in P wave morphology sometimes observed on the ECGs of dogs (and rarely cats) during changes in autonomic tone and is called the *wandering pacemaker*.

Why does the heart continue to beat? Within the pacemaker cells of the SA node, the heartbeat is born of several ionic shifts, especially the predominantly sodium-carrying (but also potassium-carrying) inward current, I_f.[6,12-14] This "funny current" is so named because of its unusual characteristic of being activated by hyperpolarization rather than depolarization (the hyperpolarization-activated, cyclic nucleotide-gated channel, HCN4, being the channel that gives rise to I_f). This activation begins the process of spontaneous depolarization; a time-dependent decay in the repolarizing potassium currents I_{Kr} and I_{Ks}, the effect of transmembrane I_{NCX} exchanging sarcoplasmic reticulum-derived cytosolic calcium for extracellular sodium, and local (cytosolic) calcium releases,[12] also play important roles in raising the SA nodal cell membrane potential to a less negative value between heartbeats. This process of spontaneous, or phase 4, diastolic depolarization is the hallmark of a normal pacemaker cell. The resulting increase in cell membrane potential leads to the crossing of a threshold level, at which point a combination of transient ($I_{Ca\text{-}T}$, T-type) and long-lasting ($I_{Ca\text{-}L}$, L-type) inward calcium currents cause depolarization of the cell. Depolarization ends when the repolarizing potassium currents, including the transient outward, fast delayed rectifier, and slow delayed rectifier currents (I_{to}, $I_{K,r}$, and $I_{K,s}$, respectively), are activated, evacuating potassium ions from the cell. Overall, this entire panoply of depolarizing and repolarizing currents, which form the cornerstone of initiation of the heartbeat, recently have been grouped together within the SA node's membrane clock and calcium clock paradigm (Figure 248-1).[6,12]

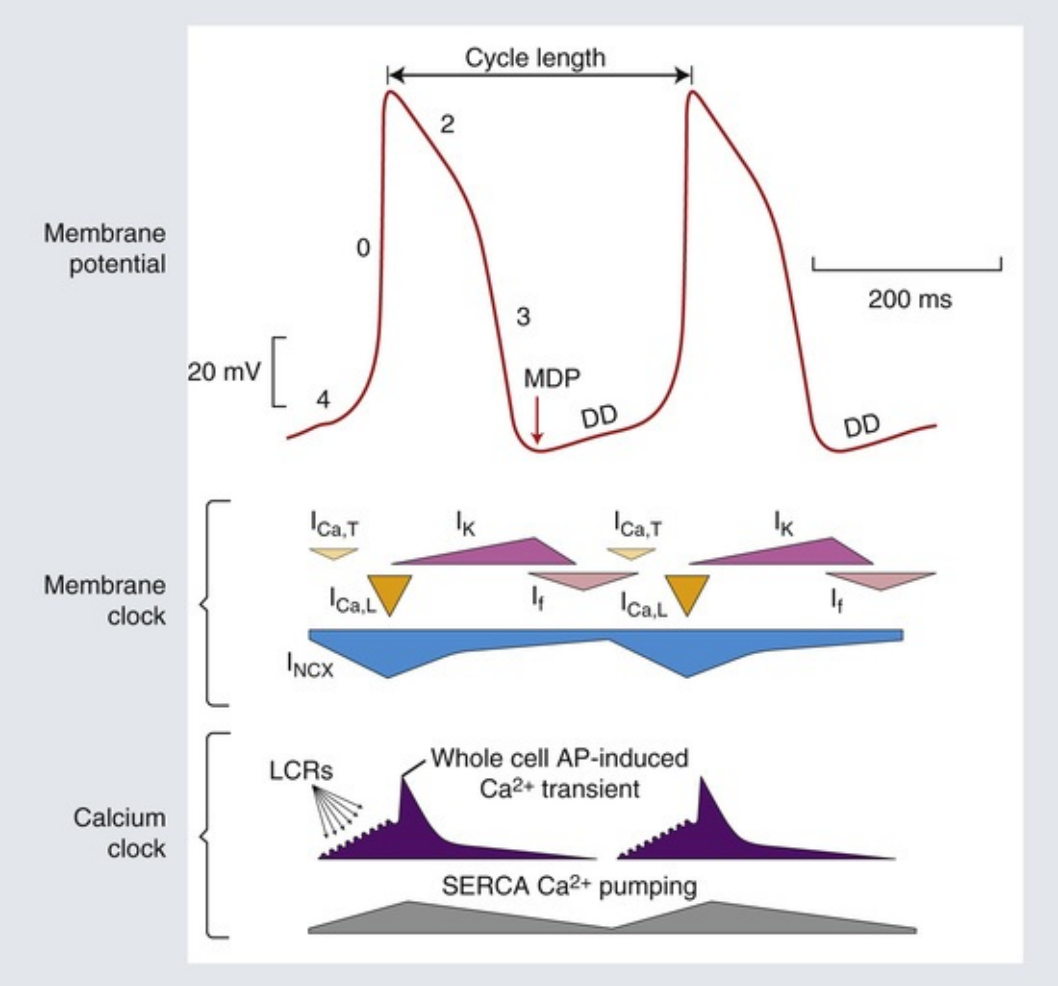

FIGURE 248-1 Components of the membrane clock and calcium clock that are responsible for sinoatrial node depolarization. *DD,* Diastolic depolarization; $I_{Ca,L}$, L-type voltage-dependent Ca^{2+} current; $I_{Ca,T}$, T-type voltage-dependent Ca^{2+} current; I_f, funny current; I_K, delayed rectifier potassium current; I_{NCX}, sodium-calcium exchange current; *LCRs,* local Ca^{2+} releases; *MDP,* maximum diastolic potential; *SERCA,* sarco-endoplasmic reticulum ATPase. (From Monfredi O, Maltsev VA, and Lakatta EG. Modern concepts concerning the origin of the heartbeat. *Physiology (Bethesda)* 28:74-92, 2013. Reproduced with permission.)

The impulse thus formed spreads from the SA node through both atria, forming the P wave on the ECG (Figure 248-2). Specifically, part of the impulse that propagates from the SA node travels along three sets of specialized fibers in the atria called the *internodal pathways or tracts,* consisting of the paired ventral (anterior) pathways, which carry electrical activity directly to the atrioventricular (AV) node, and the dorsal (posterior) pathway called Bachmann's bundle, which is responsible for left atrial activation.[15,16] All three converge on the AV node in the floor of the RA.[7,17] Thus the outward movement of electrical activity from the SA node both triggers the muscular contraction of the atria and carries a sequence of electrical activity to be transmitted to the ventricles.

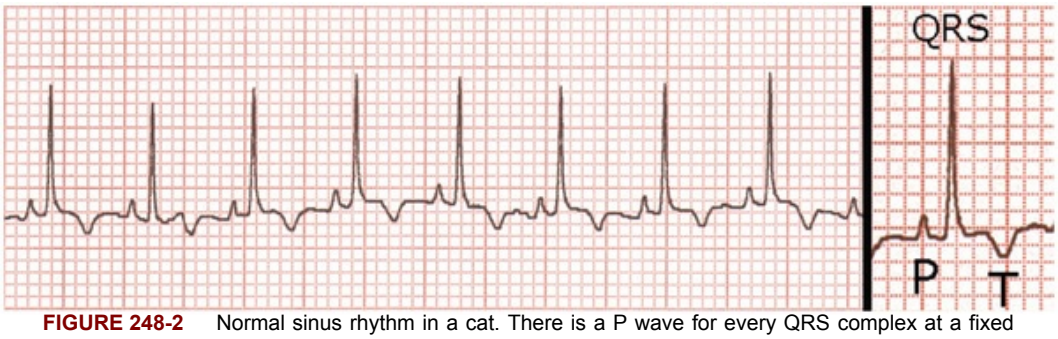

FIGURE 248-2 Normal sinus rhythm in a cat. There is a P wave for every QRS complex at a fixed PR interval, and the P wave and QRS complex morphologies do not change. The R waves are slightly taller than normal, consistent with left ventricular hypertrophy in this cat with hypertrophic cardiomyopathy (R wave height; 1.0 mV; feline reference range: <0.9 mV). The heart rate is 155 beats/min. Lead II, 25 mm/sec, 1 cm = 1 mV.

At the level of the AV node, the electrical impulse depolarizing the heart is purposefully delayed due to a low concentration of gap junctions between cells, which slows intercellular conduction.[9] This delay is a normal process and indeed, failure of the impulse to pause in the AV node is an abnormality called preexcitation (see Macroreentrant Syndromes, later). The purpose of this delay is to optimize ventricular filling by allowing the atria to finish contracting. The period of relative electrical quiescence during which the impulse slowly passes through the AV node is reflected on the ECG as a flat segment between the P wave and QRS complex, the PR segment; in terms of nomenclature, the PR *interval* consists of the PR segment plus the P wave (see later). In addition to transmitting impulses from the atria to the ventricles, the healthy AV node acts as a gatekeeper, blocking unwanted atrial impulses from crossing to and activating the ventricles, such as when these impulses are premature or excessive (e.g., atrial fibrillation [AFib]). This characteristic depends on the refractory period of AV nodal cells and varies among individuals, and even within individuals depending on autonomic inputs. In normal individuals, the unidirectionally conducting fibers of the AV node–His bundle complex make up the only electrical connection between the atria and the ventricles.

The AV node is sometimes considered to have three components: the atrionodal (AN), nodal (N), and nodal-His (NH) regions, from proximal (furthest from the ventricles) to distal (closest to the ventricles), respectively.[18] This division is based on experimental demonstration of differences in action potentials of the three regions and is of limited clinical significance. Of importance is the automaticity of the N region, an ability to form impulses spontaneously much in the same way as the SA node normally does, but at a slower rate. In this manner, the AV node usually is overridden (and its pacemaking ability suppressed) during normal sinus rhythm by normal sinus impulses, which pass through—and reset—the latent pacemaker cells in the AV node before they have had a chance to depolarize. This normal phenomenon prevents the AV node from competing with the SA node as the natural pacemaker for the heart. Still, the N region of the AV node can assume the role of pacemaker for the heart if sinus impulses do not reach it—a failsafe mechanism that is activated only when the need occurs, and which is called an *escape mechanism* or *escape rhythm.* Specifically, an escape rhythm originating from the N region is termed a *junctional escape rhythm*, highlighting that it originates from the AV junction rather than the His-Purkinje system in the ventricles. Because the N region is in the center of the AV node, it can be seen that AV block (such as that caused by AV nodal fibrosis) affecting the proximal (AN) region would allow a junctional escape rhythm to emerge, whereas with AV block occurring in the N or NH regions, the ability for a junctional escape rhythm to exist would be lost, and a generally slower His-Purkinje/ventricular escape mechanism would become activated instead.

Having crossed through the AV node, the electrical impulse of a normal heartbeat travels rapidly and uniformly through the ventricles via the His-Purkinje system.[9,16] This network of conductive fibers ensures that the impulse is carried quickly and distributed uniformly, such that the ventricles depolarize, and can then contract, in a synchronized fashion.[19] The fibers begin as a thick cable, the His bundle, that accepts transmission from the AV node and crosses through the endocardial cushion to the ventricles. The His bundle quickly divides into right and left bundle branches (RBB and LBB), directed to their respective ventricles, and the left bundle in turn divides into left anterior, left posterior, and septal fascicles of highly variable shape and pattern of arborization.[16] The clinical relevance of this division into bundles relates to interruptions of electrical conduction through the bundles, which can occur under various pathologic, and occasionally normal, conditions (see Bundle Branch Blocks, later). Overall, depolarization of the ventricles is apparent on the ECG as the QRS complex. When the ventricles have completely finished depolarizing, a sequence of

repolarization returns the myocardial cells to their resting state. This repolarization sequence, which follows in the wake of the depolarization sequence, is seen as the T wave on the ECG.

Repolarization of the ventricles occurs transmurally: epicardial myocytes repolarize first, creating the ascending limb of the T wave. The T wave's amplitude is limited by the onset of repolarization in endocardial myocytes, which then contributes to the descending limb of the T wave. Repolarization is complete when the last population of midmural ventricular myocytes, called M ("midmyocardial") cells, is repolarized.[20] Alterations in this complex process can be pathologic, producing changes such as "J" or Osborn waves in hypothermic patients, or can be normal variants, such as the T wave of healthy dogs, which can be positive or negative. It should be noted that the atria also repolarize, but the amount of electrical activity involved in this process is generally directed in an orientation that registers a trivial deflection, if any, in most leads of the ECG, and whatever deflection occurs can routinely be masked by the subsequent QRS complex.[21,22] Severe atrial repolarization changes occasionally may be observed as an atrial T wave, or T_a wave, and these tiny deflections may be more apparent in the presence of AV block, when the post-P wave ECG is unfettered by an ensuing QRS complex.[21,22]

The heart rate is constantly governed by autonomic influences. A dog of medium body size without autonomic control of the heartbeat has an intrinsic heart rate of 142 beats/min, as shown with simultaneous parasympathetic and sympathetic antagonism, instead of a normal resting heart rate of approximately 100 beats/min.[23] Holter studies support the large moment-by-moment variability of autonomic inputs to the heart: over a 24-hour cycle, the heart rate varies from 55 to 243 beats/min in healthy Beagles[24] and 77 to 282 in healthy cats.[25,26]

Diagnostic Manipulations with Electrocardiography

Vagal Maneuver

Artificially increasing a patient's vagal tone has potential value both diagnostically and therapeutically. Diagnostically, slowing the heart rate and increasing AV nodal refractoriness through vagal maneuvers may slow a rapid tachycardia, allowing some of its features to be more apparent and facilitating the ECG diagnosis (Figure 248-3). Therapeutically, an increase in vagal tone that interrupts macroreentrant circuits occasionally can terminate such arrhythmias as AV nodal reentrant tachycardia and orthodromic AV reciprocating tachycardia (see Pre-excitation/Macroreentrant Syndromes, later).

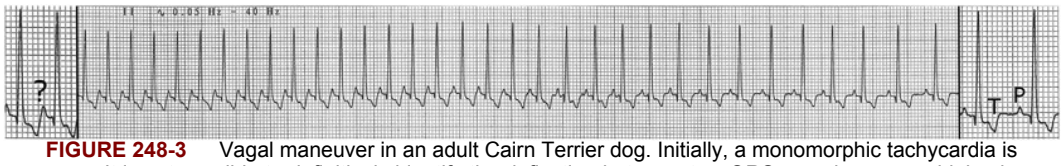

FIGURE 248-3 Vagal maneuver in an adult Cairn Terrier dog. Initially, a monomorphic tachycardia is seen. It is not possible to definitively identify the deflection between two QRS complexes as a biphasic T wave, summated T and P waves, or T waves and flutter waves (left inset, "?"). Carotid sinus massage was begun 5 seconds earlier; by the end of the tracing, P waves and T waves are clearly separated (right inset), allowing the diagnosis of sinus tachycardia. Lead II, 25 mm/sec, 1 cm/mV.

Carotid sinus massage is one type of vagal maneuver. It involves the simple application of gentle, sustained digital pressure by the clinician to one or both of the patient's carotid sinuses, located just caudal to the dorsal aspect of the larynx (sometimes to the point of eliciting a gag reflex), for 5 to 10 seconds, while the ECG tracing is being recorded. The patient should tolerate such a maneuver, and signs of discomfort, resentment, or a marked change in heart rate warrant immediate termination of the maneuver. Because dogs and cats very rarely suffer from carotid artery atherosclerosis, concern for thromboembolic consequences of carotid sinus massage as expressed in human cardiology is unlikely to be relevant to small animal practice. Ocular pressure over closed eyelids is another form of vagal maneuver. It consists of applying firm but controlled gentle digital pressure to both globes through closed eyelids. The distance of retropulsion of the globes depends on the shape of the orbit, and subjectively, the amount of pressure applied is the best guide; it should not exceed the digital pressure one would place on a ripe grape without rupturing it. Ocular pressure is contraindicated in patients with ocular problems. There appears to be interindividual variation in response to vagal maneuvers, with some individuals demonstrating a stronger effect during carotid sinus massage and others ocular pressure. Another simple method of eliciting a vagal response without inflicting pressure on a body

part is to immerse the patient's face or distal limb into a small bucket of ice water for a short period.[27] In the awake dog or cat, this usually will rapidly evoke a vagally mediated decrease in sinus heart rate.

Atropine Response Test

Administration of atropine sulfate 0.04 mg/kg IV can be used diagnostically to evaluate bradycardias.[3] It allows the differentiation between physiologic bradycardias that are purely of vagal origin (atropine increases the heart rate) and pathologic bradycardias that are caused by intrinsic disturbances of impulse formation or conduction (atropine has no effect). The response occurs within seconds to minutes (within 15 minutes) after injection.[3] A positive response to atropine is poorly predictive of a beneficial effect of oral vagolytic drugs such as hyoscyamine or propantheline in dogs with AV block,[28] but is associated with a beneficial effect of medical treatment of sinus node dysfunction (sick sinus syndrome, SSS).[28a]

Cardiac Rhythm Disturbances

The terms "dysrhythmia" and "arrhythmia" are used interchangeably, although "arrhythmia" is preferred.[29] For evaluation and management of patients with cardiac arrhythmias, a useful and practical classification scheme is one that separates arrhythmias into three groups: (1) disturbances of impulse formation (cardiac excitability), (2) disturbances of impulse transmission (cardiac conduction), and (3) complex disturbances involving abnormalities both of excitation and conduction. Some rhythm disturbances fit poorly into any category. Some disturbances of cardiac excitability are secondary to conduction disturbances (e.g., junctional or ventricular escape rhythms). Disturbances are presented in this chapter according to the anatomic level of their origin (i.e., atrial, junctional, or ventricular).

Excitation disturbances can cause either excessive or inadequate functioning of the heart or its parts. Increased excitability produces extrasystoles if intermittent, and tachycardia if sustained. Ectopy is the term that describes spontaneous production of impulses anywhere in the heart other than the SA node. Decreased excitability replaces impulse formation with electrical quiescence, resulting in bradycardia or asystole.

Conduction disturbances within the heart are called *blocks*. Their categorization depends on the anatomic location of the block and its extent or degree (see below). Block can occur at the SA node (rarely identified), the AV node, or in branches of the His bundle (bundle branch blocks, BBBs).

Finally, disturbances combining excitability and conduction abnormalities also are clinically relevant. Serum electrolyte abnormalities commonly have repercussions on the rhythm of the heartbeat, which can involve alterations in excitation, conduction, or both. In preexcitation and macroreentrant syndromes, accessory conduction pathways bypass part of the normal AV conduction pathway. Sinus node dysfunction, also called *sick sinus syndrome* (SSS), generally involves periods of bradycardia and tachycardia caused by dysfunction of the SA node and supraventricular and ventricular conductive tissues.

Clinical Impact of Rhythm Disturbances

The rhythm disturbances discussed above carry varying degrees of clinical importance. Their clinical impact can range from harmless (some are benign variations of normal) to severely detrimental (life-threatening). In cats, ventricular extrasystoles, preexcitation, and isorhythmic AV dissociation have been associated with feline cardiomyopathies. In the dog, disturbances of excitability, especially extrasystoles and AFib, are more common than are disturbances of conduction, the majority of which are AV blocks.[1,2,30]

A cardiac arrhythmia's impact on the patient—the hemodynamic consequences—depends on at least eight factors: (1) the ventricular rate, (2) the duration of the abnormal rhythm, (3) the temporal relationship between the atria and ventricles, (4) the sequence of ventricular activation, (5) inherent myocardial and valvular function, (6) cycle length irregularity, (7) drug therapy, and (8) extracardiac influences.[1-3] Ultimately, the sum of these factors—not just the appearance of the ECG—determines the impact of the arrhythmia on the patient. This is the reason that some animals with ventricular tachycardia (VT) appear overtly normal, whereas others are moribund, for example.

Identification of Rhythm Disturbances

Today, most clinical electrocardiography in veterinary medicine relies on single-lead, in-hospital ECGs. Multilead ECGs provide an additional level of information that is sometimes indispensable (see Figure 248-13).

Rhythm disturbances are identified on the ECG using a methodical, five-point examination. First, a rapid, cursory evaluation from left to right of the entire tracing gives a general idea of the cardiac rate and rhythm and an initial diagnostic orientation. This step reveals whether a single rhythm or many rhythms exist. (Are all QRS complexes of the same morphology? Are the R-R intervals, or *coupling interval*, the same, or do they vary? If so, does the variation occur in a predictable manner?) One grossly assesses the heart rate (slow, normal, or fast), whether the rhythm is regular or irregular (R-R intervals the same, or variable, respectively), and detects premature or delayed complexes.

Second, the R-R intervals are evaluated in representative sections of the entire tracing. In cats in the clinical setting, variability of the R-R interval is not normally seen and is considered pathologic.[31] In dogs, a cyclical (i.e., rhythmic, patterned, "regularly irregular") variation of the R-R interval, respiratory sinus arrhythmia, is normal (Figure 248-4). Patternless, irregularly irregular R-R intervals are always abnormal in both species.

FIGURE 248-4 Respiratory sinus arrhythmia and wandering pacemaker in a dog. Lead II, 25 mm/sec, 1 cm/mV.

Third, the examination of individual QRS complexes consists of determining whether they are narrow or wide. Narrow QRSs generally identify normal ventricular depolarization (i.e., of supraventricular origin) (see Figures 248-2 to 248-4). Wide QRSs represent the asynchronous depolarization of the two ventricles, which may be due to the ventricular origin of a depolarization, to BBB, or to preexcitation/macroreentry (see later). Because repolarization follows directly in the wake of depolarization, a QRS complex of abnormal shape should also have a T wave of abnormal or different shape. If the T wave is normal, the possibility of artifact, rather than a truly abnormal QRS, should be considered as the explanation for a wide, bizarre deflection.

Fourth, examination of the P waves (present, absent; positive, negative) provides information on the depolarization of the atria. Examination of the P-R interval (1) determines if a P wave exists for every QRS complex and a QRS complex for every P wave (to assess AV synchrony) and (2) assesses AV nodal conduction, which is confirmed by a constant P-R interval duration.

Finally, the basic underlying rhythm and any additional or secondary rhythms that are superimposed are identified. Normally, a P wave exists for every QRS complex (an atrial depolarization for every ventricular depolarization). Abnormalities causing more than one P wave for each QRS complex include second- and third-degree AV blocks, and abnormalities producing QRS complexes without P waves include ventricular arrhythmias, AFib, and atrial standstill.

Disturbances of Excitability

An important subdivision involves classifying disturbances of excitability broadly as disturbances of supraventricular excitability,[32,33] including STach, premature atrial complexes (PACs), atrial tachycardias, atrial flutter, and AFib; or as disturbances of ventricular excitability, including ventricular extrasystoles (PVCs, VPCs), VT, torsade de pointes (TdP), ventricular flutter, and VF. Proper classification is clinically important: the inciting factors that produce the arrhythmias in these two subgroups often are specific to the subgroup, and antiarrhythmic treatment is also usually different between the two subgroups.

Disturbances and Alterations of Sinus Excitability

These arrhythmias are variations of sinus rhythm, and are most commonly linked to normal or excessive autonomic inputs.

Respiratory (Normal) Sinus Arrhythmia

Even in the hospital setting, the balance between the sympathetic and parasympathetic inputs to the heart generally tilts in favor of the parasympathetic system in most resting dogs.[23] In the veterinary clinic, this

characteristic is in contrast to the average cat. Vagal predominance in the dog produces two particular features of sinus rhythm on the canine ECG: respiratory sinus arrhythmia (RSA) and wandering pacemaker (WP).

RSA is the result of vagal and hemodynamic effects that occur within the thorax during each respiratory cycle (see Figure 248-4). In dogs, it is a normal physiologic phenomenon requiring no treatment. The result is a correlation between heart rate and respiratory rate, with slowing of the heart rate during expiration and acceleration of the heart rate during inspiration. The repeating, cyclic nature of this arrhythmia is its hallmark. RSA is first noted in the puppy after 4 weeks of age,[1] generally disappears when the heart rate exceeds 150 beats/min at any age (because sympathetic tone overtakes parasympathetic tone in most situations that produce such rapid heart rates),[1,2] and can be enhanced when severe dyspnea is present (pneumothorax, pulmonary fibrosis, emphysema, upper airway obstruction) due to exaggerated changes in intrathoracic pressure.[1] In cats, respiratory sinus arrhythmia occurs commonly during sleep[34] and in the home environment in general,[25] but an adrenergic surge brought about by the clinical environment likely explains its rarity in the hospital setting. In dogs, the presence of RSA can constitute a valuable diagnostic clue in a common clinical situation, namely in the coughing, small- to medium-breed adult dog. It is common for these dogs to have concurrent myxomatous/degenerative mitral valvular heart disease (DMVD; typical murmur is ausculted) and a primary respiratory disorder such as chronic sterile bronchitis. It might be difficult to pinpoint whether congestive heart failure (CHF) or a primary respiratory problem is responsible for the animal's respiratory signs, yet the need for immediate and long-term treatment and the prognosis both depend on knowing which disease process predominates. The presence of RSA makes decompensated DMVD as the sole cause of respiratory signs unlikely because the cardiogenic pulmonary edema of CHF would almost invariably be associated with increased sympathetic tone and loss of RSA.

Successful treatment of CHF can bring about the reappearance of RSA in a patient previously with sinus or other supraventricular tachycardia, particularly if treatment includes digoxin. This return of RSA is due to the reduction of sympathetic tone associated with resolving CHF; an additional benefit of digitalization, albeit a theoretical one in veterinary practice, is reactivation of baroreceptors, which otherwise remain downregulated ("exhausted") by the ongoing sympathetic stimulation of CHF.

Ventriculophasic Sinus Arrhythmia

Ventriculophasic sinus arrhythmia refers to an uncommon phenomenon consisting of variation in the P-P interval in patients with high-grade second-degree, or third-degree, AV block.[35,36] Specifically, the P-P interval that flanks the QRS complex is shorter than the P-P interval during block (see Figure 248-22). Since the sinus rate should be constant during AV block, this cyclical, repeating variation in P-P interval is unusual, and can be explained either by an increase in SA nodal arterial perfusion after ventricular contraction, or triggering of the Bainbridge reflex with atrial filling. There is no clinical importance specific to the finding of ventriculophasic sinus arrhythmia other than to not mistake it for an atrial arrhythmia.

Wandering Pacemaker

WP is a normal, physiologic phenomenon in dogs that is not associated with pathologic conditions and requires no treatment (see Figure 248-4). As discussed previously, the origin of depolarization in the canine heart is not fixed but can move within the RA, or even between the SA node and the AV node. On the ECG, the result is variation in the P wave amplitude, with a constant P-R interval and QRS complexes that retain a normal, supraventricular appearance. This variability in the P wave is often cyclic and often associated with RSA (see Figure 235-3). In this situation the amplitude of the P wave increases with an increased heart rate (inspiration) and decreases with decreased heart rate (expiration), sometimes to the point of disappearance (isoelectric P wave) or, rarely, negativity of the P wave in leads II, III, and aVF.[1,2] The ECG differential diagnosis for WP includes morphologic abnormalities (e.g., P pulmonale) and supraventricular extrasystoles. In some individuals with marked resting vagal tone (e.g., brachycephalic dogs), an exaggerated but normal RSA and WP can be difficult to differentiate from a pathologic arrhythmia, namely PACs (supraventricular extrasystoles). Both PACs and the combination of WP and RSA produce a P wave of different morphology, a shorter R-R interval, and QRS complexes of normal morphology. Differentiation rests on the degree of prematurity (WP and RSA should not occur so prematurely as to produce a P wave inside the preceding T wave), heart rate (WP and RSA do not occur at a rate above 150/min), P wave morphology (as described above, RSA produces P waves that are taller, not shorter, when the heart rate is faster, whereas with PACs the P wave can be taller or shorter than the normal P wave), and the appearance of a series or "paroxysm" of such beats closely coupled to each other (corresponding to multiple supraventricular extrasystoles [i.e.,

supraventricular tachycardia], not RSA). If none of these characteristics is apparent, a Holter monitor can be used for assessing a large number of heartbeats.

Sinus Bradycardia

Sinus bradycardia (SB) is a sinus rhythm in which the heart rate is abnormally low (Figure 248-5). A 1 : 1 ratio of normal-appearing QRS complexes and P waves exists, with a constant P-R interval. Although some approximate normal ranges of heart rate exist for dogs and cats (e.g., 70-160 beats/min for dogs, and 140-220 beats/min for cats; see ch. 103), the notion of bradycardia varies according to species, age, breed, and especially environment; older or brachycephalic dogs tend to have slower heart rates than average, and both dogs and cats have normal heart rates that can be markedly influenced by environmental stimuli.

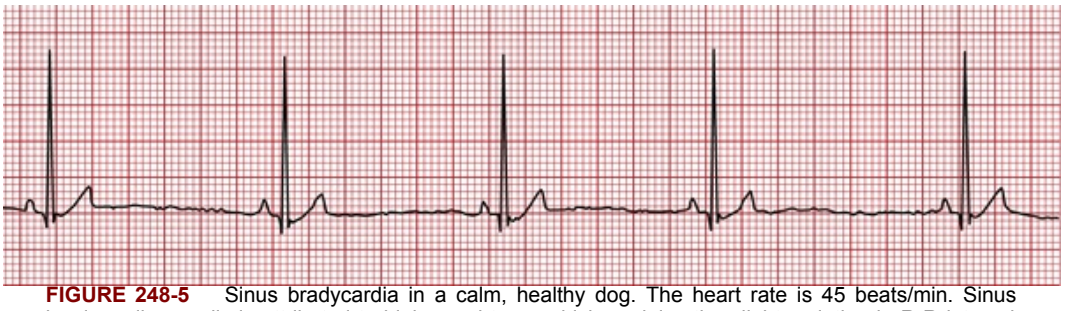

FIGURE 248-5 Sinus bradycardia in a calm, healthy dog. The heart rate is 45 beats/min. Sinus bradycardia usually is attributed to high vagal tone, which explains the slight variation in R-R interval (respiratory sinus arrhythmia). Lead II, 25 mm/sec, 1 cm = 1 mV.

SB generally indicates the physiologic (e.g., brachycephalic, athletic individual, sleep) or pathologic (e.g., systemic intoxication) predominance of the parasympathetic system. A diagnostic aid is the response to an intravenous injection of atropine (see previous discussion), which should convert physiologic SB into normal sinus rhythm or sinus tachycardia.[37] As a general concept, severe bradycardias directly linked to overt clinical signs (syncope, malaise, seizures) warrant specific treatment with drugs or pacemaker implantation, and SB is almost never the cause of such clinical manifestations. SB may occur as the cardiac manifestation of asphyxiation (e.g., upper airway obstruction due to foreign body, neoplasm, nasopharyngeal polyp, or elongated soft palate; closed pop-off valve in an intubated patient) and in such a situation, treatment of SB with atropine (e.g., 0.04 mg/kg IV) or low-dosage epinephrine (e.g., 0.01 mg/kg IV) can be appropriate if immediate relief of the airway obstruction is not possible or, if accomplished, fails to immediately raise the heart rate. In virtually all instances, SB is the effect, rather than the cause, of a patient's problem. Hypothermia, an excessively deep anesthetic plane, and high vagal tone of any origin (gastrointestinal [GI], respiratory, neurologic, ophthalmic) are common causes of SB, and treatment of the bradycardia mainly consists of treating the underlying cause first. Perhaps the only exception is the occurrence of SB as part of sinus node dysfunction/SSS, where indeed SB can be a primary, pathologic bradycardia, in which case it is typically accompanied by AV block and/or extrasystoles (see sinus node dysfunction/SSS, later). Finally, a potentially dangerous situation is the instantaneous transition from a tachycardia to SB (or other bradycardia [e.g., ventricular escape rhythm]; see ventricular escape rhythm) in a debilitated, unstable, often unconscious patient. Such a rapid change can herald an upcoming cardiac arrest and should be addressed with immediate assessment of the patient for underlying causes and preparation for cardiopulmonary resuscitation (see ch. 140 and 141).[38]

Sinus Tachycardia

STach is a sinus rhythm that occurs at an elevated rate (Figure 248-6). The wide range of resting heart rates in normal cats and dogs makes the cut-off between NSR and STach an approximate one. In dogs, STach is defined as a heart rate greater than 160 beats/min but of SA nodal origin (i.e., P-QRS-T complexes of normal shape and sequence). Diagnosing this arrhythmia on the ECG can be difficult when the heart rate is extremely elevated, causing T and P waves to blend together. A vagal maneuver, which temporarily slows the heart rate, separates the P and T waves and clarifies that the tachycardia is of sinus origin (see Figure 248-3).

FIGURE 248-6 Sinus tachycardia in a cat with cardiomyopathy. The heart rate is 210 beats/min. Lead II, 25 mm/sec, 1 cm = 1 mV.

The causes of STach are diverse and are all marked by sympathetic predominance over parasympathetic inputs. STach is almost invariably a result of, rather than a cause of, a patient's problems. Therefore, it can be expected to resolve (return to NSR) when the causative disorder, such as hypovolemia, CHF, anemia, or pain, has been treated appropriately. Deliberate suppression of STach in an attempt to restore a more normal heart rate, especially in an acutely ill patient, can be (and has been) catastrophic, because in many instances, STach is a compensatory response. In these cases, suppression of STach using beta-blockers or calcium-channel blockers reduces an essential component of adequate cardiac output (heart rate) and can cause hypotension, circulatory collapse, and cardiac arrest. Therefore, treatment of STach consists of identifying the underlying cause and addressing the cause appropriately.

An important aspect of cardiovascular treatment is the prevention of STach in patients with structural heart disease.[14,39] The rationale is intuitive: tachycardia increases myocardial oxygen consumption, and also reduces the duration of diastole, the part of the cardiac cycle during which most coronary perfusion of the myocardium occurs. Therefore, tachycardia could force the heart to do more with less, which can be especially detrimental in patients with heart disease. To avoid this situation, tachycardia can be limited in dogs and cats with heart disease through lifestyle management: replacing periods of intense, off-leash running in dogs with lower-intensity leash walks, or avoiding chasing and intense game play with cats. Even so, experience in humans with heart disease indicates that prevention of tachycardia through pharmacologic means can increase survival.[39] In preclinical (compensated, "asymptomatic") heart disease in small animals, such an approach has involved beta-blockers, calcium-channel blockers, and Na^+/K^+ funny-current blockers. None has proven to prolong survival, however. Atenolol can be given safely to cats with subclinical (occult) hypertrophic cardiomyopathy (see ch. 253),[40] and to dogs with subclinical (occult) subaortic stenosis (see ch. 250);[41] no difference in outcome has been observed between treated animals and untreated control animals, but a uniform benefit also was not observed. Dogs with DMVD[42] or with dilated cardiomyopathy[43] that were treated with carvedilol did not have better outcomes than control animals. Importantly, only one of all of these studies was prospective,[43] meaning that the low strength of evidence of retrospective studies leaves room for additional evaluation of heart rate modulation, using beta-blockers or other drugs,[44] in dogs and cats with heart disease.

Disturbances of Atrial Excitability

Disturbances of atrial excitability are common, especially in the dog. Indeed, in the most common forms of heart disease in dogs (DMVD, cardiomyopathy, many congenital malformations), atrial distension leads to pathologic alterations of the atrial tissue, which can then generate ectopic atrial impulses. Such changes also have been noted with natural aging.[44a,44b]

Premature Atrial Complexes

PACs (synonyms: premature atrial contractions, atrial premature complexes or contractions [APCs], atrial premature depolarizations or extrasystoles, supraventricular [or atrial] premature beats]) are premature depolarizations that originate in an ectopic atrial focus (Figure 248-7).

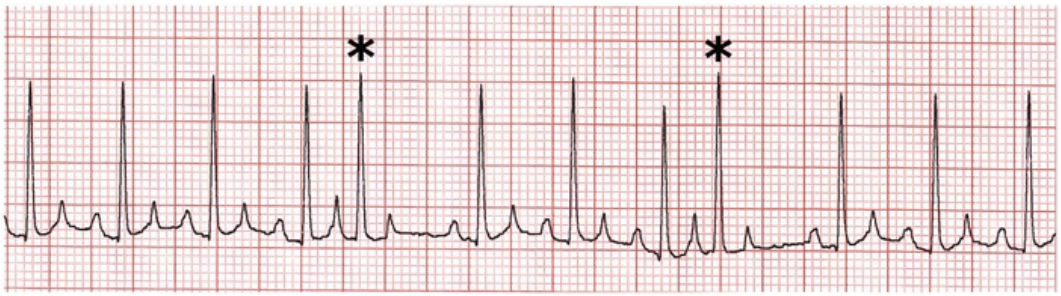

FIGURE 248-7 Premature atrial complexes (PACs) in a 3-year-old Newfoundland dog; the arrhythmia was an incidental finding. Note the normal sinus rhythm that is interrupted twice by beats that have QRS complexes with a morphology similar to sinus QRS complexes (i.e., PACs [asterisks]). There is superimposition of the premature P wave on top of the preceding sinus T wave; this can be inferred by noting the PR interval of the sinus beats and counting back to the expected location of the P wave of each PAC. Both PACs are followed by resetting with pause (see Figure 248-8). Lead II, 25 mm/sec, 1 cm = 1 mV.

Identification of PACs is based on a combination of the first two, and often all five, of the following ECG features: (1) prematurity of the P-QRS-T sequence; (2) QRS complexes that have a supraventricular appearance, in that they are narrow and comparable in shape to the sinus QRS complexes (uncommonly, QRS complexes can be absent or widened in cases of PACs that are exceptionally early and thus occur during the total or partial refractory period, respectively); (3) a P wave of different amplitude than sinus P waves, including negative, biphasic, or positive P waves, but always preceding the QRS complex; (4) a P-R interval that may be slightly different from the sinus P-R interval, be it shorter or longer;[2] and (5) a postextrasystolic pause that most often is noncompensatory (Figure 248-8).

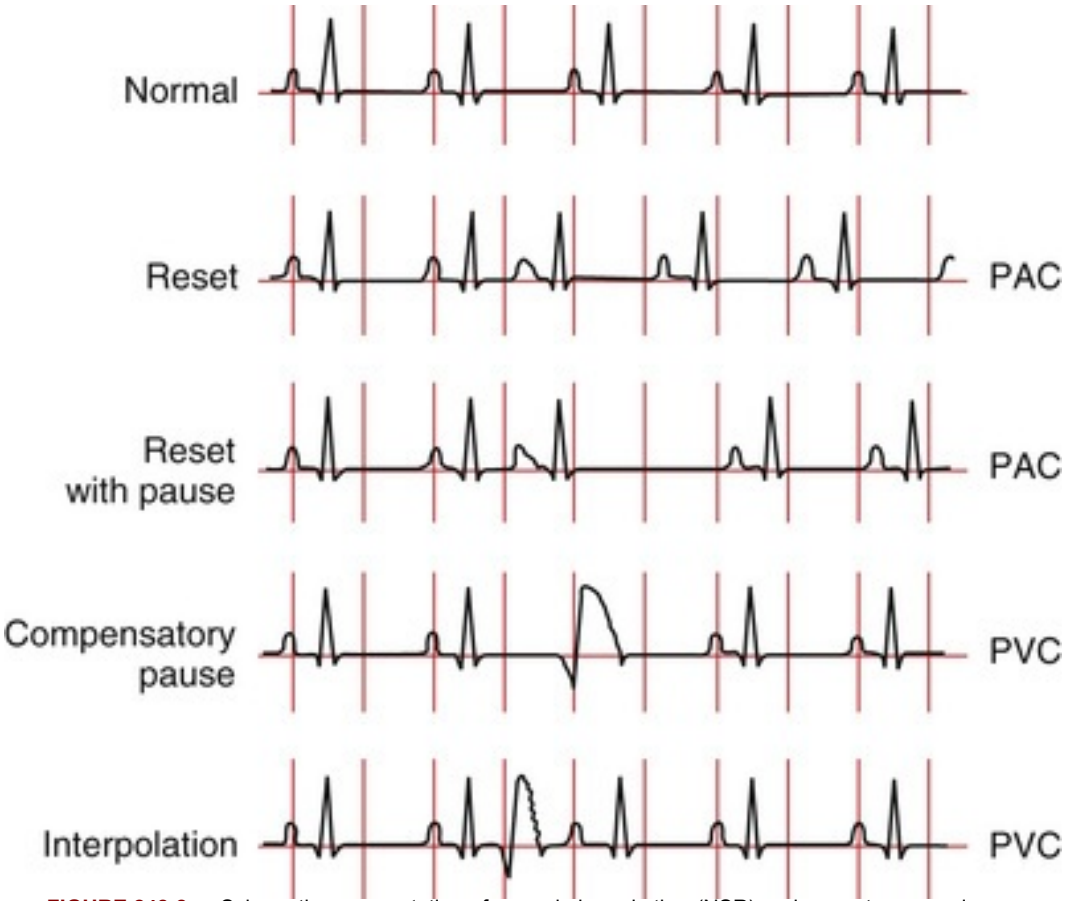

FIGURE 248-8 Schematic representation of normal sinus rhythm (NSR) and premature complexes. **Normal:** The heart rate remains constant, and the intervals from P to P and from R to R do not change. **Resetting:** A premature atrial complex (PAC; beat 3) resets the sinus rhythm so that the period from the beginning of the premature P wave to the next normal P wave is equal to exactly one P-P interval. **Resetting with pause:** The PAC (beat 3) is followed by a pause greater than one P-P interval but less than two P-P intervals. Both resetting and resetting with pause are examples of noncompensatory pauses (the rhythm of the SA node is affected by the premature beat, which alters the SA node's ability to provide a normally timed, "compensatory" beat after the premature beat). **Compensatory pause:** The premature ventricular complex (PVC; beat 3) is followed by a compensatory pause; that is, the period from the normal P wave in the beat preceding the PVC to the normal P wave of the beat after the PVC is equal to exactly two P-P intervals. During the PVC, the sinus P wave occurs on time, but it is not conducted through the atrioventricular (AV) node to the ventricles, which are in a refractory state due to the PVC. **Interpolation:** A PVC (beat 3) occurs between two normal sinus complexes without disrupting the normal sinus rhythm. Concealed conduction of the PVC into the AV node can be inferred to have occurred: interpolated PVCs commonly delay AV nodal transmission of the next beat, which manifests as prolongation of the P-R interval for the heartbeat that follows the interpolated PVC. This characteristic is useful for differentiating interpolated PVCs from motion artifact.

The pathogenesis of PACs most commonly is related to a structural cardiac (atrial) lesion. Distension of the atria is the main cause of these ectopic foci, but atrial tumors (hemangiosarcoma), hyperthyroidism in the cat, digitalis toxicosis, and other systemic disturbances also are recognized causes.[3,5]

Clinical repercussions of PACs are minor, except in cases of multiple repeated bursts (see Supraventricular Tachycardias, later), and the main interest in identifying PACs on an ECG is to raise the suspicion of atrial disease. Therefore, treatment for PACs first is aimed at addressing the underlying cause rather than resorting to antiarrhythmic drugs.

Atrial Tachycardias

Supraventricular tachycardias are defined broadly as any tachycardia originating from the SA node, atrial myocardium, AV node/junction, or veins entering the atria.[45] Specifically included are sinus tachycardia, sinus node reentrant tachycardia, automatic atrial tachycardia, intraatrial reentrant tachycardia, atrial flutter, atrial fibrillation, AV nodal reentrant tachycardia (AVNRT), orthodromic atrioventricular reciprocating tachycardia (OAVRT), and automatic junctional tachycardia.[46] Sinus tachycardia has been discussed (earlier),

and atrial flutter and atrial fibrillation are presented separately (see later), as are AVNRT and OAVRT, both forms of macroreentrant arrhythmias (see Macroreentrant Syndromes, later). The remaining arrhythmias are generally grouped in the broad category of "atrial tachycardias." This simplification is excessive for the occasional patient whose tachycardia can be cured with radiofrequency catheter ablation,[47] and indeed the 12-lead ECG provides important clues for localizing the ectopic focus in dogs, as it does in humans.[48] Still, this regrouping of sinus node reentrant tachycardia, automatic atrial tachycardia, intraatrial reentrant tachycardia, and junctional tachycardia into one basic category called atrial tachycardias is adequate for practical purposes in most veterinary clinical settings. An atrial tachycardia may be defined as a series of three or more consecutive PACs occurring at a rate greater than the sinus rate (Figure 248-9).

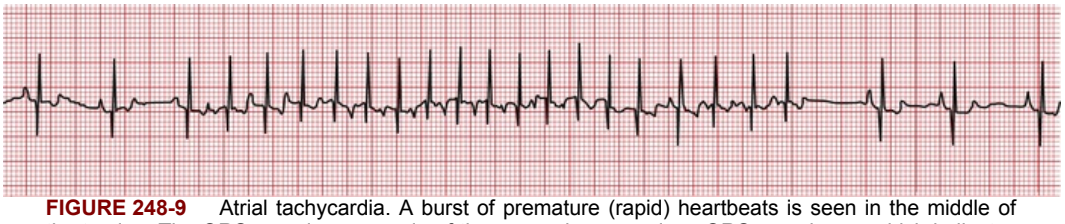

FIGURE 248-9 Atrial tachycardia. A burst of premature (rapid) heartbeats is seen in the middle of the tracing. The QRS complexes remain of the same shape as sinus QRS complexes, which indicates a supraventricular origin. During much of the tachycardia, P and T waves are not clearly seen; however, because the QRS complexes are unchanged in shape, so too must the T waves be of the same shape. Therefore, the negative deflections between QRS complexes (middle of the tracing) must be a superimposition of normal T waves and very different, deeply negative P waves, indicating an ectopic atrial focus of origin for the tachycardia. No clinical signs were present in this older Golden Retriever dog, either at admission or during follow-up, and an echocardiogram was unremarkable. Lead II, 25 mm/sec, 1 cm = 1 mV.

Atrial tachycardias can be intermittent or continuous, and the impulses all can be transmitted to the ventricles or physiologic AV block can occur as a protective mechanism if the rate of the atrial impulses is excessively high and the patient's AV node is suitably discriminating. The mechanism of atrial tachycardias can involve microreentry (e.g., sinus node reentrant tachycardia, intraatrial reentrant tachycardia) or spontaneous automaticity of an ectopic atrial focus (e.g., automatic atrial tachycardia, automatic junctional tachycardia).[32,46] Identifying intermittent atrial tachycardias usually is straightforward: The ECG shows a burst of PACs (see Figure 248-9). Establishing a diagnosis of atrial tachycardia when it is sustained can be difficult, however, because P waves might not be clearly evident, each one potentially being buried within the previous QRS complex or T wave. Differentiation between sustained atrial tachycardia and "high" ventricular (i.e., originating near the AV node) tachycardia therefore can be helped by exteriorizing the P waves, which can be elicited with a vagal maneuver (see previous discussion) and subsequent slowing of the tachycardia or even sinus capture (i.e., resumption of sinus rhythm) (see Figure 248-3).

The same short-term goal also can be reached pharmacologically using graded doses of an intravenous agent. Intravenous treatment is reserved for dogs or cats with very rapid atrial tachycardias (e.g., sustained heart rate >200/min in dogs, >260/min in cats). Treatment options include diltiazem (0.05-0.1 mg/kg slow IV boluses, repeated to effect or to cumulative maximal dosage of 0.25-0.35 mg/kg),[46,49] propranolol (0.02 mg/kg IV PRN, typically q 2-10 min; 3 doses over 2 hours in 1 case report),[27] esmolol (25 mcg/kg/min IV CRI,[50] with reports of up to 100-500 mcg/kg/min IV CRI[51] or 500 mcg/kg IV bolus over 1 minute[46]), edrophonium (0.05-0.1 mg/kg IV; have atropine and endotracheal tube available),[52] or phenylephrine (0.004-0.01 mg/kg IV).[52] These treatments require the patient to have normal systolic and diastolic function and no evidence of CHF, which could make the dosages listed above dangerous (hemodynamically compromising). Intravenous adenosine used for this purpose subjectively appears to be much less effective in dogs than in humans,[46] probably at least in part because of the rare occurrence of AVNRT in dogs compared with people.[53] Long-term oral treatment is discussed below.

Causes for atrial tachycardias are the same as those listed for PACs (see previous discussion). A significantly higher incidence of atrial tachycardias has been noted in association with age: in one study of dogs monitored for 1 week after undergoing pneumonectomy, 7/8 dogs that were ≥8 years old developed episodes of atrial tachycardia compared to 0/7 dogs <4 years old that underwent the same procedure.[54] Two important findings were that the older dogs had a progressive increase in sinus heart rate beginning 15 minutes before the onset of atrial tachycardia, and that the older dogs had evidence of atrial fibrosis and

inflammation that the younger dogs did not.[54]

The clinical impact of an atrial tachycardia depends on its duration, rate, and underlying cardiac lesions. With rapid atrial tachycardias, intermittent AV block can limit the ventricular rate, allowing for improved diastolic ventricular filling and a lessened clinical impact. When atrial tachycardia produces a persistently elevated heart rate (and/or syncope), as described above, treatment is necessary to avoid such long-term complications as tachycardia-mediated cardiomyopathy.[49,55] Such oral treatment is initiated at the low end of the dosage range, and only after any signs of CHF have been resolved (e.g., eliminating pulmonary edema with diuretics). Treatment options include a beta-blocker (e.g., atenolol 0.3-1.5 mg/kg PO q 12 h, or metoprolol 0.2-0.4 mg/kg PO q 12 h, or carvedilol 0.2-0.3 mg/kg PO q 12 h), a calcium channel blocker (e.g., diltiazem regular [not sustained-release] 0.8-1.5 mg/kg PO q 8 h),[49] digoxin (0.005 mg/kg PO q 12 h), or a combination of these if monotherapy is ineffective. Up-titration of the dosage can be undertaken to achieve the desired effect, which requires Holter monitoring for obtaining the optimal heart rate (whether through producing AV block to a degree that results in an appropriate ventricular rate, or suppressing the atrial tachycardia to a degree that the dominant rhythm is NSR). Atrial tachycardias often precede the development of AFib, probably in large part because of a common disease substrate (atrial enlargement and interstitial fibrosis).[56] Treatment of the underlying disease is an essential part of managing these arrhythmias.

Atrial Flutter

Atrial flutter classically is characterized by a rapid and regular series of atrial depolarizations, without a rest phase between them (Figure 248-10 and Video 248-1).[32,46] The time-honored ECG characteristics are (1) rapid, rhythmic waves of atrial electrical activity referred to as *flutter (F) waves*, usually occurring at a very high rate (280 to 400/min); (2) absence of a return to baseline between F waves, giving a "sawtooth" baseline appearance; (3) QRS complexes of a normal, supraventricular appearance; and (4) a variable, irregularly irregular R-R interval if some atrial impulses are blocked, as is often the case.

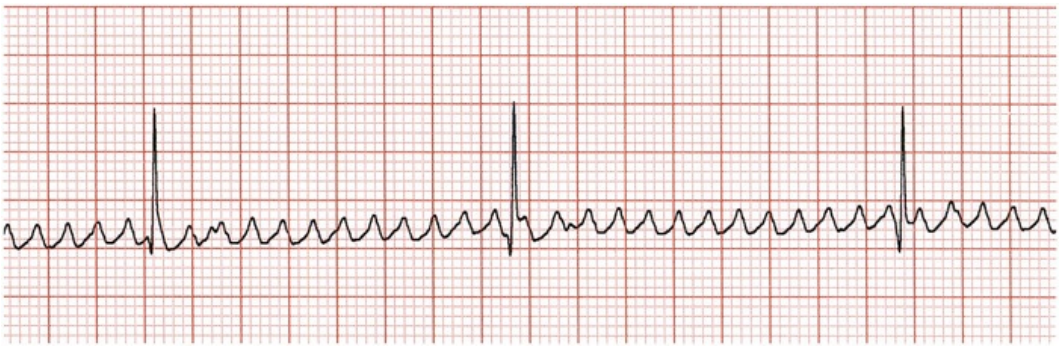

FIGURE 248-10 Atrial flutter. Atrial depolarizations occur in a distinct and organized fashion (F waves), without a return to baseline between each, in this 10-year-old Cocker spaniel. This produces the characteristic sawtooth baseline of atrial flutter. In this dog, the resulting heart rate is slow (approximately 40 beats/min), which is unusual for atrial flutter and which suggests concurrent AV nodal disease. Lead II, 25 mm/sec, 1 cm = 1 mV.

Atrial flutter occurs as a result of impulse propagation through a macroreentrant circuit; that is, self-perpetuating electrical conduction that occurs along a preexisting, closed loop of rapidly conductive tissue in the right atrium.[32,46] Termination of atrial flutter sometimes can occur spontaneously; more often, treatment is necessary when most or all of the flutter waves are conducted because of the resulting markedly elevated heart rate (risk of tachycardia-mediated cardiomyopathy if a heart rate of >240/min persists incessantly in a dog for >3 weeks).[49]

The diagnosis of atrial flutter can be very challenging when each flutter wave is transmitted through the AV node to the ventricles. Such 1 : 1 conduction leaves the F waves buried in the preceding QRS complexes or T waves, making the diagnosis difficult and usually requiring a vagal maneuver to induce transient AV block and reveal the F waves (see above). Intracardiac electrophysiologic assessment in dogs with atrial tachycardias has shown that the classic features of atrial flutter are not always apparent on the surface ECG.[57] This insight is important when minimally invasive therapies are being considered as a cure for an atrial tachycardia. However, all pharmacologic treatment choices for atrial flutter remain the same as those of atrial fibrillation (see below). Permanent abolition of atrial flutter is achieved with radiofrequency catheter–based

interruption of the flutter circuit.[57,58]

Atrial Fibrillation

AFib is a common and important arrhythmia. It represents 14% of all canine arrhythmias, including a 50% prevalence in cases of dilated cardiomyopathy in dogs, and it can trigger clinically overt hemodynamic changes requiring specific treatment.[32,59,60] A prevalence of AFib in up to 2% of the human population is estimated,[60] but a similar statistic is not available in veterinary medicine. AFib is characterized by complete electrical disorganization at the atrial level, leading to a chaotic, rapid series of atrial depolarizations (400 to 1200 per minute) (Figures 248-11 to 248-14).[61]

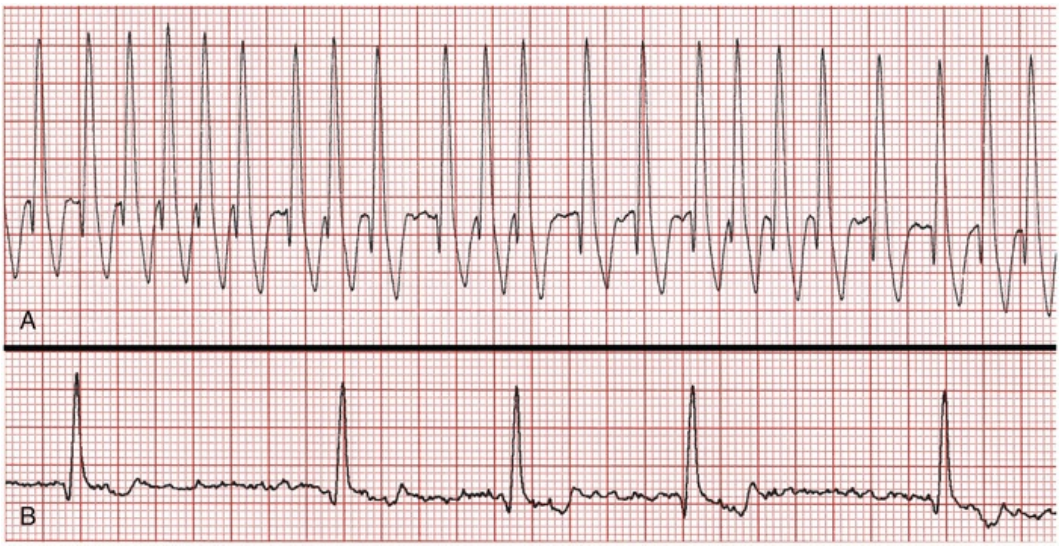

FIGURE 248-11 Atrial fibrillation in 2 dogs: poorly-controlled **(A)** and well-controlled **(B).** Both tracings show the characteristic features of atrial fibrillation: irregularly irregular R-R interval, absence of P waves, and a fine, undulating baseline (f waves). These features are clearer in the dog in panel **B,** because this ECG was made when the patient was stable. The heart rate (ventricular response rate) is 115 beats/min. Gradual up-titration of diltiazem with digoxin achieved this result. The heart rate in panel **A** is 240 beats/min. The dog in panel **A** had the ECG obtained on initial presentation, and such rapid ventricular response rates make the irregularity of the rhythm much less obvious in atrial fibrillation. Panel **A** also shows left bundle branch block (QRS duration = 0.08 second, with positive QRS in lead II), consistent with the dog's underlying dilated cardiomyopathy. **(A),** Lead II, 25 mm/sec, 1 cm = 1 mV. **(B),** Lead II, 50 mm/sec, 1 cm = 1 mV.

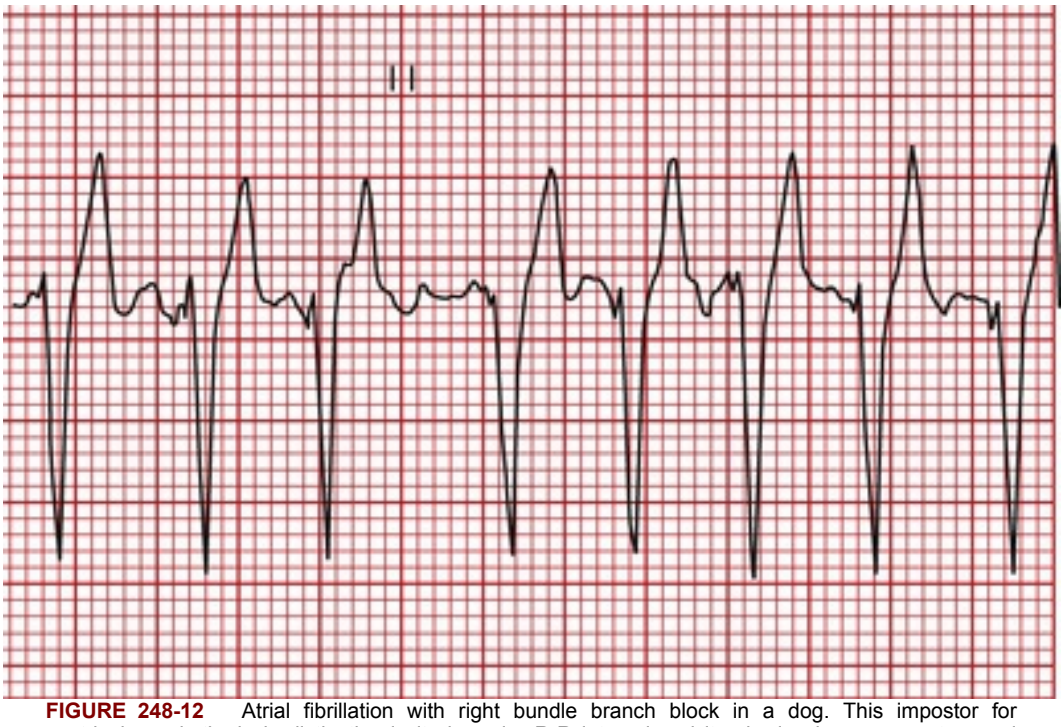

FIGURE 248-12 Atrial fibrillation with right bundle branch block in a dog. This impostor for ventricular arrhythmia is distinctive in its irregular R-R interval and its slowing in response to vagal maneuvers. Lead II, 25 mm/sec, 1 cm = 1 mV.

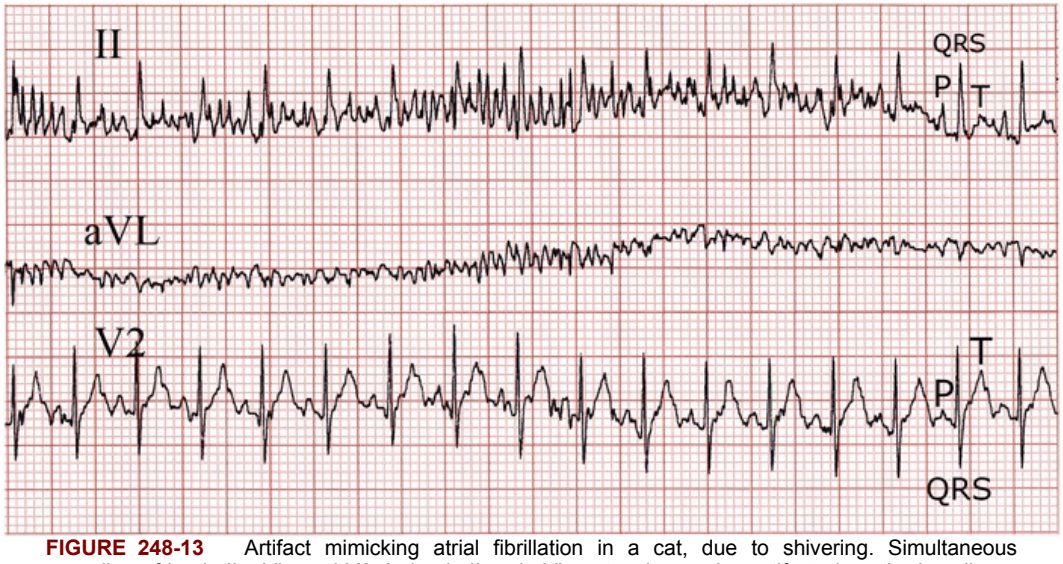

FIGURE 248-13 Artifact mimicking atrial fibrillation in a cat, due to shivering. Simultaneous recording of leads II, aVL, and V2. In leads II and aVL, extensive motion artifact gives the baseline a coarse undulating appearance. The rhythm is normal sinus rhythm, which is more clearly apparent when the animal stops shivering (last 3 heartbeats) and throughout the entire tracing in lead V2. This ECG shows the advantage of recording multiple leads simultaneously, because artifact often can affect one or more leads but not all of them. 25 mm/sec, 1 cm = 1 mV.

FIGURE 248-14 Artifact mimicking atrial fibrillation in a cat, due to purring. The beginning, middle, and end of this tracing show sinus tachycardia. In between them, two instances of purring artifact produce a coarse undulation of the baseline. Lead I, 25 mm/sec, 2 cm = 1 mV.

In contrast to atrial flutter, the fibrillatory impulses of AFib appear on the ECG as tiny deflections of highly variable—essentially random—shapes that cannot be identified as organized atrial electrical activity. The AV node acts as a "gatekeeper" for this chaotic electrical activity, allowing only those electrical depolarizations with optimal intensity, timing, and orientation to pass through to the ventricles and thus controlling the ventricular rate to some extent.

The three ECG characteristics of AFib are (1) supraventricular-appearing QRS complexes (narrow, upright, and of only slightly variable amplitude in lead II, unless ventricular aberrancy/BBB is concurrent); (2) an irregularly irregular rhythm, meaning a variable R-R interval, with a ventricular rate that can be low, normal, or most commonly without treatment, high; and (3) no visible P waves (replaced by a fine undulation of the isoelectric line, termed *f waves*) (see Figures 248-11 and 248-12, and Video 248-2). During diastole, ventricular filling is optimized by atrial contraction, which can account for up to 30% of total ventricular filling. Therefore, its absence can reduce ventricular volume to suboptimal levels, producing overt clinical signs during peaks of cardiac activity like intense physical exercise. Furthermore, the rapid overall ventricular rate commonly resulting from AFib can limit diastolic filling when insufficient time has occurred during diastole before the ventricles are triggered to depolarize again. For these reasons, some contractions intermittently can be ineffective, and one or more ausculted heartbeat(s) can occur without a corresponding palpable arterial pulse (i.e., a pulse deficit). AFib is one of the few arrhythmias that may be suspected from the moment of auscultation and palpation during the physical examination, based on the chaotic irregularity of the cardiac rhythm on auscultation and palpation of the chest, together with pulse deficits. Polymorphic VT, atrial tachycardias, and frequent PVCs or PACs, however, should be included in the differential diagnosis of this physical examination finding (see following).

An uncommon but important diagnostic impostor on ECG is the combination of AFib and BBB (see Figure 248-12), which produces wide QRS complexes and therefore can appear to mimic VT, but without P waves to conclusively indicate AV association (BBB) or dissociation (VT). In such a situation, a vagal maneuver can be performed (see previous), and its effect on the AV node could reduce the ventricular rate with AFib + right bundle branch block (RBBB) but not with VT. In addition, sustained, monomorphic VT is generally characterized by regular R-R intervals, whereas AFib with BBB is not.

AFib in dogs most often occurs in association with primary, underlying cardiac disease involving atrial enlargement.[62] However, AFib also can occur in individuals with structurally normal hearts ("lone AFib") in association with anesthesia (especially with opiates)[63]; hypothyroidism; rapid, large-volume pericardiocentesis; GI disease; and volume overload causing atrial stretch, if those hearts contain sufficient atrial myocardial mass to perpetuate fibrillation (i.e., medium- to large-breed dogs).[62] In giant-breed dogs, lone AFib is recognized commonly.[62,64,65] Lone AFib carries a better prognosis than does AFib associated with structural heart lesions, perhaps because it also is associated with a slower ventricular rate (mean: 120 beats/min) compared to AFib in dogs with subclinical structural heart disease (mean heart rate: 155 beats/min) or with structural heart disease and CHF (mean heart rate: 203 beats/min).[64] It remains to be determined whether those patients with AFib and structurally normal hearts that progress to dilated cardiomyopathy do so because of their arrhythmia, or whether, conversely, AFib is only the arrhythmic prelude to a disease that inherently involves subsequent cardiac chamber dilation and systolic dysfunction.

In cats, AFib occurs less commonly than in dogs and is virtually always associated with structural heart disease causing atrial enlargement.[66] Feline AFib is an incidental finding in 20% to 25% of cases. AFib does not necessarily confer a worse prognosis than the underlying heart disease: more than half of cats with AFib live for 6 months or longer (6 to 12 months: 21%; 1 year or more: 33%).[66,67]

AFib usually is a persistent, permanent arrhythmia. It can occur paroxysmally in the dog[68,69] and very

rarely does so in the cat. Paroxysmal AFib usually is of short duration and often will resolve spontaneously in <4 days if inciting triggers causing high vagal tone (e.g., GI disturbances, opiate drugs) are eliminated. In some dogs with structurally normal atria, and nearly all dogs with severe atrial enlargement, paroxysmal AFib progresses to persistent (permanent) AFib.

The onset of AFib carries prognostic implications in medium- to large-breed dogs with DMVD and CHF and probably other disease groups too. Those with AFib live a median of 142 days (range: 9-478 days) after the onset of CHF, compared to those without AFib (median: 234 days; range 13-879 days).[70] This difference could be due to deleterious effects caused by AFib, or to AFib's role as a marker of DMVD that is more advanced or more rapidly progressive.

In most cases of AFib, two goals of treatment exist: (1) managing the underlying heart disease and (2) maximizing cardiac output by controlling (slowing) the rate of conduction through the AV node if needed (see Figure 248-11). In small animal medicine, the ideal ventricular rate varies for each patient depending on many factors, including presence or absence of CHF and body weight. One substantiated guideline suggests that treatment should target a ventricular rate for dogs with AFib weighing 20 to 25 kg of approximately 130 to 145 beats/min.[71] A practical approach used by this chapter's authors is to aim for a ventricular response rate that corresponds approximately to the expected sinus rate under the environmental conditions (physical location, state of arousal, etc.) at the time the ECG/Holter is recorded. Ideally, Holter monitoring is used for assessing baseline and again for response to therapy, since the influence of autonomic variability is very substantial from one patient to another, and within the same patient in different environments. Specifically, in-hospital ECG has overestimated the ventricular response rate in dogs with AFib by an average of 26 beats/min (range 3-48 beats/min) when compared with Holter monitoring.[72] Auscultation alone for measuring the heart rate in atrial fibrillation also is suboptimal: in one study, the level of accuracy of auscultation compared to ECG ranged from 64% to as low as 12% for veterinary students and some veterinarians.[73]

Treatment of atrial fibrillation can involve conversion to NSR (rhythm control) or acceptance that AFib will persist and a focus on optimizing the resultant ventricular/heart rate if it is too rapid (rate control).[60,74-76] The latter approach has been validated in humans[60,74,77] and is the more widely used treatment strategy in canine and feline AFib. The medications of choice are sustained-release diltiazem (3 mg/kg PO q 12 h) and digoxin (0.005 mg/kg PO q 12 h) given together.[78] The exact dosage needs to be adjusted to produce an optimal ventricular response rate (heart rate), as described above; adjustments generally involve changing the diltiazem dosage and keeping a fixed digoxin dosage, unless there are signs of digoxin toxicosis (lethargy, inappetence, vomiting, diarrhea), which would warrant decreasing the digoxin. The duration of treatment usually is indefinite, unless spontaneous conversion to NSR occurs. In dogs with AFib, the combination of digoxin and diltiazem produces better heart rate control (median heart rate: 126 beats/min, from 194 beats/min pre-treatment) compared to digoxin alone (164 beats/min) or diltiazem alone (158 beats/min).[78] Beta-blockers, notably atenolol, have been less successful at reducing the ventricular rate in dogs with AF compared to digoxin + diltiazem.[70] Adequate heart rate control is important because it is associated with improved survival: in a study of medium- and large-breed dogs with DMVD and CHF, digoxin + diltiazem produced a median heart rate of 144 beats/min and a median survival time of 130 days, compared to a median survival time of only 35 days (and median heart rate of 180 beats/min) with diltiazem alone.[70] Initial, low-dose treatment to begin to reduce the ventricular response rate is undertaken at the same time as initiation of diuretics in patients with new-onset rapid AFib; medication uptitration to achieve heart rate control more precisely is undertaken once the patient's clinical signs of CHF are eliminated with ongoing diuretic treatment, and the patient is stable (alert, eating).

In dogs with AFib, improved defibrillation technology has renewed interest in converting AFib electrically to NSR.[79-82] Biphasic defibrillation converted 36/39 dogs (92.3%) in one study, with a median duration of NSR of 120 days thereafter (postcardioversion treatment: amiodarone 12-15 mg/kg PO q 12 h × 2 weeks, then 5-7 mg/kg PO q 24 h; hematologic and serum biochemical monitoring q 6 months).[79] Recent-onset AFib and absence of structural heart disease were associated with longer maintenance of NSR.[80] Ranolazine 22 mg/kg PO q 12 h, added to amiodarone and initiated after successful cardioversion of AF, is under investigation for efficacy and safety in dogs with naturally-occurring atrial fibrillation (Dr. Janice Bright, personal communication, 2016). Acute AFib has been converted pharmacologically in dogs using intravenous amiodarone (0.33-0.5 mg/kg/min IV infusion to effect; 3.78-8.3 mg/kg cumulative dose to convert AFib to NSR in 2 reported cases),[83] procainamide (14.3 mg/kg slow IV bolus; conversion to NSR 12 minutes after end of bolus in 1 case),[84] or lidocaine (for AFib associated with high vagal tone [e.g., laryngeal paralysis, opiate

drugs]: 2 mg/kg single IV bolus; can be repeated once if ineffective; conversion is expected in 20-90 seconds).[85,86] In an experimental model, ranolazine (3.2 mg/kg IV bolus, then 0.17 mg/kg/min) terminated AFib in 3/4 episodes (75%) in dogs; safety and efficacy in clinical veterinary patients is unknown.[87] Overall, treatment of most canine AFib patients at the present time involves medications for ventricular rate control.

Atrial Dissociation

The occurrence of two organized but independent atrial rhythms, one of which traverses the AV node normally and triggers ventricular activity while the other is constantly confined to the atria, is referred to as *atrial dissociation.* This uncommon, apparently benign, incidental finding is characterized electrocardiographically by two populations of P waves, one of which (generally the larger P waves) is followed consistently by QRS complexes, and the other of which shows exit block—the smaller P waves (called *P' waves*) do not activate the ventricles. The resulting appearance is a superimposition of normal sinus rhythm and an independent atrial rhythm, either of which may or may not be influenced by autonomic inputs (altering the P-P and/or P'-P' intervals). No disease link is known to exist between atrial dissociation and any other cardiac disorder, and no treatment or intervention is required.[88,89]

Disturbances of Ventricular Excitability

Disturbances of ventricular excitability are important because they involve the main element in the cardiac pump and may therefore produce severe hemodynamic and clinical repercussions. However, it must be recognized that ventricular arrhythmias have very diverse mechanisms and causes (especially noncardiac), such that severity, treatment, and prognosis depend on more than ECG findings alone.

Ventricular Extrasystoles or Premature Ventricular Complexes

Ventricular extrasystoles (synonyms: premature ventricular contractions, beats, or depolarizations [PVC; VPB, VPC, VPD, ventricular ectopy]) are premature depolarizations generated by an ectopic focus located in the ventricular tissue.[1-5] These arrhythmias are the most common of all pathologic rhythm disturbances in dogs and cats.[59,90] Hallmarks on the ECG are a short R-R interval (i.e., prematurity), and a wide QRS complex, which has a different morphology (shape) than normal sinus QRS complexes. Most ventricular extrasystoles have a wide, often bizarre-appearing QRS complex (>0.07 second in dogs), without an associated P wave, and a different (often very large) associated T wave (Figure 248-15).

FIGURE 248-15 Premature ventricular complexes (PVCs) in a 10-year-old domestic shorthaired cat with cardiomyopathy. The rhythm is normal sinus rhythm, with 3 monomorphic (same-shaped) PVCs apparent as wide, bizarre, premature deflections. Note that atrial function is undisturbed: P waves are still apparent, but are not responsible for the wide, bizarre QRS complexes because the PR interval between the P waves and the PVCs is too short to be consistent with AV nodal transit time as shown in the PR interval of the sinus beats. That is, the PVCs are, by definition, premature depolarizations that preempted the normal SA node/atria/AV node/ventricles sequence. PVCs do not alter SA nodal function; therefore, the pause that follows each one is compensatory (see Figure 248-8). Lead II, 25 mm/sec, 2 cm = 1 mV.

Single PVCs usually are followed by a compensatory pause (see Figure 248-8) but can be interpolated instead. 1 : 1 alternation between sinus beats and PVCs is referred to as ventricular bigeminy; multiples of two PVCs are referred to as a pair; and three or more PVCs in a row constitutes ventricular tachycardia (VT; see following).

For purposes of identifying an underlying cause and for accurate therapy, it is important to differentiate ventricular extrasystoles from PACs. It is also essential to differentiate ventricular extrasystoles from the other major causes of altered QRS morphology: (1) changes due to cardiomegaly and axis shift; (2) intraventricular conduction disturbances within the bundle branches (see Figures 248-24 and 248-25); (3) abrupt motion or other artifact (see Figure 248-19); (4) the wide but nonpremature QRS complexes of ventricular escape beats (see Figure 248-23); and (5) QRS morphology changes caused by severe hyperkalemia. These five causes for wide QRSs are not ventricular arrhythmias, do not involve a pathologic focus in the ventricle, and therefore are not treated with antiarrhythmic drugs (Figure 248-16)

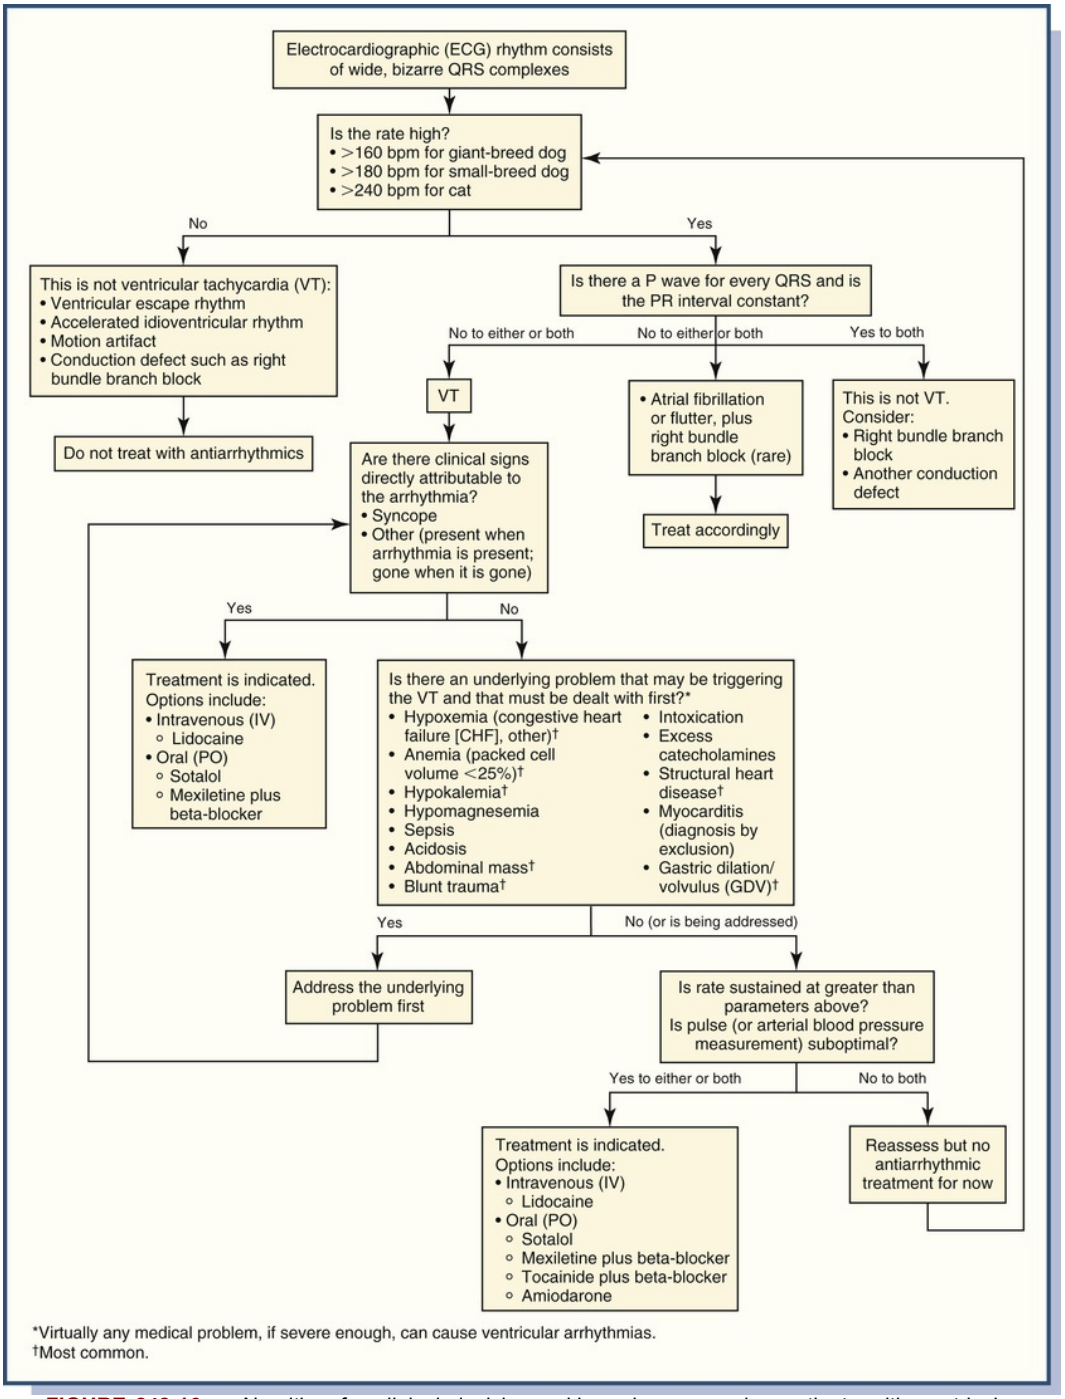

FIGURE 248-16 Algorithm for clinical decision-making when managing patients with ventricular arrhythmias.

Causes of ventricular extrasystoles include virtually any cardiac or systemic disorder, with the most

common of these including such primary cardiac diseases as cardiomyopathy,[91-93] valvular heart disease, congenital heart disease, and endocarditis[94] and such systemic problems as hypokalemia, anemia, hypoxemia, blunt trauma,[95] gastric dilatation-volvulus,[96,97] abdominal masses (commonly splenic or hepatic),[98-100] intoxication, and acidosis. Normal dogs commonly have up to 24 PVCs daily as recorded on Holter studies.[24,101] In cats, ventricular extrasystoles are associated predominantly with myocardial disease. In a retrospective study of 106 cats with ventricular extrasystoles, a significantly higher proportion of cats with ventricular extrasystoles had an abnormal echocardiogram (102/106, 96%) compared with an equivalent cohort of dogs with ventricular extrasystoles (95/138, 69%; $p < 0.001$), suggesting that ventricular extrasystoles more often coexist with structural heart disease in cats than in dogs.[93] The most challenging aspects of managing ventricular extrasystoles remain the evaluation of their severity and the assessment of the need for treatment. Treatment options and approaches are discussed below (see Ventricular Tachycardia).

Two specific heart diseases of dogs are almost exclusively arrhythmogenic: they produce PVCs and VT, and often overt clinical manifestations of acute arrhythmia (malaise, syncope, hypoxic/anoxic seizures, or sudden death) as the chief abnormality. The first, arrhythmogenic right ventricular cardiomyopathy (ARVC, familial ventricular arrhythmia of Boxer dogs, Boxer cardiomyopathy, arrhythmogenic RV dysplasia) causes ventricular extrasystoles and VT, and is described in ch. 252. The second is inherited sudden cardiac death of German Shepherd dogs. This disorder can exist in a latent state or may produce overt clinical signs.[102,103] The disease occurs rarely but is international in distribution and has affected several generations.[102] The predominant abnormality is paroxysmal, rapid VT. Dogs with this disease often develop clinical signs early in life, and these include both syncope and a high prevalence of sudden death. Therefore, the disease causes clinical manifestations mainly in puppies or young adult dogs (mean age: approximately 1 year; age range: 4 to 30 months). As a rule the arrhythmia does not coexist with structural cardiac changes, and thoracic radiographic and echocardiographic results are expected to be normal in affected dogs. A myocardial repolarization defect appears to be the cause of the arrhythmia.[104] Although treatments that limit bradycardia (e.g., vagolytic drugs, ventricular pacing) reduce the occurrence of arrhythmia, no definitive treatment exists for the disorder at this time. Most commonly, affected dogs that survive the first year of life outgrow the disease and live normal lives thereafter.

Accelerated Idioventricular Rhythm

Accelerated idioventricular rhythm (AIVR) is a ventricular rhythm of intermediate rate. AIVRs have the same ECG characteristics as VT except rate, which is slightly below that of VT. Therefore AIVR clinically is considered as a slower subset of VT, and indeed it was given the logical but oxymoronic name "slow VT" at first. On the ECG, AV dissociation, wide and bizarre QRS complexes, and the possibility of capture beats and fusion beats, are seen, just as in VT. However, in a typical medium-size dog, the rate of AIVR by definition is between 70 and 160 beats/min, which places it between idioventricular (i.e., escape) rhythms (<70 beats/min) and true VT in terms of rate. The causes of AIVRs are similar to those of ventricular extrasystoles, but the lower ventricular rate is less compromising of diastolic ventricular filling time; as a result, AIVRs are generally well-tolerated.[105] Treatment therefore is directed at the underlying cause; antiarrhythmic medications are not considered unless management of the underlying cause is ineffective at abolishing the arrhythmia and the rate increases to the point that the criteria for VT are met.

Ventricular Tachycardia

VT is a series of three or more ventricular extrasystoles occurring at a high rate (Figure 248-17 and Video 248-3). It can be continuous (sustained) or intermittent (paroxysmal). Causes are the same as those listed for ventricular extrasystoles (PVCs; see previous discussion). Clinical manifestations are frequent (weakness, syncope, hypoxic/anoxic seizures) but their occurrence depends directly on the hemodynamic consequences of the rhythm. An increasingly rapid VT, for example, will cross a threshold of ventricular rate beyond which a greater number of beats will not translate into greater cardiac output. This "point of diminishing returns," which varies according to the variables described previously, exists because diastolic filling time is most compromised at high heart rates. Thus, very rapid VT, like any other very rapid tachycardia, can produce overt clinical signs of reduced cardiac output.

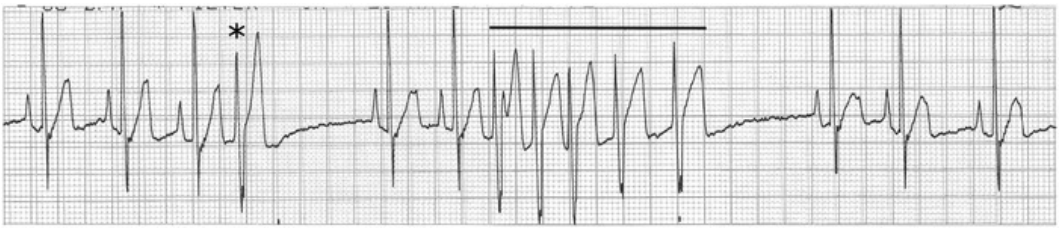

FIGURE 248-17 Ventricular tachycardia in a 5-month-old puppy immediately after thoracotomy and patent ductus arteriosus ligation. Normal sinus rhythm/respiratory sinus arrhythmia is interrupted by one premature ventricular complex (asterisk), and then a series of 5 monomorphic (same-shaped) PVCs, i.e., a run of ventricular tachycardia. The arrhythmia resolved with management of inciting factors (see Figure 248-16). 25 mm/sec, 1 cm = 1 mV.

The identification of VT is easier when the VT is intermittent. The typical appearance is one or several series of QRS complexes that are wide (>0.07 second in the dog, >0.04 second in the cat), do not resemble the sinus QRS complexes, are associated with different-looking, often giant T waves, are not linked to P waves, and may include a capture beat (the first normal sinus P-QRS complex after a paroxysm of VT) and fusion beats (QRS complexes with a morphology that is intermediate, between sinus QRS complexes and ectopic QRS complexes due to intraventricular electrical collision between a normal sinus beat and a PVC); the latter 2 are diagnostic of VT. In VT, P waves are present (the atria depolarize, but the impulse is blocked at or just after the AV node because the more rapid rhythm [VT] dominates the ventricles) but are often engulfed by the wide, bizarre QRS complexes and T waves. Thus the presence of P waves at regular intervals but not fixedly associated with QRS complexes is consistent with VT (see Figure 248-17)—the atria are not "aware" of VT. The ECG diagnosis can become more challenging when VT is continuous, particularly if it is of septal or RV origin and thus produces QRS complexes that are fairly narrow and that could resemble supraventricular complexes. Wide QRS complexes caused by other factors (see previous discussion of ventricular extrasystoles) must not be mistaken for VT.

Treatment of VT begins with confirmation of the ECG diagnosis (i.e., ruling out other causes of wide, bizarre QRS complexes) and identification and treatment of the underlying cause. Given the risk of proarrhythmia with any antiarrhythmic treatment, and the lack of evidence that elimination of VT significantly reduces the risk of death in affected dogs or cats, elimination of the inciting factors responsible for the VT should be considered the first and most definitive form of treatment.[106] When elimination of the cause is not possible, the presence or absence of overt clinical signs caused by VT (especially syncope, or presyncope—episodic stumbling and disorientation without loss of consciousness) justifies antiarrhythmic treatment. In the absence of such signs, antiarrhythmic drugs should be given if the VT is hemodynamically severe; in turn, this generally depends on the heart rate (ventricular rate) caused by the VT. A step-by-step approach, and drug dosages and applications, are shown in algorithmic form in Figure 248-16.

Ventricular Flutter

Ventricular flutter is a very rapid, often prefibrillatory stage of VT. The ECG appearance of this rhythm is a series of identical, tight, tall sinusoidal waves in which it is impossible to separate QRS complexes and T waves (Figure 248-18). This intermediate stage between VT and VF is rare, brief, and either improves (slows to VT ± converts to NSR) or worsens to VF and cardiac arrest. It must be differentiated from motion artifact. Artifact masquerading as ventricular flutter still shows evidence of coordinated ventricular activity (normal QRS complexes within the "flutter" impostors) on close inspection (Figure 248-19). Ventricular flutter is considered a severe ventricular arrhythmia and warrants immediate correction of predisposing causes, intravenous antiarrhythmic treatment (beginning with lidocaine 2 mg/kg IV bolus), and possibly electrical defibrillation (see ch. 140 and 141).

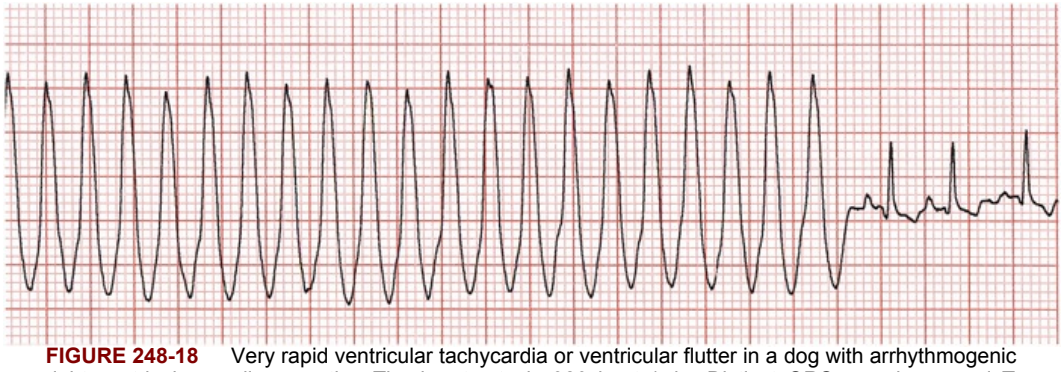

FIGURE 248-18 Very rapid ventricular tachycardia or ventricular flutter in a dog with arrhythmogenic right ventricular cardiomyopathy. The heart rate is 320 beats/min. Distinct QRS complexes and T waves are not seen until the last 3 heartbeats when the rhythm converts to sinus tachycardia at a rate of 180 beats/min. A tachycardia that is this rapid can be expected to markedly reduce diastolic filling of the ventricles, decreasing cardiac output and often producing such clinical signs as syncope or sudden death (Video 248-3). 25 mm/sec, 1 cm = 1 mV.

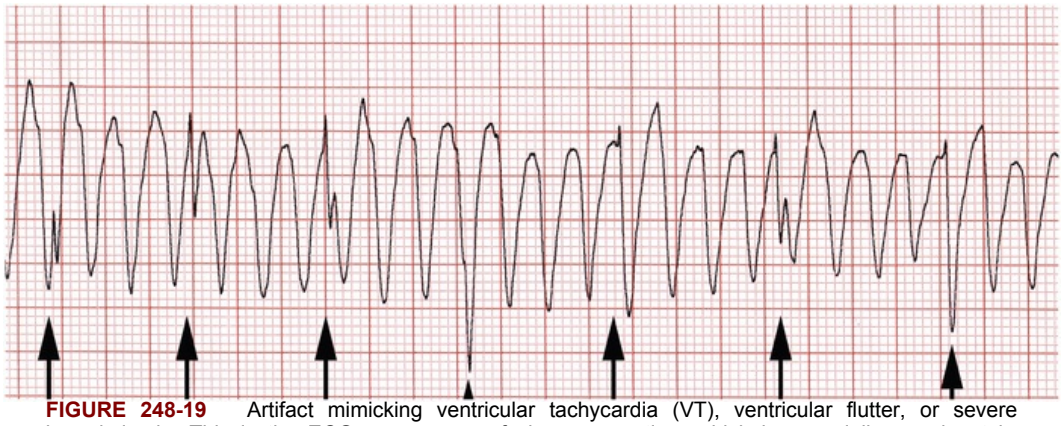

FIGURE 248-19 Artifact mimicking ventricular tachycardia (VT), ventricular flutter, or severe hyperkalemia. This is the ECG appearance of vigorous panting, which is especially prominent in precordial leads like this one. The rhythm is normal sinus rhythm. Close inspection shows evenly-spaced, narrow, positive upstrokes (arrows) that represent the normal sinus QRS complexes emerging through the artifact. This would not be apparent in true VT, ventricular flutter, or hyperkalemia. Lead V2, 25 mm/sec, 1 cm = 1 mV.

Ventricular Fibrillation

VF is a terminal (fatal), disorganized, chaotic pattern of ventricular depolarizations involving complete desynchronization of ventricular electrical activity. Hemodynamically, it produces circulatory collapse and arrest. Therefore it is a preagonal state leading to death within seconds to minutes. Indeed, the cardiac rhythms that define cardiac arrest are VF, asystole, and pulseless electrical activity (notably pulseless VT), not just asystole.[107] The ECG appearance of VF consists of erratic, patternless waves of variable morphology, amplitude, and frequency (Figure 248-20).

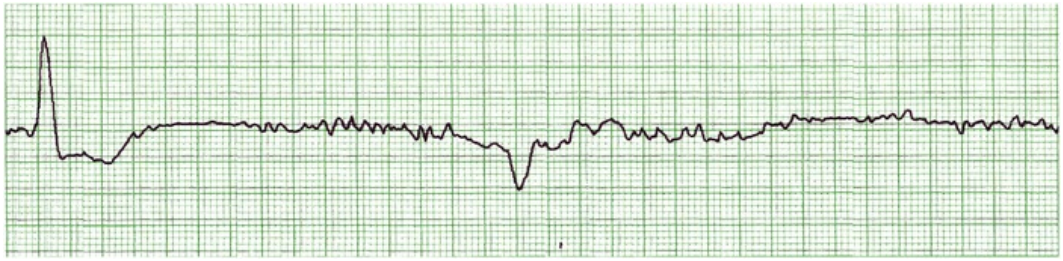

FIGURE 248-20 Ventricular fibrillation in a cat with syncope caused by severe hypertrophic cardiomyopathy. After the final QRS complex, the ventricles fibrillate, producing a fine undulation of the

baseline and no synchronized ventricular or atrial activity. This rhythm signifies cardiac arrest and requires electrical defibrillation or withholding of resuscitation for a humane death. External movement artifact explains the wider deflection in the middle of the tracing. 25 mm/sec, 1 cm = 1 mV.

The underlying cause is by definition a severe disorder, such as myocardial trauma, anoxia, severe electrolyte disturbance, and advanced states of shock. If VF is suspected on ECG, artifact must immediately be ruled out; poor electrical connection between the patient and the ECG leads can mimic VF. Rapid confirmation of VF consists of (1) applying isopropyl alcohol to the skin-ECG lead interface to improve conductivity (help rule out artifact); (2) assessing that the arrhythmia is present in multiple leads, not just lead II; (3) feeling for the arterial pulse (any palpable pulse rules out VF); and (4) noting that the patient is unconscious, because VF is inconsistent with adequate cerebral perfusion. VF is often preceded, and therefore heralded, by ventricular extrasystoles (possibly demonstrating the R-on-T phenomenon), then sustained VT, then possibly ventricular flutter.[2] Unfortunately, treatment of PVCs/VT with antiarrhythmic drugs does not reliably reduce the risk of VF,[106] and rather, the underlying cause and other inciting factors that can be arrhythmogenic (hypokalemia, anemia, etc.) must be addressed. When the rhythm has reached VF, treatment (cardiopulmonary resuscitation), though often unrewarding, must be instituted immediately and generally involves electrical defibrillation if available (see ch. 140 and 141). Prevention of initial VF or of VF recurrence can be pursued through surgical placement of an implantable cardioverter-defibrillator. This form of therapy, which is vastly more effective and safer that antiarrhythmic medications in human patients, is gaining interest in veterinary medicine.[108,109]

Torsade de Pointes

Torsade de pointes (TdP) is a ventricular arrhythmia that arises from prolongation of the Q-T interval.[110,111] The rotation of the peaks of the QRS complexes on the horizontal axis of the ECG is due to the ever-changing geometry of the reentry circuit, which oscillates within the ventricles. The diagnosis of TdP is based on the following criteria: (1) the rhythm immediately prior to onset of TdP is slow, and the Q-T interval is prolonged (>0.25 second in the dog); (2) the onset of TdP involves an R-on-T ventricular extrasystole (e.g., depolarization [R wave] occurs during the vulnerable part of the T wave); (3) the ensuing rapid (>180 beats/min) ventricular rhythm has QRS complexes that are more regular than in VF but that are continuously changing in amplitude and polarity.

The total duration of a self-resolving paroxysm of TdP usually is very brief (5 to 10 seconds), but it can persist for longer; in those instances it often evolves lethally into VF. TdP is not commonly recognized in the dog but can be caused by any disorder that prolongs the Q-T interval[111]: congenital long QT syndrome (Dalmatian), hypokalemia, hypocalcemia, and overdose or toxicosis due to antiarrhythmic drugs, particularly class 1A antiarrhythmics such as quinidine. The treatment is highly specific and requires discontinuation of all antiarrhythmic drugs and institution of intravenous magnesium sulfate (20-60 mg/kg slow IV bolus).[111]

Ventricular Parasystole

Ventricular parasystole ("two hearts beat as one") is a complex arrhythmia that results from the concurrent and independent activity of two pacemakers, one being a normal supraventricular pacemaker and the other existing in a protected site in a ventricle.[112] By definition, parasystole has (1) a ventricular focus with independent, abnormal automaticity and a rate that is greater than an escape focus and (2) a unidirectional (entry) block that shields this focus from sinus depolarizations. Parasystole is most often benign, does not warrant antiarrhythmic treatment, and regardless is usually refractory to antiarrhythmic therapy.

Isorhythmic Atrioventricular Dissociation (IAVD)

Isorhythmic atrioventricular dissociation (IAVD) is a rhythm disturbance in which atria and ventricles are driven by independent pacemakers at equal or nearly equal rates. It has been identified in a group of 11 Labrador Retrievers, possibly correlated to focal junctional tachycardia.[113] The authors of this chapter have seen it disproportionately more often in Samoyed dogs, usually as an incidental finding (Figure 248-21). The characteristic ECG finding is of P waves that drift into the QRS complex and even precede it (IAVD with type I synchronization). This can occur periodically, with periods of identical atrial and ventricular rate ("accrochage") giving the appearance of AV synchrony.[113] The clinical implications of IAVD are not known to be harmful: there is no proven association with progressive heart disease, and at the present time, IAVD is considered an incidental electrocardiographic finding.

FIGURE 248-21 Isorhythmic atrioventricular dissociation in a Samoyed dog. P waves and QRS complexes are closely associated but the drifting of P waves into and out of QRS complexes indicates lack of atrioventricular synchrony. Hallmarks of this arrhythmia are a supraventricular-appearing (narrow, positive in lead II) QRS complex and similar, but not perfectly identical, atrial and ventricular rates. Lead II, 25 mms/sec, 1 cm = 1 mV.

Disorders of Conduction

Disorders arising from faulty intracardiac electrical conduction are simply referred to as *blocks*. Blocks are grouped according to anatomic and functional criteria. Anatomic criteria separate them depending on their level of physical location: SA blocks, AV blocks, BBBs, and fascicular blocks. Functional criteria characterize blocks according to their degree of severity. First-degree block produces a delay in conduction; second-degree block causes complete but intermittent block; and third-degree block causes complete, sustained block.

Atrioventricular Block

In a healthy heart, the AV node serves an important gatekeeper function that introduces a normal delay with each sinus beat, allowing the atria to finish contracting. The AV node also prevents excessive atrial impulses from reaching the ventricles in supraventricular tachycardias (see Atrial Fibrillation, previously). This normal and vital electrical filtering function helps preserve a more normal heart rate when supraventricular tachycardias occur, and this effect can be enhanced if needed using negative dromotropic (AV nodal conduction-delaying) medications, as described above for the treatment of AFib. However, the function of the AV node may be excessive or extreme, hindering the passage of normal sinus impulses. Failure of normal AV nodal conduction from the atria to the ventricles is called *AV block* and its clinical significance depends on the characteristics described below.

First-degree AV block

First-degree AV block is simply a delay in AV conduction. Conduction through the AV node is slower than normal, but every impulse crosses the node successfully. It can be permanent or transient and can arise from a structural lesion or simply be functional. The ECG diagnosis is based on normal, sinus-appearing QRS complexes and a prolonged PR interval. The clinical manifestations are nil; first-degree AV block is an ECG finding only and it neither produces overt clinical signs nor warrants treatment. It should draw the clinician's attention to possible causes of high vagal tone, which generally are physiologic but occasionally can be toxic (e.g., digitalis glycoside toxicosis). First-degree AV block does not progress to second-or third-degree AV block except in cases of drug toxicosis.

Second-degree AV block

Second-degree AV blocks involve the complete (but transient) interruption of AV conduction. Therefore, a P wave exists for every QRS complex, but a QRS complex does not exist for every P wave. Two important subtypes of second-degree AV block exist.[28] The first, Mobitz type I second-degree AV block, is characterized by a progressive lengthening of the P-R interval until ultimately a P wave is blocked (P wave without QRS complex), an entity known as the *Wenckebach phenomenon.* Anatomically, Mobitz type I second-degree AV block originates high in the AV node and is said to carry a good prognosis because it is closely related to first-degree AV block and virtually never causes clinical signs (Figure 248-22).

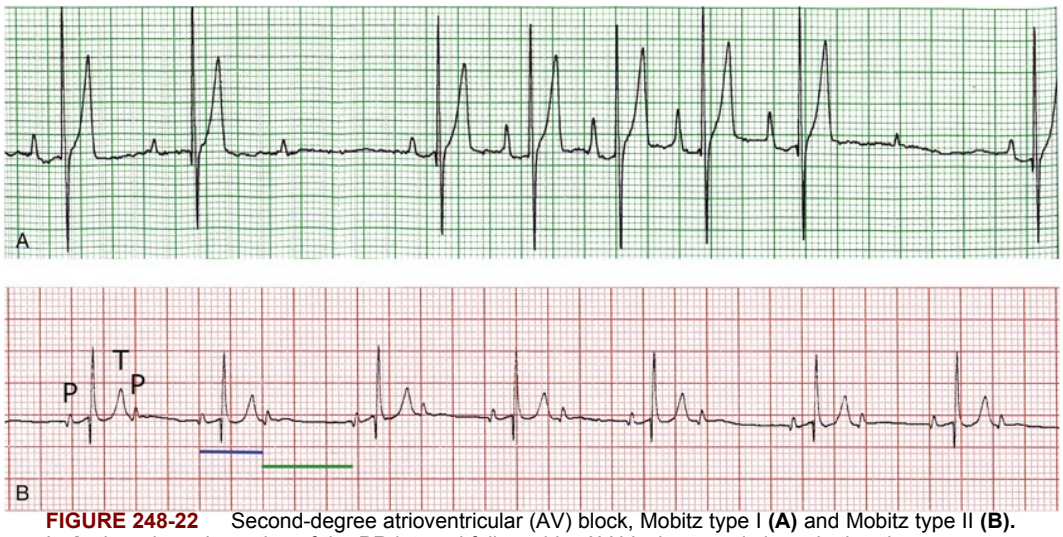

FIGURE 248-22 Second-degree atrioventricular (AV) block, Mobitz type I **(A)** and Mobitz type II **(B).** In **A,** there is prolongation of the PR interval followed by AV block; normal sinus rhythm then resumes, with a normal PR interval, until prolongation and block occurs again. This is considered a harmless physiological variant (i.e., manifestation of high vagal tone). The change in P wave height reflects a wandering pacemaker (see Figure 248-4), which is another manifestation of high vagal tone. In **B,** the atrial impulse is blocked with no lengthening of the preceding PR interval. Specifically, this is 2 : 1 block; there are two P waves for each one that is conducted. Causes include pharmacologic (e.g., alpha-2 agonist drugs), physiologic (less commonly), and pathologic (e.g., AV node fibrosis) etiologies. The resulting ventricular rate is 70 beats/min. Depending on progression—especially to 3 : 1, 4 : 1, or higher grades of block—and presence of clinical signs, such patients can require pacemaker implantation. Note that ventriculophasic sinus arrhythmia is an incidental finding: instead of a constant P-P interval throughout the tracing, the P-P interval that flanks the QRS complexes (blue line) is shorter than the P-P interval during block (green line). Lead II, 25 mm/sec, 1 cm = 1 mV.

The second, Mobitz type II second-degree AV block, by contrast, demonstrates perfectly regular P-R intervals, until one or more P waves is/are blocked (see Figure 248-22). Mobitz type II second-degree AV block arises from the AV bundle and is said to carry a more guarded to poor prognosis because it more closely resembles third-degree AV block. However, objective evidence is lacking to support this extrapolation of severity in Mobitz types I and II from human cardiology to veterinary patients. In "simple" Mobitz type II second-degree AV block, more conducted P waves occur than blocked P waves, whereas in "advanced" or "high-grade" Mobitz type II second-degree AV block (as in Figure 248-22), more blocked P waves occur than conducted P waves. The presence or absence of clinical signs appears to be related to the ventricular rate. Specifically, dogs with high-grade Mobitz type II second-degree AV block have an expected survival that is no different than that of dogs with third-degree AV block, and pacemaker implantation significantly improves survival in both groups, regardless of the presence or absence of bradycardia-associated clinical signs.[28]

Therefore, Mobitz type I and simple Mobitz type II second-degree AV blocks rarely produce clinical manifestations such as exercise intolerance, whereas the more advanced Mobitz type II second-degree AV blocks, by virtue of blocking more impulses in the AV node and resulting in a lower ventricular rate, commonly produce clinical signs that are similar to those of third-degree AV block: weakness, lethargy, syncope, and Stokes-Adams hypoxic-anoxic seizures (true convulsions caused by critical, bradycardia-induced cerebral hypoperfusion)[114] even with minimal exertion. The presence of such clinical signs, and the ventricular rate, are principal determinants of whether the patient requires treatment (pacemaker implantation; see ch. 249).

Third-degree AV block

Third-degree, or complete, AV block is a complete and sustained interruption of AV conduction. The ventricles depolarize according to a slow, regular, independent rhythm, called an *escape rhythm* (junctional or ventricular; see following) (Figure 248-23 and Video 248-4). It is important to recognize the lifesaving salvage function of a ventricular escape rhythm because it prevents asystole. Therefore, even though ventricular escape QRS complexes are wide and bizarre, ventricular antiarrhythmic therapy is absolutely contraindicated.

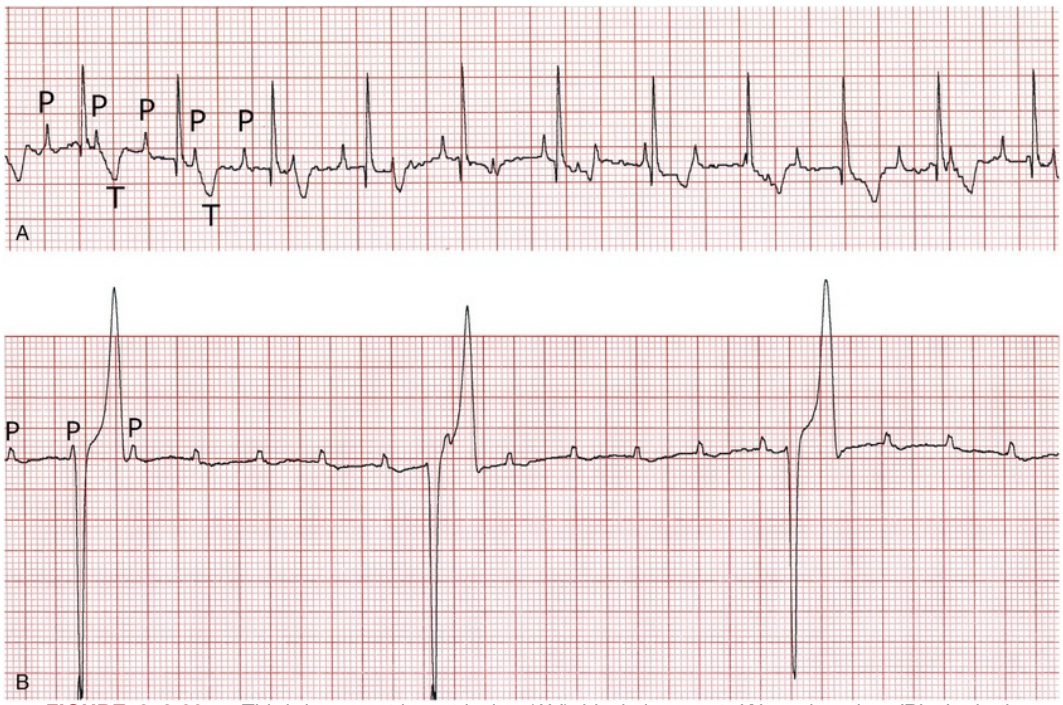

FIGURE 248-23 Third-degree atrioventricular (AV) block in a cat **(A)** and a dog **(B).** In both instances, the atria and ventricles depolarize independently. In each tracing, the P-P interval is constant and the R-R interval (escape rhythm) is constant. The main difference is in ventricular escape rate. As is often noted in cats with third-degree AV block, the ventricular rate is rapid for an escape rhythm (**A,** 120 beats/min), whereas in dogs, it often is much slower (**B,** 30 beats/min). Both tracings: lead II, 25 mm/sec, 1 cm = 1 mV.

In third-degree AV block, electrical communication between the atria and ventricles is nonexistent (complete AV dissociation). Therefore, the ECG diagnosis is based on the complete absence of P wave conduction (P waves occur with a constant P-P interval but are not followed immediately and consistently by QRS complexes; no repeatable PR interval) and slow, regular (constant R-R interval) ventricular rhythm, where the QRS complexes are usually of a uniform, but wide, bizarre morphology. Third-degree AV blocks typically produce marked exercise intolerance, weakness, and syncope. Even so, it is possible to encounter older animals, not very active by nature, that have "asymptomatic" third-degree AV block; pacemaker implantation may reveal the extent and duration of clinical signs restrospectively, when the patient shows a substantial improvement in exercise tolerance and vigor at home postoperatively. In cats, especially, third-degree AV block can exist with a ventricular escape rhythm that is only minimally less than the normal sinus heart rate at home (e.g., 110-140 beats/min) and the block is an incidental finding (see Figure 248-23).[3,5,115]

The causes of AV blocks are diverse. First-degree AV and Mobitz type I second-degree AV blocks often are functional (high vagal tone in healthy individuals; negative dromotropic effects of digitalis, antiarrhythmics, or alpha 2–stimulating sedatives) and thus are normal physiologic variants or resolve with drug discontinuation. Rarely, cardiac disease with atrial dilation and AV nodal lesions can be present as a cause of first-degree or Mobitz type I second-degree AV block. Mobitz type II second-degree AV block and third-degree AV block sometimes are functional (hyperkalemia, digitalis toxicosis, alpha 2–receptor agonists like dexmedetomidine) but are more commonly associated with a structural lesion, be it inflammatory (endocarditis, Lyme myocarditis, traumatic myocarditis) or degenerative (physical disruption of the AV node arising from cardiomyopathy, endocardiosis, or fibrosis).[116-118] In dogs, third-degree AV block usually is considered irreversible but it has been shown to return spontaneously to NSR in 7% of cases and to second-degree AVB in 5% of cases.[119]

Treatment of AV block is aimed at the underlying cause when possible. In clinically overt, advanced, Mobitz type II second-degree AV blocks or third-degree AV blocks, response to parasympatholytic or sympathomimetic drugs tends to be disappointing because these agents do not reverse the disease process in the AV node, nor do they typically overcome the AV block to a clinically meaningful degree.[28] Pacemaker implantation (see ch. 249 and Video 248-4) is more effective and it leads to significantly longer survival: the one-year survival rate for dogs with high-grade second-degree AV block or third-degree AV block that receive a pacemaker is 80-85% compared to 50-55% for those that do not, and the 2-year survival rate is 70-

75% versus 30-35%, respectively.[28]

It is important to note that the decision to implant a pacemaker can be a dilemma for owners who question whether an older dog is reaching the end of its natural lifespan because the dog "has been showing signs of getting older lately." Such owners should understand that these signs often were the progressive manifestations of the bradycardia, not of aging, and that pacemaker implantation—while not a panacea—can produce a quality of life that owners had not seen in their dogs for months or years. Therefore, comorbidities (e.g., chronic kidney disease), nonspecific signs, and an advanced age, while relevant to the patient, should be seen as factors that pacemaker implantation could help, rather than reasons to automatically forgo the procedure.

Cats with third-degree AV block have distinct features that are clinically important. Many (11/18, 61% in one case series)[115] have such underlying structural heart diseases as cardiomyopathy, which will not be reversed by pacemaker implantation. Ventricular escape rates approximate NSR (80-140, median 120 beats/min in one case series),[115] such that third-degree AV block can be an incidental finding in cats. Survival without a pacemaker can be surprisingly long (median 386 days; range, 1-2013 days in one case series),[115] regardless of presenting signs.

Bundle Branch Blocks

BBBs are slowings or interruptions of conduction involving one or more of the ventricular branches of the His bundle. Blocks can be functional (transient interruptions due to a depolarization's occurring during the refractory period) or structural (permanent interruptions due to a physical disturbance). The ECG diagnosis of BBBs is based on the abnormal shape of the QRS complexes, which become widened due to the desynchronization of the two ventricles. BBBs cannot be considered arrhythmias because they do not alter the rhythm of the heartbeat; therefore, the ECG diagnosis is stated as "rhythm" (e.g., normal sinus rhythm) "with [right or left] bundle branch block" (or "BBB pattern"). The duration of the QRS complexes is >0.07 second in dogs with BBB (>0.04 second in cats with BBB), and the polarity is positive in lead II for left BBBs and negative in lead II for RBB blocks[111] (Figures 248-24 and 248-25).

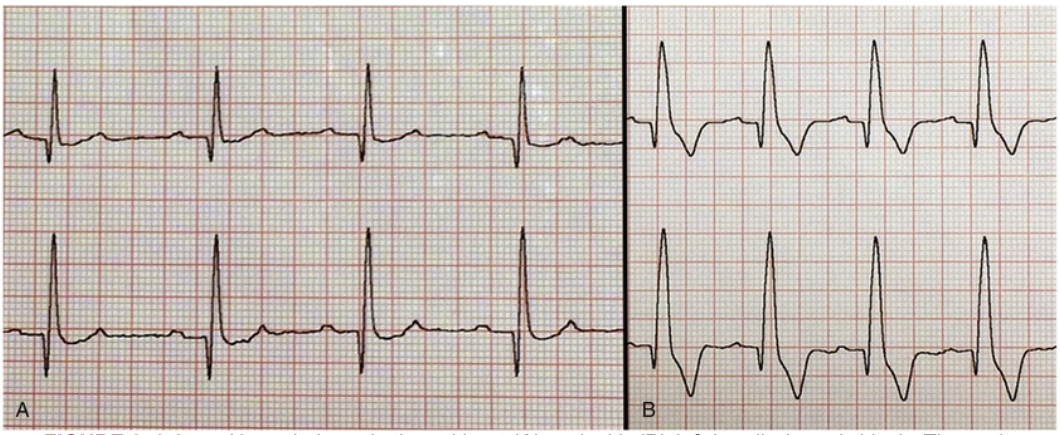

FIGURE 248-24 Normal sinus rhythm without **(A)** and with **(B)** left bundle branch block. The main difference is in the width of the QRS complexes (0.09 second in panel **B**), which exceeds the normal range for dogs (up to 0.06 second). Panel **A** was obtained before doxorubicin treatment for this dog's neoplasia. Panel **B** was obtained after a lifetime cumulative dose of 150 mg/m^2, an amount that sometimes can be associated with cardiotoxicosis. Both tracings: leads I and II, 25 mm/sec, 1 cm = 1 mV. (Courtesy Dr. Glenna Mauldin, Animal Cancer Centre, Western Veterinary Specialist and Emergency Centre, Calgary, AB, Canada.)

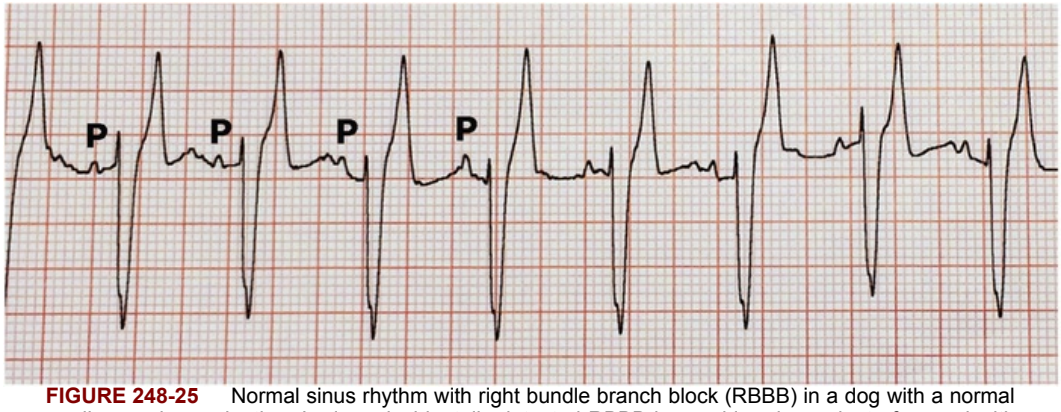

FIGURE 248-25 Normal sinus rhythm with right bundle branch block (RBBB) in a dog with a normal cardiovascular evaluation. In dogs, incidentally detected RBBB is considered a variant of normal with no clinically significant consequences. The wide, bizarre QRS complexes can be misinterpreted as PVCs if the association between a P wave and each QRS complex, at a constant PR interval, is overlooked. Lead II, 25 mm/sec, 1 cm = 1 mV. (Courtesy Dr. Glenna Mauldin, Animal Cancer Centre, Western Veterinary Specialist and Emergency Centre, Calgary, AB, Canada.)

If BBBs occur during sinus rhythm, the ECG diagnosis is straightforward because other than the very abnormal appearance of the QRS complexes, the P-QRS-T sequence throughout the ECG is normal: A P wave occurs before each QRS and the PR interval is fixed and normal. Still, care must be taken to properly identify the rhythm as normal sinus rhythm and avoid misdiagnosis of VT based on wide, bizarre QRS complexes alone. If the block occurs concurrently with a nonsinus rhythm, such as AFib, establishing a diagnosis in BBB can be much more challenging (see Figure 248-12). A BBB together with AFib mimics ventricular extrasystoles or VT, which may misdirect therapeutic decisions (see previous discussion of atrial fibrillation). Cats with heart disease (especially cardiomyopathy) are classically described as being prone to developing block in a subdivision of the LBB known as the *left anterior fascicle* (LAF).[5] This electrocardiographic observation is supported by the histologic finding in 63 cardiomyopathic feline hearts that 54 left bundles (86%) showed degeneration, fibrosis, osseous metaplasia, and other lesions, compared to 20 right bundles (32%).[121] LAF block produces a tall R wave in lead I and aVL and a deep S wave in leads II, III, and aVF, and therefore, a left-axis deviation.[122]

The causes of BBB are many, because BBBs can be due to a variety of pathologic changes including concentric hypertrophy (as seen in hypertrophic cardiomyopathy),[121] dilation (as seen in dilated cardiomyopathy), and inflammation (endocarditis, traumatic myocarditis). In the dog, RBB block usually is a completely normal, unnecessarily worrisome ECG finding. Conversely, LBBB almost always is associated with left ventricular enlargement (see Figure 248-24). Clinical manifestations of BBBs alone generally do not occur.[120,122] These disturbances therefore do not warrant specific treatment beyond that of their underlying problem if one exists. The importance of recognizing BBB lies in the fact that LBBB could be the first indicator of underlying cardiac disease, which itself warrants further diagnosis and treatment; and that they can—and should not—be misinterpreted as ventricular arrhythmias.

Atrial Standstill (Silent Atrium)

This rhythm disturbance is characterized by the total absence of atrial depolarization (Figure 248-26). The three differential diagnoses for atrial standstill are (1) moderate to marked hyperkalemia ($K^+ > 7.5$ mEq/L; see later discussion), (2) atrial myopathy, and (3) ECG artifact (P waves too small, or isoelectric, preventing them from being seen properly). Although hyperkalemia is the most common cause of atrial standstill (and the only reversible one), atrial standstill can occur due to marked atrial stretch,[123] as occurs particularly in cats with various forms of cardiomyopathy, or atrial parenchymal hypoplasia, as is seen in association with a dystrophic form of neuromyopathy, particularly in the Springer Spaniel. Regardless of cause, the ECG appearance is of a regular rhythm (constant R-R interval), usually with QRS complexes that are of a supraventricular appearance, and with a low or normal rate but without detectable P waves in any lead on the ECG. Differentiating between the two main causes of this rhythm using the ECG alone is difficult, and immediate measurement of serum potassium concentration is warranted.

FIGURE 248-26 Atrial standstill in a 10-year-old Labrador Retriever dog. No P waves are seen on this lead, nor were they present in any other lead. The rhythm is regular, at a rate of 120 beats/min. The most important possible cause is hyperkalemia, which can be life-threatening, but which was ruled out with a normal serum potassium concentration in this dog. Therefore, the diagnosis by exclusion is atrial myopathy. Lead II, 25 mm/sec, 1 cm = 1 mV.

Electromechanical Dissociation

Electromechanical dissociation (EMD) is not, strictly speaking, an abnormality of cardiac rhythm. EMD refers to the failure of conversion of an electrical rhythm into the mechanical forces of systole and diastole.[124,125] The ECG therefore can show virtually any rhythm, and the diagnosis rests on the combination of a hemodynamically collapsed patient with an ECG that shows any rhythm but asystole. The arterial pulse usually is barely perceptible or absent, the patient typically is unconscious, and EMD most commonly is a prearrest or terminal condition. Treatment requires correction of underlying causes if possible and then is aimed at increasing circulation to improve myocardial perfusion (see ch. 140 and 141). Because EMD generally indicates profound myocardial hypoxia, the prognosis is grave irrespective of treatment.

Complex Disorders Involving Abnormalities of Both Excitability and Conduction

Cardiac Effects of Systemic Potassium and Calcium Abnormalities

Because cardiac activity depends fundamentally on transmembrane movements of ions, pathologically high or low systemic concentrations of potassium and calcium can lead to disturbances in cardiac function. Such disturbances can have important effects on the heart's rhythm.

Hypokalemia

Serum potassium concentrations are most accurate if measured on blood drawn into lithium heparin (green top) tubes. Purple top tubes contain tripotassium EDTA, which produces an artifactually high test result incompatible with life, and red top tubes allow coagulation, a process that, during platelet activation and aggregation, releases potassium and can artifactually raise the measurement by small but clinically significant levels.

A low serum potassium concentration produces two major effects in cardiomyocytes. First, it makes the resting membrane potential increasingly negative (Figure 248-27),[126,127] which decreases myocyte excitability. This effect is a result of the greater difference between intracellular and extracellular potassium concentrations in hypokalemia compared with normokalemia (hyperpolarization) and in cardiomyocytes is generally mild and transient. Second, hypokalemia prolongs repolarization, increasing action potential duration.[126,127] Myocyte repolarization depends principally on the activity of potassium currents, notably the delayed rectifiers $I_{k,r}$ and $I_{k,s}$. With hypokalemia, these currents function more slowly. This prolongation of repolarization lengthens the normally very brief period of repolarization during which the diastolic membrane potential is near the threshold potential. Therefore, hypokalemia-induced prolongation of repolarization opens a window of increased excitability during which spontaneous ectopic activity (such as atrial or ventricular extrasystoles) can occur based on the threshold being reached after the absolute refractory period by a slowly repolarizing cell. Clinically, the second (arrhythmogenic) effect predominates over the first

(suppressive), and the dominant cardiovascular effect of a serum potassium concentration <3.5 mEq/L in dogs and cats is an increased risk of spontaneous depolarizations, notably ventricular extrasystoles (PVCs). Other ECG manifestations of hypokalemia can include evidence of prolonged, abnormal repolarization in the form of U waves, Q-T interval prolongation, and AV dissociation.[128]

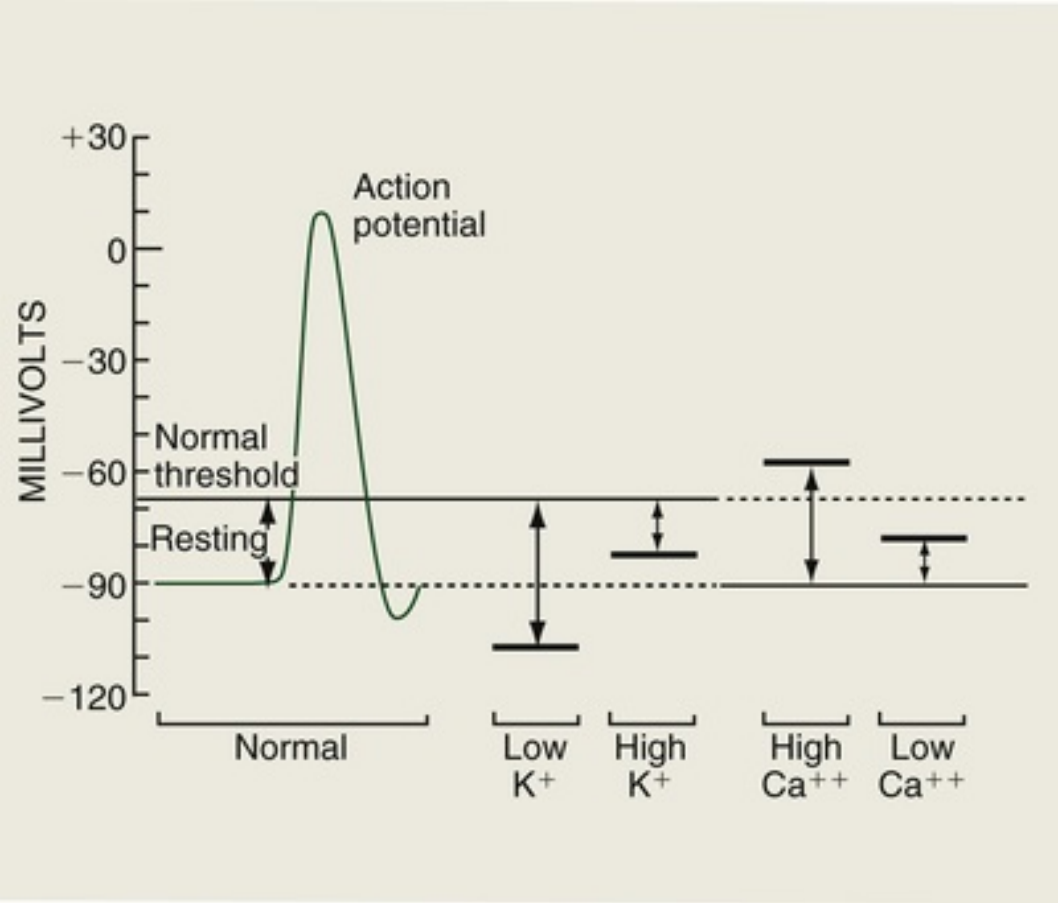

FIGURE 248-27 Effects of abnormal serum calcium and potassium concentrations on cell membrane characteristics in excitable tissues. The concentration of potassium in extracellular fluids affects the resting potential, whereas the concentration of calcium in extracellular fluids affects the threshold potential. Equally or more important, though not shown here, are the effects of these abnormalities on repolarization. (Reproduced with permission from Leaf A, Cotran R: *Renal pathophysiology*, New York, 1976, Oxford University Press, p 116.)

Because class I antiarrhythmics (e.g., lidocaine, mexiletine, quinidine) act on sodium channels that require normal serum potassium concentrations to function, hypokalemia also is important as a cause of antiarrhythmic drug refractoriness: a patient whose PVCs are caused by hypokalemia generally will return to normal sinus rhythm with potassium supplementation alone, whereas treatment with lidocaine during hypokalemia is unlikely to alter the ventricular arrhythmia but still can cause lidocaine toxicosis (neurologic disturbances such as seizures) if dosing is readministered repeatedly for lack of conversion to sinus rhythm. This important observation has wide-ranging implications in patients with dilutional hypokalemia (e.g., gastric dilatation-volvulus patient with large-volume fluid resuscitation) or potassium-wasting metabolic illness (e.g., chronic kidney disease) when PVCs/VTs occur and the question "When should I treat this arrhythmia with an antiarrhythmic?" arises. An important initial step toward answering this question should always be to ensure that normokalemia is present before considering antiarrhythmic therapy. The maximum safe rate of IV potassium chloride infusion is 0.5 mEq/kg/h (see ch. 68).

Hyperkalemia

Mildly elevated serum potassium levels (5.6 to 6.5 mEq/L) are associated with greater cell membrane permeability to potassium during repolarization. These repolarization effects predominate over depolarization effects shown in Figure 248-27, and such mild hyperkalemia has been described as a rhythm-

stabilizing condition. Thus, mild hyperkalemia in dogs can be reflected on the ECG as faster ventricular repolarization (i.e., a shorter than normal Q-T interval and an abnormally narrow, often peaked or "tented" T wave).[126,127,129,129a] It is a common but serious mistake to think that tented T waves must always equal hyperkalemia: in a case series of 205 dogs with hypoadrenocorticism, many were hyperkalemic but only 15% of these hyperkalemic dogs had "tented" (tall, narrow) T waves.[130] Similarly, of 37 dogs or cats with naturally occurring hyperkalemia, only 2 (5%) had tall T waves,[131] and both were more hyperkalemic than expected with this ECG finding (serum $[K^+]$ = 7 − 9.99 mEq/L). The reverse also can be a pitfall: many normal, healthy dogs may have T wave parameters that exceed the normal range. Therefore T wave amplitude abnormalities are insensitive and nonspecific and, particularly in cases of hypoadrenocorticism, should be taken with a grain of salt.

Sinus bradycardia can occur (33% of hyperkalemic dogs with hypoadrenocorticism) because hyperkalemia decreases the activity of normal pacemaker tissue. Specifically, it decreases the slope of phase 4 of diastolic depolarization,[126] which slows the heart rate. However, naturally-occurring hyperkalemia also routinely coexists with abnormalities in acid-base status or other serum electrolytes, pain, fear, sepsis, hypovolemia, and other disorders, all of which tend to cause the opposite—sinus tachycardia. The routine observation that many cats and dogs with even severe hyperkalemia have elevated heart rates makes heart rate unreliable for inferring a patient's serum $[K^+]$.[131,132]

Mild to moderate increases in serum potassium (6.6 to 7.5 mEq/L) can begin to interfere with cell-to-cell transmission velocity in the ventricles. In dogs that are hyperkalemic due to hypoadrenocorticism, wide QRS complexes are observed in 32% of cases.[130] A decrease in R-wave amplitude has been reported in 47% of these same dogs.

Moderate to severe hyperkalemia (7.0 to >8.5 mEq/L) can cause P-R interval prolongation (45%) or absence of P waves altogether (47%, for a total of 92% of hyperkalemic dogs with hypoadrenocorticism), which are probably the most characteristic ECG findings for hyperkalemia.[130] The atria are more sensitive to hyperkalemia than are the ventricles, and within the atria, the myocardium is more sensitive to the effects of hyperkalemia than are the internodal tracts. The result when severe hyperkalemia occurs is a *sinoventricular rhythm*, so named because the heartbeat originates in the SA node as usual, crosses the atria through the internodal tracts (but the impulse does not spread outward—no atrial activation, no P wave), and then passes through the AV node and His-Purkinje system in the usual sequence. The ECG appearance is a regular rhythm with normal or slightly widened QRS complexes and no P waves in any lead.

Very high serum potassium concentrations (>8.5 mEq/L) can be lethal. So many other factors influence the rhythm in these catastrophically ill patients that an exact cutoff for lethality cannot be established for serum potassium concentration alone. With rising concentrations comes further widening of the QRS complex and of the T wave, and these can blend into a sine-wave type of regular but poorly functional or nonfunctional rhythm, or a ventricular-type of escape rhythm at a very low rate (both likely preagonal rhythms). If not corrected immediately, critical hyperkalemia that has produced these dramatic ECG changes can cause cardiac arrest (ventricular fibrillation, escape rhythm with electromechanical dissociation) within minutes (see ch. 140 and 141).

Hypocalcemia

Low serum calcium concentrations have modest and often clinically insignificant cardiac effects; instead, the skeletal muscle effects dominate the clinical picture. Altered calcium concentrations affect the threshold of a myocyte's action potential rather than the resting membrane potential (see Figure 248-27). Hypocalcemia lowers the threshold, facilitating depolarization. The clinical expression is fine skeletal muscle fasciculations progressing to generalized tremors if calcium is not normalized. This effect is minimal in cardiomyocytes. Hypocalcemia also prolongs the initial phase of ventricular repolarization, which can manifest as a prolongation of the Q-T interval on the ECG.[126]

These effects help explain why intravenous calcium infusions are considered "cardioprotective" in severe hyperkalemia, even though they do not change the circulating potassium concentration. Hyperkalemia raises the resting membrane potential (see Figure 248-27), and providing additional calcium raises the threshold for depolarization, re-establishing a more normal ionic gradient across the cell membrane. Considering that 75% of cats with urethral obstruction concurrently have mild, moderate, or severe hypocalcemia,[133] IV calcium gluconate (50 mg/kg slow IV over 10-30 minute period, given to effect) is a logical first-line treatment for severe hyperkalemia in these patients.

When infusing calcium intravenously (always as a slow infusion and with ongoing ECG monitoring), the

ECG parameters sometimes attributed to hypercalcemia can be used as markers of excessively rapid infusion. A sudden slowing of the heart rate, shortening of the Q-T interval, or appearance of ventricular extrasystoles are grounds for stopping the infusion and resuming later if necessary. Here, as with hyperkalemia, the ECG is particularly valuable because ECG recordings are obtained at admission, and it is possible to determine whether the patient's parameters are changing during treatment compared with his or her own baseline.

Hypercalcemia

Similarly, hypercalcemia generally is of greater concern for its extracardiac effects than for any alterations in cardiac rhythm. Severe hypercalcemia raises the threshold of the cardiomyocyte, which should hinder depolarization. It also shortens early ventricular repolarization, making the Q-T interval shorter.[126,134] These consequences of severe hypercalcemia are of secondary concern compared with dystrophic mineralization of the kidneys and other soft tissues, for example.

Preexcitation and Macroreentrant Syndromes

In preexcitation, the normal impulse originating from the SA node is split at the end of atrial depolarization, with part of the impulse traveling normally through the AV node and another part of the impulse traveling simultaneously through an abnormal segment of rapidly conductive fibers that links the atria and the ventricles (the *accessory pathway* or *bypass tract*), thus bypassing the AV node. The result is partial, premature, immediate activation of the ventricles through the bypass tract, without the benefit of a pause in the AV node —i.e., preexcitation. With one major exception (see later), the effect of this abnormal pattern of activation is minimal because only a part of the atrial contribution to ventricular filling is lost. The ECG demonstrates that the normal delay through the AV node was preempted by conduction through the bypass tract (little or no segment separates the P wave from the QRS complex) and that conduction through the bypass tract caused asynchronous activation of the ventricles (the bypass tract and the normal AV nodal conduction ultimately each activates its share of the ventricles), resulting in a notched QRS complex. The size and location of the QRS complex's notch, the *delta wave*, depends on the distance that separates the bypass tract and the AV node in the individual's heart (Figure 248-28). Bypass tracts usually are single but can be multiple, and most originate in the right atrium, rather than the left, in dogs.[135] This makes them more readily accessible for radiofrequency ablation.

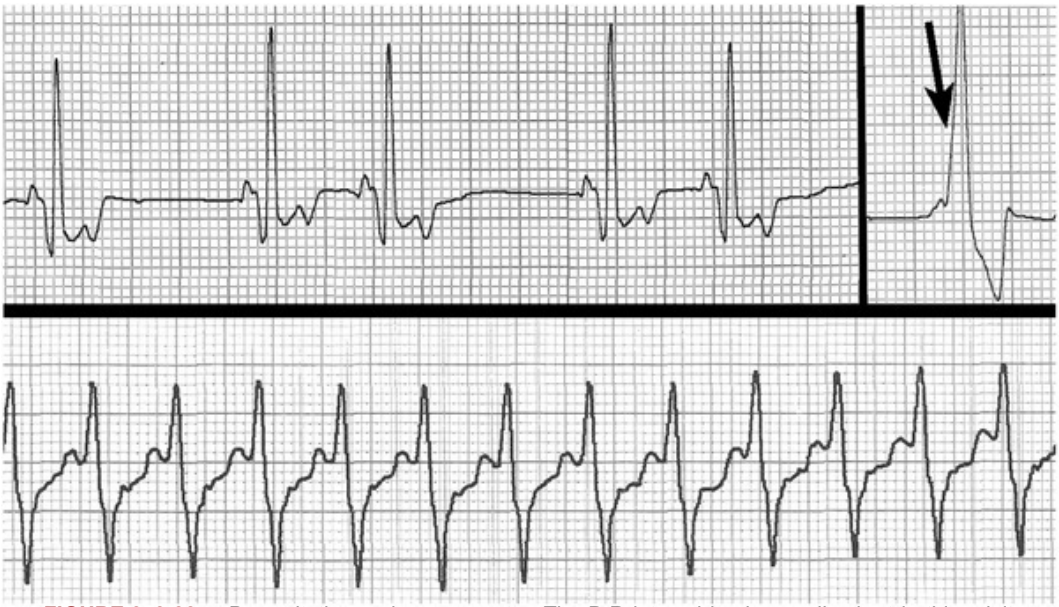

FIGURE 248-28 Preexcitation and macroreentry. The P-R interval is abnormally short in this adult Golden Retriever (upper tracing). A delta wave also is present, seen best in lead V2 (upper tracing inset, which also shows the PR interval shortening more clearly). The diagnosis is respiratory sinus arrhythmia with evidence of ventricular preexcitation. The heart rate is 90 beats/min. Lead II, 25 mm/sec, 1 cm = 1 mV. The same dog was hospitalized due to a sudden onset of severe tachycardia detected by the owner (lower tracing). The tracing shows a wide-complex monomorphic tachycardia at a rate of 330 beats/min. Together with the baseline ECG finding of preexcitation, the most likely diagnosis is macroreentrant tachycardia. The short PR interval during the tachycardia is unusual for the Wolff-Parkinson-White syndrome (orthodromic atrioventricular reentrant tachycardia). Modified

precordial lead (intensive care monitoring), 50 mm/sec, 1 cm = 1 mv.

Under usual circumstances, preexcitation is an incidental, clinically silent finding. However, in individuals with preexcitation, a premature depolarization can initiate a macroreentrant cycle that can produce extremely rapid, persistent tachycardias. Although bypass tracts conduct impulses rapidly, their refractory period typically is longer than that of the AV node. Therefore, the timing of a premature supraventricular depolarization can fail to conduct through the bypass tract but be able to conduct through the AV node, depolarizing the ventricles normally. As the impulse completes the depolarization of the ventricles, the bypass tract has repolarized and is able to conduct. Bypass tracts often can conduct impulses in either direction, such that the ventricular impulse conducts retrograde through the bypass tract to the atria, then again through the AV node in the normal direction and again through the bypass tract, initiating an endless loop. This type of self-perpetuating cycle is a macroreentrant circuit, and it can produce a potentially very rapid and clinically overt (apparent discomfort, gastrointestinal signs, exercise intolerance, lethargy, syncope)[53] tachycardia called *orthodromic* (the impulse travels in a normal, "normograde" direction through the AV node) AV reentrant tachycardia (OAVRT), the main form of clinically manifested ventriculoatrial macroreentry, or *Wolff-Parkinson-White syndrome,* in the dog.[32,46,53,136] Dogs with this syndrome can have unrelenting heart rates >300 beats/min. Initial treatment can involve vagal maneuvers that, through slowing of AV conduction (i.e., negative dromotropic action), break the cycle of reentry (see Figure 248-3). More definitive treatment is achieved using IV diltiazem or esmolol as described for atrial tachycardias, above.

Sinus Node Dysfunction/Sick Sinus Syndrome

Sinus node dysfunction (sick sinus syndrome [SSS], bradycardia-tachycardia syndrome) is a well-recognized cardiac arrhythmic syndrome that is the second-most frequent indication for pacemaker implantation in dogs (after AV block).[28a,137-139] It involves a complex disturbance of the cardiac conductive tissues, producing simultaneous defects in sinus activity (SB and sinus arrest), AV conduction disturbances (first-degree and second-degree AV blocks), and disturbances in supraventricular and ventricular excitability (Figure 248-29). Therefore, the disturbance is not a problem involving only the SA node, as the name SSS suggests, but rather is an illness that affects cardiac pacemaking and conductive tissues at all levels.

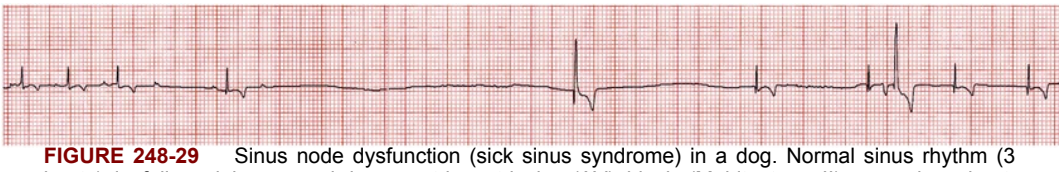

FIGURE 248-29 Sinus node dysfunction (sick sinus syndrome) in a dog. Normal sinus rhythm (3 beats) is followed by second-degree atrioventricular (AV) block (Mobitz type II), one sinus beat, another instance of Mobitz type II second-degree AV block, and a period of asystole lasting 3.5 seconds. Asystole terminates with a wide, bizarre-appearing ventricular escape beat, followed by asystole for 2 seconds, a junctional escape beat, a premature ventricular complex (PVC), and two junctional escape beats. This highly varied mixture of bradycardic rhythms and tachycardia (PVC) is characteristic of sinus node dysfunction. Lead II, 25 mm/sec, 1 cm = 1 mV.

The cause of SSS is unknown. Some human beings with SSS have autoantibodies directed at SA nodal tissue or at cholinergic receptors,[140,141] and such mechanisms bear investigating in veterinary medicine because they could explain the panoply of arrhythmias noted in dogs with this disorder. Certain epidemiologic features stand out from cases reported in the veterinary literature. The disease is recognized almost exclusively in dogs, and the stereotypical breed predilection for female Miniature Schnauzers is not exclusive. Many other breeds, notably Cocker Spaniels,[137,138] West Highland White Terriers,[137,142] and mixed breed dogs, represent an ever-increasing proportion of patients with this disorder.[28a] The spectrum of disease described as SSS likely regroups more than one distinct disorder that future research will categorize into separate entities.

The age of onset typically is mid- to late adulthood (6 to 10 years), and the association with DMVD is common but not obligatory. Histopathologically, depletion of SA nodal cells is seen with fibrous/fibrofatty replacement causing effacement between the SA node and atrial myocardium.[143] The ECG diagnosis often requires repeated and sufficiently long (2- to 3-minute) tracings, to convincingly demonstrate some or all of the aspects of SSS:SB (often with first- or second-degree AV block), prolonged sinus pauses with variable

escape beats, and bursts of supraventricular tachycardia or ventricular extrasystoles at various rates (see Figure 248-29). In some cases, only SB occurs. Because these features occur intermittently, the diagnosis often is only made by obtaining an ECG during an episode of syncope, stumbling, or ataxia (near syncope), which are the most common overt clinical manifestations of this arrhythmia. Ambulatory ECG, especially cardiac event recording, is ideally suited for establishing the diagnosis of SSS when the in-hospital ECG is unhelpful (see ch. 103). Such technology has identified that episodes occur during bradycardia rather than tachycardia. An atropine response test (see above) can confirm the heart's ability to respond to vagolytic treatment, and such a response has recently been shown to translate into long-term response to vagolytic drugs in many affected dogs.[28a] Such drugs (e.g., propantheline 0.5-3 mg/kg PO q 8 h[142] or hyoscyamine 0.005 mg/kg PO q 8 h[144] or aminophylline/theophylline 10 mg/kg PO q 8 h)[145] can improve the situation by reducing the impact of bradycardia episodes and pauses; 54% of dogs with sinus node dysfunction were controlled with pharmacologic treatment according to a recent retrospective.[28a] Definitive treatment when episodes are recurrent generally requires the implantation of a pacemaker (see ch. 249).

CHAPTER 249

Cardiac Pacing

Amara H. Estrada

Client Information Sheet: Cardiac Pacing

Indications for Pacing

Bradycardia causing overt clinical signs remains the most compelling indication for pacemaker therapy in dogs and cats. Detailed classification schemes are established for pacing in people, where categories of "generally indicated," "may be indicated," and "not indicated" guide treatment decisions. In veterinary medicine, the indications are similar and cardiac pacing is most commonly performed in dogs with complete (third-degree) atrioventricular (AV) block or sinus node dysfunction (Figure 249-1). Less commonly, pacemakers are placed in veterinary patients with persistent atrial standstill (not associated with hyperkalemia) and high-grade second-degree AV block.

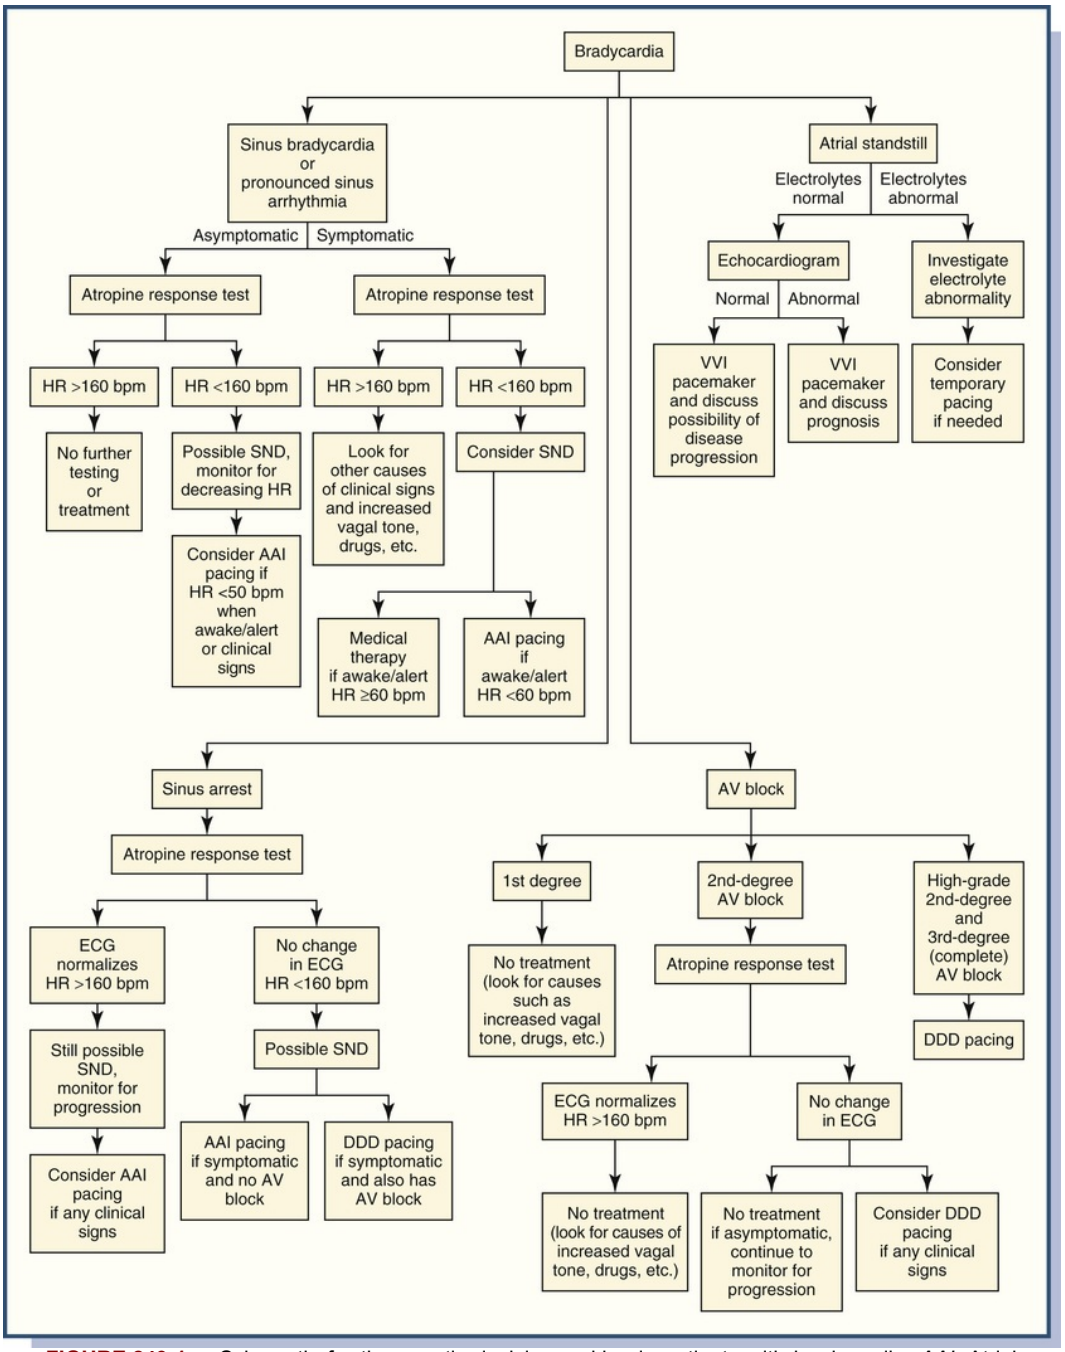

FIGURE 249-1 Schematic for therapeutic decision making in patients with bradycardia. *AAI,* Atrial pace, atrial sense, inhibit; *AV,* atrioventricular; *DDD,* dual chamber pace, dual chamber sense, inhibit; *ECG,* electrocardiogram; *HR,* heart rate; *SND,* sinus node dysfunction; *VVI,* ventricular pace, ventricular sense, inhibit.

Atrioventricular Block (see ch. 248)

Dogs with high-grade second degree or complete AV block should almost always be considered candidates for permanent pacemaker therapy (see ch. 30). Even escape rhythm rates > 50 beats/minute (bpm) have the potential to decrease over time. Cats differ in terms of their escape rhythm rates when AV block develops, typically having a faster ventricular escape rhythm (90-120 bpm) such that they do not frequently require cardiac pacing. Occasionally, cats with cardiomyopathy develop bradycardias with escape rhythms that are slow enough to require pacemaker therapy to either keep them out of congestive heart failure or, if physical activity is affected, to improve quality of life.

Sinus Node Dysfunction (SND; "Sick Sinus Syndrome"; see ch. 248)

Patients with sinus node dysfunction that is causing overt signs such as syncope represent a definite indication for pacing (see ch. 30). Patients with ECG findings compatible with SND but whom the owners feel are not showing clinical signs represent a dilemma. Many of these patients are older and clinical signs may exist but be mistaken for "slowing down due to old age." The degree of bradycardia at which pacing should be considered is controversial even in human medicine, and each patient should be considered individually. It is the author's opinion that sinus rates consistently <50 bpm during alert/awake periods are an indication for pacing. Additionally, sinus pauses >3 seconds during alert/awake times should also be considered abnormal and warrant pacing if the patient has signs of exercise intolerance or lethargy. Pauses that occur during sleep (usually detected during Holter monitoring or inpatient telemetry) are less of a concern. Some dogs with SND exhibit an excessive response to enhanced vagal tone. This is likely because there is an autonomic component that contributes to the disease process. Administration of an anticholinergic drug such as atropine may allow for a higher sinus rate and elimination of sinus pauses, but that does not mean that the sinus node dysfunction is benign and pacemaker therapy should still be considered in these cases, especially if there are clinical signs that could be attributed to the bradycardia.

Atrial Standstill

Persistent atrial standstill is an uncommon arrhythmia associated with atrial myocarditis causing the atria to be unable to depolarize from a sinus-initiated impulse. Although the sinus node continues to fire, it is ineffective in depolarizing the atria and penetrating the AV node. P waves are absent on the ECG and a junctional or ventricular escape rhythm is usually present. Pacemaker implantation is indicated in this disease, as increasing the heart rate can both improve clinical signs of exercise intolerance or syncope and assist in the management of congestive heart failure if it is present. The prognosis following pacing depends on the severity or presence of underlying myocardial disease and often is not as favorable as pacing for SND and AV block. Temporary atrial standstill caused by hyperkalemia is discussed further in ch. 248 and 309, and is not an indication for permanent cardiac pacing.

Less Common Uses for Pacing Therapy

There is still controversy regarding cardiac pacing for *vasovagal syncope* (see ch. 30) when medical therapy fails. It has been shown in human clinical trials[1,2] that vasovagal syncope can be aborted or blunted with dual-chamber pacing, and even if syncope does occur, pacing can prolong consciousness to avoid injury. Newer pacing algorithms are currently being investigated in a clinical trial specifically for people with vasovagal syncope. Enrollment in this clinical trial is complete and the study is ongoing.[3]

Pacing for *tachyarrhythmias* is not commonly used in veterinary medicine at this time. However, chronic supraventricular tachyarrhythmias (such as atrial fibrillation, re-entrant atrial arrhythmias, atrial tachycardia) that are refractory to medical management have become an indication for permanent pacing in people. Various techniques have been used, including the so-called "ablate and pace" for chronic atrial fibrillation wherein the AV node is radiofrequency-ablated and a pacemaker inserted within the ventricle to achieve heart rate control. Another approach has been aimed at the prevention of atrial fibrillation in patients with refractory atrial tachyarrhythmias involving biatrial synchronous pacing.[4-6] This "dual site" atrial pacing has been shown to decrease the number of episodes of paroxysmal atrial fibrillation and flutter.[7] In addition to these alternate pacing techniques, pacing algorithms have been incorporated into pacemakers in an effort to decrease the number of premature atrial complexes and maintain consistent atrial pacing. Another common indication for permanent pacemaker implantation in people is for refractory ventricular tachycardia, especially for disorders such as long QT syndrome known to have a high incidence of sudden death due to degeneration of ventricular tachycardia to ventricular fibrillation. Many trials have identified a clear benefit of dual chamber pacemakers/intracardiac defibrillators (ICDs) over medical therapy alone in the prevention of sudden death.[8-11] There are now several reports in the veterinary literature on the successful use of ICD therapy.[12-14]

More than 25 years ago, dual chamber pacing was promoted as a specific treatment remedy for patients with *hypertrophic obstructive cardiomyopathy,* in the absence of conduction system disease. The hypothesis was that by shortening the AV interval to prevent normal conduction through the AV node, "pure" right ventricular apical (RVA) pacing could be guaranteed. With this approach there would then be delayed contraction of the basal portion of the interventricular septum with resultant reduction or elimination of

outflow tract obstruction.[15-18] This approach has now been abandoned because of lack of efficacy[19,20] and concern regarding the negative effects of long-term RVA pacing.

Cardiac resynchronization therapy (CRT) is the term applied to reestablishing synchronous contraction between the left ventricular (LV) free wall and the ventricular septum by simultaneous or near simultaneous pacing of the right ventricular apex and the LV free wall (BiV pacing). This type of pacing therapy is now an accepted and cost-effective treatment for human patients with advanced heart failure, impaired LV function, and a wide QRS complex.[21] This therapy is now also a realistic option for patients with mild heart failure and may ultimately replace RVA pacing as a more physiologic means of cardiac pacing. For now, devices are expensive and only obtainable through donation to veterinary patients, and lead placement, and subsequent programming of devices, take considerable practice for the clinician to become proficient.[22]

Types of Pacemakers and Hemodynamics of Pacing

Once an indication for pacing has been identified, consideration should be given to selecting the most appropriate pacing mode for the patient. Factors that should be considered include: (1) the underlying rhythm disturbance; (2) overall physical condition of the patient and any associated medical problems; (3) exercise/activity capacity of the patient; (4) chronotropic response to exercise/excitement; (5) effect of pacing on long-term morbidity and mortality.

Pacing Nomenclature

Pacemaker nomenclature is labeled using Roman numerals I-V. Position I refers to the chamber or chambers being paced: *A* = atrium; *V* = ventricle; *D* = dual chamber, meaning both A and V. Position II refers to the chamber or chambers in which sensing occurs. The letter options are the same as in the first position. The designation *O* refers to absent sensing (and thus refers to fixed, asynchronous pacing). Position III refers to the device's response to sensed events. An *I* represents the inhibited mode, meaning that when an event is sensed, the device will be inhibited from further pacing; this is the most common form of sensing. *T* indicates a triggered response. When the pacemaker senses an event and is programmed in this mode, it will trigger the device to deliver a pacing stimulus. *D* means that both *T* and *I* responses can occur. In single-chamber pacing situations, the sensed event and triggered impulse occur within the same chamber so this function is never used in single-chamber pacing. In dual-chamber application, however, an atrial-sensed event inhibits atrial stimulation and triggers the delivery of a ventricular stimulus with an AV interval delay programmed to be similar to that of a normal PR interval. Position IV indicates programmability and rate modulation. In practice, *R* is the only indicator commonly used in this position and indicates that the pacemaker incorporates a sensor to modulate the rate independently of intrinsic cardiac activity. Position V is used to indicate whether multisite pacing is present in none of the cardiac chambers *(O),* one or both atria *(A),* one or both ventricles *(V),* or any combination of atria and ventricles *(D).* For instance, to describe a patient with a dual-chamber rate adaptive pacemaker with biventricular stimulation, the code would be DDDRBiV.

Single Chamber

From a practical standpoint, there are essentially only two forms of single-chamber pacing: VVI and AAI, with the former being the most common in veterinary medicine.[23] Rate modulation is an option in both of these pacing configurations (VVIR or AAIR).

Ventricular-Inhibited Pacing (VVI)

VVI pacemakers have one pacing lead placed within the ventricle and are capable of pacing only in the ventricle (V in the first position of the pacemaker code), sensing only in the ventricle (V in the second position), and, if a native ventricular beat is sensed, the pacemaker is inhibited from firing (I in the third position) (Figure 249-2). Although VVI pacing protects the patient from lethal bradycardias, it is substantially limited because it does not restore or maintain AV synchrony and, compared to VVIR pacing, does not provide rate responsiveness in the chronotropically incompetent patient—that is, in the patient in whom the spontaneous sinus heart rate does not increase in response to a physiological demand. In addition, some patients with VVI pacing experience the onset, or worsening, of clinical signs during ventricular pacing. Adverse hemodynamic effects associated with a normally functioning pacing system are referred to as "pacemaker syndrome." This term is used to refer to a complex of clinical signs and symptoms related to the adverse hemodynamic and electrophysiologic consequences of ventricular pacing. Neurologic signs or those

suggesting low cardiac output or congestive heart failure are the clinical signs indicative of the pacemaker syndrome. In a study of human patients with dual chamber pacemakers (DDD) who were randomized to DDD or VVI pacing mode, some degree of pacemaker syndrome was thought to be present in 83 percent of the patients implanted with VVI pacing systems.[24] Key concepts identified as causes of the pacemaker syndrome included: (1) improper sequencing of atrial and ventricular contraction and (2) no ability to allow for physiologic rate modulation, and such effects may underlie the pacemaker syndrome observed in dogs as well.

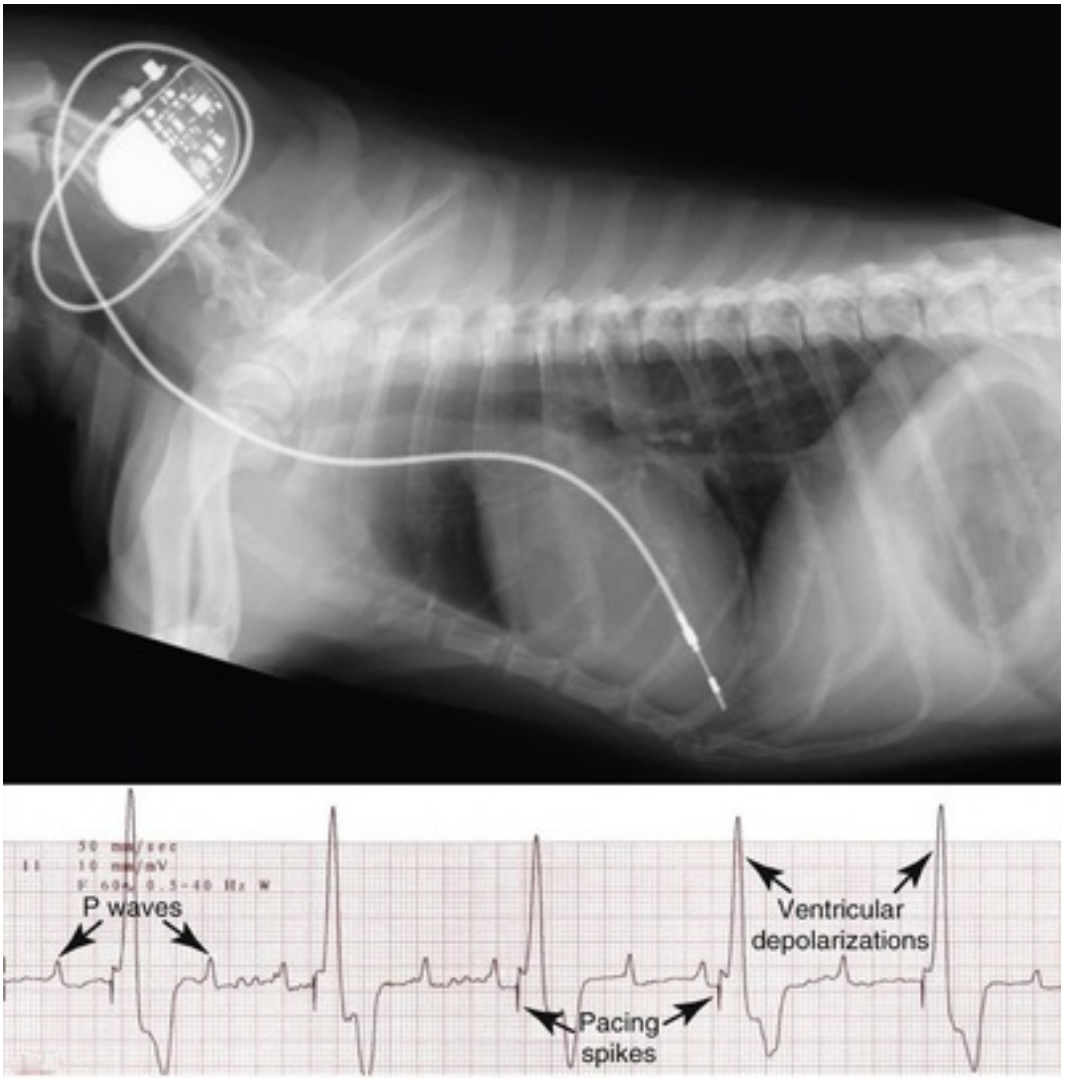

FIGURE 249-2 Lateral thoracic and cervical radiograph and ECG from a patient with complete heart block implanted with a permanent transvenous VVI pacemaker. Note the dissociation between the P waves and QRS complexes. Each QRS complex is preceded by a pacing spike generated by the pacemaker and transmitted through the lead in the right ventricular apex.

Atrial-Inhibited Pacing (AAI)

Single-chamber atrial pacing is selected only for patients in whom the bradyarrhythmia is a sinus mechanism and AV block is not a problem. In this situation, a lead is placed only within the atrium (right auricular appendage or atrial septum). Pacing occurs only in the atrium (A in the first position of the pacemaker code) if there is lack of native activity sensed within the atrium (A in the second position) at or below a specific programmed lower rate limit. If a native atrial/sinus beat is sensed within the atrium, then the pacemaker is inhibited from firing (I in the third position). Such pacing is appropriate for patients that have SND with normal AV conduction (Figure 249-3). The obvious disadvantage of AAI pacing is lack of ventricular support should AV block occur. If the patient with SND is assessed carefully for AV nodal disease at the time of

pacemaker implantation, the occurrence of *clinically significant* AV nodal disease in the future is rare.[25] Assessment of AV nodal function before use of an AAI system should include incremental atrial pacing at the time of pacemaker implantation. The criterion used at the author's institution is that the patient should be capable of 1 : 1 AV nodal conduction up to rates of 120 bpm while under anesthesia. If AV block occurs at lower rates, dual chamber pacing systems are utilized. The benefit of AAI pacing in a patient with SND lies not only in the maintenance of AV synchrony, but also in the maintenance of the normal activation pattern in the heart (via the AV node). Moreover, retrograde conduction of impulses through the AV node is common in dogs paced with ventricular-based pacing systems, often resulting in retrograde conduction and echo beats. It is therefore important that when VVI pacing is used in dogs with SND, the pacemaker is programmed at a low rate and functions only as a "backup" for periods of bradycardia, in order to retain as much AV nodal conduction as possible.

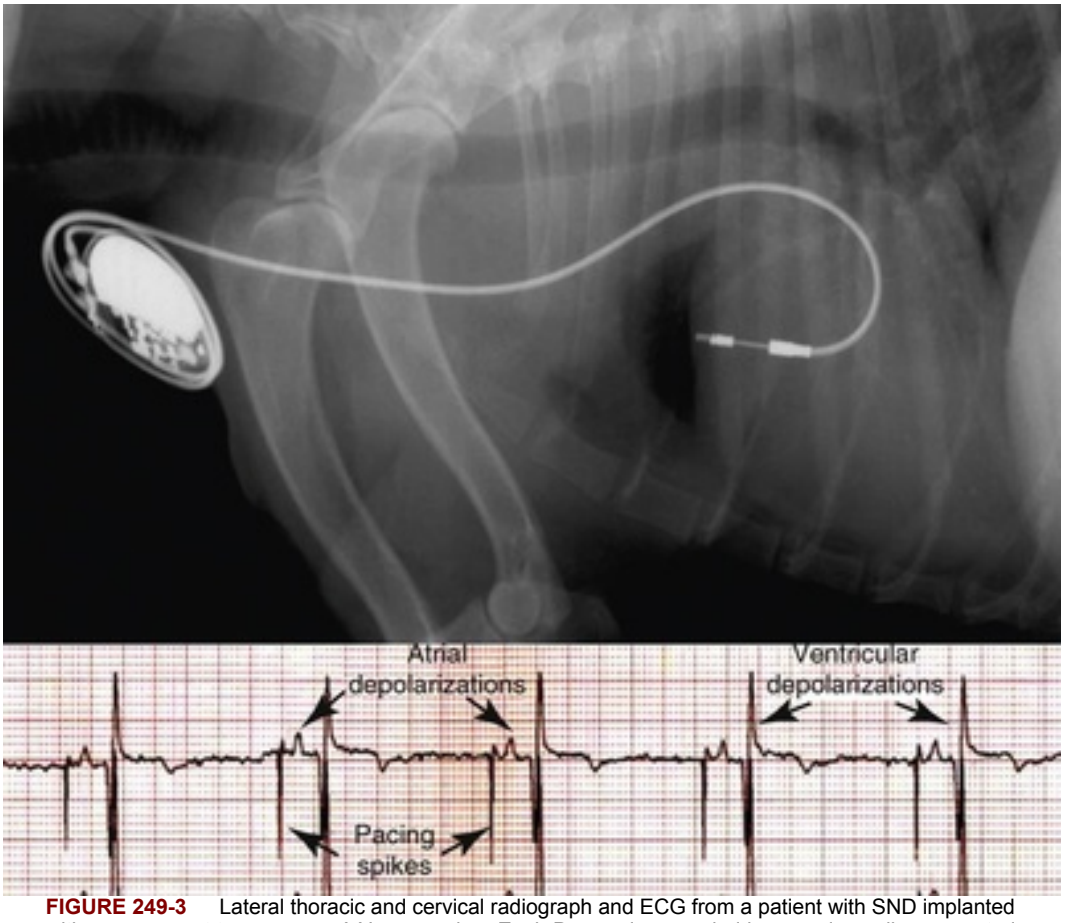

FIGURE 249-3 Lateral thoracic and cervical radiograph and ECG from a patient with SND implanted with a permanent transvenous AAI pacemaker. Each P wave is preceded by a pacing spike generated by the lead in the right auricular appendage.

Dual Chamber

Maintenance of AV synchrony (physiologic pacing) provides substantial beneficial effects on hemodynamics and patient mortality. For this reason, physiologic pacing for AV block must involve a system that "replaces" the AV node's ability to conduct atrial depolarizations to the ventricular myocardium. Currently, the most widely used dual chamber pacing systems are VDD, DDD or DDDR pacing with mode switching (discussed below).

Atrial Synchronous Pacing (VDD)

This mode paces only in the ventricle (V in the first position of the pacemaker code), senses in both chambers (D in the second position), and can respond by either inhibition of ventricular output if intrinsic ventricular

activity is sensed, or by triggering a response in the ventricle if atrial activity is sensed (D in the third position). This mode of pacing is termed atrial synchronous pacing as it "tracks" native (sinus) P waves. This mode of pacing allows for maintenance of AV synchrony and the ventricular rate is modulated by the inherent autonomic tone of the patient as it is driven by the patient's own sinus rate. If there is a sinus pause and no atrial event is sensed, the pacemaker is able to escape with a paced ventricular event at the lower programmed rate. That is, the pacemaker will display VVI activity in the absence of a sensed atrial event. VDD pacing is appropriate for the patient with normal sinus node function and conduction disease of the AV node. This atrial synchronous, ventricular inhibited (VDD) pacemaker utilizes one pacing lead which incorporates both a pacing electrode within the right ventricle and a floating atrial electrode in the intra-atrial portion of the ventricular lead to sense P waves propagated through the blood. These native P waves are sensed by the pacemaker, and then following an appropriately programmed AV delay, the system delivers a ventricular pacing impulse (Figure 249-4). The set distance between the floating atrial electrode and ventricular pacing tip often prevents its use in small dogs.

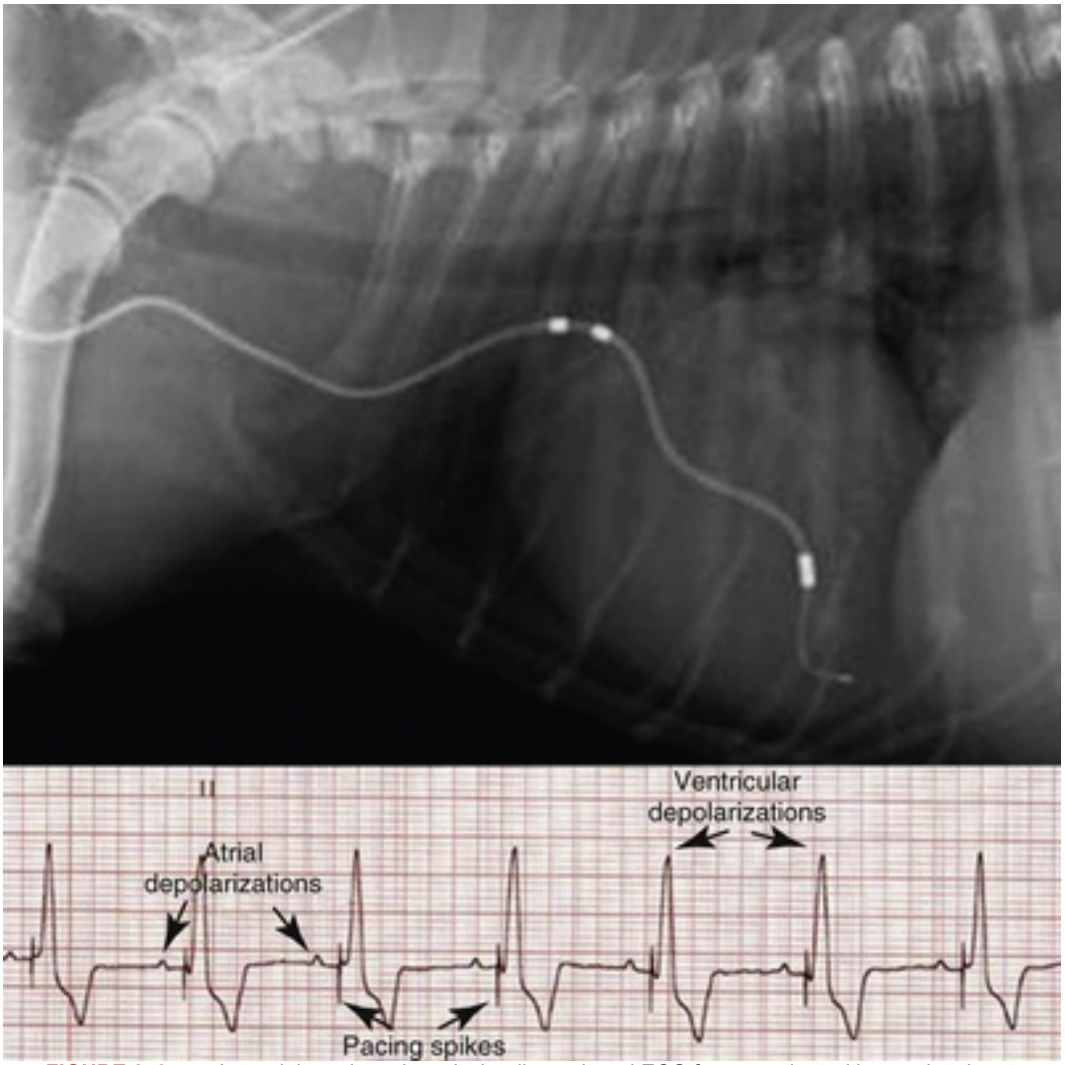

FIGURE 249-4 Lateral thoracic and cervical radiograph and ECG from a patient with complete heart block implanted with a permanent transvenous VDD pacemaker. Note the floating atrial electrode within the right atrium. This electrode senses the native P waves generated by the sinus node and a ventricular pacing spike is then delivered by the lead positioned within the right ventricular apex to cause a ventricular depolarization.

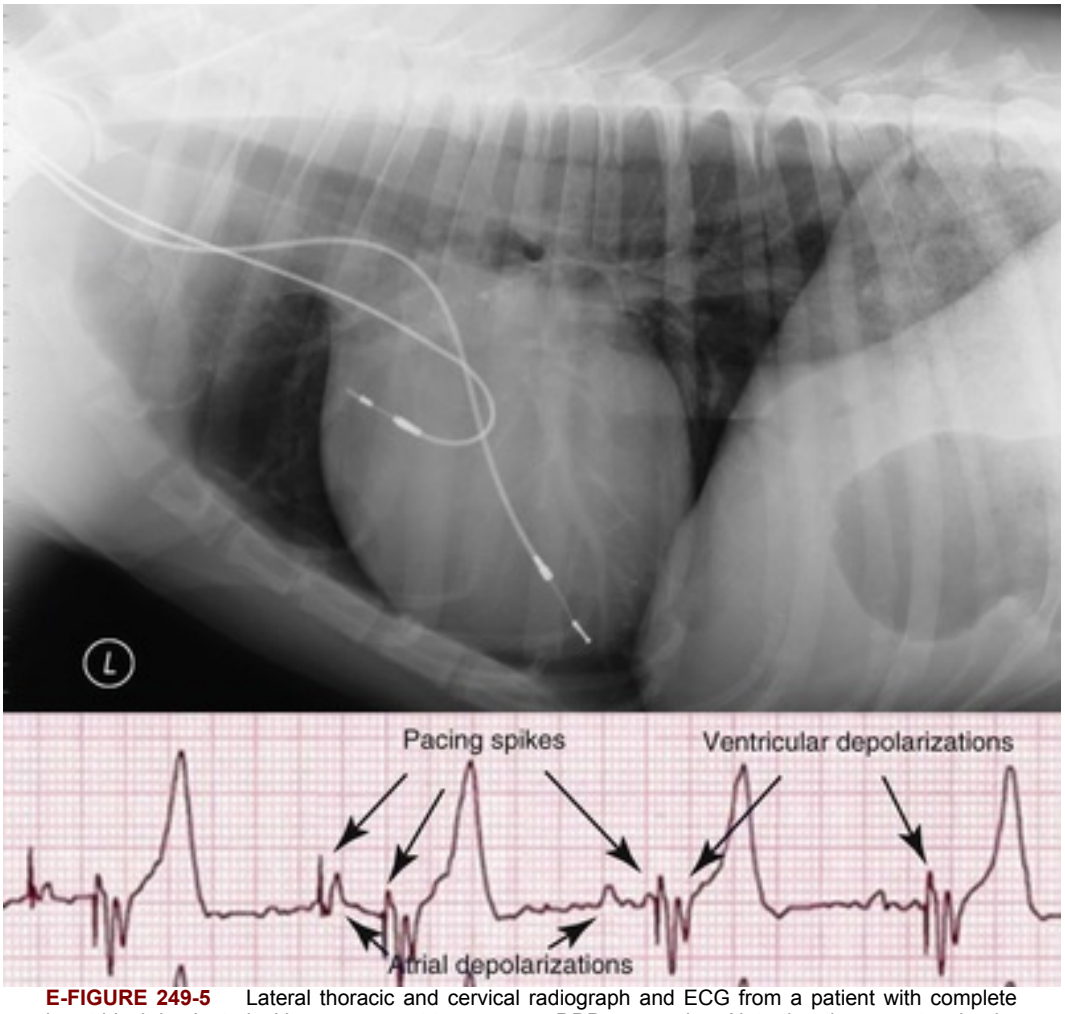
Dual-Chamber Pacing and Sensing with Inhibition and Tracking (DDD)

Known as the "fully automatic pacemaker," DDD pacing is capable of sensing and pacing in both the atrium

and the ventricle. This type of pacing mode would be appropriate for patients with SND where there is also AV block, or for patients with complete or high-grade second-degree AV block. Because it is capable of performing dual functions in both chambers, normal DDD function can appear electrocardiographically as (1) normal sinus rhythm, (2) atrial pacing only, (3) AV sequential pacing, or (4) atrial synchronous pacing (E-Figure 249-5).



E-FIGURE 249-5 Lateral thoracic and cervical radiograph and ECG from a patient with complete heart block implanted with a permanent transvenous DDD pacemaker. Note that there are two leads: one in the right auricular appendage capable of sensing and pacing the atrium; and another lead in the right ventricular apex also capable of sensing and pacing. On the ECG, there are periods where both the atrium and ventricle are paced but there are also periods where native P waves are sensed and then a ventricular impulse is delivered.

Previously, it has been suggested that dual-chamber pacing systems, particularly those with 2 leads, are more difficult and more time-consuming to place and require more complex programming. Thus, it has been assumed that implantation of dual-chamber pacemakers would produce higher complication rates both initially and in the long term. Recently published data show that while multiple-lead implantation (Figure 249-6) does prolong anesthesia and procedural time, dogs do not have any increased incidence of either short-term or long-term complications.[26]

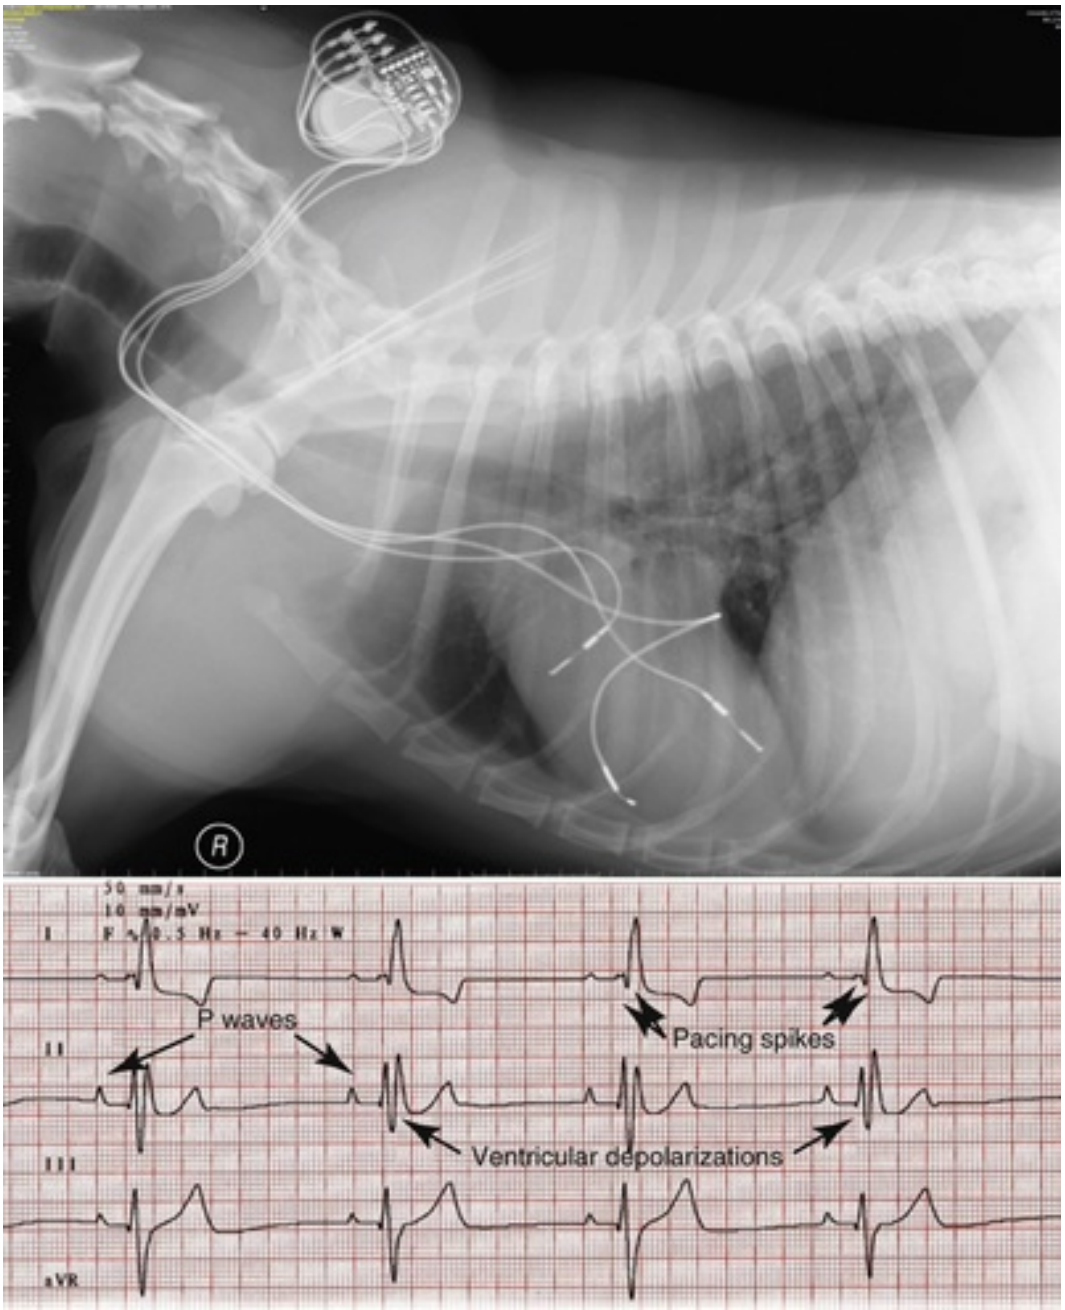


FIGURE 249-6 Lateral thoracic and cervical radiograph and ECG from a patient implanted with a CRT system. There is one lead in the right auricular appendage, one lead within the coronary sinus and down a lateral coronary vein for pacing of the left ventricular free wall, and a third lead placed in a standard right ventricular apical position.

Transvenous Pacemaker Implantation

Temporary Pacing

For patients with bradyarrhythmias, the safest way to implant a permanent pacemaker is after some method of temporary pacing has been implemented (Video 249-1). This allows for a normal heart rate, more stable patient, and less rushed surgical procedure during permanent pacemaker implantation. Temporary pacing can be accomplished transvenously, transthoracically or transesophageally, with pros and cons for each technique.[27-32]

Implantation of Permanent Pacemaker

The procedure is shown in Video 249-1; detailed descriptions of the implantation procedure also are available elsewhere.[33] The majority of permanent pacemakers are placed transvenously through a jugular approach. Exceptions to this are patients who repeatedly dislodge transvenous leads, patients with a risk of hypercoagulability, or, for some clinicians, in cats and smaller breed dogs, where epicardial placement of leads is desired. There have been reports of cranial vena caval obstruction[34] and resultant development of chylothorax[35] with transvenous pacing, and thus most cardiologists choose to place an epicardial lead on the left ventricular apex through an abdominal/transdiaphragmatic approach in cats and in dogs < 2.2 kg if pacing is required. There are, however, small diameter leads (4.1 French, Medtronic SelectSecure Model 3830) that may be suitable to use in small patients, but thus far the veterinary experience with this lead model is minimal.[36]

Pacemaker Programming

Pacemakers can be programmed and evaluated noninvasively to adjust and fine-tune the pacing parameters. Programming and interrogation of pacemakers will typically occur in the immediate (24-hour) post-operative period, at a 4-6 week recheck, at 3 and 6 months, and then yearly to assess function and battery life. Pacemaker programmers are not interchangeable and a specific pacemaker will require a certain programmer. Programmers can either be borrowed for use or donated to veterinary institutions by pacing manufacturers. Some local sales representatives will also come to a specific institution for recheck evaluations of patients. A detailed description of pacemaker programming is beyond the scope of this text but a few of the most critical parameters merit mention here.

Pulse Width and Voltage Amplitude Programmability

There are two aspects of energy output that can be programmed: the *voltage*, or amplitude of the impulse; and the *pulse width*, or how long this voltage is applied to the myocardium. The combination of these make up the output delivered to the myocardium. The output must be high enough to trigger depolarization plus allow an adequate pacing margin of safety but should also be programmed with the intent of maximizing pacemaker longevity. To determine appropriate output settings, first, the pulse width is left constant and the voltage is gradually decreased until a loss of capture is seen on the ECG. The opposite is next performed where the voltage is left constant and the pulse width is gradually decreased. A strength duration curve is generated, which allows determination of appropriate values to ensure an adequate safety margin. Values are usually set at either twice the voltage amplitude or three times the pulse width, at threshold. The less output used, the longer the battery will last. Some pacemakers will automatically determine output parameters and others continually do surveillance of the capture threshold (termed capture management) and automatically adjust output on a day-to-day basis. Thresholds for pacing do not remain static and can change throughout the day rapidly, which is the reason for programming with a margin of safety. Time produces probably the most important change in threshold. A pacing lead usually has its lowest threshold at the time of implantation. Over a period of 2 to 6 weeks, the threshold rises to its highest level ("matures") and then falls to a chronic threshold that is usually stable at approximately two or three times the acute level.

Rate Programmability

Rate-adaptive programming can be programmed into all currently manufactured pacemakers in most pacing modes (e.g., AAIR, VVIR, DDDR). A typical programmable rate is 30 to 180 bpm with some pacemakers capable of pacing as fast as 220 bpm. Sensors that detect physical movement and minute ventilation allow patients to have slower paced rates when sleeping or resting and higher rates when exercising. Lowering the rate when a higher rate is not needed also preserves the battery life of the pacemaker. Pacing algorithms are incorporated to tell the pacemaker when to speed up and when to slow down. While these algorithms work very well for people and long-term reliability is excellent, it is unknown whether they function as well for veterinary patients, especially those that pant or scratch frequently!

Sensitivity

Sensing is the pacemaker's ability to recognize the intrinsic activity of the heart. Sensing is vital to a pacemaker because it allows the pacemaker's internal computer to respond to the heart's own activity, which

means that it will inhibit pacing when it is not needed and the pacing will not compete or interfere with the patient's own rhythm. In dogs with complete heart block and a dual chamber device, sensitivity is important for tracking of native P waves and delivering a ventricular impulse in response. In dogs with SND, it is important that the system recognize normal beats and only pace when necessary. All patients with pacemakers could potentially have arrhythmias such as atrial or ventricular premature complexes (APCs or VPCs) that must be "seen" by the pacing system to ensure that pacing during the vulnerable period in the T wave does not occur.

The two main challenges to sensing are *oversensing* (i.e., sensing events that are not really there or that should not be sensed) like motion artifact, and *undersensing*, which refers to not sensing events that ought to have been sensed. Oversensing is usually seen on an ECG as inappropriately long pauses between pacing spikes and can be definitively diagnosed by watching a programming marker channel. Undersensing occurs when there is an intrinsic event (P wave or QRS complex) that the pacemaker ought to have detected, but somehow missed. An ECG with undersensing will show intrinsic activity followed too closely by a pacing spike.

Sensitivity is a programmable parameter measured in millivolts (mV). Although it may seem counterintuitive initially, increasing the sensitivity (making the device more sensitive) means decreasing the mV setting, while decreasing sensitivity means increasing the mV setting.

Refractory Period

The refractory period is a brief period where the pacemaker's sensing function is turned off or ignored after either a sensed QRS signal or a pacemaker spike. It is programmed to the patient's QT interval as measured on the surface ECG. The advantage of a refractory period is that it does not allow the pacemaker to sense either the T wave of the preceding QRS complex or the pacemaker after-potential, which is residual electric activity occurring after a paced beat. The disadvantage is that early VPCs or APCs may not be sensed. The refractory period can be lengthened to eliminate inappropriate sensing of a QRS signal, T wave, or after-potential. It can also be shortened to allow frequent VPCs or APCs to be sensed and thus reduce the risk of pacing within the T wave of the premature beat.

Special Features

Pacemaker technology has evolved to such a degree that it is impossible to incorporate a discussion of all the special features available in one book chapter. Different companies use different terminology and the programming might work a little differently with each device. When working with pacemakers, it is advisable to have device manuals on hand for reference or to take advantage of training materials from the various manufacturers. Regional technicians or technical support lines can also be helpful in programming and interpreting/trouble shooting during evaluations.

Pacemaker Complications

Complications following pacemaker implantation have been shown to be directly related to the experience of the implanter in both veterinary and human medicine.[37-39] Development of a seroma is a fairly common occurrence but can be easily managed with wrapping of the neck with gentle pressure. Some cardiologists also empirically treat with antibiotics to reduce the risk of infection. It is important to note that drainage of fluid surrounding the generator, with a needle and syringe, not be performed because of the risk of introduction of bacteria to the site and also for concern of damage to the leads and generator within the pocket.

Partial or silent venous thrombosis of the jugular vein likely is common following transvenous lead placement but does not typically cause clinical signs. Thrombus adherence/formation on the lead also is sometimes visualized on recheck echocardiograms without clinical signs having been noted by the owner. In the author's experience, these types of thrombi do not typically dislodge or grow bigger over time. It is advisable, however, to treat patients with antithrombotic agents such as low-dose aspirin or clopidogrel if a thrombus is recognized.

Atrial or ventricular perforation by a lead is a possible, although rare, occurrence.[36,37] Cardiac tamponade is the most dramatic outcome from perforation but lack of clinical signs is common. In fact, the only signs of perforation may be a rising stimulation threshold, a change in depolarization pattern on surface ECG, or diaphragmatic contraction with each output stimulus.

The most common complication, especially in the immediate post-operative period, is lead dislodgment or malposition of the lead causing loss of capture. Loss of capture appears on ECG as pacing spikes that are not followed by electrical capture of the appropriate chamber. To minimize the risk of this complication, it is important that patients are rested and not allowed to run or jump following implantation. At the author's institution, sedation is given prior to recovery from anesthesia, and upon discharge from the hospital, owners are instructed to keep the pet quiet and restricted in activity with leash walks only for the first 6 weeks. Following this time period, patients are allowed to resume normal activity.

Arrhythmias occurring as a result of the inflammation and irritation associated with lead placement can be safely treated if needed with antiarrhythmic agents (see ch. 248) and will typically resolve in a couple of days following implantation.

Sometimes, dogs will have contraction of the neck or diaphragm with each pacing stimulus ("pacemaker twitch"; Video 249-2). This is usually due to either high voltage output or phrenic nerve stimulation and can be avoided by lowering the voltage output. Pacemakers that are donated from pacing manufacturers often have etching on the back to indicate they are not for use in humans. This can sometimes lead to voltage leak around the generator and it should be implanted with the etched side down in attempt to avoid contraction of the overlying musculature.

Pulse generators have a life span of 10 to 12 years when manufactured. Most generators implanted in veterinary medicine have not been used previously but remaining battery life at implant is variable and can be assessed using a programmer prior to implantation. Various programming changes can increase or decrease the life span of the pulse generator. When a generator is close to, or near, the end of its battery life, an *end of life* or *elective replacement indicator* (EOL or ERI) is turned on. Most commonly, this is signaled by a gradual decrease in pacing rate, thus giving ample time to replace the generator prior to complete failure of the generator.

Infections

In veterinary medicine, the incidence of infection following pacemaker implantation is reported to be 5-10 percent,[40] which is much higher than in human medicine with an incidence of <2 percent.[41,42] Careful attention to surgical detail and sterile procedure is of extreme importance in avoiding pacemaker site infection. At the author's institution, implantation is delayed (if possible) if there are signs of more than mild skin infection or urinary tract infections, and urinalysis with culture and sensitivity is routinely performed prior to implantation. Prophylactic use of antibiotics before implantation and in the immediate post-operative period remains controversial but is routinely performed.[43] Most human studies do not show any significant difference in the rate of infection between patients who have had prophylactic antibiotics and those who have not. The optimal treatment of an infected pacemaker (Figure 249-7) is removal of the entire system (lead and generator) if possible, appropriate long-term antibiotic therapy (via culture and sensitivity) and replacement of the pacing system on the opposite side of the neck if delay is not feasible.[44] Treatment with antibiotic therapy alone is rarely associated with eradication of the infection.[40-42]

Congenital Heart Disease: General Considerations
Patent Ductus Arteriosus
Subvalvular Aortic Stenosis (Subaortic Stenosis)
Pulmonic Stenosis
Ventricular Septal Defect
Cyanotic Congenital Heart Disease

Introduction

The term congenital heart disease (CHD) encompasses a large number of morphologic and functional abnormalities of the heart and contiguous blood vessels that are present at birth. These malformations generally arise from some altered or arrested development of the embryonic heart triggered by genetic or environmental factors. The severity of CHD can range from trivial to life-threatening, and clinical signs might manifest anytime from the neonatal period—before the first veterinary examination—to relatively late in life. Although some types of CHD are well-tolerated, severe functional consequences can occur, including congestive heart failure (CHF), hypoxemia, cardiac arrhythmia, or sudden cardiac death. This chapter provides an overview of CHD in dogs and cats along with principles of diagnosis and management of commonly encountered defects. The reader is also referred to ch. 122 for a description of interventional techniques used for correcting congenital heart defects, ch. 257 that addresses some forms of venous vascular anomalies and to ch. 273 for additional consideration about the diagnosis and management of esophageal obstruction caused by vascular ring malformations.

In most cases, successful management of CHD begins with the prompt recognition of a cardiac disorder by the family veterinarian, followed by referral to a cardiologist for detailed evaluation. In most situations, a definitive diagnosis of CHD can be attained noninvasively following a complete echocardiographic examination. However, precise definition of some complex forms of CHD—as well as certain vascular malformations—can demand advanced imaging techniques, as discussed later. The prognosis for any CHD relates to the type and the severity of the underlying malformation. Some forms of CHD require no treatment and carry a favorable prognosis. Other defects are amenable to definitive therapy or to some form of palliative treatment.

Etiology

Congenital cardiac malformations can be caused by genetic or environmental factors, and in most cases a single causative agent cannot be conclusively identified. The potential interaction of toxicologic, nutritional, infectious, and genetic factors makes it difficult to determine a definitive cause. The observation that certain congenital defects display a species or breed predilection[1-4] strongly suggests a heritable basis in many cases (Table 250-1). This hypothesis has been demonstrated for several specific defects in certain canine breeds.[1,5-12] A number of studies indicates a simple Mendelian basis for transmission, supporting the concept that identifiable genetic factors contribute to development of the embryonic heart and relate to specific types of CHD. Other genes can demonstrate additive or modifying effects and produce a discrete phenotype once a Mendelian trait has been inherited, including variability in the penetrance of that characteristic.[13-17]

TABLE 250-1

AS, Aortic stenosis; *ASD*, atrial septal defect; *CTD*, cor triatriatum dexter; *MVD*, mitral valve dysplasia; *PDA*, patent ductus arteriosus; *PPDH*, peritoneopericardial diaphragmatic hernia; *PS*, pulmonic stenosis; *SAS*, subaortic stenosis; *ToF*, tetralogy of Fallot; *TVD*, tricuspid valve dysplasia; *VSD*, ventricular septal defect.

The complexity and uncertainty surrounding the exact mode of inheritance of many cardiac defects hamper the counseling of owners who want to use individual dogs for breeding. Although cardiologists often attempt to identify CHD in breeding animals during screening clinics, these efforts are confounded by the limited sensitivity and specificity of the available diagnostic studies. Certainly, a normal physical examination does not equate with genetic normalcy. Moreover, many soft murmurs are difficult to interpret,[18-20] and echocardiographic screenings often yield equivocal findings in the absence of true, gold-standard criteria for

the diagnosis of mild disease. Even with careful attention to pedigree and the results of breeding trials, it can be very difficult to influence the overall prevalence of a specific defect in the larger population. Progress in this regard hinges on the development of economical genetic tests that can detect the presence of the genetic mutations responsible for specific malformations.

The situation in cats is even more complicated and there are no detailed genetic studies of cats with CHD. A number of possible breed predispositions has been reported, such as tricuspid valve dysplasia (TVD) and atrial septal defect (ASD) in the Chartreux cat,[21,22] and older reports link endocardial fibroelastosis and supravalvular mitral stenosis to Siamese cats. Other feline breed predispositions are listed below under specific defects.

Prevalence

In surveys of dogs from the 1960s conducted by Patterson and Detweiler,[23,24] the prevalence of CHD in dogs was approximately 0.56% of hospital cases. Subsequent studies have indicated an overall prevalence of CHD in dogs between 0.46% and 0.85% of hospital admissions with Buchanan reporting a prevalence of approximately 0.68% for all dogs examined at the University of Pennsylvania.[25] Most studies have stemmed from university hospitals, and these surveys likely encompassed a significant number of cases referred for cardiac evaluation. By contrast, in a recently published study from a shelter population, Schrope reported a comparably lower prevalence of CHD of 0.13% in 76,301 mixed-breed dogs (screened by shelter veterinarians and subsequently evaluated by a cardiologist).[26]

Despite these differences in prevalence, the most common cardiac malformations in dogs have been largely unchanged for the last half-century.[2-4,24-27] Patent ductus arteriosus (PDA), subaortic stenosis (SAS), and pulmonic stenosis (PS) have topped the list of most surveys. In the studies of Patterson and Detweiler[23,24] the reported frequencies of diagnoses were approximately 28% for PDA, 20% for PS, 14% for SAS/aortic stenosis (AS), 8% for persistent right aortic arch, 7% for ventricular septal defect (VSD), and less than 5% for tetralogy of Fallot (ToF), persistent left cranial vena cava, and ASD. The report by Buchanan,[25] which included prevalence information from a North American database of over 1300 cases, indicated that PDA was most frequently reported (31.7% of cases), followed by SAS (22.1%) and PS (18.3%). However, in the aforementioned study of CHD in mixed-breed shelter dogs, the most common malformations were PS (31% of CHD cases), PDA (17%), SAS (15%), and VSD (14%).[26] European studies have indicated a higher prevalence of SAS and PS compared to PDA, with the largest retrospective study of 976 dogs reporting a prevalence of approximately 32% for PS, 27% for SAS/valvular AS, and 21% for PDA. The shifting popularity of some dog breeds over time certainly influences the regional prevalence of a particular defect. For example, Golden Retrievers, Labrador Retrievers, and Bull Terriers have likely increased the number of dogs diagnosed with SAS, TVD, and mitral valve dysplasia (MVD),[28] respectively. Scansen and colleagues[29] have tabulated 4,694 reported malformations from the literature and calculated the relative distribution of specific defects. As shown in Table 250-2, *A*, PDA, SAS/AS, and PS are the most common overall cardiac malformations affecting dogs.

TABLE 250-2

A, Congenital Heart Disease in Dogs: Data from Combined Studies[1,3,4,25,28,167,341-345]

DEFECT	NUMBER	PERCENTAGE
Patent ductus arteriosus (PDA)	1207	25.7
Subaortic stenosis (SAS)	1102	23.5
Pulmonic valve stenosis (PS)	1039	22.1
Ventricular septal defect (VSD)	413	8.8

Several surveys of CHD in cats have been reported.[30-36] The largest series stem from urban centers and include the Animal Medical Center (New York) and Angell Memorial Animal Hospital (Boston). The prevalence of CHD in cats worldwide is uncertain. The two largest surveys indicated a prevalence of 0.02% to 0.1% of hospital admissions and 1.95 to 2.9% of autopsies, as summarized by Harpster and Zook and by Liu and colleagues.[32-34] In a smaller autopsy study, 3.5% of 368 kittens were identified with CHD.[31] The study of 57,025 mixed-breed cats from a shelter population reported an overall prevalence of 0.14%.[26]

In terms of specific feline cardiac malformations, there are notable differences across surveys, which might represent sampling methods or true geographical differences.[37] Scansen and colleagues[29] have tabulated the results of the larger surveys (Table 250-2, *B*). The most commonly diagnosed defects in the combined surveys were VSD (18.4%), PDA (11.3%), TVD (10.8%), MVD (10.1%), atrioventricular (AV) septal defects (9.7%) and AS (7.1%). Some surveys showed a male predilection. In a retrospective study of mixed-breed shelter cats,[26] VSD was most common (21%) with SAS and valvular AS combining for 17% of the feline CHD diagnoses. Obstructions across the span of the right ventricular outflow tract (RVOT) also were relatively common in this population.

Classification

While a number of schemes has been devised to classify CHD, the standard in human pediatrics today is for a sequential segmental analysis that models the heart as three major segments: atria, ventricles, and great arteries. The relationships between these segments—atrioventricular and ventriculoarterial—are also critical to the scheme. In segmental analysis, the atria and ventricles are not defined by their venous, arterial, or other connections, but by their morphology. The position (situs) of each atrium is also relevant to the classification system. This approach is especially appealing for complex CHD and the interested reader is referred to the writings of Richard Van Praagh and Robert Anderson,[38,39] the two major (though sometimes opposing) forces who have redefined the anatomy of CHD. An example of this scheme applied to cats has recently been

published.[37]

Older and simpler organizational schemes are still relevant to veterinary medicine, and these include classifying lesions as anomalies of the cardiac valves; obstructions to ventricular outflow; and defects allowing left-to-right, right-to-left, or bidirectional shunting. Other types of malformations can involve the cardiac position or situs (as with ectopia cordis and situs inversus)[37]; defects or cysts affecting the pericardium (see ch. 254) and a number of vascular anomalies involving or connecting to the heart (see ch. 257).

Clinical Approach

While assembling the history, it is important to note the species and breed, as many congenital diseases have a suspected or proven genetic basis, and most canine cardiac malformations show breed predilections (see Table 250-1). Whenever possible, the health records of the sire, dam, and any siblings should be reviewed. The clinical diagnosis of CHD is usually stimulated not by clinical signs but by the identification of a cardiac murmur during a routine examination or health clinic. Most young animals with CHD are asymptomatic when first examined. Even those dogs and cats with hemodynamically severe regurgitant, obstructive, or shunting defects seem completely normal to many owners, especially during the first 6 to 12 months of life. The clinician should not necessarily conclude from an unremarkable history that the underlying defect is mild. A useful rule-of-thumb is that when a dog or cat with CHD does exhibit clinical signs of heart disease, the patient is at high risk of death unless some therapy can be instituted relatively soon.

There are no specific historical features or clinical signs of CHD. When respiratory signs such as tachypnea are attributed to heart disease, the potential for CHD should at least be entertained, especially in younger animals. The authors have evaluated many patients in which clinical signs of CHD manifested during middle age or even later in life. Sometimes an arrhythmia, such as ventricular tachycardia or atrial fibrillation, will supervene and incite syncope or CHF. Clinical signs of significant CHD can include exercise intolerance, exertional collapse or syncope, sudden cardiac death, or clinical signs of CHF. The occasional cat is presented for arterial thromboembolism, especially when there is LA dilatation secondary to obstruction of the mitral valve inlet.[40]

Physical Examination

A cardiac murmur is a hallmark feature of CHD (see ch. 55); however, a significant number of murmurs are missed in clinical practice. Intractability, panting and purring, rapid heart rates, cardiac rotation, and closely spaced auscultatory areas typical of puppies and cats pose challenges to auscultation. Additionally, a failure to auscult over the left, craniodorsal cardiac base (for PDA) and over the tricuspid valve area (for tricuspid regurgitation) are common examination errors. Soft murmurs are common in puppies and in kittens, and in most instances are benign (functional) in origin.[18,20,41-43] Unfortunately, there are no specific auscultatory findings distinguishing a functional murmur from that associated with mild CHD. The systolic murmur that is soft, brief, and musical or vibratory is more likely to represent a functional (innocent) murmur, but these characteristics are not absolute. Even murmurs that come and go can be associated with malformations, as with MVD with dynamic left ventricular outflow tract (LVOT) obstruction. Especially problematic is the diagnosis of trivial-to-mild SAS and AS in dogs, especially in breeds prone to those diseases. There are simply no gold standards for the diagnosis of clinically insignificant, but potentially heritable conditions (see later). In contrast, a moderate to loud systolic murmur or a murmur with a palpable thrill will be indicative of CHD in a young animal. These should be promptly investigated by Doppler echocardiography,[20] remembering that the intensity of a murmur can but might not correlate with the severity of the lesion. The typical characteristics of the heart murmurs associated with the most common congenital defects are discussed under specific malformations.

Most healthy puppies and kittens with faint or soft murmurs—especially those not intended for breeding—can reasonably be followed with repeated physical examination during the vaccine sequence. Physiologic reasons for murmurs, such as fever, infections, and anemia,[43] should be excluded. Many functional murmurs fade during the vaccination period, but those murmurs that increase in intensity or duration, especially in larger-breed dogs prone to SAS or TVD, should be further evaluated with echocardiography. A client should probably be offered echocardiography for the pet when a soft murmur persists. Early detection of CHD allows definitive treatment when applicable (see ch. 122). Accepting that most people quickly develop a bond with their pets, the early detection of CHD is valuable to that pet owner who is willing to accept a healthy

replacement for one affected by a cardiac malformation.

Murmur intensity and duration do correlate with the severity of some lesions, especially with SAS and PS. Conversely, a murmur can be inconspicuous in some cases of serious CHD. In theory, a large VSD might have only a soft murmur due to equilibration of ventricular pressures, but practically, most cases have at least a moderately loud murmur unless there is concurrent pulmonary hypertension. In the setting of severe pulmonary hypertension, as with reversed PDA, murmurs can be completely absent and only a tympanic- or split second heart sound identified. Secondary erythrocytosis in right-to-left shunting also reduces the likelihood of turbulence associated with murmurs. The murmur associated with severe AV valve dysplasia can be faint, especially in the setting of pure AV valve stenosis.

Ancillary physical examination findings are sometimes useful in the differential diagnosis and clinical assessment. Palpation for a ventricular heave (a prominent apical impulse indicating ventricular enlargement) or a precordial thrill (indicating the point of maximal intensity of a loud cardiac murmur) can be instructive regarding the underlying lesion. Arterial and venous pulses can also offer insight about the underlying defect; however, the rapid heart rates and small sizes of many patients diminish the sensitivity and specificity of physical diagnosis, especially for inexperienced examiners. Hyperkinetic ("waterhammer") arterial pulses are characteristic of lesions causing abnormal diastolic run-off of aortic blood flow and low arterial diastolic pressure; classic causes are PDA and severe aortic regurgitation. Hypokinetic or late-rising arterial pulses are typical of moderate to severe LVOT obstruction (i.e., SAS) or severe defects accompanied by low left ventricular (LV) output. A prominent jugular venous pulse or jugular venous distension indicates an abnormality of the right side of the heart, as occurs with TVD or PS.

The finding of cyanosis in a young animal, especially in the absence of dyspnea or overt pulmonary disease should strongly signal consideration for a cardiac malformation and "cyanotic heart disease." (see ch. 52) The term "cyanotic congenital heart disease" is used for categorizing those congenital defects causing admixture of venous and arterial blood, such as tetralogy of Fallot (ToF). Right-to-left shunting refers to situations wherein desaturated blood flows into the systemic arteries allowing admixture of desaturated and oxygenated blood, leading to hypoxemia. This can occur as a result of defects such as transposition of the great vessels or a combination of a communicating defect connecting the two sides of the circulation and some mechanism elevating pressures on the right side as with ToF. Reversed shunting has been observed with PDA, aorticopulmonary window, VSD, ASD and PS or TVD with patent foramen ovale. Visible cyanosis develops when the partial pressure of arterial oxygen falls below ≈45 mm Hg and desaturated arterial hemoglobin reaches 5 g/dL. Differential cyanosis is typical of a reversed PDA (see below).

Physiology of Right-to-Left Shunting

The term Eisenmenger's syndrome (physiology) is invoked to describe those circumstances wherein increased pulmonary vascular resistance causes reversal of a left-to-right shunt and causes cyanotic heart disease.[44-46] The factors underlying the development of Eisenmenger's syndrome are incompletely understood but are most likely related to shear stresses caused by the high flow rates in the pulmonary vasculature and proliferative changes within the vessel wall.[44,46-49] Eisenmenger's syndrome usually develops rapidly in affected dogs and almost always before 6 months of age. Development of pulmonary vascular disease in cats can be more gradual. Pulmonary arterial intimal thickening, medial hypertrophy, and plexiform lesions of dogs and cats with Eisenmenger's physiology are similar to those of humans as described by Edwards and Heath and amended by Roberts.[50] In some cases, a component of increased pulmonary vascular resistance is related to arterial vasoconstriction. These patients can respond clinically to phosphodiesterase V inhibitors such as sildenafil that function as pulmonary vasodilators. However, plexiform lesions are generally considered irreversible. Surgical closure of the shunt pathway forces the right ventricle (RV) to work against a tremendous pulmonary resistance, resulting in outcomes that can include RV failure, circulatory collapse, and death.

Systemic responses to arterial hypoxemia include an increase in red blood cell mass in an attempt to improve systemic oxygen delivery. Hypoxia of the renal tissue incites erythropoietin release and induces secondary erythrocytosis. As packed cell volume (PCV) increases, the high viscosity of the blood predisposes patients to thrombosis and microvascular complications.[44,47] This hyperviscosity syndrome, which typically occurs once the PCV exceeds 68%, is the primary cause of morbidity and mortality in affected animals rather than CHF, which is rare. Clinical manifestations include weakness, hemostatic deficiencies, renal dysfunction, metabolic acidosis, iron deficiency, cerebrovascular events, syncope, and seizures.[51-54]

The direction of blood flow across shunting lesions depends on the relative resistances of the systemic and pulmonary circulations. Exercise promotes systemic arteriolar vasodilation and decreases systemic resistance,

thereby increasing the magnitude of right-to-left shunting. In cases of RV hypertrophy and VSD, tachycardia or elevated sympathetic tone can increase the magnitude of right-to-left shunting by exacerbation of dynamic infundibular obstruction and increased resistance to RV ejection.[55] Nonspecific beta-adrenergic blocking drugs are sometimes used to blunt or prevent this phenomenon, particularly in patients with ToF.[53,56] Beta-blockers also tend to limit exercise, offering another explanation for their efficacy in some patients. Anemia, absolute or relative, reduces the ratio of systemic to pulmonary resistance when pulmonary resistance is fixed.[52] By this mechanism, overzealous phlebotomy can increase the severity of arterial hypoxemia as it decreases the oxygen carrying capacity of blood.

Right-to-left shunting leads to compensatory increases in nutritive systemic blood flow to the lung via the bronchial arteries. These systemic collateral vessels are easily recognized at angiography. While uncommon, it is possible for these vessels to rupture, leading to hemoptysis. Paradoxical embolization is another potential complication of right-to-left shunting defects. Normally, the pulmonary vasculature filters systemic venous emboli before they can reach the left side of the circulation. With reversed shunting, the possibility of a venous embolus reaching the coronary, cerebral, or other systemic arteries must be considered, particularly when intravenous catheters are present. By this mechanism, a thrombus, infectious agents, or air might gain access to vital systemic organs. Animals with cyanotic heart disease sometimes experience adverse reactions (particularly bradycardia) to sedatives and tranquilizers.

Diagnostic Studies

The diagnostic workup in the patient with suspected CHD centers today on echocardiography with Doppler studies. Additional examinations including radiography, electrocardiography, and clinical laboratory tests can be contributory, but rarely definitive, in terms of a diagnosis. Advanced imaging such as computed tomography (CT) with contrast (CT angiography) or magnetic resonance angiography is most useful for the diagnosis of complex CHD or vascular anomalies. Cardiac catheterization with angiography[30,57-60] is still a gold-standard method for diagnosis but is rarely undertaken except during catheter-delivered therapies (see ch. 122).

Thoracic radiographs should be obtained in all cases with respiratory signs. In addition to recognizing CHF, radiographs can also help stage severity of disease, especially in volume-overload states caused by AV valve malformation or left-to-right shunts.[61-64] Key features include identification of specific chamber enlargements, dilation of the great vessels, and pulmonary circulation. However, concentric hypertrophy will be underestimated by radiography, and might only be recognized by apex elevation (for the RV) or mild cardiac elongation (for the LV). Dilation of the main pulmonary artery is suggestive of PS, left-to-right shunt, or pulmonary hypertension. Dilation of the aorta is observed with SAS, aortopathies,[65] and PDA. Increased pulmonary vascularity is compatible with a significant left-to-right shunt, whereas scant vascular markings are often found with right-to-left shunts or with pulmonary hypertension.

In the absence of a cardiac arrhythmia, the value of the multiple-lead electrocardiogram (ECG; see ch. 103) recording is lower in the era of Doppler echocardiography. A normal ECG does not exclude a diagnosis of CHD. Nevertheless, the ECG can often identify moderate to severe atrial or ventricular enlargement or conduction disturbances that might be suggestive of one or more specific disorders.[66,67] As examples, increased QRS voltages in caudal and left precordial leads are typical of PDA, a right axis deviation is common with moderate to severe PS, and splintered QRS complexes are reported with TVD.[68] The frequent finding of a cranial frontal axis often mitigates the value of the standard limb leads in cats. Importantly, the principal indication for an ECG in CHD is the identification of arrhythmias or evidence of myocardial ischemia that might indicate a more complicated form of CHD. An ambulatory (Holter) ECG can be useful to detect exercise-induced arrhythmias or ischemia that might prompt treatment. It should be noted that some heart rhythm disorders should be considered a form of CHD: in particular, accessory pathways associated with ventricular pre-excitation and re-entrant supraventricular tachycardias (see ch. 248). These have been observed in Labrador Retrievers with TVD.

Aside from a PCV, routine laboratory tests are of little consequence except in cases complicated by CHF, arterial thromboembolism, or other comorbidities. Hypoxemia can be verified by pulse oximetry or arterial blood gas analysis, but these tests are rarely needed.

Echocardiography

Echocardiography with Doppler studies (see ch. 104) has largely supplanted cardiac catheterization and angiography for the diagnosis and assessment of most congenital heart lesions. This diagnostic study is

described in detail in ch. 104 and in many examples and references within the present chapter.[69-85] Saline contrast echocardiography is sometimes performed to identify right-to-left shunting, especially across a patent foramen ovale (PFO), ASD or VSD.

The major outcomes of the echocardiographic study in CHD can be summarized as follows: (1) identifying morphologic lesions such as septal defects, PDA, valvular malformations, and outflow tract obstructions using 2D and 3D imaging; (2) characterizing secondary responses such as dilation of cardiac chambers and great vessels and identifying myocardial hypertrophy using 2D, 3D, and M-mode studies; (3) delineating abnormal blood flow such as shunts and valvular dysfunction using color- and spectral-Doppler methods; (4) quantifying systolic and diastolic ventricular function using multiple modalities; and (5) assessing pressures, flow, and resistances using mostly Doppler methods. These detailed evaluations generally require an examiner with specialty training because many evaluations have to be modified during the examination based on contemporary findings. Transesophageal echocardiography is also highly relevant to CHD, not only for the diagnosis of some lesions, but also for guidance during interventional catheterization procedures.[86] Epicardial echocardiography is also used during so-called hybrid procedures—those combining surgical and catheter-based techniques—for guidance of devices delivered transmurally across the atrial or ventricular wall.

Both qualitative (subjective interpretation) and quantitative aspects of echocardiography are relevant to the diagnosis and assessment of CHD. Owing to differences in body size and growth, it can be difficult to quantify cardiac size relative to a breed or body weight standard. This is a challenge, but most experienced examiners can subjectively assess moderate to severe chamber enlargements in CHD. Important aspects of this modality, such as the modified Bernoulli equation, are presented in detail in ch. 104 and are illustrated with examples in the present chapter.

Cardiac Catheterization

Cardiac catheterization is an invasive hemodynamic and angiographic procedure performed for diagnostic or therapeutic reasons. Most catheterization procedures involve measurement of hemodynamics—mainly intracardiac and intravascular pressures (Figure 250-1)—along with angiography and some form of catheter-based intervention. Owing to anesthetic effects, hemodynamic measurements, especially blood pressures and cardiac output, are markedly depressed compared to the awake or lightly tranquilized states and will not correspond to Doppler-derived measurements unless they are performed under the same conditions.[75] Today, cardiac catheterization is mainly reserved for procedures designed to repair or palliate CHD. Specific examples include balloon valvuloplasty for PS, delivery of an occluding device to close a PDA or an ASD, and an electrophysiologic study used to identify and then ablate an accessory electrical pathway. Principles and examples of interventional catheterization procedures are discussed more fully in ch. 122.

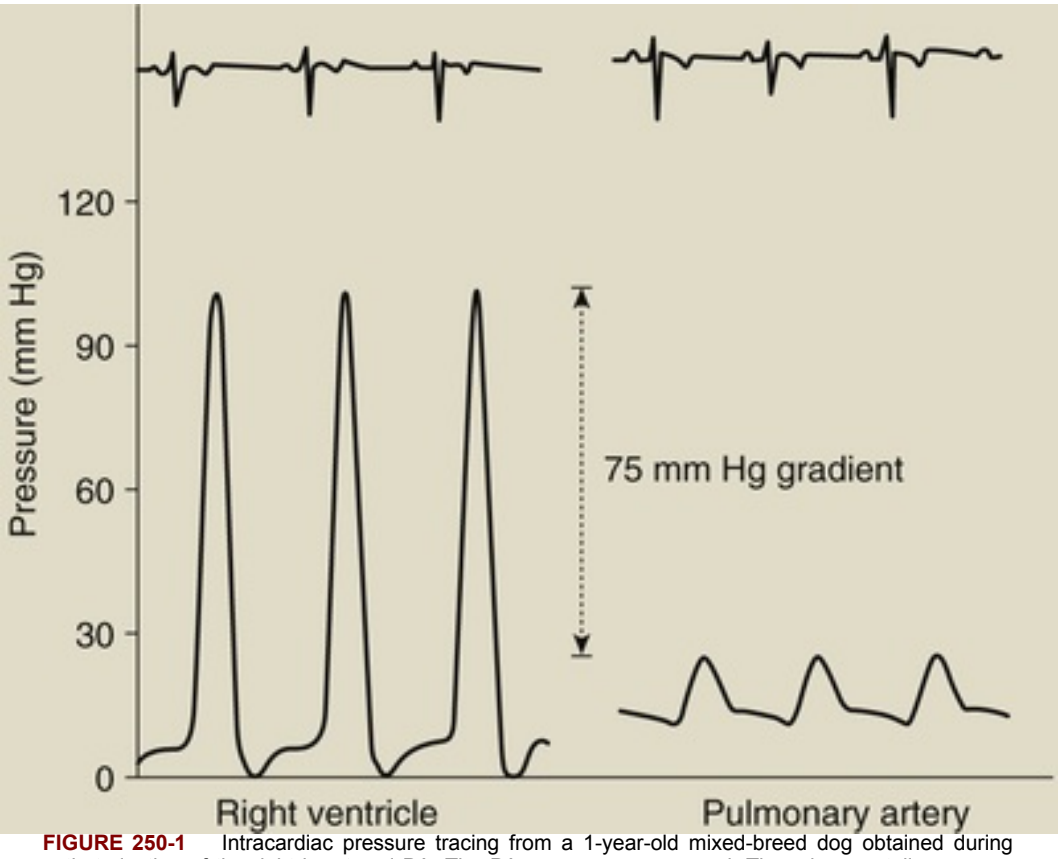

FIGURE 250-1 Intracardiac pressure tracing from a 1-year-old mixed-breed dog obtained during catheterization of the right heart and PA. The PA pressures are normal. There is a systolic pressure gradient of 75 mm Hg between the RV and PA, indicating the presence of an obstruction to RV outflow (in this case, valvular pulmonic stenosis [PS]). There is also a small diastolic pressure gradient between the PA and RV, which is caused by the diastolic closure of the pulmonic valve, and is a normal finding. The ECG displays a deep S wave, which is often found in animals with PS and secondary RV hypertrophy.

Patent Ductus Arteriosus

The ductus arteriosus develops from the embryonic left sixth aortic arch. This vital fetal structure shunts unoxygenated blood from the pulmonary artery through the descending aorta to the placenta where the blood is oxygenated, thereby diverting the majority of the RV output away from the nonfunctional fetal lungs. Following parturition and the onset of breathing, pulmonary vascular resistance falls, flow in the ductus reverses, and the resulting rise in arterial oxygen tension inhibits local prostaglandin release. These processes lead to constriction of the vascular smooth muscle within the vessel wall and functional closure of the ductus arteriosus. While the ductus may be probe-patent in puppies less than 4 days of age, it is usually closed securely by 7 to 10 days after birth.[2,87,88] Persistence of an opened ductus arteriosus beyond the early neonatal period is called PDA and is the first or second most commonly diagnosed congenital cardiac defect in dogs, depending on the survey. Cats are also affected but much less commonly than dogs.

Pathogenesis

Failed ductal closure in dogs and cats results from distinct histologic abnormalities within the ductal wall. The normal fetal ductal wall contains a loose branching pattern of circumferential smooth muscle fibers throughout its length, whereas in prenatal puppies bred to have a high probability of PDA, varying portions of the ductal wall are comprised of elastic fibers only. Increased prevalence of PDA in many breeds (see Table 250-1) indicates that genetic factors are likely involved in the pathogenesis. A mixed-breed, Poodle line of dogs with hereditary PDA has been extensively investigated, and a polygenic pattern of inheritance has been suggested.[89] Increasing genetic liability to PDA results in "extension of the noncontractile wall structure of the aorta to an increasing segment of the ductus arteriosus, progressively impairing its capacity to undergo

physiologic closure."[2] In humans, abnormalities in the genes that interfere with the remodeling of vascular smooth muscle cells of the ductal media, the putative cause of PDA, have been identified.[90] It is likely that similar genetic defects might be operational in the vascular smooth muscle of dogs with PDA.

In its mildest, clinically silent form, the ductus closes completely at the pulmonary arterial end and a blind, funnel-shaped pocket in the ventral aspect of the aorta, known as a ductus diverticulum, develops. This type of PDA, characterized by incomplete ductal closure (the *forme fruste* of the disease) can only be diagnosed by angiography or necropsy, but indicates that the dog carries a genetic liability for this defect.[2,89] Echocardiographic diagnosis of a ductus diverticulum has not been reported in dogs or other animals. Increasing genetic liability results in a tapering, funnel-shaped ductus arteriosus that remains patent after the early postnatal period and allows blood to flow from the aorta to the pulmonary artery, where intravascular pressures are lower (Figure 250-2, *A* and *B*). This is the most common form of PDA observed in dogs.[91] The most severe, but relatively uncommon, form is the cylindrical, nontapering ductus with persistent postnatal pulmonary hypertension (Eisenmenger syndrome or reaction) and bidirectional or right-to-left shunting (Figure 250-2, *C* and *D*). PDA may also be identified in animals with complex forms of CHD. For additional information regarding the morphology and pathogenesis of PDA, the reader is referred to several outstanding reviews of the subject.[92-94]

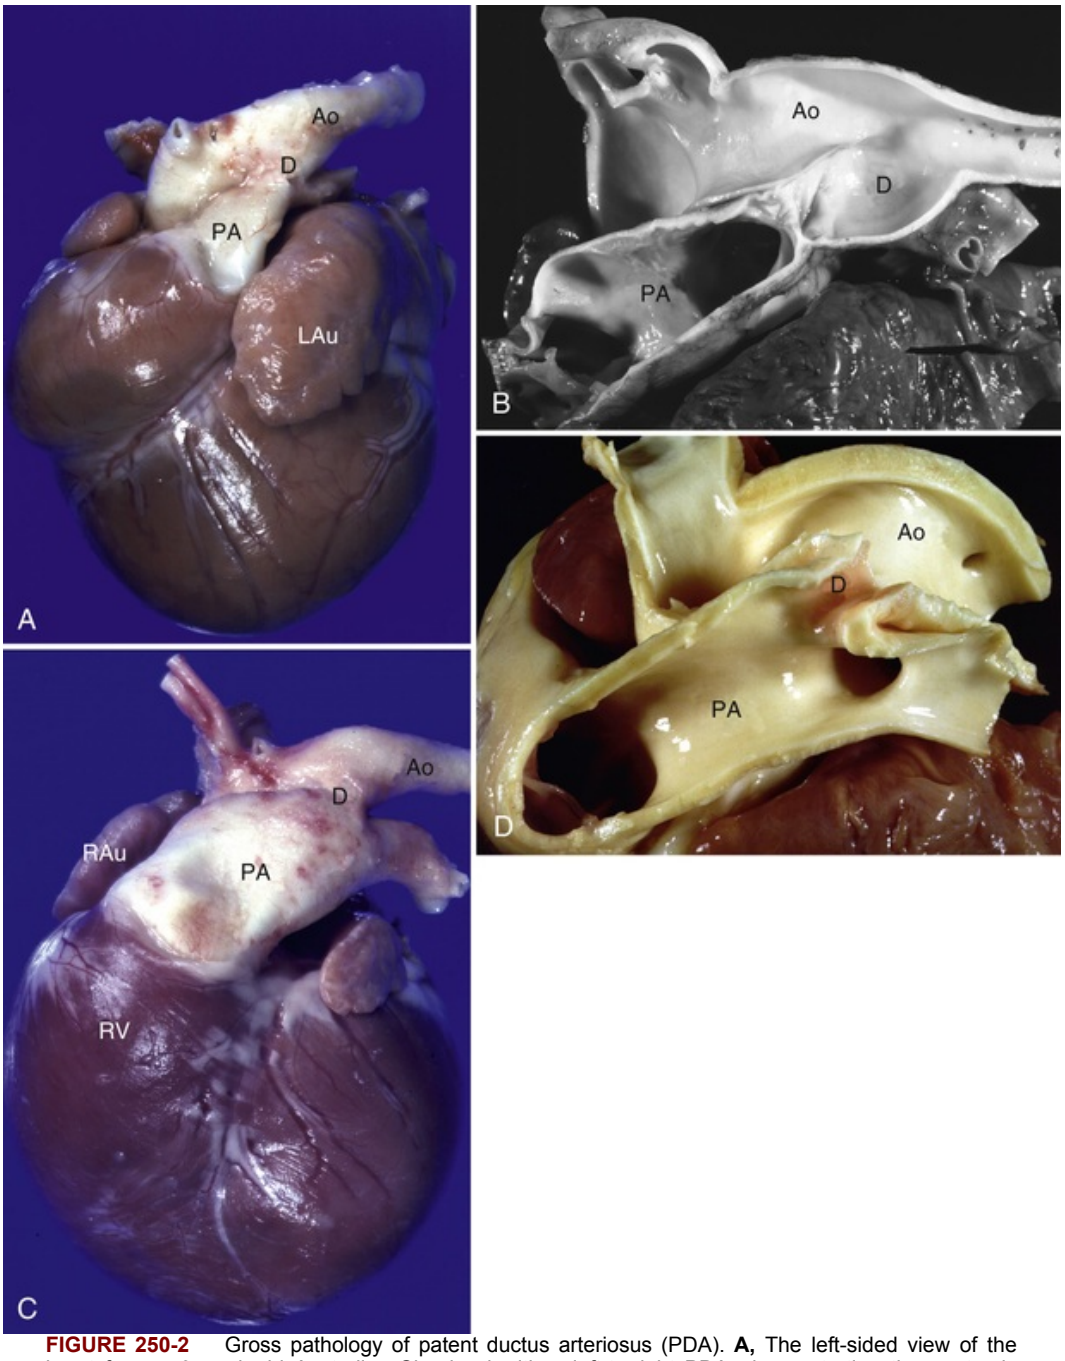

FIGURE 250-2 Gross pathology of patent ductus arteriosus (PDA). **A,** The left-sided view of the heart from a 9-week-old Australian Shepherd with a left-to-right PDA, demonstrating the anatomic location of the ductus (D) between the descending aorta (Ao) and main pulmonary artery (PA). The left auricle (LAu) is enlarged. **B,** Cut-away view of a left-to-right PDA in a dog. The ductus is funnel shaped, tapering toward the PA end. **C,** The left-sided view of the heart from a dog with a right-to-left shunting PDA. Note the enlargement of the right ventricle (RV) and right auricle (RAu). The pulmonary artery (PA) is enlarged. **D,** Cut-away view of a right-to-left shunting PDA in a dog. Note the cylindrical nature of the ductus (D) and the fact that the anatomic location of the ductus is distal to the aortic branches that supply the cranial portion of the body.

Pathophysiology

The direction of blood flow through a PDA is determined by the relative resistances of the pulmonary and systemic vascular beds, and in the vast majority of cases it proceeds from left to right (i.e., from the aorta to the pulmonary artery). The extent of shunting is determined by the relative pressure gradient between the systemic and pulmonary circulation, as well as the level of resistance within the PDA. Most often, the flow-

limiting region is at the level of the pulmonary ostium, where the ductus is at its narrowest. Flow through the PDA results in pulmonary overcirculation as blood is shunted from the aorta to the pulmonary artery. Higher LV stroke volume resulting from an increase in pulmonary venous return and end-diastolic volume associated with eccentric hypertrophy contributes to a rise in systolic aortic pressure. In diastole, rapid run-off of blood from the aorta to the lower-pressure pulmonary artery via the PDA causes a reduction in aortic diastolic pressures. The resultant pressure difference between systolic and diastolic blood pressures creates the hyperkinetic (waterhammer) arterial pulse detected in dogs with substantial shunts (see ch. 56). Since blood shunts continuously across the PDA during both systole and diastole, a continuous murmur arises, and is typically loudest near the time of the second heart sound (see ch. 55). All vascular structures involved in the transport of the shunted blood enlarge to accommodate the extra volume flow, with dilation of the proximal aorta, main pulmonary artery, and pulmonary vasculature. Dilation of the left atrium (LA) and eccentric hypertrophy of the LV develop in proportion to the volume of flow across the shunt. This mechanism permits compensation of the volume overloaded state for a variable period of time; if the shunt is large, however, myocardial failure (cardiomyopathy of volume overload) develops together with progressive elevation of LV end-diastolic pressure and overt pulmonary edema. Because the left-to-right shunt occurs at the level of the great vessels, the RV and RA are not directly exposed to the shunted blood, and these structures remain normal unless pulmonary hypertension develops.

In a small percentage of canine cases, the lumen of the PDA remains wide without tapering at the pulmonary ostium. The absence of a restrictive ductal orifice allows aortic pressures to be transmitted to the pulmonary circulation without impedance, thus precluding the normal postnatal decline in pulmonary vascular resistance. In this circumstance, the aortic and pulmonary arterial pressures equilibrate, the RV remains concentrically hypertrophied after birth, and reversal of flow through the shunt might develop. In Patterson's colony of dogs, this pattern of pulmonary hypertension and reversed (right-to-left) shunting developed within the first few weeks of life.[89] These observations fit the usual clinical presentation of most dogs diagnosed with a (reversed) PDA, in which there is usually no history of a continuous murmur and no evidence of LV enlargement or large left-to-right shunt earlier in life. Most dogs with reversed PDA flow exhibit diminished pulmonary blood flow, a normal to small LV, and marked concentric hypertrophy of the RV. On rare occasions, dogs with a moderate to large left-to-right shunting PDA will experience a sudden increase in pulmonary resistance due to necrotizing pulmonary vasculitis. Equally rare to detect is the gradual reversal of the direction of shunting, typically at several months to several years of age following a history of left-sided CHF.[49] Substantial residual LV enlargement is evident on thoracic radiographs and by echocardiography. Pulmonary blood flow is reduced but RV hypertrophy is less pronounced than in dogs that reverse the direction of shunting at an early age. The precise pathogenesis of pulmonary hypertension is not completely understood, but anatomic descriptions of the pulmonary vasculature are similar in humans and animals. Histologic changes within small pulmonary arteries include hypertrophy of the media, thickening of the intima and reduction of lumen dimensions, and development of plexiform lesions of the vessel wall.[49,50,95] Most of these changes are considered to be irreversible, precluding surgical correction of the reversed PDA, except possibly in rare cases where pulmonary arterial pressures remain subsystemic, something observed in cats with PDA and less often in dogs.[96]

Clinical Findings

PDA is the only congenital cardiac defect where there is a published sex predisposition for females (2.49/1000 in females versus 1.45/1000 in males).[1] Many breed predilections for PDA have been reported (see Table 250-1). Severely affected pups and kittens might develop stunting, poor body condition, or tachypnea from left-sided CHF, and it is likely that some puppies die from heart failure prior to the first veterinary examination that typically occurs at 6 to 8 weeks of life. Most puppies are reported to be asymptomatic with normal physical development at the time of diagnosis.

Left-to-Right Shunting PDA

A thorough physical examination usually suffices to suggest the initial diagnosis. Usually, the arterial pulses are hyperkinetic. Mucous membranes are pink unless severe left-sided CHF is present. The precordial impulse is often exaggerated and covers a larger area across the thoracic wall than normal because of LV enlargement. A thrill is commonly palpated craniodorsally in the left axillary region, and a classic continuous murmur is best heard in the same location (Figure 250-3 and see ch. 55). The murmur's point of maximal intensity is located over the main pulmonary artery at the craniodorsal left heart base, and it may radiate

cranially to the thoracic inlet and to the right base, where it is almost always softer.[89,97,98] Frequently, only a systolic murmur is audible over the mitral area. This murmur may result from radiation of the loudest portion of the continuous murmur from the heart base or may be due to secondary mitral regurgitation which has developed as a consequence of severe LV dilation. In cats, the continuous murmur of a PDA may be heard best somewhat more caudoventrally than in affected dogs and the murmur is often confused with a "long" systolic murmur, especially if pulmonary hypertension is developing. Other differential diagnoses for this presentation with a continuous murmur as a hallmark include aortopulmonary shunts, coronary arteriovenous fistula, rupture of sinus of Valsalva aneurysm, aorticopulmonary window, anomalous left coronary artery and arteriovenous shunts, although these are relatively rare compared with the prevalence of PDA.[99-102]

FIGURE 250-3 Phonocardiogram recorded at the left heart base from a dog with left-to-right patent ductus arteriosus (PDA). The lead II ECG is recorded simultaneously for timing purposes (ventricular mechanical systole is approximately the period from the middle of the QRS complex to the end of the T wave; the remainder of the time is diastole). The recorded murmur is continuous, increasing in intensity during systole, peaking near the end of systole, and decreasing in intensity during diastole.

Thoracic radiographs indicate left heart enlargement and pulmonary overcirculation in proportion to the magnitude of the left-to-right shunt (Figure 250-4). On the dorsoventral projection, the aortic arch, left auricle, and main pulmonary artery may be abnormally prominent. The most specific radiographic finding is the appearance of an aortic bulge ("ductus bump"), which is caused by abrupt narrowing of the descending aorta just caudal to the origin of the ductus, aneurysmal dilatation of the aorta, and/or the ductus itself (see Figure 250-4). Moderate to severe LV enlargement sometimes causes the cardiac apex to shift to the right (common in cats). Pulmonary edema is present following the onset of CHF.

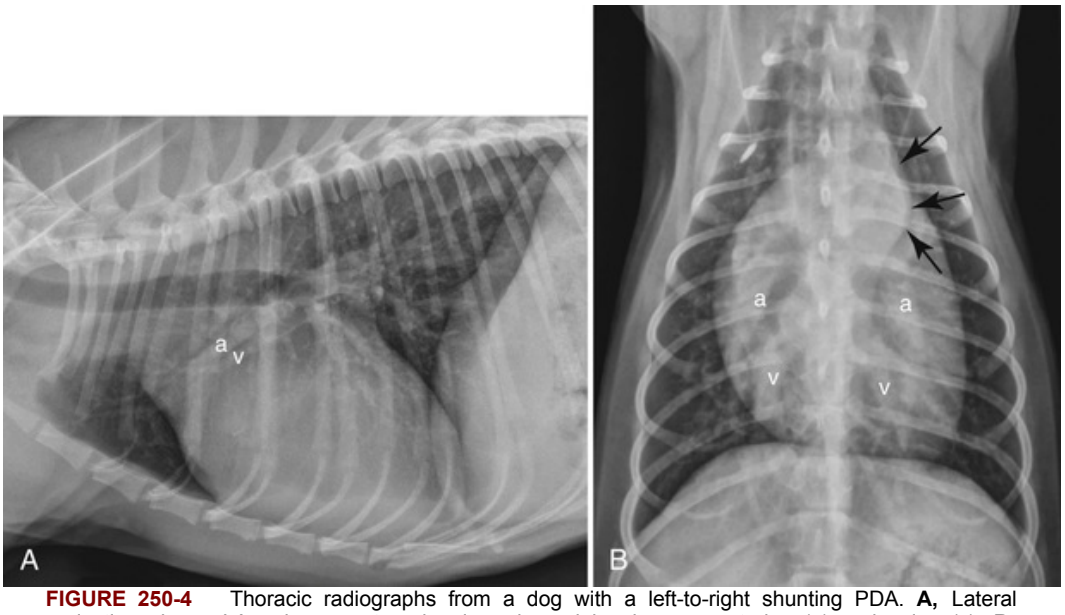

FIGURE 250-4 Thoracic radiographs from a dog with a left-to-right shunting PDA. **A,** Lateral projection shows LA enlargement and enlarged cranial pulmonary arteries (a) and veins (v). **B,** Dorsoventral projection shows moderate cardiomegaly, a characteristic bulge in the descending aorta (arrows) and dilation of the main pulmonary artery. The pulmonary vasculature is prominent.

When the rhythm is normal, the ECG contributes little to the overall diagnosis. Indications of LV enlargement (increased Q wave and R wave voltages in leads II, III, aVF and in the left precordial leads, V2 and V4) and LA enlargement (widened P waves) may be found. An arrhythmia is the principal indication for recording an ECG, and in dogs with long-standing PDA, atrial fibrillation, as well as supraventricular and ventricular premature complexes, may develop (see ch. 248).

The diagnosis of a PDA can be confirmed by a complete Doppler echocardiographic study in almost all cases. 2D and M-mode echocardiography demonstrate eccentric LV hypertrophy and dilatation of the LA, ascending aorta, and pulmonary artery (Figure 250-5, *A* and Videos 250-1 and 250-2). Reduced ventricular systolic function might be observed, and is suggested by findings of reduced fractional shortening, increased E-point to septal separation, and/or increased LV end-systolic volume. The ductus may be imaged and its size estimated from the left cranial parasternal view (Figure 250-5, *B* and Video 250-3).[103] Doppler interrogation of the main pulmonary artery demonstrates high-velocity, continuous ductal flow directed towards the pulmonic valve (Figure 250-5, *C* and Video 250-4). In the typical case, the peak velocity of this jet is at least 4.5 to 5.0 m/s and occurs at end-systole (Figure 250-5, *D*). Other common echocardiographic findings include mildly increased LV outflow velocity (1.8 to 2.3 m/s, but sometimes higher) and mild secondary mitral (Video 250-5), aortic, and pulmonic valve insufficiency, although in some dogs, moderate to severe mitral regurgitation might be identified. In dogs with PDA, associated cardiac defects are uncommon; nonetheless, it is still worthwhile to exclude, via a carefully performed echocardiographic examination, the presence of concurrent congenital defects such as PS. Owing to increased ejection volume and flow velocity across the LVOT, the diagnosis of mild SAS/AS can be difficult to achieve, and in the setting of overt SAS, its severity might not be evident until the ductus is closed. In animals that develop pulmonary hypertension, RV concentric hypertrophy may also be present, along with marked PA dilatation. Transesophageal echocardiographic techniques have also been described and may provide enhanced visualization of the ductal anatomy.[86,104] Cardiac catheterization and angiocardiography are usually not required to confirm a diagnosis of PDA (Video 250-6) and are not advised unless the Doppler echocardiographic evaluation is ambiguous or additional congenital malformations are suspected.

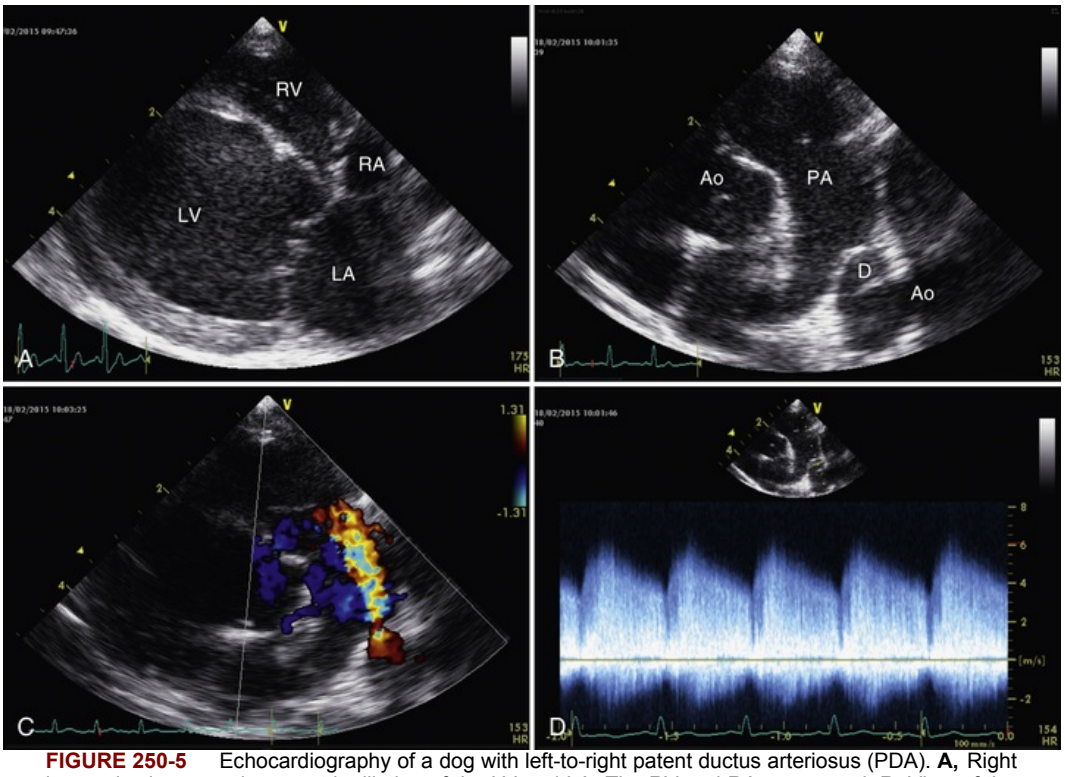

FIGURE 250-5 Echocardiography of a dog with left-to-right patent ductus arteriosus (PDA). **A,** Right long-axis view reveals eccentric dilation of the LV and LA. The RV and RA are normal. **B,** View of the ductus (D) imaged from the left heart base. The typical left-to-right ductus is widest at the aortic (Ao) end and tapers near the main pulmonary artery (PA). **C,** Color flow Doppler imaging applied to the echocardiographic view in **B,** demonstrating turbulent left-to-right blood flow through the ductus. **D,** Continuous wave Doppler tracing of the PDA jet obtained from the left heart base demonstrating continuous flow and a peak velocity of around 6.0 m/s.

PDA with Pulmonary Hypertension (Right-to-Left Shunting PDA)

High pulmonary vascular resistance causing right-to-left shunting through a PDA defines the clinical syndrome commonly referred to as a "reversed PDA."[49,51,89,95,105-109] Right-to-left shunting is observed in a very small minority of dogs with a PDA, but the prevalence of this phenomenon is probably underestimated and may be increased in dogs living at altitudes greater than 5000 feet (1500 meters) above sea level. Clinical signs are usually evident during the first year of life, but many owners do not recognize clinical signs in their pets during the first 6 to 12 months of life, and some animals are not diagnosed until 3 to 4 years of age or later. Reported signs include exertional fatigue, hind limb weakness, shortness of breath, hyperpnea, differential cyanosis, and, more rarely, seizures. Clinical examination is very different from the more common left-to-right PDA. Right-to-left flow through a wide PDA exhibits little turbulence and physical examination reveals either no murmur or only a soft, systolic murmur at the left base. The most common auscultatory finding is an accentuated and split second heart sound. Differential cyanosis (cyanosis of the caudal mucous membranes with pink cranial membranes) may be observed, but recognition may require examination after exercise. Differential cyanosis is caused by the location of the PDA, which shunts right-to-left from the pulmonary artery into the descending aorta (see Figure 250-2, *C* and *D*) but spares the proximal branches of the aorta, which provide normal oxygen delivery to the cranial portion of the body. Perfusion of the kidneys with hypoxemic blood triggers elaboration of erythropoietin and secondary erythrocytosis and hyperviscosity as the PCV gradually increases to 65% or greater.[51] Erythrocytosis may occur during the first year of life, but often does not become severe until 18 to 24 months of age.

The ECG of dogs with a reversed PDA virtually always reveals evidence of RV hypertrophy (right axis deviation, increased S wave amplitude in leads I, II, III, and the left precordial leads, V2 and V4). Thoracic radiographs indicate right heart enlargement, dilatation of the main pulmonary artery, a visible "ductus bump" and variable appearance of the lobar and peripheral arteries. Echocardiography demonstrates RV concentric hypertrophy and a dilated main pulmonary artery (Figure 250-6). In some cases, a wide and cylindrical ductus may be imaged (see Figure 250-6). Pulmonary hypertension can be verified in some cases

by Doppler interrogation of tricuspid or pulmonic insufficiency jets (see Figure 250-6). Contrast echocardiography, nuclear scintigraphy, oximetry, or angiography can be used to demonstrate the presence of right-to-left shunting should Doppler interrogation prove inadequate. Contrast echocardiography (see ch. 104) is performed by injecting air-agitated saline into a cephalic or saphenous vein, thereby opacifying the right heart, pulmonary artery, and the descending aorta (best observed by imaging of the abdominal aorta dorsal to the bladder). Cardiac catheterization can demonstrate pulmonary artery hypertension with equilibration of RV and LV and aortic systolic pressures; oximetry verifies decreased oxygen saturation distal to the entrance of the PDA in the descending aorta, and RV angiography demonstrates RV hypertrophy and usually outlines a wide PDA that appears to continue distally as the descending aorta (Figure 250-7). The lobar pulmonary arteries may appear normal angiographically, especially during the first year of life, or may show increased tortuosity. Aortic or LV contrast injections permit visualization of an often extensive bronchoesophageal collateral circulation (see Figure 250-7).

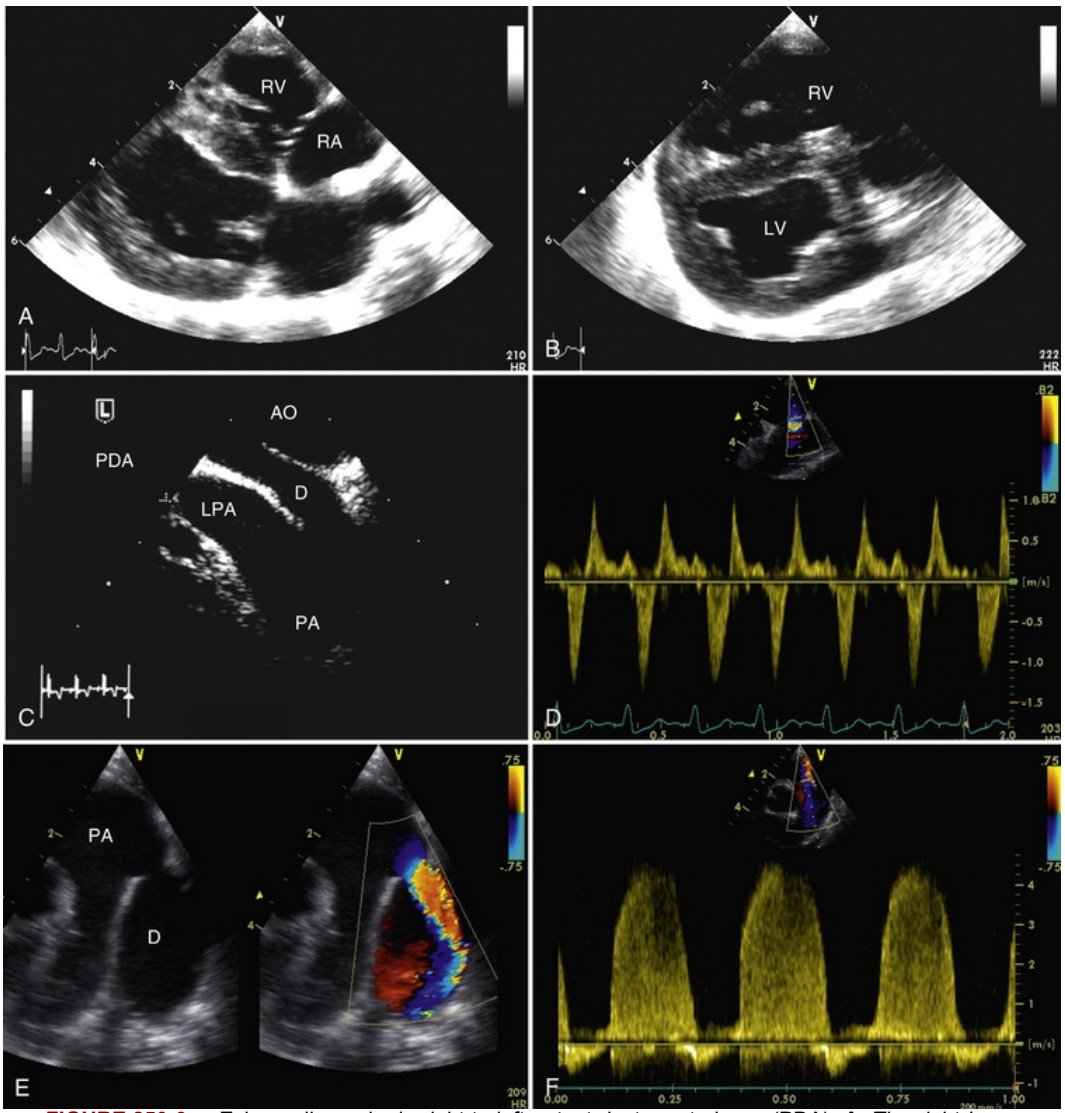

FIGURE 250-6 Echocardiography in right-to-left patent ductus arteriosus (PDA). **A,** The right long-axis view from an American Eskimo dog shows enlargement of the RV and RA. **B,** The right short-axis view shows enlargement of the RV and flattening of the interventricular septum toward the LV. This finding is highly suspicious for pressure overload of the RV. **C,** Transesophageal echocardiogram of a dog with a right-to-left PDA. The ductus (D) connects the aorta (Ao) with the pulmonary artery (PA), and is wide and cylindrical in shape. Both the PA and left pulmonary artery (LPA) are enlarged. **D,** Continuous wave Doppler study of the dog in **A** showing bidirectional flow through the ductus. Right-to-left flow (below the baseline) occurs during systole, while left-to-right flow (above the baseline) occurs during diastole. **E,** Simultaneous two-dimensional and color flow Doppler study of the dog in **A.** Flow from the pulmonary artery (PA) can be seen moving right-to-left into the large ductus (D). **F,** Continuous wave Doppler study of pulmonic insufficiency from the dog in **A.** The peak velocity of

insufficiency is 4.5 m/s, indicating a pulmonary artery diastolic pressure of approximately 80 mm Hg. This finding is consistent with a diagnosis of pulmonary arterial hypertension and the presence of a right-to-left shunt.

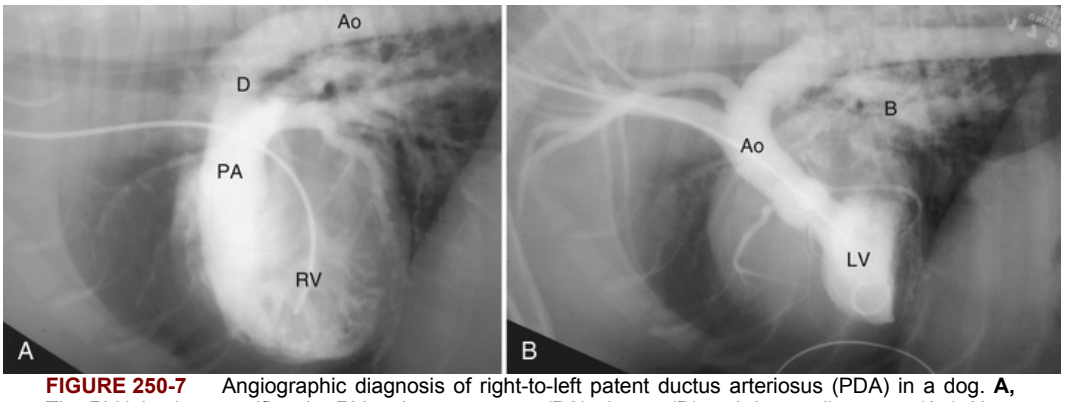

FIGURE 250-7 Angiographic diagnosis of right-to-left patent ductus arteriosus (PDA) in a dog. **A,** The RV injection opacifies the RV, pulmonary artery (PA), ductus (D) and descending aorta (Ao). Note that the systemic arteries to the cranial portion of the dog are not opacified. **B,** An LV injection of the same dog opacifies the LV, aorta (Ao), and prominent collateral bronchoesophageal circulation (B).

Natural History

Puppies and kittens with PDA are frequently clinically unaffected by their defect at the time of diagnosis. However, if left uncorrected, PDA typically leads to complications related to chronic left-to-right shunting (i.e., left-sided cardiomegaly, mitral valve regurgitation, arrhythmias, left-sided CHF, and death). The natural progression of untreated PDA in small animals is limited to a single study of 100 sequential cases in which the defect was not occluded in 14 affected dogs; 64% of these 14 dogs died within a year of examination.[110] While these numbers are relatively small, they provide a clear recommendation for most cases of PDA to receive a closure device or surgery. Pulmonary artery dissection is a recently recognized potential complication of uncorrected PDA in the dog. Dogs with this complication are more likely to present at an older age than the typical dog diagnosed with PDA.[111] In cats, literature regarding the natural history of PDA is scarce. Cats may develop significant pulmonary hypertension from left-to-right shunting more frequently than dogs do.[109,112-114] Importantly, pulmonary hypertension due to PDA can develop more slowly and might be arrested with prompt intervention.[113,114] When persistent pulmonary hypertension in the neonate leads to reversed shunting, clinical signs result from hypoxemia, erythrocytosis, hyperviscosity, and cardiac arrhythmias. CHF almost never develops but sudden death and complications from hyperviscosity are common. Dogs and cats with milder forms of PDA often survive to maturity and may live beyond 10 years of age.[115,116]

Clinical Management

Correction of uncomplicated PDA is considered to be curative. Furthermore, PDA closure results in an immediate decrease in left-sided volume overload, gradual reversal of LV eccentric hypertrophy over time,[117] and an excellent prognosis.[118] Correction may not be warranted in older pets if the shunt volume is small and cardiomegaly is minimal or absent. Generally, closure of PDA is an elective procedure that should be scheduled immediately when the diagnosis is made, and at the earliest age possible to prevent the condition from acutely deteriorating. If the patient presents in CHF with LV myocardial failure, the patient should be stabilized for a short period of time with medications for CHF (furosemide, pimobendan, ACE inhibitors) before considering anesthesia. Medical therapies for CHF are often continued for several months following repair in these animals. In some cases with atrial fibrillation, consideration can be given to electrocardioversion at the time of ductal closure or later; however, chronic medical management (digoxin and diltiazem, with or without beta-blocker; see ch. 248) might be needed.

Closure of reversed (right-to-left) PDA is generally accepted to be contraindicated due to case-based evidence of poor outcomes. Closure of left-to-right PDA with concurrent pulmonary hypertension of varying

severity has been reported to be successful in both dogs[96] and cats.[113,114] Treatment with prostaglandin inhibitors is not effective in dogs and cats, most likely because of the absence of smooth muscle in the ductal wall. Some dogs have shown clinical benefit to treatment with sildenafil citrate (1-3 mg/kg PO q 8-12 h), and this should be tried for at least 3-4 weeks to gauge clinical response.

The typical PDA can be surgically ligated, or closed by transcatheter techniques using thrombogenic coils or an occluder such as the Amplatz Canine Duct Occluder (ACDO). The latter transcatheter approaches represent the most important advance in PDA management over the past two decades and are widely employed today. These interventional catheterization procedures for PDA are discussed in ch. 122. Despite the substantial advances in transcatheter techniques, surgical ligation by means of a left thoracotomy remains a very successful method for PDA occlusion and should not be viewed as an inferior approach. Determining the appropriate treatment is dependent on ductal morphology, patient size, operator experience, and owner preference. Some advantages of per-catheter PDA occlusion over thoracotomy and surgical ligation include lower morbidity, shorter hospitalization, and faster recovery. In a large retrospective study comparing surgical ligation and transcatheter coil occlusion for treatment of PDA, surgical ligation was associated with a higher risk of major complications, whereas transcatheter occlusion using coils was associated with a lower initial success rate which was due to inability to stabilize coils, coil migration, and significant residual flow after appropriate coil placement.[119] In the current era of the ACDO, it is difficult to know how to compare transcatheter and surgical methods without a suitable prospective study. There are some disadvantages of catheter-based approaches, including: the need for fluoroscopy and radiation exposure; the requirement for specialized catheterization equipment and operator training; the inability to safely close cylindrical lesions lacking a tapering morphology; and, in some situations, the longer duration of the procedure (considering highly experienced surgeons can accomplish closure in less than 40 minutes). The inability currently to deliver an ACDO into very small patients (<2 to 2.5 kg) might be overcome by the availability of low-profile ACDOs.[120] In light of these points, the greatest advantage of surgical ligation is that it can be performed in animals with all ductal morphologies and body weights, and is therefore the method of choice for very small dogs and cats, as well as animals with a type III (nontapering) ductal morphology. Recovery is usually rapid with contemporary pain management. Complications of surgical PDA repair in dogs include intraoperative hemorrhage (11-15% of cases), infection, pneumothorax, cardiac arrhythmias, cardiac arrest, and heart failure, and perioperative mortality rates between 0-5.6% have been reported.[98,119,121]

After ductal closure, most dogs experience an uneventful recovery. Although overall cardiac size decreases after surgery, in many dogs some left-sided heart enlargement persists.[122-125] Postoperative Doppler examination may indicate a small residual shunt,[98,126] although the continuous murmur is usually absent and the clinical outcomes are very good. A soft left apical systolic murmur, usually from residual secondary mitral regurgitation, is often heard for a variable period after ductus ligation.[97] Postoperative ductal recanalization has been reported but is uncommon, occurring in less than 2% of cases and most commonly associated with an infection.[92] Postoperative fever and pulmonary infiltrates may indicate infection at the surgical site and hematogenous pneumonia.[127]

Animals with reversed PDA have irreversible obstructive pulmonary vascular disease. Morbidity and mortality are usually the result of complications related to erythrocytosis and chronic hypoxemia rather than CHF. Treatment of these patients consists of exercise restriction, avoidance of stress, preventing dehydration, and maintenance of the PCV between 58% and 65% by periodic phlebotomy.[94] As mentioned above, treatment with sildenafil citrate can also improve clinical signs. Long-term management by these techniques is possible.[128] Phlebotomy should be performed cautiously to avoid weakness or collapse, and intravascular volume may be supported during phlebotomy by administration of crystalloid solutions. Attempts to reduce the red cell volume of reversed PDA cases using drug therapy (e.g., hydroxyurea) have been reported and may be an alternative to repeated phlebotomy.[129] Activity restriction is usually advised, as exercise-induced systemic vasodilation increases the degree of right-to-left shunting and predisposes to hind limb paresis or collapse and cyanosis. Closure of reversed PDA is strongly contraindicated, as it invariably leads to late operative or early postoperative acute right heart failure and death.

Atrial and Ventricular Septal Defects

During cardiac embryonic development, the atria and ventricles begin as a common chamber. The heart is subsequently partitioned into the normal four-chambered heart by the growth of cardiac septa and AV valves. The atria are partitioned by a wall formed mainly from two septa: the septum primum, which forms

first, and the septum secundum, which develops to the right of the septum primum. The foramen ovale, a slit-like passageway which persists between these septa, permits right-to-left atrial shunting in the fetus, but functionally and anatomically closes in the neonate once the lungs expand and LA pressures rise. The major portion of the ventricular septum forms by inward growth from the ventricular walls. The area of AV confluence, including the upper ventricular septum, lower atrial septum, and AV valves, is formed primarily by growth and differentiation of the endocardial cushions. The AV valves normally insert at different levels of the ventricular septum, with the tricuspid valve connecting slightly apically to the mitral valve. The resultant offset, defined as the AV septum, essentially forms an atrial septum on the right and a ventricular septum on the left.[130]

Defects in the development of the embryonic ventricular septum, the primum or secundum atrial septa, or the endocardial cushions, can result in a VSD, an ASD, or both lesions, respectively, along with malformations in the AV valves. Congenital septal defects are common in both dogs and cats as isolated lesions or as components of more complex lesions such as complete AV septal defects (AVSD) and ToF.[22]

Pathogenesis of the Septal Defects

Except for the proven genetic basis of VSD in the Keeshond with so-called conotruncal malformations,[11] there are no data on the cause(s) of spontaneous septal defects in dogs or cats. ASDs are usually classified based on the anatomic region of the malformation. Defects at or near the foramen ovale are most common and are referred to as ostium (or septum) secundum defects (Figure 250-8). Defects of the lower atrial septum are called ostium primum defects and can occur in isolation or as a component of partial or complete AVSD. The rarely observed sinus venosus ASD is most often found dorsocranial to the fossa ovalis near the entrance of the cranial vena cava[131] and often involves the entry of a pulmonary vein into the RA. Since the endocardial cushions are largely responsible for partitioning the lowermost atrial septum, defects in the region immediately adjacent to the AV valves (septum primum) have been called "endocardial cushion defects"; however, this term is less preferred today. A defect in this area can also involve anomalous development of the AV valves. These can range from a "cleft" in the septal leaflet of the mitral valve to a common AV septal leaflet that bridges across the two sides of the heart. A complete AVSD (endocardial cushion defect) consists of a large defect of the lower atrial septum, an inlet VSD (ventral to the septal tricuspid valve leaflet), and a common (bridging) AV valve that includes a cleft in the septal mitral leaflet. Older terminologies for these severe malformations include a common AV canal defect, since the embryonic AV canal area never partitions and there is communication between all four cardiac chambers. Partial and complete AVSDs are more commonly detected in cats[132,133] and can cause left-sided or bilateral CHF; conversely, AVSDs are comparably rare in dogs.[134,135] Patent foramen ovale is not a true ASD inasmuch as the atrial septum forms normally, but the walls bordering the foramen are pushed apart. Most often, a PFO is due to conditions that increase RA pressure; however, severe LA dilation can also lead to persistent patency of the foramen ovale. A PFO usually achieves clinical significance when it allows right-to-left shunting, as might occur with severe PS[136] or TVD.

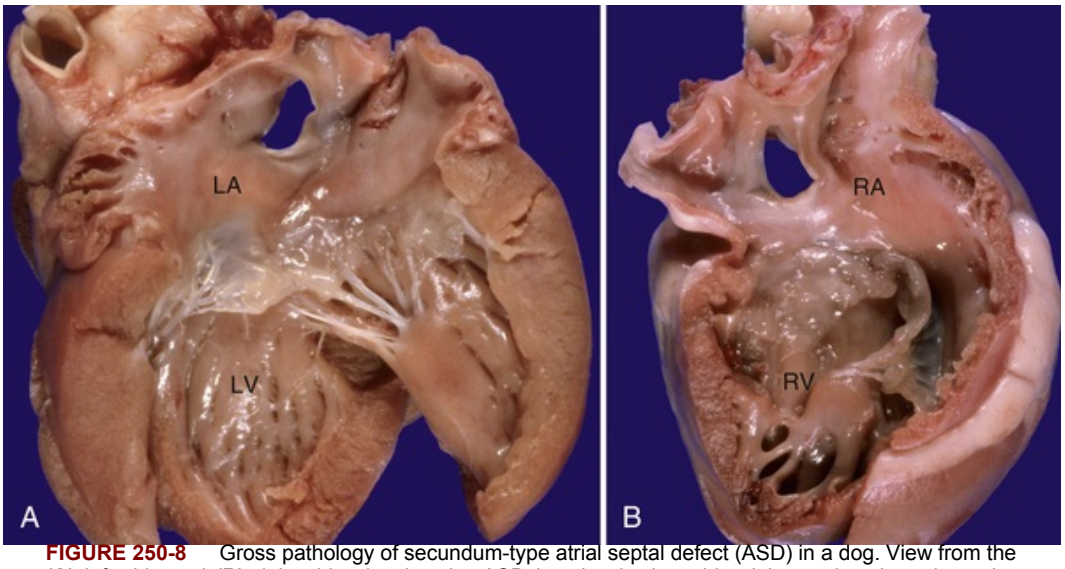

FIGURE 250-8 Gross pathology of secundum-type atrial septal defect (ASD) in a dog. View from the **(A)** left side and **(B)** right side showing the ASD location in the mid-atrial septal region where the foramen ovale would exist.

Most VSDs are located within or adjacent to the membranous portion of the upper ventricular septum, just below the aortic valve and cranial to the septal tricuspid leaflet (Figure 250-9, *A*).[137] These are variously termed "membranous," "perimembranous," and "paramembranous" defects by different authors and "infracristal" defects in older literature. Membranous ventricular septal aneurysm with or without a small, patent perimembranous VSD has also been described by echocardiography in both dogs and cats.[138]

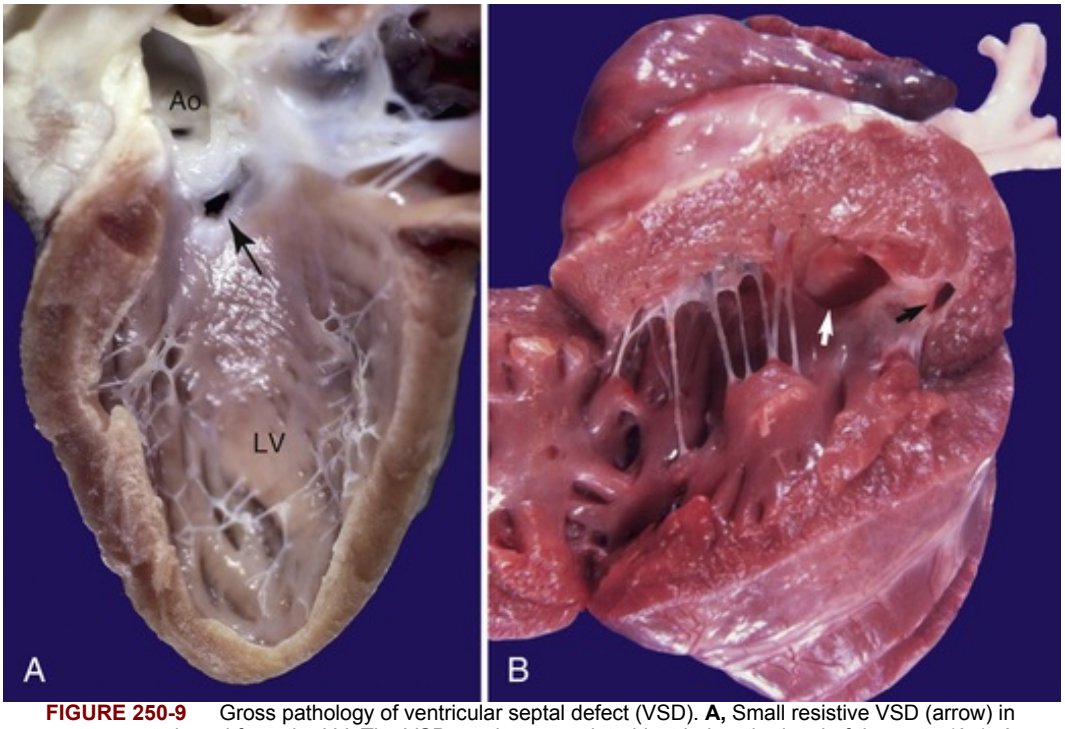

FIGURE 250-9 Gross pathology of ventricular septal defect (VSD). **A,** Small resistive VSD (arrow) in a young cat viewed from the LV. The VSD can be appreciated just below the level of the aorta (Ao). A fine network of excessive moderator bands/false tendons is an unrelated finding. **B,** Large, nonresistive VSD in a young dog with ToF, viewed from the RV. The large defect (white arrow) is located just cranial to the tricuspid valve apparatus. The RV is markedly thickened and a narrow subvalvular fibrous ring of subvalvular PS is present (black arrow).

The typical membranous VSD, when viewed from the left side of the ventricular septum, is located just

below the aortic valve, most often centered between the right coronary and noncoronary cusps. On the right side of the septum, the opening is often described by its position relative to the supraventricular crest (crista supraventricularis), the muscular ridge that separates the inflow from the outflow tracts. Membranous defects are subcristal (infracristal), whereas subarterial defects are located in a supracristal position just below the pulmonic valve. Large membranous defects can obliterate the crista and these are often associated with additional defects such as ToF (Figure 250-9, *B*). The right side of the root of the aorta, including the right coronary and noncoronary cusps, can be displaced to the right (dextropositioned) so that the aorta straddles the defect, creating a "malalignment" VSD. Extreme cranial and rightward deviations of the aortic root are observed in the spectrum of ToF-pulmonary atresia-double outlet right ventricle. However, the altered geometry of the aortic root that accompanies many VSDs can result in substantial aortic valve regurgitation without involving these severe malformations. Defects in the muscular ventricular septum are rare in dogs and cats and can be located dorsally or apically. Inlet VSDs were mentioned previously under AVSD.

Pathophysiology

Shunting across small (resistive or restrictive) defects depends primarily on the size of the defect and the pressure difference between the two chambers, while shunting across large (nonresistive) defects depends primarily on relative resistances within the systemic and pulmonary vasculature.[137,139-141] In the absence of other abnormalities, left heart pressures exceed those on the right and the direction of shunting is left-to-right. With left-to-right shunts, cardiac chambers in the circuit of the shunt enlarge to accommodate the excess blood volume, and the pulmonary vasculature becomes overcirculated. Large-volume left-to-right shunts can eventually result in myocardial failure, elevated filling pressures, and the development of overt CHF. Right-to-left shunting occurs via a septal defect when PS, tricuspid dysplasia (ASD), or pulmonary hypertension raises pressures on the right side of the heart. The consequences of "reversed" shunting include cyanosis from arterial hypoxemia, erythrocytosis, hyperviscosity, and sudden death (see Physiology of Right-to-Left Shunting, above).

Atrial Septal Defect

Flow across an ASD occurs primarily during ventricular diastole. The pressure difference across the defect is low and the direction and magnitude of the shunt is determined mainly by the defect size and relative diastolic resistance to inflow for each ventricle. Normally, the RV is more compliant than the left and offers little resistance to filling, causing blood to preferentially shunt from the LA into the RA and RV. The result is dilation of the RA, eccentric hypertrophy of the RV, and pulmonary overcirculation. At cardiac catheterization, oxygen saturation in the right heart and pulmonary arteries is increased. The LA receives the shunted blood, but most of the increased pulmonary venous return is shunted immediately into the RA, resulting in minimal LA dilation. If considerable LA enlargement is observed in an animal with an ASD, an AVSD with mitral regurgitation should be suspected.

The flow across an ASD does not usually generate an audible heart murmur because the pressure gradient and flow velocity across the defect are both low. When the shunted blood joins with blood entering from the vena cava, the volume and velocity of flow through the right heart is increased, resulting in a murmur of relative PS (common) or tricuspid stenosis (uncommon). Delayed closure of the pulmonic valve (and early closure of the aortic valve) causes splitting of the second heart sound.[139,142] Since the volume overload affects the RV and not the LV, large shunts culminate in the development of right heart failure or pulmonary vascular injury with clinical signs related to pulmonary hypertension and right-to-left shunting.

Ventricular Septal Defect

Flow across a VSD occurs primarily during ventricular systole. In the absence of other cardiovascular defects, peak LV systolic pressure is about five times that of the RV, and flow proceeds from the LV to the RV. The magnitude of left-to-right shunting with small (resistive) defects is mainly determined by the diameter of the defect and the systolic pressure difference (gradient) between the ventricles. The peak pressure difference across the defect can be estimated noninvasively with Doppler echocardiography (see ch. 104). A resistive defect with relatively normal RV and LV pressures (approximately 20-25 mm Hg and 100-120 mm Hg, respectively) is expected to have a peak jet velocity through the defect >4.5 m/s, corresponding to a peak pressure gradient >80 mm Hg. This high-velocity flow creates a prominent systolic murmur. If the peak velocity is lower than predicted, RV systolic pressure is most likely increased, caused either by the presence of PS or increased pulmonary artery pressure that can stem from high pulmonary flow, left heart failure, or

increased vascular resistance.

When a small VSD is located high in the membranous septum, blood is ejected by the LV directly towards the RVOT and out the main pulmonary artery; the right heart experiences only a modest volume overload and right heart enlargement is minimal. Right heart enlargement is more prominent when the VSD is large or is located in the muscular portion of the interventricular septum (IVS). In the setting of a membranous or subarterial VSD, cardiac catheterization shows oxygen saturation in the RVOT and pulmonary artery that is higher than that measured within the RA or apex of the RV. Large shunts (pulmonary to systemic flow ratio >3 : 1) can overload the left heart enough to increase ventricular diastolic pressures and cause signs of left-sided CHF. Very large, nonresistive VSDs cause the pressures in both ventricles to equilibrate, and the two ventricles behave as a common pumping chamber. Unless a stenotic pulmonic valve protects the pulmonary circulation, the development of CHF or pulmonary hypertension is unavoidable. With both small and large malalignment VSDs, aortic regurgitation can occur because of prolapse of the right aortic valve cusp into the VSD during diastole. This can increase LV wall stress, and predispose to CHF.

Clinical Findings

Atrial Septal Defect

Canine breed predispositions for ASD are presented in Table 250-1. In cats with ASD, one study found an overrepresentation of domestic shorthair, Persian, and Chartreux breeds.[22] Clinical findings of the typical left-to-right ASD include a soft, grade 2-3/6, systolic ejection murmur over the left heart base and splitting of the second heart sound (Figure 250-10).[22,143] The murmur is often misinterpreted as one arising from mild PS or as an innocent murmur. A low-frequency, right-sided diastolic murmur of relative tricuspid stenosis may occur, but this it is usually inaudible, especially in smaller patients. Cyanosis is absent unless there is an additional defect such as PS or TVD,[144] or the infrequent complication of pulmonary hypertension, to cause right-to-left shunting.[22] Signs of right-sided CHF may be present in dogs or cats with large defects.

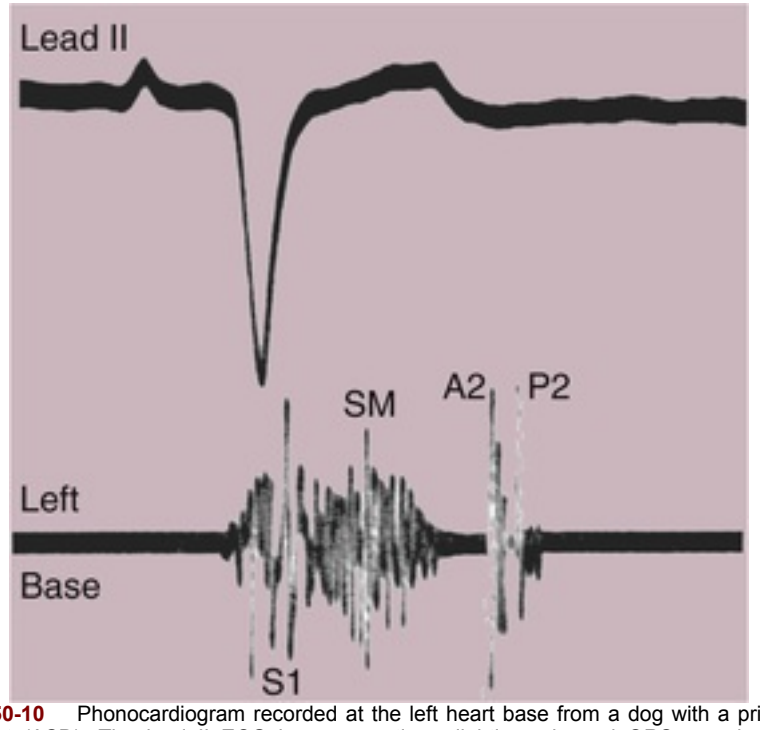

FIGURE 250-10 Phonocardiogram recorded at the left heart base from a dog with a primum atrial sepal defect (ASD). The lead II ECG has a negative, slightly prolonged QRS complex, which is indicative of an RV conduction disorder (partial or incomplete right bundle branch block). The phonocardiogram shows a systolic ejection murmur (SM) that ends well before the second heart sound, which is widely split. *S1,* First heart sound; *A2,* aortic component of the second heart sound; *P2,* pulmonic component of the second heart sound.

The main cardiac structural changes caused by an ASD include dilation of the RA and eccentric

hypertrophy of the RV. The ECG may indicate RV enlargement (right axis shift, increased S wave depth in leads I, II, III), but intraventricular conduction disturbances, especially partial or complete right bundle branch block, are also seen, especially with ostium primum defects or AVSD.[2,133] The latter can also exhibit a left-cranial axis deviation in the frontal axis. Thoracic radiographs show enlargement of the right heart, main pulmonary artery, and pulmonary hypervascularity proportional to the magnitude of the shunt (Figure 250-11). The LA is only modestly enlarged unless there is concurrent mitral regurgitation from a mitral valve malformation or an AVSD. 2D echocardiography permits direct imaging of ASD,[22] but false positive impressions of an ASD are common because of imaging artifacts caused by beam orientation and the thinness of some portions of the normal interatrial septum. Doppler evidence of transatrial shunting is more reliable and typically shows laminar or mildly turbulent diastolic flow through the ASD (Figure 250-12 and Video 250-7), and increased RVOT and pulmonary artery velocities. Doppler studies are also helpful for demonstrating associated problems such as mitral regurgitation or other associated defects.[145] One pitfall is confusing normal venous return from the caudal vena cava for left to right atrial shunting, as this flow enters along the atrial septum in the parasternal long-axis view. Additionally, in short axis image planes, the atrial septum can be foreshortened, confusing the location of a secundum ASD with that of a primum defect. Contrast echocardiography is helpful (see ch. 104), particularly when the defect is large or when elevated right heart pressures cause reversed flow across the defect. Cardiac catheterization of animals with an ASD might be helpful for evaluating the magnitude and direction of shunting and pulmonary vascular resistance. In cases of left-to-right shunting, oximetry samples from the vena cava, RA, and RV indicate an increase in oxygen saturation between the vena cava and the atrium and/or ventricle, and the magnitude of systemic to pulmonary shunting can be estimated. Central venous and RV diastolic pressures are elevated when CHF is present or imminent. Increased systolic flow across the pulmonic valve may result in "relative" PS, identified by a mild systolic pressure gradient (5 to 15 mm Hg) between the RV and pulmonary artery.[142] Flow through the ASD can be demonstrated by angiocardiography. When introduced via a femoral vein, a catheter can often be easily passed from the RA through an ASD or PFO into the LA to perform a contrast study for visualization of left-to-right shunting. Alternatively, contrast injection into the pulmonary artery will outline left-to-right shunting defects during the left-sided phase of the study. Following pulmonary venous return, the atrial septum usually can be seen between the LA and aorta on the lateral projection. Passage of contrast from the LA into the RA and vena cava confirms the presence of the defect. When a more extensive endocardial cushion defect is suspected, a contrast injection into the LV can be performed to demonstrate the VSD, mitral regurgitation, and occasionally, left ventricular-to-right atrial shunting through the ASD.

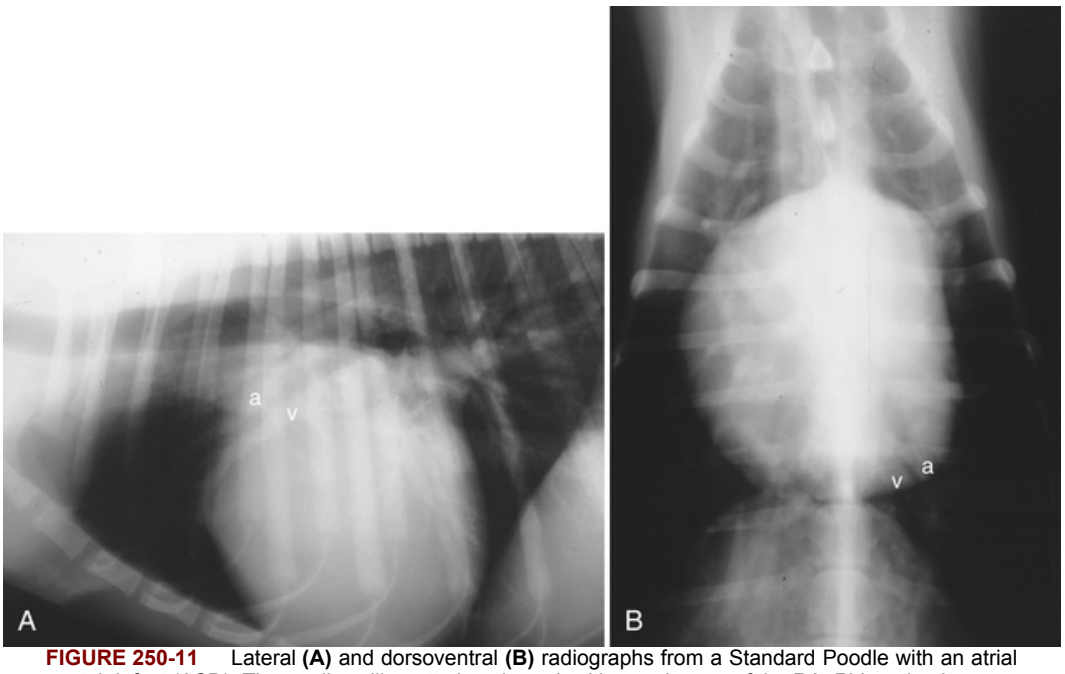

FIGURE 250-11 Lateral **(A)** and dorsoventral **(B)** radiographs from a Standard Poodle with an atrial septal defect (ASD). The cardiac silhouette is enlarged, with prominence of the RA, RV, and pulmonary arteries (a) and veins (v).

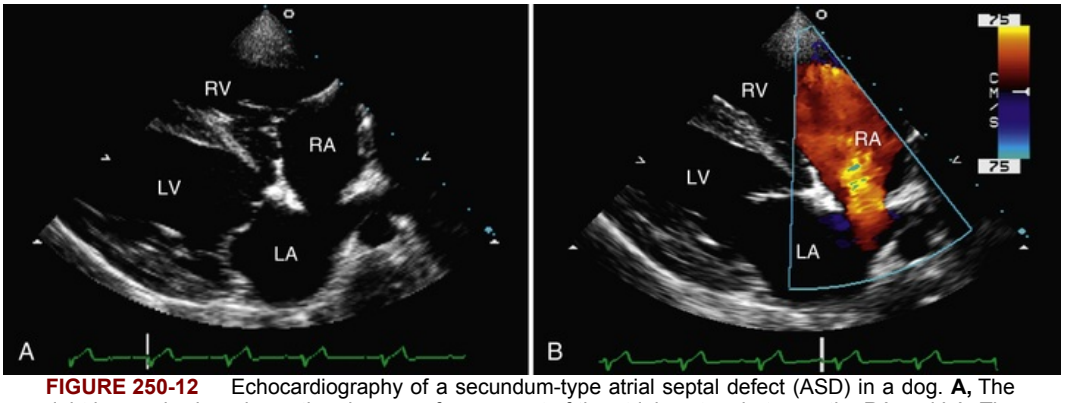

FIGURE 250-12 Echocardiography of a secundum-type atrial septal defect (ASD) in a dog. **A,** The right long-axis view shows the absence of a segment of the atrial septum between the RA and LA. The RA and RV are moderately enlarged. **B,** Color flow Doppler study indicates low velocity left-to-right flow through the ASD.

Ventricular Septal Defect

Canine breed predispositions for VSD are indicated in Table 250-1. VSD is one of the most frequent congenital anomalies in cats,[36] and no known breed predispositions have been reported, although clinical experience suggests they are relatively common in the Maine Coon cat. In contrast, certain breeds of dogs including English Springer Spaniels, West Highland White Terriers and Lakeland Terriers have been reported to be predisposed to VSDs. The clinical features of VSD depend on the magnitude of the shunt and presence of complications or other defects. Animals with a typical small, membranous VSD are asymptomatic and they present with a harsh, holosystolic murmur that is heard best over the right, ventral, mid- to cranial precordium.[137,146,147] In rare cases of subarterial VSD, the defect opens just under the pulmonic valve, and the systolic murmur is heard best at the left heart base. Splitting of the second heart sound can occur but is often unrecognized because of the superimposition of the murmur on the second heart sound. If distortion of the aortic root causes significant aortic regurgitation, a blowing, decrescendo diastolic murmur can be evident over the LV outflow area. This results in a combination of systolic and diastolic murmurs that can be readily confused with a PDA. Aortic regurgitation can also flow into the RV to produce a diastolic murmur best heard on the right hemithorax. Systolic murmurs over the AV valves may also be detected if a VSD is part of a complete AVSD.

ECG findings in animals with a VSD are variable. With moderate or large left-to-right shunts, there is often evidence of LA or LV enlargement, but RV conduction defects also can occur. Frontal plane leads may demonstrate a subtle abnormality in early ventricular septal activation, characterized by a Q wave that is wide or contains high-frequency notching.[148] Right axis deviation and a narrow QRS complex in a dog with VSD usually indicate RV hypertrophy and a more complex lesion, such as VSD with PS or pulmonary hypertension. Thoracic radiographs are very useful in assessing the magnitude of left-to-right shunting VSDs. Pulmonary hypervascularity and LA and LV enlargement are observed in proportion to shunt magnitude (Figure 250-13).[61] The main, lobar, and peripheral pulmonary arteries are usually prominent. In animals with small defects, thoracic radiographs may appear entirely normal. With large defects, the RV may also enlarge. A large pulmonary artery segment, underperfused lungs, and scant peripheral pulmonary vasculature suggest the possibility of PS or pulmonary hypertension and right-to-left shunting.

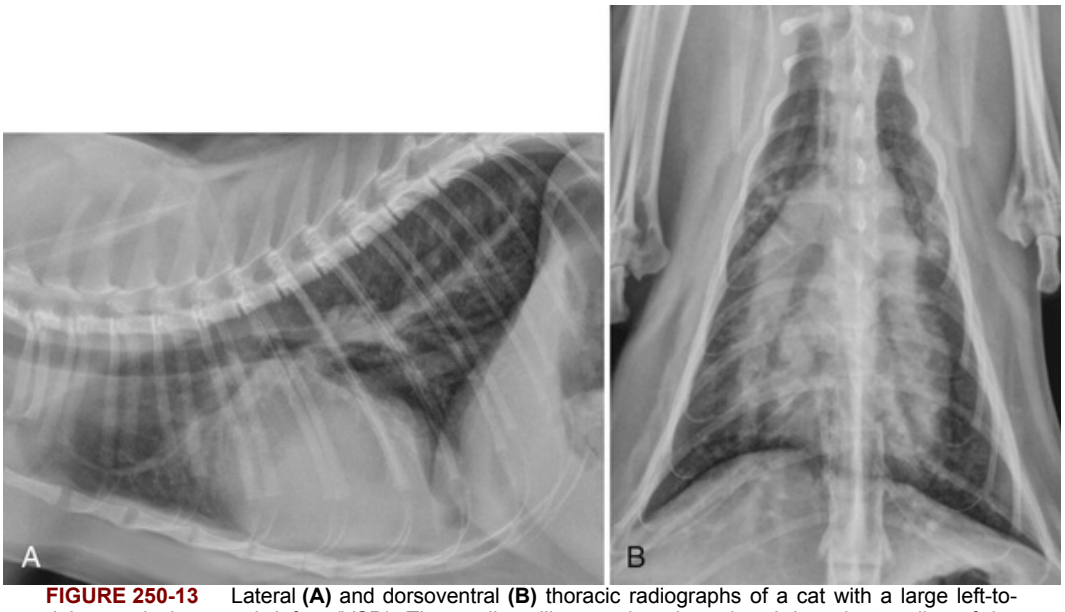

FIGURE 250-13 Lateral **(A)** and dorsoventral **(B)** thoracic radiographs of a cat with a large left-to-right ventricular septal defect (VSD). The cardiac silhouette is enlarged and there is rounding of the cranial border of the heart on the lateral view. The pulmonary arteries and veins are enlarged on the dorsoventral view.

On echocardiography, LA and LV enlargements of variable degrees are observed. With moderate to large VSDs, right heart enlargement may also be present. Two-dimensional echocardiography from the right thorax is most often utilized to identify the membranous VSD, located just below the aortic valve (Figure 250-14, *A*) and found adjacent to the cranioventral edge of the septal tricuspid leaflet. The rare subarterial VSD is best identified on short axis images at the level of the aorta that include the RV inlet and RV outlet into the pulmonary artery. Off-angle views are often needed. The left apical four-chamber image is best for visualizing an AVSD. As a general rule, when the maximal diameter of the VSD is <40% of the aortic root diameter, the lesion is likely to be restrictive/resistive and often well tolerated as long as there is no aortic regurgitation. Small aneurysms of membrane-like tissue may occasionally be seen protruding into the RV from the margins of the VSD.[138] As for ASDs, Doppler studies of VSDs should be performed to confirm the presence of the shunt, and color Doppler is particularly useful for identification of small lesions. For a perimembranous defect, a jet of blood moving toward the transducer can be observed in the long- or short-axis views from the right side (Figure 250-14, *B* and *C* and Videos 250-8 and 250-9). Continuous-wave (CW) spectral Doppler studies are useful to quantify the high-velocity jet through small, resistive VSDs, as previously mentioned (Figure 250-14, *D*). The larger the VSD, the smaller the pressure difference between the ventricles, and the lower the velocity of blood flow through the VSD. Thus, the peak velocity of blood flow through the VSD on CW Doppler can also be used for helping to define the size of the defect. The region of the aortic valve should also be interrogated for aortic regurgitation. Contrast echocardiography may also be used for identifying flow through the defect, but it is usually not necessary if careful 2D and Doppler examinations have been performed.

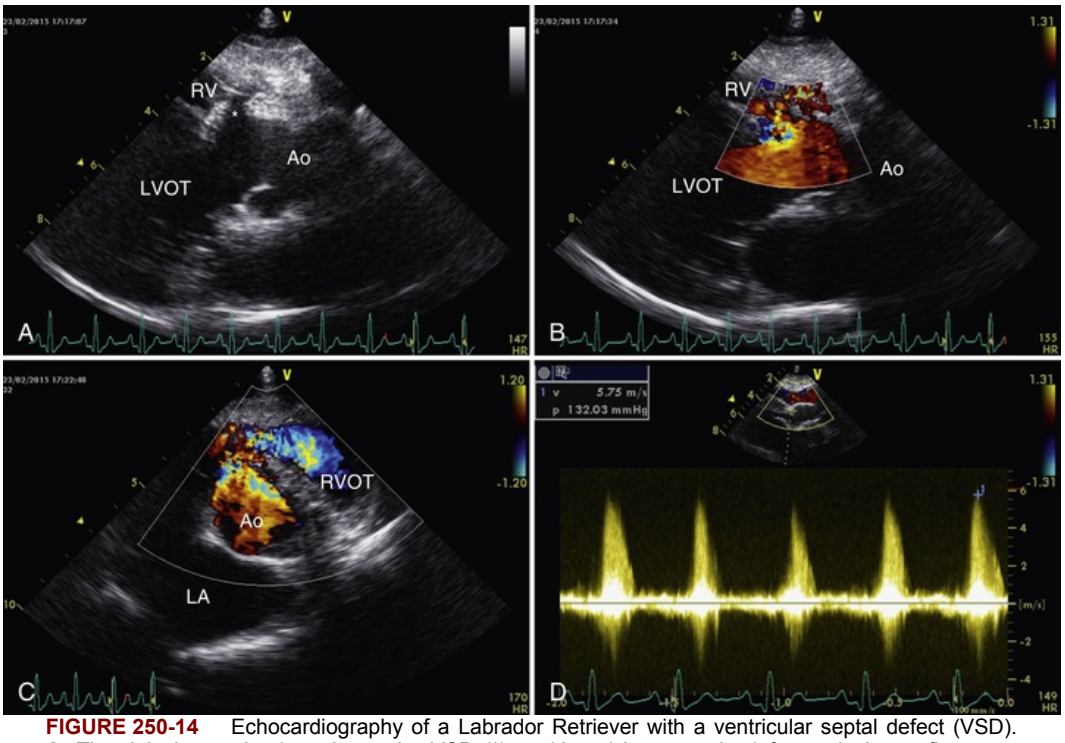

FIGURE 250-14 Echocardiography of a Labrador Retriever with a ventricular septal defect (VSD). **A,** The right long-axis view shows the VSD (*) positioned between the left ventricular outflow tract (LVOT) and aorta (Ao) and opening into the RV. Note the proximity of the VSD to the root of the Ao and origin of the aortic valve. **B,** The right long-axis color flow Doppler study reveals systolic left-to-right shunting across the VSD into the RV. **C,** The right parasternal short-axis color flow Doppler study reveals systolic left-to-right shunting across the VSD into the right ventricular outflow tract (RVOT). **D,** Spectral Doppler recording through the VSD, showing turbulent high-velocity left-to-right flow in systole (QRS complex to T wave).

Today, cardiac catheterization is rarely conducted to diagnose VSD. However, if a patient is considered a surgical candidate, catheterization allows further delineation of the anatomic defect and estimation of the degree of shunting.[146] Additionally, catheter-based methods are now available to occlude some VSDs (see ch. 122). At catheterization, oximetry samples demonstrate a "step-up" in oxygen content between the RA and pulmonary artery. Intracardiac and pulmonic artery pressures are usually normal in dogs and cats with a small VSD. RV pressures are often elevated 5 to 15 mm Hg above the pressure in the pulmonary artery. More dramatic increases in RV systolic pressure indicate pulmonary hypertension or concurrent PS, and the development of elevated end-diastolic ventricular pressures and central venous pressure herald the onset of CHF. Bidirectional or right-to-left shunting is observed when RV systolic pressure reaches and exceeds LV systolic pressure. Anatomic changes of the semilunar valves or great vessels, especially of the aortic root, are best visualized by injection of contrast in the proximal aorta, which is also the preferred location to determine the presence and severity of aortic regurgitation.

Atrioventricular Septal Defect

A partial defect with a primum ASD and relatively normal AV valvular function should behave like an isolated ASD. When an AVSD includes significant AV valve malformation, there can be substantial valvular regurgitation, including mitral regurgitation, tricuspid regurgitation, and mitral regurgitation into the RA across the ASD. The classic appearance of a complete AVSD on echocardiography includes an ASD, inlet VSD, and a "floating," bridging AV valvular leaflet that serves both ventricles. Outcomes can include clinical signs of CHF or of pulmonary hypertension due to secondary pulmonary vascular disease. Some of these details have been described elsewhere.[132] One unique manifestation of an AVSD is the so-called double outlet right atrium (see below).

Natural History

The morbidity and mortality associated with ASDs and VSDs depend on defect size and location, magnitude and direction of shunt flow, and the presence of additional lesions. Spontaneous closure of small VSDs often

occurs in children, but this is seemingly an uncommon occurrence in cats and dogs.[149] Animals with uncomplicated and small defects that result in only modest shunting usually live a normal lifespan without ever developing recognizable clinical signs. Larger shunts causing moderate to severe cardiomegaly can lead to intractable CHF, although it is likely that most of these cases die once pulmonary vascular resistance falls and the animal is never seen by a veterinarian. Moderate to severe aortic regurgitation, an uncommon complication of VSD, presents a very substantial risk of left heart failure and shortened survival, although it might take more than five years for CHF to supervene. When VSD is associated with obstruction to RV outflow—from a double-chambered right ventricle, infundibular stenosis, or obstruction near the valvular level—right-to-left shunting can lead to signs similar to those of ToF. It is often difficult to predict outcome in very young animals with a VSD until they grow closer to adult size at 6 to 12 months of age. Cats with severe AVSD often develop marked cardiomegaly and biventricular CHF. Some will succumb at an early age (<2 years), while others survive much longer.[132] Animals that develop pulmonary hypertension (Eisenmenger's syndrome) have a guarded short-term and very guarded to poor long-term prognosis, although survival beyond 7 years is possible.

Clinical Management

Medical therapy, surgery, and catheter-based treatments are possible but rarely needed for small isolated ASDs or VSDs. Patients with CHF (unilateral or biventricular) should be treated as any other patients with volume-overloaded hearts, using furosemide, an angiotensin-converting enzyme (ACE) inhibitor, spironolactone, and pimobendan (see ch. 247). These patients are also candidates for palliative or definitive repair, although these procedures are not widely available to veterinary patients.

Closure is the definitive treatment for all atrial and ventricular septal defects. Open-heart correction is uncommonly attempted in animals because of the requirement for cardiopulmonary bypass or other techniques to arrest and perfuse the heart.[135,142,150-156] Palliative surgical treatment of a large VSD can be considered without bypass by applying a constrictive band around the main pulmonary artery. This technique creates a supravalvular PS and increases the RV systolic pressure, thereby reducing the magnitude of left-to-right shunting.[157] This procedure is recommended for dogs and cats showing signs of rapidly progressive cardiomegaly and overt or impending CHF. Overaggressive banding should be avoided, because it is often unnecessary, and if too tight, the band can result in pressure overload, acute right heart failure or, in surviving animals, right-to-left shunting. Alternatively, systemic arterial vasodilators can be administered to reduce systemic vascular resistance and the magnitude of left-to-right shunting.[158] Successful closure of both ASDs[159,160] and VSDs[161-164] can be accomplished using percutaneous closure devices that have been developed over the last decade as well (see ch. 122). Hybrid procedures involving thoracotomy and transmural cardiac delivery of the device with ultrasound guidance also have been reported.[165,166] As noted for reversed PDA, surgical correction of animals with Eisenmenger's syndrome should not be attempted. Restricted physical activity is probably the most prudent and effective strategy in such cases. Sildenafil citrate treatment can also improve clinical signs. Periodic phlebotomy may be useful in some patients developing extreme erythrocytosis. Maintenance of the PCV at 58% to 65% is recommended.

Valvular Dysplasia

Pulmonic and Aortic Valve Regurgitation

Pulmonic Regurgitation

While inconsequential pulmonic regurgitation is a common finding in dogs and cats of all ages,[167] primary congenital pulmonic regurgitation (PR) is an uncommon abnormality resulting from abnormal development of valve leaflets or dilation of the pulmonary artery annulus.[168] PR causes RV volume overload and eccentric hypertrophy. The main and proximal branches of the right and left pulmonary arteries enlarge to accommodate the concomitant increase in RV stroke volume. Isolated PR is often well tolerated. Congenital PR is more likely to cause CHF if pulmonary vascular resistance subsequently increases as a result of severe pulmonary parenchymal or vascular disease or if the tricuspid valve is also diseased. Trivial PR is often observed in dogs with a PDA, presumably from dilation of the main pulmonary artery. Most dogs with PS have mild valvular insufficiency, but severe concurrent PR is sometimes observed. PR of varying degrees of severity usually occurs as a result of surgery or balloon dilation to relieve PS. PR is a potential consequence of any disorder prompting the development of pulmonary hypertension.

Clinical features of PR include variable systolic (caused by increased outflow or another lesion) and diastolic murmurs best heard at the left heart base. This "to-and-fro" murmur should not be confused with the continuous murmur of PDA. ECGs from dogs with congenital PR may be normal or reflective of RV enlargement. Thoracic radiographs in severe, isolated PR usually show enlargement of the main pulmonary artery and RV, giving the erroneous impression of PS. Contrast injection into the main pulmonary artery using a small diameter catheter documents valvular insufficiency. Slow clearance of contrast from the dilated and thin-walled RV also supports a diagnosis of PR. Color flow Doppler echocardiography can elegantly demonstrate these same features noninvasively and permit visualization of the rudimentary or misshapen valve leaflets (see ch. 104). Furthermore, Doppler studies also aid in the recognition of pulmonary hypertension. When the velocity of the pulmonary regurgitant jet exceeds 2 m/s, pulmonary hypertension is the likely cause of the arterial dilation and valvular insufficiency. Treatment for congenital PR has not been described in companion animals. In dogs suffering from CHF, conventional medical therapy with diuretics, ACE inhibitors and pimobendan is a reasonable palliative approach (see ch. 247).

Aortic Regurgitation

Isolated congenital aortic regurgitation (AR, aortic insufficiency) is a rare disorder. It is occasionally detected in young or older dogs with idiopathic dilation of the aorta (annuloaortic ectasia). Mild to moderate AR has also been reported in dogs with bicuspid[169] or quadricuspid aortic valves[170,171] (Figure 250-15, *A* and *B* and Videos 250-10, 250-11, and 250-12). Because of the increasing application of Doppler echocardiography, AR is being recognized with increasing frequency as a complication of other cardiac malformations.[172,173] AR often accompanies SAS and has been observed with VSD, ToF, and following balloon catheter dilation for AS/SAS. The potential mechanisms for aortic valvular insufficiency in these conditions have been reviewed.[173] As in congenital PR, the murmur resulting from AR can be both systolic and diastolic (to-and-fro) and is best heard over the left hemithorax. However, many dogs with AR do not have an audible murmur. In contrast, when AR is audible, the valvular incompetency is generally severe. The diagnosis of clinically significant AR is supported by palpation of a hyperkinetic arterial pulse resulting from the combination of higher stroke volume and reduced diastolic pressures owing to diastolic run-off of aortic blood back into the LV. Eccentric to mixed hypertrophy of the LV develops in proportion to the severity of the insufficiency. Severe AR commonly results in left-sided CHF. Documentation of AR and estimation of its severity requires angiocardiography or, more practically, Doppler echocardiography. Definitive repair requires cardiac bypass surgery and valve replacement. Use of arterial vasodilators can reduce the regurgitant volume and may delay the onset of CHF but at the risk of reducing coronary perfusion. Treatment with diuretics, ACE inhibitors, and pimobendan are indicated if CHF is present (see ch. 247).

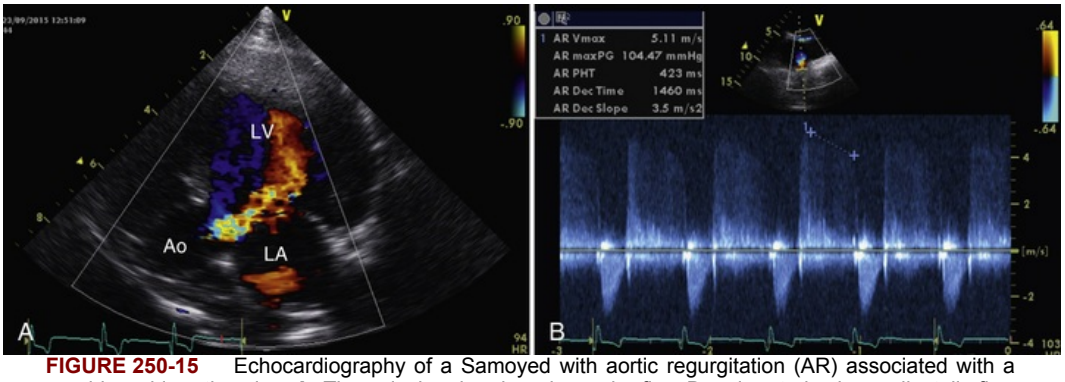

FIGURE 250-15 Echocardiography of a Samoyed with aortic regurgitation (AR) associated with a quadricuspid aortic valve. **A,** The apical 5-chamber view color flow Doppler study shows diastolic flow from the aorta into the LV. **B,** Spectral Doppler recording of the aortic insufficiency jet, demonstrating diastolic flow and a peak velocity of 5.11 m/s and a pressure half-time (PHT) of 423 ms.

Atrioventricular Valve Dysplasia

Congenital malformations of the mitral and tricuspid valves are reported in both cats and dogs. In cats, mitral valve dysplasia (MVD) is one of the most common congenital anomalies described. Consequences of these malformations include (1) mitral or tricuspid valve regurgitation (most common); (2) inflow obstruction (i.e.,

mitral or tricuspid valve stenosis); and (3) dynamic obstruction of the LVOT via inappropriate, systolic displacement of the mitral valve into the LVOT. Fixed obstruction of the LVOT has also been described from mitral malformation.[174] The pathophysiology and clinical course of congenital mitral regurgitation are similar to that described in acquired degenerative valvular disease in the dog (see ch. 251). Ebstein's anomaly is a congenital defect reported in dogs related to TVD, whereby the origins of the tricuspid valve leaflets are apically displaced into the RV.[21,175,176] It may or may not be associated with leaflet dysplasia.

Systolic anterior motion (SAM) of the mitral valve apparatus and dynamic LVOT obstruction in cats and dogs, long regarded solely as a manifestation of hypertrophic cardiomyopathy (see ch. 252 and 253), may be caused primarily by architectural changes in the mitral valve apparatus in some animals. When the primary disorder is valve dysplasia, concentric LV hypertrophy often resolves if the obstruction is abolished by treatment (beta-receptor blocking drugs).[177-179]

Pathogenesis

TVD has been shown to have a genetic basis in some of the most commonly afflicted breeds,[9,10,180] and in Labrador Retrievers an autosomal dominant mutation with incomplete penetrance has been mapped to chromosome 9.[10] A wide spectrum of congenital morphologic abnormalities of the mitral and tricuspid valves has been described, including shortening, rolling, notching, and thickening of the valve leaflets; incomplete separation of valve components from the ventricular or septal wall (failure of delamination); elongation, shortening, fusion, and thickening of the chordae tendineae; direct insertion of the valve edge into a papillary muscle; and atrophy, hypertrophy, fusion, and malpositioning of the papillary muscles and chordae tendineae.[175,181-185] The usual consequence of these changes is valvular insufficiency. Examples of mitral and tricuspid valve dysplasia are shown in Figures 250-16 and 250-17. Some dogs and cats with mitral or tricuspid dysplasia have a PFO or a concurrent ASD, resulting in left-to-right or right-to-left shunting.

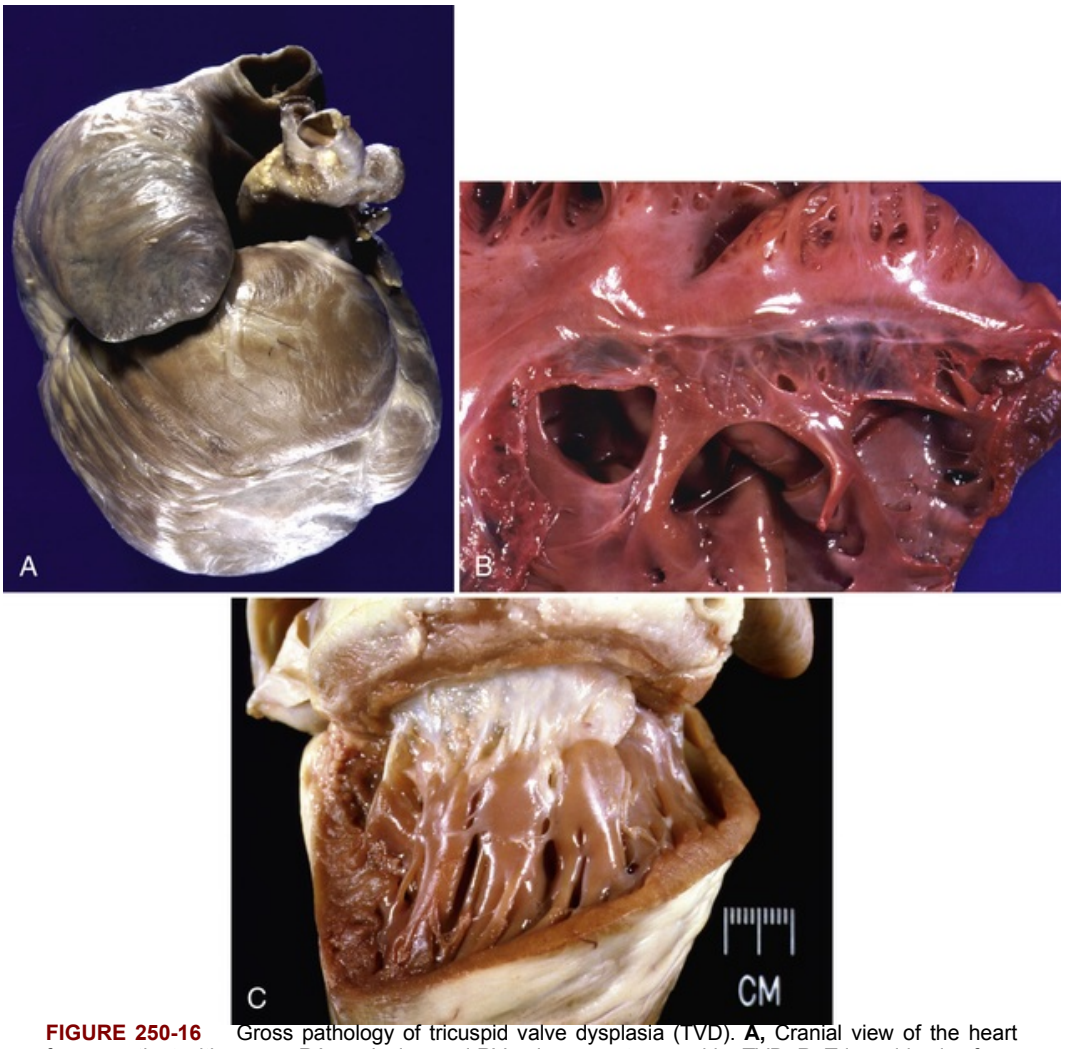

FIGURE 250-16 Gross pathology of tricuspid valve dysplasia (TVD). **A,** Cranial view of the heart from a patient with severe RA, auricular, and RV enlargement caused by TVD. **B,** Tricuspid valve from a 2-year-old Labrador with severe TVD. The edges of the valve leaflets insert directly into the papillary muscles and there is conspicuous absence and shortening of the chordae tendineae. The RA and RV are dilated. **C,** Curtainlike deformity of the tricuspid valve from a 2-year-old Samoyed with TVD and tricuspid stenosis. The tricuspid valve is thickened and opaque. There are multiple large and fused papillary muscles with short chordae tendineae.

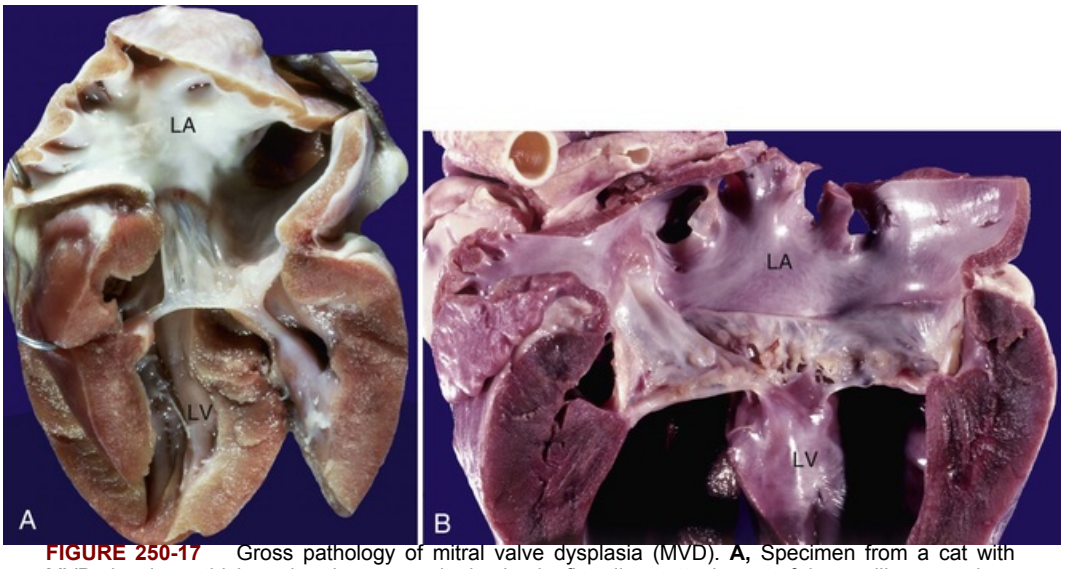

FIGURE 250-17 Gross pathology of mitral valve dysplasia (MVD). **A,** Specimen from a cat with MVD showing a thickened and opaque mitral valve leaflet, direct attachment of the papillary muscle to the leaflet edge, and LA enlargement. **B,** Specimen from a dog with MVD showing short chordal attachments from the LV papillary muscle to the leaflet edge, a thickened and nodular mitral valve leaflet, and marked LA enlargement.

Pathophysiology

The fundamental pathophysiologic abnormality of AV valve malformations is valvular insufficiency that produces volume overload and manifests as atrial dilation and eccentric hypertrophy of the affected ventricle. Some dogs and cats have survived for 8 years or more with relatively severe AV valve malformations, but more often CHF develops at a young age, especially with MVD. The development of atrial fibrillation is especially destabilizing to patients with these lesions. In some cases of TVD, cyanosis is observed as a consequence of right-to-left shunting across a PFO or ASD. Severe AV valve stenosis limits cardiac output so that hypotension, syncope, or collapse with exertion can be observed. Tachycardia abbreviates diastole and increases the transvalvular diastolic gradient further, explaining exercise intolerance. Pulmonary hypertension and right-sided CHF frequently develop secondary to severe mitral stenosis as a consequence of chronic elevations in LA pressure; this is more common in cats. As a result, some patients initially presenting with signs of left-sided CHF from mitral stenosis can re-present months later with signs of right-sided CHF. As indicated above, dogs and cats with AV valvular dysplasia are predisposed to atrial fibrillation as well as paroxysmal or sustained supraventricular tachycardias (see ch. 248); their onset typically results in sudden clinical deterioration.

Clinical Findings

Increased prevalence of MVD and TVD in several breeds (see Table 250-1) indicates that genetic factors are likely involved in the pathogenesis. Mitral valve stenosis, in particular, is common in Bull Terriers, where it often occurs together with valvular aortic stenosis.[186] Cats of all breeds, Great Danes, German Shepherds, Bull Terriers, Golden Retrievers, Newfoundlands, Dalmatians, and Mastiffs are predisposed to MVD.[182,187,188] Although TVD has been described in cats, it appears to occur most commonly in large male dogs and especially in the Labrador Retriever breed.[189]

Dogs and cats with valvular dysplasia can appear clinically well. Clinical signs arise from exertional fatigue, or right-sided, left-sided, or biventricular CHF, pulmonary hypertension, or right-to-left shunting. Hemoptysis can occur with mitral stenosis. The hallmark of valvular insufficiency is a holosystolic murmur heard best over the affected valve area. A loud gallop may also be detected.[187] A soft, late diastolic murmur and opening "snap" is sometimes auscultated in dogs or cats with valvular stenosis, but this finding is often absent or missed. In cases of TVD, murmur intensity may not always reflect the severity of disease. In severe cases, a murmur may be very soft or absent as the valve offers no resistance to regurgitant blood flow. Jugular venous distension and pulsations are common findings in cases of TVD, and hepatomegaly and ascites are present in dogs that present with right-sided CHF. Animals with right-sided CHF often have a poor body

condition.

Splintered QRS complexes (e.g., Rr′, RR′, rR′, rr′) are a distinctive and common ECG finding in dogs and cats with TVD (Figure 250-18).[68] Right heart enlargement patterns may also manifest. Tall or wide P waves are observed with all types of valvular dysplasia, but ventricular enlargement patterns are mainly limited to animals with regurgitant physiology and are not observed with isolated valve stenosis, except when pulmonary hypertension develops secondary to mitral stenosis. Atrial arrhythmias, including atrial premature complexes, atrial tachycardia, and atrial fibrillation (see Figure 250-18), are often recorded. The pattern of chamber enlargement on thoracic radiographs generally reflects the involvement of the affected valve and resulting physiologic consequences (Figure 250-19). In cases of TVD, the degree of cardiomegaly is often impressive, and may resemble the globoid appearance of pericardial effusion. The possibility of valvular stenosis should be considered whenever the atrium is markedly dilated without enlargement of the ipsilateral ventricle.

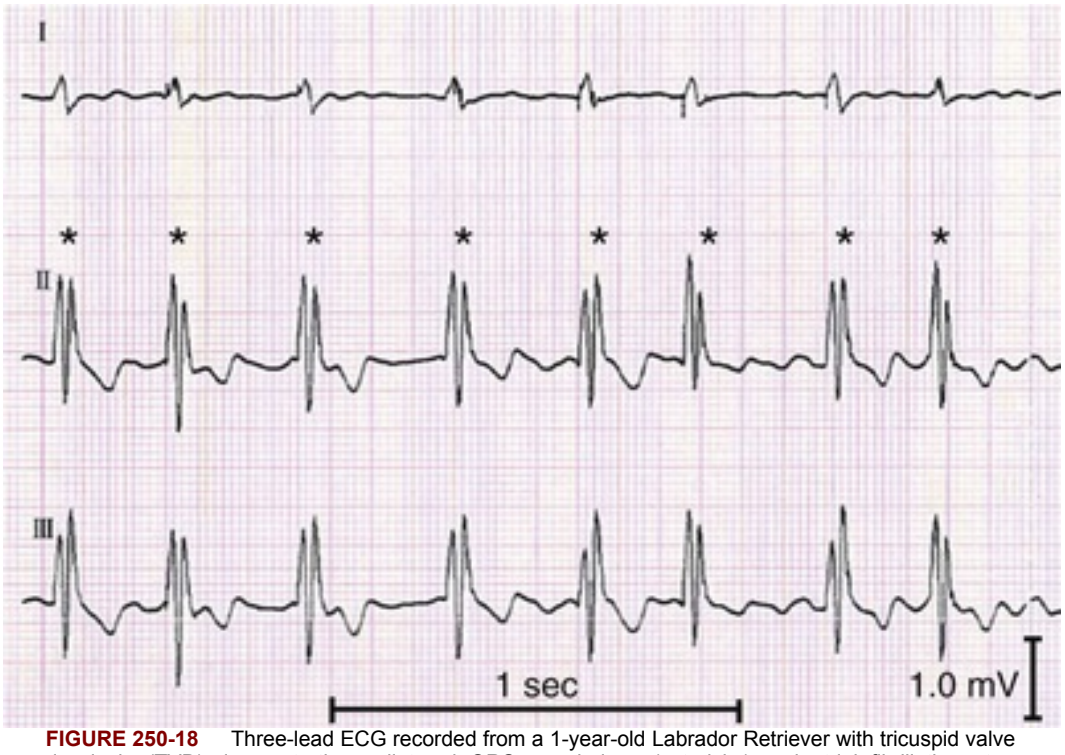

FIGURE 250-18 Three-lead ECG recorded from a 1-year-old Labrador Retriever with tricuspid valve dysplasia (TVD) demonstrating splintered QRS morphology (asterisks) and atrial fibrillation at a ventricular rate of 200 depolarizations per minute. Sensitivity 10 mm/mV at a paper speed of 50 mm/sec.

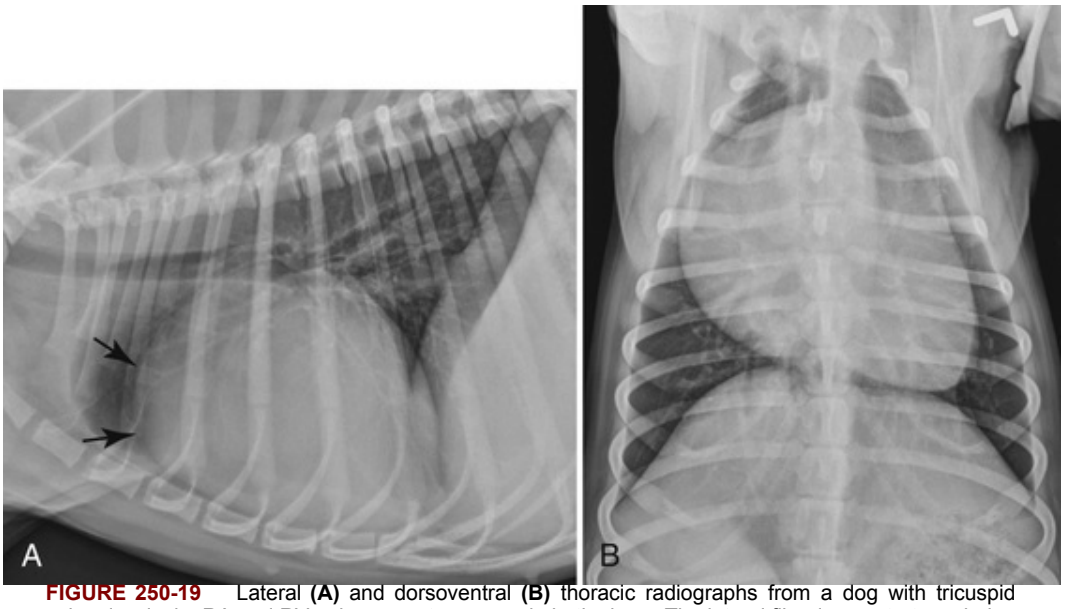

FIGURE 250-19 Lateral **(A)** and dorsoventral **(B)** thoracic radiographs from a dog with tricuspid valve dysplasia. RA and RV enlargement are seen in both views. The lateral film demonstrates a bulge in the cranial waist (arrows), most likely caused by right auricular enlargement.

Definitive diagnosis of AV valve malformation requires echocardiography (see ch. 104). Abnormal location, shape, motion, or attachment of the valve apparatus is easily observed with this technique (Figure 250-20, *A-D* and Videos 250-13 and 250-14). With valve insufficiency, volume overloading of the respective atrium and ventricle can be seen, and Doppler studies demonstrate regurgitant jets streaming from the ventricle into the atrium through the incompetent valve (Video 250-15). With isolated valve stenosis, the ventricle appears small and the atrium enlarged, and the thickened valve leaflets can be observed to "dome" into the ventricle during diastole. Color flow Doppler studies in AV stenosis show a high-velocity jet (often >2.0 m/sec) entering the LV or RV during early diastole, and a prolonged pressure halftime, as determined by measurement along an abnormally shallow E-F slope. With MVD and dynamic LVOT obstruction, variable degrees of concentric LV hypertrophy (see Figure 250-20, *A*), and high-velocity turbulent flow within the LVOT accompanied by a posterolaterally directed jet of mitral valve insufficiency can be seen. Continuous wave Doppler interrogation of the LVOT in such cases will display a dynamic and labile pressure gradient secondary to SAM of the mitral valve (see Figure 250-20, *B*). TVD is identified by a marked apical dislocation of the tricuspid valve insertions (see Figure 250-20, *C* and *D*). In human Ebstein's anomaly, apical dislocation with atrialization of the proximal part of the RV is observed. However, the diagnosis of apical dislocation should be made with caution as the normal insertion point of the tricuspid valves is slightly more apical than the normal insertion point of the mitral valve and the reason for apical displacement is typically a failure of the valve to delaminate from the walls. Confirmation of Ebstein's anomaly is best made at cardiac catheterization, where a ventricular electrogram is recorded along with an atrial pressure tracing within the supravalvular chamber.

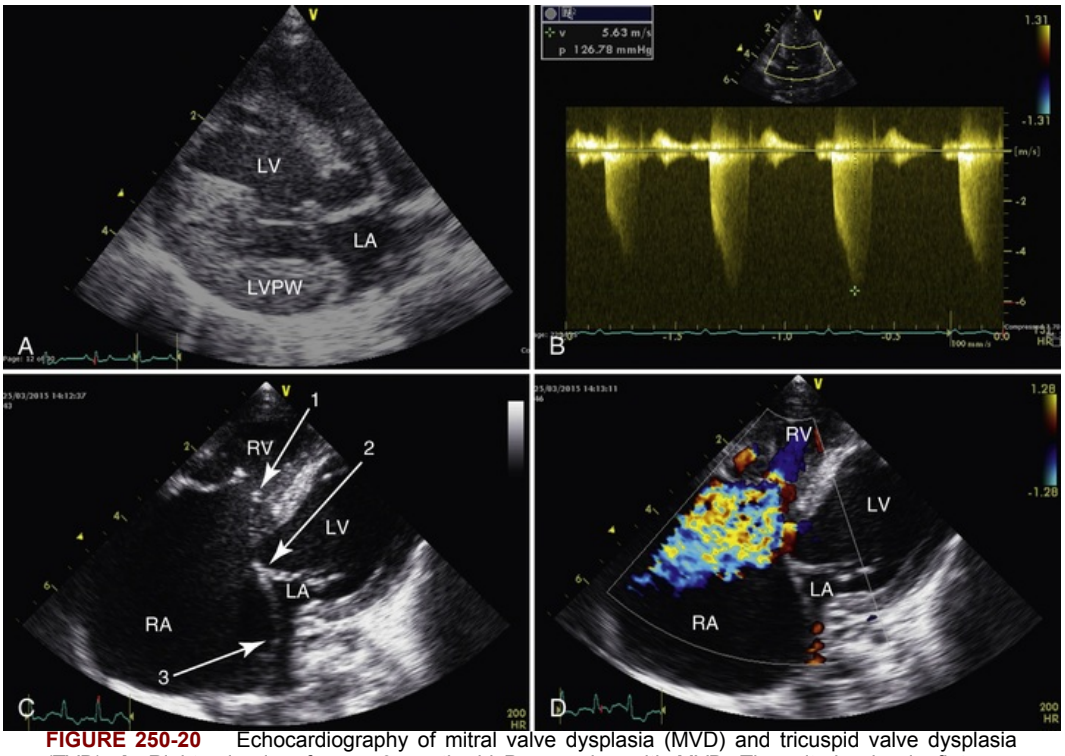

FIGURE 250-20 Echocardiography of mitral valve dysplasia (MVD) and tricuspid valve dysplasia (TVD). **A,** Right-axis view from a 6-month-old Pomeranian with MVD. The mitral valve leaflets are markedly thickened and the chordae tendineae are shortened. The LV (especially the LV posterior wall) is concentrically hypertrophied. **B,** Continuous wave Doppler study from the same dog demonstrating dynamic LVOT obstruction. The cursor is aligned along a systolic signal that abruptly increases in velocity at the time of systolic anterior motion of the mitral valve. **C,** The left apical view from a dog with tricuspid valve dysplasia. The origin of the tricuspid valve is displaced apically and the septal leaflet is fused to the interventricular septum (1). The origin of the mitral valve leaflet (2) is shown for comparison. The atrial septum is bulging severely to the left (3). **D,** The left apical color flow Doppler study from a dog with severe tricuspid regurgitation caused by TVD.

Although echocardiography is diagnostic, cardiac catheterization and angiography can also be performed, especially if some intervention is planned. Diastolic pressure gradients (valve stenosis) and varying degrees of ventricularization of atrial waveforms (from severe valve insufficiency) can be recorded. Angiographic visualization of valvular insufficiency is best appreciated by ventricular injections of contrast, while valve stenosis is best demonstrated following an atrial injection, which in the case of mitral stenosis often requires a transseptal puncture.

Natural History

The morbidity and mortality associated with mitral or tricuspid dysplasia depend on the form and severity of valvular dysfunction, and the presence of additional lesions. Animals with small insufficiencies usually live a normal lifespan without ever developing recognizable clinical signs. Large insufficiencies and/or severely stenotic valves causing moderate to severe cardiomegaly often lead to atrial arrhythmias and intractable CHF. These outcomes are not invariable, however, and survival to six or eight years of age is not uncommon, especially with TVD.

Clinical Management

Repair of the affected valve has been performed, and surgical replacement of dysplastic AV valves has been successfully accomplished in dogs with mitral[190-192] or tricuspid dysplasia.[193] Cardiac bypass is required for these infrequently performed procedures. Balloon valvuloplasty has been described in dogs with mitral[194,195] and tricuspid[196,197] stenosis, and is further discussed in ch. 122. Medical treatment is instituted once heart failure develops; treatment of CHF caused by valvular insufficiency largely consists of diuretics, ACE inhibitors, and pimobendan (see ch. 247). The value of any "preventative" therapy is unknown. In dogs with TVD and refractory heart failure, periodic paracentesis despite concurrent medical therapy is often needed (see ch. 90 and 102). Inasmuch as tachycardia is poorly tolerated in AV valve stenosis patients, every effort should be made to avoid stress and to restrict exercise. Administration of beta-blockers, calcium channel blockers, and/or digoxin is helpful in some cases for the management of atrial fibrillation or other supraventricular tachyarrhythmias (see ch. 248). Animals with significant LVOT obstruction secondary to SAM of the mitral valve, regardless of the presence or absence of clinical signs, are commonly treated with beta-blockers (such as atenolol), which has been reported to successfully alleviate the dynamic LVOT obstruction.[177-179] Some patients tolerate serious defects surprisingly well for many years. In other cases, there is rapid progression to heart failure and death.

Ventricular Outflow Obstructions

Pulmonic Stenosis

Pulmonic stenosis is the third most common congenital heart defect in dogs (see Table 250-2)[3,167] and it is occasionally recognized in cats.[198-202] PS occurs in the majority of cases as an isolated heart defect, but it is also frequently accompanied by additional cardiac anomalies, such as TVD. Congenital outflow tract obstructions of the right heart can develop in the subvalvular and supravalvular regions, but primary malformation of the pulmonic valve (dysplasia) is the most frequently observed defect in dogs. Patterson and associates, who studied the heritability and pathology of pulmonic valve dysplasia in the Beagle, initially suggested a polygenic mode of transmission for this defect.[203] These breeding studies did not, however, exclude the possibility of a single gene mechanism with variable penetrance. The pattern of inheritance of PS has not been studied in other predisposed dog breeds or in cats.

Pathology

Valvular lesions consist of varying degrees of valve thickening, leaflet fusion, and hypoplasia of the valve annulus components. While some dogs manifest a thin, dome-shaped valve with a central orifice (Figure 250-21), many dogs have more complicated lesions resembling atypical PS in children.[47,203,204] The valve leaflets are often thickened, misshapen, or fused (see Figure 250-21). In addition to thickening and commissural fusion, the distal edges of the leaflets can be tethered to the pulmonary arterial wall, mimicking a supravalvular obstruction. The annulus of the pulmonic valve is hypoplastic in some dogs, further narrowing the area available for RV ejection. Histologic abnormalities include thickening of the valve spongiosa and the presence of bands of fusiform cells in a dense collagen network. These changes are thought to represent overproduction of normal valve elements or a failure of conversion of the cushion-like embryonic valve primordia. Some dogs with valve dysplasia also have a fibrous ring just below the valve leaflets accompanying the valvular changes. In other dogs and cats[198] the obstructive lesion occurs in the infundibular region of the RVOT. On occasion, the RVOT is partitioned from the body (inflow region) of the RV by a well-developed, fibromuscular ridge, resulting in an anomaly referred to as double- or dual-

chambered right ventricle or primary infundibular stenosis.[205,206] The distinction between infundibular PS and double-chambered right ventricle is not always clear, especially in cats.[198] Supravalvular PS is uncommon, and in the authors' experience, is most often observed in Giant Schnauzers. Subvalvular PS has been associated with anomalous development of the coronary arteries, especially in English Bulldogs and in Boxers.[207,208] In this condition, the coronary circulation is derived from a single ostium located in the right aortic sinus of Valsalva, and both left and right coronary arteries branch from a single large coronary artery (Figure 250-22). From this location, the anomalous left coronary artery encircles the RVOT just below the pulmonic valve. Whether this lesion contributes to the subvalvular component of this malformation or is simply a comorbidity is undecided as it has been observed in Bulldogs without PS. Regardless, it is clinically relevant because vigorous balloon valvuloplasty of the subvalvular lesion has been associated with sudden death (see Figure 250-22).

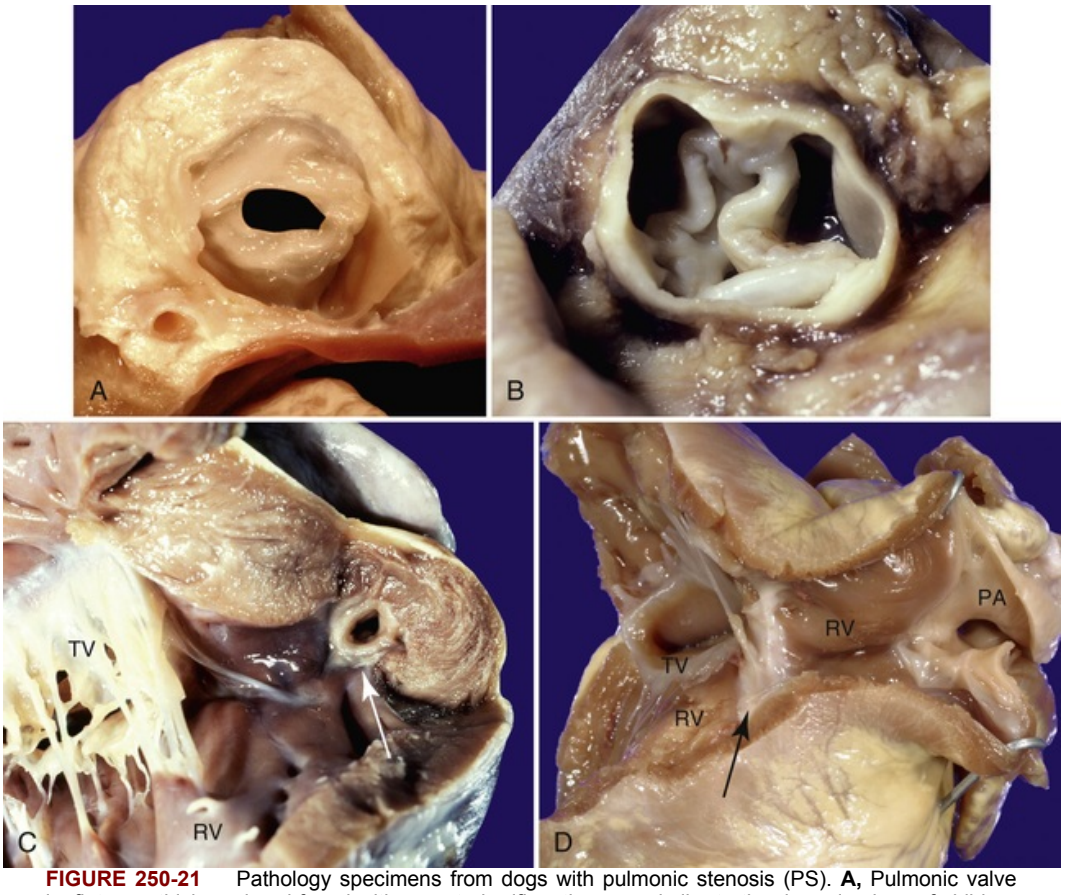

FIGURE 250-21 Pathology specimens from dogs with pulmonic stenosis (PS). **A,** Pulmonic valve leaflets are thickened and fused with a central orifice; they are similar to the domed valves of children with PS. **B,** Very thick (dysplastic) valve cusps in a dog with PS. **C,** Fibrous ring of subvalvular PS (arrow). **D,** Fibrous ring (arrow) in the infundibular area of the RV several centimeters below the pulmonic valve and pulmonary artery (PA). *TV,* Tricuspid valve.

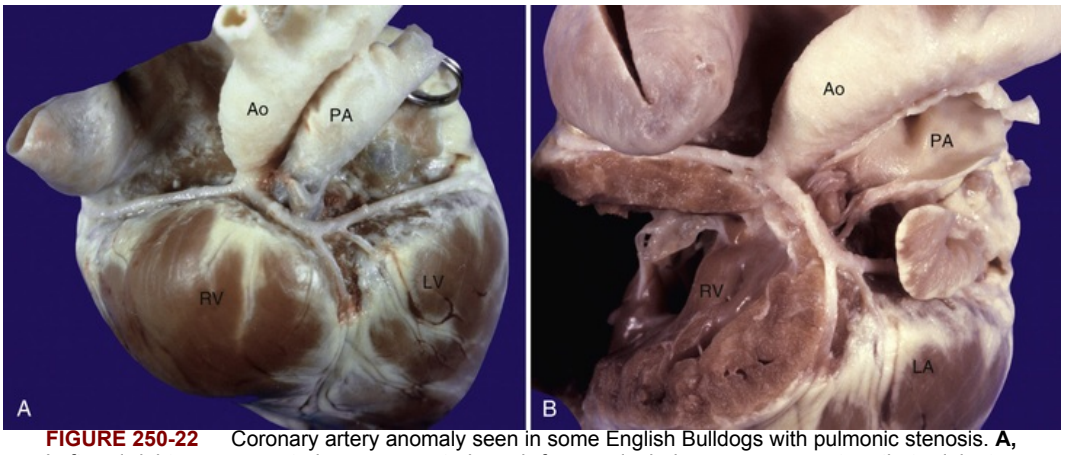

FIGURE 250-22 Coronary artery anomaly seen in some English Bulldogs with pulmonic stenosis. **A,** Left and right coronary arteries are seen to branch from a single large coronary artery that originates from the right aortic sinus of Valsalva. From this location, the left coronary artery encircles the RVOT just below the level of the pulmonic valve. **B,** Anterior walls of the pulmonary artery and RV have been removed to show the hypoplastic annulus, the diminutive proximal pulmonic artery (PA), and the crowded and thickened pulmonary valve leaflets. *Ao,* Aorta.

Increased resistance to systolic ejection results in concentric RV hypertrophy, which likely begins *in utero* and develops in proportion to the severity of the obstructing defect. While this compensatory response serves to normalize wall stress, it can have deleterious consequences on RV diastolic function as well as myocardial oxygen supply and demand. In some dogs with PS, secondary hypertrophy of the infundibular region of the RVOT contributes to a mainly dynamic outflow tract obstruction, particularly evident during exercise or stress. The presence of this additional mechanism of obstruction can complicate the clinical outcomes of surgical valvotomy or interventional balloon valvuloplasty. Other cardiac defects can complicate the physiology and alter the clinical presentation and prognosis of patients with PS. For example, PS and TVD can be a particularly injurious combination. Insofar as the volume of tricuspid regurgitation is a function of the size of the regurgitant orifice (severity of dysplasia) and the RV pressure (severity of PS), severe tricuspid regurgitation tends to develop in affected dogs, leading to intractable right-sided heart failure. Atrial fibrillation can also destabilize the patient with PS.

Meticulous ultrasonic examination, often using contrast echocardiography, will reveal that patent connections between the right and left heart occur in a substantial percentage of dogs with PS, and some dogs with severe PS become cyanotic as a result of right-to-left shunting through an ASD, PFO, or VSD. Some of these defects and consequences are discussed more thoroughly under the heading of ToF.

Pathophysiology

Obstruction to RV outflow increases resistance to ejection, causing a proportional increase in ventricular systolic pressure. Concentric hypertrophy of the RV develops in an attempt to normalize wall stress. During systole, blood ejected from the RV accelerates as it traverses the obstructive orifice. Blood flow velocity increases and becomes turbulent distal to the obstruction. A poststenotic dilation develops in the main pulmonary artery as the turbulent jet of blood decelerates and expends some of its kinetic energy against the vessel wall.

Concentric hypertrophy reduces RV diastolic compliance, impairs ventricular filling, and often results in elevated RA pressure. Tricuspid regurgitation from progressive ventricular dilation, valvular dysplasia, or a combination of these factors, can contribute to further increases in atrial pressure. As RA pressure approaches 15 mm Hg, jugular distension, ascites, pleural effusion, and other signs of right-sided CHF develop. Syncope secondary to transient hypotension is presumed to develop as a consequence of reduced cardiac output (secondary to bradycardia or worsening of a dynamic infundibular obstruction) and in combination with peripheral arteriolar vasodilation (especially with or in anticipation of exercise). Stimulation of mechanoreceptors in the pressure-overloaded RV might also trigger reflex bradycardia and vasodilation. Reduced right coronary blood flow has been documented in some dogs with PS and may contribute to the development of syncope due to arrhythmias, exercise intolerance, and myocardial failure. On rare occasions, severe septal hypertrophy and diminished LV size caused by PS results in dynamic LV outflow tract obstruction.[209]

Clinical Findings

PS is common in certain breeds of dogs including Beagles, Samoyeds, Chihuahuas, English Bulldogs, Miniature Schnauzers, Cocker Spaniels, Boykin Spaniels, Labrador Retrievers, Mastiffs, Chow Chows, Newfoundlands, Basset Hounds, and other terrier and spaniel breeds (see Table 250-1).[25,105,108,210] Miniature Doberman Pinschers also seem predisposed. Most dogs with PS are asymptomatic during the first year of life when the condition is usually discovered via detection of a heart murmur. Approximately 35% of dogs with severe disease demonstrate clinical signs, which can include exertional fatigue, syncope, or ascites.[211] Signs of right-sided CHF, such as ascites, are most often reported in dogs that are older.[204] In cats with severe PS, exertional dyspnea and lethargy may be present.[199] Cyanosis may be noted when PS is complicated by right-to-left shunting across a PFO or coexisting ASD or VSD.

The most prominent physical examination finding of PS is a systolic ejection murmur that is best heard over the left heart base and that often radiates dorsally. In some cases the murmur is heard well on the right cranial thorax. In dogs with concurrent severe pulmonic valvular insufficiency, the systolic ejection murmur is accompanied by a soft decrescendo diastolic murmur heard best just ventral to the pulmonic valve region. Less often a systolic ejection click is detected which presumably indicates a fused but mobile valve. A holosystolic murmur of tricuspid regurgitation may be noted over the right hemithorax. Large-amplitude jugular pulses may result either from a giant a wave caused by atrial contraction into the stiff RV or from cv waves indicating significant tricuspid regurgitation. Jugular venous distension and prominent jugular pulses are evident in most dogs with right heart failure and ascites. Peripheral arterial pulses are usually normal.

Evidence of RV enlargement is usually present on the ECG unless the lesion is very mild.[66,212,213] Right axis deviation, and deep S waves in leads I, II, III, aVF, and the lower left precordial chest leads (V2, V4) are common indicators of right heart enlargement (Figure 250-23). Thoracic radiographs typically show a prominent right heart and poststenotic dilation of the main pulmonary artery (Figure 250-24).[61,105,204,214] These changes are usually most evident on the dorsoventral view. Additional and more variable findings include dilation of the proximal left pulmonary artery, diminished size of the pulmonary vasculature, and enlargement of the caudal vena cava.

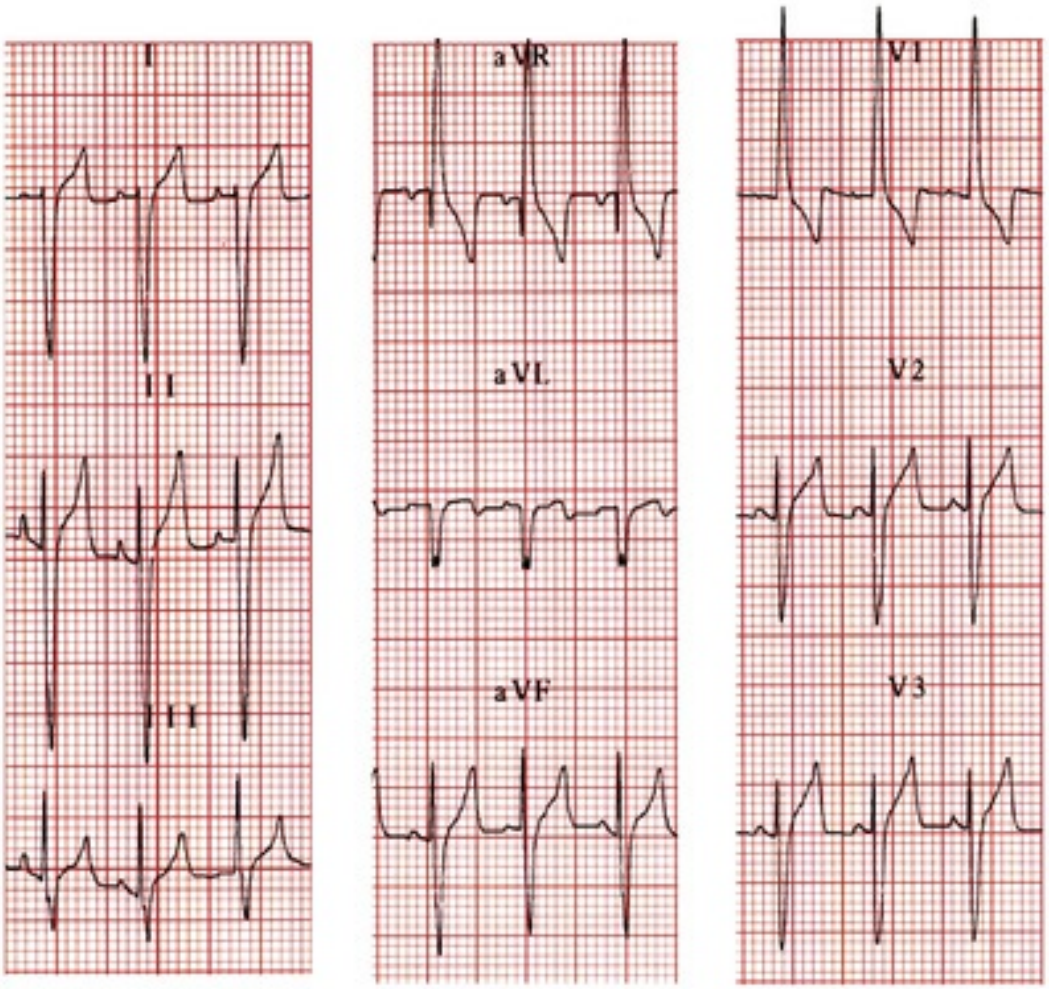

FIGURE 250-23 ECG from a dog with pulmonic stenosis showing a typical RV enlargement pattern. The mean electrical axis is shifted to the right (−130°), and there are prominent S waves in leads I, II, aVF, V2, and V3 (V4).

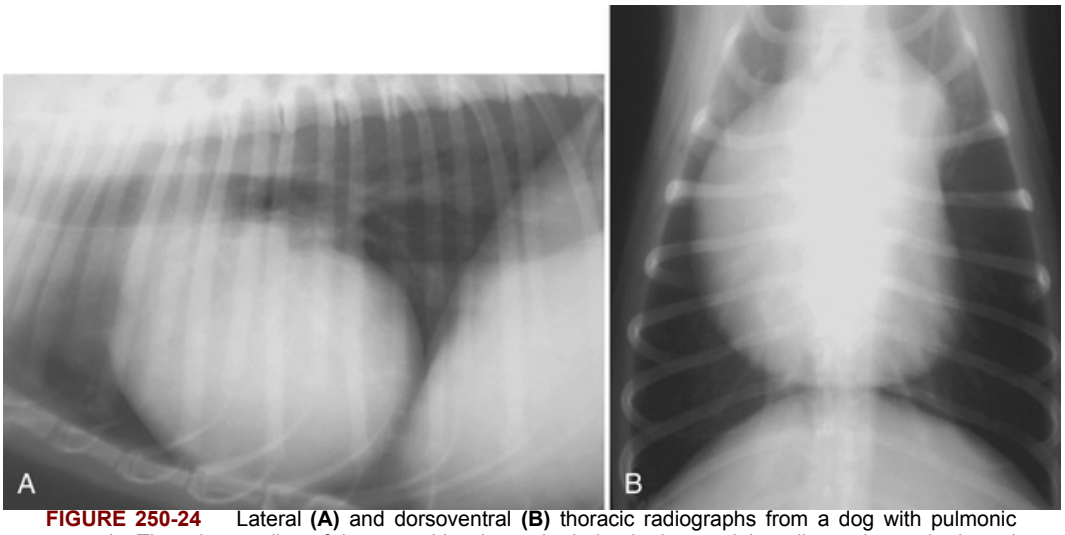

FIGURE 250-24 Lateral **(A)** and dorsoventral **(B)** thoracic radiographs from a dog with pulmonic stenosis. There is rounding of the sternal border and a bulge in the cranial cardiac waist on the lateral view. There is right heart enlargement and a bulge in the main PA segment on the dorsoventral view. The pulmonary vessels are diminished even in the absence of a right-to-left shunt.

Echocardiography is the most commonly used method for confirming a diagnosis of PS. M-mode and 2D imaging typically show concentric hypertrophy of the RV, increased prominence of the papillary muscles, deformity in the region of the obstruction(s), narrowing of the RVOT, varying degrees of RA enlargement, and poststenotic dilation of the main pulmonary artery (Figure 250-25).[76,215] Of the four cardiac valves, the pulmonic valve is usually the most difficult to visualize clearly by transthoracic echocardiography. Thus, it might be impossible to visualize the exact location and nature of the obstruction in some dogs without additional imaging modalities such as transesophageal echocardiography. It is often particularly difficult to identify a discrete subvalvular obstruction in close proximity to the pulmonic valve. The pulmonic valve leaflets are typically thickened, often fused, and appear to dome upwards into the pulmonary artery during systole (see Figure 250-25). The distal edges of the leaflets can appear partially tethered to the pulmonary artery wall, creating an hourglass appearance relative to the sinuses. This is not supravalvular stenosis *per se*, but does indicate a supravalvular component to the stenotic, dysplastic valve. In comparison, isolated supravalvular obstruction with otherwise-normal pulmonic valves is considered rare. When present, hypoplasia of the pulmonic valve annulus can further obscure the valve anatomy and confound the treatment. Color flow Doppler echocardiography is useful in establishing the anatomic location of the obstruction, as a region of flow acceleration changes to a turbulent, high-velocity jet that can usually be seen emerging just distal to the obstructive orifice (see Figure 250-25). Careful inspection of the coronary artery anatomy, especially as these vessels arise from the aortic sinuses, can help identify cases of coronary artery anomalies. This is particularly important with subvalvular PS in Boxers and English Bulldogs (Figure 250-26). Mild to moderate pulmonic valve insufficiency is also apparent in many dogs affected with valvular PS.

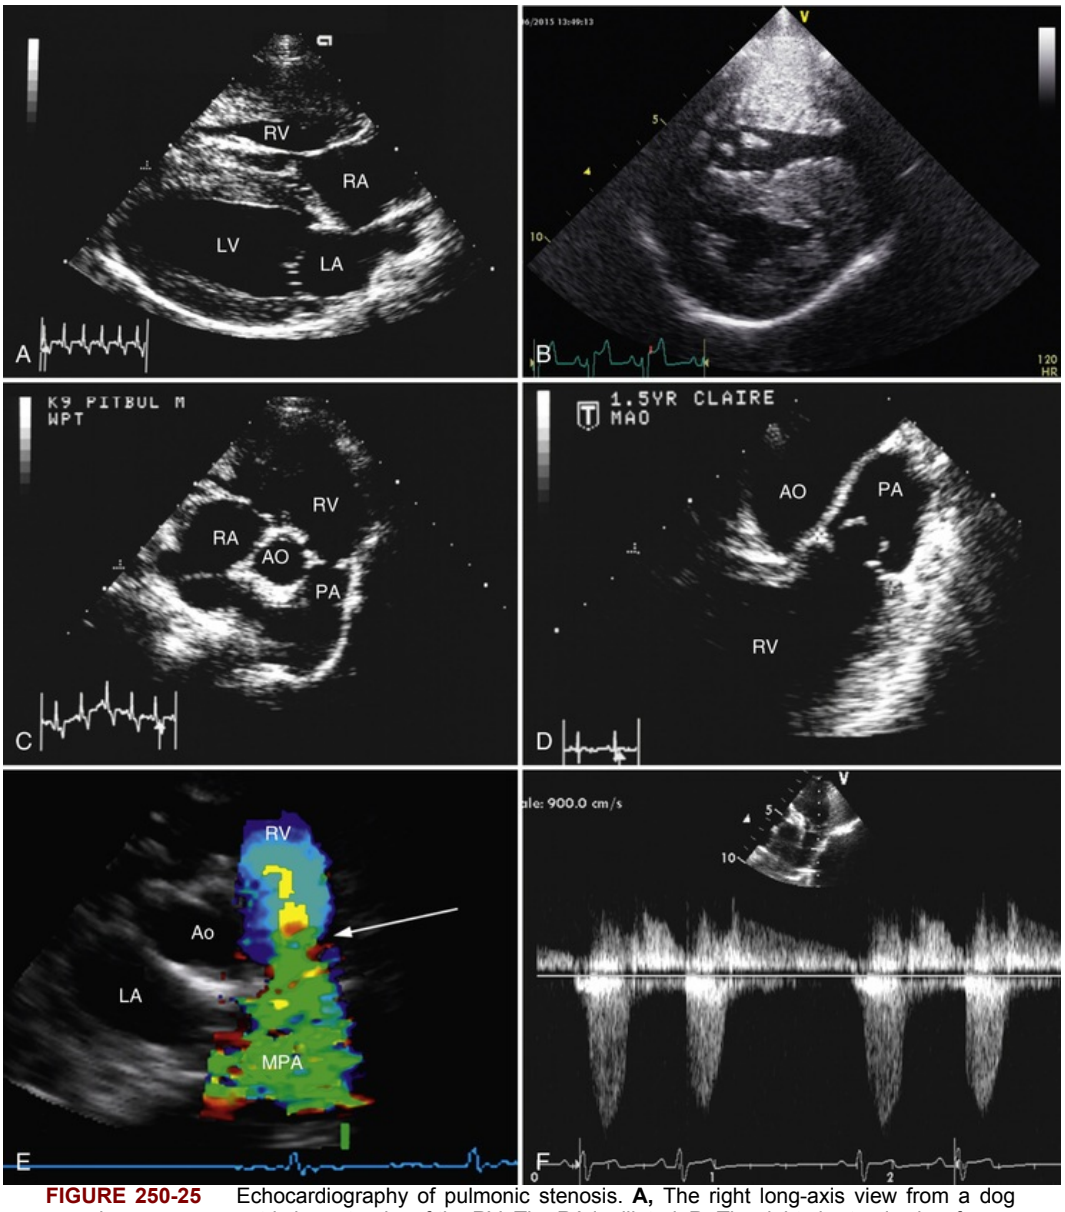

FIGURE 250-25 Echocardiography of pulmonic stenosis. **A,** The right long-axis view from a dog reveals severe concentric hypertrophy of the RV. The RA is dilated. **B,** The right short-axis view from a dog shows flattening of the interventricular septum and RV concentric hypertrophy caused by pressure overload. **C,** The right short-axis view of the heart base from a dog with valvular PS shows thickened pulmonic valves. There is a poststenotic dilation of the pulmonary artery (PA). **D,** Transesophageal ultrasound of a young Rottweiler with valvular PS. The pulmonic valve leaflets can be seen doming into the PA during systole. **E,** The color flow Doppler study in a dog shows high velocity and turbulent blood flow moving from the RV through the stenosis (arrow) and into the main pulmonary artery (MPA). **F,** A continuous-wave Doppler tracing obtained from a view similar to **E** shows high-velocity (5.0 m/s) systolic flow through the obstruction. The presence of pulmonic insufficiency is also noted during diastole. *Ao,* Aorta; *RA,* right atrium; *RV,* right ventricle.

FIGURE 250-26 Echocardiography of a Bulldog with subvalvular pulmonic stenosis (PS) associated with a coronary artery abnormality. The right short-axis view shows an aberrant coronary artery (arrow) arising from the aorta (Ao) and extending along the subvalvular region of the right ventricular outflow tract (RVOT) just below the pulmonic valve (arrowhead). The main pulmonary artery (PA) shows a poststenotic dilation.

To accurately quantify the severity of the obstruction, the peak velocity of the blood flow jet must be recorded on a spectral Doppler tracing acquired with the continuous-wave Doppler beam in parallel alignment with the direction of flow (see Figure 250-25 and ch. 104). As a general rule, Doppler-derived gradients are 40% to 50% higher than the gradient measured during cardiac catheterization in an individual dog, mainly due to general anesthesia needed for the latter procedure.[216] In addition, hemodynamic studies typically indicate the severity of obstruction as a peak-to-peak pressure gradient, and such measures are almost always lower than the instantaneous peak pressure gradient calculated from Doppler measures of peak flow velocity.[75] Underestimation of the gradient in the awake patient is usually caused by excessive angle of incidence between the ultrasound beam and the pathologic flow pattern. Overestimation might be more common and is due to spectral recordings that are overpowered during ultrasound transmit and overgained during the receiving phase. The RV systolic pressure can be estimated by subtracting a normal PA systolic pressure (20 to 25 mm Hg) from the pressure gradient as PA pressure is invariably normal in cases of isolated PS. In dogs with both dynamic (infundibular) and fixed (valvular) stenosis, Doppler interrogation of the outflow tract and pulmonary artery can produce a tracing that displays the temporal and velocity relationship between the two components of the stenosis. Doppler interrogation of the right heart can also identify any coexisting tricuspid valve insufficiency, and RV systolic pressure can also be estimated using the Bernoulli relationship and assuming the RA pressure is 0 to 5 mm Hg (in dogs without CHF). This approach offers a quality control on the estimate obtained from RV outflow tract signal. Measuring the velocity of this regurgitant jet is particularly helpful for assessing the severity of the PS obstruction when it is not possible to attain proper alignment with flow through the outflow tract.

Angiocardiography is often performed just before balloon valvuloplasty (Video 250-16) or to clarify right heart anatomy in anticipation of surgery (see ch. 122). Such studies clearly demonstrate the anatomic location of the obstruction(s), the degree of RV hypertrophy, presence of tricuspid regurgitation, and the poststenotic dilation of the pulmonary artery. The angiographic features of valvular stenosis consist of any combination of the following: narrowing at the immediate base of the valve sinuses, asymmetrical valve sinuses, hypoplasia of the annulus or a valve sinus, thickening of individual valve leaflets producing a lucent filling defect,

narrowing of the contrast column with a central or asymmetric jet of contrast observed within a narrowed valve orifice, systolic doming of the valve (indicating fusion of the commissures), or supravalvular leaflet tethering (Figure 250-27).[203,204] Dynamic muscular obstruction of the RV infundibulum is often visible in dogs with PS (Figure 250-28). The term double-chambered right ventricle is applied when the RV is divided into a low-pressure region (the infundibulum) and a region of high pressure (the apex and inlet portion of the RV) by a muscular or fibromuscular ridge deep in the infundibulum (Figure 250-29). Some confusion can develop between this lesion and a subvalvular PS that is not immediately adjacent to the valve leaflets. LV angiography or coronary arteriography should be performed when abnormalities of the left heart or coronary circulation are suspected. Such studies must be performed whenever surgery or balloon valvuloplasty is contemplated in an English Bulldog or Boxer dog. Even in breeds at lower risk for coronary anomalies, the "follow through" levophase of the right ventriculogram can be instructive by identifying discrete right and left coronary arteries. Enlargement of the right coronary artery is an expected finding in all dogs with PS and well-developed RV hypertrophy.

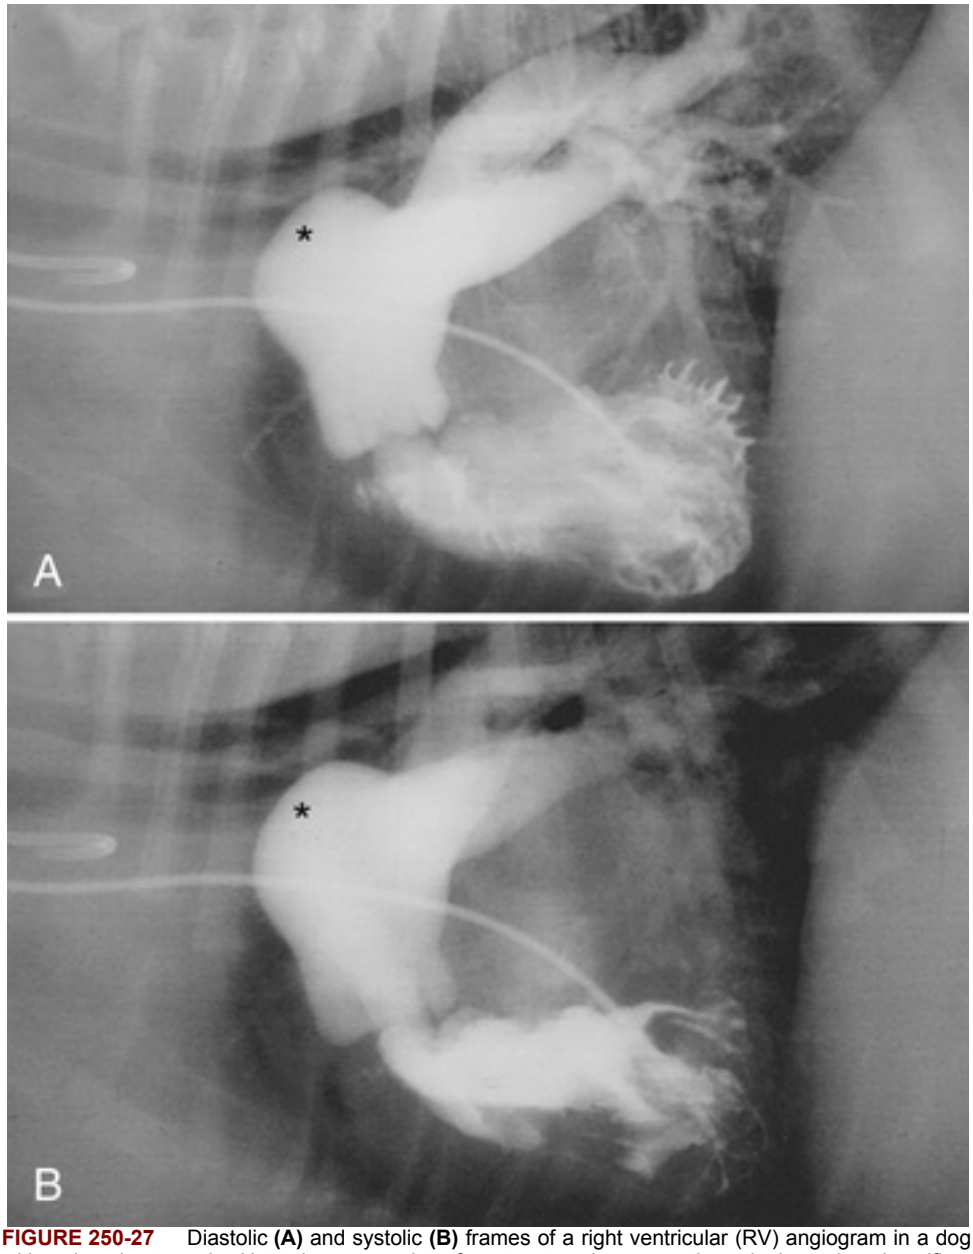

FIGURE 250-27 Diastolic **(A)** and systolic **(B)** frames of a right ventricular (RV) angiogram in a dog with pulmonic stenosis. Note the narrow jet of contrast as it passes through the pulmonic orifice. Poststenotic dilatation (asterisk) of the pulmonary artery is visible in both frames, as is hypertrophy of the RV wall and papillary muscles.

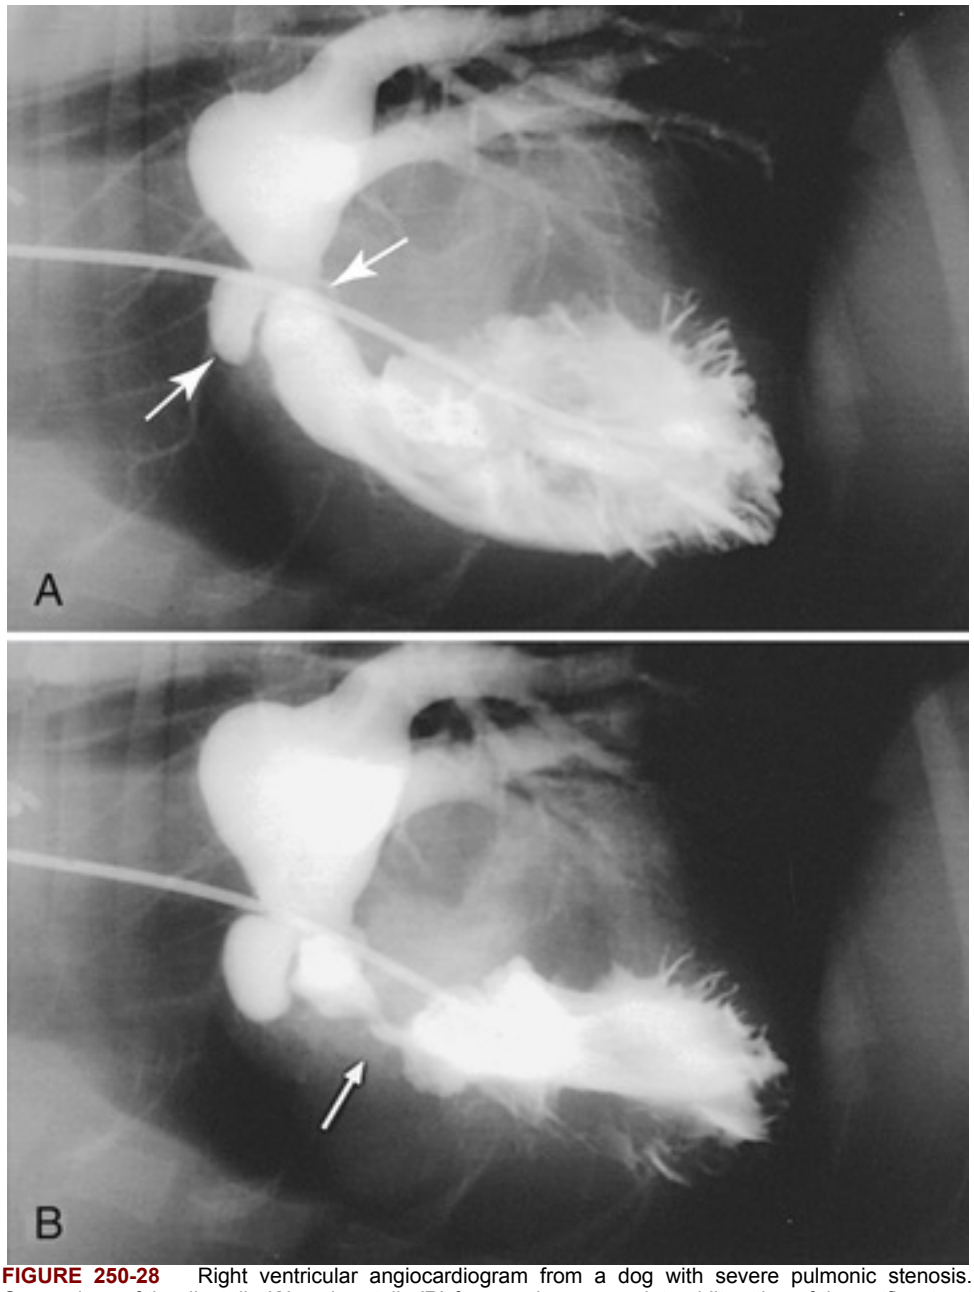

FIGURE 250-28 Right ventricular angiocardiogram from a dog with severe pulmonic stenosis. Comparison of the diastolic **(A)** and systolic **(B)** frames shows complete obliteration of the outflow tract caused by vigorous contraction of the hypertrophied infundibulum (arrow in frame B). Compare with Figure 250-27. Also note the distortion of the pulmonic valve sinuses (arrows in frame A).

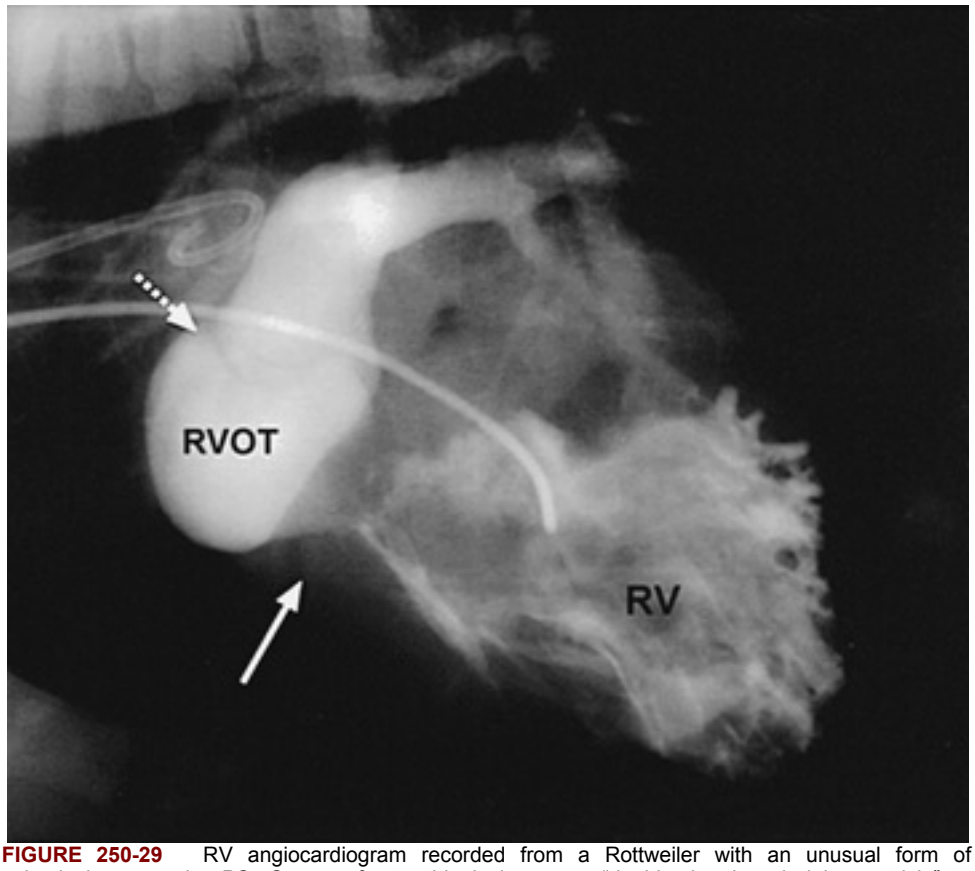

FIGURE 250-29 RV angiocardiogram recorded from a Rottweiler with an unusual form of subvalvular muscular PS. Some refer to this lesion as a "double-chambered right ventricle" to distinguish it from dynamic collapse of the hypertrophied infundibulum (see Figure 250-28). Others use the term only when the lesion is deeper within the RV, and some avoid the term altogether. Solid arrow indicates the muscular obstructing lesion in the RVOT. Dashed arrow indicates the location of the pulmonic valve.

Hemodynamic confirmation of outflow tract obstruction is accomplished by measuring a systolic pressure gradient across the lesion (see Figure 250-1). The severity of the obstruction is usually defined as the difference in peak systolic pressures measured above and below the obstruction (peak-to-peak pressure gradient). Inasmuch as the recorded gradient varies with the rate of flow across the obstruction, this measurement is greatly affected by myocardial contractility and the anesthetic regimen selected. Despite these limitations, the systolic pressure gradient has been used for dividing patients with PS into mild (<50 mm Hg), moderate (50 to 80 mm Hg) or severe (>80 mm Hg) categories.[204,217,218] A more accurate approach requires the measurement of cardiac output and calculation of the functional area of the constricted orifice (see ch. 104). Additional potential catheterization findings include a giant a wave in the RA, giant c-v wave in the setting of severe tricuspid regurgitation, or increased RV end-diastolic pressure due to vigorous RA contraction or development of RV failure.

Natural History

Precise criteria for establishing an accurate prognosis have not been developed for dogs and cats with PS. Clinical experience indicates that most dogs with mild and even moderate PS (Doppler derived gradient < 80 mm Hg) usually live normal or nearly normal lives, especially if no clinical signs are evident.[219] This generalization does not encompass those dogs with other complicating defects. The problem of concurrent TVD and its relation to developing heart failure has already been discussed. While systolic pressure gradients are not always predictive of clinical outcome, there appears to be a general correlation between pressure gradient and survival. Dogs with Doppler-derived RV-PA gradients > 125 mm Hg frequently develop secondary tricuspid regurgitation, heart failure, exertional syncope, or a serious cardiac arrhythmia (e.g., atrial fibrillation). When an ASD, PFO, or VSD coexists with PS, there is the potential for right-to-left shunting. If that shunting is pronounced, consequences include arterial hypoxemia, erythrocytosis, and serious debilitation. Sudden death occurs in some dogs with severe PS, but this occurrence is uncommon.

Clinical Management

Patients with uncomplicated and asymptomatic PS of mild or moderate severity usually do not require treatment. Serial echocardiographic examinations can be performed to monitor the degree of ventricular hypertrophy, development of secondary infundibular stenosis, and development of tricuspid regurgitation. Exercise restriction is usually unnecessary. Some dogs will develop more severe obstruction over time. Dogs with severe or symptomatic disease are candidates for surgery or balloon valvuloplasty (see ch. 122). No prospective trials investigating the effect of balloon valvuloplasty on survival have been performed. Data from retrospective studies suggest that balloon valvuloplasty in dogs with severe disease is associated with reduced risk for cardiac-related death.[219-221] The exact pressure gradient warranting intervention cannot be stated with certainty. Dogs with a Doppler gradient exceeding 100 to 125 mm Hg should be considered candidates for balloon valvuloplasty or surgery. Dogs with lesser gradients are also candidates for these procedures if they are symptomatic or have a large amount of tricuspid regurgitation. Intervention at a young age should be encouraged, as the development of overt CHF substantially lessens the chance for a successful outcome, regardless of the method of repair or palliation. Because of a high likelihood of heritability, even mildly affected dogs should not be bred.

The goals of intervention in dogs with severe PS are to abolish the systolic pressure gradient or reduce it to the mild range and to provide symptomatic relief in dogs experiencing clinical signs. For many years, surgery was the only available option for treating PS, and several surgical techniques have been advocated, including valve dilation, patch grafting, or the placement of a conduit from the RV to the pulmonary artery.[217,218,222-228] The open patch-graft technique, while challenging to perform, is a particularly versatile and cost-effective method for treating dogs with PS, particularly when there is a substantial subvalvular obstruction.[226-228] This technique is well-suited to the treatment of some defects not amenable to balloon valvuloplasty (e.g., dogs with muscular RVOT obstructions, double-chambered right ventricle, or severe hypoplasia of the pulmonic annulus). The patch-graft technique should not be performed in dogs with subvalvular PS associated with an anomalous coronary artery as severing of the artery will result in death.

Catheter-based percutaneous balloon valvuloplasty is a preferred alternative to surgery and should be recommended for dogs with valvular PS. This interventional catheterization procedure for PS is discussed in ch. 122. Successful reduction of the obstructive gradient by 50% or more has been reported in 75% to 80% of the dogs treated with this technique.[211,221,229,230] Retrospective analysis of 40 dogs that underwent balloon valvuloplasty indicated a 53% reduction in mortality as compared with 41 dogs that did not undergo the procedure.[220] Dogs with hypoplasia of the pulmonary annulus or anomalous development of the coronary arteries and subvalvular PS are at particular risk for serious complications of balloon valvuloplasty, including avulsion of the coronary artery or rupture of the pulmonary annulus.[231] Conservative balloon valvuloplasty using balloon sizes 0.6-1.0 times the diameter of the pulmonic valve annulus is reported in a small number of such cases, with variable results.[232]

Aortic Stenosis

Subvalvular aortic stenosis (SAS) is the most common congenital cardiac malformation in large breed dogs.[4,172,173,233-242] Most cases of SAS result from a fixed ridge or ring of fibrous tissue located in the LVOT, just below the aortic valve. SAS is a problematic disorder for several reasons. It is very difficult to diagnose in mildly affected dogs and it is difficult to treat when it is severe. The phenomenon of dynamic SAS is also being recognized with increasing frequency in dogs and cats with a variety of cardiac disorders, including fixed SAS, MVD, hypertrophic cardiomyopathy, and other conditions causing hypertrophy of the interventricular septum and reduced LV size (i.e., PS, ToF).[243] Bull Terriers are predisposed to valvular aortic stenosis wherein the leaflets are thickened and the aortic valve annulus is mildly hypoplastic. Normal Boxers also demonstrate aortic annulus diameters that are smaller than those of other breeds of dogs, and this confounds diagnosis of mild disease in this breed.[244] Mild AS caused by a bicuspid valve occurs on rare occasions.[169] Fixed aortic stenosis has been described in a small number of cats,[32-34,245] including one case of supravalvular stenosis.[246]

Pathology and Pathogenesis

SAS has been most extensively studied in the Newfoundland dog. Breeding studies in this and other breeds have established a genetic basis for the perpetuation of SAS.[2,247-249] An autosomal dominant abnormality in

the PICALM gene has been associated with SAS in Newfoundland dogs,[12] although these data might require further validation.[250] An autosomal recessive mode of inheritance is reported in the Dogue de Bordeaux.[180] Thus, it is likely that SAS in the dog can be the result of different genetic abnormalities. The breeding colony studies of Pyle and Patterson further indicate that the obstruction may not be present at birth, but instead develops during the first 4 to 8 weeks of life.[2,235-237,247] This progression has particular significance relative to the identification of cardiac murmurs in pups of breeds known to be at risk for SAS. Recent work in Golden Retriever dogs has suggested that an aortopathy or narrow, abnormal septal-aortic angle might play a role in the development or progression of SAS in dogs, a situation previously reported in children.[251]

The lesions of SAS in Newfoundlands have been described in postmortem studies as mild (grade 1), consisting of "small, whitish, slightly raised nodules on the endocardial surface of the ventricular septum immediately below the aortic valve"; moderate (grade 2), consisting of a "narrow ridge of whitish, thickened endocardium" extending partially about the LVOT; and severe (grade 3), consisting of "a fibrous band, ridge, or collar completely encircling the LVOT just below the aortic valve."[2,247] This ring is raised above the endocardium, extends to—and may involve—the cranioventral leaflet of the mitral valve and the base of the aortic valves (Figure 250-30). The stenotic ring consists of loosely arranged reticular fibers, mucopolysaccharide ground substance, and elastic fibers. Discrete bundles of collagen and even cartilage are found in advanced lesions.[247] Cardiac catheterization of dogs with grade 1 lesions failed to reliably detect the lesion that is visible at postmortem, whereas grade 2 lesions often were associated with soft cardiac murmurs and minimal systolic pressure gradients. As evidenced by these studies and discussed below, clinical detection of mild SAS is often quite difficult, and genetic counseling may be fraught with error. A variety of cardiac abnormalities can accompany SAS, most notably MVD, PDA, and a host of aortic arch abnormalities. The valvular lesions seen in Bull Terrier dogs, including myxomatous degeneration and cartilaginous metaplasia of the valve leaflets, resemble those in humans with calcific valvular stenosis.[252] Most dogs with SAS exhibit some degree of aortic dilation distal to the stenosis. This poststenotic dilation can range from trivial to severe and can extend into the arch vessels. The degree of poststenotic dilatation is often greater with severe obstructions, but this relationship is quite variable.

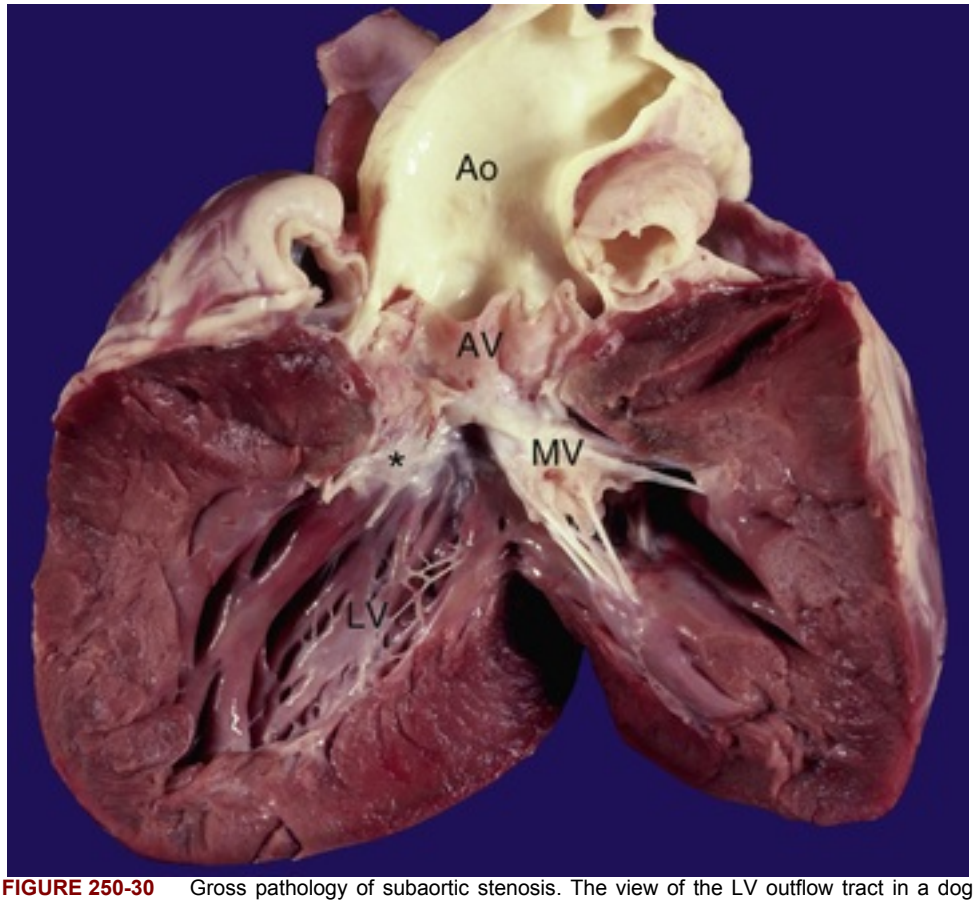

FIGURE 250-30 Gross pathology of subaortic stenosis. The view of the LV outflow tract in a dog

shows the presence of a circumferential ring of fibrous tissue directly below the aortic valve (AV). A ridge of thick fibrous tissue is seen just below the aortic valve and extending onto the ventricular septum (asterisk). The ventricular walls are markedly thickened. A thickened anterior mitral valve (MV) leaflet and associated chordae tendineae are seen to the right of the lesion. A poststenotic dilation of the proximal portion of the aorta (Ao) is noted.

In some affected dogs, the pathologic findings diverge from the classical description. The anterior mitral valve leaflet is thickened in apposition to a septal plaque of endocardial fibrosis where the mitral leaflet impacts the IVS as a consequence of dynamic obstruction.[253] Instead of a fibrous collar, the septum is uniformly hypertrophied or a broad fibromuscular ridge, arising from the base of the interventricular septum, protrudes into the LVOT. Malformed, malpositioned, or misaligned papillary muscles, thickened chordae tendineae, and elongated or distorted mitral leaflets contribute to the development of obstruction.[254] Mitral valve malformations are also associated with SAS in cats, although the disorder is relatively rare in this species.[245,255] In some cats, relatively long, tunnel-like obstructions have been observed.

Concentric hypertrophy of the LV develops in dogs with valvular, fixed, or dynamic SAS more or less in proportion to the severity of the outflow obstruction, albeit that the correlation between wall thickness and the magnitude of the measured gradient is often poor.[77] Structural and functional abnormalities of the LV[78] and coronary circulation are well documented in dogs with SAS.[235,237] Abnormal coronary flow has also been measured in the larger, extramural arteries with diminished baseline diastolic flow and reversal of coronary flow during systole.[105,237] Focal areas of myocardial infarction and fibrosis are commonly observed in the papillary muscles and subendocardium of dogs with severe SAS, often in association with abnormal intramural coronary arteries. Histologic changes of the intramural coronary arteries in these locations include intimal proliferation of connective tissue and smooth muscle, and medial degeneration. These changes are presumably related to the high wall tension found in this condition, and their genesis may be related to the elaboration of angiotensin II or other biochemical mediators of hypertrophy and remodeling.[256-258] Moreover, these arterial lesions may be important in the genesis of malignant ventricular arrhythmias and sudden death.

Pathophysiology

Obstruction to LV outflow causes an increase in LV systolic pressure and concentric hypertrophy. Consequent to fixed obstruction, the rate of LV ejection is delayed, causing a diminished and late-rising arterial pulse (parvus et tardus). High velocity and turbulent flow across the stenotic area produces the systolic ejection murmur and contributes to poststenotic dilation usually involving the ascending aorta, aortic arch, and brachiocephalic artery. Left atrial hypertrophy develops as a consequence of impaired relaxation and reduced compliance of the hypertrophied LV. Mild aortic regurgitation is commonly present, presumably because of thickening of the valve leaflets or dilation of the ascending aorta. Damage to the aortic valvular endothelium (jet lesions) predisposes dogs with SAS to infective endocarditis.[259,260] Dogs with severe SAS can develop left-sided CHF from myocardial failure, diastolic dysfunction, mitral regurgitation, atrial fibrillation, or a combination of these factors. More often, exertional syncope or sudden death is reported, presumably as a result of myocardial ischemia and the development of malignant ventricular arrhythmias. Congruous with this finding is that exercise ECGs can reveal significant, labile ST-segment depression. In some dogs, exertional collapse might be caused by hypotension precipitated by exercise-induced increases in LV pressure, activation of ventricular mechanoreceptors, and inappropriate bradycardia or vasodilation.[261]

Clinical Findings

Congenital SAS is common in many canine breeds (see Table 250-1), especially in Newfoundlands, Boxers, Rottweilers, Golden Retrievers, and German Shepherd Dogs.[167,262] Valvular AS is common only in Bull Terriers. The clinical findings of SAS vary with the severity of the obstruction and the presence of concurrent cardiac defects. Clinical findings in pups with mild SAS are often subtle and easily overlooked. Asymptomatic dogs have a soft to moderately intense ejection murmur that can easily be confused with an innocent or functional heart murmur.[263] More sophisticated time-frequency or heart rate turbulence analysis of soft murmurs may provide clues as to which murmurs are associated with mild disease.[264,265] Insofar as the lesions of SAS can develop during the postnatal period, the murmur may become increasingly prominent during the first 6 months of life. In rapidly growing breeds, such as the Newfoundland, the grading of SAS severity in a puppy should be reserved until the dog has attained nearly full maturity, because progression

from mild to severe has been observed during this interval.[247,251,266] Severely affected dogs can present with exertional fatigue, syncope, or left-sided CHF, but the vast majority of dogs are asymptomatic. In dogs with severe disease, a common client observation is that the affected dog is smaller than its healthy littermates. Sudden death, without premonitory signs, is common in severely affected dogs aged 1-3 years.[260]

Recognition of severe SAS is not difficult, as the systolic murmur generally becomes louder and later-peaking-to-holosystolic when the obstruction is more severe.[267] The murmur of severe SAS is usually best heard at the left heart base, recognizing that in some dogs, the systolic murmur is equally loud or louder at the right cardiac base, presumably from radiation into the ascending aorta. The murmur of aortic stenosis often radiates up the carotid arteries and can be auscultated over the ventral cervical region. Frequently, the murmur projects towards the apex and can be confused with mitral regurgitation. In fact, a substantial percentage of dogs with SAS also have mitral regurgitation, but these murmurs are usually difficult to separate given their similar timing and overlapping areas of maximal intensity. Despite the frequent occurrence of aortic regurgitation captured by Doppler echocardiography, a soft diastolic murmur secondary to aortic valve insufficiency is infrequently detected. Other physical abnormalities detected in moderately to severely affected dogs include a diminished and late rising arterial pulse and a prominent LV precordial impulse arising from the hypertrophied LV.

The ECG is often normal, but may, in severe cases, indicate LV hypertrophy (increased R wave amplitude in leads II, III, aVF, V2, V4). Depression of the ST segment and T wave changes suggest secondary repolarization changes or myocardial ischemia; the latter is especially likely when ST changes are precipitated by exercise or occur in the company of ventricular ectopia (Figure 250-31). Compared with the resting ECG, 24-hour ambulatory (Holter) ECG recordings offer a more sensitive method of detecting intermittent or exercise-induced ventricular arrhythmia and ST segment changes. The severity of arrhythmias detected in this fashion often corresponds to the severity of disease.[268]

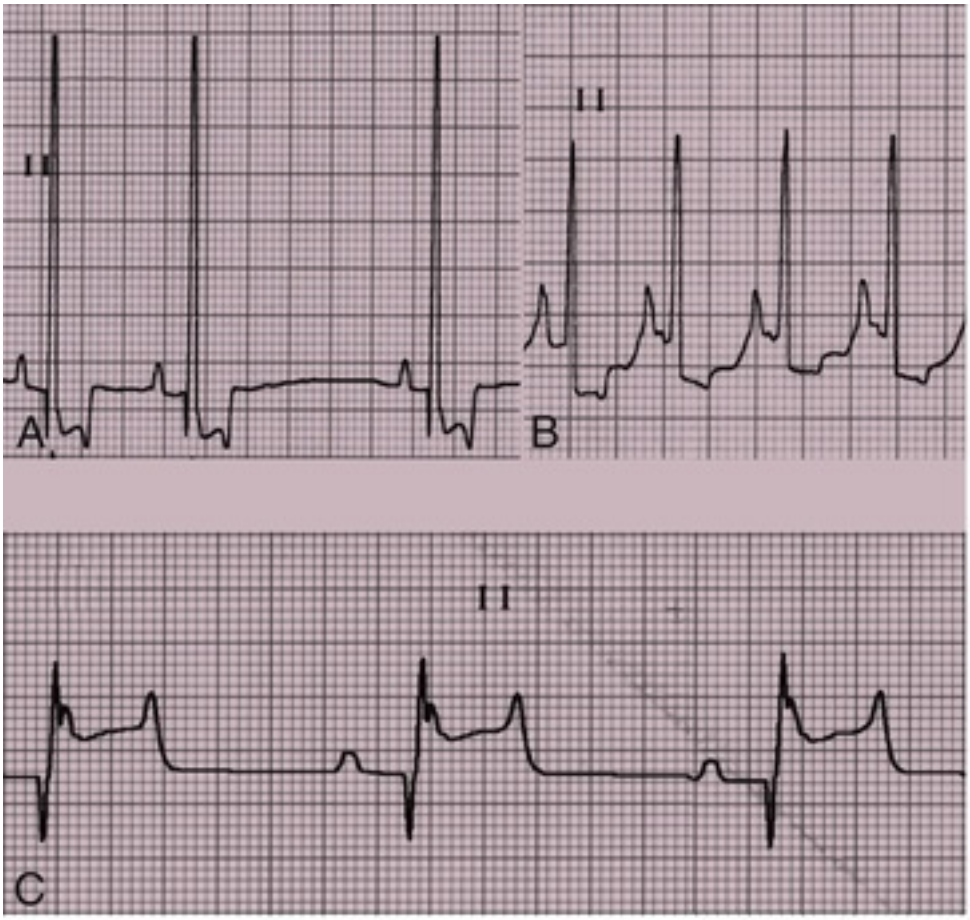

FIGURE 250-31 ECGs demonstrating ST segment depression **(A, B)** and elevation **(C)** in three dogs with severe SAS are suggestive of myocardial ischemia. Sensitivity, 10 mm/mV. **A,** Tracing from a 1-year-old Golden Retriever at 25 mm/sec. **B,** This 6-month-old Newfoundland dog collapsed and died suddenly 1 hour after the ECG was performed, 25 mm/sec. **C,** Tracing from a 1-year-old Golden

Retriever, 50 mm/sec.

Thoracic radiographs can be normal or may indicate LV hypertrophy.[61,105,214] Poststenotic dilation of the horizontally inclined ascending aorta causes loss of the cranial waist on the lateral radiograph and widening of the mediastinum on the dorsoventral radiograph in severe cases (Figure 250-32). Mild LA enlargement is common in dogs with moderate or severe SAS but marked LA enlargement suggests concurrent mitral regurgitation, LV failure or concurrent left-to-right shunt. Although unnecessary for the diagnosis, angiocardiography is useful for delineating the site and geometry of obstruction, which is usually most evident in the ventral aspect of the outflow tract when viewed on the lateral projection (Figure 250-33 and Video 250-17). Other angiographic findings include poststenotic dilation of the ascending aorta, enlargement of the left coronary artery and its extramural branches, a small LV cavity, and hypertrophy of the papillary muscles and LV wall. Supravalvular aortic injections can be performed to identify insufficiency of the aortic valve, but Doppler echocardiography is a more sensitive technique. Hemodynamic recordings document the presence and severity of a systolic pressure gradient across the obstruction (Figure 250-34). Such recordings are also useful for detecting elevated LV end-diastolic pressure and impending CHF.[105,269] Pressure gradients recorded from dogs with SAS are depressed by general anesthesia to approximately 40% to 50% of those measured in the unanesthetized state as a result of diminished flow (stroke volume).[270]

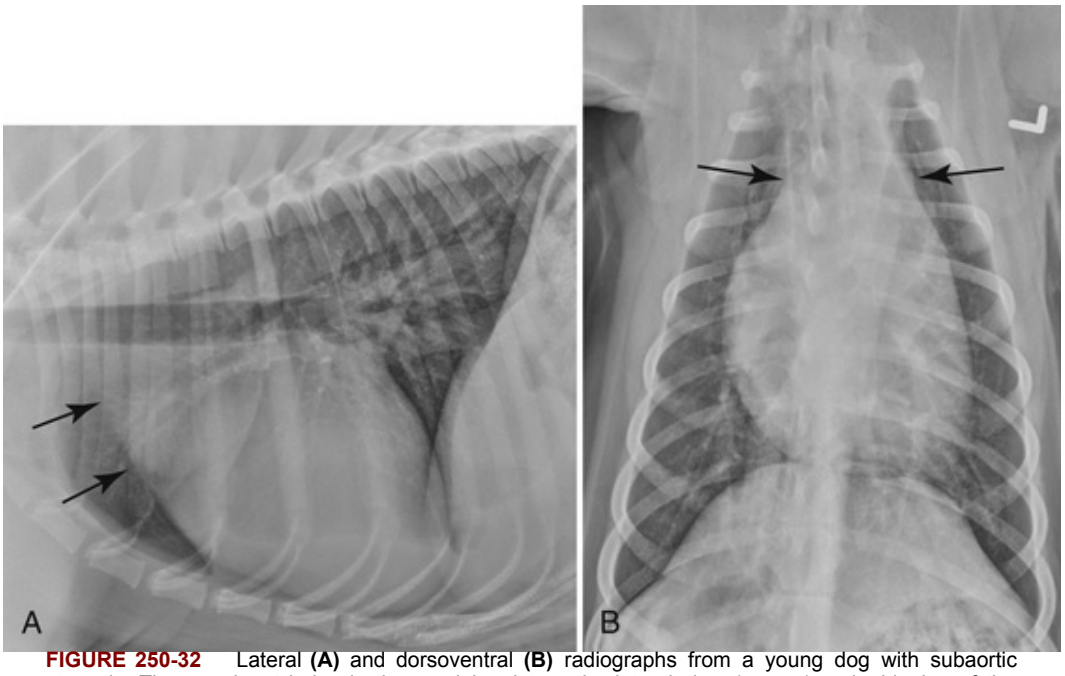

FIGURE 250-32 Lateral **(A)** and dorsoventral **(B)** radiographs from a young dog with subaortic stenosis. The prominent bulge in the cranial waist on the lateral view (arrows) and widening of the cranial mediastinum on the dorsoventral view (arrows) are consistent with a poststenotic dilation of the ascending aorta.

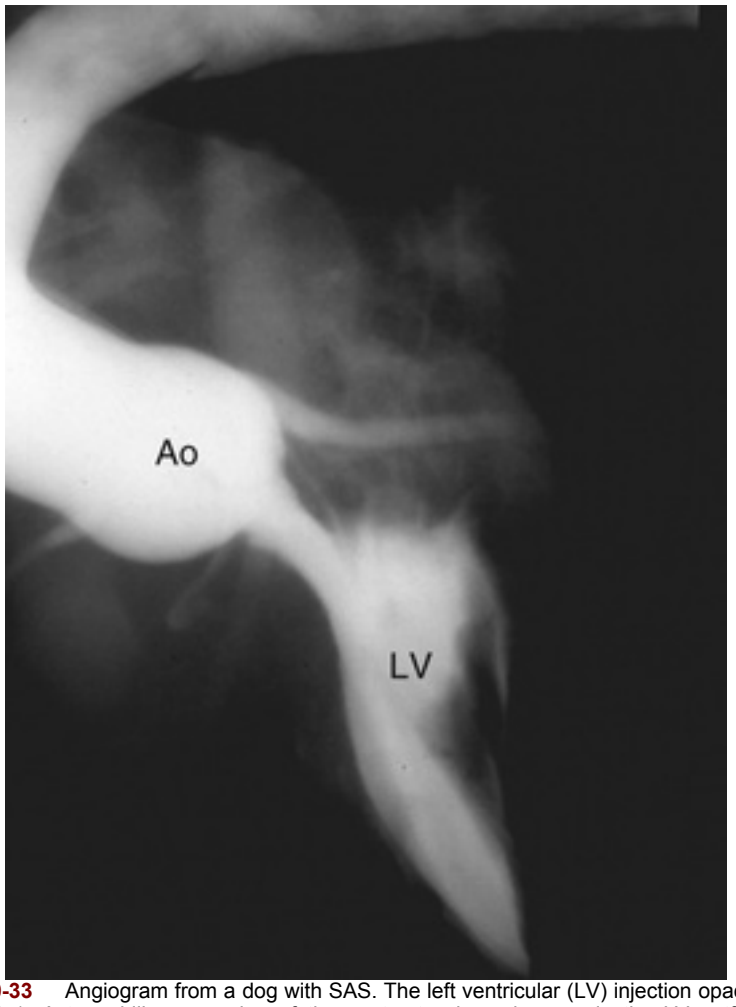

FIGURE 250-33 Angiogram from a dog with SAS. The left ventricular (LV) injection opacifies the LV and aorta (Ao). A tunnel-like narrowing of the contrast column is seen in the LV outflow tract. A prominent left circumflex coronary artery is also seen.

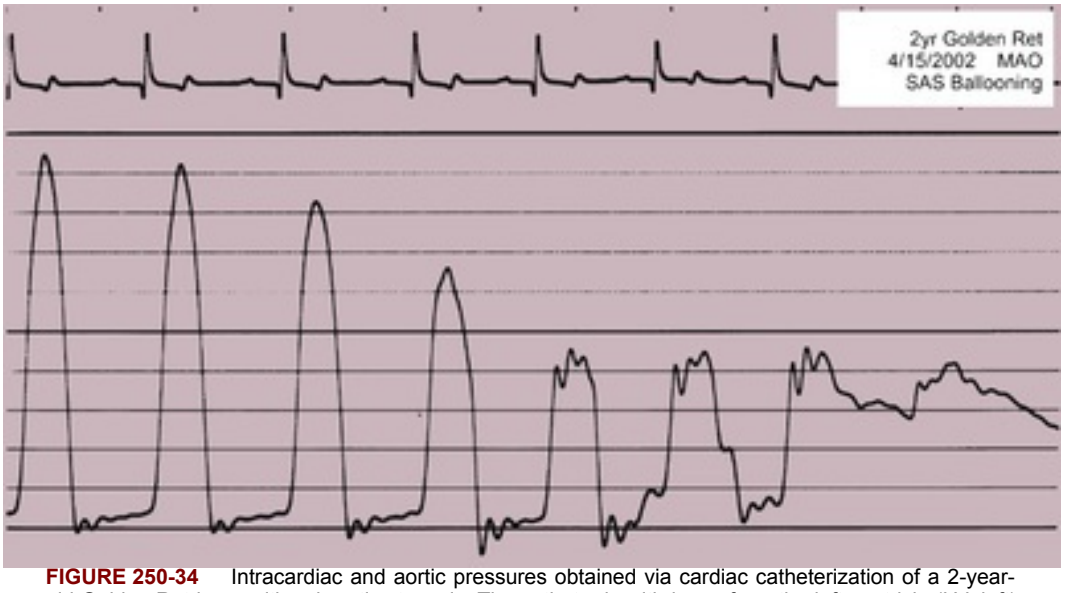

FIGURE 250-34 Intracardiac and aortic pressures obtained via cardiac catheterization of a 2-year-old Golden Retriever with subaortic stenosis. The catheter is withdrawn from the left ventricle (LV; left) into the left ventricular outflow tract (LVOT; center) and into the ascending aorta (right). A 100 mm Hg systolic pressure gradient is demonstrated between the LV and LVOT, indicating the subvalvular

location of the obstruction. (Catheter motion artifact superimposed on the outflow tract and aortic recordings.)

Moderate to severe SAS is easily confirmed by 2D and Doppler echocardiography (see ch. 104). Typical findings include concentric LV hypertrophy, a subvalvular obstructing lesion, reduced LV orifice area, and poststenotic dilation of the aorta (Figure 250-35).[71,76,201,215,239] In Golden Retriever dogs, a more acute angle between the ascending aorta and IVS (aortoseptal angle) has been associated with increased LV outflow tract velocities and development of SAS (Figure 250-36).[251] The papillary muscles and endocardial surface of the ventricular myocardium often appear hyperechoic in severe disease, presumably as a result of myocardial ischemia and replacement fibrosis or calcification. Structural changes in the mitral valve can often be appreciated and abnormal motion of the mitral valve (systolic anterior motion, SAM) is evident in those cases with coexisting mitral valve dysplasia and dynamic obstruction.[253] Spectral Doppler interrogation of the LVOT is used to assess disease severity by measuring the peak velocity of flow in the LVOT.[271] Such measures show excellent correlation with invasive measures (see Figure 250-35).[75] Doppler measurements can be made from a variety of parasternal or subcostal imaging windows, although velocities obtained from the subcostal position generally display the highest values.[272] While Doppler-estimated pressure gradients between 80 and 100 mm Hg (peak flow velocities ranging from 4.5 to 5.0 m/s) are used for indicating moderate LVOT obstruction, and higher velocities used for indicating severe obstructions, these designations are somewhat arbitrary. Doppler-derived pressure gradients are affected by the amount of flow (stroke volume) crossing the obstructive orifice, and may either overestimate the severity of obstruction if cardiac output is high (e.g., in dogs that are stressed or excited, or affected with a PDA), or underestimate the severity if flow is subnormal (e.g., in dogs under anesthesia or with concurrent myocardial failure). In these cases, indexing the gradient to stroke volume or some related measure or simple estimation of the two-dimensional orifice area may provide a better estimate of disease severity.[77,201,273] Color flow Doppler recordings are valuable for detecting and estimating the severity of coexisting aortic or mitral valve insufficiency, although focusing solely on jet area is likely to result in overestimation of severity.[202]

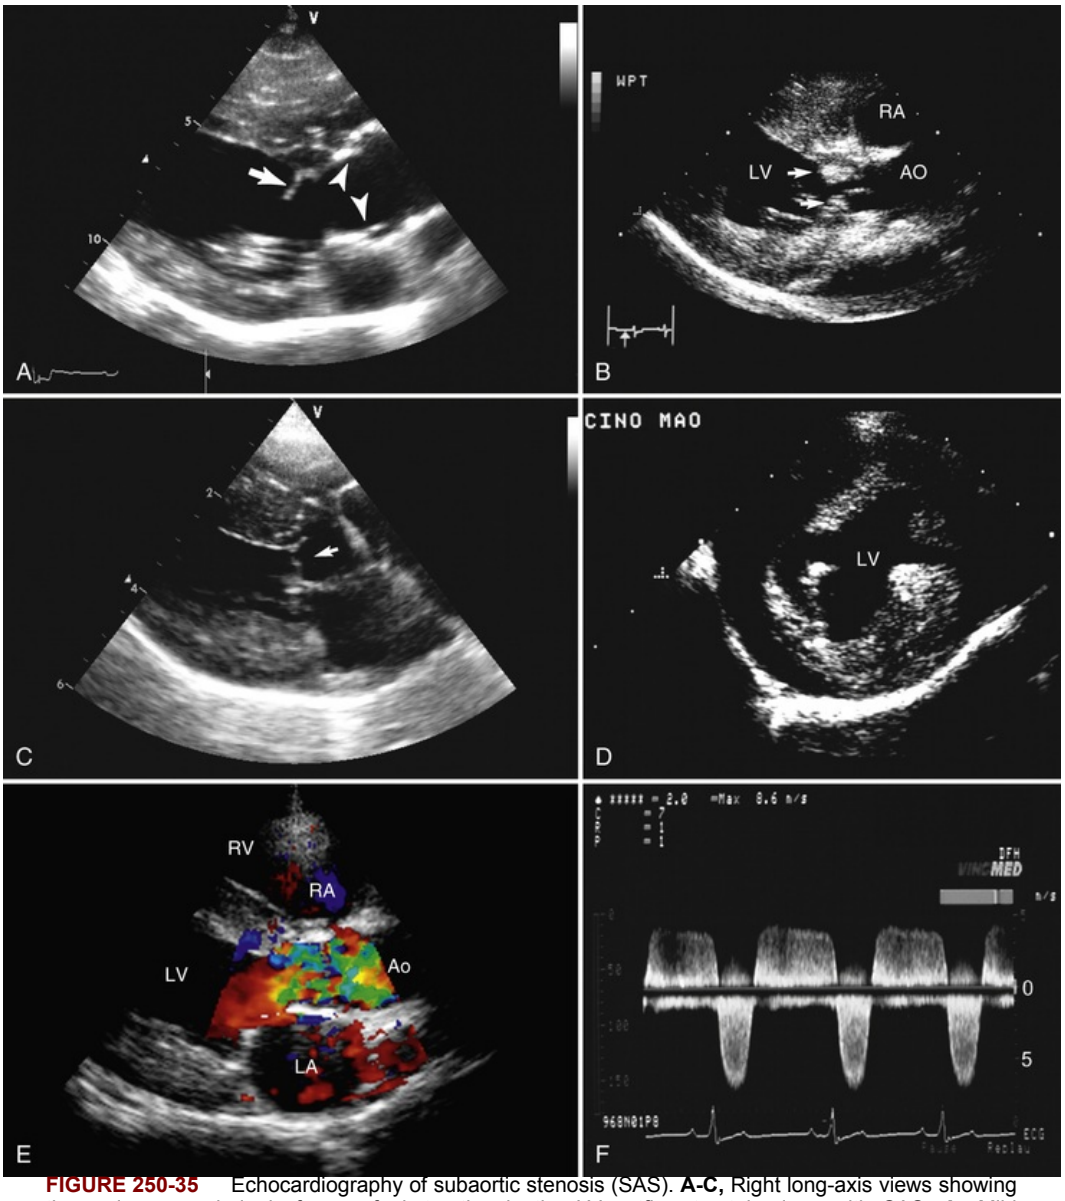

FIGURE 250-35 Echocardiography of subaortic stenosis (SAS). **A-C,** Right long-axis views showing the various morphologic forms of obstruction in the LV outflow tract in dogs with SAS. **A,** Mild membranous SAS in a 5-year-old Rottweiler. A thin membranous flap of tissue extends from the interventricular septum. No appreciable LV concentric hypertrophy is noted. The open aortic valve leaflets are indicated by the arrowheads. **B,** Severe tunnel-like SAS in a 4-year-old Golden Retriever. Two ridges of hyperechoic tissue are present at the base of the aortic valve (arrows). The LV is hypertrophied, with a hyperechoic endocardial surface. **C,** Dynamic SAS in a Poodle. Systolic anterior motion of the mitral valve is seen projecting into the left ventricular outflow tract (arrow). The LV shows concentric hypertrophy. The blood flow velocity across the obstruction was in excess of 5.5 m/s, indicating a severe degree of pressure overload to the LV. **D,** The right short-axis view from a 3-month-old mixed-breed dog shows LV concentric hypertrophy and marked hyperechogenicity of the subendocardial tissue and papillary muscles. This finding is thought to represent areas of myocardial ischemia and replacement fibrosis. **E,** The right long-axis color flow Doppler study from a dog with SAS reveals high velocity and turbulent blood flow in the LVOT and aorta (Ao). **F,** The continuous wave Doppler tracing from the left apical view in a dog with severe SAS shows a peak systolic velocity of 6.5 m/s, indicating a pressure gradient of 169 mm Hg across the obstruction. The presence of aortic insufficiency is also detected.

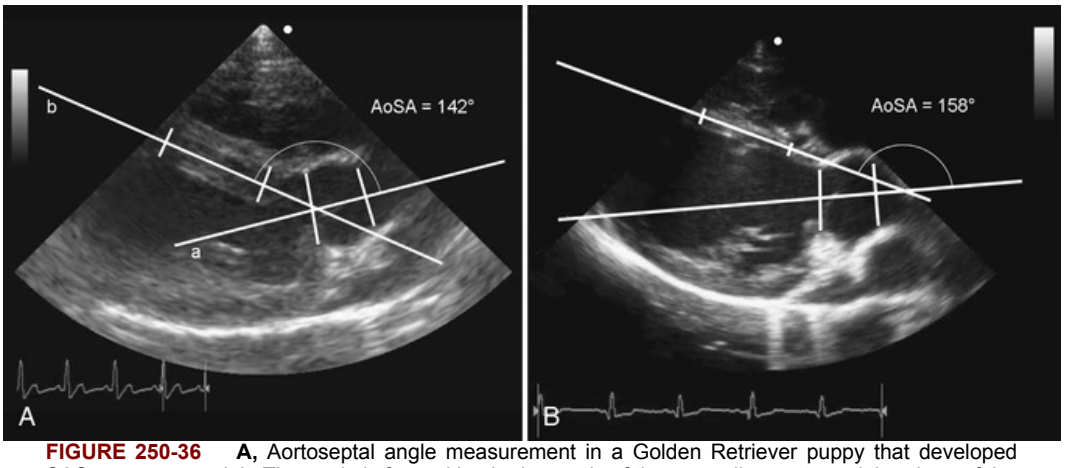

FIGURE 250-36 **A,** Aortoseptal angle measurement in a Golden Retriever puppy that developed SAS as a young adult. The angle is formed by the long axis of the ascending aorta and the plane of the IVS. The midline axis of the aortic root is constructed by bisecting the aortic root at the level of the annulus and above the sinotubular junction (line a). The midline axis of the IVS is constructed by bisecting the septum at the level of the mitral leaflet tips and 2 cm apically from that point (line b). AoSA = 142°. **B,** Aortoseptal angle measurement in a normal Golden Retriever puppy. AoSA = 158°. *AoSA,* Aortoseptal angle; *IVS,* interventricular septum; *SAS,* subaortic stenosis. (From Belanger MC, Cote E, Beauchamp G: Association between aortoseptal angle in Golden Retriever puppies and subaortic stenosis in adulthood. *J Vet Intern Med* 28:1498-1503, 2014.)

Antemortem detection of the mildest forms of SAS by auscultation, angiography, or echocardiography is often not achievable and the precise outflow velocity at which the diagnosis of AS becomes both sensitive and specific is controversial and undefined by any gold standard. Dogs with subtle abnormalities (i.e., grade 1 lesions as described previously), escape detection by even the most accomplished examiners. Even in dogs with grade 2 lesions, segregation from normal dogs solely on the basis of LV velocities is problematic. An upper limit for aortic velocity in normal dogs has been reported but is not well established for differing breeds and examination conditions.[274] The averaged, maximum pulsed-wave aortic velocity in the authors' laboratory for healthy dogs without any cardiac murmur is 1.7 m/s, and this is similar to values reported in a study of healthy dogs without cardiac murmurs in which maximal LVOT velocities were <1.8 m/s when measured from the left apex (upper limit of the 95% confidence interval).[275] Velocities recorded using CW Doppler from the subcostal position are minimally faster but generally <2 m/sec in dogs without murmurs. However, LVOT ejection velocities in excess of these values are often recorded in dogs with soft ejection murmurs but with no 2D evidence of discrete outflow tract obstruction. Such velocities are especially common in breeds characterized by slightly diminished outflow tract dimensions (Boxers and Bull Terriers). A diagnosis of mild SAS is more secure once averaged maximal velocity measurements exceed 2.3 to 2.4 m/s and are accompanied by other findings, particularly: disturbed flow on PW Doppler; an anatomic lesion on 2D imaging; holodiastolic aortic regurgitation; and when flow velocity abruptly accelerates over a discrete region in the LVOT. Some investigators consider an echocardiographic LV outflow tract area indexed to body surface area <1.46 cm/m^2 or aortoseptal angle <145° as indicators of mild or developing SAS in Golden Retriever pups.[201,251] The inability to reliably detect mild SAS is a great source of frustration when attempting to provide genetic counseling to breeders, who are interested in reducing the incidence of disease.

Natural History

Severe SAS is a discouraging condition, since many affected dogs die prematurely. In a retrospective survey of 96 dogs with SAS, 21 died suddenly, most often during the first 3 years of life.[260] Eleven dogs developed endocarditis and/or CHF, and 32 dogs evidenced exercise intolerance or syncope. Dogs with minimal ventricular hypertrophy, mild ventricular outflow obstruction, and a maximal Doppler pressure gradient <50 mm Hg are more likely to live normal lives, whereas dogs with pressure gradients >125-130 mm Hg are very likely to develop serious complications or to experience sudden death.[276] Complicating factors that contribute to an adverse outcome include: progressive LV diastolic and systolic dysfunction, mitral regurgitation, aortic regurgitation, aortic valve endocarditis, and atrial fibrillation.[266,277,278] Sudden death is most likely to occur during or shortly after vigorous activity.

Clinical Management

Dogs with mild SAS are not treated other than administration of prophylactic antibiotics during periods of anticipated bacteremia, such as during dental procedures, surgery, or whenever a concurrent infectious disease is suspected. This practice remains common despite the fact that the efficacy of prophylactic antibiotics for reducing the risk of infective endocarditis in dogs with SAS has not been definitively established.[278] A number of treatment options can be considered for dogs with moderate to severe SAS, but most are of uncertain value. Open resection of the obstructing lesion during cardiopulmonary bypass clearly offers the best opportunity to substantially and permanently reduce the systolic pressure gradient[279,280]; however, an otherwise successful procedure does not appear to substantially alter the prevalence of sudden death.[280] Other surgical procedures employed to dilate or bypass the obstruction have either failed to achieve a sustained reduction of the systolic pressure gradient or they entail an unacceptable risk of complications.[281,282] Moreover, these remedies are usually limited in their availability and prohibitively expensive to be considered practical options.

Balloon dilation of SAS has been attempted in dogs as an alternative to surgery or lifelong medical therapy. On average, catheter-based balloon dilation is able to reduce the severity of SAS obstruction in dogs by 50%[283]; however, this short-term benefit is attenuated in some (and perhaps a majority) of dogs over time,[271] and balloon valvuloplasty has not been shown to improve survival versus medical therapy with atenolol.[284] The use of "cutting" balloons that score or lacerate the stenotic lesion followed by dilation with high-pressure balloons has been described (see ch. 122) but whether this procedure produces superior outcomes over traditional balloon dilation is thus far unknown.[285] Balloon dilation of SAS is more challenging than balloon valvuloplasty of PS. Life-threatening complications of ballooning include fatal arrhythmia, development of aortic valve endocarditis, rupture of the aortic annulus, and avulsion of the brachiocephalic artery during balloon withdrawal. Moreover, the inability of surgical resection to prevent sudden death suggests that effective treatment requires more than reduction of the pressure gradient.

The authors typically recommend avoidance of prolonged vigorous exercise, recognizing that in young and otherwise healthy dogs, even this conservative recommendation is not always practical. Based on clinical and pathologic evidence of myocardial ischemia, the authors also consider administration of beta-adrenergic receptor blockers to dogs with high gradients or a history of syncope. Beta-blockers (such as atenolol) reduce maximal heart rate, decrease myocardial oxygen consumption, and increase the time for diastolic coronary artery flow, thereby offering a theoretic protective benefit to the myocardium against ischemia and the development of arrhythmias. Moreover, dogs receiving high dosages of beta-blockers seem less willing (or are less able) to indulge in prolonged vigorous exercise. Despite these theoretic advantages, a retrospective study found no survival benefit of atenolol in dogs with SAS (Figure 250-37).[276] In theory, treatment with calcium channel blockers or angiotensin-converting enzyme inhibitors may also be of value in dogs with SAS; however, none of these medical strategies has been evaluated in placebo-controlled clinical trials.

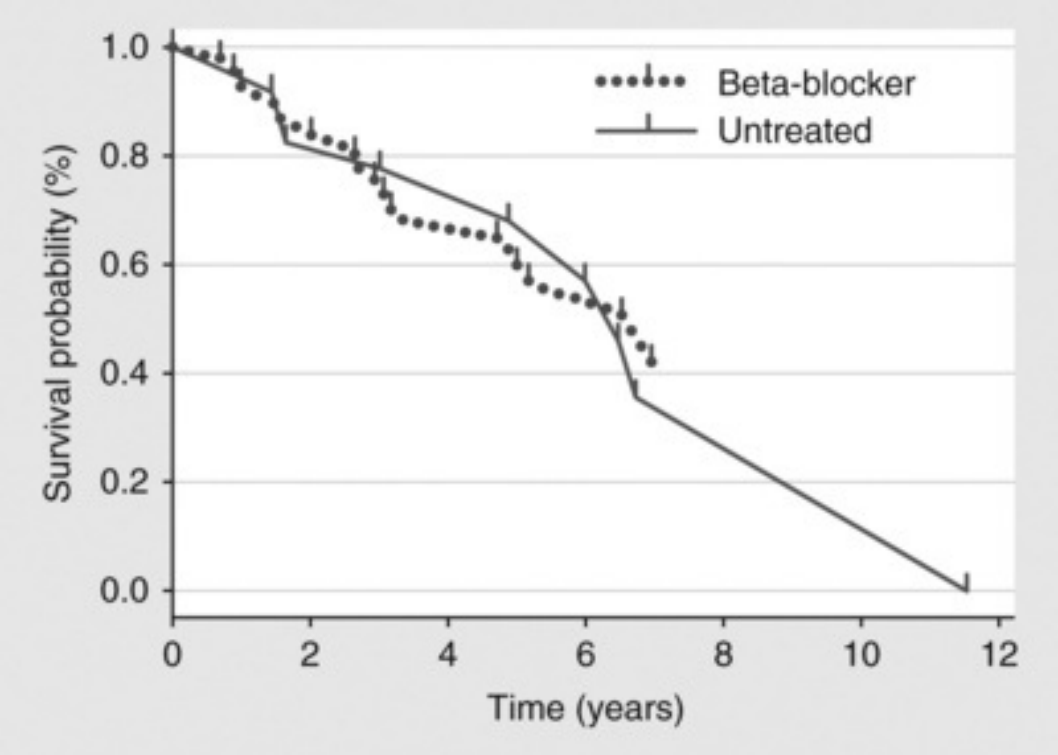

FIGURE 250-37 Cox-adjusted survival curve of cardiac-related death in dogs with severe SAS receiving beta-blocker therapy (n = 27) versus untreated (n = 23). There was no significant difference in survival function between groups (P = 0.97). (From Eason BD, Fine DM, Leeder D, et al: Influence of beta blockers on survival in dogs with severe subaortic stenosis. *J Vet Intern Med* 28:857-862, 2014.)

Tetralogy of Fallot

The defining anatomic features of ToF are RV outflow obstruction due to infundibular obstruction, secondary RV hypertrophy, a typically large perimembranous VSD, and a rightward-positioned aorta (dextroaorta) (Figure 250-38). The pulmonic valve is often hypoplastic in ToF and can contribute to RVOT obstruction in addition to, or instead of, purely valvular PS. Valvular PS occurring in combination with an isolated VSD produces similar pathophysiology and clinical findings of ToF; however, the infundibular septum is not malaligned, the aorta is normally positioned, and the infundibulum of the RV is not narrowed.[286] In children, pulmonary atresia is considered the extreme variant of ToF.

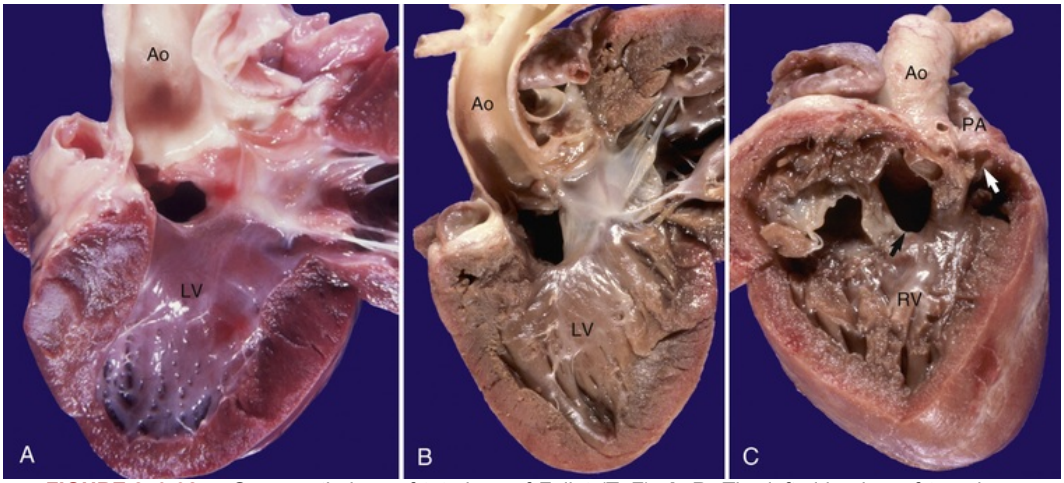

FIGURE 250-38 Gross pathology of tetralogy of Fallot (ToF). **A, B,** The left-side view of two dogs with ToF shows a large nonresistive ventricular septal defect (VSD) located between the aorta (Ao) and LV. Note the close proximity to the root of the aorta and the possibility for prolapse of an aortic

valve leaflet into the VSD. **C,** Right-side view of the dog from **B** showing the large VSD (black arrow), PS (white arrow), and hypertrophy of the RV. *PA*, Pulmonary artery.

Pathogenesis

ToF has been extensively studied in Keeshond breeding colonies and is likely oligogenic in etiology.[11] The pathogenesis of this malformation likely relates to ventrocranial deviation of the ventricular outlet septum.[287] In veterinary medicine, the term "conotruncal septal defects" has persisted. Regardless of the terminology, a spectrum of lesions, ranging from the subclinical to the clinically complicated, has been identified.[6,288-291] Patterson et al. graded the conotruncal defects as follows: grade 1—subclinical malformations involving persistence of the conus septum fusion line, aneurysm of the ventricular septum, and absence of the papillary muscle of the conus; grade 2—PS or VSD in addition to the grade 1 lesions; and grade 3—ToF: PS, VSD, and dextropositioned aorta (with secondary RV hypertrophy).[6] Additional abnormalities found in some dogs included a dilated and tortuous ascending aorta, pulmonary atresia, hypoplasia of the supraventricular crest, and anomalies of the aortic arch system. Based on extensive breeding studies and sophisticated genetic analysis, conotruncal defects have been shown to be an inherited autosomal recessive trait with variable expression.[8]

Pathophysiology

The predominant components of ToF are severe subvalvular RVOT obstruction and a VSD. As a result of the outflow obstruction and elevated RV systolic pressure, desaturated blood shunts from the right heart through the septal defect to mix with oxygenated blood coming from the LV.[292,293] Pulmonary arterial blood flow and pulmonary venous return are reduced, and the LA and LV are small and underdeveloped. The addition of desaturated blood from the RV to the systemic side of the circulation causes arterial hypoxemia, decreased hemoglobin oxygen saturation, cyanosis, and secondary erythrocytosis. Systemic collateral circulation to the lung increases via the bronchial arterial system. These vessels supply blood to the capillaries of the pulmonary parenchyma either directly or via anastomosing connections with a larger pulmonary artery. A substantial portion of this blood can participate in pulmonary gas exchange. Other aspects of clinical pathophysiology have been previously described.

Clinical Findings

ToF is common in the Keeshond, English Bulldog, and in some families of other breeds.[167] It has also been recognized in the cat.[108] Presenting complaints and clinical signs are as previously described for cyanotic heart disease. In most cases, the murmur of ToF is produced by high-velocity, turbulent blood flow through the obstructed RVOT.[286] Exercise or excitement may induce or enhance detection of peripheral cyanosis by accentuating right-to-left shunting. Radiography usually reveals a small or normal-sized heart with rounding of the RV border (Figure 250-39). The main pulmonary artery is not enlarged on survey radiographs, in contrast to the usual case of PS with intact ventricular septum. The pulmonary vasculature is diminished and the left auricle may be inconspicuous as a consequence of decreased venous return. The ECG typically exhibits criteria for right heart enlargement including right axis deviation, although left- or cranially directed vectors may be found in some cats.[294] Echocardiographic findings include RV hypertrophy, increased RV chamber dimensions, reduced LA and LV dimensions, a large perimembranous-outlet VSD, and RV outflow obstruction (Figure 250-40). Echocardiographic saline contrast or angiography can be employed to document right-to-left shunting at the ventricular outflow level.[76,295] On Doppler studies, shunting is usually bidirectional but predominantly right-to-left and of low-velocity owing to the small pressure gradient across the ventricles.

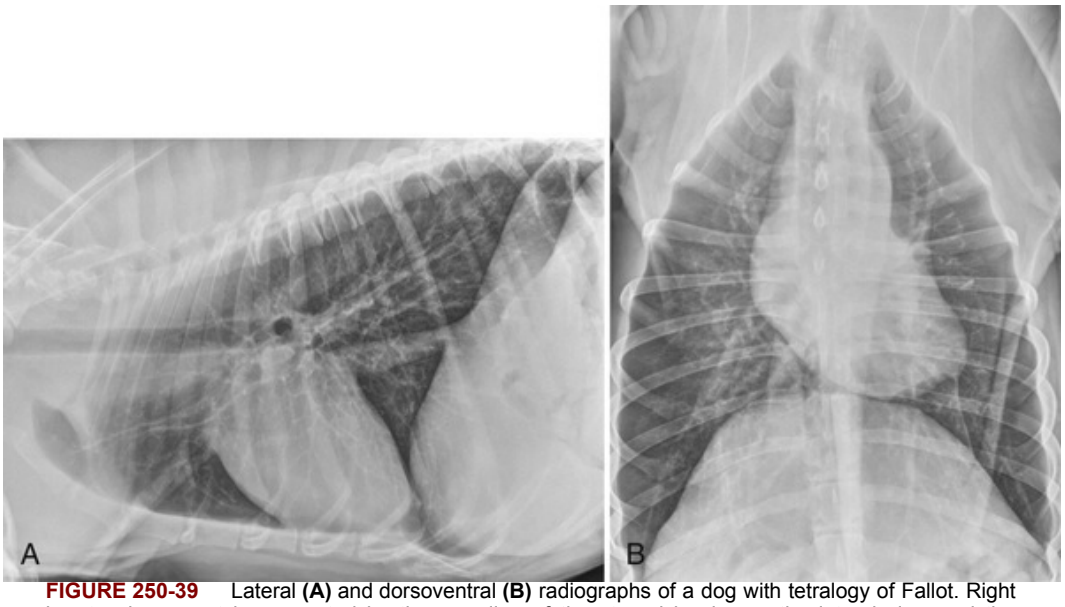

FIGURE 250-39 Lateral **(A)** and dorsoventral **(B)** radiographs of a dog with tetralogy of Fallot. Right heart enlargement is suggested by the rounding of the sternal border on the lateral view and the reverse D appearance on the dorsoventral view. The main pulmonary artery and peripheral pulmonary vessels are diminished.

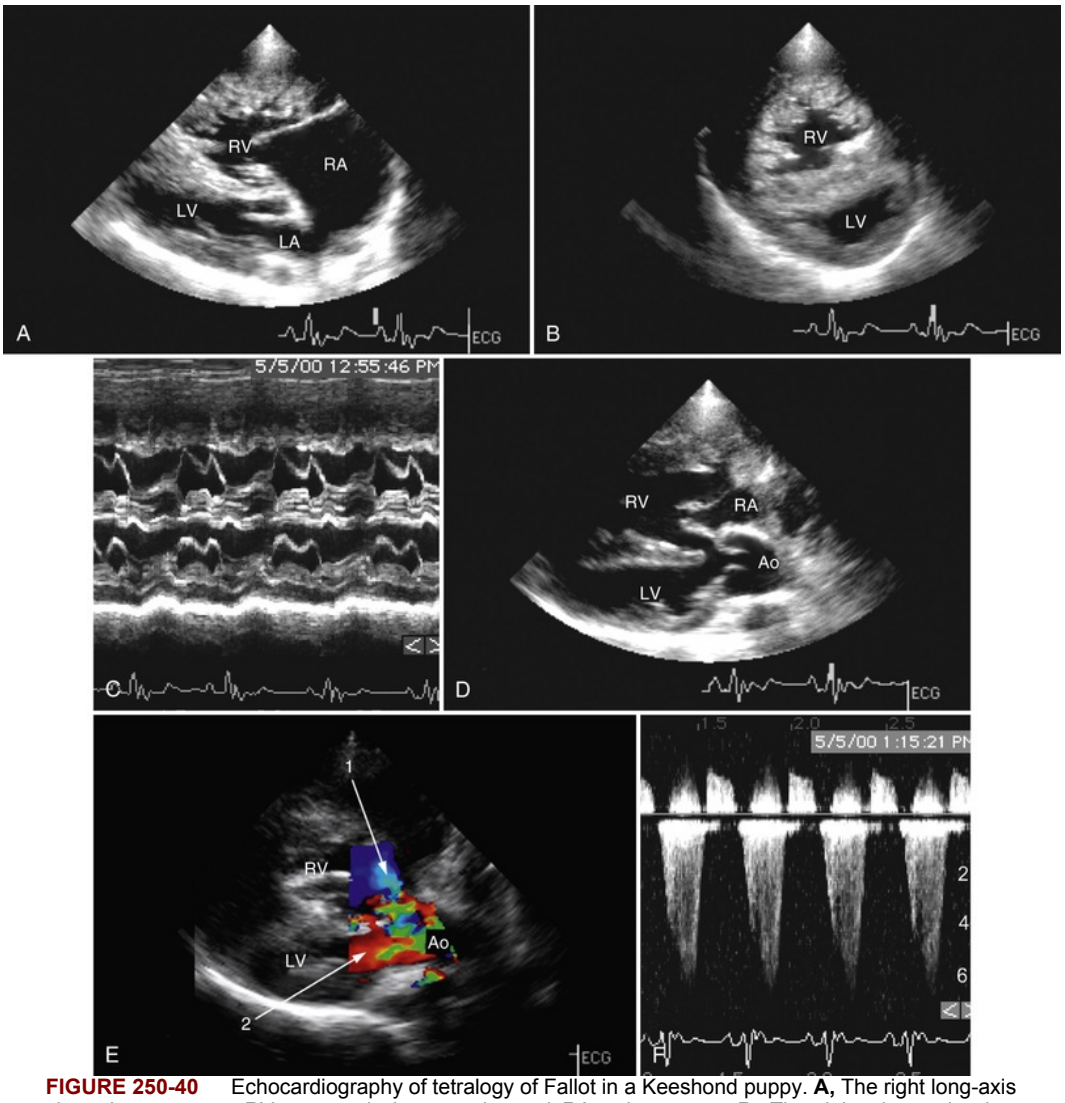

FIGURE 250-40 Echocardiography of tetralogy of Fallot in a Keeshond puppy. **A,** The right long-axis view shows severe RV concentric hypertrophy and RA enlargement. **B,** The right short-axis view shows severe RV concentric hypertrophy, flattening of the interventricular septum, a small underloaded LV, and hyperechogenicity of the RV subendocardium. **C,** The M-mode study shows enlargement of the RV as compared with the LV. The tricuspid and mitral valves are seen moving in the center of their respective ventricles. There appears to be paradoxical septal motion toward the RV during systole. **D,** The right long-axis view shows the VSD and rightward (dextropositioned) displacement of the aortic root and aorta (Ao). **E,** The color flow Doppler study of an image similar to that in **D** shows right-to-left shunting of blood from the RV (1), across the VSD, and merging with blood from the LV (2) into the Ao. **F,** The continuous wave Doppler study from the left heart base across the pulmonic valve indicates the presence of high-velocity blood flow caused by PS.

Cardiac catheterization demonstrates equilibration of LV and RV systolic pressures, compatible with RVOT obstruction and a large nonrestrictive (nonresistive) VSD.[291] Oximetry samples reveal a step-down at the LV outflow level and the aortic blood is relatively desaturated. Angiocardiography reveals both morphologic features and functional consequences of the malformation, including: RV hypertrophy; narrowing of the RV infundibulum; PS (typically from a hypoplastic pulmonary valve); minimal poststenotic dilatation of the pulmonary artery; varying degrees of pulmonary artery hypoplasia; a large perimembranous VSD; a small, dorsally displaced LV; enlarged, cranioventrally displaced and rightward-positioned aorta; and prominent bronchial circulation (Figure 250-41).[6,288-291] Bidirectional shunting across the VSD is common. In cases of pulmonary atresia, the pulmonary blood flow will be derived from the ductus arteriosus, bronchial arteries, or systemic collaterals. Cardiac catheterization is rarely needed for diagnosis but if performed anticoagulation therapy (e.g., heparin) should be considered to prevent systemic embolization during and immediately after the procedure.

FIGURE 250-41 Angiogram from a Keeshond with tetralogy of Fallot. The RV injection opacifies the RV, pulmonary artery, and aorta. Contrast can be seen in the region of the suspected VSD (*). The contrast column narrows in the RV outflow tract and region of the pulmonic valve (arrow). There is a large poststenotic dilation of the main pulmonary artery (arrowhead). A wide and rightward-positioned aorta can be appreciated.

Clinical Management

The natural history and survival times of dogs and cats with ToF are not well characterized. Like other cyanotic heart diseases, ToF can be tolerated for years, provided pulmonary blood flow is maintained and hyperviscosity is controlled.[128] Most affected animals have severely limited exercise capacity. Sudden death is common because of the combined consequences of hypoxemia, hyperviscosity, or cardiac arrhythmia. Unlike PS with intact ventricular septum, CHF is an unusual outcome in ToF.

Options for treating animals with ToF include medical and surgical approaches. Definitive correction of the defect (closing the VSD and removing or bypassing the stenosis) can be done under cardiopulmonary bypass, but such surgery is rarely performed in animals.[296,297] As a general rule, the stenosis should not be completely relieved if the VSD cannot be closed because the loss of RV pressure results in marked left-to-right shunting with subsequent left-sided CHF.[291,298] Some dogs have been treated with "gentle" ballooning of the RVOT to increase pulmonary blood flow. As an alternative to definitive correction, surgical palliation through the creation of a systemic-to-pulmonary shunt can be quite rewarding.[291,299-301] Some variant of the subclavian to pulmonary artery shunt (Blalock-Thomas-Taussig) has been created most often in dogs and cats. Some surgeons prefer to use a graft instead of turning down the subclavian artery. By creating a left-to-right shunt distal to the cyanotic defect, pulmonary perfusion is increased and there is a greater contribution of oxygenated blood to the systemic circulation. The size of the accessory shunt must be controlled to prevent overloading of the diminutive LV and subsequent pulmonary edema. The extent to which these shunts remain patent over long periods of time in veterinary patients has not been reported, but one of us followed a dog with a Blalock-Thomas-Taussig shunt that remained patent for over a decade. Another option, if a ductus arteriosus is still patent, is catheter-based stenting of the PDA to maintain or increase pulmonary blood flow.

Maintenance of hydration is important. Periodic phlebotomy, performed to maintain the PCV between 62% and 68%, produces a satisfactory result in many cases.[128] Excessive withdrawal of blood should be avoided, and the blood volume withdrawn should be replaced with crystalloid fluids to maintain cardiac output and

tissue oxygen delivery.[52] Some children with ToF benefit from nonspecific beta-blockade with propranolol to reduce hyperdynamic contraction of the RV that can increase outflow obstruction; however, controlled studies of the clinical efficacy of this treatment in animals are lacking.[53,56] Severe hypoxemic spells should be treated with cage rest, oxygen, IV fluids, and sodium bicarbonate (if metabolic acidosis is evident). Treatment with vasoconstrictive agents such as phenylephrine can also help reduce the amount of right-to-left shunting in an urgent situation. Drugs with marked systemic vasodilating properties, including acetylpromazine, should be avoided.

Other Causes of Cyanotic Congenital Heart Disease

Valvular Atresia

Pulmonary atresia with a VSD is the exaggerated form of ToF (Figure 250-42). All of the blood ejected from the right heart is shunted right-to-left across a large VSD and into an enlarged aorta. The tricuspid valve is usually normal. The term "pseudotruncus arteriosus" has been used for describing this defect. It differs from a true truncus arteriosus because the pulmonary arteries do not arise from the truncus and at necropsy careful dissection reveals an imperforate pulmonic valve and a vestigial pulmonary trunk connecting to the left and right pulmonary arteries. On occasion, both the pulmonic and tricuspid valves are atretic (see Figure 250-42). The RV is small or hypoplastic and blood returning to the RA shunts through a PFO or ASD to produce cyanosis. The lungs are supplied via a PDA or an extensive bronchoesophageal collateral circulation.

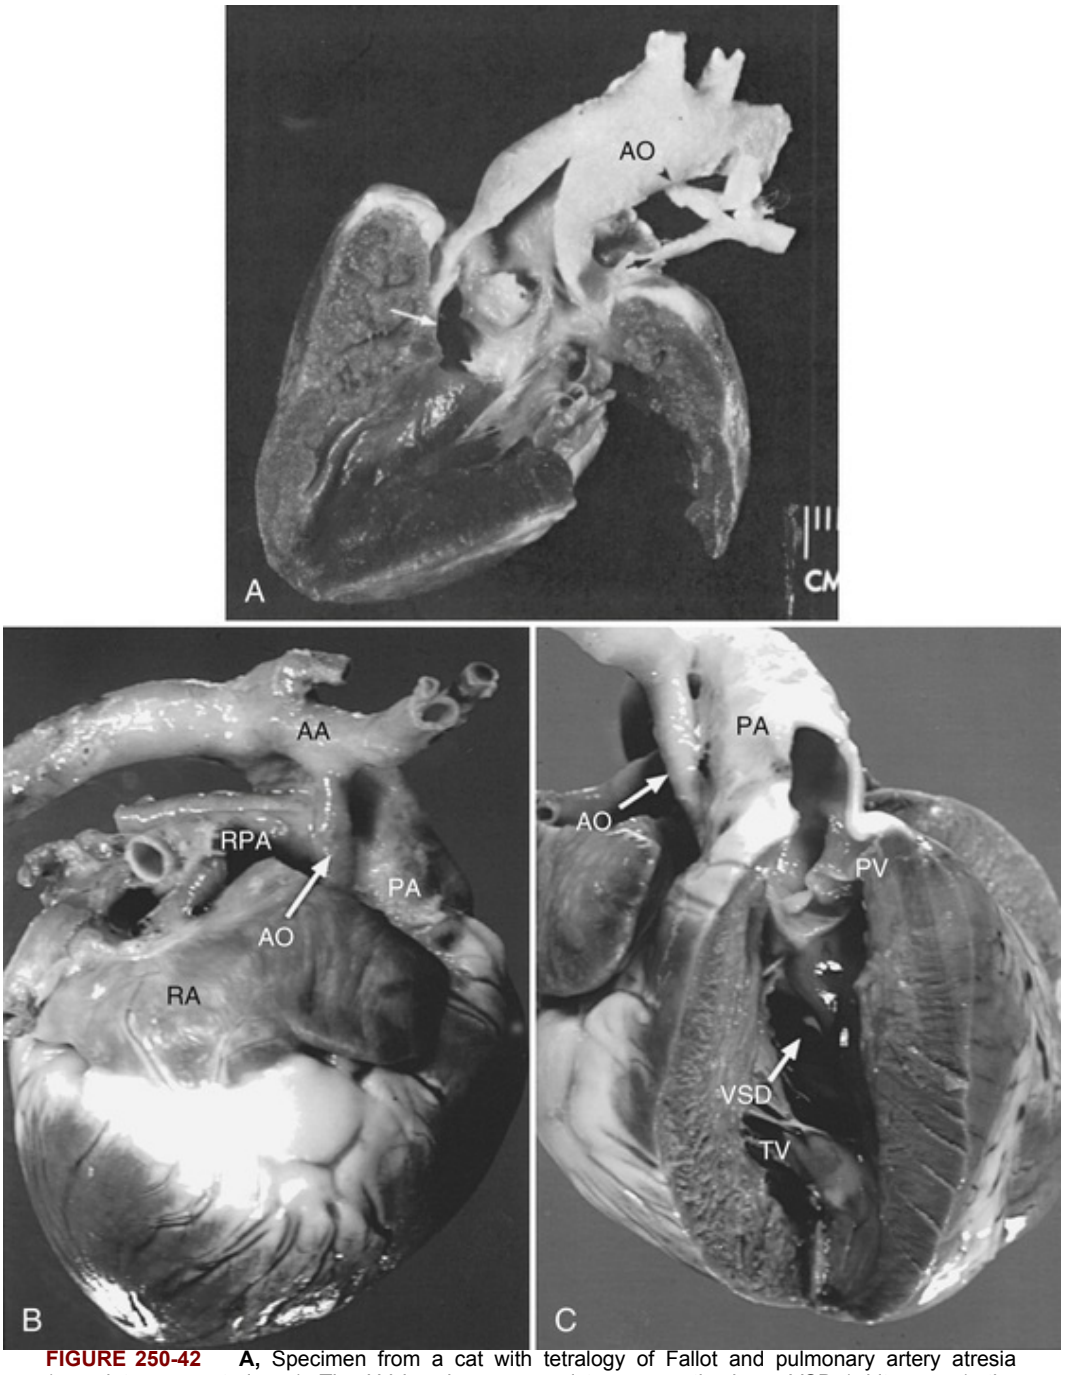

FIGURE 250-42 **A,** Specimen from a cat with tetralogy of Fallot and pulmonary artery atresia (pseudotruncus arteriosus). The LV has been opened to expose the large VSD (white arrow), the hypoplastic pulmonary artery (small black arrow), and the dilated aorta (AO). Pulmonary flow was through the ductus arteriosus, the origin and termination of which are shown by arrowheads. Although the lobar pulmonary arteries were patent, almost no blood was found in the main pulmonary artery. **B,** Specimen from a dog that exhibited severe cyanosis from birth. The proximal aorta is hypoplastic, and an aortic opening (valve) could not be identified (aortic valve atresia). A huge pulmonary artery (PA) gives origin to the right and left pulmonary branches, and a large patent ductal segment connects to the aortic arch (AA), supplying the brachiocephalic vessels, the descending aorta, and the hypoplastic aorta. **C,** Same dog as in **B.** Note the marked hypertrophy of the opened right ventricle, as well as the ventricular septal defect (VSD), which received blood from the underdeveloped left heart. *PV,* Pulmonic valve; *RA,* right atrium; *RPA,* right pulmonary artery; *TV,* tricuspid valve.

Aortic atresia with a hypoplastic left heart is a rare form of cyanotic heart disease in dogs. The aortic orifice is often imperforate and the ascending aorta is hypoplastic and the mitral valve is usually atretic or hypoplastic. In the absence of a VSD, the LV is very small; when a VSD is present, the LV is better developed. The right heart supplies the entire pulmonary and systemic circulations, resulting in profound cyanosis and, in most cases, early death.

Double Outlet Right Ventricle

Double outlet right ventricle (DORV) describes a heterogeneous group of malformations in which both great vessels exit from the RV. This has been reported in both dogs and cats (Figure 250-43).[302,303] A VSD provides the LV an avenue for outflow into the great vessels. Depending on the location of the VSD in relation of the origin of the great vessels, DORV can manifest as either pulmonary overcirculation or as a form of cyanotic heart disease. Concurrent abnormalities such as PS, pulmonary hypertension, and coarctation of the aorta can also affect the development of clinical signs. Surgical correction of this condition in dogs has been attempted.

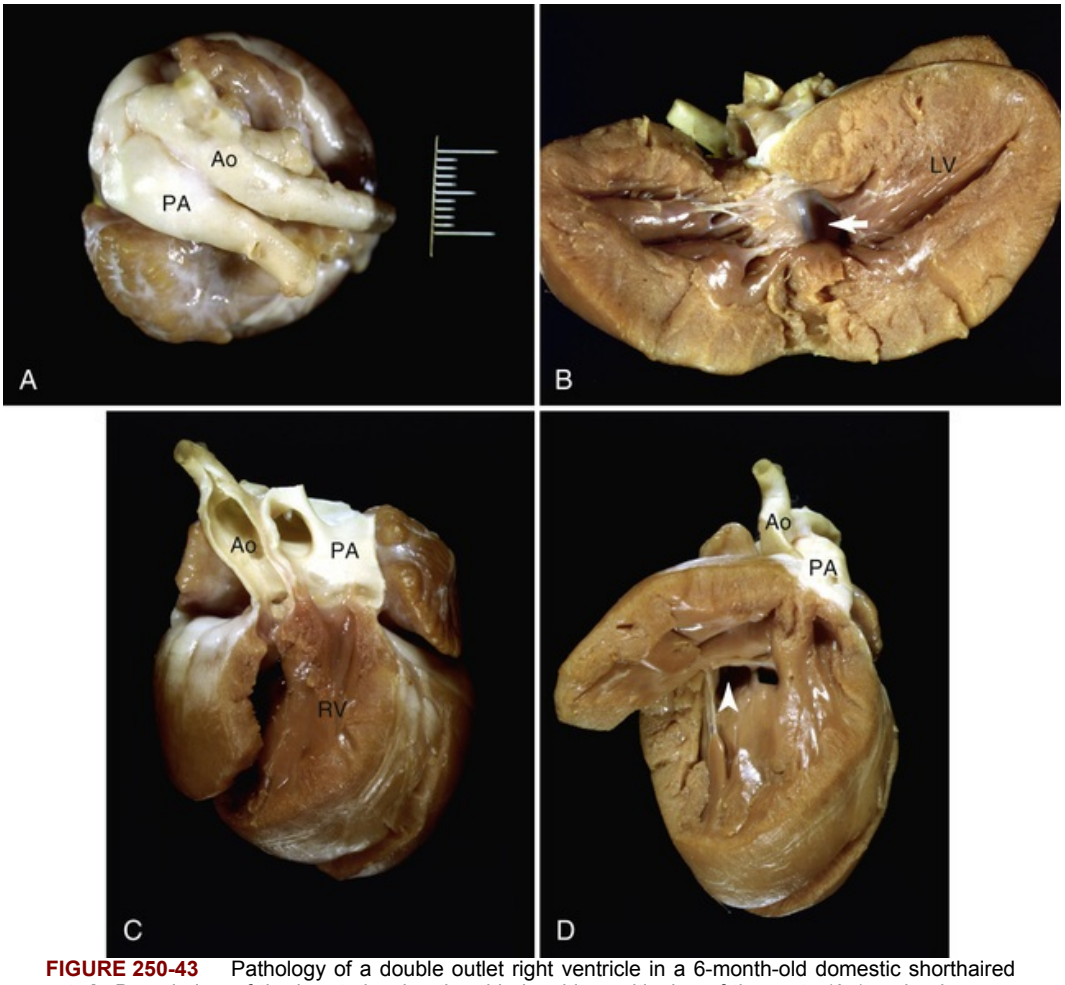

FIGURE 250-43 Pathology of a double outlet right ventricle in a 6-month-old domestic shorthaired cat. **A,** Dorsal view of the heart showing the side-by-side positioning of the aorta (Ao) and pulmonary artery (PA) at the cranial right edge of the heart. **B,** View of the VSD (arrow) from the LV side. Note the absence of an LVOT and aorta originating from the LV, and the discontinuity between the mitral valve apparatus and the missing aorta. **C,** View from the right cranial aspect showing the origin of the Ao and PA from the RV. The opening of the VSD into the RV is below the crista supraventricularis and is not easily seen in this view. **D,** The view of the right side of the interventricular septum reveals the location of the VSD (arrowhead) near the origin of the aorta (aortic-committed double outlet right ventricle). (Courtesy Dr. Richard Kienle).

Transposition of the Great Arteries

In D-transposition of the great arteries, the aorta originates from the RV and the pulmonary trunk from the LV.[47,304] In the pure and fatal case, two independent circulations coexist and the systemic arteries never receive oxygenated blood. Survival of an animal with D-transposition depends on the presence (or development) of shunts between the two circulations to allow for mixing of blood to prevent fatal hypoxemia. These defects are complex, generally lethal, and most likely underdiagnosed in animals, relative to children, since most animals probably die undiagnosed at a very young age.

Miscellaneous Cardiac Defects

The potential for variations in cardiac situs, for abnormalities in venoatrial, atrioventricular, and ventriculoarterial connections, and for malformation of the individual cardiac chambers, septa, and valves is tremendous.[38,39] It is beyond the scope of this chapter to discuss the spectrum of all potential or reported cardiac malformations in animals. It should be noted that ectopia cordis is extremely rare in cats and dogs in comparison to the situation in cattle. More often encountered are congenital abnormalities of the sternum. Some of these occur with some congenital heart defects, including peritoneopericardial diaphragmatic hernia (see ch. 254).

Atrial Malformations

Congenital heart defects affecting the atria include the previously mentioned forms of ASD along with defects that are more complex. These latter malformations include cor triatriatum sinister (CTS), cor triatriatum dexter (CTD), supravalvular mitral ring, and double outlet right atrium. As implied by the name, cor triatriatum refers to a partitioning of the left (sinister) or right (dexter) atrium into two chambers creating "three atria." Cor triatriatum is characterized relative to blood flow by a proximal (usually caudal) chamber in continuity with venous return and a distal chamber in continuity with the atrioventricular valve. The intra-atrial membrane obstructs venous return from the proximal chamber leading to venous congestion behind the affected side of the heart. Partitioning of the LA appears quite rare in veterinary medicine and is more often observed in cats while CTD (see below) is seemingly more common in dogs. With CTS, the left auricle is located distal to the obstructing membrane. One important differential diagnosis for CTS is supravalvular mitral stenosis or supramitral ring. This is a form of mitral stenosis characterized by an obstructive membrane between the mitral valve and the LA.[40,305] The left auricle is incorporated in the proximal, high-pressure chamber of the LA and the mitral valve can be normal or malformed. Both of these obstructions to pulmonary venous return are more often reported in cats and lead to clinical signs of pulmonary congestion. Management options are limited but one successful hybrid (surgical-catheter) procedure has been reported.[306] The differential diagnosis of obstructed pulmonary venous return must also include the so-called double-outlet right atrium. This malformation is characterized by extreme leftward deviation of the ventral atrial septum with insertion of the membrane dorsolateral to the mitral valve. Pulmonary venous return enters the LA and crosses a primum ASD into the RA, which connects to both atrioventricular valves. There are variations of this defect that can lead to clinical signs of pulmonary venous congestion or to desaturation and signs of cyanotic heart disease.[307]

Of the complex atrial malformations, CTD is most often reported and appears to occur mainly in dogs.[308-316] This condition involves an intra-atrial obstruction that impedes venous return from the caudal vena cava and coronary sinus. The distal (cranial) part of the RA includes the right auricle, which receives cranial venous return normally. This defect can develop in isolation or as part of a more general hypoplasia or obstruction within the right heart. Tricuspid valvular or supravalvular stenosis,[316] hypoplastic RV, and PS have all been observed in dogs with CTD. The typical case of isolated CTD leads to posthepatic venous obstruction with the clinical presentation of ascites most common. The degree of inflow obstruction varies and presumably can worsen over time, as some cases present after two years of age. In most cases, cranial vena caval blood drains normally into the cranial chamber and tricuspid orifice. The absence of a murmur can lead to an erroneous diagnosis of hepatic or intra-abdominal disease. Echocardiography is diagnostic. Both catheter-based and surgical interventions have been used to successfully manage CTD in dogs.

Ventricular Malformations

In addition to VSD and double-chambered right ventricle discussed previously, there are several relatively rare disorders of the ventricles reported in dogs and cats. The near absence of RV myocardium with replacement by fibrous tissue and fat (similar to Uhl's disease in humans) has been reported in cats and perhaps one dog.[317-319] The condition should be considered in the differential diagnosis of RV dilation and failure.

Endocardial fibroelastosis (EFE) has been reported in dogs and cats[3,320,321] and was believed to be familial in some lines of Burmese and Siamese cats. It is a rare diagnosis today and must be distinguished from secondary endocardial thickening associated with chronic LV dilation. Inasmuch as some of the gross and clinical features of the disease are similar to those of taurine deficiency in cats, there is speculation that some

of the previously reported feline cases might have been dilated cardiomyopathy with secondary EFE. The gross anatomic findings of primary EFE include LV and LA dilatation, with severe endocardial thickening characterized grossly by diffuse, white, opaque thickening of the luminal surface (Figure 250-44). Obstruction or abnormalities of lymphatic drainage of the myocardium is a suggested cause. Affected dogs can also have thickening of the mitral valve leaflets. Histologic lesions in well-studied feline cases include diffuse hypocellular, fibroelastic thickening of the endocardium with layering of thin, randomly organized collagen and elastic fibers. Edema of the endocardium with dilation of lymphatics is prominent, and there is no evidence of myocardial inflammation or necrosis. The clinical features of EFE include early development of left-sided or biventricular failure, generally before 6 months of age. Mitral regurgitation might be detected. Left ventricular and atrial dilation are evident on radiographs, ECG, and echocardiography. The clinical and necropsy differential diagnoses include MVD, AS/SAS, restrictive and dilated cardiomyopathy, and myocarditis with secondary EFE. Affected animals fail to thrive. Medical treatment of CHF (see ch. 247) might prolong life, but recovery is unlikely.

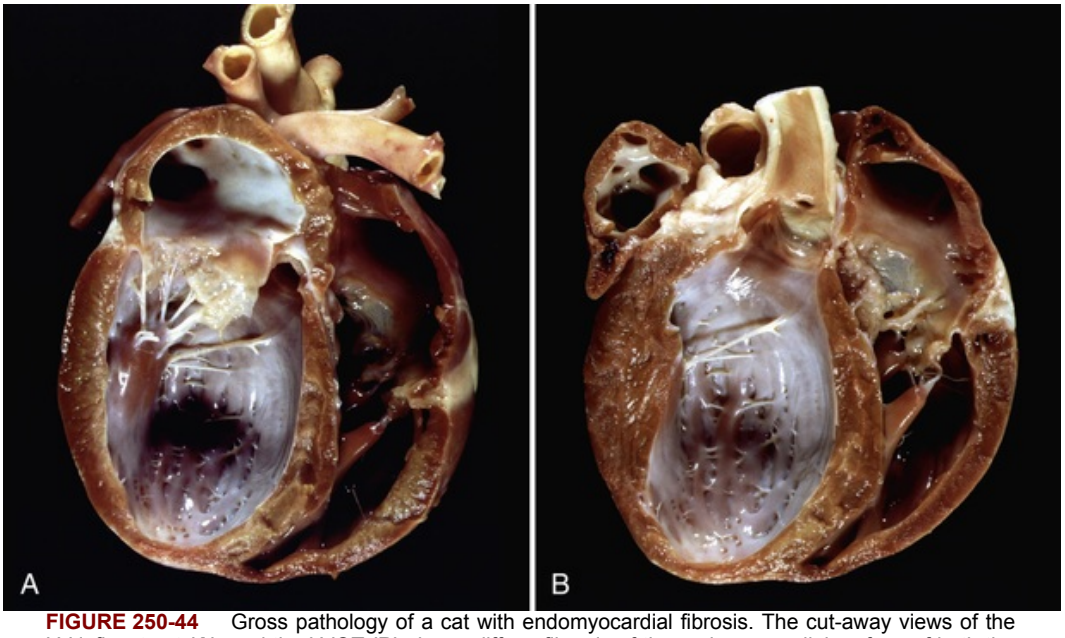

FIGURE 250-44 Gross pathology of a cat with endomyocardial fibrosis. The cut-away views of the LV inflow tract **(A),** and the LVOT **(B)** shows diffuse fibrosis of the endomyocardial surface of both the atrium and ventricle.

Vascular Anomalies

Arterial and venous vascular anomalies can be classified based on their location within the vascular system as systemic, pulmonary, or coronary. A number of vascular malformations has been reported, of which PDA represents the most important and has been previously discussed. Peripheral vascular disorders, including abnormal abdominal and hepatic venous drainage and arteriovenous fistulas, are detailed in ch. 284 and 257, respectively.

Arterial Anomalies

Malformations of the fetal truncus include persistent truncus arteriosus and aorticopulmonary septal defect (window). Truncus arteriosus communis is caused by failure of septation in the fetal truncus arteriosus and is characterized by a large VSD, a single great vessel exiting the heart, and is further classified by the origin and number of pulmonary artery branches originating from the truncus. The condition has been observed rarely in dogs and in cats,[322-325] and clinical signs depend largely on whether pulmonary blood flow is increased (i.e., left-to-right shunt) or restricted (in which case cyanosis is likely). An aorticopulmonary septal defect is caused by failure of the truncus arteriosus to fully differentiate, causing a common opening between the aorta and pulmonary artery, and shunting between the left and right sides of the circulation.[100] While a clinical

condition similar to that of PDA can develop, in other cases pulmonary hypertension develops during the first year of life and clinical signs are then similar to dogs that develop Eisenmenger's physiology associated with other defects. Management is similar to that for a reversed PDA. Surgery is difficult without cardiopulmonary bypass and should not be attempted if pulmonary vascular resistance is markedly elevated.

Coronary arteries can develop anomalously, but rarely cause documented clinical disease except in cases of single right coronary ostium with prepulmonary passage of the left branch of the coronary artery. This is most common in English bulldogs and was discussed previously under PS. However, coronary malformations also can be observed in the absence of PS in some dogs (including English Bulldogs) and other coronary variations are recognized in dogs with PS. For example, single left coronary ostium has been reported in English Bulldogs with valvular PS.[326] Rarely, shunting has been reported involving coronary arterial connections to the pulmonary arteries or to the heart.[327,328] The authors have observed other coronary malformations during angiography, including cameral fistulas and abnormal connections of coronary vessels to other systemic arteries.

Aortic abnormalities are often associated with SAS. As mentioned previously, these aortic dilations or aneurysms can occur in the absence of overt SAS and might represent aortopathies in some affected breeds including Rottweilers, Golden Retrievers, and Leonberger dogs.[65] Coarctation of the aorta, a shelf-like narrowing near the ductus arteriosus, and more extreme examples of aortic obstruction such as tubular hypoplasia or interruption of the aorta are rarely observed in dogs and cats (two cases are reported in English Bulldogs).[329,330]

In veterinary medicine, vascular ring anomalies refer to malformations that entrap the esophagus leading to regurgitation in weanlings. Persistence of the right aortic arch, as opposed to the left fourth aortic arch, is the most commonly reported. Vascular ring anomalies include this common malformation along with other total or partial ring anomalies. These include esophageal compression formed by retroesophageal subclavian arteries, double aortic arch, or left aortic arch with right-sided ligamentum arteriosum.[4,25,29,37,331-334] Such disorders are relatively common in German Shepherd dogs and have been recognized in many other canine breeds including Irish Setters, Great Danes and German Pinschers. Vascular ring anomalies are less common in cats but have been seen.[37,102,331,334] Occasionally, other cardiac defects are present, including PDA and persistent left cranial vena cava (Figure 250-45). Diagnosis of persistent right aortic arch can usually be made from the history and by inspecting a VD or DV radiograph that shows leftward deviation of the trachea at the heart base.[335] More complicated lesions require CT, MRI, or standard angiography. These conditions are described more fully in ch. 273 and in the references.[29,37]

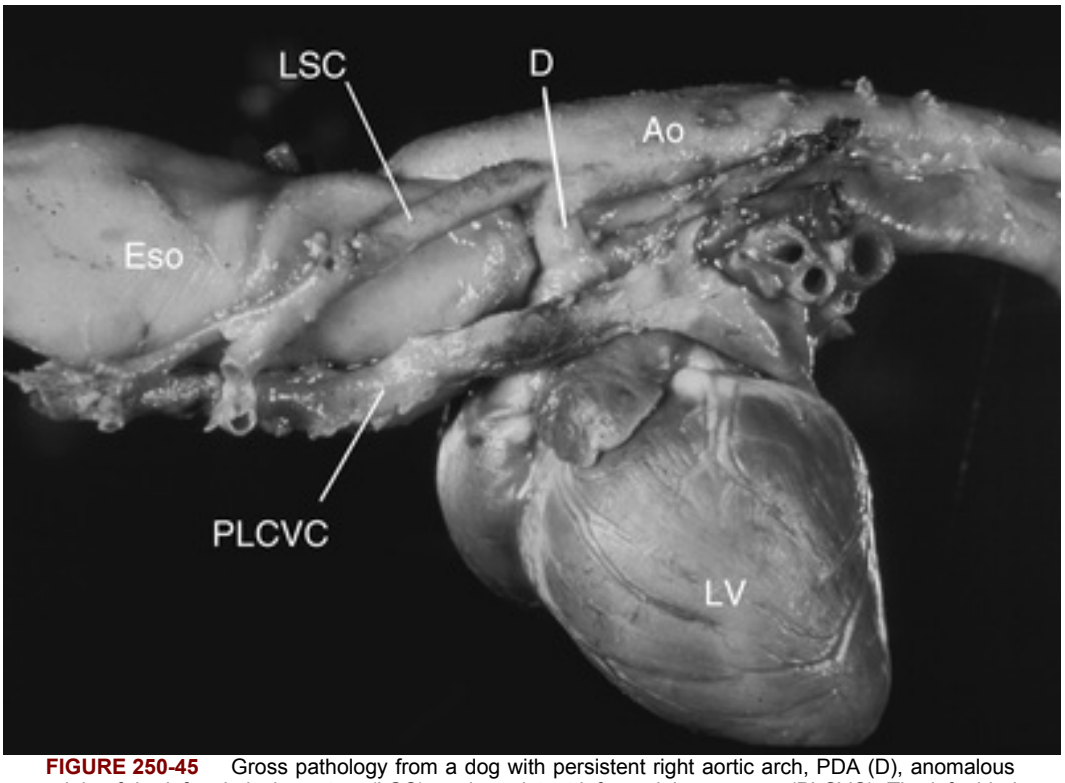

FIGURE 250-45 Gross pathology from a dog with persistent right aortic arch, PDA (D), anomalous origin of the left subclavian artery (LSC), and persistent left cranial vena cava (PLCVC). The left-sided view of the heart, great vessels, and esophagus (Eso) shows the entrapment and cranial dilation of the esophagus by the vascular ring. The origin of the left subclavian artery is moved distal from its usual location and is dorsal to the esophagus. The PLCVC can be seen extending laterally alongside the esophagus and left heart base, and coursing around the caudal waist of the heart. *Ao,* Aorta.

Abnormalities of the pulmonary arteries can be observed under a number of conditions. Unilateral atresia or hypoplasia of a pulmonary artery has been recognized in cats. Pulmonary artery dissection is reported as a complication of PDA in dogs.[111] An overlooked diagnosis is that of systemic-to-pulmonary arterial vascular malformations.[102,336,337] These arteriovenous malformations are typically multiple, and can connect the aorta, brachiocephalic artery, or other systemic arteries to the pulmonary arterial system. The result is volume overloading of the left side of the heart. Murmurs are often difficult to detect, but can include continuous murmurs related to the shunts or systolic murmurs due to functional mitral regurgitation from LV dilation and increased aortic blood flow. The diagnosis can be suspected from color Doppler imaging of the pulmonary artery and failure to identify a typical ductus arteriosus. CT angiography or contrast angiography are diagnostic. Management can include surgical intervention or coil occlusion of the vascular malformation; however, the clinician should always suspect multiple shunts and the potential for opening of new arteriovenous malformations with the closure of others.

Venous Anomalies

Venous anomalies, especially those unrelated to the heart, are discussed more fully in ch. 257. Venous malformations rarely cause cardiac problems in small animals. Total or partial anomalous pulmonary venous return has been reported rarely, and it behaves functionally as a left-to-right shunt at the atrial level. This is most commonly associated with a sinus venosus–type ASD with partial anomalous venous drainage into the right atrium across the ASD. Abnormalities of abdominal venous drainage, such as patent ductus venosus, can induce hepatic encephalopathy (see ch. 284).

A relatively common venous abnormality of clinical significance during thoracic surgery or cardiac catheterization is the persistent left cranial vena cava (Figure 250-46).[70,338-340] This structure, normally present in the fetus as part of the left cardinal venous system, can persist and drain into the embryonically related coronary sinus in the caudal aspect of the RA. Diagnosis is straightforward in most cases and can be made using 2D echocardiography by recognizing a dilated coronary sinus near the atrioventricular groove. The diagnosis can be confirmed by contrast (saline) echocardiography, CT angiography, or contrast angiography

(see ch. 104). A persistent left cranial vena cava can interfere with surgical exposure, particularly during surgical treatment of persistent right fourth aortic arch, or confound cardiac catheterization, but otherwise it is of no known functional significance (Figure 250-47). As with persistence of the right fourth aortic arch, this vascular anomaly is common in German Shepherd dogs, and has been reported in other canine breeds as well as in cats. Division of this vessel generally poses no clinical problem provided the normal right cranial vena cava is also present (see Figure 250-47).

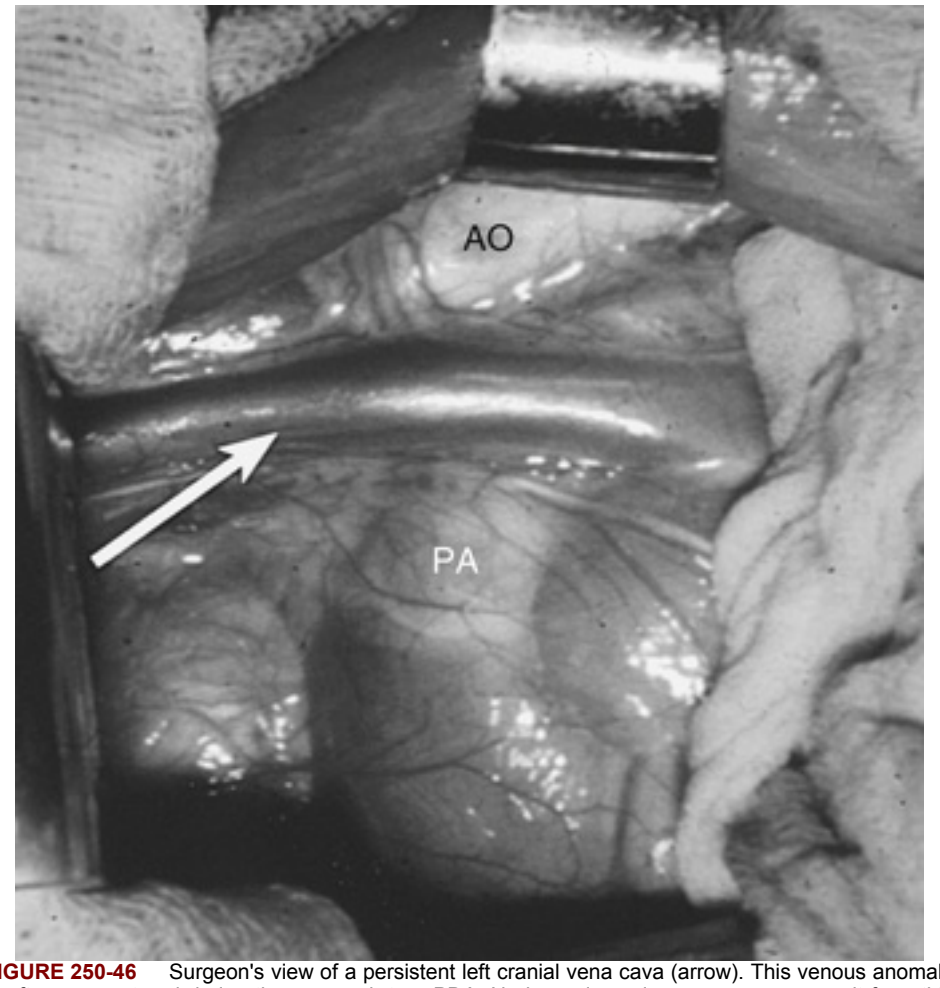

FIGURE 250-46 Surgeon's view of a persistent left cranial vena cava (arrow). This venous anomaly is often encountered during the approach to a PDA. No hemodynamic consequences result from this anomaly. *AO*, Aorta; *PA*, pulmonary artery.

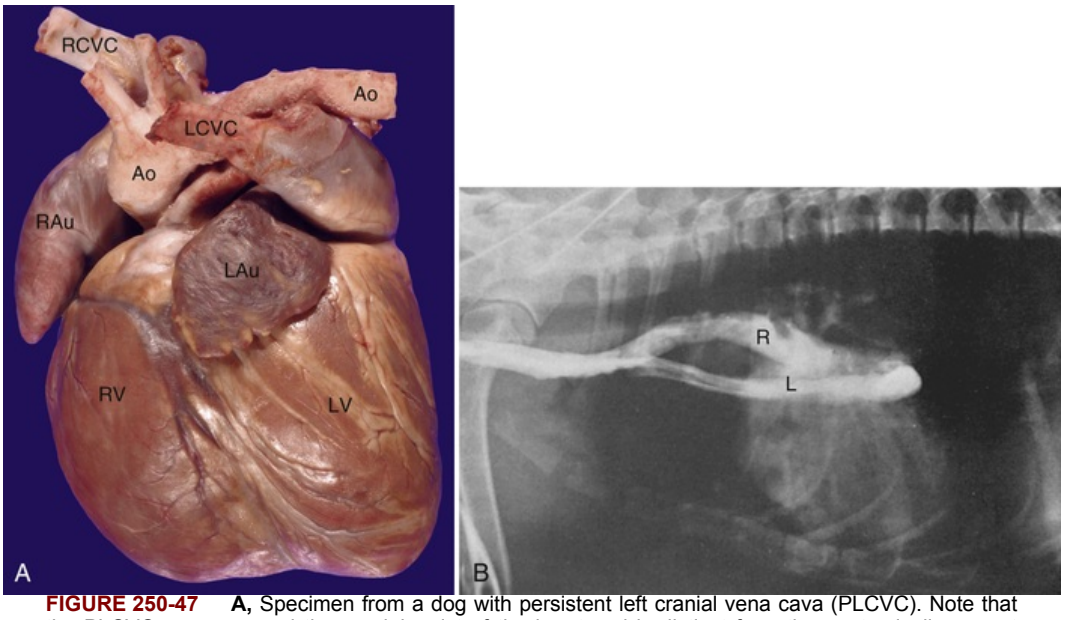

FIGURE 250-47 **A,** Specimen from a dog with persistent left cranial vena cava (PLCVC). Note that the PLCVC wraps around the caudal waist of the heart and is distinct from the anatomically correct right cranial vena cava (RCVC). **B,** Nonselective angiogram from a dog. Contrast is injected into the right and left jugular veins. The normal right cranial vena cava (R) is evident, as is the PLCVC (L). Note that the PLCVC wraps around the caudal aspect of the heart and enters into the caudal portion of the RA. *Ao,* Aorta; *LAu,* left auricle; *RAu,* right auricular appendage.

CHAPTER 251

Adult-Onset Valvular Heart Disease

Ingrid Ljungvall, Jens Häggström

Client Information Sheet: Myxomatous Mitral Valve Disease

Myxomatous Mitral Valve Disease

Myxomatous mitral valve disease (MMVD) is characterized by a slow progressive myxomatous degeneration of the mitral valve apparatus with subsequent left atrial (LA) and ventricular (LV) dilatation.[1-4] Although the myxomatous degeneration most commonly affects the mitral valve, any of the four intracardiac valves can be affected. However, the pulmonary and aortic valves (the semilunar valves) rarely develop pronounced degenerative changes.[2,3,5] The condition has been given many names, such as chronic valvular disease, degenerative mitral valve disease, mitral valve disease, endocardiosis, and more recently myxomatous mitral valve disease. The term "myxomatous" describes a characteristic histologic feature of this disease and excludes most, if not all, other forms of mitral valve disease, but MMVD does not necessarily exclude involvement of other valves. Thus, MMVD accurately and succinctly defines the pathophenotype of this condition.

Occurrence

MMVD is the most prevalent cardiac disease in dogs, and has been estimated to account for 75% to 80% of canine cardiac diseases.[1,6-9] MMVD is encountered in all breeds, but the highest prevalence is seen in small to medium-sized dog breeds, such as Cavalier King Charles Spaniel (CKCS), Dachshunds, miniature Poodles, and Yorkshire Terriers.[8-13] Affected dogs have no signs of valve abnormalities at birth, but develop MMVD later in life. The prevalence increases with age and is, at a given age, higher in males.[1,2,6,7,9,12] The prevalence of MMVD in cats without primary myocardial disease is unknown, but seems to be low. Similar changes of the mitral valve are also seen in humans, horses, and pigs.[14-16]

Inheritance and Breeding

The etiology of MMVD has not been ascertained but heredity has long been suspected to play a major role; owing to the strong association of this disease with certain small to medium-sized breeds. Studies of families of CKCS and families of Dachshunds provide evidence that genetic factors play a large role in the etiology.[17-19] These studies suggest that the disease has a polygenic inheritance; that is, multiple genes influence the trait and a certain threshold has to be reached before MMVD develops.[17,18] The polygenic mode of inheritance means that a combination of a sire and a dam, that both have an early onset of MMVD, will give offspring that have, on average, an early onset of MMVD (and CHF). A combination of dogs with late onset will give offspring that manifest the disease at old age or never. Males have a lower threshold than females, which means that males will develop the disease at a younger age than females within a family of dogs in which the offspring on average have the same genotype. Two loci, located on chromosomes 13 and 14, have been shown to be associated with an early onset of MMVD in CKCS dogs.[20] This finding is likely to herald causative mutations in the future, and such discovery will clearly increase the knowledge of disease pathways, and may lead to genetic tests, but no such tests are currently available. The major role played by genetic factors implies that other factors, such as level of exercise, degree of obesity, and diet, have minor influence on disease development. Breeding programs aimed at reducing the prevalence of MMVD have been launched in Europe and North America and elsewhere for CKCS and Dachshunds. In the absence of reliable genetic tests, these

breeding programs use auscultation to identify the presence of a heart murmur, and/or echocardiography to detect and quantify mitral valve degeneration and/or mitral regurgitation (MR). Dogs that are under a specific age and have developed a certain degree of heart murmur or echocardiographic findings consistent with MMVD are not allowed to breed within the programs. Some programs are also partly based on assessments of MMVD status of the parents. The age limit for potential breeding dogs and parents is very important: The age limit should be set at an age at which dogs with an early onset of MMVD are excluded, but not too high because this may impoverish the breeding population and reduce it to unacceptable low numbers.[21] A recent evaluation of a breeding shows a reduction in prevalence of heart murmurs and severity of mitral valve lesions assessed by echocardiography.[22]

Pathology

Macroscopic appearance of myxomatous degeneration depends on at which stage of disease the valve is examined, and macroscopic findings in cases of mild myxomatous degeneration might be overlooked if not investigated thoroughly.

The changes begin in the area of apposition of the leaflets and are usually most pronounced in sections where chordae tendineae insert. The free edges of the leaflets, which normally are thin, translucent and soft, become thickened and irregular, with areas showing bulging/ballooning towards the LA side (Figure 251-1, *A* and *B*).[1-3,23,24] The chordae tendineae themselves might also become affected by the myxomatous degeneration.[3,13,23] With progression, the bulging becomes worse, and the lesions spread into other parts of the leaflets (Figure 251-2, *B*). In late stages, fibrosis can cause marked thickening and contraction of leaflets and chordae tendineae. The chordae tendineae might rupture, which leads to an unattached free edge. Atrial endocardial lesions (fibrosis) opposite the mitral orifice (i.e., "jet lesions") might be observed. In severe cases, varying degrees of atrial rupture, such as endomyocardial splits, ruptured pectinate muscles in the atrial appendage, acquired atrial septal defect, and hemopericardium might be seen (see ch. 254).[2,25]

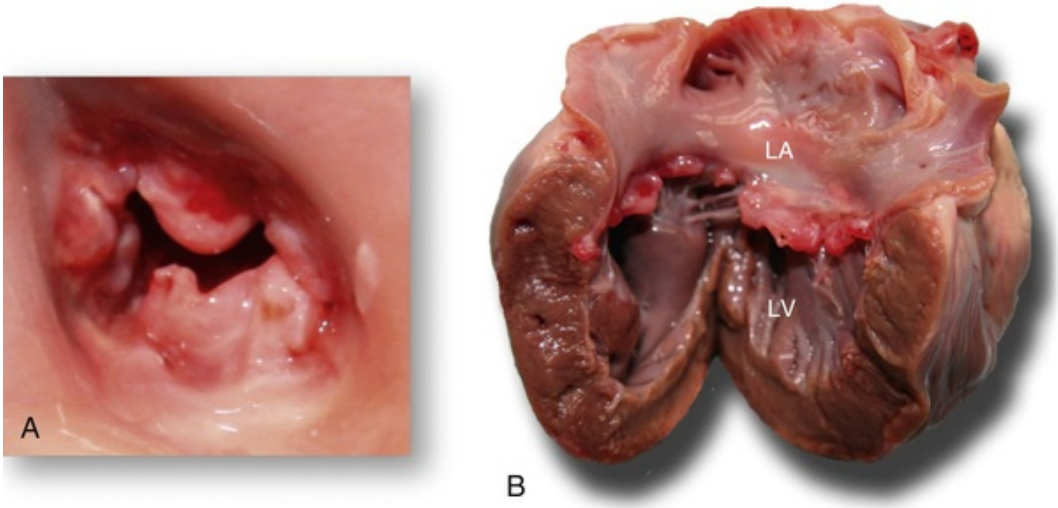

FIGURE 251-1 Postmortem specimen of a dog that suffered from severe myxomatous mitral valve disease (MMVD) viewed from the atrial **(A),** and lateral side **(B)** with the left atrium (LA) and ventricle (LV) opened. The mitral valve leaflets are thickened and contracted, with nodules rolling in the free edges and with areas bulging/prolapsing towards the left atrial side. Chordal rupture, particularly of lesser-order chordae, is a common finding. A jet lesion, which is present on the atrial wall, is a result of the high velocity regurgitant stream of blood from the LV striking the atrial wall.

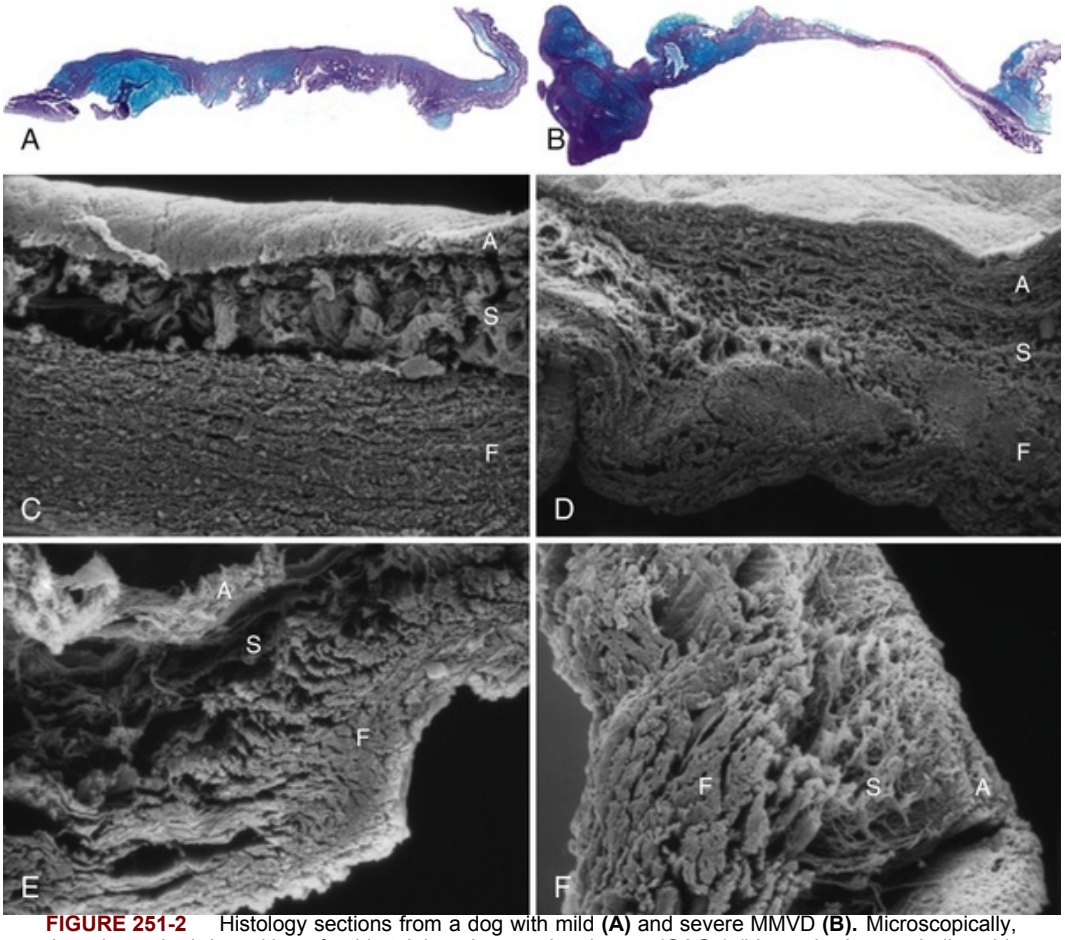

FIGURE 251-2 Histology sections from a dog with mild **(A)** and severe MMVD **(B).** Microscopically, there is marked deposition of acid-staining glycosaminoglycans (GAGs) (blue color in a periodic acid-Schiff [PAS] reaction/alcian blue staining) in the spongiosa and fibrosa layers of the leaflets. Scanning electron micrographs of a cell-macerated abnormal canine mitral valve at the level of the mid-zone **(C-F).** The images illustrate the damage to the valve leaflet that occurs as the disease progresses through the different Whitney grades (micrographs **C-F** corresponding to Whitney grades 1-4).[5] There is a loss and distortion of the layered structure with advancing disease and concurrent reduction in collagen density in all three layers. *A,* Atrialis layer; *S,* spongiosa layer; *F,* fibrosa layer. (**A** and **B,** Courtesy Lisbeth Höier Olsen, University of Copenhagen, Denmark. **C-F,** From Han RI, Impoco G, Culshaw G, et al: Cell maceration scanning electron microscopy and computer-derived porosity measurements in assessment of connective tissue microstructure changes in the canine myxomatous mitral valve. *Vet J* 197:502-505, 2013. Published with permission from the publisher.)

Histopathological findings in the valve leaflets include myxomatous degeneration (Figure 251-2, *A* and *B*), which refers to a characteristic pathological weakening and disturbance in the organization of the connective tissue in which the spongiosa component is unusually prominent, and the collagen fibers are disorganized in the fibrosa layer (Figure 251-2, *C-F*).[26,27] Increased amounts of mucopolysaccharides, and glycosaminoglycans are commonly seen within affected valves.[3,27,28] Characteristic findings of endothelial cells covering the valve surface include pleomorphism and damage to the cell lining. The endothelial damage, which is most commonly evident near the edges of the valve leaflets, can cause regional loss of endothelial cells, hence exposing underlying basement membranes or subendothelial matrix.[23]

Histopathological findings in the left heart chambers include changes in composition and structure of both the extracellular matrix (ECM) and the myocytes, but the underlying cellular and molecular bases for these changes remain poorly understood. Both myocardial fibrosis and intramyocardial arteriosclerosis, especially in the papillary muscles, have been described in dogs with advanced stages of MMVD.[29,30]

Pathogenesis

Little is known about the pathogenesis of the progressive thickening and degeneration of the leaflets. Probably, one or more primary inciting factors increase(s) the risk of disease in predisposed dogs as not all

dogs develop atrioventricular valve myxomatous degeneration.

It likely plays an important role for the progression of the disease that the endothelium is damaged or even missing in diseased areas,[23,24,31] because endothelial cells are known to communicate extensively with subendothelial cells (e.g., valvular interstitial cells, VICs). Endothelial damage induces release of vasoactive peptides, such as endothelin-1, which potentially is involved in transforming subendothelial VICs from a predominantly fibroblast phenotype into more active myofibroblast and smooth muscle cell phenotypes.[23,26,32] The transformation of VICs has also been suggested to be initiated by serotonin (5-HT),[33-35] and serum concentrations of 5-HT have been shown to be higher in CKCS dogs compared to dogs of some other breeds,[33,36] and also increased in mitral valve and left ventricular (LV) myocardial tissue in MMVD dogs.[37] Likewise, expression of 5-HT receptors and extracellular matrix signaling molecules are altered in diseased mitral leaflets.[34,38,39] Proteolytic enzymes, such as the matrix metalloproteinases (MMPs), might also be involved in the degenerative processes, leading to atypical organization of connective tissue components.[38,40-42]

Pathophysiology

Mitral Regurgitation Caused by Myxomatous Mitral Valve Disease

Distortion of the valve architecture and the corresponding chordae tendineae leads to systolic atrial displacement of the mitral valve leaflets (i.e., mitral valve prolapse),[43] and abnormal coaptation of the mitral valve leaflets during ventricular systole. Thus, a percentage of the LV stroke volume is ejected backwards into the LA. Elongation and potentially rupture of the chordae tendineae structures worsens MR by causing leaflets to partially or completely prolapse (valve flail) into the LA.[13]

The MR volume has been described to depend on the mitral valve orifice area, and the systolic pressure gradient between the LA and the LV,[44,45] of which the latter is influenced by the intra-atrial pressure, LV function, as well as the systemic arterial blood pressure. The myxomatous degeneration of the mitral valve apparatus causes an abnormal leaflet apposition, and hence primary MR, whereas left-sided cardiac dilation exaggerates the abnormality in valve apposition, leading to secondary MR.[2,46] Consequently, regurgitation begets regurgitation. Most commonly, dogs with MMVD have a laterally directed MR jet, presumably because the anterior leaflet is longer and has a greater mobility than the posterior leaflet (as described in dogs and people),[46,47] and hence, is more likely to prolapse than the posterior leaflet. However, the spatial orientation of the jet is not constant, particularly not in mild cases of MR, probably due to changes in the shape and orientation of the mitral orifice area during LV contraction.[48]

Primary MR of lesser degree does not induce any apparent change in indices of cardiac size or function. The forward stroke volume is maintained, and the small regurgitant volume is easily accepted by the LA. With progression of the valve lesions, the regurgitant part of the total LV stroke volume increases, but several cardiac and non-cardiac (e.g., renal, neurohumoral, and vascular) compensatory mechanisms contribute to maintain the forward stroke volume.[49] Expansion of the LA, buffers the increasing MR volume, thereby allowing the intra-atrial pressure to remain comparably low, and blood can easily be ejected into the LA during ventricular systole, even in dogs with severe MMVD. More than 75% of the total LV stroke volume has been reported to be ejected into the LA during systole in dogs with severe MMVD.[50] The severity of left-sided cardiac dilation is linked to MR severity, suggesting that MR volume is the major determinant factor for the degree of left-sided cardiac dilation.[50,51]

The extra pathway (into the LA) for stroke volume ejection reduces the LV afterload (the resistance to LV emptying), whereas the increased volume load leads to an increased preload.[52] The retrograde ejection of LV stroke volume starts in early systole, leading to a short isovolumetric contraction period (defined as the interval between closing of the atrioventricular valves and opening of the semilunar valves).[53,54] The LA has an important function by allowing the regurgitant volume to be absorbed within the atrial cavity, and it protects the pulmonary vascular bed from hypertension.[55] Increased LA pressure results in pulmonary venous congestion and edema. The effect of regurgitant volume on LA pressure and volume, and consequently pulmonary capillary pressure, depends on the LA size, as well as on the compliance of the LA wall. Consequently, LA compliance is determined by the rate of increase in regurgitant volume, which itself is determined by the rate of progression of MMVD, and by remodeling in response to the volume overload. In cases with slowly progressing MMVD, there is often a drastic enlargement of the LA, whereas pulmonary congestion and pulmonary edema develop late. The edema is also delayed by the development of a more

effective lymphatic drainage of the pulmonary interstitium in chronic pulmonary congestion.[56] In cases with acutely increased MR, as in rupture of a first order, or several, chordae tendineae, the LA is unable to adapt, which results in a rapid elevation of LA and pulmonary capillary pressure, and consequently rapid development of pulmonary congestion and edema.

The passive back-transmission of increased LV filling pressure to the pulmonary capillaries can furthermore lead to development of pulmonary hypertension, and dogs with more severe MR, and therefore higher LA pressure, have an increased risk of developing pulmonary hypertension.[57]

The LV compensates for the loss of forward stroke volume by increasing the end diastolic volume, and in order to accommodate the increased filling pressure (preload), the LV undergoes various compensatory responses (see ch. 246). The volume overload triggers an unnatural growth—so-called eccentric hypertrophy, which is characterized by chamber enlargement but with maintained relative wall thickness. This is sufficient to normalize pressure in the volume-overloaded LV and maintain an adequate forward stroke volume.[58-60] Myocardial hypertrophy has also been suggested to be stimulated by increased neurohormonal activation, such as by increased formation of angiotensin II (AII),[61] although circulating levels of AII appear comparably unchanged during progression from mild MMVD to overt CHF.[62] However, the canine myocardium is most likely capable of forming AII locally in the heart in response to hemodynamic wall stress: Angiotensin converting enzyme (ACE), chymase and cathepsin D have all been reported capable of promoting tissue AII formation in the volume-overloaded canine heart.[61,63]

Although both long- and short-axis dimensions increase in response to chronic volume overload, the short-axis dimension increases more, which leads to a change in LV shape from elliptical to more globular.[64] The increase in global LV sphericity might allow myocardial adaptation to abnormal regional wall stress. A more globular LV shape might contribute to a further increase in volume overload by stimulating secondary MR due to disruption of normal mitral annular geometry.[49]

The compensatory mechanisms, such as LV hypertrophy, dilation, and enhanced activity of the neurohormonal system, are all initially considered beneficial in order to provide the hemodynamic support needed to maintain sufficient cardiac output despite MR. However, with progression of disease, these mechanisms themselves become factors leading to deterioration of the failing heart, such as by myocyte injury and accumulation of collagen fibers (i.e., myocardial fibrosis).[49,60]

The cardiac remodeling by chronic volume overload in MMVD dogs will, in turn, impact mechanical function of the heart. The increased preload causes an increased force of contraction according to the Frank-Starling mechanism.[65] Depending on severity of MR, these changes lead to normal to hyperdynamic LV contraction (hyperkinesia), even in the presence of intrinsic myocardial dysfunction. Although myocardial systolic function declines with progression of disease, the remodeling process allows the LV to retain a relatively well-preserved forward cardiac pump function even in advanced MMVD.[49,66] Nevertheless, because of chronic volume overload and the fact that the hypertrophy, while necessary, is a pathologic remodeling, myocardial contractility decreases slowly, but progressively and inexorably, even in clinically compensated dogs.[67-69] An increased amount of myocardial fibrosis has been suggested to influence the Frank-Starling mechanism in heart failure dogs,[65] and thereby disable an optimal transduction of contractile force generated by the myocytes in systole. However, increased pulmonary blood volume, and not decreased forward stroke volume, has been shown to be the main cause of abnormal cardiopulmonary function in dogs with MMVD.[51] This finding corresponds with the clinical observation that dogs with severe MR suffer more commonly from pulmonary congestion and edema (which cause respiratory signs) than signs caused by reduced forward cardiac output (lethargy, weakness, exercise intolerance).[70]

Tricuspid Regurgitation Caused by Myxomatous Valve Disease

Tricuspid regurgitation (TR) is a common incidental finding in dogs and cats.[71] Tricuspid regurgitation commonly occurs concomitantly with myxomatous degeneration of the mitral valve as a consequence of primary valvular changes, and/or secondary to pulmonary hypertension due to left-sided myxomatous degeneration. The degenerative changes of the tricuspid valve apparatus are identical to those found when the mitral valve is affected (see Pathology section).[72]

Myxomatous degeneration of the tricuspid valve commonly leads to TR of mild to moderate degree. Tricuspid regurgitation, in the absence of concurrent obstruction of the pulmonary valve or pulmonary artery hypertension, is comparably well tolerated.[73] However, because the right ventricle (RV) is designed to contract against a low-pressure artery, it is vulnerable to increases in pressure. It responds poorly to the

increased work; even relatively small acute increases in pulmonary artery pressure cause sharp decreases in RV stroke volume.[74] Thus, TR is of significance if pulmonary hypertension is present. In addition to the RV dilatation, right atrial (RA) enlargement develops and adds to the tricuspid annular dilatation and TR. Enlargement of the RA may result in atrial tachyarrhythmias, such as atrial fibrillation and supraventricular tachycardia. As a consequence of increased RA pressure, ascites, pleural effusion (especially in cats), pericardial effusion, hepatomegaly, and splenomegaly may develop.

Clinical Signs

Mild to moderate MMVD (ACVIM Stages A and B) is usually not associated with any signs of disease. Most dogs with MMVD are free of clinical signs for most of the time they have a murmur, although exercise intolerance might be noted. Cough is a common presenting complaint in MMVD. Although this sign is not specific for heart disease it should merit further evaluation (see ch. 26). Dogs with left mainstem bronchial compression, but without pulmonary congestion or edema, may have coughing spells at any time during the day, especially during physical exercise or excitement. Otherwise, mild to moderate MMVD dogs do not demonstrate clinical signs of heart disease.

The first clinical signs of decompensated CHF (ACVIM Stage C) are usually mild but may be aggravated within days or sometimes weeks (see ch. 246). Since these signs are vague and not specific for decompensated CHF, the differential diagnostic challenge in MMVD is commonly not to establish whether the disease is present, but whether or not MMVD is responsible for the clinical signs. The signs relate to the presence and degree of one or several of the following pathophysiologic events, listed in order of their relative importance: (1) increased LA and pulmonary venous pressure, which might result in respiratory distress and cough due to pulmonary edema and mainstem bronchial compression; (2) reduced LV or RV forward flow, which might result in weakness and reduced stamina; (3) increased RA and systemic venous pressures, which might result in pleural effusion and ascites; and (4) acute decompensation due to rupture of chordae tendineae, atrial rupture, or ventricular fibrillation, which might cause sudden death.

Tachypnea and dyspnea are present when pulmonary congestion and edema have developed.[75] Coughing is also commonly observed, and in the case of advanced MMVD, the cough may be caused by pressure of the LA on the left mainstem bronchus, by pulmonary congestion and edema or, most commonly, a combination.[76] Dogs in decompensated CHF are often anxious and restless during the night, and they commonly prefer lying in sternal recumbency. Abnormal respiratory sounds, such as wheezes may be audible. Dogs in decompensated CHF are often inactive and have varying degrees of inappetence. Cardiac cachexia may develop, although loss of body weight may be masked by concurrent fluid retention and edema.

Syncope (see ch. 30) is encountered in some dogs with MMVD. Syncope may be associated with a tachyarrhythmia, but the character of these events often resembles vasovagal syncope.[77-79] The frequency of the syncope varies from occasional spells to several attacks per day. Other causes of syncope include tussive fainting that may occur in conjunction with paroxysms of coughing or exercise in the presence of pulmonary hypertension (see ch. 243).[76]

Isolated TR in the absence of pulmonary hypertension rarely results in clinical signs of disease.[72,76,80] Evidence of reduced exercise tolerance, weakness, or syncope occurs mainly in instances with pulmonary hypertension, developing as a consequence of longstanding severe MR, or tachyarrhythmia. It is common for these animals to show signs of right-sided CHF that may include respiratory distress due to pleural effusion; abdominal distention due to ascites, hepatomegaly, or splenomegaly; or gastrointestinal signs such as diarrhea, vomiting, and anorexia.

Although myxomatous degeneration is sometimes evident at postmortem on one or both semilunar valves,[72,76,80] myxomatous degeneration of these valves rarely results in significant leakages associated with clinical signs.

Physical Examination

A mid-systolic click might be encountered in early stages of MMVD (Audio 251-5),[81,82] but a systolic heart murmur is a more prominent clinical finding when performing cardiac auscultation on dogs affected by MMVD (Figure 251-3). However, lack of an audible murmur cannot rule out mild regurgitation.[83] The sound begins as a soft systolic murmur with the point of maximal intensity over the mitral valve area on the left side of the thorax, and may be intermittent (Audio 251-1).[84,85] In the early stages of MMVD, the murmur can

often be augmented by physical maneuvers, such as a short run.[81] A soft murmur in a small-breed dog with MMVD is indicative that disease severity is mild and that CHF is unlikely.[85] With further disease progression, a murmur of "harsher" and more intense quality, and longer duration (holosystolic) develops (Audios 251-2 and 251-3; see Figure 251-3).[21,82,83,86,87] Moderate to severe murmurs radiate over to the other puncta maxima of the left and right side of the thorax, and loud heart murmurs are also accompanied with a palpable thrill on the left thoracic surface (cardiac apical area; see ch. 55). Dogs presenting with a precordial thrill rarely have mild disease, and are at higher risk of developing CHF and/or pulmonary hypertension.[85] Musical murmurs (whoop sounds) of high intensity occur less frequently, and murmurs of such character do not necessarily reflect the severity of MMVD (Audio 251-4).[82] Trivial, physiologic TR is common in dogs and this regurgitation is usually silent to auscultation. Pathological TR can be characterized by a systolic murmur with varying intensity and with the point of maximal intensity over the tricuspid area.

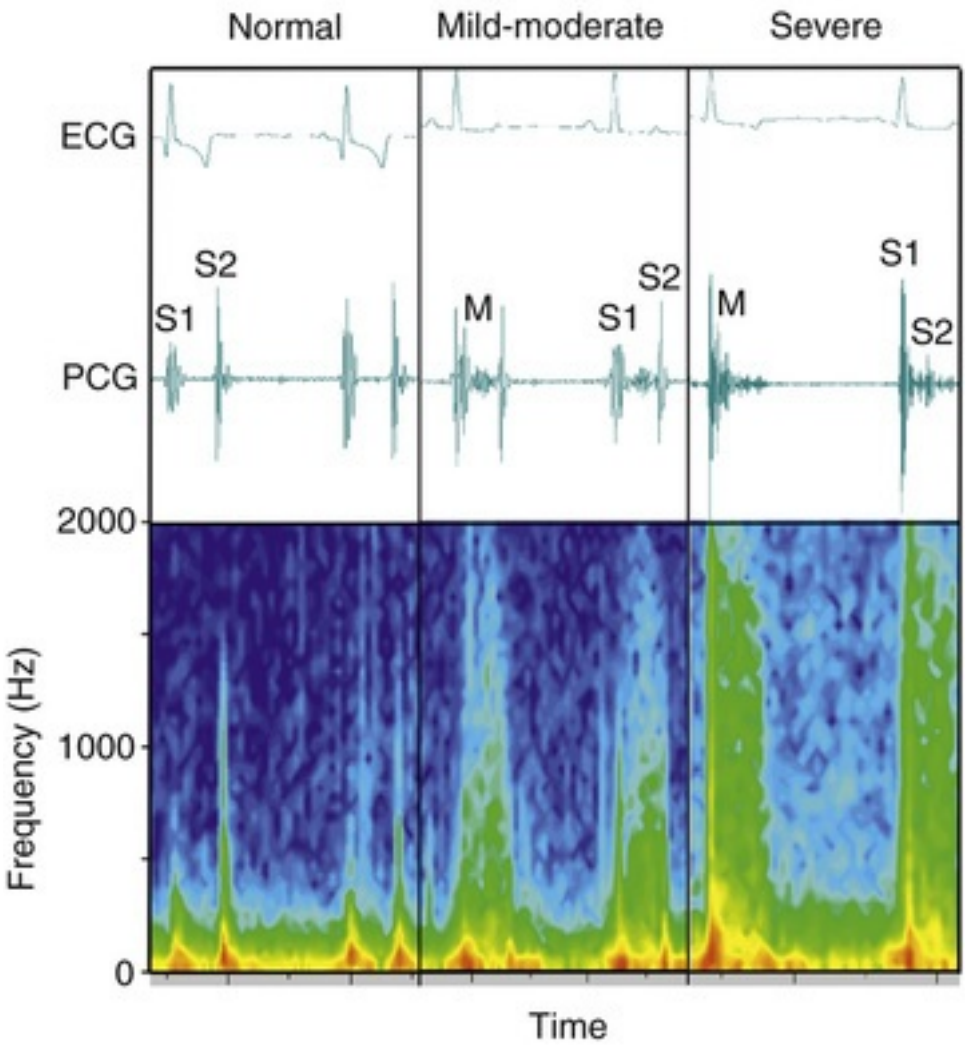

FIGURE 251-3 Phonocardiogram (PCG) in dogs with different stages of myxomatous mitral valve disease (MMVD). The recording is displayed in two modes, which are timed with respect to each other: The upper mode shows synchronous electrocardiographic (ECG Lead II) and phonocardiographic (PCG) traces; and the lower mode shows a time-frequency graph where different frequencies are displayed according to intensity, with high-intensity frequencies in red and low-intensity frequencies in blue. A holosystolic murmur (M) is present on the phonocardiograms from the dogs with mild-moderate and severe disease. Note that the frequency components of the murmur changes with disease severity. *S1,* First heart sound; *S2,* second heart sound.

Merging of the first heart sound (S1) with the forceful murmur might give an impression of increased intensity of the S1 when subjectively assessed by cardiac auscultation. However, advanced signal analysis has

shown that intensity of S1 remains comparably unchanged with increasing MR severity.[83] The sound intensity of S2 has been found to decrease with increasing disease severity (see Figure 251-3).[83,86] The intensity of S2 is considered to primarily depend on the rate of change in the pressure gradient across the aortic valve at closure,[88] and a decreased forward stroke volume[51] might explain why the intensity of the S2 decreases with increasing MMVD severity. A low-intensity third heart sound might be present, but this sound is often difficult to detect by standard auscultation.[82,86,87] The presence of a clearly audible third (gallop) sound is a strong indicator for myocardial failure.[82]

In dogs with MMVD without signs of CHF, the lung sounds and respiratory rates at rest are expected to be normal.[75] In dogs with more severe MMVD that show signs of CHF, the pulmonary sounds are usually more pronounced, and crackles, snaps, and popping sounds, best heard at end of inspiration, may be detected. Similar abnormal sounds are common in dogs with small airway disease,[89] and if occurring concurrently it may be a diagnostic challenge to determine the cause of the clinical signs. In the case of pulmonary congestion and edema, respiratory rates at rest or sleep are expected to be increased (i.e., >30 breaths/min).[75,90]

Mucous membranes are usually normal, even in dogs with CHF, but may occasionally be cyanotic, grayish, or ashen in advanced cases of CHF. Weak pulses may be noted in CHF. Weak and variable pulses with deficits can also be observed with rhythm disturbances (see ch. 248). If tamponade occurs, owing to pericardial hemorrhage due to a tear in the LA, the femoral pulse will be weak, and jugular venous distention may be present (see ch. 254).

Ascites in isolated MMVD is uncommon, but progressive MMVD often tends to involve the right side of the heart as a consequence of pulmonary hypertension and/or advanced myxomatous degeneration of the tricuspid valve, or due to development of a tachyarrhythmia. In these dogs, signs of right-sided CHF such as venous distention with signs of hepatomegaly and/or splenomegaly, pulsations in the jugular veins, in addition to ascites, may be present. The heart sounds may be muffled by pleural effusion.

Electrocardiographic Findings

Most ECG abnormalities associated with MMVD are the result of accentuations of the normal ECG. Electrocardiographic findings in MMVD vary from normal tracings to marked abnormalities in rate, rhythm, or configuration of complexes. With the exception to document and classify a certain arrhythmia, the ECG is of limited use in the diagnosis or management of MMVD.

Sinus arrhythmia is usually preserved early in the course of MMVD (see ch. 248). In dogs with CHF, sinus tachycardia and a loss of sinus arrhythmia are common. Supraventricular premature beats are commonly seen in MMVD dogs,[79,91] but this finding is of little hemodynamic significance in most dogs. Atrial fibrillation, paroxysmal supraventricular tachycardia, atrioventricular dissociation, ventricular premature beats, and ventricular tachycardia are less common. These arrhythmias are most often encountered in advanced cases and hence often indicate a poor prognosis.

ECG is an insensitive indicator of cardiac enlargement and cannot detect CHF (see ch. 103 and 248). The mean electrical axis in the frontal plane often remains within the normal range throughout the progression of the disease. In cases with significant LA enlargement, the P wave may be prolonged. In cases of significant LV enlargement, the QRS complex may be prolonged and the R wave amplitude in lead II increased.[92]

In significant TR with pulmonary hypertension, the ECG changes may include evidence of RA enlargement (tall P wave), an RV enlargement pattern, and a right deviation of the mean electrical axis.[92] However, even in severe cases of TR and pulmonary hypertension secondary to MMVD, these signs may not be obvious because of the concurrent changes to the left side of the heart. In these cases, the recording may only show evidence of left-sided involvement.[72,76]

Radiographic Findings

Left-Side Cardiac Chambers

The value of radiography is in assessment of the hemodynamic consequences of MMVD (global cardiac size and presence of pulmonary congestion and edema). Furthermore, radiography helps to exclude other possible causes for the clinical signs. In dogs with MMVD, important structures to evaluate are the LA, the LV, the mainstem bronchi, the pulmonary vessels, and the lung field. Dogs with mild MMVD usually have a normal heart size, normal lung fields, and normal vascular markings.

LA enlargement is one of the earliest and most consistent radiographic features of MMVD. The LA and LV

continue to enlarge with progression of the disease. Heart chamber enlargement, assessed by vertebral heart score (VHS), has been characterized by a slow phase of steadily progressing MMVD until about 6 to 12 months before onset of CHF, when the rate of change of enlargement is fast.[93] Signs of LA and LV enlargement on the lateral projection include dorsal elevation of the caudal portion of the trachea and carina, dorsal displacement of the left mainstem bronchus, and visible prominence of the LA causing the caudal border of the heart to appear straight or bulge dorsocaudally (Figure 251-4, *B*). In the dorsoventral (or ventrodorsal) projection, the enlarged LA appendage may be identified as a bulge in the left cranial part of the cardiac border (between the 2 and 3 o'clock positions). The border of the enlarged LV appears rounded and there may be a shift of the cardiac apex to the left or right.

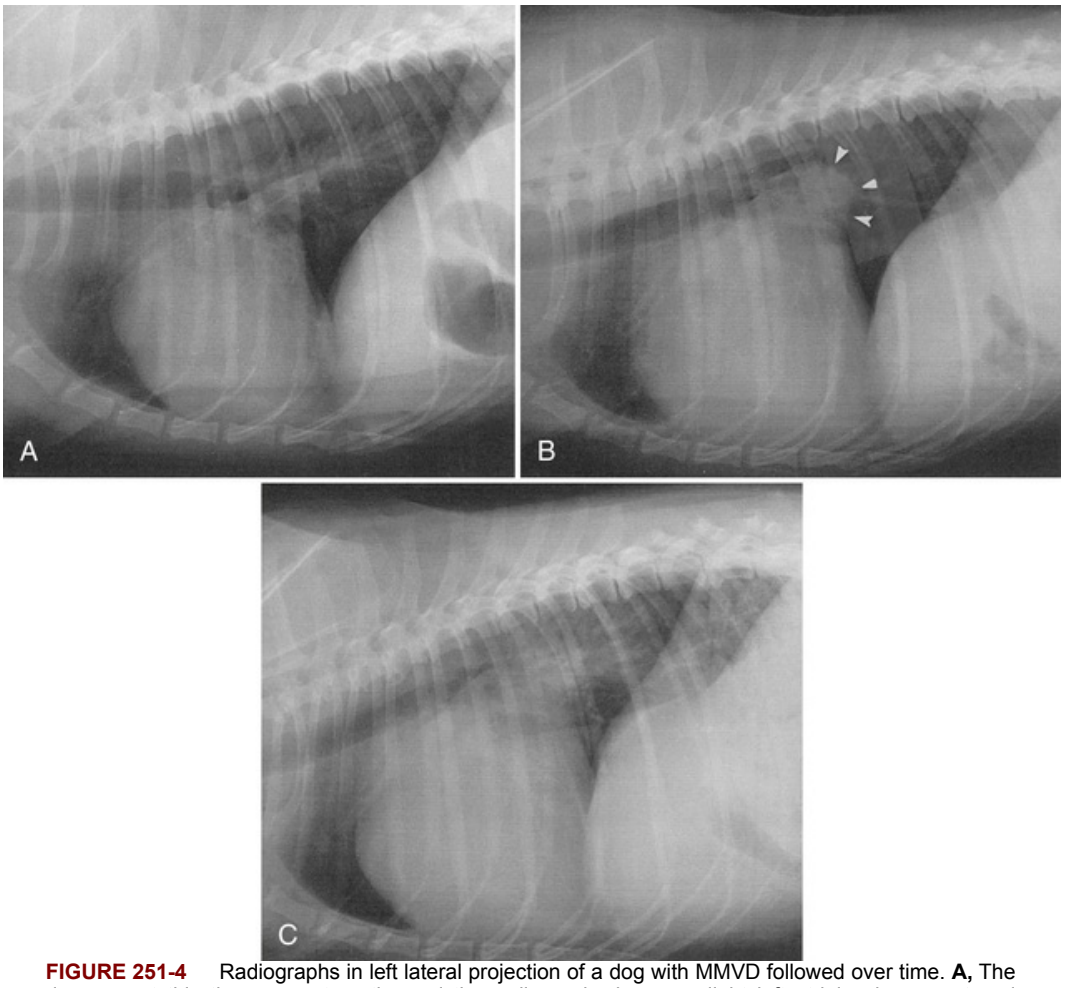

FIGURE 251-4 Radiographs in left lateral projection of a dog with MMVD followed over time. **A,** The dog was at this time asymptomatic, and the radiograph shows a slight left atrial enlargement and normal vascular perfusion. **B,** Radiograph of the same dog 4 years later. The dog had developed exercise intolerance and persistent cough. Marked left atrial (white arrowheads) and left ventricular enlargement, and elevation and slight compression of the left mainstem bronchus are visible, whereas the vascular markings are within normal limits. **C,** Six months later the dog had also developed dyspnea and had suffered episodes of syncope. In addition to the findings in the previous radiograph **(B),** there is a more obvious compression of the left mainstem bronchus and evidence of pulmonary congestion and interstitial edema. (Courtesy Kerstin Hansson, Uppsala, Sweden.)

During the progression of MMVD, radiographic signs of pulmonary congestion and edema may develop (Figure 251-4, *C*). Pulmonary congestion and edema are more likely to be present in a dog with significant heart enlargement (indicating advanced MMVD) than in a dog with normal or slightly increased heart size. However, the degree of cardiac enlargement is poorly related to the severity of pulmonary congestion and edema. Pulmonary venous distension, when present, is an early indication of pulmonary congestion; the diameter of the veins is greater than that of the corresponding pulmonary arteries and they often become tortuous (especially in cats). However, venous distention is not a consistent finding even in dogs with pulmonary edema, and in some dogs, the outlining of the distended vein is indistinct as interstitial edema

partially obscures the pulmonary vessels. In dogs, pulmonary edema is often first detected in the perihilar region and the dorsal parts of the caudal lung lobes, sometimes more prominent on the right side, but acute edema may involve the cranial lobes. In cats, the location of cardiogenic pulmonary edema is not as predictable as in MMVD dogs. It commonly has an ill-defined, patchy appearance.

Pulmonary findings may be inconclusive, as early radiographic changes of pulmonary interstitial edema and bronchial pattern resemble the radiographic appearance of chronic airway disease, and the tendency is to overdiagnose pulmonary edema when investigating radiographs from dogs with signs of cardiac enlargement.

Right-Side Cardiac Chambers

Mild RA and RV enlargement are usually not associated with detectable radiographic signs. Signs of moderate to severe RA enlargement on a lateral projection include bulging of the RA in the craniodorsal direction. This causes the cranial border of the heart to appear straight rather than convex and elevates the trachea as it courses dorsally over the RA. In addition to elevation of the trachea and dilation of caudal vena cava, signs of RV enlargement include increased sternal contact and rounding of the right heart border. In the dorsoventral (or ventrodorsal) projection, the enlarged RA may be identified as a bulge in the right cranial part of the cardiac border (in the 9 to 12 o'clock position). The border of the enlarged RV appears rounded and, if severely enlarged, it may resemble an inverted letter "D". There is a shift of the cardiac apex to the left. Signs of right-sided CHF may be observed, including pleural effusion, abdominal effusion, hepatomegaly, and splenomegaly. If biventricular failure occurs, the global cardiac size will be increased and signs of both left and right CHF may be present.

Echocardiographic Findings (see ch. 104)

Mitral Valve and Left-Side Cardiac Chambers

Echocardiography is useful for obtaining a diagnosis of MMVD, and thereafter to monitor the condition. Although some echocardiographic variables have been suggested to be useful for predicting the presence of CHF,[94] none of these variables has been shown to be more accurate and sensitive than other clinical tests, such as respiratory rate. Two-dimensional echocardiography allows the ultrasonographer to evaluate the anatomy of the mitral valve and to identify leaflet thickening and systolic leaflet protrusion (mitral valve prolapse) of one or both leaflets into the atrial side of the mitral annulus (Figure 251-5, *B*). Transthoracic real-time three-dimensional (RT3D) echocardiography has been reported to provide a more precise, extensive, non-invasive, *in vivo* evaluation of valvular anatomy in human cardiac patients (Video 251-16 and Figure 251-5, *C* and *D*),[95] and its potential in canine patients is currently under evaluation. Mitral valve prolapse is an early indication of MMVD and it might be present in dogs with or without MR (Videos 251-1, 251-2, 251-3, and 251-4).[96,97] The presence and severity of protrusion of the leaflets may be measured in the right parasternal long-axis view, and the degree of displacement is reported to correlate well with the severity of MR.[18,97,98] The gross pathologic changes of the two leaflets (anterior and posterior) are often equally severe at postmortem examination, but the degenerative changes commonly appear more prominent on the anterior leaflet in the right parasternal long axis view on the echocardiogram.[99] With progression, the degenerative changes become more prominent (Videos 251-5, 251-6, 251-7, 251-8, 251-9, 251-10, 251-11, 251-12, 251-13, 251-14, 251-15, and 251-16) and the leaflets often have a "club-like" appearance with greatest thickening at the tip (see Figure 251-5, *B* and *C*). Chordal thickening or a valve flail may be identified (Video 251-17; see Figure 251-5, *B* and *C*).[100,101] Valve flail is said to be present when the edge of a leaflet or, in severe cases, a complete leaflet moves into the LA in systole, and indicates rupture of one or more chordae tendineae, which may occasionally be identified in the LA or in the LV.[100-102]

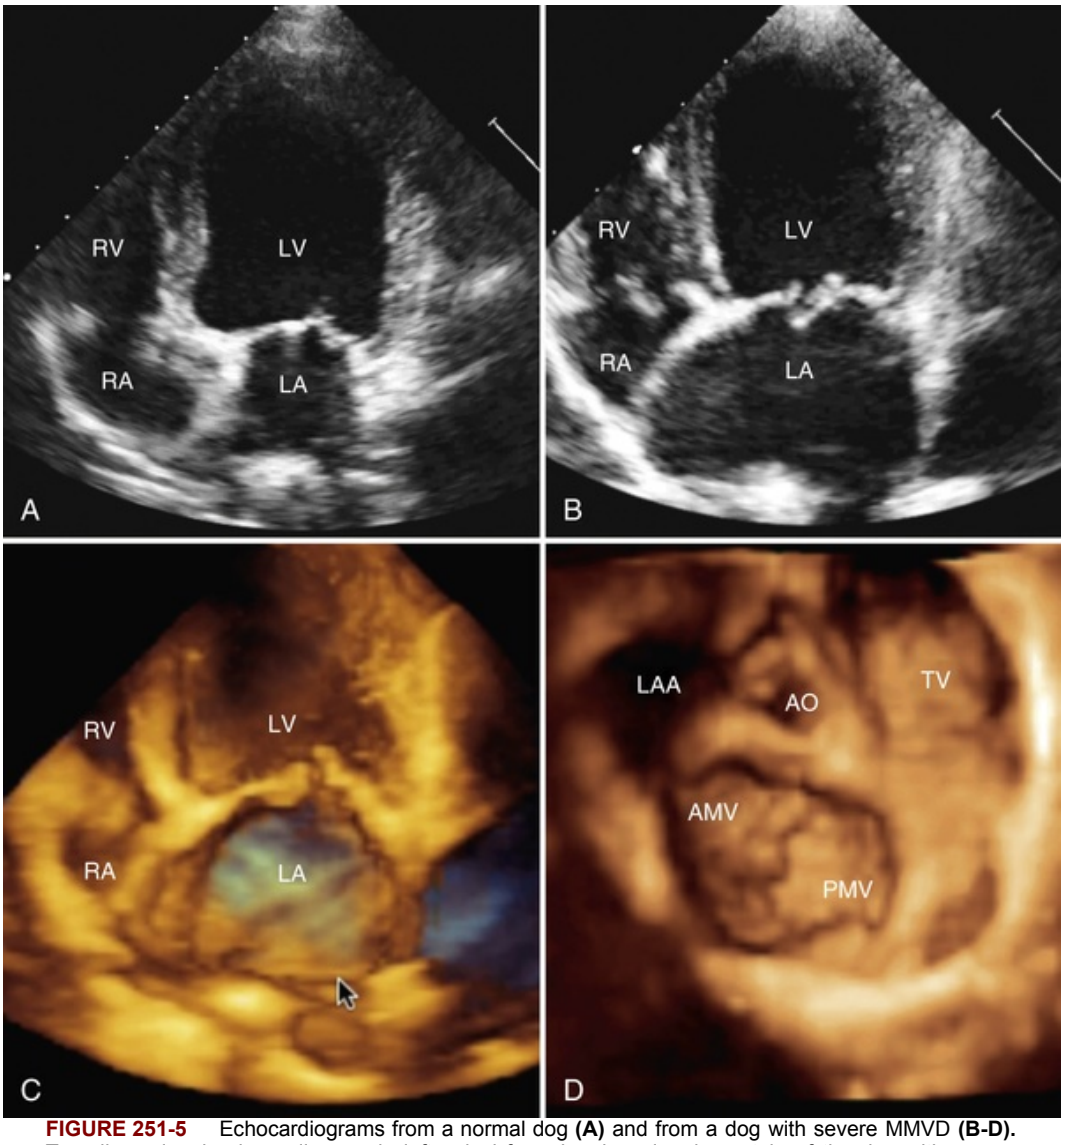

FIGURE 251-5 Echocardiograms from a normal dog **(A)** and from a dog with severe MMVD **(B-D).** Two-dimensional echocardiogram in left apical four-chamber view in systole of the dog with severe MMVD **(B)** shows bilateral prolapse of the mitral valve leaflets, prolapse of the tricuspid valve leaflet and left atrial and ventricular dilatation. Three-dimensional (3D) echocardiogram from the same dog in the same view in late diastole **(C),** and the mitral valve viewed *en face* in a 3D echocardiogram from the atrial side **(D)** during systole. Prolapse is evident at several locations on both leaflets. *Ao,* Aorta; *AMV,* anterior mitral valve leaflet; *LA,* left atrium; *LAA,* left atrial appendage; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle; *PMV,* posterior mitral valve leaflet; *TV,* tricuspid valve.

The LA is an important structure to evaluate in dogs with MMVD because its size reflects disease severity.[50] Although the LA may be examined from several views, the view of choice is the right parasternal short axis view with the aortic root, the LA body and the auricle in view. The most useful information from this view is the LA size because it can be compared with the size of the aortic root, which is relatively constant for a given dog size. In dogs with MMVD, the diameter of the LA body may be considerably greater than that of the LA appendage.[103] Early cases of MMVD with a small degree of MR have no echocardiographic signs of LA enlargement. With progression of MMVD, the LA dimension increases and dogs in CHF often have an LA to aortic root ratio (LA/Ao) of 2 or greater.[104] Real time 3D echocardiography allows for more accurate volume estimations of the LA, and the potential of LA volume assessment by RT3D echocardiography has recently been demonstrated in MMVD dogs.[105] However, a shortcoming of the RT3D technique is that it is more time-consuming compared to traditional echocardiographic techniques, and a normal reference range for LA volume is currently not available.

LV anatomical dimensions, volume and function can be assessed subjectively or by using various echocardiographic quantitative techniques. Traditional clinical echocardiographic assessments of the LV rely

on dimension estimates from 1-dimensional (M-mode) and/or two-dimensional (2D) images. However, LV size can also be evaluated using volume estimates based on either 2D (Simpson's modified disc method) or 3D imaging techniques (Figure 251-6, *A*).[106] The potential of LV volume assessment has been demonstrated in MMVD dogs,[64,107] but normal reference range for LV volumes is currently only available for a few breeds. Normal LV size, or only a mildly enlarged LV is seen in dogs with mild MMVD. With progression, the LV end-diastolic short axis dimension and volume increase, whereas the end-systolic measurements do not increase at the same rate.[64,93] The rate of change increases and is highest when the dogs are in close proximity to CHF (Figure 251-6, *B* and *C*).[93] The LV wall thickness is usually within normal limits. The increased size of the LV combined with a normal wall thickness indicates presence of volume overload and eccentric hypertrophy.

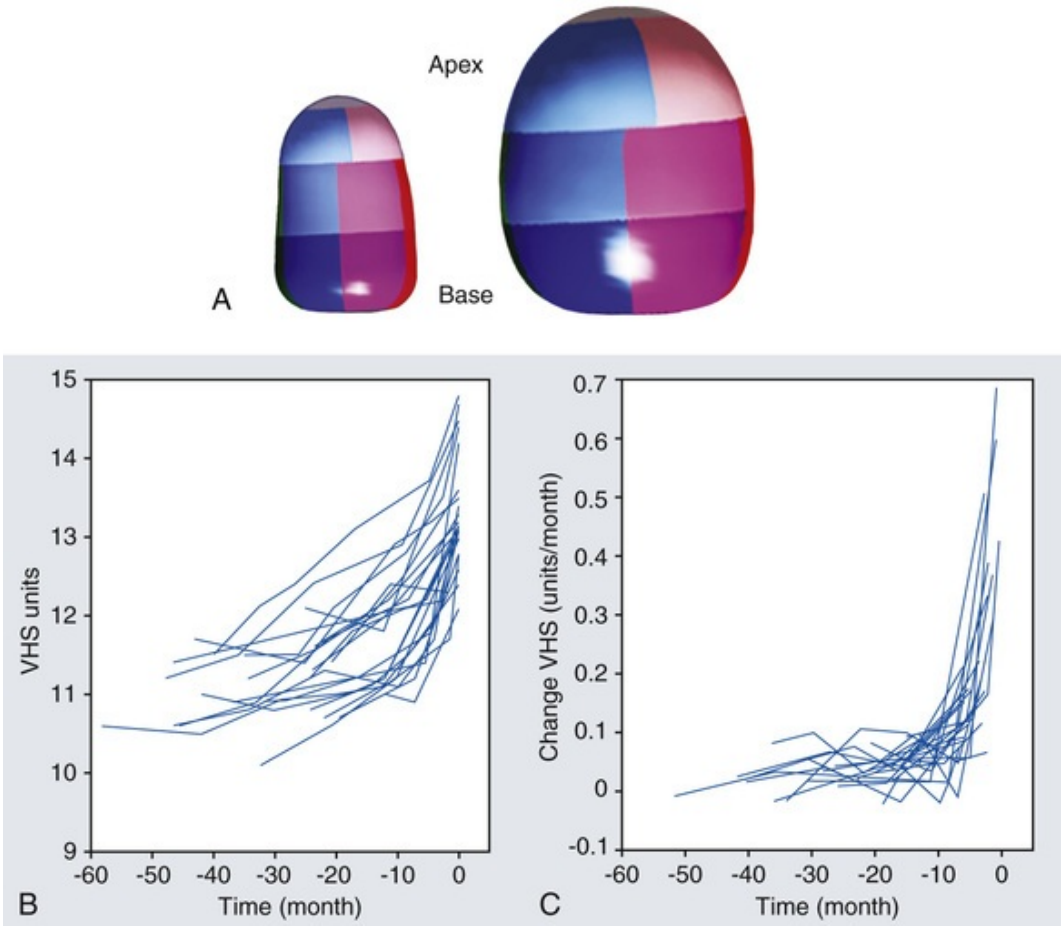

FIGURE 251-6 **A,** Left ventricular (LV) casts obtained from the 3D dataset of a healthy dog (left) and a dog with severe MMVD (right). The LV cast is automatically divided into 17 segments. The LV volume is clearly increased in the diseased dog, and the shape is changed from an elliptical to a more globular form (increased sphericity) in response to the increasing volume overload. Plots of radiographic vertebral heart score (VHS) **(B)** rate of change of VHS and **(C)** against time in ACVIM stage B dogs progressing into CHF (time 0). During the progression of MMVD, heart size is characterized by a slow rise until about 6 to 12 months before the onset of CHF, after which the rate of change increases as the dogs are progressing into CHF. (**B** and **C,** From Lord P, Hansson K, Kvart C, et al: Rate of change of heart size before congestive heart failure in dogs with mitral regurgitation. *J Small Anim Pract* 51:210-218, 2010. Published with permission from the publisher.)

Changes in LV shape, accompanying LV dilation, can be evaluated using a sphericity index, either on 2D or 3D echocardiographic images.[64] A RT3D echocardiographically derived sphericity index, which can be obtained by dividing the end-diastolic volume by the volume of a sphere, has been demonstrated as an earlier and more accurate predictor of remodeling compared to other echocardiographic variables in people.[108] The sphericity index is usually not included in the routine echocardiographic protocol when assessing LV remodeling in MMVD dogs, but this index might be useful for evaluation of LV remodeling progression in

dogs.[64]

Although myocardial systolic function declines with progression of MMVD, the remodeling process allows the LV to maintain a relatively well-preserved forward cardiac pump function even in advanced MMVD.[51,66] Identification of systolic dysfunction using echocardiographic modalities is challenging in dogs with MMVD.[109] Many of the commonly used echocardiographic indices for evaluating systolic function, such as the ejection phase indices (e.g., LV fractional shortening, ejection fraction, and mean velocity of circumferential shortening) are, besides being dependent on intrinsic contractility, also known to be influenced by hemodynamic load and sympathetic tone, thereby potentially masking significant myocardial dysfunction in dogs with MR.[109] In dogs with mild MMVD, values of ejection phase indices are often normal, whereas the values can be greater than normal in dogs with moderate to severe MMVD. Therefore, in the setting of moderate or severe MMVD, a normal fractional shortening commonly represents a reduction of myocardial contractility. Assessment of LV end-systolic dimension or volume has been suggested to better reflect systolic dysfunction in the presence of MR.[66,110] The end-systolic dimension or volume increases as the systolic function declines, despite increasing retrograde LV stroke volume into the low resistance LA.[66] But if the LV contractile function is preserved, the fully compensated LV will shorten to an almost normal end-systolic dimension.[109] The end-systolic volume indices have been shown to increase in dogs with more severe MMVD, indicating systolic dysfunction.[64,110] The more recently introduced tissue Doppler imaging (TDI) and speckle tracking techniques have been considered comparably independent of loading conditions, but studies suggest that these techniques are affected by loading conditions and sympathetic tone activity to a greater extent than previously expected. Similar to fractional shortening, LV strain and strain rate values appear to be increased in moderate-to-severe MMVD, but the values can decrease (return to values found in normal dogs) at more advanced stages, indicating myocardial failure.[111] This might limit the additional informative value obtained from this technique, compared to when using end-systolic volume indices in MMVD dogs.

Valvular regurgitations can be detected and quantified by spectral and color-flow Doppler (Figure 251-7, *A*).[81] Ideally, the regurgitant flow should be aligned with the ultrasound beam and this is most often achieved in the left apical four-chamber view. As the flow direction depends on the orientation of the regurgitant orifice, which in turn depends on the leaflet morphology, other views may also give good alignment.

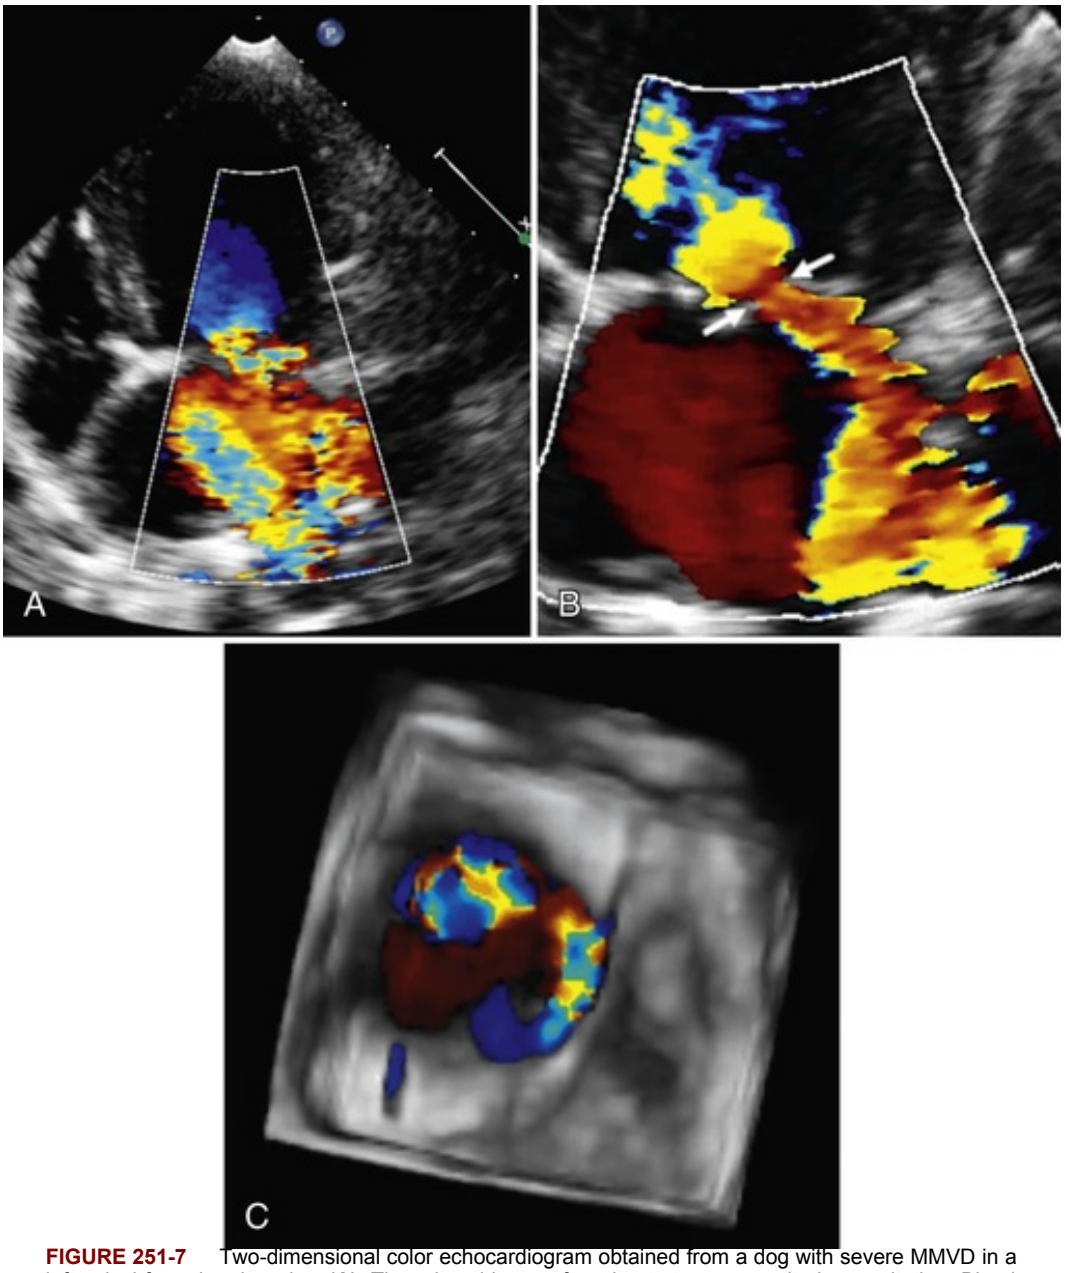

FIGURE 251-7 Two-dimensional color echocardiogram obtained from a dog with severe MMVD in a left apical four-chamber view **(A).** There is evidence of moderate to severe mitral regurgitation. Blood accelerates on the ventricular side towards the regurgitant orifice of the valve, and there is a laterally directed jet and turbulent flow in the left atrium. Severity of mitral valve regurgitation may be assessed by relating the area of the jet to the left atrial area, or by using the radius of the hemicircle created when the blood flow converges on the ventricular side before it passes the regurgitant orifice (proximal isovelocity surface area [PISA] method; see text for details), or as illustrated in a zoomed color Doppler echocardiogram in **(B),** by measuring the diameter of the vena contracta, which is the narrowest central flow region of a jet that occurs at, or just downstream to, the orifice of the regurgitant valve (arrows). The area of the vena contracta, which is approximately the same as the effective regurgitant orifice, may be assessed using color Doppler 3D echocardiography as illustrated in **C,** where the mitral valve is inspected from the atrial side and mitral regurgitation is evident at two sites.

Color-flow Doppler echocardiography confirms the presence of a regurgitant jet, and the size of the jet can be compared with the size of the LA (see Videos 251-2, 251-4, 251-6, 251-8, 251-11, 251-13, and 251-15, and ch. 104). This measurement is dependent on the ultrasound system settings, and is semiquantitative in dogs and cats. A small jet rules out moderate to severe MR, but it is often difficult to clearly discriminate between moderate and severe regurgitation based on information from the jet size. Small jets in the vicinity of the mitral valve should not be over-interpreted in dogs without any other valve abnormality, as trivial regurgitations may often be detected in normal dogs.

Spectral Doppler gives information of the velocity of the regurgitant jet and velocity time tracings may help

in estimating regurgitant volume (see ch. 104). The systolic transmitral pressure gradient can be estimated by calculating the peak MR gradient using the simplified Bernoulli equation: Peak MR pressure gradient = 4 × (MR velocity)^2. Typically, dogs with MMVD without significant myocardial failure have a velocity of the regurgitant jet of 5 to 6 m/sec.[80] However, the velocity may be increased in individuals with systemic hypertension, and decreased in individuals with hypotension, significantly increased LA pressure and/or myocardial failure. Accordingly, the velocity of the regurgitant jet is typically below 5 m/sec in dogs with acute fulminant CHF.

Regurgitant fraction is the percent of total LV stroke volume that flows back into the LA chamber. Measurements of regurgitant fraction in dogs with moderate to severe MR indicate that they can eject more than 75% of the total stroke volume into the LA.[50] There are several ways to estimate regurgitant volume and fraction. The MR stroke volume may be estimated indirectly using the volumetric method by calculating the difference between total stroke volume and forward stroke volume into the aorta. The total stroke volume may be estimated using 2D based disc summation method (modified Simpsons' rule) of LV volume, and the forward stroke volume may be estimated by multiplying the aortic cross-sectional area with the velocity time integral obtained from the spectral Doppler tracing of the aortic flow (see ch. 104). Alternatively, the total stroke volume may be estimated by multiplying the annular cross-sectional area of the mitral valve obtained from the two-dimensional mode with the velocity time integral obtained from the spectral Doppler tracing of the diastolic flow over the valve. Both these methods involve multiple measurements, each with its own errors, which means that they will only provide estimates of regurgitant volume. Regurgitant fraction is calculated by dividing the regurgitant stroke volume by the total LV stroke volume.

The regurgitant fraction may also be quantified with use of the proximal isovelocity surface area (PISA) color-flow method in dogs with MR (Figure 251-7, *B*).[50,112] In MR, blood flow converges on the ventricular side of the mitral valve orifice before it passes the regurgitant orifice, and this area is characterized on the color Doppler echocardiogram as a hemisphere. Based on the values of the radius of this hemisphere, the aliasing velocity, the maximal velocity of the regurgitant jet, and the velocity time integral of the regurgitant flow (the latter two are obtained from spectral Doppler measurements), the regurgitant stroke volume may be calculated. The regurgitant fraction is obtained by dividing the regurgitant volume with the sum of the forward and regurgitant stroke volumes. Although this method has significant advantages compared to other methods of measuring regurgitant fraction, it has several practical limitations and may not be readily applicable in all cases of MR. Furthermore, none of the Doppler methods has been shown to be more reliable indicators of disease severity than LA size in dogs and cats with MR.

Another, more straightforward method to assess severity of MR is to measure the diameter of the vena contracta on the color echocardiogram, a method that has been applied in dogs.[101,113] The vena contracta is defined as the narrowest central flow region of a jet that occurs at, or just downstream to, the orifice of a regurgitant valve, and where the blood velocity is highest (see Figure 251-7, *B*).[114] The vena contracta in MR or TR is usually measured on the 2D color echocardiogram as a diameter in the left apical four-chamber view, but 3D color echocardiography can provide measurements of vena contracta area, which may provide a more accurate estimate of effective regurgitant orifice. In fact, the vena contracta area in MR or TR is not a circle; it is more spherical owing to regurgitation occurring along the line of leaflet coaptation (Figure 251-7, *C*). Regardless of whether the vena contracta diameter or area is measured, the method has shown good agreement with angiocardiographic grade of MR and regurgitant volume in people.[114]

Spectral Doppler may also be used to study the transmitral flow during diastole. Significant MR is usually associated with increased diastolic filling velocities as a consequence of increased diastolic transmitral flow.[115] Furthermore, abnormal diastolic ventricular function, as a consequence of severe volume overload, may be detected. It is important to time the events when evaluating the transmitral flow to separate systolic regurgitation from diastolic flow to avoid a false-positive diagnosis of clinically significant MR. Diastolic regurgitation is common in cases with bradycardia (and second-degree AV block), or arrhythmias, and probably indicates small reverse pressure gradients during cardiac filling.[116]

Tricuspid Valve and Right-Side Cardiac Chambers

The echocardiographic appearance of the tricuspid valve affected by myxomatous degeneration is similar in two-dimensional mode to the myxomatous lesions on the mitral valve already described. With the use of color-flow Doppler, TR may be detected and semiquantified. The RA is, however, not as easily accessible as the LA owing to the anatomy, and the orientation of TR jets is not consistent. Pulmonary hypertension is a common complication in dogs with MMVD, and echocardiography is the standard veterinary non-invasive

technique for diagnosing the condition (see ch. 243).[57] Spectral Doppler may be used to estimate RV stroke volume and to identify pulmonary hypertension by estimation of RV systolic pressure and pulmonary arterial systolic and diastolic pressures.[80] The pressure gradient between the RA and RV may be calculated with use of the peak velocity of the regurgitant jet and the modified Bernoulli equation as outlined above.[57,117] The RV systolic pressure is obtained by adding an estimate of the RA pressure to the calculated pressure gradient over the AV valve. It is arbitrarily considered to be 5 mm Hg in the absence of RA dilatation, 10 mm Hg in the presence of RA dilatation but no sign of right-sided CHF, and 15 mm Hg in dogs with right-sided CHF.[117]

Similarly, the peak velocity of a pulmonic valve regurgitation and an estimate of RV diastolic pressure may be used to predict pulmonary artery diastolic pressure.[118]

Pulmonary hypertension can be diagnosed if the peak TR velocity is >3 m/sec corresponding to a peak TR gradient >36 mm Hg.[57] Lack of TR on an echocardiogram cannot preclude a diagnosis of pulmonary hypertension in MMVD dogs. Additional echocardiographic findings indicating pulmonary hypertension include signs of hypertrophy and dilatation of the RV, dilatation of the pulmonary artery, and flattening or paradoxical motion of the interventricular septum.[57]

Significance and Progression

Myxomatous mitral valve disease accounts, in comparison to many other canine diseases, for a high morbidity and mortality in affected breeds, and the disease has been reported to account for 75% of the cases of CHF in dogs,[70] a proportion of which is considerably higher in affected breeds.[12,21,119] Progression of the disease varies between individuals, but affected dogs can usually compensate the MR for a very long time. The progression of MMVD from the detection of a soft heart murmur to end-stage disease is often a matter of years in small dogs, but some large dogs appear to be less tolerant to MMVD: In these dogs, the disease has a more drastic progression with more severe clinical signs than in small dogs.[120] It is important to stage the severity of disease for risk assessment, for treatment decisions and for establishing prognosis. In 2009, an ACVIM Consensus statement was published and it was recommended to stage dogs with MMVD into four groups of dogs: From Stage A to D (Table 251-1).[121]

TABLE 251-1

ACVIM Consensus Recommends Staging MMVD Dogs Into Four Classes (A to D)[121]

<table>
<tr><th>STAGE A</th><th colspan="2">STAGE B</th><th>STAGE C</th><th>STAGE D</th></tr>
<tr><td rowspan="2">Dogs at risk for developing heart disease but that currently have no identifiable structural disorder of the heart (e.g., Cavalier King Charles Spaniels without heart murmur)</td><td colspan="2">Dogs without clinical signs, but presenting with a systolic click (early stage) and/or systolic heart murmur</td><td rowspan="2">Dogs with past or current clinical signs of CHF associated with structural heart disease. Severity of clinical signs of CHF range from mild to severe, the latter requiring aggressive therapy that more typically would be reserved for those with refractory disease (see Stage D).</td><td rowspan="2">Dogs with end-stage disease presenting clinical signs of heart failure caused by AV valve regurgitation that are refractory to standard CHF therapy. Such patients require advanced or specialized treatment strategies in order to remain clinically comfortable with their disease.</td></tr>
<tr><td>B1</td><td>B2</td></tr>
<tr><td></td><td>Dogs presenting with evidence of mild MR (heart murmur and echocardiographic signs of AV valve regurgitation) but no signs of cardiomegaly</td><td>Asymptomatic dogs that have hemodynamically significant AV valve regurgitation, as evidenced by radiographic or echocardiographic findings of cardiomegaly</td><td></td><td></td></tr>
</table>

Although a risk exists for future development of CHF, many affected dogs will never develop clinical signs from the disease during their lifetime.[87,99,121,122] Risk factors for progression from mild to severe MMVD include age, sex, breed, severity of valve lesion, severity of MR, LA and LV dilatation, heart rate, circulating concentrations of N-terminal pro-B-type natriuretic peptide (NT-pro BNP) and cardiac-specific troponin I (cTnI), arrhythmias and syncope.[4,21,70,87,98,99,101,123-128]

Differential Diagnosis

Mitral Regurgitation

Although the usual cause for MR is myxomatous degeneration, other causes of MR are noteworthy: dilated cardiomyopathy and other myocardial diseases; bacterial endocarditis of the mitral valve; or previously undiscovered congenital heart disease, such as mitral valve dysplasia or patent ductus arteriosus (PDA). However, the signalment, clinical signs, and physical examination findings are often of such character that they strongly suggest MMVD. Early cases of MMVD may have a mild and early-systolic heart murmur that may be confused with physiologic flow murmur or murmurs due to congenital heart disease, such as mild aortic or pulmonic stenosis. However, dogs with physiologic flow murmurs or aortic or pulmonic stenosis are usually young and have a murmur with maximal intensity over the heart base, whereas dogs with mild MMVD are usually older and have a murmur with maximal intensity over the mitral area. However, the age of onset of MMVD is variable and an echocardiographic examination should always be performed to confirm the diagnosis. The exclusion of dilated cardiomyopathy and hypertrophic cardiomyopathy also requires an echocardiographic examination.

The echocardiographic appearance of a mitral valve affected with endocarditis may appear very similar to nodular thickening of valve leaflets characteristic for myxomatous degeneration. However, lesions of endocarditis may be more echogenic and more isolated. Furthermore, bacterial endocarditis patients often have a history of fever, arthritis, systemic disease, a recently developed heart murmur, and clinical signs that may indicate thromboembolic disease,[129] whereas dogs with MMVD often have had a heart murmur for years, and do not have fever or other signs of systemic disease.

Tricuspid Regurgitation

Secondary or functional TR may occur as a consequence of RV dilatation in all conditions associated with an acquired increase in RV pressure. These include heartworm disease, pulmonary thromboembolism, pulmonary hypertension secondary to left heart disease, and idiopathic pulmonary hypertension. In addition, secondary TR occurs in biventricular or dilated cardiomyopathy and in congenital pulmonic stenosis. It is unusual for the tricuspid valve to be affected by infective endocarditis or chordal rupture.[72,80] Tricuspid regurgitation can be seen in cats with cardiomyopathy and hyperthyroidism.[130]

Nonspecific Clinical Signs

Although MMVD may readily be diagnosed in a patient with clinical signs, the true diagnostic challenge lies in determining if decompensated CHF is the underlying cause of the clinical signs present. Most dogs with MMVD are older, small to medium-sized, and many of these dogs have rather minor demands on daily exercise level. Thus, exercise intolerance may be difficult to identify. Furthermore, the clinical hallmarks of left-sided CHF, such as coughing, dyspnea and tachypnea, may be caused by several conditions, such as small airway disease (see ch. 241), tracheal instability (see ch. 241), pulmonary fibrosis (see ch. 242), neoplasia (see ch. 242), heartworm disease (see ch. 255), and pneumonia (see ch. 242). Many of these differential diagnoses can be excluded by different clinical tests, particularly radiography, but in some cases, the results may be inconclusive. This includes measurement of natriuretic peptides, which may aid in distinguishing mild from severe MMVD, and distinguishing dyspnea from primary respiratory disease from dyspnea caused by CHF.[131,132] Dogs may present with a combination of significant MMVD and primary respiratory disease, and the additional value of natriuretic peptides is limited in this setting. In these inconclusive cases, a 48- to 72-hour diuretic therapy trial followed by evaluation of respiratory rate (respiratory rate is then compared with values prior to initiation of diuretics) and repeat radiographs may help to identify the underlying etiology.

Management

Ideally, the therapy of MMVD should halt the progression of the valvular degeneration, or improve valvular function. No therapy is currently known to inhibit or prevent the valvular degeneration, whereas surgical repair or valve replacement has the potential to improve valvular function. Case series with comparably good outcomes have been reported for surgical mitral valve repair,[133] but this procedure is only available at very few sites in the world, and, therefore, not technically, economically, or ethically possible for most canine and feline patients. The management of MMVD is therefore mainly concerned with improving quality of life, by prolonging the preclinical (asymptomatic) phase, ameliorating the clinical signs, and improving survival. This

usually means that therapy is tailored for the individual patient, owner, and practitioner, and often involves concurrent treatment with two or more drugs once signs of CHF are evident. Management of MMVD will be discussed in four groups of patients: (1) dogs without signs of CHF (ACVIM Stage B); (2) dogs with mild to moderate signs of CHF (ACVIM Stage C); (3) dogs with recurrent CHF (ACVIM Stages C or D); and (4) dogs with severe and life-threatening (fulminant) CHF (ACVIM Stages C or D).[121] Possible complications are discussed separately. It is unusual to treat cases of isolated MMVD in cats and details of drug dosages for cats are therefore not included in this section.

Dogs without Signs of CHF (ACVIM Stage B)

Dogs belonging to ACVIM stage B are a comparably heterogeneous group of dogs ranging from dogs having only mild MR and normal heart size (ACVIM Stage B1) to dogs having severe MR and significant LA and LV dilatation (ACVIM Stage B2). This dilemma leads to the questions of when to start therapy, and if therapy before the onset of decompensated CHF is beneficial, ineffective or harmful. ACE inhibitors are frequently prescribed to dogs with MMVD before the onset of CHF, even to dogs in ACVIM Stage B1. At present, however, there is no evidence that ACE-inhibitor therapy has a preventive effect on development and progression of clinical signs of CHF, or improves survival in ACVIM Stage B MMVD dogs. Two large placebo-controlled multicenter trials, the SVEP and the VETPROOF trials,[87,122] have been conducted to study the effect of monotherapy of the ACE inhibitor enalapril on the progression of clinical signs in asymptomatic MMVD in dogs. Both failed to show a significant difference between the placebo and the treatment groups in time from onset of therapy to confirmed CHF,[87,122] regardless of whether the dogs were in ACVIM Stage B1 or B2.[87] Beta-receptor antagonists have shown to have some beneficial effects in experimental MR by improving the hemodynamic situation and myocardial contractility.[134] There are, however, very few studies of the effect of beta-receptor antagonists in naturally occurring MMVD,[135,136] and there is currently no conclusive evidence that these drugs have a preventive effect in asymptomatic MMVD. Indeed, a large, prospective, placebo-controlled clinical trial including ACVIM Stage B MMVD dogs was terminated prematurely because of lack of efficacy. Arterial vasodilators, such as amlodipine, have been suggested to be beneficial in stage B2 MMVD, because a reduction of aortic impedance may theoretically reduce MR. Amlodipine has been studied at a dosage of 0.57 mg/kg PO q 12 h in dogs.[137] The clinical documentation of amlodipine is scarce, but it has been assessed in a non-blinded echocardiographic study of dogs with MMVD, where a significant improvement in regurgitant stroke volume and regurgitant orifice area, as well as blood pressure reduction (10%) was reported.[138] The inodilator (a combined calcium sensitizer/phosphodiesterase III inhibitor) pimobendan has, in addition to its inotropic effect, arterial vasodilatory effects in dogs.[139,140] Pimobendan has been shown to decrease cardiac size in MMVD dogs, both in the short and long term,[141,142] an effect which potentially could delay the onset of signs of CHF in ACVIM Stage B2 dogs. The EPIC trial is a large prospective placebo controlled multicenter trial including ACVIM Stage B2 MMVD dogs and was designed to compare the effectiveness of pimobendan to placebo in the prevention of the onset of signs of CHF. In 2015, the trial was terminated prematurely because an interim analysis concluded that there was clear evidence of benefit of pimobendan administration in prolonging the time to development of left-sided CHF, or death presumed to be cardiac in origin. The interim analysis did not raise any concern over the safety of pimobendan administration. Full and final results of the EPIC trial were not yet available at the time of writing this chapter.

Disease progression may be monitored at regular rechecks at 3 to 12 months if cardiomegaly is present. Milder cases do not warrant as frequent monitoring (see Significance and Progression). Owners of dogs with asymptomatic MMVD should be instructed about signs of developing CHF and, in case of breeding, about the fact that the disease is significantly influenced by genetic factors. Owners should be instructed to count sleeping/resting respiratory rates at home, and be informed that a respiratory rate consistently >30 breaths/minute is abnormal and warrants further investigation as this can be an indication of CHF.[75]

At present, there is little evidence-based information concerning the effects of exercise and diet on the progression of MMVD in dogs. Dogs with mild MMVD do not need any dietary or exercise restriction, and it is our experience that dogs with advanced asymptomatic MMVD usually tolerate comparably long walks at their own pace, have a better quality of life with this type of exercise, and do better if obesity is avoided. However, from a pathophysiological standpoint, strenuous exercise or diets with high sodium content should be avoided in advanced MMVD Stage B2 dogs as this may promote pulmonary edema.

Dogs with Mild to Moderate Signs of CHF (ACVIM Stage C)

The stage when a patient starts to show clinical signs of MMVD (i.e., has developed decompensated CHF) is the end of a process started much earlier with the onset of valve leakage. Considering the pathophysiology of MMVD, therapy should be directed toward: (1) reducing the venous pressures to alleviate edema and effusions, (2) maintaining adequate cardiac output to prevent signs of weakness, lethargy and prerenal azotemia, (3) reducing the cardiac workload and valvular regurgitation, and (4) protecting the heart from negative long-term effects of neurohormones.

Dogs with mild to moderate pulmonary edema can often be managed on an outpatient basis with regular re-examinations. Cases with moderate to severe pulmonary edema may need intensive care, including cage-rest and sometimes oxygen supplementation (see ch. 131 and 141). The cornerstone of the CHF therapy is a diuretic, most often furosemide, and drugs with other modes of action are added to the diuretic agent (see ch. 247). A commonly used combination of drugs in this setting includes triple therapy of a loop diuretic (furosemide or torsemide), pimobendan and an ACE inhibitor. Spironolactone and/or digoxin are also frequently used.

The dosage of furosemide should preferably be based on clinical signs rather than radiographic findings. A patient may breathe with ease even in the presence of radiographic signs of interstitial edema, or vice versa. The usual course of treatment of a case with mild to moderate CHF is an initial intensive treatment with furosemide (2-4 mg/kg IV, IM, SC q 8-12 h) for two to three days, after which the dosage of diuretic is decreased to a maintenance level, such as 1-2 mg/kg PO q 12-48 h or lower. More severe cases of CHF may require higher dosages. It is important to use an appropriate dosage of diuretic to relieve clinical signs, but avoid an unnecessary high maintenance dosage. Overzealous use of diuretics may lead to weakness, hypotension, syncope, aggravation of prerenal azotemia and acid-base and electrolyte imbalances. Accordingly, the lowest dosage of diuretics possible, that can keep the dog free from clinical signs of CHF, should always be used. The owner should be informed about the need for regular contact with the veterinarian for an optimized treatment strategy for the individual dog. Oftentimes, the owner can be instructed to vary the dosage, within a fixed dose range, according to the need of the dog. Torsemide is an alternative to furosemide. It is also a loop diuretic, but with longer duration of action, decreased susceptibility to diuretic resistance, and adjunctive aldosterone antagonist properties compared with furosemide.[143] The recommended dosage of torsemide is 1/10 of the furosemide dosage.[143]

Several clinical trials indicate that pimobendan is indicated as first-line treatment in dogs with CHF caused by MMVD. Indeed, pimobendan is now approved for veterinary use in dogs with DCM or MMVD in many countries at a dosage of 0.25 mg/kg PO q 12 h. Data from two multicenter controlled clinical trials (the VetSCOPE and the QUEST trials)[124,144] and one single-center clinical study[145] concerning the efficacy of pimobendan in dogs with CHF caused by MMVD are available. The results show that dogs with CHF caused by MMVD receiving pimobendan as adjunct therapy to diuretics show less severe signs of CHF and have a longer survival time (as indicated by a prolonged time from onset of therapy to a composite endpoint of death/euthanasia from a cardiac cause or a treatment failure) than those receiving an ACE inhibitor and diuretics.[124,144,145] Indeed, pimobendan therapy was shown in the QUEST trial to prolong survival (measured as time from onset of therapy to the composite endpoint) by 91%, and a 32% overall risk reduction to reach the composite endpoint first, as compared with the positive control (benazepril).[124] The median survival times were 267 days in the pimobendan group and 140 days in the benazepril group, and the maximum difference between the two treatments (>20% difference in risk reduction) was found between approximately 150 to 330 days, indicating that the beneficial effect of pimobendan was not only occurring early in the trial.

The benefit of pimobendan on outcome in MMVD dogs is probably mediated through the combination of vasodilatation and increased contractility, which reduce MR by decreasing the size of the LV and the mitral valve annulus through an improved forward stroke volume. Indeed, clinical trials report a decreased cardiac size in dogs receiving pimobendan in comparison to a positive control.[141,142,144] The results from the pimobendan clinical trials indicate that the risk of this type of therapy to promote increased MR (due to the increased systolic pressure gradient across the mitral valve) or to promote chordal rupture is comparably small. Other beneficial effects of pimobendan in treating MMVD dogs in ACVIM stage C include a reduction in heart rate and pulmonary transit times,[142] and a reduced tendency for retention of free water in comparison to a positive control.[141]

ACE inhibitors are indicated in combination with diuretics in advanced MMVD with CHF, because dogs in large placebo-controlled clinical trials receiving an ACE inhibitor have been shown to have less severe clinical signs of disease, better exercise tolerance,[146,147] and to live longer than those not receiving an ACE inhibitor.[148,149] However, it is currently not known if the combination of pimobendan and ACE inhibitor

confers a better outcome compared to pimobendan alone, when either is added to ongoing diuretic therapy. The dosage of ACE inhibitor (e.g., enalapril, benazepril, lisinopril, ramipril and imidapril) is usually fixed and depends on the specific ACE inhibitor used. In the dose range that is recommended for use in dogs and cats, the vasodilating actions of the drugs are not prominent and side-effects associated with hypotension, such as fainting and syncope, are rare.[87,122,146,147,150] A reason for this may be that the short-term effects of ACE inhibitors on the circulation are dependent on the activity of the RAAS prior to administration of the drug: The higher activity, the more pronounced effect of the drug.[151] In combination with diuretics, such as furosemide, the ACE inhibitors have a synergistic effect with the diuretic by counteracting the reflex stimulation of RAAS that occurs in diuretic therapy. Thus, ACE inhibitors decrease the tendency for fluid retention and counteract peripheral vasoconstriction and other negative effects on the heart.

Spironolactone, which is an aldosterone antagonist and a potassium-sparing agent, is currently approved within the European Union with the indication of adjunct therapy with other ongoing CHF therapy in dogs with MMVD. This approval was based on registration trials, which showed that spironolactone, when added to other CHF therapy, reduced the risk of reaching the primary endpoint of the study, which was a composite of cardiac related death, euthanasia or worsening of CHF.[152] This suggests that it might be more advantageous to initiate spironolactone therapy at an earlier stage than previously practiced (see recurrent CHF). This trial also showed that spironolactone therapy in dogs is comparably safe and that the risk for hyperkalemia is low.

Digoxin is controversial in treating dogs with MMVD. There is a general lack of scientific evidence supporting the use of digoxin. Some cardiologists, however, initiate digoxin therapy when signs of CHF first appear. Digoxin is a comparably weak positive inotrope, compared to pimobendan, but has a place by reducing reflex tachycardia, by normalizing baroreceptor activity and by reducing central sympathetic activity.[153] Thus, digoxin may be useful to slow sinus tachycardia, or to treat supraventricular tachycardia such as atrial fibrillation, and to abolish or limit the frequency of syncopal episodes (see above).

The way dogs with mild to moderate CHF are managed after initiation of therapy varies. Regular contacts with the owner by phone or email should be maintained when the dog is managed on an outpatient basis in order to monitor therapeutic outcome and to establish a suitable maintenance dosage of diuretic. Re-examinations should be scheduled after one to two weeks of therapy, and thereafter every 3 to 6 months. More severe cases may require more frequent monitoring of the disease. The owner should be instructed to count sleeping respiratory rates at multiple times (preferably it should be <30/min), and also be informed about complications that may develop in the future. In areas with a seasonal climate, it may be valuable to re-examine the dog before the temperature increases and instruct the owner to avoid high ambient temperatures for the dog if possible. The use of low-sodium diets as complementary therapy in CHF patients is controversial. Currently, there are no clinical studies to support that they are beneficial in managing CHF in dogs and cats. However, dogs with symptomatic MMVD should avoid excessive intake of sodium. Dogs that are stable on their heart failure therapy usually tolerate walks at their own pace, but strenuous exercise should be avoided.

Dogs with Recurrent CHF (ACVIM Stages C or D; see ch. 247)

The maintenance dosage of diuretic (furosemide) in a MMVD patient usually has to gradually be increased over weeks or years to prevent clinical signs of CHF from recurring. Reasons for increasing the dosage often include recurrent dyspnea caused by pulmonary edema or, less commonly, development of ascites. Severe ascites, which compromises respiration, may require abdominocentesis (see ch. 90). However, many MMVD cases with less severe ascites respond to increased dosages of diuretics. Even in cases requiring abdominocentesis, the diuretic dosage should be increased, as the ascites will re-occur without a change in medication after evacuation. When the dosage of furosemide has reached a level of approximately 4-5 mg/kg PO q 8-12 h, a switch from furosemide to torsemide may be considered. Furthermore, sequential blocking of the nephron should be considered by adding another diuretic. The drug of choice is spironolactone (1-3 mg/kg PO q 12-24 h) (see above under mild to moderate CHF). However, a thiazide such as hydrochlorothiazide (2-4 mg/kg PO q 12 h) or triamterene (1-2 mg/kg PO q 12 h) or amiloride (0.1-0.3 mg/kg PO q 24 h) may be considered. The documentation of triamterene and amiloride in veterinary medicine is limited. Because furosemide treatment precedes and is used concomitantly with these drugs, the risk of hyperkalemia is low, even when they are added to a patient that is currently treated with an ACE inhibitor. The risk of inducing prerenal azotemia, hypotension and acid-base and electrolyte imbalances increases with the intensity of the diuretic treatment. However, the practitioner usually has to accept some degree of such disturbances when treating a patient with CHF and although such disturbances might occur, they seldom

result in clinical problems.

Dogs with Severe and Life-Threatening (Fulminant) CHF (ACVIM Stages C or D)

Causes of acute severe CHF often include undertreatment of existing CHF, a ruptured major tendinous chord, development of atrial fibrillation, or intense physical activity, such as chasing birds or cats, in the presence of significant MMVD. Patients with severe CHF have radiographic evidence of severe interstitial and/or alveolar edema, and have significant clinical signs of CHF at rest. They are often severely dyspneic and tachypneic and have respiratory rates in the range of 40 to 90. They may cough white or pink froth, which is edema fluid. These dogs require immediate hospitalization and aggressive treatment. It is important not to stress dogs with severe or fulminant CHF as stress may lead to death. A light sedation, in order to calm the dog, may be indicated in dogs struggling to breathe (see ch. 138). A commonly used sedative in this setting is butorphanol (0.25 mg/kg IM, IV, repeated in 30 to 60 minutes) or combinations of buprenorphine (0.0075-0.01 IM mg/kg) and acepromazine (0.01-0.03 mg/kg IV, IM, or SC). Furthermore, thoracic radiographs and other diagnostic procedures may have to wait until the dog has become more stabilized as a result of furosemide therapy. Dogs with significant dyspnea benefit from intravenous injections of furosemide at a dose of 1-4 mg/kg IV q 2-6 h or higher (see ch. 141).[121,154] The furosemide may be administered intramuscularly should placement of an intravenous catheter not be impossible. The exact dosage of furosemide depends not only on severity of clinical signs but also on whether or not the dog is already on oral furosemide treatment. Should the initial response to a furosemide bolus be poor, with failure of dyspnea and respiratory rate to improve over 2 hours, furosemide may be administered as an IV constant rate infusion (CRI) at a dosage of 1 mg/kg/h IV after the initial bolus.[121,154] Pimobendan treatment may be considered, administered either as a single IV dose at 0.15 mg/kg and continued after 12 h by pimobendan PO at a dosage of 0.25-0.3 mg/kg q 12 h, or as PO administration only.[121] The clinical documentation of pimobendan's efficacy in severe acute CHF is limited, but its use here is supported by its hemodynamic actions,[155,156] experimental studies (pacing model) in dogs,[157] and clinical experience.

Oxygen therapy is always beneficial in hypoxemic patients and it can preferably be administered using an oxygen cage provided that the temperature can be controlled inside the cage (see ch. 131). Nasal insufflation or a facial mask may also be used provided that the animal accepts them without struggle.

For the most critically ill patients, an arterial vasodilator and/or a venodilator may be considered, to reduce afterload and stabilize the CHF (see ch. 247). Commonly used vasodilating agents in this setting are the venodilator nitroglycerin ointment (4-12 mg topically q 12 h), which acts to unload the heart, and arterial vasodilators such as amlodipine PO, hydralazine PO, or intravenous nitroprusside to reduce afterload. Dosages of arterial vasodilator may need adjustment in dogs already on an ACE inhibitor. Amlodipine is administered at 0.1 mg/kg q 24 h, and it has been shown to reduce LA pressure in dogs with experimental MR,[158] and MR severity in dogs with MMVD.[138] Hydralazine has been used in patients with MMVD at an initial dosage of 0.5-2 mg/kg PO q 12 h, but should be used with caution because of potential adverse reactions. Furthermore, the dosage is increased at daily to weekly intervals to an appropriate maintenance dose of 1-2 mg/kg PO q 12 h, or until hypotension develops, detected either by blood pressure measurements or by clinical signs. Reflex tachycardia may develop in response to hypotension, and gastrointestinal problems are sometimes observed. In dogs judged to be too sick to wait for the effects of oral afterload reduction or inotropic support (e.g., pimobendan with or without hydralazine or amlodipine), nitroprusside (for afterload reduction in life-threatening pulmonary edema) or dobutamine (for inotropic support of the hypotensive patient) must be administered by IV CRI (see ch. 141). Both drugs can be administered at dosages of 0.5-1 mcg/kg/min and up-titrated every 15-30 minutes to a maximum of approximately 10 mcg/kg/min. These drugs, either separately or in combination, can be used for 12-48 hours to improve hemodynamic status and control refractory cardiogenic pulmonary edema. Continuous electrocardiographic and blood pressure monitoring is recommended to minimize the potential risks of this therapy (see ch. 99 and 103).

Patients with severe or fulminant CHF need frequent initial monitoring of the respiratory rate because it reflects the clinical response to the furosemide treatment. Significantly decreased respiratory rate within the first hours indicates successful therapy, whereas absence of change indicates that furosemide is required at a higher dose or more frequent administration. Once the respiratory rate has decreased, the dosage of furosemide may be reduced according to the status of the dog and clinical judgment. Abnormal laboratory findings such as prerenal azotemia, electrolyte imbalances, and dehydration are common after high dosages of furosemide. Again, these abnormalities are seldom a clinical problem and the laboratory values often tend to shift towards normal with clinical improvement and as the dog starts to eat and drink. Dehydration is usually not severe even after intensive furosemide treatment and intravenous rehydration should be

performed slowly and with caution in cases where it is needed, as the volume challenge may produce pulmonary edema.

From an ethical standpoint, euthanasia should also be considered in dogs in severe or fulminant CHF if the dog is already on high dosages of diuretics and other heart failure therapies, owing to a poor long-term prognosis, an increased risk of unresponsiveness to further intensification of CHF therapy, and/or increased likelihood of adverse side-effects.

Prognosis after the Onset of CHF

Some clinical variables have been shown to provide prognostic information after the onset of CHF in dogs with MMVD. It has been shown that the type of adjunct therapy influences the survival (increased survival shown in dogs treated with pimobendan and the ACE inhibitors enalapril and benazepril).[124,148,149] Furthermore, the expected survival time decreases with higher maintenance dosages of furosemide, with worsening exercise tolerance, with severity of mitral valve prolapse, with increased cardiac size and severity of MR (VHS score, LA size [LA/AO], LV end-diastolic dimension, and diastolic E wave velocity), with worsening systolic function (increased LV end-systolic dimension), and with decreasing serum creatinine concentration (indicating cardiac cachexia in development).[4,101,124,148] There are some indications that breed also affects the outcome after the onset of CHF, but the results are currently not conclusive. Finally, the development of a complication (see below) may be associated with a worse clinical outcome.

Complications Associated with MMVD

Coughing Due to Left Mainstem Bronchial Compression

Severe LA enlargement may produce coughing even in the absence of pulmonary congestion and edema by compressing the left mainstem bronchus, which may be identified on the lateral radiograph. However, coughing due to other respiratory problems, such as tracheal instability, is also commonly seen in breeds frequently affected by MMVD. The severity of coughing may range from a few coughs per day to constant coughing. Mild occasional coughing does not necessitate daily medication owing to the effort of giving medication and potential adverse side-effects. Furthermore, very little evidence is available concerning effect of the types of drugs at hand to alleviate or reduce coughing. With significant coughing likely caused by left mainstem bronchial compression, therapy is aimed at suppressing the cough reflex or reducing the influence of the underlying cause for the compression, the LA enlargement. Cough suppressants such as hydrocodone bitartrate (2.5 to 10 mg/dog PO q 6-12 h), butorphanol (0.55 to 1.1 mg/kg PO q 6-12 h), or dextromethorphan (0.5 to 2 mg/kg PO q 6-8 h) may alleviate coughing in some cases. Dogs with evidence of concurrent tracheal instability or chronic small airway disease may improve with a bronchodilator, or a brief course of glucocorticoids. Different xanthine derivatives, such as aminophylline (8-11 mg/kg PO q 6-8 h), theophylline (sustained duration) 20 mg/kg PO q 12 h, and oxitriphylline (sustained action) 25-30 mg/kg PO q 12 h, are commonly used bronchodilators, although the efficacy of these drugs varies considerably between individuals. Beta-2 receptor agonists such as terbutaline and albuterol should be used with caution in MMVD dogs, as these drugs may produce unwanted elevations in heart rate and contractility as a consequence of myocardial beta-2 receptor stimulation.

Theoretically, coughing due to left mainstem bronchial compression could improve by reducing LA and LV size. This may be achieved either by reducing the MR or by reducing pulmonary venous pressure, or a combination of both. The actual clinical benefit from such treatments on severity of coughing is currently unknown. Drugs with a potential to reduce the MR, by reducing afterload, include the arterial vasodilators amlodipine and hydralazine, and to a lesser extent ACE inhibitors (see above under Severe and Life-Threatening [Fulminant] CHF [ACVIM Stages C or D]). Furthermore, the inodilator pimobendan has been shown to reduce cardiac size in MMVD dogs, both in the short and long term.[141,142] Diuretic monotherapy may be considered to decrease the MR by contracting the blood volume and thereby the LV size. However, diuretics activate the renin-angiotensin-aldosterone system (RAAS),[159] and in the long term may cause electrolyte disturbances. Accordingly, diuretics should be reserved for patients with signs of pulmonary congestion and edema or patients where cough suppressants, glucocorticoids, and vasodilators have failed to alleviate more severe clinical signs of coughing.

Right-Sided CHF Due to Pulmonary Hypertension

Many patients with longstanding history of MMVD develop right-sided CHF. It is presumed that this condition develops as a consequence of concurrent chronic TR attributable to myxomatous degeneration, or

development of pulmonary hypertension, or a combination of both (Figure 251-8). In MMVD, the pulmonary hypertension is thought to develop secondary to the persistent elevation of the LA and pulmonary venous pressures, but concurrent chronic airway disease may also contribute. Individuals with pulmonary hypertension are sensitive to exercise, with signs of weakness or collapse even at mild exercise. A physical examination may reveal evidence of right-sided CHF, such as ascites, pleural effusion, hepatic and splenic congestion, and distention of the jugular veins with abnormal pulsations. The presence and degree of pulmonary hypertension may be indirectly quantified by Doppler echocardiography (see ch. 104 and 243). A pressure gradient > 55 mm Hg has recently been shown to be an independent negative predictor of outcome.[57]

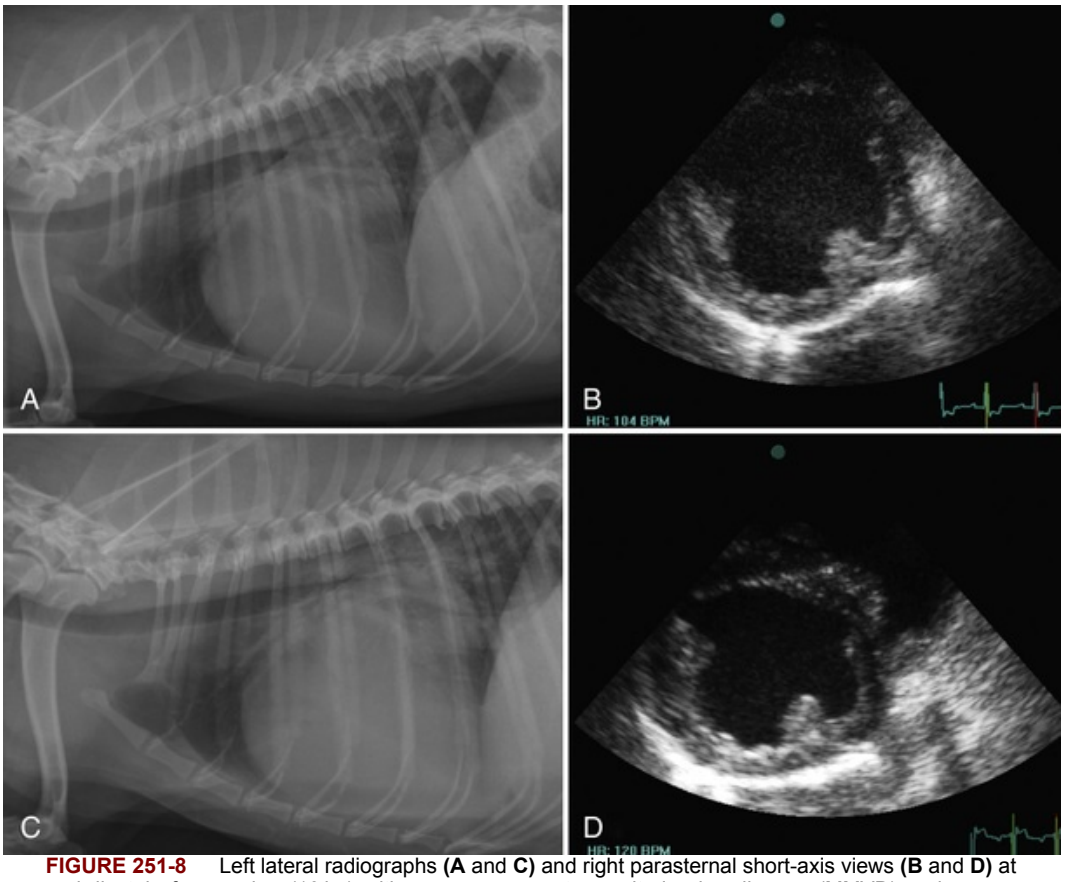

FIGURE 251-8 Left lateral radiographs **(A** and **C)** and right parasternal short-axis views **(B** and **D)** at end-diastole from a dog (10 kg) with severe myxomatous mitral valve disease (MMVD) and severe cardiac enlargement showing development of pulmonary hypertension. The dog had developed CHF but was stabilized on heart failure therapy when images **A** and **B** were obtained. Images **C** and **D** were obtained one year later when the dog had developed more pronounced exercise intolerance and evidence of right-sided CHF. At this stage, the radiographic cardiac size had increased from vertebral heart scale of 13.8 in **A** to 15.0 in **C,** but the left ventricular end diastolic diameter had decreased from 5.5 cm in **B** to 4.0 cm in **D,** and the left ventricle was displaced further away from the transducer owing to right ventricular enlargement. There is also evidence of septal flattening, and the systolic tricuspid regurgitation pressure gradient was 64 mm Hg.

Dogs with pulmonary hypertension may be difficult to manage. The goal of therapy is to eliminate contributing factors and restrict exercise. Oxygen supplementation is indicated in cases of acute collapse (see ch. 131). Since persistently increased pulmonary venous pressures are in large part responsible for the condition, therapy should be directed as for MMVD with pulmonary congestion (see Management). In addition, sildenafil at a dosage of 0.5-2 mg/kg q 8-24 h (2-3 mg/kg PO q 12 h may be required in some cases) is a commonly used pulmonary arterial vasodilator.[160,161] Published case series of sildenafil treatment in dogs are available, in which many of the included dogs had pulmonary hypertension due to longstanding severe MMVD.[160,161] A major disadvantage of this drug is that it is comparably expensive. A less expensive alternative to sildenafil therapy to treat pulmonary hypertension in this setting is pimobendan. This drug has been shown to decrease pulmonary arterial pressure in experimental dogs, mediated through its suppression

of phosphodiesterase III,[139] and in a short-term crossover study in MMVD dogs.[162] Thus, dogs with MMVD and longstanding CHF that have developed pulmonary hypertension probably benefit from this therapy if not yet already receiving it. Bronchodilator therapy may also be indicated, and methylxanthines and beta-2 selective agonists may be considered, but the latter should be used with caution in MMVD dogs. Aggressive diuretic treatment may be required to resolve ascites, if present. Physically draining the abdomen of fluid will also provide temporary relief from the ascites, giving the medications prescribed additional time to take effect (see ch. 90).

Development of Arrhythmia Leading to Syncopal Events and/or Acute Exacerbation of Signs of CHF

With advancing MMVD, it is not uncommon that episodes of syncope develop (see Clinical Signs and ch. 30). In dogs with MMVD with syncopal events, it is important to ascertain that the patient is actually fainting and not suffering from neurological or other disease. Furthermore, it is important to rule out the presence of CHF, pulmonary hypertension, or bradyarrhythmias such as third-degree AV block or sustained tachyarrhythmia such as atrial fibrillation. An enlarged LA predisposes to supraventricular premature beats, atrial fibrillation, and supraventricular tachycardia (see ch. 248).[91] Although ventricular tachyarrhythmias do occur in MMVD dogs, usually at advanced stages of the disease, intermittent supraventricular tachyarrhythmia is far more common.[79,91] Typically, the 24 hour (Holter) ECG shows episodes of a rapid supraventricular rhythm immediately followed by a bradycardia during which the dog faints.[79,91] Dogs developing sustained atrial fibrillation or supraventricular tachycardia often have a longstanding history of MMVD, with an acute onset of pulmonary edema. In addition to other characteristic findings in MMVD, these cases have a change in cardiac rhythm. The goal of therapy is to relieve the pulmonary edema, as described earlier under management, and to reduce heart rate to an acceptable rate for improving cardiac output. Diliazem and/or digoxin are the drugs of choice in dogs with supraventricular tachycardia.

Management of dogs with syncopal events, outlined above, or sustained atrial fibrillation/supraventricular tachycardia often includes digoxin (0.22 mg/m^2 or less, PO q 12 h) to control the supraventricular tachyarrhythmia. Should this fail to control frequency and duration of intermittent tachycardia (and syncopal events), or, in the case of atrial fibrillation with a high ventricular rate, diltiazem (0.5-2 mg/kg PO q 8 h) or a beta-1 receptor antagonist such as atenolol (0.25-2 mg/kg PO q 12-24 h) or metoprolol (0.5-1 mg/kg PO q 8-12 h) could be added. See ch. 248. It should be noted that individuals with MMVD usually are sensitive to negative inotropic drugs, such as beta-receptor antagonists, and they should be avoided in dogs with acute CHF. Therefore, these drugs should be initiated at the lowest possible dosage and then gradually increased with careful monitoring. In cases of CHF, another goal of therapy is to relieve the pulmonary edema, as described earlier under management.

Acute Exacerbation of Pulmonary Congestion and Edema Due to Ruptured Chordae Tendineae

Ruptured chordae tendineae may be suspected in all dogs suffering from MMVD with acute development of pulmonary congestion and edema (see Video 251-17), whereas it is a rare finding in cats. The most important ruptures involve those of first order chordae that are attached to the septal leaflet, and these patients are expected to die rapidly from acute volume overload and fulminant pulmonary edema. Ruptures of lesser order chordae or perhaps first order chordae that are attached to the free wall leaflet may result in minor clinical signs or none at all.[100] Significant chordae tendineae rupture causes acutely increased MR, and the clinical findings may differ from those encountered in chronic MR. Due to the acute increase in MR, there may be a marked increase in LA and pulmonary venous pressures, leading to acute pulmonary edema, pulmonary hypertension and right heart failure.[55,67] The physical examination of these patients often reveals a heart murmur of lower intensity than that of chronic MMVD, an S_3 gallop is more likely to be present (see ch. 55), and jugular venous distention is more likely to be present with pulsations than in chronic MMVD. The radiographic and echocardiographic findings of cardiac size vary, depending on how far the MMVD had progressed before the onset of ruptured chordae tendineae. Doppler echocardiography shows severe MR, and a flail segment of the mitral valve leaflet may be detected using 2D views. Thoracic radiographs show a markedly increased interstitial and alveolar pattern with distention of the pulmonary veins. These patients require intensive care to stabilize the condition, and thereafter maintenance therapy for MMVD (see under Management section and ch. 141). As long as a first order chorda attaching to the septal leaflet has not ruptured, many of these cases may be sustained with the aid of appropriate medication.

Left Atrial Rupture and Cardiac Tamponade

As a consequence of the dilatation in MMVD, the LA becomes thin-walled and more vulnerable to increases

in pressure. Endocardial splitting is a frequent postmortem finding in dogs with a history of longstanding MMVD (Video 251-18).[72] The significance of this finding is that it may progress to rupture of the LA with the sudden development of hemopericardium, cardiac tamponade and sudden death (Video 251-19). Most cases with atrial rupture and cardiac tamponade are expected to die suddenly. There is often a history of trauma, excitement or physical exercise preceding the atrial rupture and sudden death. For those dogs surviving the initial event, clinical signs of cardiac tamponade together with signs of MMVD can be found. Acute development of ascites, collapse, or marked exercise intolerance is to be expected. The physical examination may reveal signs of pericardial effusion (see ch. 254). Echocardiography is required for a definitive diagnosis by identifying the presence of significant pericardial effusion in combination with MMVD, whereas the tear often is difficult to detect on an echocardiogram. Treatment of atrial rupture with hemopericardium and cardiac tamponade is usually futile. Immediate pericardiocentesis is indicated (see ch. 102), and pericardial fluid should be removed to alleviate the tamponade without removing so much that further bleeding is stimulated. If the bleeding continues after pericardiocentesis, the final option is emergency thoracotomy with pericardiectomy and closure of the tear, but the prognosis for this procedure is very guarded.

Infective Endocarditis

Infective endocarditis (IE) is a life-threatening disorder caused by microorganisms colonizing the endocardium, commonly resulting in proliferative or erosive lesions of the valve and other cardiac structures, and, consequently, valve leakage (Figure 251-9, *A*). Vegetation may cause thromboembolism or metastatic infections involving multiple body organs, producing a large variety of clinical signs, which makes diagnosis difficult.

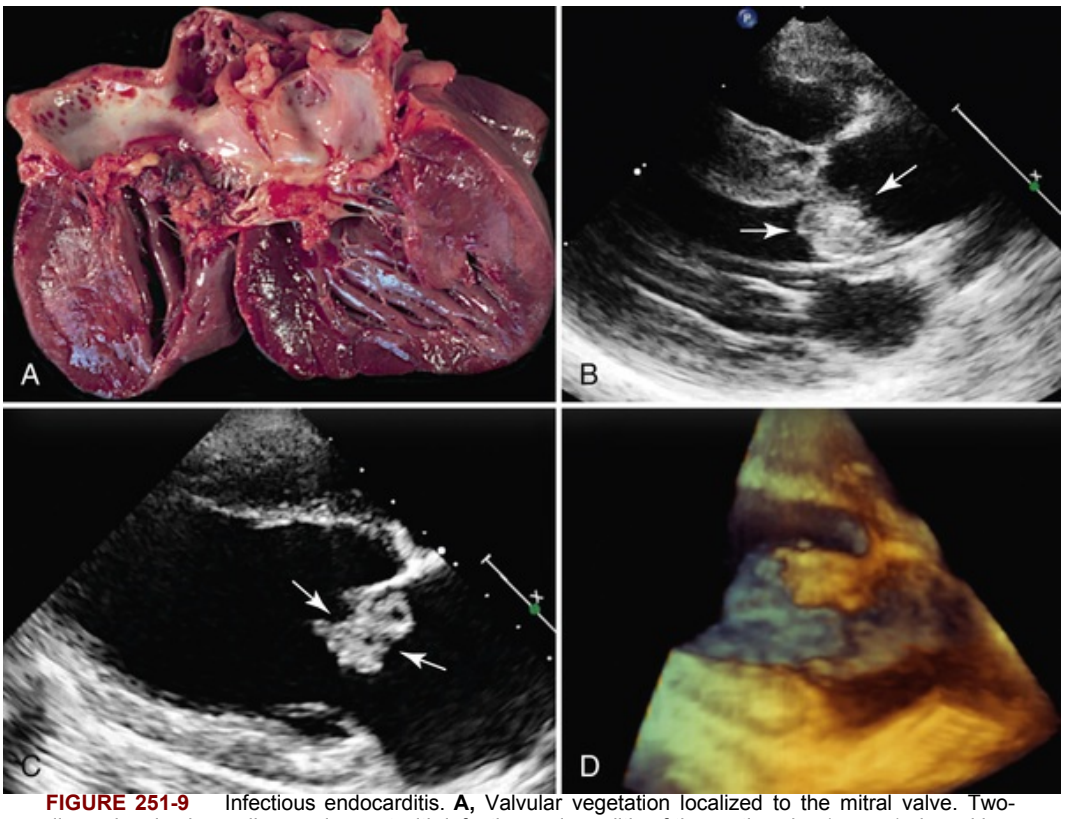

FIGURE 251-9 Infectious endocarditis. **A,** Valvular vegetation localized to the mitral valve. Two-dimensional echocardiogram in a cat with infective endocarditis of the aortic valve (arrows) viewed in a right parasternal long axis view **(B).** Infectious endocarditis affecting the mitral valve (arrows) viewed in a right parasternal long axis view **(C).** 3D echocardiogram from the same dog as in **(C),** but the view is slightly rotated to allow inspection of the mitral valve from the atrial side **(D).** Notice the size of the irregular-shaped echogenic mass attached to the septal mitral valve leaflet. *LA,* Left atrial chamber; *LV,* left ventricular chamber. (**A,** Courtesy Páll S. Leifsson, University of Copenhagen, Denmark.)

Occurrence

The prevalence of infective endocarditis in necropsied dogs has been reported to range from 0.09 to 6.6%.[163] Evaluation of data from dogs referred to a veterinary teaching hospital indicates that IE is a comparably rare clinical condition with prevalences ranging from 0.04 to 0.13 percent.[164,165] However, given the difficulty in diagnosing the condition, the non-specific clinical signs, and the comparably low proportion of dogs undergoing necropsy, the true incidence is presumably considerably higher. Medium to large breeds, mainly purebred, middle-aged male dogs are reported to be at higher risk for developing endocarditis.[166,167] The prevalence in cats, based on clinical experience, is considered to be 7 to 10 times lower than in dogs.[165,168,169] Animals with congenital heart disease have a low incidence of IE,[129] but associations have been reported with subaortic stenosis,[170] and with PDA.[171] IE has not been found to have any association with MMVD in dogs, despite dental procedures and other causes of bacteremia.[129]

Etiology and Pathogenesis

Transient or persistent bacteremia is a prerequisite for the development of IE. The origin of the bacteremia may be active infection localized somewhere within the body. A proportion of cases with IE has no clinically detectable source of infection.[172,173] Possible routes for bacteria to reach and infect the endocardium are by direct contact with the surface endothelium via the bloodstream or from capillaries within the valve (vasculitis).[174] Most bacteria require predisposing factors to cause IE, such as depression of the immune system or endothelial tissue damage,[129] sometimes associated with depositions of platelet-fibrin complexes, to adhere to the valve and create IE.[175] Extracellular matrix proteins, thromboplastin, and tissue factor all trigger coagulation. Coagulum forms on the damaged endothelium and inflammatory factors are activated. The inflammatory process together with enzymes released from the bacteria both contribute to the degradation of valve tissue.

A large number of bacteria has been identified in dogs with bacteremia[176] (see section on Blood Culture below), and some are known to cause IE.[172,173] Organisms that commonly cause IE are indeed those with the greatest ability to adhere to damaged valves, and they include *Staphylococcus* and *Streptococcus* spp. Bacteria such as *Staphylococcus aureus* and *Bartonella* may become internalized within the endothelial and other cells and remain undiscovered by the immune system. Furthermore, the bacteria are also protected from the immune system and from antibiotic substances by being embedded within the coagulum.

The consequences of IE depend on several factors: virulence of the infective agent; site of infection; degree of valvular destruction; influence of vegetation on valvular function; production of exo- or endotoxins; interaction with the immune system with the formation of immunocomplexes; and development of thromboembolism and metastatic infections. Gram-negative bacteremia often results in a peracute or acute clinical manifestations, while Gram-positive bacteremia typically results in a subacute or chronic condition. Necrosis and destruction of the valve stroma and/or chordae tendineae proceed rapidly in peracute or acute IE, causing valvular insufficiency and cardiac failure. Deposition of immunocomplexes in different organs may cause glomerulonephritis, myositis, or polyarthritis.[177] Thromboembolic complications as a cause of clinical signs have been reported in approximately 30-40% of dogs with IE,[129,167] and the lungs have been shown to be the most common site for embolization followed by the kidneys and the distal part of aorta.[129]

Pathology

Vegetation associated with IE mainly affects the left heart, with a higher prevalence of lesions involving the mitral valve compared to the aortic.[129,167] Mural endocardial involvement may be present, with or without concurrent valvular lesions,[129] but right heart involvement is uncommon.[129] Pathological findings vary and depend on the virulence of the infecting organism, the duration of infection and the immunological response. An intracardiac vegetation consists of different layers of fibrin, platelets, bacteria, red and white cells, and is often covered by an intact endothelium. Bacteria may continue to grow despite antibiotic therapy, owing to the location deep within the vegetation and a slow metabolic rate.[175]

History and Clinical Signs

The diagnosis of IE can easily be overlooked because the case history and clinical signs are not specific and

there may be an absence of predisposing factors to raise the suspicion of IE. Predisposing factors that, in combination with clinical signs, should raise the suspicion of IE are: immunosuppressive drug therapy such as corticosteroids,[129,166] non-oral surgery within 3 months, trauma to mucosal surfaces in the oral or genital tract and infections in these body regions, indwelling catheters, infected wounds, abscesses, or pyoderma.[129,178]

Clinical signs are variable and occur in different combinations. Lameness has been described as the most frequent presenting complaint in dogs with IE, followed by non-specific signs such as lethargy, anorexia, respiratory abnormalities, weakness, fever (often recurrent), weight loss, and GI disturbances.[166,167] Stiffness and pain originating from joints or muscles may be caused by immunomediated responses, and abdominal pain may be caused by secondary renal or splenic infarction, septic embolization, or abscess formation. If the condition leads to severe valvular damage, signs of CHF and syncope from arrhythmias may occur. Arrhythmias, primarily ventricular, have been reported in 62% of dogs with aortic IE.[172,173]

Physical Examination

Most clinical signs lack specificity for IE. However, fever, heart murmur (particularly if newly developed), and lameness are considered classical signs.[129] Fever is reported to occur in 50 to 90% in dogs with IE.[166,167] Absence of fever is reported to be more common in cases with aortic valve involvement,[167,172] a finding which may be attributable to *Bartonella* infections. *Bartonella* infections have been reported to be more frequently afebrile,[167] but this finding may also be attributed to treatment already initiated with antibiotics. Because severe aortic insufficiency is otherwise uncommon in dogs, the finding of a diastolic murmur and bounding peripheral pulse should raise the suspicion of IE of the aortic valve. Systolic murmurs may be caused by destruction of the mitral valve, resulting in MR, or by vegetations obstructing the aortic outflow tract leading to stenosis (Audio 251-6).[166] It should be noted that 26% of dogs with IE are reported to lack audible murmurs.[166] Lameness is also an inconsistent finding in IE with an incidence of 34% in one study.[163] A range of other physical findings may be present, depending on which organs are affected by circulating immunocomplexes or septic embolization. Possible findings are pain reactions from muscles or abdomen (spleen, intestines or kidneys), cold extremities, cyanosis and skin necrosis from severe embolization, and a variety of neurological disturbances if the central nervous system is affected.

Diagnostic Testing

Echocardiographic Findings

Echocardiography significantly improves the possibilities for diagnosing and monitoring animals with IE.[178] Valvular vegetations may be detected using 2D echocardiography. The valvular vegetations appear hyperechoic (Videos 251-20 and 251-21 and Figure 251-9, *B-D*), are often irregularly outlined, and often move independently of the valve. Some of these smaller lesions may be very difficult to distinguish from myxomatous lesions. Erosive lesions may be more difficult to identify on the echocardiogram, but the presence of moderate to severe aortic regurgitation, identified on the color echocardiogram, should raise the suspicion of aortic IE. Other causes that are associated with aortic regurgitation include congenital valvular or subvalvular stenosis, myxomatous lesions (usually only mild aortic regurgitation), severe systemic hypertension and quadricuspid aortic valve (a very uncommon congenital malformation). The aortic valve needs to be viewed from several planes to help exclude the differential diagnoses and to identify the erosive lesion. Mitral or aortic regurgitation may be detected using continuous or color-flow Doppler echocardiography. The severity of aortic regurgitation may be estimated in the left apical five-chamber view either by assessing the slope of the regurgitant flow tracing by continuous wave Doppler (steeper slope indicates more severe insufficiency), or by assessing the size of the regurgitant jet on the color echocardiogram, which gives a semiquantitative estimate. Assessment of severity of MR is described elsewhere in this chapter and in ch. 104. Likewise, secondary LA and LV dilatation may be identified using 2D, 3D, or M-mode echocardiography as previously described. In cases where the clinical suspicion of IE is great, but no valve lesion may be identified by transthoracic echocardiography, transesophageal echocardiography may be considered to obtain a more detailed evaluation of the aortic and mitral valves.

Electrocardiographic Findings

Arrhythmia is reported to occur in 50 to 75% of dogs with IE.[166,167,172] Ventricular premature beats and

ventricular tachyarrhythmias are the most commonly encountered arrhythmias, but they are usually not life-threatening. Deviation in the ST-segment might suggest myocardial hypoxia and may indicate coronary artery embolism or myocardial ischemia of other etiologies.[92] Evidence of chamber enlargement may occur in chronic IE. All the mentioned ECG abnormalities are, however, non-specific.

Radiographic Findings

Radiography often does not add any information specific for IE. In cases of chronic IE with aortic or mitral insufficiency, left-sided cardiac enlargement may be detected. Approximately 50% of dogs with IE were reported to present with CHF, as indicated by perihilar and caudodorsal pulmonary infiltrates, with no difference between those with IE of the mitral valve or aortic valve.[164,167] Surprisingly, significant LA enlargement was reported absent in a comparably large proportion of the dogs with CHF, presumably indicating an acute onset of severe valve leakage and CHF.[164,176]

Blood Culture

Positive blood cultures are essential for establishing a diagnosis of IE and for selecting appropriate antimicrobial treatment. Unfortunately, 60-70% of obtained blood cultures in dogs with IE have been reported to be negative.[164,172] The high proportion of dogs receiving antimicrobial therapy prior to the time of sampling presumably contributes to the lack of bacterial growth.[164] Other causes for negative blood cultures include chronic "encapsulated" infections, non-infectious IE (only platelets and fibrin in vegetation) or failure to grow organisms from samples. Some bacteria may grow slowly and samples should not be regarded as definitely negative until they have been cultured for 10 days (*Bartonella* requires culture for up to 4 weeks). In those cultures that are positive, 90% will be so within 72 h of incubation.[179] PCR methodology may be used to amplify and identify bacterial nucleic acid in blood, and thereby potentially increase the likelihood of detecting bacteremia. However, it appears that this method is not more sensitive than blood culture for detection of bacteremia in dogs with suspected endocarditis.[180] The risk of negative cultures is reduced when collection and handling of samples is conducted properly.[175] The time for sampling is probably not critical, but avoiding sample contamination is. The technique for obtaining samples aseptically and anaerobically is important and described in detail below. In cases of positive blood culture, it is important to evaluate if the microorganism is consistent with the diagnosis of IE. Microorganisms known to cause IE in dogs are *Staphylococcus* spp. (*S. aureus, S. intermedius,* coagulase-positive and coagulase-negative), *Streptococcus* spp. (*S. canis, S. bovis,* and beta-hemolytic), *Bartonella* spp., *Escherichia coli, Pseudomonas aeruginosa, Corynebacterium* spp., and *Erysipelothrix rhusiopathiae.*[164,172,177] *Bartonella vinsonii* and related proteobacteria *(B. henselae, B. clarridgeiae, B. washoensis)* have been recognized as potential causes for endocarditis in dogs.[164] In a study comprising dogs from California, *Bartonella* spp. were the cause for IE in 28% of the cases, and in 45% of the IE cases with negative blood cultures.[164] *Bartonella* is also a potential cause for IE in cats.[169] Epidemiological studies suggest that ticks and fleas may be vectors for *Bartonella.* Indeed, concurrent seroreactivity to *Ehrlichia canis, Anaplasma phagocytophilum* and *Rickettsia rickettsii* is common in dogs with IE caused by *Bartonella* spp.[164] (see ch. 215 and 216).

Obtaining Blood Cultures

The reference laboratory should ideally be contacted concerning the preferred type of vials before obtaining a sample. To avoid contamination, strict aseptic sampling should be observed. Three or four samples of approximately 5-10 mL each (the likelihood for a positive blood culture increases with increasing blood volume) should be collected aseptically from different puncture sites at least 30 minutes to 1 hour apart. Samples should be submitted for aerobic and anaerobic culture. Lysis centrifugation tubes may increase diagnostic yield. Sampling through indwelling catheters should be avoided but may be used as a last option. For culture of *Bartonella* spp., 2 mL EDTA blood collected aseptically is frozen at −70°C until cultured.[173] The samples are cultured on a special culture medium for *Bartonella* for up to 4 weeks (see ch. 215 and 216).

Other Laboratory Findings

Mild regenerative anemia is found in 50 to 60% of cases with IE.[129,166,167,172] The anemia implies chronic inflammation, usually being normocytic and normochromic. Leukocytosis is found in about 80% of dogs with IE, usually due to neutrophilia and monocytosis (left shift). Other findings that may be encountered include elevated blood urea nitrogen (BUN) or creatinine concentrations due to embolization, metastatic infection,

CHF or immune-mediated disease. Elevated serum alkaline phosphatase and hypoalbuminemia are probably caused by circulating endotoxins and reduced hepatic function.[163,178] Serum glucose concentration may be decreased and serological tests for immune-mediated disease, such as Coombs' test, may be positive.[178] Urinalysis may reveal hemoglobinuria, hematuria, pyuria, bacteriuria and/or proteinuria. Urine culture (preferably performed by cystocentesis) should always be obtained in dogs with a suspicion of IE in attempt to isolate the infective microorganism.

Diagnosis

Since the clinical signs of IE are often a result of complications, rather than reflecting the intracardiac infection, the diagnosis may easily be overlooked. Although IE may be suspected in many dogs, definite diagnosis of IE requires pathologic examination of tissue, which is not possible in the living dog. The diagnosis of IE is often established by identification of more major and minor criteria for IE. A scoring system, adapted from the modified Duke criteria for IE in people,[181] has been proposed to determine a possible clinical diagnosis of IE in dogs (Table 251-2).[173]

TABLE 251-2

Suggested Criteria for Diagnosis of Infective Endocarditis in Dogs

MAJOR CRITERIA	MINOR CRITERIA	DIAGNOSIS
Positive echocardiogram: Vegetative or erosive lesion, or abscess **New valvular insufficiency:** >Mild aortic insufficiency without subaortic stenosis or annuloaortic ectasia **Positive blood culture:** ≥2 positive blood cultures, or ≥3 if common skin contaminant	**Fever** **Medium to large dog (>15 kg)** **Subaortic stenosis** **Thromboembolic disease** **Immune-mediated disease: polyarthritis glomerulonephritis** **Positive blood culture not meeting major criteria listed in this table** ***Bartonella serology ≥ 1 : 1024**	**Definite** Histopathology of valve 2 major criteria 1 major and 2 minor criteria **Possible** 1 major and 1 minor criteria 3 minor criteria **Rejected** Other disease diagnosed Resolution of regurgitation or valvular abnormality within 4 days of treatment No pathologic evidence endocarditis on postmortem examination

*Not officially accepted yet as a criterion in veterinary medicine.

The veterinary criteria are modified from the Modified Duke criteria used in human medicine for the diagnosis of endocarditis.[181,184]

Modified from MacDonald KA: Infective endocarditis. In Bonagura JD, Twedt D, editors: *Kirk's current veterinary therapy XV,* Philadelphia, 2015, WB Saunders, p 786.

Management

The goal of therapy is to eradicate the infective microorganism and to treat all secondary complications. A successful outcome of therapy is based on early diagnosis and immediate and aggressive treatment. A blood culture (see section above) and an antibiotic sensitivity profile should be obtained. A blood sample for serology is indicated in cases where *Bartonella* can be suspected to be the cause for IE. While waiting for results from cultures and sensitivity tests, intravenous treatment should commence using a bactericidal broad-spectrum antibiotic IV (e.g., beta-lactam antibiotics [such as timentin, which is a combination of ticarcillin and clavulanate] 50 mg/kg IV q 6 h or imipenem 10 mg/kg IV q 8 h).[173] The aminoglycoside amikacin 20 mg/kg q 24 h can be combined with either of the above mentioned beta-lactam antibiotics to obtain a more complete spectrum.[173] The initial treatment is similar for dogs with suspected IE caused by *Bartonella.* Aminoglycosides are potentially nephrotoxic and are only recommended for limited time usage. Patients receiving aminoglycoside therapy IV should be supported with IV fluids. Concurrent furosemide therapy is contraindicated because it can enhance the nephrotoxicity. This limits the use of aminoglycosides

in dogs with IE and CHF. An alternative to an aminoglycoside is enrofloxacin for suspected Gram-negative IE, but the resistance to this antibiotic for different bacteria appears to be variable at different geographic sites. A significant resistance pattern in the local geographic area may limit the use of enrofloxacin as a first-line antibiotic. The choice of antibiotic is also dependent on the site of infection as organ distribution and tissue penetration of antibiotics differ. The primary source of the infection should be sought and treated as aggressively as possibly (e.g., using surgical drainage or debridement).[182] It is important to identify possible secondary problems, such as CHF or kidney injury, which may affect the choice of an antibiotic, or may need specific therapy, or may indicate a poorer prognosis. Dogs in CHF and/or with arrhythmia require treatment as outlined above and in ch. 247 and 248. When results are available from blood cultures, the appropriate antibiotics should be selected and aggressive IV treatment might be continued for 1 to 2 weeks, whilst the patient is closely monitored, in particular with respect to renal function. If results from cultures are negative, the decision to continue antibiotic therapy should be based on clinical improvement. Depending on the early outcome of therapy, subcutaneous administration may, replace IV treatment after 1-2 weeks, and later, oral preparations. The duration of therapy should be at least 6 weeks on the effective antibiotic. In patients with positive blood cultures, it is recommended to obtain a new blood culture 1-2 weeks after initiation and 1-2 weeks after the termination of the antibiotic therapy. Repeat echocardiographic examinations, blood panels, and urinalyses are recommended during and after the antibiotic therapy to monitor the therapeutic success and identify possible complications. Dogs diagnosed with IE caused by *Bartonella* may be monitored with repeat serology 1 month after the initiation of antibiotic therapy.[173] A significantly reduced titer indicates effective treatment; an increased titer suggests ineffective treatment and indicates that a change of antibiotic is needed (see ch. 215 and 216).

Prognosis

Factors that may indicate a poor prognosis include: late diagnosis and late start of therapy, aortic valve involvement,[184] valvular vegetation,[183] *Bartonella* infections (leads most commonly to aortic IE),[176] Gram-negative infections, heart or renal complications that do not respond to therapy, septic embolization or metastatic infection, thrombocytopenia,[167] elevation of serum alkaline phosphatase and hypoalbuminemia (70% mortality is reported if this is found in cases with IE),[163] concurrent treatment with corticosteroids, regardless if antibiotics are given simultaneously,[167] treatment with bacteriostatic antibiotics or premature termination of antibiotic therapy. Factors that have been reported to indicate a more favorable prognosis include: mitral valve involvement only (median survival time of 476 days in one study),[164] Gram-positive infections, infection originating from the skin, abscesses, cellulitis, or wound infections.[178]

Prevention

Prophylactic antibiotics may be indicated 1-2 hours before and 6 hours after cardiovascular procedures in cases where turbulent blood flow is suspected to have damaged the endothelium (e.g., aortic stenosis, PDA or VSD). In these cases, early treatment of all infections is important to avoid bacteremia and reduce the risk for IE. Amoxicillin may be the first choice, but other antibiotics, such as clindamycin, may also be considered depending on the organ system involved and site of infection.[175] Finally, it is very uncommon that dogs with MMVD develop IE as a consequence of dental procedures, which indicates that prophylactic treatment of these dogs is redundant.[129]

CHAPTER 252

Myocardial Disease

Canine

Joshua A. Stern, Kathryn M. Meurs

Client Information Sheet: Myocardial Disease in Dogs

Canine myocardial disease is one of the most common forms of acquired heart disease in the dog.[1] The most common form of myocardial disease in the dog is dilated cardiomyopathy, but arrhythmogenic right ventricular cardiomyopathy, hypertrophic cardiomyopathy and myocarditis, among others, are also reported.

Canine Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM) is a primary myocardial disease characterized by cardiac enlargement and impaired systolic function of one or both ventricles (Figure 252-1). Diastolic dysfunction may also be observed.[2] An increased understanding of the etiology of both the human and canine disease has led to the development of the theory that DCM is the final result of a variety of myocardial insults including viral, nutritional, toxic and genetic.[3] In human beings, the disease has been shown to be familial in at least 30-50% of the cases and causative mutations have been identified in more than forty genes.[4,5] The etiology remains undetermined in many cases and they are thus considered idiopathic.

FIGURE 252-1 Heart from a Doberman Pinscher with dilated cardiomyopathy. The left ventricle and left atrium are grossly dilated. (Courtesy Dr. Bruce Keene.)

Although canine DCM is described as one disease, significant variation in the presenting complaint, clinical evaluation and rate of progression has been observed depending on the breed of dog and underlying etiology.[6-12]

Generally DCM is a disease of large and medium sized dog breeds. Some breeds are clearly overrepresented, particularly in specific geographical regions. Surveys in North American publications find an increased incidence in the Doberman Pinscher, Irish Wolfhound, Great Dane and Cocker Spaniel.[13,14] European sources suggest an increased incidence of the Airedale Terrier, Doberman Pinscher, Newfoundland and English Cocker Spaniel.[15] The differences in breed prevalence between the canine populations may suggest an influence of environmental factors on the development of DCM, but more likely is related to the strong genetic influences of certain popular dog breeds within an area. This population stratification is seen when genetic studies of the same disease in a single breed identify regionally specific results. To date, two genetic mutations associated with the development of DCM are reported in dogs and are detailed under the breed-specific sections below.[16,17]

Clinical Presentation

Dilated cardiomyopathy is an adult-onset disease, with the exceptions of the Portuguese Water Dog and Toy Manchester Terrier in which it is most frequently diagnosed before one year of age.[12,18]

There appear to be two stages of DCM: an "asymptomatic" stage, referred to as occult, which may be

detected by careful screening; and a stage at which clinical signs appear, referred to as overt. Clinical signs may include coughing, dyspnea, tachypnea, syncope, exercise intolerance and occasionally, ascites.

Physical Examination

A soft systolic murmur consistent with mitral valve regurgitation and/or a gallop sound (S_3) may be ausculted at the left apex (see ch. 55). A tachyarrhythmia of ventricular or atrial origin may be noted. In some cases, these may be the first signs of the occult form of disease and should not be overlooked. Since primary valvular disease is relatively uncommon in large breed dogs (see ch. 251), and the detection of DCM before the development of congestive heart failure (CHF) may be beneficial in the long-term management of the case, identification of a new murmur, gallop or tachyarrhythmia in suspect breeds may warrant a thorough cardiac work-up. Although canine DCM is predominantly a left ventricular disease, biventricular involvement and heart failure with jugular venous distension and ascites is frequently noted, particularly in the giant breeds.

Diagnostic Testing

Electrocardiography

Many dogs with DCM have normal electrocardiograms but atrial and/or ventricular enlargement patterns may be observed (see ch. 103). Additionally, tachyarrhythmias, particularly atrial fibrillation and/or ventricular tachyarrhythmias, are common (see ch. 248). Sinus tachycardia may be observed, particularly in the face of CHF.

Radiography

Dilated cardiomyopathy is a progressive myocardial disease. If the disease is diagnosed in the early stages, radiographic findings may be subtle. Therefore, depending on the stage of the disease, thoracic radiographs may be within normal limits or may indicate atrial and ventricular enlargement (typically left) with or without pulmonary venous distension and pulmonary edema. In some cases, biatrial and biventricular enlargement may be noted, particularly with more advanced disease and in conjunction with tachyarrhythmias.

Echocardiography

Echocardiography is the diagnostic test of choice for diagnosing canine DCM and is also an important test for occult disease (see ch. 104). Echocardiographic findings in the patient with overt disease should include left and sometimes right atrial and ventricular dilation as quantified by M-mode and two-dimensional measurements (Figure 252-2, *A* and *B* and Video 252-2, *A* and *B*). The measurements should be compared to the normal values for that particular breed or size (body surface area) of dog. In some cases, the ventricular wall thickness may appear thin during diastole, but generally when it is measured it is found to be within normal limits as DCM is characterized by eccentric hypertrophy. An important part of the diagnosis is usually concurrent left ventricular systolic dysfunction based upon decreased fractional shortening (FS%), ejection fraction (EF%) or shortening area, and increased end-systolic volume. Many dogs may demonstrate diastolic dysfunction as well, as determined by evaluation of transmitral flow, tissue Doppler and pulmonary venous flow.[2] Doppler echocardiography may be used to document a central jet of mitral regurgitation that may be associated with dilation of the ventricle. A differential diagnosis for DCM is severe atrioventricular (AV) valve disease (see ch. 251) since severe ventricular dilation and systolic dysfunction may be occasionally observed in these cases. Consideration of the breed of dog may be helpful in differentiating between DCM and AV valve disease since it is uncommon for many of the large breed dogs to develop significant primary valve disease. Additionally, DCM is supported in cases that lack the typical AV valve thickening associated with classic AV valve degeneration. An exception to this may be the Cocker Spaniel, a breed that has a high incidence of primary valve disease, and also is at increased risk of DCM.

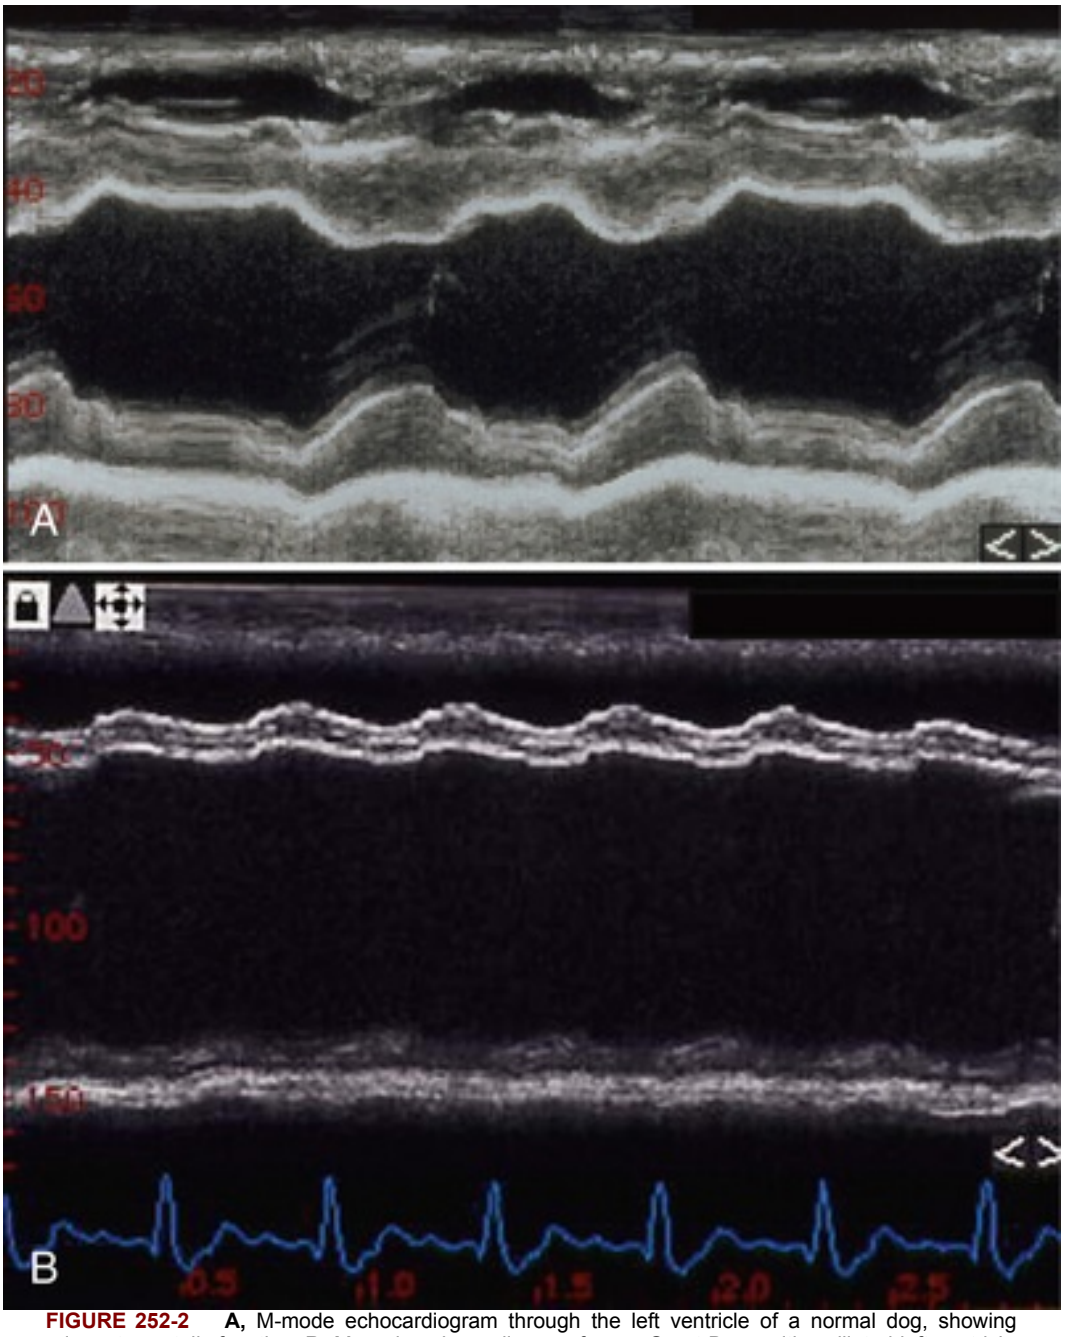

FIGURE 252-2 **A,** M-mode echocardiogram through the left ventricle of a normal dog, showing adequate systolic function. **B,** M-mode echocardiogram from a Great Dane with a dilated left ventricle with a markedly decreased systolic function.

Unfortunately, the diagnosis of the occult stage of DCM is much more difficult. In some cases, dilation of the ventricle precedes the development of systolic dysfunction and is an early indicator of DCM.[20] However, this is not always the case and systolic dysfunction may precede dilation. Annual two-dimensional and M-mode echocardiography is recommended for adult dogs of at-risk breeds or if early signs (heart murmur, gallop, tachyarrhythmias) are detected. Additional studies that have been suggested for additive information when evaluating borderline cases include measurement of the mitral valve annulus motion, sphericity index, E-point-to-septal-separation, systolic time intervals, Simpson's method of disc functional assessment, systolic and diastolic performance index and stress echocardiography.[21-25] Because desirable breeding age may precede the age of onset for DCM, early identification of disease is of paramount importance for reducing the prevalence of this disease in the population.

Biomarkers

Cardiac biomarkers are biological substances of cardiac stress and myocyte injury (see ch. 246).[26] Atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP) and troponin I (cTnI) are biomarkers shown to be important in the evaluation of cardiac disease in the dog.[21-31]

Atrial natriuretic peptide, a peptide released in response to increased atrial pressure and stretch, has been shown to be significantly increased in both occult and overt dilated cardiomyopathy in the Doberman Pinscher.[28] However, an additional study of dogs of various breeds with DCM found that ANP was not specific or sensitive enough to be useful as a screening tool for the occult stage of DCM.[27] The ability of ANP to suggest the presence of cardiac disease is likely dependent on the stage of the disease, with earlier cases still having normal levels.

Cardiac troponin-I (cTnI) is also a marker of myocardial injury. Plasma cTnI levels were found to be increased in Doberman Pinschers with overt DCM.[29] Cardiac troponin-I levels were also observed to be increased in dogs with occult DCM; however, cTnI levels appeared to lack the sensitivity and specificity to be used as a marker of early DCM in this group of dogs.[27] High sensitivity assays for cTnI have recently become available. Their utility in evaluating occult DCM is not yet reported.

B-type natriuretic peptide (BNP) and N-terminal pro-BNP (NT-proBNP) are cleaved from a pre-prohormone BNP that is synthesized in the myocytes (see ch. 246). Prohormone BNP is released when the ventricles are dilated, hypertrophic or subjected to increased wall tension and cleaved into the two polypeptides.[26] Levels of BNP have been shown be increased in dogs with congestive heart failure and can be used to help diagnose or exclude a diagnosis of heart failure in dogs that presented for cough or dyspnea.[30] A more recent study measured NT-proBNP in dogs with dilated cardiomyopathy and determined that NT-proBNP levels were significantly higher in affected dogs.[31] BNP screening was quite sensitive even for dogs in the occult stage of disease. Doberman Pinschers were shown to have elevated plasma concentrations of NT-proBNP when affected with DCM and up to 1.5 years prior to the development of DCM.[32] Therefore, it would appear that BNP may be the most useful biomarker for both the occult and overt stages of the disease, although additional studies are needed.

Pathology

Gross pathology of DCM typically demonstrates dilation of both left and right atria and ventricles, although in some cases, the left side is more affected than the right.[33-35] Myocardial eccentric hypertrophy should also be evident by an increased heart to body weight ratio.

Histopathologic findings may vary and are generally fairly nonspecific. Common findings can include attenuated wavy myofibers, fibrosis, vacuolization of myocytes, necrosis and in some cases fatty infiltration.[33,35]

Etiology

The term *cardiomyopathy* can be used to define myocardial diseases caused by a variety of factors including genetic, viral and nutritional, among others (see ch. 253).[3] In many canine cases, the cause is unknown. It is clear that several breeds appear to be overrepresented and some breeds seem to have unique characteristics of the disease that may suggest that this is a unique disease for their breed. A familial form of DCM has now been identified in several breeds and is suspected in others.[9,17,18,36,37] Occasionally, atypical breeds of dogs develop DCM. The etiology of the disease in these cases is unknown and external factors that can insult the myocardium, including infectious organisms or nutritional imbalances, should be considered.[38-44]

Breed-Specific Dilated Cardiomyopathy

Cocker Spaniels

Dilated cardiomyopathy has been reported in both American and English Cocker Spaniels.[1,6,45] An association between the development of DCM and low plasma taurine levels has been reported in some American Cocker Spaniels.[6] American Cocker Spaniels with low taurine levels that were provided taurine and L-carnitine supplementation showed an increase in FS% and a decrease in left ventricular end diastolic and end systolic diameter over a 4-month period, although myocardial function did not return to normal.[46] This study suggested that at least some American Cocker Spaniels with DCM may benefit from

supplementation with taurine and, perhaps, L-carnitine.

Taurine levels may be assessed by evaluation of blood or plasma taurine levels, although blood levels are less affected by sample handling and recent feedings compared to plasma levels. American Cocker Spaniels with DCM should have blood or plasma levels of taurine measured and should be treated with 500 mg of taurine and 1 gram of L-carnitine PO q 12 h.[46] Additional treatment should be given as needed to address any other complications of the disease, including congestive heart failure and arrhythmias. In many cases, supportive cardiovascular medications can be gradually withdrawn after the left ventricular fractional shortening increases to at least 20% (usually after 3-4 months of supplementation). Supplementation with taurine, and L-carnitine if possible, should be continued for life.

In some cases of Cocker Spaniel DCM, taurine deficiency is not identified. The prognosis is generally poorer in these cases.

English Cocker Spaniels also get a form of DCM but a relationship to taurine or carnitine levels has not been identified. Many reported dogs were from the same kennel, which may suggest a heritable component.[47,48] Evidence of profound left ventricular enlargement on the electrocardiogram with R wave amplitudes > 3.0 mV in lead II was frequently observed.[45] Some of the reported dogs died suddenly, but many have a prolonged, fairly asymptomatic course of disease, or a long survival (years) with medical management.[47]

Dalmatians

Dalmatians are occasionally diagnosed with DCM, although not as commonly as some of the other breeds such as Doberman Pinschers, Great Danes and Irish Wolfhounds.[1] Male dogs appear to be overrepresented in Dalmatian DCM, although large studies have not been performed.[7] All dogs had adult-onset disease and presented for signs consistent with left heart failure (cough, dyspnea) or syncope. None of the dogs had evidence of biventricular heart failure. Electrocardiography frequently demonstrated sinus rhythm or sinus tachycardia with occasional ventricular ectopy. Atrial fibrillation was not observed in any of the dogs. Duration of survival ranged from 1.5 to 30 months with euthanasia due to refractory CHF. None of the dogs died suddenly. Interestingly, the majority (8/9) of reported dogs had been fed a low protein diet for all or part of their lives for prevention or treatment of urate stones. The low protein diet may have resulted in an imbalance that could have led to the possible development of dilated cardiomyopathy; however, in the dogs that were tested, there was no evidence of L-carnitine or taurine deficiency. The cause and effect of these diets on the development of DCM is not known, but Dalmatians that develop DCM that are being fed a low protein diet should be switched to a more balanced diet if possible.

Occasionally Dalmatians develop acquired AV valve disease so this should be considered as an important differential diagnosis (see ch. 251).

Doberman Pinschers

The Doberman Pinscher is one of the most commonly reported breeds of dogs to be diagnosed with DCM in North America.[8,14,49,50] It is an adult onset disease that results in the development of left and/or biventricular failure, often with atrial fibrillation or sudden cardiac death.[51] The occult stage can be characterized by infrequent ventricular premature complexes, mild ventricular dilation and/or systolic dysfunction.[51] Diastolic function is often present.[2] The overt stage is often characterized by atrial fibrillation, ventricular premature complexes and congestive heart failure. Many affected dogs will first present for symptoms from their ventricular tachyarrhythmias including syncope and sometimes, sudden cardiac death.[52,53] Although, syncope is often associated with the presence of ventricular tachyarrhythmias, bradycardia associated episodic weakness and syncope has also been observed in cardiomyopathic Doberman Pinschers.[53] Therefore, every attempt should be made to determine the cause of the syncopal episodes with a Holter or event monitor before treatment is started.

Pathologic evaluation of the hearts of affected Doberman Pinschers identified a variety of nonspecific findings. Moderate to severe dilatation of all four cardiac chambers was often observed, although the left side was typically worse than the right. Heart weight to body weight ratios are often increased (11.5 +/− 2.4 g/kg; normal = 6.6 +/− 0.3 g/kg, p <0.001).[53b] Histologic lesions have been characterized by marked myofiber degeneration and atrophy, myocardial replacement by thick bands of collagen fibers, interstitial fibrosis, aggregates of fat, multifocal myocytolysis and myocardial necrosis.

Dilated cardiomyopathy in the Doberman Pinscher appears to be familial. An autosomal dominant mode of inheritance has been defined by the appearance of the disease in multiple generations, equal gender

representation and evidence of male-to-male transmission[36] (Figure 252-3). In North American Doberman Pinschers, a splice-site mutation in the pyruvate dehydrogenase kinase 4 (*PDK4*) gene has been identified and associated with development of DCM. A mutation test is available and may be utilized to inform breeding decisions. This mutation is incompletely penetrant, meaning that not all dogs with the mutation will develop disease and the expression of disease is variable.[16] Ongoing studies in Europe aim to identify a second mutation in Doberman Pinschers, as the PDK4 gene does not appear to be the only cause of US Doberman DCM, it was not associated with a European cohort of DCM Dobermans, and a different chromosomal region of interest was identified by genome-wide association analysis in European dogs.[54,55]

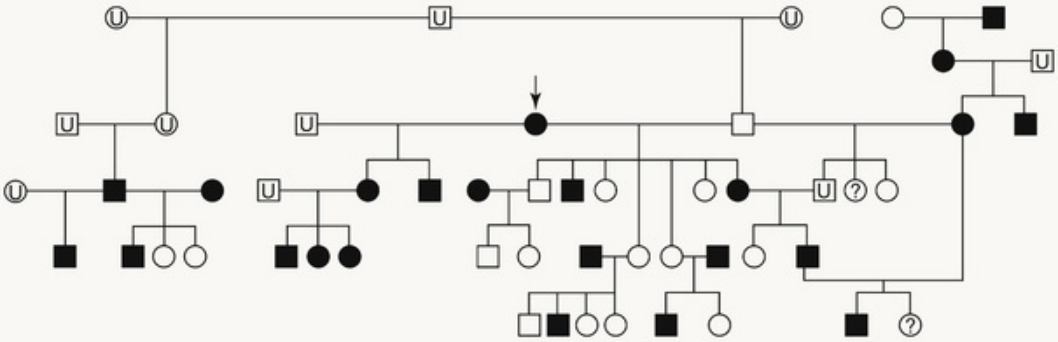

FIGURE 252-3 Pedigree from a Doberman Pinscher family with dilated cardiomyopathy and an autosomal dominant mode of inheritance. The proband is indicated by an arrow. Circles represent female dogs; squares represent male dogs. Solid black symbols represent affected animals; a U in the symbol represents dogs classified as indeterminate; solid white symbols represent unaffected animals; a question mark in the symbol represents animals not available for evaluation. (Previously published in Meurs KM, Fox PR, Norgard M, et al: A prospective genetic evaluation of familial dilated cardiomyopathy in the Doberman pinscher. *J Vet Intern Med* 21:1016-1020, 2007.)

Evidence that the disease is familial and the suggestion that early intervention may increase survival has led to significant interest in screening asymptomatic dogs for signs of occult disease. Annual echocardiography and ambulatory electrocardiography (Holter monitoring) are believed to be the best predictors of early DCM.[50,56] Criteria that are believed to be indicators of occult disease include an echocardiographically determined left ventricular end diastolic diameter greater than 4.6 cm and a left ventricular end systolic diameter greater than 3.8 cm, even in the absence of systolic dysfunction.[22] These numbers are based on average sized DCM dogs and may be less valid for very large dogs (Videos 252-1 and 252-3). Annual Holter monitoring has also been recommended to detect Doberman Pinschers that may develop ventricular arrhythmias before ventricular dilation and systolic dysfunction (Figure 252-4). Adult Doberman Pinschers with greater than 50 ventricular premature complexes (VPCs) per 24 hours, or with couplets or triplets are suspect for the development of DCM.[56] Measurement of circulating BNP or NT-proBNP may also be useful for early detection of disease.[27,32] Genetic testing for the associated PDK4 mutation may aid in the development of screening protocols.[16] Owners should be advised that since this is an adult-onset disease with variability in the age of onset, screening tests should be performed annually.

FIGURE 252-4 Adult Doberman Pinscher with a Holter monitor used for screening for occult disease.

Great Danes

Dilated cardiomyopathy in the Great Dane appears to be a familial disease.[9] In one study, affected male dogs were overrepresented, suggesting an X-linked pattern of inheritance in at least some families.[9] If this is true, sons of affected females are at high risk of developing the disease; daughters of affected fathers are likely to be silent carriers. Affected Great Danes presented most commonly for weight loss and/or coughing. Left-sided heart murmurs, a gallop and ascites were frequently observed. The most common electrocardiographic findings included atrial fibrillation with an occasional ventricular premature complex. In some cases, atrial fibrillation developed before any other evidence of underlying myocardial disease (chamber enlargement or systolic dysfunction). Therefore, dogs with atrial fibrillation should be carefully evaluated for early DCM and should be followed annually to monitor for possible development of disease.

Irish Wolfhounds

Dilated cardiomyopathy appears to be a familial trait in the Irish Wolfhound.[37,57] The mode of inheritance is autosomal recessive with sex-specific alleles. Male dogs may be overrepresented.[10] As in the Great Dane, atrial fibrillation frequently preceded the development of a heart murmur, clinical signs and CHF. Atrial fibrillation was present in the majority of Irish Wolfhounds by the time they developed DCM.[10,58] The progression of the disease is not well understood but appears to be slow, with the development of atrial fibrillation preceding the development of CHF by an average of 24 months.[10] Occasionally, additional electrocardiographic abnormalities have been described including ventricular premature complexes and left anterior fascicular block patterns. Affected Irish Wolfhounds occasionally died suddenly, but more commonly were euthanized due to heart failure, most commonly biventricular, and sometimes with chylothorax.[58,59] Low whole blood taurine levels are occasionally encountered in Irish Wolfhounds, but no clear relationship between taurine levels and DCM can be established in this breed.[60]

Newfoundlands

Adult-onset DCM without a gender predisposition has been reported in the Newfoundland.[11,23] Clinical presentation included dyspnea, cough, inappetence and ascites with left or biventricular heart failure. Interestingly, a heart murmur was auscultable in only a very small percentage of the dogs (4/37).[11] The most common electrical abnormality was atrial fibrillation, but isolated ventricular premature complexes were also observed.

Portuguese Water Dogs

A juvenile form of familial DCM has been reported in the Portuguese Water Dog and is thought to be inherited as an autosomal recessive trait that is linked to a region on canine chromosome 8.[12,61] Affected puppies were from seemingly unaffected parents and typically died between 2 and 32 weeks of age, either from sudden collapse and death without any preceding signs or the development of congestive heart failure.[61]

Standard Schnauzers

Familial DCM in the standard Schnauzer has been reported and recently a deletion and frame-shift mutation in the RNA binding motif protein 20 *(RBM20)* gene was identified. This mutation is inherited in an autosomal recessive pattern. Although clinical reports of this disease and mutation in the breed are currently lacking, a genetic mutation test is available and may be used to inform breeding decisions.[17]

Toy Manchester Terriers

A rapidly progressive juvenile form of familial DCM has been reported in the Toy Manchester Terrier and is clinically similar to the Portuguese Water Dog with DCM. Most affected dogs are less than 1 year of age and typically die suddenly without signs of overt congestive heart failure.[18]

Nutritional Cardiomyopathy

Taurine Related Cardiomyopathy

The development of dilated cardiomyopathy due to low taurine is much less common in the dog than in the cat since dogs have a much greater ability to synthesize taurine than cats. However, as mentioned above, a relationship between taurine and L-carnitine abnormalities and DCM has been previously described in the Cocker Spaniel.[6,46] There have now been additional reports of the development of DCM in the dog in which low blood or plasma levels of taurine have been documented.[43,44] The dogs were all adult at the time of onset and were breeds that would be considered to be in the large breed dog groups. A common factor observed in several dogs that developed DCM and were determined to have low taurine was the feeding of a diet of a dry dog food with lamb meal, rice or both as the primary ingredient.[44] It has been hypothesized that rice bran or whole rice products may result in decreased taurine levels in some dogs. However, there is also a report of a family of Golden Retrievers with an apparent familial taurine deficiency and dilated cardiomyopathy. In a separate study of plasma taurine concentrations in dogs with heart disease, 4 out of 6 Golden Retrievers with DCM had low taurine levels.[43] These findings suggest that there may be some breed variations in taurine handling that could result in the development of DCM in certain breeds.

A blood level of less than 150 nmol/mL or plasma levels less than 40 nmol/mL indicates a diagnosis of taurine deficiency. If taurine deficiency is suspected, taurine supplementation should be started while waiting for the results of the blood or plasma levels. Published dosages for taurine supplementation appear to vary slightly, although 1000 mg/day (PO, divided or once a day) appears to be a consistent recommendation.[43,44] Additional cardiac medications should be provided as needed including inotropic support such as pimobendan and treatment of heart failure if needed (see ch. 247). Taurine-deficient dogs with dilated cardiomyopathy appear to respond to supplementation fairly rapidly and improvement in echocardiographic measurement should be observed in 3-6 months. Ideally, blood levels of taurine should be reevaluated in 1-2 months to confirm that the levels have increased.[43]

Treatment

Treatment of the Dog with Dilated Cardiomyopathy

The ideal treatment for dilated cardiomyopathy would be directed at the primary insult to the myocardium. Unfortunately, in the majority of cases, the underlying cause is not known and treatment should be directed

to the identified cardiac abnormalities—for example, systolic dysfunction, presence of heart failure (see ch. 247) or arrhythmias (see ch. 248).

Treatment of the Dog with Occult Dilated Cardiomyopathy

There are very few studies that have evaluated the benefit of medical therapy for dogs diagnosed in the occult stage of the disease; however, this area is likely to expand with our increasing ability to diagnose the disease early. Administration of angiotensin converting enzyme (ACE) inhibitors may have some benefit for the dog with early ventricular dilation, with or without systolic dysfunction. The use of ACE inhibitors in the Doberman Pinscher with ventricular dilation was associated with a longer period of time before the onset of CHF.[19] Although this study was limited to evaluation of Doberman Pinschers and was retrospective in nature, the use of ACE inhibitors for other breeds of dogs with occult DCM should be considered.

Administration of beta-blockers to the dog in the occult stage of DCM for a cardioprotective effect is still being evaluated. The addition of low-dose beta-blockers to the treatment of human patients with DCM and stable heart failure has demonstrated a reduction in both mortality and morbidity.[63] However, many human patients with DCM cannot tolerate even very low dosages of beta-blockers and demonstrate rapid cardiac decompensation. One prospective, placebo-controlled canine study that looked at the effect of three months of the beta-blocker carvedilol at a gradually increasing dosage did not identify any differences between the beta-blocker and placebo effect in echocardiographic indices of left ventricular size or function, neurohormonal activation, radiographic heart size, heart rate or owner perceived quality of life.[64] It is possible that a greater effect might be observed if the medication was given over a longer period of time or at a higher dosage. Overall, the use of beta-blockers for the canine patient with DCM has not yet been well studied and a consensus opinion on use of these drugs for the canine patient is not yet available. Beta-blockers might be considered for the patient with occult disease, but such patients should be very carefully monitored and the beta-blocker should not be given if there is evidence of heart failure until it is very well stabilized. It cannot be over-emphasized that the addition of beta-blockers in canine DCM patients should be done very cautiously with gradual increases in dosing after a two-week period and careful monitoring of heart rate, blood pressure and clinical signs.

Administration of pimobendan, an inodilator, with calcium-sensitizing and phosphodiesterase inhibition effects, is widely utilized in the treatment of canine congestive heart failure (see ch. 247).[65] The PROTECT study, a multicenter double-blinded placebo-controlled evaluation, identified a clear survival benefit in Doberman Pinschers given pimobendan during the occult phase of their disease process. The median time to onset of congestive heart failure or sudden cardiac death was found to be significantly longer (718 days versus 441 days) for Dobermans with occult DCM that received standard doses of twice-daily pimobendan.[66] Although this study was limited to the evaluation of Doberman Pinschers, the use of pimobendan for other breeds of dogs with occult DCM should be considered.

Treatment of the Dog with Dilated Cardiomyopathy and Congestive Heart Failure

Dogs with DCM and heart failure will benefit from inotropic support. Ideally, this would be with pimobendan, a phosphodiesterase III and V inhibitor with calcium-sensitizing properties that acts as a positive inotrope as well as vasodilator (inodilator).[65] Pimobendan has balanced vasodilatation and positive inotropic effects and has been shown to increase survival (median of 130 days versus a median of 14 days for the placebo in one study) in Doberman Pinschers with DCM when given at a dosage of approximately 0.25 mg/kg PO q 12 h[62,65] (Video 252-6, *A* and *B*).

Additional medications for heart failure such as ACE inhibitors and diuretics should be started as needed (see ch. 247). Nonspecific treatments including nutritional supplementation with compounds like taurine should be considered in dogs that may be suspected of having low levels until proven otherwise.[67] Supplementation with fatty acids may be considered for patients with cachexia (see ch. 177 and 183). Treatment of confounding supraventricular or ventricular arrhythmias must be considered (see ch. 248). The use of digoxin and/or diltiazem is frequently utilized in the co-management of atrial fibrillation and congestive heart failure.

Treatment of the Dog with Ventricular Arrhythmias

There is little consensus for the decision of when and how to treat ventricular arrhythmias in the dog with DCM. Rapid ventricular tachycardia, complex ventricular arrhythmias or the combination of ventricular arrhythmias, ventricular dilation and systolic dysfunction are thought to be associated with a higher risk of

sudden cardiac death and to be indications for treatment, but this has not been well studied. Additionally, some dogs die suddenly without having any of these arrhythmias documented. If treatment is warranted, consideration might be given to the use of one of several ventricular antiarrhythmics (see ch. 248). Sotalol, a combination beta-blocker and potassium channel blocker, may be beneficial in some cases, but should be used a bit more cautiously (low-dose) if systolic dysfunction is present. Mexiletine at a dosage of 5-6 mg/kg PO q 8 h can be very effective at decreasing the arrhythmia. In a small number of cases it can cause nausea but this can be significantly reduced if it is given with at least a small meal, so it should never be given on an empty stomach. Amiodarone has been studied in the affected Doberman Pinscher at a dosage of 10 mg/kg PO q 12 h for 5 days and then 5 mg/kg q 24 h. Careful evaluation of serum drug concentrations, complete blood counts (neutropenia has been reported) and serum liver enzyme activities on a monthly basis is suggested.[51] Although the goals of treatment include decreasing the number of ventricular premature complexes, decreasing clinical signs and decreasing the risk of sudden death, the ability of any antiarrhythmic to reach these goals has not been well studied.

Prognosis for the Dog with Dilated Cardiomyopathy

Prognosis is likely to be dependent on the underlying cause, which is generally not known. However, for the canine population with DCM, certain negative predictors of survival have been identified including age of onset of clinical signs, pleural effusion, pulmonary edema, ascites, atrial fibrillation, end systolic volume index, ejection fraction and a restrictive pattern of transmitral flow.[68,69]

Arrhythmogenic Right Ventricular Cardiomyopathy in the Boxer

Since the early 1980s, the term Boxer cardiomyopathy has been used to describe adult Boxer dogs that present with ventricular arrhythmias, and sometimes, syncope.[70] Recent studies have demonstrated that the disease has many similarities to a human disease called arrhythmogenic right ventricular cardiomyopathy (ARVC). The similarities between the diseases include clinical presentation, etiology and a fairly unique histopathology that includes a fibrous fatty infiltrate of the right ventricular free wall[71] (Figure 252-5). The disease is most commonly characterized by ventricular arrhythmias, syncope and sudden death. However, systolic dysfunction and ventricular dilation are seen in a small percentage of cases.

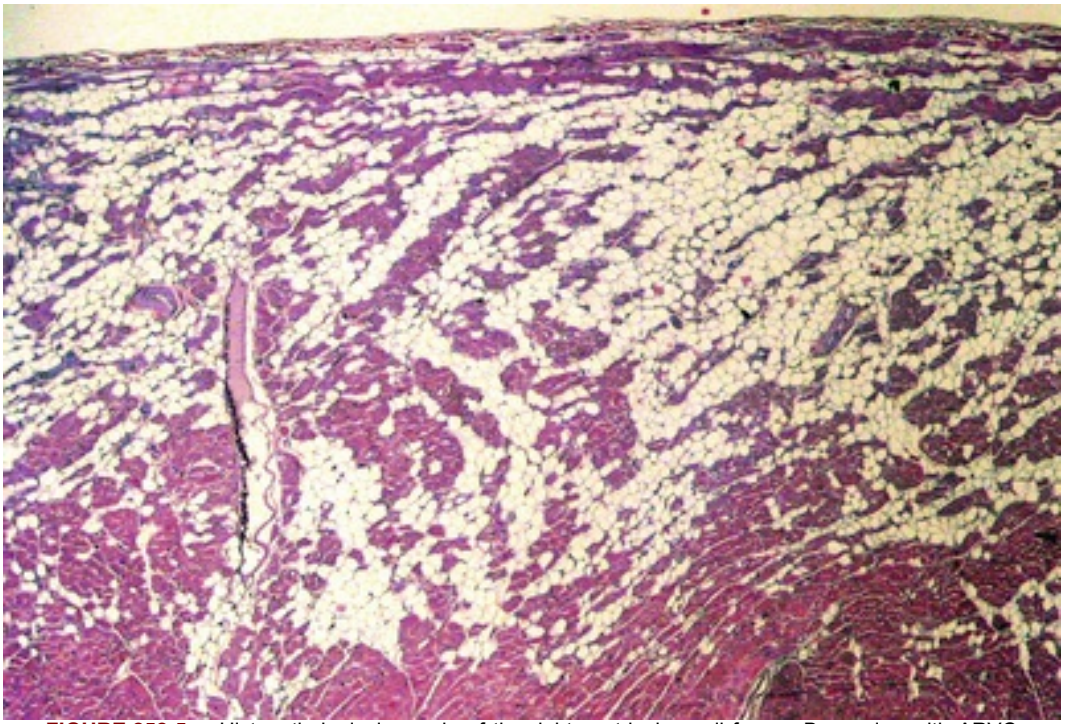

FIGURE 252-5 Histopathological sample of the right ventricular wall from a Boxer dog with ARVC demonstrates multifocal myocyte vacuolization, myocyte loss, and significant fatty infiltration. 20× magnification, hematoxylin and eosin stain.

Arrhythmogenic right ventricular cardiomyopathy is a familial disease in the Boxer and appears to be inherited as an autosomal dominant trait.[72] Unfortunately, the disease also appears to be a disease of variable genetic penetrance and affected dogs can have many different presentations including asymptomatic, syncope, sudden death and systolic dysfunction with CHF. A genetic deletion mutation in the gene striatin was found to be associated with development of ARVC in Boxers. This mutation is inherited in an autosomal dominant pattern with incomplete penetrance. Importantly, homozygous mutant dogs exhibit more severe forms of ARVC including higher number of ventricular arrhythmias, sudden death events and the rare structural heart disease variety of this condition, termed type III ARVC.[73,74]

Diagnosis

The most common presenting complaint is one of syncope (see ch. 30). Episodes of syncope may be associated with a period of exercise or excitement, but are not always. Some dogs present for exercise intolerance or lethargy and others die suddenly without ever developing symptoms. Infrequently (approximately 10% of affected dogs), a dog may present with signs of left or biventricular heart failure.

Most affected Boxers have a completely normal physical examination. However, a tachyarrhythmia may be ausculted. In the small percentage of cases with ventricular dilation and systolic dysfunction, termed type III ARVC, a systolic murmur and/or gallop (S_3) may be ausculted at the left apex. Infrequently, signs of right heart failure (ascites and jugular venous distension) may be observed. The Boxer breed also has a very high incidence of left basilar systolic murmurs. These murmurs may be associated with aortic stenosis, or potentially may be physiologic. Many Boxers with ARVC have these murmurs in addition to their arrhythmic disease, but left basilar systolic heart murmurs are not an indication of Boxer ARVC.

Biomarkers appear to be of variable value in the diagnosis of Boxer ARVC. Cardiac troponin I has been shown to be significantly elevated in Boxers with ARVC and correlated with both VPC number and grade, or complexity, of the arrhythmia[75] (Figure 252-6). However, some affected dogs had lower levels of cTnI that overlapped with normal Boxers. Therefore, although measurement of cTnI may provide supportive information in a dog in which a diagnosis of ARVC is suspected, further study is needed before it can be an independent screening test. B-type natriuretic peptide measurement in similar groups of Boxers did not identify a difference in affected dogs in comparison to normal Boxers and normal unaffected boxers; therefore, BNP does not appear to be a useful indicator of disease.[76]

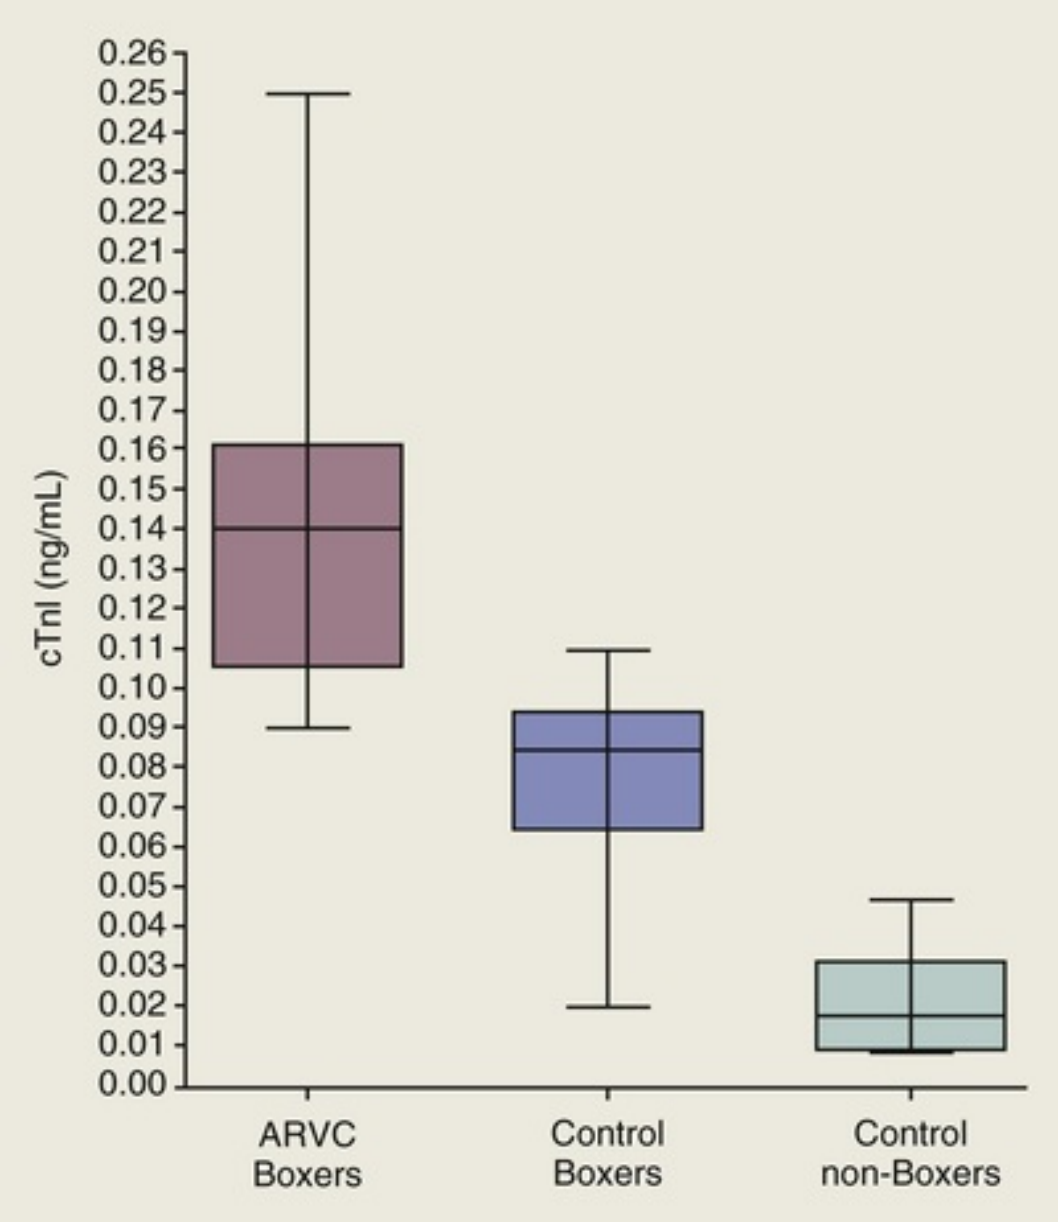

FIGURE 252-6 Box plot of serum cTnI concentrations obtained from ARVC Boxers (n = 10), control Boxers (10), and control non-Boxers (10). Troponin I was significantly elevated in ARVC Boxers. Solid horizontal lines within boxes represent mean values. Each box represents 95% confidence intervals. Whiskers represent the range of values. (Previously published in Baumwart RD, Orvalho J, Meurs KM: Evaluation of serum cardiac troponin I concentration in Boxers with arrhythmogenic right ventricular cardiomyopathy. *Am J Vet Res* 68:524-528, 2007.)

A 2-5 minute electrocardiogram (see ch. 103) is frequently normal in the affected Boxer; however, ventricular premature complexes may be present singly, in pairs and in runs of paroxysmal ventricular tachycardia (Figure 252-7). The ventricular premature complexes typically have a left bundle branch block morphology in leads I, II, III, and AVF, consistent with the right ventricular origin of this arrhythmia.[77] In some cases, the ventricular arrhythmias that cause syncope may not be observed on the electrocardiogram and a 24-hour Holter monitor should be performed to evaluate for arrhythmias.

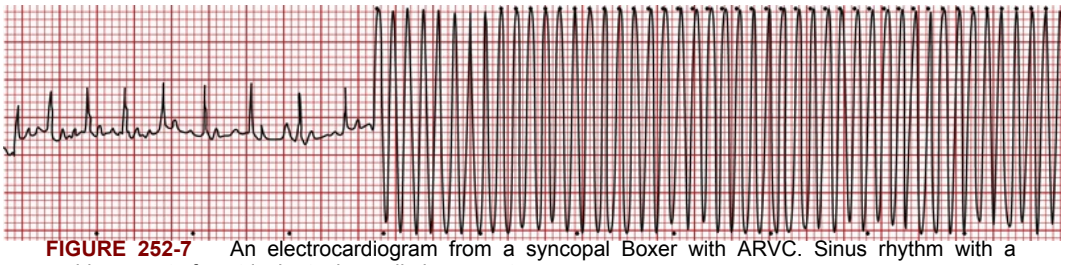

FIGURE 252-7 An electrocardiogram from a syncopal Boxer with ARVC. Sinus rhythm with a sudden onset of ventricular tachycardia is present.

Interpretation of the Holter results can sometimes be challenging because strict criteria for this diagnosis do not exist. However, since it is unusual for a normal dog to have any VPCs in a 24-hour period, the observation of >100 VPCs, or periods of couplets, triplets or runs of ventricular tachycardia are abnormal and may be diagnostic in a dog with clinical signs.[78] Supraventricular premature complexes may also be observed, particularly in Boxers with ventricular dilation and systolic dysfunction.

Thoracic radiographs are usually within normal limits. However, in the small number of cases with left ventricular dilation and systolic dysfunction (Type III ARVC), generalized cardiomegaly with pulmonary edema and/or pleural effusion may be noted (Video 252-5).

Echocardiography is an important part of the evaluation because ventricular dilation and systolic dysfunction may occur, but in most cases affected dogs have normal chamber sizes and systolic function. In some cases, careful evaluation will allow the identification of right ventricular enlargement (Video 252-4).

The familial etiology of ARVC has led to a widespread interest in screening dogs before selecting them as breeding animals. Genetic mutation testing for the striatin mutation is available and may be used to guide breeding decisions and make recommendations for reevaluation schedules.[73,74] However, since ARVC-positive Boxers have been identified without the striatin mutation, it is prudent that continued clinical screening be carried out, as at least one other cause of ARVC exists.

Since ARVC presents as an electrical abnormality more often than one of myocardial dysfunction, screening efforts should be based on annual Holter monitoring as well as annual echocardiography. Unfortunately, clear criteria for the diagnosis of occult ARVC do not exist. However, dogs that are symptomatic show clinical signs (syncope, heart failure) or have evidence of ventricular tachycardia on a Holter should not be used for breeding. Additionally, dogs that have over 100 left bundle branch block morphology VPCs/24 hours are probably highly suspicious of being affected. However, not all affected dogs will ever develop clinical signs and many may live a normal lifespan. It is likely that there are multiple factors that may influence which dogs develop overt clinical signs of the disease. To help decrease the risk of making an error when adding or removing a dog from a breeding program, owners should be encouraged to screen annually rather than putting significant emphasis on a single Holter monitor reading. Since the disease is adult in onset and an increase in VPCs has been observed with age in affected animals, an animal that is clear at the age of two is not guaranteed to stay clear. Additionally, an animal with a few hundred VPCs at the age of two years may have more, fewer, or the same number the next year. Until a greater understanding of disease inheritance and disease progression exists, caution should be used when advising breeders to remove dogs from breeding programs. Overzealous removal of animals based on the results of a single Holter monitor may have a significant negative impact on the breed.

Treatment

If an arrhythmia is detected on routine examination in an asymptomatic dog, a Holter monitor should be performed to evaluate for the frequency and complexity of the arrhythmia. Although a strict relationship between the development of clinical signs and the number of VPCs does not exist, treatment is generally started if >1000 VPCs/24 hours, runs of ventricular tachycardia, or evidence of the R on T phenomenon exist. One may consider an earlier treatment intervention in Boxer dogs known to be homozygous positive for the striatin mutation as they have been shown to have more severe disease.[74] Owners should be advised that ventricular antiarrhythmics have the potential for proarrhythmic effects and that treatment is not known to decrease risk of sudden death. At this time, there is no evidence that treatment will significantly alter the outcome for affected dogs. However, treatment has been shown to decrease the number of ventricular premature complexes as well as syncopal episodes.[79]

Dogs with syncope and ventricular arrhythmias are generally started on treatment. There are two choices

for treatment that are well tolerated and have been shown to decrease VPC number and complexity: sotalol 1.5-3.5 mg/kg PO q 12 h or mexiletine 5-6 mg/kg PO q 8 h.[79] In some cases, the combination of sotalol and mexiletine at the dosages stated above is indicated for optimal control of the arrhythmia. It is likely that there is individual variation for drug response and if a poor response is observed with one drug, a different one or the combination of the two may prove to be more effective. Ideally, a Holter monitor would be placed before starting therapy and repeated two to three weeks after starting therapy to monitor the effect of the medication. Significant day-to-day variation in VPC number exists but a therapeutic effect is likely to exist if at least an 85% reduction in VPC number is observed after starting medication.[80]

In one study, fish oils (780 mg EPA and 497 mg DHA PO per day) given orally for six weeks were shown to decrease the number of VPCs but not to a degree that was beyond what might be due to day-to-day variation. Thus, antiarrhythmics are still indicated for management, perhaps in combination with fish-oil supplementation.[81]

If echocardiography demonstrates systolic dysfunction and ventricular dilation, treatment for DCM (pimobendan, ACE inhibitors, diuretics) may be warranted. Additionally, supplementation with L-carnitine might be considered at a dosage of 50 mg/kg PO q 8-12 h, since a small number of affected Boxers have demonstrated improvement in systolic function and prognosis after supplementation.[41]

Prognosis

Dogs with ARVC are always at risk of dying of sudden cardiac death. However, many dogs may live for years on antiarrhythmics without clinical signs, but some of these may eventually develop ventricular dilation and systolic dysfunction. Boxers without systolic dysfunction and ventricular dilation maintain a prognosis that is comparable to that of non-ARVC Boxers, with a median survival age of 11 years.[82]

Myocarditis

Myocarditis is a form of myocardial disease characterized by the presence of myocardial necrosis or degeneration and inflammation. A variety of physical, chemical and infectious agents can damage the myocardial tissue and evoke an inflammatory response, which may result in chamber enlargement, myocardial dysfunction similar to that observed in DCM and a variety of tachyarrhythmias and bradyarrhythmias.[83,84] Plasma cardiac troponin I (cTnI) levels are often elevated, suggesting myocardial injury. In the dog, protozoal and viral organisms are reported most commonly.

Chagas' disease, caused by the protozoan parasite *Trypanosoma cruzi*, is common in the dog, particularly in the southern part of North America. Three stages of infection have been described: acute, latent and chronic. The acute stage is characterized by lethargy, generalized lymphadenopathy, pale mucous membranes, increased capillary refill time and hepato-splenomegaly.[85] This stage is associated with a variety of electrocardiographic abnormalities including sinus tachycardia, prolonged PR interval, decreased R wave amplitude, axis shifts and conduction disturbances.[86] Sudden death may be observed. Dogs that survive the acute stage may enter a prolonged latent period during which the clinical signs appear to regress.[86] The chronic stage of Chagas' disease is associated with signs of progressive right-sided cardiac dysfunction, ascites, pleural effusion, hepatomegaly and jugular venous distention. Occasional ventricular tachycardias have been reported.[86] In one study, almost half of the dogs diagnosed histopathologically with Chagasic myocarditis at necropsy were dogs that died suddenly and fifty percent of those dogs were less than 1 year of age.[84] The diagnosis of Chagas' disease is most commonly performed by serology, and the acute form can sometimes be diagnosed by the presence of circulating trypomastigotes on thick blood smears. In general, treatment of Chagas' disease is directed at palliation of clinical signs, since destruction of the intracellular form of the parasite may result in severe exacerbation of the host inflammatory response. However, there is some preliminary work in dogs which suggests that a cysteine protease inhibitor may be very effective for reducing the severity of the cardiac aspects of the disease.[81]

Leishmania are protozoal organisms that are endemic in certain geographical regions including the Mediterranean basin (see ch. 221).[87] Clinical signs of the myocarditis associated with *Leishmania* are thought to be a result of direct action of the parasite within the myocardium as well as intense inflammation in response to the parasite. Cardiac arrhythmias including first degree AV block have been observed, and both epicarditis and myocarditis have been identified at necropsy. Additional protozoan parasites that have been associated with the development of myocarditis include *Neospora caninum* and *Toxoplasma gondii*.[88-90]

Parvovirus myocarditis is an uncommon form of myocardial disease (also see ch. 225). It may present with a peracute form that affects puppies between 3 and 8 weeks of age. Puppies present with acute dyspnea consistent with severe left heart failure and die within hours.[39] At necropsy, the hearts are found to be dilated with multifocal myofiber necrosis, mononuclear cell infiltrate and intranuclear inclusion bodies in the myocardial nuclei.[39,91] A second form of the disease affects juvenile dogs (generally less than 1 year of age) and has a clinical presentation similar to that of DCM.[39,40]

West Nile virus has been observed uncommonly in the dog and clinical signs are often vague and include lethargy, inappetence, neurologic signs, arrhythmias and fever.[92,93] Severe lymphocytic, neutrophilic myocarditis and vasculitis have been observed with focally extensive hemorrhage and myonecrosis. The diagnosis can be confirmed in a variety of ways including immunohistochemistry, reverse-transcriptase polymerase chain reaction testing, virus isolation and serology.[92]

Fungal myocarditis due to *Blastomyces* has been reported, although this does not appear to be a common form of this fungal infection (see ch. 233).[94] Three dogs presented for syncope, one for sudden death and three had newly diagnosed heart murmurs. Cardiac findings included sinus tachycardia as well as one dog with ST segment elevation and one dog with third degree AV block. Two dogs had cardiac compression due to an extracardiac granuloma while others had myocardial, epicardial, pericardial or valvular involvement. Although only a small number of cases have been reported, generally the dogs with cardiac involvement with blastomycosis had a poor prognosis.

Infrequently, infectious organisms including bacteria, *Bacillus piliformis, Citrobacter koseri* and the spirochete, *Borrelia burgdorferi* have been associated with the development of myocarditis.[95,96]

Atrial Myocarditis

A form of myocarditis limited to the atria has been reported.[97-99] Unexplained atrial arrhythmias including atrial fibrillation have been associated with inflammation or infectious organisms in the atria. Multifocal myocarditis of both atria was observed at necropsy in a case with atrial fibrillation.[97] Intermittent asystole with syncope was observed in a dog with lymphocytes, macrophages, and neutrophils throughout the right, and to a lesser extent, the left atrium.[98] One case of atrial myocarditis was associated with a concurrent diagnosis of polymyositis.[99] The dog had significant right atrial dilation, atrial premature complexes and increased troponin levels. Histopathologic analysis identified right atrial lymphocytic infiltration.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is a primary myocardial disease characterized by concentric hypertrophy of the interventricular septum and left ventricular free wall (see ch. 253). Hypertrophic cardiomyopathy and the variant hypertrophic obstructive cardiomyopathy are infrequent forms of canine myocardial disease (Video 252-7). There appear to be significant differences between the canine disease and the disease more commonly observed in cats and human beings with regard to etiology and pathological findings.[100,101] An inheritable form of hypertrophic obstructive cardiomyopathy has been observed in the Pointer dog, but most canine cases appear to be sporadic.[100-103] Because of the relative infrequency that hypertrophic and hypertrophic obstructive cardiomyopathy are observed in the dog, suspect patients should be carefully evaluated for other causes of concentric hypertrophy of the left ventricle including the much more common left ventricular outflow tract obstruction observed with subvalvular and valvular aortic stenosis.

Hypothyroidism

Some dogs with hypothyroidism have been observed to have a reduction in left ventricular fractional shortening percentage and an increase in left ventricular dimensions; however, the values had significant overlap with normal dogs.[104] Thus, although evaluation of thyroid levels might be considered in dogs that have minor echocardiographic changes in addition to other signs of hypothyroidism, it should not be considered a common cause of myocardial dysfunction nor ventricular dilation.[105] Despite many investigations into hypothyroidism of Doberman Pinschers, a recent study identified no role of hypothyroidism in the etiology or progression of Doberman Pinschers DCM.[106]

Myocardial Infarction

Acute myocardial infarctions are an uncommon form of myocardial disease in dogs and appear to be most commonly associated with concurrent systemic or cardiac disease that has led to a thromboembolic state. These conditions might include endocarditis, neoplasia, renal disease, immune-mediated hemolytic anemia and pancreatic disease. Dogs with infarcts were very rarely diagnosed with atherosclerosis as opposed to human beings, who have a high incidence of infarcts associated with atherosclerosis.[107]

CHAPTER 253

Feline Myocardial Diseases

Valérie Chetboul

Client Information Sheets:
Feline Myocardial Diseases—General Presentation
Focus on Feline Hypertrophic Cardiomyopathy

Introduction: Classification (Nosological Considerations) and Prevalence

Myocardial diseases refer to a broad spectrum of heterogeneous diseases of the heart muscle, and are by far the most common cardiac disorders in the cat.[1-5] Over the last 4 decades, several classifications of human myocardial diseases have been proposed and modified, due to the increased knowledge of their various underlying causes, molecular and genetic basis and complex pathophysiological features as well as the discovery of new pathological entities.[6-14] In 1980, the World Health Organization (WHO) identified "*heart muscle diseases of unknown cause*" as cardiomyopathies, which were differentiated from specific heart muscle diseases (of known cause).[6] In 1995, the next WHO classification redefined cardiomyopathies as "*diseases of myocardium associated with cardiac dysfunction*" and added two newly recognized myocardial diseases to the list[7], i.e., arrhythmogenic right ventricular cardiomyopathy (ARVC) and restrictive cardiomyopathy (RCM), both described several years later in the cat.[15-17] Cardiomyopathies were thus classified into 5 groups according to their dominant pathophysiology, i.e., dilated cardiomyopathy (DCM), hypertrophic cardiomyopathy (HCM), RCM, ARVC, and unclassified cardiomyopathies (UCM) including cases that did not fit into the 4 other phenotypes.[7] An additional group named "specific cardiomyopathies" was also recognized, including myocardial diseases associated with specific cardiac or systemic disorders (e.g., ischemic, valvular, hypertensive, inflammatory, metabolic, toxic cardiomyopathies, and myocardial disorders associated with neuromuscular or general system diseases). In 2006, an expert committee of the American Heart Association (AHA) defined cardiomyopathies as "*a heterogeneous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilation and are due to a variety of causes that frequently are genetic.*"[8] The AHA 2006 expert consensus panel excluded all pathological myocardial processes secondary to other cardiovascular abnormalities from this definition and proposed a new classification of cardiomyopathies with 2 major groups (primary *vs* secondary) based on predominant organ involvement: primary cardiomyopathies (genetic, non-genetic, or mixed) are those solely or predominantly confined to the myocardium, whereas secondary cardiomyopathies show myocardial involvement as part of numerous generalized systemic or multiorgan disorders.[8] In 2008, the European Society of Cardiology Working Group on Myocardial and Pericardial Diseases proposed an updated classification of cardiomyopathies mainly based on the 5 phenotypes of the 1995 WHO classification (i.e., HCM, DCM, ARVC, RCM and UCM), and each myocardial phenotype was then subdivided into familial/genetic and non-familial/non-genetic forms.[11] However, the nosological approach to myocardial diseases still remains debated[18,19] as a given etiology may be associated with a spectrum of myocardial phenotypes, morphological and functional phenotypes can overlap and even evolve over time, while our etiological knowledge of previously named idiopathic cardiomyopathies continues to improve. To avoid confusion and be clearer for the reader, this chapter on feline myocardial diseases will refer to the following "combined" classification system better suited to practical use in feline cardiology. As proposed in the AHA 2006 classification system,[8] cardiomyopathies will refer to heart muscle disorders non-secondary to other cardiovascular disorders, and primary cardiomyopathies will be distinguished from secondary cardiomyopathies of systemic origins. Primary cardiomyopathies will be

further subdivided into the 5 1995 WHO phenotypes (Figure 253-1).[7] The primary cardiomyopathies are the most common feline heart diseases, and therefore constitute the central part of this chapter. In a study of 287 cardiac cats, HCM was the most common diagnosed heart disease (68%), whereas congenital disorders only accounted for 12% of the recruited cases.[20] Similarly, in a report focusing on HCM, RCM and secondary cardiomyopathies, HCM represented 53% of the included cases *vs* 15% and 32% for RCM and secondary cardiomyopathies, respectively.[21] In another study on primary cardiomyopathies,[22] HCM was also by far the most common disease (58%), followed by RCM (21%), DCM (10%) and UCM (10%), with no reported case of ARVC (the rarest feline primary cardiomyopathy).[1,20] In the latter report, one cat showed echocardiographic changes compatible with so-called moderator band "cardiomyopathy." Left ventricular (LV) moderator bands, also named false tendons, are cord-like structures of varying length stretching across the LV cavity, attached to the interventricular septum (IVS), LV free wall (LVFW), and/or LV papillary muscles and apex,[23-25] and composed of varying amounts of Purkinje fibers, collagenous fibers, myocardial and fibrous connective tissue, adipose tissue, and blood vessels covered with endothelium.[23-27] As in people,[23-25,28] false tendons are common incidental echocardiographic findings in cats, with no consequence on cardiac morphology and function (Figure 253-2, *A* and *B*).[29,30] However, similar to people,[23] excessive networks of LV moderator bands have been reported in the cat, with various secondary deleterious effects, such as LV myocardial dysfunction and LV remodeling, arrhythmias, congestive heart failure (CHF), and arterial thromboembolism (ATE), potentially leading to death even in kittens (Figure 253-2, *C* and *D* and Videos 253-1 and 253-2).[1,26,27] Because LV moderator bands are of congenital origin, the term "moderator band cardiomyopathy" is commonly used to define this diseased state and does not fit into the AHA definition of cardiomyopathies.[8] Nevertheless, the prevalence of false tendons in the LV outflow tract (LVOT) is higher in cats with obstructive HCM (OHCM, also called hypertrophic obstructive cardiomyopathy or HOCM), as compared to healthy cats and cats with non-obstructive HCM, which suggests a possible role of false tendons in the pathogenesis of dynamic LVOT obstruction (LVOTO, Figure 253-2, *E*).[29]

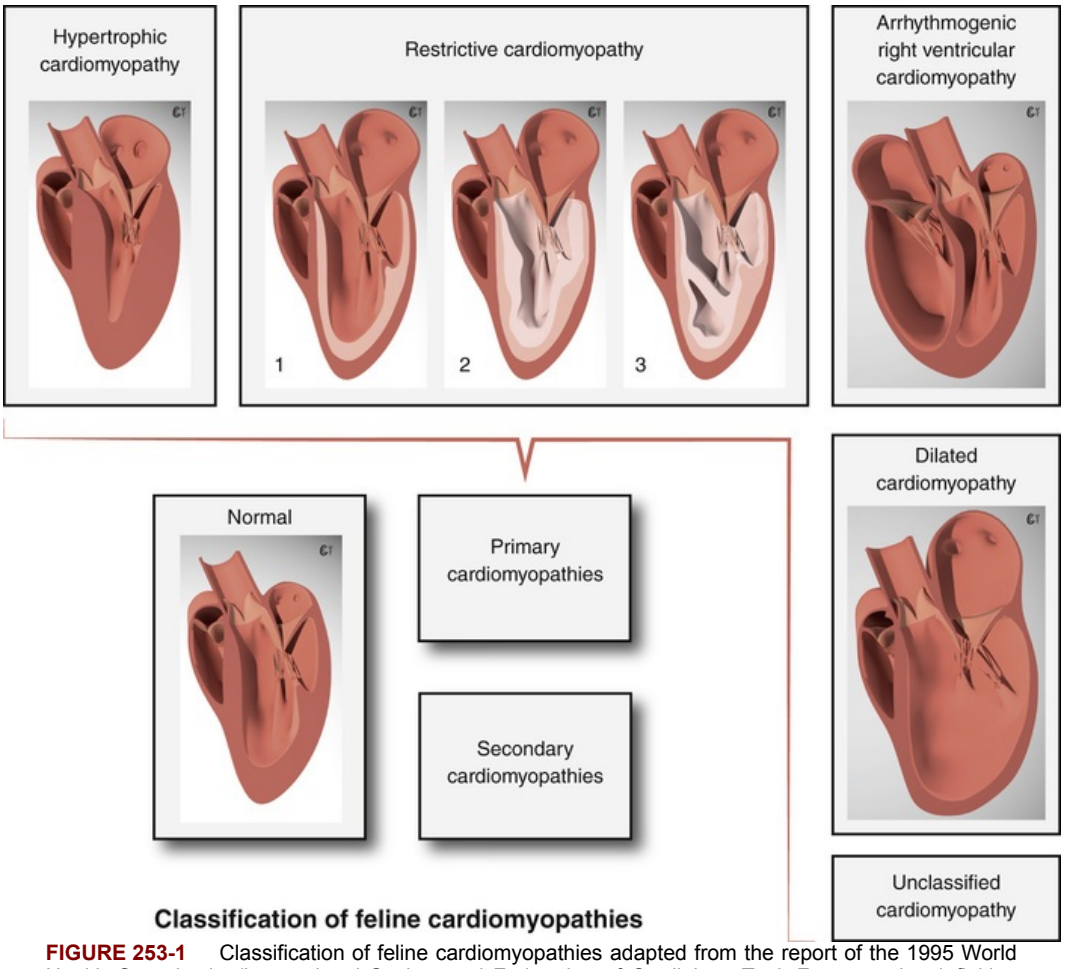

FIGURE 253-1 Classification of feline cardiomyopathies adapted from the report of the 1995 World Health Organization/International Society and Federation of Cardiology Task Force on the definition and classification of cardiomyopathies.[7] Primary cardiomyopathies encompass hypertrophic cardiomyopathy, restrictive cardiomyopathy (RCM), dilated cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, and unclassified cardiomyopathy (which includes cases that do not fit into any other group). Hypertrophic cardiomyopathy consists of left (or left and right) ventricular hypertrophy. Restrictive cardiomyopathy is characterized by restrictive filling and reduced diastolic volume of either ventricle (mainly left ventricle) or both, with normal or near-normal systolic function and wall thicknesses. Two basic RCM forms have been identified in the cat[16], i.e., myocardial RCM (the most common, n°1) and endomyocardial RCM (also known as endomyocardial fibrosis) with either a diffuse endomyocardial scar reducing the left ventricular cavity (n°2) or exuberant bridging scar connecting the interventricular septum and the left ventricular free wall (n°3). Dilated cardiomyopathy is characterized by dilation and impaired contraction of the left ventricle or both ventricles. Lastly, arrhythmogenic right ventricular cardiomyopathy consists of progressive fibrofatty replacement of the right ventricular myocardium, global right enlargement (and also potential left ventricular involvement). (Illustrations: execution and conception by Dr. Charlotte Taton and Prof. Valérie Chetboul.)

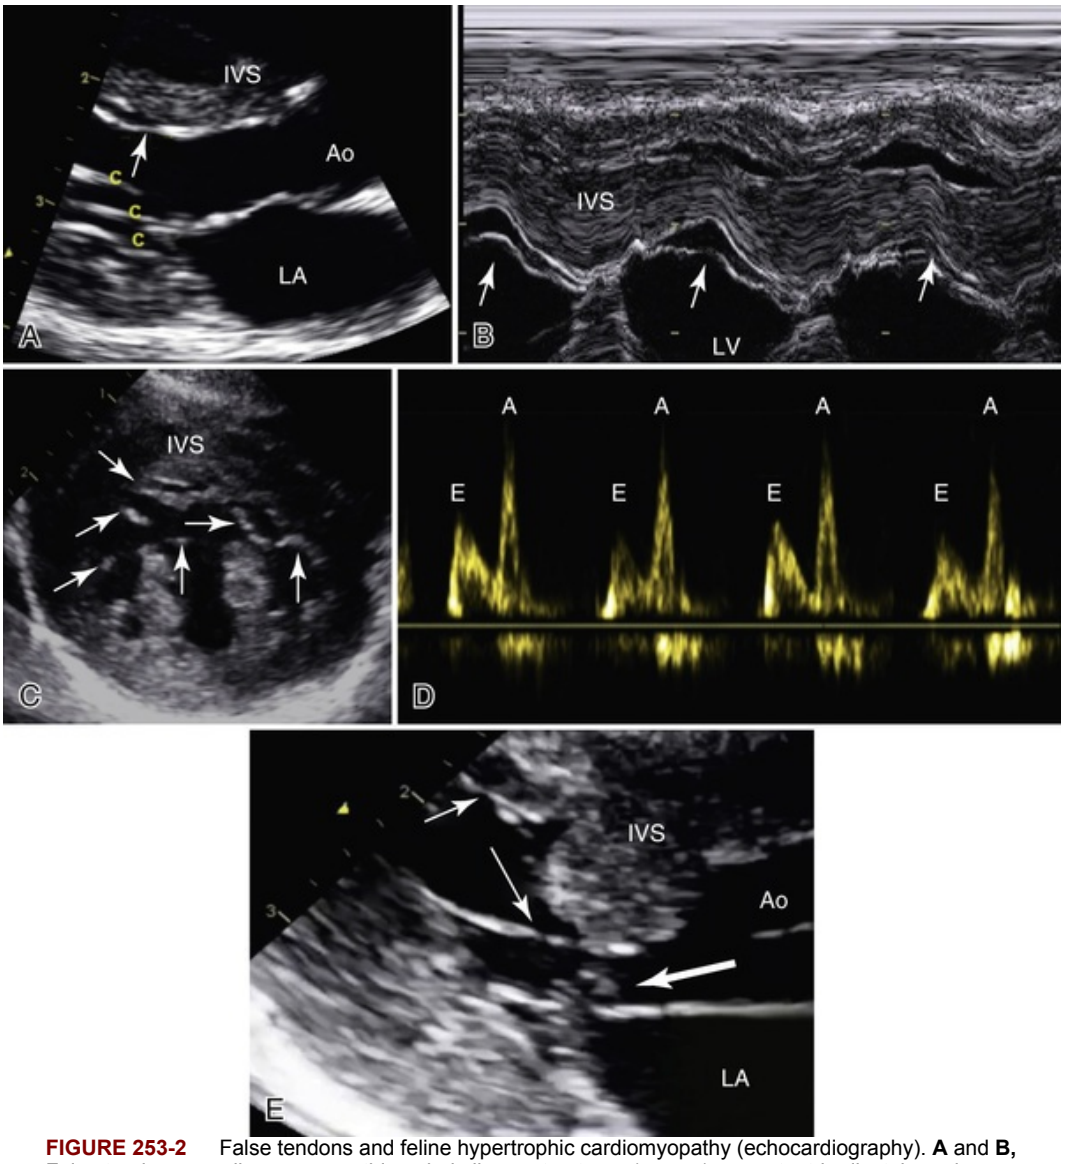

FIGURE 253-2 False tendons and feline hypertrophic cardiomyopathy (echocardiography). **A** and **B,** False tendons usually appear as thin echoic linear structures (arrows), more taut in diastole and more lax in systole, here incidentally found along the interventricular septum (IVS) in a healthy cat on the two-dimensional echocardiogram (right parasternal 5-chamber view, **A**) and on the M-mode echocardiogram **(B).** *Ao,* Aorta; *C,* chordae tendineae; *LA,* left atrium; *LV,* left ventricle. **C** and **D,** Transventricular short-axis view showing excessive network of false tendons (arrows) in an 8-month Bengal cat **(C),** resulting in diastolic alteration as confirmed by pulsed-wave Doppler assessment of mitral inflow velocity **(D).** An impaired relaxation pattern characterized by an early (E) to late filling wave (A) ratio <1 (E : A = 0.66) associated with a prolonged (>100 ms) E deceleration time (132 ms) is observed.[66] **E,** Right parasternal 5-chamber view obtained at end-systole from a cat with severe obstructive hypertrophic cardiomyopathy. The IVS bulges into the left ventricular outflow tract. Note the presence of false tendons (thin arrows) including one attached to the subaortic IVS as well as the systolic anterior motion of the mitral valve (large arrow), both contributing to worsen obstruction of the left ventricular outflow tract.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is phenotypically characterized by increased cardiac mass due to a hypertrophied non-dilated LV in the absence of an obvious cause of LV hypertrophy (LVH), such as pressure overload (e.g., systemic arterial hypertension) or hormonal stimulation (e.g., hyperthyroidism).[1,31]

Left Ventricular Hypertrophic Patterns, Gross Pathology and Histopathology

As in people, feline HCM is characterized by marked phenotypic variability, including mild to severe, diffuse or segmental, concentric LVH (Figures 253-3 and 253-4).[31-34] In most cats with HCM (up to two thirds), LVH is diffuse, involving portions or all of both the IVS and the LVFW, with hypertrophy of the LV papillary muscles and a consequently reduced LV cavity (see Video 253-3).[31,34] Diffuse LVH can be symmetric or asymmetric with predominant thickening of the IVS or LVFW. In about one third of cases, LVH is confined to only one segment, i.e., usually the basal IVS and less commonly the apex.[31,34] In some cases, the thickened basal IVS protrudes into the LVOT, resulting in mild to severe LVOTO, thus defining OHCM forms (see Videos 253-4, 253-5, and 253-6). Marked combined LVH and hypertrophy of the papillary muscles can result in systolic mid-ventricular cavity obstruction, associated with the presence of endocardial contact plaques.[2,35] Although rare, myocardial infarction of the LVFW may also occur (see Video 253-12).[31] Such varied geometric patterns are also revealed by two-dimensional (2D) and M-mode echocardiography (see ch. 104), with breed variations.[36,37] In one study, Persians and Chartreux showed significantly more OHCM (44%) than other cats (18%), whereas almost half of Maine Coons had diffuse symmetric LVH (see Figure 253-4).[37]

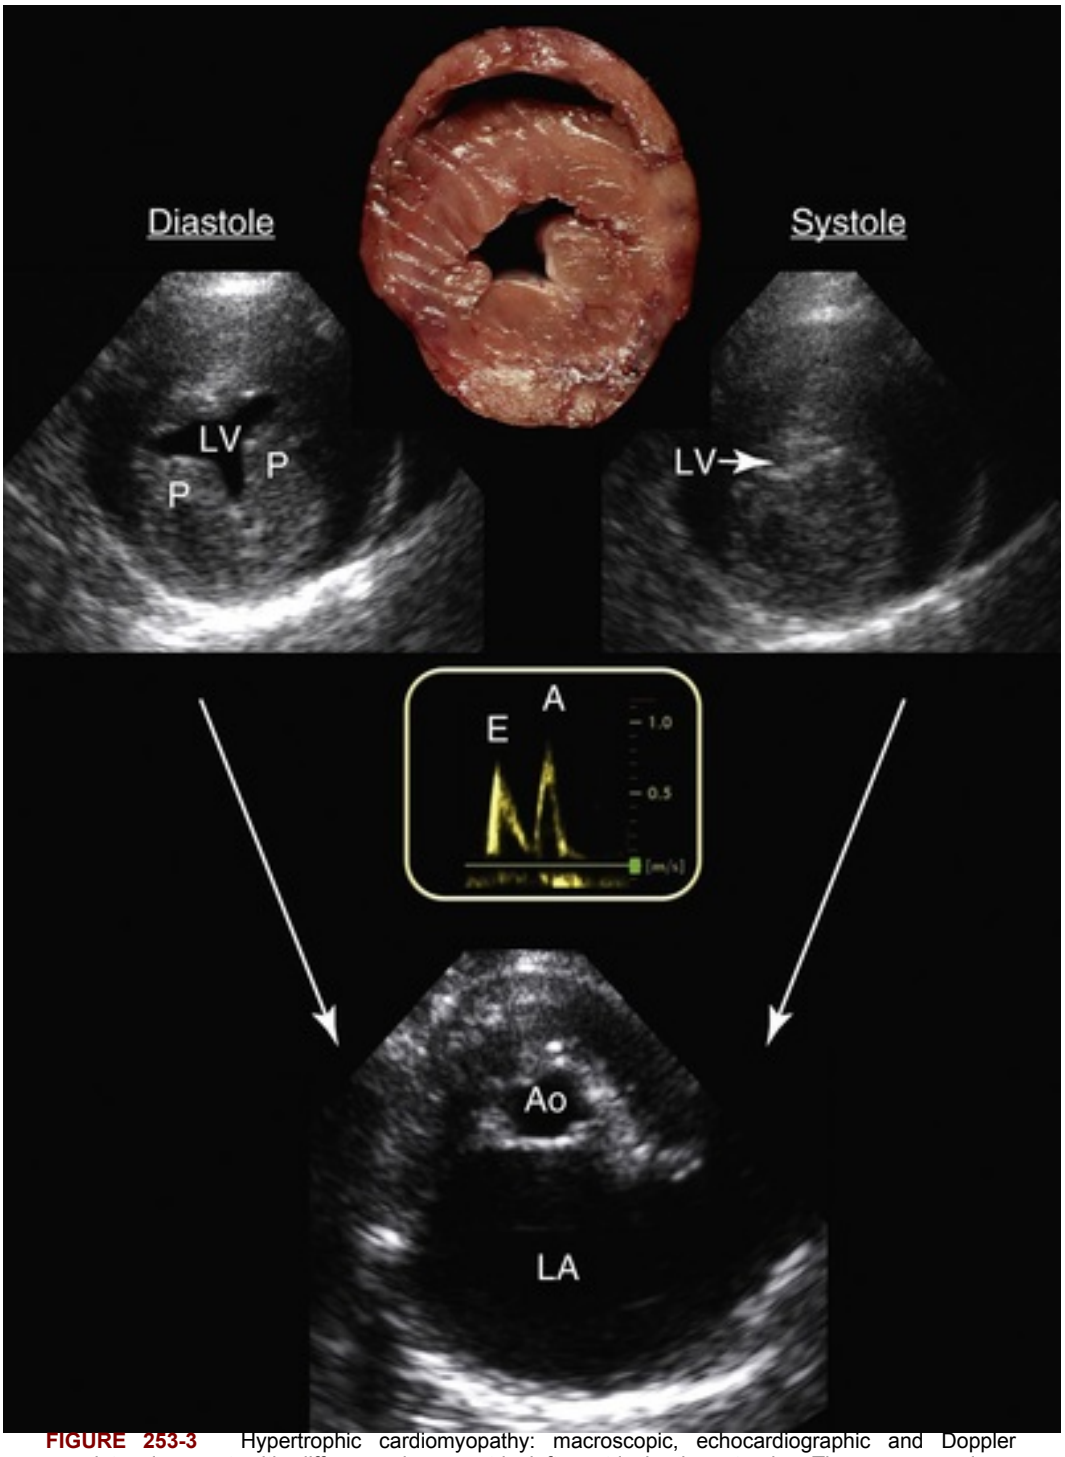

FIGURE 253-3 Hypertrophic cardiomyopathy: macroscopic, echocardiographic and Doppler correlates in a cat with diffuse and symmetric left ventricular hypertrophy. The gross specimen sectioned transversely and the right parasternal short-axis views (top figures) both show severe left ventricular hypertrophy, resulting in a reduced lumen of the left ventricle (LV), with a secondary markedly enlarged left atrium (LA), as observed on the right parasternal transaortic view (bottom figure; end-diastolic LA : Ao ratio of 3.7; values obtained from a population of 100 healthy cats: 0.5 to 1.2).[78] Note the disappearance of the LV cavity at end-systole. Transmitral pulsed-wave Doppler examination obtained from the left apical 4-chamber view (central figure) reveals an impaired LV relaxation pattern characterized by a reversed (<1) E : A ratio (E and A, peak velocities of early and late diastolic transmitral flow, respectively), confirming both decreased early LV filling due to impaired relaxation and a greater LA contribution to LV filling (with LA contraction).[66] *Ao,* Aorta; *P,* LV papillary muscles. (Pathology: courtesy Prof. Jean-Jacques Fontaine, Pathology Department, National Veterinary School of Alfort, France.)

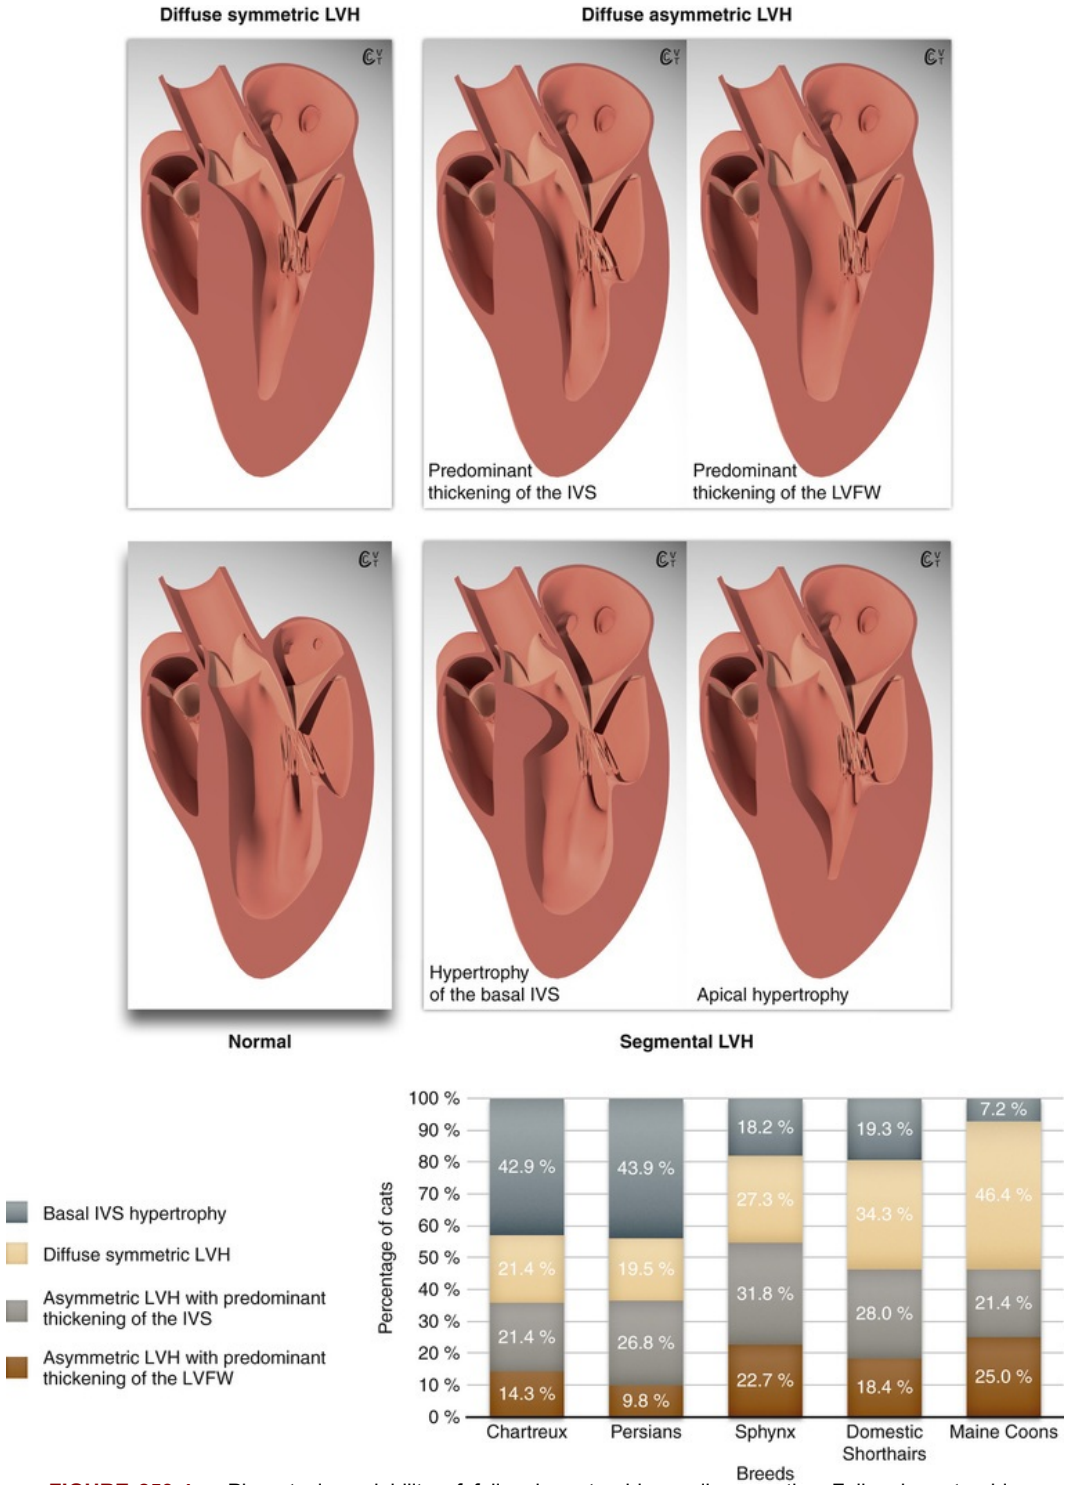

FIGURE 253-4 Phenotypic variability of feline hypertrophic cardiomyopathy. Feline hypertrophic cardiomyopathy is characterized by various left ventricular (LV) geometric patterns, including diffuse symmetric and asymmetric LV hypertrophy (LVH) with predominant thickening of the interventricular septum (IVS) or the LV free wall (LVFW), and segmental LVH (e.g., apical or subaortic IVS hypertrophy). Subaortic IVS hypertrophy can be either isolated or associated with LV diffuse geometric patterns. Hypertrophy of the LV papillary muscles is often present. All these forms can lead to left atrial enlargement and congestion of the pulmonary veins as shown here. Below: histograms representing distribution of the LV geometric patterns by breed assessed by echocardiography in a population of 344 cats with hypertrophic cardiomyopathy, including 239 Domestic Shorthairs, 41 Persians, 22 Sphynx, 28 Maine Coons, and 14 Chartreux (values on the bars represent the percentage of cats).[37] (Illustrations: execution and conception by Dr. Charlotte Taton and Prof. Valérie Chetboul.)

In cases of mild to moderate LVH, the left atrium (LA) is usually normal.[2] Severe LVH is often associated

with mild to severe LA enlargement (LAE; see Figure 253-3 and Videos 253-7 and 256-2).[31] Right ventricular (RV) hypertrophy may also be present, associated or not with right atrial (RA) enlargement.

Histopathology

As in people,[33] histological features of feline HCM include various degrees of myocardial fiber disarray within the LV myocardium (less commonly the RV myocardium), associated with mild to severe arteriosclerosis of intramural coronary arteries, interstitial myocardial fibrosis and replacement fibrosis (Figure 253-5).[2,31,32,34] In one report, disorganized cardiac muscle cells were identified in the IVS of 30% of HCM cats. Disorganized architecture of the LVFW was less common (14%) and systematically associated with IVS disorganization.[32] Such histological differences impact regional diastolic myocardial function, as observed using tissue Doppler imaging (TDI).[38,39] In both people and cats, myocardial fiber disorganization can also be observed in non-severely thickened, even in non-hypertrophied, LV myocardial segments,[2] which from a practical point of view, explains why TDI can detect regional myocardial dysfunction in apparently normal myocardial segments of HCM cats (Figure 253-6).[38] In OHCM forms, a LVOT fibrous contact plaque can be observed on the IVS surface due to systolic apposition of the mitral valve leaflets to the IVS. Increased myocardial collagen deposition, associated with neutrophilic and lymphocytic infiltrates, has also been found in the myocardium of cats with pre-clinical HCM, suggesting the possible contribution of an early inflammatory process to myocardial fibrosis (e.g., [involving] inflammatory cytokines), which will require further investigation.[40]

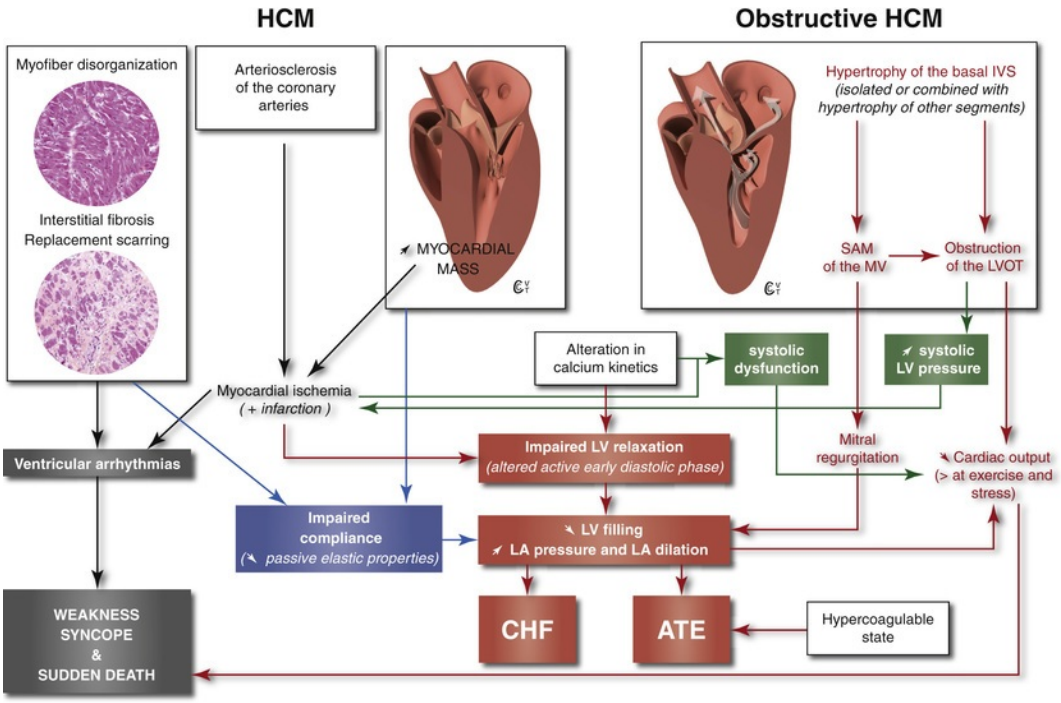

FIGURE 253-5 Main pathophysiological consequences of feline hypertrophic cardiomyopathy (HCM): myocardial dysfunction, arrhythmias and left ventricular outflow tract obstruction. (1) Diastolic dysfunction typically refers to abnormalities of active myocardial relaxation and passive compliance, leading to abnormal left ventricular (LV) filling with decreased end-diastolic volume or adequate end-diastolic volume only at the expense of increased filling pressures.[66] In the case of HCM, relaxation and compliance are both altered, but relaxation abnormalities dominate and occur early, thus affecting the early rapid LV filling phase. The rate and volume of early LV filling are decreased, resulting in a compensatory increase in the contribution of left atrial (LA) contraction to LV filling, associated first with an elevation of LA pressure at end-diastole.[66] Reduced LV compliance, resulting from several factors (LV hypertrophy *per se,* interstitial fibrosis, replacement scarring, and disorganized myocardial cells), also contributes to increased LV diastolic pressure and subsequent increase in LA pressure. The latter worsens with disease progression, which in turn leads to LA dilation, and is finally transmitted back into the pulmonary vascular system leading to venous congestion and congestive heart failure (CHF). Left atrial dilation also predisposes to blood stasis and arterial thromboembolism (ATE), especially as a systemic hypercoagulable state has been evidenced in cats with HCM, even without concurrent CHF and ATE.[70,71] (2) Although not predominant, systolic dysfunction resulting from myocardial ischemia,

alteration in calcium kinetics, increased matrix connective tissue and regional myocardial asynchrony, can contribute to the decrease in cardiac output, particularly at end-stages of the disease and/or in the case of obstructive HCM.[38,39,72] (3) Histopathological lesions associated with HCM also represent an electrically unstable substrate for reentrant ventricular tachyarrhythmias, responsible for weakness, syncope, and sudden death. (4) In obstructive forms of HCM, dynamic left ventricular outflow tract (LVOT) obstruction may produce high systolic intraventricular pressure gradients (even >100 mm Hg) with several deleterious consequences, including decreased cardiac output and worsening of both myocardial hypertrophy and ischemia (by increasing myocardial wall stress and oxygen demand). In these particular HCM forms, the subaortic obstruction results from both protrusion of the thickened basal interventricular septum (IVS) into the LVOT and systolic anterior motion of the mitral valve (SAM), characterized by abnormal mid- to late systolic IVS contact (see also Figure 253-8). In human patients with obstructive hypertrophic cardiomyopathy, the longer the mitral-IVS contact duration, the greater the severity of LVOT obstruction.[33,73] The presence of SAM may also result in loss of coaptation of the mitral leaflets, leading to a postero-laterally directed mitral valve regurgitation, that potentially contributes to increased LA pressure.[33,73] *MV,* Mitral valve. (Illustrations: execution and conception by Dr. Charlotte Taton and Prof. Valérie Chetboul. Histopathology: courtesy Prof. Jean-Jacques Fontaine, Pathology Department, National Veterinary School of Alfort, France.)

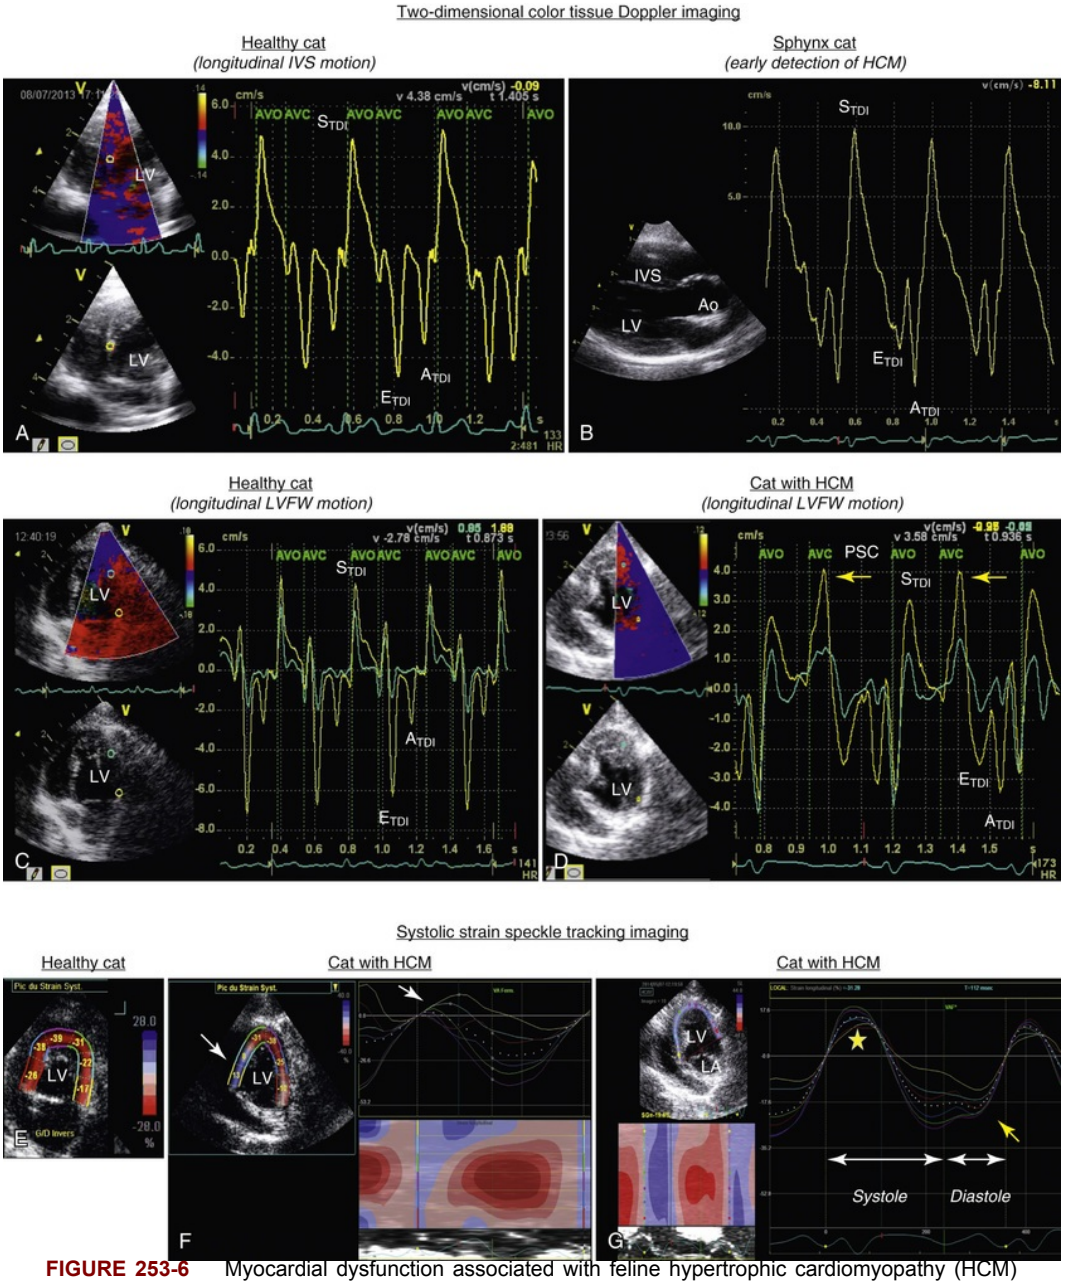

FIGURE 253-6 Myocardial dysfunction associated with feline hypertrophic cardiomyopathy (HCM)

using two-dimensional color tissue Doppler imaging (TDI, **A-D**) and speckle tracking imaging **(E-G). A-D** show longitudinal myocardial velocity profiles of the interventricular septum (IVS, **A** and **B**) and the left ventricular free wall (LVFW, **C** and **D**), obtained from left parasternal long-axis views. S_{TDI}, E_{TDI}, and A_{TDI} are peak myocardial velocities recorded during systole, early diastole, and late diastole, respectively. **A** and **B,** As compared with the healthy cat **(A),** the velocity profile recorded at the IVS base in the Sphynx cat **(B)** shows a typical diastolic alteration; i.e., an inverted $E_{TDI} : A_{TDI}$ ratio ($E_{TDI} : A_{TDI}$ <1), despite the absence of myocardial hypertrophy on two-dimensional and M-mode echocardiography (as shown here by the right-parasternal 5-chamber view). Six months later, this cat developed moderate subaortic IVS hypertrophy followed by diffuse asymmetric obstructive HCM. *Ao,* Aorta; *AVO* and *AVC,* aortic valve opening and closure, respectively; *IVS,* interventricular septum; *LV,* left ventricle. **C** and **D,** As compared with the healthy cat **(C),** longitudinal velocity profiles recorded simultaneously at the base and apex of the LVFW (yellow and green curves, respectively) in the cat with HCM **(D)** show several signs of regional diastolic dysfunction: (1) an inverted $E_{TDI} : A_{TDI}$ ratio at the base and (2) the presence of post-systolic contraction waves (PSC, yellow arrows), occurring after S_{TDI} waves (and after AVC) and greater than the latter, particularly at the base. This marked PSC motion, which was confirmed by using strain imaging (data not shown), delays the two subsequent diastolic events (E_{TDI} and A_{TDI} waves). **E-G** show several longitudinal systolic strain recordings using speckle tracking echocardiography from the left parasternal 4-chamber view. Strain represents the deformation of a myocardial segment over time and is expressed as the percentage of change from its original dimension. In these 3 examples, longitudinal systolic strain was recorded in 6 myocardial segments of the left ventricle (LV), 3 within the IVS and 3 within the LVFW. **E,** In this healthy cat, all segments undergo a systolic regional shortening. The systolic strain is therefore negative and homogeneously encoded in red (peak values are superimposed on the two-dimensional color-coded view). **F,** In this cat with segmental hypertrophy of the IVS, the affected septal segments undergo an abnormal lengthening at early systole (arrow) and are therefore encoded in blue (left panel). The right panel shows the six corresponding LV longitudinal strain *vs* time curves, confirming an abnormal positive strain for these two abnormal IVS segments (arrow). **G,** In this cat with diffuse HCM, note the presence of PSC (yellow arrow), occurring during the diastolic phase. Note also that all myocardial segments undergo an abnormal lengthening at early systole (yellow star).

Epidemiology

In large HCM populations, males are overrepresented (70% to 79%), with a predominance of Domestic Shorthairs (65% to 70%), followed by Domestic Longhairs (9% to 22%) and Persians (3% to 12%).[37,41,42] Other commonly reported breeds vary according to studies (British Shorthair, Chartreux, Himalayan, Maine Coon, Sphynx, Ragdoll).[37,41-43] Burmese, Siamese, Oriental Shorthairs and Abyssinians are less commonly affected.[1,37,41,42] Most HCM cats are middle-aged at diagnosis (median age: 5 to 7 years), but with wide age ranges ([0.5-19], [0.2-18.3], and [0.2-16.7] years in 3 reports involving 127 to 344 HCM cats)[37,41,42] and breed variations: In one report, Maine Coon and Sphynx cats were younger at diagnosis than other cats (Figure 253-7, *A*).[37] In another, Ragdoll cats were younger (2.5 [0.5-4.5] years) than others (5.0 [0.2-16.7] years).[42]

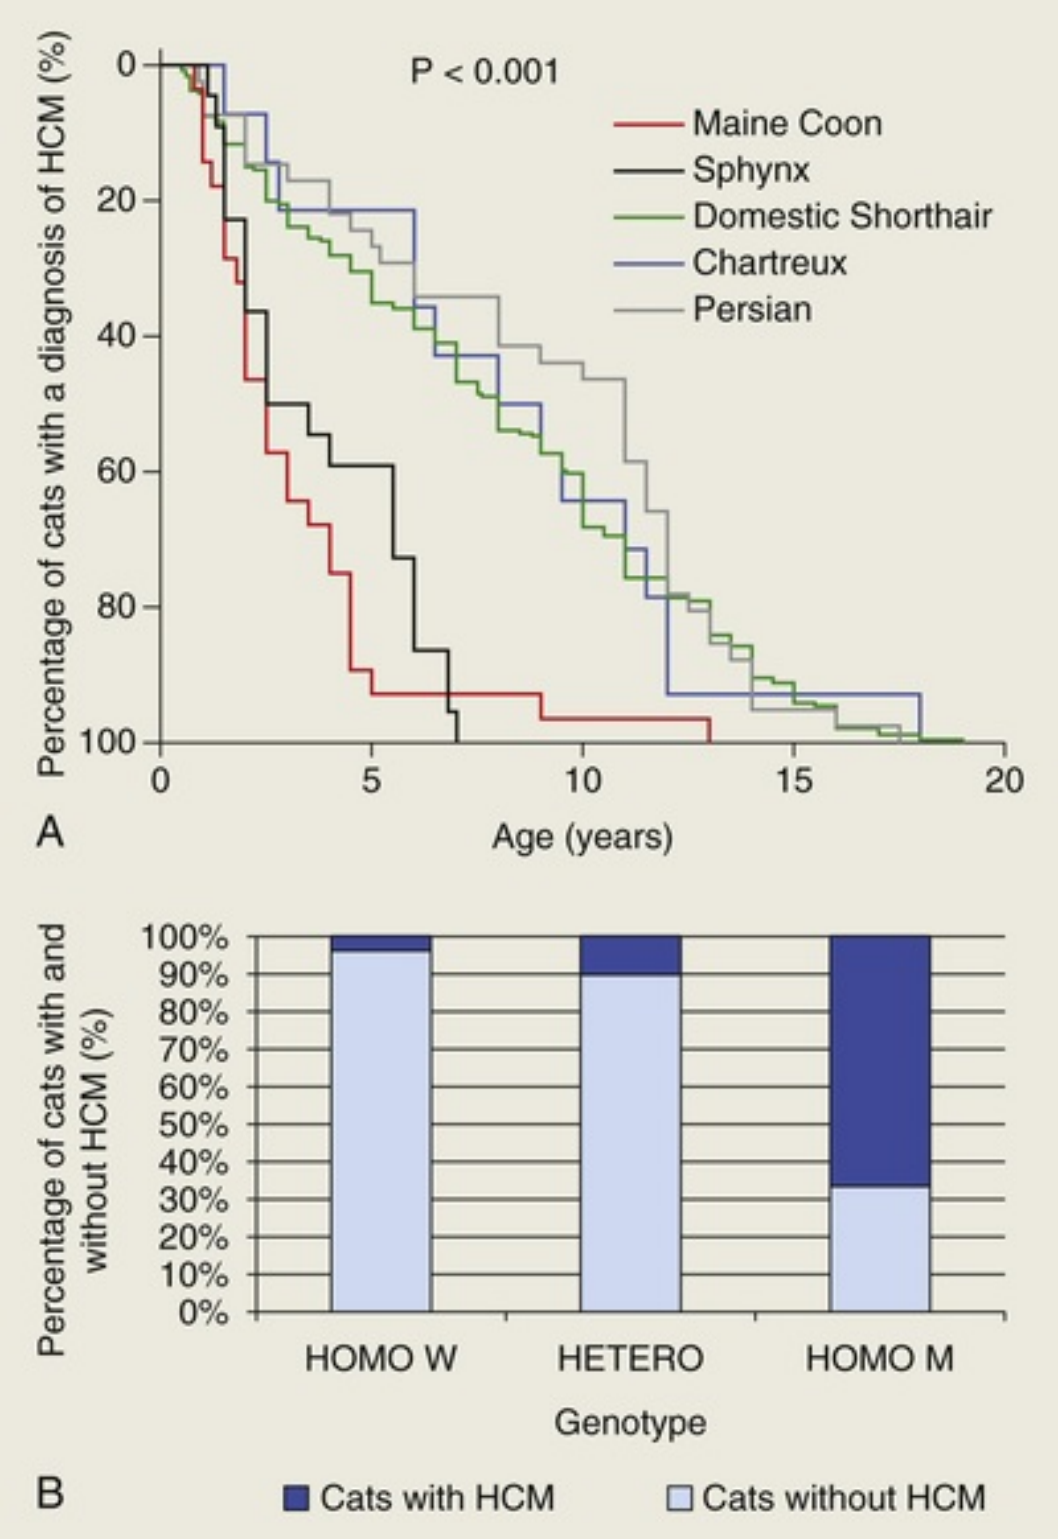

FIGURE 253-7 Feline hypertrophic cardiomyopathy (HCM) and breed specificities. **A,** Age at the time of HCM diagnosis in a population of 344 cats affected by HCM, including 239 Domestic Shorthairs, 41 Persians, 22 Sphynx, 28 Maine Coons, and 14 Chartreux. Kaplan-Meier curves show the percentages of cats with a diagnosis of HCM, according to age.[37] **B,** Distribution of a Maine Coon cat population (n = 96) according to the genotype (Homo WT, Hetero, Homo M) and phenotype (presence or absence of HCM).[39] HOMO W group: homozygous wild-type cats (i.e., without the *MyBPC3*-A31P mutation). HETERO and HOMO M groups, respectively, heterozygous and homozygous mutated cats.

Genetic Basis: Relationship Between Genotype and Phenotype

Human HCM

Human HCM is a familial disease in at least 50% to 60% of cases, with autosomal dominant inheritance most commonly identified.[44,45] Hypertrophic cardiomyopathy was the first human heart disease for which a molecular genetic cause was demonstrated, and the gene responsible (*MYH7*, coding for the beta-myosin heavy chain protein) identified in 1990.[46] At the time of writing, more than 1400 mutations associated with HCM have been identified, with most implicated genes encoding for proteins of the myofilaments or Z-discs of the sarcomeres.[44,45]

Maine Coon Breed

A causative mutation in the cardiac Myosin Binding Protein C sarcomeric gene *(MyBPC3)* for inherited HCM, with autosomal dominant inheritance, was similarly identified in the Maine Coon breed in 2005.[47] This report was the first to demonstrate a spontaneous mutation causing HCM in a non-human species.[47] The *MyBPC3* gene was shown to be mutated in exon 3, with a single base pair change (guanine to cytosine) causing an alteration of the protein structure owing to the replacement of one conservative amino acid (i.e., alanine (A) in the 31st codon) by proline (P).[47] In one study (n = 3310 cats of 17 different breeds from Asia, Europe, Australia, and North America with 3238 Maine Coon cats), the latter accounted for 100% of all cats positive for the *MyBPC3*-A31P mutation.[48] In one European report (n = 3757 cats of 17 different breeds including 2744 Maine Coons), the mutation was only found in Maine Coon cats and one British Longhair.[49] Thus the *MyBPC3*-A31P substitution mutation appears to be specific to the Maine Coon breed, although potential marginal events may occur.[48,49] The prevalence of the mutation in this breed is high, ranging from 31% (Asia, North America) to 42% (Europe) and 46% (Australia), with a marked predominance (up to 92%) of the heterozygous status.[48-50] The prevalence of the HCM phenotype varies from 7 to 10%, increases with age and is strongly dependent on the genetic status (Figure 253-7, *B*).[49,50] The *MyBPC3*-A31P mutation is associated with an increased risk of HCM and the risk is much higher for homozygous cats (relative risk = 9.9 and 35.5, respectively), with incomplete penetrance for heterozygous cats at least at middle age.[49,50] In one study, more than 80% of the heterozygous cats remained healthy at least until 4 years of age.[50] Inversely, some homozygous wild-type Maine Coon cats may develop HCM, suggesting involvement of other causes or mutations.[39,50,51]

Other Feline Breeds

A second substitution mutation in *MyBPC3* associated with HCM has been identified in the Ragdoll breed.[52] This *MyBPC3* R820W mutation is also characterized by a single base pair change (cytosine to thymine in codon 820), with secondary change of one amino acid (arginine to tryptophan).[52] In a survey of 236 Ragdoll cats, the prevalence of the mutation was 34%, with marked predominance of the heterozygous status (85%).[53] Familial forms of HCM have also been reported or suggested in several other breeds, including British Shorthairs,[42] Sphynx,[54,55] Norwegian Forest cats,[56] and non-pedigree cats.[57,58] An autosomal dominant inheritance pattern with incomplete penetrance was shown in the Sphynx breed.[55]

Pathophysiological Consequences (See Detailed Explanations in Figure 253-5)

Ventricular arrhythmias, myocardial dysfunction and dynamic LVOTO are the main pathophysiological consequences of HCM. Diastolic dysfunction, which is considered the major mechanism explaining the development of CHF,[33,34,59-62] occurs early in the course of HCM, even before detectable chamber remodeling as confirmed by TDI studies (see Figure 253-6).[33,38,39,61-66] It results in progressively increased LA pressure with secondary LAE, and CHF (pulmonary edema). Because visceral pleural veins drain into the LA in cats, increases in LA pressure can also lead to pleural effusion due to a decrease in visceral pleural venous drainage.[67] As confirmed by decreased blood velocities in the LA appendage,[68] blood stasis is another common complication of LAE, predisposing to thrombus formation and ATE (see ch. 256 and Videos 253-10 and 253-11).[69-71] Regional and, more rarely, global systolic dysfunction of various causes may also be

present (see Figure 253-6).[38,39,72] Lastly, an abnormal motion of the mitral valve (systolic anterior motion, SAM; see Figures 253-5 and 253-8) contributing to both LVOTO with decreased cardiac output and mitral valve regurgitation, is frequently reported in cats with HCM (29% to 67%).[29,34,41,42,60,62,73] The length of the anterior mitral valve leaflet and prevalence of false tendons in the LVOT are higher in cats with OHCM than in cats with non-obstructive HCM forms (41% *vs* 22%), suggesting a possible role of these abnormalities in LVOTO (see Figure 253-2).[29]

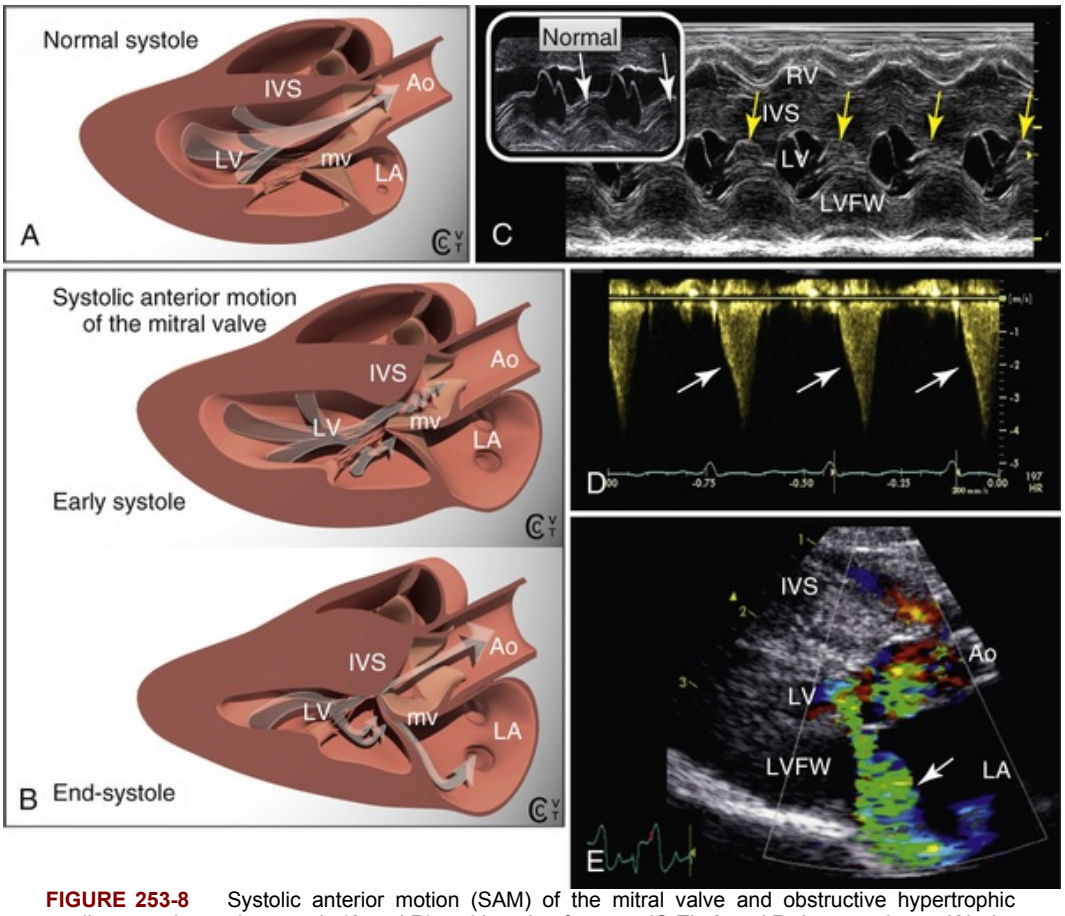

FIGURE 253-8 Systolic anterior motion (SAM) of the mitral valve and obstructive hypertrophic cardiomyopathy: pathogenesis (**A** and **B**) and imaging features **(C-E). A** and **B,** In normal cats **(A),** the mitral valve does not protrude into the left ventricular outflow tract (LVOT) during systole. Obstructive hypertrophic cardiomyopathy (OHCM) is characterized by a dynamic LVOT obstruction, resulting from hypertrophy of the basal interventricular septum (IVS) and/or SAM of the mitral valve, which is an abnormal motion of the mitral valve towards the LVOT during systole **(B),** with a mid- to late systolic contact between the mitral valve and the IVS. The nature of the hydrodynamic systolic forces responsible for SAM of the mitral valve has been debated.[29,33,73] A Venturi mechanism, whereby high velocity flow in the left ventricular outflow tract lifts the mitral valve toward the IVS, was first proposed, but more recent echocardiographic and Doppler studies in humans with OHCM support the hypothesis that drag, the pushing force of flow, is the dominant hydrodynamic force that initiates SAM of the mitral valve, as shown here.[73] In the case of OHCM the systolic LV flow is able to push the underside of both mitral valve leaflets towards the IVS, owing to the abnormally increased "angle of attack" between the flow direction and mitral valve leaflets at early systole. This increase in the angle of attack results from 2 combined mechanisms: (1) local changes in intra-LV flow direction (coming closer to the mitral valve) owing to the IVS bulge; (2) protruding mitral valve leaflets (with the mitral leaflet coaptation point closer to the IVS than normal) owing to hypertrophy of the papillary muscles, also contributing to increased chordal mobility.[73] As shown here, systolic protrusion of the chordae tendineae in the LVOT, either isolated (14%) or combined with SAM of the mitral valve (45%), is reported in 59% of OHCM cases (*vs* 16% and 56% in healthy cats and cats with non-obstructive HCM, respectively).[29] *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *LVFW,* left ventricular free wall; *mv,* mitral valve; *RV,* right ventricle. **C,** M-mode tracing obtained from a cat with OHCM showing marked SAM of the mitral valve, characterized by a prolonged systolic contact (yellow arrows) between the anterior mitral valve leaflet and the thickened IVS, which is not the case for the healthy cat (left upper panel, white arrows). **D,** Continuous-wave Doppler recording in a cat with OHCM and SAM of the mitral valve, showing an increased peak systolic aortic velocity (4 m/s; normal maximal value of 1.9 m/s)[78] and a

late peaking flow profile, characterized by a typical concave asymmetrically-shaped waveform, owing to a sudden flow acceleration at mid-systole (arrows). This confirms dynamic LVOT obstruction. Using the modified Bernoulli equation, the corresponding pressure gradient is 64 mm Hg, indicating a moderate LVOT obstruction. **E,** (Same cat as in Figure C.) The color-flow Doppler mode applied to the right parasternal 5-chamber view confirms a double systolic turbulent jet, including an aliased ejection flow within the abnormally narrowed LVOT and a typical aliased mitral regurgitation jet within the enlarged LA. As commonly observed in the case of SAM of the mitral valve and also illustrated in Figure **B** (bottom figure), the mitral regurgitation jet originates from the mitral valve–IVS contact point, follows the posterior mitral valve leaflet direction (arrow), and then reaches the posterior part of the LA wall. (Illustrations: execution and conception by Dr. Charlotte Taton and Prof. Valérie Chetboul.)

Clinical Presentation at Diagnosis

Clinical Signs

Many cats with HCM show no clinical signs at the time of diagnosis (33% to 77%).[37,41,42,60,74] These cats are usually referred because of an abnormal cardiac auscultation detected on routine examination, for screening purposes before mating, or for cardiovascular evaluation before anesthesia. Most symptomatic cats (70% to 80%) with HCM show clinical signs of CHF (i.e., mainly tachypnea and dyspnea related to pulmonary edema and/or pleural effusion, reported in 18% to 46% of HCM cats at presentation; see Videos 253-8 and 253-9).[37,41,42,74] Coughing is more rarely reported than in dogs.[1] Ascites related to right-sided CHF is also rare.[37] Anorexia and lethargy are common in cats with CHF and can even precede the onset of CHF by 24-72 hours. An antecedent event that may have precipitated decompensation is reported in 14% to 50% of cases, 7 to 15 days prior to CHF onset (e.g., intravenous [IV] fluid therapy, recent anesthesia, surgery or corticosteroid administration, and trauma).[37,41] The second most common clinical signs are related to ATE, detected in 4 to 17% of HCM cats at diagnosis with or without concomitant CHF, and mainly characterized by acute bilateral and painful hindlimb paresis, and less commonly, forelimb paresis (see ch. 256).[37,41,42,60] Other clinical signs include syncope and weakness observed in 1 to 6% of HCM cats at diagnosis.[37,41,60] Lastly, open-mouth breathing and dyspnea despite the absence of radiographic and echocardiographic signs of CHF are reported in HCM cats.[42] One possible explanation is that these cats are suffering from angina-like chest pains, similar to those reported in human patients with HCM.[42]

Cardiac Auscultation

Cardiac auscultation is abnormal in most HCM cats (78% to 92%).[37,41,42] The commonest abnormalities are systolic heart murmurs (64% to 89% of HCM cats) heard best over the left apex or the cranial sternum, and respectively resulting from mitral regurgitation and LVOTO (see ch. 55).[37,41] These murmurs are often dynamic (i.e., of variable grade, increasing with heart rate) and more commonly found in asymptomatic (89% to 92%) than in symptomatic cats (77%).[37,42] This may be explained by the fact that heart murmurs are one of the main reasons why practitioners refer asymptomatic animals for echocardiography. A gallop rhythm and arrhythmias are detected in up to 33% and 6 to 10% of HCM cats, respectively.[37,41,42] Unlike heart murmurs, both are uncommon in cats with subclinical HCM (<10% and ≤5%, respectively), probably because they reflect severe myocardial lesions.[37,42]

Electrocardiographic Findings

Various nonspecific morphological electrocardiographic (ECG; see ch. 103) alterations are associated with feline HCM, resulting from LVH (QRS amplitude >0.9 mV) and LAE (P wave duration >0.04 seconds, PR interval >0.09 seconds).[1,75] The latter P wave-related ECG indices have low sensitivity (12% to 60%) but high specificity (81% to 100%) for predicting LAE in cats with cardiomyopathy.[75] A left axis deviation suggestive of left anterior fascicular block is reported in 11% to 33% of HCM cats, more commonly than in those suffering from other cardiomyopathies.[1] Arrhythmias are also frequently diagnosed (in about one third of HCM cats in one report, with a predominant proportion of ventricular premature complexes: 65%; see ch. 248).[60,76] Myocardial diseases, predominantly HCM, represent the most common cause of ventricular arrhythmias in cats.[77] Other reported arrhythmias include supraventricular premature complexes, atrioventricular blocks or atrioventricular dissociation (1%), and atrial fibrillation (0.5%).[1,37,60] Use of 24-hour Holter monitoring, which is more sensitive than "in-clinic ECG" for arrhythmia detection, showed that cats

with asymptomatic HCM had more frequent and complex ventricular and supraventricular arrhythmias than normal cats, despite similar heart rates.[76] All asymptomatic cats had ventricular arrhythmias, with 82% exhibiting complex arrhythmias *vs* 20% for normal cats, and 87% had supraventricular arrhythmias with 23% exhibiting complexity *vs* respectively 60% and 13% for normal cats.[76] Whether such arrhythmias are associated with an increased risk of sudden cardiac death or a shorter life span requires further investigation.

Clinical Course and Prognosis

Survival time of HCM cats is highly variable. Some live for years, even have a normal life expectancy, and die from non-cardiac causes, whereas others die several days after diagnosis or even die suddenly before an *ante-mortem* diagnosis of HCM can be established. For example, an overall median survival time of 709 days with a wide range (2-4418 days) was reported for HCM cats that survived >24 hours.[41] This highly variable survival time was also shown in another study (1276 days, 0-3617 days).[42] Cardiac deaths related to HCM mainly include spontaneous deaths or euthanasia either secondary to ATE or CHF (each representing about 33% to 50% of all cardiac deaths), and also sudden death (10% to 25% of all HCM-related deaths).[37,41,60] Various clinical, breed, genetic and imaging risk factors associated with cardiac death have been identified.[37,41,42,53,60]

Clinical Signs

The reported percentage of HCM cats dying for cardiac reasons varies from 37% to 81%, depending on the proportion of cats presenting with clinical signs at diagnosis.[21,37,41,42,60] Much longer survival times have been reported for asymptomatic cats than those of symptomatic cats, depending strongly on the types of clinical signs that occur, but with wide ranges of lifespans for each clinical status category.[37,41,42,74] In the report by Rush et al, cats with occult HCM lived the longest (median = 1129 days), followed by cats presenting with syncope (654 days), CHF (563 days), and ATE (184 days).[41] Payne et al also found that cats without CHF (>3617 days) survived longer than those with CHF (194 days),[42] and Trehiou-Sechi et al showed that 80% of asymptomatic cats at diagnosis died from non-cardiac related causes, whereas 80% of symptomatic cats died for cardiac reasons.[37] Other negative clinical predictors of cardiac death include age, presence of a gallop sound and arrhythmia at diagnosis.[60]

Breed

Ragdolls have shorter survival times than other cats (median survival, 19 days *vs* 1297 days respectively).[42] In one study with no Ragdolls, the age at first cardiac event (CHF, ATE, syncope, sudden death) was lower in Maine Coon cats (median age, 2.5 years) than in other cats (7.0 years), with half of the Maine Coon deaths attributed to cardiac causes whereas most (>75%) deaths of Chartreux and Persian cats were attributed to non-cardiac causes.[37]

Genetic Status

Ragdoll cats homozygous for the *MyBPC3* R820W mutation are more likely to die from cardiac causes and have a shorter time to cardiac death than do heterozygous and wild-type cats (median age at cardiac death of 5.7 years *vs* >16.7 years and >15.2 years, respectively).[53]

Imaging Variables

Left atrial enlargement, assessed using several methods,[66,78] is consistently negatively associated with survival time in both occult and overt HCM.[21,41,42,60,62] Median survival of HCM cats with normal LA size (>3617 days) is thus greater than that of HCM cats with LAE (229 days).[42] Other imaging predictors of increased risk of cardiac death include severe LVH (≥9.0 mm), decreased systolic function (fractional shortening [FS%] ≤30%), decreased LA function (assessed by LA-FS%), RV enlargement, regional wall hypokinesia, spontaneous echo-contrast/thrombus or both, and a restrictive diastolic filling pattern.[21,41,42,60,79]

Restrictive Cardiomyopathy

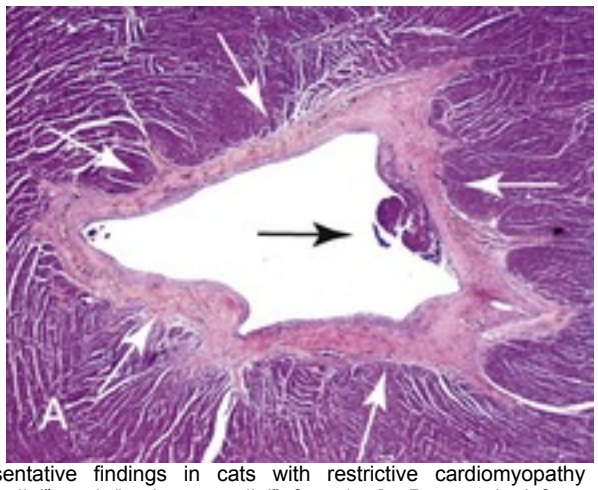
Definition: Pathological Lesions

Human RCM

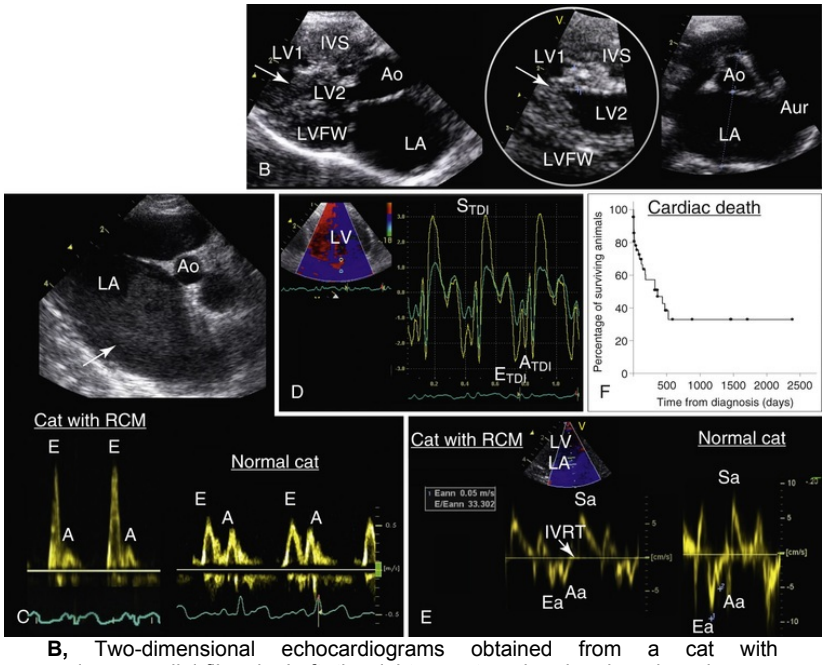
Human RCM is an uncommon heart muscle disease primarily characterized by impaired ventricular filling due to increased myocardial stiffness (or reduced ventricular compliance) of either ventricle (mainly LV) or both, with normal or near-normal systolic function and wall thicknesses.[7,80-83] The reduced ventricular compliance restricts ventricular filling (hence the term "restrictive"), with secondary increased end-diastolic ventricular filling pressure, resulting in marked LA or biatrial enlargement. In the early stages, global systolic function is normal, but altered systolic function is usually observed as the disease progresses.[11,83] Human RCM actually represents a heterogeneous group of heart disorders subdivided into primary and secondary RCM.[11,82,83] Causes of secondary RCM are various including infiltrative diseases (e.g., amyloidosis, sarcoidosis, Gaucher and Hurler diseases) and storage diseases (e.g., hemochromatosis, glycogen storage disorders, and Fabry disease). Secondary RCM, especially endomyocardial fibrosis, is also reported in the hypereosinophilic syndrome and as an iatrogenic complication (radiation, drugs).[80,83] Primary human RCM is characterized by patchy to diffuse interstitial myocardial fibrosis with possible fibrosis of the sinus and atrioventricular nodes resulting in atrioventricular blocks.[80] Endomyocardial fibrosis is a specific form of primary RCM, characterized by marked endocardial fibrosis in addition to myocardial fibrosis.[84,85] Similarly to HCM, familial forms of primary RCM are reported, with most identified genes encoding for sarcomere or Z-disk proteins (e.g., cardiac troponin genes and *MYH7*).[86-88] Interestingly, in addition to these genetic similarities, "overlap" or "crossover" phenotypes of RCM and HCM have been observed in families with mutations in sarcomeric genes, suggesting that some RCM cases may be considered as "minimally hypertrophic" HCM phenotypes.[83]

Feline RCM

"Myocardial RCM" and "endomyocardial fibrosis RCM," similar to human forms of primary RCM, have been identified in the cat,[1,16,17,89] with greater frequency than reported in humans[17] as RCM is currently the second most common feline primary cardiomyopathy (Figure 253-9).[22] At the time of writing, no causal mutations for either feline RCM form have been identified. Nevertheless and interestingly, Fox et al reported that histopathological features of feline HCM (e.g., myocyte disarray, abnormal intramural coronary arterioles, patchy replacement scarring) are found in most cats with RCM, thus suggesting that feline RCM could be the phenotypic expression of sarcomere mutations.[17] The hallmark feature of feline endomyocardial fibrosis is severe endomyocardial scar commonly appearing as a distinct "tubular" lesion bridging the IVS and LVFW, that may result in mid- to apical intra-cavity stenosis (see Figure 253-9, *B*).[16] The less common form of feline endomyocardial fibrosis is characterized by diffuse endomyocardial scar resulting in reduction or obliteration of the LV cavity (see Figure 253-9, *A*). In both endomyocardial forms, endocardial thickening may also involve atrial chambers, the RV (rarely), and is associated with myocardial interstitial fibrosis, various degrees of myocyte hypertrophy and necrosis, intramural coronary arteriosclerosis and inflammatory infiltrates.[16] Such inflammatory infiltrates are also described in the feline "myocardial RCM" form, suggesting a possible role of viral infection and/or immune-mediated induced lesions.[90] In one report, interstitial pneumonia was found in >25% of RCM cats and a question raised by the authors was whether the same agent or process could affect both the heart and lungs.[89]



Representative findings in cats with restrictive cardiomyopathy (RCM, "myocardial" and "endomyocardial" forms). **A,** Panoramic left ventricular cross-sectional view demonstrating a severe and diffuse circumferential left ventricular endocardial scar (white arrows) in a cat with endomyocardial fibrosis that died suddenly. A mural thrombus is also present (black arrow). (Hematoxylin-Eosin-Saffron stain). (Courtesy Prof. Jean-Jacques Fontaine, Pathology Department, National Veterinary School of Alfort, France.)



B, Two-dimensional echocardiograms obtained from a cat with endomyocardial fibrosis. Left: the right parasternal 5-chamber view shows a large heterogeneous bridging scar (arrow) connecting the interventricular septum (IVS) and the left ventricular free wall (LVFW), thus dividing the left ventricular cavity into two apical (LV1) and basal (LV2) parts, with secondary dilation of the left atrium (LA) as compared to the aorta (Ao). Center: zoomed view of the bridging scar (arrow) with focal hyperechoic areas (fibrosis). Right: right parasternal transaortic short-axis view demonstrating marked auricular (Aur) and LA enlargement (end-diastolic LA : Ao ratio = 2.2; values obtained from a population of 100 healthy cats: 0.5 to 1.2).[78] **C,** Echocardiography and Doppler features in a cat with RCM. Top figure: the severely enlarged LA (end-diastolic LA : Ao ratio = 3.7) contains smoke-like echoes (arrow) indicative of blood stasis. Bottom figures: as compared with a normal cat (right), transmitral pulsed-wave Doppler examination of the cat

with RCM (left) obtained from the left apical 4-chamber view reveals a typical restrictive filling pattern characterized by an increased ratio (>2)[66] between the peak velocities of early (E wave, m/s) and late (A wave, m/s) diastolic flow resulting from both increased LA pressure and reduced ventricular compliance with secondary elevated LV diastolic pressure (i.e., E : A = 4.6 *vs* 1.4 [0.65 : 0.45] for the normal cat). Decreased LA function may also contribute to the small A wave amplitude. The cat with RCM also shows a short E-wave deceleration time because of rapid equalization of LA and LV pressures after early diastolic filling (30 ms *vs* 92 ms for the normal cat; values obtained in 41 healthy cats: 54 to 192 ms).[17] **D,** Radial diastolic dysfunction diagnosed in a cat with RCM using two-dimensional color tissue Doppler imaging (TDI, right parasternal short-axis view). The radial velocity profiles are recorded simultaneously in 2 LVFW segments, i.e., subendocardium (yellow) and the subepicardium (green). The diastolic dysfunction is characterized by low diastolic waves, especially in the subendocardium (e.g., subendocardial E_{TDI} wave of 2.6 cm/s; normal values recorded in a population of 100 healthy cats: 5.7 ±1.5 cm/s [3.5-10.8]).[78] A_{TDI}, peak myocardial velocity during late diastole; E_{TDI}, peak myocardial velocity during early diastole; *LV,* left ventricle; S_{TDI}, peak myocardial velocity during systole. **E,** Pulsed-wave TDI recording from the lateral mitral annulus in a cat with RCM (left) showing markedly reduced diastolic velocities (Ea and Aa, cm/s), reflecting a diminished velocity of longitudinal diastolic motion, as compared with the normal cat (right, same animal as in **C**). The peak annular velocity during early diastole (Ea) is only 5 cm/s (*vs* 9.8 cm/s for the normal cat; normal values >6 cm/s).[66] Additionally, in the diseased cat, the ratio between mitral E wave (1.66 m/s, data not shown) and Ea is high (33 *vs* 0.65 : 0.098 = 6.6 for the normal cat; normal values <12).[66] By combining peak mitral E wave (mainly determined by LV filling pressure and relaxation) with Ea (which mainly depends on relaxation) the E : Ea ratio is an index reflecting LV filling pressure (as the effect of relaxation on E is minimized),[66] although prospective studies involving the use of this ratio in cats with RCM are missing. *Aa* and *Sa,* Peak annular velocities during late diastole and systole, respectively. **F,** Kaplan-Meier curve illustrating the time to cardiac death after the initial diagnosis of RCM at the Alfort Cardiology Unit in 73 cats with an available follow-up and that survived >24 hours after the initial examination. Median survival time was 364 days (range, 2-525). (Figure from Prof. R Tissier, INSERM U955 and Pharmacology-Toxicology Unit, National Veterinary School of Alfort, France.)

FIGURE 253-9

Epidemiology: Clinical Presentation at Diagnosis

In the report by Fox et al on 35 RCM cats, mean age at diagnosis was 10 ±4 years with a wide range (1.5-17.1).[17] Similarly, in a retrospective study performed at the Alfort Cardiology Unit (UCA) on 112 RCM cats (2000-2011), age at diagnosis was 10.0 ±4.8 years (0.1-18.9) with only 10% of animals >12 years old. In a case series of 22 RCM cats, most were females (73%).[22] However most were males (71%) in the report by Fox et al,[17] whereas males (52%) and females (48%) were equally represented in the UCA population. In all 3 studies, different breeds were affected (e.g., Burmese, Siamese, Persian, Birman, Maine Coon), with a predominance of Domestic Shorthairs (59 to 78%), but no reported familial link.

Almost all cats with RCM show clinical signs at the time of diagnosis, predominantly related to CHF.[17,21,22] In the report on 35 RCM cats, 91% presented with CHF, 6% with lethargy and 3% with syncope and transient paresis.[17] Similarly, most of the 112 RCM cats (94/112, 84%) recruited at the UCA were symptomatic at diagnosis, with 76% presenting at least 2 clinical signs. The remaining cats (16%) were referred for echocardiography owing to the presence of heart murmurs or arrhythmias detected during routine cardiac auscultation. The most common clinical signs detected in the 94 symptomatic RCM cats were dyspnea (76%), followed by non-specific signs (lethargy, weakness, hypothermia, anorexia [56%], ascites [17%], and paresis/paralysis related to ATE [10%]). Dyspnea was related to pleural effusion for most cats (71%) and to pulmonary edema for others. A heart murmur (left apical systolic heart murmur in 90% of cases) and a gallop rhythm were respectively reported in 66% and 31% of RCM cats (see ch. 55).

Electrocardiographic Findings

Various arrhythmias are commonly associated with feline RCM, predominantly including ventricular premature complexes (23% to 29%) and supraventricular tachycardia (9% to 23%) (see ch. 103 and 248).[17,22] Atrial fibrillation is much less common. Six of the 112 RCM cats diagnosed at the UCA presented with atrial fibrillation (5%), and all showed severe LAE (LA: Ao ratio = 2.5 ±0.7).

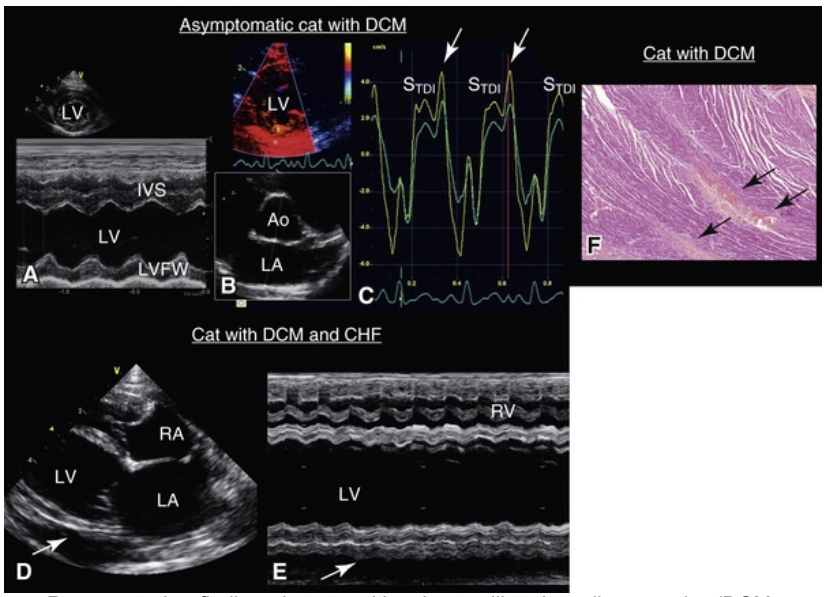
Clinical Course and Prognosis

The overall prognosis of human RCM is poor, with most patients requiring cardiac transplantation.[91] Feline RCM is similarly associated with a poor prognosis, with most animals dying from cardiac-related causes (60% to 86%).[17,21,22] Median survival times of 132 days and 273 days were reported in 16 and 14 RCM cats.[21,22] Spontaneous death or euthanasia for refractory CHF (associated with ATE in >25% of cases) and sudden death were reported in 51% and 9% of 35 RCM cats, respectively, with a median survival of 3.4 months (0.1-52).[17] Similarly, 47/87 cats in the UCA population with an available follow-up died during the study period, i.e., 14 (30%) from non-cardiac-related causes and 33 (70%) from cardiac-related causes (including 9% of sudden death), with one third of the latter occurring within the first 24 hours after diagnosis (spontaneous death or euthanasia for acute CHF). Excluding cats that survived less than 24 hours (n = 14, including 11 that died suddenly), the median survival time was 364 days (2-525) considering cardiac death (see Figure 253-9, *F*).

Dilated Cardiomyopathy

Definition and Prevalence

Dilated cardiomyopathy, a primary cardiomyopathy characterized by a dilated LV with systolic dysfunction (Figure 253-10 and Video 253-15),[8,83] was previously recognized as the second most common feline heart disease.[1] However, since the demonstration by Pion et al in 1987 that most cases of feline DCM were actually not "primary" but instead related to taurine deficiency, and that they could be reversible and preventable with oral supplementation of taurine,[92-100] commercial cat foods have been subsequently supplemented with taurine (Box 253-1). Other causes of DCM phenotypes such as sustained tachycardia are also reported.[101] The prevalence of what was initially thought to be a primary myocardial failure has thus decreased markedly, and DCM currently represents only 5% to 10% of primary cardiomyopathies.[20,22] A large number of genetic causes of DCM has been recognized in humans, with most of the implicated genes encoding sarcomere, Z-disk, or cytoskeleton proteins.[83] A mutation in the gene encoding for a mitochondrial protein (PDK4) is similarly associated with the development of DCM in the Doberman Pinscher.[102] However, at the time of writing, no causal mutation has been identified for feline DCM, although a genetic involvement with complex pattern of inheritance was evidenced in a large colony of Domestic Shorthairs.[103]



Representative findings in cats with primary dilated cardiomyopathy (DCM, **A-F**) and taurine deficiency-induced myocardial failure **(G). A** and **B,** M-mode **(A)** and two-dimensional **(B)** echocardiograms from an asymptomatic Maine Coon cat with DCM referred for echocardiographic examination before mating. Myocardial failure is confirmed by a mildly decreased fractional shortening (27%; values obtained from a population of 100 healthy cats: 33 to 66%).[78] The left atrium (LA) is still normal (end-diastolic LA : Ao ratio = 1; values obtained from a population of 100 healthy cats: 0.5 to 1.2).[78] *Ao,* Aorta; *IVS,* interventricular septum; *LV,* left ventricle; *LVFW,* left ventricular free wall. **C,** (Same cat as in **A** and **B.**) Radial myocardial velocity profiles of the LVFW obtained from a right parasternal short-axis view using two-dimensional color tissue Doppler imaging. The simultaneous recording of myocardial velocities in a subendocardial (yellow) and subepicardial (green) segment shows that the subendocardium is moving more rapidly than the subepicardium in systole and also in diastole, thus defining systolic and diastolic radial myocardial velocity gradients. However, the mean systolic gradient is here within low normal ranges (0.9 cm/s; values obtained in a population of 100 healthy cats: 2.2 ±0.7 cm/s).[78] Post-systolic contraction waves (arrows), occurring after S_{TDI} waves and greater than the latter (particularly in the subendocardium) are also seen. Radial post-systolic contraction waves, defined as abnormally delayed radial myocardial contractions occurring during the early diastolic phase (rather than during the systolic phase), were not observed in a population of 100 healthy cats.[78] *S_{TDI},* Peak myocardial velocities recorded during systole. **D** and **E,** Echocardiograms obtained from a cat with DCM and pleural effusion (arrows) related to congestive heart failure. Dilation of the 4 cardiac chambers is observed on the right parasternal 4-chamber view **(D).** A poor LV function is confirmed by the low fractional shortening value (15%) and hypokinesia of both the IVS and the LVFW on the M-mode echocardiogram **(E).** *RA,* Right atrium; *RV,* right ventricle. **F,** Broad bands of fibrosis (arrows) replacing myocardial fibers associated with diffuse interstitial fibrosis in a cat with DCM that died suddenly (Hematoxylin-Eosin-saffron stain, ×25). Box 253-1

The Particular Case of Taurine Deficiency-Induced Myocardial Failure, an Example of Nutritional Secondary Cardiomyopathy

Taurine (or 2-aminoethanesulfonic acid) is a sulfonic acid that was first identified in bull bile (hence the name, from the Latin word *Taurus,* meaning bull).[151,152] Taurine is widely distributed in animal tissues, with highest concentrations found in heart, retina, skeletal muscles, and central nervous system.[151-153] It has many different biological actions including conjugation of bile acids, normal retinal and myocardial function, and development and function of central nervous system and skeletal muscles.[96,151-155]

Why Taurine Deficiency in Cats?

Cats can synthesize a limited amount of taurine from cysteine owing to low tissue concentrations of cysteine-sulfinic acid decarboxylase, a key enzyme required for its synthesis.[96,156] Additionally, even when dietary taurine is restricted, cats exclusively use taurine for bile acid conjugation rather than using the alternate glycine conjugation.[157] Taurine loss in the feces as bile acids together with a low synthetic ability predisposes the cat to becoming taurine deficient, particularly when dietary intake of taurine is restricted.[96,157,158] Owing to the various roles of taurine, its deficiency results in a wide range of organ and clinical alterations, which can be prevented and/or reversed with adequate dietary taurine. These include retinal central degeneration, reproductive abnormalities (e.g., infertility, increased incidence of fetal resorptions and abortions, low birth weight), compromised immune function, and myocardial failure as discovered by Pion et al in 1987 (see Videos 253-17, 253-18, and 253-19).[92,96,153,156] However, not all taurine-deficient cats develop overt myocardial failure (about 25%), thus suggesting the influence of other undetermined factors.[96]

Diagnostic Issues Regarding Taurine Deficiency-Induced Myocardial Failure

Routine supplementation of commercial feline diets with taurine has led to a dramatic decrease in the prevalence of taurine deficiency-induced myocardial failure, which is currently rarely diagnosed in cats, except in particular conditions, e.g., use of vegetarian and vegan diets (see Videos 253-17, 253-18, and 253-19).[4,96] However, it is highly likely that a small number of cases continues to be the result of

commercial feline foods containing inadequate amounts of taurine.[96,159] Therefore, the diagnosis of taurine deficiency in cats with echocardiographic DCM phenotype relies mainly on the dietary history together with low plasma and/or whole blood taurine concentration, and systemic evidence of taurine deficiency (e.g., retinal central degeneration; Figure 253-10, *G*).[95,96] Plasma and whole blood taurine concentrations are not affected by age or body weight of cats,[160] and the best clinical method to evaluate the taurine status in cats is ideally the determination and interpretation of both plasma and whole blood taurine concentrations,[155] with whole blood taurine concentration being less subject to change than plasma taurine concentration during the postprandial period or with food deprivation.[95] Normal plasma and whole blood taurine concentrations are usually >60 and >200 nmol/mL, respectively, and risk of developing taurine deficiency–induced myocardial failure occurs for values <30 and <100 nmol/mL, respectively.[96] However, 24 hours of fasting can result in low plasma taurine concentration values, leading to "false positive taurine deficiency" results. Inversely, diet-induced taurine deficiency may be misdiagnosed in some cats with myocardial failure as (1) taurine deficient diets may be difficult to identify as taurine bioavailability may decrease with heat processing (during the canning process), potassium depletion, acidification, and rice bran or whole rice content,[100,161,162] (2) false negative results (i.e., normal taurine concentrations) can be found in several situations (postprandial sampling, recent ATE or dietary changes), and (3) central retinal degeneration is inconsistently found in cats with taurine deficiency–induced myocardial failure (about one third) and does not provide proof of current taurine deficiency (as it may also be the sign of past taurine deficiency).[92,94-96] Assessment of the response to taurine supplementation can therefore be an additional indirect method to help identify taurine deficiency in cats with a DCM phenotype, and taurine supplementation is recommended for all of them regardless of the taurine concentration values.[93,96,105]

Taurine Supplementation, Other Treatments and Prognosis

Therapy of taurine deficiency–induced myocardial failure includes taurine supplementation (250 mg PO q 12 h) together with standard treatment of CHF (e.g., diuretic and ACE inhibitors; see paragraph on treatment). Hypothermia and ATE are associated with an increased risk of early death, which occurs within the first month in more than one third of cats.[93] However, nearly all cats that survive more than 1 month show both marked clinical and echocardiographic improvement. Clinical improvement including the cat's demeanor and appetite is usually observed within 2 weeks and, for most cats, evidence of progressive echocardiographic improvement (firstly a decreased LV systolic diameter and increased FS%) is reported 3 to 9 weeks after beginning taurine supplementation.[93,98] Treatment of CHF can be progressively discontinued when signs of CHF resolve and taurine supplementation can also be stopped once echocardiographic values normalize (usually within 4 months) if adequate taurine intake is ensured by food, which should be confirmed by periodic monitoring of plasma and/or whole blood taurine concentrations.[96] Even if most cats undergo a complete reversal of the myocardial disease, others may show persistent mild myocardial failure (FS% between 25 to 30%) despite taurine supplementation.[96] However these animals are usually asymptomatic and do not require specific therapy except for taurine.[96]

Pathophysiological Consequences

As in humans and dogs,[83,104] feline DCM is characterized by degenerative myocardial lesions of the LV or both ventricles, with various degrees of myocytolysis, fibrosis, coronary arteriosclerosis and some inflammatory infiltrates.[1,90] These lesions are responsible for decreased systolic function, with secondary systolic and then diastolic dilation of affected ventricles. Dilation of the ventricular cavities commonly results in enlargement of the corresponding atrioventricular valve annulus, with secondary valve insufficiency potentially contributing to atrial dilation, subsequent CHF, and increased risk of ATE.[22,105] In one report, valve insufficiency was evidenced in 69% of 32 DCM cats, with mitral and tricuspid valves concomitantly affected in half of the cases and spontaneous echo contrast in the LA of 9% of the cases.[105]

Epidemiology: Clinical Presentation at Diagnosis

A higher proportion of females (73%) with a mean age of 9.1 years (range 2-15.5 years) was reported in one

case series of 11 DCM cats, whereas a higher proportion of males (two thirds) of similar age (10 years, range: 3-16 years) was reported in 32 DCM cats, without any breed predisposition.[22,105] Most DCM cats present with clinical signs of CHF at diagnosis,[22,105] predominantly dyspnea resulting from pleural effusion and/or pulmonary edema (diagnosed in 69% and 34% of cases, respectively)[105] and ascites (6 cases in a series of 11 DCM cats).[22] Signs of systemic hypotension (e.g., weakness) are reported (55%),[22] as well as ATE (9%) and collapse (3%).[105] Feline DCM can also be incidentally diagnosed in asymptomatic animals (see Figure 253-10, *A-C*), indicating the evidence of an occult phase of the disease, but this is currently not as well characterized as that of canine DCM.[104] Cardiac auscultation abnormalities are detected in most DCM cats (97%), including gallop sound (72%), systolic heart murmur (34%), muffled heart sounds (3%) and arrhythmias (28%).[105]

Electrocardiographic Findings

Most ECG tracings from cats with DCM are abnormal (8/11 DCM cats with ECG tracings in two case series) (see ch. 103).[20,22] Non-specific morphological ECG alterations resulting from cardiac chamber enlargement are commonly found.[20,22] Various arrhythmias are also frequently diagnosed, predominantly including ventricular premature complexes and supraventricular tachycardia (see ch. 248).[105] Atrial fibrillation is much less common (only 1 out of 11 DCM cats in one case series).[20]

Clinical Course and Prognosis

Among cats with primary cardiomyopathies, those with DCM have one of the shortest survival times. A median survival time of 11 days was reported in a case series of 11 DCM cats.[22] Similarly in a recent report, survival of cats with DCM was short despite addition of inotropic therapy (pimobendan) to standard therapy (furosemide, taurine, ACE inhibitor, and/or digoxin), (i.e., 49 days [1 to >502 days] *vs* 12 days [1-244 days] for cats receiving the standard therapy alone). In most cases, death was due to euthanasia for refractory CHF (42%) or ATE (19%), and a high proportion of sudden death was also reported (36%; see Figure 253-10, *F*).[105] Hypothermia at presentation and a FS% <20% were both associated with reduced survival.[105]

Arrhythmogenic Right Ventricular Cardiomyopathy

Definitions: Comparative Knowledge in Humans and Small Animals

Humans

ARVC is predominantly a rare genetically determined cardiomyopathy, primarily affecting the RV and pathologically characterized by fibrofatty replacement of RV myocytes, leading to RV dysfunction and failure, ventricular tachyarrhythmias, and increased risk of sudden cardiac death.[106-116] In early stages of the disease, structural myocardial changes are mild and confined to localized RV areas.[110,112] At a later stage, RV myocardial fibrofatty lesions become diffuse, with potential involvement of the LV.[112] Besides this "classic right-dominant form" of the disease, two less common forms are reported: a biventricular form and a left-dominant form characterized by early occurrence of LV involvement, while RV remains preserved.[112,114] Owing to these biventricular and left-dominant subtypes, the term ARVC does not strictly reflect actual myocardial lesions, explaining why the broader term "arrhythmogenic ventricular cardiomyopathy" has been proposed.[111] Interestingly, ARVC was first described by French cardiologists in 1978,[106] and the term "ARV dysplasia" initially chosen for the disease, as myocardial lesions were thought to result from embryological aberrations.[106-108] Nowadays ARVC is known as an acquired heart disease with a causal mutation in genes encoding proteins of the intercalated disk, mainly desmosomal proteins (e.g., plakoglobin, desmoplakin, desmocollin-2, plakophilin-2, and desmoglein-2) in more than 60% of patients.[109,110,112] The cardiac desmosome plays various important roles: it supports structural stability of the myocardium, maintains proper electrical stability and conductivity through regulation of gap junctions and calcium homeostasis, and regulates transcription of genes involved in adipogenesis and apoptosis.[110] The ARVC genetically determined disruption of desmosomal integrity therefore results in myocyte detachment, apoptosis, and necrosis, with inflammatory infiltration (as a reactive process to cardiac death), and subsequent fibrofatty replacement (presumed to represent a "reparative" myocardial process).[110,112] These lesions result in atrophy of the RV

myocardial wall, with secondary RV hypokinesia and dilation, potentially leading to tricuspid regurgitation, RA enlargement, and right-sided CHF. Disruption of desmosomal integrity also promotes ventricular arrhythmias at early stages of the disease, owing to electrical instability and alteration in myocyte electrical coupling.[112,115] Myocardial inflammation associated with ARVC could also represent immune or infectious mechanisms. A predisposition of human patients with ARVC to viral or bacterial myocarditis has been suggested, and myocarditis is known to potentially mimic ARVC lesions. However, the link between myocarditis and ARVC remains to be clarified.[112,116]

Small Animals

Spontaneous AVRC is reported in the dog,[117-124] and is a familial disease in the Boxer breed (autosomal dominant trait, incomplete and age-related penetrance; see ch. 252) frequently associated with a deletion in the striatin gene on chromosome 17.[120,121] Striatin is localized at the intercalated disc region of cardiomyocytes and co-localized with other desmosomal proteins involved in the pathogenesis of human ARVC.[109,110,112] In the cat, ARVC is a recently-recognized cardiomyopathy, accounting for <5% of all myocardial diseases (Figure 253-11).[1,20,125] A series of 12 cases of feline ARVC was extensively described in 2000.[15] Since then, a few sporadic cases have been reported.[126-128] At the time of writing, unlike human and canine ARVC, no genetic transmission has been identified in association with feline ARVC, which remains, therefore, of uncertain origin. In the series of 12 ARVC cats,[15] morphological lesions were similar to those described in humans, including diffuse (7/12) or segmental (5/12) thinning of the RV wall, RV aneurysms of various importance and RA enlargement in 6/12 and 7/12 cats, respectively (see Video 253-16). Histological lesions were also similar to human ARVC, including marked RV myocardial atrophy with fibrous or fibrofatty (9/12) and fatty (3/12) replacement in all cats, apoptosis and focal or multifocal myocarditis in 9/12 and 10/12 cats, respectively. As described in humans and dogs,[112,117] similar lesions were observed in the LV of most cats (10/12), with even severe LV involvement reported.[127]

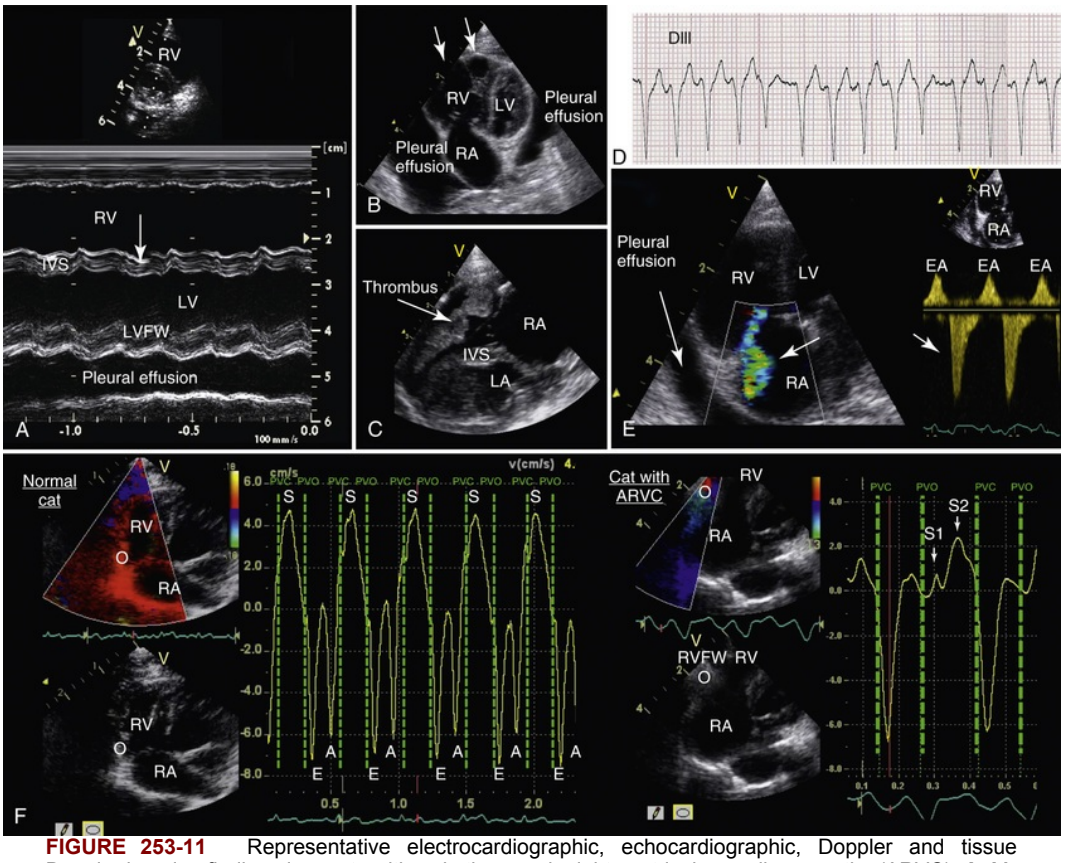

FIGURE 253-11 Representative electrocardiographic, echocardiographic, Doppler and tissue Doppler imaging findings in 4 cats with arrhythmogenic right ventricular cardiomyopathy (ARVC). **A,** M-mode echocardiogram confirming a severe dilation of the right ventricle (RV) with a paradoxical motion (arrow) of the interventricular septum (IVS). Note also the presence of pleural effusion as a sign of

congestive heart failure. *LV,* Left ventricle; *LVFW,* left ventricular free wall. **B,** Two-dimensional echocardiogram obtained from another cat with ARVC (left apical view) showing severe aneurismal RV dilation (arrows), associated with enlargement of the right atrium (RA), and pleural effusion as well. **C,** Two-dimensional echocardiogram obtained from a third cat with ARVC (right parasternal 4-chamber view) showing severe dilation of both right cardiac chambers with a voluminous thrombus in the RV cavity. *LA,* Left atrium. **D,** Atrial fibrillation with right bundle branch block configuration in a cat with severe ARVC (same animal as in **A**). Lead III, paper speed = 25 mm/s, 2 cm = 1 mV. **E,** Tricuspid insufficiency (arrows) documented with color-flow (left panel) and continuous-wave (right panel) Doppler modes from the left apical 4-chamber view in a fourth cat with ARVC. No heart murmur could be heard because of muffled heart sounds owing to the presence of pleural effusion. Note the markedly enlarged right cardiac chambers. *EA,* Fused early (E) and late (A) diastolic tricuspid waves. **F,** Severe right myocardial systolic dysfunction assessed by two-dimensional color tissue Doppler imaging in a cat with ARVC (right panel, same animal as in **B**) compared to a normal cat (left panel). In the diseased cat, recording of longitudinal velocities in a basal segment of the right ventricular free wall (RVFW) shows an abnormal double systolic wave (S1 and S2), with a decreased and delayed peak systolic wave (S2) occurring at end-systole, instead of mid-systole (S) for the normal cat. *S, E,* and *A,* Peak velocities of the right myocardial wall during systole, early diastole, and late diastole, respectively; *PVC* and *PVO,* pulmonic valve closure and opening, respectively.

Epidemiology: Clinical Presentation at Diagnosis

Most ARVC cats are middle-aged at diagnosis (mean age = 7.3 years),[15] even though the age range is wide (1 to 20 years).[15,126,127] No breed or sex predisposition has been reported. The familial aspect of the disease has been evoked, but not demonstrated.[125] Most ARVC cats show clinical signs of right-sided CHF at presentation (see Figure 253-11).[15,126,127] Syncope related to ventricular tachyarrhythmias is a less common clinical expression.[15,125] As in humans and dogs, ARVC cats may remain asymptomatic for a variable period of time. The disease can thus be diagnosed in apparently healthy cats referred for echocardiography, mainly because of an abnormal cardiac auscultation (heart murmur and/or arrhythmias).[125,128] A soft right apical systolic heart murmur consistent with tricuspid regurgitation is detected in most ARVC cats (8/12 cats in the series by Fox et al).[15,125] Arrhythmias may also be detected. However, cardiac sounds may be muffled in cases of pericardial or pleural effusion.[125,126] Nonspecific general signs (e.g., lethargy, anorexia) are also reported in ARVC cats, even in those without evidence of CHF.[15,125]

Electrocardiographic Findings

As reported in humans and dogs, cats with ARVC display a large variety of ECG alterations, including ventricular premature complexes/tachycardia of RV and LV origin (particularly with LV involvement), atrial fibrillation, supraventricular tachycardia, right bundle branch block, and first- and third-degree atrioventricular blocks (see Figure 253-11, *D*, and ch. 248).[15,125,126]

Clinical Course and Prognosis

Although cats with ARVC may remain asymptomatic for an unknown duration, the prognosis of overt ARVC is usually poor. Most cats with ARVC-related CHF soon die of cardiac causes (spontaneous death or euthanasia due to worsening or unresponsive CHF and/or ATE despite therapy), several days or weeks after the initial diagnosis.[15,126,127] In the report by Fox et al, 6 of the 12 ARVC cats died of CHF 2 days to 4 months after clinical onset (median = 1 month).[15]

Unclassified Cardiomyopathies

This category is reserved for cardiomyopathies that do not fit under other headings (HCM, RCM, DCM, and ARVC).[7] In other words, UCM does not characterize a single distinct myocardial disease, but instead encompasses the uncommon primary cardiomyopathies whose echocardiographic changes do not correspond to the typical features of the 4 above well-defined cardiomyopathies. In cats, echocardiographic examination most commonly reveals a mix of alterations including segmental LVH, regional hypokinesia, and marked LAE.[4] In humans, primary UCM also include other forms of cardiomyopathies (e.g., myocardial non-compaction).[11,129] Although of unclear pathogenesis, at least some UCM could represent specific forms or stages of other cardiomyopathies, in particular HCM, as a result of more or less extensive areas of myocardial ischemia and/or infarction (secondary to coronary arteriosclerosis, decreased coronary blood flow secondary

to increased LV filling pressure, functional coronary constriction, inadequate capillary density related to increased myocardial mass, and/or coronary vascular thromboembolism).[130-133] The follow-up of human and feline HCM patients has thus highlighted a "dilated" HCM stage characterized by LV dilation, relative thinning of LV myocardial walls, diffuse or regional decreased contractility, and usually severe LAE.[131-134] In addition to the role of myocardial ischemia and/or infarction, apoptosis and genetic mutations have been evoked to explain this phenotypic HCM evolution in humans.[135,136] These particular HCM forms are also characterized by multifocal myocardial scarring with large regions of replacement fibrosis that can mimic RCM lesions.[133] Therefore, the diagnosis of UCM should be established with caution and the hypothesis of evolution of another primary cardiomyopathy, in particular HCM or RCM, should first be ruled out. However, a differential diagnosis may be difficult to establish in the absence of previous sequential echocardiographic examinations. In one study, UCM represented only 10% of 106 primary cardiomyopathies.[22] Most affected cats were adult females, with a mean age of 8.8 ± 4.8 (0.8-15 years) and more than half presented with signs of CHF. Surprisingly, a greater survival time was observed for cats with UCM (925 days) as compared with HCM (492 days), RCM (132 days) and DCM (11 days).

Secondary Cardiomyopathies

The final diagnosis of any primary cardiomyopathy should be established after exclusion of secondary cardiomyopathies and other heart diseases characterized by similar echocardiographic phenotypes. Although sometimes difficult, the differential diagnosis should for instance include hyperthyroidism particularly in elderly cats,[137-140] infiltrative tumor (lymphoma) or myocarditis, muscular dystrophy,[141,142] acromegaly,[143,144] steroid-induced cardiomyopathy,[145] and cardiovascular causes of LVH (e.g., aortic stenosis and systemic arterial hypertension)[146-149] in cases of the HCM phenotype,[150] as well as taurine deficiency (see Box 253-1),[92-99,151-162] drug toxicosis (e.g., doxorubicin), or sustained tachyarrhythmia in cases of the DCM phenotype.[4,92-99,101]

Diagnostic Approach to Feline Primary Cardiomyopathies

Thoracic Radiography

Cardiomegaly

Cardiomegaly is the most common radiographic abnormality associated with feline cardiomyopathies (Figure 253-12).[41,163-165] As in dogs, the vertebral heart score (VHS) may be used to objectively assess and compare heart size in sequential radiographs, with normal values of 7.5 ±0.3 vertebrae (v) on lateral radiographs, very few breed variations (unlike dogs), and usually accepted upper limits of ≤8.1 and 9 v on lateral and dorsoventral or ventrodorsal views, respectively.[165-167] However, thoracic radiographs present some diagnostic limitations. Asymptomatic HCM cats with mild to moderate LVH and no LAE do not show any radiographic alteration, and similarly to dogs, pulmonary edema or pleural effusion can obscure margins of the cardiac silhouette, precluding accurate evaluation of heart size and shape. Guglielmini et al demonstrated that VHS is relatively specific but not sensitive to predict cardiac enlargement in cats.[165] For example, with a VHS cut-off >8.2 v on lateral views, the specificity for predicting any degree of LAE was 92%, but the sensitivity ranged from 63% to 78% in cats with mild to severe LAE, respectively. With the same cut-off, the specificity for distinguishing cats with left-sided heart diseases from healthy cats was 100%, but the sensitivity was only 52%.[165] Nevertheless, VHS remains a useful tool to help differentiate cardiac from non-cardiac causes of respiratory distress in emergency situations when echocardiography is not immediately available or technically achievable: In cases of acute dyspnea, a VHS >9.3 v on lateral radiographs is highly specific for presence of an underlying heart disease.[168]

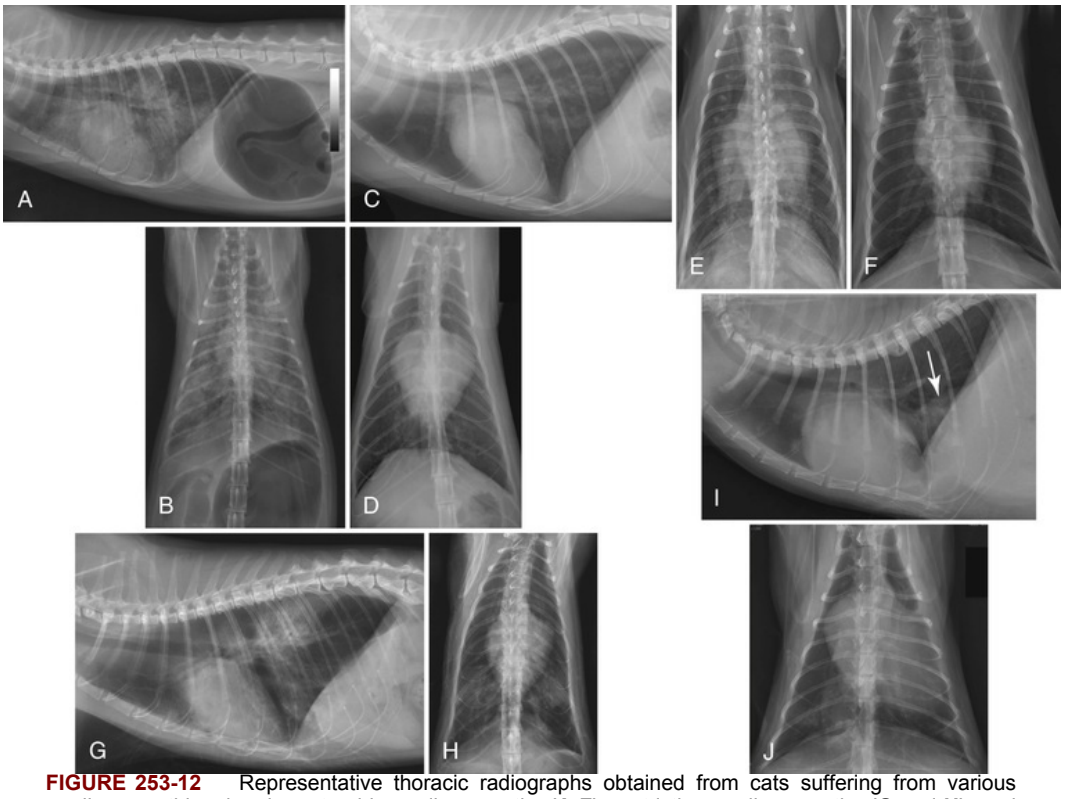

FIGURE 253-12 Representative thoracic radiographs obtained from cats suffering from various cardiomyopathies, i.e., hypertrophic cardiomyopathy **(A-F),** restrictive cardiomyopathy **(G** and **H),** and arrhythmogenic right ventricular cardiomyopathy **(I** and **J). A** and **B,** These right lateral and dorsoventral projections show marked cardiomegaly with a vertebral heart score (VHS) of 8.9 on the lateral projection and a valentine-shaped heart on the dorsoventral projection. The echocardiographic examination confirmed a severely enlarged left atrium without any right atrial enlargement. Note the alveolar lung pattern with symmetrical mainly cranioventral and caudoventral distribution. A severe gaseous distension of the stomach secondary to respiratory distress is also seen. **C** and **D,** These right lateral and ventrodorsal projections show severe cardiomegaly (VHS = 9.4 on the lateral projection) and a valentine-shaped heart on the ventrodorsal projection. The echocardiographic examination confirmed a severely enlarged left atrium (end-diastolic left atrium : aorta ratio = 2.2; normal maximal value = 1.2)[78] without any right atrial enlargement. Pulmonary edema is here characterized by a diffuse uniform unstructured interstitial lung pattern. **E,** This dorsoventral projection obtained from a Maine Coon cat with hypertrophic cardiomyopathy shows a marked enlargement of the pulmonary vessels in comparison with the thickness of the ninth rib where they cross each other. Note the severely increased width of the cardiac silhouette (>2/3 of that of the thoracic cage), without identification of a valentine-shaped heart. Cardiogenic pulmonary edema is characterized by a marked diffuse unstructured interstitial lung pattern. **F,** (Same cat as in **E.**) The ventrodorsal projection obtained the following day after treatment with furosemide shows regression of the pulmonary edema, decreased size of the cardiac silhouette, but persistent enlargement of the pulmonary vessels. **G** and **H,** These right lateral and ventrodorsal projections obtained from a cat with restrictive cardiomyopathy show severe cardiomegaly (VHS of 9.2 on the lateral projection) and a valentine-shaped heart on the ventrodorsal projection. On echocardiography, severe enlargement of only the left atrium was documented (end-diastolic left atrium : aorta ratio = 1.7). Note also the multifocal alveolar patches in the cranioventral and caudodorsal lung fields consistent with pulmonary edema. There is no perihilar distribution as seen in the dog. **I** and **J,** These right lateral and ventrodorsal projections obtained from a cat with arrhythmogenic right ventricular cardiomyopathy show an increased contact between the cardiac silhouette and the sternum and a left cardiac shift consistent with right-sided cardiomegaly, with a VHS of 9.0. A marked enlargement of the caudal vena cava (arrow) is also seen (twice the height of the thoracic aorta). Note also the presence of two alveolar patches in the caudal lung lobes. Differentials to consider include pulmonary edema or pulmonary thromboembolism. (Courtesy Dr. Pascaline Pey, Diagnostic Imaging Department, National Veterinary School of Alfort, France.)

Cardiac Shape

Until recently,[169,170] the typical valentine-shaped heart, assessed on dorsoventral or ventrodorsal views (see Figure 253-12, *D*), was considered to be related to biatrial enlargement and relatively specific to feline HCM.[1,164] However, a strong positive correlation between LA size and severity of the valentine shape was recently demonstrated, without any effect of RA size on the latter, except when concurrent with severe LAE.[170] Similarly, in a recent report, the majority (83%) of cats with a valentine-shaped heart were suffering

from cardiomyopathies, but only 32% had HCM (RCM and UCM accounting for 17% and 34% of the remaining cases; see Figure 253-12, *H*), with biatrial enlargement confirmed in only one third of cats.[169] In both reports, 10% to 19% of cats with a valentine-shaped heart were diagnosed with conditions other than cardiomyopathies (e.g., congenital heart diseases and volume overload), and up to 7% did not even show any echocardiographic abnormality.[169,170] The valentine-shaped heart should therefore no longer be considered as a specific feature of feline HCM. Neither does it predict the presence of biatrial enlargement, as its primary cause is LAE alone.[169,170] In the particular case of ARVC, thoracic radiographs typically show enlargement of the cardiac silhouette related to RV and RA dilation, frequently associated with a dilated caudal vena cava (see Figure 253-12, *I* and *J*).[1,15,125] Global heart enlargement can also be seen in cases of pericardial effusion and/or dilation of the left cavities.

Signs of CHF

As in dogs, radiographic signs of CHF include vascular enlargement, pulmonary edema, and/or pleural effusion. Thoracic radiographs usually show pleural effusion in cats with decompensated ARVC, whereas pulmonary edema is more commonly diagnosed than pleural effusion in cats with decompensated HCM (66% *vs* 34%; see Figure 253-12, *A-E*).[41] Unlike dogs, the perihilar to caudodorsal distribution of cardiogenic pulmonary edema does not predominate in cats. Pulmonary edema related to CHF is instead characterized by an increased opacity with a range of mixed patterns of variable distribution. In one study of 23 cats with CHF, diffuse (uniform or non-uniform) distribution was the most common, and all cats had evidence of a reticular or granular interstitial pattern.[171] Diffuse interstitial patterns may be similar to those associated with chronic bronchitis (see Figure 253-12, *C* and *D*), which can be confusing. A ventral distribution is also common (see Figure 253-12, *A*), mimicking pulmonary opacities related to bronchopneumonia, and leading, therefore, to another risk of misdiagnosis.[171]

Echocardiographic and Doppler Examination (Table 253-1 and ch. 104)

Two-Dimensional and M-Mode Echocardiography

Two-dimensional and M-mode echocardiography combined with Doppler examination (Videos 253-3, 253-4, 253-5, 253-6, 253-7, 253-8, 253-9, 253-10, 253-11, 253-12, 253-13, 253-14, 253-15, 253-16, 253-17, 253-18, and 253-19) is the most accurate non-invasive tool to identify myocardial diseases and assess myocardial phenotypes (HCM, RCM, DCM, or UCM). However, the following basic principles should be considered to limit the risk of misdiagnosis:

1. If technically possible, complete echocardiographic examinations should always be performed. For example, HCM is characterized by a wide spectrum of LVH patterns of variable severity. Multiple 2D imaging views (long-axis and short-axis views from the base to the apex) are therefore needed to confirm LVH and accurately assess its distribution and severity. The presence of spontaneous echo contrast, more specifically in the LA and LA appendage, should also be systematically and thoroughly sought to determine cats at high risk for ATE (see Videos 253-9, 253-10, 253-11 and 253-13).
2. Volume depletion can induce several changes, e.g., increased IVS and LVFW thicknesses, decreased LV diameters with possible end-systolic cavity obliteration, potentially leading to an erroneous HCM diagnosis.[172] Conversely, IV fluid administration can increase diastolic LV diameter, FS% or LA : Ao ratio above normal limits, with even the appearance of systolic heart murmurs. Thus, the hydration status and ongoing diuretic treatment should always be taken into account when interpreting echocardiographic measurements in cats.
3. The influence of the observer's experience on the variability of echocardiographic measurements in cats has been demonstrated, with a higher variability for less skilled observers and a frequent tendency of the latter to overestimate myocardial wall thicknesses (up to 2 mm), with a subsequent risk to "over-diagnose" HCM of which practitioners should be aware.[173]
4. A breed and body weight effect has been demonstrated for some echocardiographic measurements (e.g., end-diastolic LV diameter, LVFW and IVS thicknesses).[55,78] For example, the end-diastolic cut-off value commonly used to define LVH is ≥6 mm, but lower cut-offs (e.g., 5.0 mm and 5.5 mm) should be used in Sphynx cats weighing <4 kg and ≥4 kg, respectively.[55]
5. Left atrial measurement is of great importance as LAE is considered as the structural expression of chronicity and severity of diastolic dysfunction in HCM and RCM cats, with a high prognostic

value.[34,42,60,62,66] Guidelines on the optimal technique for LA size estimation in cats are currently not available.[66] Some cardiologists measure the LA diameter, parallel to the mitral valve plane, from the middle layer of the atrial septum to the blood-tissue interface of the posterior LA wall, and a diameter of <16 mm is considered as normal in most cats, with ranges between 16 mm to <20 mm, 20 mm to <25 mm, and >25 mm used to categorize LAE as mild, moderate, and severe, respectively.[66] The LA : Ao ratio is also commonly used to assess LAE (see Figure 253-9, *B*). In the author's lab, LA : Ao is preferentially measured at end-diastole (when LA is minimal) from 2D short-axis images, as it is highly reproducible, with no body weight, breed, or gender effect, and likely more closely reflects the LV end-diastolic pressure than early-systolic measurement (normal values = 0.5-1.2).[66,78,173] When measuring LA at end-systole or early diastole (first diastolic frame in which aortic valve closure is evident), a LA : Ao >1.5 is consistent with LAE (2D and M-mode methods, respectively).[174] Nevertheless, a systematic subjective evaluation of LA size as compared with other adjacent structures (aorta, atrial septum) is recommended.[66]

TABLE 253-1

Echocardiographic Diagnostic Criteria for the 4 Main Primary Cardiomyopathies (see also Figures 253-3, 253-6, and 253-8 through 253-11)*

		HYPERTROPHIC CARDIOMYOPATHY	RESTRICTIVE CARDIOMYOPATHY	DILATED CARDIOMYO
Echocardiography (2D and M-Mode)	Most common features & specific forms	• Diffuse or segmental, symmetric or asymmetric concentric LV hypertrophy with end-diastolic LVFW and/or IVS ≥ 6 mm† • Hypertrophy of papillary muscles • Possible obliteration of the LV cavity at end-systole • Normal to increased systolic function • LA dilation • *OHCM:* specific form with hypertrophy of the subaortic IVS and SAM of the mitral valve and/or the chordae tendineae resulting in dynamic LVOT obstruction	• Severe LA or biatrial enlargement • Normal LVFW and IVS thicknesses (or within upper reference ranges) • Normal FS% (or within lower reference ranges) • Focal or diffuse hyperechoic myocardial and endocardial areas (fibrosis) • *EMF:* specific form with bridging scar between the LVFW and the IVS and/or diffuse circumferential hyperechoic endocardial thickening with reduced LV cavity	• Increased and systol (≥12 mm)[1] diameters • Decreased (<30%)[1] • Thinning LVFW, the and/or pap muscles • Increased valve M-m point to se separation • LA enlarg
	Other potential findings	• RVMW hypertrophy • RA dilation • Myocardial infarction (thin and akinetic myocardial wall)	• Mildly decreased systolic function during disease progression • Mild to moderate LV hypertrophy in the case of severe myocardial fibrosis	RA and RV enl
Pulsed-Wave Doppler Mode	Mitral inflow	Relaxation pattern: inversed E : A ratio (<1), prolonged E DT‡ and IVRT (>60 ms)§,‖	Restrictive pattern: increased E : A ratio (>2) with increased E wave and decreased A wave, shortened	Variable patter depending filling press

			E DT‡ and IVRT (<34 ms)§,‖ 	loading con Restrictive p possible at e stages of the with high L. pressure
	Pulmonary vein inflow	Systolic-dominant flow pattern with a prominent AR wave (and Adur : ARdur ratio >1 if LV filling pressure still normal) 	S : D reversal (diastolic-dominant flow pattern) with a small or absent AR wave (and Adur : ARdur ratio <1) predictive of poor LA contraction 	
Mitral Annulus Pulsed-Wave Tissue-Doppler Imaging (TDI)		Low diastolic waves (with Ea <6 cm/s) but mitral E : Ea ratio normal (<12) if LV filling pressures not yet elevated (if elevated, E : Ea ≥12)[66] 	Low diastolic waves,[66] i.e., Ea <6 cm/s, with inversed (<1) or normal (>1) Ea : Aa ratio associated with E : Ea ratio >12 	
Color-Flow Doppler Mode		• Mitral regurgitation • *OHCM:* 2 turbulent systolic jets (aliased ejection jet in the LVOT and posterior-directed aliased jet of mitral regurgitation)		

• Mitral regurgitation • *EMF with bridging scar:* systolic obstruction of the mid LV cavity	Mild to moderate mitral and/or tricuspid regurgitation owing to dilation of the corresponding annulus	Mild to moderate tricuspid regurgitation			
Continuous-Wave Doppler Mode		• *OHCM:* late peaking ventricular outflow profiles (typical concave asymmetric shaped waveform) and high mitral regurgitation velocities • Doppler signs of pulmonary arterial hypertension	• Doppler signs of pulmonary arterial hypertension • *EMF with bridging scar:* increased blood flow velocity in the mid LV cavity	Doppler signs of pulmonary arterial hypertension	Moderate to severe increased velocity of tricuspid regurgitation owing to increased RV pressure
2D Color TDI Examination of Radial and Longitudinal Myocardial Motion		• Early signs of diastolic dysfunction (may be present before overt LV hypertrophy): inversed longitudinal E_{TDI} : A_{TDI} ratio (<1)[38,39] with PSC waves (>50% of cases) in the LVFW and the IVS, and prolonged longitudinal regional TDI IVRT; earlier IVS diastolic dysfunction for some cats (e.g., Maine Coon cats)[39] • Later stages: inversed radial E_{TDI} : A_{TDI} ratio (<1)[38,39] • Decreased S_{TDI} (mainly for the longitudinal LVFW and IVS motions)[38,39]	• Low radial and longitudinal diastolic LVFW and IVS waves (E_{TDI} and A_{TDI})[¶] • Low radial and longitudinal S_{TDI} in severe forms of the disease[¶]	• Decreased radial systolic MVG mainly due to decreased subendocardial S_{TDI}; radial and/or longitudinal PSC waves; myocardial regional dyssynchrony[¶] • Decreased longitudinal S_{TDI} in the LVFW and IVS[¶] • Less commonly: inversed radial and/or longitudinal E_{TDI} : A_{TDI} ratio[¶]	• Delayed, low (usually <3 cm/s) and/or biphasic S_{TDI} for the longitudinal motion of the RVMW at the base[¶] • ± Inversed E_{TDI} : A_{TDI} ratio (<1) of the RVMW at the base[¶]

[*] **Other ultrasound imaging features include signs of congestive heart failure (e.g., pleural and pericardial effusion, dilatation of the caudal vena cava and ascites), and spontaneous echo contrast or thrombus in dilated atrial chambers. The definitive diagnosis of primary cardiomyopathy should never be based solely on these imaging criteria. Secondary cardiomyopathies characterized by the same phenotype should always be excluded first.**

[†] Lower cut-off values should be used according to body weight and breeds.[55,78] See text for explanation.

[‡] Various reference intervals of E DT have been reported (most often <100 ms, but ranging from 45 to 192 ms, thus rendering this variable less reliable in clinical decision-making).[17,66]

[§] The lower and upper range of the reference interval for IVRT assessed in 100 healthy awake cats of various breeds was 34 ms and 56 ms, respectively,[78] with a lower minimal IVRT cut-off value (28 ms) in the Sphynx breed.[55] An upper IVRT cut-off of 60 ms is often used in practice.[66]

[‖] In late stages of hypertrophic cardiomyopathy, a restrictive pattern (E : A ratio >2 with shortened E DT and IVRT) preceded by a "pseudonormal" pattern may be observed whereas in early stages of restrictive cardiomyopathy, an abnormal relaxation mitral inflow

pattern (E : A ratio <1 with prolonged E DT and IVRT) may be found.

¶Unpublished data (Cardiology Unit of Alfort).

2D, Two-dimensional; *A,* peak velocity of late diastolic transmitral flow; *Aa,* peak velocity of late diastolic mitral annular motion as assessed by pulsed-wave TDI; *Adur,* duration of mitral A wave; *AR,* peak velocity of pulmonary vein flow reversal at atrial contraction; *ARdur,* duration of the AR wave; *ATDI,* peak myocardial velocity assessed by 2D color TDI during late diastole; *D,* peak velocity of diastolic pulmonary vein flow; *E,* peak velocity of early diastolic transmitral flow; *Ea,* peak velocity of early diastolic mitral annular motion as assessed by pulsed-wave TDI; *E DT,* mitral E wave deceleration time; *EMF,* endomyocardial form of restrictive cardiomyopathy; *ES,* end-systole; *ETDI,* peak myocardial velocity assessed by 2D color TDI during early diastole; *FS%,* fractional shortening of the left ventricle; *IVRT,* isovolumic relaxation time; *IVS,* interventricular septum; *LA,* left atrium; *LV,* left ventricle; *LVFW,* left ventricular free wall; *LVOT,* left ventricular outflow tract; *MVG,* myocardial velocity gradients assessed by 2D color TDI and defined as differences between subendocardial and subepicardial velocities (radial MVG) or between basal and apical velocities (longitudinal MVG); *OHCM,* obstructive hypertrophic cardiomyopathy; *PSC,* post-systolic contraction; *RA,* right atrium; *RV,* right ventricle; *RVMW,* right ventricular myocardial (free) wall; *S,* peak velocity of systolic pulmonary vein flow; *SAM,* systolic anterior motion; *STDI,* peak myocardial velocity assessed by 2D color TDI during systole.

Pulsed-Wave Doppler Mode

Pulsed-wave Doppler mode provides surrogate measures of LV diastolic function (e.g., mitral inflow velocities, deceleration time of early transmitral flow [E], isovolumic relaxation time) which are commonly used in cats with HCM and RCM together with mitral annular velocities assessed by pulsed-wave TDI (see Figure 253-9),[66,175] because early mitral annular velocity (Ea) and the E : Ea ratio are considered as surrogate measures of LV relaxation and filling pressure (see Table 253-1).[66] Lastly, **continuous-wave and color-flow Doppler modes** are used to assess dynamic LVOTO and atrioventricular valve regurgitations (see Table 253-1 and Figure 253-8).

Tissue Doppler Imaging for Assessment of Myocardial Motion (See Table 253-1)

Tissue Doppler imaging quantifies myocardial velocities in real time and offers a sensitive and quantitative analysis of regional myocardial function.[176,177] Several studies have demonstrated the ability of the 2D color TDI mode to analyze LV myocardial function in awake healthy cats[78,178,179] and in awake cats with HCM.[38,39] Other TDI modes (pulsed-wave mode and color M-mode) may also be used, although velocity measurements are then limited to a single segment or line, respectively, which decreases the diagnostic abilities of the technique.[63,64,72,180] Another drawback of the pulsed-wave TDI mode is the impossibility of changing the position and size of the region of interest within the myocardium with post-processing.

Radial and longitudinal diastolic LVFW and IVS motions assessed by 2D color TDI are similarly altered in HCM cats (Videos 253-20 and 253-21) and cats with LVH due to systemic arterial hypertension.[38] Longitudinal regional systolic dysfunction is an additional component of HCM-associated myocardial alteration characterized by a decrease in systolic myocardial velocities and gradients as well as TDI systolic strain despite normal or increased FS%.[38,181] Most importantly, the 2D color TDI mode has been shown to be more sensitive than conventional echocardiography in detecting regional myocardial dysfunction in both feline HCM and a feline HCM model before occurrence of or in the absence of overt myocardial hypertrophy.[38,39,65,142] However, it is important to emphasize that to optimize the abilities of TDI to detect early myocardial dysfunction, the 2D color TDI mode should be preferred for the above-mentioned reasons. Cats should not be sedated, and the use of summated early and late diastolic velocities should be avoided. As performed in the author's lab, calm animal handling in a relaxing environment with minimal restraint by performing ultrasound examinations with the cat standing is highly recommended to reduce stress, thus avoiding fusion of diastolic waves in about 90% of cats.[66,78] The TDI technique is also commonly used to differentiate constrictive pericarditis from RCM in humans.[182] However, TDI data on feline RCM are currently lacking.

Cardiac Magnetic Resonance Imaging

Cardiac magnetic resonance imaging (cMRI), which has emerged as a powerful tool in human patients with cardiomyopathies, providing data on cardiac volumes and function and on tissue characterization (fibrosis and fatty infiltration).[183] It has been used in Maine Coon cats with moderate to severe HCM, but no difference in the cMRI indices of diastolic function was found between control and HCM cats, whereas TDI could detect diastolic dysfunction in all HCM cats.[184-186]

Other Diagnostic Tools (Genetic Tests for HCM and Biomarkers)

Genetic Tests

Genetic tests (from blood or buccal swab samples) are available to identify the *MyBPC3*-A31P and *MyBPC3* R820W mutations for Maine Coon and Ragdoll cats, respectively, which is useful for breeding programs and to determine the risk of a given cat developing and dying from HCM.

Biomarkers (see ch. 246)[187-197]

Serum/plasma cardiac troponins I and T (cTnI and cTnT) are highly sensitive and specific indicators of acute myocardial cell injury, and should be assayed in cases of echocardiographic suspicion of myocardial infarction, a rare HCM complication.[31,133] Feline HCM is associated with elevated cTnI and cTnT, with cTnI revealing a higher percentage of cats with myocardial injury (67%) than cTnT (28%).[188-190] Both are also predictors of death, but with low sensitivity and specificity, and without correlation between concentration changes and LV thicknesses over time.[188] cTnI is higher in cats with CHF-related dyspnea than in cats with non-cardiac dyspnea, but with a marked overlap between the two.[191] Conversely, plasma N-terminal pro-B-type natriuretic peptide (NT-proBNP), which primarily increases in response to myocardial wall stress, distinguishes CHF from primary respiratory diseases in cats with respiratory signs with approximately 90% diagnostic accuracy, and its use in addition to conventional diagnostic tests significantly increases the accuracy of differential diagnosis for general practitioners.[194,195] NT-proBNP also reliably discriminates normal cats from cats with occult cardiomyopathy (specificity and sensitivity of 100% and 70.8%, respectively, for a >99 pmol/L cut-off, with a positive correlation between NT-proBNP and LV thicknesses or LA : Ao ratio).[196,197]

Management of Feline Primary Cardiomyopathies

Medical Therapy of Feline Cardiomyopathies: An Attempt at an Evidence-Based Approach

Both evidence-based human and veterinary medicine rely on current evidence,[198-201] and ranking such evidence after critical appraisal of the literature is pivotal.[202-205] Different systems have been developed to stratify evidence in human medicine.[206] As few clinical trials are reported in cardiac cats, a simplified 3-level classification of evidence strength seems more suitable in this species:[207] **level 1** (i.e., best evidence), based on data from at least one prospective randomized controlled clinical trial (PRCT); **level 2,** based on data from at least one well-designed clinical trial without randomization, cohort or case-controlled analytic studies, studies using acceptable laboratory models or simulations in target species, or dramatic results in uncontrolled experiments; and **level 3,** based on opinions of respected authorities from their clinical experience, descriptive studies (case reports, cases series), studies in other species, pathophysiologic justification, or reports of expert committees. The American College of Cardiology (ACC)/AHA classification used in the consensus statement on chronic canine valvular disease may also be applied to feline heart diseases to clarify the different therapeutic situations:[208,209] **stage A** corresponds to cats at risk for developing heart disease but with no currently identifiable structural heart disease (no treatment indicated, as no disease present); **stage B** includes cats with structural heart disease, but that have never developed clinical signs caused by the latter; **stage C** refers to cats with past or current mild to moderate clinical signs (e.g., dyspnea due to CHF) related to a structural heart disease; and lastly **stage D** applies to cats with severe clinical signs due to end-stage heart disease.

Medical Therapy of Feline Hypertrophic Cardiomyopathy (Stages B to D; Table 253-2)

Therapeutic Goals: Main Drug Classes

The general goal in stages C and D is to relieve clinical signs or prevent their recurrence in order to improve quality of life and survival. Ideally, the specific therapeutic goal should be to decrease myocardial lesions (remodeling and ischemia) and counteract the main pathophysiological events (diastolic dysfunction and dynamic LVOTO), to improve LV filling and increase cardiac output. Beta-blockers, ivabradine, calcium channel blockers, ACE inhibitors, and spironolactone may be indicated for this purpose. The potentially

beneficial effects of beta-blockers on HCM are mainly attributable to their negative chronotropic and inotropic effects, with subsequent prolongation of the diastolic phase and reduced LVOTO, respectively, both resulting in reduced myocardial oxygen demand (i.e., reduced ischemia), associated with antiarrhythmic properties.[210-212] Atenolol, a beta 1–selective beta-blocker, is usually preferred to non-selective agents (e.g., propranolol) because of the reduced risk of bronchospasm.[5] The potentially beneficial effect of ivabradine relies on its negative chronotropic effect through inhibition of the I_f current in the sinoatrial node (see ch. 248).[213,214] Ivabradine improves diastolic function in healthy cats (level 1 evidence),[61] but its benefit in feline HCM needs further assessment. The rationale for using calcium channel blockers includes negative chronotropic and inotropic effects, direct LV relaxation improvement, coronary vasodilation, and antiarrhythmic properties.[210,215-219] Owing to their potent vasodilatory effects, dihydropyridine calcium channel blockers (e.g., amlodipine) may be deleterious in human OHCM,[210] and should also be avoided in feline OHCM (level 3 evidence). Diltiazem (a benzothiazepine calcium channel blocker) is more commonly used in cats than phenylalkylamine calcium channel blockers (verapamil), because of its less potent negative inotropic and vasodilatory effects.[1,5,218,219] Lastly, there are various level 3 evidence data for using antagonists of the renin-angiotensin-aldosterone system (RAAS) (e.g., ACE inhibitors and spironolactone) in feline HCM. Angiotensin II and aldosterone can induce myocardial hypertrophy and fibrosis *in vitro* and *in vivo*, and in LVH animal models, spironolactone and angiotensin II blockers may reverse such lesions and improve diastolic function, with additional vasodilatory effects for ACE inhibitors.[220-226]

TABLE 253-2

Drugs Most Commonly Used for Treatment of Feline Cardiomyopathies*

DRUGS		PHARMACOLOGICAL ACTION OF INTEREST	REPORTED ROUTES AND DOSAGES	INDICATIONS	CONTRAI
Aldosterone Antagonist	***Spironolactone***	Selective aldosterone receptor antagonist, thus potassium-sparing diuretic action and potential reduction of cardiac remodeling and hypertrophy	≤2 mg/kg PO q 24 h or 0.5 to 1 mg/kg PO q 12 h	CHF refractory to standard therapy	Hyperkale
Drugs Used as Antiarrhythmic Agents	***Digoxin***	Antiarrhythmic properties with mild positive inotropic action	0.007 mg/kg PO q 24 h q 2 d or 0.03 mg/cat q 24 h each day (cats > 4 kg) or q 2 d (cats < 4 kg)	• Supraventricular tachyarrhythmias including atrial fibrillation • Myocardial failure (e.g., DCM)	Ventricula tachya
	Esmolol	Short-acting beta-blocker	50-200 mcg/kg/min IV CRI or 50 to 200 (up to 500) mcg/kg/min IV bolus every 5 min	Acute management of supraventricular and ventricular tachyarrhythmias refractory to lidocaine	• Hypo • Sever failur

	Ivabradine	Selective funny current (I_f) inhibitor in the sinus node (negative chronotropic effects)	0.3 mg/kg PO q 12 h	CM with sinus tachycardia	Bradycard
	Lidocaine	Class Ib antiarrhythmic	10-30 mcg/kg/min IV CRI or 0.2-0.75 mg/kg slow bolus (over 5 minutes), repeat 1 to 2 times only	Initial emergency treatment of ventricular tachyarrhythmias	• Hypo • Sever failur
	Sotalol	Beta-blocker with class III antiarrhythmic properties	10 mg/cat PO q 12 h or 2 mg/kg PO q 12 h	Chronic oral treatment of ventricular tachyarrhythmias	• Hypo • Sever failur
Antiplatelet Drugs	***Aspirin***	Nonsteroidal anti-inflammatory drug with inhibition effect on platelet aggregation	5 to 81 mg/cat PO q 3 d or 5 mg/cat to 5 mg/kg q 3 d administered with food	Prevention of ATE: • Mild to moderate LAE and/or spontaneous echo contrast at echocardiographic examination • History of ATE	• Dehy • Hypo • Gastr signs • Bleed
	Clopidogrel	Thienopyridine derivative (inhibitor effect on platelet aggregation induced by adenosine diphosphate, ADP)	18.75 mg/cat PO q 24 h		• Gastr symp • Bleed
ACE Inhibitors	***Benazepril***	• RAAS inhibition; thus venous and arterial vasodilatory effects (reduced ventricular preload and afterload & decreased	0.25 to 0.5 mg/kg PO q 24 h to q 12 h	• CHF in association with furosemide • Myocardial remodeling associated with HCM and RCM	• Dehy • Acut injur • Hypo
	Enalapril		0.25 to 0.5 mg/kg PO q 24 h to q 12 h each day or q 2 d		
	Imidapril		0.25 to 0.5 mg/kg PO		

		myocardial ischemia), decreased water and Na retention, potential reduction of cardiac remodeling and hypertrophy • Renal protective effect	q 24 h (increase the dose if given with food)		
	Ramipril		0.25 to 0.5 mg/kg PO q 24 h		
Beta-Blocker (Other Than Esmolol and Sotalol; see above)	*Atenolol*	Beta-blocker (with relatively selective beta-1 antagonist activity): • Improves diastolic function through negative inotropic (resulting also in decreased LVOTO) and chronotropic effects • Antiarrhythmic properties (supraventricular and ventricular tachyarrhythmias)	6.25 to 12.5 mg/cat PO q 24 h to q 12 h	Mainly indicated in cats with stage B OHCM or with stage B HCM with ventricular tachyarrhythmias	Severe my
Calcium Channel Blockers (Benzothiazepine)	*Diltiazem*	• Improves diastolic function through negative inotropic and chronotropic effects, and dilation of coronary arteries • Directly improves relaxation • Antiarrhythmic properties	1 to 3 mg/kg PO q 8 h For emergency treatment of supraventricular arrhythmias: 0.1 to 0.2 mg/kg IV bolus and then 2-6 mcg/kg/min IV	• Diastolic dysfunction (HCM, RCM) • Supraventricular arrhythmias	• Brad • AV b • Hyp • Hepa • Myo (e.g.,
Diuretics	*Furosemide*	Highly efficient diuretic effect (loop diuretic)	Emergency: 1 to 4 mg/kg IV/IM/SC to be adapted according to RR	CHF (first-line treatment)	Stage B ca with n cavitie

			(maximum 8 mg/kg/day) Chronic therapy: usually 0.5-2 mg/kg PO q 24 h to q 8 h		
	Hydrochlorothiazide	Diuretic effect	1 to 2 mg/kg PO q 24 h to q 12 h	CHF refractory to furosemide	Same as al
Inotropes	***Dobutamine***	Adrenergic agonist (positive inotropic properties)	1-5 mcg/kg/min CRI	Acute management of myocardial failure	Severe ver tachya
	Pimobendan	Inodilator (calcium sensitizer and PDE III inhibitor)	0.1-0.25 mg/kg PO q 12 h 1 h before food	• DCM • Systolic dysfunction as complication of any other CM except OHCM • CHF refractory to standard therapy	OHCM
Sedative/Analgesic Agent	***Butorphanol***	Synthetically-derived opiate Kappa agonist-Mu opioid antagonist	0.1-0.4 mg/kg slow IV or IM (repeat if needed every 1 to 4 hours)	Decreased stress (acute CHF)	Depressed
Taurine		2-aminoethanesulfonic acid (sulfonic acid)	250 mg/cat PO q 12 h	• Taurine-deficient myocardial failure • DCM • Systolic dysfunction as complication of any other CM	

*For treatment of arterial thromboembolism; see ch. 256.

ACE, Angiotensin converting enzyme; *ARVC,* arrhythmogenic right ventricular cardiomyopathy; *ATE,* arterial thromboembolism; *AV,* atrioventricular block; *CHF,* congestive heart failure; *CM,* cardiomyopathy; *CRI,* constant rate infusion; *DCM,* dilated cardiomyopathy; *GI,* gastrointestinal; *HCM,* hypertrophic cardiomyopathy; *IM,* intramuscular route; *IV,* intravenous route; *LAE,* left atrial enlargement; *LVOTO,* left ventricular outflow tract obstruction; *OHCM,* obstructive HCM; *PDE,* phosphodiesterase; *PO,* orally; *q 2 d,* every 2 days; *q 3 d,* every 3 days; *RAAS,* renin-angiotensin-aldosterone system; *RCM,* restrictive cardiomyopathy; *RR,* respiratory rate; *SC,* subcutaneous route.

Stage B

Asymptomatic HCM cats may live years and most (80%) die from non-cardiac causes.[37,41,42] Thus, as in people, prophylactic therapy to prevent or delay onset of clinical signs remains a subject of debate. According to the ACC/ESC Clinical Expert Consensus on human HCM, some cases at particularly high risk of sudden death should receive medical treatment at that stage.[210] If this document is applied to cats (level 3 evidence), it would be prudent to similarly consider "risk categories" of cats with stage B HCM that could require medical treatment (e.g., homozygous mutated Ragdoll or Maine Coon cats, cats with ventricular tachyarrhythmias, severe LVOTO or LVH, and cats with LAE [a risk factor of cardiac death and ATE,[21,41,42,60] even at stage B[62]]). However, data supporting the clinical or functional benefit of such early treatment are currently lacking. A prospective, observational, open-label, clinical cohort study failed to demonstrate an effect of atenolol on 5-year survival in cats with stage B HCM (level 1 evidence).[62] Nor did atenolol decrease

biomarkers in 6 Maine Coon cats with stage B HCM, thus suggesting a lack of beneficial effect on myocardial ischemia and myocyte death (level 2 evidence).[227] Lastly, atenolol decreases LA function and flow velocity in the left auricle of healthy cats, two known risk factors for LAE and ATE, raising the issue of potential deleterious effects if used in feline HCM.[61] Thus, if the treatment option is chosen rather than "watchful waiting," many clinicians now favor calcium channel blockers or RAAS antagonists (mainly ACE inhibitors) over atenolol in stage B feline HCM, except in cases of severe LVOTO and/or ventricular tachyarrhythmias. However, no benefit on survival or onset of clinical signs has been evidenced for either therapeutic class, and their effects on diastolic function remain unclear. A double-blinded randomized prospective study in cats with stage B HCM (level 1 evidence), revealed an increased mitral E : A ratio in the benazepril group but not the diltiazem group; but without any difference between the two at the end of the study.[228] Ramipril or spironolactone did not improve diastolic function in Maine Coon cats with stage B HCM assessed by a hybrid pulsed-wave TDI index in a non-myocardial location (based on Ea for some cats, summated Ea and late annular velocities for others).[186,229] Further studies are therefore required to accurately assess the effect of RAAS antagonists on myocardial function in occult HCM, using various non-hybrid diastolic indices from different imaging techniques (conventional Doppler combined with pulsed-wave TDI as well as 2D color TDI applied in several myocardial segments) in cats of various breeds. In one report, ulcerative facial dermatitis was found in 31% cats about 2.5 months after starting spironolactone treatment (2 mg/kg PO q 12 h).[229] This adverse skin reaction (level 1 evidence),[229] reversible after drug discontinuation, suggests that lower spironolactone doses should be used in cats (≤2 mg/kg PO q 24 h, level 3 evidence). Cats with LAE or spontaneous echo contrast could also benefit from antiplatelet therapy, although its prophylactic efficacy at that stage has not been demonstrated.

Stage C

The first-line agent for controlling CHF signs is furosemide (loop diuretic).[230,231] In acute CHF, hospital-based therapy typically includes parenteral administration of furosemide, oxygen (see ch. 131), sedation to minimize stress (e.g., butorphanol; see ch. 138), thoracocentesis in cats with severe pleural effusion (see ch. 102), and cage rest (level 3 evidence).[231] As furosemide has potential deleterious effects on renal perfusion and electrolytes, the initial emergency dosage should be reduced as soon as CHF signs have improved, with re-evaluation of renal parameters and electrolytes (Na, K) within the first week of discharge for outpatients.[231] Once initiated, furosemide is maintained at the lowest effective dose every day for the rest of the cat's life (q 8-24 h) or every 2 to 3 days in very rare cases of CHF related to stressful events. Antiplatelet drugs are also prescribed owing to the risk of ATE (see ch. 256). A "specific" treatment (most commonly ACE inhibitors)[232] is usually added to furosemide, although beneficial effects on long-term survival warrant further investigation. As shown with enalapril,[233] diltiazem therapy in cats with stage C HCM was associated with improved clinical signs and several imaging variables (e.g., isovolumic relaxation time), with 94% survival at 6 months in a non-placebo controlled prospective study (level 2 evidence).[218] In a non-blinded non-placebo prospective trial, addition of benazepril to long-acting diltiazem was well tolerated with some beneficial effects on clinical signs and LVH (level 2 evidence), but no reported survival data.[234] Lastly, the interim results of the Multicenter Feline Chronic Heart Failure Study (level 1 evidence) for cats with CHF treated with furosemide (including 80% HCM cats), showed that survival rate was highest in those receiving enalapril (median survival = 920 days), similar in cats treated with diltiazem (227 days) or placebo (235 days), and lowest for the atenolol group (72 days).[235] However, the differences between treatment groups were not statistically significant, partly due to the few cats/group (personal communication from Dr. Philip Fox).

Stage D

In cases of medical-refractory pleural effusion, periodic pleurocentesis is needed (see ch. 102). Spironolactone can also be used (level 3 evidence). In some severe cases, the daily furosemide dosage can be greatly increased (e.g., cumulative daily dose of 6-12 mg/kg or even more for some authors) if the cats continue to eat and drink (level 3 evidence), although dehydration and azotemia are common at these dosage and concomitant ACE inhibitors should be used with much caution.[232,236] Another diuretic (hydrochlorothiazide) can be cautiously added to furosemide (level 3 evidence).[232] Lastly, pimobendan, a potent inodilator licensed for the treatment of canine CHF, can be prescribed in cats with refractory CHF and/or echocardiographically identified LV systolic dysfunction and renal insufficiency, at similar dosages as in dogs (level 2 evidence), although data from PRCT are still lacking at the time of writing.[231,237-240] Pimobendan is not recommended in OHCM

owing to its positive inotropic action potentially worsening LVOTO with subsequent systemic hypotension, as already reported (level 3 evidence).[239] Because of the potential cardiac remodeling effects of pimobendan shown in other species (level 3 evidence for cats),[241-243] an echocardiographic follow-up of treated HCM cats is recommended.

Other Primary Cardiomyopathies

No PRCT has been specifically conducted in cats with RCM. Management of feline RCM and HCM is therefore similar, as both diseases are pathophysiologically characterized by diastolic dysfunction with subsequent CHF (level 3 evidence).

Owing to the limitations regarding identification of cats with taurine deficiency–induced myocardial failure, taurine supplementation is recommended in all cats with echocardiographic DCM phenotype (level 1 evidence), regardless of blood/plasma taurine concentrations (see Box 253-1).[92,93,96,105] Positive inotropic therapy is also indicated whereas negative inotropic agents (e.g., diltiazem, atenolol) should be avoided. Digoxin is a weak inotrope agent, and therefore it is mainly prescribed for its antiarrhythmic properties (in cases of supraventricular tachycardia).[244] Pimobendan is therefore preferred for treating DCM cats. Added to standard therapy (furosemide, taurine, ACE inhibitor, with or without digoxin) pimobendan improves survival in cats with non-taurine responsive DCM although the prognosis remains poor (median survival time = 49 days, level 2 evidence).[105]

Management of feline ARVC is similar to that of DCM (level 3 evidence). Antiplatelet therapy is usually prescribed due to the risk of ATE related to marked RA enlargement. Refractory cases of symptomatic ventricular tachycardia can be treated with lidocaine IV or esmolol IV. Sotalol may be prescribed for long-term oral treatment but its negative inotropic effects can be problematic.[125,219]

Management of feline UCM is aimed at controlling CHF if present and also based on the predominant myocardial phenotype (i.e., medical treatment of predominant diastolic or systolic dysfunction being similar to that of HCM or DCM, respectively [level 3 evidence]).

Acknowledgments

The author is grateful to the whole team at the Alfort Cardiology Unit, more specifically Dr. Vassiliki Gouni, Dr. Cécile Damoiseaux, Dr. Charlotte Misbach, Dr. Emilie Trehiou-Sechi, and Prof. Jean-Louis Pouchelon, and also to Prof. Renaud Tissier (INSERM U955 and Pharmacology-Toxicology Unit, National Veterinary School of Alfort), Dr. Philip Fox (Animal Medical Center, NYC, USA), Prof. Jean-Jacques Fontaine and Dr. Nathalie Cordonnier (Pathology Department, National Veterinary School of Alfort,) Dr. Marc Simon (Paris), Dr. Pascaline Pey (Diagnostic Imaging Department, National Veterinary School of Alfort), Dr. Patrick Verwaerde (National Veterinary School of Toulouse), Mrs. Diana Warwick, and Dr. Charlotte Taton (illustrator) for their precious help in compiling this chapter. The author would also like to sincerely thank Drs. Stephen Ettinger and Etienne Côté for their confidence and great honor in requesting her to contribute to the 8th edition of the *Textbook of Veterinary Internal Medicine.*

CHAPTER 254

Pericardial Diseases

Kristin MacDonald

Client Information Sheet: Pericardial Effusion

Introduction

Pericardial effusion is the most common pericardial abnormality in dogs and cats. When it causes cardiac tamponade, it is a common cause of right-sided congestive heart failure in dogs, yet the treatment is very different from most other causes of right heart failure. Pericardial effusion is a multi-etiologic disorder, including infectious, inflammatory, and neoplastic causes, with a wide spectrum of prognoses ranging from good to grave.[2] Congenital defects including peritoneal pericardial diaphragmatic hernia (PPDH), pericardial defects, or pericardial cysts are less commonly diagnosed in dogs and cats. Constrictive pericarditis is an uncommon acquired pericardial disease in dogs and is extremely rare in cats.

Pericardial Anatomy and Physiology

The pericardium is formed by two membranes: an outer, fibrous, parietal membrane, and an inner, serous, visceral membrane that forms the epicardium. The base of the fibrous pericardium is continued on the great arteries and veins that leave and enter the heart and blends with the adventitia of these vessels. The apex of the fibrous pericardium is continued to the ventral part of the diaphragm as the phrenicopericardiac ligament or caudomedial mediastinal reflection.[7-9] The parietal and visceral membranes join at the cardiac base, and the space around the heart between the two membranes is the pericardial cavity. A small volume of fluid (0.3-1 mL) is normally present in the pericardial cavity, and it serves to lessen friction between the two membranes.

The parietal membrane is composed of mesothelial cells and connective tissue including compactly arranged collagen fibers in a multi-layered orientation, interspersed with less abundant elastin fibers. This structure provides fibroelastic properties, so that it is easily distensible at low volumes but less distensible with large volumes of pericardial fluid. In the presence of chronic increases in pericardial volume, the pericardium stretches to increase the intrapericardial volume and thereby shift to a more distensible, compliant part of the pressure volume curve (see Pericardial Effusion—Pathophysiology, below). The intrapericardial pressure is normally subatmospheric through most of the cardiac cycle (with a nadir at ventricular ejection), and parallels the intrapleural pressure. The visceral pericardium is composed of mesothelial cells that overlie connective tissue and elastin.

Although the pericardium has several functions for the heart, it is not a vital requirement to maintain normal cardiovascular function, and surgical removal or congenital agenesis is not associated with deleterious effects. The pericardium functions to provide restraint to prohibit cardiac overdilation, protects the heart from infection and forming adhesions to surrounding tissue, maintains the heart in a fixed position within the thorax, regulates the interrelationship between stroke volumes of the two ventricles, and prevents tricuspid regurgitation when ventricular diastolic pressure is increased. The lubricant effect of pericardial fluid allows the heart to move easily within the pericardial sac during systole and diastole.[10]

Congenital Pericardial Disorders

Peritoneopericardial Diaphragmatic Hernia (PPDH)

A PPDH is a congenital defect that causes a communication between the pericardial and peritoneal cavities, allowing abdominal organs to enter the pericardial space while keeping the pleural space intact. A PPDH

forms when there is abnormal embryologic development of the ventral aspect of the diaphragm due to abnormal fusion of the septum transversum with the pleuroperitoneal folds.[3] The most commonly herniated organs are liver and gallbladder, followed by small intestine, omentum, spleen, stomach, and omentum.[4-6] PPDH is an uncommon defect, with prevalence ranging from 0.02 to 0.15% in dogs and 0.05 to 0.59% in cats.[5-7] Medium- and long-haired cats are overrepresented (24/31 cats in one study), and predisposed breeds include Maine Coon cats (prevalence 12.9%), Himalayans (2.2%), domestic long hair cats (2.2%), and Persians (1%).[6] Weimaraner dogs also are predisposed.[5,6]

Clinical Signs

Clinical signs with PPDH vary depending on the herniated organs or tissue. Approximately half of dogs and cats in a case series had no clinical signs and PPDH was an incidental finding.[5] In symptomatic animals, signs referable to the respiratory and gastrointestinal (GI) systems predominate: tachypnea, respiratory distress, vomiting, and anorexia are common. Other signs can include lethargy, weight loss, diarrhea, exercise intolerance, and coughing.

Diagnosis

Physical examination abnormalities in affected dogs and cats most frequently include muffled heart sounds, a displaced or absent apical beat, muffled lung sounds, tachypnea, and thin body condition. Other less common abnormalities include presence of a heart murmur, fever, thoracic borborygmus, an empty abdomen on palpation, or a full, painful abdomen on palpation.[5,6,10] Common associated abnormalities in dogs include sternal malformations (incomplete xiphoid; pectus excavatum; and absent, deformed, or fused sternebrae), cranioventral abdominal hernias, and other congenital heart defects (pulmonic stenosis, ventricular septal defect). Associated abnormalities in cats are less common and usually are limited to sternal malformations and cranioventral abdominal hernias.

Thoracic radiographs typically are diagnostic for PPDH (Figure 254-1).[5,10] Abnormalities consistent with PPDH include increased size of the cardiac silhouette and a loss of distinction between the heart and the diaphragm, with superimposed soft tissue opacity. The cardiac silhouette often contains gas-filled bowel loops and structures of differing radiopacities (see Figure 254-1). The hepatic silhouette can be small or absent in the cranial abdomen, causing a cranial shift in the gastric axis. Various other organs (small intestine, spleen) can be absent from the abdomen. In cats, a dorsal peritoneopericardial mesothelial remnant, which represents the dorsal border of the hernia, may be recognized on the lateral view as a curvilinear opacity between the cardiac silhouette and the diaphragm, either ventral to, or superimposed over, the caudal vena cava.[4-6] The use of standard thoracic radiographs and echocardiography have eliminated the need for performing upper GI barium series to diagnose PPDHs.

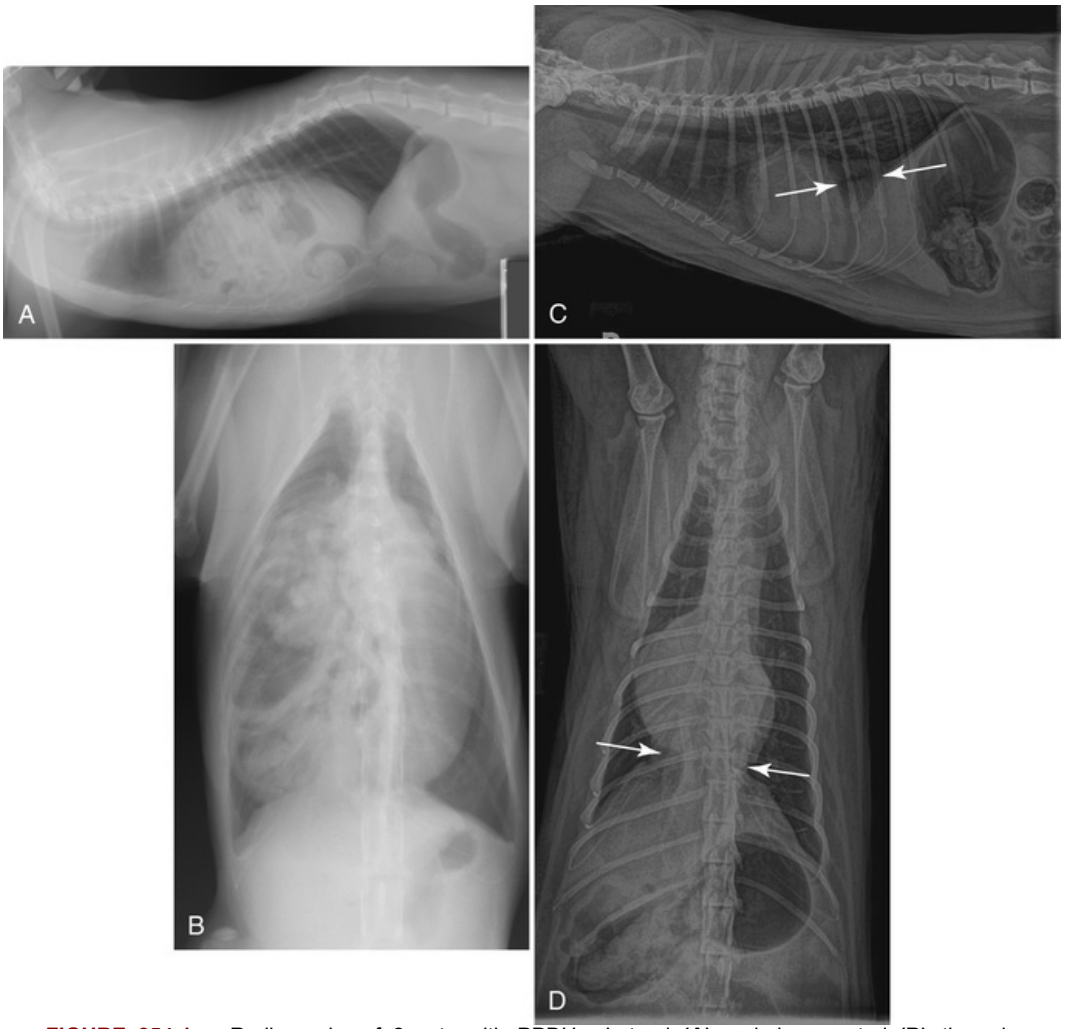

FIGURE 254-1 Radiographs of 2 cats with PPDHs. Lateral **(A)** and dorsoventral **(B)** thoracic radiographs of a cat with a large PPDH. The cardiac silhouette is severely enlarged, and the pericardial space contains differential opacities and gas-filled bowel loops. Most of the abdominal contents, including the liver and small intestines, are displaced into the pericardial sac. Lateral **(C)** and dorsoventral **(D)** radiographs of a different cat with PPDH. While abnormalities are less striking, the lateral view clearly shows a persistence of the dorsal mesothelial remnant (arrows).

Echocardiography serves as a confirmatory test for the diagnosis of PPDH, where abdominal organs (most commonly liver) can be visualized adjacent to the heart within the pericardial space (Figure 254-2; Video 254-1). An important differential diagnosis is consolidation (hepatization) of the accessory lung lobe; thoracic radiographic findings help differentiate this from PPDH. Mild pericardial effusion can be present, but severe pericardial effusion and cardiac tamponade are uncommon. Electrocardiograms can be normal or show low-voltage complexes and abnormal orientation of the mean electrical axis. Complete blood count and serum biochemistry profile results often are unremarkable, and the most common abnormalities include elevated serum alanine aminotransferase activity in dogs (n = 10/26 dogs), and an elevated serum calcium concentration in cats (9/29).[6]

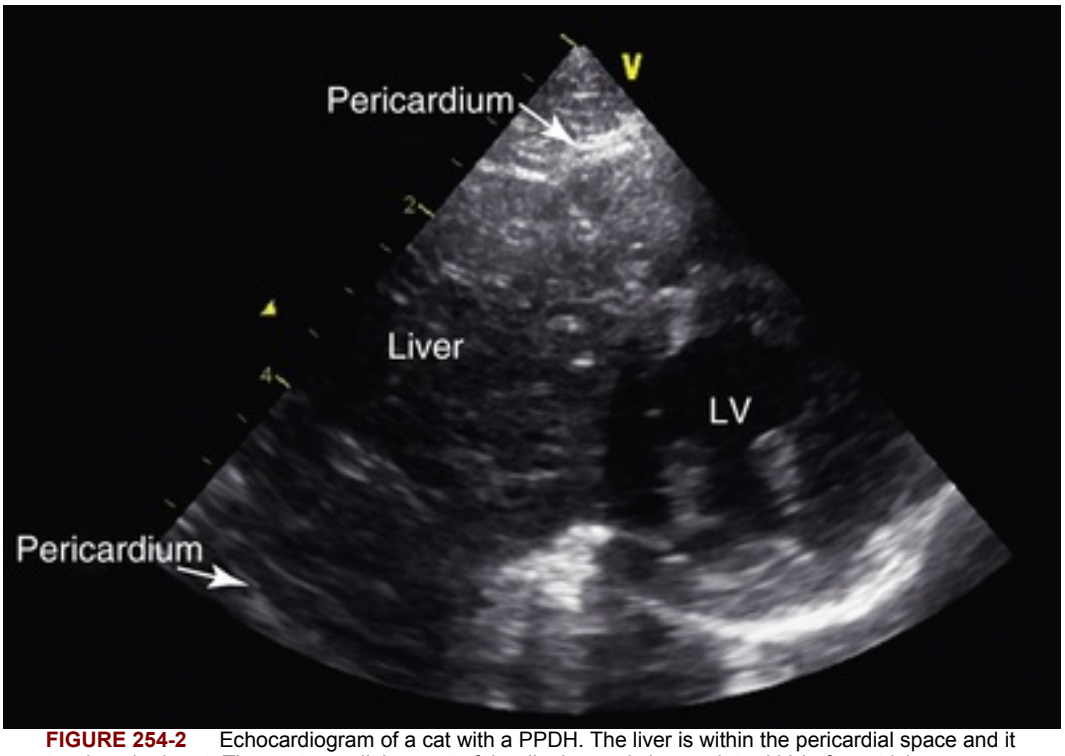

FIGURE 254-2 Echocardiogram of a cat with a PPDH. The liver is within the pericardial space and it touches the heart. The ventromedial aspect of the diaphragm is incomplete. *LV,* Left ventricle.

Treatment

Surgical correction of the PPDH is indicated for animals showing clinical signs (Figure 254-3). Presence of clinical signs or small intestines within the pericardial space was significantly associated with surgical treatment in a group of 34 dogs and cats with PPDH. Prognosis with successful surgery is excellent, with postoperative mortality rates ranging from 5-14%.[6,10] Intraoperative complications arose in 38% of 37 cats in one case series, and postoperative complications within 3 days of surgery and between 3 days-6 months were seen in 78% and 41% of cats, respectively, most being classified as mild.[10] Resolution of clinical signs is seen in 75-85% of cases with surgical repair, yet one case series reported no difference in long-term survival between surgically and nonsurgically treated animals.[5,10] Adhesions between herniated organs and the pericardium can complicate or preclude PPDH reduction in older animals. Consequently, in an asymptomatic older animal where PPDH is an incidental finding, it may be prudent to recommend continued observation rather than surgical repair.

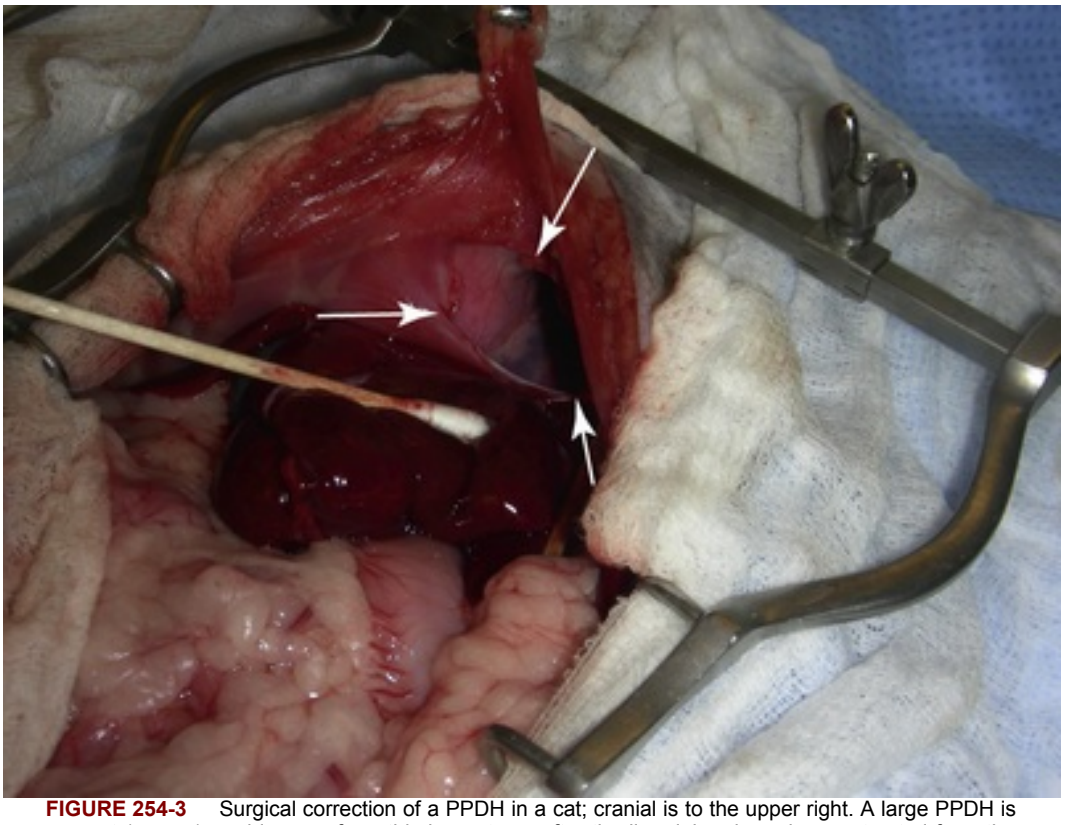

FIGURE 254-3 Surgical correction of a PPDH in a cat; cranial is to the upper right. A large PPDH is present (arrows), and is seen from this laparotomy after the liver lobes have been retracted from the pericardial space into the abdominal cavity.

Pericardial Cysts

Pericardial cysts are rare in dogs and have not been reported in cats. In humans, pericardial cysts may arise from anomalous pericardial development, lymphatic elements, bronchial cysts, and teratomas. In dogs, pericardial cysts appear to resemble cystic hematomas. Since they are mostly seen in young dogs, this suggests a congenital or developmental anomaly. Characteristic pathologic abnormalities include encapsulation of cysts within adipose tissue, with extensive hemorrhage and necrosis, or organizing cystic hematomas. In some cases, the benign intrapericardial cyst is associated with a small PPDH. In other cases, the cyst is attached by a pedicle to the apex of the pericardium; the pedicle results from prenatal herniation of omentum or falciform fat from the peritoneum into the pericardium and subsequent closure of a PPDH. Vascular obstruction of the herniated tissue and repeated trauma from the beating heart lead to cyst formation.[19,20] Intrapericardial cysts cause cardiac tamponade by direct cardiac compression and associated pericardial effusion in some cases. Treatment involves surgical removal of the cyst and its associated pedicle, pericardectomy, and herniorrhaphy in cases with a PPDH.

Pericardial Defects

Pericardial defects are rare in dogs and have not been reported in cats. They can be congenital or acquired secondary to trauma, and range from partial to complete absence of the pericardium.[11] Left- and right-sided defects appear to be equally represented based on literature review of 15 dogs (left-sided, n = 7; right-sided, n = 6; left- and right-sided, n = 1; and complete absence of pericardium, n = 1).[11-14] Until recently, most cases were discovered incidentally on necropsy or during thoracic surgery for unrelated causes. Herniation with incarceration of the left or right auricle can lead to severe clinical consequences of collapse or syncope.[13,14]

The most common diagnostic finding in pericardial defects is an unusual shape of the cardiac silhouette on thoracic radiographs, due to an abnormal bulge of the left or right auricle. This bulge can be mistaken for a cardiac mass or atrial dilation secondary to atrioventricular (AV) valve disease. Echocardiography is necessary to distinguish the cause of the abnormal cardiac silhouette, and it can show disproportionate

dilation of the auricle compared to the atrium and possible constriction of the atrium/auricle by a ring-like fibrotic orifice of the pericardial defect. Treatment of pericardial defects in symptomatic animals includes either pericardial repair if the defect is small, or pericardectomy for larger defects.

Acquired Pericardial Disorders

Pericardial Effusion

Pericardial effusion is the most common pericardial disease in dogs and cats, and, overall, is a fairly common acquired cardiac condition in dogs. Prevalence has been reported to be 0.43% (1 dog/233 cases) for dogs examined at a referral veterinary hospital, and it accounts for approximately 7% of dogs with clinical signs of cardiac disease.[1] It is a multiple-etiologic disorder, with a wide spectrum of prognoses that range from good to grave depending on the cause.[2] The most common causes of pericardial effusion in dogs include hemangiosarcoma (HSA; see also ch. 347), idiopathic pericarditis, mesothelioma, and chemodectoma.[3-5] Determination of the cause of pericardial effusion provides valuable information regarding appropriate treatment, clinical progression, and prognosis.

Pathophysiology

Pericardial effusion increases the intrapericardial pressure, which is transmitted equally to all cardiac chambers during diastole and systole. However, the thinner-walled, more compliant right heart bears the brunt of the effects of increased intrapericardial pressure, and this leads to cardiac tamponade. Cardiac tamponade is defined as the impairment of ventricular filling due to accumulation of fluid within the pericardial space, leading to reduction in stroke volume and cardiac output. Cardiac tamponade has different pathophysiologic characteristics based on the rate of increase in the intrapericardial pressure, and is divided into acute cardiac tamponade and chronic cardiac tamponade.

In acute cardiac tamponade, rapid accumulation of pericardial effusion leads to rapid increase in the intrapericardial pressure, at volumes as low as 50-150 mL (for a 20 kg dog) (E-Figure 254-4).[15] If additional fluid accumulates chronically, it stretches the pericardium to accommodate several hundred milliliters of fluid without clinically relevant increases in intrapericardial pressure (Figure 254-5).[16] Collapse of the right atrium and ventricle increases right atrial and ventricular diastolic pressures. Diastolic collapse of the right heart decreases right ventricular filling and right ventricular stroke volume, thereby reducing venous return to the left heart. Left ventricular stroke volume is decreased (seen as decreased LV diastolic diameter on echocardiography), which decreases cardiac output and causes arterial hypotension and cardiogenic shock. Diastolic collapse of the right atrial and ventricular chambers occurs early in this process, typically when the cardiac output has decreased by approximately 20%, and prior to a reduction in arterial blood pressure.[17] In an experimental canine model of acute cardiac tamponade, mean arterial pressure was maintained until intrapericardial volume had increased to approximately 100 mL, and intrapericardial pressure was approximately 10 mm Hg. Left ventricular systolic function is maintained in acute cardiac tamponade and is not the cause of the arterial hypotension; rather, decreased left ventricular diastolic filling is the cause of the low cardiac output.[18] Increased sympathetic activity in response to arterial hypotension in cardiac tamponade is differentially controlled: Based on an experimental canine model of cardiac tamponade, it is increased to the heart, adrenal gland, and liver, but is inhibited to the kidneys, reducing urinary output in attempts to maintain blood volume.[19]

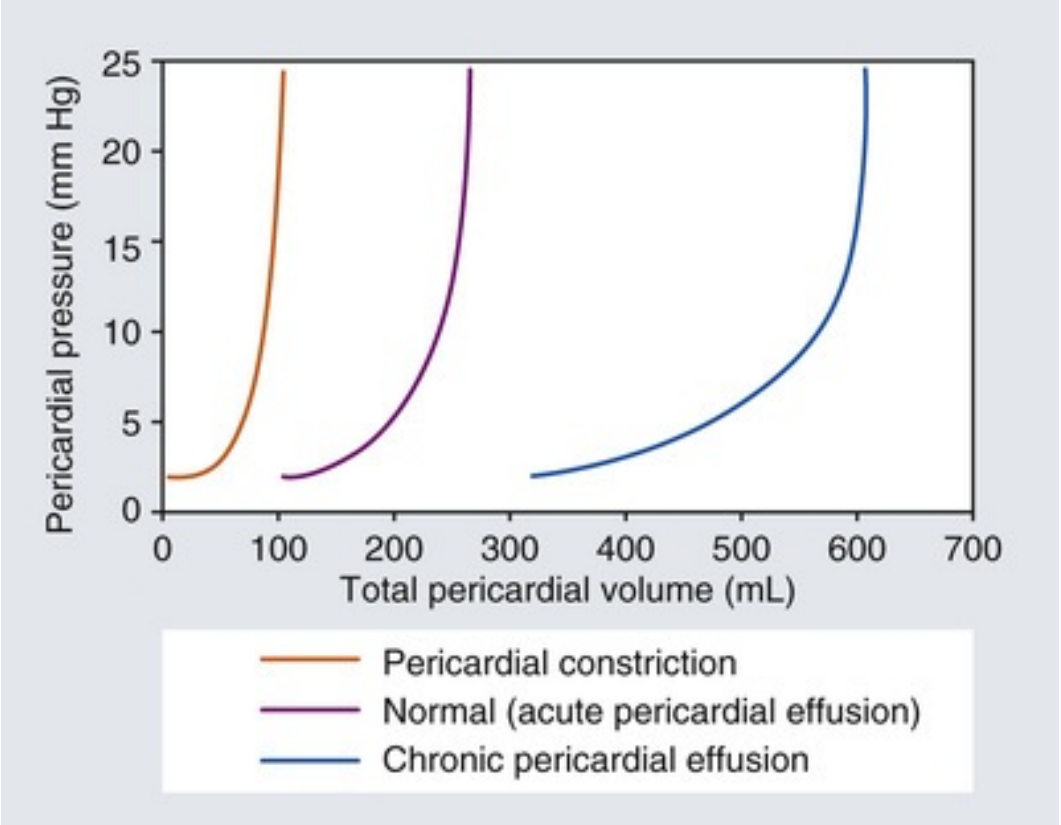

FIGURE 254-5 Effects of acute pericardial effusion, chronic pericardial effusion, and constrictive pericarditis on intrapericardial pressure. Intrapericardial pressure increases dramatically with only 50-150 mL of pericardial effusion in the acute setting. During chronic, slow accumulation of large volumes of pericardial effusion, the pressure volume curve is shifted to the right due to pericardial stretching and pericardial hypertrophy to accommodate large volume of fluid without a marked increase in pressure. Conversely, in constrictive pericarditis, the pressure volume curve is shifted to the left, due to the noncompliant, stiff pericardium, which operates on a steep curve of dramatic increases in pericardial pressure for slight increases in pericardial volume. (Obtained with permission from Kittleson MD, Kienle RD: *Small animal cardiovascular medicine*, St Louis, 1998, Mosby, Chapter 25, p 414.)

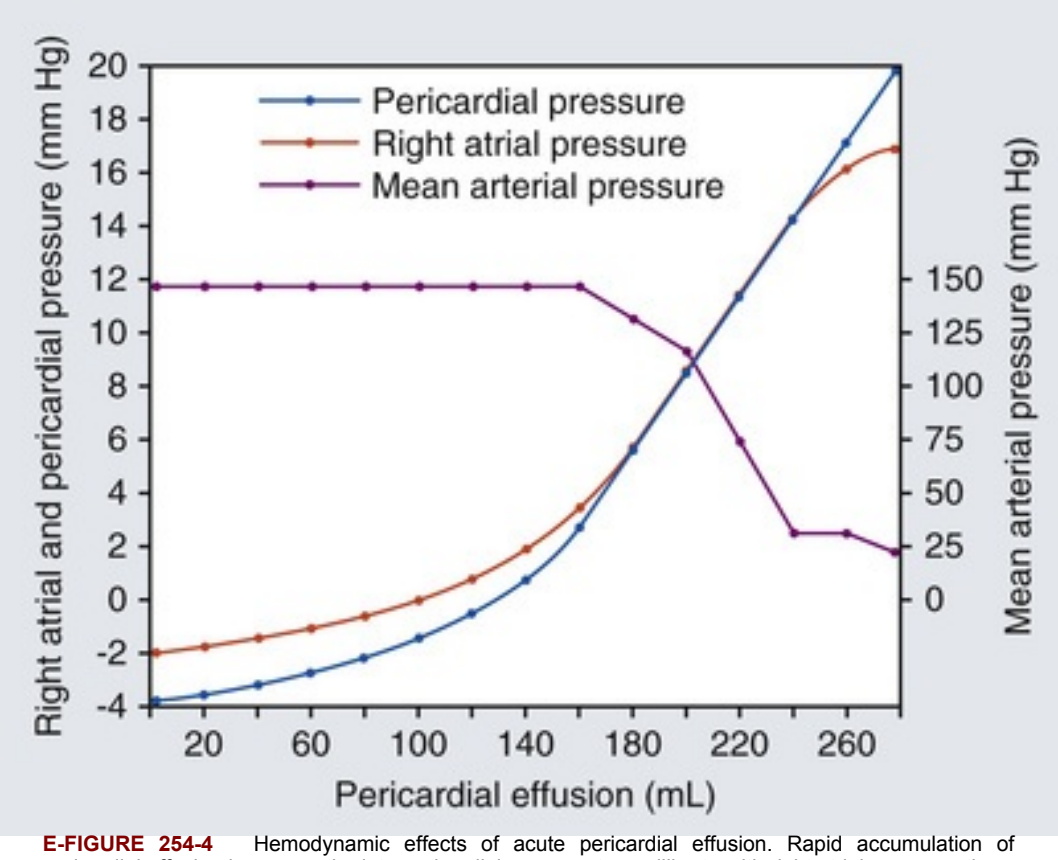

E-FIGURE 254-4 Hemodynamic effects of acute pericardial effusion. Rapid accumulation of pericardial effusion increases the intrapericardial pressure to equilibrate with right atrial pressure; then, both rise steeply, leading to arterial hypotension and cardiogenic shock. (Obtained with permission from Kittleson MD, Kienle RD: *Small animal cardiovascular medicine*, St Louis, 1998, Mosby, Chapter 25, p 414.)

Chronic cardiac tamponade is manifested as elevated right heart diastolic pressures and right-sided congestive heart failure. Although all cardiac chambers are subjected to the same increased intrapericardial pressure, the increase in diastolic pressure required to cause leaking of systemic capillaries is much lower (10-15 mm Hg) than it is for pulmonary capillaries (25-30 mm Hg), so right heart failure is seen rather than a combination of left and right heart failure. Chronic, slow accumulation of pericardial effusion causes the pericardium to stretch to accommodate often hundreds of milliliters of fluid without a clinically significant increase in pressure (see Figure 254-5). The precise mechanisms of pericardial expansion are uncertain and could include slipping of the layers of collagen followed by stretching of the wavy collagen fibers, or possibly fibroblast proliferation with new connective tissue deposition.[20] Based on the viscoelastic properties of pericardium, initial stretching of the pericardium causes straightening of the wavy collagen bundles with concomitant stretching of the elastin fibers, but when it is stretched further, there is an inextensibility due to the inelasticity of the straightened collagen fibers.

Neurohormonal activation in cardiac tamponade occurs in response to decreased cardiac output. This includes activation of the sympathetic nervous system and the renin angiotensin aldosterone system, in efforts to increase cardiac output. However, unlike other forms of cardiac disease with elevated diastolic filling pressures, atrial natriuretic peptide does not increase in cardiac tamponade, which limits natriuresis and sustains volume overload and elevated venous pressure.[21,56,57] Consequently, with chronic pericardial effusion, signs of increased systemic venous pressure predominate and manifest primarily as right-sided congestive heart failure.

Pulsus Paradoxus

Pulsus paradoxus is defined as a fall of systolic arterial blood pressure >10 mm Hg during the inspiratory phase of normal breathing (Figure 254-6).[22] The paradox described by Adolf Kussmaul in 1873 was a "pulse simultaneously slight and irregular, disappearing during inspiration and returning upon expiration," despite the continued presence of the cardiac impulse during both respiratory phases.[22] Pulsus paradoxus is an

accentuation of the normal small decline of left ventricular stroke volume and systemic arterial blood pressure that occurs with inspiration. Normally during inspiration, intrathoracic pressure decreases and blood flows preferentially into the low pressure, highly compliant vena cavae, pulmonary veins, right atrium, and right ventricle. Blood pooling in the right heart and pulmonary veins reduces preload to the left heart and consequently reduces left ventricular stroke volume. In humans, left ventricular stroke volume normally decreases by an average of 7% during inspiration, and this is associated with a 3% drop in systolic arterial blood pressure. Right ventricular stroke volume, on the other hand, increases during inspiration due to increased right-sided filling.

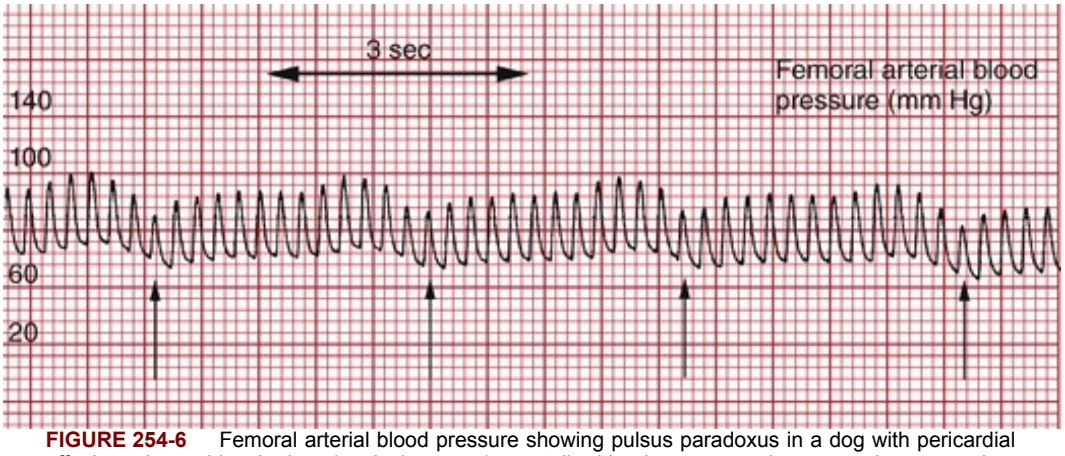

FIGURE 254-6 Femoral arterial blood pressure showing pulsus paradoxus in a dog with pericardial effusion. At end-inspiration (vertical arrows), systolic blood pressure decreases by more than 10 mm Hg and pulse pressure narrows.

Reciprocal and phasic changes with respiration in left and right ventricular filling and stroke volume are exaggerated in the presence of pericardial effusion. Outward expansion of the ventricles is limited in the face of pericardial effusion, and any increase in the volume of one ventricle can only occur at the expense of the other, a process called ventricular interdependence. Thus, greater right ventricular filling during inspiration increases the pressure within the pericardial sac and pushes the interventricular septum leftward, both of which reduce the left ventricular chamber size, reducing left ventricular filling. This interaction between the ventricles is superimposed upon the normal decrease in left ventricular stroke volume that occurs during inspiration, and leads to pulsus paradoxus. In the clinical veterinary setting, pulsus paradoxus can be challenging to identify, especially when intrathoracic pressures change rapidly, as they do with panting.

Etiology

Pericardial effusion is caused by a wide spectrum of disorders, including neoplastic, infectious, metabolic and toxic, cardiovascular, traumatic, and idiopathic.[23-26] In a case series of 107 dogs with pericardial effusion, the following etiologies were identified: HSA (33.6%; n = 36/107), idiopathic pericarditis (19.6%; n = 21/107), mesothelioma (14.0%; n = 15/107), chemodectoma (8.4%; n = 9/107), thyroid gland adenocarcinoma (5.6%; n = 6/107), infective pericarditis (4.7%; n = 5/107), lymphoma (2.8%; n = 3/107), sarcoma (1.8%; n = 2/107), and carcinomatosis, ruptured left atrium secondary to severe mitral valve regurgitation, sterile foreign body, and granuloma (each 0.9% and each n = 1/107).[23]

Neoplasia

Neoplastic disease is the most common cause of pericardial effusion in dogs. In a case series of 107 dogs with pericardial effusion, 71% of cases were caused by neoplastic disease.[23] HSA is the most common neoplastic cause of pericardial effusion, and it has a predilection for the right atrium (88% of right atrial masses were HSA[23]; Figure 254-7), and uncommonly occurs at the heart base (13% of heart base masses were HSA[23]).

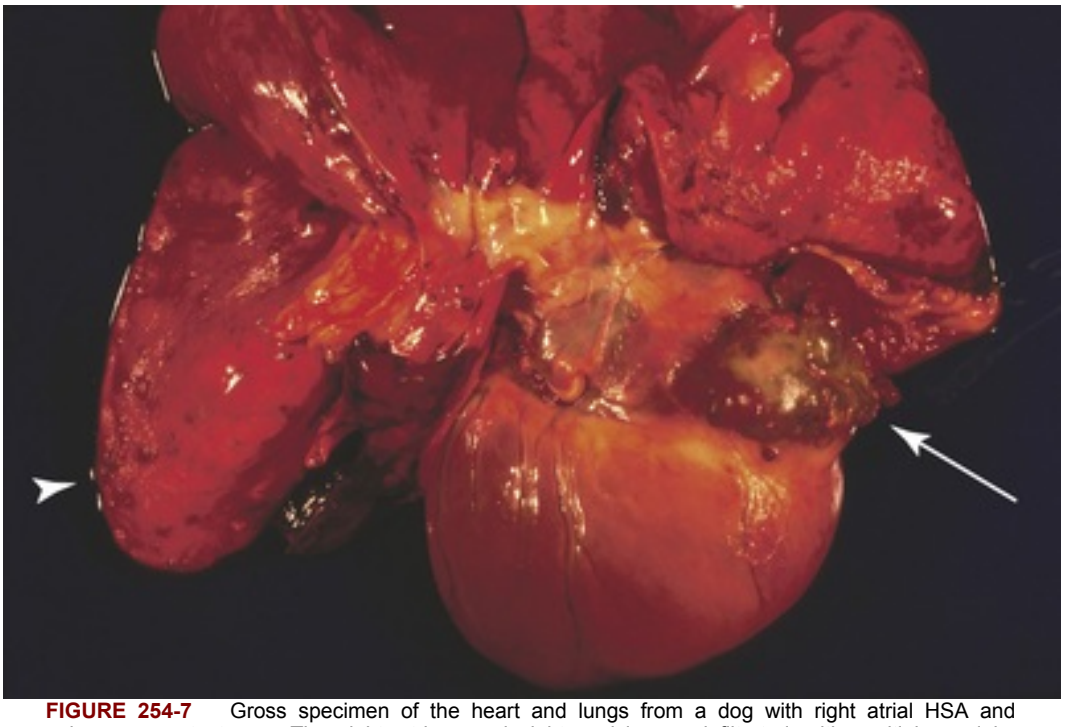

FIGURE 254-7 Gross specimen of the heart and lungs from a dog with right atrial HSA and pulmonary metastases. The right atrium and right auricle are infiltrated with multiple nodular hemorrhagic masses (arrow), characteristic of cardiac HSA. There are many small metastatic nodules throughout the pulmonary parenchyma (arrowhead), which were not visible on thoracic radiographs.

Heart base masses are characterized by a mass growing on the ascending aorta at the aortic body (Figure 254-8), and are caused by an array of neoplastic etiologies, including neuroendocrine tumors (chemoreceptor cell tumors including aortic body tumor, chemodectoma, non-chromaffin paragangliomas; 9/23 [39.1%]), thyroid gland adenocarcinoma (6/23 [26.1%]), mesothelioma (5/23 [21.7%]), and HSA (3/23 [13%]).[23] Mesothelioma typically causes a neoplastic seeding of the serosal surfaces of the pericardium and often pleura, without causing a discrete cardiac or pericardial mass, although discrete masses can be seen with mesothelioma at the heart base or rarely the right atrium. Other less common neoplastic causes of pericardial effusion are lymphoma and sarcomas (e.g., undifferentiated, rhabdomyosarcoma, fibrosarcoma).[23]

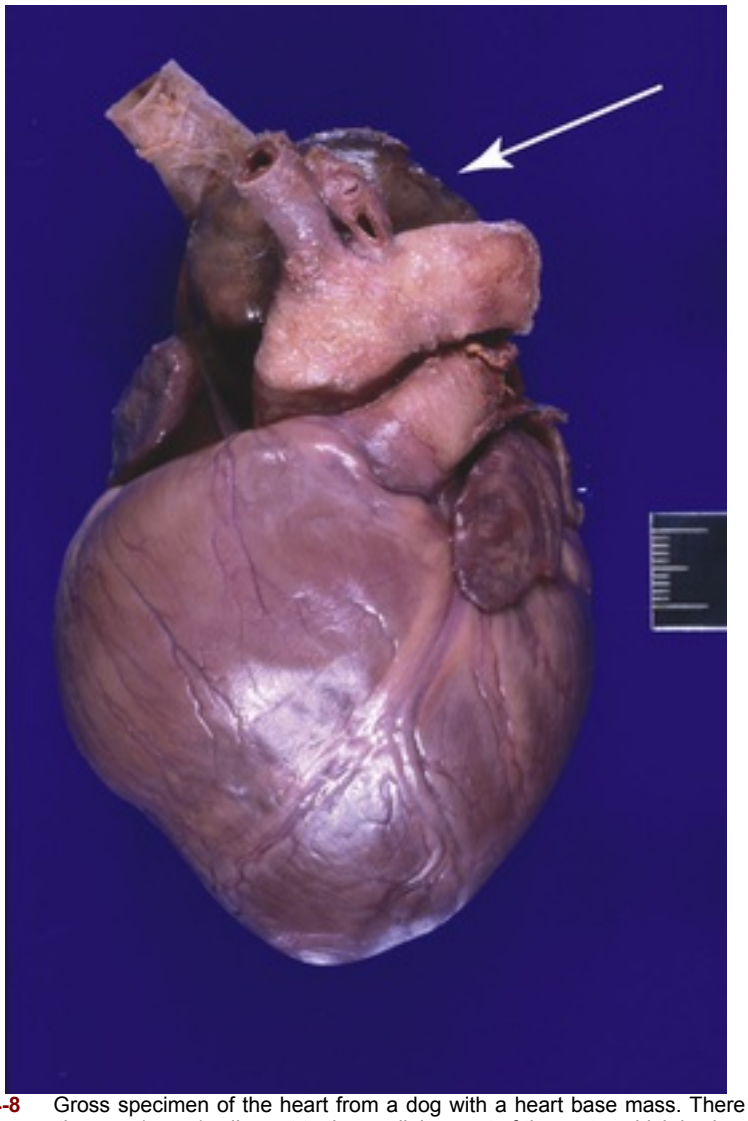

FIGURE 254-8 Gross specimen of the heart from a dog with a heart base mass. There is a large, well-defined, smooth mass (arrow) adherent to the medial aspect of the aorta, which is characteristic of a heart base mass.

Metastasis of cardiac tumors is common, and appears equally common among different neoplastic etiologies: HSA (67.9%; n = 19/28), mesothelioma (55.6%; n = 5/9]), thyroid gland adenocarcinoma (50%; n = 2/3), and chemodectoma (66.7%; n = 4/6).[23] Concurrent splenic HSA occurs in approximately 30% of dogs with cardiac HSA based on 2 different case series.[23,27] The lungs are the most common site of metastasis for the combined group of all neoplastic etiologies (30.5%; n = 18/59). In dogs with cardiac HSA, the most common sites of metastasis include the lungs (42.8%; n = 12/28), spleen (28.6%; n = 8/28), liver (28.6%; n = 8/28), and kidneys (14.3%; n = 4/28).[23] The most common sites of metastasis in dogs with mesothelioma include the intrathoracic lymph nodes (66.7%; n = 6/9), lungs (22%; n = 2/9), and pleura (22%; n = 2/9).[23] In dogs with neuroendocrine tumors, 50% of dogs (n = 3/6) had metastases involving the lungs, followed by the spleen (16.7%; n = 1/6) and liver (16.7%; n = 1/6).[23] The most common site of metastasis for dogs with thyroid gland adenocarcinoma was the pericardium (66.7%; n = 2/3), followed by the lungs (33.3%; n = 1/3), transcoelomic (33.3%; n = 1/3 dogs), and myocardium (33.3%; n = 1/3).[23]

Idiopathic Pericarditis

Second to HSA, idiopathic (hemorrhagic) pericarditis is the next-most-common cause of pericardial effusion in dogs (etiology in 20-75% of cases).[23,28,29] True to the name, the cause of idiopathic pericarditis is unknown, but is postulated to be pericardial inflammation secondary to viral or immune-mediated disease. Inflammation from mononuclear cell infiltration and fibrosis appear to target the pericardial blood vessels

and lymphatics.[30] Damaged pericardial blood vessels are the likely source of the hemorrhagic pericardial effusion. The effusion typically accumulates slowly, making a common clinical presentation of chronic cardiac tamponade. This process may spontaneously resolve after pericardiocentesis in approximately half of cases, and the remaining half suffer from recurrent pericardial effusion within days to a couple of years and require a subtotal pericardectomy. Constrictive pericarditis is a possible chronic sequela to idiopathic pericarditis.

Infective Pericarditis

Infective pericarditis is an uncommon cause of pericardial effusion in dogs, and was reported in only 4.7% of 107 dogs with pericardial effusion.[23] A common nidus of infection is migrating grass awns (3/5 dogs in that case series) or other intrapericardial penetrating foreign body. The pericardial effusion typically appears flocculent and suppurative grossly, which is different from the typically dark, hemorrhagic effusion of other causes, and pericardial fluid analysis typically distinguishes infective pericarditis from other causes of pericardial effusion (see below). Bacterial or fungal agents that have been reported most commonly include: *Bacteroides* spp., *Actinomyces* spp., *Streptococcus canis*, *Pasteurella* spp., *Peptostreptococcus* spp., and *Coccidioides immitis.*

Cardiovascular Causes

A less common cause of pericardial effusion is rupture of the left atrium in dogs with severe mitral regurgitation from myxomatous mitral valve disease. Endocardial tears can occur in dogs with severely elevated left atrial pressure and dilation, accompanied by jet lesions from the high velocity mitral regurgitation jet hitting the left atrial wall. The clinical scenario is one of acute cardiac tamponade, weakness, cardiogenic shock, and often acute death. Small breed dogs with severe mitral valve degeneration are at greatest risk for left atrial tear, with Shetland Sheepdogs, male Poodles, Dachshunds, and Cocker Spaniels appearing to have a higher predilection for left atrial rupture.[31,32]

Pericardial effusion is frequently detected in dogs and cats with congestive heart failure, but seldom in sufficient quantity (and essentially never with sufficiently high intrapericardial pressure) to cause significant hemodynamic compromise.

Metabolic and Toxic

Metabolic and toxic causes of pericardial effusion are rare. They include pericardial effusion secondary to uremia and cholesterol-based pericardial effusion associated with hypothyroidism.[33] Coagulation disorders leading to pericardial effusions occasionally occur with anticoagulant rodenticide intoxication and secondary to disseminated intravascular coagulation, warfarin intoxication, and other coagulopathies.[4,34] Although a bleeding disorder is an uncommon cause of pericardial effusion, assessment of bleeding status (blood clotting times, platelet count) is necessary prior to pericardiocentesis.

Patient History and Clinical Characteristics

Two different clinical scenarios exist in patients with pericardial effusion causing overt clinical signs: acute cardiac tamponade and chronic cardiac tamponade. Patients with acute cardiac tamponade typically have a rapid onset of weakness or collapse, prompting an emergency visit, with little prior history of abnormalities. Patients with chronic cardiac tamponade often have a vague history of inappetence, lethargy, exercise intolerance, progressive abdominal distension, and respiratory abnormalities such as tachypnea or dyspnea.

Male, medium- to large-breed dogs, particularly Golden Retrievers, are overrepresented in dogs that develop pericardial effusion. However, any size, sex, or breed of dog may develop pericardial effusion. As expected, dogs with cardiac masses are typically older (mean, 9.7 years) than dogs without masses (mean, 7.9 years).[23] Middle-aged to older English Bulldogs, Boxers, and Boston Terriers are predisposed to neuroendocrine tumors of the heart base (chemodectomas), but these tumors also occur in nonbrachycephalic breeds. Chronic hypoxia-induced hyperplasia and neoplasia of chemoreceptors may explain the predisposition of brachycephalic dogs to aortic body tumors.[35]

Physical Examination Abnormalities

Muffled heart sounds, a weak pulse, tachycardia, and pale mucous membranes are the hallmark physical abnormalities of acute cardiac tamponade. In addition to muffled heart ± lung sounds, signs of right heart failure, such as distended jugular veins or jugular pulsation, a positive hepatojugular reflux test,

hepatomegaly, and ascites with a ballottable fluid wave (see ch. 17) are typical abnormalities in animals with chronic cardiac tamponade. In a case series of 107 dogs with pericardial effusion, 67 dogs (62.6%) had evidence of right heart failure.[23] More than half of dogs with right heart failure (36/107 [33.6%]) had concurrent pleural effusion and ascites, while fewer had isolated ascites (17/107 dogs [15.9%]) or pleural effusion (14/107 dogs [13.0%]).[23] There was no difference between dogs with neoplastic or non-neoplastic causes with regard to presence of bicavitary effusion, pleural effusion, or ascites.[23] Cardiac arrhythmias may be auscultated in some cases, the most common being sinus tachycardia due to cardiogenic shock. A left apical systolic murmur should be present in dogs with left atrial rupture, and is typically softer in intensity compared to previous examinations. Pulsus paradoxus, though uncommon (10-20% of cases), may be identified in dogs with cardiac tamponade and a regular slow respiratory pattern (i.e., not panting).

Diagnosis

Echocardiography is the essential diagnostic test to diagnose pericardial effusion, and to help differentiate etiologies of pericardial effusion. Radiographs and electrocardiograms are insensitive and nonspecific, but may increase suspicion for pericardial disease in some cases.

Thoracic Radiographs

Although the quintessential thoracic radiographic abnormalities of globoid cardiomegaly with crisp cardiac margins are classic for pericardial effusion (Figure 254-9), the reality is that radiographs are both insensitive and nonspecific for pericardial effusion. In fact, radiographic appearance of globoid cardiac silhouette was only 41.9% sensitive and 40% specific for diagnosis of cardiac tamponade and pericardial effusion in 50 dogs in one series, and was present in approximately half of 107 dogs in another study.[23,36] Cardiomegaly, defined as vertebral heart size >10.7, also was insensitive (sensitivity = 77.6%) and nonspecific (specificity = 47.8%) for cardiac tamponade, likely due to rapid accumulations of small volume pericardial effusion in acute tamponade.[36] Pulmonary hypoperfusion and diminished caudal vena caval size are common in dogs with cardiogenic shock from acute cardiac tamponade. Conversely, dilated caudal vena cava, loss of abdominal detail, and pleural effusion may be seen with more chronic cardiac tamponade, and often are accompanied by the more classical globoid cardiomegaly appearance. Identification of a cardiac mass on radiographs (see Figure 254-9) is insensitive but specific (100% in one study), and was identified in 10 of 63 dogs with cardiac masses.[23] Pulmonary metastases commonly occur (see Figure 254-9), but radiographs have a low detection rate of only 1/3 of cases with pulmonary metastases confirmed at necropsy or thoracotomy.[23]

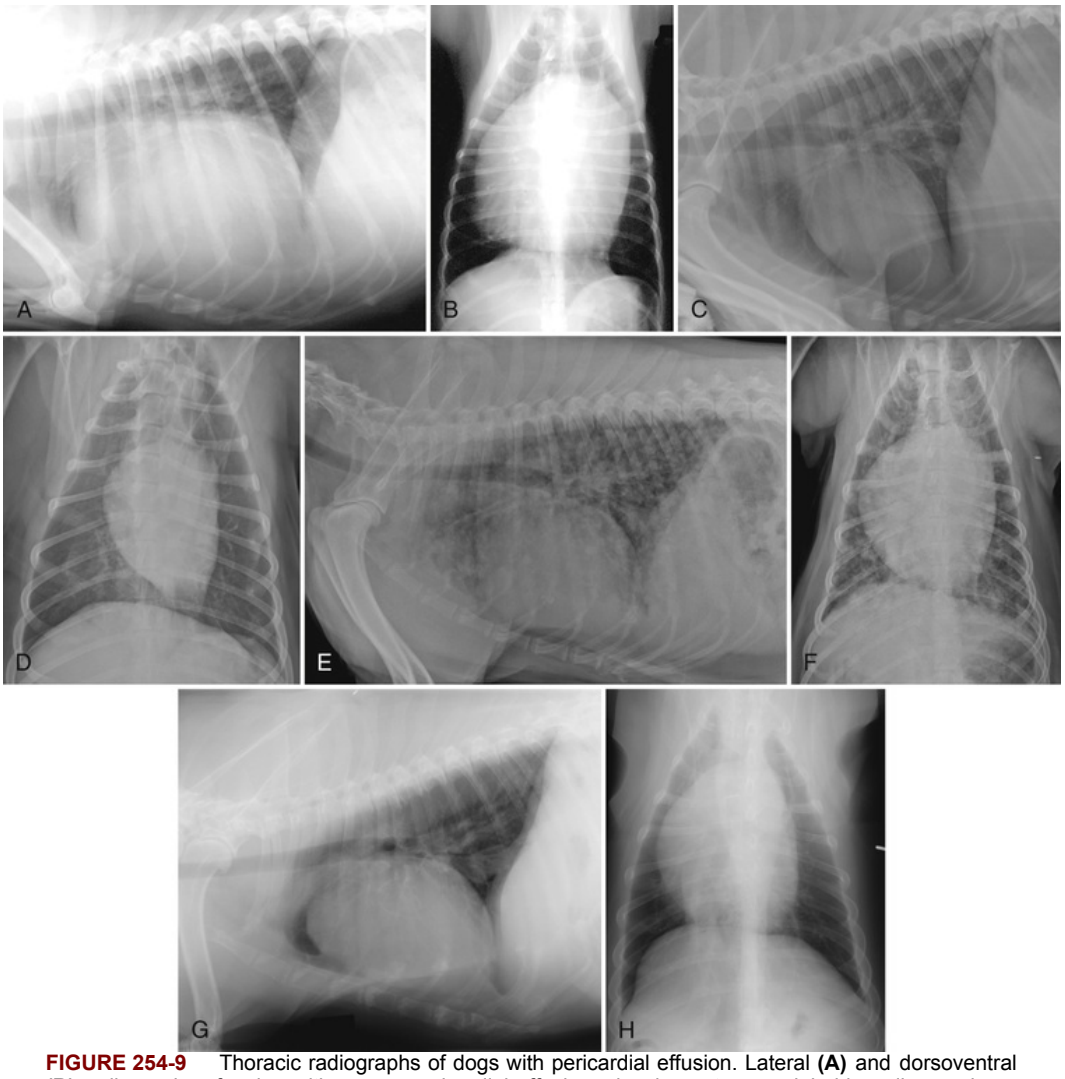

FIGURE 254-9 Thoracic radiographs of dogs with pericardial effusion. Lateral **(A)** and dorsoventral **(B)** radiographs of a dog with severe pericardial effusion, showing extreme, globoid cardiomegaly as well as crisp cardiac margins supportive of the diagnosis of pericardial effusion. There is loss of abdominal detail suggestive of ascites. Radiographs obtained post-pericardiocentesis show normalization of cardiac silhouette **(C** and **D).** Radiographs from another dog with pericardial effusion show mild globoid cardiomegaly due to acute pericardial tamponade and presence of a diffuse nodular pulmonary pattern consistent with pulmonary metastases (**E** and **F**); see Video 254-4 for echocardiogram. Radiographs from a dog with a large heart base mass (**G** and **H**) show a bulge at the cranial cardiac waist at the heart base on the lateral view, with less obvious changes on the DV view, and mild globoid cardiomegaly is present.

Tomographic Imaging

The use of multidetector computed tomography increases the diagnostic sensitivity for detection of pulmonary metastases compared to thoracic radiography, but does not increase the diagnostic yield for detection of cardiac masses compared to transthoracic echocardiography.[37] Likewise, cardiac magnetic resonance imaging (MRI) does not increase diagnostic yield for detection of cardiac masses in dogs with pericardial effusion compared to echocardiography, but may provide descriptive information on extent of disease, location, and tumor characteristics if performed by specialists with extensive additional training in cardiac MRI.[38]

Electrocardiography

An electrocardiogram is indicated for any patient with an arrhythmia auscultated on physical examination, but is not an accurate diagnostic test for pericardial effusion (see ch. 103). Abnormalities are variably present, and in a series of 107 dogs included, in order of occurrence: electrical alternans (30/107 dogs [28.0%]), sinus tachycardia (30/107 dogs [28.0%]), dampened QRS voltage (R wave < 1 mV) (26 dogs [24.3%]), and ventricular

arrhythmia (14/107 dogs [13.1%]).[23] Electrical alternans is the beat-to-beat variation in QRS amplitude caused by the heart swinging back and forth in a large volume of pericardial effusion, and is rather specific for pericardial effusion in dogs (Figure 254-10). Dampening of the QRS voltages is due to pericardial effusion insulating the electrical signal from being transmitted to the body surface, and it also may occur with pleural effusion, obesity, large thoracic masses, or hypothyroidism. Other less common electrocardiographic abnormalities in dogs with pericardial effusion can include supraventricular tachycardia (3/107 dogs [2.8%]), premature atrial complexes (2/107 dogs [1.9%]), atrial fibrillation (2/107 dogs [1.9%]), and ST segment changes (2/107 dog [1.9%]).[23]

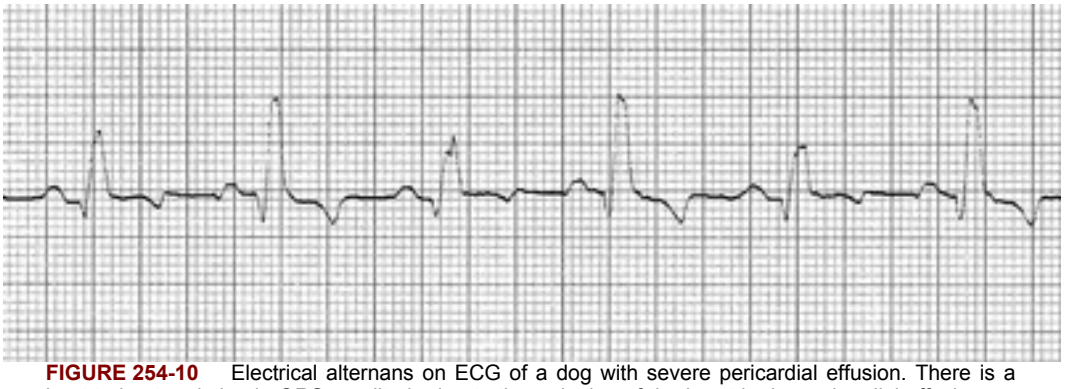

FIGURE 254-10 Electrical alternans on ECG of a dog with severe pericardial effusion. There is a beat to beat variation in QRS amplitude due to the swinging of the heart in the pericardial effusion, as well as dampened QRS complexes (<1 mV). 50 mm/sec; 1 cm = 1 mV.

Echocardiography

Echocardiography is the essential test not only to confirm the diagnosis of pericardial effusion on a triage-level scan, but, using higher level scans, to provide additional information on possible etiology of the effusion, whether pericardiocentesis is needed, and if there is underlying structural or functional cardiac disease (see ch. 104). Echocardiographic detection of a cardiac mass is sensitive (82%) and specific (100%) when performed by a cardiologist, which is similar whether the mass is right atrial (82% and 99%, respectively) or heart base (74% and 98%, respectively).[23] Repeat echocardiographic evaluation within weeks to months increases sensitivity (88%) for detection of cardiac masses.[23]

Pericardial effusion appears as an anechoic space surrounding the heart, within the pericardial space. The pericardium is seen external to the anechoic fluid, and is often highlighted by the concurrent presence of pleural effusion. Along with characteristic physical examination findings, echocardiographic diagnosis of cardiac tamponade is important to help define treatment strategies and timing of pericardiocentesis. A relatively low pericardial fluid volume can cause acute tamponade if it occurs very quickly, as may be seen in acute hemorrhage from HSA. Conversely, in cases of slowly accumulating pericardial effusion, there may be an extremely large volume of pericardial effusion that ultimately causes chronic tamponade and right heart failure. Echocardiographic evidence of cardiac tamponade includes diastolic compression of the right atrium with concave bowing of the wall inward into the right atrial chamber, and often right ventricular compression or collapse seen as an inward bowing of the right ventricular free wall or right ventricular chamber obliteration in severe tamponade (E-Figure 254-11; Video 254-2). The left ventricle appears underloaded, with a reduced chamber size, especially in cases of acute cardiac tamponade. Chronic tamponade also often causes hepatic venous distension, generalized hepatomegaly, ascites, and pleural effusion. Pulsus paradoxus may be diagnosed echocardiographically using pulsed wave Doppler interrogation of the aortic blood flow velocity, which, as described above, shows a cyclical reduction in aortic blood flow velocity during inspiration and increase in velocity during expiration (and the converse for pulmonic blood flow velocities).

E-FIGURE 254-11 Echocardiogram of a dog with cardiac tamponade. This right parasternal long-axis view **(A)** shows pericardial effusion and collapse of the right atrial free wall (arrow) consistent with cardiac tamponade. The right parasternal short-axis view **(B)** shows severe compression and obliteration of the right ventricle (arrow) during diastole, due to cardiac tamponade, but the right ventricular chamber (arrow) is visible during systole **(C)** when intracardiac pressures are higher than intrapericardial pressure. *LA*, Left atrium; *LV*, left ventricle; *PE*, pericardial effusion; *RA*, right atrium; *RV*, right ventricle.

Careful examination of all chambers, with particular focus on the heart base and right atrium/auricle, is needed to evaluate for cardiac masses. Masses typically are characterized as heart base, right atrial/auricular, or other. The reason for this characterization is that there is a predilection of tumor types for anatomic locations in the heart and there is a different biologic behavior for each of the different neoplastic etiologies. For example, 88% of right atrial masses in a case series were HSA, whereas heart base masses are more likely to be neuroendocrine tumors (40%) or thyroid adenocarcinoma (25%).[23] Despite the generalization of tumor predilections for right atrium and heart base, there is an overlap of tumor etiologies at each location. For example, right atrial masses other than HSA include the following (each accounting for 2.5% of cases): neuroendocrine tumor, thyroid adenocarcinoma, mesothelioma, lymphoma, and sarcoma.[23] Similarly, heart base tumors other than neuroendocrine tumors or thyroid adenocarcinoma include mesothelioma (20%) and HSA (15%).[23]

The echocardiographic tissue characteristics of right atrial or auricular HSA consist of an irregular, heterogeneous mass that moves with the chamber, and has intratumoral hypoechoic or cavitary spaces consistent with hemorrhage. The mass may be localized to the right auricle, which must be visualized using the left cranial parasternal long-axis view (Figure 254-12; Videos 254-3 and 254-4), or more commonly may extend along the right atrial wall and/or right atrioventricular groove (Videos 254-3 and 254-5). Sometimes, there are concurrent right atrial and heart base masses, most likely from spread of the primary mass but rarely from two different neoplastic causes. Sometimes, right atrial masses penetrate into the right atrial lumen, and can obstruct venous return to the right atrium or impair right ventricular filling (see Videos 254-3 and 254-5; see also ch. 122).

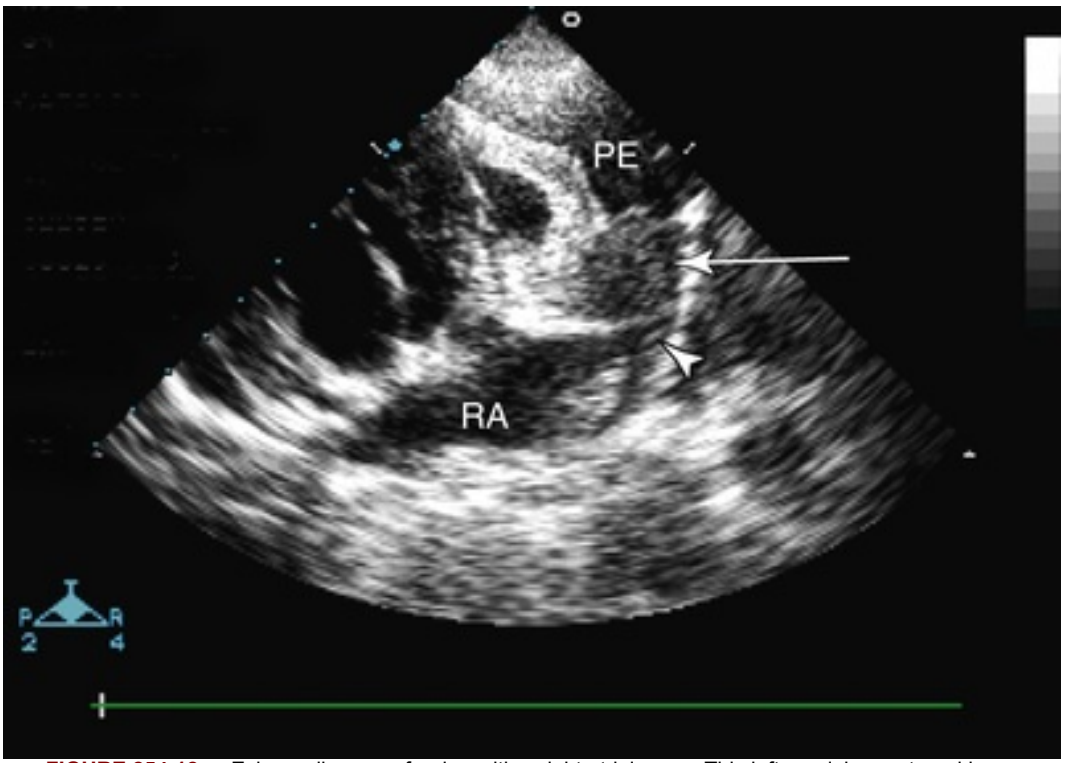

FIGURE 254-12 Echocardiogram of a dog with a right atrial mass. This left cranial parasternal long-axis view shows a heterogeneous, mottled right auricular mass (arrow) as well as pericardial effusion (PE). Arrowhead indicates the right auricle. *RA*, Right atrium.

Heart base masses that are neuroendocrine tumors usually are homogeneous, encapsulated masses growing from the ascending aorta, adjacent to but separate from either the left atrium or right atrium (Figure 254-13; Video 254-6). Since heart base masses comprise a variety of neoplastic etiologies, echocardiographic characteristics also may vary. Some heart base masses are small and easy to overlook unless the ascending aorta is carefully examined in the right parasternal long-axis left ventricular outflow tract view as well as short-axis views along the base of the heart. Other heart base masses can be so large that the site of origin is challenging to determine. Large heart base masses may externally compress the right ventricular outflow tract or pulmonary artery in some cases. Sometimes, heart base masses do not cause pericardial effusion, and are incidentally diagnosed based on suspicion of a heart base mass on radiographs or during workup of a heart murmur.

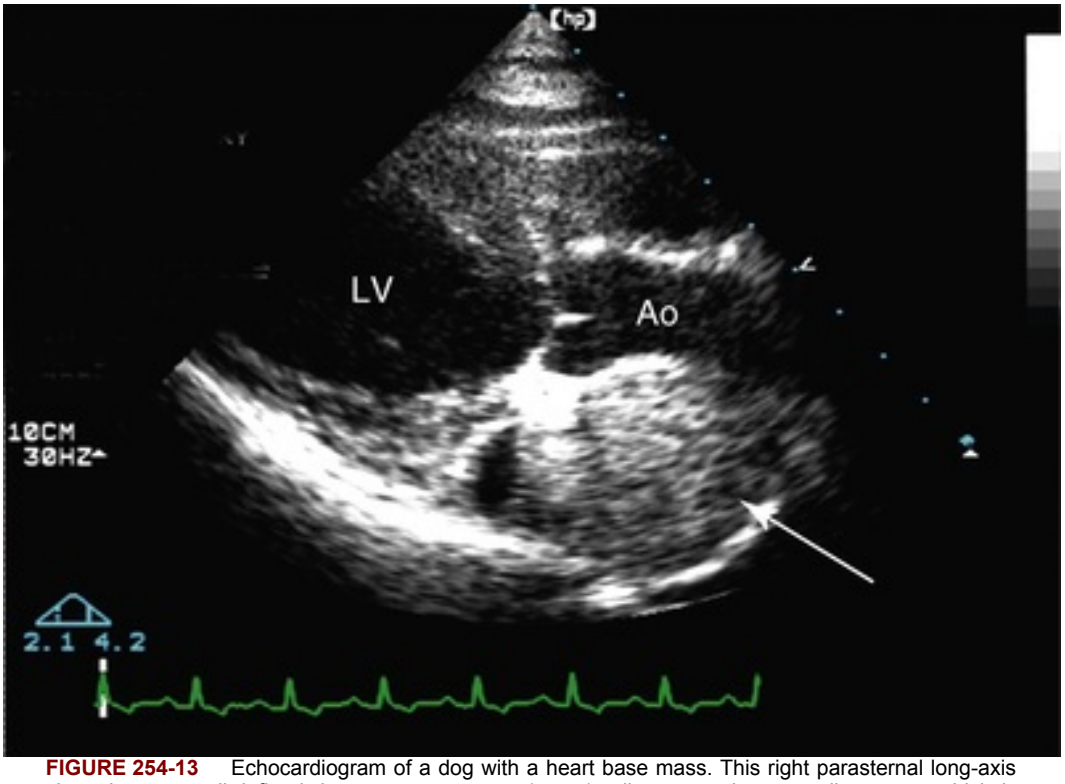

FIGURE 254-13 Echocardiogram of a dog with a heart base mass. This right parasternal long-axis view shows a well-defined, homogeneous mass (arrow) adherent to the ascending aorta, which is characteristic of a heart base mass. *Ao*, Aorta; *LV*, left ventricle.

The presence of pericardial effusion greatly facilitates the detection of intrapericardial masses, especially cardiac HSA and heart base tumors, because fluid forms an anechoic zone around the right atrium and auricle, as well as the ascending aorta. Consequently, if the clinical condition permits, pericardiocentesis should be deferred until a thorough echocardiographic examination has been completed. However, in dogs with cardiac tamponade and cardiovascular collapse, pericardiocentesis should not be delayed as it is a lifesaving procedure.

Pericardial effusion secondary to left atrial rupture accompanies echocardiographic evidence of myxomatous mitral valve disease and severe left atrial dilation (see ch. 251). An elongated hyperechoic thrombus usually is visualized extending from the epicardial surface of the left atrium into the pericardial space (Video 254-7).

In cases where no mass is seen, the main differential diagnoses include idiopathic pericarditis, mesothelioma, infective pericarditis, or a mass that is too small or too remote to be imaged. It is impossible to distinguish between idiopathic pericarditis and mesothelioma by echocardiography. Diagnosis requires histopathologic and immunohistochemical evaluation of the pericardium to help differentiate these two diseases in dogs with recurrent pericardial effusion that undergo pericardectomy. Sometimes, a definitive diagnosis of mesothelioma is impossible, but the suspicion is increased in dogs with recurrent pleural effusion within 4 to 6 months of subtotal pericardectomy.

Pericardial Fluid Analysis

Pericardial fluid analysis with cytologic evaluation typically is nonspecific,[39] and the fluid usually is characterized as hemorrhagic. Nevertheless, fluid analysis remains an essential diagnostic step to diagnose infective pericarditis and certain neoplastic causes such as lymphoma. Pericardial fluid may be characterized as hemorrhagic (40/47 [85%]), suppurative inflammatory (6/47 [12.7%]), pyogranulomatous inflammatory (4/47 [8.5%]), modified transudative (2/47 [4.2%]), or chylous (1/47 [2.1%]). Pericardial cytology has been found to be nondiagnostic in 87-92.3% of dogs, yet was able to identify a specific neoplastic etiology in 4.6% of 250 dogs (n = 7 round cell neoplasia, n = 3 atypical epithelioid cells, n = 1 hemic neoplasia) and all cases of infective pericarditis (n = 8; 3.1%).[23,40] Therefore, despite a low diagnostic yield, it is essential to submit pericardial fluid for analysis. Mesothelial reactivity was identified in 25 of 47 (53.2%) dogs, and is not typically helpful to differentiate idiopathic pericarditis from mesothelioma. Since hyperreactive mesothelial cells may be inadvertently mischaracterized as mesothelioma, the diagnosis of mesothelioma is made by histopathologic evaluation of the pericardium after pericardectomy or on necropsy. Among cardiac tumors, cardiac lymphoma is unique because cytologic evaluation of the pericardial fluid establishes the diagnosis in many cases (11/12 dogs [88%] in one case series) and the tumor may be amenable to combination chemotherapy.[35,38,55] Aerobic and anaerobic culture of pericardial effusion should be submitted in cases with gross evidence of flocculent light-colored fluid, and/or when fluid is characterized as an exudate on fluid analysis. Serologic testing for *C. immitis* is indicated in dogs with inflammatory pericardial effusion that live in endemic areas (see ch. 232). Pericardial fluid pH has a wide overlap between neoplastic and non-neoplastic etiologies, and its measurement is not considered reliable.[41,42] Measurement of serum cardiac troponin I (cTn-I) has produced different results in different studies. Serum (cTn-I) is consistently higher in dogs with pericardial effusion than in normal dogs, but some results identify a higher level in dogs with HSA compared to dogs with other tumors or to non-neoplastic disorders, whereas other results do not demonstrate such a difference.[43-45]

Treatment

In patients with cardiac tamponade and hemodynamic compromise, pericardiocentesis and rapid intravenous fluid resuscitation are immediately lifesaving (see ch. 102). The timing of pericardiocentesis depends on the severity of cardiovascular compromise, and should not be delayed if cardiogenic shock is present. In stable patients, pericardiocentesis should be delayed if a high-level echocardiogram is possible, then performed after the echocardiogram. Abdominocentesis (see ch. 90) ± thoracocentesis (see ch. 102) may be palliative in patients with chronic cardiac tamponade and ascites or pleural effusion, respectively.

Approximately 50% of idiopathic pericarditis cases have recurrent pericardial effusion, which requires subtotal pericardectomy. In cases of recurrent pericardial effusion without an identifiable mass, subtotal pericardectomy is necessary, and histopathologic evaluation of the pericardium should be performed (often with special immunohistochemical stains) for differentiation of idiopathic pericarditis from mesothelioma. Subtotal pericardectomy is curative for idiopathic pericarditis: dogs with idiopathic pericarditis treated with subtotal pericardectomy never reached a median survival time during a 3 year study (100% survival rate), yet dogs with idiopathic pericarditis undergoing thoracoscopic pericardial window did much more poorly, with a disease-free interval of 11.6 months and a median survival time of 13.1 months.[46]

Mesothelioma may be clinically suspected during thoracotomy by the gross appearance of abnormal serosal surfaces of the pleura and pericardium, which mandates biopsy of pleura and lymph nodes. The median survival time of patients with mesothelioma undergoing subtotal pericardectomy was 10.3 months, and not significantly different from pericardial window (median survival time of 8.6 months). Intracavitary infusions of carboplatin have been used for treatment of mesothelioma, with sparse clinical reports published. A case report documented one dog that was disease-free 27 months after treatment with intrathoracic carboplatin and intravenous doxorubicin.[47] Another case report documented two dogs with peritoneal mesothelioma treated with intracavitary carboplatin and daily piroxicam who lived for 8 months and >3 years.[47,48]

Partial pericardectomy is indicated for dogs with heart base masses, as it relieves cardiac tamponade and is associated with a significant prolongation of survival time (median survival time of 730 days with pericardectomy versus 42 days without pericardectomy).[49] In that study of 24 dogs with aortic body tumors, only pericardectomy, and not other treatments including chemotherapy, was found to increase survival time.[49] A second study showed similar results.[50] Other additional treatments have not been assessed for efficacy. Three-dimensional conformal radiation therapy was performed in a dog with histopathologically

confirmed chemodectoma; there was >50% reduction in tumor volume 25 months after therapy, and the dog was still alive 42 months after therapy (after undergoing pericardectomy for recurrent pericardial effusion).[51]

Pericardectomy is controversial for dogs with presumptive HSA, unless it is combined with mass resection, which is rarely possible. In one study, partial or subtotal pericardectomy in dogs with all neoplastic causes combined resulted in disappointing survival rates of 2.7 and 3.8 months respectively.[46] In dogs with isolated right auricular HSA, surgical resection is a feasible option, followed by chemotherapy, yet results still remain underwhelming. In a small study of 23 dogs with surgically resected right atrial or right auricular HSA, administration of chemotherapy increased survival time (median survival time with chemotherapy and surgery 175 days versus 42 days with surgery alone).[52] A retrospective study evaluating 64 dogs with presumptive HSA (i.e., right atrial/auricular masses with a characteristic heterogeneous appearance) treated with doxorubicin compared to 76 dogs without doxorubicin showed an extension in overall survival time with doxorubicin treatment (116 days vs. 12 days, respectively), yet dogs in the doxorubicin treatment group underwent more pericardiocenteses and owners could have been more motivated to continue therapy than those in the no-treatment group.[53] Only 14% of doxorubicin-treated dogs had a probability of surviving >6 months. Neither group underwent pericardectomy or mass resection. Presence of metastases was not related to overall survival, but mass size and thrombocytopenia were negative prognostic indicators. Lastly, a retrospective study of dogs without surgical resection of cardiac HSA that were treated with doxorubicin ± other chemotherapies reported a median survival time of 139.5 days (range 2-302 days), yet no control group was evaluated for comparative purposes.[54] In the author's experience, recurrent acute hemorrhage and cardiac tamponade is common in dogs with cardiac HSA, and usually is lethal before the animal succumbs to metastatic disease.

Cardiac lymphoma is classified as stage V, substage b. Dogs with stage III lymphoma or higher and clinical signs (substage b) have a poor prognosis for remission and survival. In a retrospective study of 12 dogs with cardiac lymphoma and pericardial effusion that were treated with various combinations of pericardiocentesis, pericardectomy, and chemotherapy, median survival time was 41 days. However, three dogs were still alive 328 days after the initial diagnosis, suggesting that cardiac lymphoma does not always warrant a poor prognosis.[55]

Subtotal pericardectomy, postoperative chest tube drainage, and long-term (at least 6 months) antibiotic therapy is the treatment of choice for infective pericarditis. The prognosis is good for dogs undergoing pericardectomy and receiving long-term antibiotics.[56] Long-term antifungal treatment for many months to years may be necessary in dogs with *C. immitis* infections (see ch. 232).

Constrictive Pericarditis

Constrictive pericarditis occurs when the parietal pericardium, the visceral pericardium, or both develop(s) fibrosis, with or without fusion of the parietal and visceral layers to each other. This process decreases compliance and possibly intrapericardial volume (Figure 254-14). The fibrotic pericardium constricts the cardiac chambers and increases atrial and diastolic ventricular pressures. A small volume of pericardial fluid sometimes is present, in a process called constrictive-effusive pericarditis, such that for any mild increase in pericardial effusion volume, there is a dramatic increase in intrapericardial pressure. The pathophysiologic consequence of pericardial constraint is similar to chronic cardiac tamponade. Ascites is a consistent feature, and jugular venous distension is common.[57] Pulsus paradoxus is an uncommon finding in constrictive pericarditis, probably because the rigid, stiff pericardium does not transmit the respiratory variations of intrathoracic pressures to the heart as a structurally normal pericardium would. Causes of constrictive pericarditis are unclear, but case reports cite the following causes: previous idiopathic pericarditis, previous infective pericarditis (especially *C. immitis* infections), intrapericardial foreign body, osseous metaplasia of the pericardium, or idiopathic disease.[57-59] Medium- to large-breed dogs are most commonly affected.

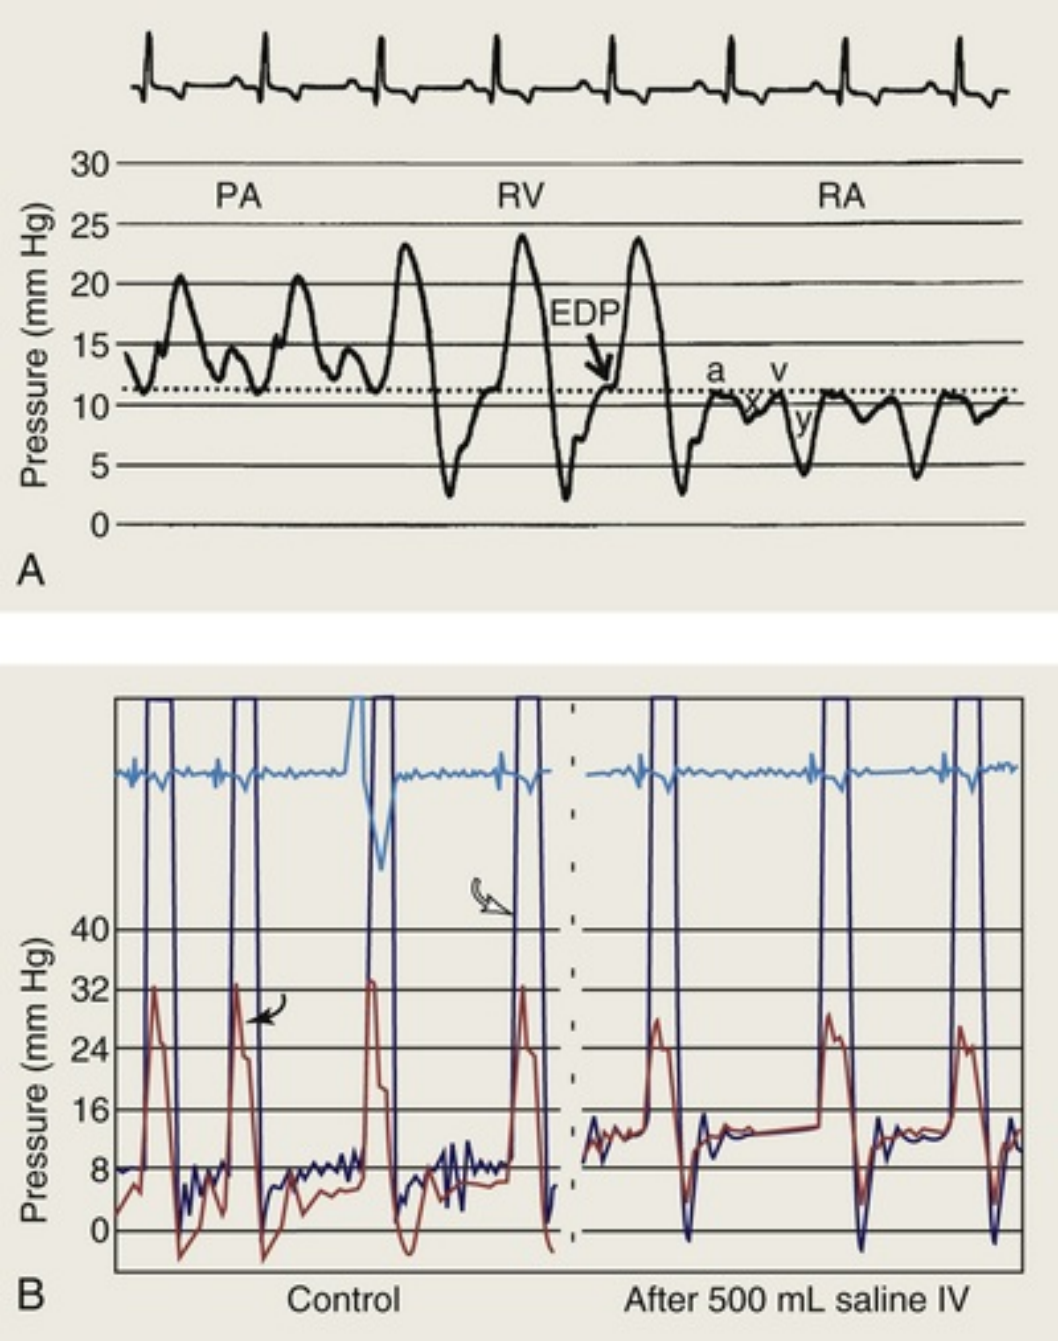

FIGURE 254-14 Hemodynamic abnormalities associated with constrictive pericarditis. **A,** Elevation and equilibration of end-diastolic pressure (EDP) in pulmonary artery (PA), right ventricle (RV), and right atrium (RA). Right atrial pressure waveform has an M-shaped pattern due to a reduced X descent and a prominent Y descent. **B,** Simultaneous recordings of left ventricular (open arrow) and right ventricular (solid arrow) pressures before and after saline infusion. Under control conditions, the pressure waveforms show slight elevations in end-diastolic pressures. Unmasking of pathognomic constrictive physiology occurs after rapid intravenous infusion of 500 mL saline, resulting in elevation and equilibration of left and right ventricular diastolic pressure, and emergence of the dip-and-plateau diastolic filling pattern. (From Sisson D, Thomas WP: Pericardial diseases and cardiac tumors. In Fox PR, et al, editors: *Textbook of canine and feline cardiology*, ed 2, Philadelphia, 1999, Saunders, pp 697-698.)

In contrast to other forms of pericardial disease, echocardiography is not sufficient to provide a diagnosis, and typically it shows minimal or no pericardial effusion and no right atrial and ventricular collapse, yet there is usually evidence of hepatic venous distension and ascites.

Diagnosis of constrictive pericarditis requires right heart catheterization. Pericardial constriction does not limit early active diastolic filling, but limits diastolic filling in mid-diastole as the heart is confined by the stiff

pericardium. This results in a characteristic "dip and plateau" pressure waveform (the square root sign) when measuring right ventricular diastolic pressures during cardiac catheterization (see Figure 254-14). The dip portion of the pressure tracing is the enhanced rapid early diastolic filling of the heart operating in low volumes not limited by the pericardial constraint. The plateau occurs once the chamber volume expands to be limited by the pericardial constriction, which creates a rapid increase in filling pressure in mid- to late diastole and cessation of diastolic filling, which may be more obvious during rapid saline intravenous infusion. A characteristic W- or M-shaped right atrial diastolic pressure tracing also is present in constrictive pericarditis, where there is accentuated early diastolic filling after ventricular systole (y descent), and a rapid decrease in RA pressure after atrial systole (x descent) (see Figure 254-14).

Treatment for constrictive pericarditis requires subtotal pericardectomy and removal of the constricting pericardium from the underlying myocardium if possible (Figure 254-15). Overall prognosis depends on whether the process is limited to the parietal pericardium (better prognosis) or if it extends to the visceral pericardium which may become adhered to the epicardial surface (grave prognosis). In a case series of 13 dogs, 8 dogs had parietal pericardial constriction, 5 dogs had visceral pericardial constriction, and parietal pericardectomy was successful in relieving the syndrome in 6 of 10 dogs.[57] Perioperative mortality was most often due to pulmonary thromboembolism in those cases. In cases where constrictive pericarditis is a complication of systemic *C. immitis* infection, adjunctive long-term antifungal therapy is necessary. In a retrospective study of 17 dogs with constrictive pericarditis from *C. immitis,* perioperative mortality was high (23.5%). However, surgery was successful in relieving clinical signs in some dogs for >2 years.[58]

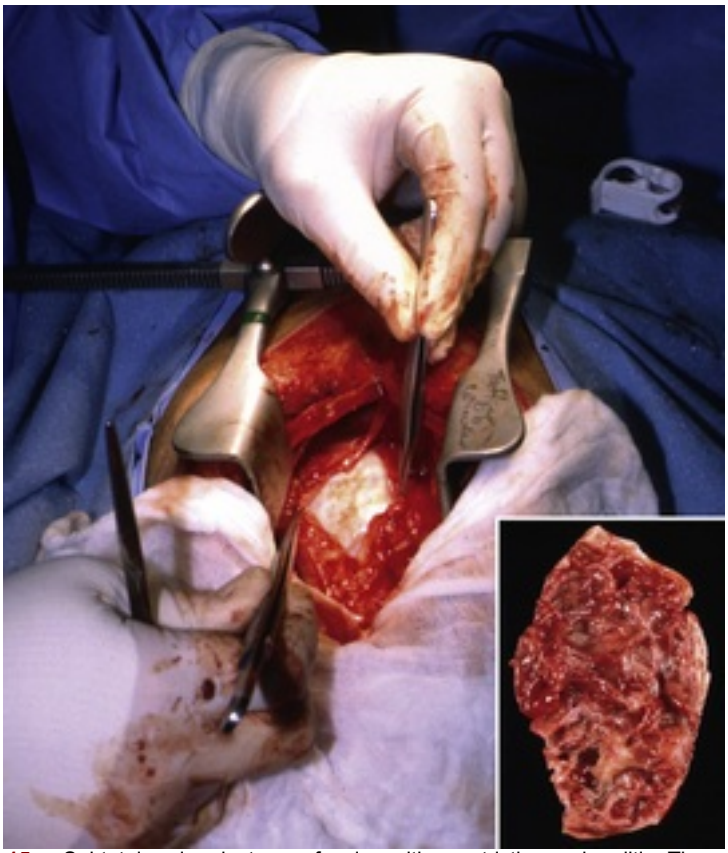

FIGURE 254-15 Subtotal pericardectomy of a dog with constrictive pericarditis. The pericardium is markedly thickened, irregular, constrictive, and fibrotic. Although the epicardial surface was pale, there was no visceral pericardial constriction, and a subtotal parietal pericardectomy was performed. Inset: gross specimen of resected, thickened pericardium.

Feline Pericardial Effusion

Pericardial effusion is the most common type of pericardial abnormality in cats, and is present in approximately 6% of feline cardiology patients.[60] Most cases are mild and not caused by pericardial disease

but by elevated intracardiac filling pressures secondary to congestive heart failure (44-75% of feline cases of pericardial effusion) through the same pathophysiologic mechanism as pleural effusion development in heart failure.[60,61] Unlike dogs, cats rarely develop pericardial effusion that is severe enough to cause cardiac tamponade or clinical signs, or require pericardiocentesis.[61,62] After congestive heart failure, neoplasia is the second most common cause of pericardial effusion in cats (19% of 83 cases, including lymphoma, adenocarcinoma, thymoma, and mesothelioma).[61] Cardiac neoplasia is a rare cause of pericardial effusion in cats, and reports include chemodectoma and rhabdomyosarcoma. Pericarditis is also rare in cats, and was only found in 3 of 83 cats in that case series.[61] Likewise, infective pericarditis is rare in cats, and reported causes of infection are *E. coli, Staphylococcus aureus, Enterococcus*, and *Actinomyces.* Other uncommon causes include: peritoneopericardial diaphragmatic hernia, feline infectious peritonitis, hypoalbuminemia, systemic infection and inflammation, and disseminated intravascular coagulation.

Pericardiocentesis (see ch. 102) is necessary in cats with echocardiographic evidence of cardiac tamponade. The pericardial fluid usually has a gross appearance similar to pleural effusion, and, unlike in dogs, is rarely hemorrhagic. Fluid analysis and cytologic evaluation ± microbial culture should be submitted to evaluate for infectious, neoplastic, or inflammatory etiologies.

Canine Heartworm Disease

Heartworm infection (HWI, dirofilariasis, dirofilarosis), caused by *Dirofilaria immitis,* primarily affects members of the family Canidae. Dirofilarosis is widely distributed, being recognized in northern and southern temperate zones, in the tropics, and in the subtropics. Infections are recognized in most of the United States, although the distribution favors the Southeast and Mississippi River Valley (Figure 255-1). In some endemic areas in the United States, infection rates approach 45%, and in some hyper-endemic tropical regions, virtually all dogs are infected. Dirofilarosis is generally infrequent in Canada, but there are endemic areas of concern in southern Ontario. A 2001 survey of veterinarians indicated that there were approximately 240,000 cases diagnosed in the United States, but realistic estimates put the prevalence at >1,000,000 cases.[1]

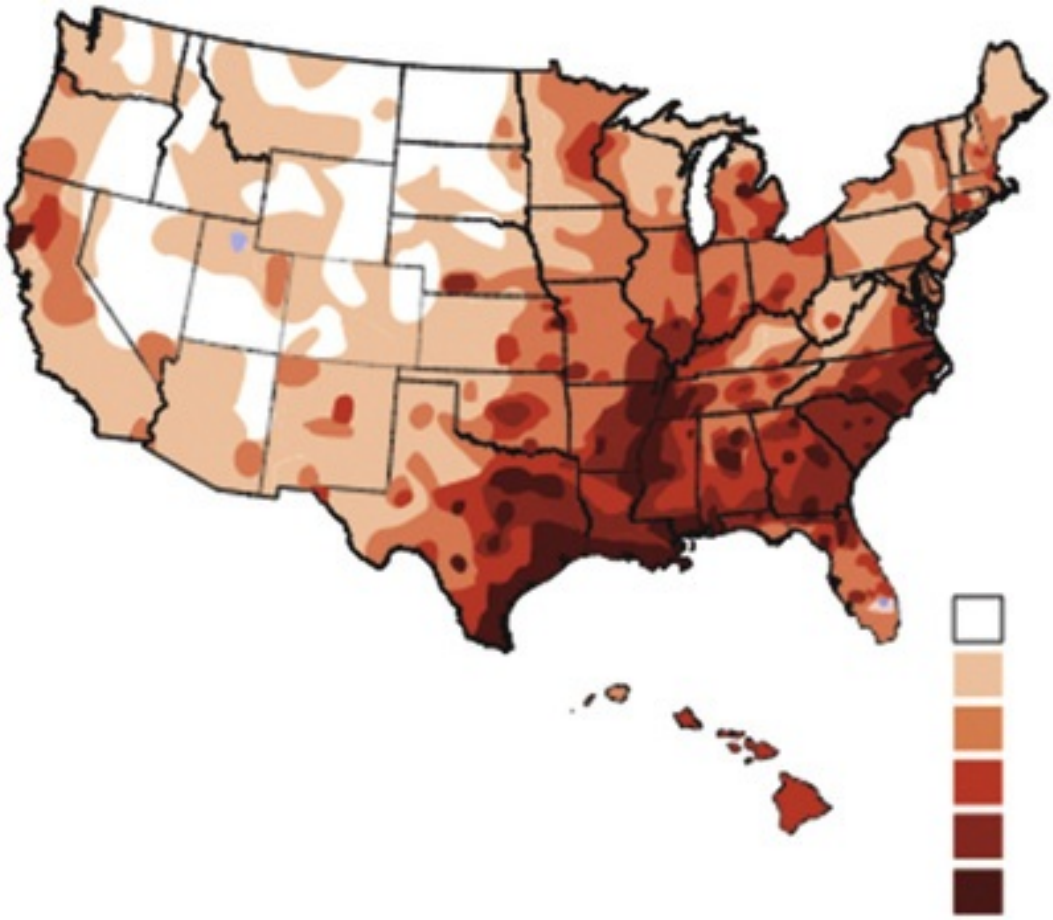

FIGURE 255-1 American Heartworm Society map, demonstrating relative prevalence of heartworm infection in the United States in 2013, based on practice surveys. (Courtesy the American Heartworm Society.)

Species known to have been infected with *D. immitis* include the domestic dog, wolves, foxes, coyotes, domestic cats, ferrets, muskrats, sea lions, nondomestic cats, coatimundi, and humans. The species of greatest interest to the practicing veterinarian include the dog and domestic cat. Because the consequences, treatment, and prognoses differ between the two species, clinical aspects of canine and feline heartworm disease (HWD) are discussed separately.

When HWI is severe or prolonged, it may result in the pathologic process called *heartworm disease (HWD).* This may vary from asymptomatic (radiographic lesions only) to severe, life-threatening, chronic pulmonary artery, lung, and cardiac disease. In chronic HWI, glomerulonephritis, anemia, and thrombocytopenia may also be recognized. Severe dirofilarosis may, in addition, produce acute and fulminant multi-systemic presentations, such as caval syndrome (CS) and disseminated intravascular coagulation (DIC).

Life Cycle

D. immitis is transmitted by over 70 species of mosquitoes, although important mosquito vectors probably number fewer than fifteen. Understanding the complex life cycle of *D. immitis* is imperative for veterinary practitioners in heartworm endemic areas (Figure 255-2). The terminology for the larval stages can be confusing. For the final heartworm stage, *L5* (last stage or 5th larval stage) is no longer the preferred term. The nomenclature has been updated, because, although far smaller than a mature adult, this stage does not molt again so is not a larval stage. Preferred terminology for this pre-cardiac stage includes immature Stage 5 ([S5], immature or juvenile adult). For the purposes of this chapter, *L5, Stage 5, juvenile, juvenile adult, immature adult,* and *mature adult* are terms used to describe the final stage in the heartworm development. Additionally, the term *L1* (1st larval stage) refers to the 1st stage larvae after ingestion by the female mosquito, while prior to this, in the host, these earliest HWs are termed *microfilariae.*

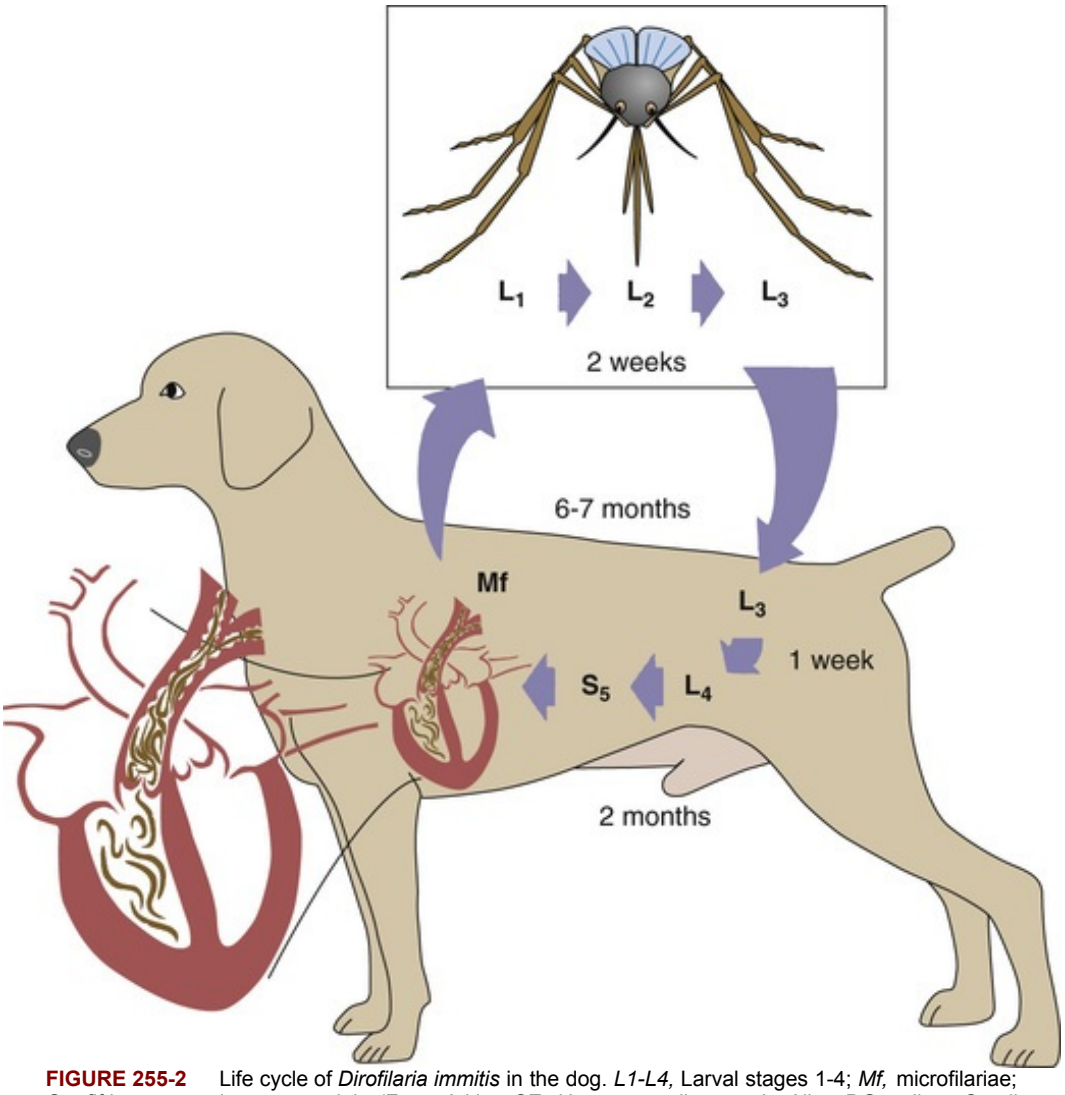

FIGURE 255-2 Life cycle of *Dirofilaria immitis* in the dog. *L1-L4,* Larval stages 1-4; *Mf,* microfilariae; *S5,* fifth stage or immature adult. (From Atkins CE: Heartworm disease. In Allen DG, editor: *Small animal medicine*, Philadelphia, 1991, JB Lippincott, pp 341-363.)

Adult heartworms reside in the pulmonary arteries and, to a lesser extent (in heavy infections), the right ventricle. After mating, microfilariae (Mf; first stage larvae) are produced by mature adult female heartworms (mature S5) and are released into the circulation. These Mf are ingested by feeding female mosquitoes and undergo two molts (L1 to L2 to L3) over an 8- to 17-day period. It is important to note that this process is temperature-dependent; in times of the year when insufficient numbers of days occur in which the ambient temperature is adequate, molting in the mosquito does not occur during the lifetime of the female mosquito and transmission cannot occur.[2,3] Larval molts and maturation are also dependent on the presence of an intracellular symbiotic bacterium, *Wolbachia pipientis*.[4] The resultant L3 is infective and is transmitted by the feeding mosquito to the original or another host, most often a male dog. Another molt to L4 occurs in the subcutaneous, adipose, and skeletal muscular tissues shortly after infection (1 to 12 days), with a final molt to S5 (immature adult) occurring 2 to 3 months (50 to 68 days) after infection.

This immature adult (1 to 2 cm in length) soon enters the vascular system, migrating to the heart and lungs, where final maturation (mature male adults range from 15 to 18 cm and females from 25 to 30 cm) and mating occur. Under optimum conditions, completion of the life cycle takes 184 to 210 days. The canine host becomes microfilaremic as early as 6, but typically by 7 to 9 months after infection. Microfilariae, which are variably present in infected dogs, show both seasonal and diurnal periodicity, with greatest numbers appearing in the peripheral blood during the evening hours and during the summer. Adult heartworms in dogs are known to live 5 to 7 years and Mf up to 30 months. Dillon has emphasized that the disease process in HWD begins with the molt to S5 (as soon as 2 to 3 months post-infection), at which time these immature adults enter the vascular system, initiating vascular and possibly lung disease, with eosinophilia and eosinophilic infiltrates

and signs of respiratory disease.[5] It is important to note that this antedates the profession's current ability to diagnose HWI.

Pathophysiology

Heartworm is a misnomer because the adult actually resides in the pulmonary arterial system for the most part, and the primary insult to the health of the host is a manifestation of damage to the pulmonary arteries and lung. The severity of the lesions and hence clinical ramifications are related to the relative number of worms (ranging from one to >250), the duration of infection, and the host and parasite interaction. Immature and mature adult heartworms reside primarily in the caudal pulmonary vascular tree, occasionally migrating into the main pulmonary arteries, the right heart, and even the great veins in heavy infections.

Obstruction of pulmonary vessels by living worms is of little clinical significance, unless worm burdens are high or the patient small. The major effect on the pulmonary arteries is produced by worm-induced (toxic substances, immunological response, and physical trauma) villous myointimal proliferation, inflammation, pulmonary hypertension (PHT; see ch. 243), disruption of vascular integrity, and fibrosis (E-Figures 255-3 and 255-4). This may be complicated by arterial obstruction and vasoconstriction caused by live worms,[6] dead worm thromboemboli and HW products.[7] Pulmonary vascular lesions begin to develop within days of worm arrival (as early as 3 months post-infection), with endothelial damage and sloughing, villous proliferation, and activation and attraction of leukocytes and platelets. The immigration of such cells and the release of trophic factors induce smooth muscle cell proliferation and migration, with collagen accumulation and fibrosis. Proliferative lesions eventually encroach upon and even occlude vascular lumina. Endothelial swelling with altered intracellular junctions increases the permeability of the pulmonary vasculature. Worms, which have died naturally or have been killed, elicit an even more severe reaction, inciting thrombosis, granulomatous inflammation, and rugous villous inflammation. Grossly, the pulmonary arteries are enlarged, thick-walled, and tortuous, with roughened endothelial surfaces. These changes are at least partially reversible.[7]

E-FIGURE 255-3 Post-mortem example of severe left caudal lung lobe inflammation. Also note enlarged bronchial lymph node.

E-FIGURE 255-4 The left caudal lobar pulmonary artery from a dog with heartworm disease is opened for the majority of its length. Note the roughened endothelial hypertrophy evident in this dog. This demonstrates the extensive damage produced by heartworms.

Although the role of exercise in exacerbation of the signs of thromboembolic HWD is accepted, its role in the development of pulmonary vascular disease and PHT is less clear. While Rawlings[8] was unable to show an effect of 2.5 months' controlled treadmill exercise on PHT in heavily infected dogs, Dillon[9] showed more severe PHT in lightly infected, mildly exercised dogs than in more heavily infected but unexercised dogs. Clinical observation suggests that outdoor dogs, particularly hunting dogs, have more severe lesions and PHT, possibly related to exercise, but the role of increased exposure and worm burden must also be considered.

Diseased pulmonary arteries are thrombosed, thickened, dilated, tortuous, noncompliant, and functionally incompetent, thereby resisting recruitment during increased demand; hence, exercise capacity is diminished. Vessels to the caudal lung lobes are most severely affected. Pulmonary vasoconstriction results secondary to vasoactive substances likely released from heartworms, as well as endothelin-1 produced in excess by vascular endothelial cells[10] and vasoconstrictive substances, such as serotonin, adenosine diphosphate (ADP), and thromboxane A_2, produced by activated platelets. Furthermore, hypoxia (induced by ventilation-perfusion mismatching secondary to pulmonary thromboembolism [PTE; see ch. 243], eosinophilic pneumonitis, pulmonary consolidation, or all three) further contributes to vasoconstriction. The result is PHT, increased right ventricular afterload, and compromised cardiac output.[9-11] PHT is exacerbated by exercise or other states of increased cardiac output. The right heart, which is an efficient volume pump but does not withstand pressure overload, first compensates by eccentric hypertrophy (dilatation and wall thickening) and, in severe infections, decompensation (right heart failure). In addition, hemodynamic stresses, geometric changes, and cardiac remodeling may contribute to secondary tricuspid insufficiency, thereby complicating or precipitating cardiac decompensation. Further compromise occurs with the advent of cardiac arrhythmia (see ch. 248). Pulmonary infarction is uncommon because of the extensive collateral circulation provided the lung and because of the gradual nature of vascular occlusion. Because of increased pulmonary vascular permeability, perivascular edema may develop. Although, along with an inflammatory infiltrate, this fluid accumulation may be evident radiographically as increased interstitial and even alveolar density, in and of itself, it is seemingly of minimal clinical significance and certainly does not indicate left heart failure (in other words, it is not cardiogenic pulmonary edema and furosemide is not indicated).

Spontaneous or post-adulticidal PTE with dead worms may precipitate or worsen clinical signs, producing or aggravating PHT, right heart failure or, in rare instances, pulmonary infarction. Dying and disintegrating worms worsen vascular damage and enhance coagulation. Pulmonary blood flow is further compromised

and consolidation of affected lung lobes may occur. With acute and massive worm death, this insult may be profound, particularly if associated with exercise. Exacerbation by exercise likely reflects increased pulmonary artery flow with escape of inflammatory mediators into the lung parenchyma through badly damaged and permeable pulmonary arteries (see Figure 255-12). Dillon has suggested that the lung injury is similar to that seen in adult respiratory distress syndrome (ARDS; see ch. 242).[9]

Pulmonary parenchymal lesions also result by mechanisms other than post-thromboembolic consolidation. Eosinophilic pneumonitis is most often reported in true occult HWD, in which immune-mediated destruction of Mf in the pulmonary microcirculation produces amicrofilaremia. This syndrome results when antibody-coated Mf, entrapped in the pulmonary circulation, incite an inflammatory reaction (eosinophilic pneumonitis).[12] A more sinister, but rare form of parenchymal lung disease, termed *pulmonary eosinophilic granulomatosis,* has been associated with HWD. The exact cause and pathogenesis are unknown, but it is felt to be similar to HWD-related eosinophilic pneumonitis.[13] It is postulated that Mf trapped in the lungs are surrounded by neutrophils and eosinophils, eventually forming granulomas and associated bronchial lymphadenopathy.

Antigen-antibody complexes, formed in response to heartworm antigens, can produce glomerulonephritis in heartworm-infected dogs (see ch. 325).[14] The result is proteinuria (albuminuria), uncommonly associated with renal failure.

Heartworms may also produce disease by aberrant migration. This uncommon phenomenon has been associated with neuromuscular and ocular manifestations because worms have been described in tissues such as muscle, brain, spinal cord, and anterior chamber of the eye. In addition, systemic arterial thrombosis with S5 has been observed when worms migrate aberrantly to the aortic bifurcation or more distally in the digital arteries (see ch. 256).[15] Adult heartworms may also passively "migrate" in a retrograde manner from the pulmonary arteries to the right heart and venae cavae, producing caval syndrome (CS), a devastating complication, described later.[16]

It has been recently been recognized as important that the bacterium *W. pipientis* inhabits filarid parasites, including *D. immitis.* Importantly, these bacteria live in a symbiotic relationship with the filarid parasites, being necessary for molts within the mosquito and the canine host (L3-L4, L4-S5). The exact role of *Wolbachia* in the pathogenesis of HWD is unclear, but *Wolbachia* proteins (*Wolbachia* surface proteins [WSP]) have been identified in the glomerulus and lung of heartworm-infected dogs.[17,18] In addition, proteins produced by the bacteria are thought to contribute to the hosts' inflammatory reaction to worm death.

Clinical Signs

The clinical signs of chronic HWD depend on the severity and duration of infection and, in most chronic cases, reflect the effects of the parasite on the pulmonary arteries and lungs and, secondarily, the heart. It is important to point out that the vast majority of dogs with HWI are asymptomatic. Historical findings in affected dogs variably include weight loss, diminished exercise tolerance, lethargy, poor condition, cough, dyspnea, syncope, and abdominal distension (ascites). Physical examination (see ch. 2) may reveal evidence of weight loss, split-second heart sound (13%), right-sided heart murmur of tricuspid insufficiency (13%), and cardiac gallop (see ch. 55).[19] If right heart failure is present, jugular venous distension and pulsation typically accompanies hepatosplenomegaly and ascites (E-Figures 255-5 and 255-6). Cardiac arrhythmias and conduction disturbances are uncommon in chronic HWD (<10%). With pulmonary parenchymal manifestations of HWD, cough and pulmonary crackles may be noted and, with granulomatosis (a rare occurrence), muffled lung sounds, dyspnea, and cyanosis are also reported. When massive PTE occurs (see ch. 243), the additional signs of dyspnea, fever, and hemoptysis may be present.

E-FIGURE 255-6 Jugular venous distension apparent in a dog with heartworm disease and jugular venous distension.

Diagnosis

Microfilarial Detection

Ideally, the diagnosis is made by routine evaluation prior to the onset of clinical signs (i.e., HWD). Dogs in areas in which heartworms are endemic should undergo a heartworm test yearly, particularly if not receiving heartworm preventive. This was accomplished most commonly in the past by the microscopic identification of Mf on a direct blood smear, above the buffy coat in a microhematocrit tube, using the modified Knott test, or after millipore filtration. The accuracy of these tests, typically used for routine screening and for the diagnosis of suspected HWI, is improved by multiple testing. The modified Knott test and millipore filtration are more sensitive because they concentrate Mf, improving chances of diagnosis. The direct smear technique allows examination of larval motion, helping in the distinction of *D. immitis* from *Dipetalonema reconditum* (now termed *Acanthocheilonema reconditum*); other useful diagnostic criteria are included in Table 255-1. This distinction is important because the presence of the latter parasite does not require expensive and potentially harmful arsenical therapy, as does *D. immitis*. None of these tests can rule out HWI conclusively because of the potential for amicrofilaremic infections (reported to be 5% to 67% of cases, with 10-20% being generally accepted[20]) and the fact that false-negative results may occur, particularly if microfilarial numbers are small, a small amount of blood is collected, or direct smears are relied upon. The number of circulating Mf in the peripheral blood does not correlate well with the number of adult heartworms and therefore cannot be used to determine the severity of infection. In most practices, microfilarial testing has been largely supplanted by immunodiagnostic antigen testing (i.e., enzyme-linked immunosorbent assay [ELISA], lateral flow immunoassay, and rapid immunomigration techniques; Table 255-2). The modified Knott test, millipore filter test, or wet mount direct smear should *always* be performed, however, in antigen-positive dogs to determine microfilarial status. The reasons for this include knowing if large numbers are present, which allows pre-treatment or a scheduled observation time after the first dose of a macrocyclic lactone (ML). Secondly, there is concern that HW resistance to ML may be favored when these drugs are administered to HW-positive, microfilaremic dogs. Some veterinarians choose to combine the antigen and microfilarial tests. This practice is most useful in dogs receiving no preventive (MLs typically render the dog amicrofilaremic). The generally accepted 1% of infected dogs that are Mf positive and antigen negative[20] may be an underestimate, based on new information about antibody-antigen complexing in HWI.[21-23]

TABLE 255-1

Differentiating Characteristics of *Dipetalonema reconditum* and *Dirofilaria immitis*

	NUMBER IN BLOOD	MOTION	SHAPE	LENGTH (MODIFIED KNOTT TEST)
D. reconditum	Usually few	Progressive	Curved body Blunt head Curved or "buttonhook" tail	263 microns (250-288 microns)
D. immitis	Usually many	Stationary	Straight body and tail Tapered head	308 microns (295-325 microns)

Immunodiagnostic Antigen Tests

In dogs not having received ML preventive therapies, the prevalence of amicrofilaremic infections is typically 10% to 20%.[24] This may be observed in prepatent (young) infections, in single-sex infections, with immune-mediated destruction of Mf, and with drug-induced amicrofilaremia. Dogs receiving ML preventives are typically amicrofilaremic. Hence, immunodiagnostic tests are now regularly used for both screening and in suspected HWI. These tests are popular because of their high sensitivity and specificity and ease of performance (see Table 255-2).[25-28] The weakness of these tests is that they detect antigen from adult female heartworms and hence will produce negative results during the first ≈6 (5 to 8) months of any infection, in all-male infections, and in infections with low female worm burdens. In fact, in a study of the performance of three commercial test kits in detecting low worm burden (≤4 females), naturally acquired infections demonstrated an overall (median for three test kits) sensitivity of 79% and a median specificity of 97%.[29] The sensitivity was relatively low (64%) for infections of only one female worm but improved with increasing female worm burden (median of 85%, 88%, and 89% for two, three, and four female worms, respectively). Of course, with higher worm burdens, better sensitivity is experienced. Nevertheless, despite overall excellent results in detection of small worm burdens, false-negative results do occur (Figure 255-7).[29]

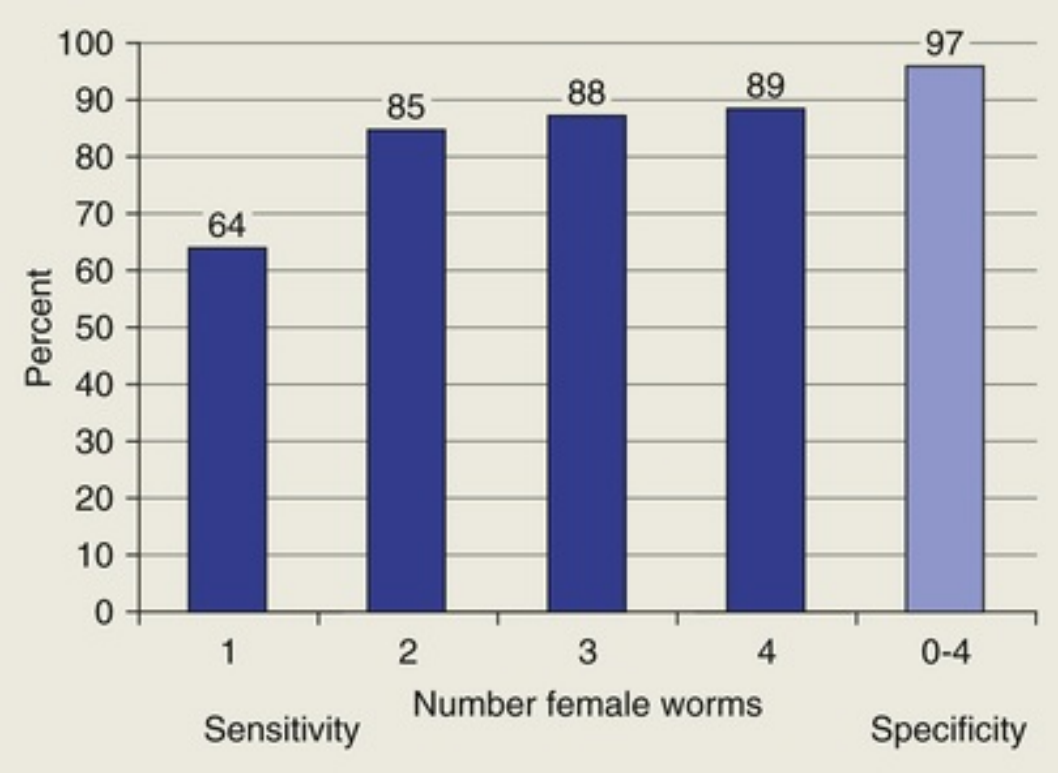

FIGURE 255-7 Comparison of sensitivity and specificity of three commercial heartworm test kits on known sera from naturally infected dogs with low worm burdens (zero to four adult female heartworms). Dark blue bars represent median sensitivity of the three tests for sera of dogs with one, two, three, and four adult female heartworms. Light blue bar represents the median specificity of the three tests for sera from dogs infected with zero to four adult female heartworms. (Data from Atkins CE: Comparison of results of three commercial heartworm antigen tests in dogs with low heartworm burdens. *J Am Vet Med Assoc* 222:1221-1223, 2003.)

Certain ELISA antigen tests are designed to quantitatively predict worm burdens, based on antigen concentrations. Semiquantitative ELISA (SNAP Canine Heartworm PF) has been used to successfully predict antigen load and hence approximate worm burden. Rawlings and colleagues[30] have shown this to be useful in predicting thromboembolic complications, with dogs bearing greater worm burdens being more likely to experience such complications after adulticide. This application is most useful, however, in instances of low antigen concentration (suggesting low worm burden) because high antigen concentrations might be recognized when all or most worms are dead, having released a large amount of antigen into the circulation. ELISA technology also allows determination of the efficacy of adulticide therapy. ELISA antigen concentration typically falls to undetectable levels 8 to 12 weeks after successful adulticide therapy, so a positive test persisting beyond 12 weeks post-therapy has been suggested to indicate persistent infection.[31] However, antigen tests may remain positive for longer periods, and this author does not assume a failure in adulticidal therapy unless the antigen test is positive >6 months after adulticidal therapy and does not advocate routine retesting until 8-12 months post-treatment.

The American Heartworm Society (AHS) now prefers "no antigen detected" to the term "negative," when referring to antigen test results that are not positive. This is to emphasize the fact that negative tests do not rule out immature, small, or all-male HWI.

As previously suggested, ML therapy with either ivermectin, milbemycin oxime, moxidectin, or selamectin results in clearance of Mf within 6 to 8 months.[31-36] In addition, embryostasis may be permanent. Thus the sole use of direct smears, the modified Knott test, or the millipore filter test (i.e., microfilarial tests) in dogs receiving ML heartworm preventives is inappropriate, though they certainly play a supplemental role. The only routinely effective testing modality in dogs receiving monthly preventive is the use of antigen assays. A general approach to the diagnosis of HWI is demonstrated in Figure 255-8.

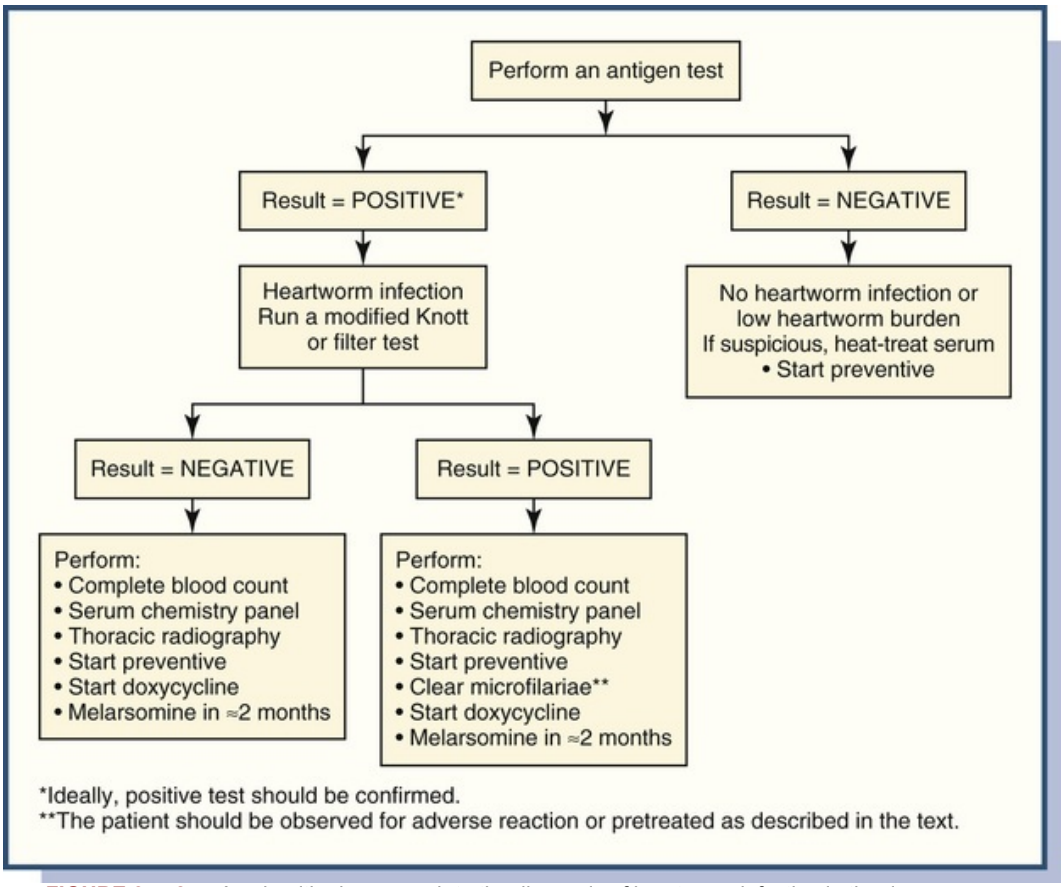

FIGURE 255-8 An algorithmic approach to the diagnosis of heartworm infection in the dog.

Radiography

Although not an effective screening test for HWI, thoracic radiography offers an excellent method for detecting HWD, for determining its severity, for evaluating pulmonary parenchymal changes, and for discovery of differential diagnoses. Radiographic abnormalities, which develop relatively early in the disease course, are present in approximately 85% of cases. According to the study of 200 heartworm-infected dogs by Losonsky and colleagues,[37] radiographic features (Figure 255-9) include right ventricular enlargement (60%), increased prominence of the main pulmonary artery segment (70%), increased size and density of the pulmonary arteries (50%), and pulmonary artery tortuosity and "pruning" (50%). If heart failure is present, enlargement of the caudal vena cava, liver, and spleen, as well as pleural effusion, ascites, or both, may be evident. Thrall and Calvert[38] suggested that pleural effusion is uncommon in heart failure due to HWD, demonstrating that marked enlargement of the cranial lobar pulmonary artery was a more sensitive indicator of HWD-associated heart failure than enlargement of the caudal vena cava.

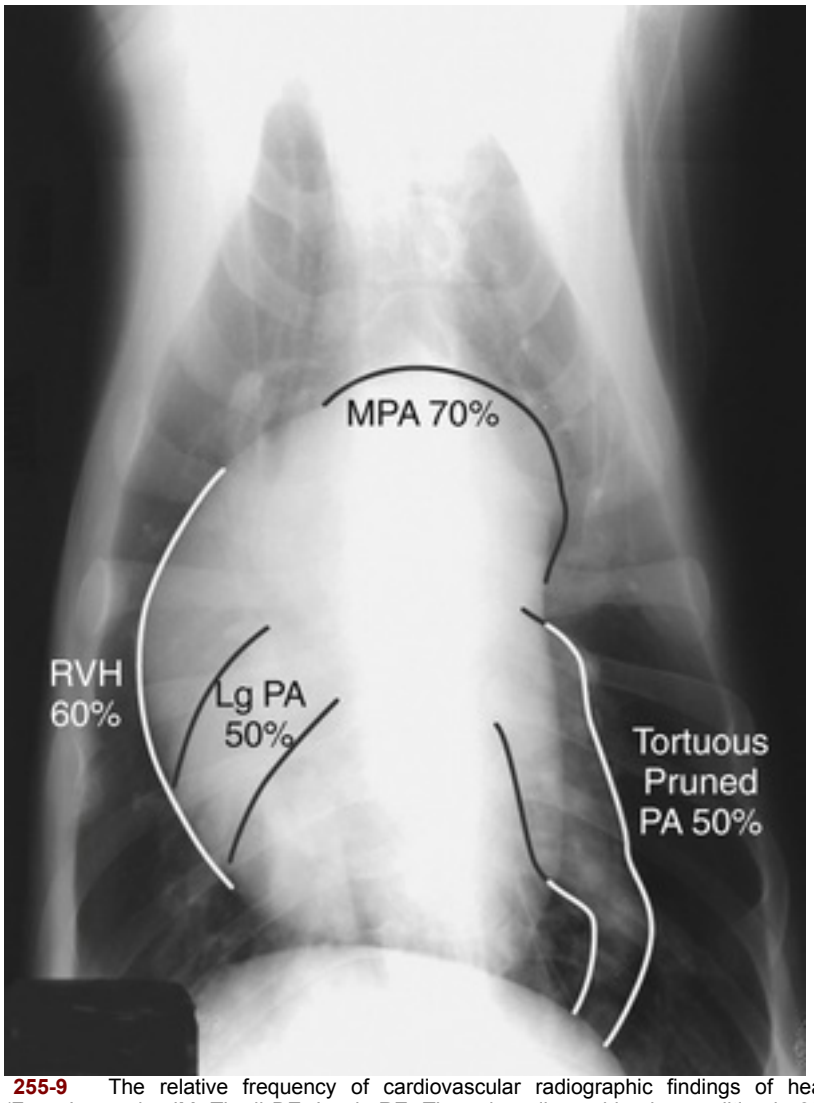

FIGURE 255-9 The relative frequency of cardiovascular radiographic findings of heartworm disease. (From Losonsky JM, Thrall DE, Lewis RE: Thoracic radiographic abnormalities in 200 dogs with heartworm infestation. *Vet Radiol* 24:120-123, 1983.)

Thoracic radiographs obtained in the ventrodorsal projection are preferable for cardiac silhouette evaluation and ease, and they often minimize patient stress. However, the dorsoventral projection is superior for the evaluation of the caudal lobar pulmonary vessels, which are considered abnormal if larger than the diameter of the ninth rib where the rib and artery intersect (Figures 255-9 and 255-10). The cranial pulmonary artery is best evaluated in the lateral projection and should normally not be larger than its accompanying vein or the proximal one third of the fourth rib (Figure 255-11).

FIGURE 255-10 Dorsoventral thoracic radiograph obtained from a dog with chronic heartworm disease. Reader should note the enlarged main pulmonary artery, right ventricular enlargement, and enlarged, tortuous caudal lobar pulmonary arteries. (See Figure 255-9 for schematic of radiographic abnormalities.)

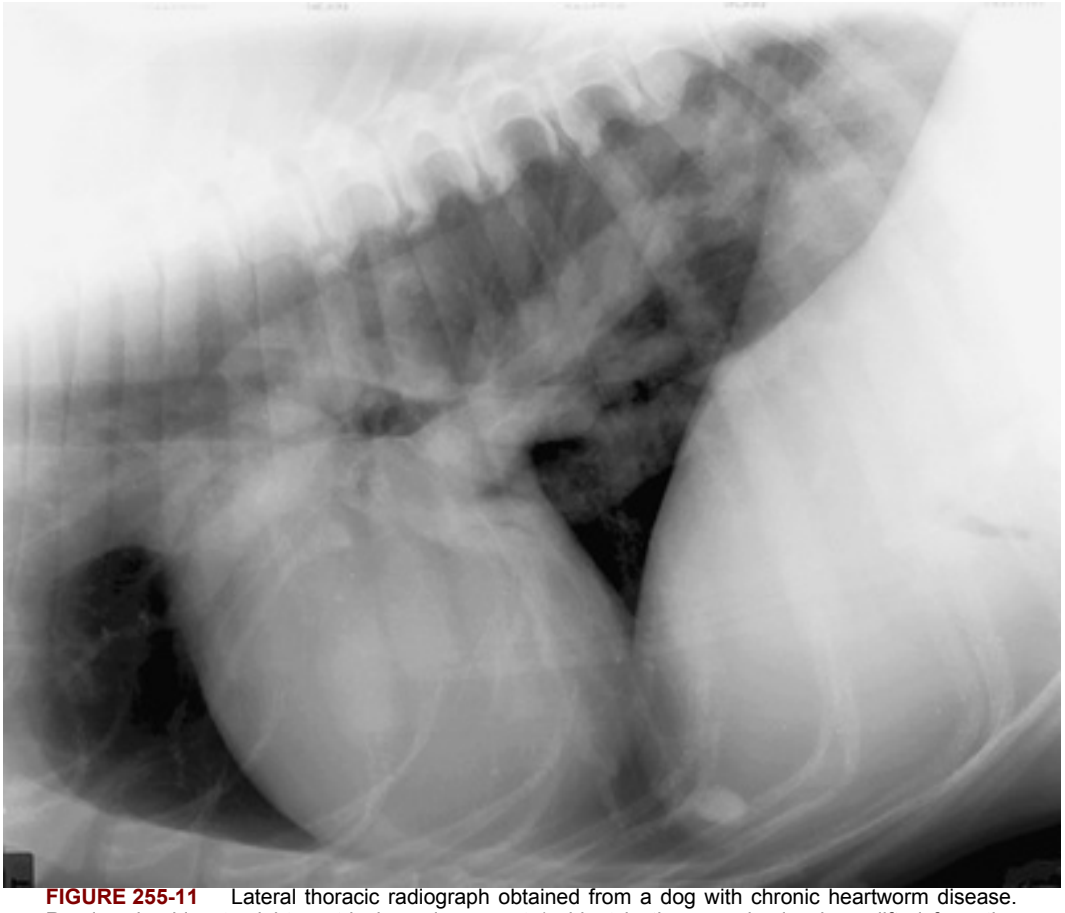

FIGURE 255-11 Lateral thoracic radiograph obtained from a dog with chronic heartworm disease. Reader should note right ventricular enlargement (evident in the apex having been lifted from the sternum), enlarged apical pulmonary artery, and an interstitial infiltrate in the caudal lung lobes.

The pulmonary parenchyma can best be evaluated radiographically. With pneumonitis, the findings include a mixed interstitial to alveolar density, which is typically most severe in the caudal lung lobes (Figure 255-12). In eosinophilic nodular pulmonary granulomatosis, the inflammatory process is arranged into the interstitial nodules, associated with bronchial lymphadenopathy and, occasionally, pleural effusion. With PTE, the radiographic findings of coalescing interstitial and alveolar infiltrates, particularly in the caudal lung lobes, reflect the increased pulmonary vascular permeability and inflammation described previously (see Figure 255-17). Consolidation may accompany massive embolization, pulmonary infarction, or both.

FIGURE 255-12 Lateral thoracic radiograph obtained from a coughing dog with chronic heartworm disease. The diffuse interstitial to alveolar infiltrate is severe and represents eosinophilic pneumonitis. Cardiac and pulmonary arterial changes are less severe than seen in Figures 255-10, 255-11, and 255-17.

Electrocardiography

Electrocardiography is useful in detecting arrhythmias but is generally insensitive in detection of cardiac chamber enlargement in HWD, when compared with radiography and echocardiography. If radiography does not suggest HWD, it is unlikely that the electrocardiogram (ECG) will be useful in the absence of arrhythmias. With the exception of CS and heart failure, arrhythmias are rare (2% to 4%).[39,40] Nevertheless, the finding of a right ventricular enlargement pattern (see ch. 248) is supportive evidence for HWD. Lombard and Ackerman[39] demonstrated that ECG abnormalities were present in 38% to 62% of dogs with moderate and severe echocardiographic changes of HWD, while Calvert and Rawlings[41] found that only 6% of 276 dogs with dirofilarosis had ECG changes suggestive of right ventricular enlargement. These investigators[41] also showed that the most sensitive ECG parameters for detection of HWD are lead II S waves deeper than 0.8 mv, mean electrical axis greater than 103 degrees, and greater than three ECG parameters of right heart enlargement. The latter ECG finding (more than three criteria) is considered to be the most accurate. P-pulmonale (tall P waves, indicative of right atrial enlargement) is unusual in HWD.

Echocardiography

Echocardiography is relatively sensitive in the detection of right heart enlargement because the right ventricular end-diastolic dimension and septal and right ventricular free wall thicknesses are all increased (Figure 255-13). Lombard reported abnormal (paradoxical) septal motion in 4 of 10 dogs with HWD.[42] The ratio of left-to-right ventricular internal dimensions is a useful calculation, being reduced from a normal value of 3 to 4 to a mean value of 0.7 in dogs with HWD. In some instances, two-dimensional echocardiography can be used to demonstrate worms in the pulmonary artery (see Figure 255-30). Although heartworms can occasionally be demonstrated in the right ventricle, this method is insensitive except in dogs with CS or very heavy worm burdens, because the worms infrequently inhabit this location.[42]

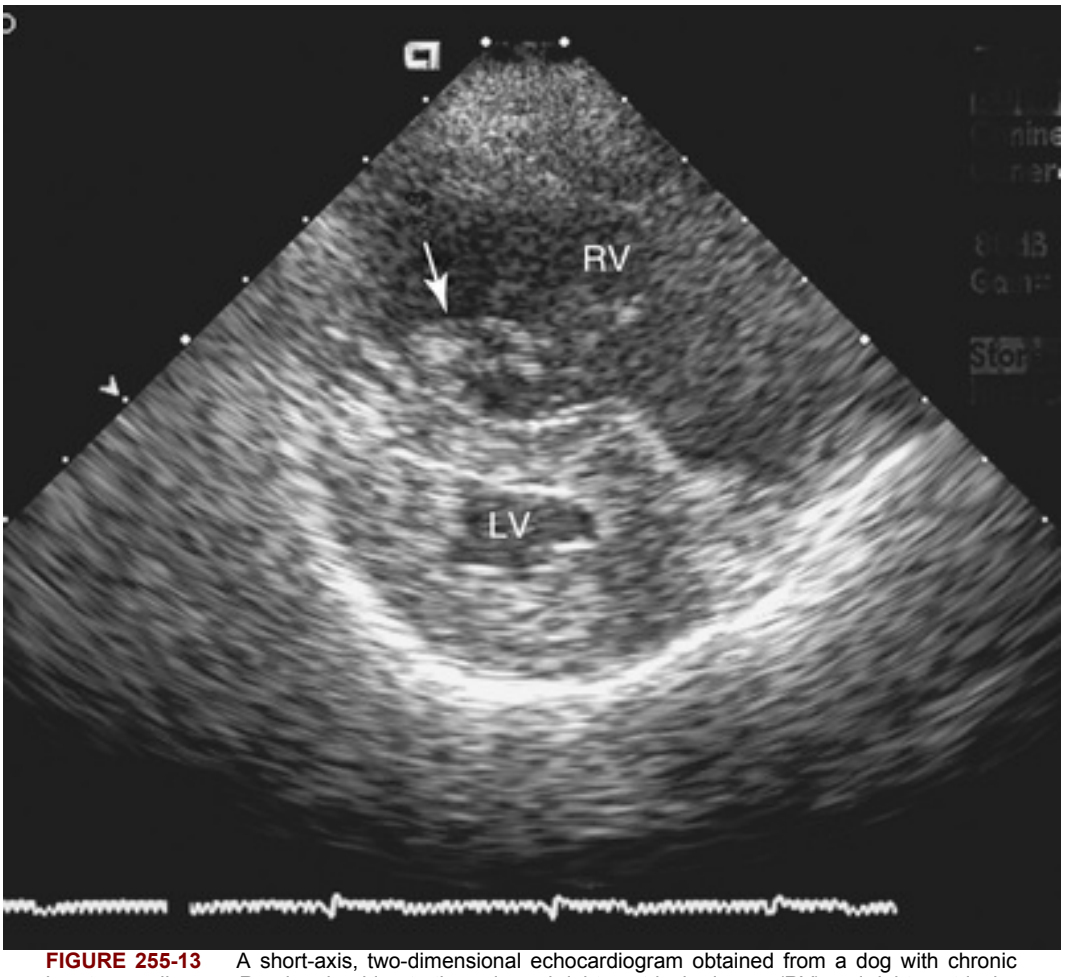

FIGURE 255-13 A short-axis, two-dimensional echocardiogram obtained from a dog with chronic heartworm disease. Reader should note the enlarged right ventricular lumen (RV) and right ventricular papillary muscle (arrow). The septum is flattened and bows toward the small left ventricle (LV). The electrocardiogram at the bottom of the figure demonstrates that this is a diastolic frame.

Clinical Pathology

Hematologic and serum chemical abnormalities, although of limited use in making a diagnosis of HWD, are frequently useful in providing supportive evidence and for evaluating concurrent disease processes that may or may not be related to HWD. Calvert and Rawlings[41] report that the dog with HWD in Georgia is typically found to have a low-grade, nonregenerative anemia (present in 10% of mildly to moderately affected dogs and up to 60% of severely affected dogs), neutrophilia (20% to 80% of cases), eosinophilia (≈85% of cases), and basophilia (≈60% of cases). Thrombocytopenia, which may be noted in chronic HWD, CS, and DIC, is most common 1 to 2 weeks after arsenical therapy. In severe HWD, especially if heart failure is present, liver enzyme activities may be increased (10% of cases) and occasionally hyperbilirubinemia is noted. Azotemia, seen in only 5% of cases, may be prerenal in origin if dehydration or heart failure is present or may be secondary to glomerulonephritis. In 10% to 30% of cases, albuminuria is noted. If glomerular disease is severe, hypoproteinemia (hypoalbuminemia) has the potential to complicate the clinical picture. Not surprisingly, the most severe clinicopathologic findings are associated with the most severe clinical findings.

Evaluation of tracheobronchial cytology (see ch. 101) is at times useful, particularly in the coughing dog with pneumonitis, occult HWD, and minimal radiographic evidence of HWD. Microscopic examination reveals evidence of an eosinophilic infiltrate. In microfilaremic dogs, Mf may occasionally be detected in this manner. Abdominal fluid analysis in cases of congestive heart failure (CHF) typically reveals a modified transudate. Dogs with HWD and right heart failure have central venous pressure (CVP; see ch. 76) that ranges from 12 to more than 20 cm H_2O, but ascites may develop at lower CVPs if hypoalbuminemia is present.

Only recently has the use of biomarkers been evaluated expressly for HWI/HWD. Venco et al[43] reported on C-reactive protein (CRP), which binds to dead and dying cells in response to increased cytokine plasma

concentrations. The CRP level in serum of dogs with and without HWI/HWD was shown to be higher in HWD than in controls and correlated to degree of pulmonary artery damage and PTE. The hope is that this biomarker, which rises and falls quickly with disease and its resolution, respectively, may be useful in staging HWI, monitoring therapy, and evaluating therapeutic outcome. Carreton et al have shown that D-dimer, cardiac troponin I and myoglobin, are abnormally elevated in HWD, indicating PTE and myocardial damage, respectively.[41,44,45] While the results of these preliminary studies are encouraging, the exact clinical use of biomarkers in diagnosis and evaluation of HWI/HWD requires further study.

Medical Management

The medical management of HWI is complex because of the complicated parasite life cycle, the marked variability in clinical manifestations and severity of HWD, prophylactic considerations, adulticidal and microfilaricidal considerations, and the relative toxicity and complications associated with adulticidal therapy. For these reasons, the diagnosis, prevention, and treatment of HWI remain a challenge.

Prevention of Heartworm Disease

Prevention of HWD in pets is an obvious and attainable goal for the veterinary profession. Prevention failure results from ignorance or misunderstanding on the part of owners as to the presence or potential severity of HWI, lack of owner compliance, or from inadequate instruction on preventive measures by the attending veterinarian.[1,46-48] Studies of owner compliance have revealed that approximately 55% of dog owners using veterinary care purchase heartworm preventive, and enough medication is dispensed only to meet the needs of approximately 56% of those dogs. Hence the proportion of "cared for" dogs in the population that receive adequate heartworm prophylaxis is less than one third.[47] If one takes into consideration doses purchased but not administered and dogs that are never taken to a veterinarian, the percentage of protected dogs falls drastically. The latter point was emphasized in North Carolina in 1999, when Hurricane Floyd caused extensive flooding and disruption in the poorest part of the state. Of dogs rescued from the floodwaters, 67% were infected with heartworms (personal communication, Dr. Kelli Ferris, North Carolina State University, 2003). In addition, evidence suggests that the veterinary profession is falling short in client education. A survey of veterinary clients purchasing ML preventives found that 38% did not realize that their prescribed drug's spectrum was broader than solely preventing HWI.[49] Another study utilized "client-actors" with pets to probe the role of veterinarians in compliance failure and found that only 60% of dog owners and ≈25% of cat owners received HW mention, questions, or medication during their scheduled visit.[50]

Macrocyclic Lactone Antibiotics

The 1987 introduction of the ML ivermectin was followed by the development and release of milbemycin oxime, selamectin, and moxidectin. MLs include the avermectins (ivermectin, doramectin, eprinomectin, and selamectin) and milbemycins (milbemycin oxime and moxidectin) and are derived from soil microorganisms belonging to the genus *Streptomyces.* This drug class has provided the veterinary profession with highly effective heartworm preventives in a variety of formulations, drug combinations, spectra, and modes of administration. These agents, because they terminate tissue stage larval development (L3 and L4) during the first 2 months after infection, have a large temporal window of efficacy, and are administered orally or topically monthly or by injection every 6 or 12 months (12-month product not available in the USA), thereby being very convenient. Additionally, they produce less severe reactions than previously experienced with diethylcarbamazine[51] when inadvertently given to microfilaremic dogs. They also variably allow a grace period ("reach-back," "retroactive efficacy," or "safety net") for inadvertent lapses in administration, being at least partially effective with treatment lapses of up to 2 to 3 months, when used continuously for the next 12 months.[52] Additionally, they have a dual role as microfilaricides[28,52-54] and some MLs have adulticidal activity, if used continuously for prolonged periods.[54-57] It bears emphasizing that, at the time of this writing, HWs have shown resistance to this class of drugs (all molecules and formulations) and reach-back and continuous systemic ML presence,[58] while offering potential advantages in making up for failures in purchase, administration, or absorption, *should not be relied upon.* Regardless, if MLs are administered without interruption (i.e., every month or every 6 months, depending on product), these advantages accrue.

Ivermectin

Ivermectin, a ML derived from avermectin B_1 that is obtained from *Streptomyces* spp., is effective against a

range of endoparasites and ectoparasites and is marketed as a once-monthly heartworm preventive. It is also marketed in a form combined with pyrantel pamoate (hookworms and roundworms) and one with pyrantel pamoate and praziquantel (hookworms, roundworms, and tapeworms) to improve efficacy against intestinal helminths (Table 255-3). These combination products are safe in puppies as young as 6 weeks of age. The ML provides a wide window of efficacy and provides some protection when lapses in therapy occur ("reach-back"). Ivermectin is effective as a prophylactic with lapses of up to 2 months. Protection in experimental infections is extended, with continuous 12-month administration post-exposure, with lapses of 3 months (98% efficacy) and of 4 months (95% efficacy).[52] As stated previously, ivermectin is microfilaricidal at preventive dosages (6 to 12 mcg/kg/month), resulting in a gradual decline in microfilarial numbers. Despite this gradual microfilarial destruction, generally mild, adverse reactions (transient diarrhea) can occur if administered to microfilaremic dogs.[52] Individuals with the *ABCB1* (aka, multidrug resistance 1 *[MDR1]* and P-glycoprotein 1 *[PGP1]*) gene mutation (most often, but not exclusively Collies, Shetland Sheepdogs, and other herding breeds) are susceptible to ivermectin (and other ML) toxicosis at *high, extra-label* dosages that can lead to neurologic signs.[59] This has typically occurred with the use of concentrated livestock preparations, with clinical signs recognized with doses greater than 16 times the recommended dosage.[36] For this reason, only preparations designed for pet use should be administered to dogs. When used appropriately, ivermectin is very effective in preventing HWI. Additionally, it has been shown to have adulticidal properties when used continuously for 16 months[55] and to be 95% effective with continuous administration for 30 months[56] (see Controversies). This adulticidal feature is enhanced with the addition of a 30-day course of doxycycline therapy. Ivermectin and doxycycline appear to be synergistic in a number of ways related to HWI (see Anti-*Wolbachia* Therapy).

TABLE 255-3

Spectra of Macrocyclic Lactones in Dogs

Milbemycin Oxime

Milbemycin oxime is a non-macrolide member of a family of milbemycin ML antibiotics and is derived from a different species of *Streptomyces.* At 0.5 to 1 mg/kg, it has efficacy against developing L3 and L4 larval stages, stopping development in the first 6 weeks. It can therefore be given at monthly intervals with a "reach-back" effect of 2 months when doses are inadvertently delayed. With 12 months' continuous treatment post-exposure, this "safety net" can be extended to 3 months (97% efficacy), falling to 41% with lapses of 4 months.[52] At the preventive dosage, milbemycin oxime is a broad-spectrum parasiticide, being also effective against certain hookworms, roundworms, and whipworms (see Table 255-3) and can be initiated in puppies as young as 2 months of age. In microfilaremic dogs, milbemycin oxime has potential for adverse reactions because it is an excellent microfilaricide at the preventive dosage.[32,33] Rare adverse reactions, similar to those observed with ivermectin at microfilaricidal dosages, may be observed in microfilaremic dogs receiving milbemycin oxime at preventive dosages.[33] Based on the fact that label claims of marketed ML, regarding Mf

death and reactions, are very similar, the importance of this phenomenon has been questioned.[35] As with microfilaricidal dosages (50 mcg/kg) of ivermectin, diphenhydramine (2 mg/kg IM) and dexamethasone (0.25 mg/kg IV) may be administered prior to milbemycin oxime to eliminate the possibility of adverse reactions in Mf-positive dogs, particularly in those with high Mf counts. Milbemycin oxime, like other MLs, is safe for use in dogs with the *ABCB1* mutation at the preventive dosage. With appropriate use, milbemycin oxime is highly efficacious as a heartworm prophylactic. Today, milbemycin oxime is available as a single agent and combined with lufenuron or spinosad, to expand its spectrum to include ectoparasites (see Table 255-3).

Moxidectin

Moxidectin was originally marketed as an oral, narrow-spectrum (heartworm and hookworm) heartworm preventive. It has been shown to be safe and effective at 3 mcg/kg PO, given monthly up to 2 months post-infection.[60,61] Oral moxidectin (currently not marketed in the U.S., but it and a topical formulation are Federal Drug Administration–Center for Veterinary Medicine [FDA-CVM] approved) is gradually microfilaricidal at this dosage, and did not produce adverse reactions in a small number of microfilaremic dogs treated with the prophylactic dosage.[53] At 15 mcg/kg, 98% reduction in Mf numbers was documented 2 months post-treatment. Moxidectin is safe in Collies and other breeds with the *ABCB1* mutation,[62] but cannot be administered orally to dogs <6 months of age or to cats.

A parenteral, narrow-spectrum (HWs and hookworms) liposomal formulation of moxidectin, which provides the potential to improve owner compliance, gives 6 months' protection with one subcutaneous injection. With 12 months' (two injections) continuous treatment, injectable moxidectin is 97% effective at preventing infection after a 4-month lapse in preventive therapy but, surprisingly, appears to have limited adulticidal properties.[61] It cannot be administered to dogs <6 months of age or to cats of any age.

Most recently, moxidectin (2.5% for dogs and 1% for cats) has been combined with imidacloprid (10%) and marketed as a broad-spectrum topical product (see Table 255-3).[63,64] This combination product produces high and sustained concentrations of moxidectin in the body and has increased endoparasitic and ectoparasitic efficacy. It is safe, has excellent reach-back capabilities, and is highly efficacious for heartworm prevention when applied monthly at approximately 2.5 to 6.8 mg/kg moxidectin for dogs (1 to 2.5 mg/kg for cats). At the recommended dosage, this preventive is also effective at preventing and killing fleas; treatment and control of hookworms, roundworms, and whipworms; as well as eliminating heartworm Mf and sarcoptic mange. Bathing twice, as soon as 90 minutes after application, does not alter efficacy. Safety has been shown at three-fold and five-fold topical doses in ivermectin-sensitive collies. This product can be administered to puppies at 7 and kittens at 9 weeks of age.

Selamectin

Selamectin is a semisynthetic ML. It is unique in that a single molecule provides broad-spectrum protection with once-monthly topical use (see Table 255-3). Its efficacy against HWI is similar to that of other MLs in both dogs and cats.[66] At 6 to 12 mg/kg topically, this preventive is effective against heartworms and kills fleas and flea eggs, sarcoptic mange mites, ticks, and ear mites.[46] Bathing and swimming, as soon as 2 hours after application, does not alter efficacy. Safety has been shown at tenfold topical doses, with oral consumption of single doses and, in ivermectin-sensitive Collies, at recommended dosages and five-fold overdosing for 3 months.[67] Like other MLs, selamectin has at least a 2-month reach-back effect and, with 12 months' continuous administration, is 99% protective after 3-month lapses in prophylaxis.[66,68] Selamectin has slow microfilaricidal activity similar to other MLs.[68] Selamectin can be administered to puppies as young as 6 weeks of age. Chronic, continuous selamectin administration has adulticidal efficacy, although no published data indicate that it is as effective in this role as ivermectin.

Eprinomectin

Eprinomectin, the amino-avermectin derived from avermectin B_1 (modified terminal oleandrose moiety called 4(OO)-epiacetylamino-4(OO)-deoxy-avermectin B_1) was originally used as a highly effective topical formulation against internal and external parasites of cattle. This ML is also formulated in a combination pharmaceutical for cats[69] with excellent bioavailability, distribution, and systemic activity following topical application.[70] After topical application, the average eprinomectin maximum plasma concentration was reached 24 h after topical dosing in the majority of the cats, with an average bioavailability of 31%. The

average terminal half-life is 114 hours, due to slow absorption, compared to the rapid mean elimination half-life of 23 hours, following intravenous administration.[70] The combination product (BROADLINE; fipronil, (S)-methoprene, eprinomectin, and praziquantel) has been approved in Europe for the treatment/prevention of *D. immitis, Aelurostrongylus,* tapeworms, hookworms, *T. cati,* and fleas. Multiple studies have shown this product to be an efficacious and safe topical HW preventive at the minimum intended dosage of 0.5 mg/kg monthly.[70]

In summary, the ML class offers a convenient, effective, and safe method of heartworm prophylaxis with varying spectra and modes of administration (see Table 255-3). All are safe in Collies and other breeds with the *ABCB1* mutation, when used as directed, at preventive dosages. They all have microfilaricidal efficacy, although only the imidacloprid-moxidectin topical formulation has FDA-CVM approval for this use, and are thought to render female heartworms sterile. Hence, Mf testing for HWI cannot be reliably used in dogs receiving these products. Prophylaxis should be commenced no later than 6 to 8 weeks of age in endemic areas or as soon thereafter as climatic conditions dictate.[27,71] Although safer than diethylcarbamazine (the original daily HW preventive, eventually replaced by the ML) in microfilaremic dogs, there is a variable risk when MLs are administered to these dogs. Before first-time administration, any dog older than 6 months of age and at risk of infection should be tested (antigen test, followed by a Mf test, if antigen positive; or ideally, in all cases) and tested a second time in 7-8 months.

Understanding the "reach-back" capability of this class of drugs is important because it is an advantage unto these molecules, but it should not be considered in the routine preventive protocol. Even though protective in experimental situations for at least 8 weeks post-exposure, MLs should be administered *precisely* as indicated by the manufacturer. MLs can, however, be used to "rescue" dogs that have experienced lapses in preventive administration.[27,71] If accidental lapses of more than 6-8 weeks occur (depending on location and time of year), the preventive should be reinstituted at the recommended dosage and maintained for at least 12 consecutive months to attain reach-back and adulticidal benefits.[36] In the event of a lapse in preventive administration during a time of known exposure risk, an antigen heartworm test should be performed 7 to 8 months after the last possible exposure to determine if infection has occurred.

Both the AHS (https://www.heartwormsociety.org) and the Companion Animal Parasite Council ([CAPC], www.CAPCvet.org) advocate yearlong prevention, regardless of geographic location.[72] This stance remains controversial as it is known that HWs are not transmitted all year long, other than in sites in the very southern tip of the U.S. Because many veterinarians and pet owners in northern climes still use a seasonal approach to HW prophylaxis, the AHS recommends beginning ML HW preventives within 1 month of the anticipation of transmission season[36] and continuing 1 month beyond the transmission season.[27,71] This author advocates yearlong prevention, at the very least, below the Mason-Dixon line in North America (see Controversies [addendum in electronic edition at ExpertConsult.com]).

In the last decade, concern of HW resistance to MLs has surfaced (see Controversies [addendum in electronic edition at ExpertConsult.com]). While this is important, the ML class is still largely effective in preventing HWI, and the use of these products should continue.

Blocking Agents: Repellent Insecticides

Permethrin, a third-generation pyrethroid, is an insecticide which has a rapid knockdown effect against a variety of species of insects. This molecule is currently found in an oral form in at least 2 repellents that have utility against mosquitoes and, thereby, heartworms. One has been shown to provide month-long repellence and lethality to 3 heartworm vectors *(A. aegypti* and *albopictus* and *C. pipiens).*[73] The second has been shown to repel and kill *A. aegypti* mosquitoes allowed to feed on dogs infected with JYD-34 HW strain.[74] Feedings on untreated control dogs yielded ≈80-95% engorgement rate, with 95% of mosquitoes harboring L1. However, only 2% of mosquitoes became engorged on treated dogs 28 days after the medication was applied. The implication from these studies is that a monthly application of permethrin can repel and kill mosquitoes, effectively eliminating HW transfer to and from the feeding victims, also reducing the discomfort of mosquito bites and local mosquito populations. This approach is also effective for protecting against ML-resistant HW and promises to be an effective adjunct to current preventive measures.

Adulticidal Therapy

Melarsomine

In most cases of HWD, it is imperative to rid the patient of the offending parasite. Thiacetarsamide

(Caparsolate), for decades the only drug approved for this purpose, is no longer marketed, though some stockpiles exist. It has been replaced by melarsomine (Immiticide), an organoarsenical, superior in safety and efficacy to thiacetarsamide.[75,76] In a study of 382 dogs with HWI receiving melarsomine, none required cessation of therapy due to hepatorenal toxicosis (as compared with 15% to 30% with thiacetarsamide), and no case of severe PTE was observed.[77]

Melarsomine has a mean retention time five times longer than thiacetarsamide, and its metabolites are free in the plasma (on which heartworms feed).[75,76] Hence, it has superior efficacy. With two doses (2.5 mg/kg IM q 24 h for two treatments), the efficacy approximates 90%, with 99% efficacy achievable with repeated two-dose therapy in 4 months or with the split dosage described later. It is important to realize that a 90% worm kill does not translate into 90% of treated dogs being cleared of infection. Estimates are that only 70% of dogs are cleared with the 2-injection protocol, even though their worm burden is drastically reduced.[76]

Despite the enhanced safety of this product, adverse reactions are still noted.[19,24,78,80] In fact, successful pharmacologic adulticidal therapy, by definition, dictates thromboembolic events. The clinician can diminish the severity of this complication by restricting exercise after melarsomine administration. Perhaps the drug's biggest asset is the possibility of flexible dosing ("split-dose"—1 injection, followed in no less than 30 days, by 2 injections, the latter spaced by 24 hours), allowing the potential for a safer 50% initial worm kill, followed by subsequent injections to approach 100% efficacy. Studies have shown that patients treated with the split-dose regimen have a higher seroconversion to a negative antigen status than patients previously treated with either Caparsolate or with the standard melarsomine dosing regimen.[81,82]

A split-dose protocol can be used in severely afflicted individuals or in those in which PTE is anticipated (Table 255-4). This method allows for destruction of only one-half the worms initially (one injection of 2.5 mg/kg IM), thereby lessening the chance for embolic complications. This single dose is followed by a two-dose regimen in 1 month, if clinical conditions permit; the author has waited as long as 3 months when there was significant adversity with the first injection. Although the manufacturer recommends this protocol for severely affected dogs, the author uses it for all cases, unless financial constraint or underlying concern for arsenic toxicosis exists (e.g., pre-existent severe renal or hepatic disease; Figure 255-14).[78] Disadvantages to the split-dose method include additional expense, increased total arsenic administration, and the need for 2 months' exercise restriction.

Manufacturer's Recommendations for the Use of Melarsomine Dihydrochloride, Based on Patient Status

CLASS 1	CLASS 2	CLASS 3	CLASS 4
Heartworm infection (asymptomatic, no radiographic lesions)	**Symptomatic heartworm disease (mild to moderate signs)**	**Symptomatic heartworm disease (severe signs)**	**Caval syndrome**
Two doses melarsomine 24 hours apart (2.5 mg/kg IM)	Two doses melarsomine 24 hours apart (2.5 mg/kg IM)	One dose melarsomine (2.5 mg/kg IM), followed in approximately 1 month with 2 injections 24 hours apart	Melarsomine not indicated for acute care

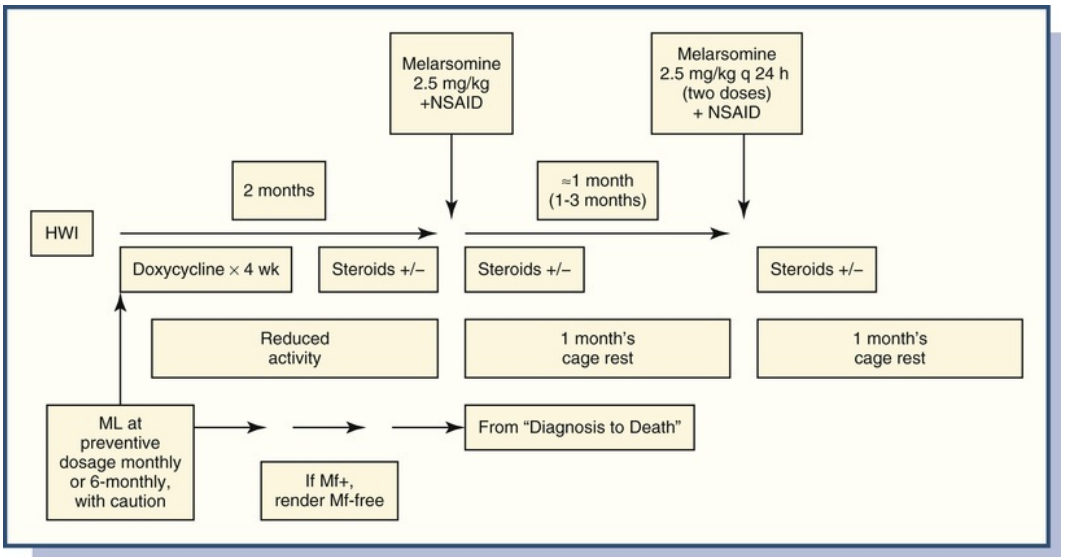

FIGURE 255-14 An approach to the management of heartworm infection in the dog. *HWI*, Heartworm infection; *Mf*, microfilariae; *ML*, macrocyclic lactone preventive drug; *NSAID*, nonsteroidal anti-inflammatory drug. (Adapted from Atkins CE, Miller M: Is there a better way to administer heartworm adulticidal therapy? *Vet Med* 98:310-317, 2003.)

In 55 dogs with severe HWD that were treated in this manner, 96% had a good or very good outcome with more than 98% negative for antigenemia 90 days post-therapy.[77] Of the 55 severely affected dogs, 31% had "mild or moderate PTE," but no fatalities resulted. The most common sign was fever, cough, and anorexia 5 to 7 days post-treatment. This was associated with mild perivascular caudal lobar pulmonary radiographic opacities and subsided spontaneously or after corticosteroid therapy. A recent small study demonstrated reduced biomarker evidence of lung and cardiac damage with the split-dosage protocol, as compared to the standard 2-dose method.[82] Furthermore, the split-dose protocol provided better resolution of proteinuria.

It is now known that administration of doxycycline therapy and monthly ivermectin, for a month prior to administration of melarsomine, reduces the severity of lung lesions in dogs with heartworms, as well as providing other benefits (see Doxycycline).[83]

At the time of diagnosis (usually by positive heartworm antigen test), a minimum database is completed. This includes a Mf test, chemistry panel, complete blood count (CBC), urinalysis, and thoracic radiographic evaluation. If liver disease is suspected from clinical and laboratory findings, serum bile acid determination may be useful in evaluating liver function. At this time, a ML preventive is prescribed (see Figure 255-14).[78] This approach, which has been adopted by the AHS,[84] is used to prevent further infection, to reduce or eliminate Mf (chronic therapy renders the dog less dangerous to itself or other dogs and cats), and to destroy developing L4 (not yet susceptible to adulticidal therapy). Today, concerns around HW resistance to MLs dictate that Mf must be cleared more rapidly than occurs with dosages as preventive agents. The Mf may be dispatched more quickly, though not always completely, with imidacloprid-moxidectin, doxycycline + ivermectin, milbemycin oxime, or high-dose ivermectin (50 mcg/kg; not advised). The addition of doxycycline to this protocol offers numerous advantages discussed below. In microfilaremic dogs, the first ML dose is administered in the hospital or at home with observation, so an adverse reaction might be recognized and treated promptly. Corticosteroids with or without antihistamines (dexamethasone at 0.25 mg/kg IV and diphenhydramine at 2 mg/kg IM; or prednisolone 1 mg/kg PO 1 hour before ±6 hours after administration of the first dose of preventive) may be administered to reduce the potential for adverse reaction in highly microfilaremic patients. It is important to emphasize that adverse reactions are unusual with MLs at preventive dosages but caution should be exercised, particularly with milbemycin oxime.

Depending on the time of year, up to 2 to 3 months has traditionally been allowed to lapse before adulticidal therapy is administered.[78] While initiation of ML administration prevents further infection, this delay allows larval maturation to adulthood, ensuring that the only stage of the life cycle present is the adult, the stage vulnerable to melarsomine therapy. This is more important if the diagnosis is made during or at the end of a mosquito exposure season. If the diagnosis is made in the spring or late winter, when infective larvae have matured, adulticidal therapy may be commenced (see Figure 255-14). This window to possible HW larval escape is also largely closed with 30 days' pre-treatment with doxycycline (98-100% larval kill-rate, if

administered during first 60 days post-infection, and 70%, if given on days 65-94 post-infection; see Doxycycline).[85]

Adulticidal Procedure

Approximately 60 days after diagnosis, including 30 days' treatment with doxycycline (10 mg/kg PO q 12 h), 2 monthly treatments or 1 injection of ML, adulticidal therapy is begun. The second month of waiting is optional, but, while there are no supportive data, it is logical that in killing *Wolbachia* and degrading the HW, an extra 30 days is thought to further lessen the worms' biomass and potential protein release upon their demise.

In the author's clinic, a nonsteroidal anti-inflammatory drug (NSAID) is given the morning before the injection and continued for a total of 4-5 days, in most cases. The first injection of melarsomine is administered by deep intramuscular injection (2.5 mg/kg) in the lumbar musculature (as described in the package insert) and the injection site recorded. Before injection, the needle is changed and care is taken to inject deep into the muscle and nowhere else. Some in the author's practice employ sedation and surgical preparation of the injection site. Care is taken to ensure that the dog does not move during the injection and we accomplish this by supporting the hindquarters to prevent sitting/collapsing, potentially misdirecting the injection. Patients are typically, but not necessarily, hospitalized for the day. The need for exercise restriction for 1 month is *strongly emphasized,* and sedation is provided if necessary. Owners are also advised as to adverse reactions (fever, local inflammation, lassitude, inappetence, cough, dyspnea, collapse), to call if they have concerns, and to return for a second series of two injections in approximately 1 month.

If serious systemic reaction results, the second stage of the adulticidal treatment is delayed or occasionally even cancelled. Typically, however, even with severe reactions, the entire treatment protocol is completed within 2 to 3 months (see Figure 255-14). After a minimum of 1 month, the melarsomine injection procedure is repeated, again with a record of the injection site. If significant local reaction was noted after the first injection, dexamethasone or oral NSAIDs to minimize pain at the injection site accompany subsequent injections. The next day (approximately 24 hours after the first injection) the process is repeated with melarsomine injection into the opposite lumbar area. Client instructions are similar to those previously given, with reemphasis of the need for 1 month's strict restriction of exercise. Antigen testing is repeated 8-12 months after the second series of injections, with a positive test result indicating incomplete adulticidal efficacy. It is emphasized that despite the proven efficacy of melarsomine, not all worms are killed in every patient. The worm burden is typically markedly reduced, but if as few as one to three adult female worms remain, positive antigen tests are likely. Whether to repeat adulticidal therapy, under these circumstances, is decided on a case-by-case basis, with input from the owners.

Macrocyclic Lactones as Adulticides

It is now known that certain MLs have adulticidal properties.[54-56] When these drugs are used to clear a dog of adult HW, the terms *soft-kill* and *slow-kill* are used to describe the approach. Ivermectin has been most studied and is most used for this practice, which should generally be avoided (see Controversies). In this chapter, the terms *soft-* and *slow-kill* are used interchangeably.

Ivermectin, when administered monthly for 31 consecutive months, has ≈95% adulticidal efficacy in young HWIs.[56] Selamectin, when administered continuously for 18 months, killed approximately 40% of transplanted worms.[54] Monthly imidacloprid-moxidectin coupled with 30 days' doxycycline therapy (10 mg/kg q 12 h) is effective at eliminating 5-month-old experimental infections.[57] Milbemycin oxime and sustained-release injectable moxidectin appear to have minimal adulticidal efficacy.[55,61] Although there may be a role for this therapeutic strategy in cases in which financial constraints or concurrent medical problems prohibit melarsomine therapy, the current recommendations are that MLs not be adopted as the primary adulticidal approach (see Controversies).

Exercise Restriction

Cage rest is an important aspect of the management of HWD after adulticidal therapy, after PTE, or during therapy of heart failure. This can often be best, or only, accomplished in the veterinary clinic. If financial constraints preclude this, crating or housing in the bathroom or garage at home, with or without tranquilization, and allowing only gentle leash walks is a useful alternative solution. Nevertheless, some owners do not or cannot restrict exercise, resulting in or worsening thromboembolic complications. In the author's opinion, failure to restrict exercise post-adulticide is the major association with severe thromboembolic complication.

Surgical Therapy

Sasaki, Kitagawa, and Ishihara[86] have described a method of mechanical worm removal using a flexible alligator forceps (Figure 255-15 and Video 255-1). This method was 90% effective in 36 dogs with mild and severe HWD. Only two of the severely affected dogs (n = 9) died of heart and renal failure over 90 days post-operatively. These data suggest that, in skilled hands, the technique is safe. Subsequent studies by Morini and colleagues[87] demonstrated superior results as compared with melarsomine, producing less PTE and CS. It is important to note that the majority of dogs treated surgically required subsequent melarsomine administration to effect a cure. Advantages to this technique include its diminished potential for arsenic complications (subsequent adulticidal therapy would be administered to an asymptomatic dog, using just 2 doses) and relative freedom from thromboembolic complication. Disadvantages include the need for general anesthesia, required operator skill and fluoroscopy, potential for anesthetic or surgical misadventure, and incomplete HW eradication. Nevertheless, it remains a potential alternative for the management of high-risk patients.

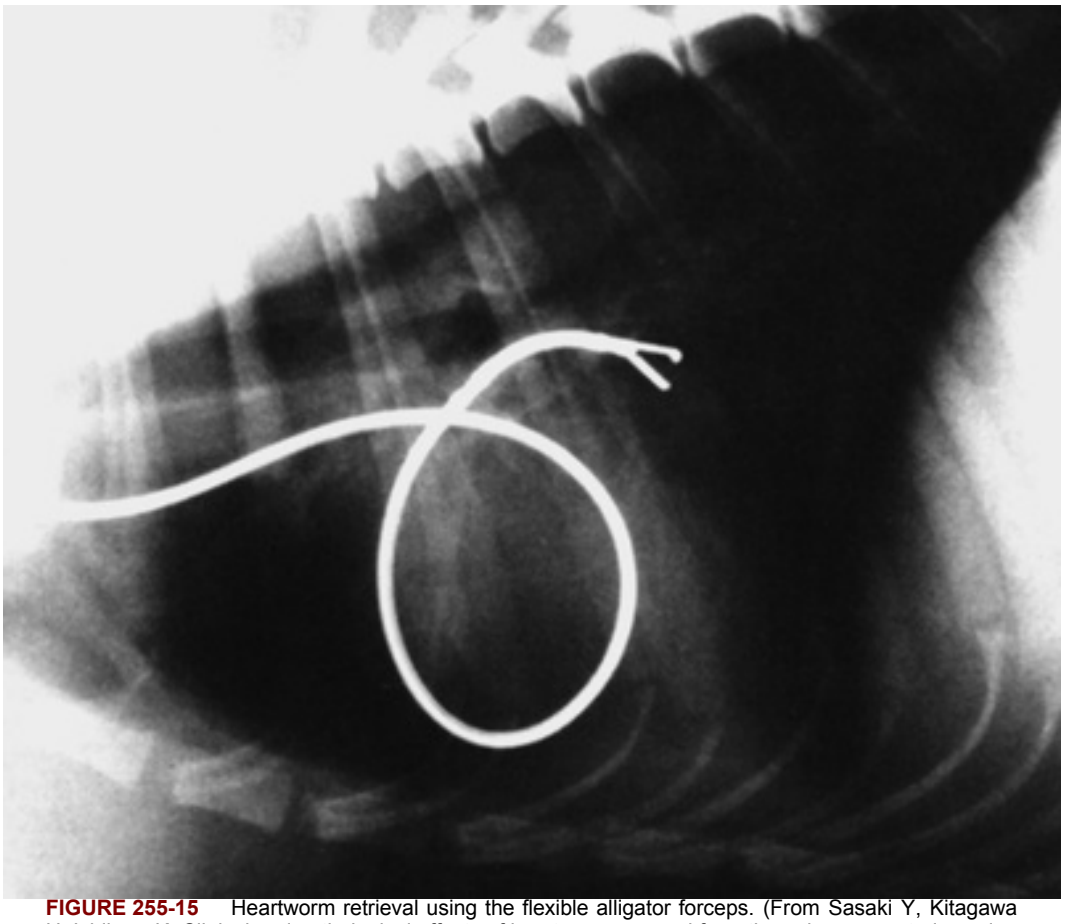

FIGURE 255-15 Heartworm retrieval using the flexible alligator forceps. (From Sasaki Y, Kitagawa H, Ishihara K: Clinical and pathological effects of heartworm removal from the pulmonary arteries using flexible alligator forceps. In Otto GF, editor: *Proceedings of the 1989 American Heartworm Symposium*, Batavia, IL, 1990, American Heartworm Society, p 45.)

Ancillary Therapy

Corticosteroids

The anti-inflammatory and immunosuppressive effects inherent to corticosteroids are useful for treatment of some aspects of HWD. Prednisone, the steroid most often advocated, reduces pulmonary arteritis but actually worsens the proliferative vascular lesions of HWD, diminishes pulmonary arterial flow, and reduces the effectiveness of thiacetarsamide (there are no data to reflect this effect on melarsomine). For these reasons,

corticosteroids are indicated in HWD only in the face of pulmonary parenchymal complications (eosinophilic pneumonitis, eosinophilic granulomas, and PTE), to treat or prevent adverse reactions to microfilaricides, and possibly to minimize tissue reaction to melarsomine. For pneumonitis, prednisone (1 mg/kg/day) is administered orally for 3 to 5 days and discontinued or tapered as indicated.[12,24] The response is generally favorable. Prednisone has also been advocated, along with cage rest, for the management of PTE at 1 to 2 mg/kg/day PO, continued until radiographic and clinical improvement is noted.[24] Because of the potential for steroid-induced fluid retention, such therapy should be used cautiously in the face of heart failure. In addition, caution is warranted because early studies demonstrated that corticosteroid therapy reduced pulmonary blood flow and worsened intimal disease in a model of HWI[88] and corticosteroids are also procoagulant.[24] As mentioned with adulticidal (previously discussed) and microfilaricidal (discussed below) therapies, corticosteroids may be used to minimize potential adverse reactions to melarsomine and to MLs given to rapidly kill Mf.

Aspirin

Antithrombotic agents have received a good deal of attention in the management of HWD[88-92] and the subject has recently been reviewed.[93] Potential benefits include reduction in severity of vascular lesions, reduction in thromboxane-induced pulmonary arterial vasoconstriction and PHT, and minimization of post-adulticidal PTE.[90] Aspirin has shown success in diminishing the vascular damage caused by segments of dead worms,[90] reducing the extent and severity of myointimal proliferation caused by implanted living worms,[91] and in improving pulmonary parenchymal disease and intimal proliferation in dogs with implanted worms, receiving thiacetarsamide.[88] More recent studies, however, have produced controversial results. Four dogs with implanted heartworms, receiving adulticide and aspirin, showed no improvement in pulmonary angiographic lesions, and treated dogs had more severe vascular tortuosity than did controls and dogs receiving heparin.[89] Boudreau and colleagues[92] demonstrated that the aspirin dosage required to decrease platelet reactivity by at least 50% was increased by nearly 70%, with HWI (implantation model) and by nearly 200% with a model (dead worm implantation) of PTE. There were not significant differences in severity of pulmonary vascular lesions in aspirin-treated versus control dogs. For these reasons, the AHS does not endorse antithrombotic therapy for routine treatment of HWD.[28] Calvert and colleagues[24] have, however, successfully used the combination of aspirin and strict cage confinement with adulticidal therapy for severe HWD. If used, aspirin (5-7 mg/kg) is administered PO daily beginning 1 to 3 weeks prior to and continued for 4 to 6 weeks after adulticide administration. With protracted aspirin therapy, packed cell volume (PCV) and serum total protein should be monitored periodically. Aspirin is avoided or discontinued in the face of concurrent corticosteroid therapy, gastrointestinal bleeding (melena or falling PCV), persistent emesis, thrombocytopenia (<50,000/mm^3), and hemoptysis.[24] Clopidogrel (Plavix) has not been evaluated in HWD.

Heparin Therapy

Low-dose calcium heparin has been studied in canine HWD and shown to reduce the adverse reactions associated with thiacetarsamide in dogs with severe clinical signs, including heart failure.[94] In this study, calcium heparin, administered at 50 to 100 IU/kg SC q 8-12 h for 1 to 2 weeks before and 3 to 6 weeks after adulticidal therapy, reduced thromboembolic complications and improved survival, as compared with aspirin and indobufen. Dogs in both groups also received prednisone at 1 mg/kg/day. It is emphasized that this therapy has not been studied with melarsomine adulticidal therapy. Calvert and colleagues[24] advocate sodium heparin (50 to 70 U/kg) in dogs with thrombocytopenia, DIC, or both, continuing until the platelet count is greater than 150,000/mm,[3] for at least 7 days, and possibly for weeks.

Doxycycline

Wolbachia pipientis, first recognized in the 1920s in mosquitoes, is now known to be an endosymbiont in filarid and other parasites, including *D. immitis.* It is essential for the filarids' development, reproduction, infectivity, well-being and survival. Kramer and Genchi have published an excellent review of the relationship between *Wolbachia* and *D. immitis.*[18] With the relatively recent realization that *Wolbachia* may contribute to the pathogenesis of HWI and the adverse reactions to spontaneous and pharmacologically-induced worm death, methods to clear *Wolbachia* have come under study.[17,18,57,83,85,95-100] While doxycycline has many benefits in managing and preventing HWI, ivermectin and doxycycline appear to work synergistically in this regard. In

experimental infections (jugular adult worm transplantation), it has been shown that a complex regimen of ivermectin (weekly at preventive dosages [i.e., four times typical dosage]) and doxycycline (10 mg/kg/day in an interrupted treatment regimen for 14 of 36 weeks) for 36 weeks reduced/eliminated *Wolbachia* in HW, produced parasite uterine involution, eliminated Mf within 8 weeks, reduced PTE after melarsomine therapy, and reduced heartworm burden with ivermectin in a soft-kill protocol, compared with that of control dogs by 78% after 9 months' therapy.[17,18,83,96-98] It should be recognized that this treatment regimen is preliminary, proof of concept, off-label, complex, and impractical. It does, however, demonstrate a potential role for wolbachicidal therapy with doxycycline or other drugs in HWI. Also, the PTE-protective characteristic was not lost in a study of ivermectin monthly at recommended dosage and 30 days' doxycycline therapy. A more practical protocol, employing ivermectin at preventive dosage two times per week for 6 months and 30 days' doxycycline (10 mg/kg/day), hastened slow-kill heart worm therapy, with 73% of experimentally-infected dogs converting to antigen negative status by day 300 post-infection.[100] Additionally, at 10 mg/kg q 12 h, doxycycline monotherapy has demonstrated efficacy in destroying developing tissue stage larvae, as mentioned above.[85,99] Combination therapy with doxycycline and ivermectin renders all host stages "*Wolbachia*-free" and subsequent mosquito-borne L3 non-infectious.[97,99] Doxycycline monotherapy at 10 mg/kg q 12 h for 30 days has also been shown to have negative effects on HWs at all stages of development.[97,99] This is particularly important because it breaks the HW transmission cycle, thereby reducing/eliminating subsequent infections from the treated host and lessening chances of resistant HW isolates being propagated in down-stream hosts. The data at hand indicate that doxycycline or other wolbachiostat is indicated in all dogs with HWI.

Microfilaricidal Therapy

Despite the fact that, prior to 2014, no agent was approved by the FDA-CVM for the elimination of Mf, microfilaricidal therapy has traditionally been instituted 3 to 6 weeks after adulticide administration.[24,36] The MLs offer a safe and effective alternative to previously used levamisole and dithiazanine. Microfilariae are rapidly cleared with ivermectin at 50 mcg/kg (approximately eight times the preventive dosage) or milbemycin oxime at 0.5 mg/kg (preventive dosage), although this represents an extra-label use. Adverse reactions, the severity of which is likely related to microfilarial numbers and the rate at which they are cleared, were observed in 6% of 126 dogs receiving ivermectin at the microfilaricidal dosage.[101] Signs included shock, depression, hypothermia, and vomiting. With fluid and corticosteroid (dexamethasone at 2 to 4 mg/kg IV) therapy, all dogs recovered within 12 hours. One fatality, however, was observed 4 days after microfilaricidal therapy. Similar, but less severe, findings and frequency have been reported with milbemycin oxime at the preventive dosage.[33] Dogs so treated should be hospitalized and carefully observed for the day. Dogs weighing less than 16 kg, harboring more than 10,000 Mf per milliliter of blood, are more apt to suffer adverse reactions.[101] Diphenhydramine (2 mg/kg IM) and dexamethasone (0.25 mg/kg IV) can be administered to prevent adverse reactions to microfilaricidal dosages of ML.

A slower microfilarial kill rate is achieved with ivermectin, selamectin, and topical imidacloprid-moxidectin at preventive dosages.[31,32,53,54,65,66,101,102] Using either the more rapid or slower approach rids the patient of most Mf and sterilizes the female heartworm. The only drug with an FDA-CVM label claim as a microfilaricide is imidacloprid-moxidectin.[102] Doxycycline with ivermectin (or, possibly, another ML) also eliminates Mf promptly and safely. There is currently neither need nor reason to use the bovine ivermectin product to eliminate Mf in dogs.

This author chooses an alternative approach (see Figures 255-8 and 255-14), beginning the administration of ML and doxycycline at the time of diagnosis, often days to weeks prior to adulticidal therapy.[78] This approach is simpler, safer, and invokes immediate protection from further HWI. With the slower-acting microfilaricides (ivermectin, moxidectin, or selamectin *at preventive dosages*), little chance exists of an adverse reaction. However, in treating microfilaremic dogs, the owner should be warned of the possibility and advised to administer the medication (1) on a day when he or she will be at home, (2) in the hospital, or (3) with pre-treatment, as described below. If milbemycin oxime preventive is used, while reactions seem to be rare, the first dose is administered in the hospital and/or may be preceded by administration of dexamethasone and diphenhydramine, when large microfilarial burdens are recognized (see Adulticidal Therapy).

Complications and Specific Syndromes

Asymptomatic Heartworm Infection

Most dogs with HWI are asymptomatic, even though many of these have HWD (radiographic and pathologic lesions). Treatment is as described previously, using melarsomine in the split-dose regimen, along with a ML preventive. Asymptomatic dogs may, however, become symptomatic after adulticidal therapy due to PTE and lung injury (as described elsewhere in this chapter). The risk of PTE can be imperfectly predicted by semi-quantitation of the worm burden, using certain antigen tests, and by the severity of radiographic lesions.[30] Clearly a dog with severe radiographic lesions will not tolerate thromboembolic complications well, but not all dogs with radiographic signs have heavy worm burdens. For example, a dog with moderate to severe radiographic lesions and high antigenemia may not be at high risk for post-adulticidal PTE, because it is possible that the worms have died, explaining both the antigenemia (release from dead worms) and radiographic abnormalities (chronic HWD). This conclusion might also be valid in the dogs with severe radiographic lesions and negative or low antigenemia (assumes most or all worms have died, and antigen has been cleared). Alternatively, antigenic evidence of a heavy worm burden in a dog with minimal radiographic signs might still portend a severe reaction after melarsomine because the findings are compatible with large worm numbers but without natural worm attrition (i.e., a relatively young infection with minimal disease). Of course, low worm burden and minimal radiographic lesions would suggest the least risk of an adverse reaction to adulticide.

It bears emphasis that with each scenario, some guesswork is involved and precautions should be taken. When the risk of PTE is greatest, a 10-14 day tapering dosage of prednisone initially at 5 to 7 mg/kg/day PO at diagnosis and after each melarsomine treatment or clopidogrel (18.75 mg/kg/day PO; no data available for HW) is sometimes employed. Corticosteroids or even heparin are advocated by some.[24] Forced exercise restriction is most important. The owners should be educated as to the risk, the signs suggestive of PTE, and the importance of prompt veterinary assistance in case of an adverse reaction.

Glomerulonephritis

The majority of dogs suffering from chronic HWI have glomerulonephritis, which can be severe (Figure 255-16 and ch. 325).[14] Therefore, when a dog demonstrates glomerular disease, HWI should be considered as a differential diagnosis. Although it is generally felt that the glomerular lesions produced by HWI are unlikely to produce renal failure, a therapeutic dilemma results when a dog is presented with proteinuria, azotemia, and HWI. Logic suggests that adulticidal therapy is indicated because HWI contributes to glomerular disease, but it likewise carries risks. The approach embraced by this author is to hospitalize the patient and to administer intravenous fluids (lactated Ringer's solution at 2 to 3 mL/kg/h; see ch. 129) for 48 hours (beginning 12 hours prior to the first melarsomine dose in the split-dose protocol). The patient is then released, and a 48-hour recheck appointment for blood urea nitrogen (BUN) and creatinine determination is advised. The second and third injections are tentatively scheduled for 1 to 3 months, with the treatment decision based on age, general health, renal function and the patient response to initial adulticidal therapy.

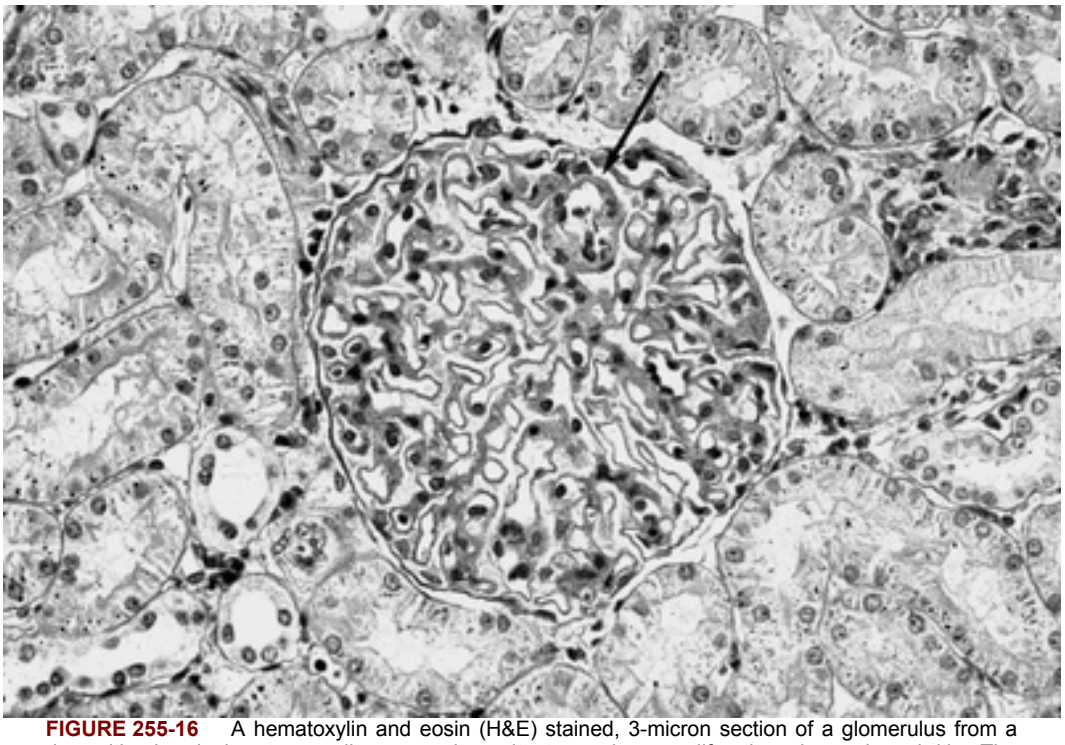

FIGURE 255-16 A hematoxylin and eosin (H&E) stained, 3-micron section of a glomerulus from a dog with chronic heartworm disease and resultant membranoproliferative glomerulonephritis. The capillary walls are thickened, and an overall increase in cellularity is seen. The reader should note a thick-walled capillary containing intraluminal microfilariae (arrow). (Courtesy Dr. Greg Grauer.)

Eosinophilic Pneumonitis

Eosinophilic pneumonitis, which is reported to affect 14% of dogs with HWD, is a relatively early development in the disease course.[12,24] In fact, the pathogenesis probably involves immunologic reaction to dying Mf in the pulmonary capillaries. Clinical signs include cough and sometimes dyspnea and other typical signs of HWD, such as weight loss and exercise intolerance. Specific physical examination findings may be absent or may include dyspnea and audible crackles in more severe cases. Radiographic findings include those typical of HWD with an interstitial to alveolar infiltrate, often worse in the caudal lung lobes (see Figure 255-12). Eosinophils and basophils may be found in excess in peripheral blood and in airway samples.

Corticosteroid therapy (prednisone or prednisolone at 1 to 2 mg/kg/day PO) results in rapid attenuation of clinical signs, with radiographic clearing in less than a week. The drug can then be stopped in 3 to 5 days if clinical signs subside. Although microfilaricidal therapy is typically not indicated because infections are often occult, ML prophylaxis is indicated to avoid further infection. Adulticidal therapy can be employed after clinical improvement.

Eosinophilic Granulomatosis

A more serious, but rare, manifestation, pulmonary eosinophilic granulomatosis, responds less favorably. This syndrome is characterized by a more organized, nodular inflammatory process, associated with bronchial lymphadenopathy and, occasionally, pleural effusion. With pulmonary granulomatosis, cough, wheezes, and pulmonary crackles are often audible; when very severe, lung sounds may be muffled and associated with dyspnea and cyanosis. Treatment with prednisone at twice the dosage used in pneumonitis is reported to induce partial or complete remission in 1 to 2 weeks. The prognosis remains guarded because recurrence within several weeks is common. Prednisone may be combined with cyclophosphamide or azathioprine in an effort to heighten the immunosuppressive effect (see ch. 165). The latter combination appears to be the most effective. Adulticide therapy should be delayed until remission is attained. Because the prognosis for medical success is guarded, surgical excision of lobar lesions has been advocated.[103]

Pulmonary Embolism

Spontaneous thrombosis or PTE associated with dead and dying worms (the most important heartworm complication) may precipitate or worsen clinical signs, producing or aggravating PHT, right heart failure or, in rare instances, hemoptysis and pulmonary infarction (see ch. 243). Acute fatalities may result from fulminant respiratory failure, exsanguination, or DIC (see ch. 197), or they may be unexplained and sudden (arrhythmia or massive pulmonary embolism). The most common presentation, however, is a sudden onset of lethargy, anorexia, and cough 7 to 10 days after adulticidal therapy, often after failure to restrict exercise. Dyspnea, fever, mucous membrane pallor, and adventitial lung sounds (crackles) may be noted on physical examination.

Thoracic radiographs (Figure 255-17) reveal significant pulmonary infiltrates, most severe in the caudal lung lobes. Severity, as compared with pre-treatment radiographs, is typically dramatic. The infiltrate, usually alveolar, is most severe in the caudal lobes, and occasionally areas of consolidation are noted. Laboratory abnormalities vary with the severity of signs but may include leukocytosis, left shift, monocytosis, eosinophilia, and thrombocytopenia. The degree of thrombocytopenia may provide prognostic information.

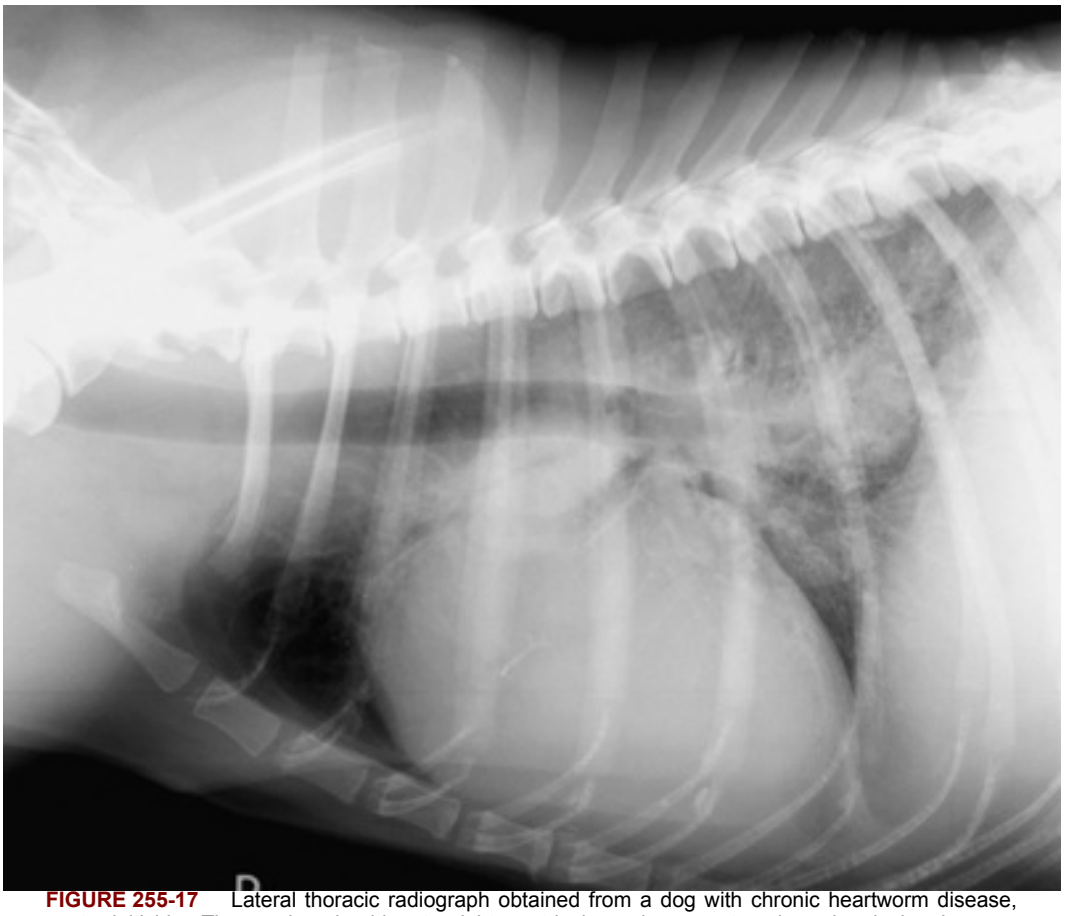

FIGURE 255-17 Lateral thoracic radiograph obtained from a dog with chronic heartworm disease, post-adulticide. The reader should note right ventricular enlargement, enlarged apical pulmonary arteries partially obscured by pulmonary infiltrate, and an interstitial and alveolar infiltrate, most severe in the caudal lung lobes.

Medical management of thromboembolic lung disease is largely empiric and without general agreement. It is generally agreed that strict cage confinement, oxygen administration via oxygen cage or nasal insufflation (50 to 100 mL/kg/min; see ch. 131), and prednisone (1 mg/kg/day for 3 to 7 days) are indicated in the most severe cases.[19,24,104] Some advocate careful fluid therapy (see Caval Syndrome) to maximize tissue perfusion and combat dehydration.[104] The use of heparin (75 IU/kg SC three times a day until platelet count has normalized [5 to 7 days]) and aspirin (5 to 7 mg/kg/day) has been advocated by some[41] but remains controversial.[5,88-93]

Other therapeutic strategies might include cough suppressants, antibiotics (if fever is unresponsive), and, although speculative at this time, vasodilators (amlodipine, sildenafil, hydralazine, diltiazem; see discussion of heart failure below and in more depth in ch. 247).[105,106] If vasodilator therapy is employed, one must monitor blood pressure because hypotension (see ch. 159) is a potential side effect. Clinical improvement may be rapid, with possible release from the hospital after several days' treatment. For less severely affected dogs, careful confinement and prednisone at home are often adequate.

Congestive Heart Failure

Right heart failure results from increased right ventricular afterload (secondary to chronic pulmonary arterial disease and thromboemboli with resultant PHT; see ch. 246). When severe and chronic, PHT may be complicated by secondary tricuspid regurgitation and right heart failure. Congestive signs (ascites) are worsened in the face of hypoproteinemia (Figure 255-18). Calvert suggests that up to 50% of dogs with severe pulmonary vascular complication to HWD will develop heart failure.[24] Clinical signs (see Figure 255-18) variably include weight loss, exercise intolerance, ashen mucous membranes with prolonged capillary refill time, ascites, dyspnea, jugular venous distension and pulsation (Video 255-2), arrhythmias with pulse deficits, and adventitial lung sounds (crackles and possibly wheezes). Dyspnea may be due to pulmonary

infiltrates with eosinophils (PIE) or PTE, but *not* cardiogenic pulmonary edema; abdominal distension; or pleural effusion.

FIGURE 255-18 Adult male Labrador Retriever with congestive heart failure due to heartworm disease. The reader should note the distended abdomen (ascites) and cardiac cachexia.

Adulticide therapy is delayed until clinical improvement is noted. Treatment involves dietary, pharmacologic, and procedural interventions. Specific aims include reduction in signs of congestion (diuretics, sodium restriction, and paracentesis), reducing PHT (vasodilator therapy, ideally with sildenafil and/or pimobendan; see ch. 243), improving cardiac output (reducing afterload and improving systolic function with inotropic therapy [pimobendan]); and blunting the neurohumoral response to a fall in cardiac output (renin-angiotensin-aldosterone system [RAAS] and sympathetic nervous system with angiotensin-converting enzyme [ACE] inhibitors and mineralocorticoid receptor blockers [spironolactone]).

Moderate salt restriction is logical and probably useful in diminishing diuretic needs. To achieve this, the author chooses a diet designed for senior patients or early heart failure. Diuretics may be useful in preventing recurrence of ascites but are typically not able to mobilize large fluid accumulations effectively. This then requires periodic abdominal and/or thoracic paracentesis when discomfort is apparent (see ch. 102). Furosemide is typically used at 2 to 6 mg/kg/day, depending on severity and patient response. Additional diuretics, which provide a supplemental effect by using differing parts of the nephron, include spironolactone (2 mg/kg/day PO), and hydrochlorothiazide (1 to 2 mg/kg PO q 12-48 h). Torsemide, a more potent loop diuretic, can be used to replace furosemide at 10% of its current dosage (see ch. 247).[107]

The ACE inhibitors (e.g., enalapril, benazepril, lisinopril, ramipril), by their effect on the RAAS, may be of use as mixed vasodilators, in blunting pathologic cardiac remodeling and in reducing fluid retention, particularly cases of refractory ascites. The arterial vasodilator, hydralazine, has been shown by Lombard[105] to improve cardiac output in a small number of dogs with HWD and heart failure. It has also been demonstrated to reduce pulmonary artery pressure and vascular resistance, right ventricular work, and aortic pressure without changing cardiac output or heart rate in dogs with experimental, severe HWD (but without heart failure).[106]

Clinical experience suggests that, in order of preference, pimobendan, sildenafil, hydralazine, amlodipine, and diltiazem might all have a role in this setting. Further studies are necessary. In heart failure, the author's first choice is the combination of pimobendan (0.25 mg/kg PO q 12 h) and sildenafil (0.5-1 mg/kg PO q 8-12 h). If finances play an important role in drug choice, hydralazine at 0.5 to 2 mg/kg PO q 12 h, amlodipine at 0.1-0.25 mg/kg PO q 24 h, or diltiazem at 0.5 to 1.5 mg/kg PO q 8 h or a long-acting formulation up-titrated to 2 to 4 mg/kg PO q 12-24 h, may be substituted. The risk of hypotension with these therapies must be realized and blood pressure monitored. In the author's practice, the inodilator pimobendan is employed under these circumstances, either alone or with sildenafil, to provide pulmonary artery vasodilation and inotropic support to reduce the chances of hypotension.

Because of the risk of toxicity and pulmonary vasoconstriction associated with the use of digoxin, it is not routinely utilized by the author in the management of HWD-induced heart failure. However, digoxin accompanied by diltiazem may be beneficial in the management of atrial fibrillation, by controlling the ventricular response rate.

Aspirin or clopidogrel, theoretically useful because of their ability to ameliorate some pulmonary vascular lesions and platelet-induced vasoconstriction, may be used at 5 and 2-3 mg/kg/day PO, respectively. Strict exercise restriction of indefinite duration is strongly advised.

Often, heart failure follows adulticidal therapy, but if it is present prior to adulticidal therapy, the difficult question arises as to when (or whether) to administer melarsomine. If clinical response to heart failure management is good, adulticidal therapy may be offered in 4 to 12 weeks, as conditions allow. Melarsomine is generally avoided if heart failure is refractory, with reliance on a slow-kill approach (ivermectin and 30 days' doxycycline therapy).

Caval Syndrome

Heartworm CS is a relatively uncommon, but severe variant or complication of HWD. Most studies have shown a marked sex predilection, with 75% to 90% of CS dogs being male. It is characterized by heavy worm burden (usually >60, with the majority of the worms residing in the right atrium and venae cavae) and a poor prognosis.[26] Studies performed in the author's laboratory indicate that retrograde migration of adult heartworms to the cava and right atrium, from 5 to 17 months after infection, produces partial inflow obstruction to the right heart and, by interfering with the valve apparatus, tricuspid insufficiency (with resultant systolic murmur, jugular pulse, and CVP increase).[108] Affected dogs also exhibit preexistent heartworm-induced PHT, which markedly increases the adverse hemodynamic effects of tricuspid regurgitation. These combined effects substantially reduce left ventricular preload and hence, cardiac output. Cardiac arrhythmias may further compromise cardiac function (Figure 255-19).

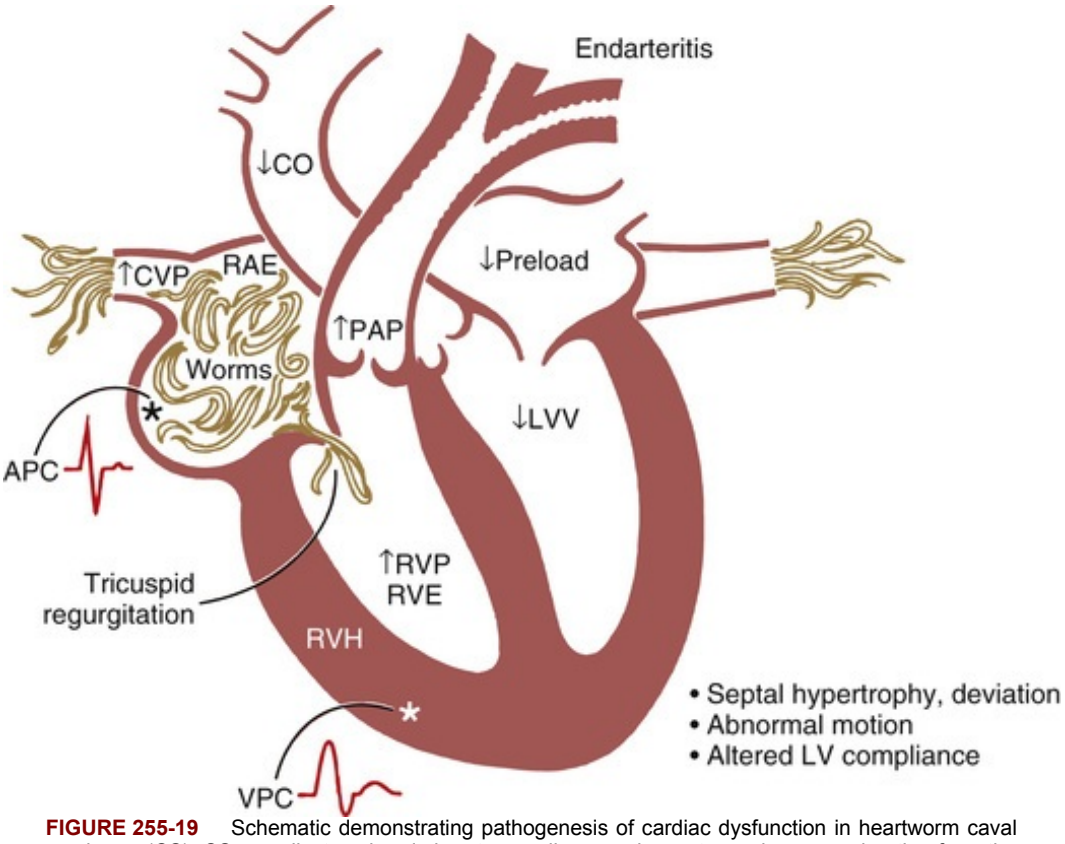

FIGURE 255-19 Schematic demonstrating pathogenesis of cardiac dysfunction in heartworm caval syndrome (CS). CS complicates chronic heartworm disease when retrograde worm migration from the pulmonary arteries occurs, with the majority of worms relocating in the venae cavae and right atrium. Tricuspid valvular function is altered, resulting in incompetence. Tricuspid regurgitation is superimposed on pulmonary hypertension. Left ventricular preload is diminished. Congestive and low-output heart failure ensues. Septal deviation to the left and abnormal, rightward septal motion contributes to preload starvation of the left ventricle. Right ventricular inflow obstruction due to heartworms and cardiac arrhythmias may further contribute to cardiac dysfunction but are probably less important. *APC,* Atrial premature complex; *CO,* cardiac output; *CVP,* central venous pressure; *LVV,* left ventricular volume; *PAP,* pulmonary artery pressure; *RAE,* right atrial enlargement; *RVE,* right ventricular enlargement; *RVH,* right ventricular hypertrophy; *RVP,* right ventricular pressure; *VPC,* ventricular premature complex; *arrows,* increased or decreased. (From Atkins CE: Pathophysiology of heartworm caval syndrome: recent advances. In Otto GF, editor: *Proceedings of the 1989 American Heartworm Symposium*, Batavia, IL, 1990, American Heartworm Society, pp 27-31.)

This constellation of events precipitates a sudden onset of clinical signs, including hemolytic anemia (see ch. 198) caused by trauma to red blood cells (RBCs) as they pass through a sieve of heartworms occupying the right atrium and venae cavae, as well as through fibrin strands in capillaries if DIC has developed. Intravascular hemolysis, metabolic acidosis, and diminished hepatic function with impaired removal of circulating procoagulants contribute to the development of DIC. The effect of this traumatic insult to the erythron is magnified by increased RBC fragility, due to alterations in the RBC membrane in dogs with HWD. Hemoglobinemia, hemoglobinuria, and hepatic and renal dysfunction also are observed in many dogs. The cause of hepatorenal dysfunction is not clear, but it probably results from the combined effects of passive congestion, diminished perfusion, and the deleterious effects of the products of hemolysis. Without treatment, death frequently ensues within 24 to 72 hours due to cardiogenic shock, complicated by anemia, metabolic acidosis, and DIC. A sudden onset of anorexia, depression, weakness, and occasionally coughing are accompanied in most dogs by dyspnea and hemoglobinuria. Hemoglobinuria has been considered pathognomonic for this syndrome. Physical examination reveals mucous membrane pallor, prolonged capillary refill time, weak pulses, jugular distension and pulsation, hepatosplenomegaly, and dyspnea. Thoracic auscultation may disclose adventitial lung sounds; a systolic heart murmur of tricuspid insufficiency (87% of cases); loud, split S2 (67%); and cardiac gallop (20%) (see ch. 55). Other reported findings include ascites (29%), jaundice (19%), and hemoptysis (6%). Body temperature varies from subnormal to mildly elevated.[18]

Hemoglobinemia and microfilaremia are present in 85% of dogs suffering from CS.[26] Moderate (mean PCV,

28%) regenerative anemia characterized by the presence of reticulocytes, nucleated RBC, and increased mean corpuscular volume (MCV) is seen in the majority of cases. This normochromic, macrocytic anemia has been associated with the presence of target cells, schistocytes, spur cells, and spherocytes. Leukocytosis (mean white blood cell [WBC] count, approximately 20,000 cells/mm^3) with neutrophilia, eosinophilia, and left shift has been described. Dogs affected with DIC (see ch. 197) are characterized by the presence of thrombocytopenia and hypofibrinogenemia, as well as prolonged one-stage prothrombin time (PT), partial thromboplastin time (PTT), activated coagulation time (ACT), and high fibrin degradation product concentrations. Serum chemistry analysis typically discloses increases in liver enzymes, bilirubin, and indices of renal function. Urine analysis reveals high bilirubin and protein concentrations in 50% of cases and, more frequently, hemoglobinuria. CVP is high in 80% to 90% of cases (mean, 11.4 cm H_2O; normal, <5 cm H_2O; see ch. 76). Electrocardiographic abnormalities include sinus tachycardia in 33% of cases and atrial and ventricular premature complexes in 28% and 6%, respectively (see ch. 248). The mean electrical axis tends to rotate rightward (mean, +129 degrees), with an S1,2,3 pattern evident in 38% of cases. The S wave depth in CV6LU (V_4), the most reliable indicator of right ventricular enlargement (>0.8 mv), is present in 56% of cases. Thoracic radiography reveals signs of severe HWD with cardiomegaly, main pulmonary arterial enlargement, increased pulmonary vascularity, and pulmonary arterial tortuosity, recognized in descending order of frequency (see Figures 255-9 to 255-11). Massive worm inhabitation of the right atrium with movement into the right ventricle during diastole is evident echocardiographically (Video 255-3). This finding on M-mode and two-dimensional echocardiograms is pathognomonic for CS in the appropriate clinical setting (Figure 255-20). The right ventricular lumen is enlarged and the left diminished in size, suggesting PHT accompanied by reduced left ventricular loading. Paradoxical septal motion, caused by high right ventricular pressure, is commonly observed. No echocardiographic evidence of left ventricular dysfunction exists. Cardiac catheterization documents pulmonary, right atrial, and right ventricular hypertension and reduced cardiac output.

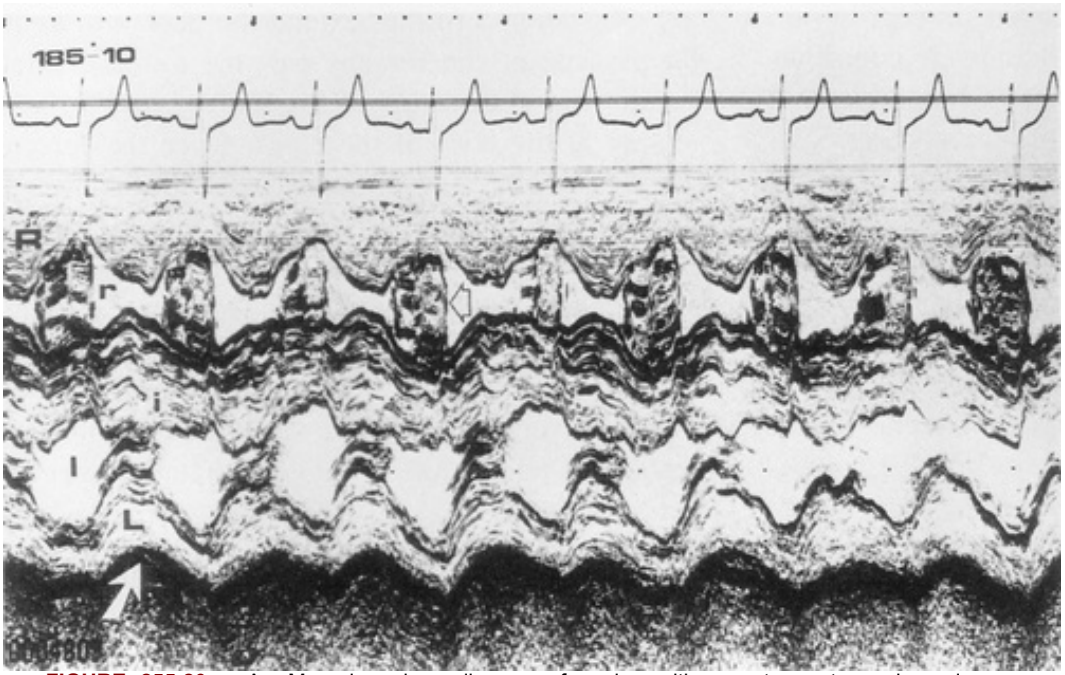

FIGURE 255-20 An M-mode echocardiogram of a dog with recent onset caval syndrome, demonstrating thickening of the right ventricular and intraventricular septal walls, right ventricular eccentric hypertrophy, and a small left ventricle. An echogenic mass (upper arrow) of heartworms can be seen "falling" into the right ventricle with each diastole. Paradoxical septal motion is evident. The lower arrow denotes the pericardium. *i,* Intraventricular septum; *l,* left ventricular lumen; *L,* left ventricular posterior wall; *r,* right ventricular lumen; *R,* right ventricular wall. (From Atkins CE: Heartworm caval syndrome. *Semin Vet Med Surg* 2:64-71, 1987.)

Prognosis is poor unless the cause of the crisis—the right atrial and caval heartworms—is removed. Even with this treatment, mortality can approximate 40% or more. In a retrospective study of 21 dogs with CS,

perioperative mortality (6) or retrieval failure (1) occurred in 33%.[109] All 14 dogs which underwent successful worm removal were discharged from the hospital, with 10 surviving 18 months or longer.

Fluid therapy (see ch. 127) is necessary to improve cardiac output and tissue perfusion, to prevent or help to reverse DIC, to prevent hemoglobin nephropathy, and to aid in the correction of metabolic acidosis. Over-exuberant fluid therapy, however, may worsen or precipitate signs of CHF. In the author's clinic, a left jugular catheter is placed (see ch. 76) and intravenous fluid therapy instituted with 5% dextrose in water or one-half strength saline and 2.5% dextrose. The catheter should not enter the cranial vena cava because it will interfere with worm embolectomy. A cephalic catheter may be substituted for the somewhat inconvenient jugular catheter, but this does not allow monitoring of CVP. The intravenous infusion rate for fluids is dependent on the condition of the animal. A useful guideline is to infuse as rapidly as possible (up to 1 cardiovascular volume during the first hour) without raising the CVP or without raising it above 10 cm H_2O if it was normal or near normal at the outset. Initial therapy (see ch. 127 and 129) should be aggressive (10 to 20 mL/kg for the first hour) if shock is accompanied by a normal CVP (<5 cm H_2O), and it should be curtailed to approximately 1 to 2 mL/kg/h if CVP is 10 to 20 cm H_2O. Whole blood transfusion is not indicated in most cases because anemia usually is not severe, and transfused coagulation factors may worsen DIC. Sodium bicarbonate is not indicated unless metabolic acidosis is severe (pH 7.15 to 7.20). Broad-spectrum antibiotics and aspirin (5 mg/kg daily) may be administered. Treatment for DIC is described elsewhere (see ch. 197) in this text.

Jackson developed the technique for surgical removal of caval and atrial heartworms.[110] This procedure should be undertaken as early in the course of therapy as is practical. Sedation may not be necessary in the moribund patient, in which case, the procedure can be accomplished with only local anesthesia. To facilitate the procedure and maintain aseptic technique, general anesthesia is typically employed in the author's practice. The dog is restrained or laid in left lateral recumbency after surgical clipping and preparation. The jugular vein is isolated distally. A ligature is placed loosely around the cranial aspect of the vein until it is incised, after which the ligature is tied. Alligator forceps (20 to 40 cm, preferably of small diameter) are guided gently down the vein while being held loosely between the thumb and forefinger. The jugular vein can be temporarily occluded with umbilical tape. If difficulty is encountered in passage of the forceps, gentle manipulation of the dog by assistants to further extend the neck will assist in passage of the forceps past the thoracic inlet; medial direction of the forceps may be necessary at the base of the heart. Once the forceps have been placed, the jaws are opened, the forceps are advanced slightly, the jaws are closed, and worms are removed. One to four worms are usually removed with each pass. This process is repeated until five to six successive attempts are unsuccessful. An effort should be made to remove 35 to 50 worms. Care should be taken not to fracture heartworm during extraction. After worm removal, the jugular vein is ligated distally, and subcutaneous and skin sutures are placed routinely. Other catheters, such as urethral stone basket catheters, horsehair brushes, snares and flexible alligator forceps, have also been used.[111] Fluoroscopic guidance, when available, is useful in this procedure. Successful worm retrieval is associated with a reduction in the intensity of the cardiac murmur and jugular pulsations, absence of HW echo shadows on ultrasound examination, rapid clearing of hemoglobinemia and hemoglobinuria, and normalization of serum enzymatic aberrations. Immediate and latent improvement in cardiac function occurs over the next 24 hours. It is important to realize that removal of worms does not adequately reduce right ventricular afterload (PHT), and hence fluid therapy must be monitored carefully before and after surgery to avoid precipitation or worsening of right heart failure. Cage rest should be enforced for a period of time, dependent on patient progress.

Worm embolectomy through a jugular venotomy is frequently successful in stabilizing the animal, allowing adulticide therapy to be instituted to destroy remaining heartworms in a minimum of 1 month. Careful scrutiny of BUN, creatinine and serum liver enzyme concentrations should precede the latter treatment. If aspirin or other anticoagulant therapy is employed, it is continued for 3 to 4 weeks after adulticide therapy. Substantial improvement in anemia should not be expected for 2 to 4 weeks after worm embolectomy. ML preventive therapy, as described previously, is administered at the time of release from the hospital.

Aberrant Migration

Although heartworms in the dog typically inhabit the pulmonary arteries of the caudal lung lobes, they may find their way to the right ventricle, and rarely (see Caval Syndrome) the right atrium and venae cavae. Much less frequently, immature S5 aberrantly migrate to other sites, including the brain, spinal cord, epidural space, anterior chamber of the eye, the vitreous, the subcutis, scrotum, and the peritoneal cavity. In addition, the worms may inhabit the systemic circulation, producing systemic thromboembolic disease.[15] Treatment of aberrantly migrating heartworms requires either nothing (e.g., peritoneal cavity), surgical excision of the offending parasite, adulticidal therapy, or symptomatic treatment (e.g., seizure control with brain migration).

The method for surgical removal from internal iliac and femoral arteries has been described.[15]

Prognosis

The prognosis for asymptomatic HWI is generally good and, although the prognosis for severe HWD is guarded, a large percentage of such cases can be successfully managed.[112] Once the initial crisis has passed and adulticidal therapy has been successful, resolution of underlying manifestations of chronic HWD begins. The prognosis is poorest with severe DIC, CS, massive pulmonary embolism, eosinophilic granulomatosis, severe pulmonary artery disease, and heart failure. After adulticidal therapy, intimal lesions regress rapidly, though not completely, based on their severity.[113-115] Improvement is noted as early as 4 weeks post-treatment in the main pulmonary artery, with all pulmonary arteries having undergone marked resolution within 1 year. Radiographic and arteriographic lesions of HWD begin to resolve within 3 to 4 weeks, and PHT is reduced within months and may be normal within 6 months of adulticide therapy. Pulmonary parenchymal changes are worsened during the 6 months after adulticidal therapy and then begin to lessen in severity, with marked resolution within the next 2 to 3 months. Persistence of such lesions is suggestive of ongoing infection. Corticosteroid therapy hastens the resolution of these lesions. Likewise, irreversible renal disease is uncommon, with glomerular lesions resolving within months of successful adulticidal therapy. Signs of heart failure are also reversible with symptomatic therapy, cage rest, and successful clearing of infection.

Controversies and Areas of Concern

Yearly Testing

The remarkable efficacy of ML preventives and the reduced danger of Mf-induced reactions with their use (see Preventives) have caused some to question the need for yearly testing.[75] Most or all experts, however, currently advocate this practice, including the AHS and the CAPC. In fact, the majority of practicing veterinarians advocate this but experience some client resistance. The issue of yearly testing is clearly important because it deals with financial and ethical, in addition to medical, issues. The veterinary profession must walk the fine line between adequate testing, by which we protect the public, and excessive testing, by which the public may feel "gouged." This is difficult because only sparse scientific detail exists to answer this question, and the answer likely differs by geographic region and even within regions, based on socioeconomic strata and client compliance. That said, the revelation about resistance has changed the dynamics, making the arguments for yearly testing more compelling.

Arguments can be put forth both for and against yearly testing.[26] Proponents might argue that this practice gets animals into the clinic yearly (vaccination no longer does [see ch. 208]), thereby ensuring yearly examination and resultant health benefits and income, and provides inexpensive insurance against unrecognized infection caused by poor compliance, resistance, or dogs that surreptitiously expectorate orally administered medications. In addition, yearly antigen testing is very specific (i.e., little risk of false-positive results), prevents long-term infections from becoming established during the period between heartworm checks, and would seem to limit liability to the practicing veterinarian. They might well also point out that recent reports have demonstrated poor compliance for heartworm prophylaxis nationwide,[46-48] and even though ML preventives provide the safety net of the so-called reach-back effect (retroactive efficacy, safety net), discussed elsewhere, this benefit is realized only with lapses of less than 3 to 4 months, varies between products, and requires continuous administration for 1 year after the lapse.[56] Finally, yearly testing for heartworm antigen is useful to pick up latent (infections that have progressed too far to be eliminated with preventive, but are not patent at the time that preventive was prescribed), incompletely eradicated infections, and product failure.

On the other hand, the opponent of yearly testing might point out that if as a profession we emphasize the efficacy and importance of preventive agents, we may lose credibility by also promoting yearly testing. Additionally, the ML preventives are very efficacious, possessing reach-back potential in the hands of conscientious clients, and the risk of severe adverse reactions in dogs with undisclosed infections, which receive ML, is small. The reason that adverse reactions are less likely is that an infected dog on preventive is rendered either amicrofilaremic or is left with a small microfilarial burden. In addition, the reactions to ML in microfilaremic dogs are less severe than previously encountered with the use of diethylcarbamazine. Furthermore, the argument can be made that the small worm burdens, most likely to result when preventive lapses are brief, will be minimally harmful and might even escape detection by immunologic tests, and that

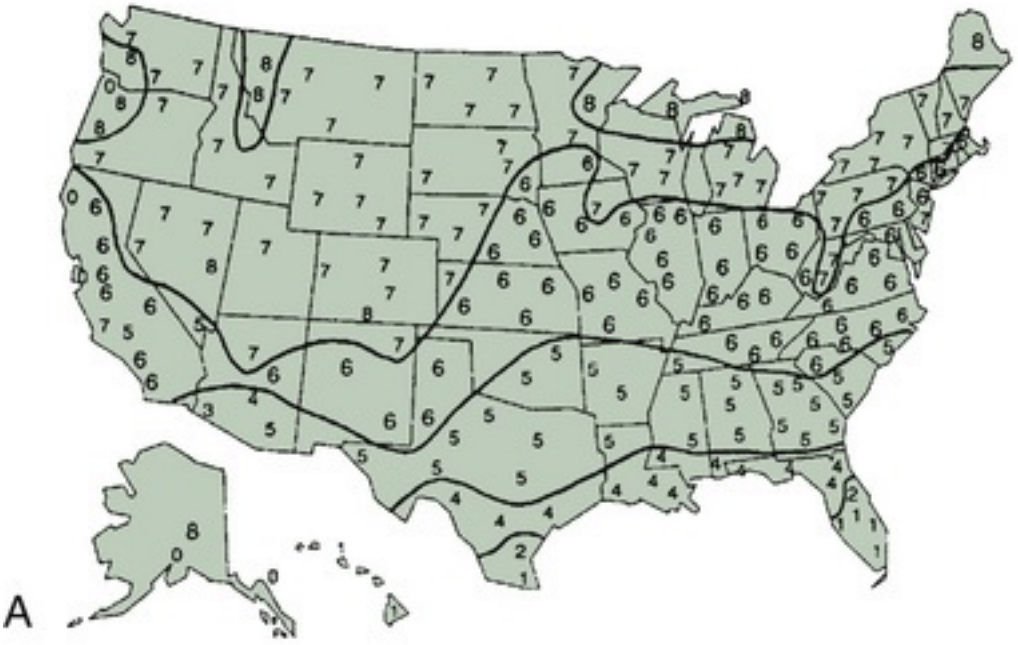
the chances of false-positive tests increase with low prevalence (as would be expected in a population of pets receiving preventive and yearly evaluation).

The AHS addressed this question in 1995.[116] It stated "after the initial retest, if it appears that monthly chemoprophylaxis is being given as prescribed, retesting at intervals greater than 1 year may be sufficient. However, reasonable doubt that administration has been adequate would justify retesting at shorter intervals, perhaps on an annual basis." Unfortunately, existing data on owner compliance are alarming. Cummings and colleagues[47] surveyed dispensing records of 50 veterinary practices in heartworm-endemic areas in the United States and found that, based on the practices' own recommendations, only enough medication was dispensed to adequately protect 41% of the canine clients. This was largely due to the fact that medication was dispensed for less than 50% of the dogs in the practices. It is important to add that this study did not identify compliance failure in which dispensed medications were not administered or in which administered medication was not applied or was not swallowed. These data suggest that the majority of our canine patients *should* undergo yearly testing. Positive test results in this population should be carefully scrutinized, however. In 2005, the AHS stated, "As lack of efficacy has been reported for all macrocyclic lactones (MLs), annual retesting is an integral part of ensuring that prophylaxis is achieved and maintained" and today, both the AHS and the CAPC recommend annual testing.[79]

Yearlong Prevention

Because of the necessity of the mosquito as an intermediate host for HWI, it has been logical and accepted practice to discontinue preventives during the winter months in the more northern climates. In warmer climates, where mosquitoes may be encountered 12 months of the year, yearlong prophylaxis has been the practice. With the advent of monthly, very effective prophylactic agents, and with improved understanding of the temperature dependence of heartworm transmission by mosquitoes, this yearlong practice has been called into question.[3] Although no supportive data exist, it might be assumed that the ease of administration of monthly preventives may improve owner compliance and that the reach-back effect will make up for short lapses in therapy or unexpected exposures at the beginning or end of the transmission season, thereby making the effective period of prevention longer. More importantly, studies have shown that transmission, even in the most heartworm-endemic areas, does not occur during the final quarter of the year.[2] This is because the mosquito, which is generally assumed to live 30 days, requires a minimum average daily ambient temperature to allow larval development to the infectious (L3) stage. This requirement is defined in heartworm development units (HDUs). An HDU is the degree days (in °C) that the average ambient temperature surpasses the developmental threshold of 14° C (57° F).[2] Restated, for each day that the average ambient temperature exceeds the threshold, an HDU is attained; if the average temperature is 16° C for 1 day, for example, then 2 HDUs are attained. For development of infective larvae, 130 HDUs must be attained and, to be effective, these must be attained in the lifetime of the female mosquito (≈30 days). If the average temperature is 16° C, for example, it would take 65 days for L3 to develop, thereby making transmission impossible. On the other hand, a 24° C average temperature would allow the molt to L3 to occur in 13 days, well within the mosquito's life expectancy. In a very innovative approach to this question, Knight and Lok[3] surveyed temperature extremes in 200 weather stations over a 30-year period and calculated the worst-case scenario for transmission of heartworms. The resultant isotherm maps (E-Figure 255-21) constructed from this information indicate the month to begin and to cease heartworm preventive therapy by geographic region. In only Hawaii, southern Florida, and the southern tip of Texas is yearlong preventive deemed necessary, using this model.

Macrolide heartworm chemoprophylaxis
estimated timing of first monthly dose
first day of month administration



A

B

E-FIGURE 255-21 Isotherm maps demonstrating the month to begin **(A)** and stop **(B)** heartworm monthly preventative therapy based on data from nearly 200 weather stations (see text for detailed description). A zero (0) indicates no preventative necessary. (From Knight DH, Lok JB: *Seasonal timing of heartworm chemoprophylaxis in the United States. Proceedings of the 1995 American Heartworm Symposium*, Batavia, IL, 1996, American Heartworm Society, pp 37-42.)

Arguments may be drawn against this theory and in support of yearlong prevention, or at least for a longer prevention season than indicated by the isotherm maps, published by Knight and Lok.[3] First, though fascinating and backed by scientific fact, this approach represents only a theory, and one that can never be proven. It cannot be proven because this would require testing the hypothesis in every locale in the country in an infinite number of years and seasonal variation. Second, some aspects of the HDU model fall under question:

- Do all female mosquitoes really live only 30 days?
- Do not some mosquito species live longer than others?
- Are there not other climatic factors such as humidity that play a role in larval development?
- Are there not microclimates within isotherm regions that might allow more HDUs to be attained?
- Might not mosquitoes seek microclimates (indoors perhaps) with temperatures to allow heartworm larval development?
- Climate change is not taken into consideration in this scheme.

Recent work indicates that HDUs calculated on an hourly, rather than daily basis, are more accurate and that the method used for the Lok-Knight maps may underestimate the risk of HWI.[117] Third, owner compliance has been shown to be far less than optimal, making any compromise in HW prevention questionable.[46-48] Fourth, the ML reach-back benefit, which protects dogs for which compliance is imperfect, falls after a maximum 4-month lapse in therapy, varies among preventives, and requires 12 to 14 months of continuous therapy after the lapse to be effective, which does not happen with seasonal prevention programs.[52,55,56] Additionally, should an adult infection be present, ML adulticidal efficacy requires at least 2 years' continuous therapy.[56] Fifth, sometimes significant differences exist in adjacent isotherm regions, rendering decision making confusing and potentially hazardous. For example, in Florida, the model describes adjacent regions exist which require 10 or 12 months of preventive treatment. How, in this instance, does an owner or veterinarian know which protocol to use? Furthermore, in some areas, the change from current recommendations to those based on the isotherm maps is minimal. For example, in Wisconsin, current seasonal recommendations would dictate starting heartworm preventive in May and continuing through November, whereas the isotherm map suggests July through October, a difference of two doses. Sixth, animals travel, often to warmer climates during winter. Seventh, because some ML and ML combination products have broad spectra, their use in other parasite control might argue for their use for longer than just the projected heartworm transmission season. Eighth, the savings to clients is relatively small. If a client in North Carolina (June 2015) changes from yearlong prevention to the Knight-Lok recommendation (12-month administration to 7-month administration), the savings for 40-lb and 20-lb dogs is about $35 and $24 per year, respectively. Ninth, most clients do not want to take a chance when the risks/options are carefully and thoughtfully explained to them. Tenth, and most importantly, the Knight-Lok recommendations were made prior to the discovery of ML-resistant strains. This knowledge makes the prospect of altering policy to that which increases the risk potential for HWI to be harbored and spread very questionable, indeed.

The Knight-Lok model provided novel and useful information, indicating that the risk in other than prime heartworm season is less than previously believed, and that in some instances heartworm prophylaxis might be excessive. The Knight-Lok model should stand as a suggestion for planning the timing of seasonal prophylaxis, with practice erring to the conservative. This means extending the isotherm map suggestion 1 month in either direction and taking the earliest implementation date and the latest cessation date surrounding one's geographic region. As a profession, we are faced with the dilemma of providing the best care with fiscal responsibility. We now have the information to decide what is best in a given geographical area and recommendations from two organizations advising year-round HW prevention. Once explained honestly, it then falls upon the shoulders of the client to determine if the risk of possible, but generally unlikely, infection is worth the savings.

Macrocyclic Lactones as Adulticides

It is now proven that ivermectin and probably selamectin have adulticidal efficacy that can approach 100%

with prolonged, continuous administration.[55,56,68] Ivermectin was demonstrated to be 95% successful as an adulticide in experimental, young infections with 31 months' continuous administration.[55] A more recent study by the same investigator demonstrated less optimistic results (only 71% in 24 months).[118] The exact role of MLs in the management of HWI, other than as preventives, is unclear and likely will continue to stir controversy for years to come.

The appeal of MLs for this use is that it takes the veterinarian out of the "complication loop." Complications might indeed still occur but would not as likely to be temporally linked to the ML administration (as they are to arsenical use). In addition, reduced cost, patient discomfort, and inconvenience are appealing. Lastly, and importantly, ivermectin coupled with 30 days' doxycycline therapy has been shown to shorten the time to worm death, while ridding the patient of microfilariae, thereby lessening the concern that this protocol lends itself to the development of ML resistance.[100]

Arguments against the use of ivermectin in this way include the following:

- Represents an off-label use of ivermectin
- Requires continuous compliance from a client who often has allowed HWI to occur—most often by poor compliance
- Lack of knowledge about the timing and degree of exercise restriction necessary; safe use might require >31 months of continuous exercise restriction
- Absence of a controlled kill as seen with melarsomine, reducing the ability to effectively monitor for adverse effects
- Lack of knowledge as to the effect of chronic antigen release from slowly dying adult heartworms on the kidneys and lungs
- Knowledge that ML "slow adulticidal therapy" does not stop progression of lung disease associated with HWI and that lung disease progresses as long as worms are present[119]
- Proven efficacy is only in young (<8 months old) experimental HWI[56]; however, efficacy may vary with different ages of HW
- More recent studies in natural infections showed only 71% efficacy at 24 months, based on positive antigen tests[118]
- McCall, instrumental in discovering the adulticidal efficacy of MLs, based on worsening of clinical parameters in dogs with natural HWD, now states "monthly administration of IVM to dogs with clinical, radiographic or echocardiographic evidence of heartworm disease is ill-advised and such treatment of even the asymptomatic dog should be done only with much caution and frequent monitoring"[118]
- Concern that this approach predisposes to heartworm resistance to ML[120,122,149]

In 2001, prior to knowledge of doxycycline's use in HW control, at the American Heartworm Symposium, the audience and a panel of experts were polled by this author as to their beliefs regarding the role of ivermectin as an adulticide in their own practices.[123] Five percent of the audience and none of the expert panelists used *only* ivermectin for adulticidal therapy. Approximately one third of both groups did not, or would not, use ivermectin as an adulticide, under any circumstances. Finally, approximately 70% of the expert panel and 50% of the audience stated that they would use ivermectin for this purpose only under mitigating circumstances of financial or medical constraint. An unpublished survey of veterinarians attending heartworm seminars at the North American Veterinary Conference in 2012 showed that while 18% of attendees used the slow-kill approach as their primary method of HW treatment, only 7% used this approach *without* doxycycline.

The author recommends that melarsomine be the primary adulticidal tool and recommends or accepts the *limited* use of ivermectin in instances where a preventive is necessary in a heartworm-positive dog and the owner cannot afford arsenic therapy or in which medical conditions preclude its use; in the event of residual infection after appropriate treatment with melarsomine (assumes low worm burden); and, obviously, in unrecognized infections. In addition, whenever slow-kill methodology is intentionally utilized, it should be accompanied by 30 days' doxycycline therapy to reduce microfilarial numbers and propagation efficiency, thereby reducing the risks of development of resistance (see Anti-*Wolbachia* Therapy, below).

Anti-*Wolbachia* Therapy

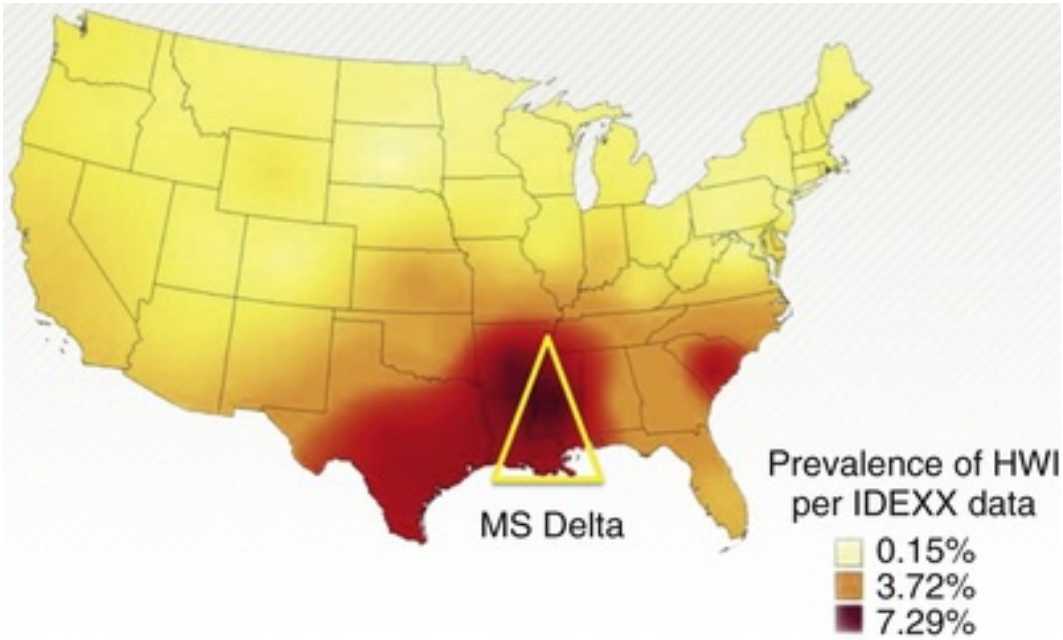
The interactions of *Wolbachia*, filarid parasites, and their hosts, as well as the use of doxycycline therapy, has been reviewed and is covered above in the Treatment section.[4,18] The use of doxycycline to destroy *Wolbachia*,

which lives in a symbiotic relationship within the HW, is logical as there is evidence that the HWs are debilitated or killed, that larval development is inhibited, that HW fertility and transmission are lessened, that adulticidal efficacy of ivermectin is enhanced, that immune-mediated processes (e.g., glomerulonephritis) might be reduced, and that the pathology produced by living or dead/dying worms and *Wolbachia* is lessened. Published evidence of the efficacy of doxycycline in the treatment of natural HWI is still rather sparse, the ideal protocol is far from understood, and doxycycline is not without side effects.[124,125] This author, nevertheless, combines doxycycline (20 mg/kg/day, divided into 2 doses × 30 days) with monthly ivermectin for soft-kill (when used because of lack of an alternative) to hasten worm demise, kill developing tissue stages of *D. immitis,* and rid the patient of Mf. When adulticidal therapy is chosen, this author employs doxycycline (along with ivermectin) in an attempt to reduce melarsomine-associated PTE, eliminate Mf, and kill tissue larval stages (see Figure 255-14).[4,18]

Heartworm Resistance to Macrocyclic Lactones

Prevention failure most often results from a lack of understanding on the part of owners as to the risk of HWI, a lack of owner compliance, or from inadequate instruction on preventive measures by the attending veterinarian.[1,46-48] Another potential source of prevention failure is the very real and frightening prospect of HW drug resistance, with the potential loss of this important drug class from the armamentarium of the practicing veterinarian.

Since the earliest part of this century, there has been growing concern that heartworms are becoming resistant to the ML class. This concern is based on reports from the field of increasing instances of drug failure to prevent HWI, termed LOEs (lack of efficacy reports). These reports have largely emanated from a region termed the Mississippi Delta (MS Delta), including parts of Tennessee, Arkansas, Louisiana, and Mississippi. Veterinarians in this area (E-Figure 255-22) have reported increased drug failure in dogs considered to have received adequate ML preventives and an increase in the difficulty with which Mf are cleared, using this class of drugs.



E-FIGURE 255-22 Map showing the Mississippi (MS) Delta, as the term is used in the context of heartworm infection. Landmarks include Memphis, TN and Jonesboro, AR at the northern borders and Gulfport, LA and Port Charles, MS as the southern borders. *HWI*, Heartworm infection. (Courtesy Auburn University and Novartis Animal Health.)

Based on the growing number of veterinary reports, the FDA-CVM formally reported this concern in 2005, subsequently requiring that manufacturers remove product claims of 100% efficacy.[126] During the next decade, millions of dollars have been spent to explore the validity and suspected mechanisms behind LOE.[127-149] *In vivo* microfilarial resistance to MLs was documented in a Hurricane Katrina canine survivor,

which could not be cleared of Mf, regardless of dosage and combination of MLs (but not doxycycline) utilized.[127]

Other early studies focused on a handful of dogs with medical records supporting claims of good preventive compliance and a history of difficulty in clearing Mf with ML.[128] Using an *in vitro* assay, Mf isolated from 4 of these dogs were subsequently demonstrated to be less susceptible to all currently marketed ML molecules, as compared to Mf from control dogs. Subsequent genetic analysis showed a close relationship between these Mf isolates, with a particularly high degree of homozygosity in the *P-gp* gene.[129] Importantly, in three isolates studied, there was a significant negative correlation between the susceptibility of the Mf to MLs and the percentage of homozygous (GG-GG) P-gp genes.[129]

Independent of these findings, a HW isolate (MP3) from Athens, Georgia, produced infection, despite treatment with either ivermectin or milbemycin oxime in the FDA-CVM (1-dose, 30 days post-infection) test of efficacy, the first ever recorded.[130] Expanding our understanding of the breadth of the problem and its therapeutic variability, Blagburn used a heavy MP3 challenge (100 L3) to demonstrate failure of one dose of ivermectin, milbemycin oxime, and selamectin, while topical imidacloprid-moxidectin experienced no failures in preventing HWI.[131] The infection rate was high (7/8 dogs in each group), but the worm burden of infected dogs was small. Subsequent tests showed that milbemycin oxime, given for 3 consecutive monthly doses, was 100% protective, temporarily alleviating some, but not all concern.[132] Furthermore, 2 of the aforementioned Blagburn isolates (Td2008 and Jd2009) and 2 separate LA isolates (LSU10 and LSU13) were used to challenge dogs receiving ivermectin.[133,134] All were successful in creating infection, as was Jd-2009 in dogs having received moxidectin in the six-month injectable formulation.[135]

Finally, and most concerning, is the isolate JYD-34, whose L3 produced infection in 7 of 8 dogs (worm burdens 1/3 to 1/2 that of control group) per group, despite *3 monthly doses* of ivermectin, milbemycin oxime, or selamectin,[136] while topical imidacloprid-moxidectin, with high and prolonged tissue levels, protected against JYD-34 in the FDA-CVM *one-dose* protocol.[136] It is noteworthy that, in a separate 1-dose study of JYD-34, 1 of 8 dogs was infected with 2 worms, despite having received imidacloprid-moxidectin.[136]

Importantly, resistance to ML in HW-challenge was proven in all 6 isolates referred to above. Also, the MP3 strain is considered by some to be only partially resistant because it can be prevented with traditional preventive molecules, administered for *3* consecutive months after exposure.[122] The JYD strain is highly resistant to all ML molecules, but only partially resistant to topical imidacloprid-moxidectin.

At the time of this writing, the concept of *hereditary* HW resistance to ML in certain isolates or biotypes is well accepted by clinicians and HW researchers.[122,127-142] It also is now clearly apparent that Mf exist which have reduced or absent susceptibility to this drug class.[127,128]

Other areas remain controversial, unclear, or both. At least one expert believes that the off-label use of ML as a "slow-kill" HW adulticide has produced this resistance, with the MS Delta LOE explosion being the result (Dwight Bowman, personal communication, 2014). Bowman, who has long warned against use of the soft-kill technique and long predicted the development of resistance, succinctly explains the hypothesized role treating microfilaremic dogs with ML. "The concern with the extended presence of microfilariae in dogs on a long-term preventive regimen … [is that] … these microfilariae are persisting in the presence of the macrocyclic lactones. The worry is that these microfilariae have been selected for resistance to these molecules, and the mosquitoes have the ability to transfer worms that have already been selected for their ability to survive in the presence of these products."

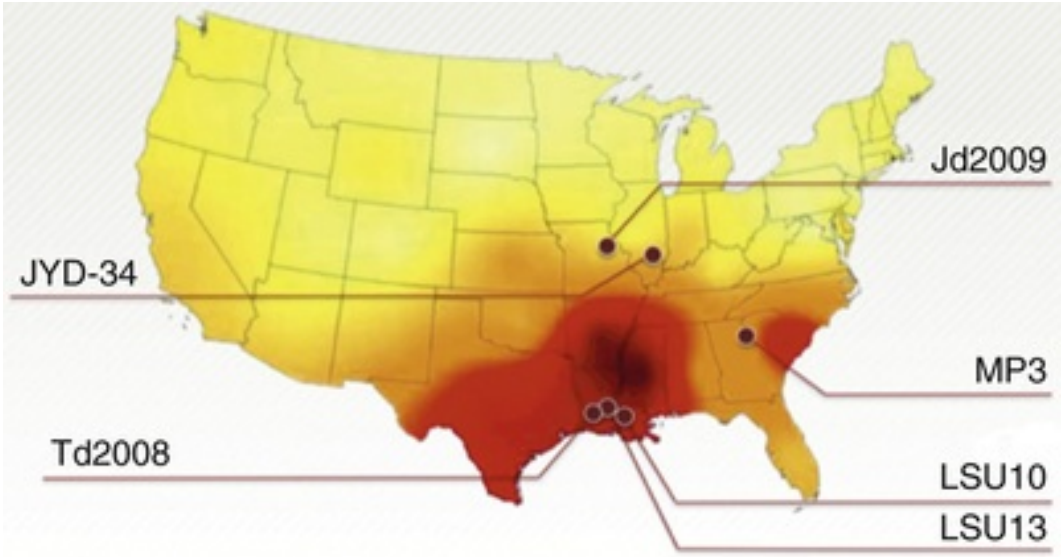
Some parasitologists, veterinarians, and laypeople also believe, or are concerned, that the problem is not just wide-spread, but also spreading north from the Delta.[139-142] While believing in the existence of HW resistance and *advocating against* the use of the slow-kill approach, this author takes a somewhat less alarmist perspective on the range and immediate danger of resistance. This is based on published and unpublished data and personal observation. Importantly, however, he does *strongly advocate* for careful surveillance and taking appropriate steps to do what we can to prevent further resistance development and spread, which at its worst, has the potential to render this class of drugs useless to us for HW control (see What Do We Do?).

While it is accepted that there are HW biotypes that are resistant or less susceptible to MLs, when compared to our historical perspective, there is an alternative to the "man-made resistance" explanation. This is the possibility that a bell-shaped curve of susceptibility, due to spontaneous mutation,[122,137] naturally exists, with HW biotypes being variably susceptible to MLs. This possibility is supported by experts on resistance and by the fact that early (1980s) range-finding studies of ivermectin showed that some heartworms were able to break through at a dosage of 3 mcg/kg (one-half the recommended dosage), even

though the majority of infections were prevented.[134] Indeed, it is at least conceivable, since no one had ever looked for resistant biotypes until circa 2005, that less susceptible HWs have always been there. If true, this neither reduces the risk nor diminishes the importance of these recently discovered resistant HWs.

While not an advocate of the soft- or slow-kill adulticidal approach, this author does *not* feel that the LOE rise reported from the Delta is likely due solely to resistance arising from off-label use of MLs as adulticides. First, the validity of the vast majority of such claims has been called into question. In a study carried out by the author and colleagues, 301 cases of HWI in 271 proven HW-infected dogs from 19 Delta practices expressing concern regarding resistance were scrutinized.[143] Each of the dogs evaluated was the source of an owner satisfaction guarantee claim to the pharmaceutical company making the heartworm preventive in question. Computerized analysis (Window of Infection Tool, Merial, Ltd.) of the medical records from the dogs involved in the claims revealed that *only* 1.7% of the 301 infections had a perfect purchase history (no lapses in purchasing HW preventive >45 days in duration), evident in the medical record. Another 19% of claims, while they did not have purchase gaps >45 days, within the window of infection, were associated with multiple HWIs per dog, sporadic purchase histories, and significant (often prolonged and multiple) purchase gaps outside the window of infection, casting aspersions on the reliability of the preventive care provided to these dogs. Nearly 80% of the claims were invalidated by careful investigation of the owners' purchase histories and over 98% drawn into question. Several conclusions can be drawn from these data. First, compliance is a problem. Second, the majority of claims are invalid and the vast majority are, at the very least, questionable. And third, the LOE problem has been vastly over-reported.

Still another argument against slow-kill driven resistance being the cause of the Delta "epidemic" is that in 10 years' exploration, only 6 dogs have been discovered from which Mf have been able to develop into proven resistant L3.[130,133,134,136] The origin of these dogs has been varied and somewhat scattered (E-Figure 255-23), only 3 of which were isolated from the Delta. It is difficult to look at this number and distribution and conclude resistance is widespread, with "scattered" and "sporadic" being more appropriate adjectives. Furthermore, 2 of the 6 (MP3 and JYD-34) were found in geographical sites without resistance concerns and far from the MS Delta (Illinois and Georgia).



E-FIGURE 255-23 Sites of discovery of macrocyclic lactone–resistant heartworm isolates. (Courtesy Auburn University and Novartis Animal Health.)

That the MS Delta's increase in LOEs is resistance-driven is also challenged by the fact that the three major tenets of resistance have not been met.[122,144-147] These tenets are:

1. Resistance does not develop where there is a large refugia (susceptible animals not receiving preventive). The Delta has likely the largest refugia in the nation, with wildlife, a high percentage of unprotected pets, a low per capita income, and a massive mosquito population with a high infection rate.[144-146,148]
2. Resistance spreads rapidly.[122,147] The *lack of spread* of "resistance" beyond the Delta over the last 10 years is impressive, with cities 1-2 hours' drive beyond its boundaries (e.g., Tupelo, MS; Mobile, AL; and

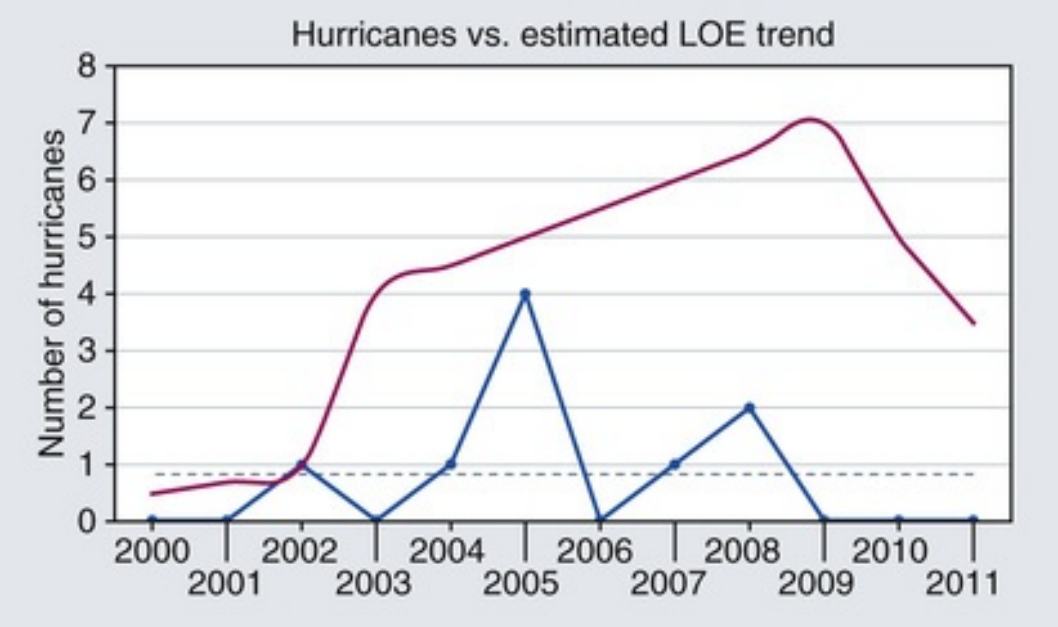
Pensacola, FL) voicing little concern over escalating LOE (Atkins, personal observation). Furthermore, while most of the "resistant" isolates are similar in that they share the GG-GG P-gp genotype, two isolates (MP3 and JYD34), which came from dogs far from the Delta and from areas with no current resistance concerns, do not exhibit this polymorphism, arguing that these isolates did not originate in the Delta. Three of 4 remaining "resistant" isolates had the P-gp genotype and were found in the Delta, supporting the viewpoint that "resistance" has been largely static and is not spreading.

3. Resistance is forever.[147] Since peaking in 2009, the number of Delta LOE claims made to manufacturers has dropped substantially, according to industry sources. Pulaski has confirmed this in Louisiana, where the peak was in 2009.[134] This decline is not consistent with drug resistance being the primary driver of LOE claims.[122]

The Delta LOE spike appears to meet none of these three "necessary" criteria needed to support ascribing this increase in LOE solely to resistance. There are, however, potential alternative explanations for failure of these tenets to hold true for HW resistance in the MS Delta.[122] Certainly, while resistance *does* indeed exist, the possibility that it might *not* be the sole, or even major, reason for the rise in Delta LOEs, must at least be entertained.

If the Delta LOE dilemma is not entirely due to resistance, as has been suggested herein, then what other factors have contributed?

1. As stated above, compliance failure is the biggest association/causative factor, explaining the vast majority of Delta LOEs.[143]
2. Also, for maintaining owner satisfaction guarantees, yearly heartworm tests are required. It only stands to reason that if we test more frequently, we will find more heartworms.
3. Another important factor, in the author's opinion, is that the climatic disasters that hit the Gulf Coast, and particularly ravaged the MS Delta, contributed to the HWI "explosion." The tremendous rise in the number of LOEs from 2004 to 2009 occurred during the heaviest Gulf Coast hurricane incidence in recorded history. During 2004-2008, the time of ramping up of LOE reports, there were 8 hurricanes, 2.2/year (nearly 3 times the average of 0.83/year).[150] Between 2009 and 2011, there were no hurricanes in the Gulf. The peak in LOE reports was in 2009, with a steady decline since then, through 2013 (E-Figure 255-24). Though, clearly circumstantial, the relationship in timing between the major storms and a marked increase in LOEs suggests a cause and effect. There are several explanations as to how this might occur. First, major storms leave broken trees, debris, and water in their wake to act as breeding grounds for mosquitoes. Second, mosquito populations may change after storms, with repopulation by different species, potentially increasing (or lowering) possible heartworm vectors. Finally (and possibly most importantly), the resultant devastation of storms such as Katrina leaves lost and abandoned animals (250,000 in New Orleans, alone) in a heavy heartworm endemic area without veterinary care, including heartworm preventive. This scenario is quite plausible as a (major) contributor to the upswing in LOE reports between 2000 and 2009. A recent study by the author demonstrates that a large HW epidemic began circa 2002 and peaked in 2011. This epidemic dwarfed and preceded the LOE epidemic by 3 years. Between 1997 and 2015, HW prevalence was significantly associated with MS Gulf hurricane numbers (Atkins C, et al, unpublished data, 2016).



E-FIGURE 255-24 The number of hurricanes striking Gulf Coast from 2000-2011 (blue line) and a unitless estimate of LOE claims filed (red line) during the same time period.[126,134,150]

4. Lastly, if there is a reward for filing an owner satisfaction claim for failure of a ML, there will be more claims submitted. LOEs have been grossly over-reported.[143] As was shown in a study of over 300 canine HWIs, for which whose owners and veterinarians filed for reimbursement for product failure, between 80% and 98% could not be justified with careful examination of the purchase history.[143]

The previous points are not intended to deny the existence of heartworm resistance, nor do they infer that resistance is an unimportant threat to our patients, clients and profession. But they offer evidence that heartworm resistance alone cannot explain the rise in LOEs in the MS Delta and that resistance likely cannot be ascribed to a single factor such as the overuse or misuse of slow-kill methodology.

What Do We Do?

There are numerous ways in which the practicing veterinarian can help slow the spread of resistance.

- The most important step that veterinarians can take is to ensure that MLs are used appropriately, year-round, at adequate dosage, and without lapses in administration. This effort should be buttressed by efforts to ensure compliance for those clients who purchase preventive, both in refilling and administering preventive. This can be done in a number of ways, including reminders using smart phone apps, the telephone, and postcard mailers. If compliance is an impossibility, consideration should be given to the use of 6-month injectable moxidectin.
- In addition, yearly testing is imperative because if a drug or an owner fails, the resultant HW continues to be exposed to ML, which has been shown to change the genetic make-up of the Mf, with greater expression of genetic markers associated with resistance.[149] In addition, this testing practice will reveal infected dogs so that adulticide can be administered, rather than allowing unrecognized HWI to progress into HWD. The unwanted results of this being the ultimate development of clinical signs, with the conditions for potential spread of HW, rendered less ML-susceptible, after having been exposed to ML.
- Adulticidal therapy with melarsomine (after 30 days' doxycycline and monthly ivermectin) should be administered as soon after diagnosis as is medically and logistically possible.
- Because administration of ML to microfilaremic dogs risks pushing HW toward ML resistance, all HW antigen-positive dogs should be tested for Mf and, when present, Mf should be eliminated. This can be accomplished with either doxycycline and ivermectin or with imidacloprid-moxidectin. While the AHS recommends either a modified Knott or millipore filter test, the less arduous direct smear also gives valuable information as to the presence and numbers of Mf. Knowledge of the presence of Mf is important in the fight against resistance and the numbers are important in assessing if precautions need be employed to avoid an adverse reaction.

- Slow-kill approach to HWI eradication *should be avoided*! If mitigating circumstances dictate otherwise, doxycycline should be administered and eradication of Mf confirmed (see Macrocyclic Lactones as Adulticides in Controversies).
- The use of doxycycline in antigen-positive dogs plays another role in reducing infectivity of L3 by eliminating *Wolbachia* from all HW stages. This, of course, reduces not only the potential of resistant HW being propagated, but reduces the spread of HWI in general.
- Puppies should be started on preventive as early as drug label claims allow, and kept indoors or in screened enclosures prior to institution of preventive therapy. Doing this alone has the potential to eliminate nearly 15% of the MS Delta LOE reports, as was shown in the study by Atkins et al, described above.[143] Ancillary measures include topical or oral repellents/insecticides, mosquito abatement programs, avoiding walking dogs at dawn and dusk, and keeping dogs indoors or in screened enclosures at night.
- The profession could also lobby to require negative microfilarial status for health certificates, needed for interstate travel or relocation.
- Research into the incidence and spread of resistance should continue to be studied and the development of genetic markers of resistance in Mf, as is being done at McGill University, should be encouraged.[138]
- Finally, in practices experiencing true LOEs, changing to a preventive with the best spectrum for known resistant biotypes is logical, as is emphasizing reduced mosquito exposure through changes in housing or via permethrin-containing, knock-down repellants.[73,74]

Treatment of Heartworm Infection When Finances Are of Concern

HWI is strongly and inversely correlated to the per capita income.[148] Clinicians are well aware of the fact that HWI is more common in lower socioeconomic strata of the country. This dictates that a "one-size fits all" approach will be doomed to failure and alternatives are presented in E-Table 255-5. The approach advocated in this chapter and by the AHS is considered to be the ideal approach, sparing no expense. Many cannot afford this approach and this is why many veterinarians advocate the soft-kill method, while others reluctantly choose it when finances dictate that there is no alternative.

E-TABLE 255-5

Guide to Choosing Heartworm Therapeutic Protocol

	PROTOCOL	ADVANTAGES	DISADVANTAGES	UTILITY*
1	Split-Dose (3 Inj.) Melarsomine Doxycycline Thoracic radiographs Lab (CBC, UA, Chem, Coag)	Incr. efficacy Decr. PTE risk Safety of phased HW kill No resistance concern	$$$$ 2 months' exercise restriction	Appropriate for all Best approach for severe heartworm disease
2	Std. Dose (2 inj.) Melarsomine Doxycycline Thoracic radiographs Lab (CBC, UA, Chem, Coag)	Reduced cost Decr. PTE risk (vs. std. dose) Only 1 month's rest No resistance concern	$$$ Incr. PTE risk (vs. split-dose) Decr. kill efficacy (vs. split-dose)	Appropriate when financial constraints and mild-moderate heartworm disease
3	Std. Dose (2 inj.) Melarsomine	Reduced cost Only 1 month's rest Easier for shelters No resistance concern	$$ Incr. PTE risk (vs. std. dose) Decr. kill efficacy (vs. split-dose) Cage rest is imperative!	Appropriate when financial constraints and mild heartworm disease
4	Slow-kill with ivermectin	Reduced cost Easy, no inj.	$ Incr. risk of resistance	Appropriate only when severe financial or other constraints

	Doxycycline	Appeals to shelters No hospitalization Shorter Rx duration than slow-kill	Not AHS-approved ≈12-month course Lung disease progression Time of HW death unknown	
5	Slow-Kill with ivermectin	Inexpensive Easy, no injections Appeals to shelters	Incr. risk of resistance 30-month course Lung disease progression Time of HW death unknown	This approach should be avoided

*None of these is appropriate for initial management of caval syndrome but may be used to complete therapy after worm removal.

AHS, American Heartworm Society; *CBC*, complete blood count; *Chem*, chemistry panel; *Coag*, coagulation profile; *Decr.*, decrease; *HW*, heartworm; *Incr.*, increase; *Inj.*, injection; *Lab*, laboratory; *PTE*, pulmonary thromboembolism; *Std.*, standard; *UA*, urinalysis; *X-Ray*, radiographs; *$*, relative cost.

The classical 2-dose melarsomine approach is still a viable alternative if finances dictate a compromise, and when coupled with doxycycline, ivermectin, and strict exercise restriction post-treatment makes sense when administered to asymptomatic, young and otherwise healthy patients. While the safety advantage of "split-" or 3-dose therapy (killing approximately 50% of the worms with the first and 50% with the second and third injections) is lost, the reduction in pathology with doxycycline/ivermectin and careful attention to exercise restriction makes it reasonably safe. It is much cheaper than the split-dose approach and requires one, rather than two months' exercise restriction. It is ethically superior to the slow-kill approach in terms of resistance concerns and is medically superior in that heartworms are eliminated much more quickly without ongoing, progressive lung damage over the months-to-years of slow-kill.

There are clients who cannot afford any adulticide therapy at all. In this instance, the soft-kill approach is the only option, though arguments to the contrary can be put forth to clients and, if persuasive, may open alternative treatment avenues.[121] If clients cannot be convinced, assuring that Mf are eradicated and that prevention efforts are redoubled largely removes resistance concerns. Ideally, 30 days' doxycycline therapy should be administered to minimize lung damage as HWs expire. While the soft-kill approach cannot be advocated, this modification is preferable to owners "giving up" and deciding to just settle for a heartworm-infected pet, which in addition to being a major health compromise, increases the risk of other unprotected dogs and of resistance development. If veterinarians find themselves in the latter position, doxycycline and ivermectin therapies should be advocated to lessen infectivity of the current HWI and to lessen host response to dying worms.

Feline Heartworm Disease

Life Cycle

The life cycle of *D. immitis* is similar in the cat and the dog (see Figure 255-2). Heartworm infection differs in cats, in that they are not generally the preferred target for feeding mosquitoes; that to be an effective vector for cats, a mosquito has to have first fed on a canid; and that, as an unnatural host, cats are inherently resistant to HWI. Infections in cats therefore tend to be relatively infrequent and small. In addition, the life cycle takes longer in the cat, such that patency (noted in <20% of cats) does not occur until 7 to 8 months post-infection. Lastly, the cat is subject to pulmonary and pulmonary vascular pathology, even if an infection never matures.

This phenomenon, called heartworm-associated respiratory disease or HARD,[152,153] has produced confusion in the nomenclature regarding HW infection vs. exposure. In most infectious and parasitic disease, the presence of antibodies without an established (mature) infection is termed "exposure," meaning the host was either exposed and rejected the infection or was (or currently is) infected. But in HWI, because antibody-positive status occurs when HW larvae enter the host and molt twice, with potential of ultimately producing disease, some now refer to this as "infection," *even if the infection is aborted*, prior to the parasites' maturation. In this section of the chapter, the author will use the term "mature HWI" for mature adult infections (or HWD, being due to mature HWI, with identifiable pathology), and will refer to those infections, that are ultimately aborted, as "immature infections" for individual cats or "exposure" when referring to populations, with the acknowledgment that an estimated 50% of such cats may develop lung disease from their exposure

(HARD).[152,153]

Pathophysiology

The domestic cat, though an atypical host, can be parasitized by *D. immitis,* with resultant HWD. The clinical manifestations of the disease are different and often more severe in this species, but if one considers mature infections only, the infection rate is only 5% to 20% of that of the dog.[154] Experimental infection of the cat is more difficult to establish than in the dog, with less than 25% of L3 reaching adulthood.[155] This resistance is also reflected in natural infections, in which feline heartworm burdens are almost always less than 10 and typically only 1 to 4 worms.[154] Other indications of cats' inherent resistance to this parasite are a shortened period of worm patency, high frequency of amicrofilaremia and low Mf counts, and shortened life span of adult heartworms (generally thought to be 2 to 3 years, with new evidence suggesting that it may be longer in natural infections—up to 4 years).[156] Nevertheless, studies have shown a mature HWI prevalence as high as 14% in shelter cats[154] and a study performed on well-cared-for cats in Texas and North Carolina revealed mature HWD in 9 of 100 cats with cardiorespiratory signs.[157] Furthermore, antibody testing showed 26% of these cats had been "exposed" to HWI.[157] Recent studies have failed to support the belief that males were at greater risk for natural HWI, although in experimental infections, males harbor greater worm burdens.[157,159] Aberrant worm migration has been suggested as being a more frequent occurrence in cats than in dogs.

At the risk of repetition, it is important to clarify the distinction between mature HWI (adult HW living in pulmonary arteries, or elsewhere) and aborted infections ("exposure" without parasite maturation). The death of immature adults (immature or juvenile S5, immature or juvenile adults, or juveniles) may create pulmonary and pulmonary vascular lesions in cats, prior to maturation. Uniquely, the disease process develops *even in cats that ultimately resist the mature infection,* and clinical signs and disease antedate clinicians' ability to diagnose the disease through conventional means. Studies have shown that pulmonary anatomical and radiographic lesions develop in experimentally-infected cats,[152,153,160] and that pulmonary vascular lesions are documented in naturally-infected cats[151] in which maturation of immature adults *does not* occur. Furthermore, experimental infections, pharmacologically aborted before HW maturation, have recently been shown to produce not only proliferative and inflammatory pulmonary arterial lesions, but proliferative and inflammatory disease of bronchioles and lung parenchyma as well.[152,153] Presumably, these findings are associated with the respiratory signs often seen in cats without mature HWI and have been called HARD.[152,153] These important studies showed that cats "exposed" (infected without allowing full HW maturation) to HW develop respiratory lesions and clinical signs of HWD. These findings are important in that they not only demonstrate that HWI that is ultimately rejected often produces asthma-like clinical signs, but that many more cats develop signs of HWD than was previously believed. This is because 38% to 74% of cats with mature HWI develop clinical signs, as do an estimated 50% of those that abort the infection (HARD, estimated to be 5 to 10 times more common than mature infections).[156,160] This distinction is also important in communicating to the pet owner that the cat with HARD will likely recover, while the cat with mature HWI has the potential to die from the disease.

The exact clinical importance of HARD, however, is difficult to gauge because it is a diagnosis of exclusion and the inherent suspicion of veterinarians for feline HWI is low. Thereby, it is likely that a large percentage of cases are not recognized. Also, the experimental model used a very high infection rate (100 L3 per cat), far higher than a cat would acquire naturally. So it is difficult to directly transfer our knowledge of experimental HARD to the naturally infected cat.

The pulmonary arterial response to mature adult heartworms is more severe in cats than in dogs (due, in part, to the presence of pulmonary intravascular macrophages [PIMs][162]), although PHT has infrequently been reported. Dillon[5] demonstrated pulmonary enlargement within 1 week of transplantation of adults, suggesting an intense host-parasite interaction. This has been confirmed by post-mortem examination, which revealed a severe endarteritis with villous intimal hyperplasia.[158] Such severe myointimal and eosinophilic response produces pulmonary vascular narrowing and tortuosity, thrombosis, and possibly PHT (Figure 255-25).[163,164] Maia et al demonstrated diffuse pulmonary arterial inflammation and hypertrophy, bronchiolar lesions, and intense interstitial pneumonitis, within 6 weeks of introducing 2 adult HWs via the jugular vein.[164] Type II pneumocyte hyperplasia was evident, using scanning electron microscopy, indicative of pulmonary parenchymal damage. Because the feline pulmonary artery tree is smaller than that of the dog and has less collateral circulation, embolization, even with small numbers of worms, produces disastrous results

with infarction and even death. Although uncommon, cor pulmonale and right heart failure can be associated with chronic feline HWD and is manifested by pleural effusion (hydrothorax or chylothorax), ascites, or both.

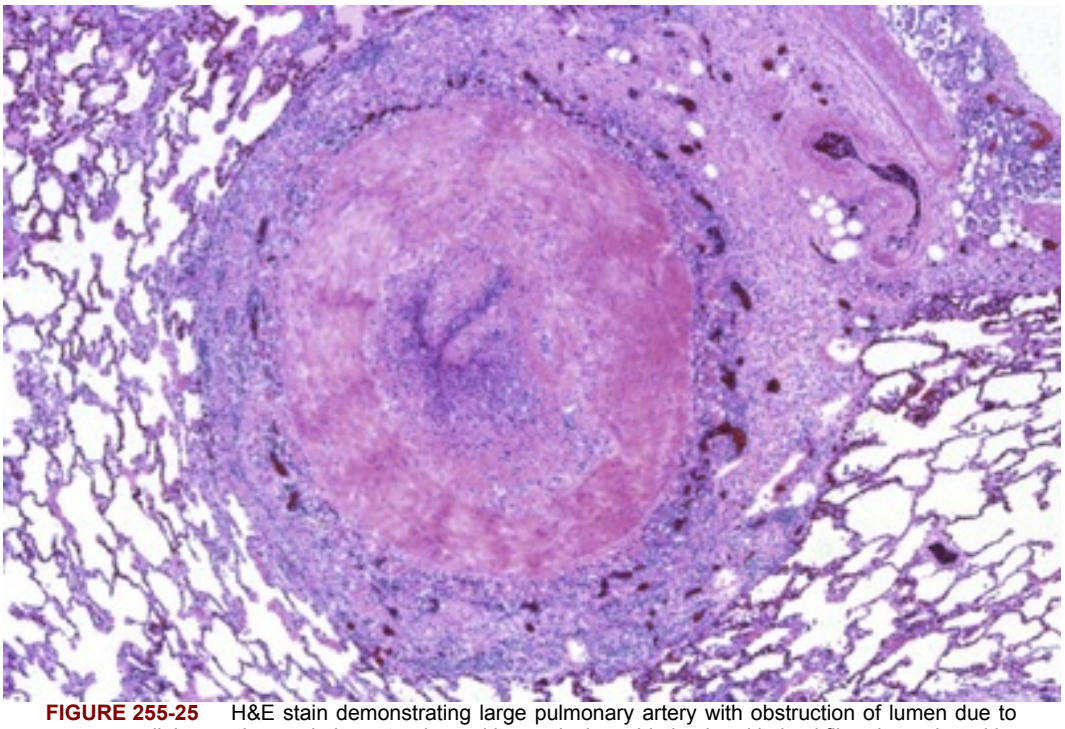


FIGURE 255-25 H&E stain demonstrating large pulmonary artery with obstruction of lumen due to severe medial smooth muscle hypertrophy and hyperplasia, subintimal and intimal fibrosis, endarteritis, and possibly thrombosis. The reader should also note the periarterial interstitial (probably eosinophilic) pneumonia.

The lung *per se* is also insulted by HWI, with eosinophilic infiltrates in the lung parenchyma (pneumonitis) and pulmonary arteries (Figure 255-26). The pulmonary vessels may leak plasma, producing pulmonary edema (possibly acute respiratory distress syndrome). Also, PIM-induced type II cell proliferation is recognized. Together, this combination of insults to the respiratory system alters O_2 diffusion, producing hypoxemia.[162] In addition, radiographic findings suggest air trapping, compatible with bronchoconstriction.[158,160]

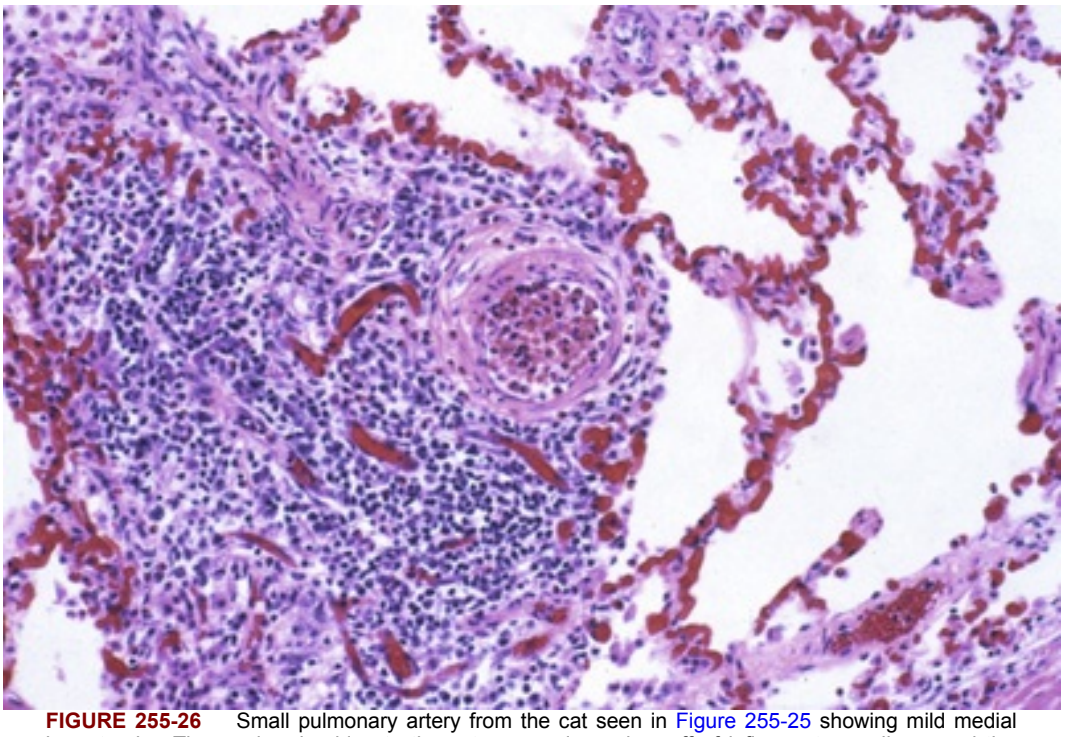

FIGURE 255-26 Small pulmonary artery from the cat seen in Figure 255-25 showing mild medial hypertrophy. The reader should note the extreme perivascular cuff of inflammatory cells around the vessel, representing an eosinophilic infiltrate.

The actual role of bronchoconstriction in this process is unclear, and experimental studies have led to differing conclusions. Studies have concentrated on aspects of both mature HWI and HARD, using mature and immature experimental infections, *Wolbachia* antigen-positive and antigen-negative natural infections, HW obtained from dogs having received doxycycline and from those which had not, and infusions of HW homogenate.[166-170] While an in-depth review of these manuscripts is not possible, salient findings are summarized below.

Despite increased bronchiolar wall thickness in heartworm-infected cats, a hyperreactive response of the bronchiolar smooth muscle does not appear to be the primary mechanism of respiratory tract clinical signs. The recognized attenuated response of the airway to isoproterenol may, however, indicate refractoriness to catecholamine-induced bronchiolar relaxation in heartworm-infected cats.[165] Possibly contradictory results have been obtained using plethysmography to evaluate airway function in symptomatic cats with serologic evidence of HWI. There were significant differences in several *in vivo* indicators of bronchoconstriction between cats with HWD and normal controls.[166] Subsequent studies, using this technique to compare *Wolbachia* specific protein-positive to WSP-negative cats, demonstrated significant abnormalities in indices of bronchoconstriction in antibody-positive, symptomatic cats.[167] This indicates the possibility of a role for *Wolbachia* or, more likely its proteins, in the pathogenesis of bronchoconstriction in feline HWD. On the other hand, a study of normal cats receiving 18 days' intravenous injection of HW homogenate demonstrated no difference in pulmonary lesions or indicators of bronchoconstriction, whether the HW used had been harvested from doxycycline-treated dogs or those which had not been so treated.[168] This study also revealed that homogenate infusion produced interstitial and peribronchial smooth muscle and myofibrocyte proliferation, apparently caused by a humoral substance, as lesions were not clearly related to areas in which HWs are typically found.

Inflammatory mediators (eicosanoids) appear to contribute to the lesions associated with HWD. Morchon et al demonstrated that naturally infected cats showed significantly higher serum levels of prostaglandin E_2 (PGE_2), thromboxane B_2 (TXB_2) and leukotriene B_4 (LTB_4) than uninfected cats.[170] In experimentally-infected cats, followed sequentially for 180 days, PGE_2 increased significantly during the first 60 days post-infection, then progressively decreased until day 180 post-infection, while TXB_2 and LTB_4 increased progressively, reaching maximum levels 180 days post-infection. This suggests that PGE_2 may be related to immature S5 parasite death (HARD), while TXB_2 and LTB_4 may be involved in reaction to mature HW.

The end result of this multifaceted insult is diminished pulmonary function, hypoxemia, dyspnea, cough, and even death. Sudden death in heartworm-infected cats may involve an anaphylactic-like reaction to dying worms with or without ARDS.[171] It appears unlikely to be due to WSP antigen.[169]

Clinical Signs

Clinical manifestations of HWD in cats may be peracute,[171] acute, or chronic.[157,158,173-175] However, in a retrospective study, 28% of cats with mature HWI, seen at a referral center, were presented for signs not referable to HWI.[174] Furthermore, newer, prospectively derived data from two Italian studies of 77 cats seen in general practice, revealed that only 58% of asymptomatic cats ultimately developed clinical signs of HWD, with one third of these being fatal.[156,161]

Acute or peracute presentation is usually due to worm death and/or embolization or aberrant migration, and signs variably include salivation, tachycardia, shock, dyspnea, hemoptysis, vomiting and diarrhea, syncope, dementia, ataxia, circling, head tilt, blindness, seizures, and death. Post-mortem examination often reveals pulmonary infarction with congestion and edema. More commonly, the onset of signs is less acute (chronic form). Reported historical findings in chronic feline HWD include anorexia, weight loss, lethargy, exercise intolerance, signs of right heart failure (pleural effusion; uncommon), cough, dyspnea, and vomiting. The author and colleagues have found dyspnea and cough to be relatively consistent findings and, when present, should cause suspicion of HWD in endemic areas.[174] Chylothorax, pneumothorax, and CS have also been recognized as uncommon manifestations of feline HWD (E-Figure 255-27).

E-FIGURE 255-27 Lateral thoracic radiograph revealing pneumothorax produced by HWD. There is probable atelectasis, as is seen in the increased opacity in the dorsocaudal lung fields. There is likely pulmonary disease as well.

In a report of 50 natural cases of feline HWI in North Carolina, presenting signs were most commonly related to the respiratory system (32 cats; 64%), with dyspnea (24 cats; 48%) being most often noted, followed by cough (19 cats; 38%) and wheezing (Figure 255-28).[174] Vomiting was reported in 17 (38%) cats and was noted frequently in 8 (16%). Five (10%) heartworm-infected cats were reported to have exhibited vomiting without concurrent respiratory signs and vomiting was a presenting sign in seven (14%). Neurologic signs

(including collapse or syncope [10%]) were reported in seven (14%) cats. Five (10%) of the cats were dead at the time of presentation. Murmurs were infrequently noted in cats that did not have concurrent heart disease, independent of HWI. Heart failure was present in one cat, but it had concurrent hypertrophic cardiomyopathy. HWI was considered to be an incidental finding in 14 (28%) of the cats in this study. It is noteworthy that studies of natural asymptomatic feline HW infections in a hyper-endemic region in Italy revealed that approximately 80% of infected cats self-cured.[156,161]

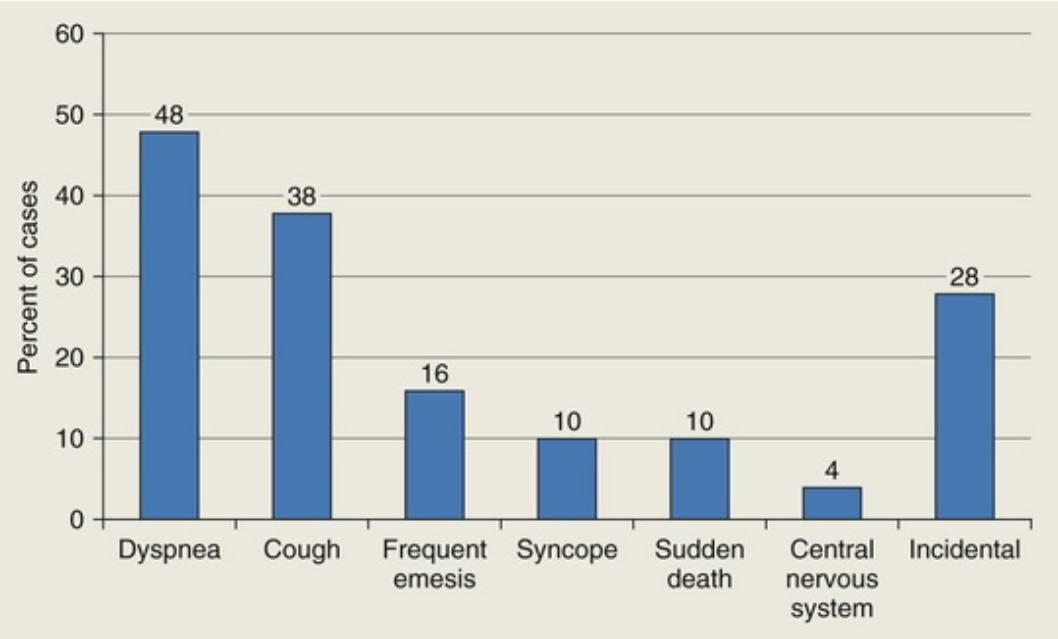

FIGURE 255-28 Clinical signs recorded in 50 cats with proven heartworm infection. (Data from Atkins CE et al: Heartworm infection in cats: 50 cases [1985-1997]. *J Am Vet Med Assoc* 217:355-358, 2000.)

Physical examination is often unrewarding, although a murmur, gallop, or diminished or adventitial lung sounds (or a combination of these findings) may be noted (see ch. 55). In addition, cats may be thin, dyspneic, or both. If heart failure is present, jugular venous distension, dyspnea, and rarely ascites are detected.

Diagnosis

The diagnosis of HWI in cats poses a unique and problematic set of issues.[5] First, clinical signs are often absent, and when present, quite different from those of the dog. In addition, the overall HWI incidence in cats is low, so suspicion is lessened; eosinophilia is transient or absent; immunologic tests are often falsely negative; electrocardiographic findings are minimal; radiographic signs are inconsistent and may be transient; and most cats are amicrofilaremic. Finally, the clinician must understand that antigen-positive cats nearly always have mature HWI and antibody-positive (antigen-negative) cats typically do not have mature HWI. However, approximately 50% of antibody positive/antigen negative cats develop pulmonary lesions of HARD. The diagnosis of HARD is one of exclusion and requires a high index of suspicion (Table 255-6).

TABLE 255-6

Comparison of Heartworm-Associated Respiratory Disease (HARD) Produced by Death of Immature Adult Heartworms in the Pulmonary Vasculature and Feline Heartworm Disease Produced by Mature Adult Heartworms

PARAMETER	HARD	CHRONIC HEARTWORM DISEASE
Onset of clinical signs after infection	≈3 months	>7 months

Etiology	Arrival and death of immature heartworms in pulmonary arteries	Pulmonary vascular, parenchymal, and cardiac response to the presence, death, and deterioration of adult heartworms
Clinical signs	Dyspnea, coughing, wheezing	Dyspnea, coughing, hemoptysis, collapse, vomiting, neurological signs, heart failure, sudden death
Serological test results		
Antigen	Negative	Positive or negative
Antibody	Often positive	Often positive
Microfilaremia	Absent	Occasionally present
Radiographic findings	Bronchointerstitial pattern	Variably bronchointerstitial pattern, pulmonary artery enlargement, and pulmonary hyperinflation; less commonly pleural effusion or pulmonary consolidation
Echocardiographic findings	Normal (no heartworm discernible)	Heartworm(s) often found in pulmonary artery, right atrium, or right ventricle; possible pulmonary hypertension

From Lee ACY, Atkins CE: Understanding feline heartworm infection: disease, diagnosis, and treatment. *Top Companion Anim Med* 25:224-230, 2010.

No compelling medical reasons exist to screen cats for HWI prior to administration of ML preventives because the risk of adverse reactions associated with microfilarial death is small (cats are amicrofilaremic or have small microfilarial numbers, and adverse reactions are minimized with ML preventives). Nevertheless, screening allows the clinician to alert pet owners if their cats have been exposed (antibody positive) so that they might choose to pursue confirmation of the diagnosis of mature HWI. It also minimizes public relations difficulties if the cat develops HWI, while on preventive. In addition, routine screening allows the clinician to understand the risk of heartworm pressure in his or her own practice area. The author's approach to routine screening of cats for heartworms differs somewhat from that when suspicion of infection exists (Figure 255-29).

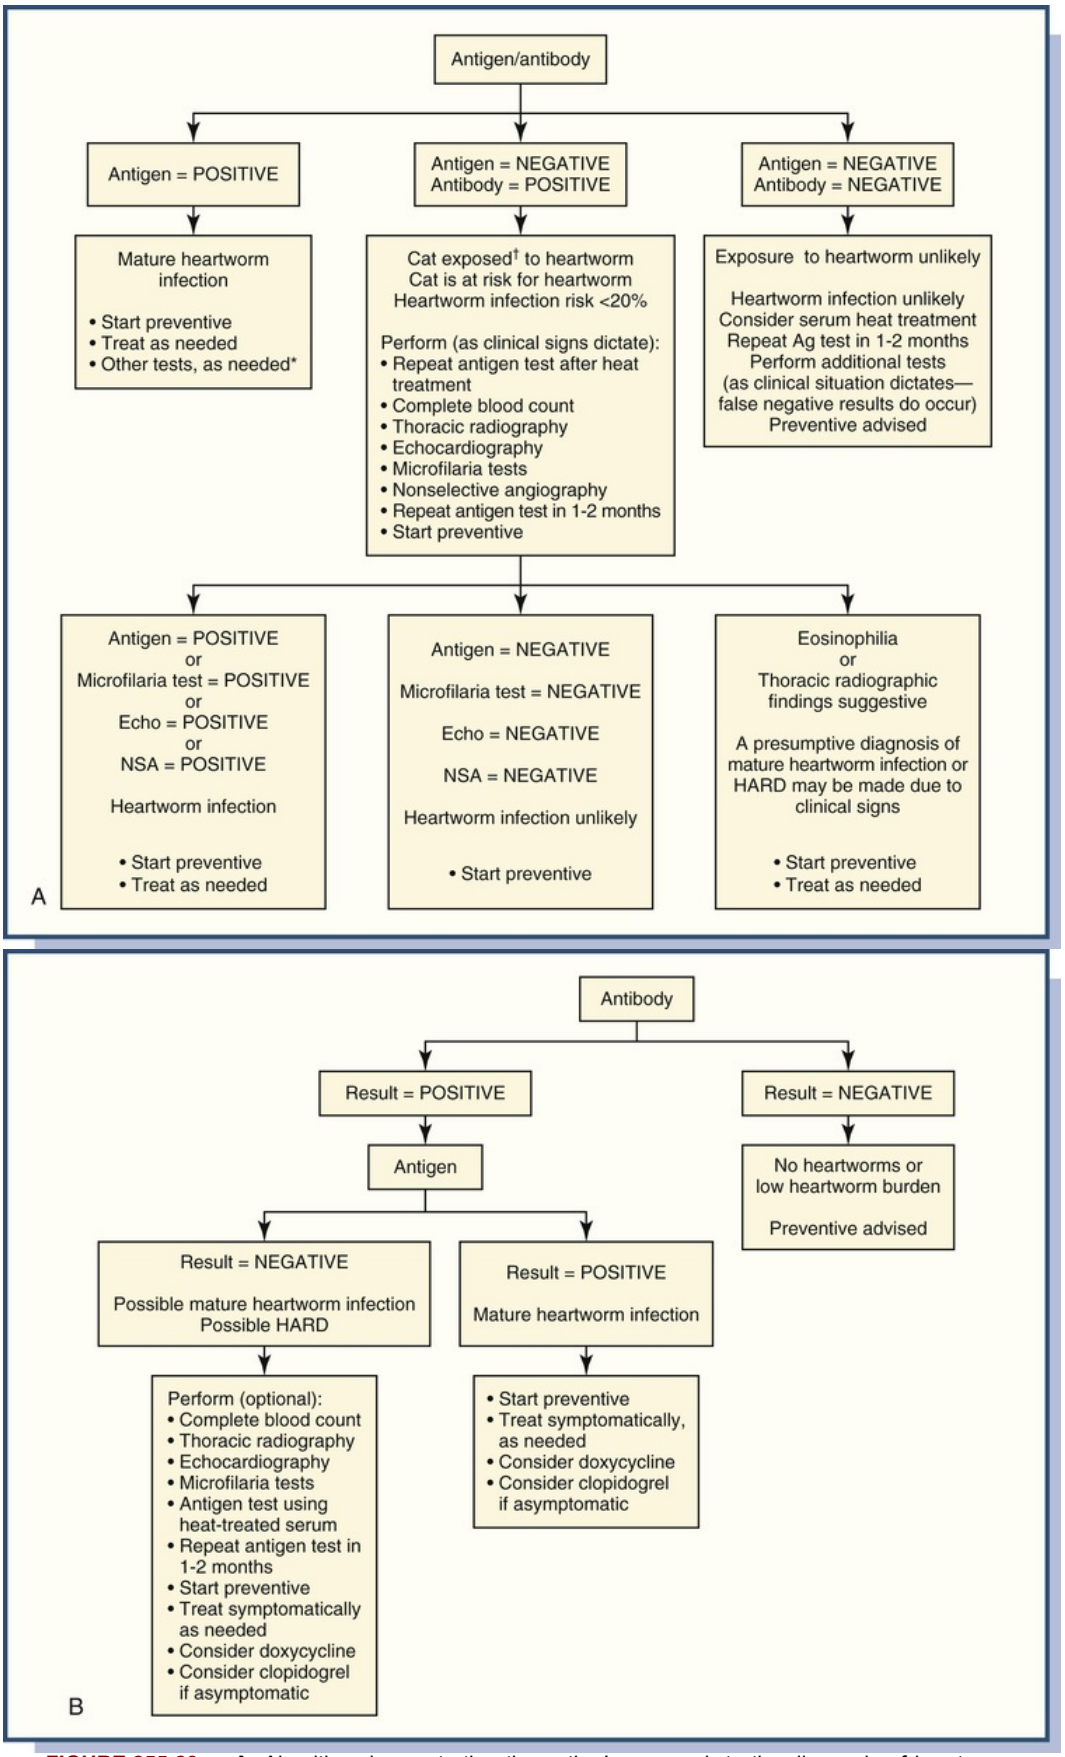

FIGURE 255-29 **A,** Algorithm demonstrating the author's approach to the diagnosis of heartworm infection in cats in which infection is suspected. **B,** Algorithm demonstrating the author's approach to screening cats for heartworm infection. *HARD,* Heartworm-associated respiratory disease; *NSA,*

nonselective angiography. *Thoracic radiographs and blood tests; †, *exposure* means that cat was exposed and allowed development to L4 stage, but may or may not have allowed parasite maturation. Some prefer to refer to this cat as *infected*, since the infection was probably eliminated at the immature S5 stage and clinical signs may be present.

Immunodiagnostic methods (see Table 255-2) are imperfect in cats because of the low worm burdens and hence, antigenic load.[175] In one study, ELISA antigen tests performed on sera from experimentally infected cats were positive on sera from 36% to 93% of 31 cats harboring 1 to 7 female heartworms, with sensitivity increasing as female worm burden increased.[176] Cats with only a male worm or only male worms were not detected as positive. Therefore false-negative tests occur frequently, depending on test used, maturity and gender of worms, and worm burden. All tests were, however, virtually 100% specific. It is important to realize that infection with signs may be present prior to the presence of detectable antigen (from adult females). McCall and colleagues[177] report that, in natural infections, the antigen test detects less than 50% of proven cases, while Snyder and colleagues[178] present differing data (from natural infections in which blood was obtained as long as 2 hours post-euthanasia) that show that the antigen test is more sensitive (74%) than previously reported. Also, because antigen tests continue to improve, their exact sensitivity is somewhat obfuscated, but is estimated to be 50% to 75% in *natural* mature infections.

Antigen tests detect 0% of cats afflicted with HARD, but the antibody tests are routinely positive in such cats (see Table 255-6).[175] An antigen test (IDEXX's SNAP Feline Heartworm Antigen Test) has been marketed for cats and is part of the snap platform for feline infectious diseases. This is an adaptation of the canine test, with a reported increase in sensitivity of 15% over conventional antigen tests.

Although less specific for mature infections, heartworm antibody tests are of use in the detection of feline HWI, even when antigen tests are negative. In a study of 257 HW antibody-positive cats, only 13.1% were antigen positive.[179] The antibody test also serves as a marker for exposure to and risk of HWI (even if the cat never develops a mature infection) and for the possibility of HARD. An in-clinic feline heartworm antibody test is also available (HESKA: Solo Step FH). It is important to emphasize that it is estimated that half of antibody-positive, antigen-negative cats have post-mortem manifestations of HWD and that, in these cats, the antibody-positive state may wane with time. Often, the antibody test is used in conjunction with the antigen test; each is available in a cage-side and send-off format.

Recently, the utility of detecting *Wolbachia* antigens (WSP, *Wolbachia*-specific proteins) and the use of PCR to disclose *Wolbachia* DNA have shown promise in diagnosing feline HWI[180,181] and it has been demonstrated that heat treatment of serum may increase the sensitivity of the antigen test.[22] In 6 cats with experimental infections, testing false-negative on 4 commercial antigen tests, treatment of the serum at 103° F for 10 minutes, rendered the serum derived from the resultant coagulum to give positive results in 5 of 6 cats. This has potential to be a needed boost in our ability to definitively diagnose HWI in cats; it is unlikely that it will disclose all-male infections.

Thoracic radiographs are useful in diagnosing HWD (or other diseases mimicking HWD). However, asymptomatic cats rarely have radiographic lesions, so this modality is not ideal for screening purposes.[161,182] The most sensitive radiographic criterion (left caudal pulmonary artery greater than 1.6 times the ninth rib at the ninth intercostal space on the ventrodorsal projection) was only detected in 53% of cases. Furthermore, even though most cats with clinical signs have some radiographic abnormality, the findings are not specific to HWD. In addition, a study by Selcer and colleagues[160] demonstrated that radiographic findings were often transient, and radiographic abnormalities were found in cats that ultimately resisted heartworm maturation and were negative on post-mortem examination, therefore likely having suffered what later became known as HARD. Radiographic findings include enlarged caudal pulmonary arteries (Figure 255-30), often with ill-defined margins, pulmonary parenchymal changes that include focal or diffuse infiltrates (interstitial, bronchointerstitial, or even alveolar), perivascular density, and occasionally, atelectasis (Figures 255-31 and 255-32). Pulmonary hyperinflation may also be evident, and the misdiagnosis of feline bronchial disease can easily be made (see Figures 255-25, *A* and 255-26, *A*). Pulmonary angiography has also been used to demonstrate radiolucent linear intravascular foreign bodies and enlarged, tortuous, and blunted pulmonary arteries (Figure 255-33).

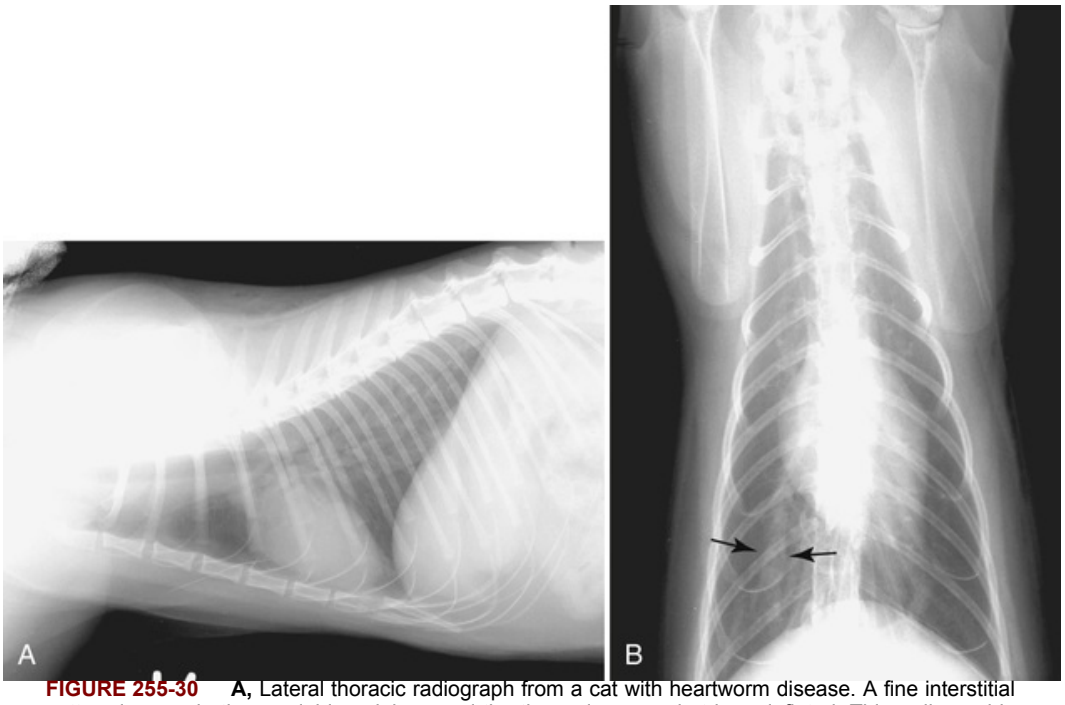

FIGURE 255-30 **A,** Lateral thoracic radiograph from a cat with heartworm disease. A fine interstitial pattern is seen in the caudal lung lobes, and the thorax is somewhat hyperinflated. This radiographic pattern is similar to—and hence confused with—that of feline bronchial disease. **B,** Dorsoventral thoracic radiograph from the same cat shown in **A.** Again, the changes are not dramatic, but the right caudal lobar pulmonary artery is enlarged (>1.6 times the ninth rib at the ninth intercostal space; arrows). The opposite pulmonary artery can be seen to be somewhat tortuous.

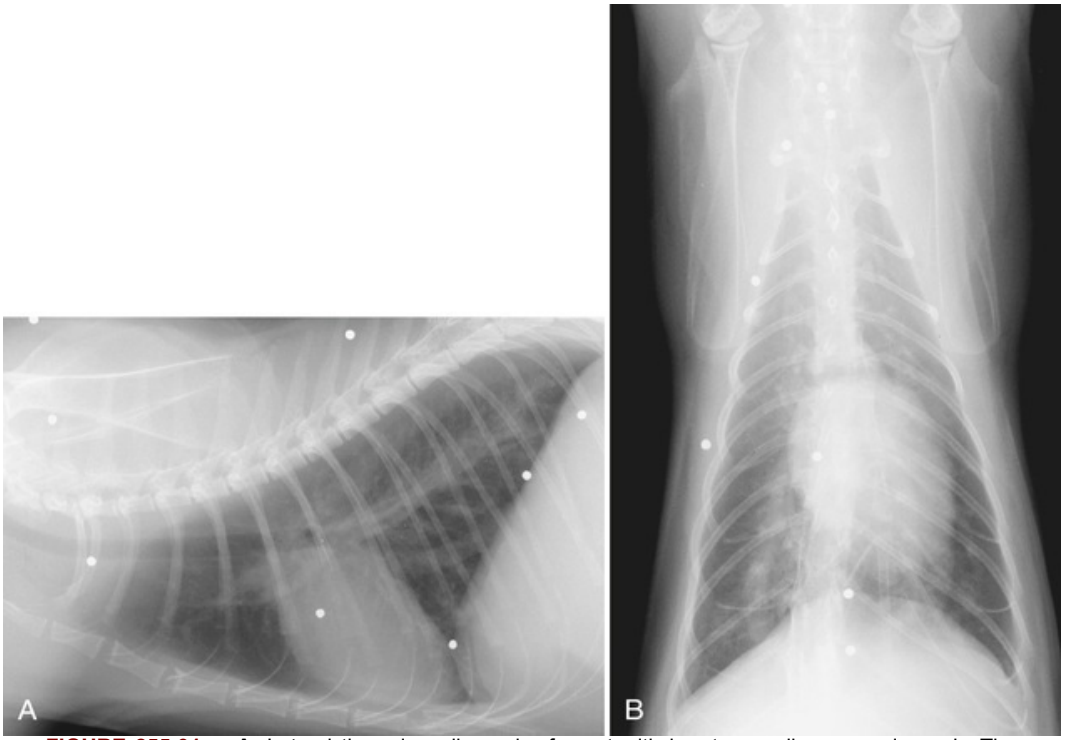

FIGURE 255-31 **A,** Lateral thoracic radiograph of a cat with heartworm disease and cough. The reader should note the hyperinflated chest, flat diaphragm, and moderate interstitial pulmonary infiltrate. The right ventricle is mildly enlarged. **B,** Dorsoventral thoracic radiograph from the same cat shown in **A.** The pulmonary infiltrate is more readily appreciated in this view in the right caudal lung lobe. The reader should note the enlarged right caudal lobar pulmonary artery.

FIGURE 255-32 Lateral thoracic radiograph of a cat with severe respiratory distress and heartworm disease. The reader should note the alveolar infiltrate in the ventral lung field and the less severe interstitial infiltrate more dorsally in caudal lung lobes. This severe lung disease is probably due to heartworm death and may represent acute respiratory distress syndrome.

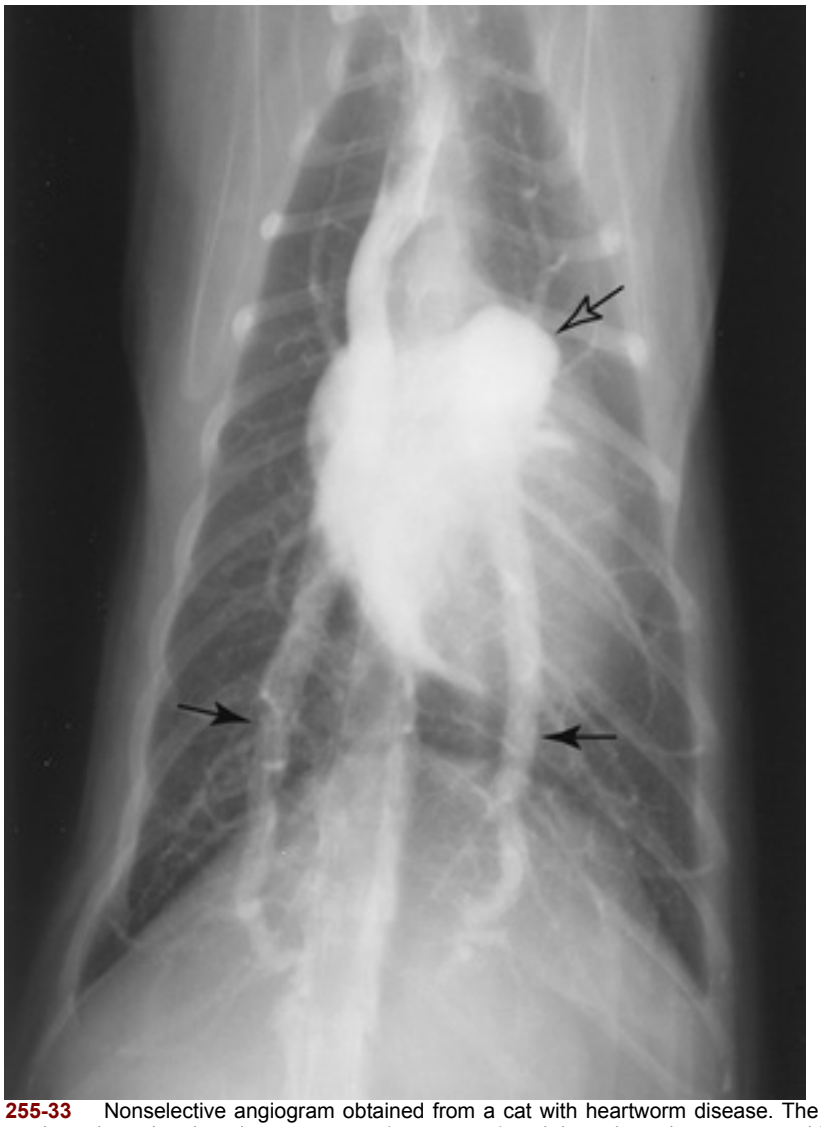

FIGURE 255-33 Nonselective angiogram obtained from a cat with heartworm disease. The reader should note the enlarged main pulmonary artery (open arrow) and the enlarged, tortuous, and blunted caudal pulmonary arteries (arrows). Careful scrutiny reveals linear radiolucencies in the right caudal pulmonary artery. (Courtesy Dr. Kathy Spaulding. From Atkins CE: Heartworm disease. In Allen DG, editor: *Small animal medicine*, Philadelphia, 1991, JB Lippincott, pp 341-363.)

Echocardiography, in the author's experience, is more sensitive in cats than in dogs.[157,183,184] Typically, a double-lined echodensity is evident in the main pulmonary artery, one of its branches, the right ventricle, or occasionally at the right atrioventricular (AV) junction (Figure 255-34 and Video 255-4). Atkins et al[157] visualized heartworms via echocardiography in 78% of nine clinical cases, as did Selcer and colleagues[160] in 16 experimental infections.

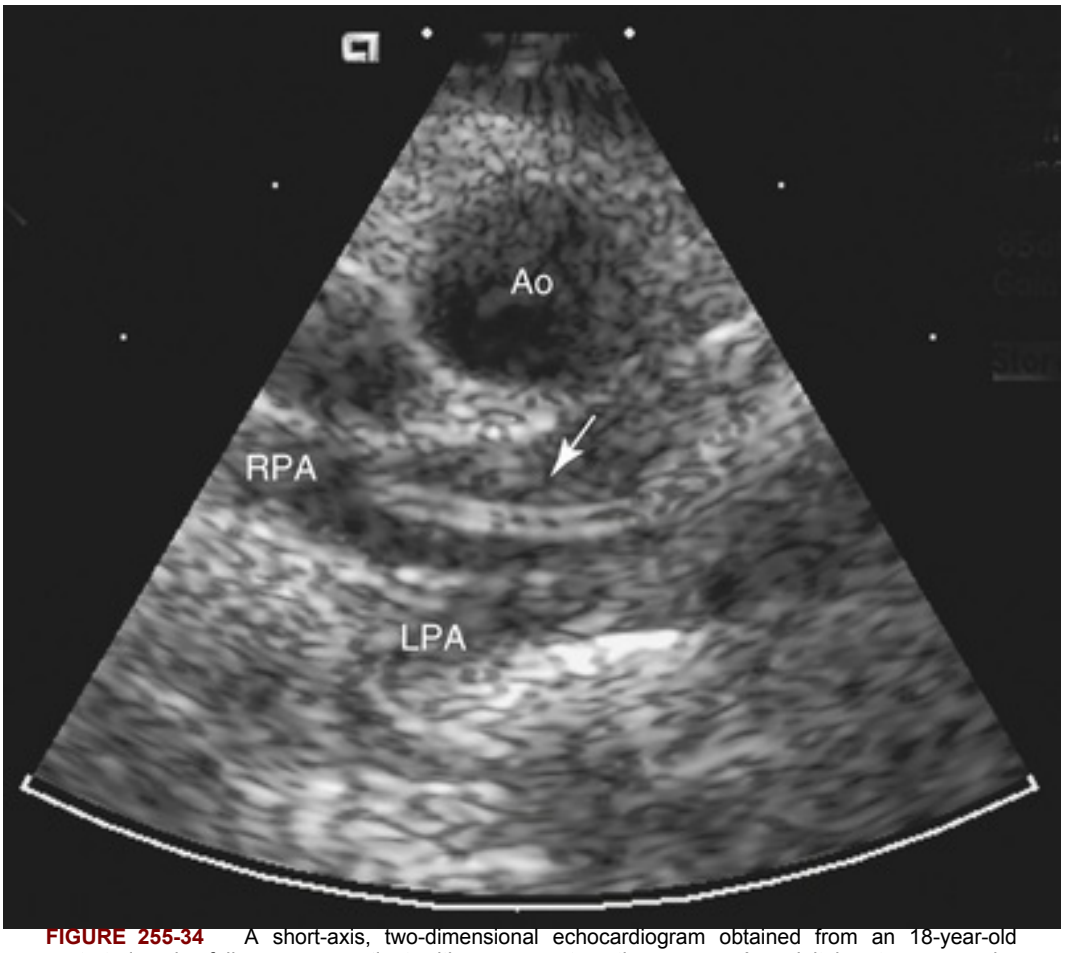

FIGURE 255-34 A short-axis, two-dimensional echocardiogram obtained from an 18-year-old castrated male, feline cancer patient with an asymptomatic murmur. An adult heartworm can be identified by two echo-dense parallel lines, in the right pulmonary artery (arrow). *Ao,* Aorta; *LPA,* left pulmonary artery; *RPA,* right pulmonary artery.

Treatment and Prevention

The question arises as to whether heartworm prophylaxis is warranted for cats because they are not the natural host and because the incidence is low. Necropsy studies of feline HWI in the Southeast have yielded a mature HWI prevalence of 2.5% to 14%, with a median of approximately 5% (Figure 255-35).[154] When considering the question of institution of prophylaxis, it is worth considering that this prevalence approximates or even exceeds that of feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) infections. A 1998 nationwide antibody survey of over 2000 largely asymptomatic cats revealed an exposure prevalence of nearly 12% (Figure 255-36)[185] and has been suggested as being as high as 16%,[186] though other estimates have been lower (1% to 8%).[187] If one assumes that a 12% antibody-positive rate indicates a prevalence of mature HWI of 1% to 2% and of 5% to 6% for HARD, then a nationwide feline morbidity (mature cases and HARD cases) associated with HWI might be expected to approach 6% to 8%. It is also noteworthy that, based on owners' information, nearly one third of cats diagnosed with HWD at NCSU were housed solely indoors.[174] Lastly, the consequences of feline HWD are potentially dire, with no clear therapeutic solutions. Therefore the author advocates preventive therapy in cats in endemic areas—anywhere dogs are on preventive.

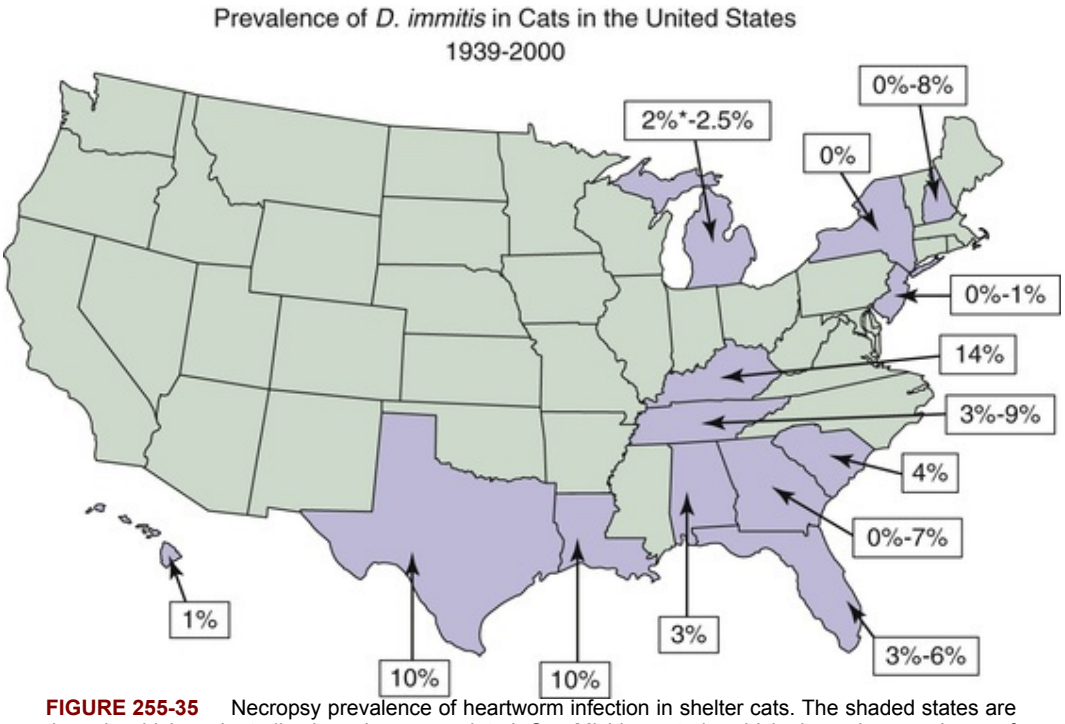

FIGURE 255-35 Necropsy prevalence of heartworm infection in shelter cats. The shaded states are those in which such studies have been completed. One Michigan study, which showed a prevalence of 2%, was an antigen study. *, This number represents antigen test positives, not necropsy-based positives, as are all the others. (Adapted from Ryan WG, Newcomb KM: Prevalence of feline heartworm disease—a global review. Five broad-spectrum endo- and ecto-parasiticides, with FDA-CVM approval, are marketed (or will be) for use in cats in the U.S. (Table 255-7). Ivermectin is provided in a chewable formulation, milbemycin oxime as a flavored tablet, and selamectin, moxidectin/imidacloprid, and eprinomectin/fipronil/praziquantel come in

topical formulations. The spectrum and the formulation of these products vary; hence the clients' individual needs are easily met in most cases.

TABLE 255-7

Heartworm (HW) Preventive Agents for Cats Available in the U.S., with Spectra

DRUG	HW	HOOKWORMS	WHIPWORMS	ROUNDWORMS	TAPEWORMS	FLEAS & EGGS	TICKS
Ivermectin (Chewable) Heartgard for Cats	+	+					
Milbemycin-oxime (Flavored tablet) Interceptor	+	+		+			
Selamectin (Topical) Revolution	+	+		+		+/+	
Moxidectin/Imidacloprid (Topical) Advantage Multi	+	+		+		+/−	
Eprinomectin/Fipronil/Praziquantel* (Topical) BROADLINE	+	+			+	+	

*Not currently marketed in U.S.; label claims are for Europe and anticipated in the U.S. European label claim also includes *Aelurostrongylus abstrusus*.

Because the vast majority of cats are amicrofilaremic, microfilaricidal therapy is unnecessary in this species. The use of arsenical adulticides is problematic. Thiacetarsamide (sodium caparsolate), if available, poses risks even in normal cats. Turner et al reported death due to pulmonary edema and respiratory failure in 3 of 14 normal cats given thiacetarsamide (2.2 mg/kg, given twice, 24 hours apart).[188] Dillon and colleagues[189] could not confirm this acute pulmonary reaction in 12 normal cats receiving thiacetarsamide, but one cat did die after the final injection. More importantly, a significant, though unquantified, percentage of cats with HWI develop PTE after adulticidal therapy.[172-174] This occurs several days to 1 week after therapy and is often fatal. In 50 cats with HWI, seen at NCSU, 11 received thiacetarsamide. There was no significant difference in survival between those receiving thiacetarsamide and those receiving symptomatic therapy.[174]

Data on melarsomine in experimental (transplanted) HWI in cats are limited and contradictory. Although an abstract report exists in which one injection (2.5 mg/kg; one half the recommended canine dosage) of melarsomine was used in experimentally infected cats without treatment-related mortality, the worm burdens after treatment were not significantly different from those found in untreated control cats.[190] Diarrhea and heart murmurs were frequently noted in treated cats. A second abstract report, using either the standard canine protocol (2.5 mg/kg, given twice, 24 hours apart) or the split-dose (one injection, followed by two injections, 24 hours apart, in 1 month) gave more favorable results.[191] The standard treatment and split-dose regimens resulted in 79% and 86% reduction in worm burdens, respectively, and there were no adverse reactions. Although promising, these unpublished data need to be interpreted with caution because the transplanted worms were young (<8 months old and more susceptible), and the control cats experienced a 53% worm mortality (average worm burden was reduced by 53% by the act of transplantation). Additionally, the clinical experience in naturally infected cats has been generally unfavorable, with an unacceptable mortality. Because of the inherent risk, lack of clear benefit, and the short life expectancy of heartworms in this species, this author does not advocate adulticidal therapy in cats.

Surgical removal of heartworms has been successful and is attractive because it minimizes the risk of thromboemboli. The mortality seen in the only published case series was, unfortunately, unacceptable (two of five cats).[192] We have recently had success in cats with HWD-associated heart failure, using a nitinol snare to remove worms via the jugular vein.[193] Even with its advantages, this approach is still impractical for the vast majority of cases. Cats with HWI should be placed on a monthly preventive and short-term corticosteroid therapy (prednisolone 1 to 2 mg/kg SC 8-48 h) to manage respiratory signs. If signs recur, alternate-day steroid therapy (at the lowest dose that controls signs) can be continued indefinitely. For embolic

emergencies, oxygen, corticosteroids (dexamethasone 1 mg/kg IV or IM, or prednisolone sodium succinate 50 to 100 mg/cat IV), and bronchodilators (aminophylline 6.6 mg/kg IM q 12 h, theophylline sustained release 15 to 20 mg/kg PO q 24 h, or terbutaline 0.01 mg/kg SC) may be used. Bronchodilators have logic, based on the ability of agents, such as the xanthines (aminophylline and theophylline), to improve function of fatigued respiratory muscles. In addition, the finding of hyperinflation of lung fields may indicate bronchoconstriction, a condition for which bronchodilation would be indicated. Nevertheless, this author does not routinely use bronchodilators in feline HWD.

The use of aspirin has been questioned because vascular changes associated with HWI consume platelets, increasing their turnover rate and effectually diminishing the antithrombotic effects of the drug. The conventional dosage of aspirin did not prevent angiographically detected vascular lesions in experimental HWI.[194] Aspirin dosages required to produce even limited histologic benefit approached the toxic range. Because the quoted studies were based on relatively insensitive estimates of platelet function and pulmonary arterial disease (thereby possibly missing subtle benefits), because therapeutic options are limited, and because at conventional dosages (40 to 80 mg PO q 72 h), aspirin is generally harmless, inexpensive, and convenient, the author continues to advocate aspirin for cats with HWI. Aspirin is not, however, prescribed with concurrent corticosteroid therapy. Recent data on systemic arterial thromboembolism show that clopidogrel is a better anti-platelet drug than aspirin in the cat, as in man.[195] Although clopidogrel (18.75 mg/cat q 24 h) has not been studied in feline HWI, it would appear to be a better, though more expensive, choice for cats with HWI than is aspirin. Management of other signs of HWD in cats is largely symptomatic.

Prognosis

In the aforementioned study of 50 cats with natural HWI, at least 12 cats died of causes other than HWD. Seven of these and two living cats were considered to have survived HWD (lived >1000 days).[174] The median survival for all heartworm-infected cats, living beyond the day of diagnosis, was 1460 days (4 years; range, 2 to 4015 days), whereas the median survival of all cats (n = 48 with adequate follow-up) was 540 days (1.5 years; range, zero to 4015 days). Survival of 11 cats treated with sodium caparsolate (mean, 1669 days) was not significantly different from that of the 30 managed without adulticide (mean, 1107 days). Likewise, youth (<3 years of age), presence of dyspnea, cough, ELISA-positivity for heartworm antigen, presence of echocardiographically identifiable worms, or gender of the cat did not appear to affect survival.[174] Recent aforementioned data indicate that approximately 40% to 75% of infected cats may be asymptomatic and that as many as 80% of these cats may self-cure.[156,161] This is interpreted as indicating that HWI in cats is probably much more common than currently appreciated and that the adverse effects may be less dire than currently believed. The effect of HWI on survival has been compared with that of other cardiovascular diseases (Figure 255-37).[196]

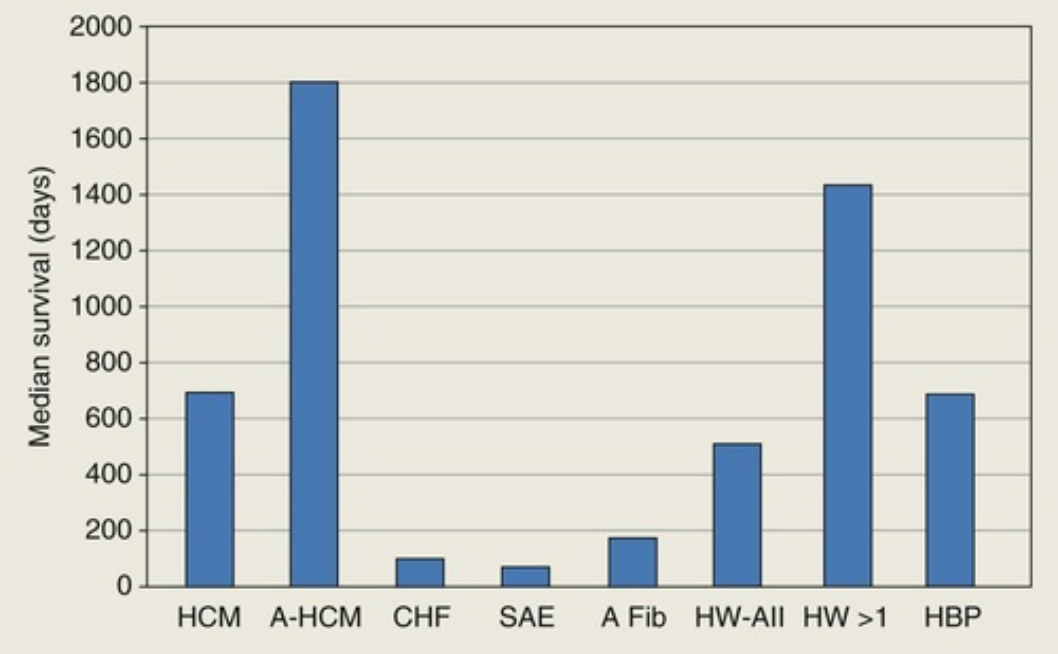

FIGURE 255-37 Median survival from four previous reports for cats with varying cardiovascular diseases. Median survival shown as 5 years was actually more than 5 years. *A Fib,* Atrial fibrillation; *A-HCM*,* asymptomatic hypertrophic cardiomyopathy; *CHF,* hypertrophic cardiomyopathy with heart failure; *HBP,* high blood pressure; *HCM,* hypertrophic cardiomyopathy; *HW-All,* heartworm infection, all cases; *HW>1,* heartworm infection with survival beyond day 1; *SAE,* hypertrophic cardiomyopathy with systemic embolism. CHAPTER 256

Arterial Thromboembolic Disease

Daniel F. Hogan

Background

Arterial thromboembolism (ATE) is defined as the infarction of one or more arterial beds by embolic material usually derived from a thrombus at a site distant to the infarcted arterial bed. It is important to differentiate ATE from arterial thrombosis for multiple reasons. First, the underlying lesion usually is very different. The endothelial surface of the infarcted vessel is normal in cases of ATE, while disruptions to the vascular endothelium and/or vascular wall are hallmarks of arterial thrombosis. Second, ATE usually is associated with stagnant flow or blood stasis while arterial thrombosis is associated with high shear flow within a narrowed blood vessel. Third, ATE occurs commonly in veterinary patients while true arterial thrombosis is exceedingly rare.

In some instances, the site of the initiating thrombus is either known or reliably suspected. With cardiogenic embolism (CE), thrombi most often are found within a dilated left atrium or auricle. The heart also is the source of emboli that develop with endocarditis (see ch. 251). However, many times the source of the thrombus cannot be determined and these include conditions such as neoplasia and protein-losing nephropathy. Some have suggested that deep venous thrombi are the source of the embolic material, but this would not explain the arterial location of the embolus in the absence of a right-to-left shunting cardiovascular defect. *Paradoxical embolism,* which is an arterial thromboembolic stroke resulting from deep venous thrombosis, occurs in humans and is usually associated with an interatrial communication such as a persistent foramen ovale that allows passage of an embolus from venous to arterial circulation. This has been reported in veterinary medicine[1] and could be the situation for many more of our domestic animal species as a recent study suggests that atrial septal defects are much more common in the dog than originally suspected.[2] Pulmonary neoplasia is unique in that thrombosis within a pulmonary vein could generate an embolus that enters the systemic arterial circulation.

Pathogenesis

In the normal healthy state, there is an equilibrium between thrombus formation and thrombus dissolution. This delicate balance allows for continuous repair of endothelial injury while preventing unregulated thrombus development. Primary hemostasis begins with the exposure of subendothelial collagen and is characterized by adhesion of platelets to the subendothelial site. Platelet activation and aggregation follow, with release of agents exhibiting pro-aggregating and vasoconstrictive properties. These substances, in conjunction with circulating factors within the plasma, initiate the coagulation cascade, resulting in secondary hemostasis. As the hemostatic plug is formed and endothelial healing is taking place, profibrinolytic mechanisms are activated to break down the developing hemostatic plug, thereby preventing excessive thrombus formation. Pathologic thrombosis happens when the balance between thrombus formation and fibrinolysis is deranged in favor of the former.

The development of pathologic thrombosis classically has been described through Virchow's triad: endothelial injury, blood stasis, and the presence of a hypercoagulable state. Endothelial injury could result from a dilated left atrium in a cat with hypertrophic cardiomyopathy, damaged aortic valve in a dog with subaortic stenosis, or tumor invasion of the arterial tree. Blood stasis can be associated with dilated cardiac chambers (Video 256-1) or restricted blood flow from tumor growth. The presence of a hypercoagulable state is much more difficult to identify specifically, especially in our domestic animal species. Known hypercoagulable states in humans include inherited abnormalities in the procoagulant factors IIa (thrombin), Va, and VIIIa, and the antithrombotic proteins antithrombin (AT), protein C, and protein S.[3-7] Additional hypercoagulable states have been associated with platelet hypersensitivity, and increases in homocysteine,

lipoprotein(a), plasminogen activator inhibitor (PAI-1), and thrombin-activatable fibrinolysis inhibitor (TAFI). Clinical thrombosis in dogs and cats has been associated with increased platelet hypersensitivity, decreased AT and protein C activity, and increases in factors II, V, VII, VIII, IX, X, XII, and fibrinogen.[8-14] It seems prudent to view the development of pathologic thrombosis through the concept of cumulative risk, where each arm of Virchow's triad can contribute to an increased risk of thrombosis.

Early pathologic thrombus composition is platelet-rich but progressively becomes more fibrin-rich as the thrombus continues to grow. As the thrombus matures, it will become lamellated, where superficial portions can break off, forming emboli that infarct distant arterial beds. The level of infarction depends on the size and stability of the embolus, as obstruction occurs where the size of the embolus reliably exceeds vessel diameter.

Clinical Signs

Clinical signs attributable to ATE depend on the degree of infarction and the location of the infarcted vascular bed. The severity of clinical signs is inversely proportional to the amount of arterial blood flow. Many organs have a collateral network that can be recruited to provide blood flow around a site of obstruction to a major artery. However, these networks develop more fully with gradual loss of blood flow and there is strong evidence that the acute infarction caused by ATE is associated with an impaired development of these networks.[15,16]

Renal infarction has been associated with signs of renal pain and acute kidney injury while mesenteric infarction can result in evidence of abdominal pain, vomiting, and diarrhea. Splenic infarction can be associated with lethargy, anorexia, vomiting and diarrhea.[17] Profound neurologic deficits and seizures have been associated with cerebral infarctions as well as sudden death in severe cases.[1]

Although cerebral, renal and splanchnic infarction occurs occasionally, infarction of the aortic trifurcation accounts for the majority of ATE cases in dogs and cats.[18] Infarction of the aortic trifurcation (classic saddle embolus) results in a loss of blood flow to the pelvic limbs and causes ischemic neuromyopathy (INM) (Figure 256-1). Clinical signs of INM include paresis or paralysis of the pelvic limbs with absence of segmental reflexes, firm and painful pelvic limb musculature, and cold and pulseless limbs with cyanotic nail beds (Video 256-2). The changes can be bilaterally symmetrical or asymmetrical, or unilateral, depending on the degree of arterial obstruction and collateral vessel development. Clinical signs develop acutely and can worsen but usually remain stagnant or improve over the next several days to 3 weeks. A major contributing factor to the development of INM appears to be the release of vasoactive substances from activated platelets, reducing collateral flow around the site of obstruction. Similar pathophysiologic changes have been identified in humans suffering from thrombotic stroke, cardiogenic embolism, cardiogenic thromboembolic stroke, and pulmonary embolism.[19-22] With experimental aortic obstruction, blood flow in cats is maintained through an extensive collateral circulation in the vertebral system and epaxial muscles (E-Figure 256-2 and Video 256-3).[15,16,23] However, this collateral circulation is lost to varying degrees with the presence of a thrombus in the aortic segment and clinical signs of INM are evident. Serotonin, released from activated platelets, appears to be at least one major factor for this finding. Research models have demonstrated that the presence of serotonin in an isolated aortic segment results in loss of the collateral network and signs of INM while pretreatment with serotonin antagonists prevents these changes.[16,24]

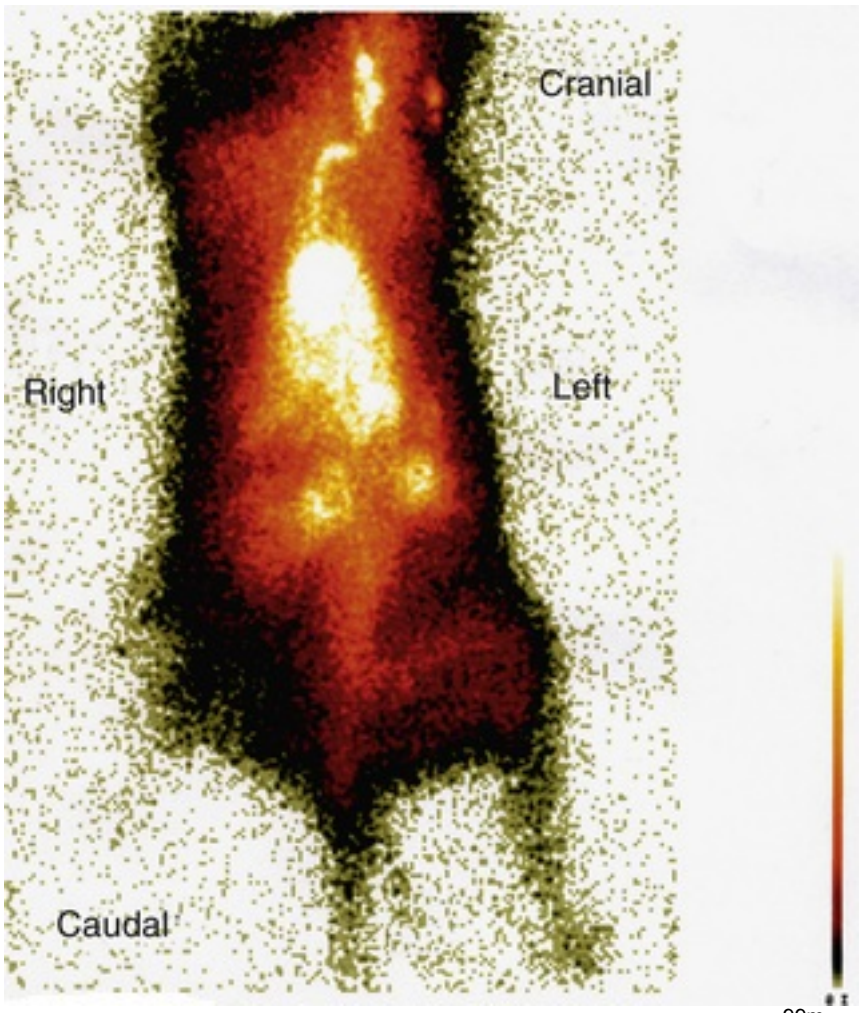

FIGURE 256-1 Nuclear perfusion scan in a cat with asymmetric ATE using unbound ^{99m}Tc. There is a dramatic reduction in perfusion of the right pelvic limb and below the stifle in the left pelvic limb.

E-FIGURE 256-2 Angiographic image from an experimental model of aortic infarction. The collateral circulation network (arrows) can be seen bypassing the aortic infarction (embolization coil) providing blood flow distal to the site of infarction.

Infarction of the right subclavian artery is the second most common site of ATE in cats with underlying cardiac disease. The clinical signs associated with infarction of this site are essentially identical to those for infarction of the aortic trifurcation, although the signs are confined to the right forelimb.[25]

In addition to the clinical signs associated with the infarcted vascular bed, additional clinical signs related to the underlying disease can be present. These could include fever, depression and dyspnea with sepsis; depression, tachypnea and pallor with immune-mediated hemolytic anemia (IMHA); depression and ascites or peripheral edema with nephrotic syndrome; tachypnea, weakness and polyuria/polydipsia with hyperadrenocorticism; dyspnea, and cardiac murmur or gallop sounds with underlying cardiac disease. In cats with cardiogenic embolism, concurrent congestive heart failure (CHF) has been reported in 44%-66% of cases.[18,26,27]

Treatment

Key elements in the acute management of ATE include preventing continued thrombus formation associated with the embolus, improving blood flow to the infarcted organ, pain management when appropriate, treating concurrent clinical conditions, and supportive care.

Reduce Thrombus Formation

Unfractionated heparin (UH) is a group of heterogeneous molecules with a mean molecular weight of ≈15,000 Daltons (range of 3,000 to 30,000 Daltons). Due to variability in molecular size, pharmacokinetic and anticoagulant properties can vary. Heparin molecules contain a pentasaccharide sequence that binds to AT, facilitating the inhibition of IIa, Xa, IXa and XIIa. There is also an inhibition of thrombin-catalyzed activation of factors V and VIII. Unfractionated heparin also exhibits an antiplatelet effect in normal humans by inhibiting thrombin-induced platelet aggregation, and binding to and inhibiting von Willebrand factor (vWF). The most common adverse effect of heparin therapy in humans is bleeding, while heparin-induced thrombocytopenia can develop in up to 10% of patients. Objective studies evaluating the bleeding risk in dogs

and cats receiving heparin therapy do not exist although bleeding has certainly been reported. To the author's knowledge, there is no clinical report of heparin-induced thrombocytopenia in dogs or cats. Ideally, a bleeding profile including platelet count, prothrombin time (PT), activated partial thromboplastin time (aPTT), and possibly thromboelastography (TEG) should be submitted prior to heparin therapy (see ch. 196). This determines baseline coagulation function and identifies bleeding disorders, such as disseminated intravascular coagulation, that could be associated with the ATE or its underlying cause. Adequate dosing of heparin in dogs and cats has been shown to be quite variable and dosing requirements can change over time due to a decrease in circulating AT levels.[28-30a] Reasonable dosing regimens include 250-375 IU/kg IV initially followed by 150-250 IU/kg SC q 6-8 h for cats and 200-300 IU/kg IV initially followed by 200-250 IU/kg SC q 6-8 h for dogs. Historically, serial measurement of the aPTT has been used to monitor heparin therapy with a target of 1.5-2.0 times the baseline value, and this methodology is readily available.[29] However, one study in cats suggests that aPTT does not correlate well with plasma UH levels.[28] Therefore, anti-Xa monitoring may be considered, although assays have not been evaluated with regard to effective inhibition of thrombus growth.[31]

The low-molecular-weight heparins (LMWH) are smaller in size than UH and could be used in lieu of UH. The cost for these agents is much higher than UH (approximately $3-$5/dose) but they can be administered SC q 12 h in humans for acute management of thrombotic conditions. Dalteparin and enoxaparin have been used in dogs and cats at 100 IU/kg SC q 24-12 h and 1-1.5 mg/kg SC q 24-12 h, respectively.[32,33] However, clinical trials evaluating inhibition of thrombus growth with these agents do not exist in veterinary medicine so the exact dosage and clinical response are unknown at this time.

Improve Blood Flow

Arterial Flow—Thrombolytic Therapy

An ideal goal with infarction is to re-establish arterial flow to the infarcted organ. This requires removal of the embolus either through embolectomy or dissolution with thrombolytic drugs. Thrombolytic drugs have been used in dogs and cats to dissolve emboli and re-establish arterial flow.[34-39] Ideally, they should be administered as soon as possible after the embolic event but effective dissolution has been noted as late as 18 hours after initial clinical signs.[34] Severe adverse effects can be associated with thrombolytic therapy; therefore, caution should be exercised when considering these drugs. The sudden resumption of arterial flow to infarcted organs can result in the rapid development of life-threatening hyperkalemia and severe metabolic acidosis. This is *reperfusion injury,* and it is most likely to occur with terminal aortic infarction. The frequency of reperfusion injury following thrombolytic therapy in cats with CE is 40-70%.[34-36] Reperfusion injury represents the most common cause of death in cats receiving pharmacologic thrombolytic therapy with survival rates reported from 0% to 43%.[34-36] Due to potential adverse effects and cost, thrombolytic therapy should not be used in all cases of ATE. However, thrombolytic therapy should be strongly considered in cases of cerebral, splanchnic or renal infarction, as the re-establishment of arterial flow is of principal importance.

Streptokinase

Streptokinase (SK) combines with plasminogen to form an activator complex that converts plasminogen to the proteolytic enzyme plasmin. Plasmin degrades fibrin, fibrinogen, plasminogen, coagulation factors and SK. The SK-plasminogen complex converts circulating and fibrin-bound plasminogen and is therefore considered a nonspecific activator of plasmin. Streptokinase is produced by streptococci, which can lead to antigenic stimulation, especially with repeated administrations. These anti-SK antibodies also can reduce the efficacy of the drug. Streptokinase typically is administered by giving 90,000 IU IV over 1 hour followed by an infusion of 45,000 IU/hour for up to 12 hours in dogs and cats. In one study, all eight treated cats experienced respiratory distress and died suddenly during the maintenance phase.[36] In a second study, ≈50% of 46 cats with CE had a return of femoral pulses within 24 hours of initiating SK[35]; motor function returned in 30%, most (80% of these) within 24 hours. Cats with single limb infarction did dramatically better, with 100% regaining pulses and 80% regaining motor function. Spontaneous bleeding occurred from oral, rectal, or catheter sites in 24% of cats and reperfusion injury in ≈40%. Bleeding was severe enough to require transfusions in 27% of the cats, with only 18% of these cats surviving SK therapy. The overall survival rate was 33% during hospitalization. There is one published report of three dogs treated with SK for ATE.[37] Partial resolution of the thrombus was noted in one dog while the other 2 had complete resolution after 1-3 doses of SK. All three experienced partial or complete resolution of clinical signs with only minor bleeding

that resolved with discontinuation of SK infusion. There was no evidence of reperfusion injury in any of the dogs. Streptokinase is no longer available in the United States, although there is some limited availability in a small number of other countries.

Urokinase

Urokinase (UK) is similar in activity to streptokinase but is considered more fibrin-specific due to the physical characteristics of the compound. Commercial preparations consist of both high-molecular-weight (HMW) and low-molecular-weight (LMW) fractions. There is a much higher concentration of HMW molecules in the commercial solution but they are quickly and continuously converted to the LMW form in the circulation. The LMW molecules bind with greater affinity to the lysine-plasminogen form of plasminogen, which preferentially accumulates within thrombi. This confers some of the fibrin-specificity of UK. Urokinase has been administered IV to cats and dogs for ATE with a 4,400 IU/kg loading dose given over 10 minutes followed by 4,400 IU/kg/h for 12 hours.[38,39] Of 12 cats treated with UK, 56% regained motor function while only 27% regained pulses. No bleeding was seen, but evidence of reperfusion injury was noted in 25% of treated cats. Overall, 5/12 (42%) survived treatment.[38] The clinical experience was much less rewarding in dogs where the mortality rate was 100% in UK treated dogs.[39] Urokinase is no longer available in the United States.

Tissue Plasminogen Activator

Tissue-plasminogen activator (t-PA) is the primary activator of plasmin *in vivo;* however, it does not readily bind circulating plasminogen. Plasminogen and t-PA both have a high affinity for fibrin, thereby forming an intimate relationship within thrombi, resulting in a fibrin-specific conversion of plasminogen to plasmin. However, the fibrin specificity is relative and when t-PA is administered at high dosages, a systemic proteolytic state and bleeding can be seen.[40]

There is very little clinical experience with human recombinant t-PA in dogs and cats with spontaneous ATE.[34,41,42] The drug has been administered IV either as a constant rate infusion in cats (0.25-1 mg/kg/h IV for a total dose of 1-10 mg/kg) or multiple bolus therapy in dogs (1 mg/kg IV). In two dogs treated for arterial thromboembolism, one had gradual return of femoral arterial pulses[43] after multiple boluses of t-PA while the other dog showed no response.[41] There has been one reported clinical trial of t-PA therapy in six cats with CE.[34] Complications included minor hemorrhage from catheter sites (50%), fever (33%) and reperfusion injury (33%). The acute survival rate was 50%, with deaths attributed to reperfusion injury and cardiogenic shock. Of the cats that survived, 100% had infarction of both limbs. Perfusion was restored within 36 hours and motor function returned within 48 hours in 100% of surviving cats. Tissue plasminogen activator currently is the only pharmacologic thrombolytic approved for human use in the United States.

Improve Collateral Flow

If dissolution of the embolus is unsuccessful or not attempted, then increasing perfusion to the infarcted organ can be attempted by increasing flow through the collateral network. The use of vasodilators, such as acepromazine, generally has been unsuccessful and clinical hypotension may result, further reducing perfusion. The platelet release products serotonin and thromboxane have been implicated as potential agents responsible for loss of collateral flow associated with aortic infarction. Therefore, antiplatelet agents might help improve collateral flow by reducing the amount of vasoactive substances released from platelets. Aspirin reduced the amount of thromboxane released from activated cat platelets and improved collateral flow in an experimental cat model of aortic infarction, but a very high dosage of aspirin (associated with toxicosis in clinical cases) was used.[44] Clopidogrel has been shown to reduce serotonin release from activated platelets in cats while studies in other species have demonstrated reduced production of thromboxane.[45,46] There is also evidence that clopidogrel exerts an *ex vivo* vasomodulating effect (reduced vasoconstriction) in rats, rabbits, and dogs[47,48] and a similar effect experimentally in cats *in vivo,* including a significant reduction in clinical signs.[49] While maximal antithrombotic effects of clopidogrel are achieved within 72 hours of daily administration of 2-4 mg/kg PO in dogs and cats,[45,50] an oral loading dose of ≈10 mg/kg given to dogs resulted in comparable antithrombotic effects within 90 minutes with no adverse effects.[50] Additionally, daily administration of 75 mg PO to cats (≈15 mg/kg) has been well-tolerated and not associated with adverse effects. Therefore, while there are no objective data to support this assertion, the acute administration of clopidogrel on presentation for ATE could be helpful in improving collateral flow and should not be

associated with adverse effects.

Pain Management

Arterial thromboembolism can result in severe pain and controlling this pain is a critically important aspect of acute ATE treatment (see ch. 126). Narcotic agents are most commonly used and they work very well. Butorphanol (0.1-0.4 mg/kg SC, IM, IV q 1-4 h; dogs and cats), hydromorphone (0.08-0.3 mg/kg SC, IM, IV q 2-6 h; dogs and cats), buprenorphine (0.005-0.02 mg/kg SC, IM, IV q 6-12 h; dogs and cats), or oxymorphone (0.05-0.2 mg/kg SC, IM, IV q 1-3 h; dogs and cats) have been widely used and appear to provide good analgesia with few adverse effects. In severe or refractory cases, fentanyl (4-10 mcg/kg IV bolus followed by 4-10 mcg/kg/h IV infusion; dogs and cats) can be used. Injections should be given cranial to the diaphragm to assure adequate absorption.

Survival

Reported survival rates for initial CE events in cats are remarkably similar whether conservative (35%-39%)[18,26,27] or thrombolytic (33%)[35] therapy is used. Cats with single pelvic limb infarction do dramatically better (68%-93%)[18,26,27,35] than do cats with bilateral pelvic limb infarction (15%-36%) regardless of therapy used.[18,26,27,35] Nonsurvival rates range from 61%-67% with natural death rates (28%-40%) similar to euthanasia rates (25%-35%).[18,26,27,35] Nonsurvival has been significantly associated with hypothermia,[18,35] reduced heart rate[18] and absence of motor function.[18] Reported long-term median survival times following the initial CE event have ranged from 51 days to 345 days.[18,26,27,35,51,52]

Prevention

Primary prevention of ATE is defined as therapy that reduces the risk of the first thromboembolic event in an animal at risk for ATE. While primary prevention would be an ideal and logical goal, there is a poor understanding of thrombotic risk in our patients. We do know that some underlying conditions are associated with ATE but we cannot accurately predict which animals will actually go on to develop ATE. The greatest body of evidence is associated with CE in cats. Cats appear to be at a greater risk for ATE if they have larger left atrial size or evidence of systolic dysfunction.[52] Similar patterns have been identified in humans. These findings combined with clinical experience have led to the recommendation that prophylactic antithrombotic therapy be considered in cats with echocardiographic measurements of an end-systolic left atrial diameter >1.7 cm or left atrium-to-aortic ratio (LA/Ao) >2.0.[53] Prophylactic antithrombotic therapy is also indicated in cats with spontaneous contrast in the left atrium on echocardiography (see Video 256-1).[53]

Secondary prevention has received more attention in veterinary medicine and is defined as preventing a subsequent ATE event in an animal with a history of ATE. Again, the largest body of evidence in veterinary medicine is related to CE in cats. The reported recurrence rates from non-controlled, retrospective studies for cats receiving some antithrombotic agent range from 17% to 75%[18,26,27,34,35] with a 1 year recurrence rate of 25% to 50%.[27,35] Recently, the first prospective study evaluating secondary prevention of CE in cats was published.[54] The Feline Arterial Thromboembolism; Clopidogrel versus Aspirin Trial (FAT CAT) was a double-blind, randomized, and positive-controlled multicenter study that enrolled 75 cats after they survived a CE event. Clopidogrel 18.75 mg/cat PO q 24 h was associated with a significantly reduced likelihood of recurrent CE compared to aspirin and a longer median time to recurrence (443 days vs. 192 days). Clopidogrel also was associated with a significantly reduced likelihood of the composite endpoint of recurrent CE or cardiac death with a longer median time to event (346 days vs. 128 days).

Antithrombotic Drugs

Due to their direct effect on thrombus formation, antithrombotic agents have become a mainstay for primary and secondary prevention of ATE in dogs and cats. However, it should be emphasized that a goal of complete prevention of recurrent embolic events in animals with chronic diseases such as cardiac disease or nephrotic syndrome probably is not realistic. The goal should be to delay the time to the next ATE event or to reduce the clinical signs associated with the event.

Antiplatelet Agents

These agents inhibit some aspect of platelet adhesion, aggregation, or release reaction, and impair the formation of the initial platelet-rich thrombus at the injured endothelial site. Some of these agents also exhibit some vasomodulating effects by interfering with vasoactive substances such as serotonin and thromboxane.

Aspirin

Aspirin is the most used and studied antiplatelet agent available today. It irreversibly acetylates platelet cyclooxygenase, preventing the formation of thromboxane A_2, which has potent pro-aggregating and vasoconstrictive properties. Aspirin is considered a modest and indirect antiplatelet agent that inhibits secondary but not primary platelet aggregation. Aspirin exerts a similar effect on cyclooxygenase in endothelial cells, reducing the production of prostacyclin, a substance that exhibits anti-aggregating and vasodilating properties. However, endothelial cells are able to overcome this inhibition, unlike platelets, so antithrombotic properties predominate in the clinical setting. The pharmacologic, analgesic, and antiplatelet effects of aspirin have been evaluated in the dog and cat.[55-58] Recurrence rates in retrospective studies range from 17% to 75%.[18,26,27,34] Adverse effects are typically gastrointestinal (GI; e.g., anorexia, vomiting) and have been reported in up to 22% of treated cats.[18] One study evaluating a low-dosage aspirin protocol did not identify a significant difference in recurrence rates compared to a standard aspirin dosage but there was a reduced rate of adverse GI events.[18] There was only one case of reported adverse GI effects associated with aspirin in the FAT CAT study, although one additional cat that died from a recurrent CE event had a large gastric ulcer on necropsy.[54] The FAT CAT study protocol required that the study drugs be administered in a gelatin capsule, and this may have resulted in less gastric irritation.

There is very little published clinical evidence regarding the use of aspirin for the prevention of thrombosis in dogs. One study reported greater survival in dogs with IMHA that received a low dosage of aspirin in addition to immunosuppressive therapy.[59] Additionally there is a retrospective study of thrombosis treatment in dogs where 3/9 (33%) experienced improvement or resolution of the thrombus.[59a] Healthy dogs receiving aspirin have been reported to have uniformly developed moderate gastroduodenal endoscopic lesions including erosions and submucosal hemorrhages, although at dosages considerably higher than those used clinically.[60] In that study, vomiting was noted in approximately 7% of the dogs during the treatment period with no evidence of diarrhea.

Clopidogrel

Clopidogrel is a second-generation thienopyridine that induces specific and irreversible antagonism of the ADP_{2Y12} receptor along the platelet membrane. It inhibits both primary and secondary platelet aggregation in response to multiple agonists. These effects are more potent than those induced by aspirin. The ADP-induced conformational change of the glycoprotein IIb/IIIa complex also is inhibited, which reduces binding of fibrinogen and von Willebrand factor.[61] It also impairs the platelet release reaction, decreasing the release of pro-aggregating and vasoconstrictive agents such as serotonin and ADP.[46] Vasomodulating effects also have been seen *in vitro* and *in vivo*.[48,49] The parent compound does not possess antiplatelet effects; it must undergo hepatic biotransformation to form an active metabolite. Unlike aspirin, clopidogrel is not associated with gastroduodenal ulceration. In normal cats given 18.75 mg/cat PO q 24 h, maximal antiplatelet effects occur after 3 days of drug administration and are lost within 7 days after drug discontinuation[45]; similar results have been noted in dogs treated with 1-3 mg/kg PO q 24 h.[50,62] Stimulation of the hepatic P450 enzyme system in dogs results in antiplatelet effects at lower dosages, presumably due to an increase in the biotransformation of the parent molecule. No adverse effects were noted during either study, but there are anecdotal reports of sporadic vomiting in cats receiving clopidogrel clinically, which could be due to the extreme bitterness of the drug. Regarding thromboprophylaxis, one small study compared 90-day survival in dogs with IMHA that received clopidogrel, ultralow-dose aspirin, or both.[63] Most of the dogs in all groups survived the first 90 days with very small numbers experiencing clinically suspicious thrombosis and none experienced bleeding complications. Platelet aggregation was not monitored with either drug so it is not known if there was an actual pharmacodynamic effect from aspirin or clopidogrel. In cats, clopidogrel is associated with a significantly reduced likelihood of recurrent CE compared to aspirin in cats (see Aspirin, above). To date, there are no reported cases in dogs or cats of agranulocytosis or thrombotic thrombocytopenic purpura (TTP), possible adverse effects in humans receiving clopidogrel.

Anticoagulant Agents

This group of drugs inhibits the coagulation cascade by interfering with the formation of one or more active coagulation factors. Some of these drugs also exhibit minor antiplatelet effects.

Warfarin

Warfarin inhibits the formation of the vitamin K–dependent coagulation factors II, VII, IX and X as well as the anticoagulant proteins C and S. After warfarin administration in humans, circulating levels of protein C fall prior to the decrease in coagulation factors, theoretically resulting in a hypercoagulable state for 4-6 days. For this reason, UH typically is administered during this period. Warfarin is indicated in many diseases in humans with a risk for ATE including atrial fibrillation and prosthetic heart valves. Numerous studies have demonstrated the efficacy of warfarin for primary and secondary prevention of CE with atrial fibrillation, even when lower-intensity anticoagulation protocols are used. Bleeding is the most common complication in humans.[64] Warfarin has numerous interactions with other medications that could increase or decrease the anticoagulation effect. In humans, warfarin therapy is adjusted by monitoring a parameter that is normalized for different thromboplastin reagents in different laboratories, the international normalized ratio (INR). Medium anticoagulation intensity (INR of 2-3) is recommended for most conditions in humans.

Pharmacokinetic and pharmacodynamic studies in dogs and cats[65,66] have demonstrated that absorption after oral administration is rapid. Enterohepatic recirculation occurs, which could contribute to the known widely variable inter- and intra-individual anticoagulant response.[66] Warfarin is not evenly distributed throughout the tablet so the tablet should be crushed and compounded by a pharmacist rather than split. Close and careful monitoring is required, and owners should be aware of this prior to beginning therapy as it requires dedication and expense for the owner. It has been recommended that adjustments to warfarin dosing should be done by changing the total weekly dose and not daily dose in response to INR monitoring.[67] While unsubstantiated, an INR of 2-3 has been considered an indicator of adequate anticoagulation in dogs and cats. Objective clinical trials evaluating the efficacy of warfarin for the prevention of thrombotic events in dogs and cats do not exist. Published CE recurrence rates for cats receiving warfarin range from 42% to 53% in retrospective studies, with estimated mean survival times from 210 to 471 days.[26,35] Bleeding (both major and minor) is the most common complication, seen in 13-20% of cats, and with fatal hemorrhage reported in up to 13% of cats.[26,33,35]

Low-Molecular-Weight Heparins

The low-molecular-weight heparins (LMWHs) are smaller in size (4,000 to 5,000 Daltons) compared to UH but they maintain the pentasaccharide sequence that binds to AT, inhibiting factor Xa, with a greatly reduced inhibition of IIa. The reduced anti-IIa activity translates into a negligible effect on the aPTT and thromboelastography (TEG) with LMWH therapy.[68] For this reason, monitoring of LMWH treatment has been performed through measurement of anti-Xa activity.[69,70] In humans with active thrombosis, enoxaparin therapy can produce peak anti-Xa levels of 0.6-1.0 U/mL at 4 hours and these levels are correlated with reduced thrombotic events.[69,71] There is not a commonly accepted therapeutic range of anti-Xa activity with once daily thromboprophylactic LMWH therapy in humans although a mean peak (4 hours) activity of 0.42 IU/mL and median trough (24 hours) activity of 0.03 IU/mL (0.00-0.188 IU/mL) has been reported.[72] The most common human adverse effect of LMWH is minor (5-27%) or major (0-6.5%) bleeding, which is similar to UH.

In healthy cats,[32,68] dalteparin and enoxaparin have produced similar results: peak anti-Xa levels at 4 hours that decrease below the limit of detection at 8 hours.[32,68] These results might suggest the need for a short interdose interval; however, as mentioned previously, peak anti-Xa levels in humans are not meant to be maintained throughout the entire dosing period. Indeed, in a modified venous stasis model in healthy cats, enoxaparin (1 mg/kg SC q 12 h) resulted in 100% thrombus inhibition at 4 hours and 91.4% thrombus inhibition at 12 hours after drug administration. There was a poor correlation between the antithrombotic effect of enoxaparin and the anti-Xa level, however, as there was no measurable anti-Xa activity 12 hours after drug administration.[73] In the author's opinion, enoxaparin exhibits an antithrombotic effect at the currently reported dosing regimen of 1 mg/kg SC q 12-24 h, and peak anti-Xa levels need to be correlated to reduced thrombotic events through clinical trials before dosing regimens that are more accurate can be recommended.

In a similar study of enoxaparin in dogs, pharmacokinetic modeling was used for determining whether anti-Xa levels were maintained throughout the dosing period.[75] As this is not the goal of LMWH therapy, current dose recommendations of 1 mg/kg SC q 12-24 h could be followed until clinical trials provide accurate dosing information.

A retrospective study comparing dalteparin to warfarin for the prevention of recurrent CE in cats demonstrated a comparable recurrence rate and median survival time between treatment groups.[33] None of the cats receiving dalteparin experienced bleeding complications, and infrequent bleeding was noted with dalteparin therapy in another study in cats.[74]

Newer Anticoagulants

Recently, new anticoagulant drugs developed for the human market have been designed with excellent efficacy; they generally do not require monitoring and have relatively low bleeding risks. The first drug to challenge the clinical dominance of warfarin was the direct thrombin inhibitor dabigatran, which was noninferior to warfarin for preventing CE associated with atrial fibrillation.[76] There is no known published study on the clinical use of dabigatran in dogs or cats.

A larger class of drugs is the Xa inhibitors. As suggested by the name, these drugs inhibit factor Xa either directly or through the potentiation of antithrombin. They, too, have been shown to be noninferior to warfarin for preventing CE associated with atrial fibrillation.[77,78] The most common adverse effect is bleeding, occurring with a similar frequency as with the LMWHs. These drugs have not been critically evaluated in dogs or cats to date, but basic pharmacologic data are accumulating. Fondaparinux is a synthetic Xa inhibitor that potentiates antithrombin activity. In a small number of healthy cats, fondaparinux (0.06 mg/kg SC q 12 h) produced anti-Xa activities that approximated therapeutic levels in humans.[79] Currently, this protocol is more expensive than LMWH, and since a superior clinical response is not expected, fondaparinux cannot be strongly supported for clinical use. Rivaroxaban and apixaban are oral, direct Xa inhibitors that are approved for use in humans. Both of these agents exert a dose-dependent *in vitro* effect on coagulation assays in cats.[80,81] Additionally, apixaban has been used in experimental dogs for the prevention of thrombosis associated with an implantable heart valve.[82]

The Xa inhibitor class of drugs is likely to have a major impact on clinical prophylaxis over the next 5-10 years. A therapeutic option that can be administered orally, does not require monitoring, has a low risk of bleeding, and is cost-effective would dramatically improve the clinical management of dogs and cats at risk for thrombosis.

CHAPTER 257

Venous and Lymphatic Disorders

Brian A. Scansen, John D. Bonagura

Client Information Sheet: Venous and Lymphatic Disorders

Clinical signs resulting from disorders of the peripheral veins or lymphatics are uncommonly encountered in veterinary practice. However, diseases of these vessels should be considered in the differential diagnosis of the dog or cat with swelling of the extremities (including the head and neck), in patients with cavitary effusions, or in cases of unexplained edema (see ch. 18). Changes in the microcirculation that alter venous hydrostatic or oncotic pressures, increase vascular or lymphatic permeability, or impede venous or lymphatic drainage can underpin such clinical signs. These disorders can be primary, including developmental anomalies or inherited syndromes, or be secondary to compression, inflammation, or infiltration of venous or lymphatic vessels. This chapter briefly reviews systemic venous and lymphatic physiology, imaging techniques for evaluation of these vascular beds, and finally considers selected conditions associated with abnormalities of systemic veins or lymphatics (Box 257-1).

Box 257-1

Venous and Lymphatic Disorders

Diseases of Veins

Phlebectasia
Varicosis
Phlebitis and thrombophlebitis
Venous thrombosis
Venous malformations

Diseases of Lymphatics

Lymphangitis
Lymphedema
Lymphangiectasia
Lymphatic hypoplasia, aplasia, hyperplasia
Lymphangioma, lymphocysts
Lymphangiosarcoma

Tumors of Peripheral Blood Vessels

Angioma, hemangioma, hemangiosarcoma

Physiology of Systemic Venous and Lymphatic Flow

The systemic veins serve as a low-pressure, compliant reservoir for the intravascular volume, with approximately 60% of blood volume contained within these vessels.[1] Systemic venous return is controlled by a number of forces. These include the positive intravascular pressures behind *(vis a tergo)* and the more negative intracardiac pressures ahead *(vis a fronte)* of a column of venous blood; lateral forces *(vis a latre),* especially the alternating contraction and relaxation of skeletal muscles; gravity and posture; vascular resistance modulated by autonomic traffic, hormones, and local vasoactive mediators; and changes in

intrathoracic pressures operative during both spontaneous ventilation and mechanical ventilation. In health these forces drive systemic blood back towards the right atrium, assisted by one-way venous valves that prevent backflow.[2] Dysfunction or insufficiency of the systemic veins is common in humans related to abnormalities in the venous valves, dysfunction of muscular pumps, venous reflux, venous dilatation, venous thrombosis, or venous outflow obstruction.[2] Similar conditions in small animals are rarely recognized, though thrombotic conditions do occur, particularly with indwelling central venous catheters. Venous insufficiency and outflow obstruction can also develop secondary to extraluminal compression or from intraluminal narrowing, phlebitis, and thrombosis.

The lymphatic system plays a critical role in regulating body cavity and interstitial fluid volumes. Lymphatics also assist in the removal of inorganic material from subcutaneous tissues and the modulation of fat absorption in the gastrointestinal tract, while contributing to antigen transport and immune surveillance.[3] Additionally, the lymphatic system is the preferred metastatic route for many forms of cancer. This diversity of function highlights the pivotal role played by the lymphatic system in both health and disease.

Lymphatics originate within the interstitium as specialized endothelial-lined capillaries transporting fluid, solutes, and macromolecular particles back into the venous system. Fluid, protein, cells, and macromolecular particles from the interstitial space empty into the initial lymphatics that are composed of a series of small lymphatic capillaries beginning blindly in the tissues. The lymph then flows through a system of lymphatic vessels, which progressively increase in diameter. As lymph flows centrally it passes through at least one lymph node before emptying into larger lymphatic trunks.[4] The deep trunks unite to form two major lymphatic vessels: the thoracic and right lymphatic ducts. The thoracic duct drains most of the body and returns lymphatic fluid into the venous system at the brachycephalic vein or the left subclavian vein. The right lymphatic duct drains the right side of the head and neck and right forelimb.

Lymphatic vessels contain many junctions between individual endothelial cells, which are connected to the surrounding extracellular matrix by reticular fibers and collagen. These junctions open when tissue hydrostatic pressure becomes elevated and the anchoring filaments stretch, allowing fluid to move into the vessel.[5] As the fluid is cleared from the interstitium, the connecting fibers contract and the junctions between the endothelial cells close. The opening and closing of these junctions allow them to act as inlet valves preventing the backflow of lymph into the interstitium. The larger vessels of the lymphatic system have progressively fewer open junctions, increasingly muscular walls, and frequent intra-lymphatic valves that also prevent backflow of lymph. The action of external muscular contraction along with intrinsic contractility of the lymphatic vessels aids in the movement of lymph through the lymphatic system and lymph nodes. While in the lymph node, the lymph is in contact with the blood circulation and approximately half of the fluid is drained before leaving into the larger lymphatic ducts.[4] In addition to its transport function, the lymph system plays a major role in the immunologic responses to infectious agents.[3] It serves as a filtering system to impede the spread of microorganisms and neoplastic cells. The cellular components, in particular the lymphocytes, are indispensable for immunologic reactions and antibody formation.[3,5]

Techniques Used to Evaluate Venous and Lymphatic Disease

Angiography

Angiography is the traditional diagnostic test for evaluating peripheral vascular diseases due to its ability to characterize and visualize normal and abnormal vascular anatomy. Diagnostic outcome requires careful attention to three important elements: selection of radiopaque contrast agent, technique for vascular delivery of contrast material, and high-quality radiographic imaging.

As discussed in ch. 122, iodine-based particles are almost singularly used as contrast agents in the vascular system. Today, second-(iohexol, iopamidol) and third-(iodixanol) generation contrast agents are administered due to a greater safety profile than first-generation agents. Factors to be considered when selecting a contrast agent include patient safety, image quality, and cost. For animals with renal impairment, conservative administration of contrast agents should be employed and concurrent fluid diuresis performed.

Venography is far easier to accomplish than lymphangiography and is generally less challenging than arterial angiography owing to easier vascular access and the lower pressures of the venous system. A small gauge intravenous catheter can be placed in a superficial vein distal to the site of the suspected vascular lesion and contrast material injected. Images are acquired during and following the injection to evaluate anatomy and rate of venous clearance. Venography may be used to detect venous thrombi or vascular invasion by a neoplasm (each appearing as vascular filling defects), venous stenosis (Figure 257-1; Video 257-1), or

complete obstruction. With fluoroscopic cine imaging, venous insufficiency can also be appreciated. The presence of prolific collateral vasculature suggests chronic obstruction.

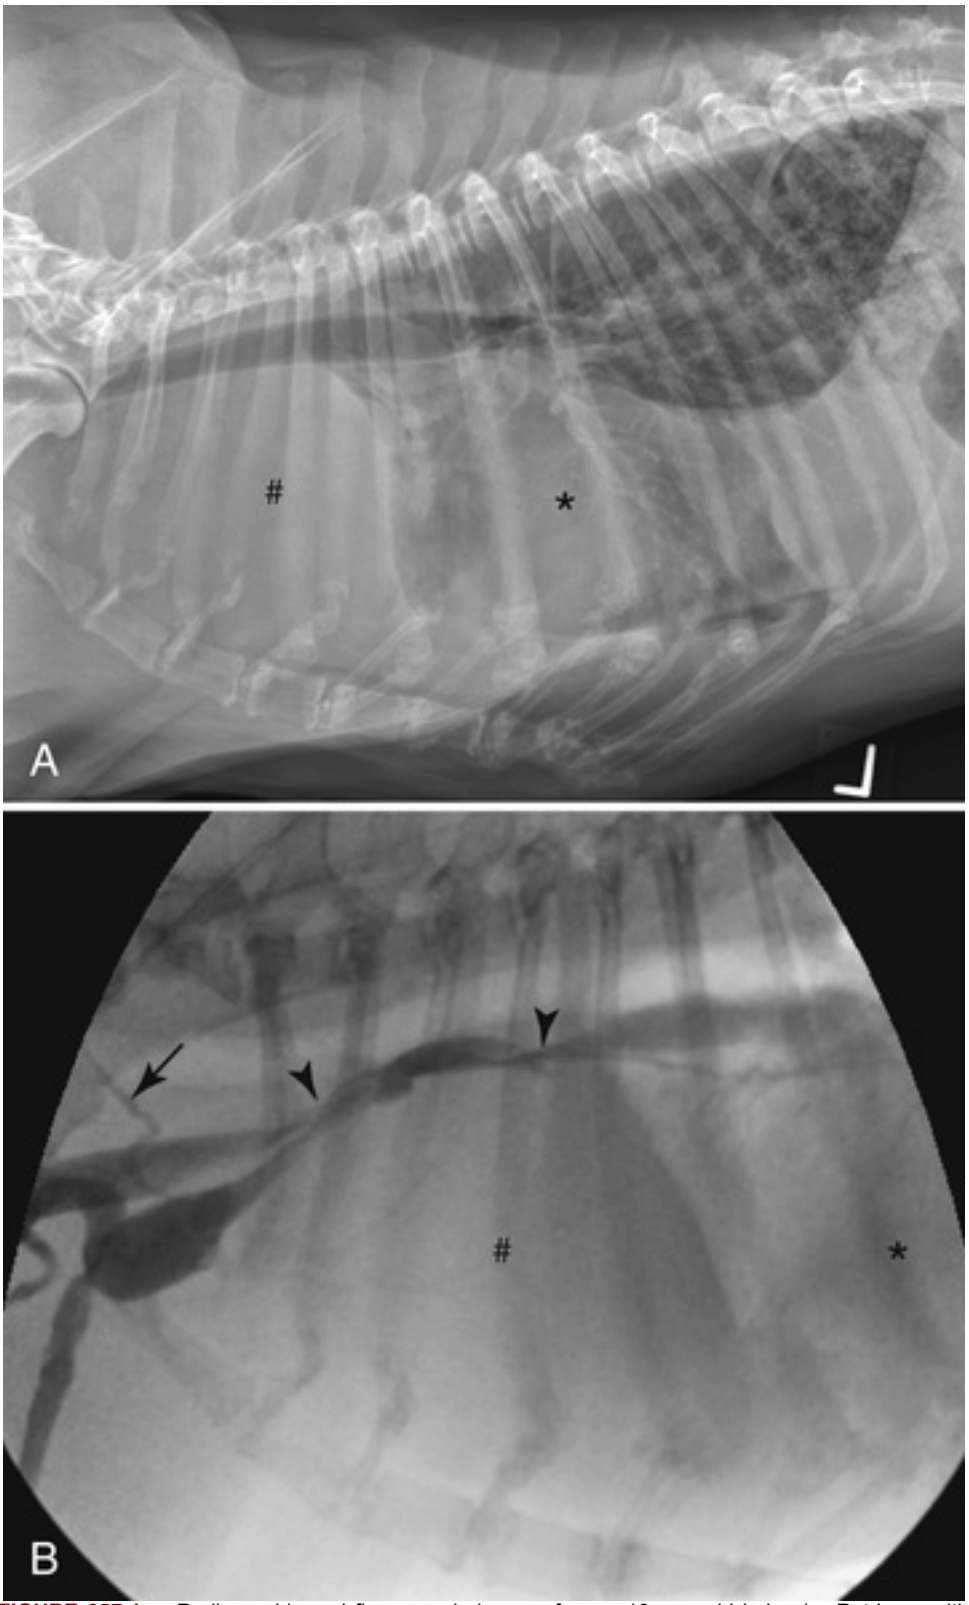

FIGURE 257-1 Radiographic and fluoroscopic images from a 10-year-old Labrador Retriever with thymoma. A large soft tissue mass (#) is present cranial to the heart (*) on the lateral thoracic radiograph in panel **A** with mild pleural effusion apparent. Nonselective venography via a cephalic catheter is shown in panel **B,** revealing a narrowed and extraluminally compressed cranial vena cava

(arrowheads) and development of collateral venous varicosities (arrow).

Lymphangiography facilitates regional assessment of the lymphatic system. The technique of indirect lymphangiography relies on a contrast agent, infused into tissue, to be selectively absorbed and transported through lymphatic channels.[6] Direct lymphangiography is more challenging (unless lymphangiectases have formed) but provides superior results when successfully performed (Video 257-2). Selective lymphatic cannulation requires aseptic cut-down over the lymphatic region of interest (note—the identification of lymphangiectases may be facilitated by subcutaneous injection of vital dyes [e.g., 3% Evans blue dye or 11% patent blue violet] into the toe web or consumption of a high fat meal for intestinal lymphatics). The lymphatic vessel is then cannulated with a 27- or 30-gauge needle or a special lymphatic cannula.[6] An iodine-containing soluble contrast medium as discussed above is then injected slowly into the vessel. Because water-soluble contrast media rapidly diffuse through lymphatic walls into surrounding tissues, the radiographic detail is blurred unless radiographs are taken shortly after contrast injection. Alternatively, oily iodine-containing contrast agents (e.g., Lipiodol) are used, reducing leakage of contrast from the lymphatic vessels. The oily contrast agents are sequestered within the lymphatics and lymph nodes along the draining pathways; some human reports suggest lymphangiography with this agent can even be curative for chylous leaks.[7] During lymphangiography, patency of the lymphatic channels can be appreciated in addition to the size of regional lymph nodes. Metastatic disease to the lymph nodes or granulomas appears as filling defects within the contrast-filled node. Lymphangiography can also be used to identify the location of lymphatic leakage or thoracic duct localization in small animals with chylous effusion.[8-10]

Diagnostic Ultrasound

Ultrasound imaging provides a direct, noninvasive technique for assessing venous abnormalities, patency, and function.[11,12] Ultrasound can aid in the diagnosis of venous thrombosis, aneurysms, traumatic vascular disease, and compression of vascular structures from local disease processes (Figure 257-2). Specialized ultrasound methods have been used in people to image the venous entry of the thoracic duct, but these have not been reported in dogs or cats.

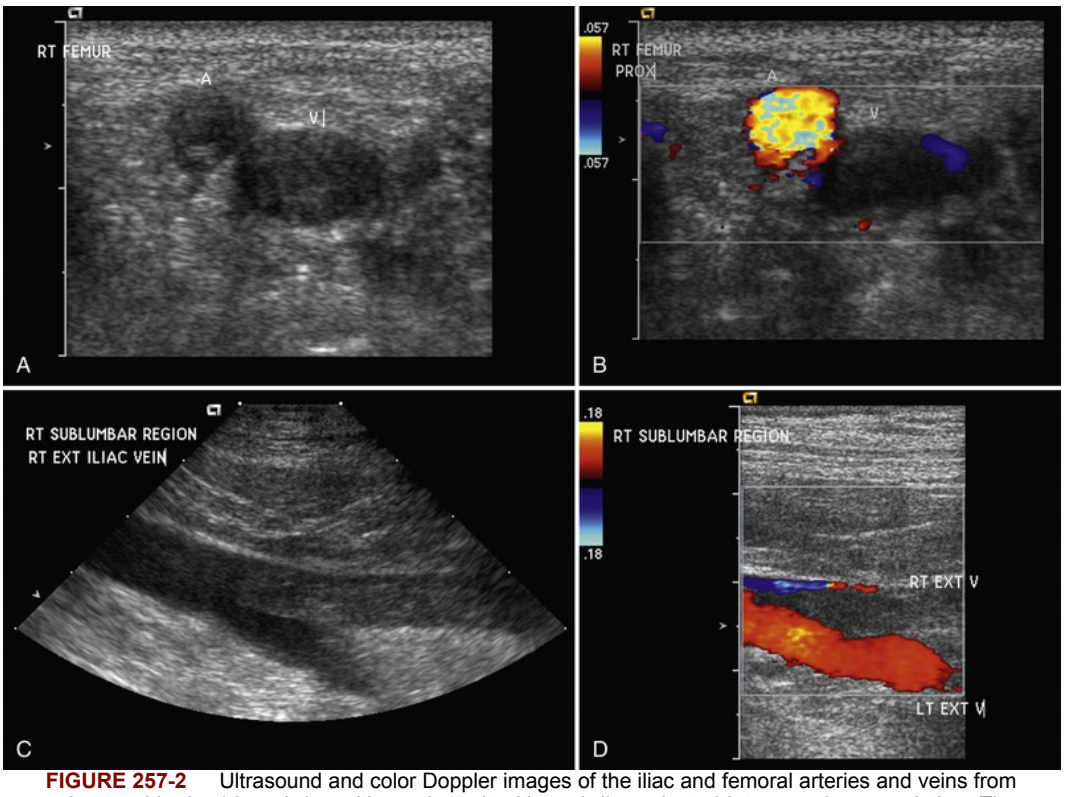

FIGURE 257-2 Ultrasound and color Doppler images of the iliac and femoral arteries and veins from a 9-year-old mixed breed dog with septic peritonitis and disseminated intravascular coagulation. The cross-sectional image in panel **A** shows that the lumen of the right (RT) femoral vein (V) is filled with a

hyperechoic thrombus and is noncompressible, while panel **B** shows normal color Doppler flow in the proximal (PROX) femoral artery (A), but nearly absent flow in the vein (V). Panels **C** and **D** show sagittal images of the external (EXT) iliac veins with hyperechoic thrombus and obstructed flow in the right external iliac vein (RT EXT V), compared to a patent lumen and flow in the left external iliac vein (LT EXT V).

Duplex ultrasonography incorporates grayscale two-dimensional imaging, coupled with simultaneous pulsed and color flow Doppler techniques.[12,13] Thrombi, foreign bodies, compression, and abnormal vascular anatomy can be identified with two-dimensional imaging.[13] Color Doppler superimposed on the two-dimensional image can further define anatomy and identify turbulence associated with vascular malformation and stenotic lesions.[11] Failure of a vein to compress with pressure from the ultrasound probe is a marker of partial or complete thrombosis.[13] Ultrasound assessment of venous flow reversal duration following the Valsalva maneuver or calf muscle compression and release are diagnostic tests for venous insufficiency in people, but are challenging if not impossible to adapt to animals.[14]

Lymphoscintigraphy

Lymphoscintigraphy involves injection of a radioactive tracer, monitored by a gamma camera. Although commonly employed in human medicine for evaluation of lymphatic drainage and oncologic staging,[15] it is not routinely utilized in veterinary medicine. Lymphoscintigraphy to evaluate lymphatic drainage from the mammary glands of dogs has been described.[16]

Cross-Sectional Imaging

Three-dimensional imaging of vascular structures is now possible using computed tomography angiography (CTA) or magnetic resonance angiography (MRA). Both CTA (Figure 257-3) and MRA (Figure 257-4) have been employed to evaluate vascular structures in animals.[17-19] The benefit of cross-sectional imaging such as CTA or MRA is the avoidance of selective central catheterization since only peripheral venous access is required for these techniques. Most of the published literature on these modalities has focused on anatomic delineation of portosystemic shunts,[17,20,21] though these methods can be used to investigate any vascular structure. Respiratory gating, or subjecting the animal to a breath-hold or apneic period during the scan, is preferred to avoid movement during scan acquisition, particularly if the abdominal or thoracic veins are being evaluated; this may not be required for CTA of the limb vasculature.

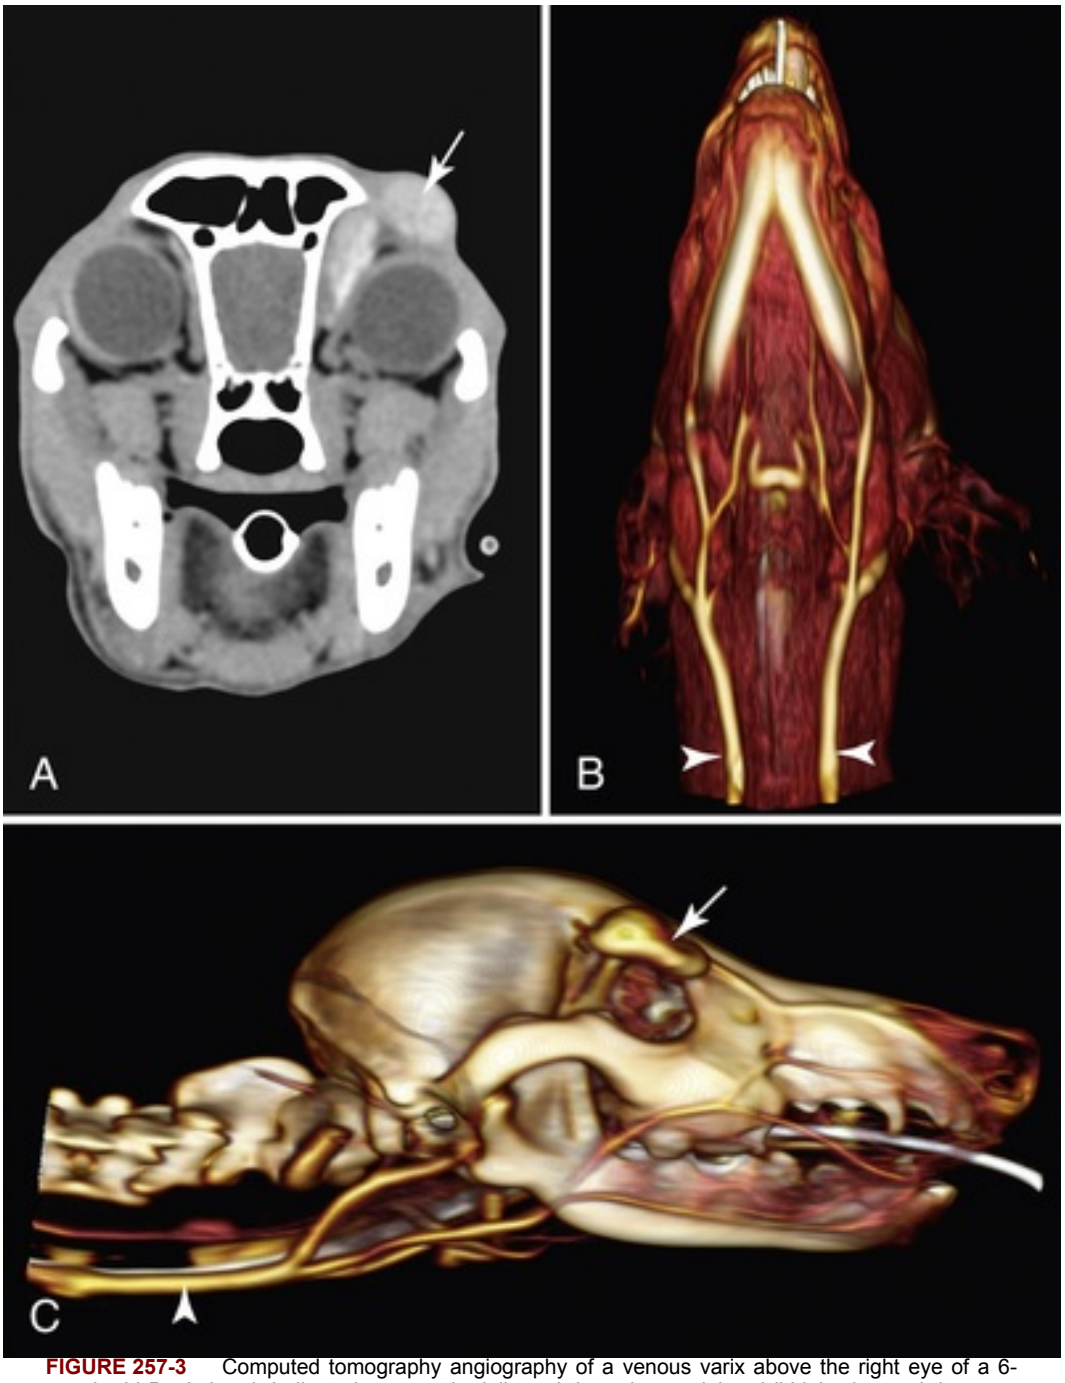

FIGURE 257-3 Computed tomography angiography of a venous varix above the right eye of a 6-month-old Dachshund. Iodinated contrast is delivered through a peripheral IV injection and the scan timed to the arrival of contrast at the lesion of interest. In this case, the transverse image in panel **A** shows an axial view of the head with a large venous structure (arrow) above and medial to the right orbit. Three-dimensional reconstructions in the ventral **(B)** and lateral **(C)** projection show the venous anatomy overlying musculoskeletal structures with the external jugular veins denoted by arrowheads and the varix denoted by the arrow.

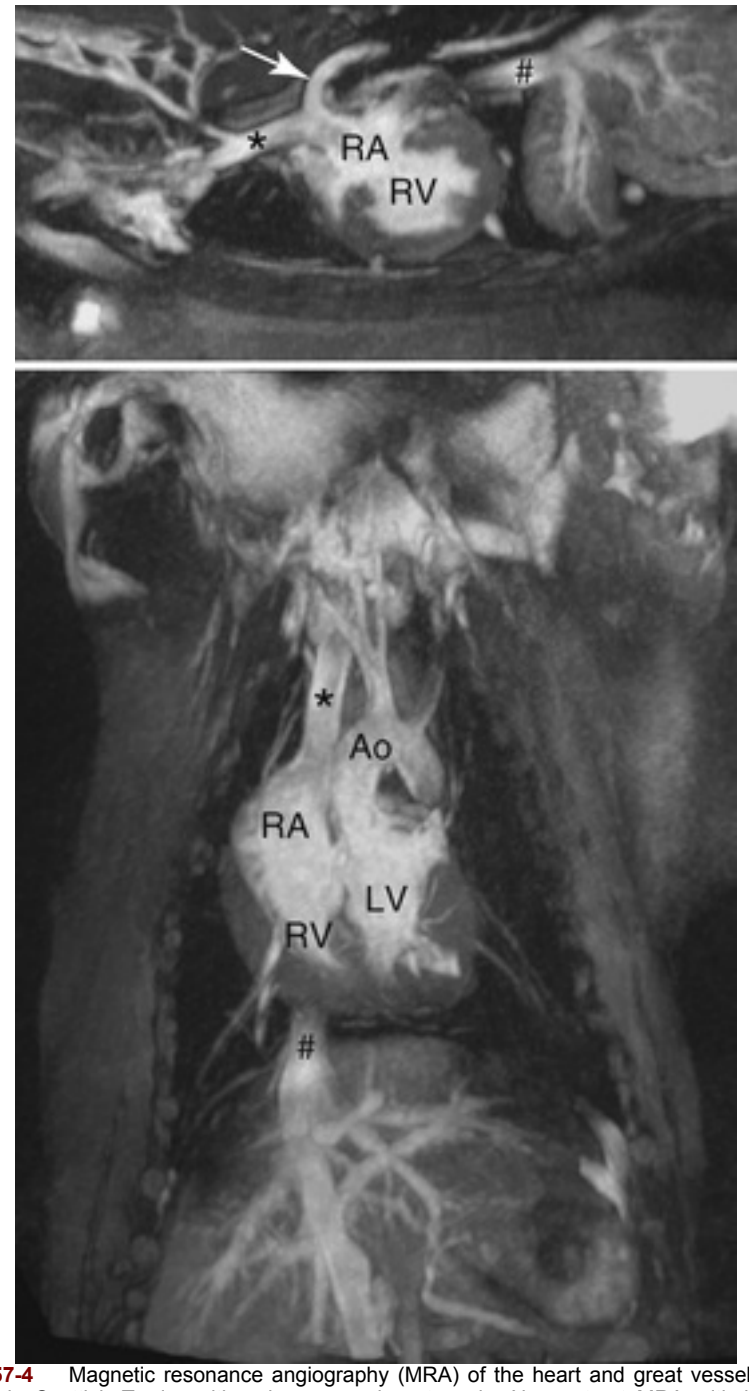

FIGURE 257-4 Magnetic resonance angiography (MRA) of the heart and great vessels from a 2-year-old male Scottish Terrier with pulmonary valve stenosis. Noncontrast MRA with bright blood imaging highlights both venous and arterial anatomy allowing visualization of the cranial (*) and caudal (#) vena cava, azygous vein (arrow), right atrium (RA), right ventricle (RV), left ventricle (LV), and aortic arch (Ao).

In addition to gating or breath holding, the method of processing and viewing images obtained during a CTA or MRA can dramatically enhance the information gained from the study. Viewers that support maximum intensity projections (MIP), minimum intensity projections, and three-dimensional volume rendering with the ability to stack images can improve image interpretation—particularly for vascular studies. The MIP is a technique whereby the image viewing software creates a single image by projecting the voxel with the highest attenuation value on a series of images, or slab, onto a two-dimensional image. When stacks of images are processed in this manner, the entire course of a vessel and its relationship to surrounding structures can be more clearly appreciated. Three-dimensional volume rendering of a CTA allows for the full spatial relationship of the vasculature to be realized and can greatly enhance surgical or interventional

planning.

Unique to MRA, imaging techniques are available to visualize blood clearly on the image without the administration of contrast (see Figure 257-4). Contrast agents may still be used and are preferred for some studies (such as perfusion scans), but may not be necessary for anatomic delineation of blood vessels.

Computed tomography lymphangiography is commonly employed in people to evaluate lymphatic structures, and has been applied to canine imaging (Figure 257-5), particularly for evaluation of thoracic duct anatomy prior to surgery for idiopathic chylothorax (Video 257-3).[9,22,23] Improved identification of lymphatic branches and digital subtraction of superimposing anatomic structures are two benefits seen with CT lymphangiography over radiographic lymphangiography in dogs.[9] Magnetic resonance lymphangiography is now performed in humans,[24,25] with preliminary work suggesting similar utility in veterinary medicine.

FIGURE 257-5 Computed tomography lymphangiography in a 6-year-old male Irish Wolfhound with lymphedema of the left pelvic limb. Three-dimensional maximum intensity projection images of the rear limbs and pelvis in a dorsal **(A)** and sagittal **(B)** perspective highlight normal lymphatic drainage within the left rear limb after injection of iodinated contrast into the left popliteal lymph node (arrow). Note mild soft tissue swelling of the left distal limb consistent with lymphedema of uncertain etiology. *D*, Dorsal; *L*, left; *R*, right; *V*, ventral.

Diseases of Veins

Diseases of the venous system seldom result in significant morbidity in small animals, despite the fact that trauma, thromboembolism, edema, local inflammation, tumor invasion, and septic processes commonly affect

veins. Many conditions, however, go unrecognized. Venous disorders include traumatic injuries, superficial and deep phlebitis and thrombosis (thrombophlebitis), catheter embolization, venous aneurysms, venous compression syndromes, and varices.

Venous thrombi form in the venous circulation under low blood flow conditions and are composed of fibrin and erythrocytes. Venous thrombi are understood to develop secondary to the classic components of Virchow's triad—flow stasis, endothelial disruption, and a hypercoagulable state.[26] Venous thrombosis causes fewer overt clinical abnormalities than arterial thrombosis and, consequently, is often undetected. Deep venous thrombosis is a major risk factor for pulmonary embolism in humans, but is not known to be a risk factor for pulmonary thromboembolism in animals. Pulmonary thromboembolism (PTE) is a common and often life-threatening complication associated with a variety of systemic and metabolic diseases. A thrombus that is formed in the peripheral veins, vena cavae, or right heart may embolize to the pulmonary arterial vasculature. Development of PTE can occur in several prothrombotic disease states including the nephrotic syndrome, hyperadrenocorticism, immune-mediated hemolytic anemia, thrombocytosis, cardiac disease, sepsis, disseminated intravascular coagulation, heartworm disease, and neoplasia.[27-35] Antithrombin (AT) deficiency may be involved in thrombogenesis in a number of these diseases by altering intravascular blood chemistry and increasing the risk for thrombosis. In immune-mediated hemolytic anemia, for example, destruction of red blood cells releases thrombogenic substances.[34] Thrombin and other clotting factors are inhibited by AT such that even mild reduction in AT can result in thrombosis or thromboembolism. The presence of multiple concurrent disorders in animals with thromboembolism is common. For example, 47% of cats with necropsy confirmed PTE had multiple predisposing disorders.[36] Massive pulmonary thrombi may also occur *in situ* and have been described primarily in the Cavalier King Charles Spaniel[37] (Figure 257-6) or in dogs or cats with heartworm disease (see ch. 255). Pulmonary thromboembolism is covered in detail in ch. 243.

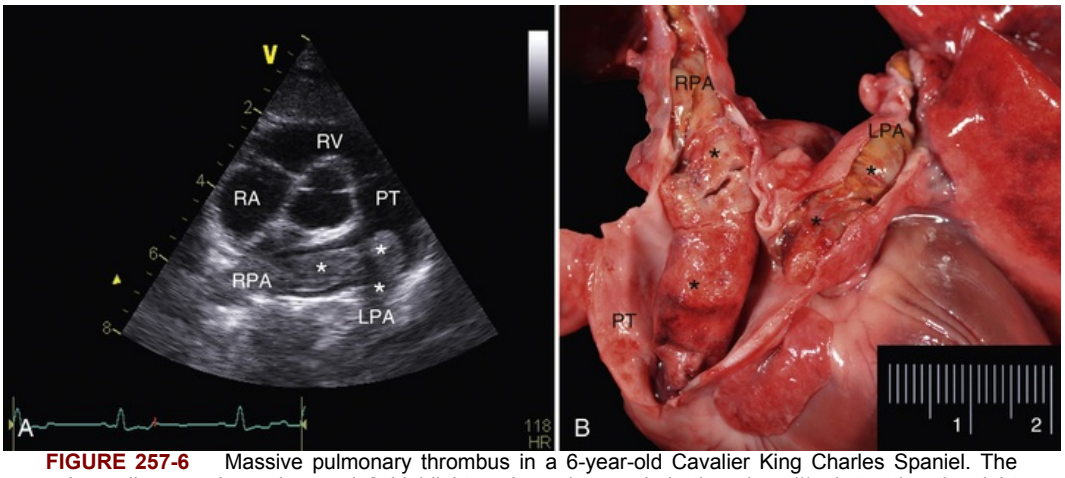

FIGURE 257-6 Massive pulmonary thrombus in a 6-year-old Cavalier King Charles Spaniel. The echocardiogram shown in panel **A** highlights a large hyperechoic thrombus (*) obstructing the right (RPA) and left (LPA) pulmonary arteries and extending into the pulmonary trunk (PT). Panel **B** is the autopsy image from the same dog revealing organized thrombus (*) throughout the PT and branch pulmonary arteries. *RA*, Right atrium; *RV*, right ventricle.

Venous varicosis, a condition of tortuous and dilated veins, is rare in dogs and cats (Figure 257-7). When detected, venous varices may accompany arteriovenous fistulae[38] or develop as a consequence of chronic venous obstruction (see Figure 257-1), with a recent review categorizing four pathways for collateral venous flow in the setting of caudal vena caval obstruction in dogs.[39] Cutaneous phlebectasia is a benign lesion sometimes erroneously called telangiectasis. It is reported almost exclusively in dogs with spontaneous or iatrogenic Cushing's syndrome (see ch. 306).[40] Phlebectasia is an abnormal dilatation, extension, or reduplication of veins or capillaries or a combination of these changes.

FIGURE 257-7 Varicose veins in a 4-year-old male Mastiff with a history of immune-mediated thrombocytopenia, right pelvic limb swelling and edema, and suspected deep vein thrombosis. Note the distended and tortuous superficial veins that have developed to provide collateral drainage as seen from the cranial **(A)** and lateral **(B)** perspective.

Venous perforation or blunt trauma to veins is usually well tolerated because rapid clotting results in venous occlusion and prevents serious hemorrhage. When venous occlusion is severe, resultant edema and cyanosis are usually temporary because of collateral circulation. If all veins draining an area are compromised, marked edema and necrosis can ensue. Blunt trauma has been associated with caudal vena caval obstruction or kinking of the intrathoracic caudal vena cava and subsequent ascites.[41-43]

Venous malformations are often incidental findings and may occur as duplication, interruption, transposition, or as an anomalous connection; persistence of the left cranial vena cava is noteworthy.[44] Dogs and cats normally have a right-sided cranial vena cava. When the embryologic left anterior cardinal vein fails to regress in these species, a persistent left cranial vena cava occurs (see ch. 250). The left cranial vena cava may occur singularly or, more often, both left and right cranial cava are present (Figures 257-8, 250-45, and 250-46). Buchanan described two types of persistent left cranial vena cava in the dog—complete and incomplete.[45] The left cranial vena cava enters the caudoventral aspect of the right atrium at the coronary sinus, in contrast to the entrance of the right cranial vena cava at the cranial aspect of the heart. The persistent left cranial vena cava generally poses no clinical problem for the animal, although a case report of an incomplete persistent left cranial vena cava in a Brittany Spaniel did suggest the possibility of this structure causing megaesophagus if it is partially atretic.[46] Transpositional venous anomalies are common in animals with transpositional arterial anomalies such as persistent right aortic arch. Reports of pacemaker implantation and heartworm extraction through a persistent left cranial vena cava can be found,[47,48] although this approach is technically more challenging than the standard route.

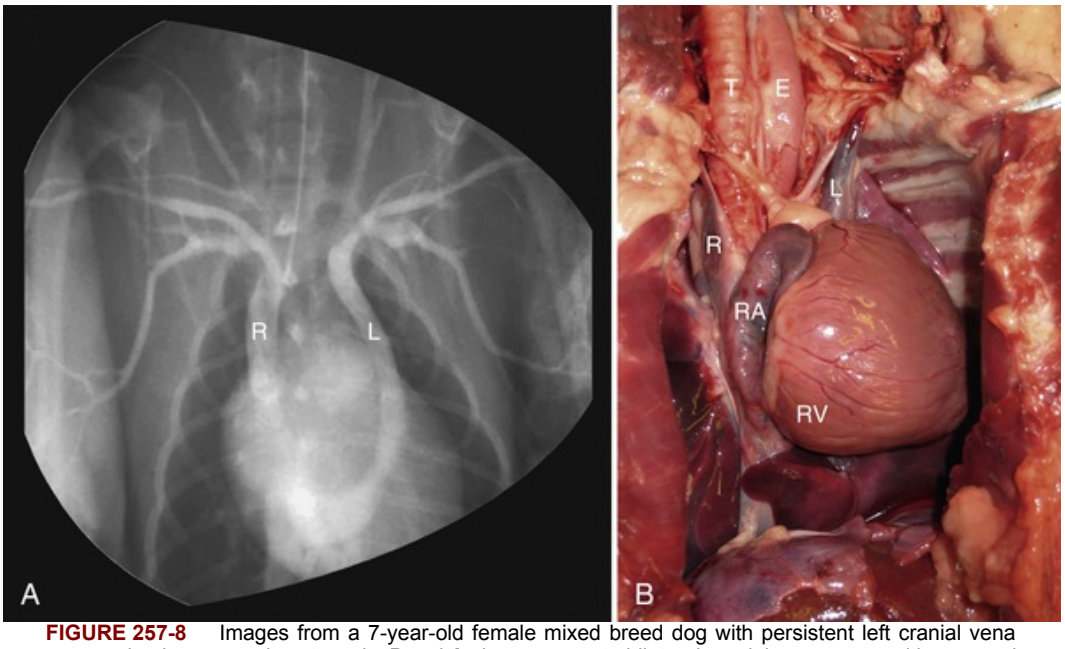

FIGURE 257-8 Images from a 7-year-old female mixed breed dog with persistent left cranial vena cava and pulmonary valve stenosis. Panel **A** shows separate bilateral cranial vena cavae with a normal right cranial vena cava (R) and a persistent left cranial vena cava (L); note the entrance of the persistent left cranial vena cava into the coronary sinus at the caudal aspect of the right atrium. Panel **B** shows an autopsy image of the same dog with both vena cava apparent. *E,* Esophagus; *RA,* right atrium; *RV,* right ventricle; *T,* trachea.

Additional venous anomalies have been reported. Notably, unilateral absence of the left external jugular vein has been described in the cat[49] and the author has observed absence of the right external jugular vein in two English Bulldogs.[50] A left azygous vein is present in some species, but is typically absent in the dog and cat. If present, it is a remnant of the left supracardinal system, which also enters the coronary sinus. Case reports of left azygous vein have been reported in the dog, occasionally as the sole source of caudal venous return if concurrent with interruption of the caudal vena cava.[51,52] Numerous abnormalities of the caudal vena cava have been reported in animals.[18,53-63] The caudal vena cava may display duplication, leftward transposition, or interruption with azygous continuation; these malformations are sometimes associated with portosystemic shunts (see ch. 284). Most of these malformations cause no clinical signs (unless concurrent with portocaval shunting), but might appear during surgical exploration or diagnostic imaging studies and should therefore be appreciated. Venous malformations, or venous hemangiomas, may be considered benign vascular growths that may develop locally or extensively, falling within a spectrum of abnormalities that are anatomically categorized into capillary, lymphatic, venous, or arteriovenous malformations.[64,65] The veterinary literature has not fully defined a categorization scheme or standardized nomenclature for these lesions in animals, although a histopathologic review of vascular tumors suggested parallels to human schemes.[66] Arteriovenous malformations are covered in more detail in ch. 284.

Cystic dilation of veins may also occur; venous dilation or aneurysm generally permits only low-velocity blood flow and small lesions are asymptomatic. Expansion of the lesion may occur, however, especially following trauma. Thrombosis can result from sluggish blood flow, resulting in localized swelling and tenderness. Larger lesions in dependent areas may enlarge, causing significant vascular dilation, potentially causing changes in skin color, dermal ulceration, and hemorrhage. Affected areas appear as a warm, soft, compressible mass. No thrills or bruits are present due to the low flow. Pain may result from pressure exerted on deep tissues and nerves. Diagnosis is made using history, physical examination, and ultrasound. Venography or cross-sectional imaging such as CTA or MRA may be necessary to define the lesion, particularly for intraabdominal aneurysms.[67] Symptomatic therapy using light, compressive wraps is sometimes helpful for acute management. Surgical excision of affected vessels is occasionally required, but complete resection is difficult and local recurrence is common.

Venous aneurysms are rarely recognized in veterinary medicine. Aneurysms of the external jugular, linguofacial, and maxillary veins, as well as the cranial vena cava have been reported.[68-70] In these cases, the lesions were considered to be congenital vascular anomalies and not associated with an obstructive or

traumatic process. The author has recognized caudal vena caval aneurysms in association with caudal vena caval interruption and azygous continuation in a dog (Figure 257-9). Fifteen cases of portal venous aneurysms were described in a CTA review of over 3000 dogs; none of the dogs of this study showed clinical signs, though portal venous thrombosis at the site of an aneurysm was described in one case.[67]

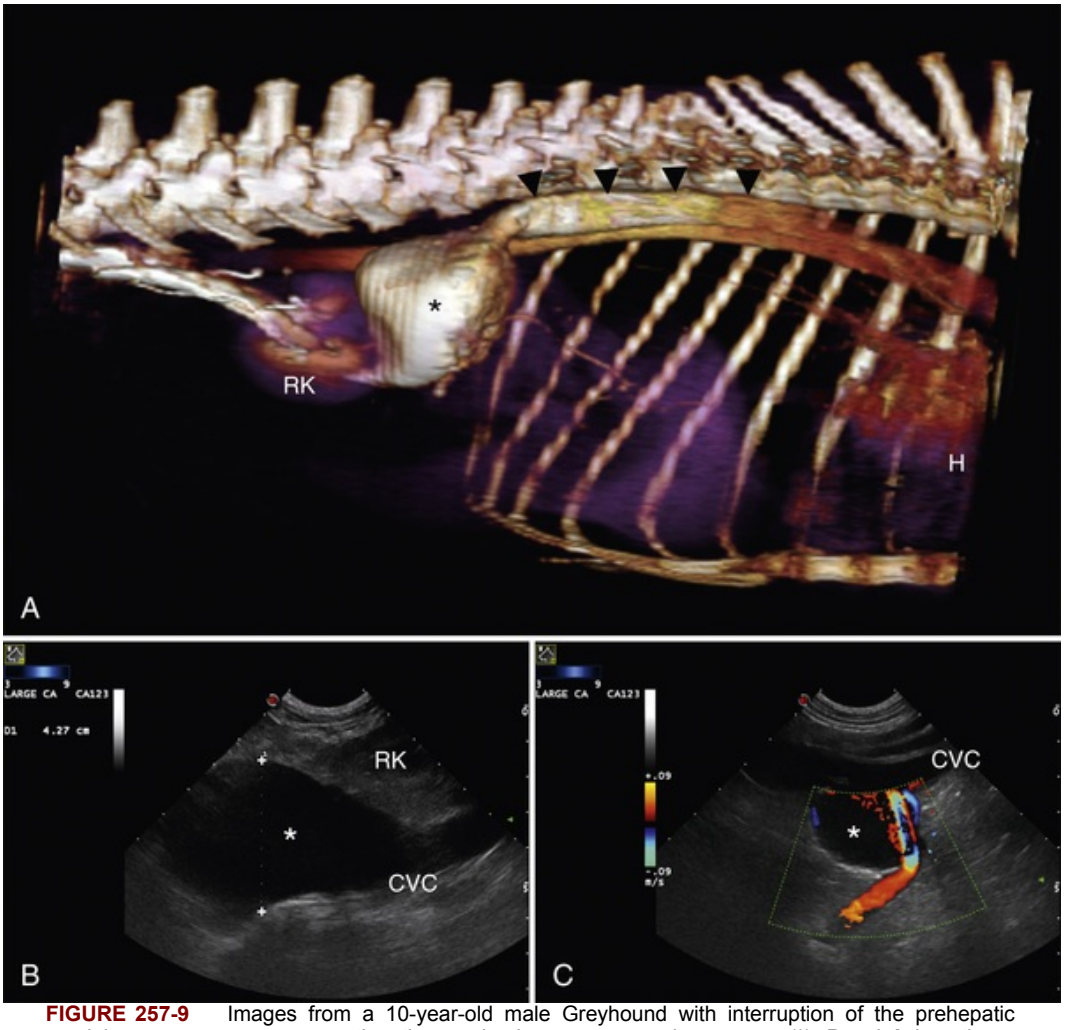

FIGURE 257-9 Images from a 10-year-old male Greyhound with interruption of the prehepatic caudal vena cava, azygous continuation, and a large vena caval aneurysm (*). Panel **A** is a three-dimensional sagittal reconstruction from a computed tomography angiography scan showing the large aneurysmal dilation of the caudal vena cava and continuation through the azygous vein (arrowheads). Panels **B** and **C** represent grayscale **(B)** and color Doppler **(C)** ultrasound images of the aneurysm, which measures about 4.3 cm in diameter. *CVC*, Caudal vena cava; *H*, heart; *RK*, right kidney.

Embolization of severed intravascular catheter fragments is an occasional complication of intravenous catheter placement.[71-73] In humans, reported complications of catheter embolization include perforation of cardiac walls, endocarditis, pulmonary embolism, and severe arrhythmias.[74,75] Therefore, it is generally considered prudent to remove catheter fragments. Nonsurgical, transvenous removal of catheter fragments using loop-snare catheters, forceps, and basket catheters have been described in animals.[72,73] Whenever possible, steps should be taken to avoid situations predisposing to catheter fragmentation including inadequate restraint during catheter placement, withdrawal of catheters through their placement needles during repositioning, failure to properly secure catheter to the patient, inadvertent severing of catheters during bandage changes, and the use of resterilized but damaged cardiac catheters.

Phlebitis can occur from a local inflammatory process extending to the veins or can originate from a venous intimal lesion. Common causes of venous intimal lesions are perivenous or intravenous injection of irritating drugs, infusion of large amounts of fluid, and long-term placement of intravenous catheters. Infusion-related phlebitis occurs in three forms: (1) chemical (injury to vein by irritating drugs), (2) physical (trauma to the

intima by catheters, needles, hypertonicity or particulate matter in infused fluids), and (3) microbial (infected fluids, skin, or catheter tip). Either sterile or septic thrombophlebitis may result. Thrombophlebitis is typically localized and is characterized by pain, swelling, and exudation (Figure 257-10). Patients with serious illnesses or compromised immune systems, however, may develop sepsis, thromboembolic pneumonia, or endocarditis.

FIGURE 257-10 Caudal (left) and lateral (right) views of the right rear limb of a young dog with severe edema caused by thrombophlebitis. The problem developed after placement of a saphenous vein catheter. The limb is markedly swollen and edema fluid (arrows) is leaking through a small ulcer in the skin. Thrombosis of the vein prevents venous drainage and increases lymphatic fluid formation.

Phlebitis is a major cause of intimal damage leading to venous thrombosis. The thrombosis is usually of little local consequence if localized to smaller vessels. However, emboli may be carried to the lung and cause PTE. In most animals, blood clots carried to the lung are rapidly lysed and cause no complications. However, when inflammatory disease, dehydration, or circulatory failure occurs, thrombus formation may continue in the pulmonary vessels and lead to vascular occlusion, dyspnea, pain, and death.[31] In infectious thrombophlebitis, bacterial emboli may be carried to the lungs and cause thromboembolic pneumonia. Spontaneous venous thrombosis is rare, although thrombosis of the portal venous system including the splenic veins is occasionally diagnosed in dogs (Figure 257-11).[76] In the majority of cases, underlying hepatic disease or conditions associated with a prothrombotic state (protein-losing nephropathy, immune-mediated hemolytic anemia, or hyperadrenocorticism) or compression (splenic torsion) are identified.[76] Clinical signs include ascites, abdominal pain, acquired portosystemic shunting, and hypovolemic shock.[76]

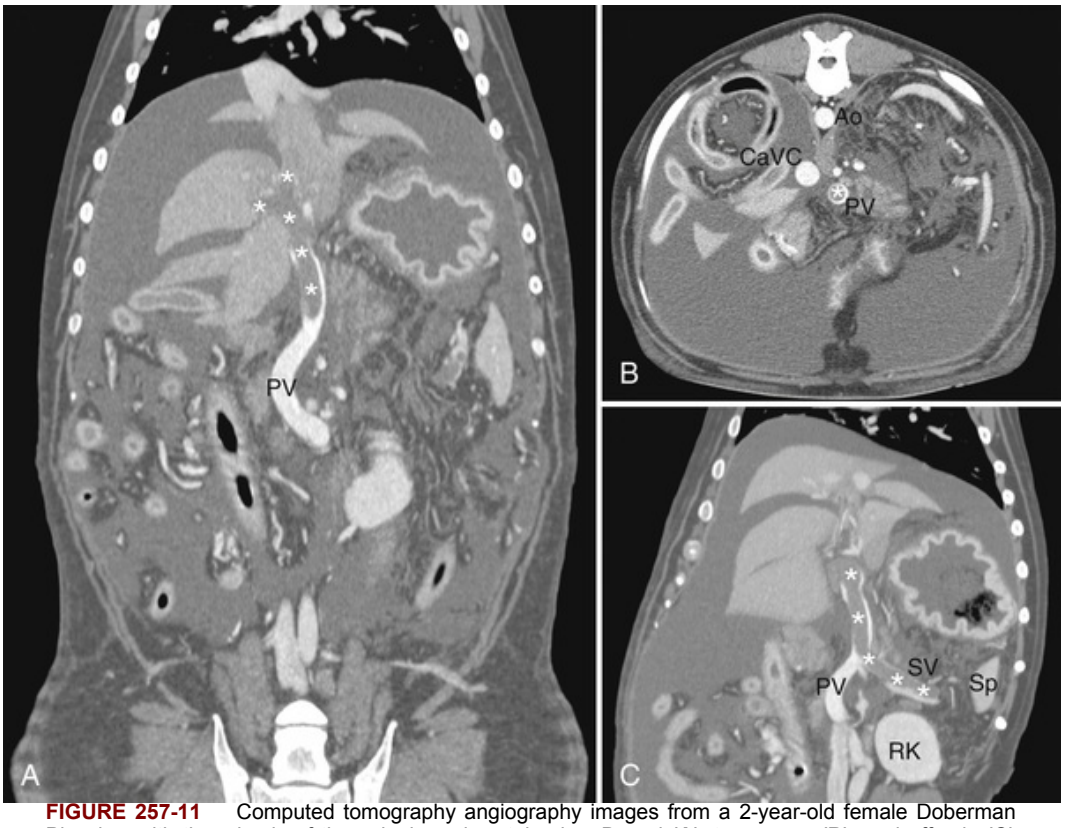

FIGURE 257-11 Computed tomography angiography images from a 2-year-old female Doberman Pinscher with thrombosis of the splenic and portal veins. Dorsal **(A),** transverse **(B),** and off-axis **(C)** maximal intensity projection reconstructions show a hypoattenuating structure consistent with thrombus (*) within the splenic vein and extending into the portal trunk and intrahepatic branches. Moderate ascites is also apparent. *Ao*, Aorta; *CaVC*, caudal vena cava; *PV*, portal vein; *RK*, right kidney; *Sp*, spleen; *SV*, splenic vein.

In cases of venous occlusion, clinical signs depend on the anatomic location, extent, and duration of the obstruction. Acute obstruction of centrally located, deep systemic veins causes edema, cyanosis, discomfort, and venous dilatation distal to the obstruction site. Obstruction of the cranial vena cava causes edema in the neck, head, front limbs, and dependent portions of the cranial thorax (Figure 257-12; see ch. 18). Pleural effusion commonly results from central venous obstruction. Common causes of cranial vena caval obstruction include cranial mediastinal masses, indwelling central venous catheters, and transvenous pacemaker leads.[77-85] Clinical disorders resulting in kinking, compression, neoplastic obstruction, or thrombosis of the intrathoracic caudal vena cava have also been reported with animals showing signs of ascites and subcutaneous edema (Figure 257-13).[41,86-89] Obstructions of the intraabdominal or pelvic venous systems cause edema of the hindlimbs and the scrotum. Clinical signs depend upon collateral vessel reserve and capacity of regional lymphatics to drain interstitial and serous cavity fluid. In addition to thrombosis, causes of venous obstruction include invasive malignant processes and venous compression by abscesses, hematomas, tumors, and lymphadenopathy. Several tumors have a tendency for venous invasion, including chemodectomas, adrenal tumors such as pheochromocytoma, and hemangiosarcomas (Figure 257-14). Angiography may indicate the occlusive or compressive lesion or highlight increased collateral circulation (see Figure 257-1). Diagnostic ultrasonography is useful to detect masses or flow disturbances; CTA or MRA can define the three-dimensional anatomy of the obstruction and evaluate extraluminal causes (see Figure 257-14). The prognosis and therapy of venous obstruction depends on the primary disease. These are discussed in various chapters throughout this book.

FIGURE 257-12 Cranial vena cava syndrome in a dog associated with a mediastinal mass and compression of the cranial vena cava. Severe peripheral edema of the cranial extremities is present.

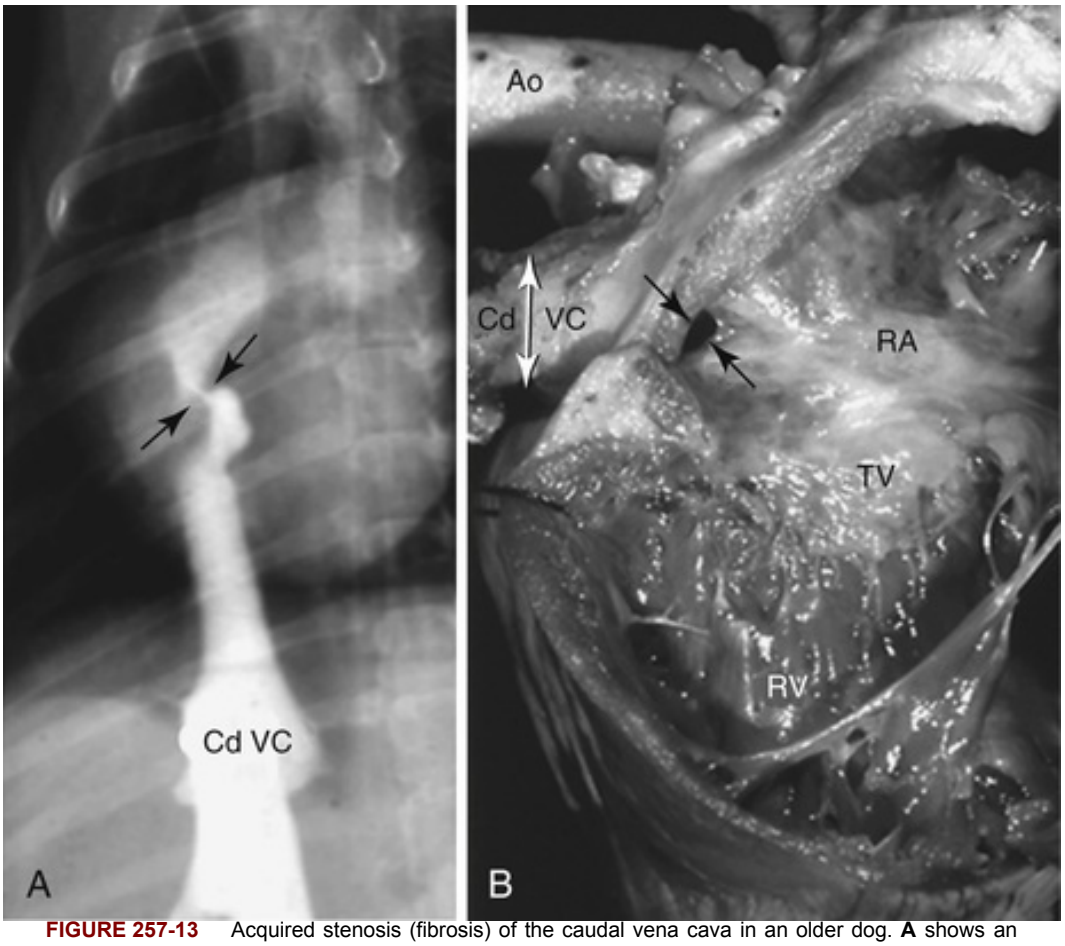

FIGURE 257-13 Acquired stenosis (fibrosis) of the caudal vena cava in an older dog. **A** shows an

angiogram of the caudal vena cava (Cd VC), which demonstrates a severe narrowing of the dye column (arrows) at the venous entry into the caudal right atrium. **B** is a postmortem view of the heart taken from the right lateral perspective. The right atrial and ventricular walls have been retracted to demonstrate the stenotic, caval orifice (small arrows). The reader should compare this opening with the diameter of the caudal vena cava (to the left, vertical double arrow). The right ventricle (RV), tricuspid valve (TV), right atrium (RA), and descending aorta (Ao) are shown.

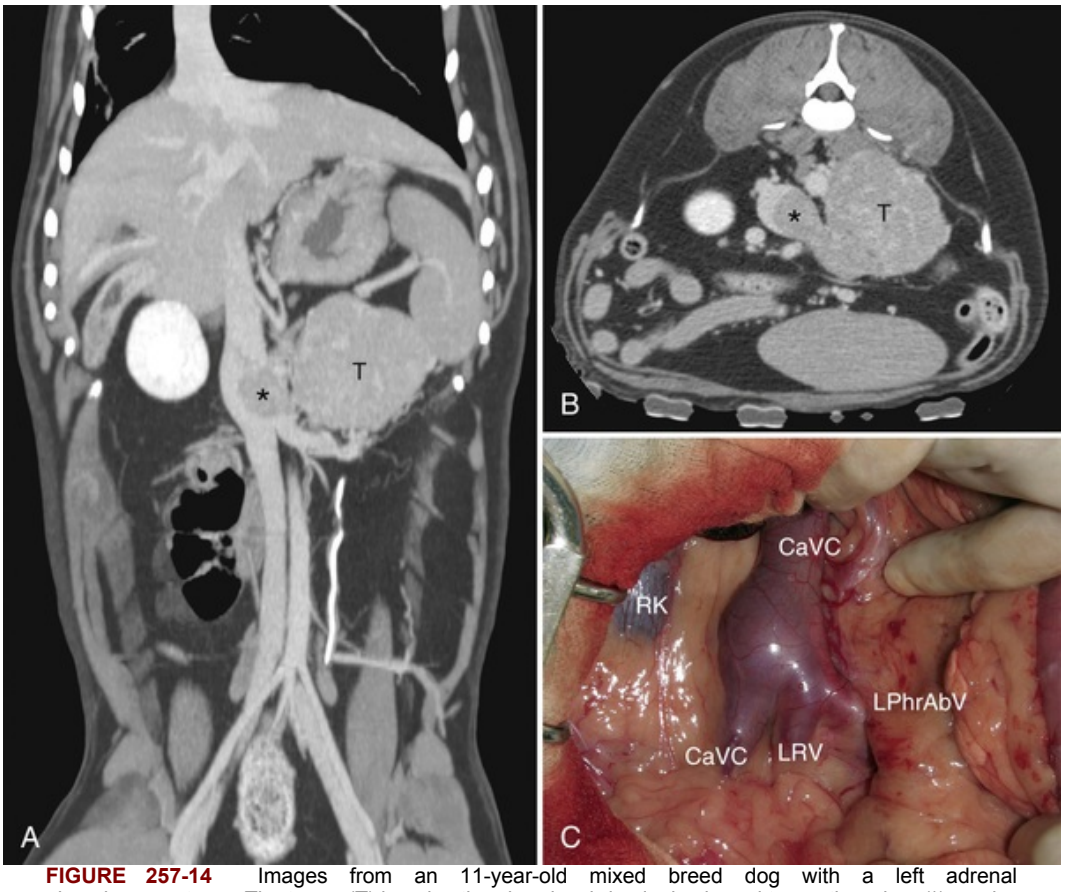

FIGURE 257-14 Images from an 11-year-old mixed breed dog with a left adrenal pheochromocytoma. The tumor (T) invades the phrenicoabdominal vein and tumor thrombus (*) can be seen extending into the lumen of the caudal vena cava. Surgical exposure of the same dog is seen in panel **C,** highlighting the anatomy of the caudal vena cava (CaVC), left renal vein (LRV), left phrenicoabdominal vein (LPhrAbV), and right kidney (RK). The tumor and left kidney are not visible, obscured by omentum. (Surgical image courtesy Kathleen Ham, DACVS.)

Diseases of the Peripheral Lymphatics

Lymphatic disorders can be subdivided into those of internal organs, such as intestinal lymphangiectasis, and peripheral lymphatic disorders. Several lymphatic diseases including lymphedema, intestinal lymphangiectasia, chylothorax, lymphadenitis, lymphocysts, lymphoma, lymphangioma, and lymphangiosarcoma have been recognized in animals. Types and causes of peripheral lymphatic disorders are summarized in Box 257-2.

Box 257-2

Causes of Peripheral Lymphatic Disorders

Lymphangitis, lymphedema, lymphadenitis, lymphadenopathy
- Infection
- Neoplasia
- Reactive hyperplasia

- Granuloma
- Lymphedema
  - Primary—developmental abnormality of lymphatics
    - Hypoplasia
    - Aplasia
    - Lymphangiectasia
    - Hyperplasia
  - Secondary—acquired abnormalities of lymphatics
    - Surgical excision of lymphatics or lymph nodes
    - Posttraumatic lymphangiopathy
    - Neoplastic invasion
    - Extrinsic compression of lymph vessels or tissue
    - Acute obstructive lymphadenitis
    - Chronic sclerosing lymphadenitis/lymphangitis
    - Lymphatic atrophy with interstitial fibrosis
    - Radiation therapy
  - Lymphocysts
- Cystic hygroma, lymphoceles, pseudocyst
- Lymphangiomas
- Lymphangiosarcomas

Inflammatory Lymphatic Disorders (Lymphangitis and Lymphadenitis)

Lymphangitis and lymphadenitis often occur secondary to local inflammation, particularly involving the skin, mucous membranes, and subcutaneous tissues. Lymphangitis can also result from bacterial or fungal infection or adjacent neoplastic and inflammatory disease. Lymphatics may be affected and occluded as they drain inflammatory agents and their by-products from tissue spaces. In lymph nodes, microorganisms are phagocytized and inactivated or killed by humoral and cellular mechanisms. During this process, lymph nodes may become obstructed, enlarged, warm, and painful. Affected limbs may be locally swollen and lameness can result. Pyrexia, anorexia, and depression are common and leukocytosis may be present with acute, severe lymphangitis.

Lymphangitis may become chronic when associated with a granulomatous or static lesion such as a foreign body or with unsuccessfully treated acute inflammation. Lymphangitis has been associated with cutaneous coccidioidomycosis in a dog and cat, intestinal lymphadenitis secondary to bite wounds, sporotrichosis, and chronic lipogranulomatous lymphangitis in chronic protein-losing intestinal disease (see ch. 276).[90-94] Persistence of inflammatory edema in cutaneous infections results in mesenchymal cell proliferation, which in turn can cause irreversible thickening of the skin and subcutis. The prognosis is variable depending on the cause and in general more favorable with early treatment. Therapy consists of moist, warm, local compresses or soaks, which reduce swelling and promote drainage. Aggressive local and systemic antibiotic therapy usually promotes recovery in animals with fever and anorexia. Bacterial culture and sensitivity testing and cytologic examination of regional lymph nodes should be performed if acute lymphangitis fails to respond to treatment and in cases of chronic lymphangitis. Contrast studies and surgical exploration may be indicated if fistulous tracts or abscesses are present, or if a foreign body is suspected.

Lymphedema

Pathologic fluid accumulation occurs in the interstitium when the microvascular filtration rate exceeds lymphatic drainage.[3] Starling's forces conceptualize the interplay of oncotic and hydrostatic pressure, coupled with vascular permeability, which drive microvascular filtration.[5] In the microvascular bed, there is a net movement of ultrafiltrate to the interstitium such that in states of inadequate or impaired lymphatic flow, the ultrafiltrate accumulates leading to lymphedema. Lymphedema specifically refers to an accumulation of fluid in the interstitial space resulting from abnormal lymphatic drainage.[4] This term should not be used for other forms of edema, such as edema related to venous obstruction or generalized edema related to hypoproteinemia. The protein-rich fluid of lymphedema (2 to 5 g/dL) causes a high osmotic gradient and exacerbates fluid accumulation.[95] Numerous classification schemes have been used to categorize lymphedema. Commonly used etiologic categories of lymphedema include overload, inadequate collection

into lymphatic capillaries, abnormal lymphatic contractility, insufficient lymphatics, lymph node obstruction, and main lymphatic ductal defects.

Traditionally, clinical effort is undertaken to differentiate primary versus secondary lymphedema. Primary lymphedema refers to an abnormality of the lymphatic vessels or lymph nodes. Secondary lymphedema refers to disease in the lymphatic vessels or lymph nodes due to a different pathologic process. Secondary lymphedema can occur as a result of neoplasia, surgery, trauma, parasites, radiation therapy, or infection and is more common than primary lymphedema. Distinguishing between primary and secondary lymphedema is often difficult. A disease process involving a lymph node can result in fibrosis and obstruction with secondary lymphedema developing.

Primary Lymphedema

Primary lymphedema can result from three principal morphologic and functional abnormalities including (1) abnormalities of large vessels such as aplasia or hypoplasia of the thoracic duct and cisterna chyli, (2) aplasia of the peripheral lymphatics or congenital valvular incompetence, and (3) lymph node fibrosis or a deficient lymph node size and number.[96]

Lymphedema caused by aplasia, hypoplasia, or dysplasia of proximal lymph channels or lymph nodes occurs most often in the hindlimbs of young dogs (Figure 257-15). The edema can be transient, observed only during the juvenile period, or permanent. Mild cases are restricted to the hindlimbs, whereas severe cases may progress to whole-body edema.[97-101] Although the condition is frequently bilateral, one limb is often more swollen than the other. A number of cases of suspected congenital lymphedema have been reported, though nearly all represent single case reports from decades ago.[100-102] A small series of dogs with familial primary lymphedema was described and studies of this family suggested an autosomal dominant mode of inheritance, variable severity of symptoms, and a high rate of mortality in severely affected dogs.[97,103] Reported breeds include Bulldogs, Poodles, Old English Sheepdogs, and Labrador Retrievers, although it is not clear whether these breeds are at increased risk.

FIGURE 257-15 Marked, nonpainful edema of the left rear limb in a young dog with congenital lymphatic dysplasia.

The history may identify chronic limb swelling since birth or edema appearing later in life. The swelling represents a pitting edema of varying magnitude that is neither warm nor cold (see ch. 18 and Video 18-1). The edema is not usually accompanied by lameness or pain unless there is massive enlargement or cellulitis. Growth and activity are usually normal but rest and limb massage do not typically reduce the severity of edema. Regional lymph nodes, normally prominent in growing puppies, are sometimes difficult to identify. Total plasma protein, serum protein electrophoresis, hemogram, and blood chemistry are generally unremarkable. The diagnosis of primary lymphedema is based on history (age of onset, disease progression, affected limbs, and distribution of edema) and clinical signs. Previous surgery, trauma, or infections should also be noted. Radiographic lymphangiography may be necessary to confirm the diagnosis in subtle cases and is helpful in determining morphology of anomalous lymphatic systems (Figure 257-16).

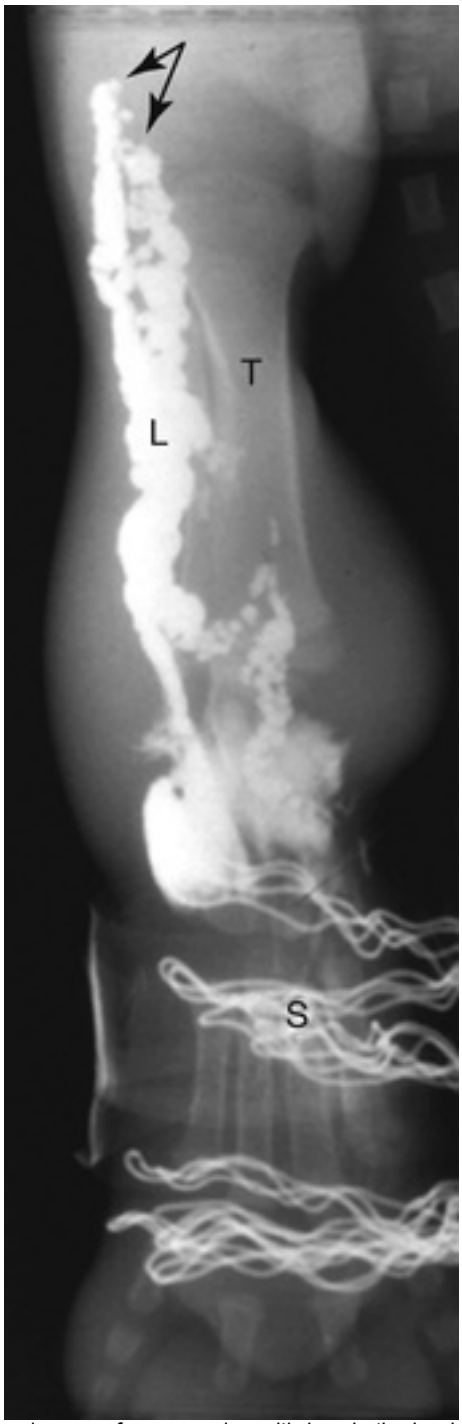

FIGURE 257-16 Lymphangiogram of a young dog with lymphatic dysplasia. After cannulation of a distal lymphatic vessel, contrast medium was infused into the lymphatic system. The reader should note the dilated, tortuous, lymphatic channels (L) that end blindly at the stifle (arrows). *S,* Radiopaque surgical sponges; *T,* tibia.

The prognosis for resolution of congenital lymphedema is guarded and depends on the etiology. Some dogs that develop hindlimb edema during the neonatal period improve spontaneously. Dogs with severe edema of the limbs and trunk are more likely to succumb during the first few weeks after birth.[97,98] Chronic lymphatic vessel dilation leads to permanent lymphatic valvular dysfunction. Metabolic by-products accumulate and lead to collagen deposition and fibrosis. Complications such as abrasions and recurrent infection often develop. Dogs with primary lymphedema should not be used for breeding—as noted above, test matings of dogs with congenital lymphedema support the hypothesis of autosomal dominant inheritance with variable expression.[97]

Secondary Lymphedema

Persistent lymphedema occurs only after destruction or blockage of a considerable number of major lymph channels or several sequential lymph nodes with their afferent or efferent lymphatics.[95] Factors that can delay or prevent edema formation include opening of collateral vessels, rerouting of lymph flow through peripheral lymphaticovenous anastomoses and perilymphatic routes of lymph drainage, and increased venous fluid uptake. Secondary lymphedema is often related to a combination of lymphatic and venous obstruction.[104] Inhibited venous return increases lymphatic flow by altering Starling's forces toward increased tissue fluid accumulation. This overloads the lymphatic capillaries and results in the accumulation of fluid in the interstitial space.[95] Distal lymphatics may become more distended, causing loss of valvar competency, stagnation of lymph flow, mural insufficiency, and further accumulation of proteinaceous fluid in subcutaneous tissues. Other common etiologies include posttraumatic, postradiation therapy, or postsurgical interruption of lymphatics; lymph node excision; and blockage of lymph nodes and lymph vessels by compression or invasive neoplasms.[105-108] Lymphedema resulting from local neoplasia is usually a sign of a widely disseminated and highly invasive malignant process.

Clinical signs associated with secondary lymphedema vary depending on the underlying cause and any systemic response and overlap with clinical signs of systemic venous obstruction. Accordingly, physical diagnosis and appropriate imaging should assess both systems. Lymphedema may be localized to the periphery of an extremity (Figure 257-17) or extend proximally to the subcutaneous tissues.[105] The location and severity of obstruction determine the extent of edema formation. For example, sublumbar or intrapelvic obstruction induces bilateral hindlimb edema and edema of the thighs and external genitalia. Mediastinal masses and thrombosis of the cranial vena cava induce bilateral edema of the front limbs and tissues of the ventral thorax, neck, and head. The clinician must palpate all lymph nodes carefully for enlargement and pain. With bilateral hindlimb edema, it is important to perform rectal or abdominal palpation to assess sublumbar lymph nodes. The prostate and anal region or mammary glands and vaginal area should be carefully inspected for neoplasms, which can lead to obstructive intrapelvic processes. Intrapelvic masses should be suspected in all dogs with hindlimb edema and vague signs of sublumbar pain, discomfort during ambulation, or difficulties with defecation or urination. Depending on the type and extent of underlying systemic illness, limb edema may be the only detectable abnormality or may be accompanied by fever, anorexia, and weight loss. Clinicopathologic findings depend on the underlying primary disorder.

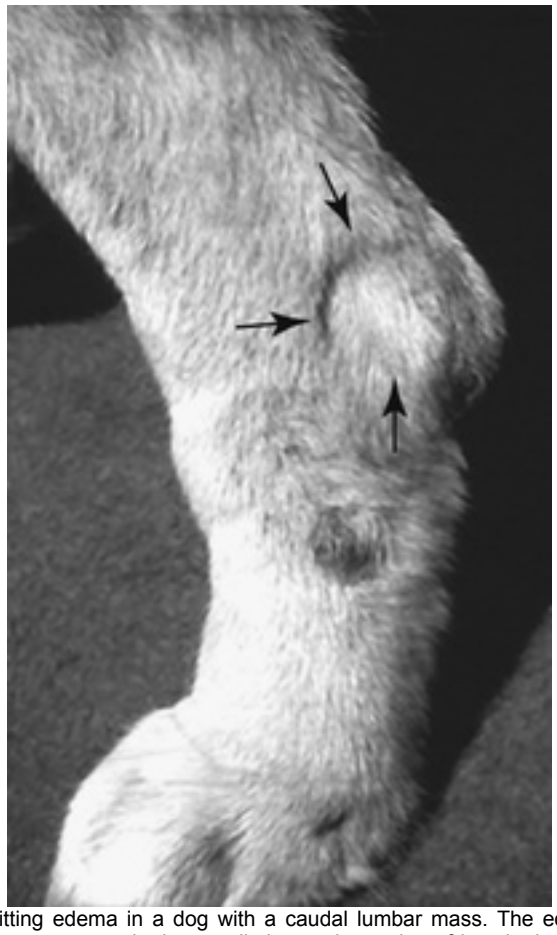

FIGURE 257-17 Pitting edema in a dog with a caudal lumbar mass. The edema was caused by either obstruction of venous return in the rear limbs or obstruction of lymphatic drainage. Tissue fluid was deformed by light digital pressure, resulting in a visible subcutaneous pit in the rear limb (arrows).

The diagnosis of lymphedema is based largely on history and physical examination and is facilitated by diagnostic imaging and the ruling out of venous obstruction. Survey radiographs should be taken of suspicious areas, which often include the pelvis or cranial thorax. In a substantial number of cases, soft tissue masses or destructive bony lesions can be detected. Occasionally, the identification of subclinical pleural effusions in cases of peripheral edema suggests a more generalized lymphatic disorder. Ultrasonography can provide information about soft tissue masses and readily identifies enlarged lymph nodes and other structures, both peripherally and within the abdomen. Duplex imaging, as described previously, should be used to exclude venous thrombosis or obstruction. Lymphangiography, lymphoscintigraphy, venography, or CTA may be indicated to evaluate venous and lymphatic anatomy and luminal integrity if the diagnosis remains unclear. Lymphangiography was traditionally relied upon for definitive diagnosis of lymphatic disorders. In some cases, the lymphatics are hypoplastic throughout their course. When aplastic, lymphatics suitable for cannulation and injection of radiocontrast agent may not be found. Failure to outline a lymph node after lymphography is not absolute proof of its absence.[6] Lymphangiographic features of primary lymphedema include lymph node aplasia and small lymphatics that end blindly or anastomose into collateral vessels around (instead of into) the locations where lymph nodes would normally be found.

Differential diagnoses for dogs with edema confined to one limb include inflammation, trauma, vascular obstruction, hemorrhage, cellulitis, phlebitis, and AV fistula (see ch. 18). Diagnostic considerations for dogs with edema involving both forelimbs include thrombosis or compression or invasion of the cranial cava by a mediastinal mass. With the latter, edema usually involves the head and neck regions, as well as the limbs. Causes of only bilateral hindlimb edema include obstruction of sublumbar lymph nodes by neoplastic infiltration, right-sided congestive heart failure, and pericardial effusion, accepting that in some dogs no cause is ever identified—in the authors' experience, the Irish Wolfhound appears overrepresented in cases of idiopathic lymphedema (see Figure 257-5). If all four limbs are involved, the differential diagnoses should include hypoproteinemia, congestive heart failure, renal failure, portal hypertension, or a lymphatic neoplasm (lymphangiosarcoma). As noted earlier, the close association of lymphatic and venous structures

can make it difficult to distinguish between lymphatic and venous obstruction, and both can occur at the same time. Ulceration, dermatitis, cyanosis, weeping varices, or fat necrosis are signs of venous obstruction rather than lymph stasis.

Therapy is usually unrewarding unless the edema is due to an underlying cause of elevated venous pressure (as opposed to true lymphedema). In the early stages of lymphedema, medical management is directed to maintaining the animal's comfort and reducing swelling. Infectious disorders require long-term antimicrobial therapy. Some neoplastic conditions may benefit from chemotherapy or radiation therapy. Long-term heavy bandage application (comparable to compression stockings in people) and physical therapy may encourage lymphatic flow and reduce subcutaneous lymph accumulation (see ch. 355).[109] Local topical skin care and intermittent antibiotic therapy are helpful in reducing secondary cellulitis. With the exception of isolated cases, pharmacologic therapies are generally unrewarding. The benzopyrones (e.g., rutin) are a group of drugs that have been advocated to reduce high-protein lymphedema by stimulating macrophages, promoting proteolysis, and enhancing absorption of protein fragments, though proof of efficacy in the treatment of lymphedema is lacking.[110,111] Long-term diuretic administration is considered as contraindicated because reduction of interstitial fluid will concentrate proteins in the residual interstitial space, which may promote tissue injury.[6] Surgical options may include (1) procedures to facilitate lymph drainage from affected limbs (lymphangioplasty, bridging procedures, shunts, omental transposition) and (2) procedures to excise abnormal tissue. Surgical excision of the subcutaneous edematous tissue should be staged to decrease devascularization.[6] Short-term administration of anti-inflammatory agents, bandaging, and physical therapy may be helpful in cases of traumatic or postsurgical lymphedema.

Lymphangioma, Lymphangiosarcoma

Lymphangiomas are benign tumors of small-caliber lymphatic vessels and are thought to develop when primitive lymphatic sacs fail to establish venous communication.[112] In a 5-year survey of 221 vascular tumors of dogs, only one case of lymphangioma was definitively identified, suggesting these are rare lesions.[66] Lymphangiomas can be classified into three categories based on their histologic appearance: (1) capillary lymphangiomas composed of a network of capillary-sized lymphatic channels, (2) cavernous lymphangiomas composed of dilated lymphatics that infiltrate the surrounding tissue, and (3) cystic hygromas (unilocular or multilocular, cystic masses lined by a single layer of endothelium supported by a connective tissue stroma and containing a straw-colored, proteinaceous [1.3 to 4.5 g/dL] fluid).[113] The lesions present as large, fluctuant masses in the subcutaneous, fascial, mediastinal, hepatic, lymph nodes, and retroperitoneal spaces.[114-117] Lymphangiomas have also been diagnosed on the extremities, metacarpal pads, nasopharynx, axilla, inguinal and mammary region, retroperitoneal space, and skin of dogs.[112,118-120] Clinical signs are related to the size, location, and extent of the lymphangioma. They can exert pressure on surrounding structures and may interfere with muscle function, breathing (compression of the trachea), urination, or intestinal function. Lymph may ooze to the skin surface through single or multiple fistulous tracts. Differential diagnoses include other space-occupying masses such as abscesses, enlarged lymph nodes, neoplasms, and congenital cysts of nonlymphogenic origin. The prognosis can be good after appropriate surgical excision, marsupialization, or radiation therapy.[121] Risk of recurrence is high due to inherent inability to identify distinct boundaries.

Lymphangiosarcoma originates from lymphatic endothelial cells.[122] It is a rare malignant tumor in dogs and cats, although it is frequently reported secondary to chronic lymphedema in humans.[123-125] The diagnosis can be challenging by light microscopy with hematoxylin and eosin staining, as features of the neoplasm are shared with hemangiosarcoma. Prior reports suggest hemangiosarcoma and lymphangiosarcoma can be distinguished by a lack of erythrocytes in the vascular spaces of lymphangiosarcoma.[122] Newer immunohistochemical stains appear to better characterize these neoplasms.[66,122] A breed or sex predisposition has not been detected, but medium to large breeds may be at highest risk, and both young and older animals are affected.[107,122,126-131] Metastasis occurs commonly in dogs and cats, estimated to be present in a third to half of cases at diagnosis.[122,129,132] Clinical signs include pitting edema of the extremities, inguinal region, axilla, and head and neck.

In a report of 12 cats with lymphangiosarcoma, 9 presented with fast-growing, noncircumscribed subcutaneous masses and the others presented with a thoracic or abdominal mass.[129] In all cats affected, the tumor was invasive and complete surgical resection was not possible.[129] The presenting complaints were similar in a series of 12 dogs with lymphangiosarcoma in which 10 of the cases were presented for swelling of

the neck, ventral abdomen, or limbs—nearly all with serosanguineous discharge from the overlying tissue.[122] Associated chylous effusions (pleural, abdominal, subcutaneous) have been reported.[133-135] Pulmonary lymphangiosarcoma was diagnosed in one dog presenting with a chylous thoracic effusion.[136] Cytology of the mass or swelling is unrewarding, with most cytologic reports finding mild inflammation without signs of malignancy.[122] Diagnosis is confirmed by obtaining a biopsy specimen. Histologically, tumors of lymphatic endothelial origin are characterized by a neoplastic proliferation of endothelial cells. Immunocytochemical stains, such as prospero-related homeobox gene 1, have been used to confirm the diagnosis in dogs and cats.[122,137,138] The prognosis with lymphangiosarcoma is guarded to poor, with a high rate of local recurrence and metastasis. In early reports, most animals were euthanized or died due to severe lymphedema, pleural effusion, or distant metastases. In one case report, lack of recurrence and absence of metastatic disease was documented over 9 months following mass resection and doxorubicin treatment.[139] In the case series of 12 dogs,[122] variable treatment strategies were employed with incomplete surgical excision in 5 dogs having a mean survival time of 513 days, chemotherapy alone having a survival time of 182 days in 1 dog, prednisone alone in 1 dog having a survival time of 90 days, combination therapy (surgery, chemotherapy, +/− radiation therapy) having survival of 574 days in one dog and more than 248 days in another. The three dogs that did not receive therapy had a mean survival of 368 days.[122] Currently, the optimal therapy for lymphangiosarcoma in dogs and cats is unknown.

CHAPTER 258

Neurophysiology

Dennis P. O'Brien, Joan R. Coates

Nervous system function is based on excitable membranes. The potential to pass excitation on to other neurons begins with the resting membrane potential, the rechargeable battery that powers the process. Fluctuating conductance of voltage-gated Na^+ and K^+ channels in the axon will transmit the excitation on as the action potential. This transmission is facilitated by the insulating myelin sheath, which permits saltatory propagation to jump rapidly down the axon. The action potential ends at the nerve terminal, opening voltage-gated Ca^{++} channels that trigger a cascade of synaptic docking proteins and release a neurotransmitter. The neurotransmitter binds with a post-synaptic receptor and then is terminated by specific reuptake proteins or enzymatic inactivation. The neurotransmitter affects the post-synaptic neuron, either short term or long term, making it more or less likely to pass that excitation on. The graded excitatory and inhibitory inputs to a neuron summate at the axon hillock, where the "decision" is made to stop any further signal or begin the process again with a new action potential. This basic process of excitation and inhibition plays out in the complex anatomy of the nervous system to generate attention, perception, motivation, and action.

Excitable Membranes: Resting Membrane Potential and Ion Channels

At rest, an excitable cell like a neuron has an electrical charge across the membrane with the inside of the cell negative relative to the outside: the resting membrane potential. This potential is created by the active transport of ions across the membrane resulting in concentration differences inside and outside the cell. Na^+/K^+ ATPase utilizes energy from ATP to pump 3 Na^+ ions out of the cell in exchange for 2 K^+ ions. This creates a concentration gradient with sodium concentrations [Na^+] much greater outside the cell and potassium concentrations [K^+] much greater inside the cell. Since one more Na^+ is pumped out than K^+ pumped in, an electrical gradient is also established. Negatively charged anions such as proteins and amino acids, which cannot diffuse through the membrane, maintain the negative charge on the inside of the membrane. For neurons, this potential difference is about −65 to −70 mV. A disease process such as hypoglycemia will impair the ability of neurons to supply enough ATP to the Na^+/K^+ ATPase. When the cell cannot maintain the resting membrane potential, it will decay toward a more depolarized state, which can trigger seizures or progress to coma.

The permeability of the membrane to an ion is determined by the state of channels in the membrane, which are selectively permeable to different ions. The degree and direction of flow will depend on the concentration gradients and the charge of the membrane. When, for example, a K^+ channel opens, the ion will diffuse down the concentration gradient: in the case of K^+, from inside the cell to outside. Balancing this force, however, is the difference in electrical charge. The negatively charged anions inside the cell attract the positively charged K^+ and oppose their diffusion out of the cell (Figure 258-1). The voltage difference across the membrane at which these forces are in balance and no diffusion occurs is the equilibrium potential (E_k). This depends on the concentration differences driving diffusion ($[K^+]_{out}/[K^+]_{in}$) and is calculated by multiplying the log of that quotient by a constant (the Nernst equation).

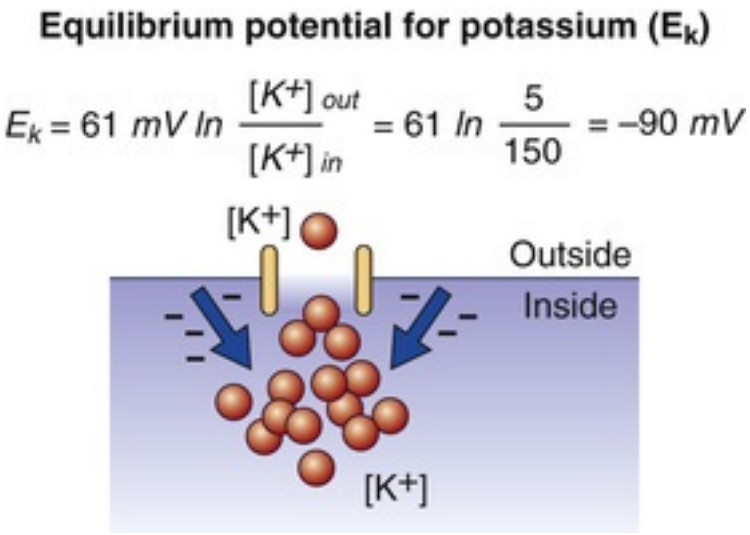

FIGURE 258-1 The higher concentration of K^+ inside the cell encourages diffusion from the cell. This force is opposed by the negative charge inside the membrane, which attracts the positively charged K^+. The membrane voltage where these two forces are in balance is the equilibrium potential *(E_K)* calculated by the Nernst equation. Thus, when the membrane is at −90 mV, there will be no diffusion of K^+. (From O'Brien, D.P. Vet Med 8415: Advanced Veterinary Neurology, http://bblearn.missouri.edu, 2015. Used with permission.)

Opening and closing of these ion channels is regulated by the membrane voltage or by a neurotransmitter binding to a receptor linked to the channel. When the channel is open, the ion that it is permeable to will diffuse to reach the equilibrium potential. If a K^+ channel opens, K^+ would diffuse out of the cell down the concentration gradient until the inside of the cell reached the equilibrium potential of −90 mV when the forces of voltage and diffusion would be in balance. Thus, this would make the cell more negative (hyperpolarized). On the other hand, $[Na^+]$ outside the cell is much greater than $[Na^+]$ inside and the electrical gradient favors diffusion into the cell. The cell is very impermeable to Na^+ at rest, but when a sodium channel opens, Na^+ will diffuse into the cell until its equilibrium potential is reached at 59 mV, depolarizing the cell. The other ion critical to the resting potential is Cl^-. It has its own active transport mechanisms that create a gradient with the $[Cl^-]$ outside the cell much greater than inside, giving an E_{Cl} of −70 mV.

The concentration gradients and the resting permeability of the neuronal membrane for these different ions all contribute to the resting membrane potential. The Goldman, Hodgkin, Katz equation predicts the membrane potential based on the balance of these variables. At rest, the $[Na^+]$ and $[Cl^-]$ are large outside the cell compared to inside and the opposite is true for $[K^+]$. The resting permeability for K^+ (P_K) is large, as numerous "leak" channels are open at that voltage. The P_{Cl} is much less while the P_{Na} is even less still. The summation of all these factors gives rise to the potential of the membrane at rest of about −65 mV for neurons.

Channelopathies are diseases that affect ion channel function and alter the excitability of the neuronal membrane. Cats with complex partial seizures have antibodies against voltage-gated potassium channels and dogs with a mutation in the gene that codes for a portion of this potassium channel complex have benign familial juvenile epilepsy.[1,2] These diseases alter P_k and thus the excitability of the cell membrane, predisposing to excessive neuronal activity and seizures.

Transmitting Excitation: the Action Potential

When a neuron depolarizes past a threshold (−55 mV), voltage-gated Na^+ channels in the axon will open, beginning the action potential that will transmit that signal on to other neurons (Figure 258-2, *A*). The amount of Na^+ that diffuses into the cell through a permeable channel is expressed as conductance (g_{Na}). As Na^+ diffuses into the cell, it further depolarizes the membrane until it approaches the equilibrium potential for Na^+ (E_{Na}) of 59 mV. Na^+ channels have a secondary gating mechanism, the inactivation gate, which closes the channel preventing further diffusion of sodium through that channel for a brief period of time (Figure 258-2, *B*). Voltage-gated K^+ channels will open in response to the depolarization produced by the g_{Na}. K^+ now

diffuses through these ion channels toward its equilibrium potential of −90 mV. Since this is below the normal resting membrane potential of −65 mV, there is an after-hyperpolarization of the membrane until the normal resting conductances bring the voltage back to rest. Antiepileptic drugs such as phenytoin enhance inactivation of sodium channels, making it less likely that an action potential will be propagated.[3] Toxins such as pyrethrins block sodium channel inactivation, increasing action potential generation and causing tremors and seizures (see ch. 152).[4]

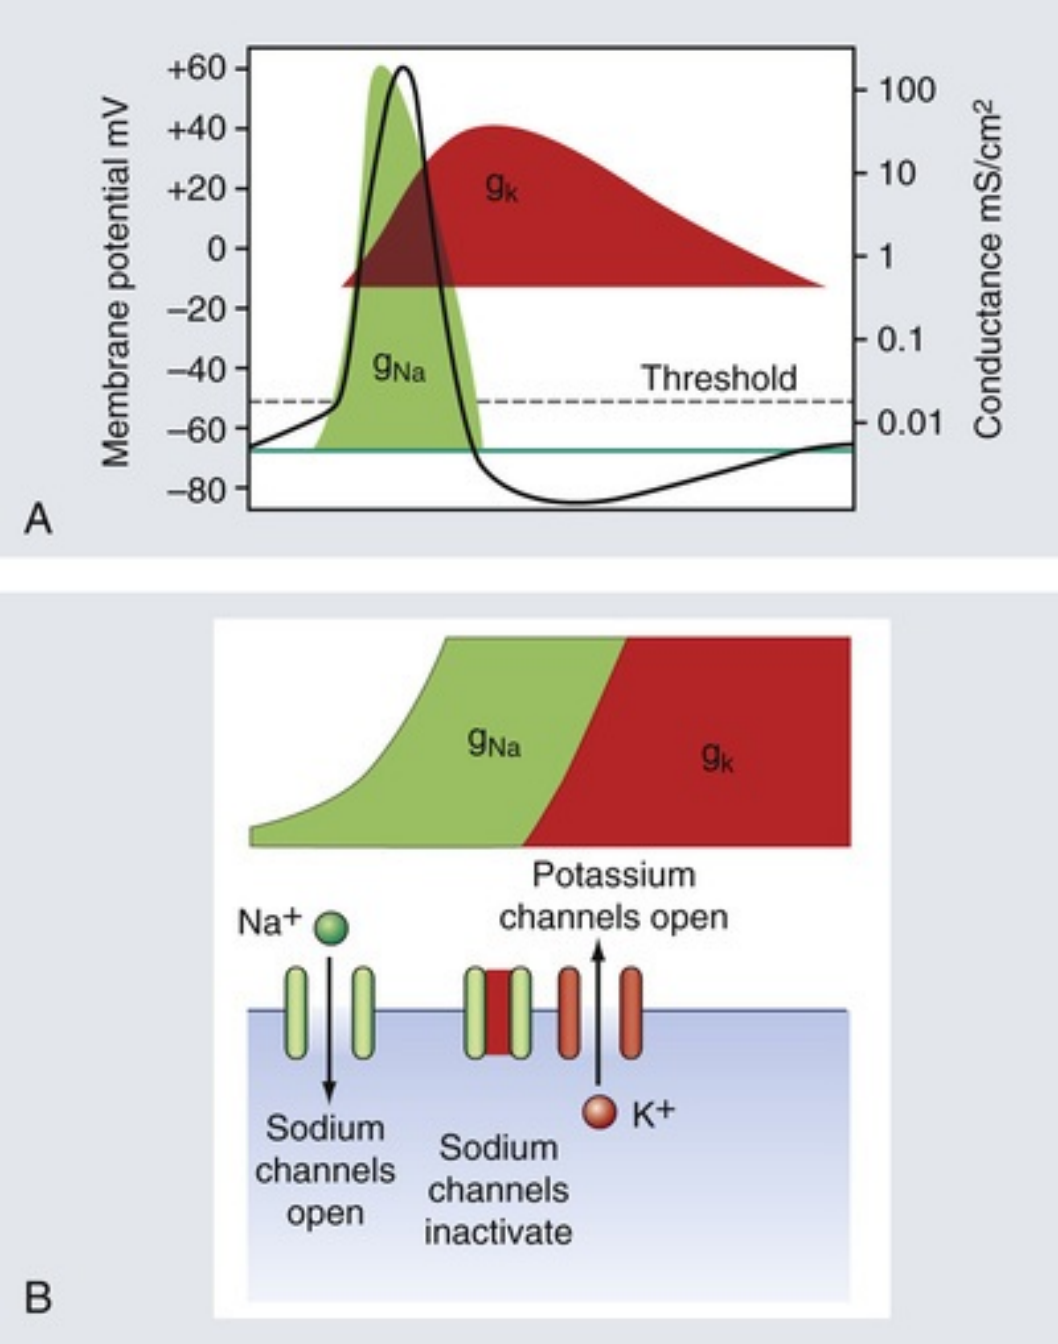

FIGURE 258-2 **A,** The action potential (black line) is generated by changes in the conductance of Na^+ (g_{Na} in green) and K^+ (g_K in red). When the cell depolarizes past a threshold of −55 mV, Na^+ channels open **(B)** and Na^+ diffuse into the cell until it reaches the equilibrium potential of 59 mV. Na^+ channels inactivate, preventing any further diffusion of that ion. Voltage-gated K^+ channels open with depolarization, permitting K^+ to diffuse out of the cell until its equilibrium potential of −90 mV is reached. (From O'Brien, D.P. Vet Med 8415: Advanced Veterinary Neurology, http://bblearn.missouri.edu, 2015. Used with permission.)

Two factors influence the speed at which the action potential travels down an axon: axonal diameter and myelin. Increasing the diameter of the axon increases the number of ions available for currents to flow (i.e., it decreases the resistance to ion flows). At the same time, however, it increases the surface area where the difference in charge between the inside and outside is stored (i.e., it increases the capacitance which resists ion flow). Adding an insulating layer of myelin decreases the ability of the membrane in that area to store a charge (decreases the capacitance) without affecting resistance to ion flows within the axon, and permits the ions to flow between the unmyelinated areas (nodes of Ranvier) in a saltatory fashion. Demyelinating diseases such as polyradiculoneuritis (see ch. 268) increase the capacitance of the axonal membrane, thus slowing the conduction velocity and potentially blocking propagation of the action potential.

Communication Between Neurons: the Synapse

Neurons communicate with each other via synapses. While some synapses permit a direct flow of ions between neurons (electrical synapses or gap junctions), most utilize chemical signals via neurotransmitters. Neurotransmitters are packaged into vesicles stored in the nerve terminal. When the action potential depolarizes the nerve terminal, voltage-gated calcium channels open, allowing Ca^{++} to flow into the cell. The Ca^{++} activates a series of synaptic vesicle proteins that dock the vesicle to the presynaptic membrane where it fuses with the cell membrane, releasing the neurotransmitter into the synaptic cleft. Botulism toxin binds to one of the vesicle docking proteins, preventing release of acetylcholine at the neuromuscular junction (see ch. 214).[5]

The neurotransmitter diffuses across the synaptic cleft and binds to a receptor on the membrane of the post-synaptic cell, which can be another neuron, a muscle or another effector like an endocrine cell. Receptors can be divided into ionotropic receptors which regulate ion channels and metabotropic which act through second messengers. The effects of the neurotransmitter will be terminated by diffusion from the synapse, enzymatic degradation, or an active uptake mechanism.

The classic ionotropic receptors have subunits composed of membrane spanning domains that form a central pore, which is selectively permeable to certain ions. Several structural molecules are important in adhering the pre- and post-synaptic zones together as well as anchoring the ion channels, docking protein, receptors and various second messengers to the membrane in those zones. When the neurotransmitter binds to an extracellular ligand binding site, it alters the conformation and the permeability of the pore. The three families of ionotropic receptors are (1) nicotinic acetylcholine (ACh), gamma-amino butyric acid (GABA) and glycine, (2) glutamate, and (3) ATP or purine P2X receptors.[6] The effects on the post-synaptic cell can be either excitatory or inhibitory depending on which ion diffuses through the open pore.

When ACh binds to the nicotinic receptor, the pore becomes permeable to cations.[6] At a resting membrane potential, Na^{+} will be the major ion to diffuse into the cell, depolarizing the post-synaptic membrane. When recording the membrane potential in the post-synaptic cell, this depolarization appears as an excitatory post-synaptic potential (EPSP) (Figure 258-3). Acetylcholinesterase in the synaptic cleft breaks down ACh to choline and acetic acid, which are taken up into the presynaptic terminal and used to resynthesize ACh. In myasthenia gravis, autoantibodies directed against the alpha1 subunit partially block the ACh receptor in the neuromuscular junction (see ch. 269).[7] This makes it more difficult for ACh to open the channel and produces the fatigue that is the hallmark of the disease. Acetylcholinesterase inhibitors prolong the interaction of ACh with the receptor and reverse the clinical signs.

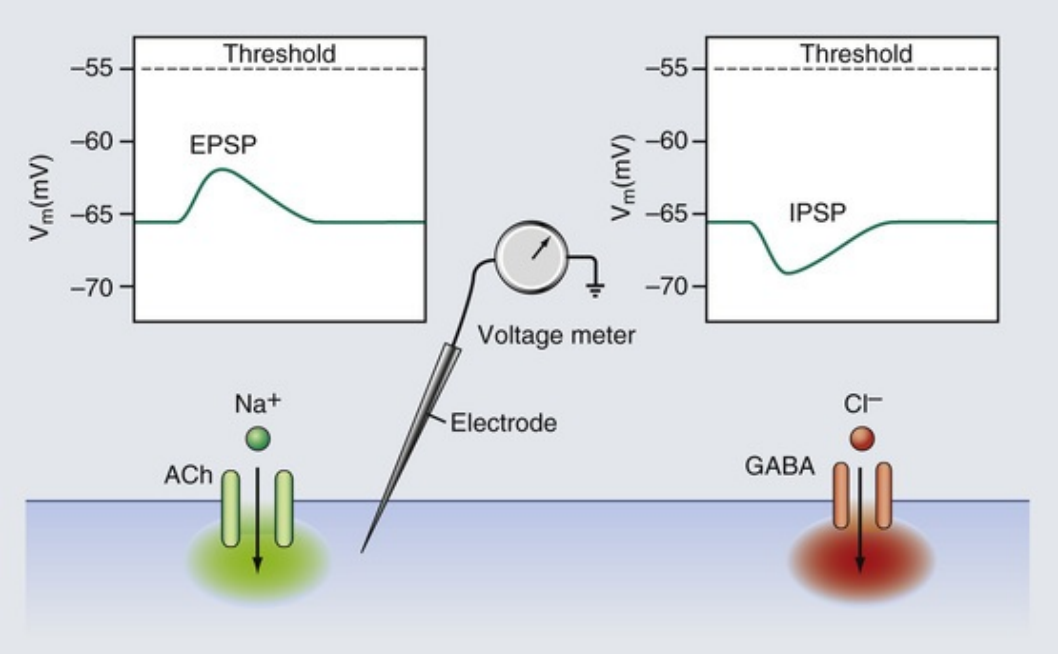

FIGURE 258-3 When the nicotinic ACh channel opens and Na^+ diffuses into the cell, a subthreshold depolarization of the membrane can be recorded as an excitatory post-synaptic potential (EPSP). When an inhibitory neurotransmitter like gamma-amino butyric acid (GABA) binds to its receptor, the influx of Cl^- further polarizes the cell and is recorded as an inhibitor post-synaptic potential (IPSP). (From O'Brien, D.P. Vet Med 8415: Advanced Veterinary Neurology, http://bblearn.missouri.edu, 2015. Used with permission.)

GABA is the major inhibitory neurotransmitter. The GABA-A receptor and the closely related glycine receptor have a similar structure to the ACh receptor, but the ion channel is only permeable to the anion Cl^-.[6] When channel opens, Cl^- can diffuse into the cell, creating an inhibitory post-synaptic potential (IPSP) that hyperpolarizes the cell (see Figure 258-3). Since the resting membrane potential in many neurons is close to the equilibrium potential for Cl^-, there may not be much movement of Cl^- across the membrane when the ion channel opens. Nonetheless, the open channel makes it less likely that the post-synaptic cell will reach threshold to generate an action potential since any depolarization will shift the balance towards diffusion of Cl^- into the cell. Commonly used antiepileptic drugs such as diazepam and phenobarbital bind to extracellular sites on the GABA-A receptor. They do not open the ion channel, but they alter the kinetics of the channel, increasing the time the pore is open when GABA binds to its receptor.[8]

The function of the major excitatory neurotransmitter in the central nervous system, glutamate, is more complicated.[6,9] There are two subtypes of ionotropic glutamate receptors named for the drugs which were first used to differentiate them, the AMPA (alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate) and the NMDA (N-methyl-D-aspartate) receptors, which are often found in close proximity. Glutamate must bind to both receptors to produce an effect. Binding to the AMPA receptor partially depolarizes the membrane, releasing a Mg^{++} ion which blocks the NMDA channel. Binding to the NMDA receptor can then allow additional Na^+ conductance, which enhances the EPSP produced by activation of the AMPA receptor. The NMDA channel is permeable to Ca^{++} as well. The increase in intracellular Ca^{++} that results can trigger second messenger systems that have more prolonged effects on the synapse, as discussed below. With excessive NMDA receptor activation, the accumulation of intracellular Ca^{++} can trigger cell death, a process called excitotoxicity.[10]

The second class of neurotransmitter receptors, the metabotropic receptors, includes muscarinic acetylcholine receptors, metabotropic glutamate receptors, GABA-B receptors, and most serotonin receptors, as well as receptors for norepinephrine, epinephrine, histamine, dopamine, neuropeptides and endocannabinoids.[6,9] These receptors act through second messenger systems such as G-proteins and produce more prolonged influences on function. Sometimes these systems indirectly affect ion channel conductance and the same neurotransmitter can have opposite effects depending on the receptor. When ACh binds to the M2 muscarinic ACh receptor, a G-protein binds GTP and dissociates a subunit that then binds to the G-

protein–coupled inward-rectifying potassium channel (GIRK). This opens the ion channel and permits K^+ to diffuse from the cell, hyperpolarizing the membrane. In contrast, M1 receptor activation closes the M-type K^+ channel, producing a prolonged EPSP.[9]

Metabotropic receptors can also mediate long-term changes in synaptic function. For example, the metabotropic glutamate receptor mGluR1 is found in high concentration on Purkinje cells in the cerebellum. When glutamate binds to this receptor, it activates a G-protein, which works through a series of other second messengers to ultimately activate a protein kinase C (Figure 258-4). This removes a phosphate from the AMPA receptor, causing internalization and degradation of the receptor. This makes that synapse less responsive to excitatory glutamatergic stimulation, a process termed long-term depression, which is an essential part of learning and memory. Coton de Tulear dogs with a mutation in the mGluR1 gene *(GRM1)* cannot make these changes as they develop. Thus they have impaired motor learning and severe cerebellar ataxia (Video 258-1).[11] Other metabotropic neurotransmitters will produce long-term potentiation of synaptic strength.

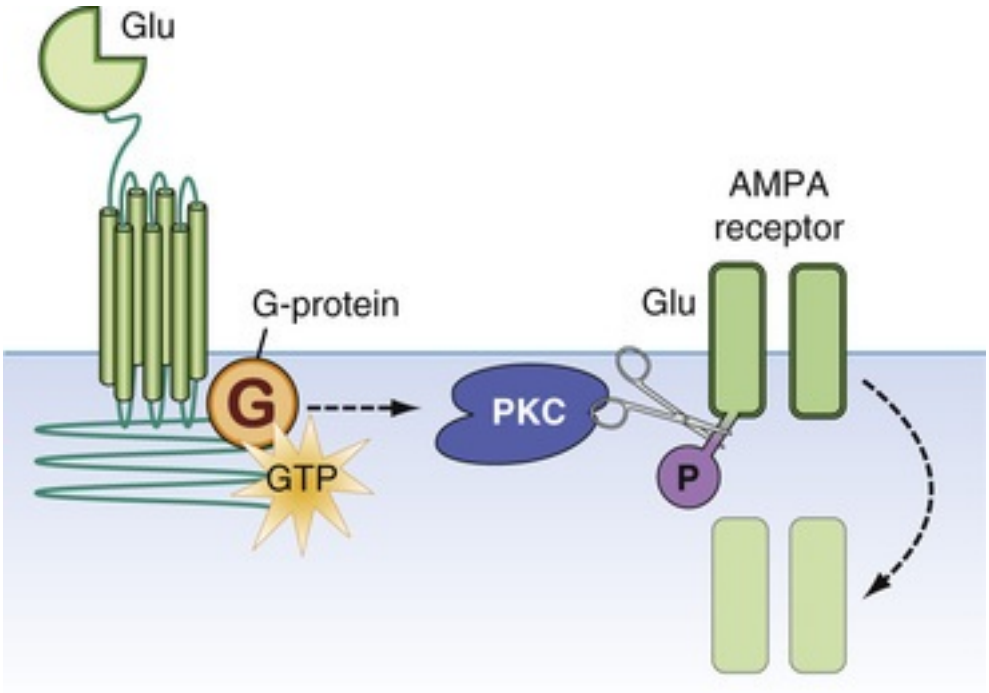

FIGURE 258-4 Activation of the metabotropic glutamate receptor mGluR1 produces long-term changes in synaptic function. Through a series of intermediate steps, the G-protein activates a protein kinase C (PKC), which removes a phosphate from the AMPA receptor. This leads to internalization and degradation of the receptor, weakening the strength of the synapse. This long-term depression of synaptic function is one of the building blocks of synaptic plasticity and learning. (From O'Brien, D.P. Vet Med 8415: Advanced Veterinary Neurology, http://bblearn.missouri.edu, 2015. Used with permission.)

Another class of neurotransmitters that work through metabotropic receptors are the monoamines such as dopamine or serotonin. Dopamine and adenosine act through separate receptors to affect cyclic AMP activity. Stimulating the D2 dopamine receptor decreases cyclic AMP levels and increases arousal. Stimulating the adenosine receptor increases cyclic AMP levels and decreases arousal. Drugs like caffeine block adenosine receptors, leaving dopaminergic activity unopposed and thus increasing arousal.[12]

Serotonin is an important neurotransmitter in the regulation of mood, and deficiency of serotonin activity is thought to be responsible for clinical depression. The activity of serotonin on its post-synaptic receptor is terminated by reuptake of serotonin into the presynaptic terminal by the serotonin transporter. Drugs like fluoxetine selectively block serotonin transporters with fewer effects on the other related monoamine transporters. Such drugs are used to treat separation anxiety and compulsive behaviors in dogs.[13,14]

Maintaining the Machinery: Axonal Transport

All the proteins are synthesized near the nucleus and must be transported through the cytoplasm to the place they are needed. Neurons differ from other cells in that the proteins, vesicles and mitochondria must be transported down the length of the axon, which in an animal like a horse may be meters in length. Damaged proteins and other byproducts must then be transported back to the cell body for degradation and recycling. Thus, a system of axonal transport has evolved to accomplish this task. The cellular railway along which this cargo is transported is composed of microtubules, which run the length of the axon. Two separate molecular engines carry the cargo along the microtubules: kinesins for transporting from the cell body to the nerve terminals (anterograde transport) and dyneins for transporting from the nerve terminal back to the cell body (retrograde transport). These motors utilize ATP to undergo conformational changes and "walk" down the microtubules. Vesicular cargoes move at a consistent, rapid speed. Cytosolic proteins, cytoskeletal proteins and mitochondria were originally thought to move more slowly. Recent research, however, has shown they travel at the same speed but make frequent stops along the way.[15] Toxins or mutations that disrupt axonal transport can result in an accumulation of material in the form of spheroids at the cell body or in the nerve terminal. Failure to supply the nerve terminal adequately can result in dying-back of the longest axons.[16]

Simple Circuitry in the Nervous System

The basic process of excitation and inhibition permits simple circuitry, which can be layered to produce the complex processes of nervous system function. When a single action potential releases an excitatory neurotransmitter, the EPSP produced typically does not reach the threshold to generate another action potential in the post-synaptic neuron. EPSPs from a run of several action potentials can summate to depolarize the post-synaptic membrane above threshold, the process of temporal summation. Alternatively, axons from multiple pre-synaptic neurons may converge on a single neuron. When more than one action potential converges on the neuron simultaneously, the EPSPs can also summate to depolarize the post-synaptic neuron above threshold in the process of spatial summation. In contrast, one excitatory neuron may branch and synapse on many post-synaptic neurons. Such divergent circuits allow for the spread of a signal through multiple second order neurons.

Inhibitory neurons typically function as interneurons in circuits to control excitation. They often synapse closer to the cell body where they can block the propagation of the EPSP to the axon hillock where the action potential would be generated. The Renshaw cell in the spinal cord is an example of an inhibitory interneuron. An excitatory impulse to a motor neuron will also activate the Renshaw cell. The Renshaw cell then inhibits surrounding motor neurons in a process of collateral inhibition. Tetanus toxin blocks glycine release, resulting in excessive excitation of the motor neurons and the classic clinical sign of tetany (see ch. 214).

The inhibition can also be directed at the origin of the excitation. The large pyramidal cells in the cerebral cortex are excitatory, glutaminergic neurons that send long projection fibers from the cortex. A branch of this axon synapses on GABAergic interneurons within the cortex that then synapse back on the pyramidal cell. This feedback inhibition helps prevent excessive firing of the pyramidal cells and a failure of this inhibition may underlie some seizure activity.[17]

Sensory Processing

Combining some of these simple circuits illustrates how the nervous system processes information (Figure 258-5). A sensory stimulus such as touch or light will activate receptors immediately beneath the stimulus more strongly than surrounding receptors. The more strongly stimulated receptors will generate more action potentials than those on the periphery. Divergent innervation from each of these receptors will innervate a number of adjacent post-synaptic cells. Axon branches from both the highly excited central receptors and the less excited peripheral receptors converge on the central, second order neuron. The combination of temporal and spatial summation ensures that the second order neuron reaches threshold to generate an action potential. Branches off this second order neuron's axon synapse on inhibitory interneurons that project to the surrounding second order neurons: lateral inhibition. Though these neurons receive some excitatory inputs, these inputs are much weaker and the lateral inhibition prevents these neurons from reaching threshold. This focuses the excitation on the center of the stimulus while inhibiting the surrounding neuron. When this center-surround programming is spread across whole populations of sensory circuits, it can be used to detect edges and shapes. When combined with the duration and timing of activation of adjacent areas, movement is detected.

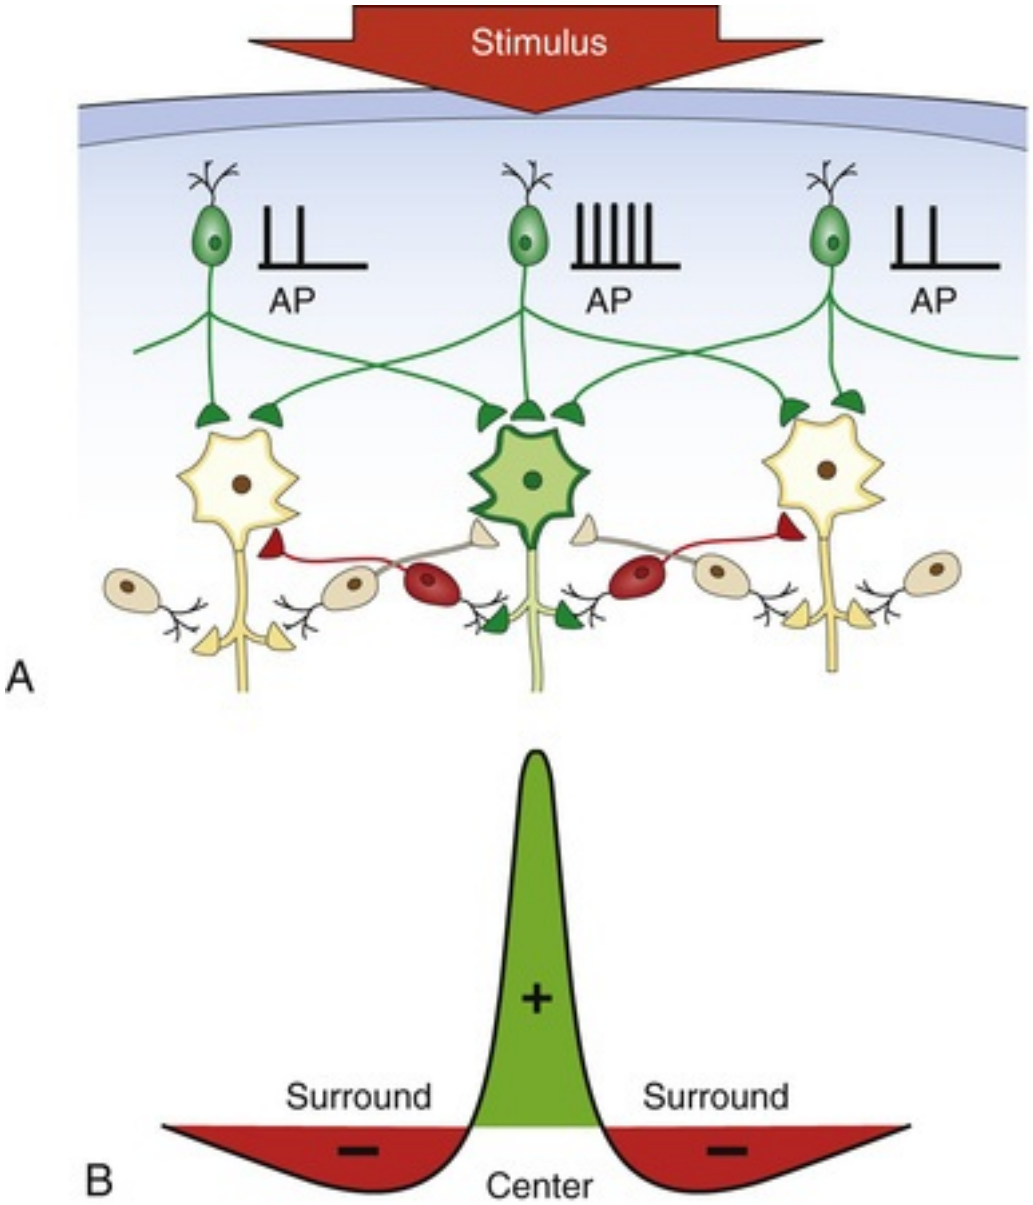

FIGURE 258-5 In sensory systems, the stronger the stimulus on a receptor, the greater the number of action potentials (AP) generated. Convergence of strong and weak excitation from adjacent receptors activates second order neurons at the center of the stimulus **(A).** Lateral inhibition of surrounding second order neurons creates a halo of inhibition that focuses the response to a select group of second order neurons **(B).** (From O'Brien, D.P. Vet Med 8415: Advanced Veterinary Neurology, http://bblearn.missouri.edu, 2015. Used with permission.)

Cognitive Function, Attention and Motivation

In the cerebral cortex and subcortical areas, sensory information is acted upon based on the level of arousal, motivational state, and past experiences of the animal. Arousal of the brain is essential for consciousness and attention. This process is largely mediated by projections to the forebrain from monoaminergic (primarily norepinephrine, dopamine, serotonin and histamine) and cholinergic neurons in the brainstem and basal forebrain,[9] a system sometimes referred to as the reticular activating system. Large lesions within these projection pathways can produce stupor and coma while more selective lesions can affect different aspects of attention or motivation without loss of consciousness.

Motor Control

As in the sensory system, understanding the function of the motor system begins with simple circuits. When a

muscle is stretched, receptors in the muscle spindle are stimulated. The action potentials generated by the stimulus travel to the spinal cord where they synapse directly on the motor neuron that innervates that muscle, producing a contraction. This stretch or myotatic reflex is part of a circuit designed to regulate muscle length and tension but it is also an essential tool of the neurologic examination (see ch. 259). The withdrawal or flexor reflex, another important reflex in the neurologic examination, has a more complex circuitry. When an animal steps on a thorn or the clinician pinches a toe, pain afferents will synapse on interneurons within the spinal cord as well as project to the cerebral cortex, where the pain will be perceived. Completely independent of any perception, however, reflex circuits will respond to protect the limb. Excitatory interneurons within the spinal cord will synapse on the motor neurons to the flexor muscles of the limb, withdrawing it from the noxious stimulus. This sudden flexion of one limb shifts additional weight to the opposite limb. To provide the support needed for that shift, another interneuron crosses over to the opposite side of the spinal cord and excites motor neurons to the extensor of the contralateral limb (Figure 258-6). In normal animals, the crossed-extension component of the reflex will be inhibited by descending motor controls if the animal is in lateral recumbency, and there will be only the withdrawal. If that descending control is abolished by a lesion affecting the upper motor neurons, the crossed-extension reflex is released from inhibition and it occurs when withdrawal is induced. Taking this crosstalk between neurons to another level, central pattern generators can generate rhythmic activities such as walking. Some pattern generators are composed of cells that undergo spontaneous burst firing, but patterns can also be generated through a system of reciprocal inhibition called a half-center.[9] The descending upper motor neuron system facilitates or inhibits these local pattern generators through neuromodulatory inputs to produce normal walking rhythm, which is further modified at the spinal cord level based on sensory feedback. If the normal upper motor neuron control of this process is lost due to a spinal cord lesion, these spinal pattern generators can function spontaneously, resulting in "spinal walking" (Video 258-2).

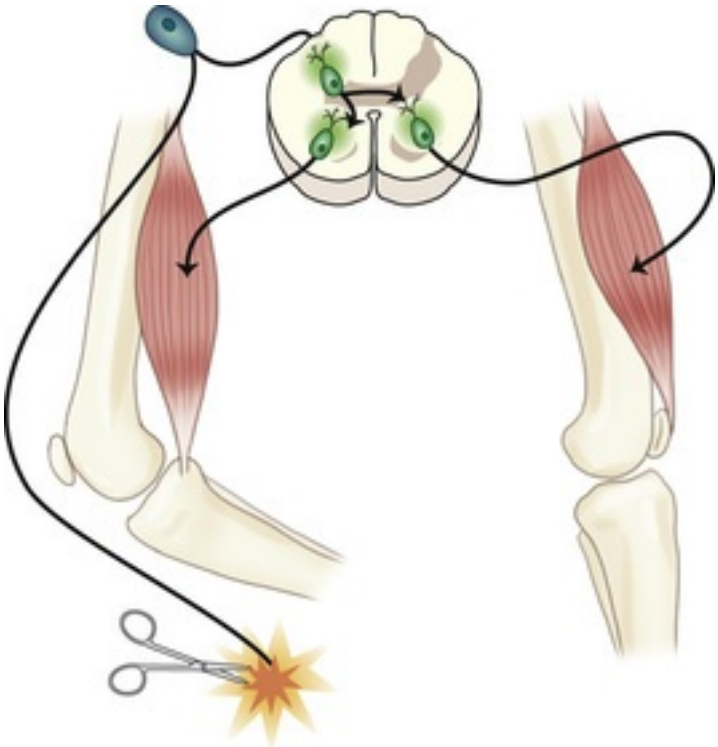

FIGURE 258-6 A painful stimulus to the paw elicits two reflex responses: withdrawal and crossed extension. Pain afferents synapse on an interneuron that excites motor neurons innervating the flexors of the limb. This withdrawal is a reflex independent of conscious perception. Other interneuron fibers cross to the contralateral side and synapse on extensors to bear the increased weight shifted to that side by the withdrawal. The crossed extension component is only seen when there is loss of UMN inhibition of the reflexes. (From O'Brien, D.P. Vet Med 8415: Advanced Veterinary Neurology, http://bblearn.missouri.edu, 2015. Used with permission.)

This hierarchy of control of movement is continued centrally. The position of the head and neck influence

the tone of extensors and flexors in the limbs through tonic neck reflexes, preparing the body for movements based on where the head and neck are directing attention. Different modulatory signals to the spinal pattern generators will produce different gaits. The brainstem locomotor areas that generate these modulatory signals are in turn directed by the cortical and basal nuclear motor systems. These systems are regulated by past experiences through the monoaminergic projections that mediate motivation and arousal.

CHAPTER 259

Neurologic Examination and Neuroanatomic Diagnosis

Scott J. Schatzberg

A precise *neuroanatomic diagnosis* remains indispensable for the generation of an appropriate differential diagnosis. The differential diagnosis allows the clinician to, in turn, interpret neurodiagnostic tests correctly. This chapter is meant to provide the clinician with the basic, functional neuroanatomy and clinical examination skills necessary to make an accurate neuroanatomic diagnosis. It is modeled heavily upon the examination recommended by de Lahunta.[1] Video clips for this chapter demonstrate various components of the neurologic examination and show the salient abnormalities associated with the most common neuroanatomic diagnoses.

The past 15 years have been marked by a dramatic increase in the availability of advanced, neurodiagnostic testing for veterinary patients. Magnetic resonance imaging (MRI), in particular, has enhanced our ability to diagnose complex and elusive neurologic disorders. The "downside" to such advances is that clinicians have developed a natural tendency to rely heavily (or exclusively!) on advanced imaging in patients with neurologic disorders. Although MRI and computed tomography (CT) scans are sensitive for the identification of abnormalities of the central and peripheral nervous systems (CNS and PNS), both imaging modalities lack specificity and may be misleading when interpreted outside the context of the neuroanatomic and differential diagnosis. Despite the exceptional availability of cross sectional imaging, the clinician's ability to successfully diagnose, prognosticate and treat patients with neurological disease remains critically reliant on the neurological examination.

Neurologic Examination

The neurologic examination can be divided into five parts. These include evaluation of (1) sensorium and behavior; (2) posture and gait; (3) postural reactions; (4) muscle mass, tone, spinal reflexes, and cutaneous sensation; and (5) cranial nerves. The order in which the neurologic examination is performed is not critical, but the clinician should develop a consistent routine for evaluating each dog or cat.

Sensorium and Behavior

The owner is often the best judge of changes in a pet's mental attitude and behavior and should be questioned carefully. Examples of behavioral changes include docile pets that have become aggressive (and vice versa) or pets that have forgotten learned habits. Procurement of an accurate history may prove to be critical because behavioral changes may be secondary to intracranial lesions that otherwise have no impact on the neurological examination (also see ch. 9 and 13).

Sensorium should be assessed carefully in recumbent pets. Recumbency may be associated with brainstem, cervical spinal cord, or diffuse neuromuscular disorder (NMDs). Of the three localizations, only brainstem lesions should affect the sensorium. An alteration in sensorium is typically due to a disturbance in the ascending reticular activating system (ARAS) and/or limbic system components of the cerebrum or rostral brainstem (diencephalon). Numerous terms have been used to describe changes in sensorium and/or behavior and include: depression, lethargy, unresponsiveness, stupor, coma, anxiety, disorientation, hyperactivity, hysteria, propulsion, and aggression. Also see ch. 148.

Posture and Gait

Posture

The clinician should evaluate posture when the pet is standing and walking. The patient should be assessed for a head tilt (e.g., vestibular disease); a head or body turn (e.g., rostral brainstem or cerebral disease); neck position (e.g., lowered with cervical spinal cord or diffuse neuromuscular disease); hock angle (e.g., plantigrade with peripheral neuropathies); evidence of trembling (e.g., neuromuscular disease) and tail position (e.g., flaccid with lumbosacral disease). The clinician also should recognize breed-specific alterations in posture such as sunken tarsi in German Shepherd Dogs.

Severe intracranial lesions may lead to two separate opisthotonic postures: *decerebrate* or *decerebellate rigidity*. Decerebrate rigidity is characterized by opisthotonus with rigid extension of the neck and all four limbs, and is typically associated with midbrain or rostral cerebellar lesions. Decerebellate rigidity results from severe cerebellar lesions and is characterized by opisthotonus with extensor rigidity of the limbs, but with the hips flexed.

Pleurothotonus refers to the deviation of the head and neck to one side and may be present with mid to rostral brainstem or cerebral lesions.

Gait

Strength and coordination are the key gait components to be evaluated. Gait should be assessed in an area where the pet may move with or without a leash (if possible), and always on a non-slippery surface. Pattern recognition of gait abnormalities is a key component of the neuroanatomic diagnosis.

Paresis

Paresis refers to an inability to support weight or a deficiency in the ability to generate a gait. In neurologic patients, paresis may result from a lesion in the lower motor neuron (LMN)/neuromuscular system, the upper motor neuron (UMN) system, or both.

Animals with "LMN paresis" manifest a wide variation in their ability to support weight. Thoracic or pelvic limbs (or both sets of limbs with diffuse LMN disease) may be affected. A dog with a mild to moderate NMD may be ambulatory with a "short and choppy" stilted gait (Videos 259-1 and 259-41), whereas a patient with a severe NMD actually may be tetraplegic. Some ambulatory pets with LMN disease advance both pelvic limbs simultaneously, but this also may occur with orthopedic and spinal cord disorders.

Animals with "UMN paresis" also may have considerable variation in their ability to generate a gait. Depending on the location of a spinal cord or mid-to-caudal brainstem lesion, thoracic and/or pelvic limbs may be affected with UMN signs. Ambulatory pets with UMN paresis walk with a long-strided, spastic gait that is typically accompanied by *general proprioceptive (GP) ataxia* (Videos 259-2 and 259-39). The latter occurs because the majority of the key UMN pathways (reticulospinal and rubrospinal tracts) that function in gait generation are anatomically adjacent to GP pathways (spinocerebellar tracts and conscious proprioceptive pathways). Spinal cord and mid- to caudal brainstem lesions disrupt descending UMN pathways and ascending GP pathways, resulting in variable degrees of paresis and ataxia.

Some clinicians utilize a grading scheme for spinal cord lesions to help prognosticate and monitor treatment response. Such grading schemes evaluate the gait with respect to strength and proprioception. Grading schemes typically are on a 0 to 5 scale but are somewhat inconsistent; some utilize grade 0 as normal, whereas others are reversed (e.g., grade 5 is normal). If a grading scheme is utilized, clinicians should qualify the grade with descriptors of strength, proprioception, and nociception (in recumbent pets) to avoid confusion. For spinal cord lesions, the degree of dysfunction recently has been classified using a modified Frankel score.[2,3]

Grade 0: tetraplegia or paraplegia with no deep nociception
Grade 1: tetraplegia or paraplegia with no superficial nociception
Grade 2: tetraplegia or paraplegia with nociception
Grade 3: nonambulatory tetraparesis or paraparesis
Grade 4: ambulatory tetraparesis or paraparesis and GP ataxia
Grade 5: spinal hyperesthesia only (grade 5) or no dysfunction

Ataxia

Three clinical forms of ataxia (incoordination) exist: (1) GP ataxia, (2) vestibular ataxia, and (3) cerebellar ataxia.

GP ataxia previously was mentioned in relation to UMN paresis because the two typically occur simultaneously. GP ataxia results from disruption of the ascending long tracts that relay the spatial location and the degree of muscle contraction of the limbs, trunk, and neck. When ascending GP information fails to

reach the brain, incoordination results. This incoordination may include crossing the limbs, scuffing or dragging of the digits, standing or landing on the dorsal aspect of the paws, and sometimes a delay in the swing phase of the gait. Together with the UMN signs, this produces a relatively characteristic gait that reflects both UMN paresis and GP ataxia (see Videos 259-2 and 259-39).

Vestibular ataxia results from a loss of orientation of the head with respect to the eyes, neck, limbs, and trunk. Pets with vestibular disease may lose their balance and have a tendency to drift, lean, or fall in one direction (Video 259-3). A head tilt and abnormal nystagmus commonly accompany vestibular ataxia (Video 259-28). With peripheral vestibular lesions, pets maintain normal strength and proprioception, but with central vestibular lesions, UMN tetraparesis and GP deficits typically are present (Video 259-34).

Cerebellar ataxia is characterized by a hypermetric gait with sudden bursts of motor activity (Video 259-4). Cerebellar hypermetria may be differentiated from a UMN gait by a marked *overflexion* of the limbs on protraction; occasionally, this differentiation is challenging. Because of the close connection between cerebellum and vestibular systems, a head tilt, loss of balance, and abnormal nystagmus may be seen with cerebellar lesions (Video 259-35).

Postural Reactions

Following the gait observation, postural reactions should be evaluated to identify subtle deficits of strength and coordination. A pet's ability to perform postural reactions requires that all major sensory (GP) and motor (UMN and LMN) components of the central nervous system (CNS) and peripheral nervous system (PNS) be intact. Although many clinicians use postural reactions to assess conscious proprioception, or "CP," this is a misnomer because all postural reactions rely on both the motor and proprioceptive systems. Furthermore, when assessing postural reactions, both the conscious and unconscious sensory pathways are tested; deficiencies in these two key components of GP cannot be separated practically.[1]

The clinician should be cautious when interpreting postural reaction deficits because they are not of localizing value when performed without other components of the neurologic examination (Figure 259-1). For example, a recumbent dog or cat with a severe and diffuse NMD *or* one with a severe cervical spinal cord lesion may have delayed (to absent) postural reactions in all four limbs. Close assessment of spinal reflexes, as well as muscle mass and tone, is necessary to differentiate between these two localizations. Another example would be that of a patient with unilateral postural reaction deficits, which has several possible localizations including a unilateral lesion of the prosencephalon (cerebrum and/or thalamus), brainstem, or spinal cord. Unilateral prosencephalic lesions typically result in *contralateral* postural reaction deficits with a normal gait (and potentially accompanied by a contralateral menace deficit, contralateral sensory deficits, and changes in sensorium) (Video 259-33). Unilateral (caudal) brainstem or spinal cord lesions cause *ipsilateral* postural reaction deficits. The presence of cranial nerve abnormalities and/or changes in sensorium may help to differentiate between the two localizations and suggest brainstem dysfunction.

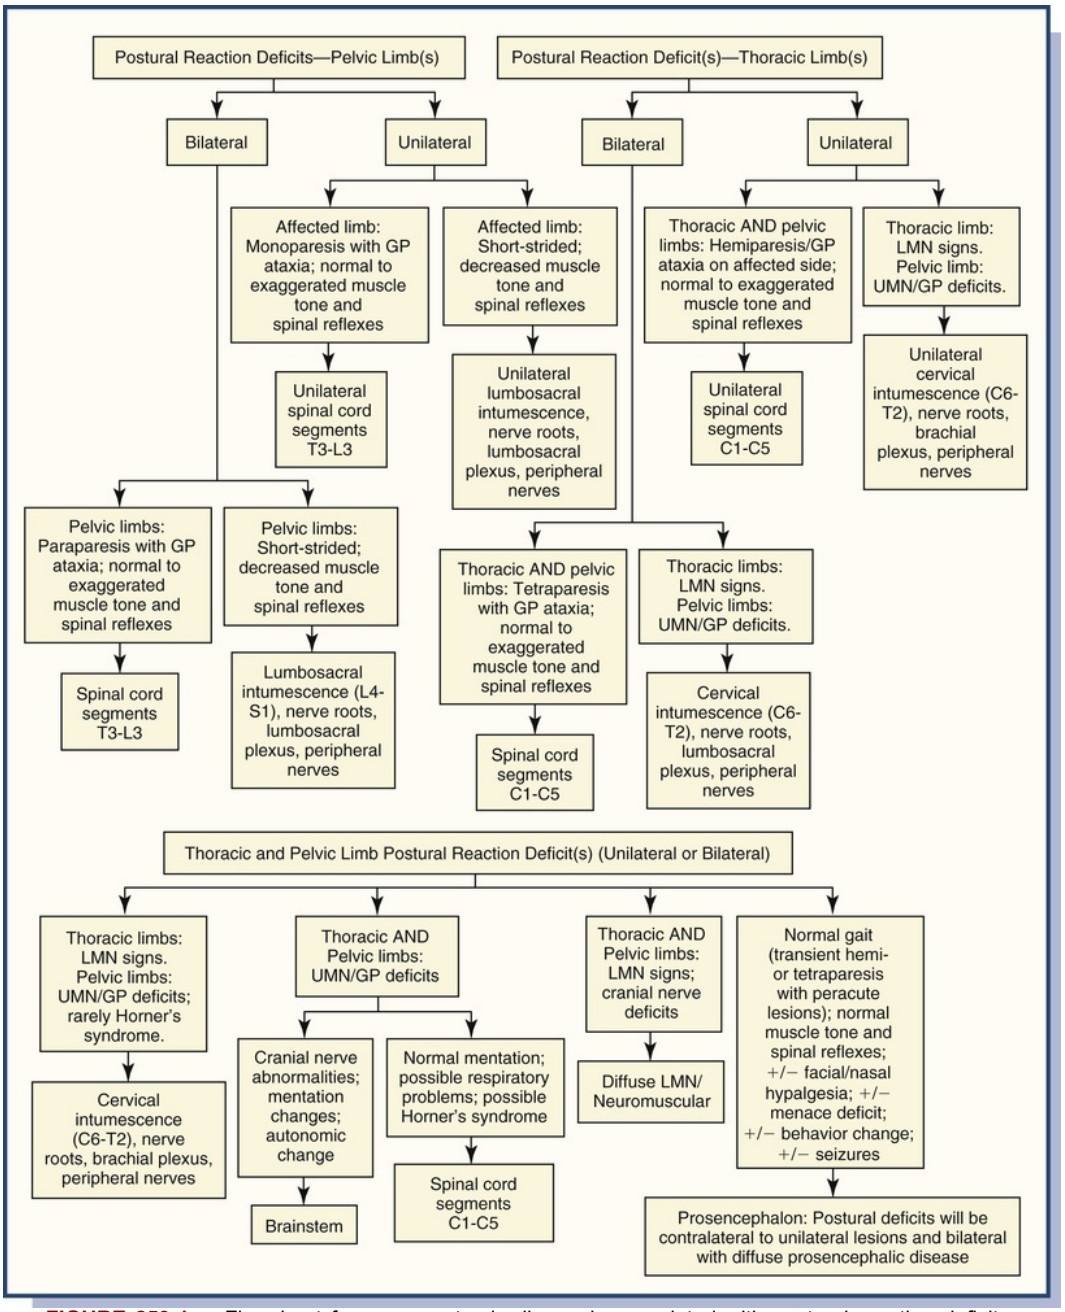

FIGURE 259-1 Flowsheet for neuroanatomic diagnosis associated with postural reaction deficits. *GP,* General proprioceptive; *LMN,* upper motor neuron; *UMN,* upper motor neuron.

In recumbent patients, postural reaction testing may help to differentiate between UMN and LMN tetraparesis. A dog with "pure" LMN disease that maintains some voluntary movement should have relatively normal postural reactions (if most of the body weight is supported) (see Video 259-41). This is because the GP system is unaffected by pure LMN disease. Conversely, a recumbent pet with a brainstem or spinal cord lesion will have delayed to absent postural reactions in all four limbs.

Hopping and placing responses are the most useful postural reactions (Videos 259-5, 259-6, and 259-7). However, additional testing (e.g., wheelbarrowing, extensor postural thrust) may prove useful when these responses are equivocal.

Postural Reaction Tests

Hopping

While supporting the pelvic limbs, the pet should be hopped on one thoracic limb while the other thoracic

limb is held off the ground. The pet should be moved laterally. Limb strength and coordination should be observed in comparison with one another (see Video 259-5). The clinician should observe the lateral aspect of the thoracic limb being tested; the limb should move as soon as the shoulder is moved laterally over the paw. Any delay, irregularity, or exaggeration in this response is abnormal. Delayed hopping (symmetric or asymmetric) may occur with a motor (UMN or LMN) or sensory (GP) lesions. Commonly, both the UMN and GP systems (e.g., brainstem and spinal cord diseases) are affected simultaneously and the abnormal hopping response is a reflection of both (e.g., UMN/GP deficits). Lesions in the GP system or cerebellum may produce exaggerated responses (see Video 259-6).

Hopping responses in the pelvic limbs should be evaluated similarly. While supporting the chest and thoracic limbs, one pelvic limb should be held up and the dog or cat hopped laterally on the supporting limb. The pelvic limb hopping responses should be compared with one another (not to thoracic limbs) (see Video 259-6). Typically, pelvic limb hopping responses are more spastic, with a slightly larger excursion than the thoracic limbs.

Paw Replacement, Tactile Placing Responses

Paw replacement responses assess whether the dog or cat corrects its paw position after it has been flexed so that weight is borne on its dorsal surface (see Video 259-7). Normal pets quickly return their paw to the normal anatomic position. Paw replacement responses should be performed on both thoracic and pelvic limbs individually. The clinician should support most of the pet's weight during the test. Although some clinicians attribute a delay in paw replacement response to diminished CP (e.g., "CP deficit"), this is a misinterpretation of the test for three reasons: (1) A severely paretic animal with a pure LMN disease (e.g., myasthenia gravis) may have delayed (or even absent) paw replacement, despite having no lesion in the CP system (e.g., the dog may be too weak to return its paw to the normal anatomical position); (2) paw replacement responses do *not* isolate the CP pathways from the other afferent sensory pathways (e.g., spinocerebellar tracts) of the PNS and CNS; and (3) rarely (and inexplicably!) some pets without neurologic disease have delayed paw replacement responses.

Tactile placing responses typically are performed in cats or small dogs. The pet should be supported off the ground and its thoracic limbs should be brought to the edge of a table so that the dorsal surface of the paws makes contact (Video 259-8). The pet should step quickly onto the table with the correct anatomic position. The test should be performed on the thoracic limbs simultaneously and individually. It may help to cover the pet's eyes because vision may compensate for sense of position when the GP system is abnormal.

Extensor Postural Thrust

Although this test is performed only occasionally, it may be helpful in patients with subtle pelvic limb signs. The pet should be held off the ground and supported caudal to the scapulae, lowered to the ground, and allowed to extend its pelvic limbs to support its weight. Moving the pet forward and backward tests symmetry of pelvic limb strength and coordination (Video 259-9).

Hemiwalking

This postural reaction is not performed routinely but it may be useful in large dogs. On one side of the body, the thoracic and pelvic limbs should be held off the ground and the dog then forced to walk forward or to the side. Healthy dogs hop smoothly on both thoracic and pelvic limbs (Video 259-10).

Wheelbarrowing

This postural reaction also is performed rarely, but it may be helpful in patients with subtle thoracic limb deficits. The pet should be supported under the abdomen so that the pelvic limbs are held off the ground and then walked on its thoracic limbs (Video 259-11). With this posture, vision is compromised and the animal relies heavily on GP. With the head extended in normal position, dogs and cats should walk with symmetric movements of both thoracic limbs. With severe lesions, patients may carry their head flexed with the nose oriented close to the ground for support.

Muscle Mass, Tone, Spinal Reflexes, and Cutaneous Sensation

Muscle mass and tone, spinal reflexes, and cutaneous sensation should be evaluated when a dog or cat is relaxed, preferably in lateral recumbency. It is helpful to evaluate responses to noxious stimuli last, to maintain cooperation.

Muscle Mass and Tone

The head, neck, and thoracolumbar epaxial muscles should be evaluated for symmetry and any evidence of atrophy. Each thoracic and pelvic limb should be assessed similarly, from proximal to distal. Muscle tone should be evaluated by passive range of motion of each limb. Degree of resistance should be assessed as normal, hypotonic, or hypertonic/spastic. Degree of hypertonicity/spasticity may vary from mild to marked, with the latter occasionally associated with a "clasp knife" response ("clasp knife" refers to attempts made to flex the limb that actually *increase* the degree of extension of the limb until it suddenly gives way to complete flexion without resistance).

Hypertonia or spasticity typically results from lesions in the UMN pathways (although it also may be seen with myotonic disorders) (Videos 259-12 and 259-15). The UMN normally influences activity of the LMN to facilitate voluntary motor activity and to maintain muscle tone, supporting the body against gravity. Lesions disrupting the UMN pathways may "release" the LMNs from inhibition, leading to overactivity of the facilitatory mechanism (see ch. 258).

Conversely, hypotonia is associated with LMN/neuromuscular disease (Video 259-13). The functional integrity of the complete "LMN unit" (cell body, nerve root, peripheral nerve, neuromuscular junction, and muscle) is necessary to produce muscle cell contraction and to effectively maintain muscle tone. When the LMN unit is diseased, one consequence is a loss of muscle tone. With LMN disease, denervation also may lead to muscle cell degeneration and neurogenic atrophy may be appreciable.

Tetraplegic dogs should be supported in a standing position, and the clinician should evaluate limb muscle tone and voluntary responses. Dogs with cervical spinal cord disease often have hypertonic limbs while the trunk and limbs may feel spastic. Occasionally, the hypertonia associated with cervical spinal cord disease is so profound that the pet can maintain a standing position even when unsupported. Conversely, tetraplegic dogs with diffuse LMN/neuromuscular disease typically are hypotonic (or atonic) and collapse when the clinician attempts to support them in a standing position. It is critical to differentiate between UMN and LMN tetraplegia because the differential diagnoses are markedly different, as are diagnostics, management, and treatment recommendations.

Spinal Reflexes

Although most neurology textbooks describe numerous tendon and muscle reflexes, the majority are of limited use because they are not present in all normal small animals. The most reliable reflexes are the patellar reflex and withdrawal-flexor reflexes described later. The other spinal reflexes are considered briefly.

Patellar Reflex

The most reliable tendon reflex is the patellar reflex, which is mediated by the femoral nerve through spinal cord segments L4-L7. With the limb held in partial flexion, the clinician should elicit this reflex by lightly tapping the patellar tendon with a plexor or pediatric hammer (Video 259-14). This reflex should be tested with the pet in *both* lateral recumbencies. For inexplicable reasons, this reflex commonly is elicited more easily in the limb adjacent to the floor. It is noteworthy that one or both patellar reflexes may be absent in older dogs with no other neurologic signs.[4] Responses are typically graded as absent (0), hyporeflexive (+1), normal (+2), hyperreflexive (+3), or clonic (+4). An absent or hyporeflexive reflex occurs when there is a disease of a portion of the reflex arc (most commonly in the LMN unit). Hyperreflexia or clonus may be present in UMN diseases (see Video 259-15).

Biceps and Triceps Reflexes

In the thoracic limb, the biceps and triceps reflexes often can be elicited in relaxed pets that are in lateral recumbency. The clinician should place a finger on and tap the distal ends of both biceps and brachialis muscles at the level of the elbow. A normal response is slight flexion of the elbow. The musculocutaneous nerve mediates the biceps reflex through spinal cord segments C6-C8. The triceps reflex is elicited by lightly tapping the tendon of insertion of the triceps muscle proximal to the olecranon. This causes slight extension of the elbow. The radial nerve mediates the triceps reflex through spinal cord segments C7-T2.

Withdrawal-Flexor Reflexes—Thoracic and Pelvic Limbs

Withdrawal-flexor reflexes assess the integrity of the thoracic and pelvic limb withdrawal reflex arcs. They are elicited by applying pressure to the base of the toenail with a firm, manual pinch or with hemostats (Videos 259-16 and 259-17). A normal response is an immediate, strong withdrawal of the limb with complete

flexion of all joints. Animals with reduced withdrawal-flexor reflexes occasionally extend or kick the limb in response to the noxious stimulus (Videos 259-18 and 259-19). In the thoracic limb, the thoracodorsal, axillary, musculocutaneous, median, ulnar, and radial nerves are responsible for flexion of the shoulder, elbow, carpus, and digits. The nerves responsible for this reflex arise from spinal cord segments C6-T2. The specific sensory nerve stimulated depends on the location of the noxious stimulus. The median and ulnar nerves innervate the skin of the palmar surface of the paw; the radial nerve innervates the dorsal surface and the cranial and lateral surfaces of the antebrachium. The ulnar and musculocutaneous nerves innervate the caudal and medial surfaces, respectively. One must be cautious not to overinterpret the autonomous zones because there is some overlap of the cutaneous innervation supplied by these nerves and a degree of individual patient variation.

Deficiencies in the thoracic limb withdrawal-flexor reflex (see Videos 259-18, 259-39, 259-41, and 259-42) suggest a C6-T2 lesion (spinal cord segments, nerve roots, brachial plexus, peripheral nerves) or potentially a more diffuse LMN/NMD (the latter would be accompanied by reduced pelvic limb reflexes, reduced tone, and other neuromuscular signs). It has been suggested that dogs with C1-C5 spinal cord lesions may *mislocalize* to C6-T2 because of reduced withdrawal reflexes that may be present in the thoracic limbs.[5] The explanation for this phenomenon is unclear.

In the pelvic limb, the withdrawal-flexor reflex is mediated by the sciatic nerve through spinal cord segments L6-S1. Lesions of the motor component of the sciatic nerve (distal to the pelvis) may result in hypotonia, atrophy, and paralysis of the flexors of the stifle, tarsus, and digits, as well as of the extensors of the hip, tarsus, and digits. With sciatic lesions, pelvic limb withdrawal-flexor reflexes will be reduced to absent (see Video 259-19). Dogs and cats can walk with sciatic nerve paralysis, but the tarsus is typically "dropped," or closer to the ground than normal, on the affected side (tibial dysfunction) and the paw is often misplaced on the dorsal surface (peroneal dysfunction); however, the limb can support weight if the femoral nerve is intact.

Sensory branches of the peroneal and tibial nerves innervate the dorsal and plantar surfaces of the pelvic limb paw, respectively. The saphenous nerve (branch of the femoral entering the spinal cord at L4-L6) innervates the medial aspect. Therefore, animals with a severely contused sciatic nerve typically maintain sensation to the medial aspect of the paw. If the medial surface of the paw is stimulated in a pet with a pure sciatic injury, the animal will flex the hip because of intact innervation of the iliopsoas muscle, but the stifle, tarsus, and digits will *not* flex. Therefore, both the medial and lateral surfaces of the pelvic limb paw should be tested for the withdrawal-flexor reflex and also for nociception (see later).

Crossed Extensor Reflex

Recumbent pets with lesions of the UMN pathways may have a crossed extensor reflex when the withdrawal-flexor reflex is evaluated. Reflex extension may occur in the opposite limb to that being tested. Although typically abnormal and indicative of UMN disease, normal dogs occasionally have crossed extensor reflexes. To avoid voluntary extension of the contralateral limb as a response to the noxious stimulus, the withdrawal-flexor reflex should be elicited with a *mild* pinch while the opposite limb is observed.

Perineal Reflex

The perineal reflex is elicited by stimulation of the anus with a mild, noxious stimulus. The anal sphincter and tail should be observed for contraction and flexion, respectively. The perineal reflex is mediated by branches of the sacral and caudal segments of the spinal cord through the pudendal nerve.

Cutaneous Trunci Reflex

This reflex is observed as a contraction of the cutaneous trunci muscle in response to mild stimulation of the dorsal skin of the trunk. It can be elicited from the thoracic and most of the lumbar region. Regional segmental spinal nerves carry sensory impulses (Video 259-20) into the spinal cord, where they are relayed cranially to spinal cord segment C8. At this level, a synapse occurs on the LMNs of *both* lateral thoracic nerves that innervate the cutaneous trunci muscle. This reflex may require multiple attempts to elicit; rarely, normal dogs and cats manifest no reflex. This reflex may be particularly useful in diagnosing the level of a transverse thoracolumbar spinal cord lesion or for monitoring a progressive spinal cord injury (e.g., ascending or descending myelomalacia). Typically, the reflex is preserved for one to two vertebral bodies caudal to the level of the spinal cord lesion.

Nociception (Pain Perception)

In recumbent animals, the clinician may apply a noxious stimulus to a digit (Video 259-21). This generates afferent impulses that enter the spinal cord via peripheral nerves and associated dorsal nerve roots that are relayed to bilateral tracts in the lateral funiculi of the spinal cord. These tracts ascend the spinal cord and continue through the medulla, pons, and midbrain to specific nuclei in the thalamus for relay to somatic sensory areas of the cerebral cortex. A positive response is evidenced by vocalization, turning of the head, or dilation of the pupils when the impulses reach the thalamus or cerebrum.

Although several grading schemes for spinal cord injury differentiate between superficial and deep pain perception, this can be extremely challenging and is not typically necessary. However, it is *critical* to differentiate nociception from the withdrawal component of the withdrawal-flexor reflex (see earlier). *Animals with transverse spinal cord lesions maintain the withdrawal reflex and this should* ***not*** *be mistaken for intact nociception*.

Cranial Nerves

It is important to develop a systematic method for evaluation of the cranial nerves. This component of the neurologic examination is ideally performed with a dog or cat that is cooperative. This section offers a stepwise approach for evaluation of the cranial nerves by assessment of (1) vision and pupillary light responses (PLRs), (2) palpebral fissure and third eyelid symmetry, (3) eyeball position and movement, (4) vestibular function, (5) facial and trigeminal function, and (6) tongue and laryngeal-pharyngeal function. The clinical signs associated with cranial nerve dysfunction are summarized in Table 259-1.

TABLE 259-1

Function, Testing, and Clinical Signs Associated with Cranial Nerve Dysfunction

CRANIAL NERVE	FUNCTION	TEST	CLINICAL SIGNS OF DYSFUNCTION
CN I Olfactory	Smell	Not routinely tested	Anosmia; hyposmia
CN II Optic	Vision; response to light	Menace response; PLR; obstacle course; tracking moving objects	Blindness; dilated or unresponsive pupils
CN III Oculomotor	Motor to extraocular muscles; parasympathetic to pupil	Physiologic nystagmus; resting eyeball position; pupillary light responses	Ventrolateral strabismus; ptosis; dilated pupils; diminished to absent PLRs
CN IV Trochlear	Motor to dorsal oblique muscle	Resting eyeball position (cat); fundic examination (dog)	Dorsomedial strabismus (cat); lateral deviation of retinal vein (dog)
CN V Trigeminal	Motor to muscles of mastication (mandibular); sensory to face (ophthalmic and maxillary)	Jaw tone; muscle bulk; sensation to face, cornea, and nasal mucosa	Masticatory muscle atrophy; dropped jaw if bilateral; decreased or absent facial/nasal sensation
CN VI Abducent	Motor to lateral rectus and retractor bulbi	Physiologic nystagmus; resting eyeball position	Medial strabismus
CN VII Facial	Motor to muscles of facial expression; parasympathetic to lacrimal glands; sensory (taste) to rostral tongue	Menace response; palpebral reflex; lip retraction; ear movement; Schirmer tear test	Inability to close eyelid, move ear, or retract lip; hemifacial tetany; deviation of nasal philtrum (contralateral); dry eye
CN VIII Vestibulocochlear	Balance; hearing	Body and head posture; gait; eye movement and position; hearing	Head tilt; vestibular ataxia; nystagmus; positional strabismus; deafness
CN IX Glossopharyngeal	Sensory and motor to pharynx	Gag reflex; ability to swallow	Diminished gag reflex; dysphagia
CN X Vagus	Sensory and motor to pharynx, larynx, and viscera	Gag reflex; oculocardiac reflex	Diminished gag reflex; dysphagia; laryngeal paralysis; megaesophagus

CN XI Accessory	Motor to trapezius	Evaluation of muscle mass	Atrophy of trapezius
CN XII Hypoglossal	Motor to tongue muscles	Evaluation of tongue	Atrophy of tongue; inability to retract tongue if bilateral

PLR, Pupillary light response.

Vision and Pupillary Light Responses (II, III, VII)

The menace response is the most reliable test for vision assessment in animals. It is a learned response that may not be present until 10 to 12 weeks of age in puppies and kittens (tracking of moving objects may be helpful in such young animals). The menace response requires a functional optic nerve, optic tract (diencephalon), and optic radiation up to the occipital cortex, as well as the efferent pathway that includes the facial neurons. Although the exact mechanism is unknown, a functional cerebellum also is required for the menace response.[1] The majority of the visual pathway caudal to the optic chiasm is contralateral to the eye being tested. With one pet eye covered, the clinician should make a menacing gesture toward the open eye (with careful attention not to touch or stimulate the pet with air currents!) (Video 259-22).

A normal menace response is manifested as complete eyelid closure. Eyelid closure is dependent on normal facial nerve innervation of the orbicularis oculi muscle. If the menace is absent or delayed, the eyelids must be assessed for their ability to close by eliciting the palpebral reflex (Video 259-23). If facial paralysis is present, eyeball retraction, elevation of the third eyelid, and head retraction may help in the assessment of vision (Video 259-29). Alternatively, the patient's ability to navigate an obstacle course can be evaluated.

Following the menace responses, the clinician should evaluate pupil size and PLRs (Video 259-24). Pupils should be assessed for symmetry in ambient light and a dark room. A bright light source should then be directed into each eye individually (Video 259-25). Normal pets have rapid constriction of the pupil into which the light is directed (direct PLR) and the opposite pupil also should constrict (indirect or consensual PLR). The indirect response occurs because the majority of the optic nerve fibers cross at the optic chiasm and again at the level of the pretectal nucleus, stimulating the parasympathetic oculomotor nuclei bilaterally.

In addition to optic and oculomotor nerve lesions, there are several possible localizations for PLR deficits (Table 259-2). If a direct PLR is not elicited in one eye, the clinician should direct the light as close to that eye as possible and move the light to all aspects of the ocular fundus. If no response is present, the clinician should swing the light to the responsive pupil and the nonresponsive pupil should be assessed for constriction. If nonresponse is the result of an ocular or optic nerve lesion, it will constrict when light is directed into the contralateral eye (e.g., positive indirect PLR). Such testing may need to be repeated multiple times to differentiate between an ocular/optic and oculomotor nerve problem.

TABLE 259-2

Lesion Locations (Right-Sided Lesions Only, as an Example) and Associated Resting Pupil Size, Pupillary Light Responses (PLRs), and Menace Responses

	LESION LOCATION				
RESTING PUPIL SIZE, PLRs, MENACE	**RIGHT CN II *(OPTIC NERVE)***	**RIGHT CN III *(OCULOMOTOR NERVE)***	**RIGHT RETROBULBAR**	**RIGHT OPTIC TRACT *(THALAMUS)***	**RIGHT OCCIPITAL CORTEX**
Left Pupil					
Resting size	Normal size	Normal size	Normal size	Normal size	Normal size
PLRs	Light in left eye, both pupils constrict	Light in left eye, only left pupil constricts	Light in left eye, only left pupil constricts	Light in left eye, both pupils constrict	Light in left eye, both pupils constrict
Left menace	Positive	Positive	Positive	Severe deficit	Severe deficit
Right Pupil					
Resting size	Normal to partial dilation	Complete dilation	Complete dilation	Normal size	Normal size

PLRs	Light in right eye, neither pupil constricts	Light in right eye, only left pupil constricts	Light in right eye, neither pupil constricts	Light in right eye, both pupils constrict	Light in right eye, both pupils constrict
Right menace	Negative	Positive	Negative	Mild deficit	Mild deficit

Palpebral Fissure and Third Eyelid Symmetry (III, V, Sympathetic Nerves)

The clinician should observe the palpebral fissures for size and symmetry. A reduced fissure size (ptosis) may be due to dysfunction of cranial nerve III (oculomotor) with secondary paresis of the levator palpebrae superioris muscle, dysfunction of cranial nerve V (mandibular branch of trigeminal nerve) with secondary atrophy of the masticatory muscles (Video 259-26), or sympathetic dysfunction with loss of orbitalis smooth muscle tone. Atrophy of the masticatory muscles or sympathetic dysfunction both may result in third eyelid elevation.

Eyeball Position and Movement (III, IV, VI, VIII)

While examining the head, the clinician should assess whether or not each eye is in a central position within the orbit, which requires normal function of the peripheral and central components of the vestibular system; cranial nerves III (oculomotor), IV (trochlear), and VI (abducent); and the extraocular muscles that they innervate. Ventrolateral strabismus is associated with oculomotor nerve dysfunction, a medial strabismus with abducent nerve dysfunction, and eyeball extorsion with trochlear nerve dysfunction. Trochlear dysfunction in cats causes a lateral rotation of the dorsal aspect of the pupil, which cannot be recognized on external ocular examination in dogs because their pupils are round. In dogs, fundic examination is required and would show lateral deviation of the retinal vein.

Vestibular Function (VIII)

Physiologic nystagmus (oculocephalic or oculovestibular responses) is evaluated by moving the head in a horizontal plane from side to side (Video 259-27). This stimulates cranial nerve VIII to relay impulses to the brainstem, on to the vestibular nuclei and the medial longitudinal fasciculus, and finally to abducent and oculomotor neurons for abduction and adduction of the eyeball, respectively.

Strabismus and nystagmus commonly are associated with dysfunction of the vestibular system. A positional, ventrolateral strabismus commonly is associated with vestibular disease. Nystagmus is an involuntary oscillation of the eyeball (see Video 259-28). Resting or spontaneous nystagmus is continual and observed when the head is in any position, whereas positional nystagmus is seen only when the head is held in certain positions. The latter often is seen in patients that have accommodated for lesions in the vestibular system. Occasionally, positional nystagmus can be elicited in compensated patients placed on their backs with their head and neck extended. Utility of nystagmus for vestibular lesion localization is reviewed in the Neuroanatomic Diagnosis section of this chapter.

Facial and Trigeminal Nerve Function (V, VII)

The clinician should evaluate the palpebral reflex by gently touching the medial and lateral canthi of the eye (see Videos 259-23 and 259-29). A normal response is an immediate, complete closure of the palpebral fissure. Sensory branches (ophthalmic—medially, maxillary—laterally) of the trigeminal nerve mediate the afferent arm of the palpebral reflex, and the palpebral branch of the facial nerve mediates the efferent motor arm. The clinician also should assess the symmetry of the face. A lip or ear droop (see Video 259-29) or unilateral salivation suggests facial nerve dysfunction. Occasionally, the nasal philtrum will be deviated toward overstimulated facial muscles due to facial tetany.

To evaluate the mandibular branch of the trigeminal nerve, the clinician should evaluate the temporalis and masseter muscles for size and symmetry. With unilateral mandibular nerve dysfunction (e.g., trigeminal nerve sheath neoplasm), no loss of jaw function will be appreciable but profound muscle atrophy may be present (see Video 259-26). With bilateral mandibular nerve dysfunction (e.g., idiopathic trigeminal neuritis), the patient may have a dropped jaw and drool excessively (Video 259-30). Mandibular paralysis may be accompanied by facial hypalgesia depending on the extent of involvement of the ophthalmic and maxillary sensory nerves.

Trigeminal sensory function is most easily evaluated by testing nasal sensation. The clinician should gently touch the medial aspect of the nasal mucosa with the tip of a pen or closed hemostats (Video 259-31).

Normal patients will quickly pull their head away (stoic patients occasionally will not object). This test evaluates two neural pathways. First, it tests the ipsilateral branch of the ophthalmic nerve that innervates the nasal mucosa. It also tests the nociceptive pathways that project to the contralateral thalamus and somesthetic cerebral cortex. Therefore, nasal hypalgesia must be interpreted in light of the remainder of the neurological examination. It may indicate an *ipsilateral* trigeminal nerve lesion or a *contralateral* prosencephalic lesion (see Video 259-33).

Tongue and Laryngeal-Pharyngeal Function (IX, X, XII)

The clinician may use the "gag-reflex" to simultaneously evaluate the glossopharyngeal, vagus, and hypoglossal cranial nerves. Upon opening the patient's mouth, the tongue first should be evaluated for atrophy and movement to assess hypoglossal function. Depending on patient cooperation, the clinician then may insert a finger through the oral cavity into the oropharynx and laryngopharynx. The muscle tone and gag should be evaluated to assess pharyngeal branches of glossopharyngeal and vagal nerves. Clinical utility of this test is limited due to the variability in normal responses. Dysphagia (see ch. 38 and 273) is a more reliable indicator of cranial nerve IX and X dysfunction.

Neuroanatomic Diagnosis

After performing the complete neurologic examination, the clinician should attempt to make a neuroanatomic diagnosis to one of five major regions of the nervous system: (1) prosencephalon (cerebrum and/or thalamus); (2) mid- to caudal brainstem (midbrain, medulla, pons); (3) cerebellum; (4) spinal cord; and (5) LMN/neuromuscular system. Neurologic signs associated with lesions in each of these regions are tabulated (Tables 259-3 through 259-6); key neurologic deficits and examination patterns are expanded for each region.

TABLE 259-3

Neurologic Signs That May Be Associated with Prosencephalic Disease

NEUROLOGIC TEST	POSSIBLE ABNORMALITIES
Sensorium/behavior	Seizures; abnormal behavior; propulsive activity; depression to coma
Posture/gait	Head turn, ***normal gait*** (unless peracute lesion); propulsive circling (usually ipsilateral to lesion) or pacing; aimless wandering; head pressing; movement disorders (rare)
Postural reactions	*Contralateral* deficits
Muscle mass/tone	Normal
Spinal reflexes	Normal
Cutaneous sensation	*Contralateral* (often facial/nasal) hypalgesia
Cranial nerves	*Contralateral* menace deficits with normal (optic radiation and occipital cortex) or abnormal (optic chiasm, optic tracts) PLRs; facial; tongue or pharyngeal weakness (rare)
Other	Abnormalities in thirst, appetite, thermoregulation

PLRs, Pupillary light responses.

TABLE 259-4

Neurologic Signs That May Be Associated with Mid- to Caudal Brainstem Disease

NEUROLOGIC TEST	POSSIBLE ABNORMALITIES
Sensorium/behavior	Depression—coma
Posture/gait	UMN tetraparesis (or tetraplegia) and GP deficits; vestibular ataxia (pontine or medullary lesions); opisthotonus (midbrain lesions)

Postural reactions	Ipsilateral deficits (pons and medulla), contralateral deficits (rostral midbrain)
Muscle mass/tone	Normal to increased (all four limbs)
Spinal reflexes	Normal to increased (all four limbs)
Cutaneous sensation	Hypalgesia of trunk and limbs may be present (rare)
Cranial nerves	Anisocoria (III, sympathetics); dropped jaw (V bilateral); atrophy of muscles of mastication (V); facial hypalgesia (V); head tilt (VIII); resting or positional nystagmus (VIII); abnormal physiologic nystagmus (III, IV, VI, VIII); resting or positional strabismus (III, IV, VI, VIII); facial paresis or paralysis (VII); dysphagia (IX, X); tongue paresis or paralysis (XII)
Other	Respiratory or cardiac abnormalities

GP, General proprioceptive; *UMN,* upper motor neuron.

TABLE 259-5

Neurologic Signs That May Be Associated with Cerebellar Disease

NEUROLOGIC TEST	POSSIBLE ABNORMALITIES
Sensorium/behavior	Unaffected
Posture/gait	Intention tremor of head, neck or eyes; opisthotonus and extensory rigidity of all limbs with hips flexed (severe, rostral lesions); truncal sway; head tilt; hypermetric/spastic gait with *strength preserved;* loss of balance
Postural reactions	Delayed and then exaggerated in all limbs with diffuse disease or in ipsilateral limb with unilateral lesions
Muscle mass/tone	Muscle tone may be exaggerated
Spinal reflexes	Normal to exaggerated
Cutaneous sensation	Unaffected
Cranial nerves	Menace deficit (ipsilateral); anisocoria (rare)

TABLE 259-6

Thoracic and Pelvic Limb Signs Associated with Spinal Cord Lesions

LESION LOCATION	THORACIC LIMBS	PELVIC LIMBS	SEVERE LESIONS
C1-C5	UMN paresis; GP deficits; normal withdrawal reflexes* and muscle tone	UMN paresis; GP deficits; normal to exaggerated spinal reflexes and muscle tone	Spastic tetraplegia; potential respiratory complications; UMN Horner's syndrome
C6-T2	LMN paresis (short and choppy gait); reduced withdrawal reflexes and muscle tone	UMN paresis; GP deficits; long-strided gait; normal to exaggerated spinal reflexes and muscle tone	Flaccid LMN paralysis in thoracic limbs, spastic paraplegia in pelvic limbs; potential respiratory complications; Horner's syndrome (T1-T3)
T3-L3	Normal	UMN paresis; GP deficits; long-strided gait; normal to exaggerated spinal reflexes and muscle tone	Spastic paraplegia; Schiff-Sherrington may occur in thoracic limbs; possible paradoxical LMN signs (spinal shock) in pelvic limbs
L4-S3	Normal	LMN paresis (short and choppy gait); GP deficits (white matter); reduced patellar reflexes (L4-L6) or withdrawal reflexes (L6-S1)	Flaccid paraplegia in pelvic limbs that may include flaccid anus and tail with reduced to absent sensation of perineum

*C1-C5 lesions may be associated with reduced thoracic limb withdrawal reflexes.[5]

GP, General proprioceptive; *LMN*, lower motor neuron; *UMN*, upper motor neuron.

The clinician initially should attempt to reconcile all neurologic deficits with a single lesion. If a single lesion cannot explain all signs, the neuroanatomic diagnosis is likely to be multifocal or diffuse (see later). After localizing the lesion to one of the five major regions of the CNS or PNS, a more precise localization should be determined (e.g., side of lesion; specific anatomic segments affected: C1-C5, C6-T2, etc.). As mentioned previously, an accurate neuroanatomic diagnosis provides critical information for establishing an appropriate differential diagnosis and for selecting and interpreting neurodiagnostic tests.

Prosencephalon

Although commonly used as an embryologic term to denote the area of brain composed of the telencephalon (cerebral hemispheres) and diencephalon (epithalamus, thalamus, and hypothalamus), this large region is a key neuroanatomic diagnosis. Because of overlap in clinical signs associated with cerebral and thalamic disease, lesions affecting the two areas cannot be reliably differentiated. When neurologic signs suggest cerebro-thalamic ("forebrain") disease, a prosencephalic neuroanatomic diagnosis is made.

Animals with prosencephalic disease often have a history of generalized or partial seizures and/or abnormal behavior (see Table 259-3). Typical behavior changes include depression (due to lesions of the ARAS), lethargy, disorientation, loss of training, increased aggression or docility, irritability, hysterical or maniacal behavior, head pressing, propulsive pacing or circling (Video 259-32). Abnormalities in autonomic and endocrine function (thirst, appetite, temperature, electrolyte and water balance) and sleep patterns also may be present.

Although seizures, behavioral, and autonomic/endocrine changes support a prosencephalic neuroanatomic diagnosis, these abnormalities rarely help to lateralize the lesion to one side of the cerebrum or thalamus. Animals with prosencephalic lesions commonly manifest visual, sensory (facial/nasal hypalgesia), and postural reaction deficits, all contralateral to the side of the lesion (see Video 259-33). Despite having postural reaction deficits (a true "CP" deficit), animals with prosencephalic disease typically have a normal gait (a transient gait deficit may be present with peracute lesions such as a cerebrovascular accident). The gait is normal with prosencephalic lesions because the critical UMNs responsible for gait generation in domestic species (rubrospinal and reticulospinal tracts) are spared, being located more caudally in the midbrain, pons, and medulla.

An unusual phenomenon known as the *adversive (hemi-neglect or hemi-inattention) syndrome* occurs sometimes with unilateral prosencephalic lesions. With this syndrome, the pet "ignores" all sensory input perceived from its environment that is contralateral to the prosencephalic lesion. The pet may circle propulsively or eat out of one side of a bowl (ipsilateral to the lesion). Table 259-3 summarizes the potential clinical signs associated with prosencephalic disease.

Brainstem

The brainstem is ventral to the two cerebral hemispheres and the cerebellum. Although anatomically the diencephalon is the rostral extent of the brainstem, it is considered part of the prosencephalic localization (above). A neuroanatomic diagnosis of "brainstem" is used to denote lesions that include the midbrain, pons, and medulla oblongata. Functionally, the brainstem contains the paired cranial nerve nuclei, the regulatory centers for consciousness (ARAS) and respiration, and descending motor and ascending sensory pathways. Thus, cranial nerve abnormalities, behavioral changes, loss of key autonomic functions, and a loss of strength and coordination may be present with brainstem disease (see Table 259-4).

The brainstem connects the cerebral hemispheres to the spinal cord via ascending sensory (GP) and descending motor pathways (UMNs). As with C1-C5 spinal cord lesions, UMN tetraparesis (through tetraplegia) and GP deficits may accompany brainstem disease. Because of the presence of vestibular nuclei in the pons and medulla, vestibular ataxia may be present and superimposed upon GP ataxia (see Video 259-34).

Depending on the region of the mid- to caudal brainstem affected, dysfunction of cranial nerves III-XII may be present. The neurologic examination allows for assessment of the diverse motor and sensory functions of the cranial nerves (see Tables 259-1 and 259-4). Lesions affecting the cranial nerves in the caudal brainstem typically cause ipsilateral postural reaction deficits because of their impact on the UMN and GP systems. The presence of cranial nerve abnormalities and normal postural reactions suggests a peripheral (cranial) neuropathy; however, an early or slowly compressive brainstem lesion cannot be excluded. If there is

ambiguity in postural reaction testing, a neurodiagnostic workup should be considered.

Vestibular Disease

A head tilt, vestibular ataxia, nystagmus, and strabismus are seen commonly with vestibular disease (see Videos 259-28, 259-34, and 259-35). However, these neurologic signs rarely help the clinician to differentiate between central and peripheral vestibular disease. The key differentiating feature between central and peripheral vestibular disease is the presence or absence of postural reaction deficits. With vestibular lesions involving the caudal brainstem, ipsilateral postural reaction deficits will be present due to involvement of the UMN/GP pathways (see Video 259-34). Conversely, postural reactions will be normal with peripheral vestibular lesions because there is no involvement of the UMN/GP pathways.

Lesions affecting the peripheral vestibular nerve result in a head tilt that is ipsilateral (lower ear is on the side of the lesion) to the lesion; this is less predictable with brainstem lesions. Although most pets with central vestibular disease have an ipsilateral head tilt, those with brainstem lesions involving the caudal cerebellar peduncle (or flocculonodular lobules of the cerebellum) may manifest a contralateral, or so-called paradoxical head tilt (see Video 259-35).

Resting or positional nystagmus commonly accompany both central and peripheral vestibular disease (see Video 259-28). The direction of nystagmus is defined by the fast phase of the jerk of the eyeball. The plane of rotation may be *rotatory, horizontal,* or *vertical.* Typically, vertical nystagmus is associated with central vestibular lesions (see Video 259-34), whereas rotatory or horizontal nystagmus may be present with *either* central or peripheral lesions. With peripheral vestibular lesions, the fast phase of the nystagmus is away from the lesion; this is not reliable with central disease and may be in either direction. Moreover, the fast phase of nystagmus occasionally changes direction with brainstem lesions.

Additional cranial nerve deficits commonly accompany vestibular disorders. Facial nerve disorders are the most common and may be seen with *both* peripheral and central vestibular disease. Occasionally, Horner's syndrome accompanies peripheral vestibular lesions because the sympathetic fibers pass through the middle ear en route to the orbit. Rarely, a Horner's syndrome may be associated with a brainstem lesion because of involvement of the UMN (hypothalamo-tecto-tegmental) sympathetic pathway; this typically requires a severe brainstem lesion and usually the pet is tetraplegic with marked mentation changes. Sensorium is unaffected with peripheral vestibular lesions, whereas animals with central vestibular disease may be dull to comatose depending on the extent of involvement of the ARAS.

Cerebellum

The cerebellum functions as a *regulator* rather than a primary initiator of motor activity. It functions to coordinate movements in relation to the animal's posture providing synergy of muscular activity. Cerebellar disease produces a unique *dysmetria* characterized by an inability to regulate the rate, range, and force of a movement (see Video 259-4). Although a dog or cat with cerebellar disease may be incapacitated and unable to stand, voluntary movements should be elicited with normal strength.

Ambulatory animals with cerebellar ataxia typically manifest "bursty" hypermetric movements in all ranges of motion. Voluntary movements typically are delayed in onset and, once initiated, exaggerated. When walking, the limbs usually are raised excessively and returned forcefully to the ground with each step. Muscle tone commonly is increased, and spinal reflexes may be normal to exaggerated. Although CP is unaffected with cerebellar disease, postural reactions typically are delayed and exaggerated. When the head of a pet with cerebellar disease is extended and then support is withdrawn suddenly, a *rebound phenomenon* may be present in which the head drops excessively in a ventral direction.

Because of the close connection to the vestibular system, a head tilt (usually paradoxical) and other vestibular signs may accompany cerebellar disease (see Video 259-35). Commonly, a mild *intention tremor* of the head, neck, or eyes is present with cerebellar diseases (Video 259-37). This should not be confused with generalized, whole body tremors that are associated with diffuse CNS disorders (Video 259-38). Finally, it is noteworthy that cerebellar disease may be associated with an ipsilateral (bilateral with diffuse cerebellar disease) menace deficit. Although the cerebellum most commonly is affected diffusely (e.g., cerebellar hypoplasia or abiotrophy), occasionally unilateral or focal cerebellar lesions (cerebellar infarction or neoplasm) produce ipsilateral cerebellar signs (see Videos 259-35 and 259-36). Table 259-5 summarizes the potential clinical signs associated with cerebellar dysfunction.

Spinal Cord

A spinal cord segment is defined as a portion of the spinal cord, which gives rise to one pair of spinal nerves. There are 8 cervical, 13 thoracic, 7 lumbar, 3 sacral, and at least 2 caudal spinal cord segments in dogs and cats. Functionally, the spinal cord can be divided in four neuroanatomic regions: cranial cervical (C1-C5), cervico-thoracic (C6-T2), thoracolumbar (T3-L3), and lumbosacral (L4-S3).

The LMN cell bodies for the thoracic and pelvic limbs are located within the ventral gray matter of the cervico-thoracic (C6-T2) and lumbosacral (L4-S3) intumescences, respectively. The ascending (sensory) and descending (motor) pathways comprise the white matter of the spinal cord and are located more superficially. With rare exceptions, spinal cord lesions predictably result in a sequential loss of general proprioception, motor and bladder function, and nociception. Recovery of function typically occurs in the reverse direction.

As discussed in the gait and posture section, spinal cord lesions typically produce a combination of UMN and GP deficits in the limbs caudal to the level of the lesion (see Videos 259-2 and 259-39). If the spinal cord lesion is in the cervical or lumbar intumescence, it will produce LMN signs in the corresponding thoracic or pelvic limbs. Spinal cord lesions may produce a combination of UMN and LMN signs in thoracic or pelvic limbs (see Video 259-39). For example, a herniated disk at the C6/C7 intervertebral disk space may cause a long-strided thoracic limb gait (UMN sign) but reduced thoracic limb withdrawal reflexes (LMN sign). Ambulatory patients with C6-T2 lesions typically have a disconnected, "two-engine" gait in which the thoracic limbs are "short and choppy" (LMN sign) and pelvic limbs are long strided (UMN sign) with GP ataxia[1] (Video 259-40).

Establishing a neuroanatomic diagnosis to one of the four spinal cord segments typically is straightforward and is based upon four potential combinations of normal, LMN, and UMN signs that may be present in the thoracic and pelvic limbs (Tables 259-7 through 259-10; see Figure 259-1 and Table 259-6). However, there are a few clinical scenarios that may create confusion with T3-L3 spinal cord disease. These situations are considered below.

TABLE 259-7

Neurologic Abnormalities Associated with C1-C5 Spinal Cord Dysfunction

NEUROLOGIC TEST	POSSIBLE ABNORMALITIES
Sensorium/behavior	Normal
Posture/gait	Variable: ranges from UMN tetraparesis/GP ataxia through spastic tetraplegia
Postural reactions	Delayed to absent in all four limbs
Muscle mass/tone	Normal muscle mass (mild atrophy due to disuse in chronic disease), normal to exaggerated muscle tone in all four limbs; possible UMN bladder
Spinal reflexes	Normal to increased in all four limbs, occasionally reduced withdrawal reflexes in thoracic limbs*
Cutaneous sensation	Hypalgesia caudal to a focal lesion (rare)
Cranial nerves	Ipsilateral miosis (rare due to UMN Horner's syndrome)
Other	A focal, severe lesion between these segments may result in death due to respiratory dysfunction

*C1-C5 lesions may be associated with reduced thoracic limb withdrawal reflexes.[5]

GP, General proprioceptive; *UMN*, upper motor neuron.

TABLE 259-8

Neurologic Abnormalities Associated with C6-T2 Spinal Cord Dysfunction

NEUROLOGIC TEST	POSSIBLE ABNORMALITIES
Sensorium/behavior	Normal
Posture/gait	Variable: LMN gait in thoracic limbs, UMN paresis/GP ataxia in pelvic limbs through spastic tetraplegia

Postural reactions	Delayed to absent in all four limbs
Muscle mass/tone	Thoracic limb neurogenic atrophy (chronic lesions); reduced tone in thoracic limbs; normal to exaggerated tone in pelvic limbs; possible UMN bladder
Spinal reflexes	Normal to reduced withdrawal reflexes in thoracic limbs; normal to exaggerated patellar and withdrawal-flexor reflexes in pelvic limbs
Cutaneous sensation	Hypalgesia or normal in all four limbs or hypalgesia in thoracic limbs only
Cranial nerves	Ipsilateral Horner's syndrome (T1-T3 lesions)
Other	A focal, severe lesion between these segments may result in death due to respiratory dysfunction

GP, General proprioceptive; *LMN*, lower motor neuron; *UMN*, upper motor neuron.

TABLE 259-9

Neurologic Abnormalities Associated with T3-L3 Spinal Cord Dysfunction

NEUROLOGIC TEST	POSSIBLE ABNORMALITIES
Sensorium/behavior	Normal
Posture/gait	Variable: UMN paresis/GP ataxia in pelvic limbs through spastic paraplegia
Postural reactions	Normal in thoracic limbs; delayed to absent in pelvic limbs
Muscle mass/tone	Normal tone in thoracic limbs (unless Schiff-Sherrington spasticity in thoracic limbs); normal to exaggerated tone in pelvic limbs; normal muscle mass unless disuse atrophy in pelvic limbs; possible UMN bladder
Spinal reflexes	Normal withdrawal reflex in thoracic limbs; normal to exaggerated patellar and withdrawal reflexes in pelvic limbs; cutaneous trunci "cut-off" may be present slightly caudal to the lesion
Cutaneous sensation	Normal in thoracic limbs; hypalgesia, analgesia, or normal in pelvic limbs
Cranial nerves	Normal
Other	L4-L7 lesions of the *white matter* may produce similar signs

GP, General proprioceptive; *UMN*, upper motor neuron.

TABLE 259-10

Neurologic Abnormalities Associated with L4-S3 Spinal Cord Dysfunction

NEUROLOGIC TEST	POSSIBLE ABNORMALITIES
Sensorium/behavior	Normal
Posture/gait	Variable: flaccid paraparesis and GP ataxia in pelvic limbs through flaccid paraplegia
Postural reactions	Delayed to absent in pelvic limbs
Muscle mass/tone	Normal tone in thoracic limbs; reduced tone in pelvic limbs, reduced muscle mass in pelvic limbs (chronic); UMN (rare) or LMN bladder
Spinal reflexes	Hyporeflexia through areflexia of patellar (L4-L6), withdrawal (L7-S1), and perineal reflexes (S1-S3)
Cutaneous sensation	Normal in thoracic limbs; normal, hypalgesia or analgesia in pelvic limbs, tail, perineum, anus (penis)
Cranial nerves	Normal
Other	L4-L7 *(white matter)* lesions may produce signs that mimic T3-L3

GP, General proprioceptive; *LMN*, lower motor neuron; *UMN*, upper motor neuron.

Thoracolumbar (T3-L3) spinal cord lesions typically spare the thoracic limbs and cause a combination of UMN signs and GP deficits in the pelvic limbs (see Video 259-2). However, peracute T3-L3 lesions may produce a marked spasticity in the thoracic limbs referred to as the *Schiff-Sherrington syndrome.* This phenomenon results from disruption of *ascending* inhibitory axons arising from interneurons (border cells) located in the dorsolateral border of the ventral gray column of spinal cord segments L1-L7.[1] These ascending interneurons exert an inhibitory influence on the LMNs of the cervical intumescence, which may be lost with peracute, transverse T3-L3 lesions. Postural reaction testing will discriminate between a severe C1-C5 lesion and Schiff-Sherrington syndrome. Postural reactions will be delayed in the former because of the involvement of the UMN and GP pathways, but it will be normal in the latter despite the presence of spasticity.

A second challenging clinical scenario is associated with acute T3-L3 lesions that produce contradictory LMN signs (reduced spinal reflexes and hypotonia) in the pelvic limbs. This situation commonly is accompanied by Schiff-Sherrington syndrome, and the LMN signs in the pelvic limbs have been referred to as *spinal shock.* It is thought to be secondary to a transient disconnection between the descending UMNs and the LMNs of the lumbosacral intumescence.[6] Although spinal shock can persist for weeks in humans, it generally is transient (hours to days) in dogs and cats.

Occasionally, T3-L3 lesions produce LMN signs in the pelvic limbs that are *not* accompanied by the Schiff-Sherrington syndrome. This is most common with fibrocartilaginous embolic myelopathy (FCEM) and rarely occurs with intervertebral disk disease.[7] For hours, upwards of days, contradictory LMN signs may be appreciated in the pelvic limbs with such T3-L3 lesions. It has been hypothesized that this also represents a variation of spinal shock.[6]

A third challenging situation relates to L4-L7 lesions that may produce UMN signs and GP ataxia, rather than the predicted LMN signs, in the pelvic limbs. This may result from lesions affecting predominantly the white matter of the spinal cord at this level.

Peripheral Nervous System

Lower Motor Neuron/Neuromuscular System

The LMN unit consists of the nerve cell body in the ventral gray matter of the CNS, ventral nerve root, peripheral nerve, and muscle. Disease of any component of this unit will produce LMN signs. Normal strength depends not only on functional LMN unit, but also on effective neuromuscular transmission via acetylcholine (ACh) across the neuromuscular junction (NMJ). Diseases affecting neuromuscular transmission (e.g., myasthenia gravis, tick paralysis), so-called junctionopathies, may produce LMN signs that are indistinguishable from neuropathies and myopathies.

Because NMDs may mimic one another, the neurologic examination rarely confirms the exact component of the LMN unit that is affected. The clinician may require ancillary tests (serum creatine kinase [see ch. 66] and aspartate aminotransferase [see ch. 65], edrophonium testing, acetylcholine receptor antibody titer [see ch. 269], electrodiagnostics [see ch. 117], nerve and muscle biopsies [see ch. 116]) to further localize the problem to the nerve, muscle, or NMJ. The LMN unit may be affected diffusely or individual peripheral or cranial nerves may be affected. When cranial nerve deficits (e.g., facial paresis) are present, these must be interpreted with other neurologic findings in order to differentiate neuromuscular disease from a brainstem disorder.

Neuromuscular weakness is characterized by flaccidity and depressed or absent spinal reflexes. Postural reactions typically are normal with pure NMDs (no sensory nerve involvement) (see Video 259-41), although the patient must be well supported or may fail postural testing on account of weakness. Ambulatory patients with pure NMDs typically have a "short and choppy" gait *without* ataxia because GP is unaffected (see Videos 259-1 and 259-41). Exercise intolerance may be the only abnormality present in some patients with NMDs.

An important exception to the classic "short and choppy" pattern of neuromuscular disease is the pelvic limb gait associated with sciatic dysfunction in dogs and cats that have polyneuropathies. Because sciatic dysfunction does not affect weight bearing, the pelvic limb gait is not short-strided. Despite being a LMN problem, an exaggerated pelvic limb gait is present in which the pet repeatedly initiates the gait from a plantigrade position and "flings" its pelvic limbs forward (see Video 259-42). This should not be confused with T3-L3 or cerebellar hypermetria. Hip flexion is exaggerated due to the lack of antagonistic contraction of the caudal thigh muscles. Patients with polyneuropathies also may have delayed postural reactions because of involvement of the sensory nerve fibers in the peripheral neuropathy.

In some NMDs (e.g., polyneuropathies), involvement of the recurrent laryngeal nerve may lead to a change in, or loss of, voice (dysphonia) and increased inspiratory noise (stridor). The development of megaesophagus

in various NMDs may cause regurgitation, often with accompanying aspiration pneumonia. The NMDs also carry the risk of hypoventilation due to involvement of the respiratory muscles. Finally, changes in muscle mass may vary from severe neurogenic atrophy (e.g., brachial plexus avulsion) to "pseudohypertrophy," which accompanies myopathies (e.g., muscular dystrophy) (Table 259-11).

TABLE 259-11

Neurologic Abnormalities Associated with LMN/Neuromuscular Dysfunction

NEUROLOGIC TEST	POSSIBLE ABNORMALITIES
Sensorium/behavior	Normal
Posture/gait	Variable: flaccid paresis in affected limb(s) through flaccid paralysis of affected limb(s); exercise may exacerbate the paresis
Postural reactions	Delayed to absent in affected limb(s); normal in "pure" LMN disease if patient maintains some voluntary motor function
Muscle mass/tone	Decreased tone of affected limb(s); neurogenic atrophy may be severe; pseudohypertrophy in certain myopathies; possible LMN bladder
Spinal reflexes	Variable: hyporeflexia through areflexia of affected limb(s); possibly reduced perineal reflexes (S1-S3)
Cutaneous sensation	Normal in "pure" LMN disease (but if a polyneuropathy with a sensory component, hypalgesia may be present)
Cranial nerves	Variable: multiple cranial nerves may be affected
Other	Laryngeal paralysis, dysphagia, megaesophagus common with LMN disease

LMN, Lower motor neuron.

Peripheral Sensory Nerves

Sensory afferent nerve fibers run together with the LMNs within the peripheral nerves. Sensory axons have a cell body in the dorsal nerve root ganglion or in homologous ganglia of cranial nerves. A cutaneous region innervated by afferent nerve fibers from a single spinal or cranial nerve is called a *dermatome.* Diseases exclusively affecting the sensory system are rare (e.g., sensory neuropathies, ganglioradiculoneuritis) and they are characterized by variable sensory deficits ranging from hypalgesia to analgesia of various body parts.

Multifocal Localizations and Diffuse Central Nervous System Disorders

With various neurologic disorders, the deficits cannot be explained by a single lesion. For example, a Pug with necrotizing meningoencephalitis might manifest both prosencephalic (seizures) and vestibular (head tilt, vestibular ataxia) signs. In this scenario, a multifocal, intracranial localization is made.

Multifocal localizations are not analogous to disorders that affect the CNS diffusely, in which the majority of the neural axis is affected. The most common neurologic sign associated with diffuse CNS disease is a fine, whole body tremor (see Video 259-38). Whole body tremors should not be confused with the brief, intentional tremors of the head, neck, or torso that may be present with cerebellar disease (see Video 259-37). The differential list for a diffuse CNS localization is relatively narrow and includes dysmyelinogenesis, diffuse meningitis (idiopathic tremor syndrome, disseminated granulomatous meningoencephalomyelitis, infectious meningitis) and various toxicoses (e.g., molds, algae, ethylene glycol).

CHAPTER 260

Brain Diseases

Degenerative, Anomalous, Metabolic, Neoplasia, Idiopathic Epilepsy, and Vascular

Joan R. Coates, Dennis P. O'Brien

"All the most acute, most powerful, and most deadly diseases and those most difficult to be understood…fall upon the brain."

Hippocrates

Client Information Sheets:
Brain Tumors in Dogs
Idiopathic Epilepsy in Dogs
Hydrocephalus

Response of the Brain to Injury

General Responses and Their Results

The nervous system has relatively few responses to damage and the complexity of neurologic signs in response to trauma depends upon the location of the injury (Table 260-1). Because neurons are excitable cells, one potential response to disease is excessive discharge; its most dramatic example would be seizure activity. If a condition destroys the neurons of a system, it will lose function. For example, destruction of a cranial nerve nucleus in the brainstem will lead to paralysis of the muscles innervated by that nerve. If the system lost is an inhibitory pathway, then the system that is no longer inhibited may show an exaggerated response. The classic example of such disinhibition is the exaggerated reflexes seen with upper motor neuron (UMN) loss. When dealing with higher brain functions, such responses can be complex. For example, paradoxical aggression sometimes seen in dogs given benzodiazepines or barbiturates may represent a disinhibition of aggressive behavior. The nervous system is especially sensitive to genetic mutations since many genes are only expressed for brief periods during development. Few neurons are capable of reproducing after maturity because the initial systematic and complex construction process cannot be duplicated. Mutations which interfere with the ability of cells to respond to insults such as oxidative stress or enzyme deficiencies can lead to accumulated damage and early or late onset of degeneration.

TABLE 260-1

Summary of Pathophysiologic Mechanisms Associated with Categories of Brain Diseases

Increased Intracranial Pressure

In addition to local effects, a disease process in the brain can produce generalized effects secondary to increased intracranial pressure. Because the calvarium is a bony globe, the three major components within it (brain, cerebrospinal fluid [CSF], and blood) are confined to a fixed space. Any increase in one of these components would then have to be accompanied by a decrease in one of the others (the Monro-Kellie doctrine). A gradual increase in volume of one component, such as slowly progressive hydrocephalus, can be compensated for, to some extent, by atrophy of brain tissue. Acute disease does not allow time for compensatory atrophy, and even chronic disease (brain tumor) will eventually exceed the ability to compensate, and increased intracranial pressure results. With increasing intracranial pressure, generalized forebrain signs develop, even if the inciting cause is a localized process such as neoplasia. Systemic blood pressure increases to maintain cerebral perfusion which can cause reflex increase in vagal tone and decrease in heart and respiratory rates (the Cushing's phenomenon). Vomiting may also occur.

Continued increases in intracranial pressure will lead to herniation. Brain tissue can either herniate laterally under the falx cerebri or caudally under the tentorium or through the foramen magnum.[1] Tentorial herniation leads to a progressive rostral-caudal deterioration of neurologic status when the midbrain, pons, and terminally the medulla are compressed. Resulting brainstem compression causes pupillary changes, and disruption of UMN and respiratory pathways. The progression can be rapid or can evolve slowly over a matter of hours or even days. Herniation is most commonly associated with forebrain lesions, such as neoplasia or trauma. Increased pressure arising below the tentorium (e.g., a cerebellar tumor) will cause herniation of the cerebellum through the foramen magnum, mimicking the terminal events of tentorial herniation without any of the earlier signs.

Brain Edema

Three types of brain edema (cytotoxic, vasogenic, interstitial), a common response to insults, can coexist. Cytotoxic edema results from fluid accumulation in neurons. Energy depletion due to failure of the ATP-dependent Na^+/K^+ ATPase pump and other ion channels results in intracellular translocation of extracellular water. Cytotoxic edema usually occurs as a result of ischemia or processes that alter the cellular membrane. Vasogenic edema results from physical or functional disruption of the vascular endothelium, often in association with the blood-brain barrier (BBB). Fluid accumulation is extracellular and preferentially distributed within the white matter because its myelinated neuronal fibers are diffusely distributed within a matrix of glia and capillaries. Interstitial edema often accompanies obstructive hydrocephalus, causing compartmentalized CSF to cross ependymal linings and creating extracellular periventricular interstitial brain edema. Determining edema type allows for the most appropriate treatment. Cytotoxic and interstitial edemas are managed by treating the underlying cause, whereas vasogenic edema can be treated using osmotic and corticosteroid therapies.

In addition to primary CNS inflammatory diseases, neuroinflammation plays a role in the pathophysiology of many brain conditions in animals.[2] It is characterized by a broad range of immune responses, differing from peripheral inflammation primarily in the principal cells involved, most notably the astrocytes and microglia.[3] The BBB (including the blood–spinal cord barrier) refers to the flow of cells and macromolecules from the systemic circulation to the CNS being protected.[4] This selectively permeable barrier is composed of endothelial cells, basement membranes, and neighboring perivascular pericytes, glial cells (astrocytes, microglia) and neurons. Together, they temper the intensity of CNS inflammatory responses.[4-6] However,

although the CNS traditionally has been considered "immunologically privileged," current data confirm that the CNS is immunocompetent and actively interacts with the peripheral immune system.[7] Peripheral inflammation can trigger a neuroinflammatory response involving BBB endothelia, glia and neurons through inflammatory mediators and cytokines.[2]

Localizing the Lesion

One aim of the neurologic examination is to localize the lesion into one of four areas within the brain: (1) forebrain (cerebrum and diencephalon), (2) midbrain, (3) pons and medulla, or (4) cerebellum (Table 260-2). While one may further localize a lesion within one area, correctly placing a lesion in one of the broad divisions is sufficient to have a reasonable list of differential diagnoses and a diagnostic plan (see ch. 259 and Video 260-1). When localizing the lesion, the first question the clinician must answer is whether the signs reflect focal, diffuse, or multifocal disease. Focal lesions are suspected if signs exhibited are strongly lateralizing (e.g., circling, focal onset seizures, lateralized cranial nerve deficits). A focal lesion is most suggestive of a neoplasm, vascular disease, or localized infection. Usually, degenerative processes or a metabolic or toxic insult are expected to affect the brain more generally and not preferentially affect one side. Although symmetric forebrain signs suggest a diffuse disease process, they do not rule out focal disease. Focal disease can produce diffuse signs through mechanisms like obstructive hydrocephalus, diffuse edema and increased intracranial pressure. Every effort should be made to explain the clinical signs on the basis of a single lesion. If a single lesion cannot explain all signs, multifocal disease is suspected. For example, a single lesion cannot explain an animal that has both seizures (cerebral cortex) and unilateral facial palsy (medulla or facial nerve).

TABLE 260-2

Clinical Signs Associated with Intracranial Localization

LOCALIZATION SITE	CLINICAL SIGNS
Cerebrum	Seizure, abnormal behavior and mentation, normal gait, propulsive gait, ipsilateral circling and head turn, contralateral postural reaction deficits, and contralateral menace response and facial sensory deficits
Diencephalon	Abnormal behavior and mentation, circling either direction, normal gait, postural reaction deficits, anorexia or polyphagia, temperature dysautoregulation, endocrine abnormalities, visual deficits
Midbrain	Abnormal mentation, circling and turning, postural reaction deficits, hemi- or tetraparesis, GP ataxia, CN III deficits
Brainstem	Normal to abnormal mentation, ipsilateral head tilt and circling, vestibular ataxia, ipsilateral postural reaction deficits, hemi- or tetraparesis, ipsilateral CN V-XII deficits
Cerebellum	Normal mentation, wide-base stance, paradoxical vestibular dysfunction, decerebellate posture, intention tremor, cerebellar ataxia, may see ipsilateral menace response deficit

CN, Cranial nerve; *GP*, general proprioceptive.

Differential Diagnoses

Age, Gender, Breed

Once a lesion has been localized, a list of differential diagnoses can be generated and a diagnostic plan developed. Most diseases in veterinary medicine are categorized by their clinical presentation and/or pathologic changes, but clinical signs can be nonspecific. Signalment often provides the first clue to a diagnosis. Congenital and hereditary diseases are most common in young purebred animals. Congenital anomaly refers to any malformation present at birth, including both genetic conditions and those resulting from external influences during gestation, such as toxin, malnutrition or infection. Many hereditary neurologic diseases will be congenital or at least apparent at an early age, but there are notable exceptions. Some lysosomal storage diseases require time for accumulation of byproducts. Animals with hereditary cerebellar ataxia (abiotrophy) may be normal clinically and histologically for an unpredictable time period

until clinical signs follow the death of Purkinje neurons. Finally some conditions (idiopathic epilepsy or neuronal ceroid lipofuscinosis) will not cause signs until early or even late adulthood. While infection, trauma, and intoxication can occur anytime, young animals are more likely to be affected. With increasing age, neoplasia, metabolic encephalopathies, and degenerative diseases become increasingly common.

Onset, Progression, and Type of Signs

Onset and progression of signs can provide important clues in prioritizing a differential diagnosis list. Congenital malformations are present from birth and relatively static. However, conditions like hydrocephalus could progress over time. Acute onset of signs is most likely with vascular disease, trauma, most toxins, and many infectious/inflammatory or metabolic diseases. Waxing and waning signs can be characteristic of inflammatory and metabolic diseases. Some infectious/inflammatory, metabolic, cancerous and degenerative conditions are chronic and progressive. Episodic onset is characteristic for epilepsy, some disorders associated with abnormal movements and channelopathies.

Results of the neurologic examination may suggest the type of disease process (see ch. 259). Some diseases will have a predilection for specific regions of the brain. Generally, lateralizing signs (circling, hemiparesis, or unilateral cranial nerve deficits) suggest a localized disease process such as an infection, vascular disease, neoplasia, or traumatic injury. Likewise, focal onset seizures would suggest localized cortical damage, although idiopathic epilepsy can produce focal seizures.[8,9] Of these, infectious/inflammatory, vascular, or metastatic neoplasia would be the most likely to produce multifocal signs. Metabolic or toxic insults usually do not cause focal or asymmetric signs. Because the cerebral cortex is the most metabolically demanding area of the brain, forebrain signs tend to predominate. However, localized disease processes can result in diffuse forebrain signs through increased intracranial pressure. The clinician should have a high index of suspicion of hereditary diseases in cases of young, pure-breed animals with diffuse, symmetrical signs of brain disease when toxic, routine metabolic and infectious etiologies have been ruled out. Breed tables can be consulted for specific diseases that have been reported.[10-12]

Diagnostic Approach to Brain Disease

Routine Laboratory Assessment

When considering the diagnostic approach to diseases affecting the brain (Figure 260-1), clinicians should consider cost, imaging availability, risks, and potential yield. The value of a thorough history and neurologic examination should never be underestimated (see ch. 259). Even if advanced imaging reveals a clear lesion, if that lesion does not correspond to results of the neurologic examination, its significance needs to be questioned. Routine clinical pathology can provide critically important information, and is readily available, cost-effective and not invasive. Even with apparently focal disease, reviewing the minimum database on any ill animal is essential. Complete blood count (CBC) may suggest infectious/inflammatory etiologies as well as provide clues to other causes. Serum biochemistry profile and urinalysis will be essential to rule out energy deficiencies, electrolyte disturbances, or accumulation of endogenous toxins. Pets with diffuse forebrain signs or seizures should have liver function assessed with bile acids or ammonia tolerance (see ch. 284). If inborn errors of metabolism are suspected, urine assays for abnormal metabolites may be necessary. Assays for specific exogenous toxins, such as lead or organophosphate, may be indicated if signs and history are suggestive (see ch. 152). Screening for all possible neurotoxins is not feasible. Since hypothyroidism (see ch. 299), hyperadrenocorticism (see ch. 306), insulin secreting tumors (see ch. 303) and other endocrine conditions can be accompanied by neurologic signs, endocrine testing should be considered if indicated by gathered information. Thoracic and abdominal imaging will be important, particularly in geriatric patients, to rule out metastatic and co-existing diseases.[13,14]

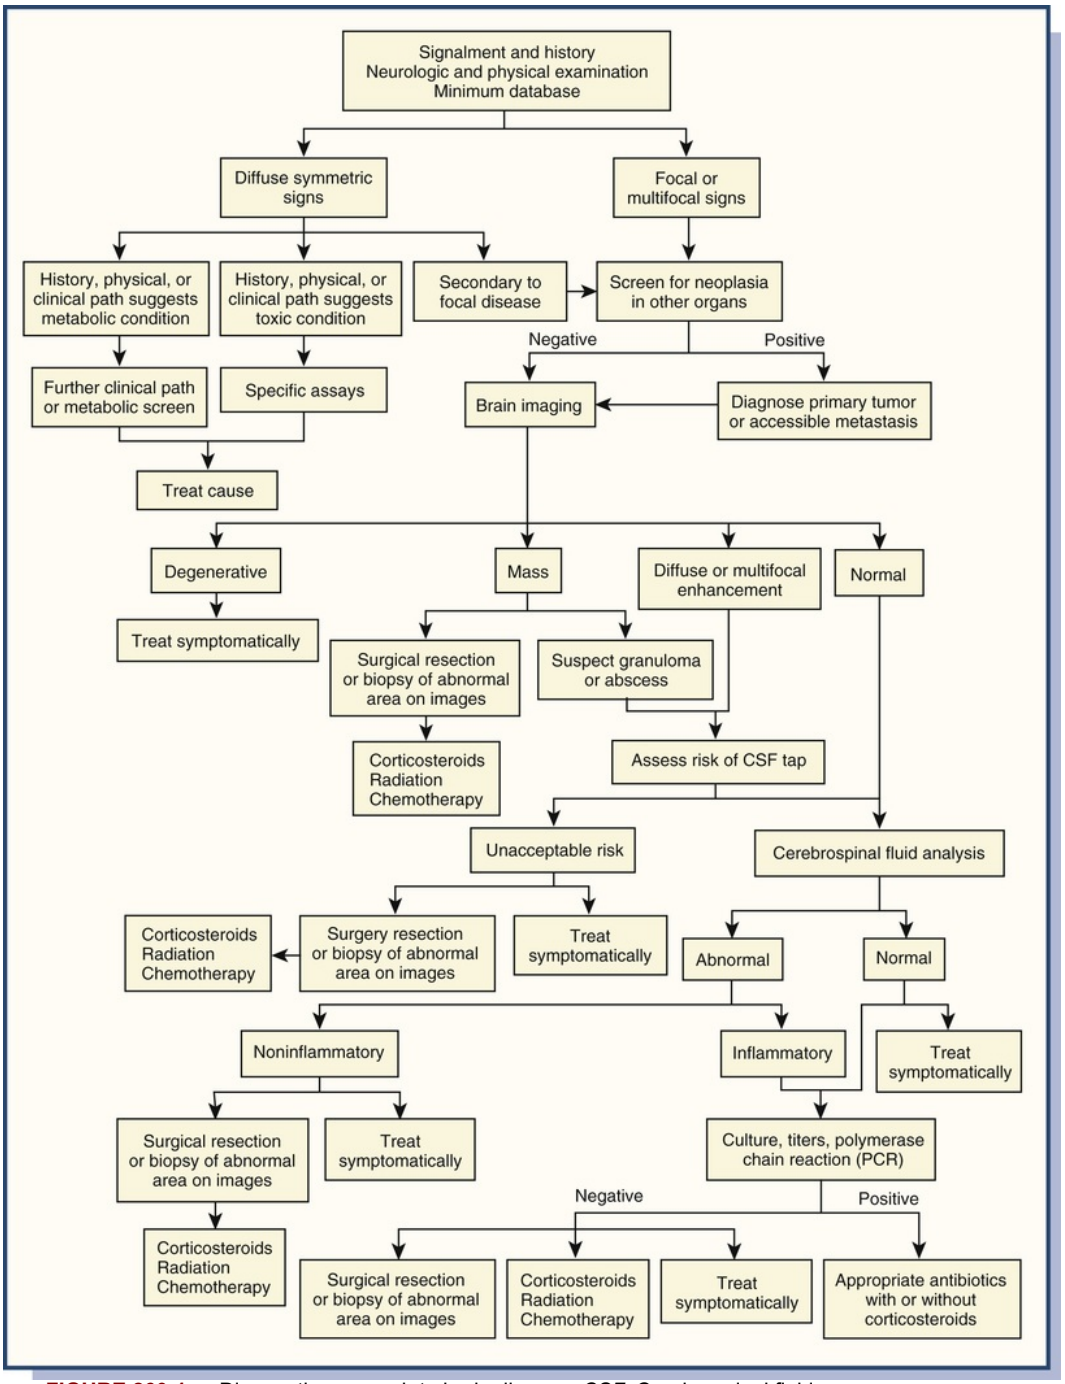

FIGURE 260-1 Diagnostic approach to brain disease. *CSF*, Cerebrospinal fluid.

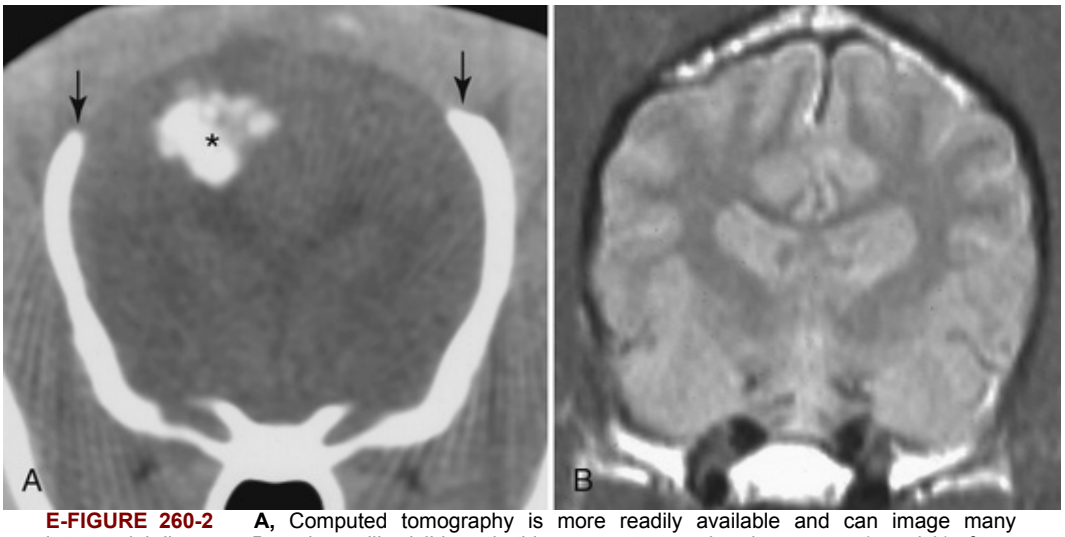
Brain Imaging

Overview

The availability of computerized tomography (CT) or magnetic resonance imaging (MRI) scans for animals with brain disease has revolutionized neurology. While expensive, information gained usually justifies the investment. Routine skull radiographs are of little value in diagnosing brain disease because only the skull can be imaged without contrast studies or angiography and superimposition of structures makes interpretation difficult. Ultrasound (US) imaging of the brain, while useful, is only an option when an open fontanelle or craniotomy provides an acoustic window. Cross-sectional imaging with a CT or MRI scan allows detection of structural changes within the brain.[15,16] CT and MRI scans produce images that are slice oriented,

thereby eliminating the summation effects associated with conventional radiography. MRI scans provide better contrast resolution of nervous tissues whereas CT provides better spatial resolution and rapid imaging (E-Figure 260-2). With CT scans, reconstruction of sagittal and dorsal plane images from the transverse causes inferior spatial resolution. The direct multiplanar images acquired by MRI result in better spatial resolution of each plane, although the scans are more time-consuming. The shorter time needed to acquire CT images may be advantageous in post-trauma patients. MRI cannot be used when metal implants or cardiac pacemakers are present. Sometimes even identification microchips can interfere with MRI scans.



E-FIGURE 260-2 **A,** Computed tomography is more readily available and can image many intracranial diseases. Bone is readily visible as in this recurrent osteochondrosarcoma (asterisk) after a prior craniectomy (arrows). **B,** Magnetic resonance imaging provides much greater detail of brain parenchymal lesions. This proton density image of normal brain clearly delineates gray and white matter.

Computed Tomography

CT relies on traditional radiographic principles. A shade of gray assigned to a pixel by the computer, normalized to the absorption characteristics of water, is assigned a number referred to as a Hounsfield unit (HU; Table 260-3). Only cross-sectional images are acquired, although computer reconstructions can generate images in a sagittal plane, dorsal plane, or in three dimensions. CT has the advantage of being able to image bone, which is useful in detection of mineralization and hemorrhage. The ventricular system is readily appreciated on CT, but fine anatomical detail of parenchymal lesions is often not visible. Edema may be visible as a reduced density of the parenchyma, while hemorrhage or calcification produces increased density. CT resolution is limited by X-ray attenuation by the skull. The density of petrosal bones at the base of the skull limits CT image quality to the tentorium cerebelli. The attenuation of the X-rays will be similar to that of the gamma rays used in radiation therapy, so CT images can be used to calculate dose delivery.

TABLE 260-3

Hounsfield Units for Various Intracranial Tissues

TISSUE	HOUNSFIELD UNIT (HU)
Air	−1000
Fat	−50 to −100
Water	0
CSF	0 to 15
Brain	25 to 50
Hyperacute to acute blood	60 to 100

Mineral and bone	100 to >1000
Metal (e.g., metallic iodine contrast)	Variable on dilution, 100 to >3000

Magnetic Resonance Imaging

MRI orients hydrogen atoms, with their unpaired electron, in alignment based on their magnetic properties. When energy—a radiofrequency pulse—is applied, there are changes in the alignment of the atoms and when the pulse is removed, the realigned atoms return to their previous orientation, while releasing energy back into the environment. It is this energy release that helps form images. The rate at which energy is released is based on inherent tissue characteristics. Two time constants, termed T1 and T2, describe this process. A series of images, called a pulse sequence, can be acquired based or "weighted" on the T1 or T2 properties, referred to as T1-weighted (T1W) or T2-weighted (T2W) images. The resultant images are gray-scale images in which the degree of relative brightness is referred to as intensity (Table 260-4). T1W images are characterized by bright fat and dark water and T2W images are characterized by bright water and dark fat. Edema is readily apparent as increased signals on T2W images. Proton density is an in-between sequence that characterizes areas with high proton density (bright) and areas with low proton density (dark). The contrast decreases between the ventricles and the brain, but increases between gray and white matter, revealing fine anatomic detail. Several sequences have been developed to suppress the signal of certain tissues, e.g., CSF and fat. The fluid attenuated inversion recovery (FLAIR) sequence suppresses signal from fluid with low or no protein (i.e., CSF) so that it is hypointense and allows improved identification of pathologies (tissue edema) and lesions near the ventricles. Short-tau inversion recovery (STIR) sequences allow for fat suppression. Gradient echo (GRE) T2W imaging (T2*) is used to detect artifact from blood products that are formed in hemorrhage.

TABLE 260-4

Commonly Used MRI Sequences to Define Tissue Intensity* and Indications

	T2W	FLAIR (T2W)	T1W	STIR	GRE (T2*)
Fat	Hypo	Hyper	Hyper	Hypo	Hyper
CSF	Hyper	Hypo	Hypo	Hyper	Hyper
Edema	Hyper	Hyper	Hypo	Hyper	Hyper
Indications for Selected Sequence	Allows distinction between fluid and tissue; perform on every MRI study	Suppression (nulling) of low-protein fluid (i.e., CSF), allowing for visualization of periventricular lesions	Comparison of pre- and post-contrast images to assess for tissue vascular supply and BBB disruption	Allows for suppression of hyperintense fat signal	Most sensitive for detecting signal void on hemorrhage, bone, mineralization

*Tissue intensity appearance on sequence compared to brain cortex (gray matter).

FLAIR, Fluid attenuated inversion recovery; *GRE*, gradient echo; *STIR*, short-tau inversion recovery.

More advanced MRI techniques can be used to investigate functional disturbances in the CNS. MR spectroscopy (MRS) evaluates brain chemistry and metabolism (molecular content of tissues) that can be altered in disease and provide chemical signatures for pathologic processes as in neoplasia and inflammation. Diffusion weighted imaging (DWI) depends on the molecular motion or diffusion of water, altered in many disease processes. Accompanied by calculated "apparent diffusion coefficients" (ADC), DWI can aid in identifying issues like cytotoxic edema associated with ischemic infarction. Diffusion tensor imaging (DTI), also known as fiber tracking, evaluates the direction of diffusion (anisotropy) in white matter to provide more information on neuronal connectivity. MR angiography (MRA) uses gradient echo sequences to detect signal changes of flowing blood (vessels) in tissues.

Lesion Description for Cross-Sectional Imaging

For both CT and MRI, a standard approach is used to characterize primary and secondary structural abnormalities. Primary lesion descriptions are based on their number (single or multiple) and density/intensity (hypo-dense, hyper-dense, iso-dense) (Table 260-5) with respect to the adjacent normal area,

its distribution (homo- or heterogeneous), borders, anatomic location, and location in reference to the CNS (extra-axial, intra-axial) and meninges (intradural, extradural, intraparenchymal). Secondary effects on the surrounding anatomy are also described to include extent and type of edema, and mass effect causing a shift of midline structures, tissue herniation or distortion of the ventricles. Alterations of CSF flow may cause periventricular edema, obstructive hydrocephalus or ventriculomegaly and syringohydromyelia.

TABLE 260-5

Pathologies with Increased CT Density or MRI Intensity

CT DENSITY	T1W INTENSITY	T2W INTENSITY
Bone proliferations Mineralized tissue Hemorrhage (hyperacute, acute) Iodine-enhanced lesion Tissues of high cellular density (fibrous) Metallic object	Fat Methemoglobin stage in hemorrhage Mucinous fluid Cortical laminar necrosis Gadolinium-enhanced lesion Melanin Iron deposition	CSF and other fluids Edema Necrosis Demyelination Cellular changes (gliosis, inflammation, neoplasia)

Contrast agents can be employed with either CT or MRI scans to improve tissue resolution for detection of pathologic processes. Images can be obtained immediately after IV contrast to evaluate vasculature or they can be delayed several minutes to evaluate tissue uptake. Contrast agents used for CT are iodinated and alter X-ray attenuation, whereas contrast agents used for MRI are paramagnetic and function by changing the relaxation rates of protons. Lesions are characterized on the degree and distribution of contrast enhancement. Following IV administration, the BBB would normally exclude such agents. The presence or absence of contrast enhancement with CNS disease depends upon the degree of BBB disruption or presence of vasodilation or neovascularization and, as such, is a nonspecific finding associated with a variety of CNS diseases.[17-19] Breakdown of this barrier by neoplasia or inflammation will result in accumulation and contrast enhancement of the lesion, thereby increasing the ability to identify primary lesion(s).

Other Imaging Modalities

Positron emission tomography (PET) and single photon emission computed tomography (SPECT) are functional imaging techniques that allow for qualitative and quantitative measurements of tissue metabolism and are gaining utility in veterinary medicine.[20] Major uses include defining metabolically active areas for biopsy versus inactive ischemic lesions. Images produced from PET are co-registered with CT or MRI to obtain anatomic relationships. PET imaging has been evaluated on normal canine brains and in dogs with intracranial disease.[21-24]

Brain Biopsy

While advanced imaging provides excellent views of the nervous system, it cannot provide definitive diagnoses which, for many brain diseases, is based on histology. Antemortem brain biopsy may yield a more definitive diagnosis to guide treatment approaches, although such procedures are dependent upon obtaining biopsy material from representative portions of the lesion. Image-guided biopsy techniques decrease morbidity and increase availability. Minimally invasive techniques such as CT or MRI-guided stereotactic systems, free-handed techniques that utilize US, CT, or MRI, and endoscopic-guided biopsy have been developed for brain biopsy in dogs.[25-35] Diagnostic yield for biopsy of brain lesions may be influenced by sample size and difficulty in distinguishing between the primary lesion and secondary lesion changes such as edema and necrosis. Intraoperative cytologic evaluation of a biopsy sample may improve diagnostic accuracy.[36,37] In addition to limitations in accuracy of diagnosis from biopsy, there are also risks that cannot be overlooked; a recent study on dogs with encephalitis suggested mortality and morbidity rates of 6 and 29%, respectively.[34] Modern neuro-navigation may further refine biopsy techniques and decrease morbidity.[31,38,39] Combined use of rigidly fixed external markers for landmarks within and outside the cranial vault and labeled surgical instruments provide real-time feedback during the procedure.

CSF Analysis

Because a mass lesion producing increased intracranial pressure significantly increases the risk of complications, imaging should precede CSF collection. CSF is most useful for identifying inflammatory disease, but can provide other clues (increased protein with neoplasia). In some, CSF analysis can be diagnostic. In cryptococcosis (see ch. 231), for example, organisms may be seen on examination. More commonly, CSF analysis simply confirms inflammation or presence of disease. Further tests are necessary to make a definitive diagnosis. Culture of CSF has low yield. Microbial culture of blood or urine may be considered with suspected bacterial infection.

CSF, serum or both can be analyzed for antibodies to infectious diseases, most notably *Neospora caninum, Toxoplasma gondii, Ehrlichia* spp., *Anaplasma* spp., *Rickettsia rickettsia,* and *Coccidioides immitis*. Prevalence varies with geographic location. Infection by *Cryptococcus* spp. is usually detected by antigen testing. Other microbial DNA or RNA can be detected by the highly sensitive and specific polymerase chain reaction (PCR) assays.[40-42] Results should be interpreted carefully to avoid false positives and rigorous negative controls must be evaluated in parallel (see ch. 207). A negative PCR result may indicate that undetectable levels of nucleic acid are present, an agent may be in neural tissue but not in CSF, or that the disorder may have been triggered by an agent no longer present.[41] Other analyses on CSF have been studied for CNS diseases but lack disease specificity. CSF protein composition can be further defined by semiquantitative electrophoretic techniques and abnormalities have been reported to be useful in identification of inflammatory, neoplastic and degenerative disease.[43-45] Flow cytometry and immunophenotyping, used to identify mononuclear cells in CSF inflammatory disorders[46] and lineage identification of neoplastic cells, is not practical because of the need for large volumes (4 to 5 mL) of CSF unless the cell count is very high.

Electroencephalogram (EEG), Genomics, Response to Therapy, and Other Diagnostics

The EEG is used primarily to confirm epileptic activity in brains of suspected seizure patients. It is particularly useful in status epilepticus to confirm that seizure activity has been stopped. The brainstem auditory evoked response (BAER) is used primarily to assess cochlear function, but latter wave intervals can also evaluate brainstem conduction.[47,48] Somatosensory and visual evoked potentials can assess function of these systems.

Advances in animal genomics have allowed identification of disease-causing mutations and development of DNA tests to detect mutant alleles. This has simplified diagnosis of many hereditary brain diseases, most of which in dogs and cats are autosomal recessive traits or the result of a complex inheritance. Dominant traits can be eliminated from a breed by not breeding affected animals. Familial diseases are not necessarily genetic, however, because families may share the same diet, environment, infection exposure, and so on. Breed predilection for a disease suggests a genetic contribution, but again, could reflect other factors such as the typical use of a particular breed or administration of supplements in vogue. Ultimately the hereditary nature of some disorders will be classified on the gene or its product that is altered. Many websites are now available to identify laboratories performing these tests. However, the clinician must be able to select the test and interpret results appropriately.[49-51] This requires an understanding of the terminology used, the types of genetic tests available and appreciating the potential pitfalls of DNA testing (see ch. 4).

Response to therapy can be important diagnostically, particularly when financial or other factors limit testing. Therapy for the most likely condition can be started and response monitored. For example, dramatic improvement with a tetracycline would support a presumption of tick-borne disease. While corticosteroids play an important role in treating brain disease, the risk of side effects, including exacerbation of an infectious disease, need to be weighed carefully. Dramatic improvement with corticosteroids would be consistent with a neoplasia or infectious/noninfectious inflammatory disease. Improvement with neoplasia is usually short-lived, while some noninfectious inflammatory disease may be kept in remission with prolonged treatment. Infectious diseases may also often respond dramatically to corticosteroids, only to worsen if appropriate antibiotics are not also instituted. Response to antiepileptic drugs (AEDs) helps to confirm a seizure disorder, but does not rule out an underlying cause to the seizures.

Specific Brain Diseases

The brain is the most metabolically demanding organ in the body. A large portion of the body's energy is reserved for maintaining resting membrane potentials and neurotransmission. The nervous system has more

limited energy metabolism pathways than other tissues, and is thus more sensitive to disturbances of glucose or oxygen supply. The brain is also sensitive to exogenous or endogenous toxins, with the highest centers most sensitive to metabolic insults. Therefore, forebrain signs are a common manifestation of systemic diseases (see ch. 12). The disorders will be described according to the DAMNITV (*d* = degenerative, *a* = anomalous, *m* = metabolic, *n* = neoplastic and nutritional, *i* = idiopathic epilepsy and inflammatory, *t* = traumatic, *v* = vascular) classification scheme. Inflammatory disease processes, most of which are multifocal, and head trauma are discussed in ch. 148 and 261, respectively.

Primary Brain Degenerative Diseases (E-Box 260-1)

E-Box 260-1

Degenerative Primary Brain Diseases and Brain Anomalies

Degenerative

Central Myelinopathy

Many of the central myelinopathies manifest with signs of spinal cord dysfunction but also cause encephalopathy.[52,53] Disorders of myelin development may not be apparent until the animal relies on adequate myelination for walking. Some disorders cause severe destruction of the central or peripheral myelin and lead to axon loss. Primary CNS myelin degenerative disorders can be classified as myelin dysgenesis (hypomyelination, dysmyelination), the leukodystrophies (necrotizing encephalomyelopathy and leukoencephalomyelopathy), and spongy degeneration.[52-54] Diagnosis is based on clinical signs in a breed at risk, DNA testing for some, and confirmation at necropsy based on disease pattern.

In hypo- and dysmyelinogenesis, numbers of oligodendrocytes are decreased or are unable or retarded in producing functional myelin.[53] Typically, myelin throughout the CNS is affected but peripheral nerves are spared. Reflexes are normal or exaggerated. These disorders clinically manifest with whole body tremors, dysmetria noticeable from the first attempts at walking and nystagmus. Breeds documented with this disorder include the Dalmatian, Springer Spaniel, Samoyed, Chow Chow, Weimaraner, Lurcher and Bernese Mountain Dog.[55-62] In some breeds like the Chow Chow, improvement occurs with time, but others, like the Springer Spaniel, are permanently disabled. Both X-linked and autosomal recessive forms have been described and a mutation of one of the myelin proteolipid proteins (PLP) has been identified in the Springer Spaniel.[52,54,63] In the autosomal recessive demyelinating disorder of Weimaraner pups, a mutation was found in the folliculin interacting protein 2 gene *(FNIP2),* which may be responsible for a delay in migration or differentiation of a subpopulation of oligodendrocyte progenitor cells.[64] Toy Fox and Rat Terriers affected by congenital hypothyroidism with goiter (see ch. 299) have regional CNS hypomyelination, most evident in the corpus callosum. In Rat Terriers, this is associated with a mutation in the thyroid peroxidase gene.[65]

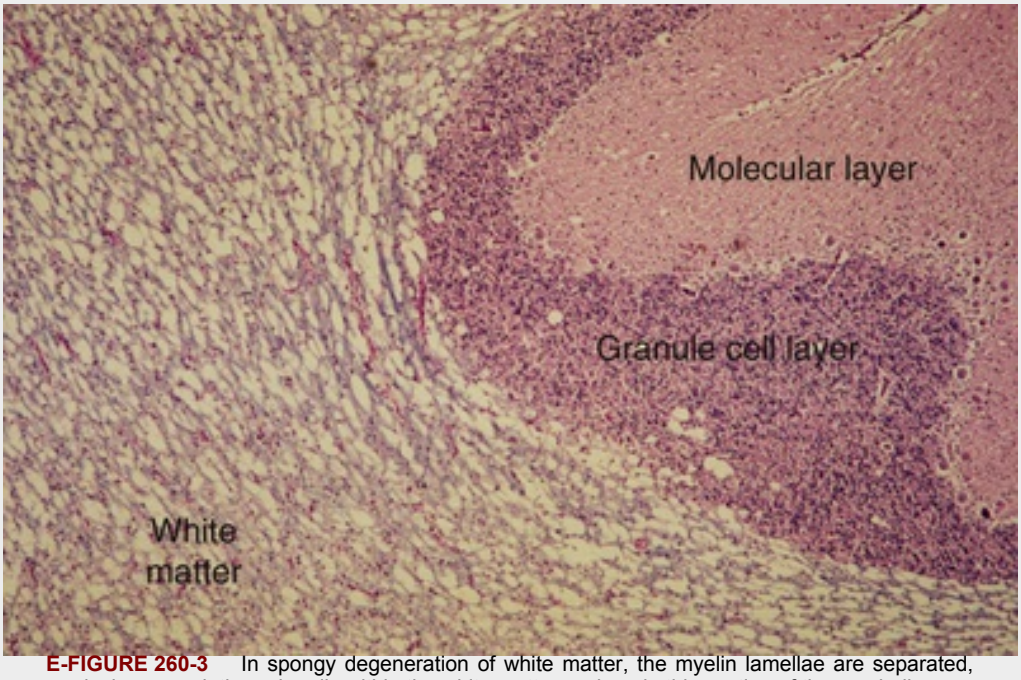
The leukodystrophies are a broadly classified group of diseases that include varieties of leukodystrophies, necrotizing encephalomyelopathies and leukoencephalomyelopathies.[53] Often conditions are inherited and diagnosed in younger animals with defective myelin synthesis. Myelin is formed early in life followed by a bilaterally symmetrical destruction of myelin with eventual loss of axons in some. Alexander's disease (fibrinoid leukodystrophy) has been reported as a sporadic occurrence in several breeds. Leukodystrophies have been reported in 3- to 6-month-old Dalmatians, Labrador Retrievers, Scottish Terriers, Bull Mastiffs, Shetland Sheepdogs, and Miniature Poodles.[66-72] Clinical signs initially manifest as general proprioceptive (GP) ataxia and upper motor neuron (UMN) paraparesis, which progress to tetraparesis. Signs of cerebellar involvement and seizures may occur. Histopathology reveals myelin degeneration without producing vacuolation, that is replaced by severe astrogliosis or Rosenthal fibers (astrocytic processes) and is widespread throughout the brain and spinal cord.

Myelinolysis is characterized by disintegration of initially normally formed myelin. These disorders are presumed due to an autosomal recessive inheritance and have been described in the Afghan Hound, Miniature Poodle, and Dutch Kooiker.[73-77] Age at onset varies from weeks to a few years and the paraparesis is acute. There is bilateral and symmetrical loss of myelin and there are cavitations that are most severe in all spinal cord funiculi with tapering extension into the brainstem. Myelin is

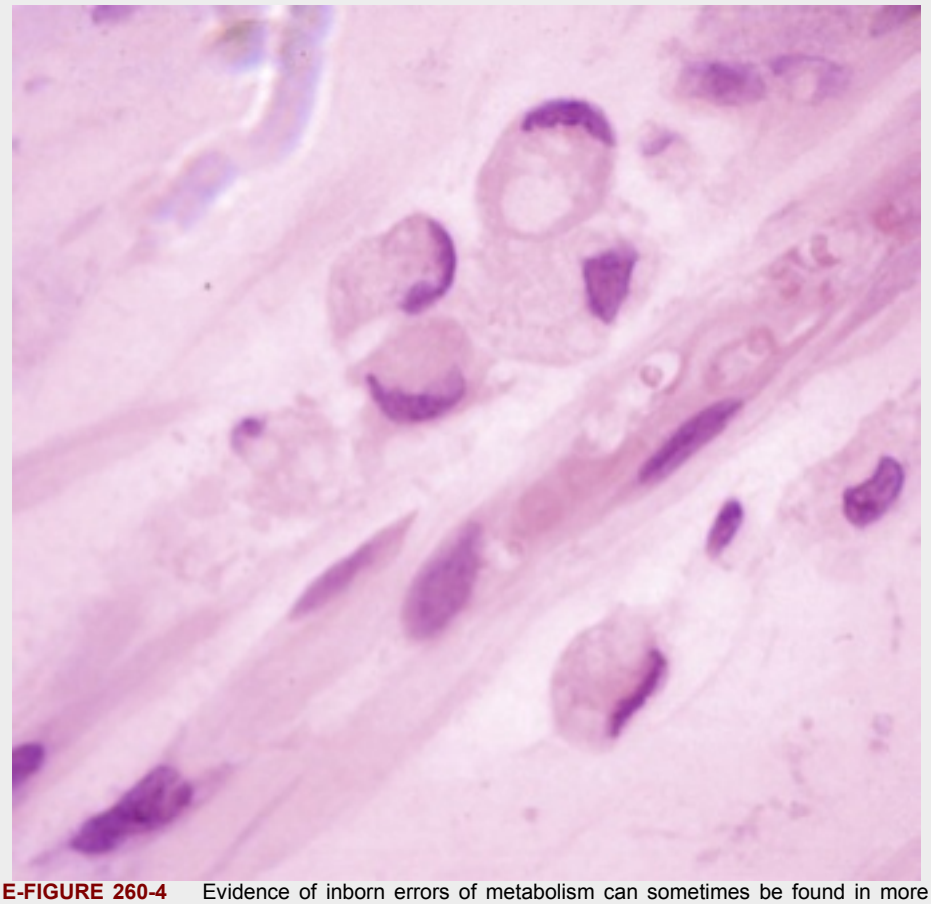
predominantly affected but the axons are usually spared in the Afghan Hound myelopathy, indicating primary myelinopathy, whereas prominent Wallerian degeneration in the Dutch Kooiker is more indicative of axonopathy. If the type of myelin degeneration cannot be determined, a more general term for inherited or acquired conditions, leukoencephalomyelopathy, is used. Specific leukoencephalomyelopathies have been documented in the Rottweiler, and Leonberger.[78-80] Myelin and axons are affected and there may be evidence of active remyelination. The age at onset of signs is within a few months to over 3 years and disease progression is slow and insidious.

Spongy Degeneration Involving Myelin

Spongy degeneration is a nonspecific term used to denote affected tissue vacuolation, seen in disorders that involve separation of the myelin sheath or that involve the neuronal cell body, as in the prion diseases, transmissible spongiform encephalopathy (TSE). Spongy white matter degeneration, similar to Canavan's disease of humans, has been reported sporadically in breeds of dogs and cats.[81] Spongiform leukoencephalomyelopathies have been reported in the Border Terrier, Silky Terrier and Labrador Retriever.[82-85] Onset of signs occurs within 1 to 9 months of age and the signs are progressive. Clinical signs manifest as cerebellar ataxia, seizures and opisthotonus. At necropsy in the Labrador Retrievers, splitting of the myelin resulted in vacuolation of the white matter throughout the brain (E-Figure 260-3) and to lesser extent the spinal cord.[84,85] Some lysosomal storage diseases (globoid cell leukodystrophy) cause vacuolar-like demyelination (E-Figure 260-4) by accumulating psychosine, a metabolite toxic to myelin-forming oligodendrocytes and Schwann cells.[86,87]



E-FIGURE 260-3 In spongy degeneration of white matter, the myelin lamellae are separated, producing vacuolation primarily within the white matter such as in this section of the cerebellum.



E-FIGURE 260-4 Evidence of inborn errors of metabolism can sometimes be found in more accessible tissues such as white blood cells, liver, or peripheral nerve. Macrophages with lysosomal storage product in vacuoles (globoid cells) were found in this peripheral nerve of a Cairn Terrier with globoid cell leukodystrophy.

Central Axonopathy

Axonal degeneration results from disease within the neuronal cell body or the axon itself. Central axonopathy usually consists of bilateral and symmetrical degeneration of both axon and myelin, affecting spinal cord sensory and motor tracts with the longest fibers being the most vulnerable.[88] Lesions appear as diffuse myelinated fiber loss of varying severity in the cerebellar white matter and/or in the dorsal funiculi and pyramidal tracts in the spinal cord that extend into the brainstem. Clinical signs can manifest as GP or cerebellar ataxia and UMN paresis. Breeds at risk include Jack Russell Terriers, Smooth Fox Terriers, Scottish Terriers, and Labrador Retrievers.[89-95] Jack Russell Terriers and related breeds manifest a spinocerebellar ataxia that varies in onset, early or late, and is progressively insidious. Histopathologic changes of neuronal fiber loss and astrogliosis are most severe in the spinal cord and brainstem. Signs of early onset spinocerebellar ataxia are observed by about 3 months of age and has included myokymia, seizures or both. A missense mutation in the gene coding for the inwardly rectifying potassium channel Kir4.1 *(KCNJ10)* was significantly associated with the disease.[96] "Late-onset ataxia," with clinical signs limited to spinocerebellar ataxia, usually begins by 6-12 months of age. A missense mutation in *CAPN1* that encodes for a cysteine-related protease mutation was strongly associated with the late-onset spinocerebellar ataxia in Parson Russell Terriers.[97]

The axonal degenerative diseases that selectively involve axons in the long tracts of the CNS and in the nerve fibers of PNS are as described in central-peripheral distal axonopathy. Segmental spinal reflex abnormalities reflect the PNS involvement. Disease with clinical signs and lesions limited to the PNS are classified as neuropathies.[98,99] Central-peripheral axonopathy of young dogs has been described in the Ibizan Hound, Alaskan Husky, Boxer, Pyrenean Mountain dog and New Zealand Huntaway.[81,100-104] Canine degenerative myelopathy associated with mutations in the superoxide dismutase-1 gene *(SOD1)* is a central-peripheral axonopathy of older-aged dogs seen in many breeds.[105,106] A sensory central-peripheral axonopathy of maternal inheritance has been described in Golden Retrievers. Onset of signs,

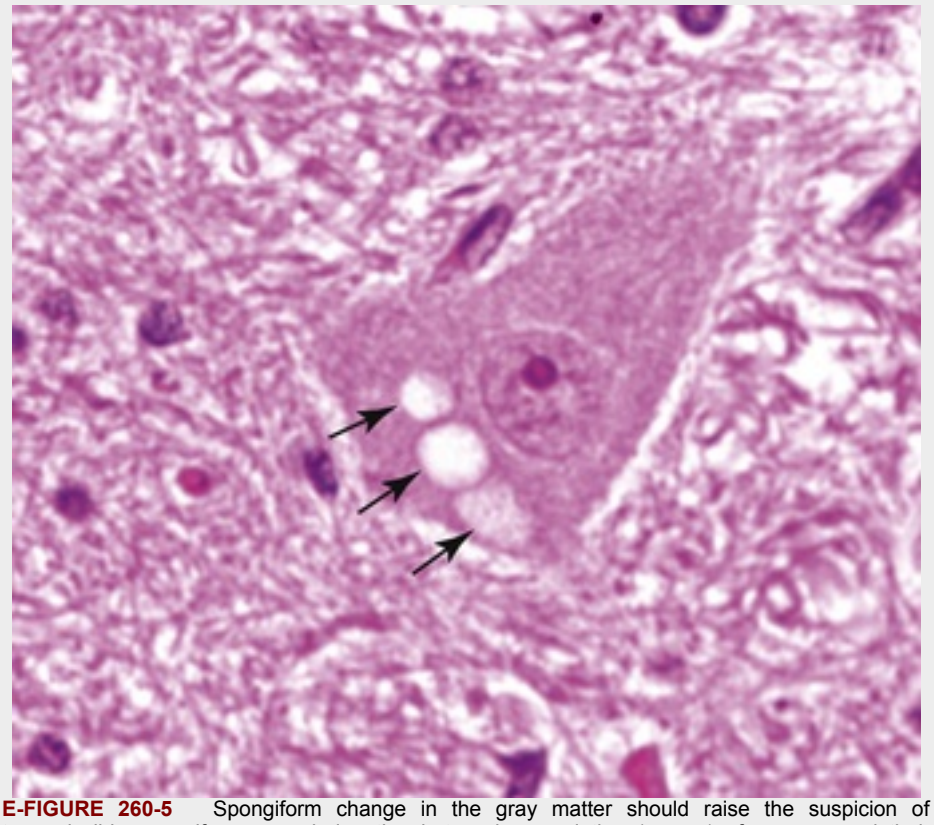
ataxia and dysmetria, is seen at 2-8 months of age.[107] The causative mutation has been found in the *MT-TY* gene *(tRNA-Tyr)* that impairs respiratory chain enzyme activity.[108] A central-peripheral axopathy has been reported in Birman cats.[109]

Neuroaxonal Dystrophy

Neuroaxonal dystrophies are primary disorders of axonal transport, characterized by swellings within the axons. These "spheroids" may be indicative of disordered cytoskeletal element trafficking, which accumulate in axons or synaptic terminals and represent the histologic abnormality necessary to be categorized in this group.[81] Because longer axons have farther to transport such elements, spheroids are most prominent in the termination of long proprioception tracts in brainstem nuclei (i.e., nuclei gracilis and cuneatus). If peripheral nerves are involved, the disease can be diagnosed by nerve biopsy (see ch. 116). Afflicted dogs (<1 year of age) usually have progressive cerebellar ataxia and tetraparesis. In dogs, neuroaxonal dystrophy has been described in the Rottweiler, Chihuahua, Working Collie Sheepdog, Jack Russell Terrier, German Shepherd Dog, and Papillion.[110-117] Neuroaxonal dystrophy has been sporadically described in cats.[118-120] A family of Scottish Terrier pups developed progressive tremors, ataxia, and paraparesis beginning at 10-12 weeks of age. They differed from the neuroaxonal dystrophies previously described in that their axons were diffusely swollen rather than concentrated in spheroids.[94] A fetal-onset neuroaxonal dystrophy (FNAD) has been reported in a colony of Giant Schnauzer-Beagle cross dogs.[121] Affected pups have a constellation of gross abnormalities, including joint contracture, scoliosis, cerebellar hypoplasia and respiratory failure. Neuronal lesions are present throughout the cerebellum, brainstem, spinal cord and peripheral nerves affecting specific nuclei. A mutation was found in the mitofusin 2 gene *(MFN2),* which is a multifunctional, membrane-bound GTPase of mitochondria and endoplasmic reticulum.[122]

Spongiform Polioencephalopathies

Spongiform degenerative conditions are subdivided into those with vacuolation within white matter myelin sheaths (leukoencephalopathies) or within neuronal gray matter (E-Figure 260-5). The spongiform polioencephalopathies encompass a heterogeneous group of diseases associated with neuronal spongiform changes at necropsy.[123] Some lysosomal storage diseases (see below) may also be characterized by vacuolation of neurons, but in those conditions, vacuoles are lysosomes distended with storage products. In the spongiform polioencephalopathies, vacuoles appear empty, and if intraneuronal, they are not membrane-bound. Large intraneuronal vacuoles are an uncommon pathologic finding seen in relatively few diseases including transmissible spongiform encephalopathies (prion diseases), some metabolic encephalopathies and a few viral infections such as human immunodeficiency virus or rabies.[124] Some reference sources reserve the term spongiform encephalopathy for the transmissible spongiform encephalopathies (TSEs), caused by an enigmatic agent, the prion.[53] Scrapie was the first TSE described. The outbreak of bovine spongiform encephalopathy (BSE) in England, and the subsequent recognition that this disease may be spread to cats and humans by ingestion of meat products from affected cows, has made these diseases of general interest.[125,126] The prion is unique in that it is not a nucleic-acid-based organism, but rather a rogue protein isoform (the prion protein). An alpha-helical isoform of the prion protein is found in normal neurons. The disease isoform (the "scrapie isoform") of the protein forms a beta-sheet similar to amyloid, which renders it resistant to degradation by proteases. Abnormal prions then accumulate in neurons as scrapie-associated fibrils that interfere with cell function and produce intraneuronal vacuolation. The scrapie isoform apparently propagates by inducing, via unknown processes, conversion of normal isoforms to the beta-sheet conformation.[127] A long latency period characterizes the TSEs. Cats affected with feline spongiform encephalopathy (FSE) show signs reminiscent of BSE: ataxia, behavioral changes, and hyperesthesia to touch or sound. At necropsy, the TSEs are characterized by vacuolation of nerve processes and to a lesser extent their cell bodies. In cats, such lesions occur throughout brain gray matter.[126] Control of BSE may decrease concerns of TSEs in dogs and cats, but future outbreaks are possible. Maintaining an index of suspicion will permit early recognition of the disease.[128]



E-FIGURE 260-5 Spongiform change in the gray matter should raise the suspicion of transmissible spongiform encephalopathy, but such vacuolation (arrows) of neurons and their processes can be seen in hereditary diseases such as hereditary spongiform encephalopathy in this Rottweiler dog.

Hereditary or Metabolic Encephalopathies

Hereditary spongiform polioencephalopathy has been identified in the Rottweiler, Black Russian Terrier, Australian Cattle Dog, Shetland Sheepdog, Lagotto Romagnolo, and an Egyptian Mau cat.[129-134] A maternal inheritance pattern has been determined in Australian cattle dogs and Shetland sheepdogs. The first signs recognized in affected <1-year-old dogs were seizures. After variable periods, progressive ataxia, vestibular signs, thoracic limb atrophy and muscle rigidity was noted, ultimately causing recumbency[71,131,135] Symmetrical increased signal was apparent on T2W MRI in the cerebellar, vestibular, and other brainstem nuclei.[135] At necropsy, there is vacuolar degeneration in the neuropil, astrocytes and myelin within the ventral horns of the spinal cord, cerebellar and brainstem nuclei. A mutation was found in mitochondrial encoded cytochrome *b (CYTB).*[136] In Rottweilers and Black Russian Terriers, beginning at 6-8 weeks of age, affected pups develop progressive laryngeal paralysis, tetraparesis and proprioception deficits most prominent in the pelvic limbs, and cerebellar ataxia.[129] No abnormal prion proteins were detected in these dogs,[129] and mutations have not been found in the prion protein gene. Malinois Shepherd crosses and Malinois with congenital generalized tremors have been reported with diffuse vacuolation of the cerebellar nuclei, and Bull Mastiffs with hydrocephalus and cerebellar ataxia have cerebellar roof nuclei spongiform changes.[137-139] While these conditions are rare, it is important to differentiate them from TSEs, with their public health implications.

Polioencephalomyelopathies

Because neurons have a high metabolic demand, they are particularly susceptible to disturbances of energy metabolism and involvement of gray matter suggests a metabolic deficit that creates dysfunction in neurons or glia. The clinical signs of polioencephalopathies vary widely, but because neurons of the cerebral cortex are often affected, seizures and behavior changes are common, as are cerebellar ataxia, and sensory or motor deficits. Thiamine deficiency has propensity to involve the periventricular gray matter, lateral geniculate nuclei, caudal colliculi and vestibular nuclei.[140-143] Polioencephalomyelopathy, associated with altered mitochondrial metabolism, has characteristic bilaterally symmetrical cavitating lesions of necrosis and spongy degenerative changes in the neuropil of the thalamus, basal nuclei

midbrain and brainstem. These changes are characteristic of subacute necrotizing encephalopathy, also referred to as Leigh or Leigh-like syndrome in people. Subacute necrotizing encephalopathy has been described in several breeds of dogs including Australian Cattle Dogs, Alaskan Huskies, Yorkshire Terriers, and American Staffordshire Bull Terriers.[145-149] Please see the "inborn errors of metabolism" section of this chapter for additional discussion.

Brain Neuronal Degeneration

Multisystem neuronal degeneration involves CNS axonopathies, neuronopathies and, in some, neuropathies. These disorders can resemble the motor neuron diseases.[150] A diffuse multisystemic chromatolytic neuronopathy, involving loss of Nissl bodies in motor neurons without neuron loss in the spinal cord, brainstem and thalamus has been reported in the Cairn Terrier.[151-153] Cocker Spaniels present with abnormal gait, tremors and thalamocortical dysfunction.[154] A central-peripheral axonopathy with motor neuron depletion has been reported in the Golden Retriever.[155]

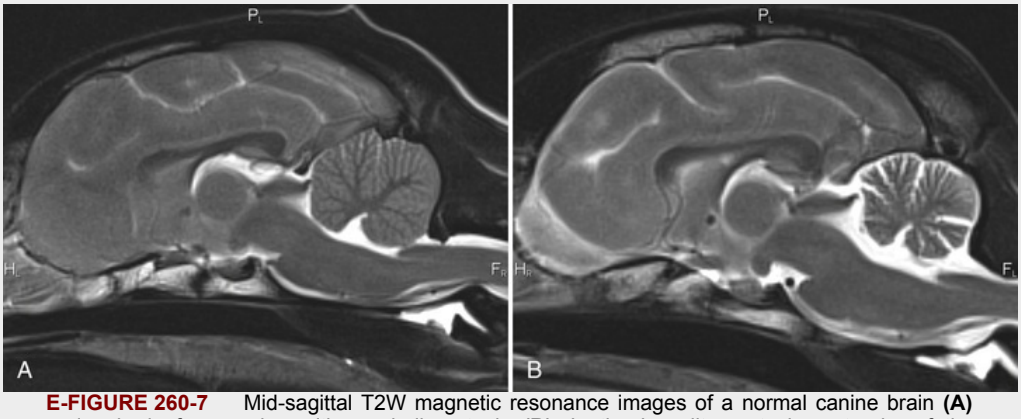
Multiple Systems Degenerations

When the cerebellum and basal ganglia are involved in a disease process, the conditions are referred to as multiple systems degenerations. The basal ganglia, such as the caudate nucleus and substantia nigra, are important in movement and are affected in Huntington's and Parkinson's disease in humans. The best characterized syndrome of this type in animals is the disease of Kerry Blue Terriers and Chinese Crested dogs called progressive neuronal abiotrophy (PNA) by breeders.[156-159] In these dogs, cerebellar ataxia begins at 8-12 weeks of age, but is followed at 6-12 months of age by degeneration of the basal ganglia. As the basal ganglia degenerate, affected dogs have increasing difficulty initiating movements and maintaining balance. Some exhibit "festinating locomotion" in which the dog begins to lose balance and then runs that direction to keep from falling (E-Figure 260-6). The degeneration of the basal ganglia is visible on MRI as an increased T2 signal. Severe motor difficulties are usually noted before 1-2 years of age.[159]

E-FIGURE 260-6 As Chinese Crested dogs with multiple system degeneration progress from cerebellar ataxia to basal ganglia degeneration, they develop difficulty initiating movements. They may shift weight forward until they begin to fall, and then they are able to move forward.

Cerebellar Degenerations

Cerebellar degeneration, in dogs, is in the hereditary ataxia subgroup, a heterogeneous group of neurodegenerative diseases characterized by symmetrical cerebellar ataxia.[160] Primary cerebellar cortical degeneration can be further subdivided into diseases that primarily affect the Purkinje and/or granular neurons. Numerous descriptions of different cerebellar degenerations have been reported in purebred dogs and cats. Signs may manifest as neonatal, juvenile or adult onsets and are progressive. Routine laboratory testing and CSF analysis are normal and will rule out other acquired causes. MRI can reveal atrophy of the cerebellum (E-Figure 260-7).[161] Genetic tests for some of these disorders have been developed and enable a definitive diagnosis.[160]



E-FIGURE 260-7 Mid-sagittal T2W magnetic resonance images of a normal canine brain **(A)** and a brain from a dog with cerebellar ataxia **(B).** In the hereditary ataxias, atrophy of the cerebellar cortex may be apparent as shrinkage and flattening of the cerebellum with an increased space between the folia **(B).**

Anomalies

Disorders of Mesoderm Induction

The calvaria develops from axial mesoderm induced by development of brain parenchyma.[162] Typically, cranial mesodermal defects are most apparent in midline structures. In some, concurrent malformation of overlying tissues allows protrusion of meningeal (meningocele) or brain tissue (meningoencephalocele; E-Figure 260-8).[53,164] Some cranial defects can be surgically treated.[165,166] Craniofacial malformations in Burmese cats, selected for a brachycephalic facial appearance, have an autosomal dominant inheritance pattern.[167] The genetic defect causes abnormal migration of neural crest cells (neuroectoderm) secondarily causing varying severities of meningoencephalocele and hydrocephalus.[168]

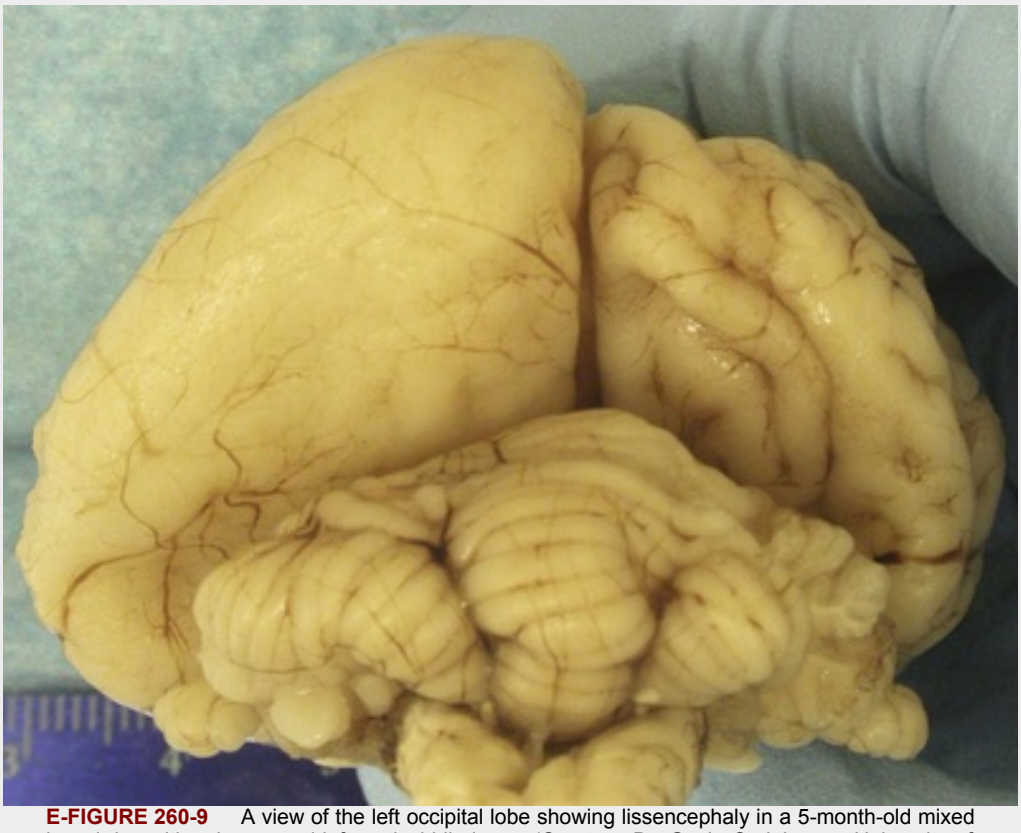
E-FIGURE 260-8 Mid-sagittal **(A)** and dorsal **(B)** T2-W magnetic resonance images of a unilateral ethmoidal meningoencephalocele in a 6-month-old Rottweiler with seizures. A portion of the olfactory bulb (asterisk) is herniated into the left caudal nasal cavity.

Disorders of Forebrain Induction

Forebrain developmental disorders include holoprosencephaly, arrhinencephaly and cyclopia. In holoprosencephaly, the cerebrum and other midline structures fail to separate and there may be incomplete formation of other midline areas. Agenesis of the corpus callosum usually is accompanied by other defects but can be a distinct malformation. The most common presenting clinical sign identified in association with corpus callosum agenesis was hypodipsia/adipsia that led to episodes of hypernatremia.[169]

Disorders of Neuronal Migration

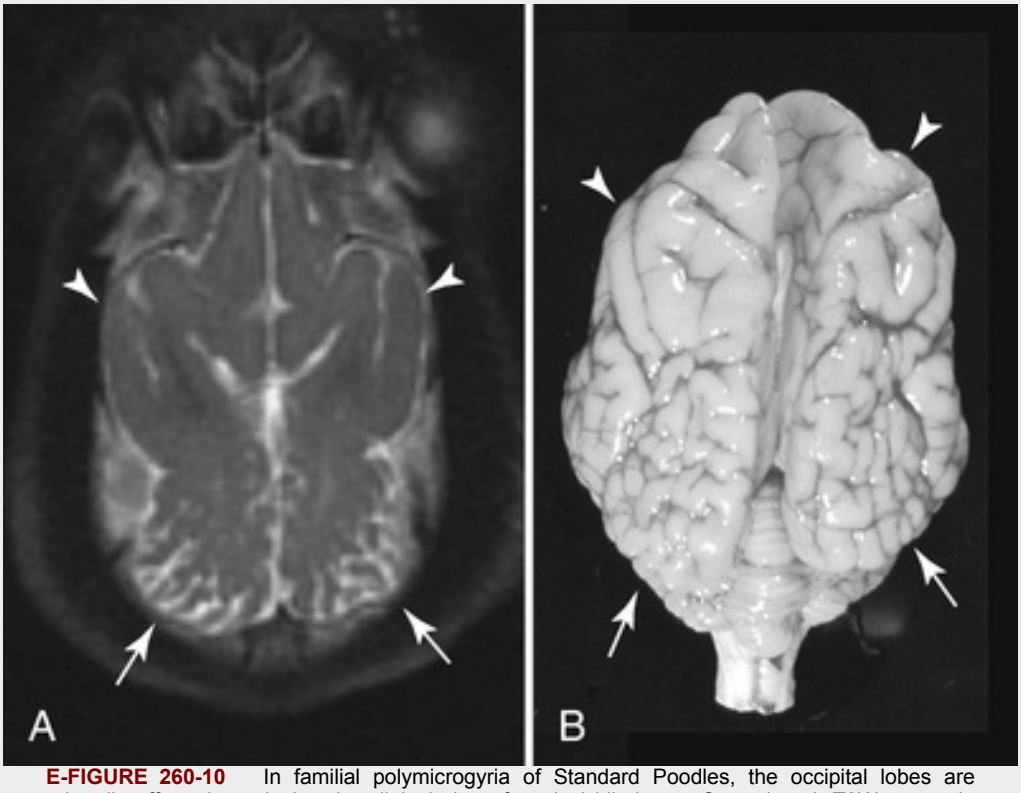
Once the neural tube has formed, differentiation of various brain components occurs which can be disrupted by genetic or environmental influences. Migration of neurons within the cerebral cortex leads to the characteristic sulci and gyri and the normal laminar arrangement of neurons within the cortex. Brain malformations can be caused by abnormalities in neuronal migration. In lissencephaly, some or the entire surface of the cortex is smooth (agyria; E-Figure 260-9) and reflected by microscopic thickening of the cortical laminae, which can be visualized on MRI in dogs.[163,170] In humans, a variety of mutations has been associated with lissencephaly and a genetic etiology is suspected in dogs because it has been recognized primarily in purebreds, including the Lhasa Apso, Irish Setter, Wire Fox Terrier and Samoyed.[164,170,171] Affected dogs showed behavioral changes, vision deficits and seizures.



E-FIGURE 260-9 A view of the left occipital lobe showing lissencephaly in a 5-month-old mixed breed dog with seizures and left cortical blindness. (Courtesy Dr. Gayle C. Johnson, University of Missouri.)

Polymicrogyria is a disorder of cerebrocortical development resulting in excessive production of small gyri and often accompanied by hydrocephalus. It has been reported as a familial disease of Standard Poodles (E-Figure 260-10). The occipital lobes are preferentially affected, with cortical blindness being the primary clinical sign.[172,173] In other conditions such as heterotopia, the gross structure of the brain is

normal, but the laminar arrangement of neurons and white matter within the cortex is disrupted, leading to abnormally placed nests or rows of neurons. Such dysplasia has been observed in the cerebellar cortex but was associated with severe motor problems suggesting that more than cerebellar function was disrupted even though dysplasia was not apparent in other areas.[174]



E-FIGURE 260-10 In familial polymicrogyria of Standard Poodles, the occipital lobes are primarily affected, producing the clinical sign of cortical blindness. On a dorsal, T2W magnetic resonance image **(A)** or necropsy **(B)** the multiple, small gyri can be seen (arrows) in contrast to the more normal gyri in the frontal lobes (arrowheads).

Cerebellar hypoplasia is seen most commonly in cats following *in utero* or early neonatal infection with the feline panleukopenia virus (see ch. 225). The rapidly multiplying granule cells of the cerebellum are sensitive to damage by the virus at this stage of development.[53,175] Though apparently much less common, there is now evidence that canine parvovirus infection can produce similar damage to the developing cerebellum.[176] Cerebellar aplasia or hypoplasia can also occur as an isolated malformation without evidence of infection, or as part of a more generalized brain development abnormality. The Dandy-Walker syndrome of humans is characterized by agenesis of the cerebellar vermis and hydrocephalus. A similar malformation has been described in dogs and cats.[53,164,177-180] Recently a mutation in *VLDR,* encoding the very low density lipoprotein receptor, was found to underlie a Dandy-Walker malformation in the Eurasier dog.[181,182]

Hydrocephalus

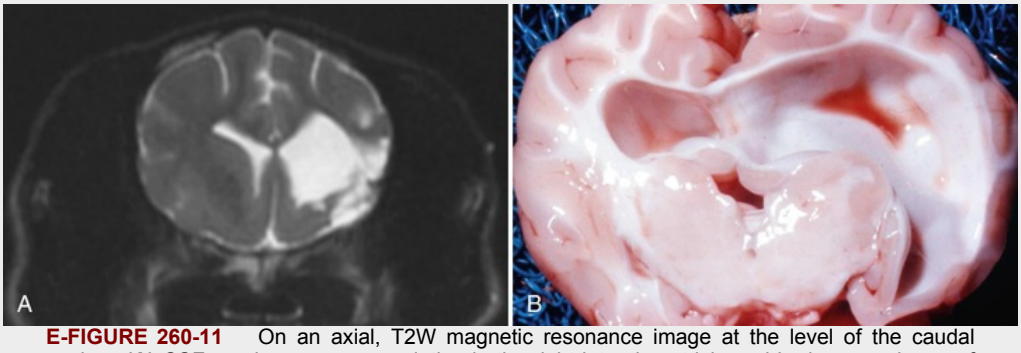
Definitions

Hydrocephalus is broadly defined as an active distension of the ventricular system of the brain related to inadequate passage of CSF from its point of production within the ventricular system to its point of absorption into the systemic circulation.[183] An animal diagnosed as being hydrocephalic has clinical signs of neurologic dysfunction related to the dilated ventricles. The term "ventriculomegaly" is used to describe an incidental imaging finding in animals with subjectively dilated lateral ventricles and no clinical signs of dysfunction caused by the enlargement. Hydrocephalus can be classified as communicating or noncommunicating based on its involvement with the ventricular system and subarachnoid space.

Hydrocephalus is further classified as intraventricular and extraventricular obstructive

hydrocephalus.[183,184] In intraventricular obstructive hydrocephalus, the blockage of CSF flow through the ventricular system is most commonly seen at recognized bottle-necks: the connection between the lateral ventricle and the third ventricle (the interventricular foramen) or most commonly, the connection between the third and fourth ventricle (the mesencephalic aqueduct). Obstruction of one interventricular foramen will result in unilateral dilation of the lateral ventricle. With obstruction of the mesencephalic aqueduct, both lateral ventricles and the third ventricle will dilate. Obstruction at the lateral apertures usually shows marked enlargement of the 4th ventricular and to a lesser degree the rostral aspects of the ventricular system. Diffuse dilation can be seen when absorption of CSF from the subarachnoid space into the venous drainage is impeded—for example, by inflammation or neoplastic infiltrates of the arachnoid villi or in the subarachnoid space.

Extraventricular hydrocephalus occurs with obstruction at the level of the subarachnoid space or arachnoid villi and the entire ventricular system and subarachnoid space dilate. Ventricles also dilate in response to atrophy or necrotic processes of surrounding brain tissue, called compensatory hydrocephalus or hydrocephalus *ex vacuo* (E-Figure 260-11). Rarely, fluid can accumulate outside the ventricular system. External hydrocephalus results from CSF accumulating in the subarachnoid space, presumably due to obstruction of flow secondary to inflammation.[185] Another common site of fluid accumulation is in the quadrigeminal cistern between the cerebellum and cerebrum that has been recognized as an intracranial intraarachnoid cyst or quadrigeminal cyst.[186-189] This can be an incidental finding but will produce clinical signs if causing excessive compression, particularly on the cerebrum and cerebellum.[187,190]



E-FIGURE 260-11 On an axial, T2W magnetic resonance image at the level of the caudal nucleus **(A)** CSF can be seen accumulating in the right lateral ventricle and brain parenchyma of the parietal and temporal lobes. On necropsy at the level of the thalamus **(B),** hydrocephalus *ex-vacuo* was confirmed in a Pug dog with right persistent circling and central blindness.

Causes of Hydrocephalus

Causes of obstructive hydrocephalus are classified as congenital or acquired. Acquired hydrocephalus usually occurs when a disease process such as neoplasia, hemorrhage or inflammation occludes the flow of CSF. Neoplasia can cause compression of a segment of the ventricular system or ventricular occlusion by drop metastasis that impedes CSF flow. Brain injury from hydrocephalus is due to effects of tissue compression or indirectly caused by damage to the blood vasculature.[184] The intraventricular increase in CSF pressure may eventually lead to focal destruction of the ependymal lining, compromise of cerebral vessels and damage to the periventricular white matter.[191-193] The resulting interstitial edema in severe cases leads to neuronal injury and neuronal loss in the cerebral cortex.

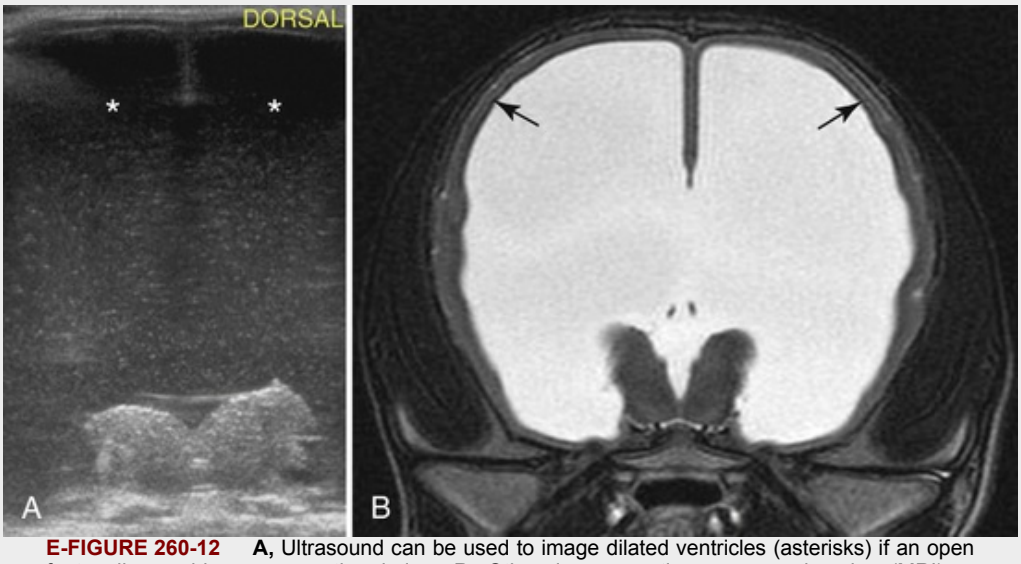
Congenital hydrocephalus is a common and defined entity in some toy and brachycephalic breeds but there is little published research on the condition.[194] It is occasionally seen in conjunction with other congenital problems such as Chiari-like malformations, polymicrogyria or cerebellar ataxia in Bull Mastiffs.[139,173,195] A commonly identified cause in predisposed breeds is stenosis or absence of the mesencephalic aqueduct associated with fusion of the rostral colliculi.[53,164,196] Neonatal infections, such as parainfluenza virus in dogs, can result in stenosis without leaving any trace of the etiology once the initial ependymitis has resolved.[197,198] The strong breed predilection, however, suggests a hereditary basis. Presence of an open fontanelle is common in many toy breeds (e.g., Chihuahua), but does not necessarily indicate presence of hydrocephalus.

Onset of signs and their rate of progression is variable in dogs and cats with congenital hydrocephalus.

A retrospective study showed that 30% of dogs were >2 years of age.[194] Clinical signs of hydrocephalus include behavioral changes, ataxia, visual deficits and seizures. Physical features may include an enlarged and dome-shaped calvaria, persistent cranial sutures and fontanelle. Ventrolateral strabismus is common in congenital hydrocephalus, but it is not clear whether this is due to oculomotor nerve damage, brainstem compromise, or orbital malformation. Lateralized signs (circling) are evident with obstruction of the intraventricular foramen causing dilation of one lateral ventricle. Even in congenital cases, the disease may follow a waxing and waning course. Sometimes dramatic hydrocephalus may be present and the owners report few clinical signs other than learning deficits.[199] Increased intracranial pressure can lead to tentorial herniation, particularly in acute, obstructive hydrocephalus.

Diagnosis

Hydrocephalus can be diagnosed with electrophysiologic and imaging studies. EEG may show a characteristic pattern of high voltage synchronous activity, but imaging the dilated ventricles is necessary to confirm the diagnosis. If a persistent fontanelle is present, the ventricles can often be adequately imaged with ultrasound. If not, cross-sectional imaging of the dilated ventricles is necessary to rule out obstructive disease or another congenital anomaly (E-Figure 260-12). Criteria of clinical relevance, based on MRI findings of canine brains, were suggested for supporting diagnosis of symptomatic internal hydrocephalus.[200] The ventricle/brain-index was significantly higher in dogs with clinical signs of hydrocephalus and a threshold value of 0.6 was specified to differentiate between internal hydrocephalus and ventriculomegaly.[200,201] Other anatomic findings indicative of clinical hydrocephalus included elevation of the corpus callosum, flattening of the interthalamic adhesion, periventricular edema, dilation of the olfactory recesses, effacement of the cortical sulci, attenuation of the subarachnoid space and disruption of the internal capsule.[200]



E-FIGURE 260-12 **A,** Ultrasound can be used to image dilated ventricles (asterisks) if an open fontanelle provides an acoustic window. **B,** Otherwise magnetic resonance imaging (MRI) or computed tomography (CT) is necessary. On axial T2W MRI for the dog in **B,** only a rim margin of brain parenchyma (arrows) at the level of the thalamus was evident. The chief complaints from the owners was their dog's irritability on restraint and inability to become house-trained.

Treatment

The choice of treatment is guided by the patient's neurologic and physical status and age, and the underlying cause. Medical management of hydrocephalus is largely directed at reducing intracranial pressure, CSF production, and seizure activity.[184] Anti-seizure drugs are administered as needed and diuretics (e.g., furosemide), carbonic anhydrase inhibitors (e.g., acetazolamide) or proton pump inhibitors (e.g., omeprazole) in combination with corticosteroids or corticosteroids alone are used to decrease CSF production. Mannitol can be administered for acute decompensation, but benefits are transient. While medical therapy may ameliorate the signs, hydrocephalus tends to be a progressive disease.

Surgical treatment involves either resection of the mass lesions causing the ventricular obstruction or

shunting of CSF away from the obstructed regions of the ventricular system. Surgical treatment is reserved for animals with worsening neurologic signs that do not respond or become refractory to medical therapy. Contraindications include infection of the shunt placement sites and the procedure's inability to change the outcome with respect to severity of brain atrophy and presumptive neuronal injury, based on clinical signs.[184] Placement of a drainage device (shunt) diverts CSF from the lateral ventricle through a one-way ultra-low pressure valve and reservoir to another site such as the peritoneal space, atrium of the heart or SC space.[202-204] A pressure valve is necessary to prevent excessive drainage of CSF which could collapse the overlying cerebrum and cause subarachnoid hemorrhage, and to prevent pressure in the abdomen during coughing or exertion from being transmitted to the ventricles.

Prognosis

Prognosis for severe congenital hydrocephalus is usually guarded as clinical signs are often severe at presentation. In a retrospective study of 30 dogs and 6 cats with congenital hydrocephalus and ventriculoperitoneal shunt placement, 72% had improvement of clinical signs within a median time of 4 months.[203] Based on retrospective studies, the rate of complications varies from 22 to 30%.[203-205] Complications are most likely to develop within the first 3 months after surgery and include shunt migration from the calvaria, mechanical failure, infection and occlusion of the shunt.[203-205]

Chiari-Like Malformations and Syringohydromyelias

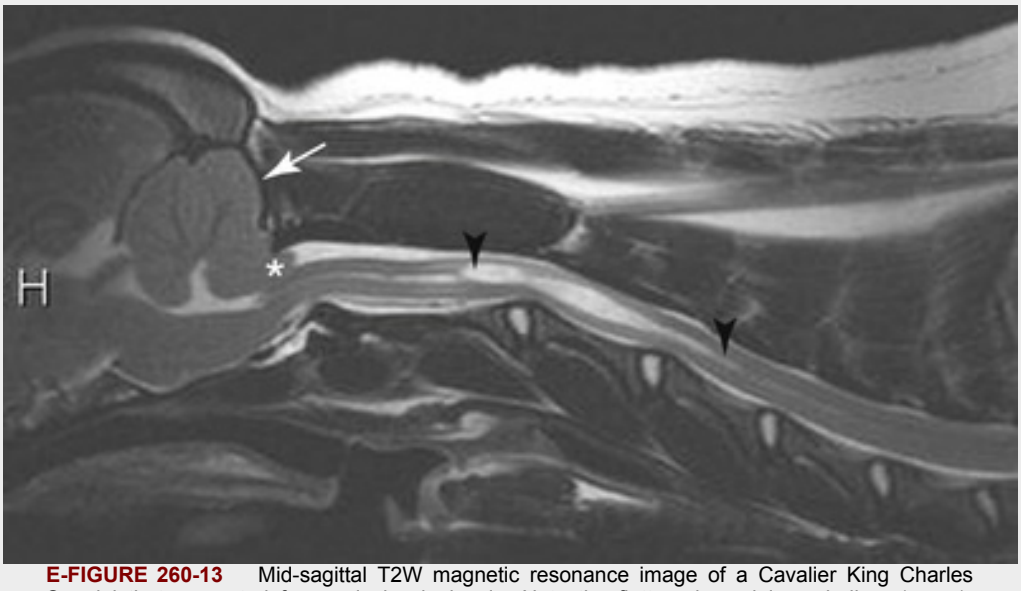
Chiari-like malformations (CM) and syringohydromyelias are recognized in small breed dogs, especially the Cavalier King Charles Spaniel (CKCS) and Brussel Griffon,[206-210] and the terminology is adopted from similar disorders in humans. In dogs, CM is characterized by herniation of the cerebellar vermis and medulla into or through the foramen magnum and indention of the cerebellum by the occipital bone.[211] In the CKCS, CM has been associated with premature closure of the spheno-occipital synchondrosis that may contribute the brachycephalic skull conformation and CM.[212,213] Additionally, a failed communication between mesodermal cartilaginous precursors of the occipital bone and neural tube closure could lead to reduce capacity of the caudal cranial fossa to contain the brain parenchyma.[206,214]

Thus, the pathophysiology of CM involves mismatch between the caudal cranial fossa volume and contained brain parenchyma leading to cerebellar herniation, medullary kinking, hydrocephalus, obstruction of the dorsal craniocervical subarachnoid space, and/or alteration of CSF flow.[214-218] A sequela of CM is development of syringohydromyelia: formation of fluid-filled cavities within the spinal cord, most commonly the cervical cord, but they can form in multiple locations.[219] In the CKCS there is an association between increased cerebellar volume and syringohydromyelia.[214] The development of syrinxes and association between CM and syringohydromyelia is complex, but it is suspected to be multifactorial including obstruction of the subarachnoid space and abnormal CSF dynamics.[220-222] There are significant associations between medullary elevation (i.e., medullary kinking), dorsal compressive atlantoaxial bands, and the presence of syringohydromyelia.[223,224] Development of hydrocephalus is likely related to reduced craniospinal compliance due to failed CSF absorption into the venous sinuses.[225] Syringohydromyelia secondary to CM in the CKCS is considered to have a complex inheritance pattern.[226-229]

In addition to signs caused by hydrocephalus or cerebellar compression, clinical signs of syringohydromyelia secondary to CM include thoracic and pelvic limb general proprioceptive ataxia, postural reaction deficits and neuropathic pain. Excessive scratching of the ear, neck, or shoulder, vocalization and facial rubbing may be the chief complaint reported by the owner.[195,230-232] Size (diameter) and asymmetry of the syrinx are the strongest predictors of pain.[231,233] The mechanisms by which syringohydromyelia leads to neuropathic pain may involve the anatomic distortion of dorsal horn resulting in abnormal processing of sensory information.[232,233] Recent studies have demonstrated decreased expression of substance P and interleukin-6 in CSF and spinal cord tissue of CKCSs with syringomyelia and persistent pain; interestingly, expression of these same mediators was increased caudal to the syringomyelia.[234,235]

Management of syringomyelia is based on an imaging diagnosis combined with severity of clinical signs. Chiari-like malformation and syringohydromyelia are readily diagnosed on midsagittal MRI on which the herniation of the cerebellum and any concurrent hydrocephalus or syringomyelia can be identified (E-Figure 260-13). Dogs exhibiting pain, neurologic deficits or with progressive signs can be

treated medically or surgically, but clinical signs can be frustrating to treat given the variability in disease progression. Initial medical therapy involves use of analgesics, including gabapentin for neuropathic pain and drugs to reduce CSF production. Surgical treatment of CM in dogs may have importance in restoring craniospinal compliance but there is limited information regarding patient selection or other criteria on which to base decisions. With improved CSF dynamics after decompressive surgery, clinical signs may resolve but recurrence is common and neuropathic pain may persist.[236-238]



E-FIGURE 260-13 Mid-sagittal T2W magnetic resonance image of a Cavalier King Charles Spaniel that presented for cervical spinal pain. Note the flattened caudal cerebellum (arrow), herniated cerebellar vermis (asterisk), brainstem medullary kinking and extensive syringohydromyelia (arrowheads) extending from C2 to C4 vertebrae.

Neurodegenerative brain diseases have a progressive course and are usually diagnosed in quite young or geriatric pets (also see ch. 263). Degenerative encephalomyelopathies can be selective, diffuse, or multifocal since the neuron or myelin often involve both brain and spinal cord (E-Table 260-6). Thalamocortical, brainstem, spinal cord and/or cerebellar signs may predominate. Findings on brain MRI may show bilateral and symmetrical selective lesions in the gray or white matter that can have a regional or diffuse distribution. Additionally, MRI findings of brain atrophy can also be regional or diffuse. However, a definite diagnosis for many of these disorders is made on biopsy or necropsy. DNA testing may be of use. Currently, there is no effective treatment for most of the neurodegenerative diseases. Genetic discoveries have enabled better understanding of the underlying disease-causing pathways that can provide targeted therapeutic studies. These therapeutic strategies include somatic gene transfer therapy, enzyme replacement therapy, heterologous cell transplantation, and RNA silencing. They hold promise and clinical trials on several disease models of dogs and cats are underway.

E-TABLE 260-6

Classification of Degenerative Encephalopathies/Encephalomyelopathies

NEUROANATOMIC PATHOLOGY	SPECIFIC DESCRIPTION
Myelinopathy	Hypo- or dysmyelogenesis
	Leukodystrophy
	Myelinolysis
	Leukoencephalomyelopathy
	Spongy degeneration involving myelin

Spongy degeneration	Neuronal vacuolation
	Myelin vacuolation
Axonopathy—Wallerian degeneration, distal axonopathy (dying-back neuropathy), segmental degeneration	Central-peripheral axonopathy
	Central-peripheral distal axonopathy
	Neuroaxonal dystrophy
Spongiform polioencephalopathy	Transmissible spongiform encephalopathy
	Spongy degeneration involving gray matter (neuronal vacuolation)
Polioencephalopathy	Necrotizing encephalopathy
Brain neuronal degeneration (neuronopathy and involving axonopathy)	Multisystem neuronal degeneration
Multiple systems degeneration	Cerebellar and basal neuron (ganglia) degeneration
Cerebellar degenerations	Primary cerebellar cortical degeneration involving primary Purkinje and/or granular neuron degeneration

Brain Anomalies (see E-Box 260-1)

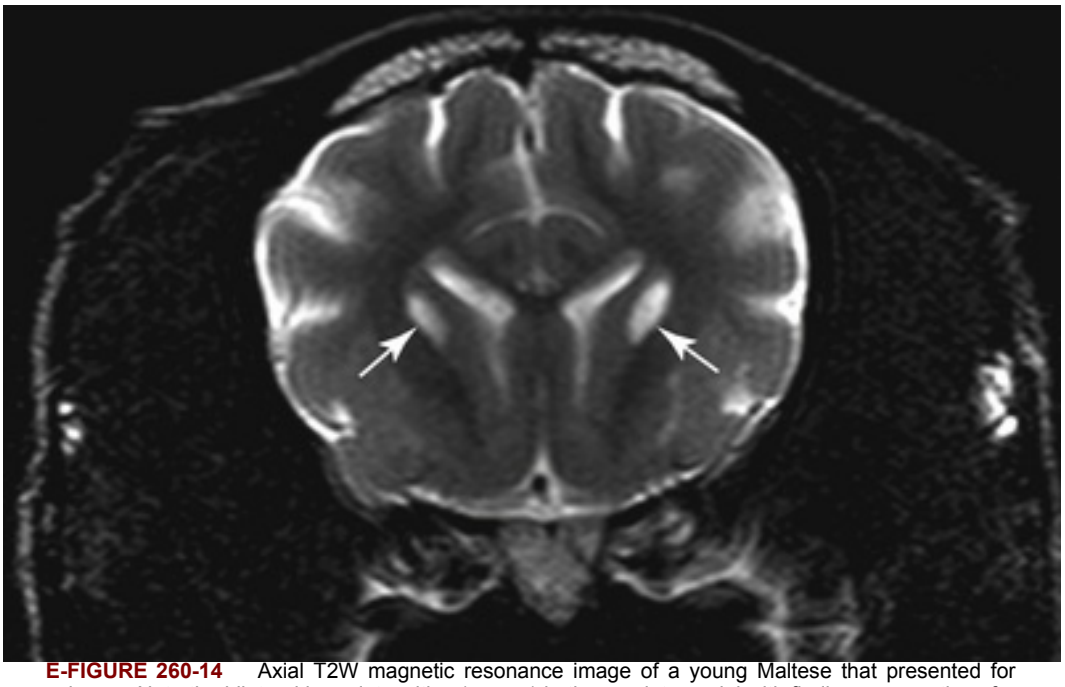
Congenital malformations of the brain would typically be present from birth and nonprogressive. A few exceptions, such as congenital hydrocephalus, can manifest later in life with progressive signs. The nervous system originates from a plate on the dorsal surface of the embryo, which folds in to form the neural tube, beginning in the thoracic area and extending rostrally and caudally. Genetic defects and *in utero* infection, intoxication, or malnutrition may cause failure of normal closure of the neural tube, typically seen at the rostral or caudal ends of the developing nervous system. Cranial neural crest cells are required for folding the tube and become the mesenchyme of the face and base of the calvaria.[162] Neural tube closure defects of the brain can vary in severity, the most severe being anencephaly with complete lack of brain development and no induction of the calvaria formation.

Severe malformations are apparent on physical examination and brain imaging.[163] Post-mortem examination may be necessary to detect more subtle deficits. Brain anomalies may accompany other defects such as cleft palate or cardiac anomalies. For most congenital malformations, treatment is symptomatic and prognosis depends on severity of the condition. History and serology can help rule out treatable toxic or infectious etiologies. Genetic, vaccine and nutritional counseling may help prevent future occurrences in breeding facilities.

Metabolic Encephalopathy

Inborn Errors of Metabolism

Inborn errors of metabolism interfere with function at a biochemical level or lead to premature neuronal death. Often signs manifest as waxing and waning diffuse and symmetric encephalopathy in neonates or the young. The earliest and most consistent signs are abnormal mentation and seizures. Neonatal encephalopathy with seizures (NEWS), for example, is a hereditary disease of standard poodles characterized by developmental delay with seizures and death before weaning with few biochemical or histological clues as to cause. A mutation in a major transcription factor (ATF2) has been identified which affects the normal programming of neuronal development.[239] Other neurologic signs vary with the regional distribution of lesions and severity of metabolic disturbance. Some diseases show characteristic bilateral and symmetric signal changes on brain MRI (E-Figure 260-14). Diet may influence severity of signs.



E-FIGURE 260-14 Axial T2W magnetic resonance image of a young Maltese that presented for seizures. Note the bilateral hyperintensities (arrows) in the caudate nuclei with findings suggestive of a metabolic encephalopathy that was diagnosed as malonic aciduria.

Some inborn errors of metabolism may be apparent on laboratory testing. Deficiencies in urea cycle enzymes increase blood ammonia concentrations while ketonuria or acidosis, without a clear underlying cause like diabetes mellitus, may reflect errors in mitochondrial metabolism. If there is accumulation of an abnormal metabolite, that product can sometimes be detected, such as blood lactate and pyruvate abnormalities in mitochondrial disorders. Identification of abnormal concentrations of certain metabolites in urine can be an ideal diagnostic aid, since metabolites may be excreted via the kidneys in high concentrations and sufficient urine volumes for assays can be collected, even from neonates. Simple urine screening tests are available for some inborn errors of metabolism, but most require testing at specialized laboratories. Serum or CSF may need to be assayed for metabolites that are not detected in urine while other tests measure specific enzyme activities.

Bilaterally symmetrical CNS lesions may be either manifestations of selective susceptibility of cellular populations to altered metabolisms or be determined by vascular anatomy (ischemia). Many inborn errors of metabolism affect other organs evaluated more readily than the brain. If peripheral nerves are involved, a nerve biopsy may yield clues—e.g., the presence of vacuolated macrophages in globoid cell leukodystrophy (see E-Figure 260-4). Occasionally such vacuolated cells may be visible on routine blood smears or CSF analysis. Because muscle also has a high metabolic demand, diseases affecting energy metabolism may show changes on muscle biopsy. If there is hepatomegaly or lymphadenopathy accompanying neurologic signs, a biopsy of one of these more accessible organs may reveal storage products.[240,241]

Mitochondrial Encephalopathy

Subacute necrotizing encephalopathy, known as Leigh syndrome or Leigh-like syndrome in people, consists of defects of the mitochondrial respiratory chain or pyruvate metabolism. Lesions are attributed to vascular congestion, caused by lactic acidosis resulting in hypoxemia and necrosis. Clinical signs include ataxia, paresis, movement disorders, cognitive deficits, nystagmus and seizures. Mitochondrial encephalopathy has been recognized as acute proprioceptive ataxia, seizures, behavior changes, central blindness, tetraparesis, and/or facial sensation deficits in Alaskan Huskies <1 year of age. Cavitating and spongiform lesions of the gray matter are seen symmetrically in the thalamus and striatum and junctional gray and white matter in the cerebral cortex, brainstem and cerebellar vermis.[145-147] These lesions are clearly visible on MRI as T2W hyperintensity.[147,242] A mutation in *SLC19A3*, encoding a thiamine transporter protein, was determined to play a role in Alaskan Husky encephalopathy.[146,242] Subacute necrotizing encephalopathy associated with combined respiratory chain defects also has been reported in Yorkshire Terriers and American Staffordshire Bull Terriers.[148,149,243]

Organic Acidurias

These diseases are characterized by abnormal organic acids due to errors in a metabolic pathway. While relatively few have been described in veterinary medicine, they are common in humans and probably occur on occasion in some purebred dogs. They can be diagnosed by urine organic acid screens and have the potential for therapeutic intervention if the deficient pathway can be bypassed. Cellular malonic acid levels regulate use of carbohydrates or fatty acids as energy sources in fed versus fasted states, respectively. A Maltese dog from a family with malonic aciduria developed seizures, stupor, hypoglycemia, acidosis, and ketonuria after a brief period of anorexia. Frequently feeding a high-carbohydrate, low-fat diet eliminated the need to rely on fatty acids as an energy source and ameliorated the clinical signs.[244]

Cobalamin (vitamin B12) is a necessary cofactor in the conversion of methylmalonyl CoA to succinyl CoA, a significant step in the Krebs cycle. Hereditary selective cobalamin malabsorption has been reported in Giant Schnauzers, Beagles, Border Collies and Australian Shepherd dogs.[245-247] Mutations in either the amnionless gene *(AMN)* or cubulin gene *(CUBN)* lead to Imerslund-Grasbeck syndrome (IGS) or selective cobalamin malabsorption. Genetic studies in dogs have demonstrated mutations in *AMN* in Giant Schnauzers and Australian Shepherds and *CUBN* in Beagles and Border Collies.[248-251] Typical clinical signs include altered mentation, inappetence and seizures associated with hyperammonemia and blood dyscrasias. Identifying high urinary methylmalonic acid (MMA) and low serum cobalamin concentrations confirms the diagnosis. Urea cycle dysfunction is a consequence of MMA accumulation. Clinical signs resolve with parenteral administration of cyanocobalamin. Cobalamin deficiency has been associated with elevated urine MMA and neurologic signs in cats, presumably due to a deficiency of intrinsic factor necessary for absorption of vitamin B12 (cyanocobalamin).[252] Gastrointestinal disease in cats can also interfere with cobalamin absorption in cats.[253,254] Cats with gastrointestinal disease can also develop a D-lactic acidosis, presumably due to excessive bacterial production of the D isoform in the intestines.[255] D-lactate is not detected by most routine lactate assays which are designed to detect the L isoform produced by mammals, but is much more likely to produce an encephalopathy.[256]

Increased concentrations of methylmalonic and malonic acids, as well as other intermediary metabolites, were found in the urine of a 12-week-old Labrador Retriever pup with progressive neurologic signs. The pup was not ketoacidotic or hyperammonemic, and cobalamin levels were normal. Diffuse atrophy of the CNS was found at necropsy, but no specific metabolic defect identified.[257] Staffordshire Bull Terriers and Yorkshire Terriers with hereditary L-2-hydroxyglutaric aciduria develop seizures, ataxia and altered behavior, usually between 4 and 5 years of age. On T2W MRI, diffuse hyperintensity is seen in the cerebral, cerebellar, thalamic, and brainstem gray matter.[258] L-2-hydroxyglutaric acid levels were elevated in urine, CSF and plasma from affected dogs.[258,259] Mutations in the dehydrogenase *(L2HGDH)* that metabolizes the organic acid have been described in Staffordshire Bull Terriers and Yorkshire Terriers.[259-261]

Lysosomal Storage Diseases

Definitions

Lysosomal storage diseases are characterized by accumulation of metabolic byproducts within lysosomes, the cellular organelle responsible for breakdown of complex macromolecules. Lysosomes maintain an acidic pH and substrates for catabolism that include sphingolipids (a major component of myelin), oligosaccharides, mucopolysaccharides, glycoproteins, and proteins (Table 260-7). The storage diseases are caused by key enzyme deficiencies, resulting in a failure to break down molecules and substrate accumulation. Most syndromes are named for the accumulated product. Proteases are less substrate-specific and single protease deficiencies are uncommon and less likely to produce problems, although ceroid lipofuscinosis may be one such defect.[240,241,262,263] Some defects interfere with cells' ability to utilize a normal enzyme. In I-cell disease (mucolipidosis) of cats, for example, there appears to be a disorder in trafficking enzymes into the lysosome, with multiple enzymes affected.[264] Some substrates must be engulfed into a double wall organelle, the autophagosome, and then delivered to the lysosome for degradation. Mutations in genes that would disrupt this process (autophagy) have recently been associated with neurodegenerative diseases in dogs. Hereditary cerebellar ataxia in Gordon Setters and Old English Sheepdogs and a neurodegenerative disease in Lagotto Romagnolos characterized by cerebellar ataxia, personality changes and neuronal vacuolation have been associated with mutations in the autophagy genes *RAB24* and *ATG4D*, respectively.[133,265] Recent reviews of storage diseases in animals are available.[240,241,262,263,266,267] Accumulation of storage products occurs over

time and onset of signs is delayed with most storage diseases despite enzyme deficiency since birth. Age of onset and severity can depend on residual enzyme function and on systems affected, since some storage diseases affect multiple organs and others only affect the nervous system. How accumulated storage products produce neurologic disease is not clear. In globoid cell leukodystrophy, one of the storage products is clearly toxic to oligodendroglia. In others, spheroid formation may be related to neuronal death.[240,241,263,268]

TABLE 260-7

Classification of Canine and Feline Lysosomal Storage Diseases

STORAGE DISEASE (HUMAN DISEASE)	ENZYME/PROTEIN DEFICIENCY (*MUTATED GENE*)	SPECIES—BREED	CLINICAL SIGNS
Glycoproteinoses			
Fucosidosis	Alpha-L-fucosidase *(FUCA1)*	C-*English Springer Spaniel*	Cerebellar ataxia, behavioral change, dysphonia, dysphagia, seizures
Mannosidosis (alpha-mannosidosis)	Alpha-D-mannosidase *(MANB)*	F-DSH, DLH, *Persian*	Cerebellar ataxia, tremor, corneal opacity, skeletal anomalies, neuropathy
Lafora's disease	Alpha-glucosidase *(EPM2A)*	C-Beagle, Basset Hound, Poodle, *wirehaired Dachshund;* F-DSH	Myoclonic epilepsy, dullness
Oligosaccharidoses/Glycogenoses			
GSD type 1 (von Gierke disease)	Glucose-6-phosphatase *(M121I)*	C-Silky Terrier, *Maltese,* other toy breeds; F-DSH	Weakness, seizures, stupor
GSD type 2 (Pompe disease)	Acid alpha-glucosidase *(GAA)*	C-Lapphund dog; F-DSH	Ataxia, muscle weakness
GSD type 3 (Cori disease)	Amylo-1,6-glucosidase *(AGL)*	C-Akita, German Shepherd, *Curly-Coated Retriever (IIIA)*	Lethargy, exercise intolerance, organomegaly
GSD type 4 (Andersen disease)	Glycogen branching enzyme *(GBE1)*	F-*Norwegian Forest cat*	Cerebellar ataxia, tremor, neuromuscular, organomegaly
GSD type7 (Tarui disease)	Phosphofructokinase *(PFKM)*	C-*English Springer Spaniel, American Cocker Spaniels, Whippets, mixed breeds, Wachtelhund Dog*	Exercise intolerance, rhabdomyolysis
Mucolipidosis			
Mucolipidosis II (I-cell disease)	N-acetylglucosamine-1-phosphotransferase *(GNPTA)*	F-*DSH*	Facial dysmorphism, dullness, retinal, ataxia
Sphingolipidoses			
GM1-gangliosidosis type 1 (Norman-Landing disease)	Beta-D-galactosidase *(GLB1)*	C-Beagle cross, *Portuguese Water Dog,* English Springer Spaniel, *Siberian Husky, Shiba dog;* F-*DSH, Siamese, Korat*	Cerebellar ataxia, corneal clouding, tremor, seizures, paralysis, skeletal facial dysmorphism
GM2-gangliosidosis (Tay-Sachs disease) (variant B)	Beta-N-acetyl hexosaminidase A (alpha subunit) *(HEXA)*	C-German Shorthair Pointer; *Japanese Chin*	Cerebellar ataxia
GM2-gangliosidosis (Sandhoff disease)	Beta-N-acetyl hexosaminidase B	C-Golden Retriever, *Toy Poodles;* F-*DSH-Japan, Korat, Burmese-Europe*	Cerebellar ataxia

(variant O)	(beta subunit) *(HEXB)*		
GM2AB-gangliosidosis (Bernheimer-Seitelberger disease) (variant AB)	GM2 activator protein deficiency *(GM2A)*	F-*DSH*	Cerebellar ataxia
Galactosialidosis	Galactosialidosis with alpha-neuraminidase	C-Schipperke (5 yr)	Cerebellar ataxia
Glucocerebrosidosis (Gaucher's disease)	Beta-D-gluco cerebrosidase	C-Sydney Silky dog	Cerebellar ataxia
Globoid cell leukodystrophy (Krabbe's disease)	Beta-D-galactosyl ceramidase *(GALC)*	C-*West Highland White Terrier, Cairn Terrier, Beagle, Poodle,* Australian Kelpie; Basset Hound, Blue Tick Hound, Pomeranian, *Irish Setter;* F-DSH, DLH	Cerebellar ataxia, tremor, paraparesis, neuropathy
Metachromatic leukodystrophy	Arylsulfatase A	F-DSH	Progressive motor dysfunction, seizures, opisthotonus, neuropathy
Sphingomyelinosis (Niemann-Pick disease type A)	Sphingomyelinase	C-Miniature Poodle; F-Balinese, Siamese	Cerebellar ataxia, tremor, paraparesis, neuropathy; biopsy
(Niemann-Pick disease type C)	Cholesterol esterification deficiency *(NPC1, NPC2)*	C-Boxer; F-*DSH*	C-cerebellar ataxia, hepatomegaly, neuropathy; F-cerebellar ataxia
Mucopolysaccharidoses			
MPS I (Hurler's syndrome)	Alpha-L-iduronidase *(IDUA)*	C-*Plott Hound,* Rottweiler, mixed breed; F-*DSH*	Growth retardation, facial deformity, lameness, corneal opacity
MPS II	Iduronate-2-sulfate sulfatase	C-Labrador Retriever	Cerebellar ataxia, exercise intolerance, corneal opacity, facial dysmorphism
MPS III (A, B, E)	A: Heparin sulphamidase *(SGSH)* B: N-acetyl-alpha-D-glucosaminidase *(NAGLU)* E: Arylsulfatase G *(ARSG)*	C-*Huntaway dog* (IIIA), wirehaired Dachshund (IIIA) *Schipperke* (IIIB) *American Staffordshire Terrier* (IIIE)	Cerebellar ataxia, tremor, retinal degeneration, corneal opacity
MPS VI (Maroteaux-Lamy disease)	N-acetylgalactosamine 4-sulfase (Arylsulfatase B) *(ARSB)*	C-Miniature Pinscher, Miniature Schnauzer, *Miniature Poodle,* Welsh Corgi; F-*Siamese cat,* DSH	Growth retardation, facial deformity, corneal opacity, spinal proliferations
MPS VII (Sly syndrome)	Beta-D-glucuronidase *(GUSB)*	C-mixed breed; F-*DSH*	C-paraparesis, cardiac; F-growth

			retardation, facial deformity, corneal opacity, spinal proliferations
Neuronal Ceroid Lipofuscinoses (Batten's Disease)			
CLN 1	Palmitoyl protein thioesterase 1 *(PPT1)*	C-*Miniature Dachshund*	Visual deficits, cerebellar ataxia, cognitive impairment, myoclonus, seizure
CLN 2	Tripeptidyl-peptidase *(TPP1)*	C-*Longhaired Dachshund*	Same
CLN 5	Soluble lysosomal protein CLN5 *(CLN5)*	C-*Border Collie; Golden Retriever*	Same
CLN 6	Transmembrane protein CLN6 *(CLN6)*	C-*Australian Shepherd*	Same
CLN 7	Major facilitator superfamily domain MFSD8 *(MFSD8)*	C-*Chinese Crested dog*	Same
CLN 8	Transmembrane protein CLN8 *(CLN8)*	C-*English Setter; Australian Shepherd Mix*	Same
CLN 10	Cathepsin D *(CTSD)*	C-*American Bulldog*	Same
CLN 12	P-type ATPase *(ATP13A2)*	C-*Tibetan Terrier*	Same
Others	Unknown gene mutation	C-Australian Shepherd, Chihuahua, Cocker Spaniel, Collie, Dachshund, Dalmatian, Golden Retriever, Japanese Retriever, Labrador Retriever, Miniature, Poodle, Polish Lowland Sheepdog, Saluki, Spitz, Welsh Corgi; F-Siamese cat, Japanese DSH, European DSH	

Breeds in *italics* signify gene mutation discovered.

C, Canine; *CLN*, ceroid lipofuscinosis; *DLH*, domestic longhaired cat; *DSH*, domestic shorthaired cat; *F*, feline; *GSD*, glycogen storage disease; *MPS*, mucopolysaccharidosis.

Signs

Cerebellar signs of dysmetria, truncal ataxia, and nystagmus are often the first signs of storage diseases.[241] The cerebellum, dependent on fast conduction for sensory feedback during movement, is quite sensitive to disorders affecting myelin or information processing and even subtle deficits may cause signs. More profound learning or mentation deficits may be necessary in other conditions to reach a threshold for signs, which often progress to UMN weakness, behavioral abnormalities, and seizures.[241] Some diseases (e.g., neuronal ceroid lipofuscinosis) cause forebrain and visual dysfunctions before cerebellar dysfunction is noted.[269] Peripheral nerves are involved in some conditions such as globoid cell leukodystrophy, fucosidosis, glycogenosis type IV, mannosidosis and Niemann-Pick disease.[98,270] In some lysosomal storage diseases, signs of other organ involvement may be apparent. Visible retinal or cataract formation may be seen (see ch. 11). Bony and connective tissue abnormalities frequently characterize the mucopolysaccharidoses, mucolipidosis and alpha-mannosidosis, whereby radiographic examination reveals dysmorphic bony malformations of the spine and/or face. Cardiac, hepatic, splenic or lymph node enlargement may accompany the neurologic signs.

Diagnosis

The multisystemic distribution of lysosomal storage disease abnormalities affords the ability to obtain a diagnosis from extraneural tissues. Storage vacuoles may be apparent in white cells on a peripheral blood smear or, in globoid cell leukodystrophy or fucosidosis, on CSF analysis. Lymph nodes (see ch. 95), liver (see

ch. 89 and 91), spleen or muscle (see ch. 116) can be biopsied or aspirated to reveal storage vacuoles. With some lysosomal storage diseases, cross-sectional imaging using MRI can show various hyperintensities and brain atrophy.[241,267] Necropsy may be necessary to demonstrate accumulated storage products when only the nervous system is involved. Electron microscopy can demonstrate storage material contained within lysosomes. Abnormal metabolites may be detectable in urine with some of the storage diseases. Definitive diagnosis is based on molecular testing for the known mutation (see Table 260-7) and/or demonstration of deficient enzyme activity in affected tissues, leukocytes or cultured fibroblasts.

Neuronal Ceroid Lipofuscinosis (NCLs)

Definitions

NCLs, also known as Batten disease, are a subset of lysosomal storage diseases in which the storage products are proteins with characteristic autofluorescence, similar to ceroid and lipofuscin pigments which accumulate normally with aging. The storage products in NCLs are subunit c of mitochondrial ATP or sphingolipid activator proteins (saposins A and D), due to deficient soluble enzymes. Membrane proteins are located in the lysosome, endoplasmic reticulum, or in synaptic vesicle-associated-proteins.[271,272]

Signs

Clinical signs due to NCLs include progressive visual impairments (usually the first sign, especially in dim light), decline in cognition and motor functions, seizures, generalized brain atrophy and death in young to middle age. Behavior changes become prominent with disease progression and include timidness, hyperesthesia, confusion, unprovoked aggression, seizures, jaw chomping, bruxism, and myoclonus. General proprioceptive and cerebellar ataxia tend to be later manifestations in many breeds although they are the most prominent sign in American Bulldogs with cathepsin D deficiency.[273,274]

Diagnosis and Treatment

Generalized brain atrophy can be seen on cross-sectional imaging in later stages of the disease but definitive diagnosis requires recognition of autofluorescent material in the brain or other tissues (E-Figure 260-15). Mutations responsible for many of the canine NCLs have been identified and DNA tests are available (see Table 260-7). Genetic mutations of the canine NCLs include *CLN1* (Dachshund), *CLN2* (longhaired Dachshund), *CLN4* (American Staffordshire Terrier), *CLN5* (Border Collie, Golden Retriever), *CLN6* (Australian Shepherd), *CLN7* (Chinese Crested Dog), *CLN8* (English Setter, Australian Shepherd mix), *CLN10* (American Bulldog), *CLN12* (Tibetan Terrier).[274-285] These tests assist with confirming a diagnosis and assist dog breeders in efforts to reduce the incidence of NCL in the breeds. There is no effective therapy for the storage diseases. Gene therapy, stem cell therapy and enzyme replacement therapy hold promise.[262,266,267] Symptomatic therapy for seizure control and behavior altering drugs can help ameliorate some of the signs.

Note the generalized brain atrophy with increased CSF hyperintensity between the gyri (arrows) of the cerebrum and folia (asterisk) of cerebellum, and ventriculomegaly. A diagnosis of NCL was based on the autofluorescent material (arrows) in neurons **(C).** (Courtesy Martin L. Katz, University of Missouri.)

Neoplasia

Intracranial neoplasia is a common condition in dogs and cats. Reviews highlight diagnosis, treatment,

imaging, and histology.[17,286-290] Tumors in brain tissue are broadly classified as primary or secondary. Primary intracranial neoplasms (Table 260-8) include tumors derived from neural, glial, or meningeal tissues, whereas secondary intracranial neoplasms are extraneural and locally invade or spread to neural tissues from a distant site.

TABLE 260-8

Primary Intracranial Neoplasms

TYPE	HISTOLOGIC EXAMPLES
Tumors of Neuroepithelial Tissue	
Astrocytic tumors	Pilocytic, subependymal giant cell, pleomorphic xanthoastrocytoma, diffuse (fibrillary, gemistocytic, protoplasmic), anaplastic, gliobastoma, gliomatosis cerebri
Oligodendroglial tumors	Oligodendroglioma, anaplastic oligodendroglioma
Oligoastrocytic tumors	Oligoastrocytoma, anaplastic oligoastrocytoma
Ependymal tumors	Subependymoma, myxopapillary, ependymoma (cellular, papillary, clear cell tanycytic), anaplastic ependymoma
Choroid plexus tumors	Choroid plexus papilloma, atypical choroid plexus papilloma, choroid plexus carcinoma
Other neuroepithelial tumors	Astroblastoma, choroid glioma, angiocentric glioma
Neuronal and mixed neuronal-glial tumors	Dysplastic gangliocytoma of the cerebellum, desmoplastic infantile astrocytoma, dysembryoplastic neuroepithelial tumor, gangliocytoma, ganglioglioma, anaplastic ganglioglioma, central neurocytoma, extraventricular neurocytoma, cerebellar liponeurocytoma, papillary glioneuronal tumor, rosette-forming glioneuronal tumor of the 4th ventricle, paraganglioma
Tumors of the pineal region	Pineocytoma, pineal parenchymal tumor of intermediate differentiation, pineoblastoma, papillary tumor of the pineal region
Embryonal tumors	Medulloblastoma (desmoplastic/nodular medulloblastoma, medulloblastoma with extensive nodularity, anaplastic medulloblastoma, large cell medulloblastoma), CNS primitive neuroectodermal tumor (CNS neuroblastoma, CNS ganglioneuroblastoma, medulloepithelioma ependymoblastoma), atypical teratoid/rhabdoid tumor
Tumors of the Meninges	
Tumors of meningothelial cells	Meningioma (meningothelial, fibrous, transitional, psammomatous, angiomatous, microcystic, secretory, lymphoplasmacyte, metaplastic, chordoid, clear cell, atypical papillary, rhabdoid, anaplastic)
Mensenchymal tumors	Lipoma, angiolipoma, hibernoma, liposarcoma, solitary fibrous tumor, fibrosarcoma, malignant fibrous histiocytoma, leiomyoma, leiomyosarcoma, rhabdomyoma, rhabdomyosarcoma, chondroma, chondrosarcoma, osteoma, osteosarcoma, osteochondroma, hemangioma, epithelioid, hemangiopericytoma, anaplastic hemangiopericytoma, angiosarcoma, Kaposi sarcoma, Ewing sarcoma
Primary melanocytic lesions	Diffuse melanocytosis, melanocytoma, malignant melanoma, meningeal melanomatosis
Other neoplasms related to meninges	Hemangioblastoma
Lymphoma and Hematopoietic Neoplasms	Malignant lymphomas, plasmacytoma, granulocytic sarcoma
Germ Cell Tumors	Germinoma, embryonal carcinoma, yolk sac tumor, choriocarcinoma, teratoma (mature, immature, with malignant transformation), mixed germ cell tumor

Tumors of the Sellar Region	Craniopharyngioma (adamantinomatous, papillary), granular cell tumor, pituicytoma, spindle cell oncocytoma of the adenohypophysis

Primary Brain Tumors

Types, Metastasis, Incidence

Meningiomas comprise about 50% of primary brain tumors in dogs, gliomas 30-40% and choroid plexus tumors are less common (Table 260-9).[291-293] Primary brain tumors also include histiocytic sarcoma, granular cell tumors, lymphoma and primitive neuroectodermal tumors (PNETs). In cats, meningiomas represent about 60% of all tumor types with gliomas occurring at lower frequency.[294,295] Rarely, primary intracranial neoplasms can disseminate throughout the CNS by hematogenous or CSF ("drop metastasis") routes. Tumors with potential for extraneural spread include meningiomas, PNETs, and malignant gliomas, histiocytic tumors, and choroid plexus tumors. Narrowed ventricular system areas are predisposed to obstructive hydrocephalus and its clinical signs. Olfactory meningiomas of dogs may invade the brain through the cribriform plate.[296] Rarely, meningioma may metastasize outside the CNS to lung or pancreas.[297,298] Glial tumors rarely metastasize unless there is ventricular involvement. Ependymomas and choroid plexus tumors have the potential to implant along CSF pathways and seed to distant spinal cord tissue.[299-301] The incidence for primary CNS tumors has been reported as 14.5 in 100,000 dogs (similar to people) and 3.5 in 100,000 cats.[302-304] The prevalence of intracranial neoplasia in dogs based on necropsy data has been reported to be 2-4.5% with a prevalence of primary neoplasms at 2.3% of total population (2.8% in dogs > 1 year) and secondary neoplasms at 2.2% (2.6% in dogs > 1 year).[291]
